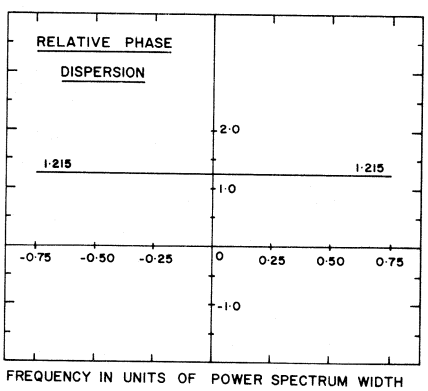

Fig. 11. Relative phase dispersion in frequency units of power-spectrum bandwidth for the data reported in [13]. Essentially, there is no phase dispersion. Phase change is constant for pulses in the tail region of long quasi-continuous pulse trains.

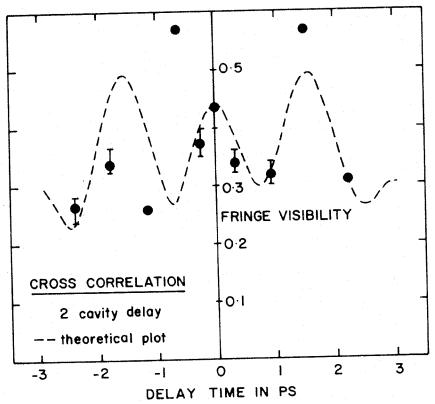

Fig. 12. Theoretical and experimental fringe visibilities for 2 cavity-delay cross correlation. The experimental points of Fig. 8 have been included for comparison. The theoretical curve was obtained by extrapolation of the analysis for 1 cavity-delay cross correlation with the parameter values calculated for Fig. 10.

phase dispersion, which tends to indicate that the pulses in the latter part of the train of such quasi-continuous pulse trains are almost identical in phase.

Since, as was pointed out earlier, the experimental curve for cross correlation between pulses that are two cavity transit times apart should be taken only qualitatively (see Section III), we did not carry out explicit numerical analysis. Instead, we have assumed that in the region of the pulse train investigated, the phase dispersion and bandwidth modulation between any two successive pulses remain the same. Hence we extrapolated our analysis for one cavity delay correlation by taking the relative phase dispersion to be $2\Delta\chi$ and the net ratio between bandwidths to be r^2. The resulting FV is plotted in Fig. 12 together with the data points. The agreement between these two curves lends some degree of confidence to the techniques of analysis.

The train of pulses produced by a mode-locked Nd:glass laser have been difficult to measure and analyze because of the short duration of the pulse train, the rapid variation from pulse to pulse, and the fact that they possessed subpicosecond substructure and internal frequency chirping. It is shown in this paper that the auto- and cross-correlation data obtained by time-resolved linear interferometry can make it possible to determine accurately the changes in mode phase and amplitude taking place from pulse to pulse. If the initial pulses are measured to be minimum bandwidth pulses, as they are in most systems, then the succeeding pulses are consequently known. As a result, the method of measurement and analysis presented here is especially valuable for determining the form of the output pulses from a Nd^{3+}:glass mode-locked laser system.

Correspondence

Generation of a Short Optical Pulse of Arbitrary Shape and Phase Variation

ELI YABLONOVITCH

Abstract—**It is shown that the problem of generating an optical pulse of arbitrary shape and phase may be reduced to the problem of producing an arbitrary spectral filter. This generalizes the short-pulse generation techniques, which are based on the laser breakdown switch, as the active element. We examine the extent to which any desired filter may be realized in practice, and some examples are given.**

INTRODUCTION

In recent years there has been great progress in the generation of short optical pulses by techniques that do not depend upon mode locking. Instead, they depend on the laser breakdown switch [1] which cuts off transmission with a fall time in the picosecond range. This step function is then converted into a short optical pulse by transmission through an appropriate spectral filter as shown in Fig. 1.

Among the types of optical filters which have been suggested are the Michelson interferometer [2], the Fabry–Perot etalon [3], the grating monochromator [4], and resonant-material absorbers [5]. Each of these filters produces a pulse with a characteristic shape and phase variation. In this correspondence we will turn the problem around: For a given pulse shape we will derive the specific spectral transmittance function which is required to generate it.

Thus the problem of generating an optical pulse of arbitrary shape and phase may be reduced to the problem of producing an arbitrary spectral filter. Furthermore, we will examine the extent to which any desired filter may be realized in practice.

Fig. 1 is a block diagram showing the basic concept of short-pulse generation from a laser spark. A long-pulse laser produces a breakdown plasma between a lens pair. This blocks off transmission of the beam, thereby amplitude modulating it. In the frequency domain, sidebands are associated with the amplitude modulation. The spectral filter rejects the incident laser wavelength but transmits the sidebands produced at the instant of breakdown. After the plasma has fully formed, again nothing is transmitted. Thus a step function is converted into a short pulse.

THEORY

Let $E(t)$ represent the incident laser pulse whose duration is assumed to be much longer than any of the other times of interest in this problem. We will choose $t = 0$ as the instant at which the plasma forms, blocking off the beam. Then the electric field of the light wave transmitted through the lens pair may be represented as

$$E(t) = 1, \quad \text{for } -\infty < t < 0$$

$$E(t) = 0, \quad \text{for } 0 < t < \infty \tag{1}$$

i.e., a step-function amplitude modulation. This electric field

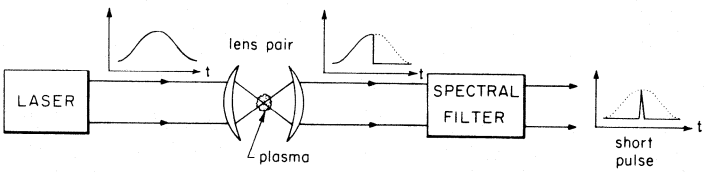

Fig. 1. A block diagram of the basic laser breakdown pulse-shaping scheme. The spectral filter rejects all but the plasma-induced sidebands on the laser pulse.

may also be written in terms of its Fourier amplitude

$$E(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} E(t) \exp(i\omega t)\, dt$$

$$E(\omega) = \frac{1}{\sqrt{2\pi} i\omega}. \tag{2}$$

(In this correspondence, the factor $\exp\{i\omega_0 t\}$ in the time dependence of the electric field will be suppressed. Frequencies ω are generally measured relative to ω_0, the center frequency of the laser, unless otherwise noted.)

From (2) we see that the sidebands of the step-function amplitude modulation fall off inversely with the frequency shift from line center.

Let $G(\omega)$ represent the electric-field spectral transmittance function of the optical filter. $G(\omega)$ has both an amplitude and a phase and should be distinguished from the intensity transmission function $|G(\omega)|^2$ which has no phase information. The output electric field in the frequency domain $E_0(\omega)$ is then simply $G(\omega)\, E(\omega)$ or, using (2),

$$E_0(\omega) = \frac{G(\omega)}{\sqrt{2\pi} i\omega}. \tag{3}$$

The output pulse in the time domain is simply the inverse Fourier transform of (3).

Equation (3) determines the output field amplitude for a given spectral transmittance function. The relationship may readily be inverted

$$G(\omega) = \sqrt{2\pi} i\omega E_0(\omega). \tag{4}$$

This tells us the function G, which is required to produce a desired output pulse of Fourier amplitude $E_0(\omega)$. Equation (4) is the central result of this correspondence. It may also be written

$$G(\omega) = \int_{-\infty}^{\infty} \exp(i\omega t) \frac{dE_0(t)}{dt}\, dt \tag{5}$$

which expresses $G(\omega)$ directly in terms of the output field in the time domain $E_0(t)$.

To satisfy causality, $G(\omega)$ must be analytic in the upper half-plane. This requires $([dE_0(t)]/dt) = 0$ for $t < 0$; i.e., no change in output until the spark forms. We will make the stronger restriction $E_0(t) = 0$ for $t < 0$, thereby both satisfying causality and demanding that $G(0) = 0$. This last condition ensures that the incident laser beam does not leak through the filter in the absence of a spark.

EXAMPLES

a) What spectral filter is required to produce a δ-function pulse? A δ-function pulse has Fourier amplitude $E_0(\Delta\omega)$ = constant, independent of frequency over its bandwidth. (In this section we will use the sumbol $\Delta\omega$ to distinguish relative frequency from absolute frequency ω; i.e., $\Delta\omega = \omega - \omega_0$.) Using (4) the transmittance function should be

$$G(\Delta\omega) = \sqrt{2\pi}\, i\Delta\omega \times \text{constant}. \tag{6}$$

Thus we require a filter whose transmittance is linearly proportional to the frequency difference from the laser frequency. It turns out that a quarter-wave antireflection coating, when used in reflection, has precisely this behavior over a wide bandwidth (see Fig. 2)

$$\text{reflection coefficient} = \frac{E_R}{E_{in}} = \frac{1-n}{1+n}\left[1 + \exp\left\{\frac{i2nt\omega}{c}\right\}\right]. \tag{7}$$

Using the condition for zero reflection at the laser frequency, (7) becomes

$$\frac{E_R}{E_{in}} = \frac{1-n}{1+n}\left[1 - \exp\left\{\frac{i\pi\Delta\omega}{\omega_0}\right\}\right].$$

If $\Delta\omega \ll \omega_0$, then we may expand the exponential in a power series keeping only the first two terms

$$\frac{E_R}{E_{in}} = i\pi\frac{(1-n)}{(1+n)}\frac{\Delta\omega}{\omega_0} \tag{8}$$

which is the required functional form.

It is interesting to note in passing that a filter described by (8), or equivalently (6), is an optical differentiator. Its output is the time derivative of its input. This is proven in the Appendix.

b) What spectral filter is required to produce a rectangular pulse of duration T? Such a pulse has a Fourier amplitude

$$E_0(\Delta\omega) = \frac{1}{\sqrt{2\pi}i\Delta\omega}\left[\exp(i\Delta\omega T) - 1\right].$$

Therefore, the required spectral transmittance function is

$$G(\Delta\omega) = \sqrt{2\pi}\, i\Delta\omega E_0(\Delta\omega) = \left[\exp(i\Delta\omega T) - 1\right]. \tag{9}$$

A Michelson interferometer [2], used as shown in Fig. 3, and adjusted for destructive interference of the output beam, satisfies (9). In particular

$$\frac{E_0}{E_{in}} = \left[1 - \exp(i\omega T)\right] = \left[1 - \exp(i\omega_0 T)\exp(i\Delta\omega T)\right].$$

Destructive interference at the laser frequency requires $\exp\{i\omega_0 T\} = 1$, where T is the difference in optical path between the two arms of the interferometer. Therefore, the Michelson interferometer satisfies (9).

c) What spectral filter is required to produce an exponentially decaying pulse of time constant τ? Such a pulse has a Fourier amplitude

$$E_0(\Delta\omega) = \frac{\tau}{\sqrt{2\pi}\,(1 - i\Delta\omega\tau)}.$$

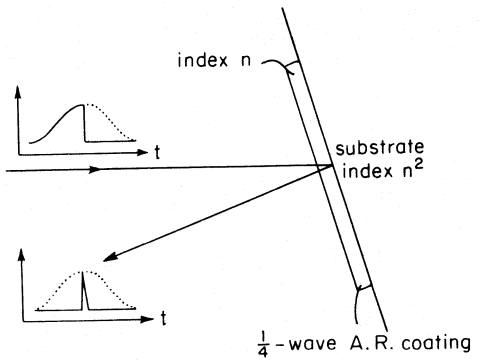

Fig. 2. A quarter-wave antireflection coating, when used in reflection, acts as an optical differentiator (see Appendix). It converts the step function into a δ-function pulse.

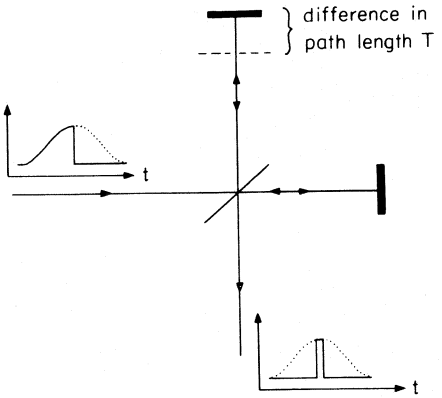

Fig. 3. A Michelson interferometer is used to generate a rectangular pulse of duration T which is the difference in path length between the two arms of the interferometer.

Therefore, the required spectral transmittance function is

$$G(\Delta\omega) = \sqrt{2\pi}\, i\Delta\omega E_0(\Delta\omega) = \frac{i\Delta\omega\tau}{1 - i\Delta\omega\tau}. \tag{10}$$

Such an optical filter may be realized as shown in Fig. 4. It requires two filter elements in series, the $G(\Delta\omega)$ of the combination being the product of the individual G's. One element is simply an optical differentiator (see the Appendix), such as the quarter-wave antireflection coating which supplies the factor $i\Delta\omega$ to the numerator. The other element is a Michelson interferometer, this time adjusted for equal-length arms. In one of the arms is an optically thin, homogeneously broadened, resonant absorber. It is readily shown that such an element contributes the factor $(1 - i\Delta\omega\tau)$ in the denominator of (10). The homogeneous linewidth of the absorber is $1/\tau$. If it is off-resonance, then an oscillatory decaying pulse is produced. A somewhat different pulse shape was recently generated by using an optically thick resonant medium as the filter [5].

DISCUSSION

The previously given examples are meant to indicate the generality of the pulse-shaping approach being proposed here. Since spectral filters are linear elements, many of them may be combined in series to produce the required transmittance function. There is great versatility in using media, both resonant and nonresonant, as filtering elements.

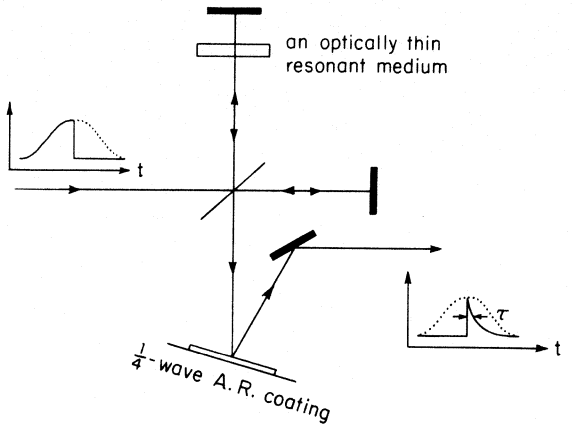

Fig. 4. A composite filter element, consisting of a Michelson interferometer and a quarter-wave antireflection coating used in series. An optically thin resonant medium of homogeneous linewidth $1/\tau$ unbalances one of the arms of the interferometer. The output is an exponentially decaying pulse of time constant τ.

A type of filter which was not mentioned in the previously given examples, but which has great potential, is the multilayer dielectric-coated interference filter. These are now mainly used in bandpass applications, for which only $|G(\omega)|^2$ is important. If designed to take account of both the phase and amplitude of $G(\omega)$, they could be used in pulse-shaping applications. It should be possible to closely approximate any given function by using enough layers. Complicated pulse shapes, such as those which have been proposed for laser fusion [6], may require computer design to optimize the layer spacing and other parameters.

Practical Limitations

There are, of course, practical limitations to these pulse-generation techniques. For example, many of the filters which we have been discussing have the property of zero transmission at the center laser wavelength; i.e., $G(0) = 0$. This is important for rejecting the laser light at $t < 0$ before the breakdown spark has formed. In practice, a perfect null is not always possible and the rejection may not be 100-percent complete.

Another limitation is related to the finite fall time T of the light as it passes through the breakdown plasma. Equation (1) assumes an instantaneous fall time, which is only approximate. In particular, (2) is correct only for frequency shifts $\Delta\omega \lesssim 1/T$. Therefore, the techniques described in this correspondence are useful for generating pulses whose overall frequency spectrum is no wider than $2/T$. Understandably, it is not possible to generate pulses which are shorter than the fall time T. Recent measurements indicate that T is in the picosecond range for CO_2-laser-produced plasmas. There is speculation that even faster fall times are possible.

Conclusion

We have shown that the problem of generating an arbitrary optical pulse $E(t)$ may be reduced to the problem of producing a matched filter as given by (5). Some examples of specific pulse shapes and their matching filters were also presented.

Appendix

We wish to show that a filter whose spectral transmittance function is described by (6) acts as an optical differentiator. By definition

$$E_{\text{out}}(\omega) = \sqrt{2\pi}\, i\omega E_{\text{in}}(\omega).$$

Taking the inverse Fourier transform

$$E_{\text{out}}(t) = \int_{-\infty}^{\infty} i\omega \exp(-i\omega t)\, E_{\text{in}}(\omega)\, d\omega$$

$$= -\frac{d}{dt}\int_{-\infty}^{\infty} \exp(-i\omega t)\, E_{\text{in}}(\omega)\, d\omega$$

$$= -\frac{d}{dt} E_{\text{in}}(t).$$

Therefore, the output of such a filter is the time derivative of its input. Several such filters may be used in series to obtain higher order derivatives.

Excitation of Cold Cavity Modes in a Coupling-Modulated CO_2 Laser

A. L. SCHOLTZ

Abstract—**The amplitudes of cold longitudinal cavity modes excited as an unwanted side effect of coupling modulation were studied in a CO_2 laser. Experimental observations agree well with the results of an analytical approach treating the effect of coupling modulation on the cavity field as loss modulation.**

Introduction

Intracavity coupling modulation [1] is an efficient method to modulate CO_2 lasers [2]–[4]. With this modulation scheme, the unwanted excitation of cold cavity modes is of particular interest [5], [6]. Cold modes are longitudinal modes of the optical resonator which do not coincide with the laser transition. They can be excited by any kind of intracavity modulation if the modulating frequency f_m is approximately an integer multiple of the cavity mode spacing $c/2l$ (l

Manuscript received February 25, 1975; revised May 20, 1975. This work was supported by the Fonds zur Förderung der wissenschaftlichen Forschung as part of project Elektronik in Nachrichtentechnik und Automatisierung.

The author is with the Institut für Hochfrequenztechnik, Technische Hochschule, Vienna, Austria.

is the optical length of the cavity). In the case of coupling modulation, the cold modes distort the modulated output signal by reducing the sideband amplitude, as has been observed in He–Ne lasers [7]. However, no experimental data concerning inherently single-mode lasers, such as the CO_2 laser, have been reported up to now. This correspondence reports on the first experimental study of the excitation of cold modes by coupling modulation of the CO_2 laser. In particular we investigate the relative amplitudes of the cold modes adjacent to the active mode. A theory is presented which predicts these amplitudes in good agreement with the experimental observations.

Theory

The well-known scheme of coupling modulation [1] is shown in Fig. 1. The relation between the optical field $E_i \cos \omega t$ incident on the modulator and the perpendicular field component E_c produced after two passes through the modulator is [6]

$$E_c(t) = E_i \sin \Gamma(t) \sin \omega t. \tag{1}$$

Here $\Gamma(t)$ is the single-pass phase retardation induced by the modulating signal via the electrooptic effect. The power extracted from the incident optical field follows as:

$$P_c(t) = \tfrac{1}{2}\,[1 - \cos 2\Gamma(t)] \quad P_i = c_m(t)\,P_i \tag{2}$$

where P_c and P_i correspond to E_c and E_i, respectively, and c_m is the coupling coefficient. Evidently, coupling modulation introduces time-varying cavity losses. This suggests extension of the theory of loss modulation, as derived by McDuff and Harris [8], to calculate the amplitudes of the cold modes which are excited by coupling modulation as an unwanted side effect. Without loss of generality, calculations can be restricted to the lowest resonant modulation frequency $f_m \doteq c/2l$.

For sinusoidal modulation with a voltage $V(t) = V_0 + V_m \sin \omega_m t$ applied to the modulator, the phase retardation is

$$\Gamma(t) = \Gamma_0 + \Gamma_m \sin \omega_m t \tag{3}$$

and, with (2) and (3), the coupling coefficient becomes

$$c_m(t) = \tfrac{1}{2}\,[1 - J_0(2\Gamma_m) \cos (2\Gamma_0)] + J_1(2\Gamma_m) \sin (2\Gamma_0) \sin \omega_m t - \cdots. \tag{4}$$

The single-pass power loss introduced by the modulator $\alpha_m(t)$ may be defined in the form

$$\alpha_m(t) = \alpha_a(1 + m \sin \omega_m t) \tag{5}$$

where α_a is the time-average single-pass power loss introduced by the modulator and m is the depth of the time-dependent loss variations. For $\Gamma_0, \Gamma_m \ll 1$, (2), (4), and (5) yield

$$\alpha_a = [1 - J_0(2\Gamma_m) \cos (2\Gamma_0)]/4 \tag{6}$$

and

$$m = 2J_1(2\Gamma_m) \sin (2\Gamma_0)/[1 - J_0(2\Gamma_m) \cos (2\Gamma_0)]. \tag{7}$$

Note that m is equal to the depth of modulation of the coupled-out signal when no coupling to cold modes takes place, as can be seen from (7) and (4). Now assuming that the single-pass power loss α of the cavity does not depend on the frequency, further, that the modulator is located near one of the cavity mirrors (see Fig. 1), a calculation similar to [8] can be performed. The two cold modes next to the active one, both having the same amplitude E_1, are of main interest; all others are negligible if one considers only first-order effects. One obtains

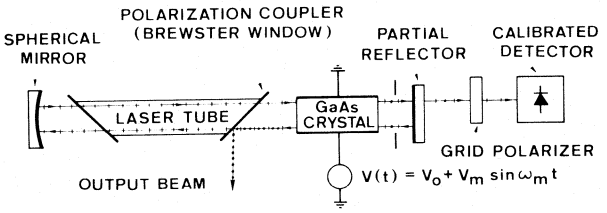

Fig. 1. Experimental setup used for cold-mode coupling measurements. States of polarization parallel and perpendicular to the laser oscillation are indicated by dashes and dots, respectively. A conventional coupling modulation arrangement is modified by replacing the flat mirror by a 6.1-percent transmission partial reflector. A small fraction of the cavity field is passed through a grid polarizer to a SAT HgCdTe detector, whereas the modulated signal beam is directed to an absorber. In order to prevent oscillation of higher order transverse modes, an aperture of 3-mm diameter is inserted near the partial reflector.

$$\frac{E_1}{E_0} = \frac{\alpha + \alpha_a}{m\alpha_a} - \left(\left(\frac{\alpha + \alpha_a}{m\alpha_a}\right)^2 - 1\right)^{1/2} \tag{8}$$

where E_0 is the amplitude of the active mode. For $\alpha_a \ll \alpha \ll 1$, (8) takes the simple form

$$E_1/E_0 = m\alpha_a/(2\alpha). \tag{9}$$

In this limit, E_1/E_0 increases linearly 1) with the modulation depth m of the introduced loss and 2) with the ratio of the average introduced loss α_a to the cavity loss α.

For modulation frequencies other than the resonant one, E_1/E_0 decreases according to the frequency response of the cold cavity [5].

Experiment

The relative amplitudes of the cold modes were measured in an experimental setup shown in Fig. 1. A CO_2–N_2–He laser containing a water-cooled flowing-gas discharge tube (500-mm active length, 10-mm inside diameter (ID), 10-torr total pressure, 10-mA discharge current) was used. The optical resonator (length 1080 mm) consisted of a spherical mirror and a plane 6.1-percent transmission partial reflector. A Lansing lock-in stabilizer was used to maintain stable operation at the center of one molecular transition. The modulator consisted of a $5 \times 5 \times 50\text{-mm}^3$ GaAs crystal. The fact that one mirror is a partial reflector has no effect on the modulation mechanism other than increasing the cavity loss to a total of $\alpha = 0.29$.

A fraction of the cavity field emerges through the partial reflector and contains components polarized parallel and perpendicular to the active mode, as indicated in Fig. 1 by dashes and dots, respectively. The presence of cold modes in the cavity results in amplitude modulation of the parallel component. In order to isolate this effect, the perpendicular component is suppressed by an IGP 225 grid polarizer. Keeping in mind that $E_1/E_0 \ll 1$, a square-law detector can be used to measure E_1/E_0. A SAT HgCdTe detector, type C1, served for this purpose and had been calibrated [9] previously in an external modulation setup.

Fig. 2 shows the results of typical measurement runs. Choosing $V_0 = 300$ V and $V_m = 177$ V ($V_m = 78$ V) one obtains $m = 1$ ($m = 0.5$) and $\alpha_a = 6.1 \times 10^{-3}$ ($\alpha_a = 5.4 \times 10^{-3}$) with the electrooptic data of GaAs as given in [10]. Here and in the following, values in parentheses correspond to $m = 0.5$. The measured relative cold-mode amplitudes versus frequency indicated by circles closely follow the normalized frequency response of the cavity, calculated for $\alpha = 0.29$. The resonant values of $E_1/E_0 = 0.0170$ ($E_1/E_0 = 0.0079$) are higher than the calculated maxima $E_1/E_0 = 0.0103$ ($E_1/E_0 = 0.0046$). The

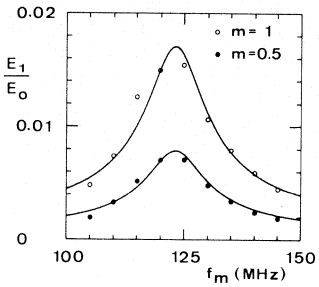

Fig. 2. Relative cold-mode amplitude E_1/E_0 versus frequency. The cases $m = 1$ ($m = 0.5$) correspond to $V_m = 177$ V ($V_m = 78$ V) and to $\alpha_a = 6.1 \times 10^{-3}$ ($\alpha_a = 5.4 \times 10^{-3}$), with $V_0 = 300$ V kept constant. The single-pass cavity power loss was $\alpha = 0.29$. Measured values indicated by circles closely follow the frequency response of the cold laser cavity calculated for this power loss and normalized for best fit.

difference is probably due to the finite extinction ratio [11] of the external modulator used to calibrate the detector; it is readily explained assuming an extinction ratio of some 600, which agrees well with the data for GaAs given in [11]. This explanation is further supported by the following observation: The ratio of the values of E_1/E_0 associated with $m = 1$ and $m = 0.5$, respectively, was measured to be 2.15 in good agreement with 2.24, which results from (8).

From the preceding one can conclude that the presented approach predicts the amplitudes of cold modes excited by coupling modulation with good accuracy. The results of the analysis should prove useful in the design of low-distortion wide-band communication systems.

ACKNOWLEDGMENT

The author wishes to thank Dr. E. Bonek and Dr. G. Schiffner for stimulating discussions.

A Comment on the Theory of Mode Locking and Frequency Doubling

C. J. KENNEDY

Abstract—**The time-domain theory of the mode-locked and frequency-doubled laser by J. Falk depends greatly on the particular Gaussian approximation to the pulse transmitted from the frequency doubler. This correspondence examines an alternative approximation which appears to be a better fit to the actual pulse shape and which gives substantially different results for pulsewidth.**

Probably the most important aspect of any theory which proposes to explain the characteristics of the mode-locked and intracavity frequency-doubled laser is that which predicts the pulsewidth given the depth of modulation of the mode locker and other laser parameters. For communication system purposes, the pulsewidth is defined at a low relative intensity such as $1/e^2$, or 10-percent power width, because pulse-gating modulation techniques lose efficiency rapidly when the gate width is less than $1/e^2$, or 10-percent width of the laser pulse.

The time-domain approach to this laser system involves the balancing mechanisms for a hypothetical pulse making a round trip in the laser cavity. Let us refer our time coordinate to the center of the pulse ($t = 0$) and assume for simplicity that the round-trip time of the pulse is synchronized with the peak transmission of the loss modulator. Also let us assume that the gain medium has a negligible tendency to broaden the pulse. *It is a general rule that the total losses as a function of time referred to the center of the pulse must be constant for a steady-state pulse of whatever shape* [3]. Otherwise the shape of the pulse will vary with time until a steady state is reached. Mathematically, this relation may be stated as

$$\alpha + \alpha_{ML}(t) + \alpha_{FD}(t) = g \tag{1}$$

where α represents continuous losses, α_{ML} is the time-dependent mode-locker loss, α_{FD} is the time-dependent frequency-doubler loss, and g is the saturated gain. (All are single-pass power quantities.) The time dependance of α_{ML} and α_{FD} may be expanded in a power series, but we shall retain only the second order in t. It has been shown by Kuizenga and Siegman [1] that

$$\alpha_{ML}(t) \simeq \delta_l \omega_m^2 t^2/2 \tag{2}$$

where δ_l is the modulation depth and ω_m is $2\pi C/2L$.

However, α_{FD} depends on the exact functional form of the incident and transmitted pulses to the frequency doubler. Since the peak losses in intracavity frequency doubling are very small (~0.5 percent), it is reasonable to approximate with a Gaussian pulse both the input and output of the doubler. There are several ways to choose the Gaussian fit to the output. The loss is proportional to the intensity of the input pulse and, for small conversion efficiency, one obtains Falk's [2] analysis

$$I'(t) = I(t)\,[1 - (k/2)^2 I(t)]^2 \tag{3}$$

where $I(t)$ is the intensity envelope of the mode-locked pulse. If $I(t)$ is Gaussian, then the output $I'(t)$ must be approximated by a Gaussian. Letting

$$I(t) = I_0 e^{-2\gamma t^2} \tag{4}$$

Manuscript received March 4, 1975; revised May 16, 1975.

The author is with the Advanced Development Program 405B, Space Laser Communications, U.S. Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio 45433.

we show in Fig. 1 the incident and transmitted pulses for an exaggerated conversion efficiency of 38 percent to show the effects of various fits to the non-Gaussian $I'(t)$. The curve labeled "output" is the approximation of (3) to the actual shape, which is a sech^2 function.

Falk fits this function with a Gaussian that matches the height and curvature of $I'(t)$ at $t = 0$. This fit is shown against $I'(t)$ in Fig. 1 and is labeled "Fit 1." Fit 1 is a better match than it appears in Fig. 1, because, for small conversion efficiency, the mismatch in height is much less. However, Fit 1 is considerably broader at the $1/e^2$ points than $I'(t)$. The excess broadening of Fit 1 remains significant even for the more realistic conversion efficiency of 1 percent, although the percentage of broadening per pass is reduced. Since the action of the frequency doubler to broaden pulses is balanced exactly by the loss modulator in the steady state, a slight excess broadening may be significant when it is to be balanced against a small loss modulation depth. Consequently, we would expect the broadening tendencies of the frequency-doubler model to be greater than the real world. The fitted function is

$$I_f(t) = I_0 e^{-k^2 I_0/2}\, e^{-2\gamma(1-k^2 I_0/2)\, t^2}. \tag{5}$$

The time-dependent loss is then

$$\alpha_{SH}(t) = k^2 I_0/2 - k^2 I_0 \gamma t^2. \tag{6}$$

Substituting into (1), we find that this expression becomes independent of t when

$$\frac{\delta_e \omega_m^2}{2} = k^2 I_0 \gamma. \tag{7}$$

If we note that

$$\alpha_{SHG} = \frac{k^2 I_0}{2\sqrt{2}} \tag{8}$$

we have

$$\gamma = \frac{\delta_l \omega_m^2}{4\sqrt{2}\,\alpha_{SHG}} \tag{9}$$

and since the 10-percent full-frequency-doubled pulsewidth is

$$\tau_g = \sqrt{\frac{\ln 10}{\gamma}} = \frac{2\sqrt{\sqrt{2}\ln 10}}{\omega_m}\left(\frac{\alpha_{SHG}}{\delta_l}\right)^{1/2} \tag{10}$$

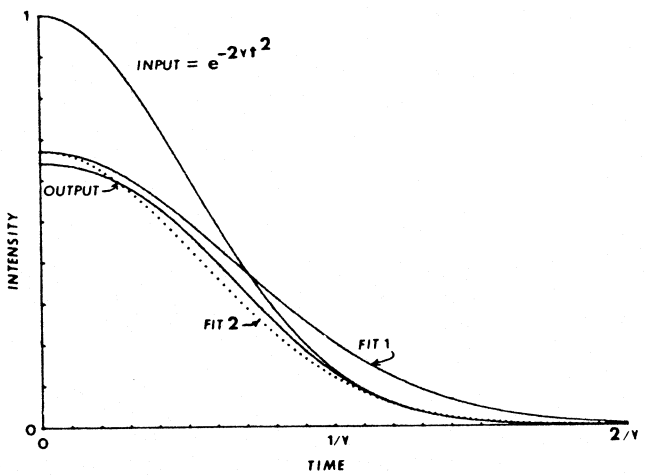

Fig. 1. Gaussian approximations to the transmitted pulse of the frequency doubler. The functions of the output pulse, Fit 1, and Fit 2 are given in the text.

which is precisely Falk's result, in the limit that gain–bandwidth broadening is negligible in comparison with frequency-doubling broadening.

However, if we were to choose a fitted Gaussian which matched $I'(t)$ closely at both $t = 0$ and the $1/e^2$ point, one might obtain what we refer to as "Fit 2" in Fig. 1, or

$$I_f(t) = I_0 e^{-k^2 I_0/2}\, e^{-2\gamma(1-k^2 I_0/6) t^2}. \tag{11}$$

Now α_{SH} is

$$\alpha_{SH}(t) = k^2 I_0/2 - k^2 I_0 \gamma t^2/3 \tag{12}$$

from which we obtain

$$\tau_g = \frac{2}{\omega_m}\sqrt{\frac{\sqrt{2}\ln 10}{3}}\left(\frac{\alpha_{SHG}}{\delta_l}\right)^{1/2} \tag{13}$$

which is $1/\sqrt{3}$ times the pulsewidth obtained for Fit 1.

In conclusion, the theoretical pulsewidth seems to be very sensitive to the curve fit employed. The final word must come from a general analysis or a careful experiment to determine the coefficient of $(\alpha_{SHG}/\delta_l)^{1/2}/\omega_m$. A more exact analysis has been performed by Bernecker [3] which deserves consideration since a Gaussian pulse is not assumed. However, Bernecker's theory ignores the effect of gain broadening and possible etalon effects, which occur in practical laser systems, which will alter the functional form of the pulse.

Holocoupler: A Novel Coupler for Optical Circuits

H. NISHIHARA, S. INOHARA, T. SUHARA, AND J. KOYAMA

Abstract–**A novel type of optical coupler, which is based on the principle of holography, is designated as "holocoupler," and the potentiality of application is stressed. The holocouplers for optical fibers are fabricated for demonstration, and the experimental results are presented.**

Recent developments of optical communication systems require various types of couplers for optical devices, such as light-emitting sources, transmission circuits and lines, modulators, and detectors. Optical couplers currently in use may be classified into three groups: 1) direct couplers; 2) wave-vector converting couplers; and 3) wavefront converting couplers. The prism coupler [1] and the grating coupler [2] may belong to group 2), and the holocoupler is a typical example of group 3). "Holocoupler" has been given by the authors as a general name for couplers whose working principle is based on holography. The idea of holographic coupling and resolution capabilities have been demonstrated for a thin-film waveguide by Ash *et al.* [3], whereas the holographic mode discriminator [4] has been proposed for optical fibers. The purpose of this

Manuscript received March 24, 1975; revised June 5, 1975.

The authors are with the Faculty of Engineering, Osaka University, Suita, Osaka, Japan.

correspondence is to point out some interesting properties of the holocoupler, and to report some experimental results when holocouplers were used as direct coupling elements for optical fibers.

The holocoupler corresponds to the hologram in holography, and therefore the feature of the wavefront conversion is attributed to the holographic principle. Just as the reference wave is diffracted into the signal wave by a hologram, the wavefront of the input signal is converted into that of the output signal by a holocoupler, as shown in Fig. 1, where the wavefronts of the input and output signals are not necessarily planar or spherical, but can be arbitrary. Because of this wavefront-conversion property, the feasibility of various performances can be expected of the holocoupler. Some of the properties are as follows.

1) Easy fabrication of lens holocoupler of the arbitrary F number and the arbitrary focal length.

2) The mode-conversion holocoupler, which can convert, for example, the modes of an optical fiber of the round cross section into those of a thin-film integrated circuit.

3) The mode-filter holocoupler: the wave-conversion efficiency is low when the illuminating wavefront is other than what has been used for making the hologram.

4) The sharp-corner holocoupler, as shown in Fig. 2(a).

5) The multibranching holocoupler, which can couple one line into several lines of a different cross section, as shown in Fig. 2(b).

6) Compound holocouplers, which reduce the requirement of accurate alignment for line connection, as shown in Fig. 2(c).

In addition, replicas of a holocoupler can be easily produced only by the optical method [5], and the copying method provides some degree of freedom for choosing the material and the light source.

Since the highest diffraction efficiency may be expected in a hologram of the volume and phase type [6], the conversion efficiency of the holocoupler of this type has been approximately analyzed for the arrangement, as shown in Fig. 1, by means of the coupled-mode technique. It has been found that one can theoretically predict a maximum value of 100 percent by choosing the appropriate values of the relevant parameters. These values will be reported elsewhere.

Here two typical holocouplers are briefly described, with some preliminary experimental results for demonstration. We have used the materials and techniques of holography for fabrication.

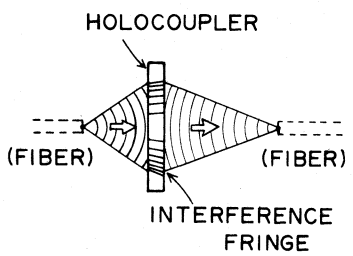

Fig. 1. Illustration of the principle of the holocoupler.

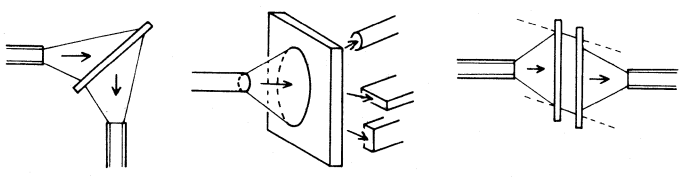

Fig. 2. Several types of holocouplers. (a) Sharp-corner holocoupler. (b) Branching holocoupler. (c) Compound holocoupler with accurate alignment not required.

The first example is a branching holocoupler for coupling a multimode fiber with two fibers, as shown in Fig. 3(a). The input and output fibers are arranged so that this holocoupler may also have the property of a sharp-corner holocoupler. In fabrication, a He–Ne laser beam was divided into three beams: one beam was made diverging and the other two were made converging by lenses in such a way that each beam may have the same cone angle as that of a beam emerging from each fiber end which is to be coupled. Unfortunately, the holocoupler cannot be made practical by using the radiation field from a multimode fiber because of the random mutual interference of a few hundred modes during the exposure time. The authors, however, have found theoretically that the conversion efficiency is reduced by only less than 1 percent, even if a hologram fabricated by a spherical reference wave is illuminated by a diverging wave from a multimode fiber. The material used was a high-resolution photographic plate (Kodak 649F) with a gelatin thickness of 15 μm. The plate was bleached after processing. A photograph of the resulting output pattern is shown in Fig. 3(b). The conversion efficiency for each output beam is approximately 15 percent.

The second example is a mode-conversion holocoupler—that is, a holocoupler between a fiber and an optical integrated circuit, as shown in Fig. 4. The material used was the amorphous semiconductor films of As_2S_3. The 5145-Å line of an Ar-ion laser was used for fabrication, and the 6328-Å line of a He–Ne laser was used for coupling. The beam from a fiber of 100-μm diameter was successfully converted into a beam of 150 × 800-μm^2 rectangular cross section, as shown in Fig. 4(b), with a conversion efficiency of approximately 20 percent.

In spite of the theoretical prediction, unfortunately, the maximum available conversion efficiency would be 60 percent at most, in practice, which is less than the value reported in direct coupling. Therefore, the holocoupler would be better

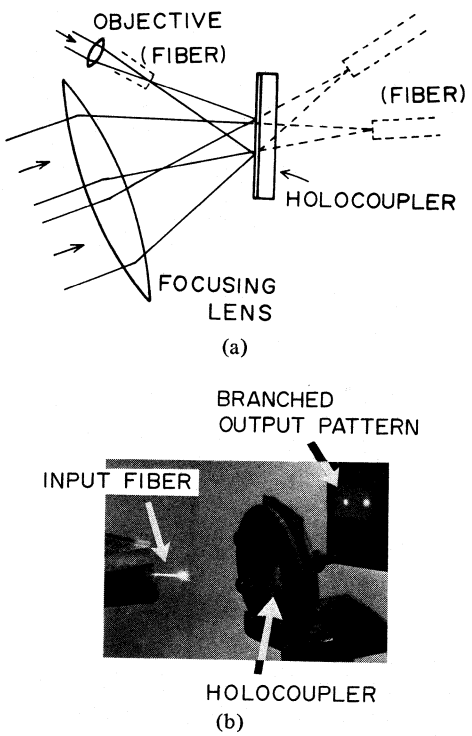

Fig. 3. The branching holocoupler. Fiber diameter: 100 μm; light-emitting cone angle: 6°; size of holocoupler: 4 mmϕ; the output-beam diameters were measured to be less than 100 μm. (a) Fabrication arrangement. (b) Coupling arrangement.

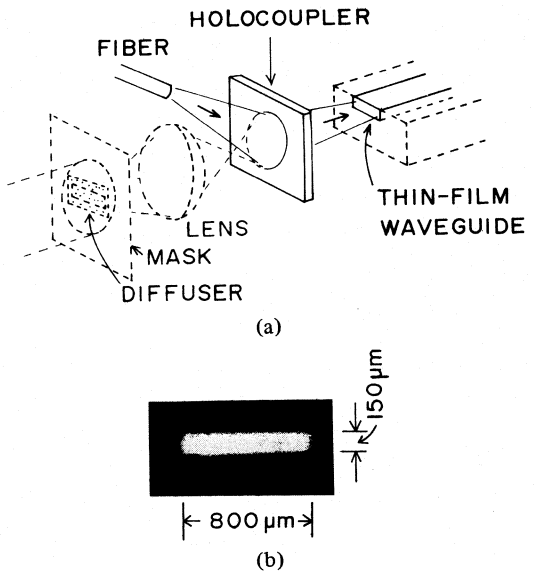

Fig. 4. The holocoupler for a fiber and an optical integrated circuit. Some of the optical components used for fabrication are drawn by dotted lines in (a). (a) Coupling arrangement. (b) Output pattern.

applied to complex wavefront-converting processes, as, for example, the conversion from a light-emitting diode (LED) or a semiconductor injection laser to a fiber, since the conversion efficiency would be much improved compared with the amount (the order of 1 percent) that is attained by the direct-coupling method. In the process of fabrication, the recently developed technique of computer-generated holograms and kinoforms should be taken into consideration, thus providing more possibilities of various types of holocouplers. Since the holocoupler has the capability of making feasible the complicated and functional couplings of optical fibers, integrated circuits, and elements, it shows promise for future optical communication systems.

Coupling Considerations for Ring Resonators

ALAN C. ECKBRETH

Abstract—**Analyses of the extraction efficiency from traveling-wave (ring) resonators indicate that for media with low gain-length product ($g_0 l$), the coupling fraction from a properly designed ring resonator must be substantially lower than that employed in equivalent standing-wave (linear) configurations.**

Manuscript received April 7, 1975: revised May 7, 1975.
The author is with the United Technologies Research Center, East Hartford, Conn. 06108.

Introduction

Recently, much attention has been directed toward the use of stable [1] and unstable [2] ring resonators for both dye- and molecular-laser applications. Unstable-ring geometries are particularly attractive for large-volume molecular-laser applications because of their characteristically large mode volumes and their design flexibility in regard to the expansion optics. It is also anticipated that unstable rings will be increasingly applied to dye lasers. This follows from the order-of-magnitude increase in beam quality obtained by Ewanizky [3] employing a linear unstable resonator on a flashlamp-pumped dye laser. However, for dye-laser applications which employ intracavity tuning or spectrum-condensing elements, purely collimated beam regions are desired, such as are provided in unidirectional confocal unstable ring resonators. Freiberg *et al.* [2] have experimentally shown that the fractional output coupling exhibited by standing-wave and traveling-wave unstable-resonator configurations is the same when the equivalent Fresnel numbers, appropriately defined, are equal. However, the optical extraction efficiency from traveling-wave resonator configurations can be substantially below that obtainable in the equivalently coupled standing-wave resonator. Physically, from a wave viewpoint, this is due to the fact that, in the traveling-wave case, the optical flux makes only one pass through the active medium prior to coupling; whereas, in the standing-wave case, two passes are made through the medium prior to extraction. It is the purpose of this correspondence to compare quantitatively the extraction efficiency obtainable in traveling-wave geometries with that characteristic of standing-wave configurations and to calculate the optimum coupling to employ in traveling-wave geometries, i.e., that coupling which maximizes power extraction from the medium.

Traveling-Wave Extraction Efficiency

A generalized traveling-wave configuration is displayed in Fig. 1. Solid lines indicate reflecting elements, e.g., mirrors, denoted by M, gratings; and dashed lines indicate partially transmitting elements, e.g., windows, lenses, prisms, etalons, denoted by O. In the analysis which follows, it will be assumed that the ring is operating in a unidirectional fashion, achieved, for example, by inclusion of a feedback mirror M_S to suppress the reverse traveling wave. The output coupler C would normally be provided by either a partially transmitting reflector (stable geometries) or an annular coupler (unstable configurations). In the latter case, the degree of coupling is determined by the magnification and equivalent Fresnel number in accordance with [2] and [4]. In the active medium, the traveling waves will be assumed to be collimated (e.g., confocal unstable rings) and having a uniform intensity profile. The analysis will be similar to that of Rigrod [5] for standing-wave geometries.

In Fig. 2 the traveling-wave configuration of Fig. 1 is replaced by the equivalent periodic system. The active medium will be assumed to be homogeneously broadened and characterized by a spatially uniform small-signal gain g_0 and saturation parameter I_s. β is the traveling-wave flux normalized to the saturation flux. The optical elements between the output

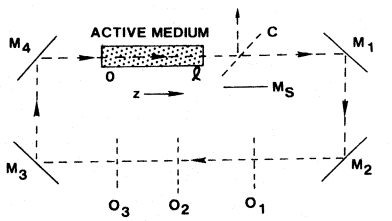

Fig. 1. Typical traveling-wave resonator configuration. Solid lines indicate reflecting elements; dashed lines partially transmitting elements. The active region is shown shaded. Unidirectional operation is achieved by means of the mirror M_S placed behind the coupler.

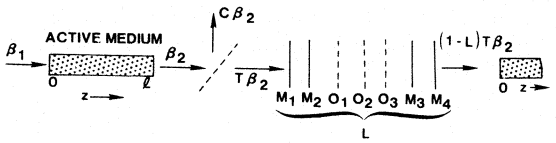

Fig. 2. Equivalent periodic system for Fig. 1 traveling-wave resonator.

coupler and active medium are lumped into a general element of loss L, or equivalently a "transmissivity" of $(1 - L)$. Integrating the gain equation (1)

$$\frac{1}{\beta}\frac{d\beta}{dz} = g = \frac{g_0}{1+\beta} \tag{1}$$

from 0 to l and applying the boundary conditions (2)

$$\beta_1 = (1 - L)T\beta_2$$
$$\beta_{\text{out}} = C\beta_2 \tag{2}$$

leads to the following expression for the normalized output flux:

$$\beta_{\text{out}} = \frac{C}{1 - T(1 - L)}\{g_0 l + \ln T(1 - L)\} \tag{3}$$

where T and C are the fractions of flux incident on the coupler which are transmitted and extracted, respectively. The extraction efficiency, i.e., the output power normalized to the total available optical power, namely $g_0 I_s A l$, where A is the cross-sectional area of the medium, is thus given by

$$\eta_e^{\text{TW}} = \frac{C}{1 - T(1 - L)}\left\{1 + \frac{\ln T(1 - L)}{g_0 l}\right\}. \tag{4}$$

It is important to note that the traveling-wave extraction efficiency would be decreased from the values calculated using (4) if loss elements are situated in the region between the output end of the active medium and the coupler. Thus it is best to configure the ring with all of the loss elements between the coupler and the input end of the active medium, i.e., in the area of least flux as shown in Fig. 1. In those instances, e.g., due to geometric constraints, where loss elements occur on either side of the coupler, the extraction efficiency becomes

$$\eta_e^{\text{TW}} = \frac{C(1 - L_1)}{1 - (1 - L_1)(1 - L_2)T}\left\{1 + \frac{\ln T(1 - L_1)(1 - L_2)}{g_0 l}\right\} \tag{5}$$

where L_1 is the lumped loss situated between the output end of the active medium and the coupler, and L_2 is the lumped loss between the coupler and input to the medium.

Extraction-Efficiency Comparisons

Following an analysis similar to that in [5] it can be shown that the extraction efficiency from the asymmetric (extraction only from one end) standing-wave resonator depicted in Fig. 3 is

$$\eta_e^{\text{SW}} = \frac{C(1 - L)\sqrt{1 - A}}{[1 - (1 - L)\sqrt{(1 - A)(1 - A - C)}]\,[(1 - L)\sqrt{1 - A} + \sqrt{1 - A - C}]}\left\{1 + \frac{\ln (1 - L)\sqrt{(1 - A)(1 - A - C)}}{g_0 l}\right\} \tag{6}$$

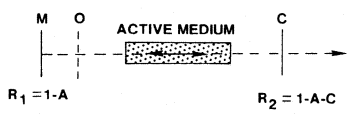

Fig. 3. Standing-wave configuration containing a discrete lumped-loss element O.

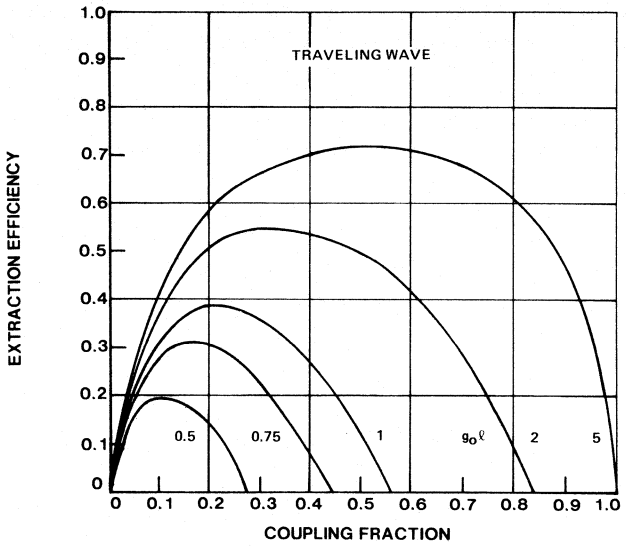

Fig. 4. Traveling-wave extraction efficiency variation with output coupling fraction for various $g_0 l$ products for Fig. 1 configuration containing only one optical element O with single-pass loss of 10 percent. All other optical elements are assumed to have an absorption loss of 1 percent.

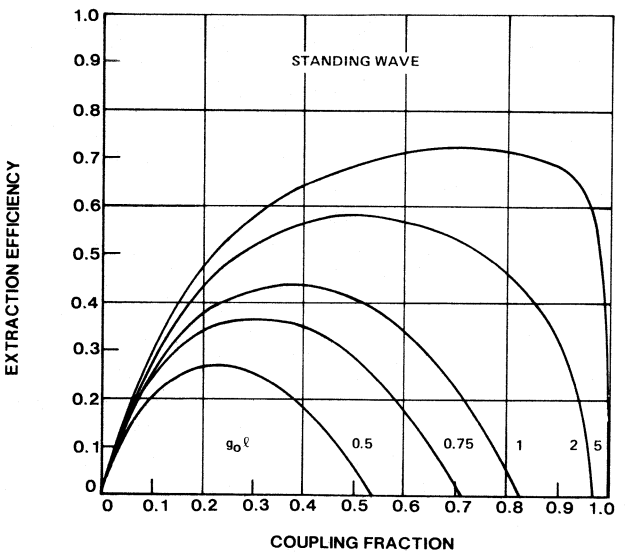

Fig. 5. Standing-wave extraction efficiency variation with output coupling for various $g_0 l$ products for Fig. 3 configuration. Optical element O is assumed to posses a single-pass loss of 10 percent. All other optical elements are assumed to have an absorption loss of 1 percent.

where C is the fractional coupling from the cavity, and L is the single-pass loss of optical element O. Both mirrors are assumed to possess equal absorption coefficients A.

As an example, Figs. 4 and 5 compare the extraction efficiencies obtainable from equivalent traveling-wave and standing-wave configurations, respectively, as a function of coupling for various (small-signal gain) (active-medium length) products. For both cases, all mirrors, including the couplers, were assumed to have an absorption coefficient A equal to 0.01. The results displayed in Fig. 4 correspond to the Fig. 1

ring configuration containing only one such optical element O, e.g., a tuning etalon, which is assumed to possess a single-pass loss of 10 percent. Hence, in (4), $(1 - L) = (0.99)^4 \cdot (0.90) = 0.86$. The Fig. 5 results for the equivalent standing-wave cavity correspond to the Fig. 3 configuration in which optical element O is assumed, as in the traveling-wave example, to have a single-pass loss L, (6), of 10 percent.

Comparing Figs. 4 and 5, it is seen that for high $g_0 l$ products (i.e., > 2), the traveling- and standing-wave cases exhibit comparable performance in regard to maximum extraction efficiency and optimal coupling. However, for low $g_0 l$ values, generally less than 2, these differences become pronounced, particularly with respect to the selection of the output-coupling fraction. The optimal-coupling fraction for the traveling-wave case is generally about half of the value found optimal in the standing-wave case. The maximum extraction efficiency obtainable in the traveling-wave configuration is decreased by about 5 percent ($g_0 l = 2$) to 25 percent ($g_0 l = 0.5$) from that obtainable in the equivalent standing-wave case. However, if the optimal coupling fraction for standing-wave geometries is employed on an equivalent $g_0 l$ traveling-wave configuration, significant decreases in extraction efficiency will occur for low $g_0 l$ media, i.e., $g_0 l < 2$. Accordingly, care must be exercised in the design of traveling-wave resonators to avoid overcoupling the active medium.

Nonradiative Relaxation of Rare-Earth Ions in Silicate Laser Glass

C. B. LAYNE, W. H. LOWDERMILK, AND M. J. WEBER

Abstract—**Rates for nonradiative decay by multiphonon emission are measured for rare-earth ions in silicate laser glass and used to estimate quantum efficiencies.**

Three important properties of lasers doped with rare-earth ions are determined by the nonradiative decay rates of the excited states of these ions. First, the pump conversion efficiency[1] is large when the nonradiative decay rate from the pump band to the upper laser level is much greater than the rate for radiative decay from the pump band. Second, for a high radiative quantum efficiency, the nonradiative decay rate from the upper laser level should be small compared to the radiative rate. And third, for a four-level laser system, the relaxation rate of the terminal laser level is important in determining the saturation flux for a laser pulse of given duration. We have determined the nonradiative decay rates for rare-earth ions doped into Owens-Illinois ED-4 glass in order to estimate these properties. ED-4, a widely used commercial laser glass, is a silicate glass modified by the addition of LiO_2, CaO, and Al_2O_3. When doped with Nd^{3+}, this glass is designated as ED-2.

The lifetime of an excited state is determined by all the competing radiative and nonradiative decay processes; the latter include decay by both ion–ion interactions and the emission of phonons. To reduce the probability of nonradiative decay by ion-pair interactions in this work, the rare-earth concentrations of our samples were less than 1 mol%. When the energy gap between the excited ionic energy level and the next-lower level is greater than the energy of the most energetic lattice vibration, the nonradiative decay must involve the emission of several phonons. The multiphonon relaxation rates among the $4f^n$ levels of rare-earth ions have been investigated in many crystals including several laser materials [2]. These studies have shown that, in these high-order processes, the detailed features of the electronic states and phonon modes involved in the transition average out. Thus the multiphonon decay is adequately described in many cases by the stimulated emission of phonons, all of a single frequency ω, leading to a decay rate of the form

$$W_{NR} = Ce^{-\alpha \Delta E}[n(\omega, T) + 1]^p \tag{1}$$

where C and α are constants characteristic of the host material, ΔE is the energy gap to the next-lower ionic level, and $p = \Delta E/\hbar\omega$ is the number of phonons which must be emitted in order to conserve energy in the transition. The explicit temperature dependence of W_{NR}, through the Bose-Einstein occupation number $n = (e^{\hbar\omega/kT} - 1)^{-1}$, provides a way to determine experimentally the number and energy of the phonons involved in the decay process.

It has been established that the nonradiative decay of rare-earth ions in crystals involves emission of the highest energy phonons in the lowest order, and therefore most probable, process consistent with energy conservation and the lattice vibrational spectrum [2]. The highest energy vibrations of a lattice are, in general, the most localized modes characterized by the short-range order of the material. This statement is borne out by the similarity of the infrared and Raman spectra of vitreous materials and their crystalline polymorphs. One would expect that the nonradiative decay of rare-earth ions in glasses would also be dominated by these highest energy lattice vibrations. The glass-lattice vibrational frequencies of ED-4 may be obtained from the Raman spectrum [3]. The highest frequency band at 900–1100 cm^{-1} is attributed to the Si–O–Si

Manuscript received April 28, 1975. This work was performed under the auspices of the U.S. Energy Research and Development Administration.

The authors are with the University of California, Lawrence Livermore Laboratory, Livermore, Calif. 94550.

[1] Our definitions of pump conversion efficiency and radiative quantum efficiency differ from conventions used by other authors [1]. We separate the total efficiency into two parts: 1) pump conversion efficiency is defined as the number of ions in the upper laser level divided by the number of absorbed pump photons, and 2) radiative quantum efficiency is defined as the fraction of ions in the upper laser level which decay radiatively. Both concentration quenching and multiphonon relaxation may decrease radiative quantum efficiency. The present measurements pertain only to the multiphonon contribution, while previous measurements determined the product of pump conversion efficiency and radiative quantum efficiency including concentration quenching.

stretching mode of the silicate-lattice network. Based on a fit to our measurements of the temperature dependence of W_{NR} using (1), we conclude that this highest frequency vibrational mode plays the dominant role in the nonradiative decay. We have found in addition that the strength of ion-lattice coupling in glasses is about the same as it is in crystals. Consequently, since the highest vibrational frequencies of the glass lattice are much greater than the highest phonon frequencies of most crystals, the multiphonon decay rates in glasses are much greater than in crystals.

In order to establish the dependence of the nonradiative decay rate on the energy gap, the rates for eight excited states of four different trivalent rare-earth ions in ED-4 glass were measured. The decay rates were determined from measurements of the transient fluorescence following pulsed selective excitation. Two different laser sources were used to excite the various ionic energy levels. One source was a Nd:YAG laser which produced a 100-mJ pulse at 1.06 μm with a duration of 1 ns. This pulse was used to produce pulses at the second- and third-harmonic frequencies by frequency doubling and mixing in KD*P. The second source was a tunable $LiNbO_3$ optical parametric oscillator which was pumped by the frequency-doubled output of a Chromatix Nd:YAG laser with a pulse duration of 200 ns. (Details of the experimental apparatus and techniques used will be published elsewhere.) The total fluorescence decay rate measured in this experiment consists of both a radiative and a nonradiative contribution. Fortunately, the measured rates in ED-4 were much larger than the estimated radiative rates, and thus the latter were neglected.

The measured nonradiative decay rates for the various ionic energy levels are plotted in Fig. 1 as a function of the energy gap to the next lower level. An approximate exponential dependence on the energy gap, independent of the rare-earth ion or electronic level, is obtained. This systematic dependence can be used to estimate the nonradiative decay rates from other rare-earth energy levels of interest in ED-4. The exponential dependence of the decay rate should not, however, be extrapolated to values of the energy gap corresponding to the excitation of less than approximately two quanta of the highest frequency lattice vibrational mode. For relaxation processes involving only one or two vibrational quanta, the averaging effect of high-order processes is not present, and in this case the decay rate is expected to depend on the details of the electronic state and vibrational mode excited in the decay. This effect is apparent in the deviation from the exponential fit of the decay rate for the $^4G_{7/2}$ level of Nd^{3+} with an energy gap of 1400 cm^{-1}. The results shown in Fig. 1, of course, apply only to the silicate glass. The characteristic vibrational frequencies of other glasses are significantly different, leading to large variations of the nonradiative decay rates [4].

We conclude by applying the results of this experiment to the Nd^{3+}-doped ED-2 glass to estimate the pump conversion efficiency, the radiative quantum efficiency of the $^4F_{3/2}$ upper laser level, and the lifetime of the $^4I_{11/2}$ terminal laser level. Since the nonradiative rate depends exponentially on the energy gap, the decay time from the optical pump bands to the $^4F_{3/2}$ level is determined by the largest energy gap encountered in the cascade. The largest gap, of approximately 2300 cm^{-1}, occurs below the $^2P_{3/2}$ level. The fluorescence lifetime of this level was measured to be 50 ns. The radiative lifetimes of all the excited states in the pump bands have been calculated using the Judd–Ofelt intensity parameters for ED-2 [5]. These lifetimes are all longer than 10^{-5} s. Thus, since ion-pair interactions are believed to be negligible, the pump conversion efficiency is found to be greater than 99 percent. The nonradiative decay rate for the $^4F_{3/2}$ level, based on the extrapolation shown in Fig. 1 to an energy gap of 4800 cm^{-1},

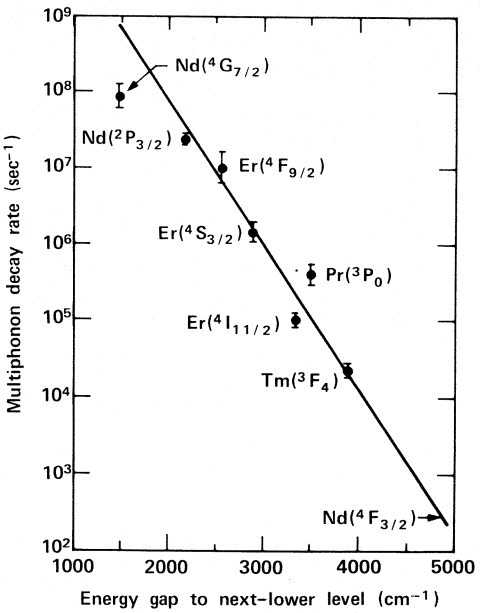

Fig. 1. Multiphonon decay rates as a function of energy gap to the next-lower level for rare-earth ions in ED-4 silicate glass at 300 K. The extrapolation to the Nd ($^4F_{3/2}$) nonradiative rate is indicated.

is estimated to be 200 s^{-1}. The radiative decay rate for this level is about 3×10^3 s^{-1}, leading to a radiative quantum efficiency of approximately 95 percent in the absence of concentration quenching. An estimate of the radiative quantum efficiency which is in agreement with this value was obtained from measurements of the temperature dependence of the fluorescence lifetime of the $^4F_{3/2}$ level. This temperature dependence arises from thermal population and decay of levels above the $^4F_{3/2}$ in addition to the temperature dependence of W_{NR} shown in (1). This result is, however, less accurate since the change in the measured rate over the available temperature range is small compared to the uncertainty in the measurement. Finally, the lifetime of the $^4I_{11/2}$ terminal level with a gap of 1500 cm^{-1} is predicted to be approximately 10 ns. This value is in good agreement with estimates based on attempts to measure this lifetime directly [6].

Comments on "Picosecond Optical Sampling"

JAMES D. MACOMBER

Abstract—**An optical sampler recently reported by Vogel *et al.* is revealed to have been invented six and one-half years previously by Macomber.**

In the above paper,[1] a device designed to measure "single-shot" optical events by multiple sampling was reported. Each sampling channel is fed by a mirror in the path of the beam: the signals from the several channels are then fed into optical fibers of different lengths which serve as delay lines. The amount of delay of the signal increases from one channel to the next so as to reduce the effective rise time of the event. The signals may then be processed at a rate which does not exceed the rise time of commercially available photodetectors and oscilloscopes.

Manuscript received May 12, 1975.

The author is with the Department of Chemistry, Louisiana State University, Baton Rouge, La. 70803.

[1] G. C. Vogel, A. Savage, and M. A. Duguay, *IEEE J. Quantum Electron.*, vol. QE-10, pp. 642–646, Sept. 1974.

The purpose of this correspondence is to publicize the fact that the device in question had actually been invented six and one-half years before the submission date of the subject manuscript. On June 16, 1967 I wrote an invention disclosure, subsequently submitted to the Department of Health, Education, and Welfare (DHEW) in accordance with the terms of Grant 1 RO1 NB 07891-01 RAD (although the grant did not officially begin until September 1, 1967). A patent application was filed by DHEW on February 10, 1969, and the patent [1] was awarded on July 27, 1971.

The device described in the subject paper is identical not only in its general purpose, but also in the details of the construction of most of its various parts. Therefore, there is no doubt that the two devices are identical. There is no evidence, however, that the authors knew of my work prior to the publication of theirs—indeed, they are to be congratulated for building and testing the device which I conceived so long ago. But perhaps your readers might be interested in knowing that "Great minds think alike!"

Long-Pulse Generation in Rhodamine-6G Pumped by a CO_2-Laser-Heated Plasma

ROBERT T. BROWN

Abstract—**Results obtained using a laser-heated plasma as the pumping source for a dye laser are described. A small dye laser using a cylindrical close-coupled pumping arrangement was operated at various xenon pressures. Dye-laser pulses with 20-ns rise times and 800-ns pulsewidths were obtained.**

It has recently been shown [1], [2] that a laser-heated xenon plasma is potentially a very effective pumping source for a dye laser. In [1] lasing was obtained using a close-coupled arrangement with no pumping cavity, but it was found that the dye-laser pulse terminated prematurely, apparently due to thermal distortions in the dye solution. If this effect were to persist in large-scale breakdown-pumped dye lasers, it would severely limit the potential efficiency of this approach. This note describes results obtained with a somewhat different pumping arrangement in which the dye-laser pulse shape tended to follow the TEA pumping pulse shape, indicating that efficient coupling with breakdown pumping should be possible.

Breakdown-pumped dye-laser studies were carried out using a dye cell 3 mm in diameter by 7 cm long, as shown in Fig. 1.

Manuscript received May 7, 1975.

The author is with the United Technologies Research Center, East Hartford, Conn. 06108.

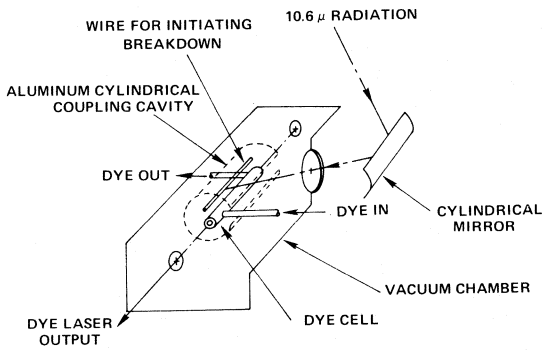

Fig. 1. Experimental arrangement used in breakdown-pumped dye-laser studies.

A thin tungsten wire for initiating the breakdown was located adjacent to the cell, near the centerline of a cylindrical close-coupled pumping cavity. The dye cell, coupling cavity, and wire were contained in a chamber filled with xenon at various pressures, and the 10.6-μ radiation was focused onto the wire with a 6-cm focal-length mirror. The dye-laser cavity consisted of plane-parallel mirrors separated by 17 cm, with one total reflector and an 80-percent reflecting output coupler.

Fig. 2 shows typical pulses from the TEA pumping laser and corresponding pulses from the dye laser, operating with a 3×10^{-3}-M solution of rhodamine-6G in ethanol and a xenon pressure of 20 torr. The pulse in Fig. 2(c) had an energy of $\sim$0.3 mJ, a circular near-field pattern with a diameter of 4 mm, and a full-angle beam divergence of 5 mrad. It can be seen

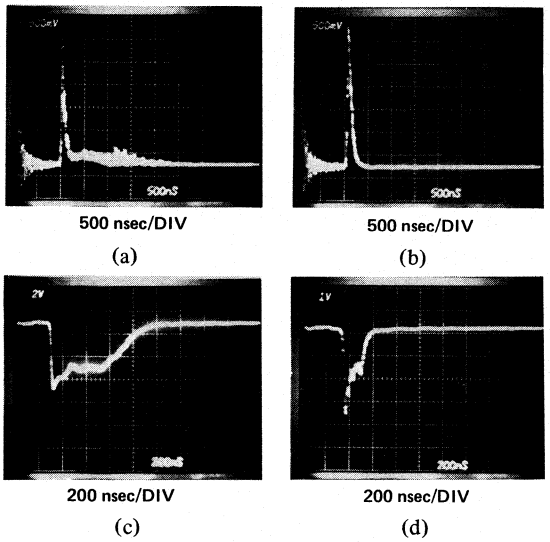

Fig. 2. Pulse shapes. (a) 10.6-μ TEA laser pulse with nitrogen. (b) TEA laser pulse without nitrogen. (c) Dye-laser pulse shape corresponding to (a). (d) Dye-laser pulse shape corresponding to (b).

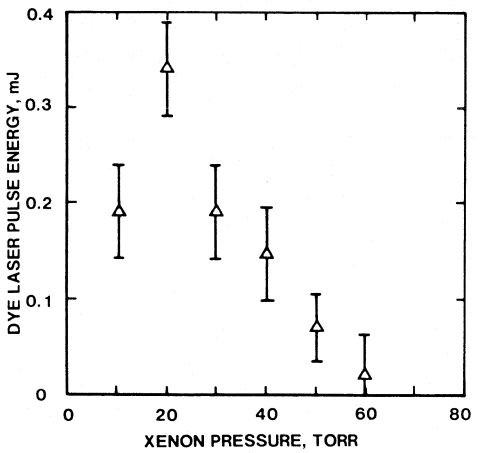

Fig. 3. Laser pulse energy at various xenon pressures.

from these traces that the pumping which occurred during the tail of the 10.6-μ pulse was still well above threshold, and that the dye-laser pulse length was comparable to the intense portion of the 10.6-μ pulse.

Photographs showed that the laser-heated plasma was not cylindrical, as originally intended, but instead had a rather complicated wedge shape of roughly the same dimensions as the 10.6-μ laser focal volume. Because of this, the coupling between the plasma and the dye cell was not efficient. However, even with this preliminary arrangement, a dye-laser output energy of 0.5 mJ was obtained for 1.0 J of 10.6-μ energy. Improved coupling geometries are currently being studied.

Fig. 3 shows the laser energy for various xenon pressures, and, as expected, based on [2], shows a maximum at pressures well below those used in conventional xenon flashlamps.

Observation of Stimulated Emission at 0.3159 μm in the Nitrogen Second-Positive System at Room Temperature

JOHN S. KRUGER

Abstract—**Pulsed electrical discharges in pure nitrogen have produced laser oscillation on an ultraviolet band of the nitrogen triplet system not previously reported above liquid-nitrogen temperature.**

This note reports observation of laser oscillation on the $C^3\pi_u$–$B^3\pi_g$ (1–0) band in nitrogen at room temperature. This band is one of three laser bands that have been seen in the second-positive system (C–B electronic–vibrational transitions) of nitrogen.

Oscillation in the ultraviolet was first reported on the 0–0 band (0.3371 μm) of the second-positive system by Heard [1]. Lasing in the 0–0 and 0–1 (0.3577-μm) bands was observed by Kaslin and Petrash [2] and Massone *et al.* [3]. By cooling the walls of the discharge tube with liquid nitrogen, Kaslin and Petrash [4] were also able to detect a new oscillation on the 1–0 band (0.3159 μm). With electron-beam-pumped Ar–N_2 mixtures Searles and Hart [5] and Ault *et al.* [6] reported lasing on the 0–1 and 0–2 (0.3805) and 0–1 bands, respectively. The present work noted this band at room temperature, in nitrogen alone, with a conventional longitudinally excited discharge.

In this work pulsed electrical discharges were produced in commercial-grade (water-pumped) nitrogen at about 3 torr, flowing at < 1 Standard l/h. The laser discharge tube had an 8-mm ID, with 40 cm of plasma length along the laser axis. The tube was fitted with fused-silica Brewster's-angle windows and tungsten electrodes. A 2.4-nF ceramic capacitor was charged to 20 kV and then discharged via a triggered spark gap through the laser tube at an 11-Hz repetition rate. The resonant cavity was formed by two highly reflecting Ag-coated mirrors placed 50 cm apart. One mirror was flat and the other was a 2.17-m-radius hole-coupled spherical mirror, which served as the output mirror.

The oscillation from the laser was detected through a 1-m Czerny–Turner spectrometer with a thermoelectrically cooled S-1 photomultiplier. Table I summarizes the results obtained for both spontaneous and stimulated emission on all three second-positive-system bands. The spontaneous emission was distinguished from the stimulated emission by blocking the rear cavity reflector and noting a drop in detected intensity of several orders of magnitude.

TABLE I
ULTRAVIOLET BANDS OBSERVED IN NITROGEN AT ROOM TEMPERATURE IN A LONGITUDINALLY EXCITED DISCHARGE

Emission Band	Band Edge λ_{vac} (μm)	Relative Spontaneous Intensity	Relative Stimulated Intensity	Optimum N_2 Pressure (Torr)
1-0	0.3159	0.01*	3	3.2
0-0	0.3371	0.10	300	3.0
0-1	0.3577	0.07	30	2.5

*Comparable to fluctuations in photomultiplier dark current.

Manuscript received May 15, 1975.

The author is with the Harry Diamond Laboratories, 2800 Powder Mill Rd., Adelphi, Md. 20783.

Rajiv R. Shah (S'74) was born in Pulgaon, Maharashtra, India, on July 11, 1953. He received the B.Sc. degree in physics from the University of Poona, Poona, India, in 1972, and the M.S. degree in electrical engineering from Rice University, Houston, Tex., in 1974.

In 1969 he was selected as a National Science Talent Search Scholar by the Government of India and was awarded a scholarship for pursuing studies in physics while at the University of Poona. Also, under the same program, he par-

ticipated in advanced summer training institutes at Jodhpur, Vishakapatnam, and Bangalore, India, in 1970, 1971, and 1972, respectively. He is currently working towards the Ph.D. degree in electrical engineering in the area of holographic storage of data on crystals at Rice University, Houston.

Mr. Shah is a student member of the American Physical Society and the Optical Society of America.

*

Donald S. Stark was born in Calcutta, India, in 1925. He received the B.Sc. degree in physics from the University of London, London, England, in 1944.

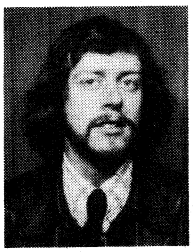
After holding posts at the Research Department of EMI Ltd., Hayes, England, and at the City College of Technology, Liverpool, England, he has been working since 1951 at the Services Electronics Research Laboratory of the United Kingdom Ministry of Defence, Baldock, Herts., England. He has been principally engaged in research and development in the fields of vacuum physics, neutron generators, and (currently) CO_2 lasers.

*

William H. Steier (S'58-M'60-SM'72) was born in Kendallville, Ind., on May 25, 1933. He received the B.S. degree in electronic engineering from Evansville College, Evansville, Ind., in 1955, and the M.S. and Ph.D. degrees, both in electrical engineering, from the University of Illinois, Urbana, in 1957 and 1970, respectively.

From 1960 to 1962 he was an Assistant Professor in the Department of Electrical Engineering, University of Illinois. From 1962 to 1968 he was a member of the Technical Staff, Bell Telephone Laboratories, Holmdel, N.J. He is currently a Professor of Electrical Engineering, University of Southern California, Los Angeles. He is also a Consultant to the Northrop Corporate Laboratories, Hawthorne, Calif. In September 1970, he became Chairman of the Department of Electrical Engineering–Electro-Physics at USC. He has been active in research in millimeter waves, optical transmission lines, coherent optical devices, and air-pollution monitoring.

Dr. Steier is a member of Eta Kappa Nu and Sigma Xi.



*

Armand L. Waksberg (M'63-SM'70) received the B.Sc. degree in honors mathematics and physics and the M.Sc. degree in physics from McGill University, Montreal, P.Q., Canada, in 1956 and 1960, respectively.

He joined Canadair in 1956, where he worked on aerodynamic and dynamic problems of aircraft, as well as performing system studies on various vehicles. In 1960 he joined the Canadian Aviation Electronics Research and Development Department, where he worked on various electronic systems. He joined the Research Laboratories of RCA Limited, Ste-Anne de Bellevue, P. Q., in 1963. He has made theoretical studies of the He-Ne laser system, noise in lasers, detection of weak laser signals, and the feasibility of laser pumping with monoenergetic electrons. Experimental studies have included work on off-axis laser modes, measurement of high-speed detectors, and side-light properties of lasers. More than 25 papers have been published on these subjects. More recently, he has developed techniques to stabilize CO_2 lasers, and he is currently working on laser communication experiments.

*

Andrew C. Walker was born in Harrow, England, on June 24, 1948. He received the B.A. degree in physics, the M.Sc. degree in quantum electronics, and the Ph.D. degree in physics, all from Essex University, Colchester, Essex, England, in 1969, 1971, and 1973, respectively. His Ph.D. research was based on an investigation of the photon drag effect.

In 1972 he joined the Laser and Plasma Physics group at the National Research Council of Canada, Ottawa, as a postdoctoral fellow, and worked on high-pressure CO_2 lasers and the generation and detection of short, 10-μm radiation pulses. He is currently an SRC fellow at Essex University, and his research interests include high-pressure and waveguide CO_2 lasers.

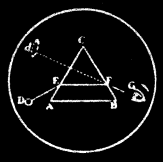
Yoshihisa Yamamoto (S'75) was born in Tokyo, Japan, on November 21, 1950. He received the B.E. degree in electrical engineering from the Tokyo Institute of Technology, Tokyo, Japan, and the M.E. degree in electronic engineering from the University of Tokyo, Tokyo, Japan, in 1973 and 1975, respectively. He has been working toward the Ph.D. degree in electronic engineering at the University of Tokyo; his current interest is in integrated optics.

Mr. Yamamoto is a member of the Institute of Electronics and Communication Engineers of Japan and the Japan Society of Applied Physics.

*



Hisayoshi Yanai (M'57-SM'63) was born in Okayama, Japan, on May 19, 1920. He received the B.E. degree in electrical engineering from the University of Tokyo, Tokyo, Japan, in 1942, and the Ph.D. degree in electrical engineering from the University of Tokyo in 1953 for research on measurements of dielectric properties in the delta-modulation wave region. From 1954 to 1955 he studied at the Institute of Technology, Munich, Germany.

In 1945, after three years of military service, he joined the staff of the Electrical Engineering Department at the University of Tokyo. In 1947 he became an Associate Professor, and since 1960 he has been a Professor at the University of Tokyo, where he is currently concerned with semiconductor devices, integrated circuits, and optoelectronics. He has published a number of research papers and articles in the area of semiconductor devices and circuits, especially in the microwave region.

Dr. Yanai received the Paper Award for two of these papers and the Distinguished Services Award from the Institute of Electronics and Communication Engineers of Japan for his excellent research works in 1970. He is a member of the Institute of Electrical Engineers of Japan, the Institute of Electronics and Communication Engineers of Japan, and the German Society of Electrical Engineers.

Dye Lasers

Chairman: John P. Goldsborough, *Spectra-Physics Inc., Mt. View, Calif. 94040*

1.1 A 3400 Å Dye Laser and a 1.315 μm Photodissociation Laser Efficiently Pumped by a CO_2 Laser-Produced Plasma,

W. T. Silfvast and O. R. Wood II, *Bell Telephone Laboratories, Holmdel, N. J. 07733*

(15 min)

A cylindrically shaped CO_2 laser-produced plasma has been used to optically pump lasers in gases[1] and organic dyes. Using a transverse pumping arrangement, a 3400 Å p-terphenyl dye laser[2] was optically pumped by UV radiation from a xenon plasma produced with a high pressure pulsed CO_2 laser. Dye laser output powers greater than 10 kW at 3400 Å, in an active length of 4.2 cm, were produced by a 10.6 μm input pulse energy of 5.6 joules. In addition, more than 30 kW of laser power has been obtained at 5875 Å from Rh6G using the same pumping geometry. Laser action has also been obtained at 1.315 μm by photodissociation of C_3F_7I.[1] In this case, the laser output intensity was measured to be at least a factor of 5 greater than that obtained using a linear flashlamp. The potential scaling of CO_2 laser-produced plasmas to larger dimensions, higher repetition rates and shorter risetimes makes them an attractive alternative to a conventional flashlamp as sources for optical pumping.

A spectral radiance of 2 W/mm²-ster-nm at 230 nm from an elongated xenon plasma can be produced by focused 10.6 μm laser radiation for input energies/length of 0.8 Joules/cm. In the ultraviolet region (2000-3000 Å) the spectral radiance for a laser-produced plasma in xenon gas is 2-3 times greater than that produced by a xenon flashlamp of comparable size and input energy.[3] Thus, for a CO_2 laser that is 30 percent efficient in converting electrical energy to 10.6 μm radiation,[4] the two pumping sources would be approximately equal in overall efficiency. Furthermore, since the rate of increase of ultraviolet emission with increasing input energy is much greater for the laser-produced plasma than for a flashlamp (for input energies up to 0.8 Joules/cm,[3] this comparison is expected to improve with increasing input energy, eventually favoring the laser-produced plasma source. While the risetime of a CO_2 laser-produced plasma source is a function of the 10.6 μm input power, even for the modest CO_2 laser energies used in the present experiment, risetimes less than 5 nsec can readily be achieved.

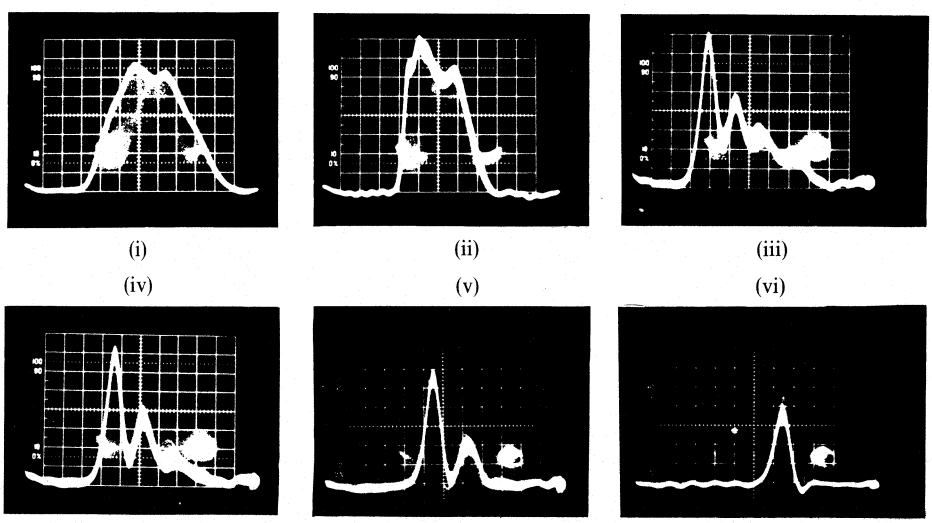
Dye laser pumping was accomplished by focusing the output from a high pressure pulsed CO_2 laser having a 2.5 × 5 cm rectangular cross-section with a 7.5 cm focal length cylindrical lens onto an aluminum target inside a cell filled with xenon gas. An approximately cylindrically shaped plasma, 4.5 cm in length, was formed in xenon gas adjacent to a 0.9 cm × 0.9 cm × 4.5 cm quartz cuvette which had been filled with a solution of p-terphenyl in cyclohexane. Stimulated emission was observed from a layer of dye solution immediately inside the 0.9 cm × 4.5 cm side window of the cuvette.

For initiation of an iodine photodissociation laser, a laser-produced plasma was formed in xenon gas adjacent to a 4 mm diameter quartz tube (30 cm in length) filled with i-C_3F_7I. For comparison with the lawer-produced plasma, an E G & G FX38C linear flashlamp was mounted adjacent to the laser tube. This lamp, having approximately the same dimensions as those of the laser-produced plasma, was excited with an electrical pulse of comparable duration to the CO_2 laser pulse and with the same energy input per unit length.

The application of this technique to other gases (particularly other chemical lasers), liquids (particularly other organic dyes), and solids is strongly indicated. In systems having high gains and very short lifetimes, the possibility of traveling-wave optical pumping using laser-produced plasma sources also seems possible.

1.2 Subnanosecond Tunable Dye Laser Pulse Generation by Controlled Resonator Transients,

Chinlon Lin and C. V. Shank, *Bell Telephone Laboratories, Holmdel, N. J. 07733*



(15 min)

We describe a general technique for generating a single subnanosecond pulse from a laser pumped dye laser. Our technique makes use of the resonator transients which are in the form of damped relaxation oscillations or "spiking," a well known phenomenon observed and studied extensively in solid state masers and lasers.[1] These resonator transients are a consequence of the interaction between the excess population inversion and the photons in the cavity.

Fig. 1 shows the observed transient behavior of a N_2 laser-pumped 7-diethylamino-4-methylcoumarin dye laser at various levels of the pumping power. The damped relaxation oscillations are clearly seen. For this experiment a dye

cell of 1 cm length is used with its uncoated windows to form a cavity, with a photon cavity decay time of ~50 psec. Similar behavior is observed in all laser dyes we tested under appropriate conditions. The characteristics of these damped relaxation oscillations and their functional dependence are found to have good qualitative agreement with computer solutions of the coupled rate equations.[2] This study leads to the applications using the idea of controlled transient response of laser-pumped dye lasers. By proper control of photon cavity decay time and the level of pumping one can vary not only the number of oscillation periods but also the pulse duration, as is evident from computer solutions as well as experimental observations. Based on this general technique of controlled resonator transients we have demonstrated generation of high repetition rate subnanosecond pulses tunable in the near UV and the visible region from N_2 laser-pumped dye lasers.

1.3 Picosecond Pulse Generation, Amplification and Nonlinear Mixing with a Synchronous Mode-Locked Dye Laser Pumped by Nd:YAG, L. S. Goldberg and C. A. Moore,[1] *Naval Research Laboratory, Washington, D.C. 20375*

(15 min)

Dye lasers pumped by mode-locked lasers can emit very short pulses in exact time synchronization with the pump pulses when their respective cavity lengths are matched. We report studies with a streak camera of picosecond pulse formation in a synchronously mode-locked dye laser pumped by a frequency doubled, passively mode-locked Nd:YAG laser. We have used the synchronous nature of this source to operate a high gain short-pulse dye amplifier, and to generate tunable short pulses of near transform limited bandwidth in the UV and IR spectral regions by nonlinear mixing.

The performance of the synchronous dye laser replicates the main features of the Nd:YAG pump source, namely high repetition rate, fundamental-mode beam quality, high peak power, and uniform pulse trains. The dye laser comprises a two-mirror linear cavity with Brewster-angle dye flow cell and narrow gap Fabry-Perot etalon tuning element. It is longitudinally pumped by pulse trains of 1 mJ energy at 532 nm. Significant performance characteristics obtained for the dye laser are: (1) pulse duration of 12 psec, nearly 1/3 as short as the pump pulses; (2) transform limited bandwidth of 2 cm^{-1}, readily achieved with two Fabry-Perot etalons; (3) wavelength tunability of 549-662 nm, using rhodamine 6G, rhodamine B, and crestyl violet perchlorate laser dyes; (4) energy conversion efficiency of 15% untuned (R6G), 5% transform limited bandwidth; (5) pulse temporal characteristics independent of lasing wavelength; requiring no saturable absorbing dyes.

The temporal character of the dye laser pulses was found to depend critically on adjustment of the relative lengths of dye and pump cavities. At cavity match, a recycling of population through the lasing states was discovered to occur in the dye medium during simultaneous passage of intense pump and dye pulses. This effect enhances the efficiency of energy extraction from the pump pulses, but causes the dye pulse length to approximate the 30 psec duration of the pump. For deviations of cavity length from match, a pronounced asymmetry in conversion efficiency and temporal character of the pulses was observed, depending on whether the circulating dye pulses arrived at the dye cell earlier or later than the gain. The shortest pulses of 12 psec duration were generated when the dye cavity length was slightly longer than match, where the process of gain depletion could operate free of recycling effects. Dye pulses sampled from different portions of a single mode-locked train, and displayed simultaneously on the streak camera, showed progressive shortening as the pulse train developed.

The suitability of synchronous pumping to short-pulse dye amplification was studied. A dye amplifier cell was pumped with amplified and doubled 1.06 μm pulses separately available from the Nd:YAG laser. An optical delay line permitted the adjustment of the relative arrival times of the pump and dye pulses at the amplifier cell. In the initial measurements a peak small-signal gain of 100 and a saturated gain of 4 were obtained using R6G. No significant changes in dye pulse length were observed for a single pass through the amplifier cell under gain saturation conditions.

The intense 1.06 μm and 532 nm pulses were individually sum- and difference-frequency mixed with the synchronous dye laser output in non-linear crystals of ADP and $LiIO_3$. The spectral ranges obtained by mixing and by frequency doubling were 270-331 nm and 362-408 nm in the UV and 1.1-1.7 μm and 2.7-5.6 μm in the IR. Efficiencies of 20% and 2% were measured for the conversion of the dye pulse train energy to the UV and IR when mixing with the 1.06 μm pulse train. Thus, the synchronous mode-locked dye laser with the use of nonlinear methods is capable of generating intense picosecond duration pulses of minimum bandwidth that are tunable over substantial spectral regions.

1.4 Energy Transfer Processes in Organic Dye Laser Mixtures, S. A. Ahmed, J. S. Gergely, and D. Infante, *Electrical Engineering Department, City College of New York, New York, N. Y. 10031*

(15 min)

Energy transfer processes in organic dye mixtures in solutions have received some consideration in the past.[1,2] This paper presents the results of an experimental study on energy transfer processes in organic dye mixtures. The work includes the study of simultaneous laser action at three primary colors from a mixture of three dyes.

Quantitative measurements demonstrated that in a mixture of two or more laser dyes in a solution, excitation energy may be very efficiently transferred from an excited molecule of one dye species to an unexcited molecule of another species, and that process may be repeated successively to a third and fourth dye with the excitation energy being efficiently cascaded to longer wavelengths.[3]

In the first series of experiments carried out, we were concerned with dye mixtures from which simultaneous laser outputs at useful spectral combinations could be obtained. Coumarine, Acriflavine and Rhodamine B constituted a mixture from which dye laser outputs could be obtained at three primary colors. The absorption bands of Acriflavine and Rhodamine B overlap the flourescence bands of the Coumarine and the Acriflavine respectively. This overlap in the energy gaps of these dyes would permit, in principle, excitation energy transfer from Coumarine to the Acriflavine and from the Acriflavine to Rhodamine B either by collisions or optically.

It was therefore possible to use the 337.1 nanometer output of an N_2 laser to excite the Coumarine dye and obtain excitation transfer to, and simultaneous emission (including laser emission) from all three dyes.

The optimum concentrations for three color laser operation with a 1 mm optical path length were found to be: Coumarine -5×10^{-3} molar, Acriflavine -1×10^{-4} molar, Rhodamine B -1.5×10^{-4} molar. Excitation for the front surface fluorescence measurements was by means of the 365.0 nanometer output obtained from a mercury discharge lamp. This is absorbed by the Coumarine, which transfers excitation to the Acriflavine, which in turn transfers excitation to the Rhodamine B.

The different concentration used for each of the three dyes arises from the fact that the excitation source for laser action in the dye mixture was the N_2 laser output at 337.1 nanometers. The absorption of this pump light was therefore predominantly by the Coumarine dye, hence its large concentration requirements relative to its other two dyes. With the three dye mixture, laser action was obtained simultaneously at three wavelengths, centered at 440, 490 and 620 nanometers. These outputs could be individually tuned over a range of approximately 6 nanometers.

That excitation transfer is the predominant mechanism for exciting laser action in the Acriflavine and Rhodamine B is confirmed by the fact that it was not possible to obtain laser action from Acriflavine alone, at any concentration, using the 337.1 nanometer N_2 laser output for excitation; while laser action by direct excitation (at 337.1 nanometers) of Rhodamine B alone was

found to require an order of magnitude higher concentration of Rhodamine B (with the optical arrangement used).

Experiments were also carried out on several pairs of dye mixtures, including Dichlorofluorescein as donor and Rhodamine B and DODC as acceptors, and using the 488.0 nanometer output of an argon ion laser to excite the donor alone. The results showed that excitation transfer rates were related (i) to the overlap of absorption and emission spectra of the acceptor and donor dyes respectively and (ii) to the dye concentration.

The efficiency of excitation transfer, as measured by the total fluorescent quantum yield for the mixture, over the quantum yield for the donor dye alone was found to be ~90% for single step transfer. This was the case for several of the dyes tested, including those used for three color laser operation.

The high efficiency of the energy transfer processes makes the use of dye mixtures attractive for a variety of applications including three color lasers for display purposes, and for increasing the efficiency of flashlamp pumped dye laser systems by utilizing more effectively the wide spectral output of the pump bands.

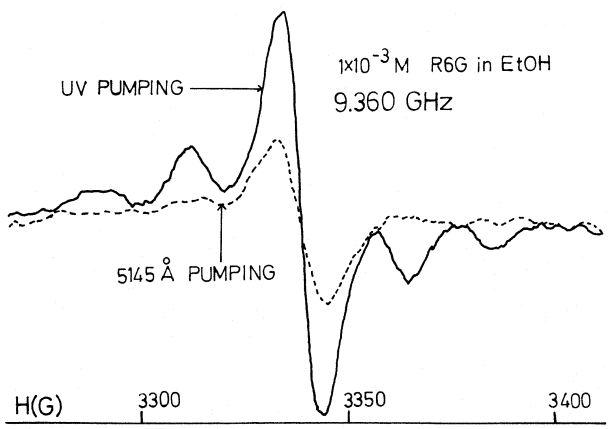
1.5 Investigation of Photodegradation Mechanism in Laser Dyes by Detection of Triplet-Molecules and Free Radicals Induced by Laser Light,

Mikio Yamashita and Hiroshi Kashiwagi, *Electrotechnical Laboratory, Tokyo, Japan,* and Hidenori Ikeda, *Keio University, Yokohama, Japan*

(15 min)



Photodegradation of organic dyes has severely limited the life of the laser, but the degradation mechanism is not yet well understood. The study on the degradation has been made so far by measuring changes in the absorption and fluorescent spectra of the dye solution before and after photodegradation. We are investigating the photodegradation mechanism by a quite different method where laser-induced free radicals and triplet-dyes are directly monitored at 77 K using an esr technique during and after laser irradiation. In comparison with measuring optical spectra our method has the following merits; (1) the dye molecules in the first triplet excited state and the photochemically produced free radicals can be directly detected, and (2) this method is much more sensitive for the photochemical paramagnetic-products in the dye solution.

Each dye – R6G, RB, RS, AR, and FDS – from the Eastman Kodak and Tokyo Kasei Kogyo Cos., was dissolved in ethanol, methanol or DMSO at 1×10^{-3} M concentration. The oxygen-free solution was outgassed by a freeze-thaw process and sealed in a 4 mm-o.d. quartz tube. Both the esr spectra of the H_{min} line corresponding to $\Delta m = \pm 2$ transitions in the triplet-dyes and of the free radicals induced by laser light were recorded with a Varian E-4 spectrometer with an optical transmission cavity. The glassy solution, cooled by inserting into liquid nitrogen in a quartz Dewar, was irradiated by an unfocused beam with the UV (3511 + 3638 Å) or 5145 Å wavelength of an Ar ion laser.

At first it was found that continuous excitation for several minutes by UV or 5145 Å beams produced the esr signals of the free radicals and decreased the intensity of the H_{min} line which is proportional to the triplet-dye concentration. These phenomena appeared in the case of UV excitation under less excitation-power and -time than in the case of visible excitation, and the shapes of the spectra due to the free radicals produced were different, as shown in Fig. 1. The peak-to-peak esr signals due to the free radicals produced after laser irradiation with 5145 Å for five minutes and those due to the triplet-dyes (which were recorded during irradiation of 5145 Å beam with very low power after the degradation) are given as a function of the continuous irradiation power in Fig. 2.

Furthermore, the investigation of the effects of different dyes (R6G, RB, RS, AR, and FDS) and solvents (ethanol, methanol, and DMSO) on the UV laser-produced radical-spectra has shown the spectrum shape depends on the solvent molecule but hardly depends on the molecular structure of the dye. The dependence of the peak-to-peak radical signals on the triplet molecular concentrations was examined for 1×10^{-3} M ethanolic R6G solutions with different COT concentrations after UV irradiation, as shown in Fig. 3. From these results, we consider that the chemical reaction between the triplet-dye molecules and the solvents dissolving the dye causes the photodegradation of the dye solution and produces the free radicals.

Fig. 1. Observed laser-induced derivative esr spectra of free radicals in 1×10^{-3} M ethanolic R6G solution at 77 K.

1.6 Lasing Efficiency and Photochemical Stability of Laser Dyes Spanning the Infrared Spectral Region 710-950 nm,

P. E. Oettinger, *Thermo Electron Corp., Waltham, Mass. 02154,* C. F. Dewey, Jr., *MIT, Cambridge, Mass. 02139*

(15 min)

Although substantial effort has been devoted analyzing lasing dyes in the 300-700 nm near UV and visible spectral regions, near IR (700-1000 nm) dyes are less well researched.[1-5] Such

[5] J. P. Webb and F. G. Webster, presented at 8th Int. Quantum Electronics Conf., June 1974.

long wavelength dyes consist, in general, of long polymethine chains, which because of their fragility decompose readily when exposed to radiation. Since all lasing dyes are at present excited by radiative sources, it is important to know their photochemical stability to the exciting photons. Optimum dyes would be those with the highest combination of lasing efficiency and resistance to photochemical bleaching.

Using a 5 pps, 50 nsec Q-switched, multimode ruby laser with output averaging 1.4 MW per pulse, we angle-pumped (14°) a 1 or 2 mm long quartz spectroscopic cell sequentially filled with a number of dye-solvent mixtures. A UV blocking filter shielded the dye from the bleaching effects of nondesirable high frequency radiation of the ruby laser's flash lamp. The cell formed the active region of either a broad band lasing cavity composed of a fully reflecting mirror and a 45 % reflecting output coupler, or a narrower band (5 Å) oscillator wherein the fully reflecting mirror was replaced by a 600 1/mm grating. Output measurements from this cavity determined the dye lasing efficiency. The observed degree of absorption of the incident ruby by the dye before and after exposure to 1500 ruby pulses was used to calculate the number of dissociated dye molecules per ruby photon absorbed, i.e. the probability of bleaching of the dye. The experiments included four new Kodak modified tricarbocyanine salt IR dyes[5] containing ring structures to strengthen the normally chain-like molecules against bleaching. Our results show that three (IR-125, 132, 144) of the four are substantially more photochemically resistant than other molecules we analyzed. However, one of the new dyes (Kodak 123), although lasing well, shows only average photochemical stability. Sixteen of the best dyes were studied in detail. Of these the following seven dyes cover the entire spectral region 710-950 nm: 3, 3′-dimethyl-2, 2′-(5, 5′-dimethyl)-thiathiazolinotricarbocyanine iodide (710-735 nm); 3, 3′-diethyl-2, 2′-oxatricarbocyanine iodide (725-770 nm); Eastman Kodak IR-123 (765-815 nm); 3, 3′-diethyl-2, 2′-thiatricarbocyanine bromide (DTTC Bromide) (810-830 nm) 3, 3′-diethyl-2, 2′-(5, 5′-dimethoxy)-thiatricarbocyanine iodide (820-875 nm); Eastman Kodak IR-125 (840-920 nm); 3, 3′-diethyl-12-acetoxy-2, 2′-thiatetracarbocyanine perchlorate (920-950 nm); The optimum solvent for these dyes was found to be DMSO. Lasing efficiencies for 2 (10^{-4}) M concentrations varied from 18 to 43%. Bleaching probabilities ranged from 1.2 (10^{-5}) to 3.0 (10^{-4}). Quality factors, Q, defined as the ratio of the lasing efficiency to bleaching probability, varied from 1.3 to 11.7.

1.7 Transverse Flow Flashlamp Pumped Dye Laser, H. W. Friedman and R. G. Morton, *Avco Everett Research Laboratory, Inc., Everett, Mass.*

(15 min)

Pulsed operation of flashlamp pumped dye lasers at high repetition rates is usually limited to a frequency roughly equal to the reciprocal of dye interchange time. By flowing the dye at a given rate transverse to the laser axis, the maximum pulse repetition rate is increased over that of the axial configuration by essentially the aspect ratio of the laser channel, i.e., by length/diameter.

A transverse flow dye laser pumped by two linear flashlamps in a close coupled configuration has been built. The lamps are water cooled and easily replaceable without disturbing dye seals or optical alignment.

The laser system is comprised of three sections: the laser head with pulse modulator, liquid flow system, and power supply. The cross section of the laser channel resembles that of a convergent-divergent nozzle and discourages the onset of parasitic modes. The linear, xenon filled flashlamps are housed in trough shaped reflectors which also serve as the cooling water channel and low inductance current return path. No adhesive or epoxy seals are used and hence the laser is compatible with a wide variety of solvents. The side windows may be pyrex or one of the varieties of quartz and are interchangeable to control the UV content of the flashlamp light. Optical distortions arising from temperature gradients in the lasing medium are minimized by thermal insulation and boundary layer control. A high voltage pulse preionizes each flashlamp prior to the main discharge to increase the lamp performance and lifetime and to facilitate triggering as the lamps age. Thyratron switchgear is used for both the preionization and main discharge to insure good pulse to pulse reproducibility and low jitter. Spectral narrowing and tuning are achieved with a telescope and multiprism ring.

The transverse flow dye laser operates at a repetition rate of up to 100 Hz and with smaller bore lamps, up to 500 Hz. An average power level of 6 watts (Rhodamine 6G at 30 Hz) under broadband conditions and 3 watts at a bandwidth of 2 Å has been achieved. The pulse duration varies from one-half to one microsecond depending upon the choice of discharge capacitance and the beam divergence is typically a few milliradians.

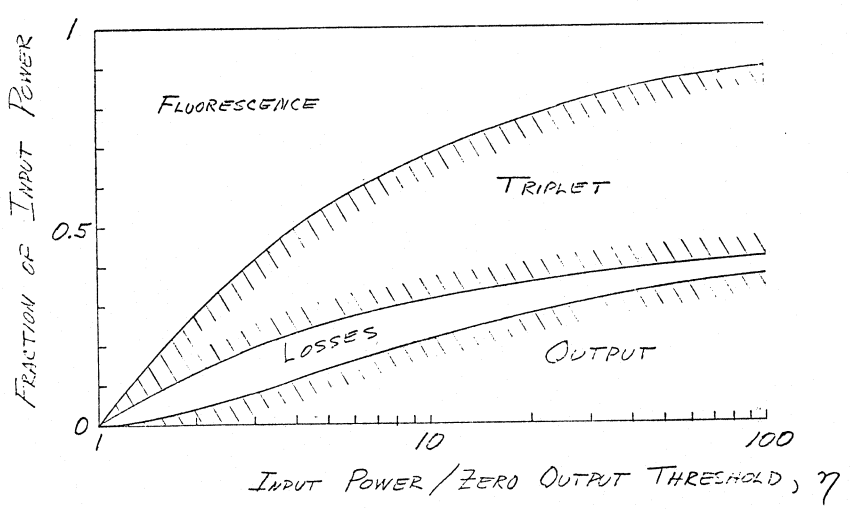
The performance of water/alcohol mixtures of several dyes has been tested. A general reduction in beam divergence and bandwidth has been observed with water/methanol solvent mixtures as compared to 100% methanol. The spectral brightness of Rhodamine 6G, for example, is increased by 40% using a 30% water/70% methanol solvent over that of 100% methanol. A similar enhancement in spectral brightness occurs with solvent mixtures of 50% water/50% alcohol but at this point the average power is falling off.

Results with water/alcohol solvent mixtures indicate that potential safety problems associated with storage and handling of large volumes of alcohol may be substantially reduced without loss of laser efficiency or beam quality.

1.8 Thermo-Optical Limitations on High Average Power Dye Lasers,[1] O. G. Peterson, A. A. Pease, and W. M. Pearson, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The application of organic dye lasers to isotope separation requires the simultaneous achievement of high average power and single mode, spectrally narrow output, $\Delta\lambda/\lambda = 10^{-6}$. Previously reported narrow line lasers[2] have been limited to low average powers to minimize thermal effects which severely restrict single mode operation. This represents the ultimate limitation on the scalability of dye lasers to high average powers.



This limit is critically dependent upon the properties of the solvent used for the lasing molecules. The most sensitive of these properties is the variation of refraction index with temperature. The solvent of choice is usually water because of its large heat capacity and small variation of index with temperature.

The determination of the high average power limit must be based on an evaluation of the efficiency of the laser at some suitable operating

[1] This work was performed under the auspices of the U.S. Atomic Energy Commission.

[2] H. Walther, *Physica Scripta*, vol. 9, p. 297, 1974.

Fig. 1.

point. The fraction of absorbed quanta that are contributing to fluorescence, triplet state absorption, non-dye resonator losses and useful output have been calculated and are displayed as a function of input power in Fig. 1. These calculations were based on the dye parameters characteristic of rhodamine 6G and assumed that the laser inversion, n^*/n, is proportional to the sum of the resonator losses, L, and the output transmission, T; $n^*/n \propto (L + T)$. The distribution of power depends on evaluating the optimum output coupling at each value of the input power. It was found that this optimum output coupling was independent of effects due to dye triplet state. The mirror transmission then reduces to the familiar[3] $T = (P\tau L/K)^{1/2} - L$ where P is the input power per cross-sectional area of laser bore and τ is the dye fluorescence lifetime.

From the figure it is clear that a dye laser should be operating with a minimum input intensity of ten times the zero output threshold. For incoherently pumped lasers where pumping intensity is limited, this becomes the operating point of choice. At this point the output coupling is twice the internal resonator losses and the laser intensity in the resonator is approximately twice the saturation value. The fraction of the input quanta that are converted into useful output is then 20% while 40% goes into solution heating via triplet state absorption.

Using this operating point together with published efficiency data on flashlamps,[4] dyes,[5] and pumping cavities[6] the ultimate output efficiency of narrow line dye lasers has been estimated to be 0.1%. Similarly, the solution heat load has been estimated to be 3% of the input power.

Only a limited amount of energy can be absorbed by a given volume of solvent before the lasing wavelength is shifted more than the specified limit. For a pulsed laser this limit implies a maximum pulse length which is of the order of 1 to 20 μs for the excitation intensities required for dye lasers.

The time required for the thermally induced optical inhomogenities to become significant has been measured interferometrically. A Michelson interferometer has been set up to probe the active volume of the laser under lasing conditions. Data will be presented from this time resolved interferometry and compared with the predictions made using the steady state values of the thermo-optic parameters of the dye solvent. Comparisons will be made between different solvent systems under different levels of excitation. These experiments provide the basic parameters which allow calculations to be made setting limits on the maximum average power available from single mode dye lasers.

1.9 A Free Stream Jet for High Power Dye Lasers,[1] R. J. Foley, T. C. Kuklo, and O. G. Peterson, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

High-power, narrow linewidth tunable dye lasers are required for laser isotope separation processes. Although high-power lasers exist, the combination of high power and narrow linewidth, of the order $(\Delta\lambda/\lambda) \approx 10^{-6}$ have been difficult to achieve since the linewidth stability is easily destroyed by temperature and velocity fluctuations[2] within the dye solutions. In enclosed dye cells, the excitation intensities required for high laser output have introduced thermal gradients into the dye fluid as a result of the low heat transfer in the boundary layer at the cell wall.

To eliminate the thermal problems at the boundary, a free jet stream of liquid dye solution has been investigated as a substitute for the dye cell in the laser cavity. A geometry was investigated which would be applicable to high average power, incoherently pumped dye lasers. For this application it is necessary to have the excitation illumination direction, solution flow, and laser mode axes mutually perpendicular. The excitation is focused through the air-liquid interface. The edges of the jet stream are bounded by quartz plates which serve as windows for the laser emission. Jet streams 76 mm in width have been investigated with thickness varying from 1 to 3 mm. To be effective in the laser the surface of the liquid-air interface must not distort the focus of the excitation illumination. Also, the jet must be stable at liquid flow velocities large enough to replace the dye solution in the active volume between every flash of a pulsed laser. Most importantly, the clear aperture in the direction of the laser mode axis must be essentially identical to the stream thickness.

The development of a nozzle and flow system that is capable of establishing a stable free stream jet is quite complex. Exact analytical solutions to describe the jet velocity profile and surface wave phenomena are difficult to obtain. However, hydrodynamic theories have been helpful in establishing guidelines for an experimental approach.

An experimental evaluation of three nozzle configurations was performed to establish the merits of each. The configurations tested were: (1) flow between two long parallel planes with 90° edges at the exit and width to thickness ratios of 20:1; (2) orifice flow with knife edges at the exit; and (3) flow from a converging slit. This testing established the magnitude of the effects of several parameters on the production of surface waves on the jet stream, namely: (a) fabrication imperfections of the nozzle; (b) end window contacts; (c) hydraulic pulsations and supply plenum turbulence; and (d) air friction.

The configuration with slot flow between long parallel planes has given the highest quality planar surfaces at fluid velocities up to 6 m/sec. The surface quality was improved by fabricating a nozzle with parallel planar walls and optical quality finishes on the walls and exit edges. The hydraulic pulsations and fluid turbulence were damped by use of a fluid accumulator and grids at the nozzle entrance. The fluid/air friction instabilities for a water jet have a critical relative velocity of $\Delta V \approx 6.5$ m/sec.[3] For velocity above this, a reduction of the air pressure in the region of the jet stream has reduced this surface effect.

The jet stream clear apertures were evaluated for each design over a range of Reynold's numbers in the laminar and turbulent regions by the use of laser interferometry. The laminar flow jets produce the highest quality surfaces, however, the clear aperture is not adversely effected by the transition into the turbulent regime.

Results will be presented on the operation of the jet in a flashlamp pumped dye laser. The laser output was measured as a function of solution flow rate to evaluate the reduction in coupling efficiency caused by scattering of the excitation illumination from turbulence induced surface waves.

2.1 Streak Camera Studies Using Picosecond Pulses of Photosynthesis and Plastic Scintillators. S. L. Shapiro, V. H. Kollman, R. C. Hyer, and A. J. Campillo,[1] *Los Alamos Scientific Laboratory, Los Alamos, N. M. 87544*

(15 min)

Picosecond laser techniques provide a unique opportunity to monitor the initial steps in photosynthetic processes. We have used a streak camera to study the fluorescent decay times of

[1] Work performed under the auspices of the U. S. Atomic Energy Commission.

several photosynthetic systems including the blue green algae *anacystis nidulans* and also *chlorella pyrenoidosa*. We have found that the high efficiencies for the conversion of solar energy is related to the high concentration of pigment dye molecules in cells. Specifically, the low quantum efficiency of these species can be simulated by mixing component dye species in a cell in about the same concentration and proportions present in the live cells.

An experimental result showing the fluorescence decay curves for chlorophyll *a* at two different concentrations is shown in Fig. 1. Chlorophyll *a* is present in living cells in about a concentration of 0.1 M. The decay time for this molecule in chloroform was measured to be as short as 10 ± 5 psec at 0.1 M concentration. Living cells show similar decay characteristics, and *anacystis nidulans* decays smoothly in intensity with a lifetime of 75 ± 10 psec. Careful calibration shows that the decay curves for photosynthetic species and for pigments at high concentrations are not exponential, but are very nearly of the same form as predicted by Förster.[2] The concentration quenching mechanism responsible for the observed fluorescent decay curves will be discussed.

Previous measurements on fluorescent decay times for *anacystis nidulans* and *chlorella pyrenoidosa* have indicated longer lifetimes than we report. Our results are more in accord with the known quantum efficiencies, and are made possible by the improvement in technique because of the application of the streak camera.

There has been much interest lately in resolving events on the picosecond time scale; however, it has been generally believed in the literature[3] that the typical fluorescent risetimes of commercial plastic scintillators were at best 300 ps. The measured risetime of NE 102, for example, under excitation of picosecond bursts of beta radiation was 0.9 ns in Ref. 3. Recently, however, Duguay and Olsen[4] have measured much faster fluorescent risetimes (~ 60 ps) when exciting NE 102, a commonly used plastic scintillator, with ultrashort bursts of X-ray radiation. This result has great potential importance as these scintillators can be used with optical gates or streak cameras to resolve ultrafast high-energy events. We have excited NE 102 with picosecond light pulses in an attempt to resolve any risetime discrepancy. We find that the risetime of the resulting 4200 Å fluorescence is less than 50 and 20 ps, for 0.265 and 0.353 μm, respectively. The rapid risetime of the observed fluorescence cannot be explained by pure radiative transfer of the energy between the dye molecules but is consistent with the Förster mechanism.[2] Our results are consistent with Duguay and Olsen.[4]

The experiment consists of a mode-locked Nd:glass laser which emits pulses of about 8-ps duration at 1.06 μm. These pulses are frequency doubled and/or summed in two consecutive

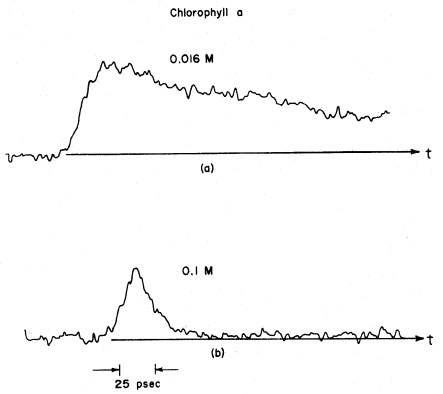

Fig. 1. Densitometer traces of streak photographs of chlorophyll *a* in chloroform showing strong dependence of fluorescent lifetime with concentration. 1(a) and 1(b) show, respectively, concentrations of 0.016 and 0.1 Molar.

KDP crystals to produce 0.353- and 0.265-μm radiation. Due to the dispersive properties of KDP, it is necessary to use a short fourth harmonic crystal (~ 3 mm) to insure that the resultant 0.265-μm pulses are not temporally stretched. We estimate that our exciting pulses were 10 ps in duration (FWHM). These harmonic pulses then excite the sample (thickness 0.3 mm) which emits fluorescence which is collected by a glass lens onto the slit of a LASL streak camera. Because of limitations inherent in the collection of light, the resolution of the 0.265- and 0.353-μm excited fluorescence was limited to about 50 ps and 20 ps, respectively. Data were recorded on both Polaroid and Kodak 2484 film.

The function of a ternary scintillator, composed of a solvent (x) and two solute dye molecules, is to convert the energy supplied by a particle or electromagnetic wave into the emission of light waves in a wavelength range best adapted for photomultiplier sensitivity. The energy first goes to the main constituent X, is then transferred nonradiatively to the primary solute molecule Y, and is finally transferred to the molecule Z which emits light near 4200 Å. In our experiment, the 0.353-μm radiation was used to directly excite molecule Z while the 0.265-μm radiation excites both X and Y molecules. The risetime of the resulting fluorescence at 4200 Å thus gives a measure of the nonradiative transfer time. A typical result is shown in Fig. 1.

The rapid risetimes of the fluorescence observed, i.e. <50 and <20 ps for 0.265- and 0.353-μm excitation respectively, cannot be explained by pure radiative transfer of the energy between the dye molecules. Rather, as first pointed out by Förster,[2] a nonradiative dipole-dipole interaction can account for the very rapid observed transfer times.

2.2 High-Speed Radiation Camera Using a PTM Ruby Laser and Hydrated Electron Absorption Phenomena,[1] Gerald W. Coutts and LaMar B. Olk, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

High-speed radiation cameras typically employ fast scintillators and framing cameras constructed of electronically shuttered image-intensifier arrays. With these systems, high-speed photographs of pulsed radiation sources are possible. For such systems, the meaningful time resolution is limited by the 1.7-ns fluorescence lifetime of the scintillator material and by the gating potential of commercial image intensifiers. To avoid these limitations, we have developed an ultra-high-speed radiation camera which makes use of the photo-absorption phenomena associated with the hydrated electron and of the picosecond pulses obtainable from a mode-locked dye laser.

Previous work has shown that the photo-absorption phenomena of the hydrated electron can be used as a sub-nanosecond pulse dosimetry mechanism. Acidic aqueous solutions can function as absorption mechanisms which convert rapidly changing radiation patterns into corresponding optical absorption patterns. Separate, time-resolved, high-resolution images of these transient absorption patterns can be transferred to photographic film with short laser pulses. The effective exposure time for the transferred image is limited by the absorption center lifetime and the width of the sampling laser pulse. Since mode-locked laser pulses of less than 5 ps can be obtained, the potential time resolution for such a system should be about 20 ps. The potential time resolution for such a system is far superior to existing scintillator-type framing camera systems.

In order to investigate the technical difficulties and develop the technique associated with the radiation camera outlined above, we have built and operated a 12-frame camera. A frame exposure time of 2.5 ns is achieved with a Pulse Transmission Mode (PTM) ruby laser. An optical beam-splitter delay arrangement provides 12 frames with an interframe time of 3 ns (3×10^8 frames per second). With this radiation camera, we have obtained photographs of a 60 ns (FWHM) burst of high-energy electrons absorbed in an aqueous cell.

Employment of a mode-locked dye laser and electronically gated image intensifiers has yielded a second-generation camera which obtains picosecond images and minimizes the synchronization problems inherent in the first-generation system. With the synchronization problems minimized, a six-frame camera with picosecond exposures and a 1-ns interframe time has been made a useful diagnostic tool. With this picosecond framing camera, we have obtained six frames containing 66- and 400-ps images of a 3-ns burst of high-energy electrons absorbed in an aqueous cell. These photographs contain previously unavailable information concerning the time-resolved electron-energy spectrum of a 706 Febetron.

2.6 Optical Sampling Transient Analyzer (OSTA) System,[1] Terence J. Davies and Melvin A. Nelson, *EG&G, Goleta, Calif. 93017*

(15 min)

The OSTA data acquisition system, shown in Fig. 1, has been developed to measure and digitally record the time-amplitude characteristics of a fast, high-voltage, large-dynamic-range, single transient electrical signal. It has a bandwidth response of about 1 GHz. A typical signal of interest might range in amplitude from about 10 V to many kilovolts, and in time from a few nanoseconds to tens of nanoseconds duration.

The system takes successive 350 ps-wide samples of a signal every 350 ps, or longer as desired, and converts the samples to a digital number. The number of amplitude samples that can be taken by the present system is 21, but the technique will accommodate many times that number of samples.

Duration of the sampling window is determined by the selected sampling interval in combination with the number of samples taken. Sampling intervals from 350 ps to 2 ns, or a total signal window as narrow as 7 ns to as wide as 40 ns for all samples are provided for in the present system. Time resolution between signal samples is better than 50 ps, and amplitude resolution is 0.1 percent.

Sensitivity of the present system (equivalent "trace width" sensitivity) is approximately 10 V. This is not a fundamental limit. The system will measure signal amplitudes to the breakdown limit of the electro-optical modulator (greater than 20 kV).

Using the OSTA technique, the sensitive sampling circuitry is completely isolated electrically from the input signal since sampling is carried out on the optical analog of the input signal. The input signal is unaffected by the sampling process and later signal values do not affect the sampled data. Also, the dynamic measurement range of the sampling circuitry is independent of the signal voltage and is always within prescribed limits.

The four major subsystems that constitute the OSTA system are an electro-optical modulator assembly, a short-pulse laser subsystem, optoelectronic charge-collection circuitry, and digitizing and recording apparatus. The diagnostic signal being measured is connected to the traveling wave Kerr cell-type electro-optical modulator, which appears electrically as a section of liquid-dielectric transmission line. The electrical signal passes down the cell at a velocity of approximately 5 cm per nanosecond, where nitro-benzene is the dielectric fluid. The electrical signal then passes out of the cell and into a get-lost line for further measurement or termination. This line is also used to connect a dc bias voltage source to the Kerr cell. Bias enhances the signal sensitivity of the cell.

When the signal to be measured is present in the cell, a short-pulse laser is triggered to emit a single high-intensity 350-ps wide optical sampling pulse. This pulse is divided into multiple sampling pulses by directing it onto one end of a fiber optic light guide bundle which is separated at its other end into a multiplicity of individual light guides, each a different length and each directed through the Kerr cell at a different point along its body. The graduated length variations cause the sampling pulses to arrive at each Kerr cell location at a different time. This preselected time difference determines the signal sampling rate.

Optical transmission at each sampling point (in conjunction with polarizer and analyzer) is a function of the instantaneous voltage across the cell electrodes at that sampling point. Hence, the sampling pulse intensities transmitted through the cell are optical analogs of that voltage. Each sample is collected into a separate light guide and channeled to its own semiconductor detector. There, the optical flux is converted to electrical charge and temporarily stored using charge-hold circuitry for the time required to multiplex all analog samples into a digitizer. The digitized data are stored in a memory and printed out on command, or transmitted to permanent storage in a computer memory where the electrical input signal amplitude at each sampled point can be reconstructed and other processing and analysis effected.

3.2 A Near Real-Time Coherent Optical Processing System Using Two Itek PROM Devices,[1] S. Iwasa, *Itek Corporation, Lexington, Mass. 02173*

(15 min)

A near real-time coherent optical processing system has been demonstrated using two Itek PROM devices[2] and a TV monitor. The PROM (Pockels Readout Optical Modulator) is a recyclable electro-optic device for image storage developed by Itek. A reflection-type device was placed in the input plane as an incoherent-to-coherent image converter, and a transmission-type device in the Fourier transform plane as a laser addressed programmable Fourier filter. A video camera with a TV monitor was placed in the output plane for the observation of the filtered images.

A scene is incoherently imaged on, and stored in, the first PROM from a transparency using the 436 nm line of a mercury arc lamp. A He-Ne laser 633 nm line coherently reads out the stored scene and the optics is so arranged that the Fourier transform of the scene falls on the location of the second PROM. Preprogrammed filter patterns are generated on the second PROM by means of a krypton laser 476 nm line, an electronic programmable pattern generator, an electro-optic modulator and an *xy* deflection system composed of an acousto-optic deflector and a galvanometer. The intensity-only filter patterns include wedges, circles, rings and spirals. The PROM device is capable of electrically reversing the image contrast; therefore, a wedge pattern provides either a slit or a line-stop in the Fourier plane. Similarly, a circle provides either a high pass or a low pass; a ring, a band pass or a band rejection. The spiral pattern generates a transmission function proportional to the square of the spatial frequency and is used to demonstrate spatial differentiation (edge enhancement). The TV camera monitors the reconstructed scene before and after the programmable filtering operation.

In the present experiment, the first PROM is exposed at an energy density of about 200 ergs/cm^2 typically, in less than 1/10 sec with a 100 W mercury lamp. Concurrently, one programmed pattern is generated on the second PROM in about one second. The erasure and prepoling of the devices take approximately 3 msec. The total cycle therefore takes one second plus the inspection duration on the TV monitor. The slow speed of the present electronic pattern generator is the limiting factor. With improved instrumentation, the processor should operate at a much faster rate. Needless to say, a scene can be entered into the first PROM via another laser addressed scanning system allowing full automation of the processor.

3.3 Selective Erasure and Parallel Processing in Holograms Superimposed in $LiNbO_3$ Crystal, J. P. Huignard, J. P. Herriau, F. Micheron, and J. M. Rouchon, *Thomson-CSF, Laboratoire Central de Recherches, Orsay, France*

(15 min)

It has been demonstrated that high storage densities can be achieved by recording three-dimensional holograms stacked in photosensitive electrooptic crystals. Nevertheless, read-write operations in such optical memories are limited by existing erasure techniques; optical and thermal erasures are both bulk processes, which do not discriminate between different volume holograms.

We report a new technique which provides selective erasure of any hologram superimposed in the crystal volume, and selective erasure of any block in a recorded data set. This technique is called a coherent erasure since it is based on recording a hologram complementary to the one to be erased; this we obtain by recording the same object as previously recorded, but with a 180° phase shift in the reference wave. This operation is shown to cancel refractive index changes induced during recording.

Experiments were performed in reduced $LiNbO_3$:Fe single crystals, which show strongly asymmetrical write-erase cycles. Erasure during continuous readout, at the recording wavelength, requires a light energy density much larger than for recording. When using the coherent erasure technique, the write-erase cycle becomes quite symmetrical. The number of such write-erase cycles achievable in the same volume of the crystal is limited to an order of ten by scattering effects which occur after long exposure to a coherent light beam.

This technique can be used in a read-write optical memory, as described in Fig. 1. Different holograms $H_1 \dots H_i \dots H_n$ of objects $O_1 \dots O_i \dots O_n$ are superimposed in the $LiNbO_3$ crystal, using, for example, a liquid crystal page composer. Erasure of the hologram H_i is achieved as follows. The corresponding object O_i is reconstructed on the photodetector array, and the out-going electrical signals are used for composition of O_i on the page composer. A 180° phase shift is introduced in the reference wave, and O_i is recorded with the same geometrical conditions as used for the first recording. This operation results in complete erasure of H_i only.

Coherent erasure can be applied to a block b_i of data contained in O_i. After having reconstructed O_i on the photodetector array, the part corresponding to b_i in the electrical signals is used to recompose b_i. Recording b_i with the 180° phase shift erases b_i in the object O_i. Demonstration of this partial erasure is given in Fig. 2; (a) shows the reconstruction on a TV camera of the recorded object, and (b) the reconstruction with partial erasure. We have shown that such partial erasure can be achieved in any hologram superimposed in the crystal volume.

When an object O_1 has been recorded, recording an object O_2 under the same geometrical conditions, but with a 180° shift, produces

erasure of common parts of O_1 and O_2. This operation provides the difference between O_1 and O_2, and the Boolean Exclusive OR between two digital objects. Since the Boolean OR is easily obtained by recording successively two digital objects, any Boolean operation can be performed by combinations of these two operations. This is the first demonstration of parallel processing between data blocks optically recorded in a three dimensional storage material.

3.4 Laser Color Video Printer Breadboard, R. E. Baldwin, B. G. Fike, and J. H. Ladd, *Eastman Kodak Company Research Laboratories, Rochester, N. Y. 14650*

(15 min)

The laser color video printer breadboard was built to investigate the effect of laser raster exposure upon conventional color photographic materials; to demonstrate feasibility to read a color negative and to expose a color print in synchronism by a single raster; to determine what factors limit print quality; and to determine what factors limit throughput rate. The photometer section of the breadboard scans a $2\frac{1}{4} \times 2\frac{1}{4}$ inch color negative with a single 2560-line raster by means of two galvanometers. Simultaneously, the printer section of the breadboard exposes an 8×10 inch color print. The red, green, and blue wavelengths for negative photometry and for print exposure are 647, 521, and 476 nanometers, all from one 0.4-watt krypton ion laser. A color video signal processor is inserted between photometer and acousto-optic modulator.

If throughput rate for such a printer were limited only by the red, green, and blue radiant power available from the laser, printing rate could be about one 8×10 inch print per second. However, total time per print in the breadboard is determined by the speed of and the mass carried by the fast galvanometer. Exposure time is about 2.5 microseconds per picture element and the raster is completed in about 20 seconds.

Galvanometer instability and pincushioning are compensated for in the breadboard by scanning the negative and exposing the print simultaneously with two-faced mirrors mounted on the two galvanometers. To a first approximation, timing jitter between adjacent scan lines and nonlinearity of individual scan lines do not degrade picture quality because "identical" jitter and nonlinearity occur both at the negative plane and at the paper plane. Nevertheless, print sharpness and resolution are limited primarily by the size and flatness of the two mirror faces carried by the fast galvanometer. These two mirror faces do not fill the entrance pupils of the two special achromatized lenses in the scanner and printer optics.

A set of 8×10 inch color prints were exposed in a conventional optical enlarger. Replicate color negatives were printed on the laser color video printer breadboard. Direct visual comparison of the 8×10 inch prints permits the following inferences: (1) D_{max} in the optical prints is noticeably higher than in the laser prints. This is a consequence of video signal processing parameters, not inherent in laser prints. (2) The optical prints are definitely sharper. (3) Small, whitish "noise" spots appear on the laser prints, but not on the optical prints. The spots would be eliminated if the laser photometer were to have diffuse, rather than specular, collection of the light transmitted by the color negative. (4) Laser prints have the same color saturation and can provide about the same color balance as optical prints. However, some exposure of the green-sensitive layer from the 476-nanometer blue wavelength produces orangish yellows.

The breadboard includes electronic circuits by which to generate a variety of line and dot patterns for raster studies, and to generate a set of 64 colored patches with set proportions of red, green, and blue exposure. The patch generator has been used for sensitometric exposure experiments with many kinds of color photographic films and papers. The sensitometry has disclosed some speed and contrast shifts for 2.5-microsecond exposures of products which are customarily exposed at 1/50 second. However, macro densitometry of patches from laser exposures of the products tested showed no sensitometric phenomena which would discourage laser raster exposure of color photographic films and papers. Indeed, the point-to-point signal processing possible in such a printer offers potential advantages not attainable in any conventional optical printer.

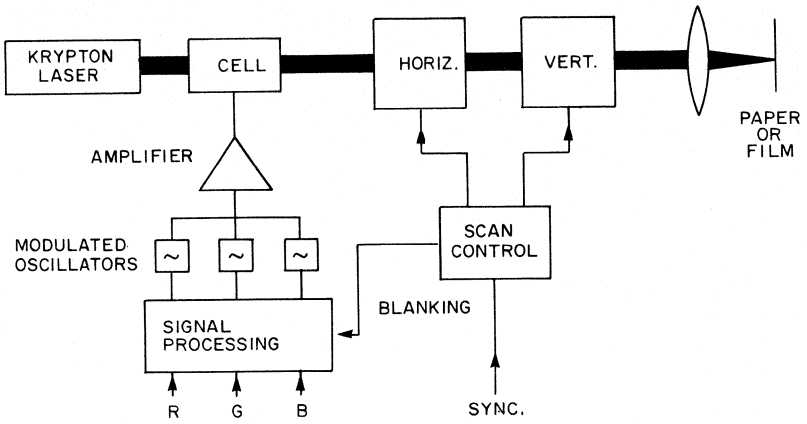

Fig. 1. Laser printer concept.

3.5 Interferometric Measurement and Display of Ultrasonic Waves, R. Mezrich, K. F. Etzold, and D. Vilkomerson, *RCA Laboratories, Princeton, N. J. 08540*

(15 min)

The optical arrangement for a new system[1] to measure and display ultrasonic waves is described. Using interferometric techniques, combined with a deflection method, displacement amplitudes as small as .05 Å, over apertures as large as 150 mm and with submillimeter lateral resolution can be observed. The system also includes a simple but effective open loop method to stabilize the interferometer and at the same time minimize the flatness requirements of the optical elements used.

The arrangement is schematically shown in Fig. 1. The basic structure is that of the Michelson interferometer. One mirror is a thin flexible metallized membrane, or pellicle, suspended in the water bath, and through which the acoustic waves pass. The pellicle is transparent to the acoustic waves, so its motion at every point is almost exactly equal to the displacement amplitude of the acoustic wave at that point. The second mirror is external to the water tank.

A deflection system, using mirror galvanometers, is included in the pellicle leg of the interferometer and is arranged so the virtual pivot point of the orthogonal deflections is at the front focal point of lens L_4. As the beam is scanned the light is normally incident on the pellicle and is thus reflected back through the optical system to interfere with the light from the reference mirror.

A component of the interference is proportional to the motion of the pellicle, and hence displacement amplitude of the acoustic wave. This component is measured and then processed for display. Maximum response occurs when the light from the pellicle and reference are in phase quadrature. To obtain this maximum response, even in the presence of thermal or mechanical disturbances, the reference mirror is vibrated or "wiggled" with a maximum excursion of at least $\lambda/4$ (which causes a $\lambda/2$ phase shift). At least once per cycle of the "wiggler" the relative phase between the pellicle and reference must pass through 90°; by peak detecting the output (which is maximum at this point) the response is as if the system were stable and always in quadrature. The frequency of the "wiggler" must be large compared to the frequency components of material velocities, but low enough so that high harmonics of the wiggler do not fall into the signal band. To measure acoustic frequencies in the range from .5 to 10 MHz, wiggler frequencies of 20-100 KHz are used. A further benefit of the use of the wiggler is that the requirement on optical flatness is reduced; with its use, a pellicle flatness of 3

[1] *IEEE Ultrasonic Symposium*, Milwaukee, Wisconsin, November 1974.

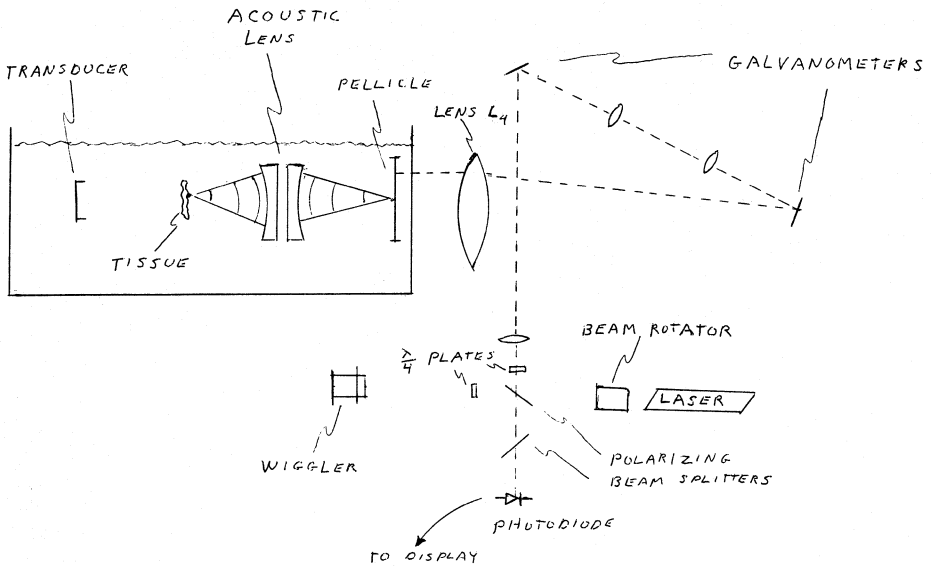

Fig. 1.

waves/inch gives 90% of the response of an ideally flat mirror.

To isolate the laser from the interferometer, and to provide means for varying the beam balance in the two legs, a polarizing beam splitter (PBS) with a quarter wave plate in each leg of the interferometer is used. The polarization angle of the incident beam is varied to change the beam balance. A second PBS is used to analyze the interference. By using both outputs from this second PBS, which has a 180° relative phase shift, the response is doubled and common mode noise is minimized.

This system, with associated electronics and display circuitry, has been used to measure and display ultrasonic waves, and some examples are given. It is being used to measure ultrasonic transducer response, to measure and display the interaction between biologic tissue and ultrasound, and as an aid in the design of ultrasonic lenses. In this paper we want to stress the optical design of the system and discuss other applications in the measurement of small motions of mechanical objects.

3.6 Wideband Guided - Wave Acoustooptic Bragg Devices Using Multiple Tilting Surface Acoustic Waves,[1] C. S. Tsai, M. A. Alhaider, LeT. Nguyen, and B. Kim, *Department of Electrical Engineering, Carnegie-Mellon University, Pittsburgh, Pa. 15213*

(15 min)

Experimental results with guided-wave acoustooptic devices, utilizing coplanar Bragg diffractions, have suggested that these devices are capable of performing a number of important functions such as deflection/switching, modulation and spectrum analysis of rf signals.[2] However, all of the various forms of the devices which have been reported employ only a single surface acoustic wave (SAW) interdigital transducer and, therefore, a single SAW. The inherent limitation of devices which employ a single interdigital transducer is a relatively small acoustic bandwidth and thus a small device bandwidth. A further limitation is that in order to achieve a large device bandwidth (assuming a sufficiently large acoustic bandwidth) the aperture of the acoustic wave must be chosen very small. This in turn results in a drastic decrease in diffraction efficiency. Recently, we have explored a wideband device configuration which employs multiple tilting SAWs which are staggered in their center frequency and tilted in their propagation direction, and have achieved some preliminary experimental results.[3] For example, by employing just two tilting SAWs on a *Y*-cut $LiNbO_3$ out-diffused waveguide, a bandwidth of 200 MHz at 50% diffraction efficiency was obtained, requiring a total electric driving power of only 200 mW.[3] This performance figure greatly exceeds those obtained in previous devices which employ only a single SAW.[2]

We report in this paper theoretical results relating to the wideband device configuration, namely, guided-wave Bragg diffraction from multiple tilting SAWs, and a number of new experimental results which serve to verify the theoretical predictions, including the performance characteristics of a device which is capable of a 300 MHz bandwidth. In addition, the results of a number of experiments which are designed to demonstrate the potential applications of this type of wideband device are presented.

The theoretical results have established the relevant device parameters as well as the important design considerations. Experiments using two to four tilting SAWs on single-mode *Y*-cut $LiNbO_3$ out-diffused waveguides were carried out to verify the theoretical predictions. In particular, the theory and experiments have established the relationships among the three most important design parameters required for large bandwidth: acoustic angular spread of individual SAW, tilting angle between adjacent SAWs and the phase difference between adjacent SAWs. In one of the wideband units being studied, a device bandwidth of 300 MHz has been achieved, requiring a total electric driving power of 350 mw at 50% diffraction efficiency. Also, a diffraction efficiency as high as 85%, requiring a total electric driving power of 197 mw, has been obtained with one of the lower bandwidth units. A further reduction in the electric driving power should be possible by connecting matching networks to the transducers. A device bandwidth of 300 MHz enables the device to deflect a guided-light beam of 1 cm aperture into 862 resolvable spot diameters with a switching time of 2.8 μs. Equivalently, the same device is capable of switching a guided-light beam into 10 beam positions with a switching time of 33 ns. The devices being studied consistently provide a through-put coupling efficiency of greater than 20% and good optical beam quality.

The experiments that have been designed to demonstrate the potential applications of the wideband guided-wave acoustooptic Bragg devices include: 1) RF spectrum analysis, 2) multiport beam deflection and switching, 3) optical pulse modulation, and 4) signal processing of RF signals. Some of the performance figures obtained are reported.

3.7 Multichannel Interferometry, C. R. Pond and P. D. Texeira, *The Boeing Aerospace Company, Seattle, Wash. 98124*

(15 min)

The multichannel interferometer[1] is well suited for applications requiring simultaneous measurements over several optical paths. A substantially improved version of the referenced interferometer has been used as a dilatometer to measure the coefficient of thermal expansion of low expansion composite structural forms ($\alpha \simeq 10^{-8}$ cm/cm−°K) during the engineering phase of the Large Space Telescope (LST) metering truss development program.

[1] This work was supported jointly by the ONR and the NSF.

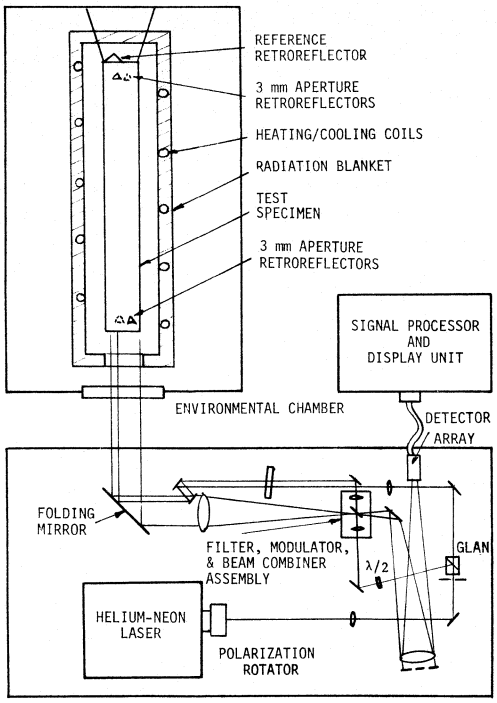

Fig. 1. Multichannel Interferometer setup for dilatometry.

The multichannel interferometer consists of several parallel fringe counting interferometers with a single laser as the source. Common optical elements – modulator, beamsplitters, collimator, folding mirrors, etc. – are used to reduce environmental effects. A common reference beam eliminates errors due to variation in reference beam path length.

Fig. 1 shows the basic configuration of the interferometer as used for dilatometry. (The folding mirror will be replaced by an array of seven adjustable mirrors when the interferometer is used for testing the full scale LST truss.) The laser is a single frequency, stabilized helium-neon laser. The polarization rotator, Glan prism, and $\lambda/2$ plate form a variable, low loss beamsplitter for optimizing the relative power in the signal and reference beams. The reference beam is retroreflected at the test specimen to compensate for gross relative motion between the interferometer and the specimen.

The interferometer employs a novel electro-optical element (designated FMC for filter-modulator-combiner) which performs the functions of spatially filtering the beams, modulating the relative phase of the signal and reference beams, and combining the reference with the signal beams that return from the test specimen. The FMC consists of a 1.5 mm square glass plate, 0.2 mm thick, mounted on the end of a piezoelectric bender and held between two 10x microscope objectives. A 7×10 micron elliptical mirror is deposited on either side of the glass plate, using microcircuit fabrication techniques. These mirrors are the reflection analog of a pinhole spatial filter, where the input signal and reference beams (parallel polarization) are focused onto the elliptical mirrors. The filtered beams are reflected near Brewster's angle, while the unfiltered light passes through the glass. The mirrors are offset so the filtered reference beam coincides with the return signal beams, insuring misalignment between the input beams. This effectively prevents feedback into the laser. The relative phase modulation needed for bidirectional fringe counting is provided by a low voltage drive on the bender.

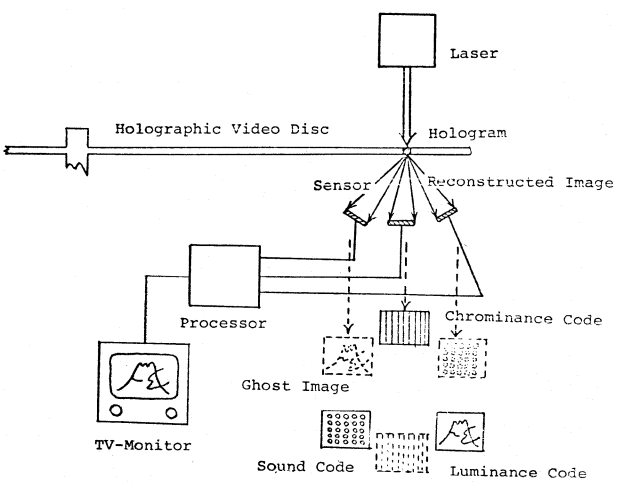
The outgoing signal beam is spatially filtered and recollimated to 5 cm diameter. Small cube corner reflectors at each test point reflect signal beams back to the spatial filter, forming diffraction patterns that are large compared to the filter mirror. The obstruction loss is less than 1%. Specimen orientation variation necessitates two retroreflectors at each end. The spherical mismatch in the signal and reference wavefronts is removed by fine adjustment of the collimating lens. The detector array is seven phototransistors. The signal processor produces an up or down pulse for each 90% phase change between signal and reference beam. These $\lambda/8$ increments are accumulated in the display unit which provides binary coded decimal output in addition to a decimal display.

3.8 Optical Video Disks (*Invited*), Eric Spitz, *Central Research Laboratory, Thomson-CSF, Domaine de Corbeville, France*

(30 min)

The optical video disk is expected to become a new, inexpensive medium capable of carrying information, educational or entertainment material. Players and disks now under development in a number of laboratories handle information densities of about 10^8 bits/cm^2. This paper reviews the fundamental considerations and optical design principles of these developmental systems, discusses the problems encountered and describes the solutions presently envisaged.

3.9 A Holographic Video Disk: An Alternative Approach to Optical Video Disks, Y. Tsunoda, K. Tatsuno, and Y. Takeda, *Central Research Laboratory, Hitachi, Ltd., Tokyo, Japan*



(15 min)

One of the problems with optical video disks employing FM coding is the precise focusing and tracking adjustment needed in a player intended for use in the home. To resolve this problem, a holographic video disk is proposed and examined at a fundamental stage.

Construction of the player is explained in Fig. 1. A disk of 300 mm diameter contains 54,000 holograms, each of which stores luminance, chrominance and sound codes in a small area of 1 mm diameter. The extremely high packing density is realized by combining the random phase sampling technology[1] with the

[1] Y. Tsunoda and Y. Takeda, *Appl. Opt.*, vol. 13, p. 2046, 1974.

Fig. 1. Basic concept of the holographic video disk player.

method of coherent superposition of holograms. Interference between the ghost images and the reconstructed images is eliminated by setting the incident angles of the three information light waves in three axially symmetric directions. Reconstructed images are focused on the image sensors (such as solid state sensor arrays) whose output signals are processed and displayed on a TV monitor. As a light source, a compact laser is used. There is no need for precise focusing or tracking of the laser beam. To obtain rotational immobility of successively reconstructed images, the laser waves are chopped or directly modulated.

To clarify the above design considerations, several fundamental experiments were carried out.

Photoresist was selected as the storage medium in order to make a master disk for duplication by stamping. The restricted dynamic range of the photoresist was controlled by pre-exposure. For the luminance and the chrominance signals, conventional EVR coding was used. The sound signal was converted into sampled pulse code modulation. The optical axes of these three information signals onto the hologram plane formed an angle of 120° with each other. For each information signal a sampling mesh and a random phase shifter were closely attached and set in the optical path of a He-Cd laser (4416 Å). Almost all of the light energy of the information signals was uniformly distributed in the restricted hologram area. The diameter of the hologram was related to the diameter of the sampling hole by the Rayleigh Criterion. As a result, the three information signals could be stored in a hologram of 1 mm in diameter without speckle noise. More than two thousand holograms were arranged on a photoresist disk to give several minutes of play of motion pictures in color. The signal-to-noise ratio of the reconstructed images was found to be 38 ± 2 db in both single and superimposed holograms. Continuous rotation of the disk at 6 RPM gave color motion pictures and sound on a TV monitor. Each hologram had information corresponding to 1/30 seconds. Chopped illumination of each hologram facilitated smooth motion of the pictures and assured immobility.

Session 4

Wednesday, May 28, 1975 1:30-5:00 P.M.

Solid State Lasers

Chairman: L. G. DeShazer, *University of Southern California, Los Angeles, Calif.*

Organizer: A. J. Glass, *Lawrence Livermore Laboratory, Livermore, Calif.*

4.1 Active Mirror: An Alternative Design for a High Power Nd:Glass Amplifier, J. Hoose and J. Soures, *University of Rochester, Laboratory for Laser Energetics, Rochester, N. Y. 14627*
(15 min)

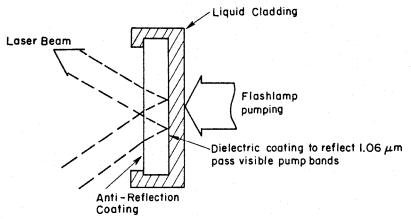


Fig. 1. Schematic of active mirror amplifier.

At present only two general types of amplifiers are being used in high energy short pulse glass laser systems. These are the face pumped disk[1,2] and large diameter rod[3] amplifiers. The inherent disadvantages of the open face disk geometry are:

(i) Relatively low pumping efficiencies,

(ii) Maintenance problems due to high light flux loading on the interior surfaces of the amplifier, and

(iii) Low repetition rates due to the relatively slow air cooling.

The basic drawbacks of rod amplifiers are:

(i) Stored energy is not as high as with disk amplifiers,

(ii) Repetition rates are also low due to thermal lensing and thermally induced stress birefringence.

In an attempt to overcome some of these problems, we have re-examined a relatively old design, the active mirror.[4] The principle of operation of such an amplifier is shown in Fig. 1. This design combines the advantages of the larger diameter possible with disk amplifiers, with the characteristic higher efficiencies attained by rod amplifiers. In addition, because it lends itself to liquid cooling, considerably higher repetition rates could probably be achieved with this type of amplifier than with either rods or open disks. The possible problem areas of such a design are:

(i) Possible coating damage due to large pump fluxes,

(ii) Warping of the disks due to heating, and

(iii) Possible beam deflection due to flashlamp induced acoustic shock incident on active mirror.

[2] M. Lubin, J. Soures, and L. Goldman, *J. Appl. Phys.*, vol. 44, p. 347, 1973.

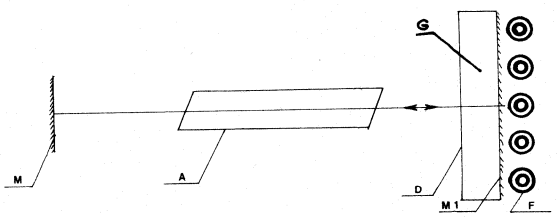
[3] J. Soures, S. Kumpan, and J. Hoose, *Appl. Opt.*, vol. 13, p. 2081, 1974.

[4] J. P. Chernoch, U. S. Patent 3,525,053, August 28, 1970.

Several prototype amplifiers of this design have been built and tested. The largest unit tested so far utilizes a 15 × 10 × 1.4 cm thick slab of ED-2 laser glass. It was found that average stored energy densities in excess of 0.6 J/cm^3 could be achieved with pumping efficiencies well over 1%. At these flux levels no coating damage has been observed for hundreds of shots.

The results of experiments to measure beam distortion and deflection will be reported and the staging of a large glass laser system utilizing active mirror amplifiers will be discussed.

4.2 Face-Pumped Mirror-Like Structure as an Alternative to Disk Amplifiers, G. Bret, M. C. Hurand, and J. C. Boltz, *Energetic S. A., Vigneux, France*
(15 min)



In the design of high energy, high power, light amplifiers, efficiency and reliability are of prime importance. Reliability depends strongly on the self trapping of small scale spatial fluctuations related to the nonlinear index of refraction. This effect can be limited by using high gain systems and low power density beams.

In conventional design, where pumping efficiency is poor, increasing the overall efficiency requires an increased extraction efficiency, accomplished by raising the power density in the beam.

It is easy to understand that a design with a much larger pumping efficiency would permit a now impossible trade-off, by lowering the power density, giving a much better reliability, but still keeping the total efficiency at an acceptably high level.

We have studied a structure made of a plate of glass coated on one side with a dielectric mirror which is transparent to the pump light, but reflects the 1.06 μm light to be amplified. A sketch of the design is given on Fig. 1, where *F* is an array of linear flash lamps, *M*1 is a mirror reflecting the 1.06 μm light to be amplified, but transparent for the pumping light, and *G* is a disk of Owens-Illinois glass 2.5 cm in thickness with a 3% neodymium concentration. The figure also indicates the system that was used to measure the gain of the design using the known variations of gain of a rod amplifier *A*, together with a second mirror *M*. Data are presented showing the linear increase of measured small-signal gain with pump energy, and of energy

Fig. 1. Design of face-pumped mirror-like structure.

stored per unit surface area with pump energy per unit surface area. These data show that a maximum pumping efficiency of 2% is possible. This represents a nearly ten-fold increase compared with standard disk designs.

Such a system is very promising for large beam amplification since it is scalable. Several problems related to mirror deformation, induced birefringence, cooling and pump light filtering have been solved, and will be discussed during the presentation of this paper.

4.3 Tailoring Nd-Doped Glasses for Laser Applications: Dependence of Induced-Emission Cross Sections on Composition,[1] R. R. Jacobs and M. J. Weber, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The spectroscopic and optical properties of Nd laser glasses are dependent upon the chemical composition of the host. Thus it is possible, by compositional changes, to tailor Nd glasses for specific laser applications. We have conducted an extensive program directed toward the development of an optimal Nd^{3+} glass medium for laser fusion experiments. Many glasses have been investigated, ranging from simple fused silica to complex multi-component oxide glasses. In these studies, the induced-emission cross section for the $^4F_{3/2} \rightarrow {}^4I_{11/2}$ lasing transition was varied by a factor of four as a result of changes in glass composition.

Radiative intensities in Nd-doped glasses are analyzed using the Judd-Ofelt theory of electric-dipole transition probabilities for rare-earth ions. In this treatment the line strength for a transition between two J states is expressed as a sum of three terms involving products of matrix elements and phenomenological intensity parameters $\Omega_2, \Omega_4, \Omega_6$. The latter are determined experimentally from a least-squares-fit of absorption spectra. These parameters, in turn, are used to calculate the probabilities for optical transitions between any electronic states of interest and hence properties such as absorption intensities, fluorescence intensities, branching ratios, and radiative lifetimes can be evaluated. By combining the results of these intensity calculations with linewidth data from emission spectra, induced-emission cross sections are obtained.

Recently Krupke[2] applied the Judd-Ofelt model to predict induced-emission cross sections at ≈ 1.06 μm for four Nd-doped silicate laser glasses with results which were in good agreement with experiment. We have extended Krupke's technique to investigate a large variety of possible laser glasses. The Judd-Ofelt parameters are found to depend upon the specific ions used both as glass network formers and network modifiers. As an example, measurements of alkali alkaline-earth silicate glasses have shown a systematic trend in the absorption and emission properties as the network modifying ions are varied. By changing the alkali ion in the series K_2O-Na_2O-Li_2O, both the Ω's and the predicted transition probabilities increase with decreasing ion size. The result is in agreement with the experimental determinations of cross section by Sarkies *et al.*[3] and fluorescence lifetime data of Rapp.[4] Another example of the use of the Judd-Ofelt model is to evaluate the branching ratios of the fluorescence from the $^4F_{3/2}$ state to the ^4I states of Nd^{3+}. These ratios can be expressed in terms of the ratio of intensity parameters Ω_4/Ω_6. Thus to optimize the emission intensity for a particular transition, appropriate compositional changes can be made to obtain, as nearly as possible, the desired Ω values. Variations in the emission wavelengths and peak induced-emission cross sections for the $^4F_{3/2} \rightarrow {}^4I_{11/2}$ and $^4F_{3/2} \rightarrow {}^4I_{13/2}$ transitions of several different glass compositions will be presented and compared with commercial laser glasses.

In addition to silicate glasses, the intensity parameters have been determined for several borate, silicate, phosphate, germanate, tellurite, aluminate, and titanate glasses. Changes in the Judd-Ofelt parameters for these glass compositions will be discussed with respect to their usefulness in designing glasses for specific laser applications.

Finally, the intensity parameters for any Nd glass medium can be used to determine the optical pumping efficiency, radiative lifetime, saturation parameter, and probability for parasitic oscillation in large amplifier disks. These considerations, which are important for arriving at an overall figure of merit for a laser glass, will be discussed in connection with a final selection of glass composition.

4.4 2.06 μm Laser Performance and Design Options for Rangefinder and Illuminator Applications,[1] D. P. Devor, *Hughes Research Laboratories, Malibu, Calif. 90265*

(15 min)

The highest unit rod volume laser efficiency occurs for Ho^{3+} ($^5I_7 \rightarrow {}^5I_8$) output from Er-Tm sensitized Ho:YLF. Spectrally broad, high optical density pump bands and high laser efficiency result from Er-Tm sensitization. These effects allow large reductions in design scale in addition to other new design options for sources using $Y_{1-x-y-z}Er_xTm_yHo_zLiF_4$. Operating at 2.06 μm, laser applications include efficient, alternative wavelength sources for target designator/illuminators and eye-safe rangefinders for both civilian and military devices.

[1] Supported in part under U. S. Army Electronics Command contract.

Ho:YLF is easily and rapidly grown using a reactive atmosphere crystal growth process. A 6-hr growth cycle Czochralski ingot yields several laser rods of glass-like optical quality. Because of easy growth, systematic variation of ion concentrations x-y-z has been possible and allowed study of effects on laser performance. Horizontal Bridgman crystal growth method can be used for large scale, inexpensive rod production when x-y-z values are fixed. Thermal and elastic properties of birefringent Ho:YLF are satisfactory. Maximum power dissipation of fracture stress limit is 60% of the Nd:YAG value.

New laser design options result from significant changes in laser performance occurring with variation of Er-Tm sensitizer concentrations x-y and Ho activator concentration z. Trade-offs can be made for pump-band optical densities, laser threshold, slope efficiency, and output pulse power. Design options therefore occur for choice of pump lamp and lamp parameters, resonator configuration, rod dimensions, and cooling system. The options are generally interdependent. Optimum Er-Tm-Ho concentrations exist for particular laser applications of Ho:YLF.

Rod colling requirements have more flexibility for 2.06 μm laser design than for similar performance Nd:YAG systems. The Ho:YLF laser transition terminal level is 300 cm^{-1} above ground and is thermally populated at 300°K. For ambient temperature operation the minimum possible metastable level excitation necessary for laser gain requires 2.4 J per unit rod volume (cm^3) per atomic percent Ho concentration. For light weight, portable sources where minimum laser threshold is an important system requirement, a small diameter laser rod will also minimize rod thermal gradients. With simple lamp-rod imaging optics, rod and lamp dimensions are 1-to-1 and reliable lamp performance requires about a 1 mm bore lamp, implying a minimum 1 mm rod diameter. Selective variation of rod diameter depends on efficiency of rod pump light absorption. Consequently, pump level optical densities and efficient pump-to-metastable level energy transfer requirements provide additional design constraints.

The Ho:YLF pump band spectral distribution covers 90% of a pulsed xenon lamp spectral output. Respective Er^{3+}, Tm^{3+} and Ho^{3+} levels account for 45, 13, and 42% of the spectral distribution of pump levels. Threshold consideration requires modest Ho concentration, indicating variation of Er concentration for control of pump band optical density. Although Tm^{3+} levels weakly contribute to pump light absorption, Tm concentration is necessary for fast pump-to-metastable energy transfer rate. Extensive recorded data on Ho:YLF concentration effects indicate an Er-Tm-Ho energy transfer interaction contrasting with results reported for other ion interaction systems. However, the data do provide empirical criteria satisfactory for laser design for specific application requirements.

For a heavy system with low duty-cycle requirements, such as high output energy rangefinders, a design option different from threshold minimization occurs. The Ho:YLF x-y-z con-

centration performance data show a cross-over where laser slope efficiency improves although threshold also increases.

4.5 Barium Sodium Niobate Acoustooptic Mode-Locker/Frequency-Doubler (AOML/FD) for Nd:YAG,[1]

R. R. Rice and G. H. Burkhart, *McDonald-Douglas Astronautics Company East, St. Louis, Mo. 63166*

(15 min)

One highly promising space laser communication system utilizes a frequency doubled Nd:YAG laser transmitter mode-locked at 500 MHz. In such a laser, intracavity acoustooptic loss modulation is superior to electrooptic phase modulation for achieving narrow mode-locked pulses and stable operation, and resonator loss must be minimized for maximum efficiency. We have developed an acoustooptic mode-locker and frequency doubler (AOML/FD) that uses a single barium sodium niobate (BSN) crystal to both frequency double and acoustooptically mode-lock a Nd:YAG laser. Thus, one intracavity component is eliminated.

A typical AOML/FD unit measures only 4.5 cm × 4.2 cm × 1.9 cm. A BSN crystal was cut in the form of a rectangular parallelopiped 5 mm × 5 mm × 2 mm with the crystal axes parallel to the edges. The 2 mm × 5 mm faces normal to the *c*-axis were polished flat and parallel to form the acoustic resonator. A longitudinal transducer was bonded to one of the *c*-faces using a vacuum cold welding technique, and the transducer was mechanically polished for half wave resonant operation at 250 MHz. The thin upper electrode was sputtered on and connected to the RF matching section. The RF matching was accomplished by a novel transmission line technique involving line sections having different characteristic impedance. The crystal was mounted in a solid copper heat sink fitted with heater windings, a thermistor, and a thermocouple. The faces normal to the *b*-axis were AR coated for both 1.06 μm and 0.53 μm.

The acoustooptic figure of merit (FOM) for BSN was measured by the method of Dixon and Cohen.[2] For longitudinal acoustic waves propagating down the *c*-axis (001) direction, the FOM relative to fused silica was 2.07 and 7.25 for light polarized perpendicular ("O") and parallel ("E") to the *c*-axis, respectively. The longitudinal acoustic velocity down the *c*-axis was 6250 M/S, and the temperature coefficient of longitudinal phase velocity was -3.1×10^{-4}/°C. For light propagating normal to the *c*-axis polarized "O" for efficient SHG and with the sound column propagating at an angle θ to the *c*-axis in the *a*-*c* plane, the angular dependence of the FOM is $A \cos^2\theta + B \sin^2\theta$ for longitudinal waves and $C \sin 2\theta$ for shear waves, where $A:B:C \simeq 1:.2:2.5$.

[1] The experimental results reported have been accomplished as part of the USAF 405B Space Communications Program.

[2] R. W. Dixon and M. G. Cohen, *Appl. Phys. Lett.*, vol. 9, p. 205, 1966.

TABLE 1
PERFORMANCE CHARACTERISTICS OF TYPICAL AOML/FD UNIT

Polarization	1.06 "O" wave 0.53 "E" wave
RF frequency	250 MHz
Transducer conversion loss	0.5-0.1 dB
Diffraction efficiency (Time averaged @ 1.06 μm)	3.0-3.5%/W, polarized 1 *c*-axis
Effective SHG coherence length	$>0.9l$ @ 1W RF, $>0.8l$ @ 2W RF
Ratio diff. loss Resonant:antiresonant	<2:1
Optical insertion loss*	0.1-0.3% (No RF)
External Bragg angle	2.43°
Angular width of diffraction peak (1.06 μm)	0.75°
Angular width of SHG vs angle	−4° @ 1.0W RF
Oven temperature peak SHG	−75°C @ 1.0W RF
Temperature width of SHG vs temperature	−2°C @ 1.0W RF

*BSN crystals grown under Air Force contract by Union Carbide Corporation.

Operation was well within the Bragg regime, and the diffracted intensity showed a $\text{sinc}^2 x$ dependence on the angle of incidence. The external Bragg angle was 2.43°, and the measured external half width was 0.75° for 1.06μm light, consistent with the 3.8 mm sound column length. The SHG showed a nearly ideal $\text{sinc}^2 x$ dependence on temperature and on angle of incidence. Longitudinal thermal gradients produced by RF heating distort the SHG versus temperature curves and reduce the effective SHG coherence length, but careful thermal design minimized this effect. In Table I, we summarize the performance characteristics of a typical AOML/FD.

Excellent results were routinely obtained in laser operation using an AOML/FD to mode-lock and frequency double a Nd:YAG laser. SH power outputs greater than 200 mW have been achieved, and SH conversion efficiency greater than 70% were achieved in properly designed resonators. The 1.06 μm pulse width depends on the modulation depth and the SH conversion efficiency.[3] In general, the pulse-width decreases as modulation depth increases or the SH conversion decreases. Under typical operating conditions, at 150 mW SH output (~70% SH conversion efficiency) with 2W RF drive, a 1.06 μm pulse width of about 300 ps (FWHM) is obtained.

4.6 Solar-Pumped, Mode-Locked, Frequency-Doubled Nd:YAG Laser,[1]

Joel Falk, L. Huff[2] and Joseph D. Taynai, *GTE Sylvania Inc., Electronic Systems Group—Western Division, Electro-Optics Organization, Mountain View, Calif. 94042*

(15 min)

Direct solar pumping of a Nd:YAG laser permits the construction of a long life, low prime-power laser that is useful for a satellite-borne optical communications transmitter. We report recent progress in the development of a frequency-doubled, solar-pumped laser to be used for space communications. Improvements reported here for the first time include: (1) the simultaneous mode-locking and internal frequency-doubling of the solar pumped laser; (2) achievement of average power outputs of 5.6 watts multimode and 2.05 watts TEM_{00} mode at 1.06 μm; (3) construction of a laser structure and collecting optics that are designed to meet weight, vibration and temperature specifications appropriate to a satellite environment, i.e., construction of a preliminary space qualified laser.

The solar pumped laser (shown schematically in Fig. 1) consists of a telescope and sunlight

[1] This work was supported by Air Force Contract F33615-74-C-1062, as a part of the Advanced Development Program 405B, Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio.

Fig. 1. The solar pumped laser.

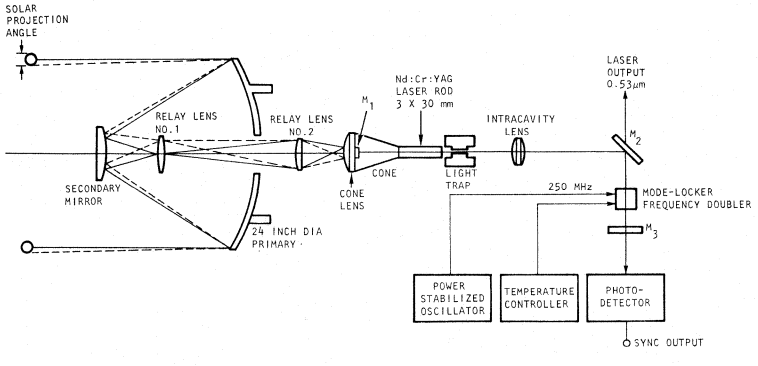

TABLE I
SUN-PUMPED LASER: OUTPUT POWERS

λ	Multimode	TEM_{00} CW	TEM_{00}: Mode Locked
1.06 μm	5.6 W	2.05 W	0.4 W
0.53 μm*	–	0.5 W	0.16 W

*Solar-simulator results.

collection assembly, and an L shaped optical cavity which contains a conductively cooled Nd:YAG laser rod, an internal focusing lens, and a barium sodium niobate crystal that is used both for mode locking and frequency doubling of the laser. The laser, aside from the collecting telescope, is designed to occupy 200 in^3 and weigh approximately 10 lbs.

The solar light collection assembly uses a series of optical elements to efficiently end pump the laser rod. The pump light is collected by a telescope whose dielectric secondary mirror is highly reflecting for wavelengths within the Nd:YAG 0.40 μm to 0.90 μm pump bands and has low reflectivity for $\lambda > 0.90$ μm. This filtering reduces the thermal load on the laser rod. The output of the telescope is relayed by three lenses to a hollow condensing cone which concentrates the light on the 3 mm diameter × 30 mm long Nd:YAG or Nd:Cr:YAG laser rod. The residual sunlight not absorbed by the laser rod (approximately 50 watts) is collected in a light trap. Heat from the light trap as well as the condensing cone and laser rod is conductively transferred to heat pipes.

The heat sink that cools the laser rod contacts it over its entire circumference. In spite of this circular symmetry, the non-uniform cooling of the heat sink produces preferred laser polarizations parallel and perpendicular to the direction of heat flow from the heat sink. This unusual laser polarization behavior has important consequences for the operation of a conductively cooled laser and will be discussed in detail.

Various concentration Nd:YAG and Nd:Cr:YAG laser rods have been evaluated in the solar pumped laser. The use of Cr as a co-dopant to Nd increases the fraction of sunlight absorbed in the laser rod and, because of excitation transfer to the upper laser level of the Nd^{+3} ion, increases the laser efficiency. Laser rods with 1% Nd, 0.1% Cr doping have yielded the highest laser output.

The laser is simultaneously frequency-doubled and acoustooptically modelocked using a single 5 × 2.5 × 5 mm barium sodium niobate crystal. This acoustooptic mode-locker frequency doubler, developed at McDonnell-Douglas Astronautics East, will be described in detail elsewhere.

The L shaped resonator structure allows efficient combination of the 0.53 μm beams generated in two directions within the $Ba_2NaNb_5O_{15}$ frequency doubler crystal. The focal length and location of the intracavity lens are selected to provide a maximum TEM_{00} mode size in the laser rod and a beam size in the $Ba_2NaNb_5O_{15}$ crystal that will provide maximum output power at 0.53 μm.

The performance of the solar-pumped laser has been evaluated both directly pumped by sunlight and pumped by a high pressure Xe arc lamp whose output approximates that of the solar spectrum. The power outputs achieved at 0.53 μm and 1.06 μm for both CW and mode-locked operation are given in Table I. These represent the highest output powers observed to date from a solar-pumped laser at either wavelength. The solar pumped results were achieved with a 24 inch diameter collecting aperture.

The 0.53 μm results given in Table I represent the results of preliminary experiments. Extensive work at 0.53 μm is in progress and will be reported in detail.

4.7 Lamp-Pumped Engineering Feasibility Model Laser Subsystem,[1] Dan J. Radecki, *GTE Sylvania, Inc., Mountain View, Calif. 94042*

(15 min)

We report on the state of development of the lamp-pumped Nd:YAG Laser Subsystem for use in a 1 GBPS Space Communication System. The Engineering Feasibility Model (EFM) Laser Subsystem incorporates components and techniques which have been developed over the past five years at various laboratories including GTE Sylvania, McDonnell-Douglas Astronautics-East, and ILC Technology Incorporated, for the Air Force Advanced Development Program 405B. Previous theoretical and experimental work has been reported elsewhere.

The EFM Laser Subsystem includes a mode-locked and frequency-doubled Nd:YAG laser operating at 500 Mpps. A heat-pipe cooling system effectively transfers heat generated in the conduction-cooled rod and infrared heat generated by the K-Rb pump lamps to a simulated space radiator. The associated electronics include an automatic power controlled alkali-metal lamp power supply, a power controlled RF drive for the mode-locker, a frequency doubling crystal oven controller, and a photo detector, bias supply, and amplifiers which provide a clock output for the remainder of the communication system. The laser system specifications are listed in Table I.

The heart of the system is the preliminary space qualified model (PSQM) laser head. Modelocking and simultaneous frequency doubling is accomplished with a $Ba_2NaNb_5O_{15}$ (BSN) acoustooptic loss modulator developed at MDAC-E, whose performance characteristics are reported elsewhere. A monolithic invar structure supports all of the internal components and maintains cavity length stability within required tolerances over an operating temperature range of 20°C ± 5°C. Unique lockable mirror mounts utilizing beryllium-copper flexures have been developed which maintain alignment over wide temperature variations and survive sinusoidal vibration to 5 g's. The pump cavity has dielectric cold-mirror inserts bonded to copper cavity inner walls. The coatings are highly reflecting at Nd:YAG absorption band wavelengths and transmit unwanted IR wavelength light to the conduction cooled cavity walls where it is absorbed and conducted away. A 4 × 63 mm Nd:YAG rod is indium bonded over one-third of its surface area to a copper heat sink. A folded-cavity resonator design with an intracavity lens, is used to obtain the maximum TEM_{00} mode volume in the rod simultaneously with the optimum mode diameter in the BSN crystal giving maximum second-harmonic generation. In addition to mode-size control, the folded cavity configuration is used to obtain the second-harmonic generated in

[1] This work was supported by the Advanced Development Program 405B, Air Force Avionics Laboratory, Wright-Patterson Air Force Base, Ohio, through a subcontract from McDonnell Douglas Astronautics Company-East, Contract No. Y3E-247R.

TABLE I
LASER SYSTEM SPECIFICATIONS

Intensity profile	TEM_{00} mode, Gaussian
Wavelength	0.53 μm
Power output	150 mW
Pulse repetition rate	500 MHz ±50 kHz
Pulse duration	300 pico-seconds
Amplitude stability	±2%
Polarization	100:1 horizontal (±1°)
Prime power	300 watts reservoir heater/lamp 15 watts – control/drive electronics
Weight (laser head)	14 lbs.
Operating temperature	20°C ±5°C
Vibration (non-operating)	5g, sinusoidal sweep, 2 oct/min 10 to 2000 Hz

both directions as useful laser output.

The primary pump-lamp being developed for use in the laser is a 5 mm ID × $2\frac{1}{2}$ inch arc length potassium-rubidium alkali-metal vapor lamp. Development problems prevent reporting of final results as of this writing. However, they are expected to be available at the time this paper is formally presented. Preliminary testing in an EFM prototype laser with 280 watts input has resulted in 70 mW of second harmonic output with a 280 picosecond pulse duration.

In addition to preliminary K-Rb lamp data, a large amount of data has been obtained with a more optimal laser configuration, utilizing a water-cooled krypton lamp which is mechanically interchangeable with the K-Rb lamp. With the input power adjusted to give an unsaturated laser gain which is equivalent to that observed when pumping with a K-Rb lamp (~2.9%), a power output of 120 mW with a pulse duration of 350 picoseconds has been obtained. Reduction of the rod temperature to 0°C should provide power output in excess of 150 mW. These results compare favorably with theoretical predictions based on Kennedy's[2] and Falk's[3] analysis of the mode-locked frequency doubled laser.

4.8 CW Pumping of Nd:YAG with Electrodeless Arc Lamps,[1] D. A. Huchital and G. N. Steinberg, *The Perkin-Elmer Corp., Norwalk, Conn. 06852*

(15 min)

In many applications, the utility of CW-Nd:YAG lasers is limited by the short life of the krypton-arc pumping source. It is shown that most failures of arc lamps arise at the electrodes and the associated, fused-silica-to-metal seals, and that the electrodes are essentially irrelevant to the pumping mechanism.

The pumping of Nd:YAG lasers with electrodeless krypton arc lamps is described. It is established that power output levels and overall efficiencies comparable to that achieved with conventional lasers are obtained while lifetime and reliability of the device is markedly improved.

The arc lamps are toroidal and are located either adjacent to the laser rod or surrounding it. Electrical energy at 27 MHz is coupled to the lamp by an induction coil acting as the primary of a transformer of which the arc lamp is a single-turn secondary winding.

Factors influencing the coupling efficiency are analyzed. The electric field necessary to maintain the arc is usually of the order of some tens of volts per centimeter, which translates to some tens of thousands of volts across the coupling coil. Generation of such voltages requires radio-frequency currents of the order of thirty or forty amperes and since the skin depth of copper conductors is approximately 10^{-3} cm at these frequencies, the problem of joule heating losses in the coupling coil is not trivial. However, it is shown that by proper design, electrical coupling efficiency of 80% or more is achievable.

Both lamp and laser rod are surrounded by a diffusely reflecting surface which contains the pump energy until it can be absorbed by the rod. The optical coupling is analyzed both theoretically and experimentally. It is shown that a high value of diffuse reflectivity is essential, since a change in reflectivity of 2% can reduce laser output by 50%. A further constraint is imposed by the requirement that the reflectivity remain high for thousands of hours in a UV-rich environment.

It is shown that coupling efficiencies of 35% and 65% are achieved for 4 mm and 6 mm diameter laser rods respectively. These values are comparable to those achievable in the usual elliptical imaging geometry.

A medium power laser which developed 25 watts multimode and 10 watts TEM_{00} for 1.5 kW of RF power is described. A controlled life test was performed in which the arc was extinguished and reignited regularly in the course of 1000 hours of continuous operation. At the administrative termination of the test the power output has decreased by only a few percent. Lasers capable of developing 80 watts multimode and 20 watts TEM_{00} are also described.

The issue of RF power supply and efficiency has also been addressed. Both high-level-oscillator and master-oscillator-power-amplifier configurations have been considered. A single tube unit will be described which generates 1.5 kW of radio-frequency energy with 67% efficiency.

4.9 Laser Diode Pumped Nd^{3+}:YAG Laser,[1] C. W. Reno, *RCA, Advanced Technology Laboratories, Camden, N. J. 08102*

(15 min)

GaAs and complex structure AlGaAs laser diodes offer attractive pump sources for low power Nd^{3+}:YAG lasers. Their output spectra are narrow and can be matched to various lines of the Nd absorption spectra. The "high" radiance of the source when combined with a novel coupling scheme leads to efficient pumping. Absorption efficiencies of 50% have been achieved into the YAG rod using the 8680 Å absorption line for a 1.5 mm diameter rod and side pumping.

Fig. 1 shows output power versus rod temperature for the laser operating TEM_{00} with various output couplings. The pump source consisted of two GaAs homojunction arrays at 175°K heat sink temperature. Total input power to the laser drivers was 50 watts. Output in this case consisted of pulses at a rate of 35 kHz.

A second experiment shows the output waveform using 14 AlGaAs LOC laser subarrays at a heat sink temperature of 250°K and driven in sequence at an average rate of 70 kHz for each subarray with each subsequent subarray driven when the preceding one is turned off (14 arrays at 70 kHz each are approximately 1 MHz total). Of significance is the CW output with ripple components almost wholly restricted to frequencies less than the master clock rate of 1 MHz. This is in accordance with published theoretical results.[2] The output wavelength of the AlGaAs was 8850 Å which matches a major absorption line of the Nd^{3+}:YAG. The average output power was about 40 mW. The technical approach and capability for the construction of an AlGaAs LOC laser pumped Nd^{3+}:YAG laser of greater than 100 mW CW TEM_{00} output for a 250°K heat sink and 50 watt input power now exists.

4.10 Picosecond-Pulse, Fieldable Frequency-Doubled Nd:YAG Laser System for Ultra-Precision Ranging,[1] E. G. Erickson and L. L. Harper, *GTE Sylvania Inc., Mountain View, Calif. 94042*

(15 min)

A unique picosecond-pulse Nd:YAG laser system has been developed for NASA for use in precision satellite ranging applications. It is the

Fig. 1. Power output vs. temperature.

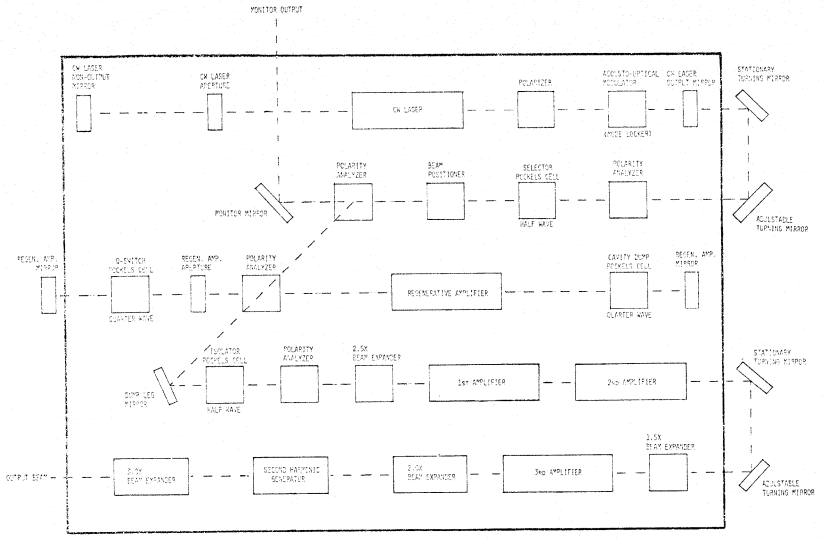

Fig. 1. Optical system diagram.

first frequency-doubled, picosecond-pulse Nd:YAG laser designed and packaged for stable operation in a field environment. This system emits an adjustable 100 to 1000 picosecond pulse containing 0.25 joule at 532 nanometers or 0.60 joule at 1064 nanometers. The pulse repetition rate is variable from 1.0 to 5.0 pps and the pulse-to-pulse amplitude stability is $\pm 5\%$. The output beam diameter is 3.6 centimeters and the divergence is less than 200 microradians. These performance characteristics are maintained for altitudes between sea level and 15,000 feet, temperatures between 40°F and 125°F, and a relative humidity up to 50%. The laser system also maintains performance in the vibration environment of a mobile electronic van. The basic design concept of this system is the regenerative amplification of a single mode-locked pulse from a CW, mode-locked, Nd:YAG laser.

The laser transmitter is a sealed unit measuring 13 in × 26 in × 56 in and consists of an electronic deck and an optical deck and support structure. The optical deck and support structure is fabricated entirely from invar for thermal stability. The heat exchanger and operator console are contained in identical cabinets measuring 60 in × 24 in × 27 in. The operator console contains a pulsed laser power supply, a CW laser power supply, and a control unit.

The optical train of the picosecond-pulse fieldable laser system is diagrammed in Fig. 1. This train consists of 33 optical subassemblies all mounted to the invar optical deck. The CW Nd:YAG laser generates 2.5 watts of TEM_{00} mode radiation modelocked at 150 megahertz. The single pulse energy is 16.7 nanojoules, the pulse duration is nominally 200 picoseconds, and the pulse spacing is 6.67 nanoseconds. The extraction and amplification of a single 16.7 nanojoule pulse is accomplished in three steps. First, a pulse train consisting of approximately 15 pulses is electrooptically switched into the regenerative amplifier by the selector Pockels cell. Second, all pulses in the train, except the first pulse, are electrooptically switched back out of the regenerative amplifier by the Q-switch Pockels cell. Third, the single pulse remaining in the regenerative amplifier is electrooptically switched out by the cavity dump Pockels cell after a suitable delay to allow multi-pass amplification to 5 millijoules. The fourth Pockels cell, in conjunction with the polarizers immediately preceeding and following it in the optical train, functions as an optical isolator between the regenerative and single-pass amplifiers. Following this isolator are three beam expanders and three single-pass amplifiers as shown in Fig. 1. The 5 millijoule output of the regenerative amplifier is amplified to 100 millijoules by two 0.25-inch diameter Nd:YAG amplifiers which is in turn amplified to 600 millijoules by a 0.375-inch Nd:YAG diameter amplifier. A 18 mm × 18 mm × 10 mm CD*A crystal frequency-doubles this output to 0.25 joules of 532 nanometer radiation. The final 3.0x power beam expander collimates both the green and IR beams to less than 0.2 milliradians.

The advantages for field systems of the above-outlined approach for achieving the stated output performance will be discussed. This discussion will include the presentation of the techniques for pulse-width adjustment and the circumvention of laser damage.

4.11 A Negative-Branch Unstable Resonator Nd:YAG Laser,

T. F. Ewanizky and J. M. Craig, *Combat Surveillance & Target Acquisition Laboratory, US Army Electronics Command, Fort Monmouth, N. J. 07703*

(15 min)

Numerous publications describing the application of various forms of the positive-branch unstable resonator have been presented in recent years.[1] These applications have been virtually restricted to large bore, high energy gas or chemical laser systems, exploiting the primary feature of unstable resonators—good beam quality over an arbitrarily large mode volume.

Based on previously successful experience[2] with rhodamine 6G as a laser medium, we investigated the properties and beam quality of a Q-switched Nd:YAG laser employing a negative-branch form of confocal, unstable resonator. The Nd-YAG laser was flashlamp excited and of moderate dimension and input energy and normally fitted with the conventional plane mirror-porro prism cavity. In a comparison we found that the negative-branch unstable resonator equalled the plane mirror cavity in energy extraction from the excited medium, however produced near diffraction-limited beam divergence.

The far-field intensity profile of the Nd:YAG unstable resonator system was detected by a linear array of pyroelectric elements. The measured angular divergence to the first, second, and third intensity minima corresponded, within a few percent to the far-field angles predicted by theory for a Fraunhofer diffraction pattern produced by an appropriately dimensioned annular source.[3]

Burn patterns made by the beam in the near-field were of high contrast and evolution through the Fresnel regime of diffraction could be clearly traced, implying a high degree of coherence of the emitted radiation. Experiments performed with both normal and Q-switched modes of oscillation gave substantially identical results in beam quality.

TABLE I
COMPARISON OF UNSTABLE RESONATOR WITH PARALLEL PLANE MIRROR RESONATOR

	Unstable*	Plane
Full-angle beam divergence	0.4×10^{-3} rad	2.2×10^{-3} rad
Pulse duration FWHM	1×10^{-8} sec	1.3×10^{-8} sec
Beam radiance	6×10^{13} W/cm^{2}sr	1.7×10^{12} W/cm^{2}sr

*Beam divergence and radiance of central maximum in far-field pattern.

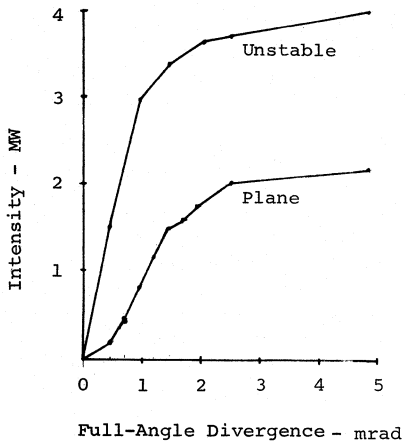

Fig. 1. Integrated angular intensity distribution.

Fig. 1 illustrates the measured angular intensity distribution of the Q-switched laser using either the unstable or parallel-plane mirror resonators and pertinent parameters are compared in Table I.

A significant practical advantage of the negative-branch unstable resonator was found in its relative insensitivity to angular misalignment. Initial alignment could be easily achieved and maintained over long periods without resort to special components.

In conclusion, we have found that efficient energy extraction and near diffraction-limited beam quality together with stable, non-critical alignment could be achieved with a negative-branch unstable resonator applied to a Q-switched Nd:YAG laser. Comparison of experimental results clearly shows the superiority of the unstable resonator form over the conventional parallel-plane mirror system.

5.2 Tunable $Hg_{1-x}Cd_xTe$ Infrared Lasers, J. P. Sattler, B. A. Weber, and J. Nemarich, *Harry Diamond Laboratories, Adelphi, Md. 20783*

(15 min)

We report on the development of new magnetically-tunable infared lasers using the semiconductor alloy $Hg_{1-x}Cd_xTe$. Tunable spin-flip Raman lasing and tunable recombination lasing have been obtained from this material using chopped-CW and TEA CO_2 lasers for optical pumping.

