Formation of Lettucenin A in Different Lettuce. To understand the formation of lettucenin A in the plant more accurately, three varieties of lettuce were divided into four parts (green and yellow leaves, leaf panicle, and butt end) and browned at room temperature. After a browning period of 24 or 40 h, samples were collected and freeze-dried. From the samples, the lettucenins were extracted and lettucenin A as a specific marker was quantitated (Figure 5). As shown in the graphic, different concentrations of compound **1** occurred in the different parts of the Iceberg lettuce. A similar distribution was found in the varieties Butterhead and Lollo Bionda. After 24 h, the highest concentrations of compound **1** and all other lettucenin derivatives were analyzed, always in the lettuce butt end. This confirmed the visual impression of strong browning in the lettuce butt end.[8]

Because compound **1** is a reactive intermediate, there was no accumulation in the plant. This was proven by comparison to the lettuce butt end browning after 40 h. Only 5% of the concentration found in the 24 h sample could be quantitated. Figure 6 shows the time-course formation of compounds **1** and **3**, where concentrations of compound **1** reached a maximum after 24 h. After that, compound **1** degraded almost to the initial level at 40 h. This also confirmed the difference between the butt end samples in Figure 5. In contrast to compound **1**, compound **3** reached a maximum 16 h later at significantly lower concentrations. This strongly suggested compound **1** as the precursor structure in the formation of compound **3**.

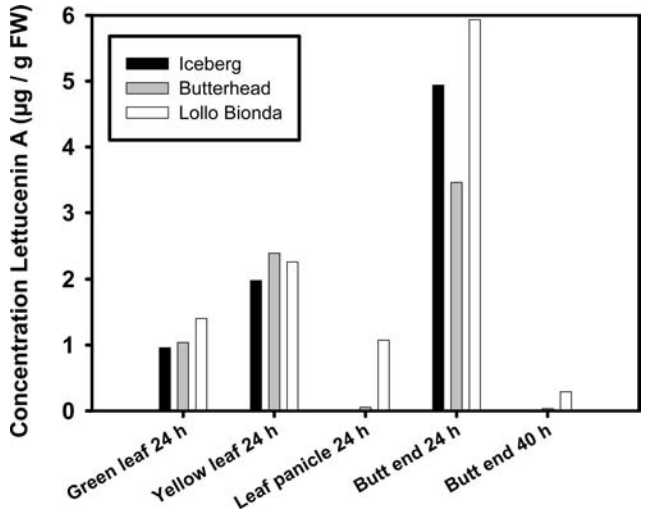

Figure 5. Lettucenin A accumulation in different parts of three varieties of lettuce after 24 and 40 h of cutting.

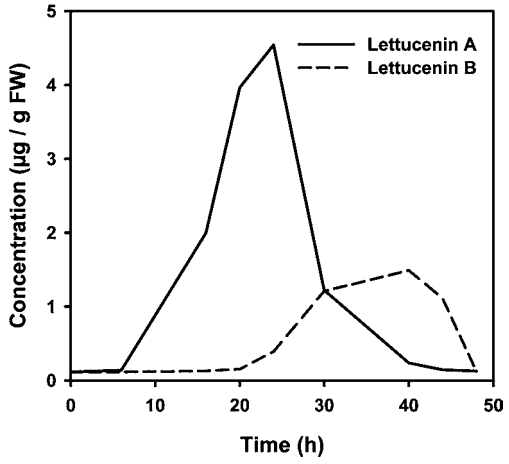

Figure 6. Time-course formation of lettucenin A and lettucenin B in sliced Iceberg lettuce.

The temperature is a crucial factor in the formation of lettucenins. At elevated temperature, the maximum concentration of compound **1** was reached much earlier (data not shown). According to studies by Tahara et al., Takasugi et al., and Sessa et al., the pathogenic bacterium *P. cichorii* or cupric chlorid and cupric sulfate also increase the concentration of lettucenin A with a maximum of 3 μg/g of FW.[12,13,21] Other microorganisms (*Pseudomonas syringae* pv. *phaseolicola* and *Botrytis cinerea*) generated yields reaching up to 9 μg/g of FW. Lettucenin A was found within cotyledons with the red spot syndrome (6.2 μg/g of FW) and is therefore related to a microbial infestation.[22] Observations by Bestwick et al. suggest that there is a correlation of irreversible membrane damage and induction of phytoalexin accumulation.[23] Thereby, threshold levels of membrane dysfunction lead to the induction of endogenous mechanisms that cause the lettucenin biosynthesis.[23] In the present paper, samples were mechanically injured, by cutting them with a ceramic knife. Thus, a deliberate infection with microorganisms or heavy metals has to be excluded.

Importance of Lettucenin A in Different Varieties of Lettuce. In previous studies, lettucenin A was one of the most important phytoalexins in the group of composites.[14,15] It was

dx.doi.org/10.1021/jf500413h | J. Agric. Food Chem. 2014, 62, 4747–4753

identified in some European and Asian species: *Taraxacum officinale*, *Taraxacum hondoense*, *L. sativa*, *Lactuca dentate*, *Lactuca scariola*, *Sonchus oleraceus*, *Sonchus asper*, and *Ixeris repens*.[12,13,24] As depicted in Figure 7, 10 types of Cichorieae, a

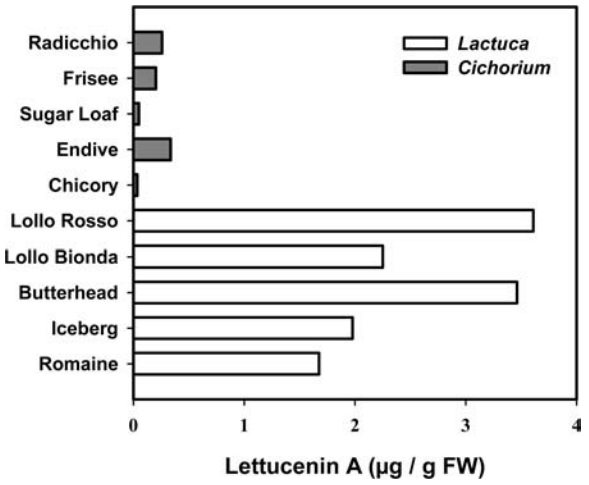

Figure 7. Lettucenin A accumulation in 24 h aged sliced stem material of 10 varieties of Cichorieae (5 varieties of *Lactuca* and 5 varieties of *Cichorium*).

tribe of flowering plants in the daisy family Asteraceae, were examined for lettucenin A, all of which are popular commercial lettuce, with 5 species belonging to the genus *Chichorium* and 5 species belonging to the genus *Lactuca*. In the genus *Cichorium*, compound **1** was detected with a maximum of 0.34 μg/g of FW, whereas in the genus *Lactuca*, concentrations ranged from 1.68 to 3.61 μg/g of FW. The levels of compound **1** in varieties of *Lactuca* were at least 5 times higher than those in varieties of *Cichorium*. Thus, there is a significant difference between these two genera. Thus far, lettucenin A was not found in uninfected samples of *L. sativa* L. (Iceberg) and, therefore, was not considered as a chemosystematic marker.[25] However, the present data strongly suggest that lettucenin A can indeed be used as an identity marker within the genus *Lactuca*.

In conclusion, we succeeded to extend the range of sesquiterpene yellow chromophores in Iceberg lettuce. In contrast to published data on microbial and heavy metal stress, lettucenin formation was induced solely by mechanical distortion. The main compound was confirmed to be the phytoalexin lettucenin A. In addition, we identified unequivocally two novel colored derivatives of lettucenin A. A third structure related to lettucenins was assigned on the basis of mass spectrometric data. Color-dilution analyses revealed the major importance of lettucenins as key chromophores in browned Iceberg lettuce. Thus, sesquiterpene-based discoloration has to be added as a new aspect to the concept of enzymatic browning in vegetables previously only attributed to polyphenolic chemistry.

ABSTRACT: A common protocol for the extraction of phenolic aglycons or bound phenolics in plants generally involves hydrothermal hydrolysis in an aqueous methanol or ethanol solution containing 2−4 N HCl. However, as shown in the present study, this process also forms 5-(hydroxymethyl)furan-2-carbaldehyde (HMF) and its derivative products 5-(methoxymethyl)-furan-2-carbaldehyde (MMF) and 5-(ethoxymethyl)furan-2-carbaldehyde (EMF), as identified by HPLC-DAD−ESI-MS/MS and NMR. These compounds are commonly misidentified as phenolics due to similar UV absorption at 280 nm. In this study, production of HMF, MMF, and EMF was shown to be dependent on the solvent condition and duration and temperature of hydrolysis. Fruits and vegetables produced HMF more readily than grains. HMF and its derivatives were subjected to various spectrophotometric antioxidant assays [2-diphenyl-1-picryhydrazyl radical scavenging activity (DPPH), ferric-reducing antioxidant power (FRAP), and oxygen radical absorbing capacity (ORAC)] and displayed antioxidant activity mainly in the ORAC assay. Results of this study help avoid overestimation of phenolic content and antioxidant activities of plant foods.

INTRODUCTION

Plants produce a wide variety of secondary metabolites known as phenolic compounds or polyphenols that possess various biological functions in plants, including phytoalexins, attractants for pollinators, plant pigmentation, antioxidants, and protection against UV light.[1,2] Extraction of phenolic compounds depends on the specific forms in which they are present in plants. Extractable phenolics can be in free or in conjugated forms; the latter are generally soluble glycosides of phenolic acids and flavonoids.[3] Many phenolic compounds are insoluble, being bound to cell wall polymers through ester and glycosidic links, and are therefore not extractable using organic solvents alone.[3] Hydrolysis under alkaline, acidic, or enzymatic conditions is often performed to release these bound phenolics.[2] Typical acid hydrolysis conditions for cleaving glycosidic bonds of conjugated phenolic acids or flavonoids to obtain their respective aglycons involve heating at high temperature (>80 °C) for 1−3 h in an aqueous methanol or ethanol solution containing 2−4 N HCl.[4,5]

Chemical hydrolysis under acid and alkaline conditions has been a major tool commonly used when studying conjugated and bound phenolics in many food crops. The HPLC-DAD phenolic profiles of plant-derived acid hydrolysates consistently showed at least one or two major peaks, dependent on solvent used, eluting at comparable retention times as certain benzoic acids when monitored at 280 nm.[6] In fact, acid hydrolysis performed by other investigators of dry bean (*Phaseolus vulgaris* L.),[6,7] quinoa (*Chenopodium quinoa* Willd.),[8] red clover (*Trifolium pretense* L.),[9] wheat bran,[10] and cranberry juice[11] all showed the presence of peaks bearing LC−UV characteristics similar to those of simple phenolic acids. Our efforts in identifying the structures of these peaks have led to the conclusion that these peaks are not those of phenolics. Such misidentification of phenolics in the literature can lead to significant overestimation of total phenolic content and could affect the outcome of chemical antioxidant assays.[3,6,12]

Under similar hydrothermal acidic conditions, sugar molecules (e.g., fructose, glucose, sucrose) undergo dehydration reactions to form 5-hydroxymethyl-2-furfural (HMF, **1**; Figure 1).[12,13] This furanic compound can also be formed during a Maillard reaction;[14] therefore, it is found in many processed foods, particularly sugar- or starch-rich foods.[15,16] Like other furan derivatives, HMF has been found to induce a significant number of chromosome aberrations and a lowering of mitotic activity.[17] HMF and its derivatives have found their use as intermediates for the production of plastics, polymers,

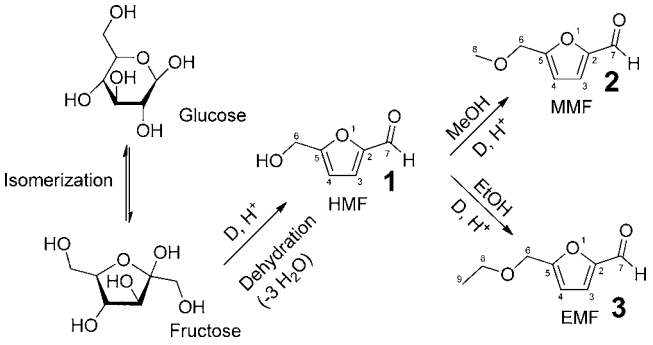

Figure 1. Formation of HMF, MMF, and EMF during thermal acid hydrolysis of conjugated polyphenols in food samples.

pharmaceuticals, and transportation fuel. The ability to produce HMF from carbohydrate-rich biomass is of great interest.[18] Reaction conditions can dictate the formation of methyl or ethyl ethers of HMF such as 5-methoxymethylfuran-2-carbaldehyde (MMF, **2**) or 5-ethoxymethylfuran-2-carbaldehyde (EMF, **3**).[19,20] MMF and EMF can be converted to a wide range of mono- and dialkoxymethyl ethers for biofuels[20] and has been used for the synthesis of novel biomass-based vinyl polymers.[21−23]

In our current study, we have identified major compounds in the acid hydrolysates of cranberry bean (*Phaseolus vulgaris* L.), quinoa (*Chenopodium quinoa* Willd), lentil (*Lens culinaris* L.), and buckwheat (*Fagopyrum esculentum* Moench) seed extracts to be HMF and its methyl and ethyl ethers. A previous report on the acid hydrolysis of flax seed led to the accurate identification of HMF; however, its derivatives remained unknown.[24] In this study, we have obtained evidence for the formation of HMF and its derivatives MMF and EMF, in model systems and in actual food samples, using HPLC-DAD−ESI-MS/MS and NMR. Overestimation of total phenolic content and antioxidant capacity in these food extracts due to HMF and its derivatives was investigated using in vitro chemical methods. Our results will help others to accurately assess the phenolic composition of food, especially those in bound or conjugated forms, and the antioxidant and other biological activities of acid hydrolysis products.

METHODS AND METHODS

Chemicals and Reagents. HPLC-grade acetonitrile was obtained from EMD Chemicals (Gibbstown, NJ), anhydrous ethyl alcohol (ethanol) from Commercial Alcohols (Brampton, Canada), and methanol from Caledon Laboratories (Georgetown, Canada). MMF standard was obtained from Enamine LLC (Monmouth Jct, NJ). Hydrochloric acid (HCl) and sodium carbonate were supplied by Fischer Scientific (Nepean, Canada). Formic acid, 2-diphenyl-1-picryhydrazyl radical (DPPH), fluorescein, Folin−Ciocalteu reagent, L-ascorbic acid, 2,4,6-tri(2-pyridyl)-*s*-triazine, 2,2′-azobis(2-amidinopropane) dihydrochloride, 6-hydroxy-2,5,7,8-tetramethlchroman-2-carboxylic acid (Trolox), anhydrous methylene chloride, deuterated chloroform ($CDCl_3$), gallic acid, catechin, furfural, HMF, EMF, fructose, glucose, sucrose, and inulin standards were obtained from Sigma-Aldrich Chemical Co. (St. Louis, MO). Distilled and deionized water was obtained in house from a Thermo Scientific Barnstead Nanopure ultrapure water purification system (Ottawa, Canada).

Food Materials. Whole cranberry bean seeds ("Hooter") were kindly provided by Dr. Peter Pauls, Department of Plant Agriculture, University of Guelph. Quinoa, lentil, and buckwheat seeds were purchased from local stores. Fruit and vegetables including apple, cucumber, and carrot were also purchased from local stores. The grain samples were ground directly using a commercial grinder (Stanley Black & Decker Inc., New Britain, CT). The fruit samples were lyophilized using a Bulk Tray Dryer (Labconco, Kansas City, MO) prior to grinding. The powdered samples were kept at −20 °C until analyzed.

Extraction and Acid Hydrolysis. Briefly, powdered plant materials (0.25 g) were accurately weighed and mixed with 10 mL of 2 N HCl in either 70% methanol or 70% ethanol (v/v). The mixture was vortexed for 10 s using a minishaker (IKA Works, Wilmington, NC), sonicated for 15 min (VWR, Mississauga, Canada), and then shaken by rotatory mixing at room temperature for 2 h (Scientific Industries, Bohemia, NY). Hydrolysis was carried out at 85 °C for 1 h using a hot water bath (IKA, Wilmington, NC), and the extract was syringe filtered using 0.45 μm PVDF filters (Sigma-Aldrich Co., St. Louis, MO) prior to HPLC analysis. The effect of hydrolysis duration and temperature on HMF and MMF formation was further studied by adjusting reaction time (30, 60, 120 min) and temperature (65, 75, 85, 95 °C) in a model system using quinoa seeds. All extractions were carried out in triplicates.

Identification and Quantitation with HPLC. HPLC analysis was carried out using an Agilent 1100 series HPLC system (equipped with a model G1329A auto sampler, a model G1322A degasser, a model G1311A quaternary solvent delivery system, and a model G1315B diode-array detector) and using Agilent ChemStation software. The analytical column used was a Phenomenex Luna phenyl-hexyl 5 U (250 × 4.6 mm). The binary mobile phase consisted of 5% formic acid in water (v/v) (solvent A) and 95% methanol:5% acetonitrile (v/v) (solvent B). The gradient solvent system used was as follows: 0−40 min, 80% B; 40−42 min, 80%−100% B; 42−44 min, 100% B; 44−44.5 min, 100%−0% B. Peaks were monitored at 280 nm. Flow rate was kept at 1.0 mL/min for a run time of 50 min.

HMF, MMF, and EMF were first identified by comparing the retention time and UV absorption spectrum of individual peaks with those of the standards. Quantitation was performed with external standards using HPLC analysis data and establishing a standard curve by plotting peak areas against the concentrations (0.78−200 mg/L) of the standards.

Liquid Chromatography−Mass Spectrometry Analysis. Quinoa seed sample from previously described extraction and acid hydrolysis was injected into a Dionex UHPLC UltiMate 3000 liquid chromatograph interfaced to an amaZon SL ion trap mass spectrometer (Bruker Daltonics, Billerica, MA). A C18 column (Agilent Poroshell 120 2.7 μm particle size, 150 mm × 4.6 mm) was used for chromatographic separation. The initial mobile phase conditions were 0.1% formic acid in water (v/v; mobile phase A) and 0.1% formic acid in acetonitrile (v/v; mobile phase B). The gradient went to 98% solvent B, with the flow rate maintained at 0.4 mL/min, in 30 min. The mass spectrometer electrospray capillary voltage was maintained at 4.5 kV and the drying temperature at 220 °C with a flow rate of 10 L/min. The nebulizer pressure was 40 psi. Nitrogen was used as both nebulizing and drying gas and helium was used as collision gas at 60 psi. The mass-to-charge ratio was scanned across the range m/z 50−1200 in enhanced resolution positive ion auto MS/MS mode. The smart parameter setting (SPS) was used to automatically optimize the trap drive level for precursor ions. The instrument was externally calibrated with the ESI TuneMix (Agilent). UV monitoring was at 280 nm for HMF derivatives.

NMR Preparation and Analysis. HMF, MMF, and EMF formed during extraction under thermal acidic conditions of quinoa seeds were prepared using 2 N HCl in deionized water, methanol, and ethanol, respectively, in separate experiments as described above. Samples were neutralized using sodium bicarbonate prior to liquid−liquid extraction with methylene chloride. The organic layer was subsequently dried over magnesium sulfate and filtered with anhydrous methylene chloride rinses. The resulting extract was dried using rotary evaporation in vacuo. Prior to acquisition of NMR spectra, each dried sample was mixed with $CDCl_3$. ^{1}H NMR spectra were recorded on a Bruker Avance 400 MHz spectrometer equipped with a Cryoplatform Prodigy cryoprobe. Chemical shift (δ) values for ^{1}H NMR spectra are reported in parts per million (ppm) from

tetramethylsilane with the solvent resonance as the internal standard ($CDCl_3$, 7.24 ppm).

Total Phenolic and Flavonoid Contents. Total phenolic (TPC) and total flavonoid (TFC) content of authenticated HMF, MMF, and EMF standards was determined using a model EL 340 UV/vis microplate reader (Biotek, Inc., Winooski, VT). A modified Folin–Ciocalteu assay was employed to determine the TPC value measured at 765 nm against reagent blank.[25] TPC was expressed as milligrams of gallic acid equivalents per gram of standard (mg GAE/g) determined using the standard calibration curve of gallic acid with a linear range of 0.0156–0.5 mg/mL (r = 0.999).

Total flavonoid content (TFC) was determined using a modified 96-well microplate method.[26] Absorbance was measured at 510 nm and TFC value was expressed as milligrams of catechin equivalents per gram of standard (mg CAE/g) using a calibration curve of (+)-catechin with linear range of 0.0156–0.5 mg/mL (r = 0.999).

Antioxidant Assays. Radical DPPH scavenging activity and ferric-reducing antioxidant power (FRAP) of authenticated HMF, MMF, and EMF standards were determined using a UV/vis microplate reader (Biotek, Inc., Winooski, VT).[26,27] The DPPH value was expressed as micromoles of Trolox per gram of standard (μmol TE/g) calculated on the basis of the Trolox standard calibration curve. Absorbance was measured at 517 nm against reagent blank. The FRAP value was expressed as micromoles of ascorbic acid equivalent (AAE) per gram of standard (μmol AAE/g). DPPH and FRAP values were determined using respective Trolox and L-ascorbic acid standard curves with a linear range of 62.5–1000 μM (r = 1.0).

Oxygen radical absorbing capacity (ORAC) of authenticated HMF, MMF, and EMF standards was measured using a fluorescence method. The excitation wavelength was set to 485 nm and emission wavelength was 520 nm.[27] A PLX 800 fluorescence spectrophotometer equipped with an automatic thermostatic holder (Bio-Tek, Inc., Winooski, VT) was used. The ORAC value was expressed as micromoles of Trolox

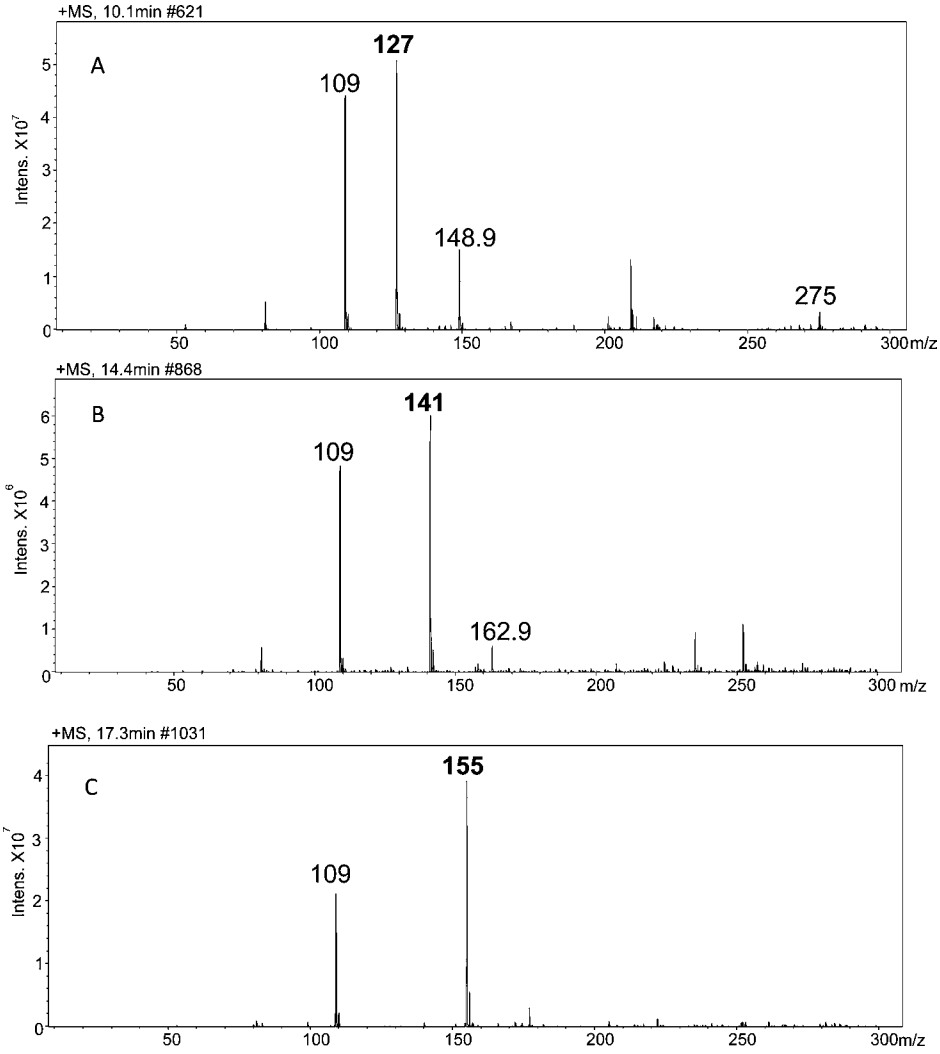

Figure 4. LC−ESI-MS spectra of (A) HMF, (B) MMF, and (C) EMF from hydrolysis of quinoa seeds scanned from m/z 50−1200 in enhanced resolution positive ion auto-MS/MS mode.

per gram of standard (μmol TE/g) calculated on the basis of the Trolox standard calibration curve with linear range of 6.25−100 μM (r = 0.973).

Statistical Analysis. Significant differences among grain samples and standards for each of the parameters were assessed with a one-way analysis of variance (ANOVA test) using SPSS Version 18.0 statistical package for Windows (IBM, Chicago, IL). Statistical differences among the means were evaluated using the LSD test at the $p \leq 0.05$ level to evaluate the significance of the analysis.

RESULTS AND DISCUSSION

Detection and Identification of HMF and HMF Derivatives. Acid hydrolysis of plant materials contains major peaks that are early eluting and detected at 280 nm. These compounds tend to be mistaken for phenolic acids bearing similar retention times.[6] Our results show that these peaks are in fact furans and not phenolic compounds and that this distinction should be made clear in order to prevent the overestimation or interference when quantitating phenolics or assaying for chemical antioxidant activity.

Figure 2 shows a representative chromatogram overlay of the acid hydrolysis products of cranberry bean, quinoa, lentil, and buckwheat seeds along with a standard reference mixture consisting of HMF and its derivatives measured at 280 nm. In fruit and vegetable samples (carrot, cucumber and apple), HMF and its derivatives were also identified and were produced at significantly higher levels compared to grain samples (Figure 3). The high concentration of HMF, MMF, and EMF in fruit and vegetable samples is due to the high presence of carbohydrate sugars acting as substrate.[18] Plant materials and acidic solvent solution were refluxed at 85 °C for 1−3 h (final HCl concentration 2 N). These conditions are commonly used for hydrolysis of various plant materials in the extraction of aglycons or bound phenolics from various plant materials.[28,29] Sequential and direct 2 N HCl hydrolysis of dry beans also undoubtedly yielded HMF and its derivative product in a previous report by Ross et al., although this finding remained unreported.[6] The authors noted that these compounds (denoted X and Y) coeluted with gallic acid and protocatechuic acid, respectively; however, the UV spectra did not agree. HMF has also previously been reported in flaxseed extracts following 40−140 min acid hydrolysis (final HCl concentration of 1 N) at 95 °C.[24] However, the structure and identity of derivative products remained unknown. In our current study, extraction and hydrolysis of cranberry bean, quinoa, lentil, and buckwheat seeds in a solution of 70% methanol (v/v) in 2 N HCl produced three major peaks, corresponding to HMF, furfural, and MMF upon HPLC separation and detection at 280 nm.

dx.doi.org/10.1021/jf500518r | J. Agric. Food Chem. 2014, 62, 4754−4761

Similarly, the presence of 70% ethanol (v/v) in 2 N HCl produced three major peaks in all samples tested detected at 280 nm.

It is likely that the formation of HMF in our study was the result of a dehydration reaction converting sugars to HMF (Figure 1).[18] This is all the more likely as cranberry bean seeds previously soaked in water, therefore leaching them of their sugar content, only contained trace amounts of HMF upon acid hydrolysis. This was verified by subjecting fructose, glucose, sucrose, and inulin standards to acid hydrolysis conditions and detecting the formation of HMF (data not shown). Additionally, the conversion of HMF to its respective derivatives MMF and EMF in the presence of methanol and ethanol has previously been established.[13,19,30] The identity of HMF, MMF, and EMF in all samples studied was verified by comparing retention times and UV spectra against authenticated standards (Figure 2).

ESI-MS analysis of quinoa seeds hydrolyzed under acidic conditions showed that the peak corresponding to HMF (**1**) (t_R = 9 min) (Figure 2) had an abundance of molecular ions with m/z 127 $[M + H]^+$ and 148.9 $[M + Na]^+$ and MS/MS fragment m/z 109 (Figure 4), matching it with authenticated HMF standard. The fragment ion m/z 109 is likely formed after loss of a water molecule (H_2O). The secondary product formed in the presence of methanol (t_R 12 min) (Figure 2) showed a molecular ion of m/z 141 $[M + H]^+$ and 162.9 $[M + Na]^+$ and a fragment ion of m/z 109 and was identified as MMF (**2**). In the presence of ethanol, EMF (**3**) (t_R 13.5 min) (Figure 2) was identified and showed molecular mass of m/z 155 $[M + H]^+$ and 177 $[M + Na]^+$, exactly one CH_2 (m/z 14) unit more than MMF. The same fragment ion of m/z 109 was observed (Figure 4). This common fragment ion is from the furan ($C_6H_5O_2^-$) backbone structure, further confirming that these three peaks are furan derivatives. In the case of MMF, fragmentation resulted in a loss of m/z 32 (CH_3−OH), while EMF lost m/z 46 (CH_3−CH_2−OH). MMF and EMF were produced from pure HMF under the same thermal acidic conditions in aqueous methanol and ethanol, respectively, as opposed to actual food samples, such as quinoa. All MS data for the HMF, MMF, and EMF formed during thermal acidic reaction matched those of the standards, further supporting the identification of the HMF derivatives.

HMF and its derivatives MMF and EMF were prepared from quinoa seeds under optimal conditions so as to maximize the yield and purity of each individual compound for ^{1}H NMR analysis for further structural confirmation (Table 1). NMR spectra show the presence of a furanic ring in all samples denoted by the presence of protons at C3 and C4. Other common protons include a pair of protons on C6 and a single proton on C7. NMR data of HMF also was previously reported, and results are comparable.[31] However, samples were dissolved in D_2O. In the present study we used $CDCl_3$, which allowed for the weak signal of the hydroxyl proton attached to C6 of HMF to be intensified. Distinguishing structural features of MMF and EMF are observed by the presence of methyl protons on C8 in the case of MMF, and methylene protons (C8) and methyl protons (C9) are present in EMF (Table 1, Figure 1).

Table 1. Proton NMR Data of HMF, MMF, and EMF Produced during Acid Hydrolysis of Aqueous Methanol or Ethanol Mixture of Quinoa Seed Flower

	^{1}H NMR data, δ (ppm)		
proton	HMF, **1**	MMF, **2**	EMF, **3**
C3−H	7.22 (d, 1, H)	7.18 (d, 1, H)	7.20 (d, 1, H)
C4−H	6.52 (d, 1, H)	6.49 (d, 1, H)	6.51 (d, 1, H)
C6−H	4.71 (s, 2, H)	4.44 (s, 2, H)	4.51 (s, 2, H)
C6−OH	2.62 (s, 1, H)		
C7−H	9.58 (d, 1, H)	9.54 (s, 1, H)	9.59 (s, 1, H)
C8−H		3.40 (s, 3, H)	3.57 (q, 2, H)
C9−H			1.22 (t, 3, H)

Previous reports have thoroughly demonstrated the production of EMF from the etherification of HMF with ethanol.[19,30] This one-pot reaction is catalyzed under heat and addition of organic acids, producing EMF, which is a good candidate as a biofuel alternative due to its high energy potential.[22] MMF is not as useful and popular as EMF as a biofuel alternative; however, its precursor methanol is widely used in the extraction of polyphenols from plant matter.[6,7,12,17,19,32,33] Extraction of phenolic compounds in the presence of alcohol, acid, and heat may catalyze the formation of HMF and its furanic derivatives that are otherwise unidentified and may impact identification of coeluting phenolic compounds. Identification of HMF, MMF, and EMF as described above led us to the hypothesis that, during the acid hydrolysis of conjugated plant polyphenols, a methyl or ethyl ether was formed through further acid catalyzed condensation between the methanol or ethanol molecule and the HMF molecule (Figure 1).

HMF, MMF, and EMF Formation As Affected by Temperature, Duration, and Solvent Conditions. Table 2 shows the amount of HMF and derivatives produced in a one-pot reaction involving quinoa, buckwheat, lentils, and beans at 85 °C for 2 h in the presence of either acidified aqueous methanol or ethanol. The results suggest that MMF is produced more readily than EMF. Buckwheat in the presence of methanol yielded significantly less HMF and MMF compared to the other samples tested ($p < 0.05$). This may be due to buckwheat's relatively low sugar content.[34,35] While other catalysts are commonly used, such as Al^{3+} and Z-SBA-15, HCl provides higher EMF yield (93%) in one-pot reaction in hydrothermal conditions.[18,30]

The effects of temperature and duration of reaction on the formation of HMF and MMF were further studied using quinoa seeds (Table 3). At temperature extremes (65 and 95 °C), HMF formation is not favored. Increasing the reaction time slightly increased HMF yield at 65 °C but reduced the yield at 95 °C. Increasing the temperature to 75 and 85 °C produces the highest concentration of HMF in quinoa seeds and is optimal when reaction duration is between 0.5 and 1 h. A further increase in time or temperature of hydrolysis resulted in decreased HMF content mirrored by the increased MMF content. Optimal MMF production was observed at 95 °C for 30 min. However, increased reaction duration may compensate for lowered reaction temperature. Low water content typically favors HMF production, as the formation of 1 mol of HMF from 1 mol of fructose or glucose releases 3 mol of water; therefore, the presence of too much water may inhibit the reaction producing HMF.[36] HMF formation generally starts at an average water activity of 0.40, independent of temperature.[32] In our study, water content was kept consistent among all the samples, as the reaction took place in sealed glass vials and in a closed system, preventing loss of water due to evaporation at high temperatures.

Table 2. Concentrations of HMF, MMF, and EMF in the Hydrolysate of Grain Samples Subjected to 2 N HCl Hydrolysis at 85 °C for 2 h in 70% Methanol or Ethanol[a]

	methanol		ethanol	
samples	HMF, **1** (μg/mL)	MMF, **2** (μg/mL)	HMF, **1** (μg/mL)	EMF, **3** (μg/mL)

[a] $n = 3$. Results are reported as mean ± SD. Values followed by the same letter for the same compound (HMF and MMF treated separately) are not significantly different ($p < 0.05$).

Effect of HMF, MMF, and EMF on in Vitro Chemical Assays. Colorimetric assays such as TPC and TFC are commonly used to quantitate general classes of phenolic compounds;[1,10] however, these assays are not necessarily highly specific to the phenolic or flavonoid groups and are often interfered by other coexisting chemical classes. Because acid hydrolysis is a common practice in studying phenolics, and HMF and its ether derivatives can be formed under the hydrolysis conditions, the effect of these compounds on the TPC and TFC content must be studied to avoid overestimation. Similarly, HMF derivatives may also affect the total antioxidant capacity in chemical-based assays (Table 4). When HMF, MMF, and EMF standards were examined in both TPC and TFC assays, no interfering effect was found below 200 μg/mL. However, the effect was compound- and concentration-dependent. For example, MMF showed a TPC value of 2.9 mg GAE/g at 625 μg/mL. HMF and EMF only began to show TPC values at 2500 and 1250 μg/mL, respectively. In terms of the antioxidant assays, while HMF and its derivatives MMF and EMF did not show any antioxidant activity in DPPH and FRAP assays at concentrations below 200 μg/mL, they did significantly affect the ORAC assay even at the lowest concentration tested (1.563 μg/mL), and the effect was also dose-dependent. At elevated concentrations, however, HMF, MMF, and EMF began to show FRAP values as well. At 625 μg/mL, MMF and EMF showed 7.71 and 10.32 μmol AAE/g, respectively, while HMF did not show any interference with the FRAP assay until 1250 μg/mL. The effect of these compounds on FRAP values was also dose-dependent. This should be considered in future studies, as concentrations of HMF, MMF, and EMF can reach >2500 μg/mL during common acid hydrolysis assisted extraction procedures for many food samples (data not shown). ORAC is one of the most frequently used antioxidant assay methods. At its lowest concentration tested (1.563 μg/mL), HMF displayed antioxidant activity comparable to that previously reported in the insoluble-bound phenolic extract in quinoa seeds extracted in 3 M HCl at 80 °C for 2 h.[37] This would suggest that the presence of HMF in the acid hydrolysate could be contributing to the majority if not all of the reported antioxidant activity misappropriated to insoluble-bound phenolics. Chemical antioxidant assays function on the basis of two major mechanisms, hydrogen atom transfer (HAT) and single electron transfer (SET).[1] ORAC exploits the HAT reaction mechanism, while FRAP relies totally on an SET-based reaction mechanism, and DPPH color loss occurs through either HAT or SET reaction. DPPH acts both as the radical probe and oxidant and is limited by its steric accessibility favoring smaller molecules. The structure of HMF contains a hydroxyl group that has hydrogen atom donating potential and some electron-dense groups such as double bonds, an aldehyde group, and an oxygenated furan ring.[38] DPPH activity in HMF was previously reported, and the activity was time- and dose-dependent.[38,39]

Table 4. ORAC, TPC, and FRAP values of HMF, MMF, and EMF Authenticated Standards[a]

μg/mL	HMF	MMF	EMF
	ORAC (μmol TE/g)

The present study revealed that HMF can be produced from hydrothermal acid hydrolysis of plant materials during extraction of phenolic aglycons or bound phenolics. When the extraction was in aqueous methanol or ethanol, two of the most frequently used solvent systems for phenolic extraction, the hydrolysis conditions favored the production of MMF or EMF, respectively. HMF and its two ether derivatives were confirmed by HPLC-DAD−ESI-MS/MS and NMR. Under the same conditions, methanol was more reactive than ethanol with HMF, forming higher concentrations of MMF than EMF in different foods. Formation of HMF and its derivative products are dependent on temperature and reaction duration. Indisputable identification of HMF and its ether derivatives in the hydrolysate of plant foods helps avoid misidentification as phenolics; this is particularly important when using acid hydrolysis to study aglycons and bound phenolics. Misidentification can lead to overestimation when using HPLC in quantitating phenolic compounds as HMF and its derivatives also show absorption at 280 nm, at which wavelength many phenolics are detected. HMF, MMF, and EMF also displayed a dose-dependent response to ORAC at low concentrations ($\geq$1.563 μg/mL) and to TPC and FRAP at high concentrations ($\geq$625 μg/mL). Caution must therefore be taken when using in vitro chemical assays to assess antioxidant activity and phenolic content of plant materials after acid hydrolysis.

Factors Limiting the Enzymatic Hydrolysis of Wheat Gluten

L. Giesler,* D. Linke, and R. G. Berger

Institut für Lebensmittelchemie, Leibniz Universität Hannover, Callinstraße 5, Hannover 30167, Germany

ABSTRACT: The enzymatic hydrolysis of wheat gluten for the production of seasonings using mixtures of endo- and exopeptidases results in yields typically below 40%. Possible limiting parameters, such as an increasing product inhibition, autopeptidolysis of the enzymes, and lack of cleavage sites, were studied using novel peptidases from *Flammulina velutipes* or the commercial Flavourzyme preparation. Seven intermittent electrodialysis steps (10 g/L gluten and 10 kaU/mL) for the in situ removal of amino acids minimized the product inhibition. During 16 h, hydrolysis progressed nearly linearly. Compared to the batch control, a 3-fold yield of amino acids released was obtained indicating that an integrated product removal alleviates the problem of product inhibition. Autopeptidolysis, as shown using sodium dodecyl sulfate polyacrylamide gel electrophoresis and enzyme activity assays, was suppressed with increasing concentrations of competing gluten substrate. Peptidases of *F. velutipes* showed product inhibition only, whereas a combined effect of product inhibition and lack of cleavage sites was observed for Flavourzyme.

KEYWORDS: *wheat gluten, hydrolysis, electrodialysis, autopeptidolysis, cleavage site, Flavourzyme, Flammulina velutipes*

INTRODUCTION

Enzymatic protein hydrolysis is widely used in the food industry for applications such as the production of seasonings from soy or wheat proteins or the improvement of the functional properties of dairy products and confectionary.[1] So far, total hydrolysis of the protein as obtained by the former hydrochloric acid catalyzed process was not achieved, even if complex enzyme preparations were used.[2] Previous studies suggested limitations, such as product inhibition, autopeptidolysis, and the decline of sufficient cleavage sites in the substrate in the course of the process.[3−5] An advanced cleavage of peptide bonds might result in the formation of bitter tasting peptides. Thus, the technical aim is often not just to improve the degree of hydrolysis but preferably to bring the reaction to completion.

To date, research focused on product inhibition as the limiting factor.[6] As shown previously, Flavourzyme and *Flammulina velutipes* peptidases were both inhibited by the hydrophobic L-amino acids L-isoleucine, L-leucine, L-valine, and L-phenylalanine. L-Serine inhibited only *F. velutipes* peptidases, while L-histidine and L-glutamine inhibited only Flavourzyme peptidases.[4] The same study[4] confirmed that electrodialysis (ED) equipped with four ultrafiltration membranes (UF, cutoff 4 kDa) was suitable to minimize the product inhibition. After applying the ED twice for 1 h during the 20 h of hydrolysis, a large increase of the degree of hydrolysis (DH) of up to 145% for *F. velutipes* peptidases and of 70% for Flavourzyme compared to the control batch was observed.[4] To fully explore the potential of ED, the membrane surface was increased,[7] and the ED step repeatedly was implemented during the hydrolysis.

The phenomenon of autopeptidolysis was described for individual enzymes, such as subtilisin-like serine peptidases,[8] retroviral aspartyl proteases,[9] or neutral peptidases.[10] A pure peptidase is generally not susceptible to autopeptidolysis under native conditions. After an irreversible inactivation by high temperature or chemical denaturants, the native structure becomes impaired, and autopeptidolysis by residual active peptidase may occur.[10,11] Thus, the application of mixtures of endo- and exopeptidases bears the risk of peptidases degrading each other. In this study, the robustness and reaction behavior of Flavourzyme, a commercial preparation from *Aspergillus oryzae*, was compared to a mixture of peptidases from the edible basidiomycete *F. velutipes*, previously proven for the hydrolysis of wheat gluten.[4] Autopeptidolysis and the availability of cleavage sites in the substrate were studied.

MATERIALS AND METHODS

Materials. All chemicals and solvents were of analytical or HPLC grade and obtained from Carl Roth (Karlsruhe, Germany), Merck (Darmstadt, Germany), Sigma−Aldrich (Taufkirchen, Germany), and VWR International GmbH (Darmstadt, Germany), respectively.

Cultivation of *F. velutipes*. Cultivations were carried out as described previously.[4]

Peptidase Activity. The peptidolytic activity was determined with the azocasein assay as a photometric end-point method following ref. 4.

Two more specific peptidase assays were performed in 96-well microtiter plates: first, 50 mM Tris buffer pH 7 and 10 μL of *Z*-Ala-Ala-Pro-Phe-*p*-nitroanilide (2 mM AAPF), or second, 25 mM sodium acetate buffer pH 5 and *Z*-Gly-Pro-*p*-nitroanilide (2 mM) from Sigma−Aldrich (Taufkirchen, Germany) with each substrate in dimethyl sulfoxide and 20 μL of enzyme preparation in a total volume of 150 μL. The molar extinction coefficient of *p*-nitroaniline was determined at $\varepsilon^* = 4567\ \mu L/\mu M$ at 405 nm in a BioTek Synergy 2 microtiter plate reader (Bad Friedrichshall, Germany). The absorption was measured at 37 °C and 405 nm over 90 min. One unit of peptidolytic activity was calculated as the amount of enzyme required to produce 1 μM *p*-nitroaniline per minute.

Preparation of Wheat Gluten Hydrolysate. Various hydrolysis experiments were carried out with dry sterilized (130−135 °C, 8 h) wheat gluten (5−100 g/L) at 180 rpm, 45 °C, and pH 6.0 in 25 mM

sodium acetate buffer with two different peptidase mixtures, *F. velutipes* or Flavourzyme from Novozymes (Copenhagen, Denmark), using standardized peptidase activities per milliliter of hydrolysate. For each hydrolysate, the concentration of L-amino acids (mM), soluble protein (mg/L), and the DH were investigated over time as described in ref 4.

Electrodialysis. ED equipped with six ultrafiltration membranes (UF, cutoff 4 kDa, UH004P from Microdyn-Nadir, Wiesbaden, Germany) was used to increase the transfer rate of L-amino acids from the diluate into the concentrate solution. The stack configuration with UF membranes is shown in Figure 1.[4] To check the transfer increase, the recovery of the model solution consisting of L-glutamic acid, L-asparagine, L-serine, and L-leucine (50 mM in 25 mM sodium acetate buffer, pH 6) was calculated. ED experiments were carried out using the laboratory-scale EDL02 (Hescon GmbH, Engstingen, Germany), equipped with a DSE electrode at pH 6, 12 V with a current density of 14.0 mA/cm^2 and 0.25% Na_2SO_4 as electrolyte solution, to separate the L-amino acids from the wheat gluten hydrolysates during the hydrolysis following. The recovery of the L-amino acids was calculated as reported previously.[4] Two alternating hydrolysis samples (sample 1 (S1) and sample 2 (S2)) were used, and the ED was integrated alternating 4-fold or 7-fold into the 20 or 26 h hydrolysis process. For every experiment, a batch control was carried along.

Autopeptidolysis and Thermal Stability. The peptidase mixtures of *F. velutipes* or Flavourzyme were incubated in 25 mM sodium acetate buffer pH 6 at different temperatures (4, 20, and 45 °C) over 20 h with or without addition of gluten (10 or 100 g/L) as substrate. After the incubation at defined temperatures or substrate concentrations, residual peptidase activity was assayed with the azocasein and the AAPF assay as described above. Gycerol, $(NH_4)_2SO_4$, $MgC1_2$, $CaC1_2$, ethylenediaminetetraacetic acid (EDTA), and phenylmethylsulfonyl fluoride (PMSF) were tested as protectants against thermal inactivation of the peptidases. The inactivation (%) was calculated using the change in activity compared to the initial activity. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) was used to follow autopeptidolytic process of the enzymes.

Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis. SDS-PAGE analyses were performed using 12% (*w*/*v*) polyacrylamide separation gels after Laemmli.[12] Samples were prepared by mixing 10 μL of enzyme solution and 10 μL of loading buffer (0.1 M Tris/HCl (pH 6.8), 0.2 M DTT, 4% SDS, 20% glycerol, 0.2% bromophenol blue) and boiling for 10 min. After electrophoresis at 18 mA per gel, the gels were stained with Instant Blue (Gentaur GmbH, Aachen, Germany). Marker proteins from 10 to 250 kDa (BioRad, Munich, Germany) were used for molecular mass determination.

Cleavage Sites. To determine whether enough cleavage sites for the peptidases were present in the wheat gluten, the following hydrolysis experiments were performed. Prehydrolysis for 3 h was performed at 180 rpm, 45 °C, and pH 6 in 25 mM sodium acetate buffer with two different peptidase mixtures from either *F. velutipes* or Flavourzyme. Thereafter, the hydrolysate was centrifuged (10 min, 5000 rpm, 4 °C). Fresh peptidases and buffer were added to the gluten that was already partly hydrolyzed (C1). To the already used peptidases and buffer solution, fresh wheat gluten was added (C2). Both mixtures were then further incubated for 17 h. For every experiment, a batch control was carried out. Hydrolyzed samples were analyzed for peptidolytic activity, the concentration of L-amino acids (mM) and the soluble peptides (mg/mL).

Statistical Analysis. The ED, autopeptidolysis, and cleavage site studies were subjected to statistical analysis (error probability $p < 0.05$) using the one-way ANOVA of the Origin 6.1 software (OriginLab Corporation, Northampton, MA, USA). All data presented are averages of duplicate measurements. Numerous experiments were conducted, and single parameters, such as enzyme activity, were changed to distinguish critical from insignificant factors; for the bulk of these measurements, the standard deviation of repetitions was typically below 5%.

RESULTS AND DISCUSSION

Electrodialysis Using Six Ultrafiltration Membranes. In order to reduce inhibition by the recently identified amino acids (L-isoleucine, L-leucine, L-valine, L-phenylalanine, L-histidine, and L-glutamine) for *F. velutipes* and Flavourzyme peptidases, the transfer rate of the ED unit was increased by using six UF

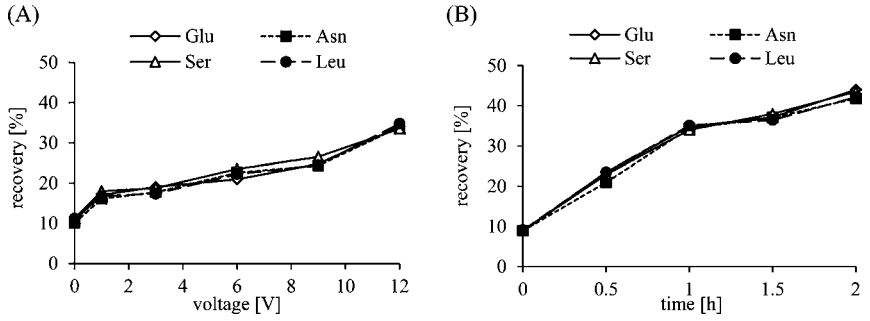

Figure 2. Effect of different voltages on the transport from diluate into concentrate using UF membranes (A) at different voltages per hour or (B) over 2 h at 12 V, expressed as recovery of the L-amino acids: L-asparagine, L-glutamic acid, L-serine, and L-leucine (50 mM model solution, pH 6).

membranes (previously four).[4] The three diluate circuits and six concentrate circuits of the ED stack led to an enhanced recovery (Figure 1). As previously described,[4] all of the L-amino acids measured were transported at similar rates, and the recovery increased with higher voltages (Figure 2A). After 1 h of ED at 12 V with six UF membranes, the best transfer rates were achieved: L-asparagine, 34 ± 1%; L-glutamic acid, 34 ± 2%; L-serine, 34 ± 3%; and L-leucine, 35 ± 2% per hour. Without an electric potential applied, the transfer rates varied between 8% and 9%. With increased time of ED, the recovery increased as well, as did the conductivity of the concentrate. After 2 h of ED at 12 V, transfer rates of 42−44% were reached (Figure 2B), and a higher conductivity in the concentrate solution (16.2 mS/cm) compared to the diluate (13.5 mS/cm) was observed. With converging conductivity in both circuits, the transport of ions through the membranes slowed down (Figure 2B). With the commonly used stack configurations, that is, AMX/CMX (anionic/cationic membrane) or four UF membranes, lower transfer rates of 8−10% and 22−30%, respectively, were obtained.[4] Similar results were reported by Poulin et al.[7] who found a 4-fold increase of the peptide transfer when stacking four UF membranes instead of one.

L-Amino acids possessing inhibitory properties were effectively removed from the hydrolysates obtained using either Flavourzyme or/ *F. velutipes* peptidases: L-isoleucine (34%/33%), L-leucine (33%/33%), L-valine (34%/32%), L-phenylalanine (34%/31%), L-glutamine (33%/33%), L-histidine (34%/35%), and L-serine (32%/34%). Furthermore, soluble peptides less than 4 kDa were transported, with transfer rates ranging from 10% to 12% per hour.

A further improvement of the efficiency of hydrolysis was achieved by combining the increased area of the UF membranes with a more frequent application of the ED step. During 20 h of hydrolysis (10 g/L gluten and 1 kaU/mL peptidase mixture) and a 4-fold ED, each for 1 h, an increased release of L-amino acids of 94% for Flavourzyme and of 153% for *F. velutipes* was recorded (Table 1). These results indicated an improvement compared to previous studies with 2-fold ED and four UF membranes (Flavourzyme: 70%; *F. velutipes*: 145%[4]). The best yields of hydrolysis (batch: DH 35%; ED: DH 76%) were achieved with a low substrate concentration (5 g/L gluten) and a high peptidase activity of 75 kaU/mL *F. velutipes* peptidases. With a 7-fold integrated ED (10 g/L gluten and 10 kaU/mL), a nearly linear progression for the first 16 h of the hydrolysis process (Figure 3A) and a 3-fold concentration of amino acids released was obtained (Table 1). Thus, the manifold integration of ED proved to be suitable for overcoming product inhibition.

Table 1. Efficiency of Electrodialysis (ED) Compared to the Batch Process[a]

[a]Hydrolysis of wheat gluten for 20 h plus electrodialysis (1 h prehydrolysis) at pH 6 and 45 °C using Flavourzyme (Fx) or *F. velutipes* (Fve) peptidases, respectively.

Transfer rates decreased during the seven steps of the ED from initially 32−35% to 26−27%. This is explained by clogging of the membrane pores over time, as there was no washing step after each step. Poulin et al.[13] reported a weak fouling, if one UF membrane was used in the ED stack, which was removed by rinsing the membrane with distilled water. Although fouling is of minor importance due to the absence of pressure in a ED stack with UF membranes, various interactions between the clogging membranes and the peptides may take place that influence the migration.[14]

Peptidase activity decreased in the batch as well as in the ED process over time. After 26 h, around 9% of the introduced peptidase activity remained in the ED experiment and about 18% in the batch (Figure 3B). Cui et al.[15] also observed a decrease of Alcalase activity during the hydrolysis of wheat gluten in an enzyme membrane reactor. There are two possible explanations: First, some peptidases remained adsorbed at the membranes, which would explain the difference between the ED and batch experiments. Second, peptidases were lost due to a high autopeptidolytic activity. Hence, two washing steps were integrated after every ED step. The first washing step, refreshing the buffer solution in the diluate and rinsing for 10 min, recovered 3−4% of initial *F. velutipes* and 8−9% of initial Flavourzyme peptidase activity. Afterward, the buffer solution was refreshed for a second time, and the poles were switched for a further 10 min. One percent of the initial *F. velutipes* peptidase activity and up to four percent of Flavourzyme activity were recovered. The recovery rate showed no differences with or without the use of wheat gluten as the substrate.

Autopeptidolytic Activity of Peptidase Mixtures. An extensive hydrolysis, preferably using mixtures of endo- and exopeptidases, is desired to reduce the bitterness of the hydrolysate as well as to obtain a high DH.[2] Besides the degradation of the substrate, peptidases may hydrolyze each other. An intermolecular mechanism by which peptidases digest other peptidases has been suggested.[8] The autopeptidolysis of *F. velutipes* and Flavourzyme peptidases was monitored by measuring the residual activity after different incubation studies at various temperatures without substrate and at different substrate concentrations (Table 2). With increasing incubation temperature, the recovered peptidase activity decreased. Incubation at 45 °C, corresponding to the temperature optimum of the applied peptidases, showed a decrease of the peptidase activity (initially 10 kaU/mL) of 86.2% for *F. velutipes* and 34.3% for Flavourzyme. Bajorath et al.[16] observed a constant slow decrease in proteinase K (initial concentration 0.01 mg/mL) activity at room temperature. With higher initial

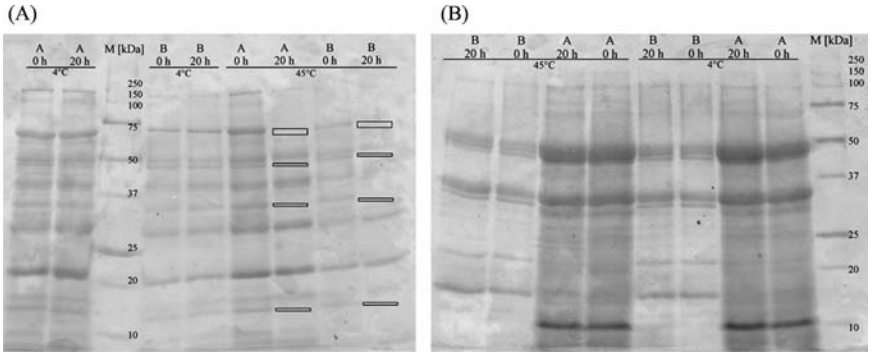

Figure 4. SDS-PAGE (12%) to study autopeptidolysis without substrate at 4 and 45 °C with two different initial peptidase activities (A: high activity; B: low activity) for (A) *Flammulina velutipes* and (B) Flavourzyme; changes in the band pattern after 20 h were marked with a box. M [kDa] Precision Plus Protein-Standard unstained (BioRad, Germany).

peptidase activity, the residual activity for *F. velutipes* and Flavourzyme peptidases decreased (Table 2). The absence of gluten in these incubations implied that the peptidase breakdown was an autopeptidolytic event. These data were confirmed with a second peptidase activity test using AAPF, in addition to the azocasein assay, as the substrate. Similar results were obtained by Abraham and Breuil.[8] The incubation with different substrate concentrations (10 and 100 g/L wheat gluten) resulted in the competitive minimization of autolysis (Table 2). Thus, autolysis became negligible in the presence of excess substrate.

To achieve a more detailed picture of the products of autopeptidolysis, the enzyme solutions without substrate were analyzed by SDS-PAGE. At the lower incubation temperature (4 °C), no changes of the electrophoretic patterns were detected, neither for *F. velutipes*, nor for Flavourzyme peptidases (Figure 4A, B). After 20 h at 45 °C, four bands (73, 48, 32, and 15 kDa, Figure 4A, black boxes) of the mixture from *F. velutipes* disappeared in the SDS-PAGE gel. The bands at 20, 27, 37, and 50 kDa did not change after 20 h. Gelatin zymography visualized active peptidases in the supernatant of *F. velutipes* at 15, 27, 32, 37, 75, and 150 kDa.[17] Flavourzyme showed no modifications of the pattern on the SDS-PAGE gel (Figure 4B) and in the gelatin zymography after 20 h of incubation at 45 °C. Thus, it is supposed that hypothetical degradation products were smaller than 10 kDa.

At 45 °C and an initial peptidase activity of 10 kaU/mL, *F. velutipes* and Flavourzyme released 80 and 110 μM L-amino acids, respectively. With increased initial peptidase activity, the release of L-amino acids increased as well: *F. velutipes* [80 kaU/mL] and Flavourzyme [250 kaU/mL] gave 0.76 and 0.84 mM L-amino acids, respectively).

To minimize autopeptidolysis, the peptidase mixtures (1 U/L) were incubated with various presumed protectants:[8] glycerol (1.9 M), $(NH_4)_2SO_4$ (0.5 M), $MgCl_2$ (9 mM), and $CaCl_2$ in different concentrations. Glycerol (1.9 M), $(NH_4)_2SO_4$ (0.5 M), and $MgCl_2$ (9 mM) did not protect the peptidases from *F. velutipes* or Flavourzyme, as proven by AAPF peptidase activity assay (Table 2). Additionally, the effects of the specific serine peptidase inhibitor PMSF and the metallopeptidase inhibitor EDTA on the degradation of *F. velutipes* or Flavourzyme peptidases were studied. The peptidase mixtures were completely inhibited by PMSF (100 μM) and EDTA (100 μM). No protection against autopeptidolysis was detected. A similar study reported that the addition of a protease inhibitor did not lead to an increased stability, as the autopeptidolysis is usually not sufficiently suppressed.[18] Only $CaCl_2$ significantly extended the peptidase activity of both enzyme mixtures. Increasing $CaCl_2$ concentrations (0.9, 3.9, 9.0, 18.0, 27.0 mM) minimized the loss of initial activity (1 U/L). A 25% lower inactivation for *F. velutipes* peptidases and 22% for Flavourzyme compared to the control without supplementation was determined at 27 mM $CaCl_2$. A further increase of $CaCl_2$ up to 36 mM had no better effect (Table 2). When the peptidases of *F. velutipes* were incubated with 9 mM $CaCl_2$, the protein band at 32 kDa in the SDS gel (Figure 4A) was not degraded as in the control without $CaCl_2$ (data not shown). Calcium ions are required by some peptidases for folding of the peptide chain and hence activity (for example, thermolysin and proteinase K). Abraham and Breuil[8] showed an improvement of the half-life time of the purified subtilisin-like serine protease secreted by *Ophiostoma piceae* (7.7 min at 40 °C) by adding 27 mM $CaCl_2$ up to 2 h at 40 °C.

To prevent peptidases against autopeptidolysis, two strategies are available: the identification and removal of the primary cleavage sites and restricting their accessibility. It has been suggested that especially the loop with the peptidolysis site could be stabilized by Ca^{2+}-binding against unfolding.[8] Braxton and Wells[19] identified two sites of autopeptidolysis of subtilisin BPN′. They also evaluated stabilization by site-directed mutagenesis in regions of autolytic susceptibility. The data indicated that the peptidase mixtures of *F. velutipes* and Flavourzyme contained subtilisin-like peptidases that were stabilized by Ca^{2+} ions.

It was examined how $CaCl_2$ (9 mM) affected the hydrolysis of wheat gluten (10 g/L) with *F. velutipes* or Flavourzyme peptidases (10 kaU/mL). The loss of peptidase activity was minimized in the presence of $CaCl_2$ (without gluten) by 6% for *F. velutipes* and by 4% for Flavourzyme. During the incubation of wheat gluten in the presence of $CaCl_2$, the autopeptidolysis was lowered by around 4% for *F. velutipes* and 2% for Flavourzyme peptidases. However, the DH was not significantly increased (*F. velutipes*: 12.6 ± 1.0%; Flavourzyme: 14.7 ± 0.4%) compared to the control without supplementation (*F. velutipes*: 11.3 ± 0.1%; Flavourzyme: 14.9 ± 0.9%). Neither autopeptidolysis nor product inhibition were significantly affected by the presence of Ca^{2+} ions. It was concluded that the lack of cleavage sites in wheat gluten was another factor likely to limit hydrolysis.

Cleavage Sites. Since no single purified peptidase was used for the hydrolysis of wheat gluten, the incubations were evaluated by adding either substrate or peptidases after 3 h of

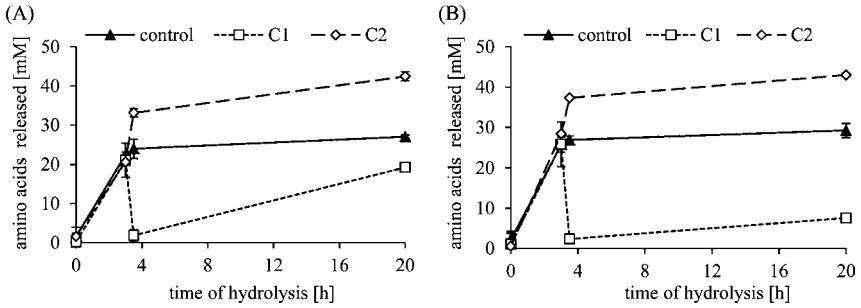

Figure 5. Cleavage sites study: Release of L-amino acids [mM] using peptidases of (A) *F. velutipes* and (B) Flavourzyme (28 kaU/mL hydrolysate each) for 20 h, 10 g/L gluten at pH 6, 45 °C. After 3 h of prehydrolysis, (C1) addition of fresh peptidases and buffer to the prehydrolyzed gluten and (C2) addition of fresh wheat gluten to the already used peptidases and buffer solution compared to the control.

preincubation. The initial rate of hydrolysis was affected in a positive way by the additional supplementation of substrate (C2, Figure 5A, B). Product inhibition increased because of a higher release of L-amino acid compared to the control. This observation was also described by Ravallec-Plé et al.[20] for the hydrolysis of cod (*Gadus morhua*) muscle with alcalase. They assumed that the substrate cleavage sites were limiting, as the DH did not increase upon another addition of enzyme. Different observations were made in the present study for the two enzyme preparations after the second addition: In the case of peptidases from *F. velutipes*, the addition of fresh enzyme and buffer after 3 h of prehydrolysis led to a further increase of the rate of hydrolysis. A similar release of L-amino acids after 20 h of hydrolysis between the sample C1 (additional enzyme) and the control was observed (Figure 5A). This is an indication that there were still enough cleavage sites in the substrate for the action of the peptidases from *F. velutipes*. Flavourzyme showed the opposite effect. Despite the elimination of inhibitory L-amino acids and the supply of fresh enzyme, the DH of the control was not reached within another 17 h of hydrolysis (C1, Figure 5B). Similar experiments with a higher activity of Flavourzyme (280 kaU/mL) confirmed the results. After 9 h of hydrolysis, no further increase of the DH was determined for C1 (data not shown). With a higher initial enzyme activity, it is expected that the lack of cleavage sites appears even earlier. An increased substrate concentration will delay the effect. Overall, the lack of suitable cleavage sites in wheat gluten limited the efficiency of the peptidases in Flavourzyme. A possible explanation could be a lack of prolyl-specific peptidases in the enzyme mixture. L-Glutamine and L-proline (13−23%) together account for half or more of the peptide-bound amino acids in wheat gluten.[21] Due to the unique structure of L-proline, peptide bonds involving L-proline are often less susceptible to the action of peptidases. Using *Z*-Gly-Pro-*p*-nitroanilide as a substrate for prolyl-specific peptidases,[22] no activity was detected in Flavourzyme, whereas the culture supernatant of *F. velutipes* possessed an activity of 1.8 ± 0.3 U/L. The supernatant of *F. velutipes* contained numerous gelatin-cleaving peptidases that were not purified yet,[17] a glutaminase (85 kDa with 13 kDa subunits indicating a hexameric protein)[23] and a serine protease (34.5 kDa) with caspase- and legumain-like activities.[24] Flavourzyme is a commercial enzyme preparation of *A. oryzae* with endo- and exopeptidolytic activity. So far, the sequence analysis of peptidases of *A. oryzae* demonstrated about 18 peptidases, while the genome of *A. oryzae* was supposed to code for 134 putative peptidases.[25] Depending on the cultivation conditions, different peptidases were expressed. Liang et al.[26] described extracellular peptidases of *A. oryzae*, for example, oryzin, aspergillus-pepsin O, chain A of deuterolysin, leucine aminopeptidase, glutaminase, metallopeptidase, alanyl dipeptidyl peptidase, and Xaa-Pro aminopeptidase from the culture of a soybean koji. There are no data on which of these peptidases is present in Flavourzyme.

The peptidase mixtures used in the past were unable to hydrolyze wheat gluten completely. To compose an ideal peptidase mixture for the total hydrolysis, the peptidases of Flavourzyme or *F. velutipes*[17] will have to be purified individually and biochemically characterized for substrate specificity. The presence of a prolyl-specific peptidases[22] and a glutaminase[27] and a balanced ratio of exo- to endopeptidases appears essential to produce taste-active amino acids and peptides.[2]

Compared to *F. velutipes* peptidases (Table 1), the experiments showed that Flavourzyme peptidases suffered from a combination of a lack of cleavage sites, pronounced product inhibition, and the lack of prolyl-specific activity. Peptidases of *F. velutipes* were adversely affected by product inhibition only.

The integration of electrodialysis equipped with UF membranes was shown to be an effective means to overcome product inhibition. The autopeptidolytic activity of the peptidase mixtures is a minor issue, because it is easily suppressed by increased dosages of substrate.

ABSTRACT: Sea cucumber (*Stichopus japonicus*) autolysis during transportation and processing is a major problem and the specific proteinases responsible for autolysis have not yet been identified. In the present study, a 34 kDa serine proteinase (SP) was isolated to high purity from sea cucumber intestinal tract by a series of column chromatographies. Peptide mass fingerprinting revealed that six peptide fragments were identical to a proprotein convertase subtilisin/kexin type 9 preproprotein from sea cucumber *A. japonicus*. The enzyme hydrolyzed gelatin effectively at pH 6.0−9.0 and 35−40 °C, and the enzyme activity was strongly inhibited by SP inhibitors. Sea cucumber collagen was hydrolyzed significantly by purified SP at 37 °C and more gradually at 4 °C, suggesting that SP may be involved in autolysis. In addition, the SP gene that codes for 377 amino acid residues was cloned into an *E. coli* expression vector and expressed *in vitro*. A polyclonal antibody against rSP was prepared and found to react specifically against both rSP and endogenous SP, which may prove useful for future studies on the physiological functions of SP.

KEYWORDS: *sea cucumber intestinal tract, serine proteinase, purification, molecular cloning, in vitro expression, autolysis*

INTRODUCTION

Sea cucumber (*Stichopus japonicus*) is traditionally regarded as a seafood delicacy and is widely consumed in China, Japan, Korea, and other Asian countries.[1] In China, the total output of sea cucumber production is increasing annually to meet consumer demand.[2] However, sea cucumbers are easily subject to autolysis, which is a major problem in transportation and processing.[3]

Autolysis, or self-digestion, is a common phenomenon that occurs in various aquatic products[4−6] and some species of fish.[7] After the death of these animals, biochemical reactions responsible for anabolism cease while endogenous proteinases involved in catabolism retain their function. Major digestive organs secrete proteinases such as trypsin, chymotrysin, and cathepsin. Among these proteolytic enzymes, serine proteinase (SP) have significant activity in the hydrolysis of collagen[8−10] and myofibrillar proteins.[11,12]

In the edible portions of sea cucumbers, the highly insoluble collagen fibers account for about 70% of total protein.[13] As a result, collagen hydrolysis is likely the main factor in sea cucumber autolysis. Recently, we identified a gelatinolytic metalloproteinase (GMP) from the body wall of sea cucumber active in collagen degradation.[14] Considering the significant autolysis rate of harvested sea cucumbers, we propose that yet unidentified proteinases in the sea cucumber intestinal tract may also play an important role during collagen degradation. Although several reports regarding enzymes from the intestinal tract of sea cucumber have been published, including a highly alkaline proteinase,[15] a novel β-1,3-glucanase,[16] and a cathepsin L-like proteinase,[17] little information exists on how they may act on collagen.

In this paper, we report the identification of a unique SP from the intestinal tract of sea cucumber and investigated its enzymatic characteristics while focusing in on its activity on collagen. The gene encoding this SP was cloned, overexpressed in *Escherichia coli*, and the recombinant SP (rSP) was purified to homogeneity. A specific polyclonal antibody against rSP was produced, which reacted positively with SP purified from sea cucumber. Our present study provides valuable information for further analysis of the relationship between SPs and sea cucumber autolysis.

MATERIALS AND METHODS

Intestinal Tract Removal. Sea cucumbers with body weight of 150−200 g were purchased alive from January to March from an aquaculture base in Quangang, Fujian Province, China. Following purchase, the sea cucumbers were placed in cold seawater and transported to the laboratory within 4 h. The digestive tracts were immediately removed, rinsed carefully with cold distilled water and either used for experiments or stored at −80 °C.

Chemicals. DEAE-Sephacel, Sephacryl S-200 HR, Mini-Q, HisTrap HP, and Protein A Sepharose were purchased from GE Healthcare (Waukesha, WI, U.S.A.). Protein markers and bovine serum albumin were purchased from Bio-Rad (Richmond, CA, U.S.A.). The t-Butyloxy-carbonyl-Phe-Ser-Arg-4-methyl-coumaryl-7-amide (Boc-Phe-Ser-Arg-MCA) and other synthetic fluorogenic peptide substrates (MCA-substrates) were purchased from Peptide Institute (Osaka, Japan). Benzamidine, 1,10-phenanthroline monohydrate,

EDTA, EGTA were purchased from Sigma (St. Louis, MO, U.S.A.). Bovine gelatin, L-3-carboxytrans-2, 3-epoxypropionyl-L-leucine-4-guanidinobutylamide (E-64), and Triton X-100 were products of Amresco (Solon, OH, U.S.A.). Pepstatin A was purchased from Roche (Mannheim, Germany). The 4-(2-aminoethyl)-benzenesulfonyl fluoride hydrochloride (Pefabloc SC) was a product of Merck (Darmstadt, Germany).

Purification of SP. All procedures were performed at 4 °C. Briefly, the digestive tracts of sea cucumbers (200 g) were homogenized in 4-fold (v/w) of 20 mM Tris-HCl (pH 8.0) with 0.02% NaN_3 (buffer A) and centrifuged at 10000 g for 20 min. The supernatant was then collected as the crude enzyme fraction and subsequently applied to an ion-exchange column DEAE-Sephacel (2.5 × 10 cm) previously equilibrated with buffer A. After washing the column with buffer A until the absorbance at 280 nm reached baseline, bound proteins were eluted with a 0 to 0.5 M linear NaCl gradient in buffer A. Active fractions were pooled and concentrated by ultrafiltration using a YM-10 membrane (Millipore) and loaded on a gel filtration column of Sephacryl S-200 (2.5 × 98 cm) equilibrated with buffer A containing 0.15 M NaCl. Active fractions were collected, dialyzed against buffer A, and applied to a Mini-Q high performance ion exchange column (1 mL). A linear gradient elution using 0−0.5 M NaCl was performed at a flow rate of 0.5 mL/min. Active fractions were collected as purified proteinase and were used for enzymatic characterization.

Protein Concentration Analysis. Protein concentrations were estimated by measuring the absorbance at 280 nm using a Lambda 35 spectrophotometer (PerkinElmer, U.S.A.). The concentration of proteins after each purification step except the Mini-Q was determined by the method of Lowry[18] using bovine serum albumin as the standard.

Assay of Enzyme Activity. SP activity was measured as described by Guo et al.,[11] using Boc-Phe-Ser-Arg-MCA as a substrate. The reaction was initiated by adding 50 μL of enzyme solution to the reaction mixture containing 900 μL of 20 mM Tris-HCl (pH 8.0) and 50 μL of 10 μM substrate and incubated at 37 °C for 10 min. The reaction was stopped by adding 1.5 mL stopping agent (methyl alcohol/*n*-butyl alcohol/distilled water = 35:30:35, v/v/v), and enzyme activity was detected by measuring the fluorescence intensity of the liberated 7-amino-4-methylcoumarin (AMC) at an excitation wavelength of 380 nm and emission wavelength of 450 nm in a fluorescence spectrophotometer (FP-6200, Jasco, Japan). One unit of enzyme is defined as the amount of enzyme required to liberate 1 nmol of AMC per min.

SDS-PAGE and Gelatin Zymography. SDS-PAGE was performed based on the protocol of Laemmli.[19] Samples were separated using 12% polyacrylamide gels and stained with silver. Gelatin zymography was performed according to the method described by Herron et al.[20] Samples were mixed 3:1 with 4 × SDS sample buffer (200 mM Tris-HCl, pH 6.8 containing 8% SDS, 0.4% brommophenol blue and 40% glycerol) and were electrophoresed in 12% polyacrylamide gels containing 0.1% bovine gelatin at 4 °C. After electrophoresis, the gels were washed with 2.5% (v/v) Triton X-100 for 30 min by gently shaking to remove SDS, followed by a deionized water rinse. After incubation at 37 °C for 12 h in 20 mM Tris-HCl (pH 8.0), the gel was stained with Coomassie Brilliant Blue (CBB) R-250. The area of enzyme activity appeared as a clear band on the CBB-stained dark blue background, and the clarity of the band correlates positively to enzyme activity.

MALDI-TOF/TOF-MS/MS Analysis. Purified SP was separated on a 12% SDS-PAGE gel and stained with silver and the target protein band was selected for mass spectrometry analysis.[21] The target protein band was excised and destained using 30 mM $K_3Fe(CN)_6$ and 100 mM $Na_2S_2O_3$, followed by addition of 100 mM NH_4HCO_3 and incubated at room temperature for 15 min. The band was digested with trypsin at 37 °C overnight. Peptides were extracted with 100 μL of extraction solution containing 50% acetonitrile and 0.1% trifluoroacetic acid for 15 min. Obtained peptide solution was desalted using Ziptip C-18 columns (Pierce), lyophilized, and analyzed by 4800 plus MALDI-TOF analyzer (Applied Biosystems, Foster City, U.S.A.) in the School of Life Science, Sun Yat-Sen University, China.

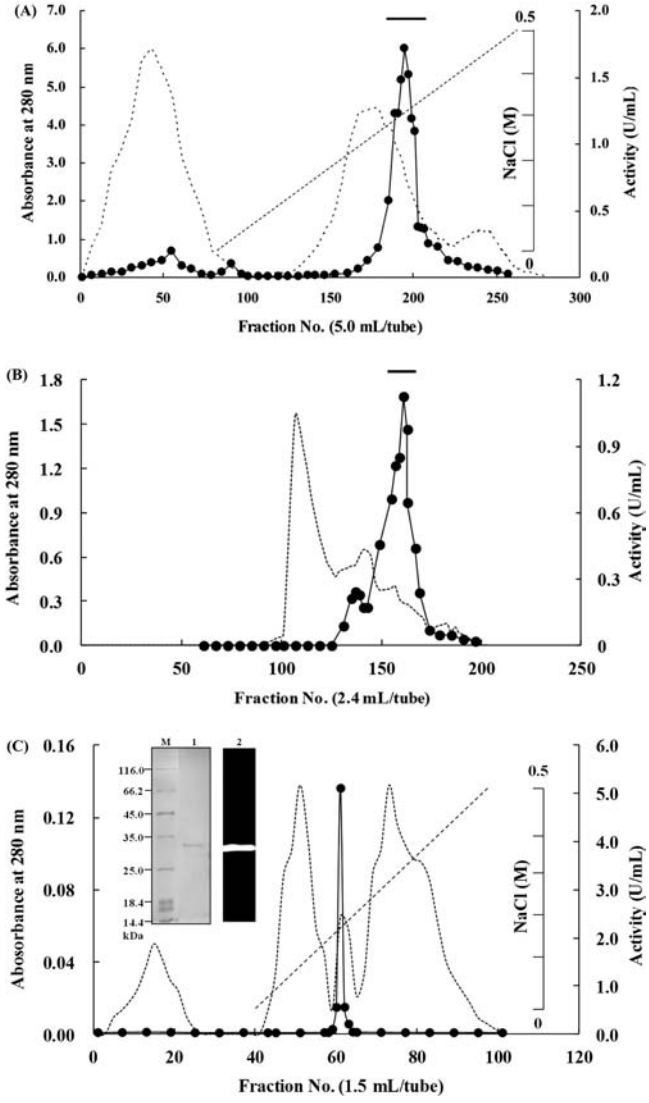

Figure 1. Column chromatography purification of the SP from the intestinal tract of sea cucumber. (A) DEAE-Sephacel chromatography. (B) Sephacryl S-200 chromatography. (C) Mini-Q chromatography. Absorbance at 280 nm (---); Enzymatic activity to Boc-Phe-Ser-Arg-MCA (-●-). SDS-PAGE and gelatin zymography of purified proteinase are shown in the inset of part C. Lane M, protein marker; lane 1, purified SP on silver stained 12% SDS-PAGE gel; lane 2, purified SP on gelatin zymography.

The resulting data were searched against the NCBI database using Matrix Science's Mascot 2.2 search engine.

Effect of Proteinase Inhibitors. To investigate the effects of different proteinase inhibitors on the proteinase, gels resulting from gelatin zymography gel electrophoresis were washed and rinsed as described above and subsequently allowed to incubate in buffer A with inhibitors at 37 °C for 12 h, followed by CBB staining. Control tests were performed in the absence of proteinase inhibitor. The effect of proteinase inhibitors on the proteinase was also analyzed using Boc-Phe-Ser-Arg-MCA as substrate. Briefly, purified SP was preincubated with corresponding inhibitors at different final concentrations for 30 min at 4 °C in 20 mM Tris-HCl buffer (pH 8.0), and the remaining enzymatic activity was determined as described above.

Preparation of Sea Cucumber Collagen. All procedures were performed at 4 °C as described.[14] Briefly, sea cucumber body wall (80 g wet weight) was minced and orderly washed by distilled water, 0.1 M Tris-HCl (pH 8.0) containing 5 mM EDTA, distilled water and 0.1 M NaOH with continuous stirring to remove noncollagenous material and pigment. The insoluble component was digested with

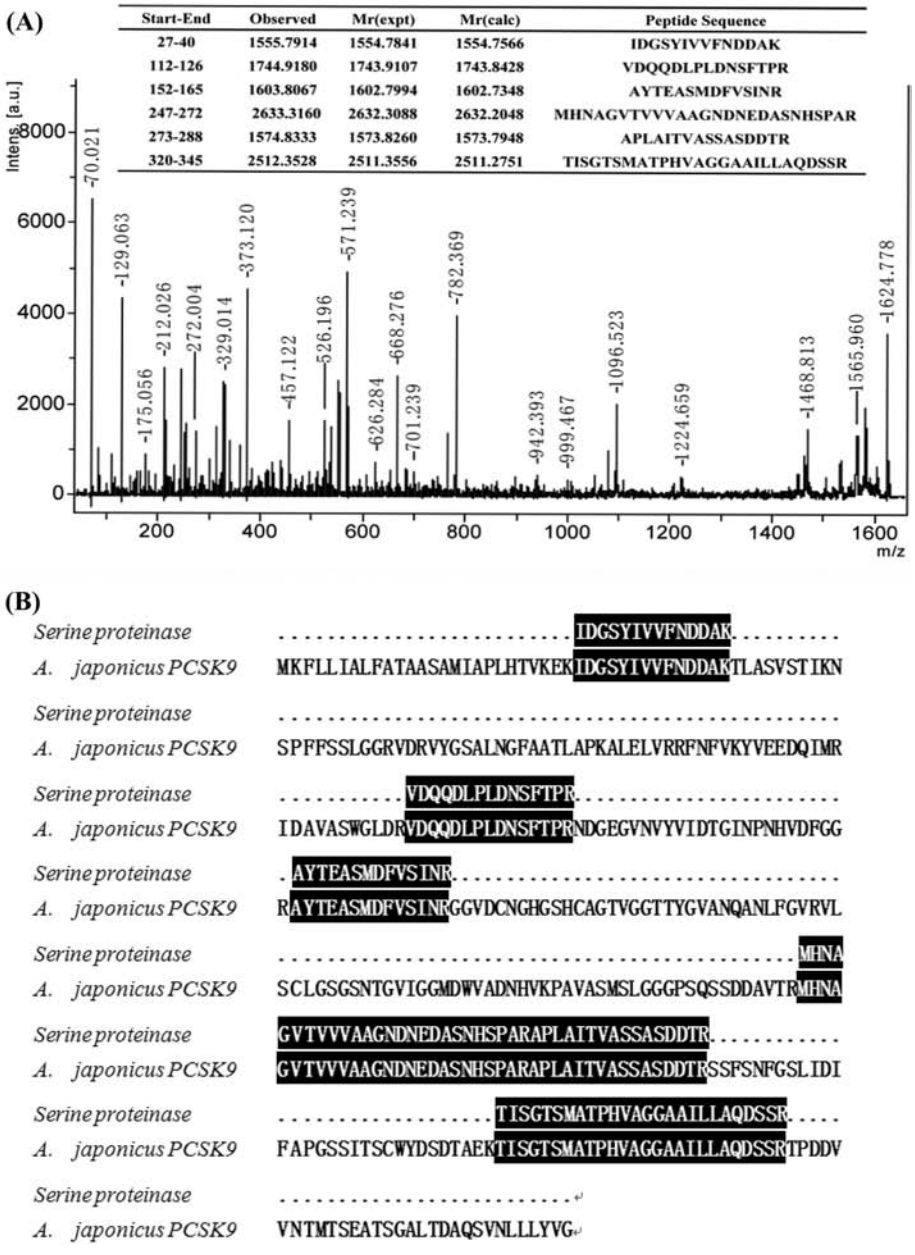

Figure 2. Peptide mass fingerprinting of purified SP. (A) Ions identified using mass spectrometry (MS). The sequences of six peptide fragments are shown in the above table. (B) Protein sequence alignment of SP with the sequence of proprotein convertase subtilisin/kexin type 9 preproprotein (gi:86277304) from *A. japonicus*. Identical amino acid residues are shown with black background.

porcine pepsin in 0.5 M acetic acid overnight, followed by centrifugation at 12000 g for 30 min. Collagen in the supernatant was salted out by adding NaCl to a final concentration of 0.8 M. After centrifugation, the collagen was collected and dissolved in 0.5 M acetic acid, and extensively dialyzed against 0.02 M sodium phosphate buffer (pH 8.0). The purified collagen was lyophilized and stored at −80 °C until analysis.

Degradation of Sea Cucumber Collagen. The purified enzyme was allowed to react with sea cucumber collagen in buffer A at 37 °C for different time intervals. After incubation, samples were applied to 7.5% gel for electrophoresis followed by CBB staining.

RNA Preparation and cDNA Synthesis. Total RNA was isolated from the intestinal tract of sea cucumber using the Trizol method.[11] First strand cDNA was synthesized with TIANScript RT Kit according to the manufacturer's instructions.

Reverse Transcription Polymerase Chain Reaction (RT-PCR). Degenerate primers (PF1 5′-TTGACCAACAAGACTTACCTC-3′ and PR1 5′-GTCATCACTAGCAGAGGAAGC-3′) to amplify partial sequences of the SP gene were designed according to the MALDI-TOF mass spectra results. Using these primers and the synthesized cDNA, a 500 bp fragment of the SP gene was amplified by PCR in a Gene Amp 9700 (Applied Biosystems, U.S.A.) thermal cycler. The PCR program was as follows: 5 min at 94 °C followed by 30 cycles of 30 s at 94 °C, 45 s at 55 °C, 60 s at 72 °C, and a final extension of 10 min at 72 °C. The PCR product was purified by agarose gel electrophoresis and cloned into pMD-18T vector (TakaRa) followed by DNA sequence analysis. DNA sequencing was performed at Invitrogen Biotechnological Co. Ltd. (Guangzhou, China) using the ABI Prism 3730 (CA, U.S.A.) DNA sequencer.

5′- and 3′- Rapid Amplification of cDNA Ends (5′- and 3′- RACE). The full-length sequence was obtained by 5′-RACE and 3′-RACE with several gene-specific primers (PF 5′-TGCTCCTC-TGGCTATCACTG-3′ and PR 5′-CACAGTGAGAACCATGTC-CAT-3′). RACE and RACE-PCR were performed with the SMART RACE cDNA Amplification Kit and Advantage 2 PCR Kit (Clontech, U.S.A.). Touchdown PCR was used to improve the

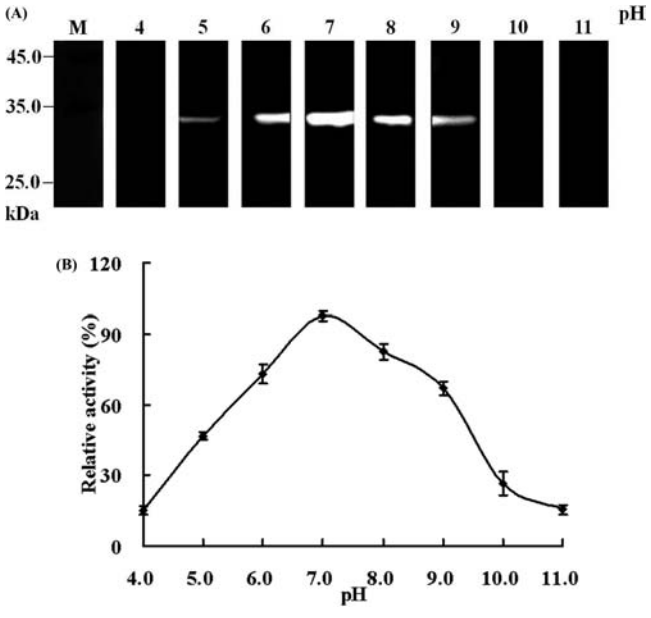

Figure 3. Optimal pH of SP. (A) Gelatin zymography analysis of pH on SP. Gelatin-incorporated gels were allowed to incubate at 37 °C for 12 h in different buffers at pH 4.0−10.0. (B) Effect of pH on purified SP using Boc-Phe-Ser-Arg-MCA as substrate.

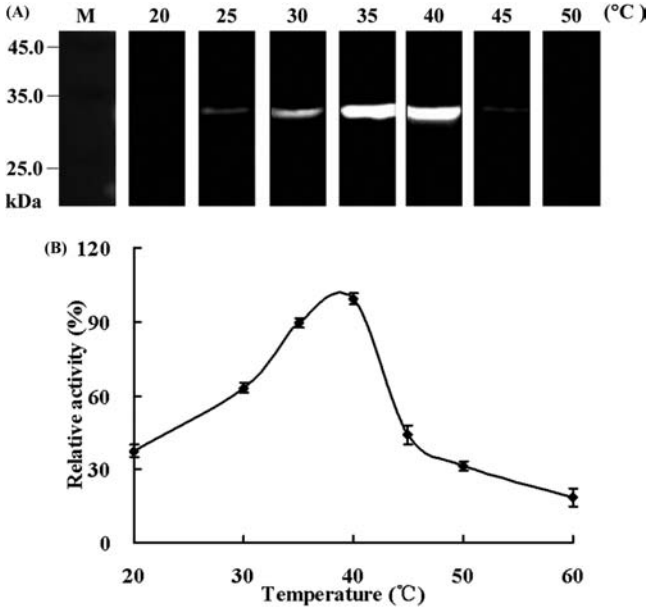

Figure 4. Optimal temperature of SP. (A) Gelatin zymography analysis of temperature on SP. Gelatin-incorporated gels were allowed to incubate in buffer A for 12 h at different temperatures from 20 to 50 °C. (B) Effect of temperature on purified SP using Boc-Phe-Ser-Arg-MCA as substrate.

specificity of SMARTer RACE amplification. The PCR products, 5′-RACE (550 bp) and 3′-RACE (500 bp) were purified, cloned and sequenced. The RT-PCR fragments as well as the 3′-RACE and 5′-RACE fragments were combined using the DNAman program to generate the full-length SP cDNA.

Construction of Recombinant Plasmids. The SP fragment without signal peptide was amplified by primers P5F 5′-CATATGATTGCACCTCTCCAC −3′ (containing the *Nde*I site) and P3R 5′- GAATTCACCAACATACAAGAGCAG −3′ (containing the *Eco*RI site). The plasmids containing PCR products and the pET-28a plasmid were digested with restriction enzymes *Nde*I and *Eco*RI.

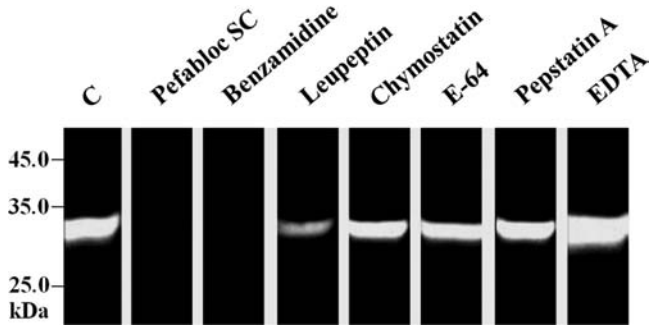

Figure 5. Effect of proteinase inhibitors on the purified SP. Gelatin zymography was conducted to investigate the inhibitory effect of proteinase inhibitors on the purified SP at 37 °C for 12 h in buffer A, followed by CBB staining. Lane C, control (without inhibitor); Lane 1, Pefabloc SC (2 mM); Lane 2, benzamidine (5 mM); Lane 3, Leupeptin (5 mM); Lane 4, Chymostatin (5 mM); Lane 5, E-64 (0.01 mM); Lane 6, Pepstatin A (0.015 mM); and Lane 7, EDTA (10 mM).

PCR products were ligated into the digested pET-28a (+) plasmid to generate pET-28a-*SP* recombinant plasmids.

Expression and Purification of the Recombinant SP. pET-28a-*SP* was transformed into *E. coli* BL21 (DE3) to make the expression strain BL-pET-*SP*. Overnight culture of the transformants (2 mL) was transferred into 200 mL kanamycin-containing Luria−Bertani broth for large scale culture while shaking at 37 °C. When the optical density at 600 nm reached 0.6, isopropyl β-D-1-thiogalactopyranoside (IPTG) was added to the final concentration of 1 mM for induction of recombinant proteinase expression. After culturing at 37 °C for 4 h, bacteria were collected by centrifugation at 9000 g for 5 min and resuspended in 1/10 cold buffer (50 mM Tris-HCl, 150 mM NaCl, pH 8.0). The bacteria were lysed by sonication and centrifuged at 12000 g for 20 min to remove the supernatant. The inclusion bodies were solubilized in a denaturing solution (20 mM Tris-HCl, pH 8.0 containing 150 mM NaCl and 4 M urea) and the His-tagged recombinant proteinase was purified using a Ni-NTA agarose affinity column and eluted with denaturing solution containing 100 mM imidazole. Following elution, the purified rSP was dialyzed against a renaturation buffer (20 mM Tris-HCl, 150 mM NaCl, pH 8.0) and its enzyme activity and purity were analyzed.

Preparation of Antiserum Against rSP. Purified rSP was used as antigen to produce polyclonal antibodies. Approximately 100 μg highly purified rSP was mixed with 1 mL complete Freund's adjuvant. The thoroughly mixed samples were subcutaneously injected into a rabbit. The same amount of antigen (100 μg) was mixed with incomplete Freund's adjuvant and injected subcutaneously into the rabbit on a biweekly basis and repeated four times. Blood sample was collected after the last booster. Anti-rSP polyclonal antibodies were purified by passing the sera through a Protein A Sepharose column.

RESULTS

Purification of SP. Following a series of column chromotogaphy purifications, a SP was purified to homogeneity. As shown in Figure 1**A**, SP was eluted from DEAE-Sephacel with a linear gradient of 0−0.5 M NaCl. Active fractions from the first column were further purified by Sephacryl S-200 gel filtration (Figure 1**B**). After Mini-Q ion exchange column purification, the enzymatically active peak migrated as a single band with a molecular mass of 34 kDa on SDS-PAGE (Figure 1**C**). Gelatin zymography analysis showed a corresponding gelatinolytic active band, suggesting that the proteinase was purified to homogeneity. The purification steps were summarized in Table 1. Approximately 0.1 mg of highly purified SP was obtained from 200 g of sea cucumber intestinal tract, the specific activity was 85.0 U/mg with a 331.7-fold increase and 1.6% recovery.

Table 1. Summary of the Purification of SP from the Intestinal Tract of Sea Cucumber

purification steps	total protein (mg)	total activity (U)	specific activity (U/mg)	yield (%)	purification (fold)
crude enzyme	2024.8	518.8	0.3	100.0	1.0
DEAE-Sephacel	302.4	125.9	0.4	24.3	1.6
Sephacryl S-200	9.9	23.7	2.4	4.6	9.3
Mini-Q	0.1	8.5	85.0	1.6	331.7

MALDI-TOF/TOF-MS/MS. To determine the amino acid sequence of the purified protein, the protein band was excised from SDS-PAGE and in-gel digested with trypsin. The resulting peptide mixture was analyzed by MALDI-TOF/TOF-MS/MS. Peptide mass fingerprinting (PMF) shown in Figure 2A revealed peptide fragments in the 800−5000 Da m/z range, and peaks with signal-to-noise ratios (SNR) > 50 were compared with the NCBI. It is interesting to note that the amino acid sequence of six peptide fragments containing a total of 111 amino acid residues were 100% identical to a proprotein convertase subtilisin/kexin type 9 preproprotein (gi:86277304) from *Apostichopus japonicus*, which is also a SP (Figure 2B).

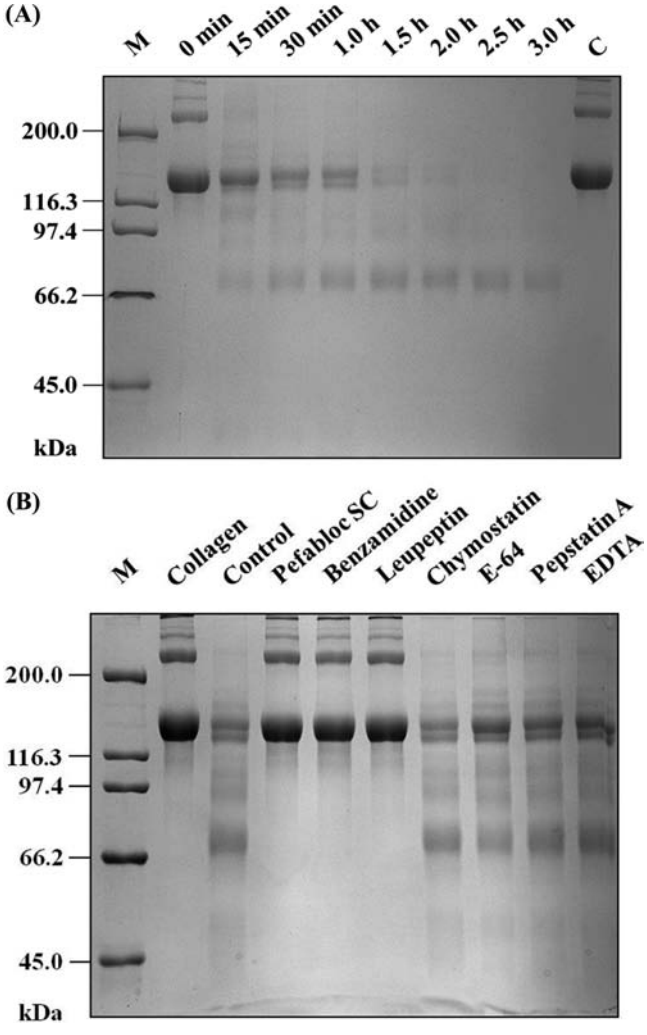

Figure 6. Degradation of sea cucumber collagen by SP. (A) SP (≈20 ng) and sea cucumber collagen (≈40 μg) were incubated in buffer A at 37 °C for different intervals. (B) Proteolysis patterns of collagen incubated with or without SP in the presence of various proteinase inhibitors at 37 °C in buffer A for 15 min. Lane M, protein marker; Lane 1, sea cucumber collagen; Lane 2, control (without inhibitor); Lane 3, Pefabloc SC (2 mM); Lane 4, benzamidine (5 mM); Lane 5, leupeptin (5 mM); Lane 6, chymostatin (5 mM); Lane 7, E-64 (0.01 mM); Lane 8, pepstatin A (0.015 mM); and Lane 9, EDTA (10 mM).

Effects of pH and Temperature. We sought to determine the maximum gelatinolytic activity of the purified SP. At 37 °C, a clear proteolytic band can be observed between pH 4.0−11.0. As shown in Figure 3A, the clearest band can be seen at pH 7.0 and the proteolytic band is negligible below pH 5.0 or above pH 9.0. Using Boc-Phe-Ser-Arg-MCA as the substrate, the maximum activity of SP was also detected at pH 7.0 (Figure 3B). The temperature-dependence of SP activity was determined using gelatin zymography (Figure 4A) and fluorogenic substrate hydrolyzing activity (Figure 4B). The results from both methods demonstrated that SP is maximally active at 40 °C.

Effect of Proteinase Inhibitors on the Purified SP. By gelatin zymography (Figure 5) and fluorogenic substrate hydrolyzing activity assays as readouts, the purified SP was almost completely suppressed by Pefabloc SC and benzamidine, which are known as specific SP inhibitors (Table 2). As an inhibitor both to serine and cysteine proteinases, leupeptin could not completely suppress the activity of purified SP. On the other hand, inhibitors to the other three types of proteinases (cysteine proteinase, aspartic proteinase, and metalloproteinase) did not show any inhibitory effect toward SP. These results strongly suggest that the purify enzyme is a SP.

Table 2. Effect of Proteinase Inhibitors on the SP Activity

inhibitor	concn. (mM)	relative activity (%)
control	0	100
Pefabloc SC	0.2	12.5 + 0.1
	2	7.4 + 0.4
benzamidine	0.5	15.9 + 0.3
	5	9.1 + 0.5
leupeptin	0.01	55.2 + 0.8
	0.1	43.5 + 1.2
chymostatin	0.01	85.7 + 0.6
	0.1	86.9 + 1.4
E-64	0.015	90.4 + 2.0
	0.1	91.2 + 1.2
pepstatinA	0.015	86.3 + 3.6
	0.1	84.7 + 2.8
EDTA	1	103.6 + 2.8
	10	127.6 + 2.3

Collagen Hydrolysis by SP. To confirm the involvement of SP in sea cucumber autolysis, its activity in the hydrolysis of collagen was investigated. As shown in Figure 6A, in the presence of SP, the β- and γ-chains of sea cucumber collagen were hydrolyzed after incubation at 37 °C for 15 min, and the original collagen bands (α, β and γ) completely disappeared after 3 h incubation. However, in the presence of SP inhibitors, collagen hydrolysis was completely suppressed when incubated with SP (Figure 6B). Leupeptin also significantly suppressed collagen hydrolysis although it only partially inhibited the activity of SP in gelatin zymography. Aspartic proteinase, cysteine proteinase and metalloproteinase inhibitors, on the other hand, did not show any inhibitory effects on collagen

dx.doi.org/10.1021/jf500923y | J. Agric. Food Chem. 2014, 62, 4769−4777

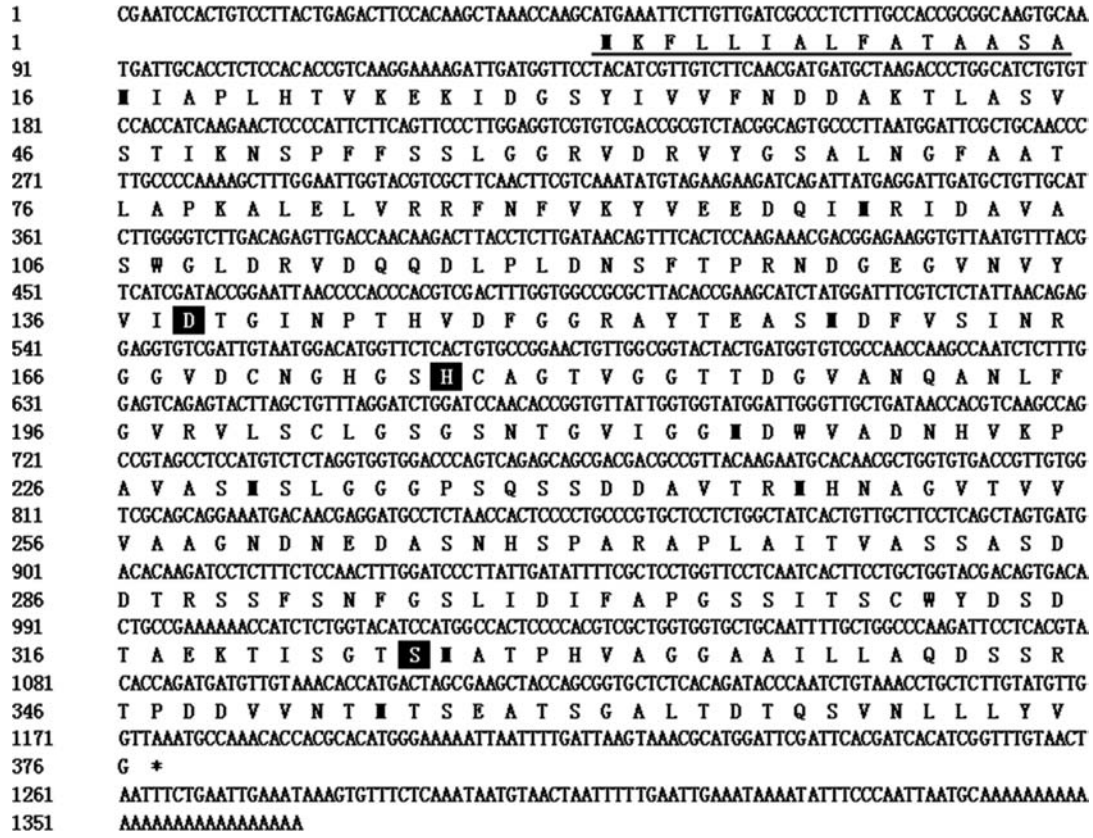

Figure 7. Nucleic acid and deduced amino acid sequences of SP. Base pair numbers and amino acid residue numbers are indicated to the left of each row. The signal peptide sequence is underlined. The Asp[138], His[176] and Ser[325] that form the catalytic triad of SP are shown with a black background.

hydrolysis. Proteolysis of collagen by SP at 4 °C was slower than that at 37 °C, but a similar proteolysis pattern was also be observed (data not shown).

cDNA Cloning of SP. The complete sequence of SP was cloned from *S. japonicus* and has been deposited in GenBank under the accession number KF888630. The full-length sequence of SP (1367 bp) contains an open reading frame (ORF) of 1131 bp encoding a putative protein of 377 amino acid residues with a 15 amino acids signal peptide located at the N-terminus (Figure 7). The molecular mass of mature SP is predicted to be 37.51 kDa and the p*I*, 4.44. BLASTp analysis showed that SP shares 99% identity to proprotein convertase subtilisin/kexin type 9 preproprotein (serine proteinnase-like) from sea cucumber (*A. japonicus*), 53% to an extracellular serine proteinase-like from sea urchin (*Strongylocentrotus purpuratus*) (Figure 8).