Semiconductor band theory and experimental results have indicated that crystals of $Hg_{1-x}Cd_xTe$ with small band gaps should have highly tunable Raman and recombination radiation, owing to the small conduction band effective mass. In addition, by selecting the appropriate composition of this material with respect to a pump-laser line, one should be able to reduce the spin-flip lasing threshold because of resonant enhancement effects. Our experiments indicate that these expectations are indeed warranted for this material, which offers great promise as a tunable infrared laser. Initial measurements using a TEA CO_2 pump laser have yielded a large first-Stokes tuning rate of $3.4\ cm^{-1}/kG$[1].

The experiments with the chopped-CW source utilized a conventional grating-tunable CO_2 laser that produced 2 W in the TEM_{00} mode. The output beam was externally chopped to a 2% duty cycle at 73 Hz to reduce crystal heating. This radiation with $E_p \| H$ was focused using a 26-cm focal length Ge lens onto the $Hg_{1-x}Cd_xTe$ crystal held at 12 K on a cold finger in a superconductive magnet. The crystal was a 0.5 × 3 × 6-mm parallelopiped, and was pumped in collinear geometry parallel to the 3-mm length and perpendicular to H. The crystal had an n-type carrier concentration of $5.4 \times 10^{14}\ cm^{-3}$, a mobility of $1.1 \times 10^5\ cm^2/V\text{-sec}$ and a cadmium fraction, x, of 0.234. The output radiation was analyzed using a 0.5 m spectrometer, a Ge:Cu detector, and a lock-in amplifier. The spin-flip radiation could be produced using all pump lines of the CW laser from the $P(16)$ to the $P(30)$ of the (00°1-02°0) band. Using the 9,52-μm line, the emission tuned from 9.67 to 9.96 μm by varying the magnetic field from 4 to 13 kG. A greater tuning range was obtained with the TEA laser pump.[1] The threshold for stimulated emission was measured to be 150 mW, corresponding to an intensity of $200\ W/cm^2$. The output polarization was perpendicular to the pump polarization in accordance with spin-flip selection rules.

The recombination radiation was observed for all CW-CO_2 laser pump lines between 9.22 and 9.55 μm. When using the 9.22-μm pump line, the emission tuned from 9.59 to 9.36 μm by varying the magnetic field from 0 to 20 kG. Various cavity modes could be selectively excited by adjusting the focusing and alignment of the pump laser beam with respect to the crystal faces. The wavelength, polarization, and output power of the recombination radiation depended on the magnetic field and pump wavelength.

The tuning data of these lasers for $Hg_{0.766}Cd_{0.234}Te$ have been analyzed using band theory, and the effective-mass ratio has been determined to be 9.77×10^{-3}. This value compares favorably with those obtained by other experimenters using other techniques for similar alloy ratios. The results obtained are used to project the tuning behavior of $Hg_{1-x}Cd_xTe$ crystals with different x-factors and electrical parameters.

5.3 A Highly Stabilized, Tunable CW Dye Laser and an Accurate Determination of the Rydberg Constant, J. B. West, R. L. Barger, and T. C. English, *National Bureau of Standards, Boulder, Col. 80302*

(15 min)

Recently it has been demonstrated[1] that remarkable frequency stability may be obtained from a CW dye laser. By using a wide-band (0-100 kHz) servo system to lock the dye laser frequency to a transmission fringe of a high finesse optical cavity, residual frequency fluctuations of less than 50 kHz for short times (20 μ sec) and 100 Hz for long times (10 sec) were obtained. However, due to thermal fluctuations in the reference optical cavity, long term drifts on the order of 1.5 MHz/min were observed.

Modifications to the laser system have resulted in a significant improvement in performance.[2] A high optical quality dye jet has replaced the dye cell and wavelength tuning is now accomplished using a tilted birefringent filter. Lasing in a single longitudinal cavity mode is achieved with two intracavity etalons. Error signals for the frequency control servo are derived from the signal difference between the transmission fringe of an external high finesse cavity and a reference beam bypassing the cavity. Low frequency corrections (0-1 kHz) are applied directly to the laser output mirror using a piezioelectric driver. High frequency corrections (1 kHz-5 MHz) are applied by varying the voltage across a deuterated KDP crystal in the laser cavity. Present frequency fluctuations are 1 kHz for short times and 300 Hz for 300 seconds. Long term frequency drifts are virtually eliminated by locking the length of the servo cavity to a fringe of a 3.39 μm He-Ne local oscillator laser which is frequency-offset-locked to a methane stabilized laser.[3] By using this technique, the long term frequency drifts of the dye laser should approach that of the methane-stabilized laser (about a part in 10^{13}), and the variable frequency-offset-locking technique allows the dye laser frequency to be tuned over 2.5 GHz while stabilized to this degree.

The amplitude of the dye laser output is stabilized to one part in 10^4 with a high speed

[1] R. L. Barger, M. S. Sorem, and J. L. Hall, *Appl. Phys. Lett.*, vol. 22, p. 573, 1973.

[2] R. L. Barger, J. B. West, and T. C. English, in preparation.

[3] R. L. Barger and J. L. Hall, *Phys. Rev. Lett.*, vol. 22, p 4, 1969.

servo system which uses an ADP crystal and linear polarizer combination. Present plans call for the entire dye laser and servo cavity to be enclosed in a pressure box. This will allow continuous pressure tuning of the laser over a 0.2 nm wavelength range without disturbing the frequency servo lock.

Presently, experiments are in progress which use this stabilized laser to saturate the Balmer α transition of the hydrogen atom. The result of these experiments should be a significant improvement in the accuracy of the Rydberg constant. Saturation of the transition in a beam offers specific advantages over experiments done with a discharge. In particular, shifts and broadening due to collisions and the Stark effect should be nearly eliminated. For these reasons, our experiments use a beam of metastable hydrogen atoms.

An RF discharge is used to produce ground state hydrogen atoms which are then collimated using a multichannel array of 5 μm diameter capillary tubes. Metastable hydrogen atoms (2^2S) are produced by bombarding ground state atoms with electrons near threshold energy ($\approx$11 eV). Metastable atoms in the beam are detected downstream by applying a dc electric quenching field. A photomultiplier tube monitors the resulting Lyman-α emission which is proportional to the number of metastable atoms in the beam. Laser saturation of the hydrogen 2^2S-3^2P transition occurs just upstream from the detector. Thus, the saturation is observed as a decrease in the Lyman-α emission.

The laser wavelength is measured with a frequency-controlled Fabry-Perot interferometer[4] which is accurate to about 10^{-5} order.

Saturation of the 2^2S-3^2P transition should provide a linewidth on the order of 30 MHz. If, however, the 3^2P state is used as an intermediate state and an RF field is simultaneously applied to induce transitions from the 3^2P to 3^2S state, a linewidth of 1 MHz should be realized.[5] After careful corrections for systematic errors, this method should provide an accuracy of at least one part in 10^9 for the Rydberg constant.

5.6 Application of Photodeflection to Spectroscopy,[1] A. F. Bernhardt,[2] D. E. Duerre, J. R. Simpson, and L. L. Wood, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The laser deflection of a single isotopic component of an atomic beam has recently been demonstrated. The technique relies on the selective absorption of laser beam photons by one isotopic component of an atomic beam to transfer momentum from the laser beam to that component. In a well-collimated atomic beam, the momentum acquired by many absorption and spontaneous re-emission events per atom will be sufficient to deflect the isotopic component out of the original beam.

This physical separation permits mass analysis of the deflected beam and highly reliable mass assignment of various isotopic hyperfine components. In addition, peaks from different isotopic components which cannot be relatively resolved optically, can be unequivocally resolved from the associated mass spectrometer data. A plot of mass peak height as a function of laser frequency gives a separate absorption curve for each mass number. The isotopic hyperfine structure of the barium 5536 Å resonance was investigated in this manner. Frequency shifts for all peaks of isotopes 134 through 137 were measured relative to 138 with $\leqslant$8 MHz error. The natural linewidth of the transition is 20 MHz. The absorption peaks of ^{134}Ba, ^{136}Ba and ^{135}BaF = 5/2, which could not be resolved optically, were resolved from the mass spectromer data. This is the first experimental resolution of these peaks.

The accuracy of the photodeflection method of spectroscopy is limited by reading error of the reference peak and the peaks plotted from mass spectrometer data. In the limit of a spectrum analyzer of great finesse and negligible laser linewidth, this method has an accuracy of about one tenth the natural linewidth of the transition. Since the natural linewidth of 5535 Å Ba resonance is $\sim$20 MHz, it would be possible to achieve an accuracy of about $\pm$2 MHz in the determination of the hyperfine structure of this resonance line.

The separation efficiency in the barium experiment has been measured. A simple expression for this efficiency has also been derived. The most important parameter in this expression is the branching ratio into the metastable 6s5d $^1D_2$ state from the upper 6s6p $^1P_1$ level of the 5536 Å resonance. The deflection process terminates for a given atom when it decays into the $^1D_2$ level rather than returning to the ground state. The previously accepted value for this ratio is 1/24. This would imply a separation efficiency in our experiment of less than 10^{-4}. Instead, we measured an efficiency of more than 70%. Our result implies that the accepted branching ratio of 1/24 is high by just over a factor of 30.

5.7 Experimentally Measured Photoionization Cross Sections and Excited State Lifetimes in Uranium Vapor,[1] R. W. Solarz, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The chemistry and spectroscopy of uranium are especially complicated and a complete knowledge of the behavior of this important element is required in order to assess the promise of various schemes for an isotope separation process. Some of the parameters needed for assessing the varied approaches are, for example, hyperfine splittings, lifetimes, bound state absorption cross sections, and relative photoionization cross sections from laser populated excited states. Until now most of the available spectroscopic information has been obtained using classical techniques such as high resolution absorption spectroscopy. Attempts to analyze the resulting spectra have been partially successful; nonetheless much of the data has defied analysis making it clear that alternate experimental approaches are required. While there is currently an excellent line list available for the U I and U II systems, many levels have not been assigned. In addition little information exists concerning hyperfine structure and no data exists on lifetimes, ionization cross sections, and high lying levels of the neutral and ionized species. Furthermore there are several experimental problems unique to the uranium system which require attention in any experimental set-up. This paper will present recent laser spectroscopic experiments aimed at measuring lifetimes and photoionization cross sections in uranium vapor. Experiments to map out high lying odd parity levels in uranium will also be presented.

It is well known that most isotope separation schemes, whether employing physical or chemical extraction processes, require a relatively long-lived laser populated level in order to function at peak efficiency. In a search for such long-lived states we have begun a systematic effort to map the lifetimes of uranium levels in the visible region of the excitation spectrum. A uranium oven operated at about 2000°C provides a cloud of primarily $^5L_6^\circ$ ground state and $^5K_5^\circ$, 620 cm^{-1} populated vapor. A Molectron commercial N_2 pumped dye laser is used to bring either population to a predetermined excited state. The resulting fluorescence decay is monitored through a half meter monochromator-phototube-boxcar arrangement. Advantages of this method over alternate techniques will be discussed and the experimental results presented.

Also well known is that a primary difficulty in a two step photoionization process is that the cross sections for ionization are typically quite small resulting in the requirement of a large laser for the second state of the separation process. In order to minimize this requirement an experiment to determine relative photoionization cross sections in uranium vapor has been carried out. In this experiment a high temperature uranium oven is again utilized. The resulting

[1] This work was performed under the auspices of the U. S. Atomic Energy Commission.

uranium beam is brought to a preselected excited state by a CW dye laser and simultaneously struck by a 3 Å bandwidth UV source which is swept in wavelength. Ions are counted as a function of UV intensity and wavelength with the result that relative photoionization cross sections from laser populated levels are obtained.

Finally, brief mention will be made of a two photon experiment which is designed to uncover and assign high lying odd parity levels in uranium vapor. The experiment is one which takes advantage of the black body radiation which is normally a hindrance in optical spectroscopy. In this experiment a chopped CW laser beam excites the vapor to a preselected even parity level. The black body radiation is monitored through a slow monochromator phase-sensitive detection scheme. Detected modulations of the black body radiation are interpreted as absorption of laser populated levels into high lying odd parity states. Reasons for the difficulty in assigning such levels via classical techniques will be outlined and the importance of such assignments will be discussed.

The impact of the above measurements on various isotope separation proposals will be outlined.

5.8 Selective Isotope Excitation of CuI,[1] C-Y. R. Wu and D. A. Dows, *Department of Chemistry, University of Southern California, Los Angeles, Calif. 90007*

(15 min)

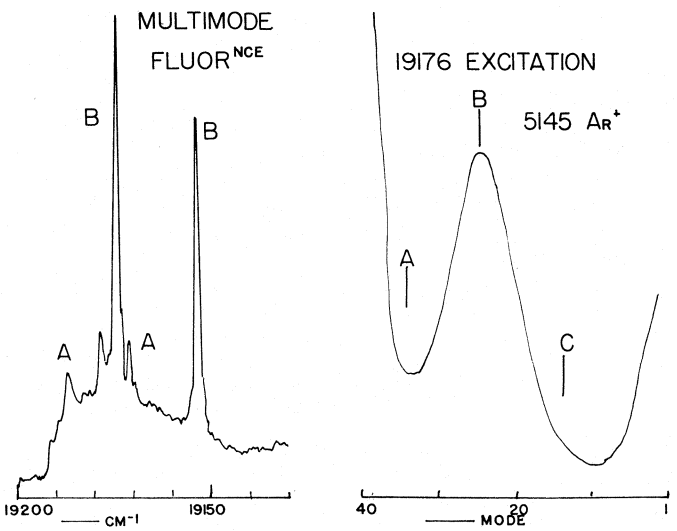
Resonance fluorescence (RF) occurs when a molecule absorbs a photon and subsequently emits a photon from the same excited state reached in absorption, i.e. before energy transfer to other excited states can take place. The phenomenon is normally observed only for gases at pressures low enough so that collisions do not occur during the fluorescence lifetime. Analysis of the RF can yield information about the excited and ground states of the molecule.

We have carried out studies of the resonance fluorescence of copper iodide (CuI) vapor, exciting the RF with Argon ion laser radiation at 5145, 5017, 4880 and 4579 Å. The laser was operated single mode in order to obtain narrow lines which would excite only single upper state levels. RF was observed using a Spex double monochromator. Ground state parameters obtained from the analysis of the observed spectra are in agreement with existing literature data. The rotational constant in the excited state of the A-bands, which has not been previously obtained, was found from combination of data from several different excitations.

By adjusting the intracavity etalon to select different modes within the gain curve of the 5145 Å line, three distinct patterns of fluorescence, one much stronger than the other two, can be seen. Fig. 1(a) shows the excitation spectrum for fluorescence at 19176 cm^{-1} versus modes of the 5145 Å line. Fig. 1(b) is the fluorescence spectrum of the first Stokes bands taken with multi-mode excitation. The doublets *A-A* and *B-B*, and the remaining singlet, are obtained when single mode excitation at the corresponding points *A*, *B* and *C* in Fig. 1(a) is used. In Fig. 1(b) one may notice that the sharp RF lines are superimposed on a broader background spectrum, which we call the normal fluorescence (NF).

The sample consists of solid CuI with a small amount of excess Cu metal (to suppress I_2, a strongly fluorescent molecule under Argon laser excitation), in a quartz cell. When the sample temperature is below about 300°C all the fluorescence is NF, i.e. a banded spectrum similar to the absorption spectrum in general appearance is seen. As the temperature is increased the sharp RF lines begin to show up superimposed on the NF. The intensity of the sharp lines increases more rapidly with temperature than does the NF. This may be understood if the degree of trimer-monomer dissociation increases as the temperature rises. In the temperature range studied (about 300 550°C) the dominant species is the trimer, and the total pressure is below 0.1 Torr. We assume that absorption of light by the trimer results in monomer emission from a large number of excited levels.

From the ground state rotational and vibrational constants and the RF spectra excited by the 5145 Å Argon line, the sequences of doublets corresponding to *A-A* and *B-B* in Fig. 1(a) are assigned to the R(70) and P(44) rotational line absorptions in the 0 ← 1 A-band of $Cu^{65}I$. The singlets corresponding to absorption of the mode at *C* arise from excitation in the 0 ← 1 A-band of $Cu^{63}I$. The rotational constant of the A-band excited state is found to be 0.0676 cm^{-1} (compare the ground-state value of 010735 cm^{-1}).



The assignments and isotopic species being excited by other Argon laser lines are summarized in Table I. As shown in this table, one may preferentially excite a particular isotopic species of CuI to an excited state from which chemical reaction, sequential two-photon dissociation or resonance-pressure deflection could possibly be used to conduct a practical isotope separation of Cu^{63} and Cu^{65}.

TABLE I

Line	Assignment	System	Isotope
5145	0 ← 1 P(44)	*A*	65

6.1 Automatic Laser Inspection/Laser Repair System for Masks, D. L. Fehrs, D. F. Munro and J. D. Cuthbert, *Bell Telephone Laboratories, Inc., Allentown, Pa. 18103*, and G. S. Yanochko, *Western Electric Co., Allentown, Pa. 18103*

(15 min)

The high degree of perfection required of chrome masks used in the manufacture of hybrid integrated circuits (HIC's) can be achieved only when thorough inspection and suitable repair procedures are made an integral part of the mask fabrication process.

Chrome masks for HIC's have patterned areas of up to $\sim 3\frac{1}{2}$ in $\times$ $4\frac{1}{4}$ in and pattern options include a large number of *regular* geometric shapes (lines, circles, squares, etc.) occurring at an unlimited number of orientations. Common defects consist of extraneous chrome spots, pinholes, and other defects which are in general irregular in shape. Comparative techniques would in principle seem to provide the simplest way to inspect such patterns. Our studies have shown that such techniques are indeed feasible; however, they are unattractive because of the complex procedures required to align one pattern with respect to the other with sufficient accuracy. Furthermore, comparative methods are excluded when one-of-a-kind masks are made.

For inspection and repair of chrome masks for HIC's we have taken the *noncomparative* approach shown in Fig. 1. No critical mask alignment is required since the mask is scanned using a *single* focussed laser spot. At any given instant the light transmitted and diffracted from a given point on the mask is collected, immobilized by a descan mirror, and then directed into the optical processing head. The processing head divides the beam into segments to allow a determination of the radial and angular characteristics of the diffraction patterns. If the laser spot size is arranged to be smaller than the minimum feature size on the pattern then the "regular" nature of valid features results in diffraction patterns with a limited set of radial and angular characteristics. With few exceptions pattern defects result in anomalous diffraction patterns having radial and angular characteristics which fall outside the set unique to valid features.

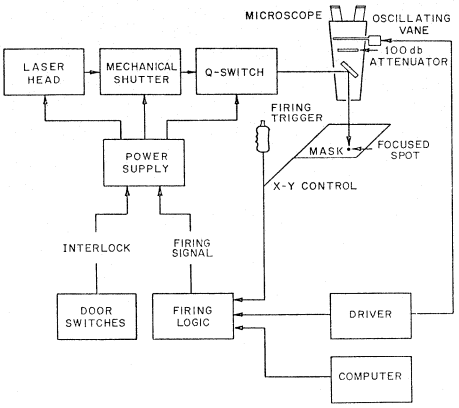

Fig. 2.

The position of both the scanned laser spot and the translation table are at all times encoded so that, once a defect is detected, its position can be stored in a minicomputer. After the entire mask has been scanned the plate is transferred to a motorized *x-y* stage which, under the control of the minicomputer, moves defect locations into the field of view of a microscope/laser machining system shown in Fig. 2. For removal of extraneous chrome spots, the operator centers the defect on the crosshairs of the microscope and then fires the machining laser. Pinholes are touched up with epoxy.

Compared with the old procedure of visual inspection and manual repair of chrome masks for HIC'S, the newly automated procedure is superior in terms of both speed and reliability.

6.2 Correction of Mask Defects by Laser Beam, F. Lee and J. Mitchell, *RCA, Somerville, N. J. 08876*

(15 min)

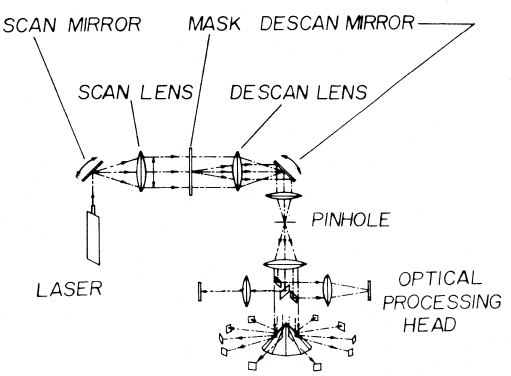
Microprocessors and other high density large scale integrated circuits now are made on silicon substrates measuring over 200 mils square. The standard $2\frac{1}{4}$ in wafer used in the industry can contain less than 50 of these devices. Masks are used for photolithographic processing of the wafers. Masks with 50 to 100 defects were acceptable for use with small area devices where each wafer could contain 1000 to 2000 pieces. Such masks would cause very low yield on large scale integrated circuits.

In order to improve masks, one must first define the defects. These are of three types, glass plate flaws, excess material in the information part of the mask such as black spots or overrun, and voids or breaks in this material. Perfect glass plates are obtainable. Voids cannot easily be filled in. Excess material, however, can be removed by laser beam. This excess material is the cause of perhaps forty percent of the defects. With perfect glass plates and use of laser beams to eliminate excess material, the masks may be made at least twice as good as present masks. While this improvement might not double the yield, it would certainly improve it.

With the end in mind of producing nearly perfect masks, a xenon laser was used to vaporize thin films of chrome, iron oxide, and emulsion. The laser is a pulsed xenon laser with a 0.5 microsecond pulse at 150 microjoules. The repetition rate is one to thirty pulses per second. Spot size is adjustable from one to twenty microns, and the optical system allows convenient identification of the defects and alignment of the beam.

Use of the laser for soft emulsions necessitates adjusting simultaneously the spot size and the attenuation of the power supply, to reduce spalling of the glass underneath.

The use of the laser for improving masks used for the RCA microprocessor is shown in a series of photomicrographs. These pictures show a mask defect and the mask after correction by laser beam. The improvement in yield from one set of wafers using the corrected masks over a second set of wafers using the uncorrected masks is given.



6.3 A Precision, High Speed Galvanometer Deflection System, D. P. Jablonowski and J. Raamot, *Western Electric Co., Engineering Research Center, Princeton, N. J. 08540*

(15 min)

An *X-Y* galvanometer deflection system capable of high precision in a random access mode of operation is described in this report. Beam positional information in digitized form is obtained by employing a Ronchi grating with a sophisticated optical detection scheme. This information is used in a control interface to locate the beam to the required precision. The system is characterized by high accuracy at maximum speed and is designed for operation in a variable environment, with particular attention placed on thermal insensitivity.

The present system configuration provides a 100 mm $\times$ 100 mm field size with a scan lens which produces a 25 μ spot size in its back focal plane, resulting in a 4000 $\times$ 4000 spot array. Address structure is located on 1.25 μ centers, implying an 80,000 $\times$ 80,000 address. The sys-

Fig. 1.

tem is capable of positioning the center of the 25 μ spot to any field address with a precision of ± 5 μ (1 part in 20,000). It is also configured to operate in a scan mode between any two field points while maintaining the same ± 5 μ precision. Scan rate is 50 cm/sec, a speed limited by the present laser and, to a lesser degree, the control interface.

The optical system consists of the basic beam deflection components – laser, X and Y galvanometers, and scan lens – plus the required grating for position monitoring. Beam position detection is accomplished by combining a low power CW (detection) beam of a different wavelength with the primary (recording) beam. By superimposing the two beams before detection, both will be focused to the same field position. A dichroic beam splitter placed beyond the scan lens will send the primary beam to a recording or machining plane, and the low power CW beam to the grating plane. Detectors record the modulated waveforms that result as the beam moves across the grating surface. To obtain directional information, two signals (a sine and cosine) are obtained for each axis. Fine resolution is obtained by dividing the waveform into 16 segments. Our waveform, corresponding to 40 μ, provides a final detection resolution capability of 2.5 μ.

A unique interference optical scheme is employed for detection. The low power beam is shaped by a special aperture prior to its combination with the primary beam. By so doing, the grating is used as a modulator of light amplitude, rather than light intensity. Diffraction orders produced by the grating interfere at the detectors, resulting in an intensity modulation that is an exact cosine. By controlling the spatial phase distribution of the beam, a sine waveform is also obtained. The use of circularly polarized light with linear polarizers at the detectors provides a constant 90° phase relationship over the full field. Because light amplitude modulation is employed, the period of the output signal is halved. thereby providing twice the resolution. In addition, detection with the interference method provides excellent phase stability, and is insensitive to dust or defects on the grating surface.

Control of the beam position is accomplished by sending the positional information to a control interface. A PDP-15 computer provides input data. The control interface is used primarily to *predict* the beam position when shaped driving waveforms are applied to the galvanometers. If the prediction is correct, the beam is accurately placed at the desired location. If the prediction is incorrect, the positional information is used to make a second prediction; this process will continue until the beam position is correct within the specified tolerances. By employing this philosophy instead of the standard servo control, high accuracy has been achieved without materially sacrificing system speed.

Since all positional information is obtained from the grating, absolute positional accuracy is directly related to grating accuracy. Precision rulings, therefore, are used in the system. Their stability results in excellent accuracies for a wide variety of environmental variations, including temperature.

This precision galvanometer deflection system has been used for generating thin film photomasks in a manner that has been previously described.[1] A high power Q-switched YAG laser is deflected by the galvanometers to selectively machine a metallic thin film from a glass substrate. The result is a one-step process for generating the mask, thereby eliminating photolithography and its inherent disadvantages. The use of the system in this particular application has verified its operation as a precision, high speed galvanometer deflection system.

6.5 Laser Interferometric Check-out of Granite Surface Plates, H. J. Rabal,[1] J. J. Lunazzi, and M. Garavaglia, *Departamento de Física, Universidad Nacional de La Plata, La Plata, Argentina*
(15 min)

This communication reports on the successful results obtained with the application of a grazing incidence triangular interferometer to check the quality of a granite surface plate for metrological inspections. The interferometer can be used when the surface is completely free and in such a case the observed fringes reveal details located between the successive points adjusted by the autocollimation method. The most important feature is that the interferometer can be used when the granite surface is occupied with metrological inspection pieces. In this case, it is possible to measure the deformation of the granite plate due to the weight of those pieces and subsequently to apply the appropriate correction to the observed figures. Experiments performed on a Johansson laboratory grade AA black diabase plate show that its surface reflectivity depends upon the incidence angle and polarization plane of the impinging light. A maximum reflectivity of about 20% was observed when the incidence angle ranged from 0° to 26.5°. Such a maximum was achieved with the polarization plane parallel to the granite surface. Optical flats or the Twyman-Green interferometer cannot be used in the surface inspection because these instruments work at normal incidence. Optical flats present another difficulty: the tremendously large difference in their reflectivity compared with that of the

[1] Member of the Laboratorio de Ensayos de Materiales e Investigaciones Tecnológicas de la Provincia de Buenos Aires, Argentina.

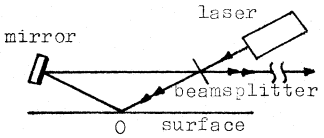

Fig. 1.

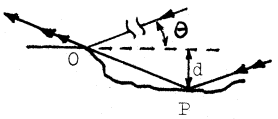

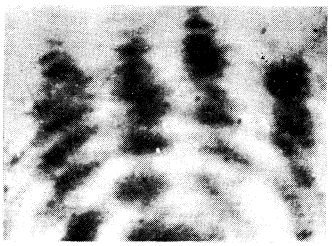

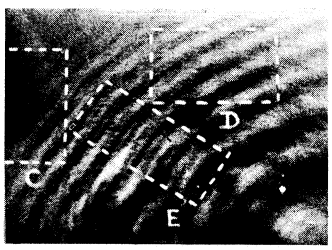

Fig. 2.

(a)

(b)

Fig. 3.

diabase. The grazing incidence triangular interferometer works in the following way: The laser beam is divided into two rays by using a beamsplitter, the beam passing through it is directed to the granite surface making an angle of less than 20° with it, the reflection of the granite surface is collected by a high-quality first-surface plane mirror and directed to the beamsplitter to combine with the reference beam. If the optical path difference is less than the coherent length of the laser light, interference fringes are observed directly with the naked eye, projected onto a screen, or photographed. Fig. 1 shows a line drawing of the experimental installation. Fig. 2 shows the behavior of a parallel laser beam in the vicinity of a depression on the granite surface.

The geometrical analysis of this situation results in the following expressions for the optical path difference or the phase difference: $\Delta x = d \sin \theta$, or $\Delta \Psi = 2\pi d \sin \theta$, respectively. The factor $\sin \theta$ acts like a damping term reducing the sensitivity of the interferometer and consequently permitting the observation of simple interferograms of the granite surface whose microstructure is several times larger than the wavelength used. Fig. 3 reproduces interferograms obtained with a 2 mW He-Ne laser and

photographed with a 35-mm camera using panchromatic film. Fig. 3(a) shows fringes produced by the reflection on a stainless steel plane block gauge located on the granite surface, while Fig. 3(b) shows fringes produced by the granite surface itself. It is very easy to separate regions *C*, *D* and *E* which correspond to a plane, to a convex or concave surface and to a valley surrounded by borders or its specular image, respectively. To decide about the sign of the surface the beamsplitter must be moved to observe the corresponding behavior of the fringes. When the granite surface plate was loaded with 500 N at an extremity a fringe shift of two fringes was clearly observed at 80 cm from that point. Such a fringe shift corresponds to a deformation of about 4 μm.

6.7 Laser Generated R. C. Networks, M. A. Saifi, *Western Electric Co., Engineering Research Center, Princeton, N. J.,* and O. T. Masopust, *Western Electric Co., Chicago, Ill.*
(15 min)

An important application of series resistive-capacitive (R.C.) networks is that of providing protection for electrical contacts during closure. These networks are normally made with discrete resistors and capacitors. The high voltage rating (typically 250 V) of these capacitors requires use of either polyester film-metal foil sandwich construction or metallized polyester films. This paper describes a new technique for generating integrated series R.C. networks by laser machining nonconductive paths in metallized polyester films.

The laser generated networks have only $\frac{1}{9}$ the volume of the comparable discrete component networks. To determine their suitability for long life applications, several networks were subjected to one billion pulses of 250 V under actual operating conditions but at an accelerated rate. None of the networks showed any degradation in either physical or electrical characteristics.

A typical laser machined pattern for a series R.C. network is shown in Fig. 1. Machining is done with a *Q*-switched YAG laser (1.06 μm wavelength) during the capacitor winding operation. The two capacitor plates consist of 6 μm thick polyester films metallized with .04 μm thick zinc coating. The low frequency resistance value of this network largely depends upon the length and width of the segment between the two laser machined lines. Since the resistance is generated in a capacitively coupled region of the plates, its electrical characteristics are essentially that of a distributed R.C. network.

The network reliability under operating conditions is largely dependent upon the electrical isolation provided by the laser machined line. Good adherence of the metal film at the edges of the machined line is required, with no loose

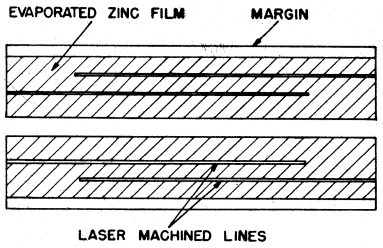

Fig. 1. A resistance pattern produced by machining metallized mylar.

metal particles. This entails careful control of the laser pulse intensity and spot overlap. A further restriction on the laser machining parameters is imposed by the fact that the 6 μm thick polyester film (the dielectric body of the network) should not be thermally damaged due to evaporating metal film.

An important laser parameter is the machining threshold intensity. This was determined by studying the machined spot structure as a function of radiation intensity. Additional information on the threshold intensity was obtained by monitoring the beam transmitted through the opaque metal film while machining with a single *Q*-switched pulse. The intensity at which the transmission occurs near the end of the pulse is defined as the threshold intensity. For an .04 μm thick zinc on the polyester film and for 70 ns long laser pulse the experimentally determined threshold intensity is 0.45×10^6 W/cm^2. This compares well with the 0.35×10^6 W/cm^2 threshold intensity determined from the machining model discussed by Maydan.[1] Considering the simplifying assumptions of the model and the experimental errors, the agreement is good.

It is shown that machining with intensities much above the threshold value is desirable. This reduces the width of the molten zone and also maintains a practically constant line width ($\pm 2\%$) for the nominal $\pm 5\%$ pulse to pulse stability of the commercially available lasers.

Other aspects of this process, such as the system schematic, and in particular the characteristics of various integrated R.C. networks generated by this technique will be discussed.

6.9 Lasers in Supermarket Point of Sale Systems (*Invited*), L. Dickson and R. L. Soderstrom, *IBM Corp., Rochester, Minn.*
(30 min)

In April of 1973, the Supermarket Industry adopted the Universal Product Code (UPC) and associated bar code symbol. This symbol will ultimately appear on more than 90% of all items sold in supermarkets, and is a major factor in the development of more efficient supermarkets. The UPC symbol, designed to be read by an optical scanner at the checkout counter, contains manufacturer, item, and size information. When the label is scanned, the decoded information is transmitted to an in-store computer which retrieves, from its memory, the price of the item. This information is rapidly transmitted back to the checkout counter where item description and price are produced simultaneously on the display and the customer receipt. All of this, of course, occurs at millisecond rates.

The heart of such a system is an accurate, reliable optical scanner. However, selection of a linear bar code and the establishment of stringent scanner performance specifications by the Supermarket Industry placed heavy burdens on scanner development programs. One of the early labels proposed for the UPC symbol was the circularly symmetric bull's-eye label. Designing a scanner for this label is a much easier task since it simply requires a single linear scan. But the industry committee rejected this symbol in favor of the linear bar code, mainly because the latter can be free of objectionable ink smear, when printed in the proper orientation, in an on-the-fly printing process. The bull's-eye label will always have smear problems regardless of pattern orientation during printing.

After adopting the symbol, the Supermarket Industry established performance specifications for label-reading scanners. Among the specifications were the following requirements. The scanner must be able to read labels: (1) which may vary in size from 0.8 × nominal to 2.0 × nominal; (2) crossing the scan window at a maximum velocity of 100 inches per second; (3) in any orientation in the scan window plane; (4) under normal store lighting conditions, (5) up to one inch above the scan window. These requirements can only be met by a laser scanner. Even then, developing a reliable, accurate scanner is no mean task.

The UPC symbol is actually two separate half-symbols which are independently read and combined in the terminal. Each half-symbol is oversquare, that is, the half-symbol dimension parallel to the bars is greater than the dimension perpendicular to the bars. This allows the half-symbol to be read by a minimum of two orthogonal scan lines regardless of symbol orientation in the plane of the scan window. The amount of oversquare combined with the 100 inches per second maximum item velocity determines the pattern repetition rate which in turn establishes the video rate at the detector.

Minimum optical requirements of the scanner call for a focused spot size of 0.2 mm to 0.25 mm and a depth of field of at least 25 mm. Use of a laser allows rejection of ambient light via the use of a narrow band filter on the detector. Specular reflection can be minimized by proper geometrical considerations or totally eliminated by using a polarized laser. Finally, typical scan repetition rates result in detector video rates of several MHz for the smallest label.

A variety of scanner systems have been developed by a number of manufacturers to read the UPC symbol. Scan patterns include

(1) single, large X, (2) multiple X's, (3) stitch-bar, (4) sinusoidal and (5) Lissajous. Each has its merits.

We will discuss the general problems in the development of a supermarket scanner and our specific solutions to these problems.

Session 7

Spectroscopy and UV Lasers

Chairman: R. A. Andrews, *Naval Research Laboratory, Washington, D.C.*

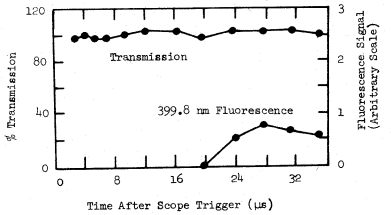
7.1 A Dye Laser Spectrometer for the Analysis of Pulsed Vacuum Arcs,[1] P. J. Hargis, Jr. and M. M. Robertson, *Sandia Laboratories, Albuquerque, N. M. 87115*

(15 min)

The high degree of spectral purity and high peak power available from pulsed tunable dye lasers allows detailed spectroscopic measurements to be made on the plasma formed by a pulsed vacuum arc discharge. The dye laser spectrometer we have developed for analyzing these plasmas is used to obtain three spectroscopic measurements: (1) transmittance of the dye laser radiation through the plasma, (2) the absorption line profile, and (3) the lifetime of laser induced fluorescence radiation. Neutral and ionized atomic number densities and electron number densities are unfolded from these measurements which are all obtained with one pulse from the dye laser.

A schematic diagram of the dye laser spectrometer is shown in Fig. 1. The N_2 pumped dye laser used in the spectrometer is based on the Hansch design. Using the dye α-NPO, the tuning range of the dye laser extends from 387 nm to 415 nm. When tuned to the 399.8 nm TiI resonance line, the dye laser output is a 10 kW peak power, 5 ns duration, 0.025 nm FWHM spectral width pulse of 3 mrad full angle divergence. The transmittance of the dye laser radiation through the plasma is measured from the ratio of the outputs from diodes D1 and D2. Radiation transmitted through the plasma is passed through a Fabry-Perot interferometer with a free spectral range of 0.05 nm. A 500 element image intensified diode array placed in back of the interferometer intercepts the Fabry-Perot ring pattern which is used to measure the spectral distribution of the transmitted radiation. Because of the good resolution of the diode array (5×10^{-4} nm) and broad bandwidth of the dye laser radiation (2.5×10^{-2} nm) in comparison with that of a typical absorption line (2×10^{-3} nm), this technique is used to measure the absorption line profile with one pulse from the dye laser. The time distribution of the laser induced fluorescence radiation is monitored by PMT2. A narrow-band filter (F2) is used to restrict the spectral bandwidth of the radiation detected by this tube. The visible radiation (200 nm to 900 nm) emitted by the plasma is monitored by PMT1. A spectrograph with a 1000 element diode array mounted at the exit slit is used to tune the dye laser radiation to absorption lines of the plasma constituents using a hollow cathode lamp. The arc is mounted on an x, y, z translator so that the spatial distribution of constituents in the plasma can be measured. The measurements reported below were obtained with a spatial resolution of 0.5 mm. When desired, much better spatial resolution can be obtained.

[1] Work supported by the U. S. Atomic Energy Commission.



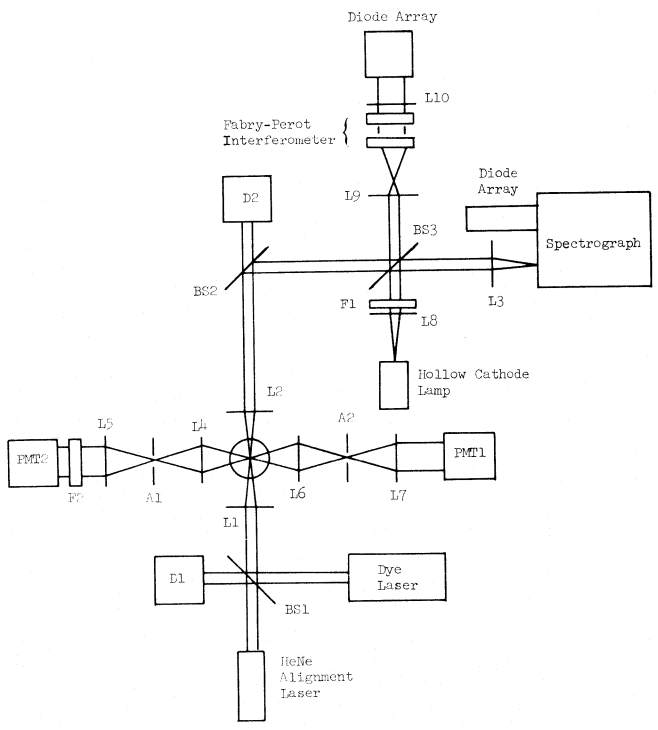


Fig. 2. Experimentally observed transmission and fluorescence signals at 399.8 nm.

An example of the results obtained with this spectrometer is shown in Fig. 2. These measurements were made on the plasma formed by the discharge between a Ti anode and kovar cathode. The dye laser was tuned on and off the 399.8 nm TiI resonance line ($a^3F_4 \rightarrow y^3F_4^0$). The fluorescence signal shows the expected 20 ns decay of the $y^3F_4^0$ level. Fig. 2 is a plot of the time distribution of the peak value of the 399.8 nm fluorescence signal. No signal is seen in the transmitted radiation (ratio of D2 to D1) since its detectivity limit corresponds to a number density of $\sim 10^{11}/cm^3$. These results show that buildup of neutral Ti atoms does not occur until very late in the lifetime of the arc. The early history of the arc is dominated by the presence of ionized Ti atoms.

Fig. 1. Schematic diagram of the dye laser spectrometer.

7.2 Collisional Studies of $^{12}CH_3F$ Using Doppler Free Two Photon Absorption Techniques, W. K. Bischel, P. J. Kelly, and C. K. Rhodes, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The technique of Doppler broadening reduction in two photon absorption via oppositely directed photons which has been previously demonstrated in atomic vapors[1] is especially interesting in molecular applications. Not only will this method provide new and detailed spectroscopic information about molecules, but it will also reveal additional information about molecular collision processes.

We have therefore extended this technique to a molecule ($^{12}CH_3F$) using two fixed frequency CW CO_2 lasers operating in combination with molecular Stark tuning. In particular we have utilized the near coincidences of the P14 and P30 lines of the 9.4 μm branch with the $R(1, 1)$

transition of the $0 \rightarrow \nu_3$ band and the $R(2, 1)$ transition of the $\nu_3 \rightarrow 2\nu_3$ band.[2] Shown in Table I are the transitions observed to date for the above described case. The column describing the relative coupling is determined from the magnitude of the direction cosine matrix elements associated with the two photon absorption cross section.

Through the use of phase sensitive detection methods, we were able to accurately determine the broadening and center frequency measurements at various pressures for different perturbers and for different polarizations between the laser and Stark fields. This information is listed in Table II. The pressure broadening mechanisms constitute those processes which transfer angular momentum. These mechanisms are of the energy changing (T_1) type and include molecular reorientation and rotational transitions. The shift of the resonant frequency is determined by the difference in the collisional perturbations on the initial and final states of the transition under investigation. Elaboration on the aforementioned processes are presented and compared with the results of Table II.

interaction studies, including self-phase modulation and transient Raman scattering, resolution has proved inadequate. In the last year at Imperial College we have further developed the technique of chronoscopy, to what is probably the practical limit of electron-optical technology, to achieve sub-picosecond time-resolution. For some applications of picosecond light pulses, particularly in photo-chemistry and X-ray laser studies, sub-picosecond time-resolution has to be maintained throughout the spectrum of sensitivity of the photocathode. The extraction mesh electric-field strength must be sufficiently greater than that necessary to produce the desired time-resolution with radiation of wavelength close to the photo-cathode cut-off. To permit such a substantial increase in the photocathode extraction electric-field strength we redesigned the electron-optics of the original Photochron tube,[1,2] at the same time improving the spatial resolution to increase the information content and to reduce triggering jitter. The resultant reduction in magnification also increased the recording speed. With this new Photochron II tube, direct sub-picosecond time-resolution was first achieved.[3]

Fig. 1 shows the tube electrode arrangement which is similar to that employed in the Photochron I tube. The mesh-photocathode separation is reduced to 0.5 mm and with an applied mesh-voltage of 1 kV the photocathode field strength is 20 $kVcm^{-1}$. Comparison of the performance characteristics is given in Table I. The reduced magnification produces a speed gain of ×3 while the improved streak spatial resolution increases the information content by ×2, for the same streaking speed, and reduces the jitter by the same factor. The Krytron deflection voltage ramp circuit has also been improved to increase the writing speed to $> 2 \times 10$ cm sec^{-1} and to reduce the jitter to < 50 psec. Photochron II tubes with S1 and S20 cathodes have been constructed[4] to the new design and tested.

In an effort to demonstrate directly the sub-picosecond time-resolution capability of the camera we made many streak records of a mode-locked Rhodamine 6G dye laser. Occasionally in the initial laser intensity fluctuation two equal intensity spikes occur close together. This fluctuation pattern then develops[5] to produce a suitable time-resolution test pulse (Fig. 2). The

recorded width of each peak is 1 picosecond and a camera instrumental width of 0.5 psec is unambiguously determined. At selected wavelengths sub-picosecond resolution down to 0.1 picosecond is obtained, depending upon the type of photocathode employed. With the higher light gain the range of usefulness of a camera employing the Photochron II tube is extended to weaker light sources. As a result the art of time measurement of light pulses is again ahead of the techniques of ultra-short pulse generation. Test measurements employing transient Raman generated sub-picosecond pulses will be discussed and a new camera system employing fibre-optic coupling to a channel plate intensifier array will be described. Results with VUV sensitive tubes will also be reported.

7.6 Optically Pumped Superfluorescent Na_2 Molecular Laser, M. Henesian, R. L. Herbst, and R. L. Byer, *Stanford University, Stanford, Calif. 94305*

(15 min)

Using a *Q*-switched internally doubled Nd:YAG laser operating at 0.473 μm, we have optically pumped molecular Na_2 and observed superfluorescent laser emission on a series of green and yellow molecular transitions. The observed superfluorescent gain agrees with our calculated gains for the B band based on an upper state lifetime of 64 nsec.[1] Sodium vapor was contained in a 10 cm long heat pipe with helium and argon used as a buffer gas. Na_2 vapor pressures up to 1 torr at buffer gas pressures of up to 50 torr have been used. The threshold pump energy was approximately 500 μJ in a 1.5 cm^{-1} bandwidth which overlapped a large number of absorbing molecular transitions. The high gain and low threshold energy indicate that flashlamp pumping should be possible.

Unlike recently demonstrated molecular vapor phase dye lasers, the Na_2 molecular laser is stable against dissociation. We have also observed laser action on the Na_2 A band at 0.75 μm to 0.85 μm when pumped at 0.659 μm. Laser action on the A band has recently been reported in Japan.[2] Extension of laser operation to the other alkali diatomic molecules gives the possibility of obtaining quasi tunable laser operation over the entire visible to near infrared spectral range.

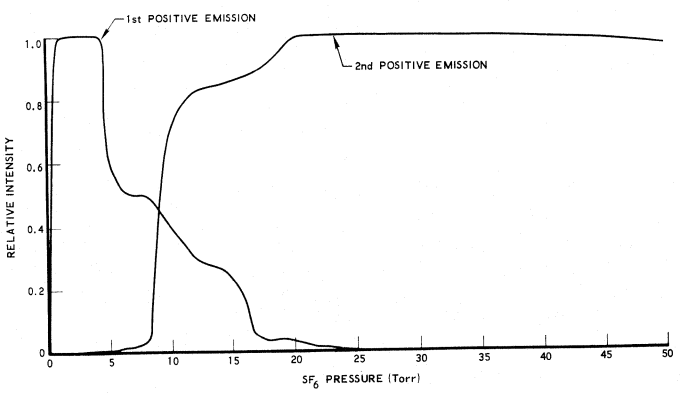
7.7 Behavior of the First and Second Positive Emission in the N_2/SF_6 Laser, S. N. Suchard, R. F. Heidner, III, and D. G. Sutton, *The Aerospace Corp., El Segundo, Calif. 90245*

(15 min)

Recently, several of us reported the observation of a long pulse nitrogen second positive laser.[1] The primary differences between this nitrogen laser and those that have been reported previously is the addition of SF_6 to the laser gas and the duration of the observed laser pulse. In a conventional nitrogen second positive laser, pulse durations on the order of 5-15 nsec have been observed[2]; however, in the N_2/SF_6 laser, pulse durations longer than 75 nsec have been measured.[1] Experimental measurements of the effect of SF_6 on the behavior of both the first and second positive band systems in N_2 will be discussed.

The discharge apparatus utilized for the fluorescence, superfluorescence, and laser measurements of the N_2/SF_6 mixtures has been described previously.[1] It consists of two 1.5 m Lucite pipes fitted with a double helix of 470 ohm resistors. One of the helices forms the anode of a pulsed power supply and the other helix is connected to ground. This configuration results in 502 pin-pair opposed electrodes across a 2-cm gap. For the laser experiments, an optical cavity was formed around the discharge tube by a concave Al coated mirror with a 12 m focal length and a variety of partially transmitting flat output couplers. For the flowtube measurements of the deactivation of specific electronic-vibrational levels of N_2 by SF_6, the apparatus employed was similar to that described by Setser,[3] using a conventional nitrogen first positive laser as a pump source to produce $B^3\Pi_g$ state N_2.



Experimental measurements of the relative output intensity of the N_2/SF_6 laser on the first positive and second positive bands of N_2 as a function of the added SF_6 have provided some insight into the role of the SF_6 in the laser. Fig. 1 displays the relative first and second positive laser outputs as a function of the added SF_6. The first and second positive laser outputs were normalized within themselves and not relative to each other; the second positive emission is approximately 10^2 more intense than the first positive emission. With 50 Torr N_2 in the laser cavity and no SF_6, no laser emission is observed at any discharge voltage below 120 KV, the

Fig. 1. Relative first and second positive N_2 laser emission as a function of added SF_6. N_2 pressure = 50 Torr, discharge voltage = 60 kv, output coupling = 92%.

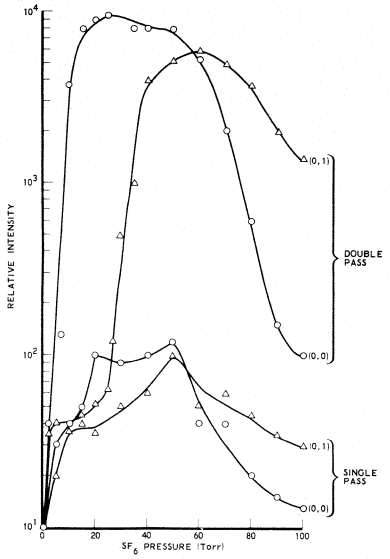

Fig. 2. (0, 0) and (0, 1) bands of the N_2 second positive system under both single and double pass conditions as a function of the added SF_6. N_2 pressure = 50 Torr, discharge voltage = 100 kv.

highest voltage accessable with the apparatus. As SF_6 is added, the mixture very quickly reaches threshold on the first positive ($B^3\Pi_g$-$A^3\Sigma_u^+$) bands. Continued addition of SF_6 quenches the first positive laser emission and the second positive ($C^3\Pi_u$-$B^3\Pi_g$) laser reaches threshold. Addition of more SF_6 has only a small effect upon the second positive laser output until the SF_6 pressure approaches 70 Torr, where a slow falloff of relative intensity is observed.

These changes in the relative laser intensities upon addition of SF_6 can possibly be explained in terms of increased pumping of the upper laser levels and electronic deactivation of the lower laser levels by the SF_6. Addition of SF_6 to a nonelectronegative gas causes the average electron energy in the discharge, to increase, hence increasing the rate of pumping of the upper laser levels. Addition of more SF_6 quenches the first positive laser, even though the rate of pumping of the $B^3\Pi_g$ state should have been increased. This fact, in addition to the temporal history of the N_2/SF_6 laser, indicates the $B^3\Pi_g$ state is being deactivated by the SF_6.

Fig. 2 presents spectrally resolved results of the relative emission of the (0, 0) and (0, 1) bands of the second positive system as a function of SF_6 pressure under both single pass and double pass conditions. Gain is not observed on other second positive bands. It is interesting to note the change-over in intensities of the two bands as the SF_6 is increased. Since both transitions originate from the same upper laser level these results indicate that the rates of electronic and vibrational deactivation of the $B^3\Pi_g$ states are different.

Flowtube experiments are now underway to measure the deactivation of the different vibrational levels of both the $B^3\Pi_g$ and $C^3\Pi_u$ states by SF_6 under non-discharge conditions. The results of these experiments will be used in conjunction with the laser results in order to elucidate the operating mechanisms of the N_2/SF_6 laser.

7.8 Collision-Induced Auroral Line Lasers,

H. T. Powell, J. R. Murray and C. K. Rhodes, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

Laser oscillation has been recently reported[1] on the green bands of the XeO and KrO excimers correlating with the 5577 Å, $^1S - {}^1D$, auroral line of atomic oxygen. As previously described an electron beam was used to excite a mixture of Xe and Kr at several atmospheres pressure containing a few Torr of oxygen bearing species. Stimulated emission has now been achieved from ArO at 5577 ± 1 Å; time dependent gain measurements have been made of all three excimer systems using a CW dye laser; and the parameters of these lasers have been investigated with respect to their suitability as lasers for fusion.

The radiative lifetime of the $^1S - {}^1D$, electric quadrupole transition of an isolated oxygen atom is 0.8 s. However, the overall transition probability for unresolved green emission is known to exhibit a linear dependence on buffer gas pressure. This collision-induced emission phenomenon is believed caused[2] by the formation of weakly bound excimers of $O(^1S)$ (binding $\leqslant 500$ cm^{-1}) where the proximity of another specie causes the forbidden atomic transition to become a dipole allowed molecular emission, $^1\Sigma^+ - {}^1\Sigma^+$ or $^1\Sigma^+ - {}^1\pi$. The overall radiative lifetime is dictated by the fraction of $O(^1S)$ bound in such excimers and is typically 10-100 μs at the rare gas pressures used.

The molecular emission spectrum depends, of course, on the binding between the additive gas and $O(^1S)$ and $O(^1D)$. In xenon a vibrationally banded emission centered at 5450 Å having a halfwidth of 200 Å is observed while for Kr and Ar the emissions are diffuse, violet degraded bands centered at 5577 ± 1 Å having a 30 Å halfwidth. At the typical operating pressures the rotational lines are merged giving a continuum spectrum.

The intensity and time dependence of collision-induced emission has been studied for O_2-rare gas mixtures excited by a 2 × 10 cm, 1 MeV electron beam with variable currents of 1-50 kA. The fluorescence decays exponentially with a rate depending on both rare gas and O_2 pressure as well as excitation level. This evidence suggests that the quenching in such mixtures is usually dominated by three body processes involving an $O(^1S)$, an $O(^3P)$, and a rare gas atom. In pure Ar, Kr, or Xe, collision-induced emission is believed the primary deactivation channel of $O(^1S)$. Inversion is produced by the rapid deactivation of $O(^1D)$ in the high pressure rare gas.

Single-pass gain measurements have been made using a tunable CW dye laser. During the *E*-beam pulse the medium is highly absorbing throughout the visible ($\alpha_{abs} \geqslant 0.5$ cm^{-1}); only in the afterglow does gain appear within the emission bandwidth ($\alpha_{gain} \leqslant 0.01$ cm^{-1}). The absorption has been tentatively ascribed to ground state molecular ions. Their decay after the current pulse is highly dependent on gas purity and apparently involves subtle ionic processes.

The energy storage in the green has been computed from both fluorescence intensity and gain measurements. A value of ~10 J liter^{-1} with an overall efficiency of ~1% of the *E*-beam deposition is consistent with both measurements for all three rare gases. The excitation mechanism has not been determined, however, the process $0(^3P) + e \rightarrow 0(^1S)$ is not inconsistent with these results.

7.9 Ion Laser Performance and Spectroscopy—New Pulsed and CW Transitions below 3000 Å

J. B. Marling, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The performance and spectroscopy of ion lasers has been investigated below 3000 Å. Many new pulsed ion laser transitions were found below 2500 Å, several of which exhibited anomalously high peak power for ion lasers, as indicated in Table I. Additionally, CW operation has been observed below 3000 Å for the first time, principally in third spectrum noble gas transitions.

Investigations of pulsed ion laser performance and spectroscopy was performed with a 7 mm bore, 150 cm arc length tube, with electrical driver specially designed for short duration, high peak current excitation pulses. Third, fourth, and fifth spectrum laser transitions were observed with excitation pulses of 250 ns FWHM and up to 10,000 amp/cm^2. Current saturation of third spectrum transitions was observed near 5000 amp/cm^2. Fourth spectrum transitions in krypton and xenon did not exhibit current saturation. Wavelengths of new and previously known transition were measured to about 0.006 Å, and relative peak powers were measured in order to identify the strong transitions. Results of this investigation are presented in Table I.

CW operation of several ion laser transitions has been observed below 3000 Å for the first time. Data on observed CW transitions, threshold current values and output performance in watts are presented. Principally, the strong

third spectrum noble gas transitions in Table I were observed in CW operation. Data were taken from a 3.5 mm segmented tungsten bore laser at anode currents up to 55 amperes.

7.10 Co-Axial Electron-Beam Pumped VUV Laser Oscillators and Amplifiers, E. G. Arthurs, D. J. Bradley, C. B. Edwards, A. I. Ferguson, D. R. Hull, M. H. R. Hutchinson, C. C. Ling, and M. W. McGeoch, *Imperial College, London, England*

(15 min)

High pressure, quasi-molecular noble gas VUV lasers have many potential applications in photochemistry, plasma diagnostics, and for the generation of XUV lasers either by nonlinear interactions or by direct pumping of appropriate plasma media. In these and other applications, efficient oscillator and amplifier systems are required to produce tunable frequency, low divergence beams in variable duration pulses, covering the nanosecond to picosecond temporal range. For photochemical studies a moderate power (~1 MW) high repetition rate oscillator would be particularly valuable.

Earlier oscillator systems employed transverse pumping with indefinite and variable active media cross-sections and pumping energies of several hundreds of joules were required. To produce an efficient and convenient laser system with low energy pumping (<10 J), yet with megawatt power, we designed and constructed a coaxial diode electron-beam system.[1] Mirror damage limited this laser, employing 10 kTorr Xenon gas, to peak powers of ~1 MW. The 3 nsec 60 π (10 KA, 600 KV) generator has been altered to produce a 5 nsec, 20 J output pumping pulse of 0.5 MeV electrons. The coaxial diode has also been reconstructed so that both ends of the tubular anode are open (Fig. 1) and there is adequate space to insert various mirror-disperser combinations. With the increased gain an output power of 3 MW (10 mJ) is readily obtained with an $AlMgF_2$ mirror and a single plate BaF_2 resonant reflector. The upper power limit is still set by damage to the mirrors and the output window. By inserting a dispersive prism (quartz, BaF_2 or sapphire) the laser spectral bandwidth (<1 nm) is tunable from 170 nm to 175 nm. At present thermal effects[1] limit the repetition rate and a gas flow system has been designed to permit up to 10 pps operation. While the overall efficiency of the oscillator is

[1] D. J. Bradley, D. R. Hull, M. H. R. Hutchinson and M. W. McGeoch, *Opt. Commun.*, vol. 11, p. 335, 1974.

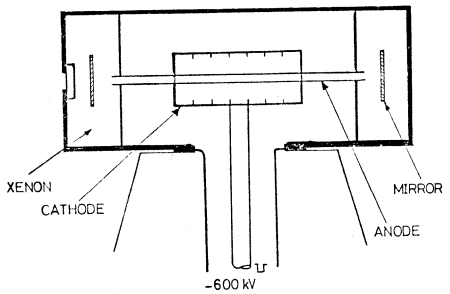

Fig. 1. Details of open-ended coaxial diode construction.

~0.1% the energy storage efficiency is ~10% with gains of ~0.25 cm^{-1}. The high storage capacity and well defined geometry of the coaxial diode system has been scaled to construct an efficient amplifier with a pumping duration of 20 nsec and a single pass gain of ~150, for an incident 1 MW pulse. Amplification of picosecond pulses is also being investigated, the initial pulse being produced by generation of the 4th harmonic of a mode-locked ruby laser using consecutive stages of second harmonic generation and four wave mixing in magnesium vapour.

Investigations with frequency shifted picosecond tunable pulses from dye lasers will be described, together with spectroscopic studies of the atomic and molecular excited states. The latest results obtained with other noble gases and gas mixtures in these systems are also reported.

Session 8

Thursday, May 29, 1975 8:45-11:45 A.M.

Laser Fusion I

Chairman: W. F. Krupke, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

Organizer: E. Beckner

8.1 Characterization of Optical Nonlinearity in Transparent Dielectrics and Implications for Fusion Laser Design (*Invited*), A. J. Glass, E. J. Goodwin, and J. B. Trenholme, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(30 min)

In the design of a large glass laser for fusion experiments, the principal limitation of high power, short pulse operation is imposed by the index nonlinearity of the laser material. This includes not only the laser glass, but also any other transparent solid dielectric material present in the optical path, including Faraday rotators, lenses, beam splitters, and polarizers. Insofar as it is possible to choose materials for use in a fusion laser, those materials with the lowest index nonlinearity are clearly preferred.

The index nonlinearity arises from several

sources. The main contribution is from the direct electronic nonlinearity. In most glasses, this comprises from 75 to 90 percent of the total nonlinear index. Other contributions arise from Raman-active modes of the medium, two-photon resonances, and changing anomalous dispersion. Estimates of the importance of these contributions for laser materials will be given. The compositional dependence of the index nonlinearity for optical materials will be discussed.

In a high power laser, the presence of index nonlinearity gives rise to both self-focusing of the beam as a whole, and beam breakup (small-scale self focusing). Recent experimental results on both beam breakup and whole beam distortion will be reviewed and compared with theoretical analyses. In order to maintain the optical quality of the beam, the integrated nonlinear index along the optical path, given by the parameter

$$B = (2\pi/\lambda n_0)\int n_2 < E^2 > dz \qquad (1)$$

must be kept below a critical value. We will discuss the maximum tolerable value of B, and its dependence on gain staging, spatial filtering, and apodization.

In subsequent papers in this session, various aspects of the problem of beam quality control will be examined in detail.

8.2 Loss of Focusable Energy Due to Small-Scale Nonlinear Effects, E. S. Bliss, G. E. Sommargren, and H. J. Weaver, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The nonlinear growth of small-scale intensity and phase irregularities on an intense laser pulse is predicted by linearized instability theory[1] and is well documented experimentally.[2,3] In a large laser system the resulting intensity and phase profiles are complicated and not easily characterized in detail. Qualitatively, linear propagation theory predicts that the far field diffraction pattern of a beam which has experienced this sort of spatial breakup will contain significant energy outside of the diffraction limited spot size of the corresponding unperturbed beam.[4] We report two sets of experiments to determine the effect of small-scale beam breakup on the focusing properties of an initially high quality beam propagating through the simplest possible system, a single unpumped rod of ED-2 laser glass.

In the first experiment a collimated input pulse containing up to 0.75 J in approximately 100 psec (FWHM) with a $1/e$ beam diameter of 1 cm propagates through a 50 cm long sample rod. The near and far field profiles of the pulse are then compared with those of an identical beam which propagated around the rod. Severe beam breakup is evident in the near-field of the transmitted beam, and at the focus of a 1 meter lens some distortion of the transmitted beam can be seen. However, the most dramatic far field effect is that the fraction of input energy which is contained within a 500 μr angular aperture at the focus decreases dramatically with increasing pulse intensity, which is consistent with the angular distribution of light predicted by linearized instability theory for a beam experiencing small-scale beam breakup.

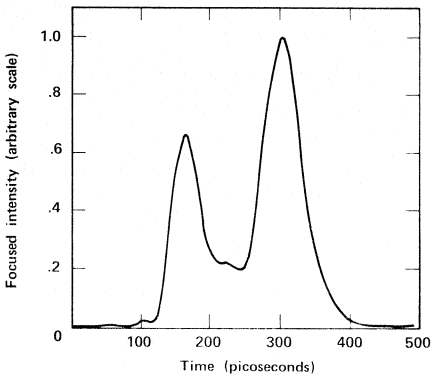

Fig. 1. Temporal distortion in the far field.

The preceding observations are based on temporally and spatially integrated measurements. Since the modulation of the beam profile grows exponentially with intensity and the loss from the focal spot increases nonlinearly with modulation depth, the fraction lost at the temporal and spatial peak of a pulse is expected to be considerably larger than the average over the whole pulse. Severe temporal and spatial distortion could occur as a result of preferentially depleting the high intensity parts of the pulse. Recognition of this fact led us to conduct a second set of experiments with a streak camera added. The streak photographs show obvious distortion of an intense pulse's temporal profile in the focal plane. In fact, above a certain value of intensity, growing losses are seen to overcome further increases in input intensity leading to a minimum in the focused on-axis intensity at the peak of the input pulse as seen in Fig. 1. Detailed measurements of the far field distribution of power as a function of instantaneous input intensity over an angular aperture of up to 3 mr will be presented, and the relative contributions of small-scale breakup and whole-beam self-focusing[5] to the results will be discussed.

The far field effects described here strongly suggest the use of one or more strategically placed spatial filters to remove accumulating beam breakup in a large system. These results also demonstrate the necessity of using target diagnostics capable of determining how much energy actually reached the target and to what extent the spatial and temporal profiles of the focused beam were altered by nonlinear propagation effects in the laser.

8.3 Focusing Properties of an Aberrated Laser Beam, J. T. Hunt and R. G. Nelson, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The focal volume properties of an intense, aberrated light beam are of great importance in laser fusion experiments. Computer simulation studies of the beam for the prototype laser developed at Lawrence Livermore Laboratory indicate the beam as a whole accumulates two distinct types of phase distortion in traversing the laser. One of the phase distortions is classical astigmatism[1] and it is independent of both time and beam intensity, and therefore it can be corrected. This aberration results from the expanding beam passing through a refracting medium whose surface normal is not parallel to the optical axis of the laser. The source of the second type of phase distortion is the intensity dependent portion of the index of refraction of both the pumped medium and the transparent optical components of the laser system through which the beam passes. This aberration depends upon both the temporal and spatial properties of the intensity distribution of the laser beam. However, for the system configurations and intensity profiles considered, the bending of the light rays is small due to the nonlinear index of refraction. The condition of no bending of the light rays over the path of propagation leads to an unchanging intensity profile and a phase distortion whose spatial profile is identical to the intensity profile. The magnitude of the phase distortion, B, is given by

$$B = \frac{2\pi}{\lambda_0}\int \frac{\Delta n}{n} dl \qquad (1)$$

where Δn is the nonlinear index change and λ_0 is the wavelength of the light in a vacuum. The integration path is along the trajectory of the ray at the center of the beam.

A computer code has been developed to investigate the effect that this second type of distortion has on the focused beam properties. The computational algorithm utilizes the self-similar propagation modes which were discovered in laser cavity work.[2] These modes or functions are orthonormal with respect to the scalar product

$$<f, g> = \int_{-\infty}^{\infty}\int_{-\infty} f^* g \, dxdy, \qquad (2)$$

where f^* denotes the complex conjugate of f. These modes are a complete set of functions in the infinite spatial domain (x,y).

The Laguerre-Gaussian modes are the appropriate propagation modes if the laser beam has circular symmetry. These modes are characterized by three parameters; the transverse beam size or waist, $w(z)$, the radius of curvature of the phase front $R(z)$, and the model phase $\phi_m(z)$.[3]

[1] M. Born and E. Wolf, *Principles of Optics.* Oxford: Permagon Press, 1970, p. 214.

[2] A. G. Fox and T. Li, "Resonant modes in a laser interferometer," *Bell System Tech. J.*, vol. 40, p. 453, March 1961.

[3] Maitland and Dunn, *Laser Physics*, North-Holland, 1969, p. 157.

The dependence of these propagation parameters on the propagation coordinate z is given by the expressions

$$w^2(z) = w_0^2[1 + (z/kw_0^2)^2] \quad (3)$$

$$R(z) = z\left[1 + \left(\frac{kw_0^2}{z}\right)\right] \quad (4)$$

$$\phi_m = (2m + 1)\tan^{-1}\left[\frac{kw_0^2}{z}\right] \quad (5)$$

where w_0^2 is the beam size parameter in the focal plane.

Since these modes are a complete set, the transverse wave function or field ψ can be decomposed into these functions; i.e.

$$\psi = \sum_m \gamma_m \Gamma^m \quad (6)$$

where Γ^m is the mth Laguerre-Gaussian mode.

The computational algorithm truncates the infinite series expressed by (6) after the first N terms. The set of N complex coefficients, $\{\gamma_m\}$, and the waist size w are obtained by minimizing the residual F, where

$$F = \int_0^{2\pi}\int_0^{\infty}\left|\psi - \sum \gamma_m \Gamma^m\right|^2 r dr d\phi \quad (7)$$

The radius of curvature of the phase front associated with the Laguerre-Gaussian modes is chosen equal to the radius of curvature of the beam that is to be propagated. After the beam parameters and the set of complex coefficients $\{\gamma_m\}$ are calculated in one transverse plane they are obtained in any other plane using (3)-(5).

This algorithm has been used to calculate the diffracted light rays and the intensity distribution throughout the focal volume of the focused laser beam for various proposed beam intensity distributions. The effect of nonlinear phase distortions of $0 \geqslant B \leqslant 4\pi$ on the focused beam characteristics will be shown.

8.4 A High Energy Spatial Filter for Removal of Small Scale Beam Instabilities in High Power Solid State Lasers,

W. W. Simmons, S. Guch, Jr., F. Rainer, and J. E. Murray, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

We have fabricated and measured the performance of an evacuated 10 cm aperture spatial filter using the LLL prototype solid state laser CYCLOPS. In this paper we shall discuss the rationale for this filter, its design and construction, and its transmission characteristics for high power laser pulses incident upon it. In conclusion, we shall present data gathered from the entire CYCLOPS chain, illustrating the impact and importance of spatial filtering upon the design and performance of large solid state laser amplifiers.

It is now well known that for pulses with high enough intensity, I, the nonlinear index of refraction of the propagating medium (amplifier laser glass in situations of interest here) will cause small scale beam amplitude and phase irregularities to grow with propagation distance. In one formulation of the instability problem,[1] a small, one dimensional intensity modulation of spatial wave number K, superimposed upon a uniform intensity background, will undergo approximately exponential growth with gain coefficient g given by $g = K(\gamma I - K^2\lambda^2/16\pi^2)^{1/2}$, where I is the background beam intensity in watts/cm^2, γI is the nonlinear part of the index of refraction, and λ is the wavelength.

In the simplest application of this formula to an amplifier, the instability, assumed to initiate at $z = 0$, will grow by an amount $\exp[B(K)]$, where $B(K) = \int g(K)\,dz$. For an amplifier chain such as CYCLOPS, K scales toward smaller wave numbers as z increases, due to beam divergence. Including the effect of divergence in the integration for the CYCLOPS amplifier (the geometry is shown in Fig. 1), we find that a reasonable approximate first representation of the result is a flat spatial spectrum;

$$B(K) = bP, \qquad K < K_{co} = aP^{1/2},$$

where P is the instantaneous power at the spatial filter input, and a and b are constants that depend upon the details of the amplifier staging.

The spatial filter is an element which transmits only those spatial frequency components with $K < K_{sf}$ (including, of course, the main beam). Thus if $K_{sf} < K_{co}$, some of the instabilities are removed from the ongoing beam before they can propagate further. If we assume that $\rho(K)$ is the initial distribution of instabilities, that each ripple grows independently, and that the net fractional power parametrically[2] removed from the main beam is small, then the instantaneous transmission of the spatial filter can be expressed in the approximate form

$$T_p = 1 - \int_{K_{sf}}^{K_{co}} \rho(K)\exp B(K)\,dK.$$

[1] V. I. Bespalov and V. I. Talanov, *JETP Lett.*, vol. 3, p. 307, 1966.

[2] R. Y. Chiao, P. L. Kelley, and E. Garmire, *Phys. Rev. Lett.*, vol. 17, p. 1158, 1966.

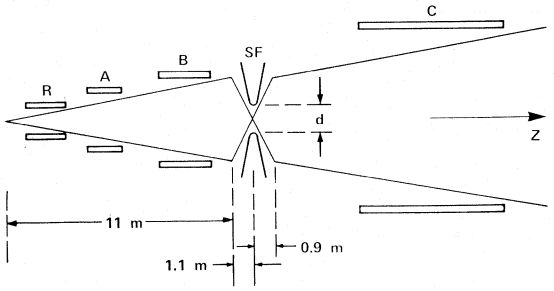

Fig. 1. Foreshortened schematic of CYCLOPS amplifier chain, showing extreme beam rays and pertinent dimensions. Amplifier stages are as follows: R = rods, 24 mm C.A.; A = disk amp, 3.6 cm C.A.; B = disk amp, 8.8 cm C.A.; C = disk amp, 20 cm C.A.; SF = spatial filter. Beam diameter at spatial filter input is 9.5 cm; pinhole diameter $d = K_{SF}/270$.

We have compared measured transmissions, as a function of peak power P_p, for several K_{sf}, with phenomenological transmission functions based upon time integrated versions of T_p. As an example of our results, for $P_p = 170$ GW and $K_{sf} = 10$ cm^{-1}, $T = 0.71$, while for $K_{sf} = 17$ cm^{-1}, $T = 0.93$. The ripple distribution thus appears to maximize (at this power level) for $K \simeq 10$-20 cm^{-1}.[3] This conclusion is confirmed by inspection of time integrated beam profile photographs.

These and other time-resolved results to be presented imply an upper limit for *focusable* peak power from any large amplifier chain, which is dependent primarily upon final amplifier aperture size. This limit can be approached through careful amplifier staging and judicious use of spatial filters throughout the chain.

8.5 Enhanced Parasitic Suppression in Large Aperture Disk Lasers Using Liquid Edge Claddings,

S. Guch, Jr., *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

Development of large aperture Nd:glass disk laser systems requires extreme care in suppression of parasitic oscillations. Current designs employ solder glass claddings applied to disk edges to absorb fluorescence, reducing reflection back into the disk and minimizing regenerative amplification. Present claddings have significant limitations, including poor refractive index matching to the base glass, insufficient absorption at 1.06 μm, large bubble and crystalline inclusion content, and lack of reproducibility in application. Calculations of parasitic thresholds indicate that these claddings may limit αD, the product of small signal gain coefficient (α) and disk major axis dimension (D) to a maximum value near 2.5. In the present work, a liquid edge cladding system with excellent index matching to laser glasses and satisfactory fluorescence absorption was successfully developed and employed in a high performance large aperture disk laser amplifier.

A detailed survey of candidate liquids revealed that solutions of zinc iodide with

refractive index of up to 1.63 at 1.06 μm could be prepared, handled, and employed with common laser amplifier materials. While an excellent index match to laser glasses, zinc iodide solutions possess negligible absorption at 1.06 μm. Two procedures were developed to correct this deficiency. Addition of nickel chloride provided a capability for fluorescence absorption of 4.6 cm^{-1} in a solution of 1.58 refractive index at 1.06 μm. Alternatively, coating of the inner surface of the liquid containment channel with chrome black was found to produce equally satisfactory suppression of parasitic oscillations.

Preliminary evaluation of the liquid concept was accomplished using two small disk amplifier test modules. Successful testing in over 600 laser firings led to integration of the design in a high performance, 20 cm clear aperture disk laser amplifier. A zinc iodide solution of 1.58 refractive index at 1.06 μm was employed. Limitations on disk holder size restricted the cladding flow channel sufficiently to require use of an extrinsic chrome black absorber alone for fluorescence absorption. The fluid flow channel was sealed on the disk faces using standard "o" ring seals. Disk holders used were slightly bulkier than for solid edge clad designs, reducing amplifier clear aperture by approximately 5%. The fluid system, configured to allow continuous circulation, suffered no leaks within the laser head in over 120 laser firings.

Amplifier performance was evaluated through small signal gain measurements. These measurements determined the maximum value of αD attainable for comparison with similar results obtained with two different solid edge claddings. The solid clad disks reached an αD value of 2.55, while the liquid system achieved a peak αD of 3.05, an increase of approximately 20%. This represents a significant improvement in energy storage capability and efficiency over that attainable with curent solder glass edge claddings. These results indicate both the superior parasitic suppression and the practicality of liquid edge claddings in large aperture Nd:glass disk laser amplifiers.

8.6 Terawatt Laser Performance, W. W. Simmons, F. Rainer, R. D. Boyd, C. C. Fetterman, and J. A. Glaze, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*
(15 min)

The LLL solid state laser CYCLOPS was constructed as a single chain prototype unit for advanced multi-arm laser systems intended for laser fusion experiments. It has been operated through its 20 cm clear aperture amplifier stages (C stages), and is presently undergoing performance characterization with a 10 cm aperture spatial filter inserted just prior to the C stages. In this paper we shall present details of CYCLOPS performance to date, including near and far field beam profiles, stage gains, and time-resolved power measurements. Details of CYCLOPS staging and examples of system performance are presented in the following summary.

Staging has been described previously[1] and is summarized in Fig. 1. The oscillator, Nd:glass preamps, spatial filter, apodized aperture, and 2.5 cm clear aperture rod amplifiers deliver a pulse of nominal energy 0.5-1.0 joules contained within a Gaussian temporal envelope of FWHM duration 150-200 ps to the disk amplifiers. The apodized aperture imposes the desired intensity profile (both exp. $-r^5$ and quadratic aperture functions have been employed) and divergence

[1] Lawrence Livermore Laboratory Laser Fusion Semiannual Report, July-December 1973, p. 19.

(4.3 mrad full angle) upon the beam. The three rod amplifiers are protected from self oscillation by Faraday rotators and rooftop multilayer dielectric polarizers following each rod. This combination provides more than 25 dB of isolation per rod against back reflections.[2]

Each amplifier stage (*A*, *B*, and *C*) consists of 12 disks, 2 multilayer polarizers, and one Faraday rotator. Clear apertures are as follows: *A* stage, 3.6 cm; *B* stage, 8.8 cm; *C* stage, 20 cm. The energy storage required is approximately 1.6 MJ (for all disk stages).

At each of the diagnostic stations (P_1, P_2, P_3, and P_4), approximately 5% of the beam is back reflected from both front and back surfaces of the Faraday rotator glass, which is tilted at 5° from the beam line for this purpose. One of these beams is directed into a calorimeter; the other is used for obtaining near or far field beam information photographically. Data from a number of shots has been analyzed and will be discussed during the talk. As a representative example, we present the results of a single shot in Table I. Corresponding near field beam profiles are shown in Fig. 2.

The major problems encountered in CYCLOPS operation to date have been associated with maintenance of disk surface quality in the presence of hard optical pumping from the flashlamps. Small, flashlamp-induced damage sites act as sources for small scale beam breakup, ultimately leading to self focused filaments and component damage. Discussion of spatial filtering for control of small scale instability growth, will be presented in another paper at this meeting.

8.7 10 Kilojoule SHIVA Laser System for Fusion Experiments at LLL (*Invited*), T. J. Gilmartin, R. O. Godwin, J. W. Davis, W. F. Hagen, C. H. Hurley, G. W. Leppelmeier, G. J. Linford, J. O. Myall, W. C. O'Neal, and J. B. Trenholme, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*
(30 min)

Large, multi-beam, neodymium glass laser systems are playing an important role in near term laser fusion experiments. Although the primary purpose of these laser fusion experiments is to demonstrate inertial confinement of a thermonuclear reaction in a manner which is ultimately scalable to commerical power generation, there are many intermediate scientific goals. These goals include: understanding plasma physics associated with high power laser and matter interactions; developing fuel target design models; designing and fabricating efficient targets; advancing the state of laser/optics engineering; and developing reactor chambers. Several significant laser fusion programs in pursuit of these goals are currently underway.

In describing the capability of the fusion glass laser systems, several parameters are important. The energy yield from a thermonuclear reaction with reactor fuel targets of solid D-T (deuterium-tritium) is critically dependent on the illumination geometry and the focusable power available from the laser system. However, the yield from the currently used experimental targets, glass bubbles containing gaseous D-T, is also dependent on the energy output of the laser system. Since nonlinear optical effects limit the flux in the laser output aperture, a fourth important system parameter is the area of the total system aperture. The Lawrence Livermore Laboratory 10 kilojoule SHIVA laser system, the highest performance glass laser system currently on the drawing boards in the U. S., will be described in detail.

The detailed laser system performance requirements are determined by the characteristics of the fuel target. The size and shape of the target and its sensitivity to nonuniformity in the illumination determine the accuracy with which the laser beams must be apodized, aligned and focused. The temporal response of the target determines the laser pulse shape and the accuracy of synchronism required among the illuminating beams. For example, the 20 beam SHIVA laser system will give an initial illumination uniformity of $\pm 10\%$ over 4π. This will require that the beams be aligned to within 2% and focused within 5% of the target diameter, typically 100 to 500 μm. Simple pulses 100 psec long must be synchronized to within 10 psec (3 mm) and the relative power output in the several laser beams must be within 5%. As the laser system power increases, larger targets can be burned and the absolute beam alignment tolerance is relaxed. With fewer faster (lower f/ # beams) the alignment tolerance may be relaxed because the achievable illumination uniformity is already poorer.

In addition to the linear optical alignment requirements, nonlinear optical effects which deflect the beams, move the focal plane, modify the beam apodization near focus, and temporally modulate the pulse shape, must be minimized. A brief discussion of these effects vis-à-vis the illumination and alignment requirements of fusion laser systems with emphasis on the SHIVA system will be given.

Finally, since these large laser systems contain literally hundreds of laser amplifiers, thousands of flashlamps and energy storage capacitors, and large part counts of all components, reliability and maintainability are essential. A brief discussion will highlight the engineering aspects of the major subsystems, including the laser space frame, control and data management, energy storage and power conditioning, and the target chamber.

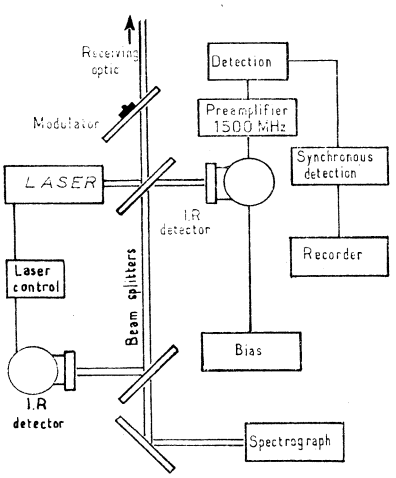
Pollution Monitoring and Remote Sensing

Chairman: S. F. Jacobs, *Optical Sciences Center, University of Arizona, Tucson, Ariz.*

9.1 Measurement of Atmospheric Absorption Using Solar Infrared Heterodyne Radiometer and Its Application to the Knowledge of Pollutant Densities, B. Christophe and D. Camus, *S.A.T., Paris, France,* and J. Gay and A. Journet, *C.E.R.G.A., Grasse, France*
(15 min)

The object of this experiment is to use the Solar Infrared Heterodyne Radiometer to measure the atmospheric absorption at high resolution. It is a technique which has been described by J. McElroy[1] and has been applied before[2] to measure vertical absorption. We wish to describe here an experiment to measure the variation of the absorption coefficient with altitude and therefore obtain pollutant concentration.

The beat signal produced in the mixer between the sun and the local oscillator radiations are detected and analysed in connection with the rising of the sun. The signal depends only on the integrated absorption path in the atmosphere given by:



$$k(v,Z) = \int_0^\infty \frac{k(v,h)\,dh}{\sqrt{1 - \left(\frac{R}{R+h}\right)^2 \sin^l Z}}$$

in which formula, h is the altitude, R the earth radius and Z the zenithal angle of the observed object. The technique gives k as a function of the zenithal angle and by inversion of the above integral equation one can recover $k(v,h)$, the absorption function of the altitude.

Fig. 1.

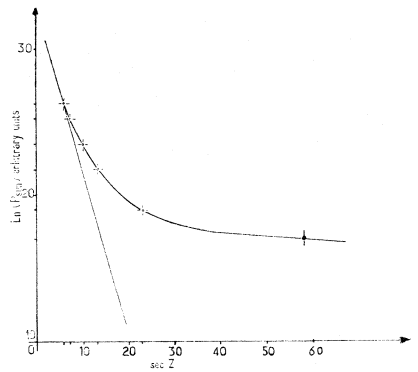

Fig. 2. Graph of the recieved solar power versus the secant of the zenith angle. Taken 29 Oct. with P22.

The detection chain (Fig. 1) consists of a Telescope following an heliostat, a beam splitter, a CO_2 laser, as local oscillator (which is tunable over 40 transitions between 9.2 and 11.2 μ), a Hg Cd Te photovoltaic mixer with a bandwidth larger than 1 GHz followed by an amplifier Avantek and a synchronous detection. When the local oscillator photon current shot noise is preponderant, the signal to noise ratio is given by:[4,5]

$$\frac{S}{N} = Q\chi(B\tau)^{1/2}Tf[\exp h\nu/kT - 1]^{-1}$$

Q is the quantum efficiency, χ the wave mixing factor,[3] B the equivalent bandwidth, τ the integration time, Tf the optical transmission, ν the local oscillator frequency, T the source temperature. In our experiment the theoretical S/N is 34 dB taking $\chi = Tf = 1$ and we have measured $(S/N) = 20$ dB.

One of the results obtained is shown on Fig. 2 and using measurements at low sec z can lead to the vertical transmission which was for this day of 80% on P_{22}. The use of high number sec z, enables us to observe the repartition of CO_2 or any absorbant in the atmosphere (Ozone for example). To improve experimental results and obtain the excitation of CO_2, we can also measure absorption on all rotational lines and also obtain measurements at low altitude by looking away from the center line (1.5 GHz).

This technique used to obtain information on pollutants is different from any other technique using IHR[6,7] since it needs an outside atmosphere source.

It has the advantage, however, to have a better sensitivity and it enables us to measure the altitude of the polluted layer.

9.2 Ambient Air Pollutant Measurements with a Bistatic, Heterodyne System, R. T. Menzies and M. S. Shumate, *Jet Propulsion Laboratory, California Institute of Technology, Pasadena, Calif. 91103*

(15 min)

We have performed several ambient-air monitoring experiments in the Pasadena, California area with a bistatic, long path differential absorption technique. Both cube corner reflection and diffuse reflection from ordinary surfaces were used to provide the return signal. Two pollutants were monitored over a round trip path of nearly one kilometer: nitric oxide and ozone. The transmitter used in the nitric oxide monitoring experiments was a CW $C^{12}O^{16}$ laser. The laser lines chosen to interact with NO were the 7-6 band, $P(15)$ line at 1052.194 cm^{-1} and the 9-8 band, $P(9)$ line at 1900.049 cm^{-1}. The transmitter used to monitor ozone was a CW $C^{12}O_2^{16}$ laser. The $C^{12}O_2^{16}$ laser 00°1-II band, $P(14)$ line at 1052.194 cm^{-1} interacts strongly with the ozone ν_3 band. This line and several other P-branch lines up to $P(24)$ were used in the experiments. Both lasers were stabilized with Invar cavity spacers and fitted with gratings for line-to-line tuning capability.

Heterodyne detection is an effective means of obtaining high sensitivity to a weak return laser signal in a bistatic system. In this system, the Dicke-type heterodyne radiometer could easily detect a return laser signal from a Lambertian reflector surface at a distance of 0.5 km, whose reflectivity was 1%, when only a few milliwatts of power were transmitted. The heterodyne radiometer was operated with a beat frequency of a few MHz and an IF bandwidth of 1 MHz. The detection system was also operated in a homodyne mode, i.e., there was no frequency shift between the local oscillator and return signal frequencies. The comparative sensitivity of the homodyne mode was degraded somewhat by gain variations in the amplifiers and by excess local oscillator noise in the frequency region near the chopping frequency. However it is a simpler technique to employ in certain cases and still provides high sensitivity.

Ozone and nitric oxide were monitored during several days, some of which showed the obvious signs of photochemical smog. Typical plots of the daily concentration trends agreed with the classic pattern of NO buildup during early morning hours and subsequent decay via photochemical reactions, with O_3 concentrations peaking in the early afternoon hours. A 2% differential absorption could normally be detected, the limitation being mainly due to atmospheric turbulence. This corresponded to a sensitivity of less than 0.02 ppm average concentration for both ozone and nitric oxide. Smaller differential absorption signals can be detected with modifications in the optics and processing electronics. However, the initial limitation in accuracy, expecially for NO measurements, was found to be due to water vapor differential absorption at the laser wavelengths. Inadequate knowledge of water vapor absorption led to inaccuracies of the order of 0.1 ppm for NO measurements. Independent water vapor absorption measurements were made which reduced this source of error considerably. The accuracy of the laser measurements was substantiated with supporting data from chemiluminescent monitors of NO and O_3.

Plans are in progress to convert this pollutant monitoring technique to an airborne system, with a downward pointing transmitter. With such an instrument, one can obtain altitude profiles of pollutants, with high sensitivity at all altitude levels. Because the instrument can operate effectively with short integration times, high spatial resolution can be achieved also.

9.3 Absorption of CO_2 Laser Radiation by Water Vapor, M. S. Shumate and L-G. Rosengren, *Jet Propulsion Laboratory, Pasadena, Calif. 91103*

(15 min)

In recent years, the proliferation of optical systems that utilize carbon dioxide lasers has produced considerable interest in the effects of atmospheric absorption upon CO_2 laser radiation. One of the most common constituents of the atmosphere, water vapor, can have a sizable effect upon operation of these laser systems. In this present work, we report measurements of the absorption coefficients of water vapor at the emission lines of the normal isotope of carbon dioxide, $C^{12}O_2^{16}$. The measurements were made using an acoustically resonant optoacoustic detector, at room temperature, with an atmospheric pressure background of air.

Measurements of water vapor absorption at CO_2 laser wavelengths has been previously reported by McCoy, *et al.*,[1] and by Trusty.[2] The most interesting feature of their results was a nonlinear variation in the absorption coefficient with a change in the partial pressure of water vapor. Benedict and Kaplan[3] have presented a detailed theoretical prediction of the dependence of water vapor absorption with pressure that differs significantly from McCoy, *et al.*, and Trusty's results. Furthermore, the values they report are not in agreement with each other. These discrepancies together with the need for accurate absorption coefficients on several CO_2 laser lines motivated the present investigation.

The experimental technique used for our measurements utilized an acoustically resonant optoacoustic detector, or spectrophone, in conjunction with a passive stabilized, grating tunable carbon dioxide laser. The optoacoustic detector was constructed in a cylindrical shape out of pyrex glass, with barium fluoride infrared windows. The detector has a first order radial

This paper represents the results of one phase of research carried out by the Jet Propulsion Laboratory, California Institute of Technology, under Contract Number NAS 7-100, sponsored by the National Aeronautics and Space Administration.

[2] G. L. Trusty, "Absorption measurements of the 10.4 micron region using a CO_2 laser," Dissertation, Ohio State University, 1972.

[3] W. S. Benedict and L. D. Kaplan, *J. Quantum Spectrosc. Radiat. Transfer*, vol. 4, p. 453, 1964.

resonant frequency at 2.8 KHz, and used a conventional condenser microphone mounted in the detector side wall as a pressure transducer. With the laser radiation modulated by a mechanical chopper, and using a commercial lock-in amplifier, the minimum detectable absorption strength was 2×10^{-5} m^{-1}

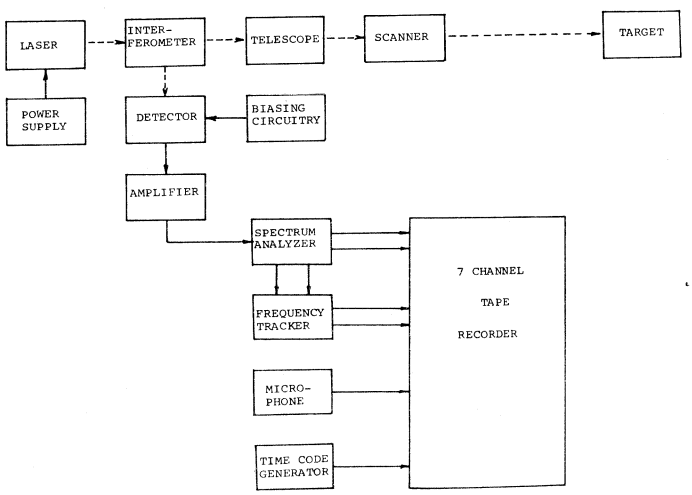
The optoacoustic detector was attached to a vacuum station that permitted evacuation of the detector prior to filling. Since water vapor adsorbs to almost all materials, care was taken to assure that the walls of the system were saturated with water vapor before admitting dry air to the detector. Four different water vapor partial pressures were used: 5, 10, 15, and 20 torr. The detector was then filled with dry air to a final pressure of 730 torr. Measurements were made with a laser operating on the $P(10)$-$P(32)$ and $R(10)$-$R(32)$ lines of the 00°1-02°0 band and the 00°1-10°0 band of the normal isotope of carbon dioxide, $C^{12}O_2^{16}$.

In order to measure the contribution to the detector signal that was due just to the water vapor, background signals were measured using a detector fill of only dry air at the same laser wavelengths. Thus, the contributions to the signal caused by CO_2 and trace contaminants in the dry air could be subtracted. Background signals due to window absorption effects are likewise cancelled out of the final result.

The results obtained with the apparatus described consistently showed larger absorption coefficients for water vapor than have been previously reported. Furthermore, the variation in absorption with water vapor pressure was linear, to within the accuracy of our method. This result supports the theory of Benedict and Kaplan. The paper will present a detailed description of the experimental apparatus, including the procedures followed to minimize the effects of water vapor adsorption on the optoacoustic detector walls. A detailed analysis of the error sources will be presented.

9.4 Progress in Laser Radar *(Invited)*, H. Inaba, *Research Inst. of Electrical Communication, Tohoku University, Sendai, Japan*
(30 min)

No summary.



9.5 A Laser Doppler Velocimeter for Remote Power Plant Effluent Measurements, C. R. Miller and C. M. Sonnenschein, *Raytheon Co., Sudbury, Mass. 01776* and W. F. Herget, *Environmental Protection Agency, Research Triangle Park, N. C. 27711*
(15 min)

A CO_2 Laser Doppler Velocimeter (LDV) System was assembled into a mobile test van and field tested during the weeks of 23-30 August 1974 and 12-19 January 1975 to prove the feasibility of remotely detecting and measuring the velocity of effluents from the smoke stacks of power plants. The LDV was a coaxial homodyne system which detected the Doppler shift, $\Delta\nu_D$, on the 10.6 μ radiation backscattered from the smoke stack effluents. Since the angle, α, between the smoke stack and the transmitted laser beam was known, the velocity, v, of the effluent could be determined from the equation:

$$v = (\lambda/2 \cos \alpha) \cdot \Delta\nu_D$$

A block diagram of the effluent detection system is shown in Fig. 1. The optical portion of the system consisted of a 20 W CW CO_2 laser; a Mach-Zehnder interferometer; a 12-inch diameter, f/8 telescope; and a copper doped Germanium detector. This equipment was mounted on a common base plate which was in turn shock mounted to a support table to isolate against vibration. The transmitted beam was directed to the target by an 18-inch elliptical scanning mirror. The system could be scanned over $\pm 10°$ angles in both elevation and azimuth before coarse mirror adjustments became necessary. The system was bore-sighted to an alignment telescope and it was found that pointing accuracies of 0.2 mrad were easily maintained.

Fig. 1. Block diagram of effluent detection system.

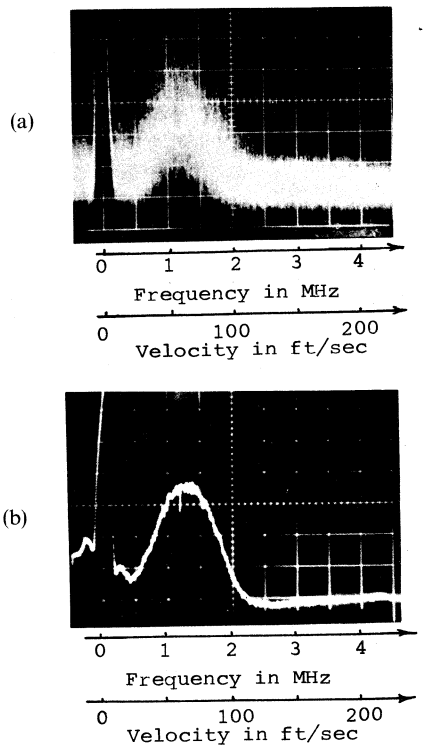


Fig. 2. (a) 2 second duration photograph of the spectral distribution of effluent backscatter signals. (b) Spectral distribution of effluent backscatter signals after 7 seconds of signal averaging.

The *IF* Doppler signals were detected in a shot noise limited detector and after amplification were displayed on a spectrum analyzer. The spectrum analyzer's vertical output was recorded on magnetic tape for further processing.

Overall system efficiency was measured by calibrating the LDV against a standard target of known reflectivity. This calibration allowed estimates of the effluent backscatter coefficient, $\beta(\pi)$, to be made.

A variety of measurements were made against a smoke stack at the River Bend Steam Plant of Duke Power in Mt. Holley, North Carolina.[1] Duke uses electrostatic precipitators to remove the larger particles from their stacks. Under typical operating conditions the plume is invisible with an opacity of about 3-10%. Effluent backscatter signals were detected across a 1310 ft range at an elevation angle of 10° (α = 80°). Typical spectrum analyzer waveforms are shown in Fig. 2(a) and 2(b). These photographs indicate the spectral distribution of smoke stack effluent backscatter signals before and after signal averaging. Effluent velocities were measured as a function of power load conditions to be in the 100 to 140 ft/sec range. Estimates of the effluent backscatter coefficient have been made. Velocity profile measurements above the

[1] W. F. Herget, C. R. Miller, and C. M. Sonnenschein, "Remote measurement of power plant stack effluent velocity," to be published.

stack lip had a variety of distributions with the velocities varying from 80 to 160 ft/sec.

Two areas currently under investigation are the effect of plume turbulence on the LDV signal and the relationship between backscatter signal strength and plume opacity.

The authors would like to acknowledge the cooperation of Duke Power Co. in these measurements. The technical assistance of R. E. Schaaf of Raytheon Co., R. M. Huffaker of NASA MSFC, and J. A. Thompson of Physical Dynamics was greatly appreciated. This work was supported by the EPA and NASA.

9.6 Performance of a CO_2 Laser Vortex Detection System, C. M. Sonnenschein and C. A. DiMarzio, *Raytheon Co., Sudbury, Mass. 01776*, and H. Jeffreys, *NASA, Marshall Space Flight Center, Huntsville, Ala. 35812*

(15 min)

Two CO_2 laser Doppler velocimeters have been built to detect and measure the characteristics of aircraft trailing vortices. The systems, currently operating at Kennedy International Airport, use a CO_2 laser in a heterodyne configuration to determine the transport and velocity distribution of the vortex flow field. The optical portion consists of a CW laser, a Mach-Zehnder interferometer, a 12-inch telescope that focuses and scans in range, an output mirror that scans in elevation, and a shot noise limited Hg:Cd:Te detector. Following the detector is a sophisticated signal processor, a PDP-11 computer, several tape recorders, and displays.

The system operates by propagating a laser beam into the atmosphere and collecting the Doppler shifted signal scattered by aerosols naturally suspended. A signal at the Doppler frequency is obtained by detecting the superposition of the scattered signal and a stable local oscillator. The presence of a vortex is determined by high frequency components in the detector output.

The signal processor frequency analyzes the signal. The signal at each frequency is integrated and recorded on a high speed tape. Since there are 104 distinct frequency channels and a typical integration time is 2 msec, this produces approximately 50,000 pieces of data per second.

In order to reduce the data stream, the signal processor performs other functions. An amplitude threshold can be set to remove the noise floor and a velocity threshold discriminates against the ground wind. Data from the thresholded spectrum indicating the maximum velocity, the highest signal amplitude and its frequency, and the number of filters excited are recorded and processed by a computer in real time.

Results from both thresholded and raw data have been analyzed in detail. Calibration measurements against a spinning wheel have shown excellent repeatibility. Signal - to - noise ratio measurements against the atmosphere have been carried out to yield an atmospheric backscatter coefficient.

The vortex is an extended target, whose area is much greater than the system resolution. The vortex position is obtained by an algorithm that locates the centroid of the maximum intensities above appropriately selected amplitude and velocity thresholds. Vortex tracks from hundreds of aircraft landing at Kennedy have been collected and several will be presented. A comparison of vortex locations obtained from the two systems show an average error of less than 10 ft.

The authors would like to acknowledge the assistance of the many agencies, companies, and people who made this work possible. The program was funded by NASA, Huntsville, and the FAA, both of whom provided valuable technical assistance. The equipment was built and operated by personnel from Raytheon Company and Lockheed Missiles and Space Company. M&S Computing provided the computer hardware and much of the software, and Physical Dynamics, Inc., helped in the data evaluation.

9.7 Resonant Doppler Velocimeter, R. B. Miles, *Aerospace and Mechanical Sciences Department, Princeton University, Princeton, N. J. 08540*

(15 min)

Tunable narrow linewidth laser sources permit the inclusion of resonant absorption and fluorescence among the tools for analysis of gas flow and turbulence. The concept may be demonstrated by the introduction of trace amounts of sodium vapor into a helium or nitrogen flow. A narrow bandwidth tunable dye laser incident in the direction opposed to the flow is absorbed at the Doppler shifted resonant frequency, and the light is reradiated by the sodium atom after some characteristic time equal to or shorter than the natural lifetime of 16.3 n sec. The detected fluorescence intensity for optically thin sodium may be correlated with the absorption constant, the maximum occurring when the tunable laser is matched to the Doppler corrected resonant absorption linecenter of the observed region. Measurement of the laser frequency, then, yields the velocity of the observed region. Pressure and temperature discontinuities such as shock waves and boundary layers are observable as intensity variations, rendering this tool a convenient device for qualitative flow visualization as well as quantitative measurements.

The Doppler shift for sodium is 1.7 MHz for each meter/sec of flow velocity. Since the natural linewidth is 9.8 MHz, the limiting resolution of the resonant Doppler technique is several meters/sec. Pressure and thermal broadening will substantially increase the minimum velocity sensitivity, depending on the particular configuration chosen. Several experimental configurations with their minimum velocity resolution and other pertinent information are given in Table I for helium and nitrogen.

Further extensions of this tool beyond the flow visualization and average velocity measurements are obvious. The atoms or molecules will microscopically follow the flow field; thus the thermally broadened linewidth, while to some

extent obscuring the average velocity, yields a microscopic static temperature profile. The frequency difference between the fluorescent light and the incident laser suggests methods for measuring Reynolds shear stress, and variations of the absorption line with velocity, temperature, and pressure fluctuations suggest methods for turbulence measurement.

9.8 Remote Measurement of Ozone by Resonance Raman Scattering and Differential Absorption, C. M. Penney, *General Electric Corporate Research & Development, Schenectady, N. Y. 12301*

(15 min)

We have measured the absolute magnitude, spectral distribution and depolarization of resonance Raman scattering[1] from ozone excited in its dissociative Hartley absorption band between 286 and 294 nm. These measurements were accomplished using a line-narrowed doubled dye laser, 3/4 meter Spex monochromator and timing/photon-counting detection, providing 5 nsec incident pulses with spectral bandwidth less than 0.1 nm and scattered light resolutions of 0.1 nm and 5 nsec. Measurements of absolute magnitude were obtained by comparison of Raman scattering signals from O_3 and O_2 and an auxiliary absolute measurement of the O_2 scattering cross section using techniques described previously.[2] Typical results shown in Fig. 1 reveal a progression of harmonics characteristic of the type of resonance Raman scattering described by Holzer, Murphy and Bernstein[1] in their observations on halogen molecules excited above the dissociation limit. We find that the cross section for scattering into the $\nu_1(+\nu_3?)$ is 1.1×10^{-26} cm^2/sr $\pm$ 20% for excitation at 286.6 nm. This is 600 times stronger than the ordinary Raman scattering from O_2 excited at the same wavelength. Also, the cross section appears to increase in proportion to the absorption coefficient over the observed spectral range. In the case of ozone, the harmonics appear to arise from both the ν_1 and ν_3 vibrations, revealing in the latter case an expected breaking of selection rules for ordinary Raman scattering. The overall characteristics of the ozone scattering are consistent with the distinctions between scattering and fluorescence which are set forth in Ref. 1.

These results are used to compare the resonance Raman scattering and differential absorption techniques for remote, spatially-resolved LIDAR measurements of ambient ozone near the ground, and in its stratospheric layer roughly between altitudes of 10 and 30 km. Raman LIDAR directly observes the ozone, which is a minor species (10 ppb to 10 ppm), ideally providing a signal directly proportional to ozone concentration. Differential absorption LIDAR determines ozone concentration from

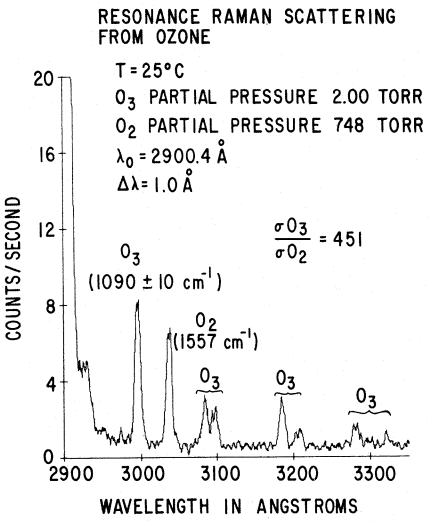

Fig. 1. Resonance Raman scattering from ozone.

the difference between two signals, a situation that, in general, is less favorable from signal-to-noise (S/N) considerations. However, since differential absorption LIDAR is based on scattering from a major species and can use a stronger scattering process (Rayleigh vs Raman scattering) it often provides a substantial S/N advantage. We shall show how the general expressions for S/N differ for the two techniques and use the general and specific results to establish that ozone is a particularly favorable target for ground-based and satellite-based differential absorption LIDAR measurements.

9.10 Laser Optoacoustic Detection of Explosive Vapors,[1] P. C. Claspy, Y-H. Pao, S. Kwong, and E. Nodov, *Department of Electrical Engineering and Applied Physics, Case Western Reserve University, Cleveland, Ohio 44106*

(15 min)

The illegal use of explosives in public crimes has reached a level such that a critical need exists for a method of detection of the presence of such materials in locations such as airports and postal facilities. While effective methods for indirect detection using tagging schemes have been proposed, a reliable method for direct detection of the explosive vapors in the presence of normal atmospheric pollutants is still required. This paper presents the results of the application of a laser optoacoustic detector to the direct detection problem. The results indicate that such a device can provide a sensitive, reliable direct detection system.

The laser optoacoustic detector makes use of a cell containing an air sample which is suspected to contain the vapor to be detected. The cell is illuminated with chopped infrared radiation of a wavelength known to be absorbed by the vapor being sought. If that vapor is present in the sample, a periodic heating of the gas in the cell occurs. The resulting pressure fluctuations are then detected with a sensitive capacitive microphone which has been placed in the cell. Kreuzer, *et al.*,[2] have reported the application of usch a device to the detection of low molecular weight pollutants in the atmosphere. In performing direct detection of explosive vapors, consideration must be given to several factors in addition to the determination of the optoacoustic spectrum of the materials. These factors include:

1) a strong tendency of all explosive molecules to adhere to the surface of most materials;

2) the low vapor pressure of most explosives (vapor pressure of TNT at 20°C $\approx 10^{-6}$ Torr;

3) the problem of interference by pollutant gases normally found in the atmosphere.

The detector used in this experiment was an acoustically resonant device of the same general type as those used by Dewey[3] and by Goldan and Goto.[4] Our detector, however, is designed such that the dominant acoustic mode is a mixture of the fundamental radial mode of the large diameter cylindrical end sections and the fundamental longitudinal mode of a small diameter coaxial cylindrical microphone. The microphone is thus a part of the resonant system rather than a perturbation to it. The cell design provides acoustic amplification of the small signals which result from very low vapor concentrations (typically 0.01 ppm or less). In addition, to reduce the tendency for surface absorption of the explosive molecules the cell is operated at a nominal temperature of 50°C. The light source was a dry ice cooled CW CO laser which could be grating tuned over the wavelength region from 5.8 microns to 6.7 microns. This tuning range coincides with the symmetrical stretching vibration of the NO_2 group which is present in all of the explosives studied. A fixed set of 16 laser lines, spanning the above spectral range, was used to study all explosives. This set of lines was also used to determine the spectra of five common atmospheric pollutants, which included water vapor, methane, butane, nitrogen dioxide, and nitric oxide. Of these only nitrogen dioxide appears to offer potential interference with the explosive spectra.

TABLE I
EXPLOSIVE OPTOACOUSTIC SPECTRA (NORMALIZED)

Wavelength (microns)	EGDN + 10% NG	PETN
6.626	2.4	1.2
6.539	4.8	1.7
6.466	0.6	0.8

6.003	100.	2.5
5.942	61.8	2.0
5.881	6.7	5.5

Eight explosives were investigated in the course of this program. These include nitroglycerine, ethylene glycol dinitrate (EGDN), dinitrotolnene (DNT), trinitrotoluene (TNT), TOVEZ, dynamite, cyclotrimethylene trinitramine (RDX), and pentaerythritol tetranitrate (PETN). Normalized optoacoustic spectra for three of these explosives are given in Table I. Our high resolution optoacoustic spectra show good agreement with the low resolution data reported by Pristera, *et al.*[5]

Our results demonstrate the feasibility of direct laser optoacoustic detection of explosive vapors in the atmosphere at partial pressures of 10^{-6} Torr or less in the presence of normal atmospheric pollutants.

10.3 Epitaxially Grown Single Crystal KTN for Thin Film Optical Modulators,[1] R. E. Fontana, Jr., D. J. Epstein and A. Linz, *Center for Materials Science and Engineering and Department of Electrical Engineering, Massachusetts Institute of Technology, Cambridge, Mass. 02139*

(15 min)

We report here on the growth, by liquid phase epitaxy, of single crystal thin films of potassium tantalate niobate (KTN), and the preliminary evaluation of these films as light guides and modulators. The material KTN exists over the complete solid solution range $0 \leqslant x \leqslant 1$ in the formula $KTa_{1-x}Nb_xO_3$, and exhibits a ferroelectric state for all compositions except those close to $x = 0$. By suitable choice of x the cubic-to-tetragonal ferroelectric transition can be made to occur near room temperature. Advantage of the enhanced electrooptic coefficients[2] accompanying the transition has been taken in designing room temperature bulk electrooptic devices[3] characterized by a particularly low half-wave voltage. Typically, this voltage is a factor ten smaller than for comparable devices using $LiNbO_3$ or $LiTaO_3$.[3,4]

[1] This work was supported by the Advanced Research Projects Agency under Contract DAHC-15-73-C-0316.

[2] The electrooptic coefficients referred to here and elsewhere in the discussion are those relating the index change to the applied electric field.

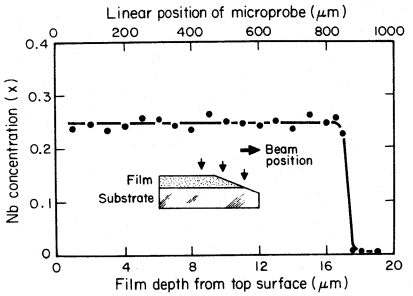

Fig. 1. Nb concentration in $KTa_{1-x}Nb_xO_3$ vs. film depth as determined from microprobe results of a lapped film-substrate.

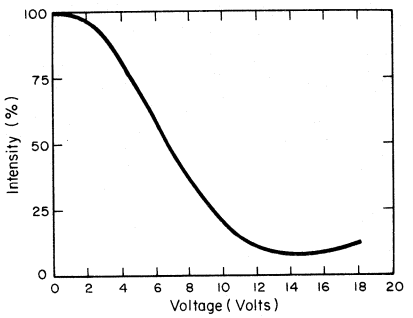

Fig. 2. Central beam light intensity for KTN modulator vs. applied d.c. voltage. Results are for a TE_0 mode in a 26 mole percent Nb film at 633 nm.

Because the index of refraction of KTN increases with increasing Nb concentration it is possible to obtain light guiding in thin films of KTN^+ (higher Nb concentration) grown on KTN^- (lower Nb concentration) substrate. By combining the high electrooptic effect available in this system with the more favorable geometry associated with thin film devices it becomes possible to fabricate electrooptic modulators requiring only a few volts for full modulation. Our materials effort has focussed on films with Nb content less than 40 mole percent. For this compositional range, KTN is paraelectric at room temperature, with cubic symmetry and a quadratic electrooptic effect. The index of refraction, the cubic lattice constant and the cubic-tetragonal Curie temperature all increase with increasing Nb content.

To obtain KTN waveguiding structures we have grown KTN single crystal films on (100) potassium tantalate ($KTaO_3$) substrates by liquid phase epitaxy. We employ a dipping method similar to that used for growing magnetic garnet films.[5] Because $KTaO_3$ has the lowest index of refraction in the KTN system, any composition $x > 0$ grown on this substrate will support guided modes. We grow from a melt containing a non-stoichiometric ratio of K_2CO_3, Ta_2O_5, and Nb_2O_5; a 7 mole percent excess of K_2CO_3 serves as the flux. Using a 60:40 mole ratio of Nb:Ta in the melt, we have obtained, by varying the growth temperature, films with Nb content ranging from $x = 0.11$ to 0.28.

The compositional uniformity of our films has been verified by electron-beam microprobe techniques. Fig. 1 shows the results for a 17 μm thick film lapped at 1°. Within experimental accuracy the film-substrate interface appears to be abrupt. After growth, the films are carefully polished to reduce the film thickness to 3-5 μm in order to limit the number of guided modes. Rutile prisms were used to couple the light into and out of the films.

For a 26 mole percent Nb film, electrooptic modulation of guided modes with an interdigital beam deflector has been achieved at 633 nm. The interdigital electrodes were 3 mm long with 25 μm wide fingers spaced 50 μm center-to-center. Fig. 2 shows the central beam output intensity as a function of d.c. voltage for an input TE_0 mode. An applied d.c. voltage of 15 volts, corresponding to a maximum surface electric field of 6000 volts/cm, gives 90% amplitude modulation. An improved electrode pattern now being fabricated (with 8 μm finger width and gap spacing) should reduce this voltage to about 5 volts. A further reduction in drive voltage should be possible by using KTN films in the range $x = 0.33$ to $x = 0.38$ thereby placing the Curie point closer to room temperature and, accordingly, increasing the value of the electrooptic coefficients.

The wide range of dielectric, optical and electrooptical properties available in the KTN system provides a design flexibility not possessed by other electrooptic materials thus far considered for thin film optics. In particular, it should be possible in this system to fabricate, by multiple dip liquid phase epitaxy, multilayered thin film structures which can be used for a host of applications including filters, switches, couplers and deflectors.

10.4 Diffused Two-Dimensional Optical Waveguides in GaAs, E. Garmire,[1] D. Lovelace, G. H. B. Thompson, *Standard Telecommunication Laboratories, Ltd., Harlow, Essex England*

(15 min)

In this talk we describe the first studies of passive optical waveguide properties of diffused stripe geometry pn junctions in GaAs. The two-dimensional waveguides were ~2 μm deep and had widths varying from 2 to 6 μm. Single mode propagation at 1.15 μm was observed in both fundamental and first order modes, depending on stripe width. Photographs of guided light profiles and cleaved and stained end faces will be shown. These results indicate that diffusion is a convenient method of fabricating two-dimensional optical waveguides in GaAs.

The stripe pn junctions were fabricated by zinc diffusion into *n*-type GaAs through SiO_2 stripe masks, resulting in surface hole concentrations of 10^{19} cm^{-3}. We studied first the properties of planar diffused guides, comparing measured light profiles to theoretical ones. We assume that contributions to the refractive index

[1] Present address: University of Southern California, University Park, Los Angeles, Calif. 90007.

profile come from the free-carrier population, due only to plasma effects. The diffusion profile causes the hole concentration to decrease linearly from its surface value down to zero at the 2 μm depletion depth. At depths below the depletion layer, the electron population grows linearly until it reaches its substrate value. To calculate the resulting refractive index profile, we used the fact that the plasma contribution of the holes is ten times smaller than that of the same density of electrons. To calculate approximate mode profiles, averaged square refractive index profiles were assumed (typical values were $\Delta n \sim 0.01$). Excellent agreement was obtained between the theoretical guided light intensities and the measured profiles, both in position and width of the intensity peaks. Several diffusion depths and substrate carrier concentrations were studied, including a sample which was just below waveguide cutoff. From these experiments we were able to determine that after free-carrier contributions are subtracted, zinc-diffused GaAs has the same refractive index as n-type substrates (to <0.0006) at 1.15 μm.

With an understanding of planar guides, we can compare two-dimensional guided light profiles with theory. Because of the nature of diffusion, the width of the stripe junction depends strongly on the depth at which it was measured. We define an effective guide width measured at a depth corresponding to the peak of the guided light distribution. It should be pointed out that the pn junction width at the surface is larger than the SiO_2 mask stripe width because of diffusion under the edges of the mask. It is an interesting fact that for our range of stripe widths and diffusion depths, the effective guide width was the same as the mask stripe width in all cases. Using this effective width and refractive index profiles determined by plasma effects, we calculated theoretical transverse guided light profiles. We found excellent agreement between the theory and experiment for all our stripe widths, varying from 2 to 6 μm, and for first order modes as well as fundamental modes.

The results of both planar and stripe guides tell us that diffused pn junction optical waveguides in GaAs at 1.15 μm can be understood by considering free-carrier effects only. There is no evidence for additional effects, such as are observed near the lasing wavelength.

Crucial to the possible use of these guides for integrated optics is the question of optical losses. In the guides studied so far, the losses have been quite high, with an exponential loss coefficient the order of 15 cm^{-1}. This is because the surface hole concentration was still fairly large. We found agreement between this guided wave loss and an estimation based on measured bulk losses in p and n GaAs at 1.15 μm. These losses are much larger than estimates based on purely free carrier loss. The bulk loss measurements allow us to estimate how low the loss can be made by lowering the surface hole concentration. As an example, diffusion with a surface zinc concentration of 5×10^{18} cm^{-3} into n-type 4×10^{18} cm^{-3} GaAs to a depletion depth of 1 μm will have roughly the same average refractive index profile as the guides we report here and an estimated loss of less than 2 cm^{-1}.

Because zinc-diffused guides will usually have a substantial number of holes, their losses will always be relatively high. However, they have the advantage of being easy to fabricate, without requiring ion implantation or epitaxy. Furthermore, because of the pn junction, they are electrically active and may be used to make channel waveguide modulators. We feel that this technique for fabricating optical waveguides in GaAs will have many important applications.

10.5 Planar Optical Waveguides in Ion-Implanted ZnTe, S. Valette, G. Labrunie, J-C. Deutsch and J. Lizet, *Laboratoire d'Electronique et de Technologie de l'Informatique, Centre d'Etudes Nucléaires de Grenoble, Grenoble Cedex, France*

(15 min)

Zinc telluride (ZnTe) is a II-VI semi-conductor compound exhibiting physical properties particularly interesting for the achievement of monolithic integrated optical circuits of signal transmission and processing: 1) a direct gap allowing laser emission in the visible[1] ($\lambda_g \simeq 0.55$ μm at 300°K or in the near infrared with the ternary compound $Cd_xZn_{1-x}Te$, 2) the best electrooptical figure of merit of all semiconductor compounds,[2,3] 3) and very favorable photodetection properties.[4]

We present a preliminary study concerning the achievement, by ion-implantation of various ion species, of planar optical waveguides integrated in ZnTe.

Wafers have been implanted with boron, helium, and protons, under energies of 240 keV.

Doses ranging from 10^{13} to 2.10^{14} cm^{-2} (boron), from 5.10^{13} to 5.10^{14} cm^{-2} (helium) and from 10^{14} to 10^{15} cm^{-2} (protons) have been tried up to now. He-Ne laser ($\lambda = 6328$ Å) and dye laser ($\lambda = 5800$-6100 Å) beams are then coupled into the waveguides by means of a GaP prism,[5] and the propagation constants β of the guided modes are measured with the m-lines.[6] The experimental results will be presented in details.

Waveguides obtained under these conditions are characterized by thicknesses in the range 3-7 μm and a mean relative index variation $\Delta n/n$ of about 10^{-3}. Two contributions have been separated in this index variation: Δn_c due to the carriers compensation and Δn_d due to the defects induced in the crystal by implantation.

It can be noticed that:

1) Δn obtained in the guides is equal to Δn_d for low substrate carrier densities N_S ($N_S < 10^{17}$ cm^{-3}) because $\Delta n \gg \Delta n_c$ as deduced from usual expression.[7]

2) Observations achieved on samples with N_S ranging between 2.10^{15} cm^{-3} and 2.10^{18} cm^{-3} lead to the following conclusions: for high values of N_S (and particularly $N_S > 3.10^{17}$ cm^{-3}), propagation constants (and therefore substrate indices) are lower, and many more modes can be observed.

Elsewhere, losses in the range 1-5 db/cm have been measured at 0.633 μm for low order modes without any thermal annealing. This can be partly due to the fact that waveguides are somewhat buried, but also to a very low intrinsic absorption in the implanted guide.

10.6 Phase-Matched SHG in Thin-Film Nonlinear Optical Waveguide Incorporated with Substrate Nonlinearity,

H. Ito and H. Inaba, *Research Institute of Electrical Communication, Tohoku University, Sendai, Japan*

(15 min)

For nonlinear optical effects in guided wave structures, such as SHG and optical parametric coupling, interaction can take place through either the optical nonlinearity of the substrate or of the film. Most of the previous work was performed using only the substrate nonlinearity, because of the difficulty of fabricating single-crystal thin films of sufficient optical quality. Recently we reported phase-matched SHG in an oriented polycrystalline ZnS film deposited on a glass substrate.[1] However, it should be pointed out that deposited nonlinear thin films have a great advantage in that the combination of film and substrate can be selected to make the interaction most efficient. As an evidence of the feasibility of this novel idea, we present in this paper the experimental verification of phase-matched SHG in a guided wave structure utilizing the nonlinearities inherent in both the thin film and the substrate made by the deposition of polycrystalline ZnS thin film on a $LiNbO_3$ single crystal substrate. Tunable optical parametric oscillator in the near infrared region was employed for a fundamental input.

For a ZnS thin film waveguide fabricated by vacuum deposition on an x-cut $LiNbO_3$ substrate, the (111) plane was found to be oriented parallel to the surface of the substrate by X-ray analysis. The calculation of the effective second-order nonlinearity $<d^2>$ of the oriented ZnS thin film waveguide was performed by fixing the [111] direction normal to the substrate surface. For the case of TE modes for both the fundamental and harmonic waves (TE + TE → TE), $(i/3)d_{14}^2$ is evaluated for $<d^2>$ of the oriented ZnS thin film.

In the optical waveguide, nonlinear interactions of optical waves can be phase-matched by utilizing proper mode dispersion. Taking into account the transverse spatial coupling coefficient and other experimental parameters of the ZnS-$LiNbO_3$ optical waveguide, the phase-matchable mode combination of TE_0 for fundamental and TE_2 for harmonic waves was selected for 1.1 μm-SHG. The estimated phase-matched film thickness was around 0.8 μm. The thickness of the ZnS film was controlled by a calibrated thin-film deposition monitor to within an accuracy of 200 Å. The precise control of the phase-matching condition was realized by means of a coherent tunable optical source for the fundamental.

[1] H. Ito, N. Uesugi and H. Inaba, *Appl. Pays. Lett.*, vol. 25, p. 385, 1974.

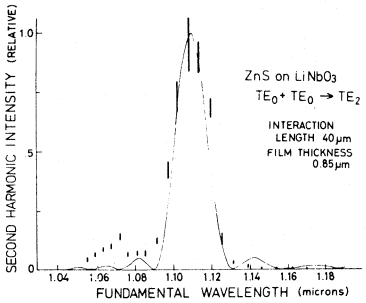

Fig. 2. The dependence of the phase-matched second harmonic intensity in the ZnS-$LiNbO_3$ waveguide on the fundamental wavelengths from the optical parametric oscillator. The interaction occurred between the TE_0 mode for the fundamental and TE_2 for the harmonic.

Phase-matched SHG was performed using the experimental setup shown in Fig. 1. In this experiment, the coupling and decoupling prisms were placed closely to each other, and a Chromatix optical parametric oscillator operated at the wavelength region of 1.1 μm was employed as the fundamental. The complete phase-matching profile as a function of fundamental wavelength is shown in Fig. 2. It is known from the result that the phase-matched wavelength is 1.11 μm for this ZnS film. From this wavelength, the thickness of the waveguide for SHG of 1.11 μm fundamental is calculated to be 0.85 μm, while the deposition monitor gives 0.82 μm. The input fundamental power in front of the prism coupler was nearly 70 W, and measured decoupled SH power was 5 μW. The theoretical value for SHG is estimated to be 23 μW, which is within the experimental error. Based upon the measured tuning curve in Fig. 2, the effective interaction length was calculated to be about 40 μm from mismatching behavior of nonlinear interaction between propagating modes. The solid curve in Fig. 2 corresponds to this length. From the fact that the spot size of the fundamental beam on the film was approximately 45 μm (the interaction length was restricted by the prism couplers) and the coherence length of the interaction was only about 5 μm for 1.1 μm-SHG, the calculated effective interaction length seems quite realistic.

Although most of the fundamental energy was confined in the ZnS film for the selected combination of the propagating modes in this experiment, the collaboration of both the nonlinearities of the film and substrate were demonstrated for the first time. Hence, the capability of phase-matched SHG in oriented polycrystalline thin film waveguides formed on nonlinear substrates suggests attractive applications of various nonlinear thin film materials for use in optical integrated circuits.

10.7 Integrated Optical Silicon Photodiode Array,[1]

J. T. Boyd and C. L. Chen, *Department of Electrical Engineering, University of Cincinnati, Cincinnati, Ohio 45221*

(15 min)

We describe the fabrication and operation of integrated optical silicon photodiode arrays. These structures consist of a relatively low-loss KPR optical waveguide[2] ($n = 1.61$) deposited on a layer of SiO_2 ($n = 1.46$) which in turn is grown on a silicon substrate. Utilizing an n-type substrate with an epitaxially-grown intrinsic layer, a row of p-type diffusions form a diode array. A profile of this structure is shown in Fig. 1. Note that over most of the Si surface the SiO_2 layer is sufficiently thick so that there is no significant coupling of optical energy from the waveguide into the Si substrate. However, as light propagates into the detector region the SiO_2 layer is tapered to a much smaller thickness, allowing significant optical coupling into the Si substrate to occur in this region. In the detector region the waveguide structure thus has the same configuration and behaves in the same manner as the prism-coupler, the detector region being formed in the coupling prism. Because of the similarity with the prism coupler, the detector region can be designed so that essentially complete transfer of optical energy from the waveguide to the detector region occurs.[3] Allowing light to optically tunnel into the detector region in this manner avoids reflection loss associated with previous designs of integrated optical detectors.[4,5,6] The present waveguide-detector design also allows use of a thicker SiO_2 layer in the detector region so that only a small fraction of the light would couple to the detector; the remainder would continue to propagate. Such a structure would be useful for continuous beam monitoring.

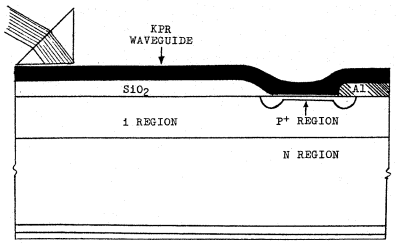

Fig. 1. Profile of waveguide-photodiode structure.

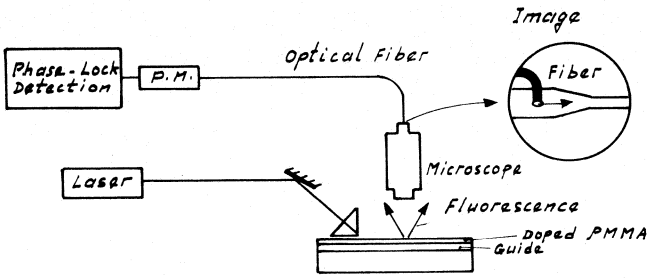

Fig. 1. Schematic of fluorescent light measurement.

The detector array structures described above have been fabricated using the established processes of silicon device technology. A special etching procedure is necessary to properly form the tapered region. A diffused guard ring structure is incorporated in order to improve device performance. Formation of the waveguide utilized a previously described procedure.[2]

Operation of one of the integrated optical photodiode array structures is illustrated in Fig. 2. On the right portion of the Si wafer a row of photodiode bonding pads is visible. The detector region is directly adjacent to each bonding pad. On the left portion of the Si wafer a prism coupler (n_p = 1.8) couples He-Ne laser light into the optical waveguide. By viewing scattered light we see that the light beam propagates until it reaches the detector region. As the transverse extent of the light beam is greater than the detector width, only the central portion is absorbed, as illustrated in Fig. 2. Light outside this central portion continues to propagate between adjacent devices, finally terminating at a scratch intentionally introduced. The bright spots at the scratch provide a qualitative indication that the waveguide is characterized by low propagation losses. Experimental results regarding light coupling and propagation as well as photodiode responsivity and device quantum efficiency will be discussed. We will also discuss array geometry with regard to performance in integrated Fourier optical processing systems.

We acknowledge the technical assistance provided by J. T. Garrett.

10.8 Visualization of Optical Fields in Integrated Optical Tapers and Bifurcations, D. B. Ostrowsky, A. M. Roy and B. Séjourné, *Thomson-CSF, Orsay, France*

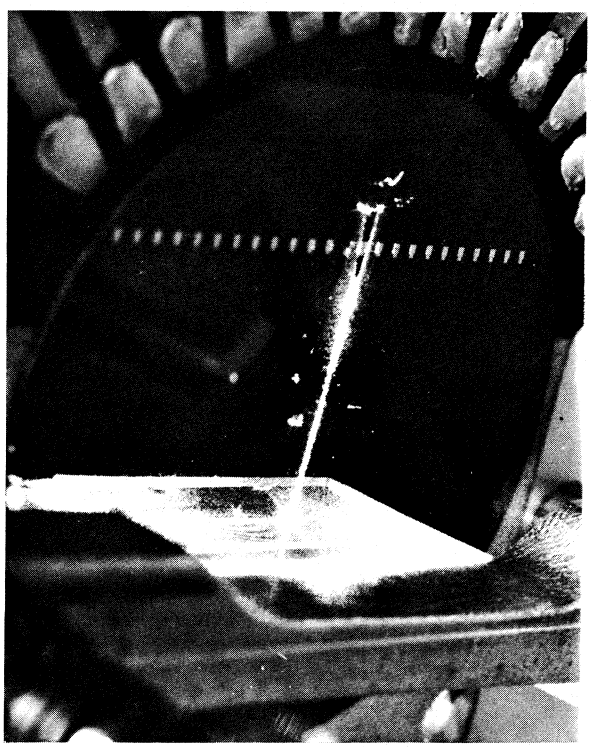
(15 min)

In this paper we report the first detailed quantitative measurements of optical fields propagating in passive integrated optical components.

The components were fabricated by direct electron beam writing in PPS, an electron resist which serves as an optical waveguide[1] (n = 1.57). The optical fields of guided 6328 Å light were visualized by depositing a thin (~2000 Å) Rhodamine B doped PMMA film on the guiding structure and observing the anti-stokes fluorescence (5900 Å) induced by the guided light.[2]

The fluorescence (which is directly proportional to the local guided intensity) was measured using the device schematized in Fig. 1.

A scanning fiber optic probe is used which accepts light emitted from a 1 to 5 μm diameter (depending upon the magnifying power of the objective) region of the structure being observed and transports this light to a photomultiplier.



Among the components examined to date we wish to report on: triangular transitions between wide and narrow guides (Fig. 2(a); bifurcations dividing light from one guide into two separate guides (Fig. 2(b).

In the first case we have measured the power density augmentations one can obtain in passing from 20, 10 and 5 μm wide guides to 5, 2 and 1 μm waveguides.

Power density augmentations of 30% have been attained for a 20-5 μm transition.

In the second case we have measured the

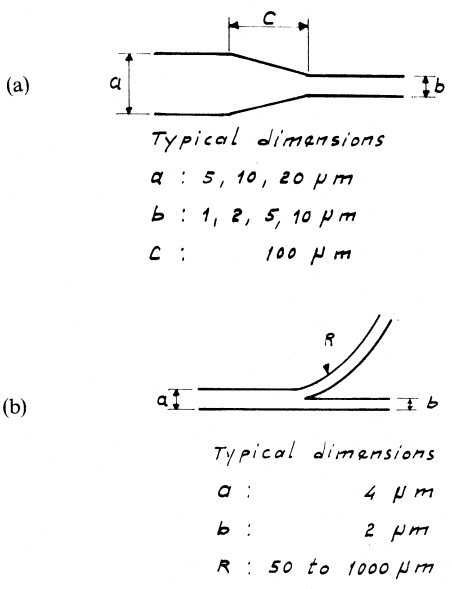


Fig. 2. Waveguide-photodiode operation. Note that only the central portion of the light beam encounters the diode region.

polarization dependence of the fraction of light which passes into each of the arms of the bifurcation. Typically TM modes have a tendency to continue in the straight section and TE modes have a tendency to leave via the curved section. Discrimination ratios of up to 80% have been measured.

10.9 A New Optical 3-dB Coupler, W. K. Burns, A. F. Milton, E. J. West and A. B. Lee, *Naval Research Laboratory, Washington, D.C. 20375*

(15 min)

Three-dB couplers or power dividers are expected to be important components in optical waveguide amplitude modulators or switches which operate by interferring two phase-shifted guided waves.[1] The conventional 3-dB coupler operates by maintaining a degree of velocity synchronism between two coupled waveguides over a coupling length L. Fabrication tolerances pose a difficult problem in construction of such a coupler, since the necessary length L for 50-50 power division between the coupled guides depends on the coupling constant. Also the degree of synchronism must be maintained over the coupling length L.

We propose a novel device which allows 50-50 power division between two coupled waveguides with reduced fabrication tolerances. It requires a degree of mode synchronism only at a single point, and the exact length of the coupler is not critical. The coupler (Fig. 1) consists of two coupled, planar waveguides with a small section of overlaid superstrate which makes that section of the device symmetrical. The overlay is introduced abruptly and removed slowly by constructing it with fast and slow tapers. Precise mode synchronism between the two guiding regions is required only at $z = 0$ where the overlay is introduced. Sections of the device without the overlay are nonsynchronous.

In the local normal mode picture, operation of the coupler is as follows. An input local normal mode from the left, confined to guide b, propagates to the point $z = 0$ where synchronism between the two guides is abruptly introduced. At this point the symmetrical (i) and anti-symmetrical (j) local normal modes of the coupled structure are excited, each with one-half of the input power. Synchronism is then slowly removed so that modal evolution causes mode i to select guide b, while mode j selects guide a. Since this operation is slow, the 50-50 power division between i and j is retained, and 3-dB coupling is achieved.

To analyze this coupler we revert to a coupled mode theory formulism and recognize the coupler's similarity to a tapered velocity coupler, divided at the point of mode synchronism. The slow and fast tapers must be designed to provide negligible and cumulative mode conversion between the two local normal modes respectively.[2] The slope of the slow and fast tapers must satisfy respectively,

$$\left|\frac{d\Delta\beta}{dz}\right|_{-} \leqslant .8KK^* \quad \text{and} \quad \left|\frac{d\Delta\beta}{dz}\right| \geqslant 150KK^*. \quad (1)$$

Here $\Delta\beta = \beta_a - \beta_b$ and K are the coupled mode theory synchronism and coupling coefficients. Effective indices for the modes associated with the individual guiding regions, a and b, are shown in Fig. 2. A second design requirement is for the local normal modes to contain essentially all their power in a single guiding region at each end of the coupler where $\Delta\beta$ is large. In particular if we allow 1% of the local normal mode power to be in the second guide then at both ends we must maintain:

$$\left|\frac{K}{\Delta\beta}\right| \leqslant .1 \quad (2)$$

We have chosen an experimental system of 7059 glass guiding layers and SiO_2 cladding layers. Indices in Fig. 1 are $n_1 = 1.457$, $n_2 = n_4 = 1.561$, $n_3 = 1.476$, $n_5 = 1.476$ or 1. Layer thicknesses that satisfy (2) are $d_2 = .525$ μm, $d_3 = .76$ μm, $d_4 = .5$ μm, $d_5 = 1$ μm. Then $|\Delta\beta/k| = .012$, (where $k = 2\pi/,6328$ μm), in the non-synchronous regions. Application of (1) then requires that the fast and slow tapers have lengths of $\leqslant 5.4$ μm and $\geqslant 1.0$ mm respectively. These taper lengths have been experimentally achieved by photolithographic and sputter etching techniques for the fast taper and by masking techniques for the slow taper. Prism coupling measurements of mode effective indices are in progress and experimental results of power transfer will be reported.

Thursday, May 29, 1975 1:30-5:00 P.M.

Laser Fusion II

Chairman: A. J. Alcock, *National Research Council, Ottawa, Canada*

Organizer: E. Beckner, *Sandia Laboratories, Albuquerque, N. M.*

11.1 The Pulsed High Power Iodine Laser Asterix III, G. Brederlow, K. J. Witte, E. Fill, K. Hohla, and R. Volk, *Max-Planck-Institut für Plasmaphysik, EURATOM-Association, Garching, W. Germany*

(15 min)

A system description and first results of the high power iodine laser Asterix III, designed to yield an output energy of 1 kJ in 1 ns is given. This laser ($\lambda = 1.315$ μ) is an optically pumped single-beam version intended for use in laser fusion investigations.

The system consists of a mode-locked oscillator and three amplifiers. The oscillator delivers a mode-locked pulse train from which a single pulse is extracted by means of a pulse cutting system. The beam divergence is 0.8 mrad in keeping with the TEM_{00} mode of the oscillator. The pulse length is dependent on the gas pressure and varies between 3 and 0.7 ns. The first amplifier has an internal diameter of 2.5 cm and

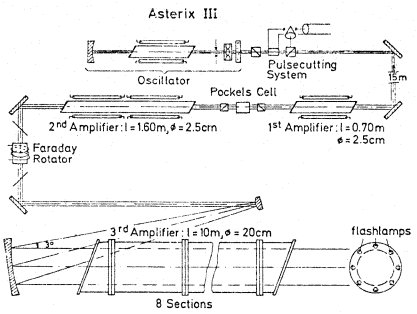

Fig. 1. Schematic set-up of Asterix III.

is located 15 m behind the oscillator. This distance is chosen such that the beam emanating from the oscillator and widening owing to its natural divergence fits the diameter of the amplifier tube. The second amplifier has the same internal diameter as the first one. It is optically isolated from the latter by a Pockels cell. Behind the second amplifier the beam is expanded from 2.5 cm to 20 cm by means of an off-axis Cassegrain system. The distance between the second and third amplifier is about 50 m. Optical isolation is further improved by means of a Faraday rotator.

The third amplifier provides the actual energy amplification. The input energy of 6 J is supposed to be amplified here to about 1 kJ. This amplifier consists of a stainless steel tube assembled from eight sections with an active length of 1 m each.

While the oscillator and the first and second amplifiers consist of quartz tubes pumped by external flashlamps, the third amplifier has the flashlamps inside the metal tube, there being eight lamps in each section with an energy intake of 5 kJ each.

The laser medium in the amplifiers consists of a mixture of C_3F_7I and CO_2. The partial pressure of the C_3F_7I is chosen such that the most uniform possible illumination of the amplification cross-section is ensured. The partial pressure of the CO_2 for the individual amplifier, on the other hand, is chosen such that the stimulated emission cross-section is reduced so much that the maximum small signal amplification of which the amplifier is capable is not exceeded.

The oscillator, the pulse cutting system and the first and second amplifiers could be taken over with appropriate modifications from Asterix II, the 100 J/l ns pulse laser. The choice of the final concept for the third amplifier, however, required a number of basic investigations.

We measured the inversion profile as a function of the C_3F_7I pressure and of the pumping energy. It turned out that at a C_3F_7I pressure of 4 Torr the inversion at the edge is 15% higher than in the center. Reducing the C_3F_7I pressure makes the inversion profile more homogeneous but also decreases the energy stored. At the pressure value mentioned the energy stored per section is 210 J at a capacitor energy of 37 kJ. The storable energy increases at the same rate as the pump energy.

In order to keep the storable energy at the required value, CO_2 has to be added in such an amount that the small signal amplification V_{th} of which the amplifier is capable is not exceeded. Extrapolation of measurements made with two sections yielded a value of $V_{th} \approx 10^5$ for all eight sections.

The optical homogeneity of the active medium will be disturbed by shock waves caused by the evaporation of deposits on the walls by the pump light. These waves propagate with low supersonic speed ($V = 0.3$ mm/μs) towards the center of the tube. Therefore the pumping time of this amplifier should not exceed 20 μs.

With the results reported the conditions under which the entire system has to be operated are known. As the laser is scheduled for completion in the next two months, first experimental results on the performance of the complete system can be expected soon.

11.2 Pressure Broadening and Saturation Behaviour of the Iodine Laser, W. Fuss and K. Hohla, *Max-Planck-Institut für Plasmaphysik, EURATOM-Association, Garching, W. Germany*

(15 min)

Storable energy of a high power laser is inversely proportional to the maximum of the stimulated emission cross section σ. Addition of a foreign gas broadens the emission line by collision and thereby lowers σ. In the iodine laser line complications arise from its hyperfine structure (hfs). Whereas for a single hfs line, $1/\sigma$ linearly depends on the partial pressures P_i,

$$1/\sigma = \beta_0 + \sum_i \beta_i P_i$$

no simple relationship can be expected if overlap of lines varies. In this case also the saturation behavior changes: The saturation energy per cm^2

$$e_s = \frac{h\nu}{\sigma(1 + g_u/g_l)}$$

can no longer be calculated with the level degeneracies g_u and g_l of a single transition. We were able to determine the saturation energy as well as the degeneracy factors – and thereby σ – as functions of the pressures of some gases [Ar, N_2, CO, CO_2, SF_6, CF_3Br, C_3F_7I, CF_2Cl_2, $(CF_3)_2$ CO]. The saturation energy e_s has been determined by measuring high and low signal gain (V and V_{lo}) and the input energy e_{in}, using the equation

$$V = \frac{e_s}{e_{in}} \ln\left(1 + \left[\exp\frac{e_{in}}{e_s} - 1\right] V_{lo}\right)$$

Because the spectrum is inhomogeneous, only a fraction a can respond to a single input frequency. The saturation energy must then be written

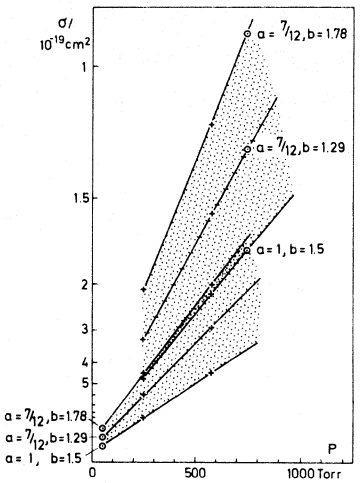

Fig. 1. $1/\sigma$ as a function of pressure (50 torrs C_3F_7I; balance CO_2); Θ "absolute" measurements based on e_s assuming different a and b parameters; + relative measurements based on the high and low pressure values, respectively.

$$e_s = a\frac{h\nu}{b\sigma},$$

where $b = 1 + g_u/g_l$. If a/b is known, σ can be calculated from e_s. Furthermore we determined relative σ values at different pressures from the ratios $\log V(p)/\log V(p_0)$ (V = low signal gain). These ratios of $\sigma(p)/\sigma(po)$ are independent of the respective a/b value at the pressure p. These ratios can be multiplied by $\sigma(p_0)$ calculated from e_s inserting all possible values of a and b. In the figure this has been done with two different values of p_0. It turns out that the measurements are only consistent if $a = 7/12$, $b = 1.78$ at low pressure and $a = 1$, b = 1.5 at high p_0. These a and b parameters are valid for ns pulses, by which they have been measured. a/b rises for longer pulses by the influence of relaxations between hfs sublevels as well as by the recombination of the radicals (from photolysis) with ground state iodine atoms.

For all gases investigated, $1/\sigma$ plotted versus pressure results in straight lines. This yet unexplained fact is not expected because the overlap of the hfs lines can be calculated to vary considerably over the respective pressure range.

For the purpose of energy storage CO_2 seems to be the best compromise between pressure broadening and deactivation of I*. At one atmosphere of CO_2 about 7 J cm^{-3} can be stored, hfs is extensively blurred, the energy can be extracted by a short single frequency input pulse, and amplification of pulses shorter than 100 ps should be possible. The "broadening coefficient" β_{CO_2} is by a factor of two higher than the Ar value. Our $\beta_{Ar} = 3.55 \cdot 10^{-15}$ cm^{-2} $Torr^{-1}$ compares favorably with former measurements.[1]

11.3 "Valkyrie," A CO_2 Laser System for Laser Fusion Experiments,[1] K. R. Manes, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The Livermore CO_2 laser system, Valkyrie, was constructed to provide an experimental facility capable of delivering 50 J in a diffraction limited beam at 10.6 μm in ~1 nsec. This device has met all of its design goals and is in operation as a target irradiation facility. On a typical day, Valkyrie provides 40 J ± 10% in ~1 nsec at a repetition rate limited by the time required to replace targets.

In order to design Valkyrie a CO_2 amplifier modeling computer program predicted the output of individual amplifier modules. This information was fed into a laser system simulation routine in order to determine amplifier staging. Once specified and manufactured, Valkyrie's amplifiers were subjected to an exhaustive series of tests. Small signal gain as a function of gas mixture, E/n, pump pulse duration, and spatial position was measured.

Valkyrie's oscillator employs a specially designed UV preionized TFA gain medium (Lumonics 142A), a Ge Brewster's angle acoustooptic mode-locker, and an NaCl etalon as an output mirror. This oscillator generates a burst of 1 nsec duration pulses with peak pulse energies in excess of 50 mJ distributed reproducibly among ~six rotational lines centered on the $P20$ transition of the 10.4 μm band. A single pulse is selected by a switch-out assembly consisting of a laser triggered spark gap and CdTe Pockel's cells. The pulse is then directed through a second Lumonics 142A which serves as a preamplifier and into a 3× Keplerian beam expander with a spatial filter at its focus. Expended and collimated, the pulse propagates through a nine centimeter aperture UV-preionized TEA amplifier (Lumonics 602A) followed by two eleven centimeter aperture cold-cathode E-beam sustained amplifiers operated at two atmospheres. Emerging in the target area, the pulse contains ~50 J in 1 nsec with an approximately Gaussian spatial intensity distribution. Two NaCl beamsplitters which are wedged and anti-reflection coated with NaF on one face provide diagnostic beams for intensity profile, energy, temporal character and spectral measurements. The main beam is finally focussed to an ~80 μm diameter spot by an f/2 aspheric NaCl lens mounted inside a spherical vacuum vessel. When this laser-target chamber system became available in September, attention was concentrated on assembling and calibrating diagnostics, suppressing parasitic oscillations, and other laser system related problems.

By December X-ray spectral measurements, ion studies and electron spectral measurements were underway on CD_2 and CH_2 targets. Slab acceleration studies are planned for the first months of 1975. In these experiments, targets such as that illustrated in Fig. 1 will be illuminated from one side by the laser and the development of plasma density and temperature gradients as a function of time will be recorded.

[1] Work performed under the auspices of the Atomic Energy Commission.

11.4 Measurement of Beam Quality from Short Pulse CO_2 Lasers,[1] I. Liberman, *Westinghouse Research Laboratories, Pittsburgh, Pa.*, and M. J. Bennett, J. J. Hayden, and S. Singer, *Los Alamos Scientific Laboratory, Los Alamos, N. M. 87544*

(15 min)

Lasers built for fusion application must not only be capable of delivering high power, but this power must be focused onto extremely small pellets. The minimum laser spot size obtainable is known from well established diffraction theory. However, in high power laser systems, phase distortion due to apertures, imperfections in large optics, inhomogeneities in heated active laser media, etc., results in laser beam quality which can deviate significantly from the diffraction limit. This paper describes two methods of measuring the beam quality of a nominal 1 J, 1 ns, CO_2 TEA laser oscillator preamplifier chain which drives a 2.5 kJ amplifier for fusion application.

The mode-locked oscillator and switch-out crystal provide about a 5 mJ 1.6 ns single pulse and about 0.1 mJ total of unwanted mode-locked pulses. The output beam is expanded and amplified by two nearly identical TEA laser discharge volumes having a 3.5 cm square discharge region and each discharge length being about 1.3 m. At the output of the second preamplifier the gain medium is saturated and we assume (somewhat inaccurately) for purposes of comparing measured results with theory that the desired output beam has a uniform intensity across a 3.5 cm diameter circle. The measured total energy is about 2 J of which 1.5 J is in a single 1.6 ns pulse.

Using our primary method for measuring the laser optical quality, the beam is focused with a 1.5 m focal length mirror. A grating is placed about 30 cm after this mirror. The grating diffracts the beam into multiple orders with each order of essentially identical shape, but different intensity.[2] The grating spacing is .180 cm with an open width of .033 cm resulting in a transmission, T, of 18.3%. From elementary grating diffraction theory the intensity of the first five orders relative to the zero order are .89, .63, .33, .10, .008 respectively. At the focal plane of the diffracted spots a film of UV sensitized Kalvar 100 is placed. The properties of this film have been extensively studied[3] and it has been found that it has a resolution greater than 100 l/mm and a calibrated energy density range of ~0.75-3.1 J/cm^2. Under the existing experimental conditions, exposed spots are observed for the zero and first four orders. Since the diffracted intensity variations overlap the dynamic range of the Kalvar film, a composite spot pattern is obtained. A smooth transition from spot pattern to spot pattern requires multiplying the recorded 1st to 4th order intensities by .91, .62, .37, and .15 respectively, which agrees reasonably well with the grating formula calculation. After multiplying the energy by T^{-2} the results show that the focal spot without the grating present has a peak energy density of 433 J/cm^2 and that at 30 J/cm^2, the lowest energy density measured, the spot radius is 0.55 mm. The diffraction limited spot is calculated to have a peak energy density of 761 J/cm^2 and an Airy disk radius of 0.55 mm. Therefore, based on the ratio of peak energy densities, the beam is 1.76 times diffraction limited.

The second measurement depends on knowing the breakdown strength of argon vs. pressure. Rockwood[4] has calculated this function which agrees favorably with the measured results of Alcock[5] and Franzen.[6] Our measurement of breakdown threshold of 225 Torr from a 1.5 J, 1.6 ns pulse focused in an argon cell with a 2.5 m focal length mirror results in a peak power density of 7.1×10^{10} W/cm^2. The diffraction limited power is calculated to be 12.8×10^{10} W/cm^2. Therefore from this measurement the beam is 1.80 times the diffraction limit.

The two methods agree with each other to better than the accuracy of each measurement. These techniques are a rapid, relatively simple, accurate way of measuring the optical quality of a broad range of high powered lasers.

11.5 The LASL 2-5 kJ CO_2 Short-Pulse Laser System (*Invited*), S. Singer, *Los Alamos Scientific Laboratory, Los Alamos, N. M. 87544*

(30 min)

The design and performance of the LASL CO_2 2.5 kJ laser will be described. It is intended to deliver to a target system two 35 cm diameter beams, with 1250 J per beam in a 1 nsec pulse,

focused to an intensity of 10^{15} W/cm^2. The system will be used to study techniques of gain suppression and target isolation as well as laser-plasma interaction at 10.6 μm at energy inputs an order of magnitude larger than previously available. This laser system will form the basis for the LASL 10 kJ laser now under construction.

11.6 The Physics of Laser Fusion (*Invited*), G. H. McCall, *Los Alamos Scientific Laboratory, Los Alamos, N. M. 87544*

(30 min)

The results and interpretation of laser fusion experiments at 1.06 μ and 10.6 μ will be presented.

11.7 Investigations of Laser Fusion by CO_2 Laser, C. Yamanaka, M. Yokoyama, S. Nakai, M. Matoba, and C. Yamabe, *Institute of Laser Engineering, Osaka University, Osaka, Japan*

(15 min)

Experiments on laser plasma interaction using a CO_2 laser (wavelength 10.6 μm) give us detailed information on the interaction mechanisms. The feasibility of laser fusion is going to require high power CO_2 lasers. For this purpose we have been developing a high power E-beam controlled CO_2 laser system with 200 J output in one nsec and a double discharge CO_2 laser of 100 J in 100 nsec. For the former, to improve the energy extraction we have made a two band, multiline TEA laser oscillator and also investigated the high pressure ($\sim$15 atm) *E*-beam CO_2 laser oscillator.

The *E*-beam controlled CO_2 laser system consists of the following parts: oscillator, with Ge acoustooptical mode locker in the cavity; GaAs optical shutter combined with Ge polarizer to select one pulse from the mode-locked pulse train, or to chop out a pulse of nsec duration from *Q*-switched pulse; pre-amplifier; *E*-beam controlled main amplifier stages of No. 1 (5 cm × 5 cm × 80 cm), No. 2 (10 cm × 10 cm × 100 cm) and No. 3 (20 cm × 20 cm × 200 cm).

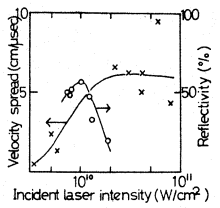

Fig. 1. Variation of reflectivity and velocity spread of blow-off plasma against incident laser intensity.

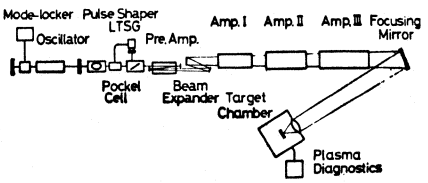

Fig. 2. *E*-beam controlled CO_2 laser system, 200 J, 1 ns.

For the experiments on laser interaction with plasma, we have used various diagnostic methods. They are an X-ray pinhole camera to make an X-ray image of the target, thermofluorescence X-ray dosimeter, and scintillator photomultiplier combinations with different absorbers to analyze X-ray energy, incident and reflected beam monitors to measure the reflectivity at the plasma surface, time of flight measurements by charge collectors, interferometric measurements to measure the plasma density and measurements of higher harmonic components in reflected light.

We measured the reflectivity for the frequency ω_0 and back scattering of frequency $2\omega_0$. The reflectivity at frequency ω_0 showed a maximum ($\sim$56%) at a laser power intensity of about 1.1×10^{10} W/cm^2, and above this value, the reflectivity decreased (Fig. 1). It was also observed that the velocity spread of ions, that may indicate the ion temperature of blow-off plasma, increased at the incident laser power intensity which showed the decrease of the reflectivity.

The electron temperature was also estimated from the X-ray measurements. The plasma seemed to be heated by the anomalous absorption due to parametric instability. Energetic X-rays were also observed due to high energy electrons.

For the alternative study of the absorption mechanism, we use a double discharge TEA CO_2 laser and the dense plasma of a plasma focus device as a target plasma. A Mather type coaxial cylindrical gun with maximum available input energy 14 KJ (12 μF, 50 kV) was used. Preliminary experiments show enhancement of X-ray emission from the plasma focus with CO_2 laser irradiation. Neutron measurements are also made.

The arrangement of our *E*-beam controlled CO_2 laser system is shown in Table I and Fig. 2.

11.8 A Nd Laser System Developed for Target Irradiation Studies at the Lawrence Livermore Laboratory,[1] D. R. Speck and J. F. Holzrichter, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

The LLL JANUS laser uses a Nd:YAG oscillator and Nd:glass amplifiers to provide one and two beam irradiation of laser fusion targets with 100 pico-second duration pulses. The system is constructed from components which are under development at LLL for the planned 10 KJ laser system (SHIVA). It is devoted to irradiation experiments to study the physics of laser plasma interaction and to evaluate laser fusion target designs.

The JANUS system consists of a dye mode-locked Nd:YAG oscillator, a Nd:YAG preamplifier, beam shaping optics, three 25 mm × 250 mm Nd:glass rod preamplifiers with optical isolators and a series of Nd:glass disk amplifiers with Faraday rotator optical isolators. Two sizes of disk amplifiers are used; the "A" size with a 35 mm clear aperture containing 6 15 mm thick brewster angle disks, and the "B" size with an 85 mm clear aperture containing 6 23.5 mm thick brewster angle disks. Prepulses and amplified spontaneous emission which cause premature target damage are controlled with bleachable dye cells. Their use will be discussed.

The principal design criterion used in assembling the system has been to minimize self-focusing effects which limit the output of short pulse glass lasers. This has been done by maintaining a temporally and spatially smooth pulse and by minimizing the integrated gain for the growth of self-focusing instabilities, *B*, through the amplifier train;[2]

$$B = \frac{8\pi^2}{\lambda_{vac} C} \int_0^z \frac{n_2}{n_0} I \, dZ.$$

The pulse is spatially smoothed and shaped

TABLE I
E-BEAM CONTROLLED CO_2 LASER SYSTEM "GEKKO II"

	Oscillator TEA	Pre-Amp. TEA	Amp.-I Hot Cathode	Amp.-II Cold Cathode	Amp.-III Cold Cathode
Active size (cm)	2.5 × 2.5 × 60	2.5 × 2.5 × 60	5 × 5 × 80	10 × 10 × 100	20 × 20 × 200
Volume (l)	0.4	0.4	2	10	80
Pressure (atm)	1	1	2	2	2

[1] Work performed under the auspices of the U. S. Atomic Energy Commission.

[2] Bliss, Speck, Holzrichter, Erkkila, and Glass, *Appl. Phys. Lett.*, vol. 25, p. 448, 1974.

before it enters the amplifier system with a spatial filter and apodized aperture. The shape generated is $I(r) = I_0 e^{-(r/r_0)^5}$ which propagates the length of the amplifier free of diffraction irregularities. B is minimized by employing high gain amplifiers, minimizing the length of glass in components, minimizing losses and by proper staging.

Experimentally it is observed that the energy which can be focused onto fusion targets is limited by beam break-up. This arises from self focusing instabilities. Beam break-up is manifested by: 1) high intensity spots in the beam which may be many times the average intensity and cause damage to components, 2) an apparent decrease in amplification of the chain resulting from losses caused by filament formation, and, 3) a catastrophic increase in focal spot size caused by self-induced phase distortions as the beam breaks-up. These three effects have been observed; (3) is particularly important in limiting the energy coupled to small targets employed in laser fusion. Time integrated and time resolved far field photographs of the JANUS output have been taken and the fraction of the beam energy intercepted by fusion targets has been measured as the output energy increases. This data will be presented and correlated with the gain for instability growth, B.

11.9 Laser Plasma Interaction Studies at LLL,[1] J. F. Holzrichter, H. G. Ahlstrom, and R. A. Haas, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

This paper describes the results of studies which are being pursued on the interaction of high intensity laser radiation with laser fusion targets. The purpose of these studies is to provide an experimental basis for achieving efficient laser fusion. Two lasers, a 20 Joule, 100 psec Nd:glass laser system (JANUS) and a 30 Joule, 1 nsec CO_2 laser (VALKYRIE), have been used for the irradiation experiments. Both of these systems are described elsewhere.

The main thrust of the experiments has been to account for optical propagation and energy transport in fusion targets which are smaller than 200 μ Dia. Accurate measurements of the absorption, reflection and transmission of the optical energy are most important because they determine the overall energy balance. The absorbed energy is subsequently partitioned into fluid motion (electrons and ions), X-rays, and eventually neutrons. The results of absorption and energy distribution measurements will be described.

Detailed studies on the focusing properties of the 1.06 μ laser beam from the Janus system have been carried out by time resolving the focal spot of an f/1 lens. It has been found that the focal spot is well behaved at a power output of 0.1 terrawatt. As the laser power is raised above this level, the beam begins to break up. Little additional beam energy is stopped by the target and the scattered radiation completely confuses the target interaction experiments.

Another problem arises when optical energy reaches the target before the main laser pulse. This radiation can alter the target and make the experimental results meaningless. Amplified spontaneous emission (ASE) levels above 10 mJ and laser pre-pulses above 0.1 mJ can damage fusion targets. The Janus system when not isolated will produced 20 mJ of ASE and 1.0-2.0 mJ prepulses. Examples of these problems and corrective techniques will be given.

In order to determine the energy budget in targets, the incident and scattered energy fluxes have been measured. The energy scattered backward and forward, into the focusing lenses, and energy scattered into a 2π steradian parabola is measured with calorimeters. Energy scattered into the remaining 2π steradian is detected with photodiodes. Accounting for all scattered energy indicates that for some of these targets greater than 60% of the incident laser radiation is absorbed. The details of optical propagation experiments in these targets, with particular emphasis on refraction and time resolved transmission will be described. Also details concerning the X-ray emission and plasma motion will be presented.

Laser produced plasmas vary in temperature from $\sim$100 ev to $\sim$2.3 keV. As a consequence X-ray radiation is the most useful diagnostic for determining the state of the target. A variety of techniques have been developed at LLL and elsewhere to diagnose this radiation. They include absolute X-ray spectrometry, from <1 keV to 80 keV, X-ray imaging with <7 micron resolution at 1 keV, and time resolution of <100 psec at 1 keV. These diagnostics are being employed to determine the state of glass ball fusion targets and metal foil X-ray targets. The X-ray performances of these targets will be described.

The most important objective of our experiments is to cause target compressions which will lead to efficient laser fusion. Such compressions (>1000 $\times$ solid density) require a detailed knowledge of the conversion of optical radiation to plasma motion. To this end, the motion of thin slab targets is observed while they are being irradiated by intense laser radiation. In these experiments streak camera photography and interferometric techniques are employed in concert with ion and X-ray diagnostics to measure the evolution of the accelerated foil. Because the motion of a thin slab simulates the motion of a thin shell section, the effect of fluid instabilities, electron preheat effects, etc., which would occur in an imploding shell can be observed. Experiments to date show that the slab motion is governed by high energy electron preheat of the back surface. Effects due to the initial breakdown of the target have also been observed.

12.1 High Power CO_2 Lasers for Industrial Applications (*Invited*), R. Hella, *Avco Corp., Everett, Mass.*

(30 min)

No summary.

12.2 Laser Processing in the Automotive Industry (*Invited*), M. Yessik and D. J. Schmatz, *Scientific Research Staff, Ford Motor Co., Dearborn, Mich. 48121*

(30 min.)

The types of laser processing of interest to the automotive industry fall into three categories: cutting and drilling, surface hardening, and welding. The desirability of using a laser for these applications is mainly the result of the high power densities, the ability to control precisely both the total power and the power density, and the small size and ease of manipulation of the beam. Because of the need for high average power outputs, in addition to the high power densities, the continuous CO_2 lasers have received the most attention for these applications.

Laser cutting and drilling is of interest for a wide variety of materials including metals, ceramics, plastics, rubber, and composites. The major advantages are simplified fixturing, fast cutting rates, and no limitation on the configuration of the cut. The particular characteristics of the oxygen-assisted laser cutting of steel are narrow kerf widths, small heat-affected zones and little or no slag. One potential application is the automatic cutting of option holes in the dash panel. Advantages of this system are greater precision in the location and size of the holes and the ability to cut other-than-circular holes. A laser-drilling application presently under development involves the drilling of the oil-metering holes in a rifle-bore camshaft. The high hardenability of the iron makes conventional drilling or punching very difficult, but does not affect the laser-drilling process.

Laser hardening has two major advantages over conventional techniques. The first is the ability to localize the hardening at the exact spot where it is needed. This minimizes the total heat input to the material and thus eliminates the distortions which often accompany other hardening techniques. Second is the ability to apply the heat to otherwise inaccessible areas, for example, small bores or complicated shapes not amenable to induction hardening. Both of these advantages stem from the small size and ease of manipulation of the beam. A particular applica-

tion presently under investigation is the hardening of the inner bore of the gray iron valve guides. The hardening is achieved through a solid-state transformation with no melting of the surface. No measurable distortion is produced and thus no additional machining is required.

Laser welding has similar advantages to the other laser processes: no contact with the work, small heat-affected zones, easy manipulation of the beam and high processing speeds. In addition, because of the deep penetrations obtainble, laser welds do not require the use of filler metals. The effect of the laser weld on the metallurgical structure is highly dependent on the particular material being welded, and as a result, some metals are much more amenable to laser welding than others. A potential laser welding application is the joining of a stack of laminations to form a motor stator. Another welding application which has reached the pilot-operation stage is the welding together of several stamped panels to form a car underbody. In both of these applications, the automated motion of the beam is of major importance.

A more extensive review of our current laser processing interests are to be published shortly.[1]

12.3 Influence of Spatial Intensity Distribution of Laser Beam on Deep Welding Geometry, V. Boedecker and K.-H. Drake, *Institut für Angewandte Materialforschung, Bremen, Institut für Angewandte Physik, T.-U. Hannover*

(15 min)

With laser beams of high power and high power density the deep penetration welding effect can be obtained. Early models describing the influence of beam parameters on the welding geometry have been made for electron beam welding. In these theoretical models, the incident beam is considered to be parallel and the intensity distribution of the focussed beam is neglected. Therefore, in calculating the welding zone geometry, one can get information about the welded volume but not the depth and width of the fusion zone.

In this paper we present a new theoretical model describing the influence of welding parameters on the total welding geometry. This theory includes the welding velocity and the thermophysical properties of the material as well as the spatial intensity distribution of the focused laser beam. These considerations are valid for deep welding capillaries which are surrounded by a zone of molten metal.

To calculate the geometry of the fusion zone, the whole laser beam is divided into many small parts. Then the shape of the deep welding capillary results from the equilibrium condition that the energy of such a small beam incident on a small area of the capillary wall must be transported by heat conduction from this area. The temperature of the capillary wall is the vaporizing temperature of the material.

From these conditions a formula can be derived describing the total geometry of the vapor filled channel and the melting zone as a function of the welding velocity, the thermophysical properties of the material, and the spatial intensity distribution of the beam. This formula includes also the distance between the focal plane of the welding lens and the workpiece. Furthermore, the broadening of the beam due to scattering effects at the plasma cloud surrounding the welding zone can be considered. Also, estimations about the effects of non-constant temperatures within the capillary are possible.

The influence of all the above mentioned parameters on deep welding geometry has been calculated and proved by experimental investigations. Measurements have been carried out with high power lasers and with electron beams. The experimental results are in good agreement with the theory.

From this theory the optimum degree of focussing to get the desired welding geometry as a function of laser power, beam divergence and all the other welding parameters can be calculated.

12.4 Investigations on Laser-Welding, M. Montanarini and J. Steffen, *LASAG SA, Thun, Switzerland*

(15 min)

Laser welding has become an important process in many industrial production lines, since the laser promises several advantages compared with conventional welding means. The thermal influence of material outside the welding deposit is extremely low because of the short heating duration ($\simeq 1$ msec). The physical properties of the material are not influenced and therefore thermal sensitive materials, as e.g. springy, hard and brittle materials or magnets, can be welded.

The laser also overcomes certain problems of welding dissimilar materials with different thermal or electrical properties; however, the metallurgical problems of intermixing (formation of intermetallic compounds) and the resulting effects as reduced strength, generation of hot cracks, etc. have not yet been studied satisfactorily.

This paper presents some investigations on the influence of different laser parameters on the intermixing of dissimilar materials. The different intermixing states and some intermetallic compounds were detected in the weld with an electron beam microprobe analysis. By this analysis the most endangered zone (that is, the intermetallic interlayer between the deposit and the basic material) could be studied.

As a result of these investigations, a procedure to improve the weldability and the welding strength of materials showing bad weldability is demonstrated. This procedure is characterized by adding a welding agent to the weld and by intermixing it homogeneously in the deposit. Different metallurgical problems, such as formation of hot cracks and material softening, could be avoided by choosing appropriate agent materials.

As an example, a weld between a spring (Co, Cr, Ni, Fe-alloy) and a Fe piece was realized by adding Nb as welding agent. Laser parameters were suitably adapted in order to get a homogeneous Nb distribution in the deposit. In that way the difference of hardness between the deposit and the basic material is diminished and the weldability is improved.

This laser procedure differs from conventional techniques by the possibility to control the intermixing and recrystallization by an appropriate time performance of the laser emission. In addition the laser technique offers a larger selection of different welding partners. Control of the laser emission also allows one to influence the shape and the size of the weld and gives the possibility to optimize the constructive conditions.

12.5 Formation of SiC Heating Elements Using a CO_2 Laser, F. J. Hierholzer, *Emerson Electric Corp., St. Louis, Mo. 63136*

(15 min)

High-temperature resistors or heating elements are formed using a 250 watt CO_2 laser. The resistor elements are fabricated by placing particulate SiC grains into a "boat." An X-Y table moves the boat beneath the focused 10.6 μ beam. After the programmed motion is complete, the boat is removed from the X-Y table. A pair of tweezers is used to lift the resistor element from the remaining SiC grains. A metallization of the two ends of the resistor element completes the fabrication process.

The electrical properties of the resulting heating elements or resistors are measured by soldering or "clipping" leads to each of the two metallized regions. With heavily nitrogen doped (N type semiconductive) SiC, voltage, current and temperature of the resistors with increasing AC 60 Hz voltage show a slight negative temperature coefficient of resistance until a temperature of about 1400°F is reached. From 1400°F to 2600°F the resistor has a positive temperature coefficient of resistance. When the SiC is heavily aluminum doped (P type semiconductive), the resistor has a positive temperature coefficient of resistance throughout the entire temperature span. With either the P or N doped SiC the resistors had a resistance tracking from unit to unit (using the same material) during laser fabrication very close to $\pm 1\%$.

The CO_2 laser beam has a 10.6 μ wavelength which is almost completely absorbed by the SiC particles in the "boat." The beam strikes the surface of the particles in the boat and almost instantaneously raises the temperature of the SiC particles within the beam pattern to their sublimation temperature of about 2300°C. The SiC "burns" with a small flame within the energy beam and this temperature was measured using an optical pyrometer. The beam essentially "burns" a hole into the SiC powder and creates a cloud of SiC vapor as well as a deep "valley" in the powder. When the laser beam transverses the

surface of the SiC grains, this SiC vapor settles upon the clean SiC grains and "grows" the grains together. A self-bonded SiC heating element results. In addition to the "valley" and the "core" of the heating element, a "rind" is formed which when compared to the "core" is non-conductive. The "rind" is bonded together primarily by SiO_2 which is rapidly formed when SiC is heated above 1800°C in air.

Not all particle sizes of SiC will form a heating element using a laser beam of 250 watts CW. Particle sizes of 5 microns or less will not form a cohesive element. Particle sizes of 300 microns or greater will not bond together well.

12.6 Use of Pulsed Laser Treatment to Change Physical Properties of Metals and Semiconductors, I. Ya. Dekhtar, L. I. Ivanov, N. V. Karlov, A. M. Prokhorov, and N. N. Rykalin, *USSR*

(15 min)

(Received late; see page 83)

12.7 Laser Spot Welding and Real Time Evaluation, M. A. Saifi and S. J. Vahaviolos, *Western Electric Co., Inc., Engineering Research Center, Princeton, N. J. 08540*

(15 min)

This paper will discuss a technique for laser welding of insulated copper wires to terminal posts, and real time analysis of weld quality by stress wave emission (SWE) tests. The copper wire is 0.3 mm diameter polyurethane insulated and the terminal material used in this study is a Cu-Ni alloy commercially known as Monel. Typical welding (100 watt pulsed YAG welding system) parameters are: pulse length – 3.5 ms, energy/pulse – 10 joules, spot size – 1 mm.

The utility of this material combination is best illustrated by discussing the welding process as a function of time during the laser pulse. The beam is focused on the terminal shoulder. Its absorption causes an increase in the Monel's surface temperature and a transfer of heat towards the Monel-Cu interface. Surface temperature and depth of the melt zone can be estimated.[1,2] The calculations show that for a 0.3 mm thick shoulder, the surface reaches its vaporization temperature (3000°C), and the molten zone penetrates to the Monel-Cu interface within 1 to 1.5 ms. Since the melting point of Monel is about 150°C higher than that of copper, (with comparable specific heats) this results in rapid melting of the copper wire (insulation is burned out instantaneously) and wetting of the Monel surface with copper. In general, the melting point of copper rich Monel is always lower than that of Monel and higher than that of copper. Furthermore, the high thermal conductivity of copper soaks in the heat from the terminal and inhibits a rapid-rise in its temperature, which would tend to cause evaporation and welding instability.

We have found this Monel/Copper system to consistently produce good quality welds. The structure of the weldment was studied by the usual metalographic techniques which will be discussed. The welds were also pull tested, and the wire strength in close proximity to the weld was found to be over 50% of the original wire strength.

In many applications it is important to determine the weld quality during the welding cycle. This is particularly important in order to realize the full potential of high speed spot welding now possible with high repetition rate pulsed lasers. We have investigated SWE[3] during the laser welding cycle. As a criterion of weld quality, we have successfully used the number of zero crossings over a biased line, generally known as SWE counts. We have found good correlation within a well defined narrow band.

We will discuss in detail a model which describes the welding process, and the results of the SWE tests.

12.8 Pulsed Laser Welding of Clad Metals, S. R. Bolin, *Raytheon Co., Waltham, Mass. 02154*

(15 min)

Pulsed laser welding is a widely accepted technique of metal joining. It is estimated that over 100 machines are in operation in this country. The advantages over conventional welding techniques (low heat input, welding of inaccessible locations, noncontact, etc.) are extensively detailed elsewhere.

High reflectivity materials have proven intractable to pulsed laser welding due to the large energy required to overcome reflective losses.

The approach taken here is to investigate the use of a high reflectivity base material clad with a layer of material of lower reflectivity which can be alloyed into the base material.

Literature suggests that welding may be promoted in highly reflective materials by application of a nonreflective coating to the metal surface. From a practical standpoint, this is effective only if the coating material will not contaminate the weld joint and if the coating is not removed by the laser pulse.

As the cladding material is not removed by the laser pulse, but rather is alloyed into the welded joint, the cladding and base materials must be metallurgically compatible. Pure copper sheet clad with a thin layer of nickel provides a most desirable combination to demonstrate this. Because the reflectivity of copper is much higher than that of nickel, approximately one fourth the energy required to weld bare copper is required for clad copper. Due to the wide range of solid solutions formed between copper and nickel, and the high cooling rates of laser welds, welds are of very high quality.

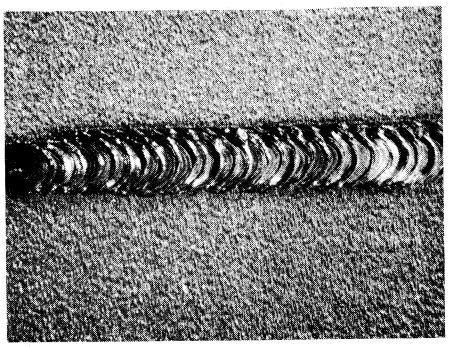

Fig. 1. Weld seam in nickel clad copper.

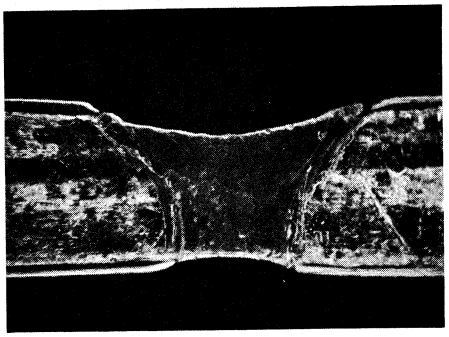

Fig. 2. Cross section of weld in nickel clad copper showing full penetration.

Fig. 1 shows a butt weld produced by overlapping spot welds. The material is pure copper 0.48 mm thick clad with .04 mm of pure nickel. A cross section of the same weld is shown in Fig. 2. Laser parameters were two pulses per second, each pulse being 9 milliseconds long, 18 joules energy. When the same conditions were used on unclad copper, only superficial melting occurred with no weld joint.

A unique feature observed in pulsed laser welding of clad materials is that penetration may be substantially increased by either slowing the advance of the laser or making multiple passes. This occurs as a result of increased alloying as the material is remelted by subsequent laser pulses. The penetration shown in Fig. 2 was achieved by applying 2 pulses in each position; penetration from a single pulse was typically about 0.23 mm.

The same material has also given good results for terminals and where lap welds are required. In production applications, the cladding material need only be placed in the actual weld area, thus reducing cost. This technique should be easily applicable to gold and silver. Application to aluminum may prove more difficult in terms of finding an appropriate cladding material which will alloy well with aluminum.

12.9 Change of Reflectivity of Metallic Surfaces during Irradiation by CO_2-TEA Laser Pulses, J. F. Ready, *Honeywell Corporate Research Center, Bloomington, Minn. 55420*
(15 min)

The reflectivity of metallic surfaces can undergo large changes during irradiation by high power laser pulses. This factor is important for applications involving welding and drilling, because it affects the amount of laser energy that actually is absorbed by the surface. It is especially significant for CO_2 lasers, because the initial reflectivity of metallic surfaces tends to be very high at the CO_2 laser wavelength. Despite the fact that this phenomenon has been recognized for some time, there is little quantitative data on how the reflectivity changes during irradiation.

We measured the change in reflectivity of metallic surfaces as a function of time during irradiation by pulses from a CO_2-TEA laser operating at 10.6 μ. The pulse duration could be varied from 100 nanoseconds (FWHM) to several microseconds by varying the gas mixture in the laser. The laser power density at the target could be varied up to 3×10^8 W/cm^2.

The reflectivity was monitored by a second probing beam from a low power continuous CO_2 laser, which used a grating reflector to control the wavelength at 9.6 μ. This beam was focused onto the same area struck by the TEA laser pulse. The amount of 9.6 μ light reflected from the surface was monitored by a fast pyroelectric detector or by a photovoltaic mercury cadmium telluride detector. The 9.6 μ probing beam was separated from scattered 10.6 μ radiation by interference filters. We measured both the specular reflectivity and the diffuse reflectivity within a specified solid angle surrounding the specularly reflected beam. Additional measurements of the transmission of the blowoff material were made and the reflectivity results were corrected for absorption therein. The results yielded the reflectivity of the target surface as a function of time during irradiation. The target assembly was contained in a vacuum chamber so that the ambient air pressure could be varied. In addition, measurements were made of the absorptivity and of the hemispherical diffuse reflectivity on areas which had been irradiated by the TEA laser. These latter measurements were not time-resolved.

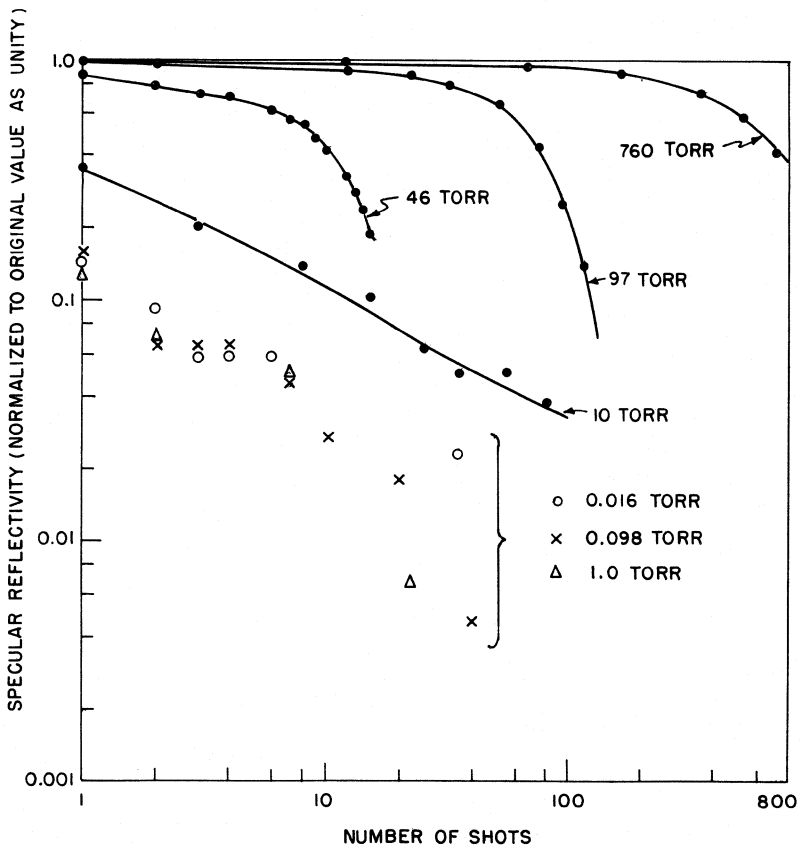

Fig. 1 shows the specular reflectivity of a stainless steel target as a function of the number of laser shots incident on a given area. The laser power density was 3×10^8 W/cm^2 and the laser pulse duration was around 3 microseconds. At one atmosphere ambient air pressure, it requires several hundred shots to produce an appreciable change in reflectivity. This is because a laser-supported detonation wave is kindled in front of the target, which absorbs much of the incoming laser energy. At reduced ambient pressures, the shielding is diminished and the effect on the surface is increased. For pressures below 10 torr, the specular reflectivity can drop to low values in a single shot. For a shorter laser pulse ($\sim$100 nanoseconds) the results are qualitatively similar to those shown in Fig. 1, but it requires a larger number of laser pulses to produce a given decrease in specular reflectivity. For an aluminum target, the results are also qualitatively similar, but the effect is somewhat less, presumably because of the greater initial value of the reflectivity.

The time resolved data show that, in cases where a substantial decrease in reflectivity occurs in a single shot, there is a rapid drop over a period of several hundred nanoseconds. For the longer laser pulses, the specular reflectivity continues to decrease slowly for several microseconds.

The data on diffuse reflectivity indicate that the diffuse reflectivity within a given solid angle surrounding the specular angle first increases and later decreases. Simultaneously, the total diffuse reflectivity increases. This indicates that the diffuse scattering moves into a progressively larger cone of solid angles. For a well damaged steel surface (specular reflectivity $\lesssim 0.001$), the total hemispherical reflectivity is ~ 0.85. The absorptivity has increased to 0.15, as compared to an initial value of 0.025.

"This work was supported by the Air Force Office of Scientific Research under contract F44620-73-C-0022."

12.10 Laser Heating of Metallic Surfaces,[1] S. Marcus, J. E. Lowder, S. Manlief, and D. L. Mooney, *MIT, Lincoln Laboratory, Lexington, Mass. 02173*
(15 min)

In those laser applications which involve heating of metals, the heating efficiency is characterized by the thermal coupling coefficient, i.e., the ratio of absorbed to incident energy. We report here the use of fast-response, thin-film thermocouples to measure temperature histories with microsecond time response. These thermocouples, whose junctions can be positioned at various points in the target less than 1 μm from the surface, can thus be used to obtain coupling coefficients for pulsed-laser irradiation with both temporal and spatial resolution. We have used this technique to investigate coupling to both copper and aluminum targets as a function of laser intensity, and have found in each case a marked increase in coupling when the intensity was sufficient to cause breakdown on the target surface.

In order to measure surface temperature changes outside the focal spot ($\approx$2 mm), a target incorporating a linear array of five thermocouples was used, each thermocouple separated by 3.2 mm. The source of laser radiation was a pulsed electron-beam laser capable of producing approximately 5 joules at 10.6 μm in 10-100 μsec pulses. After passing through a KCl beam-splitting wedge, used to monitor the pulse shape and energy, the beam was focused on the middle thermocouple of the target. A photomultiplier viewing parallel to the target surface was used to detect plasma luminosity.

The thermal coupling with no detectable plasma formation at the target surface was first measured by attenuating the incident laser

[1] This work is supported by the Advanced Research Projects Agency of the Department of Defense.

intensity to less than 10^5 W/cm^2. Under these conditions, a temperature increase was registered on the middle thermocouple only. Upon increasing the laser intensity to the point where surface-induced breakdown occurred ($\sim 10^6$ W/cm^2), temperature increases were sensed by all five thermocouples. A plot of distance from the middle thermocouple vs. arrival time of the thermal disturbance shows that the disturbance spreads outward at supersonic velocities typical of blast wave expansion, much too fast to be due to surface conduction. The observed time delay also indicates that the plasma heating of the target is predominantly due to electron conduction or very short range radiative transfer.

The instantaneous front surface heating rate of metallic surfaces may be determined by measuring the front surface temperature history and then calculating the heating rate with the relation[2]

$$F(0,t) = \frac{K}{\sqrt{\pi k}} \int_0^t \frac{\frac{d}{dt'} T(0,t')}{\sqrt{t - t'}} dt'$$

for the case of a thermocouple located at the absorbing surface.

After the absorbed flux is extracted from the data for each thermocouple, it is integrated in time to give a radial profile of the absorbed energy fluence. This profile, which can be fit to an exponential, is in turn integrated spatially to give the total absorbed laser energy. In the case where no plasma is generated, the absorbed energy is simply the product of absorbed fluence and the measured focal spot area. In each case, the thermal coupling coefficient is defined as the ratio of absorbed to incident laser energy.

The coupling coefficients thus determined for copper and aluminum are shown below:

Surface	Low Intensity	With Breakdown
Aluminum	.039	.27
Copper	.036	.33

It is seen that for both these metals, there is a large coupling enhancement when laser-induced breakdown occurs.

We are currently extending our technique to investigate spot size scaling, using a 500-joule laser. In addition, other metallic surfaces of interest are being investigated.

14.1 A Pulsed UV Rangefinder, T. P. Davis and M. A. Nelson, *EG&G, Inc., Santa Barbara Operations, Goleta, Calif. 93017*

(15 min)

There are many applications for a rangefinder capable of operation against moving targets over distances of a few kilometers with a range precision of less than a meter. A system based on a pulsed UV source has been developed in this laboratory. Key to the performance of the instrument is a unique source, which generates short, intense pulses of UV at 337 nm by amplified spontaneous emission from electrically excited nitrogen.[1] In rangefinder applications, this source offers a number of advantages: 1) an inherently eye-safe wavelength; 2) high peak power; 3) very short pulse duration; 4) high PRF's; 5) reasonable atmospheric transmission; 6) multiplier phototube detectors available with high efficiency at the operating wavelength.

The prototype instrument reported here has demonstrated these advantages. A description of the instrument and preliminary evaluation results follow.

The rangefinder consists of a transmitter and receiver mounted on a common optical rail, plus associated power supplies and readout. The transmitter includes the pulsed nitrogen laser, a 200 mm focal-length quartz collimating lens, and a 45° turning mirror. The lens provides beam divergence of slightly less than 5 milliradians, and the turning mirror mount gives convenient alignment of the transmitted beam with the receiver.

The latter consist of a Newtonian reflector with a 10 cm diameter f/2 primary mirror. A 1 mm stop at the primary focus provides a field of view matching that of the transmitter. A field lens images this stop onto the photocathode of the detector. A line filter with 100 Å bandwidth and peak transmission of about 40% at 337 nm is positioned ahead of the field lens. A 4 × finder telescope is rigidly attached to and aligned with the receiver.

[1] E. T. Gerry, *Appl. Phys. Lett.*, vol. 7, 1965.

The laser power supply is a special unit which furnishes a 30 kV pulse to the laser head at rates up to about 50 pps. The receiver power supply furnishes 1000 V to the detector PMT. For preliminary evaluation, readout was by fast oscilloscope.

The prototype instrument was tested against various targets. A highway sign at 890 meters presented an adventitious "cooperative" target in the form of two 8 cm diameter glass reflector buttons normal to the line of sight. The receiver noise was immeasurably small compared to the return signal. At this same range, a concrete bridge yielded a return signal-to-noise ratio of about 80. A simplified analysis[2] of this situation leads to a predicted signal-to-noise ratio of about 100, which is in good agreement with the measured value.

The eye hazards associated with a pulsed UV nitrogen laser have been analyzed in detail in an earlier document.[3] The wavelength of the nitrogen laser is such as to minimize both these hazards. The rangefinder here studied is safe at all ranges.

Preliminary results from measurements made with the prototype system described support the conclusion that range precision of tens of centimeters can be achieved at ranges of at least one kilometer. The instrument is compact, rugged, and readout is relatively simple. Most importantly, the system does not present a significant eye hazard.

14.2 A Phase-Comparison Monopulse Laser Rangefinder/Altimeter, G. Ammon, D. Herzog, C. Reno, and H. Zadell, *Advanced Technology Laboratories, RCA Corp., Camden, N. J. 08102*

(15 min)

A unique laser rangefinder was developed as part of a Precision Hover Sensor for the flight control system of a Heavy Lift Helicopter. This sensor provides the pilot with the capability, without visual reference to the ground, to position the helicopter and load to a prescribed heading at any height above the terrain from 25 to 125 feet and within 4 inches of a reference point near the ground. In addition the sensor provides hands off capability to maintain a given hover position of the aircraft's center of gravity to within 4 inches in the vertical and horizontal directions.

This laser rangefinder measures absolute altitude to within 4 inches and changes in altitude from a desired hover point with a resolution of 0.5 inch. In addition the rangefinder provides a velocity output which can detect rates as small as one inch per second.

The rangefinder uses an eye-safe GaAs pulsed injection laser for an optical source and a silicon avalanche photodiode for a detector. Both of these units are temperature controlled with

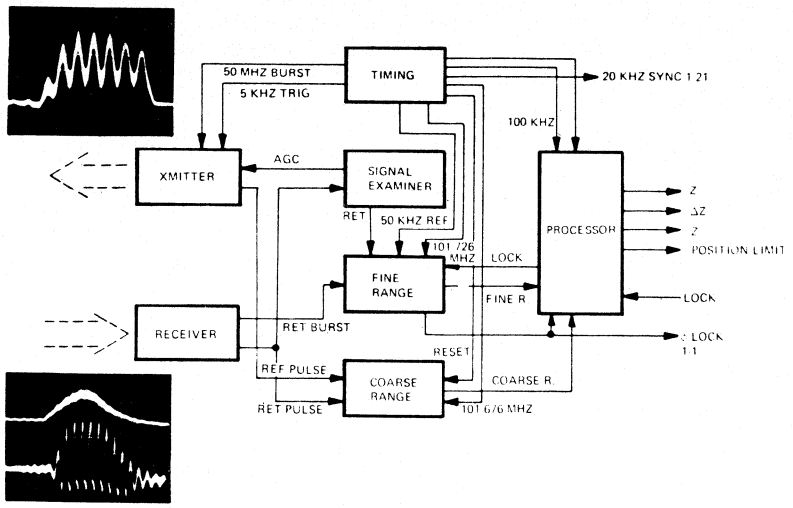

Fig. 1. Laser rangefinder.

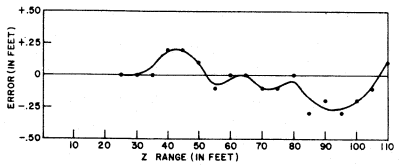

Fig. 2. Absolute range error vs. range.

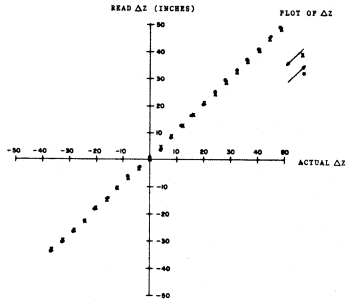

Fig. 3. Measured Z vs. actual.

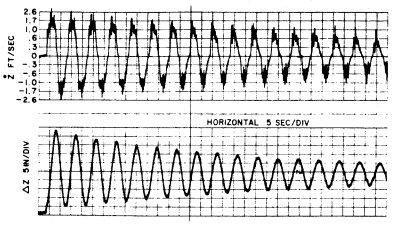

Fig. 4. Velocity and position change outputs with pendulum target.

thermoelectric modules to maintain a constant laser output wavelength and a constant photodiode gain level. Fig. 1 shows a functional diagram of the rangefinder along with some important waveforms.

The pulsed output from the laser is modulated with approximately five cycles of a 100 MHz sinewave. This is accomplished by driving an acoustooptic modulator with 30 watts of 50 MHz RF during the time the laser is being pulsed. The modulated laser output is focused into a narrow beam and transmitted towards the ground and reflected back to the receiver. The laser receiver detects this modulated signal and separates it into pulse and burst waveforms.

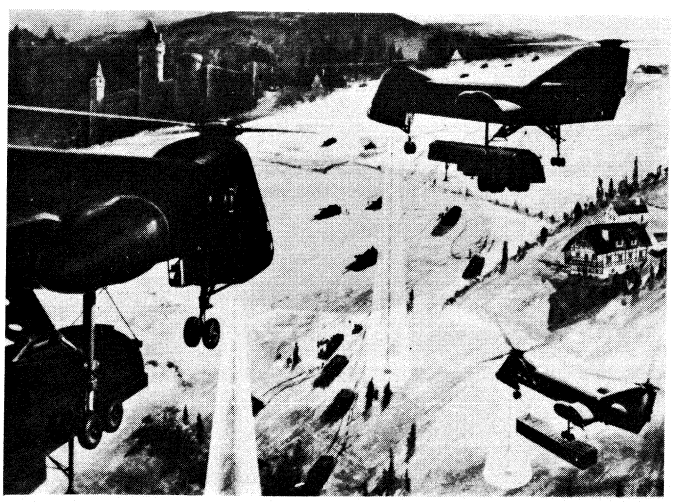
The absolute range to the target is determined by measuring the time of flight of the laser pulse. The laser output is sampled as it is transmitted with a silicon photodiode and amplifier. This signal, the reference pulse, and the detected return pulse are processed in two identical circuit channels in the coarse range circuitry and the time difference is measured with a digital time interval counter. The results of many measurements are averaged to yield an overall accuracy of 4 inches. Fig. 2 shows a plot of measured absolute range error versus range.

Range changes or fine range information is obtained by comparing the phase of the 100 MHz burst signal as it is transmitted with the phase of the return burst. A gated phase-locked loop is used to obtain a continuous 100 MHz signal which has the same phase relationship as the return burst. This signal is then phase-compared to the signal which modulates the laser to yield fine range information with a resolution of 0.5 inch. Fig. 3 shows a plot of measured range change versus actual as a target was moved away from a reference position.

Velocity information is obtained by differentiating the high resolution fine range measurement. Fig. 4 shows the rangefinder Z and $\dot{Z}$ outputs while operating off of a large pendulum which was pulled 24 inches from its rest position and released.

This rangefinder combines the advantages of both pulsed and CW systems to provide a system with unique capabilities. Operating in a pulsed mode allows the range to be measured unambiguously. It also allows the use of gating techniques to discriminate multiple targets or to blank out backscatter. Modulating the pulse with a sinewave enables the use of phase detection to obtain a very high resolution range change measurement. The 0.5 inch capability is equivalent to a time interval of about 85 picoseconds.

14.3 A Laser Precision Hover Sensor for HLH Helicopter,



D. G. Herzog and G. Ammon, *Advanced Technology Laboratories, RCA Corp., Camden, N. J. 08102* and C. Stephenson, *Boeing Vertol Co., Philadelphia, Pa. 19142*

(15 min)

A Heavy Lift Helicopter is being designed to have a load handling capability up to 73,000 lbs. (80% of a Boeing 707-320c capability). Specific use is for cargo handling from truck, rails and even ships under running conditions in high sea state. Damage easily reuslts from mishandling of large loads thereby requiring the helicopter to have the capability of "freezing" in mid-air or dynamically matching the motion of a heaving deck. An experimental sensor and performance is described.

Concept drawing Fig. 1 shows the sensor beams illuminating two areas beneath the helicopter: (1) an outer 20 ft. diameter region used to measure translation characteristics in a plane parallel to the ground (Δx, Δy, $\dot{x}\dot{y}$) via image

Fig. 1. Precision hover sensor beam patterns from the helicopter.

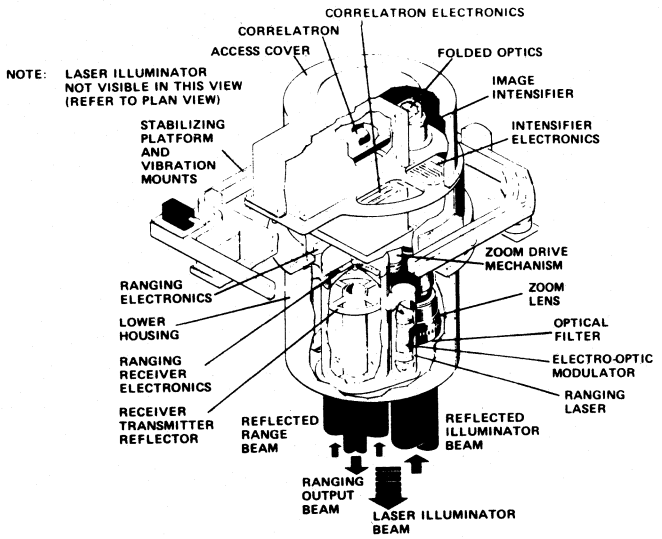


Fig. 2. Concept of precision hover sensor.

TABLE I
PERFORMANCE CHARACTERISTICS

Hover precision (ΔX, ΔY, ΔZ)	1.0 in
Detectable velocities ($\dot{X}$, $\dot{Y}$, $\dot{Z}$)	2.0 in/s
Data bandwidth	10 Hz
Beep interval (X, Y, Z)	1.0 in
Creep interval ($\dot{X}$, $\dot{Y}$,$\dot{Z}$)	1-18 in/s
Maximum displacement (X, Y, Z)	$\pm$4.0 ft
Altitude	25-125 ft
Lock-on and relock-on time	1.0 s
Hover time (nominal)	10 min

correlation tracking and (2) an inner (dotted) 3 inch area used to measure altitude characteristics (Z, ΔZ, $\dot{Z}$) via a very precise pulse sinewave modulated laser rangefinder.

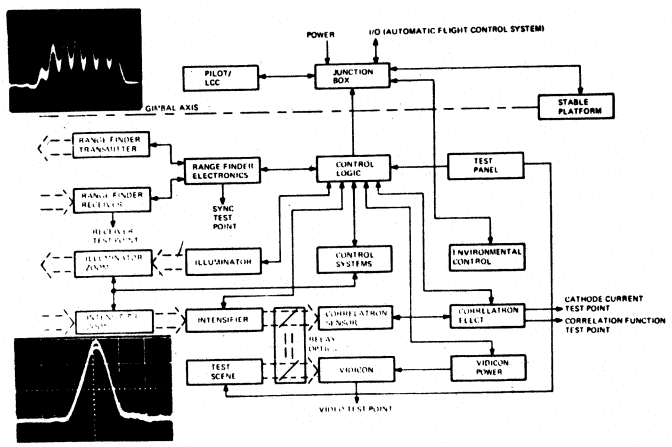

Table 1 summarizes the sensor's performance. Fig. 2 is a concept description of the sensor including the pendulum referenced gyro stabilized against helicopter pitch and roll induced errors.

Upon "hover position initiation" the scene below is electronically stored as a reference and all future scene information is dynamically compared in a special correlation tracker using all the scene information rather than depending on particular highlights, edges, patterns or beacons. Cooperation from the ground is highly undesirable because of extra logistic and communication problems.

Micro-positional control is provided by allowing the pilot to offset the sensor by 1 inch offset intervals (beeps) and continuous velocity offsets (creeps) without having the sensor relock up to 2 feet. Beyond 2 feet, automatic relock occurs allowing the helicopter to "walk" over extended distances.

Figure 3 is a block diagram and points out how the problems of all-weather, day/might and heavy dust environment (particularly because of the downwash of large rotor blades) were addressed by using a very narrow pulsed GaAlAs illuminator and an ultra-fast gated intensifier to provide the required images to the correlation tracker. Thus backscatter was rejected from the image and a "punchthrough" of very dusty environment that would eliminate normal seeing of the ground down to pathlength as small as 15 feet was simulated on the ground.

Fig. 3. Functional block diagram of PHS system.

The correlation tracker (closest substitute for the combination human eye-nerves-brain) uses a GAC system, conceptually shown in Fig. 4, operates using an electron storage meash for the initial scene which is then used to multiply the dynamic scene electron image producing the auto-correlation value. By use of a hill climbing servo the dynamic image is deflected to maintain a maximum output. The deflection is the linearized position offset Δx and Δy. Pick off before deflection feedback intergration provides velocities ($\dot{x}$ and $\dot{y}$). Typical error functions are shown in Fig. 5.

The zoom optical system on the illuminator and intensifier maintain the illuminated and tracked scene to 20 feet diameter independent of the altitude (information obtained from rangefinder) of the helicopter thereby maintaining a constant calibration for the tracker. The experimental performance will be presented.

The rangefinder optical pulse (Fig. 3) shows the 5000 pps, 50 ns pulse width, 100 MHz modulated transmitted waveform. Coarse ranging is provided with a time-of-flight measurement using the silicon avalanche detector and counter to process the pulse to 3 inch accuracy. The 100 MHz modulated signal is stripped from the pulse and its phase is compared to the transmitted phase to obtain the 0.5 inch position and 1 inch/sec velocity precision at an error output bandwidth of 10 Hz.

Even though substantial problems were encountered with scene lock on these problems are not insurmountable and excellent stablization and meaneuvering potential of the HLH helocpter was demonstrated using available high constrast ground scenes. Movies taken from the aircraft will be shown.

14.4 Polarization Reference Imaging Systems: Basic Principles,[1] W. P. Brown, Jr., and T. R. O'Meara, *Hughes Research Laboratories, Malibu, Calif. 90265*

(15 min)

Polarization reference imaging (PRIM) systems are a new approach to achieving diffraction-limited imaging through a turbulent atmosphere, with laser target illuminators. They may be implemented either as add-ons to existing telescopes or as large-baseline optical arrays.

The approach is fundamentally different from that employed in competitive adaptive optical systems in that neither rubber mirrors nor electrooptic compensation is employed. Conceptually, the approach is closest to on-axis holography in that one or more bright target glints provide the reference which beats against the image wavefront and, by virtue of an (essentially) common path, cancels the propagation and/or optical figure errors. However, the fold-over problems of on-axis holography are completely avoided, even though the reference typically falls near the middle of the image. Further, photographic film is not employed to record the resultant fringe patterns.

[1] Work partially supported by DARPA contract no. DAAH01-73-C-0629 and monitored through U. S. Army Missile Command, Redstone Arsenal, Ala.

In a PRIM system, a cooperative laser transmits two polarization states which are at two closely spaced wavelengths, or are otherwise distinctly modulated. The image information is obtained from the depolarized portion of the diffusely reflected component of one of these polarization states. The reference information is obtained from the nondepolarized return of the other polarization state. Since the initial polarization states are at different frequencies, the image and reference signals produce a heterodyne beat in the detector output at a difference frequency. From another viewpoint, the image and reference components generate a fringe pattern at the receiver aperture plane which is modulated at the beat or difference frequency. This fringe pattern is sampled by an array of receivers, either in the aperture plane or (with conventional telescopes) at an image of the aperture plane. We will show that the beat frequency output of each receiver is a sample of the Fourier transform of the irradiance distribution of the target. Further, we will show that these samples are unaffected by atmospheric turbulence, given target isoplanatic assumptions.

The samples obtained from each receiver must be further processed in order to generate an image. In the present system, the receiver output at the beat frequency is synchronously detected and A/D converted. These digital samples are then inverse transformed to generate a true image of the target. The inverse transform may be computed in (substantially) real time if desired. Operation at both visible wavelengths and at 10.6 μm will be considered; each has advantages for certain applications.

Key problem areas to be discussed are (1) signal-to-noise ratio and S/N optimization, (2) target reflectivity characteristics, (3) techniques for reducing the required number of sampling receivers, and (4) operation with multiple glint references.

Computer simulations of a visible PRIM system will be discussed in a companion paper: 14.5 "Polarization reference imaging system: computer simulation studies" by D. Y. Tseng.

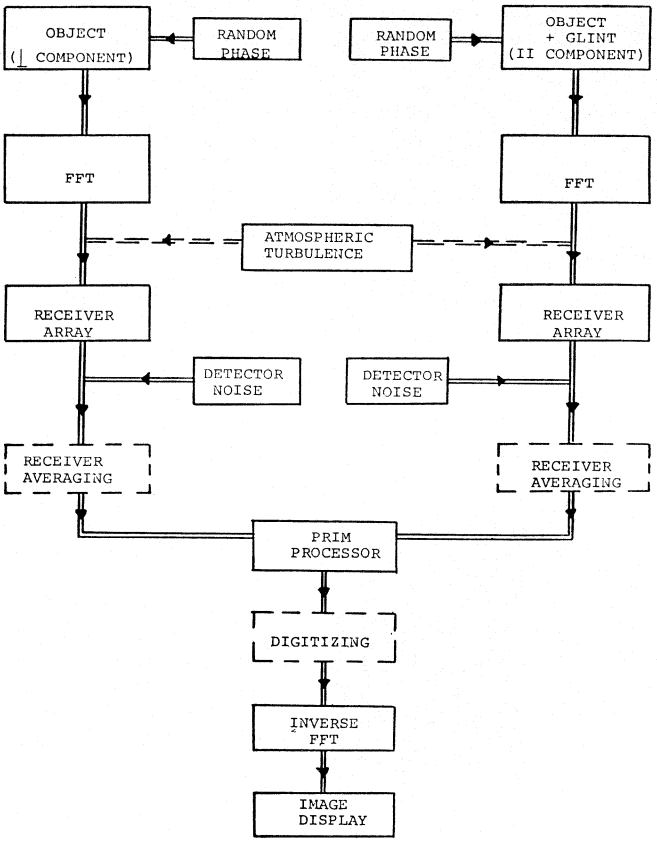

Fig. 1. Block diagram of PRIM simulation computation.

14.5 Polarization Reference Imaging System: Computer Simulation Studies,[1] D. Y. Tseng, *Hughes Research Laboratories, Malibu, Calif. 90265*

(15 min)

The polarized and coherent output characteristic of lasers can be utilized to eliminate image distortion caused by atmospheric turbulence. One approach which takes advantage of this characteristic is the Polarization Reference Imaging (PRIM) system. It has the capability of achieving diffraction limited image resolution through turbulent atmosphere. The basic principles and analytic details of the PRIM concept are presented in a companion paper: 14.4 "Polarization reference imaging system: basic principles," by W. B. Brown, Jr. and T. R. O'Meara.

This paper presents a comprehensive computer simulation study of the PRIM system. The simulation scheme incorporates all of the system parameters of interest, such as signal-to-noise ratio, glint amplitude, glint distribution, system aperture size, and receiver size. Speckle effects are also included. The simulation study was carried out using a DEC/PDP-10 digital computer. A block diagram of the computational scheme is shown in Fig. 1. The PRIM-processed reconstructed images, exhibited as grey-scale displays on a CRT, were evaluated extensively as a function of system parameters. An example of a turbulent image and the corresponding PRIM-processed diffraction-limited image is shown in Fig. 2.

The PRIM-processed images will be shown as a function of the system parameters, some of which have been listed above. The image quality dependence on particular parameters will be displayed and discussed in detail. Conclusions drawn on the values and ranges of system parameters which produce good quality images based on the computer simulation studies will be presented.

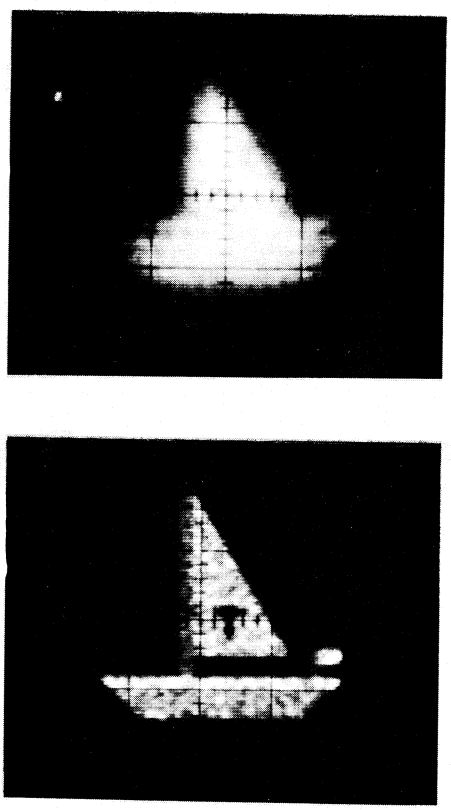

Fig. 2. Top: turbulent image. Bottom: PRIM processed image.

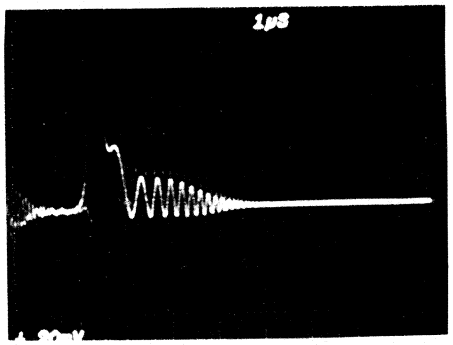

Fig. 1. Time resolved beat frequency between TEA laser and stable CW laser.

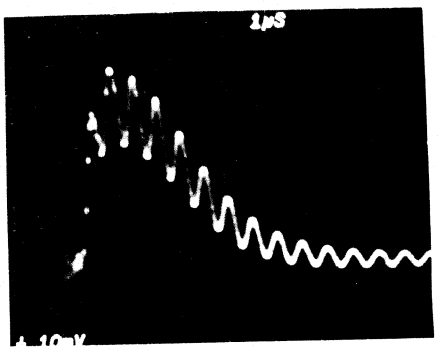

Fig. 2. Time resolved beat frequency between hybrid laser and stable CW laser.

14.6 Temporal Coherence Measurements of a Double Discharge CO_2 TEA Laser, R. I. Rudko, *Raytheon Research Division, Waltham, Mass. 02154*

(15 min)

The CO_2-TEA laser, because of its high peak powers, high efficiency, and relatively small size, is an attractive device to use as a laser radar transmitter. However, if it is to be used in a Doppler rader or any other type of radar which uses coherent detection, the temporal coherence of the laser must be good enough to meet the system requirements. The object of this investigation was to measure the temporal coherence of a CO_2-TEA laser, including frequency chirp during a single pulse and pulse-to-pulse repeatibility; determine the causes of any lack of coherence; and see whether any improvements can be made.

Initial measurements were carried out on a simple double-discharge TEA laser in a stable optical frame. An SF_6 cell, grating, and aperture were used to force the laser into single radial and longitudinal mode operation. The output of this laser was heterodyned with the output of a stable single-frequency CW laser whose frequency was offset by several MHz from the TEA laser oscillation frequency. A typical result for the time-resolved beat frequency between these two lasers is shown in Fig. 1. The frequency chirp rate in this case is more than several MHz/μsec.

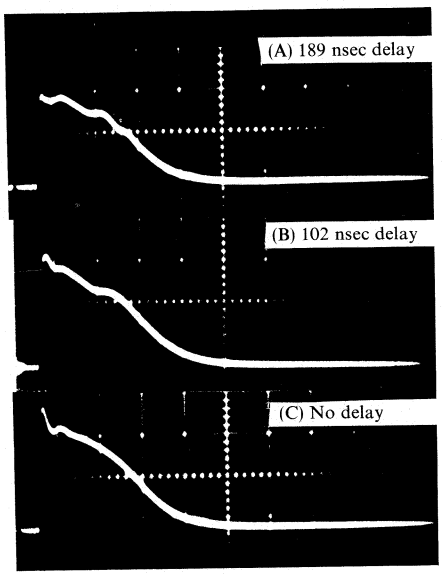
Next, measurements were made on a hybrid CO_2 laser consisting of the same TEA laser used in the initial measurements along with a low pressure CW laser inside the same optical cavity. In this case, the grating and the SF_6 cell were not needed to force the laser to run single longitudinal mode. In addition, the low pressure CW laser provided the aperturing for single radial mode operation. The output of this laser was then heterodyned with the stable single-frequency CW laser with a typical result for the time-resolved beat frequency between these two lasers shown in Fig. 2. In this case, the frequency chirp rate is less than 100 kHz/μsec, considerably better than that observed with the TEA laser by itself. In addition, the initial gain-switched spike, which usually occurs at the beginning of the TEA laser pulse, does not occur with the hybrid laser because of the CW power which exists in the cavity before the pulse. Furthermore, the output pulse occurs with less delay after the current pulse.

The frequency chirp on the output of these lasers is caused by an index of refraction change as a function of time in the laser gas. This index change could be caused by various effects such as resonance or anomalous dispersion, plasma electron density variation, gas dissociation, or gas density variation. It is believed that the major effect comes from gas density variations. The reduced chirp observed with the hybrid laser apparently results from the fact that its pulse occurs earlier in time, before density variations start.

14.7 Chirp Measurement of CO_2 TEA Laser Using Interferometric Pulse Delay Techniques, H. Hieslmair, C. J. Bickart, and J. N. Fulton, *Combat Surveillance & Target Acquisition Laboratory, US Army Electronics Command, Fort Monmouth, N. J. 07703*

(15 min)

Several authors[1-3] have measured the frequency chirp of a TEA-CO_2 laser pulse by observing the chirp of the beat signal between the TEA laser pulse and a stable CW CO_2 laser. In this paper the frequency chirp of a TEA laser pulse is observed by beating one part of the laser pulse with a delayed part of the same laser pulse. This is experimentally accomplished by using a Michelson type interferometer with a large path difference in the two arms. Fig. 1 illustrates the experimental arrangement. The TEA laser cavity is defined by a gold coated mirror of 1.6 m radius and a flat 60% reflecting germanium mirror with an intracavity aperture to control the transverse mode pattern. A low inductance 0.01 μF capacitor charged to 20 kV is discharged through the 25 cm long flat electrodes with a Rogowski profile via a triggerable spark gap.



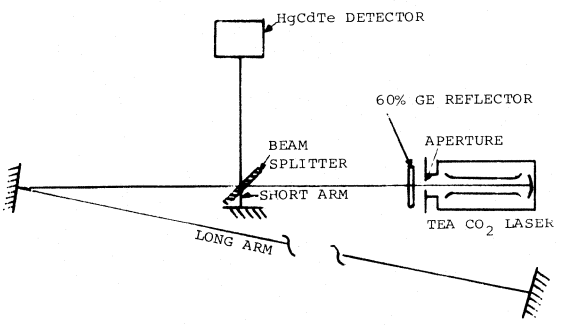


Fig. 2. Beatnote between delayed pulses (timescale: 1 microsecond/Div.).

Curve A and B of Fig. 2 show typical time resolved beat signals superimposed on the TEA laser pulse. In curve A the long arm was 28.3 m long which corresponds to a time delay of 189 ns long which corresponds to a time delay of 189 ns. The beat signal is 1.4 MHz, which corresponds to a frequency chirp of 7.5 MHz/μs. On curve B the time delay is 102 ns and a lower frequency beat signal than in A is obtained, which corresponds to a comparable frequency chirp of 7.8 MHz/μs. In curve C of Fig. 2 the two arms of the interferometer were of equal length. No beat note can be observed. The above figures of frequency chirp correspond to results obtained with a helical pin type TEA laser of comparable length as reported by Stiehl, *et al.*[1] The potential of using the tail of a TEA laser pulse as a local oscillator for the return signal of the same pulse in radar applications will be discussed.

14.9 Recent Advances in Multidither Coherent Optical Adaptive Techniques (COAT),[1] J. E. Pearson, *Hughes Research Laboratories, Malibu, Calif. 90265*

(15 min)

High power optical beams propagating in the atmosphere can experience severe distortions caused by two effects: atmospheric turbulence (a linear process) and thermal blooming (a power-dependent or nonlinear process). Coherent Optical Adaptive Techniques (COAT) have been proposed to compensate for both types of distortion and at present appear to be essential for efficient utilization of high power 10.6 μm and 3.8 μm lasers now being developed. Early prototype 3- and 7-element multidither COAT systems reported at the 1973 CLEA meeting[2] have been superseded by a more advanced 18-element visible wavelength system.[3] Recent outdoor range tests with this system[4] have proven conclusively that multidither COAT can nearly eliminate the linear beam distortions caused by atmospheric turbulence and by static optical system errors. This paper reports the results of preliminary experimental investigations aimed at answering two of the remaining fundamental questions about COAT: (1) What are the limitations on a COAT system's ability to compensate for nonlinear thermal blooming distortions? (2) How do diffuse or multi-glint moving targets affect the performance of a multidither COAT system in compensating for turbulence and blooming?

All measurements were made with the 18-element COAT system[3] in a laboratory environment. The optical path and blooming distortions are properly scaled, however, so that the results are directly applicable to longer ranges at 3.8 μm and 10.6 μm by use of well-developed scaling laws. The turbulence distortions are not accurately scaled, but are reasonably characteristic of the magnitude and spectrum of atmospheric turbulence.

In studying target effects, the important parameters are γ_{RT}, the ratio of the receiver resolution to that of the transmitter and β_{RT}, the ratio of the receiver to transmitter area. Our studies have used single pinhole receivers ($\gamma_{RT} < 1$, $\beta_{RT} < 1$) and multiple pinhole and annular receivers ($\gamma_{RT} > 1$, $0.5 < \beta_{RT} < 5$). The targets studied to date have included single and multiple glints (both resolved and unresolved) and diffuse surfaces (curved scotchlite).

Initial experiments, supported by computer simulation,[5] have indicated little, if any, COAT correction for thermal blooming. Initial speculation on reasons for the lack of correction have emphasized the finite number of transmitter elements, the fact that the strongest blooming distortions do not correspond to phase changes at the transmitter, and the possibility that a high speed (1000 Hz) multidither servo is not the optimum correction algorithm for thermal blooming. The results of more refined experimental studies in both gas and liquid blooming media will be presented. In addition, we will discuss the limitations of using transmitter phase control to compensate for thermal blooming distortions.

Recent computer simulations[6] have indicated that returns from moving multiglint or diffuse targets can contain significant amplitude modulations which could swamp the COAT error signals and thus disable or "confuse" the COAT system. Our initial observations without turbulence and with single pinhole receivers ($\gamma_{RT} < 1$, $\beta_{RT} < 1$) have supported this conclusion for diffuse targets, but have been contrary to it for multiple, unresolved glint targets. When using larger receivers ($\gamma_{RT} > 1$, $\beta_{RT} > 1$) or multiple pinhole or annular receivers, we see no target effects; the COAT system performs exactly the same as with a single retroreflecting glint. The detailed results and conclusions from these experiments and from experiments which include the effects of turbulence and blooming will be presented along with the results of studies using "calibrated surface" targets of different shapes.

15.1 DC Pump Sources for the Optically Pumped 546.1 nm Hg Laser,[1] N. Holmes, *Microwave Laboratory, Stanford University, Stanford, Calif. 94305*

(15 min)

Djeu and Burnham[2] have reported operation of an optically pumped CW Hg laser at 546.1 nm, using the two-step optical pumping scheme shown in Fig. 1, and employing a low-pressure RF-excited mercury lamp coaxial with the laser tube. The laser tube contains, in addition to the Hg vapor, nitrogen at a pressure of 10-100 torr to produce quenching of the 6^3P_2 lower laser level. Djeu and Burnham's analysis showed that for sufficient pumping at 253.7 nm the laser power output should be proportional, with high quantum efficiency, to the available pump power at 404.7 nm.

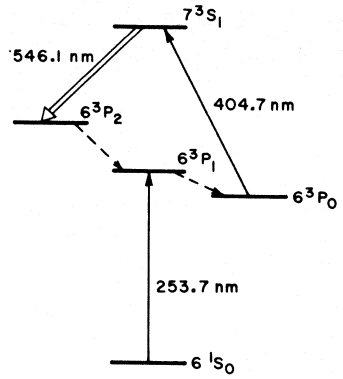

Fig. 1. Important energy levels of HgI for Hg-N_2 laser.

We are presently developing efficient Hg pump lamps intended to obtain CW operation in this same system with separate, replaceable, dc-excited lamps. Highly luminous and efficient Hg 253.7 nm emission is readily obtained in low-pressure (~10 mtorr) Hg resonance lamps. Efficient Hg 404.7 nm emission, however, is obtained from higher-pressure Hg arc lamps, in which the 253.7 nm radiation is strongly self-absorbed. The required line-center Hg 253.7 nm emission from these higher-pressure lamps is, in fact, almost totally absorbed and self-reversed at line center by cooler Hg vapor near the lamp walls. Hence, separate 253.7 resonance lamps and 404.7 nm arc lamps in a double-elliptical pump cavity appear to be desirable for optimum pumping.

A series of measurements on dc arc discharge lamps are being conducted to optimise tube geometry, discharge conditions and Hg pressure for maximum line-center 404.7 nm radiation. Computer modelling is being employed to guide the experimental studies. To date, best results have been obtained with a quartz arc tube of 4 mm i.d. with an arc length of 70 cm. Dispenser cathodes are employed, and argon is added to facilitate starting. The mercury vapor pressure is controlled by a small air-cooled heat sink on the tube wall. At a mercury pressure of ~25 torr and a power input of 400 W this lamp delivers ~1% of this power in the central lobe of the 404.7 nm line, or an ~10× improvement over typical low-pressure lamps. Use of isotopically pure even isotope mercury should increase this power by ~40%. Further increases in Hg pressure lead to self-absorption and broadening effects that limit the useful line-center output at 404.7 nm.

To test these lamps a mercury laser using a polished aluminum double-elliptical cavity 80 cm long is being built. Results of these experiments and their applications will be discussed.

15.2 Electron-Beam-Driven Chemical Lasers (*Invited*), J. B. Gerardo, *Sandia Laboratories, Albuquerque, N. M.*

(30 min)

Results will be presented of electron-beam-driven chemical lasers, with emphasis on HF laser output from high-pressure mixtures of $H_2 + F_2$. The physics of electron-beam deposition in gases and the subsequent chemical reactions leading to laser action will be stressed. Experimental results include: parametric studies of gas mixtures, cavity effects, and pilot beam studies.

15.3 Lasing at 5578.5 Å in *E*-Beam Excited Kr/O_2 Mixtures, A. W. Johnson, F. W. Bingham, and J. K. Rice, *Sandia Laboratories, Albuquerque, N. M. 87115*

(15 min)

The ^1S-^1D transition of oxygen (as well as other isoelectronic elements) has in principle many favorable attributes for use as the very high power laser necessary for compression of pellets in the laser fusion program. Some of these attributes are 1) statistical weight of upper level less than lower level; 2) relatively long-lived upper energy level; 3) energy extractable in one line; 4) visible wavelength; 5) cross-section of $\sim 10^{-19}$ cm^2 at low gas pressure; and 6) potentially efficient excitation by electron beam. One of the most critical unknown parameters is the behavior of the gain cross-section at the high pressures necessary for efficient utilization of electron-beam machine.

A relativistic-electron-beam machine has produced lasing action at 5578.5 ± 0.3 Å in mixtures of high-pressure krypton ($\leq 1.25 \times 10^4$ torr) and molecular oxygen (~ 5 torr). The upper state of the lasing transition is associated with the lowest ^1S state of atomic oxygen; the transition occurs in either the isolated atomic oxygen or the KrO molecule. The electron beam energy is deposited primarily in the Kr atoms and Kr_2 molecules. This energy transfers to O_2, forming $O(^1S)$.

The 0.7-MeV, 50-nsec electron beam, from a long carbon cathode, was approximately 100 cm long and 5 cm wide. The laser axis was parallel to the cathode in the 100 cm dimension. The electronic energy deposited in the gas at the optical axis of the laser was determined by evaluating the density of Kr_2^* formed by the electron beam with no O_2 present. The total density of Kr_2^* was $\sim 2 \times 10^{16}$ cm^{-3} at 250 psi of krypton.

Mirrors with reflectivities of 99.8% and ~96% were mounted on the two ends of the laser cavity 125 cm apart. The radiation spontaneously emitted perpendicular both to the laser axis and to the direction of the E-beam was monitored by a photodiode after being filtered by a broadband filter. Studies using a spectrometer indicated that the only significant radiation transmitted by the filter was in a band near the 5577 Å atomic line of oxygen; this band arises from perturbation of the atomic line by Kr atoms. The total radiation emitted through the higher-transmission mirror was also monitored with a photodiode and an interference filter (5577 ± 5 Å). Fig. 1 shows both the laser light and the spontaneously emitted light.

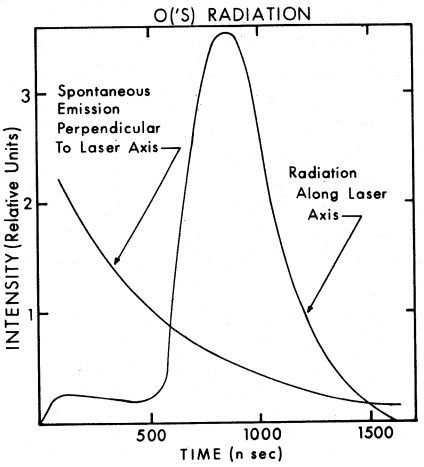

Fig. 1. Laser light and spontaneous emitted light from a mixture of 5 torr of O_2 and 1.25×10^4 torr of krypton.

The net gain of the lasing medium was evaluated in two ways. The total radiation intensity I emitted spontaneously in the 5578 Å band was 6×10^{18} photons/sec cm^3 at 600 nsec after the start of the E-beam pulse. The spectral width ν_w of the spontaneously emitted radiation was measured to be 2.5×10^{11} hertz. The gain coefficient g is evaluated from

$$g = \frac{\lambda^2}{8\pi} \frac{I}{\nu_w} = 1.5 \times 10^{-3} \text{ cm}^{-1}$$

for a wavelength λ of 5578 Å. Since the excited length of laser medium along the axis of the laser was 100 cm, the total gain per pass G is 15%.

The laser growth observed in Fig. 1 furnishes the second estimate of G. An approximation to the net gain is $\exp(g_N ct)$ where g_N is the net gain coefficient and t is the time the lasing pulse spends in the active volume for a given growth of laser intensity. To obtain the gain per pass of the lasing medium, a correction must be made to account for the mirror losses and for the fact that the excited laser medium does not completely fill the volume between the mirrors. The second estimate for G is 10% per pass. Within the accuracy of the present measurements, the two estimated values of G are in agreement.

15.4 A Discharge Heated Copper Vapor Master Oscillator Power Amplifier, R. S. Anderson, B. G. Bricks, L. W. Springer, and T. W. Karras, *GE Space Sciences Laboratory, King of Prussia, Pa.*

(15 min)

The copper vapor laser emitting at 5105 Å and 5782 Å is potentially a high power, high efficiency visible laser. In practice, however, its efficiency has been limited by the energy required to vaporize copper and its output power has been limited by superradiant losses associated with the high gain of the laser. Recent experiments at our laboratories have attacked these two problems directly and have produced some interesting results.

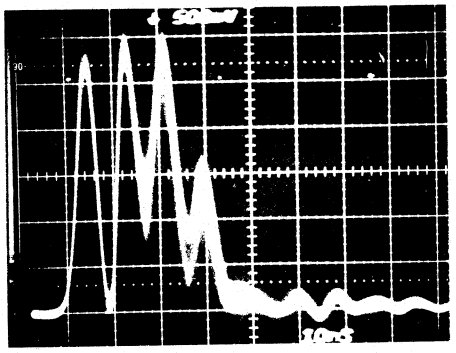

Fig. 1. 5105 Å laser pulse at copper densities $> 10^{16}$ cm^{-3}.

Copper lasers[1,2,3] generally require two sources of input energy. One source vaporizes the copper and the second source produces an electrical discharge and inversion in this vapor. The efficiency of the laser can be increased by using the electrical discharge energy to vaporize the copper, completely eliminating the first energy source. This type of laser, first demonstrated by Isaev,[4] has been built at our laboratories.[5,6]

This laser uses a high density alumina tube whose walls have been lined with thin copper foil. Refractory metal tubes inserted into both ends of the alumina serve as electrodes. This combination of electrodes and alumina tubes is surrounded by radiation shields and placed in a vacuum chamber such that buffer gases can be added inside the tubing while maintaining the outside regions at very low pressures.

An inductively charged capacitor bank is discharged between the electrodes through the buffer gas using a hydrogen thyratron as the switch. The discharge heats the alumina tube to temperatures up to 1800°C, producing copper vapor densities of 3×10^{16}/cm^3, the highest thus far reported in a copper vapor laser. This same discharge also produces a transient inversion in the copper producing very strong superradiance and lasing.

Using this design, a 2 watt average power copper laser operating at 6 kHz has been pro-

duced. This corresponded to a specific energy density of 40 $\mu J/cm^3$/pulse. The efficiency of the entire system was 0.2 percent considering all the input energy to the system. In addition, this laser has operated for periods of 12 hours unattended at power levels greater than 1 watt.

The discharge current pulses used in these experiments were long, varying between 125 nsec and 175 nsec. The laser pulse moreover, occurred within the first 25 nsec of the current pulse at a time when the current densities were 100 Amp/cm^2.

The laser pulse at low copper densities ($< 3 \times 10^{15}$ cm^{-3}) is approximately 20 nsec. FWHM with little structure, but as the copper density increases, the pulse assumes a modulated structure, and at densities greater than 10^{16} cm^{-3}, it is composed of four distinct 5-6 nsec spikes (Fig. 1). Interferometric studies of the laser indicate that each pulse is a slightly different frequency.

This laser is highly superradiant and indications are that a large fraction of the inversion energy is lost due to radial superradiance. To compound this problem, optical feedback is provided by the walls of the alumina tubing, further increasing radial losses. A Master Oscillator Power Amplifier (MOPA) configuration has been constructed to reduce the losses. In this configuration, a laser pulse from the oscillator is present in the amplifier when inversion is attained. The presence of the oscillator field results in stimulated emissions preferentially in the direction of this field. This produces amplification of the oscillator pulse, preventing radial superradiance losses, and permits higher extraction of the available energy in the amplifier compared to a simple oscillator.

This MOPA configuration has been initially tested using a low power oscillator (100 mW) with a pulse width of 20 nsec FWHM. The amplifier was very similar to the oscillator and produced 225 mW with a 20 nsec modulated pulse when operated as a laser. When operated in a MOPA configuration, the output power rose to 450 mW and the output pulse narrowed to a single 5 nsec peak.

This increase in output presumably was produced by stimulated emission of the inverted atoms along the optic axis which would otherwise have radially superradiated.

Further tests using a higher power oscillator and a higher gain amplifier are being conducted. Better synchronization of oscillator pulse and amplifier discharge will also be used. A substantial increase in specific energy density, laser power, and efficiency are expected.

Special thanks to B. Fox and T. E. Buczacki for their excellent help.

15.5 High Repetition Rate Flowing Copper Vapor Laser, B. G. Bricks, T. W. Karras, T. E. Buczacki, L. S. Springer, and R. S. Anderson, *GE Space Sciences Laboratory, King of Prussia, Pa.*

(15 min)

A flowing metal vapor laser suitable for high repetition rate, fast-discharge operation has been constructed and is now undergoing study.

The fundamental technology, originally reported elsewhere,[1] is based upon a copper vapor generator that provides the flowing metal. The generator consists of a thin graphite channel ($0.005'' \times 0.260'' \times 5.0''$) fed at both ends by reservoirs filled with copper. One side of the channel has an array of a large number of 0.015″ holes. Surface tension forces prevent the flow of liquid copper through the holes. When the generator is heated by currents above ~200 amperes, liquid copper flows from the reservoirs into the channel. Copper is vaporized at the hole array and flows into the optical cavity.

Neon is present as a buffer gas, and this reduces the flow so that vapor densities in the range of 10^{15}-10^{16} cm^{-3} can be maintained for periods of an hour. This gas also serves to carry the discharge.

Transverse discharge electrodes are oriented perpendicular to both the optical axis and the direction of flow of metal vapor. A low-inductance transmission line-vacuum feedthrough integrates the internal electrode configuration with the external discharge circuitry. In the design of the feedthrough, particular effort was taken to minimize the circuit inductance, to withstand the thermal loading, and to confine the electrical discharges to the laser cavity.

Oscillation is obtained by discharging a capacitor (0.5-20 nF) through a quenching spark gap switch.[2,3] This capacitor is run in bursts of 50-1000 pulses since it is pulse-charged by a 1.0 μF capacitor. With charging resistance < 3 KΩ, discharge rates above 100 kHz can be achieved. Also, with the 0.5 nF capacitor, discharge pulses of ~10 ns FWHM (as measured by Pearson Model 4100 current probe and Tektronix 7904 oscilloscope) have been obtained. It is observed that as long as the discharge time is less than that required for streamer formation, the discharge will fill a volume 10 cm × 0.6 cm in cross section and 1.4 cm long.

Lasing and supperadiant emission have been obtained at both 5105 Å and 5782 Å. Using a clear glass output mirror, pulse energies up to 10 $\mu J/cm^3$ have been measured. Increasing specific energy was found to correlate with increasing copper vapor density, current density, and initial capacitor voltage.

High repetition rate capability was also found to follow from increasing capacitor voltage. Thus, lasing could not be obtained at rates above a few kHz when the discharge voltage (5.0 nF) was ~2 kV. However, at 5 kV, the range was extended to 15 kHz with no reduction in the specific output energy per pulse. At this voltage, oscillation was also observed up to 70 kHz with a corresponding decrease in pulse amplitude.

The presence of Ne as a buffer limits the copper vapor flow velocity to about 200 cm/sec. Thus, the same copper atoms must be reused from pulse to pulse within a burst. Consequently, some mechanism is active in quenching the metastable lower laser state. We suggest that collisions of the second kind between electrons and the metastables are responsible for the quenching. Thus, for the conditions of Fig. 1, enough metastables were deexcited to allow attainment of laser threshold after ~14 μs and full deexcitation was reached after ~ 67 μs.

15.6 Frequency-Stable, Single-Mode CW Chemical Lasers for Mid-IR Heterodyne Applications, R. J. Freiberg and J. J. Hinchen, *United Aircraft Research Laboratories, East Hartford, Conn. 06108*

(15 min)

The multiline capability coupled with the mid-IR atmospheric transmission associated with CW chemical lasers, results in their being potentially very attractive sources for applications such as laser communications and frequency-diversity ladars. Moreover, in contrast to CO_2 lasers, chemical lasers require electrical energy only to initiate the chemical reaction rather than to sustain lasing. Consequently, with the inherently higher efficiencies available, potential reductions in the overall size and weight of the chemical laser and its peripheral electronics exist. However, mid-IR systems have not at the present time become serious contenders with 10.6 μ systems due to the unavailability of a suitable CW frequency-stable, single-mode mid-IR local oscillator required by the heterodyne receiver.

The present paper explores the feasibility of employing a low power CW, electrically initiated, chemical mixing laser[1] as a local oscillator for middle-infrared laser heterodyne applications. In the chemical mixing laser, atomic fluorine is produced by a dc electrical discharge in a flowing gas mixture of SF_6 and He. Molecular hydrogen or deuterium, which is subsequently mixed downstream in the subsonic gas flow, reacts with the atomic fluorine to produce the vibrationally excited lasing species. Laser power is extracted slightly downstream of the mixing region using a resonator whose optical axis is oriented transverse to the gas flow. Single fundamental mode operation is achieved by employing intracavity irises to discriminate against higher order transverse modes and by employing a cavity length which is sufficiently short such that only a single longitudinal mode can exist within the Doppler broadened linewidth.

The frequency stability of the chemical mixing laser output is limited primarily by the mechanical properties of the resonator in conjunction with the variations of the active medium initiated by the turbulent gas mixing. The long term frequency stability of these devices was investi-

gated using a scanning Fabry-Perot interferometer. The data consisted of multiple scans of a single Fabry-Perot fringe which were photographically recorded over various exposure times. The frequency variations exhibited by these multiple traces indicate that over a period of 1 sec, long term frequency stabilities of better than 3 parts in 10^8 are achievable with a relatively straight forward resonator design. Similar data obtained over shorter time durations indicated an approximate inverse square root dependence upon the observation time. For times shorter than 100 msec, the frequency stability was less than 1 part in 10^8 and could not be resolved by the present scanning Fabry-Perot technique.

The frequency spectrum produced by heterodyning two identical HF mixing lasers, both operating on P_2-1 (6), was displayed on a low frequency spectrum analyzer. The data indicated that the frequency stability of the present device is predominantly limited by the low frequency disturbances coupled to the mechanical resonator structure from the environment and not by the mixing within resonator medium. Consequently, significantly better frequency stability should be attainable by further sophistication of the resonator's mechanical properties before the influence of the active medium imposes limitations upon the device's performance.

To evaluate the suitability of these chemical lasers for applications such as laser communications, where frequency and amplitude stability is required over very long time periods, active stabilization techniques were investigated. A particularly attractive technique which was developed is that of locking the HF laser output to the minimum of the Lamb dip by using active dither stabilization. The laser cavity was tuned in frequency such that the dither was symmetrically applied about the minimum of the Lamb dip which was located at the center of the 300 MHz Doppler broadened gain curve. A comparison of the open and close loop performance of the chemical laser was made. In the open loop mode when the cavity length was changed due to thermal or mechanical influences, substantial variations in both the intensity and frequency of the laser were observed. However, when the laser was actively locked to the Lamb dip by means of an electronic servo system, the laser intensity and frequency remained constant within the limits associated with the dither stabilization over periods in excess of an hour and for a wide range of conditions.

Data will also be presented comparing the performance of a premixed, CW electrically-initiated, chemical laser[2] with that of the chemical mixing laser and the suitability of these CW chemical lasers as frequency-stable local oscillators for mid-IR heterodyne applications will be discussed.

15.7 Recirculating DF/HF Chemical Lasers Suitable for Portable System Applications,[1] P. P. Chenausky, R. J. Freiberg, and D. W. Fradin, *United Aircraft Research Laboratories, East Hartford, Conn. 06108*

(15 min)

The recent demonstration of a self-contained, pulsed recirculating DF laser (Ref. 2 and 3) has extended the range of potential applications for DF and HF chemical lasers. This device, which uses a unique combination of pellet beds to scrub the laser effluence directly in the gas flow channel, circumvents the safety and convenience problems associated with open-cycle operation. Furthermore, because a light weight gas blower can be used instead of the heavy vacuum pump required by conventional systems, the recirculating laser is well suited for portable operation. In this paper, work that extends the basic feasibility demonstration of Refs. 2 and 3 is described. The operating characteristics of the recirculating DF laser are investigated in detail, and various component design trade-offs are considered. A portable laboratory recirculating pulse DF laser system that uses unstable resonator optics and a specially designed flex-vane blower is described. Finally, it is shown that with proper modification the recirculating mode of operation is also feasible for certain types of CW DF/HF chemical lasers.

The design parameters for the scrubber beds are discussed as a function of average laser power, pulse repetition frequency and period of recirculating operation. In particular, experimental relationships relating required bed volume to total optical energy output are presented for various scrubber bed designs. Scrubber bed designs which are capable of rejuvenation are also considered. A comparison between recirculating pulsed laser operation with DF and HF is made. This data indicates that only slightly higher average powers are attainable from the HF system.

Using the basic pulsed laser design described in Refs. 2 and 3, a portable recirculating SF_6/D_2 laser system has been built. This laser, which operates at average power levels of about 1 W, contains a specially designed, light weight flex-vane blower. Unstable resonator optics are used with this device in order to extract substantially all the optical power available from a multimode stable resonator but in a single unstable resonator mode. High-resolution beam quality measurements indicate that near diffraction-limited operation has been achieved.

The feasibility of operating a CW DF/HF chemical laser in a recirculating mode is discussed. It is shown that a CW premixed SF_6/D_2 can be operated as a recirculating laser using a gas channel design that is fundamentally the same as that used with the pulsed DF chemical laser. Chemical scrubber beds and gas flow requirements are discussed. Possible designs for operating a CW SF_6/D_2 mixing laser in the recirculating self-contained mode are also considered.

The results of this work demonstrate that safe, fully portable DF/HF chemical lasers using the recirculating mode of operation can be developed. Such systems may considerably expand the range of applications for chemical laser technology.

15.8 A New Look at Unstable Resonators, C. Santana and L. B. Felsen, *Polytechnic Institute of New York, Brooklyn, N. Y. 11201*

(15 min)

Unstable resonators have traditionally been analyzed by numerical solution of the resonator integral equation. These numerical solutions have exhibited some very peculiar behavior of the eigenmode losses and eigenmode fields which have not been adequately explained. It has been realized that these peculiarities are intimately connected with diffraction caused by the edges of the mirror configuration, but it has not been possible to isolate and quantify edge diffraction effects in a simple way.

In an earlier paper,[1] it has been shown that the unstable resonator problem can be attacked by a new method whereby the resonator configuration is regarded as a waveguide in the direction transverse to the resonator axis. Guided modes capable of propagating in this waveguide are reflected, transmitted (by radiation) and coupled at the resonator edges, which thus appear explicitly as constituent building blocks in the eigenmode resonance equation. By postulating a mechanism of selective coupling between two adjacent waveguide modes, it was found possible to produce and explain the intricate interweaving of the resonator eigenmode loss curves obtained previously by what have been referred to as "brute-force numerical methods."[2] The same approach, but without the quantitative formulation of the mode coupling concept, was followed recently (and independently) in the Soviet literature.[3]

In the earlier work,[1] which dealt with sharp-edged cylindrical mirrors of hyperbolic shape, emphasis was placed on small equivalent Fresnel numbers N_{eq}; the analysis accordingly contained approximations (for example, the local modeling of the edge configuration) suitable for this range of parameters. An attempt was made to extend the range of applicability to moderately large N_{eq}. But to achieve agreement with the numerically produced data,[4] it was necessary to make some heuristic modifications of the formulas. While the results[1] predicted correctly

[4] R. L. Sanderson and W. Streifer, *Appl. Opt.*, vol. 8, p. 2129, 1969.

the intricate interweaving of the eigenmode loss curves, there was a question concerning the validity, or not, of the low-loss detached mode for sufficiently large N_{eq}.

To understand the cause of the difficulty in the earlier work[1] with respect to large values of N_{eq}, the analysis has been re-examined, with emphasis on two of the essential constituents that appear in the eignemode resonance equation: the waveguide mode reflection coefficient due to the modal caustic near the resonator axis, and the waveguide mode reflection coefficient due to the edges of the mirrors. Improved and more accurate formulas for both reflection coefficients have been developed. When these are inserted into the eigenmode resonance equation and the procedure described previously[1] is followed, it is found that the resonance curves for the uncoupled waveguide modes now are changed in such a way as to predict clearly the existence of a detached resonator eigenmode for sufficiently large N_{eq}. In the earlier study (see Sec. VI of ref. 1, the solution of the uncoupled-mode resonance equation did not exhibit unambiguously the possibility of eigenmode detachment whence the verification of that phenomenon was left unresolved. The present more accurate analysis confirms completely and quantitatively all aspects of the numerical solution of the resonator integral equation,[4] for small and large Fresnel numbers, without the need for heuristic assumptions. Thus, the original theory of Chen and Felsen[1] has been proved adequate for furnishing unstable resonator eigenmode behavior for small and large N_{eq} in terms of the simple model of either a single resonant waveguide mode (near eigenmode loss minima) or two coupled resonant waveguide modes (in high-loss regions). Numerical comparisons to that effect will be presented.

The theory has also been extended to circular mirrors of hyperbolic shape. The waveguide modes are now found to be solutions of Whittaker's differential equation. When a resonance equation for azimuthally symmetric fields is constructed by the method used for the cylindrical mirror case, and when caustic and edge reflection coefficients are calculated by the improved methods alluded to above, one finds that the solutions of the eigenmode resonance equation reproduce completely the curves of Siegman and Miller[5]; our analysis confirms the absence of a low-loss detached mode in this instance. It is to be noted that our improved method predicts naturally, and within the same basic framework, the existence of a detached eigenmode for cylindrical mirrors and the absence of such a mode for circular mirrors. This does not appear to be the case for other analytical procedures.[6]

The waveguide method can be extended to accommodate resonators filled with inhomogeneous media and with media exhibiting a gain profile. Necessary modifications of the analysis are discussed.

15.9 A 700 Meter Long Mode-Locked Argon Ion Laser,[1] P. P. Tripathi and R. H. Lovberg, *Institute of Geophysics and Planetary Physics, University of California, San Diego, La Jolla, Calif. 92037*

(15 min)

A visible argon ion laser, on the high gain 4880 Å transition, has been made to operate in a long vacuum optical cavity. Single frequency CW operation was achieved. The laser was also actively amplitude-modulated to produce mode-locked pulses, at a repetition rate of 204 kHz. Also, by utilizing electrooptical feed back[2] self-sustained mode-locked pulse opeartion was achieved.

The only other very long cavity lasers reported in literature[3,4] were operated at infrared wavelengths; Xenon at 3.508 μ, and Nd:YAG at 1.064 μ. These utilized long atmospheric cavities, and reflecting optics for beam expansion. It appears that in those experiments actively mode-locked pulses were not achieved; however in [4], evidence of self-locking of the modes in the pulsed Nd:YAG laser is indicated.

Our long laser project was undertaken as a feasibility study for making a device for measuring geophysical strain accumulated in the earth's crust. The basic principle of this device is the following: It is essentially a long laser of cavity length L in which the longitudinal modes separated in frequency by $c/2L$ are actively phase-locked with each other by utilizing electrooptical feed back. Then it becomes possible to measure L very precisely, by frequency measurement of a higher harmonic of $c/2L$, say at 100 MHz. A 10-second integration time can then produce data accurate to 1 part in 10^9. As opposed to optical interferometric method,[5] this device would preserve absolute strain value in case of a seismic event strong enough to cause power failure.

The present system consists of an approximately 700 meter long evacuated pipe with windows on the ends. Refractive optics are used for beam expansion and retro-reflection. (See Fig. 1.) Optical gain is provided by a conventional size (20 cm long × 2 mm bore diameter) laser discharge tube (Hughes 3066H Ar^+ laser head) located at one end. Because of many inherent sources of loss per round trip in the long laser configuration, a high gain laser medium is essential.

The frequency spacing ($c/2L$) of the longitudinal modes for this cavity is near 200 kHz, which is much less than the expected Lorentzian line width of 500 MHz for the Ar^+ laser transition; it can therefore be expected that the spectral cross-relaxation (CR) should be strong, inhibiting oscillation of all modes except one at the line center. However, initially, intermode beats at $n(c/2L)$ were observed for n up to 5. The appearance of these beats was rather random in time. This can be explained with the hypothesis of energy being pumped into these cavity modes because of the nonlinear coupling through the laser plasma, as the discharge current fluctuated with its inherent 60 Hz ripple. An additional experiment indicated that the amount of energy in these side modes was at least 5 orders of magnitude lower than the central mode. The intermode beats vanished and true single frequency operation was obtained on switching to dc supply for heating the laser cathode filament, eliminating the source of the 60 Hz ripple in the discharge current.

Intra-cavity Pockels cell was utilized to provide loss modulation at intermode beat frequency $c/2L$ (= 204 kHz). Mode-locked pulses of width 1 μsec at a repetition period of about 5 μsec were obtained. Modulation at c/L produced two pulse operation, and thus an effective repetition period of 2.5 μsec and a pulse width of 0.5 μsec.

These optical pulses were detected by a photodetector, amplified, properly delayed and fed back to the modulator, closing the feed back loop. Self-regeneratively driven mode-locked-pulse operation was achieved. This experimental evidence indicates that it is possible to further engineer this long laser into operating in its original concept of measuring the strain in the earth's crust.

16.2 Suppression of Relaxation Oscillation in Semiconductor Lasers, R. Lang and K. Kobayashi, *Central Research Laboratories, Nippon Electric Co., Ltd., Kawasaki-shi, Japan*

(15 min)

Semiconductor lasers are considered to be especially desirable sources for optical communication systems because of their unique characteristics including the ability to be modulated directly by varying the injection current. Direct modulation of the output intensity of a GaAs laser at a rate of 46 GHz has been reported.[1] However, the practical rate has been limited to several hundred MHz, owing to the serious distortion of the output signal caused by relaxation oscillations, or spiking, in the modulated output. We have analyzed various schemes for suppression of these oscillations and found that optical injection,[2] where a small amount of external radiation is continuously injected into resonant modes of the laser cavity, is quite effective.

Computer simulation indicates that the light injection can improve the response characteristics in pulse modulation in the following fashion: i) the height of the initial spike and the delay of the onset of lasing is reduced, ii) the residual relaxation oscillation damps faster. In addition, stabilization of the output wavelength is expected due partly to selective excitation of laser modes by the injected light.

The effectiveness of the light injection method has been confirmed in a series of experiments which employed two GaAs DH lasers. The two lasers (diode *A* and *B*) were excited by current pulses of 10 nsec duration, and a small portion of the output of diode *B* was fed into diode *A*. Care was taken to insure that diode *B* was lasing stably when diode *A* was excited. In Fig. 1 the output responses of diode *A* are compared. With light injection (upper trace), suppression of the relaxation oscillation is seen to take place. Typical output spectra are shown in Fig. 2. The spectra of diode *A* with and without light injection from diode *B*, having spectrum B_O, are denoted respectively as A_B and A_O. In A_B, spectral peaks appear in the wavelength region where the closest matching of the characteristics of the two diodes are attained.

In conclusion, the light injection method has been shown to be effective in suppressing relaxation oscillation. Although the small amount of optical injection sufficient for the effective suppression can be achieved without difficulty employing a separate laser diode as the external source, the alignment problem may be eliminated by using, for example, a double section diode with two independent optical cavities. With the use of this technique, the practical upper limit for the rate of direct modulation of semiconductor lasers is expected to increase greatly.

16.3 Spatially Coherent Radiation from an Array of Three GaAs Lasers—Phase Controlled or Free Running Mode,[1] E. M. Philipp-Rutz, *IBM Corp., Federal Systems Division, Gaithersburg, Md. 20760*

(15 min)

A spatially coherent GaAs laser with an external optical cavity and transverse mode control, using a single laser diode, has been described previously.[2] Also, a technique was reported[3] of phase coherent coupling three GaAs lasers in a monolythic array, with the objective of obtaining higher optical power in the spatially coherent mode. In this paper, the phase controlled mode of spatially coherent beam formation, reported previously,[3] is compared with the free running mode which recently has been verified experimentally. While in the phase controlled mode the far-field of the spatially coherent radiation is an interference pattern with the zero-order and also the first-

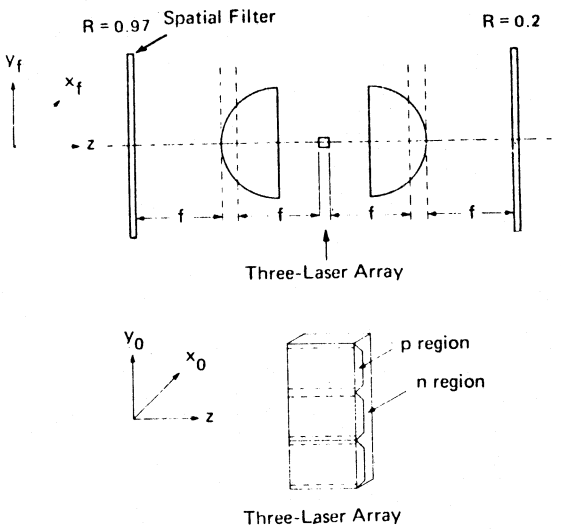
Fig. 1. GaAs laser device with three-laser array.



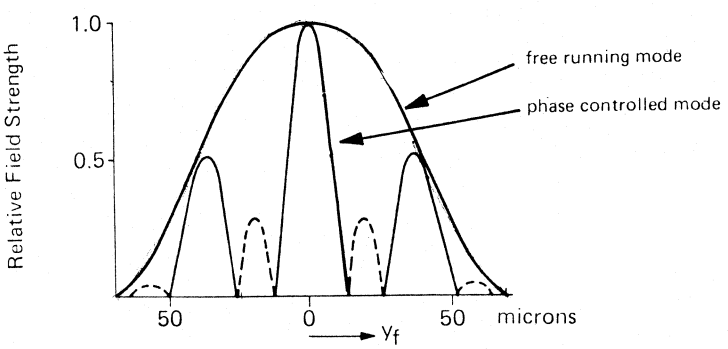


Fig. 2. Field distribution of three-laser array at second focal plane of internal lenses.

order grating lobes, in the free running mode the far-field has a single maximum and no grating lobes.

For spatially coherent radiation, the GaAs lasers in the monolythic array, with their mirror faces antireflection coated, are operated with an external optical cavity. The cavity is built of spherical lenses and plane mirrors, as shown in Fig. 1. The laser array and the plane mirrors are placed at the focal planes of the internal lenses. A spatial filter which selects the spatially coherent mode is formed by one or several highly reflecting strips on one of the plane mirrors of the cavity.

The transverse mode control makes use of the Fourier transform property of the lenses in the optical cavity. The transformation of the field of each laser in the array by the internal lenses, yields the identical amplitude distribution at the second focal plane. Since the waves from the lasers in the array, at the second focal plane of each lens, occupy the same space, the resultant field distribution is determined by the phase relations among the waves. When the waves are all in phase, their superposition at the second focal plane will result in an interference pattern, as shown in Fig. 2. (Fig. 2 was computed for an array of 3 lasers where the junction of each laser is 180 microns wide and the spacing between centers is 230 microns.)

To select the phase controlled mode of the three laser array, a spatial filter is used in the external optical cavity, formed by three gold stripes of 25.5 microns width which are spaced 12.5 microns apart. The spatial filter reflects only the dominant in-phase components of the interference function in Fig. 2. The Fraunhofer diffraction pattern of the laser array, when restored by an external lens, is similar to the interference function in Fig. 2.

For most system applications, the energy contained in the first-order grating lobes cannot be utilized. In the phase controlled mode the off-axis lobes cannot be eliminated, though, by making the spacings between lasers smaller, the energy in these lobes can be reduced. The free running mode of a laser array yields a single spatially coherent beam without grating lobes. To select the free running mode a spatial filter is used in the optical cavity which only controls the field of each laser to be in the lowest order transverse mode; it does not influence the phase angles of the fields. The spatial filter at the second focal plane of one of the internal lenses, is formed by a single gold strip of 120 microns width. The spatial filter reflects nearly the entire field of each of the lasers in the array. This type of spatial filter which does not reproduce an interference function, does not exert any control other than the transverse mode selection. Without control the longitudinal modes of the laser array with the external optical cavity, have slowly varying amplitudes and phase angles. These variations are random. The fluctuations of an optical field, resulting from the summation of randomly phased, monochromatic waves with randomly varying amplitudes, are completely random. The random fluctuations of the optical fields of the lasers in the array prevent the formation of a stationary interference pattern. The field distribution at the output mirror of the optical cavity is that shown in Fig. 2.

The Fraunhofer diffraction pattern of an array of lasers in the free running mode, when restored by an external lens, has a single beam along the optical axis of the internal lenses and no grating lobes.

We have synthesized the far-field distributions of the laser array in our laboratory by the use of two external lenses. The synthesized far-fields of the three laser array in the phase controlled mode and in the free running mode were measured. They are similar to the distributions in Fig. 2. In both modes the optical peak pulse power, measured at room temperature, was close to 5 watts; 3 times the power of a single laser in the array.

16.5 Packaged Semiconductor Lasers for Optical-Fiber Transmission, M. Takusagawa, K. Hori, H. Ishikawa, H. Takanashi, T. Toge, and T. Kudo, *Fujitsu Laboratories Ltd., Kawasaki, Japan*

(15 min)

In the application of semiconductor lasers to optical-fiber transmission, it is important to obtain stable laser output power for long times over a wide temperature range. Since the light emitted from the semiconductor laser goes in two directions it is possible to use the output from one end as the transmitted signal and from the other for feedback control through the operating current or temperature. A new method of packaging semiconductor lasers which is appropriate to obtaining constant laser output power has been developed. The method of packaging has been presented elsewhere.[1] This paper describes the characteristics of the packaged laser, the methods of automatic optical-power control, and the results obtained.

GaAlAs DH laser was packaged with a fiber F_s for signal transmission and a fiber F_c for signal monitoring. The two fibers are directly coupled with the DH lasers. We used F_s and F_c with numerical apertures of 0.14 and 0.5, core diameters of 90 μm and 570 μm, and lengths of 10 cm and 6 mm, respectively. The curves of output from F_s and F_c vs diode current were similar. The DH lasers used were modified stripe-geometry planar structures whose stripe width was 15-30 μm.[2] The wavelength was 0.80-0.85 μm. The lasers operate stably over 5000 hrs with very slight increase of threshold current when the output from F_s is larger than 1 mW. Several packaged lasers exhibited stable operation for over 3000 hrs. Significant relative changes were not observed between the output from F_s and that from F_c. The characteristics of the long lived packaged lasers will be shown.

We examined two methods of automatic optical-power control, namely, control of operating current and control of operating temperature by changing the current of thermo-electric elements on which the packaged laser was mounted. The output from F_c was detected by a photodiode and the signal compared with a given standard voltage. The current of the laser diode or the thermo-electric elements was controlled to give a zero voltage difference with the reference.

In the control of operating current of the laser diode, constant output at room temperature ($\sim$1 mW) has been obtained from F_s for over 1000 hrs. When the temperature of the packaged laser was changed from 10 to 70°C, low thermal-resistance diodes showed constant output ($\sim$1 mW) from F_s by the automatic optical-power control technique.

In the control of operating temperature, the fluctuation of the output from F_s was kept below 5% with the environmental temperature range of 10 to 40°C. In this temperature range no change was observed in a light pulse waveform modulated at 100 Mb/s. The thermal response time of the experimental system was about 200 sec which was good enough to follow the slow change of optical power.

The comparison between the two methods will be discussed.

16.6 Progress in Nd-Pentaphosphate Lasers, H. P. Weber, B. C. Tofield,[1] and P. F. Liao, *Bell Telephone Laboratories, Holmdel, N. J. 07733*

(15 min)

Nd-pentaphosphate (NdP_5O_{14}) is a high Nd-concentration material, well suited for fabrication of miniaturized optically pumped lasers.[2] We report here new results concerning material characteristics and laser properties.

A direct measurement of energy-diffusion distance is reported, based on a novel measurement technique.[3] An upper limit of 32 nm along the supposedly fast migration direction[4] is determined. This value is too small to significantly influence laser emission.

The quasi-orthorhombic symmetry of the crystals is shown to undergo a second order phase transition into orthorhombic symmetry

at 174°C. The transition is directly observed by the disappearance of the twin boundaries at that temperature. At room temperature, ferroelastic movement[5] of the twin boundaries is observed. A shear stress of σ = kN/m^2, produces this ferroelastic reorganization. This stress is two orders of magnitude lower than has been reported for any other material and allows undesired twin boundaries to be easily removed mechanically.

A CW NdP_5O_{14} laser was pumped with a Kr laser and had a threshold of 1.6 mW. By monitoring the fluorescence light a precise value for the internal quantum efficiency, η can be obtained, yielding for this laser $\eta = 63\%$.

Bistable operation between oscillating and nonoscillating regimes was observed as a result of a thermal lens created in the pumped zone. If feedback is temporarily blocked during pumping, this lens becomes strong and makes the nearly concentric Nd laser resonator unstable, so that stimulated emission cannot build up after removing the blockage. If the pump beam is temporarily blocked, the crystal cools and when the blockage is removed, laser action is reinstated. The resonator then remains in the stable regime, because the stimulated emission competes with nonradiative quenching processes (cooling effect via stimulated emission). The temperature increase above room temperature for the two situations is measured using Raman spectroscopy. From the intensity variation of an anti-Stokes line of a probe beam, temperature increases of 18° and 11°C for the nonlasing and lasing situations are established. From these values we determine a fluorescence quenching rate of 68% for the upper laser state. This number is in close agreement with the value of 62.5% found by interpretation of lifetimes for different x in $Nd_xLa_{1-x}P_5O_{14}$ and supports observed concentration independence of the emission cross section.[6] It is in disagreement with suggested[4] lifetime shortening due to increased emission cross section when $x = 1$.

Heat development per unit volume in $Nd_{0.5}La_{0.5}P_5O_{14}$ would be reduced by 2/3; whereas because of reduced quenching, the small signal gain for equal pump power should be twice as high. These facts together with the absence of any advantage due to strong energy diffusion in undiluted NdP_5O_{14} renders the less concentrated material more attractive for device applications.

16.7 Low - Threshold, Transversely - Excited NdP_5O_{14} Laser,[1] S. R. Chinn, J. W. Pierce, and H. Heckscher, *Lincoln Laboratory, MIT, Lexington, Mass. 02173*

(15 min)

We have measured room-temperature CW lasing thresholds of NdP_5O_{14} (NdPP) excited by a dye laser. The pump beam was incident on the sample in a direction perpendicular to the lasing axis, simulating the geometry for excitation by a narrow-junction, edge-emitting LED or laser diode.

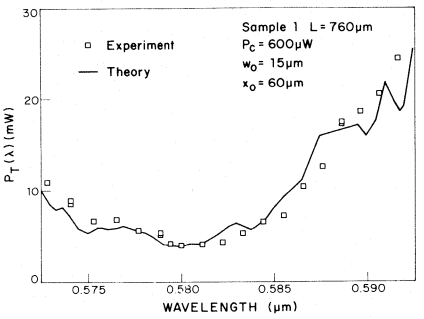

Fig. 1. Experimental and theoretical transverse pump threshold, $P_T(\lambda)$, as a function of wavelength near 0.58 μm for NdPP sample #1, 760 μm long.

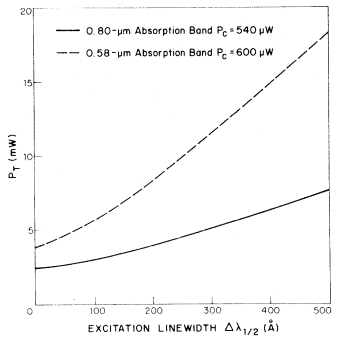

Fig. 2. Theoretical transverse pump threshold vs. FWHM excitation bandwidth, $\Delta\lambda_{1/2}$, for NdPP sample #1 using a tightly focused pump beam.

The NdPP laser crystal was located at the center of a nearly-spherical optical cavity having mirrors with nominally 100% and 99.7% reflectivity at the lasing wavelength, 1.052 μm. The pump radiation was focused on the side of the sample by two crossed cylindrical lenses to form a narrow line image parallel with the NdPP laser mode. By tuning the Rhodamine 6G dye laser about the wavelength of peak absorption at 0.580 μm, we have measured the threshold as a function of pump wavelength from 0.575 to 0.590 μm. Typical minimum thresholds were 4 mW at the absorption line center, increasing to 25 mW at wavelengths 0.01 μm away (Fig. 1). With 20% duty-cycle, quasi-CW excitation, we have measured power conversion efficiencies ~8% at output powers ~3 mW.

Using a simple theoretical model, we have obtained a good fit to the experimental data for threshold vs pump wavelength. In this treatment, the calculated transverse threshold, $P_T(\lambda)$, was normalized to the experimentally measured collinear-pumping threshold at 0.58 μm, P_C (typically six times smaller than the transverse value). Using measured values for the pump absorption coefficient, and adjustable parameters for the laser mode waist, w_0, and depth, x_0, inside the crystal, we calculated the values of $P_T(\lambda)$ shown in Fig. 1 (the results were relatively insensitive to the choice of w_0 and x_0 over a wide range of these parameters). This analysis was then used to calculate thresholds for wider-bandwidth pump sources, such as LED's or laser diodes, emitting near 0.80 μm, a favorable wavelength for electro-luminescent device operation and the location of the strongest absorption band in NdPP. The threshold vs pump bandwidth calculations for the dye-laser configuration are shown in Fig. 2. Taking account of the larger pump beam divergence from a semiconductor light source placed next to the laser crystal, it is estimated that thresholds ranging from 4 mW for an extremely narrow-band laser pump, to 8.5 mW for a 300 Å (FWHM) bandwidth LED, should be attainable with our present 760 μm long NdPP sample.

We have also succeeded in lowering the threshold and increasing the laser efficiency by using a thin NdPP sample mounted on an aluminized surface which reflected any transmitted pump radiation back into the sample. With this arrangement a transverse threshold (at 0.58 μm) of 2.7 mW was obtained, with a reduction of 60% in the ratio of transverse/collinear threshold. A sample only 36 μm thick also lased in this configuration, indicating a possible compatibility with integrated optical technology.

In preliminary experiments, we have obtained laser action in NdPP using a single $Al_xGa_{1-x}As$ laser diode provided by RCA. The diode was cooled to obtain the desired 8000 Å wavelength, and driven by 300 μs current pulses to avoid heating. This pulse length was sufficient to produce quasi-CW NdPP lasing. The pump radiation was collected by a single f/.9 lens and focused transversely on the room-temperature NdPP sample, mounted as described above. Because of the non-optimum diode dimensions and collection optics, the overall performance was degraded. Nevertheless, we have obtained thresholds of 12.4 mW for the thick 760 μm long sample and 7.2 mW for the thin sample described above. The respective optical power conversion efficiencies were 7.5% and 6.8%. Detuning the pump wavelength to 7930 Å increased the threshold for the thin sample only to 7.9 mW, in good qualitative agreement with the wavelength dependence described by our theory.

16.8 CW Laser Operation of $LiNdP_4O_{12}$ by Transverse Pumping, T. Yamada and K. Otsuka, *Musashino Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corp., Musashino-shi, Tokyo, Japan*

(15 min)

One of the laser materials in which the Nd ion is a constituent of the compound[1] is lithium neodymium tetraphosphate ($LiNdP_4O_{12}$, abbreviated as LNP). The crystal belongs to the monoclinic system (pseudo-orthorhombic system). The Nd content is 4.37 × 10^{21} cm^{-3} and

[1] This work was sponsored by the Department of the Air Force.

[1] T. Yamada, K. Otsuka, and J. Nakano, *J. Appl. Phys.*, vol. 45, Nov. 1974.

TABLE I
CRYSTAL DIMENSIONS AND OBSERVED CHARACTERISTICS OF LNP LASER

dimensions (mm)								
l	t	w	P_{th}	ω_0	L_c	η	σ_s	σ_1
2.57	0.44(2)	2.0	168 mW	61 μm	0.10(3)	0.37(5)	0.04	3.0×10^{-19} cm^2
3.67	0.44(5)	2.0	196	66	0.12(1)	0.40	0.04(5)	3.3×10^{-19}

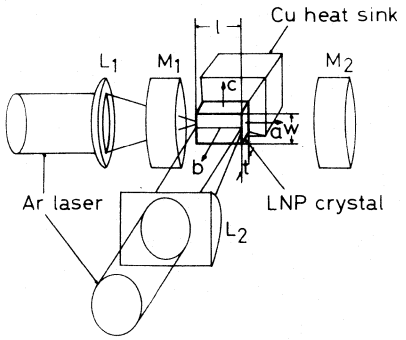

Fig. 1. Experimental arrangement of CW LNP laser.

the fluorescent lifetime is 120 μs at room temperture. The single crystals of about $5 \times 5 \times 5$ mm^3 have been obtained by the top-seeded Kyropoulos method from a melt.

The largest effective emission cross section at the line peak [1.047(7) μm] was spectroscopically determined with a 25 μm thick plate, employing the method described by Singh *et al.*,[2] as 3.2×10^{-19} cm^2 for the electric vector parallel to the pseudo-orthorhombic c-axis.

The present paper reports the characteristics of LNP CW laser transversely pumped with Ar laser to know the power requirement of LED to lase LNP.

Two polished crystals with different lengths were used for the experiment (Table I). The experimental setup as well as the crystal mounting are shown in Fig. 1. The laser cavity consisted of mirror M_1 [radius curvature r_1 = 20 cm, transmittance at 1.047(7) μm T_1 = 0.1, 1%] and mirror M_2(r_2 = 9 cm, T_2 = 0.1, 1, 2%) separated by about 9 cm. The crystal was placed just in front of M_1 and pumped by Ar laser (5145 Å) longitudinally or transversely through a circular lens L_1 or a cylindrical lens L_2. The transverse pumping efficiency η was measured by the ratio of threshold P_{th} between these two pumping geometries. The spot size ω_0 was approximately determined by using the equation $\eta = 2 \sinh (2.1\alpha\omega_0) \exp(-\alpha D)$, where α is the absorption coefficient of pump light and D is the distance between the crystal surface and the center axis of the oscillating beam. Here, α is 23 cm^{-1} for the light polarized along c-axis and D was 200 μm. The round-trip loss L_c was directly measured by the change of threshold with T_1 and T_2.

The results obtained are shown in Table I, where T_1 and T_2 were fixed as 0.1 and 1%, respectively. In Table I, σ_s is the slope efficiency and σ_1 is the effective emission cross section calculated using the listed data. The values of σ_1 agreed with that obtained spectroscopically.

The LNP laser emission was linearly polarized along c-axis.

The propagation loss of the lasing crystal α_c was calculated from the two measured L_c as 0.0084 mm^{-1}, which is mainly attributed to the self-absorption of inverse $^4I_{11/2} \rightarrow {}^4F_{3/2}$ transition.

Comparing the threshold of the two crystals, the threshold power per unit crystal length p_{th} was found to decrease from 65 mW/mm to 53 mW/mm, because $p_{th} \propto \alpha_c + \beta_c/2l$, where β_c is the transmission loss of the cavity mirrors plus the diffraction loss and l is the crystal length.

Since the absorption coefficient of LNP, as in the case of NdP_5O_{14},[3] is about 30 times higher than that of Nd:YAG, the Nd-compound laser transversely pumped by LEDs is considered to be a candidate as a light source in an optical communication system. From the data in Table I the optical power of LEDs to lase a 5 mm LNP crystal is calculated as 30 mW/mm ($\omega_0 \approx 70$ μm).

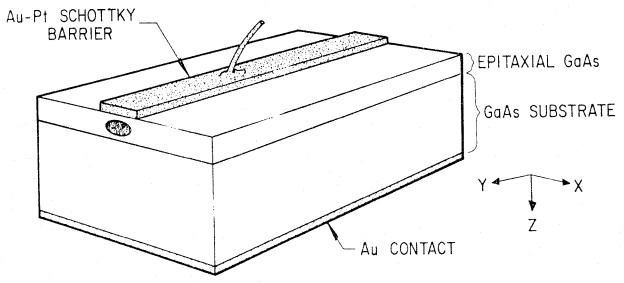
Modulators, Parametric and Nonlinear Optical Devices

Chairman: J. A. Giordmaine, *Bell Laboratories, Murray Hill, N. J.*

17.1 GaAs Electrooptic Channel-Waveguide Modulator, J. C. Campbell and F. A. Blum, *Texas Instruments Incorporated, Dallas, Tex. 75222*
(15 min)

We report a new type of high-speed GaAs channel-waveguide modulator for integrated optical circuits (IOC's). These devices utilize the electrooptic effect to (1) confine light in the vicinity of a narrow Schottky-barrier strip and/or (2) modulate the trapped beam.



A schematic diagram of the electrooptic channel-waveguide modulator is shown in Fig. 1. A planar asymmetric waveguide is formed by growing a 2-3 μm thick, lightly-doped ($N_d \sim 10^{15}$/cm^3) GaAs epitaxial layer on a heavily-doped ($N_d \sim 10^{18}$/cm^3) {100} GaAs substrate. Schottky barriers are then made by opening narrow strips parallel to the y axis (see Fig. 1) in an oxide mask using standard photoresist techniques and selectively electroplating Pt-Au contacts. For the crystal orientation indicated in Fig. 1, GaAs is biaxial i.e., if an electric field is applied in the z direction, the electrooptic contribution to the refractive index, for a wave polarized along x is

$$\Delta n_{eo} = (n_0^3 r_{41} E_z)/2$$

where r_{41} is the linear electrooptic coefficient and E_x is the electric field strength. At zero bias, light propagating in the epitaxial layer spreads out laterally along the x direction. When the Schottky-barrier strip is reverse biased much of the light coupled into the waveguide is trapped under the metal contact, (Fig. 1) because of the electrooptic contribution to the refractive index in that region. This scheme permits confinement in the x direction as well as the z direction thus forming a channel-waveguide. If the applied voltage is modulated, the signal seen by a small aperture receiver such as an optical fiber is amplitude modulated.

Light is coupled into the waveguide by focus-

Fig. 1.

ing a 1.06 μm Nd:YAG laser beam onto the cleaved edge of the waveguide. To observe the electrooptic channeling effect, a magnified image of the near field intensity pattern at the waveguide output is focused on an infrared vidicon and displayed on a T.V. monitor. When the input laser beam is focused directly underneath the Schottky barrier at zero bias, little light emerges from the waveguide because of the high attenuation associated with the Pt-Au contact. When 40 V reverse bias is applied to the Schottky barrier, the output intensity increases by a factor of 18. A loss coefficient of 3-8 cm^{-1} has been determined for these waveguides by measuring the transmission of several lengths of the same sample.

The time response of an electrooptic channel waveguide operating as a modulator is determined by focusing the output on an RCA 7102 photomultiplier and driving the device with a delay line pulser having a 2 nsec rise time. A phototube limited rise time of 5 nsec has been measured for a 21 μm wide device implying a minimum bandwidth of 150 MHz. The combined capacitance of this modulator and the transistor header to which it is attached is 7 pF. This gives an RC time constant across 50 Ω of 0.35 nsec and a projected bandwidth of 900 MHz. The actual device capacitance is estimated to be 5 pF, yielding an ultimate bandwidth limitation of 1.2 GHz. With a reverse bias of 40 V, the modulator current is less than 1 mA. For the measured bandwidth of >150 MHz, the required modulator power per unit bandwidth is <300 μW/MHz.

17.2 Electrooptic Modulation in Grain-Oriented ZnO Films,[1] Chenming Hu, *Massachusetts Institute of Technology, Cambridge, Mass. 02139*

(15 min)

Most of the waveguide electrooptic modulators that have been reported to date involved the use of single crystal films.[2] It appears that sputtered or evaporated polycrystalline films would be easier to fabricate and more versatile in forming composite systems with other optical films or metal electrodes. Gia Russo *et al.*[3] have investigated sputtered $LiTaO_3$ modulators and found that the effective electrooptic coefficients of the films were only a few percent of the single crystal value, presumably due to the randomness of the polycrystalline structure.

However, many materials, notably ZnO and CdS, are known to form grain oriented polycrystalline films, usually with the *c*-axis of the crystallites perpendicular to the substrate (Fig. 1). This is the case whether the substrate is glass, single crystal, or metal.[4] Utilizing this fact, it

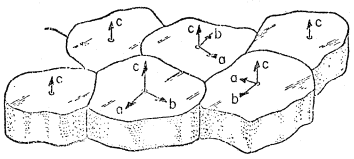


Fig. 1. Grain oriented polycrystalline film.

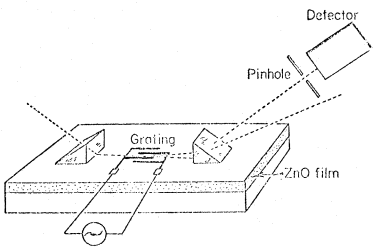
should be possible to construct polycrystalline modulators that have nearly the same electrooptic coefficient, and voltage and power requirement as single crystal modulators.

We have sputtered a series of ZnO films on glass slides under varying conditions in a dc diode sputtering system. Besides the usual parameters such as pressure and sputtering rate, the temperature of the substrate during the sputtering process was found to be an important parameter. Heating the substrate to 300°C resulted in highly aligned films, which also had lower waveguide losses. X-ray diffraction studies indicated that the *c*-axes of the crystallites were 97% aligned within two degrees. The optical waveguide loss was around 25 dB cm^{-1} at 6328 Å and could be reduced to 10 dB cm^{-1} by slightly polishing the film surface.



On the surface of a rather thick ZnO film (1.8 μm) we defined a silver interdigital electrode having 8 μ line width and 1.2 mm long by a photoresist-lifting technique. Both the thick film and the silver metal were chosen to minimize the effect of the electrodes on the waveguide modes. A 6328 Å laser beam was coupled into the TEO mode (Fig. 2), directed to pass under the electrode at the proper Bragg angle, and then coupled out by a second prism. The transmitted and diffracted beam intensities were measured as functions of the applied voltage. The results were fit to the formula

$$\frac{I_{diffracted}}{I_{incident}} = \left(\frac{\pi L}{2\lambda} n_0^3 \gamma_{13} E_3\right)$$

to determine the electrooptic coefficient γ_{13}. Because of the uncertainty in E_3, γ_{13} could only be estimated to be 1×10^{-12} m/v, which is close to the bulk value of 1.4×10^{12} m/v.

In order to measure the electrooptic coefficient more accurately the ZnO film should be sandwiched between two electrodes and, probably, buffer films. Such geometry will also result in more savings of the modulator power requirement.

Fig. 2. Modulator configuration.

17.3 Resonant Piezo-Electrooptic Modulation, D. Halido[1] and Raoul Weil, *Technion-Israel Institute of Technology, Haifa, Israel*

(15 min)

Resonant Piezo-electrooptic (RPEO) modulation is achieved when an electrooptic modulator is operated at its piezo-electric resonance. The resonant frequency is a function of the material properties and the geometry of the modulator. When a device is operated in this mode, full modulation can be achieved with several orders of magnitude less voltage than needed in the usual electrooptic mode. Because the device is resonant, it has a narrow bandwidth.

In a previous paper[2] an experimental study of RPEO modulation was presented along with a one dimensional theory. The theory gave only order of magnitude agreement with the measurements on samples of the geometry used. In the present paper, experiments are reported of measurements on samples which have plate geometry (sides greater than 10 times the thickness) and for which the one dimensional theory actually applies. This allows us not only to verify the soundness of the theoretical model, but also to determine one of the elastooptic coefficients. Furthermore, the effect of mechanically loading the samples is studied with a view of looking at the increase in bandwidth obtainable by this method. Finally it is shown that the RPEO modulator does not require an external oscillator to drive it.

Experiments were performed on the modulation of a CO_2 laser beam. The modulating single crystals were suitably oriented plates of semi-insulating GaAs.

The effect of applying "heavy" electrodes (silver paint) on a crystal was calculated by use of an electrical equivalent circuit obtained through the application of the schemes described by Mason[3] for piezo-electric crystals. Measurements were made of the Q of the crystal and of the voltage, V_π, at which the samples become optical half wave plates, as a function of electrode thickness. A good fit was obtained between the experimental and calculated curves. Specifically, the V_π curves show a flat region in which the crystal's own attenuation is the dominant factor, and a linear region where the attenuation increases linearly with electrode thickness. An increase of electrode thickness from 7 microns to 40 microns of silver paint resulted in a bandwidth increase from 300 Hz to 3200 Hz in a crystal whose resonant frequency was 1.4 MHz. The half wave voltage increased from 5.0 volts to 61 volts. The accuracy of the measurements was $\pm 10\%$. The same crystal, operated as a wide band electrooptic modulator, would have a V_π of 5000 V.

Our measurements also yielded a value of

$(8.6 \pm 1.3) \times 10^{-2}$ for the elastooptic coefficient p_{44} of GaAs at 10.3 μ and room temperature. This is consistent with, but more precise than, the value of $(9.9 \pm 5) \times 10^{-2}$ obtained from measurements by Carleton and Soref.[4]

In principle, because the modulator crystal is operated at resonance, it can be used as both the load and the controlling element of an oscillator circuit. To verify this, a simple one transistor oscillator was built. It is shown that, optically, the performance of the RPEO modulator is the same when self or externally driven. As expected, self drive also prevents drift from the resonant frequency.

17.4 High Repetition-Rate (kHz) Lithium Iodate Optical Parametric Oscillator,[1] E. O. Ammann, *GTE Sylvania, Mountain View, Calif. 94042*

(15 min)

Lithium iodate has previously been used successfully in optical parametric oscillators by several different workers.[2-5] Past oscillator experiments have utilized flash-pumped lasers to pump the oscillator, and hence operation has been limited to relatively low pulse repetition rates. In this paper, we report on a lithium iodate optical parametric oscillator operating at kHz pulse repetition rates. This oscillator has yielded the first substantial average output powers ob-obtained from a lithium iodate parametric oscillator.

The configuration used for the oscillator is shown in Fig. 1. An internal oscillator configuration[6] is employed, with the lithium iodate crystal placed inside a Nd:$YA1O_3$ laser operating at 1.08 μm. The laser is continuously pumped by two krypton-arc lamps and is repetitively Q-switched by a fused quartz acoustooptic Q-switch. Three different lithium iodate crystals have been employed; each is 15 mm long and has AR coati: gs on its faces. Rotation of the lithium iodate crystal produces angle tuning of the oscillator. The oscillator resonator consists of two flat mirrors which are separate from the crystal and which are independently adjustable. The oscillator mirror separation is approximately 19 mm.

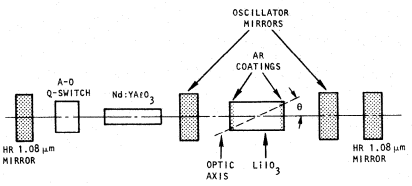

Fig. 1. Configuration of lithium iodate internal optical parametric oscillator.

Parametric oscillation has been obtained both near degeneracy and well away from degeneracy. In the near-degeneracy case, a doubly-resonant configuration was used, with the left and right-hand oscillator mirrors of Fig. 1 being HR and 5% transmitting, respectively, in the 2.16 μm region. The lithium iodate AR coatings were centered at 1.3 μm. Strong parametric oscillation was observed, with average power outputs of up to 530 mW obtained (signal and idler combined) at a repetition rate of 5 kHz. For comparison purposes, the Q-switched laser output power was measured with all oscillator components in the laser cavity, but with oscillation extinguished. For this test, one of the laser HR mirrors was replaced by a 4% transmitting mirror. The 1.08 μm average output power obtained was 1.1 watts, which indicates that approximately 50% of the available 1.08 μm power is being converted to tunable oscillator output. The oscillator output was tuned via crystal rotation over the entire mirror reflectivity range from 1.98 to 2.37 μm. The output spectrum was quite broad, however, due to the nearly vertical slope of the tuning curve near degeneracy (Fig. 2).

Doubly-resonant lithium iodate oscillator experiments were also carried out in the 3 to 4 μm region of the spectrum using a second lithium iodate crystal (designated 2B). This crystal was fabricated at a slightly larger phase-matching angle than the first crystal. The mirrors employed were HR over the signal range (1.45 to 1.65 μm) and approximately 10% transmitting over the idler range. Rotation of the crystal provided continuous tuning of the output from 3.25 μm through 4.05 μm. The best average output power obtained thus far in this range is 50 mW at a 5 kHz repetition rate.

Measured and calculated tuning curves for the lithium iodate parametric oscillator are shown in Fig. 2. The measured points were obtained from oscillator experiments and from sum-frequency generation experiments utilizing the output from a lithium niobate parametric oscillator.[6] The slight offset of about 0.1° between the curves for the two lithium iodate crystals used is within the 0.15° accuracy with which their orientations are known. The calculated tuning curve makes use of unpublished Sellmeier equations of Byer and Herbst.[7]

Experiments have also been carried out using 15 mm long crystals in which we attempted (unsuccessfully) to obtain parametric oscillation in the 4.5-4.9 μm region. These experiments are being continued using longer crystals, and using multiple crystals. The results of the continuing experiments will be reported.

17.5 Generation of Frequency-Stable, Narrow-band Optical Pulses by High Gain Parametric Amplification, G. A. Massey and J. C. Johnson, *Oregon Graduate Center, Beaverton, Oreg. 97005*

(15 min)

This paper describes a method of obtaining brief, intense pulses with narrow spectral linewidths, diffraction-limited divergences, and accurately controlled frequencies, by amplifying the output of a low power reference light source in a traveling-wave parametric amplifier. Using intense pump pulses at 266 nm (the 4th harmonic of the Nd:YAG laser) in crystals of ammonium dihydrogen phosphate, it has been demonstrated that traveling-wave gains as high as 10^{11} per pass at visible frequencies can be achieved.[1,2] Previously these high gains have been used to produce beams of nearly collimated parametric fluorescence, but light generated in this manner typically has had a spectral spread in the range 0.5 to 5 nm. However, the effective fluorescence noise input in these amplifiers is of the order of 10^{-6} W or less, and it is therefore easy to obtain an external optical signal input which exceeds the zero-point noise by several orders of magnitude, even on a continuous basis, from gas or dye lasers. We have used this approach to produce frequency-stable pulses from 438.5 nm to 676.4 nm by injecting CW gas laser signals into an ADP parametric amplifier pumped by 10 nsec pulses at 266 nm.

Table I shows the results of preliminary experiments. Input light was obtained from transitions of a mixed-gas Ar-Kr ion laser and from a He-Ne laser. The spectral spread of the pump was about 3 GHz, and that of the gas laser varied from 1.5 GHz for Ne to about 8 GHz for one of the Ar lines. The pump light was focused to produce a gain of 10^5 to 10^6 in a 6-cm ADP crystal. The visible output pulse lengths were between 1 and 2 ns, with bandwidths less than 0.01 nm, and the beam was diffraction limited. Since both signal and idler frequencies are generated, a new "complement" wavelength at the difference frequency between the pump and the input frequencies appears in the output. In each case output measurements were performed on the complement line to avoid interference with the CW input.

This technique has obvious applications in radar and in pulse-probe experiments in which coherence must be preserved between an exciting pulse and a probe signal applied later to the system under study.

We have performed similar experiments in which the input light was parametric fluorescence filtered by a Fabry-Perot etalon, and we are now beginning experiments with a mode-locked pump beam which will permit higher gains without optical damage to the amplifier.

17.6 A Tunable Collinear Acoustooptic Filter for the Intermediate Infrared Using Single Crystal Tl_3AsSe_3,[1] J. D. Feichtner, M. Gottlieb and J. J. Conroy, *Westinghouse Research Laboratories, Pittsburgh, Pa. 15235*

(15 min)

The tunable collinear acoustooptic filter was first proposed by Harris and Wallace[2] and later realized by Harris and his co-workers using $LiNbO_3$ and $CaMoO_4$.[3,4,5] Noncollinear and walkoff-type tunable acoustooptic filters have been investigated by Chang[6,7] and by Yano and Watanabe.[8]

The materials used for these first filters have limited applicability in the infrared for two reasons. The acoustic power density required for 100% transmission at band center increases as λ_0^2, and their acoustooptic efficiency is such that at the longer wavelengths this power density causes excessive heating. In addition, such oxide materials generally exhibit strong lattice absorption beginning at about 4.5 μm, becoming opaque at longer wavelengths.

Tl_3AsSe_3, a single crystal material of the sulfosalt group, was first investigated as a nonlinear optical material,[9] but we also found that like many materials of this group, its low acoustic velocity and high refractive index yielded favorable infrared acoustooptic properties. It also is one of a small number of single crystal materials with the proper symmetry (Tl_3AsSe_3 belongs to crystal class 3 m) for collinear tunable acoustooptic filter operation.

The filter was designed to operate in the reflection mode, as shown in Fig. 1. Collimated polarized light from the source at the right traverses an MgF_2 Rochon Prism, from which it enters the Tl_3AsSe_3 crystal, traveling parallel to the Tl_3AsSe_3 crystal *a*-axis. The light is reflected back from an evaporated aluminum layer at the far end of the crystal and reverses its path. Interaction with the phase-matched col-

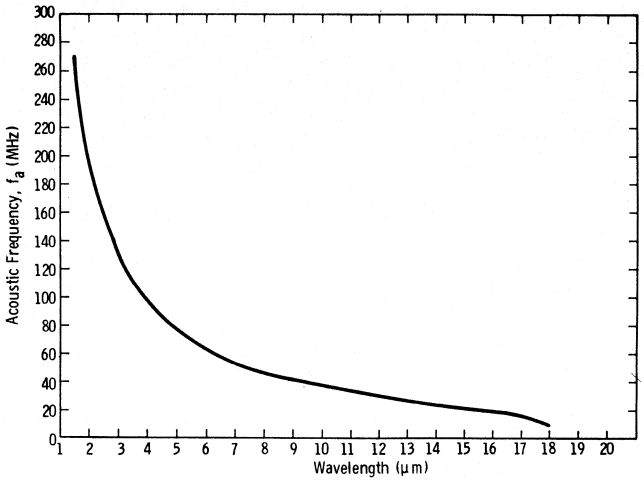

Fig. 2. Theoretical tuning curve for a collinear tunable acoustooptic filter based on Tl_3AsSe_3.

linear longitudinal acoustic wave, generated by a $LiNbO_3$ transducer bonded to the Al reflecting layer, diffracts part of the light beam into the orthogonal polarization. In retracing its path back through the MgF_2 Rochon Prism, this 90° rotated polarization component is spatially separated from the incident component, picked off by a mirror, and reflected to an InSb detector. The diffracted signal is displayed on an oscilloscope along with the pulsed acoustic signal applied to the transducer.

A tuning curve for the filter, calculated from the relation

$$f = \frac{v_{acoustic}(n_o - n_e)}{\lambda}$$

is shown in Fig. 2. It can be seen that tuning can be achieved over the range of transparency of crystal Tl_3AsSe_3 (1.3 μm to 18 μm) with acoustic frequencies ranging from about 300 MHz (at 1.3 μm) to 22 MHz (at 18 μm).

Experimental verification of the tuning curve has been achieved at two wavelengths, 3.39 μm and 5.3 μm. In the first experiment, a 40 MHz $LiNbO_3$ transducer operating on the 3rd harmonic at 120 MHz was used to tune the filter pass band to the 3.39 μm wavelength of a He-Ne laser. The measured required acoustic frequency of 115.65 MHz is in agreement with the value calculated. The acoustic power density required to give 20% transmission for 1.6 cm crystal path length at the peak of the filter pass band was 60 mW/mm², in order of magnitude agreement with the calculated value. This can be compared with the higher calculated required power density in $CaMoO_4$ for the same crystal path length of 133 mW/mm². In the second experiment, the frequency doubled output of a CO_2 laser, at 5.3 μm, was used as the infrared source. The measured acoustic frequency was 72 MHz, in agreement with the calculated value.

In the configuration of Fig. 1, the filter is potentially operable out to 7 μm, which is the limit of transparency of the MgF_2 prism. Efficient birefringent polarizing elements operating beyond 7 μm will be required if the filter is to be operated in the reflection mode at longer wavelengths. However, we have also designed mission-type filters using Tl_3AsSe_3.

Potential applications of a tunable infrared filter, which include infrared spectroscopy, pollution monitoring, and infrared laser frequency selection, will also be discussed.

17.7 Electrooptical Compensation for Self-Heating in CD*A During SHG, D. Hon, *Hughes Aircraft Co., Culver City, Calif. 90230* (15 min)

Self-heating in a second harmonic generating (SHG) crystal tends to disrupt the phase-matching (PM) condition and could cause serious output instabilities. This limitation of the power each crystal can handle is well known. The optical absorptivities of many crystals increase significantly *during* SHG. For CD*A, α exceeds 7% cm^{-1}! Even a preprogrammed oven could not manage this problem for input powers ≥5 or 6 watts, particularly in the presence of ambient temperature fluctuations. Our solution is electrooptical compensation. The E-O effect on SHG has been known.[1,2] In this paper. this principle is analyzed and its application in solving the self-heating problem in CD*A is reported.

The optimal orientation of CD*A (a KDP isomorph) for SHG is a 45° z-cut.[3] The 1.06 μ is polarized ⊥ to, while the 0.53 μ ∥ to the z-axis. An E-field ΔE applied in the z direction rotates the x and y axes by 45° in their own plane, and the new principal indices are

$$\begin{pmatrix} nx \\ ny \end{pmatrix} = n_0 \pm (n_0^3 \Delta E/2)(r_{63} + p_{66}d_{36}),$$

$$n_z = n_e \text{ (unchanged)} \quad (1)$$

where the symbols are standard.[4,5] If the ΔE pulse duration is short compared to the typical mechanical response time of the crystal bulk of 1-2 × 10^{-5} sec, contribution from the $p_{66}d_{36}$ term vanishes and one has a "clamped" E-O effect. (1) describes an electrooptical mechanism to fine-tune the SHG phase-match condition.

Pulsed E-fields were applied to the crystal synchronously with the laser pulses. The resultant SHG efficiency versus temperature curves are illustrated in Fig. 1. The E-fields translated the zero-field curve horizontally. Two families of curves were obtained for the two representative pulsewidths of ~200 ns (clamped) and ~200 μs (unclamped). From such SHG versus T curves, and with (1) and the familiar equation[4]

$$P_\omega^2/(P_\omega^2)_{max} = \sin^2(\Delta Kl/2)/(\Delta Kl/2)^2$$

for the relative SHG efficiency as a function of crystal length l and phase-mismatch $\Delta K = K_{2\omega}$, we obtained

Fig. 1. 200 μsec pulses. ΔE = 0, ±.85, ±1.8, ±2.75, ±3.25 kV/cm.

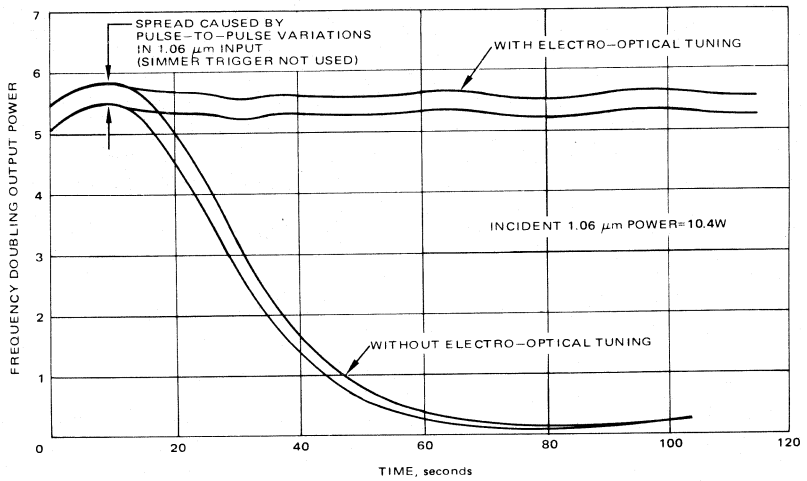

Fig. 2.

$$r_{63} = 14.1 \pm .4 \times 10^{-10} \text{ cm/V}$$

and

$$p_{66}d_{36} = 10.2 \pm .4 \times 10^{-10} \text{ cm/V}$$

for $T_{PM} \sim 102°C$, in good agreement with conventional measurements.

The 200 μs E-field pulses were modulated and the SHG output was monitored. A feedback loop was built which compensates electrooptically for self-heating in the crystal. A 0.52 J/15 ns/20 Hz laser was used with an uncoated 1 × 1 × 2 cm CD*A housed in a Hughes-built dry oven with maximum thermal conductivity and minimum thermal mass. The output normally vanished after one minute – long compared with other oven types (Fig. 2). But E-O compensation kept it steady indefinitely at an efficiency of 57% (Fresnel reflection considered). The response time of the loop was four times faster than the maximum self-heating rate of ~0.5°C/sec. The E-field range of ±5 kV corresponded to ±~3°C. But additional circuitry from the loop control the oven temperature to provide a total compensation range of 20°C. Ambient fluctuations of ±60°C has not affected the performance.

This technique will work for considerably higher powers than the equipment-limited 10.4 W reported here until severe crystal temperature gradients ultimately drop the efficiency. E-O compensation should be useful also for other SHG materials and, perhaps, parametric oscillators too.

17.8 Use of a Resonant Atomic Dispersion to Convert Frequency Modulated CW Light into a Train of Subnanosecond Pulses, J. E. Bjorkholm, E. H. Turner, and D. B. Pearson, *Bell Telephone Laboratories, Holmdel, N. J. 07733*

(15 min)

A frequency modulated pulse of electromagnetic radiation can be compressed (pulsewidth reduced and peak power correspondingly increased) by passing it through a medium or structure which has group velocity dispersion. This is the basis of chirp radar and similar schemes have been suggested for compressing pulses of light. Atomic vapors exhibit very strong group velocity dispersion for frequencies close to a resonance transition. Grischkowsky has recently made use of this fact to reshape and compress (to nsec pulsewidths) frequency modulated pulses of near-resonance light from a pulsed dye laser by passing them through rubidium vapor.[1] In our work we demonstrate the conversion of near-resonance CW light, from a CW dye laser, into a train of repetitive subnanosecond pulses by sinusoidally frequency modulating the light and then passing it through sodium vapor. The light was modulated using a $LiNbO_3$ electrooptic modulator driven at 200 MHz and the resulting pulses occurred once every 5 nsec. The sharpest pulses we obtained had a 240 psec pulsewidth and a peak power of 6.3 times the input power; average power was 77% of the input power. By varying the light frequency (on a scale of GHz) and the strength of the modulation, pulsewidths from 250 psec to 2 nsec could easily be obtained. The experimental pulses are in excellent quantitative agreement with computer calculations carried out using linear dispersion theory. Detailed comparison of calculation with experiment will be given.

The pulse trains are very reproducible and quite controllable. With precisely tunable CW dye lasers now commerically available, the technique we have demonstrated is a useful and simple way of obtaining continuous trains of repetitive short pulses in the vicinity of atomic resonance lines.

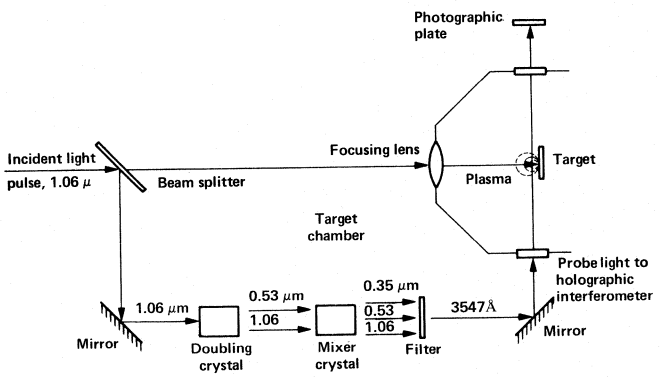
17.9 Conversion Efficiency and Pulse Shortening of a Frequency Tripled, Subnanosecond, 1.06 μm Pulse,[1] D. T. Attwood, E. L. Pierce, and L. W. Coleman, *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)



The interferometric study of plasmas produced by high intensity, subnanosecond pulses from a Nd laser, requires short wavelength, short duration probing pulses. Because of very steep density gradients within these plasmas, it is very important that the probe pulse be at least frequency tripled if critical electron densities for 1.06 μm are to be studied; shorter wavelengths are desirable. In addition, the temporal duration of the probe pulse should be short so as to minimize fringe smearing within the interferometer due to plasma density contour motion. In this paper we report high conversion efficiency of 1.06 μm pulses to 3547 Å,[2] as well as the concomittant shortening of the pulse.

The schematic diagram in Fig. 1 illustrates the procedure for obtaining synchronous frequency tripled probe pulses. A mode locked Nd laser produces a nominal 1 joule, 150 ps pulse at 1.06 μm which is used for target irradiation. A small portion of this radiation is split off and frequency doubled in an angle tuned KDP crystal. Fifty percent energy conversion to 5320 Å is regularly obtained with an incident 1.06 μm intensity of 10^9 W/cm^2. Type II phase matching is then employed to frequency mix the unconverted fundamental and its harmonic in a second KDP crystal. An overall energy conversion efficiency of 30% is regularly obtained for the frequency tripling process. Pulse shortening has

Fig. 1. Schematic diagram showing target irradiation as well as the generation of a frequency tripled probe pulse.

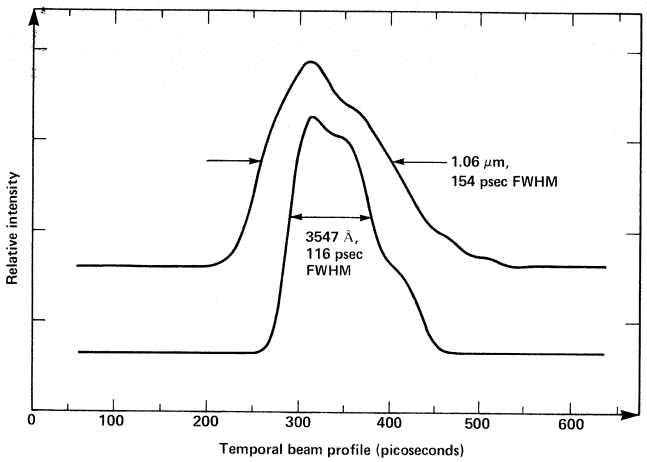

Fig. 2. Pulse compression via frequency tripling in KDP crystals. Incident 1.06 μm intensity of 10^9 W/cm^2; overall energy conversion of 32%.

been observed in this configuration by using two 10 ps resolution streak cameras[3] to simultaneously measure temporal profiles of the 1.06 μm and 3547 Å radiation. A sample of the incident 1.06 μm pulse was made to multiply reflect from a calibrated mirror pair giving a series of 1.06 μm pulses of known amplitude rations which were then recorded with the S-1 photocathode streak camera.[4] A similar mirror pair was used in conjunction with an S-20 streak camera to record the 3547 Å pulse. A sample result of these experiments, obtained simultaneously with the multiple exposure technique, is shown in Fig. 2 for an incident 1.06 μm intensity of 10^9 W/cm^2 and an overall energy conversion of 32%. The frequency tripled pulse displays a 25% temporal compression for this single laser firing.

17.10 A Transient Induced Grating System for Measuring Ultrafast Photo-Induced Phenomena,[1] A. E. Siegman, D. J. Kuizenga, and D. W. Phillion, *Stanford University, Stanford, Calif. 94305*

(15 min)

We have previously developed a continuously pumped, repetitively Q-switched, mode-locked Nd:YAG laser which produces bursts of 20 to 30 several hundred kilowatt pulses of ~60 psec duration, at repetition rates up to 500 Hz. A z-cut $LiNbO_3$ switch driven by a photodiode, fast logic circuitry and an avalanche transistor chain selects a single pulse from each burst. The resulting train of 500 single pulses per second is doubled to 532 nm with >35% efficiency in an elliptically focused $LiIO_3$ crystal, and can be doubled again to 266 nm in an ADP crystal. The output from this system has the stability, reliability and spectral purity of a CW mode-locked laser, at a usefully high repetition rate and power level, though with pulsewidths still rather wider than in flash-pumped saturable-absorber lasers or CW dye lasers.

Pulses at any of the wavelengths from this laser can be sent into the stroboscopic transient-induced-grating optical system shown in Fig. 1. Time-coincident excitation pulses in the two excitation beams arrive at an angle of a few degrees in an experimental sample (here a rotating dye cell) to create a transient interference pattern or transient hologram. The resulting photo-induced grating of excited states, free carriers, excitons, or other photo-excited phenomenon is then probed by a delayed probe pulse from a variable delay line. By measuring the diffracted probe beam intensity averaged over many pulses, while slowly varying the time delay, one can measure the decay of the photo-excited phenomenon in stroboscopic fashion.

The chart recording in Fig. 1 shows the decay of a transient grating induced by $S_0 \rightarrow S_1$ absorption at 532 nm in Rhodamine 6G. The decay curve is accurately fit by two exponential terms, first the orientational relaxation of preferentially aligned molecules with $\tau_{rot} \approx 150$ psec, then the fluorescent decay of S_1 molecules with $\tau_{fl} \approx 4$ nsec.

A variety of further studies of transient phenomena involving excitons, nonlinear phenomena, excited states, and energy transfer processes are now being undertaken with this system. Special advantages of the transient grating method for studying fast photophysical phenomena include improved sensitivity and background rejection; the ability to sense excited-state dispersive or phase-grating effects as well as excited state absorption; the ability to separate diffusion effects from lifetime effects by varying the grating periodicity; and the ability to study anisotropic diffusion effects.

17.11 Self Defocusing of Mode Locked Nd: YAG Pulses in Cesium Vapor, R. H. Lehmberg, J. Reintjes, and R. C. Eckardt, *Naval Research Laboratory, Washington, D. C. 20375*

(15 min)

In a recent publication, we reported the observation of self defocusing of mode-locked 1.06 μ pulses in Cs vapor.[1] Here, we report a measurement of the negative nonlinear refractive index responsible for this effect ($n_2 = 1.5 \times 10^{-30}$ N), and the first observation of its use in compensating the self focusing that occurs in other transparent materials. Since the useful output power from large Nd laser systems is limited by self focusing due to the laser glass ($n_2 \approx 1.6 \times 10^{-13}$ esu), these experiments suggest the possibility of increasing this power by using Cs vapor for compensation; e.g., one could

insert Cs cells at various stages of the glass amplifier chain.

At 1.06 μ, the nonlinear susceptibility of Cs vapor is determined almost entirely by interaction between the $|6s> \equiv |0>$ ground state and the $|6p> \equiv |1>$ and $|7s> \equiv |2>$ levels. We have shown that in the case of linearly polarized light, the nonlinear susceptibility can be analyzed into two distinct contributions.[1] The predominant one arises from the polarization $\rho_{02}(t)$ due to the two photon resonance between $|6s>$ and $|7s>$. The other term, which is also negative at 1.06 μ, arises from induced population changes between the $|6s>$ and $|6p>$ levels, and is analogous to the nonlinear refractive effects observed by Grischkowsky and Armstrong.[2]

In this experiment, where the pulses are much shorter than the inverse linewidth of $|6p>$, the nonlinear contribution to the refractive index becomes

$$\sigma n^{NL} = n_2 <E^2(t)>, \qquad (1)$$

where

$$n_2 = -\frac{2\pi}{h^3}\left[\frac{1}{(\nu_{10} - \nu)^2(2\nu - \nu_{20})} + \frac{1}{(\nu_{10} - \nu)^3}\right] N, \qquad (2)$$

$E(t)$ is the optical field of frequency $\nu = c/\lambda$, N is the atomic number density, μ_{ij} the dipole matrix element between levels $|i>$ and $|j>$, and ν_{ij} the corresponding frequency splitting. Nonresonant contributions have been ignored in (2), since at 1.064 μ, $\nu/c = 9398$ cm^{-1}, while $(\nu_{10} - \nu)/c = 2149$ cm^{-1} and $(2\nu - \nu_{20})/c = 260$ cm^{-1}. For circularly polarized radiation, the $|0> \rightarrow |1> \rightarrow |2>$ transition is not allowed, and only the second term of (2) remains nonvanishing. With longer pulses, one would obtain additional contributions to δn^{NL} proportional to the integrated intensity.[1]

In order to measure n_2 vs. N we studied the self-defocusing of mode-locked Nd:YAG pulses in a 100 cm long Cs vapor cell at several densities between $N = .080 \times 10^{17}$ and $.32 \times 10^{17}$ cm^{-3}. The input beam was a single 35 psec pulse of 1.1 mm $1/e$ diameter and 50-60 MW peak power. The output beam profile was recorded by imaging the exit window of the cell onto a silicon photodiode array. In analyzing the data, we used the constant shape approximation,[3] and numerically integrated the instantaneous profile over the pulse duration. We then chose the value of n_2 that gave the best theoretical fit to the measured profile. The results for linear and circular polarization are compared with theory in Table 1. The second column is obtained from (2), the third includes the nonresonant contributions to n_2, and the fourth is the value calculated by Miles and Harris.[4] The theory is in good agreement with these measurements, with the remaining discrepancy possibly due to the theoretical value of μ_{12} used in the calculation.

In the compensation experiment, a 2 cm long cell of CS_2 was inserted 45 cm from the entrance window of the Cs cell, and the beam profile was measured at the exit window. With 1 mJ pulses and no Cs in the cell, the (FWHM) width was 0.96 mm. With a Cs density of $.13 \times 10^{17}$ cm^{-3} and similar pulses, this width increased to 1.07 mm, which is close to the 1.12 mm width measured in the absence of both Cs and the CS_2. The Cs vapor thus appears to effectively compensate for the CS_2; however, no attempt was made to optimize this. Further experiments are currently in progress, and conditions required for practical application of Cs vapor compensation will be discussed at length.

17.12 A High Power Isolator for the 10 Micron Region Employing Interband Faraday Rotation in Germanium,[1] C. M. Phipps, Jr.[2] and S. J. Thomas,[2] *Lawrence Livermore Laboratory, Livermore, Calif. 94550*

(15 min)

A crucial element in the design of high power CO_2 laser systems is the provision of adequate interstage isolation. Previously, the free carrier Faraday effect in InSb has been employed to build low power isolators for the 9-10 micron region.[3-5] We report the construction and testing of a room temperature, high power isolation device based on the interband Faraday effect in intrinsic Ge.

The interband isolator has four principal advantages with respect to the earlier free carrier devices:

1. *Freedom from 2 photon absorption.* The 10.6 micron 2 photon absorption coefficient in InSb $\kappa_2 = 16 \pm 5$ cm^{-1} per MW/cm^2, with a threshold at 10^5 W/cm^2, preventing the use of this material at higher power levels.[6]

2. *Scalability.* Germanium of suitable purity is available in apertures as large as 30 cm, whereas InSb is not.

3. *Excellent Isolation Figure.* Tests with CW and pulsed probe lasers showed an isolation figure of 40 dB with our device. This improvement is due to the higher uniformity of rotation which is achieved with bound carriers vs. doped donor impurities in a crystal lattice.

4. *Decoupling of Rotation and Absorption.* Free carrier rotation and absorption are directly coupled, their ratio depending only on mobility and magnetic field strength. This is not true for the interband Faraday effect.

For frequencies well below the gap frequency of the semiconductor, the interband Faraday

TABLE I
SUMMARY OF ISOLATOR PERFORMANCE

	9.55 μ	10.59 μ	deg/kG cm
Verdet coefficient V:	0.094	0.079	deg/kG cm
dV/VdT:	0.12	0.05	%/deg C
B for 45° rotation:	39.9	47.4	kG
Figure of merit Q: (high power)	–	66	deg/dB
Isolation level A_r: (high power)	–	41.2	dB
Isolation level A_r: (CW)	–	35.5	dB

rotation is isotropic in a cubic crystal, and is given by[7]

$$\frac{\Theta}{B} = \frac{5A\gamma\,\omega^2}{64C\,\varepsilon_g}^{7/2} \quad \text{rad/cm gauss} \qquad (1)$$

A and γ are constants determined by the band parameters and the spin-orbit coupling in the presence of a magnetic field, and ε_g is the energy gap for direct transitions. For frequencies well below the energy gap, the intrinsic absorption in materials such as Ge and CdTe is dominated by residual free carrier effects and lattice absorption in the 10 micron region. In Ge, the ratio of the hole to electron absorption cross-sections is about 43,[8] but the hole transition absorption will bleach at intensities in excess of 10 MW/cm^2, leaving only the lattice absorption $\alpha_0 = 0.013$ cm^{-1},[9] which is not dependent on B to first order. Decoupling of rotation and absorption should permit figures of merit as large as 2×10^3 deg/dB for some interband materials.[10]

The isolator rotation medium for this study was a cylinder 12 cm long and 2.7 cm in diameter, cut from Ge single crystal with a maximum 10^{12} cm^{-3} impurity concentration. End faces were polished and AR coated for minimum reflectivity. The magnetic field was generated by a 5 cm bore uncompensated pulsed solenoid. 45 degree rotation was achieved 450 sec after firing the associated 8 kJ capacitor bank, corresponding to a peak on-axis field of 49 kgauss. The polarizer and analyzer each employed four wedged germanium plates. Their measured crossed extinction was -51 dB.

Detailed measurements of isolator performance were made at 9.55 μ and 10.59 μ wavelengths, in the temperature range 260 to 300 degrees C. These are summarized in Table I. In the Table, V is the Verdet coefficient Θ/B, and Q is the figure of merit, with units of degrees rotation per dB loss.

18.1 High Energy CO_2 Laser Pumped by a UV Sustained Discharge,[1] R. C. Lind, *Hughes Research Laboratories, Malibu, Calif. 90265* (15 min)

The ultraviolet sustained electric discharge has been proposed as an alternative to the E-beam sustained discharge for conditioning CO_2 laser plasmas.[2] A key question concerning this approach is scalability. This paper presents results of a program currently in progress whose objective is demonstration of UV sustained discharge pumping in a 40 liter active volume.

At the present time, the only method successfully developed to achieve high-energy, long-pulse optical output from atmospheric pressure electric-discharge molecular-gas laser systems requires a discharge in which the electron production is controlled separately from the vibrational excitation process. In particular, operation with an electric field below that required for avalanche ionization (E/p < 6 kV/cm-atm) coupled with a large background electron density (> 10^{12}/cm^3) created by an auxiliary ionization source is used. The current technique for the production of the background electron density uses an E-beam as the auxiliary ionization source.[3]

The importance of the UV sustained approach results from elimination of the E-beam and its associated high voltage gun, fragile foil, and X-ray production characteristics and its replacement by a source of UV radiation. The UV radiation from this source produces the required electron density in the laser volume by photoionizing a small amount of low ionization potential seed gas which is added to the 1 atm laser mixture.

Using this technique on a small scale device, with tri-n-propylamine as the seed gas, we earlier demonstrated output energy densities of 50 J/l-atm with pulse lengths greater than 20 μsec.[4] Additionally, we have determined that the wavelength range of 1200-1700 Å is responsible for the observed photoionization, and we have conjectured that the mean free path for this radiation, which is determined by absorption in both the CO_2 and the seed gas, is about 8 cm for an optimum laser mixture of 2.5/47.5/50 (CO_2/N_2/He). This suggests that laser devices with electrode separations up to 16 cm should be feasible. The practical limits on scaling must however be established experimentally.

A large scale, UV-sustained CO_2 laser device has been constructed using the measured mean free path as a guideline to device size with the objective of determining the scaling limits. The device consists of a large metal vacuum enclosure in which Bruce contoured electrodes are housed. A high energy (up to 50 kJ, 80 kV) dc storage bank is used to provide the sustainer voltage to the electrodes. Two UV sources, located behind metal screens which form the discharge electrode surfaces irradiate the discharge volume. Each UV source consists of 40 rows of cascaded arc discharges, each row energized by its own low inductance capacitor. The active discharge area is 20 × 100 cm^2 and the electrode gap dimension is adjustable up to a maximum spacing of 20 cm providing a maximum active volume of 40 l.

There were three objectives of the experimental program. These are: (1) energy extraction measurements using a stable cavity, (2) energy and beam quality measurements using an unstable resonator, and (3) a characterization of the medium quality using holographic interferometry and spatially resolved gain measurements.

A significant portion of objectives (1) and (3) has been achieved at this time. Extensive stable cavity energy extraction measurements have been carried out over a wide range of conditions with an electrode gap of 6 cm. Using a 25% hole coupled output mirror and a 60 m radius of curvature total reflector, an output energy of 200 J in a 30 μsec pulse has been achieved. This corresponds to approximately 30 J/l-atm energy density. Additional measurements with an electrode spacing of 10 cm are currently underway and will be reported.

The medium quality of the device is affected by the UV flux distribution, acoustic waves produced by the UV sources, and by thermally induced medium inhomogeneities. To establish the uniformity of the discharge gain profile measurements with a spatial resolution of less than 2 mm have been performed in both the width (20 cm) and height dimension. Measurements taken to date indicate a uniform gain (at a magnitude of about 0.7%/cm) distribution in both dimensions. In addition, holographic interferometry measurements were taken with a Q-switched, single mode ruby laser. Time sequenced holograms, taken at appropriate intervals after discharge initiation will be discussed.

On the basis of the performance data the feasibility of replacing E-beam sustainers with UV sustained plasma conditioning will be discussed.

18.2 Photo Ionization Parameters for TEA Lasers, H. J. J. Seguin, D. McKen, and J. Tulip, *University of Alberta, Edmonton, Alberta, Canada* (15 min)

There has recently been a revival of interest in photoionization processes as a result of the application of this technique to CO_2 lasers. Of special interest has been the emission spectra of various ultraviolet sources, propagation of ionizing radiation, and photoelectron density production in a CO_2 laser environment. These

parameters are of particular relevance both for a fuller understanding of the basic mechanisms involved, and an optimum exploitation of the technique in large scale high powered devices.

The paper describes the measurement techniques adopted and the results obtained in an extended investigation of some of the more salient parameters associated with the application of ultraviolet photoionization processes in TEA-CO_2 lasers. In particular, the points to be examined will include:

(a) A brief presentation of previous photoelectron density data obtained with microwave diagnostics. Electron density and ionization decay times are given as a function of pressure for several laser host gases and mixtures. Plasma density and penetration depths are measured in relation to UV source parameters. The effects of selected "seed" additives on photoionization is demonstrated.

(b) Details of a recent study on a variety of UV spark sources, specific data with respect to emission spectrum, time evolution of radiation and the influence of circuit parameters are given. Complementary emission-absorption measurements obtained in laser host gases clearly identify the useful source emission bands.

(c) Measurements of UV source wavelength emission with corresponding photoelectron production are also presented. This investigation, which utilizes specialized charge collection apparatus fitted to a monochromator, identifies the source emission bands which dominate the photoionization process in a CO_2 laser gas environment. The photoionization vs. wavelength data so obtained specifies a one-step process as the dominant mechanism in this type of laser. A dramatic increase in the useful portion of the spark source emission spectrum is clearly shown when low ionization threshold additives are used. These results are in good agreement with microwave diagnostic photoionization enhancement measurements reported earlier.

In general the data obtained from these investigations provided further insight into the primary mechanisms involved in photoinitiated TEA lasers, and in addition has yielded design criteria for the development of more efficient UV sources. Details of such a UV device employing a simple plasma jet geometry are also given.

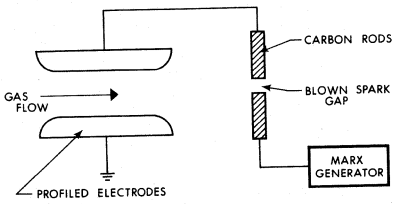

Fig. 1. Discharge region is preconditioned with UV radiation from the Marx generator gaps.

gases is low, the gaps are arranged as a Marx generator. Such an arrangement has routinely provided in excess of 100 kV at the profiled electrodes. The gaps are well coupled by UV radiation so that triggering at the first gap produces a clean jitter free pulse. Charging of the storage capacitors up to a voltage of 20 kV, is performed using a diode-inductor set. The Marx generator will free run as a relaxation oscillator or can be triggered at frequencies up to 4000 pps. This maximum frequency corresponds to a flow velocity of 40 m/s. The storage capacitors may be varied up to 0.1 μF and the hold-off inductors up to 30 mH. For discharge energies of more than a few joules a capacitor across the profiled electrodes is needed to delay the growth of voltage at the electrodes. Without this arcing will occur.

A 50 cm long and 3 cm square cross-section flow discharge is formed between the two profiled graphite electrodes. The pulse repetition frequency and the energy per pulse are power supply limited to 12 kW. A typical operating situation for the gas flow velocity of 40 m/s is shown below.

Typical Discharge Conditions
CO_2, N_2, H_e; 1, 1, 8

Supply voltage	4 kV
Supply current	3A
Storage capacitors	0.06 μF
Hold-off inductors	2 mH
Energy pulse	14 J
Repetition rate	900 pps
Pulse duration	0.9 μs
Peak current	1200 A

The discharge will operate without arcing with up to 15% CO_2 and 30% N_2 under these conditions.

The discharge duration can be increased by simply introducing an inductor between the Marx generator and the discharge.[1] The long discharge period allows glow to arc transitions time to form[2] so that reduced energy density is necessary. Two techniques have been found useful in stretching the discharge period. A small capacitor in parallel with the stretching inductor will provide a starting "kick." The low impedance path through the capacitor provides a large initial current which "forms" the discharge. This technique has permitted the discharge of 15 joules over 20 μs without arcing. The judicious choice of an inductor across the electrodes will eliminate post arcing, (small arcs which form in the discharge tail). We conclude however, that pulse stretching is best achieved by operating the discharge at sub-atmospheric pressure.

An extended structure has been constructed which provides a flow velocity of 100 m/s and has a power capacity of 50 kW. This will be used to investigate the effect of preionisation from the previous pulse which occurs at high repetition rates.

18.4 Efficient Preionization Scheme for High Gain CW CO_2 Waveguide TE Laser, O. R. Wood II, P. W. Smith, C. R. Adams, and P. J. Maloney, *Bell Telephone Laboratories, Holmdel, N. J. 07733*

(15 min)

Using a preionization scheme based on the Malter effect, quasi-continuous gains of peak value 6.6%/cm at 10.6 μm have been produced in a 1 mm^2 cross-section waveguide TE laser[1] by loading up to 500 J/L-atm into a 145 torr CO_2 laser mixture at an E/P = 6 V/cm-torr. Electron number density and field strength can be controlled independently, as is the case with

18.3 High Repetition Rate TEA Laser Discharge Using an Integrated Preionisation and Switching Technique, J. Tulip, H. J. J. Seguin, and W. Faszer, *University of Alberta, Edmonton, Alberta, Canada*

(15 min)

This paper describes a high pressure, high repetition rate pulsed discharge technique which integrates UV preionization with voltage switching. The essence of the technique is shown in Figs. 1 and 2. The switching is performed using spark gaps within the flowing laser gases. Seven gaps are arranged transverse to the profiled electrodes several cm from the downstream edge. Because the hold-off voltage of the laser

Fig. 2. Marx generator is placed in the flowing laser gases.

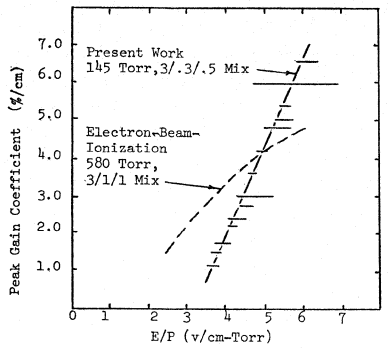

Fig. 1.

electron-beam-ionization.[2] This scheme, similar to one used previously by J. P. Reilly[3] and A. E. Hill,[4] differs from previous work, in that, in the present device the proximity of metal and insulating waveguide walls play an important role in discharge preionization, stabilization, and cooling. A 10 cm long waveguide TE CO_2 laser, based on this excitation scheme, should be capable of generating CW output powers in the range 10-100 watts.

A hollow waveguide of 1 mm^2 cross-section was constructed with slabs of fused quartz and metal in such a way that multiple transverse discharges could be formed inside the waveguide. A solid block of polished copper comprised one wall of the waveguide. A sandwich made up of alternate slabs of aluminum and quartz (each 1 mm thick) comprised the opposite waveguide wall. The remaining waveguide walls were formed by fused quartz slabs whose edges had been polished.

A train of 20 nsec duration high-voltage pulses (4-8 kV) applied (transverse to the waveguide axis) between the aluminum slabs (acting as cathodes) and the copper block (acting as an anode) increases the electron density from a low initial value (left over from the previous pulse) to a high peak value ($1\text{-}3 \times 10^{12}$ cm^{-3}). This high level of ionization is thought to result from a combination of efficient secondary emission from the aluminum cathode (the Malter effect) and electron multiplication due to the high electric fields present. After the ionizing pulse, a continuous electric field applied between the aluminum slabs (now acting as anodes) and the copper block (now acting as a cathode), with E/P = 3.5 – 6.5 V/cm-torr, provides the electron energy needed to vibrationally excite N_2 and CO_2 molecules during the recombination period. This electric field results in energy loadings from 50 to 500 J/L-atm without arc breakdown and values for peak gain from 1.2 to 6.6%/cm. The gain rises to this peak value some 70 μsec after the start of the ionizing pulse and has an overall duration of 150 μsec. Hence, at pulse repetition frequencies of 5-10 kHz nearly continuous gain can be obtained.

A comparison of the peak gain coefficient versus E/P for the present device and for an electron-beam-controlled discharge[2] is shown in Fig. 1. Possible extension of this technique to higher operating pressures and, hence, to higher projected CW output powers will be discussed.

18.5 Discharge Scaling Studies for a Continuously Operating Fast Flow Electrically Excited (Coffee) Laser, S. A. Wutzke, L. H. Taylor, J. L. Pack, T. V. George, and L. A. Weaver, *Westinghouse Research Laboratories, Pittsburgh, Pa. 15235*

(20 min)

Discharge scaling studies of a unique dc CO_2 (COFFEE) laser excitation scheme are described. The COFFEE laser is excited with a high-pressure, self-sustained glow discharge. The glow is produced between a multipin cathode and a planar anode. Current flow is mutually perpendicular to both the gas flow and the optical axis. The discharge is stabilized by the gas flow and by a ballast resistor connected in series with each cathode pin. The high-pressure continuous glow has been successfully scaled to a 10 cm square aperture along the optical axis. The experiments were performed in a closed-loop flow tunnel using a 10 × 10 × 10 cm discharge module. The cathode pin density was 1 pin/cm^2 and the electrode gap was varied between 2 and 10 cm. Flow velocities up to 150 m/sec were used.

Discharge parameterization experiments and computer simulations have been performed over a broad range of the primary variables. Specific input powers up to 115 J/1-atm (110 kJ/1b) were obtained with input power densities up to 50 W/cm^3 of discharge volume. No fundamental scaling limit has been encountered for electrode spacings up to 10 cm.

If one keeps the input power per unit volume (jE) constant in order to maintain uniform excitation, the gas temperature rises almost linearly along the flow direction, causing the gas density to decrease nonlinearly. Since the glow discharge operates at nearly constant E/N, the E field decreases in the same manner as N. In order to hold jE constant, the current density (j) must increase linearly along the gas flow direction. This is easily accomplished in the COFFEE laser by adjusting the cathode row currents.

The operating E/N for the discharge was measured as a function of j/N, ratio of current density to total gas density. The upstream values agreed with the predictions of Lowke *et al.*[1] obtained from a steady state balance between electron generation and loss mechanisms. An upstream E/N of 2.6×10^{-16} V-cm^2 was measured for a 1 CO_2:7 N_2:30 He gas mixture, and decreased by as much as 50% through the downstream portion of the discharge.

Small-signal gain measurements were performed to determine the spatial uniformity of the electrical excitation and its dependence on the operational parameters. The gain was nearly constant as a function of the distance (8 cm) between anode and cathode, and increased in value as the gas was convected through the excitation region. Peak gains of 0.25%/cm were measured for 10 CO_2 : 70 N_2 :200 He:2 H_2 gas mixtures with a current density of approximately 15 mA/cm^2. In general the peak gain varied linearly with current and approximately inversely with total pressure. Small amounts of hydrogen introduced into the laser gas mixture improved the long term discharge stability when operating near the glow-to-arc threshold, and caused a tolerable decrease in small-signal gain.

A six-temperature, CO_2 laser kinetics computer program was developed to simulate excitation and relaxation processes in the COFFEE laser mixture as a function of downstream distance. Computed gain agreed well in magnitude and spatial dependence with measured values. The gas temperature rise was calculated to be 47°K in 25 cm without mirrors, but was reduced to 36°K with mirrors due to extraction of the laser energy. Laser outputs of 21 kW at 11% efficiency are predicted for an 8 cm × 10 cm × 140 cm excitation region with a total current of 14 A.

The measured input power for an 8 cm × 10 cm × 10 cm volume was 24 kW, which is over 200 kW/m of cavity length. Since the discharge operates near the optimum E/N values for efficient excitation and provides sufficient gain for efficient energy extraction, the COFFEE laser concept appears to be scalable to the multikilowatt levels predicted by the computer simulations.

18.6 Multigigawatt Peak-Power Generation from a Tandem of TEA-CO_2 Lasers, P. A. Bélanger and J. Boivin, *Laval University, Quebec, Canada*

(15 min)

A new simple method has been successfully demonstrated for obtaining multigigawatt, ns pulses from a tandem of two TEA-CO_2 lasers. In operation, the first laser[1] is conventionally mode-locked using an acoustooptic modulator and serves as a master oscillator for the system. A propylene attenuator drastically reduces the signal from this first laser before it is optically coupled to the second by means of a small hole (500 microns) pierced in the spherical mirror. The second or slave oscillator is the same type of high-energy laser as the first and is of approximately the same length (±2 cm). Its excitation is electronically controlled through a time delay circuit so that the laser medium presents the low gain value when the pulse train from the master oscillator arrives.

The output of the tandem unit under optimum conditions (which can consistently be achieved) is depicted in Fig. 1. The pulse train resembles in every respect that which would be obtained from ordinary mode-locking but with the peak power now attaining 4 gigawatts.

[1] J. L. Lachambre, J. Gilbert, F. Rheault, R. Fortin and M. Blanchard, *IEEE J. Quantum Electron.*, vol. QE-9, p. 459, 1973.

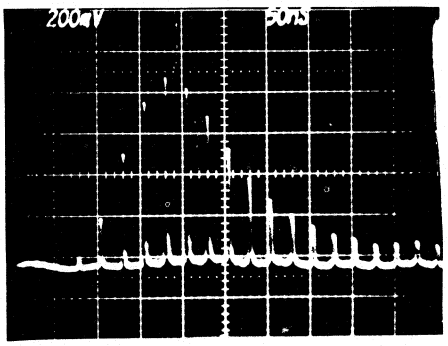

Fig. 1. Output of tandem unit under optimum conditions.

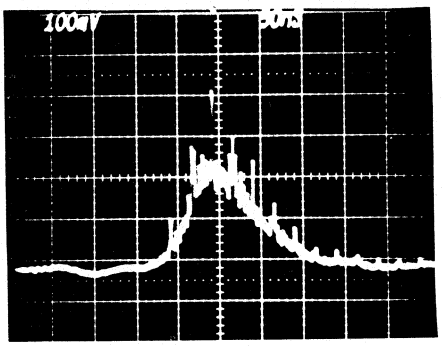

Fig. 2. Output of tandem unit with excess attenuation.

Fig. 2 illustrates the importance of determining the proper attenuation of the propylene cell. In this figure, the attenuation was too strong and the input signal to the slave was below the noise for spontaneous emission. If the input signal is too strong, the gain switching effect of the second laser is then attenuated. Optimum conditions were determined by varying the pressure of the propylene in the 30 cm cell.

It has been experimentally verified that this system works just as well as long as the ratio of the length of the first laser to that of the second forms a simple ratio: $2, \frac{1}{2}, \frac{2}{3}, \ldots$. This permits the use of higher energy slave oscillators without complication. The operation with unstable resonators has also been demonstrated.

Another variation which has been successfully demonstrated is the injection of a unique pulse into the second laser. This has been accomplished using a GaAs active polarizer followed by a saturable absorber (SF_6) to further attenuate the unwanted peaks.

This new method for producing multigigawatt pulses imposes itself not only by its reliability but by its simplicity. Its potential is far from being fully developed as no critical experimental limitations are as yet evident. In fact, we are confident of some achieving much better results with a very 400 joule slave oscillator in an unstable configuration for the resonator.

18.7 Multiline Operation of a CO_2 Oscillator/Amplifier System,[1] J. F. Figueira, W. H. Reichelt, G. T. Schappert, and B. Feldman, *Los Alamos Scientific Laboratory, Los Alamos, N. M. 87544*

(15 min)

In the design of large volume, high energy CO_2 laser systems, the overall system efficiency has a substantial inpact on the design and cost of the laser. It has been shown by previous theoretical and experimental work at LASL and elsewhere that the efficiency for amplifying nanosecond CO_2 laser pulses is limited by the rotational relaxation rates within the upper and lower lasing levels for oscillator/amplifier systems operating on a single rotational line. Theoretical studies have shown that increased efficiency is obtained if the oscillator/amplifier system is designed to operate on multiple rotational lines of the CO_2 laser transistion.

In this paper we report the results of an experimental and theoretical study comparing the efficiency of energy extraction from a CO_2 amplifier system operating on a single rotational line and one operating on multiple rotational lines. The input oscillator was of a hybrid design utilizing both high pressure (600 torr) and low pressure (20 torr) gain sections. By use of an intercavity absorption cell containing SF_6 this oscillator could be operated on either a single line ($P(20)$ 10.4 μm branch) or multiple line ($R(14)$, $R(16)$ and $R(18)$ of the 10.4 μm branch) with equal energies. Operation could be obtained on both the 9.4 μm branch or the 10.4 μm branch. From the gain swtich output pulse from this oscillator, a single nanosecond pulse was generated with an electrooptical gating technique. The amplifier system consisted of two stages of electron beam pumped gain volumes, 1 m long each, operated at a total pressure of 600 torr with a small signal gain coefficient of 4.4%/cm at $P(20)$ of the 10.4 μm branch. Input and output energies, pulse time histories and frequency distribution of the output radiation were monitored.

A theoretical analysis of multiline energy extraction, based on a model of random rotational relaxation (no ΔJ selection rule) has been performed. Applied to the above experimental conditions, such calculations predict a 50% increase in energy output and a pulse narrowing resulting in a factor of two higher peak intensity. A comparison of theory and experiment will be given.

18.8 Parametric Studies of a Multiband CO_2 Laser,[1] J. F. Figueira, G. T. Schappert, S. Singer, and S. J. Thomas, *Los Alamos Scientific Laboratory, Los Alamos, N. M. 87544*

(15 min)

In a previous paper[2] the authors have described the performance characteristics of a CO_2 oscillator capable of operating on multiple rotational lines and multiple vibrational bands. In this paper we report on a more detailed extension of this work. The experimental arrangement consisted of a conventional UV preionized TEA-CO_2 laser equipped with an intercavity gaseous absorption cell. The output energy was monitored with band pass filters and a disk calorimeter. Pulse time histories were measured using a scanning 0.75 m grating monochrometer equipped with a fast pyroelectric detector readout to a dual beam 500 MHz oscilloscope. Time integrated pulse energies were also obtained using the grating monochrometer. A 2 cm long Brewster angle intercavity absorber cell was filled with various pressures of SF_6 and the output spectra from the oscillator was measured. For a typical operating condition the output consisted of eight rotational lines, three on the 9.4 μm branch and five on the 10.4 μm branch. It was found that when the cell pressure was maintained at 15 torr, the $R(14)$, $R(16)$, $R(18)$ lines of the 10.4 μm branch and the $P(22)$ line of the 9.4 μm branch were found to contain equal energy. At 15 torr pressure the output energy from the multiline operation was essentially the same as the output energy with the SF_6 cell evacuated. As the cell pressure was increased the total output energy stayed approximately constant, but the ratio of 9 μm energy to 10 μm energy increased linearly with SF_6 pressure.

When the laser output intensity was examined several interesting features were noticed. For low SF_6 pressure ($P < 10$ torr) the 10 μm radiation consisted of a gain switched spike followed by a low level N_2 repumping tail with 30-50% of the total energy contained within the gain switched envelope, The 9 μm radiation under the same conditions consisted of a low level gain switched peak, followed 300-400 ns later by a 2 μs burst of radiation. Less than 5% of the total energy on the 9 μm band was contained within the gain switched peak. By increasing the SF_6 pressure it was possible to equalize the peak gain switched intensities in both bands, however over 50% of the total energy occurred in the 9.4 μm tail.

The variation of the output intensity with laser frequency was also observed using different gaseous absorbers, suggesting that the effect is not due to the absorption process but rather is a result of the pumping dynamics of the CO_2 laser. These experimental results are compared with the computational results derived from a simple kinetic model of the CO_2 laser gain.

In conclusion we have made a parametric study of a multiband CO_2 laser. It was found that the gain and lasing dynamics of this system cause the multiband output intensities to vary greatly with lasing wavelength.

18.9 A Frequency Tunable 15 Atmosphere CO_2 Laser, F. O'Neill and W. T. Whitney, *Naval Research Laboratory, Washington, D. C. 20375*

(15 min)

High pressure ($\sim$15 atm) CO_2 lasers are presently of interest because of their possible use as tunable sources of coherent radiation in

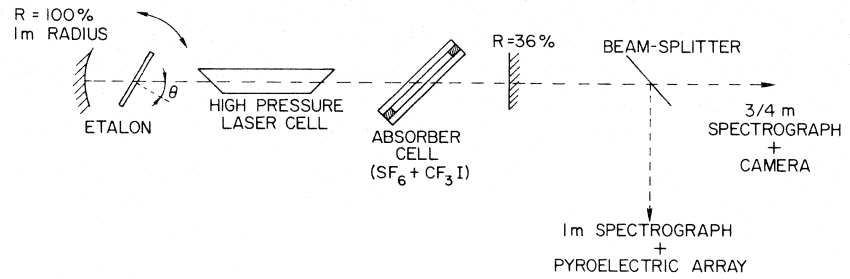

Fig. 1. Experimental arrangement used for interferometric tuning of 15 atm CO_2 laser.

the 9-11 μm spectral region. In view of their higher operating power and efficiency, these lasers will have a significant advantage over presently available tunable infrared sources for applications such as laser induced chemistry, isotope separation and infrared up-conversion studies. We have previously described[1] the characteristics of a cold-cathode electron-beam-controlled CO_2 laser which is suitable for operation at pressures up to 15 atm and in this paper we discuss experiments on frequency tuning of the laser using a Fabry-Perot etalon as a dispersive element in the laser resonator. The experimental arrangement used for this work is shown in Fig. 1.

Frequency tuning of the laser is obtained by using a 1.5 cm diameter, 0.9 mm thick, ZnSe solid etalon. The refractive index of ZnSe is 2.4 giving an etalon free spectral range ~ 2.3 cm^{-1}. The etalon was coated on both sides with 47% reflectivity dielectric coatings giving a finesse ~ 4. A gas absorber cell (thickness ~ 1 cm) is placed in the cavity and by filling it to a pressure of 50 torr with equal parts of SF_6 and CF_3I the laser is restricted to oscillation on the *R* branch of the 10.4 μm band of CO_2. The spectral behavior of the laser is monitored simultaneously using an Optical Engineering Spectrum Analyzer and a 1 m Czerny-Turner spectrograph. The laser is frequency tuned by rotating the etalon in a vertical plane and by changing the etalon angle θ (Fig. 1) over the range 0°-9° the laser wavelength is varied over one free spectral range (~ 2.3 cm^{-1}). The tuned laser spectral width is <0.2 cm^{-1} and an output energy ~ 100 mJ has been obtained for a laser peak power ~ 5 MW. This is higher than has been achieved with a diffraction grating tuned laser[2] and should be limited only by the same damage criteria as for dielectric coated mirrors. Even though the finesse of the etalon is only 4 the device was still selective enough to narrow the lasing linewidth by more than an order of magnitude and give smooth tuning over two of the CO_2 rotational lines.

Present experiments are aimed at obtaining tunable single longitudinal mode operation of the laser throughout the complete gain spectrum of CO_2. This will be achieved by using a number of interferometers simultaneously in the laser cavity. In addition the usefulness of this laser as a spectroscopic tool will be demonstrated and we will describe experiments on the measurement of absorption lines in various gases.

18.10 Suppression of Self-Oscillations in High-Gain CO_2 Amplifiers, P. Lavigne, J. L. Lachambre, and J. Gilbert, *Defence Research Establishment Valcartier, Courcelette, P. Q. Canada*

(15 min)

A major problem encountered in the design of high-gain CO_2 laser chains for generating short powerful pulses at 10.6 μm is the suppression of self-excitation arising from the amplification of spontaneous noise in the gain medium. Besides depriving the amplifier of its gain by destroying the inversion prior to the passage of the pulse to be amplified, self-excitation may in some conditions cause permanent damage to the optical components of the system. One promising way of ensuring stability against self-stimulation of the spontaneous noise is the inclusion of optical isolators between successive amplifier stages.

This paper will report the results of an experimental investigation of the use of the gas combination N_2F_4/C_2H_5OH as an interstage saturable filter. In this system the saturable gas N_2F_4 plays the role of an amplitude discriminator in the CO_2 laser band centered at 10.6 μm transmitting pulses of high intensity and preventing self-stimulation of the spontaneous noise while C_2H_5OH acts as selective absorber compensating for the limited absorption bandwidth of N_2F_4.

Direct transmission measurements performed with a low resolution spectrophotometer indicate that N_2F_4 has five strong absorption bands between 900 and 1050 cm^{-1} spanning the *P* and *R* branches of the 00°1-10°0 emission transition of CO_2 and also a portion of the *P* branch of the 00°1-02°0 transition. C_2H_5OH is essentially transparent in this region but absorbs strongly in the 00°1-02°0 band. The transmission characteristics of N_2F_4 and C_2H_5OH were also examined with a CW CO_2 laser beam over a large number of rotational transitions near 10.6 μm and 9.6 μm. The variations in the absorption of the laser radiation was found to be in good agreement with the measured low resolution spectrum. It was verified, in particular, that for pressures above 1 torr N_2F_4 does not have any narrow absorption dips that coincide with the CO_2 laser lines examined. Given the complexity of the N_2F_4 band system, this suggests that the absorption spectrum is formed by a continuum of overlapping lines in the pressure range of interest. The measured value of the small-signal absorption coefficient of N_2F_4 on the *P*(20) line of CO_2 is 0.021 cm^{-1} torr^{-1}.

The transmission of nanosecond pulses as a function of pulse intensity and gas pressure has been studied experimentally. The experiment was carried out by irradiating a 20-cm absorption cell filled with N_2F_4 at pressures between 1 and 20 torr using as a source a mode-locked laser with a single pulse selector followed by a multistage amplifier. At high intensity levels the pulse transmission exhibits a residual absorption which varies linearly with pressure over the pressure range 1-14 torr. When fully bleached the residual absorption absorption of N_2F_4 at *P*(20) line is approximately 0.003 cm^{-1} torr^{-1}.

Preliminary experiments were performed with the object of determining the isolation effectiveness of the N_2F_4/C_2H_5OH system in a practical amplifier chain. The test amplifier consisted of 4 sections of grid-type double-discharge excitation having each a 100-cm active length and an effective apertured cross-section of 15 cm^2. The measured linear amplification coefficient was 0.045 cm^{-1} and the overall gain of the complete chain reached 10^8. The two absorbing gases were contained in separate cells fitted with NaCl windows which were placed between the second and third stage of the amplifier. The N_2F_4 and C_2H_5OH cells were 30-cm and 50-cm long respectively. With 35 torr of N_2F_4 and 21 torr of C_2H_5OH, the amplifier was found to be completely free of oscillation when placed between two partially transparent mirrors of 50% reflection. This experiment served to confirm that the absorption spectrum of the isolator has a smooth contour covering the full emission bandwidth of the CO_2 molecule. Using as driving source a mode-locked laser with single-pulse switchout, pulses of 2 ns duration have been delivered to a 4% reflecting target at an energy of 7 joules without damaging the optical components. It is estimated that somewhat less than 50% of the energy carried by the pulse incident on the isolator was consumed in the bleaching of the N_2F_4 absorber. In these experiments, the isolation from target backscatter was achieved by a gaseous breakdown scheme.

The simplicity of construction together with the high resistance to optical damage and the easy adaptability to large cross-section amplifiers make this isolator attractive for high-gain CO_2 laser chains. Further tests on energy extraction, saturation and recovery time are in progress and available results will be reported.

18.11 Gain Recovery After Saturation in Short-Pulse CO_2 Amplifiers,[1] G. T. Schappert, J. S. Ladish, W. T. Leland, and M. J. Kircher, *Los Alamos Scientific Laboratory, Los Alamos, N. M. 87544*

(15 min)

Since the small signal gain of a laser power amplifier is also a measure of the stored energy, one can observe the pulse energy extraction and subsequent repumping by monitoring the small

[1] Work performed under the auspices of the U. S. Atomic Energy Commission.

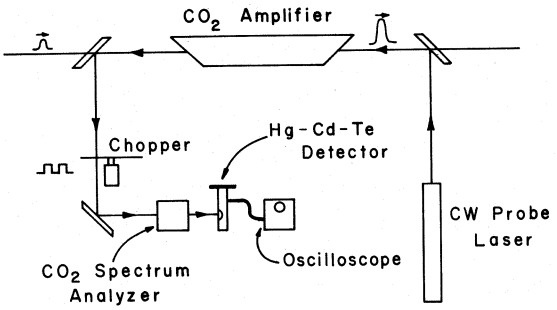

Fig. 1. Experimental layout.

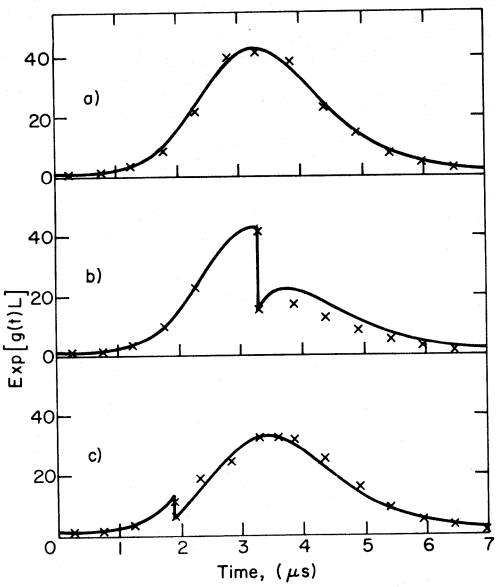

Fig. 2. Small signal gain.

signal gain as the energy is extracted. We have performed such measurements on a high pressure CO_2 power amplifier and have analyzed the results on the basis of a 4 temperature kinetics model.

Fig. 1 shows the experimental layout. A 1.5-1.8 ns (FW 1/e) pulse ($P(20)$, 10.6 μm) of 200-400 mJ energy traverses a 1 meter 1800 torr ($3/\frac{1}{4}/1$: $He/N_2/CO_2$ mixture), E-beam pumped CO_2 amplifier, extracting about 2 joules of energy. A tunable CW CO_2 laser monitors the small signal gain. This signal is chopped, passed through a CO_2 spectrum analyzer, detected by a Hg-Cd-Te photo-voltaic detector and displayed on an oscilloscope. Isolation between the CW signal and the pulse is a serious concern in this experiment because the CW signal, corresponding to 100 mW power, must be isolated from the pulse power ($\sim 10^9$ watt). To facilitate this isolation, the CW signal and the pulse traverse the amplifier in opposite directions. Furthermore, the CW laser is tuned to a line ($R(18)$, 10.26 μm) which differs from the pulse so that further isolation is achieved with the spectrum analyzer.

Fig. 2 shows the results of the experiment. The solid curve represents the calculated small signal gain, $\exp(g(t)L)$, as a function of time. In Fig. 2(a) we show the time history of the small signal gain in the amplifier. In Fig. 2(b), a saturating pulse goes through the amplifier at a gain maximum. The drop in stored energy and subsequent repumping are clearly shown. Similarly, Fig. 2(c) shows a pulse extracting energy from the amplifier about 1.4 μs before gain maximum. The experimental data transposed from scope traces are shown as points on each picture and are in good agreement with the results predicted by the kinetics model.

In comparing theory and experiment, the adjustable parameter is the fraction of the available energy extracted. For 1 ns pulses, rotational relaxation prevents some of the 100-001 vibrational population difference from contributing in the energy extraction. We find a good fit with about 0.8 of the available vibrational energy extracted. This cannot be compared directly with the drop in gain shown in Figs. 2(b) and 2(c). Within the time resolution of the experiment (20 ns) and the time scale of the kinetics model (50 ns), the population transferred from 001 into 100 by the saturating pulse is redistributed within the symmetric and bending modes, so that both experimentally, and in the kinetics model, one does not record the absolute minimum in inversion due to pulse amplification.

19.3 Measured Dispersion in Long Multimode Fiber Waveguides With and Without Joints, C. Kao, G. Bickel, and M. Maklad, *ITT Electro-Optical Products Division, Roanoke, Va. 24019*

(15 min)

Dispersion in Multimode Fibers arises from the intrinsic group velocity characteristics of each propagating mode, the material dispersion and the differences in modal velocities. For a particular waveguide under a specific launching condition the signal pulse will initially be carried by a particular mixture of propagating modes which is by and large constant along the pulse duration. As this pulse propagates the pulse shape will be modified by the dispersion effects. For an ideal guide there is no mode coupling, so that as the higher order modes are delayed relative to the lower order modes, the pulse will broaden. The start of the pulse will eventually be made up by the energy carried in the lower order modes and the tail in the higher order modes. The pulse broadening will be proportional to length and pulse shape will be governed by the relative energy carried by each mode. For a practical guide, bending, stress and structural imperfections cause mode coupling; in other words, the energy carried by each mode is given to other modes, including radiative modes, and in turn receives energy from other modes. This gives rise to the effect that the velocity of the energy propagation will have an average value and its deviation will be de-

creasing at a rate proportional to $\sqrt{L}$. Hence, the pulse spread will increase at a rate proportional to $\sqrt{L}$. There will also be radiative losses. An equilibrium situation will arise when each part of the pulse energy will be carried in a mixture of modes undergoing continuous conversion as it propagates. Before this equilibrium is reached, the pulse shape undergoes complex changes from its initial state when the pulse will have a particular mixture of propagating modes along its duration, through successive stages when the modal delay causes pulse shape changes and pulse broadening.

The distance required for equilibrium may vary from fiber to fiber. It is the spectral distribution and the spectral content of the coupling discontinuities which govern the rate and type of equilibrium. For fiber waveguides with imperfections which can cause gross modal conversion distributed along its length, equilibrium may not be established.

This paper presents the results of an experimental study of dispersion in long multimode fiber waveguides.

The fiber waveguides under study are made by a chemical vapor deposition process. The resulting fibers have a numerical aperture of approximately 0.2. Fibers of various lengths are studied including one of 4 km length.

Measurements have been carried out on a dispersion measuring apparatus consisting of a GaAs laser source switched at low repetition rate by a subnanosecond pulse and a fast detector. The optical output has a subnanosecond rise edge and the principal pulse has a duration of 1 ns. The optical output is launched into the fiber with adjustable numerical aperture from 0.1 to 0.2.

Various fiber lengths from 2 meters to 1 km are measured for dispersion. A particular fiber is destructively tested by successive reduction of length. This serves to check the consistency between different fibers. A 4 km fiber is also destructively tested to study equilibrium effect. It is then rejoined by couplers of different tolerances. The gross discontinuities are introduced by the couplers. The equilibrium effects are again studied.

The transient behaviors are discussed.

19.4 Mode Analysis of Multimode Fibers, T. Ozeki, T. Ito, and T. Tamura, *Toshiba Research and Development Center, Kawasaki, Japan*

(15 min)

For analysis of propagating mode characteristics of multimode fibers, it is desired to realize the identification of modes and the measurement of mode amplitude distribution. Also, the direct measurement of group delay of each propagating mode is important to improve the fabrication techniques of graded index fibers.

It is found that a linearly-tapered section can be used as a mode analyzer for multimode fibers. The tapered section immersed in oil radiates the cutoff modes in coaxially stacked conical sheaths. When a screen is placed in parallel with the axis of the conical sheaths, the sections of these conical sheaths appear as a group of hyperbolas. The apexes of the hyperbolas correspond to the normalized cutoff frequencies of multimode fiber as shown in Fig. 1.

The mode analyzer using the linearly-tapered section with a ring spatial filter makes it possible to measure the group delay of each propagating mode of multimode fibers. The output from a mode-locked He-Ne laser operating at 0.633 μm was injected into the fiber through a $\times 40$ microscope objective and the output pulses from the fiber became widened due to mode dispersion of a clad fiber as shown in the upper trace of Fig. 2. The lower trace in Fig. 2 shows the output pulse component carried in the He_{11} mode, which is detected separately by the mode analyzer. Fig. 3 shows relative group delays of several modes of a clad fiber with the normalized frequency of 10.4. The measured group delays show good agreement with the calculated values based on the dispersion equation.[1]

The mode conversion in the clad fiber is measured quantitatively by using mode filters. A biconical taper as a mode filter has the insertion loss of 0.2 dB for the HE_{11} mode and the rejection ratios of more than 20 dB for the higher order modes. The amount of mode conversion from the HE_{11} mode to the higher order modes is measured to be 0.3 dB for the clad fiber with a core diameter of 12.5 μm, an outside diameter of 72 μm and for the length of 300 m at a bend radius of 15 cm. The pulse broadening due to mode reconversion or mode mixing cannot be detected within the time resolution of ~ 100 ps.

19.5 An Optical-Fiber Cable Fault Location Method, Y. Ueno and M. Shimizu, *Nippon Electric Company, Ltd., Yokohama, 226 Japan*

(15 min)

For the construction of an optical-fiber cable transmission system, it is necessary to develop efficient optical cable inspection methods. As practical inspection methods, there are "reflection methods" and "transmission methods" including pulse distortion method and conventional optical loss measuring method. During experimental inspection of a 600 m long SELFOC fiber in which faults exist, distinct pulse distortion is observed. "Reflection methods" including those methods which stand on the same principles of optical radars and sonars,

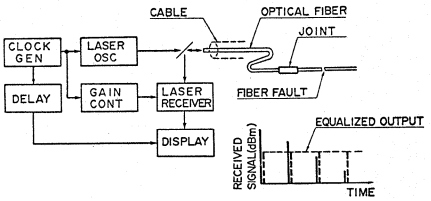

Fig. 1. Block diagram.

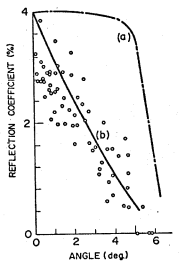

Fig. 2. Reflection coefficient.

have a merit of indicating the location of the fault.

An optical fiber fault location method using the optical pulse radar scheme is studied in detail, comparing with other methods. Optical fiber cables are tested by an experimental inspection set and effective data are obtained for the improvement of the cabling process and of the cable structure. The set is also applied to the study of the cable laying work (see Fig. 1).

In optical fibers the decay of optical pulse signals occurs exponentially to the transmission length, while available optical input power is limited by the stimulated Brillouin scattering effect.[1] Those effects and the reflection coefficient at the fault surface define the maximum detectable range. The reflection coefficient at a fault surface of an optical fiber is calculated and measured, as a function of the inclination angle between the surface and the optical axis, as shown in Fig. 2. In this figure, (a) indicates estimated value based on launching angle characteristics, (b) indicates estimated value based on geometrical optics, and the dots illustrate experimentally-measured data. The measurement is made using a mode-locked He-Ne laser and 1.5 m long SELFOC fibers.

In the block diagram shown in Fig. 1, optical pulses which are transmitted through the optical fiber and reflected at the joints and the fiber fault, are received by the optical receiver and displayed in a CRT display. The reflected signal from a joint which is nearer than the fiber fault becomes intense noise. A gain control method which increases the receiver gain synchronizing to the pulse transmission, is employed to equalize the input signals and to reduce the effect of the noise signals from the joints. Range gating is also an important technique to improve the signal-to-noise ratio. Ranging resolution can be improved by pulse shifting method or random pulsation method in which range is expressed as a statistical value of many samples.

A maximum detection range of 3 km is estimated in a ranging resolution of 2.5 m, assuming that an optical power of 0.5 W is launched into an optical fiber which has a loss of 10 dB/km. In practice, the output power of available lasers and the coupling efficiency to the optical fiber define the detection range. Reflected signal from an optical fiber fault at a distance of 1.4 km is observed by the experimental set with a GaAlAs laser diode. The input optical pulse peak power and wavelength of the laser are 0.2 W and 0.83 μm respectively, and the optical fiber loss is 17 dB/km.

[1] R. G. Smith, *Appl. Opt.*, vol. 11, p. 2489, 1972.

19.6 A 40 Mb/s and a 400 Mb/s Repeater for Fiber Optic Communications,

Y. Ueno and Y. Ohgushi, *Nippon Electric Company, Ltd., Yokohama, 226 Japan*

(15 min)

The high-performance feedback-type amplifier which makes front-end equalization unnecessary has been studied. Using amplifiers of this type, a 40 Mb/s repeater and a 400 Mb/s repeater have been built and tested for an optic PCM communication system.

The minimal optical power of the feedback-type amplifier (c.f. Fig. 1) is acquired using Personick's method[1] as follows.

$$P \text{ required} = \frac{1}{2T}(Q)^{(2+x)/(1+x)} \cdot [(Z)^{x/2+2x}(r_1)^{x/2+2x}(r_2)^{2+x/1+x}]\frac{\hbar\Omega}{\eta} \quad (1)$$

$$Z = \frac{T}{e^2}\left[S_I + 2k\theta\left(\frac{1}{R_b}+\frac{1}{R_f}\right) + S_E\left(\frac{1}{R_b}+\frac{1}{R_a}-\frac{1}{R_f}\right)\right]I_2 + \frac{(2\pi C_T)^2 S_E I_3}{Te^2} \quad (2)$$

where R_f = a feedback resistance and other symbols are used as in Ref. 1. And it is shown that we can obtain without a front-end equalizer the same performance as that of the equalizer-type integrating amplifier, if we make the feed back resistance sufficiently large.

A 40 Mb/s regenerative repeater (Fig. 1) using the feedback-type amplifier has been constructed with a 55 dB loss margin. The preamplifier is built using a 40 dB bipolar transistor amplifier, including the first stage bipolar transistor whose bias current is 0.5 mA, and a 68 kΩ feedback resistance. The gain of the main amplifier is 40 dB with 30 dB AGC. The total capacitance is 10 pF with the APD. The quantum efficiency of this APD is 70% and the excess noise coefficient is 0.5. The laser diode used here is a GaAs DH type which is driven by 200 mA current pulses. The optical output power is 0 dBm (average) at the panel connecter. The error performance of this repeater is plotted in Fig. 2. Good agreement with theoretical calculations represented by the solid line is obtained.

A 400 Mb/s repeater has also been built (Fig. 1). The 36 dBm loss margin has been obtained in this case. In higher bit-rate range, we can reduce the value of R_f without increasing noise. So, a 680 ohm feedback resistance is selected. The gain of the preamplifier is 20 dB. The first stage of this preamplifier is a bipoler transister whose collector current is 2 mA. And the total input capacitance is 13 pF with the APD. The quantum efficiency of this APD is 40% and its excess noise coefficient is 0.38. The driving condition of the laser diode is different from the case of 40 Mb/s. The 100 mA dc bias current is applied in order to reduce the delay between optical pulses and driving pulses. The

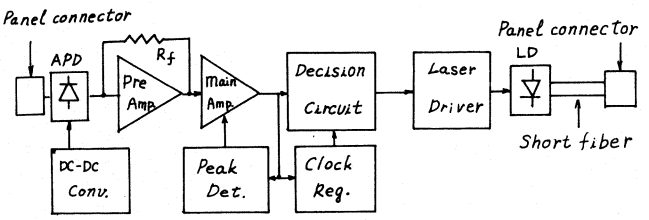

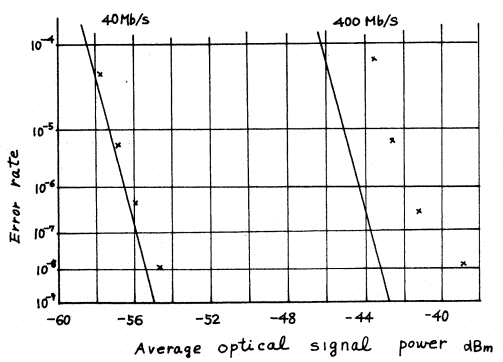

Fig. 2. Error rate performance.

100 mA pulse current is added to this bias current. The output optical power from the panel optical connecter is −3 dBm (average). Experimental results of the error-rate performance is plotted in Fig. 2. The solid line is from theoretical calculations according to (2). In this case good agreement with theory is not obtained without taking into account the 3 dB power penalty due to the intersymbol interferences caused by the APD.

19.7 Planar HgCdTe Photodiodes for Wideband Heterodyne Detection at 10.6 μm, [1] D. L. Spears, I. Melngailis, and T. C. Harman, *Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Mass. 02173*

(15 min)

ZnS films have been found to provide a sufficiently good mask for mercury diffusion to enable selective diffusions to be carried out in HgCdTe for the fabrication of planar photodiodes. Such *n*-on-*p*-type diodes, with 100 μm and 150 μm diameter clear active areas, have shown quantum efficiencies as high as 60% (uncoated) at 10.6 μm with a frequency cut-off well in excess of 1 GHz. Evaluated as detectors in a blackbody heterodyne radiometer, they have displayed a sensitivity within a factor of 3 of that of an ideal detector over a 0.5 GHz bandwidth.

Diodes were fabricated from 0.1 Ω-cm, *p*-type HgCdTe (19% CdTe) material which was mechanically lapped and polish-etched in 25% Br-methanol to a wafer thickness of about 0.2 mm. A 0.5 μm layer of ZnS was then RF-sputtered onto the wafer and openings etched in the layer with 5% HCl. A 5 μm deep, low carrier concentration *n*-type layer was produced in the open regions by a 30-minute, 240°C Hg-vapor diffusion in a sealed ampoule. The ZnS diffusion mask automatically passivated the edge of the *n-p* junction. Indium bonding pads were formed off the active region of the device. After gold plating the back contact, the wafer was diced and the devices mounted in microwave packages as shown in Fig. 1.

Electrical characteristics of these planar diodes are similar to etched mesa diodes,[2] having forward resistances of 5 to 10 ohms and reverse dynamic resistances of 200 to 1000 ohms. Most of the devices have shown a soft reverse breakdown starting at about 0.5 volts, apparently due to the high electric field at the perimeter of the planar structure. However, these planar devices, which have no surface passivation other than the ZnS diffusion mask, have shown no sign of electrical degradation over a period of more than 15 months.

Diodes made from three different HgCdTe crystals exhibited cut-off wavelengths ranging from 12.5 to 14.5 μm. Generally, the quantum efficiency was found to be almost constant from 3 μm to within 1 μm of the cut-off wavelength.

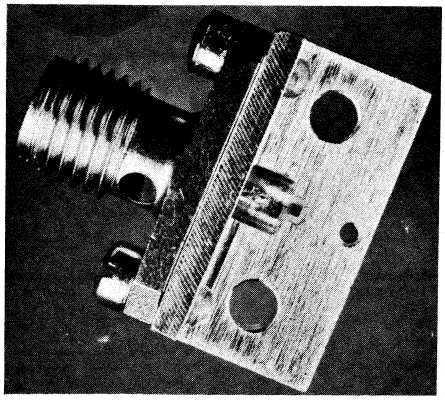

Fig. 1. HgCdTe photodiode in high frequency package. Cover plate is removed to show details.

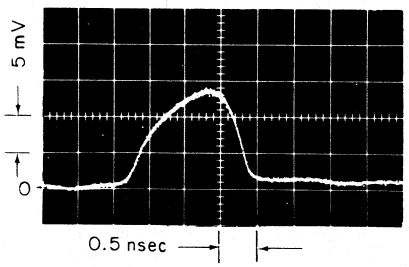

Fig. 2. HgCdTe photodiode response to a 1-nsec CO_2 laser pulse produced by an electrooptic modulator.

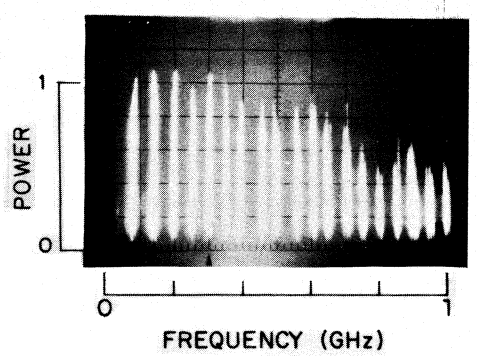

Fig. 3. Beat signals between a PbSnTe diode laser and CO_2 laser detected by a HgCdTe photodiode. Each line of the multiple exposure photograph corresponds to a different diode laser wavelength.

With a small reverse bias the peak quantum efficiencies of these uncoated diodes were typically 40 to 60%.

Detector response to a 1-nsec CO_2 laser pulse revealed RC limited response times of less than 1-nsec with only 100 to 200 mV reverse bias. With 500 mV bias, many devices had a fall time of less than 0.5 nsec, as shown in Fig. 2, which was the response time of the test equipment. Frequency response was also measured by detecting the heterodyne beat signal between a tunable PbSnTe diode laser and a CO_2 laser as the diode laser line was tuned through the CO_2 laser wavelength. Fig. 3 shows some typical results.

Blackbody heterodyne measurements[3] outlined schematically in Fig. 4 were used to obtain high frequency sensitivity information. By inserting a microwave mixer and low-pass filter between the preamplifier and RF detector, photodiode frequency response was measured by scanning the microwave local oscillator. With a 300°C blackbody temperature a signal to noise ratio of over 100 was observed with 1 sec integration time and 1.4 GHz bandwidth. This is within a factor of 7 of that expected for an ideal radiometer. With a 0.5 GHz bandwidth the detector-preamplifier combination performed within a factor of 3 of ideal, which is well over twice the sensitivity previously reported for HgCdTe diodes.[4] Only about p.5 mW of laser power was needed for quantum noise limited operation.

19.8 A Ten-Micrometer Receiver Subsystem for Wideband Space Communications, F. E. Goodwin and T. A. Nussmeier, *Hughes Aircraft Company, El Segundo, Calif.*

(15 min)

The need for wideband data relay system between satellites in space has fostered the development of 10 micrometer laser communication components over the past five years. This

paper reports the test results of an engineering model heterodyne receiver terminal for a synchronous satellite. The terminal would ostensibly serve as the receiver portion of a wideband relay link from a low altitude user satellite such as ERTS.

The receiver subsystem is comprised of components developed by a number of contractors and integrated at Hughes Space and Communications Group.[1]

An opto-mechanical design has been achieved which can operate with negligible distortion while directly exposed to the sun. This will permit the receiver to operate while tracking the transmitter signal across a solar background, a great operational advantage over other optical system concepts. The opto-mechanical portion of the receiver made almost entirely of beryllium weighs less than 30 pounds including waveguide laser local oscillator and radiation cooler. The electronics are rack-mounted at present.

The folded-Gregorian optical system utilizes a coarse pointing flat mirror having a field range of $\pm 20°$, and a set of orthogonal fine pointing mirrors having a field range of $\pm 0.1°$. Acquisition is achieved by commanding the coarse pointing mirror to within 0.1° of the transmitter beacon and searching by a raster scan pattern over the fine pointing field range. After initial pointing, the raster search routine takes less than six seconds. When the signal is sensed by the optical heterodyne detector, an RF carrier is developed in the IF amplifier which triggers a threshold and stops the search. Tracking of the incoming signal is then achieved by conical scanning of the fine pointing mirrors.

Doppler shifts of up to ± 700 MHz are encountered due to the relative velocity of a low altitude and synchronous spacecrafts. These Doppler shifts are accommodated through a wideband optical mixer and tracking RF electronics. For initial acquisition of a low altitude spacecraft, the receiver is commanded to be centered near the expected incoming signal frequency. Frequency acquisition takes place if the signal is within 85 MHz of the receiver band center.

The laser transmitter modulation format is double-sideband suppressed carrier modulation, and detection is achieved in the receiver by phase-lock or product detection of the IF signal. Data rates of 300 MBps can be accommodated by the receiver. Bit-error-rate measurements agree with theoretical within a factor of 1 dB for a bit error rate of 10^{-6}.

The optical mixer (detector) is cooled in space through the use of a radiation cooler to a temperature of approximately 100 to 120°K. In the laboratory, a temperature controlled Joule-Thompson cooler is used to simulate the space temperature.

Optical transmitter signals are simulated in the laboratory through the use of a breadboard laser transmitter using intracavity coupling modulation. The transmitter signal is attenuated to a level of approximately 10^{-15} W which compares with a receiver pre-detection NEP of 2×10^{-17} W.[2]

[1] Contributors to the effort are Hughes Research Laboratories (structural frame and waveguide laser local oscillator), Airborne Instrument Laboratory (Doppler tracking receiver electronics), Airborne Instrument Laboratory (Heterodyne receiver front end), Hughes Electro-Optical Division (optical design), and Hughes Space and Communications Group (opto-mechanical and servo system.)

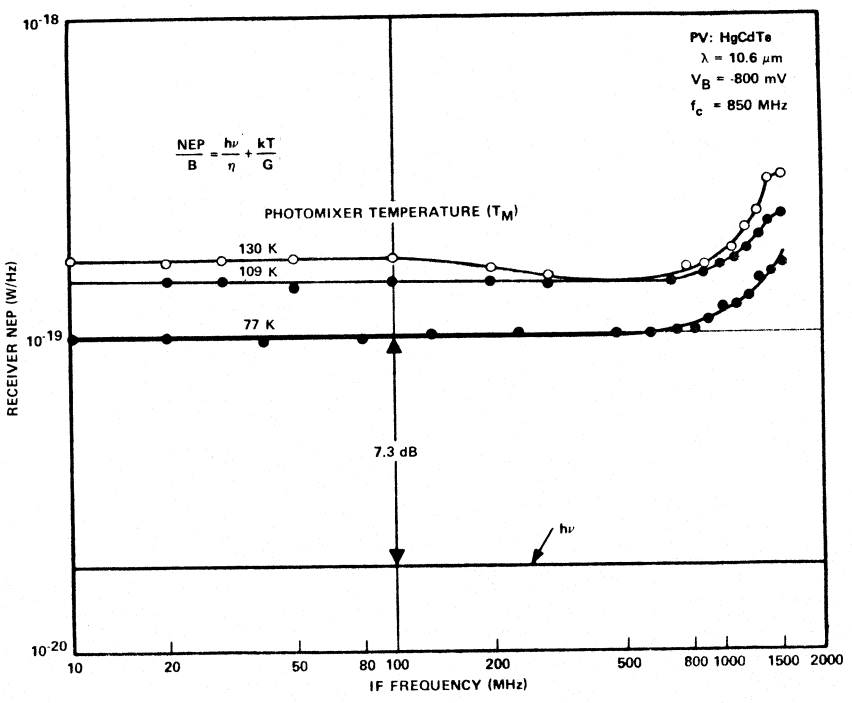
19.9 Wideband Heterodyne Receiver for CO_2 Laser Communication Link,[1] B. J. Peyton, T. Flattau, J. Wolczok, J. Mellars, and R. A. Lange, *AIL, a Division of Cutler-Hammer, Melville, N. Y. 11746*

(15 min)

This paper reports on an extremely wide bandwidth of a 10.6 μm infrared heterodyne receiver which has been developed for use in an engineering model of a simulated CO_2 space-borne communications link. For the link considered, the transmitter and the local oscillator (LO) are operated on the same laser transition. For low-altitude-satellite to synchronous-satellite and low-altitude-satellite to ground links, the transmitted signal is Doppler-shifted due to the difference in the relative velocity of the two stations.[2] The resultant Doppler frequency shift (Δf_d) varies with time and, hence, must be frequency tracked by either (a) a spectrally wide laser LO which can be rapidly tuned at infrared wavelengths, or (b) a heterodyne receiver which employs a fixed frequency laser LO and a wideband IF network which can be rapidly scanned using RF techniques. This latter type of communications receiver which utilizes RF tuning to handle the Doppler frequency offset has been adopted. Some design considerations for wideband infrared heterodyne receivers have previously been reported.[3] An electronic receiver back-end accepts the output of the heterodyne receiver front end and tracks the Doppler shifted signal so as to maintain a constant second IF at 1500 MHz. The receiver has a 300 megabit data capacity, which is compatible with the 400 MHz instantaneous IF bandwidth.