Expression and Purification of rSP. The recombinant BL-pET28a-*SP* was induced with IPTG for 4 h. The molecular mass of rSP is about 42 kDa when the 6 × His-tag (4.5 kDa) is taken into account, a mass that is similar to the theoretical value. Though the recombinant protein was mainly found in inclusion bodies, the His-tagged protein was easily purified using affinity chromatography to high purity. Subsequently, anti-rSP polyclonal antibody was successfully prepared using purified rSP as the antigen.

Western Blot Analysis. Western blot analysis showed that the anti-rSP polyclonal antibody specifically reacts both to rSP, native SP and even crude extract from the intestinal tract of sea cucumber (Figure 9), suggesting its high specificity.

DISCUSSION

Sea cucumbers are exceptionally sensitive to autolysis upon changing environmental factors such as increased temperature, change of salinity, and UV exposure. Hydrolysis of the collagen causes the disintegration of sea cucumber microstructures and the reduction of texture. As the body wall of sea cucumbers is mainly composed of collagen,[13] we propose that sea cucumber autolysis is mainly due to collagen hydrolysis. Though previous studies on sea cucumber proteinases have been reported,[14,22] information on the possible roles they play on autolysis is not available. Consequently, discovering and characterizing endogenous collagenolytic proteinases in sea cucumber may be beneficial to the elucidation of the mechanism behind sea cucumber autolysis.

Recently, we identified a GMP from the body wall of the sea cucumber *S. japonicus* and found that GMP maintains collagen proteolytic activity even at 4 °C. Considering the rapid rate of autolysis in harvested sea cucumbers, we proposed that the intestinal tract, which contains various proteinases, may be involved in autolysis. To find out what types of endogenous collagenolytic proteinases are responsible for collagen proteolysis, various proteinase inhibitors were added to crude extract from sea cucumber intestinal tract. The results showed that SP inhibitors and metalloproteinase inhibitors effectively suppressed collagen proteolysis, while other inhibitors exhibited no inhibitory effects (data not shown). It is clear then that serine proteinase and metalloproteinase are the major proteinases responsible for collagen proteolysis, which agrees well to a previously published report using casein-zymography.[23] In the present study, we purified the SP from the intestinal tract of sea cucumbers and characterized its enzymatic

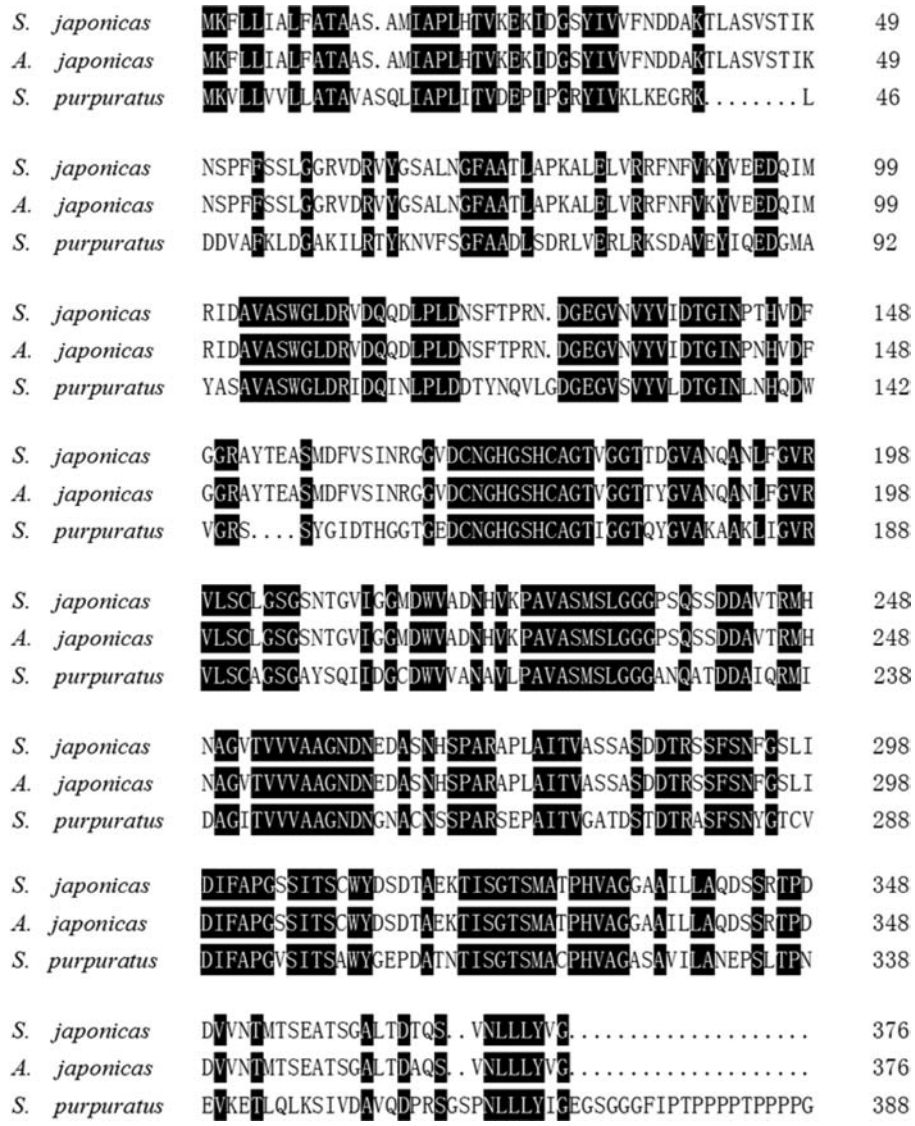

Figure 8. Alignment of primary structures of SP. The sequence of sea cucumber SP was compared with that of proprotein convertase subtilisin/kexin type 9 preproprotein (ABC87995, *A. japonicus*) and extracellular serine proteinase-like (XP_791416, *Strongylocentrotus purpuratus*). Identical amino acid residues are shown with black background.

properties. Based on an enzyme activity assay using Boc-Phe-Ser-Arg-MCA as the substrate, a SP with a molecular mass of approximately 34 kDa was purified through a series of column chromatographies. The molecular mass of the purified proteinase was close to that of a SP from sea urchin (*Strongylocentrotus purpuratus*, 35 kDa).[24]

According to the MALDI-TOF/TOF-MS/MS spectrum analysis, six peptide fragments consisting of 111 amino acid residues were identical to the sequence of a proprotein convertase subtilisin/kexin type 9 preproprotein (PCSK 9) (gi: 86277304) from *A. japonicus* (Figure 3A). PSCK9 belongs to the family of mammalian secretory kexin-like subtilases[25] and shares high homology with the C family of serine proteases.[26] Recently, Sun et al.[27] reported that PCSK9 is one of the top 10 down-regulated genes during sea cucumber regeneration.

The optimum pH for SP activity was 7.0 (Figure 4A) and the highest enzymatic activity was found at 35 °C (Figure 5A) using both gelatin zymography and fluorogenic substrates. The optimum pH of SP is similar to SPs from filefish (*Novoden modestrus*)[28] and fresh water prawn (*Macrobrachium rosenbergii*).[8]

dx.doi.org/10.1021/jf500923y | J. Agric. Food Chem. 2014, 62, 4769−4777

Meanwhile, the optimum temperature of purified SP is similar to another SP from the hepatopancreas of the northern shrimp.[10]

The enzymatic activity of the purified SP was strongly inhibited by SP inhibitors such as Pefabloc SC and benzamidine, while no significant inhibitory effects were observed using aspartic proteinase, cysteine proteinase and metalloproteinase inhibitors. Different from specific SP inhibitors such as Pefabloc SC and benzamidine, leupeptin is a reversible, competitive inhibitor both to serine and cysteine proteinases. Leupeptin could not completely suppress the purified SP during the 12 h incubation of gelatin-zymography (Figure 5). However, in collagen hydrolysis, as the reaction was performed only for 30 min, thus, no obvious degradation by SP could be observed on SDS-PAGE in the presence of leupeptin (Figure 6B). These indicate that the purified proteinase is different from trypsin-type collagenolytic SPs. Previous study showed that serine collagenase can be inhibited by metalloproteinase inhibitor EDTA as well as by SP inhibitors such as TLCK, DFP and soybean trypsin inhibitor.[7,9,28]

To ascertain the biological function of SP in sea cucumber autolysis, sea cucumber collagen hydrolysis patterns was examined using purified SP. With longer reaction times, significant degradation of the original band (α, β, and γ) of collagen was found when SP was incubated with sea cucumber collagen both at 37 °C (Figure 6A) and 4 °C (data not shown). Collagen proteolysis is completely suppressed by SP inhibitors (Figure 6B). Because SP from sea cucumber intestinal tract showed highly collagenolytic activity, we infer that endogenous SP is responsible for the degradation of collagenous fibrils in sea cucumber autolysis.

To further understand the underlying mechanism of sea cucumber autolysis, we successfully cloned the full-length cDNA (Figure 7) of SP. It contained a signal peptide, a prodomain, a catalytic domain and a carboxyl-terminal. Comparing the primary sequence of SP with other SPs, the purified SP shared relatively high identities to proprotein convertase subtilisin/kexin type 9 preproprotein and an extracellular serine proteinase from sea urchin (Figure 8), suggesting their close relationship. Like other SPs,[11] the catalytic domain consists Asp^{138}, His^{176} and Ser^{325}, which is the active site responsible for the enzymatic activity of SP. There are 4 cysteine residues at positions 170, 177, 202, and 310 that may form two intramolecular disulfide bonds in the tertiary structure. The difference in molecular mass between the native SP (34 kDa) and the calculated molecular weight from the nucleotide sequence (37.51 kDa) may be attributed to a cleavage site at ASA_{15}-MI, which may be where the signal peptide is cleaved from the protein. The theoretical p*I* of the mature protein is 4.44, which is consistent with the observation that we were able to purify SP in Tris-HCl pH 8.0 using DEAE-Sephacel weak anion exchange chromatography and Mini-Q strong anion exchange chromatography.

Thereafter, we used the *E. coli* expression vector pET28a to produce rSP. Although rSP revealed very low biological activity after following purification using denaturation buffer followed by renaturation, we were able to prepare a polyclonal antibody using rSP as the antigen and Western blot analysis (Figure 9) showed that both native SP and rSP reacted specifically with the rabbit anti-rSP polyclonal antibody. Based on its specificity, the antibody prepared in the present work can be applied to investigate the existence of SP in different tissues of sea cucumber by immunohistochemical study. It is also possible to prepare an immunoaffinity column for purification of native SP more effectively.

ABSTRACT: Blue light irradiation was applied to postharvest strawberry fruit to explore its influence on anthocyanin content and anthocyanin biosynthetic enzyme activities. Strawberry fruit was irradiated with blue light at 40 μmol m^{-2} s^{-1} for 12 days at 5 °C. The results indicated that blue light treatment improved total anthocyanin content in strawberry fruit during storage. Meanwhile, the treatment increased the activities of glucose-6-phosphate, shikimate dehydrogenase, tyrosine ammonia-lyase, phenylalanine ammonia-lyase, cinnamate-4-hydroxylase, 4-coumarate/coenzyme A ligase, dihydroflavonol-4-reductase, chalcone synthase, flavanone-3-β-hydroxylase, anthocyanin synthase, and UDP-glycose flavonoid-3-*O*-glycosyltranferase, which suggested that the enhancement of anthocyanin concentration by blue light might result from the activation of its related enzymes. Blue light might be proposed as a supplemental light source in the storage of strawberry fruit to improve its anthocyanin content.

KEYWORDS: *strawberry fruit, blue light, anthocyanin, postharvest*

INTRODUCTION

Anthocyanins are red, orange, purple, or blue water-soluble pigments occurring in fruits and vegetables, which play important biological roles in protecting plants against various biotic and abiotic stresses and in furnishing flowers and fruits with distinct colors to attract insects and animals for pollination and seed dispersal.[1] In addition to colorant properties, interest in anthocyanins has intensified due to their reported role in reducing the risk of coronary heart disease, cancer, and stroke.[2] Therefore, consumption of fruit rich in anthocyanins may be beneficial to human health.[3] It is vital to understand the regulation of anthocyanin biosynthesis thoroughly to develop anthocyanin-rich foods, thereby meeting the increasing demand for health-promoting compounds in our diet. To date, the biosynthesis pathway of anthocyanins and flavonoids has been almost completely elucidated as shown in Figure 1, and most of the structural genes encoding the enzymes responsible for each step have been isolated from different sources.[4,5]

Light is one of the most important environmental factors for plants, as a source of energy and in many other respects including anthocyanin synthesis.[6] Various types of lights might have distinct effects.[7−9] Among the different light wavelengths, blue light is one of the most effective in enhancing anthocyanin biosynthesis.[10,11] For example, anthocyanin production in apples had a strong dependence on both intensity and quality of light. Blue-violet and UV light were most effective, and far red was least effective, or even inhibitory.[7] Illumination with blue (both 455 and 470 nm) light-emitting diodes (LEDs) light resulted in higher anthocyanins content in red lettuce.[12] It is also reported that anthocyanin accumulation showed higher induction levels under blue light (465 nm) relative to green and red light during fruit development in strawberries.[14]

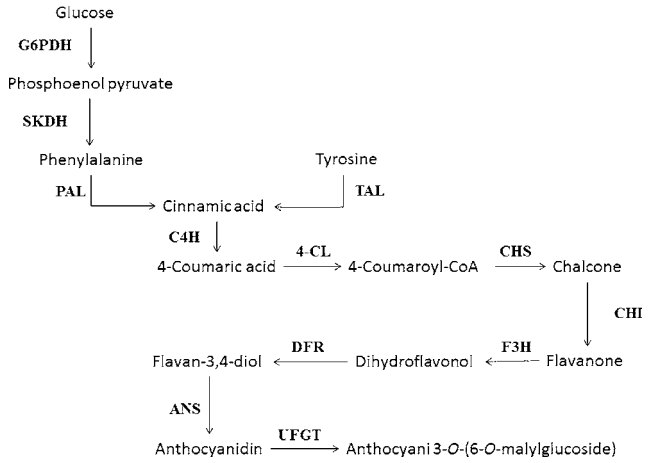

Figure 1. Simplified pathway for anthocyanin and flavonoid biosynthesis. G6PDH, glucose-6-phosphate; SKDH, shikimate dehydrogenase; PAL, phenylalanine ammonia-lyase; TAL, tyrosine ammonia-lyase; C4H, cinnamate-4-hydroxylase; 4CL, 4-coumarate:-CoA ligase; CHS, chalcone synthase; CHI, chalcone isomerase; F3H, flavanone 3-hydroxylase; DFR, dihydroflavonol 4-reductase; ANS, anthocyanidin synthase; UFGT, UDP-glucose:flavonoid glucosyltransferase.

Strawberry is one of the most commonly consumed berries and a good source of anthocyanins, which have shown potent antioxidant properties against chemically generated radicals.[13]

Previous literature showed that anthocyanin composition and anthocyanin contents in strawberries can be enhanced by ultraviolet radiation, altered gas composition, benzothiadiazole-7-carbothioic acid *S*-methylester (BTH), or application of signaling molecules.[14−18] Anthocyanin accumulation in response to different visible light wavelengths (e.g., blue, red, and green) has been investigated in strawberries during fruit development.[14] However, no information is available on the effect of blue light on anthocyanin content in postharvest strawberry fruit. In this paper, blue LED light was applied to the postharvest strawberry fruit, and the effects on anthocyanin content and related enzymes of anthocyanin synthesis were explored.

MATERIALS AND METHODS

Plant Materials. Strawberry (*Fragaria ananassa* Duch. cv. Fengguang) fruits were harvested by hand at stage of three-fourths colored based on the first appearance of red color on the fruit surface. Fruit were harvested and removed from a farm at Ningbo, Zhejiang province, and transported within 2 h to the laboratory. Fruits were selected for uniform size and color and then divided into two groups randomly.

LED Blue Light Irradiation. The first group of strawberries was irradiated with blue (470 nm) light at an intensity of 40 μmol m^{-2} s^{-1} for 12 days at 5 °C (80−90% relative humidity); this dose was chosen in our present study on the basis of our preliminary research (data not shown). GreenPower LED Research Module Blue (Koninklijke Philips Electronics N.V., The Netherlands) was used in blue light irradiation, and the flux intensity of the LEDs at the level of samples was measured with a digital visible light meter (model 9.4 Blue Light, Solartech Inc., USA). The second group of fruit was stored at 5 °C in the dark (80−90% relative humidity) and considered as the control. There were three replicates of 5 kg of fruit each per treatment, and the experiment was conducted twice. Samples were taken initially and at 2 day intervals during storage, immediately frozen in liquid nitrogen, and kept at −80 °C until required.

Total Anthocyanin Content Determination. The pH differential method[19] was applied to measure the total anthocyanin concentration of strawberry fruit. One gram samples from each replicate were homogenized with 5 mL of precooled acidified water (3% formic acid), and after centrifugation at 10000*g* for 15 min (4 °C), then another 5 mL of precooled acidified water was used to extract the residue again. The supernatant was combined to make the final volume of 25 mL for analysis. Results were expressed as milligrams of cyanidin-3-glucoside (Cy-3-Glu) equivalents per gram of fresh weight.

Enzyme Assays. G6PDH and SKDH were extracted with 0.1 M potassium phosphate buffer (pH 7.4) containing 2 mM cysteine, 2 mM EDTA, and 0.5 mM dithiothreitol (DTT). PAL and TAL were extracted with 0.2 mM sodium borate buffer (pH 8.7), containing 20 mM β-mercaptoethanol. Fruit flesh (5 g) was ground with 200 mM Tris-HCl buffer (pH 7.5) containing 25% (v/v) glycerol and 0.1 M DTT for C4H, 4-CL, F3H, and DFR. The CHS extraction was carried out by grinding the tissue with 300 μL of 50 mM KH_2PO_4 (pH 8.0) containing 20 mM ascorbic acid. The mixture was ultrasonicated in ice for 2 min. For UFGT, the samples were suspended in the buffer solution, including 100 mM Tris-HCl (pH 7.5), 10 mM sodium ascorbate, 5 mM dithiothreitol, 0.1% β-mercaptoethanol (v/v), and 10 μM *p*-aminophenylmethanesulfonyl fluoride (*p*-APMSF). The extracts were homogenized at 4 °C and centrifuged (12000*g*, 15 min). The supernatants were used for enzyme assays.

G6PDH activity was determined in reaction mixtures containing 5.88 μM NADP, 53.7 μM gluose-6-phosphate, and 88.5 mM $MgCl_2$, which followed the method of Debham and Emes with slight modification.[20] One unit of enzyme activity was equivalent to the oxidation of 1 μmol of NADPH per minute. SKDH activity was performed at 25 °C in the presence of 4 mM shikimic acid and 2.0 mM NADP in 0.1 mM Tris-HCl buffer at pH 9.0 as previously described.[21]

PAL and TAL assays were conducted according to the methods of Zucker and Kozukue et al.,[22,23] respectively. One unit of PAL activity was expressed as the amount of enzyme causing an increase in A_{290} of 0.001 unit h^{-1}. One unit of TAL was defined as the amount of enzyme causing an increase in A_{333} of 0.01 unit h^{-1}.

According to the method of Lamb et al.,[24] C4H activity was assayed in 50 mM phosphate buffer containing 2 mM 2-mercaptoethanol, 0.5 mM NADPH, and 2 mM *trans*-cinnamic acid, in a final volume of 2 mL of reaction buffer. The mixture was incubated for 1 h at 37 °C. The reaction was terminated by adding 6 M HCl, and 1 unit of C4H activity was expressed as the amount of enzyme causing an increase in A_{290} of 0.001 unit h^{-1}.

4-CL activity was determined spectrophotometrically in the presence of 50 μL of crude enzyme, 0.2 mM *p*-coumarate, 7.5 mM $MgCl_2$, 0.8 mM ATP, and 38 mM CoA in 100 mM Tris-HCl buffer (pH 7.5), as described previously.[25] One unit of 4-CL was defined as the amount of enzyme causing a decrease in A_{333} of 0.01 unit h^{-1}.

CHS activity was determined according to the method of Edwards and Kessman.[26] F3H and DFR activities were measured using the method of Liu et al.,[27] which determined the contents of F3H substrate (naringenin) and DFR substrate (dihydroquertin) with high-performance liquid chromatography (HPLC) analysis. UFGT activity was measured according to the method of Lister et al. with slight modification.[28] The reaction mixture consisted of enzyme solution (100 μL), 50 mM bicine buffer (100 μL, pH 8.5), substrate (quercetin 15 μL of 2 mg/mL), and UDP-galactose (10 μL of 15 mg/mL). Reaction tubes were incubated at 30 °C for 30 min, and the reaction was terminated by adding 75 μL of 20% (v/v) trichloroacetic acid in methanol.

The determination of ANS activity was based on that described previously.[29] The reaction mixture (500 μL) consisting of 20 mM K-Pi (pH 7.0), 200 mM NaCl, 10 mM maltose, 5 mM DTT, 40 mM sodium ascorbate, 1 mM 2-oxoglutaric acid, 0.4 mM $FeSO_4$, 1 M leucocyanidin, and ANS protein in 2 mg of crude cell extract was incubated at 30 °C for 30 min. The reaction was terminated by the addition of 5 μL of 36% (v/v) HCl, and the cyanidin formed was extracted by 500 μL of isoamyl alcohol for HPLC analysis. Cyanidin analysis was carried out by using a Waters 2695 HPLC equipped with a 2998 photodiode array detector (Waters Corp., Milford, MA, USA) according to the method of Saito et al.[29]

Protein content in the enzyme extracts was estimated using the Bradford method,[30] using bovine serum albumin as a standard.

Statistical Analysis. All statistical analyses were processed using SPSS (SPSS Inc., Chicago, IL, USA). Data were analyzed by one-way analysis of variance (ANOVA). The means were separated by Duncan's multiple-range test, and differences at $P < 0.05$ were considered to be significant.

RESULTS

Effect of Blue Light Treatment on Total Anthocyanin Content in Strawberry Fruit. The total anthocyanin content was quantitatively determined in strawberry fruit over 12 days of storage (Figure 2). The concentration of total anthocyanin in the control group increased sharply during the first 4 days of storage, but did not consistently afterward. In contrast, the content in the blue light-treated strawberry fruit increased during the whole storage. As compared to the control fruit, the values of total anthocyanin concentration were significantly ($p < 0.05$) higher after 2 days of storage.

Effect of Blue Light Treatment on G6PDH and SKDH Activities in Strawberry Fruit. G6PDH activity in both the control and blue light treatment increased during the first 8 days of storage and then declined (Figure 3A). SKDH activity increased in both blue light treatment and control samples as the storage progressed (Figure 3B). Blue light treatment enhanced the activities of both enzymes significantly ($P < 0.05$) after 2 days of storage.

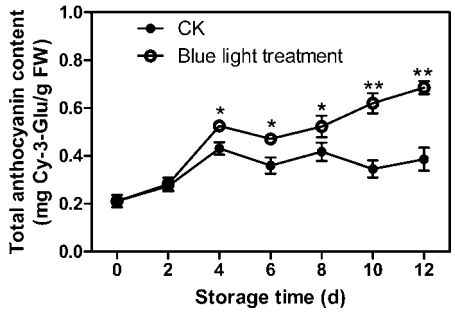

Figure 2. Effect of blue light treatment on total anthocyanin content in strawberry fruit during storage at 5 °C. Values are means ± SE. Vertical bars represent standard errors of the means. Asterisks indicate significant differences between blue light-treated and control samples (Duncan's multiple-range test; *, $P < 0.05$; **, $P < 0.01$; and ***, $P < 0.001$).

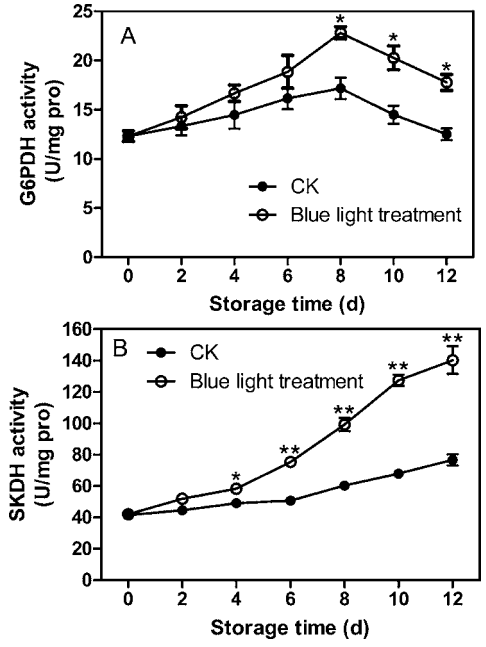

Figure 3. Effect of blue light treatment on G6PDH and SKDH activities in strawberry fruit during storage at 5 °C. Values are means ± SE. Vertical bars represent standard errors of the means. Asterisks indicate significant differences between blue light-treated and control samples (Duncan's multiple-range test; *, $P < 0.05$; **, $P < 0.01$; and ***, $P < 0.001$).

Effect of Blue Light Treatment on TAL, PAL, C4H, and 4-CL Activities in Strawberry Fruit. TAL and PAL activities in both control and blue light treatment increased during the initial 6 days of storage; thereafter they declined gradually (Figure 4A,B). In comparison with the control berries, significantly ($P < 0.05$) higher activities of TAL and PAL were observed in blue light-treated fruit after 4 and 2 days of storage, respectively.

C4H activity in the control strawberry fruit increased gradually in the first 6 days and then decreased over the next 6 days. On the other hand, the activity in blue light-treated samples increased rapidly, reached a maximum level at 8 days, and then declined afterward (Figure 4C). When compared to the control fruit, blue light treatment maintained significantly ($P < 0.05$) higher C4H activity after 6 days of storage.

4-CL activity increased in all strawberry fruits regardless of treatment at the first 2 days of storage and declined thereafter. The activity in the blue light-treated fruit was significantly ($P < 0.05$) higher than that in the control during the whole storage (Figure 4D).

Effect of Blue Light Treatment on CHS and F3H Activities in Strawberry Fruit. CHS and F3H activities in control strawberry fruit began to increase after 4 days of storage. However, a significant enhancement of these two enzymes was found in the blue light-treated fruit, and the treatment maintained higher activities of CHS and F3H after 2 days of storage (Figure 5).

Effect of Blue Light Treatment on DFR, ANS, and UFGT Activities in Strawberry Fruit. DFR activity in both control and blue light-treated fruits increased first and declined after 4 and 6 days of storage, respectively (Figure 6A). No significant changes of ANS and UFGT activities in control fruit were observed throughout the storage time. However, the activities of ANS and UFGT in blue light-treated fruit increased during the first 10 and 8 days of storage, respectively, and decreased afterward (Figure 6B,C). There was a positive effect of blue light treatment on all three enzymes whereby the treatment maintained significantly ($P < 0.05$) higher enzyme activities after 2 days of storage as compared to the control fruit.

DISCUSSION

Anthocyanins represent a group of natural flavonoid compounds in plants and are responsible for the coloration of strawberry fruit. Environmental conditions are known to induce anthocyanin accumulation across the major groups of higher plants, of these light being the best studied. It was reported that blue LED light regulated the metabolic pathways causing both increased concentrations of bioprotective compounds and plant growth of red leaf lettuce.[31] Similar to the previous study at different development stages of strawberries,[14] in our present work, we also found blue light treatment could enhance anthocyanin content in postharvest strawberries after 2 days of storage (Figure 2), which suggested that blue light could be a potential method to enhance anthocyanin accumulation and maintain a high-quality product of postharvest strawberry fruit.

Anthocyanins are secondary metabolites, primarily synthesized via the pentose phosphate pathway and shikimate, phenylpropanoid, and flavonoid pathways. These pathways consist of a number of enzymatic steps, each catalyzed by a sequential reaction for anthocyanin synthesis (Figure 1). Therefore, in this study, we examined the possible role of key regulatory enzymes in anthocyanin metabolism in response to blue light treatment. G6PDH and SKDH are the crucial enzymes in the pentose phosphate and shikimate pathways, which are both involved in anthocyanin biosynthesis. CO_2 stress enhanced phenolic accumulation in the root of *Panax ginseng* via induction of G6PDH activity. In addition, BTH treatment increased the activities of G6PDH and SKDH in postharvest strawberry fruit,[14] which was responsible for the enhancement of anthocyanin biosynthesis. Similarly, in our present study, the increased anthocyanin content in blue light-treated strawberry fruit was probably associated with the induction of these two enzymes as well.

The phenylpropanoid pathway plays an important role in anthocyanin synthesis. The result of the coordinated action of many related enzymes in the phenylpropanoid pathway might be attributed to the accumulation of anthocyanin in

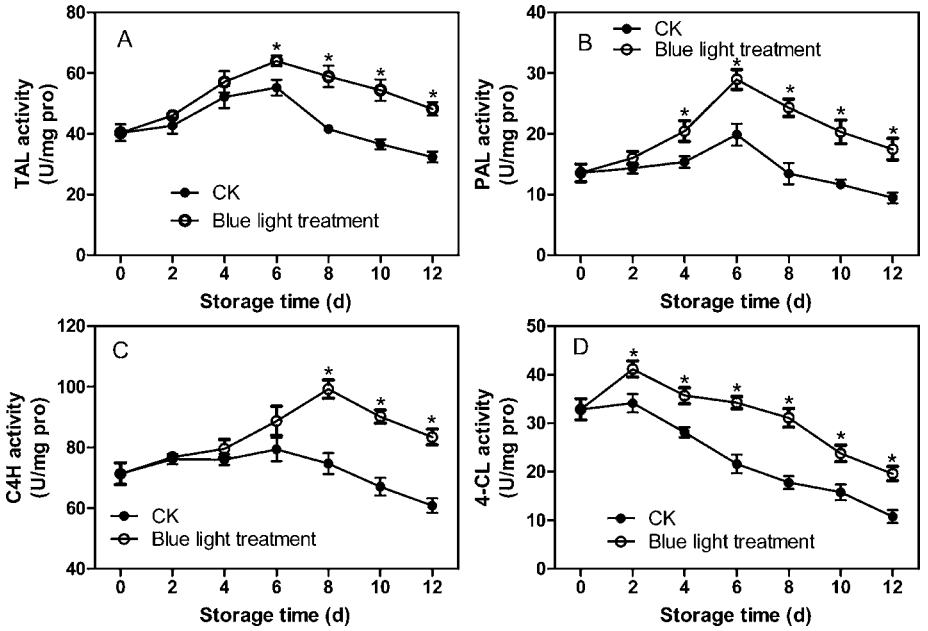

Figure 4. Effect of blue light treatment on TAL, PAL, C4H, and 4-CL activities in strawberry fruit during storage at 5 °C. Values are means ± SE. Vertical bars represent standard errors of the means. Asterisks indicate significant differences between blue light-treated and control samples (Duncan's multiple-range test; *, $P < 0.05$; **, $P < 0.01$; and ***, $P < 0.001$).

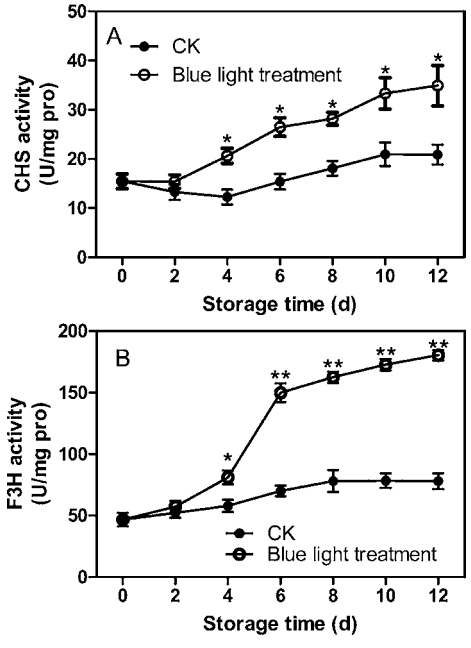

Figure 5. Effect of blue light treatment on CHS and F3H activities in strawberry fruit during storage at 5 °C. Values are means ± SE. Vertical bars represent standard errors of the means. strawberries after blue light treatment. Therefore, the four pivotal enzymes involved in this pathway, PAL, TAL, C4H, and 4-CL, were investigated. It has been shown that treatment with gibberellic acid increased PAL and TAL activities, which was correlated with the anthocyanin accumulation in ripening strawberries.[32] BTH induced anthocyanin content in postharvest strawberry fruit by enhancing activities of the four enzymes of phenylpropanoid metabolism.[14] Thus, in our present study, the higher PAL and TAL activities as well as the increased activities of C4H and 4-CL observed in blue light-treated strawberries indicated that an enhancement in anthocyanin production by blue light was accompanied by induction of the four key enzymes in the phenylpropanoid pathway of strawberry fruit.

Anthocyanin accumulation is also thought to be the result of interaction of the multiple key enzymes in the flavonoid pathway.[33] An increase of enzyme activities or gene expression involved in this pathway along with an increase in anthocyanin accumulation in response to light exposure has been reported. For example, Ju et al. have shown in 'Fuji' apples that light-reflecting mulches increased anthocyanin concentration and UFGT activity.[34] Ubi et al. demonstrated that increase in the expression levels of all five biosynthetic genes, *CHS*, *F3H*, *DFR*, *ANS*, and *UFGT*, in fruit skin of five apple cultivars coincided with increases of anthocyanin concentration.[35] When the fruit was bagged about 1 month prior to commercial harvest to prevent anthocyanin biosynthesis, the expression of *CHS*, *ANS*, and *UFGT* was substantially depressed in fruit skin, whereas that of all five genes was enhanced by UV-B treatment with the accumulation of anthocyanins.[35] Our results agreed with these authors because we found that blue light enhanced the activities of CHS, F3H, DFR, ANS, and UFGT in postharvest strawberries during storage, resulting in anthocyanin biosynthesis.[11] Previous study has revealed that blue light induced anthocyanin accumulation in strawberries during fruit development by regulating the expression of anthocyanin biosynthetic genes. Together with this study, our results suggested that blue light regulated multiple key enzymes in the anthocyanin pathway, thereby enhancing anthocyanin biosynthesis in strawberries during both fruit development and postharvest storage; however, the possible differences in regulatory mechanisms of anthocyanin accumulation by blue light applied before or after harvest need further study.

In conclusion, blue light was effective for stimulating anthocyanin accumulation in postharvest strawberry fruit. The

enhancement in anthocyanin content by blue light might result from the activation of key enzymes in the pentose phosphate, shikimate, phenylpropanoid, and flavonoid pathways. Blue light could be considered as a supplemental light source in postharvest strawberry fruit to improve levels of health-promoting compounds, especially anthocyanin accumulation.

Supporting Information

ABSTRACT: The inhibitory reagents to inhibit the activation of microglial cells may be potentially useful for the treatment of neurodegenerative diseases. The leaves of the plant *Laurus nobilis* belonging to the family Lauraceae, namely, bay leaves, have been used as a popular spice, and their extract showed moderate inhibition on microglial activation. A further phytochemical investigation of the leaves led to the isolation of two new (**1**, **2**) and eight known (**3**−**10**) sesquiterpenes. Their structures were elucidated on the basis of extensive 1D and 2D NMR (HMQC, HMBC, ^{1}H−^{1}H COSY, and NOESY) spectroscopic data analyses and Chem3D modeling. The following biological studies disclosed that these isolated compounds showed inhibitory activities on LPS-induced microglial activation. The results of our phytochemical investigation, including two new sesquiterpenes (**1** and **2**) and the first report of two compounds (**3** and **4**) from this species, further revealed the chemical composition of bay leaves as a popular spice, and the biological studies implied that bay leaves, containing bioactive substances with the inhibition of microglial activation, were potentially beneficial to human health.

KEYWORDS: *Laurus nobilis, bay leaf, sesquiterpenes, microglial activation, neurodegenerative diseases*

INTRODUCTION

As human longevity increases, chronic neurodegenerative disorders are having an increasing impact on public health. Among these neurodegenerative disorders, Alzheimer's disease (AD) and Parkinson's disease (PD) are the most common representatives, which have an about 2% incidence of the population over 65 years of age.[1] Though the mechanism of neurodegenerative diseases remains unclear, accumulating evidence strongly supports that the pathway leading to neurodegenerative diseases, such as PD and AD, involves the activation of microglial cells.[2] Microglial cells, the resident immune cells of the central nervous system (CNS), play a major role in host defense and tissue repair in CNS. The activated microglial cells release neurotoxic and inflammatory mediators, such as nitric oxide (NO), reactive oxygen species (ROS), and proinflammatory cytokines, and overproduction of these inflammatory mediators in the CNS can cause various severe neurodegenerative diseases.[3] The activation of microglial cells in the CNS is an early sign that often precedes neuronal death.[3,4] Therefore, the inhibition of microglial activation can halt the following neuronal damage in the CNS, and the inhibitory reagents to inhibit the microglial activation may be potentially effective for the treatment of neurodegenerative diseases.[5]

Laurus nobilis, belonging to the family Lauraceae, is an evergreen tree widely distributed in the Mediterranean area and Europe.[6] The leaves of *L. nobilis*, namely, bay leaves, have been used as not only one of the most popular culinary spices in all western countries but also a folk medicine for asthma, digestive disorders, cardiac diseases, diarrhea, and rheumatic pains.[7,8] Previous phytochemical investigations on *L. nobilis* revealed the main presence of sesquiterpenes, megastigmane and phenolic components, and flavonoids,[7−14] which showed NO inhibitory effects,[7,9] cytotoxic activities,[8,11−13] and inhibitory effects on alcohol absorption.[15] In the course of our survey on biologically active substances in medicinal plants, considerable attention has been given to the occurrence of compounds with inhibitory effects of the microglial activation, since these substances are expected to be potentially useful for the treatment of neurodegenerative diseases. As a continuation of our work on the search for bioactive substances from traditional folk medicines or medicinal food,[16−18] we investigated the chemical constituents of the ethyl acetate soluble part of the methanol extract from the leaves of *L. nobilis*, which showed moderate inhibitory effects on LPS-induced microglial activation. This investigation led to the isolation and identification of two new sesquiterpenes, named laurupenes A and B (**1** and **2**), and eight known analogues (**3**−**10**) (Figure 1). Their structures were elucidated on the basis of spectroscopic data analyses (IR, ESI-MS, HR-ESI-MS, and 1D and 2D NMR). This paper herein describes their isolation, structure elucidation, and inhibitory activities on lipopolysaccharide (LPS)-induced microglial activation.

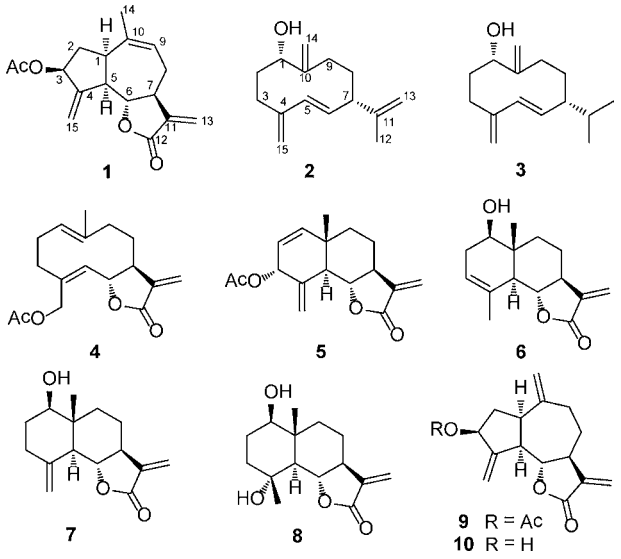

Figure 1. Structures of compounds **1**−**10** from *L. nobilis*.

MATERIALS AND METHODS

General. The optical rotations were measured in CH_2Cl_2 using a Rudolph Autopol IV automatic polarimeter. The IR spectra were taken on a Bruker Tensor 27 FT-IR spectrometer with KBr disks. The ESI-MS spectra were obtained on an LCQ-Advantage mass spectrometer (Finnigan Co. Ltd., U.S.A.). HR-ESI-MS spectra were recorded by an Agilent 6520 Q-TOF LC/MS (Agilent, U.S.A.). 1D and 2D NMR spectra were recorded on a Bruker AV 400 instrument (400 MHz for ^{1}H and 100 MHz for ^{13}C) with TMS as an internal standard. HPLC separations were performed on a CXTH system, equipped with a UV3000 detector at 210 nm (Beijing Chuangxintongheng Instruments Co. Ltd., China), and a YMC-pack ODS-AM (20 × 250 mm) column (YMC Co. Ltd., Japan). Silica gel was used for column chromatography (200−300 mesh, Qingdao Marine Chemical Group Co. Ltd., China). Chemical reagents for isolation were of analytical grade and purchased from Tianjin Chemical Reagent Company, China. Biological reagents were from Sigma Company. The murine microglial BV-2 cell line was from Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences (China).

Plant Material. The leaves of *L. nobilis* were purchased in July 2011 from Bozhou Materia Medica Market, Anhui province, China. A voucher specimen (No. 20110919) was identified by Dr. Yuanqiang Guo (College of Pharmacy, Nankai University, China) and deposited at the laboratory of the Research Department of Natural Medicine, College of Pharmacy, Nankai University, China.

Extraction and Isolation. The air-dried leaves of *L. nobilis* (6.0 kg) were powdered and extracted were with MeOH (3 × 48 L) under reflux. The organic solvent was evaporated to obtain a crude extract (375 g). The extract was suspended in H_2O (0.7 L) and partitioned with EtOAc (3 × 0.7 L). The EtOAc soluble part (260 g) was subjected to a silica gel column chromatography, using a gradient of acetone in petroleum ether (1%−30%), to give ten fractions (F_1−F_{10}) based on TLC analyses. F_2 was fractionated by middle pressure liquid chromatography (MPLC) over octadecylsilyl (ODS) eluting with a step gradient from 70% to 90% MeOH in H_2O to give four subfractions (F_{2-1}−F_{2-4}). F_{2-2} was further purified by preparative HPLC (YMC-pack ODS-AM, 20 × 250 mm, 75% MeOH in H_2O) to afford compound **1** (t_R = 22 min, 11.4 mg). Compound **2** (t_R = 26 min, 4.0 mg) was obtained from the subfraction F_{2-3} using the same HPLC system (82% MeOH in H_2O), and compound **3** (t_R = 28 min, 8.1 mg) was obtained from F_{2-4} (85% MeOH in H_2O). F_3, F_4, F_5, F_6, and F_8 were also subjected to the same MPLC over ODS, eluting with a step gradient from 60% to 90% MeOH in H_2O, to give subfractions F_{3-1}−F_{3-4}, F_{4-1}−F_{4-6}, F_{5-1}−F_{5-5}, F_{6-1}−F_{6-9}, and F_{8-1}−F_{8-8}, respectively. The further purification of subfraction F_{4-2} (73% MeOH in H_2O) with the same HPLC system led to afford compound **4** (t_R = 24 min, 23.9 mg). Compounds **5** (t_R = 21 min, 18.9 mg) and **9**

(t_R = 23 min, 35.6 mg) were obtained from subfraction F_{3-2} using the above HPLC system (73% MeOH in H_2O). With the same protocols, compounds **6** (t_R = 24 min, 32.2 mg) and **10** (t_R = 20 min, 13.2 mg) were isolated from subraction F_{5-1} (65% MeOH in H_2O), and compound **7** (t_R = 21 min, 64.2 mg) was obtained from F_{6-1} (62% MeOH in H_2O). The further purification of F_{8-1} with the above HPLC system (60% MeOH in H_2O) resulted in the isolation of compound **8** (t_R = 15 min, 41.6 mg).

Laurupene A (1). Colorless oil; $[\alpha]_D^{12}$ = +27.3 (*c* 0.55, CH_2Cl_2); IR (KBr) ν_{max} cm^{-1} 2967, 2930, 1768, 1736, 1666, 1372, 1240, 1137, 1015; ^1H NMR (400 MHz, $CDCl_3$) and ^{13}C NMR (100 MHz, $CDCl_3$) data, see Table 1; ESI-MS *m*/*z* 289 $[M + H]^+$; HR-ESI-MS *m*/*z* 289.1437 $[M + H]^+$, calcd for $C_{17}H_{21}O_4$, 289.1440.

Laurupene B (2). Bioassay for Inhibitory Activities on LPS-Induced Microglial Activation. The activated microglial cells release neurotoxic and inflammatory mediators, such as nitricoxide (NO). The amount of released NO production indicate the level of microglial activation or inhibition degree. Murine microglial BV-2 cells were selected for the experiments. The cells were cultured at 37 °C in DMEM supplemented with 10% (v/v) inactivated fetal bovine serum and 100 U/mL penicillin/streptomycin under a water-saturated atmosphere of 95% air and 5% CO_2. The cells were seeded in 96-well culture plates (5×10^4 cells/well) and allowed to adhere for 24 h at 37 °C. The cells were incubated for 20 h with or without 0.2 μg/mL of LPS (Sigma Chemical Co., St. Louis, MO, U.S.A.) in the absence or presence of the test compounds. 2-Methyl-2-thiopseudourea, sulfate (SMT), was used as a positive control. As a parameter of NO synthesis, the nitrite concentration was measured by the Griess reaction using the supernatant of the BV-2 cells. Briefly, 50 μL of the cell culture supernatant was reacted with 50 μL of Griess reagent [1:1 mixture of 0.1% *N*-(1-naphthyl)ethylenediamine in H_2O and 1% sulfanilamide in 5% phosphoric acid] in a 96-well plate, and the absorbance was read with a microplate reader (Thermo Fisher Scientific Inc., U.S.A.) at 550 nm. The experiment was performed three times, and the IC_{50} values for the inhibition of NO production were determined on the basis of linear or nonlinear regression analysis of the concentration−response data curves.

RESULTS AND DISCUSSION

Compound **1** was isolated as a colorless oil. Its HR-ESI-MS provided the molecular formula $C_{17}H_{20}O_4$, through the presence of a peak at *m*/*z* 289.1437 $[M + H]^+$ (calcd for $C_{17}H_{21}O_4$ 289.1440). The molecular formula indicated eight unsaturation degrees for **1**. The IR spectrum evidenced the presence of an α,β-saturated γ-lactone moiety (1736 cm^{-1}). The ^1H NMR spectrum of **1** exhibited two methyl singlets at δ_H 1.82 (3H, s, H_3-14) and 2.06 (3H, s, $COCH_3$), five olefinic protons at δ_H 5.58 (1H, d, *J* = 7.6 Hz, H-9), 6.22 and 5.49 (each 1H, d, *J* = 3.3 Hz, H_2-13), and 5.48 and 5.38 (each 1H, s, H_2-15), and two oxygenated methine protons at δ_H 5.52 (1H, m, H-3) and 4.08 (1H, dd, *J* = 10.7, 9.4 Hz, H-6) (Table 1). The ^{13}C NMR spectrum of **1** showed 17 carbon resonances. From the ^1H and ^{13}C NMR spectra, one acetoxy group was obvious. Apart from the two carbons (δ_C 171.0, 21.3) for the acetoxy group, there were 15 residual resonances in the ^{13}C NMR spectrum, which were classified into one methyl [δ_C 28.0 (C-14)], four methylenes [δ_C 37.5 (C-2), 29.1 (C-8), 119.6 (C-13), and 117.2 (C-15)], six methines [δ_C 43.7 (C-1), 73.8 (C-3), 51.0 (C-5), 83.3 (C-6), 45.6 (C-7), and 121.4 (C-9)], and four quaternary carbons [δ_C 147.8 (C-4), 137.0 (C-10), 139.8 (C-11), and 169.8 (C-12)] based on the DEPT and HMQC spectra. According to the unsaturation degrees, the aforementioned spectroscopic features, and the sesquiterpenes isolated from the genus *Laurus*,[8−12] compound **1** might be a sesquiterpene with three rings and an acetoxy group. In order to confirm the above assumption and elucidate the structure, the following HMBC and $^1H-^1H$ COSY experiments were performed. In the HMBC spectrum, the long-range correlations of H-1 to C-2, C-3, C-4, C-5, C-6, C-9, C-10, and C-14, and H-5 to C-1, C-2, C-3, C-4, C-6, C-7, C-10, and C-15, revealed the fusion of a five-membered ring and a seven-membered ring, which bonded with the α,β-saturated γ-lactone ring via the C-6 and C-7 unit. By the HMBC correlations of H_2-15 to C-3, C-4, and C-5, and H_2-13 to C-7, C-11, and C-12, the two terminal double bonds were accordingly assigned to C-4 and C-15, and C-11 and C-13, respectively. The oxygenated carbon at δ_C 73.8 and the residual olefinic carbons at δ_C 121.4 and 137.0 were ascribable to C-3, C-9, and C-10, respectively, by the interpretation of the HMBC spectrum. Consequently, the substituted acetoxy group was attached at C-3 by the HMBC correlation of H-3 to the carbonyl carbon at δ_C 171.0. By further analyzing the HMQC, HMBC, and $^1H-^1H$ COSY spectra (Figure 2), all the proton and carbon signals were assigned unambiguously. Thus, the planar structure of a guaianolide-type sesquiterpene for compound **1** was established.

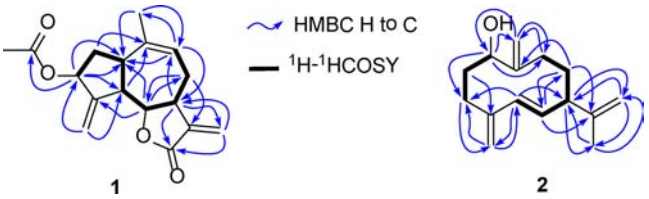

Figure 2. Selected HMBC and $^1H-^1H$ COSY correlations of compounds **1** and **2**.

The relative configuration of **1** was elucidated as follows. For the reported natural guaianolide sesquiterpene, the five-membered lactone ring, the seven-membered ring, and the other five-membered ring are *trans*- and *cis*-fused with each other, respectively, H-1, H-5, and H-7 are in α-positions on the same side, and H-6 is in β-position on the opposite side.[19] The NOESY correlations observed for H-5/H-7, H-5/H-1, H-1/H-3, H-6/H-2β, H-6/H-8β, and H-9/H_3-14 (Figure 3) and the

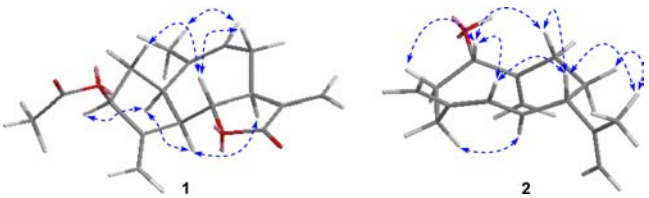

Figure 3. Key NOESY correlations of compounds **1** and **2**.

further Chem3D modeling suggested a conformation for compound **1** as depicted in Figure 3, where the C-3 acetoxy group was in a β-position. The structure of compound **1** was therefore characterized and named laurupene A.

Compound **2** possessed a molecular formula $C_{15}H_{22}O$ as determined by the HR-ESI-MS (*m*/*z* 219.1742 $[M + H]^+$, calcd for $C_{15}H_{23}O$, 219.1749), which implied five unsaturation degrees. The ^1H NMR spectrum of **2** exhibited one methyl group at δ_H 1.72 (3H, s, H_3-12), eight olefinic protons at δ_H

dx.doi.org/10.1021/jf501515v | J. Agric. Food Chem. 2014, 62, 4784−4788

6.08 (1H, d, J = 15.8 Hz, H-5), 5.54 (1H, dd, J = 15.8, 10.3 Hz, H-6), 4.73 and 4.71 (each 1H, s, H_2-13), 5.30 and 5.04 (each 1H, s, H_2-14), and 4.96 and 4.87 (each 1H, s, H_2-15), and one oxygenated methine proton at δ_H 3.78 (1H, dd, J = 11.8, 3.3 Hz, H-1) (Table 2). The ^{13}C NMR spectrum of **2** showed 15

compd	IC_{50} (μM)	compd	IC_{50} (μM)
1	>100	**7**	22.0 ± 1.1
3	>100	**8**	30.5 ± 0.8
4	23.3 ± 3.2	**9**	14.0 ± 0.5
5	39.9 ± 6.0	**10**	35.4 ± 4.1
6	25.3 ± 1.9	SMT[b]	8.1 ± 1.2

[a]Data are presented as mean ± SD based on three experiments. Compound **2** was not assayed for the inhibitory effects because of inadequate amount. [b]SMT (2-methyl-2-thiopseudourea, sulfate) was used as a positive control.

carbon signals, comprising one methyl (C-12), seven methylenes (C-2, C-3, C-8, C-9, C-13, C-14, and C-15), four methines (C-1, C-5, C-6, and C-7), and three quaternary carbons (C-4, C-10, and C-11) based on the DEPT and HMQC spectra. According to the molecular, unsaturation degrees, and the above spectroscopic features, compound **2** might be a germacrane-type sesquiterpene.[8−13] In order to confirm the germacrane-type skeleton and achieve the assignments of proton and carbon signals, a following HMBC experiment was performed. By the interpretation of HMQC and HMBC spectroscopic data, the ten-membered ring and the isopropenyl moiety attached at C-7 were deduced and defined. The additional two terminal double bonds were accordingly assigned to C-4 and C-15, and C-10 and C-14, respectively, by the HMBC correlations of H_2-15 to C-3, C-4, and C-5, and H_2-14 to C-1, C-9, and C-10. Based on the above deductions, the germacrane skeleton consisting of one ten-membered ring and an isopropenyl moiety was inferred, where the methylene groups of two terminal double bonds between C-4 and C-15, and C-10 and C-14, replaced the characteristic C-14 and C-15 methyl groups of the common germacrane skeleton. Consequently, the oxygenated carbon at δ_C 76.2 and the olefinic carbons at δ_C 129.6 and 136.6 were assigned to C-1, C-5, and C-6, respectively, by the long-range correlations of H-1 to C-9, C-10, C-14, C-2, and C-3, H-5 to C-3, C-4, C-6, C-7, and C-15, and H-6 to C-4, C-5, C-7, C-8, and C-11. The further analyses of 2D NMR spectra led to the assignments of all the protons and carbons. Thus, the planar structure of a germacrane-type sesquiterpene for **2** was established.

The relative configuration of **2** was deduced as follows. The coupling constant between H-5 and H-6 ($J_{5,6}$ = 15.8 Hz) revealed an *E*-configuration for the C-5−C-6 double bond. The NOESY correlations observed for H-5/H-1, H-5/H-7, H-7/H-9β, H-9β/H-1, H-7/H_3-12, H-8β/H_3-12, and H-6/H-3α (Figure 3) and the Chem3D modeling suggested a conformation for **2** as depicted in Figure 3, where the H-7 and H-1 were both in β-positions. The structure of compound **2** was therefore characterized, which has been named laurupene B.

Based on the spectroscopic analyses and the comparison with the literature, the known compounds were identified as *ent*-germacra-4(15),5,10(14)-trien-1α-ol (**3**),[20] 15-acetoxycostunolide (**4**),[21] 3α-acetoxyeudesma-1,4(15),11(13)-trien-12,6α-olide (**5**),[21] santamarine (**6**),[8] reynosin (**7**),[8] 1β-hydroxy arbusculin A (**8**),[22] zaluzanin D (**9**),[23] and zaluzanin C (**10**).[23]

Studies on the inhibition of microglial activation have demonstrated that reagents with inhibitory activities of microglial activation can halt the neuronal damage in the CNS and may be potentially useful for the treatment of neurodegenerative diseases.[5] In order to search for and obtain the bioactive substances inhibiting the microglial activation as candidates for the treatment of neurodegenerative diseases, these sesquiterpenes isolated from *L. nobilis* were evaluated for their inhibitory effects on LPS-induced microglial activation using murine microglial BV-2 cells (Figure 4). The level of

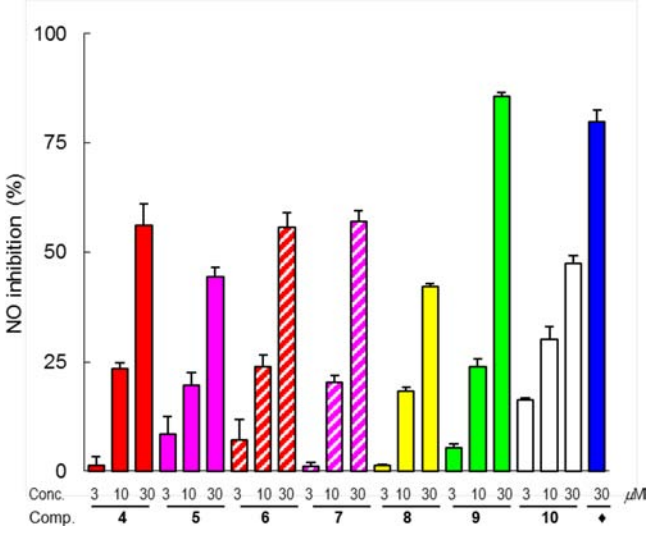

Figure 4. Inhibitory effects of compounds **4−10** on LPS-induced microglial activation. The inhibition levels of microglial activation were indicated by the amount of released NO production in BV-2 cells. BV-2 cells were treated with LPS alone or together with each compound at the concentrations indicated. After 20 h incubation, the supernatants were tested by Griess assay and the NO inhibitory rates were calculated. The experiment was performed three times, and the data are expressed as mean ± SD values. The inhibitory rate on NO production was calculated as follows: inhibitory rate (%) = (1 − (LPS/sample − untreated)/(LPS − untreated)) × 100. ◆ indicates positive control, SMT.

microglial activation or inhibition degree was indicated by the amount of released NO production.[24] 2-Methyl-2-thiopseudourea sulfate (SMT) was used as a positive control (IC_{50} 8.1 μM). All the evaluated sesquiterpenes exhibited inhibitory effects on LPS-induced microglial activation, and the inhibitory effects indicated by the amount of NO production are shown in Table 3. Compounds **4−10** inhibited LPS-induced microglial activation dose-dependently with IC_{50} values of 23.3, 39.9, 25.3, 22.0, 30.5, 14.0, and 35.4 μM, respectively. Compounds **1** and **3** showed weak activities (IC_{50} values >100 μM). Compound **2** was not assayed for the inhibitory effects because of inadequate amount. MTT assay indicated that all the assayed compounds had no significant cytotoxicity to the BV-2 cells at their effective concentration for the inhibition of microglial activation (data not shown).

In summary, two new and eight known sesquiterpenes were successfully isolated from the leaves of *L. nobilis*. Their structures were elucidated by 1D and 2D NMR spectra and Chem3D modeling. Biological studies disclosed that all of the evaluated isolates exhibited inhibitory effects on LPS-induced

microglial activation and compound **9** exerted the most inhibition against microglial activation indicated by the amount of NO production, which was comparable to the positive control (SMT). The results of our chemical investigation, including two new sesuqiterpenes (**1** and **2**) and the first report of two compounds (**3** and **4**) from this species, further revealed the chemical composition of *L. nobilis*, and the biological screening of these isolates exhibited that the leaves of *L. nobilis*, used as a popular spice, may be beneficial to human health, while the current biological data suggest that these sesquiterpenes from *L. nobilis*, especially compounds **4**, **6**, **7**, and **9** with strong inhibitory activities of microglial activation, may probably be considered as candidate agents for neurodegenerative diseases. Further biological studies on these compounds are still underway by our group.

A Comprehensive Study To Explore Differences in Mycotoxin Patterns from Agro-ecological Regions through Maize, Peanut, and Cassava Products: A Case Study, Cameroon

Emmanuel Njumbe Ediage,*[,†] Kerstin Hell,[‡] and Sarah De Saeger[†]

[†]Laboratory of Food Analysis, Faculty of Pharmaceutical Sciences, Ghent University, Harelbekestraat 72, 9000 Gent, Belgium

[‡]International Institute of Tropical Agriculture, 08 B.P. 0932, Cotonou, Benin

ABSTRACT: A total of 420 samples were collected from agrarian households. Whereas 51% (215/420) of the samples were contaminated with one or more toxins, the contamination rates for maize, peanut, and cassava products were 74, 62, and 24%, respectively. The fumonisins (20−5412 μg/kg), aflatoxin B_1 (6−645 μg/kg), roquefortine C (1−181 μg/kg), and deoxynivalenol (27−3842 μg/kg) were the most prevalent contaminants in maize. For peanut samples, aflatoxin B_1 (6−125 μg/kg) and ochratoxin A (0.3−12 μg/kg) were the main contaminants, whereas aflatoxin B_1 (6−194 μg/kg) and penicillic acid (25−184 μg/kg) were detected in the cassava products. Exposures calculated through maize intake for fumonisin B_1 and aflatoxin B_1 were several-fold higher (2−5 for fumonisin B_1 and 10^4−10^5 for aflatoxin B_1) than the health-based guidance values of 2 μg/kg bw/day and 0.15 ng/kg bw/day, respectively. The study design constitutes a good model that can be implemented in other sub-Saharan African countries.

KEYWORDS: *aflatoxin, fumonisin, ochratoxin A, mass spectrometry, feremented cassava, Africa*

INTRODUCTION

Mycotoxins are a heterogeneous group of toxic secondary metabolites produced by toxigenic fungi that contaminate a wide range of cereals, nuts, and their derived processed products with over 400 having been characterized. The aflatoxins (for example, B_1, B_2, G_1, and G_2), ochratoxin A (OTA), fumonisins (for example, B_1, B_2, and B_3), zearalenone (ZEA), and trichothecenes (deoxynivalenol, T2 toxin, HT2 toxin, and nivalenol) are considered to be significant.[1] This is due to their relatively acute and chronic effects observed in experimental animal studies and their frequent occurrence in food and feed worldwide.[2]

Formation of mycotoxins begins at preharvest plants and continues through postharvest in stored and processed products. Their occurrence in agricultural products and also in processed products significantly affects economies of developing countries and poses a serious risk for animal and human health. Preharvest and postharvest management strategies have therefore been recommended not only to reduce mycotoxin levels but also to control mycotoxin-related risks. Monitoring or surveillance of mycotoxin levels in crops and derived products is an important management tactic that is implemented along the food chain from farm to consumer.

Since the year 2000, mycotoxin monitoring programs have been carried out in several West African countries such as Benin Republic and Togo.[3,4] No surveys were done in Cameroon until 1994, when the fungal diversity in different maize species was characterized for the first time.[5−7] The presence of leaf, stem, and ear diseases in maize production areas in Cameroon was also reported.[8,6] The first data on multimycotoxin occurrence in dietary staples was reported in 2001.[6] Trace levels of aflatoxin B_1 (AFB_1) were detected in a few samples, whereas quantifiable levels of deoxynivalenol (DON; <100−1300 μg/kg), fumonisin B_1 (FB_1; 300−26000 μg/kg), and ZEA (50−110 μg/kg) were reported in maize.[6] Since 2007 there have been increasing numbers of reports on the occurrence of mycotoxins in dietary staples and their derived products from Cameroon.[9−12] Despite this upsurge in contamination data, the principal agricultural products (other than maize) such as cassava and peanuts have not yet been comprehensively investigated.

Cassava (*Manihot esculenta*) and cassava products constitute one of the main dietary staples consumed throughout West Africa, especially in Cameroon.[13] It accounts for 13% of the total energy intake of the Cameroonian population.[14] Despite its high consumption, very little is known about its mycotoxin profile. Recently, a large number of fungi (*Aspergillus* spp.) were isolated from stored cassava products, which raised serious concerns on the potential of this commodity as a natural substrate liable to mycotoxin contamination.[9] With respect to agricultural practices, cassava is often cultivated in a mixed-cropping system, which is a common practice among subsistence farmers in Cameroon. It is well documented that such practices increase the potential of mycological cross contamination.[9,15]

Cameroon is known as the bread basket of West and Central Africa with tens of thousands of tons of unprocessed agricultural food crops being exported daily to adjoining African and European countries. Traders often infiltrate the villages to purchase their desired products at low bargained prices. During trading, good-quality products are purchased for

export while the poor-quality products are rejected and left behind for household consumption by the local farmers. The poor-quality products could consist of insect-infected and/or fungi-infested grains with possibly very high mycotoxin contamination. For the export products, usually minimal or no quality control is carried out at the points of entry of the importing African countries.

Although the European Union through the European Food Safety Authority (EFSA) and other advisory and legislative bodies have established maximum levels for certain mycotoxins in some foodstuffs,[16,17] these legislations are nonbinding in countries outside the European Union. On the African continent, by the year 2003, only 15 of the 54 African countries were known to have specific mycotoxin regulations,[18] mostly for controlling aflatoxin contamination. Meanwhile, for the majority of African countries, no specific mycotoxin regulations exist, including Cameroon. The absence of elaborate surveys and reports on economic consequences (losses) resulting from rejection of poor-quality products at the international market has hindered the establishment of mycotoxin legislations in most African countries.

All surveys on mycotoxin contamination carried out in Cameroon over the past decade so far have been based on random sampling of food commodities from street vendors.[10−12] Only one study[5] assessed the occurrence of mycotoxins (aflatoxins, DON, and ZEA) in 72 maize samples from farmers in three villages. An additional drawback was that this was not a household survey. Household surveys reflect direct exposure of individuals at the household level, but surveys of street vendors do not. In remote villages, the raw food used to prepare a family meal is usually cultivated at the household level in small plots, and for this, exposure is envisaged to be constant throughout the year with the exception of some perishable seasonal crops. The bottleneck with household surveys in developing countries is the difficulty in gaining access for sampling to these the remote villages, which are often the most affected with the mycotoxin problem, due to very poor nonexisting infrastructure. Studies were therefore limited to urban and/or semiurban areas.

This study was aimed to go beyond the boundaries of previous studies by providing a comprehensive insight into the differences in mycotoxin patterns from three agro-ecological regions in Cameroon using maize, peanut, and cassava products as model food staples. Sampling in very remote areas with a potentially higher risk of the mycotoxin problem tends to give more added value to the proposed study. Furthermore, this is so far the only report on the occurrence of mycotoxins in cassava and its products from Cameroon.

MATERIALS AND METHODS

Sampling. Cameroon has five agro-ecological zones, from which three were selected for this study: the western highland (WH), the humid forest with monomodal rainfall (HFM), and the humid forest with bimodal rainfall (HFB). The climatic conditions of the three regions sampled have been described by IRA-NCRE.[19] Figure 1 shows the map of Cameroon with the five agro-ecological zones.

The WH is characterized by an annual rainfall from 1300 to >3000 mm/year depending on the topography of the land with atmospheric temperature varying from <15 to 27 °C. In the HFM, the annual rainfall is about 10000 mm/year in Debuncha, which is the fourth wettest locality in the world, with an atmospheric temperature varying from 20 to 28 °C. Rainfall in the HFB ranges between 2000 and 4000 mm/year, and mean atmospheric temperature is 23 °C. The climate of this zone comprises four seasons (unlike the two other zones, which have just two seasons), a long dry season from December to May, a short wet season from May to June, a short dry season from July to October, and a long and heavy wet season from October to November.[19]

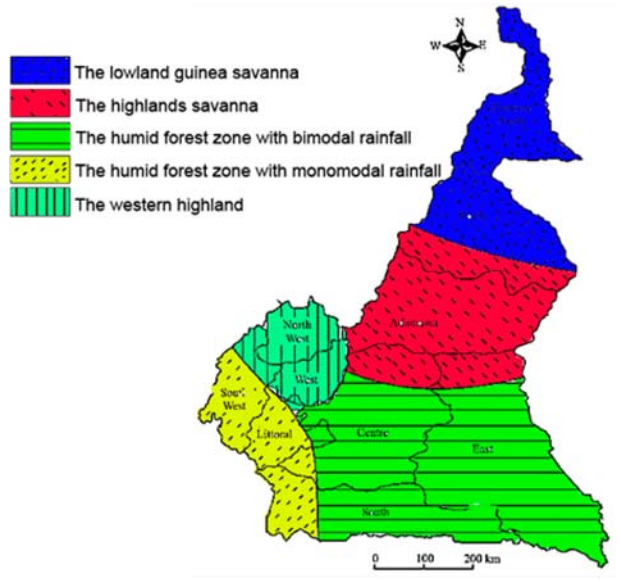

Figure 1. Map of Cameroon, showing the different agro-ecological regions.

The selection of these three zones was based on their agricultural contributions to the national food supply, which have always been greater than those of the two other nonselected regions. From these agro-ecological zones, a total of 10 villages were selected with 3 villages from each of the zones with the exception of the HFB zone, from which four villages were selected. A total of 165 maize grain (*Zea mays*), 90 peanut (*Arachis hypogaea*), and 165 cassava (*Manihot esculenta*; flakes (fermented cassava) and/or chips (nonfermented cassava)) samples intended for human consumption were collected from randomly selected households during two separate sampling sessions; July−August 2009 (rainy season) and December 2010−January 2011 (dry season). Sampling was performed by experienced and well-trained field facilitators. The villages included Malende, Kossala, and Ikiliwindi for the HFM; Bambui, Mbengwi, and Dschang for the WH; and Ndokayoka, Nkolbikong, Ngonai, and Nkolo for the HFB.

Sampling of maize and peanuts was carried out on the basis of the official guidelines described in Commission Regulation EC 401/2006[20] with some modifications. Briefly, the whole content of a traditional bag of stored maize and peanuts was considered as a lot. An aggregate sample size of 0.5 kg was composed of five incremental samples. Each incremental portion was about 100 g, and one incremental portion was taken for every 25 kg of product. In cases when the weight of the traditional bag exceeded 25 kg, the bag was subdivided into portions of 25 kg, and each section was sampled. Subsamples were taken at different depths or positions and then mixed together in a plastic container, and the 0.5 kg final sample was taken. During the first sampling session, peanuts were not collected due to time constraints. Maize and peanut samples were carefully labeled and sealed in paper bags. All samples were stored at −18 °C prior to their transportation to the Laboratory of Food Analysis, Ghent University, Belgium, by air shipment. Table 1 shows the distribution of collected samples across the three agro-ecological regions during the two sampling periods. Prior to analysis, 250 g of maize and peanut samples (unshelled) were milled to a sieve size of 0.5−1 mm using an IKA M20 universal mill (Sigma-Aldrich, Bornem, Belgium), from which a representative portion (250 g) was taken for analysis.

Materials and Reagents. Ammonium acetate was supplied by Grauwmeer (Leuven, Belgium). Acetic acid was purchased from Merck (Darmstadt, Germany). Dichloromethane, *N*,*N*-dimethylforma-

mide, and ethyl acetate were supplied by Acros Organics (Geel, Belgium). Methanol and *n*-hexane, both of HPLC grade, as well as Whatman glass microfiber filters (GFA, 125 mm) were purchased from VWR International (Zaventem, Belgium). Ultrafree centrifugal filter devices (0.22 μm) from Millipore (Billerica, MA, USA) were used. Bakerbond aminopropyl (NH_2) solid phase extraction (SPE) cartridges were obtained from Grace Discovery Sciences (Lokeren, Belgium). Water was purified on a Milli-Q Plus apparatus (Millipore, Brussels, Belgium).

Analytical standards, namely, 3-acetyldeoxynivalenol (3-AcDON), 15-acetyldeoxynivalenol (15-AcDON), alternariol (AOH), alternariol methyl ether (AME), altenuene (ALT), aflatoxin B_1 (AFB_1), aflatoxin B_2 (AFB_2), aflatoxin G_1 (AFG_1), aflatoxin G_2 (AFG_2), beauvericin (BEA), deoxynivalenol (DON), deepoxy-deoxynivalenol (DOM), fumonisin B_1 (FB_1), fumonisin B_2 (FB_2), fusarenone-X (FUS-X), nivalenol (NIV), HT2 toxin (HT2), neosolaniol (NEO), ochratoxin A (OTA), sterigmatocystin (STE), zearalenone (ZEA), and zearalanone (ZAN) were purchased from Sigma-Aldrich (Bornem, Belgium). Diacetoxyscirpenol (DAS) and T2 toxin (T2) were purchased from Biopure (Tulln, Austria). Fumonisin B_3 (FB_3) was obtained from Promec Unit (Tygerberg, South Africa). Penicillic acid (PA) was purchased from Fermentek (Jerusalem, Israel), whereas roquefortine C (ROQC) was obtained from Enzo Life Science (Lorrach, Germany). FB_2 and FB_3 standards (1 mg) were prepared in 1 mL of acetonitrile/water (50:50, v/v). Stock solutions of 3-AcDON, 15-AcDON, ALT, AFB_1, AFB_2, AFG_1, AFG_2, BEA, DON, DOM, FB_1, FUS-X, HT2, OTA, PA, ROQC, STE, T2, ZAN, and ZEA were prepared in methanol at a concentration of 1 mg/mL. AOH and AME stock solutions (1 mg/mL) were prepared in methanol/dimethylformamide (60:40, v/v). NIV, NEO, DOM, and DAS were obtained as solutions (100 μg/mL) in acetonitrile. All stock solutions were stored at −18 °C except FB_2 and FB_3, which were stored at 4 °C. New stock solutions were prepared every 6 months. From the individual stock standard solutions, a standard mixture was prepared at the following concentrations: AME, 20 ng/μL; AOH, FUS-X, HT2, NIV, and NEO, 10 ng/μL; ALT, 5 ng/μL; 15-AcDON, 2.5 ng/μL; AFB_2, 3-AcDON, DON, and ZEA, 2 ng/μL; T2, 1 ng/μL; DAS and STE, 0.5 ng/μL; FB_1, FB_2, and FB_3, 0.5 ng/μL; ROQC, AFB_1, AFB_2, AFG_1, and AFG_2, 0.2 ng/μL; BEA, 0.1 ng/μL; PA and OTA, 0.05 ng/μL. The standard mixtures were stored at −18 °C and renewed every 3 months.

Sample Preparation. The protocol used for sample preparation has been described.[21] One gram of homogenized sample was spiked with internal standards ZAN and DOM at 20 and 300 μg/kg, respectively. The fortified sample was kept in the dark for 15 min. DOM was used as internal standard (IS) for DON, 3-AcDON, and 15-AcDON, whereas ZAN was used for the other toxins. Both internal standards were used to correct for small volume changes during sample preparation.

All samples were extracted with 15 mL of extraction solvent methanol/ethyl acetate/water (70:20:10, v/v/v) for 30 min using an end-over-end shaker and centrifuged for 15 min at 3170*g*. The supernatant was transferred into a new extraction tube and evaporated at 40 °C. The residue was reconstituted in 5 mL of methanol/water (85:15, v/v) to which 10 mL of dichloromethane/hexane (30:70, v/v) solution was added. The mixture was shaken for 10 min and centrifuged at 3200*g* for 10 min. The dichloromethane/hexane phase was discarded, whereas the methanol/water phase was kept for further cleanup. The defatted extract (5 mL) was split into two parts of 2.5 mL each, for sample enrichment (cleanup). One part (of the split extract) was cleaned by passing it through a glass fiber filter, whereas the second part was cleaned up using amino propyl (NH_2) cartridges. After the equilibration step with 6 mL of methanol/water (85:15, v/v), the sample extract was loaded onto the SPE cartridge and the eluate collected in a test tube. Both parts (the NH_2 SPE and the glass fiber) of the cleaned extracts were recombined and evaporated at 40 °C. The residue was redissolved in 300 μL of mobile phase consisting of methanol/water/acetic acid (57.2:41.8:1, v/v/v) and 5 mM ammonium acetate. Ultrafree MC centrifugal devices were used to further filter the resulting solution prior to injection into the LC-MS/MS system; this was performed for 15 min at 10000*g*.

LC-MS/MS Method. Both the chromatographic and mass spectrometric conditions and settings were described previously.[21] Briefly, a Symmetry RP-C18 column of 150 mm × 2.1 mm, 5 μm, and a 10 mm × 2.1 mm Sentry guard column of the same material (Waters, Zellik, Belgium) were used for the chromatographic separation. The mobile phase constituted two solvent mixtures both containing 5 mM ammonium acetate. Solvent A was composed of water/methanol/acetic acid (94:5:1, v/v/v), whereas methanol/water/acetic acid (97:2:1, v/v/v) was used as solvent B. The solvent flow rate of 0.3 mL/min was adopted for a total gradient run time of 28 min. A 20 μL injection volume was applied.

Detection and quantitation were performed with a Waters Acquity UPLC apparatus coupled to a Micromass Quattro Micro triple-quadrupole mass spectrometer (Waters, Milford, MA, USA). The mass spectrometry analyses were carried out using selected reaction monitoring (SRM) channels in positive electrospray ionization (ESI +) mode. The following were the instrumental settings: source and desolvation temperatures, 130 and 350 °C, respectively; capillary voltage, 3.2 kV; cone nitrogen and desolvation gas flows, 200 and 800 L/h, respectively.

Commission Decision 2002/657/EC[22] and Commission Regulation 401/2006/EC[20] were used as guidelines for the validation of the analytical method. The performance characteristics of the method were in good agreement with both guidelines as earlier described.[21] Table 2 shows the limit of detection (LOD) and limit of quantitation (LOQ) of the target analytes.

Food Frequency Questionnaire (FFQ). A FFQ was administered by trained interviewers. The FFQ was developed on the basis of the consumption habits regarding the target food matrices. In addition to the target food matrices, other food items such as rice, yams, and plantain were also included to cover as many traditional foods as possible. Consumption frequency was measured by a range starting from less than once a month to three times a day. Portion sizes were chosen for each food item according to usual measures: cups for rice and peanuts, slices for yams, and weights for cereal grains and cassava products (pictures depicting the different portion sizes were presented during the interview). The FFQ was applied to 30 randomly selected households living in each village. A total of 300 households (520 individuals) from the 10 villages investigated were collected. The 300 households were evenly distributed throughout the two sampling seasons. Each participating household was expected to provide at least one of the three dietary staples. The body weight of a child and that of an adult (from the same household) were recorded together with the food intake and were used for risk assessment using the deterministic approach.

Statistical Analysis. The SPSS software version 20.0 (SPSS Inc., Chicago, IL, USA) program was used for statistical analysis. For exposure assessment, the mean of the entire sample population was used for the calculations with samples <LOD given a value of LOD/2. A nonparametric Mann–Whitney test for two independent samples and a Kruskal–Wallis test for k independent samples were used to evaluate possible differences in the mean (mean rank) mycotoxin levels across the different agro-ecological zones and sampling sessions, after evaluation of the homogeneity of variances with Levene's test. In addition, a contingency test was used to evaluate the possible differences between the incidences of each mycotoxin within the different sample categories. The mean values were calculated for the different sample categories, taking into consideration the negative samples. A p value of 0.05 was used to determine the statistical significance.

RESULTS AND DISCUSSION

General Mycotoxin Contamination Pattern. Of all food samples, 51% (215/420) were found to be contaminated with at least one of the 25 mycotoxins. The contamination rates for each sample matrix were as follows: 74, 62, and 24% for maize, peanut, and cassava products, respectively (Table 3).

Occurrence of Mycotoxins in Maize Samples. DON and its acetylated derivatives (sum of 3-AcDON and 15-AcDON (∑AcDON)), ZEA, ROQC, BEA, aflatoxins (AFB_1 and AFB_2), and fumonisins (FB_1, FB_2, and FB_3)) were detected in the maize samples. The fumonisins (sum of FB_1, FB_2, and FB_3) had the highest occurrence rate (74%, 122/165) in maize samples (Table 3) with the concentration FB_1 in all positive samples being greater than those of FB_2 and FB_3. The highest concentrations of FB_1, FB_2, and FB_3 detected were 5412, 2890, and 2180 μg/kg, respectively (Table 4), which were higher than the levels recently reported (2313 μg/kg) from the same country.[12]

[a]Data summarized from the two sampling periods. [b]DON, deoxynivalenol; PA, penicillic acid; 3-AcDON, 3-acetyldeoxynivalenol; 15-AcDON acetyldeoxynivalenol; AFB_2, aflatoxin B_2; AFB_1, aflatoxin B_1; FB_1, fumonisin B_1; FB_3, fumonisin B_3; OTA, ochratoxin A; FB_2, fumonisin B_2; BEA, beauvericin; ROQC, roquefortine C; ZEA, zearalenone; ΣAcDON, sum of 3-AcDON and 15-AcDON. [c]Ratio of positive samples to the total number of samples analyzed for that particular matrix.

For every DON positive sample, co-occurrence of 3-AcDON and/or 15-AcDON was also detected except in five samples for which the levels of ∑AcDON were below the method LOQ (16 μg/kg). The presence of DON (20/165; 27–3842 μg/kg) and its metabolites (∑AcDON (17/165)) in maize has often been associated with samples originating from temperate regions such as northern Europe and North America.[23] However, reports emerging from tropical countries, especially from sub-Saharan Africa, continue to reveal the occurrence of DON in maize and maize products.[24] Furthermore, the detection of DON in the urine of toddlers (1.5–5 years) from Cameroon[13] also affirms its presence in food commodities originating from sub-Saharan Africa. The maximum level for DON in unprocessed maize was set by Commission Regulation 1881/2006[16] at 1750 μg/kg. Despite its relatively low occurrence rate (12%), eight samples were contaminated above the maximum level set by the European Commission.[20]

AFB_1 and AFB_2 were detected in maize samples at rates of 22 and 18%, respectively, and mean levels and the range detected for AFB_1 and AFB_2 are presented in Table 4. Between the different years of sampling, there were no statistically significant differences in the mean concentrations; 111 and 127 μg/kg for AFB_1 and 23 and 18 μg/kg for AFB_2 in sampling periods 1 and 2, respectively. A total of 35% (13/37) and 24% (9/37) of the aflatoxin positive samples obtained in sampling periods 1 and 2, respectively, exceeded the maximum level of 10 μg/kg of total aflatoxins in maize as specified in Commission Regulation 1881/2006.[16]

Members of the *Penicillium* spp. are well-known colonizers of maize silages, leading to the production of ROQC. Recently, ROQC production in maize fields prior to harvesting was demonstrated, contradicting the belief that *Penicillium* toxin formation occurs exclusively during storage.[25] This might possibly explain the occurrence of ROQC in maize samples originating from Cameroon. Its presence in 19% (32/165; 1–

181 μg/kg) (Tables 3 and 4) of the maize samples should not be underestimated.

BEA was detected in 16/165 (10%) of the maize samples at levels of 15−412 μg/kg. BEA, a cyclic hexadepsipeptide, is produced by various *Fusarium* spp. such as *Fusarium avenaceum*, *Fusarium lateritium*, *Fusarium scirpi*, and *Fusarium oxysporum* and structurally relates to the enniatins.[26−28] Three percent of maize samples originating from southern Nigeria were found to be contaminated with the enniatins.[29] In this study, the majority of the BEA positive samples were detected in the HFM. Considering the close geographical location of both southern Nigeria and the HFM of Cameroon (latitude 0−10° N) the presence of BEA in maize samples from Cameroon further strengthens earlier reports that BEA and enniatins are natural contaminants in maize samples originating from sub-Saharan Africa. Recently, a 93% occurrence rate of these mycotoxins was found in maize beer from Cameroon.[12] With very little or no information on its potential toxic effects in humans and no legislation with regard to its maximum level, the potential health risk associated with its exposure cannot be estimated.

The occurrence of ZEA in agricultural commodities has not been rigorously investigated in sub-Saharan Africa. It was first reported in South African maize and subsequently recovered in maize and other commodities elsewhere on the continent.[30] The maize samples analyzed in this study showed a 14% (23/165) occurrence rate for ZEA, with none of the samples exceeding the maximum level of 350 μg/kg for unprocessed maize products.[20] The detected concentration range was 27−334 μg/kg (Table 4). Compared to other reports on the occurrence of ZEA in maize samples from sub-Saharan Africa, the levels detected in this study were lower than levels previously reported[29] in maize samples from Nigeria (up to 779 μg/kg). ZEA was also reported in maize samples from Cameroon with a mean of 68 μg/kg and a maximum concentration of 309 μg/kg.[12]

Occurrence of Mycotoxins in Peanut Samples. AFB_1 and OTA were the main contaminants in peanut samples. The occurrence rate and levels of AFB_1 (26/90, 6−125 μg/kg) were considerably higher than those of OTA (12/90, 0.3−12 μg/kg) (Tables 3 and 4). From this study, the concentrations of aflatoxins detected in peanut samples can be said to be comparatively low when compared with data from other sub-Saharan African countries. Similar results have been reported in Kenya, where 96% of raw podded peanuts had levels <4 μg/kg and only 4% had levels >10 μg/kg.[31] Meanwhile, in Botswana, concentrations of 12−329 mg/kg in raw peanuts were reported.[32]

The European Commission has fixed stringent maximum levels for total aflatoxins and AFB_1 in peanuts intended for direct human consumption at 2 and 4 μg/kg, respectively, which has led to a serious impact (export products have plummeted) on the economy of several African countries.[33] The Codex Alimentarius Commission also adopted the limit for total aflatoxins at 15 μg/kg in peanuts;[34] nevertheless, the WHO prescribed the maximum level of 5 μg/kg for AFB_1 in various foodstuffs.[35] The levels of AFB_1 in 13 of the 26 AFB_1-positive samples exceeded the maximum level as specified in Commission Regulation No. 1881/2006[16] with 8 samples exceeding 100 μg/kg.

Occurrence of Mycotoxins in Cassava Products. Fermented cassava (flakes) had a higher contamination rate (32%) than cassava chips (nonfermented products) (15%). For cassava flakes, AFB_1 and PA were detected at concentrations that ranged between 6 and 194 μg/kg and between 25 and 184 μg/kg, respectively (Table 4), whereas for the nonfermented cassava products, AFB_1 was the sole contaminant with levels of 6−95 μg/kg. PA was not detected in any of the nonfermented products, suggesting that cassava flakes constitute a suitable substrate for growth of *Penicillium* spp. and hence mycotoxin production. Significant levels of other acidic mycotoxins such as tenuazonic acid, cyclopiazonic acid, and patulin have also been

reported[36] in dried cassava products originating from Ghana. The levels of PA reported herein (25−184 μg/kg) were lower than levels (60−230 μg/kg) previously reported[36] from Ghana.

The occurrence of aflatoxins in cassava products is still a topic of debate. Studies conducted in Tanzania,[37] Nigeria,[38] and Benin[39,40] reported no aflatoxins in market cassava products. In contrast, a recent survey conducted in Tanzania and the Republic of Congo showed the occurrence of AFB_1 in market cassava samples.[41] Furthermore, studies with dried cassava products (Kokonte) from markets in Ghana[36] showed the presence of STE, a precursor of AFB_1. This necessitates further research be carried out in other African countries on cassava products to fully comprehend the aflatoxin problem in cassava products. Cassava fermentation is thought to lower the microbial load and hence mycotoxin contamination. However, if appropriate storage systems are not implemented, this might lead to fungal growth and possibly mycotoxin contamination.[42]

Given that only 3/65 nonfermented cassava samples had AFB_1 above 10 μg/kg, it can be said that consumption of nonfermented cassava products might not pose a serious risk to the populations concerned, compared with maize and peanut. However, continuous monitoring and surveys are needed to mitigate any future disease outbreaks and adverse health effects. At this moment, there are no existing regulations on mycotoxins in cassava products.

Differences in the Mycotoxin Pattern across the Different Agro-ecological Zones and Sampling Years. The mean (geometric mean) and concentration range of each of the detected toxins for a given sample matrix and agro-ecological zone are given in Table 4. To understand the distribution of mycotoxins across the different agro-ecological zones, a pairwise comparison of the mean mycotoxin concentration from a given agro-ecological zone and sample matrix was compared with the levels detected across the other two agro-ecological zones. Differences between the two different sampling years were also evaluated.

Maize Samples. Irrespective of the year of sampling, the mean FB_1 levels in samples from the HFM and WH regions were significantly higher (p = 0.01 for HFM and 0.032 for WH) than the mean levels detected in samples from the HFB (Table 4). The same trend was also observed when the sum of the fumonisins was considered. Although differences in climatic conditions across the different agro-ecological regions can explain the observed distribution of fumonisins, other determinants such as differences in preferred storage conditions across the different regions cannot be ruled out. The HFB is a transition zone from rain forest to savanna, which is characterized by four seasons, unlike the two other agro-ecological regions. Taking into consideration the prevailing weather conditions and agricultural practices in the HFB region, one would anticipate a high rate of mycotoxin occurrence as this region is characterized by two periods of seasonal rainfall during which harvesting is carried out under intense rainy conditions. Furthermore, data extracted from prevalidated questionnaires revealed that 84% of the households harvested the matured cobs while still fresh, with the remaining 16% of the cobs left in the farms to dry before being harvested. A combination of the prevailing weather conditions (four seasons), agricultural practices such as harvesting under intense rainy conditions, and allowing the cobs to dry in the field could have favored potential mold growth, but it was not the case in this study. Samples from this region showed lower levels of FB_1 contamination than samples from the two other regions.

With regard to the different years of sampling, significant differences were observed in the mean fumonisin levels (sum of FB_1 + FB_2 + FB_3) between the first and second years of sampling (p = 0.02), with significantly higher levels in the second year than in the first year of sampling. This can be explained by the long and heavy seasonal rains, which occurred from February to September 2010, whereas in 2009 the duration of seasonal rains was considered to be moderate for that time of the year.[43] Similarly, the mean levels of DON and ∑AcDON were significantly higher (p = 0.001 for DON and 0.01 for ∑AcDON) in the second year than in samples obtained during the first year of sampling. Just like the fumonisins, heavy rains, insufficient drying conditions to reach the safe water content levels, and poor storage conditions could be the contributing factors that accounted for these differences in contamination between the two sampling periods. Because *Fusarium* spp. are primarily field mycotoxin producers, mycotoxin production could have occurred in the field.

With regard to aflatoxin contamination in maize samples, the mean concentration of aflatoxins in samples from the HFB was significantly higher (p > 0.05) than those detected in samples collected from the two other regions (Table 4). This trend was not observed for samples obtained during the second sampling year.

No significant differences were observed in the mean levels of ROQC, ZEA, and BEA between the different sampling years (p > 0.05). With respect to the agro-ecological zones, a trend was observed; the mean levels of ROQC in samples from the WH region were significantly higher than those obtained from HFM and HFB. For ZEA and BEA, no significant differences were found across the different agro-ecological zones (Table 4).

Mycotoxins in Peanut and Cassava Products. The mean AFB_1 levels detected in peanut samples from the HFM were significantly higher than those detected in samples from the HFB (p = 0.012), but no significant differences (p > 0.05) were observed when levels of the toxins detected in peanut samples from the WH and the HFM were compared (Table 4). Likewise, no significant differences were observed in the mean OTA levels in peanut (p > 0.05) across the different agro-ecological zones.

Given that cassava is a root crop, the levels of mycotoxins in cassava are less known to be associated with seasonal and climatic conditions. Hence, contamination could occur only during and/or after processing.

Significant differences in the mean AFB_1 levels were observed across the different agro-ecological zones. Fermented cassava products (flakes) are mostly consumed in the WH and HFM regions, whereas cassava chips are predominantly eaten in the HFB. Irrespective of the sampling year, the mean AFB_1 levels in the fermented cassava products from the WH and HFM regions were significantly higher (p = 0.021 and 0.015, respectively) than those detected in nonfermented samples. This observation suggests that fermentation increases the microbial load, which might have led to AFB_1 production. Similar observations highlighted the fact that the distribution of aflatoxin in positive samples depended on parameters such as pH, moisture content, storage duration, type of chips (fermented cassava), size of chips, level of contamination by aflatoxin-producing fungi, processing practices, and storage facilities.[9] No significant differences (p > 0.05) were found in the mean AFB_1 levels in cassava samples (both cassava chips

and flakes) originating from both the WH and tHFM regions. As previously mentioned, PA was not detected in the nonfermented cassava products.

Consumer Risk Assessment. Exposure to mycotoxins of the different subpopulations was estimated by considering the consumption data obtained from the FFQ and the mean concentrations of mycotoxin (including samples with concentrations <LOD) for the different agro-ecological zones (deterministic approach). Data were computed for infants as well as for adults. The calculated exposure was compared with health-based guidance values (tolerable daily intake (TDI))[44−49] and also expressed as percentage of the analyte-specific TDI exceeded (%TDI calculated as ((calculated exposure/TDI) × 100)). %TDI < 100 implies the TDI for the specific mycotoxin was not exceeded.

Because AFB_1 is a genotoxic carcinogen, there is no set TDI. However, a provisional range of 0.11−0.19 ng/kg bw/day was proposed[49] for the African and Asian populations that might also be predisposed to hepatitis B virus (HBV). For the purpose of this study and for comparing the risk of the different populations, a mean value of 0.15 ng/kg bw/day was used.

Portion sizes of 0.03 and 0.2 kg per day were considered average for an infant and adult, respectively (average intake from the FFQ). Median weights of 60 and 15.2 kg were also assumed to be representative for an adult and infant (<2 years), respectively.

The calculated average exposure for all of the mycotoxins for households in the HFM and WH were in general higher than the average exposure for households in the HFB except for the aflatoxins (Tables 5 and 6). For the aflatoxins, exposure was in the order HFB > WH > HFM and HFM > HFB > WH for years 1 and 2, respectively, for both adults and infants. With regard to maize intake, the calculated exposure for FB_1 calculated for both adults and infants in both the HFM and WH regions exceeded the TDI (Tables 5 and 6). In general, exposure was higher in adults than in infants despite the higher body weight of the adults. Likewise, the TDI for AFB_1 was exceeded in the range of 10^4−10^5% TDI (Tables 5 and 6) irrespective of the agro-ecological region and growth category (infant or adult). The TDIs for ZEA, OTA, DON, and ΣAcDON were not exceeded (<100% TDI) for both the infant and adult populations for the different sampling seasons and agro-ecological regions.

With respect to peanut consumption, exposure to AFB_1 calculated for both the infant and adult populations was in the range of 2.8×10^3−5.7×10^4% TDI. On the other hand, exposure calculated for OTA was not exceeded (<100% TDI) for both the infant and adult populations (Tables 5 and 6). With respect to cassava consumption, data from Tables 5 and 6 reveal that the TDI for AFB_1 was exceeded (1.3×10^3−1.3×10^4% TDI) by both the infant and the adult populations in all three agro-ecological regions and during the different sampling seasons. The potential consequences that might arise following chronic exposure to these mycotoxins should not be underestimated.

A putative mycotoxin contamination pattern from three agro-ecological regions in Cameroon using maize, peanut, and cassava products as food models was established. Whereas significant differences in the mean mycotoxin levels were observed across the different agro-ecological zones, exposure was significantly higher in the HFM and WH regions and lowest in the HFB (but not for the aflatoxins), irrespective of the sampling period. Furthermore, the mean concentration of

the mycotoxins detected in maize samples obtained from the second year (2010−2011) of sampling was significantly higher than those of the first year (2009) of sampling, which suggests a possible influence of preharvest (e.g., climatic changes) and/or postharvest (e.g., storage practices) practices on mycotoxin contamination from year to year. To summarise, a total of 51% of the samples were contaminated with one or more mycotoxins. The rates of contamination were 74, 62, and 24% for maize, peanut, and cassava products, respectively. Hence, mycotoxin contamination constitutes a major problem in agricultural staples from Cameroon. The relative abundance of the mycotoxins was as follows: FB1 > FB2 > FB3 > AFB1 > AFB2 > ROQC > ZEA > OTA > DON > ∑AcDON > BEA > PA.

Data from the deterministic risk assessment showed that the calculated exposure for infants as well as adults exceeded the TDI through maize, peanut, and cassava consumption. On the basis of the calculated exposure, the TDI was exceeded for FB_1 and AFB_1 following maize consumption. Likewise, exposure to AFB_1 through cassava consumption was also exceeded. Particular attention should be paid to AFB_1, especially in populations with a very high prevalence of HBV (10%). Vulnerable groups and/or individuals (such as elderly or immune-compromised people and pregnant women) living in these study zones should be alerted to the potential danger arising from the consumption of mycotoxin-contaminated foodstuffs. There is a need to carry out periodic surveys and awareness campaigns in the high-risk regions (HFM and WH) to educate subsistence farmers as well as other agricultural stakeholders on the merits of good agricultural practices in relation to reducing mycotoxin exposure.

Effects of Antioxidants of Bamboo Leaves and Flavonoids on 2-Amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) Formation in Chemical Model Systems

Yan Zhang, Zhou Luo, Zeping Shao, Chundi Yu, and Shuo Wang*

Key Laboratory of Food Nutrition and Safety, Ministry of Education of China, Tianjin University of Science and Technology, Tianjin 300457, China

ABSTRACT: The inhibitory effects of antioxidants of bamboo leaves (AOB) and flavonoids against 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) formation were investigated in creatinine and phenylalanine model systems. AOB and the tested flavonoids (orientin, homoorientin, vitexin, isovitex, apigenin, luteolin, isorhamnetin, fisetin, and hesperetin) had significant dose-dependent inhibition effects on PhIP formation with different IC_{50} values. The superoxide anion ($O_2^{\bullet-}$) scavenging activities of these nine flavonoids were evaluated using the pyrogallol autoxidation system. The EC_{50} values of compounds that showed antioxidant activity were found to correlate well (R^2 = 0.8003) with the corresponding IC_{50} values representing their inhibition of PhIP formation. It was assumed that the inhibitory effects of flavonoids on PhIP formation were probably achieved by scavenging free radicals generated in the reaction system. These findings provide valuable information for the development of effective strategies to minimize heterocyclic amine content in thermally processed food.

KEYWORDS: *heterocyclic amines, 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP), antioxidants of bamboo leaves (AOB), flavonoid, free radical scavenging, chemical model systems*

INTRODUCTION

About 30 years ago, Japanese scientist Sugimura discovered a new group of highly mutagenic compounds by means of an Ames test, which were classified as heterocyclic amines (HAs).[1] HAs are generally formed in a wide variety of heated proteinaceous foods and are known to be carcinogenic and mutagenic in rodents and are considered to be potential human carcinogens. Epidemiological studies have provided evidence that the risks of colorectal adenoma and lung cancer were increased by the intake of well-done or grilled meats containing HAs mutagens.[2,3] There are two main categories of HAs, polar and nonpolar HAs. The latter category has been shown to be responsible for most of the HA-associated mutagenic activity detected in food. Among these, 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP), which is generally found in the highest abundance from normal cooking procedures, induces mammary and colon carcinomas in rats in a clear dose-dependent manner.[4,5]

In 1987, Shioya[6] discovered that PhIP was produced by heating a mixture of creatinine, phenylalanine, and glucose. It was suggested that the Maillard reaction between phenylalanine and glucose was responsible for producing the intermediates that condense with creatinine to form PhIP. In the following years, using ^{13}C-labeled phenylalanine and creatine, it was demonstrated that phenylalanine and creatine were precursors of PhIP formation under conditions of dry heating.[7] Although the complete reaction mechanism is still not fully established, phenylacetaldehyde is believed to play a key role by undergoing an aldol condensation with creatinine.[8]

In view of their potent mutagenic activity as well as the fact that they can even be formed during ordinary household cooking, a great deal of attention has been focused on developing strategies which can effectively lower the content of HAs in foods, to reduce overall human exposure.[9] Ever since the early 1980s, scientists have been researching methods such as microwave cooking marinated foods and antioxidant compounds to reduce the level of HAs generated in daily diets. Felton[10] discovered that the mutagenicity of beef cooked by microwave heating was reduced by 95% compared with beef prepared by normal cooking methods, suggesting that the amount of HAs generated by microwave cooking was reduced. Salmon[11] demonstrated that pretreating chicken with marinade reduced the amount of HAs formed. Kato[12] discovered that in a creatinine/glycine/glucose model system with butylated hydroxyanisole, propyl gallate, and other spiked antioxidants, the formation of HAs was reduced. Cheng also found that both naringenin and epigallocatechin gallate can inhibit the formation of PhIP in chemical model system, which was presumably achieved by scavenging or trapping of phenylacetaldehyde via polyphenol−phenylacetaldehyde adduct formation. This study presented a key mechanism of polyphenol to inhibit PhIP formation.[8,13]

Antioxidants of bamboo leaves (AOB) is a complex mixture of natural antioxidants that was listed in the Chinese Standard GB-2760 as a legal and safe food additive in 2004. AOB was reported to possess strong antioxidant activity and inhibition toward transition metal ions and free radical induced deterioration of macromolecules in vitro.[14] Our prior study discovered that AOB could effectively inhibit HA formation in fried pork, including PhIP formation.[15] In this study, the effects of AOB in combination with flavonoids on the formation of

PhIP were explored using a PhIP-forming chemical model system. The relationship between the inhibition effect of flavonoids on PhIP formation and superoxide anion ($O_2^{\bullet-}$) scavenging ability was also investigated in an effort to determine the inhibitory mechanism of flavonoids toward PhIP formation.