In order to prevent communication data distortion due to data foldover when $\Delta f_d < 200$ MHz, the laser LO in the heterodyne receiver front end is frequency offset by a minimum of 200 MHz with respect to the frequency of the laser transmitter. As the satellite passes through the zenith position, the polarity of the laser LO offset frequency is reversed.

A heterodyne receiver with an IF response up to 1200 MHz is required for the communications link, having a maximum Doppler frequency of 750 MHz, an IF bandwidth of ± 200 MHz, as well as a minimum IF offset of 250 MHz between the received carrier frequency and the LO frequency.



Heterodyne receiver measurements have been carried out over the 77° to 130°K temperature range to simulate operation with a passive radiative cooler which might be employed in an

Fig. 1. Measured heterodyne receiver sensitivity.

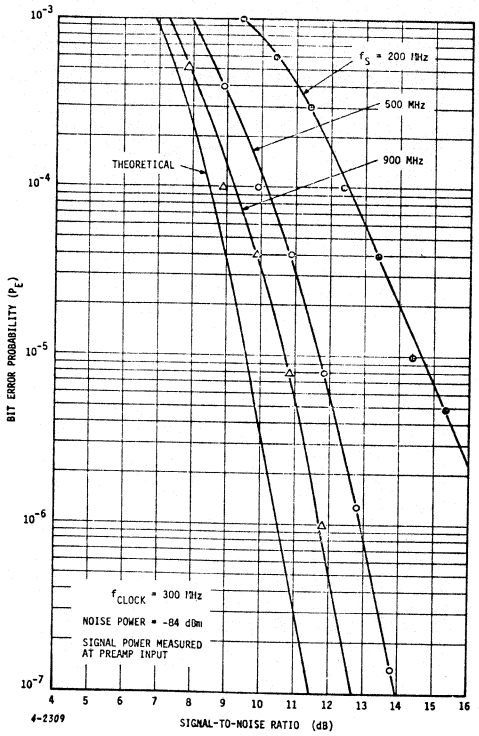

Fig. 2. Measured bit error probabilities of receiver back-end.

operational satellite receiver system. Measurement results indicate that efficient heterodyne operation can be obtained at photomixer temperatures up to 130°K and IF frequencies up to 1500 MHz for selected photo-mixer-IF preamplifier combinations. The heterodyne receiver NEP was measured as a function of IF offset at photomixer temperatures of 77°K, 109°K and 130°K with maximum incident laser LO power. The measured results (Fig. 1) indicate that the NEP near 20 MHz for an applied bias voltage of $V_B = -800$ mV is 1.0×10^{-19} W/Hz at $T_M =$ 77 K, 1.5×10^{-19} W/Hz at 109°K and increases to 1.75×10^{-19} W/Hz at 130°K. The receiver NEP improves slightly near IF = 700 MHz due to optimum impedance matching between the photomixer and the IF preamplifier, and then degrades slightly with increasing IF due to a decrease in the photomixer gain and an increase in the IF preamplifier noise. For an IF of 1500 MHz the receiver NEP is 1.65×10^{-19} W/Hz at 77 K, 2.35×10^{-19} W/Hz at 109°K and increases to 3×10^{-19} W/Hz at 130°K.

The signal entering the receiver back-end from the PV HgCdTe photomixer has a carrier frequency which can range between 250 and 1000 MHz (a greater than 20 MHz/sec rate of change can be tracked) depending upon the Doppler frequency shift encountered. It is binary double-sideband amplitude modulated with the carrier being suppressed on the order of 20 dB below the total signal power (which is nearly equivalent to binary phase shift keying). The receiver configuration employs a signal squaring tracking loop to provide the coherent reference required for optimum signal demodulation.

The bit error probabilities measured at a data rate of 300 megabits/second are given in Fig. 2 for carrier frequencies (off-set plus Doppler shift frequencies) of 200 MHz, 500 MHz, and 900 MHz. The increasing error probabilities at the lower carrier frequencies are attributable to the higher levels of signal image and VCO leakage powers appearing at the output of the second IF filter.

19.10 Direct-Detection Diversity Receiver for Optical Communication through the Atmosphere, C. M. McIntyre, J. R. Dunphy, and J. R. Kerr, *Oregon Graduate Center, Beaverton, Oreg. 97005*

(15 min)

Optical communications systems operating in the atmosphere are subject to the degrading effects of, among other things, clear air turbulence.[1] This phenomenon causes fading due to beam wander and scintillation.[2] In the case of a large beam diameter at the receiver (or when a tracking transmitter[3] is used to cancel wander) scintillation constitutes the dominant fading mechanism with a dynamic range that can approach 80 dB (defined on the photo current signal) in a small receiver. Recent experimental[4] and theoretical[5] results have revealed that under conditions of high turbulence, a transverse spatial correlation exists in the received field such that the aperture averaging expected in a large aperture receiver[6] is not completely effective. Under these conditions, an array of small aperture receivers, separated to ensure independent sampling of the received field, is expected to outperform a large aperture receiver of equivalent area.

In order to demonstrate the capability of this diversity array for overcoming the deleterious effects of atmospheric turbulence, a receiver designed to operate with a binary on-off transmitter (operating at 4880 Å) has been installed on our 1.6 kilometer field test facility. The receiver consists of: i) a four-element horizontal array, with each element composed of a 4 cm diameter lens, semiconductor detector, and preamplifier, and ii) a 25 cm diameter "photon bucket" with its associated detector and preamplifier for direct comparison. The array receiver contains electronics for processing and adding the elemental signals. Both the diversity array and the photon bucket feed common decision making electronics and then logic circuits that compare the receiver decision with a reference that is hard wired from the transmitter. The receiver decision is made by comparing the received signal (integrated over the duration of a bit interval) with an adaptive threshold that is derived by averaging the received signal over a time that is long compared to a bit interval, but short compared to the atmospheric fluctuations. The site is instrumented to record meteorological conditions; C_N^2 (a point measurement of the strength of turbulence); σ_l^2 (log amplitude variance of the received field) for i) a point detector ii) a single element of the diversity array iii) the sum of the four array elements and iv) the photon bucket; the correlation between adjacent elements of the array; and the system error probability.

Typical results are indicated in the table. During periods of low turbulence, when the transverse spatial correlation described above is not evidenced, the photon bucket outperforms the diversity array as expected due to the larger area. Note the lower variance and error probability for the photon bucket. However, under conditions of high turbulence, the diversity array constitutes a more efficient system. Note that with only one tenth of the area, the array receiver has a comparable variance and error probability. In low turbulence, the diversity array performs as well as a photon bucket with the same area, while in high turbulence the diversity array performs as well as a photon bucket with 10 times the area.

2.7 Rain Drop Measurements by Holography, V. M. Zakharov, L. N. Rasoumov, E. M. Birger, and S. P. Karlov, *Department of Hydrometeorology, Moscow, USSR*

(15 min)

At present rain drops are studied by a number of methods. Among the most frequently used methods are: filter paper; intercepting rain drops with cells filled with vaseline or castor oil; photographic recording; and a photoelectrical method, which is the most effective one at present.

In this work a method of pulsed holography which has been applied successfully to aerosol observations by a number of authors[1,2] was utilized for rain drop studies. These measurements were made with a holographical unit, laboratory operation of which has already been reported.[3] To test a working capacity of the unit in field measurements, atmospheric precipitation studies were begun in October, 1974. When processing the results of preliminary field experiments we did not undertake the task of determining integral characteristics of precipitation, but studied the form of rain drops and determined their typical size in rain of various intensities.

Fig. 1 shows a field unit in a working position. Its lens variant was capable of sounding in a 20-200 cm^3 volume while a lenseless one was within 1 litre. The time of exposure was determined by a ruby oscillator pulse length which could operate in a free generation mode ($\tau = 10^{-4}$ sec) as well as with Q-switching ($\tau = 2.0.10^{-8}$ sec). Holographical recording was made on holographical films with a resolution of not less than 1200 lines/mm and high contrast phototechnical films with a 270-450 lines/mm resolution.

When a droplet passed close enough to a photographic plate we managed to reconstruct both holographical images, bright and contrasting. When it appeared far from a plate (> 15 cm), it was impossible to observe a virtual image. The image reconstructed by the usual scheme was photographed through a microscope with variable magnification. Fig. 2 shows real images of rain drops with mean diameters of 225 and 345 μ. The total magnification is 42×. An observed eccentricity (meaning a vertical to horizontal drop size ratio) showed significant differences. In Fig. 2(a) and (b), its values are 0.95 and 0.87, respectively. From the known mean diameters stabilized fall velocities were calculated. The empirical relations from papers[4] were applied.

The most typical sizes and velocities of droplets for low intensity rain are shown in Table I. Fig. 2(a) and (b) corresponds to cases 3 and 4.

Small exposure values limit essentially the number of droplets which can be detected simultaneously. Indeed, at droplet concentration of an order of 10^3 m^{-3} which is the case in mean intensity rains, only one droplet is detected in the volume of interest simultaneously.

This causes the necessity of increasing the volume several times at such concentrations or lower concentrations. The technical difficulties of realizing such systems grow significantly and from our point of view can hardly be justified. Evidently, a sampling method is more effective in this case. However, at concentration exceeding 10^3 m^{-3} a method of pulsed holography is rather useful for obtaining information about size and form of rain drops. It should be noted that no other method except photography can provide data on droplet form.

The unit with which the results presented here were obtained detects particles with 10 μ diameters with certainty. This is by an order of magnitude lower than is provided by a photographic recording, not to mention the fact that pulsed holography in addition to sounding large volumes fits high aerosol velocities much better.

4.12 Measurement of the Cross Section for Stimulated Emission in Neodymium-Doped Glasses, E. M. Dianov, A. Ya. Karasik, L. S. Kornienko, A. M. Prokhorov, and I. A. Shcherbakov, *P. N. Lebedev Physical Institute, Academy of Sciences, Moscow, USSR.*

A knowledge of the cross section for stimulated emission (σp) of an active medium is needed in designing laser systems. But this value is difficult to measure, to within a sufficient accuracy, in the case of a four-level system and great nonuniform broadening of spectral lines, which is the case nonuniform broadening of spectral lines, which is the case with neodymium-doped glasses, so that measurement results strongly differ with authors. In the present paper a method for measuring the cross section for stimulated emission of neodymium in the glass, based on spectral absorbance and fluorescence measurements at helium temperature, is suggested. An absorption associated with a transition between the lowest components of the ground and excited states, which are the Kramers doublets, is measured and the Einstein coefficient for spontaneous transition is determined. The same transition is taken in the resonance fluorescence spectrum and it is used to normalize the whole fluorescence spectrum. This procedure requires a precision measurement of spectral distribution of the fluorescence energy over a wide wavelength range (0.85–1.8 μm), a technique which has been also developed by the authors. The values of σp have been determined for a number of silicate- and phosphate-based glasses. In the latter σp is much higher (maximum $4.6.10^{-20}$ cm^2) than in the former (maximum $2.4.10^{-20}$ cm^2). Most of the glasses studied exhibit a low thermooptic constant, thereby providing a highly directional laser beam. It follows from the above considerations that a measurement of σp by the method suggested will necessarily require the Einstein coefficient for radiative transitions. This makes it possible to determine the radiative lifetime of the metastable state. On the other hand, knowing σp, the effective fluorescence linewidth of laser transition and the ratio of fluorescence energies of all radiative transitions, one can calculate the radiative lifetime of the excited state. We have performed such calculations for the glasses for which all these data are available in the literature. All the values of σp practically proved to yield a radiative quantum efficiency from the metastable state of neodymium of over unity. Sometimes it is far more than unity. In other words, the radiative lifetime determined in the above way turns out to be shorter than the directly measured values. This circumstance uniquely suggests that the values of σp presented elsewhere are overrated. So, we have analyzed the spectroscopic methods available for determining σp. The analysis has revealed that in all the cases calculations of σp based on the experimental spectroscopic data inexplicitly assume equal probabilities of transitions connecting the Stark components of the ground and excited states. We have shown that under this assumption, the total probability of transition, and hence its cross section, can be either overrated or underrated. The experimental investigation of the ground state structure of neodymium in the glass has shown that the spectroscopic methods available tend, as a rule, to provide too high values of σp, which is the case.

5.10 The Relevance of Lasers in the Energy Shortage, E. Teller, *Lawrence Livermore Laboratory, Livermore, Calif. 94550.*

Laser fusion has captured the popular imagination as an energy source of the future. The idea is simple, but the difficulties are enormous. A thousandfold compression of the thermonuclear fuel permits an explosion approximately one millionth the size that is predicted by theory in the uncompressed liquid fuel. But appropriate lasers will be hard to develop. The symmetry needed to establish the high compression is a great challenge and even after feasibility is established, an engineering development of exceptional difficulty will have to follow.

It is more probable that lasers will make a contribution in the energy crisis by means of separating isotopes. Remarkable progress has been made on the separation of uranium isotopes, but it must be remembered that today the cost of separating uranium isotopes accounts for only 5% of the cost of generating electricity by a nuclear reactor.

The really great influence of lasers may be due to the separation of the hydrogen isotope. Today the heavy water reactor appears to be an interesting alternative, but it is handicapped by the high cost and scarcity of heavy water. Laser separation of hydrogen isotopes could decrease this cost to a fraction of its present value and could therefore revolutionize the deployment of reactors.

Laser fusion will come too late. Uranium separation will make a marginal contribution. Heavy water production may however have a thorough influence on the energy economy.

8.8 Production of Specially Tailored Laser Pulse, S. K. Vartapetov, V. I. Vovchenko, I. K. Krasjuk, S. G. Lukishova, P. P. Pashinin, and A. M. Prokhorov, *P. N. Lebedev Physical Institute of the Academy of Sciences of the USSR, Moscow, USSR.*

The production of laser light with the intensity grown according a specified law by a regenerative amplifier is considered. Formulas estimating the required amplifier characteristics due to desired light pulse parameters are presented. The combined method of control of the amplification coefficient by means of electrooptical cell and saturated filter is analysed.

The preliminary experimental results for the case of generation of a number of light pulses with growing amplitudes are represented.

12.6 Use of Pulsed Laser Treatment to Change Physical Properties of Metals and Semiconductors, I. Ya. Dekhtar, L. I. Ivanov, N. V. Karlov, A. M. Prokhorov, and N. N. Rykalin, *P. N. Lebedev Physical Institute, Academy of Sciences of the USSR, Moscow, USSR.*

The possibility of using the shock waves generated by absopriton of laser pulse irradiation in the surface layers of metals, semiconductor and skin layers which form under laser influence to change physical properties of the substances is considered.

The data are listed on the nature of radiative defects appearing in metals and semiconductors generated by the travelling shock waves caused by laser irradiation. Use of laser pulse irradiation to strength metals and alloys is shown to be promising.

The effect of laser pulse irradiation on electrical properties of semiconductor silicium and germanium single crystal whiskers is considered. An anomalous drop of electroresistence in such crystals is found when treated with shock waves.

The data are listed on the influence of laser pulse irradiation upon superconductivity. The effect of considerable change of transition temperature was found. It is discussed due to crystallo-chemical reactions stimulated by point defects caused by laser irradiation or (and) by methastable phase formation caused by fast laser heating and subsequent fast cooling.

Post-Deadline Sessions

Papers Included in Regular Daytime Sessions

4.10 CW and Self-Q-Switched Laser Operation of Nd:YVO_4, L. G. DeShazer, *University of Southern California, Los Angeles, Calif. 90007,* and A. W. Tucker, M. Birnbaum, and C. L. Fincher, *Aerospace Corp., El Segundo, Calif. 90245.*

High-efficiency low-threshold solid-state laser oscillators are needed for many communication and ranging applications. Until recently, Nd:YAG material has been the only choice for such oscillators, even though Nd:YAG lasers did not meet many system requirements. Last year, an experimental material, Nd:YVO_4 (yttrium orthovanadate), was shown to outperform Nd:YAG in a pulsed-lamp pumping configuration.[1] However, advances in Nd:YVO_4 laser development have been hindered by the lack of large-sized (3 × 30 mm) laser-grade crystals. This current scarcity resulted from control difficulties in the vanadate crystal growth; these difficulties have been identified and procedures are now being taken to grow large crystals.[2]

Meanwhile, we initiated a laser testing program to carefully evaluate the performance of Nd:YVO_4 lasers relative to Nd:YAG. Since only relatively small crystals (5 × 5 mm) of Nd:YVO_4 were available (in fact, we used only spectroscopic samples), we based our test program on solid-state lasers pumped by a CW argon-ion laser. All results were obtained with the pump at 5145 Å only, and soft-focused (25 cm fL) into the crystal through the back mirror. The pump beam waist was 180 μm, increasing only slightly over distances of 1 cm on either side of the focus. Incident pump powers up to 10 W were available.

Many advantages, both experimental and theoretical and sometimes surprising, were realized by this laser pumping procedure. The experimental advantages are centered on the longitudinal excitation ("end pumping") of the crystals which confined the laser-active region to a well-defined volume. Thus the best optical quality crystalline region could be chosen for the laser experiments, escaping obstruction by large inclusions and cracks. Further, this restricted active region leads to an effective resonator aperture producing single transverse mode (TEM_{00}) performance of the crystal laser. The effective aperture is, in fact, *tapered* ("soft aperture") due to the smooth intensity profile of the pump beam. In addition, confinement of the gain to a small volume avoids the parasitic laser oscillations which usually depump solid-state lasers in the high pumping regime. It was noted that dye lasers do not have all of these advantages.

Many advantages in the theoretical analysis of the input–output power curves are accrued by this well-controlled performance. Since the mode volume is fixed and the pump power absorbed is simply measured, the input–output (P versus W) followed the theoretical linear plot $P = P_s\,[(W/W_{th}) - 1]$, instead of the S-shaped curve common for flash-lamp pumping. The dependence of threshold power (W_{th}) upon mirror reflectivity was accurately determined to be $KW_{th} = -\ln(R_1R_2) + 2L\alpha$. Thus the loss coefficient α was determined from the intercept at $W_{th} = 0$. Only two difficulties occurred: a slight variation in the data was produced by optical feedback into the gas laser (a Faraday isolator is currently being constructed), and the back mirror can be damaged by the pump beam if its transmission is below 80 percent at 5145 A.

Therefore, in this manner, the input–output power characteristics were measured for pulsed quasi-CW (1 pulse per second), N and CW lasers of Nd:YVO_4 and YAG at both 1.0640 and 1.3395 μm. The threshold, slope efficiency (versus output reflectivity), gain, and loss were determined for both crystals. A comparison of the laser performance of a spectroscopic sample of Nd:YVO_4 (4.8 mm, 1 percent Nd) and a laser rod of Nd:YAG (13 mm, 1 percent Nd) will be presented. Resonator length was 1–2 cm and plane mirrors were used with reflectivities from 65 to 99 percent 1 W of Nd:YVO_4 laser output was obtained in CW operation at 1.0640 μm, 100 percent plane polarized (parallel to the optic axis) with 4.5 W absorbed at 5145 A. The 1.06-μm laser cross section of Nd:YVO_4 is 30×10^{-19} cm^2, which is 4.6 times greater than that of Nd:YAG. The intrinsic loss coefficient at 1.06 μm was measured to be 0.16 cm^{-1} for YVO_4 and 0.012 cm^{-1} for YAG. This high loss for YVO_4 is mainly due to the scattering from small inclusions of iridium metal and gaseous voids; the theoretical loss limit was calculated from spectroscopy to be 0.009 cm^{-1}. Undoubtedly, this loss will not be present in future YVO_4 material. Calculations based upon measured values showed that if the Nd:YVO_4 loss coefficient at 1.06 μm were equal to that measured in the Nd:YAG rod, the CW laser threshold of the vanadate would be less than half that observed for the garnet. Maximum slope efficiency was measured to be 25 percent at 20 percent output coupling.

1.34-μm CW operation of Nd:YVO_4 and YAG lasers was obtained where the laser emission was plane polarized for vanadate and unpolarized for YAG. Nd:YVO_4 clearly outperformed YAG at this wavelength and had an output of 0.35 W for 4.8 W of 5145-A pump power absorbed. The 1.34-μm laser cross section of Nd:YVO_4 was 3.6×10^{-19} cm^2, which is *18 times* greater than that of Nd:YAG at 1.32 μm. The 1.06 μm oscillation was suppressed by having mirror reflectivities below 10 percent for that wavelength.

Self-Q-switched operation of Nd:YVO_4 was observed at 1.06 and 1.34 μm, but not for Nd:YAG. These are the *first* observations of self-Q-switched operation of a Nd laser at room temperature.[3] Most of the data were obtained with the Nd:YVO_4 sample misaligned by 25 arcmin from the resonator axis. Pulsewidths of 40 ns were observed, with peak powers over 1000 times greater than the CW output of the laser. Our observations imply that the vanadate laser could operate in a repetitively Q-switched mode simply by misalignment of the resonator mirrors or rod.

6.6 Soil Compaction Checks by Means of a Laser Device, Panagiotis A. Drakatos, *Polytechnic Institute, University of Patras, Patras, Greece.**

The absorption of longitudinal sound waves by the soil surface is a function of soil compaction and depends on its elastic and plastic properties. The longitudinal waves are created by a vibrating machine during soil compaction.

The present method uses a vibrating compactor (see 4 of Fig. 1) which operates at various frequencies f from a fixed

*Present address: 1807 Ford Parkway, St. Paul, Minn. 55116.

position on compacted soil and a specially operated laser device (5 of Fig. 1) to measure the amplitudes of the sound wave, A and E, (Fig. 5. 1 and 2), and the frequency of vibration f as well as the vibration frequency f_d of the vibrating machine during soil (3 of Fig. 1) compaction (frequency of compaction).

It is achieved by directing the laser beam on the mirrors (1 and 2 of Fig. 1). The beam is reflected and enters the detectors (6 of Fig. 1) as measured by the oscilloscope (7 of Fig. 1). Forms of these signals are shown on Fig. 2. If the distance between the mirrors ($A \equiv 1$), ($E \equiv 2$) is l, then the damping constant of these waves is $r = (1/l) \ln (A/E)$.

In Fig. 3(a)-(c), is shown the change r as a function of frequency f as well as in Fig. 4(a)-(c), the change (A-E) as a function of f, after each pass J of the vibrating machine. Thus, for a given compactor, the following question arises: What should constitute the basis for predetermining the number of passes J of the

TABLE I
SOIL COMPACTION PARAMETERS

Soil	$r_{min}(m^{-1})$	J	$f(sec^{-1})$	$f_d(sec^{-1})$
Sand	0.9	10	43.5	47.0
Clay	1.105	10	45.7	47.0
Clay and Sand	1.15	10	44.75	47.0

machine in order to achieve the desired soil density at a given depth?

The minimum values obtained [Fig. 3 (a)-(c)] for the damping constant r on three kinds of soil was found as listed in Table I. The values r_{min}, J, f, and f_d in Table I correspond to the maximum desired density values.

Referring to the graphs [Fig. 4(a)-(c)] of (*A-E*), it is noticed that the curve $f_d = 47\ s^{-1}$, $J = 10(47/10)$ has a linear change in the frequencies and passes of the compactor, with which the maximum compaction is achieved. However, in the other frequencies and passes the change is not linear and a high instability of these changes is noticed due to the nonuniformity of the soil.

The preceding method for checking the quality of compaction can be applied in the study of construction of roads, electrical cable-carrying ditches, or water pipes, and numerous other projects. It constitutes an original and precise method and its implementation is simple and inexpensive.

10.10 Convolution Using Guided Acoustooptical Interaction in As_2S_3 Waveguides, K. W. Loh, W. S. C. Chang, and R. A. Becker, *Washington University, St. Louis, Mo. 63130.*

Acoustic surface waves (ASW's) have been used to achieve convolution by a number of researchers.[1-10] Use of acoustooptical (AO) interaction for convolution in the bulk medium was reported by Squire *et al.*[11] and Damon *et al.*[12] The signal-to-noise ratio and the dynamic range of the bulk convolver are low because the AO diffraction is not very efficient. Bragg diffraction of optical guided waves (OGW's) by ASW's can be very efficient in thin-film waveguides, e.g., As_2S_3 film deposited on top of a $LiNbO_3$ substrate.[13-14] Convolution by guided AO interaction may yield large dynamic range or time bandwidth product. More importantly, it will allow us to carry out signal processing in thin-film waveguides which may have many applications in single-mode optical-fiber communication systems in the future. We report here the first experimental observation of the convolution by the OGW-ASW interactions in the As_2S_3-$LiNbO_3$ waveguide.

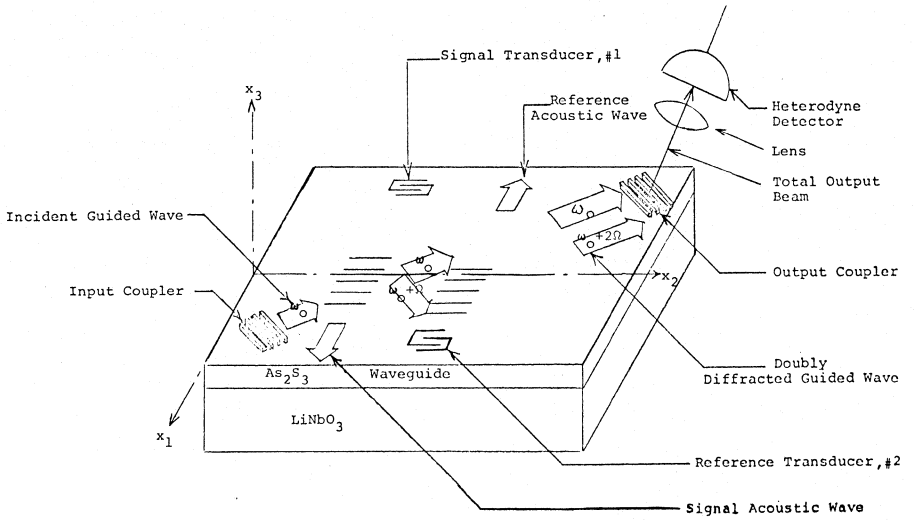

Fig. 1. Illustration of OGW-ASW convolver.

Fig. 1 illustrates the OGW-ASW convolver. For Bragg diffraction with less than 10-percent efficiency, the spatial amplitude distribution (i.e., the x_2 variation) of the OGW diffracted by the ASW of the first transducer will be proportional to the power distribution of the acoustic surface wave in the x_2 direction, i.e., $P_1(x_2)$. The ASW from the second transducer is again phase matched to the diffracted beam. Thus the spatial amplitude distribution of the twice-diffracted beam will be proportional to the product of the power distribution of the two acoustic surface waves in the x_2 direction [i.e., $P_1(x_2) \cdot P_2(\tau - x_2)$]. The twice-diffracted beam is parallel to the incident beam. It is also shifted in angular frequency by 2 ($\Omega_0 \pm \Delta\Omega$) where Ω_0 is the center frequency of the ASW and $\Delta\Omega$ is the frequency bandwidth of the ASW signal. Therefore the electrical output signal in the frequency range $2(\Omega_0 \pm \Delta\Omega)$ from an optical heterodyne receiver will be proportional to the integrated product of $P_1(x_2)P_2(\tau - x_2)$, i.e., it is proportional to the convolution of P_1 and P_2.

Experimentally, a set of ASW transducers is fabricated first on the $LiNbO_3$ substrate. A layer of As_2S_3 film is then sputter deposited on top of the entire structure. OGW at the 1.06-μm wavelength is coupled in and out by means of a pair of GaP prisms. When CW RF power is applied to one pair of the transducers, we obtain a maximum Bragg diffraction efficiency of 93 percent at 3 mW of ASW power (30 mW of electric power). When a 200-ns rectangular pulse is applied to both sets of transducers, a convolved triangular pulse is detected by the oscilloscope through the heterodyne detector. The theoretically predicted dynamic range and time bandwidth of such a convolver are quite high. However, OGW wavefront distortion observed by us in the As_2S_3 waveguide is very bad; this has prevented us from realizing the theoretical predicted performances. Theoretical and preliminary experimental data will be presented in this paper.

14.10 Atmospheric Transmission Measurements at HF/DF Laser Wavelengths,* S. R. King, F. I. Shimabukuro, E. E. Reber, and D. J. Spencer, *Electronics Research Laboratory, The Aerospace Corporation, Los Angeles, Calif. 90009.*

The measurement of atmospheric attenuation of laser radiation for an earth-to-space path presents difficult experimental problems. We have developed an earth-based system capable of making these measurements at HF and DF laser wavelengths. Experimental results for several laser lines will be presented. The heart of the absorption measurement system is a near quantum noise limited (QNL) optical heterodyne radiometer. This radiometer is similar to one previously used to make atmospheric transmission measurements at CO_2 laser frequencies.[1] The present radiometer utilizes a photovoltaic HgCdTe infrared detector as the optical mixer and a stable CW HF/DF laser as the local oscillator. The construction of this type of laser has been described elsewhere[2] with the exception that mode control apertures are permanently positioned within the optical cavity to ensure TEM_{00q} mode operation. Single-line output power is typically 100 mW.

The use of an optical heterodyne radiometer to measure atmospheric transmission has been discussed by McElroy.[3] Briefly, the sun is used as a source and the variation in received solar power with zenith angle yields the attenuation coefficient for a vertical transmission path through the entire atmosphere. The advantages of an optical heterodyne radiometer over a conventional spectrometer for this measurement are extremely high spectral resolution ($\lambda/\Delta\lambda > 10^6$) and precise knowledge of measurement wavelength relative to laser wavelength. The importance of these two properties is evident when the rapid variation of atmospheric transmission with wavelength is examined.[4]

One of the inherent difficulties in achieving QNL optical heterodyne detection is the requirement for a stable local oscillator. At CO_2 laser frequencies this problem has been solved by a number of workers. However, to our knowledge, this is the first reported work showing near QNL performance at HF laser frequencies. Fig. 1 shows predicted and measured radiometer performance as a function of laser local-oscillator induced current in the HgCdTe mixer. Much of the discrepancy between experiment and theory is caused by electromagnetic interference from the laser discharge. Although this source of noise has been reduced by over three orders of magnitude, it is still a problem because of the proximity of the laser and detector electronics in our laboratory setup. Increasing the local oscillator power would appear to be the solution to improving radiometer performance. Unfortunately, the mixer current responsivity decreases for currents above ~0.5 mA, destroying the linear relationship between radiometer output voltage and local oscillator power. Using 0.5 mA as the optimum local oscillator current, the radiometer performance (therefore the mixer performance) is seen to be within a factor of ~9 of predicted performance.

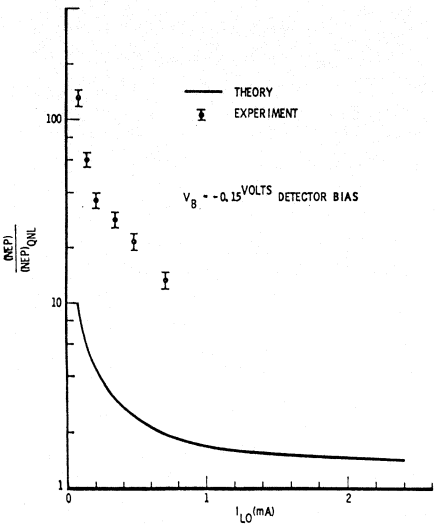

Fig. 1. Radiometer performance at HF P_2 (8).

Atmospheric transmission measurements using the previously described radiometer are presently being conducted at El Segundo, Calif. Fig. 2 shows the results of two typical radiometer measurements performed at HF laser wavelengths. High and low transmission lines have been displayed to demonstrate both the wide dynamic range and high sensitivity of this system. Theory predicts a straight line on this plot; the attenuation coefficient for zenith transmission through the entire atmosphere is given by the slope. Scatter in the data is seen to be small. A statistical analysis shows the standard error for these measurements to be ~3 percent of the measured values. A comparison of these measured values will be made with predicted values using the line atlas compiled by McClatchey *et al.*[5] Results of measurements at laser wavelengths where high transmission is found will be presented.

14.11 Frequency Stabilization and Absolute Frequency Measurements of a CW HF/DF Laser,* R. S. Eng† and D. L. Spears, *Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Mass. 02173.*

By mixing the CW output of an HF/DF laser and a frequency-doubled CO laser, we have measured the frequency of one HF laser line relative to the second harmonic of a CO laser line with an uncertainty of about ±5 MHz. The absolute frequency of the HF line is then obtained from the absolute frequency of the CO laser line which has recently been measured to about ±2.5 MHz. Extension of this measurement to other HF and DF laser lines can easily be made. The HF and DF lasers are useful high-power lasers important in atmospheric propagation, optical communications, and optical pumping applications. In particular, the heterodyne technique enabled

*This work was sponsored by the Department of the Air Force.

†Present address: Block Engineering, Inc., 19 Blackstone Street, Cambridge, Mass. 02139.

us to successfully stabilize the frequency and to some extent the amplitude of the HF laser to a much higher degree, and at the same time it provided a convenient way to study the effects of electric discharge, kinetic reactions, and gas dynamics on the laser stability.

The experimental setup consisted of CW grating controlled highly stable CO and less stable HF lasers, each operating in a single longitudinal TEM_{00} mode with piezoelectric tuning of the output mirror. The 0.5-W CO laser was focused into a $AgGaSe_2$ nonlinear crystal generating a second harmonic frequency. The second harmonic beam was collimated and then combined with the HF laser beam. The combined beam was focused on a high-speed HgCdTe detector to generate a beat signal. The beat signal was externally mixed with a microwave oscillator and the resulting IF signal was amplified and fed into a spectrum analyzer. The lasers were tuned to line centers by cavity tuning. For the second harmonic of the $P_9(16)$ line of $^{12}C^{16}O$ and the $P_0(6)$ line of HF, a 30-dB signal-to-noise beat signal of 10 783.43 ± 5.1 MHz was obtained from 10 independent measurements. This yields an absolute frequency of 110 725 697.37 ± 7 MHz for the $P(6)$ line of the 1–0 band of HF laser, which is about two orders of magnitude more accurate than the existing grating value.

Since the accuracy of the absolute frequency measurement depended greatly on the success of stabilizing the HF laser frequency, great care was taken to minimize transmission of pump vibration and acoustic noises to the laser cavity. The HF laser was a small electric discharge transverse-flow mixing laser with $H_2:SF_6:O_2:He$ pressures of 2:4:3:1 torr. It was pumped by a 40-ft^3/min mechanical pump. An amplitude fluctuation of about 1 percent was observed for a single-line output power of about 150 mW. With both lasers free running, a short-term jitter of ±5 MHz was observed in the beat signal. The rate of jitter had a strong low-frequency component due to periodic pump-speed variation, and weaker components as high as 2 kHz were present. A feedback loop consisting of a 70-MHz frequency discriminator and an operational amplifier was used to reduce the short-term jitter to about ±500 kHz, as seen in Fig. 1, and greatly increase the long-term stability. The short-term frequency instability is believed due to the nature of the SF_6 discharge, rapid gas mixing, and kinetic reactions, although some acoustic noise and structural resonances cannot be excluded.

The servo loop had a very high dc gain and a bandwidth of about 300 Hz limited by resonances in the piezoelectric element. A higher frequency piezoelectric element and a parallel phase-lock loop could be used to reduce the jitter to below 100 kHz. Since frequency modulation is not used, this technique of stabilization is especially useful in optical communications and radar applications.

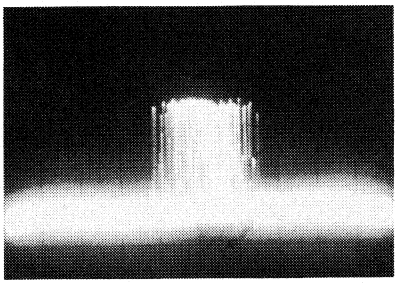

Fig. 1. Beat signal between HF and frequency-doubled CO laser. Horizontal scale: 500 kHz/div. Vertical scale: 10 dB/div. Linewidth is about 1 kHz; 1-s exposure time.

15.10 Determination of Argon Oxide 558-nm Laser Parameters, William M. Hughes, *Los Alamos Scientific Laboratory, Los Alamos, N. Mex. 87544,* T. Olsen and R. Hunter, *Maxwell Laboratories, Incorporated, San Diego, Calif. 92123.*

Experiments have been conducted using high-power vacuum-ultraviolet (VUV) flash photolysis of N_2O to produce $O(^1S_0)$. Measurements of the gain profile and the pressure and time dependence of the gain and excited state lifetime have been made. A two-chamber apparatus was employed where one chamber was used as a flashlamp.

A 50 × 1 cm^2 MgF_2 window array transmitted the VUV into a second independent chamber containing a mixture of N_2O and high-pressure argon. The complication of *in situ* processes such as electron collisions and ion recombination are removed, the volumetric deposition of energy and temperature rise can be readily characterized, the gas pressures and types in the flashlamp and experimental chambers can be independently optimized, and flashlamp background can be minimized by the spatial positioning of detectors.

The flashlamp is driven by a 40-ns pulse from a 50-cm cathode electron beam. Approximately 1.5 J of transmitted VUV has been calorimetrically measured in the second chamber. The gain of the medium is probed by a pulsed tunable dye laser (150 kW, 5 ns, 0.01 nm). The dye laser pulse is injected into a stable cavity which is constructed in the high-pressure region. The exponential decay of the trapped radiation is monitored on the far side of the cavity by a photodiode. Cavities with roundtrip losses of ~1.3 percent have been constructed. Oscillograms of the photodiode signal are taken and changes in the roundtrip loss of 0.1 percent or 10^{-5} cm^{-1} are apparent.

Roundtrip gains of 3 percent have been observed and yield greater than net break even gain. An early loss period of ~200-ns duration has been observed and appears to be broad banded and depend on the N_2O pressure. The gain profile is wide (~1.5 nm full width at half maximum), exhibits a blue wing, and is peaked slightly to the blue of the atomic line. This profile is consistent with discharge spectra of $Ar + O_2$ mixtures which exhibit vibrational–rotational structure, and strongly suggests that the gain is due to stabilized molecules rather than collisional (pseudomolecular) stimulation.

The upper state lifetime is inversely proportional to N_2O pressure and is independent of argon pressure within the limits used. The gain appears to be linearly proportional to argon pressure. If one estimates $n(^1S_0)$ production, then the effective stimulated-emission cross section can be calculated from the experimentally determined gain to be $\sigma_{EFF} = K\sigma = 3 \times 10^{-20}$ cm^2, where K is the fraction of $O(^1S_0)$ found in the molecular state and σ is the real stimulated-emission cross section. Assuming that $K = 10^{-2}$ at room temperature and 2.8 MPa (400 psia) Ar, then $\sigma \approx 3 \times 10^{-18}$ cm^2.

15.11 Optically Pumped 15.90-μm SF_6 Laser,* H. R. Fetterman and W. E. Barch, *Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Mass. 02173,* H. R. Schlossberg, *Air Force Cambridge Research Laboratory, Bedford, Mass. 01730.*

Optically pumped molecular lasers, oscillating on vibrational transitions, offer a promising means of achieving wavelength diversity in the infrared. Although numerous molecules have absorption bands coinciding with existing pulsed lasers (e.g., CO_2, HBr), to date only simple linear molecules,[1] optically pumped, have lased on vibrational tran-

*This work was sponsored by the Department of the Air Force.

[1](a) T. Y. Chang and T. J. Bridges, *Appl. Phys. Lett.*, vol. 23, p. 370, 1972. (b) H. R. Schlossberg and H. R. Fetterman, *Appl. Phys. Lett.*, vol. 26, p. 316, 1975.

sitions. We report here the first example of this type of lasing in a nonlinear molecule. Laser radiation has been generated at 15.90 μm from SF_6 by optical pumping with a pulsed CO_2 laser. Analysis of this laser indicates that it is the first optically pumped laser involving a two-photon pumping process.

In recent experiments,[2] significant sulfur isotope separation has been achieved using only a high-intensity CO_2 laser pulse whose 10.6-μm wavelength overlaps the ν_3 band of SF_6. Other important photochemical and isotope separation applications will require high-intensity infrared lasers at different wavelengths. Our 15.90-μm output falls within the ν_3 band of UF_6.[3]

Several sealed experimental laser cells were used in this study ranging from 1 to 3 in in diameter and having either internal mirrors or Brewster windows. A typical system, shown in Fig. 1, used a configuration of mirrors and lenses to focus the pump CO_2 laser beam into a hole coupled laser cavity. Simultaneous pumping with both $P(12)$ and $P(14)$ of the 10-μm CO_2 laser was required to obtain oscillation. Each of the CO_2 laser input pulses was typically about 200 ns long and each had a peak power of about 300 kW. The optically pumped laser pulse had a halfwidth of about 1 μs, was delayed from the CO_2 pulses from 3 to 8 μs, and had a measured wavelength of 15.9005 ± 0.0005 μm (628.74 ± 0.02 cm^{-1}). Operating pressures, measured using a capacitance manometer, were critical and depended on the particular cavity. As indicated in Fig. 2, the peak signal occurs (in a 3-in-diam cell) at 55 m·torr of SF_6. Addition of He or H_2 gas to the SF_6 quenched the 15.90-μm radiation at pressures of approximately 100 m·torr.

The low pressures and pulse delays in our experiments preclude vibrational relaxation as a mechanism for population inversion. At 40 m·torr of pure SF_6, for example, VV relaxation[4] takes about 27 μs. Without invoking a VV relaxation mechanism, it is not possible to assign the lasing transition on the basis of a single photon absorption. This and the necessity for two pump wavelengths imply that the upper laser level is populated via absorption of two photons. The induced transition rate at our intensity levels can be shown to be much

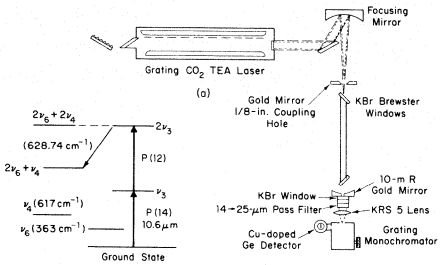

Fig. 1. Lasing from optically pumped vibration levels.

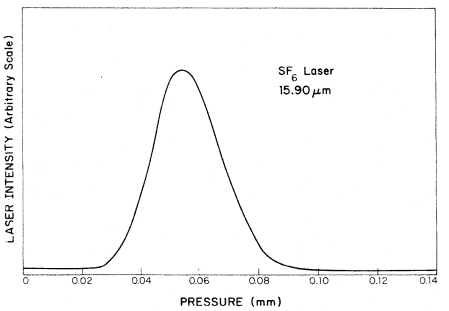

Fig. 2.

greater than $1/T_2$ (T_2, the phase coherence time, is 600 ns at 40 m·torr), indicating that direct two-photon absorption with a near-resonant intermediate state can be an important process. The possible energy levels in a two-photon absorption (simultaneous or stepwise) pumping followed by 15.90-μm laser emission can be limited greatly from considerations of odd/even symmetry of the SF_6 vibrations. A plausible model which meets all constraints is that the $2\nu_3$ level of SF_6 is pumped via near resonance of ν_3, and lasing takes place from $2\nu_3$ to $\nu_2 + \nu_4$. The latter transition could be reasonably strong because of a Fermi resonance between $2\nu_3$ and $\nu_2 + 2\nu_4$, the ν_4 band being strongly allowed. Alternatively, the Fermi resonant state could be $2\nu_6 + 2\nu_4$ and the final laser state $2\nu_6 + \nu_4$ as shown in the insert of Fig. 1.

While the quantum efficiency from 10 to 16 μm in our initial experiments is relatively small, the interpretive model suggested previously would allow high efficiencies in an optimized system. Higher pumping levels could be achieved by better temporal and spatial coincidence and increased power of the two pump laser lines. With stronger optical pumping, a greater degree of rotational relaxation (induced, for example, by a rare gas) could be tolerated and would produce some tunability of the output by lasing from adjacent rotational states. Alternatively, by using two independent CO_2 lasers with a greater choice of pump wavelengths, it may be possible to excite other states of SF_6, leading to additional wavelength selection.

17.13 Low-Power CW Generation of Coherent Anti-Stokes Raman Radiation in CH_4 Gas

J. J. Barrett and R. F. Begley, *Materials Research Center, Allied Chemical Corporation, Morristown, N.J. 07960.*

We report the first observation of coherent antistokes Raman scattering (CARS) generated by CW lasers in methane gas. Up to the present time, all four frequency mixing experiments have been performed using high-power (typically $>$ 1 kW) pulsed lasers. In comparison with pulsed lasers, CW lasers have the advantage of better frequency and amplitude stability facilitating accurate experimental measurements over long time spans.

A CW jet-stream dye laser, which was pumped collinearly by the 514.53-nm line of an argon-ion laser, consisted of a folded six-mirror astigmatically compensated resonator. The 514.53-nm beam entered the dye laser cavity through a multilayer dielectric mirror which had high transmissivity over the range of 470-530 nm and high reflectivity over the range of 560-650 nm. A pair of 30-cm radius mirrors in the dye laser cavity was used to produce a focus in a gas cell with Brewster angle windows containing 1 atm of methane. All of the mirrors of the dye laser cavity had high reflectivity over the range 560-650 nm. Wavelength selection in the dye laser cavity was accomplished by use of a prism for coarse tuning and a thin solid etalon for fine tuning. The laser linewidth was about 0.1 cm^{-1}. The coherent antistokes radiation was transmitted by the second 30-cm-radius mirror which had high transmissivity at ω_A and high reflectivity at ω_P and ω_S. It was filtered and then detected by a cooled RCA 8850 photomultiplier tube operated in the pulse counting mode.

The vacuum wavenumber ω_P of the 514.53-nm line is 19429.79 cm^{-1} and the observed Raman frequency shift for the ν_1 band of CH_4 is 2916.7 cm^{-1}. The Stokes and antistokes vacuum wavenumbers are 16513.09 cm^{-1} and 22346.49 cm^{-1}, respectively. By using data in the literature, the value of the differential Raman scattering cross section for the ν_1 band was calculated to be 2.52×10^{-30} cm^2/sr molecule and the value of Γ is 0.9 cm^{-1}. The bulk resonance susceptibility $N\chi_R$ for the ν_1 band of CH_4 is 1.75×10^{-14} cm^3/erg. In our experiment, the interaction length at the beam focus was 1.04 cm and the interaction area 4.01×10^{-6} cm^2. The measured powers in the pump and Stokes beams were 0.46 and 0.21 W, respectively. The amount of Stokes power within the interaction volume was 0.036 W. The antistokes power was

calculated to be 2.18×10^{13} W or 4.90×10^{5} photons/s which is in good agreement with the observed value of 5.72×10^{5} photons/s.

A theoretical comparison of the coherent antistokes signal from CH_4 with the Stokes signal generated by spontaneous (ordinary) Raman scattering from CH_4 was made. For input powers of less than 1 W (typical of the power levels used in this experiment), the coherent antistokes Raman signal is less than the spontaneous Raman Stokes signal scattered into a collection solid angle defined by $f/1$ optics. However, since the coherent antistokes signal has the spatial characteristics of a laser beam rather than being scattered into 4 π sr, it is possible to collect efficiently nearly all of the coherent antistokes signal. At an input power of 28.4 W, the coherent antistokes power and the ordinary Stokes power are equal for this calculation in methane.

18.12 Energy Extraction Improvement in Nanosecond Pulse TEA-CO_2 Lasers,* J. C. Farcy, A. Fertal, M. Huguet, G. Girard, and M. Michon, Laboratoires de Marcoussis, Centre de Recherches de la C.G.E., 91460 Marcoussis, France.

Energy extraction efficiency is of fundamental importance in CO_2 short pulse amplifiers. It is well known that the extracted energy is lower for shorter pulses: there is roughly a ratio of 10 between energies extracted at 1 μs and at 1 ns at atmospheric pressure.[1] Transfer times become too long with respect to pulse duration, and increasing pressure is a convenient but partial solution.

Improved energy extraction for nanosecond pulses can be obtained in two ways. First, by using a multiline–multiband (9.6 + 10.6 μ) oscillator, we observe a 35-percent increase. Second, an original setup uses several passes through the same active medium; the time delay between each pass of the same nanosecond pulse is long enough to allow good rotational and vibrational relaxation to take place so as to obtain energy extraction similar to that for longer pulse duration; an upper limit of 400-percent increase could be theoretically achieved.

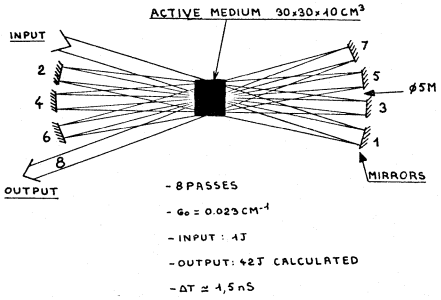

Fig. 1. Multipass amplifier.

I. Multiline and Multiband Operation

We used a 3.7-m-long oscillator mode locked by a 20-MHz acoustooptical germanium modulator. The optical cavity is made up of a gold coated mirror and a ClNa flat. The multiline (10.6 μ) and multiband (10.6 + 9.6 μ) operation is obtained through an angle tunable Fabry–Perot placed inside the optical cavity. The lines are controlled by an Opt. Eng model 16A spectrophotometer. A double gallium arsenide shutter provides a single pulse with an extinction ratio of about 10^5. Energy up to 1.5 J is provided by three double-discharge amplifiers, and is used as input into the atmospheric-pressure test amplifier, whose gain is chosen to be exactly 10 dB (0.023 cm^{-1}) for 1 m.

Energy extracted from the test amplifier versus input energy density up to 0.35 J/cm^2 shows 16- and 35-percent increase for multilines (10.6 μ) and multiband (10.6 and 9.6 μ) operation, respectively. Results are compared to a theorical model by Feldman.

II. Multipass Extraction

By allowing the time delay between passes of the same pulse through the active medium to be longer than relaxation times, stored energy in the laser level of interest can be regenerated and more energy can be theoretically extracted.

An atmospheric double-discharge 30 × 30 × 10-cm^3 amplifier is set up (Fig. 1) at the center of a circle 5 m in diameter. Seven mirrors insure multiple reflection so that time delay between passes is about 15 ns. In this way, energy is extracted 8 times successively, corresponding to 120-ns operation. Mirrors and amplifier medium are installed in the same Plexiglass housing to avoid window losses; the entire volume is occupied by the gas mixture. The 0.023 cm^{-1} small-signal gain provides a total gain of 24 dB so that a theorical 42-J output could be obtained for 1-J input.

Such a multipass system should be of great interest for pulses even shorter ($\leqslant$ 1 ns). Moreover, its principle might be applied to all gas lasers which cannot deliver their energy rapidly.

18.13 Multikilowatt CO_2 Laser Utilizing Plasma Injection, R. McLeary, R. E. Whitcher, and P. J. Beckwith, *Materials Research Laboratories, Department of Defence, Maribyrnong, Vic. 3032, Australia.*

The "plasma-injection" technique has been shown[1] to be suitable for obtaining uniform continuous discharges in CO_2-laser gas mixtures at pressures up to 1 atm. In this technique, preionization of the laser discharge volume is achieved by the injection of ionized gas from a secondary discharge. A typical plasma injector has a suitable gas, e.g., N_2, ionized in a small arc discharge originating on the pin electrode, and forced at sonic velocity into the main discharge region. The remaining constituents of the laser gas mix flow radially inwards and are mixed with the preionized gas in the main discharge region. The power dissipated in the preionizing discharge is about 20 percent of the main discharge power and the mass flow rate of gas through the preionizer is about 25 percent of the total. The main discharge characteristics are sensitive to polarity with higher conductances and power inputs obtained with the polarity shown. This asymmetry was most pronounced at low values of preionizing current, and could be due to the ease with which electrons can be extracted from what is essentially a plasma cathode. The main discharge has a positive slope resistance the value of which decreases as the amount of preionization is increased. Discharge power densities of up to 150 kW/l at pressures up to 1 atm have been achieved by the use of this technique.

A laser has been constructed in which 200 of these plasma injectors are arranged along the 3.2-m length, with the discharge axes perpendicular to the optical axis. Consecutive discharge axes were rotated by approximately 45° in a plane normal to the optical axis. Each discharge length was 28 mm, making the total discharge volume approximately

TABLE I
PERFORMANCE OF CW PLASMA-INJECTION CO_2 LASER

Pressure	33 kPa (250 Torr)
Gas Mixture	5 CO_2:76 N_2: 19 He
Mass Flow (Total)	500 g/s
Discharge Power (incl. preionizing)	70 kW
Power Output	7.5 kW
Efficiency	10.7%

2 l. As the input and hence output power density is very high in this type of device, diffraction coupling of the output from a stable resonator system was used to minimize damage to the resonator components. Although oscillation was achieved at atmospheric pressure, the efficiency was low ($<$ 1 percent) due to the combination of low small-signal gain and perturbation of the resonator by turbulence in the gas flow. Operation at pressures less than atmospheric was achieved by the use of a 10-m^3 vacuum dump tank.

Table I gives typical performance data at a pressure of 33 kPa (250 torr) where an output power of 7.5 kW at an electrical efficiency of over 10 percent was obtained. Comparison of the operating parameters of this laser with those of conventional convection-cooled types shows that the plasma-injection technique allows efficient high-power operation to be obtained at considerably higher pressures and without the use of a large proportion of He in the gas mixture.

19.11 Application of Laser with Folded Optical Delay Line in Optical Communication Systems, L. S. Kornienko, N. V. Kravtsov, E. G. Lariontsev, N. I. Naumkin, and V. N. Serkin, Moscow, USSR.

The mode-locked lasers have been used in optical communication systems.[1,2] By using a folded optical delay line in a laser cavity, one can easily change the cavity length L and the pulse repetition time $T = 2L/c$. Energy, time, and spectral characteristics of such lasers depend on the cavity length.

The peak intensity of CW laser mode-locked pulses increases significantly with increasing cavity length. In lasers with saturable absorber, the cavity length variation results in a change of mode-locked pulse duration, pulse peak intensity, contrast ratio, number of pulses in a chain, and the pulse chain duration[3-5]. With increased cavity length, the nonlinear distortions of the mode-locked pulses induced by self-focusing and self-phase modulating are significantly reduced.

Properties of such lasers have been investigated in ruby with saturable absorbers and CW YAG:Nd^{3+} lasers. It is shown that a mode-locked laser with a folded optical delay line has some advantages for application in communication systems, namely the possibility of pulse repetition frequency variation, increased contrast ratio, pulse intensity, and spectral width variation.

13.A1 Observation of Fluorescence Narrower than the Natural Linewidth, H. M. Gibbs, *Bell Laboratories, Murray Hill, N.J. 07974*, and T. N. C. Venkatesan, *Brooklyn College, City University of New York, New York, N.Y.*, and *Bell Laboratories, Murray Hill, N.J. 07974.*

We report the first direct observation of fluorescence narrower than the natural linewidth.[1] It was shown by Weisskopf[2] and popularized by Heitler that the fluorescence from a two-level system subjected to monochromatic radiation has the same spectral profile as the excitation.[3] From the points of view of conservation of energy and of a driven classical oscillator, this result is trivial.[4] However, persons accustomed to associating (via the Heisenberg Uncertainty Principle) a width $\Delta\nu = (2\pi\tau)^{-1}$ with a state of lifetime τ, often find this prediction surprising. This is because absorption and reemission are often treated as distinct processes. If the excitation is much shorter than the lifetime, such a treatment is justified and the reemitted radiation has the natural linewidth. On the other hand, if monochromatic excitation is used, the excitation and reemission processes must be treated as a single coherent process, yielding narrower-than-natural fluorescence for all intensities low enough to avoid power broadening.

In the present experiment, a fluorescence width less than half of the natural width was seen. An atomic beam of Mg, the 200-nW second-harmonic beam of a stabilized CW dye laser, and the detection axis of a spherical Fabry–Perot interferometer formed mutally perpendicular axes. Apertures limited the solid angles and reduced the $\approx$4000-MHz Doppler width to about 20 MHz. The 80-MHz linewidth[5] of the Mg 2852-Å $^1S_0$-to-$^1P_1$ transition then easily exceeded the composite detection width including the Doppler width, the 10-MHz instrumental width of the scanning spherical Fabry–Perot with small aperture, and the laser jitter of less than 5 MHz.

This direct demonstration of narrower-than-natural linewidth fluorescence points the way to careful studies of the details of the spontaneous-emission spectral profile. Sensitivity to distortion in lineshape of order α^2 would permit a test of quantum electrodynamic radiation corrections.[6]

[1]Hanle effect signals half the natural linewidth have been seen using monochromatic excitation: W. Rasmussen, R. Schieder, and H. Walther, *Opt. Commun.*, vol. 12, p. 315, 1974. Without natural-linewidth resolution it has been shown that emission occurs at the frequency of off-resonance excitation: L. S. Ditman, Jr., R. W. Gammon, and T. D. Wilkerson, *Opt. Commun.*, vol. 13, p. 154, 1975.

13.A2 High-Repetition-Rate H_2 Vacuum-Ultraviolet Laser Applications: Photoionization and Excitation of Luminescence, V. S. Antonov, I. N. Knyazev, V. S. Letokhov, and V. G. Movshev, *Institute of Spectroscopy, Academy of Sciences, Moscow, Akademgorodok, 142092 USSR.*

Development of the repetitively pulsed H_2 laser suitable for physical experiments[1,2] made it possible to carry out experiments on photoionization of molecules and excitation of luminescence of crystals by using vacuum-ultraviolet (VUV) laser radiation.

Experiments were carried out by using a repetitively pulsed H_2 VUV laser at 13 transitions $\lambda \sim 1610$ A with a 10-Hz repetition rate, ~1-ns laser pulse duration and 0.1-mW average power. The H_2-laser photon energy is sufficient for ionization of 50 percent of the elements, a substantial portion of organic compounds, and also for excitation of luminescence of crystals.

In the photoionization experiments methylaniline and dimethylaniline were choosen because of their comparatively low ionization energy (7.36 and 7.1 eV) and relatively high vapor pressure at room temperature (0.4 and 0.5 torr, respectively). Laser radiation was directed on the photoionization cells through a set of buffer volumes with LiF, BaF_2, or MgF_2 windows. The buffer volumes were filled with pure hydrogen at atmospheric pressure to prevent breakdown from the laser as well as to decrease leakage currents. The transmission of laser radiation through the system and the alignment of the cells were controlled by use of a luminescent screen.

The mean photocurrent in dimethylaniline approached 0.5 μA. Check experiments were carried out by using nitrogen UV laser radiation with the photon energy 3.7 eV, as well as by using H_2 laser radiation and helium- or oxygen-filled photoionization cells. In these experiments there was no current in the photoionization cell circuit. The maximum registered photocurrent is 0.2–0.3 μA. A rough estimate of the photoionization current in dimethylaniline gives a value of 0.25 μA, assuming a photoionization output of 0.1 and neglecting by photoelectron recombination.

H_2-laser radiation can be used in attempts to increase sensitivity of photoionization mass spectrometers and to develop basically new methods of molecular detection. The mean probability of molecular photoionization in the case of using a H_2 VUV laser with the aforementioned parameters approaches 10^{-4} s^{-1}. That is three orders of magnitude more than in the available photoionization mass spectrometers. By using the two-step laser photoionization method, it is possible to develop photoionization methods of molecular detection with sensitivity 10^4–10^5 molecules. Some details of the photoionization experiments can be found in Andreyev *et al.*[3]

The luminescence of crystals was excited by using focused H_2 VUV laser radiation and recording by a monochromator and phototube with known spectral response. The system allows sensitive monitoring of the luminescence with a quantum efficiency ~1 percent. The main limitations in this respect are connected with the false signal induced by the excitation system of the laser and scattering of the spontaneous radiation of the pulsed discharge in the region $\lambda \lesssim 2000$ Å in the crystal. The luminescence of sapphire, ZnS, NaCl, and other crystals was investigated. A strong 2300-Å peak of luminescence was observed in NaCl at 88 K.

High-repetition-rate Verner band 1200-Å H_2 VUV laser action was observed. Detailed spectral investigations of stimulated and spontaneous H_2 VUV radiation were carried out by using a 6.6-m VUV spectrograph of the Institute of Spectroscopy. The overall number of registered VUV laser lines in H_2 is ~100. The 1200-Å H_2 VUV laser is also a prospective laser for photoionization experiments and excitation of luminescence.

13.A3 Laser Action on the XeF $^2\Sigma \rightarrow {}^2\Sigma$ Band at 3540 Å,* J. J. Ewing and C. A. Brau, *Avco Everett Research Laboratory, Inc., Everett, Mass. 02149.*

We report here lasing at 3540 Å on a molecular band of XeF. Electronically excited XeF is formed when F_2/Xe/Ar mixtures are irradiated with a pulsed electron beam. This is a new laser operating on a member of a new class of molecules, the noble gas monohalides. These diatomic molecules are characterized by weakly bound or nonbound covalent lower levels having molecular symmetries $^2\Sigma_{1/2}$ and $^2\Pi_{1/2,3/2}$. The upper laser level of these species is ionic in nature, having the polarity Xe^+F^-. The lowest ionic state of noble gas monohalides has the molecular symmetry $^2\Sigma_{1/2}$, and is usually strongly bound relative to the lowest excited states of the free atoms.[1] Fig. 1 shows estimated potential energy curves for XeF. The lasing transition in XeF reported here terminates on high lying vibrational levels of the weakly bound lower state.

The excited XeF can be formed in two ways. First, xenon excited states, formed in our experiments by energy transfer from Ar* and Ar_2^*, can react with F_2 to directly produce the excited monofluoride[2]:

$$Xe^* + F_2 \rightarrow XeF^* + F.$$

Reactions of this type have large cross sections and a high probability of reaction leading to excited states. A second important pumping channel is the rapid termolecular recombination of Xe^+ ions with F^- ions,[3] both of which can be formed in these *e*-beam excited mixtures.

The laser experiments were performed in an aluminum cell with aligned quartz flats as optical windows and an aluminized Mylar foil as the window for the electron beam. The electron beam is formed by pulse charging a cold cathode gun to about 300 kV. With an anode–cathode spacing of 0.511 in, the current density through the foil is about 150 A/cm^2, over a 1.5 × 15 cm^2 area. The electron-beam pulse duration is 100 ns with approximately 15-ns rise and fall times.

The optical cavity was formed by two 1-m radius-of-curvature maximum reflectors separated by 30 cm. The output coupling at 3540 Å was $\frac{1}{2}$ percent per window. The beam output at one end was attenuated by a factor of 500 and was directed onto an ITT FW128 photodiode. The output passing through the other reflector was taken onto a spectrograph for wavelength analysis.

Fig. 2 shows the time history of the XeF stimulated emission as monitored by the photodiode for a mixture of F_2/Xe/Ar having mole fractions 0.001/0.003/0.996 at a total pressure of 70

psia. The stimulated emission signal in this case is 100 times larger than the spontaneous emission signal. A comparison of microdensitometer tracings of spontaneous and stimulated emission from XeF shows that the spectrum of laser light emitted from the cavity is narrowed compared to that of the spontaneous emission.

13.A4 A New Excimer Laser,† S. K. Searles and G. A. Hart,* *Naval Research Laboratory, Washington, D.C. 20375.*

Previous excimer lasers have been confined to stimulated emission from Xe_2^*, Kr_2^*, Ar_2^*, XeO*, and KrO*. Recent studies[1] confirmed the existence of a new class of excimers RX* where R is a rare gas atom, X is a halogen atom, and * denotes the first excited electronic state of the molecule. We wish to report the first rare-gas halide excimer laser. The kinetics of this laser are described by a three-step mechanism

$$e + Xe \longrightarrow Xe^* + e \quad (1)$$

$$Xe^* + Br_2 \longrightarrow XeBr^* + Br \quad (2)$$

$$XeBr^* \longrightarrow Xe + Br + h\nu\,(281.8\text{ nm}). \quad (3)$$

Xe* generated by a high-energy electron-beam device[2] reacts with Br_2 at a gas kinetic rate to produce XeBr* which undergoes a bound-free transition.

The experimental results consist of fluorescence (side emission) measurements for Xe with 0.01–4-percent Br_2 over the range 10–3000 torr and stimulated emission data from a 760-torr-Xe–3.8-torr-Br_2 mixture. Very close agreement with the observed fluorescence was obtained with an energy deposition and chemical kinetics model. This model indicates that the two key rate constants are given by $k_2 = (2.0 \pm .4) \times 10^{-9}$ cm^3/molecule · s and $k_3 = (5.7 \pm .8) \times 10^7$ s^{-1}. In addition, a preliminary value of 8×10^{-10} cm^3/molecule · s was found for the quenching of XeBr* by Br_2. This quenching puts a severe limit on the partial pressure of Br_2 in a potential laser mixture.

A low-loss optical cavity consisting of >99.5-percent reflectivity mirrors and aligned normal incidence windows was used to search for laser emission in gas mixtures displaying the most intense fluorescence. Laser emission was observed from a 760-torr-Xe–3.8-torr-Br_2 mixture. Proof of laser emission is as follows.

1) Laser emission disappeared when the far mirror was blocked.

2) The laser spectrum was less than 0.75 nm wide at 281.8 nm while the fluorescence is a banded continuum over the range 230–360 nm.

3) As indicated in Fig. 1, the laser full width at half maximum (FWHM) is much less than the fluorescence FWHM.

At present, laser emission is near threshold with a peak power of about 100 W. It is expected that the power of this new laser can be significantly increased and that it can also be made to operate as a tunable high-power laser in this wavelength region of photochemical interest.

13.A5 Broad-Band Continuously Tunable High-Pressure CO_2 Laser: Use for Excitation of Molecules and in Molecular Spectroscopy, V. N. Bagratashvili, I. N. Knyazev, V. S. Letokhov, and V. V. Lobko, *Institute of Spectroscopy, Academy of Sciences, Moscow, Akademgorodok, 142092 USSR.*

The main characteristics of the modified version of a high-pressure CO_2 laser[1] with continuous frequency tuning on P and R branches of laser transitions are presented. A 3-pass resonator was used to obtain continuous frequency tuning at 5-atm $CO_2:N_2 = 1:2$ mixture of gas with $0.5 \times 4 \times 50$ cm^3 active volume excited by a nonself-sustained gas discharge with preionization of the laser volume by high-energy electrons. At 1-atm gas pressure, a superluminescent mode of operation was observed proving the high overall amplification of the system.

Spectral measurements carried out with an accuracy of 0.01 cm^{-1}, by using a mechanically scanned Fabry–Perot interferometer, gave a spectral width of 0.05 cm^{-1} for the laser radiation. Completely continuous frequency tuning was observed in the region $J'' = 10$–24, while partial continuous tuning occurred for $J'' = 6$–32. For the partial frequency tuning, a spectral range of 90 cm^{-1} was covered. The laser pulse energy was of the order of 0.1 J.

Focused frequency-tuned laser radiation with a power density of 10^9 W/cm^2 was used to excite visible luminescence of molecules, ethylene in particular. Molecular ethylene was chosen for experiments due to the existence of a strong absorption band with developed rotational structure which covers the whole laser tuning range. This enables one to investigate the variation of luminescence intensity over a spectral range of 150 cm^{-1}. To observe the instantaneous state of the luminescence, a phototube is illuminated by the radiation from the region of the lens caustic.

The narrow-band tuning of the laser frequency in the wings of the ethylene absorption band gives no noticeable resonances for the excitation of luminescence, while the simultaneously measured linear absorption of the molecule reveals strong variations in accordance with the rotational structure of the band. In the case of broad-band laser frequency tuning, an excitation resonance of the luminescence was observed in the Q-branch region. The spectral width of the excitation peak is 10 cm^{-1} and is proportional to the square root of the laser pulse energy.

The existence of an excitation peak for the Q-branch luminescence indicates a definite correlation between the luminescence intensity and average absorption in a particular region of the band with an interval of averaging of some cm^{-1}. There is no correlation between the intensity of luminescence and absorption in the case of laser frequency scanning in a narrow interval about 1 cm^{-1} at any region of the band, including Q branch. These facts indicate the effective averaging of the rotational structure of the spectrum in the process of excitation of luminescence. The observed Q-branch excitation resonance of luminescence can be qualitatively interpreted in the framework of a radiative excitation mechanism of molecules in a strong field. The observed averaging of the spectral characteristics of a molecular gas occurs perhaps due to modulation splitting and corresponding broadening of the spectral lines during pulsed coherent saturation of molecular quantum states in a strong field. The broadening of molecular lines caused by coherent pulsed saturation at 10^9 W/cm^2 is 3 cm^{-1}, which is in rough agreement with the experimentally measured spectral width of the Q-branch excitation resonance for luminescence. In practice, the spectral width of the Q-branch luminescence resonances gives the value of the vibrational band isotopic shift required for isotopically selective dissociation. Some details of this experiment can be found in Bagratashvili *et al.*[2]

The first experiments were carried out by using a continuously tuned CO_2 laser and an optoacoustical detector to register weak absorption spectra of small amounts of molecular gases. By using this system, the absorption spectra of HDS in natural H_2S (10^{-2} percent of content) as well as some other molecules were detected.

13.A6 Laser Emission at 1.32 μm from Atomic Iodine Produced by Electrical Dissociation of CF_3I,* L. D. Pleasance and L. A. Weaver, *Westinghouse Research Laboratories, Pittsburgh, Pa. 15235.*

We have been investigating the dissociation of molecules by electron impact into excited electronic states. The objective of this research is the development of dissociation lasers with the potentially high excitation efficiencies and volume scaling characteristics of electrical discharges. In this paper we report the observations of laser emission at 1.32 μm from atomic iodine produced by the electrical dissociation of CF_3I. These observations are the first reported evidence that population inversions can be produced on this transition by volume electrical processes. These results raise the possibility of generation of atomic iodine lasers by electrical excitation with improved volume scaling and efficiency.

The excited atomic iodine is produced by dissociation of the CF_3I following an inelastic collision with an electron:

$$CF_3I + e^- \rightarrow CF_3I^* + e^-$$

$$CF_3I^* \rightarrow CF_3 + I^*.$$

This process is analogous to that found for excitation by photodissociation. Electrons with energies $\gtrsim$4.3 eV are required to excite the same predissociative state of CF_3I.

Fast pulse discharges between planar electrodes (TEA laser discharge) were used in this investigation. The active discharge volume is $2 \times 2 \times 50$ cm or 200 cm^3. Stable volume discharges have been obtained in mixtures of a few percent of CF_3I with N_2, Ar, or He buffer gases at total pressures of 50–300 torr. The discharge was driven by a single 20-nF capacitor charged to between 10 and 35 kV and connected to the electrodes by a triggered spark gap. This power supply produced a current pulse in the form of a damped sinusoid with a width of ~150 ns full width at half maximum (FWHM) for the first half-cycle.

Fig. 1 shows the laser output measured with an InSb detector for a discharge in 0.18 torr of CF_3I mixed with 70-torr N_2. The laser emission consists of one or more pulses delayed by 50–100 μs with respect to the discharge pulse. The small initial pulse at the beginning of the trace is laser emission from a nitrogen line emitted during the discharge pulse. No structure has been observed within each laser pulse to the time resolution of the detector (~0.5 μs). The laser intensity increases with both CF_3I pressure and discharge current density. The delay to the onset of lasing decreases with increasing laser intensity.

We have tentatively identified the mechanism responsible for the delay in the appearance of laser emission as the decay of the population in the lower laser level by the recombination reaction

$$CF_3 + I^\circ \rightarrow CF_3I^\dagger$$

where $CF_3I^\dagger$ is a vibrationally excited ground electronic state of CF_3I.

The energy output of the laser under the conditions of Fig. 1 was measured

*This work was supported in part by the Air Force Office of Scientific Research under Contract F44620-73-C-0046.

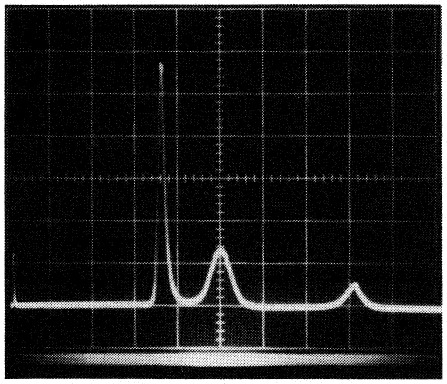

Fig. 1. Laser emission on the $I(^2P_{1/2}) \rightarrow I(^2P_{3/2})$ transition at 1.32 μm from a CF_3I-N_2 discharge; $P_{CF_3I} = 0.18$ torr, $p_{N_2} = 70$ torr, and $J = 32$ A$\cdot$ cm^{-2}. Time increases from left to right at 20 μs per major division. The initial pulse on the left is a N_2 laser line emitted during the excitation pulse. The duration of the discharge is ~0.5 μs.

with a calibrated thermopile. This measurement gave a value of 0.3 mJ which corresponds to an efficiency of 0.1 percent. Further improvements in efficiency are anticipated. Measurements of the dissociation rate gave a value of 2×10^{-8} cm^3/s at $E/N \simeq 9 \times 10^{-16}$ V-cm^2.

These results indicate that electrical dissociation of the perfluoro-iodides may represent an attractive alternative to flashlamp excitation of iodine lasers.

13.A7 A TE Copper Iodide Laser, J. A. Piper and C. E. Webb, *Clarendon Laboratory, Oxford, England.*

Substitution of copper halide vapor for the vapor of elemental copper allows operation of the potentially high-efficiency pulsed laser transitions of neutral copper at substantially reduced temperatures.[1-4] To date, the only reported experiments on copper halide lasers have been carried out with *longitudinally* excited discharge tubes. The performance of these devices in some cases suffers severely because of the erratic and irreproducible nature of the discharge path.[3,4] Consequently, it would appear difficult to scale longitudinal discharge tubes to large active volumes while retaining the essential qualities (high current and fast rise time) of the excitation pulse.

Laser tubes in which the discharge is *transverse* to the optical axis should not have these disadvantages since discharge paths can be kept short and well defined. The discharge circuit can take the form of parallel low-inductance loops, and it should therefore be possible to scale these devices to large active volumes to obtain high laser pulse energies. Unfortunately, design of transverse-discharge tubes for operation even at the relatively low temperatures (typically 500°C) appropriate to copper halide lasers is complicated by the problem of differential expansion between metal electrodes and the nonconducting material of the discharge vessel. This problem has been overcome in the present tube by segmenting the electrodes into short sections, free to expand independently. Discharge uniformity along the length of the electrode structure is promoted by providing each section with a separate current lead-through and using as a localized energy source a distributed capacitor array.

The main body of the laser is constructed from a heavy-wall fused silica tube. The electrode structure is formed by two rows of semicircular cross-sectional stainless-steel bars giving an active discharge volume approximately 700 mm long $\times$ 25 mm high $\times$ 5 mm wide. The device is capable of operation at temperatures in excess of 700°C. Experiments to date have been conducted with copper iodide vapor and neon as a buffer gas. The laser is operated in the double-pulse mode[2,4] in which the first discharge pulse dissociates the copper iodide molecules and thus provides a supply of copper atoms in the volume which are then excited by the second pulse. The circuit incorporates two independently triggered spark gaps which successively transfer energy from separate storage capacitors into the common dump capacitor array.

Although the gain is sufficient for observation of strong superradiant emission at both 5106 and 5782 Å, maximum laser output energy is obtained with an optical cavity comprising a high-reflecting mirror and an uncoated silica blank. Best laser performance occurs for pulse separation times 50–60 μs, copper iodide evaporation temperatures 480–500°C, and buffer-gas (neon) pressures about 100 torr, but satisfactory performance is obtained over a wide range of discharge parameters, including buffer-gas pressures up to 1 atm. The laser pulse duration is about 25 ns full width at half maximum (FWHM) and highest output energies achieved to date are 10 μJ/cm^3/pulse (active volume $\approx$ 100 cm^3) at conversion efficiencies, which compare favorably with those of the longitudinally excited copper halide lasers. A high degree of laser stability is indicated by excellent shot-to-shot reproducibility. Although no attempt has been made as yet to optimize the electrode profiles, the operating characteristics suggest the device can be scaled to large active volumes and input energies.

13.A8 High-Repetition-Rate TEA Laser System for Closed-Cycle Operation with Ultrapure Gases, Robert A. Olson, Dennis Grosjean, and Benjamin Sarka, Jr., *Systems Research Laboratories, Inc., Dayton, Ohio 45440,* Alan Garscadden and Peter Bletzinger, *Aerospace Research Laboratories, Wright-Patterson Air Force Base, Ohio 45433.*

A fast-flow high-pressure laser system capable of closed-cycle operation with ultrapure gases has been developed. The ultrahigh-vacuum properties of the system permit long gas-fill lifetime, as demonstrated by an undiminished laser output three weeks after filling. In experiments with He–Xe at a pressure of 700 torr, lasing was achieved at 2.03, 2.65, and 3.65 μm simultaneously. The laser pulses occurred predominantly during the afterglow of the 100-ns discharge pulse and lasted up to 5 μs after the discharge. Average output power was found to be a linear function of pulse-repetition frequency (PRF) up to 10 kHz. Multiline, multimode, average output power was $\approx$0.5 W at 10 kHz for a charging voltage of 10 kV and a discharge length of $\approx$12 cm. The rectangular output beam had approximately the same cross section as the discharge, viz., 1×3 cm^2.

The flowing gas system consists of a closed loop, constructed from 6-in-OD ultrahigh-vacuum components, through which gas is circulated by an axial fan. The fan is driven externally by a 400-Hz motor coupled to a Ferrofluidic rotary vacuum seal which maintains vacuum integrity at a fan rotation speed of 11 000 rpm. The gas-flow loop is initially evacuated through a 6-in valve by a 500-l/s vertical turbomolecular pump. Research-grade gases are admitted to the system from a gas manifold equipped with ultrapure gas regulators and ultrahigh-vacuum valves.

Converging and diverging transitions channel the flow into and out of a region of rectangular cross section where Rogowski-profile electrodes are located. The Lamberton-Pearson[1] configuration

[1] H. M. Lamberton and P. R. Pearson, *Electron. Lett.*, vol. 7, p. 141, 1971.

is employed with upstream and downstream preionization wires being located at the electrode midplane. The transverse interelectrode flow speed is calculated from the velocity pressure as measured with a pitot-static probe located upstream of the converging transition. The flow speed through a 1-cm electrode gap is 250 ft/s for the 250-ft^3/min flow achieved with atmospheric-pressure helium.

The high-repetition-rate pulser which drives the laser discharge utilizes a thyratron-switched low-inductance energy-storage capacitor charged through a tetrode pulse modulator. The tetrode isolates the charging supply from the thyratron during each pulse and permits control of the charging time and duty cycle, thereby ensuring uniform energy storage per pulse and sufficient thyratron interpulse recovery time. CaF_2 windows oriented at the Brewster angle were used for optical coupling to the discharge, and a 1-m confocal cavity was formed by a total reflector and an output mirror having 10-percent transmission from 4.4 to 5.4 μm.

For laser media such as the rare gases which are adversely affected by small amounts of impurities such as N_2, O_2, and H_2O, this system is particularly suitable because of its low background-impurity level. Since high-pressure laser action has been reported for all of the rare gases,[2,3] an evaluation of the performance of the ultrapure closed-cycle system for the rare-gas mixtures He–Ne, He–Ar, He–Kr, Kr–Xe, Ar–Xe, and Ar–Kr will be made.

13.A9 A Scalable High-Speed Switch for High-Power CO_2 Laser Radiation, A. J. Alcock, P. B. Corkum, D. J. James,* and K. Leopold, *Division of Physics, National Research Council of Canada, Ottawa, Canada.*

Fast switching of high-power 10-μm radiation by optically induced carriers in a semiconductor sample has been demonstrated. Initial studies carried out with a single-mode CO_2 TEA laser and a 2-ns ruby laser pulse have resulted in the generation of synchronized ~2-ns pulses at 0.7- and 10-μm wavelength. One application of this technique is the selection of a single pulse from the mode-locked output of a high-power CO_2 laser.

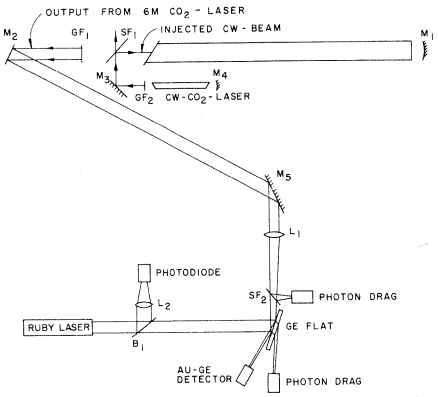

Fig. 1.

Techniques now exist for generating extremely high-power mode-locked pulses of CO_2 laser radiation.[1,2] For many applications it is desirable to select a single pulse from the train, and although several switching techniques are limited to relatively low power.

We have developed a switching technique which is readily scalable to large apertures and should thus allow the selection of extremely high-power pulses. Alternatively, the technique can be used to generate a gated 10-μm pulse in synchronism with the output of a visible laser. The switching element consists of a slab of germanium which is irradiated by a ruby laser pulse. Absorption of this radiation creates free carriers in the germanium[3-5] with sufficient density that a pulse of CO_2 laser radiation may be completely reflected. If the CO_2 laser pulse is plane polarized and incident on the germanium at Brewster's angle, high contrast switching may be achieved.

Fig. 1 shows the experimental arrangement used to investigate reflection switching. A single axial mode CO_2 laser pulse, of 200-ns duration, was generated by injecting the radiation from a low-power CW CO_2 laser into the resonator of a helical p-i-n TEA laser. The plane-polarized 10-μm radiation of ~2-MW peak power was incident at Brewster's angle on the polished surface of a slab of polycrystalline n-type germanium. A 2-ns pulse of ruby laser radiation [Fig. 2(b)] was also incident on the semiconductor and gave rise to a short pulse of reflected 10-μm radiation [Fig. 2(d)]. At a peak ruby laser intensity of ~20 MW/cm^2, the reflected 10-μm power was essentially equal to the incident power and the contrast ratio of the switch was ~300. At this ruby laser intensity damage to the germanium was not observed at CO_2 laser intensities of ~20 MW/cm^2. A decrease in transmission was also observed [Fig. 2(c)] with a fall time of approximately 2 ns and a significantly longer recovery time.

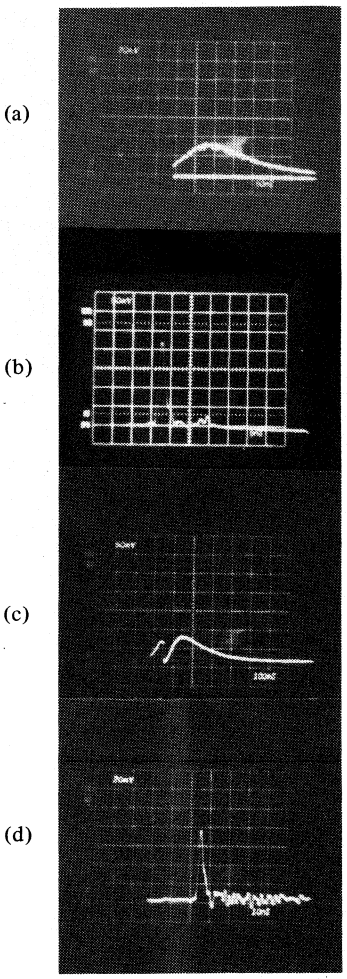

Fig. 2. (a) Incident CO_2 laser pulse; 50 ns/div. (b) Incident ruby laser pulse; 5 ns/div. (c) Transmitted CO_2 laser pulse; 100 ns/div. (d) Reflected CO_2 laser pulse; 10 ns/div.

More detailed investigations are now in progress. However, the aforementioned results clearly indicate the potential of this new approach to the control of high-power CO_2 laser radiation.

13.A10 A Direct Nuclear-Pumped Ne–N_2 Laser,* R. J. DeYoung, W. E. Wells, J. T. Verdeyen, and G. H. Miley, *Nuclear Engineering Program and Department of Electrical Engineering, University of Illinois at Urbana/Champaign, Urbana, Ill. 61801.*

Within the past year, rapid progress has been made in research on direct nuclear pumping of gas lasers. Workers at both Sandai[1] and Los Alamos[2] previously obtained lasing in CO and He–Xe, respectively, using a uranium-235 coating on the inner surface of the laser cell, demonstrating the feasibility of reactor-driven nuclear-pumped lasers. The present paper describes a new nuclear-driven laser that utilizes a boron-10 coating, Ne–N_2 gas, and provides simultaneous output at 8629 and 9393 Å in nitrogen. This laser has several distinctive features, namely the neutron flux, i.e., power input at threshold requirement is the lowest reported to date for nuclear pumping and the wavelengths fall into an attractive region in the near infrared (versus far-infrared output from the earlier lasers).

The experiment employed a 2.5-cm ID quartz laser tube containing a 60-cm section of aluminum tubing, coated on the inner surface with boron-10. The cell was placed next to the core of the Illinois TRIGA reactor such that thermal neutrons bombarding the boron coating caused emission of MeV α and Li^7-ions. These ions, in turn, ionized and excited the lasing gas. Pressure and concentration studies were carried out by utilization of a vacuum system attached to the laser external to the reactor. Lasing occurred at pressures above 75-torr Ne with very low partial pressures of N_2.

Fig. 1 shows a scope photograph of the laser output superimposed on the neutron pulse time history. The laser cavity was chopped by means of a small electric motor with fan blades which alternatively blocked and unblocked the back mirror. The large change in signal, among other things, clearly verifies that lasing occurred.[3] Note that the lasing

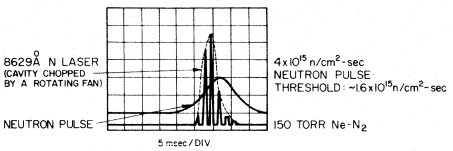

Fig. 1. Direct Ne–N_2 nuclear-pumped laser.

threshold took place at $\sim 1.6 \times 10^{15}$ neutrons/cm^2 · s, the lowest threshold of any nuclear-pumped laser to date. Since the neutron pulsewidth is much longer than the atomic and molecular processes taking place in the gas, this can be viewed as a near steady-state laser.

In summary, the significant results of this research are as follows.

1. For the first time nuclear pumping of a Ne–N_2 gas has been achieved at 8629 and 9393 Å. These transitions are at shorter wavelengths than previously reported lasers of this type. This is attractive since the photon energy is compatible with existing technology in optical components.
2. Lasing took place over 6 ms within the 10-ms neutron pulse, implying near steady-state laser operation.
3. A boron-10 coating was used, and this is the first nuclear laser using such a coating.
4. The lasing threshold was $\sim 10^{15}$ neutron/cm^2 · s, giving ~ 5 kW/l, the lowest threshold yet reported for nuclear pumping. A lower flux threshold could be expected with the more energetic ions from a uranium coating.

Because nuclear-pumped lasers can potentially be scaled up to quite high pressures and volumes, thus power levels,[4,5] such lasers must receive serious consideration for application requiring high powers.

13.B1 Fourier-Transform Holograms with X-Rays,* H. Mahr, *Cornell University, Ithaca, N.Y. 14853*, Benno Reuter, *Gesellschaft für Strahlen und Umweltforschung, Munich, Germany.*

We have recorded lensless Fourier transform[1] holograms of simple plane objects using X-rays at 44.8 Å (carbon K_α radiation). The generation of the hologram with an incoherent pointlike X-ray source was made possible through the use of a Fresnel zone plate. The zone plate acted very much like a beam splitter in that the zeroth-order radiation passing the zone plate provided the object illumination while the focused first-order radiation served as the reference point source, similar to an optical analog experiment. Original holograms were reconstructed with the visible light from a He–Ne laser to provide a 150-times enlarged image of the object taken at 44.8 Å.

Characteristic K_α radiation of carbon was generated inside a scanning electron microscope by focusing the electron beam onto a thick polished graphite target. The microscope was run at 21 kV in order to get currents of $2\text{–}4 \times 10^{-7}$ A and a small target spot size. Minimum spot size was monitored via the resolution of the scanning-electron-microscope picture of the graphite target. From experiments testing its coherence, the X-ray source size was estimated to be 2–4 μm.

X-rays emitted from the pointlike source were focused into the object plane with a Fresnel zone plate of focal length $f = 7.73$ cm for $C\text{–}K_\alpha$ radiation at 44.85 Å. A pointlike reference image of the source was obtained in the object plane at about twice the focal distance from the zone plate. About 10 percent of the intensity incident on the zone plate was transmitted into the point reference. Undeflected X-ray light proceeded through the zone plate and illuminated the object surrounding the point reference source with about 25 percent of the intensity incident on the zone plate. The superposition of this radiation, transmitted and diffracted by the object, with the reference beam produces the hologram in the film plane a distance c from the object plane.

An object that we found most suitable for a first test of the method is part of

*This work was supported by the U.S. Office of Naval Research and by the National Science Foundation through the Materials Science Center at Cornell University.

[1](a) G. W. Stroke, *An Introduction to Coherent Optics and Holography.* New York: Academic, 1966. (b) J. T. Winthrop and C. R. Worthington, *Phys. Lett.*, vol. 15, p. 124, 1965.

another zone plate, having 19 open zones in a gold foil of 440-μm diameter. if we center the reference beam through a slitlike "torn area," a "single-sided" object hologram of part of the zone rings in the right-half circle area is produced, and no superposition of the real and virtual images occurs in the reconstruction process.

Holograms were recorded with Eastman Kodak SWR film. A typical exposure laster between 20 and 40 min. We estimate that about 10^{-14} W of characteristic X-radiation was passing through the reference point and that the film received about 0.1 erg/cm^2 exposure in 30 min. This value agrees well with a measured exposure value of 0.3 erg/cm^2 (for $D = 0.6$) at 1200 Å.

Throughout the experiment, we were guided by results obtained with an optical analog setup. The image of a carbon arc source, filtered near 5800 Å with appropriate interference filters, served as a visible analog of the X-ray source of variable source size and spectral width.

The great advantage of the optical simulation was that holograms could easily be recorded under differing conditions of source size, spectral width of the source, intensity ratio of reference and object beam, steepness, graininess, and resolution of recording films, etc. By comparison with the X-ray holograms and through efforts to reconstruct these holograms, we found that the properties of the recording medium posed the most stringent conditions on the successful recording and reconstruction of X-ray holograms.

Reconstruction of the holograms was performed with a point reference source derived from a He–Ne laser at 6328 Å at approximately the distance c of the recording. A virtual image (magnified by the ratio of the wavelengths used in reconstruction and recording, or, $\lambda_{vis}/\lambda_x \approx 150$) could be seen by eye in the point reference plane or could be photographed.

The main problem with the reconstruction of the X-ray holograms was the low contrast of SWR film and the noise produced by the graininess of the film. Separate tests showed that a resolution of 120 lines/mm of SWR film is sufficient to record an object area within a radius of about 80 μm. Because of the low contrast and the graininess, the noise level in the reconstruction is much higher than the light level of the reconstructed image but for the brightest features.

Numerous tests, both with X-rays and optical simulation, were performed to determine the minimum conditions of coherence, ratio of reference to object intensity, resolution, and H–D curve of the recording material. With these minimum conditions established, we can now predict the minimum requirements for X-ray holography with laserlike sources in the vacuum–ultraviolet and X-ray region, as well as with synchrotron sources below 100 Å.

13.B2 Application of Electronically Scanned Semiconductor Lasers in Optical Data Processing, Yu M. Popov, *Lebedev Physical Institute, Moscow, USSR.*

No summary.

13.B3 Low-Divergence Beams from Grating-Coupled Composite-Guide Heterostructure GaAlAs Diode Lasers, R. D. Burnham, D. R. Scifres, and W. Streifer, *Xerox Palo Alto Research Center, Palo Alto, Calif. 94304.*

We report room-temperature operation of a new heterostructure diode laser which emits low-divergence grating-coupled output beams. The large output-beam divergence of conventional diode lasers is caused by their small emission aperture. Our device contains two closely spaced GaAs layers; one is electrically pumped, the other is corrugated. The corrugation scatters light out of the device at large angles to the waveguide plane, and since the light is emitted along the entire length of the laser, low-divergence output beams (in one dimension) are obtained.

A schematic diagram is shown in Fig. 1. The two waveguide layers (n-GaAs and active p-GaAs) are separated by a thin layer of n-$Ga_{0.7}Al_{0.3}As$. Light is generated by carrier injection into the p-GaAs active layer, but depending on the transverse mode excited, it spreads into the region occupied by the grating which is fabricated between the n-GaAs and n-$Ga_{0.7}Al_{0.3}As$ layers. This structure was chosen both for its usefulness in integrated optics and because the grating is not directly adjacent to the active region. In our experience, fabrication of the grating in the active layer causes undesirable nonradiative recombination.

Fig. 2 illustrates TE modes in the structure of Fig. 1. Since the TE_0 mode is primarily confined to the unpumped n-GaAs layer, it will experience little gain and is unlikely to lase. The TE_1 and TE_2 modes, however, do have sufficient overlap with the active region. The light in these modes also extends into the grating region and is therefore coupled out.

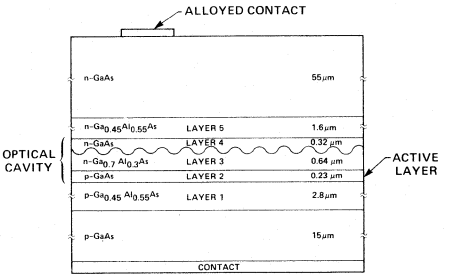

Fig. 1. Schematic diagram grating-coupled composite-guide diode laser.

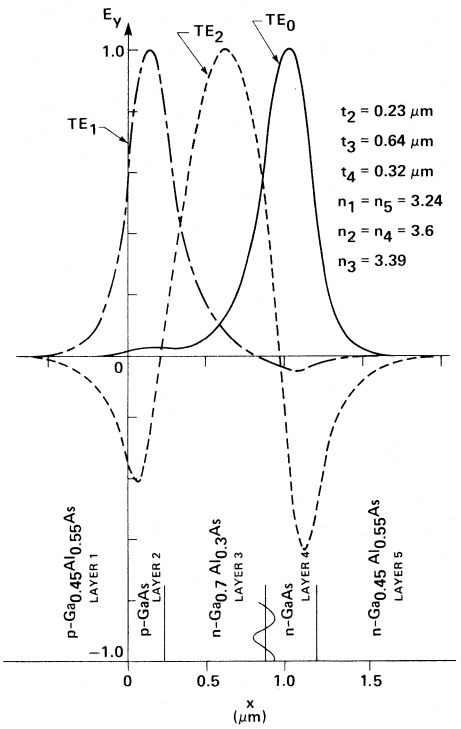

Fig. 2. TE mode patterns of composite-guide laser structure.

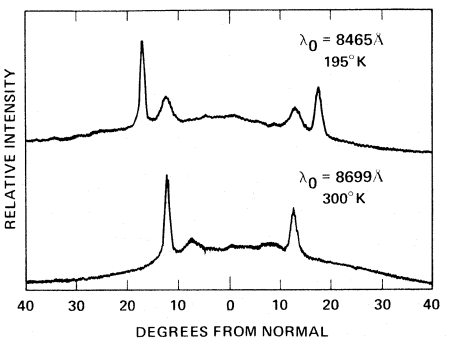

Fig. 3. Angular scan of the far-field radiation pattern of a grating-coupled composite-guide laser.

Scans of the grating-coupled far-field radiation pattern emitted through the n-side of a typical diode laser are shown in Fig. 3. At 30 K the center laser wavelength is 8699 Å at 15 A, which is twice the threshold current. Two strong beams are observed at angles of ± 12.4°

from the junction normal. Symmetric beams produced by the right and left traveling waves of the laser were always observed. However, the observed intensity of these beams is not equal. We believe this results from nonuniform pumping, as indicated by near-field observations with an IR microscope. Also observed were two weak beam modes at angles of ± 8.2°. At 195 K we also observe a total of four 8465-Å beams at ± 17.2° and ± 12.5°. All radiation was highly polarized with the E field parallel to the corrugations, which indicates that TE modes excite the radiation field. Calculations of beam angles and angular divergence agree well with the observations.

13.B4 Electrically Switched Optical Directional Coupler: COBRA, M. Papuchon, Y. Combemale, X. Mathieu, D. B. Ostrowsky, L. Reiber, A. M. Roy, B. Séjourné, and M. Werner, *Thomson–Compagnie Générale de Télégraphie sans Fil–L. C. R., 91401 Orsay, France.*

We report the realization, in titanium diffused lithium niobate,[1,2] of an integrated optical switch/modulator consisting of an active directional coupler with a novel electrode configuration (COBRA configuration: from Commutateur Optique Binaire Rapide).[3]

Switched directional coupler configurations previously suggested (but not, to our knowledge, fabricated) were based on the use of initially resonant coupled guides and three electrodes which permit changing the guide indices in opposite directions via applied, opposed electric fields, to destroy the resonance[4] in an optimum fashion. If one of the guides is initially excited, one can control the fraction of light leaving the coupler in each guide by switching between the resonant and nonresonant condition. We have used, however, the configuration shown in Fig. 1 in which there are only two electrodes, situated directly upon the guides. With the C axis of the crystal normal to the guide surface, the opposed direction of the vertical components of the fringing field in the two guiding regions gives the desired opposed index changes. The effect is maximal for TM polarized waves due to the large r_{zzz} electrooptic coefficient of $LiNbO_3$. Other

effects, which we shall discuss, also occur due to the form of the fringing field and the other coefficients.

Approximately 500 Å of titanium was RF sputtered onto the $LiNbO_3$ surface. This Ti was then masked and etched[5] to obtain the guide configuration in the Ti [Fig. 1(b)]. The Ti was then diffused into the $LiNbO_3$ in an O_2 atmosphere[6] at 1100°C for approximately 11 h to form the guide structure.

Directional couplers fabricated in this way were examined by exciting one of the guides (using a rutile prism coupler) and observing (via fluorescence[7] or scattered light) the energy exchange between the guides. Typical coupling lengths observed for couplers formed from 2-μm-wide Ti strips were approximately 500 μm for a 2-μm guide separation, and 1 mm for a 3-μm guide separation. Since the final configuration chosen had a 3-mm coupling length and a 3-μm separation, we expect that in the resonant condition (0 V applied) nearly all the guided energy, at the exit end, will be in the guide which was not initially excited, and this is, indeed, observed.

The electrodes were prepared by RF sputtering a 2000-Å-thick gold film onto the structure and masking and ion etching this film to form two 1 × 3-mm electrodes separated by 3 μm at the coupler center.

Light from an argon laser was coupled into the upper guide (Fig. 1) from the left, and the light diffused out of the guides at the output end was observed as various voltages were applied. In Fig. 2(a) we see that with 0 V applied most of the light is, as expected, in the guide which was not initially excited. With 6 V applied [Fig. 2(b)] most of the light has switched back to the upper initially excited guide.

The switching was, as expected, more efficient for TM than for TE polarized waves and, despite the incomplete switching observed, we believe these results validate the COBRA principle.

13.B5 NdLa Pentaphosphate Fiber Laser, H. P. Weber, P. F. Liao, B. C. Tofield,* and P. M. Bridenbaugh, *Bell Laboratories, Holmdel, N.J. 07733.*

*Present address: Materials Physics Division, Atomic Energy Research Establishment, Harwell, Didcot, Oxon., England.

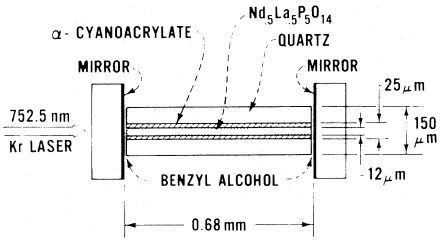

Fig. 1

We report the first successful operation of a laser using the high Nd concentration material $Nd_{0.5}La_{0.5}P_5O_{14}$ in the form of a single crystal fiber. The fiber serves both as the amplifying medium and as a waveguide.

The high concentration of Nd^{3+} ions in $Nd_{0.5}La_{0.5}P_5O_{14}$ (2×10^{21} cm^{-3}) means the length of the laser can be kept to a minimum with a resulting decrease in the number of longitudinal modes and in the total loss due to scattering from imperfections at the interface between the crystalline core and cladding. High concentration materials are also well suited for transverse pumping schemes.

Our laser was constructed with a single crystal fiber of cross-sectional area a = 12 × 12 μm and length l = 0.68 mm. The crystal was used as grown from phosphoric acid, as grown crystalline fibers are of excellent optical quality and their side faces are smooth. The axis of the fibers corresponds to the crystallographic a axis. The laser was constructed by cementing the pentaphosphate fiber into a hollow quartz fiber with alpha cyanoacrylate (see Fig. 1). The end faces were then polished and external mirrors were placed against the polished faces. To reduce loss at the mirror interface, it was immersed in benzyl alcohol.

The pentaphosphate laser was longitudinally pumped at room temperature with the 752.5-nm beam of a Kr^+ ion laser. True CW operation was obtained with a threshold of 10 mW of absorbed power. Calculated gain for this amount of absorbed power is 1.9/pass, which implies a loss of about 50 percent/pass. The diffraction loss in the absence of waveguiding would have been 90 percent and would have far exceeded the calculated gain at threshold. Hence waveguiding was an essential feature of the laser. The 50-percent loss probably resulted from scatter due to an imperfect interface between the fiber and the alpha cyanocrylate cement. We calculate that a reduction of this loss to 1 percent/pass would result in a threshold of 160 μW of absorbed power for the present geometry.

13.B6 An Organic-Dye Light Gate, David W. Vahey, *Battelle Columbus Laboratories, Columbus, Ohio 43201.*

The phenomenon of optically induced dichroism in organic-dye solutions[1] is the basis for a light gate that we have found to be competitive with the optical Kerr gate of Duguay and Hansen.[2] In our experiments, a helium–neon laser beam is partially transmitted through two crossed polarizers when there is a solution of cryptocyanine–glycerin between the polarizers, and when this solution is partially bleached by a giant ruby-laser pulse. A comparison to the optical Kerr gate is afforded by simply employing CS_2 in place of the dye.

We found that probe transmission through the dichroic device was relatively insensitive to variations in exciting intensity throughout the range ~2–20 MW/cm^2 (see Fig. 1). Over the same range the CS_2 gate transmission varied by a factor ~100. Moreover, the CS_2 gate transmission was less than that of the dye gate at intensities up to 10 MW/cm^2. These features make organic dyes attractive candidates for gates triggered by repetitively pulsed lasers that may have low peak power and some pulse-to-pulse instability. Dye light gates may also be useful at intensities beyond 10 MW/cm^2, since they employ solvents that do not exhibit the self-focusing nonlinearities of CS_2 and other molecules that display the optical Kerr effect.

Dyes are candidates as gating materials because they preferentially absorb light that is polarized along a certain molecular axis. A solution that is partially bleached by an intense pulse will tend to contain excited molecules aligned parallel to the optical polarization and unexcited molecules aligned normal to this direction. The result is a dichroism that can rotate the plane of polarization of a probe beam, enabling some component to pass through a pair of crossed polarizers. At increasingly high radiation intensities, this dichroism is quenched as all dye molecules are maintained in the excited state. Consequently, gating action may be terminated by raising the light intensity as well as by removing it. This feature should make the dye gate competitive with the CS_2 device even in the picosecond regime, despite the fact that the reorientational and excited-state relaxation times of dyes may be as large as nanoseconds. Computer simu-

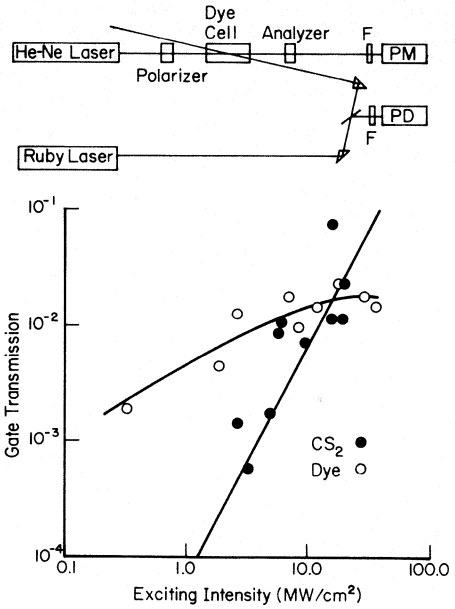

Fig. 1

lations suggest that a dye light gate based on induced anisotropy of gain can have a 0.5-ps rise time and a 3-ps open time when triggered by 10^9 W/cm^2, 10-ps pulses.

Although our experiments were not sensitive to the limiting resolution of the dye gate, we were able to observe intensity quenching of gating action on a nanosecond time scale. Triggering pulses of ~20-ns full width at half maximum duration and ~20 MW/cm^2 peak intensity occasionally passed 10–15-ns helium–neon laser signals during both the rise and fall of the exciting pulse, with little or no output during the time of peak intensity. The rise time of the gated output was as short as 5 ns, or only one-third the rise time of the ruby-laser excitation.

13.B8 Macroscopic Isotope Separation of Uranium by Selective Photoionization, Sam A. Tuccio, Richard J. Foley, James W. Dubrin, and Oscar Krikorian, *Lawrence Livermore Laboratory, Livermore, Calif. 94550.*

The enrichment of uranium in milligram quantities has been obtained by using selective photoionization. In this experiment, a vapor stream of natural uranium was irradiated by two colinear laser beams to selectively photoionize ^{235}U atoms. The ions were then electrostatically separated from the neutral atoms and collected on a beryllium plate.

For the selective photoionization process, ^{235}U atoms were excited by the 3781-Å output from a xenon ion laser and then ionized by UV radiation from a krypton ion laser. The 3781-Å emission line from XeIII overlaps a uranium transition, initiating from a low-lying metastable level at 620 cm^{-1}. At an operating temperature of 2600 K, this level has a thermal population of approximately 27 percent. The 3781-Å transition in uranium has a ^{235}U–^{238}U isotope shift of 3 GHz. The emission bandwidth of the xenon laser used, approximately 4 GHz full width at half maximum, overlaps both the ^{235}U and ^{238}U absorption lines. A temperature-stabilized intracavity etalon with 10-percent reflective surfaces was used to narrow the xenon bandwidth to ~0.3 GHz and tune the output wavelength to excite ^{235}U only. The tuned output power of the laser was 70 mW. The krypton laser used had a nominal output power of 1 W, total, from the two UV lines at 3075 and 3564 Å.

The optical arrangement of the experiment was such that a vacuum chamber with Brewster-angle windows, housing the uranium source, was placed between the xenon and krypton lasers and was intracavity to the krypton laser. The output mirror of the xenon laser acted simultaneously as an output coupler for the xenon laser and a high reflector for the krypton laser. With this arrangement, the krypton laser radiation circulating through the vacuum chamber was 30 W. Both lasers used for this experiment were modified Spectra-Physics Model 170 Argon-Ion Lasers.

The uranium source consisted of a cylindrical oven, approximately 10 cm long, operating at a temperature of ~2600 K. Effusion of uranium vapor from a 1-mm by 8-cm exit slit provided an atom density of about 3×10^{13} cm^{-3} at the slit. The xenon and krypton ion laser beams, colinear and focused to about 0.2 mm, passed over the oven, parallel and adjacent to the exit slit.

A technique was developed to prevent contamination of the Brewster windows on the vacuum chamber by uranium vapor deposition and other vacuum system contaminants. Normally, significant contamination would occur within a few minutes of operation time. A quasi-static pressure of 0.5 torr of xenon gas was maintained at the inner-window surface by flowing xenon through an aluminum tube with a 3-mm bore, situated between the window and the uranium oven. Also a dc discharge was maintained in the xenon gas in a short region near the window. Adequate vacuum-pumping speed provided an overall chamber pressure of about 2×10^{-5} torr. With this technique, no observable contamination of the windows was incurred with several hours of running time.

Photoionized ^{235}U atoms generated at the oven exit slit were separated from the uranium vapor stream by the electric field produced by a beryllium collector plate, biased at −1500 V, located near the exit slit. The ions were deflected into roughly parabolic trajectories and made a deposition on the collector plate in an area of approximately 5 mm by 8 cm. Thermally ionized ^{238}U atoms emanating from the oven were also attracted to the plate, thereby diluting the collected ^{235}U sample. The neutral uranium atoms were allowed to condense onto a water-cooled U-shaped copper block located above the oven exit slit.

A 4-mg sample of uranium was collected in about 2 h. Mass spectrographic analysis showed the sample to be enriched to reactor grade quality, which is about 3-percent ^{235}U.

The macroscopic separation of uranium isotopes has been obtained by selective photoionization. This experiment was performed as part of a program to investigate the viability of laser separation processes based upon atomic vapors. Further experimental studies will be necessary to ascertain the economics of such systems.

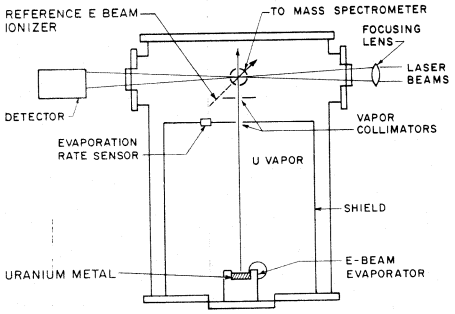

Fig. 1. Schematic diagram of vapor source and vacuum chamber.

One of the more attractive laser-isotope-separation schemes[1] involves the use of atomic uranium vapor. This paper describes experimental studies at low particle density which demonstrate selective two-step excitation and ionization of atomic uranium vapor and, additionally, measure a number of relevant parameters such as photoionization cross sections and state lifetimes. The apparatus should also prove to be a useful tool for the spectroscopic study of other atomic vapors as well.

In this experiment, uranium atoms are excited and ionized by light from short pulse-tuned lasers. The ions are detected and analyzed by a mass spectrometer. The vacuum tank is shown schematically in Fig. 1. Uranium vapor is produced at the bottom of the tank by electron beam evaporation. Only a small fraction of the vapor passes through a hole in the top of the shield and reaches the sensitive region of the mass spectrometer. The tuned laser light is provided by either a pair of pulsed dye laser systems or else by a single pulsed dye laser system for excitation followed by a pulsed nitrogen laser (3371 Å) for ionization. The exciter consists of two synchronized nitrogen lasers which transversely pump a dye oscillator and a dye amplifier. The dye oscillator is basically an Avco "Dial-A-Line"® laser with some tuning modifications.[2] The wavelength and linewidth of this dye laser are determined by the grating used as the rear reflector of the oscillator and two Fabry–Perot etalons. This combination of elements gave an oscillator linewidth of about 0.02 Å. A lens focuses the oscillator output into the amplifier. The wavelength of the exciter laser is monitored with both a standard 1.25-m spectrometer and a Fabry–Perot spectrometer. The ionizer and exciter beams are combined with a dichroic mirror prior to entering the vacuum tank through a window. A lens is used to focus this light into the sensitive region of the quadrupole mass spectrometer where it intercepts the uranium atoms. The total number of ions per pulse produced by two-step laser photoionization was small; however, the time of production was known precisely. By counting single ions, using digital logic, and multiplexing the mass spectrometer between U^{238} and U^{235}, it was possible to not only measure isotope ratios as a function of exciter wavelength, but also to estimate and correct for background effects and for ions produced by single photons. These results are shown in Fig. 2 where we demonstrate 50-percent enrichment of atomic uranium. The

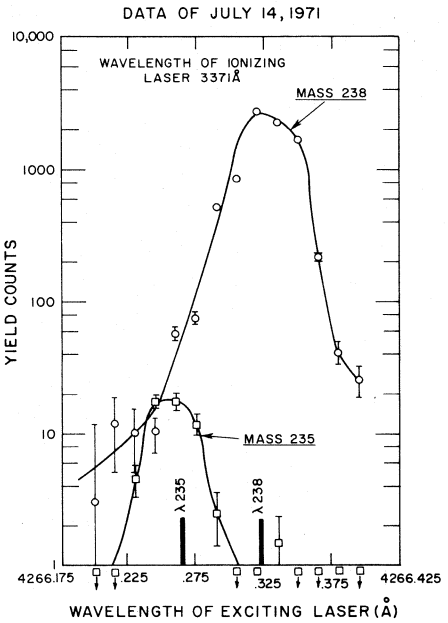

Fig. 2. Measurements of the two-step laser-induced "yield" for mass 235 and mass 238 as a function of the wavelength of the exciting laser. These data include corrections for background and for single photon yields. The error bars are due to counting statistics. Note that 50-percent enrichment has been obtained.

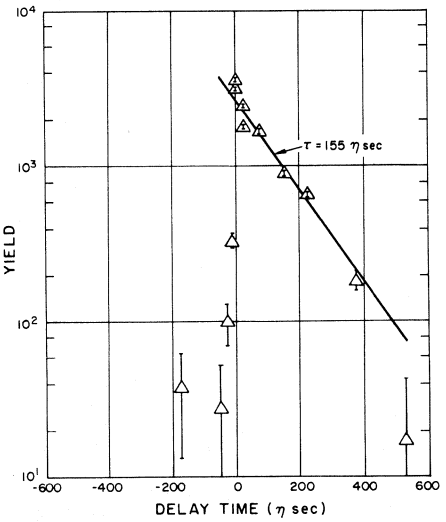

Fig. 3. Measurement of the counting rate yield due to two-step photoionization of uranium as a function of the delay between the exciting and the ionizing laser pulses. The error bars shown are due to counting statistics. The mean life of the excited state is seen to be close to 150 ns.

TABLE I
LIFETIMES OF SOME EXCITED STATES WITH LARGE ISOTOPE SHIFTS

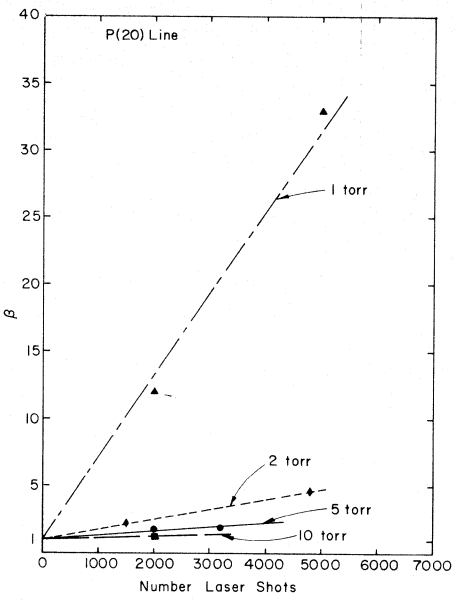
Energy (cm^{-1})	Exciting Wavelength in Air (Å)	J	Isotope Shift	Lifetime (nsec)
23 572	4241.1	6	-.076	60
23 433	4266.3	5	-.057	155
23 212	4306.8	5	-.080	170
22 862	4372.8	6	-.061	135
22 583	4426.9	6	-.055	130
22 056	4532.6	6	-.081	300

raw data without background correction yielded a 30-percent enrichment.

Excited state lifetimes have been measured by observing yields as a function of the delay between the two laser pulses. These results are given in Fig. 3 and in Table I. In addition, for an excitation wavelength of 4266.325 Å the variation of two-step photoionization efficiency was measured as a function of the wavelength of the ionizing laser. The maximum yield at an ionizing wavelength of 3609 Å corresponded to a cross section of $2 \times 10^{-17}\ G_L/G\ \text{cm}^2$ where G is the linewidth of the optical transition and G_L is the laser linewidth. The ionization potential of uranium was determined to be 6.187 ± 0.002 eV.

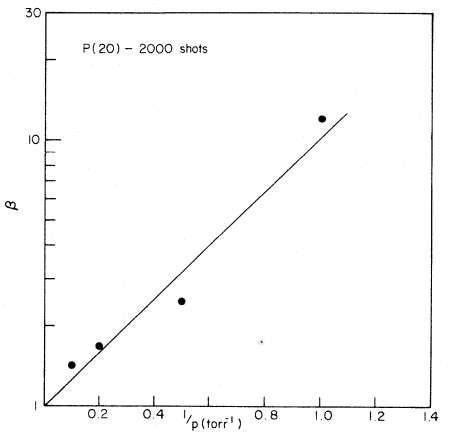
13.B10 Isotopic Enrichment by Multiple Absorption of CO_2 Laser Radiation, J. L. Lyman, R. J. Jensen, J. P. Rink, C. P. Robinson, and S. D. Rockwood, *Los Alamos Scientific Laboratory, University of California, Los Alamos, N. Mex. 87544.*

The polyatomic molecules of SF_6, BCl_3, CF_2Cl_2, and SiF_4 have been irradiated in the presence of H_2 and N_2 with intense CO_2 laser pulses. All four of the polyatomic molecules underwent isotopically selective reactions with regard to the elements S, B, C, and Si, respectively.



The CO_2 laser was a conventional double-discharge design that delivered 0.5–2 J in a 200-ns gain switched pulse, the output depending upon the laser transition selected. Laser emission could be tuned to selected lines of both the 9 and 10-μ bands by means of a diffraction grating in the optical cavity. The radiation was focused with $f/1.5$ lenses into brass sample cells containing the gas mixtures. The products and residual reagents were analyzed with IR spectrophotometry and a quadrupole mass spectometer.

Mixtures containing 10-percent SF_6 and 90-percent H_2 were irradiated with the $P(16)$, $P(20)$, and $P(32)$ lines of the 10.6-μ band. All lines lie within the ν_3 absorption band of $^{32}S\ F_6$ and yielded comparable enrichment of the residual gas in $^{34}S\ F_6$.[1] The enrichment factor β is defined as $\beta = R/R_0$ where R_0 is the normal isotope ratio and R is the isotope ratio of the unreacted material following irradiation. Fig. 1(a) displays β as a function of the number of laser pulses parametric in the total gas pressure. In all cases, β was observed to increase linearly with the number of laser shots. However, for a fixed number of shots β increases as exp $(1/p)$, as shown in Fig. 1(b).



Similar experiments were performed with BCl_3, SiF_4, and CF_2Cl_2. All three species were irradiated with a CO_2 laser frequency that coincides with a strong absorption band of one isotopic form of the central atom. In all cases, depletion of the isotopic form irradiated was observed. The pressure dependence of β was similar to SF_6; however, enrichment factors of only about 2–5 were achieved. Both BCl_3 and SiF_4 showed evidence of an isotopic rescrambling reaction within the product gases. In all cases, the quantity of material enriched was on the order of 50–100 μg.

The mechanism of the isotopically selective absorption process and subsequent chemistry is still under investigation.

Two models under current consideration are 1) sequential selective absorption of n laser quanta followed by collisional dissociation of the excited molecules. The dominant collisional process would probably be anharmonic pumping by VV collisions or 2) sequential selective absorption of n quanta followed by multiphoton to absorption. Present data tend to support the latter model. Any theoretical model should consider the high peak power and related electric field at the focus along with the very large density of states ($>> 10^5\ \text{cm}^{-1}$) present in polyatomic molecules with more than a few quanta of excitation.

(a)

(b)

Fig. 1.

[1] Prior to completion of the SF_6 experiments, we were informed that Ambartzumian *et al.* had obtained, in a similar experiment, very high enrichment of ^{34}S. (R. N. Zare, private communication).

Efficient and Practical Hydrogen Vacuum Ultraviolet Laser

I. N. KNYAZEV, V. S. LETOKHOV, AND V. G. MOVSHEV

Abstract—**Investigations of the hydrogen vacuum ultraviolet (VUV) laser carried out in the Institute of Spectroscopy of the USSR Academy of Sciences are reviewed. Data for VUV TEA H_2 and D_2 lasers at gas pressure up to 2 atm and for low-pressure high-repetition rate hydrogen lasers are presented. The upper limit quantum system efficiency for both gas discharge and *e*-beam excitation of H_2 lasers is discussed. The possibility of obtaining CW operation of the H_2-VUV laser is also discussed.**

I. Introduction

THE vacuum ultraviolet (VUV) region is very attractive for many laser applications. The electronic absorption and photoionization bands of most molecules occur in this region. In this wavelength region, the laser frequency becomes comparable with the electron plasma oscillation frequency for plasmas having charged particle concentrations of about 10^{22} cm^{-3}. The nonlinear resonance effects on the short wavelength electron transitions of atoms and molecules are increased sharply in this region. Intensive coherent VUV radiation can be utilized to optically excite tunable lasers which can in turn be utilized to investigate the ultraviolet (UV) region near the VUV cutoff limit. This region is presently unexplored by coherent radiation techniques. The most important laser parameter for the VUV photochemistry applications is the laser's average power output. Molecular excitation rates of the order of 10^{-3} molecules/h can be achieved with a laser having an average power output of 0.1 W. A power density over 1 MW/cm^2 is required for most optical pumping experiments. High power levels and comparatively high coherency are also required for performing nonlinear optical experiments. Lasers having efficiencies greater than 0.1 percent are suitable for most practical applications.

VUV laser action is presently obtained by *e*-beam excitation of condensed inert gases [1] and by frequency multiplying visible high peak power laser pulses [2], [3]. VUV laser action has been obtained by utilizing high current *e*-beam excitation of the bound-free transitions of gaseous xenon, krypton, and argon [4]. Unfortunately, lasers utilizing relativistic *e*-beam excitation present high radiation danger to the operators and the overall efficiency of the frequency multiplying laser systems is too small to be practical.

One of the most attractive VUV laser systems is the hydrogen laser [5]. The low-inductance single-shot self-sustained discharges obtained with solid-state dielectric switches [6] or with the nanosecond pulsed *e* beams [7] are widely used for exciting lasers. The average output power for the solid-state dielectric switch excited laser systems is limited to approximately 1 μW. The low average power is determined by the ratio of the laser pulse energy to the time interval required for the replacement of the dielectric in the switch.

The basic characteristics of the H_2-VUV quantum system are favorable for the conversion of electron excitation energy to the VUV laser emission energy (Table I). Effective electronic excitation cross sections of the upper laser states are comparable with the effective cross section of ionization and the total nonelastic losses of the hydrogen molecule. The ratio of laser radiation quantum energy to the excitation energy is higher than that for a CO_2 laser. The Doppler linewidth of the H_2 spontaneous radiation is four orders of magnitude less than the luminescence bandwidth of rare gas excimers. The parameter $g_{0v'}g_{v'v''}\beta_{v'J'}S_{J'J''}$ in the expression for gain, connected with the splitting of molecular electronic states into a system of vibrational-rotational sublevels, is about 10^{-2} for the H_2 laser transitions.[1]

The molecular hydrogen laser system is, therefore, capable of excellent performance. This performance at the present is far from being realized. The excessively high probability of radiative decay causes the inverted population to have an extremely short lifetime of ~1 ns. Effectively depositing the excitation energy into the active medium during such a short period of time is a rather difficult task. Low-inductance systems utilizing solid-state dielectric switches provide the formation of excitation pulses with appropriate parameters, but these systems are rather inconvenient in practice. The quantitative data on the limiting value of the excitation efficiency of laser states by *e*-beam excitation are still unknown. The operation of VUV lasers at high-repetition rates is important in order for these lasers to be widely utilized.

The main purpose of this paper is to report more precise measurements of the limiting parameters of the H_2 laser. The experimental results obtained with a single-shot TEA H_2-VUV laser and with a high-repetition rate low-pressure hydrogen laser are given. The upper limit of the laser states excitation efficiency for self-sustained discharges and for *e*-beam excitation is presented. The problem of the CW hydrogen VUV laser is also discussed.

II. Single-Shot TEA H_2-VUV Laser

A. Experimental Arrangement

The experimental arrangement of the TEA H_2-VUV laser used in our investigations is shown in Fig. 1. The 0.006 × 1 × 30-cm^3 laser volume was excited by a transverse discharge in the bipolar plane Blumlein line with a varied profile and a dielectric film switch. The probability of the corona discharge

initiation (or surface breakdown) is sharply decreased by using the bipolar charging of the plates to $\pm V/2$. At voltages of $\lesssim 100$ kV, the bipolar charging of the plates is a more convenient solution of the surface breakdown problem compared with the distilled water or oil filled systems approach.

The mechanical initiation of the electrical breakdown of a polyethylene film by an electromagnetic (EM) striker was used. The traveling-wave excitation was provided by designing the pulse forming wing of the Blumlein line at a certain angle to the optical axis of the laser cell. A capacitive voltage divider with a time constant less than ~0.2 ns and the N2-7 oscillograph were used to measure the voltage pulse at the cell. The distinguishing feature of the system was the very narrow laser channel ($h = 60\ \mu$) which provided the high current density and a satisfactory spatial homogeneity of the discharge. The narrow channel also provided a comparatively large effective voltage pulse duration in the discharge gap. As a result, the conditions for laser excitation improved greatly. Copper foil electrodes having a thickness of 50 μ and polished edges were held fixed with epoxy adhesive at a distance $l = 1 \pm 0.05$ cm between polished glass plates. These plates had a rather high reflectivity for beams traveling at a small angle to the laser optical axis and thus formed a peculiar plane waveguide for the short-wave laser radiation. The Fresnel number for the laser volume was 7×10^{-2}.

The laser pulse energy was measured by a calibrated vacuum thermopile connected to the laser cell through a buffer volume (see Fig. 1). The volume was filled with hydrogen at 1 atm in order to prevent electric breakdown to the thermopile. The absence of the false signals was controlled by filling the volume with oxygen. For visual observation of the laser radiation, the rear window of the thermopile was covered by a thin layer of sodium salycilate.

The laser spectrum was measured by means of a VMS-1 spectrograph with an accuracy of 0.1 A. The laser radiation was directed from the cell through the LiF window and the intermediate vacuum tube with a LiF lens to the entrance slit of the spectrograph.

B. Experimental Results

For pressures up to 2 atm and with the operating voltage slightly over threshold, the radiation from the laser cell was unidirectional. The intensity ratio of the forwards and backwards beams was more than 10. The radiation divergence in the plane of the laser cell was 2° and about 1° in the direction perpendicular to the cell. For a pressure change of one order of magnitude (i.e., 0.1-1 atm), the threshold voltage only increases by a factor of 2-2.5 (Fig. 2). Near threshold, laser action was observed as a "reverse" traveling wave towards the commutator. At higher voltages, the unidirectional superluminescence traveling wave in the "forward" direction was observed. For the optimum excitation conditions, $p = 0.1$ atm and $V = 5$ kV, the laser pulse energy was 0.5 mJ. The laser energy remained constant with a diminishing of the wing length to several centimeters. The energy stored by the line for this case was about 0.1 J and the corresponding measured maximum efficiency was 0.5 percent. The formation of the superluminescence traveling wave for a 30-cm active length corresponds to the laser pulse duration of approximately 0.5 ns yielding a peak power of more than 1 MW and a power density of approximately 200 MW/cm^2 at the exit laser opening (Table II).

The densitograms of the H_2 and D_2 superluminescence spectra on the $B'\Sigma_u^+ \rightarrow X'\Sigma_g^+$ transition are given in Figs. 3 and 4. Five new laser lines have been observed in hydrogen, including two lines $P(3)$ (11, 14) and $R(1)$ (8, 14) ending in the last vibrational state $v'' = 14$ of H_2 close to the dissociation limit, as well as five new laser lines in D_2. The measured wavelengths of the new laser lines and their identification are given in Table III.

The laser spectrum differed greatly from the spontaneous

radiation from the same cell by the line intensity ratio and the number of observed transitions. The 1:0.7 characteristic intensity ratio for P and R branch lines of spontaneous radiation was not observed for the laser radiation. Luminescence occurs mainly at the P branch and there are no lines of the R branch in the spectrum, as a rule. The line intensity ratio for ortho- and paramodification of hydrogen was observed to be severely distorted. Radiation was observed on only a relatively few lines. Only 23 lines were observed in the laser cell spectra compared with the hundreds of electronic vibrational-rotational lines normally observed in the transitions of the Lyman hydrogen band system in the spontaneous radiation.

The specific intensity ratio of the laser lines remained almost constant at various hydrogen pressures and charging voltages of the Blumlein line (see Fig. 3). The lines $P(3)$ (8,14) and $P(3)$ (7,13) (I and IV in Fig. 3) which end at levels close to the dissociation limit were observed to be exceptions to this rule. It is convenient to take the lines $P(1)$ (2,9) and $P(3)$ (2,9) (II and III in Fig. 3) with the rather deep-lying lower vibrational levels as the comparison lines. The line $P(3)$ (8,14) is weaker than the line $P(1)$ (2,9) at p = 0.1 atm and at low voltages. At higher voltages, the $P(3)$ (8,14) line becomes comparable in intensity with the strongest lines of the spectrum and becomes more intensive than line II. Increasing the gas pressure resulted in decreasing the laser lines' intensities, especially for the $P(3)$, (8,14) and the $P(3)$ (7,13) lines. The latter becomes weaker than line III. At a low gas pressure, the ratio between intensities of the two last lines become inversed.

The rise time of the voltage pulse applied to the laser cell τ_f is dependent on the width of the forming line (Fig. 5). For a narrow line, τ_f is determined by the commutation time of the solid-state dielectric switch. In our experiment, it was in the range of 0.3–0.6 ns. In a line with variable profile, the voltage transformation illustrated by Fig. 6 was observed.

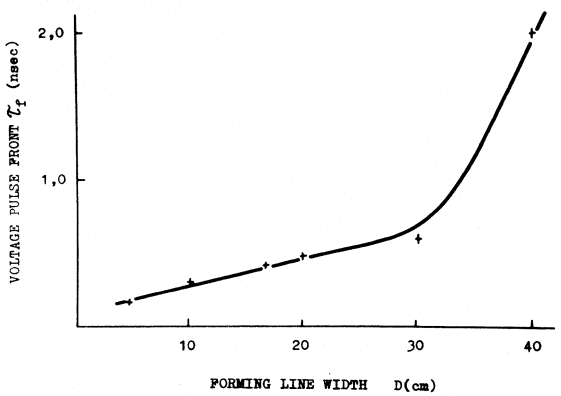

Fig. 5. Voltage pulse rise time applied to the laser cell as a function of Blumlein linewidth.

C. Discussion of the Results

Comparatively high operating performance of the single-shot H_2 laser was obtained by using supernarrow laser channels, choosing an optimum width of the line, and operation at a sufficiently high voltage. In the narrow channel, a high current density $j_{max} = V^{max}/\rho S = 10^5$ A/cm^2 was obtained. For this condition, a rather long effective pulse duration of high electrical field in the discharge, $\tau \sim \gamma_0^{-1} \ln (l/h)$, was achieved; $S = b \cdot h$ is the cross section of the discharge gap perpendicular to current direction; γ_0 is the electron avalanche growth constant; ρ is the wave impedance; and $\epsilon = 2.2$.

The single-channel switch forms in the two-dimensional line a circular wave of voltage having a width b, with variable amplitude, and having a maximum $-V$ at the commutation point. This wave is attenuated as $1/r$ as it propagates down the line. It is reflected from the rear and side edges of the line. The experimental results show that the wave becomes approximately a plane at a distance $2B$. The rise time of this wave depends on the commutation time of the switch and on the formation time of the plane wave. The quantitative analysis of the discharge wave propagation is difficult because of the necessity of solving a two-dimensional wave equation in a limited space. The main conclusion reached from the experimental data is that despite the more complicated process of wave formation in a plane line, the amplitude of the resultant wave at distance $\gtrsim 2b$ is equal to V as in a one-dimensional line. In other words, the line is recharged completely.

The voltage transformation was experimentally observed for the line with a variable profile (Fig. 6). The ratio of transformation for a linear line is $V_2/V_1 = 2(\rho_2/\rho_1)^{1/2}$ where V_1, ρ_1, V_2, ρ_2 are the voltage and wave impedance at the points 1 and 2. The factor of 2 arises due to a reflection at the open end. In accordance with the previously mentioned wave formation, the voltage transformation in a plane line may be described by the same expression with wave impedance ρ_1 averaged over the length of the wave formation. For constant wave impedance $\rho_1 = 377 H_1/b(\epsilon)^{1/2}$, where H_1 (centimeters) is the distance between the plates at the beginning of the line. For a constant linewidth, the transformation ratio is

$$K = 2\sqrt{\frac{\rho_2}{\rho_1}} = 2\sqrt{\frac{H_2}{H_1}}$$

where H_2 is the distance between the plates at the end of line. The expression is consistent with the diagram in Fig. 6.

Let us now consider the intensity anomalies of the laser lines terminating near the dissociation limit. Potential curves of some electronic states of molecular hydrogen are illustrated in Fig. 7(a). The radiation lifetimes of the upper laser states are $\tau^B = 0.8$ ns, $\tau^C = 0.6$ ns [9]. The lifetimes of the lower laser states at gas pressures $p \lesssim 0.3$ atm are determined by the wall diffusion with the characteristic time $\tau_d = (h/\pi)^2/D = 10^{-3}$ s ($p = 1$ cm). For pressures $p \gtrsim 0.3$ atm, the lifetimes of the lower laser states are determined by the vibrational-translational relaxation with the corresponding time of the order of the VT relaxation time for the lower molecular levels $\tau_{VT} = 5 \times 10^{-4}$ s · atm [10]. Thus the H_2 laser operates on the typical self-terminated scheme.

The peculiar feature of the hydrogen laser is the decay of the upper laser state $B'\Sigma_u^+$ on the vibrational-rotational levels of the ground state near the dissociation limit [Fig. 7(a) and (b)]. Laser action is observed on the last stable level of the hydrogen molecule $v'' = 14$, $J'' = 3$, located only 48 cm^{-1} below the H_2 dissociation limit. This suggests that the dissociative depletion of the lower laser states is possible with the corresponding interpretation of observed anomalies. The dissociative depletion of laser states has been considered in our paper [12] in connection with the problem of the four-level hydrogen laser.

The intensity of superluminescence is proportional to the excitation rate of the upper laser state. The relative electron excitation rate of vibrational-rotational levels within the laser electronic state does not change sufficiently with the gas pressure and voltage on the discharge gap. Corresponding specific intensity ratio of superluminescence lines should remain constant. An increase in gas pressure results in a relative intensification of intermolecular processes including the molecular dissociation from vibrationally excited states near the dissociation limit.

The depletion of the vibrationally excited molecules is possible due to collisional transitions to the unstable rotational states lying above the dissociation limit and subjected to the rotational predissociation. For laser states lying within kT from the dissociation limit, a direct collisional transition to a continuous state is also possible. The existence of unstable states is connected with the rotational deformation of the potential energy curve of the ground state. The curve of effective potential energy $V_J(r) = V(r) + J(J+1)h^2/2\mu\rho^2$ passes through the maximum [Fig. 7(b)] in the region of large internuclear distances and then approaches gradually the dissociation energy $V(\infty)$; ($V(r)$ is the molecular potential energy without regard to the rotation, and μ is the reduced mass). The rotational levels $J'' = 4,5$, $v'' = 14$ are located above the dissociation limit but below the maximum of the corresponding curve $V_J(r)$. The nonradiative lifetime for these levels due to the tunneling to a repulsive state is of the order $\tau \sim T_{vib}/D^* = 10^{-11}$ s [13] with the corresponding natural linewidth of 0.6 cm^{-1} compared with the Doppler width; T_{vib} is the period of molecular vibration and D^* is the tunneling coefficient. The corresponding comparatively narrow lines have been observed in the spontaneous radiation spectrum [11]. The states $J'' = 6$, $v'' = 14$ overlie the maximum effective potential. The lines terminating on these states have not

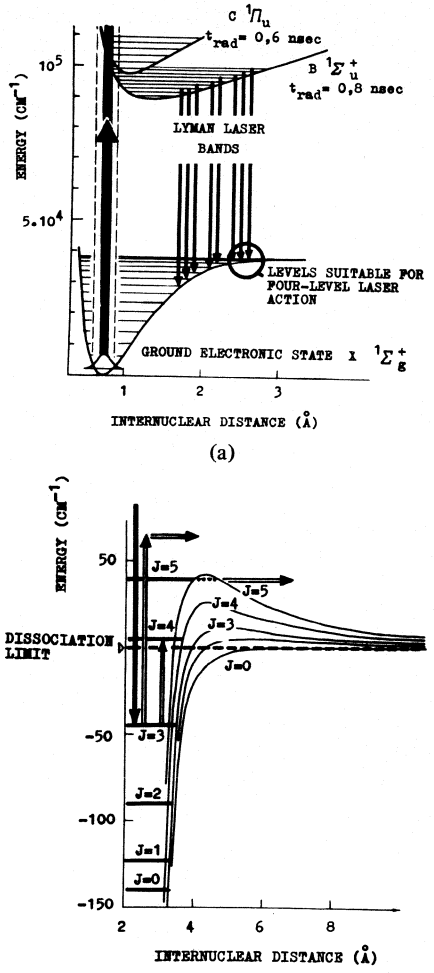

Fig. 7. (a) Potential energy curves of H_2. Lower laser level structure near the dissociation limit (circled) see Fig. 7(b) for details. (b) Energy levels of last excited vibrational state of H_2 $v'' = 14$. Dotted horizontal line denotes dissociation limit of ground state. Downward vertical line corresponds to the observed laser action on the last stable molecular level $v'' = 14, J'' = 3$.

been observed in spontaneous spectra due to the excessive natural width caused by fast molecular dissociation.

The collisional lifetime of the $v'' = 14$, $J'' = 3$ level is approximately equal to $\tau_{14,3}^{coll} \approx 4.5 \times 10^{-11}$ s · atm. At $p \gtrsim 0.05$ atm $\tau_{14,3}^{coll}$ becomes less than the radiative lifetime of the upper laser states $\tau^B = 0.8$ ns, and the four-level laser action can take place on the line $P(3)$ (8,14). The lifetime of inversion population on this transition is no longer limited by the value τ^B. Depending on the experimental conditions, at a rather long excitation pulse duration, this lifetime may be much longer than that for the rest of the self-terminated transitions. The corresponding anomalous behavior of the line intensity should show up in the superluminescence spectra. This behavior is determined mainly by the temporal dependence of the excitation rate of the laser electronic states $f_{0K}(t) = N_0 n_e(t) \langle \sigma_{0K} v \rangle t$.

The absence of a rather strong superluminescence line $P(3)$ (8,14) at $\rho \gtrsim 0.3$ atm and a considerable attenuation of the line $P(3)$ (8,13) at $p = 1$ atm indicate that gain is rapidly decreased for transitions terminating on the vibrational-rotational levels $v'' = 13,14$ of the ground state near the dissociation limit. The collisional broadening for these levels is the biggest

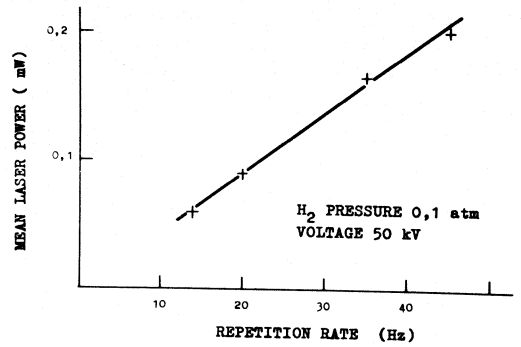

Fig. 8. Characteristics of high-repetition rate H_2-VUV laser. Average power versus repetition rate.

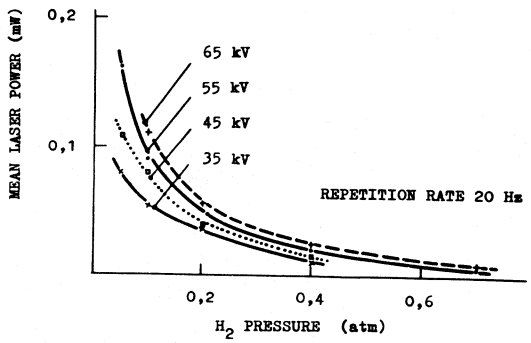

Fig. 9. Average power output versus H_2 pressure.

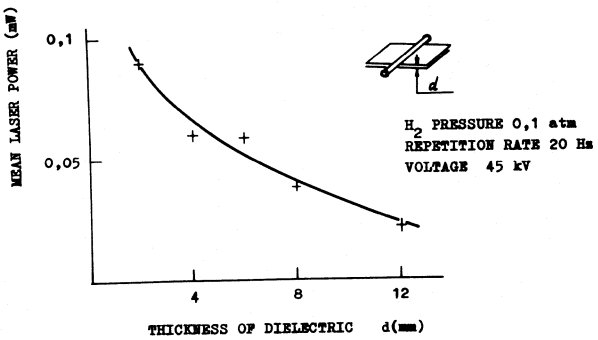
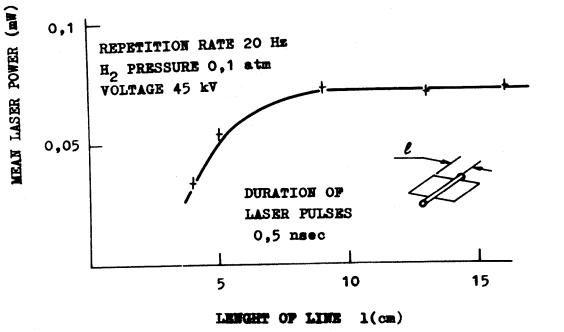


and accounts for the observed intensity drop for the broadening parameter ~0.3 cm^{-1} atm^{-1}.

The single-shot hydrogen laser with a solid-state dielectric switch is very inconvenient in practice because of the necessity of changing the dielectric film. The mean laser output for a 1-min average time of changing the dielectric switch is about 10 μW. A comparatively high voltage $\gtrsim$40 kV is needed for laser operation. In this case, the film width should be about 20 cm. For higher voltages, two changeable films are needed. Changing of the films in this case is a rather complicated operation with certain difficulties in mechanization. In this connection, the high-repetition rate H_2-VUV laser with the gas discharge spark-gap commutator is of particular interest.



III. High-Repetition Rate H_2-VUV Laser

A. Experiment

A high-repetition rate pulsed output was obtained by triggering a SF_6 spark gap pressurized at 9 atm. The measured commutation time of the spark gap was slightly longer than 1 ns. The repetition pulse rate was usually operated up to 50 Hz. The mean laser power output was directly proportional to the repetition rate (Fig. 8). The laser power increased with increasing voltage and decreased with increasing gas pressure (Fig. 9). At pressures below 40 mmHg, the system could not be operated because of breakdown. The maximum attained laser power was about 0.4 mW at $f = 45$ Hz and the laser pulse energy was about 10 μJ. The laser output power decreased with increasing dielectric film thickness of the transmission line [Fig. 10(a)]. Decreasing the length of the wings of the transmission line below $l \lesssim 8$ cm [Fig. 10(b)] begins to decrease the laser output power. The efficiency of the system was 0.03 percent (Table IV).

(a)

(b)

PARAMETERS OF HIGH-REPETITION RATE H_2-VUV LASER

λ	1610 Å
Mean Power	0.4 mW
Repetition Rate	50 Hz
Laser Pulse Duration	0.5 nsec
Peak Power	20 kW
Optimal Pressure	30 torr
Efficiency	0.03%

B. Discussion of the Results

The observed decrease in the laser output power with pressure results from the reduction in the electric field to pressure ratio (E/P) and with the corresponding reduction of the $\langle \sigma v \rangle$ parameter which determines the excitation rate of the laser levels. For fixed (E/P), the laser power increases with increasing laser gas pressure up to a range of approximately 0.1 atm. Beyond this gas pressure, the laser power remains constant. At higher pressures, the molecular quenching of excited electronic states appears to be significant. The probability of quenching is related to the radiative decay probability A at gas pressure p (atmospheres) and to the effective quenching cross section q (square centimeters) by the relationship

$$\sigma_q p = A/2.7 \times 10^{19} vp$$

where $v = 2 \times 10^5$ cm/s is the gas-kinetic velocity of the molecules at room temperature. There is no accurate data available on the value σ_q for B state of molecular hydrogen. This cross section is apparently of the same order of magnitude as for the gas-kinetic cross section [14]. The quenching is substantial in this case at a gas pressure about 0.1 atm.

The region of relatively high pressures $p \gtrsim 0.05$–0.1 atm is unsuitable because of the short time interval τ with respect to the high electrical field existing in the discharge channel where τ is inversely proportional to the rate of electron avalanche growth $\gamma_0 = N_0 \langle \sigma_{01} v \rangle$. Effective excitation of laser states is attained provided the $\langle \sigma v \rangle$ coefficient is a maximum at least during the laser pulse length Δt. This at once sets a limit on the molecular concentration $N_0 \lesssim N_0^*$. For higher molecular concentration, the time interval τ becomes shorter than Δt and the excitation efficiency of the laser states decreases. It should be noted that the same situation may also hold for the nitrogen laser as well as for any other laser excited by a self-sustained discharge.

The laser pulse duration is about 0.5 ns as stated in Fig. 10(b). Laser action in a system having short plates for the transmission line is of particular interest in connection with the ones desired to develop advanced small-size excitation systems for such lasers. As it follows from Fig. 10(a), the wave impedance of the line should be decreased. The limit is set by the electrical strength of available materials.

The laser pulse energy for a discharge system having a spark-gap commutator is approximately one order of magnitude less than for lasers having solid-state switches. This occurs because of two factors. The rise time of the voltage pulse exciting the laser cell is longer for the gas-discharge switch. This is equivalent to considerably decreasing the line charging voltage which, of course, leads to a corresponding decrease in the laser output pulse energy. The wave impedance of the gas discharge switch is comparatively high. As a result, the current density in the active volume is much smaller than when a solid-state switch is utilized. This results in decreasing gain and output laser power.

The average laser power may be substantially increased by pulse charging the line up to a voltage of 150–200 kV. Capacitors of 50–100 pF can be charged to such voltage without much difficulty. The cross section and the active volume of the laser cell can also be increased at the same time in order to obtain higher laser pulse energies. If high-repetition rate high-pressure spark-gap commutators are developed, the average laser output power can be increased by the operation of the laser at higher repetition rates. The repetition rate can be increased up to at least a few kilohertz without physical limitations. Forced cooling of the electrodes and the cell walls can be performed to remove the effects of gas heating on the redistribution of gain on the rotation–vibrational lines of the band, as well as on the tendency to increase the Doppler linewidth. A principal limitation is encountered with the H-atom recombination rate and with the depletion of the long-lived lower laser states. The corresponding characteristic times are of the order of the molecular wall diffusion time $\tau_d = (\Delta/\pi)^2 D^{-1} = 3 \times 10^{-7}$ s, where $\Delta = 10^{-2}$ cm and $D = 10$ cm/s at $p = 0.1$ atm. Thus even with present laser cells, an average power of about 30 mW can be attained at a repetition rate of 5 kHz. This is

quite sufficient for many applications for this laser. The major limitation at present is mainly with the commutator. For satisfactory laser operation, the stored electrical energy of a few tenths up to a few joules should be commutated at high-repetition rates. The development of commutators with the required parameters is essentially alleviated due to the smallness of the commutated electrical energy.

The hydrogen laser considered in the preceding operates on a three-level scheme. The main disadvantage of this scheme is an extremely short lifetime for the inversion population of ~1 ns. This short lifetime causes many difficulties. It is difficult to use the resonator effectively. This involves the necessity of having a high gain in the active medium in order to utilize the superluminescence mode of operation. The laser coherence for this mode of operation in this case is comparatively poor. Requirements on pumping power are respectively increased. The consequences are heavy demands on the excitation system. As a result, the alternative four-level laser excitation scheme is of specific interest. The excitation systems for such schemes may have ordinary parameters. Before discussing this scheme, we should consider the limiting efficiency of the H_2 laser quantum-mechanical system.

IV. The Limiting Excitation Efficiency of the Hydrogen Laser Levels

The H_2-VUV laser is excited at present by using nanosecond self-sustained discharge and relativistic electron beams. To choose optimum excitation conditions, it is necessary to have information on the excitation efficiency of the hydrogen laser levels excited by e beam or in a gas discharge. The high energy electronic excitation is of interest also in connection with the existence of accelerated electrons in discharges having rather low pressures under high voltages. These electrons may also substantially affect the laser states population.

The excitation efficiency of the B and C states [Fig. 7(a)] in the electronic energy region $0 \lesssim \epsilon \lesssim 10^2$ eV is considered by using the data on effective cross sections of electron excitation of rotational σ_r [15], [16] and vibrational σ_v [16], [17] levels of the ground state, triplet [18], [19] electronic states $a\,^3\Sigma_g^+$, $b\,^3\Sigma_u^+$, and $c\,^3\Pi_u$ with the total effective cross section σ_d. Excitation of triplet states and a subsequent radiation decay leads to molecular dissociation. We used also the data on the effective excitation cross sections of the laser states σ_{0B}, σ_{0C} [20], the singlet electronic state $E'\Sigma\sigma_{0E}$ [21], ionization with H_2^+ ion formation [22], and the data on the effective elastic collision cross section of electrons with hydrogen molecules σ_e [16].

The energy losses of electrons in nanosecond pulsed discharges occur through collisions of electrons with hydrogen molecules in the ground state. Relative energy losses in the kth collisional process are

$$\chi_K^{\text{disch}} = \frac{\langle \sigma_{0K} v \rangle \epsilon_{0K}}{\Sigma_J \langle \sigma_{0j} v \rangle \epsilon_{0j} + \left\langle \int_0^{(\epsilon-\epsilon_{0i})/2} \epsilon_s \sigma_{0i}(\epsilon, \epsilon_s)\, d\epsilon_s \cdot v \right\rangle}. \quad (1)$$

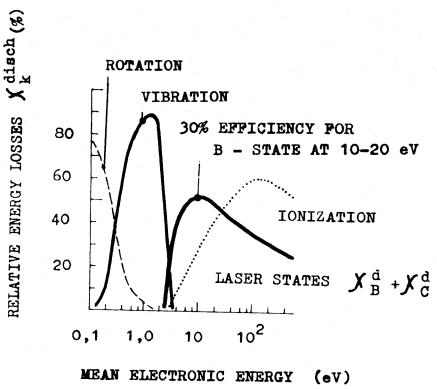

Fig. 11. Excitation efficiency of the H_2 molecular states in the gas discharge versus the mean electron energy.

Fig. 11 shows losses χ_K^{disch} versus the electron energy. At low electron energy of $\epsilon \lesssim 6$ eV, results of numerical calculations [16] are used. For 6 eV $\lesssim \epsilon \lesssim$ 100-eV energy range, effective cross sections are averaged over the Maxwellian velocity distribution of the electrons. The losses on the kinetic energy of the secondary electrons, given by the right-hand term of the denominator in (1), become substantial at $\epsilon \gtrsim 70$ eV. The maximum excitation efficiency of laser states $\chi_B^d + \chi_C^d = 50$ percent is achieved at the mean electron energy of about 10-20 eV (Fig. 11). Efficiency decreases rapidly with diminishing electric field ϵ, especially in the region $\epsilon < 5$ eV. Electronic energy over 10 eV is attained at $E/p \gtrsim 500$ V · cm^{-1} torr^{-1}. This value of electronic energy is maintained during 0.6 ns at a gas pressure $p = 0.05$ atm for a system having a wave impedance of 1 Ω for the storage line. In the following quasi-CW phase of the discharge, the mean energy $\epsilon \sim$ 2-3 eV is established in accordance with the charged particle balance in the volume. Losses of electrons and positive ions are caused by volume recombination and ambipolar diffusion. The excitation efficiency of the laser states for this phase is insufficient due to comparatively low electron energy.

The excitation efficiency of the H_2 laser states by high energy electron beam is convenient to consider on the basis of a simplified model. The optimal use of the e-beam energy is achieved in the case of complete stoppage of the electrons in the laser volume V. The corresponding conversion efficiency of the total energy of e beam to the kth electronic state excitation energy may be considered over all the volume V during the current pulse. There is no need in this case for detailed study of the space-time pattern of the electronic energy losses and the approximate analytical analysis becomes possible. The addition of energy losses of the various electrons during the generations process were implicitly used to simplify the analysis. The rather precise set of data on the effective electron cross sections available at present for many atoms and molecules makes it possible to consider the problem using characteristics of particular collisional processes.

Laser states are excited in the process of energy loss of primary and secondary electrons. To determine the total efficiency κ^K, it is convenient to introduce the following value:

$$\kappa^K = \frac{\sigma_{0K}\epsilon_{0K}}{(1/N_0 v)(d\epsilon/dt)} = \frac{\sigma_{0K}\epsilon_{0K}}{(1/N_0)(d\epsilon/dx)}$$

$$\sqrt{\frac{1}{N_0}}\frac{d\epsilon}{dx} = \Sigma_m \sigma_{0m}\epsilon_{0m} + \delta_e + \int_0^{(\epsilon-\epsilon_{0i})/2} \epsilon_s \sigma_{0i}(\epsilon, \epsilon_s)\, d\epsilon_s + \int_0^{\epsilon} \epsilon_b \sigma_b(\epsilon, \epsilon_b)\, d\epsilon_b. \quad (2)$$

The parameter κ^K is the average part of the energy expended by the monoenergetic electrons with the initial energy in the range ϵ, $\epsilon + d\epsilon$ at distance dx on the kth collisional process. The balance equation for the mean electron energy is used in (2). The parameter κ^K does not depend strictly on time and position coordinates and is only a function of energy. Terms in the denominator are, respectively, excitation of quantum states and ionization, elastic losses, losses on the secondary electron kinetic energy, and bremsstrahlung radiation. In (2), v is the velocity of electrons and $d\epsilon/dx$ is the "ionization" losses of the electrons. At comparatively low electronic energies, elastic losses are $\delta_l = 2m\sigma_l\epsilon/M$, where m and M are the mass of the electron and atom/molecule, respectively, and σ_l is the effective cross section of the elastic collisions. The mean energy loss of electrons in elastic collisions with nuclei at energies in the range 10^3-10^5 eV are negligible due to the rapid drop of the corresponding differential scattering cross section with angle.

The parameter κ^K is plotted in Fig. 12 against the electron energy.[2] In the nonrelativistic energy region, approximately up to 0.2-0.4 MeV, the first two terms in the power expansion of the effective cross sections of the optically allowed transitions and ionization, calculated in the Born approximation, may be used (expansion on powers of ϵ^{-1})

$$\sigma_{0K} = \sigma^0_{0K}\frac{\epsilon_K}{\epsilon}\ln\frac{\epsilon}{\epsilon_K}. \quad (3)$$

In (3) $\sigma^0_{0B} = 1.5 \times 10^{-16}$ cm^2, $\sigma^0_{0C} = 1.1 \times 10^{-16}$ cm^2, and $\sigma^0_{0i} = 3.5 \times 10^{-16}$ cm^2. The experimental data on ionization [22] are described by (3) with an accuracy of 20 percent over the entire energy region of $10^2 \lesssim \epsilon \lesssim 10^4$ eV where measurements have been carried out. For the relativistic energy region $\epsilon \gtrsim 0.2$-0.4 MeV, the following approximation can be used [24]:

$$\sigma^r_{0K} \simeq \sigma^0_{0K}\frac{\epsilon_{0K}}{mv^2}\ln\left[\frac{mv^2}{2\epsilon^2_{0K}}\frac{\epsilon'}{(1-\beta^2)}\right] \quad (4)$$

where m is the rest mass of electron, $\epsilon' = mc^2[(1-\beta^2)^{-1/2} - 1]$, and $\beta = v/c$.

General control of used approximations for the effective cross sections of the electronic collisional processes in hydrogen can be carried out by using the known data on energetic losses of electrons $d\epsilon/dx$ [24] according to the relation ($\epsilon \lesssim 60$ MeV)

[2] Index K takes the following values: $r, v, d, B, C, E, i, i^d, b$, and e.

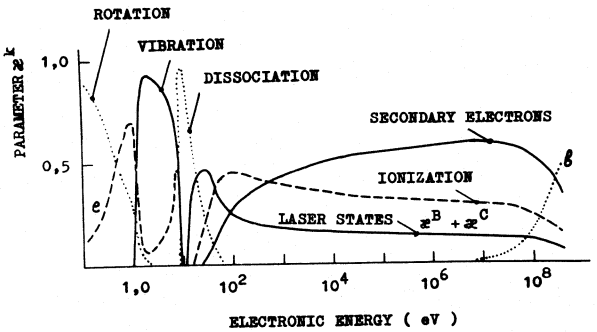

Fig. 12. Parameter κ^K dependence on energy: e—elastic collisions; b—bremsstrahlung radiation.

$$10^6\frac{\rho}{N_0}\frac{d\epsilon}{dx} = \Sigma_m \sigma_{0m}\epsilon_{0m} + \int_0^{(\epsilon-\epsilon_{0i})/2} \epsilon_s \sigma_{0i} \cdot (\epsilon, \epsilon_s)\, d\epsilon_s = \delta(\epsilon) \quad (5)$$

where $d\epsilon/dx$ (in MeV/cm^{2}g^{-1}), and $\rho = 9.10^{-5}$g $\cdot$ cm^{-3} is the density of hydrogen. The chosen effective cross sections provide descriptions of the energetic losses of electrons over a wide energy region with an accuracy of <10 percent (Fig. 13). Maximum deviations occur in a relativistic region of $\epsilon \gtrsim 1$ MeV. The energetic dependence of the effective ionization cross section $\sigma_{0i}(\epsilon, \epsilon_s)$ have substantial effect on the curves at high electronic energies. The inverse square dependence increases electronic energy losses at 1 MeV approximately 1.5 times (the curve 1 in Fig. 13). More precise results are obtained with index 2.1 [24].

The maximum excitation efficiency of B and C laser states $\kappa^B + \kappa^C \simeq 50$ percent is achieved at the electronic energy about 30 eV (Fig. 12). The efficiency drops quickly with energy and for 10 keV $\lesssim \epsilon \lesssim$ 10 MeV the efficiency is stabilized at a level $\kappa^B + \kappa^C = 14$ percent. Main energetic losses, up to 55 percent, are accounted for by the kinetic energy of the secondary electrons. In the ultrarelativistic energy region $\epsilon \gtrsim 60$ MeV, the bremsstrahlung radiation becomes a dominating channel of losses, and the excitation efficiency of the laser states drops drastically (Fig. 12). The excitation efficiency of vibration levels and triplet electronic states by the primary electrons is extremely low, of order of the ratio of molecular state energy to the initial electronic energy.

The excitation efficiency of the kth collisional process by completely stopping groups of electrons with initial energy in the interval ϵ, $\epsilon + d\epsilon$ is approximately

$$\kappa^K_0 = \frac{1}{\epsilon}\int_0^t N_0 \sigma_{0K} V \epsilon_{0K} dt = \frac{1}{\epsilon}\int_0^{\epsilon} \kappa^K d\epsilon \quad (6)$$

(t_0—time of complete stoppage of electrons). The change of variables $t = t(\epsilon)$ is used here according to the electronic energy balance equation. The electronic energy distribution function is changed for the stopping electrons and the effective width of the function $\Delta\epsilon$ is increased. The effective cross sections of ionization and laser states excitation (allowed optical transitions) at $\epsilon \gtrsim 200$ eV vary rather slowly in

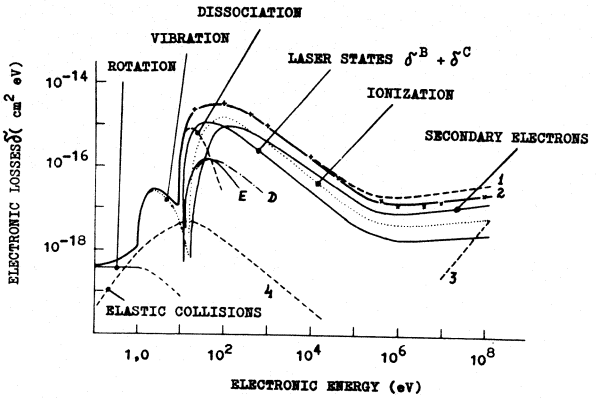

Fig. 13. Energy losses of electrons in H_2. 1—total losses for inverse square dependence of $\sigma_{0i}(\epsilon_1 \epsilon_s)$ from energy. 2—total losses for index 2, 1. 3—bremsstrahlung losses. 4—elastic collisions with nucleus. E, D—singlet electronic states.

the energy range $\Delta\epsilon$. Electrons lose energy by small portions $\sim\epsilon_{0i}$, considerable changes of energy in processes with secondary electrons are unlikely. This fact justifies to some extent the use in (6) of the product $\sigma_{0K}(\epsilon)v(\epsilon)$ at the mean electron energy ϵ instead of the coefficient $\langle\sigma_{0K}V\rangle_t$ averaged over the time-dependent electron velocity distribution.

The interaction of the primary electrons with the gas yields secondary electrons with considerable kinetic energy. These electrons also cause ionization and excitation. Part of the kinetic energy is transmitted to the secondary electrons of the following generations. Overall excitation of the electronic states is determined by the primary electrons and the secondary electrons of all generations.

The basic characteristics of secondary electrons of successive generations are the following: the total number of electrons in jth generation n_j, the energy distribution function of electrons φ_j, the total initial kinetic energy of electrons W_j, the maximum energy of electrons ϵ_j^{max}, and the excitation efficiency of kth process. Table V gives recurrent relations for these parameters, including an approximate expression for the energy distribution function of the electrons. All parameters are integral in time and space for given electron generation.

The total conversion efficiency of energy of the monochromatic electron beam with the energy ϵ_0 to the kth inelastic process, including secondary electrons, is

$$\kappa^K(\epsilon_0) = \frac{1}{W_0}\sum_{j=0} W_j\kappa_j^K = \sum_{j=0}\kappa_j^K\prod_{l=0}^{j-1}\kappa_l^s. \qquad (7)$$

The kinetic energy of the second generation electrons is ~15 percent of that of primary electron beam. The total kinetic energy of the third generation is ~2.0 percent of the initial energy of the electron beam. Fig. 14 shows the energetic dependence of total efficiency κ^K. At energies $\epsilon > 10^3$ eV, the parameters κ^K vary rather slightly. For this energy range, a certain relation between effective cross sections as well as between energetic losses for basic inelastic processes is established. The total efficiency of excitation for laser states of the Lyman and Werner band systems is somewhat less than 30 percent; κ^B = 16 percent, κ^C = 13 percent. Half of the total

energy is expended on ionization; about 7 percent on excitation of triplet electronic states. Obtained results can be controlled by comparison with the mean energy $\bar{\epsilon}$, needed for ion pair formation. This value is almost constant over wide energy region of primary electrons [23], and for hydrogen it is $\bar{\epsilon}$ = 36.5 eV. For considered scheme $\bar{\epsilon} = \epsilon_0/n = \epsilon_{0i}/\chi^i = 3$/eV ($n = \chi^i\epsilon_0/\epsilon_{0i}$ is the total number of secondary electrons produced by the primary electron). The agreement with the approximate calculations is quite satisfactory.

Performed analysis shows that the H_2-VUV laser quantum system converts the energy of e beams into the excitation energy of laser electronic states with the efficiency approximating a limiting value. Complete absorption of electrons in the laser volume is a basic condition for the effective use of electron beam energy in hydrogen. Decreasing the electron path by increasing gas pressure is possible only to a certain limit.

This limit is connected with the quenching of electronic stages and collisional broadening of the amplification lines. The electronic path decreases rapidly with diminishing of electronic energy in proportion to $l \propto \epsilon^{1.8}$. At low electronic energy, the main difficulties are connected with the injection of e beam into the laser volume and with the ability to attain a sufficient value of electronic current. It becomes necessary to use thin separating foils with thickness of 1-10 μ.

For optimal usage of the e-beam energy, the special confining systems of high-speed electrons in the active volume can be used along with methods mentioned in the preceding. Such systems are of particular importance at low gas pressure. In a simple transverse excitation system with magnetic field H = 1 kG directed along the active medium the Larmor radius of electrons with energy ϵ = 100 keV, $r = mvc/eH$ is 1 cm. Although the general picture of high energy electron scattering in a rather rarefied gas at $p \sim 0.1$-1.0 atm in a magnetic field is not clearly understood, one should expect from qualitative considerations a sharp reduction of the volume, where electronic energy is absorbed.

It is difficult at present to draw a certain conclusion in favor of self-sustained gas discharge or e-beam excitation methods for H_2-VUV laser. At present, self-sustained discharges are preferred due to the absence of effective e-beam confining systems. In small volumes with narrow laser channels, a higher specific pumping power up to 10 GW/cm^3 is obtained in gas discharges at low-pressure $p \sim 0.1$ atm.

V. On the CW H_2-VUV Laser

A. Depletion of the Lower Laser Levels

Four-level laser system of molecular hydrogen and deuterium [12] is one of the most promising for CW laser action in the VUV region due to the rather small spectral width of amplification lines ~0.6 cm^{-1} and to the corresponding comparatively low-threshold pumping energy. The practical realization of this most favorable CW VUV laser scheme is obviously a rather difficult problem. In connection with this difficulty, it is useful to consider the main kinetic processes in the scheme in some detail.

The potential energy curve of the upper state of the Lyman band hydrogen laser is highly displaced about the ground state towards long internuclear distances [Fig. 7(a)]. The result is intensive transitions to the highly excited molecular levels of the ground (lower laser) state located within kT from the dissociation limit. There are three basic mechanisms of effective depletion of these levels. Depletion of H_2 levels v'' = 14, J'' = 4,5 overlying the dissociation limit has been already considered in the preceding. It occurs due to the rotational predissociation. Dissociation in molecular collisions and depletion due to VT relaxation are also effective. The nonradiative lifetime of the levels at optimum conditions may be much less than the radiative lifetime of the upper laser levels. At moderate pumping power of molecular hydrogen in gas discharge or by CW e beam, the population of the upper laser state is determined mainly by the electronic excitation rate, radiative decay, and molecular quenching. Population of lower laser levels depends on the radiative decay rate of the upper electronic states, dissociation rate, atomic hydrogen recombination, as well as VV and VT relaxation of the vibrational level system of the ground electronic state. The most critical for CW laser action is concentration of atomic hydrogen in the discharge. This concentration is determined by electronic dissociation rate of the molecules and by the atomic recombination rate on chamber walls and during triple molecular collisions in the gas volume.

The probability of predissociation of the levels v'' = 14, J'' = 4,5, and $W^{pr}_{v''J''} = D_{v''J''}/T_{\text{vib}}$ is about two orders of magnitude more than that of radiative decay of the higher laser states. Calculations of bound-bound and bound-free transitions probabilities for molecular states are the dissociation limit is a rather difficult task of molecular-collision physics [25]. A close bound between vibration and rotation involves certain difficulties in studying the problem. The molecular vibration amplitude is not small compared with the range of intermolecular forces. The Massey parameter $\xi = 4\pi^2\,\Delta\epsilon/\alpha v h \sim 1$ ($\Delta\epsilon$—transition energy, α—constant of exponential interaction potential, v—molecular velocity). The last two circumstances present essential difficulties in using perturbation theory. The exact form of the interaction potential for vibrationally excited molecules and molecules in the ground state is unknown. The corresponding population equations are strongly bound due to rather high transition probability, and it is very difficult to solve them even by numerical methods.

Particular problems, related to dissociation, are usually considered by assuming the coefficients $\langle \sigma_{v''J'',d}\, v\rangle$ for levels $v''J''$ in the immediate vicinity of the dissociation limit to be

$$\langle \sigma_{v''J'',d}\, v\rangle = \kappa \langle \sigma_l v\rangle \exp\left(-\epsilon_{v''J'',d}/kT\right) \tag{8}$$

where σ_l is the effective cross section of elastic collisions, $\epsilon_{v''J'',d}$ is the dissociation energy for the state $v''J''$, and κ is the arbitrary parameter of the order of 1. This corresponds to the dissociation cross section

$$\sigma_{v''J'',d} = \begin{cases} \kappa\sigma_l, & \epsilon \geqslant \epsilon_{v''J'',d} \\ 0, & \epsilon < \epsilon_{v''J'',d} \end{cases} \tag{9}$$

for collisions along the center line.

Levels v'' = 14, J'' = 0, 1, 2, 3 of H_2, and v'' = 20, 21 of D_2 lying within kT($T \simeq 300$ K) below the dissociation limit are subjected to direct transitions to continuous spectrum during molecular collisions with the probability

$$W^d_{v''J''} = \kappa v/\tau^*_{0vi} = \kappa\sqrt{2}\, N_0 \pi (r_0 + r_{v''})^2\, vp,$$

$$N_0 = 2.7 \times 10^9 \text{ cm}^{-3}$$

where r_0, $r_{v''}$ are effective radii of molecules in ground and excited states, v is the molecular velocity, and parameter $\kappa \simeq 1$ is the dissociation probability of excited molecules during collisions. For v'' = 14 of hydrogen, the probability $W^d_{v''J''}$ exceeds the value A_{BX} at gas pressure $p \gtrsim 40$ mmHg.

VT relaxation is an effective depletion mechanism of molecular levels nearby the dissociation limit. The corresponding probability calculated in [26] by using the anharmonic oscillator model is

$$W^{\text{VT}}_{v''J''} \simeq \kappa P/\tau^*_{0v'}, \qquad \kappa \simeq 1.$$

An effective action of the two last mechanisms of collisional depletion is provided at gas pressure $\gtrsim$ 40 mmHg.

B. Population of Laser States

The stationary population of the upper laser state $v'J'$ under amplification mode of operation with excitation by electrons at moderate pumping power depends mainly on the excitation rate of the electronic state $N_0 f_{0B}$, radiative decay, and molecular quenching of level $v'J'$ with probabilities A_{BX} and $W_{B\cdot P}$, respectively (Fig. 15)

$$N^B_{v'} = N_0 f_{0B} g^{BX}_{0v'} \beta^{BX}_{0J'} / (A_{BX} + W_{B\cdot P}). \tag{10}$$

Population of lower laser levels is determined mainly by radiative decay of B state, volume recombination of hydrogen atoms with the concentration N_H, and by the total depletion probability

$$W_{v''J''} = W^{pr}_{v''J''} + W^{d}_{v''J''} + W^{VT}_{v''J''}$$

$$N_{v''J''} = \left[\sum_{v'J'} N^B_{v'J'} A_{BX} g^{BX}_{v'v''} S^{BX}_{J'J''} / (2J^1 + 1) + \delta N_H^2 N_0 K^{vol}_{rec} \right] W^{-1}_{v''J''} \tag{11}$$

where δ is the relative recombination yield of molecules on level $v''J''$, $K^{vol}_{rec} = 5.10^{-33}$ cm^6 s^{-1} [27]—the volume recombination constant of hydrogen atoms at room temperature. The influence of radiative decay of C state is negligible due to the smallness of the corresponding Franck-Condon factors. The contribution of the highly excited electronic states B', C', d is of no importance due to small value of the oscillator strength of these transitions. For levels near the dissociation limit, the population rate from the underlying vibrational states due to VV exchange is negligible since at gas temperature T = 300-700 K, the probability of VV exchange is small compared with that of VT relaxation.

The H-atom concentration is determined by the molecular dissociation rate connected with excitation of singlet and triplet states $\simeq N_0 f_{0D}$, volume and surface recombination as well as by nonrecombination processes which decrease H-atom concentration with the total probability R^*

$$N_H^2 N_0 K^{vol}_{rec} + N_H R = N_0 f_{0D} \tag{12}$$

where $R = R^{wall}_{rec} + R^*$. The molecular dissociation rate is determined by excitation of the repulsion $b\,^3\Sigma^+_u$ state, radiative decay of the $c\,^3\Pi_u$ state, and by the total bound-free radiative decay rate of $B\,^1\Sigma^+_u$ state with emission of the Herzberg continum [28]

$$N_0 f_{0d} \simeq N_0 f_{0b} + \frac{N_c A_c b}{A_c b + W_c \cdot p} + \frac{N_0 f_{0b} \kappa_{cont}}{A_B + W_B P}. \tag{13}$$

Chemical bonding and gas pumping are examples of effective nonrecombination processes resulting in decreasing the H-atom concentration. Use of volume recombination with this purpose is inexpedient since this channel leads to increasing the lower laser level population. In the case of surface recombination, the excess energy of the recombined molecules is transferred to the walls and the lower laser levels remain empty. The atomic recombination probability on the walls of the cylindrical cell of radius r_0 is $R^{wall}_{rec} = D(2.4/r_0)^2\,\gamma$. The parameter γ is the recombination probability of atoms during collision with the walls. For various wall materials, it ranges from 10^{-2} to 0.5 [29].

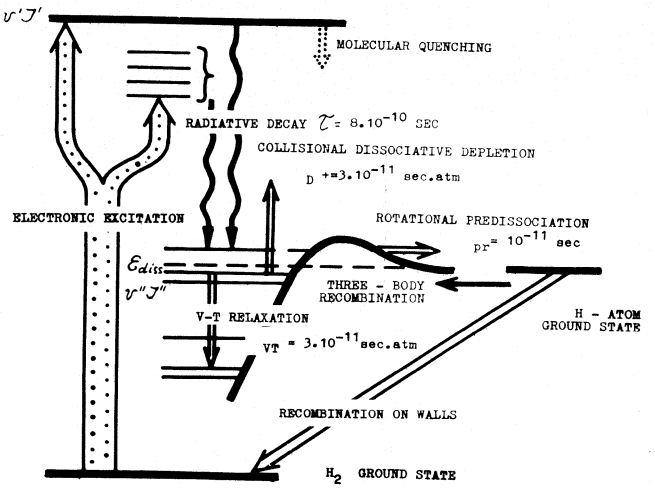

Fig. 15. Population scheme of CW H_2-VUV laser.

There are two criteria which should be fulfilled to obtain CW laser action. The requirements are applied on the excitation rate of the B state (and hence on the absolute intensity of spontaneous radiation of the laser transitions) and on the rate of decreasing the H-atom concentration. The basic condition is excess of gain over losses $K^{v'J'}_{v''J''} \gtrsim \kappa$, where

$$K^{v'J'}_{v''J''} = \mu^{v'J'}_{v''J''} P \cdot f_{0B} \left[1 - (\chi^{v'J'}_{v''J''})^{rad}\, w^{-1} - \chi_{rec} \frac{f_{0B} P^2}{R^2 w} \right] \tag{14}$$

$$\mu^{v'J'}_{v''J''} = \frac{\lambda^2 g_{0v'} g_{v'v''} \beta_{0J'} S_{J'J''} (\pi \ln 2)^{1/2} N_0}{4\pi^2 \Delta\nu_d (1 + \gamma^0 P (\pi \ln 2)^{1/2} / \Delta\nu_d)\,(2J^1 + 1)\,[1 + (W_q \cdot P / A_{BX})]} \tag{15}$$

where p (atmospheres), χ denotes numerical parameters, $w = W_{v''J''}/A_{BX}$, γ_0 is the collisional broadening parameter, $\kappa = l^{-1} \ln(1 - R)$, l is the active medium length, and R is the reflection coefficient.

In the plane of the parameters, (f, R) in logarithmic scale, the region of CW laser action corresponds approximately to a sector limited from below by the straight line $f_{min} = \kappa/\mu^{v'J'}_{v''J''}$ and from above by $f_{max} = wR^2/p^2\,\chi_{rec}$ (Fig. 16). The lower line corresponds to the threshold amplification for $N_{v''} = 0$, to the minimum excitation rate f_{0B} and the minimum spontaneous radiation power P_{min} of laser line. For the $P(4)$ (8,14) band line of pure paramodification $P_{min} = K \cdot 1.7 \times 10^3$ W/cm^3. For active medium length l = 1 m and losses of 20 percent, P_{min} = 3.4 W/cm^3. The upper line on the graph corresponds to a decrease of the gain to threshold at high pumping rate due to intense recombination population of the

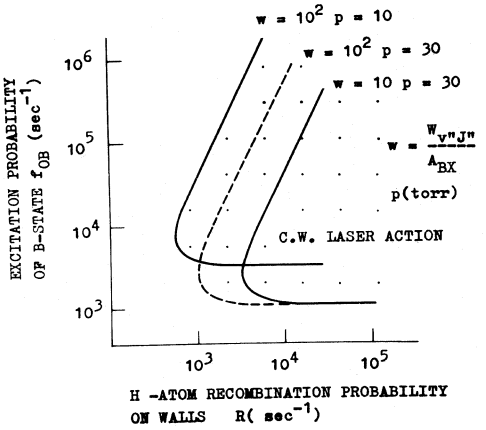

Fig. 16. Criterion of the CW H_2-VUV laser action on the $P(4)$ (8,14) line of pure parahydrogen.

lower laser levels. The minimum value of effective recombination rate

$$R_{\min} = \left(\frac{\kappa w \chi_{\text{rec}} P}{\mu_{v''J''}^{v'J'}}\right)^{1/2} \frac{2}{w - \chi_{\text{rad}}} \tag{16}$$

is of the order of 5×10^2-5×10^3 s^{-1}.

The most appropriate conditions for attaining the previously mentioned minimum rates of CW excitation and recombination could be created apparently in narrow gas discharge channels. Table V gives the wavelength of transitions suitable for CW VUV laser action in hydrogen and deuterium.

VI. Conclusion[3]

The quantum-mechanical system of the H_2-VUV laser as it is shown in this paper is characterized by rather high limiting operating laser parameters. The problem is to approach these laser parameters in practice.

In gas discharges, the effective excitation of the H_2-VUV laser can be carried out apparently only at comparatively low pressure $p \lesssim 0.05$-0.1 atm. At higher pressures, the electric field and the mean electronic energy in the discharge drop rapidly in a time interval less than the laser pulse duration. The result is low efficiency of excitation.

The main problems in practice are connected with the extremely short lifetime of the inversion population ~1 ns. These problems can be completely removed by using the four-level collisional scheme of excitation. The optimal pressure range for this scheme is rather high $p \gtrsim 0.1$ atm. The most favorable excitation conditions can be attained by using e-beam systems with electron trapping. The excitation efficiency in this case, unlike the gas-discharge systems, remains constant during the current pulse irrespective of the pressure. The region of optimum pressure depends on the value of the molecular quenching cross section of excited molecular states of hydrogen. Observed laser action in pure H_2 at 2-atm pressure is certain evidence in favor of rather high optimal pressures. Molecular quenching of laser states may be substantially decreased by the addition of inert gases such as He. In this case, the effective collisional depletion of the lower laser states is provided. The four-level laser action in H_2 could be obtained apparently also on bound-free Lyman transition on Herzberg continuum [28].

The four-level bound-bound transitions of H_2 and D_2 are favorable for achieving the CW VUV laser action on several lines in the region of 1500-1600 Å. The use of supernarrow laser channels yield high probability for wall recombinations and should be used to obtain the needed H-atom recombination rate. Simultaneously, high electronic energy should be provided in the active medium. CW pumping can be carried out by using some sort of gas discharge CW electronic beam. Pure parahydrogen is expedient to use in first experiments.

The wavelength of H_2-VUV laser is near the absolute wavelength limit about 700-1000 Å for neutral atomic and molecular laser systems without photoionization absorption from the ground state. The H_2 electronic transition $D \rightarrow X$ in the region about 900 Å near the photoionization limit remains unstudied. The effective electronic excitation cross section of D state is probably an order of magnitude less than that of the B state. A strong radiative population of the lower levels from B and C states apparently presents some difficulties for obtaining population inversion.

Small-size high-repetition rate gas discharge excited H_2-VUV laser with mean power of even several milliwatts will have wide applications in laboratory experiments. Unlike the e-beam excited inert gas excimer systems, this laser is absolutely free of penetrating radiation danger. The laser can be used in investigations of laser VUV photochemistry, including isotopic-selective processes. Dynamic and spectral features of luminescence of the complex molecular systems including biologically active materials can be carried out. Luminescence and photoionization detection of small admixtures in gases, optical pumping of lasers with continuous frequency tuning in the range 1800–3000 Å can also be performed. Applications will be expanded for these lasers in the future in accordance with the growth of the average and the peak laser power and with the simplifcation of the excitation techniques.

Mass Spectroscopy of the HCN-Laser Plasma

HANS J. SCHÖTZAU AND FRITZ KNEUBÜHL

Abstract—**We have measured for the first time the chemical composition of the HCN-laser discharge plasma. The results show the important role of hydrogen in the HCN laser. Additional experiments with different gas mixtures prove that hydrogen molecules are necessary for population inversion in the HCN laser.**

I. Introduction

LOW-PRESSURE discharges in molecular gases containing constituents of compounds made-up of hydrogen, carbon, and nitrogen show stimulated emission in the far-infrared and submillimeter-wave regions [1]. The strongest emission occurs at a wavelength of $\lambda = 337$ μm. Lide and Maki [2], [3] and Hocker and Javan [4], [5] identified this emission with the vibrational–rotational transition of the HCN molecule

$$(11^10),\ J = 10 \longrightarrow (04^00),\ J = 9.$$

However, the mechanism of the excitation of this stimulated emission is still unknown.

Usually, the HCN-laser discharge is sustained in molecular gas mixtures, e.g., CH_4 and N_2. In these mixtures the laser-active HCN molecules are formed in the low-pressure plasma. Hitherto, the formation of the laser-active molecules could not be demonstrated. However, it could be shown that chemical reactions strongly influence the laser action. This is shown by the possibility of excitation and suppression of the higher resonator modes of the 337-μm emission [6] by variation of the gas mixture. In addition, some emissions in the submillimeter-wave region are not yet explained, e.g., the emission of C/H/N compounds at wavelengths of $\lambda = 201$, 211, and 223 μm [7], the radiation of CH_3SH [8] and

Manuscript received October 1, 1974; revised May 30, 1975. This work was supported by the "Schweizerischer Nationalfonds."

F. Kneubühl is with the Solid State Physics Laboratory, Swiss Federal Institute of Technology, Zurich, Switzerland.

CH_3SCN [9] at the wavelength of 337 and 336.1 μm, respectively, as well as those of the [ICN-H_2] gas mixtures at wavelengths between 169 and 774 μm [9].

For these reasons we studied the chemical reactions in the plasma of the HCN laser with the aid of a quadrupole mass spectrometer.

II. The Experimental Arrangement

A CW HCN laser was used for the mass-spectroscopic measurements. The discharge tube of the HCN laser was water-cooled and the two plane-parallel mirrors of the resonator were separated by a distance of about 150 cm and had diameters of 6 cm. Using a special hollow cathode [10], the longitudinal electric discharge with a length of 110 cm can be sustained for a range of discharge currents between 0.1 and 2 A and at gas pressures up to 3 torr. The gas passes through the resonator with a slow flow rate. The laser radiation is coupled out by a 18-μm-thick Mylar foil tilted at an angle of 45° relative to the tube axis. A Unicam–Golay detector is used for the measurements of the laser output power. The resonator can be tuned to the different resonator modes by a variation of the resonator length [9]. A part of the gas is bled out near the cathode by a small aperture of diameters of 50–250 μm. The working pressure in the chamber of the mass spectrometer, Balzers QMG 101, is of the order of magnitude of 10^{-5}-10^{-4} torr, depending on the actual pressure in the laser tube. The different out-streaming gas species are ionized in the ion source of the quadrupole mass spectrometer at a distance of 20 cm from the hole. The electrons from the ion source have a mean energy of about 90 eV. Since we are interested in the neutral particles only (the degree of ionization is of the order of 10^{-6}), and we have used these results as a starting point for additional experiments, the system was not calibrated.

A. The Gas Mixtures and the Mass Spectrum

The laser emission at a wavelength of 337 μm can be observed with different gas mixtures, e.g., CH_3CN [11], [$(C_2H_5)_2O + N_2$] [12], C_2H_5CN [13], [$CH_3CN + NH_3$] [14], [$CH_4 + N_2$] [15], and [$CH_4 + NH_3$] [16]. On the other hand, the [$C_2H_2 + N_2$] mixture was found to be laser inactive [17]. For our experiments we selected the following three types of laser gases.

1) [CH_4-N_2]: This gas mixture used in the HCN laser gives a high laser output power.

2) [C_2H_6-, C_2H_4-, C_2H_2-N_2]: The sequence of hydrocarbons allows a variation of the hydrogen content in the plasma.

3) HCN: No chemical reaction is necessary for the formation of the laser-active molecules as in 1) and 2).

For the interpretation of the mass spectra of the laser plasma of the previously given gas mixtures, the following facts have to be taken into account.

1) Molecules with the same ratio of mass/charge = m/q are indistinguishable.

2) The ion source of the QMG generates ions as well as dissociation products, e.g.,

$$CH_n + e^- \longrightarrow CH_{n-1} + e^- + H.$$

3) Ion–molecule reactions take place in the chamber of the quadrupole analyzer. As an example, mass-spectroscopic studies of pure CH_4 frequently show new compounds CH_5 and H_2 besides the products of dissociation: CH_3, CH_2, CH, and C [18], [19].

a) *Ion source:*

$$CH_n + e^- \longrightarrow CH_n^+ + 2e^-$$

$$CH_n + e^- \longrightarrow CH_{n-1} + e^- + H.$$

b) *Secondary reactions:*

$$CH_3^+ + CH_4 \longrightarrow C_2H_5^+ + H_2$$

$$CH_4^+ + CH_4 \longrightarrow CH_5^+ + CH_3.$$

Therefore, the mass-spectroscopic data of the HCN-laser plasmas had to be checked by other experiments.

III. Experiments

A. The [CH_4-N_2] System

The mass-spectrometric measurements of the [CH_4-N_2] discharge, which yields a high laser intensity, show the formation of new molecules (Figs. 1 and 2)

$$CH_4 + N_2 \xrightarrow{\text{discharge}} H,\ \boxed{H_2},\ H_3,\ NH_x, N_2H_y, \cdots, N, N_2,\ CH_x, C_2H_y, \cdots,\ CN,\ \boxed{HCN}.$$

(0.5 torr; 0.8 A)

The concentration of HCN molecules is small compared to the concentration of hydrogen which is the main product of these reactions. The observation of the formation of higher hydrocarbons agrees well with other experiments [20]. The new compounds are generated by different processes [18] [20]-[22], for example.

1) *The Formation of Hydrogen:*

$$CH_4 + e^- \longrightarrow CH_3 + H + e^-$$

$$H + H + M \longrightarrow M^* + H_2.$$

2) *The Formation of Higher Hydrocarbons:*

$$CH_3^+ + CH_4 \longrightarrow C_2H_5^+ + H_2.$$

3) *The Formation of Hydrocyanic Acid:*

$$CH_3 + N \longrightarrow HCN + 2H.$$

The observation of H_3 ions can probably be attributed to the ion-molecule reaction in the ion source

$$H_2^+ + H_2 \longrightarrow H_3^+ + H.$$

Fig. 3 shows the concentration of different molecules as a function of the discharge current. The CH_4 concentration decreases with increasing current, whereas the hydrogen concentration increases. The HCN concentration achieves a maximum at the threshold current of the laser emission. The highest value of the laser intensity coincides with the maxi-

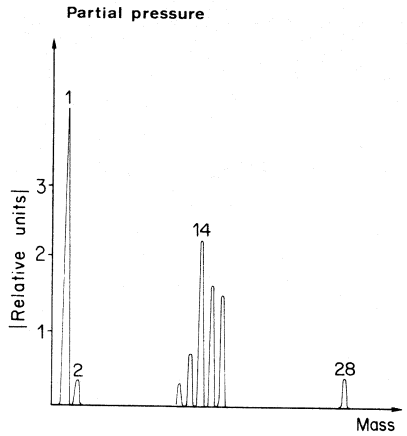

Fig. 1. Mass spectrum of the gas mixture $[CH_4:N_2] \simeq [7{:}7$ torr $\cdot$ l $\cdot$ min$^{-1}]$ at a pressure of 0.5 torr without an electrical discharge. The following masses can be identified by the ratio mass/charge: H(1); H_2(2); C(12); CH(13); N(14): CH_2(14); N_2(28/2); CH_3(15); CH_4(16); N_2(28).

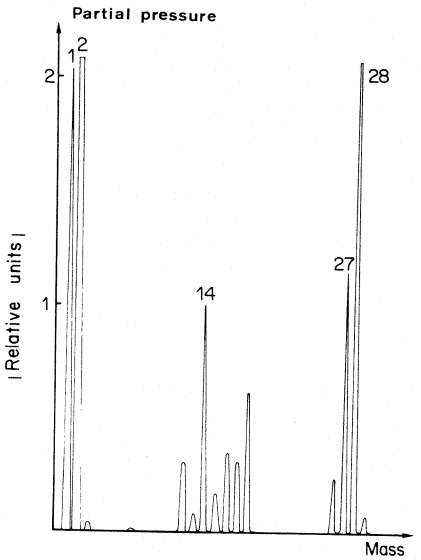

Fig. 2. Mass spectrum of the gas mixture $[CH_4:N_2] \simeq [7{:}7$ torr $\cdot$ l $\cdot$ min$^{-1}]$ at a pressure of 0.5 torr and discharge current of 0.8 A.

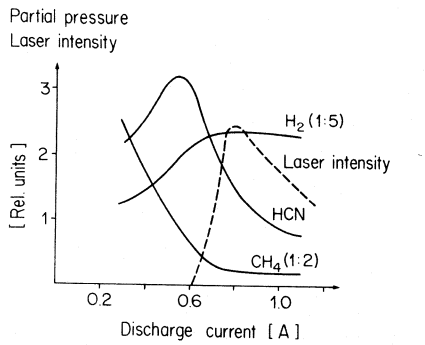

Fig. 3. The partial pressures of CH_4, H_2, and HCN and the laser intensity of the 337-μm emission of the gas mixture $[CH_4:N_2] \simeq [7{:}7$ torr $\cdot$ l $\cdot$ min$^{-1}]$ as a function of the discharge current at a total pressure of 0.5 torr.

mum concentration of hydrogen molecules. It does not correspond to the HCN maximum.

B. The $[C_2H_6$-, C_2H_4-, C_2H_2-$N_2]$ System

The observed influence of hydrogen on the laser intensity was investigated with the $[C_2H_4$-$N_2]$ system.

The addition of H_2 molecules to the optimum $[C_2H_4$-$N_2]$ gas mixture, i.e., the mixture which has the highest laser intensity, lowers the output power of the HCN laser (Fig. 4(a)). Therefore, the optimum content of the concentration of hydrogen characterizes the laser maximum.

The laser emission of another laser-active gas mixture is enhanced (Fig. 4(b)) and a laser-inactive gas composition (Fig. 4(c)) is enabled to emit the 337-μm radiation by the external addition of hydrogen.

A discharge containing a similar concentration of carbon and nitrogen gives rise to the 337-μm HCN-laser emission after addition of a sufficient amount of hydrogen. The maximum of the laser intensity occurs in a plasma with a ratio of the constituents near

$$C{:}H{:}N \cong 1{:}2{:}1.$$

The study of the $[C_2H_2$-$N_2]$ gas mixture enabled us to determine the influence of the addition of hydrogen on the chemistry in the plasma and on the collision processes involved in the laser emission. In agreement with Stafsudd *et al.* [17] we find the $[C_2H_2$-$N_2]$ mixture laser inactive. Fig. 5(a) shows that the addition of hydrogen makes possible the 337-μm emission. To demonstrate the importance of H_2 in the HCN laser, a part of the hydrogen is replaced by deuterium [23]. The D_2 molecules have no influence on the formation of the HCN. The possible generation of DCN molecules gives no contribution to the 337-μm HCN emission [3], [5]. Among the significant observations are the onset as well as the enhancement of the 337-μm emission of the

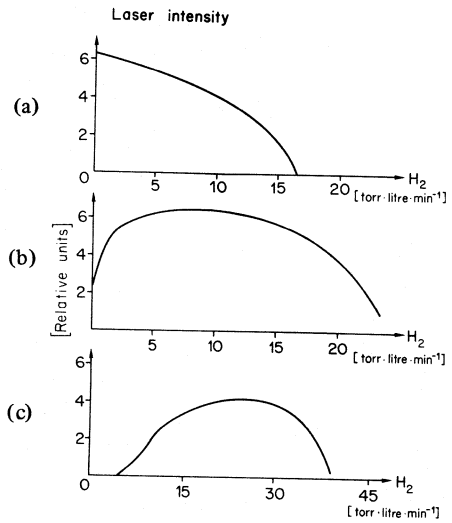

Fig. 4. Laser intensity of the 337-μm emission of the $[C_2H_4:N_2]$ gas mixtures as a function of the addition of H_2. (a) $[C_2H_4:N_2] \simeq [10{:}5$ torr $\cdot$ l $\cdot$ min$^{-1}]$, $p_{tot} \sim 0.5$ torr. (b) $[C_2H_4:N_2] \simeq [7{:}5$ torr $\cdot$ l $\cdot$ min$^{-1}]$, $p_{tot} \sim 0.4$ torr. (c) $[C_2H_4:N_2] \simeq [4{:}5$ torr $\cdot$ l $\cdot$ min$^{-1}]$, $p_{tot} \sim 0.3$ torr.

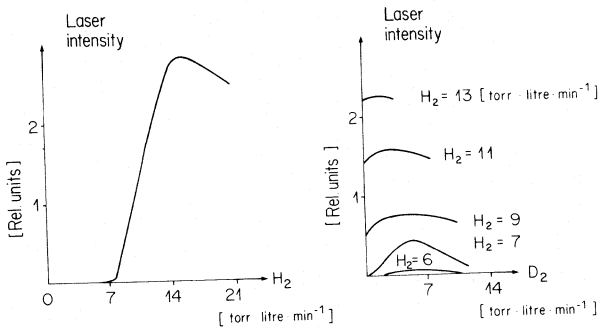

Fig. 5. The dependence of the 337-μm emission of the [C_2H_2:N_2] gas mixture of the hydrogen and deuterium addition. (a) Addition of hydrogen. (b) Addition of hydrogen and deuterium.

[C_2H_2-N_2-H_2] mixture by the addition of deuterium (Fig. 5(b)).

An enhancement of the laser radiation by the addition of helium, which has the same mass as deuterium, was not observed. In addition, the various publications on the influence of He on the HCN laser do not all reach similar conclusions [7], [14], [24]-[27].

The [C_2H_6-, C_2H_4-, C_2H_2-N_2] gas mixtures have a different content of hydrogen as well as different chemical bonds (single, double, triple, respectively). The smaller abundance of hydrogen can be compensated for by external addition of H_2, as shown above. Then the laser intensity is identical for all systems. However, these optimum mixtures have different threshold discharge currents at which laser oscillation occurs. Therefore, the electrical input power for the laser threshold differs for the gas mixtures previously mentioned.

Fig. 6 shows that the formation energies of the CH radical are correlated with the minimum input power required for the laser threshold.

C. The HCN System

To our knowledge, pure HCN gas as an active medium has only been used in a pulsed laser system [1], [28]. Pure HCN gas is desirable for the study of the laser mechanism in the CW HCN laser since no chemical reaction is necessary for the formation of the HCN molecules. The mass-spectroscopic studies demonstrate that the HCN molecules are not stable in a dc glow discharge since they are dissociated by electron impact [28], [30].

Our experiments showed that the emission in the CW laser occurs only if hydrogen is added to the HCN gas. The H_2 molecules tend to suppress the dissociation of HCN.

Furthermore, the same experiments were carried out with the pulsed HCN laser as described in [9]. The laser tube was filled with pure HCN of about 0.3 torr and sealed afterwards. Then a series of pulsed discharges were initiated. In agreement with Turner and Poehler [28], the 337-μm emission is observed after the first electrical excitation. Subsequently, the laser intensity increases to a value twice as large as the initial intensity (Fig. 7).

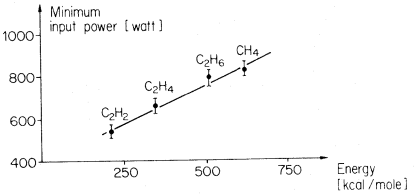

Fig. 6. The correlation between the threshold of the input power of the 337-μm emission and the energy of formation of CH radical for the different gas mixtures.

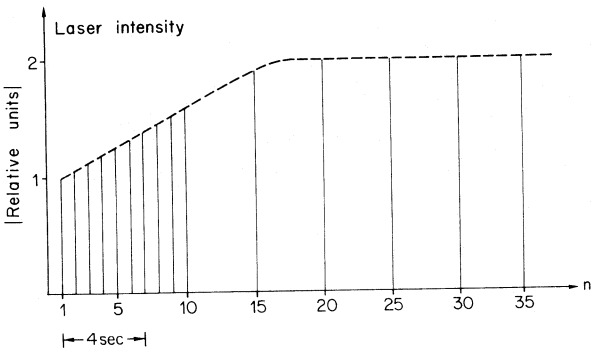

Fig. 7. The laser intensity of the 337-μm emission of pure HCN gas in a sealed-off system as a function of the electrical excitations n. Initial HCN pressure: $p = 0.32$ torr. Voltage: $V = 30$ kV. Pulse repetition rate: $f = 1.75$ Hz. Length of the resonator: $L = 432$ cm.

IV. Interpretation of the Experiment

The measurements of the chemical composition of the HCN-laser plasma with the aid of a quadrupole mass spectrometer, as well as the related experiments with the different gas compositions, show the important role of hydrogen in the HCN laser (Figs. 2-4).

The experiment with the [C_2H_2-N_2] gas demonstrates that hydrogen (or deuterium) is required as a collision partner of the HCN molecules to yield the laser emission (Fig. 5).

Flournoy and Nelson [31] showed that the metastable vibrational state of hydrogen $H_2(v = 1)$ and deuterium $D_2(v = 1)$ transfer their energy to the HCN molecule. On the other hand, long-lived electronic states of H_2, H, and N_2 near 11 eV [32] can also excite the levels of HCN in this energy range by resonance processes [33]. These levels increase the inversion population of the HCN molecules by relaxation effects. The metastable states of helium are near an energy of 19 eV, which is higher than the energy of ionization of the HCN at 13.9 eV [34]. Therefore, a resonance energy transfer is excluded. But the helium can change the gas temperature, and thus the chemical reactions in the discharge through its high heat conductivity.

The gas composition with the lowest threshold for laser oscillation also possesses the highest efficiency. Fig. 6 shows the correlation of the formation of CH radical and threshold input power. The existence of these radicals or CH^+ radical ions in a low-pressure discharge is established in [35]. The CH radical is essential in the plasma chemistry as a carrier of carbon in the gas phase. This observation agrees well with

the theory of chemical equilibrium in these plasmas developed by Vepřek [36]. Its adaptation to the HCN-laser plasma predicts the presence of these radicals for the chemical formation of HCN molecules [37].

Continuous discharges in pure HCN gas are laser-inactive, whereas the [HCN-H_2] gas mixture shows stimulated emission. On the other hand, the 337-μm radiation can be observed in pulsed discharges in pure HCN gas. However, the efficiency of this system is enhanced by the plasma-generated hydrogen. This observation proves that electron impact is not the main mechanism of the excitation of the HCN molecules, since the HCN concentration is lowered after each electrical pulse, whereas the laser intensity increases (Fig. 7).

The excitation of the HCN molecules is enhanced by molecule-molecule (H_2-HCN) collisions. The measurements of the time behavior of the gain of the pulsed HCN laser by Yamanaka *et al.* [38] support this fact, as well as the time delay between the electrical excitation and the beginning of the laser emission [9], [39], [40].

V. Conclusion

Mass-spectroscopic measurements are useful for the study of molecular far-infrared gas-laser discharges. Our experiments on the HCN-laser plasma with a quadrupole mass spectrometer, as well as experiments with different gas mixtures, have proved that molecular hydrogen is required as a collision partner for the 337-μm emission of the HCN laser. Furthermore, pulsed discharges in pure HCN gas confirmed that electron impact can be excluded as the main mechanism for the generation of the population inversion of the HCN laser.

Ultraviolet Ion Laser Performance and Spectroscopy—Part I: New Strong Noble-Gas Transitions Below 2500 Å

JOHN B. MARLING, MEMBER, IEEE

Abstract—**The performance and spectroscopy of UV ion lasers have been investigated to 1850 Å, the limit of available mirrors. New anomalously strong transitions of about 1-kW peak power were found in Xe IV? at 2315.357 Å and Kr IV at 2191.916 Å. The shortest wavelength new laser transition was Kr IV at 1949.623 Å. Wavelengths were measured for 25 new and many previously known UV laser transitions to about 0.006 Å. Optimum output in watts was also measured as a function of bore current density and gas pressure. All measurements were taken from a 7-mm-bore 150-cm-arc-length tube designed for low electrical inductance providing current excitation pulses with 250-ns full width at half maximum (FWHM).**

I. Introduction

MANY APPLICATIONS requiring the practical use of UV ion lasers, such as in photochemistry, have been hampered because of a lack of experimental performance parameters. Wavelengths of the laser transitions, measured to within the Doppler width (about 1 pm) are required, as well as relative laser performance based on optimized current density and gas pressure. An excellent tabulation of known ion laser transition is given in the *Handbook of Lasers* [1], relative performance of CW UV ion lasers is given by Fendley [2], as well as literature by the commercial vendors of ion lasers. The first systematic investigation of pulsed ion lasers in the UV was the original survey by Cheo and Cooper [3], but the only real comparative performance data on pulsed ion lasers below 400 nm are the recent results of Tucker and Birnbaum [4] on Xe, Ar, Kr, O, N, and the earlier work by Cheo and Cooper on fluorine, phosphorus, and chlorine [5]. The measured wavelength accuracy of pulsed ion lasers was about 0.06 Å, which was generally sufficient to permit classification of the lines according to known spectroscopic data for energy levels.

The available literature suggested that observations of laser transitions below 300 nm were limited by a lack of suitable mirrors in this region. Therefore, dielectric mirrors to permit laser-cavity reflectivity $R_1 \cdot R_2 > 0.8$ were obtained to investigate UV lasing down to 185 nm in noble gases. Investigation of possible ion laser transitions down to 200 nm in other elements will be reported in a future article [6]. The lower wavelength limit of ion laser transitions is currently 155 nm in carbon IV, recently observed as impurity laser emission in a mirrorless traveling-wave transverse-discharge system [7].

Since ion lasers provide convenient, stable high-intensity wavelength sources referenced to atomic transitions, they are ideal for investigations involving coincidences to within the Doppler bandwidth, e.g., with other atomic or molecular systems. Such applications require, however, that the transition wavelengths be experimentally known to 1 pm or better. Therefore, an order-of-magnitude better accuracy in measuring the wavelengths of known UV ion laser transitions was attempted. In addition, it is generally useful to know which transitions are the strongest, so the relative performance of all the UV ion lines was optimized with bore current and pressure as parameters. Such work also provided information on ionic assignment of the unclassified laser transitions. For the strong transitions of Kr IV 219 nm and Xe IV? 231.5 nm, first observed in this study, various output mirror reflectivities were also evaluated.

In order to investigate UV ion lasers, high bore currents are necessary, since most UV transitions occur in the doubly and triply ionized species. Therefore, the ion-laser discharge circuit was designed for minimum inductance, permitting peak bore current densities of 10 000 A/cm^2 to be obtained with a 0.03-μF capacitor charged to 23 kV, the highest charging voltage utilized. Circuit inductance was about 350 nH, permitting

Manuscript received March 10, 1975; revised May 13, 1975. This work was performed under the auspices of the U.S. Atomic Energy Commission.

The author is with the Lawrence Livermore Laboratory, University of California, Livermore, Calif. 94550.

a nearly critically damped current pulse with rise time of 80 ns and full width at half maximum (FWHM) which varied between 200–300 ns (depending on the gas used). This short excitation pulse definitely affected the types of ion laser transitions observed to be strongest, which will be discussed further in the section on experimental results.

It is suggested that the simple design of the laser system used in this work (relative to electron-beam or traveling-wave excitation systems) may make the entire chemical UV laser spectrum accessible to the general investigator, who may be limited by budget and interest in construction of the very sophisticated lasers previously needed for short-wavelength generation.

II. Experimental Procedure

A. Laser Design

In order to achieve high current densities with minimum pulse energy, a very low inductance, ultrahigh-speed electrical discharge is necessary. Therefore, the laser and electrical-driver circuit were designed with an all-coaxial geometry with minimum spacing between discharge-current conductors. The 0.03-μF capacitor was charged to positive high voltage, then switched to ground, using an EG&G Model HY3202 hydrogen thyratron in a grounded-grid configuration and laser tube geometry. The cathode received the negative high-voltage pulse from the capacitor. The anode was connected to ground by means of a several mill aluminum-foil sheet wrapped closely around the laser bore from the anode to within a few inches of the cathode, where it was connected to the capacitor housing, as shown in Fig. 1. Both cathode and anode were solid indium and coaxial with a hole in the center of each for the passage of the laser light. The tube was of quartz, graded to borosilicate glass to permit a Kovär ring for electrical contact to the indium cold cathode and anode.

To achieve a high pulse repetition rate without large resistive charging losses, an inductive resonant charging circuit was chosen, as shown in Fig. 2. The resonant charging time was $\pi\sqrt{LC} \approx 1.6$ ms for the 10-H charging inductor used, permitting repetition rates up to 600 pulses per second (pps) without loss of pulse voltage. Use of resonant charging naturally also offers the advantage of permitting twice the power-supply voltage to be applied to the discharge capacitor C_2, provided the source capacitor C_1 in the power supply is about an order of magnitude larger than C_2. The diodes in series with the charging inductor hold the voltage on C_2 after it resonantly swings to twice the supply voltage. (It is, of course, necessary that the inductor core of L_1 be chosen such that the charging inductor stores enough energy to swing C_2 to twice the power-supply voltage.)

The cathode end of the capacitor C_2 is held to dc ground by means of the small inductor L_2 (about 1 mH), which completes the charging circuit for C_2. This small inductor, in series with a 100-W 100-Ω resistor, permits an alternate discharge path for the applied high voltage in the event the discharge in the laser tube fails to occur. The values were chosen so that slight ringing of the discharge current occurs, in order to turn off the thyratron.

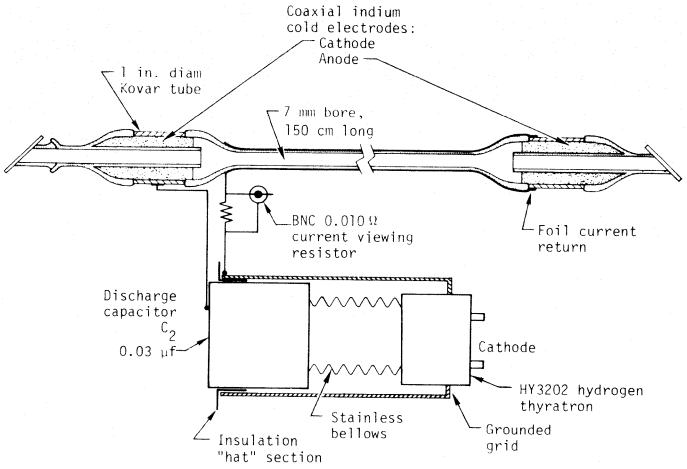

Fig. 1. Ion laser tube and electrical-driver configuration.

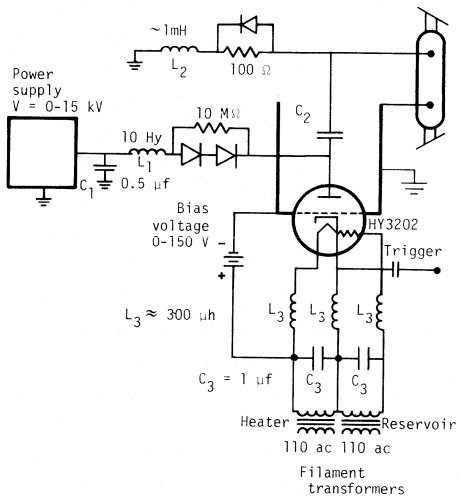

Fig. 2. Schematic diagram of electrical-driver circuit for high repetition-rate operation of pulsed ion laser.

Prepulsing of flashlamps is generally beneficial in establishing a low inductance discharge path [8]. Therefore, an ionization prepulse was applied to the cathode several microseconds before the thyratron was switched on. This was especially helpful in gases such as xenon that lase best at relatively low operating pressures. It was also indispensible if operation at low pulse voltages were desired, such as necessary for study of the singly ionized laser transitions. Generally, operation below 10-kV peak pulse voltage required a prepulse for steady discharges. Fig. 3 illustrates in block diagrams the various circuit modules as well as the gas-handling layout for the laser.

The dielectric mirrors used in this study had a 10-m concave radius for all wavelengths investigated in the range 200–600 nm. For examination of laser transitions down to about 220 nm, a standard laser configuration with suprasil quartz Brewster windows was satisfactory. However, below this wavelength the Brewster windows were eliminated by mounting the laser mirrors directly exposed to the plasma, which also eliminated possible losses by oxygen absorption in air. Vacuum seals were achieved by O rings, and mirror adjustment was achieved by connecting the mirror holder to the laser tube by a small sec-

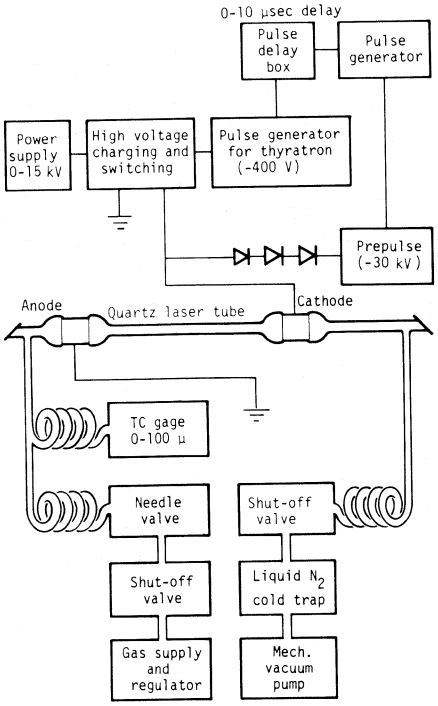

Fig. 3. Block diagram of mechanical and electrical layout for the pulsed ion laser.

tion of flexible stainless-steel bellows. However, the mirror holder must be insulated from ground, since the stainless bellows can be at a high voltage during discharge.

Gas pressure was monitored by a 100-μ full-scale thermocouple guage, and by a Schultz-Phelps ionization guage for the range 10^{-3}-500 μ; the measured pressures have been converted to absolute pressure according to conversion charts supplied by the manufacturers. Gas was continuously pumped out of the tube at the cathode end from a valved orifice through a helical gas coil (to prevent alternate discharge paths) into a liquid-nitrogen cold trap. Gas was supplied continuously at the anode end to maintain the desired operating pressure, which was monitored at the anode end. Pressure was regulated by means of a high-vacuum all-welded bellows-type needle valve. Gas was research grade (or reagent grade, if liquids were used) and held at slightly above atmospheric pressure by means of a high-purity stainless-steel regulator. As would be expected, contamination by foreign gases was noted to be completely absent, and any residual contaminants initially present were quickly swept away by the flowing gases. However, a liquid-nitrogen cold trap is essential to isolate the laser system from the vacuum pumping station, since contamination by pump oil (in an untrapped system) was found to suppress laser lines below 250 nm.

B. Spectroscopic Procedure

Spectroscopic wavelength measurement of wavelengths was performed on a 1-m scanning spectrometer using a 1200-lines/mm grating blazed for 1.2 μ, first order. Thus measurements were performed in the fourth-seventh order, permitting a resolution of 0.015 Å (1.5 pm) near 3000 Å, and a readability of spontaneous- or laser-emission line centers to 0.2 pm (0.002 Å), by comparison to wavelength calibration sources, such as hollow-cathode atomic-emission lamps.

Reference light was supplied by a series of atomic hollow-cathode lamps, such as iron, titanium, etc., and passed through a mechanical light chopper, then combined with the laser light on a beam-splitter and admitted into the spectrometer. The combined laser and reference light, modulated at the frequencies of the mechanical light chopper and laser repetition rate, was detected by a photomultiplier at the spectrometer exit. Two lock-in amplifiers then provided signals which were combined for presentation on a strip-chart recorder. Knowledge of the spectrometer scan rate, grating order used, and strip charge speed permitted display at a known linear dispersion. Values typically of 1-2 pm/cm of chart paper were used for ease in comparing the center of the laser peak to the center of the atomic reference emission peaks. Fig. 4 shows a typical data presentation used to determine laser wavelength, in this case Xe IV? 231.5 nm.

Since higher orders of dispersion were used, it was always possible to find a good atomic reference line within $\frac{1}{2}$ Å of the laser line, on the strip-chart display. This is because the laser line in one order was often near some atomic line (generally in a lower grating order), as seen by the photomultiplier. The values for the refractive index of air as needed in conversion to vacuum wavenumbers were taken from the *Tables of Wavenumbers* [9]. Iron, titanium, neon, or argon provided most of the reference wavelengths for laser-wavelength determination, and reference wavelengths to 7 or 8 significant digits were taken from *Tables of Spectral Lines of Neutral and Ionized Atoms* [10]. If one of these four elements did not provide a good reference line sufficiently near the laser line being measured, then a satisfactory reference line could always be found

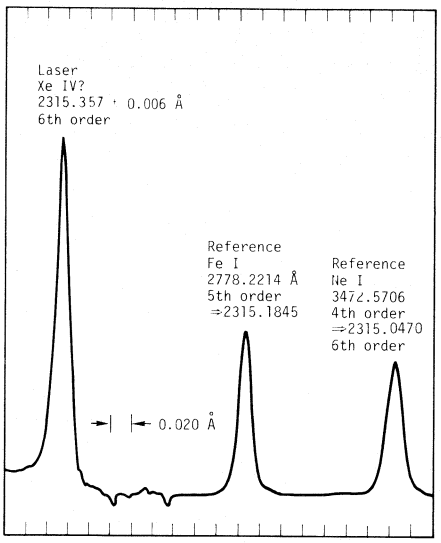

Fig. 4. Laser-wavelength calibration by simultaneous strip-chart display of laser wavelength and hollow-cathode-lamp reference wavelengths measured in air.

from the transition elements such as cobalt, manganese, etc., with reference wavelength to six significant digits taken from *Tables of Spectral-Line Intensities* [11]. Thus most laser wavelengths appearing in Tables I-VI could be specified to an accuracy of 0.01 Å or better.

Performance of the various laser lines was measured on a silicon photodiode calibrated in absolute units (milliamps per watt) throughout the spectral range of interest. Response and calibration below 3000 Å was achieved by removing the glass cover of the photodiode, thereby exposing the silicon surface directly to the incident laser light. Attenuation was achieved by use of quartz neutral-density (ND) filters, with absorption measured to 200 nm. (Typical absorption of these commercial ND filters varies by up to a factor of 3 in the range 200-400 nm.)

The laser pulses were displayed on a dual-beam oscilloscope simultaneously with the current pulse from the laser discharge. The current-pulse display on the scope was obtained by a 0.010-Ω current-viewing resistor placed in the current return of the laser tube, indicated in Fig. 1. The laser operated at 10 pps for all spectroscopic and performance measurements. For performance analysis of each line, if several oscillated simultaneously for a given set of mirrors, the laser output was reflected off a small, 1200-lines/mm grating. The first- or second-order reflection of the laser beam detected at a distance of several feet was generally sufficient to resolve adjacent laser lines at the 1-cm-aperture photodiode detector. Multiple laser lines closely separated in wavelength, such as oxygen at 375 nm or neon at 268 nm, were resolved for relative performance with the scanning spectrometer. Then absolute performance of the group was measured with the photodiode, as before. Performance was determined by generating a family of curves of output as a function of pulse voltage (i.e., current density) for different pressure settings. Generally, performance was fairly sensitive to pressure settings, and many lines could tolerate only a factor of 2 pressure variation for oscillation.

III. Experimental Results and Discussion

Experimental results are presented first for the noble gases, since they are generally the richest in laser transitions. Helium was tried, but no transitions were observed in the range 215-400 nm. The other noble gases generally exhibited laser action approximately every 10 nm throughout the portion of the UV between 200 and 400 nm. The gases are presented in order of increasing atomic weight for each column investigated of the periodic table.

A. Neon

Neon is characterized by many higher ionization states exhibiting laser action below 3000 Å. The results of neon-laser performance and spectroscopy are presented in Table I. Eleven new laser transitions were found in the range 202-261 nm. All the new transitions for neon satisfied the commonly observed characteristic of laser transitions $\Delta J = \Delta L$ [12], and all the observed neon transitions were $3p$-$3s$. The new transitions were classified directly by reference to *Tables of Spectral Lines of Neutral and Ionized Atoms* [10]. The shortest wavelength neon transitions occurred at 202 nm for Ne IV $3p\ ^2D^0 \rightarrow 3s\ ^2D$, as indicated in Table I. Both transitions of this doublet were observed to lase, but the member with the highest value of J was strongest, as was the case for all other laser transitions observed in this study to occur from the same multiplet. The Ne IV 202-nm transition was strong and would lase even using Brewster windows and intracavity air between the mirrors and laser. The transition at 206.5 nm exhibited high gain and was stronger than indicated in Table I, since nonoptimum output mirror reflectivity was used. This transition also exhibited a low threshold for laser action similar to the Ne III transitions at 247 and 268 nm. However, efforts at classification of the 206.5-nm transition were inconclusive and the ionic classification is either Ne III or Ne IV. The Ne V 2265.7-Å laser line was the only transition observed in this investigation that was definitely classified as a laser transition from a quadruply

ionized atom, and it was observed only at the upper limits of applied voltage. Unfortunately, laser operation at these settings was not sufficiently reliable for precise wavelength measurement, so the value from [10] is reported here. The most interesting aspect of neon is the strength indicated in Table I of the four lasing transitions at 236, 247, 267.8, and 267.9 nm. These were previously observed [3], [12], but it was not generally appreciated how strong they could be with suitable low-loss dielectric mirrors. High intrinsic gain was indicated by the peak power of Ne III at 247 nm, which dropped only 40 percent as the output mirror reflectivity was lowered from 80 to 35 percent. Similar high intrinsic gain was also exhibited by the other three neon lasing transitions at 236, 267.8, and 267.9 nm. The Ne III transitions appeared to saturate at about 5700 A/cm^2 in the short-pulse regime, and were generally 5 times stronger than the strong Ne II transitions near 330 nm. Saturation of Ne II under the same short excitation regime appeared at about 3000 A/cm^2, considerably higher than other singly ionized noble-gas laser transitions.

The two previously unclassified neon transitions at 247 and 289 nm have been tentatively classified as members of the Ne III singlet system. Motivation for this tentative classification appears justified by examination of characteristic isoelectronic laser transitions as indicated in Table II. Examination of Table II illustrates several other interesting features. First, it shows that isoelectronic atomic transitions are remarkably consistent in exhibiting similar laser properties. Entry *A* indicates five isoelectronic laser transitions for $3p\ ^3D_3 \rightarrow 3s\ ^3P^0_2$, and predicts furthermore that the transitions in F IV and Ne V should be quite strong at sufficiently high current densities. Entries *B* and *C* suggest possible new laser transitions at short wavelengths (see also Subsection E). Laser action was subsequently observed in Ne IV at 202 nm (see Table I), verifying entry *C* of Table II. However, laser action expected at 187.5 nm (entry *B* of Table II) was not observed, even at 10 000-A/cm^2 current density and with mirror reflectivity $R_1 \cdot R_2 > 0.95$ at 187.5 nm. However, a new transition in argon with the same electronic configuration was observed at 251.3 nm, as indicated in Table III. Entries *F*–*J* in Table II indicate that the given classifications of Ne III (247 and 287 nm in the Ne III singlet system) are plausible. Furthermore, it suggests that the Ne III transition at 268 nm is likely to be a strong CW transition as well.

B. Argon

Results of spectroscopic and performance investigation of argon are presented in Table III. Five new laser transitions were measured. However, efforts to achieve laser emission expected at 191.4 nm were not successful. This transition corresponds to Ar III $4p\ ^3P_2 \rightarrow 3d\ ^3D^0_3$ and should lase based

on sharing the same highly populated $4p\ ^3P_2$ level with the very strong Ar 351.1-nm laser transition, as well as having a lower level strongly coupled to the $3p^5\ ^3P_2$ ground state, necessary requirements for a strong ion laser. Laser action at 191.4 nm would require suppression of the 351.1-nm emission; therefore, mirrors were tried with $R_1 \cdot R_2 \geqslant 0.96$ at 191 nm and $R_1 \cdot R_2 < 0.005$ at 351 nm. Laser action was still strong at 351.1 nm and absent at 191 nm, implying excessive population of the $3d\ ^3D^0_3$ level by a different mechanism. All the argon transitions below 300 nm were similar in performance, except for the 285.5-nm laser transition, which was 100 times weaker, as indicated in Table III. The new transition at 285.5 nm does illustrate the common characteristic of pulsed lasers, namely that for transitions between the same multiplets, the transition with highest value of J in the upper level will be strongest. This is also indicated in the relative laser strengths of the Ar IV lines at 291 and 293 nm, Ar III at 351.1 and 351.4 nm, and Ar IV 262.1 and 262.5 nm.

Examination of Table III also indicates the unusually high peak power obtainable from the strong Ar III 351-nm transition. The optimized measured peak power of 1 kW is nearly two orders of magnitude stronger than the other argon transitions, except Ar III 364 nm. It was interesting to note that the saturation current density for the Ar III transitions occurred at about 6000 A/cm^2, which was roughly ten times greater than the saturation current density of 500 A/cm^2 noted for the strong visible Ar II transitions. The peak power of these Ar II visible transitions is also indicated in Table III for comparison.

The new short-wavelength argon transitions at 211 and 225 nm remain incompletely classified, although ionic classification as Ar IV appears correct, based on their laser performance at high current densities as indicated in Table III.

The previously unclassified [1] argon transitions at 275 and 300 nm have been tentatively classified as members of the Ar III singlet system, based on comparison with known isoelectric laser transitions in chlorine [5]. These tentative classifications await further spectroscopic verification.

C. Krypton

Results of spectroscopic and performance evaluation of the krypton UV laser transitions are presented in Table IV. Six new transitions were measured below 250 nm. The shortest wavelength of all laser transitions observed in this study was Kr IV 195.0 nm and is technically in the vacuum UV. It is also the shortest wavelength of any laser transition produced by a simple z-pinch excitation scheme. The laser transition, Kr IV 219 nm, is unusual because of its high peak power and high gain of at least several decibels/meter. In this respect, its performance resembles the strong Xe IV transitions discussed in the next section.

The performance of Kr IV 219 nm plotted against peak bore current density is shown in Fig. 5. Also shown is a similar plot for the other strong UV krypton transition, Kr III at 351 nm. It can be seen that saturation occurs for the Kr III transition around 6000 A/cm^2, while the transition at 219 nm was still increasing in power at 10 000 A/cm^2. Lack of apparent saturation in output power with increasing current density is the basis for classification of the krypton transitions at 195, 205, 219, 225, 234, 266, and 274 nm as occurring in Kr IV. The remaining transitions decreased in output power with increasing current density, with saturation occurring near 6000 A/cm^2, as indicated in Table IV. The new transition at 225 nm is also strong, and low gas pressures result in the best operation.

Fig. 6 shows oscilloscope traces of the output signal of

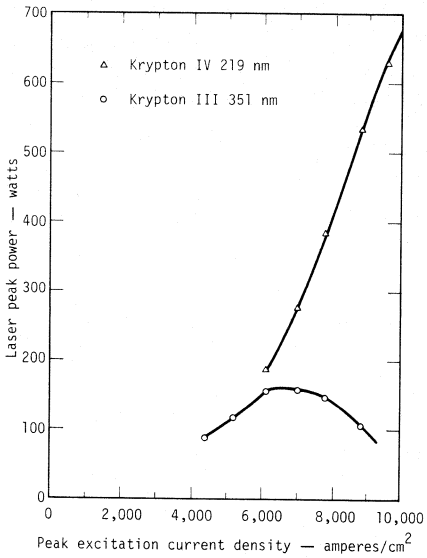

Fig. 5. Peak laser power in krypton at 219 and 351 nm plotted as a function of peak excitation current density.

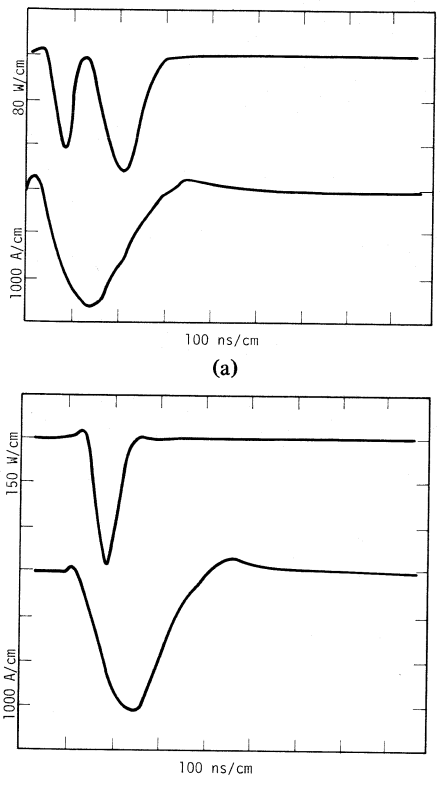

Fig. 6. Temporal display of krypton-ion laser output and excitation current pulse at 219 and 744 nm. (a) Upper trace: Laser emission in krypton IV at 219 nm (second pulse only). Kr IV 219 nm compared to the bore current of the excitation discharge. The first pulse is due to a superradiant transition at Kr II 7435.764 Å. The performance and wavelength of this near-infrared transition is also included in Table IV because of its high gain and high available peak power of several hundred watts. Fig. 6 additionally shows that the premature termination of the Kr II 744-nm transition occurs before the excitation pulse has reached maximum. Examination of Table IV also indicates that many of the Kr UV laser transitions still remain unclassified and that further spectroscopic investigation is required. The previously observed Kr III transition at 337 nm [12], [2] was not observed in this study, presumably due to the nature of the short excitation pulse used, which was generally an order of magnitude shorter than the excitation-pulse duration used by previous investigators. It is interesting to note that krypton exhibits laser action about once every 10 nm throughout the UV from 355 to 195 nm.

D. Xenon

Xenon is perhaps the most interesting of the pulsed noble-gas ion lasers because of its large number of strong transitions, due principally to Xe IV throughout the UV and visible spectral regions. Results of spectroscopic and lasing-performance investigations of xenon UV and selected visible transitions are presented in Table V. Three new transitions were observed below 260 nm and are tentatively attributed to Xe IV, as discussed below. The xenon-laser transition at 223 nm was found to be very erratic in performance, with shot-to-shot output varying by a factor of 5. It was found to lase only in the afterglow, with onset of lasing occurring 400 ns after termination of the excitation current discharge. Lasing duration was 400 ns, twice as long as all other xenon-ion transitions. Thus it could be a transition in Xe III, since third-spectrum xenon transitions did exhibit some lasing in the afterglow, as discussed below. The 231.5-nm transition is unusual in being both short in wavelength and also high in peak output power, and is exceeded in power only by the anomalously strong Xe IV 365-nm line at high current densities. In addition, it exhibited high gain, since lasing power output was higher using a 50-percent reflector than employing either 75- or 90-percent reflectors to couple out from the cavity. On the bases of high gain and output power, it resembles the Xe IV transitions, but its output power appeared to saturate at current densities corresponding to Xe III transitions (see Fig. 7). However, the strong Xe 231.5-nm transition seemed to show some anti-correlation with the strong Xe IV 365-nm transition. This might explain why this potentially high-gain laser line was not seen earlier [6], where the use of aluminized mirrors [6] permitted oscillation at 365 nm, hence suppressing oscillation at 231.5 nm. This problem is avoided with dielectric mirrors. On this basis the 231.5-nm transition would have ionic classification as Xe IV. All the Xe IV laser transitions continued to increase in power at the highest current densities tested. The Xe 231.5-nm output power as a function of current density is compared with Xe IV 365 nm in Fig. 7. Fig. 8 compares the output versus current density for Xe IV 269 nm and Xe III 308 nm. Here there is clear saturation occurring for the Xe III 308-nm transition at about 5000 A/cm^2, while the 269-nm output power continues to increase with increasing current density, suggesting the 269-nm transition should be attributed to Xe IV and the 308-nm transition to Xe III. This conclusion is in agreement with a recent study of xenon-laser ionic assignments [13] regarding the Xe III assignment at 308 nm. However, this earlier study [13] assigns the 269-nm

transition to Xe III, which cannot be justified, based on the apparent lack of saturation of this transition at high current densities, as indicated in Fig. 8. However, ionic assignments of the other xenon-laser transitions given earlier [13] are in agreement with the ionic assignments given in this study. The possible existence of a xenon transition at 298.4 nm in [1], [12], and [13] appears to be ruled out; a careful search at this wavelength was negative. However, the very strong oxygen transition at 2983.86 Å (see Table VI) is the likely source of this line as an impurity from the oxide cathode used in [12]. The use of indium cold electrodes precluded such oxygen contamination in this investigation.

Fig. 9 shows the output-power performance of the xenon transitions at 325 and 333 nm, plotted against current density. Neither transition exhibited clear saturation at the highest current densities tested, again suggesting that both belong to the Xe IV spectrum. Therefore, the assignment of the xenon 325-nm transition to Xe III $(^2P^0)\ 6p\ ^3D_3 \rightarrow 5d\ ^3D^0_3$, [3], must be in error. In confirmation of this, the measured wavelength of 3246.922 ± 0.005 Å is rather clearly outside the calculated Xe III wavelength of 3246.84, but in agreement with the originally measured wavelength of 3246.94 Å [3]. Similarly, apparent power saturation at a current density of about 4000 A/cm² would classify the xenon 330.6-nm transition in the Xe III spectrum. It may be noted that the transitions at 345, 378, and 406 nm with known Xe III classifications exhibited similar peak powers and similar apparent saturation current densities of about 4500 A/cm².

The strong Xe IV visible transitions are also included in Table V for comparison. The violet line at 430.6 nm again exhibited the high peak power of about 1 kW characteristic of these fourth-spectrum xenon transitions. Saturation current density was not reached in this investigation, and exceeds 8000 A/cm², substantiating the Xe IV assignment proposed earlier [13]-[15]. The strong Xe IV green lines were measured simultaneously and each averaged about 1-kW peak power; current saturation was not reached at 9400 A/cm². Relative strengths for the individual lines are given in [16] and [17], and a thorough parametric study is given [18].

The temporal behavior of typical xenon-ion-laser transitions is presented in Fig. 10 for the transitions at 231.5 and 308 nm, and in Fig. 11 for the transitions at 345 and 365 nm. For the short current excitation pulse used in this investigation, lasing began about 150 ns after onset of the current excitation pulse, and terminated with the current pulse for the Xe IV transitions; all Xe IV transitions exhibited similar temporal behavior, with 100-ns FWHM. The Xe III transitions often continued to lase during the afterglow for about 100–300 ns. This is well illustrated by the 308-nm transition; laser pulse FWHM was typically 200 ns for all Xe III transitions in this investigation.

Again examination of Table V reveals the large number of xenon-laser transitions that remain incompletely classified, and further investigation is certainly warranted.

E. Oxygen and Nitrogen

The atmospheric gases oxygen and nitrogen were investigated for relative performance of their UV and several visible laser transitions. Results of this investigation are presented in

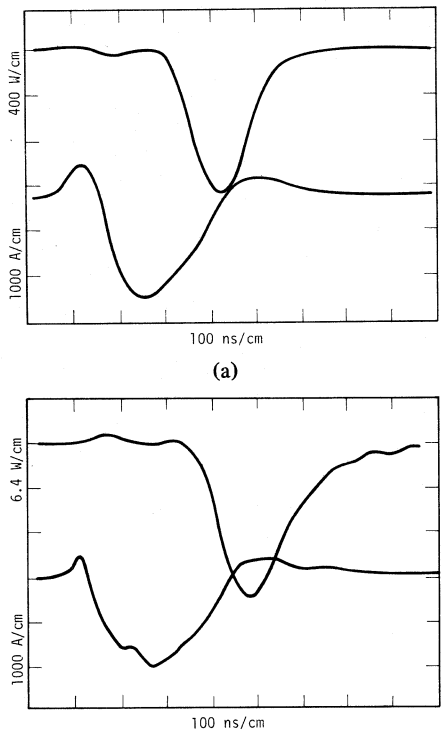

Fig. 10. Temporal display of xenon-ion-laser output pulse shape and corresponding excitation current pulse at 231.5 and 308 nm. (a) Upper trace: Laser emission in xenon IV? at 231.5 nm. Table VI. In oxygen no new transitions were observed between 215 and 298 nm, the first entry in Table VI; the recently observed O V 2781.04-Å laser transition [19] was not visually detected in this study using fluorescent paper, i.e., peak power was less than 0.1 W. The accuracy of the measured wavelengths, except as indicated in Table VI, is that reported by previous investigators [3], [20], [21]. One new transition was measured at 375.7 nm, and is the remaining member of the laser triplet O III $3p\ ^3D_{3,2,1} \rightarrow 3s\ ^3P_{2,1,0}$, for which $\Delta J = \Delta L = -1$. The O III transition at 559 nm was also included since it exhibited high peak power in this investigation.

The temporal behavior of the oxygen transitions was similar to the XE III transitions discussed in Subsection D. All exhibited FWHM of about 200 ns, with onset of lasing occurring 200 ns after onset of current excitation. However, significantly different temporal behavior occurred for the O III 375-nm triplet and O III 559 nm. For these four transitions, onset of lasing occurred in the afterglow 200 ns after termination of current excitation. The duration of lasing was typically 700-ns FWHM. Thus the energy content of these O III transitions was comparable to the strong Xe IV transitions.

The oxygen transition O II 374.9 nm exhibited "normal" behavior with 180-ns FWHM. It is to be noted that O II 374.9 nm is the strongest of all singly ionized laser transitions. Examination of the isoelectronic sequence for this transition, namely $(^3P)3p\ ^4S_{3/2} \rightarrow 3s\ ^4P_{5/2}$, would predict strong laser transitions in F III at 2484.36 Å and Ne IV at 1875 Å, which are under investigation [6] (see also Subsection A).

The oxygen-blue transitions were observed to be very weak with the short-pulse excitation used here and parametric data on performance are not reported, but are given in [4] for 4-μs-duration current excitation pulses.

Nitrogen was investigated for UV ion laser transitions, but the spectrum between 215 and 348 nm was unproductive of laser transitions. However, the only observed UV transition, N IV at 347.9 nm, exhibited high peak power of 400 W. The other nitrogen UV transitions [1] were not observed. The transition N III at 409.7 nm was also very strong and exhibited nearly superradiant behavior. Some of the known nitrogen-blue-laser transitions [1] were observed in this investigation and are included in Table VI. The wavelength of N III 451.1 nm was remeasured more accurately than previously reported [1], [20] and confirms the given classification [20]. Similar to oxygen, the nitrogen-blue transitions apparently favor longer pulse current excitation, and more complete relative performance data were reported earlier [4].

IV. Conclusion

Investigation of pulsed UV ion lasers has permitted measurement of the emission wavelengths to generally better than 0.01 Å. In addition, 25 new laser transitions were observed below 2700 Å, including transitions in Xe IV? 231.536 nm and Kr IV 219.192 nm, both of which exhibited peak pulsed powers of about 1 kW. The shortest wavelength transition was Kr IV at 194.962 nm at the edge of the vacuum UV. Measurement of peak laser power as a function of bore current density has yielded current saturation of 4000-6000 A/cm^2 for third-spectrum ion lasers, thus permitting ionic classification of the

new and previously unclassified laser transitions. Seven of these third-spectrum transitions between 275 and 324 nm have been recently observed in CW operation [27] with thresholds of about 500 A/cm^2. Optimum output performance characteristics were determined as functions of excitation current density and gas pressure for all the ion-laser transitions below 400 nm observed to lase with short-duration (250 ns) current excitation pulses. Comparison of isoelectronic sequences has permitted tentative classification of some unclassified UV transitions in neon and argon, but many krypton and xenon laser lines still remain unclassified. Investigation of pulsed UV ion laser transitions in other gases will be reported in a subsequent article [6].

Thus a simple z-pinch capacitive-discharge laser system has been described which produces laser emission completely spanning the chemical UV from 195–300 nm in 25 new and 15 previously known laser transitions in the four noble gases. Performance is equally good on many previously known laser transitions above 300 nm. In addition, system reliability permits operation for days continuously, with a system lifetime between 10^8 and 10^9 shots. This should make this kind of ion laser a powerful and reliable research tool for generation of laser light throughout the chemical UV.

ACKNOWLEDGMENT

The author wishes to thank W. R. Call and W. E. Elsholz for expert technical assistance in laser construction and glass blowing, respectively. He also wishes to thank L. L. Wood, M. L. Spaeth, and W. W. Simmons for helpful suggestions.

Production of Electronically Excited Iodine Atoms, $I(^2P_{1/2})$, Following Injection of HI into a Flow of Discharged Oxygen

ROBERT J. PIRKLE, J. R. WIESENFELD, CHRISTOPHER C. DAVIS, GEORGE J. WOLGA, MEMBER, IEEE, AND ROSS A. McFARLANE, MEMBER, IEEE

Abstract—**The emission from the transition $I^*(5\ ^2P_{1/2}) \rightarrow I(5\ ^2P_{3/2})$ at 1.315 μm following injection of HI into a microwave-discharged He/O_2 flow has been studied. Relative $I^*(5\ ^2P_{1/2})$ emission intensities have been recorded as a function of HI and O_2 flow rates and as a function of time after injection. Pulsed gain measurements using an iodine photodissociation laser as a source show that the ratio, $N_{I^*}/(N_I + N_{I^*}) \approx 0.15$–$0.25$, is less than that required for population inversion. This observation will be discussed in terms of known chemical processes involving $O(^3P)$, HI, $O_2(^1\Delta_g)$, and iodine atoms.**

I. Introduction

STUDIES of the atomic-iodine emission generated when HI is injected into a microwave-discharged flow of molecular oxygen have indicated [1] that the atomic iodine may exhibit population inversion on the transition $I^*(5\ ^2P_{1/2}) \rightarrow I(5\ ^2P_{3/2}) + h\nu$ (7603 cm^{-1}). In such a system, atomic iodine is generated by the reactions

$$O + HI \xrightarrow{k_{1a}} OH + I, \qquad \Delta H = -31 \frac{\text{kcal}}{\text{mole}} \tag{1a}$$

$$O + HI \xrightarrow{k_{1b}} OH + I^*, \qquad \Delta H = -10 \frac{\text{kcal}}{\text{mole}} \tag{1b}$$

with rapid establishment of the equilibrium

$$O_2(^1\Delta_g) + I \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} + O_2(^3\Sigma_g^-) + I^*, \qquad \Delta H = -0.8 \frac{\text{kcal}}{\text{mole}} \tag{2}$$

and the initial branching ratio, k_{1a}/k_{1b}, determining the relative populations of the two atomic-iodine states. The equilibrium constant, $K_2 = k_2/k_{-2}$, has been calculated [2] to be 2.94 at 273 deg. Given sufficient initial concentrations of $O_2(^1\Delta_g)$, the atomic-iodine transition may be inverted via electronic-energy transfer from $O_2(^1\Delta_g)$.

Using the computed value of the equilibrium constant, the fraction of oxygen molecules initially in the $O_2(^1\Delta_g)$ state

$$\frac{[O_2(^1\Delta_g)]_0}{[O_2(^1\Delta_g)]_0 + [O_2(^3\Sigma_g^-)]_0} \tag{3}$$

required to achieve the desired inversion

$$\frac{[I(^2P_{1/2})]}{[I(^2P_{3/2})]} > 0.5 \tag{4}$$

may be shown to lie in the range 0.15–0.20, depending on k_{1a}/k_{1b} and the absolute concentrations of atomic iodine and molecular oxygen present. Both atomic oxygen, $O(^3P)$ and excited molecular oxygen, $O_2(^1\Delta_g)$ are conveniently produced by passing a flow of molecular oxygen in a suitable diluent such as He or Ar through a microwave-excited discharge tube. The amount of $O_2(^1\Delta_g)$ produced in such a flow has been investigated by several authors [3]–[9] and the range of reported values overlaps the requirement mentioned previously. Here this system is studied as a possible candidate for a continuous laser on the 1.315-μm atomic-iodine transition.

II. Experimental Procedure and Results

A. Spontaneous Emission

We have observed the emission at 1.315 μm from I* generated under conditions similar to those previously described. A schematic diagram of the apparatus used in our study is presented in Fig. 1. Microwave excitation of a flowing mixture of He and O_2 in a 2.5-cm-ID quartz tube was provided by a Litton Industries 2450-MHz 1-kW magnetron coupled into a 1-m section of a *C*-band waveguide. The cross-sectional dimensions of the flow were expanded to match those of the reaction chamber (1.2 X 21.6 cm) in a transition region designed to insure uniform flow. The transition region was lined with Teflon-coated foil to minimize recombination of oxygen atoms. Hydrogen iodide was injected into the discharged oxygen flow using an injector[1] which consisted of 76 sections of ~0.08-cm stainless-steel syringe tubing separated by 0.24 cm and mounted vertically in the reaction chamber. In each injector, seven ~0.013-cm holes admitted the HI in a direction normal to the discharged flow. Fused-quartz windows were mounted at Brewster's angle and emission was observed transverse to the flow. The flow of gases through the reaction chamber was maintained by a 450-ft^3/min blower backed by an 80-ft^3/min mechanical pump. Flow velocities of 90–95 m/s were measured in the reaction chamber at total pressures of 7–10 torr.

The emission was chopped at ~200 Hz and dispersed using a 1/2-m Jarrell-Ash monochromator before being detected with a room-temperature PbS detector. At wavelengths greater than 1.0 μm, the only emission observed was a single line at 1.315 μm, the wavelength corresponding to the transition $I(5\,^2P_{1/2}) \rightarrow I(5\,^2P_{3/2})$. In order to maximize the observed signal, the monochromator was replaced with a narrow bandpass filter [104 Å full width at half maximum (FWHM)] centered at 1.313 μm. The output of the PbS detector was monitored with a PAR-HR8 lock-in amplifier.

In Fig. 2, the observed relative I* emission intensity is presented as a function of HI flow at optimum O_2 and He flows. The ratio He:O_2:HI at maximum I* emission was found to be 40:3:1. The I* emission as a function of total molecular-oxygen flow is shown in Fig. 3. The more rapid initial increase may be attributed to maximization of the $O(^3P)$ and $O_2(^1\Delta_g)$ concentrations followed by a slower decrease as the excess $O_2(^3\Sigma_g^-)$ deactivates I*. The emission intensity decreases slowly with a decrease in He flow. We determined that the emission was slightly less intense when Ar was substituted for He. The emission intensity was proportional to discharge power at low power but quickly became constant and further increases in discharge power had no effect.

Shown in Fig. 4 is the relative I* emission intensity as a function of time after injection. The emission peaks sharply at ~75 μs after injection and decreases rapidly thereafter. The rapid decrease in I* emission at later times implies that significant deactivation processes are of considerable importance and overwhelm the equilibrium pumping mechanism (2). Such processes include diffusion of $I(5\,^2P_{1/2})$ to the

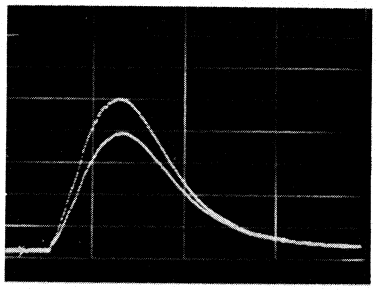
walls of the reaction chamber accompanied by efficient deactivation. In addition, the presence of the intense yellow-green fluorescence of $I_2(B^3\pi_{0^+u})$ suggests a significant concentration of I_2 which is a very rapid quencher of $I(5\ ^2P_{1/2})$ [10]. Furthermore, the presence of unreacted HI due to imperfect mixing would also result in deactivation [11] of the excited atomic iodine. These observations point to the importance of transverse-flow operation when systems of this type are considered as potential chemical lasers.

B. Absorption Measurements

In view of the intense emission observed from this system and previous reports of large I^* populations generated in similar experiments [1], we have carried out pulsed gain experiments to determine the fraction, $f(I^*)$, of atomic iodine present in the I^* state

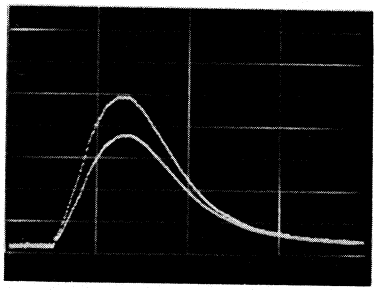


$$f(I^*) = \frac{N_{I^*}}{N_{I^*} + N_I} \tag{5}$$

where N_{I^*} and N_I are number densities of I^* and I, respectively. A schematic diagram of the apparatus used in these experiments is shown in Fig. 5. The optical source was an iodine photodissociation laser which used n-C_3F_7I at a pressure of 10 torr as a source of atomic iodine. The laser consisted of a quartz tube of 10-mm ID and 30 cm in length. The central 15-cm portion of this tube was enclosed in a polished-aluminum elliptical cavity where it was irradiated with the output of an ILC 10L6 linear xenon flashlamp. A 200-μF capacitor bank charged at voltages up to 2 kV (an input energy of 400 J) was discharged through the flashlamp and a 20-μH series inductor to yield a pumping flash of ~140-μs FWHM. At charging voltages of 2 kV, we have calculated the peak flashlamp current to be ~1100 A and the peak magnetic field at the laser tube to be ±40 G. At these low magnetic fields, shifts of the hyperfine lines are considerably smaller than the Doppler width of the zero-field lines (251 MHz at 300 K) [13]. The output of the photodissociation laser under these conditions of low input energy and small magnetic field is almost certainly on the $F' = 3 \rightarrow F'' = 4$ hyperfine component only [12]-[15].

The laser output was passed through the 1.3-μm narrow bandpass filter to minimize scattered flashlamp radiation reaching the detectors. The laser pulse was then split using quartz flats and attenuated using neutral-density filters. One portion of the split signal was sent through the reaction chamber of the flow system and both portions of the signal were monitored using RCA-7102 (S-1) photomultiplier tubes. The integrated outputs ($\tau_{RC} = 0.05$ s) of the photomultipliers were recorded simultaneously using a Biomation 8100 transient recorder which transferred a digital representation of each transient signal to a Northern Scientific NS575 digital signal analyzer.

In a typical experiment the outputs of the photomultipliers were recorded with only discharged oxygen and helium in the reaction chamber. Changes in the relative output of each photomultiplier were then recorded when HI was injected into the discharged flow. Results from one such experiment are shown in Fig. 6. A small decrease in the output of the photomultiplier monitoring the transmission through the reaction chamber (lower trace in each photograph) is clearly evident when HI is injected and corresponds to absorption of the laser pulse. Similar data for a variety of HI and O_2 inputs, and at a number of distances downstream of the HI injectors, were also recorded. Under all sets of conditions small (3-8 percent) absorptions were observed; errors in a single measurement were 0.3-0.4 percent. No changes in these observations occurred when the laser-pulse intensity through the reaction chamber was changed by a factor of 10^2.



The accuracy of the absorption measurements was checked

135 μs

He = 1200 std. cc/s
O_2 = 95 std. cc/s

(a)

135 μs

He = 1200 std. cc/s
O_2 = 95 std. cc/s
HI = 31 std. cc/s

(b)

Fig. 6. Scope traces showing reference-laser pulse (upper curve) compared to pulse through flow cavity (lower curve). (a) The curves are characteristic of the flowing medium under optimized conditions, but without HI. (b) The pulse through the flow cavity (lower curve) has been attenuated following the addition of HI.

by measuring the attenuation of the laser pulse when a clean quartz flat was placed in front of one of the photomultipliers. The calculated reflection coefficient of quartz at 1.315 μm is 6.6 percent; while the measured attenuation was 6.5 ± 0.3 percent.

Finally, we have premixed O_2 with the HI before injection and noted a decrease in spontaneous-emission intensity with a simultaneous increase in absorption. From a single absorption measurement, the population difference, ΔN, may be calculated from

$$\Delta N = 12/7 \frac{\ln I_0/I}{\alpha_0 L} \tag{6}$$

where $\Delta N = 1/2N_I - N_{I^*}$, L is the absorption path length, and α_0 is given by

$$\alpha_0 = 1/4\pi\left(\frac{\ln 2}{\pi}\right)^{1/2} \lambda^2 \frac{A_{34}}{\Delta\nu_D} \tag{7}$$

where λ is the transition wavelength and $\Delta\nu_D$ is its Doppler width. A_{34} is the Einstein coefficient for spontaneous emission on the $I^*(F = 3) \rightarrow I(F = 4)$ transition. The use of this coefficient and the factor of 12/7 in (6) arise because the probe laser operates on the $F' = 3 \rightarrow F'' = 4$ transition and thus only directly measures $\Delta N_{34} = \frac{7}{9}(I(F'' = 4)) - (I^*(F' = 3))$.

The increase in ΔN found when O_2 is premixed with the injected HI resulted from the quenching of I^* to I by the excess O_2. Assuming that the fractional decrease in observed spontaneous emission corresponds to the fractional decrease in the I^* population, the observed increase in ΔN, $\Delta(\Delta N)$ is directly related to the I^* population before addition of undischarged O_2, $N^0_{I^*}$, as

$$\Delta(\Delta N) = 3/2XN^0_{I^*} \tag{8}$$

where X is the fractional decrease in spontaneous-emission intensity. Using $N^0_{I^*}$ from (8) and $\Delta N^0 (= \frac{1}{2} N^0_I - N^0_{I^*})$ calculated from absorption data when no undischarged O_2 was added, N^0_I may easily be calculated. Thus the fraction of atomic iodine initially in the $^2P_{1/2}$ state may be calculated from (5). It is noteworthy that (5) is independent of A_{34} and $\Delta\nu_D$ since these terms occur in both the numerator and denominator and cancel.

Data from several experiments yielded values of $f(I^*)$ in the range 0.15–0.25. The uncertainty in these figures is at least a factor of 2 since the uncertainty in a single absorption measurement was a significant fraction of the total increase in observed absorption (typically, 1.5–3.0 percent). It may be noted, however, that the observation of absorption rather than gain clearly demonstrates that $f(I^*) < 0.33$, the minimum figure corresponding to population inversion.

III. Conclusions

We have determined that the atomic iodine generated when HI is injected into a discharged He/O_2 flow does not exhibit population inversion on the transition $I(5\,^2P_{1/2}) \rightarrow I(5\,^2P_{3/2})$ at 1.315 μm. However, the large population of excited species produced in this system, $f(I^*) = 0.15$–0.25, suggest that the equilibrium pumping mechanism (2) is indeed efficient and that given larger initial concentrations of $O_2(^1\Delta_g)$, the atomic-iodine transition previously discussed might well be inverted via electronic-energy transfer. To this end, a search for new sources of singlet molecular oxygen seems justified.

Far Infrared Frequency Synthesis with Stabilized CO_2 Lasers: Accurate Measurements of the Water Vapor and Methyl Alcohol Laser Frequencies

F. RUSSELL PETERSEN, KENNETH M. EVENSON, DONALD A. JENNINGS, JOSEPH S. WELLS, KENYA GOTO, AND JUAN J. JIMÉNEZ

Abstract–**A far infrared (FIR) frequency synthesis technique using saturated-absorption stabilized CO_2 lasers and a point-contact diode has been used to measure frequencies of a number of strong CW H_2O, D_2O, and CH_3OH laser lines. The first frequency measurements of the 79-μm H_2O, the 73- and 108-μm D_2O, and 11 CO_2-pumped CW $^{12}CH_3{}^{16}OH$ laser lines are reported. This measurement is the first demonstration of the general usefulness of CO_2 lasers for accurate synthesis of FIR frequencies.**

Manuscript received April 28, 1975.

DIRECT laser frequency measurements are made by frequency harmonic generation and mixing in nonlinear diodes and crystals [1], [2]. At longer far infrared (FIR) wavelengths, frequency beats between a high harmonic of a klystron and the laser line have been observed. For instance, the 337-μm HCN line has been beat with the 12th harmonic of a *V* band klystron in a commercially available diode [3], the 118.8-μm CH_3OH line has been beat with the 33rd harmonic of a *V* band klystron in a Schottky diode [4], and the 84-μm H_2O line has been beat with the 401st harmonic of a high quality *X* band klystron in a Josephson junction [5].

While this procedure is desirable insofar as it directly connects the unknown laser frequency with an easily measurable microwave frequency (and consequently to excellent frequency standards), there are a number of serious and as yet unresolved limitations. For instance, as the laser frequency increases, the harmonic number of necessity must

increase. Consequently, severe requirements are imposed on the spectral purity of the microwave source [6] as well as on the S/N capability of the harmonic generator and mixing device. While very low noise, spectrally pure oscillators together with detectors such as the Josephson junction may extend the present microwave multiplication limit, there is a current need for accurate frequency measurement in the intermediate and near infrared (IR) spectral region.

Frequencies greater than the FIR have in fact been measured; the current highest measurement is 148 THz [7]. In these experiments a chain of lasers was used to extend frequency measurements from a microwave oscillator to that of the highest laser frequency. In this chain, the nth harmonic of one laser was mixed with the next higher frequency. By using such a chain of lasers it was possible to reduce the mixing order[1] to less than 14 [3]. This procedure was necessary because the S/N decreased rapidly with increasing harmonic number [1].

This technique has been eminently successful, but for wide application, has suffered from a number of drawbacks. First, the limited number of known laser sources makes it difficult to reduce the unknown-laser synthesized-frequency difference to within the range of commonly available microwave oscillators. Second, stability and reproducibility of many laser oscillators are poor; in these cases, highly accurate measurements require continuous frequency monitoring of the lower frequency lasers during the measurement process. And finally, some of the known CW laser oscillators cannot produce, in a compact device, the power required for effective harmonic generation in a point-contact diode.

Many of these problems can be eliminated if two stabilized CO_2 lasers are chosen to synthesize the IR frequencies,[2] as shown schematically in Fig. 1. The unknown laser frequency is then given by the expression

$$\nu_L = l\nu_1 + m\nu_2 + n\nu_{\mu w} \pm \nu_B.$$

Here ν_L is the unknown laser frequency, ν_1 and ν_2 are frequencies of CO_2 lasers operating in either the 9.4- or 10.4-μm bands, $\nu_{\mu w}$ is a microwave frequency (X band or less), and ν_B is the beat frequency measured with a spectrum analyzer. l, m, and n are small positive or negative integers such that the mixing order is less than about 10. The CO_2 laser is chosen because every line in each of the two laser bands can be stabilized to a narrow saturated-absorption feature very close to the true molecular frequency [9]. These frequencies are reproducible to within 2 parts in 10^{-10}, and the laser stability is good, e.g., [3]

$$\delta\nu/\nu = 3 \times 10^{-11}, \quad \text{for} \quad \tau = 1 \text{ s}.$$

Absolute frequency measurements of two CO_2 lines, one in each band [3], coupled with a remeasurement of the rotational constants [10] resulted in absolute frequencies for

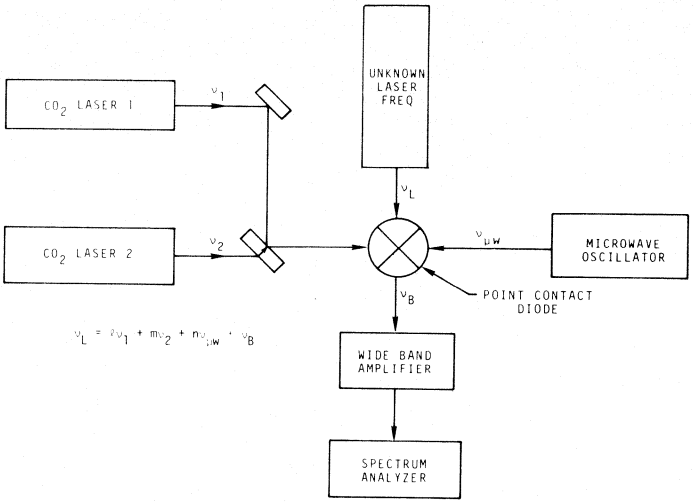

Fig. 1. Schematic diagram of the two-CO_2 laser frequency synthesis experiment.

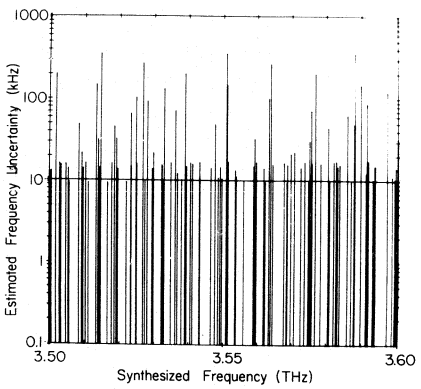

Fig. 2. Difference spectrum from the fundamentals of the first 60 lines in both the 9.4- and 10.4-μm bands of CO_2. The frequency interval taken here, 3.5–3.6 THz, is typical of much of the total frequency range covered. Estimated uncertainty for each synthesized frequency is plotted on the vertical scale.

most of the $^{12}C^{16}O_2$ laser lines with a fractional uncertainty of about 1×10^{-9} [11]. Thus, with this technique, the CO_2 lasers can be regarded as secondary frequency standards, and the measured frequency is related to the primary Cs frequency standard through experiments establishing the CO_2 molecular constants. As a result, a comb of over 100 accurately known, reproducible, and highly stable laser frequencies, all with adequate power for harmonic generation, exists in the band from 27 to 33 THz.

If the use of two stabilized $^{12}C^{16}O_2$ lasers is considered for frequency synthesis, then many thousands of additional discrete frequencies can be generated. For instance, over 7000 frequencies in the band from 0.025 to 5.8 THz, most with an uncertainty less than 30 kHz, can be produced from differences of the fundamentals of the first 60 lines in both the 9.4- and 10.4-μm bands. As an example, Fig. 2 shows this difference spectrum in the interval from 3.5 to 3.6 THz. If, in addition, sums as well as differences of harmonics from each CO_2 laser are used, then the covered frequency band is greatly extended. In fact, semiuniform frequency coverage from 0.025 to 100 THz can be attained with a mixing order less

[1]The mixing order is defined as the sum of the absolute values of the harmonic numbers of all the coherent oscillators being mixed in the diode.

[2]A multiple CO_2 laser frequency synthesis technique has been proposed for relating CO_2 frequencies to the microwave standard without the use of other lasers in the synthesis chain. See [8].

than ten. In most cases, the CO_2 combination will produce a frequency that comes within 10 GHz of the one desired. With low mixing orders, S/N ratios which are adequate for precision frequency measurements can be expected.

In order to demonstrate the experimental worthiness of this idea, we have used this CO_2 frequency synthesis technique to measure the frequencies of a number of strong CW H_2O, D_2O [12], and CH_3OH [13]-[16] laser lines. Some of these have been measured before by other synthesis techniques [4], [5], [17]-[21] and consequently provide useful comparison with the present measurements. Other motivation stems from the use of laser lines from these molecules for laser magnetic resonance spectroscopy [22], [23], radio astronomy, detector evaluation, and possible standards applications.

Four CO_2 lasers, similar to those described previously [3], were used in the experiment. Two of the lasers were frequency locked to standing-wave saturation dips observed in the 4.3-μm fluorescent radiation emanating from intracavity absorption cells [9]. Pressure in each absorption cell was 0.035-0.040 torr. No corrections to the CO_2 frequencies were made for pressure, power, or other shifts since these were considered negligible compared to other uncertainties in the experiment. The two $^{12}C^{16}O_2$ lasers used to synthesize $\nu_1 - \nu_2$ were offset locked by about 2.5 MHz from the absorption stabilized lasers. This procedure reduced the width of the beat signal caused by the frequency modulation required for line center locking. In each case, the estimated 1-standard-deviation uncertainty in $\nu_1 - \nu_2$ was less than 30 kHz and did not contribute significantly to the uncertainty in the measured frequency.[3] Power from each synthesis laser was adjusted to be about 100 mW.

The 8-m-long water vapor laser has also been described previously [3] and in this experiment was filled with H_2 and water vapor to a total pressure of 0.6 torr in a 3:2 ratio. In each measurement, the frequency of the water vapor laser was manually adjusted to the maximum power point of the laser gain curve. Power from the water vapor laser depended on the isotope as well as the transition and ranged from 0.5 to 50 mW.

The other CW FIR laser lines were produced by optically pumping a low-pressure methyl alcohol cell in a waveguide configuration [24] with a 2-m $^{12}C^{16}O_2$ laser. The polished-copper cylindrical waveguide cavity, which was also the gas cell, was 14 mm in diameter and 2 m long. Both end mirrors were flat, with one being movable for tuning purposes. CO_2 pump radiation was focused through a 1-mm-diameter hole in the movable input mirror by a 6.4-cm focal length germanium lens. FIR power was coupled out of the other end mirror through a 2.5-mm-diameter hole. Methyl alcohol vapor pressure ranged from 0.1 to 0.25 torr. The FIR laser had a tuning range of 3-16 MHz, which was both mode and wavelength dependent. Output power ranged from about 0.1 to 10 mW.

All lasers were focused onto the tungsten-nickel point-contact diode with short focal length lenses; microwave power was received from a simple antenna placed close to the diode. The beat frequency between the FIR laser and appropriate harmonic combination of CO_2 lasers and klystron was amplified and subsequently measured with a 1.2-GHz spectrum analyzer.

The CO_2 synthesis combination[4] together with the measured frequencies of four H_2O and three D_2O laser lines are presented in Table I. Although many CO_2 synthesis combinations often exist for any given FIR frequency, the lowest mixing order was usually chosen. However, in the case of the 28-μm line, a high mixing order was deliberately chosen for the purpose of measuring the S/N ratio. In spite of this high mixing order (9), the S/N observed on a spectrum analyzer with a predetection bandwidth of 30 kHz and a video bandwidth of 10 kHz was still greater than 25 dB. The uncertainty in each measured frequency was estimated to be ± 1 MHz, mainly because of difficulty in determining the center of the Doppler and pressure-broadened laser gain curve (10-20 MHz wide). In the third column, measured frequencies have been converted to vacuum wavenumbers with $c = 299\,792\,458$ m/s ($\delta c/c = \pm 4 \times 10^{-9}$), [25].[5]

Two other experiments were performed which did not use the CO_2 laser, but which gave results in good agreement with the results obtained here. In one, the difference frequency between two water vapor lasers oscillating on 78 and 79 μm, respectively, was beat with a 30-GHz klystron. The measured frequency was 31.298(3) GHz, in good agreement with 31.2968(2) GHz obtained with the CO_2 synthesis technique. In the other a 2-m-long water vapor laser oscillating on 28 μm which exhibited a Lamb dip was mixed with the 12th harmonic of a 337-μm HCN laser, of known frequency [3], and a 29-GHz klystron. The frequency of the Lamb dip was found to be within 1 MHz of the top of the gain curve and in good agreement with the results in Table I.

These two results together with previous measurements by other synthesis techniques are listed for comparison at the bottom of Table I. There is general agreement within the estimated experimental errors. The measurements most reproducible and closest to the true molecular frequency are those in which the water vapor laser frequency was set to the center of the Lamb dip. Although the Lamb dip is not necessarily in the center of the gain curve when the laser is operated at maxi-

[3]Tables of frequencies are given in [11]. Since uncertainties in the rotational constants are correlated, the estimated standard deviation of a frequency difference involves use of the variance-covariance matrix obtained from a least squares fit of the rotational constants to experimental data. The calculation here used experimental data from [10]. A NBS publication giving CO_2 synthesis combinations and estimated errors for the FIR spectral region is in preparation.

[4]Here and again in Table II, the subscripts I and II refer to the CO_2 10.4- and 9.4-μm bands, respectively, and are derived from the spectroscopic notation for the lower vibrational level of the laser transition.

[5]This value of c has been recommended by the Consultative Committee for the Definition of the Meter at their meeting in the Bureau Internationale des Poids et Mesures, Sevres, France, and by the International Astronomical Union, Fifteenth General Assembly, Sydney, Australia.

TABLE I
MEASURED FREQUENCIES FOR H_2O AND D_2O LASER LINES

WATER VAPOR LASER LINE λ (μm)	MEASURED FREQUENCY (MHz) (UNCERTAINTY: ± MHz)	VACUUM WAVENUMBER (cm^{-1})	$^{12}C^{16}O_2$ SYNTHESIS COMBINATION
H_2O			
28[a]	10 718 068.3	357.516 276	$^3P_{II}$ (10) - ^3P_I (28)
78[b]	3 821 771.3	127.480 567	R_{II} (14) - P_I (16)
79[c]	3 790 474.5	126.436 620	R_{II} (10) - P_I (18)
119[d]	2 527 952.0	84.323 402	P_{II} (8) - R_I (16)
D_2O			
73[e]	4 120 984.3	137.461 240	R_{II} (22) - P_I (22)
84[f]	3 557 147.1	118.653 665	P_{II} (12) - P_I (30)
108	2 783 066.6	92.833 109	R_{II} (10) - R_I (26)

Note: Vacuum wavenumbers were calculated from the measured frequencies with $c = 299\,792\,458$ m/s ($\delta c/c = \pm 4 \times 10^{-9}$). The CO_2 synthesis combination with appropriate harmonic numbers is also listed for each measurement. In each case, the estimated 1-standard-deviation uncertainty in the CO_2 synthesized frequency was less than 30 kHz. Microwave frequencies up to 16 GHz were used. A total uncertainty of ±1.0 MHz has been assigned to each water vapor frequency, mainly because of the difficulty in determining the center of the Doppler and pressure-broadened laser gain curve.

[a]Evenson *et al.*, 10 718 073(2) MHz [17]. From HCN laser, 10 718 068.6(5) MHz (Lamb dip). Blaney *et al.*, 10 718 068.71(3) MHz [18] (Lamb dip).

[b]Evenson *et al.*, 3 821 775(3) MHz [17]. McDonald *et al.*, 3 821 774.4(3.0) MHz [5].

[c]From 78–79-μm difference, 3 790 477(3) MHz.

[d]Frenkel *et al.*, 2 527 952.8(1) MHz [19] (Lamb dip). Hocker and Javan, 2 527 954.0 MHz [20].

[e]The 72.7-μm line was the only CW line oscillating in our laser near this wavelength. Reference [12] reports CW oscillation at 71.9, but not at 72.7 μm.

[f]Hocker *et al.*, 3 557 143(2) MHz [21].

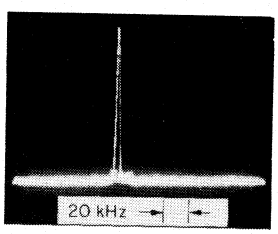

Fig. 3. Beat note at 54 MHz between the 118.8-μm CH_3OH laser line and the synthesized frequency. The spectrum analyzer was set for linear response with RF and video bandwidths of 3 and 10 kHz, respectively. The dc impedance of the diode was 550 Ω.

mum power, the shift between these two points appears to be less than 1 MHz.

A beat signal observed in the measurement of the 118.8-μm methyl alcohol line is shown in Fig. 3. *S/N* ratios varied from 10 to 20 dB. The frequency measurements along with corresponding CO_2 synthesis combinations are presented in Table II. Each CH_3OH line is identified by wavelength and CO_2 pump line. Here wavelengths were calculated from these measured frequencies and in some cases differ slightly from previously published values. In the third column, measured frequencies have been converted to vacuum wavenumbers. Methyl alcohol vapor pressure for each measurement is also given. In each case, the alcohol laser frequency was set to the center of the gain curve. Uncertainty in this procedure resulted in the assignment of a ±0.5-MHz error to each frequency measurement. In comparison, other measurement errors were considered negligible. The CH_3OH frequencies have not been corrected for any type of frequency shift.

The 170.6- and 118.8-μm lines have been measured previously by direct frequency multiplication from the microwave region [4]. The two results 1757.526(6) and 2522.78(1) GHz, are in excellent agreement with the values obtained here.

These measurements demonstrate the feasibility of synthesizing any frequency in the FIR with two $^{12}C^{16}O_2$ lasers and a microwave oscillator (*X* band or less). If, in addition, each $^{12}C^{16}O_2$ laser is stabilized to a narrow standing-wave saturated-absorption resonance in $^{12}C^{16}O_2$ itself, then the estimated fractional uncertainty in the synthesized frequency is less

TABLE II
MEASURED FREQUENCIES OF 13 METHYL ALCOHOL LASER LINES

METHYL ALCOHOL LASER LINE λ (μm)	MEASURED FREQUENCY (MHz) (UNCERTAINTY: ±0.5 MHz)	VACUUM WAVENUMBER (cm^{-1})	ALCOHOL LASER VAPOR PRESSURE (Torr)	CO_2 PUMP LINE	CO_2 FREQUENCY SYNTHESIS COMBINATION

than a few parts in 10^9. As a result, the accuracy of a measurement is often limited by the reproducibility of the unknown laser frequency. While other combinations and types of lasers can and have been used for frequency synthesis in the past, two stabilized CO_2 lasers by virtue of their large number of lines, high efficiency, simplicity, and excellent frequency reproducibility appear to be the most promising at present.[6] Since the 2nd and 3rd harmonics of CO_2 have been used to measure CO laser [27] and methane stabilized He-Ne laser frequencies [3], respectively, it is expected that the two-laser CO_2 frequency synthesis technique can be extended to even higher frequencies. Experiments to determine the highest mixing order which will produce usable signals are in progress in anticipation of demonstrating usefulness of this frequency synthesis technique to 100 THz.

ACKNOWLEDGMENT

The authors wish to thank M. Lojko for his contribution in producing the CO_2 frequency synthesis tables.

Time-Resolved Output Spectrum from a Hydrogen Fluoride Laser Using Mixtures of SF_6 and HI

N. R. GREINER

Abstract—**The time-resolved spectrum from a transverse-discharge hydrogen fluoride (HF) laser using a mixture of SF_6 and HI is reported. Because this spectrum matches that from a high-pressure H_2-F_2 laser, and because the SF_6-HI mixture is chemically stable, this laser should be a suitable and convenient source for probing H_2-F_2 amplifiers.**

In studying laser amplifiers, it is desirable to have an oscillator with output at all of the wavelengths where the amplifier has gain. H_2-F_2 chemical lasers lase on six vibrational levels, each containing several rotational levels [1], [2]. In further investigating transverse pulsed discharges in SF_6-HI mixtures [3], [4], we have found that this hydrogen fluoride (HF) laser medium provides an oscillator output spectrum that matches the spectrum from the high-pressure H_2-F_2 laser [2]. Furthermore, a large number of the transitions lase simultaneously. The greater stability of SF_6-HI mixtures makes them more convenient to use than H_2-F_2 mixtures.

The laser tube and the Marx bank have been described [5]. We used triggered spark gaps and a confocal unstable resonator with a magnification of 2, but dispensed with the double discharge. 2.5-cm-diam irises placed outside the tube allowed lasing only from the volume defined by the resonator. Individual spectral lines were isolated with a 0.5-m JaCo monochromator, and the pulse shapes were monitored with Ge:Au detectors (10–90-percent rise times, 3 ns) and displayed on oscilloscopes (10–90-percent rise times, 7 ns).

The HI was taken from a cylinder and condensed in a U tube cooled with dry ice to separate it from the H_2 impurity. It was then evaporated at dry-ice temperature into a stainless-steel tank, leaving behind the I_2 impurity. SF_6 was added to the tank to make the desired mixture. These mixtures gave good laser output after storage for a couple of weeks at room temperature. The laser tube was filled, fired, and evacuated as quickly as possible to avoid the reaction of HI with the materials in the tube.

The greatest output energies (0.5–0.8 J) and the best stability were obtained with mixtures containing 4–5 mol-percent HI. At 3.5 mol-percent HI the output ranged from 0 to 0.5 J, and at 9 mol percent the output was about 0.3 J. All of the work reported in the following was done with 4 mol-percent HI. The output energy was greatest when the tube was filled to 1.33×10^4 Pa (100 torr) with the mixture. At 8×10^3 and 2.4×10^4 Pa the average energies were 0.2 and 0.3 J, respectively. The richest output spectra were also observed at 1.33×10^4 Pa.

Fig. 1 shows the time-resolved spectrum at 1.33×10^4 Pa. Each transition is referenced to the spectrally unresolved (total) pulse to show how the transitions overlap in time. The decrease in peak power with increasing v is partly due to the decrease in grating efficiency at longer wavelengths. Absolute comparisons would also require knowledge of the detector efficiency at the different wavelengths, which we do not have. Comparisons within a vibrational band are somewhat more valid, so we can say that the transitions shown in Fig. 1 are the most important for a given band because a search with both a spectrograph [6] and the monochromator showed no other detectable transitions.

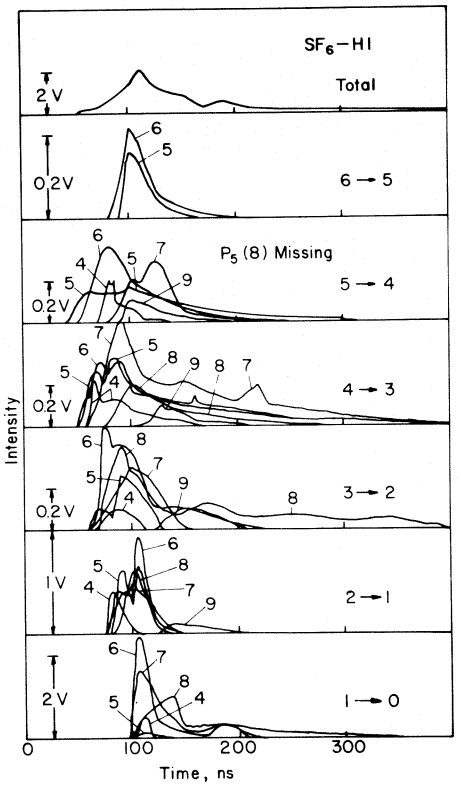

Fig. 1. Time-resolved HF laser line intensities from an SF_6 (12.8 kPa)-HI (0.53 kPa) mixture. The arrows on the right show the change in the vibrational quantum number, and the numbers on the curves show the rotational quantum number in the final vibrational state. These are all *P*-branch transitions. The peak power in the undispersed beam is 10 MW.

The sequence in which the levels begin to emit suggests cascading from $v = 5$ down to $v = 1$. This idea is supported by the observed vibrational distribution among the products of the reaction F + HI, which is strongly peaked at $v = 5$, [7]. It is interesting that nearly all of the transitions within a vibrational band turn on simultaneously. This suggests that lasing occurs before the molecule has a chance for much rotational relaxation [8]. Finally, we note the period of ~20 ns (from 100 to 120 ns in Fig. 1), during which all but two of the transitions are lasing. This feature makes this laser attractive for the stimulation of short-pulse high-pressure H_2-F_2 amplifiers, where many transitions have gain, but only for a few nanoseconds.

Continuous Oscillation of a Lithium Neodymium Tetraphosphate Laser with 200-μW Pump Threshold

KENJU OTSUKA AND TOMOAKI YAMADA

Abstract—**Room temperature CW oscillation of a lithium neodymium tetraphosphate ($LiNdP_4O_{12}$) (LNP) laser with thresholds in the fractional milliwatt range is reported. With a 5145-Å pump, observed threshold was 200 μW and the slope efficiency was 43 percent.**

Recently, Danielmeyer *et al.* reported continuous oscillation of a $(Nd,Y)P_5O_{14}$ laser with a pump threshold of 1 mW [1]. We reported quasi-continuous oscillation of a lithium neodymium tetraphosphate $LiNdP_4O_{12}$ (LNP) laser pumped longitudinally as well as transversely with an argon laser [2], [3]. We present here the CW operation of a LNP laser with thesholds in the submilliwatt range. The measured minimum threshold of 200 μW is, to our knowledge, the lowest obtained with any laser material.

An argon laser ($\lambda = 5145$ Å) served as a pump. A platelet-like LNP crystal of 0.3-mm thickness, which absorbed 50 percent of the pump light, was pumped longitudinally. The resonator consisted of mirrors M_1 (radius of curvature $R_1 = \infty$; transmission at 1.047_7 μm, $T_1 = 0.1$ percent; transmission at 5145 Å, $T' = 83$ percent) and M_2 ($R_2 = 9$ cm, $T_2 = 0.1$, 1.2, 2, 3 percent) separated by about 9 cm. The cavity was nearly semiconcentric. The mirror M_2 was movable back and forth precisely by the motor-driven micrometer screw. The crystal was cemented by a heat-sink compound on the mirror M_1. The focal length of the lens focusing the pump beam was 5 cm and the pump light was focused on an area smaller than the beam-waist spot size of the LNP laser.

Manuscript received April 22, 1975.

The authors are with the Musashino Electrical Communication Laboratory, Nippon Telegraph and Telephone Public Corporation, Musashino-shi, Japan.

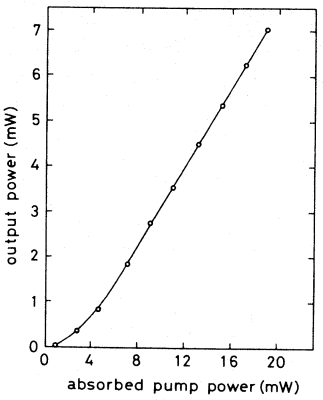

Fig. 1. The output power through the mirror M_2 ($T_2 = 1.2$ percent) as a function of the absorbed pump power at 5145 Å.

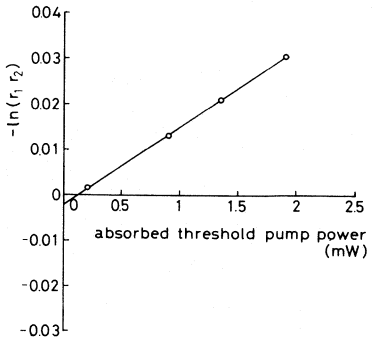

Fig. 2. The laser threshold as a function of $-\ln(r_1 r_2)$, where r_1 and r_2 are the mirror reflectivities.

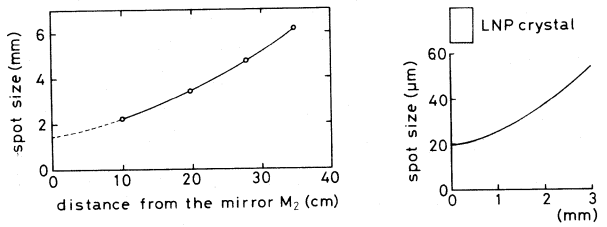
The output power through the mirror M_2 is shown in Fig. 1 as a function of the absorbed pump power at 5145 Å, where T_1 and T_2 were fixed at 0.1 and 1.2 percent, respectively. The threshold was $P_{th} = 920$ μW and the slope efficiency was 43 percent.

The round-trip loss of the cavity L_c was directly measured by the change of threshold with $-\ln(r_1 r_2)$, where r_1 and r_2 are mirror reflectivities. The round-trip loss L_c consists of propagation loss of the crystal, transmission losses of two cavity mirrors, and diffraction loss. From Fig. 2, the round-trip loss, except the transmission losses of the mirrors, is found to be 0.002. The minimum threshold of 200 μW was obtained when T_1 and T_2 were fixed at 0.1 percent. From the slope of the measured line, the round-trip gain per absorbed pump power g is determined as 1.67×10^{-2} mW^{-1}.



The output-beam spot size of the LNP-laser radiation was measured as a function of the distance from the mirror M_2, as is shown in Fig. 3(a), and we estimated the spot size at the mirror M_2 as $w_m = 1.5$ mm. With $w_m = 1.5$ mm and $R_2 = 9$ cm, the oscillating-beam spot size in the 0.3-mm-thick LNP crystal was calculated in Fig. 3(b). From Fig. 3(b), the beam spot size averaged over the crystal is found to be $w_a = 20$ μm.

The round-trip gain G is given by [4]

$$G = 2\,\Delta N \sigma_l L_{\text{crystal}}$$

$$\Delta N = P_{\text{th}} \tau_f / h\nu \pi w_a^2 L_{\text{crystal}} \qquad (1)$$

where ΔN is the absorbed Nd ion density, σ_l is the effective emission cross section, L_{crystal} is the crystal length, τ_f is the fluorescence lifetime, h is Planck's constant, and ν is the pump frequency.

(a) (b)

Fig. 3. The oscillating-beam spot size of the LNP laser. (a) The output-beam spot size as a function of the distance from the mirror M_2 ($R_2 = 9$ cm). (b) The oscillating-beam spot size in the LNP crystal. The mirror spacing is about 9 cm and the crystal is attached on the mirror M_1.

TABLE I
OBSERVED CHARACTERISTICS OF LNP LASER

thickness	w_a	η	$P_{th,m}$	g (obs.)	g (calc.)
0.3 mm	20 μm	0.5	200 μW	1.67×10^{-2} mW^{-1}	1.59×10^{-2} mW^{-1}
0.7	22	0.8	370	1.43×10^{-2}	1.32×10^{-2}

Note: $P_{th,m}$ is the observed minimum threshold and η is the pumping efficiency.

The oscillation threshold is obtained when

$$G = L_c. \tag{2}$$

From (1) and (2), the oscillation threshold is given by

$$P_{th} = L_c h\nu\pi w_a^2 / 2\sigma_l \tau_f. \tag{3}$$

Therefore one obtains the round-trip gain per absorbed pump power g as follows:

$$g = G/P_{th} = L_c/P_{th} = 2\sigma_l \tau_f / h\nu\pi w_a^2. \tag{4}$$

With $\sigma_l = 3.2 \times 10^{-19}$ cm^2 [5], $\tau_f = 120$ μs [6], $\nu = 5.8 \times 10^{14}$ Hz, and $w_a = 20$ μm, g is calculated as 1.59×10^{-2} mW^{-1}. This is in good agreement with the value of 1.67×10^{-2} mW^{-1} obtained from Fig. 2.

Then we pumped a LNP of 0.7-mm thickness, which absorbed 80 percent of the pump light, in the same cavity configuration. The observed minimum threshold was 370 μW when T_1 and T_2 were fixed at 0.1 percent. The obtained results are shown in Table I together with those for the 0.3-mm-thick LNP.

In conclusion, we have obtained continuous operation of a $LiNdP_4O_{12}$ laser with a pump threshold of 200 μW at 5145 Å. There is good agreement between theory and experiment. If we convert our result to the light-emitting-diode (LED) pumping ($\lambda = 0.8$ μm), the threshold power for a LED to lase a LNP crystal is calculated as 130 μW, assuming $w_a = 20$ μm.

ACKNOWLEDGMENT

Induced-Emission Cross Sections for the $^4F_{3/2} \rightarrow {}^4I_{13/2}$ Transition in Neodymium Laser Glasses

RALPH R. JACOBS AND MARVIN J. WEBER

Abstract—**Induced-emission cross sections for the $^4F_{3/2} \rightarrow {}^4I_{13/2}$ transition of Nd^{3+} in several commercial and experimental laser glasses have been determined using spectroscopic data and the Judd-Ofelt treatment of electric-dipole transition probabilities.**

Recently, Krupke [1] determined the induced-emission cross section for the $^4F_{3/2} \rightarrow {}^4I_{11/2}$ transition of Nd^{3+} in four silicate laser glasses using spectroscopic data and the Judd-Ofelt treatment of crystal-field-induced electric-dipole transition probabilities. We have utilized this approach to determine the cross sections for the $^4F_{3/2} \rightarrow {}^4I_{13/2}$ transition of Nd^{3+} in several silicate and phosphate glasses. These results can be used to evaluate Nd^{3+} laser action at longer wavelengths,[1] ≈1.3-1.4 μm, and to estimate losses due to amplified spontaneous emission in large Nd:glass amplifiers arising from $^4F_{3/2} \rightarrow {}^4I_{13/2}$ transitions.

In Fig. 1, the $^4F_{3/2} \rightarrow {}^4I_{13/2}$ fluorescence spectrum of Nd^{3+} is shown for two silicate glasses (ED-2 and LG 650) and one phosphate glass (P-107) at 300 K.[2] These spectra typify the variations of line shape and position observed for the different glasses investigated. In all cases, the emission bands were inhomogeneously broadened and asymmetric. Fluorescence was excited using a frequency-doubled Nd:YAG laser (≈150-ns pulsewidth at 532 nm) and observed with a 0.3-m grating monochromator equipped with a PbS detector and boxcar integrator. The detection system was calibrated for relative spectral response using a quartz-tungsten-iodine standard lamp. The spectral resolution was ≈3 nm.

The peak induced-emission cross sections σ_p for Nd^{3+} were determined from the expression

$$\sigma_p(\lambda_p) = \frac{\lambda_p^4}{8\pi c n^2 \Delta\lambda_{\text{eff}}} A(^4F_{3/2} \rightarrow {}^4I_J) \tag{1}$$

Manuscript received April 28, 1975. This work was performed under the auspices of the U.S. Energy Research and Development Administration.

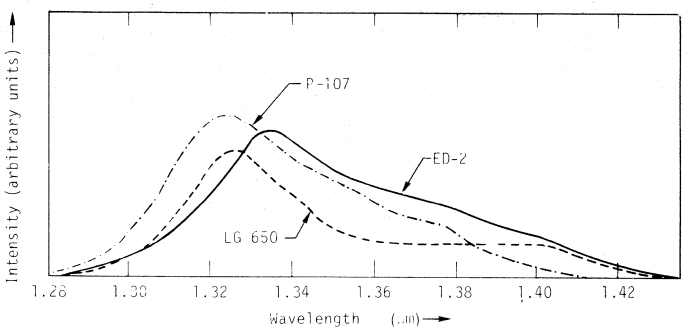

Fig. 1. Room-temperature fluorescence spectra of Nd^{3+} for the $^4F_{3/2} \rightarrow {}^4I_{13/2}$ transition in silicate (ED-2, LG 650) and phosphate (P-107) glasses. The individual curves are each corrected for the spectral response of the detection apparatus but, for clarity of presentation, the individual intensity scales are different.

where λ_p is the wavelength of the fluorescence peak, n is the refractive index at λ_p, and $\Delta\lambda_{eff}$ is the effective bandwidth. The last quantity was obtained by integration of the fluorescence band [1] and was so determined since, as previously noted, the fluorescence spectra were asymmetric. The spontaneous-emission probability A for transitions to the Jth multiplet was calculated using the Judd–Ofelt intensity parameters Ω_2, Ω_4, and Ω_6 for crystal-field-induced electric-dipole transitions. These intensity parameters were obtained from a least squares fit of measured absorption intensities, as described in [1]. The agreement between measured and calculated absorption linestrengths was generally good with rms deviations of $\lesssim 5$ percent. Details of the spectral intensities, resulting Ω parameters, and variations of induced-emission cross sections with glass composition will be presented in a future publication [2].

Measured bandwidths, peak wavelengths, and cross sections of the $^4F_{3/2} \rightarrow {}^4I_{13/2}$ transition for several commercial and experimental silicate and phosphate glasses are summarized in Table I. The sources of the glasses were as follows: 3669A—American Optical; LSG-91H, LSG-95, LHG-5—Hoya; P-25, P-107—Kigre; L-41—National Bureau of Standards; ED-2, ED-8—Owens-Illinois; and LG 650—Schott. Most of the phosphate glasses are experimental. P-25 and L-41, which are K_2O–BaO–P_2O_5 and MgO–Al_2O_3–P_2O_5 glasses, respectively, are included since they represent the extremes of the cross sections observed thus far in phosphate glasses. The uncertainties in the listed λ_p and σ_p values are estimated to be ±2 nm and ±10 percent, respectively. Included in the final column of Table I, for comparison, are the peak cross sections for the $^4F_{3/2} \rightarrow {}^4I_{11/2}$ transition. The stated values of this latter cross section for ED-2 and LSG-91H are in good agreement with the corresponding results in [1] which, in turn, agree with available experimental determinations.

A check was made on the internal consistency of the σ_p values in Table I via a separate determination of the ratio of the cross sections at ≈ 1.06 μm to that at ≈ 1.33 μm for representative silicate and phosphate glasses. An expression for calculating such a cross section ratio has been given by Singh *et al.* [3]. In addition to index and wavelength factors, it contains the ratio of corrected peak fluorescence intensities for the two bands. To within the stated accuracy of the σ_p values listed in Table I (±10 percent), the results of this method agreed with the corresponding ratio of cross sections evaluated using (1).

Whereas the $^4F_{3/2} \rightarrow {}^4I_{13/2}$ fluorescence spectra and cross sections for the lithium-alkaline earth-silicates ED-2, ED-8, LSG-91H, and LSG-95 are similar, they differ significantly from the potassium-heavier alkaline-earth-silicates 3669A and LG 650. In the phosphate glasses, the cross sections

TABLE I
EFFECTIVE BANDWIDTH $\Delta\lambda_{eff}$, PEAK FLUORESCENCE WAVELENGTH λ_p, AND INDUCED-EMISSION CROSS SECTION σ_p FOR THE $^4F_{3/2} \rightarrow {}^4I_{13/2}$ TRANSITION IN NEODYMIUM LASER GLASSES

	$^4F_{3/2} \rightarrow {}^4I_{13/2}$			$^4F_{3/2} \rightarrow {}^4I_{11/2}$

*Result from [1].

for both the $^4F_{3/2} \rightarrow {}^4I_{13/2}$ and $^4F_{3/2} \rightarrow {}^4I_{11/2}$ transitions can be larger than in the silicates. This is due to a combination of narrower emission bandwidths and larger Ω values. For all glasses studied, the peak cross sections for transitions to the $^4I_{13/2}$ state are about one-fourth as large as those to $^4I_{11/2}$, the saturation flux being correspondingly higher. The cross section to $^4I_{15/2}$, however, is very much smaller due to the small transition matrix element (the fluorescence branching ratio to $^4I_{15/2}$ is <0.01) and the larger splitting of the $J = 15/2$ manifold and resulting increased bandwidth.

Finally, it should be noted that the *net* cross sections for stimulated emission may be smaller than those given in Table I because of excited state absorption from $^4F_{3/2}$. While this is predicted [1] to be a small effect at ≈ 1.06 μm, it may not be at ≈ 1.33 μm since calculated linestrengths from $^4F_{3/2}$ to $^4G_{7/2}$, $^2K_{13/2}$ are approximately one-half as large as those to $^4I_{13/2}$. Detailed estimates of this excited state absorption require information about the spectral overlap of the absorption and emission profiles which are presently not available.

ACKNOWLEDGMENT

The authors wish to thank Dr. J. Paisner for performing the spectral calibration of the fluorescence detection apparatus. They also wish to thank C. Dobler, J. Lynch, and R. Morgret for their excellent assistance in the data acquisition and reduction.

Performance of a Compact Sealed 200-W CO_2 Laser

THEODORE S. FAHLEN

Abstract—**The performance characteristics of a compact (3-ft^3) TEM_{00}-mode single-wavelength CO_2 laser are described. The optic axis, gas flow velocity, and glow discharge are mutually orthogonal in the sealed-off laser head. The laser produces up to 300 W of TEM_{00}-mode 10.6-μm power.**

In this correspondence, the design and performance characteristics of a compact 200-W CW CO_2 laser head are described. To our knowledge, this CO_2 laser head is the smallest yet built that operates in this power regime. In order to obtain high CW power output from this compact sealed CO_2 laser, the laser head utilized a rapid recirculating gas flow, a stable folded optical cavity, and a unique CW glow discharge configuration. The advantages of using a rapid recirculating gas flow to increase the obtainable power per unit length of discharge by convectively cooling the active gas of high-power CW CO_2 lasers have been discussed previously [1]–[3]. The use of a folded optical cavity allows a long optical cavity length to be contained in a short structure. The long cavity length not only provides sufficient gain length for high output power, but also allows single-wavelength operation to be obtained [4] without the use of intracavity wavelength selectors (such as a diffraction grating) with their inherent losses. The stable optical resonator provides a TEM_{00} mode beam. The unique electrode configuration provides a stable dc glow discharge of high power density without additional radio-frequency, ultraviolet, or electron-beam sources of ionization.

The laser head dimensions are 24 in long, 16 in high, and 13.5 in wide. The 3-ft^3 head weighs 97 lb. A vaneaxial blower contained within the vacuum enclosure circulates the laser gas through the discharge region at a velocity of 50 m/s and then through a gas-to-liquid heat exchanger, also contained within the vacuum enclosure.

The optical cavity and electrode configuration are shown schematically in Fig. 1. The cathode consists of a copper tube, 1.59 cm in diameter and 33 cm long located above and upstream of the first optical beam. The anode, located directly below the optical cavity, consists of 18 copper strips, each 8.06 cm long by 1.19 cm wide and separated by 0.51 cm. Each individual anode pad is resistively ballasted with 1.4 kΩ. Both the cathode and anode are water cooled.

The optical cavity consists of two flat highly reflective folding mirrors, separated by 42 cm, a highly reflective non-output mirror of 20-m radius of curvature, and a flat output mirror of 48-percent transmission at 10.6 μm. The intracavity beam is folded to pass nine times through the discharge region. The resulting total optical-cavity length of this stable resonator is 3.9 m.

The optimum gas mixture, in terms of laser efficiency, was found to be 25-torr He, 10-torr N_2, and 2.5-torr CO_2.

The laser output power and efficiency are plotted as a function of input current in Fig. 2. The laser efficiency is defined as the laser output power divided by the total power delivered to the laser head. The maximum power attained was 300 W. The total power input includes the 215 W of power required to run the vaneaxial blower but not the power lost in the ballast resistors as no attempt was made to minimize the ballast resistance. The maximum current input, limited by arc formation in the positive column of the discharge, was about 5 A, corresponding to an input power density to the positive column of 5.8 W/cm^3.

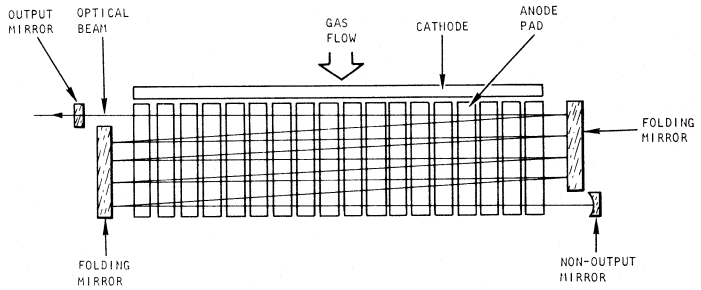

Fig. 1. Diagram of discharge and optical path region.

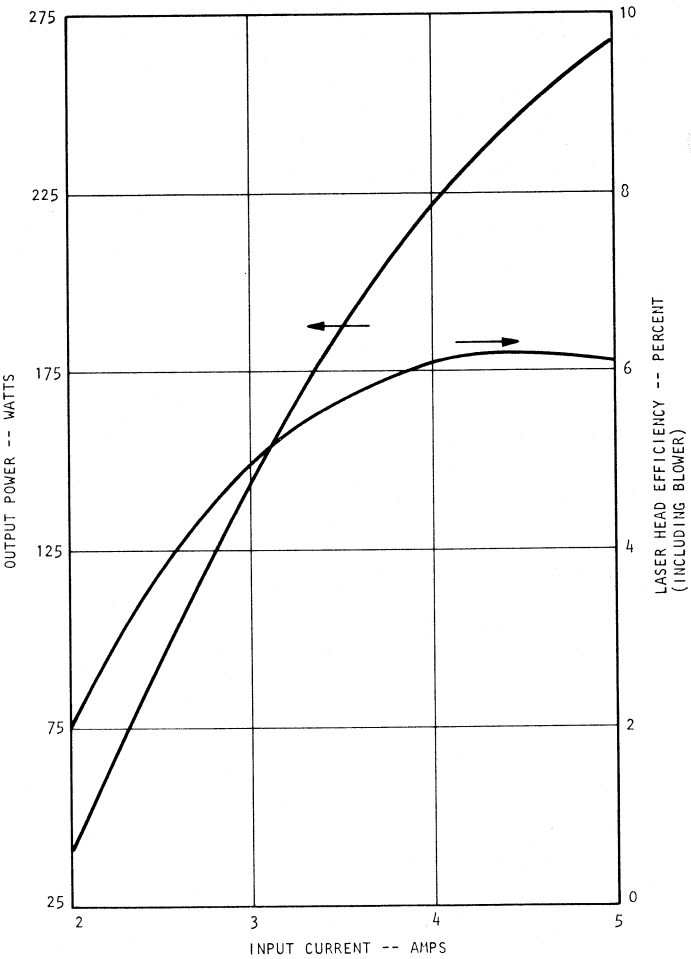

Fig. 2. Laser power and efficiency versus input current.

The laser output wavelength was measured to be 10.59 μm, corresponding to the $P(20)$ laser transition. Single-wavelength operation is obtained by virtue of the long length of the resonant cavity [4] so that no intracavity wavelength discriminating elements are required. Single-wavelength operation remained invariant as mirror alignment and applied current were varied.

The transverse mode quality of the laser was measured by scanning a small aperture through the beam in the far field as imaged by a lens. The output of a Au:Ge detector collecting the energy passing through the aperture was then displayed on an oscilloscope. The beam profile was found to be Gaussian (TEM_{00}). The full angular beam divergence θ to the $1/e^2$ in-

Manuscript received May 12, 1975. This work was supported by the Air Force Systems Command under Wright-Patterson Air Force Base Contract F33615-74-C-1056.

The author is with the Electro-Optics Organization, GTE Sylvania, Inc., Mountain View, Calif. 94042.

tensity radius was also measured with the scanning aperture and oscilloscope, and was found to be 1.6 ± 0.3 mrad.

The laser was designed to operate in a sealed-off condition, i.e., no gas was added to the system once it was filled with the proper gas mix. It was found experimentally that the power monotonically decreased from 230 to 200 W after 1 h of continuous operation at 4 A of input current, corresponding to a power decrease of 13 percent/h.

The primary factor causing the output power to diminish with time is the degradation of the laser gas mixture. One known effect is that the action of the discharge decomposes CO_2 molecules into CO and O_2. It has been shown [5] that the presence of O_2 molecules in the mix is detrimental to laser action. Furthermore, the formation of oxides of the various components within the vacuum shell tends to reduce the partial pressure of O_2 in the laser. To maintain chemical equilibrium, more CO_2 dissociates and the laser output power decreases. It was found that the power output did not decrease unless the laser was operated. Therefore, outgassing or air leakage without the presence of a discharge (or heat from the discharge) does not affect the rate of power decrease. It is then concluded that the rate of power decrease depends on some chemically contaminating reaction among the various gases and components within the vacuum shell brought about by the action of the discharge. Adding a slow-flow continuous-gas-replenishment system to the laser would drastically reduce the rate of power degradation but would add complexity to the system.

Guided-Wave Acoustooptic FM Modulator

C. P. CHRISTENSEN, W. H. STEIER, AND R. BASU

Abstract—**Phase modulation of guided optical waves by longitudinal sound is observed in a thin-film modulator of simple construction. The dependence of modulation sideband amplitudes upon acoustic strain is investigated, and device performance is found to be close to that predicted by theory.**

Manuscript received May 13, 1975. This work was supported by the Joint Services Electronics Program through the Air Force Office of Scientific Research (AFSC).

The authors are with the Department of Electrical Engineering, University of Southern California, Los Angeles, Calif. 90007.

Acoustooptic modulation schemes suitable for use in integrated optics have been the subject of several recent investigations. Bragg deflection of guided light by acoustic surface waves [1], mode conversion by bulk shear waves [2], as well as phase modulation by bulk longitudinal and shear waves have been reported [3]. Acoustic devices can often use amorphous or multicrystal films which are in general use as guiding layers for integrated optics and hence have the advantage of possibly using the same material for the wave-guiding layer and the modulator. In this correspondence we discuss a simple FM modulator design based upon the interaction of light and longitudinal sound in a thin-film waveguide.

The physical construction of the experimental device is shown in Fig. 1. A 35° Y-cut $LiNbO_3$ transducer is bonded with phenylbenzoate to the bottom of a glass substrate (n_2 = 1.51) and operated at its seventh overtone frequency of 62 MHz. Bulk longitudinal waves generated by the transducer travel through the substrate and successive overlayers of Corning 7059 sputtered glass (n_1 = 1.57, thickness = 0.6 μ), solution deposited silica film [4], (n_0 = 1.44, thickness = 1 μ), and sputtered aluminum (thickness = 25 μ). The layer thicknesses are chosen so that acoustic reflection at the aluminum–air interface produces a standing acoustic wave which has a peak at the sputtered glass layer. The sputtered glass film acts as an optical waveguide which is isolated from the aluminum overlayer by the low-index silica film. Light is introduced into the waveguide by means of prism couplers, and the guided optical waves are then phase modulated at the acoustic frequency primarily through the photoelastic effect. Qualitative results for a somewhat similar modulator utilizing an acoustic traveling wave to produce phase modulation have been given by Brandt *et al.* [3]. However, use of a standing wave geometry produces almost pure phase modulation with little AM and increases the efficiency of the device by a factor of 4, since the bandwidth of a modulator of this type is approximately that of the acoustic transducer.

This bulk acoustic wave and guided optical wave interaction is not expected to have an increased modulation efficiency over the more conventional acoustooptic interaction in which the light is not guided. Increased efficiency requires also guiding the sound as in acoustic surface waves. However, this device gives almost pure FM or PM modulation, which is difficult to achieve in interactions where both the sound and light are guided waves, or in interactions where both the sound and light are not guided waves.

The modulator output spectrum was observed with an optical hetrodyne arrangement which is similar to that used by Kaminow [5]. Examples of spectra are shown in Fig. 2. Acoustic strain in the substrate was monitored by propagating an He-Ne laser beam through the glass substrate bulk and observing the intensity of the zeroth diffraction order during the sound pulse. The standing wave diffraction results of Sanders [6] were then used to obtain the acoustic strain from the diffraction measurements.

The efficiency of a modulator of this type can be accurately

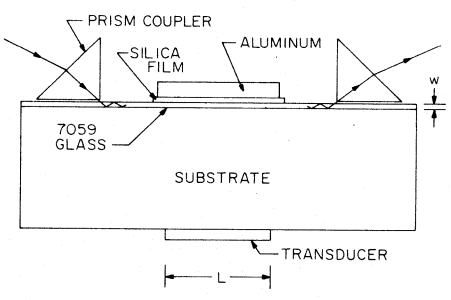

Fig. 1. Thin-film FM modulator construction (not to scale).

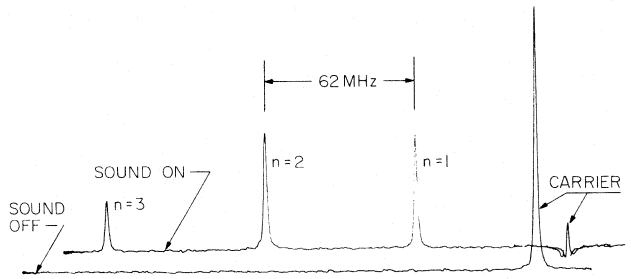

Fig. 2. Modulator output spectra obtained in the absence of an acoustic field and with an acoustic intensity corresponding to $\delta\phi = 2.55$.

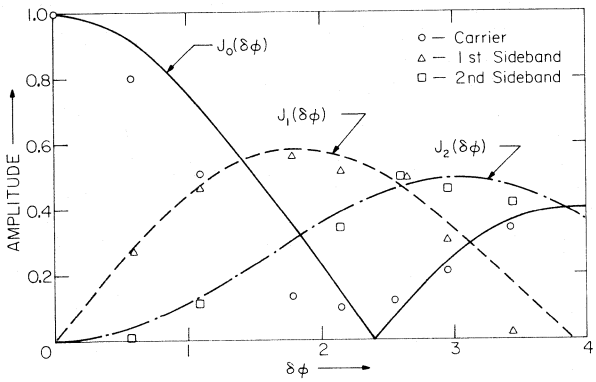

Fig. 3. Amplitude of the carrier and first two sidebands as a function of phase shift $\delta\phi$. Equation (1) was used to obtain $\delta\phi$ from the acoustic strain measured by light scattering in the substrate bulk.

estimated by using the characteristic equation of a planar waveguide [7]. For TE waves we find the phase shift corresponding to an acoustic strain S to be

$$\delta\phi = \frac{-kLS}{2\bar{\beta}\,[kw + (1/b_0) + (1/b_2)]} \left\{ n_1^4\, p_{12}^{(1)} \left[kw + \frac{b_0}{b_0^2 - b_1^2} + \frac{b_2}{b_2^2 - b_1^2} \right] + \frac{n_0^4\, p_{12}^{(0)}\, b_1^2}{b_0\,(b_1^2 - b_0^2)} + \frac{n_2^4\, p_{12}^{(2)}\, b_1^2}{b_2\,(b_1^2 - b_2^2)} + 2b_1^2\, kw \right\} \tag{1}$$

where n_i and $p_{12}^{(i)}$ are, respectively, the refractive index and photoelastic coefficient of the ith medium. The acoustic overlayer is taken to be medium zero, the optical guide to be medium 1, and the substrate as medium 2. $\bar{\beta}$ is given by the ratio of the optical waveguide propagation constant to the free-space propagation constant k. The width of the optical guide is taken to be w, the length of the interaction region to be L, and $b_i^2 = \bar{\beta}^2 - n_i^2$. The first three terms in brackets on the right side of (1) arise from modulation of the refractive indices of the three media, while the fourth term is due to modulation of the waveguide thickness. A result similar to (1) can be derived for TM waves.

Using the measured strain values in (1) with $p_{12}^{(0)} \cong p_{12}^{(1)} \cong p_{12}^{(2)} = 0.24$ and $L = 7.4$ mm, we find $\delta\phi = 3.0 \times 10^4 S$ where $\delta\phi$ is in radians. Since hetrodyne detection was used, the measured amplitude of the nth sideband should be proportional to $J_n(\delta\phi)$. The sideband amplitudes and the acoustic strain were measured at several levels of input sound power and compared to these theoretical predictions in Fig. 3. The results show the modulator is working as predicted and is producing a largely FM output spectrum.

The effect of the reflected acoustic wave on the bandwidth of the transducer can be eliminated by a small angle between the transducer and the guiding layer in the plane perpendicular to the light propagation. If the substrate is sufficiently thick, the reflected acoustic wave will be offset from the transducer and can be conveniently absorbed. The modulation power per unit bandwidth of our modulator was largely determined by the transducer efficiency; the achievable modulation efficiency, as discussed earlier, is expected to be the same as bulk acousto-optic modulators [8].

At high acoustic intensities we have also observed beam deflection phenomena similar to those described by Brandt *et al.* [3], in which the distribution of light in the plane of the waveguide is altered by the presence of the acoustic beam. Although the total optical power in the mode remains constant, scattering from the central portion of the m line into the wings and the converse effect have both been observed. The central spot intensity, however, fluctuated by about 15 percent at most, and modulator operation was not significantly affected. Variations in strain phase or amplitude in the waveguide plane could perturb the light distribution in the waveguide, but experimental verification of this is difficult and was not attempted.

In summary, we have demonstrated the feasibility of a guided-wave FM modulation technique employing an acoustic standing wave. The modulator output spectrum has been shown to be very close to that predicted by theory.

Second-Harmonic Generation in Birefringent Crystals by a Gaussian Beam with an Elliptical Cross Section

F. M. LIBRECHT AND J. A. SIMONS

Abstract—**The theory of second-harmonic generation (SHG) in birefringent crystals by a Gaussian beam with an elliptical cross section is developed in the assumption of no depletion of the fundamental beam. This study reveals that the doubling efficiency at optimum elliptical focusing is higher than at optimum circular focusing.**

The second-harmonic generation (SHG) of coherent light in birefringent crystals by a focused Gaussian beam with a circular cross section has been studied extensively [1]–[3]. At increasing focusing, the critical index-matching condition is affected considerably. This critical index matching occurs only in the plane of the direction of propagation z and the

Manuscript received May 27, 1975. F. M. Librecht holds a fellowship of the Belgisch Nationaal Fonds voor Wetenschappelijk Onderzoek.

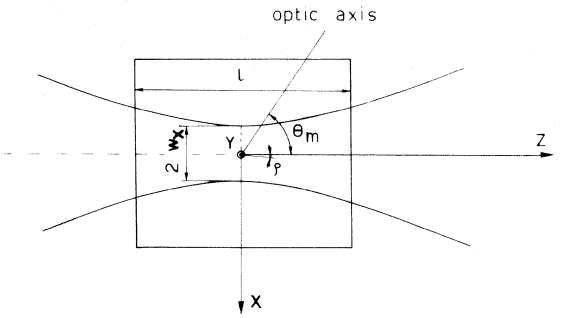

Fig. 1. Orientation of an ADP crystal in the focus of a Gaussian laser beam with an elliptical cross section.

crystal optic axis, commonly called the walkoff plane (Fig. 1). By changing the shape of the laser beam into an elliptical cross section, it is possible to focus more tightly in the nonwalkoff plane (yz plane) without affecting the critical index matching in the walkoff plane. This has been applied to parametric oscillation [4] and to SHG [5]. However, a rigorous analysis of SHG by a Gaussian beam with an elliptical cross section is not available. We therefore develop, in this correspondence, the theory of SHG by an elliptical Gaussian beam, assuming no depletion of the fundamental beam by the doubling process. As a result, using ADP crystals with a length of a few centimeters for the doubling of the 632.8-nm He–Ne light, we point out that the doubling efficiency at optimum elliptical focusing is about 25 percent higher than at optimum circular focusing.

Consider an ADP crystal of length l in the focus of a Gaussian laser beam with an elliptical cross section (Fig. 1). The beam diameters at $z = 0$ are $2w_x$ and $2w_y$ in the x and y directions, respectively. The fundamental beam is introduced in the crystal as an ordinary wave phase matched to the extraordinary second-harmonic wave. The input and output faces of the crystal are parallel and are cut so that at approximately normal incidence the laser beam passes through the crystal in the critical index-matching direction z, at an angle θ_m to the optic axis. The optic axis lies in the xz plane. ρ is the angle of double refraction. The medium surrounding the crystals is supposed to have the same refractive index as the crystal at the fundamental frequency.

The electromagnetic field of a Gaussian beam with an elliptical cross section is described by Carter [6]. In the paraxial approximation, the electric field at the fundamental frequency ω can be derived from [6, eq. (11)]

$$E_\omega(x,y,z) = E_\omega (z_{Rx} z_{Ry})^{1/2} \exp(ikz) \cdot \frac{\exp\left\{-\frac{k}{2}\left[x^2/(z_{Rx}+iz) + y^2/(z_{Ry}+iz)\right]\right\}}{(z_{Rx}+iz)^{1/2}\,(z_{Ry}+iz)^{1/2}} \tag{1}$$

where

$$z_{Rx} = \frac{kw_x^2}{2} \tag{2a}$$

$$z_{Ry} = \frac{kw_y^2}{2}. \tag{2b}$$

The constant E_ω is the fundamental electric-field amplitude in the origin, and k is the propagation constant in the crystal.

We calculate the generated harmonic field following the well-known formal approach [1], [7]. We assume no depletion of the fundamental beam by the doubling process and we neglect any absorption at the fundamental and harmonic frequencies. We take into account the additional mismatch term when the crystal is tilted away from the index-matching direction by a small angle Φ (as mentioned in [1, eq. (54)]). Eventually, the harmonic power is calculated by integrating the z component of the time-averaged Poynting's vector over the beam cross section. Describing the ellipticity of the laser beam by the parameter

$$\alpha = \frac{w_y}{w_x} \tag{3}$$

and defining a focusing parameter

$$\zeta = \frac{l}{\alpha k w_x^2} \tag{4}$$

the harmonic power $P_{2\omega}$ at the exit face ($z = l/2$) of the crystal is written as

$$P_{2\omega} = KP_\omega^2 \frac{k^2 w_x w_y}{4} \int_{-\zeta}^{+\zeta} dv \int_{-\zeta}^{+\zeta} dv' \frac{\exp\left[2ik\rho\Phi\alpha z_{Rx}(v-v')\right] \exp\left\{-\left[\rho^2\alpha^2 z_{Rx}^2 (v-v')^2/w_x^2\right]\right\}}{\left\{1+i\left[(1+\alpha^2)/\alpha\right] v - v^2\right\}^{1/2} \left\{1-i\left[(1+\alpha^2)/\alpha\right] v' - v'^2\right\}^{1/2}}. \tag{5}$$

P_ω is the power of the fundamental beam. K is a constant depending on the type of the crystal and on the fundamental frequency ω (as defined by [3, eq. (2.20)]). When $\alpha = 1$, our result (5) agrees with [1, eq. (31)] and with [3, eqs. (2.22), (2.23), (2.25)].

We calculated asymptotic and exact values of $P_{2\omega}/KP_\omega^2$, (5) as a function of w_x. The asymptotic values are listed as follows:

$$\zeta \ll 1 \qquad \frac{\rho l}{w_x} \ll 1 \qquad \frac{P_{2\omega}}{KP_\omega^2} = \frac{l^2}{\alpha w_x^2} \tag{6a}$$

$$\zeta \ll 1 \qquad \frac{\rho l}{w_x} \gg 1 \qquad \frac{P_{2\omega}}{KP_\omega^2} = \frac{\pi^{1/2} l}{\rho\alpha w_x} \tag{6b}$$

$$\zeta \gg 1 \qquad \frac{\rho k w_x \alpha}{2} \gg 1 \qquad \alpha < 1 \qquad \frac{P_{2\omega}}{KP_\omega^2} = \frac{\alpha\pi^{1/2} k w_x}{\rho} \cdot K(1-\alpha^4) \tag{6c1}$$

$$\alpha > 1 \qquad \frac{P_{2\omega}}{KP_\omega^2} = \frac{\pi^{1/2} k w_x}{\alpha\rho} \cdot K(1-\alpha^{-4}) \tag{6c2}$$

$$\zeta \gg 1 \qquad \frac{\rho k w_x \alpha}{2} \ll 1 \qquad \frac{P_{2\omega}}{KP_\omega^2} = \pi^2 \alpha k^2 w_x^2. \tag{6d}$$

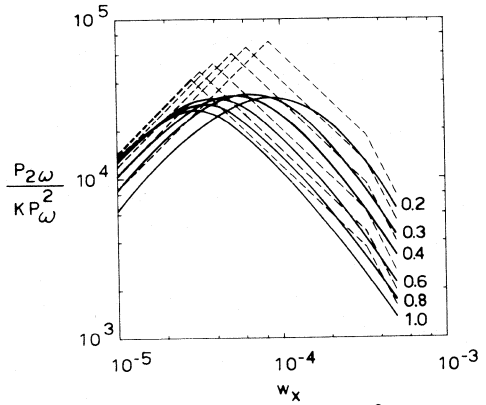

Fig. 2. Asymptotic and exact curves of $P_{2\omega}/KP_\omega^2$ (5) as a function of the beam radius w_x in the x direction for an ADP crystal with a length of 2 cm and for different values of the parameter α, (3).

$K(1-\alpha^4)$ and $K(1-\alpha^{-4})$ are complete elliptic integrals of the first kind [8]. When $\alpha = 1$ (circular cross section) our asymptotic solutions agree with the asymptotic solutions of [1] and [3]. We calculated the exact values by using an algorithm based on the Gaussian and Kronrod quadrature formulas [9].

In Fig. 2 we plotted asymptotic and exact curves on a log-log plot for an ADP crystal with a length of 2 cm and for different values of the parameter α, (3). The maximum doubling efficiency at optimum focusing occurs when α equals $\frac{1}{3}$. This maximum is not a critical function of the parameter α. The optimum shaping and focusing of the laser beam results in a 25-percent increase of the doubling efficiency with regard to the optimum focusing condition of a Gaussian beam with a circular cross section. When the length of the crystal takes on values from 1 to 4 cm, the doubling efficiency varies from 22 to 26 percent. The optimum shaping of the laser beam with these crystals is obtained when α is about $\frac{1}{3}$.

In the experimental setup, we combined commercial spherical and cylindrical lenses to shape and focus the TEM_{00} beam of a 15-mW He–Ne laser. In Table I some experimental results for an ADP crystal with a length of 2 cm are compared with theoretically predicted values.

In summary, depending on the type and the length of the nonlinear crystal, this study reveals a small increase of doubling efficiency (e.g., ADP, 2 cm, 25-percent increase) by using an optimum focused laser beam with an optimum elliptical cross section instead of using an optimum focused circular beam.

Notes and Lines

New Visible Laser Transitions in Ba I and Ba II

K. U. BARON AND B. STADLER

Abstract—**Three new visible laser transitions at λ = 7120 Å in Ba I and at λ = 6496.9 and 6141.7 Å in Ba II have been observed in a pulsed discharge with Xe, Ne, and He as carrier gas. A new all-metal hollow-cathode design was used.**

Manuscript received April 2, 1975.

The authors are with the Institut für Angewandte Physik, Universität Heidelberg, 6900 Heidelberg, Germany.

New laser transitions of barium vapor at 7120, 6496.9, and 6141.7 Å have been observed in a pulsed discharge. The laser lines were identified as the following transitions [1]:

7120 Å:

$6p'\,^1D_2$ [23074.4 cm^{-1}] – $5d\,^3D_1$ [9033.98 cm^{-1}]

in Ba I

6496.9 Å:

$6p\,^2P^0_{1/2}$ [20261.5 cm^{-1}] – $5d\,^2D_{3/2}$ [4873.85 cm^{-1}]

in Ba II

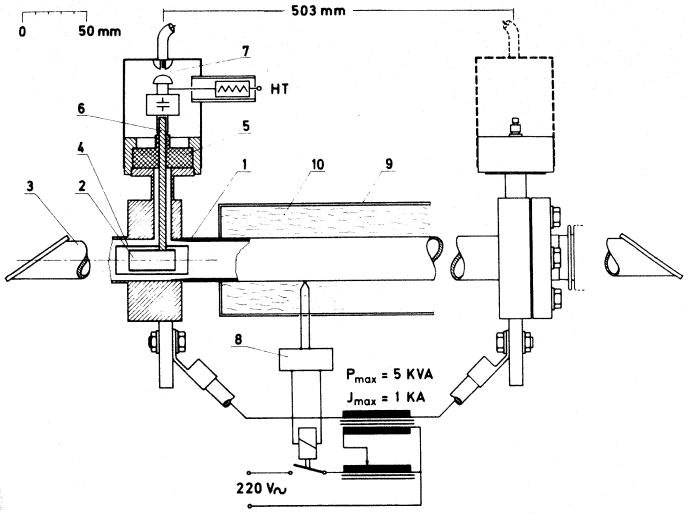

Fig. 1. Experimental laser tube. 1: Hollow cathode. 2: Hollow anode. 3: Brewster window. 4: Protective quartz tube. 5: Glass vacuum seal. 6: Electrical feedthrough (quartz tube isolated). 7: Triggered pressurized spark gap. 8: Temperature controller. 9: Metallic heat reflector. 10: Thermal isolation.

6141.7 Å:

$$6p\ ^2P^0_{3/2}\ [21952.4\ \text{cm}^{-1}] - 5d\ ^2D_{5/2}\ [5674.82\ \text{cm}^{-1}]$$

in Ba II.

We believe these are the first visible laser transitions in barium to be excited. So far only infrared lines of barium in the wavelength range longer than 1.13 μ have been observed [2]. The two laser transitions in Ba II, which seem promising for spectroscopic light sources, were suggested by Walter *et al.* [3] in 1966.

The discharge was excited inside a heated hollow-cathode structure (about 50 cm long with a 2.8-cm bore), suitable for materials of low vapor pressure. The cathode was manufactured of a nickel-chromium alloy (Sanicro 31[1]), which proved rather resistant against liquid alkaline earths and many other materials. This alloy has sufficient mechanical strength even at 1000°C and did not exhibit any deterioration after more than 200 h of operation. The hollow cathode served as vacuum envelope and was directly heated. Two hollow anodes placed inside of overlapping quartz tubes were located at the water-cooled headflanges of the envelope (see Fig. 1).

Laser action was observed with the following parameters in our experiments:

1) temperature of the hollow cathode: 710–900°C;
2) carrier gas: He at 0.4 torr, Ne at 0.1 torr, Xe at 0.04–0.1 torr;
3) pulse excitation: capacitive discharge through triggered spark gap (C = 500–9000 pF, charged up to 25 kV), either applied to both anodes, or only to one of them while dc current (I = 50–2000 mA) was supplied to the other one;
4) optical resonator: concave mirror ($f = 2m$) and plane mirror; all lines mentioned and, in addition, a laser line at 1.13 μ [2] have been also observed in superradiance;
5) operating time with 5 g of Ba: $\geqslant$ 5 h;
6) peak pulse power: $\approx$ 10 W;
7) pulse length: $\approx 10^{-8}$ s.

ACKNOWLEDGMENT

The authors wish to thank Prof. G. zu Putlitz for his suggestion of this work. They also wish to thank Prof. P. E. Toschek and his co-workers for helpful discussions and technical assistance.

New Far-Infrared Laser Lines from CO_2-Laser-Pumped CH_3OH Gas by Using a Copper Waveguide Cavity

ATSUO TANAKA, MASANOBU YAMANAKA, AND HIROSHI YOSHINAGA

Abstract—**Eleven new far-infrared (FIR) laser lines have been observed from CH_3OH pumped by a CO_2 laser. These lines are ranged from 78 to 694 μm and are obtained by using a copper waveguide cavity.**

A large number of far-infrared (FIR) laser lines have been observed in CH_3OH [1]–[5] and CD_3OD [6] by means of optical pumping. Recently, Radford [7] reported some new CW lines in CH_3OH from a FIR waveguide laser [5], [8]. We have observed independently new laser lines from CH_3OH [9], of which some lines are the same as those found by Radford [7]. In this note, we report eleven new FIR laser lines from CH_3OH pumped by a CO_2 laser. These lines are successfully obtained by using a waveguide cavity with internal end plates.

The FIR cavity consisted of a 1-m-long copper tube of 12-mm ID and two flat copper end plates. Each plate had a coupling hole of 1.5-mm diameter at the center. One plate was translated like a piston to tune the cavity [5]. The pump CO_2 laser had the cavity length of 5.5 m and Littrow configuration of the grating. The CO_2 laser was internally chopped with a 25-percent duty factor at 480 Hz, and then the CO_2 laser beam, coupled out through the zeroth-order reflection of the grating, was chopped once more with a 50-percent duty factor at 20 Hz. The signal from a Golay detector was fed into a lock-in amplifier tuned to the chopping frequency of the pump laser beam at 20 Hz. The response of the Golay detector was assumed to be flat in the 10-μm–1-mm spectral region and calibrated near 10 μm.

Table I shows the experimental results obtained in this study. The previously reported 1217-μm line [5], which was also obtained using the 1-m-long waveguide cavity of 12-mm ID, is listed for completeness. The wavelength of these lines was measured in air by means of a scanning mesh Fabry–Perot interferometer [10] within an accuracy of ± 3 μm, where the wavelength once measured was compared with that of a known laser line. The three laser lines with a dagger coincide, within experimental errors, with those found by Radford [7]. Since the piston-type end plate as an end mirror and the smaller diameter of coupling hole can lower the threshold pump power [5], [9], it seems that these FIR laser lines, not found otherwise, were obtained by using this type of waveguide cavity even for relatively lower pump power.

Manuscript received June 27, 1975.

*The pressure at which the FIR output power shows the maximum for that pump power.
**See [5].
†See [7].

In conclusion, if we adopt this low-loss waveguide cavity with internal end plates, numerous new laser lines in the FIR will be expected from some available polar molecules optically pumped by the existing CO_2 or N_2O laser.

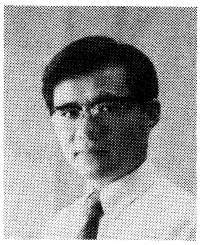
He received the B.A. and M.A. degrees from Trinity College, Cambridge, England, in 1965 and 1970, respectively, and the Ph.D. degree in physics from the University of Manchester, Manchester, in 1970. His doctoral research involved studies of excitation and relaxation processes in noble-gas lasers.

From 1969 to 1973 he was a Research Associate in the Department of Physics at the University of Manchester, where he carried out research on atomic-iodine gas-discharge lasers, electronegative plasmas, and atomic-iodine photodissociation lasers. Since 1973 he has been at Cornell University, Ithaca, N.Y., where he is currently a Research Associate in the Materials Science Center. His current research interests include photodissociation and chemical lasers, photochemical kinetics, and molecular-energy transfer.

Dr. Davis is a member of the Institute of Physics (London).

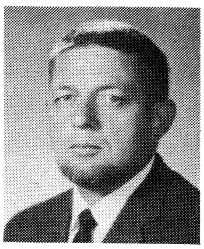


Kenneth M. Evenson was born in Wisconsin. He received the B.S. degree from Montana State University, Bozeman, and the M.S. and Ph.D. degrees from Oregon State University, Corvallis, in 1955 and 1963, respectively.

He was a Fulbright Scholar at Tübingen University, from 1955 to 1956. Since 1963 he has been with the National Bureau of Standards, Boulder, Colo.

Dr. Evenson is a member of the American Physical Society. He has received the Department of Commerce Silver Medal and the National Bureau of Standards Stratton Award.

*

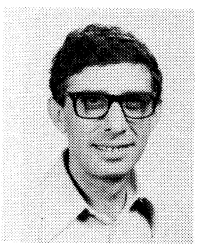


Kenya Goto was born in Fukushima, Japan, on November 3, 1938. He received the B.E. degree in electronics engineering from Tohoku University, Sendai, Japan, in March 1963.

Since April 1963 he has been a member of the Research Staff in the Laser Group at Toshiba Research & Development Center, Tokyo Shibaura Electric Company Ltd., Kawasaki, Japan, where he developed high repetition rate giant pulse Nd:YAG lasers and laser radars for air pollution monitoring. From 1973 to 1975 he was a Guest Worker at the Quantum Electronics Division of the National Bureau of Standards, Boulder, Colo., and a Research Associate at the Department of Physics and Astrophysics, University of Colorado, Boulder. His primary concerns in research at Toshiba are in laser spectroscopy and its application to isotope separation.

Mr. Goto is a member of the Optical Society of America.

*



Donald A. Jennings was born in Stanton, Mich., on October 30, 1930. He received the B.S. degree from Central Michigan College of Education, Mount Pleasant, in 1954, the M.S. degree from Michigan State University, East Lansing, in 1958, and the Ph.D. degree in physics from the University of Colorado, Boulder, in 1962.

He began work at the Boulder Laboratories, National Bureau of Standards, Boulder, Colo., in 1961 as a Physicist, and has worked in the fields of gamma-ray spectroscopy, laser spectroscopy, nonlinear optics, Raman and Brillouin scattering, dye-laser technology (both pulsed and CW), and laser frequency area. The work in calorimetric laser measurements has led to the development of probably the most precise method available for determining the energy of a laser pulse.

Dr. Jennings is a member of the American Physical Society. He received a Department of Commerce Gold Medal Award in 1970 for his work in calorimetric laser measurements.

*

Juan J. Jiménez was born in Madrid, Spain, on April 17, 1935. He received a degree in telecommunication engineering from the Escuela Tecnica Superior de Ingenieros de Telecomunicacion (ETSIT), Madrid, the equivalent of the M.S. degree in physics from the University of Toulouse, Toulouse, France, and the equivalent of the Ph.D. degree from the University of Paris Sud, Orsay, France, in 1964, 1967, and 1974, respectively.

From 1966 to 1968 he was a Visiting Engineer at Centre National d'Etudes des Télécommunications (CNET), Issy-les-Moulineaux, France, where he worked on the tunnel diode microwave equivalent circuit and noise in frequency multipliers. In 1968 he joined the Institut d'Electronique Fondamentale, Orsay University, where he worked on superconducting cavities and developed a new microwave frequency standard: The superconducting cavity stabilized oscillator (SCSO). He has contributed to the research of low-noise microwave mixers and amplifiers, Schottky diodes, and MESFET, by cooling. His research areas also include the study of noise in oscillators and the related instrumentation. Currently, he is Associate Director of the Laboratoire Primaire de Métrologie des Fréquences (LPMF) which is part of the Bureau National de Métrologie (BNM), Paris, France, where he is engaged in basic research and development of stabilized lasers and infrared detectors. He is also Chargé de Recherche au Centre National de la Recherche Scientifique (CNRS), Paris. During 1975 he is a Visiting Scientific Guest with the Precision Laser Metrology Section, National Bureau of Standards (NBS), Boulder, Colo.

Dr. Jiménez is a member of the French Physical Society and the French "Société des Electriciens, des Electroniciens et des Radioélectriciens" (SEE), Paris.

Fritz Kneubühl was born in Zurich, Switzerland, on March 7, 1931. He received the Diploma and the Ph.D. (physics) degrees, both from the Swiss Federal Institute of Technology (ETH), Zurich, in 1955 and 1959, respectively. In 1959 he spent the summer as a Ramsay Memorial Fellow at University College, London, England. The following year he spent as Graeflin Fellow in the Chemistry Department at The Johns Hopkins University, Baltimore, Md.

At the end of 1960 he entered the Solid State Physics Laboratory at the ETH, Zurich, where he was appointed Privatdozent in 1963, Assistant Professor in 1967, Associate Professor in 1970, and Full Professor of Physics in 1972. Before 1963 he was engaged in gaseous microwave spectroscopy and in paramagnetic resonance. From 1964 to the present he has been engaged in submillimeter-wave and infrared physics: i.e., spectroscopy of solids and liquids, longitudinally and transversely excited HCN, ICN, and CO_2 lasers, laser interaction with solids, spectral thermal emission and blackbody radiation, thermal imaging, and balloon-borne solar spectroscopy.

Dr. Kneubühl is a member of the Swiss and the European Physical Society. From 1967 to 1971 he acted as the Secretary of the Swiss Physical Society.

John B. Marling (M'72) was born in Cumberland, Md., on September 19, 1946. He received the B.S. degree in physics from the Georgia Institute of Technology, Atlanta, in 1967, and the M.S. and Ph.D. degrees, both in applied science, from the University of California at Davis/Livermore, in 1968 and 1971, respectively. He was a Hertz Fellow from 1967 to 1971.

In 1971 he joined the professional staff at the AVCO Everett Research Laboratory, Everett, Mass., and worked on high-power tunable dye-laser development as part of the program for laser isotope separation of uranium. During 1973 he joined the staff at Stanford Research Institute, Menlo Park, Calif., to help develop high-power dye lasers for atmospheric probing. Later in 1973 he joined the Physics Department staff at the Lawrence Livermore Laboratory, Livermore, Calif., where he has been responsible for the research and development of laser methods leading to improved isotope separation of deuterium and other light atoms. Photopredissociation of formaldehyde is being currently investigated, and highly selective laser separation of deuterium from natural abundance HDCO is described in a recent article. Short wavelength pulsed and CW ion-laser development was a by-product of the need for wavelength-stable ultraviolet laser sources for photochemistry and isotope separation.

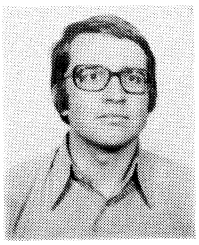
F. Russell Petersen was born in DeSmet, S. Dak., on August 21, 1930. He received the B.S. degree from the South Dakota School of Mines and Technology, Rapid City, and the Ph.D. degree from the University of California, Berkeley, both in physics, in 1952 and 1961, respectively.

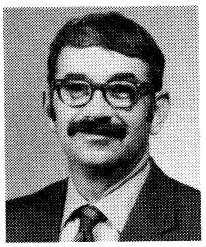


In 1961 he joined the National Bureau of Standards, Boulder, Colo., where he initially conducted molecular beam research. For the last five years he has been engaged in various CO_2 laser stabilization and IR frequency synthesis programs.

Dr. Petersen is a member of the American Physical Society.

*

Robert J. Pirkle received the B.S. and M.S. degrees in chemistry from Auburn University, Auburn, Ala., in 1963 and 1965, respectively, and the Ph.D. degree in physical chemistry, from the University of Western Ontario, London, Ont., Canada, in 1972. He studied the visible electronic spectrum of NO_2 while at this last university.



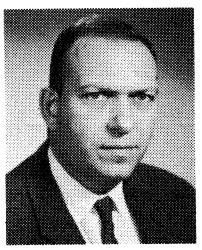
From 1965 to 1969 he worked in the Molecular Spectroscopy Branch of the Physical Sciences Laboratory DR&D at the U.S. Army Missile Command, Redstone Arsenal, Ala. From 1972 through 1974 he worked as a Postdoctoral Associate in the Laboratory for Plasma Studies at Cornell University, Ithaca, N.Y., where he studied several chemical-laser systems and also the photodissociation iodine laser. He is currently studying the kinetics of electronically excited atomic species in the Department of Chemistry at Cornell University.

Hans J. Schötzau was born in Augst, Switzerland, on January 21, 1944. He received the Diploma in physics and the Ph.D. degree, both from the Swiss Federal Institute of Technology (ETH), Zurich, Switzerland, in 1968 and 1973, respectively.

From 1968 to 1975 he was with the Solid State Physics Laboratory of the ETH, where he was engaged in the study of infrared lasers. He is currently an ESRO-Postdoctoral Fellow at the European Space Research and Technology Centre (ESTEC), Noordwijk, The Netherlands, where he is working on submillimeter heterodyne receivers.

*

Joseph S. Wells was born in Meade, Kans., on March 19, 1930. He received the B.S. and M.S. degrees from the Kansas State University of Agriculture and Applied Science, Manhattan, in 1956 and 1958, respectively, and the Ph.D. degree in physics from the University of Colorado, Boulder, in 1964.



He joined the staff of the Boulder Laboratories, National Bureau of Standards, Boulder, Colo., in 1958, where he is now employed in the Time and Frequency Division and is concurrently a Professor Adjoint in the Department of Physics at the University of Colorado.

Dr. Wells is a member of the American Physical Society and Sigma Xi.

George J. Wolga (M'71) received the B. Eng. Phys. degree from Cornell University, Ithaca, N.Y., in 1953, and the Ph.D. degree in physics from the Massachusetts Institute of Technology, Cambridge, in 1957.

He was an Instructor and Assistant Professor of Physics at the Massachusetts Institute of Technology through 1961 when he returned to Cornell University where he is now Professor of Electrical Engineering and Applied Physics. He spent 1968–1969 at the Naval Research Laboratory, where he was Branch Head of the Laser Physics Branch. His current research interests are tunable infrared lasers, molecular-energy transfer and relaxation as studied with lasers, laser-induced chemistry, and the development and study of new laser systems.

Frequency-Domain Analysis of the Mode-Locked and Frequency-Doubled Homogeneous Laser

C. J. KENNEDY

Abstract—A frequency-domain analysis of the mode-locked intracavity frequency-doubled laser is pursued. An expression for pulsewidth is derived based upon basic laser parameters and the nonlinear coupling of the frequency doubler. It is found that mode locking induces an additional loss to the cavity even in the ideal case, so that the frequency-doubled output power at optimum coupling is less than an optimally coupled fundamental frequency laser with identical losses.

Introduction

MODE-LOCKED visible lasers have considerable potential as ultrahigh data rate communication lasers. One such device is the intracavity frequency-doubled and mode-locked Nd:YAG laser. Communication efficiency with such a laser-based system depends greatly on obtaining the greatest average power at 0.53 μm while at the same time maintaining short pulsewidth. Experience has shown, however, that high power and short pulses are antithetical; that is, an effort to produce higher power also leads to longer pulses. In an effort to enhance our predictive capability for these lasers, the author has embarked on an attempt to treat the laser system theoretically.

In this attempt, we are encouraged by the previously successful analyses of mode-locked lasers by Kuizenga and Siegman [1a)], McDuff and Harris [1b)], Haken and Pauthier [1c)], and Nelson [1d)]. The analyses of Nelson and Kuizenga represent two different approaches to the mode-locking problem. Nelson describes the field in terms of discrete mode amplitudes and phases, while Kuizenga considers the propagation of a quasi-general pulse through a complete round trip through the laser. The pulse is assumed to be Gaussian, a fact which was demonstrated by Nelson to be the lowest order solution to the mode-locking equations. The introduction of intracavity second-harmonic generation (SHG) was treated in a somewhat qualitative way by Hitz and Osterink [2], but their reasoning is essential to a physical understanding of the interaction between the mode locker and frequency doubler.

Fundamentals of the Analysis

McDuff and Harris have arrived at a self-consistency equation for mode locking using the original laser theory of Lamb [3]. We will take the liberty of adding a term which represents the loss and phase shift involved in SHG, or using their notation,

$$\alpha_c(E_{n+1} + E_{n-1}) + E_n(G_n - \alpha - \alpha_a - \alpha_n^{(2)} - i\dot{\phi}\tau + in\Delta\nu\tau - i\psi_n) = 0 \tag{1}$$

where E_n is the complex electric field of the nth mode, α_c is the intermode coupling coefficient due to loss modulation, G_n is the saturated round-trip amplitude gain, α is the double-pass field amplitude loss, α_a is the continuous mode-locker loss, $\dot{\phi}$ is an overall constant rate phase shift, $\Delta\nu$ is the detuning of the laser cavity from the mode-locker frequency, τ is the cavity round-trip time, ψ_n is the round-trip residual phase shift for the nth mode, and $\alpha_n^{(2)}$ is the (complex) term describing the fraction of amplitude loss (phase shift) encountered by the nth mode on a round trip. Since SHG is a nonlinear process, $\alpha_n^{(2)}$ is dependent on all other mode amplitudes in a complicated fashion, hence the coupling of the N different mode equations is hopelessly elaborate. To this dilemma we propose the following solution. Let

$$E_n = E \exp\left[-(\delta + i\xi)n^2\right] \tag{2}$$

where δ and ξ are parameters which describe the width and frequency chirp of the mode-locked spectrum, be an adequate trial solution for the coupled-mode equations. A Gaussian distribution of the mode amplitude and phases allows for the possible presence of pulse chirping, and represents a close approximation of actual distributions in experimental mode-locked frequency-doubled lasers [4]. The Fourier transform of (2) represents the time-domain pulses, or

$$E(t) = E\sqrt{\frac{\pi}{\delta + i\xi}} \exp\left[-\frac{\Omega^2 t^2}{4(\delta + i\xi)}\right]. \tag{3}$$

We define the pulsewidth $\hat{t}$ to be the full $1/e^2$ width, or

$$\hat{t} = \frac{4}{\Omega}\sqrt{\frac{(\delta^2 + \xi^2)}{\delta}} \tag{4}$$

where $\Omega = 2\pi C/2L$. Also the time-averaged circulating intensity of the laser is the sum over the time-averaged intensity of each mode (the cross terms of $\langle(\Sigma_n E_n(t))^2\rangle$ vanish)

$$I = \frac{1}{2}\sqrt{\frac{\epsilon}{\mu_0}}\sum_n |E_n|^2 = \frac{1}{2}|E|^2\sqrt{\frac{\pi\epsilon}{2\delta\mu_0}}. \tag{5}$$

Equation (2) may then be substituted into (1) once the form of $\alpha_n^{(2)}$ has been determined, the equation expanded in powers of n, and coefficients of like powers of n equated. Expansion to second order in n gives us three complex equations in three unknowns. Taken together with the assumption of ideal mode locking, this is sufficient to produce a solution for E, δ, and ξ as a function of basic laser parameters, which completely specifies the spectrum and chirping of a steady-state mode-locked pulse in this laser.

Manuscript received July 29, 1974; revised July 15, 1975.

The author was with the Air Force Avionics Laboratory, Wright Patterson Air Force Base, Ohio 45433. He is now with SAMSO/DY (Program 405B), Los Angeles Air Force Station, El Segundo, Calif. 90009.

Second-Harmonic Term

The SHG loss may be derived in the time domain from the double-pass expression for fundamental (1.06 μm) loss (see Appendix B for the relation between κ and fundamental properties of the doubling medium),

$$\Delta E(t) = -\kappa E(t)\,|E(t)|^2 \tag{6}$$

or, using (3),

$$\Delta E(t) = \frac{-\kappa E\,|E|^2\,\pi^{3/2}}{[(\delta^2+\xi^2)(\delta+i\xi)]^{1/2}} \exp\left[-\Omega^2 t^2 \frac{(3\delta - i\xi)}{4(\delta^2+\xi^2)}\right]. \tag{7}$$

Transforming to the mode domain,

$$\Delta E_n = \frac{-\kappa E\,|E|^2\,\pi}{[(\delta+i\xi)(3\delta - i\xi)]} \exp\left[-\frac{\delta^2+\xi^2}{3\delta - i\xi} n^2\right]. \tag{8}$$

Since the field loss per round trip is defined by

$$\alpha_n^{(2)} = -\frac{\Delta E_n}{E_n} \tag{9}$$

we have, after choosing the phase of E to make the coefficient of the exponential real,

$$\alpha_n^{(2)} = \frac{\pi\kappa\,|E|^2}{[(9\delta^2+\xi^2)(\delta^2+\xi^2)]^{1/4}} \cdot \exp\left[\frac{2\delta(3\delta^2 - \xi^2 + 4i\delta\xi)}{9\delta^2+\xi^2} n^2\right]. \tag{10}$$

We note the positive (for $\xi = 0$) real coefficient of n^2, which causes the loss for outlying modes to be greater than for the central modes. This must ultimately result in a narrower spectrum and broader pulses, depending on the nonlinear coupling coefficient κ.

The second-harmonic laser output (bidirectional) is

$$\begin{aligned} I_{sh} &= \sum_n 2\alpha_n^{(2)} I_n \\ &= \frac{\pi\kappa\sqrt{\epsilon/\mu_0}\,|E|^4}{[(9\delta^2+\xi^2)(\delta^2+\xi^2)]^{1/4}} \cdot \sum_n \exp\left[-\frac{4\delta(3\delta^2+\xi^2 - 2i\delta\xi)}{9\delta^2+\xi^2} n^2\right] \\ &= \frac{\pi^{3/2}\,\kappa\sqrt{\epsilon/\mu_0}\,|E|^4}{[(9\delta^2+\xi^2)(\delta^2+\xi^2)]^{1/4}} \left[\frac{9\delta^2+\xi^2}{4\delta(3\delta^2+\xi^2)}\right]^{1/2} \end{aligned} \tag{11}$$

for small ξ.

Finally, we note that since $\alpha_n^{(2)}$ is dependent on $|E|^2$ and the latter quantity has a Gaussian (TEM_{00}) spatial dependence, the average loss over the Gaussian mode, rather than the peak loss at mode center, should be included in the coupled-mode equations. The average differs from the peak loss by a factor of $\frac{1}{2}$; therefore this factor is included in subsequent expressions for $\alpha_n^{(2)}$.

Gain and Saturation

The present paper is concerned with the class of homogeneously broadened lasers which are not subject to spatial hole burning [5], or those in which the effects of spatial hole burning are negligible. Consequently, the expression for saturated gain in our laser is

$$G_n = g_0[1 - n^2(\Omega/\gamma)^2]/(1 + I/I_s) \tag{12}$$

where I_s is the saturation intensity, g_0 the unsaturated gain, and γ is the half-gain angular frequency halfwidth of the homogeneously broadened (Lorentzian) line. In this case,

$$\psi_n = gn\frac{\Omega}{\gamma} \tag{13}$$

where g is the saturated gain at line center. The necessary elements for a prediction of laser performance are now present. Implicit in the analysis is the assumption of ideal mode locking, which is to say, the pulse arrives at the modulator precisely at peak transmission and the mode spectrum is concentric with the gain spectrum. Otherwise more variables would be needed to specify the intracavity field.

Solution to the Equations

Upon substitution of E_n, G_n, and ψ_n and $\alpha_n^{(2)}$, the self-consistency equation becomes

$$\begin{aligned} 2\alpha_c e^{-(\delta+i\xi)} \cosh[2(\delta+i\xi)n] &= -g + \alpha + \alpha_a + i\dot{\phi}\tau - in\Delta\nu\tau + gn^2\left(\frac{\Omega}{\gamma}\right)^2 - ign\frac{\Omega}{\gamma} \\ &\quad + \frac{\pi}{2}\frac{\kappa\,|E|^2 \exp\left[\frac{2\delta(3\delta^2 - \xi^2 + 4i\delta\xi)\,n^2}{9\delta^2+\xi^2}\right]}{[(9\delta^2+\xi^2)(\delta^2+\xi^2)]^{1/4}}. \end{aligned} \tag{14}$$

Expanding the functions to second order in n, equating like orders, and using (5) to obtain $|E|^2$ in terms of I results in the following three equations:

$$2\alpha_c e^{-(\delta+i\xi)} = -g + \alpha + \alpha_a + i\dot{\phi}\tau + \sqrt{\frac{2\pi\mu_0\delta}{\epsilon}}\frac{\kappa I}{[(9\delta^2+\xi^2)(\delta^2+\xi^2)]^{1/4}} \tag{15a}$$

$$-\Delta\nu\tau = g\left(\frac{\Omega}{\gamma}\right) \tag{15b}$$

$$4\alpha_c e^{-(\delta+i\xi)}(\delta+i\xi)^2 = g\left(\frac{\Omega}{\gamma}\right)^2 + \sqrt{\frac{2\pi\mu_0\delta}{\epsilon}} \cdot \frac{\kappa I}{[(9\delta^2+\xi^2)(\delta^2+\xi^2)^{1/4}} \cdot \frac{2\delta(3\delta^2 - \xi^2 + 4i\delta\xi)}{9\delta^2+\xi^2}. \tag{15c}$$

Physically, the significance of these three equations is that of conservation equations. Equation (15a) (real) represents the conservation of mode amplitude through a round trip; (15b) represents the conservation of pulse position with respect to the modulator phase; (15c) (real) represents the conservation of spectral width; and (15c) (imaginary) conserves pulse chirp.

The imaginary part of (15c) is

$$4\alpha_c e^{-\delta}\left[2\delta\xi\cos\xi-(\delta^2-\xi^2)\sin\xi\right]$$
$$=\sqrt{\frac{2\pi\mu_0\delta}{\epsilon}}\,\frac{\kappa I}{[(9\delta^2+\xi^2)(\delta^2+\xi^2)]^{1/4}}\cdot\frac{8\delta^2\xi}{9\delta^2+\xi^2} \quad (16)$$

which has the solution $\xi = 0$. Other solutions are possible, however, and one must consider the physical significance of this equation. A term is notably absent, which takes the chirping which results from pulse propagation through a dispersive medium into account. This omission results from the approximations made in the derivation of the self-consistency equation (i.e., the second-time derivative of the polarization is neglected). The existence of physical solutions with $\xi \neq 0$ may be possible due to the small progressive chirp induced by the passive (and active) medium. This is an interesting line of investigation which we will not pursue further in this paper.

Proceeding with the $\xi = 0$ case, we see that (15) becomes, for small δ (many modes oscillating)

$$2\alpha_c(1-\delta)-\alpha_a-\alpha=-g+\sqrt{\frac{2\pi\mu_0}{3\epsilon\delta}}\,\kappa I \quad (17a)$$

$$4\alpha_c\delta^2=g(\Omega/\gamma)^2+\frac{2}{3}\sqrt{\frac{2\pi\mu_0}{3\epsilon\delta}}\,\kappa I\delta. \quad (17b)$$

Ideally, $2\alpha_c = \alpha_a$; thus

$$g=\alpha+\sqrt{\frac{2\pi\mu_0}{3\epsilon\delta}}\,\kappa I+2\alpha_c\delta. \quad (18)$$

We may pause here to check the form of our equations by reducing the problem to the nonfrequency doubled case. The pulsewidth should then reduce to a form which is equivalent to those of other authors.

If we let $\kappa = 0$ in (17b) and (18), we have

$$\delta=\frac{\Omega}{\gamma}\cdot\left(\frac{g}{4\alpha_c}\right)^{1/2} \quad (19)$$

or

$$\hat{t}=\frac{4}{\Omega}\left(\frac{\Omega}{\gamma}\right)^{1/2}\left(\frac{g}{4\alpha_c}\right)^{1/4} \quad (20)$$

which is equivalent to the expression derived by Kuizenga and Siegman.

When the SHG loss is the dominant spectrum-narrowing mechanism and (Ω/γ) is negligible, (17b) yields the expression

$$\hat{t}=\frac{4}{\Omega}\left(\sqrt{\frac{2\pi\mu_0}{3\epsilon}}\,\frac{\kappa I}{6\alpha_c}\right)^{1/3}. \quad (21)$$

Proceeding to solve for E, or equivalently I, we multiply (18) by $2\delta/3$ and subtract from (17b), obtaining

$$4\alpha_c\delta^2=g\left(\frac{\Omega}{\gamma}\right)^2+(g-\alpha-2\alpha_c\delta)\frac{2\delta}{3}. \quad (22)$$

Since $(\Omega/\gamma)^2$ is small in Nd:YAG, the foregoing equation reduces to

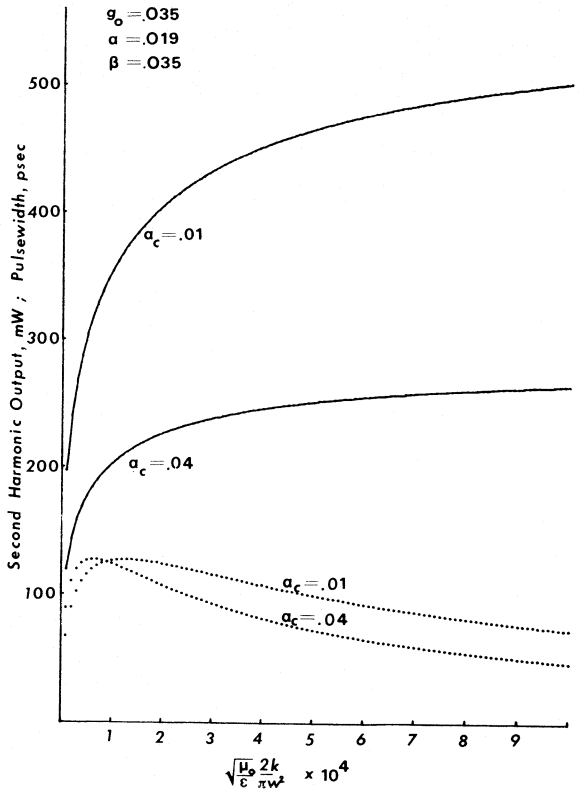

Fig. 1. 1.06-μm pulsewidth (solid) and output power (dotted) versus nonlinear coupling for two values of mode-locker coupling, plotted for the case where gain bandwidth broadening is negligible.

$$g=\alpha+8\alpha_c\delta \quad (23)$$

or, using the gain saturation relation for homogeneous lasers

$$I=I_s\left[\frac{g_0}{8\alpha_c\delta+\alpha}-1\right] \quad (24)$$

which may be substituted into (21) and the result solved for $\hat{t}$ or δ. Such a solution is illustrated in Fig. 1, which displays 0.53-μm power and 1.06-μm pulsewidth versus κ for several values of α_c.

Optimum Coupling

Equation (21) may be manipulated to show that

$$3\sqrt{6}\,\alpha_c\delta=\alpha_{SHG}$$

where α_{SHG} is the single-pass power fraction converted to the second harmonic defined (see Appendix B) by

$$P_{SH}=2\alpha_{SHG}P$$

and P_{SH} and P are the total second-harmonic power and circulating fundamental power, respectively. Equation (24) indicates that some constant factor ($q = 8/3\sqrt{6}$) which is greater than unity enters the gain saturation equation such that

$$P=\frac{1}{\beta}\left[\frac{g_0}{\alpha+q\alpha_{SHG}}-1\right] \quad (25)$$

where β is the power saturation parameter.

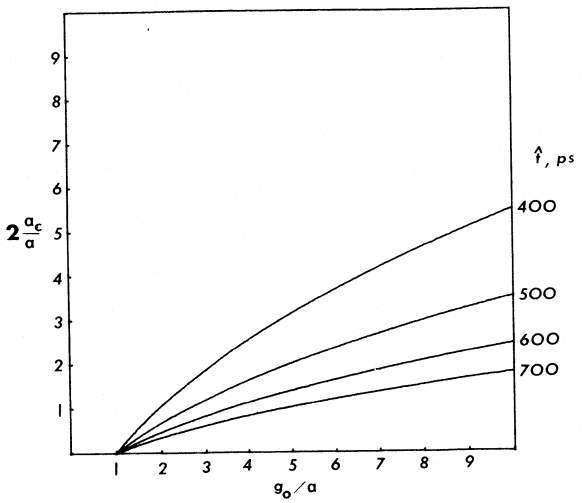

Fig. 2. Curves of modulation strength versus pumping ratio for constant pulsewidth. Optimum second-harmonic coupling is assumed.

It may be shown by differentiating P_{SH} with respect to α_{SHG} that optimum α_{SHG} is (the asterisk denotes an optimized value)

$$\alpha^*_{SHG} = \frac{1}{q}\left[\sqrt{g_0\alpha} - \alpha\right]. \tag{26}$$

This is the familiar expression for output coupling except for the $1/q$. Furthermore, it may be shown that the optimum second-harmonic power is

$$P^*_{SH} = \frac{1}{q\beta}\left[\sqrt{g_0} - \sqrt{\alpha}\right]^2. \tag{27}$$

The conclusion is that mode-locked second-harmonic operation is never as efficient as mode-locked fundamental operation, even for an ideal lossless SHG crystal. Only $1/q$, or 91 percent of the fundamental, can be converted. Physically, this is due to the extra pulse broadening induced by the frequency doubler which causes greater losses to the loss modulator. These extra losses reduce the efficiency of the laser.

The optimum nonlinear coupling is obtained by using the fact, disclosed in Appendix B, that

$$\alpha_{SHG} = \frac{2\kappa P}{\pi w^2}\sqrt{\frac{\mu_0}{\epsilon}}\frac{2\tau}{\sqrt{\pi}\,\hat{t}}. \tag{28}$$

Substituting the optimal values of α_{SHG} and P into the above relation, we obtain

$$\left[\frac{2\kappa}{\pi w^2}\sqrt{\frac{\mu_0}{\epsilon}}\right]^* \frac{2\tau}{\sqrt{\pi}\,\hat{t}} = \frac{\alpha\beta}{q} \tag{29}$$

where once again we denote the optimized quantity (in brackets) by an asterisk. This relationship is amply demonstrated in Fig. 1 where the peak second-harmonic power occurs at a coupling of $\alpha\beta/q$ divided by the mode-locking enhancement factor $2\tau/\sqrt{\pi}\,\hat{t}$.

Pulsewidth at Optimum Coupling

Having derived the optimum value for α_{SHG}, we may proceed to find the pulsewidth for an optimally coupled laser. From (26) and (28) we deduce the optimum value of

$$\kappa I\sqrt{\frac{\mu_0}{\epsilon}} = \frac{\sqrt{\pi}\,\hat{t}}{2\tau}\frac{3\sqrt{6}}{8}\left[\sqrt{g_0\alpha} - \alpha\right]. \tag{30}$$

Inserting this relation in (21) produces the result

$$\hat{t} = \frac{4}{\Omega}\left[\frac{\alpha}{8\alpha_c}\left(\sqrt{\frac{g_0}{\alpha}} - 1\right)\right]^{1/2}. \tag{31}$$

We may invert this expression to yield the depth of modulation necessary to produce a given pulsewidth, or

$$\frac{\alpha_c}{\alpha} = \frac{2}{\Omega^2\hat{t}^2}\left(\sqrt{\frac{g_0}{\alpha}} - 1\right). \tag{32}$$

This relation is plotted in Fig. 2 for various pulsewidths in a laser where $\Omega = 2\pi \cdot 5 \times 10^8\ s^{-1}$.

Fig. 2 is most essential in engineering a given laser system for communications use. Modulation requirements usually set an upper limit on pulsewidth. For instance, pulse gated binary modulation at 5×10^8 bit/s using a modulator of 1.5-ns rise time leaves room for a 0.53-μm pulsewidth of only 500 ps (or 700 ps at 1.06 μm). If the gain-to-loss ratio is 5 (achievable in a sun-pumped laser), then a modulation depth of 1 percent at a loss of 1 percent is necessary to obtain this pulsewidth. This is well within the performance range of acoustooptic devices. But if a pulsewidth of 300 ps is necessary to accommodate a slower modulator (or in higher m-ary formats), then at least 3-percent depth of modulation ($= 2\alpha_c$) becomes necessary. This modulation depth may not be practical due to acoustic heating effects in the loss modulator.

The problem of achieving optimum coupling consists of obtaining the proper value of $(\sqrt{\mu_0/\epsilon})\,2\kappa/\pi w^2$. Since κ depends only on physical parameters, only the phase-matching length is variable to a degree. Thus the beam waist is our only adjustable parameter to obtain proper coupling. Typically, it is necessary to provide a laser resonator with an intracavity lens in order to accommodate small beams in the doubling crystal to large beam diameters in the gain medium. Movement of this lens can provide some adjustability of the parameter over a small range, but usually many resonator configurations must be tried before one is assured of optimum coupling. Equation

(29) emphasizes the necessity of measuring α and β accurately to ascertain the optimum value of nonlinear coupling. The actual value of nonlinear coupling in any given configuration may then be measured either by measuring output power and pulsewidth and using formula (B2) in Appendix B or by measuring the relaxation time of the perturbed laser after the analysis of [7]. Optimum w may then be predicted and an optimal design generated to achieve this using resonator theory.

Comparison with Time-Domain Theories

Falk [8] and Kennedy [9] have devised theories which approach this laser system from the time domain. The results of these analyses are pulsewidth formulas similar to (21) which differ only in the coefficient of $(\kappa I/\alpha_c)^{1/3}$. The pulsewidth may also be expressed in terms of α_{SHG} as

$$\hat{t} = \frac{4}{\Omega}\left(\frac{1}{3}\sqrt{\frac{2}{3}}\right)^{1/2}\left(\frac{\alpha_{SHG}}{\delta_l}\right)^{1/2} \quad \text{[frequency domain]}$$

$$\hat{t} = \frac{4}{\Omega}2^{1/4}\left(\frac{\alpha_{SHG}}{\delta_l}\right)^{1/2} \quad \text{[time domain of Falk]}$$

$$\hat{t} = \frac{4}{\Omega}\left(\frac{\sqrt{2}}{3}\right)^{1/2}\left(\frac{\alpha_{SHG}}{\delta_l}\right)^{1/2} \quad \text{[time domain of Kennedy]}$$

where $\delta_l = 2\alpha_c$ is the depth of modulation of the loss modulator. The numerical results of the three theories are thus quite different, and this difference becomes important in determining maximum theoretical efficiency of mode locking and frequency doubling. In Falk's theory the factor q turns out to be $\sqrt{2}$, limiting the conversion efficiency to 0.7. This is understandable because, all other things being equal, this time-domain theory predicts much broader pulses which have a higher loss on transmission through the mode locker. The higher losses are reflected in a lowered efficiency. The second time-domain theory predicts a pulse which is shorter than Falk's theory but longer than the frequency-domain theory. One would expect that its conversion limit would lie between 0.7 and 0.9.

Physically, q is the ratio of the peak second-harmonic loss to the average, and in the real world depends on the actual pulse shape which is non-Gaussian. Bernecker's theory [10] predicts a sine^2 dependence when broadening due to gain bandwidth and etalon effects is absent. However, real lasers frequently contain these effects in significant amounts and the factor q is altered. This value may be measured experimentally, provided very fast photodiodes are available at both the fundamental and second harmonic by comparison of the pulse shapes at these frequencies.

Conclusions

The theoretical model we have chosen for the mode-locked frequency-doubled laser predicts some rather basic behavioral patterns. First, the pulsewidth becomes significantly broader as one approaches the optimum second-harmonic output, which leads to increased mode-locker losses. It is these additional losses which cause the optimum power of these lasers to be less than their nonmode-locked counterparts. Secondly, any alteration of laser parameters which increases output power also broadens the pulses if α_c is kept constant. Increasing α_c always decreases pulsewidth, but slowly compared to decreasing cavity length.

Experimental verification of this theory is possible using a technique which measures the relaxation oscillations associated with a nonlinear loss [7]. This technique offers the possibility of measuring g_0, α, β, and κ in a pair of measurements of relaxation phenomena. The author will soon publish the results of these experiments on a frequency-doubled mode-locked Nd:YAG laser.

Appendix A
Transformed Modes

The time-domain representation of the mode distribution

$$E_n = Ee^{-(\delta + i\xi)n^2}$$

must have the following properties.

1) The peak field in the time domain must equal the sum of the complex mode amplitudes.

2) The time-integrated average intensity in the time domain must equal the sum of the average intensities of the individual modes.

3) The mode-locking enhancement to SHG must be $2\tau/\sqrt{\pi}\,\hat{t}$. Since

$$\sum_n E_n = \sum_n Ee^{-(\delta + i\xi)n^2} \simeq E\sqrt{\frac{\pi}{\delta + i\xi}}$$

then from property 1 we observe

$$E(t) = E\sqrt{\frac{\pi}{\delta + i\xi}}\exp\left[-\frac{\Omega^2 t^2}{4\delta}\right]. \tag{A1}$$

The second property demands that energy be conserved under transformation. The total time-averaged intensity of all modes is

$$\sum_n |E_n|^2 = |E|^2\sqrt{\frac{\pi}{2\delta}}$$

which must equal

$$\frac{1}{\tau}\int_{-\infty}^{\infty} dt\,|E(t)|^2 = |E|^2\,\frac{2\pi}{\tau\Omega}\sqrt{\frac{\pi}{2\delta}}.$$

And the condition is satisfied by the form chosen for $E(t)$.

The final condition is a check on the validity of the method of obtaining the mode-dependent SHG loss $\alpha_n^{(2)}$. It is easily demonstrated that the SHG power converted from a Gaussian pulse of width $\hat{t}$ is $2\tau/\sqrt{\pi}\,\hat{t}$ times the SHG power converted from a square pulse of width τ and the same total energy.

Appendix B
Second-Harmonic Output Power

Assuming perfect phase matching, the equations describing SHG for a single mode are [6]

$$\frac{dE_1}{dz} = -i\,\frac{\omega}{2}\sqrt{\frac{\mu_0}{\epsilon}}\,dE_3E_1^*$$

$$\frac{dE_3}{dz} = -i\frac{\omega}{2}\sqrt{\frac{\mu_0}{\epsilon}}\,dE_1^2.$$

If E_1 is undepleted (small SHG), then

$$E_3(z) = -i\frac{\omega}{2}\sqrt{\frac{\mu_0}{\epsilon}}\,dE_1^2 z$$

and

$$\Delta E_1 = -\frac{\omega^2}{4}\frac{\mu_0}{\epsilon}d^2E_1\,|E_1|^2\,\frac{L^2}{2}$$

where L is the phase-matched crystal length. Equation (6) then implies that

$$\kappa = \frac{\omega^2}{8}\frac{\mu_0}{\epsilon}d^2L^2.$$

Since

$$I_{SH} = \frac{1}{2}\sqrt{\frac{\epsilon}{\mu_0}}\,|E_3|^2$$

and

$$E_3(L) = -\frac{i\omega}{2}\sqrt{\frac{\mu_0}{\epsilon}}\,dE_1^2\,L$$

then

$$I_{SH} = 4\kappa I^2\sqrt{\frac{\mu_0}{\epsilon}}.$$

This applies only to the center of the Gaussian mode. Total output power is obtained by integrating over the intensity in the mode of waist w at the doubling crystal, or

$$P_{SH} = \frac{\pi w^2}{4}\cdot 4\kappa I^2\sqrt{\frac{\mu_0}{\epsilon}}.$$

Hence

$$P_{SH} = \frac{4\kappa}{\pi w^2}P^2\sqrt{\frac{\mu_0}{\epsilon}}. \tag{B1}$$

Simplifying (11) for $\xi = 0$, we obtain the full expression for a mode-locked laser

$$I_{SH}(r) = \frac{1}{2}\left(\frac{\pi}{\delta}\right)^{3/2}\kappa\,|E|^4\,e^{-4(r/w)^2}\sqrt{\frac{\epsilon}{\mu_0}}.$$

Hence it can be shown that

$$P_{SH} = \frac{4\kappa}{\pi w^2}\sqrt{\frac{\mu_0}{\epsilon}}\,\frac{2\tau}{\sqrt{\pi}\,\hat{t}}\,P^2. \tag{B2}$$

Comparing this with (B1) shows a mode-locking enhancement factor of the proper amount.

Acknowledgment

The author wishes to thank J. Falk, whose review of this paper greatly enhanced its clarity.

Self-Focusing Phenomena in Air–Glass Laser Structures

C. JAMES ELLIOTT AND BERGEN R. SUYDAM, MEMBER, IEEE

Abstract—**The effect of the air space on self-focusing instability growth rates has been considered for glass laser systems. The situation may be viewed as a min-max problem in which the air space may be adjusted to minimize the fastest growing instability. A solution exists to the min-max problem which reduces the problem to the solution of a single transcendental equation. Solutions to this equation indicate that, at most, a 10-percent reduction in the effective value of the nonlinear index of refraction can occur.**

IN THE PAST the growth rate for optical instabilities such as small-scale self-focusing has been computed [1]-[4] for various models of a glass laser all of which involve a solid piece of material as the nonlinear medium. We extend the calculations to include the effect of an air gap separating a periodic structure of glass disks each of thickness z_g and separation z_a. In this calculation we do not take into account divergence of the beam, finite extent of the beam, gain of the media, nor do we correctly account for disk surfaces which are at a tilt relative to the optical axis. Rather we model the glass disks as being perpendicular to the optical axis and as having antireflecting optical coatings which introduce no phase change to the propagating beam. This model simulates Brewster angle interfaces with a simple geometry.

We find that in no case do the instabilities grow faster than in the solid glass ($z_a = 0$). We may describe the maximum growth rate in the presence of an air space by an effective nonlinear index of refraction $n_{2\,\mathrm{eff}}$, which is lower than the actual nonlinear index n_2. We find that up to a point the thicker the glass disk, the lower $n_{2\,\mathrm{eff}}$. At most an effective 10-percent reduction in the nonlinear index can be achieved by the optimal spacing. For an instability growth of one e-folding length as is representative of a conventional disk system, this reduction is 5 percent.

For the purposes of this analysis, we use the results of the general formalism by Suydam [2], [3] for self-focusing. Given the quasi-optical approximation to the wave equation

$$(2i\omega/v)\partial E/\partial z = \nabla_\perp^2 E + \gamma |E|^2 E \tag{1}$$

where v is the velocity of light in the medium, and ω is the angular frequency of the light, and where the change in index of refraction at frequency ω experienced by a small amplitude test wave is

$$\delta n = \tfrac{1}{2}\omega^{-2} v c \gamma |E|^2$$

the perturbed field of the plane wave solution may be written

$$E = A_0(1 + u\cos k_x x \cos k_y y) \cdot \exp i(\phi_0 + q \cos k_x x \cos k_y y) \tag{2}$$

where u perturbs the amplitude and q perturbs the phase. Using the relationship between ϕ_0 and A_0, Suydam has found for the case of no gain

$$\begin{aligned} (2\omega/v)(du/dz) &= -k^2 q \\ (2\omega/v)(dq/dz) &= (k^2 - 2\gamma A_0^2)u \\ k &= (k_x^2 + k_y^2)^{1/2}. \end{aligned} \tag{3}$$

These equations indicate that the growth of the fractional perturbation u with a transverse wavenumber k is

$$u = c_0 \exp(\alpha z) + c_1 \exp(-\alpha z) \tag{4}$$

where the growth rate α is given by

$$\alpha = (vk/2\omega)(2\gamma A_0^2 - k^2)^{1/2}. \tag{5}$$

The parameter z is the distance into the medium and c_0 and c_1 are free constants. We use this result in conjunction with boundary conditions to derive a propagation or scattering matrix which relates the growth coefficients $\bar{c}_0$ and $\bar{c}_1$ in a second piece of glass shown in Fig. 1 to those in the first by

$$\begin{bmatrix} \bar{c}_0 \\ \bar{c}_1 \end{bmatrix} = \begin{bmatrix} T_{11} & T_{12} \\ T_{21} & T_{22} \end{bmatrix} \begin{bmatrix} c_0 \\ c_1 \end{bmatrix} \tag{6}$$

where T_{ij} is determined by the matching procedure.

The boundary conditions on the electric field envelope at a plane perpendicular antireflecting interface are that the intensity and phase are continuous. More precisely, the electric field envelope is written as in (2), and these conditions require that in a medium with dielectric constant ϵ, $(\epsilon)^{1/2}A_0^2$ and ϕ_0 are continuous as well as u and q. The quantities u and q are determined by (3), where $v = c(\epsilon)^{-1/2}$ so that continuity of q demands a jump discontinuity in du/dz given by

$$(du/dz)_0 = (\epsilon_1/\epsilon_0)^{1/2}(du/dz)_1. \tag{7}$$

We must now do the matching. Three of the matching regions are shown in Fig. 1. We need only consider these three regions in a periodic problem since the transformation matrix will simply be raised to powers to represent the additional

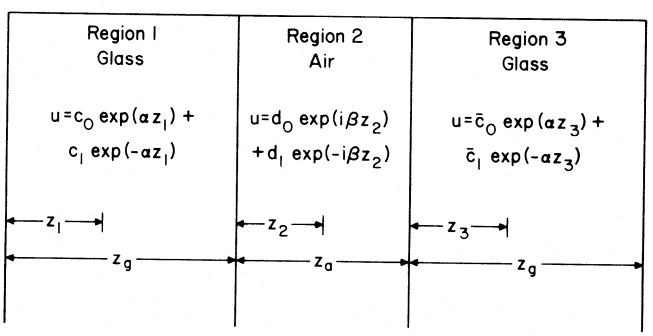

Fig. 1. The three regions in the matching which are joined by the required continuity of u and the discontinuity in its derivative given by (7).

structures. In region 2, the air space, the value of q is imaginary since no self-focusing occurs there. The procedure in solving the problem is identical to the quantum mechanical barrier penetration problem and will not be given here. The results are that

$$T_{ij} = \frac{1}{\cos\theta} \cdot \begin{bmatrix} \cos(\beta z_a + \theta)\exp(\alpha z_g), & -\sin\beta z_a \\ \sin\beta z_a, & \cos(\beta z_a - \theta)\exp(-\alpha z_g) \end{bmatrix} \tag{8}$$

where

$$\theta = \cos^{-1}[2/(\alpha c/\beta v) + (\beta v/\alpha c)]$$

and

$$\beta = vk^2/2\omega$$

also $|T| = 1$. It is the largest eigenvalue of this matrix which gives the growth of the instability.