MATERIALS AND METHODS

Chemicals and Apparatus. Phenylalanine, diethylene glycol, creatinine, luminol, and pyrogallol were obtained from Sigma-Aldrich Co. (St. Louis, MO, USA). PhIP was from Toronto Research Chemicals (Toronto, Canada). Antioxidants of bamboo leaves were from Shengshi Biology (Huzhou, China). Orientin, homoorientin, vitexin, and isovitex were purchased from Bestbiotech (Tianjin, China). Apigenin, luteolin, isorhamnetin, and fisetin were purchased from J&K Chemical (Beijing, China).

Si-SCX-2 cartridges (200 mg, 3 mL) were purchased from Silicycle Inc. (Quebec, Canada). Hypersep C18 cartridges (200 mg, 3 mL) were obtained from Thermo Electron Corp. (Bellefonte, KY, USA).

LC-MS/MS was performed on an Agilent 1200 series HPLC system coupled to an Agilent 6410 triple-quadrupole mass spectrometer equipped with electrospray ionization (ESI) (Waldbronn, Germany). Chemiluminescence analysis was carried out on a Thermo Fluoroskan Ascent FL. The vortex was purchased from IKA (Baden, Germany). The block heater (Stuart SBH200D) was purchased from a dealer of Stuart, Beijing XinKaiLong Bio Co. Ltd. (Beijing, China).

Effects of AOB and Flavonoids on PhIP Formation in Chemical Model System. The PhIP-producing model system consisted of 2.08 mg of creatinine and 3.2 mg of phenylalanine, weighed and mixed in 2 mL of diethylene glycol in Hach Cod digestion vials by vortexing. The vials were inserted into a block heater set at 120 °C and heated for 2 h. After heating, the vials were cooled in water.[16,17]

The effects of AOB and flavonoids on PhIP formation were investigated using the PhIP-producing model system. The amounts of added AOB and flavonoids (orientin, homoorientin, vitexin, isovitex, apigenin, luteolin, isorhamnetin, fisetin, and hesperetin) were 0.25, 0.5, 1, 1.5, 2, 2.5, and 5 mg/mL. Samples without any AOB or flavonoids were used as the controls. All experiments were performed in triplicate.

Extraction of PhIP from the Model System. The procedure was carried out according to that of Zhang et al. with minor modifications. Solid phase extraction (SPE) was used to extract the PhIP from the solution where the chemical reaction was conducted in the presence of precursors. The Si-SCX-2 cartridge was prewashed with 5 mL of MeOH followed by 5 mL of H_2O/0.1 M HCl (1:1, v/v). The cartridge was then dried under vacuum and washed with 3 mL of 0.01 M HCl followed by 3 mL of 0.1 M HCl/MeOH (9:1, v/v). PhIP was eluted with 10 mL of 1.5 M NH_4AC/MeOH (9:1, v/v) and further purified by C18 cartridge. C18 cartridge was preconditioned with 5 mL of MeOH followed by 5 mL of H_2O, and then the PhIP eluent from the Si-SCX-2 cartridge was loaded onto the C18 cartridge. After washing with 10 mL of ultrapure water, the PhIP was eluted with 2 mL of MeOH/NH_3H_2O (25%) (9:1, v/v). The eluent was then evaporated to dryness under nitrogen and redissolved in 1 mL of MeOH. After filtering through a 0.22 μm organic filter, 1 μL of the purified extract was analyzed by LC-MS/MS.[18]

Quantitation of PhIP by LC-MS/MS. A C18 column (2.1 × 150 mm, 3.5 μm; Agilent) was selected for the chromatographic separation and quantitation of PhIP. To achieve stable and better separation, the column temperature was 25 °C, with a binary mobile phase at a flow rate of 0.2 mL/min. Mobile phases A and B consisted of acetonitrile and 10 mM ammonium formate/formic acid (pH 3.5), respectively. The gradient program was as follows: 0 min, 10% A; 10 min, 60% A; 14 min, 10% A. The post-time re-equilibration was 9 min. Positive ion mode and multiple reaction monitoring mode were used for MS/MS detection. The electrospray ionization parameters were optimized as nebulizer pressure of 40 psi and capillary voltage of 4000 V. Nitrogen was used as the nebulizer, drying, and collision gas. The drying gas flow rate was 10 L/min, and the drying temperature was 350 °C. For each transition, the dwell time was 80 ms.

Free Radical Scavenging Activity Determination. A pyrogallol autoxidation system, in which superoxide anion ($O_2^{\bullet-}$) was generated by pyrogallol autoxidation and used to oxidize luminol to produce a proportional strong chemiluminescence signal, was employed to determine the free radical scavenging activities of AOB and flavonoids according to the method of Li et al.[19,20] with some modifications. The scavenging effect of flavonoids on ($O_2^{\bullet-}$) could be obtained by observing the decease of emission light intensity. The reaction mixture contained 50 μL of pyrogallol (1×10^{-3} M) in 10 mmol/L HCl, 140 μL of carbonate buffer (50 mM, pH 10.2), and 20 μL of luminol (1×10^{-3} M) in 50 mmol/L NaOH.

The sample solution was first placed in a Costar 96-well plate, then the carbonate buffer and luminol were added, and the contents were mixed. Then, pyrogallol was added and chemiluminescence analysis was started immediately. The emission light intensity was recorded every 5 s, and the total integral of the light intensity over 60 s was determined. The control reaction was performed in the same manner as the mixture without the sample solution, and the background was measured without pyrogallol addition.

Statistical Analysis. Data were reported as the mean ± SD for triplicate determinations. One-way ANOVA and Duncan's test were employed to identify differences in means. Statistical analyses were performed using IBM SPSS for Windows (version rel. 19.0, 2010, SPSS Inc., Chicago, IL, USA). Statistical significance was declared at $P < 0.05$.

RESULTS AND DISCUSSION

Effects of AOB on PhIP Formation in Chemical Model System. HAs can be formed when creatine, a specific amino acid, and a monosaccharide are allowed to react at elevated temperatures (usually >100 °C). In this study, the effects of AOB and flavonoids on PhIP formation were evaluated in a chemical model system. AOB comprise a complex mixture that is extracted from specific bamboo leaves from southern China. AOB is of interest as an emerging food additive because of its effects in reducing the level of toxic compounds that accompany food processing. In 2008, Zhang reported that AOB had a significant inhibition effect (percent inhibition ≥ 70%) on acrylamide formation in a low-moisture asparagine−glucose model system.[21] Previously we reported that AOB was better at inhibiting HA formation than some synthesized antioxidants in the fried pork model.[15] However, the food matrix included components such as lipids, proteins, and other unknown substances, which may interfere with HA formation. Thus, in this study, the effects of AOB on PhIP formation were evaluated in a chemical model system. As expected, AOB could effectively inhibit the generation of PhIP in the chemical model system in a similar fashion as exposure to the fried pork. There was a positive correlation between the level of AOB and the reduction in PhIP formation; that is, the more AOB was added, the less PhIP was generated. The PhIP contents were reduced by 13.49, 36.13, 41.82, 45.81, and 52.42% in the system compared with the control as the AOB levels increased (Figure 1). The percent inhibition exceeded 50% when 2.5 mg/mL of AOB was spiked in the chemical model system.

Effects of Reactive Components from AOB on PhIP Formation in a Chemical Model System. AOB, which exhibited good dose-dependent inhibition of PhIP formation in a chemical model system, mainly consists of flavone glycosides, phenolic acids, and lactones. To identify the active components of AOB that inhibited PhIP formation, four flavone glycosides from AOB, orientin, homoorientin, vitexin, and isovitex, were further evaluated. The amount of each flavone glycoside added

dx.doi.org/10.1021/jf500483y | J. Agric. Food Chem. 2014, 62, 4798−4802

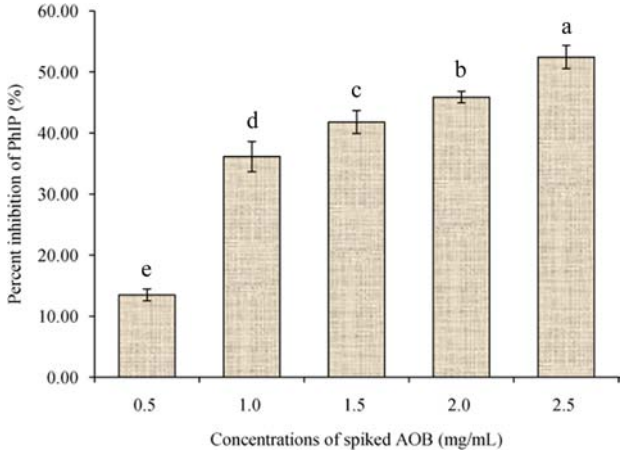

Figure 1. Inhibition effects of AOB on PhIP formation in a chemical model system. Percent inhibition results were statistically analyzed by one-way ANOVA and Duncan's test. Values with different letters are significantly different ($P < 0.05$).

was the same as their levels in the AOB. The results showed that each flavone glycoside obviously inhibited PhIP generation, and the percent inhibition increased with increases in the spiked flavonoids in a similar fashion as with AOB. As shown in Table 1, the dose−effect relationship between the spiked level

Table 1. Inhibition of PhIP Formation by Flavonoids Reported as IC_{50} Values

flavonoid	regression eq	R^2	IC_{50} (mg/mL)
orientine	$Y = e^{(4.514-0.195/x)}$	0.960	0.162
homoorientine	$Y = e^{(4.52-0.194/x)}$	0.971	0.160
vitexin	$Y = e^{(4.52-0.392/x)}$	0.978	0.301
isovitexin	$Y = e^{(4.515-0.364/x)}$	0.993	0.322
fisetin	$Y = e^{(4.729-4.481/x)}$	0.989	2.743
isorhamnetin	$Y = e^{(4.101-0.633/x)}$	0.956	1.675
apigenin	$Y = e^{(4.679-1.136/x)}$	0.981	0.382
luteolin	$Y = e^{(4.574-0.356/x)}$	0.886	0.269
hesperetin	$Y = e^{(4.326-3.519/x)}$	0.959	4.251

of flavonoids and the inhibition of PhIP formation was obtained with a high correlation coefficient. The IC_{50}, the half-maximal inhibitory concentration, was used as the index to evaluate the inhibition effect of flavonoids against PhIP formation. The larger the IC_{50} value, the smaller the inhibition effect. The IC_{50} values of the four flavone glycosides were between 0.16 and 0.322 mg/mL, suggesting slight differences in their inhibition activities on PhIP formation. Orientin and homoorientin were better inhibitors of PhIP generation than vitexin and isovitex. There was no difference in inhibiting PhIP formation between orientin and homoorientin or between vitexin and isovitex at the tested concentrations.

The IC_{50} values of the four flavone glycosides were all smaller than that of AOB, which contains 40% (m/m) flavones. When the spiked AOB was 2.5 times the amount of the added flavone glycosides, the inhibition by AOB was less effective than that of the flavone glycosides alone. This indicated that flavone glycosides may be the dominant components in AOB inhibiting the formation of PhIP.

Effects of Other Flavonoids on PhIP Formation in the Chemical Model System. Because four flavone glycosides (orientin, homoorientin, vitexin, and isovitex) all had dose-dependent effects on PhIP formation, five other flavonoids (apigenin, luteolin, isorhamnetin, fisetin, and hesperetin) were chosen to further explore the relationship between flavonoids and inhibition effects on PhIP formation. The results indicated that apigenin, luteolin, isorhamnetin, fisetin, and hesperetin all inhibited PhIP formation (data not shown). The inhibition activity increased gradually with increases in the amount of flavonoids. Luteolin was the strongest, with 87.06% inhibition at 2.5 mg/mL concentration. Apigenin showed an almost equivalent inhibition effect as that for luteolin, with 85.06% inhibition of PhIP formation. Isorhamnetin also effectively inhibited PhIP formation. Hesperetin and fisetin were weaker inhibitors at the same spiked levels, but when spiked at 5 mg/mL, their potency increased.

The IC_{50} values were obtained from fits to the data using S-curves, which provided the best correlation coefficients. The regression equations and parameters are shown in Table 1. The inhibition of PhIP formation was also found to be strongly dose-dependent upon the concentration of flavonoid added in all cases. Luteolin exhibited the strongest inhibition of PhIP formation followed by apigenin; their IC_{50} values were both <1.0 mg/mL. In summary, the order for the inhibition of PhIP formation was luteolin > apigenin > isorhamnetin > fisetin > hesperetin.

Relationship between Radical Scavenging Activity and Effects of Flavonoids on PhIP Inhibition. Chemiluminescence has been widely used as a sensitive assay for monitoring free radical scavenging by flavonoids. It is commonly accepted that flavonoids may exert their strong antioxidant activity by scavenging free radicals. To explore the connection between free radical scavenging ability and inhibition of PhIP formation, the superoxide anion ($O_2^{\bullet-}$) scavenging ability of flavonoids was investigated. The half-maximal effective concentration (EC_{50}), which is defined as the concentration required for inhibition of 50% of the chemiluminescence intensity, is normally used to express radical scavenging activities. The greater the EC_{50} value, the weaker the radical scavenging activities. Because the emission light intensity reached a maximum after 5 s and was stable, the light intensity at 5 s was selected to calculate the EC_{50} values. The results (Table 2) showed that the nine tested flavonoids

Table 2. Free Radical Scavenging Activities of Nine Flavonoids As Determined by Chemiluminescence Analysis

flavonoid	linear fitting eq	R^2	EC_{50} (μg/mL)
luteolin	$Y = -0.0008x + 0.2834$	0.959	116.9
hesperetin	$Y = -0.0002x + 0.3036$	0.999	566.7
fisetin	$Y = -0.0009x + 0.4497$	0.984	288.3
apigenin	$Y = -0.0006x + 0.2694$	0.882	131.9
isorhamnetin	$Y = -0.0006x + 0.2985$	0.962	180.4
orientin	$Y = -0.0006x + 0.3025$	0.809	187.1
homoorientin	$Y = -0.0006x + 0.2986$	0.869	180.6
vitexin	$Y = -0.0006x + 0.3104$	0.903	200.2
isovitexin	$Y = -0.0007x + 0.3342$	0.945	205.6

had different EC_{50} values, indicating their different radical scavenging activities. The order of the flavonoid EC_{50} values from large to small was luteolin, apigenin, isorhamnetin, orientin, homoorientin, vitexin, isovitexin, fisetin, and hesperetin.

To investigate the relationship between radical scavenging activity and the effects of flavonoids on PhIP formation, the

dx.doi.org/10.1021/jf500483y | J. Agric. Food Chem. 2014, 62, 4798−4802

IC_{50} and EC_{50} values were analyzed by regression analysis. A significant correlation (R^2 = 0.8003) was observed as shown in Figure 2. This indicated that the capacity of flavonoids to

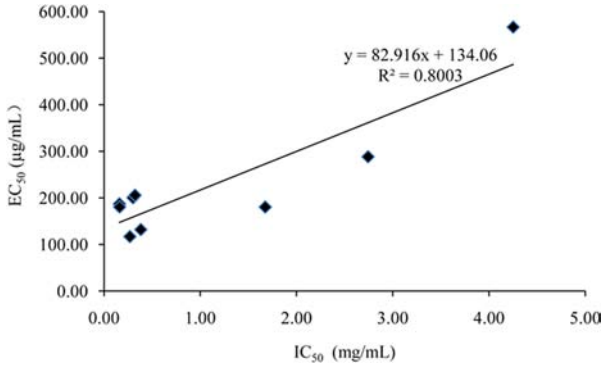

Figure 2. Linear fit of the relationship between IC_{50} (mg/mL) and EC_{50} (μg/mL) in the PhIP model system.

inhibit PhIP formation was highly correlated with their superoxide anion ($O_2^{\bullet-}$) scavenging ability, and the flavonoid-driven inhibition of PhIP formation was likely a result of free radical scavenging during the reaction. This was consistent with the postulated pathway for PhIP formation in which phenylalanine is first converted into phenylacetaldehyde, which then reacts with creatinine to produce the corresponding aldol adduct, which then forms PhIP; there may be free radicals generated during the skeleton degradation.[16] Each flavonoid has a distinct chemical structure, which results in unique antioxidant and free radical scavenging activities and, ultimately, different potencies of inhibition of PhIP formation. It was reported that the degree of hydroxylation and location of the hydroxy groups were the critical factors for determining the antioxidant capacities of flavonoids. The IC_{50} values are likely similar between the specific pairs of isomerides, orientin and homoorientin and vitexin and isovitex, because the chemical structures of the pairs differ only in the position of a hydroxyl group on the sugar moiety.

In conclusion, this study demonstrated that AOB may inhibit PhIP formation in a chemical model system. The results were consistent with previous results that AOB could effectively inhibit PhIP formation better than synthetic antioxidants in fried pork. Four flavone glycosides (orientin, homoorientin, vitexin, and isovitex) from AOB and five flavonoids (apigenin, luteolin, isorhamnetin, fisetin, and hesperetin) all showed dose-dependent inhibition of PhIP formation. The flavonoids varied in their inhibition and superoxide anion ($O_2^{\bullet-}$) scavenging abilities. The IC_{50} and EC_{50} values of the flavonoids correlated, indicating that flavonoids may inhibit PhIP formation via their free radical scavenging abilities. Our explanation is not consistent with the previously proposed mechanism whereby polyphenols were suggested to trap or scavenge phenylacetaldehyde, via adduct formation, to inhibit PhIP formation.[8,13] Indeed, free radical scavenging and phenylacetaldehyde scavenging can occur simultaneously, which may have a synergistic effect on inhibiting the formation of PhIP.

In Vitro Adsorption of Aluminum by an Edible Biopolymer Poly(γ-glutamic acid)

Yesudoss Christu Rajan,[†] Baskaran Stephen Inbaraj,[†] and Bing Huei Chen*[,†,‡]

[†]Department of Food Science and [‡]Graduate Institute of Medicine, Fu Jen University, Taipei 242, Taiwan

ABSTRACT: Accumulation of aluminum in human has been reported to be associated with dementia, Parkinson's disease, and Alzheimer's disease. The objectives of this study were to evaluate an edible biopolymer poly(γ-glutamic acid) (γ-PGA) for aluminum removal efficiency under in vitro conditions as affected by pH, contact time, aluminum concentration, temperature, ionic strength, and essential metals in both aqueous aluminum solution and simulated gastrointestinal fluid (GIF). A low aluminum adsorption occurred at pH 1.5−2.5, followed by a maximum adsorption at pH 3.0−4.0 and precipitating thereafter as aluminum hydroxide at pH > 4. Adsorption was extremely fast with 81−96% of total adsorption being attained within 1 min, reaching equilibrium in 5−10 min. Kinetic data at low (10 mg/L) and high (50 mg/L) concentrations were well described by pseudo-first-order and pseudo-second-order models, respectively. Equilibrium adsorption isotherms at different temperatures were precisely fitted by both Langmuir and Redlich−Peterson models with the maximum adsorption capacities at 25, 37, and 50 °C being 35.85, 38.68, and 44.23 mg/g, respectively. Thermodynamic calculations suggested endothermic and spontaneous nature of aluminum adsorption by γ-PGA with increased randomness at the solid/solution interface. Variation in ionic strengths did not alter the adsorption capacity, however, the incorporation of essential metals significantly reduced the aluminum adsorption by following the order copper > iron > zinc > calcium > potassium. Compared to aqueous solution, the aluminum adsorption from simulated GIF was high at all studied pH (1−4) with Langmuir monolayer adsorption capacity being 49.43 mg/g at 37 °C and pH 4. The outcome of this study suggests that γ-PGA could be used as a safe detoxifying agent for aluminum.

INTRODUCTION

Aluminum is one of the most common and abundant metallic elements in the Earth's crust.[1] Until a decade ago aluminum was regarded as an inert and insoluble mineral that does not pose any threat to human health. Consequently, aluminum containing agents have been used in many applications including food, drinking water, and medicine.[2−4] Moreover, acid rain in recent years has transformed the insoluble aluminum-containing minerals into a more soluble form resulting in accumulation of aluminum in food through drinking water sources.[3,4] Though aluminum compounds are currently used in industrial and pharmaceutical sectors as cosmetics, food additives, and household products, the major route of exposure of aluminum to human is through food.[3,4] Unprocessed foods typically contribute less than 5 mg of Al/kg, however, the use of aluminum-based foils, bowls, vessels, trays, and pans in the presence of acids and salts may elevate the level of aluminum in food.[3] For a 60 kg adult, the mean dietary exposure from food and water was estimated to range from 1.6 to 13 mg of Al/day, which corresponded to 0.2−2.3 mg/kg body weight per week.[3] Nevertheless, the tolerable weekly aluminum intake recommended by EFSA is only 1 mg of aluminum/kg body weight/week.[3] Moreover, several studies have implicated that aluminum accumulation can cause neurotoxicity leading to increased risk of neurological and bone disorders such as Alzheimer's disease, Parkinson's disease, dementia, and osteomalacia.[3−6] Thus, it is important to explore new therapeutic methods to minimize aluminum accumulation in human body.

Theoretically, aluminum mainly exists as a soluble species $Al[(H_2O)_6]^{3+}$ at pH ≤ 4, but at pH > 4, it can be precipitated as $Al(OH)_3$ through transient formation of $Al(OH)^{2+}$ and $Al(OH)_2^+$.[3,7] Accordingly, at physiological pH (5.5−7.4), aluminum should precipitate, preventing its absorption through the gastrointestinal tract. However, several in vivo studies have demonstrated increased accumulation of aluminum during simultaneous administration of aluminum hydroxide and fruit juices or organic acids (citric, ascorbic, and glutamic acids).[7−10] This is because various dietary ligands in conjugation with gastric juice solubilize the aluminum cations, resulting in the equilibrium formation of a soluble complex of aluminum for enhanced absorption and bioavailability.[8,9] Chelation therapy is one of the most common methods used for treatment of patients with metal poisoning. Several chelators such as desferrioxamine and feralex have been found beneficial for reduction of tissue accumulation of aluminum in human.[11,12] Nevertheless, these chelators may cause potential side effects including kidney overload, mineral deficiency, and cardiac arrest.[13] Therefore, it is essential to develop potential and safe detoxifying agents for treatment of aluminum poisoning.

In this study, an edible and biodegradable biopolymer poly(γ-glutamic acid) (γ-PGA) was evaluated as a safe detoxifying agent for aluminum in a batch mode under in vitro conditions. The γ-PGA consists of repetitive glutamic acid

units connected by γ-amide linkages facilitating α-carboxyl groups for conjugation to different compounds (−[−NH−CH(COOH)−$(CH_2)_2$−CO−]$_n$−).[14,15] It is commercially synthesized in different ionic forms (H, Ca, Na, Mg, and NH_4) and varying molecular masses (up to 2 million daltons) using *Bacillus* species by either the de novo method in solid state fermentation or the salvage bioconversion pathway in submerged fermentation.[15,16] Owing to its biocompatible nature, γ-PGA finds application to a wide variety of fields such as food, medicine, hygiene, agriculture, cosmetics, and the environment.[15,16] More specifically, γ-PGA has been used a drug carrier in various biomedical applications.[14−16] Our previous studies on γ-PGA as a metal-adsorbing agent have mainly focused on adsorption of divalent cations like lead (Pb^{2+}), cadmium (Cd^{2+}), and mercury (Hg^{2+}).[14,17] However, its application in adsorbing a trivalent cation like aluminum (Al^{3+}) has not been explored for possible treatment of aluminum intoxication in human. The present work aims to perform an in vitro study to evaluate the adsorbing ability of aluminum by γ-PGA as affected by different parameters like pH, contact time, aluminum concentration, temperature, ionic strength, and essential metals in both aqueous aluminum solution and simulated gastrointestinal fluid (GIF).

MATERIALS AND METHODS

Materials. Aluminum sulfate used for preparation of stock and working solutions was obtained from Sigma-Aldrich (St. Louis, MO). To study the effect of essential metals on aluminum adsorption by γ-PGA, metal salts such as anhydrous copper(II) sulfate and zinc(II) sulfate heptahydrate were procured from Sigma-Aldrich, while potassium chloride, calcium(II) chloride, and iron(II) sulfate heptahydrate were from Nacalai Tesque, Inc. (Kyoto, Japan), JT Baker (Phillipsburg, NJ), and Ajax Finechem (Sydney, Australia), respectively. Chemicals such as sodium acetate, thiourea, and 1,8-dihydroxy-2-(4-sulfophenylazo)naphthalene-3,6-disulfonic acid trisodium salt (SPADNS) used for analysis of aluminum were purchased from Sigma-Aldrich. Sodium chloride and pepsin (a 700 FIP U/g digestive enzyme) used for simulating GIF were obtained from JT Baker and Merck (Taipei, Taiwan). For preparation of different aluminum concentrations and making necessary dilution during analysis, the deionized water collected from a Milli-Q purification system from Millipore Co. (Bedford, MA) was used. The pH of aluminum solution and simulated GIF was adjusted using chemicals such as nitric acid, sodium hydroxide, and sodium bicarbonate obtained from Lab-Scan Analytical Sciences (Bangkok, Thailand), Nacalai Tesque, and Sigma-Aldrich, respectively.

Poly(γ-glutamic acid) As an Adsorbent. The acid form of γ-PGA produced from *Bacillus subtilis* var. Natto was supplied by Vedan Enterprise Corp. (Taichung, Taiwan), and a detailed procedure for synthesis of γ-PGA and its physicochemical characteristics were reported elsewhere.[15] Briefly, the γ-PGA was synthesized by a salvage bioconversion pathway through submerged fermentation generating γ-PGA mostly during the stationary phase of cell growth, and its physicochemical characteristics as provided by the manufacturer are as follows: physical appearance, white and granulate free flow powder; MW, 990 kDa; purity, 95%; particle size, 1−150 μm; clarity (OD_{400}), 0.18; moisture content, 5%; bulk density, 0.32 mg/mL; decolorizing ability (methylene blue dye), 135 mg/g; total heavy metal (as Pb), 15 mg/L; *Escherichia coli* and *Salmonella*, not detectable/1 g; pH_{zpc} value, 4.09; elemental analysis (found/calculated, %): 44.86/46.51 C; 5.91/5.43 H; 10.49/10.85 N; 0/0 S.

Batch-Mode Adsorption Experiments and Aluminum Analysis. Aluminum adsorption experiments by γ-PGA were carried out in a batch-mode by preparing initially 1000 mg/L stock solution using 6.3408 g of aluminum sulfate (Formula weight: 342.15 g) and eventually diluting with deionized water to obtain working solutions with specific concentration. Then, 50 mL of aluminum solution was taken in 125 mL Erlenmeyer flasks and the solution pH was adjusted to a desired value using a Suntex 701 pH meter (Suntex Instruments Co., Ltd., Taipei, Taiwan) connected with a Horiba 9611-10D glass electrode (Horiba Instruments Inc., CA). To the aluminum solution, a known weight of γ-PGA was added, followed by shaking in a Firstek B601D reciprocating water bath shaker (Firstek Scientific Co., Tau-Yen, Taiwan) for predetermined time intervals with speed at 150 rpm and temperature at 37 °C, and filtration through a 0.2 μm membrane filter, and the filtrate was analyzed for aluminum concentration. After several trial experiments were performed, a γ-PGA dose of 0.6 g/L was chosen based on the concentration range (5−100 mg/L) used in the equilibrium study. Blank experiments without addition of γ-PGA were also performed to nullify the possible adsorption of aluminum on experimental flask and membrane filter.

For determination of aluminum in solution, a colorimetric method reported by Rizk et al.[18] was modified and used. To 5 mL of aluminum solution, 2 mL of acetate buffer (pH 5.5), 1 mL of 0.1% (w/v) thiourea, and 2 mL of 0.002 M SPADNS reagent were added sequentially for development of purple color. Next, the intensity of color, which is directly proportional to aluminum concentration in solution, was measured using a Beckman DU 640 spectrophotometer (Beckman Instruments Inc., CA) at a wavelength of 580 nm. Prior to adsorption experiments, a calibration curve for a range of aluminum concentration (0.25−5.0 mg/L) was developed and a linear regression equation ($y = 0.2887x + 0.0377$, $r^2 = 0.995$) obtained was used for quantitative determination of aluminum (Figure 1).

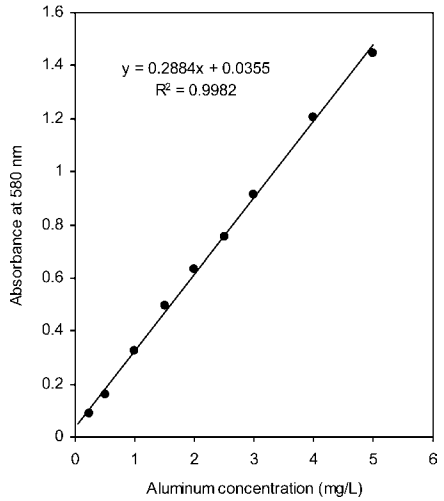

Figure 1. Standard calibration curve for aluminum obtained for a concentration range of 0.25−5.0 mg/L at 580 nm.

Scanning Electron Microscopy. Scanning electron microscopic (SEM) images of pure γ-PGA and aluminum-adsorbed γ-PGA were recorded by adding a few milligrams of each sample in dichloromethane and casting 1 μL of dispersed sample on a silicon wafer. After drying overnight, the samples were coated with platinum using Auto Fine Coater (JEO, JFC-1600, Japan) at 10 mA for 90 s and placed on the sample mount for capturing images using a JEOL JSM-6700F SEM instrument (Japan) at 10 kV. In addition, the energy dispersive X-ray spectroscopy (EDX) was done for aluminum-adsorbed γ-PGA by using an EDX machine from Oxford Instruments (X-max, Oxfordshire, U.K.) connected to the SEM instrument.

Aluminum Adsorption at Different pH. Fifty milliliters of aluminum solutions were adjusted to different pH values at 1, 1.5, 2, 2.5, 3, 3.5, 4, 5, 6, and 7 and shaken with 0.6 g/L of γ-PGA for 2 h at 37 °C. After equilibrium, the aluminum-loaded γ-PGA was filtered for analyzing free aluminum in solution. As precipitation of aluminum as aluminum hydroxide occurred at pH > 4, the pH of aluminum solution was adjusted to pH 4 in all the other adsorption experiments.

Aluminum Adsorption Kinetics. Adsorption kinetics was conducted at two different aluminum concentrations (10 and 50

mg/L) by adjusting 50 mL of aluminum solutions to pH 4 and shaking with 0.6 g/L γ-PGA at 37 °C for different intervals of time (1, 2, 5, 10, 20, 30, 60, 90, and 120 min). After each predetermined time interval, a portion of the aliquot was collected, filtered, and analyzed for aluminum remaining in solution.

Aluminum Adsorption Isotherms and Determination of Thermodynamic Parameters. For developing adsorption isotherms, the equilibrium data were obtained at 9 different aluminum concentrations (5, 10, 20, 30, 40, 50, 60, 80, and 100 mg/L) by adjusting each to pH 4 first, followed by adding 0.6 g/L γ-PGA and shaking for 2 h in a 37 °C water bath. At equilibrium, the unadsorbed aluminum in solution was analyzed for determination of adsorption capacity at each concentration. To determine the thermodynamic parameters such as enthalpy change ($\Delta H°$), entropy change ($\Delta S°$), and free energy change ($\Delta G°$), the adsorption isotherms were also constructed at two different temperatures (25 and 50 °C) and the equilibrium constants obtained were fitted into the classical Van't Hoff equation and Gibbs free energy equation.[17]

Aluminum Adsorption at Different Ionic Strengths. Aluminum removal as affected by the ionic strength encountered in biological matrix was studied based on a method reported by Inbaraj and Chen.[13] Briefly, aluminum solution at 50 mg/L was spiked into four different concentrations (0.001, 0.01, 0.1, and 1 M) of sodium acetate solution and adjusted to pH 4.0. Then, 0.6 g/L γ-PGA was added to each mixture, shaken for 2 h at 37 °C, and filtered and residual aluminum in solution was determined.

Aluminum Adsorption As Affected by Essential Metals. The effect of several biologically essential metals (potassium, calcium, zinc, iron, and copper) on aluminum adsorption by γ-PGA was studied by taking a 1:1 mixture of aluminum and an essential metal as a bisolute system at four different concentrations (5, 25, 50, and 100 mg/L) and adjusting the pH of each to 4.0. To the binary mixture, 0.6 g/L of γ-PGA was added and shaken for 2 h in a 37 °C water bath.

Aluminum Adsorption from Simulated Gastrointestinal Fluid. Initially, gastrointestinal fluid was simulated by adopting a method prescribed by US Pharmacopeia for drug dissolution studies and eventually modified as reported by Inbaraj and Chen.[13] The simulation of GIF involved mixing sodium chloride, hydrochloric acid, and pepsin for a final concentration of 0.03 M, 0.085 M, and 0.32% (w/v), respectively. For assessing the adsorption efficiency of γ-PGA toward aluminum at different gastrointestinal pH, the aluminum solution at 50 mg/L was spiked into GIF, followed by adjusting to different pH values 1, 2, 3, 3.5, and 4, adding 0.6 g/L γ-PGA to each, shaking for 2 h at 37 °C, and analyzing the filtrate for residual aluminum in GIF. Adsorption isotherm was also developed by preparing 9 different aluminum concentrations (5, 10, 20, 30, 40, 50, 60, 80, and 100 mg/L) in GIF, adjusting to pH 4.0, shaking with 0.6 g/L γ-PGA for 2 h, and determining the remaining free aluminum in GIF after adsorption to γ-PGA.

Aluminum Release at Different pH. To elucidate the nature of aluminum adsorption on γ-PGA, aluminum release from aluminum-adsorbed γ-PGA was studied by initially conducting an adsorption experiment with a mixture of 50 mg/L aluminum solution (50 mL) and 0.6 g/L γ-PGA shaking for 2 h at 37 °C. After equilibrium, the aluminum-adsorbed γ-PGA was carefully separated and the supernatant was measured for aluminum concentration. The aluminum-adsorbed γ-PGA was then washed several times with deionized water to remove any unadsorbed aluminum and shaken with 50 mL of deionized water adjusted to different pH values (1, 2, 3, 4, and 5) for 1 h for determining the level of aluminum release.

Data Analyses and Modeling. All the adsorption experiments were carried out in duplicate, and the mean values showed a maximum deviation of only ±5%. Aluminum adsorption capacity at different time intervals (q_t, mg/g) was determined based on the mass balance equation, $q_t = (C_i - C_t)/(V/W)$, where C_i and C_t are aluminum concentration at time 0 and time t, respectively, V (L) is the volume of aluminum solution, and W (g) is the weight of γ-PGA. Similarly, by replacing C_t with C_e and q_t with q_e, aluminum adsorption at equilibrium can be calculated using the equation $q_e = (C_i - C_e)/(V/W)$, where C_e and q_e are concentration and adsorption capacity at equilibrium, respectively.[13,14] Both kinetic and isotherm data were fitted with several theoretical models by using a GNUPLOT program (Copyright Thomas Williams and Colin Kelley, version 4.0 for windows) involving a nonlinear regression method based on the Marquardt–Levenberg algorithm.[13,14] The extent of deviation of theoretical models from experimental data was estimated by obtaining coefficient of determination (r^2) directly from Microsoft Excel and chi-square statistic (χ^2) by substituting the experimental (q_{ex}, mg/g) and predicted (q_{pr}, mg/g) adsorption capacities in the equation $\chi^2 = \sum((q_{ex} - q_{pr})^2/q_{pr})$.[14,17]

RESULTS AND DISCUSSION

Scanning Electron Microscopy for Pure γ-PGA and Aluminum-Adsorbed γ-PGA. Scanning electron microscopic images were recorded for pure γ-PGA and aluminum-adsorbed γ-PGA to visualize the surface changes (Figures 2A and 2B). In addition, the energy dispersive X-ray spectroscopy (EDX) was done for aluminum-adsorbed γ-PGA to confirm aluminum adsorption and its elemental weight percentage on the γ-PGA surface (Figure 2C). The surface of pure γ-PGA seems to be smooth and soft, while aluminum-adsorbed γ-PGA appears rough and agglomerated probably because of conformational change from helix into random coil during aluminum

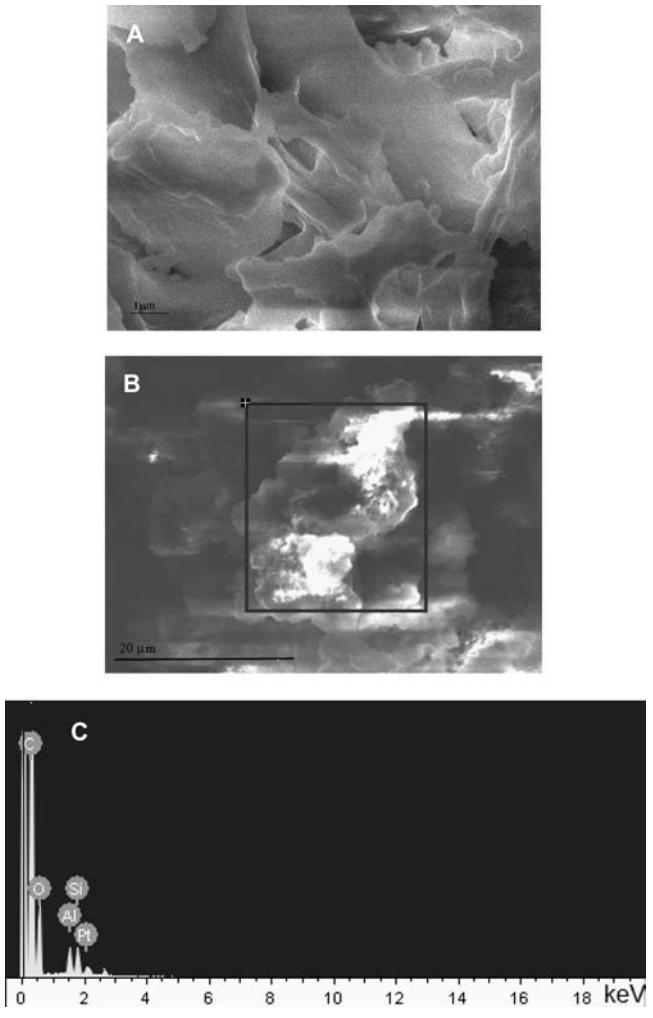

Figure 2. Scanning electron microscopic images of pure γ-PGA (A) and aluminum-adsorbed γ-PGA (B) along with energy dispersive X-ray spectra for aluminum-adsorbed γ-PGA (C). The conditions used for measurements are provided in the text.

dx.doi.org/10.1021/jf5011484 | J. Agric. Food Chem. 2014, 62, 4803–4811

adsorption under the experimental conditions studied.[14,15] The EDX analysis revealed the presence of carbon, oxygen, aluminum, platinum, and silicon at a weight percentage of 63.65, 29.53, 2.55, 2.29, and 1.98%, respectively, confirming adsorption of aluminum on γ-PGA. The presence of carbon and oxygen at high proportion may be attributed to γ-PGA, while the appearance of silicon and platinum peaks should be due to sample casting on silicon wafer and platinum coating steps carried out during sample preparation.

Aluminum Adsorption at Different pH. Given the wide variation in gastrointestinal pH (from highly acidic to slightly basic), an oral therapeutic drug undergoes interaction with varying pH conditions upon administration into the human body.[13,14,19] According to metal−solution chemistry, the variation in pH can affect the speciation of metal and stability of metal complexes.[13] Besides, for a multifunctional polymer like γ-PGA, pH can affect the dissociation ability of functional groups and structural conformation.[20] As mentioned before, the adsorption of aluminum by γ-PGA was studied as a function of different pH (1−7) (Figure 3), which showed an insignificant

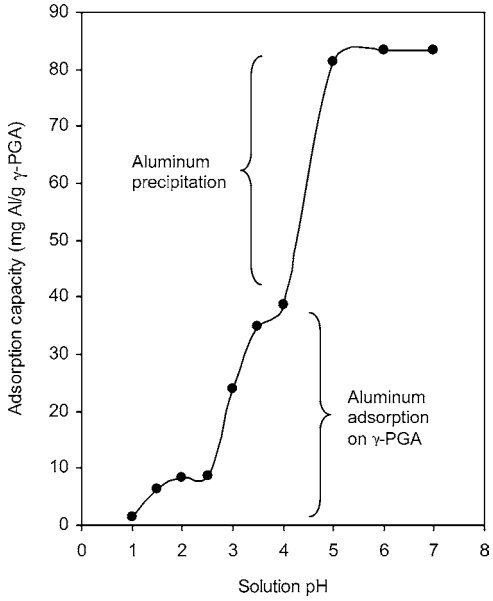

Figure 3. Influence of solution pH on aluminum adsorption by γ-PGA. Initial aluminum concentration, 50 mg/L; pH range, 1−7; γ-PGA dose, 0.6 g/L; temperature, 37 °C; shaking time, 2 h.

adsorption at pH 1, but climbed to 6.2−8.8 mg/g over the pH range 1.5−2.5 (stomach pH). However, a drastic increase in adsorption of aluminum did occur thereafter reaching a small plateau between pH 3.5 and 4. At pH > 4, a large increase in aluminum removal was mainly due to precipitation of aluminum rather than adsorption onto γ-PGA. This tendency can be attributed to the inherent characteristic of aluminum to precipitate as aluminum hydroxide ($Al(OH)_3$) through gradual formation of $Al(OH)^{2+}$ and $Al(OH)_2^{+}$.[3,7] As the maximum adsorption of aluminum on γ-PGA occurred in the pH range 3.5−4, all the subsequent studies were carried out after adjusting the aluminum solution to pH 4.

Upon raising the pH from 2.5 to 4, the adsorption of aluminum by γ-PGA reached 38.7 mg/g. Both solution pH and pH_{zpc} values are the critical factors responsible for the cation adsorption ability by materials rich in carboxyl groups.[13,14] Consequently, at pH < pH_{zpc} of γ-PGA (4.09),[14,15] the carboxyl groups in γ-PGA exist primarily in un-ionized form, thereby allowing only a low degree of metal adsorption at pH < 2.5. In addition, the γ-PGA's ability to form intramolecular hydrogen bonding because of helix conformation at acidic pH may also reduce active sites for cation adsorption.[14] Nevertheless, a more pronounced adsorption of aluminum by γ-PGA at pH > 2.5 may be due to gradual ionization of carboxyl groups in γ-PGA accompanied by a conformational transformation from helix to random coil. It is worth pointing out that when the solution pH is the same as pH_{zpc}, there is an equilibrium existence of 50% ionized and 50% un-ionized carboxyl groups in γ-PGA. Therefore, it is possible that some carboxyl groups may remain ionized even at pH < pH_{zpc}, resulting in a low degree of aluminum adsorption at pH ≤ 2.5. Additionally, the interaction between aluminum and γ-PGA at different pH levels may cause significant change in helix−coil transition thereby favoring aluminum adsorption by γ-PGA even at pH ≤ pH_{zpc}. The aluminum adsorption by γ-PGA can also be explained based on the Pearson's hard soft acid base (HSAB) principle,[14,21] which postulates that hard acids prefer to bind a hard base through ionic interaction, while soft acids prefer a soft base through covalent interaction. Accordingly, aluminum being a hard acid can interact with a hard base like carboxylate anions in γ-PGA through ionic interaction.

Although the adsorption of aluminum by γ-PGA was not practically feasible by in vitro study under physiological pH conditions ranging from 5.5 to 7.4, several in vivo studies have demonstrated an increased aluminum bioavailability during simultaneous administration of aluminum hydroxide and fruit juices or organic acids (citric, ascorbic, and glutamic acids).[7−10] It was also reported that aluminum-complexing dietary compounds in conjugation with gastric acid can solubilize aluminum cations through formation of soluble aluminum complex, thereby elevating aluminum absorption and bioavailability.[9,10] Moreover, in a study on in vitro adsorption of lead and cadmium by γ-PGA, Siao et al.[14] have shown a maximum adsorption in the pH ranging from 4 to 7, indicating that γ-PGA can bind with a metal cation in most of the physiological pH. Nonetheless, the maximum adsorption over a narrow pH range (pH 3.4−4) in this study should be due to tendency of aluminum to precipitate at pH > 4 rather than the inability of γ-PGA to bind aluminum. Moreover, as the pH_{zpc} of γ-PGA is 4.09, the adsorption capacity of aluminum by γ-PGA at pH 4 was due to only 50% ionized carboxyl groups in γ-PGA, which could greatly be enhanced at pH > 4 if the precipitation of aluminum is overcome by complexation with dietary ligands under in vivo gastrointestinal conditions as stated above. Therefore, irrespective of physiological pH, γ-PGA can still be used for aluminum adsorption under in vivo condition.

Aluminum Adsorption Kinetics. Studying the kinetics of aluminum adsorption on γ-PGA is vital for elucidating γ-PGA reactivity and assessing therapeutic efficiency as both the residence time and aluminum absorption in the human body depend on the rate of aluminum uptake.[13,14] Figure 4 illustrates the kinetics for adsorption of aluminum at two different concentrations (10 and 50 mg/L) with a rapid uptake of 81% for 10 mg/L and 96% for 50 mg/L being attained within 1 min and an equilibrium reached thereafter at 5 and 10 min, respectively. This fast adsorption characteristic of γ-PGA implies that the aluminum uptake is mainly caused by mass transfer onto γ-PGA surface with no intraparticle diffusion, which is advantageous for treatment of patients with acute aluminum intoxication. For a low aluminum concentration of

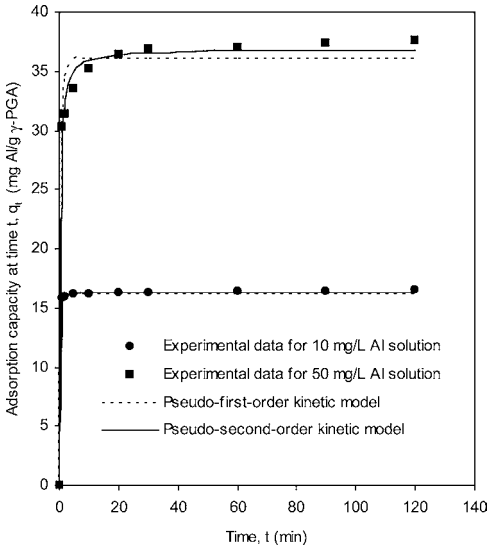

Figure 4. Kinetic profiles and their modeling for aluminum adsorption by γ-PGA. Initial aluminum concentration, 10 and 50 mg/L; pH, 4.0; γ-PGA dose, 0.6 g/L; temperature, 37 °C; shaking time intervals, 1, 2, 5, 10, 20, 30, 60, 90, and 120 min.

50 ppb, a comparable rapid kinetics of 90% and 70% aluminum adsorption within 5−10 min was shown for two different chelating resins iontosorb oxin and polyhydroxamic acid, respectively.[22] Nevertheless, a much slower adsorption rate of 300 min for 20 mg/L and 180 min for 50 mg/L was observed for aluminum uptake by chitosan[7] and date-pit activated carbon,[23] respectively. In order to determine the rate constant and adsorption capacity, the kinetic data were fitted with two classical kinetic models, namely, pseudo-first-order model (eq 1) and pseudo-second-order model (eq 2), and their nonlinear forms are shown below:[13,14,17]

$$q_t = q_e[1 - \exp(-k_1 t)] \quad (1)$$

$$q_t = \frac{t}{\frac{1}{k_2 q_e^2} + \frac{t}{q_e}} \quad (2)$$

where k_1 (L/min) and k_2 (g/mg·min) are the pseudo-first-order and pseudo-second-order rate constants, respectively. Based on error parameters, for 10 mg/L, both pseudo-first-order and pseudo-second order model precisely fitted the kinetic data, with r^2 and χ^2 being 0.998 and 0.024 for the former and 0.999 and 0.003 for the latter, whereas the pseudo-second-order model (r^2 = 0.994, χ^2 = 0.205) fitted the kinetic data for 50 mg/L better than the pseudo-first-order model (r^2 = 0.978, χ^2 = 0.741). This outcome revealed a dominant ion exchange mechanism involving carboxyl groups at low aluminum concentration.[14] On the contrary, at a higher aluminum concentration, the adsorption of aluminum onto γ-PGA may also involve chemical forces through participation of amide groups, as the pseudo-second-order model is usually applied to reactions involving valence forces via sharing or exchange of electrons.[13,14] The adsorption rate as determined by the pseudo-first-order and pseudo-second-order models were 15.142 L/min (k_1) and 1.587 g/mg·min (k_2) for 10 mg/L, respectively, while a relatively lower rate was observed for 50 mg/L (k_1 = 1.644 L/min, k_2 = 0.1018 g/mg·min). Likewise, an adsorption capacity of 16.35 mg/g for 10 mg/L and 36.89 mg/g for 50 mg/L was predicted by the pseudo-second-order model.

Adsorption Isotherms. Adsorption isotherms aid in elucidating the interaction behavior between aluminum and γ-PGA, adsorption affinity, adsorption mechanism, and maximum adsorption capacity, which is the key parameter used for comparative evaluation of materials applied as chelators or adsorbents for toxin removal.[13,14] Because of precipitation of aluminum at pH > 4, adsorption isotherms were developed at pH 4 in order to represent the gastrointestinal environment

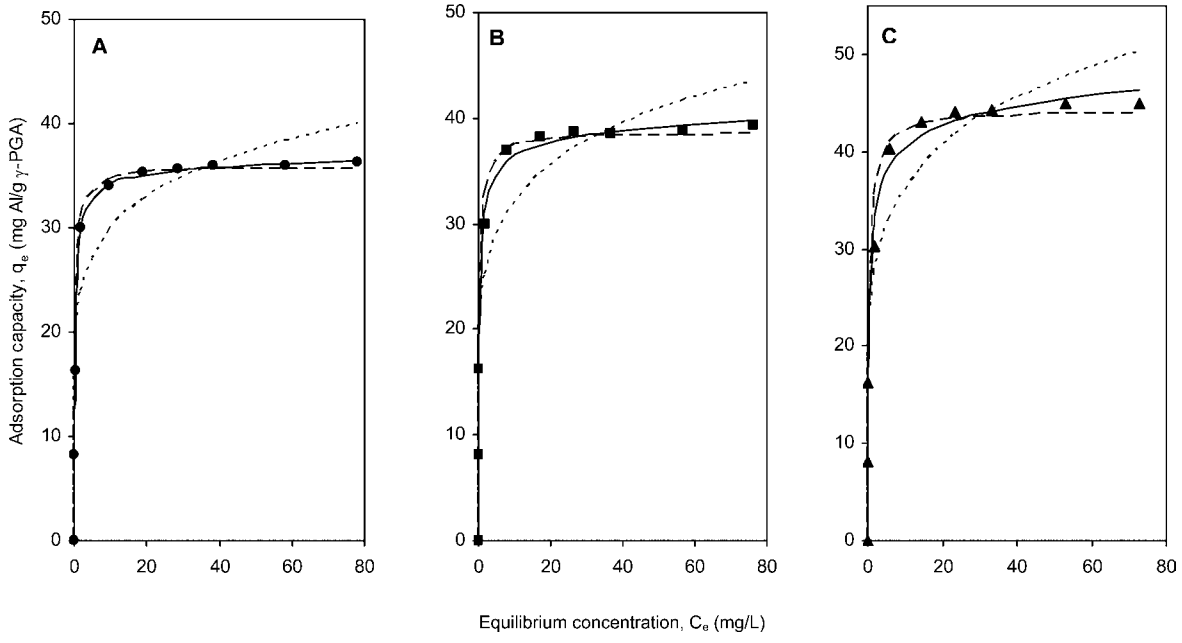

Figure 5. Adsorption isotherms for aluminum uptake by γ-PGA developed at 25 °C (A), 37 °C (B), and 50 °C (C). Initial aluminum concentration, 5−100 mg/L; pH, 4.0; γ-PGA dose, 0.6 g/L; shaking time, 2 h; (●), (■), and (▲) represent experimental data at 25, 37, and 50 °C, respectively. Modeling curves: (- - -), Freundlich isotherm; (− − −) Langmuir isotherm; (—), Redlich−Peterson isotherm.

dx.doi.org/10.1021/jf5011484 | J. Agric. Food Chem. 2014, 62, 4803−4811

(5.5−7.4), as precipitated aluminum can complex with several dietary constituents in the human body leading to formation of more soluble aluminum complex and eventual absorption,[7−10] as pointed out in a preceding section. Figure 5 illustrates the adsorption isotherms developed at three different temperatures (25, 37, and 50 °C) over a range of aluminum concentration (5−100 mg/L). The isotherm at 37 °C was developed to represent the physiological temperature, while both 25 and 50 °C were constructed to facilitate determination of thermodynamic parameters. Following a rise in aluminum level from 5 to 100 mg/L, the amount of aluminum adsorption increased from 8.18 to 36.23 mg/g, 8.19 to 39.39 mg/g, and 8.21 to 45.05 mg/g at 25, 37, and 50 °C, respectively (Figure 5), with an apparent elevation in adsorption at higher temperatures indicating an endothermic nature of the adsorption process. Comparison of the isotherm shapes with that reported by Giles et al.[24] revealed an H-type isotherm, which is an extreme case of L-type (Langmuir type), implying occurrence of chemical forces during aluminum adsorption by γ-PGA.[13] Moreover, such an isotherm shape represents a high adsorption capacity at low aluminum concentrations.[14]

Three classical isotherm models, namely, Freundlich (eq 3), Langmuir (eq 4), and Redlich−Peterson (eq 5), were employed to model the isotherm data and obtain some vital information on adsorption characteristics. The nonlinear form of these theoretical isotherm models can be represented as shown in eqs 3−5:[25−27]

$$q_e = K_F C_e^{1/n} \quad (3)$$

$$q_e = \frac{K_L C_e}{1 + K_e C_e} \quad (4)$$

$$q_e = \frac{K_R C_e}{1 + a_R C_e^{\alpha}} \quad (5)$$

where K_F (L^n mg^{1-n}/g) and n are the Freundlich constants denoting adsorption capacity and adsorption intensity, respectively; K_L (L/g) is a product of q_m (mg/g) and K_e (L/mg), representing maximum adsorption capacity and equilibrium constant or adsorption energy, respectively; and K_R, a_R, and α are the Redlich−Peterson constants. Of the three models fitted by the nonlinear regression method, both Langmuir and Redlich−Peterson models could more precisely describe the experimental data at all the three temperatures, as shown by high r^2 values and low χ^2 values compared to the Freundlich model (Figure 5 and Table 1). The best fit by Langmuir model revealed monolayer adsorption of aluminum on γ-PGA without precipitation of aluminum under the experimental conditions studied. The maximum adsorption capacity (q_m) values predicted by the Langmuir model were 35.85, 38.68, and 44.23 mg/g for aluminum adsorption by γ-PGA at 25, 37, and 50 °C, respectively, while the equilibrium adsorption constants were 3.275, 2.989, and 2.188 L/mg. Comparable q_m values of 45.45, 41.32, and 37.17 mg/g were reported for aluminum adsorption by chitosan at 30, 45, and 60 °C, respectively.[7] However, a very low q_m value was reported for several adsorbents including *Curcuma longa* (7.68 mg/g),[2] polyacrylonitrile powder and beads (0.09−0.82 mg/g),[28] date-pit activated carbon (5.83 mg/g),[23] and rice husk char (2.84 mg/g).[29]

Favorability of Aluminum Adsorption by γ-PGA. The adsorption intensity (n) obtained from the Freundlich model (6.1−7.1) ranged between 1 and 10, indicating favorable adsorption of aluminum by γ-PGA. Furthermore, based on the 4 idealized types of equilibrium behavior proposed by Hall et al.,[30] the behavior of each equilibrium type can be explained using a dimensionless equilibrium parameter or separation factor R_L, represented as $R_L = 1/(1 + bC_o)$ where b (L/mg) is the Langmuir constant. Accordingly, the R_L value indicates the shape of the isotherm to be either unfavorable ($R_L > 1$) or linear ($R_L = 1$) or favorable ($0 < R_L < 1$) or irreversible ($R_L = 0$).[20,30] Based on the equilibrium constant predicted by the Langmuir model, the R_L values were calculated to be from 0.003 to 0.058 at 25 °C, 0.003 to 0.063 at 37 °C, and 0.005 to 0.084 at 50 °C, suggesting that a favorable adsorption ($0 < R_L < 1$) of aluminum by γ-PGA occurred (Table 2).

Thermodynamic Parameters. To understand the thermodynamic aspects of aluminum adsorption by γ-PGA, the equilibrium constant (b) values obtained from the Langmuir modeling were fitted into the classical Van't Hoff equation (eq 6) and Gibbs free energy equation (eq 7) for determination of

Table 1. Predicted Isotherm Parameters for Aluminum Adsorption by PGA at Three Different Temperatures (25, 37, and 50 °C)[a]

	predicted isotherm parameters		
	25 °C	37 °C	50 °C

[a]Equation for calculating separation factor (R_L) is provided in the text.

dx.doi.org/10.1021/jf5011484 | J. Agric. Food Chem. 2014, 62, 4803−4811

enthalpy change ($\Delta H°$), entropy change ($\Delta S°$), and free energy change ($\Delta G°$):[17]

$$\Delta G° = - RT \ln K_e \quad (6)$$

$$\ln K_e = - \frac{\Delta H°}{RT} + \frac{\Delta S°}{R} \quad (7)$$

where T is the absolute temperature (K), R is the universal gas constant (8.314 J/(mol K)), and K_e (L/mol) is the equilibrium constant. The negative $\Delta G°$ values of −11.10, −11.32, and −10.95 kJ/mol for 25, 37, and 50 °C, respectively, indicated the spontaneous nature of aluminum adsorption on γ-PGA. Both $\Delta H°$ and $\Delta S°$ can be deduced by plotting ln K_e versus $1/T$ (plot not shown), and the positive $\Delta H°$ value obtained (12.91 kJ/mol) confirmed the endothermic nature of aluminum adsorption. Likewise, the positive $\Delta S°$ (5.76 J/(mol K)) implied increased randomness (decreased orderliness) at the γ-PGA/aluminum solution interface. However, an opposite trend of negative $\Delta H°$ and $\Delta S°$ values were shown for aluminum adsorption by chitosan.[7]

Aluminum Adsorption at Different Ionic Strengths. Ionic strength in biological matrices like blood and urine vary widely when compared to that in most natural waters,[13,19] and therefore it is essential to study the impact of varying ionic strengths on aluminum adsorption by γ-PGA. More importantly, some ion-exchange resins currently employed as oral drugs for toxin removal undergo either swelling or shrinking depending on the ionic strength, ultimately hampering their therapeutic application.[13,19] The aluminum adsorption ability of γ-PGA was evaluated in the presence of varying ionic strengths (0.001−1 M) prepared using different concentrations of sodium acetate. The amount of aluminum adsorption in 0.001 M sodium acetate (38.77 mg/g) did not significantly change when compared to control without sodium acetate (38.67 mg/g). However, the adsorption capacity climbed to 47.12, 50.35, and 49.42 mg/g in 0.01, 0.1, and 1 M solution, respectively. This outcome implied that the varying ionic strengths might not reduce the aluminum adsorption ability of γ-PGA, but elevated its adsorption capacity instead.

Aluminum Adsorption As Affected by Essential Metals. Chelators currently employed in detoxification therapy not only bind the target metal but also remove significant amounts of essential minerals, thereby causing deficiency of essential minerals in the human body.[13,14,19] Consequently, the effect of five essential metals including potassium, calcium, zinc, iron, and copper was studied in a bisolute system incorporating a 1:1 mixture of aluminum:essential metal at four different concentrations (5, 25, 50, and 100 mg/L) (Figure 6). Though sodium is a biologically important essential metal, it was not used for evaluating the effect of essential metals, as sodium salts such as sodium sulfate and sodium chloride were already used in determining both effect of different ionic strengths and simulated gastrointestinal fluid in this study. However, another monovalent alkali metal, potassium, was used instead. Aluminum adsorption by γ-PGA in the presence of essential metals did not show any interference at 5 mg/L for all the essential metals except copper, which reduced the aluminum adsorption by 31.2% when compared to control. Nevertheless, when the concentration rose to 25 mg/L, the aluminum adsorption diminished by 4.4, 4.8, 15.3, 17.9, and 25.8% for potassium, calcium, zinc, iron, and copper, respectively (Figure 6). At 50 and 100 mg/L, the amount of aluminum adsorption by γ-PGA further dropped by 4.2 and 5.7% for potassium, 30.3 and 37.7% for calcium, 31.2 and 55.6% for zinc, 34.2 and 70.7% for iron, and 69.4 and 79.3% for copper, with the impact of essential metals on aluminum adsorption following the order copper > iron > zinc > calcium > potassium (Figure 6). As aluminum adsorption was shown previously to involve ionic interaction, this phenomenon can be explained based on comparison of the electronegativity values of these essential metal ions with aluminum. Among all the 5 metals, the copper, zinc, and iron possessing high electronegativity values of 1.75, 1.66, and 1.64 showed a larger impact on aluminum adsorption, as was only 1.47 for aluminum. Apparently, a lesser interfering effect shown by calcium and potassium may be due to their relatively low electronegativity values, which equaled 1.04 and 0.91, respectively. Nevertheless, by appropriate supplementation of essential metal ions, the loss of aluminum adsorption efficiency by γ-PGA could be prevented during in vivo application.

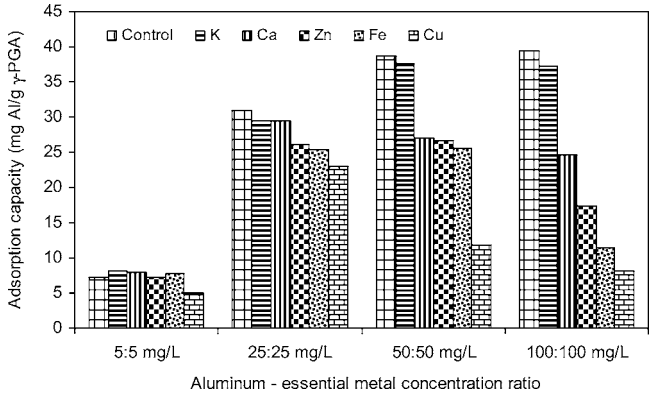

Figure 6. Influence of different essential metals on aluminum adsorption by γ-PGA. Initial aluminum:essential metal concentration, 5:5, 25:25, 50:50, and 100:100 mg/L; γ-PGA dose, 0.6 g/L; pH, 4.0; temperature, 37 °C; shaking time, 2 h.

Aluminum Adsorption from Simulated Gastrointestinal Fluid. In order to understand the effect of gastrointestinal environment, the aluminum adsorption capability of γ-PGA as affected by pH and different aluminum concentrations was determined in simulated GIF. Figure 7A shows the effect of solution pH on the aluminum adsorption efficiency by γ-PGA in GIF along with that in deionized water shown in dotted lines for comparison. A similar trend was observed for both GIF and deionized water, with the adsorption capacity exceeding at all pH levels (1−4) for the former. This outcome should be beneficial for in vivo application. Following a rise in the solution pH from 1 to 4, the adsorption capacity of aluminum from GIF soared from 5.43 to 50.23 mg/g, which was 73.7 to 23% higher than that for deionized water (Figure 7A). As GIF was rich in sodium ions (0.03 M), the high adsorption capacity of aluminum by γ-PGA in comparison with deionized water may be attributed to the extra mobility gained by aluminum ions through competition with sodium ions. Obviously, the ionic radius of sodium (97 pm) being higher than that of aluminum (51 pm) should compete effectively for the active sites on γ-PGA. Yet, when compared to monovalent sodium ions, the trivalent aluminum existing as $Al[(H_2O)_6]^{3+}$ at pH ≤ 4 should succeed in attaching onto γ-PGA through ionic interaction with carboxyl groups.

Adsorption isotherms were also developed over a range of aluminum concentration (5−100 mg/L) for determining aluminum adsorption capacity in GIF. Figure 7B depicts the

dx.doi.org/10.1021/jf5011484 | J. Agric. Food Chem. 2014, 62, 4803−4811

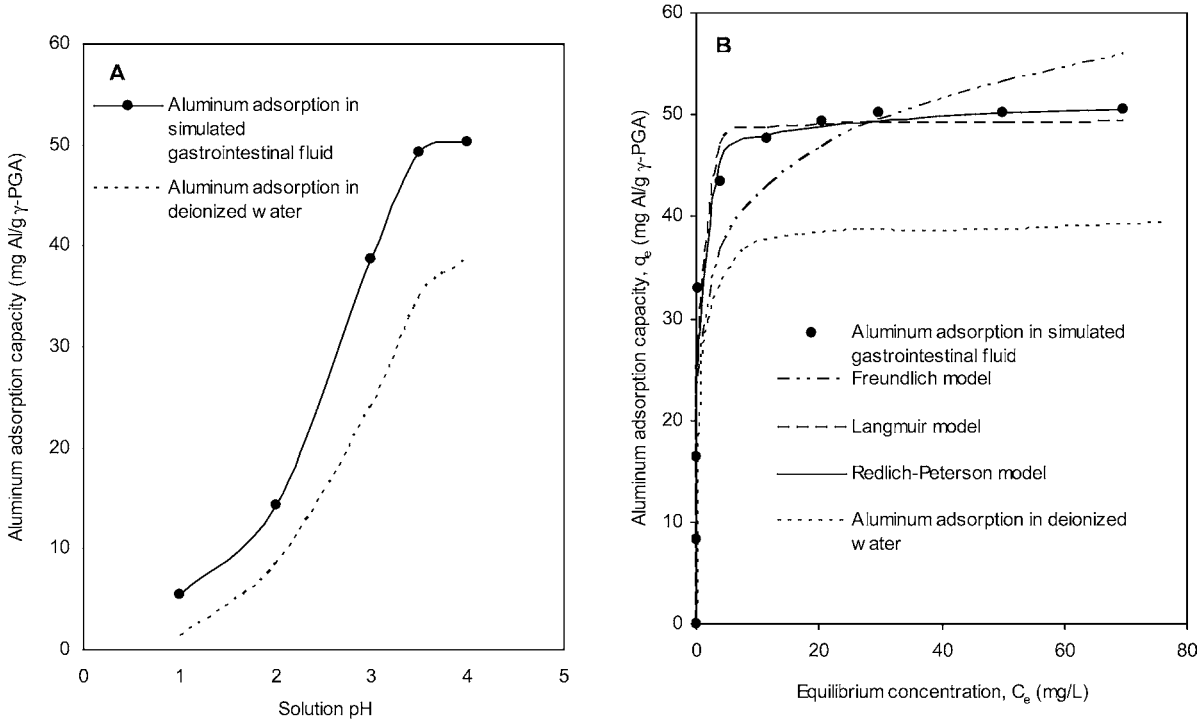

Figure 7. Influence of solution pH (A) and isotherms (B) for aluminum adsorption from simulated gastrointestinal fluid as compared to that from deionized water. (A) Initial aluminum concentration, 50 mg/L; pH range, 1−4; γ-PGA dose, 0.6 g/L; temperature, 37 °C; shaking time, 2 h. (B) Initial aluminum concentration, 5−100 mg/L; pH, 4.0; γ-PGA dose, 0.6 g/L; temperature, 37 °C.

aluminum adsorption isotherms obtained in GIF with dotted lines showing the trend in deionized water for comparison. Upon modeling of isotherm data, both Langmuir and Redlich−Peterson models were found to fit the isotherm data for GIF more precisely than the Freundlich model, with r^2 and χ^2 being 0.964 and 2.74 for the Langmuir and 0.967 and 2.80 for the Redlich−Peterson model (Figure 7B). The maximum adsorption capacity (q_m) and equilibrium constant (K_e) obtained from the Langmuir model were 49.43 mg/g and 5.394 L/mg, respectively. The isotherms developed for GIF showed a 22% increase in q_m value compared to that for deionized water.

Aluminum Release Study. To confirm the mechanism of aluminum adsorption by γ-PGA, the aluminum release from aluminum-adsorbed γ-PGA was studied as a function of different pH. Upon lowering the pH of deionized water from 4 to 1, the percentage of aluminum release rose from 0 to 98% (Figure 8). This trend was opposite to that observed for the effect of solution pH on aluminum adsorption by γ-PGA (Figure 1), suggesting that an ionic interaction occurred through exchange of hydrogen ions during aluminum adsorption onto γ-PGA.

In conclusion, this study demonstrated that the edible biopolymer poly(γ-glutamic acid) can be used as a safe detoxifying agent for aluminum. In vitro batch-mode adsorption experiments revealed that aluminum could be adsorbed by γ-PGA at an extremely fast rate, with maximum adsorption capacity as determined by the Langmuir nonlinear fit being 44.23 and 49.43 mg/g in aqueous solution and simulated gastrointestinal fluid at 37 °C, respectively. Ionic strength variation in different biological matrices did not alter aluminum adsorption capacity, while high electronegative essential metals like copper, iron, and zinc significantly reduced aluminum adsorption. Aluminum adsorption/release at different pH values indicated electrostatic interaction through exchange of hydrogen ions as a possible mechanism for aluminum adsorption by γ-PGA.

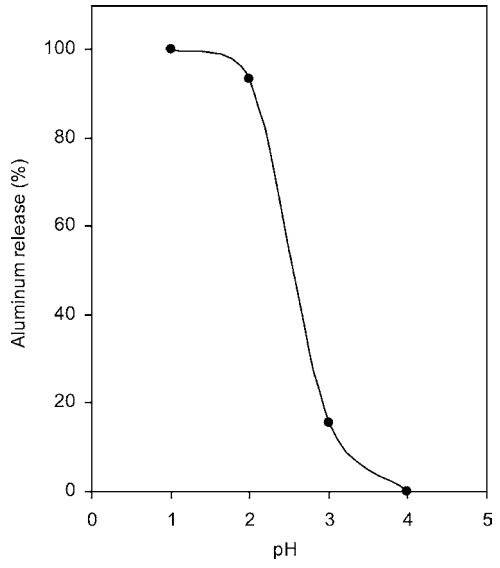

Figure 8. Influence of solution pH on aluminum release from aluminum-adsorbed γ-PGA. For adsorption study: initial aluminum concentration, 50 mg/L; γ-PGA dose, 0.6 g/L; shaking time, 1 h. For release study: release agents, deionized water adjusted to pH 1, 2, 3 and 4; shaking time, 30 min.

Supporting Information

ABSTRACT: The aim of the present study was to develop a generic analytical method for the identification and quantitation of apolar plant metabolites in biomass using liquid chromatography−photodiode array−accurate mass mass spectrometry (LC-PDA-amMS). During this study, a single generic sample preparation protocol was applied to extract apolar plant metabolites. Compound identification was performed using a single generic screening method for apolar compounds without the need for dedicated fractionation. Such a generic approach renders vast amounts of information and is virtually limited by only the solubility and detector response of the metabolites of interest. Method validation confirmed that this approach is applicable for quantitative purposes. Furthermore, an identification−quantitation strategy based on amMS and molar extinction coefficients was used for carotenoids, eliminating the need for reference standards for each carotenoid. To challenge the validated method, chili peppers (*Capsicum frutescens* L.) were analyzed to unravel their complex phytochemical composition (carotenoids, glycolipids, glycerolipids, capsaicinoids, lipid-soluble vitamins).

KEYWORDS: *LC-PDA-amMS, quantitation without reference standards, extinction coefficients, generic analysis of apolar plant metabolites, biomass composition, Capsicum frutescens L., carotenoids*

INTRODUCTION

Biomass such as algae and vegetables often contains natural components of high value including the so-called phytochemicals, such as antioxidants and essential oils, that are barely utilized from these resources today.[1,2] These natural products are thought to provide beneficial health effects and have an increasing sales market in the pharmaceutical, cosmetics, and food supplements industry.[3] Knowing the composition of these resources is thus an essential first step in a potential valorization process.

Because of the complexity of compound mixtures in biological samples, the usage of simple analytical instrumentation such as liquid chromatography−ultraviolet detection (LC-UV) has shifted toward more selective and more complex separation and detection systems such as ultrahigh-performance liquid chromatography−photodiode array−accurate mass mass spectrometry (UHPLC-PDA-amMS) instrumentation to achieve more definitive compound identification.[4] Accurate mass MS detectors allow the tentative identification of compounds without the use of analytical standards.[5] Because of the limited availability of analytical standards for plant metabolites, this utility has shown to be essential in natural products exploration.[6] Furthermore, modern high-end analytical instrumentation allows the detection of multiple compound classes, such as carotenoids, capsaicinoids, and glycolipids, in a single analysis, resulting in enormous time and consumables savings. To avoid compound discrimination during extraction, no cleanup steps should be used and the number of sample preparation steps should be limited as much as possible. Such a generic approach is virtually limited only by the solubility (extractability, chromatographic retention) and detector response (UV absorbance and ionization efficiency) of the compounds of interest. Furthermore, the use of a generic analytical screening application allows the setup of a compound database with specific chromatographic and spectrometric data. This database enables an effective dereplication during structure elucidation of the extract composition.[7]

The aim of the present study was to develop, optimize, and validate a generic analytical method for the identification and quantitation of apolar plant metabolites in biological matrices using UHPLC-PDA-amMS. Authentic standards of multiple phytochemical classes and various biological matrices were used to confirm and emphasize the generic character of the method. To challenge the validated method, the widely studied chili pepper matrix (*Capsicum frutescens* L.) was selected as it is known for its complex phytochemical composition (carotenoids, glycolipids, glycerolipids, capsaicinoids, lipid-soluble vitamins).[8−13] Finally, an identification−quantitation strategy based on the use of amMS data and extinction coefficients was applied for carotenoids, eliminating the need for reference standards for each carotenoid.

MATERIALS AND METHODS

Chemicals. LC-MS grade methanol, acetonitrile, and ethyl acetate were purchased from Biosolve (Valkenswaard, The Netherlands). Ultrapure water with a resistivity of 18.2 MΩ·cm at 25 °C was generated with a Millipore system. Dichloromethane for gas chromatography, *n*-hexane for gas chromatography, acetone for gas chromatography, sodium hydrogen carbonate, sodium hydroxide, and sodium chloride for analysis were purchased from Merck (Darmstadt, Germany). Ammonium acetate, (D-Ala^2)-leucine enkephalin, sand (quartz), and butylated hydroxytoluene were purchased from Sigma-Aldrich (Bornem, Belgium). Certified reference material BCR 485 consisting of freeze-dried mixed vegetables was bought from IRMM (Geel, Belgium). Commercially available mixtures to calibrate the mass spectrometer, that is, MSCAL5-1EA (caffeine, tetrapeptide "Met-Arg-Phe-Ala", Ultramark) for positive ion mode and MSCAL6-1EA (sodium dodecyl sulfate, taurocholic acid sodium salt, Ultramark) for negative ion mode, were purchased from Supelco (Bellefonte, PA, USA).

Lycopene, α-carotene, phytoene, lutein, zeaxanthin, tunaxanthin, astaxanthin dipalmitate, phytofluene, antheraxanthin, violaxanthin, canthaxanthin, and astaxanthin were purchased from Carotenature (Ostermundigen, Switzerland). β-Carotene, *trans*-β-apo-8′-carotenal, campesterol, stigmasterol, β-sitosterol, glyceryl trioleate, glyceryl dioleate, γ-tocopherol, α-tocopherol, phylloquinone, ergocalciferol, and cholecalciferol were purchased from Sigma-Aldrich. Glycerol dioleate and glycerol trioleate were obtained from Chem Service (West Chester, PA, USA). Monogalactosyldiacylglycerol with average MW 752.369 and digalactosyldiacylglycerol with average MW 926.767 were purchased from Avanti (Alabaster, AL. USA).

Preparation of Standard Solutions. Standard stock solutions and working solutions were prepared of each analyte separately at a concentration of approximately 200 μg/mL. Stock solutions of glyco- and glycerolipids were prepared in methanol. The stock solutions of sterols and lipid-soluble vitamins were prepared in methanol + 0.1% butylated hydroxytoluene. Stock solutions of carotenoids were prepared in dichloromethane + 0.1% butylated hydroxytoluene. Standard stock and working solutions were stored at −25 °C in the dark under an inert atmosphere (nitrogen). Dilutions of the stock solutions were prepared in dichloromethane + 0.1% butylated hydroxytoluene for analysis.

Sample Preparation. Red bell peppers (*Capsicum annuum*) and apples (*Malus domestica*) were bought in a local store. After removal of the stems and kernels, they were cut into pieces, frozen with liquid nitrogen, and immediately freeze-dried. After drying, they were milled and homogenized with a Grindomix GM 200 from Retsch (Haan, Germany) at 10000 rpm and stored in the dark under nitrogen at −25 °C.

Fruits of five chili pepper accessions (*Capsicum frutescens* L.), namely, 'Tebourba', 'Korba', 'Somâa', 'Awlad Haffouzz', and 'Souk jedid', were collected from plants cultivated in the experimental station of the Higher Institute of Agriculture, Chott Mariem, Tunisia. The peduncles of the peppers were removed, and the fruits were freeze-dried, milled, and stored at −25 °C until analysis.

Before sample preparation, the samples were allowed to equilibrate to room temperature. One gram of sample was mixed with 1 g of sodium hydrogen carbonate, spiked with *trans*-β-apo-8′-carotenal (internal standard), and mixed with sand. Ultrapure water was added until the sample was visually completely hydrated (approximately 3 mL, depending on the matrix). The mixture was kept in the dark under N_2 to allow swelling of the matrix for better analyte extraction. Afterward, the sample was mixed again with sand and loaded into a 33 mL accelerated solvent extraction (ASE) cell (Thermo Fisher Scientific, Bremen, Germany). The mixture was extracted three times (5 min static extraction) with 70:30 acetone/methanol + 0.1% butylated hydroxytoluene at 40 °C and 1050 psi, resulting in approximately 120 mL of sample extract. The three extracts were combined in a separation funnel, and 100 mL of 10% sodium chloride (aqueous) and 15 mL of hexane were added. The hexane phase was retained, and the polar phase was extracted twice more with 15 mL of hexane. The pooled hexane fractions were evaporated, dissolved in 10 mL of dichloromethane + 0.1% butylated hydroxytoluene, an aliquot was used for analysis, and the remaining extract was stored in the dark under nitrogen at −25 °C until further treatment.

For saponification 2 mL of 10% sodium hydroxide (in methanol) was added to 2 mL of dichloromethane extract and was consecutively shaken for 6 h at room temperature in the dark under an inert atmosphere. Afterward, the solution was washed five times with water to remove the alkali.[14] An aliquot of the saponified dichloromethane extract was used for analysis.

Instrumental Analysis. The analytical method was previously described[4] and is briefly summarized as follows. For analysis, 1.25 μL of extract was injected with a CTC PAL autosampler (CTC Analytics, Zwingen, Switzerland) on a 100 mm × 2.1 mm, 1.8 μm, Acquity UPLC HSS C18 SB column (Waters, Milford, MA, USA) and thermostatically (35 °C) eluted with an Accela quaternary solvent manager and a Hot Pocket column oven (Thermo Fisher Scientific, Bremen, Germany) with a chromatographic gradient. The mobile phase solvents consisted of 50:22.5:22.5:5 (v/v/v/v) water + 5 mM ammonium acetate/methanol/acetonitrile/ethyl acetate (A) and 50:50 (v/v) acetonitrile/ethyl acetate (B), and the gradient was set as follows (min/% A): 0.0/90, 0.1/90, 0.8/70, 20.0/9, 20.1/0, 20.4/0, 20.5/90, 23.0/90. For detection, an Exactive amMS (Thermo Fisher Scientific) was used in positive atmospheric pressure chemical ionization (APCI) mode. Full scan and all-ion fragmentation data were acquired with a scanning range of m/z 100−1400 at a resolution of 50000 full width at half-maximum (fwhm). The Accela PDA detector (Thermo Fisher Scientific) was set to scan from 190 to 800 nm.

RESULTS AND DISCUSSION

Method Validation. Carotenoids were chosen as model compounds for the optimization of a generic sample preparation and screening method for apolar plant metabolites. Carotenoids are apolar plant metabolites that can easily degrade or isomerize under the influence of light, oxygen, enzymes, heat, oxidants, and acid or alkaline conditions.[15] It can hence be assumed that if no isomerization or degradation occurs for carotenoids during sample preparation, most other apolar compounds should also be extracted without any artifact formation. The chromatographic gradient and MS settings were optimized on an UHPLC-PDA-amMS for a set of carotenoids representing the wide polarity range of carotenoids found in nature.[4] A validation study of the optimized method was performed for a range of compounds from several apolar metabolite classes (12 carotenoids, 5 lipid-soluble vitamins, 1 phytosterol) and different matrices. Furthermore, the extraction efficiency of other apolar plant metabolites (glycolipids, glycerolipids, steryl derivatives, chlorophyll) for which no commercial reference standards were available was investigated to confirm its generic character.

Dynamic Range and Sensitivity. High dynamic ranges (up to 4 orders of magnitude) with good linear fits were obtained in MS for most compound calibration curves. Because of the lower sensitivity of carotenoids in UV detection and the high cost of carotenoid standards, the dynamic ranges of the carotenoids were not tested to their full extent with PDA detection. However, it could be observed that smaller dynamic ranges were acquired for the very apolar carotenes in both MS and PDA, suggesting lower solubility to be the cause. Detection and quantitation limits are of less importance for valorization objectives as predominantly compounds with high concentrations are targeted.

Precision. The repeatability (intraday RSD) was obtained from the relative standard deviations (RSDs) of the recoveries from the spiking experiments. Because of the high price of

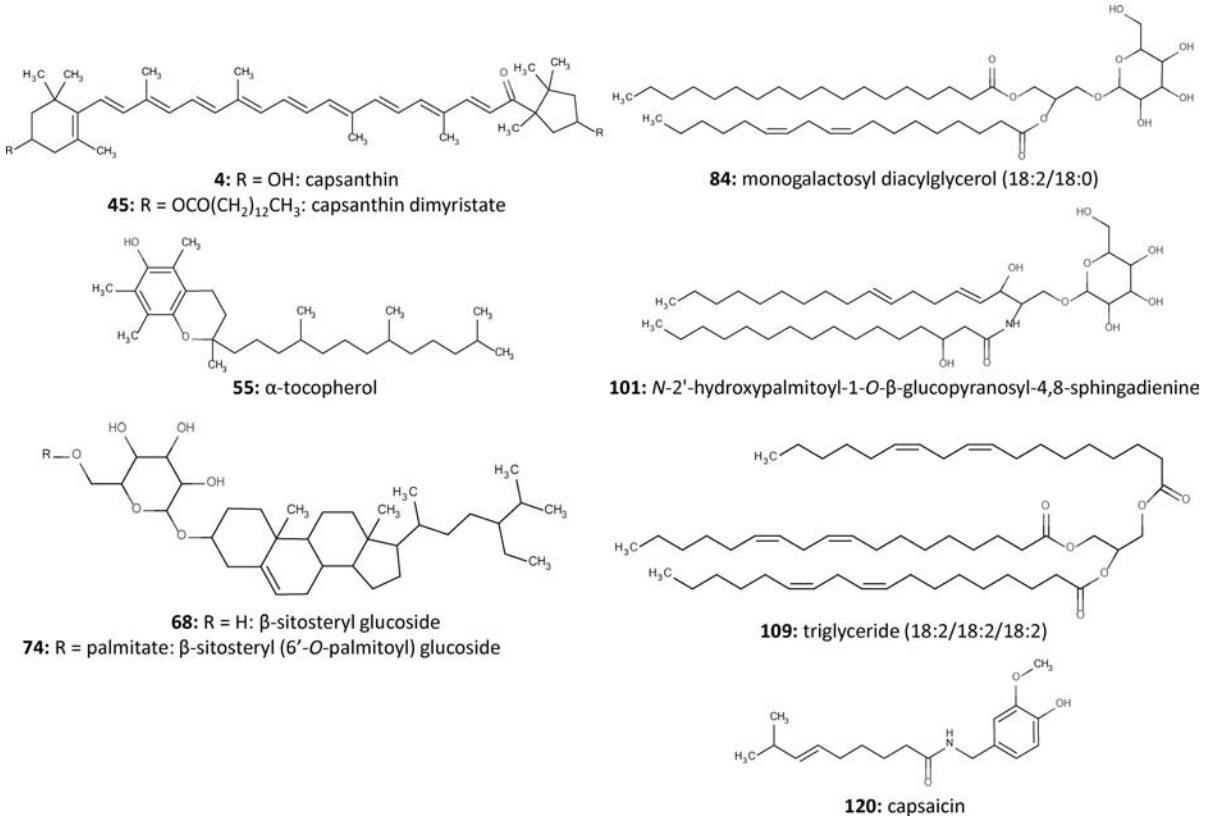

Figure 1. Representative structures of the different compound groups detected in chili peppers during this study.

analytical standards, it was chosen to obtain the intermediate precision (interday RSD) of the method with compounds natively present in red bell pepper (*Capsicum* variety). Five aliquots of freeze-dried pepper were extracted and analyzed the same day. This experiment was repeated for 3 days in total. Intraday RSDs ranged between 0.5 and 8.4% and interday RSDs between 0.0 and 6.0%.

Trueness. Certified reference material (CRM) is commercially available for only a very limited set of plant metabolites. Furthermore, reference standards are often not commercially available or very expensive for plant metabolites. Therefore, the trueness could only be assessed for a select set of compounds. A CRM of mixed vegetables, BCR 485 (consisting of sweet corn, tomatoes, and carrots), with certified concentration values for *all-trans-α-* and *β*-carotene, lutein, and lutein + zeaxanthin was extracted in triplicate. Values of 110 ± 8, 105 ± 3, 100.5 ± 2.7, and 94.5 ± 1.4% of the certified concentration values were found with MS, respectively, and 110.5 ± 2.5, 106.2 ± 1.1, 105 ± 4, and 101 ± 5% with PDA, respectively, with the uncertainties being the RSD of the three replicates. These results show good accuracy of the method for the quantitative determination of carotenoids natively present in biological matrices.

Spiking experiments were performed in triplicate on aliquots of freeze-dried apple (*M. domestica*) using an analytical standard mixture with 11 carotenoids, 6 lipid-soluble vitamins, and 1 phytosterol (concentrations ranging between 5.3 and 140 μg/g dw). The recoveries (*R* (%)) for all spiked compounds except violaxanthin ranged between 86 and 115% with MS detection, showing good accuracy. The slightly lower recoveries (74−87% in MS) found for violaxanthin can be attributed to epoxide rearrangements (which lead to large hypsochromic shifts in UV absorbance), catalyzed by the acids naturally present in the apple matrix.[16] Because of the low UV absorbance of phytosterols and lipid-soluble vitamins, only the recoveries of most of the spiked carotenoids could be calculated with PDA detection, showing similar values compared to the results calculated with MS.

Extraction Efficiency. Because of the lack of commercially available CRMs and reference standards, the conventional approach of method validation could be performed for only a select set of apolar plant metabolites. To investigate the extraction efficiency for a larger range of apolar plant metabolites, the two most critical steps in sample preparation were tested by exhaustive extraction of compounds naturally present in peppers. In a first experiment, an aliquot of freeze-dried red bell pepper was extracted five times with ASE followed by separate preparation of the obtained extracts. Assuming 100% extraction, the relative abundances of the compounds were calculated in the respective extracts. In a second experiment, the transfer of compounds to the hexane phase during liquid−liquid extraction was investigated by back-extracting the polar phase six times with hexane. After the first three hexane extracts had been pooled, an extra 240 mL of 10% sodium chloride solution was added to the polar phase. The polar phase was extracted three more times. The first two apolar extracts resulting from this second series of extractions were pooled. Subsequently, the three remaining extracts (consisting of three pooled, two pooled, and a single extract) were prepared separately for analysis. Again assuming 100% extraction, the relative abundances of the compounds were calculated in the respective extracts. The results showed that during the two most critical steps in the extraction procedure,

the greater part of compounds is extracted during the first three extractions (>90%).

Measurement Uncertainty. The results of the spiking experiments, CRM analysis, and intermediate precision were used to estimate the total expanded measurement uncertainty (U; $k = 2$). As not all compounds included during the spiking experiments were available for intermediate precision experiments, the intra- and interday RSDs of compounds of the same compound group were used to calculate U (e.g., for PDA analysis, the RSDs of β-carotene were applied for the calculation of U for α-carotene and lycopene). The obtained U values ranged between 10 and 26% (MS) and between 14 and 21% (PDA) for all compounds except violaxanthin, for which the U values were higher (44 and 59% for MS and PDA, respectively) as the bias of the lower R (%) obtained for violaxanthin was included in the calculation.

Identification Strategy. Identification of compounds is relatively easy when analytical standards are available. However, in natural products research, analytical standards are often very expensive or not commercially available. Therefore, identification is often based upon the available chromatographic and spectrometric information.[8−13] Carotenoids absorb UV light in a high-wavelength area (typical absorbance maxima at 400−500 nm) because of their conjugated system in the polyene backbone (e.g., molecular structures **4** and **45** in Figure 1).[17] PDA detectors are therefore very selective for the detection of carotenoids. However, the applicability of PDA detectors is limited as they are only useful for compounds that absorb UV or visible light and provide only very little structural information, which makes it impossible to identify unknown compounds with PDA spectra.[10] MS detectors are much more selective detectors than PDA detectors and can therefore facilitate the identification of plant metabolites. Orbitrap MS detectors can routinely generate mass spectra with a resolving power up to 140,000 at fwhm and obtain mass accuracies within 2 ppm (ppm), which enables the calculation of the most probable molecular formulas of the generated ions and fragments.[5] However, to date, even the most state-of-the-art MS detectors are often not capable of distinguishing between isomers, whereas PDA detectors in many cases are.[4,15] Furthermore, chromatography can be used to separate isomers before detection. The combination of orthogonal analytical techniques therefore provides a powerful tool for the identification of unknown compounds.

During this study carotenoids, steryl derivatives, glycolipids, glycerolipids, capsaicinoids, and lipid-soluble vitamins were tentatively identified in chili pepper samples. The information provided by the analysis alone is, however, not always enough for peak identification at an acceptable confidence level. Therefore, other sources of information such as in-house and commercial compound databases and peer-reviewed publications can give additional information for successful dereplication.[7] During this study, the *Dictionary of Natural Products*[18] and the *Carotenoids Handbook*[19] were consulted as commercial databases. Both of these databases give information on the occurrence of plant metabolites in nature. The *Carotenoids Handbook* also lists the UV absorbance spectra of most of the carotenoids known to exist in nature. These were used as reference spectra for comparison of experimental UV spectra if identification by amMS spectra resulted in several possible structures.

In the present study structures were assigned to unknown peaks only when both the mass/charge (m/z) ratios and molecular formulas of the ions were in agreement. PDA spectra often provided confirmation for the proposed structures when the reference information was available. Furthermore, the assigned identities often matched with their occurrence in chili peppers as described in the literature and databases. Figure 1 depicts the molecular structures of the identified plant metabolite classes. Tables 1 and 4 show the diagnostic amMS and PDA data used for compound identification in the chili pepper samples. These tables also specify the literature and databases used for confirmation of compound identity.

Carotenoids in Chili Peppers. *Identification of Carotenoids.* A wavelength of 470 nm is very specific to measure carotenoid absorbance. This wavelength was used to depict the carotenoids present in the 'Awlad Haffouzz' accession (Figure 2). The PDA chromatograms of the other four accessions appeared identical (not shown). All of the peaks in Figure 2 could be tentatively attributed to carotenoids as no chlorophyll peaks were detected (derived from the PDA profiles of the peaks). The greater part of PDA peaks in the chromatograms contained the same absorption profiles. As described previously,[10] carotenoid esterification with fatty acids does not affect the polyene backbone, and therefore esterification has virtually no effect on the absorption spectrum. The characteristic UV profiles of the nonesterified carotenoids, such as capsanthin, antheraxanthin, and zeaxanthin, can therefore also be used to locate their esters. Complementary to PDA detection, fatty acid esters of carotenoids easily fragment during MS ionization, and therefore information on the type of fatty acid moieties (number of carbons, number of double

bonds) can be obtained from full scan amMS spectra, as described earlier.[4,10,13] Most of the carotenoids in the chili pepper samples were esterified with laurate, myristate, and palmitate, and the major carotenoid present in the sample was capsanthin, in agreement with previuos findings.[10] Other studies[10,17,20] have shown that the *cis* isomers of carotenoids can be identified on the basis of a small hypsochromic shift (shorter wavelength) of the maximum absorbance values and a

characteristic peak around 330−350 nm. Several *cis*-carotenoids could be detected in the chili pepper samples, although in lesser amounts compared to their *trans* counterparts. It is generally known that absorbance maxima of carotenoids can shift depending on the diluent.[15] These shifts can be similar to or even greater than the shifts in maximum absorbances that occur during *trans* to *cis* isomerization of carotenoids.[15] The correct

dx.doi.org/10.1021/jf500285g | J. Agric. Food Chem. 2014, 62, 4812−4831

isomer form, *cis* or *all-trans*, was therefore attributed only when a reference standard of the compound of interest was available.

Table 1 shows the diagnostic amMS and PDA data used for carotenoid identification in the chili pepper samples. During positive APCI, carotenoids predominantly ionized to generate protonated molecules $[M + H]^+$, whereas predominantly radical molecular ions ($M^{\bullet -}$) were formed during negative APCI. A substantial amount of carotenoid product ions was detected due to in-source fragmentation, thereby providing additional structural information. Five of the 53 detected carotenoid peaks in the chili pepper accessions could be identified with reference standards. Forty-four unknown carotenoids could be tentatively identified on the basis of spectrophotometric and mass spectrometric data, chromatography, databases, and the literature. As the carotenoid content of different *Capsicum* varieties has been frequently reported, confirmation of identity was often obtained from comparison with the findings of other studies.[8,10,13] Four minor unknown carotenoids could not be assigned a tentative structure. These data show that the applied generic apolar screening method performs in the separation and identification of carotenoids as well as earlier reported methods that were optimized for the dedicated identification of carotenoids in chili peppers.[10,13]

To confirm the identity of the esterified carotenoids, the sample extracts were saponified. Due to circumstances, the saponification procedure was performed after 1 year of storage of the extracts in the dark, at −25 °C. Analysis of the extract before saponification revealed that no significant change had occurred in the carotenoid content during storage. The chromatogram of the saponified extract (Figure 3) shows the profile of the hydrolyzed carotenoids. The peaks of cucurbitaxanthin A (6.77 min), two *cis*-capsanthins (7.38 and 7.62 min), *all-trans*-capsanthin (7.78 min), *cis*-antheraxanthin (8.55 min), *all-trans*-zeaxanthin (10.05 min), and *β*-cryptoxanthin (13.61 min) augmented in the chromatogram of the saponified extract, which confirmed the presence of their esterified derivatives in the untreated extract (Figure 2). Furthermore, new peaks appeared in the saponified extract at 5.67, 8.26, 9.25, 9.82, 10.23, 13.61, and 16.88 min that could be identified as capsorubin, mutatoxanthin, karpoxanthin, *cis*-zeaxanthin, *cis*-*β*-apo-8′-carotenal, *β*-cryptoxanthin, and *cis*-*β*-carotene, respectively. Their free form was not detected before saponification, which confirms their presence as carotenoid esters in the untreated chili pepper extracts.

The three main maximum absorbance wavelengths of the isomers *all-trans*-lutein and *cis*-zeaxanthin are in close agreement and are only distinguishable in UV absorbance by a characteristic *cis* peak of *cis*-zeaxanthin. A *cis* peak was clearly detected in the PDA spectrum of peak 9 in the chromatograms of the saponified extracts (Figure 3), indicating the presence of *cis*-zeaxanthin. It has also been reported that zeaxanthin and lutein are distinguishable by in-source fragmentation in positive APCI mode by the relative heights of the $[M + H]^+$ and $[M + H - H_2O]^+$ peaks.[4] Comparison of the MS spectrum of peak 9 in Figure 3 showed close resemblance with that of a *trans*-zeaxanthin reference standard and differed from the spectrum of a *trans*-lutein reference standard. Peak 9 was therefore designated *cis*-zeaxanthin.

An overview of the chromatographic separation versus molecular mass of all the compounds identified in the chili pepper extracts during this study is given in Figure 4. Although most of the compounds were separated by chromatography, orthogonal detector selectivity remains essential for compound differentiation. This can in many cases not be achieved by PDA detection alone and highlights the added value of high-end instrumentation in this research field.

Quantitation of Carotenoids with Analytical Reference Standards. The concentrations of carotenoids for which an analytical standard was available were calculated with amMS (Table 2). The concentrations calculated with reference standards represent only a small fraction of the total number of carotenoids in the samples. Most of the xanthophylls in the samples appeared esterified, for which analytical standards are not commercially available.

Quantitation of Carotenoids with Extinction Coefficients. (a) Quantitation of Carotenoids Using Standards with the Same Polyene Backbone. In UV analysis, carotenoids can be quantitated by using reference standards having the same polyene backbone and thus extinction coefficient.[15] However, molar extinction coefficients (ε_{mol}) can be used for the calculation of the concentration expressed in weight units (e.g., μg/g) only when the molecular mass is known. To our knowledge earlier publications never used this quantification strategy in combination with amMS. Accurate mass MS enables the tentative identification of unknown carotenoids and therefore the designation of its polyene backbone and molecular weight. An LC-PDA-amMS configuration combined with the use of extinction coefficients should therefore allow unparalleled speed in the identification and quantification of unknown carotenoids. During this study, the majority of carotenoid esters, predominantly capsanthin esters, were quantitated with this procedure, that is, with a reference standard of free capsanthin (Table 2). The uncertainties represent the *U* of capsanthin estimated during method validation. Because UV absorbance profiles of carotenoids generally overlap, coeluting carotenoids could not be quantitated separately. In the few cases that coelution happened, the sum of both compounds was quantitated with the standard linked to the carotenoid with the highest contribution to the signal, as was judged from the PDA and MS spectra (Table 2).

To check the validity of quantitating carotenoid esters with standards containing the same polyene backbone, the total capsanthin content in the extracts without saponification (2100−3300 mg/kg dw) was compared to the free capsanthin concentration in the saponified extracts (2600−3800 mg/kg dw). The total capsanthin content in the extracts without saponification was calculated by conversion of the ester concentrations to free capsanthin concentrations followed by summation. The recoveries of the total capsanthin content in the extracts without saponification with respect to the capsanthin concentrations in the saponified extracts ranged between 83 and 87%, within the *U* of capsanthin (21%). These results demonstrate the suitability of using standards having the same polyene backbone as the analytes of interest for the quantitation of compounds for which no reference standards are available. The slightly lower concentrations obtained for the samples without saponification can be explained by the high density of peaks in the chromatograms, whereby the baseline is artificially elevated and integration is slightly biased. Care should, however, be taken when *all-trans*-carotenoids are used to quantitate *cis*-carotenoids, as extinction coefficients of *cis*-carotenoids are generally smaller.[21] Only small amounts of *cis* isomers were present in the chili pepper samples (4.5−6.0% for capsanthin). Higher percentages of *cis* isomers were detected (7.5−19% for capsanthin) in the saponified extracts. It is

Table 3. Concentrations of Fat-Soluble Vitamins and Free Phytosterols in the Chili Pepper Accessions, Calculated with Reference Standards

			concentration (μg/g dw)				
compd	identity	retention time (min)	'Awlad Haffouzz'	'Tebourba'	'Korba'	'Somâa'	'Souk jedid'
54	γ-tocopherol[a]	10.98	<100	<100	<100	<100	<100
55	α-tocopherol	11.87	500 ± 100	400 ± 100	400 ± 100	500 ± 100	400 ± 100
56	phylloquinone	13.37	1.55 ± 0.34	<0.7	1.11 ± 0.25	1.12 ± 0.25	1.01 ± 0.22
60	stigmasterol	14.55	80 ± 10	90 ± 10	90 ± 10	110 ± 10	100 ± 10
61	campesterol[b]	14.59	800 ± 100	500 ± 70	560 ± 70	580 ± 80	530 ± 70
62	β-sitosterol[b]	15.19	1300 ± 200	1100 ± 100	1100 ± 100	1100 ± 200	1000 ± 100

[a]Present, however, not quantifiable due to low intensity. [b]The measurement uncertainty of stigmasterol obtained with amMS was used.

generally known that saponification can induce the formation of artifacts,[15] although in this case *cis* isomer formation during 1 year of extract storage cannot be ruled out.

The shelf life of carotenoid esters in the pepper extracts was examined over a period of 1 year by correlating the concentrations of capsanthin esters in the extracts immediately after extraction (x) with the concentrations in the extracts after 1 year of storage (y). The capsanthin ester concentrations in solution did not decline over 1 year of storage ($y = 1.1629x - 21.895$). Furthermore, a coefficient of determination (R^2) of 0.9639 states a good fit between the measurements. These results indicate a long storage life for carotenoid esters in the extracts.