We find that the two eigenvalues of our transformation matrix are given by

$$\lambda_{\pm}^2 - 2F\lambda_{\pm} + 1 = 0 \tag{9}$$

where F is half the trace of the matrix

$$F = (\tfrac{1}{2})(T_{11} + T_{22}). \tag{10}$$

The product of the two eigenvalues is unity and their average is F. If F^2 is less than unity the eigenvalue is complex but has unity modulus. For F^2 larger than unity, the largest eigenvalue in absolute value λ is

$$\lambda = |F|\,[1 + (1 - F^{-2})^{1/2}] \tag{11}$$

which increases as $|F|$ increases. It is convenient to rewrite F in the form

$$F = \cos(\bar{z}\rho x^2)\cosh(\bar{z}y) + (1 - x^2)y^{-1}\sin(\bar{z}\rho x^2)\sinh(\bar{z}y) \tag{12}$$

$$y = x(2 - x^2)^{1/2}$$
$$\bar{z} = (vk_0^2/2\omega)z_g$$
$$\rho = n_g z_a/n_a z_g$$
$$x = k/k_0. \tag{13}$$

The expression in parentheses for $\bar{z}$ is the peak growth rate α_0 in solid glass; the quantity ρ is a normalized aspect ratio; and x is the transverse wavenumber normalized to the wavenumber k_0 which has the peak growth in the solid. We may look at $\bar{z}$ as being a measure of the glass thickness; $\rho\bar{z}$, a measure of the air space; and x, a measure of the transverse wavenumber of the perturbation.

In order to minimize self-focusing in this system, we may cast the analysis in the form of a min-max problem [5] in which self-focusing chooses the value of k to maximize damage (growth of instabilities) in the glass, and in which we choose the normalized aspect ratio which minimizes our loss. We wish to find

$$\lambda_{mm}(\bar{z}) = \min_{\rho}\max_{x} |\lambda(x, \rho, \bar{z})|. \tag{14}$$

It turns out that our optimal strategy does not occur at a saddle point of λ so that the usual analytical methods do not apply. However, we can ask: if we were to choose the worst value of ρ, what would our damage be? This is the max-max problem which does have a simple solution given in the Appendix. The worst we can do is the same as we did with no air space, i.e.

$$\max\max |\lambda(x, \rho, \bar{z})| = \max_{x} |\lambda(x, 0, \bar{z})| = \exp(\bar{z}). \tag{15}$$

This says that the worst case is solid glass.

A simple analogy may help us understand the min-max problem. Consider the model problem of finding the lowest constant altitude constant latitude flight path across the United States. For each latitude we find the highest altitude and then we examine this value for each east-to-west route to find the lowest of these. A typical terrain of our self-focusing problem is shown in Fig. 2; the ridges are the analogs of the mountain ranges of the United States. Latitude corresponds to the value of $\rho\bar{z}$ and longitude to x.

When we look at a side view of the terrain of our problem we see it as in Fig. 3. The important thing to notice is that the optimal point (lowest point on the envelope), occurs where two ridges have the same height at a latitude of $\rho\bar{z} = 1.5708$; *the optimal point is not a saddle point of* F. Here at increasing latitude one ridge is decreasing in height and the other is increasing in height; the inevitable crossing is the optimal point.

We may set down these observations in terms of three conditions on F. First and second, we demand we are on two ridges, one at $x_1, \rho, \bar{z}$ and the other at $x_2, \rho, \bar{z}$. This requires extrema in x and may be written

$$F_1(x_1, \rho, \bar{z}) = F_1(x_2, \rho, \bar{z}) = 0 \tag{16}$$

where the subscript 1 indicates partial differentiation with respect to the first argument. Third, we demand the two ridges be of equal height

$$|F(x_1, \rho, \bar{z})| = |F(x_2, \rho, \bar{z})|. \tag{17}$$

These equations possess solutions for all values of $\bar{z}$. These are

$$\rho\bar{z} = \pi/2, \quad x_1^2 + x_2^2 = 2. \tag{18}$$

The preceding two conditions guarantee the equality of F at x_1 and x_2, and F_1 at x_1 and x_2.

The remaining degree of freedom is fixed by a single transcendental equation which dictates we are on a ridge. The condition is

$$F_1(x_1, \pi/2\bar{z}, \bar{z}) = 0 \tag{19}$$

and this serves to determine x_1 where by convention x_1 is chosen less than unity and x_2 greater than unity. One method of solving for x_1 is to isolate the root of (19) to the nearest 0.01 and then apply Newton's method successively.

The preceding results indicate: First, that at the optimal point there are two spot sizes (values of k^{-1}), one smaller and one larger than the optimal spot in solid glass, which now have

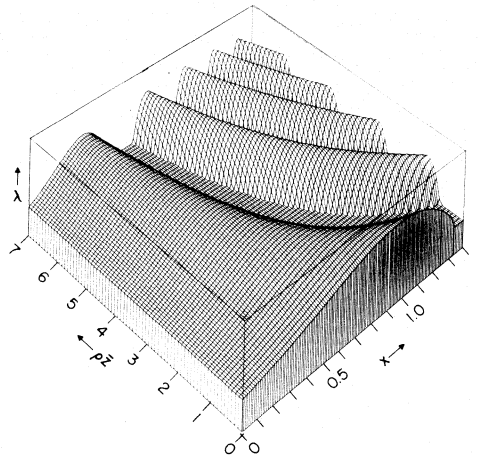

Fig. 2. A projection plot of the surface $|\lambda(x, \rho, 1)|$ which is analogous to the terrain of the United States high above the west coast. The flat regions correspond to $|F|$ less than unity, where $|\lambda|$ is taken to be unity. The ridges are analogous to mountain ranges.

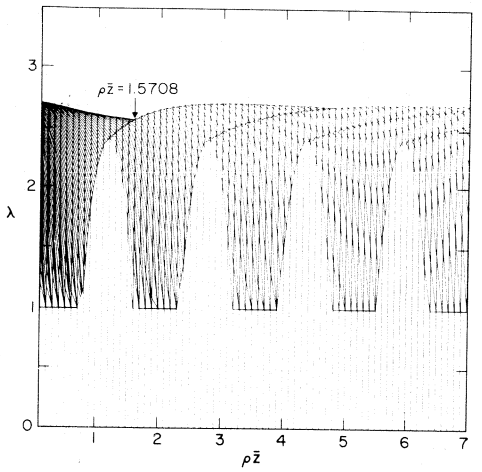

Fig. 3. A picture plot view of the terrain from the east coast ($x = +\infty$). The closest part of the plot corresponds to $x = \sqrt{2}$. Here we wish to find the lowest point at which we can see daylight; this point is indicated by the arrow.

optimal growth rates. The spot which is smaller is never smaller in radius by more than $(2)^{-1/2}(x_2 \leqslant 2^{1/2})$. The larger of the two spots increases in size if the air gap remains fixed and the width of the glass diminishes ($\bar{z} \to 0$). These results are shown in Fig. 4 where we plot x_1 and x_2 versus $\bar{z}$. As we expect, as $\bar{z}$ becomes large (ρ becomes small) we recover the solid glass results. Second, examination of the results shows us that many very thin glass structures are just as bad as one very thick glass structure—the growth rates are the same as in solid glass, the worst possible case. In between these extremes we must get the best improvement in performance of the glass. We may describe the performance by an effective value $n_{2\,\mathrm{eff}}$ of the nonlinear index which is lower than the actual value n_2 and given in terms of the growth of the instability λ_{mm} by

$$\lambda_{mm} = \exp\,(n_{2\,\mathrm{eff}}\bar{z}/n_2). \tag{20}$$

The fractional decrease $(n_2 - n_{2\,\mathrm{eff}})/n_2$ is shown in Fig. 5. As we expected a maximum decrease occurs and this corresponds to at most a 10-percent decrease in the value of n_2.

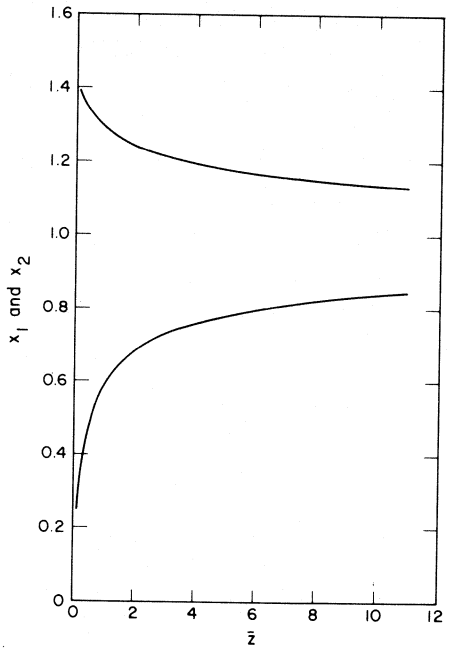

Fig. 4. A plot of $x_1(\bar{z})$ and $x_2(\bar{z})$ for the optimal solutions. Here $x_1^2 + x_2^2 = 2$ and x_1 are determined by (19). Knowing x_1 and x_2 we can then find the magnitude of both the transverse k vectors which give the optimal growth.

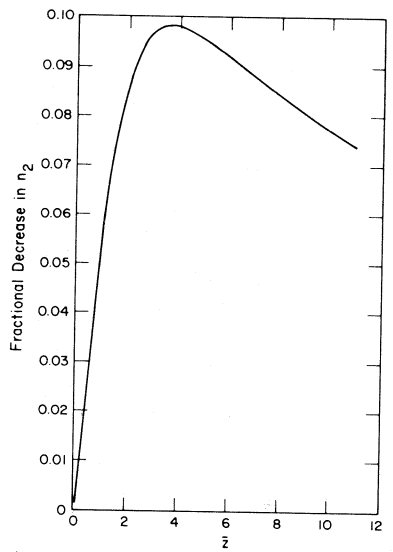

Fig. 5. The fractional decrease $(n_2 - n_{2\,\mathrm{eff}})/n_2$ in terms of $\bar{z}$ at the optimal solution. For large and small values of $\bar{z}$ there is no improvement over the worst possible case (solid glass); in between there is a maximum improvement of less than 10 percent.

In conclusion we find that periodic air-glass laser structures can at best account for a 10-percent improvement in the effective value of n_2 for small-scale self-focusing. This result should be contrasted with the result for the beam as a whole [6], [7] (large-scale self-focusing) in which the air spaces aggravate the self-focusing problem. In regards to small-scale self-focusing, these results indicate that consideration of the air space is a minimal design factor in glass-disk lasers, and that previous models which ignored these effects were adequate for many design purposes.

APPENDIX

The Max-Max Problem

We wish to find F_{mm} defined by

$$F_{mm} = \max_{\rho} \max_{x} |F(x, \rho, \bar{z})|. \tag{A1}$$

First we note that unlike the min-max problem, the two max operations commute so that

$$F_{mm} = \max_{x} \max_{\rho} |F(x, \rho, \bar{z})|. \tag{A2}$$

We may easily determine $\max_\rho |F|$ since ρ appears only as sines and cosines; that is, F of (12) may be written

$$F = C(x, \bar{z}) \cos [\rho \bar{z} x^2 + \theta (x, \bar{z})] \tag{A3}$$

where

$$\theta(x, \bar{z}) = -\tan^{-1} \{(1 - x^2) x^{-1} (2 - x^2)^{-1/2} \cdot \tanh [\bar{z} x (2 - x^2)^{1/2}]\} \tag{A4}$$

and

$$C(x, \bar{z}) = [\cosh^2 \bar{z} y + y^{-2} (1 - x^2)^2 \sinh^2 \bar{z} y]^{1/2} \tag{A5}$$

and y is given in (13). Only the amplitude $C(x, \bar{z})$ determines the maximum since the cosine factor can never exceed unity

$$\max_{\rho} |F| = C(x, \bar{z}). \tag{A6}$$

Examination of the structure of C indicates that it is monotonically increasing in y and that the maximum of C occurs at the peak value of y of unity where x is also unity and

$$F_{mm} = \max_{x} C(x, \bar{z}) = \cosh (\bar{z}). \tag{A7}$$

The growth rate which corresponds to F_{mm} is governed by (11) and it indicates that the worst possible ρ gives a growth rate of

$$\cosh (\bar{z}) [1 + (1 - \cosh^{-2} \bar{z})^{1/2}] = \exp \bar{z} \tag{A8}$$

which is the growth rate in solid glass. The worst possible growth rates occur at

$$\rho \bar{z} = n\pi - \theta (1, \bar{z}) = n\pi, \qquad n = 0, 1, 2, \cdots. \tag{A9}$$

We may see these peaks in the projection plot of Fig. 3.

Coupling Coefficients for Distributed Feedback Single- and Double-Heterostructure Diode Lasers

WILLIAM STREIFER, SENIOR MEMBER, IEEE, DONALD R. SCIFRES, MEMBER, IEEE, AND ROBERT D. BURNHAM

Abstract—**We compute coupling coefficients for TE modes as a function of tooth height, active layer thickness, and Bragg scattering order in single-heterostructure (SH) and double-heterostructure (DH) distributed feedback (DFB) diode lasers for a variety of corrugation shapes. In particular, equations for rectangular, sinusoidal, and triangular shapes are evaluated; the last both in the symmetric and sawtooth cases. It is shown that the coupling coefficient for rectangular and sawtooth gratings decreases much less rapidly with increasing Bragg order than do the sinusoidal and symmetric triangular.**

I. Introduction

DISTRIBUTED FEEDBACK (DFB) lasers differ from conventional lasers in that feedback is provided by a distributed periodic spatial variation in gain, refractive index, and/or geometry, rather than by discrete reflectors. The analysis of these devices [1] has been carried out as a function of the coupling coefficient κ, which describes the degree to which oppositely going waves transfer energy. Generally, κ has been expressed in terms of refractive index and/or gain variations, but in many cases there exist instead periodic corrugations which perturb the light. To employ the results of Kogelnik and Shank [1] for thresholds and frequencies of pure DFB lasers or similar results for DFB lasers with external reflectors [2]-[4] to geometries which employ corrugations [5]-[7], one must relate the coupling coefficients to the corrugations. This task has been formally carried out by several authors [8]-[10] using a perturbation procedure in which modes of the unperturbed structure are examined in their interaction with the corrugation. To date no extensive evaluation of the resulting integrals has been carried out except for square shaped corrugations, and therefore, no detailed comparisons of different corrugation shapes exist in the literature. Furthermore, the unperturbed mode fields used in many previous calculations were not chosen optimally and the published results are somewhat inaccurate. It is our purpose, therefore, in writing this paper to present analytic and numerical results for TE-mode coupling coefficients for various tooth shapes and Bragg scattering orders m using a more accurate formulation. We consider rectangular, sinusoidal, triangular, and sawtooth shapes in detail, but the methods employed are shown to be valid for other shapes as well. The derived formulas apply to both GaAs and dye DFB lasers, but are evaluated herein only for GaAs/GaAlAs SH's and DH's.

II. Analytic Results

In three-layer laser structures, as illustrated in Fig. 1, there exist right and left going TE and TM modes coupled by the corrugations. A perturbation analysis is used to obtain an expression for the coupling coefficients produced by the corrugations and thereby permit one to predict thresholds and lasing wavelengths as described in [1]-[4]. The result of the perturbation analysis, as given in [10], for TE modes is

$$\kappa = \frac{k_0^2}{2\beta N^2} \int_{\text{corrugation}} \Delta\,[n^2(x,z)]\; \mathcal{E}^2(x)\, dx \tag{1}$$

where κ is the coupling coefficient, $k_0 = 2\pi/\lambda_0$ (the free-space wavenumber), β is the TE-mode propagation constant, $\mathcal{E}$ is the y component of the unperturbed E-field, and N^2 is a normalization constant given by

$$N^2 = \int_{-\infty}^{\infty} \mathcal{E}^2(x)\, dx. \tag{2}$$

As shown in the following only the negative spatial harmonic of $\Delta\,[n^2(x,z)]$ (which is the perturbation in refractive index of the corrugation) appropriate to the Bragg scattering is to be retained.

In [10] the full guide width t (see Fig. 1) was employed to compute the unperturbed mode field $\mathcal{E}$, but as shown in [11], this can lead to inaccurate excessively high coupling coefficients. The optimal unperturbed mode $\mathcal{E}$ is that of a related four-layer structure (see [11]); however, we have found that one can obtain adequate accuracy without excessive complexity by judiciously choosing the unperturbed guide boundary at $t' < t$. We choose t' such that the volume of n_1 material extending into region 2 just equals the volume of n_2 material extending into region 1. The symbol t' thus refers to the distance from the n_2-n_3 interface to the line

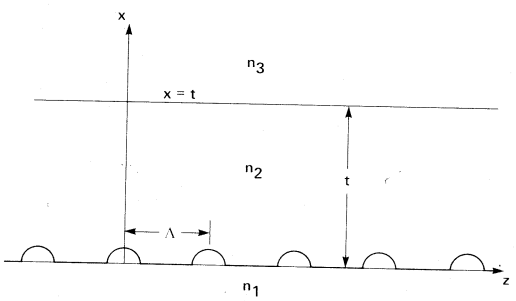

Fig. 1. Three-layer DFB laser structure.

shown in Fig. 2. That line is positioned such that the areas labeled A and B are equal. It is not coincident with the base of the teeth as in [10], [12], [13]. The unperturbed mode $\mathcal{E}(x)$ is then

$$\mathcal{E}(x) = \begin{cases} \exp(qx), & x \le 0 \\ \cos(hx) + (q/h)\sin(hx), & 0 \le x \le t' \\ [\cos(ht') + (q/h)\sin(ht')]\exp[-p(x-t')], & t' \le x \end{cases} \quad (3)$$

where

$$q = \sqrt{\beta^2 - n_1^2 k^2} \quad (4a)$$

$$h = \sqrt{n_2^2 k^2 - \beta^2} \quad (4b)$$

$$p = \sqrt{\beta^2 - n_3^2 k^2} \quad (4c)$$

and where β is found by solving

$$\tan(ht') = \frac{h(q+p)}{h^2 - pq} \quad (5)$$

and

$$N^2 = \int_{-\infty}^{\infty} \mathcal{E}^2(x)\,dx = \frac{(h^2+q^2)(t'+q^{-1}+p^{-1})}{2h^2}. \quad (6)$$

Consider now a single corrugation as shown in Fig. 2. Here

$$\Delta[n^2(x,z)] = \begin{cases} n_1^2 - n_2^2, & \text{in area } A \\ n_2^2 - n_1^2, & \text{in area } B \end{cases} \quad (7)$$

and $w_i(x)$, $i = 1, 2, 3, 4$ describe the tooth boundary. If any of these functions are not single valued the tooth shape can be decomposed into two or more curves with single valued boundaries and the results superimposed.

Since $\Delta[n^2(x,z)]$ is periodic in z it is expanded in a Fourier series whose coefficients depend on x. After some manipulation we obtain

$$\Delta[n^2(x,z)] = \begin{cases} (n_1^2 - n_2^2)\left[\dfrac{w_2(x) - w_1(x)}{\Lambda} - \dfrac{i}{2\pi}\sum_{m=-\infty}^{\infty}\dfrac{1}{m}\right. \\ \quad \{\exp[i2\pi m w_2(x)/\Lambda] \\ \quad\quad - \exp[i2\pi m w_1(x)/\Lambda]\} \\ \quad\quad \left.\cdot \exp(-i2\pi m z/\Lambda)\right], \quad x > 0 \\ (n_2^2 - n_1^2)\left[\dfrac{w_4(x) - w_3(x)}{\Lambda} - \dfrac{i}{2\pi}\sum_{m=-\infty}^{\infty}\dfrac{1}{m}\right. \\ \quad \{\exp[i2\pi m w_4(x)/\Lambda] \\ \quad\quad - \exp[i2\pi m w_3(x)/\Lambda]\} \\ \quad\quad \left.\cdot \exp(-i2\pi m z/\Lambda)\right], \quad x < 0 \end{cases} \quad (8)$$

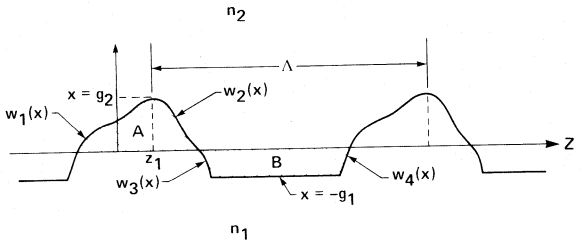

Fig. 2. Illustrating the functions defining tooth shape.

and so

$$\kappa = \frac{-ik_0^2(n_1^2 - n_2^2)}{4\pi\beta m N^2}\left\{\int_0^{g_2} \{\exp[i2\pi m w_2(x)/\Lambda] - \exp[i2\pi m w_1(x)/\Lambda]\}\,\mathcal{E}^2(x)\,dx - \int_{-g_1}^{0} \{\exp[i2\pi m w_4(x)/\Lambda] - \exp[i2\pi m w_3(x)/\Lambda]\}\,\mathcal{E}^2(x)\,dx\right\} \quad (9)$$

where, as shown in Fig. 2, g_1 and g_2 are the maximum tooth heights in media 1 and 2, respectively, and m is the Bragg scattering order.

Rectangular Grating

For rectangular teeth $w_2(x) = -w_1(x) = w/2$, $w_3(x) = w/2$, $w_4 = \Lambda - w/2$, and the area averaging conditions yields

$$g_1 = wg/\Lambda \quad (10)$$

and

$$g_2 = (1 - w/\Lambda)g \quad (11)$$

where g is the total tooth height. After integration (9) becomes

$$\kappa = \frac{k_0^2(n_1^2 - n_2^2)}{4\pi\beta m N^2}\sin\left(\frac{\pi m w}{\Lambda}\right)\left\{g_2 + \frac{\sin(2g_2h)}{2h} + \frac{q}{h^2}\cdot[1 - \cos(2g_2h)] + \frac{q^2}{h^2}\left[g_2 - \frac{\sin(2g_2h)}{2h}\right] + \frac{1}{q}[1 - \exp(-2qg_1)]\right\} \quad (12)$$

where q, h, and p are defined by (4a)-(4c).

In (12) the quantities β, N^2, q, and h all depend on the unperturbed geometry, i.e., n_1, n_2, n_3, and $t' = t - g_1$ as well as the transverse mode number. The dependence on Bragg order m is completely represented by the multiplicative factor

$$\frac{\sin(\pi m w/\Lambda)}{m}. \quad (13)$$

Clearly, κ can be zero for integral values of mw/Λ, but gen-

erally it decreases as $1/m$. Finally, the dependence on tooth height is given by the bracketed expressions, which for $2g_1h$, $2g_2h \ll 1$ reduces to $2g_1 + 2g_2 = 2g$. The dependence of κ on the various parameters is discussed more completely in [14].

Sinusoidal Grating

The tooth profile for sinusoidal teeth is

$$x = (g/2)\cos(2\pi z/\Lambda) \tag{14}$$

and so

$$w_2(x) = -w_1(x) = \frac{\Lambda}{2\pi}\cos^{-1}\left(\frac{2x}{g}\right) \tag{15a}$$

and

$$[w_4(x) - \Lambda/2] = -[w_3(x) - \Lambda/2] = \frac{\Lambda}{2\pi}\cos^{-1}\left(-\frac{2x}{g}\right) \tag{15b}$$

where it is understood that

$$0 < \cos^{-1}(U) < \pi/2.$$

The boundary line for the unperturbed modes bisects the corrugation and (9) is then

$$\kappa = \frac{k_0^2(n_1^2 - n_2^2)}{2\pi\beta m N^2}\left\{\int_0^{g/2} \sin\left[m\cos^{-1}(2x/g)\right]\mathcal{E}^2\,dx - (-1)^m\int_{-g/2}^{0}\sin\left[m\cos^{-1}(2x/g)\right]\mathcal{E}^2\,dx\right\}. \tag{16}$$

The integrals in (16) can be evaluated numerically or analytically by using trigonometric identities for $\sin[m\cos^{-1}(2x/g)]$ and expanding $\mathcal{E}^2(x)$ in power series. Details of the latter procedure and evaluation of the integrals are too lengthy to be included herein. The results for $m = 1, 2, 3$, and 4 are in the form

$$\kappa = \frac{k_0^2(n_1^2 - n_2^2)}{\beta N^2}\begin{cases}\frac{g}{8}S_1\\ \frac{g^2}{64}S_2\\ \frac{g^2}{60\pi}S_3\\ \frac{g^3}{420\pi}S_4\end{cases} \tag{17}$$

where S_i, $i = 1, 2, 3, 4$ are summations whose first terms are $S_1 = 1, S_2 = S_3 = q$, and $S_4 = (q^2 - h^2)/2$.

Symmetric Triangular Grating

Consider next a symmetric triangular grating defined by

$$w_1(x) = w_4(x) - \Lambda = \frac{x\Lambda}{2g} - \frac{\Lambda}{4} \tag{18a}$$

and

$$w_2(x) = w_3(x) = \frac{x\Lambda}{2g} + \frac{\Lambda}{4}. \tag{18b}$$

The integrals which result upon substitution in (9) are in standard form and are easily evaluated to yield

$$\kappa = \frac{k_0^2(n_1^2 - n_2^2)}{4\pi\beta m N^2}g\left\{\left(1 + \frac{q^2}{h^2}\right)\frac{[1 - \cos(\pi m/2)]}{\pi m} + \frac{q}{h}\frac{2}{[(2gh)^2 - (\pi m)^2]}[2gh\sin(\pi m/2) - \pi m\sin(gh)] - \left(1 - \frac{q^2}{h^2}\right)\frac{\pi m}{[(2gh)^2 - (\pi m)^2]}[\cos(gh) - \cos(\pi m/2)] - \frac{2(-1)^m}{[(2gq)^2 + (\pi m)^2]}[2gq\sin(\pi m/2) - \pi m\cos(\pi m/2) + \pi m e^{-gq}]\right\}. \tag{19}$$

Since $\sin(\pi m/2) = 0$ for m even and $\cos(\pi m/2) = 0$ for m odd many terms in (19) vanish for particular Bragg diffraction orders. In general, however, $\kappa \to 1/m^2$ with increasing order.

Sawtooth Grating

The sawtooth grating is defined by

$$w_1(x) = w_4(x) = x\Lambda/g \tag{20a}$$

and

$$w_2(x) = -w_3(x) = \Lambda/2. \tag{20b}$$

The integral (9) again is in standard form, and we find

$$\kappa = \frac{k_0^2(n_1^2 - n_2^2)}{8\pi\beta m N^2}\left\{g\left[\frac{(u-1)v_1}{2\pi m} + \frac{\pi m}{2d_1}\cdot\left\{v_2(1 - uC_1) - \frac{2uq}{h}S_1\right\} + \frac{\pi m}{d_2}(1 - uE_1)\right] - i\left[\frac{u}{2}\left\{v_1 g + \frac{2q}{h^2}(1 - C_1) + \frac{v_2}{h}S_1\right\} - \frac{g^2 h}{2d_1}\left\{\frac{2q}{h}(1 - uC_1) + uv_2S_1\right\} - \frac{qg^2}{d_2}(1 - uE_1) + \frac{u}{q}(1 - E_1)\right]\right\} \tag{21}$$

where

$$C_1 = \cos(gh), \quad S_1 = \sin(gh), \quad E_1 = \exp(-qg) \tag{22a}$$

$$v_1 = (1 + q^2/h^2), \quad v_2 = (1 - q^2/h^2) \tag{22b}$$

$$d_1 = (gh)^2 - (\pi m)^2, \quad d_2 = (gq)^2 + (\pi m)^2 \tag{22c}$$

and

$$u = (-1)^m. \tag{22d}$$

An examination of (21) reveals that $|\kappa| \to 1/m$ with increasing

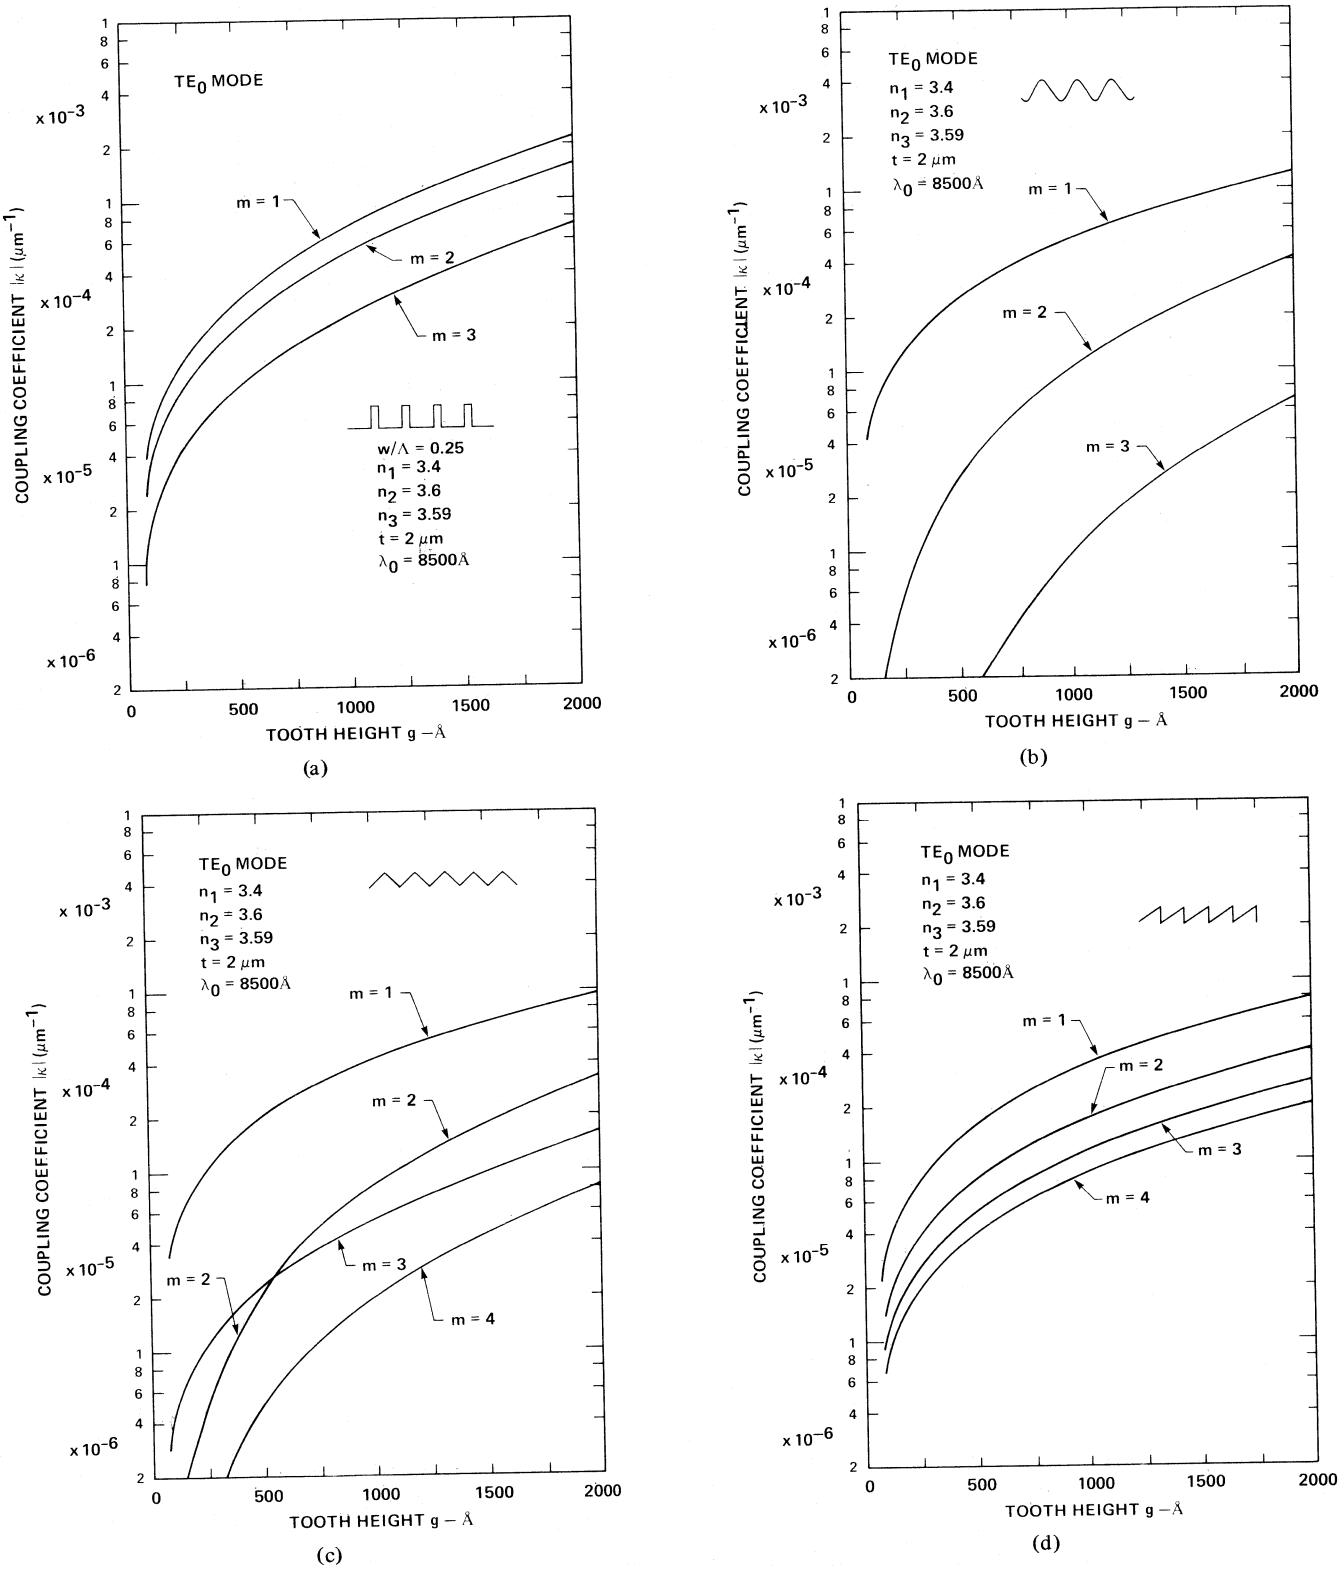

Fig. 3. Coupling coefficient versus tooth height with Bragg order as a parameter for TE_0 mode in a SH geometry. (a) Rectangular grating. (b) Sinusoidal grating. (c) Symmetric triangular grating. (d) Sawtooth grating.

m and for $gh, gq \ll 1$

$$|\kappa| \approx \frac{k_0^2(n_1^2 - n_2^2)}{8\pi\beta m N^2} g \tag{23}$$

where only the dominant inverse power of m has been retained.

III. Numerical Results

Fig. 3(a)-(d) are plots of coupling coefficient versus tooth height g in a SH GaAs DFB laser geometry for the four corrugation shapes discussed in the preceding. Interestingly enough, κ for $m = 1$ is not strongly dependent on tooth shape.

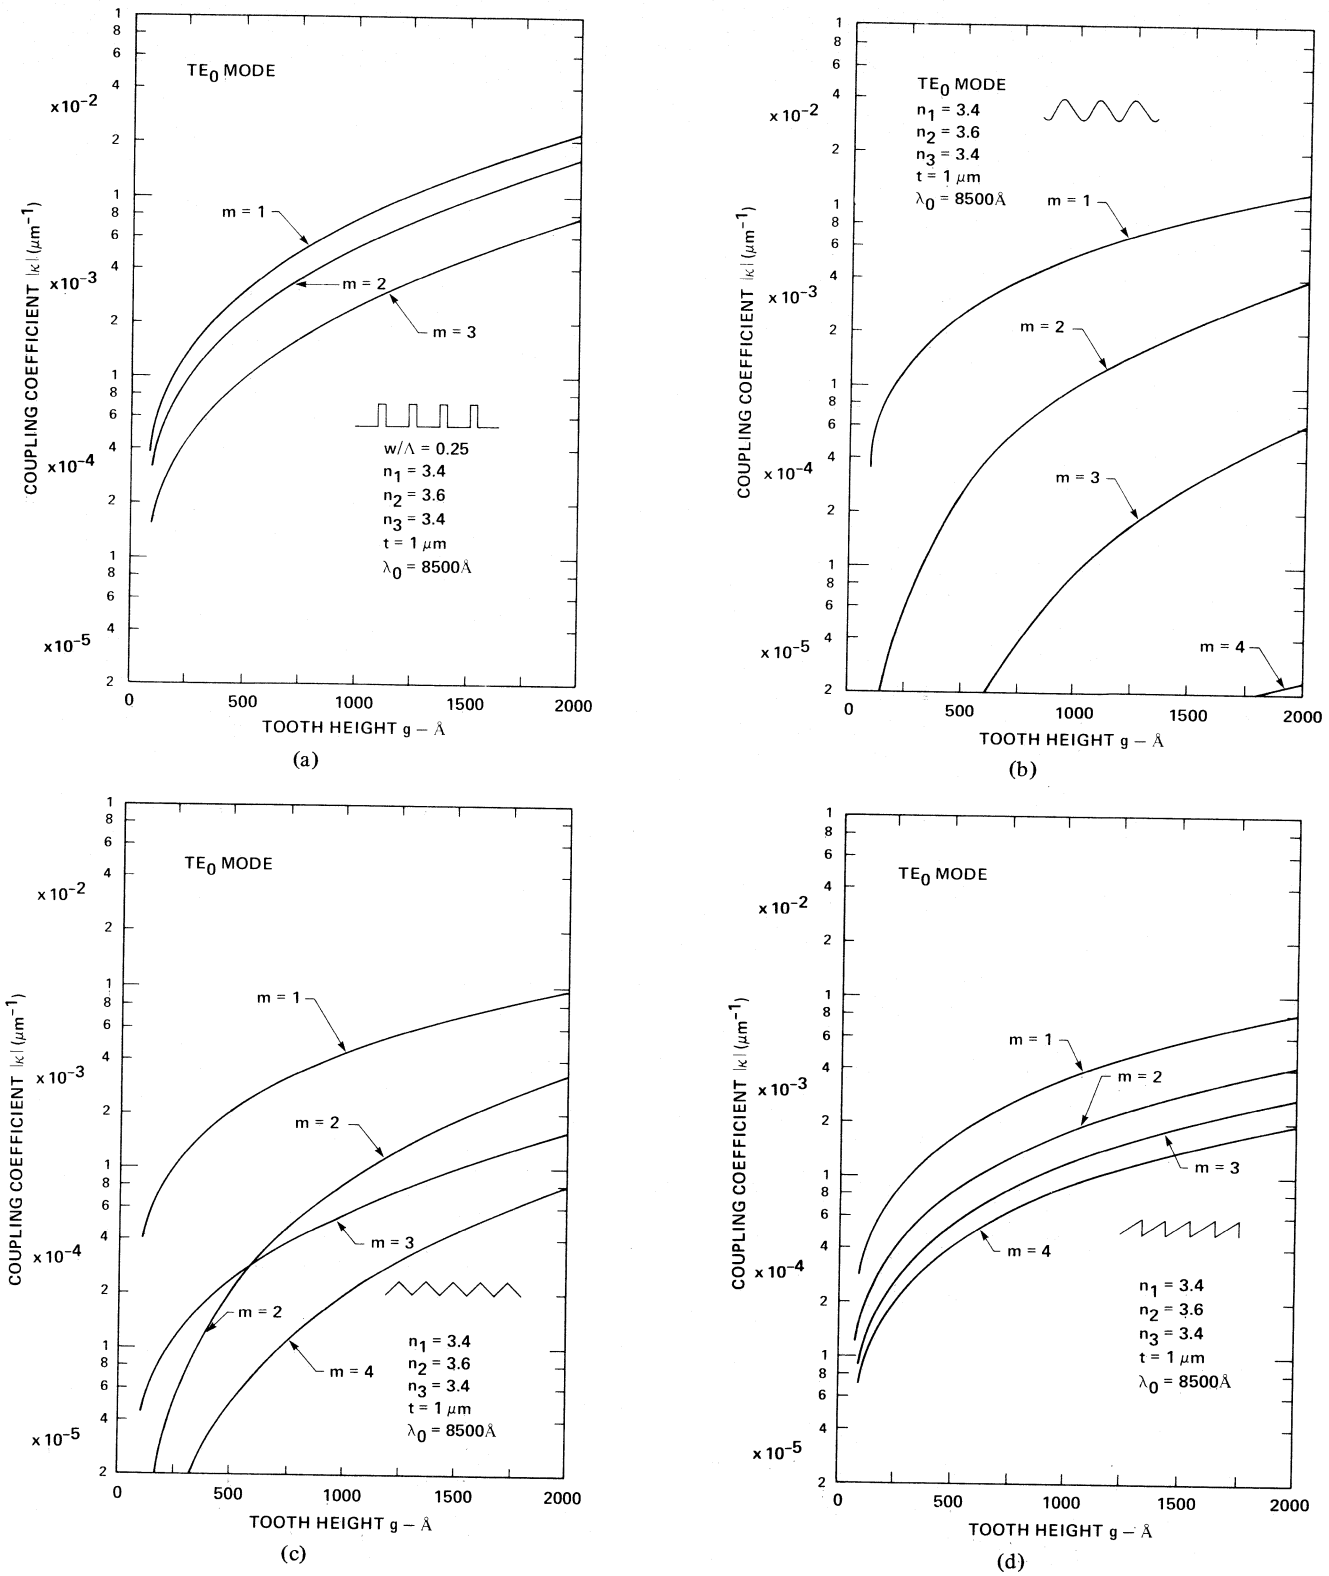

Fig. 4. Coupling coefficient versus tooth height with Bragg order as a parameter for TE_0 mode in a DH geometry. (a) Rectangular grating. (b) Sinusoidal grating. (c) Symmetric triangular grating. (d) Sawtooth grating.

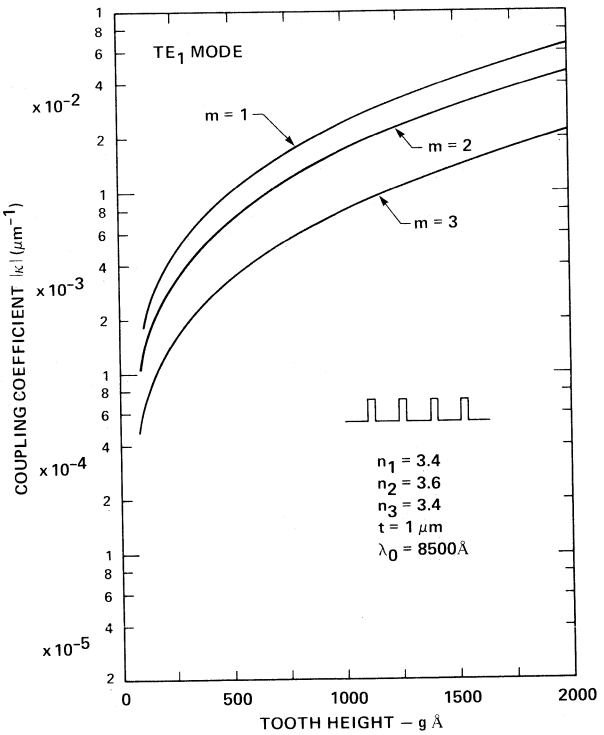
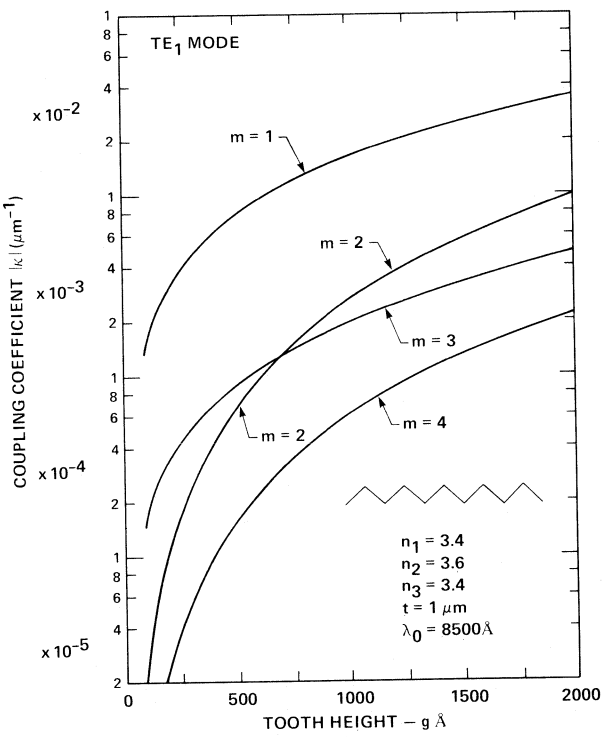


With increasing m the coupling constants for rectangular ($w/\Lambda = 0.25$) and sawtooth gratings decrease at approximately the same rate and that decrease is much less rapid than those for the triangular and sinusoidal gratings. The coupling coefficient for rectangular teeth with $m = 4$ is zero because the factor (13) is zero. Physically, when mw/Λ is an integer, reflections from the parallel vertical tooth boundaries are exactly a half-wavelength out-of-phase and therefore cancel. It is likely that $|\kappa|$ for any tooth shape with discontinuities will decrease with Bragg order at approximately the same

rate as the rectangular and sawtooth gratings. The coupling coefficient for sinusoidal teeth decreases most rapidly and for $m = 4$ values of $|\kappa|$ are all less than the lowest point on the graph. For symmetrical triangular teeth $|\kappa|$ also decreases quickly and exhibits other interesting behavior. In this case with m odd, $\kappa \propto g$ for small g, whereas with $m = 2$, $\kappa \propto g^2$ for small g; as g increases, however, the latter exceeds the former above approximately $g = 550$ Å.



Consider next the aspect ratios. Since it is often the period Λ which largely determines the maximum tooth height, one may well ask, given a fixed aspect ratio of tooth height to period, what Bragg order will maximize κ? Clearly, for rectangular and sawteeth dividing tooth height and period by m reduces κ by a greater factor. Thus, other considerations aside, one need not (in these cases) strive for lowest order Bragg scattering. Of course, this result is predicated on the assumption of constant aspect ratio, particular tooth shapes (since it is invalid in the other cases), and finally the neglect of other phenomena such as radiation losses to the lower order Bragg scattering modes.

In Fig. 4(a)-(d) we plot similar curves for the lowest order transverse mode TE_0 in a DH geometry ($n_1 = n_3 = 3.4$, $n_2 = 3.6$, and $t = 1.0$ μm). As a result of the stronger confinement and smaller thickness the coupling coefficients exceed those for the SH geometry by more than an order of magnitude. For the particular refractive indices and thickness given in the preceding the DH geometry will actually allow additional transverse electric modes to propagate, the TE_1 and TE_2. In Fig. 5(a) and (b) we plot $|\kappa|$ versus tooth height for the TE_1 mode with rectangular ($w/\Lambda = 0.25$) and symmetric triangular corrugations, respectively. Values of $|\kappa|$ are roughly a factor of 3 greater than for the TE_0 mode in the same geometry. It should be noted that the grating period Λ must be adjusted somewhat to resonate these higher order transverse modes [13]-[15]. Also as shown in [13] and [15], depending on t, $|\kappa|$ may continue to increase with transverse mode number.

DFB lasers have also been shown to produce highly collimated beams by radiation from the grating [16]-[19]. For single beam output [19] it is best to employ the grating in the 2nd Bragg order, i.e., $m = 2$ and optimum output coupling may well occur for symmetric triangular or sawtooth gratings [20]. With $m = 2$, $\Lambda \simeq 2300$ Å, and so $g = 1150$ Å and $g = 2300$ Å will give teeth with a 45° slope for symmetric triangular or sawtooth gratings, respectively. We plot $|\kappa|$ versus t for four transverse (TE) modes in a DH geometry with a symmetric triangular grating in Fig. 6. The TE_1, TE_2, and TE_3 modes all exhibit a more complex $|\kappa|$ versus t dependence then shown in Fig. 6. In Fig. 7 we plot $|\kappa|$ versus t for a small range of t just above cutoff for the TE_2 mode. The behavior illustrated can be explained mathematically by studying (19). As t increases the bracketed expression changes from positive to negative at which point $|\kappa|$ passes through zero. Physically, there is destructive interference from different parts of the tooth which exactly cancel for a particular value of t. This phenomenon is not of great significance since it is probably desirable to resonate the transverse modes well above cutoff.

Characteristics of Room-Temperature 2.3-μm Laser Emission from Tm^{3+} in YAG and $YAlO_3$

JOHN A. CAIRD, MEMBER, IEEE, LARRY G. DESHAZER, AND JOHN NELLA

Abstract—The relaxation of low-lying excited states of Tm^{3+} ions doped in YAG, $YAlO_3$, and Y_2O_3 due to photon and phonon emission is studied theoretically. Stimulated emission cross sections (integrated over frequency), fluorescence lifetimes, and radiative quantum efficiencies are calculated and their implications for laser operation on the 2.3-μm $^3F_4 \rightarrow {}^3H_5$ line of Tm^{3+} are discussed. The calculations, based on a few phenomenological parameters which have been determined by others, are easily generalizable to other host materials and other rare-earth (RE) ions.

Room-temperature pulsed laser emission from Tm^{3+} ions near 2.3 μm was observed on one line in Tm:Cr:YAG, and on four lines in Tm:Cr:$YAlO_3$. Lower oscillation thresholds were generally obtained in the $YAlO_3$ rods, consistent with the theory presented. A threshold of 31 J was obtained with a Tm:Cr:$YAlO_3$ rod at 2.274 μm. In the free-running pulsed mode, peak power levels up to several hundred watts and total output energies up to 12 mJ/pulse were observed. Other general, observed operating characteristics are discussed.

I. INTRODUCTION

THE STRONG, sharp line fluorescence from transparent crystals doped with rare-earth (RE) ions has long been recognized. As a result, these materials have been used extensively as active media in optically pumped laser devices. The choice of RE crystal combinations for use as laser materials has generally been made empirically, but quantitative theories have been used increasingly in recent years to evaluate RE laser materials. In 1968, Riseberg, Moos, and Partlow [1] discussed the application of multiphonon relaxation data to the design of quantum electronic devices. Subsequently, Moos [2] has described a three parameter model for calculating these nonradiative transition rates. Since the early 1970's the techniques developed by Judd [3] and Ofelt [4] (the J-O model) have been used in several studies to calculate radiative transition rates in RE laser materials [5]-[8]. The combination of these theories into a general evaluation procedure was proposed by Krupke [9] and has been used to study a large number of actual and potential laser devices [10]-[12]. The pertinent calculations will be described here for three thulium-doped crystals.

The need for additional laser sources operating in the 2-2.5-μm atmospheric window led to a search for a suitable RE/host system [13], [14]. As will be shown, the $^3F_4 \rightarrow {}^3H_5$ fluorescence of trivalent thulium (Tm^{3+}) was found to have characteristics favorable to laser action around 2.3 μm. A Tm:Cr:$YAlO_3$ laser rod was subsequently fabricated, and pulsed oscillation was demonstrated on two lines near 2.3μm [14], [15]. Additional study of this system has led to the observation of new laser lines, reported here, at 2.27 and 2.32 μm in Tm:Cr:$YAlO_3$ and at 2.32 μm in Tm:Cr:YAG. The pertinent energy manifolds are depicted in Fig. 1, where the sensitizing function of the Cr^{3+} ions is indicated. Laser oscillation on $^3H_4 \rightarrow {}^3H_6$ transitions has been previously reported in Tm:Cr:YAG at 2.01 μm and in Tm:YAG at 1.88 and 2.01 μm [16]. The latter part of this paper discusses the characteristics of the observed $^3F_4 \rightarrow {}^3H_5$ laser emission (e.g., wavelength, threshold, polarization, and efficiency), along with the prospects for improved performance and CW operation.

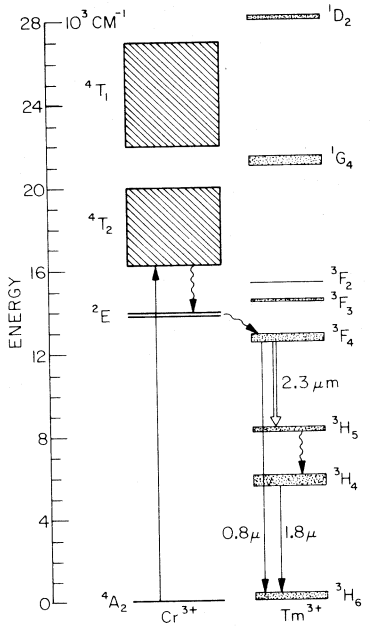

Fig. 1. Energy level diagram of the 2.3-μm Tm^{3+} laser sensitized with Cr^{3+} (after Hobrock [14]).

II. THEORETICAL CONSIDERATIONS

Since the 2.3-μm thulium laser was developed as a result of the previously mentioned theoretical work, the relevant calculations will be described here. This will show, by example, how the theories are applied, and will be compared qualitatively with the experimental results. Some of the parameters used, which will be described, were only estimated when the original analysis was performed [13], but have

subsequently appeared in the literature. The discussion will be limited to thulium-doped $YAlO_3$, YAG, and Y_2O_3, since these are the only materials for which a full set of parameters is currently available.

A. Radiative Transitions

The spontaneous emission rate between two nondegenerate energy levels due to dipolar processes is given by

$$A(\alpha,\beta)=\frac{64\pi^4}{3h\bar{\lambda}^3}\chi|\langle\alpha|\boldsymbol{D}|\beta\rangle|^2 \tag{1}$$

where $\bar{\lambda}$ is the mean wavelength of the transition and $\boldsymbol{D}$ is the electric or magnetic dipole operator. In (1), χ is a factor which corrects for the local effective field and increased density of electromagnetic states seen by an atomic system embedded in a dielectric medium. If a dielectric with refractive index n has zero magnetic susceptibility, there is no effective field correction for magnetic dipole emission and χ is given by n^3 due to the increased density of final states of the electromagnetic field. In such cases it can be shown, in the tight binding limit, that the first-order correction factor for electric dipole emission is $\chi=n(n^2+2)^2/9$ [17].

In laser devices another very important parameter is the cross section for stimulated emission which for nondegenerate levels is equal to the absorption cross section. The integrated cross section Σ can be related to the spontaneous emission rate [18]

$$\Sigma(\alpha,\beta)\equiv\int\sigma(\nu)d\nu=\frac{\bar{\lambda}^2}{8\pi n^2 c}A(\alpha,\beta) \tag{2}$$

where ν has been taken in wavenumbers ($\nu=1/\lambda$). In (2) the factor n^2 takes into account the reduced velocity of light in the medium along with the increased density of states. From (1) and (2) the integrated cross section is given by

$$\Sigma(\alpha,\beta)=\frac{8\pi^3}{3hc\bar{\lambda}}\frac{\chi}{n^2}|\langle\alpha|\boldsymbol{D}|\beta\rangle|^2. \tag{3}$$

For RE ions doped in crystals the $2J+1$ levels associated with a state of total angular momentum J are only split by a few hundred wavenumbers, so that experimental observations often involve averages over them. The total transition rate from level α to all components β of level $|bJ'\rangle$ is given by

$$A(\alpha,bJ')=\sum_{\beta}A(\alpha,\beta). \tag{4}$$

Then if the individual components α of level $|aJ\rangle$ are equally populated, the observed decay rate will be the average over the upper manifold. Thus the observed rate is

$$A(aJ,bJ')=\frac{1}{(2J+1)}\sum_{\alpha,\beta}A(\alpha,\beta) \tag{5}$$

which, using (1), becomes

$$A(aJ,bJ')=\frac{64\pi^4\chi}{3h\bar{\lambda}^3(2J+1)}\sum_{\alpha,\beta}|\langle aJ\alpha|\boldsymbol{D}|bJ'\beta\rangle|^2. \tag{6}$$

Similarly, the observed integrated emission cross section is

$$\Sigma(aJ,bJ')=\frac{8\pi^3}{3hc\bar{\lambda}(2J+1)}\frac{\chi}{n^2}\sum_{\alpha,\beta}|\langle aJ\alpha|\boldsymbol{D}|bJ'\beta\rangle|^2. \tag{7}$$

The results predicted by these equations can be in error to some extent when the equal population assumption is strongly violated.

Fundamental to the calculation of these quantities are the dipole matrix elements. Formulas for the magnetic dipole matrix elements can be found in standard texts [19]. The electric dipole matrix elements in the J-O model [3], [4] can be written as

$$\sum_{\alpha,\beta}|\langle aJ\alpha|\boldsymbol{D}|bJ'\beta\rangle|^2=e^2\sum_{t=2,4,6}\Omega_t|\langle aJ\|U^t\|bJ'\rangle|^2 \tag{8}$$

where the Ω_t are intensity parameters, usually derived empirically, and the $\langle\|U^t\|\rangle$ are reduced matrix elements of the angular unit tensor operators in the atomic $4f^n$ configuration. Intensity parameters have been published for Tm^{3+} in YAG [12], $YAlO_3$ [20], and Y_2O_3 [21] and are listed in Table I. A computer program was written to calculate the required matrix elements [10] using techniques described by Judd [22]. The wave functions for Tm^{3+} derived by Krupke and Gruber [23] were used to compute the unit tensor operator matrix elements, listed in Table II, between low-lying energy levels. Table III lists the resulting integrated emission cross sections and spontaneous emission rates calculated for each material, including both electric and magnetic dipole contributions. In a previous study [10], [11] it was found that many RE transitions with Σ values greater than 10^{-18} cm have produced laser emission provided that the relaxation of the upper level by other mechanisms is sufficiently slow, that is, provided that its radiative quantum efficiency is sufficiently high.

B. Nonradiative Transitions

For low-RE dopant concentrations the dominant nonradiative relaxation mechanism is multiphonon emission. According to Moos [2] the multiphonon relaxation rate can be approximated by

$$R(a)=Be^{-\alpha\Delta E_a}\left\{1+\left[\exp\left(\frac{E_p}{kT}\right)-1\right]^{-1}\right\}^{\frac{\Delta E_a}{E_p}} \tag{9}$$

where B, α, and E_p are characteristic of the host crystal, with negligible dependence on the dopant ion. In (9), ΔE_a is the energy gap between level a and the next lower level. The bracketed factor in (9) accounts for increased transition rates

at elevated temperatures due to emission stimulated by thermal phonons of energy E_p. This factor may be neglected at temperatures for which E_p is much greater than kT.

Transition rates due to multiphonon emission have been measured in YAG [24], $YAlO_3$ [25], and Y_2O_3 [26], [27]. Estimates of the parameters B, α, and E_p based on these data are listed in Table IV. Using these parameters the measured rates are typically within a factor of 2 of the rates predicted by (9). The predicted multiphonon decay rates for the low-lying thulium energy levels are given in Table V for each crystal. The energy gaps ΔE_a were found from the absorption spectra of Tm:Y_2O_3 [28] and Tm:$YAlO_3$ [14]. For the purposes of this calculation, the energy gaps for Tm:YAG were assumed to be equal to those of Tm:$YAlO_3$. The transition rates for the $^3F_2$ level are not expected to be accurate since the energy gap ΔE_a is less than E_p.

C. Quantum Efficiencies and Conclusions

When the RE-ion doping level is on the order of one atomic percent or less, concentration-dependent nonradiative relaxation mechanisms such as ion-pair relaxation can generally be neglected. In such cases the nonradiative lifetime τ_n is given by

$$\frac{1}{\tau_n(a)} = R(a). \tag{10}$$

The radiative lifetime τ_r of the level is defined as

$$\frac{1}{\tau_r(a)} = \sum_b A(a, b) \tag{11}$$

where the J's of (6) have been dropped for simplicity. The total lifetime τ is found from

$$\frac{1}{\tau(a)} = \frac{1}{\tau_n(a)} + \frac{1}{\tau_r(a)} \tag{12}$$

and the radiative quantum efficiency is given by

$$\eta_a = \frac{\tau(a)}{\tau_r(a)}. \tag{13}$$

These quantities were calculated for each crystal using the results from Tables III and V and are listed in Table VI.

It is evident that only the $^3H_4$ and $^3F_4$ energy levels have high radiative quantum efficiencies, and can be expected to fluoresce strongly. The previously observed $^3H_4 \rightarrow {}^3H_6$ laser emission has been noted in Section I. Here we are interested in the $^3F_4 \rightarrow {}^3H_5$ transitions around 2.3 μm. Table VI shows that the $^3F_4$ level should fluoresce in all three crystals, though somewhat more weakly in YAG. The integrated cross section of the $^3F_4 \rightarrow {}^3H_5$ transition is highest in $YAlO_3$ (Table III) which is not surprising since for this transition the $(U^{(4)})^2$ matrix element is by far the largest (Table II), while the largest Ω_4 parameter occurs in $YAlO_3$ (Table I). Additional advantages predicted for $YAlO_3$ include the fastest decay rate of the lower laser level and the fastest rate of energy transfer between the ^3F states.

However, there are additional factors to consider in choosing a laser crystal, which cannot be discussed quantitatively at present. An examination of the Tm^{3+} energy level diagram (see Fig. 1) shows the shortage of energy levels above the $^3F_4$ state which can be used for optical pumping. Efficient flashlamp to laser energy conversion therefore requires sensi-

tization by one or more additional dopants. In this case, trivalent chromium ions provide broad absorption bands in the visible and efficient energy transfer to the ^3F multiplet of thulium [16], [29]. In YAG the pulsed threshold for $^3H_4 \rightarrow {}^3H_6$ laser emission in thulium was reduced by a factor of 7 when the crystal was co-doped with chromium [16]. The effect is expected to be even greater for $^3F_4 \rightarrow {}^3H_5$ transitions because none of the transferred energy is lost to $^3F_4 \rightarrow {}^3H_6$ fluorescence at 0.8 μm (see Fig. 1).

Chromium can be doped in YAG and $YAlO_3$ where it enters the lattice substitutionally at Al^{3+} sites, but it cannot be doped in Y_2O_3. For this reason YAG and $YAlO_3$ were considered the prime candidate hosts for the 2.3-μm thulium laser. In these crystals it is possible that the overriding factor affecting laser performance is the $Cr^{3+} \rightarrow Tm^{3+}$ energy transfer efficiency. Factors affecting this energy transfer, such as energy-level proximity and orbit-lattice coupling strengths, vary from crystal to crystal, and there is no applicable predictive theory. Also, it was felt that none of the existing experimental data on energy transfer were conclusive enough to make a decision on that basis alone.

On the basis of considerations presented so far, the prime candidate laser material was Tm:Cr:$YAlO_3$. Laser rods of this type were fabricated first, and laser action near 2.35 μm was demonstrated [14], [15]. However, because of the advanced growth technology of high-optical-quality YAG crystals, and the uncertainties regarding Cr^{3+} sensitization, a rod of Tm:Cr:YAG was also fabricated for testing.

TABLE VII
LASER ROD STATISTICS

D	Tm:Cr:YAG	3 x 50	1.0	0.10	- -

III. EXPERIMENTAL RESULTS

Long-pulse laser tests were performed at room temperature with three rods of Tm:Cr:$YAlO_3$ and one rod of Tm:Cr:YAG, all antireflection coated at 2.3 μm. Pertinent rod statistics are listed in Table VII. The orientation of the $YAlO_3$ rods used in these experiments was determined through the Laue backscatter method of X-ray diffraction. The absorption spectrum of each Tm:Cr:$YAlO_3$ rod was compared to that determined by Weber [29] to derive the doping levels of the rods. The doping levels listed in Table VII assume distribution coefficients of 1.0 for Tm^{3+} and 2.5 for Cr^{3+} in Weber's Czochralski-grown $YAlO_3$ samples. The Cr^{3+} doping level in the YAG rod was determined by comparison of the rod's absorption spectrum to that of a Cr^{3+}:YAG sample with known concentration [30]. The Tm^{3+} concentration in the YAG rod is listed according to the manufacturer's specifications (Union Carbide, Crystal Products Department), but was not determined here for lack of an adequate standard of comparison. The accuracy of the concentrations listed in Table VII is estimated to be ±10 percent.

Most experiments were performed with linear xenon flashlamps (ILC7L3 or ILC7L4) in elliptical pump cavities, and highly reflective (99+ percent) mirrors spaced 25 cm apart. Flashlamp pulses were limited to 1 ms or less in duration to minimize losses due to spontaneous relaxation of the upper laser level. A summary of the thresholds and polarizations of the observed laser lines appears in Table VIII. Thresholds for rods *A* and *B* were very similar, so the 2.27- and 2.32-μm entries have been omitted for rod *A*. The 2.35-μm doublet was resolved for rod *A* at about twice threshold, but the thresholds of the individual lines were not obtained since the signal level near threshold was too small to allow their resolution. The ILC flashlamps used had an inside diameter of 7 mm and were about 1 in longer than the laser rods so that the actual thresholds should be somewhat less than the reported electrical input energies. When rod *B* was pumped by a 450-torr xenon flashlamp with a 3-mm × 1-in luminous volume (ILC L-3F1G) in a 1-in pump cavity, laser action was observed at 44-J input. A threshold of 31 J was measured in the same cavity using a 1200-torr krypton flashlamp of the same dimensions.

Since the Stark splittings of Tm^{3+} in YAG were not determined, the specific laser transition was not identified for this

Note: Stark split levels are labeled $a, b, c, \cdots$, in order of increasing energy.

host. In $YAlO_3$, thulium enters the lattice on Y^{3+} sites with reflection symmetry (C_s) in the plane normal to the c axis [14]. As a result, the atomic wave functions are either even (Γ_1) or odd (Γ_2) under reflection in this plane, and $\Gamma_i \rightarrow \Gamma_j$ transitions are either σ polarized (in the reflection plane) if $i=j$, or π polarized (parallel to the c axis) if $i \neq j$. The Tm^{3+} energy levels in $YAlO_3$ and their reflection symmetries were determined previously at 4 K [14]. However, the identification of the room-temperature laser transitions is not straightforward since the energy levels shift slightly with temperature. The laser line polarizations are useful in making these identifications.

Since $YAlO_3$ is a biaxial crystal, the laser resonator modes tend to be polarized along the major and minor axes of the cross section of the Fresnel ellipsoid cut normal to the rod axis. In rods cut along one major crystal axis, these modes are polarized along the other two major axes. A calculation of the expected polarization directions in ⟨111⟩ $YAlO_3$ was performed using previously determined refractive indices [31]. When referred to the projection of the c axis in the plane normal to the ⟨111⟩ direction the mode angles were predicted to be $-16.4°$ and $+73.6°$. Measurements of the observed laser line polarizations were consistent with this calculation ($\pm 10°$), the prime source of error being caused by the transfer of the laser rod from the X-ray goniometer to the laser cavity. In each rod, laser emission at 2.318 μm was polarized in the polarization mode farthest from the c axis projection, indicating σ polarization. The other lines were all polarized in the mode closest to the c axis, but since the rod axes were far from normal to the c axis, it cannot be concluded that they are all π polarized.

It should be noted here that the 2.27-μm line showed the lowest threshold in all rods because a high-reflectivity curved reflector was available at that wavelength to construct a folded confocal resonator. The resulting reduction of losses led to reduced thresholds. No curved mirror with high reflectivity (99+ percent) at 2.35 μm was available, so plane parallel mirrors were used.

When plane mirrors with achromatic reflectivity (99+ percent) in the 2–2.4-μm region were used, the 2.27-μm line had the lowest threshold in the ⟨111⟩ rod, while the two lines near 2.35 μm (unresolved) had the lowest threshold in the ⟨112⟩ rods. This indicates that the 2.27-μm line is π polarized since its relative threshold is increased when the c axis is closer to the direction of propagation. Comparison of the observed wavelengths with the Tm^{3+} energy levels [14] shows that the two closely spaced lines near 2.35 μm probably emanate from the same upper laser level and terminate on neighboring levels of opposite symmetry indicating one π- and one σ-polarized line. These arguments along with the 4-K energy levels [14] were used to determine the transitions listed in Table VIII and depicted in Fig. 2.

In the ⟨112⟩ axis rods it was possible to suppress 2.35-μm oscillation by using a 49-cm-radius mirror with 5-percent transmission at this wavelength, but only 0.35-percent transmission at 2.27 μm. In the anisotropic $YAlO_3$ medium, the wave vectors of the two orthogonal polarization modes are not parallel (unless propagation is along a major crystallographic axis) so that the optimum resonator alignment is not the same for both polarizations. It was found that tuning between the 2.27- and 2.32-μm lines which are of opposite polarization could be achieved by changing the alignment of the 49-cm-radius mirror. This effect was not observed when using flat mirrors. All of the available mirrors had higher reflectivity at

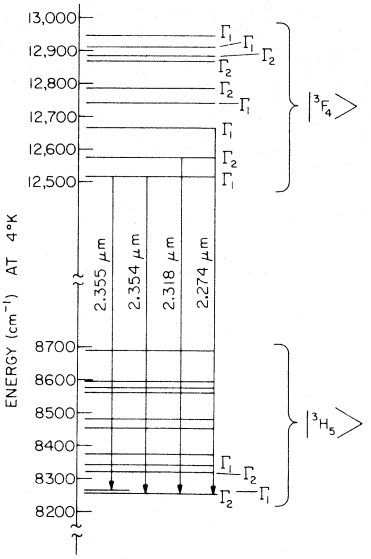

Fig. 2. $^3F_4$ and $^3H_5$ energy levels in Tm:$YAlO_3$ (4 K) and associated room-temperature laser transitions.

2.27 μm than at 2.35 μm, so it was not possible to suppress 2.27-μm oscillation in the ⟨111⟩ rod. As a result of the competing 2.27-μm laser emission, the observed 2.35-μm oscillation threshold was much higher in that rod.

The two lines near 2.35 μm were first reported to lie at 2.348 and 2.349 μm [14], [15]. The wavelengths of these lines appear to be very sensitive to operating conditions, especially with respect to the rod temperature. In the present work the average wavelength of these lines was found to be 2.353 μm under normal conditions, as indicated in Table VIII, for rods *B* and *C*. When the spectrometer slits were narrowed in an attempt to resolve the two lines, the flashlamp energy was increased to maintain the signal level. This had the effect of increasing the temperature of the convectively air-cooled rod with a resulting further increase in the wavelengths of this line pair to 2.354 and 2.355 μm. Fig. 3 is an oscilloscope display showing the resolved laser-line pair. The total scan time was approximately 1 h with the laser fired once per minute. The upper trace is a set of wavelength markers from the spectrometer at 2.3526, 2.3546, and 2.3566 μm (left to right). The lower trace gives the laser energy at the spectrometer's output slit as a function of wavelength. The signal level was held between shots by a boxcar integrator.

The laser output energy was measured as a function of flashlamp energy for rod *A* at 2.274 μm. The results appear in Fig. 4. In this experiment the flashlamp's luminous volume dimensions (7 × 75 mm) were considerably larger than the laser rod (5 × 50 mm). Therefore, the actual efficiency is estimated to be about twice as high as measured. A folded confocal resonator was used with 0.35-percent output coupling. This is undoubtedly a severely undercoupled condition, so that considerably higher efficiency should be obtainable through proper resonator design alone. The measurements were made with a PbS detector whose integrated output was calibrated in volts/joule using a repetitively pulsed Ho:YAG laser at 2.1 μm illuminating a MgO block. The average power, about 1 W, of

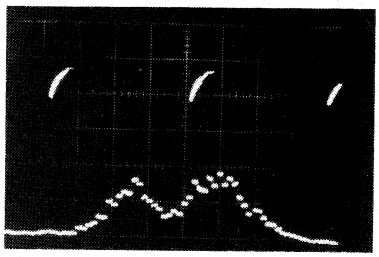

Fig. 3. Tm:Cr:$YAlO_3$ laser emission spectrum near 2.35 μm. The calibration markers are at 2.3526, 2.3546, and 2.3566 μm (left to right).

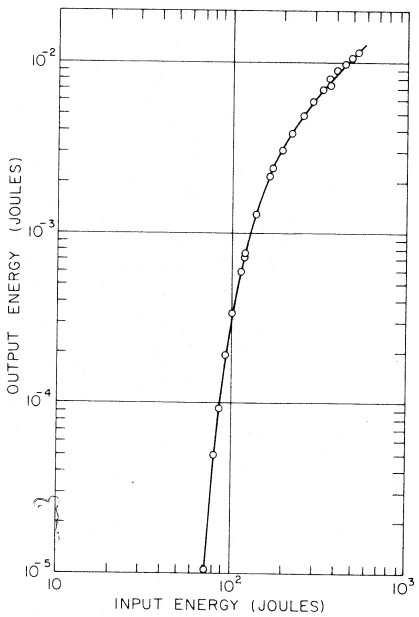

Fig. 4. Tm:Cr:$YAlO_3$ laser output energy at 2.274 μm versus electrical energy to flashlamp (0.35-percent output coupling).

the Ho:YAG laser was measured with a calibrated thermopile. The energy per pulse is given by $P_{avg} \cdot T$ where T is the pulse period. The slight increase in PbS response from 2.1 to 2.3 μm was also taken into account.

A fast InAs detector was calibrated for peak power (volts/watt) in the same manner as described above. Here the Ho:YAG peak power is given by $P_{avg} \cdot T/\tau$, where τ is the effective pulsewidth. The output of the Tm:Cr:$YAlO_3$ laser consisted of a train of relaxation oscillation spikes, typical of non-*Q*-switched insulating crystal lasers. The peak power of the pulses in the train was found to be several hundred watts.

IV. Summary and Conclusions

The long-pulse 2.3-μm laser characteristics of four thulium laser rods have been investigated at room temperature. The $YAlO_3$ rods showed lower oscillation thresholds in all cases. This is consistent with the theoretical results of Section II, if the $Cr^{3+} \rightarrow Tm^{3+}$ energy transfer efficiency is assumed to be approximately equal for YAG and $YAlO_3$. For π-polarized lines in $YAlO_3$, the gain should vary as the squared cosine of the angle between the *c* axis and the polarization direction. The *c* axis makes angles of approximately 45° and 30° with the ⟨111⟩ and ⟨112⟩ directions, respectively. Rods grown

normal to the c axis (⟨mn0⟩) should, therefore, have thresholds for π lines which are factors of 2 and 4 lower than the ⟨111⟩ and ⟨112⟩ rods, respectively. This would indicate a pulsed threshold on the order of 8 J for the 2.274-μm line with the 1200-torr krypton lamp, other things being equal.

A relatively low CW threshold is expected at room temperature for several reasons. First, the pulsed threshold is relatively low compared to other insulating crystal lasers. Second, the lower laser level lifetime is significantly shorter than that of the upper level. In addition, the thermal population of the lower laser level is negligible.

One factor which may adversely affect the CW operation is the long lifetime of the $^3H_4$ energy level. There are several possible schemes for dealing with this problem. The addition of ions such as Pr^{3+}, Eu^{3+}, Tb^{3+}, etc., would reduce the $^3H_4$ lifetime by nonradiative ion-pair interaction as, for example, was done with the $^5I_7$ level of Ho^{3+} by Johnson and Guggenheim [32]. Care would have to be taken so that the $^3F_4$ lifetime is not also reduced. A second possibility would be to take advantage of potential excited-state absorption by the $^3H_4$ state. Examination of the energy levels in Fig. 1 shows that a neodymium laser might be able to pump $^3H_4 \rightarrow {}^3F_2$ transitions in the 1.06-μm wavelength region. Finally, if the crystal temperature is lowered, laser action on the $^3H_4 \rightarrow {}^3H_6$ transitions might be obtained simultaneously around 1.9 μm to deplete $^3H_4$ population. This would result in a very interesting double laser line device.

Laser action on $^3H_4 \rightarrow {}^3H_6$ transitions has not yet been reported for Tm:$YAlO_3$, but reference to Table III shows that this transition's cross section should be higher in $YAlO_3$ than in YAG where CW emission was observed with a 160-W threshold at 85 K [16]. If only $^3H_4 \rightarrow {}^3H_6$ laser emission is considered, the threshold in $YAlO_3$ might be higher than in YAG because the fractional energy lost to $^3F_4 \rightarrow {}^3H_6$ fluorescence is $\sim A(^3F_4 \rightarrow {}^3H_6) \cdot \tau(^3F_4)$ which from Tables III and VI is predicted to be 75 percent in $YAlO_3$ as opposed to only 46 percent in YAG. However, if the $^3F_4 \rightarrow {}^3H_5$ laser action is obtained simultaneously, a portion of the loss to fluorescence would be avoided. Thus simultaneous oscillation would be beneficial to both laser lines.

The other significantly developed solid-state lasers in the 2–2.5-μm atmospheric window are Ho^{3+}:YAG at 2.1 μm and Dy^{2+}:CaF_2 at 2.36 μm. In both of these lasers the terminal laser levels are in the ground-state manifold so that efficient operation requires cryogenic cooling. The minimal cooling which the Tm:Cr:$YAlO_3$ laser might require makes it a reasonable alternative for many applications. It is likely that other transitions in the $^3F_4 \rightarrow {}^3H_5$ group (see Fig. 2) can be made to lase by using an intracavity dispersive element, with potential wavelengths from 2.2 to 2.6 μm. In an ⟨mn0⟩ rod, tuning between π and σ lines such as 2.274 and 2.355 μm could be achieved by simply rotating a polarizer or Brewster plate inside the laser cavity. Although the efficiency achieved in these experiments was fairly low, improvements are expected when attempts are made at optimization. In the final analysis the added energy savings due to reduced cooling requirements must also be considered.

Acknowledgment

The authors wish to thank Dr. W. F. Krupke for his efforts and analysis which were essential to the initiation of this research. They also wish to thank the Crystal Products Department, Union Carbide Corporation, for donation of the original ⟨112⟩ $YAlO_3$ laser rods.

Amplified Spontaneous Emission and Signal Amplification in Dye-Laser Systems

U. GANIEL, MEMBER, IEEE, A. HARDY, G. NEUMANN, MEMBER, IEEE, AND D. TREVES, MEMBER, IEEE

Abstract—**Transversely pumped dye-laser systems are investigated theoretically and experimentally. A set of coupled rate equations for the excited-state population densities and for the photon fluxes in both directions, at all wavelengths, is presented. Both the temporal and spatial dependence of these quantities are accounted for. The equations are solved numerically for a variety of practical situations, and analytical approximations for some limiting cases are discussed. The results describe the dependence of the amplified-spontaneous-emission (ASE) output flux on pumping rate, the spectral narrowing process, and the effects of gain saturation. It is found that under practical laboratory conditions the gain of such dye systems saturates rapidly. Consequently, at high pumping rates the output varies linearly with pump intensity, and the conversion efficiency from pump to ASE photons approaches unity. The performance of dye-laser amplifiers is described by the same set of equations, and the gain characteristics of such systems are analyzed as a function of input signal intensity and pumping rate. The theoretical calculations are compared with the results of a set of experiments, and good agreement is found. The operation characteristics of a dye-laser amplifier are evaluated and utilized in the design of a narrow-band oscillator-amplifier system.**

I. Introduction

EVER SINCE the first successful operation of organic dye lasers [1], these systems have become the subject of intensive research.[1] Many dye systems exhibit high gains even when pumped by flashlamps where the pumping rates are relatively low [2]. Much higher pumping rates can be achieved in laser-pumped systems, and this approach has been used extensively both in pulsed systems and in CW operation, which to date has been achieved only with a laser as the pumping source [3]. In high-gain systems, particularly under strong pumping conditions, consideration of the phenomenon of amplified spontaneous emission (ASE) [4][2] becomes all important for understanding the behavior of such systems. This is true in particular for dye solutions when excited in a transverse pumping configuration [5]. In such systems the spontaneous emission is amplified as it propagates along the excited medium, and even without feedback the emitted radiation exhibits "laserlike" properties, i.e., low divergence and spectral narrowing. Operation of dye solutions in this ASE mode has been reported in recent years [6]. The effect of ASE must also be considered in analyzing the gain characteristics of dye oscillator-amplifier systems, where the ASE can interfere with the process of amplification of the input signal, causing excessive background noise in the output.

Spectral narrowing in ASE was treated in the past by various authors. Yariv and Leite [7] considered a simple model in which they calculated an approximate expression for the narrowing of the spectrum of the spontaneous emission, due to the gain profile of the medium at which it originates. Saturation was not accounted for in this model. Casperson and Yariv [8] dealt with spectral narrowing in lasers at steady state, extending their treatment to include saturation in amplifiers

[1] A number of excellent review articles appear in F. P. Schäfer, Ed. *Dye Laser*.. New York: Springer, 1973.

[2] ASE is often referred to as "superradiance," although this term should probably be reserved for a completely different phenomenon, discussed first by Dicke [4a)].

by the amplified radiation. These authors obtained analytic results for certain limiting cases, and their results apply mainly to high-gain gas lasers with a Doppler-broadened gain profile. Casperson [9], [10] extended these results by including in the rate equations the effect of power flow in both directions, which was absent in previous treatments. Allen and Peters [11] considered ASE and amplification of external signals. Their discussion concentrated on high-gain gas-laser systems (mainly the 3.39-μ transition in He-Ne), and solutions of the relevant rate equations were obtained and fitted to experimentally determined parameters. The relevant level scheme in dye systems is generally more complex (ground-state absorption, triplet-state effects, etc.), and some of the assumptions which apply to the experimental situation in gas lasers cannot be made for dye-laser systems. Thus the extensive work of Allen and Peters [11] cannot be applied directly in the investigation of these systems. ASE in dye lasers has not been analyzed in detail in the past. Most authors dealing with dye-laser oscillators follow the approach introduced by Sorokin *et al.* [12] in which rate equations are written down for the (single-mode) photon density, the population inversion, and the triplet-state population. With various modifications, this approach was followed also by Keller [13] and by Pappalardo *et al.* [14]. In this approach the quantities are all assumed to be uniform along the cavity. Since in many laser-pumped dye-laser systems the gain is very high, and consequently the optimum output coupling rather large (in some cases a ~4-percent-reflectivity quartz wedge gives the highest output [15]), this assumption is probably invalid for such systems. Weber and Bass [16] and Snavely [17], on the other hand, considered rate equations for the populations at threshold in order to calculate the gain. They did not include stimulated emission in these equations, and hence saturation effects are excluded from this description. Recently, Atkinson and Pace [18] introduced a more complete approach, including also frequency selective elements in their analysis. Again, they assume all quantities uniform along the cavity, an approximation which, as already mentioned, can introduce serious errors in cases of high output coupling (see [19]).[3]

Dye-laser amplifiers have been considered by a number of investigators. Huth [20] measured the gain of a flashlamp-pumped rhodamine 6G (R6G) laser. His data fit into the weak pumping regime, below saturation by ASE or by the injected signal. Hence his results could be fit to calculated gain coefficients which are uniform along the medium. Shank *et al.* [21] described an elegant gain-measurement scheme in which the gain is extracted from direct measurement of the ASE. Their method, however, applies only in the regime of weak enough pumping where no saturation occurs. More recently, Flamant and Meyer [22] studied the steady-state gain of a flashpumped dye amplifier. They recognize the importance of the spatial dependence of the gain along the active medium. Spontaneous emission is excluded from their photon flux equation. Their results are thus valid only for strong enough input signals, so that the competing effect of ASE can be ignored.

In this work we shall treat the problem of a transversely pumped dye medium. Rate equations will be written in a general form so that numerical solutions can be obtained from them for both pure ASE and laser-amplifier situations. Both the temporal and spatial dependence will be accounted for so that no *a priori* assumptions will be needed concerning the magnitude of either the pumping intensity or the laser radiation. In Section II we present the rate equations and explain the details of the physical model used. Section III is devoted to a discussion of the solutions for ASE with no external input. The behavior of the solutions at the various regimes of pumping rates is explained with an emphasis on its physical significance. Some analytical approximations, which are helpful for anticipating the results in certain limiting cases, are also derived. In Section IV the characteristics of dye-laser amplifiers are discussed, and again the discussion is based both on numerical solutions of the rate equations and on some analytical approximations which are shown to be valid on physical grounds. Section V deals with a set of experiments which were aimed at checking the theory and obtaining the characteristics of the operation of dye-laser amplifiers. Finally, a narrow-band output oscillator-amplifier system is described.

II. Rate Equations

The energy level scheme we shall consider is shown schematically in Fig. 1. S_0 is the lowest singlet vibration-rotation manifold, S_1 is the first excited (electronic) singlet manifold, and T_1 is the first triplet manifold. Higher excited manifolds (S_i, T_i, $i > 1$) are not shown since radiationless transitions back to S_1 (or T_1) are known to be fast ($\sim 10^{-12}$-10^{-11} s) on the time scales of interest to us [23]. Nonradiative decay within each manifold is also a fast process, so that only the lowest level populations within each manifold will be considered. We assume a transversely excited region of length L and width $2r$ ($r \ll L$), so that the pump power $P(t)$ is uniformly incident on an area $A = 2rL$. Reduction of $P(t)$ in the transverse direction (into the medium) due to absorption is neglected. This assumption is not expected to affect the results appreciably, and it reduces the complication of the numerical treatment considerably.

Let $I^+(x,t,\lambda)$ be the photon flux per unit wavelength (photon $\cdot$ s^{-1} cm^{-3}) at coordinate x ($0 \leqslant x \leqslant L$), time t, and wavelength λ, propagating in the $+x$ direction, and let $I^-(x,t,\lambda)$ be the corresponding quantity for the radiation propagating in the $-x$ direction. Then the following coupled set of rate equations holds for the photon flux and populations:

$$\frac{\partial N_1(x,t)}{\partial t} = W(t)N_0(x,t) - \tau^{-1}N_1(x,t) - N_1(x,t)\int \sigma_e(\lambda)\,[I^+(x,t,\lambda) + I^-(x,t,\lambda)]\,d\lambda + N_0(x,t)\int \sigma_{01}(\lambda)\,[I^+(x,t,\lambda) + I^-(x,t,\lambda)]\,d\lambda \quad (1)$$

[3] For reflectivities of $R \gtrsim 50$ percent, the approximation of uniform gain coefficient along the medium is reasonable, but for low reflectivities it is no longer valid.

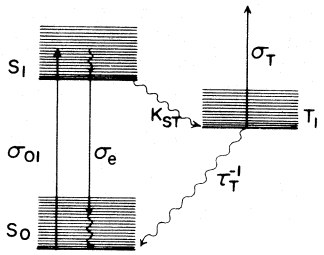

Fig. 1. Energy level scheme assumed in the calculation. Straight arrows denote radiative transitions, wiggled arrows denote radiationless transitions.

$$\frac{\partial N_T(x,t)}{\partial t} = K_{ST}N_1(x,t) - \tau_T^{-1}N_T(x,t) \tag{2}$$

$$N_0(x,t) + N_1(x,t) + N_T(x,t) = N \tag{3}$$

$$\pm\frac{d}{dx}[I^{\pm}(x,t,\lambda)] = N_1(x,t)\sigma_e(\lambda)I^{\pm}(x,t,\lambda) + \tau^{-1}N_1(x,t)E(\lambda)g^{\pm}(x) - \sigma_{01}(\lambda)N_0(x,t)I^{\pm}(x,t,\lambda) - \sigma_T(\lambda)N_T(x,t)I^{\pm}(x,t,\lambda). \tag{4}$$

The quantities in (1)-(4) are defined as follows. $N_i(x,t)$, $i = 0, 1, T$, is the population density (molecules $\cdot$ cm^{-3}) in S_0, S_1, and T_1. $W(t)$ is the pumping rate, given generally by

$$W(t) = [P(t)/A]\int\sigma_{01}(\lambda)f(\lambda)(\lambda/hc)\,d\lambda \tag{5}$$

where $\sigma_{01}(\lambda)$ is the absorption cross section (cm^2) from S_0 to S_1 at wavelength λ, and $f(\lambda)$ is the normalized spectral distribution of the pump radiation ($\int f(\lambda)d\lambda = 1$). τ is the lifetime of the S_1 state in the absence of stimulated emission. $\sigma_e(\lambda)$ is the stimulated-emission cross section, given by[4]

$$\sigma_e(\lambda) = [\lambda^4 E(\lambda)]/8\pi c\eta^2\tau \tag{6}$$

where $E(\lambda)$ is the $S_1 \rightarrow S_0$ fluorescence spectrum normalized so that $\int E(\lambda)d\lambda = \Phi$, Φ being the quantum efficiency, η is the refractive index of the dye solution, K_{ST} is the $S_1 \rightarrow T_1$ intersystem crossing rate (s^{-1}), and τ_T is the T_1 lifetime. $g^{\pm}(x)$ are geometrical factors which determine the fraction of the spontaneous emission which is emitted into the solid angle at which the output aperture is seen from position x in the medium. $\sigma_T(\lambda)$ is the absorption cross section from T_1 to higher triplet states. In (1), the first term describes excitation by the pump source from S_0 to S_1, the second term accounts for spontaneous decay from S_1 via all available channels, the third term describes the effect of stimulated emission by radiation of all wavelengths on N_1, and the last term gives the rate of increase of N_1 due to self-absorption by ground-state molecules. Equation (2) describes the temporal evolution of N_T by intersystem crossing $S_1 \rightarrow T_1$ and by relaxation to the ground state. In (4), $(d/dx)I^{\pm} = (\partial/\partial x)I^{\pm} \pm (\eta/c)(\partial/\partial t)I^{\pm}$. The terms in (4) describe, in that order, stimulated emission, spontaneous emission into the appropriate solid angle, absorption from the ground state, and triplet-state absorption. Variations in the transverse dimension of $I^{\pm}$ and N_i are not accounted for in this model. It is assumed that the active region is a cylinder of radius r, within which the rate of excitation is constant. Hence we have

$$g^{+}(x) = \tfrac{1}{2}\{1 - (L-x)/[(L-x)^2 + r^2]^{1/2}\}$$
$$g^{-}(x) = \tfrac{1}{2}\{1 - x/(x^2 + r^2)^{1/2}\}. \tag{7}$$

As long as the depth of the excited region is of the same order of magnitude as its width $2r$ ($\ll L$), its exact geometric shape is not too important, and $g^{\pm}$ will have the same x dependence. Equations (1)-(4) are written for a homogeneously broadened medium so that the same $N_1(x,t)$ is assumed for the interaction with radiation at all wavelengths λ within the fluorescence band.

Equations (1)-(4) were solved numerically on an IBM 370/165 computer for a large variety of practical solutions. We chose a solution of the dye rhodamine 6G (R6G) in ethanol for our computations since the material parameters for this system are well known. The parameters needed for the computation are given in Table I. The geometry was chosen to correspond to our experimental arrangement (see Section V), $L = 1$ cm, $r = 0.02$ cm. Although various pumps and dye concentrations were studied, we shall report here only on our studies for a nitrogen-laser-pumped dye solution. The pump is monochromatic ($\lambda_p = 337.1$ nm, $\sigma_{01}(\lambda_p) = 2.4 \times 10^{-17}$ cm^2), and a dye concentration of $N = 3 \times 10^{18}$ cm^{-3} (5×10^{-3} mol $\cdot$ l^{-1}) is used.

For a monochromatic pump source, $W(t) = \sigma_{01}(\lambda_p)I_p(t)$, $I_p(t)$ being the pump photon flux (photons $\cdot$ cm^{-2}s^{-1}). The

TABLE I
PARAMETERS USED IN THE COMPUTATIONS

Quantity	Numerical value	Reference

2) Parameters used in our numerical example		
L	1 [cm.]	
r	2×10^{-2} [cm.]	
λ_p (pump wavelength)	337.1 [nm]	
$\sigma_a(\lambda_p)$	2.4×10^{-17}[cm^2]	
N	5×10^{-3}(mole/liter) = 3×10^{18} [cm^{-3}]	
3) Conversion of pump power to pumping rate (W) for conditions given above		
1 KW $\rightarrow$ 25 KW.cm^{-2} $\rightarrow$ W = 10^6 [sec.$^{-1}$]		

[4]See [17]. $\sigma_e(\lambda)$ given in (6) differs from Snavely's expression by a factor of η^{-3}. This difference was already noted previously (see [21]).

analysis is somewhat simplified by assuming $I_p(t)$ to be of a square wave form in t. For fast rise-time pumps this is a reasonable approximation, so that in the following discussion we write $W(t) = W$ for $0 \leqslant t \leqslant T$, T being the pump pulsewidth. If T is large enough so that steady state is reached $((\partial/\partial t) = 0)$, we have from (1)-(4)

$$N_1(x) = N\{W + \int \sigma_{01}(\lambda)\,[I^+(x,\lambda) + I^-(x,\lambda)]\,d\lambda\}/ \cdot \{W(1 + K_{ST}\tau_T) + \tau^{-1} + \int [\sigma_{01}(\lambda) \cdot (1 + K_{ST}\tau_T) + \sigma_e(\lambda)]\,[I^+(x,\lambda) + I^-(x,\lambda)]\,d\lambda\} \tag{8}$$

$$N_T(x) = N_1(x) K_{ST}\tau_T. \tag{9}$$

By direct integration we have

$$I^+(x,\lambda) = I^+(0,\lambda)\exp\left[\int_0^x \alpha(\xi,\lambda)d\xi\right] + E(\lambda)\tau^{-1}\int_0^x dy N_1(y) g^+(y) \cdot \exp\left[\int_y^x \alpha(\xi,\lambda)d\xi\right] \tag{10}$$

$$I^-(x,\lambda) = I^-(L,\lambda)\exp\left[\int_x^L \alpha(\xi,\lambda)d\lambda\right] + E(\lambda)\tau^{-1}\int_x^L dy N_1(y) g^-(y) \cdot \exp\left[\int_x^y \alpha(\xi,\lambda)d\xi\right] \tag{11}$$

where

$$\alpha(\xi,\lambda) = [\sigma_e(\lambda) + \sigma_{01}(\lambda)]\,N_1(\xi) + [\sigma_{01}(\lambda) - \sigma_T(\lambda)]\,N_T(\xi) - \sigma_{01}(\lambda)N. \tag{12}$$

The first term on the right-hand side in (10) and (11) describes the amplified input signal while the second results from ASE. The gain of the medium at steady state is conveniently defined as

$$G(\lambda) = \exp\left[\int_0^L \alpha(\xi,\lambda)d\xi\right]. \tag{13}$$

In a general situation (8)-(13) are obviously not very useful, and (1)-(4) have to be solved numerically on a computer. In the following we shall use (8)-(13) as a starting point for discussing a number of limiting cases of practical interest.

III. Amplified Spontaneous Emission

A. Dependence of the ASE on Pumping Rate

In most pulsed laser-pump sources (nitrogen laser, Q-switched Nd^{3+}:YAG or ruby, and their harmonics, etc.), the pumping pulse is short (~5-30 ns) compared to K_{ST}^{-1}, so that the effect of triplet states is negligible since no appreciable population $N_T(x)$ can build up.[5] We shall therefore assume henceforth $N_T = 0$ in our analysis. The steady-state assumption, introduced previously, is still reasonable, as will be discussed in the following, and it is certainly a very good one for strong pumping sources which are of main interest here.

In Fig. 2 we plot the results of the numerical calculation of the ASE, assuming no triplet-state population. In the graph giving the results with no ground-state absorption ($\sigma_{01}(\lambda) = 0$)[6] one clearly discerns the fluorescence region, which is the regime of weak pumping rates. In this region $N_1(x)$ remains so low that there is practically no stimulated emission, and the output consists of that part of the total fluorescence which is collected at the output aperture. Therefore, in the transverse pumping configuration, the conversion efficiency from absorbed pump photons to output is very low.

As the pump rate increases, there is a smooth transition to a regime in which the output increases exponentially with W. This is obviously due to the effect of stimulated emission. It should be noted, however, that there is no discontinuity in the graph so that the concept of threshold for the onset of ASE [11] is mainly qualitative.

As indicated in Fig. 2, this exponential regime spans only about one order of magnitude of pumping intensities since the exponential dependence of $G(\lambda)$ on W causes $I^{\pm}$ to grow very quickly with W and saturation becomes important. (In the numerical example (Fig. 2), the output increases by a factor of $\sim 10^4$ as W changes from 3×10^5 to 3×10^6.)

With $\sigma_{01}(\lambda) = 0$, $I^{\pm}(\lambda)$ peaks at the peak of $E(\lambda)$ (~555 nm for R6G), but spectral narrowing sets in [7], [8]. The approximate analytical treatment by Yariv and Leite [7] is adequate in this regime, but its validity breaks down as soon as saturation effects become important. In the present treatment, $E(\lambda)$ is not available to us in analytical form, so no attempt was made to analyze this effect beyond numerical evaluation of $I^{\pm}(\lambda)$ as a function of λ. In the numerical computation, the fluorescence band of R6G (520-630 nm) was divided into segments of 5 nm each.[7] In Fig. 2 the effect of spectral narrowing is indicated by the difference between the curve describing the total photon flux and the curve giving the photon flux within a 5-nm bandwidth around the peak of the ASE. The stronger the pumping, the closer these two curves become, indicating that a larger portion of the radiation is concentrated in the central bandwidth.

The conversion efficiency from pump photons to $I^{\pm}$ is still low at the lower end ($W \gtrsim 2 \times 10^5$) of the exponential regime,

[5] This assumption is definitely invalid for flashlamp-pumped dye lasers, where the pulses are in the microsecond regime (see [13], [14]), or for CW dye lasers, where the triplet-state populations are of primary importance.

[6] In some dyes, such as 4 methyl-umbelliferone [21], the emission and absorption bands do not overlap so that $\sigma_{01} = 0$ is a realistic assumption. This is definitely not the situation for R6G, but we deal with it nonetheless since it helps in understanding the physical behavior of the system.

[7] Finer divisions were used in trial runs, and this increased the computer time needed significantly. We found that the division into segments of 5 nm was adequate, and no substantial information was gained by using a finer grid in λ.

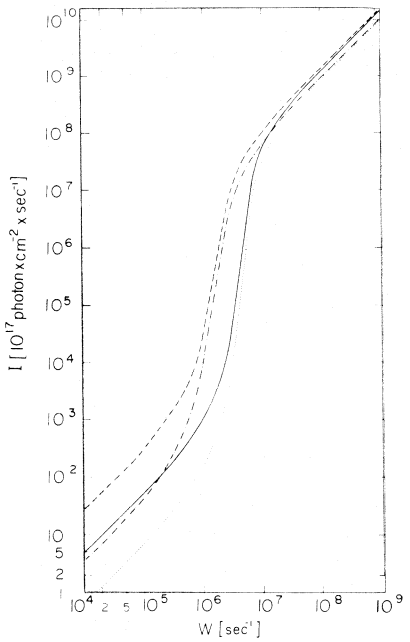

Fig. 2. Calculated ASE output (I) as a function of pumping rate (W), for R6G with parameters listed in Table I. ····· photon flux within a bandwidth of 5 nm around the peak of the ASE spectrum with $\sigma_{01} \neq 0$. -·-·- photon flux within a bandwidth of 5 nm around the peak of the ASE assuming $\sigma_{01} = 0$. ——— total photon flux with $\sigma_{01} \neq 0$. ----- total photon flux with $\sigma_{01} = 0$.

but it grows rather quickly with W as the strong pumping regime is approached.

For still larger values of W, saturation causes the dependence of $I^{\pm}$ on W to become weaker than exponential. In our numerical example, with $\sigma_{01} = 0$, about one more decade in W (2×10^6-2×10^7) spans this transition region in which this dependence changes from exponential to linear.

The effect of ground-state absorption ($\sigma_{01} \neq 0$) is twofold. First, it shifts the peak of the ASE towards longer wavelengths where σ_{01} is smaller. In our numerical example the spectrum peaks at 590 nm for $W \leqslant 10^5$ (s^{-1}), but as W becomes larger the peak gradually shifts towards shorter wavelengths. For $W > 5 \times 10^6$ (s^{-1}), the peak appears at $\lambda = 575$ nm, and it remains at this wavelength for all higher values of W for which calculations were performed. Note that at the peak of the fluorescence ($\lambda = 555$ nm) the absorption cross section is $\sigma_{01} = 0.11\sigma_e$, with $\sigma_e = 3.2 \times 10^{-16}\,\mathrm{cm}^2$, while at the peak of the ASE ($\lambda = 575$ nm), $\sigma_{01} \sim 0.008\ \sigma_e$, with $\sigma_e = 1.8 \times 10^{-16}\,\mathrm{cm}^2$.

The second effect of ground-state absorption is to lower the conversion efficiency at *low* pumping rates. At higher pumping rates this effect becomes less pronounced until at high enough values of W the efficiency is the same whether $\sigma_{01} \neq 0$ or $\sigma_{01} = 0$. This can be shown analytically as follows. Starting from (4), we have, with $N_T = 0$,

$$\frac{d}{dx}[I^+(x,\lambda) - I^-(x,\lambda)] = N_1(x)\,[\sigma_e(\lambda) + \sigma_{01}(\lambda)]\,[I^+(x,\lambda) + I^-(x,\lambda)] + \tau^{-1}N_1(x)E(\lambda)[g^+(x) + g^-(x)] - \sigma_{01}(\lambda)N[I^+(x,\lambda) + I^-(x,\lambda)]. \quad (14)$$

Integration over λ yields

$$\frac{d}{dx}[I^+(x) - I^-(x)] = N_1(x)\int[\sigma_e(\lambda) + \sigma_{01}(\lambda)]\,[I^+(x,\lambda) + I^-(x,\lambda)]\,d\lambda + \tau^{-1}N_1(x)\,[g^+(x) + g^-(x)]\,\Phi - N\int\sigma_{01}(\lambda)\,[I^+(x,\lambda) + I^-(x,\lambda)]\,d\lambda \quad (15)$$

where $I^{\pm}(x) = \int I^{\pm}(x,\lambda)d\lambda$. Since the triplet-state population is neglected, we have from (8)

$$N_1(x) = N\left\{W + \int\sigma_{01}(\lambda)\,[I^+(x,\lambda) + I^-(x,\lambda)]\,d\lambda\right\}\Big/ \cdot\left\{W + \tau^{-1} + \int[\sigma_{01}(\lambda) + \sigma_e(\lambda)]\,[I^+(x,\lambda) + I^-(x,\lambda)]\,d\lambda\right\}. \quad (16)$$

Substituting (16) into (15) we obtain

$$\frac{d}{dx}[I^+(x) - I^-(x)] = N_0(x)W - \tau^{-1}N_1(x) \cdot \{1 - [g^+(x) + g^-(x)]\,\Phi\}. \quad (17)$$

For large values of W ($W \gtrsim \tau^{-1}$) stimulated emission becomes the dominant process. Over most of the medium (except a narrow region around $x = L/2$ which we shall discuss later) we can assume $\int[\sigma_{01}(\lambda) + \sigma_e(\lambda)]\,[I^+(x,\lambda) + I^-(x,\lambda)]\,d\lambda \gg \tau^{-1} + W$ so that $N_1(x) \ll N$. This leads to the approximation

$$\frac{d}{dx}[I^+(x) - I^-(x)] \simeq WN \quad (18)$$

and since with no external signal $I^+(L) = I^-(0)$, we have

$$I^+(L) = I^-(0) \simeq \tfrac{1}{2}WNL. \quad (19)$$

This means that the total ASE output becomes linear with pumping intensity, and the conversion efficiency from absorbed pump photons to ASE approaches unity. This conclusion holds even in the presence of ground-state absorption, in spite of the shift of the peak of the ASE to longer wavelengths, where σ_e is smaller. This decrease in σ_e is compensated for by the fact that the excited-state (S_1) population $N_1(x)$ is higher than what it would have been if σ_{01} were zero. The net gain thus obtained overall (stimulated emission minus ground-state absorption) becomes equal to what it would have been for $\sigma_{01} = 0$.

Note that when excited-triplet-state absorption is neglected, as is done here based on the preceding arguments, and the quantum efficiency Φ is close to unity, there is practically no mechanism for loss of photons. In other words, the overall conversion efficiency from absorbed pump photons to photons emitted by the dye solution, including both ASE and fluorescence, is always close to unity. At low pumping rates, however, most of the emitted photons go into (unamplified) fluorescence. As the pumping rate increases, more and more of the photons are emitted into the ASE mode. For the values used in our numerical example, we find that (19) is a very good

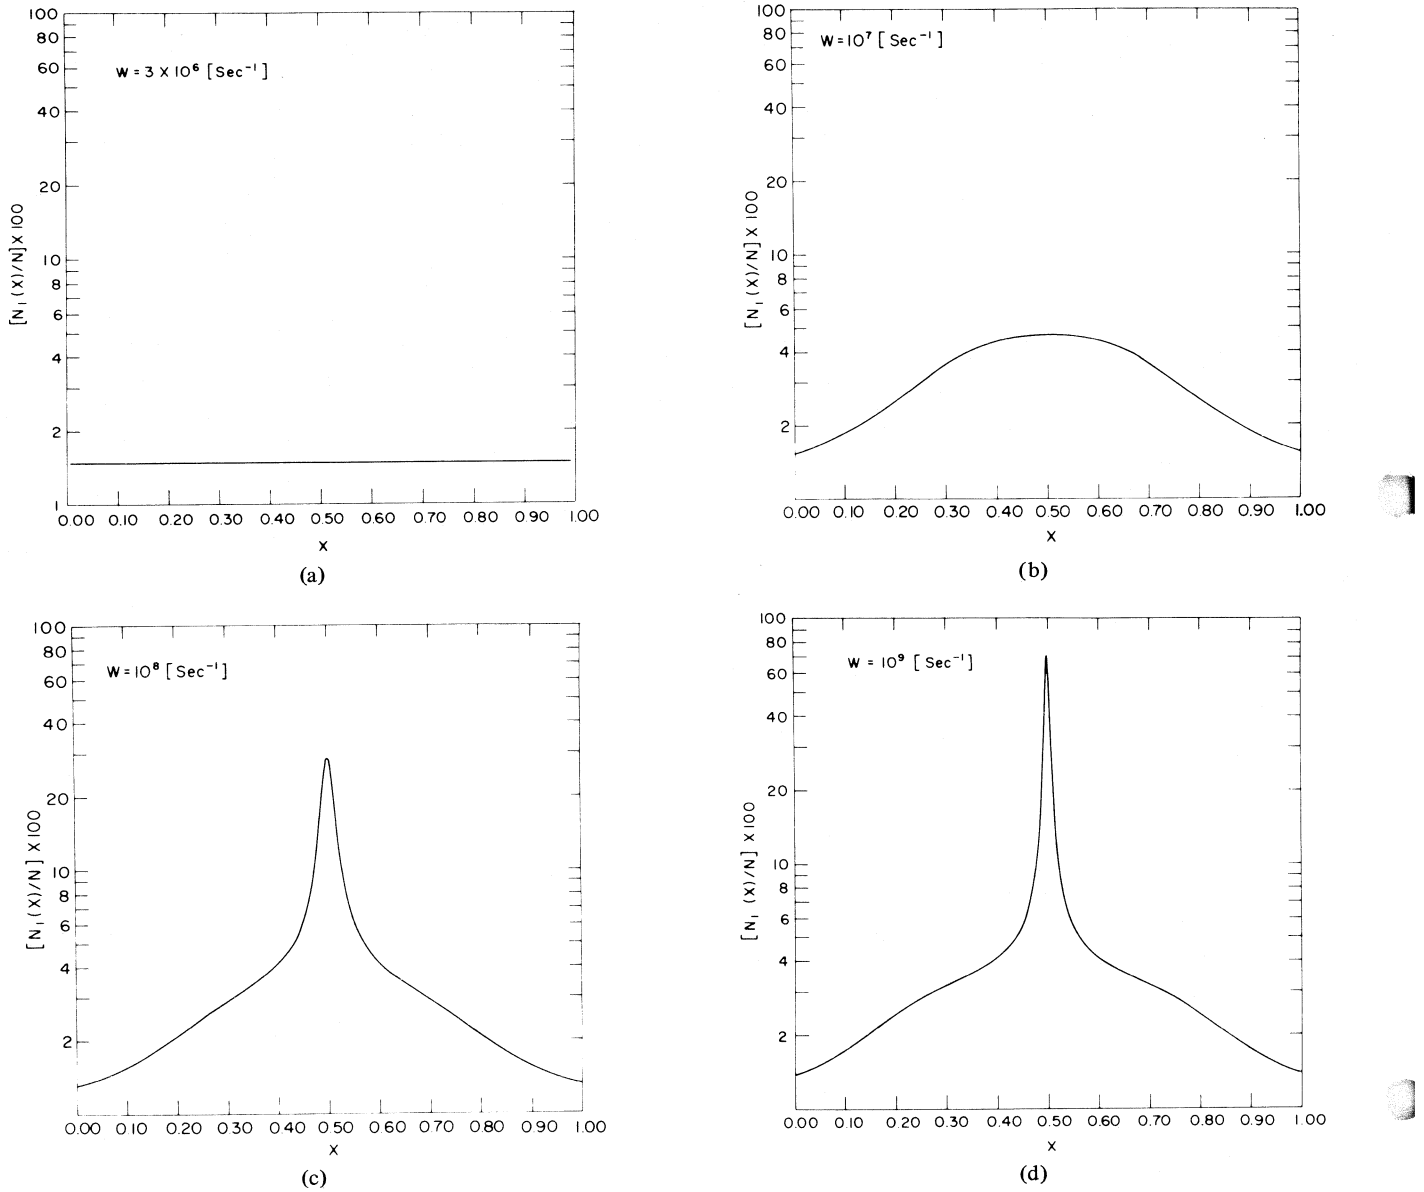

Fig. 3. Excited-state population ($N_1(x)$) in percent of total concentration (N), as a function of position in the medium (x), for various pumping rates. Material parameters are listed in Table I. (a) $W = 3 \times 10^6$ (s^{-1}). (b) $W = 10^7$ (s^{-1}). (c) $W = 10^8$ (s^{-1}). (d) $W = 10^9$ (s^{-1}).

approximation at pumps for which $W > 2 \times 10^7$ (Fig. 2) (corresponding to intensities above ~ 500 kW $\cdot$ cm^{-2} at 337.1 nm, or ~ 20 kW for the geometry we deal with).

The process of spectral narrowing, which starts already in the exponential regime, continues to take place in the saturated regime, as can be clearly seen from Fig. 2. For $W = 10^9$, about 70 percent of the total radiation is contained within the bandwidth of 5 nm around the peak of the spectrum. The rate of spectral narrowing with increasing W is much slower here than in the exponential (intermediate pumping) regime, as is obvious from Fig. 2. This fact agrees with the analysis of Casperson and Yariv [8] for a homogeneously broadened medium.

B. Spatial Distribution of the Gain: $N_1(x)$

Let us consider the saturated (strong pumping) regime first, and values of x in the vicinity of $x = L$. By symmetry, the same considerations will apply for $x \sim 0$. From (18) and (19) we have

$$I^+(x) = I^-(x) + WN(x - L/2), \quad (x \sim L). \tag{20}$$

For $x \sim L$, $I^+(x) \gg I^-(x)$, so that we obtain from (16)

$$N_1(x) \sim [1 + \bar{\sigma}_{01} N(x - L/2)] / [(\bar{\sigma}_e + \bar{\sigma}_{01}) \cdot (x - L/2)], \quad (x \sim L) \tag{21}$$

where $\bar{\sigma}_{01}$ and $\bar{\sigma}_e$ are some appropriate weighted average values of $\sigma_{01}(\lambda)$ and $\sigma_e(\lambda)$ over the bandwidth for which $I^+(\lambda)$ is significantly large. Equation (21) and a similar one for $x \sim 0$ (obtained by replacing x by $L - x$ on the right-hand side) are useful approximations at the edges of the medium at strong pumping intensities, and show $N_1(x)$ to be independent of W. On the other hand, we know from the previous discussion that the total output (whether $\sigma_{01} = 0$ or $\sigma_{01} \neq 0$) is proportional to W in this regime, so that for λ in the region of the spectral peak, $\int_0^L \alpha(\lambda, \xi) d\xi$ must increase with W approximately with a

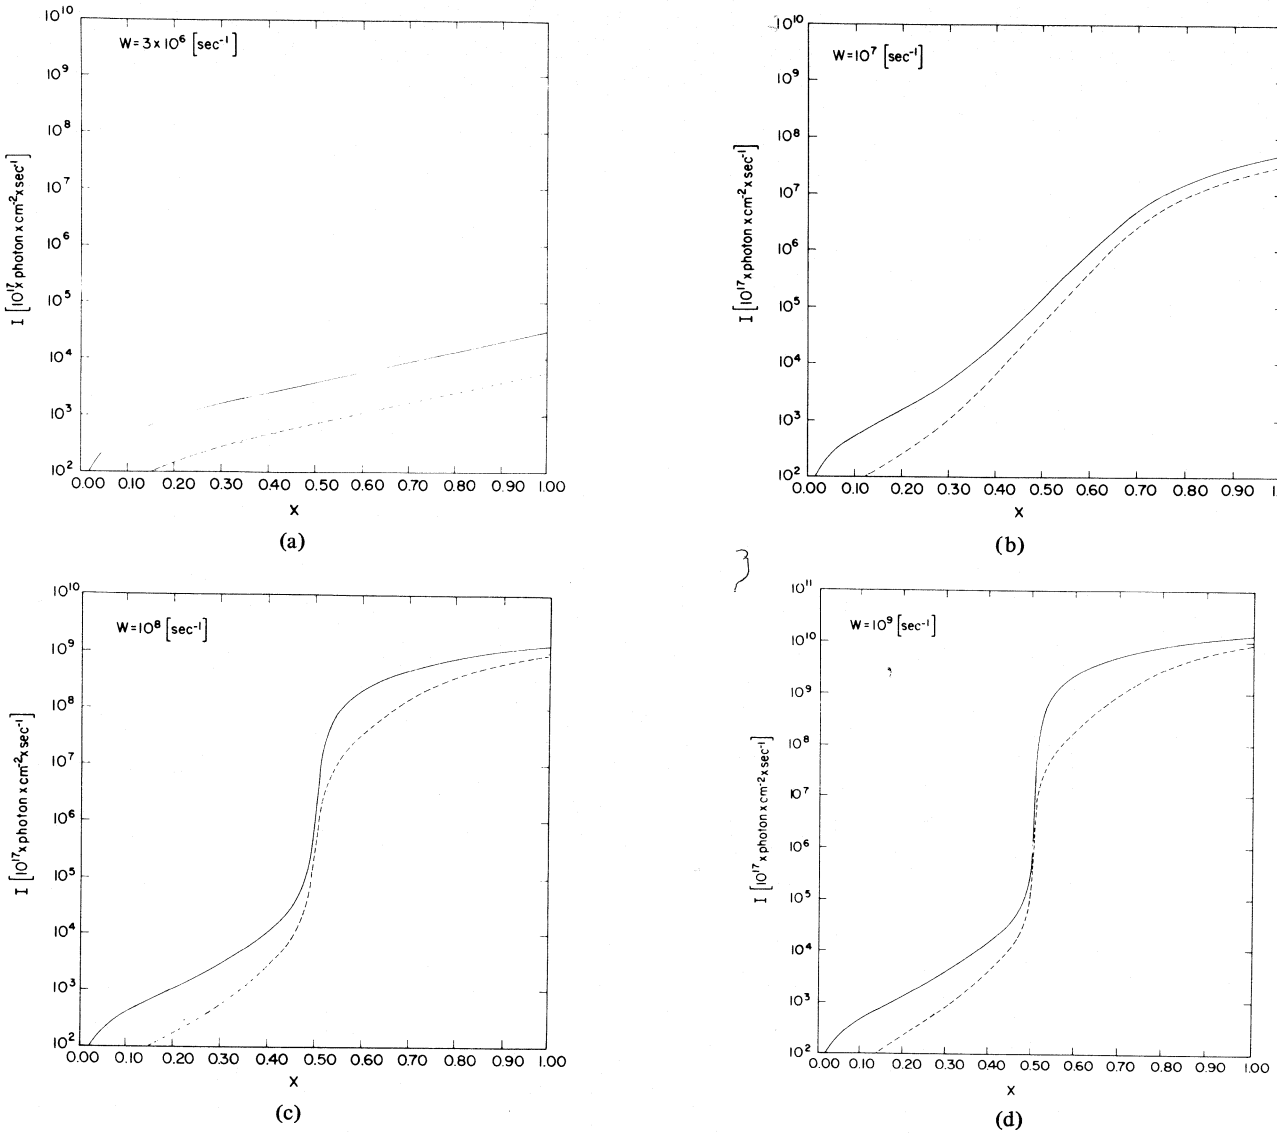

Fig. 4. Photon flux (I) as a function of position in the medium for various pumping rates. Only $I^+(x)$ is plotted. Solid line–total flux. Broken line–photon flux within 5 nm around the peak of the ASE spectrum. Material parameters are listed in Table I. (a) $W = 3 \times 10^6$ (s^{-1}). (b) $W = 10^7$ (s^{-1}). (c) $W = 10^8$ (s^{-1}). (d) $W = 10^9$ (s^{-1}).

logarithmic dependence, as can be seen by a detailed analysis of (10). This increase comes about mainly by an increase of $N_1(x)$ in the central region of the medium, where $I^+(x) + I^-(x)$ is smaller than at the edges. The behavior of $N_1(x)$ for various values of W is plotted in Fig. 3. At the low and intermediate pumping regimes, where saturation is not important yet, $N_1(x)$ is constant along the medium. However, as W increases and saturation effects become important, the function $N_1(x)$ develops a peak around $x = L/2$. It is seen clearly that at $x \sim 0$ and $x \sim L$, for large W, $N_1(x)$ does not change much, but the central peak increases sharply so as to render the correct total gain [(12), (13)]. This particular behavior of $N_1(x)$ (or a similar behavior of the fractional gain $\alpha(x, \lambda)$) comes about by the simultaneous effect of I^+ and I^-.

A similar effect to the one described here has been described by Allen and Peters [11] who calculated the saturated gain coefficient for a He-Ne (3.39-μm) system as a function of position in the medium. However, as pointed out by these authors, observation of this central peak is not feasible in laboratory He-Ne. In the dye system we consider, our calculations show that the peak in $N_1(x)$ should be easily observable in the laboratory.

In the discussion leading to the approximation (18), we have assumed $N_1(x) \ll N$ over most of the region $0 \leqslant x \leqslant L$. Around $x = L/2$ this assumption fails, but although (18) is not valid in the vicinity of $x = L/2$, our numerical analysis shows that the integrated result (19) is still a very good approximation. This is explained by the fact that the central region, where $N_1(x)$ becomes large, is very narrow so that it does not appreciably affect the integration leading from (18) to (19). The narrow region around $x = L/2$ is, however, of primary importance in the evolution of the intensity. Consider $I^+(x)$ in the strong pumping region. It starts from fluorescence at $x = 0$ and increases rather slowly with x, since for $0 < x < L/2 - \epsilon$ (with ϵ some typical half-width of the central peak) $N_1(x)$ is quenched to small values by the intense $I^-(x)$. As we enter the central peak region, $N_1(x)$ becomes large and $I^+(x)$ increases very rapidly. Once we move out of the central peak

$(x > L/2 + \epsilon)$, $I^+(x)$ is already very large, $N_1(x)$ accordingly small, and the growth becomes approximately linear with x. The same behavior is exhibited by $I^-(x)$, which is the mirror image of $I^+(x)$ around $x = L/2$. This qualitative description is verified by the numerical results shown in Fig. 4, where we plot $I^+(x)$ for various pumping rates W. Clearly, the larger W, the more the behavior fits the previously given description.

It should be emphasized that this spatial behavior of $N_1(x)$ and of $I^{\pm}(x)$ is typical of ASE, and a different behavior is expected in the case of a laser oscillator. There $I^+(0)$ and $I^-(L)$ are not zero, and due to the feedback from the mirrors both $I^+(x)$ and $I^-(x)$ reach high values all over the medium. Since at steady state $1 - R_1R_2G^2 \simeq 0$ in a laser (R_1, R_2 are the mirror reflectivities), G is much smaller than in the case of ASE, and hence $N_1(x)$ is also much smaller. The problem of a laser oscillator will be treated in more detail elsewhere.

C. Temporal Behavior

All the discussion in Sections III-A and III-B, as well as Figs. 2–4, refer to steady-state solutions. In cases where the pumping pulse has a temporal width of ~10 ns, the validity of the steady-state assumption may be questioned. In the weak and intermediate pumping regimes (unsaturated regime, $W \lesssim 5 \times 10^6$ s^{-1}), and assuming very fast rise times of the pump pulse, the typical time constant for the evolution of $N_1(x, t)$ to steady state is $\sim\tau$. The evolution of $I^+(L, t, \lambda)$ (or $I^-(0, t, \lambda)$) is not exponential, in general. For very weak pumps, $I^+(L, t)$ is simply proportional to $N_1(t)$, and hence approaches steady state exponentially at the same rate as $N_1(t)$. For W in the intermediate regime, $N_1(x, t)$ still evolves exponentially in time, but since $I^+(L, t, \lambda)$ depends approximately exponentially on the integral of $N_1(x)$ along the medium, it will approach steady state more slowly than N_1. The exact details depend on the particular set of parameters which are used in the calculation. In general, it can be stated that in the exponential regime ($5 \times 10^5 < W < 5 \times 10^6$), the intensities $I^{\pm}$ will reach steady state more slowly than an exponential with a time constant τ (typical times of 2τ–4τ were found to elapse before $I^+(L, t, \lambda)$ reached ~70 percent of its steady-state value). The situation is different at strong pumps (saturated regime) since there the stimulated-emission terms begin to dominate the temporal evolution of both $N_1(x, t)$ and of $I^{\pm}(x, t, \lambda)$ very quickly. As a result, steady state is reached at times much shorter than τ. For the numerical parameters chosen as previously, we find that for $W = 10^8$ equilibrium is reached in less than 2 ns, whereas at $W = 10^9$ the system is at steady state already after 0.5 ns. Hence for intense laser-pump sources, with pulses of ~10 ns, the steady-state description is certainly a good approximation to the actual physical situation.

IV. Dye-Laser Amplifiers

The general expressions (10) and (11) are valid as before, but here we shall consider an input signal given by $I^+(0, \lambda)$ such that $I^+(0, \lambda) \neq 0$ over some bandwidth $\Delta\lambda$.

A useful concept in dealing with amplifiers in general is the equivalent noise input signal. In the systems we consider, background noise is inherently present in the form of spontaneous emission, so we have a distributed noise source. Let us define $I_0(\lambda)$ such that

$$\sigma_e(\lambda) I_0(\lambda) N_1 = E(\lambda)\tau^{-1} g N_1 \tag{22}$$

where $g = g^+(0)$. This can be interpreted to mean that $I_0(\lambda)$ is that input photon flux per unit wavelength for which the rate of stimulated emission equals the rate of spontaneous emission into the same spatial mode [in (4)]. Using (6), we have

$$I_0(\lambda) = 8\pi\eta^2 g c/\lambda^4 \tag{23}$$

so that $I_0(\lambda)$ depends only on wavelength and on the geometrical configuration, and not on the particular gain medium. Typically, for $g = 10^{-4}$, $I_0(\lambda) \sim 10^{17}$ [photon · cm^{-2} s^{-1}/Å] in the visible, or ~35 [mW · cm^{-2}/Å].

Assuming first $\sigma_{01} = 0$ and an input signal of $I^+(0, \lambda) = pI_0(\lambda)$, we obtain from (10) and (11), neglecting triplet states as before,

$$\begin{aligned} I^+(L, \lambda) &= pI_0(\lambda)G(\lambda) + I_0(\lambda)[G(\lambda) - 1] \\ I^-(0, \lambda) &= I_0(\lambda)[G(\lambda) - 1] \end{aligned} \tag{24}$$

where $G(\lambda) = \exp[\sigma_e(\lambda) \int_0^L N_1(\xi) d\xi]$. In deriving (24), we assumed $g^{\pm}(x) = g^+(0) = g$. This approximation can be seen to be valid if the contribution of fluorescence to $I^{\pm}(x, \lambda)$ is important mainly at the edges of the medium. This is indeed the situation for large enough values of W. The weak pumping regime, for which this assumption is not correct, is of no practical interest in amplifier applications since there $G \simeq 1$.

In cases of interest for amplifier applications, $G(\lambda) \gg 1$ so that $I_0(\lambda)$ represents an input signal ($p = 1$) for which the output at wavelength λ is double its value with no input, which justifies its identification as a noise equivalent input signal. In (24) the second term on the right-hand side represents the background due to ASE, while the first term is the amplified input signal. One can therefore define the amplified signal to background noise $S/N \simeq p$.

The amplification is properly given by $G(\lambda)$ since

$$G(\lambda) I^+(0, \lambda) = I^+(L, \lambda, \text{total}) - I^+(L, \lambda, \text{background}). \tag{25}$$

In the *exponential regime* and in the *strong pumping* regime, $G(\lambda) \gg 1$ for not-too-large input signals. When the input signal is small, i.e., when

$$\sigma_e(\lambda) I^+(0, \lambda) \Delta\lambda < \int \sigma_e(\lambda') I_0(\lambda') d\lambda' \tag{26}$$

(the integration performed over the fluorescence bandwidth) $G(\lambda)$ will be approximately equal to its value in the absence of an input signal since the population of the excited state is then unaffected by the addition of the input signal. Hence the *small-signal gain* at each wavelength is simply proportional to the ASE output at that wavelength in the absence of an input signal (24), except for a weak λ^{-4} dependence (23). As p becomes larger, saturation by the amplified signal will cause a decrease in $G(\lambda)$. However, even in this case one sees from (24) that $S/N \simeq p$ (provided G is still large enough).

When $\sigma_{01}(\lambda) \neq 0$, we obtain from (10), assuming again

$$I^+(0,\lambda) = pI_0(\lambda),$$

$$I^+(L,\lambda) = pI_0G(\lambda) + I_0(\lambda)\{\sigma_e(\lambda)/[\sigma_e(\lambda) + \sigma_{01}(\lambda)]\}[G(\lambda) - 1] + I_0(\lambda)\sigma_{01}(\lambda) \cdot N\{\sigma_e(\lambda)/[\sigma_e(\lambda) + \sigma_{01}(\lambda)]\} \int_0^L \cdot \exp\left[\int_y^L \alpha(\xi,\lambda)\,d\xi\right] dy \quad (27)$$

where $G(\lambda) = \exp[\int_0^L \alpha(\xi,\lambda)\,d\xi]$, $\alpha(\xi,\lambda)$ is defined in (12), and we assume as before $N_T(\xi) = 0$. This expression is similar to (24), the two last terms on the right-hand side representing the background due to ASE. In Fig. 5 we plot the calculated values of $G(\lambda)$, as a function of $I^+(0,\lambda)$, for a wide range of pump intensities W. In the calculation we concentrated on amplification of narrow-band signals, assuming an input signal with a bandwidth of 0.05 nm at a wavelength of $\lambda = 575$ nm, which is the peak of the ASE spectrum and hence the peak of $G(\lambda)$ at all pump intensities for which $W > 3 \times 10^6$. It turns out that also in this case the small-signal gain is approximately proportional to the ASE output at the same wavelength. Since spectral narrowing of this output is significant at high pump intensities, the small-signal gain of a dye-laser amplifier will drop sharply away from the peak of the ASE (see also Section V). In Fig. 5 the initial range of values for which $G(\lambda)$ is independent of the input is clearly seen. For higher input signals there is a gradual decrease of $G(\lambda)$ with increasing inputs.

Finally, for very high input signals, such that

$$\sigma_e(\lambda)I^+(0,\lambda)\,\Delta\lambda >> \int I_0(\lambda')\sigma_e(\lambda')\,d\lambda' \quad (28)$$

and high pumping rates, $G(\lambda)$ becomes inversely proportional to $I^+(0,\lambda)$, as is expected in the regime where the conversion efficiency is close to unity. This can also be shown analytically as follows. Integrating (17) with $I^+(0) = I^+(0,\lambda)\,\Delta\lambda$, $I^-(L) = 0$, yields

$$I^+(L) - I^+(0) + I^-(0) = W \int_0^L N_0(x)\,dx - \tau^{-1} \int_0^L N_1(x)\{1 - [g^+(x) + g^-(x)]\Phi\}\,dx. \quad (29)$$

The assumption (28) means that $I^-(x)$ is quenched to negligible values everywhere in the medium so that $I^-(0)$ can be neglected in (29). Furthermore, the high pumping-rate assumption means that $WN_0(x) >> \tau^{-1}N_1(x)$ so that (29) simplifies to

$$I^+(L) \simeq I^+(0) + WNL \quad (30)$$

from which

$$G(\lambda) \simeq 1 + NWL/I^+(0) \quad (31)$$

so that as long as $G(\lambda) >> 1$, it is inversely proportional to $I^+(0)$, as stated in the preceding. The strong signal regime was also treated by Flamant and Meyer [22] in their study of the dependence of the total gain of a flashlamp-pumped dye-laser amplifier on its length.

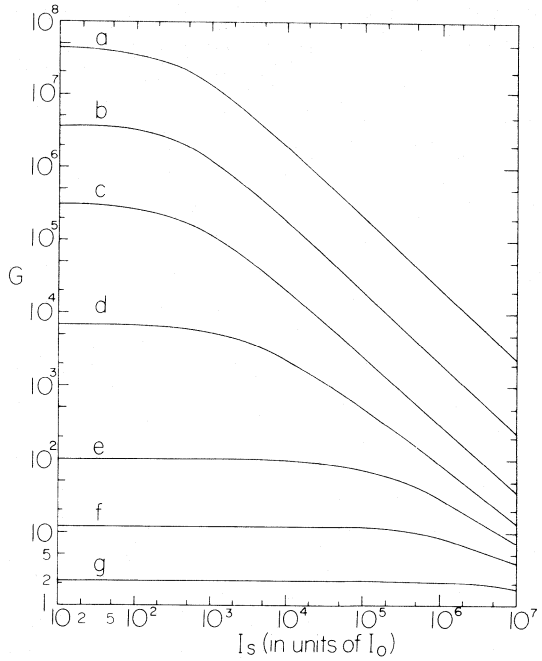

Fig. 5. Calculated gain (G) of a dye-laser amplifier as a function of input signal (I_S). I_S is given in units of I_0 [in (23)]. A bandwidth of 0.05 nm is assumed at $\lambda = 575$ nm. Material parameters are listed in Table I. (a) $W = 5 \times 10^8$ (s^{-1}). (b) $W = 5 \times 10^7$ (s^{-1}). (c) $W = 10^7$ (s^{-1}). (d) $W = 5 \times 10^6$ (s^{-1}). (e) $W = 3 \times 10^6$ (s^{-1}). (f) $W = 2 \times 10^6$ (s^{-1}). (g) $W = 10^6$ (s^{-1}).

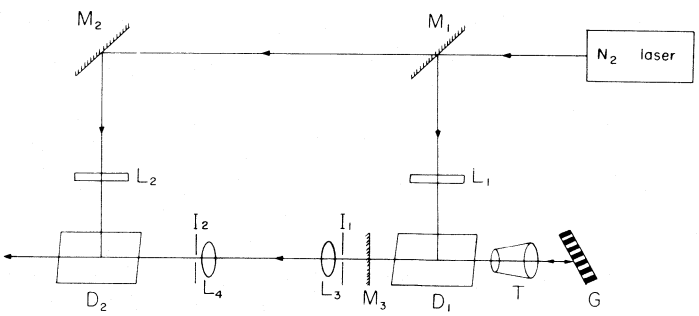

Fig. 6. Experimental setup. M_1—beam-splitting mirror for $\lambda = 337.1$ nm. M_2—totally reflecting mirror at $\lambda = 337.1$ nm. L_1, L_2—cylindrical lenses ($f = 50$ nm). G—reflection grating. T—telescope (magnification; 20×). D_1—oscillator dye cell. M_3—output coupler. I_1, I_2—iris diaphragms. L_3—collimating lens. L_4—focusing lens. D_2—amplifier dye cell.

V. Experiment

A. Experimental Setup

Our experiments were performed using the setup shown schematically in Fig. 6. The pump beam of a longitudinally excited pulsed nitrogen laser ($\lambda = 337.1$ nm, full width at half maximum (FWHM) of 8 ns) is divided by the beam-splitting mirror M_1 into two beams with equal intensities. The two beams pump transversely a laser oscillator and an amplifier. One beam is focused by the cylindrical lens L_1

(focal length 50 mm) into the dye cell D_1. The dye cell is wedged at 8° to prevent feedback by reflection from the cell's windows. D_1 in conjunction with the output coupler M_3 (a quartz wedge), the telescope T (magnification: 20X) and the grating G form the dye-laser oscillator. The part of the pump beam which is transmitted by M_1 is reflected by the mirror M_2 through the cylindrical lens L_2 into the dye cell D_2. L_2 and D_2 are identical to their counterparts in the oscillator branch of the system. The cylindrical lenses focus the nitrogen laser beam to a strip of 1 cm by 4×10^{-2} cm on the dye cell, centered in a 3-cm-long dye region. The optically pumped dye cell D_2 forms the amplifier in the system. Optical coupling between the oscillator and the amplifier is accomplished through a lens system L_3 and L_4. Lens L_3 is used to collimate the oscillator output and lens L_4 focuses it into the amplifier. The diaphragms are used for spatial filtering. The parallelogram $M_1M_2D_2D_1$ provides equal path length for the paths $M_1D_1D_2$ and $M_1M_2D_2$. This assures temporal overlap in the amplifier between the pump beam and the input beam from the oscillator to the amplifier. With this simple configuration, the problem of synchronization, which is very critical when the oscillator and the amplifier are pumped by two different nitrogen lasers [27], is easily overcome. Throughout the experiment, we used a concentration of 5×10^{-3} mole · l^{-1} rhodamine 6G in ethanol.

B. Measurements of the ASE

The first experiment we performed consisted of measuring the total ASE output of the dye cell D_2 as a function of pump power. To this end the mirror M_1 was removed from the system. In Fig. 7 we show the results of this experiment. The circles represent the measured total photon flux, averaged over the pulse length (total pulse energy divided by the FWHM of the pulse), as a function of pumping rate W. The absorption cross section of rhodamine 6G at 337.1 nm is $\sigma_a = 2.4 \times 10^{-17}$ cm^2, and with a pumped area of 0.04 cm^2 the pumping rate W is related to the nitrogen laser power P by $W(s^{-1}) = 10^6 P(\text{kW})$ (see Table I). Again, P is the average of the measured nitrogen laser power. The experimental results are compared to the steady-state solutions of (1)-(4) (solid curve), assuming, however, $N_T = 0$. As previously discussed, this is an appropriate approximation at high pumping rates. At low pumping rates, steady state may not be reached during the short pump pulses, so that one would expect the measured values to be somewhat below the calculated ones. The absorption depth $(\sigma_a N)^{-1}$ at the dye concentration used is 1.4×10^{-2} cm. This dimension was used for calculating the ASE photon flux I (photons · cm^{-2} s^{-1}) from the measured ASE power. As the dye region in D_2 is 3 cm long, self-absorption of the ASE in the pumped dye region must be taken into account. The computer calculations used to generate the continuous curve took into consideration the fact that the ASE generated in the 1-cm-long excited region is attenuated by traveling through 1 cm of unpumped region. No adjustable parameters were used in the calculation. The measurements could be performed accurately over two decades of W. As seen in Fig. 7, there is good agreement between theory and experiment. We conclude that the model analyzed in Section III gives a satisfactory description of the physical situation.

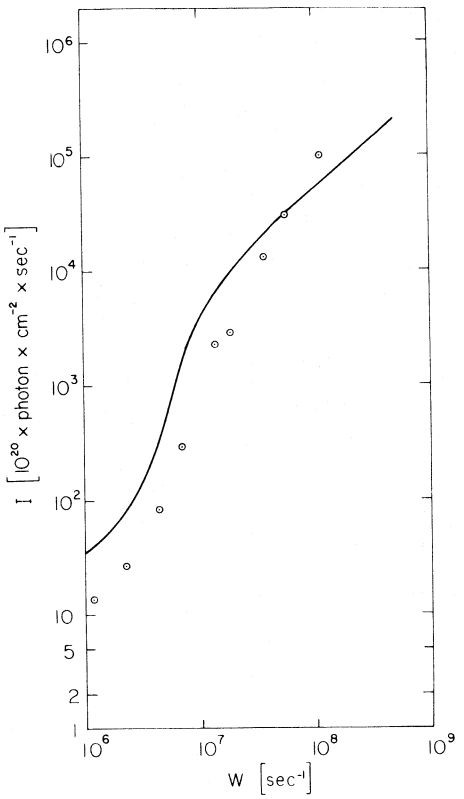

Fig. 7. ASE output (I) as a function of pumping rate (W). Circles denote experimentally measured values; the solid curve is calculated as explained in the text.

C. Gain Measurements

In order to measure the gain of the dye amplifier as a function of the signal input for various amplifier pumping rates, we replaced the mirror M_1 in the dye system. In this arrangement the oscillator output serves as the amplifier input. By placing calibrated filters between M_1 and M_2, and L_3 and L_4, both the amplifier pump rate and the amplifier input could be easily controlled. In this experiment G was a ruled grating with 1200 lines/mm and the oscillator linewidth was 5×10^{-2} nm. The oscillator temporal FWHM was 5 ns. The experiment was performed with the oscillator tuned at 595 nm since at this wavelength the amplifier output was largest. This wavelength is considerably larger than $\lambda = 555$ nm, the fluorescence peak, and it reflects the tradeoff between gain and self-absorption in our oscillator-amplifier system. The experimental data and a calculated curve are shown in Fig. 8.

In order to compare the experimental data with the theoretical calculation, the data were corrected to account for self-absorption in the unpumped regions of the amplifier cell. The dashed curve is calculated for the highest pumping rate used ($W = 6.9 \times 10^7$ s^{-1}, corresponding to ~70-kW nitrogen laser power), and again no adjustable parameters are used in the calculation. The difference between the calculated and the corresponding experimental curve represents a difference of at most 15 percent in the value of $\int_0^L \alpha(\xi, \lambda) d\lambda$ [(12), (13)]. This

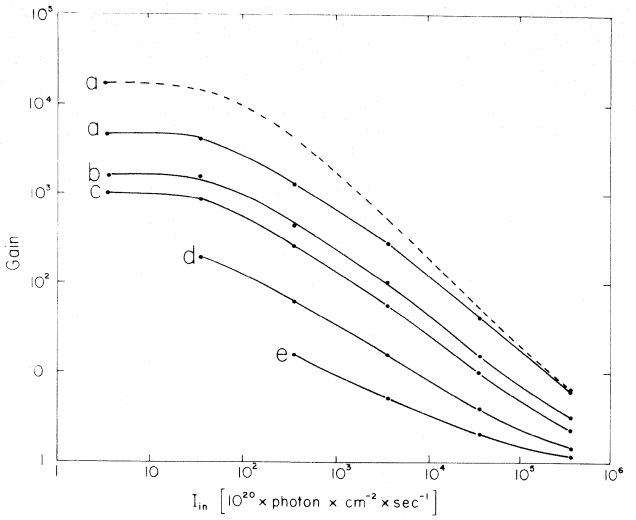

Fig. 8. Measured gain of a R6G amplifier, at $\lambda = 595$ nm, as a function of input photon flux (I_{in}), for various pumping rates. Points represent the measured values, and the solid curves are hand drawn through them. The dashed curve is calculated for the value of W that corresponds to the highest pumping rate. (a) $W = 6.9 \times 10^7$ (s^{-1}). (b) $W = 3.4 \times 10^7$ (s^{-1}). (c) $W = 2.2 \times 10^7$ (s^{-1}). (d) $W = 1.2 \times 10^7$ (s^{-1}). (e) $W = 6.9 \times 10^6$ (s^{-1}).

represents a much better fit than one would expect in view of the uncertainty of the constants used in the calculation and the approximation of the model. The behavior of the experimental curves in Fig. 8 agrees with the description given in Section IV and these curves are qualitatively similar to the theoretical curves shown in Fig. 5. For very small input signals the gain is constant, but as the input signal becomes more intense saturation effects reduce the gain. As explained previously in (31), at high pump rates and high enough input signals, the gain becomes approximately proportional to the pump rate and inversely proportional to the signal input.

D. Narrow-Band Amplification

From Fig. 8 it can be seen that with the amplifier pumped by 70 kW, its peak power output at 5950 Å (with $\Delta\lambda = 5 \times 10^{-2}$ nm) was 40 kW for an input of 6.7 kW. However, for a 20-dB attenuation of the input signal the amplifier output is reduced by 3 dB only. Consequently, if a Fabry-Perot etalon is placed in the space between the lenses L_3 and L_4, we can expect to greatly reduce the linewidth of the dye system without suffering a serious reduction in the power output. As already noted by Hänsch [5b)], in nitrogen-laser-pumped systems, the oscillator linewidth will not be much smaller than that of the intracavity Fabry-Perot filter because of the short duration of the pulse. However, a high-finesse intracavity etalon causes an appreciable reduction of the oscillator narrow-band output power due to insertion losses. We therefore found it advantageous for further line narrowing to place the etalon between the oscillator and amplifier stages of the system. We replaced the ruled grating in Fig. 6 by a holographic grating with 2900 lines/mm, and placed a Fabry-Perot etalon with a free spectral range of 2×10^{-2} nm and a reflective finesse of 20 between the lenses L_3 and L_4. With the amplifier pumped by 70 kW, this system gave an output peak power of 20 kW at 595 nm with a linewidth of $\Delta\lambda = 2 \times 10^{-3}$ nm. These results demonstrate that a dye-laser oscillator-amplifier system is a convenient tool for generating high-power narrow-band emission.

Theory of the Nitrogen Laser Excited by a Relativistic Electron Beam

DAVID A. McARTHUR AND J. W. POUKEY

Abstract—**The 3371-Å nitrogen laser power produced by a relativistic electron beam propagating into nitrogen gas is calculated. The excitation contribution of cascade electrons is found to be negligible, compared to the excitation caused by plasma electrons drifting in the inductive electric field produced by the beam. The extensive experimental data on nitrogen are used wherever possible in the calculation, and the sensitivity of the calculation to the various input data is given. The mechanism of excitation by plasma electrons alone yields agreement within experimental uncertainty for such parameters as the peak laser power, the laser pulsewidth and delay, and the dependence of the laser power on gas pressure. For a larger drift tube radius, the plasma electron mechanism predicts higher power and a different pressure dependence, in agreement with experimental trends. In calculating the laser power, the beam propagation details, excitation to the upper and lower laser levels, collisional quenching, a threshold for amplified spontaneous emission, and excitation and deexcitation by plasma electrons are included, but coherent dipole moment effects are neglected.**

I. Introduction

PULSED relativistic electron beams [1]–[4] have recently been used to excite laser action in gases such as N_2 and H_2, providing intense sources of short wavelength radiation useful in applications such as plasma heating and spectroscopy. The theory of such laser action has not been treated in detail, probably because the interaction of a relativistic electron beam with an initially neutral gas is complex, involving strong spatial and time variations of the plasma parameters [5]. It has been proposed that in the case of the N_2 laser, excitation proceeds via a cascade of secondary electrons produced in ionization events caused by the primary beam electrons, the presence of an electric field in the beam-produced plasma being of little importance [2].

Manuscript received May 15, 1975.
The authors are with the Sandia Laboratories, Albuquerque, N. Mex. 87115.

In order to understand the propagation of relativistic electron beams, a detailed model of the plasma produced by the beam was recently developed for the well-understood case of N_2 gas [5], [6]. In this model, the electrons produced initially by the primary beam drift through the weakly ionized N_2 gas, because the plasma contains an axial electric field. The electric field in the relativistic electron beam case is the inductive electric field caused by the rapidly rising beam current waveform. As a result of this drift process, the initial secondary electrons acquire a new energy distribution determined by the electric field and the gas pressure. The measured transport coefficients of this distribution can then be used to calculate the resulting avalanche ionization and further plasma current production in the gas. The additional plasma current caused by avalanche ionization subtracts from the primary beam current, tending to reduce the inductive electric field, and eventually "shutting off" the avalanche ionization process. Fig. 1 shows representative waveforms of the beam current (I_b), plasma current (I_p), and net current ($I_n = I_b - I_p$). The resulting plasma properties thus vary rapidly in space and time. Without adjustable parameters, the model has been shown to describe the measured net current waveform well for beams of different peak currents and energies, over a wide pressure range [6].

The detailed time- and space-dependent plasma properties provided by the model can equally well be applied to the N_2 laser situation, provided accurate measurements of the excitation cross sections to the upper and lower laser levels are available. In this paper detailed calculations are made for the case studied experimentally by Patterson [7], with certain simplifying assumptions concerning the calculation of the laser power since we are primarily concerned with identifying the excitation mechanism. Preliminary calculations have already been reported briefly [8], and also a summary of more com-

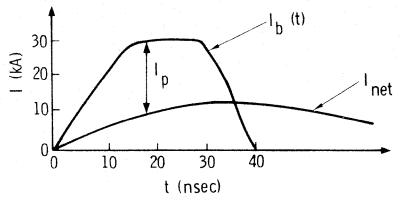

Fig. 1. Representative current waveforms produced by a high-current electron beam propagating into neutral gas. I_p changes sign near the end of the I_b pulse (the plasma electrons reverse direction at late times).

plete calculations [9]. In Section II we describe the additional measurements made by Patterson to define the primary beam characteristics, in Section III we describe the laser model, in Section IV the comparison between theory and experiment, and in Section V we present our conclusions.

II. Measurement of Primary Beam Characteristics

Reference [7] describes the measurement of the laser output power and pulsewidth as a function of the nitrogen pressure, the primary beam current, and the length of the laser tube. Since lasing occurs primarily on the rapidly rising initial part of the net current waveform, the measured velocity v_b of the primary beam front is used [7]. For an accurate calculation of the laser power additional details about the primary beam are needed, because of the long drift tube length L and the relatively small tube radius r_0 (see Fig. 2). The plasma current and the electric field depend on the radial shape $S(r)$ of the primary beam if the beam radius is comparable to r_0 [6]. Representative time-averaged functions $S(r)$ measured with 4-chlorostyrene films [7] are shown in Fig. 3. Finally, the primary electron beam current I_b is attenuated exponentially (within the experimental error of ±10 percent), with a characteristic decay length Λ

$$I_b(z) = I_b(0) \exp(-z/\Lambda).$$

Λ was measured as a function of the N_2 pressure P by comparing the peak $I_b(z > 0)$ with the simultaneously measured peak anode current $I_b(0)$, for two values of z (see Fig. 4).

III. The Laser Model

The net current model of [6] permits the calculation of the plasma current density j_{pz} and the electric field E_z as a function of radius r and length z along the laser tube, assuming cylindrical symmetry. At high gas pressure and low electron density, E_z controls the characteristic electron energy ϵ_k, and thus the relative excitation to the upper and lower laser levels. To a good approximation ϵ_k is a function of (E_z/N_g), where N_g is the initial density of N_2 molecules [6]. E_z and j_{pz} are calculated from a varying primary beam current density j_{bz} which includes the effects of the measured beam front velocity v_b, shape $S(r)$, and beam loss length Λ (see Section II)

$$j_{bz}(r, z, t) = S(r)\, I_b \left(t - \frac{z}{v_b}\right) \exp(-z/\Lambda) \qquad (1)$$

where I_b is the primary beam current measured at the anode, corresponding to $z = 0$. The calculated j_{pz} and E_z yield calculated plasma electron excitation rates X_u and X_l to the upper and lower laser levels, respectively, which are discussed in Section III-A. In Section III-B we discuss the calculation of the laser power which results from these excitation rates.

A. Calculation of the Excitation Rates X_u, X_l

The 3371-Å N_2 laser transitions occur between rotational levels of the $v' = 0$ vibrational state of the $C^3\Pi_u$ electronic level (denoted here by the subscript u), and the $v'' = 0$ vibrational state of the $B^3\Pi_g$ electronic level (denoted by the subscript l). The rates X_u and X_l are given in general by

$$X_{u,l} = n_s N_g \langle \sigma_{u,l} v \rangle = j_{pz} N_g \langle \sigma_{u,l} v \rangle / ew \qquad (2)$$

where σ_u, σ_l, respectively, are the energy-dependent electron excitation cross sections, v is the velocity of a plasma electron of energy ϵ, w is the drift velocity of the electron distribution, n_s is the plasma electron density, and e is the electron charge. $\langle \sigma v \rangle$ represents the average of the product σv over the distribu-

tion of plasma electron energies, given by

$$\langle \sigma v \rangle \propto \int_0^\infty \sigma \epsilon^{1/2} f(\epsilon)\, d\epsilon \tag{3}$$

where $f(\epsilon)$ is the electron distribution function. In the general case, it would be necessary to solve the Boltzmann transport equation to obtain $f(\epsilon)$ as a function of E_z/N_g. However, in the case of excitation to the $C^3\Pi_u$ and $B^3\Pi_g$ levels of N_2, we are able to use experimental data for $\langle \sigma_u v \rangle$, and to obtain $\langle \sigma_l v \rangle$ approximately from calculated $f(\epsilon)$ [10].

Legler [11] has measured a transport coefficient δ_0 for N_2, which is analogous to the Townsend first ionization coefficient, and is closely related to $\langle \sigma_u v \rangle$. The light emitted from several vibrational states of the $C^3\Pi_u$ level was observed as a function of the E_z/N_g present in the weakly ionized gas. δ_0 is related to $\langle \sigma_u v \rangle$ by [11]

$$\langle \sigma_u v \rangle = K \delta_0 w / N_g \tag{4}$$

where K is a correction factor to remove contributions from $C^3\Pi_u$ vibrational levels with $v' > 0$. Since the $v' = 1, 2$, and 3 levels comprise most of the unwanted contribution [11], K is given by

$$K = \left(\sum_{v'=0}^{3} \left[\left(\frac{\sigma_{Cv'}}{\sigma_{C0}} \right) \sum_{v''=0}^{9} P_{v'v''}\, \eta_{v'v''} \right] \right)^{-1} = 0.53. \tag{5}$$

Here $\sigma_{Cv'}$ is the measured peak cross section for electron excitation to the v' level of the C state [12], the $P_{v'v''}$ are the measured relative probabilities of emission from the v' level to the various v'' levels of the B state ($\Sigma_{v''} P_{v'v''} \equiv 1$) [13], and $\eta_{v'v''}$ is the photomultiplier quantum efficiency at the wavelength of the $v' \rightarrow v''$ band, relative to the average value used by Legler in determining δ_0. At $E_z/N_g \sim 6 \times 10^{-15}$ V · cm^2 it is possible that a small contribution ($\sim$ 5 percent) may be present from the $B^2\Sigma_u^+$ level of the N_2^+ ion, but this effect is smaller than the errors in most of the input data to the model, and can be ignored. The resulting function $\langle \sigma_u v \rangle / w$ is shown in Fig. 5, as a function of E_z/N_g.

No measurement of the corresponding transport coefficient for the lower laser level has been made, presumably because of the long radiative lifetime of the $B^3\Pi_g$ level, the long wavelengths of the bands originating from the $B^3\Pi_g$ level, and the presence of important cascade contributions from the $C^3\Pi_u$ levels which would result from a broad electron energy distribution [13]. Measurements have, however, been made of the excitation cross sections $\sigma_{Bv''}$ to several vibrational levels of the $B^3\Pi_g$ state, as a function of the precisely defined energy of an electron beam [12], [14], [15]. From the calculations of [10] it can also be seen that for $\epsilon \gtrsim 3.5$ eV in N_2, $f(\epsilon)$ is given approximately over a wide range of E_z/N_g by

$$f(\epsilon) \cong A' \epsilon^{1/2} \exp(-\epsilon/\epsilon_k') \quad (\epsilon \gtrsim 3.5 \text{ eV}) \tag{6}$$

where A' and ϵ_k' are independent of ϵ but do depend on E_z/N_g. Note that the single exponential form of $f(\epsilon)$ is retained even when several sharp thresholds of inelastic processes are crossed, ϵ_k' is equal to the measured electron characteristic energy ϵ_k

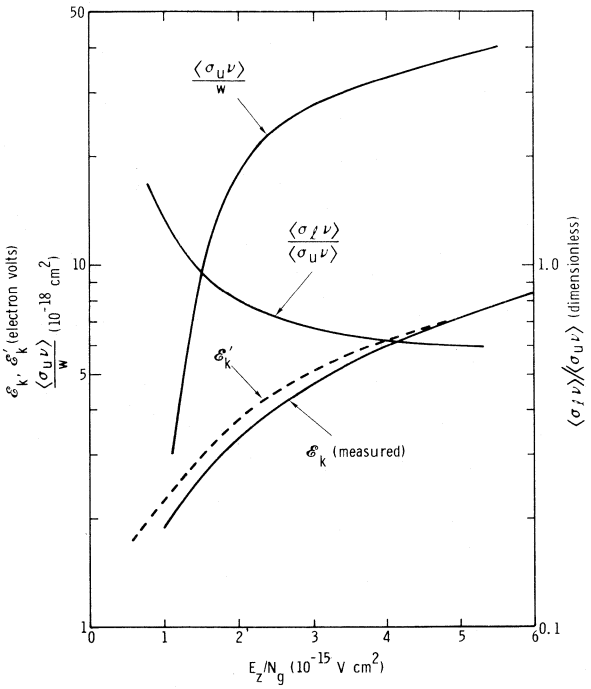

Fig. 5. Variation with E_z/N_g of transport coefficients used to calculate excitation to upper and lower laser levels. The curve labeled ϵ_k shows the experimentally measured characteristic energy of the electron distribution [10].

within <20 percent over the range of large $\langle \sigma_u v \rangle / w$ (see Fig. 5), but A' depends strongly on E_z/N_g and the set of cross sections used to calculate $f(\epsilon)$. On the other hand, A' does not appear in the ratio $\langle \sigma_l v \rangle / \langle \sigma_u v \rangle$ for a particular value of E_z/N_g, since it can be taken outside the integral in (3) and cancels in the ratio

$$\frac{\langle \sigma_l v \rangle}{\langle \sigma_u v \rangle} \cong \frac{\int_0^\infty d\epsilon \sigma_{B0} \epsilon \exp(-\epsilon/\epsilon_k')}{\int_0^\infty d\epsilon \sigma_{C0} \epsilon \exp(-\epsilon/\epsilon_k')}. \tag{7}$$

Thus a calculation of the ratio depends on knowledge of excitation cross sections and the parameter ϵ_k', which at high E_z/N_g is nearly equal to the measured characteristic energy ϵ_k, and is available at lower E_z/N_g from the calculations of [10] (see Fig. 5).

To calculate the ratio $\langle \sigma_l v \rangle / \langle \sigma_u v \rangle$, we use the measurements of [16] for the shape of σ_{C0}. σ_{B0} as measured directly contains cascade contributions from the $C^3\Pi_u$ level [14], [15]. The σ_{B3} cross section has been corrected for cascade contributions in [14], so the shape of this "corrected" σ_{B3} was used for the shape of σ_{B0}. In calculating the ratio it is important to have correct *relative* magnitudes for σ_{B0} and σ_{C0}; since [12] appears to take more accurate account of the long lifetime of the $B^3\Pi_g$ level in measuring $\sigma_{Bv''}$, we use [12] for the peak cross sections for both σ_{B0} and σ_{C0}. (An alternative shape for σ_{B0} can be obtained from the measured $v' = 9$ to $v'' = 6$ transition cross section [15], which has negligible cascade. This shape is only 25 percent wider than that assumed in the preceding and results in little change in the calculated ratio.) The resulting ratio $\langle \sigma_l v \rangle / \langle \sigma_u v \rangle$ is shown in Fig. 5 as a function of

E_z/N_g.[1] Since the uncertainties in ϵ_k', σ_{C0}, and σ_{B0} are $\lesssim$20 percent [10]-[12], we estimate that $\langle\sigma_l v\rangle/\langle\sigma_u v\rangle$ is accurate to ±20 percent for $E_z/N_g \geq 10^{-15}$ V · cm^2. Therefore

$$X_l = n_s N_g \left(\frac{\langle\sigma_l v\rangle}{\langle\sigma_u v\rangle}\right)\langle\sigma_u v\rangle. \tag{8}$$

1) Excitation by Cascade Electrons: Thus far we have considered only excitation by the swarm of plasma electrons produced by avalanche or primary electron ionization, which have an energy distribution determined by E_z/N_g. However, there exist two groups of electrons which would have energies $\gtrsim$10 eV even if I_b were so small that $E_z \cong 0$ as follows: a) the energetic primary electrons; and b) the distribution of energetic "first secondary" electrons produced when primary electrons ionize N_2 molecules. The primary electrons have negligible probability of undergoing the electron-exchange type of collision required to excite an N_2 molecule from the singlet ground state to the triplet laser levels, because of their high energy [17]. The "first secondary" electrons, on the other hand, have an energy distribution $\rho_f(\epsilon)$ extending to low energies [18] and thus have an appreciable probability of exciting the triplet laser levels. The "first secondary" electrons are assumed to be responsible for essentially all the laser excitation in the model of Dreyfus and Hodgson [2]. The amount of excitation to the upper laser level by these first secondary electrons can be estimated because ρ_f changes slowly with primary electron energy and is roughly constant in shape above a primary electron energy of a few kiloelectronvolts. The relative ionization contribution η_f of these first secondary electrons in N_2 has been measured [19]

$$\dot{N}_{ip} \propto (1 + \eta_f)\,\sigma_{ip0}$$

where $\dot{N}_{ip}$ is the total primary electron ionization rate, σ_{ip0} is the ionization cross section for the primary electrons alone, and $\eta_f = 1.8 \pm 0.7$. The relative contribution ξ_f for excitation to the upper laser level can be estimated from the distribution ρ_f, the cross section σ_{C0} [12], [16], and the N_2 ionization cross section σ_i [20]

$$\frac{\xi_f}{\eta_f} = \frac{\int_0^\infty \sigma_{C0}(\epsilon)\rho_f(\epsilon)\epsilon^{1/2}\,d\epsilon}{\int_0^\infty \sigma_i(\epsilon)\rho_f(\epsilon)\epsilon^{1/2}\,d\epsilon} \cong 0.05.$$

(This ratio is also in rough agreement with the ratio of $C^3\Pi_u$ excitation to ionization which has been measured to be 0.092 for 4.3-MeV α particles incident on N_2 [21].) The function $\rho_f(\epsilon)$ yields a calculated value of η_f which is ≈ 0.8 rather than the 1.8 measured. This discrepancy may be real, corresponding to an added contribution from cascading high-ϵ electrons in ρ_f. Therefore, in our estimate of this small contribution, we use $2\xi_f/\eta_f$. Thus the estimated excitation rate by first secondary electrons at a given point in the gas is

$$X_{uf} \cong \frac{2\xi_f}{\eta_f}\frac{\eta_f \dot{N}_{ip}}{(1+\eta_f)} \tag{9}$$

where $\dot{N}_{ip}$ is the total ionization rate by primary and first secondary electrons. Using calculated values of X_u and $\dot{N}_{ip}$, we find $X_u/X_{uf} \cong 100$ at the peak of the laser pulse at 1.5- and 7.5-torr N_2, and $X_u/X_{uf} = 30$ at $P = 50$ torr where the primary and plasma avalanche ionization rates are comparable. Therefore, excitation by first secondary electrons appears to be a small effect compared to plasma excitation, and we therefore neglect excitation by primary electrons throughout the pulse, even when $X_u = 0$. The neglect of primary electron cascade excitation and the dominance of plasma electron excitation is in strong contrast to the model presented by Dreyfus and Hodgson [2]. The difference between the two models will be discussed further in Section IV.

We also neglect excitation by collisions between excited molecules, which may influence the plasma parameters significantly late in the primary beam pulse [22], because the calculated laser pulse occurs close to the beginning of the primary beam pulse.

2) Distribution of Molecules Among Sublevels: Each vibrational state of the C and B levels is split into multiplet components, into rotational levels denoted by the rotational quantum number J, and into two Λ-doublet components [23]. In calculating the small-signal gain for each possible laser transition we assume equal populations of the three multiplets, we ignore the small Λ-doublet splitting and the associated alternation of intensities caused by varying nuclear spin state degeneracies [24] (at most a ±35-percent effect in the small-signal gain, and a much smaller effect in the total power, as discussed as follows in Section IV), and we assume for the rotational levels a Boltzmann distribution with a temperature equal to the gas temperature T. Over most of the pressure range of interest here (1.5 torr $\leq P \leq$ 50 torr [7]), the measured N_2 rotational relaxation time τ_r ($\cong$ 370 ns/P(torr) [25]) is greater than the laser pulsewidth, so that rotational relaxation effects during lasing are small. For 0.5 torr $\lesssim P \lesssim$ 3 torr experiments [26], [27] have shown that the assumption of a rotational temperature close to the initial gas temperature describes the intensities of the lasing transitions well, although this approximation may begin to fail at $P \cong$ 30 torr [24]. Because the plasma model is already sufficiently complex and the peak of the measured laser power occurs at $\approx$10 torr, we ignore high-pressure rotational relaxation effects.

B. Calculation of the Laser Power

We are concerned primarily with the laser excitation mechanism, and therefore with the order of magnitude of the laser power, and the dependence of the laser power on such parameters as the gas pressure, drift tube diameter, and the primary beam current. We therefore neglect several details of the lasing process which are expected to make relatively small changes in the laser pulse shape and peak power. We neglect the possibility of laser beams directed both parallel to the primary electron beam (forward wave), and antiparallel to the primary

[1] As a check on the numerical integration and $f(\epsilon)$ used to obtain $\langle\sigma_l v\rangle/\langle\sigma_u v\rangle$, δ_0 was calculated as a function of E_z/N_g, using the calculated ϵ_k' and A' from [10]. The shape of the resulting δ_0 was equal to that of the data of [11] or the calculations of [10] within ±15 percent.

beam (backward wave). In the traveling-wave-excited H_2 laser, more than 90 percent of the laser energy is emitted in the forward direction [28]. In the electron-beam-excited N_2 laser [2], more than 65 percent of the energy is emitted in the forward direction, even if the weak second laser pulse observed is assumed to be a backward wave and the Ti anode reflectivity is included. Based on these experiments we assume that all laser energy is emitted in the forward direction.

Finally, we neglect coherent dipole moment effects analogous to self-induced transparency [29]. These are expected to be important to an exact treatment because for $P < 50$-torr N_2 the phase memory time T_2 is greater than the laser pulsewidth τ_L (we estimate that $T_2^{-1} \cong \tau_r^{-1} + \tau_{su}^{-1}$, where $\tau_{su} = 38$ ns is the spontaneous lifetime of the upper laser level). For T_2 much greater than the preparation time of an inversion, it has been observed [30] that the laser pulse is considerably delayed and has a pulsewidth which depends strongly on the inversion density, even if the initial inversion density is constant in space and time. However, our case differs considerably from that of [30] because the excitation is incoherent and because the delay time τ_D and the radiation damping time τ_R are much shorter even if coherent excitation is assumed. From the gain calculations described in the following and in [30], we can estimate that $\tau_D \cong 1$ ns and $\tau_R \cong 0.1$ ns, at a time of 2 ns after the gain becomes nonzero. Since τ_D and τ_R are much shorter than the risetime of the gain pulse, the laser pulse shape is likely to be determined to a large extent by the excitation pulse shape. To treat this in detail would require a considerable generalization of the theory of [30], which is beyond the scope of this paper. We therefore use rate equations to calculate the population of the upper and lower laser levels, calculate the small-signal gain, and assume that lasing begins on a particular transition when a threshold value of the gain is reached, as explained in detail in the following.

We neglect the slowing of the laser pulse in the high-gain region of the laser tube where the laser transition is not yet saturated [31], because the high-gain region is much shorter than the laser length for the most intense laser lines (estimates show that this is about a 10-percent effect). Estimates show that some of the larger Zeeman splittings in the applied magnetic guide field are of the same size as the Doppler linewidth; these splittings are ignored in the model, however, because the calculated power is relatively insensitive to the precise magnitude of the gain, and because many of the Zeeman splittings are small.

The laser field extracts energy efficiently from the excited laser medium only if the laser intensity I_J on a particular rotational transition is of the order of a threshold intensity I_1. This intensity, which corresponds to the onset of a constant and maximum dI_J/dz rather than exponential growth, is much greater than the saturation intensity I_S because the N_2 laser lines are inhomogeneously broadened in this pressure region. The experimental N_2 laser saturation studies of Leonard [32] show that efficient energy extraction begins at a threshold gain $\exp(G_0)$, where

$$G_0 \equiv \int \alpha dz \cong 13 \tag{10}$$

and α is the small-signal gain coefficient. The saturation threshold condition is most important at high and low pressures where the gain is lower and many lines are prevented from efficient laser action. If no backward laser wave exists, the region near the anode will never become saturated; then the laser power from an element of laser volume is assumed to be zero unless the element is located a distance

$$z > z_{sJ}(r, t) \tag{11}$$

from the anode, where z_{sJ} is a saturation threshold length given by

$$\int_0^{z_{sJ}(r,t_0)} \alpha_{gJ}\left(r, z', t_0 + \frac{z'}{c}\right) dz' = G_0. \tag{12}$$

Here α_{gJ} is the small-signal gain of the P-branch transition originating from the Jth rotational level of the $C^3\Pi_u v' = 0$ state in one of the multiplet components, and t_0 is the laboratory frame time at which the light beam of interest left the anode region ($z = 0$). z_{sJ} is a strong function of t and r because of variations in the plasma properties which determine α_{gJ}.

Laser action is assumed to occur only on the P-branch transitions because of the rotational distribution discussed in Section III-A, which results in slightly less gain for the R-branch transitions. The P-branch transitions will reach the saturation threshold first and because of competition will further decrease the gain on the R-branch transitions, resulting in only P-branch lasing. Experiments also show that only a few R-branch lines [24] and one Q-branch line [26] lase weakly.

The gain α_{gJ} is calculated from

$$\alpha_{gJ} = \frac{1}{3}\left(\frac{\ln 2}{\pi}\right)^{1/2} \frac{B_{00} S_J \lambda^2}{4\pi \tau_{su} \Delta\nu_D}\left[\frac{N_{CJ}}{(2J+1)} - \frac{N_{BJ+1}}{(2J+3)}\right] \tag{13}$$

where the $\frac{1}{3}$ factor accounts for the multiplet splitting, $S_J \cong J$ [33], $\tau_{su} = 3.8 \times 10^{-8}$ s is the spontaneous lifetime of the upper laser level [13], $B_{00} = 0.49$ is the relative probability of the $v' = 0$ to $v'' = 0$ transition, $\lambda = 3371$ Å is the average laser wavelength, N_{CJ} and N_{BJ+1} are the populations of the upper and lower laser levels of the Jth P transition (if we neglect the multiplet splitting), and $\Delta\nu_D$ is the Doppler linewidth

$$\Delta\nu_D = \frac{2}{\lambda}\left(\frac{2kT\ln 2}{M}\right)^{1/2}.$$

Here T is the translational temperature in degrees kelvin and M is the molecular mass of the N_2 molecule.

The populations are obtained from the equations

$$\frac{dN_{CJ}}{dt} \cong f_J X_u - \frac{N_{CJ}}{\tau_u} - \frac{N_{CJ}D}{\tau_{su}} + K' D N_{BJ} \frac{B_{00}}{\tau_{su}} \exp\left(-\frac{h\nu}{\epsilon_k}\right), \quad (0 \leqslant J \leqslant 20) \tag{14a}$$

and

$$\frac{dN_{BJ}}{dt} \cong f_J X_l - \frac{N_{BJ}}{\tau_l} + \frac{K'' B_{00} N_{CJ}}{\tau_{su}}[1 + D], \quad (1 \leqslant J \leqslant 21). \tag{14b}$$

X_l and X_u are the excitation rates discussed in Section III-A and τ_u and τ_l are the total lifetimes of the upper and lower laser levels, respectively, including collisional deactivation [34], [11][2]

$$\tau_u^{-1} = \tau_{su}^{-1} + 0.036 \times 10^7 P\,\mathrm{s}^{-1} \quad (15a)$$

$$\tau_l^{-1} = \tau_{sl}^{-1} + 0.245 \times 10^7 P\,\mathrm{s}^{-1} \quad (15b)$$

$\tau_{sl}^{-1} = 1.12 \times 10^5$ s^{-1} [12], and P is the N_2 pressure in torr. f_J gives the relative rotational populations

$$f_J = x(2J+1)\exp\left[-xJ(J+1)\right] \quad (16)$$

where $x = Bhc/kT$, $B = 2.01$ cm^{-1} is the rotational level constant for the N_2 ground state [23], h is Planck's constant, k is Boltzmann's constant, and T is the rotational temperature, which is assumed equal to the translational temperature.

On the right-hand side of (14a), the third term ($\propto D$) represents the effect of collisional deexcitation of the upper laser level to all the $B^3\Pi_g(v'')$ levels by plasma electrons, and the fourth term ($\propto K'D$) represents the excitation of molecules from the $B^3\Pi_g(v'')$ levels to the upper laser level by plasma electrons. On the right-hand side of (14b) the third term ($\propto K''$) represents spontaneous emission from the $C^3\Pi_u(v')$ levels into the lower laser level, and the fourth term ($\propto K''D$) represents collisional deexcitation from the $C^3\Pi_u(v')$ levels into the lower laser level. To uncouple the equations for different J values, the further approximation required to obtain (14) is that terms such as

$$\left[\frac{J}{2J+1} + \left(\frac{N_{CJ+2}}{N_{CJ}}\right)\left(\frac{J+1}{2J+5}\right)\right] \cong 1$$

for those J values having the peak small-signal gain and contributing most of the laser energy ($J \approx 8$). Using (16) and assuming $T = 300$ K, this approximation is satisfied for the strongest laser lines to $\approx \pm 10$ percent, which is within the experimental error of other input data to the problem. In calculating contributions from other vibrational levels the measured $P_{v'v''}$ are used [see (5)] and it is assumed that excitation to various vibrational levels is proportional to the measured $\sigma_{Cv'}$ and $\sigma_{Bv''}$ [12]. For example

$$K' = \sum_{v''=0}^{4}\left(\frac{\lambda_{0v''}}{\lambda_{00}}\right)^3\left(\frac{P_{0v''}}{P_{00}}\right)\left(\frac{\sigma_{Bv''}}{\sigma_{B0}}\right) \cong 4.8$$

where $\lambda_{0v''}$ is the wavelength of the transition form the $C^3\Pi_u \cdot (v' = 0)$ level to the $B^3\Pi_g(v'')$ level. By a similar calculation, $K'' = 1.57$. The function D is given by

$$D = \frac{7.33}{\epsilon_k^{1/2}}\left(\frac{n_s}{10^{15}\ \mathrm{cm}^{-3}}\right)P\left(\frac{h\nu}{\epsilon_k}\right)$$

where $h\nu$ is the energy of a 3371-Å photon and $P(y)$ is a tabulated function associated with the effective Gaunt factor [35]. Deexcitation of the lower laser level by plasma electrons is neglected because it is smaller than the molecular collisional deexcitation rate at all pressures.[2] The net excitation from the $A^3\Sigma$ state to the $B^3\Pi_g$ state by plasma electrons is expected to be small, since the B–A energy difference is much smaller than ϵ_k during the laser pulse, and since the A state population is expected to be comparable to the B state population.

Typical calculated z_{sJ} are shown in Fig. 6, as a function of the laboratory frame time t_{sat} when the condition of (12) is satisfied (note that the saturation condition is not defined at a given point until the beam reaches it). The straight line shows the progress of the electron beam front down the laser tube. Regions of the laser tube far from the anode saturate as soon as the beam arrives, because of the gain acquired at smaller z. The region near $z = 0$ never saturates, and the unsaturated region is larger for lines with lower gain. As the pressure is varied from $\approx$10 torr the gain becomes lower and less energy is extracted efficiently from the anode region, which has the largest stored energy density because of the exponential primary beam loss. z_{sJ} increases later in the pulse as the small-signal gain again decreases, either because of spontaneous emission losses from the upper laser level or because of decreasing excitation. Because of the radial variation of α_{gJ}, the central portion of the tube may be lasing, yet the region near the walls may be far from threshold and can even be absorbing because of a low ϵ_k which preferentially excites the lower laser level. In an actual laser [7] light waves can propagate at appreciable angles to the drift tube axis and could possibly extract some energy from the lower gain regions even though they do not satisfy (12). Our model does not attempt to treat the angular details because of the complexity of the problem. Calculations with $G_0 = 0$ (which include on-axis contributions from low-gain J transitions as well as the contributions from off-axis regions) show that the peak laser power increases by about a factor of 2 over the $G_0 = 13$ case. Therefore, including the off-axis regions can increase the peak power at most by a factor of 2.

For particular volume element at distance z, when $z_{sJ} < z$ equations (14) are no longer valid because they neglect satura-

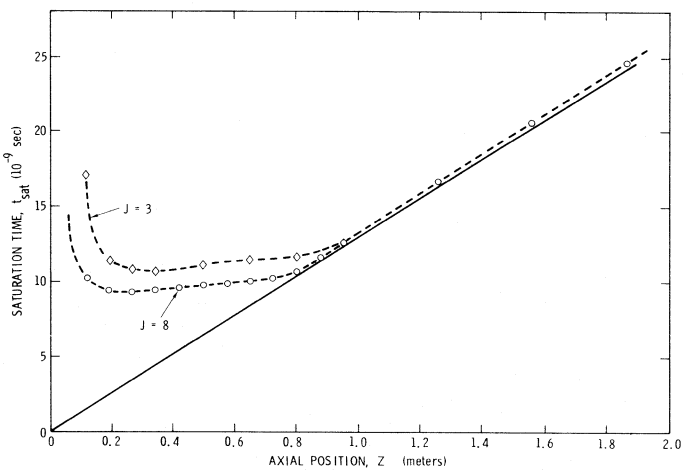

Fig. 6. Dependence of the saturation time t_{sat} on the axial position z, for the $P(4)$ and $P(9)$ laser transitions at $r = 0$ and 15-torr N_2. The higher gain line saturates earlier and leaves a smaller portion of the laser tube unsaturated. The straight line is the beam front trajectory.

[2] The collisional deactivation rate has been measured to ±30 percent only for the $v'' = 3$ vibrational level of the B state [11]; this value is used for the $v'' = 0$ level.

tion. The laser power per unit volume is then calculated from equations similar to those of Gerry [36] and Ali *et al.* [37], in which it is assumed that laser action almost equalizes the populations of the upper and lower laser levels. The equations used here include the degeneracies $g_u = 2J + 1$ and $g_l = 2J + 3$, quenching through collisions with other N_2 molecules, and by the coefficient X_l the recent careful measurements of excitation to the lower laser level.

If two new variables N_J and ΔN_J are defined

$$N_J = \frac{1}{2}\left(\frac{N_{CJ}}{g_u} + \frac{N_{BJ+1}}{g_l}\right) \tag{17a}$$

and

$$\Delta N_J = \frac{1}{2}\left(\frac{N_{CJ}}{g_u} - \frac{N_{BJ+1}}{g_l}\right) \tag{17b}$$

then saturation of the laser transition corresponds to a small value of the saturated population difference ΔN_J, and N_J is the average population per degenerate rotational level. If P_J is the rate of stimulated transitions per unit volume required to maintain ΔN_J at its low value in the presence of excess excitation to the upper level, the equations for N_J and P_J become

$$(g_u + g_l)\dot{N}_J = (f_J X_u + f_{J+1} X_l) - \left(g_u\left[\tau_u^{-1} + \frac{D}{\tau_{su}} - \frac{K'' B_{00}}{\tau_{su}}(1 + D)\right] + g_l\left[\tau_l^{-1} - \frac{K' B_{00} D \exp\left(-\frac{h\nu}{\epsilon_k}\right)}{\tau_{su}}\right]\right) N_J \tag{18a}$$

and

$$P_J = \frac{1}{2}\left[(f_J X_u - f_{J+1} X_l) - \bar{g}\,(f_J X_u + f_{J+1} X_l)\right] - \frac{N_J}{2}\left[g_u\left(\tau_u^{-1} + \frac{D}{\tau_{su}}\right)(1 - \bar{g}) + \frac{g_u K'' B_{00}}{\tau_{su}} \cdot (1 + D)(1 + \bar{g}) - g_l \frac{K' B_{00} D \exp\left(-\frac{h\nu}{\epsilon_k}\right)}{\tau_{su}}(1 - \bar{g}) - \frac{g_l}{\tau_l}(1 + \bar{g})\right] \tag{18b}$$

where $\bar{g} = (g_u - g_l)/(g_u + g_l) = -1/2(J + 1)$. The Jth level here includes all three multiplet transitions, since they all have the same threshold according to (13). The initial conditions for (18) are obtained from the solutions of (14) at the instant $t_{sat}(z, r)$ when z_{sJ} becomes less than the particular z of interest. The initial value of ΔN_J represents stored energy which we assume is released from each volume in an initial laser pulse of constant width = 1.0 ns, which is estimated from the calculated small-signal gain and the calculations of [30]. The detailed calculations show that the maximum contribution to the peak power because of the energy stored in a particular transition is $\lesssim 5$ percent of the peak laser power. Energy extraction from a volume element ceases when $P_J \lesssim 0$, which corresponds to the onset of absorption; for $P \lesssim 15$ torr, absorption begins typically as $\dot{I}_b$ begins to decrease after the initial rise of I_b.

The laser power per unit length at the position z along the drift tube, dP_L/dz, is given by

$$\frac{dP_L}{dz} = h\nu \int_0^{r_0} 2\pi r dr \sum_J{}' P_J(r, t) \tag{19}$$

where the prime on the summation indicates that at a given r, only those J are summed over for which $P_J > 0$ and which satisfy (11). Fig. 7 shows dP_L/dz at two pressures, in relation to the primary beam current I_b and the net current I_n at the same axial position.

The detailed shape of dP_L/dz depends strongly on both the time variation of j_{pz} and E_z/N_g, and on the upper and lower laser level lifetimes τ_u and τ_l. The peak values of dP_L/dz are similar at the two pressures, but the widths of the pulses differ with the details of E_z and j_{pz}. The structure on the initial dP_L/dz pulse at 20 torr is sensitive to the structure on the measured I_b. At $P \gtrsim 20$ torr the laser is no longer self-terminating, the collisional quenching of the lower laser level[2] resulting in a second dP_L/dz pulse at $t = 45$ ns, and a small nonvanishing dP_L/dz throughout the primary current pulse. The second dP_L/dz pulse, which is not observed experimentally and will be discussed further in the following, results from the increase of E_z/N_g as the net current decreases late in the I_b pulse.

To obtain the laser power P_L emitted from the end of the laser tube, we sum contributions from each axial element dz, phased in time according to the speed of light in vacuum since the gain is saturated above the threshold [31]

$$P_L(z = L, t) = \int_0^L dz' \frac{dP_L}{dz'}\left(z', t - \frac{(L - z')}{c}\right). \tag{20}$$

The peak value, full width at half maximum (FWHM), and the delay of P_L relative to the I_b pulse are compared in Section IV with the measurements of Patterson [7].

IV. Comparison with Experiment

In contrast with the experimental tests of the net current model [5], [6], in the laser experiment it is not possible to measure for the same electron beam pulse both the laser power and the detailed input data required to calculate the laser pulse. Therefore, we have neglected shot-to-shot variations, and compare calculated and measured laser powers under the same nominal conditions of pressure, magnetic field, beam current, etc. The experimental variations in the electron beam input data to the calculation result in some scatter in the theoretically calculated laser powers.

Fig. 8 shows typical laser pulse shapes calculated from the model of Section III for the experimental conditions of [7], assuming a gas temperature $T = 300$ K. At the zero of time the primary electron beam enters the drift chamber through the anode. To obtain the delay before lasing [7], the time required for a light pulse to travel the length of the drift chamber (6.3 ns) must be subtracted from the times of Fig. 8. This yields the calculated delay curve shown in Fig. 9, which has a weak pressure dependence which is opposite to the measured dependence [7]. This difference is not understood at present

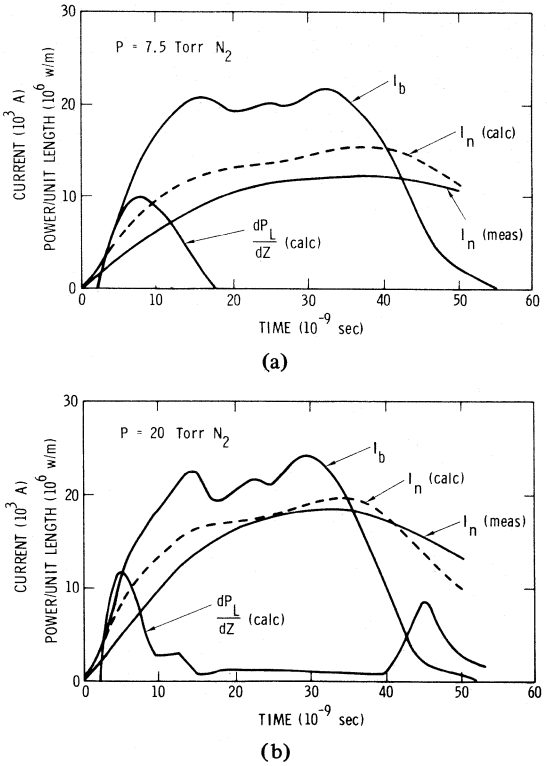

Fig. 7. Time relationship between the measured beam and net currents, and the calculated net current and laser power per unit length, at one axial position. The second pulse of laser power at $t = 45$ ns for 20 torr results from collisional quenching of the lower laser level and an increase of E_z as the net current decays late in the beam pulse.

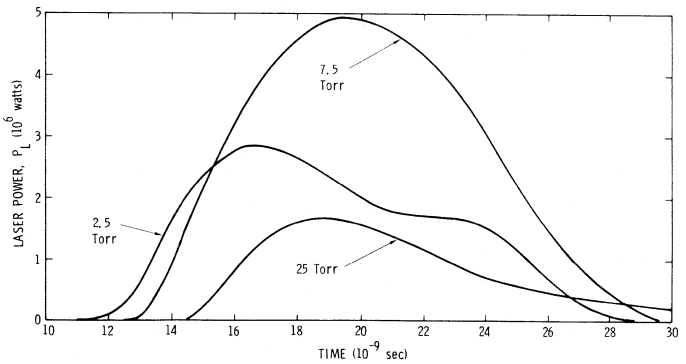

Fig. 8. Calculated laser pulses at end of laser tube, for three representative pressures. The electron beam enters the laser tube (length 2 m) at $t = 0$. $T = 300$ K.

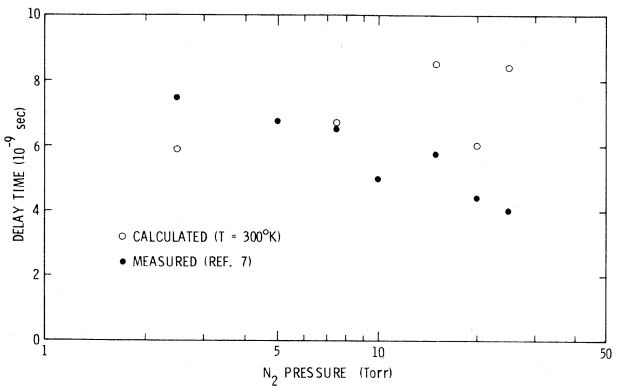

Fig. 9. Pressure dependence of time delay between beginning of laser pulse as seen at end of drift tube, and entrance of beam into laser tube.

but may be associated with the simplified threshold model or the difference between the calculated and measured net current curves in Fig. 7. (It is possible that some plasma is trapped ahead of the primary beam by the longitudinal magnetic field, providing some preionization.) However, the average calculated delay equals the average measured delay within 25 percent. The pulse shapes are similar to the measured shape shown in [7, fig. 2(e)], except that at very high pressures the calculated laser pulse has a longer tail, which probably results from the assumed collisional deactivation of the lower laser level.[2] The weak structure (shown, for example, in the 2.5-torr laser pulse of Fig. 8) is sensitive to the details of the measured I_b time dependence.

Fig. 10 shows the comparison between the calculated peak laser power P_p for $T = 300$ K and 550 K, and the measured peak power [7]. By exciting N_2 gas with a Nereus electron beam and measuring the spectrum of the N_2^+ ion 3914-Å band, a crude measurement of the rotational temperature T was made [38]. Within the experimental error T ranges from 340 to 550 K at $P = 2$ torr, thus providing the choice of temperatures used in the calculation. Most of the experimental points fall between the calculated points for the two temperatures. The pressure at which maximum power occurs agrees with experiment within 30 percent, the magnitude of peak power agrees within 40 percent, and the pressure width agrees within 15 percent. These errors are quite reasonable in view of the experimental errors in several of the input parameters to the calculation. The calculated power does not approach zero as fast as the experiment at high and low pressures, perhaps because of the simple threshold approximation.