The above results demonstrate that the combination of amMS and PDA allows the identification and quantitation of esterified carotenoids without the need for individual standards for each and every carotenoid or for a saponification procedure.

(b) Quantitation with Extinction Coefficients from the Literature. A group of carotenoids, for which no reference standards with the same polyene backbone were available, could not be quantitated as described above. This group of carotenoids was quantitated with a carotenoid standard containing a different polyene backbone. To correct for the differences in absorbance between the standard and the carotenoid of interest, the calculated concentrations were subsequently converted to the concentration of the carotenoid of interest with the ε_{mol} values as tabulated[17] for 86 carotenoids. The results are shown in Table 2. The extinction coefficients reported[17] were compared to in-house experimentally determined extinction coefficients for four carotenoids and the deviations were 4.8, 22, 2.6, and 11% for α-carotene, β-carotene, lycopene, and zeaxanthin, respectively. These deviations were considered acceptable and confirmed that the ε_{mol} values from the literature can be used to estimate the concentrations of carotenoids for which no standards are available. The measurement uncertainty was estimated by combining the average U value obtained for carotenoids during method validation and the highest of the above-mentioned deviations between the experimentally determined and literature-described ε_{mol} values, resulting in an uncertainty of 31%. Carotenoids for which no extinction coefficients were available from the literature were quantitated in a similar manner, using the ε_{mol} values of carotenoids with an analogous polyene backbone (Table 2). The values of the listed extinction coefficients[17] differed up to a factor of 4 over the whole range of carotenoids, predominantly due to the very small and atypical conjugated system of phytoene, which results in a very low extinction coefficient. Carotenoids with similar polyene backbones have similar extinction coefficients, for example, 137,900 for zeaxanthin, 126,600 for β-carotene, 137,200 for antheraxanthin, 121,000 for capsanthin, and 132,000 for capsorubin. An additional uncertainty in the concentration is thus introduced by choosing an extinction coefficient of an analogous polyene backbone (estimated around 11%, corresponding to 2 × RSD of the above extinction coefficients). Combined with the average U value obtained for carotenoids during method validation and the highest of the above-mentioned deviations for the ε_{mol} values, this allowed the estimation of the measurement uncertainty at 33%. The combination of LC, amMS, and PDA thus allows the identification of unknown carotenoids and simultaneous estimation of their concentrations without the need for reference standards for each carotenoid.

(c) Comparison of the Carotenoids Content of the Different Accessions. As only one analysis was performed per chili pepper accession, the different peppers could not be compared using ANOVA. Pair-wise comparison resulted in good correlations ($R^2 \geq 0.90$). Only slightly lower concentrations were found for the 'Souk jedid' accession. The carotenoid profiles were thus very similar for the five chili pepper accessions.

Lipid-Soluble Vitamins and Phytosterol Derivatives in Chili Peppers. The generic method that was developed for carotenoids has a wider scope than first envisaged. Other compounds that are extracted and elute within the set chromatographic window can be analyzed. The lipid-soluble vitamins phylloquinone and α-tocopherol and phytosterols stigmasterol, campesterol, and β-sitosterol were identified and quantitated using MS and analytical standards (e.g., molecular structures **55**, **68**, and **74** in Figure 1; Tables 3 and 4). The concentrations of α-tocopherol were in line with the concentrations found previously.[12] Although γ-tocopherol was previously reported to be present in the seeds of chili peppers, it was detected only in small signal intensities during this study (most probably attributable to the difference in studied tissue), which prevented their quantitation.[22] As was found for the carotenoids, the concentrations for lipid-soluble vitamins and free phytosterols were very similar for the five studied cultivars.

It is known that phytosterols occur in plant tissues as the free alcohol, as fatty acid esters, as steryl glycosides, and as acylated steryl glycosides.[23] The free phytosterols thus represent only a fraction of the phytosterols in the chili peppers. Several steryl glucosides, acylated steryl glucosides, and acylated sterols were identified in the chili pepper extracts by amMS (Table 4 and Figure 4). The locations of the fatty acid double bonds could not be retrieved from the LC-MS data. However, the fatty acid composition of phytosterol derivatives in *Capsicum* oil, obtained by consecutive purifications and dedicated analytical methods, has been described in the literature and allowed for the correct fatty acid moiety assignment.[9,24] Most interestingly,

[a]Acetate adduct formed in negative APCI mode. [b]Identification with analytical standard. [c]Identified by Matthäus et al.[24] [d]Identified by Yamauchi et al.[9] [e]Described by www.lipidmaps.org. [f]*Dictionary of Natural Products*:[18] present in *Capsicum annuum*.

dx.doi.org/10.1021/jf500285g | J. Agric. Food Chem. 2014, 62, 4812−4831

linoleic, linolenic, and palmitic acids were bound to the steryl and steryl glucoside moieties, corresponding to the results reported by Yamauchi et al.[9] This is different from the distribution of fatty acids bound to carotenoids (lauric, myristic, and palmitic acids) (Table 1). The elution order of the acylated steryl glucosides was predominantly influenced by the level of saturation of the fatty acid moieties, as the retention time increased in the order C18:3 < C18:2 < C16:0 (Figure 4).

Cholesterol, Δ5- and Δ7-avenasterol, and derivatives thereof were also tentatively identified by amMS, corresponding to the findings of Matthäus et al.[24] (Table 4). Due to the lack of reference standards for sterol derivatives and the complex relationship between detector response and concentration, the various molecular species could not be quantitated. Extinction coefficients could not be used as phytosterols were not detected by using PDA detection. An alkaline saponification procedure to assess the total concentration of phytosterols would require the use of both the free sterols and steryl glucosides, as the ether bonds of the steryl glucosides are stable during saponification.[25] Steryl glucoside bonds can otherwise be cleaved by acid hydrolysis.[26] During this study, it was chosen to calculate the relative abundances per group of the sterol derivatives (e.g., steryl glucosides) to enable quantitative comparison. This was achieved with the product ions corresponding to the m/z of the free sterol alcohols with the loss of water, found for all derivatives in positive APCI. Liengprayoon et al.[27] have previously reported this calculation strategy, with the hypothesis that the response to ionization is similar within a group of similar structures. Campesterol, β-sitosterol, and their derivatives were found to be the main phytosterols present in the five chili pepper accessions. The profiles of sterol derivatives were very similar between the samples; however, the total content did vary significantly between the samples for steryl glucosides and acylated steryl glucosides, being most abundant in the 'Awlad Haffouzz' and 'Souk jedid' accessions, respectively.

Yamauchi et al.[9] previously reported the detection of free phytosterols and phytosterol glucoside derivatives in chili pepper by performing consecutive prefractionations before analysis. During this study, a single generic sample preparation protocol was applied to extract all of the compounds reported in this paper. Subsequently, compound identification was performed using a single generic screening method for apolar compounds without the need for dedicated fractionation (Figure 4).

Monogalactosyldiacylglycerols and Digalactosyldiacylglycerols in Chili Peppers. In total, 23 monogalactosyldiacylglycerols and digalactosyldiacylglycerols were identified in the chili pepper accessions (e.g., molecular structure **84** in Figure 1; Table 4). Their identification was based on the ionization and in-source fragmentation pattern of a reference standard of monogalactosyldiacylglycerols and digalactosyldiacylglycerols. In positive APCI mode, predominantly product ions with the loss of the galactosyl moiety (and water) were found in the spectra. During negative APCI mode, predominantly acetate adducts were found. Differentiation between isomeric lipids containing different fatty acid moieties (e.g., C18:2/C18:2 and C18:1/C18:3) could be made by the fatty acid product ions obtained by in-source fragmentation in negative APCI mode. Almost all detected monogalactosyldiacylglycerols and digalactosyldiacylglycerols were separated with the generic chromatographic gradient. Faster elution was obtained for galactosyldiacylglycerol lipids with fatty acids of shorter chain length and/or a higher number of double bonds (Figure 4). The fatty acid moieties that were found to be part of the galactosyldiacylglycerol lipids consisted of C18:3, C18:2, C18:1, C18:0, C16:3, C16:2, C16:1, and C16:0, which corresponds with previous findings.[9]

Relative abundances were calculated for the monogalactosyldiacylglycerol and digalactosyldiacylglycerol families with the acetate adducts obtained in negative APCI mode. Monogalactosyldiacylglycerol (18:3/18:3), digalactosyldiacylglycerol (18:3/18:3), digalactosyldiacylglycerol (18:3/16:0), and digalactosyldiacylglycerol (18:3/18:0) were the most abundant galactosyl diacylglycerol lipids present in the chili pepper accessions, as previously found.[9] The profiles were very similar for the galactosyl diacylglycerol lipids between samples. However, the total content of monogalactosyldiacylglycerol and digalactosyldiacylglycerol per sample varied significantly, which showed to be highest in the 'Awlad Haffouzz' accession and lowest in the 'Souk jedid' and 'Tebourba' accessions, respectively.

Cerebrosides in Chili Peppers. Yamauchi et al.[9] identified seven molecular species of glucocerebrosides in *C. annuum* L. after HPLC purification to single compounds and consecutive NMR analysis. Owing to this work, these compounds were easily identified during the current study (e.g., molecular structure **101** in Figure 1; Table 4). The protonated molecules of these sphingolipids were detected together with several product ions such as the ceramide moiety, owing to the loss of the sugar moiety, and the α-hydroxy fatty acyl moieties, because of extensive in-source fragmentation during APCI positive mode.[9] Ionization in negative APCI mode rendered acetate adducts, deprotonated molecules, and ceramide product ions due to in-source fragmentation. For each of the identified compounds, two almost baseline separated peaks appeared in the chromatograms (Figure 4). A study reported by Whitaker et al.[28] showed that glucose is the only sugar present in the bell pepper cerebrosides and that both the 8-*cis* and 8-*trans* isomers of 4,8-sphingadienine and 8-sphingenine and the *cis*−*trans* isomers of 4-hydroxy-8-sphingenine are present in the fruits. The two isomeric peaks are explained by the respective *cis*- and *trans*-cerebrosides.

Relative abundances in MS detection were calculated for the cerebrosides by combining the chromatographic *cis*−*trans* peaks obtained for the acetate adducts in negative APCI mode. The profiles were very similar for the cerebrosides between the samples. The content per sample did vary significantly, which showed to be highest in the 'Awlad Haffouzz' accession and lowest in the 'Tebourba' accession.

Glycerolipids in Chili Peppers. Nine triglycerides and three diglycerides were identified in the chili pepper accessions (e.g., molecular structure **109** in Figure 1; Table 4). Their identification was based on the ionization and in-source fragmentation pattern of a glyceryl trioleate and glyceryl dioleate standard. As in most cases the order of the fatty acids bound to glycerol (i.e.*sn*-1, *sn*-2, or *sn*-3 position of the glycerol backbone) could not be deduced from the MS spectra, the lipids were noted as 'triglyceride (C18:2, C18:2, C16:0)" instead of "triglyceride (C18:2/C18:2/C16:0)" (Table 4). Predominantly triglycerides were present in the extracts. Faster elution was obtained with fatty acids of shorter chain length and/or a higher number of double bonds (Figure 4). The fatty acid moieties that were found to be part of the glycerolipids consisted of linolenic acid (C18:3), linoleic acid (C18:2), oleic acid (C18:1), and palmitic acid (C16:0), which is in line with

the fatty acid composition of the acylated steryl glucosides, the acylated sterols, monogalactosyldiacylglycerols, and digalactosyldiacylglycerols that were identified during this study.

Relative abundances in MS detection were calculated for the diglycerides and triglycerides with the protonated molecules obtained in positive APCI mode. The triglyceride with three linoleic acid moieties (C18:2, C18:2, C18:2) and diglyceride with two linoleic acid moieties (C18:2, C18:2) were most abundantly present in the chili pepper accessions. The profiles were very similar for the di- and triacylglycerides in the samples. However, the content did vary significantly and was highest in the 'Somâa' and 'Korba' accessions and lowest in the 'Awlad Haffouzz' and 'Souk jedid' accession for triglycerides and diglycerides, respectively.

Capsaicinoids in Chili Peppers. Five capsaicinoids, which are known to be present in high amounts in chili peppers, were identified with amMS. Because these compounds are relatively small and polar compared to the other studied compounds (molecular structure **120** in Figure 1), they partially coeluted within the first 3 min of the chromatographic gradient. The identities of nordihydrocapsaicin, capsaicin, dihydrocapsaicin, and nonivamide were later confirmed with their respective analytical standards (unpublished results). The profiles of the capsaicinoids were similar in the samples; however, the content did vary significantly, being lowest for 'Souk jedid' and highest in the 'Tebourba' and 'Korba' accessions.

During this study, a single generic sample preparation protocol was applied to extract all of the compounds reported in this paper. Subsequently, compound identification was performed using a single generic UHPLC-PDA-amMS screening method for apolar compounds without the need for dedicated fractionation. Method validation confirmed that the generic approach is applicable for quantitative purposes and is virtually limited only by the solubility and detector response of the metabolites of interest. It was shown that although most of the compounds were separated by chromatography, orthogonal detector selectivity remains essential for compound differentiation. This can in many cases not be achieved by PDA detection alone and highlights the added value of high-end instrumentation in this research field.

Second, an identification−quantitation strategy based on the use of LC-PDA-amMS and extinction coefficients was applied for carotenoids, enabling unparalleled speed in the identification and quantification of unknown carotenoids and eliminating the need for reference standards for each carotenoid. Finally, a case study on chili pepper fruits (*C. frutescens* L.) showed that carotenoids, steryl derivatives, glycolipids, glycerolipids, capsaicinoids, and lipid-soluble vitamins could be characterized simultaneously with the analytical platform. This system is thus a powerful tool to unravel the complex apolar phytochemicals composition of biomass, as it is useful not only as a fingerprinting method but also for the detailed profiling of individual components.

ABSTRACT: Polymerization of citric acid onto the surface of oxidized multiwall carbon nanotubes led to MWCNT-*graft*-poly(citric acid) (MWCNT-*g*-PCA) hybrid materials. Because of the presence of conjugated citric acid branches, synthesized MWCNT-*g*-PCA hybrid materials were not only soluble in water but also able to trap water-soluble chemical species and metal ions. Trapping of pesticides such as zineb and mancozeb in aqueous solution by MWCNT-*g*-PCA hybrid materials led to encapsulated pesticide (EP) in the polycitric acid shell. Optimum conditions for encapsulation of zineb and mancozeb in hyperbranched polycitric acid such as pH, time of stirring, and temperature were investigated by the UV−vis spectroscopy method. Encapsulation of pesticides on CNT-*g*-PCA hybrid material was confirmed via TEM analysis. Experiments indicated that new the CNT-*g*-PCA-EP hybrid material in comparison with bulk pesticide had a superior toxic influence on *Alternaria alternata* fungi.

KEYWORDS: *zineb, mancozeb, pesticide, multiwalled carbon nanotubes, nanocomposite*

1. INTRODUCTION

Organic pesticides including insecticides and herbicides are widely used in agriculture because of their powerful biological activity.[1] Mancozeb and zineb were first introduced during the 1940s and widely used. Mancozeb as a pesticide protects many fruit, vegetable, nut, and agricultural crops against a wide range of fungal diseases. It is a grayish-yellow powder, and its chemical name is manganese ethylene bis(dithiocarbamate) (polymeric). Zineb is a light-colored powder or crystal the chemical name of which is zinc ethylene bis-(dithiocarbamate).[2−6] Figures 1a and 1b show the chemical structures of mancozeb and zineb molecules, respectively.

Encapsulation is a process of surrounding or enveloping one substance within another material on a very small scale. Another definition of encapsulation is the process by which a material is surrounded and protected from extraneous conditions that would otherwise break it down, yielding capsules ranging from less than one micrometer to several hundred micrometers in size.[7] Encapsulation can be achieved by several techniques with different purposes in mind. Encapsulation of materials may occur with the intention that the core material be confined within capsule walls for a specific period of time. Alternatively, core substances can be encapsulated so that the core material will be released either gradually through the capsule walls, known as controlled release or diffusion, or when external conditions activate the capsule walls to break, melt, or dissolve.[8] There are many applications for encapsulated materials in various fields such as agriculture, pharmaceuticals, foods, cosmetics and fragrances, textiles, paper, paints, coatings and adhesives, printing applications, and many other industries.

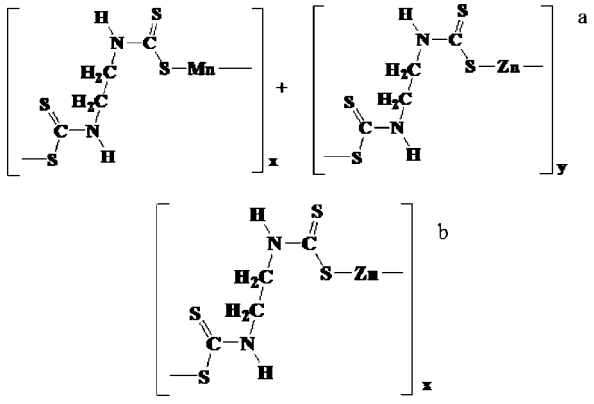

Figure 1. Structure of (a) mancozeb molecule and (b) zineb molecule.

Pesticides may be encapsulated to be released over time, allowing farmers to apply the pesticides less often rather than requiring very highly concentrated and perhaps toxic initial applications followed by repeated applications to battle the loss of efficacy due to leaching, evaporation, and degradation.[9] Protection of pesticides from full contact with the elements lessens the risk to the environment and those that might be exposed to the chemicals and provides a more efficient strategy for pest control.[10]

In the past decade, there has been increasing interest in the studies of polymer/CNT nanocomposites due to the unique combination of promising properties and construction of multifunctional structures of each component.[11] Previously

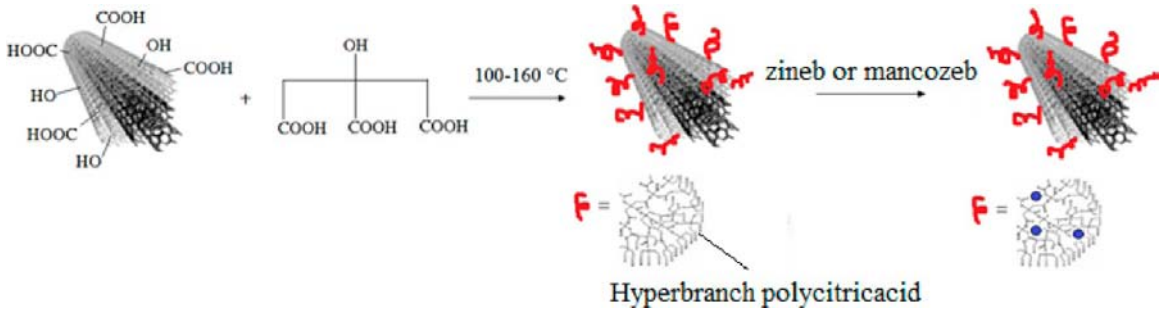

Figure 2. Synthetic scheme of CNT-*g*-PCA-EP.

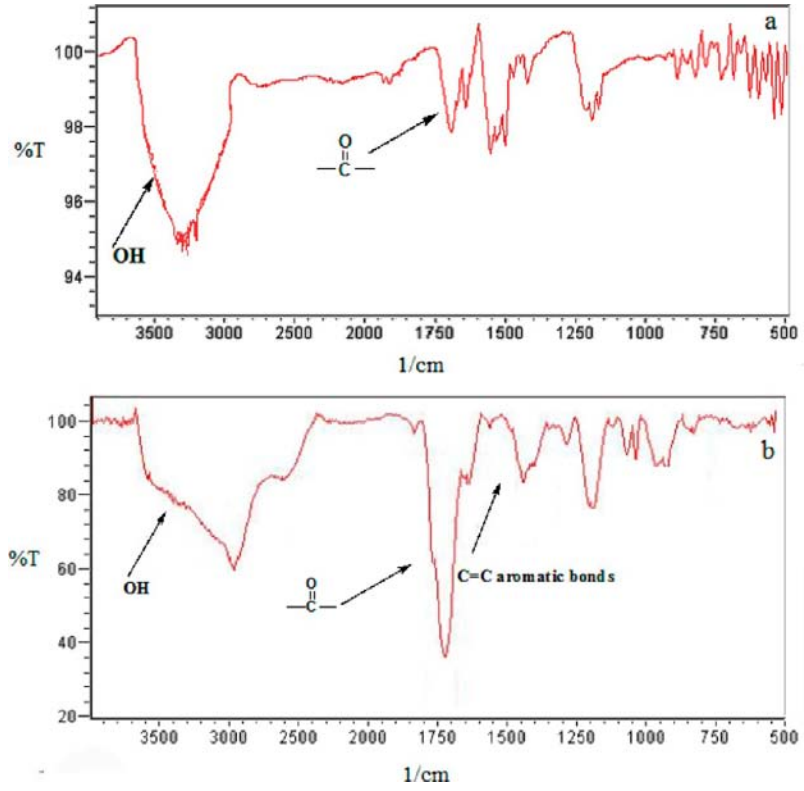

Figure 3. FTIR data for (a) MWCNT−COOH and (b) MWCNT-*g*-PCA hybrid material.

Trimnell et al.[12] investigated the encapsulation of pesticide within a starch−borate complex. In this work the starch, pesticide, and water were mixed and alkali was added to gelatinize the starch. Then the mixture was treated with boric acid.

In our study zineb and mancozeb were encapsulated into MWCNT-*g*-PCA hybrid material, which process leads to conversion of bulk pesticide to pesticide nanoparticles. Effective parameters in the encapsulation process, such as pH, temperature, and time of stirring, were optimized via the UV−vis spectroscopic method. The influence of encapsulated pesticide was studied on the malady *Alternaria alternate*, so, for this purpose, potato dextrose agar (PDA) was used as a growth medium. Results show that pesticide nanoparticles in contrast with bulk pesticide have extraordinary function. To the best of our knowledge, this paper is the first report about using water-soluble polymerized carbon nanotubes for encapsulation of pesticides and application the new nanopesticides in malady agent treatment.

In comparison with previous reports there are some novel and specific advantages as follows:

(a) Pesticide encapsulated into CNT-*g*-PCA hybrid material is more stable and effective than bulk pesticide.
(b) Pesticide usage will be decreased in agriculture.
(c) Water solubility of encapsulated pesticides will be increased.
(d) Multiwall carbon nanotubes will be dissolved in the water.

This product can be used extensively in several greenhouse and field studies and agriculture.

2. EXPERIMENTAL SECTION

2.1. Reagents. The MWCNT was purchased from Nutrino. The outer diameter of MWCNT was between 20−40 nm. Monohydrate citric acid, sulfuric and nitric acid, tetrahydrofuran, and cyclohexane were purchased from Merck. Pesticide standard was purchased from Delta Green South Corporation of Iran.

2.2. Apparatus. Fourier transform infrared (FT-IR) spectroscopic measurements were performed using a FT-IR spectrometer (Thermo

dx.doi.org/10.1021/jf404720d | J. Agric. Food Chem. 2014, 62, 4833−4838

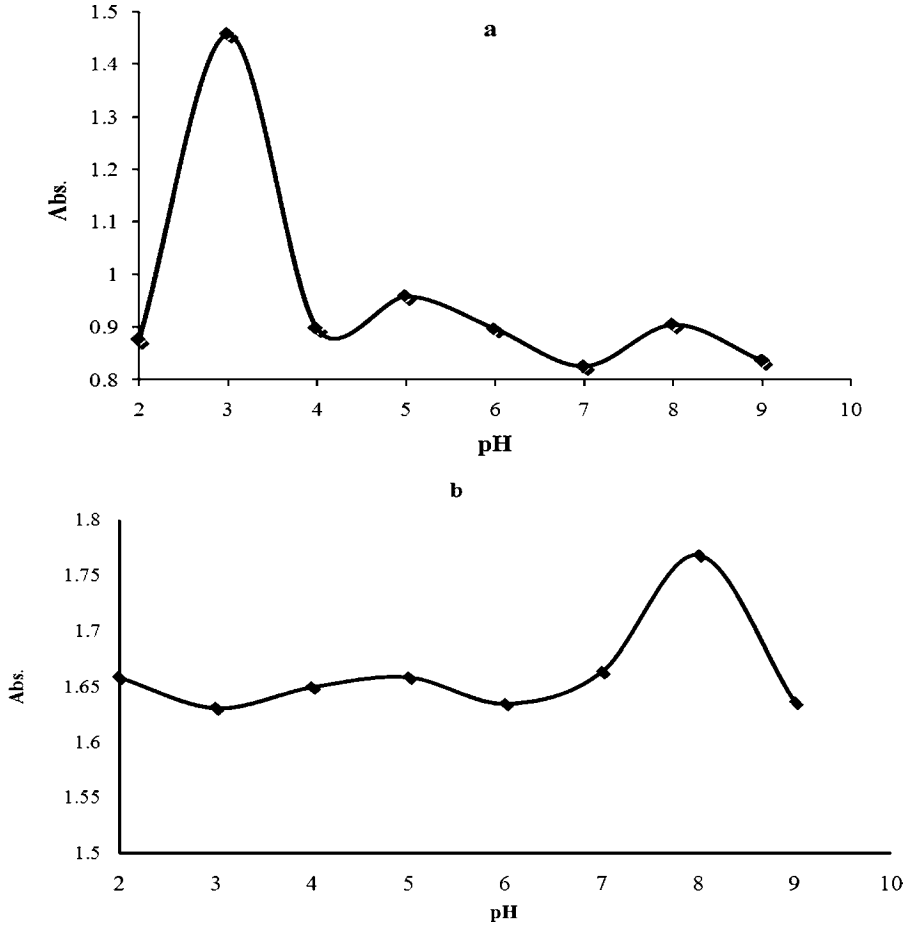

Figure 4. Effect of pH on the encapsulation of mancozeb (a) and zineb (b) with CNT-*g*-PCA.

Nicolet Magna-IR 560 spectroscope, USA). The FTIR spectra of acid modified CNTs and CNT-*g*-PCA were obtained in transmittance mode by placing a small amount of the materials in KBr pellets. The UV−vis measurements were obtained using a double beam spectrophotometer (Shimadzu 1650 UV−vis spectrophotometer, Japan) with 1 cm quartz cells. In order to well disperse pesticide in the polymeric shell of hybrid material, an ultrasonic bath (22 kHz) was used. The TEM study was carried out using a microscope operating at 100 kV. The samples for the TEM analysis were prepared by dilution of nanocomposite with distilled water. A drop of the suspension was applied onto a carbon-coated copper grid and was dried in air. A centrifuge (Eppendorf 5810) was used for separation of CNT-*g*-PCA-EP from pesticide molecules.

2.3. Preparation of MWCNT-*g*-PCA Hybrid Materials. MWCNTs were opened according to reported procedures in the literature.[13] Briefly, MWCNTs (2 g) were added to 40 mL of sulfuric and nitric acid mixture (3/1) in a reaction flask and refluxed for 24 h at 120 °C. The mixture was cooled and diluted with distilled water, and then it was filtrated and washed with distilled water until the pH reached 5; finally it was dried by vacuum oven. MWCNT-*g*-PCA hybrid materials were prepared according to the reported procedure.[14]

2.4. Preparation of MWCNT-*g*-PCA-EP. A water solution of MWCNT-*g*-PCA (39 mg/mL) with a mancozeb water solution (5.12×10^{-4} M) and also a water solution of MWCNT-*g*-PCA (28 mg/mL) with a zineb water solution (1.45×10^{-4} M) were mixed separately and placed in an ultrasonic bath for 10 min in order to well disperse pesticide nanoparticles in the polycitric acid shell. Then the mixtures were stirred for complete encapsulation of mancozeb and zineb into CNT-*g*-PCA for 35 and 80 min, respectively.

Encapsulated pesticide nanoparticles were purified by centrifugation. Pesticide molecules which were not reacted with CNT-*g*-PCA were separated from encapsulated pesticide nanoparticles using a centrifuge with rotating speed of 2000 rpm within 7 min. During the process of centrifugation the sample was separated into two phases, a pellet consisting of MWCNT-*g*-PCA-EP and a supernatant that was unreacted pesticide molecules. Then the supernatant was separated and discarded. Figure 2 shows the synthetic scheme of the CNT-*g*-PCA-EP.

2.5. Preparation of Potato Dextrose Agar (PDA) Medium. Usually for PDA medium preparation, 250 g of potatoes was boiled for 20 min and the sap of potato was taken. Afterward 20 g of dextrose agar was added to the sap under continuous stirring and slowly warmed until it was well dissolved. Then the medium was diluted to 1 L by warmed distilled water and autoclaved for 15 min at 121 °C and pressure 1.5 kg/cm^2. Finally PDA medium was chilled to 45 °C and was poured into a Petri dish.[15−17]

3. RESULTS AND DISCUSSION

3.1. Nanohybrid Characterization. The FTIR spectra shown in Figure 3 confirm the presence of functional groups in MWCNT−COOH and MWCNT-*g*-PCA hybrid materials. The carbonyl stretching frequency in MWCNT−COOH was seen at 1701 cm^{-1} (COOH); The 3200−3500 cm^{-1} band present in the MWCNT−COOH spectrum was attributed to the hydroxyl vibration of the carboxylic acid group attached through the opening. The peak around 1400−1500 cm^{-1} was assigned to the C═C stretching of the carbon skeleton. As shown in Figure 3b a broad absorbance band at 2600−3573 cm^{-1} was attributed to hydroxyl functional groups of grafted PCA. In this spectrum, a band of carbonyl groups of citric acid was seen at 1718 cm^{-1}. Also the C═C band of MWCNT appeared at 1400−1500 cm^{-1}.

dx.doi.org/10.1021/jf404720d | J. Agric. Food Chem. 2014, 62, 4833−4838

3.2. Optimization of Effective Parameters on Synthesis of CNT-*g*-PCA-EP. The effect of various parameters on encapsulation of pesticides into CNT-*g*-PCA was studied. Figure 4 shows the role of pH in the encapsulation of pesticides by MWCNT-*g*-PCA hybrid material. The maximum encapsulation of pesticide molecules into polymeric shell corresponds to maximum absorption in UV−vis spectra. Maximum encapsulation for mancozeb and zineb according to Figure 4 takes place at pH 3 and 8 respectively. Furthermore, temperature had no significant effect on the encapsulation reaction.

The required time for complete encapsulation of pesticides in CNT-*g*-PCA is very important. Figure 5 shows the effect of

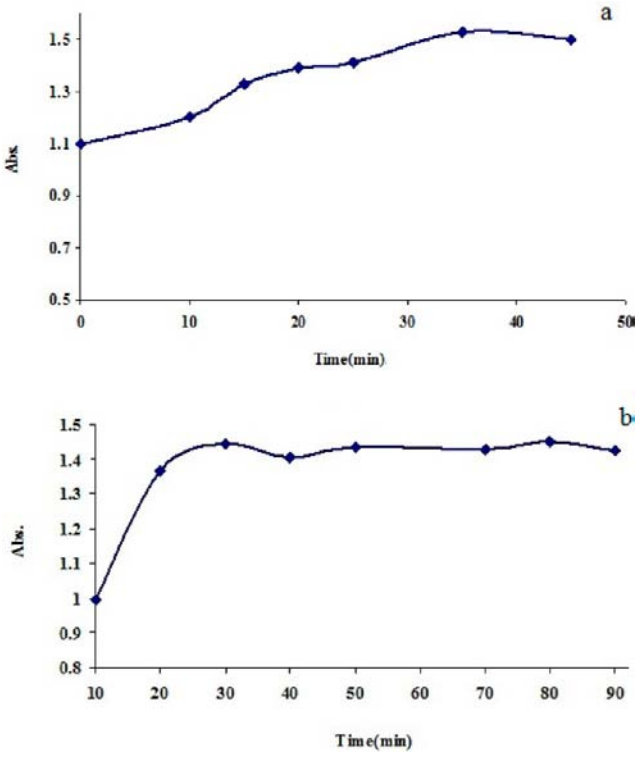

Figure 5. Effect of stirring time on encapsulation of pesticides into CNT-*g*-PCA hybrid material. Mancozeb (a) and zineb (b).

stirring time on the reaction between pesticides and CNT-*g*-PCA. As shown in Figure 5a,b with the addition of pesticide aqueous solutions to CNT-*g*-PCA the respective absorption peak increases. In other words, maximum encapsulation for mancozeb and zineb in hyperbranched polycitric acid shell takes place after 35 and 80 min, respectively.

Figure 6 shows the color change during the progress of the complexation reaction between zineb and CNT-*g*-PCA hybrid material under optimum conditions. As shown in Figure 6, the light yellow color of solution turned gradually to pale yellow after 2 h. The darkening of the solution continued and fixed after 8 h, which indicated that the encapsulation process was completed.

3.3. Encapsulation of the Pesticides by CNT-*g*-PCA: UV−Vis Study. The encapsulation of the zineb and mancozeb by polymeric shell of CNT-*g*-PCA was investigated spectrophtometrically. Figure 7a(iii),b(iii) shows the UV−vis spectra for encapsulated zineb and mancozeb by CNT-*g*-PCA respectively.

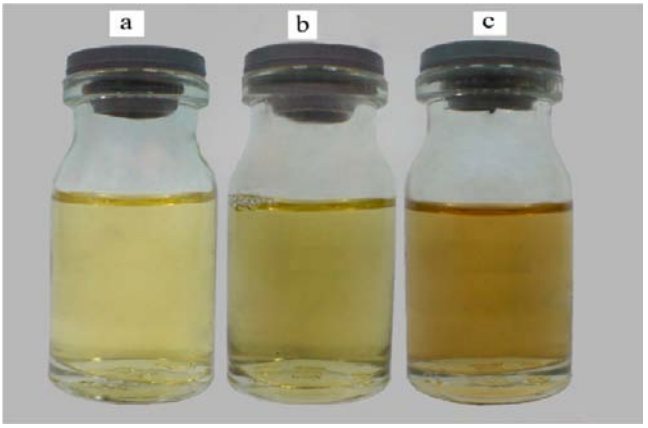

Figure 6. Color change during time progression of the encapsulation between pesticide zineb and MWCNT-*g*-PCA: (a) initial; (b) after 2 h; (c) after 8 h.

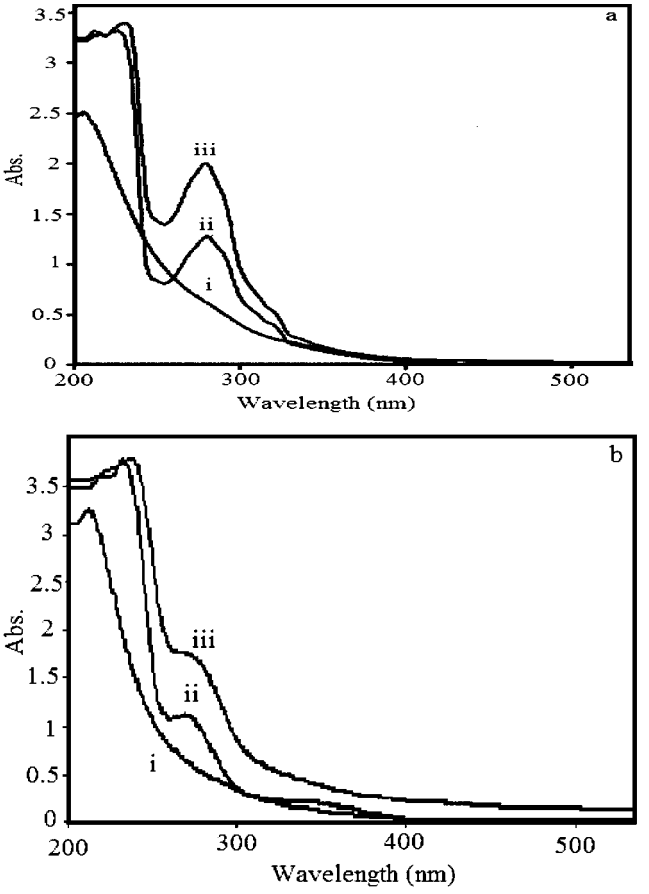

Figure 7. UV spectra for encapsulation of (a) zineb and (b) mancozeb by CNT-*g*-PCA: (i) aqueous solution of CNT-*g*-PCA; (ii) aqueous solution of pesticide; (iii) after addition of pesticide to CNT-*g*-PCA.

A simple route which clearly approves the encapsulation of pesticides in hyperbranched polycitric acid shell was attained with addition of various amounts of CNT-*g*-PCA to each pesticide and monitoring of the UV spectra. As shown in Figure 8, addition of CNT-*g*-PCA led to increasing the peak intensity while the fine structures of pesticide spectra follow the same pattern. These behaviors confirm the encapsulation of pesticides into polycitric acid hyperbranched shell.

dx.doi.org/10.1021/jf404720d | *J. Agric. Food Chem.* 2014, 62, 4833−4838

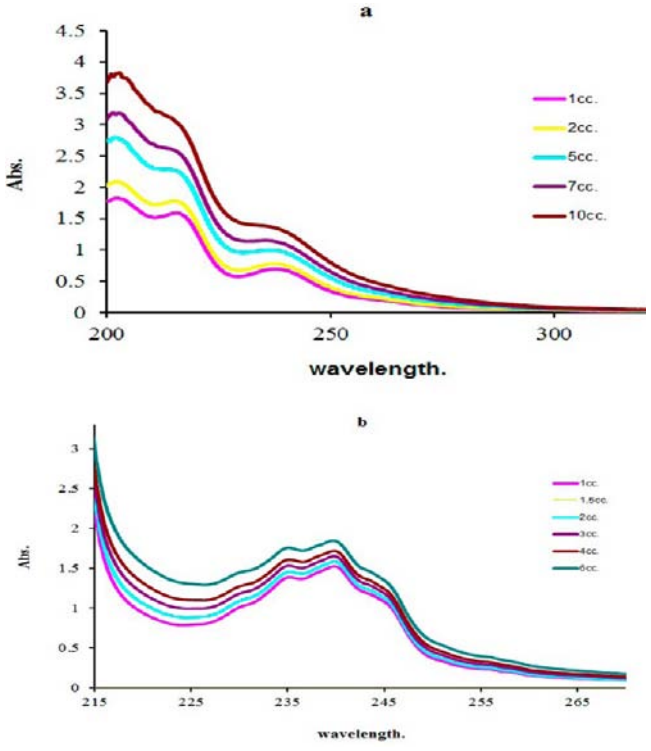

Figure 8. Addition of various amounts of a water solution of CNT-*g*-PCA to pesticides (a) mancozeb and (b) zineb.

3.4. TEM Images of Synthesized CNT-*g*-PCA-Pesticide. Finally encapsulation of pesticides by the CNT-*g*-PCA was confirmed by TEM analysis. Figure 9 shows TEM images of zineb and mancozeb encapsulation by the CNT-*g*-PCA hybrid material which clearly indicates polycitric acid (PCA) shell around CNTs and encapsulated pesticide nanoparticles.

3.5. Application of Encapsulated Zineb Nanoparticles on *Alternaria alternate* Fungi. Encapsulation of pesticide nanoparticles in hyperbranched polycitric acid results in the appearance of extraordinary characteristics. In this study, the influence of CNT-*g*-PCA-EP on the malady *Alternaria alternata* fungi was studied. For this purpose, potato dextrose agar (PDA) medium was used to grow the malady *Alternaria alternate*. Bulk and encapsulated zineb were added to the control medium, and their effects on growth of colonies were studied after 3 and 10 days (Figure 10). The results show that encapsulated zineb nanoparticles have more effect on growth restriction in comparison to the bulk zineb. This effect after 10 days reaches the maximum intensity. Probably this phenomenon is attributable to increases in the contact area which was formed between encapsulated pesticide and fungi.

3.6. Conclusion. In summary, mancozeb and zineb were successfully encapsulated into CNT-*g*-PCA hybrid material. Results showed that encapsulation of pesticides into hybrid material are dependent on pH and time of stirring but temperature has no significant effect on the encapsulation process. Experiments show that the optimum pH for encapsulation of mancozeb and zineb is 3 and 8 respectively.

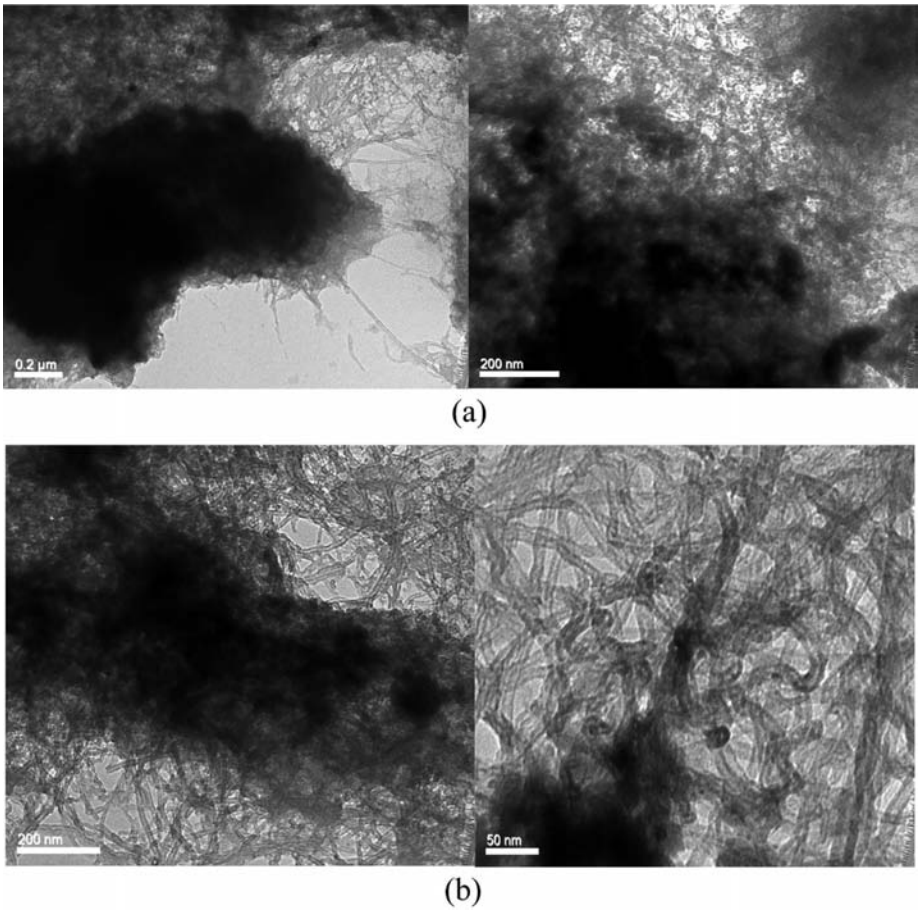

Figure 9. TEM images of encapsulation of zineb (a) and mancozeb (b) with MWCNT-*g*-PCA.

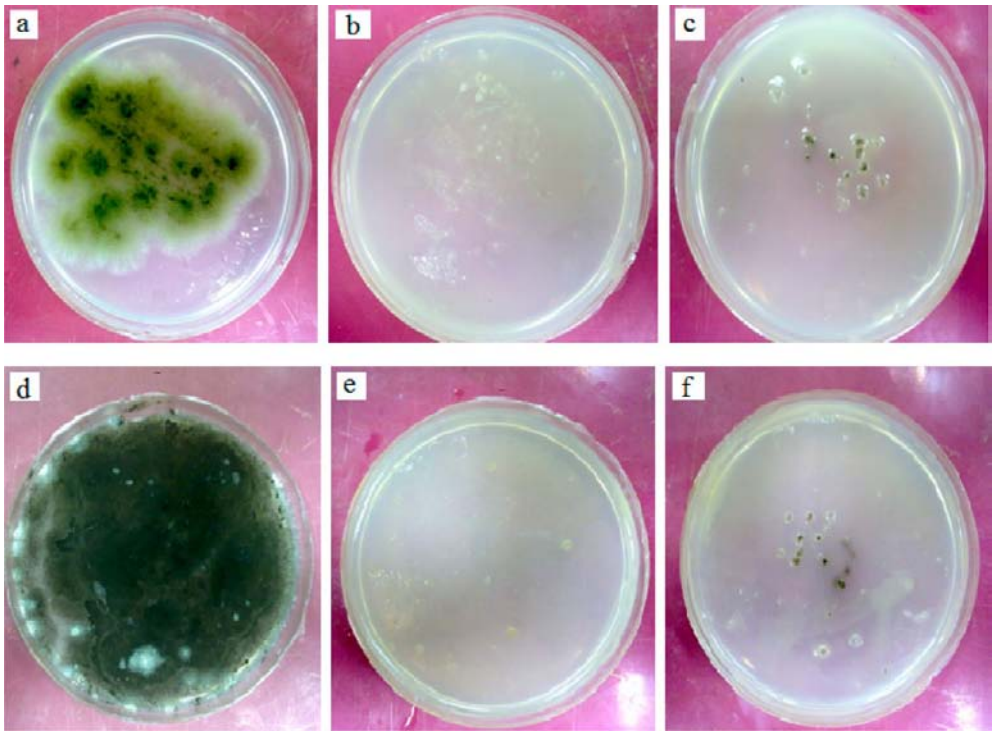

Figure 10. Influence of zineb encapsulation on *Alternaria alternate* fungi. Medium control (a and d), medium control with encapsulated zineb (b and e), and medium control with bulk zineb (c and f). Top, after 3 days; bottom, after 10 days.

Furthermore, the time of stirring for complete encapsulation of mancozeb and zineb was 35 and 80 min, respectively. As a result, in this work we could produce pesticide nanoparticles. So encapsulated zineb as pesticide nanoparticles in comparison with bulk zineb showed an extraordinary effect on the malady *Alternaria alternata* fungi, and its effect reached maximum after 10 days.

ABSTRACT: Buckwheat sprouts are a popular food item in many countries. The effects of light-emitting diodes (LEDs) on sprout growth and development, changes in mRNA transcription, and accumulation of phenylpropanoid compounds were studied in tartary buckwheat 'Hokkai T8' sprouts. The highest transcript levels were observed after 2 days of LED exposure for all genes, especially *FtPAL* and *FtF3′H*, which showed higher expression in sprouts grown under blue and white light than in those grown under red light. Catechin content in sprouts grown under red light increased dramatically throughout the 10 day time course. Maximum rutin content (43.37 mg/g dry weight (DW)) was observed in sprouts at 4 days after exposure (DAE) to blue light. Similarly, the highest cyanidin 3-*O*-rutinoside content (0.85 mg/g DW) was detected at 10 DAE to blue light. On the basis of these results, blue LED light is recommended as a light source for enhancing the content of phenolic compounds in tartary buckwheat sprouts.

KEYWORDS: *cyanidin, gene expression, light-emitting diode, phenolic compound, tartary buckwheat sprout*

INTRODUCTION

Plant products have been used as medicinal resources over the course of human history. These phytochemicals or non-nutritive substances possess disease-defensive properties.[1] Buckwheat (e.g., *Fagopyrum tataricum* L.), a pseudocereal, is recognized as a health food as it contains numerous medicinal compounds, especially rutin (quercetin-3-*O*-rutinoside), which is a major antioxidant.[2] Seed sprouts have been a part of the human diet for centuries in countries such as Japan, where they continue to be widely consumed. The interest in including fresh green sprouts in the diet has expanded across the world because of the health benefits they are thought to provide.[3]

Sprouts contain various substances (sulforaphane, sulforaphene, isothiocyanates, glucosinolates, enzymes, antioxidants, and vitamins) that can help in the prevention of cancer or provide therapeutic treatment against cancer.[4] In addition, sprouts contain much higher concentrations of some health-protecting phytochemicals than are found in the developed plant.[5] The most popular sprouts supplied in European and the Far Eastern markets are those of adzuki bean, alfalfa, broccoli, buckwheat, clover, mung bean, mustard, radish, red cabbage, and soybean.[4] Consumption of *Brassica* spp. sprouts has been shown to decrease the risk of cancer.[6,7] The use and application of foodstuffs that are rich in bioactive components can improve both food technologies and nutrition.[8] Buckwheat sprouts were first introduced and recommended as a new food source by Kim et al.,[9] who described them as having a soft and slightly crispy texture, attractive fragrance, and abundant nutrients. These authors also reported that rutin (quercetin-3-*O*-rutinoside), quericitrin (quercetin-3-*O*-rhamnoside), chlorogenic acid, and two unknown compounds were present in both buckwheat seeds and sprouts.[9]

Light-emitting diodes (LED) are artificial light sources that have many advantages for controlled-environment plant growth applications, including high energy-conversion efficiency, longer life, wavelength specificity, adjustable light intensity/quality, and low thermal energy output.[10,11] LED lights create specific wavelengths and a narrow bandwidth for plant growth compared with filters with broad-spectrum light sources.[12] Red light is crucial for the development of the photosynthetic apparatus as it can increase starch accumulation by inhibiting the translocation of photosynthates out of leaves.[13] Blue light is important for chloroplast development, chlorophyll formation, and stomata opening.[14] In addition, blue light plays a role in a wide range of plant processes such as phototropism, photomorphogenesis, stomatal opening, and photosynthesis.[15]

Flavonoid[16] and total flavonoid, polyphenol, and ascorbic acid contents have been examined in buckwheat sprouts.[17] The identification of flavonoids, accumulation of anthocyanin, and gene expression related to these compounds have been performed for tartary buckwheat sprouts under light or dark conditions.[18] On the basis of these studies, interest has developed in the ways in which gene expression patterns contribute to accumulation of specific flavonoid compounds in

tartary buckwheat sprouts grown under LED light. Thus, this study aimed to characterize the growth response of tartary buckwheat sprouts 'Hokkai T8' to different LED light spectra (blue, red, and white) to better understand the regulation of expression of flavonoid biosynthetic pathway genes (Figure 1) and to investigate the effect of LEDs on accumulation of phenolic compounds in the sprouts.

MATERIALS AND METHODS

Chemical Reagents and Standards. The applied standards (caffeic acid, ferulic acid, gallic acid, 4-hydroxybenzoic acid, rutin, and quercetin) were purchased from Extrasynthese (Genay, France). Cyanidin-3-*O*-glucoside was purchased from Fujicco Co., Ltd. (Kobe, Japan) and cyanidin-3-*O*-rutinoside from ChromaDex, Inc. (Irvine, CA, USA). Formic acid and acetonitrile were obtained from commercial sources.

Sprouting Tartary Buckwheat Seeds. Tartary buckwheat cultivar 'Hokkai T8' was procured from Hokkaido Agricultural Research Center (Hokkaido, Japan). This cultivar was derived from a pure-line selection of the Russian cultivar 'Rotundatum'.[16] An incubator (B.O.D Incubator, HB-103, Han Baek Scientific Co., Korea) was used for germination. During incubation, seeds were checked every 24 h and watered as necessary. After 2 days of germination, the sprouts were grown in plastic pots containing vermiculite soil.

Initial sprouting was carried out to obtain uniform sprouted seeds for LED exposure using double-layered plastic pots (3 × 4 × 6 cm). The bottom of the inner pot contained small holes and was filled with a thin (approximately 3 cm) layer of vermiculite soil. The outer pot did not contain holes and was filled with approximately 30 mL of 0.05% (w/v) Bio Garden nutrient solution (6:5:8 N:P:K) for plant growth. Twenty-five sprouted seeds were sown in each plastic pot. There were three replications for each of three light conditions. The pots were covered with clean wrap (30 × 100 cm) that was pierced for aeration and were placed in the dark for another 2 days prior to LED exposure.

Sprout Development under LED. Sprouts (~2 cm) sown in 109 plastic pots containing vermiculite soil were exposed under different LEDs of red (wavelength, 660 nm), blue (470 nm), and white (380 nm) at a flux rate of 50 μmol $m^{-2}s^{-1}$ for a 16 h photoperiod. Sprouts were grown in an LED growth chamber at 25 °C and 70% humidity. LED exposure day was counted from the day started to exposure under LED. Then, sprouts were harvested at 2, 4, 6, 8, and 10 days after LED exposure (DAE). Pericarps were removed, and vermiculite soil attached to the root portion was carefully washed off under tap water. Then, sprout length (from the junction point of root and hypocotyl to the growing point) and fresh weight (including root portion) were immediately measured, and the sprouts were frozen in liquid nitrogen and stored at −80 °C until used.

Total RNA Extraction and cDNA Preparation. Total RNA was extracted from the different sprout samples using modified CTAB combined with total RNA extraction kit (Geneaid, Taiwan).[19] The quality of RNA was verified by demonstration of intact ribosomal bands following agarose gel electrophoresis in addition to the absorbance ratios (A_{260}/A_{280}) of 1.8−2.0 in a NanoVue Plus spectrophotometer (GE Healthcare Bio-Science Crop, USA). For cDNA synthesis, 1 μg of total RNA was reverse transcribed using oligo $d(T)_{20}$ and a Super-Script II First Strand Synthesis Kit (Life Technologies, Carlsbad, CA, USA) following the protocol of the supplier.

Quantitative Real-Time PCR Analysis for Gene Expression. To understand the contribution of phenylpropanoid biosynthesis-related genes to the content of anthocyanins and other phenolic compounds, qRT-PCR analysis of buckwheat sprouts was performed at 2, 4, 6, 8, and 10 DAE. Transcript levels of *FtPAL*, *FtC4H*, *Ft4CL*, *FtCHS*, *FtCHI*, *FtF3H*, *FtF3′H-1*, *FtF3′H-2*, *FtFLS-1*, *FtFLS-2*, *FtDFR*, and *FtANS* encoding phenylalanine ammonium-lyase (PAL), cinnamic acid 4-hydroxylase (C4H), 4-coumarate:CoA ligase (4CL), chalcone synthase (CHS), chalcone isomerase (CHI), flavanone-3-hydroxylase

Figure 2. *F. tataricum* 'Hokkai T8' sprout development at 2 days after exposure to LED light (blue, white, and red).

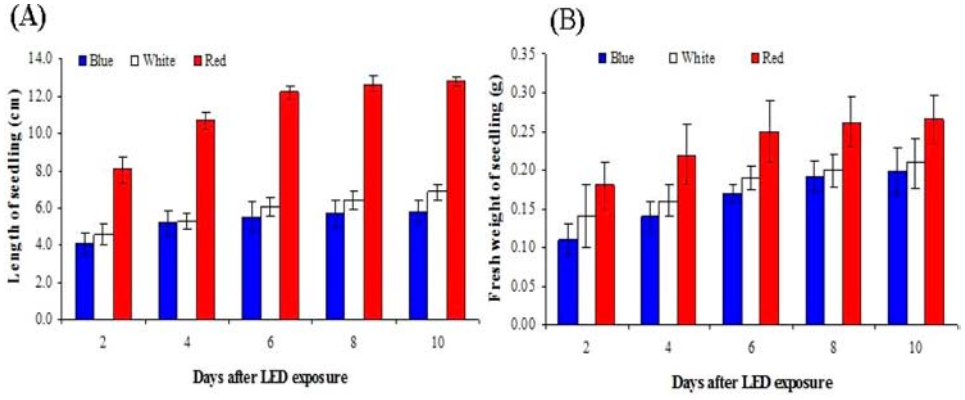

Figure 3. Growth of *F. tataricum* 'Hokkai T8' sprouts under LED light (blue, white, and red): (A) sprout length; (B) fresh weight from 2 to 10 days. Each value is the mean of three biological replicates ± standard deviation (SD).

(F3H), flavonoid-3′-hydroxylase (F3′H), flavonol synthase (FLS), dihydroflavonol reductase (DFR), and anthocyanin synthase (ANS), respectively, were analyzed relative to that of *Actin* (Genbank accession no. KC571237) as a housekeeping gene. Gene-specific primers are as follows: *FtActin* (F) 5′-GAGTTATGAGCTTCCTGA-TG-3′, *FtActin* (R) 5′-CCGCCACTCAACACAATGTT-3′. Gene expression results were evaluated as the mean of three replicates. Each PCR reaction (20 μL) contained 10 μL of SYBR green, 10 pmol of 0.5 μL primer (each), 5 μL of cDNA (diluted 1:19), and 4 μL of distilled water. The gene-specific primers used were designed as previously described by Li et al.[18] The thermal cycling conditions were 95 °C for 2 min followed by 95 °C for 30 s, 55 °C for 15 s, and 72 °C for 20 s for 40 cycles, and final extension occurred at 72 °C for 10 min.

Estimation of Phenolic Compounds and Anthocyanins by HPLC. Prior to extraction, sprout samples harvested at different days of LED exposure were powdered in liquid nitrogen by using a mortar and pestle. Then, 100 mg (dry weight) of powdered sample was extracted with 80% methanol and incubated for 1 h in a sonicator. Sample tubes were vortexed every 20 min during incubation and centrifuged at 14000 rpm for 5 min before getting the extract for further analysis by HPLC to estimate phenolic compounds content.

Quantification of Phenolic Compounds. The HPLC analysis of flavonoids was performed according to the system previously described by Li et al.[18] A Shimadzu class-VP HPLC system (Kyoto, Japan) equipped with a Capcell PAK ODS column (250 mm × 4.6 mm, 5 μm; Shiseido, Tokyo, Japan) was used. The mobile phase consisted of a mixture of (A) MeOH/water/acetic acid (5:92.5:2.5, v/v/v) and (B) MeOH/water/acetic acid (95:2.5:2.5, v/v/v). The initial mobile phase composition was 0% solvent B, followed by a linear gradient from 0 to 80% of solvent B over 48 min and then a hold at 0% solvent B for an additional 10 min. The column was maintained at 40 °C, the flow rate was 1.0 mL/min, the injection volume was 10 μL, and the eluted components were monitored at 350 nm. Different compounds were quantified on the basis of peak areas and calculated as equivalents of representative standard compounds.

Quantification of Anthocyanins. The anthocyanin filtrate was analyzed using an Agilent Technologies 1200 series HPLC (Agilent Technologies, Palo Alto, CA, USA) equipped with a Synergi 4 μ POLAR-RP 80A column (250 mm × 4.6 mm, i.d., particle size = 4 μm; Phenomenex, Torrance, CA, USA) equipped with a Security Guard Cartridges Kit AQ C18 column (4 mm × 3 mm, i.d.). The mobile phase consisted of a mixture of (A) water/formic acid (95:5, v/v) and (B) acetonitrile/formic acid (95:5, v/v). The gradient program was set as 0−8 min, 5−10% solvent B; 8−13 min, 10−13% solvent B; 13−15 min, 13% solvent B; 15−18 min, 13−15% solvent B; 18−25 min, 15% solvent B; 5% solvent B at 25.1 min; and finally 5% solvent B constant for 10 min (total = 35 min). Detection was performed at 520 nm wavelength, and the column oven temperature was at 40 °C. The flow rate was set at 1.0 mL/min, and the injection volume was 10 μL. Anthocyanin content was calculated by comparing HPLC peak area with that of authentic standards (cyanidin-3-*O*-glucoside and cyanidin-3-*O*-rutinoside).

RESULTS AND DISCUSSION

Effect of LEDs on Sprout Morphology. Normally, *F. tataricum* 'Hokkai T8' has a greenish hypocotyl color under

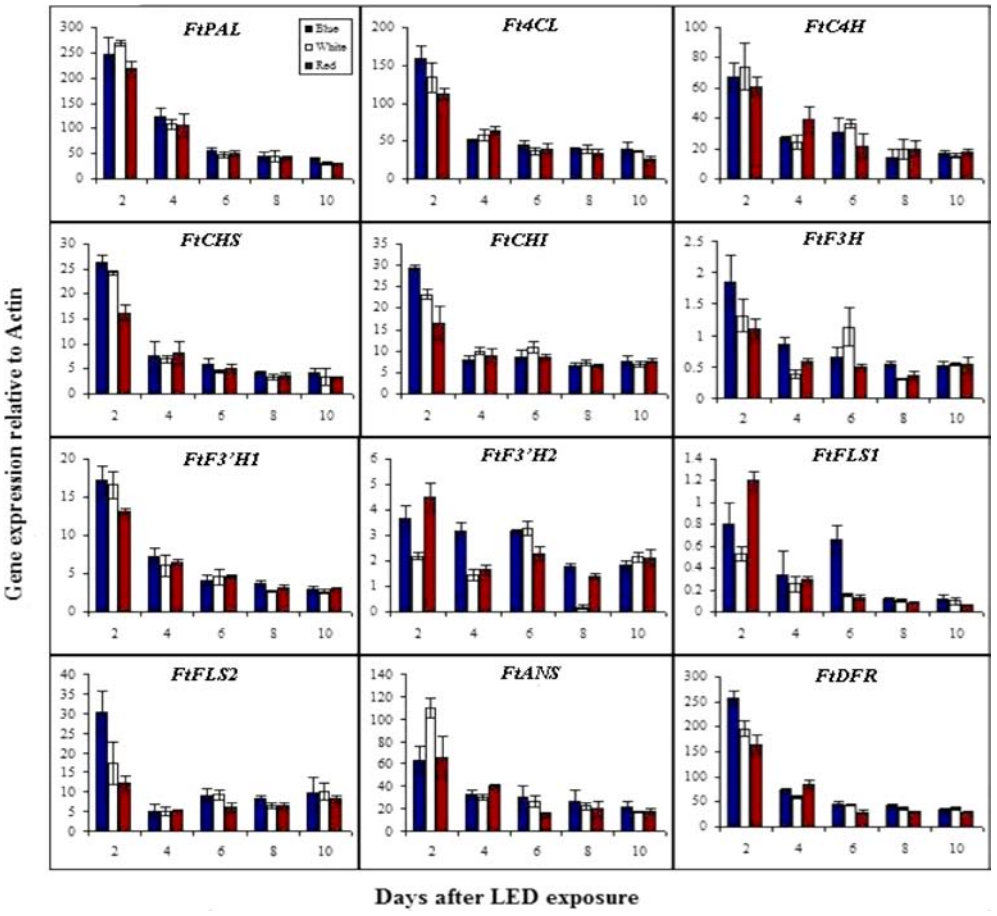

Figure 4. Expression levels of phenylpropanoid biosynthetic genes on *F. tataricum* 'Hokkai T8' sprouts grown under LED light. Transcript levels from three biological replicates were analyzed relative to that of *Actin*. Each value is the mean of three biological replicates ± SD.

light condition. Interestingly, a reddish appearance was observed in hypocotyls of blue- and white-LED-grown sprouts, and the color was more intense in sprouts grown under blue light. However, there were no color changes in sprouts grown under red LEDs (Figure 2). Light-induced color changes became apparent at 2 DAE. The red pigmentation is likely to have occurred as a result of sprouts' response to light stress after sudden transfer from dark to light (LED light) conditions. Light can advance metabolic changes during the different stages of germination.[20] These changes are most commonly due to anthocyanins, which are vacuolar flavonoids,[21] and anthocyanin (red) content is positively correlated with phenolics in several species.[22]

Sprout Length and Fresh Weight. Seedling length and fresh weight were greatly affected by different LEDs. Red light produced tall, spindly sprouts, whereas blue and white light resulted in shorter sprouts with stocky hypocotyls (Figure 2). Generally, seedling length and fresh weight of blue- and white-light-radiated seedlings were significantly less than those of red-light-radiated sprouts throughout the time course (from 2 to 10 DAE) of their development. Seedling length increased suddenly from approximately 2 cm prior to LED exposure (data not shown) to 4.0, 4.6, and 8.1 cm at 2 DAE in blue, white, and red light, respectively. Seedling length and fresh weight increased with time until 6 DAE in all sprouts under the respective light treatments (Figure 3A). Sprout length under red LEDs was almost double that under blue or white LEDs, which did not differ significantly during the observation period. Likewise, seedling fresh weight increased with time, and red-LED-grown sprouts attained greater fresh weight than sprouts grown under blue or white LEDs, consistent with their taller height (Figure 3B). However, there were no significant increases in seedling length and fresh weight beyond 6 DAE. These findings were consistent with those of McNellis and Deng,[23] who reported that blue light suppresses elongation and induces cotyledon expansion and that red light induces hypocotyl elongation and cotyledon expansion in *Arabidopsis* seedlings. Moreover, Miyashita et al.[24] revealed that red light significantly enhanced stalk elongation in pelargonium plantlets, whereas blue light inhibited elongation. After radiation for 4 days, red-light-radiated pea seedlings displayed significant increases in stem length and leaf area compared to a white light group.[25] In our study, morphological and growth parameters of seedlings, including hypocotyl color, length, and fresh weight, were controlled by light quality/intensity. Hence, LED light can be selectively utilized for plant growth by targeting the photomorphogenic pigments that are responsible for photoperception and triggering regeneration ability.[26] On the basis of the results presented here, we suggest that a sprouting period of 6 DAE would be best for achieving optimal biomass in buckwheat sprouts.

Phenylpropanoid Biosynthesis Gene Expression. Significant variability was observed in the expression levels of all pathway genes at 2 DAE in LED-exposed sprouts (Figure 4). The genes generally showed higher numbers of transcripts at 2 DAE compared with 4, 6, 8, and 10 DAE, when levels of gene

expression did not differ substantially. Although gene expression peaked at 2 DAE, it decreased suddenly after 2 DAE and plateaued until 10 DAE. Similar gene expression patterns were observed for *FtPAL* and *FtF3′H*, where sprouts grown under blue and white LEDs, in which expression did not differ significantly, showed higher transcript levels than red-LED-grown sprouts at 2 DAE.

Transcript levels of *FtPAL* gene in blue-, white-, and red-light-grown sprouts were approximately 6.3-, 8.9-, and 6.9-fold higher at 2 DAE than those at 10 DAE. The PAL enzyme plays a key role in the biosynthesis of flavonoids by catalyzing the flux of primary metabolites into the flavonoid biosynthetic pathway.[27] Similar gene expression patterns were observed for *FtC4H*, *FtCHI*, *FtFLS-2*, and *FtANS*, where the relative abundance of transcript levels was higher in sprouts grown under blue LEDs than in those grown under white or red light. The *CHI* gene is required for the synthesis of naringenin from naringenin chalcone and has been considered essential for the biosynthesis of flavonoids.[28,29] Higher expression levels of *FtDFR* were also observed at 2 DAE, and white-light-grown sprouts had 1.7-fold greater transcript numbers than sprouts grown under blue or red light. In *FtANS*, blue-, white-, and red-LED-grown sprouts showed 7.4-, 5.2-, and 5.6-fold greater expression at 2 DAE compared with expression at 10 DAE. Higher transcript levels of *FtANS*, the gene responsible for anthocyanin accumulation, might be related to the reddish appearance of hypocotyls in blue- and white-LED-grown sprouts. Except for *FtF3′H-2*, the remaining genes showed relatively higher transcript levels in sprouts grown under blue or white LEDs than in sprouts grown under red light. Li et al.[30] reported that the expression levels of almost all flavonoid biosynthesis genes peaked within 4 DAE in common buckwheat sprouts grown under either light or dark conditions and gradually decreased thereafter.

Overall gene expression was highest at 2 DAE, after which it was down-regulated over the time. These results could be related to the sudden appearance of reddish coloration in hypocotyls at 2 DAE because of seedlings' response to light, which can cause metabolic changes during different stages of germination.[20] In addition, all of the genes were highly expressed at early stages of sprout development under all light treatments, and blue- and white-light-grown sprouts showed higher transcript levels than red-light-grown sprouts.

Accumulation of Phenolic Compounds and Anthocyanins in Sprouts. Phenolic compounds and anthocyanins were analyzed in 'Hokkai T8' sprouts grown under LED. Catechin content in sprouts grown under red LED light increased dramatically from 2 to 10 DAE (Table 1); the highest catechin content was detected at 10 DAE and was 9.6- and 43.1-fold higher, respectively, than that in sprouts grown under blue or white LED light. Rutin content in all sprouts was significantly greater than the content of other compounds, and there was no significant difference in rutin accumulation according to DAE. However, the maximum rutin content (43.37 mg/g dry weight (DW)) was observed at 4 DAE in sprouts under blue LED light and was higher than that observed under fluorescent light (30 mg/g DW at 4 days) in a previous study by Li et al.;[18] this indicates that the effects of LED and fluorescent light on rutin content in sprouts are comparable. Accumulation of chlorogenic acid was not significantly different between sprouts grown under blue or white LEDs, both of which showed higher chlorogenic acid content than sprouts grown under red light. Very small quantities (almost nondetectable) of caffeic acid, ferulic acid, and quercetin were present in the sprouts (data not shown).

Accumulation of two anthocyanins (cyanidin 3-*O*-glucoside and cyanidin 3-*O*-rutinoside) was also analyzed (Table 1). Cyanidin 3-*O*-glucoside was detected only in blue-LED-grown sprouts, and its content did not change significantly during sprout development. The cyanidin 3-*O*-rutinoside content of sprouts grown under blue LEDs at 10 DAE was 2.8- and 10.6-fold higher, respectively, than that in sprouts grown under white and red LEDs.

These results demonstrated that blue LED light enhances accumulation of anthocyanin compared with white or red LED light. Li et al.[18] reported that only cyanidin 3-*O*-rutinoside was detected in 'Hokkai T8' sprouts under light/dark conditions, and only in trace amounts. However, we detected cyanidin 3-*O*-glucoside in blue-LED-grown sprouts and cyanidin 3-*O*-rutinoside in sprouts grown under all LED light conditions. Cyanidin 3-*O*-rutinoside is the main compound that may contribute to the red color of tartary buckwheat sprouts.[31,32] Blue light induces the accumulation of anthocyanins, which

play a major role in antioxidant activity.[33] All of these reports help to explain the reddish hypocotyl appearance and anthocyanin detection in blue-LED-grown sprouts described in this study.

In recent years, it was suggested that consumption of anthocyanins is related to reduced risk of coronary heart disease and improvement of visual functions. The health benefits of anthocyanins have mainly antioxidant activity, anticancer property, and visual acuity enhancement.[31,34] Takeuchi[35] noted that petals of red-flowered buckwheat are used as materials in tea, juice, and alcohols after detoxification of fagopyrin in food processing. In addition, the presence of radical-scavenging activity was reported in common buckwheat,[36] and the change in DPPH radical-scavenging activity was similar to that of total flavonoid contents in buckwheat sprouts.[37]

In plants, secondary metabolites have been noted to act as warning signals, toxins, antifeedants, or precursors to physical defense systems.[38,39] Anthocyanins may serve both direct roles as chemical repellents and more indirect roles as visual signals to potential herbivores, displaying a strong metabolic investment in toxic or unpalatable chemicals.[40] Some anthocyanins have demonstrable antiviral, antibacterial, and fungicidal activities.[41,42] Karageorgou et al.[20] hypothesized that red leaf color is less easily perceived by folivorous insect photoreceptors or that red leaf color disables insect camouflage of plant parts against their backgrounds, in the undermining of insect crypsis, and in the mimicry of defensive structures. According to these results, anthocyanins may play an important role as visual signals.

We reported that the metabolomics and regulation of anthocyanin production in red-flowered (Gan-Chao) and white-flowered (Tanno) buckwheat cultivars were carried out through qRT-PCR, HPLC, and gas chromatography time-of-flight mass spectrometry.[43] Further studies that investigate the metabolomics and regulation of anthocyanin accumulation in 'Hokkai T8' tartary buckwheat after exposure to different LED light are required.

In conclusion, LED lights are effective for enhancing phenolic content, especially rutin and anthocyanin, in buckwheat sprouts. Our findings can have useful applications for commercial sprouting and biomass production for compound analysis and also as preliminary data for further experimentation with LED light.

Accelerated Dissipation of the Herbicide Cycloxydim on Wax Films in the Presence of the Fungicide Chlorothalonil and under the Action of Solar Light

Shirin Monadjemi,[†] Alexandra ter Halle,[†,‡] and Claire Richard*[,†,‡]

ABSTRACT: Photolysis is a known dissipation pathway of pesticides on leaves just after their spraying. This pathway may be affected by the residues of other pesticides. To illustrate this idea, this study investigated the mutual effect of two pesticides (chlorothalonil and cycloxydim) under simulated solar light. Cycloxydim was added at the agricultural rate (200 g ha^{-1}) and chlorothalonil at 1.3−10% of the rate (20−150 g ha^{-1}). These compounds were studied either pure or in their commercial formulation. Both analytical and kinetic data show that chlorothalonil significantly accelerates the decay of cycloxydim on wax films, promoting its oxidation, even at the lowest tested dose. Conversely, cycloxydim does not affect the fate of chlorothalonil. Moreover, the detection of oxidized forms of wax alkanes in the extracts demonstrates that chlorothalonil may have also a degrading effect on the leaves' constituents under the action of solar light.

KEYWORDS: *photolysis, sensitization, oxidation, pesticides, leaves surface*

INTRODUCTION

On foliage and under the action of sunlight, pesticides can undergo photodegradation.[1] Nevertheless, this route of dissipation is scarcely documented, although understanding its mechanism and evaluating its rate is of utmost importance for the improvement of pesticide formulations. Besides, photochemical reactions taking place on vegetation can follow specific pathways and lead to degradation products different from those observed in water, the most commonly studied medium. For example, it has been reported that the herbicides mesotrione and sulcotrione deposited on leaf models mainly undergo an intramolecular photocyclization when irradiated in a solar light simulator, whereas this process is very minor in aqueous solution.[2,3] Moreover, photochemical reaction rates of molecules in solution cannot be generalized to the solid state. For instance, the half-life of photolysis of the herbicide mesotrione is about 90 days in water against 8 h on leaf surface models.[2] Another poorly considered issue is the mutual potential effect that pesticides may have on each other when they are applied in a mixture. To improve crop protection, it is common to apply pesticides in mixtures or to use successively different pesticides during annual crop treatments. Mixing pesticides might have consequences on their photostability and thus influence their effectiveness. For example, it was shown that mesotrione and nicosulfuron herbicides show higher rates of photodegradation in a mixture than separately.[4]

In this work, we studied the fate of two pesticides in a mixture: the herbicide cycloxydim (*E* isomer, CD) and the fungicide chlorothalonil (CT) (Scheme 1). CD and CT are foliar pesticides that are both used for the control of tomato, asparagus, and pea crops; their presence altogether on crops is thus very likely. CD, on the one hand, is a systemic herbicide used for the control of grass weeds and the control of agricultural crops. In solution, photoisomerization of the C═N bond and cleavage of the oxime occur, leading to a rather fast loss of CD (*E* isomer).[5] Only a few data are, however, available on the photostability of this molecule on plants. A recent patent proposes to stabilize the cyclohexane oxime formulations by the addition of aromatic solvents such as toluene or benzene, epoxidized oil fatty acids, or more adjuvants.[6] This confirms that CD undergoes photodegradation on leaves. CD was shown also to react with singlet oxygen in acetonitrile.[7] CT, on the other hand, is a persistent fungicide. It is also a powerful sensitizer, which has the ability to produce singlet oxygen with a quantum yield close to 1 in alkanes.[8] Therefore, one might expect that CT is able to promote the photodegradation of CT. However, this enhancing effect of CT remains to be evidenced when both compounds are in the solid state. Moreover, its actual contribution to the CD photodissipation in simulated solar light and using commercial formulations has to be evaluated. Finally, the potential effect of CD on CT phototransformation is unknown so far. Comparative experi-

ments were conducted using phenalenone, a well-known singlet oxygen producer.[9]

EXPERIMENTAL PROCEDURES

Chemicals. All solvents and chemicals were used as received. CD (98%) and CT (99%) were obtained from Fluka (Saint-Quentin Fallavier, France). Commercial formulations of CD and CT, respectively Stratos Ultra (100 g L^{-1} of CD) and Fongil FL (500 g L^{-1} CT), were obtained from a regular agricultural shop. Phenalenone (97%) and paraffin wax (mp 70−80 °C) were both purchased from Aldrich (Saint-Quentin Fallavier, France). Water was purified using a Millipore Milli-Q system (Millipore αQ, resistivity = 18 MΩ cm^{-1}, DOC < 0.1 mg L^{-1}). Acetonitrile (99%, HPLC grade) was provided by Riedel de Haën (Saint-Quentin Fallavier, France).

Sample Preparation and Irradiation. Stock solutions of pure CD and CT (10^{-4} M) were prepared in acetonitrile and stored at 4 °C. Solutions of formulated CD (Stratos Ultra) and formulated CT (Fongil FL) were prepared in Milli-Q water just before use. The exact pesticide concentration was determined using a calibration curve established for the corresponding active ingredient in acetonitrile. Paraffin wax films were made by weighing 0.8 g of wax in each dish (3.2 cm diameter) and by heating them at 90 °C for wax melting and achieving film formation. Films were allowed to cool and ready for use. In all of the experiments, the surface concentration of CD was equal to 200 g ha^{-1}, this concentration corresponding to the recommended dose applications. In the set of experiments in which CD and CT were applied as nonformulated active ingredients, the surface concentration of CT was also chosen as 150 g ha^{-1}. When Stratos Ultra and Fongil FL formulations were used, the chosen CT concentrations were 20 and 150 g ha^{-1}. This choice aimed to mimic a situation in which CT traces are remaining on leaves when CD is applied. Actually, in the case of tomatoes, for instance, the recommended field application for CT is 1500 g ha^{-1}. We chose a situation in which 10 and 1.3% of CT are still present on the leaves when CD is applied. Acetonitrile solutions of pure CD and the CD + CT mixture were deposited on wax films as 1 mL volume. Stratos (diluted 125× in water) and a mixture of Stratos (diluted 125× in water) with Fongil (diluted 833× and 4550× in water) were applied as 10 droplets of 2 μL using a micropipet (Eppendorf). The solvent was allowed to evaporate overnight. After drying, 24 dishes (3 replicates for each sampling) were irradiated inside a Suntest CPS photosimulator (Atlas) equipped with a xenon lamp filtered below 290 nm (irradiance within the range of 290−800 nm). The intensity of the lamp was set at 400 W m^{-2} to simulate the sunlight average intensity in summer in France. Cold water (16 °C) was flowed through the bottom of the photosimulator to maintain the internal temperature as low as possible. Four dishes were taken after each selected irradiation times. For each, wax was rinsed using 1 mL of acetonitrile to recover remaining pesticides and photoproducts. These mixtures were further analyzed by UPLC and LC-MS. By this method, the recovery yields of CD and CT prior to irradiation were good (~95%). Mixtures of CD and phenalenone were also applied on wax films in acetonitrile. The same procedure as for CD + CT was used for photolytic tests.

Analyses. Absorption spectra were recorded using a Cary 3 UV−visible spectrometer (Varian). Solid state spectra were recorded using a DRA-CA-30I integrating sphere accessory (Varian) and a $BaSO_4$ reflectance standard (Spectralon). Acetonitrile solutions of CD (1 g L^{-1}) and CT (1 g L^{-1}) were deposited on quartz plates as 3 drops of 10 μL, and spectra were recorded after acetonitrile was completely evaporated. For the laser flash photolysis experiments, the apparatus consisted of a laser flash photolysis spectrometer from Applied Photophysics (LKS.60) equipped with a Quanta Ray GCR 130-01 Nd:YAG laser.[10] Solutions were deoxygenated by bubbling argon directly in the quartz cell. UPLC-UV analyses were performed using an Acquity Waters UPLC system equipped with a thermostated autosampler, a degasser, a pump, and a photodiode array detector. Chromatographic separation was performed on an Acquity UPLC BEH C18 column (2.1 mm × 50 mm, 1.7 μm). The operating temperature was maintained at 25 °C, and the sample volume injected was 6 μL. The flow rate was set at 0.5 mL min^{-1}, and elution was carried out in the gradient mode. The mobile phase composition started with 58% water (acidified with formic acid, 0.5‰ v/v) and 42% acetonitrile. The percentage of acetonitrile was increased linearly to 75% over 3 min and then kept constant during 0.5 min. The mobile phase was then returned to 42% acetonitrile in 0.5 min and kept for 0.5 min. Detection was set at 280 nm. CD and CT were monitored at 280 nm (retention times of 3.1 and 2.3 min, respectively). The MS system consisted of an LC/QTOF equipped with an orthogonal geometry Z-spray ion source (Waters/Micromass, Manchester, UK). A photodiode array detector, Waters Alliance 2695, system was used for UV detection. A volume of 25.0 μL was injected on a reversed-phase column (Xterra, Waters, C18, 3.5 μm, 100 mm × 2.1 mm). A flow rate of 0.2 mL min^{-1} was set. The binary solvent system used was composed of solvent A (acetonitrile) and solvent B (water acidified with 0.5‰ v/v formic acid). The gradient elution started with 5% A and reached 95% A in 15 min linearly. The gradient was held for 10 min and then decreased to 5% A in 10 min. The desolvation chamber and ion source block temperatures were set at 250 and 100 °C, respectively. N_2 was used as the nebulizer gas (35 L h^{-1}) and the desolvation gas (350 L h^{-1}). The electrospray interface was operating in positive ion mode. The capillary voltage was 3000 V; the sample cone and the extraction cone were set at 35 and 1 V, respectively. Data were acquired over the m/z 90−1000 range at a scan rate of 1 s per spectrum. The data recorded were processed with MassLynx (version 4.0).

RESULTS AND DISCUSSION

Phototransformation of Pure CD on Wax Films. The percentage of transmission of solid CD (12 kg ha^{-1}) between 500 and 250 nm is shown in Figure 1. Absorption of CD starts below 380 nm, meaning that, upon solar irradiation, CD can undergo direct photolysis. By extrapolating absorbances of Figure 1 to a dose of CD of 200 g ha^{-1}, one gets 0.0019 at 300 nm. Dark control experiments showed no CD decay on the time scale of the experiments, indicating that other phenomena such as volatilization, thermal degradation, or penetration into the wax are negligible. Pure CD undergoes fast photolysis on wax films at the recommended agricultural rate of 200 g ha^{-1}. The apparent first-order rate constant of phototransformation is 0.11 h^{-1} (see Figure 2).

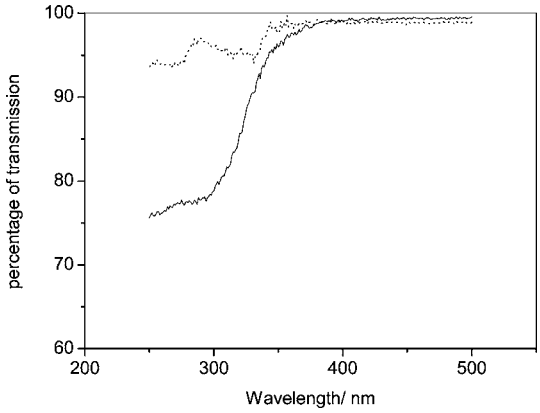

Figure 1. Transmission spectra of CD (12 kg ha^{-1}) (solid line) and CT (7 kg ha^{-1}) (dashed line) on quartz plates.

The typical chromatogram of irradiated CD is given in Figure 3a. CD in *E* form is eluted at 17.8 min and CD in *Z* form at 13.2 min. The *Z* form is very minor before and after irradiation. Thus, only the *E*-form peak variation was used for photodegradation rate determination. The small variation of the *Z*-form peak during irradiation indicates that photoisomerization

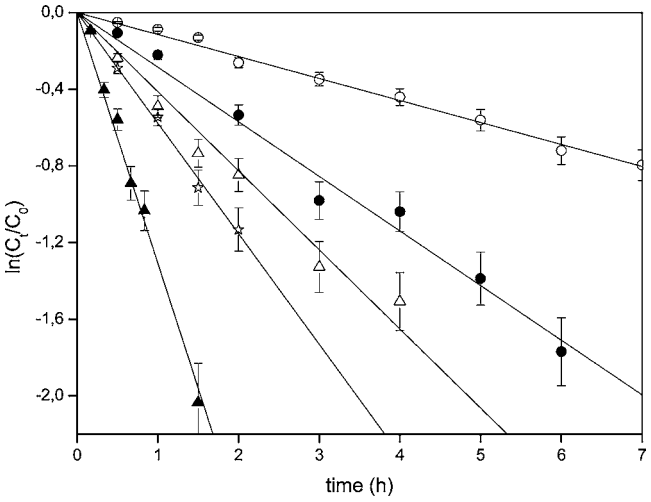

Figure 2. Decay of CD (200 g ha^{-1}) irradiated on paraffin wax in a solar simulator: CD alone (○, k = 0.11 ± 0.01 h^{-1}) and in the presence of CT at 150 g ha^{-1} (●, k = 0.30 ± 0.03 h^{-1}); Stratos alone (△, k = 0.41 ± 0.04 h^{-1}), in the presence of Fongil at 20 g ha^{-1} (☆, k = 0.58 ± 0.06 h^{-1}), and in the presence of Fongil at 150g ha^{-1}(▲, k = 1.3 ± 0.1h^{-1}).

is a minor process. Five other chromatographic peaks are detected, showing m/z at 298, 342, 282, and 358 u. Two peaks have the same m/z of 342 u. Using the exact mass measurement and MS/MS data (in the positive mode), we propose the elemental compositions given in Table 1 and the structures given in Scheme 2.

P_2, detected at 12.1 min, has gained O compared to CD. The oxidation can occur either on the sulfur atom or on the cyclohexane ring. Thanks to the MS/MS data, differentiation is possible. First, a fragment at m/z 101 u corresponding to the ion $C_5H_9S^+$ is detected in P_2 fragmentation pattern as in that of CD. This shows that the S atom is not oxidized. Second, the fragment at 324 u corresponding to the loss of water is in good accordance with the presence of an OH group on the cyclohexane ring, because the neighborhood of H atoms makes possible water elimination. The other fragments of P_2 show loss of C_2H_4O by cleavage of the N−O bond (m/z 298 u) and also subsequent loss of water (m/z 280 u).

P_3, detected at 13 min, gives a positive ion at m/z 282 u, resulting from the loss of C_2H_4O. The main fragments of the ion are at m/z 265 u (loss of NH_3), 254 u (loss of CO), and 182 u (loss of neutral C_5H_8S). Again, the fragment at 101 u

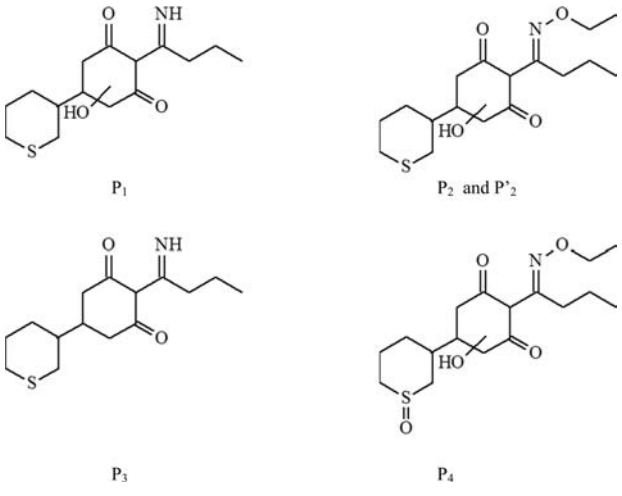
Scheme 2



corresponding to $C_5H_9S^+$ is detected. P_3 is assigned to the imine.

P_2' (retention time at 15.7 min) is a minor photoproduct giving the same mass and fragmentation pattern as P_2. This is thus an isomer of P_2.

P_1, eluted at 1.6 min, has lost C_2H_4 compared to CD. Using data on the other photoproducts, this can be understood by the replacement of the ethoxyl group by H with the formation of the imine and oxidation with O addition. By MS/MS the main fragments are m/z 280, 263, and 101 u. The presence of a fragment at 101 u is again in accordance with oxidation of the cyclohexane ring.

P_4 with m/z 358 u is detected at 16.1 min. The $[P_4 + H]^+$ ion has two extra oxygen atoms compared to the $[CD + H]^+$ ion. Among fragments, the ion at m/z 117 u is detected. This ion corresponds to $[C_5H_9SO]^+$, and thus in P_4 the sulfur atom is oxidized. The second oxygen atom is on the cychohexane ring as indicated by the fragments at m/z 340 corresponding to the loss of water as observed for the other oxidized compounds.

Phototransformation of CD in the Presence of CT. As shown in Figure 1, CT absorbs solar light between 300 and 350 nm. On the basis of the transmission spectrum recorded at 7 kg ha^{-1}, one calculates that absorption of CT (200 g ha^{-1}) should be around 0.0012 at the maximum (340 nm) and 0.0006 at 300 nm. This means that CT absorbs solar light more weakly than CD when they are applied at the same dose.

In the presence of CT (150 g ha^{-1}), there is a marked increase of the rate of CD photolysis (Figure 2). The apparent first-order rate constant of phototransformation is equal to 0.3 ± 0.03 h^{-1}, thus 3-fold higher than for pure CD. On the contrary, the concentration of CT remains unchanged after 6 h of irradiation by considering a 5% error margin. The photolysis of pure CT was previously found to be quite slow (first-order rate constant of 0.065 $days^{-1}$ under continuous irradiation at 500 W m^{-2});[8] therefore, CD does not significantly affect its photoreactivity.

The phototransformations of CD and CT on wax film were also studied using commercial formulations, Stratos and Fongil, respectively. In this case, pesticide solutions were deposited as 2 μL droplets to better represent field conditions, and the surface concentration of CD was again fixed at 200 g ha^{-1}. Stratos alone disappears with a first-order rate constant of 0.4 ± 0.03 h^{-1} (Figure 2). In the presence of Fongil, the photodissipation

dx.doi.org/10.1021/jf500771s | J. Agric. Food Chem. 2014, 62, 4846−4851

of Stratos increases. When Fongil is added at 20 and 150 g ha^{-1}, the photodegradation rate constants of formulated CD are 0.6 ± 0.03 and 1.3 ± 0.03 h^{-1}, respectively. Thus, the photoreactivity of formulated CD is 1.5- and 3.2-fold higher, respectively. The same enhancement was measured when using the pure active ingredients; therefore, one can conclude that the accelerating effect is mainly due to the active ingredient CT and not the additives present in Fongil.

This experiment shows that the lowest level of Fongil, corresponding to a 70th of the recommended application dose on tomato crops, still has an impact on the photodissipation rate of CD. This result is amazing when one takes into account that the absorption of CT at this dose is very low compared to that of CD. CT is thus a very efficient sensitizer.

Typical HPLC-MS analysis of reactional mixtures is shown Figure 3b. In this case, six peaks are observed. On the basis of retention times and MS data, P_1, P_2, P_3, and P_4 correspond to the photoproducts identified in the case of pure CD. However, TIC data show that P_1 and P_2 are formed in much greater amount in the presence of CT than for pure CD. Two new photoproducts are also detected: P_5 and P_6. The chemical formulas of the respective ions $[P_5 + H]^+$ and $[P_6 + H]^+$ are $[C_{22}H_{44}O_2 + H]^+$ and $[C_{24}H_{48}O_2 + H]^+$, and the unique fragments are $[C_{21}H_{43} + H]^+$ and $[C_{23}H_{47}O_2 + H]^+$, respectively, demonstrating the loss of CO_2H radical in both cases. Clearly, these oxidation products do not arise either from CT or from CD, but from the wax that contains long-chain alkanes $C_{22}H_{44}$ and $C_{24}H_{48}$ as main constituents.[11] It must be pointed out that CT cannot be protonated and, consequently, cannot be detected by electrospray MS in the positive mode.

Phototransformation of CD in the Presence of Phenalenone. Experiments were repeated by replacing CT by phenalenone, a strong singlet oxygen sensitizer. To conduct the tests at the same molar concentration for phenalenone and CT, the surface concentration of P on wax films was set at 100 g ha^{-1}. Considering a 10% error margin, the apparent first-order rate constant of phototransformation of CD in the presence of P measured was 0.25 ± 0.03 h^{-1}, which is close to the rate constant measured for CD in the presence of CT at 150 g ha^{-1}. However, unlike CT, P disappeared rapidly during the irradiation. The same photoproducts as in the case of CD + CT mixtures were detected. Photoproducts P_5 and P_6 corresponding to the oxidation of the wax were also formed.

Laser-Flash Photolysis. When CD is irradiated in the presence of CT or phenalenone, it may disappear by reaction with singlet oxygen produced by the CT and phenalenone triplets[8,9] or be oxidized by the triplets themselves. The reactivity of CD with the triplet of phenalenone was reported elsewhere.[7] The reaction rate constant is $(9.6 \pm 1) \times 10^6$ M^{-1} s^{-1} in acetonitrile. Here, we measured the rate constant of reaction between the triplet of chlorothalonil and CD. To this end, acetonitrile solutions of CT were irradiated at 266 nm with the fourth harmonic of a Nd:YAG laser, and the triplet decay was monitored at 320 nm. In deoxygenated medium, the first-order rate constant for the triplet decay was equal to $(1 \pm 0.2) \times 10^5$ s^{-1}. In the presence of CD (5×10^{-5} M), the triplet decayed more quickly with an apparent first-order rate constant of $\sim 1.5 \times 10^5$ s^{-1}. In the reaction, the triplet of chlorothalonil is reduced into the radical anion that absorbs in the same wavelength range as the triplet.[12] As a consequence, the rate constant of reaction of CD with the triplet of chlorothalonil cannot be obtained accurately, but the experiment demonstrates that CD is oxidized by the triplet of chlorothalonil with a rate constant $\sim 10^9$ M^{-1} s^{-1}.

DISCUSSION

The photolysis of CD in solid form on wax films is very fast in simulated solar light. This reaction mainly leads to the imine by cleavage of the oxime function and to oxidation. Analytical data demonstrate that the oxidation takes place preferentially on the cyclohexane ring and not on the S atom. It must be stressed that the oxidation product is firmly identified for the first time. Traces of oxidized imine and doubly oxidized CD with one oxygen on the cyclohexane ring and another on the S atom are detected, too. The photoreactivity of CD is similar to that observed in acetonitrile.[13] In particular, photoisomerization of the *E* isomer into the *Z* isomer, which is observed in water but not in acetonitrile, does not occur in solid form. This means that the intramolecular hydrogen bond between the OH and the N detected in acetonitrile exists also in the solid.[13] When CD is formulated, the photoreactivity is faster, probably because of the better spreading of the molecules thanks to the formulation adjuvants. Photoproducts are the same as for pure CD; therefore, adjuvants do not affect photoreactivity.

CD is also phototransformed by sensitized reactions. At the chosen level of added CT that remains well below the rate applied in the field, the accelerating effect is very significant. CD photoproducts are the same as for pure CD, but their distribution is different. In particular, the oxidized imine and the photoproduct resulting from oxidation of the cyclohexane ring are formed in much greater amounts. This confirms that sensitized reactions induce oxidation.

The oxidation can imply two pathways: oxidation by singlet oxygen and oxidation by the sensitizer triplet itself. As the two routes probably give similar products, it is difficult at this stage to delineate the role of each of them in the CD photo-oxidation. The only indication is given by comparing the effects of CT and phenalenone. Both sensitizers photogenerate singlet oxygen with a yield close to 1.[8,9] As phenalenone is much more absorbing than CT within the wavelength range of 290−500 nm,[7] one might expect a much faster photodegradation of CD in the presence of phenalenone than of CT if singlet oxygen were the involved oxidant species. Actually, this is not the case as close rates of phototransformation are measured for both sensitizers. As far as the reactivity of CD with triplets is concerned, one found that the reaction rate constant is about 100-fold higher for triplet CT than for triplet phenalenone. This higher oxidant property of triplet CT may counterbalance a lower absorptivity and finally rationalize the close rates of phototransformation measured in the presence of both sensitizers. To sum up, data are consistent with an oxidation of CD by the sensitizer triplets as the main pathway of oxidation. This oxidation occurs on CD and on P_3, the main CD photoproduct (Scheme 3).

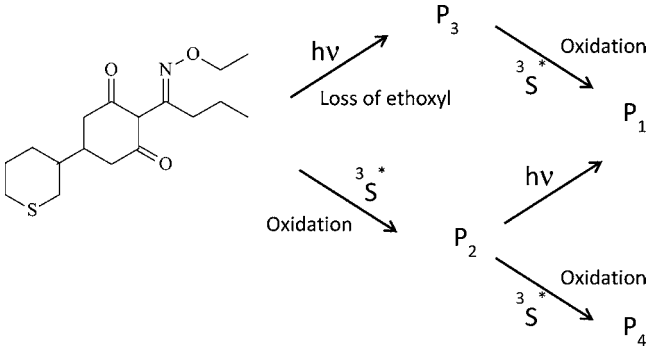
In the course of the reaction, the concentration of CT remains very stable, indicating that it is not measurably consumed, whereas phenalenone disappears quite rapidly. This difference may originate from the reactivity of the sensitizers' reduced radicals. Oxidation of CD by the triplets yields the reduced forms of sensitizers:

$$^3\mathrm{CT}^* + \mathrm{CD} \rightarrow \mathrm{CT}_{\mathrm{H}}^{\bullet} + \mathrm{CD}_{-\mathrm{H}}^{\bullet}$$

$$^3\mathrm{phenalenone}^* + \mathrm{CD} \rightarrow \mathrm{phenalenone}_{\mathrm{H}}^{\bullet} + \mathrm{CD}_{-\mathrm{H}}^{\bullet}$$

dx.doi.org/10.1021/jf500771s | J. Agric. Food Chem. 2014, 62, 4846−4851

Scheme 3



The nonconsumption of CT indicates that the radical $CT_H^{\bullet}$ gives the H atom back to oxygen, regenerating CT and producing $HO_2^{\bullet}$. From phenalenone, the hydroxylperinaphthenyl radical is expected to be formed. In solid medium, this radical is poorly reactive toward oxygen. It preferentially reacts by addition with other radicals; consequently, phenalenone is not regenerated.[14] This explains the disappearance of phenalenone and shows that, in the solid state, CT is a much better sensitizer than phenalenone.

The last but not the least interesting point here is the detection of oxidized long-chain alkanes. To our knowledge this is the first time it is shown that alkane wax constituents can be oxidized by a mild oxidation process involving light, oxygen, and an organic sensitizer. This implies that leaf constituents should be also subject to oxidation.

In conclusion, on leaf models, direct photolysis of cycloxydim leads to the loss of ethoxyl group and to the oxidation of the cyclohexane moiety. Applied at a dose 75-fold less than the recommended one, and although showing a weak absorptivity, chlorothalonil increases the phototransformation rate of cycloxydim through oxidation. Besides, chlorothalonil is also able to oxidize the wax components of the leaves. This exemplifies the necessity to test the photochemical reactivity of pesticides in mixtures. It is also worth noting that the sensitizers chlorothalonil and phenalenone do not have the same properties in the solid state. Chlorothalonil is quite stable during the irradiation experiment in the presence of cycloxydim, whereas phenalenone undergoes photodegradation.

Hydrolysis Reaction Mechanism in Atrazine Metabolism and Prediction of Its Metabolites' Toxicities

Jia Li, Jing Hu, Wenli Xu, Min Ling, and Jianhua Yao*

Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, Shanghai 200032, China

Supporting Information

ABSTRACT: Atrazine (ATR) is a widely used herbicide. There are several types of reactions in its metabolism. Herein, the mechanism of three paths of hydrolysis reactions in its metabolism and predictions of toxicities of its metabolites in the three paths will be presented. The calculation results by B3LYP (Becke, 3-parameter, Lee−Yang−Parr), one of the approaches in density functional theory, indicated that (1) there were three models in the three hydrolysis paths of ATR. The dissociation mechanisms of C(9/11)−N(8/10), C(4/6)−N(8/10), and C−Cl were dealkylation, deamination, and Cl substitution, respectively. (2) The energy barrier of C−Cl dissociation was lower. The dissociation was advantageous in dynamics and the primary reaction in the three hydrolysis paths. In these hydrolysis reactions, the different intermediates had different concentrations because of the impact of the reaction rate. (3) In addition, it was necessary to consider the solvent effect to investigate hydrolysis reaction. The conductor-like polarizable continuum model (CPCM) was used to simulate the hydrolysis reaction in bond length and energy barrier because of the solvent effect. Experimental or predictive results showed that atrazine and its metabolites in the three hydrolysis paths were carcinogenic.

KEYWORDS: *atrazine, density functional theory, hydrolysis reaction, solvent effect, prediction of toxicity*

INTRODUCTION

Atrazine (ATR; IUPAC name, 2-chloro-4-ethylamino-6-isopropylamine-s-triazine; CAS Registry No. 1912-24-9) is one of the triazine herbicides widely used in the United States.[1] Its chemical structure is shown in Figure 1. Its acute toxicity was at

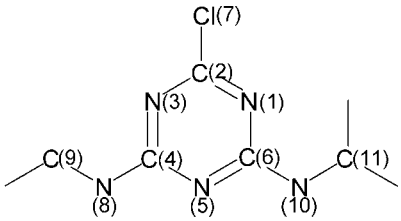

Figure 1. Structure of ATR.

a low level (rat, oral, LD_{50} = 2000 mg/kg), and AMES was negative,[2] Muntagenic (sperm from human) was positive.[3] It was carcinogenic by RTECS.[4] Its half-life depended on environmental fates. In the document reported by the U.S. EPA,[5] "Decision Documents for Atrazine", atrazine's overall half-life, water half-life, and sediment half-life were given as 608, 578, and 330 days, respectively.

Atrazine may act as an endocrine disrupter at sensitive stages in the developmental process and may subsequently significantly reduce the reproductive capacity of amphibians.[6] Therefore, the degradation rate and the properties of compounds generated in the degradation process should be attract attention.

Many works about ATR's metabolism have been reported: photolysis,[7] microbial degradation,[8,9] degradation in plants,[10] hydrolysis,[11−19] etc. All of these works focused on (1) the relationship between environmental fates and the metabolic rate of ATR and (2) metabolic processes in various environmental fates. Dr. Wen and his colleagues' showed that the salinity, pH, and temperature affected the degradation rate of ATR; the degradation of ATR in subsurface flow constructed wetland (SFCW) followed first-order kinetics, with a half-life of approximately 17.5 days.[13] Drs. Chu and Lin studied the relationship between four fates (pH, temperature, ATR concentration, and sunlight) and ATR degradation rate. The results showed that ATR's decomposition rate constant outdoors was slower in neutral pH and faster at extreme pH levels; the higher the ATR concentration was, the lower was the decomposition rate constant.[14]

Dr. Lin studied ATR degradation in selected plant species. The results showed that main product was ammeline (AMN) by N-dealkylation and hydrolysis in the metabolic process.[10] Dr. Cheney studied the degradation reaction of ATR on synthetic birnessite (δ-MnO_2). The result showed that hydrolysis of the C−Cl bond was primary in the metabolic process, and the main product was 2-hydroxy-4-ethylamino-6-isopropylamine-s-triazine (HA).[12] In other works about ATR degradation, HA is also the main product, and the hydrolysis of ATR was accelerated obviously in alkaline solution[15] or ultraviolet light.[16] Dr. Pelizzetti studied ATR degradation over TiO_2 particles under simulated solar light. The result showed that the final product, 2,4,6-trihydroxy-s-triazine (CA) was generated by photocatalytic hydrolysis via the intermediate AMN.[17]

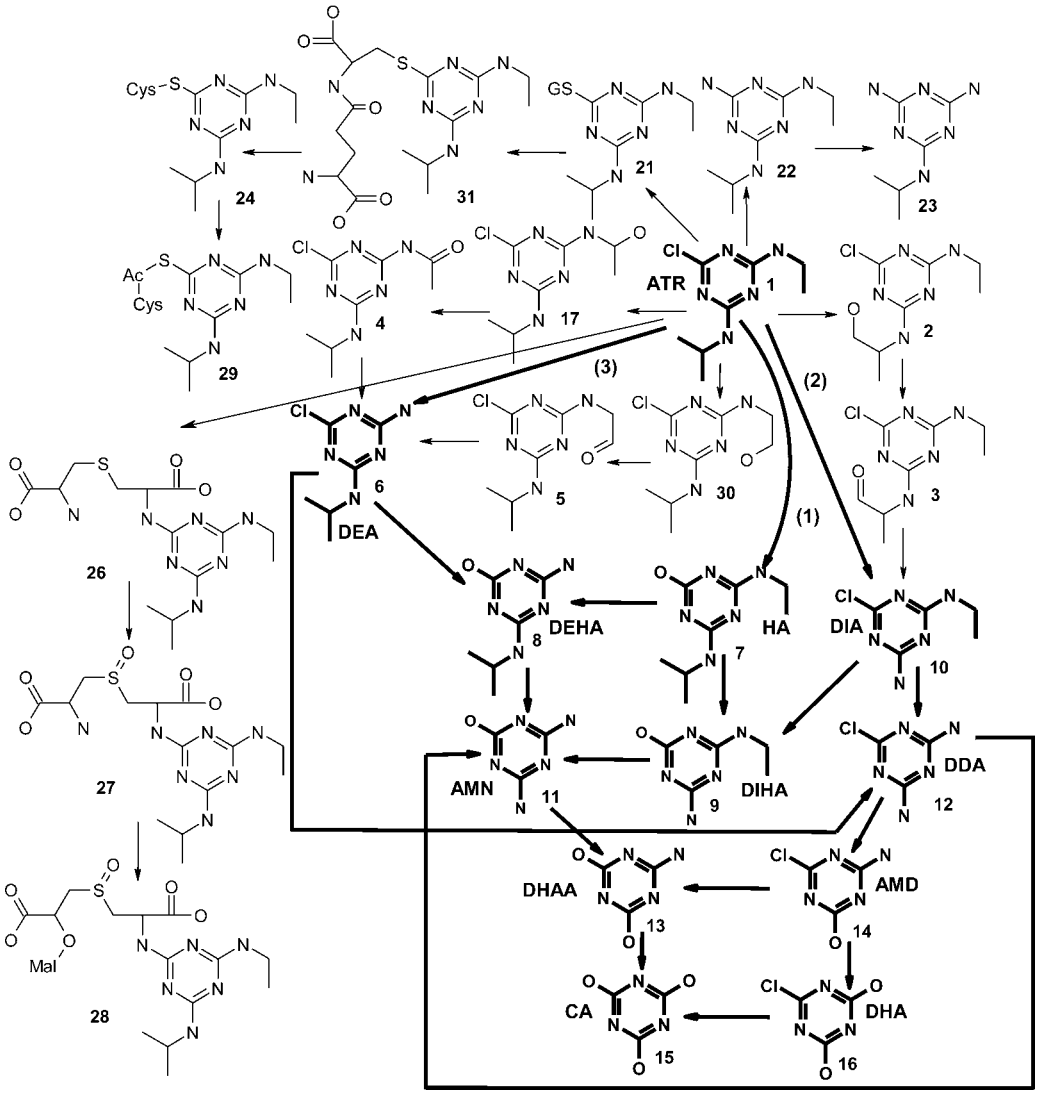

Figure 2. Metabolism pathways of ATR.

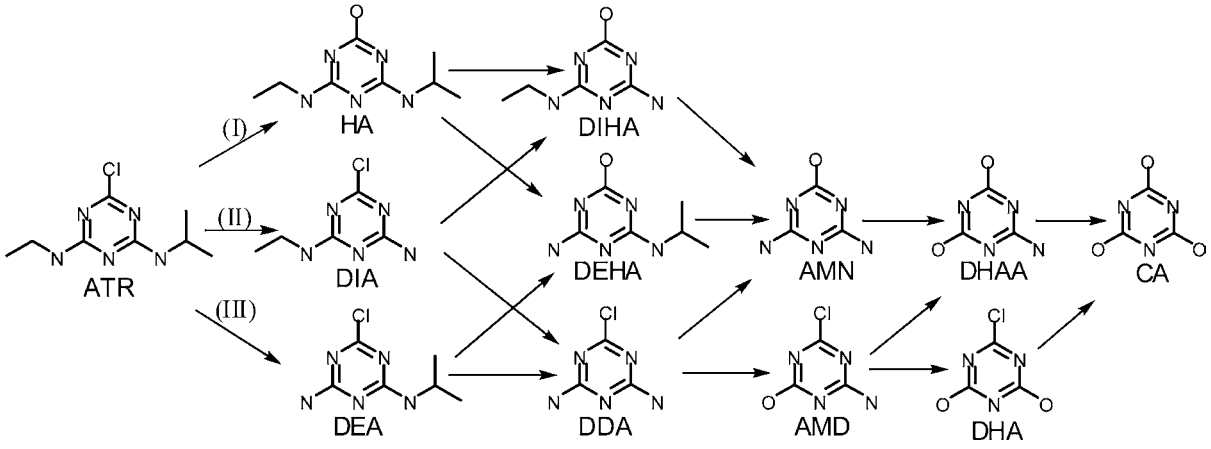

Figure 3. Part of the hydrolysis reactions in ATR metabolism (bold in Figure 2).

ATR's metabolism paths were summarized on the basis of publications[7−20] and are listed in Figure 2.

All reported studies of ATR's metabolism focused on its metabolites and metabolic conditions. Herein, the mechanism of hydrolysis reactions in three hydrolysis paths in ATR's metabolism (shown in Figure 3) was studied by B3LYP (Becke, 3-parameter, Lee−Yang−Parr)[21]/6-31++G(d, p),[22] one of the approaches in density functional theory (DFT). The calculation results explained three points related to the hydrolysis reactions in the three paths: (1) the mechanism of each hydrolysis

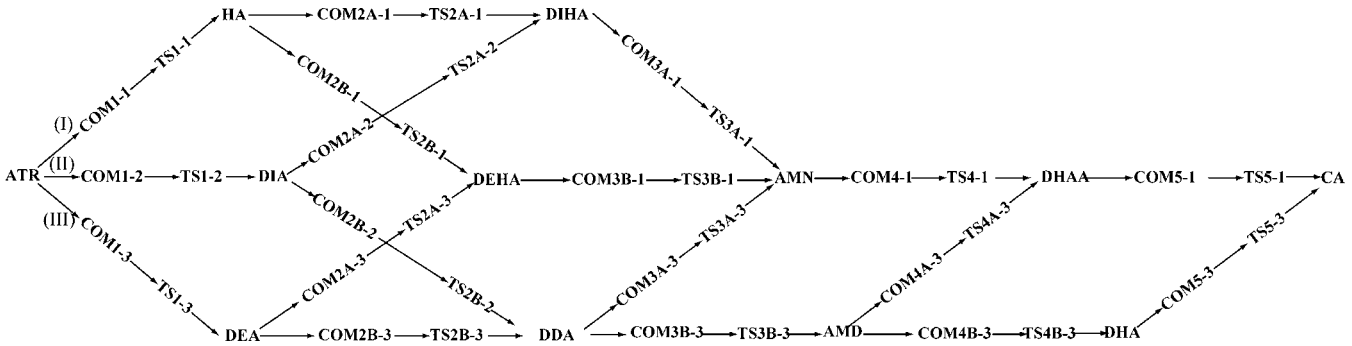

Figure 4. Hydrolysis reaction processes of ATR in the three hydrolysis paths.

reaction in the three paths; (2) the reaction path with the advantage of dynamics in the three paths and the influence of the advantage of dynamics on intermediate concentrations; and (3) in the calculation, the influence of the conductor-like polarizable continuum model (CPCM),[23] which was used to simulate the aqueous environments on the geometry and potential energy surface (PES) of hydrolysis reactions.

In this work, acute, mutagenic (AMES test)[24] and carcinogenic toxicities of ATR and its metabolites in Figure 3 were also predicted by three computer programs, CISOC-PSAT,[25] CISOC-PSMT,[26] and CISOC-PSCT,[27] respectively.

COMPUTATIONAL DETAILS

In this work, DFT calculations were performed with the Gaussian 09 program[28] using the B3LYP method and the 6-31++G(d,p) basis set. Equilibrium and transition state structures were fully optimized. For all calculated structures, harmonic vibration frequencies were calculated by numerical differentiation of the energy gradients. All structures were shown to be transition states (with one imaginary frequency) or stationary points (with no imaginary frequency). The vibrational zero point energy (ZPE) corrections were based on the corresponding frequency calculation. To analyze reaction path characters, the minimum energy path was followed in both directions (forward and backward) using the intrinsic reaction coordinate (IRC).[29] For all structures, natural bond orbital (NBO) analysis[30] was performed for further elucidation. In addition, CPCM was used to simulate the aqueous environments for interpreting the influence of the solvent effect. To gain insight into the various bond-breaking or bond-making processes in this reaction, an analysis of bond order[31−33] was carried out.

CISOC-PSAT is a program used to predict acute toxicity of an organic compound. The prediction results correspond to rat, oral and range of LD_{50}. CISOC-PSMT is a program to predict mutagenic toxicity (AMES test) of an organic compound. The prediction results correspond to mutagenicity in the test model: *Salmonella typhimurium*. CISOC-PSCT is a program to predict carcinogenic toxicity of an organic compound. The prediction results correspond to carcinogenicity in the test model: rat, oral.

RESULTS AND DISCUSSION

Atom Charge and Bond Length in This Hydrolysis Reaction. In principle, hydrolysis reactions of these groups connecting to C(2), N(8), and N(10) were able to occur. Therefore, three hydrolysis paths were observed (in Figure 3), and the reaction continued to hydrolyze the amino group connecting to C(4) and C(6). Their procedures are proposed in Figure 4. The structure parameters of the stationary points of the reactions are shown in Figure 5. Information about atomic charge of these first transition states in the three paths and the dissociation transition state of the amino group connecting to C(4) is shown in Figure 6.

In hydrolysis degradation shown in Figures 4 and 5, there were several steps in path I: (1) HA was formed. When one H_2O closed to N(1), the hydrogen bond complex COM1-1 was formed at first. The bond length of the hydrogen bond is 203.2 pm. (2) The O atom of H_2O attacked the C(2) to form the transition state TS1-1 with a four-membered ring (C(2)−O−H−Cl). In TS1-1, the bond length of C(2)−Cl increased from 176.1 to 227.5 pm and that of O−H in H_2O is elongated to 99.5 pm. The O and H atoms all closed to C(2)−Cl, and bond lengths of C(2)−O and Cl−H were 179.4 and 206.6 pm, respectively. (3) HA was generated via the transition state TS1-1. Meanwhile, one H_2O was consumed and one HCl was produced in the reaction. (4) The bond of C(11)−N(10) was hydrolyzed by H_2O. The complex COM2A-1 was formed by H_2O approaching the N(5) with the hydrogen bond. The hydrogen bond lengths of N(5)−H and O−H were 188.2 and 211.8 pm, respectively. In the transition state TS2A-1, there was a four-membered ring (N(10)−H−O−C(11)), and the C(11)−N(10) bond was elongated to 277.4 pm. The O−H bond in H_2O is slightly elongated to 103.5 pm, and C(11)−O and N(10)−H were generated in this reaction. DIHA was generated by the end of this reaction. On the other hand, the hydrolysis of C(9)−N(8) also occurred. DEHA was generated via COM2B-1 and TS2B-1. (5) DIHA was hydrolyzed to AMN. The complex COM3A-1 was formed when one H_2O closed to the C(9)−N(8); the transition state TS3A-1 was generated when a four-membered ring was formed (N(8)−H−O−C(9)). There was a difference between bond lengths of the four-membered ring in TS2A-1 and those in TS3A-1. By the end of this reaction, AMN, HCl, alcohol, and isopropanol were generated by three H_2O molecules consumed. (6) AMN was hydrolyzed to DHAA. The complex COM4-1 was formed when one H_2O closed to the amino groups connected to C(6), the transition state TS4-1 was generated when a four-membered ring was formed (N(10)−H−O−C(6)). By the end of this reaction, DHAA was generated. (7) DHAA was hydrolyzed to CA. The complex COM5-1 was formed when one H_2O closed to the amino groups connected to C(4), and the transition state TS5-1 was generated when a four-membered ring was formed (N(8)−H−O−C(4)). By the end of this reaction, CA was generated. The bond lengths of the four-membered ring in TS4-1 were a little different from those in TS5-1. We propose that the

amino group and hydroxyl affected TS4-1 and TS5-1 slightly. In path I, the pH value of the reaction system was decreased.

Reactions in path II (shown in Figures 4 and 5) also included several steps: (1) DIA was formed. When one H_2O closed to N(10), the two hydrogen bond complex COM1-2 was formed at first. The bond lengths of the hydrogen bonds were 190.8 and 208.5 pm, respectively. (2) The O atom of H_2O attacked the C(11) to form the transition state TS1-2 with a four-membered ring (N(10)−H−O−C(11)). In TS1-2, the bond length of N(10)−C(11) increased from 147.6 to 287.6 pm, and that of O−H in H_2O was elongated to 103.5 pm. Bond lengths of C(11)−O and N(10)−H were 255.3 and 157.9 pm, respectively. DIA was generated via the transition state TS1-2. (3) DIA was degraded to DIHA or DDA. If C(2) was attacked by H_2O, a four-membered ring (C(2)−O−H−Cl) generated in the transition state TS2A-2. The bond length of C(2)−Cl was increased from 175.7 to 225.8 pm, and that of O−H in H_2O was elongated to 99.4 pm. DIHA was generated when H in H_2O was transferred. If C(9) was attacked by H_2O, a four-membered ring (C(9)−O−H−N(8)) generated in the transition state TS2B-2 via complex COM2B-2. The bond length of C(9)−N(8) was increased from 146.2 to 254.9 pm. DDA was generated from DIA.

[a]The other molecules in the reaction were considered. [b]The results in gas. [c]The results by CPCM.

Reactions in path III (shown in Figures 4 and 5) were similar to those in path II and included several steps: (1) C(9)−N(8) was hydrolyzed. DEA was generated via complex COM1-3 and transition state TS1-3 including a four-membered ring (C(9)−O−H−N(8)). (2) DEA was degraded into DEHA or DDA. If C(2) was attacked by H_2O, a four-membered ring (C(2)−O−H−Cl) generated in the transition state TS2A-3, and DEHA was generated. If N(10) was attacked by H_2O, a four-membered ring (C(11)−O−H−N(10)) was generated in the transition state TS2B-2 via complex COM2B-2. DDA was generated from DEA. (3) DDA was degraded into AMN or AMD. If N(1) was attacked by H_2O, a four-membered ring (C(2)−O−H−Cl) was generated in TS3A-3 via complex COM3A-3. AMN generated from DDA. If N(10) was attacked by H_2O, a four-membered ring (C(6)−O−H−Cl) was generated in TS3B-3 via complex COM3B-3. AMD generated from DDA. (4) AMD was degraded into DHAA or DHA. The complex COM4A-3 was formed when one H_2O closed to N(1), the transition state TS4A-3 was generated when a four-membered ring was formed (C(2)−O−H−Cl). By the end of this reaction, DHAA was generated. The complex COM4B-3 was formed when one H_2O closed to N(8), and the transition state TS4B-3 was generated when a four-membered ring was formed (C(4)−O−H−N(8)). By the end of this reaction, DHA was generated. (5) DHA was hydrolyzed to CA.

All results mentioned in the front were calculated in gaseous environments. In this work, the actual reaction process was in an aqueous environment. Therefore, the reactant, intermediates, transition states, and products were calculated by simulating the aqueous environment by CPCM. Some works reported that the solvent effect little influences compound structures.[34,35] From information shown in Figure 5, normal chemical bond lengths were slightly affected, about 1 pm, but the bond lengths in the center of the transition state were effected obviously, about 30 pm. Therefore, the solvent effect must necessarily be considered in the optimization of the geometry structure, especially for transition states in reactions.

In these hydrolysis reactions, the nucleophile H_2O attacked C(2), C(4), C(9), and C(11), respectively, to form corresponding transition states. As shown in Figure 6, the O atom in H_2O did not attack these C atoms directly, but formed complexes by the interaction of the hydrogen bond first. In the process of forming transition states, C(2), C(4), C(9), and C(11) lost electrons. In these corresponding transition states, the dissociated C atoms all had positive charges (+0.674/(+0.714) C(2), +0.648/(+0.648) C(4), +0.217/(+0.313) C(9), +0.002/(+0.063) C(11)), which were good for the nucleophilic reaction. The corresponding information in detail (calculated in gaseous) is in the Supporting Information.

Potential Energy Surface of Reaction. The imaginary frequencies of transition states in the reactions and relative energies corrected by ZPVE of reactant, intermediates, transition states, and product are listed in Table1. The potential energy surfaces of the reactions are shown in Figure 7. We can discern relative energies corrected by ZPVE of various compounds and transition states in reaction coordinates according to the information in Figure 7.

Information given in Table 1 and Figure 7 shows that system energy decreased about 20 kJ/mol with formation of complexes because the influence of the hydrogen bond was weak. In the reaction process, the energy barrier of the transition state was the key factor of the reaction rate. As shown in Figure 7, the energy barriers of the hydrolysis of the C(2)−Cl bond in three paths were 185.6, 187.8, 203.7, 187.7, 186.2, and 202.0 kJ/mol, respectively, and their vibrational frequencies were 380.3*i*, 380.3*i*, 378.0*i*, 397.6*i*, 342.8*i*, and 338.8*i*, respectively. The vibration mode was the swing of the Cl between the C(2) and

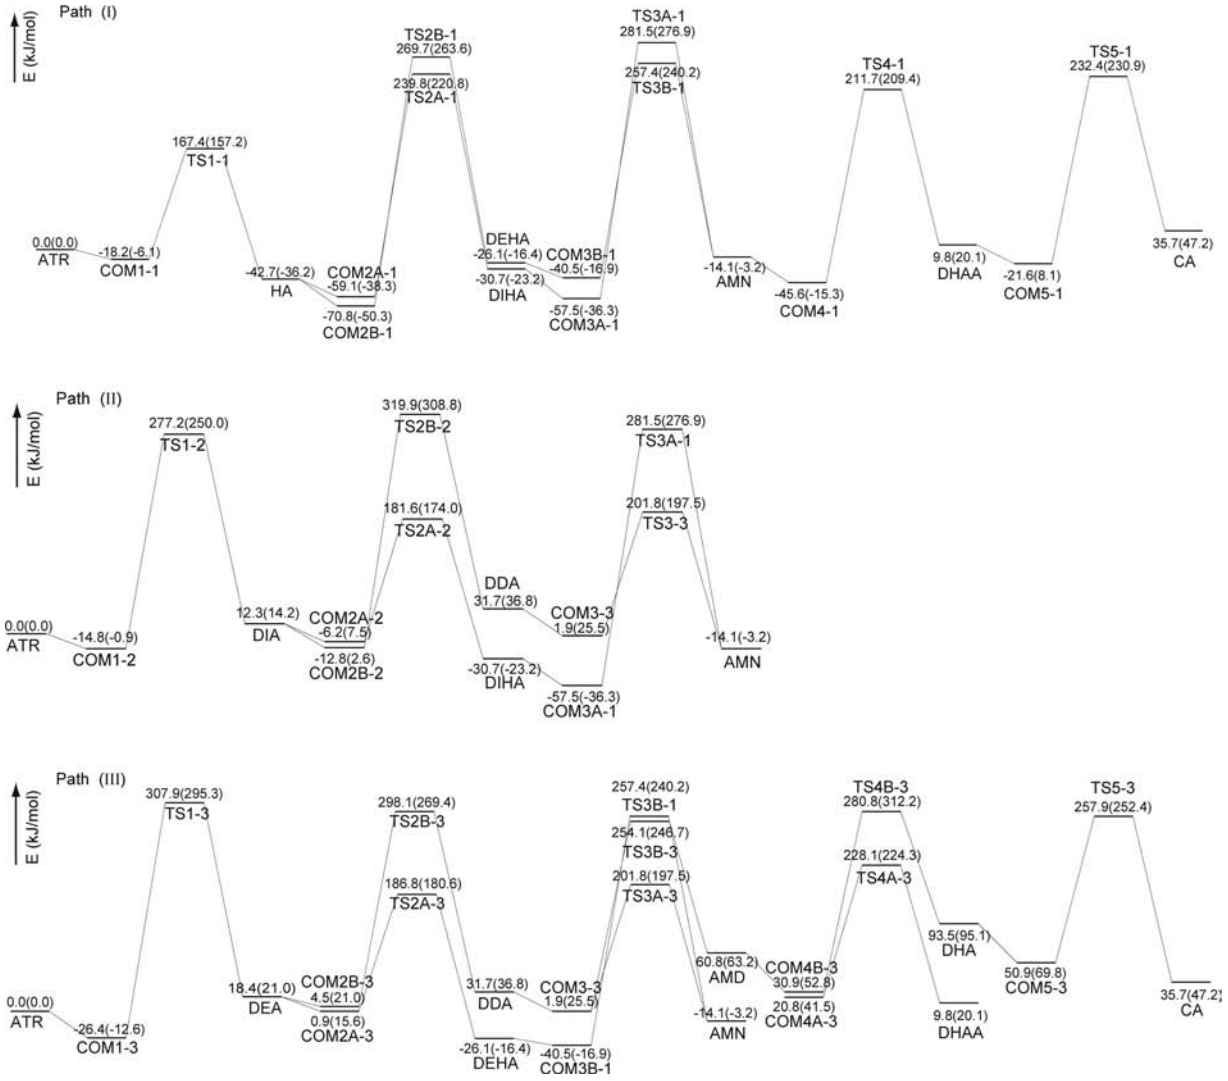

Figure 7. Potential energy profiles of ATR and its metabolites in the three paths.

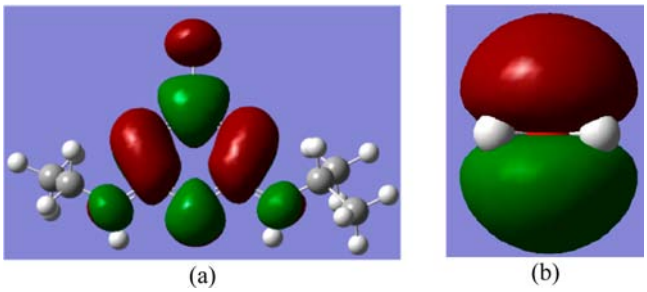

Figure 8. Schematic diagrams of (a) LUMO of ATR and (b) HOMO of H_2O.

H atom. The Cl was substituted in this step. The energy barriers of the hydrolysis of the bond of C(9)−N(8) were 340.5, 339.0, 332.7, and 334.3 kJ/mol. The energy barriers of the hydrolysis of the C(11)−N(10) were 298.9, 297.9, 292.0, and 293.6 kJ/mol. The vibrational frequencies of the C(9)−N(8) and C(11)−N(10) bonds were about 460*i* and 320*i*, respectively. Those vibration modes were all the swing of the H atom between N(8)/N(10) and the O atom, and the H atom was transferred in this step. For bonds of C(4)−N(8) and C(6)−N(10), those dissociation energy barriers were 256.3, 254.0, 256.0, and 257.2 kJ/mol, respectively, so the reaction energy barriers of the C(2)−Cl bond were obviously lower than those of the C−N bond. In this reaction, the hydrolysis reaction rate of ATR was slow because of higher reaction energy barriers.

In general, nucleophilic reactions are an interaction between the HOMO of a nucleophile and the LUMO of an electrophile. In this reaction system, there was an interaction between the HOMO of the nucleophile H_2O and the LUMO of ATR. The LUMO of ATR (the antibonding orbital of the C(2)−Cl bond) in Figure 8 shows that the bond of C(2)−Cl was elongated and dissociated by the interaction between the lone pair electrons of the nucleophile H_2O and the LUMO of ATR, so the bond of C(2)−Cl was dissociated previously by the nucleophile H_2O because of its lower energy barrier.

In principle, an energy barrier has an exponential relationship with the rate constant. The reaction energy barrier of the C(2)−Cl bond was about 110−150 kJ/mol lower than that of the C(9)−N(8) or C(11)−N(10) bond, and its reaction rate constant was obviously higher than that of the C(9)−N(8) or C(11)−N(10) bond. Therefore, there were obvious kinetics differences in the three paths. The hydrolysis of the C(2)−Cl

bond was the easiest one in the three reactions: from ATR to HA, DIA, and DEA. In this hydrolysis reaction system (shown in Figure 3), the intermediate concentration in path I was the highest, such as HA in path I. The result corresponds to some experimental works.[12,15,16] The prediction will be beneficial to expand the study of pesticide effect on the environment from the pesticide compound to the possible intermediates.

The CPCM was used to simulate these reactions in aqueous state because of the solvent effect. The results showed that the dissociation energy barriers of the C(2)−Cl bond were 163.3, 166.5, 172.0, 159.6, 165.3, and 182.6 kJ/mol and lower than those in the gaseous state. Dissociation energy barriers of the C(9)−N(8) bond were 313.9, 313.2, 306.2, and 307.9 kJ/mol, respectively, and the dissociation energy barriers of the C(11)−N(10) bond were 259.1, 257.1, 250.9, and 248.4 kJ/mol. For the C(4)−N(8) and C(6)−N(10) bonds, the dissociation energy barriers were 224.7, 239.0, 221.2, and 259.4 kJ/mol. They were all lower than those in the gaseous state. It is necessary to consider the solvent effect in the study of potential energy surface in hydrolysis reactions.

Bond Order Analysis. To gain insight into the various transition states along with the reaction coordinate, an analysis of bond order was studied. The value of Wiberg bond order was calculated by NBO calculation. With regard to the reaction mechanism, synchronicity (S_y), proposed by Moyano et al.,[33] was used to represent the global nature of bond breaking/forming processes in the decomposition reaction and expressed by eq 1.

$$S_y = 1 - [\sum_{i=1}^{n} |(E_v)_i - (E_v)_{av}|/(E_v)_{av}]/(2n - 2) \quad (1)$$

In eq 1, n denotes the number of bonds directly involved in the reaction, and the percentage of evolution of bond orders $(E_v)_i$ is given by eq 2.

$$(E_v)_i = 100 \times [B_i^{TS} - B_i^{R}]/[B_i^{P} - B_i^{R}] \quad (2)$$

Superscipts TS, R, and P refer to the transition state, reactant, and product, respectively. The average $(E_v)_{av}$ is calculated by eq 3:

$$(E_v)_{av} = \frac{1}{n}\sum_{i=1}^{n} (E_v)_i \quad (3)$$

The information about Wiberg bond orders (B_i) and percentage of evolution of bond orders (E_v) of several bonds of the first step in paths I, II, and III are listed in Table 2. The synchronicity(S_y) of the first step in paths I, II, and III was calculated by eqs 1, 2 and 3, the values being 0.495, 0.373 and 0.575, respectively. The corresponding reactions can be viewed as very asynchronous processes according to S_y.

Toxicity of the Metabolites. The toxicities (experimental and prediction results) of ATR and a part of its metabolites are listed in Table 3.

The information listed in Table 3 shows that prediction results corresponded to experimental results if the experimental data were public. The prediction results showed that (1) carcinogenic toxicity of ATR and its metabolites was positive, (2) mutagenic toxicity (AMES test) of DHHA and CA was positive, and (3) acute toxicity of ATR and its metabolites was at middle or low toxic levels. These results explained ATR's harmful impact on the environment.

In this work, the mechanism of hydrolysis reactions in the metabolism of ATR was studied by the DFT B3LYP/6-31++g (d, p) method. It is necessary to use CPCM to simulate its aqueous system. The results showed the following: (1) The three degradation mechanisms corresponded to the three hydrolysis paths, dealkylation of C(9)−N(8) and C(11)−N(10) bonds by H transferred, deamination of C(4)−N(8) and C(6)−N(10) bond by H transferred, and dehalogenation of C(2)−Cl(7) bond by Cl substituted. (2) The hydrolysis reaction of ATR was prior to path I, and the C−Cl was dissociated first because its dissociation activation energy was lower than that of the C(9)−N(8) or C(11)−N(10) bond. (3) The concentrations of intermediates in the hydrolysis depended on reaction rate.

The results of toxicity prediction and experimental reports of ATR showed that it is carcinogenic. The prediction of its metabolites showed that they are carcinogenic. The results also showed that not only ATR but also it metabolites are harmful for the environment. We propose that we should evaluate the toxicity of not only candidates of pesticides but also their metabolites by in silico methods, which also could be employed before the candidates were synthesized or isolated and in the period of design.

Table 3. Toxicities of ATR and Its Metabolites

Compound	CAS	Acut Tox. Exp.[36,d]/Pred.[a]	Mutigenic Tox. Exp.[36,d]/Pred.[b]	Carcinogenic Tox. Exp.[36,d]/Pred.[c]

ABSTRACT: The combination of dimethyl disulfide (DMDS) and dazomet (DZ) is a potential alternative to methyl bromide (MB) for soil disinfestation. The efficacy of DMDS plus DZ in controlling key soilborne pests was evaluated in a laboratory study and in two commercial cucumber greenhouses. Laboratory studies found that all of the combinations had positive synergistic effects on root-knot nematodes, two key soilborne fungi, and two major weed seeds. Greenhouse trials revealed that the combination of DMDS and DZ (30 + 25 g m^{-2}) successfully suppressed *Meloidogyne* spp. root galling, sharply reduced the colony-forming units of *Fusarium* spp. and *Phytophthora* spp. on media, maintained high cucumber yields, and was not significantly different from MB or DMDS alone, but better than DZ alone. All of the chemical treatments provided significantly better results than the nontreated control. The results indicate that the combination of DMDS and DZ is an efficient MB alternative for cucumber production.

KEYWORDS: *soil fumigation, dimethyl disulfide, dazomet, root-knot nematode, soilborne fungi, weed control*

INTRODUCTION

Together with tomato (*Lycopersicon esculentum* Mill.) and pepper (*Capsicum annuum* Linn.), cucumber (*Cucumis sativus* L.) is one of the most important greenhouse crops in northern China. In the protected cultivation of cucumber, soilborne nematodes, fungi, and weeds exhibit a very strong yield-depressing potential. The main factors leading to high pest populations and crop losses are continuous cucumber−tomato rotations or the monocropping of cucumber and two cropping seasons per calendar year.[1,2] Methyl bromide (MB) has been widely used for preplant soil fumigation against soilborne nematodes, pathogens, and weeds in northern China. However, MB has to be totally phased out in China by January 1, 2015, due to the detrimental effects on stratospheric ozone.[3] The withdrawal of MB from use as an agricultural fumigant has prompted a good deal of research to find effective and economically acceptable alternatives.[4]

The current registered chemical MB alternatives for cucumber production in China are metham sodium (MNa), fosthiazate, abamectin, and calcium cyanamide (CC). 1,3-Dichloropropene (1,3-D),[5−8] dazomet (DZ),[7] MNa,[5,9] chloropicrin (Pic),[9] 1,3-D/DZ,[7] 1,3-D/Pic,[9] and others have also been tested as chemical alternatives to MB for cucumber production in China and other countries in the world.

Dimethyl disulfide (DMDS), which has been registered in the United States and other countries, appears to be highly efficient against various nematodes, including *Meloidogyne* spp., but is less effective on fungal pathogens.[10,11] DZ, a methyl isothiocyanate (MITC) generator, is highly effective at controlling a wide range of arthropods, soilborne fungi, nematodes, and weeds, but is less effective against bacteria and root-knot nematodes.[11] Therefore, the combination of DMDS and DZ could be useful as a broad-spectrum soil fumigant. There has been much information in the literature on combinations of 1,3-D and Pic,[9,10,12−15] MNa and Pic,[15] 1,3-D and DZ,[7,16] DMDS and Pic,[14] and other combinations as MB chemical alternatives. Little information, however, has been reported to date on the combination of DMDS and DZ. Previously, Van Wambeke et al. reported the synergistic activity of combinations of DMDS and Basamid (98% DZ) at reduced dose rates for broad-spectrum soil disinfestation in soil column experiments.[17]

The following work was initiated to determine and confirm the effects of the combination of DMDS and DZ on nematodes (*Meloidogyne* spp.), key soilborne fungi (*Fusarium* spp. and *Phytophthora* spp.), and weed seeds (*Abutilon theophrasti* and *Digitaria sanguinalis*) in laboratory studies. Two greenhouse trials were also designed to evaluate DMDS and DZ combinations as an MB alternative for cucumber production in China.

MATERIALS AND METHODS

Laboratory Studies. The efficacy of DMDS and DZ, singly and in combination, was studied in the laboratory. At the end of the cucumber crop growth period, soil samples were collected from the top 20 cm of a cucumber greenhouse in Tongzhou, Beijing, where the occurrence of nematodes and soilborne pathogens was severe. The soil was composed of 57.58% sand, 39.02% silt, and 3.40% clay, with an organic matter content of 32.20 g kg^{-1} soil and pH 7.26. The soil was sieved through a 2 mm mesh and then mixed together thoroughly. The soil moisture was 19.84% (w/w). Particle size analyses were performed using the pipet

Table 2. Relevant Trial Dates and Some Other Details

site	cucumber cultivar	block area (m^2)	fumigant application	tarp removal	cucumber transplant	end of trial	preceding crop
trial I, 2010	No. 16 Zhongnong	3.2 × 5.7 = 18.24	Aug 5, 2010	Aug 27, 2010	Sept 5, 2010	Nov 25, 2010	tomato
trial II, 2012	No. 16 Zhongnong	3.2 × 5.6 = 17.92	July 27, 2012	Aug 17, 2012	Aug 28, 2012	Dec 3, 2012	tomato

method.[18] Organic carbon contents were determined by wet oxidation using the method of Walkley and Black.[19] The pH was measured in a 1:2.5 soil to H_2O extract. Soil moisture contents were measured by heating in a drying oven at 105 ± 5 °C until mass constancy was reached.[20]

Six hundred grams of soil was placed into 2.5 L desiccators. Ten *Abutilon theophrasti* seeds and 15 *Digitaria sanguinalis* seeds were buried at the depth of about 2 cm in each desiccator.[21] The following treatments were applied with three replicates: DMDS alone (20 or 40 mg active ingredient (ai) kg^{-1} soil), DZ alone (50 or 100 mg ai kg^{-1} soil), DMDS plus DZ (20 + 50, 20 + 100, 40 + 50, or 40 + 100 mg ai kg^{-1} soil), and nontreated control. DMDS was injected into the soil by pipet (Eppendorf, Germany) after sowing the weed seeds, and then the desiccators were immediately sealed with a cover. DZ was applied by mixing with soil, then the seeds were sown, and the vacuum dryer was immediately sealed with a cover. The desiccators were placed in incubators at 28 °C for 5 days. The desiccators were opened to release the residual fumigant for a day, and the weed height was then measured with a caliper. *Fusarium* spp. and *Phytophthora* spp. were isolated from the soil quantitatively according to methods described by Komada[22] and Masago et al.,[23] respectively. Root-knot nematodes (*Meloidogyne* spp.) were extracted from a 100 g subsample on the basis of methods described by Liu.[24]

Greenhouse Trials. In 2010 and 2012, two demonstration experiments were carried out in greenhouses growing cucumber on a commercial farm in Tongzhou, Beijing, which is an important production area for this vegetable. The farm has grown tomato and cucumber for more than 5 years and is facing problems caused by heavy infestations of root-knot nematode, soilborne fungi, and other pests. Details relevant to the experiments are given in Tables 1 and 2.

DMDS 99 TC (Shanghai Yuanji Chemical Co., Ltd., China, containing 99% DMDS), DZ 98 MG (Nantong Shizhuang Chemical Co., Ltd., China, a commercial product containing 98% DZ), and MB 98 TC (Changyi Chemical Plant, China, containing 98% MB and 2% chloropicrin) were used in this study. Polyethylene film (PE) (0.04 mm thick, from Baoding Baoshuo Plastic Co., Ltd., Hebei Province, China) was used as the soil mulch.

The treatments were designed as randomized blocks with three replicates (Table 3). MB as a reference treatment, DMDS alone, DZ alone, DMDS plus DZ, and nontreated control were tested. DMDS was applied by chisel injection at a rate of 60 g m^{-2}. DZ was applied by mixing with soil at a rate of 50 g m^{-2}. The DMDS plus DZ treatments were applied as follows: DZ was applied first by mixing with soil at a rate of 25 g m^{-2}, and then DMDS was applied by chemigation at a rate of 30 g m^{-2}. All of the above treatments were covered with PE film. MB was applied between a PE sheet and soil by the hot gas method at a rate of 40 g m^{-2}, and the PE sheet was left on the soil during the fumigation period.

Table 3. Experimental Program of the Greenhouse Trials

treatment[a]	rate (g ai m^{-2})	tarp type[b]	application method
DMDS 99 TC	60	PE	chisel injection
DZ 98 MG	50	PE	soil mixture
DMDS 99 TC + DZ 98 MG	30 + 25	PE	chemigation + soil mixture
MB 98 TC	40	PE	gas distribution
control	–	–	–

[a]DMDS, dimethyl disulfide; DZ, dazomet; MB, methyl bromide; TC, technical; MG, microgranule. [b]PE, polyethylene film.

Soil temperatures (at 15 cm depth) were monitored only in the plots of DMDS plus DZ treatments using a data logger (XR440 Pocket Data logger, Pace Scientific, America) for the period from fumigant application to tarp removal.

Soil fungus populations [colony-forming units (cfu) g^{-1} soil] were determined after fumigation from soil samples at the depth of 0−20 cm from the soil surface. Soil from each plot was sampled from three spots along the diagonal line in a plot. Root-knot nematode population densities in the soil were determined after fumigation from the depth of 0−20 cm. Soil from each plot was taken from three spots as above. Soil fungi and root-knot nematode populations were determined using the same methods as in the laboratory studies.

Cucumber plant height was evaluated at 4 weeks after transplant (WAT) (20 plants per plot). Root galls were assessed at the end of the trials (20 plants per plot). Plants were rated on a 0−4 scale: 0 = 0%, 1 = 1−25%, 2 = 26−50%, 3 = 51−75%, 4 = 76−100% roots galled.[4] Cucumber fruit yields were determined after each harvest and summed together at the end of the trials, and the farmer's income was calculated.

Statistical Analyses.[7] *Laboratory Studies.* Nematode mortality was calculated according to the equation

$$X = \frac{N_1}{N_1 + N_2} \times 100 \quad (1)$$

where X is nematode mortality (%), N_1 is the number of dead nematodes, and N_2 is the number of live nematodes. The numbers of dead and live nematodes were counted under a dissecting microscope. When nematodes were found to be still, they were touched with a dissecting needle lightly. If they did not move, we considered them dead. Otherwise, we considered them to be living.

Corrected nematode mortality was calculated according to the equation

$$Y = \frac{X_1 - X_2}{100 - X_2} \times 100 \quad (2)$$

where Y is the corrected nematode mortality (%), X_1 is the nematode mortality of treatments (%), and X_2 is the nematode mortality of the control (%).

The efficacy of controlling fungi or weed seeds was calculated according to the equation

$$Y = \frac{X_1 - X_2}{X_1} \times 100 \quad (3)$$

where Y is the control efficacy on fungi or weed seeds, X_1 is the fungal population or weed height in the control, and X_2 is the fungal population or weed height in treated plots.

The control efficacy of the combination of DMDS and DZ was calculated according to the following equation based on the method described by Colby:[25]

$$E_0 = X_1X_2/100 \quad (4)$$

E_0 is the expected control efficacy of the combination, X_1 is the actual measured control efficacy of the first fumigant, and X_2 is the actual measured control efficacy of the second fumigant. E is the actual measured control efficacy of the combination. If $E > E_0$, the combination was synergistic; if $E < E_0$, the combination was antagonistic.

Greenhouse Trials. The efficacy of controlling nematode or fungi was calculated according to eq 3.

The root galling index was calculated according to the equation

$$Y = \frac{R_1 + R_2 + \ldots + R_x}{r \times x} \times 100 \quad (5)$$

where Y is the root galling index, R_x is the root galling scale of the xth plant, r is the highest root galling scale, and x is the total number of plants.

Data were analyzed for ANOVA with SAS (SAS, version 8.0 for Windows). Data for soil fungal and nematode populations were transformed as necessary [square root transformations for small numbers (<100) and $\log_{10}$ for large numbers (>100) for statistical analyses], but all data are reported as nontransformed values. Significant differences among means were determined by Fisher's LSD test at $P = 0.05$.[26,27]

RESULTS

Laboratory Studies. *Root-Knot Nematodes.* All four tested rates of DMDS plus DZ combination treatments exhibited a positive synergistic efficacy on root-knot nematodes (Table 4), reducing the numbers of *Meloidogyne* spp. by at least 83.18%. The highest dose tested in our study (40 + 100 mg kg^{-1}) reduced *Meloidogyne* spp. by 93.85%.

Soilborne Fungi. The four tested rates of DMDS plus DZ also showed positive synergistic efficacy on *Fusarium* spp. and *Phytophthora* spp. (Table 4). The levels of *Fusarium* spp. and *Phytophthora* spp. were reduced by at least 91.67 and 88.29%, respectively.

Weed. The four rates of DMDS plus DZ were all synergistic on *Abutilon theophrasti* and *Digitaria sanguinalis* (Table 4), reducing the weed levels by at least 95.98 and 99.64%, respectively.

Greenhouse Trials. *Soil Temperature.* Soil temperatures (at 15 cm depth) during fumigation were similar during trial I (in 2010) and trial II (in 2012) (31.1−37.8 and 31.2−39.4 °C, respectively) in the DMDS plus DZ plots.

Root-Knot Nematodes. The untreated controls in trial I (in 2010) and trial II (in 2012) were heavily infested by *Meloidogyne* spp. (Table 5). *Meloidogyne* spp. levels were significantly higher in the untreated control compared to all fumigant treatments. However, the results of almost all of the fumigant treatments were not significantly different from each other. Nematode levels in all chemical treatments were statistically the same as with MB.

The chemical treatments reduced the nematode levels in trials I and II by at least 81.01 and 94.79%, respectively. The DMDS plus DZ combination treatment reduced the nematode levels by 84.46 and 95.83% in trials I and II, respectively; both results were not significantly different from the MB treatment, but significantly different from the untreated control.

Soilborne Fungi. The untreated controls were heavily infested by *Fusarium* spp. and *Phytophthora* spp. in both trials (Table 5). *Fusarium* spp. and *Phytophthora* spp. levels were significantly higher in the untreated control compared to all fumigant treatments (Table 5).

All chemical treatments, except for the DZ treatment, reduced *Fusarium* spp. by at least 90.15 and 95.38% in trials I and II, respectively (Table 5). The DMDS plus DZ treatments reduced *Phytophthora* spp. by at least 88.66 and 97.61% in trials I and II, respectively (Table 5). The results of the DMDS plus DZ

treatments and MB treatments were not significantly different (Table 5).

First Cucumber Fruit Yield. The first cucumber fruit yield varied with fumigation treatment (Table 6). Cucumbers grown in the untreated plots had the lowest first fruit yield (0.02 and 0.03 kg m^{-2}, respectively) in both greenhouse trials (Table 6). This was statistically different from the first yield of all chemical treatments. In trial I, plots treated with DZ had the highest yield (0.15 kg m^{-2}), although this was not statistically different from most of the other chemical treatments except for the combination, DMDS plus DZ (Table 6). In trial II the highest first cucumber fruit yield was in the DMDS plot (0.26 kg m^{-2}), but this was not statistically different from all of the other chemical treatments (Table 6).

Cucumber Plant Height, Root Galling Index, Plant Mortality, Yield, and Income. Fumigation treatments significantly

dx.doi.org/10.1021/jf501255w | J. Agric. Food Chem. 2014, 62, 4864−4869

affected cucumber plant height at 4 WAT (Table 7) in the two greenhouse trials. Cucumber height was significantly higher in all chemical treatments compared with the untreated control. In both trials, the highest cucumber height was observed in plots treated with the DMDS plus DZ and MB treatments. Plant heights in all DMDS plus DZ treatments were taller than those in plots where DMDS and DZ were used alone, except for DMDS treatment in trial II (Table 7).

Nematode infestation was evaluated at the end of the trials by calculating the root galling index. Cucumbers grown in the untreated plots had the highest root galling indices (72.50 and 36.25% in trials I and II, respectively). The root galling index of each fumigant treatment was significantly different from the untreated control; however, there were no significant differences among the chemical treatments (Table 7).

Cucumber yield varied with the fumigation treatment (Table 7). Cucumbers grown in the untreated plots had the lowest yields (2.63 and 3.48 kg m^{-2}, respectively, in trials I and II) compared to the chemical treatments. In trial I, the highest cucumber yield was observed in plots treated with MB (6.95 kg m^{-2}), followed by DMDS plus DZ, DMDS, and DZ. The DMDS plus DZ cucumber yield was statistically the same as that of DMDS alone, but significantly higher than that of DZ. In trial II, plots treated with DMDS plus DZ produced the highest yield (6.59 kg m^{-2}), which was not significantly different from the MB and DMDS treatments, but significantly higher than for DZ alone and the untreated control.

Similarly, the farmer's income from cucumber production differed with fumigation treatment (Table 7). Cucumbers grown in the untreated plots provided the lowest income in both trials (5.86 and 11.01 ¥ m^{-2}, respectively). In trial I, the plots treated with MB gave the highest income (15.68 ¥ m^{-2}), followed by DMDS plus DZ, DMDS, and DZ. The DMDS plus DZ yield was statistically the same as that of DMDS alone, but significantly higher than that of DZ. In trial II, the plots treated with DMDS plus DZ gave the highest income (20.52 ¥ m^{-2}) followed by those of DMDS, MB, DZ, and the untreated control and were statistically the same as that of DMDS and MB treatments, but significantly higher than those of other treatments.

DISCUSSION

It has been reported that no single chemical or nonchemical method can exhibit the efficacy of MB currently.[28] However, three major alternatives for preplant soil treatment (1,3-D/Pic, Pic, and MNa) either alone or in combination with other alternatives are proving as effective as MB in many situations and continue to be widely adopted as key alternatives in many applications.[14] On the basis of our greenhouse results, the combination of DMDS plus DZ was as effective as MB in terms of increasing cucumber yields and income.

Root-knot nematode control with DMDS has been demonstrated to be as good as with MB in China and elsewhere,[10,11,29] and our present laboratory studies and greenhouse trials both confirmed this. However, most DMDS formulations have poor activity against soilborne fungi and ordinary activity against weeds, and both factors were also confirmed in our laboratory studies and greenhouse trials. DMDS therefore requires additional herbicidal and fungicidal activity to improve the control of weeds and soilborne fungi. DZ, a granular MITC generator, was reported to effectively control various soilborne pests (fungi, nematodes, soil insects, and weeds).[30−32] Through our laboratory studies, we found that DZ had high activity against weeds and ordinary activity against nematodes and soilborne fungi. The combined use of DMDS and DZ for broad-spectrum soil fumigation, therefore, was at least theoretically feasible. Laboratory studies found that the four tested rates of DMDS plus DZ all had positive synergistic effects on root-knot nematodes (*Meloidogyne* spp.), two key soilborne fungi (*Fusarium* spp. and *Phytophthora* spp.), and two major weed seeds (*Digitaria sanguinalis* and *Abutilon theophrasti*). The specific synergistic mechanism of DMDS plus DZ was not clear to us; however, the above laboratory results gave a preliminary indication of the feasibility of their combined application and also confirmed the synergistic activity of combinations of DMDS plus DZ reported by Van Wambeke.[17] Our greenhouse trials revealed that the combination of DMDS plus DZ applied to the greenhouse at the rate of 30 + 25 g m^{-2} successfully suppressed *Meloidogyne* spp. root galling, sharply reduced the colony-forming units (cfu) of *Fusarium* spp. and *Phytophthora* spp. on media, maintained high cucumber yields, and was not significantly different from MB at the dose of 40 g m^{-2}. The results of DMDS plus DZ were statistically similar to those of DMDS alone (at the dose of 60 g m^{-2}), but better than those of DZ alone (at the dose of 50 g m^{-2}). The above greenhouse results also confirmed that the combination of DMDS plus DZ is a good alternative to MB.

The simultaneous application of MNa and halogenated fumigants (e.g., Pic and 1,3-D) was found to accelerate the degradation of halogenated fumigants, reducing their availability in soil.[33,34] However, the combined application of DMDS plus DZ did not exhibit degradation according to the positive synergistic effects observed from the different rates tested in our laboratory. It has been reported that relatively high application rates may possibly mask degradation;[4] however, both high and low rates were tested in our laboratory studies.

In both trials, DZ alone showed lower efficacy in controlling soilborne fungi (Table 5) and a lower yield and income than the other fumigant treatments (Table 7) and gave significantly lower results than the DMDS plus DZ combination treatment and the MB treatment. However, in both trials DZ provided a high first yield of cucumber (Table 6), although this was not significantly different from other chemical treatments. The reason could be attributed to a stronger initial plant vigor resulting from the DZ treatment, whereas the DMDS plus DZ and MB treatments produced a higher yield by the end of the season because they reduced more soilborne fungi, and this effect could also be seen in the plant height at the end of both trials (Table 7).

In summary, the fumigant combination of DMDS plus DZ was generally as effective as MB in terms of controlling the numbers of soilborne fungi and nematodes and increasing cucumber yields and farmers' income. However, more detailed work on its precise application method (formulations and so on) is necessary before the combination is recommended as an efficient MB alternative for cucumber production in China.

Supporting Information

ABSTRACT: Due to the high toxicity of silver(I) ions, a method for the rapid, sensitive, and selective detection for silver(I) ions in water, pharmaceutical products, and food is of great importance. Herein, a novel single-labeled fluorescent oligonucleotide (OND) probe based on cytosine−Ag(I)−cytosine coordination and the inherent fluorescence quenching ability of the G-quadruplex is designed to detect silver(I) ions. The formation of a hairpin structure in the OND−Ag(I) complex brings the hexachloro fluorescein (HEX) labeled at the 5′-end of the OND probe close to the G-quadruplex located at the 3′-end of the OND probe, leading to a fluorescence quenching due to photoinduced electron transfer between HEX and the G-quadruplex. Through this method, silver(I) ions can be detected quantitatively, the linear response range is from 1 to 100 nmol/L with a detection limit of 50 pmol/L, and no obvious interference occurs with other metal ions with a 10-fold concentration. This assay is simple, sensitive, and selective, and it can be used to detect silver(I) ions in actual water, drug, and food samples.

KEYWORDS: *silver(I) ions, detection, fluorescent oligonucleotide probe, hexachloro fluorescein, G-quadruplex*

INTRODUCTION

Silver(I) ions are one of the most important bioactive cations. They exhibit low toxicity to living beings within the scope of the low concentration while high toxicity in high concentration range. For example, under a low concentration range, silver(I) ions have long been known to have strong inhibitory and bactericidal effects as well as a broad spectrum of antimicrobial activities. They have a microbicidal (germicidal and bacteriostatic) effect in drinking water, enabling it to be disinfected and conserved. The recommended and maximum quantities of silver(I) ions in drinking water are usually limited to a concentration of 100 μg/L. In both the United States (United States Environmental Protection Agency, secondary drinking water regulation) and Australia (National Health and Medical Research Council), the recommended value is 100 μg/L. In Germany (Current German Drinking Water Ordinance, TrinkwV 2001), the statutory limit is 100 or 80 μg/L depending on the treatment substances and disinfecting processes. Whereas in a high concentration area, a high dose of silver(I) ions has been found to be highly toxic to aquatic organisms and humans owing to the fact that silver(I) ions have a high affinity to sulfhydryl groups and amino groups and thereby form some harmful complexes with amino acids, nucleic acids, and other compounds in the body. For example, exposed to a high dose of silver nitrate, sodium/potassium ATPase, which regulates the level of potassium and sodium ions in fish and zooplankton, was seriously interfered with the silver(I) ions. In addition, silver(I) ions are the most common pollution cations and one of the main toxic substances in the field of agriculture and food. Through polluted water sources, such as river water for irrigation and lake or seawater for aquiculture, they can accumulate to the seed of crops and fruits and the body of aquatic organisms, and thereby enter the food chain of humans. Therefore, it is very important to monitor the content level of silver(I) ions in aquicolous ecosystems and the human food chain.[1,2]

To date, several methods including colorimetric analysis,[3] atomic absorption/emission spectroscopy,[4−7] inductively coupled plasma−mass spectrometry,[8,9] surface-enhanced Raman scattering,[10] ion-selective electrodes[11] and quantum dots,[12,13] and so forth[14] have been established to detect trace level of silver(I) ions in aqueous media, and a lot of efforts has also been made to develop fluorescent chemosensors, but there are only a few successful examples for silver(I) ion detection.[15−18] In view of the interaction between metal ions and nucleic acids, some oligonucleotide (OND)-based metal ion detection method had been established,[19−26] for example, on the basis of the fact that silver(I) ions are capable of coordinating cytosine bases (C) to form a stable C−Ag(I)−C complex, leading to the development of a silver(I) ion sensor.[27−32]

As illustrated in Scheme 1a, in the absence of Ag(I) ions, two separate C-rich ssDNA separately form a random coil. However, in the presence of Ag(I) ions, the Ag(I) ions bind directly to N3 of cytosine in place of the imino proton and bridge two cytosine residues in two separate C-rich ssDNA to form the C−Ag(I)−C complexes. By applying this principle, Tanaka et al. have developed a fluorescent C-rich OND probe for silver(I) ion detection with a fluorescent dye and a quencher at its 3′- and 5′-ends, respectively.[28] Qu et al.[33] and Fan et al.[34] separately developed a single-labeled fluorescent OND probe for silver(I) ion detection by employing a single-walled carbon nanotube or graphene as an extra nanoquencher.

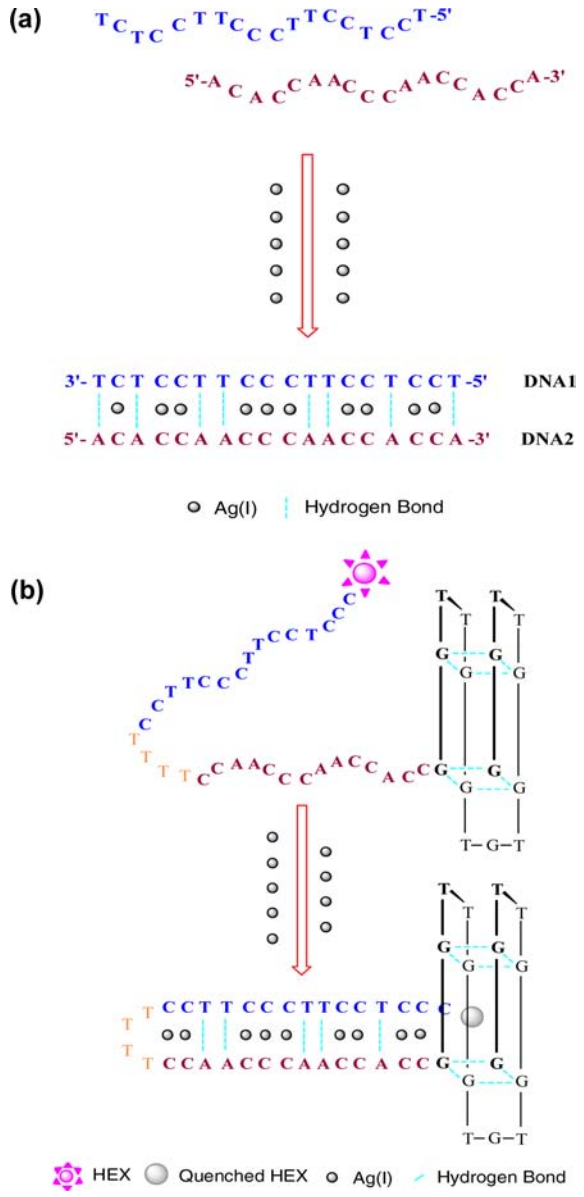
Scheme 1. Schematic Illustration of the Formation of Cytosine−Ag(I)−Cytosine Complexes



Sun et al. designed a single-labeled fluorescent OND probe for silver(I) ion detection based on the inherent quenching ability of deoxyguanosines,[35] and Luo et al. also developed a dual-output fluorescent DNA sensor for silver(I) ion and cysteine detection.[36]

Through intramolecular hydrogen-bonding interaction, a guanine base (G)-rich single-stranded DNA can form a specific secondary structure named the G-quadruplex that can serve as a very good electron donor and an extraordinary quencher for a variety of fluorescent groups due to its high density of guanosine stacking and low oxidation potential (1.25 V vs SCE).[37] Therefore, a resonant energy transfer or photoinduced electron transfer may take place between it and the fluorescent groups,[35,38] leading to the significant fluorescence quenching of the fluorescent groups in the excited state.[39]

In this work, we develop a novel single-labeled fluorescent OND probe for the sensitive and selective detection of silver(I) ions in aqueous solution based on the C−Ag(I)−C coordination and the inherent quenching ability of the G-quadruplex. In this fluorescent OND probe, a G-quadruplex (5′-GGTTGGTGTGGTTGG-3′) was designed to follow a C-rich OND (5′-CCCTCCTTCCCTTCCTTTTCCAACC-CAACCACC-3′) and a fluorescein-based dye, hexachloro fluorescein (HEX), was labeled at the 5′-end of the C-rich OND. In the presence of silver(I) ions, the C−Ag(I)−C coordination induced the labeled C-rich OND to fold into a hairpin structure that brings the fluorescent termini HEX close to the G-quadruplex, resulting in a significant fluorescence quenching of the fluorescent termini HEX owning to photoinduced electron transfer between HEX and the G-quadruplex.[40]

MATERIALS AND METHODS

Chemicals. The single-labeled fluorescent OND probe (5′-HEX-CCCTCCTTCCCT-TCCTTTTCCAACCCAACCACCGGTT-GGTGTGGTTGG-3′) was chemically synthesized by Takara Biotechnology Co. Ltd. (Dalian, China) and purified by high-performance liquid chromatography. DNA concentration was estimated by measuring the absorbance at 260 nm. 3-(*N*-Morpholino) propanesulfonic acid (MOPS) was purchased from Sigma−Aldrich Inc. (Shanghai, China). $AgNO_3$, $Ni(NO_3)_2$, $CoSO_4$, $CdSO_4$, $Cu(NO_3)_2$, $Hg(NO_3)_2$, $Mn(NO_3)_2$, $Ca(NO_3)_2$, $ZnSO_4$, $Pb(NO_3)_2$, $Mg(NO_3)_2$, $FeSO_4$, $Fe_2(SO_4)_3$, $NaNO_3$, KNO_3, KF, and $KClO_4$ were analytical grade without further purification. All the fluorescent OND probe solutions (20.0 nmol/L) and silver(I) ion solutions were prepared with 10.0 mmol/L MOPS buffer (containing 400.0 mmol/L $NaNO_3$ and 20.0 mmol/L KNO_3, pH 7.0) and stored in brown reagent bottles. The ultrapure water (18.2 MΩ·cm) was purified by a Millipore ultrapure water system.

Tap water and wastewater samples were separately taken from a household water pipe and wastewater storage tank in our laboratory. River water sample was collected from the Wei River near Xi'an. "Yin-Xin-Shuang" silver−zinc emulsion (approval no.: Henan health and diminish inflammation (2000) 0129, batch no.: 110606) and "Hong-Gao-Yao" red ointment (approval no.: Hubei pharmacy (2001) CX02-017, batch no.: 120425) are both typical ointment agents. "Bi-Luo-Chun" green tea (Tianfu Tea Industry Co., Ltd., batch no.: 20120812) and bean sprout were purchased from Walmart supermarket in Xi'an, China.

Fluorescence Emission Spectra. A 10 μL amount of 1.0 mmol/L fluorescent OND probe was first added to 490 μL of MOPS buffer and incubated at 95 °C for 10 min in order that the secondary structure of the OND was completely unwinded. Then, the mixed solution was naturally cooled down to 25 °C and was incubated overnight. The incubated solution was then transferred into a cuvette, and its fluorescent emission was scanned at 25 °C under the wavelength range 540−630 nm. The final solution contains 10.0 mmol/L MOPS, 400.0 mmol/L $NaNO_3$, and 20.0 mmol/L KNO_3 (pH 7.0), and its total volume is 500 μL. The concentration of the fluorescent OND probe is 20.0 nmol/L. After that, 1.0 μL of silver(I) ion solution with different concentrations was separately added to the above solution at 25 °C, and their fluorescent emissions were scanned under the same conditions. Fluorescent emission spectra were recorded on a Hitachi F-4500 fluorescence spectrophotometer (Hitachi Corporation, Japan). The instrument parameters were as follows: excitation wavelength, 520 nm; emission wavelength, 556 nm; excitation and emission slits, 10 nm; temperature, 25 °C.

Ultraviolet−Visible Absorbance Spectra. All the UV−visible (UV−vis) absorbance spectra were recorded on a Shimadzu UV-2450 spectrophotometer.

Detection of Silver(I) Ions. To verify the application of this method in actual samples, we determined the silver(I) ions in a tap water sample, a wastewater sample, a river water sample, two drug samples, and two food samples.

For the water sample detection, all the tap water, wastewater, and river water samples were filtered through a 0.22 μm membrane before testing. A 400 μL amount of MOPS buffer containing fluorescent

dx.doi.org/10.1021/jf404792z | J. Agric. Food Chem. 2014, 62, 4870−4877

OND probe was first incubated at 95 °C for 10 min in order that the secondary structure of the fluorescent OND probes was completely unwinded. Then, the solution was naturally cooled down to 25 °C and was incubated overnight. After that, 100 μL of different water samples were separately mixed with the incubated solution at 25 °C, and their fluorescence responses were monitored under the experimental conditions as described above. All of the final mixed solutions contain 10.0 mmol/L MOPS, 400.0 mmol/L $NaNO_3$, and 20.0 mmol/L KNO_3 (pH 7.0), and their total volumes are 500 μL. The final concentration of the fluorescent OND probe is 20.0 nmol/L, and the dilution factor is 4.0.

For the drug sample detection, about 1.0 g of the above silver−zinc cream or red ointment was accurately weighed and put in a small digestion flask, 4 mL of nitric acid was added to the digestion flask, and it was heated in order that the drug sample was fully digested. After complete digestion, the drug sample solution was transferred into a volumetric flask and diluted to 10 mL with MOPS buffer. Then, the digested sample was diluted to a proper proportion with MOPS buffer, and its fluorescence response was monitored under the test conditions as the determination of water samples.

For the tea and bean sprout sample detection, a porcelain crucible was first heated and cleaned for about 30 min on an electric furnace with a volume ratio of 1:4 hydrochloric acid solution; then, the porcelain crucible was rinsed three times with pure water and laid in a constant temperature box for drying. About 2.0 g of the tea or bean sprout sample was accurately weighed and put in the above porcelain crucible, the porcelain crucible was laid on an electric furnace making the sample be fully carbonized at low temperature until white smoke disappeared, and then, the porcelain crucible was placed into a muffle furnace at 520 °C for about 6 h in order that the sample was fully ashed. After that, it was cooled, 5 mL of 1:1 nitric acid solution was added to the porcelain crucible, and it was placed on a boiling water bath until the sample solution was fully dried. A 9 mL amount of distilled water and 1 mL of 2.0 mol/L nitric acid were added in the porcelain crucible, and it was heated at about 95 °C for 10 min. The sample solution was cooled and transferred into a 50 mL volumetric flask. The porcelain crucible was washed two times with MOPS buffer, the washes were collected into the volumetric flask, the sample solution was diluted to 50 mL with MOPS buffer, and it was mixed evenly. Finally, the sample solution was diluted to a proper proportion with MOPS buffer, and its fluorescence response was monitored under the experimental conditions as the determination of water samples.

RESULTS AND DISCUSSION

Fluorescence Quenching of the Fluorescent OND Probe. On the basis of the C−Ag(I)−C coordination and the inherent quenching ability of the G-quadruplex, a schematic diagram to illustrate the single-labeled fluorescent OND probe for silver(I) ion detection is shown in Scheme 1b. In the absence of silver(I) ions, the fluorescent HEX−OND probes form a random coil, which separates the fluorescent dye HEX and the G-quadruplex from each other, and hence, the fluorescent dye HEX exhibits strong fluorescence emission. However, in the presence of silver(I) ions, the silver-mediated base pairs are formed between cytosine residues in the fluorescent HEX−OND probes, leading to a hairpin structure. The fluorescent dye HEX and the G-quadruplex are close to each other upon formation of the hairpin structure, leading to the significant fluorescence quenching of the fluorescent dye HEX in the fluorescent HEX−OND probes.

Under the induction of different concentrations of silver(I) ions, the fluorescence quenching effect of the fluorescent HEX−OND probes was determined (Figure 1). In the absence of silver(I) ions, the fluorescent HEX−OND probes exhibit strong fluorescence emission at 556 nm, which can be attributed to the presence of the fluorescein-based dye HEX (curve a). When the molar ratios of Ag(I) to the HEX−OND probe increase from 5:1 (curve b) to 250:1 (curve d), the fluorescence quenching degree of the HEX−OND probes increases from 45% to 82%, indicating that the G-quadruplex at the 3′-end of the HEX−OND probe can quench the fluorescence of the fluorescent dye HEX labeled at the 5′-end of the HEX−OND probe. This observation also provides clear evidence to support the Ag(I)-induced formation of double helical structure.[25,33,35,36] In addition, a further experiment shows that there is no further decrease of the fluorescence intensity when the concentration of silver(I) ions is higher than 5 μmol/L, indicating the interaction between the HEX−OND probe and the silver(I) ions reaches a dynamic equilibrium.

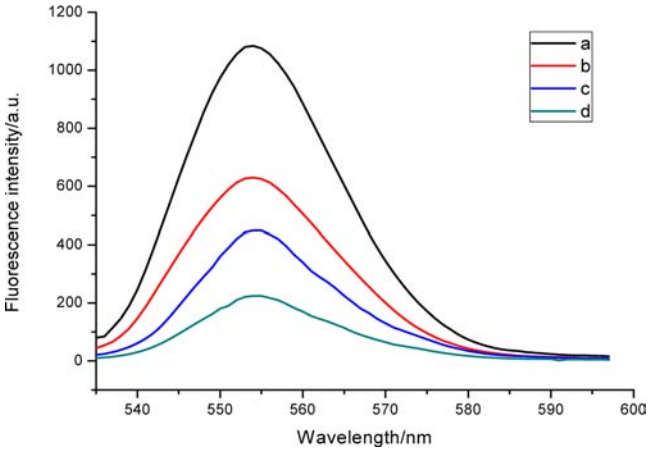


Figure 1. Fluorescence quenching of the HEX−OND probes under the induction of silver(I) ions. (a) HEX−OND probe (20.0 nmol/L); (b) HEX−OND probe (20.0 nmol/L) + Ag(I) (0.10 μmol/L); (c) HEX−OND probe (20.0 nmol/L) + Ag(I) (1.0 μmol/L); (d) HEX−OND probe (20.0 nmol/L) + Ag(I) (5.0 μmol/L). All measurements were performed in 10.0 mmol/L MOPS buffer (containing 400.0 mmol/L $NaNO_3$ and 20.0 mmol/L KNO_3, pH 7.0).

The analytical methods based on oligonucleotide probes modified with quenchers and fluorescent dyes required efficient quenching ability of quenchers. Although the fluorescence of fluorescent dyes could be quenched by the interaction between the dyes and guanosines, the quenching ability of guanosine itself was not enough to meet the need of a highly sensitive assay.[33,36] Therefore, as an effective way, the sensitivity can be improved by enhancing the quenching efficiency of the quenchers.

It has been reported that guanosine-rich tracts of nucleic acids could form four-stranded structure under appropriate condition of high sodium or potassium ionic strength. Four guanine bases can associate through Hoogsteen hydrogen bonding to form a square planar structure called a guanine tetrad, and two or more guanine tetrads can stack on top of each other to form a G-quadruplex. The quadruplex structure can be further stabilized by the presence of a cation, especially sodium or potassium, which sits in a central channel between each pair of tetrads.[41] As a structure with high density of guanosine stacking, the G-quadruplex has very good electron-donating property and extraordinary quenching ability. Therefore, it is used here as a convenient and robust tool to quench the fluorescence of fluorescent dyes.[42,43]

Fluorescence Quenching Mechanism. In order to further understand the quenching information in this Ag(I) detection method, the fluorescence spectra of HEX and UV−vis absorption spectra of HEX-labeled OND were investigated

dx.doi.org/10.1021/jf404792z | J. Agric. Food Chem. 2014, 62, 4870−4877

on addition of Ag(I) ions, and the results were listed as follows: First, by investigating the effect of Ag(I) on the HEX, it is found that the Ag(I) ions cannot quench the fluorescence of HEX under the same experimental conditions (Figure S1, Supporting Information). Second, in the presence of Ag(I) ions, no new absorption band occurred in the UV−vis absorption spectra of HEX-labeled OND, and almost no visible shift appeared in its maximum absorption (Figure S2, Supporting Information), which implied that there existed no ground-state complexes formed during the detection process.[40,44−46] Third, the absorption band of the HEX-labeled OND probe with the addition of Ag(I) ions ranging from 240 to 300 nm (Figure S2, Supporting Information) does not overlap with the emission spectra of HEX ranging from 530 to 580 nm (Figure 1), indicating the energy transfer could be neglected during the fluorescence quenching procedure.

Actually, it has been widely reported that the fluorescence of many fluorescent dyes including fluorescein and HEX that is a derivative of fluorescein are quenched by the interaction between the dyes and guanines, and this phenomenon is demonstrated to involve a photoinduced electron transfer mechanism.[35,36,40,47−49] For that reason, the fluorescence quenching in this work by the interaction between HEX and the G-quadruplex that is the guanosine stacking is also caused by the photoinduced electron transfer mechanism like the previously works mentioned.

Optimization of Detection Conditions. (i) pH. HEX belongs to a fluorescein-based dye. Although the fluorescence emission of HEX is relatively insensitive to pH compared with that of fluorescein, it can be still influenced by pH within a wider pH range. Therefore, we determined the fluorescence intensities of the HEX−OND probes and the OND−Ag(I) complexes over a pH range 4−10. As shown in Figure 2, a decreased pH leads to a decreased fluorescence intensity of the HEX−OND probes; meanwhile, as the silver(I) ions can form complex compounds or precipitates in alkaline conditions, when pH is higher than 7.0, the response of the HEX−OND probes to silver(I) ions becomes poorer and poorer with the increased pH. Therefore, all the experiments were performed in neutral condition.

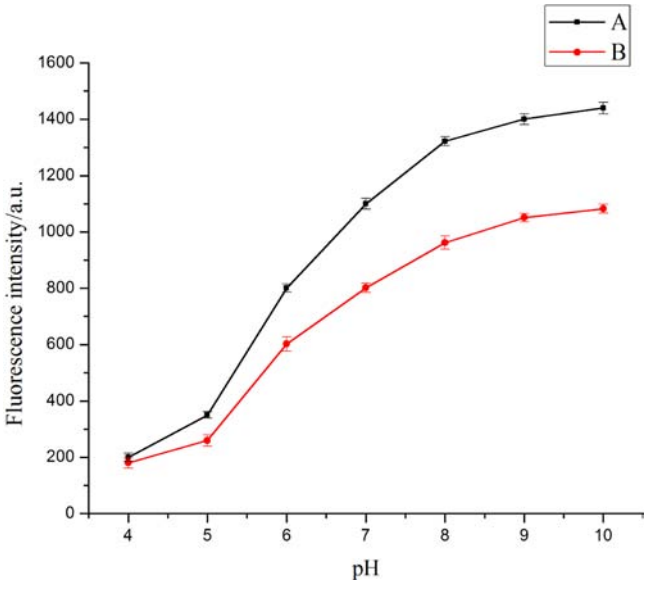

Figure 2. Fluorescence intensities of the HEX−OND probes and OND−Ag(I) complexes at different pH values. (A) HEX−OND probe (20.0 nmol/L); (B) HEX−OND probe (20.0 nmol/L) + Ag(I) (0.10 μmol/L). All measurements were performed in 10.0 mmol/L MOPS buffer (containing 400.0 mmol/L $NaNO_3$ and 20.0 mmol/L KNO_3) with different pH values.

(ii) Concentration of sodium nitrate. In the DNA hybridization system, ionic strength has an important influence on the stability and sensitivity of the molecular probes. Therefore, we further investigated the fluorescence quenching of the HEX−OND probes in the presence of 0.0−1.0 mol/L sodium nitrate (Figure 3). The quenching effect was evaluated with

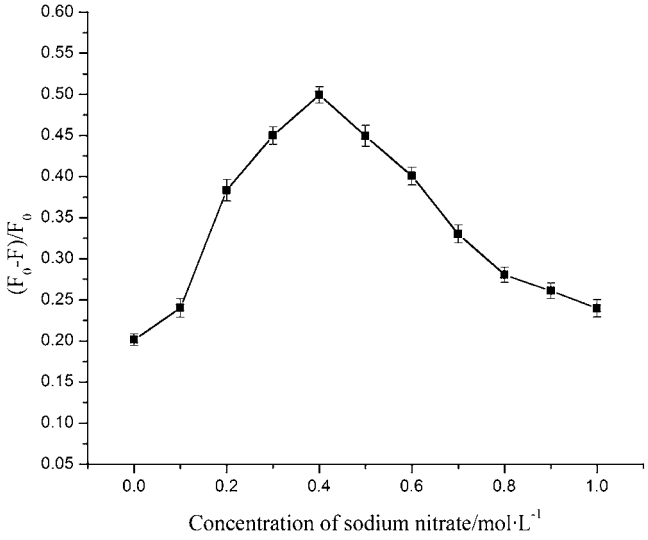

Figure 3. Fluorescence quenching extent of the HEX−OND probes in the presence of different concentrations of sodium nitrate. Concentrations of the HEX−OND probes and silver(I) ions were 20.0 nmol/L and 0.10 μmol/L, respectively. All measurements were performed in 10.0 mmol/L MOPS buffer (containing 20.0 mmol/L KNO_3, pH 7.0) with different concentrations of sodium nitrate ranging from 0.0 to 1.0 mol/L.

fluorescence quenching extent $(F_0 - F)/F_0$, where F_0 is the initial fluorescence intensity of the HEX−OND probes and F is the fluorescence intensity in the presence of 100.0 nmol/L silver(I) ions. The results show that, in the concentration of sodium nitrate ranging from 0 to 0.40 mol/L, the fluorescence quenching extents of the HEX−OND probes increase with the rising of the sodium nitrate concentrations, whereas under the concentration range 0.40−1.0 mol/L, they decrease as the concentrations of sodium nitrate increase. The highest fluorescence quenching extent (about 50%) occurs at 0.40 mol/L sodium nitrate. Therefore, we selected 0.40 mol/L as the optimum concentration of sodium nitrate.

(iii) Reaction time. In all of the above experiments, the measurement procedures were carried out right after the addition of the silver(I) ions into the HEX−OND probe solution, and the involvement of longer incubation times does not result in an observable increase in the fluorescence emission, indicating that the process of detection is very fast.

Establishment of Detection Method. (i) Sensitivity. To evaluate the sensitivity of this detection system, as shown in Figure 4, we further determined the fluorescence emission spectra of the HEX−OND probes in the presence of different concentrations of silver(I) ions ranging from 0.002 to 5 μmol/L under the above optimum condition. The results show that the fluorescence intensity of the HEX−OND probes is very

dx.doi.org/10.1021/jf404792z | J. Agric. Food Chem. 2014, 62, 4870−4877

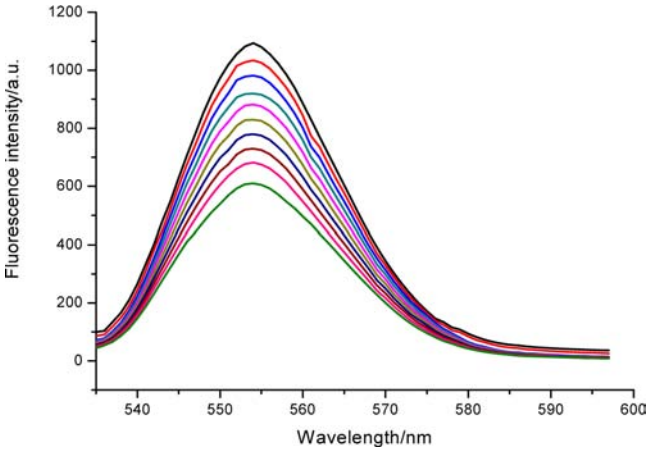

Figure 4. Fluorescence emission spectra of the HEX−OND probes in the presence of different concentrations of silver(I) ions. From top to bottom, the concentrations of silver(I) ions were 0, 0.002, 0.005, 0.008, 0.010, 0.020, 0.040, 0.060, 0.080, and 0.10 μmol/L, respectively. The concentration of the HEX−OND probe was 20.0 nmol/L. All measurements were performed in 10.0 mmol/L MOPS buffer (containing 400.0 mmol/L $NaNO_3$ and 20.0 mmol/L KNO_3, pH 7.0).

sensitive to silver(I) ions and steadily decreases as the concentrations of silver(I) ions increase from 0.002 to 5 μmol/L.

(ii) Selectivity. As shown in Figure 5a, b, the selectivity of the HEX−OND probes for Ag(I) detection was first examined with a variety of environmentally relevant metal ions including Mg(II), Mn(II), Ca(II), Cd(II), Cu(II), Hg(II), Zn(II), Fe(II), Co(II), Ni(II), Pb(II), and Fe (III) ions. Figure 5a shows the difference in the fluorescence intensity between the blank and solutions containing 1.0 μmol/L silver(I) ions and other metal ions, and Figure 5b shows the influence of these metal ions with a 10-fold concentration on the selectivity of the HEX−OND probes. The results show that, in the latter case, although the HEX−OND probes produce slightly bigger fluorescence difference than that observed at 1.0 μmol/L, the use of silver(I) ions still gives the best result. In addition, from Figure 5a, b, it can be also found that Co(II) ion is the most significant interference metal ion for Ag(I) detection. This may be due to the fact that Co(II) ion has strong binding ability with the guanine bases in DNA.[50] Then, the selectivity of the probes was examined with some environmentally relevant acid radical anions. In aqueous solution, free silver(I) ions exist mainly in the form of soluble nitrate. In addition to the limited kinds of anions, such as NO_3(I), F(I), and ClO_4(I), most of the anions, such as Cl(I), Br(I), I(I), S(II), SO_3(II), SO_4(II), CO_3(II), PO_4(III), C_2O_4(II), Ac(I), AsO_4(III), BrO_3(II), CN(I), and SCN(I), can combine with the free silver(I) ions to form insoluble or slightly soluble precipitates. Therefore, when the latter anions exist in solution, the fluorescence quenching process established in this work will not be performed due to the strong complexation of these anions to the silver(I) ions. Accordingly, here, we only examine the influence of NO_3(I), F(I), and ClO_4(I) on the selectivity of the fluorescent probe. Figure S3 (Supporting Information) shows the difference in the fluorescence intensities between the blank (no silver(I) ions) and the solution containing 1.0 μmol/L silver(I) ions and the influence of these anions with 10- and 100-fold concentrations to the silver(I) ions on the selectivity of the HEX−OND probes. The results showed that, in the presence of a high

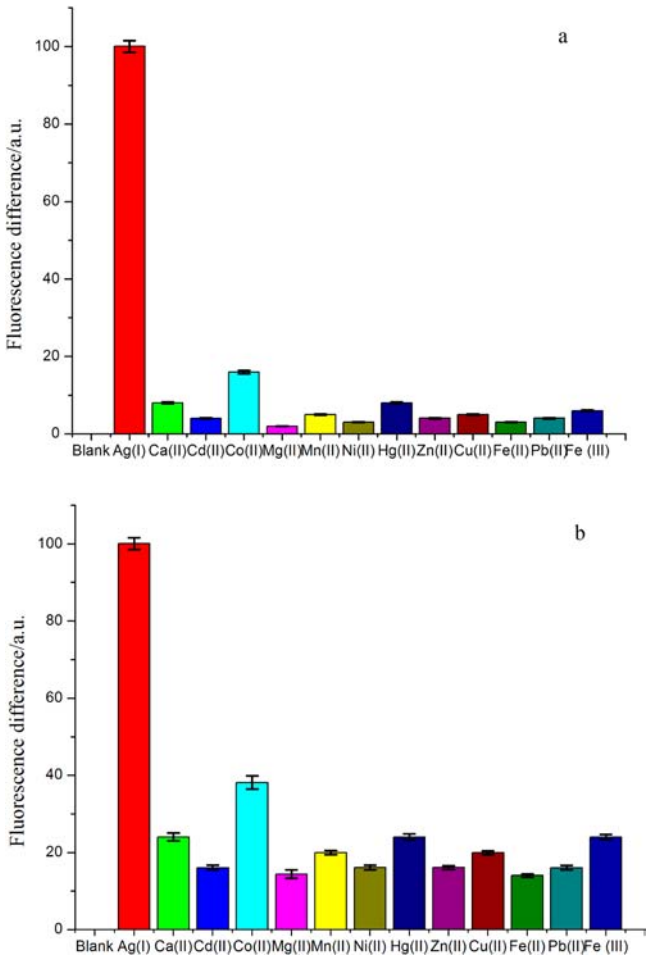

Figure 5. Difference in the fluorescence intensities between the blank and solutions containing different metal ions. (a) Concentration of all metal ions was 1.0 μmol/L; (b) concentrations of silver(I) ions and other metal ions were 1.0 and 10.0 μmol/L, respectively. The concentration of the HEX−OND probes was 20.0 nmol/L. All measurements were performed in 10.0 mmol/L MOPS buffer (containing 400.0 mmol/L $NaNO_3$ and 20.0 mmol/L KNO_3, pH 7.0).

concentration of NO_3(I), F(I), and ClO_4(I), the changes of the fluorescent signals were within 5%, indicating that the fluorescent probe has good selectivity to silver(I) ions too in this case.

(iii) Calibration curve. According to the fluorescence emission spectra of the HEX−OND probes in the presence of different concentrations of silver(I) ions, the plot of the fluorescence quenching extents $(F_0 - F)/F_0$ of the HEX−OND probes was created as the function of the concentrations of silver(I) ions (Figure 6) where F_0 and F are the fluorescence intensities of the HEX−OND probes at 556 nm in the absence and presence of different concentrations of silver(I) ions, respectively. The results show that a good linear relationship exists between the fluorescence quenching extents and the concentrations of silver(I) ions ranging from 1 to 100 nmol/L, and the equation of the calibration curve is shown as eq 1:

$$\frac{F_0 - F}{F_0} = 5.17 \cdot C_{Ag(I)} + 0.0025, \quad R^2 = 0.9999 \tag{1}$$

Through the parallel tests, it is known that the detection limit (3σ) is 50 pmol/L that is much higher than that of previous reported methods.

dx.doi.org/10.1021/jf404792z | J. Agric. Food Chem. 2014, 62, 4870−4877

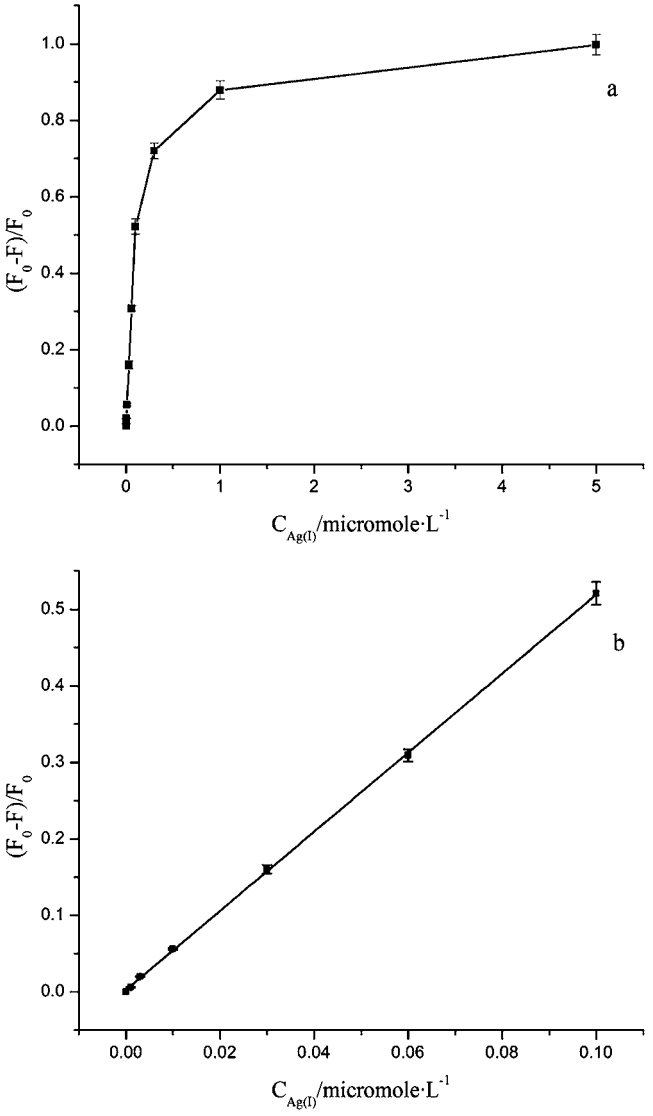

Figure 6. Fluorescence quenching extent $(F_0 - F)/F_0$ of the HEX–OND probes in the presence of different concentrations of silver(I) ions. (a) Concentration range of silver(I) ions was from 0.002 to 5.0 μmol/L; (b) concentration range of silver(I) ions was from 0.002 to 0.1 μmol/L. The concentration of the HEX–OND probe was 20.0 nmol/L. All measurements were performed in 10.0 mmol/L MOPS buffer (containing 400.0 mmol/L $NaNO_3$ and 20.0 mmol/L KNO_3, pH 7.0).

Detection of Silver(I) Ions. (i) Tap water and wastewater samples. For the silver(I) ion detection in tap water and wastewater samples, we carried out a standard addition experiment (Table 1). The results show that the recoveries are between 95% and 105% and all the relative standard deviations (RSD) are lower than 5% (n = 4), showing that this method can be used to detect silver(I) ions in tap water and wastewater samples with satisfaction.

(ii) River water sample. Wei River is a seriously polluted river near Xi 'an, and the content of silver(I) ions in it is at the level of micromoles. By means of the China National Standard (GB/T11908-1989, Cadion 2B spectrophotometry), inductively coupled plasma–atomic emission spectrometry (ICP-AES) and the single-labeled fluorescent OND probe established in this work, we separately determined the concentration of silver(I) ions in the Wei River water sample (Table 2). The results show that the detection result by this method is accurate and close to those determined by using the China National Standard and ICP-AES methods, and the relative deviation is 3.2% (n = 4).

Table 1. Determination Results of Silver(I) Ions in Tap Water and Wastewater Samples (n = 4)

	$c_{Ag(I)}$ (nmol/L)			
sample	detected	added	found	recovery (%)
tap water	24.0 ± 1.6	20.0	43.8 ± 2.0	95–104
	24.0 ± 1.6	50.0	72.0 ± 2.6	94–101
	24.0 ± 1.6	100.0	126.4 ± 3.4	99–105
wastewater	284.0 ± 6.4	200.0	486.0 ± 10.8	98–103
	284.0 ± 6.4	300.0	578.4 ± 14.2	97–101
	284.0 ± 6.4	400.0	682.2 ± 26.4	96–104

Table 2. Determination Results of Silver(I) Ions in the River Water Sample (n = 4)

sample	GB/T11908-1989 (μmol/L)	ICP-AES (μmol/L)	this method (μmol/L)	relative deviation (%)[a]
river water	0.30 ± 0.06	0.32 ± 0.06	0.32 ± 0.04	3.2

[a]The mean value determined by GB/T11908-1989 and ICP-AES.

(iii) Drug samples. "Yin-Xin-Shuang" silver–zinc emulsion and "Hong-Gao-Yao" red ointment are separately typical ointment agents. The former is made of 2% silver sulfadiazine and zinc sulfadiazine while the latter is a composite of silver sulfadiazine and the herbal ingredient salvia miltiorrhiza. Both of them have strong anti-inflammatory and antiseptic effects. By using atomic absorption spectroscopy (AAS) and the single-labeled fluorescent OND probe established in this work, we separately determined the concentrations of silver(I) ions in silver–zinc emulsion and red ointment samples (Table 3). The results again show that the detection result by this method is accurate and close to that determined by AAS, and the relative deviations are lower than 5% (n = 3).

Table 3. Determination Results of Silver(I) Ions in Drug Samples (n = 3)

sample	AAS (μmol/g)	this method (μmol/g)	relative deviation (%)
silver–zinc emulsion	55.8 ± 4.2	53.6 ± 5.4	−3.9
red ointment	60.4 ± 4.6	63.2 ± 5.6	+4.6

(iv) Tea and bean sprout samples. Through using ICP-AES and the single-labeled fluorescent OND probe designed in this work, we separately determined the concentrations of silver(I) ions in tea and bean sprout samples (Table 4). The results further demonstrated that the detection result by this method is accurate and close to that determined by ICP-AES, and the relative deviations are lower than 5% (n = 3).

Table 4. Determination Results of Silver(I) Ions in Tea and Bean Sprout Samples (n = 3)

sample	ICP-AES (μg/g)	this method (μg/g)	relative deviation (%)
tea	0.52 ± 0.08	0.51 ± 0.10	−3.7
bean sprouts	0.84 ± 1.02	0.81 ± 1.24	−3.6

dx.doi.org/10.1021/jf404792z | J. Agric. Food Chem. 2014, 62, 4870–4877

In conclusion, based on cytosine−Ag(I)−cytosine coordination and the inherent quenching ability of the G-quadruplex, a novel single-labeled HEX−OND probe is developed for Ag(I) detection. Compared with previous studies, this detection method provided several advantages, including simplicity, rapidity, and relative insensitivity to pH. In addition, the linear response range is 1−100 nmol/L with a detection limit of 50 pmol/L, and no obvious interference occurs with other metal ions with a 10-fold concentration increase, which indicates the sensitivity and selectivity are much higher than those of reported methods. Our design will provide a new method to help people to improve Ag(I) detection in water samples, pharmaceutical products, biological products, and food without the interference from other coexisting metal ions.

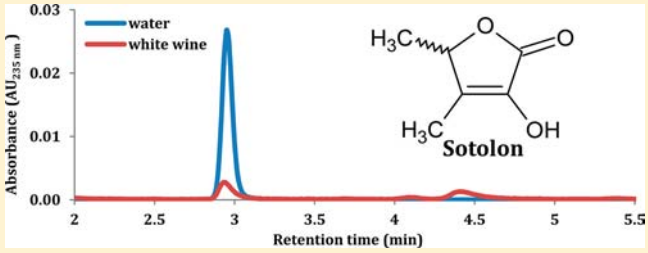
UHPLC Quantification of Sotolon in White Wine

Mario Gabrielli, Daniela Fracassetti, and Antonio Tirelli*

DeFENS—Department of Food, Environmental and Nutritional Sciences, Università degli Studi di Milano, Via Giovanni Celoria 2, 20133 Milano, Italy

ABSTRACT: Sotolon (4,5-dimethyl-3-hydroxy-2,5-dihydrofuran-2-one) is a volatile compound involved in the atypical aging of dry white wine, causing an irreversible defect when it exceeds 7−8 μg L^{-1}, and it might be adopted as a chemical marker of oxidative aging. An easier and sensitive ultrahigh-pressure liquid chromatography method for its determination in white wine is reported. The sample preparation is based on the liquid/liquid extraction by dichloromethane and the purification by solid phase extraction of the redissolved dry sample. This method showed good linearity and intermediate repeatability (<0.7 μg L^{-1}), high recovery (>89.5%), and low detection limit (0.029 μg L^{-1}). This method was usefully applied to 30 Italian sparkling and still white wine samples, where sotolon was not detected in most of them and exceeded the perception threshold only in one sparkling wine (13 μg L^{-1}). The proposed method could be used to further investigate the aging/storage conditions and the chemical−physical parameters affecting its formation in wine.



KEYWORDS: *sotolon, white wine, ultrahigh-pressure liquid chromatography, liquid/liquid extraction*

1. INTRODUCTION

Sotolon (4,5-dimethyl-3-hydroxy-2,5-dihydrofuran-2-one) is an odorous compound related to the oxidized character of wine.[1] Its flavor is usually described as curry, fenugreek, and old honey, and it is sought in oxidatively aged wines such as Madeira and Porto.[2,3] Sotolon's odor is considered a defect in young, dry, white wine, as it can decrease the intensity of the fruity and flowery flavor notes as well as the expected freshness character.[4] This defect is termed atypical aging.[1]

Sotolon is a thermolabile chiral lactone and it is stable in hydroalcoholic solution (14% ethanol v/v) at acid pH value. The chiral properties of carbon 5 in the furanic ring originate two optical isomers of sotolon with very different olfactory perception threshold: 5 and 89 μg L^{-1} in white wine for the *S* and *R* form, respectively. Since their quantitative ratio *S*/*R* can range from 1:3 to 3:1 in white wines,[5] perception threshold values up to 8 were proposed.

Detrimental amounts of sotolon in wine can rise through a number of chemical pathways mainly involving ethanal and 2-ketobutyric acid,[7] though other molecules can be involved through different chemical paths. Both hexoses and pentoses can give rise to sotolon formation via the Maillard reaction involving amino acids such as cysteine and 4-hydroxyisoleucine.[8] Sotolon formation can increase in wine containing threonine[9] and ascorbic acid,[7,10] as well as following exposure to high temperature[11] or oxygen[1] during aging or storage with oxidative aging in oak casks.[2]

The negative effect of sotolon on wine flavor and the wide number of chemical and physical factors affecting sotolon formation in wine have two important consequences on the role of this compound in wine evaluation. First, the role of wine compounds in sotolon formation should be better investigated. Second, the suitability of this off-flavor as a chemical marker of appropriate white wine aging and storage should be evaluated.

Several analytical methods were reported for sotolon quantification in water solution and wine. Nevertheless, the sensitivity of the analytical methods based on head space sampling technique (DHS and SPME) is negatively affected by both the low concentration in wine and the high boiling temperature (184 °C) of sotolon.[12,13] As a consequence, the chromatographic separation needs to be preceded by liquid/liquid extraction or solid-phase extraction (SPE) and concentration.[7,11] The analytical methods reported in the literature require long lasting sample extraction[14] and a substantial volume of sample and solvents,[7,15,16] leading to both long time and costly analysis.

This research aimed to develop an analytical method to assess sotolon by using ultrahigh-pressure liquid chromatography (UHPLC) coupled with UV detection. The availability of a fast, sensitive, and reliable analytical method could allow a better monitoring of the oxidative fate of white wine aging as well as a deeper knowledge of wine-making practices and wine compounds affecting sotolon formation.

2. MATERIALS AND METHODS

2.1. Chemicals and Reagents. Sotolon (purity exceeding 97%), methanol, ethanol, dichloromethane (DCM), heptane, chloroform, sodium chloride (NaCl), anhydrous sodium sulfate were purchased from Sigma-Aldrich (St. Louis, MO). Polyvinylpolypirrolidone (PVPP)

ACS Publications © 2014 American Chemical Society

was purchased from Dal Cin (Sesto San Giovanni, Milan, Italy). All the chemicals were of analytical grade, at least.

HPLC grade water was obtained with a Milli-Q system (Millipore Filter Corp., Bedford, MA).

The synthetic wine contained 5 g L^{-1} tartaric acid in 12% ethanol/water solution (v/v), adjusted to pH 3.5 with 12 M sodium hydroxide (Sigma-Aldrich).

2.2. Commercial Wine Samples. Sotolon content was assessed in 18 Chardonnay sparkling wine samples (Brut-nature Champenoise method, 7 months in-bottle aging) produced in one single winery (Franciacorta area, Lombardy, Italy) according to the rational wine making conditions usually adopted to produce quality wine (PDO). Moreover, 12 commercial dry white wine samples purchased at the market and produced in Italy from three different grape cultivars (Chardonnay, Catarratto, and Trebbiano) in the vintages 2011−2012 were analyzed.

2.3. Sample Preparation Development. *2.3.1. Liquid/Liquid Extraction Trials.* A water solution containing sotolon (25 μg L^{-1}) was extracted by using different solvents: heptane, chloroform, and DCM. The solution (300 mL) was liquid/liquid extracted once with 100 mL of each solvent by stirring for 30 min. The organic phase was separated from the aqueous phase by a separatory funnel, to which about 2 g of anhydrous sodium sulfate was added before vacuum-drying. The dry material was dissolved in 2 mL of water and submitted to UHPLC separation.

Partition coefficient and extraction yield were calculated as follows

$$K = \frac{C_s}{C_a} = \frac{g_s V_a}{(g_0 - g_s)V_s} \quad (1)$$

$$g_s^n = \frac{KV_s\, g_0}{V_a + KV_s}\left(1 - \frac{KV_s}{V_a + KV_s}\right)^{n-1} \quad (2)$$

$$e_y^n = \frac{\sum_1^n g_s}{g_0} \quad (3)$$

where K is the partition coefficient, C_s is the concentration of analyte in the extraction solvent, C_a is the concentration of analyte in the water solution, g_s is mass of solute in the extraction solvent obtained with a single extraction step, g_0 is the overall mass of solute, V_s is the volume of extraction solvent, V_a is the volume of water solution, g_s^n is the mass of solute in the extraction solvent following to the nth extraction step, n is the number of extraction steps, and e_y^n is the overall extraction yield after the nth extraction step.

The influence of NaCl concentration on the partition coefficient was tested. Thirty milliliters of synthetic wine solution containing 1 mg L^{-1} sotolon were added with 20, 50, or 100 g L^{-1} NaCl. The solutions were extracted once with 30 mL of DCM (30 min shaking with a Griffin flask shaker) and prepared as described as above.

Moreover, the assessment of the extraction yield after 10, 20, 30, and 40 min of shaking under the above extraction conditions was carried out on synthetic wine solution (1 mg L^{-1} sotolon) added with 100 mg L^{-1} NaCl.

2.3.2. Sample Purification Trials. Three SPE resins were tested: C18, 360 mg (Waters, Milford, MA); polymer-based, 200 mg (Phenomenex, Torrence, CA); and in-lab packed PVPP, 50 mg. The SPE columns were conditioned by 5 mL of methanol and 5 mL of water and then loaded with 2 mL of sotolon (5 mg L^{-1} in water), and the unretained sample was collected. Then one or more aqueous solutions (2 mL each) prepared with increasing amounts of methanol (20, 40, 60, 80, 100% v/v) were sequentially passed through the column. The eluted fractions were separately collected and submitted to UHPLC separation. Trials were carried out by loading the extracted wine samples recovered with 5% and 10% methanol (v/v) on the PVPP column.

2.4. Sample Preparation. Three grams of NaCl was dissolved in 30 mL of wine in a 100 mL bottle and then 40 mL of DCM was added. The bottle was hermetically closed and shaken for 10 min with a wrist action stirrer (Griffin flask shaker). The mixture was centrifuged 5 min at 5000g and the DCM was separated by a separatory funnel and recovered. The solvent extraction procedure was carried out three times, and the three organic solvent fractions were jointly collected and to them were added about 2 g of anhydrous sodium sulfate in order to remove the dispersed water. The DCM was evaporated under vacuum and the dry material was dissolved with 2 mL of 5% methanol. The solution was loaded in a conditioned SPE column containing 50 mg of PVPP, and 2 mL of the purified sample was recovered.

2.5. Calibration Curves and Method Performances. Spiked white wine (young Chardonnay/Trebbiano) samples containing 2.36, 4.67, 11.7, and 23.4 μg L^{-1} of sotolon were prepared to assess the response linearity of the analytical method as well as its intermediate precision parameters. Each sample was submitted to three replicated determinations for three different days (nine determinations per sample). Standard water solutions containing sotolon (117, 219, and 438 μg L^{-1}) were submitted to triplicated UHPLC separations on three different days to assess the response linearity of water solutions. In order to assess the recovery parameters of the method, the response factors obtained were compared to the analytical response obtained by submitting spiked wine samples containing sotolon (7.8, 14.6, and 29.2 μg L^{-1}, equivalent to a 15× dilution factor compared to the water standard solutions) to triplicated determinations performed on three different days.

2.6. Limit of Detection and of Quantification. The LOD was calculated as indicated as follows

$$\mathrm{LOD} = a + 3s_{x/y} \quad (4)$$

where a is the intercept point of the regression line and $s_{x/y}$ is the standard deviation of the linear regression.