Fig. 11 shows the calculated laser pulsewidth τ_L as a function of pressure, compared to the experimentally measured pulsewidth. There is considerable scatter in the calculated pulsewidth, perhaps because the pulse shape is sensitive to the measured primary beam velocity and current waveform. Averaging the calculated and measured pulsewidths between 2.5 and 25 torr shows that the average calculated pulsewidth is ~20 percent higher than the measured average pulsewidth for $T = 300$ K, and ~10 percent higher if $T = 550$ K.

Although these calculations involve no adjustable parameters, they require a large number of experimentally measured

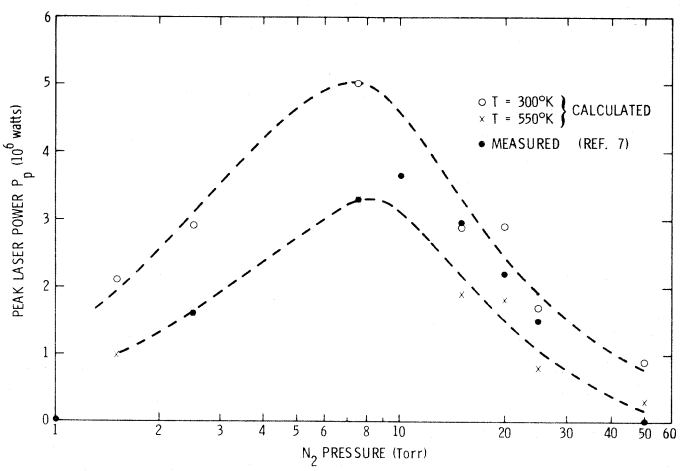

Fig. 10. Pressure dependence of peak laser power. The dashed lines are smooth curves through the calculated points.

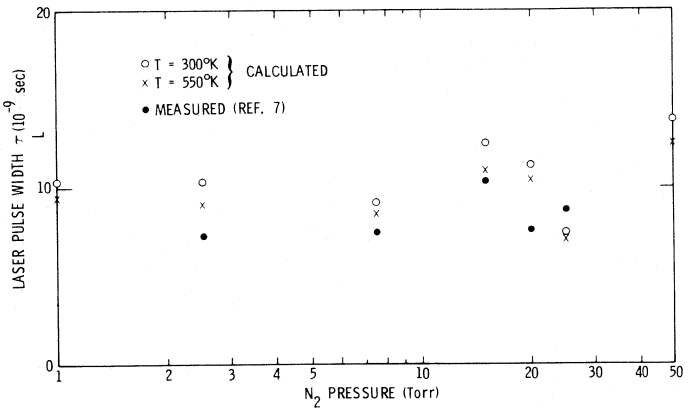

Fig. 11. Pressure dependence of laser pulsewidth (FWHM).

parameters of the laser gas and the electron beam propagation process. It is therefore of interest to know how sensitive the calculation is to each parameter. The sensitivity of the plasma calculation to the gas-discharge parameters of the gas has been discussed in [6]. Table I shows the sensitivity of the calculation to those parameters associated mainly with the laser; Figs. 12 and 13 give the variation of those parameters not characterized by a simple formula. The magnitude of variation in the parameter (Variation Factor in Table I) corresponds to the expected magnitude of experimental uncertainty, except for the parameters r_0, $S(r)$, and I_b, where reasonable but arbitrary variations were used. The "Change Factors" for τ_L and P_p in Table I represent the ratio of the new τ_L or P_p with the varied parameter, to the value of τ_L or P_p in the reference calculation at $P = 15$ torr. From Table I, it can be seen that the laser power is most sensitive to $\langle\sigma_l v\rangle/\langle\sigma_u v\rangle$, r_0, $S(r)$, v_b, and T; it is relatively insensitive to G_0, τ_u^{-1}, and τ_l^{-1}. The experimental uncertainties in $\langle\sigma_l v\rangle/\langle\sigma_u v\rangle$, $S(r)$, v_b, and I_b are clearly large enough to account for the discrepancies remaining between the calculated and measured τ_L and P_p in Figs. 10 and 11.

If we assume $G_0 = 0$ [8], the calculated power at 7.5-torr N_2 is a factor of 2 higher than for the present assumption of $G_0 = 13$. Since Table I also shows that the calculated power varies slowly for $G_0 > 13$, we believe that the error resulting from our simple threshold gain assumption does not greatly affect the magnitude of the calculated power.

The experiments in [4] used a 10-cm-diameter drift tube rather than the 5-cm-diameter tube used in [7]. The maximum laser power obtained from the larger tube was about a factor of 5 higher than for the smaller drift tube, and the peak power occurred at a pressure twice as high as for the smaller tube. No detailed measurements of Λ, v_b, or $S(r)$ were made in [4], so it is difficult to make an accurate calculation of the laser power for this case. The trend of the laser power with increasing r_0 can, however, be obtained roughly by doubling r_0, using the same primary beam parameters as in Figs. 10 and 11. The resulting P_p and τ_L are shown in Figs. 14 and 15. (No point is shown at 1.5 torr for the larger tube since the longitudinal electric field is so large that plasma electron runaway can occur and the model no longer holds [6].) The largest P_p is more than a factor of 2 higher and P_p has not begun to decrease even at 50 torr, while the calculated pulsewidth is only about 8 percent larger. This clearly indicates the trends of a

larger power and a higher pressure at which the peak power occurs, as seen in [4].

In their earlier work on N_2, Dreyfus and Hodgson [2] find good agreement between their measured energy and a calculated laser energy assuming only cascade electron excitation. However, [2] overestimates by a factor of 2.5 the relative contribution of secondary electrons to ionization, compared to the careful measurements of Hirsch *et al.* [39]. They also neglect excitation to the lower laser level, and the fact that at low pressures the laser transition is self-terminating so that only one-half the excess atoms in the upper state can undergo stimulated emission before the gain vanishes. These effects would reduce their calculated energy output by a factor of 0.24. In addition, estimates of their output intensity based on their data range from 15 to 50 kW/cm^2, which is not much greater than the measured 3371-Å saturation intensity of [32] (~30 kW/cm^2); this implies that energy is probably not extracted efficiently from the first ~1 m of the drift tube, decreasing the estimate of output energy by a factor of ~0.5. Including collisional quenching of the upper laser level and the fact that all rotational lines probably do not lase, yields a further factor of ~0.4. Thus a more realistic treatment of the details of the lasing process itself yields for the cascade mechanism alone an output energy $\sim 0.05 \times 10^3$ ergs/cm^2, far below the observed energy.

On the other hand, the estimated E_z/N_g at 20 torr, if this beam fills the drift tube, is $\sim 8 \times 10^{-15}$ V · cm^2, which means that at 20 torr the plasma electrons can multiply by a factor of 10 in ≈ 0.5 ns [6]. This can make a significant plasma contribution to the excitation of $C^3\Pi_u$ light, since the plasma current is so much more efficient at exciting these levels.

V. Conclusions

This represents the first calculation of laser excitation by a relativistic electron beam which includes the effects of the beam-produced electric field on the beam-induced plasma. The plasma properties calculated with the net current model of [6] yield calculated laser powers which agree well with experiment, if the simplifying assumption is made that all laser power is emitted in the forward direction. The calculation is most sensitive to the following laser model parameters: 1) the excitation coefficients to the lower and upper laser levels, as a function of the E_z/N_g at a point in the gas; and 2) those parameters ($S(r)$, I_b, v_b, and r_0) which are most important in determining the plasma electron density and the E_z/N_g in the gas. Incidental results of these calculations are the following.

1) The net current model of [6] can be used to calculate the net current with reasonable accuracy even in the presence of a longitudinal magnetic guide field.

2) The plasma properties produced by the model appear to be accurate near the front of the primary beam pulse, in view of the correct magnitude of the calculated laser power.

In contrast to [2], the calculation neglects excitation by primary electrons and energetic cascade electrons, which are estimated to produce at most a 3-percent effect; in addition, the cascade electron mechanism is unable to explain the variation of laser power with drift tube radius and the rapid decrease of power at high pressures.

The 3371-Å N_2 laser transition is perhaps unusual because the primary electrons themselves cannot directly excite the laser transition. The H_2 laser studied in the later work of Dreyfus and Hodgson [2] represents a case in which the primary electrons *can contribute directly* to excitation of the laser levels. However, the cascade electron model yields less power than is observed (even assuming that all molecules excited to the upper laser level yield laser energy), and is unable to explain in detail the multiple laser pulses and the laser power emitted near the end of the primary beam pulse [2]. Our calculations for N_2 show that excitation by plasma electrons is dominant, and that under some conditions a second laser pulse can appear as the plasma current decays following the primary beam pulse. It is therefore possible that the plasma electrons are making important contributions to the H_2 laser as well. Other lasers may, however, be dominated by primary electron cascade, especially at pressures $\gtrsim 1$ atm where little plasma current flows.

Note Added in Proof: J. W. Dreyer and D. Perner (*Chem. Phys. Lett.*, vol. 16, pp. 169-173, Sept. 15, 1972) have measured the collisional quenching of the lower laser level. Using this lower quenching rate in the calculation decreases τ_L by ~15 percent and P_p by ~30 percent at higher pressures. These trends yield slightly better agreement with experiment for the 300 K temperature assumption (see Figs. 10 and 11).

Acknowledgment

The authors wish to thank E. L. Patterson, who cooperated by making additional measurements to test the model.

Surface-Wave Radiation Loss from Curved Dielectric Slabs and Fibers

EDWARD F. KUESTER, STUDENT MEMBER, IEEE, AND DAVID C. CHANG, MEMBER, IEEE

Abstract—**A newly developed systematic procedure to calculate the real and imaginary parts of the change in propagation constant of a surface-wave mode on a curved open waveguide of general cross section is used here to determine these quantities for the TE modes of an asymmetric slab waveguide and for all the modes of an optical fiber. Comparison of these results with the existing literature points up the care which must be taken in making approximations in this problem, since errors of significant factors in the radiation loss have been made in previous work.**

I. Introduction

With increased interest in optical fibers and integrated optical devices as practical means of communication, one problem which has received considerable interest recently is that of the continuous radiation loss from a section of curved optical waveguiding structure [1]-[7]. Unfortunately, the results obtained by different analyses do not always agree, and the difference is in some cases a very large factor (see [6] and Section III below). In [6] and [7], the authors have developed a general, systematic technique for the calculation of this radiation loss on an arbitrary curved surface-wave structure. In the present paper, this technique is applied to the TE modes of an asymmetric slab waveguide and to all the modes of a curved optical fiber. In the process, it will be seen how the approximations made in some of the existing analyses can lead to serious errors in the expression for the radiation loss.

II. Expression for Radiation Loss on an Arbitrary Waveguide

In [6] and [7], a general method is presented for the determination of the change in the real and imaginary parts of the propagation constant for a surface-wave mode due to uniform curvature, if the fields and propagation constant of the straight waveguide mode are known. We present here only the results of that analysis; the interested reader should consult [6] or [7] for details of the derivation.

We consider the surface waveguide shown in Fig. 1, bent uniformly with radius R in a plane perpendicular to the $\hat{z}$-direction as shown. If we define the normalized propagation constant ν through an implied field dependence of $\exp \cdot (i\omega t - ik_0 \nu R\theta)$, where $k_0 = \omega(\mu_0 \epsilon_0)^{1/2}$ is the free-space wavenumber, then the correction to the real part of the propagation constant ν_0 for a given surface-wave mode of a corresponding straight waveguide is [6], [7]

$$\text{Re}\,[k_0(\nu - \nu_0)] = \Delta/P + O(1/R^2) \tag{1}$$

Manuscript received May 21, 1975; revised July 1, 1975. This research was supported by the Air Force Office of Scientific Research (AFSC) under Grant AFOSR-72-2417.

The authors are with the Electromagnetics Laboratory, Department of Electrical Engineering, University of Colorado, Boulder, Colo. 80302.

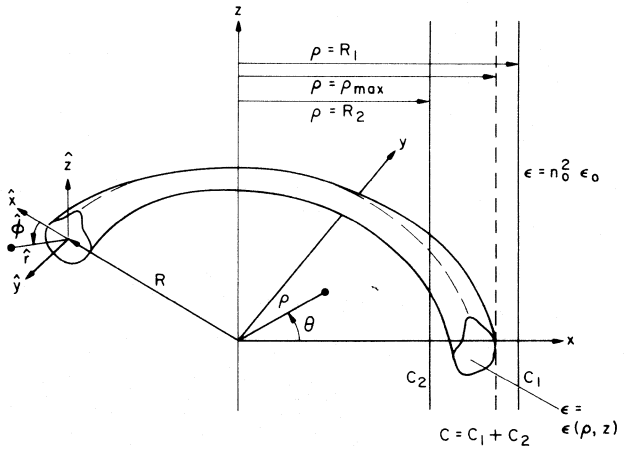

Fig. 1. Section of curved optical waveguide with Cartesian coordinate system (x, y, z), cylindrical system (ρ, θ, z), local Cartesian system $(\hat{x}, \hat{y}, \hat{z})$, and local cylindrical system $(\hat{r}, \hat{\phi}, \hat{y})$.

where

$$\Delta = \frac{1}{R}\int_S \hat{x}\left[2k_0\nu_0(E_{0\hat{z}}H_{0\hat{x}} - E_{0\hat{x}}H_{0\hat{z}}) + i\left(H_{0\hat{y}}\frac{\partial E_{0\hat{z}}}{\partial \hat{x}} - E_{0\hat{z}}\frac{\partial H_{0\hat{y}}}{\partial \hat{x}} + H_{0\hat{z}}\frac{\partial E_{0\hat{y}}}{\partial \hat{x}} - E_{0\hat{y}}\frac{\partial H_{0\hat{z}}}{\partial \hat{x}}\right)\right] dS \tag{2}$$

$$P = 2\int_S \bar{a}_{\hat{y}} \cdot [\bar{E}_0 \times \bar{H}_0]\, dS. \tag{3}$$

Here S is the (infinite) cross section of the straight waveguide, the fields $\bar{E}_0$ and $\bar{H}_0$ are unperturbed fields of the surface-wave mode being considered on the straight waveguide and $(\hat{x}, \hat{y}, \hat{z})$ describe a "local" set of Cartesian coordinates as shown in Fig. 1.

The correction to the imaginary part of ν_0 (which gives the attenuation of the mode due to continuous radiation loss) is given by

$$\text{Im}\,[k_0(\nu - \nu_0)] = -(c/P)\,\{1 + O(1/R)\} \tag{4}$$

where P is given by (3) and

$$c = \frac{2\pi\omega}{k_0^2 n_0^3}\left(\frac{\pi\lambda_0}{k_0 R}\right)^{1/2}[\epsilon_0 n_0^2 \tilde{E}^2(0) + \mu_0 \tilde{H}^2(0)] \cdot \exp(-2\tau). \tag{5}$$

In (5), n_0 is the index of refraction of the medium exterior to the waveguide, $\lambda_0 = (\nu_0^2 - n_0^2)^{1/2}$ is a measure of the field

decay outside the guide

$$\tau = \tau_0 - \frac{R\Delta}{2P} \ln\left(\frac{\nu_0 - \lambda_0}{\nu_0 + \lambda_0}\right) \tag{6a}$$

$$\simeq \tau_0 + \frac{R\Delta}{P}\left[\frac{\lambda_0}{\nu_0} + \frac{1}{3}\frac{\lambda_0^3}{\nu_0^3} + \cdots\right] \tag{6b}$$

$$\tau_0 = -k_0 R\left[\lambda_0 + \frac{\nu_0}{2} \ln\left(\frac{\nu_0 - \lambda_0}{\nu_0 + \lambda_0}\right)\right] \tag{7a}$$

$$\simeq \frac{1}{3} k_0 R \frac{\lambda_0^3}{\nu_0^2} \tag{7b}$$

and finally,

$$\left.\begin{matrix}\tilde{E}(0)\\ \tilde{H}(0)\end{matrix}\right\} = \frac{k_0 n_0}{2\pi} \exp(k_0 \lambda_0 \hat{x}) \int_{-\infty}^{\infty} \left.\begin{matrix}E_{0\hat{z}}(\hat{x}, \hat{z})\\ H_{0\hat{z}}(\hat{x}, \hat{z})\end{matrix}\right\} d\hat{z} \tag{8}$$

represent a kind of averaged amplitude for the $\hat{z}$-components of the field, with $\hat{x}$ chosen at just outside the waveguide at the location corresponding to $\rho = \rho_{\max}$ in Fig. 1. It can be shown that the expression (8) is independent of the choice of $\hat{x}$ following from the fact that $\bar{E}_0$ and $\bar{H}_0$ must satisfy the scalar wave equation outside the guide [6]. It is to be noted from (6) and (7) that the Δ/P correction to τ (which, since it is multiplied by R, is $O(1)$ by (1)-(3)) must be calculated before the c/P correction in (4) may be evaluated. We further note that the expressions in (6b) and (7b) hold for $\lambda_0/\nu_0 \ll 1$, which is typical for optical waveguides, while (6a) and (7a) are applicable to a more general case subject only to the condition on (5) that $(\lambda_0^3 k_0 R) \gg 1$, [6], [7].

III. TE Modes of an Asymmetric Slab Waveguide

The treatment of slab waveguides by this method is simplified somewhat, since the surface integrals in (2) and (3) reduce to line integrals and the expression for c, instead of (5), can be reduced to a field evaluation at a single point, because the slab fields are independent of $\hat{z}$ [6]

$$c = \frac{\lambda_0}{k_0 n_0^2} [\epsilon_0 n_0^2 \tilde{E}_{0\hat{z}}^2 + \mu_0 \tilde{H}_{0\hat{z}}^2] \exp(-2\tau) \tag{9}$$

where τ is given by (6) and (7). The condition for the validity of (9) can also be relaxed to $(\lambda_0 kR) \gg 1$, rather than $(\lambda_0^3 kR) \gg 1$. The expressions for $\tilde{E}_{0\hat{z}}$ and $\tilde{H}_{0\hat{z}}$ are simply given as

$$\left.\begin{matrix}\tilde{E}_{0\hat{z}}\\ \tilde{H}_{0\hat{z}}\end{matrix}\right\} = \left.\begin{matrix}E_{0\hat{z}}\\ H_{0\hat{z}}\end{matrix}\right\} \exp[k_0 \lambda_0 \hat{x}]. \tag{10}$$

We now examine the TE modes of an asymmetric slab waveguide. If we locate $\hat{x} = 0$ at the center of the slab, the fields are given by [8, p. 9]

$$E_{0\hat{z}} = \begin{cases} -A \exp[-k_0\lambda_0(\hat{x} - d/2)], & \hat{x} \geq d/2 \quad \text{(I)} \\ -A\left[\cos K_0(\hat{x} - d/2) - \dfrac{k_0\lambda_0}{K_0} \sin K_0(\hat{x} - d/2)\right], & -d/2 \leq x \leq d/2 \quad \text{(II)} \\ -A\left[\cos K_0 d + \dfrac{k_0\lambda_0}{K_0} \sin K_0 d\right] \exp[\gamma_0(\hat{x} + d/2)], & \hat{x} \leq -d/2 \quad \text{(III)} \end{cases}$$

with

$$H_{0\hat{y}} = \frac{1}{i\omega\mu_0} \frac{\partial E_{0\hat{z}}}{\partial \hat{x}} \qquad H_{0\hat{x}} = \frac{k_0 \nu_0}{\omega\mu_0} E_{0\hat{z}}$$

and all other field components vanishing. Here

$$K_0 = k_0(n_1^2 - \nu_0^2)^{1/2}$$

$$\gamma_0 = k_0(\nu_0^2 - n_2^2)^{1/2}$$

$$\lambda_0 = (\nu_0^2 - n_0^2)^{1/2}$$

where n_0, n_1, and n_2 are the indices of refraction in regions I, II, and III, respectively. The parameters γ^{-1} and $(k_0\lambda_0)^{-1}$ therefore have the physical meaning of penetration depths of a specific mode into the two exterior regions of the waveguide. Continuity of $H_{0\hat{y}}$ results in the eigenvalue equation

$$k_0\lambda_0(K_0 \cos K_0 d + \gamma_0 \sin K_0 d) = K_0(K_0 \sin K_0 d - \gamma_0 \cos K_0 d).$$

The P-integral is calculated in [8, p. 14]

$$P = \frac{A^2 k_0 \nu_0 L_e (n_1^2 - n_0^2)}{\omega\mu_0(n_1^2 - \nu_0^2)}, \qquad L_e = d + \frac{1}{\gamma_0} + \frac{1}{k_0\lambda_0}.$$

From (2), Δ can be expressed as

$$\Delta = \frac{1}{R}\left\{\frac{1}{\omega\mu_0} \int_{-\infty}^{\infty} \hat{x}\left[k_0^2(\nu_0^2 + n^2) E_{0\hat{z}}^2 + \left(\frac{\partial E_{0\hat{z}}}{\partial \hat{x}}\right)^2\right] d\hat{x}\right\}.$$

After considerable algebra, this can be shown to be

$$\Delta = \frac{k_0^2 \nu_0^2 A^2 (n_1^2 - n_0^2) L_e}{2\omega\mu_0 R(n_1^2 - \nu_0^2)}\left[\frac{1}{k_0\lambda_0} - \frac{1}{\gamma_0}\right].$$

Thus the real part Δ/P of the correction to $k_0\nu_0$ from (1) is simply

$$\frac{\Delta}{P} = \frac{k_0\nu_0}{2R}\left(\frac{1}{k_0\lambda_0} - \frac{1}{\gamma_0}\right). \tag{11}$$

As expected, this correction is zero in the symmetric case ($k_0\lambda_0 = \gamma_0$). Equation (11) is identical to the phase correction found by Chang and Barnes [3] for the asymmetric slab.

The quantity c can be found from (9) as

$$c = \frac{A^2}{\omega\mu_0} k_0\lambda_0 \exp(k_0\lambda_0 d) \exp(-2\tau)$$

where τ is given by (6) and (7). From (11), then, the attenuative correction becomes, for $\lambda_0/\nu_0 \ll 1$,

$$-i\frac{c}{P} = -i\frac{\lambda_0(n_1^2 - \nu_0^2)}{\nu_0 L_e(n_1^2 - n_0^2)} \exp\left[-\frac{2}{3} k_0 R \frac{\lambda_0^3}{\nu_0^2} - k_0\lambda_0\left(\frac{1}{k_0\lambda_0} - \frac{1}{\gamma_0}\right) + k_0\lambda_0 d\right]. \tag{12}$$

Once again, this is in agreement with [3], if the reference point $\hat{x} = 0$ is changed and the errors in [3, eq. (26)] are noted.[1] However, (12) differs from the result obtained by Marcuse in [2] by a factor of $\exp(-[1 - k_0\lambda_0/\gamma_0])$. As noted in [3], the extra term in the exponent resulting from the asymmetry, which does not appear in [2], can be quite significant in the case when the penetration depths γ_0^{-1} and $(k_0\lambda_0)^{-1}$ on the two sides of the slab are very different.

IV. Modes of the Step-Index Optical Fiber

We consider here the "simplified" modes of the step-index optical fiber with $n = n_0$ for $\hat{r} > a$ and $n = n_1$ for $\hat{r} < a$, as discussed by Marcuse [8]. These simplified modes assume that $(n_1 - n_0)/n_0 \ll 1$, and what is more, assume convenient forms quite naturally in the Cartesian coordinate system [8, pp. 62-77]. There exist two orthogonally polarized mode types in this approximation. One is polarized with the electric field in the $\hat{z}$ direction

$$E_{0\hat{z}} = -AJ_m(\kappa\hat{r})\cos(m\hat{\phi} - \phi_0), \qquad \hat{r} < a$$
$$= -AQ_m(\nu_0)K_m(k_0\lambda_0\hat{r})\cos(m\hat{\phi} - \phi_0), \qquad \hat{r} > a$$

$$H_{0\hat{x}} = -\frac{\nu_0 A}{\zeta_0} J_m(\kappa\hat{r})\cos(m\hat{\phi} - \phi_0), \qquad \hat{r} < a$$
$$= -\frac{\nu_0 A}{\zeta_0} Q_m(\nu_0)K_m(k_0\lambda_0\hat{r})\cos(m\hat{\phi} - \phi_0), \qquad \hat{r} > a$$

$$E_{0\hat{y}} = \frac{iA\kappa}{2k_0\nu_0}[J_{m+1}(\kappa\hat{r})\sin((m+1)\hat{\phi} - \phi_0) + J_{m-1}(\kappa\hat{r})\sin((m-1)\hat{\phi} - \phi_0)], \qquad \hat{r} < a$$
$$= \frac{iA\lambda_0}{2\nu_0} Q_m(\nu_0)[K_{m+1}(k_0\lambda_0\hat{r})\cdot\sin((m+1)\hat{\phi} - \phi_0) - K_{m-1}(k_0\lambda_0\hat{r})\cdot\sin((m-1)\hat{\phi} - \phi_0)], \qquad \hat{r} > a$$

$$H_{0\hat{y}} = \frac{iA\kappa}{2\omega\mu_0}[J_{m+1}(\kappa\hat{r})\cos((m+1)\hat{\phi} - \phi_0) - J_{m-1}(\kappa\hat{r})\cos((m-1)\hat{\phi} - \phi_0)], \qquad \hat{r} < a$$
$$= -\frac{iA\lambda_0}{2\zeta_0} Q_m(\nu_0)[K_{m+1}(k_0\lambda_0\hat{r})\cdot\cos((m+1)\hat{\phi} - \phi_0) + K_{m-1}(k_0\lambda_0\hat{r})\cdot\cos((m-1)\hat{\phi} - \phi_0)], \qquad \hat{r} > a.$$

Here

$$Q_m(\nu_0) = J_m(\kappa a)/K_m(k_0\lambda_0 a)$$
$$\zeta_0 = [\mu_0/\epsilon_0]^{1/2}$$
$$\kappa = k_0(n_1^2 - \nu_0^2)^{1/2}$$

and ϕ_0 is an angle defining the orientation of the field maxima. The other mode type is polarized with the electric field in the $\hat{x}$ direction

$$E_{0\hat{x}} = AJ_m(\kappa\hat{r})\cos(m\hat{\phi} - \phi_1), \qquad \hat{r} < a$$
$$= AQ_m(\nu_0)K_m(k_0\lambda_0\hat{r})\cos(m\hat{\phi} - \phi_1), \qquad \hat{r} > a$$

$$H_{0\hat{z}} = \frac{\nu_0 A}{\zeta_0} J_m(\kappa\hat{r})\cos(m\hat{\phi} - \phi_1), \qquad \hat{r} < a$$
$$= -\frac{\nu_0 A}{\zeta_0} Q_m(\nu_0)K_m(k_0\lambda_0\hat{r})\cos(m\hat{\phi} - \phi_1), \qquad \hat{r} > a$$

$$E_{0\hat{y}} = \frac{iA\kappa}{2k_0\nu_0}[J_{m+1}(\kappa\hat{r})\cos((m+1)\hat{\phi} - \phi_1) - J_{m-1}(\kappa\hat{r})\cos((m-1)\hat{\phi} - \phi_1)], \qquad \hat{r} < a$$
$$= \frac{iA\lambda_0}{2\nu_0} Q_m(\nu_0)[K_{m+1}(k_0\lambda_0\hat{r})\cdot\cos((m+1)\hat{\phi} - \phi_1) + K_{m-1}(k_0\lambda_0\hat{r})\cdot\cos((m-1)\hat{\phi} - \phi_1)], \qquad \hat{r} > a$$

$$H_{0\hat{y}} = \frac{iA\kappa}{2\omega\mu_0}[J_{m+1}(\kappa\hat{r})\sin((m+1)\hat{\phi} - \phi_1) + J_{m-1}(\kappa\hat{r})\sin((m-1)\hat{\phi} - \phi_1)], \qquad \hat{r} < a$$
$$= \frac{iA\lambda_0}{\zeta_0} Q_m(\nu_0)[K_{m+1}(k_0\lambda_0\hat{r})\cdot\cos((m+1)\hat{\phi} - \phi_1) - K_{m-1}(k_0\lambda_0\hat{r})\cdot\cos((m-1)\hat{\phi} - \phi_1)], \qquad \hat{r} > a$$

where ϕ_1 is another orientation angle. For either mode type the eigenvalue equation can be given in two equivalent forms [8, p. 68]

$$\kappa J_{m+1}(\kappa a)/J_m(\kappa a) = k_0\lambda_0 K_{m+1}(k_0\lambda_0 a)/K_m(k_0\lambda_0 a)$$
$$\kappa J_{m-1}(\kappa a)/J_m(\kappa a) = -k_0\lambda_0 K_{m-1}(k_0\lambda_0 a)/K_m(k_0\lambda_0 a)$$

and the P-integral (3) is also known [8, p. 70]

$$P = e_m \frac{A^2}{\zeta_0\lambda_0^2}\pi a^2\nu_0(n_1^2 - n_0^2)\,|J_{m-1}(\kappa a)\,J_{m+1}(\kappa a)| \qquad (13)$$

where $e_m = 1$ for $m \neq 0$, and $e_0 = 2\cos^2\phi_{0,1}$. Note that a lowest order mode of the $m = 0$ class corresponds to the dominant HE_{11} mode. Arbitrarily polarized modes may be constructed by multiplying an $\hat{x}$-mode by $\cos\phi_2$ and adding it to the corresponding $\hat{z}$-mode multiplied by $-\sin\phi_2$, where ϕ_2 is the angle of polarization. Such a mode will have the same P value as the $\hat{x}$ or $\hat{z}$ modes separately, except for the case $m = 0$, where we must take $e_0 = 2[\cos^2\phi_0\sin^2\phi_2 + \cos^2\phi_1\cos^2\phi_2]$.

Since m is an integer, it may be readily seen by examining (2) that Δ must vanish by reason of the angular dependences of the various field components. Thus we may immediately go about calculating the attenuation. We shall need the spectrum function for $K_m(k_0\lambda_0\hat{r})\exp(\pm im\phi)$ in order to calculate $\tilde{E}(0)$ and $\tilde{H}(0)$. We may start from an integral representation for K_m [9]

$$K_m(k_0\lambda_0\hat{r}) = \tfrac{1}{2}\int_{-\infty}^{\infty}\exp(-k_0\lambda_0\hat{r}\cosh t - mt)\,dt.$$

[1] Some typographical mistakes are seen in their expression; specifically the exponential term in (26) should be $\exp(-k\lambda_0\delta)$ instead of $\exp(-2k\nu_0\lambda_0\delta/3)$.

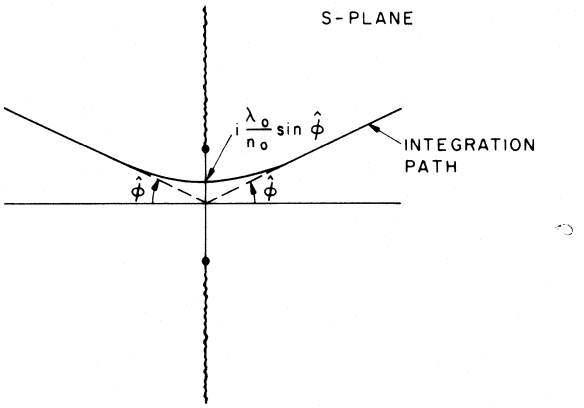

Fig. 2. Integration path in s plane for $K_m(k_0\lambda_0\hat{r})$. Branch points occur at $s = \pm i\lambda_0/n_0$.

Letting $t = \Psi - i\hat{\phi}$, $\hat{x} = \hat{r}\cos\hat{\phi}$, and $\hat{z} = -\hat{r}\sin\hat{\phi}$

$$K_m(k_0\lambda_0\hat{r}) = \tfrac{1}{2}\int_{-\infty+i\hat{\phi}}^{\infty+i\hat{\phi}} \exp\left[-k_0\lambda_0(\hat{x}\cosh\Psi + i\hat{z}\sinh\Psi) - m\Psi + im\hat{\phi}\right] d\Psi .$$

Further changing variables to $n_0 s = \lambda_0 \sinh\Psi$, so that $\lambda_s = \lambda_0\cosh\Psi$ and $n_0 ds = \lambda_s d\Psi$, where $\lambda_s = (\nu_0^2 - n_0^2)^{1/2}$ and $k = k_0 n_0$ gives

$$K_m(k_0\lambda_0\hat{r}) = \tfrac{1}{2}\int_{-\infty\exp(-i\hat{\phi})}^{\infty\exp(i\hat{\phi})} \left[\exp\left(-k_0\lambda_s\hat{x} - iks\hat{z} - m\,\mathrm{arcsinh}\,(n_0 s/\lambda_0) + im\phi\right)\right]\left(\frac{n_0 ds}{\lambda_s}\right).$$

We choose the branch cuts in the s plane from the branch points at $\lambda_s = 0$ to go along the positive and negative imaginary axes as shown in Fig. 2. The present integration path may be deformed back to the real axis because we are interested only in angles $|\hat{\phi}| < \pi/2$. Thus

$$K_m(k_0\lambda_0\hat{r}) = \int_{-\infty}^{\infty} \exp\left(-k_0\lambda_s\hat{x} - iks\hat{z} + im\hat{\phi}\right)\cdot\left(\frac{n_0}{2\lambda_s}\right)\left(\frac{\lambda_0}{n_0 s + \lambda_s}\right)^m ds.$$

Removing $\exp(im\hat{\phi})$ to the left side of this equation, we recognize that the right side is now an inverse Fourier transform, which we may invert again to give (using similar reasoning if m is replaced by $-m$)

$$\frac{k_0 n_0}{2\pi}\int_{-\infty}^{\infty} K_m(k_0\lambda_0\hat{r})\exp(\pm im\hat{\phi})\exp(iks\hat{z})\,d\hat{z} = \frac{n_0}{2\lambda_s}\left(\frac{n_0 s + \lambda_s}{\lambda_0}\right)^{\pm m}\exp(-k_0\lambda_s\hat{x}) \tag{14}$$

so that $\tilde{E}(0)$ and $\tilde{H}(0)$ may be obtained for the arbitrarily polarized mode of the previous paragraph by setting $s = 0$ in (14) and using the appropriate combinations of $\exp(\pm im\hat{\phi})$

$$\tilde{E}(0) = AQ_m(\nu_0)\frac{n_0}{2\lambda_0}\sin\phi_2\cos\phi_0$$

$$\tilde{H}(0) = -\frac{\nu_0}{\zeta_0}AQ_m(\nu_0)\frac{n_0}{2\lambda_0}\cos\phi_2\cos\phi_1 .$$

As a result, from (5), and since no correction from (6) need be made, we have

$$c = \frac{A^2}{\omega\mu_0}\left(\frac{\pi\lambda_0}{k_0 R}\right)^{1/2} Q_m^2(\nu_0)\frac{\pi}{2n_0\lambda_0^2}\left[n_0^2\sin^2\phi_2\cos^2\phi_0 + \nu_0^2\cos^2\phi_2\cos^2\phi_1\right]\exp(-2\tau_0) \tag{15}$$

where, as always,

$$\tau_0 \simeq \tfrac{1}{3}k_0 R\lambda_0^3/\nu_0^2$$

and the expression for $Q_m(\nu_0)$, as mentioned earlier, equals

$$Q_m(\nu_0) = J_m(\kappa a)/K_m(k_0\lambda_0 a), \qquad \kappa = k_0(n_1^2 - \nu_0^2)^{1/2}.$$

For the case $m = 0$, since $n_0 \simeq \nu_0$, we have that the attenuation is essentially independent of polarization and mode orientation, and is given by (making use of the eigenvalue equation)

$$-\frac{ic}{P} = -ik_0\left(\frac{\pi}{k_0 R}\right)^{1/2}\exp(-2\tau_0)\cdot\frac{(n_1^2 - \nu_0^2)\,n_0}{4\nu_0 k_0^2 a^2(n_1^2 - n_0^2)\lambda_0^{3/2}K_1^2(k_0\lambda_0 a)}f(\phi_0,\phi_1,\phi_2) \tag{16}$$

where

$$f(\phi_0,\phi_1,\phi_2) = 1 + \frac{\lambda_0^2}{n_0^2}\cdot\frac{\cos^2\phi_2\cos^2\phi_1}{\sin^2\phi_2\cos^2\phi_0 + \cos^2\phi_2\cos^2\phi_1} \simeq 1$$

since $\lambda_0/n_0 \ll 1$. This is exactly Lewin's result for the HE_{11} mode [4].[2] For the mode very far from cutoff, $k_0\lambda_0 a \gg 1$ and $\kappa a \simeq p_{0,1}$, i.e., the first zero of J_0. In this case we have

$$-i\frac{c}{P} \simeq -\frac{i}{2}k_0\left(\frac{1}{\pi k_0 R}\right)^{1/2}\exp(-2\tau_0 + 2k_0\lambda_0 a)\cdot\frac{p_{0,1}^2\,n_0}{n_1 k_0^3 a^3\lambda_0^{5/2}}.$$

[2] An error of a factor of 2 appeared in Lewin's original paper [4], which has subsequently been corrected.

This result differs from that of Arnaud [5] in two significant ways: 1) the additional $2k_0\lambda_0 a$ term in the exponent; and 2) the presence of R instead of $R + a/\lambda_0^2$ under the square-root sign. These differences are accounted for in the conclusion.

For $m \neq 0$, a similar procedure gives

$$-i\frac{c}{P} = -ik_0\left(\frac{\pi}{k_0 R}\right)^{1/2} \exp(-2\tau_0)\, \frac{(n_1^2 - \nu_0^2)\, n_0\, g(\phi_0, \phi_1, \phi_2)}{2\nu_0 k_0^2 a^2 (n_1^2 - n_0^2)\, \lambda_0^{3/2}\, |K_{m+1}(k_0\lambda_0 a)\, K_{m-1}(k_0\lambda_0 a)|} \tag{17}$$

where

$$g(\phi_0, \phi_1, \phi_2) = \sin^2\phi_2 \cos^2\phi_0 + \frac{\nu_0^2}{n_0^2}\cos^2\phi_2 \cos^2\phi_1. \tag{18}$$

This result seems to indicate that, unlike the $m = 0$ modes, these modes have both polarization and orientation-dependent losses. However, [10], we may recover the approximate $EH_{m-1,n}$ (respectively, $HE_{m+1,n}$) modes by setting $\phi_1 = \phi_0 + \pi/2$ or $\phi_1 = \phi_0 + 3\pi/2$ and $\phi_2 = \pi/4$ or $5\pi/4$ (respectively, $\phi_2 = 3\pi/4, 7\pi/4$); so that for these cases

$$g(\phi_0, \phi_1, \phi_2) = \frac{1}{2}\left[1 + \frac{\lambda_0^2}{n_0^2}\sin^2\phi_0\right] \simeq \frac{1}{2}$$

and again this result agrees with that obtained by Lewin [4]. The TE_n and TM_n modes are included as a special case of the $EH_{m-1,n}$ modes for $m = 1$. Note that all exact modes of the fiber have loss which is essentially independent of the polarization and orientation,[3] but that approximate composite $m \geq 1$ modes can be constructed using (18) to minimize the radiation (e.g., $\phi_0 = \phi_1 = \pi/2$).

V. Conclusion

The results (11) and (12) for the TE modes of the asymmetric slab are both dependent on the term $[(k_0\lambda_0)^{-1} - \gamma_0^{-1}]$, which is a measure of the asymmetry of the guide, and may in fact be an extremely sensitive function of the guide parameters [3]. These results agree with those of [3] obtained by directly perturbing the eigenvalue equation. The result of Marcuse [2] omits the asymmetry term in the attenuation constant, and the possibility of a factor of 2 or 3 difference between the two results indicates the importance of retaining the first-order correction in (6). In addition, we note that the choice of the location of $\hat{x} = 0$ (i.e., the definition of R) relative to the slab will have an effect on the phase constant which amounts to a referral of the phase velocity to the location $\hat{x} = 0$. However, the only change in the attenuation constant is a change in R (occurring in τ_0) by the appropriate amount, so that it is clear that the $k_0\lambda_0 d$ term appearing in the exponent is not removable by a redefinition of R.

The results of Section IV agree with Lewin's analysis [4] as previously noted. The apparent discrepancies with Arnaud's [5] result, in which a limiting case is treated, can be seen [12] to be a result of a referral of the propagation constant to the outer boundary, ratner than to the center of the fiber, as has been done here. This accounts for the factor $\exp(2k_0\lambda_0 a)$ discussed in Section IV, while the remaining discrepancy can be explained by Arnaud's use of an approximate spectrum function instead of the exact one obtained in Section IV. From the restrictions given in Section II on (5), this difference must be negligible so that the present result agrees with the case treated in [5].

Finally, it will be noted that (5) predicts a dependence of $R^{-1/2}$ for the attenuation of any finite cross-section guide. As pointed out in [6], field approximations which are not somehow averaged [as, e.g., in (8)] do not generally give satisfactory results, and in particular Marcatili's analysis of the rectangular cross-section guide [1] is in error by at least this term (in fact, to his approximations, the bending loss behaves as if the guide were a slab).

[3] This is a consequence of the fact (shown by Arnaud [11]) that the formulas obtained for the "simplified" modes of the fiber follow from the scalar Helmholtz equation.

Acknowledgment

The authors wish to thank Prof. L. Lewin for the idea of the spectral-function treatment of the waveguide fields which forms the basis of this approach and for many fruitful discussions. They also wish to thank Prof. S. Maley for his helpful comments and discussions, and Dr. J. A. Arnaud for his kind criticisms and comments.

Behavior of First- and Second-Positive Emission in the N_2/SF_6 Laser

STEVEN N. SUCHARD, DAVID G. SUTTON, AND R. F. HEIDNER, III

Abstract—**Experimental results for the behavior of the emission of the discharge-excited first- and second-positive bands of N_2 and flow-tube measurements for the deactivation of the $A^3\Sigma_u^+$ and $B^3\Pi_g$ levels of N_2 by SF_6 are presented. The results of both these experiments are used to explain the operating mechanisms of the N_2/SF_6 laser.**

I. Introduction

SUPERFLUORESCENT laser emission on the second-positive band of the nitrogen molecule $C^3\Pi_u$-$B^3\Pi_g$ was first reported in 1964 [1]. Since that time, many novel attempts have been made to increase both the maximum energy that can be extracted as laser emission and the overall electrical efficiency with which the laser can be operated [2]-[9]. To date, the maximum energy that has been extracted from an N_2 laser is on the order of 20 mJ from a discharge-initiated system [7] and 250 mJ from an electron-beam-initiated Ar/N_2 laser [10]. More energy has been extracted from the electron-beam-initiated N_2 laser; however, because of the inefficient coupling of the initiation source to the active volume by electron-beam initiation, the "wall-plug" electrical efficiency of the electron-beam-initiated device is several orders of magnitude smaller than the discharge device, which has an efficiency ≈ 0.1 percent.

The principal difficulty encountered in the investigation of N_2 lasers is the exceedingly small ratio of the radiative lifetime of the upper laser level $C^3\Pi_u$ to that of the lower laser level $B^3\Pi_g$, i.e., $\tau_C/\tau_B \approx 4 \times 10^{-3}$. Because of this small ratio, it is imperative that the time in which the laser inversion is produced be short with respect to the radiative lifetime of the upper state. If this pumping criterion is not met, the inversion will be destroyed by spontaneous decay of the upper state and laser threshold cannot be attained.

Recently, several of the authors reported quasi-continuous-wave (CW) laser action on the second-positive band of the nitrogen molecule by TEA discharges in a mixture of N_2/SF_6 [6], [9]. They also reported that laser emission was extremely sensitive to the alignment of the optical cavity formed about the discharge tube in contradistinction to "normal" superfluorescent N_2 laser emission. At that time, it was hypothesized that the operating mechanism for this laser could be explained solely by deactivation of the lower laser level $B^3\Pi_g$ by the SF_6 molecule. Laser and fluorescence measurements performed in this laboratory and interpretations of the results of others [7], [8] are reported in order to explain the kinetic mechanisms inherent to the N_2/SF_6 system.

II. Experimental

The experiments performed for this study fall into three distinct but interrelated categories. In the first type of experiment, the fluorescent and superfluorescent emission from both the first-positive $B^3\Pi_g$-$A^3\Sigma_u^+$ and second-positive bands of N_2 were measured as a function of the total system pressure and the N_2/SF_6 ratio. In the second type, the temporally and spectrally resolved laser emission from N_2/SF_6 mixtures were measured. In the third, measurements were performed to investigate the electronic and vibrational deactivation of the $A^3\Sigma_u^+$ and $B^3\Pi_g$ states of N_2 by SF_6 in a flowing afterglow apparatus similar to the one described by Meyer *et al.* [11].

A. Fluorescence, Superfluorescence, and Laser Measurements

The discharge apparatus employed for the fluorescence, superfluorescence, and laser experiments has been described briefly elsewhere [12]. The discharge tube consists of a 3-m Lucite pipe fitted with a double helix of 470-Ω resistors. Each helix consists of 502 resistors with one wire lead penetrating the 1-in-ID tube at equally spaced intervals. The other lead is tied to a common bus line. One helix is connected through the bus bar to ground, and the other helix forms the anode of a pulsed power supply consisting of a 0.014-μF capacitor bank triggered at 1 Hz by a spark gap (EG & G GP-14B). The capacitor is connected to a dc power supply (Universal Voltronics BAL 130-5.5) capable of delivering 130 kV. This configuration results in 502 pin-pair electrodes being opposed across a $\frac{3}{4}$-in gap. Actually, the tube is formed from two equal sections connected in the middle, where provision is made for evacuation by a mechanical pump. The ends of the tube are sealed by CaF_2 windows at Brewster's angle. The gas mixture from a metered manifold flows into the tube from both ends (Fig. 1).

For the fluorescence and superfluorescence measurements, the detection apparatus consisted of an optical multichannel analyzer with a calibrated wavelength dispersive element placed between the emission source and the detection section [Tektronix 7J20 rapid scan spectrometer (RSS)]. The spectral range of this instrument is from 2500 to 11 000 Å, which permits observation of both the first- and second-positive bands of N_2. Analog output from the RSS was stored and displayed on a storage oscilloscope (Tektronix 7704A), and photographs of the display were taken as a permanent record. In order to determine the linearity of the wavelength dispersive element, the RSS was calibrated by means of known

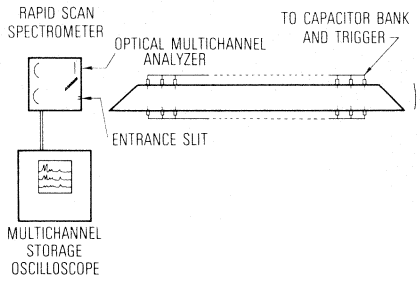

Fig. 1. Discharge apparatus used for fluorescence and laser experiments.

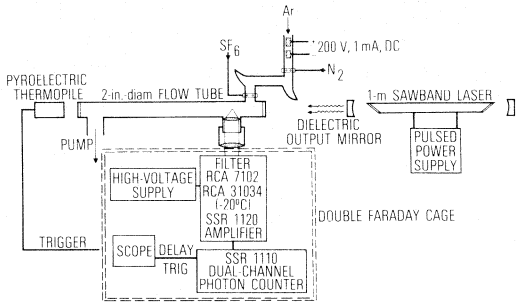

Fig. 2. Fast-flow apparatus including hollow cathode lamp for generating Ar metastables and apparatus for pumping and detection of first-positive laser-induced fluorescence.

spectral lines from a Hg pen-ray lamp and a F(I) laser [13]. For measurements of the second-positive bands, the wavelength region $3000 \leqslant \lambda \leqslant 5000$ Å was monitored, and for the first-positive bands, the region $7000 \leqslant \lambda \leqslant 11\,000$ Å. Measurements were made of both band systems under both single- and double-pass conditions. For the double-pass measurements, an Al-coated mirror aligned along the optical axis of the discharge tube was placed on the end of the discharge tube opposite the detection system.

In order to perform the laser measurements, an optical cavity was formed about the discharge tube by an internal-cavity totally reflecting concave mirror of focal length 450 in and an external-cavity totally reflecting flat mirror with a 1-mm-diam coupling hole. Both mirrors were Au coated for laser measurements in the infrared (IR) and were replaced by identical Al-coated mirrors for the study of the second-positive laser. These mirrors were spaced 6 in from the end windows, which yielded a 3.2-m-long laser cavity. Output from the laser entered a screen room and was split into two beams by a NaCl flat at 45° to the beam. The reflected beam from the flat was monitored with an InSb photovoltaic detector operated at 77 K (Barnes Engineering). The transmitted portion of the laser beam was directed to a $\frac{1}{2}$-m monochromator (McKee-Pederson) equipped with an IR grating blazed at 10 μm. Output from the monochromator was focused onto an identical InSb detector or a Ge:Au detector (Raytheon) by an Au-coated 8-in-radius of curvature mirror. Measured detector response was monitored by an oscilloscope (Tektronix 7704) to be less than 100 ns. Ultraviolet (UV) emission was monitored with a photodiode (RCA 1P28) at the exit slit of the monochromator. Energy measurements were made with a pyroelectric joulemeter (Molectron J3-05).

B. Fast-Flow System for Laser-Induced Fluorescence Measurement of $N_2(B^3\Pi_g, v)$ Kinetics

The fast-flow system geometry (Fig.2) closely resembles the apparatus used by Meyer *et al.* [11] in the $N_2(A^3\Sigma_u^+)$ kinetics study. $N_2(A)$, primarily in $v = 0, 1$, is prepared by collisions of N_2 with Ar metastable atoms. The $N_2(A)$ molecules are rapidly pumped from the upstream mixing region into a 2-in-diam flow tube. Pressure and mass-flow measurements, as well as gas-purification techniques have been previously described [14]. $N_2(A)$ concentrations of $\sim 5 \times 10^9$ molecules/cm^3 can be prepared in this manner.

A small fraction (~1 percent) of the molecules are pumped to the $B^3\Pi_g$ state by selected first-positive band laser excitation; the (0, 0) band at 1.05 μm and the (1, 0) band at 8912 Å were used in this study. The width of the pumping pulse was small (~80 ns) with respect to the time during which $B \rightarrow A$ fluorescence was monitored (3-80 μs). No cascading processes occurred since only a single vibrational state of $B^3\Pi_g$ was pumped.

The laser-introduced $B \rightarrow A$ fluorescence was detected with a cooled S1 photomultiplier (RCA 7102; -20C) in conjunction with an SSR 1100 dual-channel photon counter. This instrument was used as a photon-counting box-car integrator and has a 1-μs minimum gate width. One channel measured the fluorescence signal as a function of time following the laser pulse. The reference channel was opened 100 μs after the signal channel in order to count dark pulses, scattered light, and any small $B \rightarrow A$ signal that might occur as a result of the very fast energy pooling between two $N_2(A)$ molecules [15]. Although this latter rate is $\sim 1 \times 10^{-9}$ cm^3/molecule^2 · s, this term can amount to only 5 photons/cm^3 · s emitted in all $B \rightarrow A$ bands. By comparison, the detected fluorescence signal is 2×10^6 photons/s.

III. Results

A. Discharge Fluorescence Measurements

Nitrogen first- and second-positive band fluorescent and superfluorescent emission was monitored as a function of both the N_2/SF_6 ratio and the total system pressure. Specifically, with a fixed N_2 pressure, the emission intensity and shape of all the bands of a given system were monitored as a function of the added SF_6. The N_2 pressure was then changed, and the measurements repeated as a function of added SF_6. The dynamic range of the RSS was such that the peak intensities of all the bands monitored could be measured directly.

1) First-Positive Bands: Measurements on the first-positive band system were performed on the (0, 0), (1, 0), (2, 1), (2, 0), (3, 1), and (4, 2) bands. Other bands could have been used for these measurements; however, the ones chosen allowed the extraction of relative changes in population information from $v = 0$-4 of the $B^3\Pi_g$ state. Typical data for these bands are given in Fig. 3. These experiments were performed with a N_2 pressure of 50 torr and a discharge voltage of 100 kV under double-pass conditions. Because the sensitivity of the Si vidicon in the RSS drops off rapidly beyond 1.0 μm, the (0, 0) band was only observable under double-pass

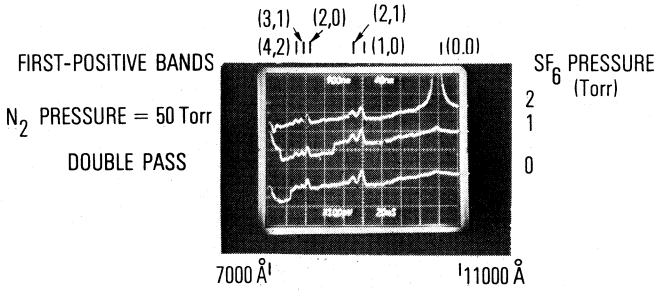

Fig. 3. Fluorescence data from the first-positive bands as a function of added SF_6. (N_2 pressure = 50 torr, discharge voltage = 100 kV, double-pass conditions.)

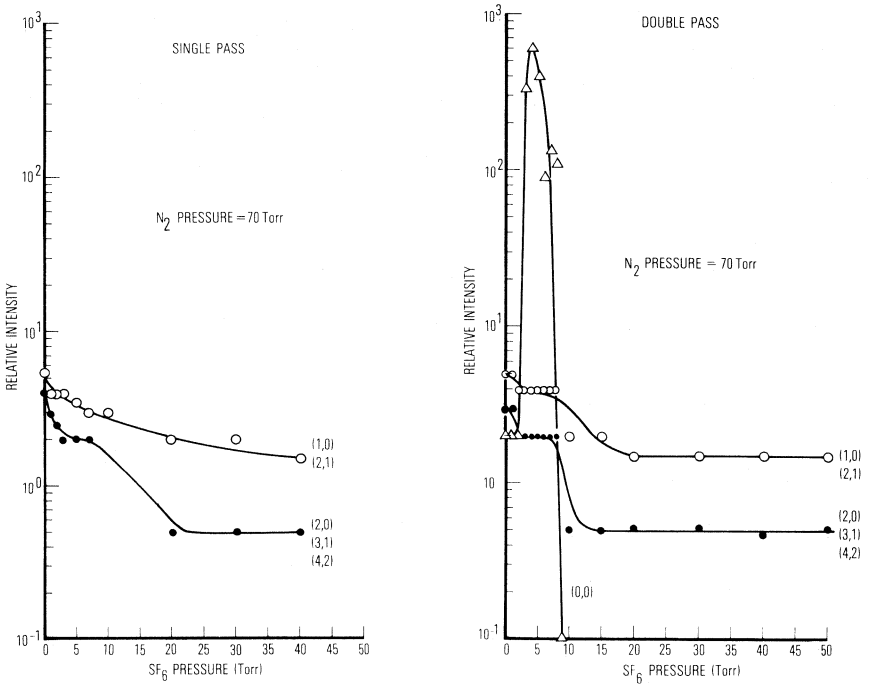

Fig. 4. Relative first-positive fluorescence intensity as a function of added SF_6. (a) Single-pass conditions. (b) Double-pass conditions. (N_2 pressure = 70 torr, discharge voltage = 100 kV.)

conditions where it would superfluoresce. Reduced data for the intensity change in the first-positive emission under both single- and double-pass conditions as a function of added SF_6 are given in Fig. 4(a) and (b). Again, the N_2 pressure was fixed at a constant 70 torr, and the discharge voltage at 100 kV. The addition of SF_6 to the N_2 decreases the intensity of all of the first-positive bands, except the (0, 0) band, by a factor of 5-10. This decrease in intensity was found to be essentially the same for all the N_2 pressures investigated.

As the N_2 pressure was increased from 30 to 70 torr, the pressure of SF_6 that had to be added to the N_2 in order to achieve the maximum superfluorescnece on the (0, 0) band also increased. The N_2/SF_6 ratio required for maximum (0, 0) superfluorescence, however, remained nearly constant at ~17.

In Fig. 4(a) and (b), single curves only are used to represent the $\Delta v = 1$ and $\Delta v = 2$ transitions, respectively. It was determined that the shape of the fluorescence intensity versus added SF_6 curves is the same for each member of a Δv progression. The relative intensities of the members of a Δv progression were found to decrease with increasing v'. The curves represent the lowest member of each progression. Previously measured excitation cross sections for the production of the vibrational levels of the $B^3\Pi_g$ state by e-N_2 collisions indicate that the vibrational levels of maximum population correspond to $v = 2$-4 [16]. The fluorescence measurements made in this study do not correlate with these results; however, since the RSS integrates the signal that it sees over the entire discharge time, it is not surprising that the measured vibrational distributions appear to be equilibrated.

2) Second-Positive Bands: For the fluorescence intensity versus added SF_6 measurements of the second-positive emission, the (0, 0), (0, 1), (0, 2), (0, 3), (1, 3), and (1, 4) bands were monitored. Typical experimental data for these bands are given in Fig. 5. These measurements were performed with a fixed N_2 pressure of 70 torr and a discharge voltage of 100 kV under single-pass conditions. The jumps observed in the

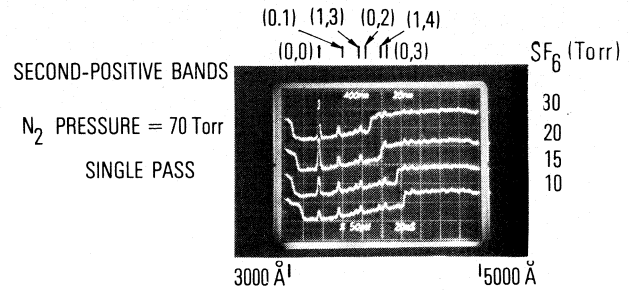

Fig. 5. Fluorescence data from second-positive bands as function of added SF_6. (N_2 pressure = 70 torr, discharge voltage = 100 kV, single-pass conditions.)

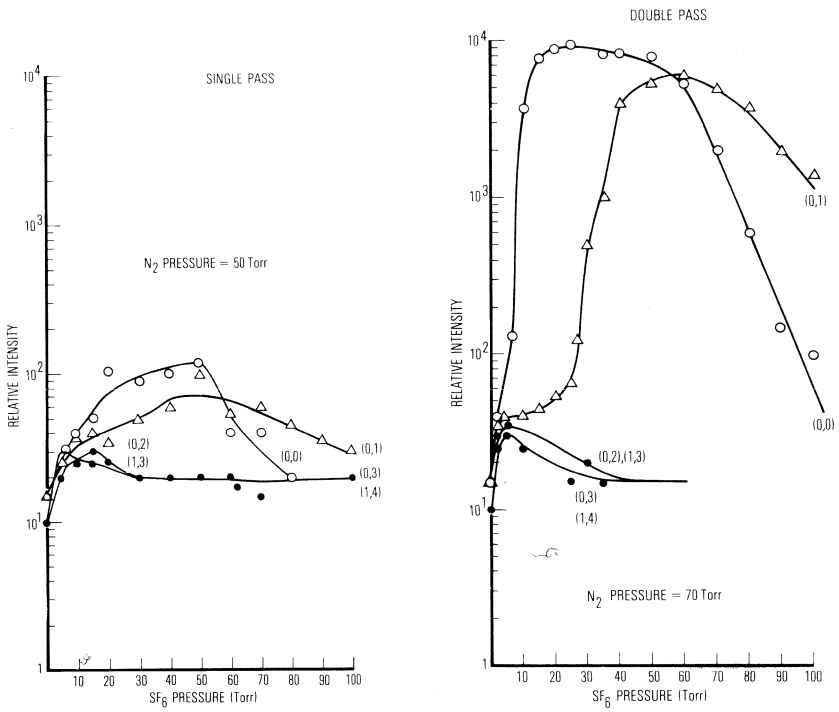

Fig. 6. Relative second-positive fluorescence intensity as function of added SF_6. (a) Single-pass conditions. (b) Double-pass conditions. (N_2 pressure = 70 torr, discharge voltage = 100 kV.)

signal baseline are not the result of radiation but electrical pickup by the RSS of the initiation discharge. A more complete display of the reduced experimental data is given in Fig. 6(a) and (b) for both single- and double-pass conditions. As in the case of the first-positive emission, only the lowest member of a given Δv progression is plotted in Fig. 5(a) and (b). The fluorescence intensities from the higher members of a progression decrease with increasing v'. Measured excitation cross sections for the vibrational levels of the $C^3\Pi_u$ state by e-N_2 collisions indicate that the vibrational level of maximum population will be $v' = 0$, decreasing with increasing v' [17]. The results of this study support this conclusion.

There are several interesting phenomena that are apparent in Fig. 6(a) and (b). The intensities of all Δv progressions increase by at least a factor of 2 as the SF_6 pressure is increased from 0 to 10 torr. Above 10-torr added SF_6, the intensities of the $\Delta v = -2$ and -3 progressions decrease; however, they do not decrease to the intensity level of the N_2 without SF_6. The (0, 0) and (0, 1) bands behave quite differently; the intensities of both of these bands continue to increase with added SF_6. This increase in intensity on only these two bands is a strange phenomenon. If it were caused only by an increase in the population of the $v = 0$ level of the $C^3\Pi_u$ state, an increase in intensity on all (0, v') bands of the second-positive system would be observed [18]. The reason for this anomalous intensity increase was found when the discharge voltage was lowered to below 75 kV. Below this voltage, the intensities of the (0, 0) and (0, 1) bands follow those of the $\Delta v = -2$ and -3 progressions. Above 75 kV, there must be sufficient gain in both the (0, 0) and (0, 1) bands such that they display single-pass superfluorescence. The realization that both the (0, 0) and (0, 1) bands display single-pass superfluorescence also helps to explain the crossover in intensities of the (0, 0) and (0, 1) band intensities at high SF_6 pressures.

A more detailed explanation of this effect is given in Section IV.

Three additional features of the second-positive emission are the following.

1) The (0, 0) band reaches its maximum intensity with 20-torr added SF_6, independent of N_2 pressure.

2) The condition under which the intensities of the (0, 0) and (0, 1) bands become equal always corresponds to $N_2/SF_6 \approx 1.0$.

3) The condition under which the (0, 1) band intensity maximizes corresponds to $N_2/SF_6 \approx 0.8$.

B. Laser Emission from N_2/SF_6 Discharges

The triplet states below 11.5 eV are *ungerade* except for the $B^3\Pi_g$ state (Fig. 7). All electric-dipole allowed transitions must, therefore, involve the B state, which includes the three laser systems $C \rightarrow B$, $B \rightarrow A$, and $W \rightarrow B$. In addition to these bands, a band laser emission near 1.82 μm and a single line at 3.355 μm also have been observed; however, these have not been positively identified. These lasers are affected by the addition of SF_6 in different ways (Fig. 8). The assignment of the 1.82-μm band to the $B(4) \rightarrow A(8)$ band is tentative. The lasers are molecular bands, which when inspected under high resolution consist of many lines except for the single line at 3.355 μm.

The electronic transitions identified in laser emission are given in Fig. 9. The 1.82-μm laser behaves temporally as a function of N_2 and SF_6 in a manner similar to the first-positive group lasers; consequently, these four bands are considered to be one laser system. Because it has not been identified, the 3.355-μm line will not be discussed.

In pure nitrogen, the lasers in Fig. 9 can be made to oscillate, except the second-positive bands. The relative laser intensities of each as a function of N_2 pressure are shown in Fig. 10. These measurements have been normalized so that the peak intensity of each band is 1.0. No comparison between individual bands is implied. The first-positive laser bands behave as the 1.822-μm line shown in Fig. 10.

The $W \rightarrow B \rightarrow A$ laser system is similar to the $C \rightarrow B \rightarrow A$ system observed with the addition of SF_6 in that the B state plays an intermediate role. In addition to the wavelength, however, there are other important distinctions. Neither of the McFarlane $W \rightarrow B$ bands III and IV [19], [20] (Fig. 10) are observed to lase unless they are preceded by first-positive laser action (Fig. 11). In addition, calculated electron impact cross sections for the excitation of the W state are lower at all energies than the corresponding cross sections for the B state [21]. This implies that the W and B states are strongly coupled through collisions with ground state N_2. Inversion requires $B \rightarrow A$ lasing to empty the low laser levels $B(v = 0, 1)$.

The $W(2) \rightarrow B(1)$ laser oscillates over a wider N_2 pressure range than the $W(1) \rightarrow B(0)$, which indicates that the inversion between the latter two levels is more susceptible to annihilation by collisions. Observation of the second-positive laser, which has oscillations terminating on the same two levels, i.e., $B(v = 0, 1)$, supports this conclusion.

The effect of SF_6 on discharges containing 10- and 50-torr N_2 was examined. At the lower N_2 pressure, the $W \rightarrow B$ and first-positive lasers are operative; at the higher pressure, only the first-positive laser is operative. With the addition of a

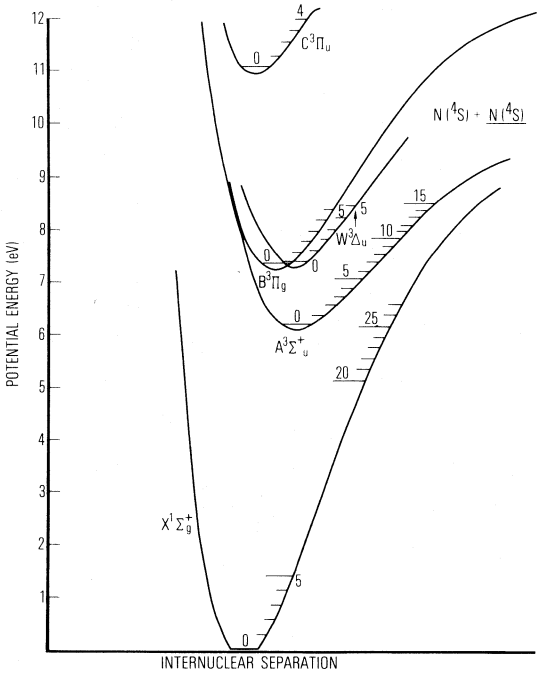

Fig. 7. Potential energy curves of the triplet states relevant to the N_2/SF_6 laser system.

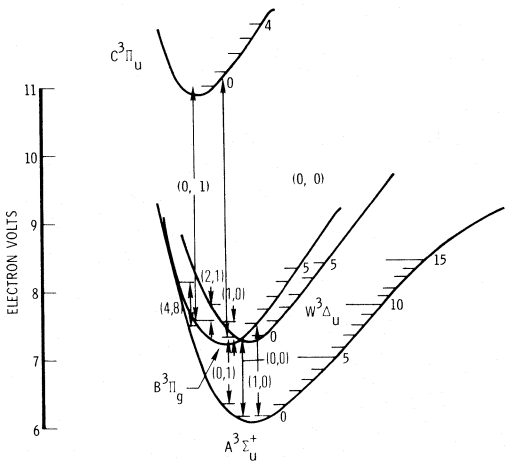

Fig. 9. Nitrogen transitions observed in laser emission.

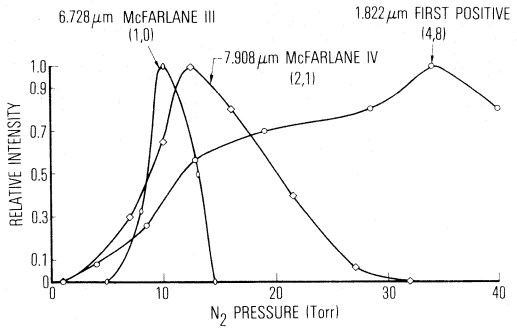

Fig. 10. Relative laser intensities as function of N_2 pressure.

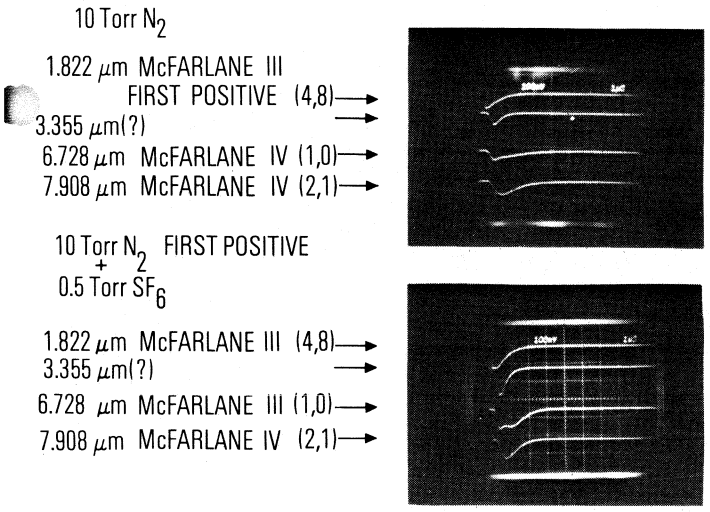

Fig. 11. Time-resolved nitrogen-laser emission at 10-torr N_2 and 10-torr N_2 + 0.5-torr SF_6.

minimum of 8-torr SF_6, the second-positive laser is observed. The results of the addition of SF_6 to discharges containing 10-torr N_2 are shown in Fig. 12. The effects on laser intensity are qualitatively similar to those produced, when the nitrogen pressure is varied; however, they are much more pronounced.

The laser transitions are enhanced, go through a maximum, and are quenched as successively more SF_6 is introduced. The $W(1) \rightarrow B(0)$ laser intensity peaks and is quenched at lower SF_6 pressures than the $W(2) \rightarrow B(1)$. Only 0.5-torr SF_6 is required to quench the $W(1) \rightarrow B(0)$ laser, while 5 torr of additional N_2 is required for the same result. A similar effect is also found for the $W(2) \rightarrow B(1)$ laser. Clearly, SF_6 is more efficient in quenching the inversion between these states than N_2.

At 50-torr N_2, with between 8- and 25-torr SF_6, both the first- and second-positive lasers oscillate. As shown in Fig. 13, however, the time to threshold for the first-positive laser follows that of the second-positive laser. Consequently, first-positive laser action can play no role in creating or maintaining inversion on the $C \rightarrow B$ transitions.

As shown in Fig. 14, up to 5 torr of SF_6 added to the 50-torr N_2 augments the peak intensity of the first-positive oscillations. Above 5 torr, however, further SF_6 addition results in a monotonic decline in first-positive laser power. At 8-torr SF_6, the second-positive laser reaches a threshold and increases in peak power until a broad maximum is reached at 25-torr SF_6.

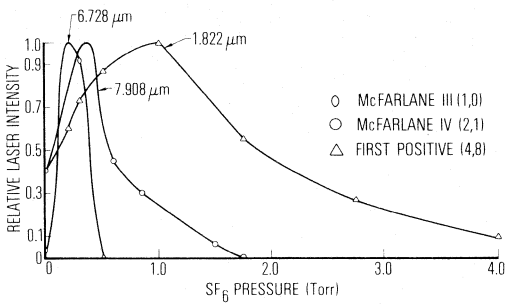

Fig. 12. Relative laser intensities as function of SF_6 pressure at 10-torr N_2.

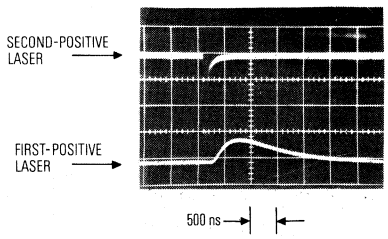

Fig. 13. Time sequencing of the first- and second-positive N_2 lasers at 50-torr N_2 + 14-torr SF_6.

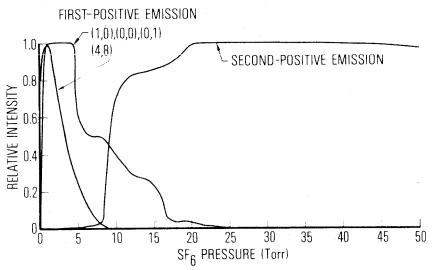

Fig. 14. Relative laser intensities as function of SF_6 pressure at 50-torr N_2.

The relative energy of the most intense second-positive laser oscillations as a function of SF_6 is shown in Fig. 15. The broad maximum in second-positive laser power is an artifact of the simultaneous decrease in the (0, 0) transition with an increase in the (0, 1) transition. These transitions both originate from the same upper state, and the Franck-Condon factor for the (0, 0) transition is approximately 30 percent larger than for the (0, 1) transition; thus the SF_6 is more effective at deactivating the $v = 1$ level of the B state than the $v = 0$ level. This conclusion is supported by the laser-induced fluorescence measurements given in Section IV.

C. *Laser-Induced Fluorescence Measurements*

Laser-induced fluorescence data for $B, v = 0$ and $B, v = 1$ are given in Figs. 16 and 17, respectively. Obviously, $B, v = 0$ has more than one decay time, while $B, v = 1$ appears to have one decay time, at least over the first decade of signal. Secondary and tertiary decay times have been observed previously when $B^3\Pi_g$ kinetics have been examined by pulsed-electric discharge techniques [22]-[24]. Since cascading (electronic and vibrational) processes occur in such experiments, only the first decay time has been considered as significant. Although our $B, v = 0$ kinetic data are similar to the data of several of these experiments, neither the cascading nor any "active nitrogen"

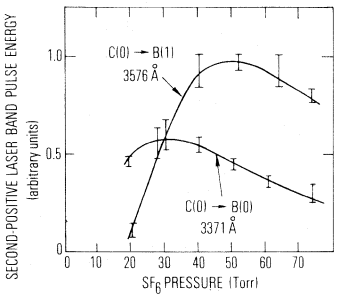

Fig. 15. Pulse energies of second-positive (0, 0) and (0, 1) bands as function of SF_6 pressure at 50-torr N_2.

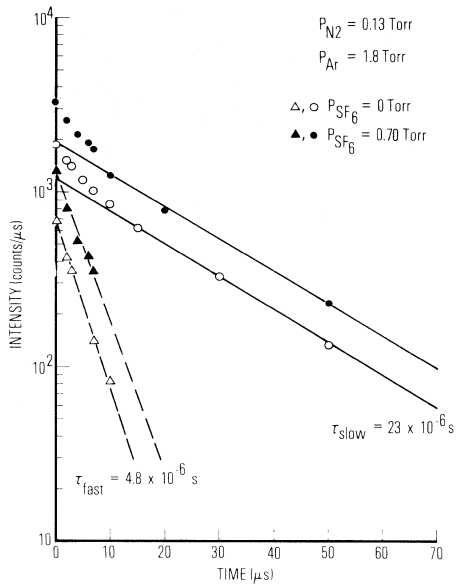

Fig. 16. Laser-induced fluorescence for (0, 0) band decay of $N_2(B^3\Pi_g, v=0)$. (Open circles are data for 1.8-torr Ar and 0.13-torr N_2. Closed circles are for the same Ar and N_2 partial pressures with 0.7 torr of SF_6. A double exponential curve fit gives identical decay times, $\tau_1 = 4.8$ μs and $\tau_2 = 23$ μs.)

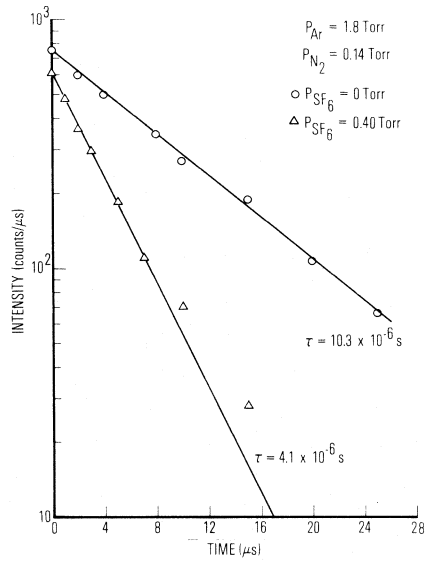

Fig. 17. Laser-induced fluorescence for (1, 0) band decay of $N_2(B^3\Pi_g, v=1)$. (Circles are data for 1.8-torr Ar and 0.14-torr N_2. Triangles are for the same Ar and N_2 partial pressures with 0.4 torr of SF_6. Decay times are 10.3 μs and 4.1 μs, respectively.)

afterflow effects [24] were observed in this study. The data of this study are consistent with a model in which strong collisional equilibrium of $N_2(B^3\Pi_g)$ and $N_2(W^3\Delta_u)$ is followed by relatively weak electronic quenching of the coupled B, W system. Analyzing the data in this manner reveals a longer radiative lifetime for $B^3\Pi_g$, $v=0$ than that reported by Jeunehomme [22].

The latest work by Benesch and Saum [25] on the spectroscopy of the $W^3\Delta_u$ state indicates that $v=0$ lies 73 cm^{-1} above $v=0$ for the $B^3\Pi_g$ state. Therefore, it is proposed [14] that the two decay times in Fig. 16 represent an equilibration between B, $v=0$ and W, $v=0$ (first decay) followed by loss of energy as a result of quenching and radiation by the coupled B, W system (second decay). The mathematical formalism applicable to these kinetics was developed by Chen and Moore [26] to deal with $V \rightarrow V$ transfer in HCl/DCl mixtures. It has been expanded subsequently [27], [28] to deal with vibrational energy exchange between diatomics with a close energy resonance.

The following kinetic processes are relevant to the quenching of $N_2(B, v=0)$ by Ar and N_2:

$$N_2(B, v=0) + Ar \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} N_2(W, v=0) + Ar \tag{1}$$

$$N_2(B, v=0) + N_2 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} N_2(W, v=0) + N_2 \tag{2}$$

$$N_2(B, v=0) \xrightarrow{k_3} N_2(A^3\textstyle\sum_u^+) + h\nu \tag{3}$$

$$N_2(B, v=0) + Ar \xrightarrow{k_4} N_2(A, X) + Ar \tag{4}$$

$$N_2(B, v=0) + N_2 \xrightarrow{k_5} N_2(A, X) + N_2 \tag{5}$$

$$N_2(W, v=0) + Ar \xrightarrow{k_6} N_2(A, X) + Ar \tag{6}$$

$$N_2(W, v=0) + N_2 \xrightarrow{k_7} N_2(A, X) + N_2. \tag{7}$$

The solution of these equations has been given previously [26] and may be written

$$N_2(B, v=0) = A \exp(-\lambda_1 t) + B \exp(-\lambda_2 t) \tag{8}$$

where λ_1 and λ_2 are the reciprocals of the measured fast and slow relaxation times. Various approximations can be made that give tractable expressions for λ_1 and λ_2 in terms of the rate coefficients for processes (1)-(7). The two most useful expressions are [26], [28]

$$\lambda_1 + \lambda_2 = k_3 + (k_2 + k_{-2} + k_5 + k_7)(N_2) + (k_1 + k_{-1} + k_4 + k_6)(Ar) \tag{9}$$

$$\lambda_2 \approx \frac{k_3}{(K_e + 1)} + \frac{(k_6 K_e + k_4)}{(K_e + 1)}(Ar) + \frac{(k_1 K_e + k_5)}{(K_e + 1)}(N_2) \tag{10}$$

where

$$K_e = k_1/k_{-1} = k_2/k_{-2} = (Q^W_{ROT}/Q^B_{ROT}) \exp(-\Delta E/kT).$$

Q_{ROT} is the rotational partition function, $\Delta E(\sim 73\ cm^{-1})$ is the energy difference between W, $v=0$ and B, $v=0$, and K_e is ~ 0.78.

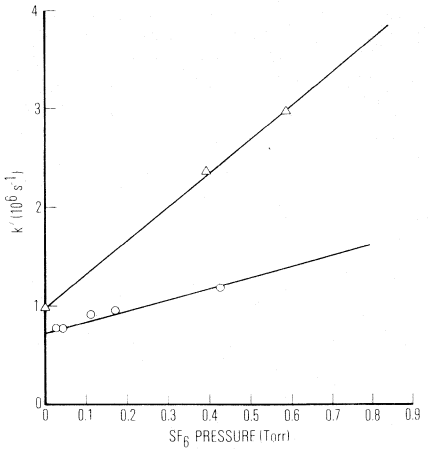

Fig. 18. Comparison of $N_2(B^3\Pi_g, v=1)$ quenching by SF_6 (triangles) and N_2 (open circles). (The derived rate coefficients are 1×10^{-11} and 3×10^{-12} cm^3/molecule · s, respectively.)

The following resulting rate coefficients for processes (1)-(7) have been previously discussed [14] and are presented here for reference only:

$$k_1 = 4 \times 10^{-13}\ \text{cm}^3/\text{molecule} \cdot \text{s}$$

$$k_2 = 7 \times 10^{-12}\ \text{cm}^3/\text{molecule} \cdot \text{s}$$

$$k_3 = 1 \times 10^{5}\ \text{s}^{-1}$$

$$0.56k_4 + 0.44k_6 \leqslant 1 \times 10^{-14}\ \text{cm}^3/\text{molecule} \cdot \text{s}$$

$$0.56k_5 + 0.44k_7 = 2 \times 10^{-12}\ \text{cm}^3/\text{molecule} \cdot \text{s}.$$

The conclusion to be drawn is that N_2 equilibrates $N_2(B)$ and $N_2(W)$ approximately 20 times more rapidly than Ar. Furthermore, N_2 electronically quenches the coupled B, W system more than 200 times faster than does Ar. Qualitatively, we have found no measurable effect of SF_6 on the N_2 $B, v=0$) relaxation rate.

With $N_2(B, v=1)$ assumed to have only one decay time (Fig. 17), the quenching rate of this state has been plotted versus N_2 and SF_6 in Fig. 18. These data must be regarded as preliminary. The rate coefficients derived from these data are

$$k_{SF_6}^{N_2(B,v=1)} = 1 \times 10^{-11}\ \text{cm}^3/\text{molecules} \cdot \text{s}$$

$$k_{N_2}^{N_2(B,v=1)} = 3 \times 10^{-12}\ \text{cm}^3/\text{molecules} \cdot \text{s}.$$

Although the product states are not known at this time from the kinetics, it is hoped that studies where one state is pumped and a second vibrational state is monitored as a function of time will be pursued.

When SF_6 is added, the population of $N_2(B, v=0)$ increases by a factor of 2 at all times following the laser pulse (Fig. 16). This results from vibrational relaxation in the $A^3\Sigma_u^+$ state since the $(A, v=1)/(A, v=0)$ measured by Setser *et al.* [29] downstream of the Ar* + N_2 flame persists at a ratio of 1. Qualitatively, SF_6 vibrationally but not electronically quenches the $A^3\Sigma_u^+$ state.

IV. Conclusions

The fluorescence, superfluorescence, and laser data were obtained in the range 0-60 torr of added SF_6. The experimental results, however, are more meaningful when considered in terms of two distinct ranges, i.e., 0-10 torr of added SF_6 and 10-60 torr of added SF_6. In the 0-10-torr SF_6 range, a complicated superposition of energy transfer processes, discharge impedance matching, and possibly new pumping processes is evident. These effects may reflect the altered electron energy distribution in the discharge or even direct excitation of SF_6 and subsequent energy transfer to N_2. In the 10-60-torr SF_6 range, results can be explained on the basis of the detailed energy transfer processes measured by the first-positive laser-induced fluorescence technique.

In 10-60-torr SF_6 range, it was observed that the (0, 1) second-positive, double-pass superfluorescence became more intense than the (0, 0) double-pass superfluorescence at a SF_6/N_2 ratio of ~1. This could not occur unless the $v=1$ level of $N_2(B)$ was being quenched to the $v=0$ level. The laser-induced fluorescence results indicate that this quenching rate $R = k_{SF_6}(SF_6) = 2 \times 10^7\ \text{s}^{-1}$ for an SF_6 pressure of 60 torr. The inverse of this rate (~50 ns) is comparable to the time to threshold (~100 ns) and the width (~100 ns) of the second-positive laser pulse in this system.

The behavior of double-pass superfluorescence on the (0, 0) first-positive band is not as clearly defined since it occurs entirely in the 0-10-torr SF_6 range. Nevertheless, the time to threshold (~300 ns) and the laser pulsewidth (~1 μs) for conditions of maximum (0, 0) output ($P_{SF_6} \approx 3$ torr) are very closely defined by the $N_2(B, v=1)$ relaxation time by SF_6 ($1/R \approx 1$ μs). Not until quantitative kinetic information concerning the $N_2(A)$ vibrational relaxation by SF_6 is available, can the first-positive laser performance be accurately predicted. Nevertheless, a comparison of the first-positive single-pass fluorescence to first-positive double-pass superfluorescence indicates that the addition of SF_6 results in vibrational cascading from $v>0$ to $v=0$ of the B state. The effect is probably more pronounced than indicated in Fig. 4(a) since increased C-state pumping in the 0-10-torr SF_6 range provides an additional B-state pumping term, i.e., $C \rightarrow B$ spontaneous and stimulated emission.

Analysis of the detailed fluorescence and laser behavior in the 0-10-torr SF_6 range is difficult, at best. In Fig. 6(a), the second-positive single-pass fluorescence increases by a factor of 2-3 with the addition of <5 torr of SF_6. Since this increase occurs on bands originating on $C^3\Pi_u$, $v=1$ as well as $v=0$, a new C-state pumping term is clearly indicated. Quite the opposite is indicated for single-pass fluorescence on the first-positive bands in the 0-10-torr SF_6 range. These observations indicate the possibility that some of the C-state production is two-step excitation involving either $B^3\Pi_u$ or $A^3\Sigma_u^+$ as an intermediate. Selective excitation of $C^3\Pi_u$ by SF_6* could also explain these results. Simpson *et al.* [30] found a strong peak in the energy loss spectrum for SF_6 at 11.5 eV, which is at threshold for $N_2(C^3\Pi_u)$ production. A final pumping possibility is ion recombination involving N_2^+ and SF_6^-, which is exoergic by 14 eV. The second-positive (0, 0) band always reaches a maximum intensity at 20 torr of added SF_6. This implies that SF_6-induced pumping processes in the 0-10-torr SF_6 range are being overtaken by the vibrational cascading into $B, v=0$ at the higher SF_6 pressures of the 10-60-torr SF_6 range.

The performance of the $W^3\Delta \rightarrow B^3\Pi_g$ laser is extremely

interesting in light of the proposed model for $B^3\Pi_g$, $v=0$ relaxation. Laser action is only observed at low N_2 pressures (<10 torr), and even at low pressures, the $B \rightarrow A$ transition always reaches threshold first, followed immediately by $W \rightarrow B$ laser action. These observations indicate that W and B are strongly coupled by N_2 collisions, i.e., $R = 2 \times 10^6$ s^{-1} at 10 torr of N_2 for B, $v=0 \rightarrow W$, $v=0$, and that stimulated emission is the only mechanism by which the lower state $B^3\Pi_g$ can be removed rapidly enough to invert the $W \rightarrow B$ transition. SF_6 helps both $W \rightarrow B$ (1, 0) and (2, 1) when added in extremely small amounts. This is clearly a 0-10-torr SF_6 range discharge effect rather than a kinetic relaxation effect by SF_6. Interestingly, $W \rightarrow B$ (1, 0) turns on first and then shuts off rather quickly with added SF_6. $W \rightarrow B$(2, 1) turns on later and shuts off more slowly with SF_6. In that sense, the behavior is qualitatively like that of the (0, 0) and (0, 1) $C \rightarrow B$ laser transitions.

Rotational-Vibrational Line Competition in a Dual-Polarization CO_2 Laser

N. E. BUHOLZ

Abstract—**A dual-polarization CO_2 laser can be caused to operate such that the two polarization modes correspond, respectively, to different rotational-vibrational lines. Interline competition effects, similar to those described previously, here also result in a mode power change with optical frequency which can be utilized as a convenient and sensitive optical frequency discriminant.**

The central component of an active laser stabilization system is the optical frequency discriminant, i.e., some quantity which changes with the laser frequency and which can be converted into a corresponding voltage increment. To be usable, the discriminant must have a noise level which is below the desired degree of stabilization, and it should have a flat frequency response in the band of laser modulation frequencies which are to be actively corrected by the system. Such a discriminant is potentially available in the case of CO_2 lasers through utilization of some of the special properties of a dual-polarization CO_2 laser. This type of laser, as first discussed by White and Gerber [1], [2], has in its output beam two polarization modes, linearly and orthogonally polarized, corresponding to an ordinary $c/2L$ cavity mode. The two modes are typically separated in frequency by a few megahertz. This behavior is produced by introducing a birefringent element into a laser cavity which is otherwise polarization isotropic. White and Gerber also demonstrated that it is possible through use of an intracavity modulator to force simultaneous oscillation of these modes within some narrow (~MHz) frequency band near the line center. It is found, under these conditions, that as the laser frequency is swept across line center, the modes exchange power content in a roughly linear manner. The slope of the power change with frequency may be adjusted by altering the modulator drive level. An optical frequency discriminant may thus be obtained through utilization of this mode power change with frequency. This behavior occurs because of gain competition effects which exist between the modes as they oscillate in a single rotational-vibrational line.

In contrast, Mocker [3] has shown that competition leading to the same sort of see-saw mode power exchange occurs when two modes oscillate on different vibrational-rotational lines. His experiments were performed using a CO_2 ring laser, in which the two modes were linearly and orthogonally polarized, and corresponded to opposite directions in the ring cavity. He also demonstrated similar competition effects in a single polarization linear laser using a heterodyne arrangement. In the latter case, to produce a usable discriminant one must separate the radiation corresponding to the two lines using some sort of dispersive arrangement since there is only a single polarization in the output.

We have also observed such line competition effects, but we utilized a dual-polarization CO_2 laser. The behavior is essentially the same as that described by Mocker, except that here we have a linear laser in which the "*s*" polarization, for example, may oscillate on the $P(18)$ line, and the "*p*" polarization may oscillate on the $p(20)$ line. The discriminant may be obtained simply by passing the output beam through a polarizer. In stabilized operation, then, the laser operates in two lines simultaneously, with the radiation corresponding to the two lines appearing primarily in orthogonal polarizations.

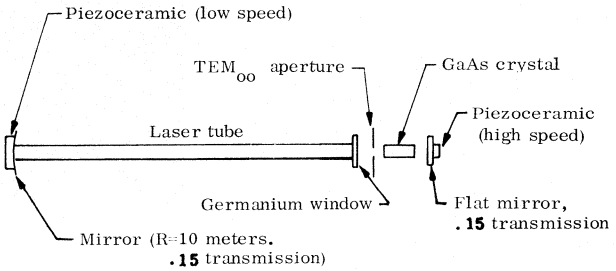

Fig. 1. Dual polarization CO_2 laser.

In the dual-polarization laser case, there appear to be certain advantages to using this discriminant over that provided by modulation near a single line center. First, the laser can presumably be constructed with fewer intracavity elements since no modulator is required. Second, it is desirable in sensitive heterodyne receiver applications to have a spectrally "clean" local oscillator (LO) beam.[1] This is difficult to obtain in the single line case, but is readily observed in the dual line case, the only probable contaminant being the radiation at the competing rotational-vibrational line frequency, which is one or more units of ~55 GHz away. The final advantage is connected with the slope and frequency response of this discriminant. Preliminary tests have shown that the slope $\Delta p/\Delta f$ can be as much as $\times 3$ greater than that obtainable with line center operation, and there are no anomalous amplitude and phase characteristics in its frequency response, as are also found in the line center case [4].

The dual-polarization laser from which these results were obtained is shown schematically in Fig. 1. This is a configuration which was used for line center operation and is not the optimum one for exploitation of the dual line discriminant. The GaAs crystal, which is the intracavity modulator in the line center scheme, is stressed mechanically as well, in order to produce the birefringence offset. The offset frequency is ~7 MHz. Piezoceramics located as shown provide optical frequency control, and an output of ~1.2-W total is obtained from each end of the laser. The laser tube is a Coherent Radiation model 42L and utilizes the standard laser mix (82:13.5:4.5, $He:N_2:CO_2$) with flow rate of 0.3 l/min and pressure of 20 torr. Excitation is provided by dc currents of ~10 mA flowing between cathodes located at the ends of the tube and the centrally located anode.

The photograph in Fig. 2 represents the power variation in each polarization mode as the laser frequency is swept through the crossover region. It was obtained by placing Ge:Au detectors on the output beams from each end after passing the beams through polarizers which were oriented along the two

[1] Spectrally "clean" as used here means that there is no detectable RF beat note in the heterodyne detector due to the presence of more than one optical frequency in the laser (LO) output.

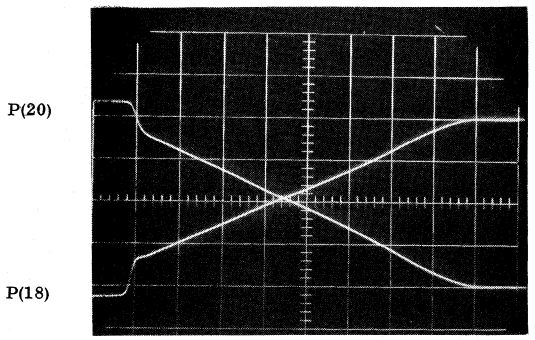

Fig. 2. Polarization mode power variation with laser frequency.

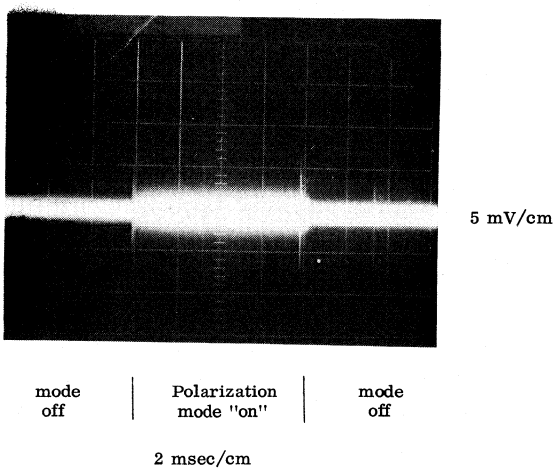

Fig. 3. Detector output $\times 100$ for one polarization mode output (approximately square wave) showing detector shot noise, amplifier noise, and polarization spectral purity.

orthogonal polarization directions. As is indicated in the figure, the two polarization modes correspond to the $P(18)$ and $P(20)$ rotational-vibrational lines (λ = 10.57, 10.59 μ, respectively). This was determined with a spectrum analyzer in place of the detectors. Also, as indicated, the slope of these traces in terms of volts per increment in laser frequency is ~6 mV/kHz. The magnitude of this slope depends upon the detector responsivity and the total power available at the detector, and so is a result of this particular experimental configuration. Thus in principle the slope may be increased if more sensitivity is required. For these detectors and the 6-mV/kHz slope, the detector self-noise level corresponds to a sensitivity limit of ~30 Hz of optical frequency deviation.

The frequency response characteristics of this discriminant in the range 0–10 kHz were obtained using a small sinusoidal drive on the high speed piezoceramic and observing the discriminant response with an hp 5480B averaging oscilloscope. The response was found to be completely flat in this range, unlike that of the discriminant established at line center using internal modulation.

As a final check, the laser output was tested for spectral "purity" using a HgCdTe photo diode placed after a polarizer oriented along one of the polarization mode directions.[1] The detector output was amplified and displayed on an oscilloscope, and the bandwidth of this arrangement was 250 kHz–20 MHz. During this experiment, the laser was swept sinusoidally in frequency such that each polarization mode was switched alternately "on" and "off" at the 60-Hz sweep rate. Thus in Fig. 3, which is a photograph of the oscilloscope display, we have an "on time" interval in which detector shot noise plus amplifier noise occurs, and an "off time" in which there is only amplifier noise. Since there is no beat note present during the mode on time, single frequency operation is indicated. The spikes in the photograph have been identified as transients with frequency near 250 kHz which originate in the amplifier.

In conclusion, we have observed the same rotational-vibrational competition effects which were reported earlier by Mocker, but we utilized a dual-polarization CO_2 laser, a device which is not a ring laser, but which can oscillate in two mutually orthogonal polarization modes, the two corresponding, respectively, to different rotational-vibrational lines. This provides a convenient optical frequency discriminant, some of the properties of which are that it has adequate sensitivity, good frequency response, is simple to obtain and utilize, and it allows active stabilization to be applied such that a single frequency output suitable for heterodyne receiver applications may be generated.

A Copper Laser Using CuI Vapor

I. SMILANSKI, L. A. LEVIN, AND G. EREZ

Abstract—**A simple CuI double-pulsed laser was built. The dependence of power output on the delay between the two excitation pulses, temperature, and the type of buffer gas has been investigated. The laser pulse duration was measured.**

Some recent papers [1], [2] have reported on metal vapor lasers operating at relatively low temperatures, utilizing the fact that the vapor pressures of some metal salts are higher than those of the metal itself.

Laser excitation is produced in two stages; in the first stage a discharge pulse dissociates the metal salt vapor to produce metal atoms, and in the second stage a second discharge pulse pumps these atoms to the upper laser levels. The minimum delay between the two pulses is determined by the time the metal atoms, produced in the excited state, require to decay to the ground state. The maximum delay time is determined by the recombination time of the dissociated molecules. An inert buffer gas is used to maintain the discharge and to keep the windows clean. The type and the pressure of the gas have an important influence on the laser's characteristics.

In this work the dependence of power output on delay time, temperature, and type of buffer gas have been investigated, and the laser pulse duration was measured. The power output was compared for two pumping capacitors.

The active part of the laser was constructed of a quartz tube, 2.5 cm in diameter and 30 cm long, enclosed in a tubular furnace. The rest of the laser tube, outside the furnace, was constructed of Pyrex with tubular aluminium electrodes. The Brewster windows were supported on short tubes with ground glass joints. The vacuum connection was in the cold zone, enabling fast gas exchange and easy pressure control. The diameter of the Brewster windows (1.2 cm) determined the beam diameter. The tube was operated under static vacuum conditions, as it was found unnecessary to change the buffer gas continuously. The discharge was always homogeneous and reproducible, as long as the buffer gas was reasonably clean.

The optical resonator consisted of a flat maximum reflectivity broad-band dielectric mirror, and a flat dielectric output coupling mirror, 1 m apart. Lasing was achieved at both 5106- and 5782-Å wavelengths simultaneously. The divergence of the beam was about 1.5 mrad. Under optimum conditions the laser operated without mirrors due to its high gain, but with a much larger divergence.

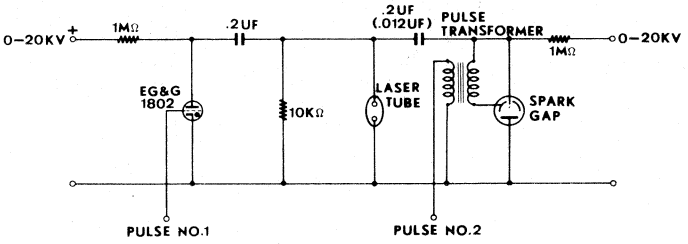

Fig. 1. Double-pulse power supply circuit.

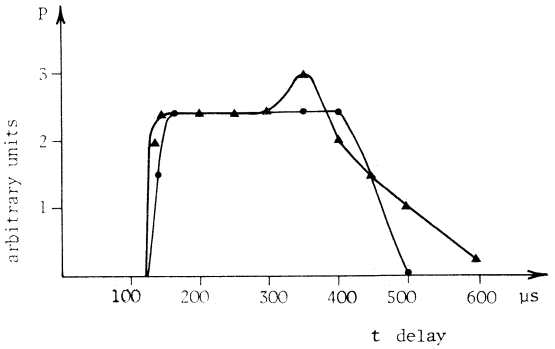

Fig. 2. Power output as function of delay time. •–20 torr He; ▲–7-torr He.

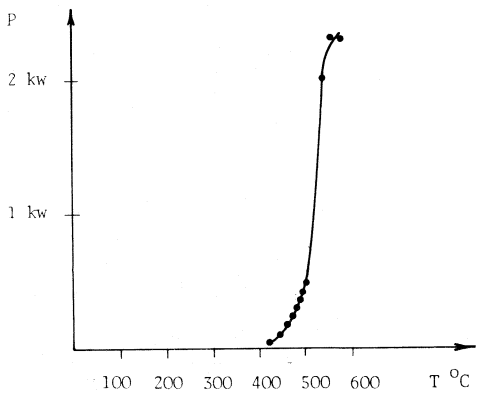

Fig. 3. Power output as function of furnace temperature. T_d = 200 μs; 7-torr He; C_{dis} = 0.2 μF; V_{dis} = 6 kV. C_{pump} = 0.012 μF; V_{pump} = 12 kV.

The electrical circuit used for the excitation is shown in Fig. 1. Separate high-voltage supplies enabled independent control of the dissociation and the pumping voltages. The maximum operating rate was 30 pps (power supply limited). The electrical leads to the tube were as short and as thick as possible.

Dependence of power output on delay time is shown in Fig. 2, and on temperature in Fig. 3 for helium buffer gas. At temperatures higher than 588°C [3] CuI melts and diffuses quickly to the colder parts of the tube. However, the laser was operated for 40 h at 550°C, with a high output, using only 5-g CuI. Power measurements were made with an EGG radi-

ometer, model 585. Measurements of pulse shape and duration (Fig. 4) were made with a p-i-n diode terminated by 50 Ω and a Model 475 Tektronix oscilloscope.

The pulsewidth reported here, 24 ns, is an order of magnitude wider than that reported by Liberman *et al.* [4]. This width is consistent with the observation that laser operation was dependent on the existence of a cavity, whose roundtrip time was 7 ns. This time is also nearer to that reported for other copper lasers [5], including a CuCl vapor laser [2].

We have also investigated power dependence on pressure and type of buffer gas (Fig. 5). Lasing was achieved more easily and over a wider pressure range with helium than with argon. The minimum dissociation pulse voltage required to operate the laser with helium was about 7 kV, while with argon 16 kV was necessary. There was no difference in minimum pumping voltage [6]. The reason for the dissociation voltage difference seems to be the higher electron temperature achieved in the helium discharge. Both higher voltage and lower pressure were needed to achieve lasing in argon. Thus it would seem that a hollow cathode configuration would improve the performance of the CuI vapor laser [7].

Reducing the pumping capacitor from 0.2 to 0.012 μF increased the power output by 20 percent, which suggests that the reduced rise time compensated the reduced overall charge, such that in both cases the current during the first 25 ns was about the same.

ACKNOWLEDGMENT

The authors wish to thank A. Dagan for his expert glassblowing.

On the Stability of Modes in a Laser Resonator with an Active Medium

G. J. ERNST AND W. J. WITTEMAN

Abstract—**A discussion is given on the stability of laser modes; particularly for those in active resonators having negative gain profiles.**

One of the most fundamental properties of any laser resonator is the fact that radiation generated in a laser is only present in a number of stable well-defined (sometimes of very complex structure) amplitude and phase distributions of the electromagnetic field at certain frequencies. In a normal continuous or quasi-continuous wave oscillator these stable distributions are independent or quasi-independent of time and they are called the modes of the resonator. The characteristics of a mode are fully determined by the geometry and

Manuscript received March 17, 1975; revised July 28, 1975.
The authors are with the Department of Applied Physics, Twente University of Technology, Enschede, The Netherlands.

optical properties of the cavity and by the plasma parameters of the active medium. Immediately after the discovery of the laser, the mode patterns of the system were the subject of intensive and detailed study. In this respect, the papers of Fox and Li [1] and Kogelnik and Li [2] can be regarded as classics. Also, for unstable resonators, comprehensive studies have been made (see, for example, the survey paper of Siegman [3]). These papers, dealing only with passive resonators, have value mainly because of the excellent fit shown between the experimentally observed intensity patterns of small cavities and the theoretical calculations. The stability of such modes and how such a mode builds up in time, however, are only fragmentarily studied.

In a recent publication [4] we calculated the mode structure of active resonators for the case where diffraction losses are small, starting from the basic work of Kogelnik [5]. We found that for a stationary state an eigenmode with a Gaussian distribution satisfies the boundary conditions for any quadratic radial gain profile; positive as well as negative ones. As a stability criterion we used the existence of an eigenmode. The justification for the stability of the calculated modes comes, of course, from experiments. For instance, it is not difficult to achieve a high-gain CW CO_2 laser oscillating in the fundamental mode [6]. For such a CO_2 system the small-signal gain has, at high-power excitation conditions due to thermal heating, a minimum in the center of the tube [7]. Moreover, because of saturation, the high intensity of the beam in the center of the tube lowers the actual gain considerably, so that in such a system a large negative gain profile (with the smaller gain at the axis of the tube) exists. Still, from the theoretical point of view, there seems to be doubt about the stability of modes in laser systems with a negative profile, because Casperson [8] and, somewhat similarly, Ganiel and Silberberg [9] try to prove mode instability for such laser systems.

In [8] and [9] the authors describe essentially the behavior of an arbitrary Gaussian pattern through a sequence of identical amplifiers and then they apply the conclusions to an oscillator. Amplifiers only transform the beam parameters by the medium and optical components, but there is no resonance effect. The absence of a resonance condition is the essential difference between an oscillator and an amplifier. For a high-quality oscillator there is the extra condition that only those fields can bounce back and forth for which the phases are not changed after a round trip through the resonator. This means that radiation that does not fit in eigenmodes of the oscillator, because of frequency, amplitude, or phase distributions, will not be amplified to a substantial level. Following the time behavior of a radiation field in an oscillator these nonfitting parts of the field can be neglected as compared with the fitting parts of the field.

A procedure to determine the time behavior can be as follows (this procedure can describe stability as well as the starting process). Suppose in a laser oscillator a certain field distribution is present at a given time t_0. When looking for stability of a mode this time point will be chosen just after a disturbance has taken place. Also spontaneously emitted radiation will be present. This radiation is in general distributed over both space and frequency.

A part of this field can be expanded in terms of the cavity eigenmodes having specific frequencies. The remaining part will disappear anyhow due to interference because of the lower quality factor of the resonator for this remaining field. Thus only the part of the radiation field that is expanded into the cavity eigenmodes can be amplified to a reasonable level.

The time behavior of the strengths of these expanded modes is rather complex. The time-dependent intensity of a mode is subject to diffraction losses, available gain, out-coupling losses, competition effects, etc. In the steady state, however, the strength of each mode comes from the equilibrium between the gain and all relevant losses. Some modes may even disappear. This, for instance, may be the case because they are below threshold, or because a finite aperture discriminates higher order modes due to higher diffraction losses. In this way, it is possible that one observes only a zero-order mode with low diffraction losses. Then the radial intensity pattern can to a good approximation be described by the infinte aperture theory; i.e., a pure Gaussian distribution as given in [4]. Anyhow, whatever the gain profile and the cavity parameters are, as long as eigenmodes can be found for such a system stable oscillations will be obtained.

Fuels for a Premixed Pulsed HCl Laser

T. J. MANUCCIA, J. A. STREGACK, AND W. S. WATT

Abstract—**HCl pulsed chemical lasing was obtained from several premixed R-Cl/HI mixtures when initiated by a transverse pulsed discharge. The relative merits of these mixtures were compared to a premixed H_2/Cl_2 mixture. For a constant stored electrical energy several mixtures have been found which give higher specific power than the H_2/Cl_2 system. In addition, it has been possible to run some of these improved mixtures without diluent with no laser performance degradation.**

The first pulsed chemical HCl laser was reported by Kasper and Pimentel [1] in 1965. Since then, several workers [2]–[7] have studied various fuel systems which produced HCl lasers using both flashlamp and pulsed discharge initiation

Manuscript received June 9, 1975; revised July 21, 1975. This work was partially supported under ARPA Order 2062.

$HI/TiCl_4$	(3.5/10)	3.0	14.0
$HI/PCl_3/He$	(2.0/4.2/3)	.4	2.7

of the chemical reactions. However, no attempt to quantify the relative merits of these fuel systems has been undertaken. Consequently, an investigation of many of the fuel systems previously studied as well as several new fuels was undertaken to compare their relative merits in producing HCl laser radiation.

Typically, pulsed HCl lasers operate using either the H_2/Cl_2 mixture which has the assumed reaction sequence

$$Cl + H_2 \longrightarrow HCl + H \quad -1 \text{ kcal/mole} \tag{1}$$

$$H + Cl_2 \longrightarrow HCl^* + Cl \quad +45 \text{ kcal/mole} \tag{2}$$

or the HI/Cl_2 system which operates on the two exothermic reactions

$$H + Cl_2 \longrightarrow HCl^* + Cl \quad +45 \text{ kcal/mole} \tag{3}$$

$$Cl + HI \longrightarrow HCl^* + I \quad +32 \text{ kcal/mole.} \tag{4}$$

In the H_2/Cl_2 system, endothermic reaction (1) is slow on the time scale of the laser pulse and therefore contributes neither to the production of excited HCl nor to the supply of H atoms for reaction (2). The requisite H atoms must come directly from the dissociation of H_2 in the discharge. HI is a better source of atomic hydrogen than H_2 and one would expect the HI/Cl_2 system to be more efficient. However, premixing of HI and Cl_2 is difficult to perform without spontaneous reaction. Alternate chlorine sources, R–Cl, were sought which would be sufficiently reactive so that the resulting HI/R–Cl mixture would outperform the H_2/Cl_2 system and, in addition, could be premixed with HI.

The laser used in the present study is a transverse electrical pin discharge laser which is constructed from aluminum tubing. The discharge region was 100 cm long with 100 evenly spaced ballasted (1 kΩ, 1 W) cathodes (Stupkopf connectors electrically isolated from the outer tube) located approximately 2.5 cm from a hemicylindrical brass anode. The electrical initiation of the chemical reactions was provided by repetitive discharge (typically 1 pps) of a 0.0027-μF capacitor charged to a voltage of 30 kV. The optical cavity was formed by two gold mirrors, one of which had an on-axis 0.5-mm hole through which the output power was coupled. The pairs of gases were premixed before entering the laser region and a small amount of He was injected as window purge. Laser radiation was detected with a Ge:Au detector. As the pulse shapes were very similar when each of the fuel–oxidizer mixtures was optimized, performance was determined from peak pulse heights.

Initial experiments performed on the apparatus gave the result that the H_2/Cl_2 mixture produced laser power which was about one order of magnitude greater than the HI/Cl_2 mixture. There was clear evidence of prereaction in the HI/Cl_2 system which could explain its lower power. An additional factor is that vibrational excitation of the H_2 or production of Cl* in the discharge for the H_2/Cl_2 experiment could make reaction (1) exothermic and promote chain behavior, with a subsequent increase in H_2/Cl_2 laser output. Efficient electron impact excitation of H_2 has been observed [8].

In order to compare the merits of the various fuels, an initial screening was performed by adding the proposed chlorine atom source to an HCl laser operating on the H_2/Cl_2 system. These runs were made with the laser operating chlorine lean such that the effect of the new chlorine source would be as large as possible. Those fuels which either enhanced or did not degrade lasing were CCl_4, CCl_3H, PCl_3, $COCl_2$, $TiCl_4$, $SOCl_2$, $SnCl_4$, CCl_3CH_3, CCl_2CHCl, CCl_2F_2, CF_3CCl_3, and C_6H_5Cl. As a result of this screening, several of these systems and one other have led to HCl lasing in premixed R–Cl/HI systems. New Cl atom sources not previously reported in the literature which produced HCl laser emission are $SiCl_4$, $SnCl_4$, CF_3CCl_3, CCl_3CH_3, CCl_2CHCl, C_6H_5Cl, PCl_3, and $TiCl_4$. In addition, lasing was observed using CCl_4 [7], CCl_3H [7], $SOCl_2$ [6], and CCl_2F_2 [7] as had been previously reported.

By optimizing conditions for each pair of fuels (at constant stored electrical energy), it has been possible to identify those fuel sources that operate at higher specific powers (power out per mole of reactants) than the H_2/Cl_2 system. These improved laser fuels and their optimized operating characteristics are summarized in Table I. The H_2/Cl_2 mixture preferred to operate in the range $0.5 < H_2:Cl_2 < 15$ with optimum operation occurring at a fuel to oxidizer ratio of 2. The HI/R–Cl mixtures all optimized at fuel-to-oxidizer ratios below 0.5 and lasing could never be maintained beyond a ratio of 2.0. The previously reported experiments [7] on the HI/CCl_4 and HI/CCl_2F_2 systems were performed under conditions of high helium dilution (>90 percent). In the present experiments these fuel mixtures were run with less than 3 torr of He, which plays little or no part in the kinetics. For example, laser power was not affected when all helium was removed from the CCl_2F_2/HI system. One anomalous effect was observed when the output more than doubled when the 3 torr of He were removed from the $TiCl_4$/HI system.

As reported by Taylor [7], HF and HCl lasing occurred simultaneously for the CCl_2F_2/HI mixture. In the present experiments, for the optimum HCl lasing conditions the HCl laser output was approximately 2.5 times that of HF.

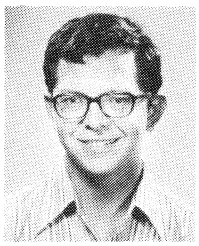
John A. Caird (S'75–M'75) was born in Brooklyn, N.Y., on December 24, 1947. He received the B.S. degree in electrical engineering from Rutgers University, New Brunswick, N.J., in 1969, the M.S. degree in physics from the University of California, Los Angeles, in 1971, and the Ph.D. degree in physics from the University of Southern California, Los Angeles, in 1975.

Since 1969 he has been with the Laser Division of Hughes Aircraft Company, Culver City, Calif., and completed his graduate studies under the company's work-study fellowship program. His research activities have centered on the development of laser sources and the analysis of rare-earth laser materials.

Dr. Caird is a member of Eta Kappa Nu, Tau Beta Pi, and the Optical Society of America.

*



David C. Chang (S'65–M'67) was born in Hupeh, China, on September 9, 1941. He received the B.S. degree in electrical engineering from Cheng Kung University, Tainan, Taiwan, China, and the M.S. and Ph.D. degrees in applied physics from Harvard University, Cambridge, Mass., in 1961, 1963, and 1967, respectively.

From 1963 to 1967 he was a Research Assistant at the Gordon McKay Laboratory, Harvard University. He joined the University of Colorado, Boulder, in 1967 and is now a Professor of Electrical Engineering. In 1972 he was a Visiting Professor at Queen Mary College, University of London, London, England. Currently, he is also a guest worker with the theoretical studies group at the Environmental Research Laboratory, NOAA/DOC.

Dr. Chang is a member of Sigma Xi and the International Scientific Radio Union Commission VI. He is currently Chairman of the IEEE-MTT-S15 Subcommittee on Microwave Theory.

*

Larry G. DeShazer, for a photograph and biography please see page 119 of the March 1975 issue of this JOURNAL.

C. James Elliott was born on January 2, 1943. He attended Lafayette College, Easton, Pa., from 1960 to 1962, and received the A.B. degree in mathematics-physics from Yale College, New Haven, Conn., and the Ph.D. degree in engineering and applied science from Yale University, in 1964 and 1972, respectively. He also attended the Summer Institute in Space Science at Columbia University, N.Y., in 1962.

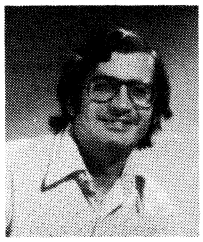
He joined the Los Alamos Scientific Laboratory, University of California, Los Alamos, N. Mex., in 1972 to work in laser-driven-fusion energy research. His professional interests include discharge physics and kinetics, nonlinear optical propagation, coherence phenomena, and numerical and computational analysis.

Dr. Elliott received the Barge Prize in Mathematics in 1962.

*

U. Ganiel (A'71–M'72) was born in Rehovot, Israel, on September 6, 1936. He received the M.Sc. degree from the Hebrew University of Jerusalem, Jerusalem, Israel, and the Ph.D. degree from the Weizmann Institute of Science, Rehovot, both in physics, in 1963 and 1968, respectively.

He did research in the fields of atomic spectroscopy, nuclear quadrupole resonance, Mössbauer spectroscopy, and magnetism. He spent a year as a Visiting Research Physicist at Carnegie-Mellon University, Pittsburgh, Pa., where he worked in Mössbauer spectroscopy. He was a Research Fellow at the California Institute of Technology for two years (1970–1971), where he worked in the field of nonlinear optics. Since 1971 he has been on the faculty of the Department of Electronics of the Weizmann Institute, where he has been working on various laser systems, problems in optical resonator theory, and specifically, on tunable dye laser systems.



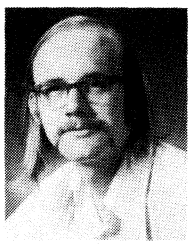
Dr. Ganiel is a member of the American Physical Society and the Israel Physical Society.

*

A. Hardy was born in Hungary on February 9, 1942. He received the B.Sc. and M.Sc. degrees from the Hebrew University of Jerusalem, Jerusalem, Israel, and the Ph.D. degree in applied physics from the Weizmann Institute of Science, Rehovot, Israel, in 1966, 1969, and 1975, respectively. His Ph.D. dissertation was in the area of optical diffraction theory.

Since April 1975 he has been with the Department of Electronics, the Weizmann Institute of Science, where he has been working on dye laser systems and some problems in optical resonator theory.

R. F. Heidner, III, was born in Corpus Christi, Tex., on July 22, 1944. He received the B.A. degree in chemistry from Rice University, Houston, Tex., and the Ph.D. degree in physical chemistry from the University of California at Los Angeles, in 1966 and 1972, respectively.



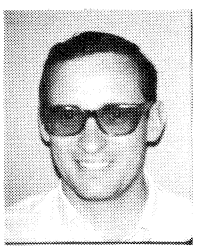
From 1972 to 1973 he was a National Science Foundation Postdoctoral Fellow with the Department of Physical Chemistry, Cambridge University, England. In 1973 he joined the Aerospace Corporation, El Segundo, Calif., where he worked on gas phase chemical kinetics relevant to chemical and energy transfer lasers.

Dr. Heidner is a member of the American Physical Society, Sigma Xi, and Phi Lambda Upsilon.

*

C. J. Kennedy, for a photograph and biography please see page 639 of the August 1975 issue of this JOURNAL.

*



Edward F. Kuester (S'73) was born in St. Louis, Mo., on June 21, 1950. He received the B.S.E.E. degree from Michigan State University, East Lansing, Mich., in 1971, and is currently working towards the Ph.D. degree at the University of Colorado, Boulder.

He has been a Research Assistant at the University of Colorado since 1972.

Mr. Kuester is a student member of the Optical Society of America.

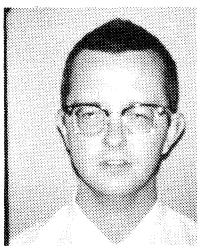
*

David A. McArthur was born in Meridian, Miss., on August 14, 1938. He received the B.S. degree in physics from the University of Arizona, Tucson, and the Ph.D. degree in physics (nuclear magnetic resonance) from the University of California, Berkeley, in 1960 and 1967, respectively. He attended the University of Munich, Germany, from 1960 to 1961 on a Fulbright Scholarship.

He was a member of the Technical Staff at Bell Laboratories, Holmdel, N.J., from 1967 to 1969 where he worked in far-infrared nonlinear optics using the water vapor laser. Since 1969 he has been a member of the technical staff at Sandia Laboratories, Albuquerque, N. Mex., where he has worked experimentally on optical techniques to measure the current, voltage, charge deposition, and plasma properties of relativistic electron beams. He has also worked on theoretical models of the plasma created and laser action induced by intense electron beams. More recently, he has experimentally studied the excitation of laser media by nuclear reactions, using laboratory nuclear reactors.

John Nella was born in Brooklyn, N.Y., on July 10, 1947. He received the B.S. degree in electrical engineering from the Polytechnic Institute of Brooklyn, Brooklyn, N.Y., in 1968, the M.S. degree in electrical engineering from the California Institute of Technology, Pasadena, in 1969, and the Ph.D. degree in electrophysics from the Polytechnic Institute of Brooklyn, Brooklyn, N.Y., in 1972.

Since 1972 he has been with the Laser Division of Hughes Aircraft Company, Culver City, Calif., where he has been engaged in the development of new coherent optical sources.



*

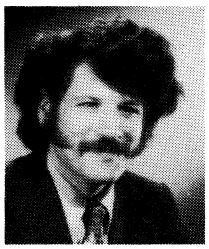
G. Neumann (M'74) was born in Petach-Tivka, Israel, on September 14, 1943. He received the B.A. degree in physics from Queens College, CUNY, N.Y., and the Ph.D. degree in optics from the Institute of Optics, University of Rochester, Rochester, N.Y., in 1965 and 1970, respectively.

From 1970 to 1971 he was a postdoctoral fellow with the Department of Physics, Hebrew University of Jerusalem, Jerusalem, Israel, working on thermally excited CO_2 lasers. Since 1970 he has been with the Department of Electronics, the Weizmann Institute of Science, Rehovot, Israel, where he has been working on tunable dye lasers, multiple wavelength dye lasers, nitrogen lasers, and dye doped polymers. For the present he is on leave of absence at Tadiran, Israel Electronic Industries.

*

J. W. Poukey was born in Indianapolis, Ind., on February 17, 1940. He received the B.S., M.S., and Ph.D. degrees in physics, all from the University of Wisconsin, Madison, in 1961, 1963, and 1966, respectively.

He has been associated with Sandia Laboratories, Albuquerque, N. Mex., since 1967. He has done theoretical research in various areas of plasma physics, including gas discharges, neutron tube design, and computer simulation of space-charge flow and plasma instabilities. His current work is concerned with the theory and simulation of relativistic electron beams and their interaction with gases and plasmas.



Dr. Poukey is a member of the American Physical Society.

*

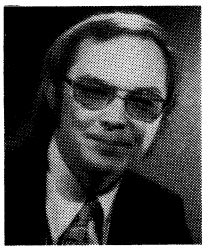
William Streifer (S'56–M'58–SM'73), for a photograph and biography please see page 180 of the April 1975 issue of this JOURNAL.



Steven N. Suchard was born in Chicago, Ill., on February 8, 1944. He received the B.S. degree in chemistry from the University of California at Berkeley, and the Ph.D. degree in chemical physics from the Massachusetts Institute of Technology, Cambridge, in 1965 and 1969, respectively. During his graduate career he was awarded a NASA Traineeship from 1965 to 1968 and an NIH Predoctoral Fellowship from 1968 to 1969.

From September 1969 to September 1970 he was a Postdoctorate Research Fellow in the College of Chemistry at the University of California at Berkeley, where his work involved the demonstration of the first hydrogen halide chemical laser to operate on an overtone transition. He joined the Aerophysics Laboratory of the Aerospace Corporation, El Segundo, Calif., in October 1970, and has studied pulse-chain and transfer chemical lasers and chemically pumped electronic transition lasers.

Dr. Suchard is a member of the American Physical Society.

*

David G. Sutton was born in San Francisco, Calif., on April 17, 1944. He received the B.S. degree in chemistry from the University of California, Berkeley, in 1966. In 1967 he entered the graduate school in chemistry at the Massachusetts Institute of Technology, Cambridge. He was a National Institutes of Health Predoctoral Fellow from 1967 to 1970, when he received the Ph.D. degree in physical chemistry.

He was a Research Associate with the Department of Chemistry, Massachusetts Institute of Technology, Cambridge. He is now with the Aerospace Corporation, El Segundo, Calif. His research interests include molecular spectroscopy, gas phase energy transfer, and gas lasers.

Dr. Sutton is a member of the American Physical Society and Sigma Xi.

D. Treves (M'69) was born in Italy on June 29, 1930. He received the B.Sc., M.S., and Ph.D. degrees, all in electrical engineering, from the Haifa Technion, Israel, in 1953, 1956, and 1958, respectively.

Since 1953 he has been associated with the Weizmann Institute and has been involved in the study of magnetization processes; magnetic materials, magnetooptic memories, and laser systems. He spent several years in the United States as a Research Associate at Pomona College, Claremont, Calif., as a member of the Technical Staff at Bell Laboratories, Murray Hill, N.J., at the Ampex Research Laboratory at Redwood City, Calif., and as World Trade Exchange Fellow at IBM, San Jose, Calif. At present he is a Professor with the Department of Electronics, the Weizmann Institute, Rehovot, Israel.

IXth INTERNATIONAL CONFERENCE 1976

QUANTUM ELECTRONICS

AMSTERDAM the NETHERLANDS JUNE 14–18, 1976

SPONSORS: EUROPEAN PHYS. SOC., DUTCH PHYS. SOC., PHYSICA (Neth.), A.I.P. and I.E.E.E. through the JOINT COUNCIL on QUANT. ELECTR. (USA)

TOPICS:
- Physics and chemistry with lasers
- Laser-induced isotope separation and chemical reactions
- Interaction of extremely intense radiation with matter
- Laser spectroscopy and environmental measurements
- Advances in coherent light sources
- Photon statistics and coherence effects
- Nonlinear optics, modulators and detectors
- New optical materials
- Integrated optics and guided waves

EXHIBITION: – During the conference at the congress site

CALL FOR PAPERS:

Both invited and contributed papers will be presented; working language in English. Original papers, not previously published or presented, are sollicited in the above mentioned areas.

Instructions are given in the call for papers available from the secretary of the Organizing Committee. Also local organisations will distribute the call for papers.

The authors are requested to submit both a 35-word abstract and a 500-word summary of their paper to the Technical Program Committee.

Deadline for contributions: December 15, 1975

Chairman Technical Program Committee
Prof. Dr. O. Svelto
c/o Prof. Dr. H. J. Frankena
Dept. Applied Physics
University of Technology
Lorentzweg 1
Delft/the Netherlands

Local Program Committee USA/Canada
Dr. J. A. Armstrong
IBM Thomas J. Watson
Research Center
P.O. Box 218
Yorktown Heights
NY 10598

Secretary Organizing Committee
Dr. J. Langelaar

FREQUENCY SYNTHESIS: Techniques and Applications.

Edited by Jerzy Gorski-Popiel, *M.I.T. Lincoln Laboratory*. 1975. 184 pages. Illustrated. ISBN—087942-039-1

This book is written for the practicing engineer faced with a need to learn about, design, or apply modern frequency synthesizers. Many advances in frequency synthesis have been made in recent years, and a variety of systems have been developed, which may be broadly divided into those using direct, indirect, and all-digital techniques. This volume describes the basic properties of synthesizers, compares the three approaches on the basis of performance and complexity, presents case studies in sufficient detail to permit the reader to confidently apply and design synthesizers, and discusses alternate configurations and the characterization and measurement of noise. Each of the six chapters was written by an expert in the subject discussed.

CONTENTS: Preface, Applications of Frequency Synthesizers, Contemporary Frequency Synthesis Techniques, Direct Frequency Synthesis, Phase-Locked Loop Frequency Synthesizers, Digital Frequency Synthesizers, Hybrid Configurations and Frequency Stability, Subject Index.

DATA COMMUNICATIONS VIA FADING CHANNELS

Edited by Kenneth Brayer, *The MITRE Corporation*. 1975. 520 pages. Illustrated. A Book of Selected Reprints. ISBN—Clothbound 0-87942-047-2; Paperbound 0-97942-048-0

The functioning of numerous aspects of modern society is dependent on the communication of data over fading channels. Now, after years of rapid development, there is a stabilization in the underlying technology, so this collection of papers appears at a fortuitous time. The papers included were carefully selected to summarize the relevant principles of propagation, modulation, signaling, and coded diversity techniques. In Part I, the fundamentals of propagation are presented, along with details of the effects of fading and multipath. The basics of signaling for the non-fading channel are covered in Part II, followed by papers extending the coverage to fading multipath channels and to diversity techniques. Part III treats error control coding. A bibliography of over 500 citations in included.

CONTENTS: Introduction, The Fading Channel, Digital Signaling on the Fading Channel, Error Control (Coded Diversity) for the Fading Channel, Bibliography, Author Index. A total of 35 reprinted papers.

LITERATURE IN DIGITAL SIGNAL PROCESSING: Author and Permuted Title Index (Revised and Expanded Edition)

Edited by Howard D. Helms, James F. Kaiser, Lawrence R. Rabiner, *Bell Laboratories*. 1975. 216 pages. Illustrated. ISBN—Clothbound 0-87942-051-0; Paperbound 0-87942-052-9.

This is a much-needed volume, since a great deal of publication activity has taken place in the field of digital processing since the previous edition was issued. It provides comprehensive coverage of digital filtering and spectral analysis, and selected titles from related areas are included. All told, 1,872 books, conference records, reports, theses, and papers are listed, an increase of 160% over the earlier edition. The book is divided into three sections: permuted title index, in which titles are listed consecutively under key words; author-title index, with all the papers of a given author listed under his name; and a complete listing of all titles indexed by year, edition number, and serial number.

CONTENTS: Introduction, Permuted Title Index, Author Index, List of References.

Near-UV Spectral Efficiency of High-Current Xenon Flashlamps

M. A. GUSINOW

Abstract—**A discussion is given of the limiting spectral efficiency of flashlamps that are used to pump lasers. Absolute measurements indicate that 4.5 percent of the capacitor-bank energy appears as radiant energy in the region 2500–2900 Å (the nominal pump band of the iodine photodissociation laser) for the flashlamps studied in this work. A large portion of the radiation in this band is due to bound–bound processes and not solely recombination radiation and bremsstrahlung as is usually assumed.**

Introduction

Intense light sources have been the subject of considerable study for many years. Since the invention of the laser there has been a greater emphasis on increasing the efficiency of high-power light sources. Higher efficiency light sources for neodymium glass (and YAG) and iodine photodissociation lasers are of interest because both of these lasers are prime candidates for laser-fusion studies. The net efficiency of these lasers is dependent upon the efficiency of converting electrical energy to radiation in the appropriate laser pump bands. A variety of schemes have been proposed to increase the pump efficiency; for example, dyes that are effectively broad-band absorbers which fluoresce at the pump-band wavelength [1] and the use of an alkali metal vapor in the flashlamp proper [2] where the alkali metal fluoresces in the appropriate pump band.

The goal of the present work is the study and determination of the physical mechanisms pertinent to the spectral efficiency of pulsed high-current gas-filled flashlamps. The spectral efficiency is defined as the ratio of the photon flux in the appropriate pump bands to the total (over all frequencies emitted) photon flux. The primary interest of the present work is the near-UV spectrum, 2500–2900 Å. While many papers and reviews [3], [4] have been published on the subject of flashlamps, some flashlamp phenomena are still not well understood. The complexity and many-faceted aspects of a spark discharge are overwhelming from an analytical viewpoint. Modeling of such a system cannot be seriously considered at present because there are so many processes and as yet undetermined quantities. This last statement is not meant to imply that calculations cannot be done to elucidate certain macroscopic features of such a discharge [5]-[9], but means only that understanding, for example, certain aspects such as the detailed spectral behavior is not, at present, quantitatively possible.

A flashlamp of the sort considered here consists of a highly ionized plasma medium contained in a quartz tube. The maximum intensity available from such a medium is determined by the radiation emitted from a backbody at the plasma temperature.[1] This latter statement is a consequence of Kirchhoff's law and it is applicable when radiative equilibrium applies and there is no net transfer of heat. Its applicability is subject to certain restrictions concerning plasma uniformity and equilibration times ([10] contains an excellent discussion of this question). It will be assumed that Kirchhoff's law is valid for the conditions studied in this work. Consequently, for a given temperature, the maximum radiation within any spectral region is given by the intensity from a blackbody at that temperature, regardless of the makeup of the plasma, i.e., independent of any dopants such as alkali metals. It is important to note that for a given spectral band there is an optimum blackbody temperature that maximizes the percentage of the total radiation appearing in that band. The temperature for maximizing the photon flux from a blackbody in the wavelength band λ_1-λ_2 is given by [11]

$$kT_{\text{opt}} = \frac{(hc/\lambda_2)\,[(\lambda_2/\lambda_1) - 1]}{3 \ln (\lambda_2/\lambda_1)}. \tag{1}$$

For example, if one considers the pump bands of the iodine laser to be from 2500 to 2900 Å, then T_{opt} = 18 000 K, and 8.6 percent of the total photon flux appears in the specified pump band. The neodymium glass laser has pump bands at several locations that result in 1.06-μ laser radiation [12]. It is not possible to maximize all of these bands simultaneously but an approximate maximization results in $T_{\text{opt}} \approx$ 7000 K and 15 percent of the radiation appears in the pump bands. Of course, account must also be taken of the actual quantum efficiency in the absorption bands. Dopants to the flashlamp can increase the brightness of the flashlamp in that they may enhance the coupling between the electrical energy deposited in the gas and the energy radiated. Specifically, they can increase the plasma temperature. They can also radiate preferentially in certain regions of the spectrum.

That high-current gas-filled flashlamps can closely radiate as effective blackbodies within restricted spectral limits has been illustrated by the opacity measurements in [13] and [14]. Additional evidence for the preceding was presented in [15]. In that work it was assumed that the plasma was fully ionized, radiated as a blackbody, and that the source of energy was Joule heating of the plasma. The result was an

Manuscript received May 8, 1975; revised May 15, 1975, and July 28, 1975. This work was supported by the Energy Resource and Development Administration.

The author is with the Sandia Laboratories, Albuquerque, N. Mex. 87115.

[1] One can define a variety of temperatures; however, for the work discussed here only two need be considered: 1) the excitation temperature which is defined in terms of the bound-state population densities; 2) the electron temperature. It is the electron temperature that determines the recombination and bremsstrahlung radiation. As a rule, the excitation temperature is not unique, but in the limit of collisional equilibrium, the excitation temperature equals the plasma electron temperature.

expression for the temperature of such a system [15], [16]

$$T = 603\ (jR^{1/2})^{4/11} \tag{2}$$

where j is the current density in the plasma in amperes · centimeter^{-2}, R is the tube radius in centimeters, and T is the temperature in degrees Kelvin. It was found that this idealization agreed with a number of experiments from different laboratories under a variety of conditions.[2] The temperature in (2) as related to actual experiments refers to the radiation color temperature and in this work will be assumed to approximate the electron temperature.

Experiment

The experiments to be discussed were performed by discharging a 13.8-μF capacitor through a flashlamp. The arrangement is shown in Fig. 1. The inner diameters of the flashlamps ranged from 8 to 16 mm with an interelectrode spacing of 30–35 cm. The gases were one of the following: helium, neon, argon, or xenon. The measurements consisted of recording the current through the discharge and the emitted radiation in the spectral range of 2500–2900 Å. The spectral measurements were done in two ways: 1) by recording the time-integrated emission on type 55 P/N film with a spectrograph; 2) by using a 0.3-m monochromator and on a shot-to-shot basis making measurements over the aforementioned spectral range at specified times after discharge initiation. The monochromator was completely calibrated including measuring the slits with a microscope and checking the instrumental line shape and width as a function of slit width and height. The photomultiplier was an EMI type 9635QB which has a bialkali cathode and a Spectrosil window. All measurements were taken with a 20-μ slit width which corresponded to an instrumental width of 0.24 Å. This slit width was used for the calibrations and experiment so that the illuminated photocathode area was constant. All attenuation of the radiation was done with neutral density filters in order to avoid saturation and detector nonlinearities. The neutral density filters were calibrated on a Cary 14 spectrophotometer. The Corning 7-54 filter eliminated scattered visible radiation in the monochromator. The wavelength calibration of the optical system (including the monochromator–photomultiplier combination) was done by utilizing an irradiance standard (a General Electric quartz iodide 200-W lamp) and a photodiode (EMP Model 543-09-00) calibrated absolutely at 2537 Å. The irradiance standard was used for relative spectral calibration while the calibrated photodiode was used for the absolute calibration. Thus the relative spectral calibration in the spectral band of interest and an absolute calibration at 2537 Å result in an absolutely calibrated system at each wavelength. The precision of the spectral measurements is estimated to be ±12 percent. (This precision accounts for the uncertainties in the irradiance standard, the calibrated photodiode, the errors introduced in the system calibration, and experimental reproducibility.) The discharge current was monitored with a calibrated current-viewing resistor. The current temporal shape was approximately triangular, reaching its peak in 1[illegible] μs with a base of about 30 μs.

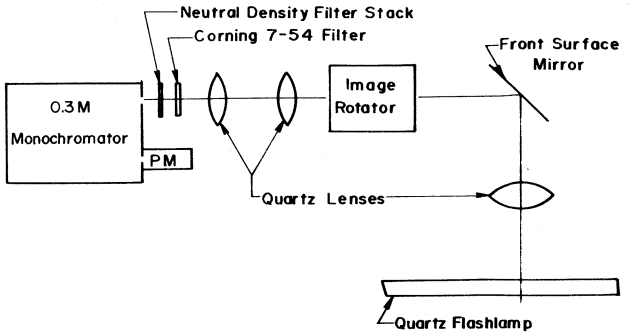

Fig. 1. The experimental arrangement utilized for spectral observations.

Results

A typical result is shown in Fig. 2. (Notice that the brightness is per unit surface area of the flashlamp.) From these types of data it was concluded that nominally (4.50 ± 0.54 percent) of the capacitor-bank energy appeared as radiation in the range 2500–2900 Å. In order to obtain the total emitted radiation it was assumed that the flashlamp radiated uniformly in both the azimuthal as well as the axial direction. To test the accuracy of this assumption would require reasonably extensive high-speed photographic measurements (as a function of flashlamp parameters) which were not available for this experiment. A measurement of the plasma resistivity was consistent with a temperature of 21 000 K (assuming the plasma to be fully ionized [16]) while (2) predicted 24 000 K. A blackbody at this temperature would radiate about 6.7 percent of its total energy in this wavelength range. If one asks for the optimum percentage of energy radiated in th[illegible] interval, then the number is about 10.5 percent at a blackbody temperature of about 14 000 K. It is important to point out that (1) is obtained by maximizing photon flux and not energy. If one seeks to optimize the blackbody photon flux in the specified bandpass, (1) predicts $T = 18\,000$ K as being the appropriate temperature. The experiment indicates that the intensity for a typical xenon-filled flashlamp is within a factor of 3 (except in the vicinity of 2500 and 2800 Å) of a blackbody (at a temperature of 24 000 K) in this spectral range.

Fig. 3 shows a comparison of the radiation from xenon and argon discharges (on a relative scale) for nominally the same current. The main difference is in the spectral intensity distributions at the shorter wavelengths. On an absolute scale, xenon is brighter than argon. Fig. 4 shows the effect of increasing the argon pressure at about the same discharge current level. Again, the prime effect is to enhance the intensity of the shorter wavelengths. This short wavelength enhancement compared to longer wavelengths is likely due to the fact that the longer wavelengths approach the blackbody limit before the shorter wavelengths as pressure and current are increased. This last statement could be recast into a discussion concerning the absorption as a function of wavelength [18], [19].

[2] In [17] experimental measurements coupled with the radiant emittance of a blackbody yielded an expression $T = 1435\ (jR^{1/2})^{2/7}$. This expression and (2) differ by about 12 percent for the conditions of the present work.

The UV spectral efficiency measured in this work is consistent with the results of [20] and [21].

It has been noticed that a double discharge technique [22] seems to produce enhanced efficiencies for UV emission. The double discharge technique utilizes a long (duration) relatively low-current discharge which is followed, after some time, by a short high-current discharge. Although there is no quantitative information concerning the physical mechanisms involved, the enhancement may be due to several effects, among which are: 1) metastable atoms produced by the weak (simmer) discharge; 2) UV photons produced by the simmer discharge [23]; or 3) a diffuse plasma produced by the simmer. The results of an experiment are shown in Fig. 5 in which the light output around 2800 Å was measured both with and without the simmer discharge. An interference filter with a center wavelength of 2800 Å and a bandpass of 200 Å was used for this latter experiment. It can be seen that the enhancement produced by the simmer is less at higher main-discharge peak currents. (The simmer current at the time of the main-discharge peak current was 10 A.) Shown in Fig. 6(a) and (b) are the spectra (uncorrected for film response) for a helium discharge with the main discharge only and the simmer discharge only. The strong emission lines in the simmer spectra and the absorption lines in the main-discharge spectra are due to silicon from the walls [4].

The data discussed previously establish that the emitted radiation is within a factor of 3 (in the near UV) of an equivalent blackbody at a temperature determined by the discharge current density [(2)]. For laser excitation purposes, it would be beneficial to increase the radiation up to the blackbody limit without utilizing higher capacitor-bank energies. In order to evaluate how this can be accomplished, it is necessary to evaluate the physical mechanisms producing the radiation. Fig. 7 is a photograph of a xenon spectrum. This picture represents the time-integrated flux (over a 30-μs interval). The presence of some strong absorption lines upon what

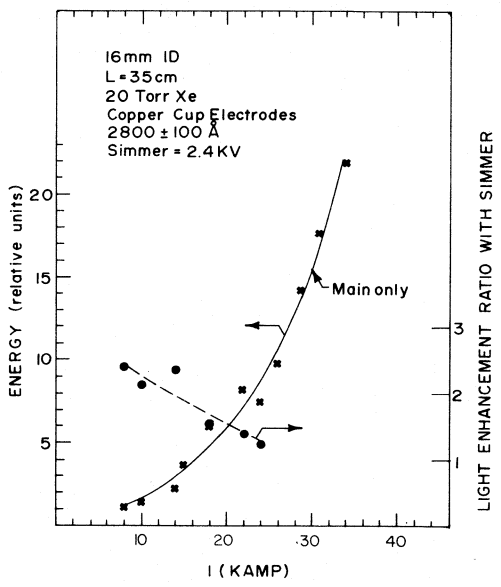

Fig. 5. The energy from a xenon-filled flashlamp (without a simmer discharge) and the light enhancement in a band centered at 2800 A due to applying a simmer discharge.

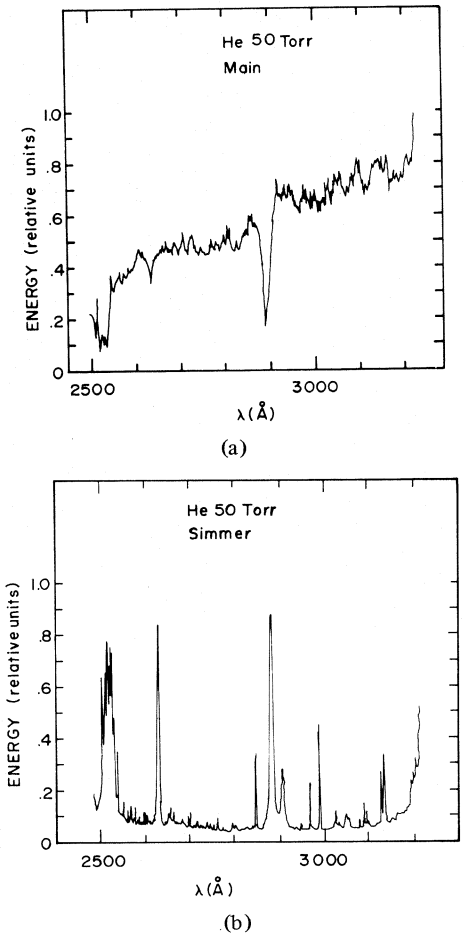

Fig. 6. (a) The spectra (uncorrected for film response) from the main discharge. (b) The spectra (uncorrected for film response) from the simmer discharge.

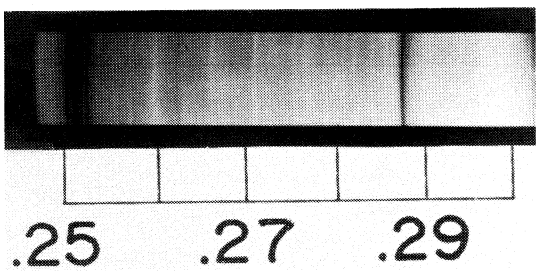

Fig. 7. A photograph of a xenon spectrum emanating from an 8-mm-ID flashlamp filled to 20 torr and 8-mm ID. The current pulse is about 30 μs long and has a peak of 20 kA. The wavelength is indicated in microns.

appears to be a continuum dominates the spectrum. The absorption lines are all due to silicon from the quartz inner surface (depending upon the discharge conditions, these absorption lines can also appear in emission). The data of Fig. 2 were taken at discrete wavelength intervals and then connected with straight lines. Except at points where line radiation is located, this procedure seems reasonably justified (in view of the time-integrated spectrogram). With a few exceptions this "continuum" has been designated in many works as being due completely to recombination and bremsstrahlung radiation. For the temperatures with which one is typically concerned in xenon-filled flashlamps (≈2-3 eV), the contribution of bremsstrahlung is small and the primary mechanism for producing continuum radiation is due to two-body radiative recombination. The continua due to bremsstrahlung and recombination are given by the following equation [24]:

$$\epsilon(\nu, T) = 6.3 \times 10^{-47}(kT)^{-1/2} N_e \sum_{i=1}^{\infty} N_i Z_i^2 \xi_i(\nu) \text{ erg} \cdot \text{s}^{-1} \cdot \text{cm}^{-3} \cdot \text{sr}^{-1} \cdot (\text{s}^{-1})^{-1} \quad (3)$$

where T is the electron temperature in degrees Kelvin, N_e is the electron density in units of cm^{-3}, N_i is the ion density of the ith ionization stage, and ν is the frequency. The radiation brightness $\epsilon(\nu, T)$, is a function of ν through the function $\xi_i(\nu)$ which accounts for deviations from a hydrogenic atom. The function $\xi_i(\nu)$ has been calculated [24] with a number of simplifying assumptions. The continuum calculated in [24] has a smooth character which is not in complete agreement with the jagged appearance predicted by more exact calculations and experiments concerning recombination radiation. It was also shown in [24] that the function $\xi(\nu)$ for ions of the same element but of different ionization stages approaches unity with increasing Z, i.e., the system becomes more hydrogenic. With increasing Z it is found that $\xi(\nu) \to 1$, but not monotonically. Equation (3) assumes that the lowering of the ionization potential and the shift of the photoionization threshold due to the presence of the plasma may be neglected. The derivation of (3) also assumes the validity of Kirchhoff's law as well as Saha equilibrium.

It is possible to predict T from (2) and it remains to find N_e and N_i. A reasonable approach to estimating N_e is via the Stark broadening of selected plasma spectral lines. In the case of xenon, there is not adequate information available to do this. The next option is to add the appropriate impurities and measure their spectral widths. Helium was added; however, due to the considerably lower ionization potential of xenon the helium was not excited (to within the sensitivity of the measurement). Hydrogen was added (about 2 percent) and an attempt was made to look at H_α and H_β emission. However, H_β was too weak relative to the continuum, and H_α, while stronger, was in the close proximity of silicon lines. It was not possible to use the silicon lines because they were not emitted from the volume but rather from the vicinity of the plasma-quartz interface and under appropriate conditions appear as absorption lines rather than emission lines.

As an approach to estimating the degree of ionization for the xenon discharge, a helium discharge was looked at under conditions of the same tube size, gas pressure, and capacitor energy. The peak current in the helium discharge was 30 kA and was underdamped. The peak current in the xenon discharge was 20 kA and was only slightly underdamped compared to the helium discharge. The current in the helium discharge peaked at 10 μs after initiation of the discharge and it was not possible to make a measurement until 20 μs due to a delay in the emission of HeI radiation. At this time, the spectral half-width of the HeI 5876-Å line was measured to be ≈20 Å which corresponded to 5.5×10^{17} electrons $\cdot$ cm^{-3}

[25]. (The instrumental width was 0.24 Å while the maximum Doppler width is estimated to have been 0.3 Å. Both were neglected and the measured width was taken to be due to Stark broadening.) At 40 μs the half-width was 16.5 Å with a shift of about 1.5 Å to the blue. The width measurement corresponded to 4.6×10^{17} cm^{-3} while the displacement corresponded to 4.2×10^{17} cm^{-3}. At an initial pressure of 20-torr helium and completely stripped helium atoms, the maximum electron density would be 1.3×10^{18} cm^{-3}. However, for electron temperatures of several electron volts, one does not expect significant quantities of HeIII (doubly ionized helium). If thermal equilibrium prevailed, Saha equilibrium would predict an electron density (and HeII) of 5.0×10^{17} cm^{-3} at an electron temperature of 28 000 K. (For the peak current in the helium discharge, (2) predicts 28 000 K.) For the xenon medium and a temperature of 24 000 K, Saha thermal equilibrium would predict the dominant heavy species to be XeII and XeIII. Again, one can place an approximate upper limit to the electron density which would be about 1.3×10^{18} cm^{-3}. It is to be expected on the basis of the ionization potentials that a xenon plasma would result in a higher electron density than a helium plasma under the same conditions. Consequently, it seems reasonable to place the electron density for the xenon plasma near the time of peak current between $5.0\text{-}13 \times 10^{17}$ cm^{-3}. If one considers the plasma to be in approximate thermal equilibrium, then the Saha relationship would predict $N_e = 9.0 \times 10^{17}$ cm^{-3} for $T = 24\,000$ K (i.e., the plasma is essentially fully ionized). So, assuming the plasma to consist of only XeII and XeIII ions ($N_e = \Sigma N_i$), it is found that the energy predicted to be radiated in the wavelength range 2500-2900 Å is 4.3 J. In calculating this quantity $\xi_i(\nu)$ was taken to be three [24]. This value is for neutral xenon and, as stated in [24], the higher stages of xenon ionization will have values of $\xi(\nu)$ closer to unity. The flashlamp was assumed to radiate from the whole tube volume, i.e., a cylinder 8-mm ID and 30 cm long. It has been assumed that over the time considered the electron density follows the discharge current. On this basis, 4.3 J is an approximate upper limit. It is to be noted that experimentally the continuum contributed 56 J for the wavelength range 2500-2900 Å. There is a discrepancy between the calculations and experiment of a factor of 13. Of course, there are a number of assumptions concerned with the calculations and the interpretation of the experiment, and consequently, it is not clear exactly how large the discrepancy actually is. In [26] there was a considerable discrepancy between electron densities interpreted from continuum and line-broadening measurements (the former predicted higher densities than the latter); [27] noted similar discrepancies. The results of [26] and [27] are consistent with those of the present work.

Consider Fig. 8, which is a schematic of the xenon line spectra in the near-UV regions of interest. All the lines indicated are due to XeII and XeIII which is consistent with the foregoing estimate of the ion makeup of the plasma at 24 000 K. Also consider that it is usual at the plasma densities and temperature nominally of interest that lines may be broadened from 10 to 100 Å and shifted by several

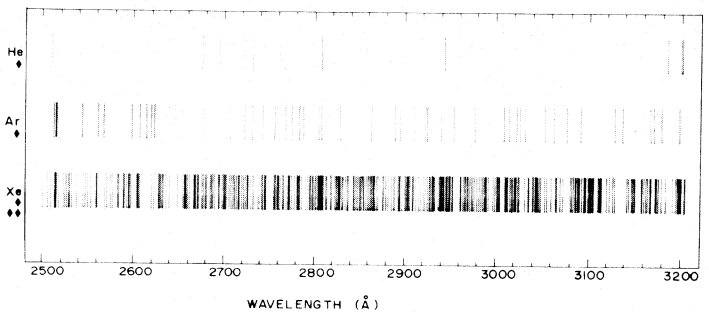

Fig. 8. A schematic representation of the location of the spectral line radiation for several important atoms. ♦ indicates [32], ♦♦ indicates [33] and [34].

angstroms. All of this, taken with the present discrepancy between calculation and experiment and the discrepancies noted in [26] and [27], strongly suggests that the so-called continuum is not due solely to free-free and free-bound processes, but a considerable portion may be due to bound-bound processes [3], [27]-[30], with the usual discrete appearance smeared out. The schematic representation of Fig. 8 cannot be taken by itself. These atoms are all capable of forming diatoms [23], [31] and, as such, one can expect molecular emission which, due to the strong plasma fields, will be very diffuse. Upon consideration of spectral broadening and displacement only, it is evident why one might expect He and Ar not to produce as bright a continuum as Xe. (It must be noted that the calculations presented in [24] would predict the same relative behavior for these gases on the basis of continuum emission alone.) Consequently, we have a situation where line radiation evidently contributes a large portion of the radiation. (The calculations presented in [29] and [30] substantiate these results.) This gives a hint as to how one might enhance the near-UV spectral efficiency. In particular, dopants that have strong and/or plentiful line spectra in this region can be used to increase the line radiation in the wavelength band of interest. The spectral enhancement produced by dopants has been demonstrated [35] which lends support to the thesis concerning the contribution of line radiation to the near-UV spectrum.

Conclusion

The limiting spectral efficiency of flashlamps used to pump lasers is determined by the emission from a blackbody at the same temperature as the flashlamp plasma. The results of such considerations are: the maximum spectral efficiency for pumping an iodine photodissociation laser occurs for an electron plasma temperature of 18 000 K with 8.6 percent of the total photon flux appearing in the pump band (2500-2900 Å). Similar considerations for the limiting efficiency of a neodymium glass laser result in a required plasma temperature of approximately 7000 K with 15 percent of the radiation appearing in the pump bands.

The double-discharge technique of Emmett and Schawlow [22] was investigated. The results of this study indicate that there is indeed an enhancement of the near-UV emission when utilizing a double discharge; however, the enhancement is dependent upon the relative magnitude of the simmer- and

main-discharge currents. Specifically, the enhancement ratio decreases (at fixed simmer current) with increasing main-discharge current.

Absolute measurements of the emission spectra and consideration of the origins of the radiation suggest that a large percentage of the near-UV emission in typical xenon-filled flashlamps is line radiation rather than continuum radiation due to bremsstrahlung and two-body radiative recombination as is usually assumed. The flashlamps studied in this work were typified by discharge current densities of 40 kA · cm^{-2} and electron temperatures of 24 000 K.

A High-Power Pulsed Xenon Ion Laser as a Pump Source for a Tunable Dye Laser

LAIRD D. SCHEARER

Abstract—**An inexpensive pulsed xenon ion laser with peak power outputs up to 4 kW has been constructed and used as a pump source for a tunable rhodamine 6G dye laser with a 0.25-Å bandpass in the yellow-red range of the spectrum. The dye laser is tunable from 5465 to 6300 Å. Over 50 W are obtained at the peak of the tuning range.**

I. Introduction

THERE has been considerable recent interest in the pulsed xenon ion laser [1]-[4]. The interest stems primarily from the simplicity of a high-gain laser system which is capable of relatively high peak power emission in the blue-green region of the spectrum accompanied by relatively long pulsewidths. We have investigated the properties of a high-power pulsed xenon ion laser and its use as a pump source for a tunable dye laser. Peak pulse powers of 4 kW and pulse durations up to 1 μs have been obtained in a 120-cm X 4-mm xenon discharge at pressures between 5 and 30 m · torr. The high peak power available in the xenon laser has enabled us to use it as a pump source for a rhodamine 6G dye laser which is tunable from 5465 to 6300 Å with a 0.25-Å bandwidth. At the peak of the dye laser output, ~ 5750 Å, we obtain over 50 W of peak power with 500-ns pulsewidths.

In the sections following we describe the operating characteristics of our pulsed xenon laser and its use as a pump source in the design and construction of the tunable dye laser system.

II. Xenon Ion Laser

Data obtained in earlier work on this type laser system are summarized in Table I along with the results of our work. It is important to note that, based on the volume of the excited gas, the work reported here represents a substantial improvement in both the peak pulse power and pulse duration obtained. In particular, we compare the results of our work with that of Hänsch *et al.* [3]. It was the report of their work on the xenon laser and dye laser that provided the initial motivation for the work we report here. The particular aspect of the Hänsch *et al.* work which attracted our attention was the low construction cost and simplicity of design of the xenon laser and the dye laser system.

The only work which reports a higher peak power than that reported here is that of Gundersen and Harper [4] who obtained approximately 80-kW peak pulse power. Their laser tube, however, was over 10 ft in length with a bore area approximately 20 times greater than the one we used.

TABLE I
SUMMARY OF RECENT WORK ON PULSED XENON ION LASERS

Workers	Active length (cm)	Bore diameter (mm)	Total Peak Power (W)	Pulse width μs
Hoffmann and Toschek[1]	175	5.0	380	0.6 - 1.5

This work	120	4.0	4,000	0.1 - 1.5

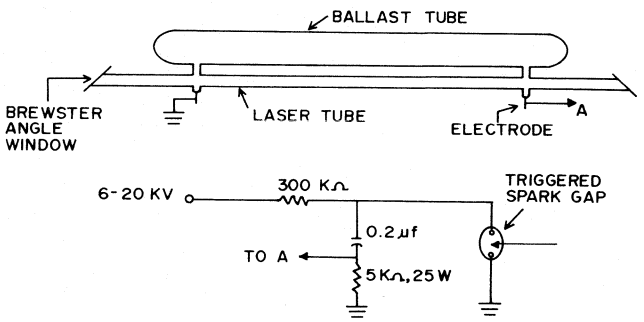

Fig. 1. Pulsed xenon ion laser and electrical discharge circuit.

The active length of the discharge tube was 120 cm with a bore diameter of 4 mm. The laser tube length was supplemented by an additional 25 cm at each end between the internal electrodes and the windows which terminated the laser tube. The electrodes are high-current indium cathodes constructed by melting pure indium metal around the tungsten electrodes [5]. The additional spacing between the electrodes and Brewster windows was provided to reduce the possibility of window contamination by sputtering of the metal at the electrodes. The laser tube also included a ballast tube as shown in Fig. 1.

We utilized a number of electrical circuits for the pulsed excitation of the laser discharge tube. The first method and probably the simplest we utilized was that described by Hänsch *et al.* in their report on the xenon laser [3]. The power supply consisted of a 15-kV 60-mA high-voltage transformer of the type used to excite neon signs and a bank of twenty-two 500-pF capacitors connected across the transformer terminals and laser electrodes. In this condition the laser tube discharged at a 120-Hz rate, i.e., on each half-cycle.

With an 80-percent output reflector in place we obtained

Manuscript received June 16, 1975. This work was supported in part by the Air Force Office of Scientific Research under Contract 2672, and in part by the Office of Naval Research under Contract N00014-75C-0477.

The author is with the Department of Physics, University of Missouri at Rolla, Rolla, Mo. 65401.

results identical with those reported by Hänsch *et al.* [3]. There were eight visible lines observed in laser emission ranging from the violet at 4306 Å to the orange at 5956 Å. The maximum peak power output obtained was 300 W with laser pulsewidths up to 350 ns.

With the circuit described previously the pulse repetition rate was erratic with many skipped pulses. We had additional difficulty with periodic failure of the doorknob capacitors. As a result of these difficulties we abandoned this excitation method and constructed a spark-gap-triggered discharge. The important features of the spark gap are its exceptionally low inductance, its capacity for holding off high voltages, and when it does break down, its capacity of transferring large quantities of electrical charge. Our triggered spark gap has properties similar to those of commercial manufacture.

The capacitive discharge circuit is shown as part of Fig. 1. When the properties of the laser system were evaluated with this circuit we obtained a substantial increase in both peak power and laser pulse duration.

The peak pulse power obtained and the pulsewidth as a function of the charging voltage on a 0.2-μF capacitor are shown in Fig. 2. These data were obtained when the laser pressure was optimized for maximum power. Table II summarizes typical peak powers obtained for seven of the eight observed transitions.

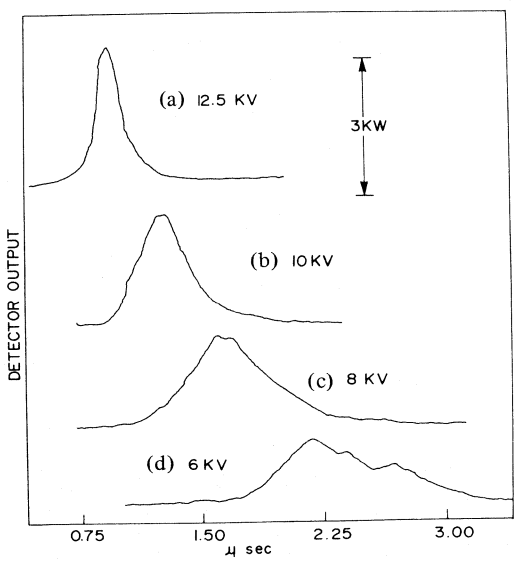

Fig. 2. Laser pulse shapes obtained at various charging voltages for a 0.2-μF capacitor. The curves were obtained with a high-speed silicon photodiode and a PAR boxcar integrator. The scale shown on the horizontal axes represents time delays after a trigger pulse is applied to the spark gap.

TABLE II
PEAK POWER ON OBSERVED LASER LINES

Wavelength (Å)	Peak power (watts)
5956	110
5395	480
5353	800
5260	680
5190	250
4954	800
4306	50

This laser system was capable of repetition rates from single shot up to 30 Hz. The upper limit is determined by the present capacity of our power supply. From the energy-per-pulse measurement and the repetition rate one can obtain the *average* laser power output. The highest average power we obtained was approximately 20 mW.

The data shown were obtained with an 80-percent broadband reflecting output mirror. In an effort to determine the optimum output coupling we repeated the power measurements for output mirror reflectivities of 98, 50, and 20 percent. At 98 percent, the power output was reduced by a factor of 2. At 20 percent the output power was down an order of magnitude, while with the 50-percent mirror similar results were obtained. We thus conclude that the mirror reflectivity required for optimum power output lies between 50 and 80 percent.

The availability of substantial laser output power even with mirrors which transmit 80 percent of the incident optical energy is an indication of the relatively large gain of several of the laser transitions. This in turn suggests that relatively lossy elements can be inserted in the optical cavity while still maintaining laser action. As a next step in this work the addition of a nonlinear crystal in the optical cavity is planned to attempt intracavity frequency doubling of the Xe ion laser emission.

III. The Tunable Dye Laser Cavity

Several dye laser cavitites have been developed in the past for use in CW dye laser applications. In these systems one needs a cavity design which provides an intracavity focus to meet the pumping requirements. In CW systems pump power is at a premium and the pump beam is generally focused to a small spot to provide a high energy density within the dye. One also desires a long cavity length as well, for tuning purposes.

Cavity configurations which satisfy these requirements are resonators with an internal lens or the equivalent three-mirror cavity [6].

Hänsch *et al.* constructed a three-mirror resonator and pumped the dye with the output of their pulsed xenon ion laser. With rhodamine 6G dye they obtained 12 W of peak power at 5700 Å. The resolution of the dye laser emission they reported as <100 Å. However, they did not include a frequency-selective element inside the dye laser cavity. Consequently, the dye laser output was not tunable and their laser output had poor resolution.

The three-mirror resonator of [6] was modified slightly by replacing the flat mirror (1) by a 1200-l/mm grating in Littrow mount as shown in Fig. 3. Mirrors 1 and 2 are highly reflective over a broad band and have radii of curvature of 5 and 10 cm, respectively. When the mirrors are separated by 10 cm there is a tightly focused spot at the center of the 2 mirrors. At this point a cell of thickness 1 mm containing a 10^{-3} M solution of rhodamine 6G dye in ethanol is inserted at Brewster's angle. The dye is contained in a sealed cell. It

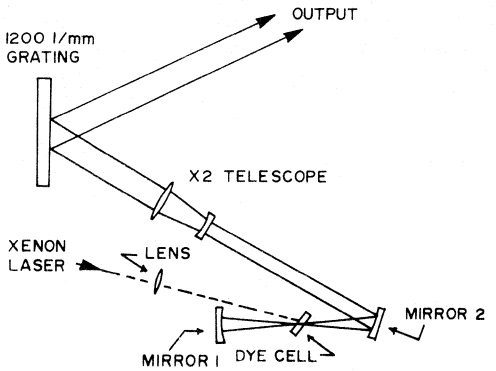

Fig. 3. The astigmatic dye cavity. A 1200-l/mm grating is used as the output reflector.

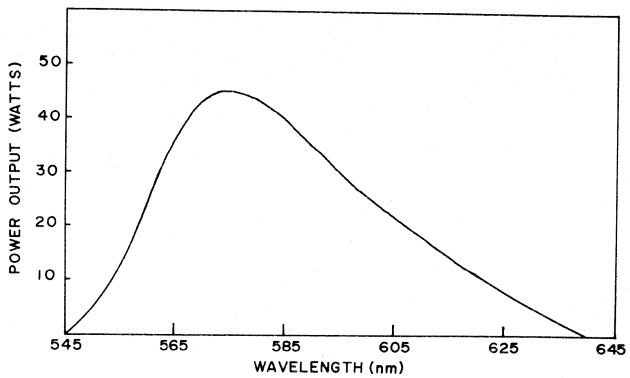

Fig. 4. Power tuning curve for rhodamine 6G. Bandwidth is less than 0.25 Å over entire range. Pulsewidth is 350 ns. Pump power is approximately 1.6 kW.

was found unnecessary to flow the dye. The grating is located 25 cm from mirror 2. A two-power telescope is used inside the cavity as shown to expand the beam on the grating.

The xenon ion laser light is focused on the dye cell by a 20-cm fL spherical lens as shown. When properly adjusted the dye system lases with no difficulty. The dye output is taken from the zero-order diffraction from the grating which was blazed for 5000 Å. No system degradation over many days was observed by using a sealed dye cell containing 0.1 ml at repetition rates to 30 Hz.

With the dye laser system described in the preceding section pumped by our xenon ion laser we were able to obtain substantially higher peak power outputs from the dye laser than that reported by Hänsch *et al.* In addition, the presence of the grating permits tuning of the dye laser output and results in a much higher resolution of the laser emission.

Our tuning width with rhodamine 6G ranged from approximately 5465 to 6300 Å, with a bandwidth of less than 0.25 Å. The peak output power at the center of the tuning range was 50 W. The dye laser pulsewidth was slightly shorter (~20 percent) than the xenon pump pulse. The power tuning range we obtained for rhodamine 6G is shown in Fig. 4. The dye laser gain pumped by the xenon laser is sufficiently great that the system lases even when a clear quartz plate is used as the output reflector.

This is the first reported instance of a tunable dye pumped by a repetitively pulsed xenon ion laser. Without the telescope, the dye laser bandwidth was about 2 Å with a peak power output of 100 W at the center of the tuning range.

Rhodamine B dye was used also; contrary to expectations it did not provide operation further into the red than rhodamine 6G. This may be more a property of the dye mirrors and grating used which were standard commercial reflectors for rhodamine 6G than any inherent difficulties with the pumping source.

The attractive features of this xenon pumped dye laser are the relatively high repetition rates and the relatively long pulsewidths available in a simple, inexpensive system. The 0.25-Å bandpass obtainable with the grating telescope combination should make this a valuable tool in atomic spectroscopy. We also note that a considerable improvement in the efficiency of the system and the bandwidth should be possible by using coated optics in the telescope and, in general, by upgrading the quality of the components.

Electrooptic Q Switching of the Nd:YVO_4 Laser Without an Intracavity Polarizer

MICHAEL BASS

Abstract—**An explanation of the excellent Q-switched lasing of Nd:YVO_4 at pump levels many times threshold with no intracavity polarizer is presented. A small wedge between the laser rod's end faces, coupled with the material's high birefringence, enables the rod to act as its own intracavity polarizer. This results in a simplification of the Q-switched optical resonator and can be applied to other birefringent laser materials.**

Pulse-pumped Nd:YAG lasers are often Q switched using the Pockels-cell–Glan-polarizer combination shown in Fig. 1(a). Since the host material is optically isotropic, both the Pockels cell and the Glan polarizer must be placed in the optical cavity to prevent premature lasing or prepulsing. As indicated in Fig. 1(a), when the voltage applied to the Pockels cell produces a one-quarter-wave, $\lambda/4$, phase retardation at the laser wavelength, the light reflected from the 100-percent R-cavity mirror enters the Glan polarizer polarized so that it is not transmitted. The combination of intracavity Pockels cell and Glan polarizer thus spoils the cavity Q by isolating the 100-percent R mirror from the optical resonator. When the voltage applied to the Pockels cell is reduced to zero, there is no phase retardation, the cavity Q is restored, and an intense Q-switched pulse of laser light is produced.

A significant simplification of the Q-switched laser could be achieved if the optical resonator did not require an intracavity polarizer for prepulse-free operation. This was attempted by McClung and Hellwarth [1] for a ruby laser and by Weber *et al.* [2] for a Nd:$YAlO_3$ laser. In both of these referenced cases, the authors attempted to use the anisotropic properties of the laser gain in a crystalline host to prevent premature oscillation in the laser cavity.

Consider a laser cavity where the active medium has gain for light polarized in one direction only. After two complete round trips through this cavity with no intracavity polarizer and $\lambda/4$ voltage applied to the Pockels cell [see Fig. 1(b)], a condition for oscillation can be reached. If this condition

$$(R_1)^2 \exp(2\beta_H l) = 1$$

is met, there will be prepulsing. Here R_1 is the output mirror reflectivity, β_H is the net laser gain [β_H is assumed to be zero for light polarized normal to the figure in Fig. 1(b)], and l is the length of pumped medium. At threshold for lasing with no voltage applied to the Pockels cell, the oscillation condition is

$$R_1 \exp(2\beta_{Th} l) = 1.$$

Thus $\beta_H = 2\beta_{Th}$ and so no holdoff is possible at pump levels which produce a gain equal to twice that at threshold. This is in agreement with the results in [1] and [2]. Recently, however, prepulse-free electrooptic Q switching of Nd:YVO_4 with no intracavity polarizer was reported at pump levels as high as eight times threshold [3] (see Fig. 2). Since the anisotropic gain of the laser crystal cannot account for such excellent performance, the explanation must lie elsewhere.

Manuscript received June 25, 1975. This work was supported by the U.S. Army Electronics Command under Contract DAAB07-74-C-0104.

(b) A Pockels cell only in a cavity which has a strong polarization-dependent gain. (c) A Pockels cell in a cavity where the laser rod is slightly wedged and strongly birefringent.

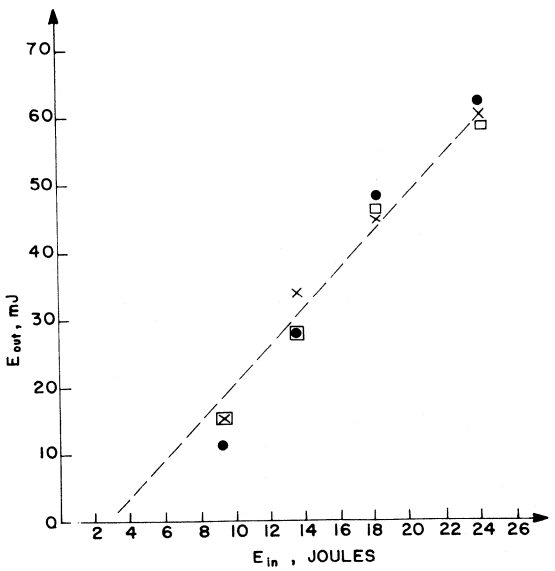

Fig. 2. Q-switched laser output versus input energy from Nd:YVO_4 using a Pockels-cell Q switch and no intracavity polarizer. The output reflector was 3 percent R at 10.6 μm. × indicates Pockels-cell Q-switched data. • indicates long-pulse lasing with Pockels cell in cavity. □ indicates long-pulse lasing, empty cavity. Rod dimensions were 3 × 30 mm, and a small gold-plated single-ellipse pump cavity was used. This figure is reproduced from [3].

The Nd:YVO_4 laser rod studied in [3] was inadvertently polished so that its flat end faces were wedged with respect to each other by $\sim 6 \times 10^{-3}$ rad. This, coupled with the very strong birefringence of the YVO_4 host ($n_O = 1.958$ and $n_e = 2.168$ at 1.06 μm^3), permitted the laser rod to act as its

own intracavity polarizer. To understand the importance of the wedge between the rod faces consider that if the flat, 0.25-percent R faces had been parallel, laser action would have occurred between the rod faces at pump levels ~3.5 times that required for lasing in the main optical resonator. Since no oscillations at all were reported with the optical-cavity mirrors misaligned, the wedge between the rod faces is sufficient to prevent unwanted lasing, and therefore is a critical factor in determining the properties of the Nd:YVO_4 laser.

Suppose, for simplicity, that the face of the rod nearest the 100-percent R mirror was normal to the rod axis and that the other face was misaligned by the wedge angle (6×10^{-3} rad) [see Fig. 1(c)]. Since the cavity mirrors were aligned for best long-pulse lasing, they were oriented so that light polarized parallel to the direction having maximum gain propagated parallel to the rod axis. In [3] the rod was nominally cut with its axis parallel to the crystalline a axis and, since maximum gain in Nd:YVO_4 occurs for light polarized parallel to the optic axis, light which propagated as an extraordinary ray in the laser rod was that which could oscillate.

When the Pockels cell voltage was on, light reflected from the 100-percent mirror entered the rod as an ordinary ray. As it left the Nd:YVO_4 rod it was not refracted far enough to be normal to the output mirror, and so no premature oscillations were possible. For the wedge angle of 6×10^{-3} rad of the Nd:YVO_4 laser rod in [3], the extraordinary ray would have been refracted by 14×10^{-3} rad and the ordinary ray by 11.8×10^{-3} rad. The resulting 2.2×10^{-3} rad (0.126°) misalignment would have been sufficient to prevent prepulsing, and thus explains the excellent results reported.

The observation that a suitably birefringent laser crystal can be prepared so that it can act as its own intracavity polarizer for electrooptic Q switching can lead to great simplification in Q-switched laser systems. This was demonstrated in the present correspondence for Nd:YVO_4, and can be adapted to the design of other birefringent laser crystals.

3547-Å Pumped Parametric Oscillation in RD*A

K. KATO

Abstract—**Efficient parametric oscillation in a deuterated rubidium dihydrogen arsenate (RD*A) crystal has been achieved by pumping with the third harmonic of a Nd:YAG laser. A peak power as high as 1.2 MW at 7095 Å and peak powers in excess of 0.5 MW from 6470 to 7850 Å have been obtained.**

Manuscript received July 7, 1975.

The author is with the 1st Research Centre, Japan Defence Agency, Nakameguro 2-2-1, Meguro, Tokyo, Japan.

It has been reported by Adhav and Wallace [1] that a deuterated rubidium dihydrogen arsenate (RD*A) crystal is 90° phase matchable for frequency doubling of dye-laser radiation at 7000–7100 Å. A frequency-tripled Nd:YAG-laser radiation at 3547 Å can be, in principle, used to pump parametric oscillators using the same nonlinear crystal with a 90° phase-matching condition. In this correspondence we wish to report the first observation of parametric oscillation in RD*A pumped by the third harmonic of a Nd:YAG laser.

The 25.5-mm-long 45°z 90°y-cut RD*A crystal used in this experiment was supplied from Quantum Technology Ltd., and they estimate that the degree of deuteration in RD*A is approximately 90 percent. Measurements of the transmission curves of this crystal were made by a Hitachi FPS-3T spectrophotometer. The 50-percent transmission range was approximately from 2700 to 14 800 Å. The transmission loss at 10 642, 5321, and 3547 Å was measured by means of the fundamental, second, and third harmonics of a Nd:YAG laser. The absorption loss per centimeter was approximately 5 percent at 10 642 Å, 2 percent at 5321 Å, and 5 percent at 3547 Å which are similar to the values reported for a normal RDA crystal [2].

Fig. 1 is a schematic diagram of the experimental setup. The basic pump source was a repetitively Q-switched Nd:YAG oscillator–amplifier system working in the TEM_{00} transverse mode and in 2–4 axial modes with a peak power of 50 MW and 12-ns pulse duration. The 10-ns 22-MW second-harmonic radiation at 5321 Å generated from a temperature-tuned deuterated cesium dihydrogen arsenate (CD*A) crystal [3] was frequency mixed with the transmitted fundamental radiation in a rubidium dihydrogen phosphate (RDP) crystal [4] orientated for type-1 phase matching at room temperature. The third-harmonic radiation at 3547 Å was characterized by a peak power of 11 MW and 8-ns pulse duration. The spatial profile of the 5-mm-diam third-harmonic beam was close to Gaussian having an angular divergence of 0.95 mrad. As shown in Fig. 1, the third-harmonic beam was physically separated from the fundamental and second harmonic by a fused-silica prism and was used to pump the temperature-controlled RD*A parametric generator crystal through a high-quality Glan polarizer incorporated in the 8-cm-long optical cavity and the output beam was coupled through an uncoated sapphire etalon. A flat, dielectric-coated rear mirror had 99.9-percent reflectivity from 5600 to 8200 Å. The effective pump power incident on the generator crystal was 7 MW. Since a single-pass parametric gain greater than 11 is necessary for the oscillator to reach threshold, due to the 86-percent output coupling of sapphire etalon and the 20-percent transmission loss through the Glan polarizer and RD*A crystal, the pump-power density at the generator crystal was increased up to 200 MW/cm^2 by means of an inverted telescope having an angular magnification of 2.5.

The output wavelengths of the oscillator were analyzed by a 1-m-grating spectrograph when the crystal temperature was varied from 97 to 110°C. Fig. 2 shows the resulting

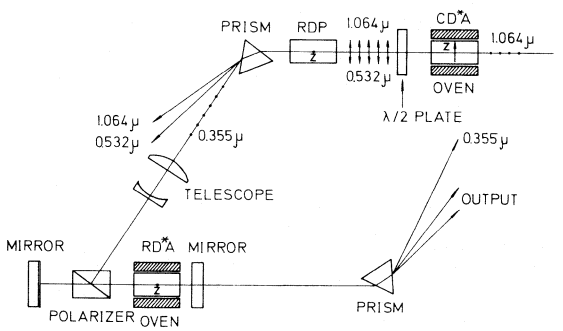

Fig. 1. Schematic diagram of experimental setup.

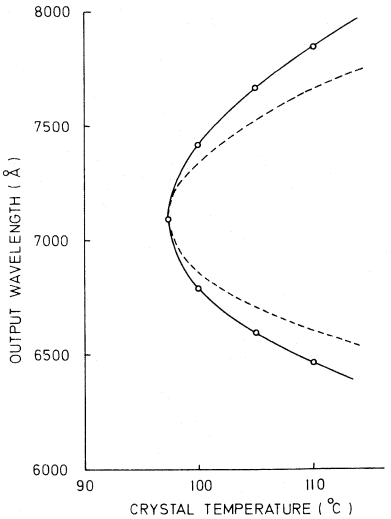

Fig. 2. Temperature tuning characteristics for the RD*A parametric oscillator pumped by 3547-Å radiation. The dashed line is the theoretical curve.

temperature-tuning curve of the RD*A parametric oscillator measured with constant pump power of 7 MW and a pulse repetition rate of 10 pulses per second (pps). The dashed line is the theoretical curve calculated from

$$\Delta\omega = k(\Delta T)^{1/2} \tag{1}$$

where

$$k^2 = (\omega_p/2)(d(n_p^e - n_s^o)/dT)/(dn_s^o/d\omega) \tag{2}$$

ω_p is the pump frequency, and n_p and n_s are the refractive indices at pump and signal, respectively. The parameters used for calculation are $\omega_p = 2.82 \times 10^4$ cm^{-1}, $d(n_p^e - n_s^o)/dT = 1.2 \times 10^{-5}$ °C^{-1}, which was deduced from the temperature bandwidth of the second-harmonic tuning curve of dye-laser radiations, and $dn_s^o/d\omega = 2 \times 10^{-6}$ cm^{-1}, which was extrapolated from the data on the refractive indices reported by Adhav [5]. The lack of agreement between theoretical and experimental curves is probably due to the difference in thermal gradients between the optical region in the crystal and the oven. The spectral bandwidth of the oscillator output was approximately 50 Å when the generator crystal was tuned to degeneracy at 7095 Å, decreasing to less than 10 Å when tuned a few hundred angstroms away from degeneracy. Although no attempt was made to reduce the bandwidth of the oscillator output, substantial reduction in the bandwidth can be expected through insertion of Fabry–Perot etalons between the high-reflectivity mirror and the Glan polarizer.

The temporal behavior of the oscillator output pulses was measured through a fused-silica prism and a high-speed photodiode-oscilloscope system having an overall rise time of less than 1 ns. With this system we have observed that the pulse shape of the oscillator output was nearly symmetric, with a pulse duration of approximately 2 ns at full width at half maximum (FWHM). Average output powers as high as 25 mW were measured near degeneracy at 7095 Å at a pump power of 7 MW and a pulse repetition rate of 10 pps. The corresponding peak output power was approximately 1.2 MW. With the oscillator tuned away from degeneracy, peak powers in excess of 0.5 MW were observed at signal and idler frequencies, respectively.

Following analyses previously used by Yarborough and Massey [6] and Massey and Elliott [7] we have estimated the parametric gain from the ratio of the observed output power to the optical noise [8] given by

$$P_f/P_i = (R_m(1 - \epsilon)^2 G)^m \tag{3}$$

where

$$P_i = h\nu B \tag{4}$$

R_m is the output mirror reflectivity, ϵ is the total transmission loss through the Glan polarizer and RD*A crystal, G is the single-pass parametric gain, m is the number of round trips during the growth of the output pulse, $h\nu$ is the signal or idler photon energy per single spatial mode, and B is the output bandwidth. For a wavelength of 7095 Å and a spectral bandwidth of 50 Å, P_i is approximately 5.9×10^{-6} W. Taking the values of $P_f = 1.2 \times 10^6$ W, $R_m = 0.14$, and $\epsilon = 0.2$, we obtain $G = 57$ for $m = 16$. Comparison of this parameter can be made by the value deduced from the following expression [9]:

$$G = \tfrac{1}{4} \exp(2gl) \tag{5}$$

where l is the crystal length and

$$g = d_{36}(4\pi/c)^{3/2}(2(\omega_s\omega_i/n_s^o n_i^o n_p^e)S)^{1/2}. \tag{6}$$

In (6), d_{36} is the nonlinear optical constant of RD*A and S is the pump-power density at the crystal. Using the following values, $S = 200$ MW/cm^2, $\omega_s = \omega_i = \omega_p/2 = 1.41 \times 10^4$ cm^{-1}, $n_s^o = n_i^o = n_p^e = 1.548$, and taking d_{36}(RD*A) $= 1.02 \times 10^{-9}$ ESU which was deduced from frequency doubling of dye-laser radiations, we find from (6) that $g = 0.76$ cm^{-1}. The corresponding single-pass parametric gain is 12 which is considerably lower than the previous estimate. The discrepancy between these two results may arise from the inaccuracy in the pump-power density and from the simplifying assumption used to calculate the optical noise power. However, we note that an increase in g by a factor of 1.4 would bring the two results in equality.

The spatial profile of the 2-mm-diam oscillator output beam exhibited some inhomogeneous structure due probably to the structural flaws in the RD*A crystal.

The system described in the preceding has been operated for several hours without noticeable deterioration in the output power, although the RD*A crystal exhibited some surface damage which seemed to be associated with the light scratches remaining from polishing.

In summary, we have reported the efficient operation of a RD*A parametric oscillator in the visible to near infrared using the third harmonic of a Nd:YAG laser as a pump source.

ACKNOWLEDGMENT

The author wishes to thank M. Yanada of Nippon Electric Company for his technical assistance in the transmission loss measurements of RD*A.

From 1966 to 1967 he held a postdoctoral appointment at the Joint Institute for Laboratory Astrophysics, Boulder, Colo. Since 1967 he has been a member of the staff at Sandia Laboratories, Albuquerque, N. Mex. His research interests are gaseous electronics and lasers.

Dr. Gusinow is a member of Phi Eta Sigma, Pi Mu Epsilon, Tau Beta Pi, Sigma Pi Sigma, and the American Physical Society.

Laird D. Schearer was born in Allentown, Pa., in 1931. He received the Ph.D. degree in physics from Rice University, Houston, Tex., in 1966.

From 1959 to 1971 he was a member of the technical staff and later, Senior Scientist with the Central Research Laboratories, Texas Instruments, Dallas, Tex. In 1971 he joined the faculty of the University of Missouri at Rolla, Rolla, as Professor of Physics and Chairman of the Department of Physics. His principal interests are in atomic physics: optical pumping, energy transfer collisions, and spectroscopy.

Dr. Schaerer is a fellow of the American Physical Society, and a member of the Division of Electron and Atomic Physics, AAAS, Phi Kappa Phi, Sigma Xi, and is currently secretary of the Gaseous Electronics Conference.

1975 Index
IEEE Journal of Quantum Electronics
Vol. QE-11

This index covers all items – papers, correspondence, reviews, etc. – that appeared in this periodical during 1975, and items from prior years that were commented upon or corrected in 1975. The index is divided into an Author Index and a Subject Index, both arranged alphabetically.

The *Author Index* contains the primary entry for each item; this entry is listed under the name of the first author and includes coauthor names, title, location of the item, and notice of corrections and comments if any. Cross-references are given from each coauthor name to the name of the corresponding first author. The location of the item is specified by the journal name (abbreviated), year, month, inclusive pages, and microfiche code. [The microfiche code, given in parentheses following the inclusive pages, consists of four characters to be interpreted as follows: the first character identifies the microfiche number within the set of fiches for the issue; the second character identifies the row in which the first frame of the particular item is located; and the last two characters designate the position of that frame within the row.]

The *Subject Index* contains several entries for each item, each consisting of a subject heading, modifying phrase(s), first author's name, and location of the item. For information on coauthors, title, comments and corrections if any, etc., it is necessary to refer to the Author Index. Some generic subject headings are used in this index in addition to the usual technical headings, e.g., *Books* (books reviewed in this periodical), *Bibliographies* (both papers that are bibliographies and any other papers which contain more than 50 references), *Conferences* (technical meetings a substanial number of whose abstracts or papers have appeared in this periodical), and *Special Issues* (issues of this periodical devoted primarily to a specific subject). The Subject Index includes subject cross-references as required by the subject matter.