2.7. Ultrahigh-pressure liquid chromatography. The UHPLC separation was performed by an Acquity HClass UPLC (Waters, Milford, MA) system equipped with a photo diode array detector (2996 Waters). The column used was a Kinetex C18 (100 × 3 mm, 2.6 μm particle size, 100 Å pore size; Phenomenex, Torrence, CA). The chromatographic separation was carried out with an isocratic elution running 5% methanol for 4 min followed by column washing (100% methanol for 1 min) and column conditioning (4 min). The flow rate was 1 mL min^{-1} and the system pressure was 6700 psi. Sotolon was detected at 235 nm wavelength (detector sampling rate fixed as five points per second). The injection volume was 20 μL and the column was thermostated at 30 °C. All the samples were filtered through a 0.22 μm pore size PVDF membrane (Millipore, Billerica, MA) before injection.

2.8. Quantification of Sotolon. Sotolon was quantified in synthetic wine solutions and white wine samples by the external standard method. Chromatographic data acquisition and processing were performed by Empower 2 software (Waters).

2.9. Statistical Analysis. The equations of the calibration curves were assessed by the linear regression analysis. Differences between the calibration curve slopes obtained in aqueous solution and white wine were evaluated by the F-test ($P < 0.05$).

3. RESULTS AND DISCUSSION

3.1. Analytical Method Development. The general physical−chemical properties of sotolon were first evaluated in order to fulfill the analytical sensitivity required. The UV spectrum of sotolon in water standard solution (5 mg L^{-1}) showed one single peak having a maximum absorbance at 235 nm and a high molar extinction coefficient (ε° = 10 255 L cm^{-1} mol^{-1}). Preliminary UHPLC runs showed that sotolon concentrations in the range 60−90 μg L^{-1} (corresponding to 8−12-fold higher values than the perception threshold) were suitable to gain the required detection/quantification levels. Therefore, wine volume as low as 20−30 mL can be used for sotolon quantification. Such values are lower than the condition required in the previous literature.[1,10] In order to obtain the required concentration, a liquid/liquid extraction procedure was developed; therefore, sotolon extraction yield was evaluated by using heptane, chloroform, and DCM, which were previously

dx.doi.org/10.1021/jf500508m | J. Agric. Food Chem. 2014, 62, 4878−4883

employed.[15,16] The DCM showed an extraction yield 32% higher than that of chloroform, whereas heptane did not extract detectable amounts of sotolon (Table 1). Comparing the

Table 1. Sotolon Amounts (as peak area) and Corresponding Partition Coefficient Obtained from Water Solution (25 μg L^{-1} of sotolon) with Different Extraction Solvents

solvents	sotolon extracted (mV s)	partition coefficient
heptane	nd[a]	0
chloroform	32	0.81
dichloromethane	47	2.1

[a]Not detectable.

analytical responses (peak areas) obtained from sotolon in the water solution and the extracted sample, DCM showed the highest extraction yield (41%) corresponding to a partition coefficient exceeding 2.1 (Table 1). Moreover, DCM volumes ranging from 40 to 60 mL were calculated from the partition coefficient (see eqs 1, 2, and 3 reported in Materials and Methods) in order to inject quantifiable amounts of extracted sotolon (1.2−1.8 ng) and taking into account about 1 order of magnitude as the concentration factor for 30−40 mL of wine sample. Since sotolon amounts up to 68−76% were extracted by using solvent/wine volume ratios in the range from 1:1 to 2:1, three consecutive extractions were needed to obtain an overall extraction yield approaching 100%.

Higher extraction yield can be obtained by increasing the ionic strength of the aqueous solution;[17] therefore, different levels of NaCl (20, 50, and 100 g L^{-1}) were evaluated. As expected, the partition coefficient increased exponentially as the salt concentration increased (Table 2). The partition coefficient for

Table 2. Extraction Parameters of Sotolon Obtained with Different Amounts of Sodium Chloride in Synthetic Wine Solution (1 mg L^{-1} sotolon) Using Dichloromethane as Organic Solvent

sodium chloride (g L^{-1})	extraction yield (%)	partition coefficient
0	65.8	1.8
20	86.5	1.9
50	88.5	2.3
100	93.0	3.5

the salt-free synthetic wine solution was lower (K = 1.8) than the value obtained with the water solution (K = 2.1) owing to the solvent properties of ethanol. The highest NaCl content (100 g L^{-1}) doubled the partition coefficient and was also effective in decreasing the foaming during the liquid/liquid extraction.

The effect of the shaking time on the extraction was also investigated. Higher extraction yield was obtained in synthetic wine solution carrying out the shaking for less than 30 min. Up to 30% sotolon was lost following 30 min of shaking (Table 3) probably due to its degradation, which can occur in DCM.[18]

In spite of the extraction procedure, some interferences were eluted in the chromatographic run. Therefore, different SPE conditions were tested in order to improve the sample purification. Three different hydrophobic resins were tested with increasing methanol concentrations as eluting solvent. Sotolon has lower hydrophobic properties than other wine compounds capable of absorbing light at 235 nm wavelength, (e.g., polyphenols) owing to the lower molecular weight and the presence of a hydroxyl group in its molecular structure.

Table 3. Effect of the Shaking Time on the Sotolon Amount (as peak area ± uncertainty) Extracted from a Synthetic Wine Solution (1 mg L^{-1} sotolon) with Dichloromethane as Organic Solvent

shaking time (min)	peak area (mV s)
10	258 ± 6
20	294 ± 36
30	207 ± 2
40	222 ± 74

Therefore, the SPE conditions effective in retaining polyphenols and eluting sotolon were evaluated. Polymer and C18 resins showed high retentive properties, and sotolon was eluted with 60% and 40% methanol, respectively. Nevertheless, interfering compounds were still found in the chromatogram. A lower retention property was obtained with PVPP. More than 50% of sotolon was unretained by the resin and a further elution with 20% methanol was needed to complete the recovery (Table 4).

Table 4. Sotolon Recovery (%) Obtained with Different SPE Resins by Loading 2 mL of Extracted Wine Samples (5 mg L^{-1} sotolon) and Eluting with 2 mL for Each Solvent Tested[a]

methanol (%)	polymer (200 mg)	C18 (360 mg)	PVPP (50 mg)		
unretained sample	nd	0.4	56.0	56.0	56.0
5	–	–	–	31.2	–
10	–	–	–	–	34.4
20	0.1	37.7	43.2	–	–
40	29.4	54.1	0.6	–	–
60	69.9	0.5	tr	–	–
80	0.4	0.5	tr	–	–
100	0.1	nd	tr	–	–
cumulative	99.9	92.3	99.8	87.2	89.4

[a]Legend: tr: trace amount; nd: not detectable.

Sotolon recoveries up to 90% were found for the wine samples recovered in 5% and 10% methanol (v/v). The latter concentration allowed a sotolon recovery 2% higher, but 5% methanol was chosen since it allows an interference-free chromatographic separation (Figure 1). In order to avoid sample dilution due to the purification step, the dried sample was dissolved with 5% methanol before the SPE procedure. So 87% of the sotolon was recovered in the unretained sample without any further elution.

Finally, the wine samples were prepared using the following optimized analytical conditions: 30 mL of wine added with 100 g L^{-1} NaCl, three extraction steps with 40 mL of DCM and 10 min shaking each, vacuum drying, sample recovery with 2 mL of 5% methanol/water solution (v/v), SPE purification on PVPP resin, and UHPLC run. The chromatographic separation occurred with low-methanol content (5%) in very short time (2.9 min) due to the low hydrophobicity and molecular weight of sotolon. Moreover, this method was solvent-saving for both sample preparation[7,16] and chromatographic separation. No interfering chromatographic peak was found, and sotolon was obtained as a baseline-separated chromatographic peak (Figure 1).

The method performances were evaluated for the sotolon concentrations (up to 25−30 μg L^{-1}) usually reported in the literature for about white wine[1,11,19] and in agreement with its perception threshold (<8 μg L^{-1}). Therefore, sotolon levels up to 23 μg L^{-1} were evaluated in both water solution and white wine.

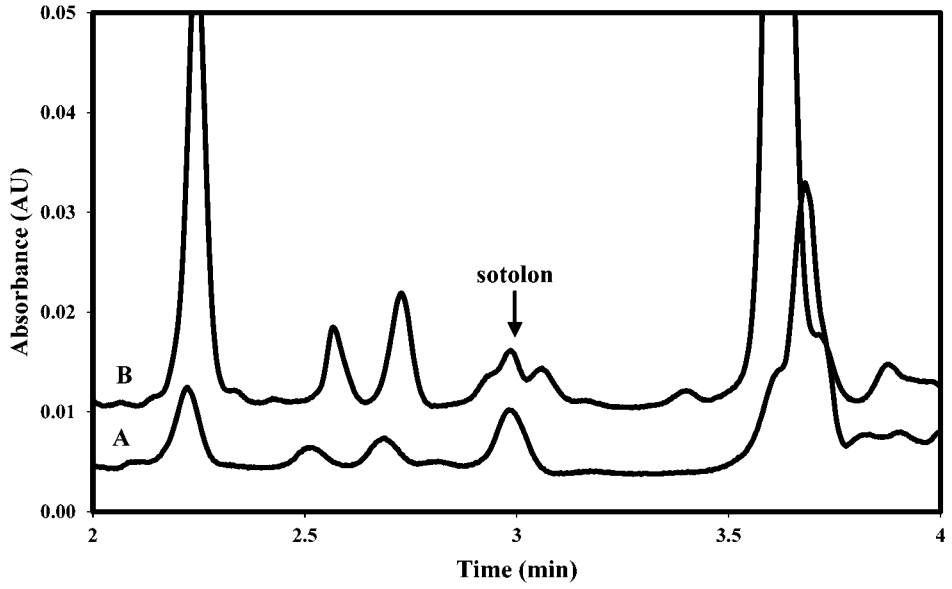

Figure 1. UHPLC separation of sotolon in white wine samples after SPE purification with PVPP by using methanol 5% (A) and 10% (B) as recovering solvent.

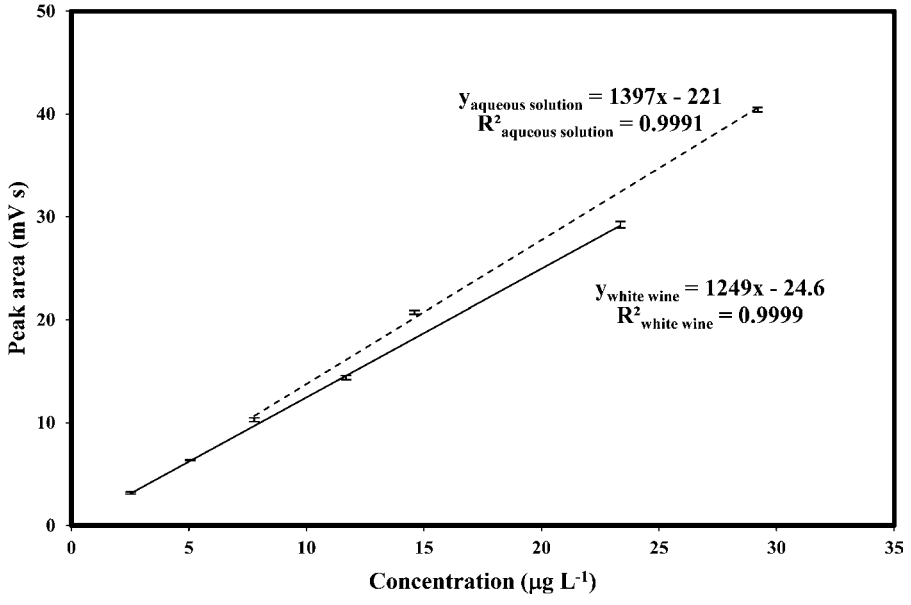

Figure 2. Calibration curves for sotolon in aqueous solution (dashed line) and white wine (solid line). Standard deviations are reported by vertical bars (n = 9).

The analytical method shows a linear response (R^2 > 0.999) in the whole range of concentrations tested with both the matrices (Figure 2), but a 10% lower response factor was calculated (as calibration curve slopes ratio) for the dry white wine compared to the corresponding water standard solution owing to the incomplete recovery of the SPE step. The calibration curves obtained are significantly different (p < 0.01), and a 10% higher sotolon amount in wine must be considered when water solutions are used as external standards.

Amounts as low as 2.5 μg L^{-1} were accurately quantifiable in wine, though with slightly higher precision values (Figure 2 and Table 5). The intermediate repeatability[20] were calculated for interday determinations; its values were close to 10% for sotolon levels as low as 2.3 μg L^{-1} and a mean value 3.1% was obtained for higher concentration values.

Table 5. Precision Parameters (n = 9) of Sotolon Quantification in White Wine[a]

av RSD (%)			1.66	

[a]Legend: SD, standard deviation (μg L^{-1}); RSD, relative standard deviation (%).

The LOD of sotolon in white wine was 0.029 μg L^{-1}, a value much lower than the perception threshold in white wine. It is lower than the LOD values reported by other researchers also

dx.doi.org/10.1021/jf500508m | J. Agric. Food Chem. 2014, 62, 4878−4883

considering the GC techniques.[1,3,6,13] The sotolon recovery was evaluated in spiked white wine and its values were 97.7%, 91.1%, and 89.5%, respectively, for sotolon concentrations of 7.78, 14.60, and 29.20 $\mu g\ L^{-1}$. Such values were higher than those previously reported.[6,19,21]

3.2. Quantification in Commercial White Wine. The proposed method was applied to the determination of sotolon in some commercial white wine samples (Brut-nature sparkling and still dry wines). In spite of the very low sugar content and the high CO_2 pressure occurring during bottle corking and storage, the highest sotolon levels (6 and 13 $\mu g\ L^{-1}$) were detected in two samples of sulfur dioxide-free and ascorbate-free sparkling wines (samples 11 and 12, respectively) stored for 7 months at 25 °C (Table 6). The role of sulfur dioxide in preventing sotolon formation is well-known,[1] even if other SO_2-free sparkling wine samples (e.g., samples 1 and 2 in Table 6) did not contain detectable amounts of sotolon. No perceptible concentrations of sotolon were found in two samples of still Catarratto dry wine (samples 19 and 20). No quantifiable or detectable amounts were obtained from the other 26 commercial samples of both sparkling wine and still wine. Such results are in agreement with other data reported in the literature[1,19,22,23] and highlight the need for deeper knowledge concerning the chemical, physical, and technological factors affecting sotolon formation in wine.

[a]Legend: nd, not detectable; nq, not quantifiable.

The proposed analytical method provides a sample preparation procedure that is faster and easier-to-apply than those previously reported for the routine analyses of sotolon. It can be a suitable easy-to-apply analytical tool to investigate the formation of sotolon in either natural or synthetic wine systems. The sensitivity parameters above-described allow sotolon formation kinetics to be investigated at adequate concentration levels.

identified at the mRNA level as one of the genes in the family of stress-induced, developmentally regulated soybean genes.[25] The physiological function of Gly m 4 is also still unknown. Gly m 4 is highly homologous with the birch pollen allergen Bet v 1.[24] The three-dimensional structures of recombinant Gly m 4 (rGlym 4) and Bet v 1 are nearly identical, thereby causing high cross-reactivity via the same IgE antibodies.[24] In a recent paper, our laboratory published a quantitative assay for the determination of endogenous intact Gly m 4 protein.[26] The endogenous Gly m 4 protein has 88.7% sequence homology with the theoretically predicted Gly m 4 sequence. The endogenous Gly m 4 protein belongs to the same stress-induced gene family as SAM 22 and H4 proteins.[26]

In this study, both HPS and Gly m 4 were isolated from soybean seeds. Following isolation, purification, and detailed characterization, a multiplexed 2DLC-based approach was developed for simultaneous quantification of the two proteins. The two orthogonal chromatographic dimensions used were strong anion exchange chromatography (SAX) and reversed phase chromatography (RPC) as the first and second dimensions, respectively. The advantage of using the 2DLC-based approach over single-dimension separation assays was the ability to completely resolve the protein of interest from other coeluting components and the ability to multiplex. The assay was evaluated for selectivity, linearity, sensitivity, and recovery and was used to determine the concentrations of Gly m 4 and HPS in different commercial soybean lines.

MATERIALS AND METHODS

Chemicals. The commercially available, non-transgenic soybean seeds were purchased from the following: H387 (lot JK1700) from Hoffman (Hoffmann, IL, USA); 363 (lot PS9-3633) from Phillips (Hope, KS, USA); William 82 (lot 9S-10-107) from Missouri Seed Foundation (Columbia, MO, USA); 3930 (lot S080184 GR01-596) from Croplan LC (St. Paul, MN, USA); C3884N (lot 1208294) from LG Seeds (Elmwood, IL, USA); pH-4396 (lot 01A (75148)) from Porter Hybrid (Wilmington, OH, USA); HS38C60 (lot SZ090151) from Hi Soy (Bloomington, IL, USA); 029311K (99915) (lot DSR-3590 029301K) from Dairyland/Precision Soya (West Bend, WI, USA); XP843-252 (lot 9E394N) from Brown Seed (Neoga, IL, USA); and Maverick (lot 8S-18-07) from Missouri Seed Foundation. Dithiothrietol (DTT), iodoacetamide (IAM), and E-64 enzyme inhibitor were purchased from Sigma (St. Louis, MO, USA). Sodium chloride, glycerol, LC-MS grade trifluoroacetic acid (TFA), HPLC grade isopropanol (IPA), tris buffer, hexanes, and acetonitrile (ACN) were purchased from Thermo Fisher Scientific (Waltham, MA, USA). A Steriflip disposable vacuum filtration system with a 0.22 μm membrane filter was purchased from Millipore (Billerica, MA, USA). Trypsin was obtained from Roche Applied Sciences (Indianapolis, IN, USA). For all analyses, Milli-Q (Millipore) deionized water was used.

Generation of HPS and Gly m 4 Reference Standards. Both HPS and Gly m 4 proteins were purified from a non-transgenic (Maverick) soybean line using similar conditions. Soybean kernels were first ground to a fine powder with a Robot Coupe grinder (model RSI 2Y-1, Robot Coupe USA, Inc.) using an equal amount of dry ice. This was followed by defatting the milled soybean seeds with hexanes (milled soybean seeds/*n*-hexanes, 1:0.19 g/mL) for 1 h at room temperature and subsequent removal of hexanes by centrifugation. The procedure was repeated two more times. The dry defatted seed material was distributed between 22 50-mL conical centrifuge tubes, with approximately 7 g of defatted soybean seeds in each tube. Allergens were extracted with 40% v/v IPA/water (seed/extraction buffer 1:5 g/mL) for 1 h at room temperature. Supernatant, containing residual fine flour particles, was filtered using a 0.45 μm filter membrane. The wet seed material was subjected to a second round of extraction with 40% v/v IPA/water, and the extract was subjected to filtration as before. The extracts were subsequently subjected to centrifugal separation at 20000*g* at 4 °C to remove the fine particles. Cold acetone precipitation of the extracted proteins was performed at −20 °C for 2 days (extract/acetone = 1:4). The resulting precipitate was subjected to centrifugal separation at 7200*g* for 15 min, and the supernatant was discarded. The protein precipitate was resolubilized in the solubilization buffer (0.1 M Na_2SO_4/0.2 M NaH_2PO_4/0.05% Tween-20/5% glycerol, pH 8). The purification of HPS and Gly m 4 from the resolubilized crude protein solutions was accomplished using reversed-phase HPLC in two steps: during the first step, HPS and Gly m 4 were crudely separated from each other and the other components in the extract; during the second step, each of the target components (HPS and Gly m 4) was purified to homogeneity. For both steps, reversed phase chromatography was performed using a linear gradient of buffer A (0.1% TFA in water) and buffer B (0.1% TFA in ACN) mobile phases on a Waters XBridge300 C4 250 × 4.6 mm column (Milford, MA, USA). During the first step, a linear gradient from 24 to 29% B was performed to crudely isolate HPS and a linear gradient from 36 to 39% B was performed to isolate Gly m 4. The HPS and Gly m 4 fractions were pooled, lyophilized to dryness, and reconstituted in 5% acetonitrile/0.1% TFA. The HPS-containing fraction was subjected to RP chromatographic separation using a linear gradient between 23 and 31% B over 40 min. HPS-containing fractions were pooled and lyophilized. The Gly m 4-containing fraction was subjected to RP chromatographic separation using a linear gradient between 35.5 and 45.5% B. The Gly m 4 fractions were pooled and lyophilized. The HPS fractions were resolubilized in dissolution buffer containing 100 mM Tris buffer at pH 8.5. For Gly m 4-containing fractions, 10 mM DTT was added to prevent dimerization of Gly m 4. For the generated reference standards, protein concentration was determined by quantitative amino acid analysis. The pooled fractions were aliquoted into vials and stored at −80 °C. Gly m 4 protein has one cysteine residue and, as mentioned, DTT was added to the reference standard to prevent dimerization. In contrast, the presence of DTT in the solvent results in a mixture of variably reduced and nonreduced species for HPS. Consequently, the two reference standards were resolubilized in different storage buffers and also analyzed separately to obtain their respective UV response factors prior to analysis of soybean extracts. The concentrations of HPS and Gly m 4 reference standards were determined by quantitative amino acid analysis based on the amino acid analyses method from Agilent Technologies.

Extraction of HPS and Gly m 4 from Soybean Seeds for 2DLC-UV/MS Assay. Milled ground soybean seeds, stored at −20 °C, were thawed at room temperature in a drybox containing Dry-Rite. Approximately 250 mg of milled soybean seeds was weighed, defatted using 1 mL of hexanes, and mixed at 1200 rpm for 1 h at 25 °C on a Thermomixer. The sample was centrifuged at 30130*g* for 5 min at 4 °C. The supernatant was discarded, and the procedure was repeated followed by removal of the residual hexane present in the defatted sample by evaporation for approximately 5 min. The resulting sample was resuspended in 1 mL of protein extraction buffer (40% v/v IPA/water fortified with enzyme inhibitor, E64 at 9.3 μM). This was followed by vortexing and overnight extraction (for 16 h) at 1200 rpm at 25 °C using a Thermomixer. Following extraction, the sample was centrifuged at 30130*g* for 30 min at 4 °C. The supernatant was transferred to a microfuge tube and subjected to additional centrifugation at 30130*g* for 5 min at 4 °C to remove residual particles. The extracts were then aliquoted for subsequent analyses by 2DLC-UV/MS analyses.

Conditions for 2DLC-UV/MS Assay. Two-dimensional liquid chromatography (2DLC) analyses with ultraviolet and mass spectrometric detection was performed in the heart-cutting mode as described previously.[26] The samples were injected as 10 μL injection volumes using a partial loop fill injection mode. A Propac SAX column (Thermo Scientific, Waltham, MA, USA) with dimensions of 250 mm × 4 mm and 5 μm particle size was used as the first-dimension column. A reversed phase Acquity BEH300 C4 column (Waters) at 70 °C with column dimensions of 100 mm × 2.1 mm and 1.7 μm particle size was used in the second dimension. The 2DLC method details are

presented in Table 1. The first-dimension window for elution of Gly m 4 and HPS reference standards was set before the analyses. The first-dimension cuts from respective time windows were diverted toward a 10 port valve containing two 5 mm × 2.1 mm Van Guard BEH300 C4 reversed phase (RP) trap cartridges (Waters). The proteins eluting between 2.2 and 6.0 min were trapped on the first RP trap cartridge, and the proteins eluting between 8.9 and 16.3 min were trapped on the second RP trap cartridge.

UV data were acquired using a variable-wavelength detector (Agilent) and a diode array detector (Agilent) for the first and second dimensions, respectively. A solution containing 7:25:68 v/v% of glycerol/acetonitrile/water was teed into the second-dimension effluent before mass spectrometric analysis. Positive-ion electrospray ionization (ESI) was performed on an Agilent 6538 mass spectrometer. The m/z scan range was 500−2500 amu, and the data were acquired at 1.32 spectra/s.

RESULTS AND DISCUSSION

Isolation and Characterization of HPS and Gly m 4 Allergens. HPS was isolated from soybean seeds using a 40% isopropanol solution on the basis of a previously published approach[26] with minor modifications. HPS elutes as two major isoforms; the main isoform (form II) consists of the complete amino acid sequence (1−80), whereas the minor isoform (Form I) is truncated at the N-termini (3−80). Truncation at the N-terminus has been attributed to the proteolytic activity in the soybean hulls and seeds. The reference standard was generated for the main isoform and was denoted as the HPS reference standard for quantification purposes. The HPS reference standard was characterized by reversed phase chromatographic analysis with UV (215 nm) and ESI-MS detection (Figure 1). The reference standard elutes as a single chromatographic peak with a retention time of 15.2 min. The transformed maximum entropy spectrum depicts intact masses for this peak at 8351.3 Da. The observed mass is within 0.006% of its theoretical average molecular mass. Further detailed characterization of the reference standard was carried out using peptide mass fingerprinting with successive in-solution proteolysis with trypsin/endoproteinase Asp-N and an in-solution limited trypsin proteolysis. The sequences were confirmed by ESI/LC/MS and tandem ESI/LC/MS/MS analyses. A summary of mass spectral data and assignments from ESI/LC/MS/MS analyses are presented in Table 2. On the basis of the application of multiple proteases, complete sequence coverage was obtained for the isolated HPS reference standard.

HPS has been interchangeably referred to as Gly m 1, a soybean allergen, in several papers. On the basis of one report, the two proteins are essentially the same protein but post-

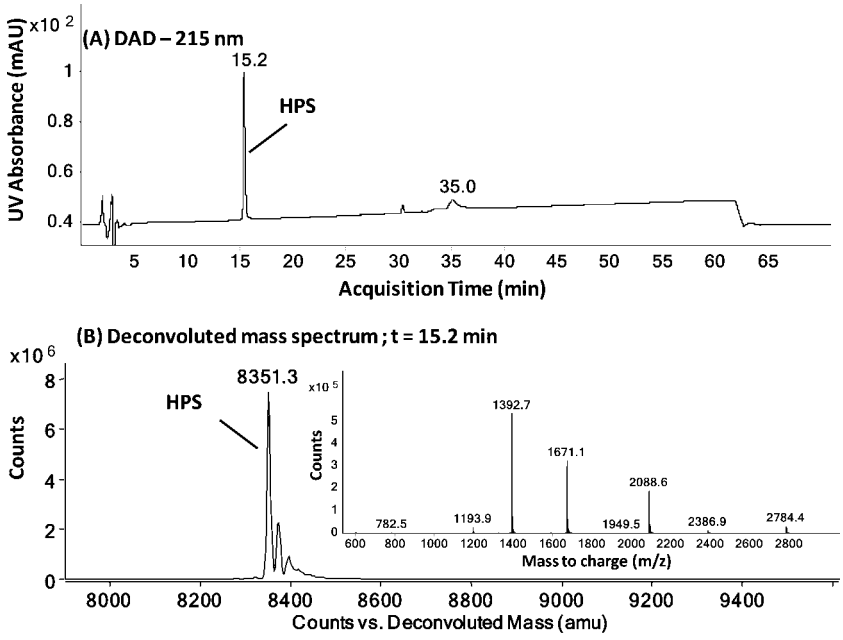

Figure 1. Characterization of reference HPS standard: (A) blank subtracted LC-UV (215 nm) chromatogram of intact reference HPS standard; (B) deconvoluted mass spectrum of reference HPS standard (inset, multiple charge envelope mass spectrum).

translationally processed in a different way.[22] Although there is a potential N-glycosylation site near the carboxyl terminus (aa 74−76), similar to other studies,[20] our laboratory did not detect the presence of glycosylation on the asparagine amino acid residue in HPS. The two purified HPS isoforms were subjected to isoelectric focusing. The p*I* of forms I and II were found to be 6.7 and 7.0, respectively (data not shown). No glycosylation was observed for either of the two isoforms of HPS. Further research is needed to unequivocally resolve whether glycosylation is indeed present on the Gly m 1 protein as stated in the literature.

The Gly m 4 reference standard was also generated from soybean seeds. Purification and detailed characterization of the Gly m 4 reference standard has been reported previously.[26] Similar to HPS, complete sequence coverage was also obtained for the Gly m 4 protein.

The concentrations of HPS and Gly m 4 reference standards were determined by quantitative amino acid analysis to be 770 and 402 μg/mL, respectively. Both HPS and Gly m 4 reference standards were diluted to the required concentration for 2DLC-UV/MS assay using 10 mM Tris, pH 8.5, buffer.

Method Development. The 2DLC-UV/MS-based Gly m 4 quantification method[26] was further expanded to accommodate quantitation of HPS in a single analysis. As aforementioned, the method consists of using a two-dimensional liquid chromatographic approach operating in the "heart-cutting" mode with strong anion exchange (SAX) chromatography and reversed phase chromatography in the first and second dimensions, respectively, followed by UV and mass spectrometric detection. The mass spectrometric confirmation for the absence of any coelution with HPS and Gly m 4 peaks during the separation of protein extracts was observed to be critical for ensuring that the required selectivity is achieved.

It was observed that HPS does not bind to the anion exchange column and elutes in the column void volume along with other nonretained proteins. The components eluting between 2.2 and 6.0 min were introduced into the second dimension. Careful method development was required in the second dimension to ensure the absence of any coelution. Figure 2 depicts the chromatographic separation achieved in the second dimension for the two major isoforms along with respective mass spectrometric characterization. As shown in Figure 2A, the optimized method has sufficient resolution to separate HPS isoforms from one another and from other components eluting from the heart-cut SAX chromatographic fraction. The raw mass spectra (Figures 2B,C) and the corresponding deconvoluted mass spectra (Figures 2D,E) further confirm the specificity of the developed 2DLC method.

In contrast, Gly m 4 elutes between 8.9 and 16.0 min during the linear salt gradient. Prior work from our laboratory has shown that the two isoforms of Gly m 4 elute in this window. The two isoforms were observed to have the same sequence but with slightly different anion exchange retention behavior, presumably due to different conformations. In this method, both of these isoforms were quantified as a single peak.

Several conditions were evaluated to optimize simultaneous extraction of the two allergenic proteins from soybean seeds. These included (i) selection of appropriate solvent, (ii) extraction time, and (iii) use of enzyme inhibitors. Once optimized for solvent, two different seed to solvent (w/v) ratios (1:4 and 1:7) were also evaluated.

The different solvents that were evaluated were 60% ethanol, 25% 2-propanol, 40% 2-propanol, and 55% 2-propanol. On the basis of the analyses, 40% 2-propanol extraction solvent was selected because of the maximum recovery obtained for both of the proteins. Of the two solvent ratios evaluated, the 1:4 ratio provided maximum extraction of the two proteins. Similarly, extraction times (2 h, 4 h, and overnight (16 h)) were compared to understand the level of recovery for the two proteins. On the basis of the analyses, overnight extraction (16 h) was selected. As reported previously, HPS elutes as two main isoforms during reversed phase chromatography along with other minor truncations. A number of enzyme inhibitors were evaluated to limit the truncations occurring during the extraction process. Of the different enzyme inhibitors evaluated, E-64, a cysteine protease inhibitor, was found to be critical in preventing further N-terminal truncation of HPS. Because the truncated version of HPS differs in only two neutral amino acids, an identical chromatographic response factor was assumed for the two isoforms, and quantitation was carried out using purified reference standard for HPS (form II). No truncations were observed for Gly m 4 in the presence or absence of E-64. A representative chromatographic and mass spectrometric profile obtained for the separation of soybean extracts is shown in Figure 3. The "heart-cuts" employed in the SAX dimension and the SAX chromatography profile are depicted in Figure 3A. The reversed-phase chromatography profiles for the first and second cuts are shown in Figure 3B.

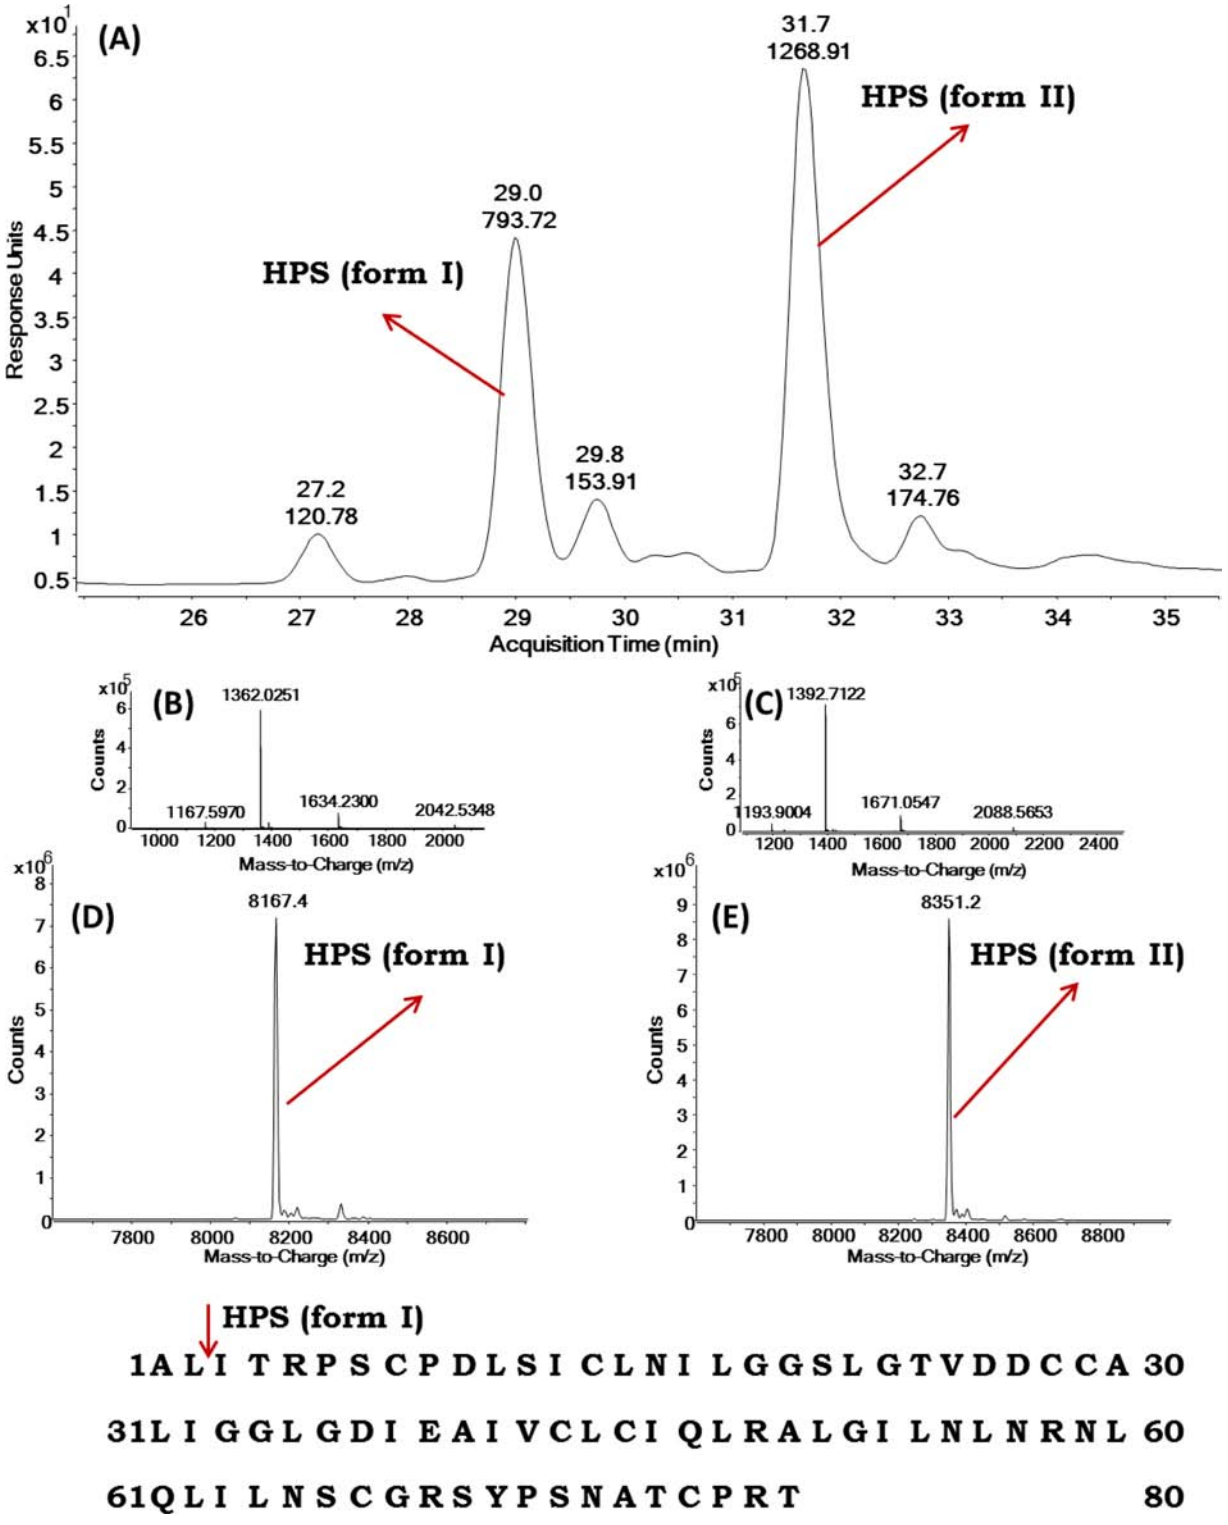

Figure 2. Representative (A) UV (215 nm) chromatogram from reversed-phased (second dimension) chromatography of soybean seed extract, (B) raw mass spectrum of HPS (form 1), (C) raw mass spectrum of HPS (form II), (D) deconvoluted mass spectrum of HPS (form I), and (E) deconvoluted mass spectrum of HPS (form II).

The deconvoluted mass spectra of HPS forms I and II and Gly m 4, shown in Figures 3C−3E, confirm the specificity of the 2DLC method.

Method Validation. Basal level of endogenous Gly m 4 and HPS was first determined in a control non-transgenic soybean sample for evaluating linearity and recovery of the 2DLC-UV/MS assay. The basal levels of endogenous HPS and Gly m 4 were observed to be 337.3 and 185.7 μg/g, respectively. Representative chromatograms from the second-dimension separation of protein extract at different HPS/Gly m 4 levels are presented in Figures 4A,B. The assay was observed to be linear over the evaluated range with R^2 values of 0.996 and 0.997 for HPS and Gly m 4, respectively. The evaluated linear ranges for HPS and Gly m 4 were from 11.9 to 599.8 μg/

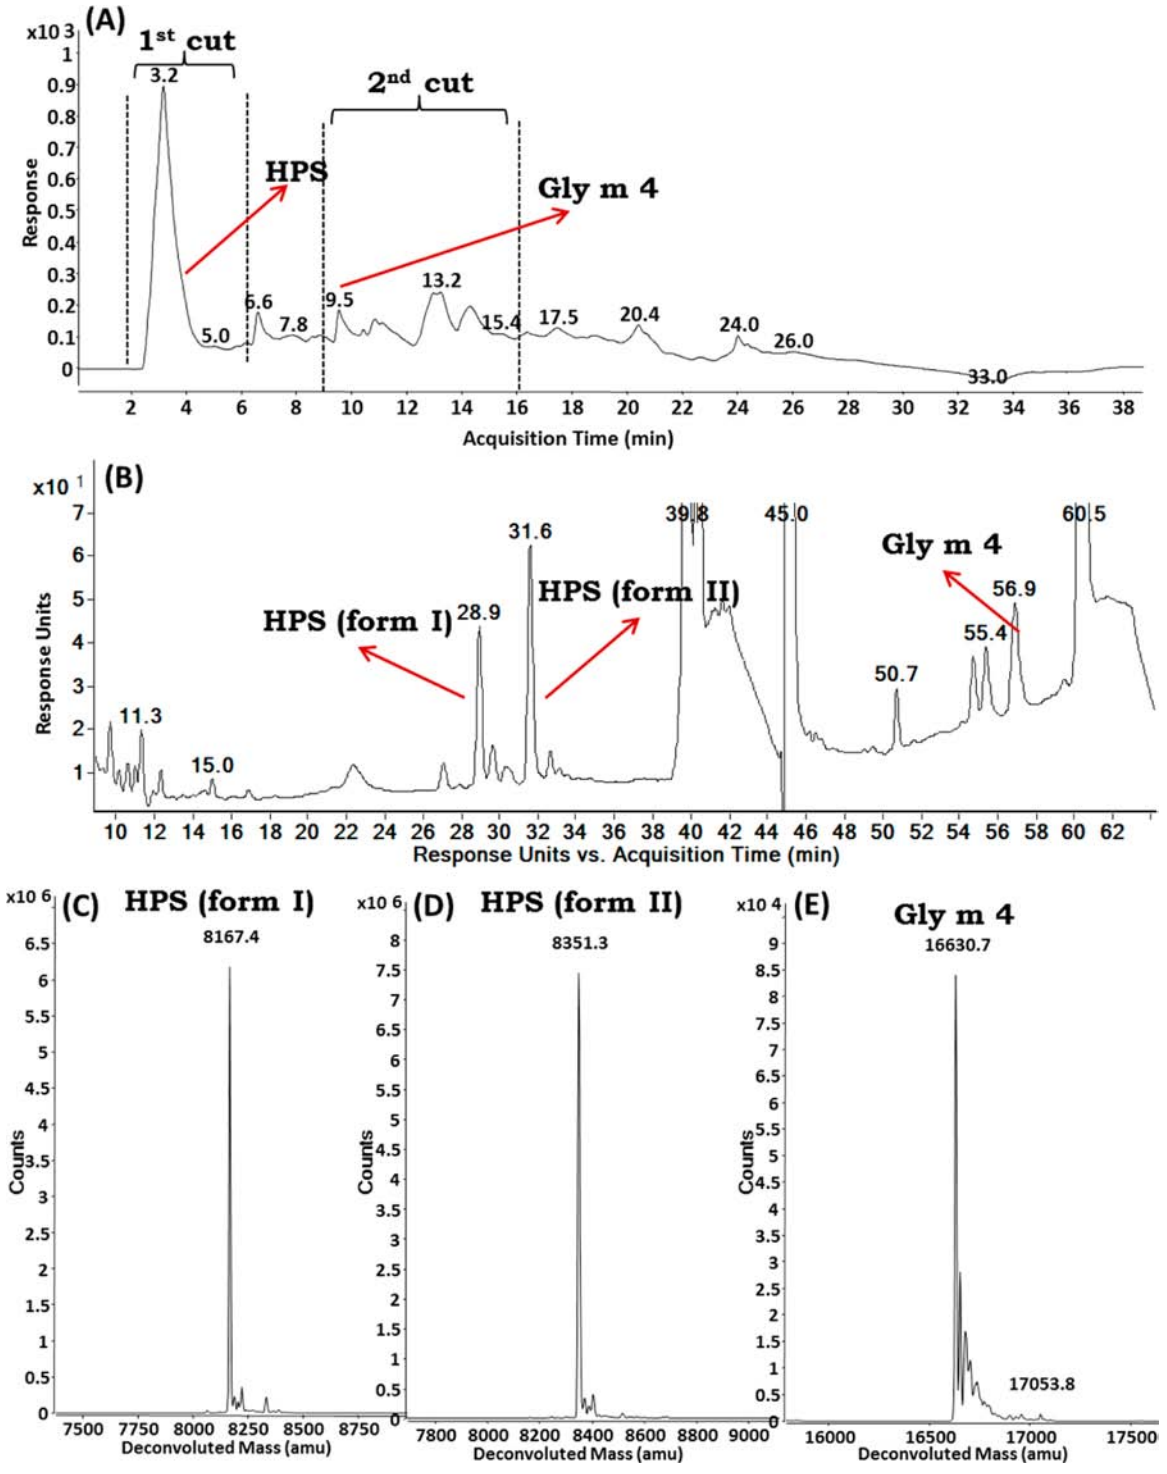

Figure 3. Representative 2DLC-UV/MS analyses of soybean extract from control soybean line: UV chromatograms (215 nm) from (A) first- and (B) second-dimension separations; (C) deconvoluted mass spectrum of component at retention time 28.9 min; (D) deconvoluted mass spectrum of component at retention time 31.6 min; (E) deconvoluted mass spectrum of component at retention time 56.9 min.

mL and from 6.9 to 355.1 μg/mL, respectively (Figure 4C,4D). The evaluated range was in the physiologically relevant range as also observed by the levels of these two allergens in the non-transgenic commercial lines.

Assay recovery (percent relative error, %RE) was also calculated for the two allergens in the respective linear range and is presented in Table 3. The recovery range (%RE) for HPS was observed to be from −1.1 to −13.7% with an average recovery of −4.8%. The recovery range (%RE) for Gly m 4 was observed to be from −3.5% to 15.2% with an average recovery of 5.6%. The validation results for assay intraday and interday precision (percent coefficient of variation, %CV) were calculated for the two allergens. The summarized results are presented in Table 4. Precision in the simultaneous measurement of two allergens at their intact level was measured by use of four different seed lines encompassing low, medium, and

347.59	332.10	−4.46	158.2	174.7	10.4
477.91	424.30	−11.22	258.6	274.7	6.2
599.87	517.88	−13.67	355.1	408.9	15.2
	av	−4.8		av	5.6

high levels of HPS and Gly m 4. For the 4 day validation study, the precision ranges (%CV) were observed to be 4.7−9.2% for HPS and 6.3−9.4% for Gly m 4 at the various allergen concentrations tested. The average precision over all the samples was found to be less than the average target precision of 15.0%.

The stability of the two allergens in seed extracts was evaluated at the autosampler temperature (5 °C) at different time intervals: 24, 47, and 69 h. For the three time intervals studied, compared with the initial time (~9 h), losses of 8.8, 3.6, and 17.1% were observed for HPS and losses of 12.4, 2.4, and 16.7% were observed for Gly m4. On the basis of the above data, the assay was determined to be stable for at least for 47 h when performed using an autosampler maintained at 5 °C.

The assay was also evaluated for its robustness with changes in column temperatures. The column temperature was systematically changed in each of the two dimensions, and the levels of Gly m 4 and HPS were compared with their levels observed with first- and second-dimension temperatures of 30 and 70 °C, respectively. Initially, the first-dimension column temperature was fixed at 30 °C, and the second-dimension column temperature was varied at two selected temperatures, 65 and 75 °C. The relative levels of HPS were observed to be 84 and 99.1%, respectively. Similarly, the relative levels of Gly m 4 were observed to be 96.1 and 106.2%, respectively. This was followed by maintaining the second-dimension temperature at 70 °C and setting the first-dimension temperatures of 27 and 33 °C. The relative levels of HPS were observed to be 103.8 and 98.7%, respectively, whereas the relative levels of Gly m 4 were observed to be 106.2 and 106.0%. The method was observed to be more sensitive to temperature changes in the second dimension. It is recommended to precisely control the assay temperatures in both dimensions.

Carry-over present in samples that followed the highest respective HPS and Gly m 4 levels was observed to be 0.1 and 0.6%, respectively. This corresponded to 4.3 and 37.9% of the area of the lowest concentration of HPS and Gly m 4, respectively.

To evaluate extraction efficiency of Gly m 4 and HPS, two successive overnight extractions were carried out. The successive extraction did not yield additional Gly m 4 and HPS protein, suggesting complete extraction of the two proteins in the first extraction.

Simultaneous Analyses of HPS and Gly m 4 in Commercial Soybean Lines. The levels of HPS and Gly m 4 were quantified using this assay in 10 selected non-transgenic commercial lines. The concentrations of the two allergens were observed to be within respective validated linear ranges. The levels of HPS and Gly m 4 in each line are presented in Figure 5. On the basis of the analyses, various levels of HPS and Gly m 4 were observed in different commercial lines with no apparent trend. In most of the samples (7 of 11), Gly m 4 levels were observed to be higher than HPS levels. Significantly greater variability (648%) was observed in expression levels of HPS in the 10 commercial lines compared with variability in expression levels for Gly m 4 (212%). Further statistically designed and replicated studies need to be carried out to determine the source of this variation.

In conclusion, this study demonstrates the use of a 2DLC-UV/MS-based assay for the simultaneous quantification of two allergens of interest at their intact level. The ability to quantify more than one allergen in a single analysis expands the applicability of these assays. Throughput of the assay can be further improved by intelligent method development in either dimension and by using novel trapping approaches. The assay was successfully applied to understand levels of HPS and Gly m 4 in 10 non-transgenic commercial soybean lines. Further research is needed to understand the biovariability of these allergens, especially as a result of growing environment. Another important aspect to understand is the level at which each of these allergen elicits an allergenic response. Moreover, several methods are currently available to quantify proteins of interest. It will be critical to compare these methods to get consistency and understand the biases, if any, inherent within each of these quantitative methods.

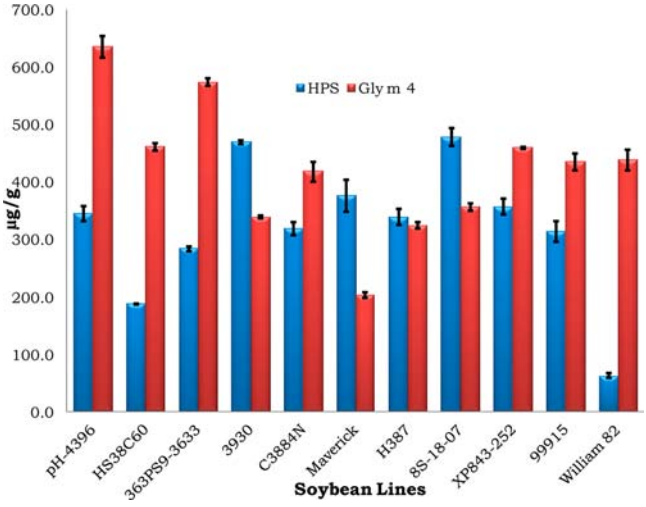

Figure 5. Determination of HPS and Gly m 4 levels in different commercially available soybean lines.

[a]Each value represents the mean of four determinations of two successive crop seasons ($n = 4$; two different samples for each crop season). [b][Δ5,23-Stigmastadienol + cholerosterol + β-sitosterol + sitostanol + Δ5-avenasterol + Δ5,24-stigmastadienol.

able to resolve triglycerides both by atom carbon number and by unsaturation using phenyl-methyl-silicone stationary phases.[25−27]

Sterols, which comprise a major portion of the unsaponifiable matter, are found in almost all fats and oils, and they are also characteristics of the genuineness of vegetable oils. Whereas sunflower, for example, contains significant levels of Δ7-stigmastenol, extra-virgin olive oil has high levels of β-sitosterol and Δ5-avenasterol, and soybean and corn oils have high levels of campesterol and stigmasterol. These apparent differences make them the most suitable for determining the botanical origin of oils and, hence, for detecting the adulteration of olive oil with other cheaper or lower quality vegetable oils.[28−30]

Many publications report the application of chemometrics such as the linear discriminant analysis (LDA) and other tools to find the best approach for the authenticity and traceability of extra-virgin olive oils.[31−35]

The utmost objective of the present research study is the detection of Chemlali EVOO adulteration with soybean, corn, and sunflower oils. For this purpose, analyses of fatty acid, sterol, and triacylglycerol profiles are performed using gas and liquid chromatography. This leads to the determination of the minimum detectable levels of vegetable oils (soybean, corn, and sunflower).

MATERIALS AND METHODS

Chemicals. Methanol (99.8%), diethyl ether (99.7%), ethanol (≥99.9%), *n*-heptane (99.0%), chloroform (99.1%), acetone (≥99.8%), and acetonitrile (≥99.9%) HPLC grade solvents were purchased from Riedel-de-Haen (Buchs SG, Switzerland). Potassium hydroxide (88.5%), pyridine (99.7%), hexamethyldisilazane (98.5%), and trimethylchlorosilazane (99.0%) were obtained from Sigma-Aldrich, Supelco (Bellefonte, PA, USA). FAME multistandards (>99.0%) were purchased from Sigma Chemical Co. (St. Louis, MO, USA).

Vegetable Oils. Four different extra-virgin olive oil samples were obtained from a Tunisian olive variety, which is the Chemlali cultivar harvested from the Sfax region (southern Tunisia) during two crop seasons (2011/2012 and 2012/2013) ($n = 4$; two different samples for each crop season).

The ripening degree was the same for the four Chemlali olive samples (maturation indices were 4.5). The olive samples were collected at the beginning of December from orchards in the same neighborhood carried out with the same cultural practices. The olive ripening index (RI) was determined according to the method developed by Boskou,[36] on the basis of the evaluation of the olive skin and pulp colors. RI values range from 0 (100% intense green skin) to 7 (100% purple flesh and black skin).

The pure soybean, corn, and sunflower oils, purchased from the local market in Tunisia and used as adulterants, were checked for their authenticity by classical tests such as iodine and refraction indices and other technical procedures, most of which are based on GC (fatty acid and sterol compositions), with some being based on HPLC (triglyceride composition). The different mixtures of extra-virgin olive oil with the aforementioned vegetable oils (at levels of 1, 2, 3, 4, 5, and 10% w/w) were prepared.

Analytical Methods. *Determination of Fatty Acid Composition.* The methyl esters for the determination of the *cis*- and *trans*-fatty acids by the use of capillary column GC were prepared according to a standard protocol (vigorous shaking of the solution of oil in *n*-heptane (0.1 g in 2 mL) with 0.2 mL of 2 N methanolic potassium hydroxide).[37,38] The GC analysis of FAMEs was performed on an AutoSystem gas chromatograph equipped with a FID detector (HP 6890N, Agilent (Palo Alto, CA, USA)). The column used was a capillary Agilent CP-Sil88 (cyanopropyl polysiloxane) (length = 50 m, i.d. = 0.25 mm, and film thickness = 0.20 μm), and the analysis conditions were as follows: the initial column temperature was settled at 165 °C for 25 min, then raised at a gradient of 5 °C/min to 195 °C;

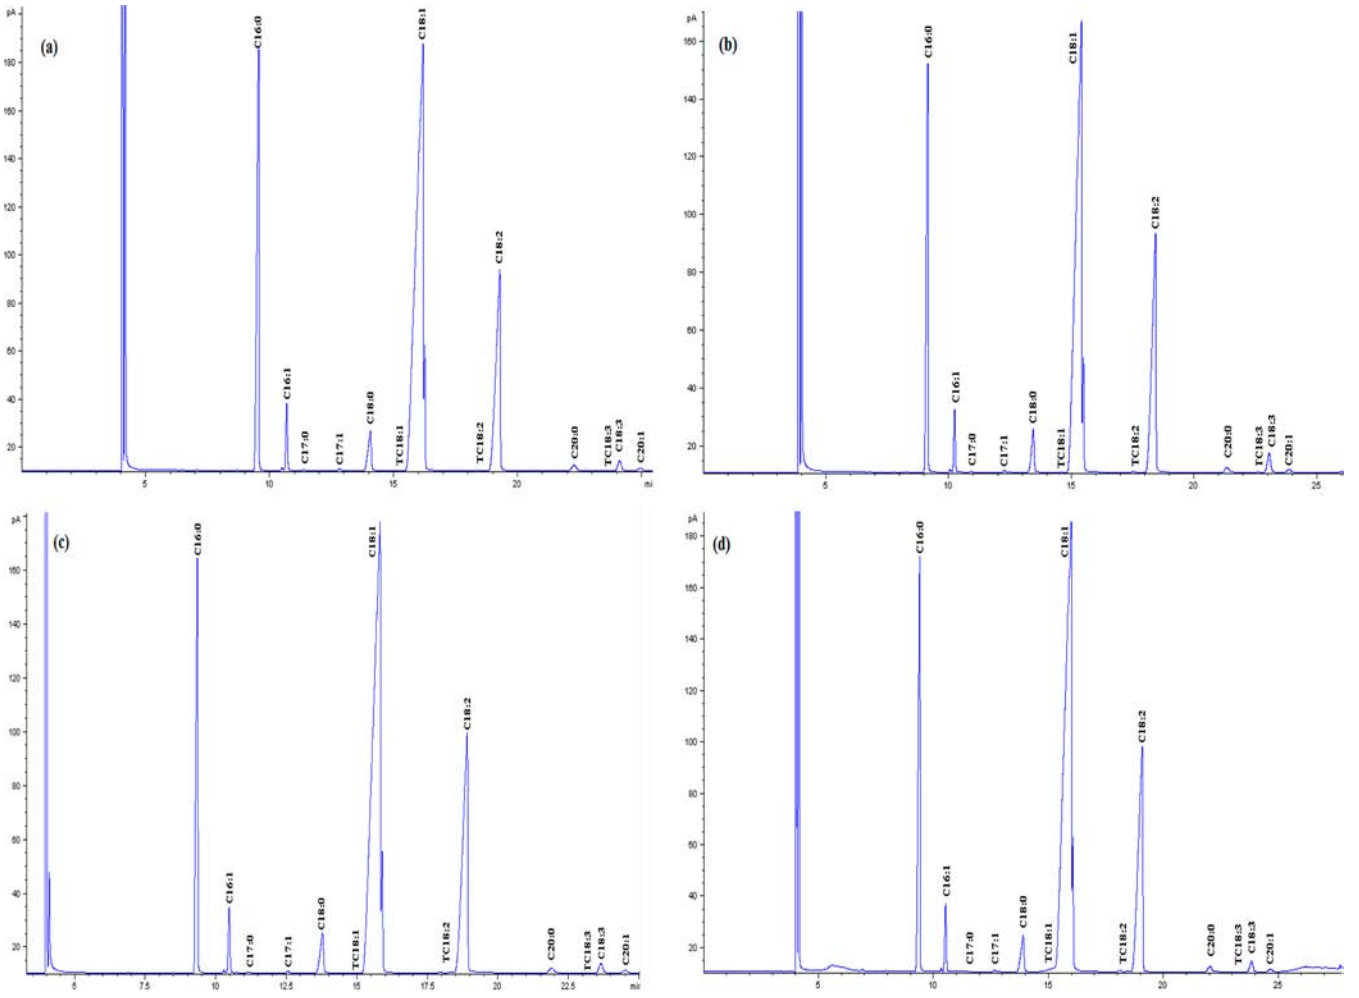

Figure 2. Gas chromatograms showing the FAMEs profiles of Chemlali EVOO (a) and binary mixtures containing 90% EVOO and 10% of either soybean (b), sunflower (c), or corn (d) oils using GC-FID.

the temperature of the injector and detector was set at 250 °C; helium was used as the carrier gas at a flow rate of 1 mL/min and 1:100 split ratio; the injection volume was 1 μL.

cis- and *trans*-FAMEs were identified through a comparison of their retention times versus pure standards analyzed under the same conditions. They were quantified according to their percentage area, obtained by the integration of the peaks (Figure 1). The results were expressed as the percentages of individual fatty acids in the lipid fraction. The 10 fatty acids (*cis*) considered in this study were palmitic (C16:0), hypogeic (C16:1n-9) + palmitoleic (C16:1n-7), margaric (C17:0), margaroleic (C17:1), stearic (C18:0), oleic (C18:1n-9) + *Z*-vaccenic (C18:1n-7), linoleic (C18:2), linolenic (C18:3), arachidic (C20:0), and gondoic (C20:1n-9) acids. The *trans*-fatty acid (TFA) content considered in this study included *trans*-octadecenoic (tC18:1), *trans*−*trans*-octadecadienoic (tt C18:2), *cis-trans*- and *trans-cis*-octadecadienoic [(ct + tc) C18:2], and *trans-cis-trans*-, *cis-cis-trans*-, *cis-trans-cis*-, and *trans-cis-cis*-octadecatrienoic [(tct + cct + ctc + tcc) C18:3] acids expressed as percentages of fatty acid methyl esters.

Determination of Triglyceride Composition. Five percent of the sample to be analyzed was prepared by weighing 0.25 ± 0.001 g into a 5 mL graduated flask and dissolved in 5 mL with acetone.[22] A HP1100 chromatograpic system from Agilent (Waldbronn, BW, Germany) equipped with a differential refractometer detector was employed. Next, the separation was carried out with a Spherisorb analytical column (250 × 4.6 mm, 5 μm particle size) from Supelco (Bellefonte, PA, USA). The optimized separation conditions were conducted by isocratic elution with a 60:40 acetone/acetonitrile mixture; column temperature, 30 °C; flow rate, 1.5 mL/min; and injection volume, 20 μL of the sample solution prepared as indicated above.

For the identification of TAGs, the retention times plotted in accordance with alternative reference chromatograms obtained from soybean oil, a 30:70 mixture of soybean oil/olive oil, and pure olive oil as described by COI.[22] It was assumed that the sum of the areas of the peaks corresponding to the various TAGs was equal to 100%, and the relative percentage of each TAG was calculated.

It is worthwhile noting that the theoretical value of ECN42 triacylglycerols was calculated by the computer program.

Determination of Sterol Composition. A mixture of each extra-virgin olive oil sample and vegetable oils (5 g) was dissolved by 50 mL of 2 N ethanolic potassium hydroxide solution, saponified, and extracted according to the official International Olive Oil Council (IOOC) method.[39] The unsaponifiable fraction was dissolved in chloroform, and approximately 20 mg was loaded on a basic silica TLC plate. The sterol and triterpene diol fraction was separated by elution with a mixture of hexane and diethyl ether 65:35 (v/v). The corresponding band was visualized under UV light after being sprayed with a 2,7-dichlorofluorescein in 0.2% ethanolic solution, than scraped off with a spatula, and extracted with chloroform. After the extract was evaporated to dryness, sterols and diols were converted to trimethylsilyl ethers by the addition of pyridine/hexamethyldisilazane/trimethylchlorosilane (9:3:1, v/v/v), left for 15 min, and then centrifuged. The analysis of sterols was performed on a 7890A Agilent gas chromatograph (Pudong, Shanghai, China) equipped with a flame ionization detector (FID). The column used was a capillary HP-5 (5% phenyl; 95% dimethylpolysiloxane) (length = 30 m, i.d. = 0.32 mm,

dx.doi.org/10.1021/jf500571n | J. Agric. Food Chem. 2014, 62, 4893−4904

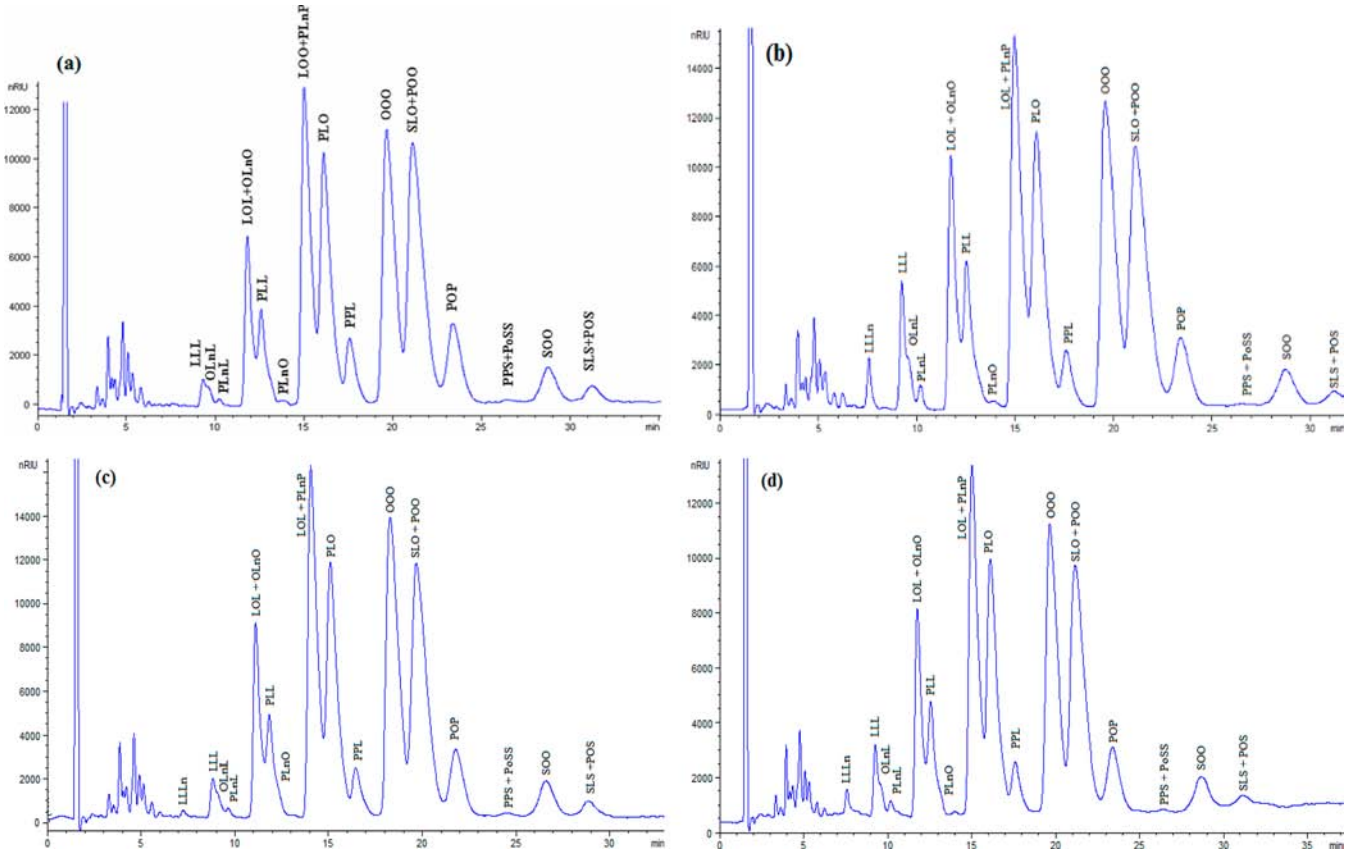

Figure 3. Chromatograms showing the TAGs profiles of Chemlali EVOO (a) and binary mixtures containing 90% EVOO and 10% of either soybean (b), sunflower (c), or corn (d) oils using HPLC-RID.

and film thickness = 0.25 μm), and the conditions for the analysis were as follows: the oven temperature was isothermal at 260 °C, the temperature of the injector was 280 °C, and the detector was set at 290 °C; helium was the carrier gas, with a flow through the column of 1 mL/min and a 1:50 split ratio, and the injection volume was 3 μL.

To identify the individual peaks of sterols, the determination of relative retention times (RRT) for sterols was carried out according to the majority compound of sterols (β-sistosterol), knowing that RRT (β-sistosterol) is equal to 1 as described by the COI.[40]

Statistical Analysis. The results were expressed as mean ± standard deviation (SD) of four measurements for the analytical determination. LDA was applied to discriminate Chemlali EVOO and the extra-virgin olive oils adulterated with different percentages of soybean, corn, and sunflower oils (1, 2, 3, 4, 5, and 10%) according to all of the parameters investigated. LDA plots were performed using SPSS Statistics 17.0 for Windows (SPSS Inc., 2008).

RESULTS AND DISCUSSION

Fatty Acid and Triglyceride Compositions in Vegetable Oils. The experimental results of fatty acid and triglyceride compositions in extra-virgin olive oil, soybean, corn, and sunflower oils are summarized in the Tables 1−3.

In the present research work, the fatty acid (FA) composition (%) of Chemlali extra-virgin olive oil was studied within the official limits established for olive oil referred to in the IOOC tade standard applied to olive oils and olive pomace oils.[7] The acid limits in olive oil are palmitic acid (C16:0), 7.50−20.00%; palmitoleic acid (C16:1), 0.30−3.50%; stearic acid (C18:0), 0.50−5.00%; oleic acid (C18:1), 55.00−83.00%; linoleic acid (C18:2), 3.50−21.00%; and linolenic acid (C18:3), ≤1.00%.

In the studied extra-virgin olive oil, the percentages of palmitic, oleic, linoleic, and linolenic acids are 15.82, 62.37, 16.21, and 0.69%, respectively. The vegetable oils, soybean, corn, and sunflower oils, exhibited considerably higher linoleic acid percentages than oleic acid percentages. Soybean oil had considerably high linolenic acid (7.77%). These differences, related to the linoleic and linolenic acid percentages, are depicted in Tables 1−3.

The detection of a triglyceride, which is not present in extra-virgin olive oil and has a number of equivalent carbons equal to 40 (LLLn), is an indicator of the presence of seed oil in olive oil. This result is in agreement with that reported by Rezanka et al.[41]

In all vegetable oils, the trilinolein (LLL) content was higher than that of the extra-virgin olive oil.[42] Actually, large differences pertaining to trilinolein contents between extra-virgin olive oil and soybean, corn, and sunflower oils, depicted in Tables 1−3, were observed.

The absolute value of the differences between theoretical and experimental ECN42 contents (ΔECN42) in all seed oils is higher than that in the extra-virgin olive oil. It ranges from 15.42 in soybean oil to 0.07 in extra-virgin olive oil. These differences are depicted in Tables 1−3.

According to the established limits, the ΔECN42 value must not exceed 0.20 in the case of edible virgin olive oil, 0.30 in the case of lampante olive oil, 0.50 in the case of olive pomace oil, and 0.60 in the case of crude olive pomace oil.

The above results reveal that there is a correlation between the linoleic acid percentage, trilinolein content, and ΔECN42. In other words, whereas soybean, corn, and sunflower oils have high linoleic acid percentages, high LLL contents, and high ΔECN42, extra-virgin olive oil exhibits low LLL content and

Table 5. Parameters Used for the Detection of Extra-Virgin Olive Oil (EVOO) Adulteration with Vegetable Oils

type of seed oil	parameter used for the detection of adulteration	COI threshold value	percentage of detectable seed oil exceeding the COI threshold value
soybean (SO)	C18:3	1%	EVOO + 5% SO (1.08%)
	ECN40	0	EVOO + 1% SO (0.27)
	ΔECN42	0.20	EVOO + 3% SO (0.30)
	campesterol	4%	EVOO + 10% SO (6.17%)
	Δ7-stigmastenol	0.50%	EVOO + 10% SO (0.59%)
	apparent β-sitosterol	93.00%	EVOO + 10% SO (89.21%)
	∑(TC18:2 + TC18:3)	0.05%	EVOO + 3% SO (0.06%)
corn (CO)	ECN40	0	EVOO + 1% CO (0.11)
	ΔECN42	0.20	EVOO + 3% CO (0.21)
	campesterol	4%	EVOO + 4% CO (4.06%)
	apparent β-sitosterol	93.00%	EVOO + 10% CO (91.86%)
	∑(TC18:2 + TC18:3)	0.05%	EVOO + 2% CO (0.06%)
sunflower (SfO)	ECN40	0	EVOO + 1% SfO (0.05)
	ΔECN42	0.20	EVOO + 1% SfO (0.21)
	Δ7-stigmastenol	0.50%	EVOO + 1% SfO (0.54%)
	apparent β-sitosterol	93.00%	EVOO + 5% SfO (92.89%)
	∑(TC18:2 + TC18:3)	0.05%	EVOO + 4% SfO (0.06%)

low ΔECN42. These results are in good agreement with literature data.[9]

Sterol Compositions in Vegetable Oils. Sterols are not only found in almost all fats and oils but also characteristic of the genuineness of vegetable oils. Indeed, the determination of the sterol composition of a vegetable oil is a very important criterion for identifying the botanical origin.

Sterol compositions (%) show higher contents in campesterol and stigmasterol in other vegetable oils compared to EVOO (Table 4). In fact, campesterol, which does not exceed 4.00% in EVOO, reaches values of 19.95, 22.06, and 8.30% in soybean, corn, and sunflower oils, respectively. Besides, stigmasterol, which always remains less than campesterol in EVOO, reaches values of 17.61, 4.96, and 5.74% in soybean, corn, and sunflower oils, respectively. Therefore, these two sterols could be used as an indicator of the adulteration of olive oil with vegetable oils. These results are in agreement with those reported by Al-Ismail et al.,[43] who suggested the presence of some refined vegetable oils in olive oil based on the sum of campesterol and stigmasterol percentages.

Moreover, sunflower oil has a high level of Δ7-stigmastenol (17.60%), whereas this sterol percentage in extra-virgin olive oil must not exceed 0.50%.

The model systems of corn, soybean, and sunflower oils at levels of 1, 2, 3, 4, 5, and 10% were prepared. These apparent differences, as shown in Table 4, make them the most suitable for the determination of the botanical origin of oils and therefore for the detection of the adulteration or contamination among vegetable oils.

Identification of EVOO Adulteration with Other Low-Cost Oils. This research study is meant to detect adulteration of EVOO by lower cost seed oils. Consequently, various blends of EVOO and soybean, corn, or sunflower oil were prepared and analyzed for fatty acid, triglyceride, and sterol compositions. The adulteration percentages ranged from 1 to 10% to determine a threshold of detection.

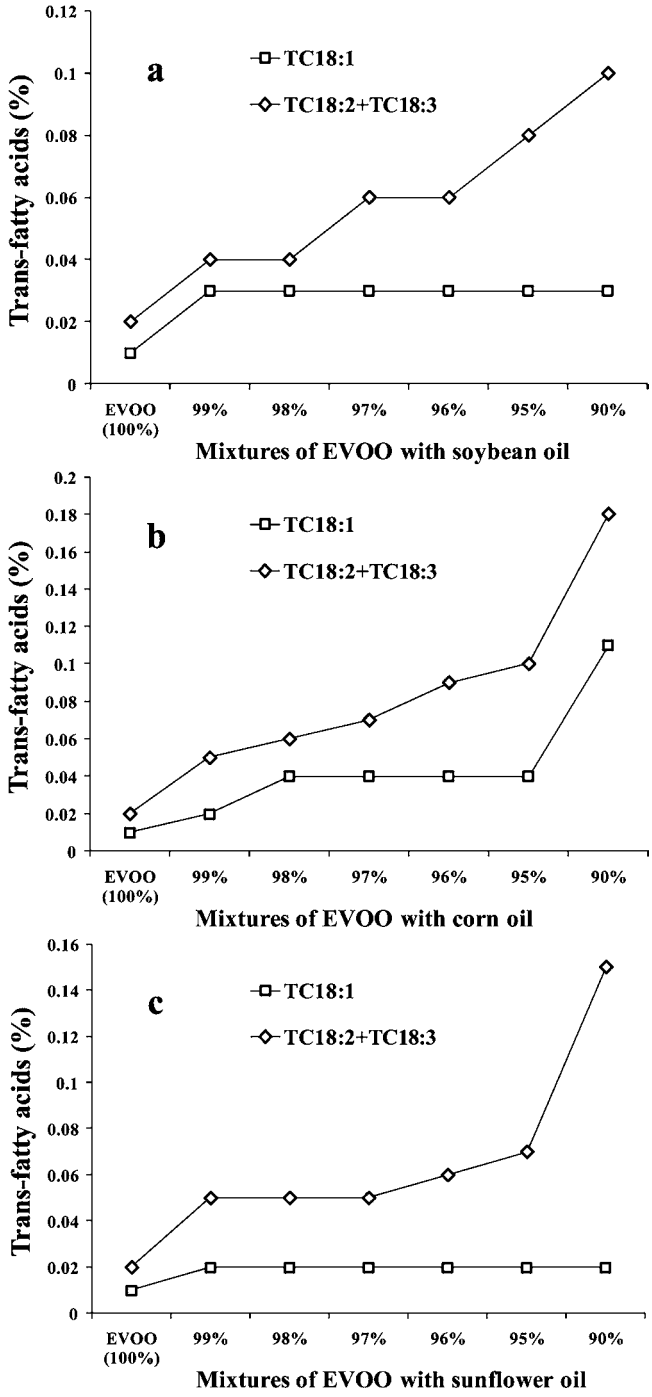

Figure 4. *trans*-Fatty acids of mixtures of extra-virgin olive oil (EVOO) with (a) soybean, (b) corn, and (c) sunflower oils. Each value represents the mean of four determinations of two successive crop seasons (n = 4; standard deviation < 0.001%).

Use of the Fatty Acid and Triglyceride Compositions for the Detection of Fraud. Fatty acid and TAG compositions of the adulterated extra-virgin olive oil mixed with 1−10% (w/w) quantities of soybean, corn, and sunflower oils are summarized in Tables 1−3 and Figures 2 and 3.

Taking into account the results presented in Tables 1−3, it could be concluded that the analysis of fatty acids does not produce satisfactory results with regard to the levels of adulteration investigated in this research study. The most effective

dx.doi.org/10.1021/jf500571n | J. Agric. Food Chem. 2014, 62, 4893−4904

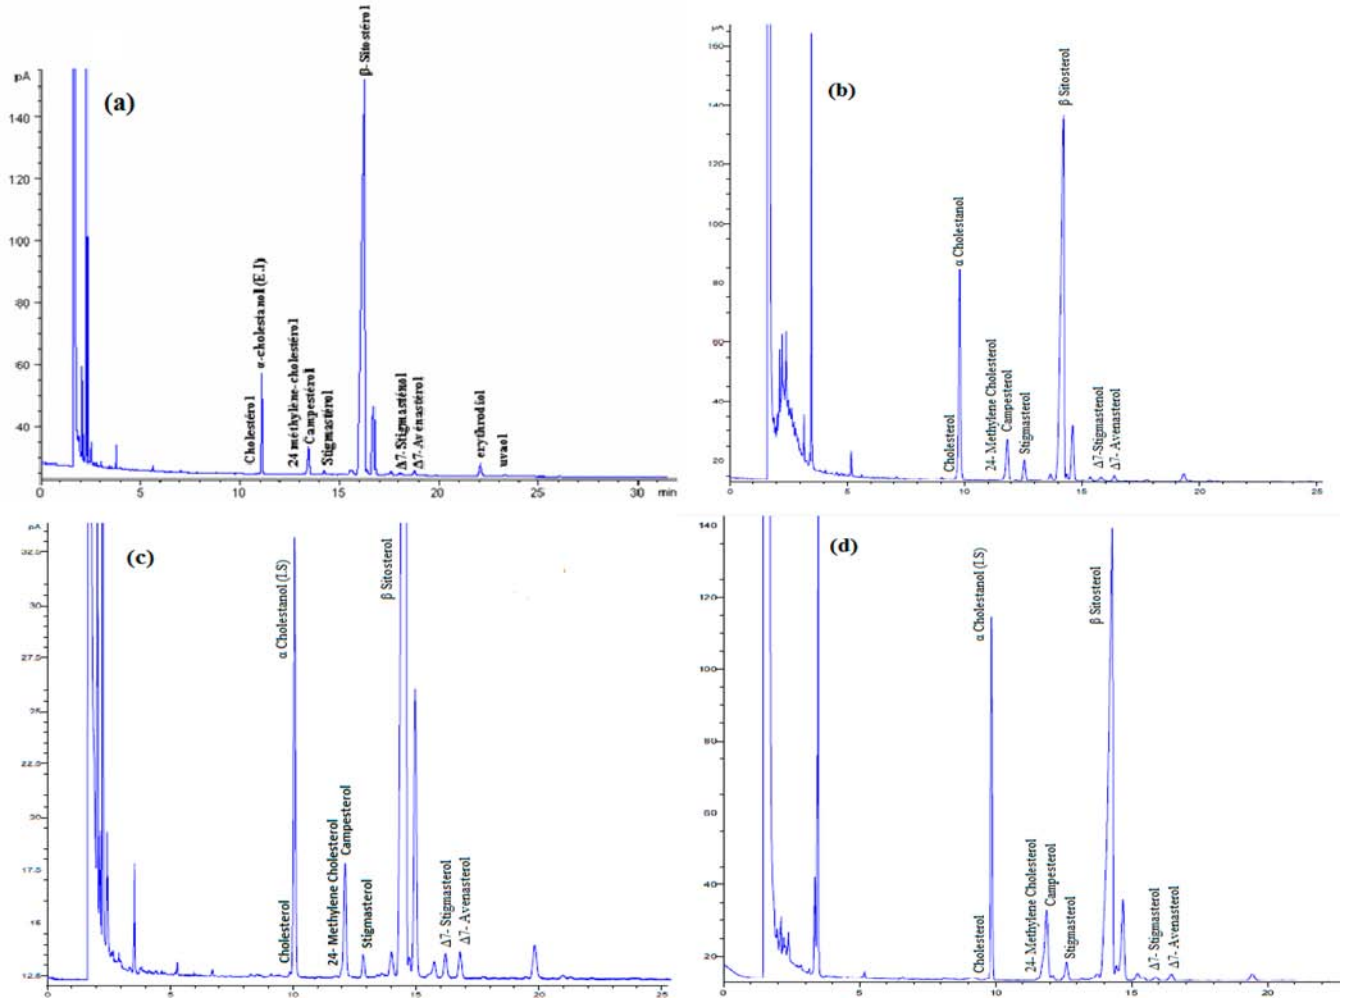

Figure 5. Typical gas chromatograms for sterols obtained in the analysis of Chemlali EVOO (a), EVOO adulterated with 10% soybean oil (b), EVOO adulterated with 10% sunflower oil (c), or EVOO adulterated with 10% corn oil (d).

parameters for the detection of adulteration are mentioned below.

The linolenic acid percentage could be used as a parameter for the detection of EVOO fraud with 5% of soybean oil as well as by the increase of *trans*-fatty acid contents with 3% of soybean oil, 2% of corn oil, and 4% of sunflower oil (Table 5 and Figure 4). None of the other fatty acids is effective for the detection of the added vegetable oil in an extra-virgin olive oil. Although the composition of fatty acids in the examined seed oils is different from that of olive oils, the fatty acids experiment could not be satisfactorily used as discriminatory parameters between olive oil and the respective vegetable oil in most cases.

According to Tables 1−3, it can be noted that the appearance of a specific triacylglycerol, normally not present in the olive oil, in oils adulterated with seed oils has a number of equivalent carbons equaling 40, known by LLLn. Thus, this triacylglycerol is an indicator of the presence of seed oil in extra-virgin olive oil.

Indeed, LLLn increases with the increase in the adulteration percentage of vegetable oils (from 1 to 10%). It ranges from 0.27 to 0.76% for the extra-virgin olive oil adulterated with soybean oil, from 0.11 to 0.69% for the extra-virgin olive oil adulterated with corn oil, and from 0.05 to 0.11% for the extra-virgin olive oil adulterated with sunflower oil. The adulteration with soybean oil produces a large increase of the areas of peak LLLn because the soybean oil is the only one rich in linolenic acid.

The addition of small quantities of seed oil can be identified in the extra-virgin olive oil by the determination of the rate of LLL because the three seed oils are rich in linoleic acid (C18:2). Similarly, the presence of soybean, sunflower, and corn oils was proven by an increase of the percentage of LLL and ECN42. The extra-virgin olive oils were adulterated by sunflower, corn, and soybean oils (from 1 to 10%). Having a content of LLL, they varied from 0.76 to 2.46% with sunflower oil, from 0.52 to 1.86% with corn oil, and from 0.54 to 1.86% with soybean oil. Besides, having a practical ECN42, they varied from 1.26 to 3.39% with sunflower oil, from 1.33 to 2.87% with corn oil, and from 1.42 to 3.59% with soybean oil. It is to be noted that olive oil is largely compared to the seed oils known by their highest linoleic acid percentages.

The use of the ΔECN42 proved to be more effective in detecting even low levels of adulteration of EVOO with most of the examined vegetable oils. According to the data on the fraudulent mixtures presented in Tables 1−3, the determination of the ΔECN42 can be used as a parameter for the detection of fraud of extra-virgin olive oils with each one of the studied seed oils: 1% of sunflower (0.21 > 0.20), 3% of soybean (0.30 > 0.20), and 3% of corn (0.21 > 0.20) (Table 5).

dx.doi.org/10.1021/jf500571n | J. Agric. Food Chem. 2014, 62, 4893−4904

This finding can be attributed to the fact that the ΔECN42 is a number calculated by the combination of fatty acids and triglyceride composition. Therefore, the difference in the composition of the triglycerides and the six fatty acids, taken into account for the calculation of the theoretical ECN42, between the initial samples and their mixtures can be expected. However, these differences do not have the expected effect on the values of the theoretical ECN42 and ΔECN42. A consequence of this is the complete lack of correlation between linoleic acid or LLL and ΔECN42 of vegetable oils and their admixtures with olive oil. These results are in agreement with those reported by Christopoulou et al.,[9] who claimed the parameter ΔECN42 is very useful and effective in the detection of adulteration of olive oils with vegetable oils.

Use of the Sterol Compositions for the Detection of Fraud. The composition of the sterol fraction of olive oil is a very useful parameter for detecting adulterations or to check authenticity, because it can be considered as a fingerprint.[44,45] The comparison between the extra-virgin olive oil and the studied seed oils reveals that there are high differences relating to sterol compositions as shown in Table 4 and Figure 5.

As stated below (Table 4), the profile of sterols is almost decisive in clarifying the contamination of some vegetable oils (EVOO) with other cheaper ones. Thus, the addition of 10% of soybean oil to EVOO can be detected by the increase of campesterol and Δ7-stigmastenol percentages, which exceed the maximum acceptable limits (6.17 > 4.00% and 0.59 > 0.50%, respectively) and also by the decrease of the apparent β-sitosterol (89.21 < 93.00%, minimal value limited by the COI).

The value of the Δ7-stigmastenol in sunflower oil is much higher (17.60%) than that in the EVOO (0.34%). This sterol is very effective for the detection of adulteration, even at the level of 1% of sunflower oil (0.54) in the extra-virgin olive oil. For example, a mixture consisting of 99% of EVOO (with 0.34% of Δ7-stigmastenol percentage) and 1% of sunflower oil (with 17.60% of Δ7-stigmastenol percentage) caused a significant increase in Δ7-stigmastenol percentage (from 0.34 to 0.54). In fact, the determined Δ7-stigmastenol percentage of the mixture was 0.54% of the total sterols (>0.50%, the maximum acceptable limit for Δ7-stigmastenol). Besides, the contamination of EVOO with 5% of sunflower oil could also be detected by the decrease of the apparent β-sitosterol (92.89% of total sterols). Similar results were reported by Aparicio and Aparicio-Ruíz.[8]

In addition, the adulteration of EVOO with 4% of corn oil increases the concentration of campesterol (4.06 > 4%), and falsification with 10% of corn oil decreases the concentration of apparent β-sitosterol (91.86% of the total sterols).

In the first conclusion, the parameters used for the detection of adulteration of extra-virgin olive oil with the studied seed oils as well as the percentages of detectable seed oil in extra-virgin olive oil mixtures are summarized in Table 5. It should be noted that the conclusions for the detection of fraud are drawn from the analyses performed on the samples examined in this research study. However, as has already been mentioned, the effectiveness of a parameter was based on the comparison of the determined value in each fraudulent sample with the maximum established limit of this parameter in EVOO. Consequently, the findings of this research study can be applied to the detection of adulteration of extra-virgin olive oil with the only reservation that the percentage of seed oil that is

LDA score plot of pure extra-virgin olive oil (EVOO), pure seed oils, and adulterated EVOO at the same level based on all of the analyses performed with four determinations: (a) EVOO + 1% of seed oil; (b) EVOO + 2% of seed oil; (c) EVOO + 5% of seed oil; (d) EVOO + 10% of seed oil; (1) EVOO; (2) soybean oil; (3) corn oil; (4) sunflower oil; (5) EVOO + % of soybean oil; (6) EVOO + % of corn oil; (7) EVOO + % of sunflower oil.

detectable in olive oil mixtures may be somewhat different from that proposed in the present study. Overall, this table could be used as a simple guide for analysts working on EVOO analysis.

Use of Other Parameters for the Detection of Fraud. The parameters calculated by the triglycerides and reported in Tables 1−3 are ECN46/LLL and (ECN44 + ECN46)/LLL. Certain researchers have pointed out the importance of these factors in the detection of adulteration of extra-virgin olive oil with certain vegetable oils.[9,46]

These parameters are based on the low LLL content of the extra-virgin olive oil in comparison with that of the other vegetable oils such as soybean, corn, and sunflower oils. The similar ECN46 and ECN44 + ECN46 values of the extra-virgin olive oil are also compared with that of the studied seed oils. Then, the values of these parameters in the seed oils are much lower than that in the extra-virgin olive oil. Besides, the values of these parameters in the mixture of extra-virgin olive oil and sunflower oil (1%) were greatly lower than that in extra-virgin olive oil, whereas in the other mixtures of extra-virgin olive oil with soybean and corn oils, these values were much lower only at 3%. All of the mixtures in the other percentages (5 and 10%) of EVOO and each seed oil type were well separated as shown in Figure 6.

The use of the two parameters ECN46/LLL and (ECN44 + ECN46)/LLL is very effective in the detection of the seed oils in percentages <5% and produced very satisfactory results with regard to the studied vegetable oils, even in percentages lower than 3%, especially in the case of sunflower oil (1%). These results agree with the study performed by Christopoulou et al.,[9] which confirmed the effectiveness of these parameters for the detection of EVOO adulteration with vegetable oils in percentages lower than 5%.

Chemometric Analysis. LDA is probably the most frequently used supervised pattern recognition method. In principle, LDA determines linear discriminant functions, which maximize the ratio of between-class variance and minimize the ratio of within-class variance. It should be noted that, whereas the principal component analysis (PCA) selects a direction that

retains maximal structure among the data in a lower dimension, LDA selects a direction that achieves maximum separation among the given classes.[47]

Because the data structure analysis gave a good sample characterization, a classification model was built. LDA was applied to find a predictive classification model able to differentiate the pure extra-virgin olive oil and the adulterated olive oils.

The plot of the discriminant functions (Figure 7) obtained by LDA showed a clear discrimination between the Chemlali EVOO and the adulterated extra-virgin olive oils mixed with different percentages of soybean, corn, and sunflower oils (1, 2, 3, 4, 5, and 10%). Discriminant function 1, which was highly related to cholesterol, campestanol, stigmasterol, campesterol, Δ7-avenasterol, apparent β-sitosterol, Δ7-stigmastenol, ECN50, and C20:1, represents the function of minor compounds, already considered as a fingerprint for a specific oil. Discriminant function 2 is highly related to C17:0, $ECN42_{theor}$, LLLn, and C18:3.

In particular, by discriminant function 1 it was possible to discriminate Chemlali EVOO and the adulterated extra-virgin olive oils whatever the percentage of seed oil added (Figure 7). All samples were correctly discriminated using the two functions.

Application of LDA, after feature selection, was sufficient to differentiate Chemlali EVOO and all adulterated extra-virgin olive oils. The success was 100% in classification and close to 100% in prediction.

It is difficult to discriminate the adulterated EVOO with 1% of sunflower oil and the pure EVOO, whereas those adulterated with other vegetables oils are clearly separated at the same level (Figure 8a). The separation improves when the percentage of adulteration increases (Figure 8b–d).

Compared to classical methods, this new approach of using LDA application could represent an alternative and innovative tool for faster and cheaper evaluation of EVOO adulteration.

In conclusion, the present study has demonstrated that the threshold of the Chemlali extra-virgin olive oils adulteration by some cheaper vegetable oils such as soybean, corn, and sunflower oils was detected using gas chromatography in combination with liquid chromatography. According to these techniques, certain compounds found in the studied oils (triacylglycerols, trilinoleins, fatty acids, and sterols) are identified, analyzed, and used for the detection of the adulteration of extra-virgin olive oils. It should also be noted that this research work aims to facilitate the work of analysts by providing a simple guide for the detection of the adulteration of extra-virgin olive oil with the most common vegetable oils.

antifungal effects of Cortex Pseudolaricis on mango anthracnose and other horticultural diseases has not been previously investigated. Our preliminarily experiments showed that ethanol extract from Cortex Pseudolaricis had a significant inhibitory activity against *C. gloeosporioides* (data not shown). Therefore, we further conducted a phytochemical study on the extract using a bioactivity-guided purification process, isolated and identified the main metabolites, and then evaluated their antifungal activity.

MATERIALS AND METHODS

General. The Cortex Pseudolaricis was collected in Yinzhou District, Ningbo City, Zhejiang Province of the People's Republic of China (29°46′6″E, 121°19′5″N) and identified by Associate Professor Jianyin Li from the Pharmacy Institute of Lanzhou University. The commercial fungicide carbendazim (nonformulated analytical grade, 98% purity) (Jiangsu Bailing Agrochemical Co., Ltd., China) was used as a positive control. *C. gloeosporioides* was obtained from Postharvest Pathology and Preservation Laboratory, Environment and Plant Protection Institute of Chinese Academy of Tropical Agricultural Science. It is carbendazim-sensitive and isolated from mango fruit. Analytical thin-layer chromatography (TLC) and preparative thin-layer chromatography (PTLC) were performed with silica gel plates using silica gel 60 GF254 (Qingdao Haiyang Chemical Co., Ltd.). Melting points were taken on a Kofler melting point apparatus and are uncorrected. Mass spectra were recorded on a Bruker Daltonics APEXII49e spectrometer with ESI source as ionization. ^{1}H and ^{13}C NMR spectra were recorded at 400 and 100 MHz on a Bruker AM-400 spectrometer using TMS as reference (Bruker Company, U.S.A.).

Isolation of Pseudolaric Acids. The Cortex Pseudolaricis (20 kg) was ground and percolated with 95% ethanol. After filtration and removal of the solvent, the ethanol extract was dissolved in 5 L of 5% $NaHCO_3$ solution to make a suspension and extracted with ethyl acetate to give a neutral ethyl acetate-soluble fraction. The aqueous solution was then treated with 5% HCl solution to about pH 6 and extracted with ethyl acetate again to afford an acidic ethyl acetate-soluble fraction. The acidic ethyl acetate-soluble fraction was subjected to silica gel column chromatography using a gradient solvent system of petrolumm-ethyl acetate (4:1), and then chloroform−methanol (10:1), and three major fractions, 1−3, were collected. Fraction 1 was then chromatographed sequentially over silica gel column using a solvent system of petroleum−ethyl acetate (4:1) to afford Pseudolaric acid A (**1**, PAA), a silica gel column petroleum−ethyl acetate (5:1), to afford Ethyl Pseudolaric acid B (**2**, EPAB). Fraction 2 was recrystallized from petroleumether−ethyl acetate (4:1) to afford pseudolaric acid B (**3**, PAB) (12.2 g). Fraction 3 was chromatographed sequentially over silica gel column using a solvent system of chloroform−methanol (20:1 to 1:1) to yield pseudolaric acid B—O-*β*-D-glucoside (**4**, PABG) (2.5 g).

Isolation of Other Compounds. The dried Cortex Pseudolaricis (20 kg) was ground and ultrasonically extracted with 95% ethanol. After filtration and removal of the solvent, the ethanol extract was dissolved in 5 L of 5% $NaHCO_3$ solution to make a suspension and immediately extracted with ethyl acetate to give a neutral ethyl acetate-soluble fraction. The aqueous solute was then treated with 5% HCl solution to about pH 2−3 and extracted with ethyl acetate again to afford an acidic ethyl acetate-soluble fraction (177g). The acidic ethyl acetate-soluble fraction was subjected to silica gel column chromatography using a gradient solvent system of petroleum−acetone (5:1−1:1), and three major fractions 1−3 were collected. The first of these fractions was then chromatographed sequentially over silica gel column using a solvent system of petroleum−acetone (3:1) to afford compound **5**. Fraction 2 was chromatographed sequentially over silica gel column using a gradient solvent system of petroleum−chloroform−acetone (5:2:2), and then petroleum−chloroform−acetone (5:1:2), and then petroleum−chloroform (1:1), to afford compounds **6**, **7**, and **8**, respectively.

4-(3-Formyl-5-methoxyphenyl)butanoic Acid (8). White amorphous powder; mp: 99−102 °C; ^{1}H NMR (400 MHz, DMSO-d_6) δ: 12.3 (1H, s, COOH), 9.82 (1H, s, CHO), 7.41 (2H, t, J = 7.2 Hz, H-2, H-6), 6.83 (1H, d, J = 8.8 Hz, H-4), 3.79 (3H, s, O—CH$_3$), 3.34 (1H, s, H-9), 2.17 (1H, t, J = 7.6 Hz, H-7), 1.46 (1H, t, J = 6.8 Hz, H-7), 1.23 (2H, m, H-8), 1.15 (1H, dd, J = 6.4, 16.4 Hz, H-9). ^{13}C NMR (400 MHz, DMSO-d_6) δ: 174.5 (COOH), 167.3 (CHO), 151.1 (C-5), 147.3 (C-3), 123.5 (C-1), 121.7 (C-6), 115.1 (C-4), 112.7 (C-2), 55.6 (O—CH$_3$), 33.7 (C-7), 28.5 (C-9), 24.5 (C-8) ; ESI-MS m/z: 223 [M + H]$^+$, 245[M + Na]$^+$.

In Vitro Effect on Mycelial Growth of *C. gloeosporioides*. The effects of the compounds from Cortex Pseudolaricis on the mycelial growth against *C. gloeosporioides* were assessed using Poison Food Technique in solid media.[21] First, the compounds were dissolved in acetone and water containing Tween-80, then mixed with sterile molten potato dextrose agar to obtain final concentrations ranging from 0.3125 to 40.0 μg/mL. The PDA was poured into 9 cm Petri plates (15 mL) that were then inoculated with 4 mm plugs of *C. gloeosporioides*. Three replicate plates were used per treatment, and PDA containing a corresponding concentration of acetone in water as a normal growth control. After the fungal growth in the control had completely covered the Petri dishes, mycelial growth diameters were measured and inhibition percentages relative to the control with acetone were calculated using the formula from Agarwal:[22]

$$I(\%) = [(C - d) - (T - d)]/(C - d) \times 100$$

where d is diameter of the cut fungus (4 mm), I is the inhibition (%), and C and T are the average colony diameters of the mycelium of the control and treatment, respectively.

Spore Germination Assay. The inhibitory activity of compounds (**1**−**8**) on spore germination and germ-tube elongation of *C. gloeosporioides* were assessed by microscopic observation.[20] Spore suspensions (1 × 10^5 spores/mL) were prepared by seeding conidia in a 0.05% Tween 80 solution. The acetone solution of the test compounds was diluted with conidial suspension to obtain six different final concentrations of 0.5, 1, 5, 10, 20, and 40 μg/mL. Then, 30 μL of these cultures were removed to concave slide and incubated in a humidity chamber at 28 °C and 90% relative humidity. Three replicates were performed and conidial suspension containing a corresponding concentration of acetone in water was regarded as control. After incubation at 28 °C for 12 h, the number of germinated spores and the length of germ tubes were examined by counting and measuring approximately 100 conidia in each field of three randomly selected fields under a biological microscope photographic system at 400× magnification. The experiments were repeated three times.

In Vivo Trials on Mango Fruits. Mango fruit (*Mangifera indica*), cv. "Tai-Nong 1#"at the green mature stage were harvested from "Yangguang Farm" located in Sanya City, Hainan Province of China). The surface of the mango fruit was sterilized by immersion in 70% ethanol for 1 min and thereafter inflicting one wound (1 mm deep) in the middle of each fruit with a sterile needle. Then, 5 μL of spore suspension (10^4 spores/mL) of *C. gloeosporioides* were inoculated into wounded site. The inoculated fruit were incubated in a sterile box overnight at 28 °C prior to being dipped in the diluted compounds that were prepared by dissolution in 5 mL of 10% DMSO and then diluted with sterile distilled water to final concentrations of 50 and 100 μg/mL. The compound treatments were compared with carbendazim and 0.5% DMSO treatment that served as a negative control. The treated fruits were stored in a moisture chamber at 28 °C and 80% RH for 9 d. Disease developments were assessed by measuring the diameter of the anthracnose lesions on the mango fruit.[9] Each treatment consisted of 3 replicates with 10 fruits per replicate, and the experiment was repeated twice.

Scanning Electron Microscopy (SEM). SEM observations on the hyphae of *C. gloeosporioides* was conducted according to the method described by Feng et al.[23] A mycelial disk (4 mm diameter) was taken from the periphery of the colony grown on PDA medium containing 2.5 μg/mL (EC$_{80}$) of test compounds and incubated for 24−72 h at 28 °C. The youngest *C. gloeosporioides* hyphae were chosen from the margin of the mycelia, and the samples were routinely fixed in 2.5% glutaraldehyde (prepared previously with 0.1 mol/L phosphate buffer, pH 7.2) at 4 °C overnight, briefly postfixed for 2 h at 4 °C in 1% OsO_4 in the same buffer, and then dehydrated in a graded ethanol series, critical point dried, and gold coated. SEM observations were performed with an FEI Quanta 400 Thermal FE Environment Scanning Electron Microscope at an accelerating voltage of 20 kV.

Statistical Analyses. Data were presented as means and standard deviations. ANOVA was used to determine whether there were significant ($P < 0.05$) treatment effects between groups, and the means were compared using the Duncan's multiple range test. Differences among different treatments were analyzed using SAS version 9.13. Dose−response curves were analyzed using a four-parameter log−logistic model[24] using R software (version 2.15.2, R Foundation for Statistical Computing, Vienna, Austria) with the drc module.[25] Means and standard deviations were obtained using the raw data, and the EC$_{50}$ values were obtained from the parameters in the regression curves. The graphs were generated with Sigma Plot (version 11, Systat Software Inc., San Jose, CA, U.S.A.).