SUBJECT INDEX

A

Absorption; **cf.** Infrared propagation, absorbing media; Laser absorbers; Optical propagation, absorbing media
Acoustic bulk waves
interferometric measurement and display. *Mezrich, R., J-QE 75 Sep* 9D-10D (2B11)
Acoustic bulk-wave devices
FM acoutooptic modulators; optical-guided-wave modulator using standing wave. *Christensen, C. P., J-QE 75 Oct* 849-850 (1D05)
Acoustic diffraction; **cf.** Acoustic surface-wave diffraction
Acoustic filters; **cf.** Acoustooptic filters
Acoustic signal processing; **cf.** Acoustic surface-wave signal processing
Acoustic surface-wave convolution
optical guided wave–acoustic surface-wave interactions in thin-film As_2S_3 guide on $LiNbO_3$ substrate. *Loh, K. W., J-QE 75 Sep* 86D (3A03)
Acoustic surface-wave diffraction
guided-wave Bragg diffraction from multiple tilting surface acoustic waves. *Tsai, C. S., J-QE 75 Sep* 10D (2B12)
light deflectors; $LiNbO_3$ acoustooptic Bragg deflectors with low electrical drive power requirements. *Schmidt, R. V., J-QE 75 Jan* 57-59 (1E03)
Acoustic surface-wave effects
optical planar waveguides; light scattering from periodic refractive-index fluctuations. *Marcuse, D., J-QE 75 Apr* 162-168 (1D02)
shock wave effects in laser-irradiated semiconductors and metals. *Dekhtar, I. Ya., J-QE 75 Sep* 83D (2G14)
Acoustic surface-wave signal processing; **cf.** Acoustic surface-wave convolution
Acoustooptic devices
explosive vapor detectors. *Claspy, P. C., J-QE 75 Sep* 37D (2D11)
mode locker/frequency doubler for Nd:YAG lasers. *Rice, R. R., J-QE 75 Sep* 14D (2C02)
Acoustooptic filters
Tl_3AsSe_3 tunable colllinear filters for intermediate infrared. *Feichtner, J. D., J-QE 75 Sep* 66D-67D (2F12)
Acoustooptic light deflectors
$LiNbO_3$ Bragg deflectors with low electrical drive power requirements. *Schmidt, R. V., J-QE 75 Jan* 57-59 (1E03)
Acoustooptic modulation
guided-optical-wave FM modulator using acoustic standing wave. *Christensen, C. P., J-QE 75 Oct* 849-850 (1D05)
Aerodynamic testing; **cf.** Gas flow visualization
Aerospace simulation; **cf.** Gas flow visualization
Aircraft; **cf.** Helicopters
Aircraft control
helicopters; precision hover sensor for heavy lift helicopter. *Herzog, D. G., J-QE 75 Sep* 51D-52D (2E11)
Aircraft wakes
vortex detection system using CO_2 laser Doppler velocimeter. *Sonnenschein, C. M., J-QE 75 Sep* 35D (2D09)
Air pollution monitoring
ambient-air pollutant measurements using bistatic heterodyne system. *Menzies, R. T., J-QE 75 Sep* 33D (2D07)
pollution concentration variations with altitude; measurement using solar infrared heterodyne radiometer. *Christophe, B., J-QE 75 Sep* 32D-33D (2D06)
power plant effluent measurements; remote measurements using laser Doppler velocimeter. *Miller, C. R., J-QE 75 Sep* 34D-35D (2D08)
Altimetry; **cf.** Optical distance measurement
Aluminum
laser-heated surfaces; thermal coupling coefficient. *Marcus, S., J-QE 75 Sep* 49D-50D (2E09)
Aluminum alloys/compounds; **cf.** Gallium alloys/compounds
Amplifiers; **cf.** Laser amplifiers; Optical amplifiers; Feedback amplifiers
Arc heating
Cu vapor laser produced by discharge heating. *Anderson, R. S., J-QE 75 Apr* 172-174 (1D12)
Arc lamps
Kr arc lamps; electrodeless lamp for CW pumping of Nd:YAG lasers. *Huchital, D. A., J-QE 75 Sep* 16D (2C04)
Argon; **cf.** Noble gases
Arsenic alloys/compounds, devices
As_2S_3 optical planar waveguides; convolution using optical guided wave–acoustic surface-wave interactions. *Loh, K. W., J-QE 75 Sep* 86D (3A03)
Atmospheric pollution; **cf.** Air pollution
Atmospheric radio propagation; **cf.** Optical radio propagation meteorological factors
Automobiles
laser materials processing in automotive industry. *Yessik, M., J-QE 75 Sep* 46D-47D (2E06)
Automotive industry; **cf.** Automobiles
Avalanche diodes
laser communications system using external polarization electrooptic modulation and avalanche diode detection; optimum carrier-to-noise ratio. *Waksberg, Armand L., J-QE 75 Sep* 778-782 (1D14)

B

Barium alloys/compounds, devices
$Ba_2NaNb_5O_{15}$ acoustooptic mode locker/frequency doubler for Nd:YAG lasers. *Rice, R. R., J-QE 75 Sep* 14D (2C02)
$Ba_2Na(NbO_3)_5$ intracavity frequency-doubling elements in Nd:YAG lasers; thermooptical effects. *Barry, James D., J-QE 75 Aug* 575-579 (1A13)
lasers; BaF, BaCl, BaBr and BaI electronic-transition chemical lasers. *Bradford, R. S., Jr., J-QE 75 Aug* 692 (2D12)
lasers; BaO electronic-transition chemical laser. *Scott, P. B., J-QE 75 Aug* 693-694 (2D13)
Beams; **cf.** Laser beams
Beam deflection; **cf.** Beam steering
Beam steering
laser beam deflection by precision galvanometer deflection system. *Jablonowski, D. P., J-QE 75 Sep* 21D-22D (2C09)
Biological cells
photosynthetic processes; streak camera studies of fluorescent decay times. *Shapiro, S. L., J-QE 75 Sep* 5D-6D (2B07)
Boron devices
lasers; pulsed lasers pumped by incomplete autoionization or ion–electron recombination. *Stricker, J., J-QE 75 Aug* 701-702 (2E07)
Boron alloys/compounds
BCl_3 isotopic enrichment by multiple absorption of CO_2 laser radiation. *Lyman, J. L., J-QE 75 Sep* 103D (3B06)
Boron alloys/compounds, devices
lasers; BO electronic-transition chemical laser. *Scott, P. B., J-QE 75 Aug* 693-694 (2D13)
Bragg scattering; **cf.** Distributed feedback lasers
Bromine compounds/mixtures, devices
lasers; excited electronic states of BrCl electronic-transition lasers. *Harris, R. A., J-QE 75 Aug* 691 (2D11)
Bulk waves; **cf.** Acoustic bulk waves

C

Cadmium devices; **cf.** Gas lasers
Cadmium alloys/compounds, devices
HgCdTe planar photodiodes for wideband heterodyne detection at 10.6 μm. *Spears, D. L., J-QE 75 Sep* 79D (2G11)
Cadmium alloys/compounds, devices; **cf.** Semiconductor defects
Calcium devices; **cf.** Gas lasers, molecular
Cameras
radiation cameras; ultra-high-speed camera using hydrated electron photoabsorption phenomena and mode-locked-dye-laser picosecond pulses. *Coutts, Gerald W., J-QE 75 Sep* 6D (2B08)
Camera tubes; **cf.** Image sensors
Carbon alloys/compounds
CH_4 gas; generation of coherent anti-Stokes Raman scattering by CW lasers. *Barrett, J. J., J-QE 75 Sep* 89D-90D (3A06)
Carbon dioxide lasers
2.5 kJ short-pulse system. *Singer, S., J-QE 75 Sep* 44D-45D (2E04)
aircraft vortex detection system using CO_2 laser Doppler velocimeter. *Sonnenschein, C. M., J-QE 75 Sep* 35D (2D09)
beam quality of short-pulse lasers; measurement. *Liberman, I., J-QE 75 Sep* 44D (2E04)
chemical lasers using $N + CS_2$ reaction. *McGee, T. J., J-QE 75 Jun* 302-304 (1F10)
chemical lasers using energy transfer from vibrationally excited CO. *Petersen, A. B., J-QE 75 Aug* 699-700 (2E05)
chirp-modulated waveguide lasers; demodulation technique. *Stein, Alexander, J-QE 75 Aug* 630-631 (1E08)
$CO_2(00°1)$ level; vibrational deactivation by H, D, O, N, F and Cl atoms. *Buchwald, M. I., J-QE 75 Aug* 697 (2E03)
cold cavity modes; amplitudes of modes excited by coupling modulation. *Scholtz, A. L., J-QE 75 Sep* 791-793 (1E13)
compact sealed 200-W laser. *Fahlen, Theodore S., J-QE 75 Oct* 848-849 (1D04)
contaminant gases; effects on CO_2–N_2–He electric-discharge lasers. *Bletzinger, Peter, J-QE 75 Jul* 317-323 (1A03)
contaminant gases; effects on flowing-gas TEA lasers. *Smith, A. L. S., J-QE 75 Jul* 335-340 (1B07)
continuously operating fast flow electrically excited (COFFEE) lasers; discharge scaling studies. *Wutzke, S. A., J-QE 75 Sep* 73D (2G05)
continuously tunable high-pressure lasers; use in molecular spectroscopy and excitation of luminescence. *Bagratashvili, V. N., J-QE 75 Sep* 94D (3A11)
CS_2/O_2 chemical lasers; flash photolysis-produced surface reactions on NaCl Brewster windows. *Petersen, Alan B., J-QE 75 Mar* 110-111 (1B02)
CW chemical transfer lasers; model. *Baumann, W., J-QE 75 Aug* 711-712 (2F03)

D_2–CO_2 transfer lasers; electric discharge gas dynamic laser. *Stregack, J. A., J-QE 75 Aug* 705 (2E11)
DF–CO_2 chemical transfer lasers; supersonic CW laser which recovers to atmospheric pressure. *Stregack, J. A., J-QE 75 Aug* 711 (2F03)
DF–CO_2 chemical transfer lasers; supersonic mixing laser experiments. *Evers, W. H., J-QE 75 Aug* 711 (2F03)
DF–CO_2 chemical transfer lasers; supersonic mixing laser theory. *Vieceli, J. J., J-QE 75 Aug* 711 (2F03)
DF–CO_2 electrically initiated pulsed chemical lasers. *Poehler, T. O., J-QE 75 Aug* 710 (2F02)
DF–CO_2 transfer chemical lasers; power extraction and chemiluminescence experiments in large-scale IRIS laser. *Tregay, G. W., J-QE 75 Aug* 672-678 (2C06)
Doppler velocimeters for remote power plant effluent measurements. *Miller, C. R., J-QE 75 Sep* 34D-35D (2D08)
far-infrared frequency synthesis using stabilized CO_2 lasers; application in laser line frequency measurements. *Petersen, F. Russell, J-QE 75 Oct* 838-843 (1C08)
frequency tuning of 15-atm electron-beam-controlled lasers. *O'Neill, F., J-QE 75 Sep* 74D-75D (2G06)
high-energy lasers pumped by nultraviolet sustained electric discharges; scalability. *Lind, R. C., J-QE 75 Sep* 71D (2G03)
high-pressure lasers; 15-atm electron-beam-controlled laser. *Harris, N. W., J-QE 75 Aug* 686-687 (2D06)
hybrid laser with active medium consisting of TEA and low-pressure gain sections; mechanism of single-frequency operation. *Gondhalekar, A., J-QE 75 Mar* 103-108 (1A09)
isotopic enrichment of polyatomic molecules by multiple absorption of laser radiation. *Lyman, J. L., J-QE 75 Sep* 103D (3B06)
materials processing applications in automotive industry. *Yessik, M., J-QE 75 Sep* 46D-47D (2E06)
metallic surface irradiation by CO_2–TEA lasers; changes in surface reflectivity. *Ready, J. F., J-QE 75 Sep* 49D (2E09)
molecular decomposition; infrared-laser-augmented decomposition of H_3BPF_3. *Lory, E. R., J-QE 75 Aug* 714-715 (2F06)
multiatmosphere transverse-discharge ultraviolet-preionized lasers; small-signal gain at pressures in 1–15-atm range. *Alcock, A. J., J-QE 75 Sep* 767-773 (1D03)
multiband lasers; parametric study. *Figueira, J. F., J-QE 75 Sep* 74D (2G06)
N_2 and CO_2(001) vibration-to-translation relaxation by alkali metal atoms. *Benson, R. C., J-QE 75 Aug* 697 (2E03)
negative ions in discharge lasers; formation and effects. *Prince, J. F., J-QE 75 Aug* 687 (2D07)
plasma-injection CW lasers with multikilowatt power output. *McLeary, R., J-QE 75 Sep* 90D-91D (3A07)
pulsed laser gain dynamics; model. *Garside, Brian K., J-QE 75 Jun* 264-270 (1C14)
pulsed lasers; multigigawatt, ns pulses from tandem of two TEA lasers. *Bélanger, P. A., J-QE 75 Sep* 73D-74D
pulsed TEA lasers; compact sealed laser. *Stark, Donald S., J-QE 75 Sep* 774-778 (1D10)
Q-switched lasers; passive *Q*-switching by N_2F_4 absorption cells. *Suart, R. D., J-QE 75 Aug* 698 (2E04)
radiation absorption by water vapor. *Shumate, M. S., J-QE 75 Sep* 33D-34D (2D07)
rotational–vibrational line competition in dual-polarization laser. *Buholz, N. E., J-QE 75 Nov* 917-919 (1E07)
semiconductor device fabrication; SiC high-temperature resistor fabrication using CO_2 lasers. *Hierholzer, F. J., J-QE 75 Sep* 47D-48D (2E07)
switching of high-power output radiation using light-activated Ge switches. *Alcock, A. J., J-QE 75 Sep* 96D (3A13)
TEA laser pulse frequency chirp; measurement using interferometric pulse delay techniques. *Hieslmair, H., J-QE 75 Sep* 54D (2E14)
TEA lasers; discharge technique that integrates ultraviolet preionization with voltage switching. *Tulip, J., J-QE 75 Sep* 72D (2G04)
TEA lasers; ultraviolet photoionization parameters. *Seguin, H. J. J., J-QE 75 Sep* 71D-72D (2G03)
temporal coherence of double-discharge TEA lasers. *Rudko, R. I., J-QE 75 Sep* 54D (2E14)
transversely excited lasers; laser dynamics model including rotational coupling effects. *Garside, Brian K., J-QE 75 Aug* 583-589 (1B03)
transversely excited CW lasers; high-gain waveguide laser using preionization scheme based on Malter effect. *Wood, O. R., II, J-QE 75 Sep* 72D-73D (2G04)

Carbon dioxide laser amplifiers
energy extraction by short-duration input pulses; effect of rotational and intramode vibrational coupling. *Harrach, Robert J., J-QE 75 Jul* 349-357 (1C07)
energy extraction from atmospheric-pressure lasers using 60 ns–1 μs pulses. *Girard, G., J-QE 75 Jun* 241-247 (1B05)
energy extraction from atmospheric-pressure lasers for nanosecond input pulses. *Girard, G., J-QE 74 Dec* 901-902 (1D09) ♦
energy extraction improvement in ns-pulse TEA lasers. *Farcy, J. C., J-QE 75 Sep* 90D (3A07)
gain recovery in short-pulse high-pressure amplifiers after saturation. *Schappert, G. T., J-QE 75 Sep* 75D-76D (2G07)
high-power electron-beam-controlled system for laser fusion. *Yamanaka, C., J-QE 75 Sep* 45D (2E05)
multiple rotational line operation for increased efficiency. *Figueira, J. F., J-QE 75 Sep* 74D (2G06)
prepulse extinction-ratio measurements on pulse-selection systems. *Manes, K. R., J-QE 75 Aug* 635-636 (1E13)
self-oscillation suppression in high-gain amplifiers using interstage optical isolators. *Lavigne, P., J-QE 75 Sep* 75D (2G07)
Valkyrie system for laser fusion experiments. *Manes, K. R., J-QE 75 Sep* 44D (2E04)
waveguide CW power amplifiers. *Klein, Marvin B., J-QE 75 Aug* 609-615 (1D01)

Carbon monoxide lasers
chemical lasers; computer modeling code for CS_2O CW laser. *Lilenfeld, H. V., J-QE 75 Aug* 660-669 (2B08)
chemical lasers; $CS_2/O_2/N_2O$ flame laser featuring nearly single-line operation. *Foster, Kenneth D., J-QE 75 Jun* 253-258 (1C03)
CO($v=1$) vibrational deactivation by atomic oxygen. *Davis, C. C., J-QE 75 Aug* 701 (2E07)
CS_2/O_2 chemical laser; role of atomic S. *Cupitt, L. T., J-QE 75 Aug* 700-701 (2E06)
$CS_2/O_2/N_2O$ chemical flame laser; near single-line operation in 5–5.5 μm region. *Foster, K. D., J-QE 75 Aug* 700 (2E06)
electric discharge lasers; time-dependent kinetics of multilevel pumping. *Boulnois, J. L., J-QE 75 Aug* 707-708 (2E13)
electron energy distributions in vibrationally excited CO, CO–He and CO–Ar mixtures; effects of superelastic collisions. *Greene, A. E., J-QE 75 Aug* 708 (2E14)
excitation by nuclear reactor products. *McArthur, D. A., J-QE 75 Aug* 707 (2E13)
kinetic modeling of high-pressure lasers; effects of resonance self-absorption. *Lacina, William B., J-QE 75 Jun* 297-302 (1F05)
O_2 additions to CO–He mixtures; effects on laser performance. *Keren, H., J-QE 75 Aug* 590-594 (1B10)
$O(^3P)+CO(^1\Sigma^+)$ collisions; vibrational deactivation and atom exchange. *Kelley, J. D., J-QE 75 Aug* 701 (2E07)
O* + CO and I* + CO electronic-to-vibrational energy transfer reactions. *Lin, M. C., J-QE 75 Aug* 710 (2F02)
scaling generalizations for high-pressure electric-discharge lasers. *Lacina, William B., J-QE 75 Jun* 235-241 (1A13)
supersonic electric discharge laser. *Plummer, M. J., J-QE 75 Aug* 700 (2E06)
vibrational–vibrational collision probability measurements on CO molecule. *Nachshon, Yehuda, J-QE 75 Aug* 654-660 (2B02)

Cathode-ray oscilloscopes
optical sampling oscilloscope for picosecond laser pulse displays. *Vogel, Gerald C., J-QE 74 Sep* 642-646 (1B02) ♦

Cavity resonators; **cf.** Laser resonators
Cell biology; **cf.** Biological cells
Cerenkov radiation; **cf.** Ultraviolet generation

Cesium
negative nonlinear refractive index of Cs vapor at 1.06 1gmm; use in compensation of self-focusing in other transparent materials. *Lehmberg, R. H., J-QE 75 Sep* 69D-70D (2G01)
vapor; third-order susceptibility. *Eicher, Hermann, J-QE 75 Apr* 121-130 (1A03)

Cesium alloys/compounds, devices
CD*A second-harmonic generating crystals; electrooptic compensation for self-heating. *Hon, D., J-QE 75 Sep* 67D-68D (2F13)

Cesium devices
lasers; electronic-transition chemical laser using Cs + F_2 reaction system. *Hall, L. H., J-QE 75 Aug* 693 (2D13)

Chemical and Molecular Lasers Conference
papers and abstracts from Oct. 1974 conference, *J-QE 75 Aug, Pt. II* 641-722 (2A03)
special issue on Oct. 1974 conference; foreword. *Jeffers, W. Q., Guest ed., J-QE 75 Aug* 641 (2A03)

Chemical lasers
electronic-transition chemical lasers using reactions of I_2, Br_2, SiH_4, GeH_4, AsH_3 or Ph_3 with F_2. *Davis, S. J., J-QE 75 Aug* 693 (2D13)

Chemical lasers; **cf.** Gas lasers

Chemistry
B isotope enrichment by laser-induced photochemical process. *Freund, S. M., J-QE 75 Aug* 702 (2E08)
Cl isotope enrichment by laser-induced photochemical process. *Lamotte, M., J-QE 75 Aug* 702 (2E08)
molecular decomposition; infrared-laser-augmented decomposition of H_3BPF_3. *Lory, E. R., J-QE 75 Aug* 714-715 (2F06)
nitric oxide reactions with laser-excited ozone. *Gordon, R. J., J-QE 75 Aug* 715 (2F07)
photochemistry; isotopic enrichment by multiple absorption of CO_2 laser radiation. *Lyman, J. L., J-QE 75 Sep* 103D (3B06)
pyrolysis; laser-powered homogeneous pyrolysis. *Shaub, W. H., J-QE 75 Aug* 714 (2F06)

Chirp modulation
CO_2 waveguide lasers; demodulation technique for chirp-modulated laser. *Stein, Alexander, J-QE 75 Aug* 630-631 (1E08)

Chirp radar; **cf.** Pulse compression-radar
Chlorine devices; **cf.** Gas lasers
Communication systems; **cf.** Optical communication; Satellite communication

Communication system fault diagnosis
optical fiber communication; fiber fault location method. *Ueno, Y., J-QE 75 Sep* 77D-78D (2G09)

Conferences; **cf.** Chemcial and Molecular Lasers Conference; Laser Engineering and Applications Conference; Semiconductor Laser Confererence

Consumer products
universal product code symbol; optical scanners using lasers for reading. *Dickson, L., J-QE 75 Sep* 23D-24D (2C11)

Control systems; **cf.** Feedback systems; Vehicle control
Convolution; **cf.** Acoustic surface-wave convolution

Copper
laser-heated surfaces; thermal coupling coefficient. *Marcus, S., J-QE 75 Sep* 49D-50D (2E09)
welding of Cu wires to Monel terminal posts; laser welding. *Saifi, M. A., J-QE 75 Sep* 48D (2E08)

Copper alloys/compounds
CuI vapor; selective isotope excitation by Ar ion laser excitation. *Wu, C.Y. R., J-QE 75 Sep* 20D (2C08)

Copper alloys/compounds, devices
lasers; CuF electronic-transition chemical laser. *Scott, P. B., J-QE 75 Aug* 693-694 (2D13)
Monel terminal posts; laser welding of insulated Cu wires to posts. *Saifi, M. A., J-QE 75 Sep* 48D (2E08)

Copper alloys/compounds, devices; **cf.** Gas lasers
Couplers; **cf.** Laser couplers; Optical couplers
Crime; **cf.** Law enforcement
Crystal defects; **cf.** Semiconductor defects

♦ **Check author entry for later corrections/comments**

Crystal growth
KTN; single-crystal thin-film growth by liquid-phase epitaxy. *Fontana, R. E., Jr., J-QE 75 Sep* 38D (2D12)
Crystal growth; **cf.** Semiconductor growth
CW lasers
AlGaAs double-heterostructure junction lasers; depolarization of lasing emission. *Paoli, Thomas L., J-QE 75 Jul* 489-494 (3A13)
Ar ion lasers using 700-m-long cavity. *Tripathi, P. P., J-QE 75 Sep* 59D (2F05)
buried-heterostructure lasers with GaAs active regions completely buried in GaAlAs; thermal properties. *Tsukada, Toshihisa, J-QE 75 Jul* 494-498 (3B04)
CO_2 laser amplifiers; high-power 10.6-μm waveguide amplifier. *Klein, Marvin B., J-QE 75 Aug* 609-615 (1D01)
CO_2 lasers; compact sealed 200-W laser. *Fahlen, Theodore S., J-QE 75 Oct* 848-849 (1D04)
CO_2 lasers; multikilowatt laser using plasma injection. *McLeary, R., J-QE 75 Sep* 90D-91D (3A07)
CO_2 transversely excited lasers; high-gain waveguide laser using preionization scheme based on Malter effect. *Wood, O. R., II, J-QE 75 Sep* 72D-73D (2G04)
CO chemical laser; computer modeling code for CS_2/O laser. *Lilenfeld, H. V., J-QE 75 Aug* 660-669 (2B08)
coherent anti-Stokes Raman scattering; generation by CW lasers. *Barrett, J. J., J-QE 75 Sep* 89D-90D (3A06)
cresyl violet perchlorate laser; pumping using dye mixture and tandem systems. *Beisser, F. A., J-QE 75 Jul* 372 (1E02)
DF–CO_2 chemical transfer lasers; model. *Baumann, W., J-QE 75 Aug* 711-712 (2F03)
DF–CO_2 supersonic chemical transfer lasers. *Stregack, J. A., J-QE 75 Aug* 711 (2F03)
DF cold-reaction lasers; analysis of small-scale laser. *Steele, R. V., J-QE 75 Aug* 719 (2F11)
DF/HF chemical lasers; portable lasers using recirculating mode of operation. *Chenausky, P. P., J-QE 75 Sep* 58D (2F04)
double-heterostructure stripe-geometry junction lasers; room-temperature intensity noise characteristics. *Paoli, Thomas L., J-QE 75 Jun* 276-283 (1D12)
double-heterostructure GaAs/GaAlAs lasers with oxide-insulated stripe geometry; CW lasing range and light-output power. *Garel-Jones, P., J-QE 75 Jul* 408-413 (2C02)
dye lasers stabilized by frequency locking to high-finesse optical cavity; frequency fluctuations of 1 kHz for short times and 300 Hz for 300 s. *West, J. B., J-QE 75 Sep* 18D-19D (2C06)
far-infrared lasers; CO_2-pumped laser lines from 254 to 1700 μm. *Jennings, D. A., J-QE 75 Aug* 637 (1F01)
GaAs/GaAlAs double-heterojunction lasers; internal optical loss in very thin lasers. *Butler, J. K., J-QE 75 Jul* 402-408 (2B10)
GaAs/GaAlAs double-heterojunction visible-light-emitting lasers using heteroisolation stripe geometry. *Itoh, Kunio, J-QE 75 Jul* 421-426 (2D01)
H_2 vacuum ultraviolet lasers. *Knyazev, I. N., J-QE 75 Oct* 805-817 (1A03)
HCl chemical lasers; transverse-flow laser using $H+Cl_2$ reaction. *Wanner, J., J-QE 75 Aug* 706 (2E12)
HF chain-reaction lasers in supersonic mixing device. *Cummings, J. C., J-QE 75 Aug* 712 (2F04)
HF chain-reaction lasers; generation of vibrationally excited HF. *Meinzer, R. A., J-QE 75 Aug* 712-713 (2F04)
HF chemical lasers; temporal characteristics of multiline–multimode lasers. *Foster, M. C., J-QE 75 Aug* 714 (2F06)
HF chemical lasers; transverse mode oscillations in lasers with stable selected-line resonators. *Boedeker, L., J-QE 75 Aug* 713 (2F05)
HF chemical mixing lasers; CW lasers as local oscillators for middle-IR heterodyne applications. *Freiberg, R. J., J-QE 75 Sep* 57D-58D (2F03)
HF/DF chain-reaction lasers. *Sadowski, T. J., J-QE 75 Aug* 705-706 (2E11)
HF/DF lasers; frequency stabilization and absolute frequency measurements. *Eng, R. S., J-QE 75 Sep* 87D-88D (3A04)
HF/DF supersonic chemical lasers; spectroscopic and infrared measurements. *Kwok, M. A., J-QE 75 Aug* 718 (2F10)
HF/DF supersonic chemical lasers; gas heater and nozzle array performance. *Giedt, R. R., J-QE 75 Aug* 718-719 (2F10)
HF/DF supersonic diffusion chemical lasers; spectrographic systems for diagnostic experiments. *Varwig, R. L., J-QE 75 Aug* 719 (2F11)
HF lasers; arc- and combustion-driven laser performance. *Grohs, G. L., J-QE 75 Aug* 717 (2F09)
Hg lasers; dc-excited Hg pump lamps for operation at 546.1 nm. *Holmes, N., J-QE 75 Sep* 55D (2F01)
hydrogen halide chemical lasers; rotational nonequilibrium. *Sentman, L. H., J-QE 75 Aug* 706-707 (2E12)
InSb lasers; tunable lasers optically pumped in longitudinal geometry. *Menyuk, N., J-QE 75 Jul* 477-481 (3A01)
$LiNdP_4O_{12}$ lasers; transversely pumped laser. *Yamada, T., J-QE 75 Sep* 62D-63D (2F08)
$LiNdP_4O_{12}$ lasers with 200-μW pump threshold. *Otsuka, Kenju, J-QE 75 Oct* 845-846 (1D01)
N_2 lasers; quasi-CW second-positive laser using SF_6 additions to N_2 in discharge region. *Suchard, S. N., J-QE 75 Aug* 685-686 (2D05)
NdLa pentaphosphate fiber lasers. *Weber, H. P., J-QE 75 Sep* 100D (3B03)
Nd:YAG lasers; pumping with electrodeless Kr arc lamps. *Huchital, D. A., J-QE 75 Sep* 16D (2C04)
Nd:YVO_4 lasers. *DeShazer, L. G., J-QE 75 Sep* 84D (3A01)
noble-gas ion lasers; CW operation below 3000 Å. *Marling, J. B., J-QE 75 Sep* 27D-28D (2D01)
self-induced intensity pulsations from junction lasers; suppression by frequency-selective optical feedback. *Paoli, Thomas L., J-QE 75 Jul* 525-527 (3D07)
submillimeter emission from optically pumped waveguide gas lasers. *Radford, Harrison E., J-QE 75 May* 213-214 (1C07)
supersonic CO electric discharge laser. *Plummer, M. J., J-QE 75 Aug* 700 (2E06)
transverse-junction-stripe lasers with GaAs homojunction sandwiched between GaAlAs layers. *Namizaki, H., J-QE 75 Jul* 427-431 (2D07)
CYCLOPS amplifier; **cf.** Laser amplifiers

D

Defocusing; **cf.** Laser-beam focusing
Deformation; **cf.** Strain
Delay lines
optical communication systems; mode-locked lasers using folded optical delay lines. *Kornienko, L. S., J-QE 75 Sep* 91D (3A08)
Demodulation; **cf.** Optical demodulation
Detection; **cf.** Demodulation
Deuterium halide lasers; **cf.** Hydrogen halide lasers
Dielectric waveguides; **cf.** Optical waveguides
Diffraction; **cf.** Acoustic diffraction; Optical diffraction
Digital communication; **cf.** PCM
Digital integrated circuits
masks for integrated-circuit fabrication; correction of defects using laser beam. *Lee, F., J-QE 75 Sep* 21D (2C09)
Dilatometry; **cf.** Length measurement
Diodes; **cf.** Semiconductor diodes
Diode lasers; **cf.** Semiconductor lasers
Dislocations; **cf.** Semiconductor defects
Displacement measurement
motions as small as .05 Å; interferometric measurement and display of ultrasonic waves. *Mezrich, R., J-QE 75 Sep* 9D-10D (2B11)
Distance measurement; **cf.** Optical distance measurement
Distributed-feedback lasers
coupling coefficients for TE modes in single- and double-heterostructure diode lasers. *Streifer, William, J-QE 75 Nov* 867-873 (1A13)
GaAs/GaAlAs double-heterostructure injection lasers; pulsed operation between 80 and 150 K. *Nakamura, Michiharu, J-QE 75 Jul* 436-439 (2E02)
GaAs/GaAlAs double-heterostructure lasers; corrugated grating-coupled laser with low-divergence output normal to waveguide plane. *Zory, P., J-QE 75 Jul* 451-457 (2F03)
GaAs lasers; single-heterostructure electrically pumped lasers. *Burnham, Robert D., J-QE 75 Jul* 439-449 (2E05)
longitudinal modes; effect of external reflectors. *Streifer, William, J-QE 75 Apr* 154-161 (1C08)
Diversity communication
optical radio communication under turbulent conditions. *McIntyre, C. M., J-QE 75 Sep* 81D (2G13)
Doppler measurements
$^{12}CH_3F$; pressure broadening and pressure shift coefficient measurements using Doppler-free two-photon absorption techniques. *Bischel, W. K., J-QE 75 Sep* 24D-25D (2C12)
aircraft vortex detection system using CO_2 laser Doppler velocimeter. *Sonnenschein, C. M., J-QE 75 Sep* 35D (2D09)
gas flow measurement and visualization using resonant Doppler velocimeter. *Miles, R. B., J-QE 75 Sep* 35D-36D (2D09)
power plant effluent measurements; remote measurements using laser Doppler velocimeter. *Miller, C. R., J-QE 75 Sep* 34D-35D (2D08)
Dyes
BDN; recovery times for transient bleaching; mode locking of Nd:glass lasers. *Greenhow, R. C., J-QE 75 Jan* 59-60 (1E05)
cryptocyanine in methanol; spectral hole burning in absorption band. *Mourou, Gerard, J-QE 75 Jan* 1-8 (1A03)
light gates using optically induced dichroism in organic-dye solutions. *Vahey, David W., J-QE 75 Sep* 100D-101D (3B03)
optically gated dye cells for optical pulse shaping; saturable absorber dye dynamics. *Massey, G. A., J-QE 75 Jul* 358-364 (1D02)
Dye lasers
amplified spontaneous emission and signal amplification in transversely pumped lasers. *Ganiel, U., J-QE 75 Nov* 881-892 (1B13)
cresyl violet perchlorate in methanol; small-signal gain in longitudinally pumped solutions. *Leheny, Robert F., J-QE 75 Feb* 70-74 (1A08)
cresyl violet perchlorate laser; pumping using dye mixture and tandem systems. *Beisser, F. A., J-QE 75 Jul* 372 (1E02)
CW lasers stabilized by frequency locking to high-finesse optical cavity; frequency fluctuations of 1 kHz for short times and 300 Hz for 300 s. *West, J. B., J-QE 75 Sep* 18D-19D (2C06)
energy transfer processes in organic dye mixtures; simultaneous laser actions at the primary colors from three-dye mixture. *Ahmed, S. A., J-QE 75 Sep* 2D-3D (1B04)
high-power lasers; mechanisms limiting operation. *Glenn, W. H., J-QE 75 Sep* 5D (2B07)
high-power lasers; thermally induced optical inhomogeneities in active volume. *Peterson, O. G., J-QE 75 Sep* 4D-5D (2B06)
high-power lasers using free jet stream of liquid dye solution. *Foley, R. J., J-QE 75 Sep* 5D (2B07)
infrared dyes; lasing efficiency and photochemical stability in spectral region 710–950 nm. *Oettinger, P. E., J-QE 75 Sep* 3D-4D (2B05)
infrared lasers; near-IR emission from 16 new flashlamp-pumped dyes. *Webb, J. Pierce, J-QE 75 Mar* 114-119 (1B06)
infrared lasers; superradiant near-IR emission from ultraviolet-pumped dye solutions. *Lin, Chinlon, J-QE 75 Jan* 61 (1E07)
oligo-mode distance control using spatial hole burning. *Hertel, Ingolf V., J-QE 75 May* 210-212 (1C04)
photodegradation of organic laser dyes; study using esr detection of laser-induced triplet molecules and free radicals. *Yamashita, Mikio, J-QE 75 Sep* 3D (2B05)
pulsed high-repetition-rate lasers; transverse-flow laser pumped by linear close-coupled flashlamps. *Friedman, H. W., J-QE 75 Sep* 4D (2B06)
pulse generation; subnanosecond tunable pulse generation in N_2-laser-pumped lasers using controlled resonator transients. *Lin, Chinlon, J-QE 75 Sep* 1D-2D (2B03)
relaxation oscillations and initial spikes in N_2 laser-pumped dye lasers; tunable nanosecond pulse generation in UV and visible region. *Lin, Chinlon, J-QE 75 Aug* 602-609 (1C08)
resonant Doppler velocimeters for gas flow measurement and visualization. *Miles, R. B., J-QE 75 Sep* 35D-36D (2D09)

Rhodamine-6G lasers; long-pulse generation in laser pumped by Co_2-laser-heated plasma. *Brown, Robert T., J-QE 75 Sep* 800-801 (1F08)
spectrometer for analysis of pulsed vacuum arcs. *Hargis, P. J., Jr., J-QE 75 Sep* 24D (2C12)
synchronous mode-locked laser pumped by frequency-doubled, passively mode-locked Nd:YAG laser; picosecond pulse generation. *Goldberg, L. S., J-QE 75 Sep* 2D (1B04)
terphenyl dye laser; optical pumping by UV radiation from CO_2-laser-produced Xe plasma. *Silfvast, W. T., J-QE 75 Sep* 1D (2B03)
tunable Rhodamine-6G dye laser; high-power pulsed Xe ion laser as pump source. *Schearer, Laird D., J-QE 75 Dec* 935-937 (1A09)
vapor laser using organic scintillator dye POPOP. *Smith, Peter W., J-QE 75 Feb* 84-89 (1B08)
visible lasers; high-power blue and violet lasers pumped by third harmonic of Nd:YAG laser. *Kato, K., J-QE 75 Jul* 373-374 (1E03)

E

Earth
soil compaction quality checking using lasers. *Drakatos, Panagiotis A., J-QE 75 Sep* 84D-86D (3A01)
Electrical dissociation pumping; **cf.** Gas lasers
Electric discharge pumping; **cf.** Gas lasers
Electric heating; **cf.** Arc heating
Electric variables measurement; **cf.** Pulse measurements
Electroluminescent devices; **cf.** Light-emitting diodes
Electromagnetic diffraction; **cf.** Optical diffraction
Electromagnetic propagation; **cf.** Optical propagation
Electromagnetic pulse generators
microwave and millimeter-wave pulse generation using Si optoelectronic switches. *Johnson, A. M., J-QE 75 Jun* 283-287 (1E05)
Electromagnetic radiation effects
microwave radiation effects; isotope separation using radiation pressure. *Gelbwachs, Jerry, J-QE 75 Jan* 52-54 (1D12)
Electromagnetic reflection; **cf.** Optical reflection
Electromagnetic refraction; **cf.** Optical refraction
Electron-beam pumping; **cf.** Gas lasers
Electrooptics
self-heating compensation in CD*A crystals during second-harmonic generation. *Hon, D., J-QE 75 Sep* 67D-68D (2F13)
Electrooptics; **cf.** Pockels effect
Electrooptic modulation
(Ga,Al)P optical planar waveguide modulators; mode-dependent modulation. *Bortfeld, David P., J-QE 75 Mar* 108-110 (1A14)
GaAs channel-waveguide modulators. *Campbell, J. C., J-QE 75 Sep* 63D-64D (2F09)
KTN single-crystal thin-film modulators. *Fontana, R. E., Jr., J-QE 75 Sep* 38D (2D12)
laser communications system using external polarization electrooptic modulation and avalanche diode detection; optimum carrier-to-noise ratio. *Waksberg, Armand L., J-QE 75 Sep* 778-782 (1D14)
mode coupling; electrooptic coupling between TE and TM modes in anisotropic slab waveguides. *Marcuse, D., J-QE 75 Sep* 759-767 (1C09)
optical planar waveguide modulators using grain-oriented polycrystalline ZnO film. *Hu, Chenming, J-QE 75 Sep* 64D (2F10)
resonant piezo-electrooptic modulation. *Halido, D., J-QE 75 Sep* 64D-65D (2F10)
ZnO optical planar waveguide modulators. *Hammer, Jacob M., J-QE 75 Apr* 138-148 (1B06)
Electrooptic switches
optical planar waveguide switches; electrode configuration for producing prism-like deflector on guide. *Kaminow, I. P., J-QE 75 Aug* 633-635 (1E11)
Energy transfer; **cf.** Relaxation processes
Environmental pollution; **cf.** Air pollution
Epitaxial growth; **cf.** Semiconductor growth
Excimer lasers; **cf.** Noble gas lasers, molecular
Excitation of lasers; **cf.** Laser excitation
Explosions
explosive vapor detection using laser optoacoustic detector. *Claspy, P. C., J-QE 75 Sep* 37D (2D11)

F

Fabrication; **cf.** Integrated-circuit fabrication; Laser materials-processing applications; Semiconductor device fabrication
Fabry–Perot interferometers
laser tuning;-frequency tunable 15-atm electron-beam-controlled CO_2 laser. *O'Neill, F., J-QE 75 Sep* 74D-75D (2G06)
Fading channels; **cf.** Diversity communication
Faraday effect
infrared isolators; Ge high-power isolator for 10 μm region using interband Faraday effect. *Phipps, C. M., Jr., J-QE 75 Sep* 70D-71D (2G03)
Far infrared; **cf.** Submillimeter-wave (300–3000 GHz)
Fault diagnosis; **cf.** Communication system fault diagnosis
Feedback amplifiers
optical fiber communication repeaters; 40-Mb/s and 400-Mb/s repeaters using feedback-type amplifiers. *Ueno, Y., J-QE 75 Sep* 78D-79D (2G10)
Feedback lasers; **cf.** Distributed-feedback lasers
Feedback systems
frequency-selective optical feedback; suppression of self-induced intensity pulsations from CW junction lasers. *Paoli, Thomas L., J-QE 75 Jul* 525-527 (3D07)
Nd:glass lasers; light emission control. *Panarella, Emilio, J-QE 75 May* 181-185 (1A03)
Q-switched ruby lasers; pulse shaping by compound feedback. *Loveberg, R. V., J-QE 75 Jan* 17-21 (1B05)
Fiber optics; **cf.** Optical fibers
Fiber waveguides; **cf.** Optical fiber waveguides
Filters; **cf.** Acoustic filters; Acoustooptic filters; Optical filters
Flashlamps
pulsed high-current gas-filled flashlamps; near-ultraviolet spectral efficiency. *Gusinow, M. A., J-QE 75 Dec* 929-934 (1A03)
Flight control; **cf.** Aircraft control
Fluid flow; **cf.** Gas flow
Fluorescence
$LiNdP_4O_{12}$. *Otsuka, Kenju, J-QE 75 Jul* 330-334 (1B02)
narrower-than-natural linewidth fluorescence in Mg atomic beams subjected to CW dye laser radiation. *Gibbs, H. M., J-QE 75 Sep* 91D (3A08)
streak camera studies in photosynthetic systems and plastic scintillators. *Shapiro, S. L., J-QE 75 Sep* 5D-6D (2B07)
FM
guided-optical-wave modulator using acoustic standing wave. *Christensen, C. P., J-QE 75 Oct* 849-850 (1D05)
FM pulse-compression methods; **cf.** Chirp modulation
Focusing; **cf.** Laser-beam focusing
Food industry
universal product code symbol; laser scanners for reading. *Dickson, L., J-QE 75 Sep* 23D-24D (2C11)
Fourier transforms
holograms of simple plane objects; recording using X-rays. *Mahr, H., J-QE 75 Sep* 97D-98D (3A14)
Frequency conversion
laser frequency doubling; mode-locked lasers with internal frequency doubling. *Falk, Joel, J-QE 75 Jan* 21-31 (1B09) ♦
Frequency conversion; **cf.** Optical frequency conversion
Frequency-domain analysis
lasers; mode-locked intracavity frequency-doubled laser. *Kennedy, C. J., J-QE 75 Nov* 857-862 (1A03)
Frequency modulation; **cf.** FM
Frequency multiplication; **cf.** Frequency conversion
Frequency stability; **cf.** Laser frequency stability
Frequency synthesizers
far-infrared frequency synthesis using saturated-absorption stabilized CO_2 lasers and point-contact diode. *Petersen, F. Russell, J-QE 75 Oct* 838-843 (1C08)
Fusion; **cf.** Nuclear fusion

G

Gallium alloys/compounds
GaAs; dislocation pinning by Group III or V impurities. *Kirkby, P. A., J-QE 75 Jul* 562-568 (3G02)
GaAs; elastooptic coefficient p_4. *Halido, D., J-QE 75 Sep* 64D-65D (2F10)
Gallium alloys/compounds, devices
(Ga,Al)P optical planar waveguide modulators; mode-dependent modulation. *Bortfeld, David P., J-QE 75 Mar* 108-110 (1A14)
GaAs channel-waveguide modulators. *Campbell, J. C., J-QE 75 Sep* 63D-64D (2F09)
GaAs diffused optical strip waveguides. *Garmire, E., J-QE 75 Sep* 38D-39D (2D12)
GaAs modulators; resonant piezo-electrooptic modulator. *Halido, D., J-QE 75 Sep* 64D-65D (2F10)
GaAs or AlGaAs laser diode array pumping of Nd:YAG lasers. *Reno, C. W., J-QE 75 Sep* 16D (2C04)
optical waveguides; rib structure for transverse-mode control in injection lasers. *Lee, T. P., J-QE 75 Jul* 432-435 (2D12)
Gallium alloys/compounds, lasers
AlGaAs CW double-heterostructure lasers; intensity fluctuation changes after degradation. *Gonda, Shun-Ichi, J-QE 75 Jul* 545-550 (3E13)
AlGaAs double-heterostructure diode lasers; rib-guide optical-waveguide structure for transverse-mode control. *Lee, T. P., J-QE 75 Jul* 432-435 (2D12)
AlGaAs double-heterostructure junction lasers; depolarization of lasing emission. *Paoli, Thomas L., J-QE 75 Jul* 489-494 (3A13)
AlGaAs multiheterostructure laser with integrated twin guide. *Suematsu, Y., J-QE 75 Jul* 457-460 (2F09)
buried-heterostructure lasers with GaAs active regions completely buried in GaAlAs; thermal characteristics and CW operation. *Tsukada, Toshihisa, J-QE 75 Jul* 494-498 (3B04)
double-heterostructure GaAs/GaAlAs lasers with oxide-insulated stripe geometry; CW lasing range and light-output power. *Garel-Jones, P., J-QE 75 Jul* 408-413 (2C02)
GaAlAs composite-guide heterostructure diode lasers; grating-coupled laser with low-divergence beams. *Burnham, R. D., J-QE 75 Sep* 98D-99D (3B01)
GaAlAs double heterostructure lasers; packaged lasers for optical-fiber transmission. *Takusagawa, M., J-QE 75 Sep* 61D (2F07)
GaAlAs–GaAs heterostructure lasers; optical-absorption loss in double-heterostructure and five-layer devices. *Thompson, G. H. B., J-QE 75 Jul* 481-488 (3A05)
GaAlAs heterojunction lasers; scanning system applications. *Gorog, I., J-QE 75 Sep* 63D (2F09)
GaAs–AlGaAs double-heterostructure lasers; integrated taper-coupled laser for optical coupling of active and passive waveguide sections. *Logan, R. A., J-QE 75 Jul* 461-464 (2F13)
GaAs–AlGaAs double-heterostructure lasers using molecular-beam epitaxy layers. *Casey, H. C., Jr., J-QE 75 Jul* 467-470 (2G05)
GaAs–AlGaAs double-heterostructure lasers; dark-line defect sources and propagation. *Ito, Ryoichi, J-QE 75 Jul* 551-556 (3F05)
GaAs–AlGaAs double-heterostructure lasers; direct modulation using Schottky-barrier-gate Gunn-effect digital device. *Yanai, Hisayoshi, J-QE 75 Jul* 519-524 (3D01)
GaAs–AlGaAs injection lasers; dark-line defects causing degradation. *Woolhouse, G. R., J-QE 75 Jul* 556-561 (3F10)
GaAs distributed-feedback lasers; effect of external reflectors on longitudinal modes. *Streifer, William, J-QE 75 Apr* 154-161 (1C08)
GaAs double-heterostructure laser amplifiers. *Schicketanz, D., J-QE 75 Feb* 65-69 (1A03)
GaAs double-heterostructure laser mirrors; near-field emission. *Hakki, B. W., J-QE 75 Apr* 149-154 (1C03)

GaAs double heterostructure lasers; suppression of relaxation oscillations by light injection method. *Lang, R., J-QE 75 Sep* 60D (2F06)
GaAs/GaAlAs double-heterojunction lasers; internal optical loss in very thin CW lasers. *Butler, J. K., J-QE 75 Jul* 402-408 (2B10)
GaAs/GaAlAs double-heterojunction lasers; stripe formation using oxygen-ion implantation. *Blum, Joseph M., J-QE 75 Jul* 413-418 (2C07)
GaAs/GaAlAs double-heterostructure lasers; stripe-geometry laser with current-confining channel formed prior to heterostructure layer growth. *Burnham, R. D., J-QE 75 Jul* 418-420 (2C12)
GaAs/GaAlAs double-heterojunction visible-light-emitting lasers using heteroisolation stripe geometry. *Itoh, Kunio, J-QE 75 Jul* 421-426 (2D01)
GaAs/GaAlAs double-heterostructure injection lasers with distributed feedback; pulsed operation between 80 and 150 K. *Nakamura, Michiharu, J-QE 75 Jul* 436-439 (2E02)
GaAs/GaAlAs double-heterostructure lasers; corrugated grating-coupled laser with low-divergence output normal to waveguide plane. *Zory, P., J-QE 75 Jul* 451-457 (2F03)
GaAs/GaAlAs heterojunction lasers; grating-coupled lasers with low-divergence output through plane parallel to waveguide layer. *Alferov, Z. I., J-QE 75 Jul* 449-451 (2F01)
GaAs/GaAlAs single-heterostructure injection lasers; *H*-pulsing. *Gründorfer, Stephan, J-QE 75 Jul* 532-537 (3D14)
GaAs injection lasers; multimode operation and mode-locking. *Bachert, H., J-QE 75 Jul* 507-510 (3C03)
GaAs large-cavity double-heterostructure lasers; mode selection perpendicular to junction plane. *Krupka, D. C., J-QE 75 Jul* 390-399 (2A12)
GaAs lasers; distributed-feedback single-heterostructure electrically pumped lasers. *Burnham, Robert D., J-QE 75 Jul* 439-449 (2E05)
GaAs lasers; spatially coherent radiation from three-laser arrays in phase-controlled or free-running mode. *Philipp-Rutz, E. M., J-QE 75 Sep* 60D-61D (2F06)
GaAs single-, double- and large-optical cavity heterostructure lasers; gain profile and time-delay effects in external-cavity-controlled lasers. *Rossi, J. A., J-QE 75 Jul* 538-545 (3E06)
InGaPAs–GaAsP single-heterojunction laser diodes; LPE growth and properties. *Coleman, J. J., J-QE 75 Jul* 471-476 (2G09)
monolithic GaInAs homojunction diode lasers. *Doerbeck, F. H., J-QE 75 Jul* 464-467 (2G02)
transverse-junction-stripe lasers with GaAs homojunction sandwiched between GaAlAs layers. *Namizaki, H., J-QE 75 Jul* 427-431 (2D07)

Gas discharges; **cf.** Plasmas

Gas flow

flowing-gas capillary lasers; gas flow in porous wall tube system. *Papayoanou, Aristotle, J-QE 75 Aug* 579-583 (1A13)

Gas flow measurement

resonant Doppler velocimeters using tunable narrow-bandwidth dye lasers. *Miles, R. B., J-QE 75 Sep* 35D-36D (2D09)

Gas flow visualization

resonant Doppler velocimeters using tunable narrow-bandwidth dye lasers. *Miles, R. B., J-QE 75 Sep* 35D-36D (2D09)

Gas lasers

$Ar–N_2$ mixtures; excitation using pulsed electron beams. *Searles, S. K., J-QE 75 Aug* 685 (2D05)
BO, BaO, CuF, SiO and SiF electronic-transition chemical lasers. *Scott, P. B., J-QE 75 Aug* 693-694 (2D13)
Chemical and Molecular Lasers Conference; papers and abstracts from Oct. 1974 conference, *J-QE 75 Aug, Pt. II* 641-722 (2A03)
chemical laser amplifiers; theoretical model. *Tripodi, R., J-QE 75 Aug* 716 (2F08)
chemical lasers for operation at visible wavelengths; reaction initiation by short-duration pulsed discharges. *Chou, M. S., J-QE 75 Aug* 691-692 (2D11)
chemical lasers; laser technique for studying dynamics of vibrationally excited species. *Kaldor, A., J-QE 75 Aug* 697-698 (2E03)
CuI vapor lasers; transversely excited pulsed laser. *Piper, J. A., J-QE 75 Sep* 95D (3A12)
Cu vapor lasers; CuI double-pulsed laser. *Smilanski, I., J-QE 75 Nov* 919-920 (1E09)
Cu vapor lasers; discharge-heated master oscillator power amplifier. *Anderson, R. S., J-QE 75 Sep* 56D-57D (2F02)
Cu vapor lasers; flowing laser for high repetition rate, fast-discharge operation. *Bricks, B. G., J-QE 75 Sep* 57D (2F03)
CW submillimeter emission from optically pumped waveguide lasers. *Radford, Harrison E., J-QE 75 May* 213-214 (1C07)
electronic-transition chemical lasers; parametric evaluation of potential diatomic molecules. *Sutton, D. G., J-QE 75 Aug* 690-691 (2D10)
flowing-gas capillary lasers; porous wall tube system. *Papayoanou, Aristotle, J-QE 75 Aug* 579-583 (1A13)
HF chemical lasers; electron-beam-driven H_2+F_2 high-pressure mixtures. *Gerardo, J. B., J-QE 75 Sep* 56D (2F02)
I lasers; pressure broadening and saturation behavior of Asterix III pulsed high-power laser. *Fuss, W., J-QE 75 Sep* 43D (2E03)
I lasers; pulsed high-power Asterix III laser for laser fusion experiments. *Brederlow, G., J-QE 75 Sep* 42D-43D (2E02)
I photodissociation lasers; photodissociation of C_3F_7I by UV radiation from CO_2-laser-produced Xe plasma. *Silfvast, W. T., J-QE 75 Sep* 1D (2B03)
metal vapor lasers; electronic-to-electronic energy transfer rates in Na vapor. *Chen, Hao-Lin, J-QE 75 Aug* 669-672 (2C03)
N_2 lasers; photopreionization of pulsed lasers. *Kurnit, N. A., J-QE 75 Apr* 174-176 (1D14)
$Na–N_2O+CO$ chemical laser; parametric study of gain. *Benson, R. C., J-QE 75 Aug* 688-689 (2D08)
output intensity; three-dimensional analysis of Gaussian mode interactions with laser transitions. *Witteman, W. J., J-QE 75 May* 198-204 (1B06)
photodissociation I laser amplifiers; kinetic model. *Turner, C. E., Jr., J-QE 75 Aug* 709-710 (2F01)
resonators; eigenmode loss behavior of unstable resonators with cylindrical and circular mirrors at small and large Fresnel numbers. *Santana, C., J-QE 75 Sep* 58D-59D (2F04)
Sn(I) lasers. *Sutton, D. G., J-QE 75 Jun* 312 (1G06)
visible chemical lasers using reactions of evaporated metal atoms with various oxidizers. *Eckstrom, D. J., J-QE 75 Aug* 691 (2D11)
V–T and V–V intermolecular potential computation; application to $N_2–CO_2$ system. *Witriol, N. M., J-QE 75 Aug* 717 (2F09)

Gas lasers; **cf.** Dye lasers; Noble-gas lasers

Gas lasers, atomic

ArO lasers; parameters of flash-photolyzed $N_2O–Ar_2$ mixtures. *Hughes, William M., J-QE 75 Sep* 88D (3A05)
B lasers; pulsed lasers pumped by incomplete uatoionization or ion–electron recombination. *Stricker, J., J-QE 75 Aug* 701-702 (2E07)
Cl atom lasers; quenching of Ar metastable atoms by Cl atoms and molecules in dc-discharge-excited Cl–Ar mixtures. *King, D. L., J-QE 75 Aug* 708 (2E14)
Cs and Rb electronic-transition chemical lasers; population inversions. *Hall, L. H., J-QE 75 Aug* 693 (2D13)
Cu vapor laser produced by discharge heating. *Anderson, R. S., J-QE 75 Apr* 172-174 (1D12)
Group VI element (^1S) lasers; production of $O(^1S)$ from N_2O and $S(^1S)$ from OCS. *Black, G., J-QE 75 Aug* 704 (2E10)
Hg lasers; dc-excited Hg pump lamps for CW operation at 546.1 nm. *Holmes, N., J-QE 75 Sep* 55D (2F01)
I lasers; 1.32 μm emission from atomic I produced by electrical dissociation of CF_3I. *Pleasance, L. D., J-QE 75 Sep* 94D-95D (3A11)
I lasers; deactivation of electronically excited I atoms. *Burde, D. H., J-QE 75 Aug* 709 (2F01)
I* lasers; direct measurement of initial yields of I and I* atoms in flash-photolyzed alkaly iodides. *Wiesenfeld, J. R., J-QE 75 Aug* 703-704 (2E09)
I lasers; emission at 1.315 μm following injection of HI into microwave-discharge He/O_2 flow. *Pirkle, Robert J., J-QE 75 Oct* 834-838 (1C04)
I photodissociation lasers; stimulated-emission cross section and inversion lifetime. *Aldridge, F. T., J-QE 75 May* 215-216 (1C09)
O(I) atomic lasers with emission at 2.652 μm. *Sutton, D. G., J-QE 75 Feb* 92 (1C02)
O lasers using $^1S–^1D$ transition; lasing at 5578.5 Å in relativistic-electron-beam excited Kr_2/O_2 mixtures. *Johnson, A. W., J-QE 75 Sep* 56D (2F02)

Gas lasers, atomic; **cf.** Noble-gas lasers

Gas lasers, ionic

Ba vapor lasers; visible laser transitions at 7120 Å in Ba I and at 549.9 and 6141.7 Å in Ba (II). *Baron, K. U., J-QE 75 Oct* 852-853 (1D08)
$He–Cd^+$ lasers emitting CW white light; single-gun hollow cathode tube with three-color outputs. *Fujii, Kan-Ichi, J-QE 75 Mar* 111-114 (1B03)
$He–Cd^+$ lasers; saturation mechanisms of power output. *Mizeraczyk, Jerzy K., J-QE 75 May* 218-220 (1C12)

Gas lasers, ionic; **cf.** Noble-gas lasers

Gas lasers, molecular

anharmonic diatomic molecular lasers; quasi-equilibrium vibrational population distributions. *Lam, S. H., J-QE 75 Aug* 715-716 (2F07)
BaF, BaCl, BaBr and BaI electronic-transition chemical lasers. *Bradford, R. S., Jr., J-QE 75 Aug* 692 (2D12)
calcium and strontium oxide and halide chemical lasers; photon yields in 250–1100 nm region and $A'^1\pi$ molecular constants. *Capelle, G. A., J-QE 75 Aug* 692 (2D12)
CH_3F far-infrared laser; pulse characteristics of optically pumped laser. *Bluyssen, H. J. A., J-QE 75 Jul* 341-348 (1B13)
CH_3OH far-infrared lasers; four-level rate equation model and output power expression for optically pumped laser. *Henningsen, J. O., J-QE 75 Jun* 248-252 (1B12)
CH_3OH lasers; far-infrared lines from CO_2-laser-pumped laser. *Tanaka, Atsuo, J-QE 75 Oct* 853-854 (1D09)
CS_2 lasers; $He/N_2/CS_2$ or $He/Co/CS_2$ mixtures directly excited in electron-beam-stabilized discharge. *Nelson, L. Y., J-QE 75 Aug* 686 (2D06)
cyanide radical photodissociation and predissociation chemical lasers; molecular electronic and vibrational lasers. *West, G. A., J-QE 75 Aug* 687 (2D07)
diatomic molecules; vibrational–vibrational collision probability measurements for large vibrational quantum numbers. *Nachshon, Yehuda, J-QE 75 Aug* 654-660 (2B02)
FeO electronic-transition chemical lasers. *West, J. B., J-QE 75 Aug* 692-693 (2D12)
GeO and SiO electronic-transition chemical lasers. *Wilson, L. E., J-QE 75 Aug* 691 (2D11)
H_2O, D_2O and CH_3OH lasers; measurement of line frequencies using far-infrared frequency synthesis technique. *Petersen, F. Russell, J-QE 75 Oct* 838-843 (1C08)
H_2 vacuum ultraviolet lasers; use in photoionization and excitation of luminescence experiments. *Antonov, V. S., J-QE 75 Sep* 92D (3A09)
H_2 vacuuum ultraviolet lasers; single-short TEA laser, high-repetition rate laser and CW laser. *Knyazev, I. N., J-QE 75 Oct* 805-817 (1A03)
HCN lasers; role of hydrogen. *Schötzau, Hans J., J-QE 75 Oct* 817-822 (1B01)
metal atom/N_2O visible chemical lasers; luminescence. *Felder, W., J-QE 75 Aug* 703 (2E09)
metal atom oxidation chemical lasers using exothermic exchange reactions; 30 new laser molecules. *Rice, W. W., J-QE 75 Aug* 689-690 (2D09)
N_2 lasers; 3371-Å laser power produced by relativistic electron-beam propagation. *McArthur, David A., J-QE 75 Nov* 892-902 (1C10)
N_2 lasers; first- and second-positive emission from N_2/SF_6 laser. *Suchard, Steven N., J-QE 75 Nov* 908-916 (1D12)
N_2 lasers; near-infrared first positive system laser using ionizer-sustainer discharge excitation. *Newman, L., J-QE 75 Aug* 686 (2D06)
N_2 lasers; quasi-CW second-positive laser using SF_6 additions to N_2 in discharge region. *Suchard, S. N., J-QE 75 Aug* 685-686 (2D05)
N_2 lasers; stimulated emission at 0.3159 μm in second-positive system at room temperature. *Kruger, John S., J-QE 75 Sep* 801-802 (1F09)
N_2O chemical lasers using energy transfer from vibrationally excited CO. *Petersen, A. B., J-QE 75 Aug* 699-700 (2E05)
N_2/SF_6 lasers; first and second positive band emission. *Suchard, S. N., J-QE 75 Sep* 26D-27D (2C14)
Na_2 molecular lasers; optically pumped superfluorescent laser. *Henesian, M., J-QE 75 Sep* 26D (2C14)
SF_6 lasers; optically pumped laser emitting at 15.90 μm. *Fetterman, H. R., J-QE 75 Sep* 88D-89D (3A05)

vibrationally excited molecules; deactivation by potentially reactive atoms. *Smith, I. W. M., J-QE 75 Aug* 696 (2E02)
vibration–vibration transfer lasers; theoretical performance. *Naismith, R., J-QE 75 Aug* 716 (2F08)
Gas lasers, molecular; **cf.** Carbon dioxide lasers; Carbon monoxide lasers; Hydrogen halide lasers; Noble-gas lasers
Gates; **cf.** Logic gates
Geophysical measurements
strain in earth's crust; measurement using 700-m long mode-locked Ar ion laser. *Tripathi, P. P., J-QE 75 Sep* 59D (2F05)
Germanium devices
optical isolators; high-power isolators for 10 μm region using interband Faraday effect. *Phipps, C. M., Jr., J-QE 75 Sep* 70D-71D (2G03)
switches; fast switching of high-power CO_2 laser radiation by optically induced carriers. *Alcock, A. J., J-QE 75 Sep* 96D (3A13)
Germanium alloys/compounds, devices
lasers; excited electronic states of GeO electronic-transition lasers. *Harris, R. A., J-QE 75 Aug* 691 (2D11)
lasers; GeO electronic-transition chemical lasers. *Wilson, L. E., J-QE 75 Aug* 691 (2D11)
Glass
Nd-doped laser glasses; tailoring for specific applications by compositional changes. *Jacobs, R. R., J-QE 75 Sep* 13D (2C01)
silicate laser glass; nonradiative relaxation of rare-earth ions. *Layne, C. B., J-QE 75 Sep* 798-799 (1F06)
Glass devices
lasers for nuclear fusion; refractive index nonlinearity of transparent dielectric material. *Glass, A. J., J-QE 75 Sep* 28D-29D (2D02)
Glass devices; **cf.** Neodymium:glass lasers; Solid lasers
Gunn devices
Schottky-barrier-gate digital device for direct modulation of GaAs–AlGaAs double-heterostructure lasers. *Yanai, Hisayoshi, J-QE 75 Jul* 519-524 (3D01)

H

Harmonic generation; **cf.** Optical harmonic generation
Heating; **cf.** Electric heating
Helicopters
flight control; hover sensor for heavy lift helicopter. *Herzog, D. G., J-QE 75 Sep* 51D-52D (2E11)
Heterodyne detection; **cf.** Optical heterodyne detection
Heterodyning; **cf.** Optical heterodyning
Heterojunctions; **cf.** Semiconductor heterojunctions
Holmium; **cf.** Rare earths
Holographic memories
erasure techniques; selective erasure of holograms superimposed in $LiNbO_3$ crystals. *Huignard, J. P., J-QE 75 Sep* 8D-9D (2B10)
Holographic recording
Fourier-transform holograms of simple plane objects; recording using X-rays. *Mahr, H., J-QE 75 Sep* 97D-98D (3A14)
optical video disks. *Tsunoda, Y., J-QE 75 Sep* 11D-12D (2B13)
Holography
optical waveguide couplers; holographic couplers for optical fiber and planar waveguides. *Nishihara, H., J-QE 75 Sep* 794-796 (1F02)
rain drop measurements using pulsed holography technique. *Zakharov, V. M., J-QE 75 Sep* 82D (2G14)
Hybrid integrated circuits
masks for fabrication; automatic laser inspection/repair system. *Fehrs, D. L., J-QE 75 Sep* 21D (2C09)
Hydrogen
isotope separation using lasers. *Teller, E., J-QE 75 Sep* 83D (2G14)
Hydrogen halide lasers
CW chemical lasers; rotational nonequilibrium. *Sentman, L. H., J-QE 75 Aug* 706-707 (2E12)
DF cold-reaction lasers; analysis of small-scale laser. *Steele, R. V., J-QE 75 Aug* 719 (2F11)
DF/HF chemical lasers; portable lasers using recirculating mode of operation. *Chenausky, P. P., J-QE 75 Sep* 58D (2F04)
DF* lasers; deactivation kinetics in combustion driven lasers using alternates for $H_2/Fd'D_2$ reactant system. *Wendelken, C. P., J-QE 75 Aug* 694-695 (2D14)
DF lasers; electrically initiated pulsed chemical laser. *Poehler, T. O., J-QE 75 Aug* 710 (2F02)
$DF(v)+HF$, $DF(v)+D_2$ and $HF(v)+H_2$ systems; room temperature relaxation rates. *Kwok, M. A., J-QE 75 Aug* 695 (2E01)
DF supersonic chemical lasers; power and pressure recovery measurements in high-Mach-number lasers. *Hyde, J. C., J-QE 75 Aug* 718 (2F10)
H_2–F_2 high-power pulsed chemical lasers; mixture stability and construction materials. *Getzinger, R. W., J-QE 75 Aug* 698 (2E04)
H_2/HCl V–V transfer lasers; theoretical performance. *Naismith, R., J-QE 75 Aug* 716 (2F08)
HCl chemical lasers; spectroscopic measurements of $Cl+HI\rightarrow$ ⁵⁄₈¹⁄₄∼ ⁵⁄₈∞⊗⊥. *Carabetta, R. A., J-QE 75 Aug* 689 (2D09)
HCl chemical lasers; transverse-flow laser using $H+Cl_2$ reaction. *Wanner, J., J-QE 75 Aug* 706 (2E12)
HCl/H_2 gas dynamic laser calculations. *Holmes, C. P., J-QE 75 Aug* 704-705 (2E10)
HCl lasers; measurement of pressure-broadened infrared linewidths in HCl–Ar mixtures. *Wormhoudt, J., J-QE 75 Aug* 704 (2E10)
HCl lasers; vibrational excitation by electron impact. *Center, R. E., J-QE 75 Aug* 687 (2D07)
HCl molecular vibrational lasers; chloroethylene photochemical laser. *Berry, M. J., J-QE 75 Aug* 687-688 (2D07)
HCl molecules; deactivation of vibrationally excited molecules by H and Cl atoms. *Wilkins, R. L., J-QE 75 Aug* 716-717 (2F08)
$HCl(v=1)$ and $DCl(v=1)$; rate coefficients for relaxation by Cl and O atoms. *Brown, R. D. H., J-QE 75 Aug* 695-696 (2E01)
$HCl(v=1)+Cl$ and $DCl(v=1)+Cl$ systems; vibrational relaxation in potentially reactive collisions. *Smith, I. W. M., J-QE 75 Aug* 696 (2E02)
HCl pulsed chemical lasers; premixed R–Cl/HI fuel mixtures initiated by transverse pulsed discharge. *Manuccia, T. J., J-QE 75 Nov* 921-923 (1E11)
HF and HCl chemical lasers; reaction mechanism and energy distribution in flash-photolyzed Cl_3–H_2 system. *Krogh, O. D., J-QE 75 Aug* 706 (2E12)
HF and HCl rotational laser emission from elimination reactions. *Cuellar, E., J-QE 75 Aug* 688 (2D08)
HF chain-reaction lasers; supersonic CW laser. *Cummings, J. C., J-QE 75 Aug* 712 (2F04)
HF chain-reaction lasers; generation of vibrationally excited HF for CW laser. *Meinzer, R. A., J-QE 75 Aug* 712-713 (2F04)
HF chemical laser amplifiers; amplification characteristics of 5 transitions. *Lynds, L., J-QE 75 Aug* 713-714 (2F05)
HF chemical lasers; electron-beam-initiated laser using mixture of SF_6 and C_2H_6. *Patterson, E. L., J-QE 75 Aug* 642-648 (2A04)
HF chemical lasers; electrically initiated pulsed atmospheric lasers. *Mangano, J. A., J-QE 75 Aug* 705 (2E11)
HF chemical lasers; repetitively pulsed operation of chain-reaction lasers. *H_2/F_2 flame propagation and repetitively pulsed hydrogen fluoride (HF) chain-reaction chemical laser, J-QE 75 Aug* 648-653 (2A10)
HF chemical lasers; temporal characteristics of multiline–multimode CW lasers. *Foster, M. C., J-QE 75 Aug* 714 (2F06)
HF chemical mixing lasers; CW lasers as local oscillators for middle-IR heterodyne applications. *Freiberg, R. J., J-QE 75 Sep* 57D-58D (2F03)
HF CW chemical lasers; transverse mode oscillations in lasers with stable selected-line resonators. *Boedeker, L., J-QE 75 Aug* 713 (2F05)
HF, DF and HCl chemical lasers; hydrogen halide molecule deactivation by atomic collisions. *Quigley, G. P., J-QE 75 Aug* 696-697 (2E02)
HF/DF chain-reaction CW lasers. *Sadowski, T. J., J-QE 75 Aug* 705-706 (2E1
HF/DF lasers; atmospheric transmission measurements. *King, S. R., J-QE 75 Sep* 87D (3A04)
HF/DF lasers; frequency stabilization and absolute frequency measurements. *Eng, R. S., J-QE 75 Sep* 87D-88D (3A04)
HF/DF lasers; intermolecular vibration-to-vibration energy transfer by dimer formation. *Shin, Hyunk Kyu, J-QE 75 Aug* 679-684 (2C13)
HF/DF supersonic chemical lasers; spectroscopic and infrared measurements. *Kwok, M. A., J-QE 75 Aug* 718 (2F10)
HF/DF supersonic chemical lasers; gas heater and nozzle array performance. *Giedt, R. R., J-QE 75 Aug* 718-719 (2F10)
HF/DF supersonic diffusion chemical lasers; spectrographic systems for diagnostic experiments. *Varwig, R. L., J-QE 75 Aug* 719 (2F11)
HF–He and DF–He mixtures and pure DF samples; vibrational relaxation between 200 and 300°K. *Hancock, J. K., J-QE 75 Aug* 694 (2D14)
HF lasers; arc- and combustion-driven CW laser performance. *Grohs, G. L., J-QE 75 Aug* 717 (2F09)
HF lasers; emission and CO population distribution studies of $O(^3P)+CHF$ reaction. *Shortridge, R. G., J-QE 75 Aug* 688 (2D08)
HF lasers; lasing of overtone transitions in electrical pulse-initiated chemical laser. *Hon, J. F., J-QE 75 Aug* 698-699 (2E04)
HF lasers using mixtures of SF_6 and HI; time-resolved spectrum from transverse-discharge laser. *Greiner, N. R., J-QE 75 Oct* 844-845 (1C14)
HF lasers; vibrational distributions of HF formed in reactions of HN_3 photolysis products with fluoromethanes. *Poole, P. R., J-QE 75 Aug* 688 (2D08)
$HF(v=1)$ deactivation by H atoms. *Heidner, R. F., J-QE 75 Aug* 696 (2E02)
HF pulsed chemical lasers; effect of rotational nonequilibrium on predicted performance. *Hough, J. J. T., J-QE 75 Aug* 699 (2E05)
HF pulsed chemical lasers; rotational nonequilibrium. *Creighton, J. R., J-QE 75 Aug* 699 (2E05)
HF; rotational relaxation effects. *Hinchen, J. J., J-QE 75 Aug* 695 (2E01)
HF vibrational lasers; potential new chain reaction mechanisms for pumpin
Schott, G. L., J-QE 75 Aug 690 (2D10)

I

Image processing
near-real-time coherent processing system. *Iwasa, S., J-QE 75 Sep* 8D (2B10)
Image sensors
streak camera tubes; Photochron II tube. *Bradley, D. J., J-QE 75 Sep* 25D-26D (2C13)
universal product code symbol; optical scanners using lasers for reading. *Dickson, L., J-QE 75 Sep* 23D-24D (2C11)
Imaging; **cf.** Holography; Photography; Radar imaging; Radiography
Impurities; **cf.** Semiconductor impurities
Indium alloys/compounds; **cf.** Gallium alloys/compounds
Indium alloys/compounds, devices; **cf.** Semiconductor lasers
Infrared (0.70–100 μm); **cf.** Submillimeter-wave (300–3000 GHz)
Infrared absorption; **cf.** Infrared propagation, absorbing media
Infrared demodulation
CO_2 waveguide lasers; demodulation technique for chirp-modulated laser. *Stein, Alexander, J-QE 75 Aug* 630-631 (1E08)
wideband heterodyne detection at 10.6 μm using planar HgCdTe photodiodes. *Spears, D. L., J-QE 75 Sep* 79D (2G11)
Infrared filters
Tl_3AsSe_3 acoustooptic filters; tunable collinear filter for intermediate infrared. *Feichtner, J. D., J-QE 75 Sep* 66D-67D (2F12)
Infrared generation
picosecond pulse generation using synchronous mode-locked dye laser and nonlinear mixing; tunable pulses over 1.1–1.7 μm and 2.7–5.6 μm. *Goldberg, L. S., J-QE 75 Sep* 2D (1B04)
Infrared isolators; **cf.** Optical isolators
Infrared lasers
2.3-μm Tm^{3+} lasers; room-temperature pulsed emission from Tm:Cr:YAG and $Tm:Cr:YAlO_3$ lasers. *Caird, John A., J-QE 75 Nov* 874-881 (1B06)
BaF, BaCl, BaBr and BaI electronic-transition chemical lasers. *Bradford, R. S., Jr., J-QE 75 Aug* 692 (2D12)
B atomic lasers; pulsed lasers pumped by incomplete autoionization or ion–electron recombination. *Stricker, J., J-QE 75 Aug* 701-702 (2E07)
calcium and strontium oxide and halide chemical lasers; photon yields in 250–1100 nm region and $A\,^1\pi$ molecular constants. *Capelle, G. A., J-QE 75 Aug* 692 (2D12)

CH_3F far-infrared laser; pulse characteristics of optically pumped laser. *Bluyssen, H. J. A., J-QE 75 Jul* 341-348 (1B13)
CH_3OH lasers; far-infrared lines from CO_2-laser-pumped CH_3OH gas. *Tanaka, Atsuo, J-QE 75 Oct* 853-854 (1D09)
CS_2 lasers; $He/N_2/CS_2$ or $He/Co/CS_2$ mixtures directly excited in electron-beam-stabilized discharge. *Nelson, L. Y., J-QE 75 Aug* 686 (2D06)
cyanide radical photodissociation and predissociation chemical lasers; molecular electronic and vibrational lasers. *West, G. A., J-QE 75 Aug* 687 (2D07)
DF and DF–CO_2 electrically initiated pulsed chemical lasers. *Poehler, T. O., J-QE 75 Aug* 710 (2F02)
dye lasers; lasing efficiency and photochemical stability of infrared dyes in spectral region 710–950 nm. *Oettinger, P. E., J-QE 75 Sep* 3D-4D (2B05)
He–Xe mixtures; simultaneous lasing at 2.03, 2.65 and 3.65 μm in fast-flow high-pressure system for closed-cycle operation. *Olson, Robert A., J-QE 75 Sep* 95D-96D (3A12)
HgCdTe magnetically tunable lasers; tunable spin-flip and recombination lasers using optical pumping. *Sattler, J. P., J-QE 75 Sep* 18D (2C06)
Ho:YLF lasers; 2.06 μm laser performance and design options for rangefinder and illuminator applications. *Devor, D. P., J-QE 75 Sep* 13D-14D (2C01)
I lasers; 1.32 μm emission from atomic I produced by electrical dissociation of CF_3I. *Pleasance, L. D., J-QE 75 Sep* 94D-95D (3A11)
I lasers; emission at 1.315 μm following injection of HI into microwave-discharge He/O_2 flow. *Pirkle, Robert J., J-QE 75 Oct* 834-838 (1C04)
I photodissociation lasers; 1.315 μm emission from C_3F_7I optically pumped by UV radiation from CO_2-laser-produced Xe plasma. *Silfvast, W. T., J-QE 75 Sep* 1D (2B03)
metal atom oxidation chemical lasers using exothermic exchange reactions; 30 new laser molecules. *Rice, W. W., J-QE 75 Aug* 689-690 (2D09)
N_2 lasers; near-infrared first positive system laser using ionizer-sustainer discharge excitation. *Newman, L., J-QE 75 Aug* 686 (2D06)
Na_2 molecular lasers; optically pumped superfluorescent laser. *Henesian, M., J-QE 75 Sep* 26D (2C14)
Nd:$LiNbO_3$ lasers; emission at 1.0845 μm. *Kaminow, I. P., J-QE 75 Jun* 306-308 (1F14)
Nd:YVO_4 lasers. *DeShazer, L. G., J-QE 75 Sep* 84D (3A01)
Ne–N_2 lasers; direct nuclear pumped laser with simultaneous output at 8629 and 9393 Å. *DeYoung, R. J., J-QE 75 Sep* 97D (3A14)
O(I) atomic lasers with emission at 2.652 μm. *Sutton, D. G., J-QE 75 Feb* 92 (1C02)
rate equation model and output power expression for optically pumped far-infrared laser. *Henningsen, J. O., J-QE 75 Jun* 248-252 (1B12)
SF_6 lasers; optically pumped laser emitting at 15.90 μm. *Fetterman, H. R., J-QE 75 Sep* 88D-89D (3A05)
Sn(I) lasers; two-electron transition at 1.061 μm. *Sutton, D. G., J-QE 75 Jun* 312 (1G06)

Infrared lasers; **cf.** Carbon dioxide lasers; Dye lasers; Hydrogen halide lasers; Neodymium:solid lasers

Infrared propagation, absorbing media
atmospheric absorption measurements using solar infrared heterodyne radiometer. *Christophe, B., J-QE 75 Sep* 32D-33D (2D06)
CO_2 laser radiation; absorption by water vapor. *Shumate, M. S., J-QE 75 Sep* 33D-34D (2D07)
infrared absorption lineshapes; measurement of pressure-broadened lines using optical parametric oscillator. *Wormhoudt, J., J-QE 75 Aug* 704 (2E10)
N_2F_4 absorption cells for passive Q-switching of CO_2 lasers. *Suart, R. D., J-QE 75 Aug* 698 (2E04)

Infrared propagation, absorbing media; **cf.** Infrared radio propagation

Infrared radio communication
receivers; 10-μm optical heterodyne receiver for satellite communication. *Goodwin, F. E., J-QE 75 Sep* 79D-80D (2G11)
receivers; wideband 10.6-μm heterodyne receiver for CO_2 laser satellite communications link. *Peyton, B. J., J-QE 75 Sep* 80D-81D (2G12)

Infrared radiometry
heterodyne radiometer for solar radiation and atmospheric transmissivity measurements. *Peyton, Bernard J., J-QE 75 Aug* 569-574 (1A03)

Infrared radio propagation
atmospheric absorption measurements using solar infrared heterodyne radiometer. *Christophe, B., J-QE 75 Sep* 32D-33D (2D06)
atmospheric transmissivity measurements in 9–11-μm band using heterodyne radiometer. *Peyton, Bernard J., J-QE 75 Aug* 569-574 (1A03)

Infrared spectroscopy
SO_2 spectral measurements using single magnetic- and current-tuned PbSe laser. *Allario, Frank, J-QE 75 May* 205-209 (1B13)

Infrared waveguides
GaAs diffused optical strip waveguides; single-mode propagation at 1.15 μm in fundamental and first-order modes. *Garmire, E., J-QE 75 Sep* 38D-39D (2D12)

Injection lasers; **cf.** Semiconductor lasers

Inspection
masks for hybrid integrated circuit fabrication; automatic laser inspection/repair system. *Fehrs, D. L., J-QE 75 Sep* 21D (2C09)

Integrated circuits; **cf.** Digital integrated circuits; Hybrid integrated circuits

Integrated-circuit fabrication
mask defects; correction using laser beam. *Lee, F., J-QE 75 Sep* 21D (2C09)
mask generation; precision galvanometer laser-beam deflection system. *Jablonowski, D. P., J-QE 75 Sep* 21D-22D (2C09)
masks for hybrid integrated circuit fabrication; automatic laser inspection/repair system. *Fehrs, D. L., J-QE 75 Sep* 21D (2C09); Integrated optics

Integrated optics
monolithic GaInAs homojunction diode lasers. *Doerbeck, F. H., J-QE 75 Jul* 464-467 (2G02)
Si photodiode arrays. *Boyd, J. T., J-QE 75 Sep* 40D-41D (2D14)
waveguide transitions and bifurcations; optical field propagation. *Roy, A. M., J-QE 75 Sep* 41D-42D (2E01)

Integrated optics; **cf.** Optical planar waveguides; Optical strip waveguides

Interferometry; **cf.** Optical interferometry

Iodine devices; **cf.** Gas lasers

Ion implantation
stripe formation in GaAs/GaAlAs double-heterojunction lasers. *Blum, Joseph M., J-QE 75 Jul* 413-418 (2C07)
ZnTe optical planar waveguides. *Valette, S., J-QE 75 Sep* 39D-40D (2D13)

Ionization; **cf.** Photoionization

Ion lasers; **cf.** Gas lasers; Solid lasers

Iron alloys/compounds, devices
lasers; FeO electronic-transition chemical lasers. *West, J. B., J-QE 75 Aug* 692-693 (2D12)

Isolators; **cf.** Optical isolators

Isotope separation
^{235}U isotope separation using selective photoionization. *Tuccio, Sam A., J-QE 75 Sep* 101D (3B04)
Cu^{63} and Cu^{65}; selective isotope excitation of CuI by Ar ion laser excitation. *Wu, C.Y. R., J-QE 75 Sep* 20D (2C08)
laser deflection of single isotopic component of atomic beam; application to particle spectroscopy. *Bernhardt, A. F., J-QE 75 Sep* 19D (2C07)
laser separation of U and H isotopes. *Teller, E., J-QE 75 Sep* 83D (2G14)
laser separation process for Ti-50. *Gross, R. W. F., J-QE 75 Aug* 702 (2E08)
radiation-pressure separation. *Gelbwachs, Jerry, J-QE 75 Jan* 52-54 (1D12)
U; photoionization cross section and excited state lifetime measurements in U vapor. *Solarz, R. W., J-QE 75 Sep* 19D-20D (2C07)
U; selective two-step laser excitation and photoionization of atomic U vapor. *Janes, G. S., J-QE 75 Sep* 101D-102D (3B04)

J

Japan
optical communication research and development. *Marubayashi, G., J-QE 75 Sep* 76D (2G08)

Junction lasers; **cf.** Semiconductor lasers

Junctions; **cf.** Waveguide junctions

K

Krypton; **cf.** Noble gases

L

Lamps
Hg pump lamps for optically pumped Hg laser. *Holmes, N., J-QE 75 Sep* 55D (2F01)
K–Rb pump lamps for Nd:YAG lasers. *Radecki, Dan J., J-QE 75 Sep* 15D-16D (2C03)

Lamps; **cf.** Arc lamps; Flashlamps

Lanthanum; **cf.** Rare earths

Lasers; **cf.** CW lasers; Distributed-feedback lasers; Dye lasers; Gas lasers; Infrared lasers; Liquid lasers; Pulsed lasers; Raman lasers; Ring lasers; Semiconductor lasers; Solid lasers; Submillimeter-wave lasers; Ultraviolet lasers; Visible lasers; Waveguide lasers

Laser absorbers
N_2F_4 absorption cells for passive Q-switching of CO_2 lasers. *Suart, R. D., J-QE 75 Aug* 698 (2E04)
slow saturable absorber mode locking; closed-form solution for pulses. *Haus, Hermann A., J-QE 75 Sep* 736-746 (1A14)

Laser amplifiers
chemical laser amplifiers; theoretical model. *Tripodi, R., J-QE 75 Aug* 716 (2F08)
Cu vapor lasers; discharge-heated master oscillator power amplifier. *Anderson, R. S., J-QE 75 Sep* 56D-57D (2F02)
CYCLOPS amplifier performance. *Simmons, W. W., J-QE 75 Sep* 31D-32D (2D05)
CYCLOPS amplifier; removal of small-scale beam instabilities using spatial filter. *Simmons, W. W., J-QE 75 Sep* 30D (2D04)
dye-laser amplifiers; gain of transversely pumped lasers. *Ganiel, U., J-QE 75 Nov* 881-892 (1B13)
dye-laser amplifiers; high gain short-pulse-laser amplifiers using synchronous pumping. *Goldberg, L. S., J-QE 75 Sep* 2D (1B04)
GaAs double-heterostructure lasers. *Schicketanz, D., J-QE 75 Feb* 65-69 (1A03)
HF chemical laser amplifiers; amplification characteristics of 5 transitions. *Lynds, L., J-QE 75 Aug* 713-714 (2F05)
JANUS Nd:glass laser system for laser fusion experiments. *Speck, D. R., J-QE 75 Sep* 45D-46D (2E05)
Nd:glass amplifiers; active mirror high-power amplifier. *Hoose, J., J-QE 75 Sep* 12D (2B14)
Nd:glass amplifiers; face-pumped mirror-like structure. *Bret, G., J-QE 75 Sep* 12D-13D (2B14)
Nd:glass laser amplifier chains; optical pulse compression. *Fisher, Robert A., J-QE 75 Jan* 46-52 (1D06)
Nd:glass lasers; parasitic oscillation suppression in large aperture disk lasers using liquid edge cladding. *Guch, S., Jr., J-QE 75 Sep* 30D-31D (2D04)
noble-gas lasers; vacuum ultraviolet lasers pumped by coaxial diode electron-beam system. *Arthurs, E. G., J-QE 75 Sep* 28D (2D02)
photodissociation I laser amplifiers; kinetic model. *Turner, C. E., Jr., J-QE 75 Aug* 709-710 (2F01)
SHIVA 10-kilojoule system at Lawrence Livermore Laboratory. *Gilmartin, T. J., J-QE 75 Sep* 32D (2D06)

Laser amplifiers; **cf.** Carbon dioxide laser amplifiers

Laser applications
chemistry; infrared-laser-augmented decomposition of H_3BPF_3. *Lory, E. R., J-QE 75 Aug* 714-715 (2F06)
chemistry; laser-induced photochemical enrichment of B isotopes. *Freund, S. M., J-QE 75 Aug* 702 (2E08)
chemistry; laser-induced photochemical enrichment of Cl isotopes. *Lamotte, M., J-QE 75 Aug* 702 (2E08)
chemistry; laser-powered homogeneous pyrolysis. *Shaub, W. H., J-QE 75 Aug* 714 (2F06)
chemistry; reactions of nitric oxide with vibrationally excited ozone. *Gordon, R. J., J-QE 75 Aug* 715 (2F07)

energy-crisis applications in nuclear fusion and isotope separation. *Teller, E., J-QE 75 Sep* 83D (2G14)
explosive vapor detection using laser optoacoustic detector. *Claspy, P. C., J-QE 75 Sep* 37D (2D11)
helicopters; precision hover sensor for heavy lift helicopter. *Herzog, D. G., J-QE 75 Sep* 51D-52D (2E11)
isotope separation by selective photoionization. *Tuccio, Sam A., J-QE 75 Sep* 101D (3B04)
isotope separation; laser deflection of single isotopic component of atomic beam for particle spectroscopy. *Bernhardt, A. F., J-QE 75 Sep* 19D (2C07)
isotope separation; photoionization cross section and excited state lifetime measurements in U vapor for separation process evaluation. *Solarz, R. W., J-QE 75 Sep* 19D-20D (2C07)
isotope separation; selective isotope excitation of CuI by Ar ion laser excitation. *Wu, C.Y. R., J-QE 75 Sep* 20D (2C08)
isotope separation; selective two-step excitation and photoionization of atomic U vapor. *Janes, G. S., J-QE 75 Sep* 101D-102D (3B04)
isotope separation; two-step photodissociation process for Ti-50. *Gross, R. W. F., J-QE 75 Aug* 702 (2E08)
molecular spectroscopy and excitation of luminescence using continuously tunable high-pressure CO_2 lasers. *Bagratashvili, V. N., J-QE 75 Sep* 94D (3A11)
nuclear fusion; development of optimum glass for Nd:glass lasers. *Jacobs, R. R., J-QE 75 Sep* 13D (2C01)
nuclear fusion; laser fusion at 1.06 μm and 10.6 μm. *McCall, G. H., J-QE 75 Sep* 45D (2E05)
nuclear fusion; optical pulse-shaping for laser-driven fusion. *Massey, G. A., J-QE 75 Jul* 358-364 (1D02)
nuclear fusion; pellet compression using electron-beam excited Kr/O_2 mixtures. *Johnson, A. W., J-QE 75 Sep* 56D (2F02)
nuclear fusion; refractive index nonlinearity of transparent dielectric material in glass lasers. *Glass, A. J., J-QE 75 Sep* 28D-29D (2D02)
photochemistry; isotopic enrichment by multiple absorption of CO_2 laser radiation. *Lyman, J. L., J-QE 75 Sep* 103D (3B06)
photoionization and luminescence excitation using H_2 vacuum ultraviolet lasers. *Antonov, V. S., J-QE 75 Sep* 92D (3A09)
printers for color photography. *Baldwin, R. E., J-QE 75 Sep* 9D (2B11)
radiation cameras; ultra-high-speed camera using hydrated electron photoabsorption phenomena and mode-locked-dye-laser picosecond pulses. *Coutts, Gerald W., J-QE 75 Sep* 6D (2B08)
rangefinder and illuminator applications; Ho:YLF 2.06 μm laser performance and design applications. *Devor, D. P., J-QE 75 Sep* 13D-14D (2C01)
soil compaction quality checking. *Drakatos, Panagiotis A., J-QE 75 Sep* 84D-86D (3A01)
streak camera studies of fluorescence in photosynthetic systems and plastic scintillators. *Shapiro, S. L., J-QE 75 Sep* 5D-6D (2B07)
supermarket industry; laser scanner for reading universal product code symbol. *Dickson, L., J-QE 75 Sep* 23D-24D (2C11)

Laser applications; **cf.** Laser materials-processing applications; Laser plasma generation; Optical communication; Optical measurements; Optical radar

Laser beams
aberrated-beam focusing properties. *Hunt, J. T., J-QE 75 Sep* 29D-30D (2D03)
amplification of beams passing through chemical laser medium; theoretical model. *Tripodi, R., J-QE 75 Aug* 716 (2F08)
CO_2 lasers; measurement of beam quality of short-pulse lasers. *Liberman, I., J-QE 75 Sep* 44D (2E04)
deflection by precision galvanometer deflection system. *Jablonowski, D. P., J-QE 75 Sep* 21D-22D (2C09)
instabilities in CYCLOPS laser amplifier; removal using spatial filter. *Simmons, W. W., J-QE 75 Sep* 30D (2D04)
low-divergence beams from grating-coupled composite-guide heterostructure GaAlAs diode lasers. *Burnham, R. D., J-QE 75 Sep* 98D-99D (3B01)

Laser-beam effects; **cf.** Laser radiation effects

Laser-beam focusing
focusable energy; loss due to small-scale nonlinear effects. *Bliss, E. S., J-QE 75 Sep* 29D (2D03)
self dofocusing of mode-locked 1.06 μm pulses in Cs vapor; negative nonlinear refractive index and self-focusing compensation in other materials. *Lehmberg, R. H., J-QE 75 Sep* 69D-70D (2G01)
self-focusing; effects on optical quality of high-power beams. *Suydam, B. R., J-QE 75 Jun* 225-230 (1A03)
self-focusing instability growth rates in glass laser systems; effect of air space. *Elliott, C. James, J-QE 75 Nov* 863-866 (1A09)
third-order nonlinear processes in isotropic media; effects of focusing. *Bjorklund, Gary C., J-QE 75 Jun* 287-296 (1E09)

Laser communication; **cf.** Optical communication

Laser couplers
GaAs–AlGaAs double-heterostructure lasers; integrated taper-coupled laser for optical coupling of active and passive waveguide sections. *Logan, R. A., J-QE 75 Jul* 461-464 (2F13)
ring lasers; comparison of traveling-wave and standing-wave resonator extraction efficiencies. *Eckbreth, Alan C., J-QE 75 Sep* 796-798 (1F04)

Laser diodes; **cf.** Semiconductor lasers

Laser Engineering and Applications Conference
digests of papers from 1975 conference, *J-QE 75 Sep* 1D-103D (2B03)

Laser excitation
standing-wave effect in laser pumping. *Gerritsen, H. J., J-QE 75 Apr* 174 (1D14)

Laser excitation; **cf.** *Specific types of laser*

Laser frequency stability
CW dye lasers; frequency stabilization by frequency locking to high-finesse optical cavity. *West, J. B., J-QE 75 Sep* 18D-19D (2C06)
HF/DF lasers. *Eng, R. S., J-QE 75 Sep* 87D-88D (3A04)

Laser heating effects; **cf.** Laser applications; Laser thermal factors

Laser machining; **cf.** Laser materials-processing applications

Laser materials-processing applications
automotive industry. *Yessik, M., J-QE 75 Sep* 46D-47D (2E06)
masks for hybrid integrated circuit fabrication; automatic laser inspection/repair system. *Fehrs, D. L., J-QE 75 Sep* 21D (2C09)
masks for integrated-circuit fabrication; correction of defects using laser beam. *Lee, F., J-QE 75 Sep* 21D (2C09)
masks for integrated-circuit fabrication; generation using precision galvanometer deflection system. *Jablonowski, D. P., J-QE 75 Sep* 21D-22D (2C09)
metallic surfaces; reflectivity changes during irradiation by CO_2-TEA lasers. *Ready, J. F., J-QE 75 Sep* 49D (2E09)
RC network generation. *Saifi, M. A., J-QE 75 Sep* 23D (2C11)
semiconductor device fabrication; SiC high-temperature resistor fabrication using CO_2 lasers. *Hierholzer, F. J., J-QE 75 Sep* 47D-48D (2E07)
welding; effect of welding parameters on deep welding geometry. *Boedecker, V., J-QE 75 Sep* 47D (2E07)
welding of dissimilar materials; effect of laser parameters on material intermixing. *Montanarini, M., J-QE 75 Sep* 47D (2E07)
welding of insulated Cu wires to Monel terminal posts; real-time analysis of weld quality. *Saifi, M. A., J-QE 75 Sep* 48D (2E08)
welding; pulsed laser welding of high-reflectivity materials. *Bolin, S. R., J-QE 75 Sep* 48D (2E08)

Laser measurement applications; **cf.** Optical measurements

Laser measurements
beam quality of short-pulse CO_2 lasers. *Liberman, I., J-QE 75 Sep* 44D (2E04)
chemical lasers; laser technique for studying dynamics of vibrationally excited species. *Kaldor, A., J-QE 75 Aug* 697-698 (2E03)
$CO_2(00°1)$ level deactivation in CO_2 lasers by H, D, O, N, F and Cl atoms. *Buchwald, M. I., J-QE 75 Aug* 697 (2E03)
CO_2 TEA lasers; temporal coherence measurements of double-discharge laser. *Rudko, R. I., J-QE 75 Sep* 54D (2E14)
energy extraction from atmospheric-pressure CO_2 amplifiers using 60 ns–1 μs pulses. *Girard, G., J-QE 75 Jun* 241-247 (1B05)
energy transfer rates; laser-excited electronic-to-electronic transfer in Na vapor. *Chen, Hao-Lin, J-QE 75 Aug* 669-672 (2C03)
gain in pulsed CO_2 lasers; ratio of upper to lower level populations. *Garside, Brian K., J-QE 75 Jun* 264-270 (1C14)
HF/DF supersonic diffusion chemical lasers; spectrographic systems for diagnostic experiments. *Varwig, R. L., J-QE 75 Aug* 719 (2F11)
I* lasers; direct measurement of initial yields of I and I* atoms in flash-photolyzed alkaly iodides. *Wiesenfeld, J. R., J-QE 75 Aug* 703-704 (2E09)
junction laser thermal impedance measurement. *Paoli, Thomas L., J-QE 75 Jul* 498-503 (3B08)
laser line frequency measurements; far-infrared frequency synthesis technique using stabilized CO_2 lasers. *Petersen, F. Russell, J-QE 75 Oct* 838-843 (1C08)
N_2 and $CO_2(001)$ vibration-to-translation relaxation by alkali metal atoms. *Benson, R. C., J-QE 75 Aug* 697 (2E03)
near-field emission measurements on GaAs double-heterostructure laser mirrors. *Hakki, B. W., J-QE 75 Apr* 149-154 (1C03)
nonlinear refractive-index coefficient of laser-system materials; interferometric measurement. *Moran, Michael J., J-QE 75 Jun* 259-263 (1C09)
optical gain–absorption in active media; amplified spontaneous emission measurement technique. *Cross, Peter S., J-QE 75 May* 190-197 (1A12)
picosecond pulses; optical sampling technique. *Vogel, Gerald C., J-QE 74 Sep* 642-646 (1B02) ♦
prepulse extinction-ratio measurements on CO_2 laser amplifier chains. *Manes, K. R., J-QE 75 Aug* 635-636 (1E13)
stimulated emission in Nd-doped glass; measurement of cross section. *Dianov, E. M., J-QE 75 Sep* 83D (2G14)
temperature measurement in optically pumped NdP_5O_{14} laser using Raman spectroscopy. *Weber, Heinz P., J-QE 75 Jul* 368-370 (1D12)

Laser measurements; **cf.** Optical measurements

Laser modes
asymmetric spectral-mode interaction in semiconductor lasers. *Bogatov, A. P., J-QE 75 Jul* 510-515 (3C06)
cold cavity modes in coupling-modulated CO_2 laser. *Scholtz, A. L., J-QE 75 Sep* 791-793 (1E13)
GaAs injection lasers; multimode operation and mode-locking. *Bachert, H., J-QE 75 Jul* 507-510 (3C03)
HF CW chemical lasers; transverse mode oscillations in lasers with stable selected-line resonators. *Boedeker, L., J-QE 75 Aug* 713 (2F05)
longitudinal mode selection in He–Ne lasers using mode-selective three-mirror reflector. *Eichler, H., J-QE 75 Apr* 168-170 (1D08)
oligo-mode distance control in CW dye lasers using spatial hole burning. *Hertel, Ingolf V., J-QE 75 May* 210-212 (1C04)
selection perpendicular to junction plane in GaAs large-cavity double-heterostructure lasers. *Krupka, D. C., J-QE 75 Jul* 390-399 (2A12)
stability in active laser resonators. *Ernst, G. J., J-QE 75 Nov* 920-921 (1E10)
transverse-mode control in injection lasers by rib-guide optical-waveguide structure. *Lee, T. P., J-QE 75 Jul* 432-435 (2D12)
transverse mode control in multimode double-heterostructure junction lasers optically coupled to single-mode fibers. *Krupka, D. C., J-QE 75 Jul* 503-507 (3B13)

Laser noise
semiconductor lasers; intensity noise characteristics of CW double-heterostructure stripe-geometry lasers. *Paoli, Thomas L., J-QE 75 Jun* 276-283 (1D12)

Laser plasma generation
CO_2 laser amplifier chains; prepulse extinction-ratio measurements on pulse-selection systems. *Manes, K. R., J-QE 75 Aug* 635-636 (1E13)
CO_2 laser amplifiers; high-power electron-beam-controlled system for laser fusion. *Yamanaka, C., J-QE 75 Sep* 45D (2E05)
CO_2 lasers; 2.5 kJ short-pulse system. *Singer, S., J-QE 75 Sep* 44D-45D (2E04)
CO_2 lasers; Valkyrie system for laser fusion experiments. *Manes, K. R., J-QE 75 Sep* 44D (2E04)
dye laser pumped by CO_2-laser-heated plasma. *Brown, Robert T., J-QE 75 Sep* 800-801 (1F08)
JANUS Nd:glass laser system for laser fusion experiments. *Speck, D. R., J-QE 75 Sep* 45D-46D (2E05)
optical propagation and energy transport in fusion targets. *Holzrichter, J. F., J-QE 75 Sep* 46D (2E06)
optical pumping of lasers using UV radiation from CO_2-laser-produced Xe plasma. *Silfvast, W. T., J-QE 75 Sep* 1D (2B03)
X-ray pulses emitted by laser-produced plasma; pulse-duration measurement. *Duguay, M. A., J-QE 75 Apr* 170-172 (1D10)

Laser processing applications; **cf.** Laser materials-processing applications

Laser pulse amplifiers; **cf.** Laser amplifiers

♦ **Check author entry for later corrections/comments**

Laser pulses; **cf.** Optical pulses; Pulsed lasers; *Q*-switching
Laser radiation effects
metallic surfaces; reflectivity changes during irradiation by CO_2-TEA lasers. *Ready, J. F., J-QE 75 Sep* 49D (2E09)
metals and semiconductors; physical property changes in laser-pulse-irradiated material. *Dekhtar, I. Ya., J-QE 75 Sep* 83D (2G14)
Laser radiation effects; **cf.** Laser applications
Laser resonators
negative-branch unstable resonator Nd:YAG laser. *Ewanizky, T. F., J-QE 75 Sep* 17D-18D (2C05)
three-mirror reflector; single-mode operation of six-mode He–Ne laser. *Eichler, H., J-QE 75 Apr* 168-170 (1D08)
unstable resonator mode profiles; prediction of fundamental mode features using Fresnel zone theory. *Steier, William H., J-QE 75 Sep* 725-728 (1A03)
unstable resonators; eigenmode loss behavior of resonators with cylindrical and circular mirrors at small and large Fresnel numbers. *Santana, C., J-QE 75 Sep* 58D-59D (2F04)
Laser thermal factors
buried-heterostructure lasers with GaAs active regions completely buried in GaAlAs; CW operation. *Tsukada, Toshihisa, J-QE 75 Jul* 494-498 (3B04)
dye lasers; high-power lasers using free jet stream of liquid dye solution. *Foley, R. J., J-QE 75 Sep* 5D (2B07)
dye lasers; thermally induced optical inhomogeneities in active volume of high-power lasers. *Peterson, O. G., J-QE 75 Sep* 4D-5D (2B06)
explosive vapor detection by laser illumination of air sample suspected of containing vapor. *Claspy, P. C., J-QE 75 Sep* 37D (2D11)
GaAs/GaAlAs double-heterostructure injection lasers with distributed feedback; pulsed operation between 80 and 150 K. *Nakamura, Michiharu, J-QE 75 Jul* 436-439 (2E02)
metallic surfaces; thermal coupling coefficient for laser-heated surfaces. *Marcus, S., J-QE 75 Sep* 49D-50D (2E09)
NdYAG lasers; mode-locked lasers using liquid absorbers. *Wilbrandt, Robert, J-QE 75 May* 186-190 (1A08)
Nd:YAG lasers; thermooptical effects of intracavity $Ba_2Na(NbO_3)_5$ crystal on frequency-doubled lasers. *Barry, James D., J-QE 75 Aug* 575-579 (1A13)
optical-pumping-induced heating in CW NdP_5O_{14} lasers; bistable laser operation. *Weber, Heinz P., J-QE 75 Jul* 368-370 (1D12)
thermal impedance of junction lasers; measurement. *Paoli, Thomas L., J-QE 75 Jul* 498-503 (3B08)
Laser tuning
CO_2 15-atm electron-beam controlled lasers; frequency tuning using Fabry–Perot interferometers. *O'Neill, F., J-QE 75 Sep* 74D-75D (2G06)
CO_2 lasers; continuously tunable high-pressure lasers. *Bagratashvili, V. N., J-QE 75 Sep* 94D (3A11)
dye lasers; tunable subnanosecond pulse generation from N_2-laser-pumped dye laser in near UV and visible region. *Lin, Chinlon, J-QE 75 Aug* 602-609 (1C08)
HgCdTe magnetically tunable lasers; tunable spin-flip and recombination lasers using optical pumping. *Sattler, J. P., J-QE 75 Sep* 18D (2C06)
InSb lasers; CW lasers optically pumped in longitudinal geometry. *Menyuk, N., J-QE 75 Jul* 477-481 (3A01)
monolithic GaInAs homojunction diode lasers. *Doerbeck, F. H., J-QE 75 Jul* 464-467 (2G02)
pulsed dye lasers; subnanosecond tunable pulse generation in N_2-laser-pumped lasers using controlled resonator transients. *Lin, Chinlon, J-QE 75 Sep* 1D-2D (2B03)
Laser welding; **cf.** Laser materials-processing applications
Law enforcement
explosive vapor detection using laser optoacoustic detector. *Claspy, P. C., J-QE 75 Sep* 37D (2D11)

light emission; laser energy redistribution using electronic feedback circuit. *Panarella, Emilio, J-QE 75 May* 181-185 (1A03)
mode-locked lasers; ultrashort output pulse analysis using time-resolved linear interferometry. *Shah, Rajiv R., J-QE 75 Sep* 783-788 (1E05)
Nd^{3+}; $^4F_{3/2} \rightarrow {}^4I_{13/2}$ laser glasses; induced-emission cross sections. *Jacobs, Ralph R., J-QE 75 Oct* 846-847 (1D02)
pulse compression methods for amplifier chains. *Fisher, Robert A., J-QE 75 Jan* 46-52 (1D06)
pulse lengths from mode-locked lasers. *Greenhow, R. C., J-QE 75 Jan* 59-60 (1E05)
stimulated emission in Nd-doped glass; measurement of cross section. *Dianov, E. M., J-QE 75 Sep* 83D (2G14)

Neodymium:solid lasers
$LiNbO_3$ lasers. *Kaminow, I. P., J-QE 75 Jun* 306-308 (1F14)
Nd:YVO_4 lasers; CW and self-*Q*-switched operation. *DeShazer, L. G., J-QE 75 Sep* 84D (3A01)
Nd:YVO_4 lasers; electrooptic *Q*-switching without intracavity polarizer. *Bass, Michael, J-QE 75 Dec* 938-939 (1A12)

Neodymium:YAG lasers
frequency-doubled lasers; thermooptical effects of intracavity $Ba_2Na(NbO_3)_5$ crystal. *Barry, James D., J-QE 75 Aug* 575-579 (1A13)
frequency-doubled mode-locked lasers using $Ba_2NaNb_5O_{15}$ acoustooptic mode locker/frequency doubler. *Rice, R. R., J-QE 75 Sep* 14D (2C02)
lamp-pumped subsystem for 1 gbps satellite communication system. *Radecki, Dan J., J-QE 75 Sep* 15D-16D (2C03)
mode-locked internally frequency-doubled lasers; output pulse duration variations. *Falk, Joel, J-QE 75 Jul* 365-367 (1D09)
mode-locked lasers with internal frequency doubling. *Falk, Joel, J-QE 75 Jan* 21-31 (1B09) ♦
mode-locking threshold above normal lasing threshold. *Wilbrandt, Robert, J-QE 75 May* 186-190 (1A08)
pumping by GaAs or AlGaAs laser diode arrays. *Reno, C. W., J-QE 75 Sep* 16D (2C04)
pumping with electrodeless Kr arc lamps. *Huchital, D. A., J-QE 75 Sep* 16D (2C04)
Q-switched lasers using negative-branch unstable resonator. *Ewanizky, T. F., J-QE 75 Sep* 17D-18D (2C05)
satellite ranging systems; picosecond-pulse, fieldable Nd:YAG laser system. *Erickson, E. G., J-QE 75 Sep* 16D-17D (2C04)
single-pass gains at 1.32 μm. *Loree, T. R., J-QE 75 Jul* 371-372 (1E01)
solar-pumped lasers with simultaneous internal frequency doubling and mode locking. *Falk, Joel, J-QE 75 Sep* 14D-15D (2C02)
third-harmonic radiation pumping of high-power visible dye lasers. *Kato, K., J-QE 75 Jul* 373-374 (1E03)

Neon; **cf.** Noble gases
Networks; **cf.** *RC* networks

Neutron radiation effects
Ne–N_2 lasers; direct nuclear pumped laser with simultaneous output at 8629 and 9393 Å. *DeYoung, R. J., J-QE 75 Sep* 97D (3A14)

Nickel alloys/compounds, devices
Monel terminal posts; laser welding of insulated Cu wires to posts. *Saifi, M. A., J-QE 75 Sep* 48D (2E08)

Niobium alloys/compounds, devices; **cf.** Neodymium:solid lasers
Nitrogen devices; **cf.** Gas lasers
Nitrogen compounds/mixtures, devices; **cf.** Gas lasers

Noble-gas devices
lamps; CW pumping of Nd:YAG lasers with electrodeless Kr arc lamps. *Huchital, D. A., J-QE 75 Sep* 16D (2C04)

Noble-gas lasers
Ar–SF_6 and He-SF_6 mixtures; pulsed-laser action on atomic transitions. *Sutton, D. G., J-QE 75 Jan* 54-57 (1D14)
fast-flow high-pressure system for closed-cycle operation with ultrapure gases; high-repetition-rate TEA system. *Olson, Robert A., J-QE 75 Sep* 95D-96D (3A12)
He–Ne lasers; five-year operation of laser using metal–ceramic discharge tube. *Kolb, W. P., J-QE 75 Jul* 374-375 (1E04)
He–Ne lasers; mode-selective three-mirror reflector for single mode operation. *Eichler, H., J-QE 75 Apr* 168-170 (1D08)
Ne–N_2 lasers; direct nuclear pumped laser with simultaneous output at 8629 and 9393 Å. *DeYoung, R. J., J-QE 75 Sep* 97D (3A14)
$Xe^*(^3P_2)$ metastable atoms; quenching with light hydrocarbons and fluoromethanes. *Velazco, J. E., J-QE 75 Aug* 708-709 (2E14)
XeO lasers; lasing on green bands using direct electron beam excitation of high pressure Xe with small additions of O_2, CO_2 or N_2O. *Powell, H. T., J-QE 75 Aug* 685 (2D05)
XeO lasers; reaction kinetics in electron-beam pumped Xe–O_2 mixtures. *Lorents, D. C., J-QE 75 Aug* 704 (2E10)

Noble-gas lasers, ionic
Ar ion lasers; CW laser using 700-m-long cavity. *Tripathi, P. P., J-QE 75 Sep* 59D (2F05)
pulsed Xe laser; operating characteristics and use as pump source for tunable Rhodamine-6G dye laser. *Schearer, Laird D., J-QE 75 Dec* 935-937 (1A09)
ultraviolet lasers; noble-gas transitions below 2500 Å. *Marling, John B., J-QE 75 Oct* 822-834 (1B06)
ultraviolet lasers; pulsed and CW transitions below 3000 Å. *Marling, J. B., J-QE 75 Sep* 27D-28D (2D01)

Noble-gas lasers, molecular
vacuum ultraviolet laser oscillators and amplifiers; pumping by coaxial diode electron-beam system. *Arthurs, E. G., J-QE 75 Sep* 28D (2D02)
XeBr* excimer lasers; 281.8-nm emission from electron-beam-excited Xe/Br_2 mixture. *Searles, S. K., J-QE 75 Sep* 93D (3A10)
XeF lasers; 3540-Å emission from electron-beam-excited F_2/Xe/Ar mixtures. *Ewing, J. J., J-QE 75 Sep* 92D-93D (3A09)
XeO, KrO, and ArO excimer lasers; collision-induced emission in electron-beam-excited O_2–rare gas mixtures. *Powell, H. T., J-QE 75 Sep* 27D (2D01)

Noise; **cf.** Laser noise
Nonlinear optics; **cf.** Laser absorbers; Optical propagation, nonlinear media

Nuclear fusion
JANUS Nd:glass laser system for laser fusion experiments. *Speck, D. R., J-QE 75 Sep* 45D-46D (2E05)
laser amplifier systems; SHIVA 10-kilojoule system at Lawrence Livermore Laboratory. *Gilmartin, T. J., J-QE 75 Sep* 32D (2D06)
laser-beam focusing; aberrated beams. *Hunt, J. T., J-QE 75 Sep* 29D-30D (2D03)
laser-driven fusion; pulse shaping using optically gated dye cell. *Massey, G. A., J-QE 75 Jul* 358-364 (1D02)
laser fusion. *Teller, E., J-QE 75 Sep* 83D (2G14)
laser fusion at 1.06 μm and 10.6 μm. *McCall, G. H., J-QE 75 Sep* 45D (2E05)
laser fusion; optical propagation and energy transport in fusion targets. *Holzrichter, J. F., J-QE 75 Sep* 46D (2E06)
laser fusion; pellet compression using electron-beam-excited Kr/O_2 mixtures. *Johnson, A. W., J-QE 75 Sep* 56D (2F02)
lasers; Asterix III pulsed high-power I laser. *Brederlow, G., J-QE 75 Sep* 42D-43D (2E02)
lasers; pressure broadening and saturation behavior of Asterix III pulsed high-power I laser. *Fuss, W., J-QE 75 Sep* 43D (2E03)
lasers; refractive index nonlinearity of transparent dielectric material in glass lasers. *Glass, A. J., J-QE 75 Sep* 28D-29D (2D02)
Nd:glass lasers; development of optimum glass. *Jacobs, R. R., J-QE 75 Sep* 13D (2C01)

O

Optical amplifiers; **cf.** Laser amplifiers; Optical parametric amplifiers

Optical communication
in Japan; status of research and development. *Marubayashi, G., J-QE 75 Sep* 76D (2G08)
mode-locked lasers using folded optical delay lines; optical communication system applications. *Kornienko, L. S., J-QE 75 Sep* 91D (3A08)

Optical communication; **cf.** Infrared communication; Optical radio communication

Optical couplers
optical waveguides; holographic couplers for optical fiber and planar waveguides. *Nishihara, H., J-QE 75 Sep* 794-796 (1F02)

Optical couplers; **cf.** Laser couplers; Optical directional couplers; Optical planar waveguide couplers
Optical deflectors; **cf.** Light deflectors

Optical demodulation
laser communications system using external polarization electrooptic modulation and avalanche diode detection; optimum carrier-to-noise ratio. *Waksberg, Armand L., J-QE 75 Sep* 778-782 (1D14)

Optical demodulation; **cf.** Infrared demodulation; Optical heterodyne detection

Optical diffraction
Bragg diffraction; noncollinear multimode diffraction in ion-exchanged optical planar waveguides with periodic surface corrugation. *Asakawa, K., J-QE 75 Jun* 304-306 (1F12)

Optical directional couplers
$LiNbO_3$ integrated optical switch/modulator; COBRA electrically switched coupler. *Papuchon, M., J-QE 75 Sep* 99D-100D (3B02)

Optical distance measurement
altimetry; laser rangefinder for heavy-lift-helicopter precision hover sensor. *Ammon, G., J-QE 75 Sep* 50D-51D (2E10)
laser rangefinders; Ho:YLF laser performance and design options. *Devor, D. P., J-QE 75 Sep* 13D-14D (2C01)
rangefinders using pulsed ultraviolet N_2 laser. *Davis, T. P., J-QE 75 Sep* 50D (2E10)
satellite ranging systems; picosecond-pulse, fieldable Nd:YAG laser system. *Erickson, E. G., J-QE 75 Sep* 16D-17D (2C04)

Optical fiber communication
fault location method for fibers. *Ueno, Y., J-QE 75 Sep* 77D-78D (2G09)
potential applications. *Goell, J. E., J-QE 75 Sep* 76D (2G08)
repeaters; 40-Mb/s and 400-Mb/s repeaters using feedback-type amplifiers. *Ueno, Y., J-QE 75 Sep* 78D-79D (2G10)

Optical fiber waveguides
couplers; holographic optical couplers for fiber–fiber or fiber–thin-film waveguide coupling. *Nishihara, H., J-QE 75 Sep* 794-796 (1F02)
dispersion in long multimode guides. *Kao, C., J-QE 75 Sep* 76D-77D (2G08)
doubly clad W-type fibers; leaky mode characteristics below cutoff; group velocity and power flow distribution slightly above cutoff. *Kawakami, Shojiro, J-QE 75 Apr* 130-138 (1A12)
four-photon mixing; phase-matched-stimulated mixing in silica-fiber waveguides. *Stolen, Rogers H., J-QE 75 Mar* 100-103 (1A06)
lasers; packaged GaAlAs double heterostructure lasers. *Takusagawa, M., J-QE 75 Sep* 61D (2F07)
mode analysis of multimode fibers using linearly tapered section. *Ozeki, T., J-QE 75 Sep* 77D (2G09)
surface-wave radiation loss for all modes. *Kuester, Edward F., J-QE 75 Nov* 903-907 (1D07)

Optical filters
optical pulse generation by laser breakdown switch technique; production of filters. *Yablonovitch, Eli, J-QE 75 Sep* 789-791 (1E11)
spatial filter for removal of small-scale beam instabilities in CYCLOPS laser. *Simmons, W. W., J-QE 75 Sep* 30D (2D04)

Optical frequency conversion
frequency tripling of 1.06 μm subnanosecond pulses to 3547 Å. *Attwood, D. T., J-QE 75 Sep* 68D-69D (2F14)
Nd:YAG lasers; solar-pumped lasers with simultaneous frequency doubling and mode locking. *Falk, Joel, J-QE 75 Sep* 14D-15D (2C02)
Nd:YAG lasers using $Ba_2NaNb_5O_{15}$ acoustooptic mode locker/frequency doubler. *Rice, R. R., J-QE 75 Sep* 14D (2C02)

Optical frequency conversion; **cf.** Optical harmonic generation; Optical heterodyning; Optical mixers

Optical harmonic generation
frequency-doubled Nd:YAG lasers; thermooptical effects of intracavity $BaNa(NbO_3)_5$ crystal. *Barry, James D., J-QE 75 Aug* 575-579 (1A13)
phase-matched second-harmonic generation in ZnS optical planar waveguides using film and substrate nonlinearities. *Ito, H., J-QE 75 Sep* 40D (2D14)

♦ **Check author entry for later corrections/comments**

second-harmonic generation; effect of two-photon absorption in semiconductors. *Schwartz, Christiane A., J-QE 75 Aug* 616-623 (1D08)
second-harmonic generation in Te; effect of two-photon absorption. *Oudar, Jean-Louis, J-QE 75 Aug* 623-629 (1E01)
second-harmonic generation; reduction of conversion-limiting effects of crystal anisotropy in critically index-matched generation. *Librecht, F. M., J-QE 75 Sep* 755-758 (1C05)
second-harmonic generation in CD*A crystals; electrooptical compensation for self-heating. *Hon, D., J-QE 75 Sep* 67D-68D (2F13)
second-harmonic generation in birefringent crystals by Gaussian beam with elliptical cross section. *Librecht, F. M., J-QE 75 Oct* 850-852 (1D06)
second-harmonic ultraviolet Cerenkov radiation generation. *Chen, Bor-Uei, J-QE 75 Apr* 177-178 (1E03)

Optical heterodyne detection
10.6-μm wideband receiver for CO_2 laser satellite communications link. *Peyton, B. J., J-QE 75 Sep* 80D-81D (2G12)
10-μm receiver for satellite communication. *Goodwin, F. E., J-QE 75 Sep* 79D-80D (2G11)
chirp-modulated CO_2 waveguide lasers. *Stein, Alexander, J-QE 75 Aug* 630-631 (1E08)
multiphoton absorption heterodyne receivers; detector response, signal-to-noise ratio, minimum detectable power. *Teich, Malvin Carl, J-QE 75 Aug* 595-602 (1C01)
wideband heterodyne detection at 10.6 μm using planar HgCdTe photodiodes. *Spears, D. L., J-QE 75 Sep* 79D (2G11)

Optical heterodyning
IR heterodyning; CW HF chemical mixing lasers as local oscillators for mid-IR applications. *Freiberg, R. J., J-QE 75 Sep* 57D-58D (2F03)
radiometers; optical heterodyne radiometers for atmospheric transmission measurements at HF/DF laser wavelengths. *King, S. R., J-QE 75 Sep* 87D (3A04)

Optical interferometry
dilatometry using multichannel interferometer. *Pond, C. R., J-QE 75 Sep* 10D-11D (2B12)
grazing incidence triangular laser interferometer; application to checkout of granite surface plate quality. *Rabal, H. J., J-QE 75 Sep* 22D-23D (2C10)
laser pulse measurements; analysis of ultrashort pulses from mode-locked lasers using time-resolved linear interferometry. *Shah, Rajiv R., J-QE 75 Sep* 783-788 (1E05)
nonlinear refractive-index coefficient of laser-system materials; interferometric measurement. *Moran, Michael J., J-QE 75 Jun* 259-263 (1C09)

Optical interferometry; **cf.** Fabry–Perot interferometers

Optical isolators
CO_2 high-gain amplifiers; suppression of self-oscillations using interstage optical isolators. *Lavigne, P., J-QE 75 Sep* 75D (2G07)
infrared isolators; Ge high-power isolator for 10 μm region using interband Faraday effect. *Phipps, C. M., Jr., J-QE 75 Sep* 70D-71D (2G03)

Optical logic devices
gates; light gates using optically induced dichroism in organic-dye solutions. *Vahey, David W., J-QE 75 Sep* 100D-101D (3B03)

Optical measurements
ambient-air pollutant measurements using bistatic heterodyne system. *Menzies, R. T., J-QE 75 Sep* 33D (2D07)
electrical signals; optical sampling transient analyzer for fast, high-voltage, single transient signals. *Davies, Terence J., J-QE 75 Sep* 7D (2B09)
pollution concentration variations with altitude; measurement using solar infrared heterodyne radiometer. *Christophe, B., J-QE 75 Sep* 32D-33D (2D06)
rain drop measurements using pulsed holography technique. *Zakharov, V. M., J-QE 75 Sep* 82D (2G14)
strain in earth's crust; measurement using 700-m long mode-locked Ar ion laser. *Tripathi, P. P., J-QE 75 Sep* 59D (2F05)
ultrafast photoinduced phenomena; measurement using transient induced grating system. *Siegman, A. E., J-QE 75 Sep* 69D (2G01)

Optical measurements; **cf.** Laser measurements; Optical distance measurement; Optical interferometry; Optical pulse measurements; Optical spectroscopy; Optical velocimeters

Optical memories; **cf.** Holographic memories

Optical mixers
tunable short pulse generation in infrared and ultraviolet using synchronous mode-locked dye laser. *Goldberg, L. S., J-QE 75 Sep* 2D (1B04)

Optical mixers; **cf.** Optical heterodyning

Optical modulation; **cf.** Acoustooptic modulation; Electrooptic modulation

Optical parametric amplifiers
optical pulse generation by pulsed parametric amplification of noble gas laser emission. *Massey, G. A., J-QE 75 Sep* 66D (2F12)

Optical parametric oscillators
infrared source for infrared absorption line-shape measurements. *Wormhoudt, J., J-QE 75 Aug* 704 (2E10)
$LiIO_3$ oscillators operating at kHz pulse repetition rates. *Ammann, E. O., J-QE 75 Sep* 65D (2F11)
RD*A parametric oscillators; efficient operation in visible to near infrared using third harmonic of Nd:YAG laser as pump source. *Kato, K., J-QE 75 Dec* 939-941 (1A13)

Optical planar waveguides
bend losses in curved guides; conformal transformation analysis. *Heiblum, Mordehai, J-QE 75 Feb* 75-83 (1A13)
Bragg diffraction; noncollinear multimode diffraction in ion-exchanged guide with periodic surface corrugation. *Asakawa, K., J-QE 75 Jun* 304-306 (1F12)
buried modes in guides with nonmonotonically varying index of refraction. *Conwell, Esther M., J-QE 75 May* 217-218 (1C11)
KTN single-crystal thin-film guides. *Fontana, R. E., Jr., J-QE 75 Sep* 38D (2D12)
mode conversion in planar-dielectric separating waveguides. *Burns, William K., J-QE 75 Jan* 32-39 (1C06)
modes in diffused guides of arbitrary index profile; phase constants. *Hocker, G. Benjamin, J-QE 75 Jun* 270-276 (1D06)
multilayer metal-clad guides with low-index dielectric buffer layer; attenuation characteristics. *Yamamoto, Yoshihisa, J-QE 75 Sep* 729-736 (1A07)
rib-waveguide structure for transverse-mode control in injection lasers. *Lee, T. P., J-QE 75 Jul* 432-435 (2D12)
second-harmonic generation in ZnS thin-film guides using nonlinearities in film and substrate. *Ito, H., J-QE 75 Sep* 40D (2D14)
slab waveguides; light scattering from periodic refractive-index fluctuations in asymmetric guides. *Marcuse, D., J-QE 75 Apr* 162-168 (1D02)
surface-wave radiation loss for TE modes in asymmetric slab waveguides. *Kuester, Edward F., J-QE 75 Nov* 903-907 (1D07)
ZnTe ion-implanted guides. *Valette, S., J-QE 75 Sep* 39D-40D (2D13)

Optical planar waveguide components
convolvers; optical guided wave–acoustic surface-wave interactions in thin-film As_2S_3 guide on $LiNbO_3$ substrate. *Loh, K. W., J-QE 75 Sep* 86D (3A03)
electrooptic switches; electrode configuration for producing prism-like deflector on planar optical waveguide. *Kaminow, I. P., J-QE 75 Aug* 633-635 (1E11)
modulators; electrooptic modulator using grain-oriented polycrystalline ZnO film. *Hu, Chenming, J-QE 75 Sep* 64D (2F10)
modulators; GaAs electrooptic channel-waveguide modulator. *Campbell, J. C., J-QE 75 Sep* 63D-64D (2F09)
modulators; mode-dependent modulation in (Ga,Al)P modulators. *Bortfeld, David P., J-QE 75 Mar* 108-110 (1A14)
modulators; ZnO electrooptic grating modulator. *Hammer, Jacob M., J-QE 75 Apr* 138-148 (1B06)

Optical planar waveguide couplers
3-dB couplers with noncritical length and mode synchronization only at single point. *Burns, W. K., J-QE 75 Sep* 42D (2E02)
holographic optical couplers for fiber waveguide–thin-film waveguide coupling. *Nishihara, H., J-QE 75 Sep* 794-796 (1F02)

Optical planar waveguides
mode coupling in anisotropic slab waveguides; electrooptic coupling between TE and TM modes in $LiNbO_3$ and $LiTaO_3$. *Marcuse, D., J-QE 75 Sep* 759-767 (1C09)

Optical propagation; **cf.** Infrared propagation; Optical radio propagation; Optical waveguides

Optical propagation, absorbing media
laser fusion targets; optical propagation and energy transport. *Holzrichter, J. F., J-QE 75 Sep* 46D (2E06)
$LiNdP_4O_{12}$; optical absorption characteristics. *Otsuka, Kenju, J-QE 75 Jul* 330-334 (1B02)

Optical propagation, absorbing media; **cf.** Infrared propagation, absorbing media

Optical propagation, guided; **cf.** Optical waveguides

Optical propagation, nonlinear media
four-photon mixing; phase-matched-stimulated mixing in silica-fiber waveguides. *Stolen, Rogers H., J-QE 75 Mar* 100-103 (1A06)
laser beam focusing; effect of small-scale beam breakup. *Bliss, E. S., J-QE 75 Sep* 29D (2D03)
second-order susceptibilities; bond-orbital model for tetrahedral compounds. *Choy, Michael M., J-QE 75 Jan* 40-45 (1C14)
third-order nonlinear processes in isotropic media; effects of focusing. *Bjorklund, Gary C., J-QE 75 Jun* 287-296 (1E09)
third-order susceptibility of alkali metal vapors. *Eicher, Hermann, J-QE 75 Apr* 121-130 (1A03)

Optical propagation, nonlinear media; **cf.** Optical resonance

Optical propagation, refraction; **cf.** Optical refraction

Optical propagation, turbulent media; **cf.** Optical radio propagation meteorological factors

Optical pulses
CO_2 laser amplifier pulse-selection systems; prepulse extinction-ratio measurements. *Manes, K. R., J-QE 75 Aug* 635-636 (1E13)
laser pulses; energy extraction from CO_2 laser amplifiers using 60 ns–1 μs pulses. *Girard, G., J-QE 75 Jun* 241-247 (1B05)
laser pulses; energy redistribution using electronic feedback circuit. *Panarella, Emilio, J-QE 75 May* 181-185 (1A03)
laser pulses; optical sampling technique for picosecond pulses. *Vogel, Gerald C., J-QE 74 Sep* 642-646 (1B02) ♦
Nd:glass lasers mode-locked with BDN; pulse lengths. *Greenhow, R. C., J-QE 75 Jan* 59-60 (1E05)

Optical pulse amplifiers; **cf.** Laser amplifiers

Optical pulse compression
1.06 μm subnanosecond pulse shortening and frequency tripling to 3547 Å. *Attwood, D. T., J-QE 75 Sep* 68D-69D (2F14)
Nd:glass laser amplifier chains. *Fisher, Robert A., J-QE 75 Jan* 46-52 (1D06)

Optical pulse generators
laser pulses with increasing intensity; generation using regenerative amplifier. *Vovchenko, V. I., J-QE 75 Sep* 83D (2G14)
Na vapor; conversion of CW dye laser light into train of repetitive subnanosecond pulses using resonant atomic dispersion. *Bjorkholm, J. E., J-QE 75 Sep* 68D (2G01)
pulsed parametric amplification of noble gas laser emission; frequency-stable, narrow-band pulses from 438.5 nm to 676.4 nm. *Massey, G. A., J-QE 75 Sep* 66D (2F12)
short pulses of arbitrary shape and phase; generation by laser breakdown switch technique. *Yablonovitch, Eli, J-QE 75 Sep* 789-791 (1E11)

Optical pulse generators; **cf.** Pulsed lasers

Optical pulse measurements
laser pulses; analysis of ultrashort pulses from mode-locked lasers using time-resolved linear interferometry. *Shah, Rajiv R., J-QE 75 Sep* 783-788 (1E05)
laser pulses; measurement of CO_2 TEA laser pulse frequency chirp using interferometric pulse delay techniques. *Hieslmair, H., J-QE 75 Sep* 54D (2E14)
subpicosecond measurements using Photochron II streak camera tube. *Bradley, D. J., J-QE 75 Sep* 25D-26D (2C13)

Optical pulse shaping
dye cells; optically gated cells using bleachable liquid dyes. *Massey, G. A., J-QE 75 Jul* 358-364 (1D02)
laser pulse shaping; *Q*-switched ruby laser with compound feedback. *Loveberg, R. V., J-QE 75 Jan* 17-21 (1B05)

Optical pumping; **cf.** Laser excitation

Optical radar
FM-chirp radar; high-resolution radar ranging at 10.6 μm. *Bicknell, W. E., J-QE 75 Jun* 308-311 (1G02)

♦ **Check author entry for later corrections/comments**

imaging; diffraction-limited imaging through turbulent atmosphere using polarization reference imaging system. *Brown, W. P., Jr., J-QE 75 Sep* 52D-53D (2E12)
imaging through turbulent atmosphere; computer simulation of polarization reference imaging system. *Tseng, D. Y., J-QE 75 Sep* 53D (2E13)
laser infrared radar (LIDAR); demodulation technique for chirp-modulated CO_2 waveguide laser. *Stein, Alexander, J-QE 75 Aug* 630-631 (1E08)
LIDAR measurements of ozone using resonance Raman scattering and differential absorption techniques. *Penney, C. M., J-QE 75 Sep* 36D (2D10)
multidither coherent optical adaptive techniques for compensation of turbulence and blooming distortions. *Pearson, J. E., J-QE 75 Sep* 55D (2F01)
transmitters; temporal coherence of double-discharge CO_2 TEA laser. *Rudko, R. I., J-QE 75 Sep* 54D (2E14)

Optical radiation effects
isotope separation using radiation pressure. *Gelbwachs, Jerry, J-QE 75 Jan* 52-54 (1D12)

Optical radiation effects; cf. Laser radiation effects; Ultraviolet radiation effects

Optical radio communication
diversity receiver for turbulent conditions. *McIntyre, C. M., J-QE 75 Sep* 81D (2G13)
laser communications system using external polarization electrooptic modulation and avalanche diode detection; optimum carrier-to-noise ratio. *Waksberg, Armand L., J-QE 75 Sep* 778-782 (1D14)
satellite communication; lamp-pumped Nd:YAG laser subsystem for 1 gbps system. *Radecki, Dan J., J-QE 75 Sep* 15D-16D (2C03)
transmitters; solar-pumped Nd:YAG laser transmitter for satellite communication. *Falk, Joel, J-QE 75 Sep* 14D-15D (2C02)

Optical radio propagation meteorological factors
CO_2 laser radiation; absorption by water vapor. *Shumate, M. S., J-QE 75 Sep* 33D-34D (2D07)
diversity receiver for optical communication under turbulent conditions. *McIntyre, C. M., J-QE 75 Sep* 81D (2G13)
HF/DF laser radiation; atmospheric transmission measurements. *King, S. R., J-QE 75 Sep* 87D (3A04)
infrared; atmospheric transmissivity measurements in 9–11-μm band using heterodyne radiometer. *Peyton, Bernard J., J-QE 75 Aug* 569-574 (1A03)
optical radar imaging through turbulent atmosphere using polarization reference imaging system. *Brown, W. P., Jr., J-QE 75 Sep* 52D-53D (2E12)
optical radar imaging through turbulent atmosphere using polarization reference imaging system; computer simulation. *Tseng, D. Y., J-QE 75 Sep* 53D (2E13)
optical radar; multidither coherent optical adaptive techniques for compensation of turbulence and blooming distortions. *Pearson, J. E., J-QE 75 Sep* 55D (2F01)

Optical recording; cf. Holographic recording

Optical reflection
metallic surfaces; reflectivity changes during irradiation by CO_2-TEA lasers. *Ready, J. F., J-QE 75 Sep* 49D (2E09)

Optical refraction
Cs vapor; negative nonlinear refractive index at 1.06 μm. *Lehmberg, R. H., J-QE 75 Sep* 69D-70D (2G01)
glass lasers for nuclear fusion; refractive index nonlinearity of transparent dielectric material. *Glass, A. J., J-QE 75 Sep* 28D-29D (2D02)
nonlinear refractive-index coefficient of laser-system materials; interferometric measurement. *Moran, Michael J., J-QE 75 Jun* 259-263 (1C09)

Optical resonance
photon-echo behavior in presence of extreme inhomogeneous broadening. *Takeuchi, Nobuo, J-QE 75 Jun* 230-235 (1A08)

Optical scattering
GaAlAs–GaAs heterostructure lasers; optical-absorption loss in double-heterostructure and five-layer devices. *Thompson, G. H. B., J-QE 75 Jul* 481-488 (3A05)
optical planar waveguides; light scattering from periodic refractive-index fluctuations. *Marcuse, D., J-QE 75 Apr* 162-168 (1D02)

Optical scattering; cf. Raman scattering

Optical signal processing
near-real-time coherent processing system. *Iwasa, S., J-QE 75 Sep* 8D (2B10)

Optical spectroscopy
$^{12}CH_3F$; pressure broadening and pressure shift coefficient measurements using Doppler-free two-photon absorption techniques. *Bischel, W. K., J-QE 75 Sep* 24D-25D (2C12)
cryptocyanine in methanol; spectral hole burning in absorption band. *Mourou, Gerard, J-QE 75 Jan* 1-8 (1A03)
dye laser spectrometer for analysis of pulsed vacuum arcs. *Hargis, P. J., Jr., J-QE 75 Sep* 24D (2C12)
laser diagnostic spectrographic systems. *Varwig, R. L., J-QE 75 Aug* 719 (2F11)
molecular spectroscopy using continuously tunable high-pressure CO_2 lasers. *Bagratashvili, V. N., J-QE 75 Sep* 94D (3A11)
Rydberg constant determination using highly stabilized CW dye laser. *West, J. B., J-QE 75 Sep* 18D-19D (2C06)

Optical spectroscopy; cf. Infrared spectroscopy

Optical strip waveguides
diffused guides in GaAs. *Garmire, E., J-QE 75 Sep* 38D-39D (2D12)

Optical strip waveguide components
lasers; AlGaAs multiheterostructure laser with integrated twin guide. *Suematsu, Y., J-QE 75 Jul* 457-460 (2F09)

Optical surface waves
radiation loss from asymmetric slab waveguides and optical fibers. *Kuester, Edward F., J-QE 75 Nov* 903-907 (1D07)

Optical tracking
satellites; ranging systems using picosecond-pulse, fieldable Nd:YAG laser system. *Erickson, E. G., J-QE 75 Sep* 16D-17D (2C04)

Optical velocimeters
aircraft vortex detection system using CO_2 laser Doppler velocimeter. *Sonnenschein, C. M., J-QE 75 Sep* 35D (2D09)
laser Doppler velocimeters for remote power plant effluent measurements. *Miller, C. R., J-QE 75 Sep* 34D-35D (2D08)
resonant Doppler velocimeters using tunable narrow-bandwidth dye lasers; gas flow measurement and visualization. *Miles, R. B., J-QE 75 Sep* 35D-36D (2D09)

Optical waveguides
optical field propagation in integrated optical transitions and bifurcations. *Roy, A. M., J-QE 75 Sep* 41D-42D (2E01)

Optical waveguides; cf. Optical fiber waveguides; Optical planar waveguides; Optical strip waveguides

Optical waveguide communication; cf. Optical fiber communication

Organic dye lasers; cf. Dye lasers

Oscillators; cf. Optical parametric oscillators

Oscillator frequency stability; cf. Laser frequency stability

Oscilloscopes; cf. Cathode-ray oscilloscopes

Oxygen devices; cf. Gas lasers

Oxygen
ozone; remote measurement by resonance Raman scattering and differential absorption. *Penney, C. M., J-QE 75 Sep* 36D (2D10)

Ozone; cf. Oxygen

P

Parallel processing
holograms superimposed in $LiNbO_3$ crystals. *Huignard, J. P., J-QE 75 Sep* 8D-9D (2B10)

Parametric amplifiers; cf. Optical parametric amplifiers

Paremetric oscillators; cf. Optical parametric oscillators

Particle spectroscopy
photodeflection method; laser deflection of single isotopic component of atomic beam followed by mass analysis of deflected beam. *Bernhardt, A. F., J-QE 75 Sep* 19D (2C07)

PCM
abbr. of Pulse-code modulation

PCM communication
optical fiber communication repeaters; 40-Mb/s and 400-Mb/s repeaters using feedback-type amplifiers. *Ueno, Y., J-QE 75 Sep* 78D-79D (2G10)

Perturbation methods
optical fiber waveguide analysis using perturbation theory. *Kawakami, Shojiro, J-QE 75 Apr* 130-138 (1A12)

Photochemistry; cf. Chemistry

Photoconducting devices
microwave switches using bulk photoconductivity produced in Si transmission lines by picosecond optical pulses. *Johnson, A. M., J-QE 75 Jun* 283-287 (1E05)

Photodetector arrays
Si photodiode arrays; integrated optical array. *Boyd, J. T., J-QE 75 Sep* 40D-41D (2D14)

Photodetectors; cf. Photodiodes

Photodiodes
HgCdTe planar photodiodes for wideband heterodyne detection at 10.6 μm. *Spears, D. L., J-QE 75 Sep* 79D (2G11)
Si integrated optical arrays. *Boyd, J. T., J-QE 75 Sep* 40D-41D (2D14)

Photodissociation; cf. Gas lasers

Photography
printers for color photography; laser color video printer. *Baldwin, R. E., J-QE 75 Sep* 9D (2B11)

Photoionization
isotope separation; selective photoionization of ^{235}U atoms by laser beam irradiation. *Tuccio, Sam A., J-QE 75 Sep* 101D (3B04)
isotope separation; selective laser two-step excitation and photoionization of atomic U vapor. *Janes, G. S., J-QE 75 Sep* 101D-102D (3B04)
laser-generated photoionization; experiments using H_2 vacuum ultraviolet lasers. *Antonov, V. S., J-QE 75 Sep* 92D (3A09)
U; photoionization cross section measurements. *Solarz, R. W., J-QE 75 Sep* 19D-20D (2C07)

Photoionization; cf. Gas lasers

Photoluminescence
laser-excited lumiinescence; continuously tunable high-pressure CO_2 lasers. *Bagratashvili, V. N., J-QE 75 Sep* 94D (3A11)
laser-excited luminescence; experiments using H_2 vacuum ultraviolet lasers. *Antonov, V. S., J-QE 75 Sep* 92D (3A09)

Photon echoes; cf. Optical resonance

Photosynthesis; cf. Biological cells

Piezoelectric semiconductor devices
ZnO optical planar waveguide modulators. *Hammer, Jacob M., J-QE 75 Apr* 138-148 (1B06)

Plasma diagnostics
laser probe pulses; 1.06 μm subnanosecond pulse shortening and frequency tripling to 3547 Å. *Attwood, D. T., J-QE 75 Sep* 68D-69D (2F14)
pulsed vacuum arcs; analysis using dye laser spectrometer. *Hargis, P. J., Jr., J-QE 75 Sep* 24D (2C12)

Plasma generation; cf. Laser plasma generation

Pockels effect
light emission control in Nd:glass lasers. *Panarella, Emilio, J-QE 75 May* 181-185 (1A03)
Q-switching of Nd:YVO_4 lasers without intracavity polarizer. *Bass, Michael, J-QE 75 Dec* 938-939 (1A12)
ZnO optical planar waveguide modulators. *Hammer, Jacob M., J-QE 75 Apr* 138-148 (1B06)

Pollution; cf. Environmental pollution

Potassium
vapor; third-order susceptibility. *Eicher, Hermann, J-QE 75 Apr* 121-130 (1A03)

Potassium alloys/compounds, devices
KTN optical planar waveguides and modulators. *Fontana, R. E., Jr., J-QE 75 Sep* 38D (2D12)

Potassium devices
lamps; K–Rb pump lamps for Nd:YAG lasers. *Radecki, Dan J., J-QE 75 Sep* 15D-16D (2C03)

Power dividers
optical planar waveguides; mode conversion in planar-dielectric separating guides. *Burns, William K., J-QE 75 Jan* 32-39 (1C06)

Power generation
power plant effluent measurements. *Miller, C. R., J-QE 75 Sep* 34D-35D (2D08)

Power stations; cf. Power generation

Pulse amplifiers; **cf.** Optical pulse amplifiers
Pulse-code modulation; **cf.** PCM
Pulse-compression methods; **cf.** Optical pulse compression
Pulse-compression radar
FM-chirp radar; high-resolution radar ranging at 10.6 μm. *Bicknell, W. E., J-QE 75 Jun* 308-311 (1G02)
Pulsed lasers
2.3-μm Tm^{3+} lasers; room-temperature pulsed emission from Tm:Cr:YAG and Tm:Cr:$YAlO_3$ lasers. *Caird, John A., J-QE 75 Nov* 874-881 (1B06)
Ar–SF_6 and He-SF_6 mixtures; pulsed-laser action on atomic transitions. *Sutton, D. G., J-QE 75 Jan* 54-57 (1D14)
B atom lasers; pumping by incomplete autoionization or ion–electron recombination. *Stricker, J., J-QE 75 Aug* 701-702 (2E07)
CH_3F far-infrared laser; pulse characteristics of optically pumped laser. *Bluyssen, H. J. A., J-QE 75 Jul* 341-348 (1B13)
CO_2 laser amplifiers; energy extraction improvement in ns-pulse TEA lasers. *Farcy, J. C., J-QE 75 Sep* 90D (3A07)
CO_2 laser gain dynamics; model. *Garside, Brian K., J-QE 75 Jun* 264-270 (1C14)
CO_2 TEA lasers; compact sealed laser. *Stark, Donald S., J-QE 75 Sep* 774-778 (1D10)
CO_2 TEA lasers; multigigawatt, ns pulses from tandem of two lasers. *Bélanger, P. A., J-QE 75 Sep* 73D-74D
CO_2 TE lasers; laser dynamics model including rotational coupling effects. *Garside, Brian K., J-QE 75 Aug* 583-589 (1B03)
CuI vapor lasers; transversely excited laser. *Piper, J. A., J-QE 75 Sep* 95D (3A12)
DF and DF–CO_2 electrically initiated chemical lasers. *Poehler, T. O., J-QE 75 Aug* 710 (2F02)
DF lasers; portable recirculating system. *Chenausky, P. P., J-QE 75 Sep* 58D (2F04)
dye lasers; high-repetition-rate transverse-flow laser pumped by linear close-coupled flashlamps. *Friedman, H. W., J-QE 75 Sep* 4D (2B06)
dye lasers; long-pulse generation in Rhodamine-6G laser pumped by CO_2-laser-heated plasma. *Brown, Robert T., J-QE 75 Sep* 800-801 (1F08)
dye lasers; picosecond pulse generation in synchronous mode-locked laser pumped frequency-doubled, passively mode-locked Nd:YAG laser. *Goldberg, L. S., J-QE 75 Sep* 2D (1B04)
dye lasers; subnanosecond tunable pulse generation in N_2-laser-pumped lasers using controlled resonator transients. *Lin, Chinlon, J-QE 75 Sep* 1D-2D (2B03)
dye lasers; tunable subnanosecond pulse generation from N_2-laser-pumped dye laser in near UV and visible region. *Lin, Chinlon, J-QE 75 Aug* 602-609 (1C08)
GaAs/GaAlAs double-heterojunction visible-light-emitting lasers using hetero-isolation stripe geometry. *Itoh, Kunio, J-QE 75 Jul* 421-426 (2D01)
GaAs/GaAlAs double-heterostructure injection lasers with distributed feedback; operation between 80 and 150 K. *Nakamura, Michiharu, J-QE 75 Jul* 436-439 (2E02)
H_2–F_2 high-power chemical lasers; mixture stability and construction materials. *Getzinger, R. W., J-QE 75 Aug* 698 (2E04)
H_2 vacuum ultraviolet lasers. *Knyazev, I. N., J-QE 75 Oct* 805-817 (1A03)
HF chemical lasers; effects of rotational nonequilibrium on predicted performance. *Hough, J. J. T., J-QE 75 Aug* 699 (2E05)
HF chemical lasers; electrically initiated atmospheric lasers. *Mangano, J. A., J-QE 75 Aug* 705 (2E11)
HF chemical lasers; repetitively pulsed operation of chain-reaction lasers. *H_2/F_2 flame propagation and repetitively pulsed hydrogen fluoride (HF) chain-reaction chemical laser, J-QE 75 Aug* 648-653 (2A10)
HF chemical lasers; rotational nonequilibrium. *Creighton, J. R., J-QE 75 Aug* 699 (2E05)
H-pulsing in GaAs/GaAlAs single-heterostructure injection lasers. *Gründorfer, Stephan, J-QE 75 Jul* 532-537 (3D14)
I lasers; pressure broadening and saturation behavior of Asterix III pulsed high-power laser. *Fuss, W., J-QE 75 Sep* 43D (2E03)
I lasers; pulsed high-power Asterix III laser for laser fusion experiments. *Brederlow, G., J-QE 75 Sep* 42D-43D (2E02)
mode-locked internally frequency-doubled lasers; output pulse duration variations. *Falk, Joel, J-QE 75 Jul* 365-367 (1D09)
N_2 lasers; photopreionization. *Kurnit, N. A., J-QE 75 Apr* 174-176 (1D14)
noble-gas ion lasers; pulsed transitions below 3000 Å. *Marling, J. B., J-QE 75 Sep* 27D-28D (2D01)
self-induced intensity pulsations from CW junction lasers; suppression by frequency-selective optical feedback. *Paoli, Thomas L., J-QE 75 Jul* 525-527 (3D07)
transverse-junction-stripe lasers with GaAs homojunction sandwiched between GaAlAs layers. *Namizaki, H., J-QE 75 Jul* 427-431 (2D07)
Pulsed lasers; **cf.** Mode-locked lasers; *Q*-switched lasers
Pulse generators; **cf.** Optical pulse generators
Pulse measurements
optical sampling transient analyzer for fast, high-voltage, single transient electrical pulses. *Davies, Terence J., J-QE 75 Sep* 7D (2B09)
X-ray pulses emitted by laser-produced plasma; pulse-duration measurement. *Duguay, M. A., J-QE 75 Apr* 170-172 (1D10)
Pulse measurements; **cf.** Optical pulse measurements
Pulse shaping; **cf.** Optical pulse shaping
Pumping of lasers; **cf.** Laser excitation
Pyrolysis; **cf.** Chemistry

Q

***Q*-switched lasers**
CO_2 lasers; passive *Q*-switching by Na_2F_4 absorption cells. *Suart, R. D., J-QE 75 Aug* 698 (2E04)
Nd:YAG lasers using negative-branch unstable resonator. *Ewanizky, T. F., J-QE 75 Sep* 17D-18D (2C05)
Nd:YVO_4 lasers; electrooptic *Q*-switching without intracavity polarizer. *Bass, Michael, J-QE 75 Dec* 938-939 (1A12)
Nd:YVO_4 lasers; self-*Q*-switched operation. *DeShazer, L. G., J-QE 75 Sep* 84D (3A01)
pulse shaping in ruby lasers. *Loveberg, R. V., J-QE 75 Jan* 17-21 (1B05)
semiconductor laser theory. *Thomas, Ben, J-QE 75 Jul* 528-532 (3D10)

R

Radar; **cf.** Optical radar
Radar imaging
optical radar; diffraction-limited imaging through turbulent atmosphere using polarization reference imaging system. *Brown, W. P., Jr., J-QE 75 Sep* 52D-53D (2E12)
optical radar imaging through turbulent atmosphere; computer simulation of polarization reference imaging system. *Tseng, D. Y., J-QE 75 Sep* 53D (2E13)
Radar transmitters
optical radar transmitters; temporal coherence of double-discharge CO_2 TEA laser. *Rudko, R. I., J-QE 75 Sep* 54D (2E14)
Radiation effects
CO laser excitation by nuclear reaction products. *McArthur, D. A., J-QE 75 Aug* 707 (2E13)
Radiation effects; **cf.** Electromagnetic radiation effects; Metal radiation effects; Neutron radiation effects; Optical radiation effects; Semiconductor device radiation effects
Radio communication; **cf.** Optical radio communication
Radio communication transmitters
optical communication transmitters; Nd:YAG transmitter for satellite communication laser. *Falk, Joel, J-QE 75 Sep* 14D-15D (2C02)
Radiography; **cf.** X-ray imaging
Radiometry
optical heterodyne radiometer for atmospheric transmission measurements at HF/DF laser wavelengths. *King, S. R., J-QE 75 Sep* 87D (3A04)
solar infrared heterodyne radiometer; atmospheric absorption measurements yielding pollutant concentrations. *Christophe, B., J-QE 75 Sep* 32D-33D (2D06)
Radiometry; **cf.** Infrared radiometry
Radio propagation meteorological factors; **cf.** Optical radio propagation meteorological factors
Rain; **cf.** Meteorological factors
Raman lasers
HgCdTe magnetically tunable lasers; tunable spin-flip and recombination lasers using optical pumping. *Sattler, J. P., J-QE 75 Sep* 18D (2C06)
Raman scattering
coherent anti-Stokes scattering in CH_4 gas; generation by CW lasers. *Barrett, J. J., J-QE 75 Sep* 89D-90D (3A06)
ozone; resonance Raman scattering. *Penney, C. M., J-QE 75 Sep* 36D (2D10)
Raman spectroscopy
temperature measurement in optically pumped NdP_5O_{14} laser. *Weber, Heinz P., J-QE 75 Jul* 368-370 (1D12)
Ranging; **cf.** Distance measurement
Rare-earth ion lasers; **cf.** Solid lasers
Rare gases; **cf.** Noble gases
***RC* networks**
integrated series networks generated by laser machining. *Saifi, M. A., J-QE 75 Sep* 23D (2C11)
Recording; **cf.** Optical recording; Video recording
Reflection; **cf.** Optical reflection
Refraction; **cf.** Optical refraction
Relaxation processes
CO_2 lasers; vibrational deactivation of $CO_2(00°1)$ level by H, D, O, N, F and Cl atoms. *Buchwald, M. I., J-QE 75 Aug* 697 (2E03)
CO_2 TE lasers; laser dynamics model including rotational coupling effects. *Garside, Brian K., J-QE 75 Aug* 583-589 (1B03)
$CO(v=1)$ vibrational deactivation by atomic oxygen. *Davis, C. C., J-QE 75 Aug* 701 (2E07)
DF* lasers; deactivation kinetics in combustion driven lasers using alternates for H_2/Fd'D_2 reactant system. *Wendelken, C. P., J-QE 75 Aug* 694-695 (2D14)
$DF(v)+HF$, $DF(v)+D_2$ and $HF(v)+H_2$ systems; room temperature relaxation rates. *Kwok, M. A., J-QE 75 Aug* 695 (2E01)
dye lasers; relaxation oscillations and initial spikes. *Lin, Chinlon, J-QE 75 Aug* 602-609 (1C08)
gas lasers; deactivation of vibrationally excited molecules by potentially reactive atoms. *Smith, I. W. M., J-QE 75 Aug* 696 (2E02)
HCl molecules; deactivation of vibrationally excited molecules by H and Cl atoms. *Wilkins, R. L., J-QE 75 Aug* 716-717 (2F08)
$HCl(v=1)$ and $DCl(v=1)$; rate coefficients for relaxation by Cl and O atoms. *Brown, R. D. H., J-QE 75 Aug* 695-696 (2E01)
HF–He and DF–He mixtures and pure DF samples; vibrational relaxation between 200 and 300°K. *Hancock, J. K., J-QE 75 Aug* 694 (2D14)
$HF(v=1)$ deactivation by H atoms. *Heidner, R. F., J-QE 75 Aug* 696 (2E02)
$HF(v=1)$, $DF(v=1)$ and $HCl(v=1)$ vibrational deactivation by atomic collisions. *Quigley, G. P., J-QE 75 Aug* 696-697 (2E02)
HF pulsed chemical lasers; effect of rotational nonequilibrium on predicted performance. *Hough, J. J. T., J-QE 75 Aug* 699 (2E05)
HF pulsed chemical lasers; rotational nonequilibrium. *Creighton, J. R., J-QE 75 Aug* 699 (2E05)
HF; rotational relaxation effects. *Hinchen, J. J., J-QE 75 Aug* 695 (2E01)
I lasers; deactivation of electronically excited I atoms. *Burde, D. H., J-QE 75 Aug* 709 (2F01)
N_2 and $CO_2(001)$ vibration-to-translation relaxation by alkali metal atoms. *Benson, R. C., J-QE 75 Aug* 697 (2E03)
$O_3^+ + NO$ reaction system; rate constant for O_3^{++} decay from 150 to 350 K. *Kurylo, M. J., J-QE 75 Aug* 702-703 (2E08)
$O(^3P)+CO(^1\Sigma^+)$ collisions; vibrational deactivation and atom exchange. *Kelley, J. D., J-QE 75 Aug* 701 (2E07)
silicate laser glass; nonradiative relaxation of rare-earth ions. *Layne, C. B., J-QE 75 Sep* 798-799 (1F06)
$Xe^*(^3P_2)$ metastable atoms; quenching with light hydrocarbons and fluoromethanes. *Velazco, J. E., J-QE 75 Aug* 708-709 (2E14)
Relay systems; **cf.** Wire communication repeaters
Remote sensing
ozone measurements using resonance Raman scattering and differential absorption. *Penney, C. M., J-QE 75 Sep* 36D (2D10)
power plant effluent measurements; remote measurements using laser Doppler velocimeter. *Miller, C. R., J-QE 75 Sep* 34D-35D (2D08)

Repeaters; **cf.** Wire communication repeaters
Resistors
SiC high-temperature resistors; fabrication using CO_2 lasers. *Hierholzer, F. J., J-QE 75 Sep* 47D-48D (2E07)
Resonance; **cf.** Optical resonance
Resonators; **cf.** Laser resonators
Ring lasers
bistable unidirectional operation. *Hambenne, J. B., J-QE 75 Feb* 90-92 (1B14)
coupling; comparison of traveling-wave and standing-wave resonator extraction efficiencies. *Eckbreth, Alan C., J-QE 75 Sep* 796-798 (1F04)
Rubidium
vapor; third-order susceptibility. *Eicher, Hermann, J-QE 75 Apr* 121-130 (1A03)
Rubidium alloys/compounds, devices
RD*A optical parametric oscillators. *Kato, K., J-QE 75 Dec* 939-941 (1A13)
Rubidium devices
lamps; K–Rb pump lamps for Nd:YAG lasers. *Radecki, Dan J., J-QE 75 Sep* 15D-16D (2C03)
lasers; electronic-transition chemical laser using $Rb + F_2$ reaction system. *Hall, L. H., J-QE 75 Aug* 693 (2D13)
Ruby lasers
pulse shaping in *Q*-switched lasers. *Loveberg, R. V., J-QE 75 Jan* 17-21 (1B05)

S

Sampled signals
optical sampling transient analyzer for fast, high-voltage, single transient electrical pulses. *Davies, Terence J., J-QE 75 Sep* 7D (2B09)
Satellite communication
optical communication transmitters; Nd:YAG laser transmitter. *Falk, Joel, J-QE 75 Sep* 14D-15D (2C02)
optical communication; lamp-pumped Nd:YAG laser subsystem for 1 gbps system. *Radecki, Dan J., J-QE 75 Sep* 15D-16D (2C03)
receivers; 10-μm optical heterodyne receiver for synchronous satellite. *Goodwin, F. E., J-QE 75 Sep* 79D-80D (2G11)
receivers; wideband 10.6-μm heterodyne receiver for CO_2 laser satellite communications link. *Peyton, B. J., J-QE 75 Sep* 80D-81D (2G12)
Satellite tracking
ranging systems; picosecond-pulse, fieldable Nd:YAG laser system. *Erickson, E. G., J-QE 75 Sep* 16D-17D (2C04)
Scanning; **cf.** Imaging
Scattering; **cf.** Optical scattering
Schottky-barrier devices
Gunn effect digital device for direct modulation of GaAs–AlGaAs double-heterostructure lasers. *Yanai, Hisayoshi, J-QE 75 Jul* 519-524 (3D01)
Scintillation detectors
fluorescent rise times in plastic scintillators; streak camera studies. *Shapiro, S. L., J-QE 75 Sep* 5D-6D (2B07)
Second-harmonic generation; **cf.** Optical harmonic generation
Self-focusing; **cf.** Laser-beam focusing
Self-pulsing lasers; **cf.** Pulsed lasers
Self-*Q*-switching; **cf.** *Q*-switched lasers
Semiconductor defects
dark-line and dark-spot defects in GaAs–AlGaAs double-heterostructure lasers. *Ito, Ryoichi, J-QE 75 Jul* 551-556 (3F05)
dislocation networks (dark-line defects) producing degradation in injection lasers; network development model. *Woolhouse, G. R., J-QE 75 Jul* 556-561 (3F10)
dislocation pinning in GaAs by group III or V impurities. *Kirkby, P. A., J-QE 75 Jul* 562-568 (3G02)
Semiconductor devices; **cf.** Piezoelectric semiconductor devices; Semiconductor plasma devices
Semiconductor device fabrication
GaAs lasers; single-heterostructure distributed-feedback lasers. *Burnham, Robert D., J-QE 75 Jul* 439-449 (2E05)
lasers; monolithic GaInAs homojunction diode lasers. *Doerbeck, F. H., J-QE 75 Jul* 464-467 (2G02)
resistors; fabrication of high-temperature SiC resistors using CO_2 lasers. *Hierholzer, F. J., J-QE 75 Sep* 47D-48D (2E07)
Semiconductor device fabrication; **cf.** Ion implantation; Semiconductor growth
Semiconductor device noise
lasers; intensity noise characteristics of continuously operating stripe-geometry double-heterostructure junction lasers. *Paoli, Thomas L., J-QE 75 Jun* 276-283 (1D12)
Semiconductor device radiation effects
laser pulse irradiation effects on metals and semiconductors. *Dekhtar, I. Ya., J-QE 75 Sep* 83D (2G14)
Semiconductor device thermal factors; **cf.** Laser thermal factors
Semiconductor diodes; **cf.** Avalanche diodes
Semiconductor doping; **cf.** Semiconductor impurities
Semiconductor growth
liquid-phase epitaxial growth of GaAs–AlGaAs double-heterostructure tsper-coupled lasers. *Logan, R. A., J-QE 75 Jul* 461-464 (2F13)
LPE InGaPAs–GaAsP single-heterojunction laser diodes. *Coleman, J. J., J-QE 75 Jul* 471-476 (2G09)
Semiconductor heterojunction devices; **cf.** Gallium alloys/compounds, devices; Gallium alloys/compounds, lasers; Semiconductor lasers
Semiconductor impurities
dislocation pinning in GaAs by group III or V impurities. *Kirkby, P. A., J-QE 75 Jul* 562-568 (3G02)
Semiconductor Laser Conference
papers from Nov. 1974 conference, *J-QE 75 Jul, Pt. II* 381-568 (2A03)
special issue on Nov. 1974 conference; foreword. *Paoli, Thomas L., Guest ed., J-QE 75 Jul* 381 (2A03)
Semiconductor lasers
asymmetric spectral-mode interaction due to stimulated scattering of laser radiation. *Bogatov, A. P., J-QE 75 Jul* 510-515 (3C06)
distributed-feedback single- and double-heterostructure diode lasers; coupling coefficients for TE modes. *Streifer, William, J-QE 75 Nov* 867-873 (1A13)
double-heterojunction lasers with very thin active regions; angular beam divergence. *Dumke, W. P., J-QE 75 Jul* 400-402 (2B08)
double-heterostructure stripe-geometry lasers operating continuously at room temperature; intensity noise characteristics. *Paoli, Thomas L., J-QE 75 Jun* 276-283 (1D12)
double-heterostructure lasers; dislocation pinning by deliberately added impurities. *Kirkby, P. A., J-QE 75 Jul* 562-568 (3G02)
HgCdTe magnetically tunable lasers; tunable spin-flip and recombination lasers using optical pumping. *Sattler, J. P., J-QE 75 Sep* 18D (2C06)
InSb lasers; CW tunable lasers optically pumped in longitudinal geometry. *Menyuk, N., J-QE 75 Jul* 477-481 (3A01)
light output intensity modulation using injected laser beams. *Nishizawa, Jun-Ichi, J-QE 75 Jul* 515-519 (3C11)
optical theory for highly doped semiconductors; spontaneous emission and threshold property calculations. *Aleksanian, A. G., J-QE 74 Mar* 297-305 (1A03) ♦
PbSe lasers; current- and magnetic-tuned laser for SO_2 infrared spectral measurements. *Allario, Frank, J-QE 75 May* 205-209 (1B13)
PbSnTe double-heterojunction laser diodes; threshold current densities. *Tomasetta, L. R., J-QE 75 Jul* 384-390 (2A06)
Q-switching theory. *Thomas, Ben, J-QE 75 Jul* 528-532 (3D10)
relaxation oscillations in modulated output; suppression by light injection method. *Lang, R., J-QE 75 Sep* 60D (2F06)
self-induced intensity pulsations from CW junction lasers; suppression by frequency-selective optical feedback. *Paoli, Thomas L., J-QE 75 Jul* 525-527 (3D07)
thermal impedance measurement. *Paoli, Thomas L., J-QE 75 Jul* 498-503 (3B08)
transverse mode control in multimode double-heterostructure junction lasers optically coupled to single-mode fibers. *Krupka, D. C., J-QE 75 Jul* 503-507 (3B13)
Semiconductor lasers; **cf.** Gallium alloys/compounds, lasers
Semiconductor plasma devices
microwave switches using bulk photoconductivity produced in Si transmission lines by picosecond optical pulses. *Johnson, A. M., J-QE 75 Jun* 283-287 (1E05)
Semiconductor switches
Ge light-triggered switches for fast switching of high-power CO_2 laser radiation. *Alcock, A. J., J-QE 75 Sep* 96D (3A13)
microwave switches using bulk photoconductivity produced in Si transmission lines by picosecond optical pulses. *Johnson, A. M., J-QE 75 Jun* 283-287 (1E05)
Sensors
hover sensor for heavy lift helicopter. *Herzog, D. G., J-QE 75 Sep* 51D-52D (2E11)
SF_6
isotopic enrichment by multiple absorption of CO_2 laser radiation. *Lyman, J. L., J-QE 75 Sep* 103D (3B06)
N_2 lasers; quasi-CW second-positive laser using SF_6 additions to N_2 in discharge region. *Suchard, S. N., J-QE 75 Aug* 685-686 (2D05)
SF_6; **cf.** Gas lasers, molecular
Shock waves; **cf.** Acoustic surface-wave effects
Signal analysis
optical sampling transient analyzer for fast, high-voltage, single transient electrical pulses. *Davies, Terence J., J-QE 75 Sep* 7D (2B09)
Signal processing; **cf.** Acoustic signal processing; Optical signal processing
Signal sampling; **cf.** Sampled signals
Silicon devices
microwave switches using bulk photoconductivity produced in Si transmission lines by picosecond optical pulses. *Johnson, A. M., J-QE 75 Jun* 283-287 (1E05)
photodiode arrays; integrated optical array. *Boyd, J. T., J-QE 75 Sep* 40D-41D (2D14)
Silicon alloys/compounds
SiF_4 isotopic enrichment by multiple absorption of CO_2 laser radiation. *Lyman, J. L., J-QE 75 Sep* 103D (3B06)
Silicon alloys/compounds, devices
lasers; SiO and SiF electronic-transition chemical lasers. *Scott, P. B., J-QE 75 Aug* 693-694 (2D13)
lasers; SiO electronic-transition chemical lasers. *Wilson, L. E., J-QE 75 Aug* 691 (2D11)
SiC high-temperature resistors; fabrication using CO_2 lasers. *Hierholzer, F. J., J-QE 75 Sep* 47D-48D (2E07)
Slab waveguides; **cf.** Optical planar waveguides
Sodium
vapor; third-order susceptibility. *Eicher, Hermann, J-QE 75 Apr* 121-130 (1A03)
Sodium devices
lasers; electronic-to-electronic energy transfer rates in Na vapor. *Chen, Hao-Lin, J-QE 75 Aug* 669-672 (2C03)
optical pulse generators; conversion of CW dye laser light into train of repetitive subnanosecond pulses using resonant atomic dispersion in Na vapor. *Bjorkholm, J. E., J-QE 75 Sep* 68D (2G01)
Sodium devices; **cf.** Gas lasers
Sodium alloys/compounds, devices
$Ba_2NaNb_5O_{15}$ acoustooptic mode locker/frequency doubler for Nd:YAG lasers. *Rice, R. R., J-QE 75 Sep* 14D (2C02)
$Ba_2Na(NbO_3)_5$ intracavity frequency-doubling elements in Nd:YAG lasers; thermooptical effects. *Barry, James D., J-QE 75 Aug* 575-579 (1A13)
NaCl Brewster windows in CS_2/O_2 chemical lasers; surface reactions produced by flash photolysis. *Petersen, Alan B., J-QE 75 Mar* 110-111 (1B02)
Soils; **cf.** Earth
Solar energy applications
laser pumping; solar-pumped Nd:YAG laser. *Falk, Joel, J-QE 75 Sep* 14D-15D (2C02)
Solar radiation
measurements using infrared heterodyne radiometer. *Peyton, Bernard J., J-QE 75 Aug* 569-574 (1A03)
Solid lasers
2.3-μm Tm^{3+} lasers; room-temperature pulsed emission from Tm:Cr:YAG and Tm:Cr:$YAlO_3$ lasers. *Caird, John A., J-QE 75 Nov* 874-881 (1B06)
glass laser systems; effect of air space on self-focusing instability growth rates. *Elliott, C. James, J-QE 75 Nov* 863-866 (1A09)
Ho:solid lasers; laser transitions. *Caird, John A., J-QE 75 Mar* 97-99 (1A03)

♦ Check author entry for later corrections/comments

Ho:YLF lasers; 2.06 μm laser performance and design options for rangefinder and illuminator applications. *Devor, D. P., J-QE 75 Sep* 13D-14D (2C01)
$LiNdP_4O_{12}$ lasers; CW laser with 200-μW pump threshold for 5145-Å pump. *Otsuka, Kenju, J-QE 75 Oct* 845-846 (1D01)
$LiNdP_4O_{12}$ lasers; CW operation of transversely pumped laser. *Yamada, T., J-QE 75 Sep* 62D-63D (2F08)
$LiNdP_4O_{12}$ lasers; quasi-continuous action. *Otsuka, Kenju, J-QE 75 Jul* 330-334 (1B02)
NdLa pentaphosphate fiber lasers. *Weber, H. P., J-QE 75 Sep* 100D (3B03)
NdP_5O_{14} lasers; material characteristics and laser properties. *Weber, H. P., J-QE 75 Sep* 61D-62D (2F07)
NdP_5O_{14} lasers; optical-pumping-induced heating resulting in bistable laser operation. *Weber, Heinz P., J-QE 75 Jul* 368-370 (1D12)
NdP_5O_{14} lasers; threshold and efficiency of transversely excited laser. *Chinn, S. R., J-QE 75 Sep* 62D (2F08)
NdP_5O_{14} transversely excited lasers; room-temperature lasing behavior. *Chinn, Stephen R., J-QE 75 Sep* 747-754 (1B11)
nonlinear refractive-index coefficient of laser-system materials; interferometric measurement. *Moran, Michael J., J-QE 75 Jun* 259-263 (1C09)
quantum efficiencies of lasers using rare-earth-doped silicate glass. *Layne, C. B., J-QE 75 Sep* 798-799 (1F06)

Solid lasers; **cf.** Neodymium:solid lasers; Ruby lasers; Semiconductor lasers
Special issues
Chemical and Molecular Lasers Conference; papers and abstracts from Oct. 1974 conference, *J-QE 75 Aug, Pt. II* 641-722 (2A03)
Semiconductor Laser Conference; papers from Nov. 1974 conference, *J-QE 75 Jul, Pt. II* 381-568 (2A03)

T

TEA lasers; **cf.** Gas lasers
Tellurium
second-harmonic generation; effect of two-photon absorption. *Schwartz, Christiane A., J-QE 75 Aug* 616-623 (1D08)
second-harmonic generation; effect of two-photon absorption. *Oudar, Jean-Louis, J-QE 75 Aug* 623-629 (1E01)
Temperature measurement
junction laser temperature rise as function of average electrical power supplied to device. *Paoli, Thomas L., J-QE 75 Jul* 498-503 (3B08)
metallic surface temperatures in laser-irradiated material; measurement using thin-film thermocouples. *Marcus, S., J-QE 75 Sep* 49D-50D (2E09)
Raman spectroscopy measurement in optically pumped NdP_5O_{14} laser. *Weber, Heinz P., J-QE 75 Jul* 368-370 (1D12)
Thallium alloys/compounds, devices
Tl_3AsSe_3 acoustooptic filters; tunable collinear filter for intermediate infrared. *Feichtner, J. D., J-QE 75 Sep* 66D-67D (2F12)
Thermal factors; **cf.** Laser thermal factors
Thermal variables measurement
dilatometry using multichannel interferometer. *Pond, C. R., J-QE 75 Sep* 10D-11D (2B12)
Thermal variables measurement; **cf.** Temperature measurement
Thin-film waveguides; **cf.** Optical planar waveguides
Time measurement
subpicosecond optical chronoscopy; Photochron II streak camera tube. *Bradley, D. J., J-QE 75 Sep* 25D-26D (2C13)
Tin alloys/compounds, devices; **cf.** Semiconductor lasers
Titanium
isotope separation; laser separation process for Ti-50. *Gross, R. W. F., J-QE 75 Aug* 702 (2E08)
Tracking; **cf.** Satellite tracking
Transfer lasers; **cf.** Gas lasers, molecular
Transforms; **cf.** Fourier transforms
Transient analysis
optical sampling transient analyzer for fast, high-voltage, single transient electrical pulses. *Davies, Terence J., J-QE 75 Sep* 7D (2B09)
Transitions; **cf.** Waveguide transitions
Transmitters; **cf.** Radar transmitters; Radio communication transmitters
Transversely excited lasers; **cf.** Gas lasers; Solid lasers
Traveling-wave lasers; **cf.** Ring lasers
Tunable filters
Tl_3AsSe_3 acoustooptic filters; tunable collinear filter for intermediate infrared. *Feichtner, J. D., J-QE 75 Sep* 66D-67D (2F12)
Turbulent media; **cf.** Optical radio propagation meteorological factors

U

Ultrasonic...; **cf.** Acoustic...
Ultraviolet generation
Cerenkov radiation generation; second-harmonic generation. *Chen, Bor-Uei, J-QE 75 Apr* 177-178 (1E03)
picosecond pulse generation using synchronous mode-locked dye laser and nonlinear mixing; tunable pulses over 270–331 nm and 362–408 cm. *Goldberg, L. S., J-QE 75 Sep* 2D (1B04)
Ultraviolet lasers
dye lasers; 3400 Å terphenyl dye laser pumped by UV radiation from CO_2-laser-produced Xe plasma. *Silfvast, W. T., J-QE 75 Sep* 1D (2B03)
dye lasers; tunable subnanosecond pulse generation from N_2-laser-pumped dye laser in near UV and visible region. *Lin, Chinlon, J-QE 75 Aug* 602-609 (1C08)
electronic-transition chemical lasers; parametric evaluation of potential diatomic molecules. *Sutton, D. G., J-QE 75 Aug* 690-691 (2D10)
H_2 lasers; use in photoionization and luminescence excitation experiments. *Antonov, V. S., J-QE 75 Sep* 92D (3A09)
H_2 vacuuum ultraviolet lasers; single-short TEA laser, high-repetition rate laser and CW laser. *Knyazev, I. N., J-QE 75 Oct* 805-817 (1A03)
N_2 lasers; 3371-Å laser power produced by relativistic electron-beam propagation. *McArthur, David A., J-QE 75 Nov* 892-902 (1C10)
N_2 lasers; stimulated emission at 0.3159 μm in second-positive system at room temperature. *Kruger, John S., J-QE 75 Sep* 801-802 (1F09)
N_2 pulsed lasers; photopreionization. *Kurnit, N. A., J-QE 75 Apr* 174-176 (1D14)
noble gas ionic lasers; transitions below 2500 Å. *Marling, John B., J-QE 75 Oct* 822-834 (1B06)
noble-gas ion lasers; pulsed and CW transitions below 3000 Å. *Marling, J. B., J-QE 75 Sep* 27D-28D (2D01)
noble-gas lasers pumped by coaxial diode electron-beam system. *Arthurs, E. G., J-QE 75 Sep* 28D (2D02)
pulsed dye lasers; subnanosecond tunable pulse generation in N_2-laser-pumped lasers using controlled resonator transients. *Lin, Chinlon, J-QE 75 Sep* 1D-2D (2B03)
rangefinders using pulsed ultraviolet N_2 laser. *Davis, T. P., J-QE 75 Sep* 50D (2E10)
XeBr* excimer lasers; 281.8-nm emission from electron-beam-excited Xe/Br_2 mixture. *Searles, S. K., J-QE 75 Sep* 93D (3A10)
XeF lasers; 3540-Å emission from electron-beam-excited $F_2/Xe/Ar$ mixtures. *Ewing, J. J., J-QE 75 Sep* 92D-93D (3A09)
Ultraviolet radiation effects
photoionization in TEA CO_2 lasers. *Seguin, H. J. J., J-QE 75 Sep* 71D-72D (2G03)
Uranium
^{235}U isotope separation using selective photoionization. *Tuccio, Sam A., J-QE 75 Sep* 101D (3B04)
isotope separation; photoionization cross section and excited state lifetime measurements in U vapor for separation process evaluation. *Solarz, R. W., J-QE 75 Sep* 19D-20D (2C07)
isotope separation; selective two-step excitation and photoionization of atomic U vapor. *Janes, G. S., J-QE 75 Sep* 101D-102D (3B04)
isotope separation using lasers. *Teller, E., J-QE 75 Sep* 83D (2G14)

V

Vehicle control; **cf.** Aircraft control
Velocity measurement; **cf.** Optical velocimeters
Video recording
optical video disks. *Spitz, Eric, J-QE 75 Sep* 11D (2B13)
optical video disks; holographic disk. *Tsunoda, Y., J-QE 75 Sep* 11D-12D (2B13)
Visible lasers
Ar ion lasers; CW laser using 700-m-long cavity. *Tripathi, P. P., J-QE 75 Sep* 59D (2F05)
ArO lasers; parameters of flash-photolyzed N_2O–Ar_2 mixtures. *Hughes, William M., J-QE 75 Sep* 88D (3A05)
BaF, BaCl, BaBr and BaI electronic-transition chemical lasers. *Bradford, R. S., Jr., J-QE 75 Aug* 692 (2D12)
Ba vapor lasers; visible laser transitions at 7120 Å in Ba I and at 549.9 and 6141.7 Å in Ba (II). *Baron, K. U., J-QE 75 Oct* 852-853 (1D08)
BO, BaO, CuF, SiO and SiF electronic-transition chemical lasers. *Scott, P. B., J-QE 75 Aug* 693-694 (2D13)
BrCl and GeO electronic-transition lasers; excited electronic states. *Harris, R. A., J-QE 75 Aug* 691 (2D11)
calcium and strontium oxide and halide chemical lasers; photon yields in 250–1100 nm region and $A'^1\pi$ molecular constants. *Capelle, G. A., J-QE 75 Aug* 692 (2D12)
chemical lasers; reaction initiation by short-duration pulsed discharges. *Chou, M. S., J-QE 75 Aug* 691-692 (2D11)
chemical lasers using reactions of evaporated metal atoms with various oxidizers. *Eckstrom, D. J., J-QE 75 Aug* 691 (2D11)
cresyl violet perchlorate laser; pumping using dye mixture and tandem systems. *Beisser, F. A., J-QE 75 Jul* 372 (1E02)
Cu vapor lasers; discharge-heated master oscillator power amplifier. *Anderson, R. S., J-QE 75 Sep* 56D-57D (2F02)
dye lasers; high-power blue and violet lasers pumped by third harmonic of Nd:YAG laser. *Kato, K., J-QE 75 Jul* 373-374 (1E03)

dye lasers; pulsed Xe ion laser pump for tunable Rhodamine-6G laser. *Schearer, Laird D., J-QE 75 Dec* 935-937 (1A09)
dye lasers; tunable subnanosecond pulse generation from N_2-laser-pumped dye laser in near UV and visible region. *Lin, Chinlon, J-QE 75 Aug* 602-609 (1C08)
electronic-transition chemical lasers; parametric evaluation of potential diatomic molecules. *Sutton, D. G., J-QE 75 Aug* 690-691 (2D10)
electronic-transition chemical lasers using reactions of I_2, Br_2, SiH_4, GeH_4, AsH_3 or Ph_3 with F_2. *Davis, S. J., J-QE 75 Aug* 693 (2D13)
FeO electronic-transition chemical lasers. *West, J. B., J-QE 75 Aug* 692-693 (2D12)
GaAs/GaAlAs double-heterojunction lasers using heteroisolation stripe geometry. *Itoh, Kunio, J-QE 75 Jul* 421-426 (2D01)
GeO and SiO electronic-transition chemical lasers. *Wilson, L. E., J-QE 75 Aug* 691 (2D11)
He–Cd^+ lasers emitting CW white light; single-gun hollow cathode tube with three-color outputs. *Fujii, Kan-Ichi, J-QE 75 Mar* 111-114 (1B03)
Hg lasers; dc-excited Hg pump lamps for CW operation at 546.1 nm. *Holmes, N., J-QE 75 Sep* 55D (2F01)
metal atom/N_2O chemical lasers; luminescence. *Felder, W., J-QE 75 Aug* 703 (2E09)
Na_2 molecular lasers; optically pumped superfluorescent laser. *Henesian, M., J-QE 75 Sep* 26D (2C14)
O lasers using ^1S–^1D transition; lasing at 5578.5 Å in relativistic-electron-beam excited Kr_2/O_2 mixtures. *Johnson, A. W., J-QE 75 Sep* 56D (2F02)
pulsed dye lasers; subnanosecond tunable pulse generation in N_2-laser-pumped lasers using controlled resonator transients. *Lin, Chinlon, J-QE 75 Sep* 1D-2D (2B03)
XeO lasers; lasing on green bands using direct electron beam excitation of high pressure Xe with small additions of O_2, CO_2 or N_2O. *Powell, H. T., J-QE 75 Aug* 685 (2D05)
XeO lasers; reaction kinetics in electron-beam pumped Xe–O_2 mixtures. *Lorents, D. C., J-QE 75 Aug* 704 (2E10)

W

Wave diffraction; **cf.** Optical diffraction
Waveguides; **cf.** Optical waveguides
Waveguide communication; **cf.** Optical waveguide communication
Waveguide junctions
optical waveguide junctions; optical field propagation in integrated optical bifurcations. *Roy, A. M., J-QE 75 Sep* 41D-42D (2E01)
Waveguide junctions; **cf.** Waveguide transitions
Waveguide lasers
AlGaAs multiheterostructure laser with integrated twin guide. *Suematsu, Y., J-QE 75 Jul* 457-460 (2F09)
chirp-modulated CO_2 lasers; demodulation technique. *Stein, Alexander, J-QE 75 Aug* 630-631 (1E08)
CO_2 laser amplifiers; high-power CW 10.6-μm amplifier. *Klein, Marvin B., J-QE 75 Aug* 609-615 (1D01)
CO_2 transversely excited lasers; high-gain CW laser using preionization scheme based on Malter effect. *Wood, O. R., II, J-QE 75 Sep* 72D-73D (2G04)
CW submillimeter emission from optically pumped gas lasers. *Radj Harrison E., J-QE 75 May* 213-214 (1C07)
flowing-gas capillary lasers; porous wall tube system. *Papayoanou, Aris... J-QE 75 Aug* 579-583 (1A13)
GaAlAs double heterostructure packaged lasers for optical-fiber transmission *Takusagawa, M., J-QE 75 Sep* 61D (2F07)
optical waveguide lasers; grating-coupled composite-guide heterostructure GaAlAs diode lasers with low-divergence beams. *Burnham, R. D., J-QE 75 Sep* 98D-99D (3B01)
Waveguide losses
optical waveguide bend losses; conformal transformation analysis of curved guides. *Heiblum, Mordehai, J-QE 75 Feb* 75-83 (1A13)
Waveguide switches
electrooptic switches for optical planar waveguides; electrode configuration fo producing prism-like deflector on guide. *Kaminow, I. P., J-QE 75 Aug* 633-635 (1E11)
Waveguide transitions
optical waveguide transitions; optical field propagation in integrated optical transitions. *Roy, A. M., J-QE 75 Sep* 41D-42D (2E01)
Wave propagation; **cf.** Optical propagation
Welding; **cf.** Laser materials-processing applications
Wire communication repeaters
optical fiber communication repeaters; 40-Mb/s and 400-Mb/s repeaters using feedback-type amplifiers. *Ueno, Y., J-QE 75 Sep* 78D-79D (2G10)

X

Xenon; **cf.** Noble gases
X-ray generators
laser-produced plasma; duration of emitted X-ray pulses. *Duguay, M. A., J-QE 75 Apr* 170-172 (1D10)
X-ray imaging
Fourier-transform holograms of simple plane objects; recording using X-ra... *Mahr, H., J-QE 75 Sep* 97D-98D (3A14)

Y

YAG lasers; **cf.** Neodymium:YAG lasers; Solid lasers
$YAlO_3$ lasers; **cf.** Solid lasers
YLF lasers; **cf.** Solid lasers
YVO_4 lasers; **cf.** Neodymium:solid lasers

Z

Zinc alloys/compounds, devices
ZnO modulators; waveguide electrooptic modulator using grain-oriented polycrystalline film. *Hu, Chenming, J-QE 75 Sep* 64D (2F10)
ZnO optical planar waveguide modulators. *Hammer, Jacob M., J-QE 75 Ap* 138-148 (1B06)
ZnS optical planar waveguides; phase-matched second-harmonic generat using nonlinearities in film and substrate. *Ito, H., J-QE 75 Sep* 40D (2D
ZnTe optical planar waveguides fabricated by ion implantation. *Valette, S J-QE 75 Sep* 39D-40D (2D13).