RESULTS

Structure Elucidation of the Bioactive Constitutes. Bioassay-guided separation of the components in the ethanol extract of the root bark of Cortex Pseudolaricis afforded eight major bioactive metabolites (Figure 1). All these compounds were purified by column chromatography, and their structures were characterized by ^{1}H NMR, ^{13}C NMR, and ESI-MS data,

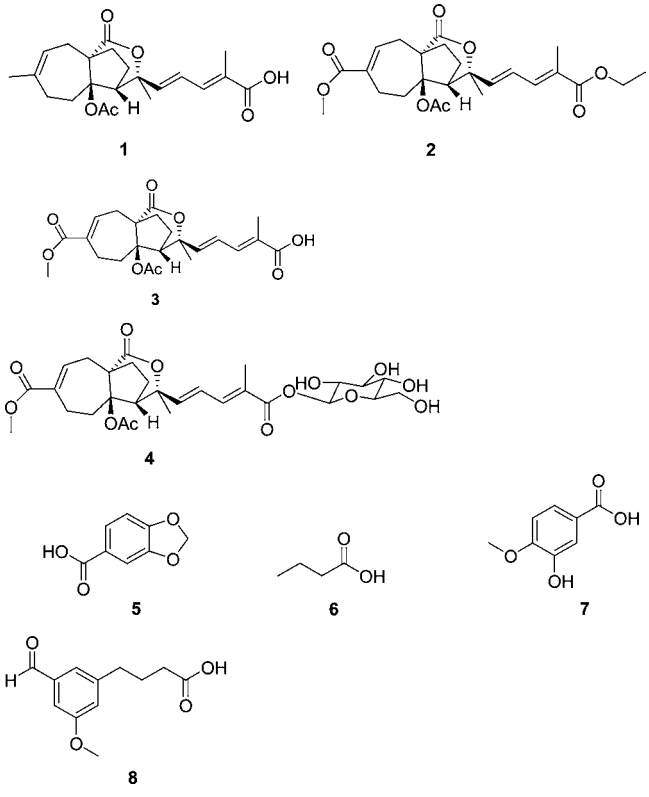

Figure 1. Chemical structures of compounds **1**−**8**.

dx.doi.org/10.1021/jf500968b | J. Agric. Food Chem. 2014, 62, 4905−4910

and their structures also were confirmed by direct comparison with previously reported spectroscopic data.[26,27] On the basis of the following data, the constituents were identified as pseudolaric acid A (1, PAA), ethyl pseudolaric acid B (2, EPAB), pseudolaric acid B (3, PAB), pseudolaric acid B—O-β-D-glucoside(4, PABG), piperonylic acid (5), propionic acid (6), 3-hydroxy-4-methoxybenzoic acid (7), and 4-(3-formyl-5-methoxyphenyl)butanoic acid (8).

Effects of Compounds on Mycelial Growth in Vitro. To evaluate the antifungal activity, the effects of the eight compounds on *C. gloeosporioides* mycelial growth on solid media were determined (Figure 2). The results showed that the

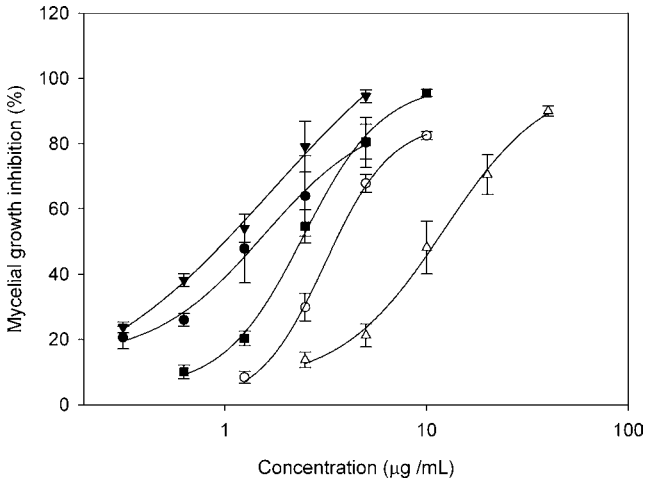

Figure 2. Dose−response curves of the test compounds on inhibition of *C. gloeosporioides* mycelial growth. ● = pseudolaric acid A; ○ = ethyl pseudolaric acid B; ▼ = pseudolaric acid B; △ = pseudolaric acid-O-β-D-glucoside; and ■ = commercial standard carbendazim.

PAB, PAA, EPAB, and PABG had high dose-dependent activities against the *C. gloeosporioides* mycelial growth with the EC_{50} value of 1.62, 3.7, 1.07, and 11.30 μg/mL, respectively. In particular, PAB and PAA showed a greater mycelial growth inhibition than that of carbendazim (2.37 μg/mL) (Figure 2). By contrast, compounds piperonylic acid, propionic acid, 3-hydroxy-4-methoxybenzoic acid, and 4-(3-formyl-5-methoxyphenyl) butanoic acid showed weaker inhibitory activity, whose mycelial growth inhibitions were all less than 30% at 40 μg/mL.

Effects of Compounds on Spore Germination and Germtube Elongation. PAB and PAA exhibited greater inhibition of spore germination and germ tube elongation than did the carbendazim standard (Table 1). PAB had an effective concentration of 50% (EC_{50}) value of of 3.80 μg/mL on spore germination and 0.75 μg/mL on germ tube elongation.

Effects of PAB on Control of *C. gloeosporioides* in Mango Fruit. The effects of four active compounds, including PAB, PAA, EPAB, and PABG, on the postharvest anthracnose of mango fruit were demonstrated in Figure 3. Results indicated that all the compounds tested at 50 and 100 μg/mL significantly suppressed lesion diameter of anthracnose in mango fruit inoculated with spore suspension of *C. gloeosporioides*. Smaller lesion development was achieved at higher concentrations of test compounds ($P < 0.05$). PAB treatment showed the greatest efficiency in controlling mango anthracnose, where the lesion diameters were 87.61% and 46.67% lower than those in control and carbendazim-treated fruit.

Table 1. EC_{50} Values (μg/mL) of Active Components from Cortex Pseudolaricis against Spore Germination and Germ Tube Elongation of *C. gloeosporioides*[a]

treatments	EC_{50} (95% FL)	
	spore germination	germ tube elongation
Pseudolaric acid A	5.69	1.14
ethyl Pseudolaric acid B	11.42	2.78
Pseudolaric acid B	3.80	0.75
Pseudolaric acid B—O-β-D-glucoside	23.57	6.35
piperonylic acid	>40	>40
propionic acid	>40	>40
3-hydroxy-4-methoxybenzoic acid	>40	>40
4-(3-formyl-5-methoxyphenyl)butanoic acid	>40	>40
carbendazim (98%)	21.34	2.04

[a] EC_{50} was determined by probit-log analysis. FL, fiducial limits.

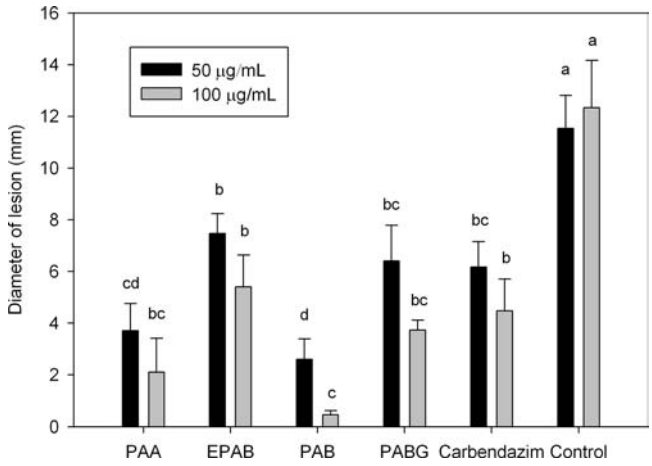

Figure 3. Efficacy of active components from Cortex Pseudolaricis in controlling anthracnose disease on mango fruits (Disease incidence was determined 9 days after inoculation). Each bar represents the mean of three independent experiments ± standard deviation. Different letters indicate that the means are significantly different at $P < 0.05$.

Changes in the Hyphae Morphology of *C. gloeosporioides*. To reveal the antifungal mechanism of PAB, the hyphae morphology of *C. gloeosporioides* treated with 2.4 μg/mL (EC_{80}) PAB was observed by scanning electron microscopy. *C. gloeosporioides* mycelium grown in PDA with 1% acetone (control) displayed characteristic morphology with lengthened, regular, homogeneous hyphae of constant diameter with smooth external surfaces and rounded apexes (Figure 4A,B). In the PAB treatment at 24 h, the hyphae morphology showed undulations along the hyphal border, a little swelling localized along the hyphae and at their extremities, and the formation of anomalous apex bifurcations (Figure 4C,D). Macroscopic morphologic alterations of *C. gloeosporioides* were more profound when the PAB treatment time was extended to 48 h. The apexes of *C. gloeosporioides* treated with PAB showed an irregular growth in dimension, with multiple ramifications in subapical expanded areas with an irregular shape (Figure 4E); several swellings of ovoidal or spherical shape were evident and were localized in the subterminal position near the apexes, or in the middle position along the hyphae (Figure 4F). Seventy-two hours after PAB treatment, hypha were distorted and collapsed (Figure 4G).

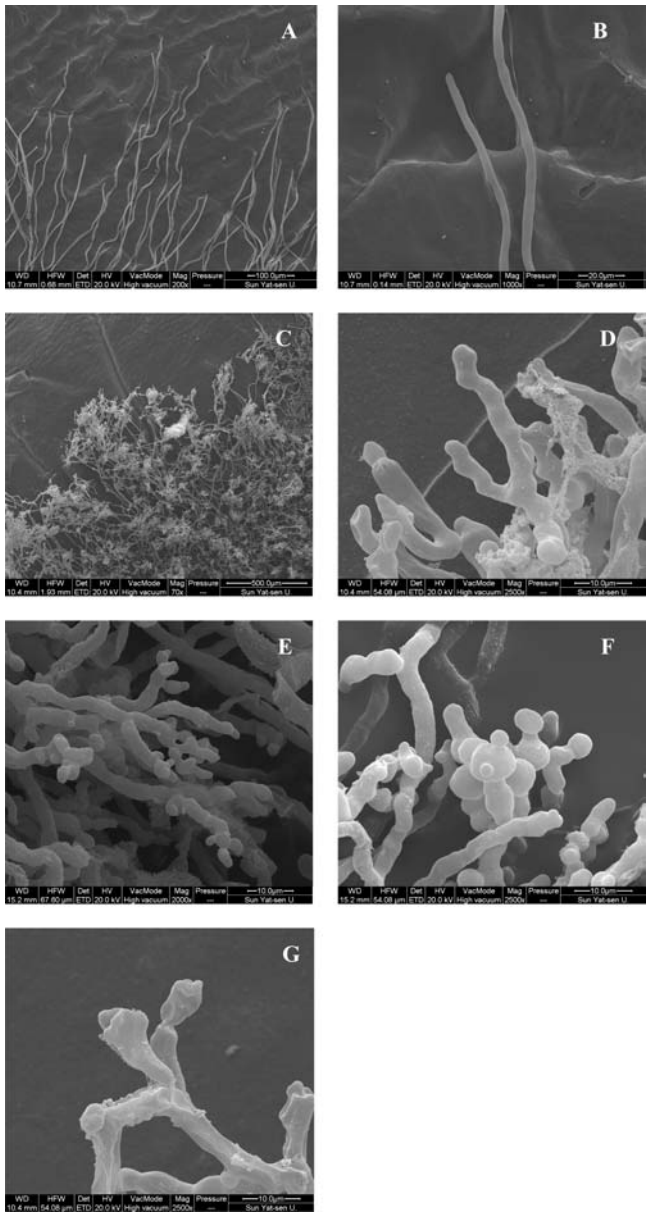

Figure 4. Scanning electron micrographs of the hyphae of *C. gloeosporioides* grown on PDA plates with or without PAB at 28 °C. (A, B) control (1% acetone); (C, D) PAB (24 h); (E, F) PAB (48 h), and (G) PAB (72 h).

DISCUSSION

In recent years, consumer demand for fresh fruits and vegetables without chemical residues has increased.[26] Susceptibility of anthracnose disease caused by *C. gloeosporioides* is one of the most serious problems affecting the mango industry worldwide. As alternatives to synthetic fungicides, the use of natural antifungal compounds isolated from plants to control mango anthracnose disease has been investigated, but few if any satisfactory compounds have been found.[9−13] The root bark of *P. kaempferi* has been successfully used in traditional Chinese medicine as an antifungal remedy and more recently, its major constituents have been isolated and characterized.[10,23,27] Although the antifungal activity and possible mechanisms of PAB against medical fungi have been well demonstrated, the effects of PAB and the pseudolaric acid analogues on plant phytopathogenic fungi were not documented. This is the first report on the potential agricultural use of these compounds isolated from Cortex Pseudolaricis against *C. gloeosporioides* in vitro and in vivo.

The present study evaluated the in vitro antifungal activity of eight compounds from the ethanol extracts of *Cortex Pseudolaricis* and their capability in controlling postharvest anthracnose. It was previously reported that pseudolaric acid analogues from Cortex Pseudolaricis were the active components.[27−29] Such observation was also supported by our study, in which pseudolaric acid analogues PAA, PAB, EPAB, and PABG, effectively suppressed *C. gloeosporioides* in mango fruit. PAB showed the strongest efficacy and had greater inhibitory activity than fungicide carbendazim. These results indicate that PAB has great potential to control postharvest mango anthracnose as a natural product based alternative to synthetic fungicides. Currently, natural PAA and PAB can only be obtained from the root bark of *P. kaempferi*. Recently, PAB was successfully achieved by manual synthesis in laboratory,[18] which could provide an ample supply of this compound and introduce a variety of novel structural modifications to the PAB molecule based on synthesis for structure activity relationships. Further studies need to be expanded to other important plant pathogenic fungi, and the indicated SAR need to be conducted on these compounds.

Research on the fungicidal mechanism of action for PAB is being carried out. Zhang et al. proposed that the mechanism of PAB could be unique and different from antibiotics with the known mechanisms of amphotericin B, nystatin, ketoconazole, and clotrimazole. It was been reported that PAB resulted in DNA damage and inhibited cell division.[30,31] Recently, Wong et al. showed that the antitumor activity of PAB could be associated with its ability to directly interact with tubulin and identified the microtubules as the molecular target of PAB.[18] In agricultural fungi, tubulin is one kind of important fungicide target. Both benzimidazole and zoxamide fungicides inhibit phytopathogenic fungus by binding to β-tubulin.[32,33] In our present study, PAB showed stronger inhibition of mycelial growth and germ tube elongation than spore germination. SEM images revealed that PAB treatments caused hyphal tip swelling, malformed branches, and swollen, distorted, concave-collapsed hyphae in *C. gloeosporioides*. Morphological changes induced by PAB are similar to those caused by tubulin inhibitors, such as benzimidazole fungicides.[34] Therefore, these findings suggest that PAB may have a similar function in inhibiting mycelial growth and germ-tube elongation in *C. gloeosporioides*.

MATERIALS AND METHODS

General. Aβ_{25-35}, *p*-CA, and UA were purchased from Sigma Chemical Co. (St. Louis, MO, USA). RPMI 1640 medium, phosphate-buffered saline (PBS), fetal bovine serum, donor equine serum, trypsin 0.25% solution, and penicillin/streptomycin solution were obtained from Hyclone Laboratories, Inc. (Logan, UT, USA). N_2 supplement and RPMI 1640 phenol red free medium were purchased Gibco BRL (Grand Island, NY, USA). Rabbit-antiphospho-iNOS, goat-antiphospho-COX-2, and goat-anti-β-actin were obtained from Santa Cruz Biotechnology, Inc. (Santa Cruz, CA, USA). Rabbit antiphospho-JNK, rabbit-antiphospho-ERK, rabbit-antiphospho-IκB-α, and rabbit-anti-phospho-p65 monoclonal antibodies were purchased from Cell Signaling Technology Inc. (Beverly, MA, USA). All other reagents used in this study were of the highest grade available.

Peptide Preparation and Cell Culture. Pheochromocytoma PC12 cells (ATCC CRL 1721) have been extensively used as an in vitro model system to study the mechanisms of neuronal toxicity.[18,19] PC12 cells were purchased from ATCC (Manassas, VA, USA). PC12 cells were maintained in RPMI 1640 supplemented with 10% heat-inactivated horse serum and 5% fetal bovine serum at 37 °C in a humidified atmosphere of 5% CO_2 and 95% air. All cells were cultured in serum-free medium for 16 h prior to sample treatment. Samples were added at indicated concentrations 1 h prior to Aβ_{25-35} treatment, and the cells were plated at a density of 2×10^6 cells/well.

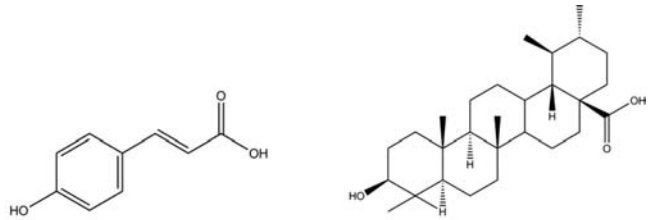
The Aβ_{25-35} peptide used in this study preserves the toxicity of the full length Aβ and is widely used to model Aβ-induced neurodegeneration. The fragment Aβ_{25-35} has the central functional domain of the whole molecules Aβ that is required for neurotoxic effect.[20,21] Aβ_{25-35} was dissolved in DMSO at a concentration of 10 mM and stored at −20 °C. The stock solution was diluted with PBS to appropriate concentration and incubated for 48 h at 37 °C for aggregation prior to each experiment. Samples were dissolved in DMSO and further diluted with PBS. The final concentration of DMSO was adjusted to <0.01%, which was found to have no effect on the cell viability in our preliminary experiments (data not shown).

Western Blot Analysis. PC12 cells were incubated at 37 °C with 50 μM Aβ_{25-35} for 1 h for MAPKs family phosphorylation, for 4 h for NF-κB and I κB formation, and for 30 h for iNOS and COX-2 activation with or without pretreatment with samples. The treated cells were washed twice with cold PBS (pH 7.4) and harvested using a cell scraper. The cell pellets were resuspended in lysis buffer on ice for 1 h, and cell debris was removed by centrifugation at 13000 rpm for 10 min. Protein concentrations were determined by the BCA protein assay (Pierce, Rockford, IL, USA). Equal amounts of proteins were mixed with 4× Laemmli loading buffer and preheated at 95 °C for 5 min. The samples were then loaded onto a 10% SDS−polyacrylamide gel and transferred onto a PVDF membrane for 1 h with a semidry transfer system (Bio-Rad, Hercules, CA, USA). The membranes were blocked with 5% nonfat milk in PBST with 0.1% Tween 20 for 1 h at room temperature and then incubated overnight with anti-COX-2, anti-iNOS, antiphospho-p65, antiphospho-IκB-α, antiphospho-ERK1/2, antiphospho-JNK, and antiphospho-p38 antibodies diluted 1:1000 in blocking solution at 4 °C. After five washes with PBS containing Tween, the membrane was incubated with anti-goat or anti-rabbit immunoglobulin G horseradish peroxidase-conjugated secondary antibodies (diluted 1:1000) and visualized using Western blotting luminal reagents (Santa Cruz Biotechnology).

Statistical Analysis. All experiments were performed in triplicate. Data of each experiment showed the mean ± SD (n = 3). The values were compared with the control using analysis of variance followed by unpaired Student's t test.

RESULTS AND DISCUSSION

Protective Effect of *p*-CA and UA on Protein Expression of iNOS and COX-2 in Aβ_{25-35}-Induced PC12 Cells. The chemical structures of *p*-CA and UA are shown in Figure 1. Our previous study demonstrated that *p*-CA and UA exhibited predominant neuroprotective effects against



p-Coumaric acid (*p*-CA) Ursolic acid (UA)

Figure 1. Chemical structures of *p*-coumaric acid and ursolic acid.

Aβ_{25-35}-induced injury via attenuating cellular oxidative stress, suppressing capsase-3 activity, and thus inhibiting apoptosis.[17] Unlike *p*-CA, UA displayed adverse effects on cell viability at the higher concentration, and treatment of high concentration of UA showed neither protection nor exacerbation against Aβ_{25-35}-induced damage.[17] Thus, the experimental concentration limit of UA in the current study was adjusted to 20 μM, which did not affect cell viability. Concentration of UA (1, 10, and 20 μM) and *p*-CA (5, 25, and 50 μM) alone did not affect cell viability (data not shown). The concentration of 50 μM was used for determining Aβ_{25-35}-induced cell damage in the present experiments on the basis of our previous study.[17] To determine whether *p*-CA and UA can suppress inflammation, the inflammatory responses were induced in PC12 cells by Aβ_{25-35}. COX-2 and iNOS are well-known pro-inflammatory enzymes that play crucial roles in inflammatory responses.[22] As shown in Figure 2, Aβ_{25-35} significantly increased the expression of COX-2 and iNOS ($p < 0.01$ and $p < 0.001$, respectively) compared with the control without Aβ_{25-35} treatment. Cells pretreated with *p*-CA at 5 and 25 μM showed significantly reduced level of COX-2 expression in comparison to the Aβ_{25-35}-treated cells ($p < 0.05$). On the other hand, pretreatment of *p*-CA at 50 μM showed a somewhat weaker effect in COX-2 expression, which exerted neither positive nor negative effect against Aβ_{25-35}-induced inflammation. Each pretreatment of *p*-CA at 5, 25, and 50 μM strongly inhibited iNOS expression in a dose-dependent manner ($p < 0.01$). Even at 5 μM *p*-CA inhibited Aβ_{25-35}-induced iNOS expression. UA dose-dependently suppressed both iNOS and COX-2 levels. Even at 20 μM UA inhibited not only COX-2 expression but also iNOS expression to a level much lower than the control.

Protective Effect of *p*-CA and UA on Aβ_{25-35}-Induced Nuclear Translocation of NF-κB Subunit p65 and Phosphorylation of IκB in PC12 Cells. When binding with IκB, NF-κB is inactive in the cytosol. However, it becomes active via phosphorylation and degradation of IκB, and subsequent nuclear translocation of NF-κB is stimulated by Aβ.[23] NF-κB signaling regulates the expression of downstream NF-κB dependent gene products such as COX-2 and iNOS.[24] Because the expression levels of COX-2 and iNOS enzymes were reduced by *p*-CA and UA treatments, we further examined whether *p*-CA and UA could inhibit the nuclear translocation of NF-κB subunit p65 by using Western blot. It has been reported that phosphorylation of p65 affects the transcriptional activity of NF-κB.[25] As illustrated in Figure 3, the p-p65/p-IκB and β-actin ratios were significantly elevated by Aβ_{25-35} in PC12 cells ($p < 0.05$). UA exhibited significant and dose-dependent inhibition of p65 phosphorylation in comparison to the Aβ_{25-35}-stimulated control group ($p < 0.05$). *p*-CA also attenuated levels of p-p65 protein, however, somewhat lower than that of UA.

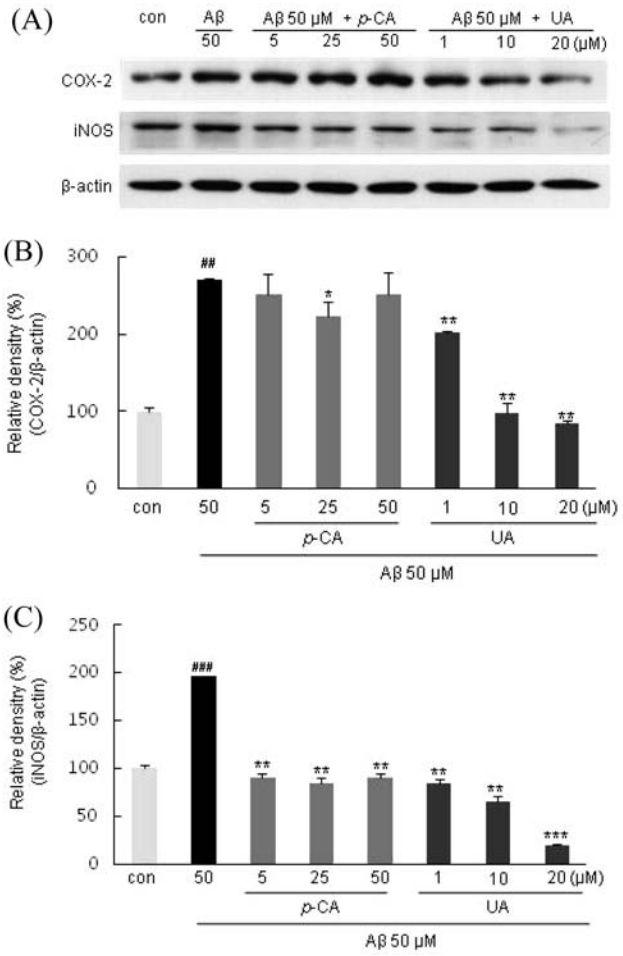


Figure 2. Effects of *p*-coumaric acid (*p*-CA) and ursolic acid (UA) on Aβ_{25-35}-induced iNOS and COX-2 expression in PC12 cells. The total lysates of the proteins were subjected to Western blot analysis, as described under Materials and Methods. Cells were pretreated with samples at the indicated concentrations for 1 h and then exposed to 50 μM Aβ_{25-35} for 30 h. The ratio of immunointensity between COX-2/iNOS and β-actin was calculated. Each bar represents the mean ± SD from three independent experiments. (###) $p < 0.001$ and (##) $p < 0.01$ versus control group. (***) $p < 0.001$, (**) $p < 0.01$, and (*) $p < 0.05$ versus the group treated with Aβ_{25-35} alone.

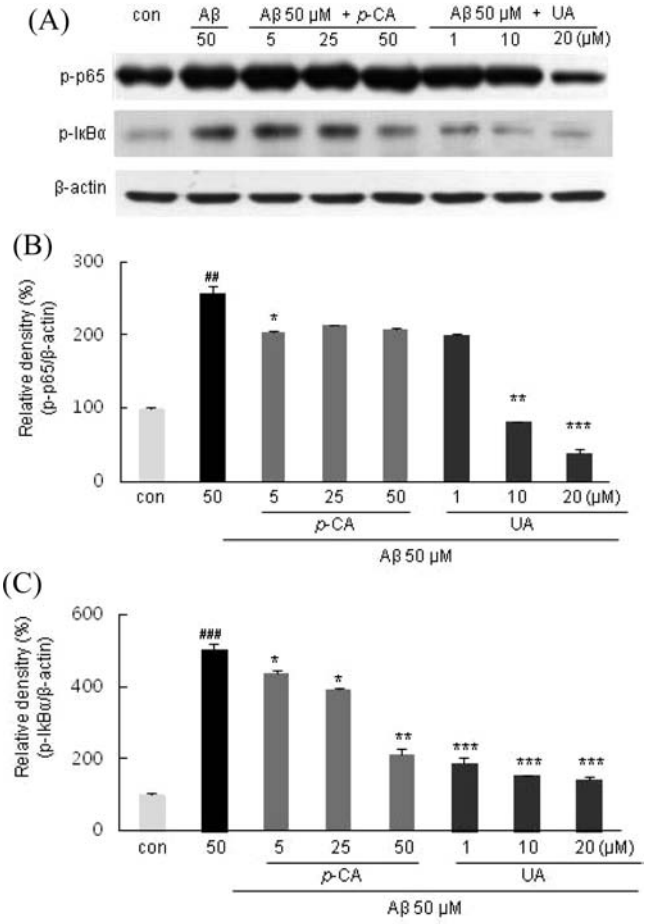

Figure 3. Effects of *p*-coumaric acid (*p*-CA) and ursolic acid (UA) against Aβ_{25-35}-induced phosphorylation of NF-κB subunit (p65) and degradation of IκB in PC12 cells. The total lysates of the proteins were subjected to Western blot analysis, as described under Materials and Methods. Cells were pretreated with the indicated concentrations of samples for 1 h and then exposed to 50 μM Aβ_{25-35} for 4 h. The ratio of immunointensity between the p-p65/IκB-α and β-actin was calculated. Each bar represents the mean ± SD from three independent experiments. (#) $p < 0.05$ versus control group. (**) $p < 0.01$ and (*) $p < 0.05$ versus the group treated with Aβ_{25-35} alone.

Protective Effect of *p*-CA and UA on MAPKs Phosphorylation in Aβ_{25-35}-Induced PC12 Cells. Because the activation of MAPKs family including ERK, JNK, and p38 is associated with the NF-κB activation and downstream inflammatory gene expression, we further investigated the activation of MAPKs.[26] The phosphorylation of p38, ERK, and JNK was significantly elevated when cells were treated with Aβ_{25-35} alone compared with the control (Figure 4). *p*-CA significantly suppressed ERK1/2 and JNK phosphorylation but relatively not that of p38 in response to Aβ_{25-35} treatment of PC12 cells. In particular, *p*-CA at a concentration of 25 μM strongly suppressed the phosphorylation of ERK1/2 and JNK even to levels much lower than that of the control. UA exclusively decreased the phosphorylation of p-38, JNK, and ERK in dose-dependent manners. In particular, the phosphorylation of ERK was markedly suppressed almost to its basal level when treated with 1 μM UA. In addition, 20 μM UA significantly reduced the phosphorylation of p38 and JNK even to a level much lower than the control. *p*-CA and UA comprehensively inhibited NF-κB activity, but the results of the upstream mechanisms were different.

A deleterious effect of Aβ against neuronal cells has been proved to be a critical cause of AD.[27] Aβ accumulation occurs at an early step in the AD cascade of events in cellular dysfunction through neuroinflammation.[28] The discovery of NF-κB as a key transcription factor in the inflammation provided a starting point that the suppression of NF-κB can be a promising therapeutic approach in inflammatory pathology such as arthritis, asthma, AD, and cancers.[29] Various researchers have proved that the activation of NF-κB is initiated by various stimuli including Aβ, ROS, and inflammatory cytokines.[23] Bioactive natural products have received much attention as predominant and promising sources in the development of novel therapeutic agents. Synthetic agents have not replaced natural products as essential substances, and many of the recently developed medicines are derived from natural sources. In addition, therapeutic properties of various natural substances with anti-inflammatory effects may result from their inhibition of NF-κB-dependent inflammation.[30]

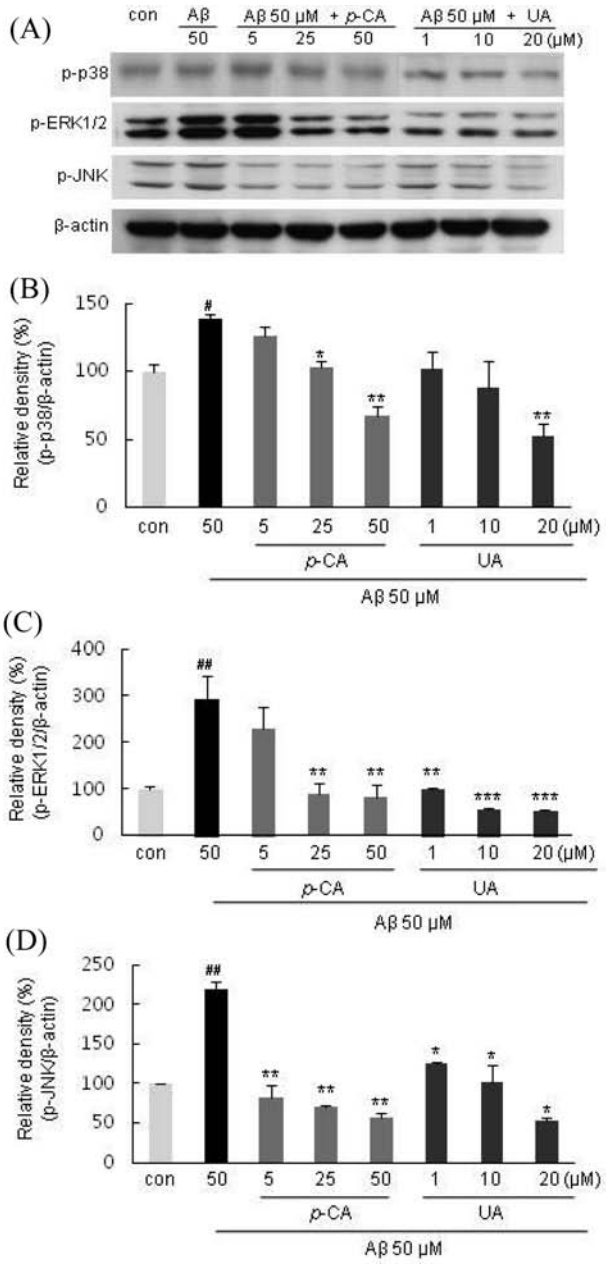

Figure 4. Effects of *p*-coumaric acid (*p*-CA) and ursolic acid (UA) against Aβ_{25-35}-induced phosphorylation of MAPKs in PC12 cells. The total lysates of the proteins were subjected to Western blot analysis, as described under Materials and Methods. Cells were pretreated with samples for 1 h and then exposed to 50 μM Aβ_{25-35} for 1 h. The ratio of immunointensity between the p-p38/ERK1/2/JNK and β-actin was calculated. Each bar represents the mean ± SD from three independent experiments. (**) $p < 0.01$ and (#) $p < 0.05$ versus control group. (**) $p < 0.01$ and (*) $p < 0.05$ versus the group treated with Aβ_{25-35} alone.

p-CA [3-(4-hydroxyphenyl)-2-propenoic acid], a ubiquitous intermediate metabolite in the synthesis of many polyphenols including flavonoids in plants, is widely found in fruits, vegetables, and cereals.[31] Previous investigators have shown that *p*-CA protected dextran sodium sulfate induced-intestinal inflammation through the suppression of COX-2 expression.[32] Apart from this, no report regarding the anti-inflammatory property of *p*-CA via suppression of the NF-κB pathway has been found so far.

UA (3β-hydroxyurs-12-en-28-oic acid) is a pentacyclic triterpene acid widely distributed in berries, flowers, and fruits. Previous research has demonstrated that UA inhibited LPS-induced inflammatory response through inhibition of NF-κB and iNOS expression in lung epithelial cells.[33] In addition, animal studies have shown that oral administration of UA (10 mg/kg·day) attenuated D-galactose-induced inflammatory response in the mouse prefrontal cortex through down-regulation of iNOS and COX-2 expression.[34] Another study has demonstrated that UA enhances collateral blood flow recovery through induction of neovascularization in a hind limb ischemia mouse model.[35]

The present study suggested for the first time that *p*-CA and UA isolated from CF efficiently suppressed the expression of iNOS and COX-2 in Aβ_{25-35}-treated PC12 cells. These inhibitions appeared to correlate with the inhibition of NF-κB activation as pretreating cells with *p*-CA and UA blocked the phosphorylation of the inhibitory subunit IκB. Similar inhibitory effects of UA on iNOS and COX-2 regulated by NF-κB inactivation have been observed in several different cell types including macrophages, platelets, and leukemic and cancer cells exposed to diverse oxidative or inflammatory stimuli.[36−38] Our results show that *p*-CA might exert its anti-inflammatory ability through inhibiting p38 and JNK pathways leading to NF-κB inactivation and thereby suppressing expressions of inflammatory target proteins including COX-2 and iNOS. On the other hand, UA may affect pro-inflammatory signaling through the inhibition of ERK, p38, and JNK, leading to NF-κB inactivation and thereby suppressing expressions of inflammatory target proteins including COX-2 and iNOS. Yeh et al. recently reported that UA suppressed migration of human breast cancer cells by reducing the level of JNK phosphorylation through inhibition of NF-κB.[39] For any compounds to exert direct neuroprotective actions they have to permeate the blood−brain barrier (BBB). UA has previously been found in the brain, which implied UA can cross the BBB.[40] Further studies regarding the BBB penetration by *p*-CA are needed. Our novel findings suggest that *p*-CA and UA have potential neuroprotective effects against Aβ_{25-35}-induced neurotoxicity through blocking iNOS and COX-2 via down-regulation of NF-κB and MAPKs pathways.

The results indicate that *p*-CA and UA derived from CF suppressed Aβ_{25-35}-stimulated expression of pro-inflammatory mediators such as iNOS and COX-2 in PC12 cells. Furthermore, *p*-CA and UA enhanced the inhibitory effects against inflammation via inactivation of both NF-κB and MAPKs signaling pathways. Even though PC12 cells display distinctive sensitivity to neurotoxicity and have been extensively used in the studies of Aβ-induced injury, they cannot thoroughly represent the primary cultured neurons. Therefore, further studies are required to concentrate on primary neurons and in vivo models. Taken together, these findings are the first to represent the anti-inflammatory effects of *p*-CA and UA against Aβ_{25-35} toxicity in PC12 cells, which may provide the pharmacological basis underlying the prevention of AD.

role played by chemical characteristics on water dynamics within the pore system of the chars.

MATERIALS AND METHODS

Feedstock. The hydrochar and pyrochar samples were prepared by using poplar (*Populus* spp. L.) wood chips that were obtained from a dedicated short-rotation forest in the Po valley (Gadesco Pieve Delmona, $45°10^{I}13^{II}$ N, $10°06^{I}01^{II}$ E). The age of the forest at the time of harvest was 5 years. The characteristics of the biomass were already described in De Pasquale et al.[10]

Pyrochar and Hydrochar Preparation. Pyrochar was produced by using an industrial gasifier at the temperature of 1200 °C. All of the details about the gasifier and the pyrolitic conditions have been already reported in De Pasquale et al.[10] Hydrochar was obtained in a b.coal 2.0 reactor from Artec Biotechnology GmbH (Bad Königshofen, Germany) at 230 °C and 40 bar. Details about the procedure have been reported already in Wiedner et al.[24] Both pyrochar and hydrochar samples were 2 mm sieved with a stainless steel sieve and dried overnight in an oven set at 105 °C before each NMR analysis.

Specific Surface Area Measurement. Samples were first dried at 200 °C for 4.5 h and then stored in a desiccator. To retrieve the specific surface area by applying the Brunauer–Emmett–Teller (BET) five-point method, samples were degassed with N_2 at 200 °C for another hour and then measured in liquid N_2 (Quantachrome NOVA 4200 calibrated with BAM-PM-104) following DIN ISO 9277:2003-05. All measurements were done in triplicate. Specific surface areas of the pyrochar and the hydrochars were 54.6 ± 0.2 and 129 ± 2 $m^2\ g^{-1}$, respectively.

The poplar pyrochar surface area measured in this study was smaller than that already reported in De Pasquale et al.[10] (i.e., 98 ± 6 $m^2\ g^{-1}$). The difference can be explained by the different sample preparation used in De Pasquale et al.[10] prior to BET analysis. In fact, the BET investigations reported in De Pasquale et al.[10] have been conducted on agate–mortar ground samples. Pyrochar grinding reduces particle sizes, thereby increasing surface area values.

Evaluation of Pore Size Distribution from the Specific Surface Area Measurements. The nonlocal density functional theory (NLDFT) equilibration model[27] was applied to elaborate the isotherms (35 adsorption and 30 desorption points) of nitrogen adsorption experiments to achieve pore size distributions. Assumption of N_2 at −196 °C on carbon (slit-pore) was used. The cumulative pore volumes and surface areas for the micropore class (i.e., <2 nm, according to IUPAC classification) retrieved by the NLDFT model were 16.3 × 10^{-3} $cm^3\ g^{-1}$ and 29.4 $m^2\ g^{-1}$ for pyrochar, whereas they were 50.9 × 10^{-3} $cm^3\ g^{-1}$ and 93.3 $m^2\ g^{-1}$ for hydrochar. NLDFT surface area and pore volume for hydrochar were around 3 times higher than those for pyrochar, thereby evidencing that the number of pores in the former sample was larger than in the latter one. In particular, the surface/volume (S/V) ratios from NLDFT elaborations were $(S/V)_{pyrochar}$ = 1.80 × 10^9 m^{-1} and $(S/V)_{hydrochar}$ = 1.83 × 10^9 m^{-1}.

CP-TOSS ^{13}C NMR Spectra. Cross-polarization magic angle spinning (CPMAS) ^{13}C NMR measurements were performed on a Bruker Avance-II 400 spectrometer (Bruker Biospin, Milan, Italy) operating at 100.6 MHz on carbon-13 and equipped with a 4 mm standard-bore solid state probe. Samples were packed into 4 mm zirconia rotors with Kel-F caps, and the rotor spin rate was set at 5000 ± 2 Hz. A spectral width of 25252.52 Hz centered at 10061.78 Hz, an optimum contact time of 1 ms chosen after evaluation of variable contact time experiments, a recycle delay of 20 s, and 2K data points over an acquisition time of 35 ms were used. The spectra were acquired with the total suppression side bands (TOSS) sequence with a 50% RAMP to prevent artifacts in the spectra interpretation. A 4.1 μs ^{1}H 90° pulse with an attenuation level of −2.4 dB was applied. Spectra acquisition was achieved with Bruker Topspin 2.0. Data processing was done with MestRe-C software (version 4.9.9.9, Mestrelab Research, Santiago de Compostela, Spain). The free induction decays (FIDs) were transformed by applying first a 2K zero filling, then a line broadening of 100 Hz, and finally an automatic baseline correction with a third-order polynomial and Bernstein algorithm.

Fast Field Cycling (FFC) NMR Relaxometry. The 2 mm sieved and dried poplar pyrochar and hydrochar samples have been prepared as slurry for FFC NMR relaxometry investigations according to the procedure reported in Dunn et al.[28] The background theory of FFC NMR relaxometry has been already described in De Pasquale et al.[10] Moreover, more general environmental applications of FFC NMR relaxometry can be found in Conte and Alonzo.[29]

^{1}H NMR dispersion profiles (i.e., relaxation rates R_1 or $1/T_1$ vs proton Larmor frequencies) were acquired on a Stelar Spinmaster FFC2000 Relaxometer (Stelar s.r.l., Mede, PV, Italy) at temperatures of 25, 50, and 80 °C. The proton spins were polarized at a B_{POL} corresponding to the proton Larmor frequency (ω_L) of 24 MHz for a T_{POL} corresponding to about 5 times the T_1 estimated at this frequency. After each B_{POL} application, the magnetic field intensity (indicated as B_{RLX}) was systematically changed in the proton Larmor frequency ω_L comprised in the range 0.01–40 MHz. The period τ, during which B_{RLX} was applied, has been varied on 32 logarithmic spaced time sets, each of them adjusted at every relaxation field to optimize the sampling of the decay/recovery curves. FIDs were recorded following a single ^{1}H 90° pulse applied at B_{ACQ} corresponding to the proton Larmor frequency of 16 MHz. A time domain of 100 μs sampled with 512 points was applied. Field switching time was 3 ms, whereas spectrometer dead time was 15 μs. For all experiments, a recycle delay of 12 s was used. The NP sequence was applied when the relaxation magnetic fields were in the range of the proton Larmor frequencies between 40.0 and 9.0 MHz. The PP sequence was applied in the proton Larmor frequencies B_{RLX} range of 9.0–0.01 MHz.[30]

FFC NMR Data Processing. R_1 values were achieved by interpolating the ^{1}H magnetization decay/recovery curves at each B_{RLX} value (i.e., ^{1}H signal intensity vs τ) with the stretched exponential function (also known as the Kohlrausch–Williams–Watts function) reported in eq 1 after exportation of the experimental data to OriginPro 7.5 SR6 (version 7.5885, OriginLab Corp., Northampton, MA, USA). This equation provided the best fitting with the largest coefficients of determination ($R^2 > 0.998$). The choice of this function was due to the large sample heterogeneity resulting in a multi-exponential behavior of the decay/recovery curves.[29,31] This approach has the advantage that it is able to handle a wide range of behaviors within a single model. For this reason, assumptions about the number of exponentials to be used in modeling NMRD data are not necessary.

$$I(\tau) = I_0 \exp[-(\tau/T_1)^k] \quad (1)$$

In eq 1, $I(\tau)$ is the ^{1}H signal intensity at each fixed B_{RLX}, I_0 is the ^{1}H signal intensity at the thermal equilibrium, T_1 is the average proton spin–lattice relaxation time, and k is a heterogeneity parameter related to the stretching of the decay process. This function can be considered as a superposition of exponential contributions, thereby describing the likely physical picture of some distribution in T_1.

Relaxation data at the proton Larmor frequency of 40 MHz were evaluated by the inverse Laplace transformation through application of the UPEN algorithm (Alma Mater Studiorum, Università di Bologna, Italy)[32,33] with the aim to obtain the T_1 distributions at such magnetic field and, therefore, information on pore distribution and grain size. The choice of UPEN analyses only at 40 MHz was due to the larger NMR sensitivity at this frequency as compared to the other proton Larmor frequencies.[30]

RESULTS AND DISCUSSION

Hydrochar and Pyrochar Chemical Composition by CP-TOSS ^{13}C NMR Spectroscopy. The cross-polarization magic angle spinning with total suppression of side bands ^{13}C NMR spectra of the two samples studied here showed the more complex nature of hydrochar as compared to pyrochar (Figure 1). In particular, two main regions can be recognized in the hydrochar spectrum (Figure 1A). The first chemical shift

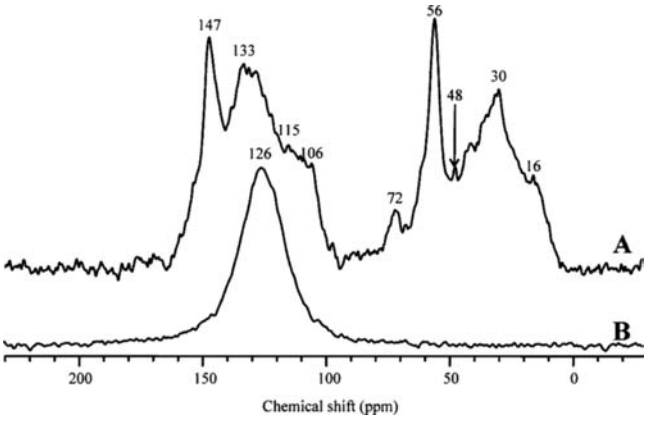

Figure 1. CP-TOSS ^{13}C NMR spectra of poplar hydrochar (A) and pyrochar (B).

interval between 0 and 80 ppm contains individual signals at 16, 30, 48, 56, and 72 ppm (Figure 1A). The first signal at 16 ppm can be attributed to methyl groups of terminating alkyl chains; the second one at 30 ppm is due to methylene groups in alkyl chains, whereas the signal at 48 ppm can be assigned to branched alkyl carbons; the signal at 56 ppm is assignable to methoxyl groups in lignin-like structures, and that at 72 ppm is due to carbons C2, C3, and C5 in the residual cellulose moiety from the poplar biomass.[24,34]

The second spectral region in Figure 1A occurred in the chemical shift interval between 90 and 160 ppm. The main signals recognized in this region are broad bands centered at 106, 115, 133, and 147 ppm. The signal at 106 ppm can be assigned to C1 in residual cellulose; that at 115 ppm is due to C5 in guaiacyl (G) and C3 and C6 in *p*-hydroxyphenyl groups; the signal at 133 ppm is due to the aromatic C−5/C−5′ in etherified 5−5 G units; finally, the signal at 147 ppm is assigned to C3 and C4 in etherified guaiacyl units.[24,34]

The spectrum reported in Figure 1B reveals only one broad band at 126 ppm, which can be assigned to polyaromatic systems.[10] The differences in the chemical composition of poplar hydrochar and pyrochar samples (Figure 1) can be explained by the different types of reactions occurring as either hydrothermal carbonization[24] or gasification[10] is applied. The hydrothermal carbonization used in this study consisted of a thermal degradation of the water-suspended biomass at high pressure and 230 °C by applying citric acid as catalyst.[24] During this process, carbohydrates in poplar biomass have been gradually transformed to aromatic and aliphatic structures, thereby providing a lignin-like material. However, the presence of signals at 56, 72, 106, 133, and 147 ppm (Figure 1A) indicates that the hydrothermal carbonization produced a carbonaceous material still containing oxygenated functionalities, but almost no polycondensed aromatic moieties as outlined in Wiedner et al.[24]

The sole aromatic signal in the CP-TOSS ^{13}C NMR spectrum of the poplar pyrochar (Figure 1B) is due to the diamagnetic currents produced by delocalized π-electrons in extended aromatic structures or graphite-like microcrystallites, which are generated by the high-temperature condensations as biomass feedstock is subjected to gasification.[10]

Effect of Pore Size on ^1H NMR T_1 Distributions. The 2 mm sieved poplar hydrochar and pyrochar samples were saturated with water and the slurry was analyzed by fast field cycling NMR relaxometry as indicated under Materials and Methods. Figure 2 reports the distributions of the longitudinal relaxation times (T_1), also referred to as relaxograms, at the

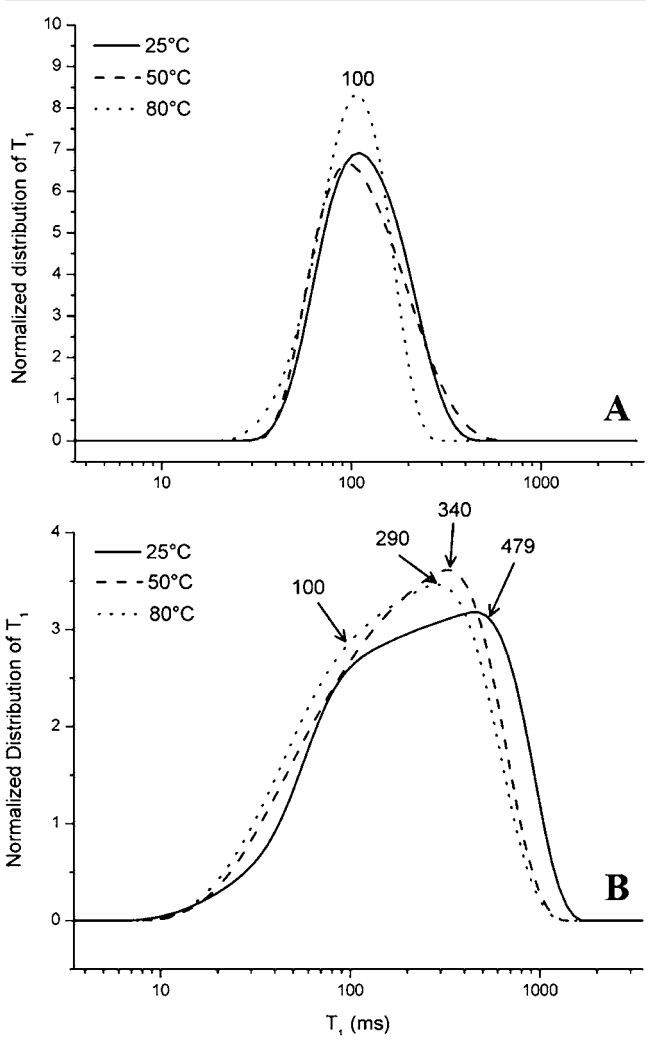

Figure 2. Relaxograms of poplar hydrochar (A) and pyrochar (B) acquired at the proton Larmor frequency of 40 MHz.

proton Larmor frequency of 40 MHz and three temperatures (25, 50, and 80 °C) as obtained by applying the inverse Laplace transformation of the relaxation data through the UPEN algorithm (see Materials and Methods).

Proton longitudinal relaxation times of water in porous media are affected by the collisions between the liquid state molecules and the walls of the porous boundaries.[35] In particular, longitudinal relaxation is dominated by the presence of a strong relaxation sink at the pore surface, which is imputable to the temporary adsorption of water on the solid surface.[36] Temporary adsorption can be achieved by formation of weak unconventional hydrogen bonds on the surface of pyrogenic char systems as already outlined in Conte et al.[26] and Conte and Alonzo.[29] However, as surficial polar groups are present, the weak unconventional H-bonds may turn toward stronger conventional ones, which may hook water molecules more strongly on the char surface. The effectiveness of the aforementioned relaxation sink depends on the ratio between the pore surface and the pore volume as well as on the diffusion rate across the pore.[37] In fact, space restriction in small-sized pores does not allow fast molecular mobility. As this condition

dx.doi.org/10.1021/jf5010034 | J. Agric. Food Chem. 2014, 62, 4917−4923

occurs, $^1H-^1H$ dipolar interactions become very efficient. Shorter relaxation times are, hence, retrieved.[35,37,38] Conversely, as pore size enlarges, molecular mobility increases and strength of dipolar interactions weakens. For this reason, longer relaxation times are expected.[35,37,38] As the number and size of the various pores present in a material is heterogeneous, water must diffuse through the differently sized pores, thereby providing a wide ensemble of longitudinal relaxation times that appear continuously distributed. The lowest limit of such an ensemble (the shortest T_1 value) is due to water moving into the smallest pores, whereas the highest limit (the longest T_1 value) is attributed to water moving into the largest pores. All T_1 values between the two limits are due to the dynamics of water inside pores having sizes lying between the two extremes.[29] According to the aforementioned mechanism, the differences observed at the same temperatures between the T_1 distributions reported in Figure 2 can be attributed to different pore size distributions present in the hydrochar and pyrochar samples. In particular, a homogeneous distribution of small-sized pores can be recognized in hydrochar rather than in pyrochar. The latter, in turn, is made by a less homogeneous distribution of pores, which are on average larger than in hydrochar. In fact, all of the hydrochar relaxograms showed a maximum centered at a T_1 value of around 100 ms regardless of the temperature used during the experiments (Figure 2A). Conversely, the relaxograms acquired for the water-saturated pyrochar span a larger interval of T_1 values (Figure 2B). Here a maximum at 100 ms independent of the applied temperature (similarly to the water-saturated hydrochar sample) can be observed. Moreover, second maxima centered at 479, 340, and 290 ms retrieved at 25, 50, and 80 °C, respectively, are also observed (Figure 2B). A wide distribution of T_1 values is included among the two longitudinal relaxation time limits in Figure 2B. We can identify water molecules relaxing at 100 ms in both carbonaceous samples as those restricted in the smallest sized pores; water molecules generating the maxima at 479 ms at 25 °C, 340 ms at 50 °C, and 290 ms at 80 °C as those tumbling in the largest pores; and, finally, water molecules relaxing in the intervals of 100−479 ms at 25 °C, 100−340 ms at 50 °C, and 100−290 ms at 80 °C as those occluded in transitional pores.

The aforementioned findings are supported by BET and NLDFT elaborations as reported under Materials and Methods. In fact, specific surface areas were 54.6 ± 0.2 and 129 ± 2 m^2 g^{-1} for pyrochar and hydrochar, respectively, thereby suggesting a larger volume of pores in the former than in the latter sample. On the other hand, NLDFT elaborations of isotherms obtained from nitrogen adsorption provided S/V ratios in the order $(S/V)_{pyrochar} < (S/V)_{hydrochar}$ (see Materials and Methods). It is well-known that the longitudinal relaxation rate $(1/T_1)$ is directly proportional to the S/V ratio[39] or by considering the reciprocal:

$$T_1 \propto \frac{V}{S}$$

Because $(S/V)_{pyrochar} < (S/V)_{hydrochar}$, it happens that $(V/S)_{pyrochar} > (V/S)_{hydrochar}$ and it is expected that the T_1 values for pyrochar must be longer than for hydrochar. The latter expectation has been evidenced in the experimental results shown in Figure 2 and discussed above.

It is interesting to note that the relaxogram reported in De Pasquale et al.[10] was obtained for the same pyrochar used in the present study. However, the T_1 distribution in De Pasquale et al.[10] revealed a larger pore size homogeneity than the relaxogram reported here in Figure 2B. This difference can be explained by considering that samples were prepared differently prior to the analysis. In fact, in the present study, we sieved the poplar pyrochar at <2 mm, whereas in De Pasquale et al.[10] the sample has been ground. As already outlined under Materials and Methods, sample grinding reduces pore size, thereby allowing larger surface area and more homogeneous pore size distribution.

Effect of Temperature on ^1H NMR T_1 Distributions. Longitudinal relaxation times are dependent not only on the pore size distribution, as outlined in the previous paragraph, but also on temperature variations.[29] In fact, it is well recognized that temperature increments accelerate molecular motions, thereby weakening the $^1H-^1H$ dipolar interactions responsible for the longitudinal relaxation of a liquid moving on the surface of porous materials.[40] When this condition occurs, an increase of T_1 values is expected because a longer time is needed for proton spin−lattice relaxation. However, it has been already shown that water retained in charred materials behaves diametrically, thereby suggesting that water dynamics is subjected to a slow-motion regime.[26] The latter is achieved when water molecules are hooked to the char surface via weak hydrogen bonds that may arise by the overlay of the electron-deficient orbitals of protons in water and the electron-rich orbitals in the organic and inorganic components of the charred system.[26] As temperature increases, the weak interactions, which allow water adhesion to the pore walls, oppose the 3D exchange with the bulk water (i.e., the replacement of water molecules hooked to the char surface with those appertaining to the bulk liquid).[40] For this reason, water preferentially diffuses more quickly within the channels connecting pores between one another through a two-dimensional (2D) motion (i.e., the diffusion of water molecules within the channels connecting either different surface pores or char surface with the interior part of the same material).[26,40] Due to the 2D surface diffusion just described, the water collision frequency with pore walls increases with temperature, thereby allowing an average residence time on pore walls longer than that retrieved at lower temperatures. Because of this, a shorter time for protons to relax is needed and lower T_1 values are achieved.[40] As a consequence, relaxograms, such as those in Figure 2, shrink as the temperature is increased. Moreover, it must be added that the larger the pore size, the more pronounced is the reduction of the relaxogram width and the reduction of the T_1 maxima. In fact, upon temperature increasing, water collision frequency in larger pores becomes higher than in the more spatially restricted ones. Because of this, the average time spent by water molecules on pore walls is higher in the transitional and largest pores than in the smallest pores. The latter is why the reduction of relaxogram widths is less pronounced in Figure 2A than in Figure 2B. Moreover, the same mechanism explains why the maximum at 100 ms due to water in the smallest pores either in hydrochar or in pyrochar is unaffected by temperature changes, whereas the T_1 maxima due to water in larger sized pores (T_1 >100 ms) shift toward shorter values.

Nuclear Magnetic Resonance Dispersion (NMRD) Profiles. Figure 3 shows the NMRD profiles (i.e., $R_1 = 1/T_1$ values vs ω_L) at 25, 50, and 80 °C for the water-saturated poplar hydrochar and pyrochar samples investigated here. In particular, the NMRD profiles of the former sample are all placed at faster longitudinal relaxation rates (Figure 3A) as compared to the NMRD profiles of the latter sample (Figure

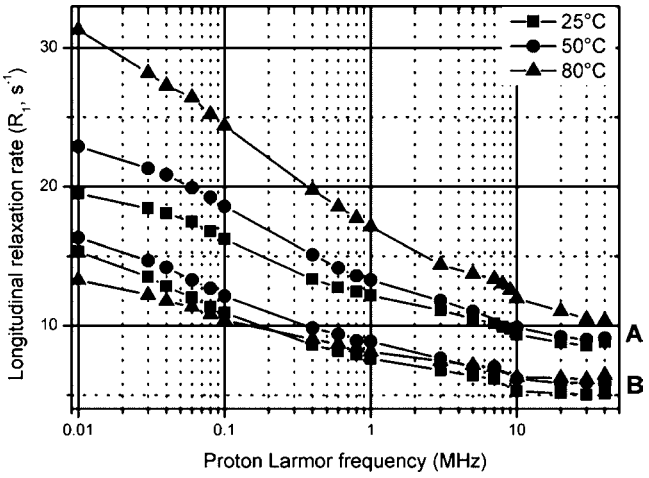

Figure 3. NMRD profiles of poplar hydrochar (A) and pyrochar (B).

3B). This is due to the differences in the surface areas between the two porous materials. In fact, $SSA_{hydrochar}$ was larger than $SSA_{pyrochar}$ (see above). The larger the surface area value, the smaller is the size of the pores. Restriction of water in small pores leads to stronger $^1H-^1H$ dipolar interactions, which, in turn, are the cause for the very efficient proton longitudinal relaxation in hydrochar (i.e., faster R_1 values) compared to pyrochar.[41]

It is worth noting that all of the NMRD profiles in Figure 3A are translated toward faster R_1 values in the whole range of proton Larmor frequencies as the temperature is increased. This behavior accords with that already described in Conte et al.,[26] thereby confirming the slow-motion regime also outlined in the previous paragraph. However, Conte et al.[26] reported that the slow-motion regime on the surface of char systems is due to nonconventional H-bonds arising by the overlay between the electron-deficient orbitals of protons in water and the electron-rich orbitals of the aromatic organic centers in the charred material. In the present study, we have reported that hydrothermal degradation did not remove all of the oxygen-containing functionalities (see above). For this reason, we cannot exclude participation of the more traditional O−H··· O bonds in the slow-motion regime observed for the hydrochar sample.

Figure 3B reveals that the NMRD profiles acquired for the pyrochar sample behaved similarly to the hydrochar only up to 50 °C. Conversely, an anomalous trend was observed at 80 °C. In fact, a slight increment of the R_1 values was retrieved between 40 and 10 MHz as the temperature was switched from 50 to 80 °C. Then the 80 °C NMRD profile crossed the one acquired at 50 °C as ω_L was set to 10 MHz and that retrieved at 25 °C as ω_L was switched to 0.2 MHz (Figure 3B). The H-bond-mediated slow-motion regime can explain the NMRD behavior up to 50 °C observed for the pyrochar sample (Figure 3B). However, as the temperature is raised to 80 °C, a chemical exchange with the bulk phase must be considered to account for the anomalous behavior reported in Figure 3B.[40]

The interesting feature that the temperature dependence of water dynamics in hydrochar is opposite than that observed in pyrochar can be explained only by considering the different pore size distribution in the two carbonaceous samples. In fact, as outlined above, the average pore size in hydrochar is smaller than in pyrochar. Water molecules are more tightly trapped in the former than in the latter material. For this reason, water can easily run toward the bulk liquid from pyrochar rather than from hydrochar surface as the temperature is increased to 80 °C.

The comparison among the temperature dependences of the NMRD profiles in Figure 3 and those in Conte et al.[26] supports the latter hypothesis on the role played by pore size in water exchange with the bulk solution. In fact, the pyrochar analyzed either in the present study or in Conte et al.[26] was obtained by the same gasification process.[10] However, whereas in Conte et al.[26] the pyrochar was ground in an agate mortar before NMRD investigations, here we have performed NMRD analyses after having sieved the same material to <2 mm. As a consequence, the surface area of the ground pyrochar[26] was larger than that used in the present study. As already noted above, larger surface area was associated with a more homogeneous pore size distribution made mainly by the smallest pores. Conversely, a more inhomogeneous distribution of pore size (with a larger contribution from transitional and larger pores) was identified in the porous charred material having a lower surface area. Hence, the more inhomogeneous pore size pyrochar used here revealed the anomalous temperature dependence behavior at 80 °C (Figure 3B) due to the higher number of larger pores, which make the exchange of surface water molecules with the bulk ones easier.

This paper reports high- and low-field NMR characterization of the physicochemical properties of hydrochar and pyrochar samples retrieved by applying either hydrothermal treatment or gasification to poplar forestry wastes. In particular, high-field NMR spectroscopy (i.e., CP-TOSS ^{13}C NMR) revealed that the thermal treatments produced two chemically different carbonaceous materials. Although poplar hydrochar appeared as a lignin-like material still containing oxygenated functionalities, poplar pyrochar emerged as a polyaromatic system where O-containing groups were not detected.

Notwithstanding the different chemical compositions, the mechanisms of water dynamics on the surface of poplar hydrochar and pyrochar were affected more by their physical characteristics rather than by their chemical peculiarities. In particular, isothermally 40 MHz acquired relaxograms revealed that water motion was more restricted in hydrochar than in pyrochar, thereby suggesting that the former sample included a larger number of small-sized pores than the latter one. On the other hand, the freer motion of water in pyrochar indicated a higher amount of transitional and very large pores.

Variable-temperature relaxometry experiments revealed that a 2D surface diffusion mechanism was the only force responsible for water motion in hydrochar up to the temperature of 80 °C. Surface diffusion was the predominating motion mechanism of water in pyrochar only up to 50 °C. Conversely, a 3D exchange with the bulk water appeared to interfere with the aforementioned 2D diffusion as the temperature was raised to 80 °C.

The differentiation between the 2D diffusion and the 3D exchange mechanisms was attributed to the different porosities in the charred materials. In fact, water constrained in small pores such as in hydrochar strongly interacts with the solid surfaces. For this reason, its fugacity toward the bulk liquid is inhibited in the whole temperature interval investigated here (25−80 °C). On the other hand, the larger pore sizes in poplar pyrochar prevent water exchange with the bulk solution only in a more restricted temperature interval (namely, 25−50 °C). As the temperature overcomes the limit of 50 °C, water surface

dx.doi.org/10.1021/jf5010034 | J. Agric. Food Chem. 2014, 62, 4917−4923

interactions become weaker and 3D exchange with the bulk liquid occurs.

Although in the present study the chemical composition of poplar hydrochar and pyrochar appeared of minor importance to the water dynamics, its contribution to the strength of water solid phase interactions is not yet clear. For this reason, more detailed studies on the effect of pore sizes and chemical composition of charred materials on water dynamics are urgently needed.

[a]Abbreviations: AGT = Australian Grain Technologies, SA, Australia; CIMMYT = International Maize and Wheat Improvement Center, Mexico; KC&ME = KV Cooper and MG Elleway, Farmers and Seedgrowers, SA, Australia; USYD = University of Sydney, NSW, Australia; UNE = University of New England, NSW, Australia. [b]TX93-19-2 is a sibling of Tickit and Speedee. [c]For more information on the alleles, see Table 2.

MATERIALS AND METHODS

Germplasm. The HMW glutenin and secalin composition was evaluated in 17 triticale genotypes (Berkshire, Bogong, Canobolas, Chopper, Crackerjack, D12/Tatu, DH265, Endeavor, Goanna, Hawkeye, Jaywick, Rufus, Tobruk, Tuckerbox, Vicuna, Yukuri, Yowie) from a diverse set of breeding programs and covering all triticale cultivars recommended for growing in Australia at the time, plus two breeding lines (Table 1). Pure seed of Berkshire, Chopper, Crackerjack, D12/Tatu, DH265, Endeavor, Tobruk, Tuckerbox, and Vicuna were sourced from the University of Sydney, NSW, Australia; Bogong and Canobolas were sourced from Robin Jessop at the University of New England, NSW, Australia; Goanna, Rufus, and Yowie were sourced from KV Cooper and MG Elleway, SA, Australia; and Yukuri was sourced from Seed Distributors, NSW, Australia. Crackerjack, Endeavor, Tobruk, and Tuckerbox and winter types, the remainder are spring types.

SDS-PAGE. Visualization of glutenin subunits was performed using SDS-PAGE based on previous methods used to characterized glutenins in Australian wheat cultivars.[15] The nongerm end of three grains were crushed individually with a pair of pliers and placed in 1.5 mL Eppendorf tubes. Nonsecaloglutenin proteins were removed by adding 200 μL of 50% (v/v) propan-1-ol, vortexing, and then incubating at 65 °C in a water bath for 30 min, with vortexing approximately every 7 min. Tubes were then centrifuged at 5000 rpm for 10 min, and supernatant was discarded. This process was repeated using only 5 min incubation time, repeated using distilled water and 5 min incubation, and then samples were oven-dried at 37 °C for 40 min to remove remaining liquid.

Extraction of secaloglutenins proceeded with vortexing and incubation of the pellet for 5.5 min at 95 °C in 150 μL of glutenin sample buffer (12.5% 0.5 M Tris−HCl at pH 6.8, 25% glycerol, 2% SDS (w/v), 0.001% bromophenol blue (w/v), and 2% mercaptoethanol). Samples were then centrifuged at 14 000 rpm for 2.5 min.

Extracted glutenins were fractionated in a vertical CBS-Scientific Dual Adjustable Mega-Gel kit (CBS-Scientific, CA, U. S. A.). The resolving gel contained 8% Acr/Bis, 24% 1.5 M Tris−HCl at pH 8.8, 0.1% SDS, 0.12% TEMED, and 0.06% APS. The stacking gel contained 4% Acr/Bis, 25% 0.5 M Tris−HCl at pH 6.8, 0.1% SDS, 0.3% TEMED, and 0.15% APS. Samples of 8 μL were resolved at 40 V overnight followed by 70 V for the final 4 h in electrode running buffer (0.3% Tris (w/v), 1.44% glycine (v/v), and 0.1% SDS (w/v)).

Gels were rinsed in water, stained in Coomassie blue solution (0.05% Coomassie blue G-250, 10% (w/v) phosphoric acid, 5% aluminum sulfate, and 20% methanol) for approximately 60 min with gentle agitation, destained in water for 33 h aided by paper towelling, and permanently stored between single layers of clear cellophane. Allele designations were defined by comparison to nine cultivars of *Triticum aestivum* (Bowie, Chinese Spring, Ellison, Federation, Gabo, QALBis, Sunco, Veery, Ventura), one cultivar of *Triticum durum* (Bellaroi), and three triticale checks (Sirius, Titan, Presto 1R.1D$_{5+10}$), for which the allele designations have been previously described.[5,16,17]

Field Trials. A subset of six triticale (Berkshire, Endeavor, Hawkeye, Jaywick, Tobruk, and Yukuri) and five wheat lines (hard wheats Ellison, Sunco, and Ventura, soft wheat QALBis, and durum wheat Bellaroi) were grown in duplicate plots under a completely randomized block design on John Pye farm at Greendale, NSW in 2009 (JP09) and at the Plant Breeding Institute, Narrabri, NSW in 2010 (NARR10). Unfortunately only one field plot of Sunco was able to be harvested at JP09. Triticale lines were selected based on their applicability to the two trial environments and to include both winter and spring types.

Sowing density for all lines was 60 kg/ha; plots were 3.75 m^2 at NARR10 and 4.68 m^2 at JP09. JP09 received 100 kg/ha of Starter 15 base dressing, 150 kg/ha urea at approximately 6 weeks followed by 2 L/ha Supa Trace and then a topdressing of Nitrophoska at 12 weeks. NARR10 received Granulock at sowing and 150 kg/ha urea at first irrigation. Both trials received limited irrigation.

Milling and Protein Content. Subsamples of approximately 50 g were ground on a Newport Scientific 600 Hammer Mill with 0.5 mm screen (Perten, Warriwood, NSW, Australia) for SDS-sedimentation testing. Subsamples of 50 g were also milled to white flour on a Quadrumat Junior Mill (Brabender, Duisburg, Germany) to determine flour protein content and mixograph parameters. Hard wheats were tempered to 15% moisture content and soft wheat (QALBis) plus all triticales to 13% (triticale is generally a soft grained species). Flour moisture and protein content were determined by NIR on an Inframatic 8100 PerCon (Perten, Hägersten, Sweden) that had been calibrated using a hard-grained wheat and is defined as proportion of moisture/protein of the flour. Wholegrain protein content and moisture content were assessed by near-infrared transmittance (NIT) on an Infratec 1241 Grain Analyzer (FOSS, Hillerød, Denmark) using triticale calibration TR260180 and wheat calibration WH002010. The proportion of grain protein that was retained in the main final commercial product (white flour) after the milling process ($P_{retained}$) is defined as

$$P_{retained} = 100 \times \frac{m_{flour}}{m_{total}}$$

where m_{total} is mass of protein in 100 g of grain, m_{flour} is mass of protein within the flour portion of 100 g of grain, and $P_{retained}$ is expressed as a percentage. Moisture content of grain and flour was standardized before calculation. Mass of protein within what would become the flour proportion of the total grain (m_{flour}) is expressed within the context of total grain weight from which it was sourced rather than as straight flour protein content to standardize the variable and hence allow determination of protein loss when milling grain to flour. The variable is defined as

$$m_{flour} = f_y \times m_{fp}$$

where f_y is flour yield and m_{fp} is the mass of protein in 100 g of flour. The difference between m_{flour} and total grain protein quantifies the amount removed as bran or pollard during milling. Thus, m_{fp} is not an exact measure of the mass of protein within the grain endosperm but rather the mass within flour that was able to be separated from bran during the milling process.

SDS-Sedimentation Test. The SDS-sedimentation height was assessed using a down-scaled version of AACC method 56-70.[18] Samples of 0.75 g wholemeal flour were added to 3 mL of 0.001% Bromophenol Blue solution (w/v) in 15 mL plastic tubes with screw-top lids, vortexed for 3 s, rested, and vortexed again before adding 9 mL of working solution (3.02% SDS w/v and 0.23% lactic acid w/v). Tubes were inverted 10 times, rested for 2 min, and then again inverted 10 times. Sediment height was read after 30 min and adjusted according to the height of the standard in each batch.

Mixographs. Mixing parameters from two replicates of each field plot were determined on a mixograph using a 10 g mixing bowl and 7 min evaluation time (National Manufacturing Co., Lincoln, Nebraska, U. S. A.). Immediately prior to mixing, 6 mL of deionized water was added to 10 g of flour. Graphs were analyzed using Mixsmart for Windows Version 1.0.404 and interpreted according to defined mixograph parameters.[19] In brief, these parameters are based on an arbitrary mixograph height scale from 0 to 100 (displayed as a percentage), plus peak time (displayed in minutes). Parameters of interest were time of peak (MPT), graph height at peak time (MPV), graph width at peak time (MPW), rate of dough breakdown (defined as the slope 1 min after peak time, RDB), and tail width at 6 min (MTW).

Statistical Analysis. Data were analyzed in Genstat v. Fourteen (VSN International, Hemel Hempstead, U. K.) with a 5% significance level. The influence of species and cultivar for all variates were analyzed using residual maximum likelihood (REML), with fixed-model terms defined as Species/Genotype and random model terms defined as Site/Block (or Site/Block/Replicate for SDS-sedimentation height). Grain protein (11% mb) and flour protein (11% mb) were analyzed on a natural log scale and SDS sedimentation on a square root scale with the distribution brought to a minimum of 1.[20] Flour protein was tested as a covariate for mixing parameters, and both grain and flour protein contents were tested as covariates for SDS-sedimentation height. Correlation between flour protein content and SDS-sedimentation was performed for both triticale and wheat in Genstat, also using a 5% significance level. Hard-grained lines Berkshire and Bellaroi were excluded from correlation analysis due to the different moisture absorption of hard grain flour.

RESULTS AND DISCUSSION

Glutenin and Secalin Classification. Despite sourcing cultivars from several breeding programs and including all cultivars recommended for sowing in the region at the time of the research, the triticale cultivars in this investigation displayed relatively little diversity in HMW glutenin profiles. This reflects the narrow source of background material: the majority are a cross between the cultivar Speedee or sibling TX93-19-2 with a CIMMYT parent or is a direct selection of CIMMYT origin (Table 1).

Only two alleles of *Glu-A1* were identified: *Glu-A1a* and *Glu-A1c* were present in 41.2% and 58.8% of the cultivars, respectively (Table 2). Six alleles were observed at the *Glu-B1* locus, with *Glu-B 1f* (13 + 16) found in 52% of lines (nine cultivars). *Glu-B 1f* is common in triticale.[5,11] Allele *Glu-B 1p* (23 + 18) is usually reported as *Glu-B1IV* in triticale owing to its original designation in durum wheat and relatively recent classification in bread wheat.[3,17]

Secalins encoded by *Glu-R1c* (6r+13r) were identified in 75% of lines surveyed (Table 2). *Glu-R1c* is the most common *Glu-R1* allele in triticale internationally, being found in 65.7% of European lines, 62.7% of French lines, and 71.4% of Portuguese lines.[3,5,10] An undefined set of rye HMW secalins was observed in Tobruk and Yukuri in the upper portion of the gel (Figure 1). These secalins may represent a new allele at *Glu-R1*; however, more extensive comparison to existing alleles found in both triticale and rye is required before a conclusion can be drawn.

Allele *Gli-R2c* (t1) was the most common of the 75K γ-secalins, being found in 59% of surveyed lines, but it was not as common as that documented in European triticales.[5] Only two of the four characterized alleles of 75K γ-secalins[5] were present among the tested cultivars; rare alleles *Gli-R2b* (d2) and *Gli-*

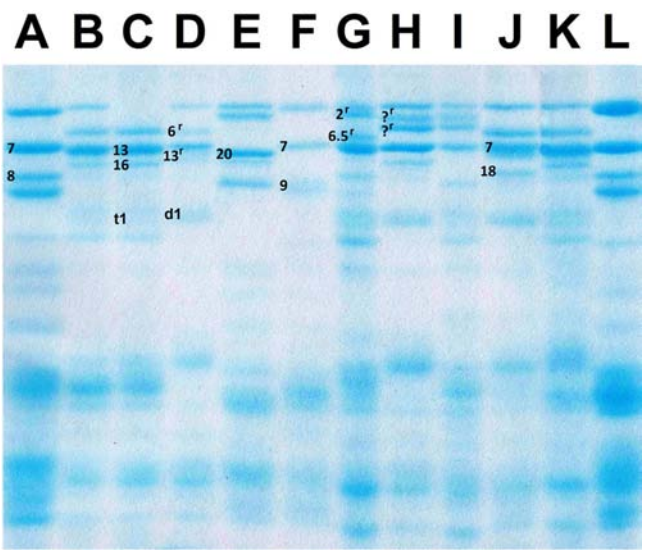

Figure 1. SDS-PAGE of selected Australian triticale cultivars with wheat standards (ws) and a triticale standard (ts): Lane A. Chinese Spring (ws); B. Jaywick; C. Hawkeye; D. Berkshire; E. Federation (ws); F. Bowie (ws); G. Titan (ts); H. Yukuri; I. Tobruk; J. Endeavor; K. Crackerjack; L. Sunco (ws). Glu-B1, GluR1 and Gli-R2 subunits are noted, including the unidentified Glu-R1 allele (Lane H).

R2d (null) were not observed. The null allele is likely the result of a 2*D*/2R translocation of CIMMYT origin.[10]

Some difficulty has been encountered with the identification and classification of glutenin subunits in triticale using SDS-PAGE. Currently the predominant nomenclature system for glutenin alleles in triticale follows that of wheat; however, the mobility of several secalins is identical to that of glutenins, particularly in the HMW range.[7] The overlap of bands on SDS-PAGE (as observed here) has led to conflicting glutenin characterization of the same cultivar, for example, Brzezinski and Lukaszewski[4] with Salmanowicz and Dylewicz.[7] Standards that are unique to triticale must be developed so that continued comparisons with wheat do not lead to misidentification of key alleles and to facilitate the development of linked DNA markers for manipulation of secaloglutenins in triticale improvement.

Furthermore, triticale cultivars are not necessarily uniform in their glutenin composition: heterogeneity in up to 41% of 139 cultivars has been reported.[4] Heterogeneity within cultivars is likely due to a combination of a lack of screening for glutenin alleles during the breeding process and a higher rate of allogamy in triticale compared to wheat.[13] No heterogeneity was observed among triticales evaluated in this study.

Because the small range in HMW glutenin diversity relative to the confounding influence of gliadins and LMW glutenins and the unknown effect of the secalins, no attempt was made to extrapolate the influence of individual HMW glutenin/secalin alleles on dough properties. The importance of gliadins and LMW (low molecular weight) glutenins in dough properties is well established both in durum[21] and in bread wheat;[22] however, practically no research has been published on the influence of individual secalin subunits in either rye or triticale. Furthermore, mixed polymers and oligomers are formed between secalins and glutenins: even the 40k-secalins of rye, which are usually monomeric, may be incorporated into polymeric gluten when expressed in wheat.[23] The HMW glutenins form an elastomeric network that acts as a "backbone" for the interactions of other proteins in addition to conferring strength and elasticity to dough.[1] Hence, the overall properties of the secalogluten network were investigated in a subset of triticale cultivars.

Protein Content and SDS-Sedimentation Height. Grain protein content greatly varied between environments and was on average 2.8% greater for triticale and 3.5% greater for wheat at JP09 (Table 3). No significant difference in grain protein content was detected between species ($P = 0.704$); however, triticale flour protein content (directly proportional to gluten/secalogluten content)[24] was significantly less than wheat ($P < 0.001$).

Furthermore, a significantly greater proportion of triticale protein was removed by the milling process compared to wheat ($P < 0.001$), most of which would have been in the outer aleurone layer and pericarp. After the milling process, triticale retained only 43.97% of its original grain protein content in the flour, whereas 53.55% of the protein was retained in wheat flour. Previous research has confirmed triticale stores a lower proportion of grain protein in flour/gluten compared to wheat.[11,24−26] This suggests triticale has a thicker seed coat. Milling yields and fiber content on the same set of cultivars as described here also provided evidence of thicker seed coat in triticale compared to wheat.[27,28] Note, however, variability existed between cultivars, for example, Tobruk retained significantly more protein following the milling process than all other triticale lines (Table 3). The environment did not have a notable effect on the proportion of protein retained following the milling process in either species, despite the higher average protein contents at JP09.

Storage of proportionately less protein in triticale flour compared to wheat has significant implications for both research and industry. First, research that reports triticale secalogluten strength based on wholegrain protein content, as opposed to flour protein content, should be interpreted with caution, particularly when comparing triticale to wheat. Triticale lines with similar wholegrain protein content to wheat lines are likely to have less flour protein content, and hence, the dough strengths cannot be equitably compared. Second, because the food industry requires a certain flour

[a] m_{flour} is the mass of protein (in grams) within the flour portion of 100 g of grain. [b] $P_{retained}$ is the proportion (expressed as a percentage) of the original protein content that was retained in white flour after the milling process.

protein content to produce the variety of end products which consumers demand, millers should be aware that the appropriate content of wholegrain protein when purchasing a batch of grain will differ between triticale and wheat.

Significant differences in SDS-sedimentation height were detected between triticale cultivars ($P < 0.001$); Tobruk and Berkshire produced notably low SDS-sedimentation heights. SDS-sedimentation results of all triticale cultivars were significantly inferior to bread wheat ($P < 0.001$, Table 3), a result consistent with previous studies.[12] QALBis soft wheat produced significantly higher SDS-sedimentation height (43.2 mm) than triticale on average (35.5 mm) but significantly lower height than hard wheat cultivars (70.0 mm). This is reflective of its weak gluten and one of the reasons soft wheat is used for cakes and cookies. Triticale has been found to be suitable for products traditionally made from soft wheat.[29,30] However, to obtain satisfactory flat and loaf breads, most research suggests triticale must be blended with hard wheat.[26,31,32] The low SDS-sedimentation of Berkshire was likely from an interaction with grain hardness as Berkshire has a hardness comparable to durum wheat.[27]

The flour protein contents (indicative of gluten/secaloglutten) of the samples varied between sites, species and cultivars. Flour protein content was a highly significant predictor of sediment height in both wheat and triticale ($P < 0.001$; Figure 2). This trend was more substantial in wheat than triticale, reflecting decades of selection for combinations of glutenin alleles associated with high loaf volume in wheat improvement, in contrast to the narrow diversity and lack of selection pressure for HMW glutenin alleles in triticale. However, the trend was still apparent in triticale, where sediment height increased by 9.6% for every 1% increase in protein content (protein contents ranging from 6.5% to 15.8%). In a European study of four

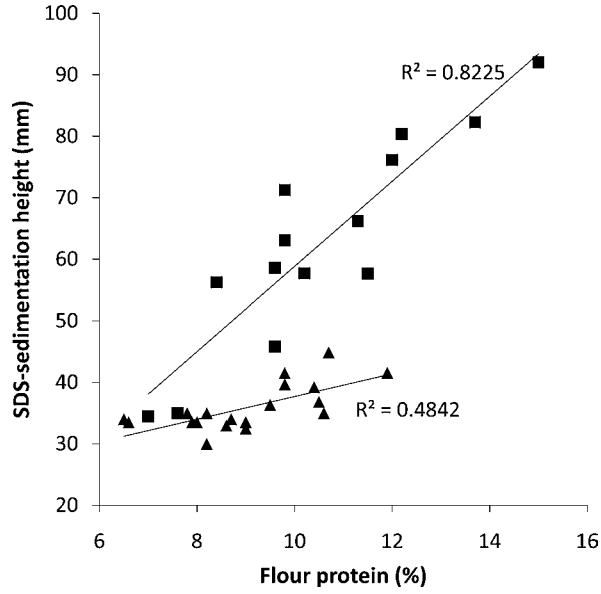

Figure 2. Relationship between SDS-sedimentation height and flour protein content in bread wheat samples (squares) and triticale samples (triangles). Each data point represents a field plot; lines represent best-fit linear trendlines.

triticale cultivars grown in four year-site environments, a significant correlation between SDS-sedimentation volume and protein content was observed.[33] Recalculation of the results revealed SDS-sedimentation volume increased by 20.3% for every 1% increase in protein content (protein content ranged from 10.9% to 17%). Similarly, recalculations from another study[32] also revealed a 25.5% increase (protein range from 5.0%

to 10.5%). The significance of flour protein content on dough properties in triticale has also been reported previously.[24,25]

The influence of flour protein content on SDS-sedimentation results illustrates the importance of comparing wheat and triticale samples with similar flour protein content. Several previous studies have drawn conclusions as to the strength of the triticale secalogluten network based on samples of widely different flour protein contents/gluten contents compared to wheat,[26,32,33] which is an inequitable comparison. It is particularly important to standardize the quantity of flour protein when attempting to ascertain the influence of the secalins on the strength of the secalogluten network. A set of four reconstituted triticale flours with identical gluten contents to two wheat standards found the triticale gluten had a comparable stretching value to wheat gluten.[25] Two of the four reconstituted triticale flours produced loaves of the same volume as the wheat standards. Extensibility has also been found to be highly correlated to both flour protein content and polymeric protein content in triticale (r = 0.96 and 0.97, respectively).[32] These results suggest that low polymeric protein content in triticale compared to wheat must be considered alongside polymeric protein quality and that the secalins are integrated into the hydrated polymeric protein network. The reduced response of triticale SDS-sedimentation height to increasing protein content compared to wheat confirms that secalogluten strength in triticale is not as high as gluten strength in wheat.

Mixing Parameters. Wheat mixing parameters were clearly superior to the mean of triticale flours evaluated from both sites (P = 0.01 or less for all parameters, Table 3). Triticale cultivars Berkshire, Tobruk, Yukuri, and to a lesser extent Endeavor and Jaywick, plus soft wheat cultivar QALBis, all exhibited a dramatic loss of dough strength and elasticity over time (Figure 3D). In several samples of low protein content, the dough collapsed completely and was wrapped around the sides of the mixing bowl. The influence of flour protein content was again apparent: flour protein content explained 62.5% of the variability in MPV in wheat samples and 84.1% in triticale samples. Several triticale lines produced the thin mixograph tails characteristic of high α-amylase activity (Figure 3D). Cultivars Endeavor, Hawkeye, and Jaywick are known to have high α-amylase activity;[28] however, this did not perfectly correlate with poor mixograph characteristics here.

All triticales exhibited a short mixing time and were in between (and not significantly different to) QALBis and Ventura, with the exception of Tobruk and Yukuri, which were significantly shorter (Table 3). The mixing time of Hawkeye was also very short; however, dough strength was maintained after reaching an early peak (Figure 3C). Short mixing times in triticale have been reported previously.[24,32] A standard volume of water was added to each sample to allow an even comparison between wheat and triticale cultivars and to clearly establish (and semiquantify) the inferiority of triticale compared to wheat. Future work should modify the water content of the dough relative to its protein content or use farinographs to accurately determine the water absorption of triticale lines.[18]

Nevertheless, some triticale cultivars displayed certain mixing parameters similar to the wheat checks. For example, no statistical difference was detected in MPW between most individual triticale and wheat cultivars, and Berkshire, Endeavor, Hawkeye, and Jaywick all had significantly later MPT than soft wheat QALBis. Other studies have also found certain triticale lines demonstrate similar dough strength to wheat standards despite inferior mixograph dough strength in triticale over-

dx.doi.org/10.1021/jf405138w | J. Agric. Food Chem. 2014, 62, 4924−4931

all.[32,34] Hawkeye did not reach the peak height of hard wheat; however, it maintained dough strength during mixing, had a wide mixograph profile (Figure 3C), and was the most suitable for end products requiring strong dough, for example, bread. Note that Hawkeye and Jaywick share similar pedigrees, polymeric storage protein profiles and flour protein contents; however, the SDS-sedimentation and mixograph results reveal different secalogluten strengths. This may be due to allelic differences in nonsecaloglutenin storage proteins, or low α-amylase activity in Hawkeye (although this appears unlikely).[28]

It is difficult to differentiate the influence on species from the influence of flour protein content when considering the inferior mixing properties of triticale compared to wheat. Flour protein content was a significant covariate in MPV ($P < 0.001$), RDB ($P < 0.001$), and MTW ($P = 0.015$). This illustrates the importance of G × E interactions and the role of agronomic practices in the production of milling-quality triticale, which has been largely overlooked in industry. Triticale often has lower protein content than bread wheat when grown under identical environmental conditions; this is due to a combination of higher yield and low (if any) selection pressure for high flour protein content during the breeding process. The effect of low flour protein was of particular significance for NARR10 results and was very apparent in both the SDS-sedimentation height and the mixographs. Agronomic interventions such as appropriate timing and rate of nitrogenous fertilizer application can improve grain storage protein accumulation.[35] Increasing the total gluten in triticale flour should be considered an important breeding aim in addition to optimizing the glutenin allele composition (indeed, the two are related).

The mixograph results imply that triticale dough should be treated differently to wheat in mechanized commercial systems due to its shorter mixing time. Nevertheless, the variation between triticale cultivars evaluated in this study suggests that dough properties can be significantly improved through targeted crossing and selection and appropriate agronomic practices, potentially to the level of bread wheat.

In summary, narrow diversity in HMW subunit expression was observed in the examined triticale cultivars; however there were still significant (statistical and commercial) differences in mixing parameters and SDS-sedimentation values. It is essential that wheat and triticale samples of similar flour (not grain) protein contents are used to assess gluten characteristics. Furthermore, it seems appropriate for the protein content of triticale flour be above 10% for both research and commercial purposes to allow the formation of an acceptable secalogluten network, as is recommended for wheat (Meiqin Lu, Pers. comm.). Provided the requirements for grain softness, flour color and α-amylase activity are met,[27,28] the results of this research suggest modern triticale is of appropriate gluten quality for use in cookies, cakes, and other products traditionally made from low-protein wheat.

Table 1. Range of Properties for the Samples Used

parameter	range of values
production areas	throughout Greece (i.e., Patras, Kalamata, Voiotia, Thessaloniki, Lesvos, Lamia, Volos, Tyrnavos, Komotini, Rhodes, Chalkidiki, Argos, Serres)
size of production	from big industry to local family run producers (9 of the 42 samples belong to the 30 most profitable Greek companies producing potable alcohol and spirits in 2006 and 2007 as judged by their gross income as published in Greek market literature)
packaging	bottled in 50, 100, 200, 300, 350, and 750 mL, sold by volume
price in 2013	2−4 €/200 mL, 6−12 €/750 mL in big supermarkets
consumption	4,000,000 bottles sold in Greece in 2010
percent of alcohol	37.5, 38, 40, 42, 45, 46%
type of alcohol	single distillation, double distillation
water source	tap water, well water, "river water"
water treatment	before and after mixing, no treatment
water treatment process[a]	deionization,[b] softening, membrane filtration, ion exchange, reverse osmosis, dechlorination
additives (according to labels on bottles and Web sites or commercials)	anise, and/or star anise, and/or fennel to be distilled, and in the case of geographical indications mastic and other aromatic seeds, plants or fruits

[a]Based on questionnaires answered by producers. [b]References 1 and 27.

MATERIALS AND METHODS

Samples. Most of the 42 samples were obtained from commercial shops. Some of the samples were provided by producers sealed in their commercial containers. Anethole was provided by one of the local producers. Alcohol was obtained from a local winery and ethanol from Merck. Deionized and distilled water samples were obtained from three different laboratories from the University of Patras. Deionized water (DI) was produced using a Dionel ion exchange system. Once-distilled and three-times-distilled water samples were produced using GFL and Jencons Autostills distillers, respectively. Tap water was obtained from the Patras municipal water supply system.

Conductivity and pH Measurements and Validation. Both conductivity and pH were measured using a Consort C862 instrument with Consort electrodes SK10B and SP10B, respectively. Conductivity standards from Hanna Instruments and Consort that corresponded to 84 and 147 μS/cm and to 1.413 and 12.88 mS/cm were used, respectively. Because the lower conductivity values to be measured were lower than the lower standard available, some samples of known conductivity were used to validate these low measurements. These "known samples" include samples having their conductivity measured by other instruments or by other investigators in the literature. pH standards were obtained from Metrohm Ltd. and Consort and were equal to 4.01, 7.0, and 10.0 at 25 °C. The known samples were also used to validate the pH measurements.

Measuring the pH with an electrode in the presence of high concentrations of solvents is problematic.[19] At 25 °C, it was found that in the presence of 40% ethanol the electrode would read the pH of a buffer solution approximately 0.7 point higher than its actual value in pure water. This value of 0.7 was used as a correction factor to correct pH solutions of the samples with ∼40% alcohol. For selected samples, the pH was additionally measured using pH indicator strips obtained from Macherey-Nagel.

Dilution Water Characteristic Measurements. For selected samples, additional physicochemical parameters were determined such as NO_3^-, NO_2^-, PO_4^{-3}, NH_4^+, total Fe, and carbonate hardness, using an Aquanal Fishwater Laboratory from Sigma-Aldrich.

Alcohol Characteristic Measurements. For selected samples, alcohol characteristics were determined. Methanol and ethanol percentages were determined on a Shimadzu GC-8A system consisting of a column packed with Porapac-S, N_2 as the carrier gas (20 mL/min), and a flame ionization detector. The injection port and detector temperatures were 210 °C, and the column temperature was 130 °C. Samples of 2 μL of each ouzo sample (1:4, 1:10, 1:20 dilutions) were injected directly in the column. The concentrations of the above compounds were determined by comparing the peak areas with those of standard solutions. Volatiles (acetaldehyde, ethanol, propanol-1, isobutyl alcohol, and amyl alcohols) were determined on a Shimadzu GC-8A system, with an 80/120 Carbopack B AW/6.6% Carbowax 20 M column, with N_2 as the carrier gas (20 mL/min) and a flame ionization detector. The injection port and detector temperatures were 210 °C, and the column temperature was set at 70−100 °C (rate at 5 °C/min). Samples of 4 μL of each ouzo sample were injected directly in the column. Two repetitions for each of two sample dilutions (1:10, 1:20) were used for each sample. Calculations were based on two different concentration standard solutions: (a) two different standards containing methanol and ethanol and (b) two different standards containing acetaldehyde, propanol-1, isobutul alcohol, ethyl acetate, and amyl alcohols. All samples were diluted with three-times-distilled water as in previous publications.[20,21]

RESULTS AND DISCUSSION

Sample Description. Table 1 presents a summary of the range of the different parameters of ouzo samples used in the present study. Almost 14% of the market was represented through the samples. The samples were produced in areas well spread out in the geographic region of Greece. Nine of the 42 samples belonged to the 30 most profitable (based on gross income in 2006 and 2007) Greek companies producing potable alcohol and spirits and not only ouzo. Samples packed in different size bottles or having different costs were tested. The percentage of the contained alcohol ranged from 37.5 to 46%. At least one ouzo sample was taken from ouzo labels containing up to six different alcohol percentages. In some cases, an alcohol percentage is represented by one label in the market. Most of the samples in the present study have 40% alcohol percentage, which is also the percentage found on the majority of the ouzo labels. Limited information on water treatment or on additives used was extracted from the labels on the bottles, the producers' Web sites, or personal contact with the producer. It seems that most producers that treat their dilution water use softening or deionization resins.

Conductivity and pH Measurement Validation. To validate the conductivity and pH measurements, known samples were tested, and the measurements are presented in Table 2. The values for the once-distilled water are different because the samples were produced in different laboratories. Also, the two values for the three-times-distilled water were obtained for water from the same laboratory but produced on different dates. The tap water results are consistent with the reports published by the local water supplier for the same sampling area (conductivity = 350 μS/cm, pH 7.7;[22]). Ethanol and anethole (the main flavor component of the anise essential

Table 2. Conductivity and pH Measurements for Some Known Samples and for Other Similar Drinks

sample	conductivity (μS/cm)	pH[a]
deionized water	17	5.6
once-distilled water	46, 36	5.6
three-times-distilled water	3.2, 3.5	5.4
tap water	311	7.5

oil), because they are organic substances, were not expected to contribute to the conductivity of ouzo, and this was evident by the measurement of the pure substances. Even the commercial alcohol sold for the preparation of homemade drinks, which is not highly purified, demonstrates a low conductivity. On the basis of literature data, the addition of alcohol in water causes the electrode to measure the pH higher than the theoretical pH value for the buffer solutions prepared.[19] However, as presented in Table 2, pure alcohol and anethole pH measurements, given by the electrode and verified by pH indicator strips, are mildly acidic. Vodka 40% is one of the vodka samples measured by Lachenmeier et al.,[9] and its conductivity was reported as 3.1 ± 0.4 μS/cm. The value measured in the present study (4.3 μS/cm) is within the 99.7% confidence interval of the values reported (1.9−4.3 μS/cm). On the basis of these findings the use of this conductivity meter was found appropriate for measuring the actual samples.

Conductivity and pH Measurements. As demonstrated in Table 2, conductivity in ouzo samples would be due to water because ethanol, which is the main constituent of ouzo, does not contribute to conductivity measurements. Conductivity values for all 42 samples ranged between 5.5 and 250 μS/cm, with an average value of 89 ± 70 μS/cm. Council Directive 98/83/EC[6] set a limit for water intended for human consumption of 2500 μS/cm. This value was too high for drinking water. Although all samples demonstrated low conductivity values, only 9 of 42 samples demonstrated conductivity values of <20 μS/cm. This value is indicated as a desirable value for dilution water conductivity in a study implementing hazard analysis and critical control points (HACCP) to a large-scale production line of Greek ouzo.[1] If the dilution of water with alcohol is considered (~60%), the conductivity value of the dilution water could be even higher than the conductivity value measured in the ouzo end-product.

It was attempted to find a trend for conductivity values. Two factors were examined: (a) alcohol degree and (b) geology of the production area (Figure 1). No trend is observed for

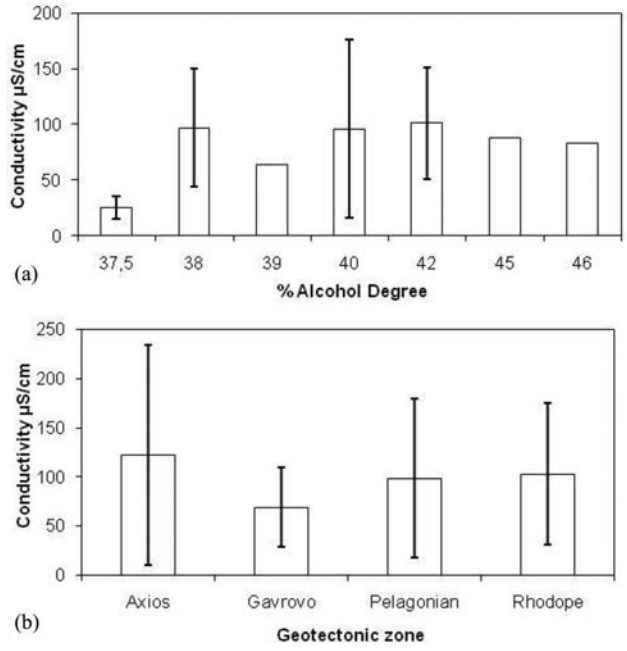

Figure 1. Conductivity measurements for all ouzo samples according to (a) alcohol degree and (b) the geology of the production area.

conductivity and alcohol degree of ouzo. For 37.5%, four samples were obtained from the same ouzo and, thus, the variability is due to differences during production. For 39, 45, and 46%, only one sample was tested. It seems that the conductivity ranges for all alcohol degrees are similar (Figure 1a), so the production of a stronger, or a lighter, ouzo does not prompt the producer to treat the dilution water before it is mixed with alcohol.

The geology of the production area was tested because it can affect the conductivity of the dilution water.[23] One would expect that in areas with hard water, producers would tend to treat the water before it is used in dilution. The geotectonic zone map of Greece presented in Demetriades[23] was used to identify the corresponding zones of each producer. Each zone corresponds to different lithology and, thus, different minerals diluted in water. The samples were grouped together on the basis of the geotectonic zones, and the average and standard deviation for the conductivity of each zone were calculated. As can be seen in Figure 1b, no trend can be identified between water treatment and water initial conductivity due to natural minerals. It seems that the quality of water that is selected (treated or not treated) is related to the producer quality goal for the final product as in other drinks such as beer and whiskey during previous years[7,8] and not to production problems as in vodka.[9] Additionally, water that does not include any harmful substances and, thus, not needing special treatment, is still abundant in most areas in Greece.[23]

Corrected pH values for all 42 samples range from 5.3 to 9.2, with a median value of 8. Most of these values are within the drinking water range from 6.5 to 9.5 (98/83/EC). The samples with low pH (~6) are the ones with low conductivity (<10 μS/cm). This suggests that deionization decreases dilution water pH. In addition, ethanol and anethole pH values are also <7

[a]g/hL pa, grams per hectoliter of pure alcohol.

(Table 2) and, thus, their mixing with low-pH dilution water results in an end-product that is slightly acidic. The drinks with high pH values are from companies utilizing high-conductivity raw water, and they use softening or desalination, resulting into end-products that have both high conductivities (~100 μS/cm) and high pH values (~9). In all cases, final product pH is regulated by the addition of water.

Similar drinks from Greece, Cyprus, and Italy were tested in the same manner. As can be seen in Table 2, no trends can be observed for the conductivity values for the Greek drinks. Drinks from Italy demonstrate consistently low conductivity values, suggesting consistent water treatment for dilution water. The pH in most cases is acidic.

Qualitative Description of Selected Examples. To further explore the characteristics of the dilution water and the alcohol used, six samples were selected and their summary characteristics are presented in Table 3. Two samples from large-scale production lines having high and low conductivity values were selected. They both belong to the five ouzo brands most consumed. One company treats its water (sample 2) and the other one does not (sample 1). Another sample (sample 3) that comes from a large-scale production line but is a private-label product is made with untreated water. Two samples from two small companies from the same area are used. They both treat their water with different methods. One of these water treatment methods is successful (sample 4), whereas the other one is not successful, leading to high conductivity values and unusually high pH (sample 5). Another sample (sample 6) is from a small-scale production line that, although famous for using double-distilled alcohol, does not treat the dilution water.

Dilution Water Characteristics. A quick screening test was used to get further information on the dilution water characteristics. Again, the method was validated against local tap water, and the results for all characteristics are comparable to the values in the reports published by the local water supplier for the same sampling area[24] as seen in Table 4.

For all samples, the results suggest that good-quality dilution water has been used. Sample 2 is the one that seems to be treated through deionization. Sample 1, although having high conductivity, does not show as high hardness, suggesting that the presence of salt such as NaCl is possible. Sample 5 shows the lowest quality (high hardness and nitrites), suggesting that softening is not performed in an appropriate way.

Alcohol Characteristics. To test the hypothesis that a drink that was made with high-conductivity water may contain low-quality alcohol, the alcohol characteristics for the selected ouzo samples are presented in Table 5. It is obvious that ethanol percentage is as expected in accordance with the label. Methanol is a bit higher in samples 1, 4, and 6 compared to samples 2, 3, and 5. Several years ago, methanol concentration in ouzo samples was measured equal to 143 ± 20 mg/L, lower than the values measured in the present study.[25] However, even

dx.doi.org/10.1021/jf501118e | J. Agric. Food Chem. 2014, 62, 4932−4937

in the present study methanol concentration is lower than in other distilled drinks such as tsipouro or cognac[25] and the recommended values for similar type drinks.[12] In the current regulation, there are only specifications for methanol content in ethanol distillates that are only 20% v/v of the final product and, thus, the results are not directly comparable with the regulation limits.[4]

There are more than 20 volatile constituents identified in ouzo samples.[26] These constituents originate from the addition of flavorings. In the present study volatile compounds that are related to the quality of alcohol used are tested. For example, acetaldehyde is a direct alcoholic fermentation byproduct that increases with aging[11] and influences the aroma and quality of the drinks.[14] Acetaldehyde is found in comparable concentrations in all samples and is lower than the recommended values for similar types of drinks.[12] Propanol-1 is a bacterial spoilage index, and isobutyl alcohol is attributed to aging.[11] In all samples, propanol-1 concentration and isobutyl alcohol concentration are at similar levels. They are both higher in samples 1, 3, and 4 compared to samples 2, 5, and 6. Amyl alcohols contribute negatively to the aroma of the distillate.[11] Amyl alcohols are only found in samples 1 and 3, with the concentration in sample 1 higher than that in sample 3. Generally, all volatile constituents are present in concentrations lower than or within the range observed for all distilled alcoholic beverages, which is 50−2000 mg/L.[27]

On the basis of these observations, high consumption companies include the highest (sample 2) and lowest alcohol quality drinks (samples 1 and 3) among these six samples. The sample with the highest alcohol quality also demonstrates the lowest conductivity (sample 2). Small-scale companies demonstrate all ranges of conductivities, even though they use high-quality alcohol. One can suggest that a low conductivity value can be found in samples from large-scale companies and can be related to high-quality alcohol but not vice versa.

Ouzo is produced by many producers at different scales and with different philosophies. In all cases, water and alcohol qualities are high. There is definitely a trend that big-scale companies use deionized water and, thus, the alcohol quality is guaranteed. However, not all large-scale companies use deionized water. Water treatment and characteristics are not predictable and are subjective based on the goals of the producer. Ouzo production is not as massive as the production of other drinks such as vodka and can be considered highly local and diverse.

Blanco), two clementines (*C. clementina* Hort. ex. Tan), five tangors (*C. reticulata* × *C. sinensis*), two tangelos (*C. reticulata* × *C. paradisi*), four satsumas (*C. unshiu* Marcovitch), two Mediterranean mandarins (*C. deliciosa* Tenore), and a King mandarin (*C. nobilis* Loureiro) (Table 1). Mandarin varieties not belonging purely to any specific subgroup, such as hybrids between different mandarin subgroups, were classified as common mandarins.

Fruit Weight, Shape, and Peel Thickness. Fruit weight was measured with a semianalytical scale (Citizen, Mumbai, India), and fruit height and diameter were measured with millimetric calipers.

dx.doi.org/10.1021/jf5002414 | J. Agric. Food Chem. 2014, 62, 4938−4946

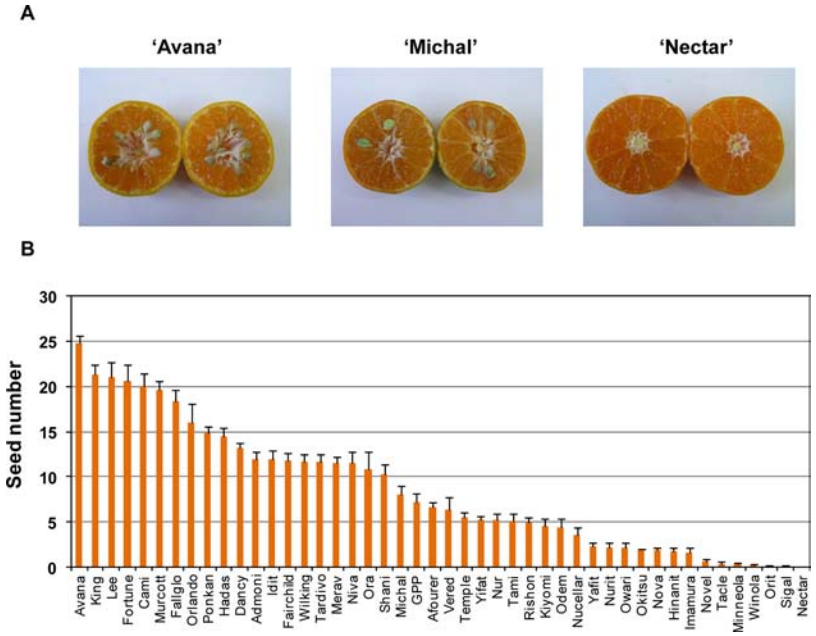

Figure 1. Diversity among mandarin varieties and subgroups in fruit seed number. (A) Photographs of 'Havana', 'Michal', and 'Nectar' mandarins containing high and moderate numbers and zero seeds, respectively. (B) Seed numbers of various mandarin varieties. Data are means ± SE of 10 fruit.

Thicknesses of the albedo (the inner white part of the peel), flavedo (the outer colored part of the peel), and the total peel were measured with a Leica MZ FLIII stereomicroscope (Leitz, Wetzlar, Germany) with the NIS-Elements Imaging software. All data are means ± SE of 10 fruit.

Seed Number and Peelability. The number of seeds per fruit was evaluated after cutting the fruit in half and extracting the juice with a hand extractor. Ease of peelability and segmentation were evaluated subjectively on a scale of 1 (very difficult) to 5 (very easy) by three laboratory personnel. The presented data are means ± SE of 10 fruit.

Color Measurement. Peel color was measured with a CR-310 Chroma Meter (Minolta, Tokyo, Japan), and the results are expressed as hue angle ($H°$), in which 0° represents red color, 45° orange, 90° yellow, and 120° green. Data are means ± SE of 10 fruit.

TSS, Acidity, and Vitamin C. Total soluble solids (TSS) content in the juice was determined with a PAL-1 digital refractometer (Atago, Tokyo, Japan), and acidity percentages were measured by titration to pH 8.3 against 0.1 M NaOH, with a CH-9101 automatic titrator (Metrohm, Herisau, Switzerland). Each measurement included four replications, each of juice collected from three different fruit (total of 12 fruit per measurement).

Vitamin C (ascorbic acid) content in the juice was determined by titration against 2,6-dichlorophenolindophenol, as described previously.[17] Ascorbic acid levels were determined by comparing the titration volumes of mandarin juices with those of 0.1% ascorbic acid (Sigma-Aldrich, St. Louis, MO, USA), and results are expressed as milligrams of ascorbic acid per 100 mL of juice. Each measurement included four replications, each of juice collected from three different fruit (total of 12 fruit per measurement).

Total Phenols and Flavonoids. Extraction of phenols and flavonoids was performed by stirring 1 mL of juice samples with 9 mL of 80% methanol for 30 min at room temperature, followed by centrifugation at 10000*g* for 10 min. Total phenolics were determined by the Folin−Ciocalteu method.[18] Briefly, the reaction mixtures included 0.2 mL of juice methanol extracts, 0.2 mL of Folin−Ciocalteu reagent, and 7 mL of 7% Na_2CO_3. The reaction mixtures were incubated for 90 min at room temperature, and the absorbance at 750 nm was measured by comparison with a prepared blank by means of a spectrophotometer. Total phenolic contents were expressed as gallic acid equivalents.

Total flavonoids were determined as described by Shin et al.[19] Briefly, the reaction mixtures included 1.0 mL of juice methanol extracts, 0.3 mL of 5% $NaNO_2$, and 0.3 mL of $AlCl_3$. The reaction mixtures were incubated for 10 min at room temperature, after which 2 mL of 1 N NaOH was added to stop the reaction, and the total volume was adjusted to 10 mL by adding double-distilled water. Flavonoid contents were measured by comparing the absorbance at 510 nm against that of a prepared blank, and the results were expressed as catechin equivalents. Total phenol and flavonoid contents are presented as means ± SE of four replications, each of juice collected from three different fruit (total of 12 fruit per measurement).

Total Carotenoid Content. Total carotenoids were extracted according to Lee and Castle.[20] In general, 1 mL of juice was homogenized with 2 mL of hexane/acetone/ethanol extraction solution (2:1:1 by volume) for 30 s and centrifuged for 5 min at 6500 rpm at 5 °C. Afterward, 100 mL of the colored top layer was diluted with 900 mL of hexane, and absorbance was measured at 450 nm with a spectrophotometer. Total carotenoid levels were calculated according to an equation provided by Schiedt and Liaaen-Jensen,[21] with a β-carotene extinction coefficient of $E^{1\%} = 2400$. Total carotenoid contents are presented as means ± SE of three replications, each of juice collected from three different fruit (total of 9 fruit per measurement).

Antioxidant Activity. Total antioxidant activity was determined by using the ABTS*$^+$ radical cation assay.[22] The reaction mixture included 1 mL of 75 μM $K_2O_8S_2$ and 150 μM 2,2′-azinobis(3-ethylbenzothiazoline-6-sulfonic acid) (ABTS*$^+$) dissolved in acetate buffer, pH = 4.3, and 10 μL of juice samples. The reaction mixtures were incubated for 15 min at room temperature. Afterward, total antioxidant activities of juice samples were compared with a 1 mM Trolox solution by determining the degree of disappearance of the blue color by comparing the absorbance at 734 nm against that of a prepared blank. Trolox equivalent (TE) was calculated according to the following formula:

$$\text{TE value (mM)} = (\text{Abs sample} - \text{Abs blank}) / (\text{Abs standard} - \text{Abs blank})$$

The results were expressed as Trolox equivalent antioxidant capacity (TEAC), calculated as

$$\text{TEAC (}\mu\text{M TE/g)} = (\text{TE} \times V)/(1000 \times M)$$

where V = sample volume and M = sample weight.

Antioxidant activity levels are presented as means ± SE of four replications, each of juice collected from three different fruit (total of 12 fruit per measurement).

Sensory Evaluations. Fruit sensory quality was tested on the day of harvest. The fruit were peeled and segments were separated, cut

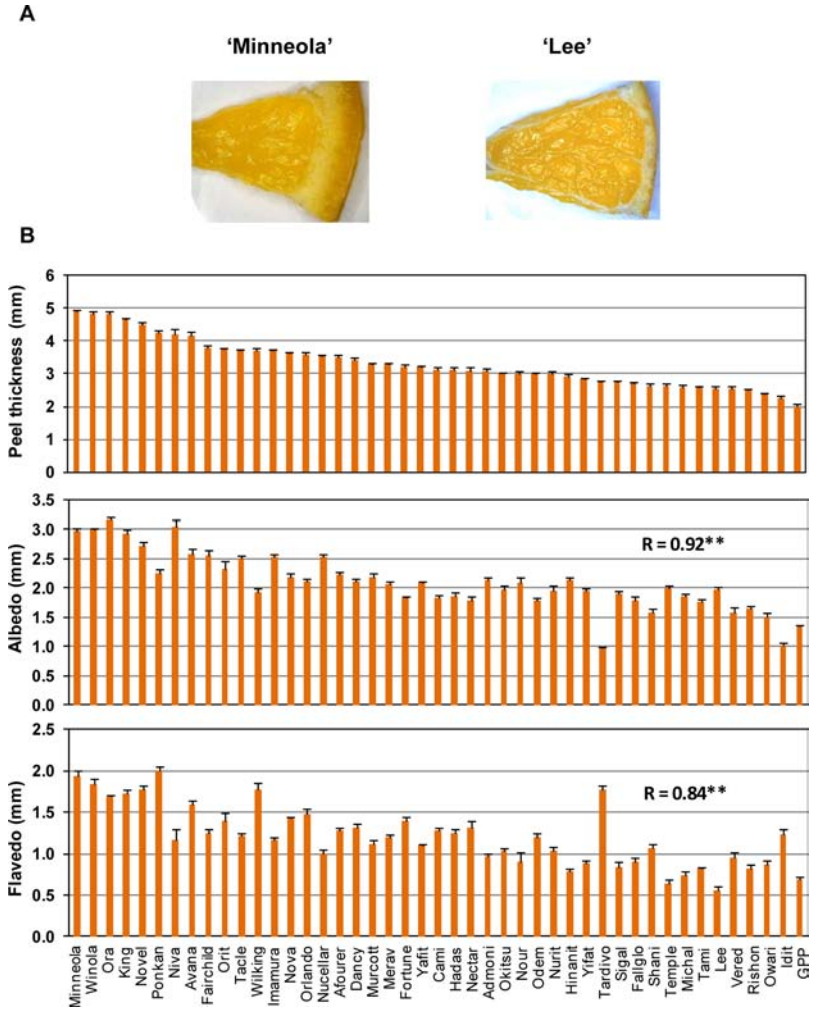

Figure 2. Diversity among mandarin varieties and subgroups in peel thickness. (A) Photographs of 'Minneola' and 'Lee' mandarins exhibiting thick and thin peel, respectively. (B) Total peel, albedo, and flavedo thicknesses of various mandarin varieties. Data are means ± SE of 10 fruit. Pearson correlation values were calculated and matched against total peel thickness; double asterisks (**) indicate significance at $P \leq 0.01$.

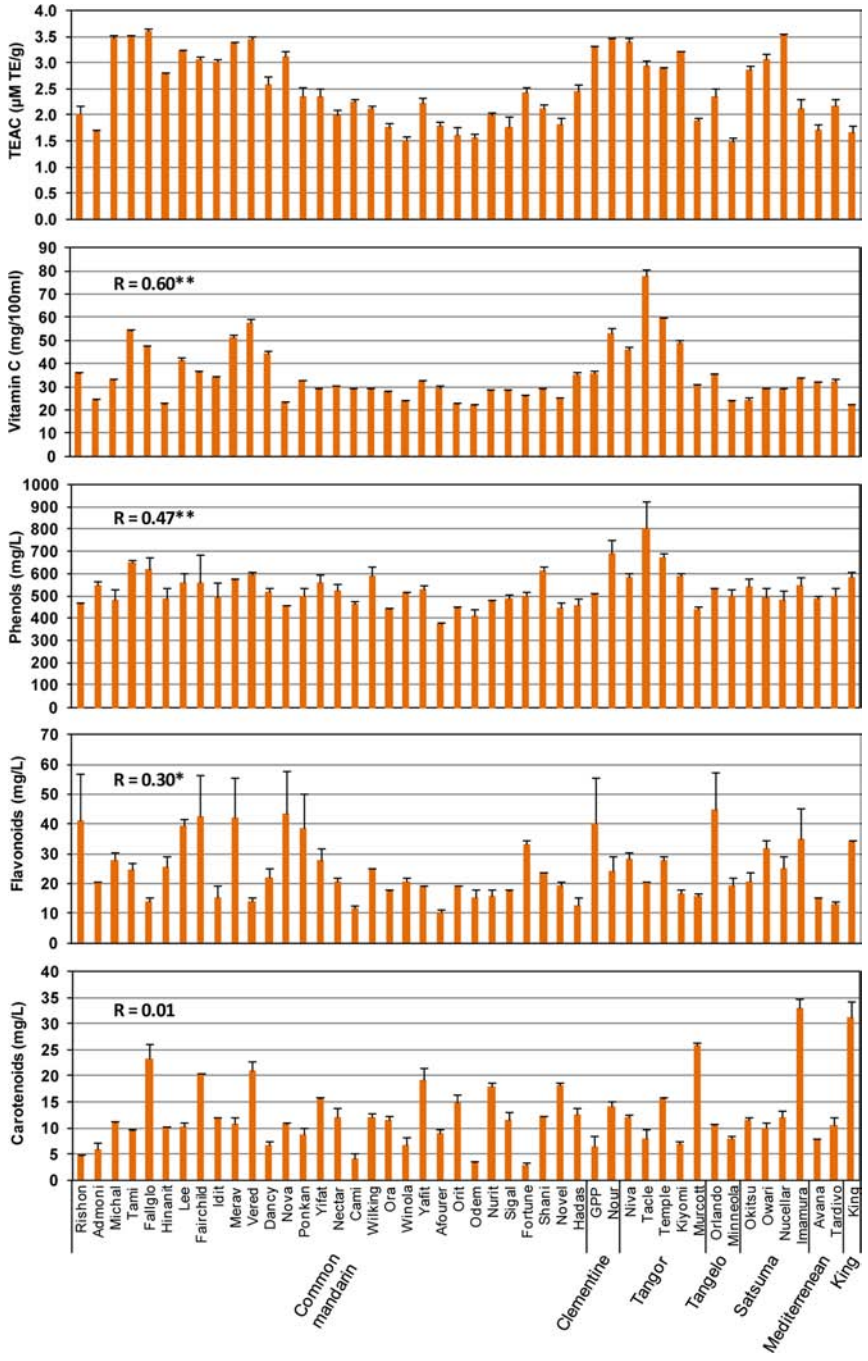

Figure 4. Diversity among mandarin varieties and subgroups in antioxidative activity and total vitamin C, phenols, flavonoids, and carotenoids levels. Data are means ± SE of four replications, each of juice from three different fruit. Pearson correlation values were calculated and matched against total antioxidant activity; single (*) and double (**) asterisks indicate significance at $P \leq 0.05$ and $P \leq 0.01$, respectively.

citrus fruit.[23,24] Each panelist assessed the taste attributes of the samples according to an unstructured 100 mm scale, on which the anchor points 'very weak' and 'very strong' for each attribute and/sensory data were recorded as distances (mm) from the origin. The samples were identified by means of randomly assigned three-digit codes. In addition, panelists were requested to rate overall fruit flavor preference on a scale of 1 to 9, where 1 = very bad and 9 = excellent.

Statistical Analysis. One-way analysis of variance (ANOVA) was applied with the Microsoft Office Excel program. Hierarchical clustering and heat-map analysis were performed with the Expander 4.1 software,[25] and Pearson correlations were calculated with the R software (http://www.r-project.org).

RESULTS

Diversity in Time of Ripening, Fruit Weight, Shape, and Peelability. We evaluated fruit-quality traits of 46 mandarin varieties within the Israeli *Citrus* breeding collection; they belonged to genetically differing natural subgroups, comprising 30 common mandarins (*C. reticulata* Blanco), two clementines (*C. clementina* Hort. ex. Tan), five tangors (*C. reticulata* × *C. sinensis*), two tangelos (*C. reticulata* × *C. paradisi*), four satsumas (*C. unshiu* Marcovitch), two Mediterranean mandarins (*C. deliciosa* Tenore), and one King mandarin (*C. nobilis* Loureiro) (Table 1). We observed great genetic variability in ripening time, which was spread over 6 months from October through March.

dx.doi.org/10.1021/jf5002414 | J. Agric. Food Chem. 2014, 62, 4938−4946

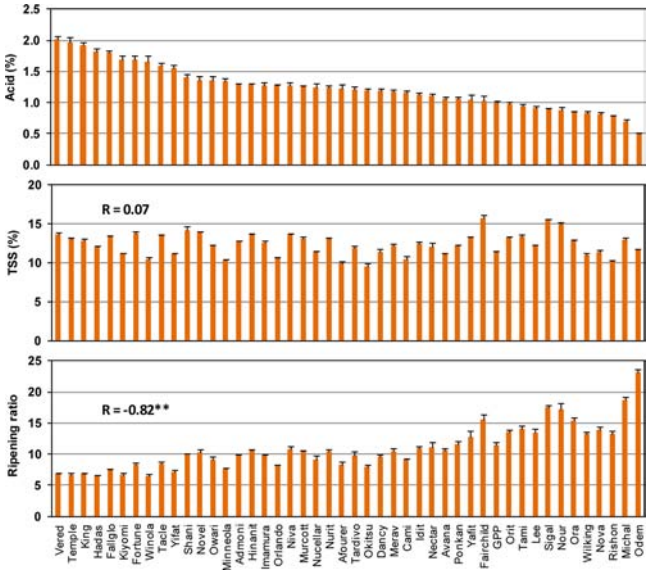

Figure 5. Diversity among mandarin varieties and subgroups in TSS and acidity contents and ripening ratios. Data are means ± SE of four replications, each of juice from three different fruit. Pearson correlation values were calculated and matched against acidity levels; double asterisks (**) indicate significance at $P \leq 0.01$.

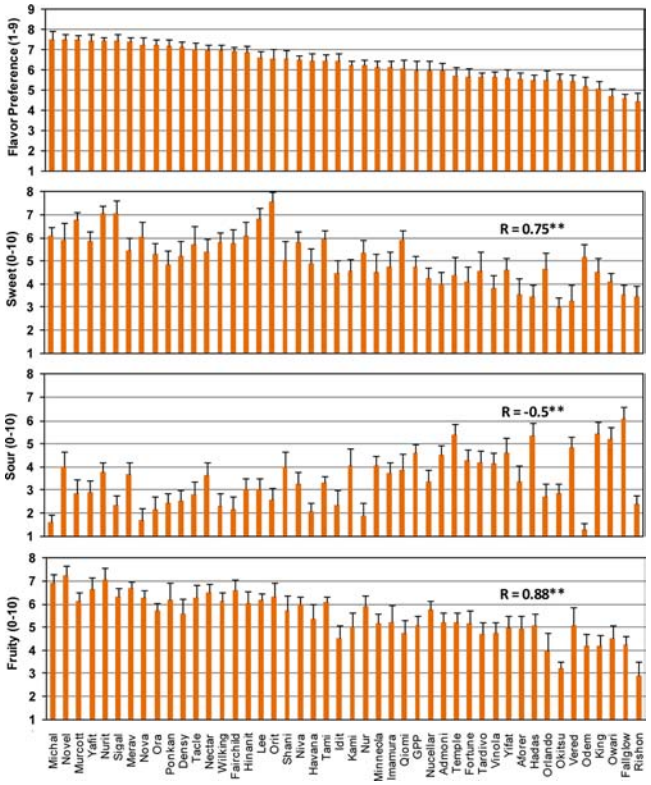

Figure 6. Diversity among mandarin varieties and subgroups in flavor preference and sensations of 'sweetness', 'sourness', and 'fruitiness'. Data are means ± SE of scores given by 10 trained testers. Pearson correlation values were calculated and matched against flavor preference scores; double asterisk (**) indicates significance at $P \leq 0.01$.

The earliest-ripening varieties, harvested in October, were the new Israeli breeding varieties 'Rishon' and 'Admoni', as well as the clementine 'GPP', and three satsumas, 'Okitsu', 'Owari', and 'Nucellar Satsuma' (Table 1). The latest-ripening varieties, harvested in March, were the common mandarins 'Novel' and 'Hadas' (Table 1).

There was also great genetic diversity in fruit weight: the variety with the largest fruit (219 g) was 'Winola', whereas the one with the smallest (58 g) was 'Nour' clementine (Table 1).

We further observed great variability in fruit shape, i.e., height/diameter ratio. Fruit of some varieties, including 'Minneola' tangelo, 'Kiyomi' tangor, 'Nour' clementine, and 'Cami' and 'Yafit' common mandarins, were nearly round, with height/diameter ratios above 0.85, whereas, in contrast, other varieties such as 'Sigal' were rather flat, with a height/diameter ratio of just 0.66 (Table 1).

Another important quality attribute of mandarins is ease of peelability and segment separation. We observed great variability in ease of peeling: some varieties, including all four satsumas, as well as 'Ponkan', 'Havana', and 'Sigal', were very easy to peel, whereas others, such as the 'Niva' tangor, 'Orlando' tangelo, and the common mandarins 'Fairchild', 'Hinanit', and 'Nurit', were very difficult to peel (Table 1). It was very easy to separate the segments of all four satsumas, as well as those of 'Ponkan', but very difficult to separate those of some others, especially the tangors 'Temple' and 'Kiyomi' (Table 1).

Diversity in Seed Number. The number of seeds per fruit is a very important quality trait, as consumers prefer seedless fruit, and we observed great variability in fruit seed number. Five varieties had an average of more than 20 seeds per fruit, with 'Avana' Mediterranean mandarin containing an average of 25 seeds per fruit (Figure 1). In contrast, seven mandarin varieties averaged ≤1 seed per fruit (Figure 1). Worth noticing is that the 'Nectar' common mandarin variety was obligatorily seedless, even under the unfavorable conditions of a mixed orchard with many pollinators (Figure 1).

Diversity in Peel Thickness. We observed substantial intervariety differences in peel thickness, which ranged from 2.0 to 5.9 mm (Figure 2). Furthermore, we observed significant correlations between overall peel thickness and thickness of the albedo ($R = 0.92$) and flavedo tissues ($R = 0.84$) (Figure 2). Most of the varieties that had a thick albedo also had a thick flavedo, and vice versa. However, some varieties differed in this respect. For example, the 'Tardivo' Mediterranean mandarin had a relatively thin albedo but a thick flavedo (Figure 2).

Diversity in Peel Color. The vast majority of mandarin varieties exhibited the typical mandarin orange color, with measurable hue angles between 50° and 70° (Figure 3). In contrast, the early ripening varieties, including 'Rishon' common mandarin, 'GPP' clementine, and three satsuma varieties, 'Okitsu', 'Owari', and 'Nucellar Satsuma', were harvested when their peel color was mostly green, with a persisting hue angle of ≥100° (Figure 3). Worth notice is that the 'Odem' and 'Shani' common mandarins had a unique deep reddish-orange color, with a hue angle of 40−45° (Figure 3).

Diversity in Fruit Nutritional Quality. The key nutritional components of citrus fruit that contribute to its overall antioxidative activity are vitamin C, phenols, flavonoids, and carotenoids. We observed significant variability among mandarin varieties and subgroups in their bioactive contents and total antioxidative activity. The total antioxidative activity ranged between 1.5 and 3.5 μM TE g^{-1} (Figure 4). Juice vitamin C levels were relatively high (i.e., between 45 and 60 mg per 100 mL) in most tangors as well as in a few common mandarin varieties, and the highest level (78 mg per 100 mL) was found in juice of 'Tacle' tangor (Figure 4). In contrast, juice from several common mandarin varieties, as well as 'Minneola' tangelo, 'Okitsu'

dx.doi.org/10.1021/jf5002414 | J. Agric. Food Chem. 2014, 62, 4938−4946

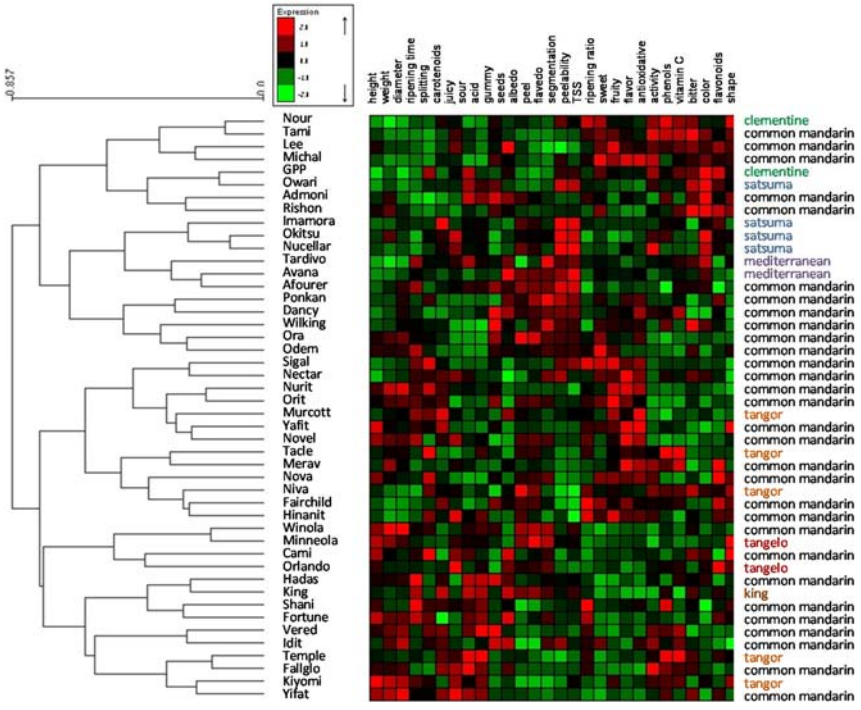

Figure 7. Hierarchical clustering of mandarin varieties and subgroups and heat-map analysis of fruit-quality traits. Red and green colors represents high and low levels, respectively. The units in the color scale are standard deviations. The various mandarin natural subgroups are listed in different colors at the right.

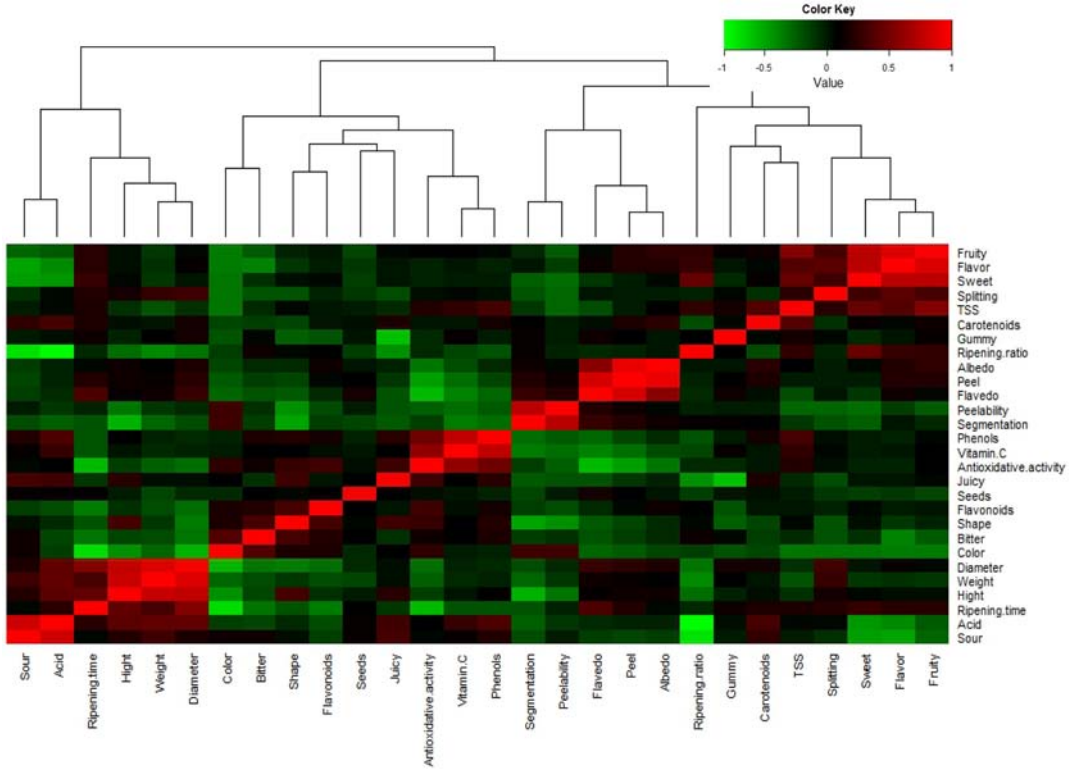

Figure 8. Hierarchical clustering and Pearson correlations among all fruit-quality traits. Red and green colors represent positive and negative correlations, respectively. Pearson correlations were calculated with the R software (http://www.r-project.org).

satsuma, and 'King' mandarin, contained relatively low vitamin C levels of 22−24 mg per 100 mL (Figure 4).

It was found that total phenol levels in mandarin juices ranged from just 375 mg L^{-1} in 'Afourer' common mandarin up to 804 mg L^{-1} in 'Tacle' tangor (Figure 4). Worth notice is that most tangors had relatively high phenol levels (Figure 4). We also observed wide variability among mandarin juices in their total flavonoid content, from just 10 mg L^{-1} in 'Afourer' common

dx.doi.org/10.1021/jf5002414 | J. Agric. Food Chem. 2014, 62, 4938−4946

mandarin up to 45 mg L^{-1} in 'Orlando' tangelo (Figure 4). However, we did not detect any clear differences among mandarin subgroups in their flavonoid contents.

We further observed wide genetic diversity among mandarin juices in their total carotenoid contents: the juices of some mandarin varieties, such as 'Fortune', were pale yellow in color and contained only 3 mg L^{-1}, whereas the juices of other varieties, such as 'King' mandarin and 'Imamura' satsuma, were dark orange in color and contained carotenoids at more than 30 mg L^{-1} (Figure 4).

Overall, we found R values of 0.60, 0.47, 0.30, and 0.01, respectively, for the correlations between total antioxidative activity of mandarin juices and vitamin C, phenol, flavonoid, and carotenoid levels. Thus, it seems that vitamin C provides the highest contribution to total antioxidant activity of mandarin fruit (Figure 4).

Diversity in Juice TSS, Acidity, and Flavor Perception. The taste of citrus fruit is principally governed by the levels of sugars and acids in the juice sacs, as well as the fruit ripening ratio. We observed remarkable differences among mandarins in their juice acidity levels, from as low as 0.5% in 'Odem' common mandarin to nearly 2.0% in 'Vered' common mandarin and 'Temple' tangor (Figure 5). The overall juice TSS levels ranged from as low as 9.6% in 'Okitsu' satsuma to 15.8% in 'Fairchild' common mandarin (Figure 5). These observed differences in juice TSS and acidity levels resulted in remarkable variability in fruit ripening ratios, from below 6.7 in the common mandarins 'Vered', 'Hadas', and 'Winola', the tangors 'Temple' and 'Kiyomi', and 'King' mandarins, up to 23 in 'Odem' common mandarin (Figure 5).

Overall, sensory analysis revealed wide genetic variability among mandarin flavor preferences, ranging from a relatively high score of 7.5 (on a 1−9 scale) for several common mandarin varieties such as 'Michal', down to scores below 5.0 for 'Owari' satsuma and 'Fallglo' and 'Rishon' common mandarins (Figure 6). In addition, descriptive sensory analysis tests conducted with the aid of a trained panel indicated differences among mandarins in their elicited sensations of 'sweetness', 'sourness', and 'fruitiness' (Figure 6). Furthermore, we observed significant positive correlations between flavor preference and perceptions of sweetness (R = 0.75) and fruitiness (R = 0.88) (Figure 6).

Hierarchical Clustering and Heat-Map Analysis. Hierarchical clustering of mandarin varieties and subgroups and heat-map analysis of fruit-quality traits demonstrated that the distinct mandarin varieties fell into two major subclusters: the first cluster included some common mandarins, satsumas, clementines, and Mediterranean mandarins; the second cluster included additional common mandarins, King mandarin, tangors, and tangelos (Figure 7). Furthermore, it can be seen that the different satsuma, clementine, Mediterranean mandarin, tangor, and tangelo varieties were clustered closely together, thus demonstrating the genetic diversity in fruit-quality traits among the various mandarin subgroups (Figure 7).

Hierarchical clustering and Pearson correlations among all of the 28 examined fruit-quality parameters demonstrated that the various quality attributes can be grouped into several subclusters (Figure 8). For example, it can be seen that peel traits, such as albedo, flavedo, and total peel thickness, were clustered together with ease of peelability and segment separation, which suggests that these traits are mutually related (Figure 8). Furthermore, many of the biochemical characteristics, including levels of vitamin C, phenols, and flavonoids, as well as total antioxidant activity, were also clustered together (Figure 8). Finally, it was found that flavor preference was clustered together with TSS levels and perceptions of 'sweetness' and 'fruitiness', whereas acidity and 'sourness' were clustered separately (Figure 8).

Table 2. Outlines of the Diversity Observed among Mandarin Varieties and Subgroups in Fruit-Quality Traits

	range of variability		
quality trait	lowest score	highest score	units
Physical Traits			
weight	57.8	219.5	g
height	39.2	68.3	mm
diameter	49.5	87.6	mm
shape	0.66	0.89	height/diameter ratio
peel color	42.4	112	$H°$
peel thickness	2.02	4.9	mm

fruity	2.9	7.2	scale of 0−10
flavor	4.4	7.5	scale of 1−9

DISCUSSION

A detailed phenotypic analysis study (phenomics) of fruit-quality traits is an obligatory requirement to enable designation of SNPs for marker-assisted breeding of new varieties with improved fruit-quality traits, as well as for selection of appropriate parents for future breeding programs.[12,13,26,27] In this respect, the present study provided the most comprehensive phenotypic analysis to date of fruit-quality traits among genetically distinct mandarin varieties and subgroups.

The data yielded by this study highlight the inclusive genetic diversity among mandarins, in their fruit-quality traits (Table 2). For example, ripening time can range from 28 to 50 weeks after blooming; fruit weight from 58 to 219 g; peel thickness from 2.0 to 4.9 mm; fruit shape from nearly round to flat; peelability from very easy to very difficult; and seed number from zero to 25 (Table 2). Regarding fruit nutritional attributes, we found that vitamin C levels ranged from 22 to 78 mg per 100 mL; phenols from 375 to 804 mg per 100 mL; flavonoids from 10 to 45 mg per 100 mL; and carotenoids from 3 to 33 mg per 100 mL (Table 2). Finally, TSS levels may range from 9.6% to 15.8%; acidity from

dx.doi.org/10.1021/jf5002414 | J. Agric. Food Chem. 2014, 62, 4938−4946

0.5% to 2.0%; and flavor preference from 4.4 through 7.5 on a 1−9 scale (Table 2).

These phenotypic analysis data are of great importance for citrus breeders worldwide, as they could assist in selection of appropriate varieties as putative parents in future breeding programs. For example, for breeding early-season varieties it would be preferable to choose 'Rishon', 'Admoni', or satsumas as putative parents, whereas for breeding late-season varieties it would be preferable to choose 'Hadas' (Table 1). In the case of breeding for high vitamin C content, it would be preferable to choose 'Tacle' tangor or other tangors as putative parents (Figure 4).

Regarding the genetic variability in fruit-quality traits among different natural mandarin subgroups, hierarchical clustering analysis revealed clear evolutionary differences among mandarins (Figure 7). For example, satsuma mandarins are early ripening, are very easy to peel, and contain few seeds, and their juice is deep orange in color and contains high carotenoid pigment contents (Table 1; Figures 1, 4). Clementines also ripen early and have relatively small fruit (Table 1). Tangors (orange × mandarin hybrids) are relatively difficult to peel, but have high vitamin C and phenol contents and high antioxidative activity levels (Table 1; Figure 4). Tangelos (grapefruit × mandarin hybrids) have a relatively thick peel (Figure 2), Mediterranean mandarins have many seeds (Figure 1), and King mandarin has many seeds and high carotenoid and acidity contents (Figures 1, 4, 5).

binding of coffee organics to familiar dissolved metal ions, Na^+, Mg^{2+}, and Ca^{2+}. We have selected five archetypal acids (**1**–**5**), caffeine (**6**), and eugenol (**7**) as representatives of the larger class of organic derivatives found in varying concentrations in roasted beans (Figure 1).[22] Of the five acids, lactic (**1**) and

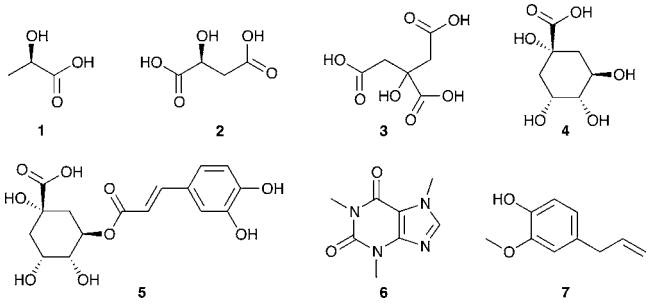

Figure 1. Seven compounds contained in roasted coffee, displaying a range of functionality. There are five carboxylic acids in increasing molecular weight: lactic acid (**1**), malic acid (**2**), citric acid (**3**), quinic acid (**4**), chlorogenic acid (**5**), an alkaloid, caffeine (**6**), and a flavor note, eugenol (**7**).

malic (**2**) acids embody sour notes, while citric acid (**3**) has an appealing sweet flavor. Quinic acid (**4**) and its larger derivative chlorogenic acid (**5**) are considered to taste pungent and unpalatable.[23,24] Caffeine (**6**) was included as an archetypal aromatic alkaloid (and is weakly basic, pK_a = 14),[25] while eugenol (**7**) is a delightful woody note found in coffee, wine, and whisky.[26,27] It should be noted that some acids exist as the potassium salt in the bean. As we will discuss later in this paper, K^+ displays significantly weaker binding to coffee constituents because it is both diffuse and singly charged. Here, we consider the acids in their free acid form, because the relative binding energies of the charge neutral molecules coordinating to ions represent the weakest possible interactions, highlighting the significance of the ionic species.

MATERIALS AND METHODS

All quantum-chemical calculations were performed using the FHI-aims quantum chemical package.[28] FHI-aims is an all-electron code that uses atomic-like orbitals numerically truncated for the inclusion of diffuse and polarization functions. The electronic wave functions are constructed using the combination of these numeric atom-centered basis functions. A converged "tight" basis was employed, which installs *d*, *f* and *g* functions on the O atoms, and scalar relativistic effects were included. Convergence criteria were set to 1×10^{-6} eV per system, corresponding to approximately 5×10^{-5} eV per atom. This criteria is comparatively high to other recent publications featuring similar methods.[29,30]

The thermodynamic relative binding energy of two compounds is defined by

$$E_T = E_{ab} - (E_a + E_b) \quad (1)$$

where the relative binding energy, E_T, is equal to the difference between the bound product, E_{ab}, and the individual components, E_a and E_b. These energies are relative to the molecular states, and thus the magnitude of these energies is only directly comparable within our experiment. Local structure optimizations were performed using the forces from the density functional, PBE (Perdew–Burke–Ernzerhof) exchange-correlation potential (V_{xc}^{KS}).[31] The PBE functional was selected for its desirable trade off between speed and qualitative energies. We tested other familiar hybrid exchange-correlation functionals such as PBE0 (Perdew–Burke–Ernzerhof with the inclusion of 25% Hartree–Fock exchange, 75% correlation) and B3LYP (Becke and Lee–Yang–Parr functional, common in organic chemistry modeling), and PBE produced the same trends in less than half the time.[32]

The consideration of the water interactions is important. There is a long-standing problem in computational modeling of water because it is unclear how many water molecules must be included before one is considering *liquid* water and not a collection of gaseous water molecules. Explicit water molecules severely increase computation time; to circumvent this problem, a familiar approximation is the inclusion of a polarizable continuum model (PCM) that mimics solvents through the application of a dielectric continuum, which acts to screen charges. The PCM (dielectric constant of H_2O, ϵ, = ca. 80) was tested for the calcium series and produced a consistent 30% decrease in relative binding energies. Given the linear nature of the adjustments using a PCM, we elected to exclude it to increase the speed and accessibility of these computations. We consider this acceptable, because values computed using PCM and explicit water are at the limitations of computational power today and still do not produce absolute energies but rather relative binding energies. As a result, our method is accessible and accurate, within the error of the methods and within the limitations of computational chemistry at the time of writing.

Furthermore, we would like to comment on the transferability of our methods to foreign systems. Following the aforementioned procedure, relative binding energies can be consistently calculated. In this case, we have neglected macroscopic variables, such as explicit water. This assumption is certainly not always applicable: this approximation yields poor results in, for instance, protein folding computations. However, there are many applications in which gas-phase computations may be informative, and we encourage the application of quantum mechanics to other chemical problems.[30]

RESULTS AND DISCUSSION

Dissolved cations interact with the nucleophilic motifs of solvated coffee constituents. This interaction may be understood with classical electrostatics:

$$U_r = \frac{(\mathbf{q}_i \cdot \mathbf{q}_s)}{r^2} \quad (2)$$

where the interaction energy U_r is proportional to the charge of both the ion and solute ($\mathbf{q}_i$ and $\mathbf{q}_s$) divided by the interatomic separation, r^2. With this considered, we would anticipate that the more localized charged species should interact more strongly with molecular multipoles. Upon geometry optimization, we recover an equilibrium local minimum energy structure, where the metal ions interact strongly with electron rich motifs. A representation of the equilibrium geometries of each ion–solute cluster is shown in Figure 2, with the notable bond lengths between metal ion and nucleophilic motif listed in Table 1.

The summary of the binding energies is shown in Figure 3, with H_2O-M^{n+} interaction included as a reference. The dissociation of metal-coordinated water is a process driven by entropy, however there is a thermodynamic competitive displacement of metal-coordinated water molecules by compounds **1**-**7**.[17] For coordination and interaction, the coffee compounds are thought to require a higher E_T than the H_2O-M^{n+}. This poses an interesting problem for Na^+ rich water: the binding of **6** and **7** are less favorable than water itself, suggesting that Na^+ does not facilitate extraction of caffeine or eugenol. The **1**-**5**-Na^+ interaction is of comparable energy to the H_2O–Na^+; the extraction of the five acids are not dramatically influenced by the presence of Na^+. First generation exchange filtration units featured a Ca^{2+}/Na^+ ion-exchange column: from our results, this only serves to decrease scale build up, at the deficit of extraction ability of some compounds.

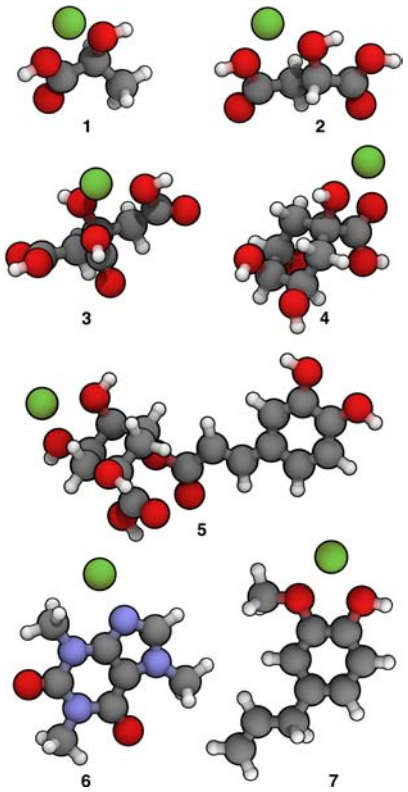

Figure 2. Equilibrium coordination environments of lactic (**1**), malic (**2**), citric (**3**), quinic (**4**), and chlorogenic acid (**5**), caffeine (**6**), and eugenol (**7**). Hydrogen, carbon, nitrogen, oxygen, and magnesium are shown in white, gunmetal, periwinkle, red and green, respectively.

Table 1. Interaction Lengths of Each Metal Ion to the Nearest/Most Nucleophilic Site, as Shown in Figure 2[a]

	1	2	3	4	5	6	7	H_2O
Ca^{2+}	2.21	2.19	2.23	2.15	2.22	2.22	2.21	2.20
Mg^{2+}	1.93	1.92	1.96	1.93	2.00	1.97	1.96	1.92
Na^{+}	2.25	2.26	2.25	2.24	2.24	2.28	2.24	2.23

[a]Distances are stated in Å.

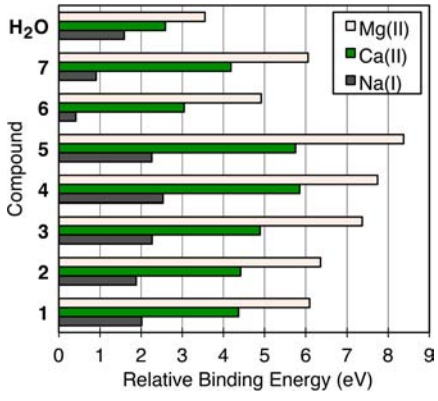

Figure 3. Gas phase binding energies of compounds **1**−**7** and H_2O to Na^{+}, Mg^{2+}, and Ca^{2+}, in gray, beige, and dark green, respectively.

The relative binding energy of (**1**−**7**)−Mg^{2+} is highest in all cases, with the E_T proportional to the charge density of compounds **1**−**7**. Mg^{2+}-rich water is paramount if increasing extraction yield is important. There is, however, a subtle but important increase in the relative binding energy of **1**−**3** relative to **4** and **5** to Mg^{2+} compared with Ca^{2+} (if only by approximately 5%). This is desirable, suggesting Mg^{2+}-rich water would bind to marginally more of the desirable flavors in coffee, although the macroscopic effects of this would be better probed experimentally. The high binding energies of the undesirable acids, **4** and **5**, is less pleasing. Relative to other ions, Mg^{2+} would significantly increase the extraction of these compounds, which may have implications for both the consumer's health and his enjoyment of the cup.[33,34] In this case, the importance of the dissolved carbonate and other bases are important. Bicarbonate/carbonate interacts strongly with **5** (pK_a = 2.66), neutralizing some of this less desirable acid, versus the interaction with the smaller acids, **1**−**3** (pK_a = 3.86, 3.40, and 3.14, respectively). This interaction is outside the scope of this article but is certainly important and is a direction we intend to explore in the future.

Similar binding trends are observed for Ca^{2+}; however, the relative binding energy is lower than that of Mg^{2+} in all cases. The binding energy of **6**−Ca^{2+} is comparable to H_2O−Ca^{2+}; this is the only instance in which one of the divalent cations interacts weakly with an electron-rich motif. This is not a surprising result as the electron density of caffeine is delocalized across the conjugated aromatic motif, resulting in low binding energies to all metal ions (in the case of Na^{+}, almost noninteractive). Considering the results from Table 1, the binding energies are evidently proportional to charge and inversely proportional to the ionic radii. Hence we do not need to explore the binding of K^{+} because it is anticipated that E_T is even lower than that of Na^{+}. Thus, the K^{+} found in the bean in the form of salts can be considered very weakly bound, if not labile (ions concerned in this paper would be anticipated to displace the K^{+}). This effect is amplified if the acids exist as the conjugate bases, and thus our study represents a conservative representation of the binding of coffee constituents to dissolved ions in water.

Based on our thermodynamic experiments, a compelling argument can be made for the favorable exchange of Ca^{2+} for Mg^{2+} to increase extraction yield, with no deficit to coffee flavor, and the additional benefit of removing the source of lime scale. We also emphasize the surprising result that Na^{+} binds weakly to most neutral compounds in coffee beans, suggesting that sodium rich water is of no benefit to the consumer, besides removing the source of scale build up. Thus, if the motivation is to extract the most coffee constituents (i.e., instant coffee), then Mg^{2+}-rich water is most suitable. If the motivation is to achieve the best balance of flavors for a given lighter roast coffee, then both Ca^{2+} and Mg^{2+} do a comparable job,[35] with Mg^{2+} having the added feature of preventing scale formation.

It should be noted that there is not one particular composition of water that produces consistently flavorsome extractions from *all* roasted coffee. Rather, there is water that has the most extracting ability (i.e., cation-rich), and the resultant flavor depends on the balance between both the cations in solution and the quantity of bicarbonate present (acting as a buffer). Furthermore, each bean is roasted to taste optimal when brewed with the water it was roasted to. We acknowledge this point, and emphasize that this work elucidates the important role that dissolved ions play in facilitating the extraction process.

(35) Indeed, the roast for Ca^{2+}-rich water is different from that of Mg^{2+}-rich water: the more powerful the extraction ability of water, the lighter the roast.

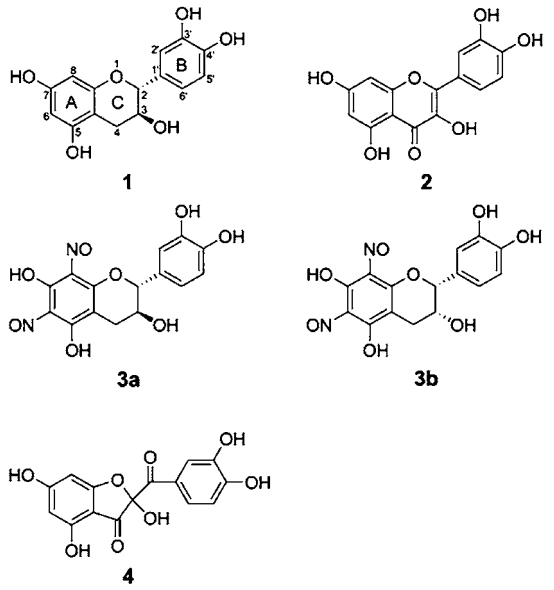

Figure 1. Compounds investigated in this study: (**1**) (+)-catechin, (**2**) quercetin, (**3a**) 6,8-dinitrosocatechin, (**3b**) 6,8-dinitrosoepicatechin, and (**4**) 2-(3,4-dihydroxybenzoyl)-2,4,6-trihydroxy-3(2*H*)-benzofuranone.

are taken into account, possible interactions between (+)-catechin and quercetin are discussed.

MATERIALS AND METHODS

Reagents. (+)-Catechin, (−)-epicatechin, and quercetin were obtained from Sigma-Aldrich Japan (Tokyo, Japan). 1-Hydroxy-2-oxo-3-(*N*-methyl-3-aminopropyl)-3-methyl-1-triazene (NOC 7) (purity > 90%) was from Dojindo (Kumamoto, Japan).

Apparatus. High-performance liquid chromatography (HPLC) was carried out using a Shimadzu LC-10AS pump combined with a SPD M10Avp photodiode array detector (Shimadzu Co., Kyoto, Japan). Atmospheric pressure chemical ionization (APCI) mass spectra were obtained with a Shimadzu LCMS QP8000α quadrupole mass spectrometer equipped with an APCI ion source. The deflector voltage of the mass spectrometer was maintained at +50 V for positive-mode measurement or at −50 V for negative-mode measurement. The sample was delivered into the ion source using an Ascentis express C18 column (15 cm × 2.1 mm inner diameter; particle size of 2 μm; Sigma-Aldrich Japan, Tokyo, Japan). The mobile phase was 35% methanol containing 0.2% formic acid, and the flow rate was 0.2 mL/min. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded with an ECX-400P FT-NMR spectrometer (JEOL, Tokyo, Japan) with dimethyl sulfoxide-d_6 (DMSO-d_6) as the solvent and tetramethylsilane as the internal standard. ^{1}H NMR was performed at 399.78 MHz, and the ^{1}H−^{1}H chemical shift correlated technique was employed to assign ^{1}H shifts and couplings.

Isolation of 6,8-Dinitrosocatechin. (+)-Catechin (29 mg) in 100 mL of 50 mM KCl−HCl (pH 2.0), which was equivalent to 1 mM (+)-catechin, was reacted with 5 mM sodium nitrite for 5 min under anaerobic conditions, and then 5 mM ascorbic acid was added to terminate the reaction. The reaction products were extracted with 50 mL of ethyl acetate 5 times. Ethyl acetate extracts were combined and washed with 50 mL of 0.1% HCl twice. After water was removed from the ethyl acetate extract with anhydrous sodium sulfate, the solvent was removed *in vacuo* with a rotary evaporator, the residue was dissolved in 1.5 mL of methanol, and then the methanol solution was diluted with 1.5 mL of 0.2% formic acid to apply to a preparative HPLC column.

Preparative HPLC was performed using a Shim-pack PREP-ODS(H) kit (25 cm × 20 mm inner diameter; particle size of 5 μm; pore size of 10 nm; Shimadzu), and the volume of samples injected into the column was 0.9 mL. The mobile phases were mixtures of methanol and 0.2% formic acid. The concentration of methanol was increased stepwise as follows: 14, 20, 25, and 33% (v/v), and each mobile phase was flowed for 5, 15, 15, and 25 min, respectively. Their flow rate was 9 mL/min. Components separated by the preparative HPLC were detected at 210, 280, and 320 nm using the spectrophotometric detector. A peak supposed to be 6,8-dinitrosocatechin was eluted at about 7 min after changing the mobile phase to 25% methanol, and the peak component was collected. Methanol of the collected solution was removed *in vacuo*, and the residue was lyophilized. The yield was 27−35%. The above procedure was repeated 6 times, and about 50 mg of the lyophilizate was obtained.

Reactions of Nitrite with Quercetin, (+)-Catechin, and 6,8-Dinitrosocatechin. Interactions of quercetin with (+)-catechin or 6,8-dinitrosocatechin were studied in reaction mixtures (1 mL) that contained 0.1 mM (+)-catechin or 6,8-dinitrosocatechin and various concentrations of quercetin (0, 10, 30, or 100 μM) in 50 mM KCl−HCl (pH 2.0). When required, 2 mM ascorbic acid or 10 mM potassium thiocyanate was added to the above reaction mixtures. Reactions were initiated by the addition of 0.1 mM sodium nitrite. After incubation for defined periods, an aliquot (50 μL) of each reaction mixture was applied to a HPLC column to quantify (+)-catechin, dinitrosocatechin, quercetin, and their reaction products (see below).

Interactions between quercetin and (+)-catechin or 6,8-dinitrosocatechin were also studied under anaerobic conditions. The reaction mixture contained 50 μM (+)-catechin or 6,8-dinitrosocatechin and various concentrations of quercetin. Air of the reaction mixtures was removed by bubbling argon gas for 2 min, and then reactions were initiated by the addition of 0.25 mM sodium nitrite. After incubation for 1 min, 50 μL of the reaction mixture was applied to the HPLC column to quantify (+)-catechin, quercetin, dinitrosocatechin, and their reaction products (see below).

Analysis of Reaction Products by HPLC. Analytical HPLC was performed using a Shim-pack CLC-ODS column (15 cm × 6 mm inner diameter; particle size of 5 μm; Shimadzu). The mixture of methanol and 0.2% formic acid (1:2, v/v) was used to separate (+)-catechin (280 nm), 6,8-dinitrosocatechin (320 nm), and the oxidation product of quercetin (293 nm), when (+)-catechin and/or quercetin were reacted with nitrous acid. When 6,8-dinitrosocatechin was reacted with nitrous acid with and without quercetin, the mixture of methanol and 0.2% formic acid (2:5, v/v) was used as the mobile phase to detect the reaction products. The ratio of 2:1 (v/v) was used to detect quercetin (360 nm) in the above systems. The flow rate of the mobile phases was 1 mL/min. The concentration of each component was estimated from the area under the peak.

Measurements of •NO Production. Nitrite-induced •NO production was studied using a Clark-type electrode at 30 °C with a polarization voltage of −0.7 V.[24−26] The reaction mixture (2.0 mL) contained 50 μM (+)-catechin or 6,8-dinitrocatechin and various concentrations of quercetin in 50 mM KCl−HCl (pH 2.0). Reactions were initiated by the addition of 0.5 mM sodium nitrite after removing air from the reaction mixture by bubbling argon gas. The rate of •NO production was estimated from the slope.

Amounts of •NO produced in the above systems were calibrated by measuring •NO production in ascorbic acid/nitrous acid systems. In the ascorbic acid/nitrous acid system, one molecule of ascorbic acid produces two molecules of •NO under acidic conditions by the following reaction if the concentration of nitrous acid is more than 2 times that of ascorbic acid:[26,27]

$$\text{ascorbic acid} + 2HNO_2 \rightarrow \text{dehydroascorbic acid} + 2^{\bullet}NO + 2H_2O \quad (1)$$

The amount of •NO produced by the addition of 50 μM ascorbic acid in the presence of 0.5 mM sodium nitrite in 50 mM KCl−HCl (pH 2.0) was essentially the same as that of •NO produced by 50 μM NOC 7 in the same buffer, one molecule of which produces two molecules of

•NO,[28] indicating the usefulness of an ascorbic acid/nitrous acid system to calibrate the amounts of •NO produced.

Presentation of Data. Each experiment was repeated 3−8 times. Typical data or means with standard deviations (SDs) are presented in figures and tables. The statistical significance of the difference between groups was evaluated by Student's *t* test.

RESULTS AND DISCUSSION

Characterization of Isolated 6,8-Dinitrosocatechin. Liquid chromatography−mass spectrometry (LC−MS) analysis of the isolated dinitrosocatechin gave two peaks (**3a** and **3b**) (Figure 1) with retention times of 2.1 and 3.4 min, respectively. Their APCI mass spectra were the same. Compound **3a** at *m/z* (relative intensity, %): 123.1 (39), 270.1 (28), 285.1 (25, $[315.1 - NO]^+$), 286.1 (38), 315.1 (100, $[349.1 - (OH)_2]^+$), 331.1 (30, $[M - OH]^+$), and 349.1 (32, $[M + H]^+$) with positive-ion mode or at *m/z* 153.0 (43), 180.1 (72), 196.0 (98), 311.1 (52), 313.1 (97, $[347.1 - (OH)_2]^-$), 331.1 (46, $[M - OH]^+$), and 347.1 (100, $[M - H]^-$) with negative-ion mode. Compound **3b** at *m/z* (relative intensity, %): 123.1 (43), 270.0 (23), 285.1 (24, $[315.1 - NO]^+$), 286.1 (35), 315.1 (100, $[349.1 - (OH)_2]^+$), 331.1 (23, $[M - OH]^+$), and 349.1 (31, $[M + H]^+$) with positive-ion mode or *m/z* 153.0 (45), 180.1 (81), 196.0 (87), 311.1 (62), 313.1 (90, $[347.1 - (OH)_2]^-$), 331.1 (33, $[M - OH]^-$), and 347.1 (100, $[M - H]^-$) with negative-ion mode, suggesting that compounds **3a** and **3b** are dinitrosocatechin isomers. This was supported by the result that compound **3b** was produced when (−)-epicatechin was incubated with nitrite in 50 mM KCl−HCl (pH 2.0), the production of which was confirmed by the retention time and ultraviolet/visible (UV/vis) absorption spectrum. The mutual transformation of these dinitroso compounds has been reported.[15] Furthermore, each peak showed a fragment ion at *m/z* 123.1 with positive mode, corresponding to a B-ring fragment of catechin. This supports that the B ring of each compound is not modified.[15,29] The major fragment ion at *m/z* 196.0 with negative mode suggests that two NO groups could add to the A ring of catechins.

The chemicals structures of compounds **3a** and **3b** were supported by NMR data. ^{1}H NMR data indicated that isolated dinitrosocatechin was a mixture of 6,8-dinitrosocatechin and 6,8-dinitrosoepicatechin. ^{1}H NMR (DMSO-d_6) δ: 2.38 (dd, J = 7 and 18 Hz, 2/3H, H_c-4_{ax}), 2.50 (dd, J = 4 and 18 Hz, 2/3H, H_c-4_{eq}), 2.57 (m, 1/3H, H_e-4_{ax}), 2.67 (dd, J = 4 and 18 Hz, 1/3H, H_e-4_{eq}), 4.00 (m, 2/3H, H_c-3), 4.13 (m, 1/3H, H_e-3), 4.95 (d, J = 6 Hz, 2/3H, H_c-2), 5.07 (s, 1/3H, H_e-2), 5.34 (br s, 1H, 4-O*H*), 6.62 (dd, J = 1 and 8 Hz, 2/3H, H_c-6′), 6.63 (m, 1/3H, H_e-5′), 6.71 (s, 1/3H, H_e-6′), 6.72 (s, 2/3H, H_c-2′), 6.73 (d, J = 8 Hz, 2/3H, H_c-6′), 6.93 (s, 2/3H, H_e-2′), 8.92 (br s, 1H, O*H*), and 9.00 (br s, 1H, O*H*), where H_c is a proton signal from catechine and H_e is a proton signal from epicatechin. No signals assigned to H bound to C6 and C8 were detected, which were observed in (+)-catechin and (−)-epicatechin.[15,30] This supported that nitrosation took place on the C6 and C8 positions of the A ring. Nitrosation on the A ring is consistent with the previous reports, which concerned the nitrosation of epicatechin and epigallocatechiin gallate by nitrous acid.[15,16] The presence of 6,8-dinitrosocatechin (**3a**) and 6,8-dinitrosoepicatechin (**3b**) in the isolate was further supported by the order of elution, because catechin eluted earlier than epicatechin in reversed-phase columns.[31]

Reaction of (+)-Catechin with Nitrous Acid. When (+)-catechin (retention time of 5.4 min) was reacted with nitrite under the conditions of simulating the gastric lumen, a component with a retention time of 5.2 min was detected by analytical HPLC (top panels of Figure 2). The component had

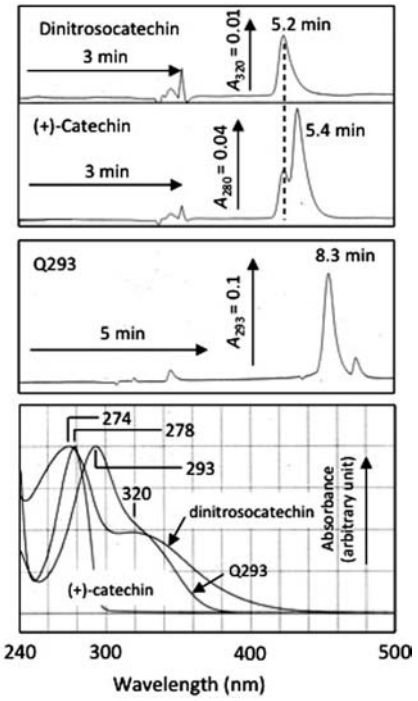

Figure 2. Formation of dinitrosocatechin and an oxidation product of quercetin, Q293. The reaction mixture that contained 0.1 mM sodium nitrite and 0.1 mM (+)-catechin or quercetin in 50 mM KCl−HCl (pH 2.0) was incubated for 5 min. (Top) (+)-Catechin and dinitrosocatechin. (Middle) Q293. (Bottom) Absorption spectrum of each peak in the mobile phase (methanol and 0.2% formic acid = 1:2, v/v).

an absorption peak at 274 nm with a shoulder at 320 nm (bottom panel of Figure 2). The retention time and absorption spectrum were identical to those of isolated 6,8-dinitrosocatechin under the conditions of Figure 2, and its formation increased with the increase in the concentration of sodium nitrite from 0 to 1 mM. It has been reported that dinitrosocatechin and dinitrosoprocyanidin B2 are formed when the methanol extract of apple fruit is incubated with acidified saliva (pH 2.0) that contains 0.4 mM nitrite.[32]

Figure 3A shows a time course of nitrite-induced formation of 6,8-dinitrosocatechin from (+)-catechin. The concentration increased nearly linearly during the incubation for 10 min. Figure 3A also shows a time course of (+)-catechin consumption. Because (+)-catechin was not completely separated from 6,8-dinitrosocatechin, the concentration of (+)-catechin was estimated by subtracting the area of 6,8-dinitrosocatechin at 280 nm, which was determined from the area of dinitrosocatechin at 320 nm, from the area of both components at 280 nm (Figure 2). Time courses of the formation of 6,8-dinitrosocatechin and the consumption of (+)-catechin indicate that the yield of 6,8-dinitrosocatechin was approximately 30% in molar ratio. The rate constant of (+)-catechin consumption was calculated from data of (+)-catechin consumed during 2 min of incubation, postulating that 1 mol of (+)-catechin reacted with 1 mol of nitrous acid, producing •NO and the (+)-catechin semiquinone radical as follows:

dx.doi.org/10.1021/jf500860s | J. Agric. Food Chem. 2014, 62, 4951−4959

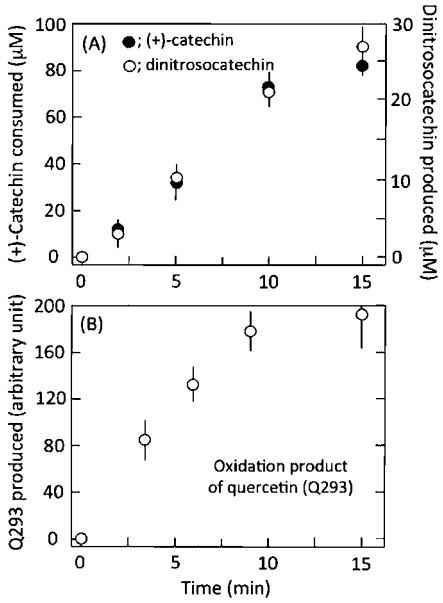

Figure 3. Time courses of the formation of reaction products of (+)-catechin and quercetin under aerobic conditions. The reaction mixture (1 mL) contained 0.1 mM (+)-catechin or 0.1 mM quercetin and 0.1 mM sodium nitrite in 50 mM KCl–HCl (pH 2.0). (A) Formation of dinitrosocatechin: (●) (+)-catechin consumption and (○) dinitrosocatechin formation. (B) Formation of the oxidation product of quercetin, Q293. Each data point represents the mean with SD (n = 3).

$$(+)\text{-catechin} + HNO_2 \rightarrow (+)\text{-catechin radical} + {}^{\bullet}NO + H_2O \quad (2)$$

The value was $(6.7 \pm 1.0) \times 10^2$ M^{-1} min^{-1} (n = 4). Nitrite-induced formation of the semiquinone radical of (+)-catechin has been reported under the conditions that simulate the gastric lumen,[14] and the unpaired electron is localized in the A ring of the (+)-catechin semiquinone radical.[23] The localization of the unpaired electron suggests that $^{\bullet}NO$ produced by reaction 2 can bind to the A ring of the semiquinone radical, generating mononitrosocatechin, and then mononitrosocatechin is oxidized in the A ring to react with $^{\bullet}NO$, generating 6,8-dinitrosocatechin as follows:

$$(+)\text{-catechin radical} + {}^{\bullet}NO \rightarrow NO\text{–catechin} \quad (3)$$

$$NO\text{–catechin} + HNO_2 \rightarrow NO\text{–catechin radical} + {}^{\bullet}NO + H_2O \quad (4)$$

$$NO\text{–catechin radical} + {}^{\bullet}NO \rightarrow diNO\text{–catechin} \quad (5)$$

In the above reactions, NO–catechin and diNO–catechin are mononitrosocatechin and 6,8-dinitrosocatechin, respectively. The formation of mononitrosocatechin in catechins/nitrous acid systems[15] and the reactions of $^{\bullet}NO$ with phenoxyl radicals[33] have been reported. Hypochlorous-acid-induced formation of 6,8-dichlorocatechins from catechins[34] supports the localization of unpaired electrons in the A ring of catechins. Panzella et al.[16] have reported the formation of 6,8-dinitroepigallocatechin-3-*O*-gallate in (−)-epigallocatechin-3-*O*-gallate/nitrous acid systems, and they proposed the reaction of epigallocatechin-gallate quinone with nitrous acid as the mechanism of 6,8-dinitrosoepicatechin-3-*O*-gallate formation. If $^{\bullet}NO$ was produced by reactions 2 and 4 under the conditions in Figure 3, namely, aerobic conditions, $^{\bullet}NO_2$ should be formed as follows ($k = 8.8 \times 10^6$ M^{-2} s^{-1}):[35]

$$2{}^{\bullet}NO + O_2 \rightarrow 2{}^{\bullet}NO_2 \quad (6)$$

$^{\bullet}NO_2$ may oxidize (+)-catechin and nitrosocatechins, producing their semiquinone radicals.

Oxidation of Quercetin by Nitrous Acid. The oxidation product of quercetin, which was referred to as Q293 in this study, had a retention time of 8.3 min in the mobile phase, and the absorption spectrum had a peak at 293 nm, with a shoulder around 320 nm (middle and bottom panels of Figure 2). We have reported the formation of the component in the acidic mixture of quercetin and nitrite[13] and determined its structure to be 2-(3,4-dihydroxybenzoyl)-2,4,6-trihydroxy-3(2*H*)-benzofuranone (**4**).[17] Figure 3B shows time courses of nitrite-induced formation of Q293 from 0.1 mM quercetin in 50 mM KCl–HCl (pH 2.0). The concentration of Q293 increased nearly linearly during incubation at least for 3 min, and the rate increased with the increase in the concentration of nitrite from 0 to 1 mM.

Reaction of Dinitrosocatechin with Nitrous Acid. Isolated 6,8-dinitrosocatechins (0.1 mM) were incubated with 0.1 mM nitrite for 5 min in 50 mM KCl–HCl (pH 2.0), and the reaction mixture was analyzed by HPLC (top panel of Figure 4). Two new components, P1 and P2, were detected, and their absorption peaks (270 nm) were shorter than those of compounds **3a** and **3b** (274 nm) (middle panel of Figure 4). The bottom panel of Figure 4 shows time courses of 6,8-dinitrosocatechin (**3a** plus **3b**) consumption and P1 and P2 formation. The formation of P1 slowed down more rapidly than that of P2, and the amount of P1 produced was smaller compared to that of P2, suggesting that P1 and P2 were formed from compounds **3b** and **3a**, respectively. The rate constant of the consumption of 6,8-dinitrosocatechin (**3a** plus **3b**) was calculated from the decrease in the concentration during 2 min of incubation. The value was $(6.5 \pm 2.5) \times 10^2$ M^{-1} min^{-1} (n = 4) under the postulation of the following reaction:

$$diNO\text{–catechin} + HNO_2 \rightarrow diNO\text{–catechin radicals} + {}^{\bullet}NO + H_2O \quad (7)$$

In addition to HNO_2, $^{\bullet}NO_2$ produced by reaction 6 can also oxidize dinitrosocatechins to the semiquinone radicals.

Because dinitrosocatechins have a catechol structure in the B ring, it is expected that the semiquinone radicals of dinitrocatechins are transformed to *o*-quinones by disproportionation. If components of P1 and P2 were quinones, the peaks should disappear by ascorbic acid.[36] In fact, when 2 mM ascorbic acid was added to the reaction mixture that had been incubated for 5 min under the conditions of Figure 4, peaks P1 and P2 disappeared, accompanying the increase in peak heights of compounds **3a** and **3b** to the original heights. This result supports the postulation that P1 and P2 are quinone forms of 6,8-dinitroscatechin and 6,8-dinitrosoepicatechin. Nitrous-acid-induced formation of quinone of dinitrosoepigallocatechin-3-*O*-gallate has been reported.[16]

o-Quinones of polyphenols, such as caffeic acid, chlorogenic acid, and rutin, react with thiocyanate at pH 2.0, producing thiocyanate conjugates, which are transformed to the oxathiolone derivatives by the addition of water and removal of ammonia.[37−39] Then, the effects of sodium thiocyanate on the formation of P1 and P2 were studied at pH 2.0.

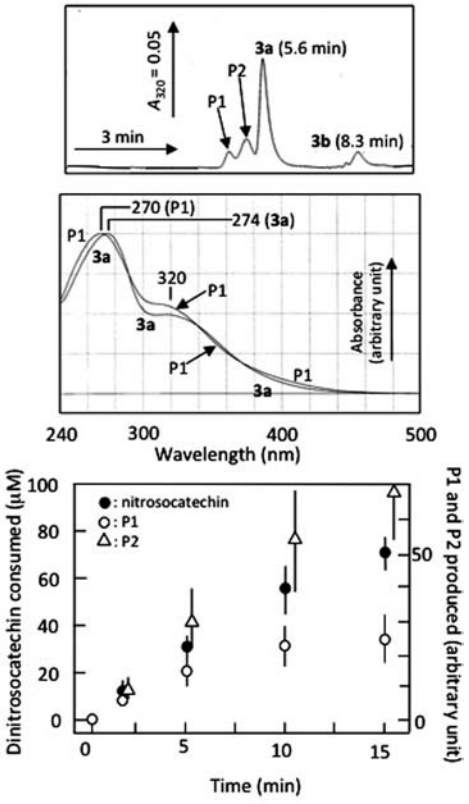

Figure 4. Reactions of dinitrosocatechin with nitrous acid. The reaction mixture (1 mL) contained 0.1 mM isolated dinitrosocatechin and 0.1 mM sodium nitrite in 50 mM KCl–HCl (pH 2.0). (Top) HPLC of reaction products of dinitrosocatechin at 5 min after initiation. Compound **3a**, 6,8-dinitrosocatechin; compound **3b**, 6,8-dinitrosoepicatechin; and P1 and P2, products of compounds **3b** and **3a**, respectively. Mobile phase, methanol and 0.2% formic acid = 2:5, v/v. (Middle) Absorption spectra of compound **3a** and P1 in the mobile phase. (Bottom) Time courses of (●) dinitrosocatechin (**3a** plus **3b**) consumption and (○) P1 and (△) P2 formation. Each data point represents the mean with SD (n = 3–4).

Thiocyanate (10 mM) suppressed the formation of P1 and P2 in the mixture that contained 0.1 mM dinitrosocatechin and 0.1 mM sodium nitrite in 50 mM KCl–HCl (pH 2.0). In addition, 2–10 mM thiocyanate decreased the concentration of P1 and P2 when added to a reaction mixture, in which P1 and P2 had been produced. These results further support that P1 and P2 were quinones. Two new components (retention times of 3.9 and 5.8 min) were produced in the dinitrosocatechin/thiocyanate/nitrous acid systems, and their molecular weights were estimated to be 405 by LC–MS, suggesting that the components were thiocyanate conjugates of 6,8-dinitrosocatechin and 6,8-dinitrosoepicatechin.

Interactions between (+)-Catechin and Quercetin. Figure 5 shows effects of 0.1 mM (+)-catechin on the formation of Q293 in the presence of various concentrations of quercetin. The formation of Q293 increased with the increase in the concentration of quercetin in the absence of (+)-catechin, when the concentration of Q293 was determined 2 min after the initiation of reactions (○). (+)-Catechin enhanced the production of Q293 independent of the quercetin concentration, and the enhancement in the presence of 10 and 30 μM quercetin was about 1.8-fold (□). The above result indicates that (+)-catechin can enhance the oxidation of quercetin. 6,8-Dinitrosocatechin was produced irrespective of

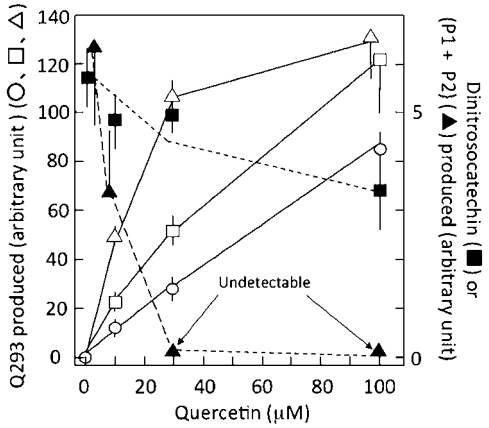

Figure 5. Interactions between quercetin and (+)-catechin or dinitrosocatechin. The reaction mixture (1 mL) that contained 0.1 mM sodium nitrite and 0.1 mM (+)-catechin or dinitrosocatechin in 50 mM KCl–HCl (pH 2.0) was incubated for 2 min. (Left vertical axis) Enhancement of Q293 production by catechin and dinitrosocatechin: (○) no addition, (□) (+)-catechin, (△) dinitrosocatechin. (Right vertical axis) Inhibition of the production of dinitrosocatechin and P1 + P2 by quercetin: (■) production of dinitrosocatechin from (+)-catechin and (▲) production of (P1 + P2) from dinitrosocatechin. Each data point represents the mean with SD (n = 3–4).

the presence and absence of quercetin, and 50 μM quercetin inhibited its production by about 60% (■). The concentration of (+)-catechin decreased during the formation of dinitrosocatechin, but the effects of quercetin on the decrease in the (+)-catechin concentration were unclear. The unclearness might be due to the small decrease in the (+)-catechin concentration during 2 min of incubation (see Figure 3) and/or quercetin-dependent preferential reduction of the mononitrosochatechin semiquinone radical rather than the (+)-catechin semiquinone radical for the inhibition of dinitrosocatechin formation.

The effects of (+)-catechin on the nitrous-acid-induced decrease in the concentration of quercetin are shown in Table 1. From the data in the absence of (+)-catechin, the rate constant of the reaction between quercetin and nitrous acid was calculated, postulating the following reaction:

$$\text{quercetin} + HNO_2 \rightarrow \text{quercetin radical} + {}^{\bullet}NO + H_2O \quad (8)$$

Table 1. Enhancement of Nitrite-Induced Quercetin Oxidation by (+)-Catechin and 6,8-Dinitrosocatechin[a]

	quercetin concentration after 2 min of incubation (μM)	
initial concentration of quercetin (μM)	10	30
no addition	7.7 ± 0.7 (n = 6)	19.6 ± 1.3 (n = 6)
(+)-catechin	3.3 ± 0.1 (n = 3)[b]	16.5 ± 1.8 (n = 3)[b]
6,8-dinitrosocatechin	2.9 ± 1.8 (n = 3)[b]	7.2 ± 2.3 (n = 3)[b]

[a]The reaction mixture (1 mL) that contained 0.1 mM sodium nitrite and 10 or 30 μM quercetin in 50 mM KCl–HCl (pH 2.0) in the presence and absence of 0.1 mM (+)-catechin or 6,8-dinitrosocatechin was incubated for 2 min. The quercetin concentration of the reaction mixture was determined by HPLC. Each data point represents the mean with SD (n = 3). [b]Significant differences in quercetin oxidation with and without the addition of (+)-catechin or 6,8-dinitrosocatechin (p < 0.05).

	(Formation of P1 and P2, Arbitrary Units)			
50 μM diNO−CAT	14 ± 3	7 ± 2[b]	c	c

[a]The reaction mixture (2 mL) contained 0, 5, 15, or 50 μM quercetin in 50 mM KCl−HCl (pH 2.0) in the presence and absence of 50 μM (+)-catechin or dinitrosocatechin. Reactions were initiated by the addition of 0.25 mM sodium nitrite, and the concentrations of reactants and products were determined at 1 min after the initiation of reactions. diNO−CAT = 6,8-dinitrosocatechin. Each data point represents the mean with SD (n = 3−6). [b]Significant differences in the decrease and increase in concentrations of quercetin and Q293, respectively, in the absence and presence of catechin or dinitrosocatechin and significant differences in the formation of diNO−CAT and formation of P1 and P2 in relation to the absence of quercetin (p < 0.05). [c]Below detection.

The value was (15.0 ± 3.6) × 10^2 M^{-1} min^{-1} (n = 6), which was about 2.2-fold the rate constants of the reactions between nitrous acid and (+)-catechin and between nitrous acid and 6,8-dinitrosocatechin (see above). The decrease in the concentration of quercetin was enhanced by 0.1 mM (+)-catechin by about 2.9- and 1.5-fold when the initial concentrations of quercetin were 10 and 30 μM, respectively. The degree of the enhancement was somewhat greater than that of the enhancement of Q293 formation by 0.1 mM (+)-catechin. (+)-Catechin-dependent enhancement of the quercetin consumption in nitrous acid/quercetin systems was observed in a concentration range of nitrite from 0.05 to 0.7 mM, suggesting that interactions between (+)-catechin and quercetin can occur under the conditions of the gastric lumen. The results in Table 1 and Figure 5 indicate that semiquinone radicals produced by reactions 2 and 4 can oxidize quercetin, enhancing the production of Q293.

Interactions between Dinitrosocatechin and Quercetin. The effects of 0.1 mM 6,8-dinitrosocatechin on the formation of Q293 were also studied in the presence of various concentrations of quercetin (Figure 5). Dinitrosocatechin enhanced the formation of Q293, and the enhancement was about 4-fold in the presence of 10 and 30 μM quercetin (△). The production of P1 and P2 was effectively suppressed by quercetin, and 50% inhibition was observed at approximately 10 μM quercetin (▲). Table 1 shows the enhancement of nitrous-acid-induced oxidation of quercetin by 0.1 mM 6,8-dinitrosocatechin. The degrees of the enhancement were about 3.1- and 2.3-fold in the presence of 10 and 30 μM quercetin, respectively. The results in Table 1 and Figure 5 suggest that the dinitrosocatechin semiquinone radical generated by the reaction with nitrous acid (reaction 7) can oxidize quercetin, suppressing the formation of dinitrosocatechin quinones and enhancing the formation of Q293.

•NO Production under Anaerobic Conditions. Table 2 shows the rate of nitrous-acid-induced •NO production determined using a Clark-type electrode under anaerobic conditions. When 50 μM quercetin, (+)-catechin, or 6,8-dinitroscatechin was present in the reaction mixture, the rate of •NO production was in the order (+)-catechin < 6,8-dinitrosocatechin < quercetin. Such order of •NO production in a system simulating gastric lumen has been reported.[40] The faster •NO production in the presence of quercetin compared to the presence of dinitrosocatechin could be explained by the difference in their reaction rate with nitrous acid (see above), and the much slower •NO production in the presence of (+)-catechin might be due to the reaction of semiquinone radicals derived from (+)-catechin with •NO by reactions 3 and 5.

The rate of nitrous-acid-induced •NO production increased nearly linearly as a function of the quercetin concentration. In the presence of 50 μM (+)-catechin, however, quercetin did not increase the rate of •NO production as expected from the rate in the absence of (+)-catechin, when the concentration of

quercetin was 5 μM. In the presence of 15 and 50 μM quercetin, quercetin increased the rate of $^{\bullet}$NO production significantly. These results support the postulation that semiquinone radicals of (+)-catechin and mononitrosocatechin can react with not only quercetin but also $^{\bullet}$NO produced by quercetin/nitrous acid systems and suggest that the rate of $^{\bullet}$NO consumption was limited by the rate of production of semiquinone radicals of (+)-catechin and mononitrosocatechin by reactions 3 and 5. 6,8-Dinitrosocatechin (50 μM) increased $^{\bullet}$NO production almost additively or more than additively at every concentration of quercetin examined. The result indicates that the reaction of $^{\bullet}$NO with the semiquinone radical of 6,8-dinitrosocatechin will be slow or negligible, supporting the above conclusion that the radical will react rapidly with quercetin. Under the conditions of Table 2, N_2O_3 generated by reaction 9[41] appears not to contribute to the formation of dinitrosocatechin, because $^{\bullet}$NO production by reaction 9 was quite slow (less than 1 μM/min in the presence of 0.5 mM sodium nitrite).

$$2HNO_2 \leftrightarrows N_2O_3 + H_2O \leftrightarrows {}^{\bullet}NO + {}^{\bullet}NO_2 + H_2O \quad (9)$$

Nitrosonium cation (NO^+) formed by reaction 10[41] might not contribute significantly, either, to the formation of dinitrosocatechin.

$$HNO_2 + H^+ \leftrightarrows H_2NO_2{}^+ \leftrightarrows NO^+ + H_2O \quad (10)$$

If NO^+ contributed to the nitrosation, 5 μM quercetin should increase the rate of $^{\bullet}$NO production in the presence of (+)-catechin, effectively inhibiting the formation of dinitrosocatechin, because quercetin might reduce NO^+ to $^{\bullet}$NO.

Interactions between Quercetin and (+)-Catechin or Dinitrosocatechin under Anaerobic Conditions. The interactions between quercetin and (+)-catechin or 6,8-dinitrosocatechin were also studied under anaerobic conditions (Table 3). (+)-Catechin (50 μM) and 6,8-dinitrosocatechin (50 μM) enhanced a nitrous-acid-induced decrease in the concentration of quercetin and the formation of Q293, irrespective of the concentration of quercetin. The results indicate that quercetin also interacted with (+)-catechin and dinitrosocatechin under anaerobic conditions. The interaction between quercetin and (+)-catechin is supported by the suppression of nitrous-acid-induced formation of 6,8-dinitrosocatechin by quercetin, and the interaction between quercetin and dinitrosocatechin is supported by the suppression of P1 and P2 formation by quercetin. Although the concentrations of (+)-catechin decreased by about 4 μM during the incubation for 1 min, effects of quercetin on the decrease in the concentration were unclear, similar to under aerobic conditions, supporting the slower reaction of the (+)-catechin semiquinone radical with quercetin than with NO. From the data in Tables 1 and 3 and Figure 5, we could conclude that the interactions between quercetin and (+)-catechin or 6,8-dinitrosocatechin were possible under semi-anaerobic conditions, such as the gastric lumen.

Possibility of Interactions between Catechins and Quercetin in the Stomach. The reactions concerned in this study are summarized in Figure 6. The (+)-catechin semiquinone radical generated by the reaction of (+)-catechin with nitrous acid will react effectively with $^{\bullet}$NO, producing mononitrosocatechin. The reaction of the semiquinone radical with quercetin will not be rapid enough to suppress nitrous-acid-induced consumption of (+)-catechin (represented as broken lines). Mononitrosocatechin also reacts with nitrous acid, producing the semiquinone radical, which can react with both $^{\bullet}$NO and quercetin, producing dinitrosocatechin and the quercetin semiquinone radical, respectively. The quercetin semiquinone radical generated by the above reactions is rapidly transformed to Q293 via the quercetin quinone form.[12,42] Q293 has been reported to decompose to more stable 2,4,6-trihydroxyphenylglyoxylic acid and 3,4-dihydroxybenzoic acid by oxidation.[17] Dinitrosocatechin produced by the above reactions also reacts with nitrous acid producing $^{\bullet}$NO and the semiquinone radical that can be transformed to quinone by disproportionation.

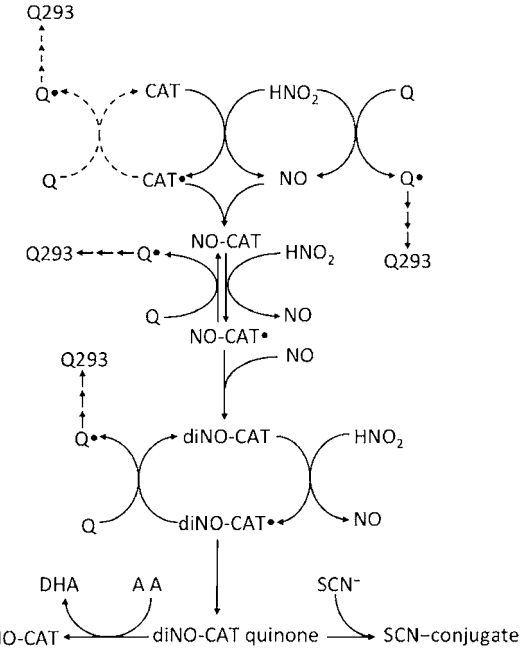

Figure 6. Possible interactions among quercetin, (+)-catechin, and 6,8-dinitrosocatechin. AA, ascorbic acid; DHA, dehydroascorbic acid; CAT and CAT$^{\bullet}$, (+)-catechin and its semiquinone radical; diNO−CAT and diNO−CAT$^{\bullet}$, 6,8-dinitrosocatechin and its semiquinone radical; diNO−CAT−quinone, quinone form of diNO−catechin; NO−CAT and NO−CAT$^{\bullet}$, mononitrosocatechin and its semiquinone radical, Q and Q$^{\bullet}$, quercetin and its semiquinone radical; Q293, an oxidation product of quercetin. Broken lines = slow reactions.

The molar ratios of (+)-catechin to quercetin glycosides were calculated to be about 0.7 and 0.5 in apple and buckwheat flour, respectively, and the ratios of (−)-epicatechin to quercetin glycosides were calculated to be about 3.2 and 3.5 in apple and buckwheat flour, respectively.[3,4] Because parts of quercetin glycosides from foods are hydrolyzed in the oral cavity, as described in the Introduction,[6−8] quercetin can coexist with (−)-epicatechin as well as (+)-catechin in gastric juice. There are no differences in the rate constants between (+)-catechin and (−)-epicatechin when these polyphenols react with superoxide anion radicals and singlet molecular oxygen,[23] and the antioxidant activity of (+)-catechin is equivalent to that of (−)-epicatechin when measured using the 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid cation radical ($ATBS^{\bullet+}$) as an oxidant.[43] Furthermore, 6,8-dinitorosoepicatechin produced in (−)-epicatechin/nitrous acid systems isomerizes to 6,8-dinitrosocatechin.[15] We can postulate from the results that (−)-epicatechin as well as (+)-catechin can interact with quercetin in the presence of nitrite under acidic conditions, as

dx.doi.org/10.1021/jf500860s | J. Agric. Food Chem. 2014, 62, 4951−4959

shown in Figure 6. The postulation was supported by the result that 0.1 mM (−)-epicatechin enhanced nitrite-induced oxidation of 10, 30, and 100 μM quercetin, increasing the formation of Q293 in 50 mM KCl−HCl (pH 2.0) under aerobic and anaerobic conditions.

It has been reported that (i) catechins can suppress nitrous-acid-induced *N*-nitrosodimethylamine formation from dimethylamine producing dinitrosocatechins and (ii) dinitrosocatechins induce toxic effects in Caco-2 cells, which are cultured colon carcinoma cells.[15] On the other hand, it is known that quinones are toxic because of their generation of reactive oxygen species and binding to DNA.[44] Thus, quercetin has an important function to prevent the formation of reactive quinone from the dinitrosocatechin semiquinone radical. In addition to quercetin, ascorbic acid in gastric juice may also prevent the formation of quinones by reducing corresponding radicals (not shown in Figure 6). If dinitrosocatechin quinone is produced in the stomach, ascorbic acid in gastric juice can reduce quinone to the mother compound and salivary thiocyanate can transform quinone to a stable thiocyanate conjugate.[37−39]

Although there are some systems to scavenge the quinones of dinitrosocatechins in the gastric lumen, it is beneficial if the formation of the quinones is prevented. Quercetin and ascorbic acid are candidates to prevent the formation of quinones in the gastric lumen. Thus, it seems to be favorable to ingest foods rich in components, which reduce semiquinone radicals derived from mononitrosocatechins and dinitrosocatechins, to prevent the formation of toxic quinones. In this way, the clarification of chemical interactions among polyphenols under the conditions simulating the stomach may be important to prepare foods that are beneficial for human health.

Steinheim, Germany); sodium chloride (Carl Roth GmbH, Karlsruhe, Germany); β-ionone (Sigma-Aldrich, Steinheim, Germany); and NMR solvents (ARMAR Chemicals, Döttingen, Switzerland). Methanol and methyl *tert*-butyl ether as HPLC solvents were purchased from Sigma-Aldrich (HPLC grade ≥99.8%). All-*trans*-β-carotene (97% isomeric purity) was purchased from Sigma-Aldrich (Taufkirchen, Germany) and all-*trans*-lutein (95% isomeric purity) from Carl Roth GmbH.

Spinach Samples. Four different sets of spinach samples were considered during this study. In cooperation with the Leibniz Institute of Plant Biochemistry (Halle, Germany) a first set (varieties 'Bella' and 'Matador') was cultivated under greenhouse conditions from August to November 2012. A light period of 8 h was chosen to simulate short-day conditions. During this period a temperature of 22 °C and a relative humidity of 70% were adjusted. Electric illumination was performed by Cool Daylight lamps (Osram, 36 W/965). Temperature was regulated down to 15 °C during the dark phase (16 h) at the same humidity. Sampling started after 9 weeks (leaf size between 8 × 4 and 12 × 7 cm) and ended after 12 weeks of cultivation. In a second set spinach of both varieties was cultivated under field-grown conditions near Halle (Germany) at the same time. Additionally, spinach of the variety 'Matador' was cultivated during spring (from March to May) and summer (from June to August) in 2012. The other two sets were commercial samples from local markets and food stores. Altogether 37 samples of fresh spinach (origin Italy and Germany) and 43 samples of frozen spinach were collected. All samples were stored at −32 °C until processing.

Sample Preparation. Preparation of spinach was performed according to prior studies,[16] where the extraction method was adopted from Sadler et al.[17] Fresh or frozen material was cut into small slices first. Per sample about 15 g of spinach homogenate was filled into Falcon tubes and stored at −21 °C, followed by freeze-drying. Dry plant materials were extracted overnight with 150 mL of hexane/ethanol/acetone (2:1:1, v/v/v) containing 0.01% BHT by shaking with an orbital shaker (ca. 170 rpm) at room temperature under exclusion of light. For saponification of fatty compounds and an effective removal of interfering chlorophylls the organic extracts were treated with 15 mL of 10% methanolic potassium hydroxide solution and were shaken overnight at room temperature after saturation with argon to avoid oxidative degradation of carotenoids.[14,18] The alkaline extracts were washed five times with 60 mL of a 2% sodium chloride solution. Aliquots of the resulting carotenoid extracts (2 mL) were dried under argon and dissolved in 1 mL of mobile phase (methanol/MTBE, 50:50).

Sample preparation was performed under reduced light using amber glassware, and the temperature never exceeded 25 °C to avoid isomerization processes induced by light or temperature.

Analytical HPLC-UV and HPLC-DAD. The HPLC method was developed and optimized on the basis of studies of Fang et al.[19] A Jasco PU-2089 Plus quaternary gradient unit pump with a degasser and a Jasco AS-2055 Plus autosampler (Gross-Umstadt, Germany) were used. Elution of materials was monitored by a Jasco UV-2075 Plus UV-detector operating at 450 nm. For DAD analyses a Jasco MD-2015 Plus detector was used. Chromatographic separations were performed on a RP-C30 column (5 μm, 250 × 4.0 mm, YMC Europe, Dinslaken, Germany) connected to a C30 guard column (5 μm, 10 × 4.0 mm, YMC Europe) using a flow rate of 0.65 mL min^{-1}. Chosen column temperature was 20 °C. The mobile phase used consisted of methanol (solvent A) and methyl *tert*-butyl ether (solvent B). Samples were injected at 40% B (held for 5 min) followed by a gradient that changed to 52% B in 15 min. The gradient then changed to 100% B in 5 min (held for 10 min) and to 40% B in 5 min (held for 10 min).

Analytical HPLC-MS^2. A Jasco PU-2080 Plus quaternary gradient pump with degasser and a Jasco AS-2057 Plus autosampler were used. The RP-C30 column and HPLC gradient program used were the same as for HPLC-UV measurements. Elution of carotenoids was monitored by mass detection. The mass analyses were performed using an Applied Biosystems API 4000 quadrupole instrument (Applied Biosystems, Foster City, CA, USA) equipped with an API source using an atmospheric pressure chemical ionization (APCI, negative mode) interface. The LC system was connected directly to the probe of the mass spectrometer. Nitrogen was used as sheath and auxiliary gas. β-Carotene isomers were detected at 536.7 amu in Q1 (DP −60 V, no fragments in Q3).

Synthesis of Authentic β-Carotene Standards. In contrast to the literature 15-*cis*-β-carotene was synthesized via a C_{15} + C_{10} + C_{15} route.[20] Thus, C_{15}-Wittig salts were generated according to the method of Hengartner et al. using β-ionone as the starting compound instead of pseudoionone.[21] The central compound, 2,7-dimethylocta-2,6-dien-4-yne-1,8-dial, was assembled according to the method of Isler et al. and was directly coupled to the Wittig salts.[20] After Lindlar hydrogenation, the 15,15′-dehydro-β-carotene was transferred to 15-*cis*-β-carotene (ca. 27 mg) with an isomeric purity of 90% (HPLC-UV). 9-*cis*-β-Carotene was generated by coupling 9-*cis*-retinal and all-*trans*-retinyl-Wittig salt. First, the C_{20}-Wittig salt was generated according to the method of Britton et al. starting with commercially available all-*trans*-retinal (Sigma-Aldrich, Taufkirchen, Germany).[22] The second precursor, 9-*cis*-retinal, was obtained after reduction of 9-*cis*-retinyl ethyl ester, which was synthesized according to the literature.[23−26] Conventional Wittig condensation resulted in 20 mg of 9-*cis*-β-carotene with an isomeric purity of 71% (HPLC-UV). All structures were established by their NMR data (^{1}H; ^{13}C; H,H−COSY; HSQC; HMBC).

Irradiation Model Systems. Various model systems were established to simulate different light conditions during the cultivation of spinach. The influence of daylight on isomerization of carotenoids was simulated by irradiation of all-*trans*-β-carotene with a halogen lamp, thus mimicking field-growing conditions. On the other hand, different optical filters, which are impermeable below specific wavelengths, were interposed between standard solution and halogen lamp to imitate light conditions during greenhouse cultivation. A 550 nm filter was used to simulate illumination with a sodium vapor lamp, which is commonly used for cultivation in greenhouses, because natural sunlight does not suffice to harvest spinach during winter months. The wavelength spectrum of these lamps is optimized for photosynthesis; that is, they emit almost no light in the range of 250−550 nm. Growing spinach under greenhouse conditions without the use of additional sources of light was simulated by interposing a 420 nm filter. PE foils, PMMA sheets, or glass are typical materials that are used for cultivation in greenhouses. These materials cause a light permeability of <90%, which in cultivation depends additionally on the level of contamination, roof pitch, and deterioration. Light with wavelengths below 400 nm is efficiently blocked by these materials.[27] All-*trans*-β-carotene solutions (21 μM in hexane) were irradiated for defined periods of time (5, 10, 15, 20, 30, 60, 120, 180, and 240 min). Aliquots (500 μL) were dried afterward under argon stream. Residues were taken up in 400 μL of mobile phase (methanol/MTBE, 50:50) to adjust final concentrations to 26 μM (according to spinach samples) followed by HPLC-UV analyses. The isomeric composition was determined by integration of all identified β-carotene peaks first. Then the areas of the separate peaks were divided by the sum of all β-carotene values to express the percentage of the respective β-carotene concentration. Contents of β-carotene (including all isomers) were calculated on the basis of the external linear calibration of all-*trans*-β-carotene standard at its wavelength maximum of 450 nm.

Thermal Treatment. Concentrated all-*trans*-β-carotene solutions were stirred at 65 °C in amber glass vials, and aliquots of 500 μL were sampled after 5, 10, 15, 30, 60, 120, 180, and 240 min. HPLC-UV analyses were performed after the samples were dried and dissolved in mobile phase (400 μL). This experiment showed differences from photoinduced isomerization processes and allowed the exclusion of thermal-induced artifacts during the extraction method.

Blanching of Fresh Spinach. Fresh spinach leaves (ca. 5 g per sample) were immersed into boiling water for a period of 0.5, 1, 2, 3, 5, or 10 min. Treated samples were immediately quenched on ice water. Sample preparation was as described above.

Nuclear Magnetic Resonance Spectroscopy (NMR). NMR spectra were recorded on a Varian VXR 400 spectrometer operating at 400 MHz for ^{1}H and at 100 MHz for ^{13}C or on a Varian Unity Inova 500 instrument operating at 500 MHz for ^{1}H and at 125 MHz for ^{13}C, respectively.

Statistical Analysis. Analyses of carotenoid concentrations were performed in duplicate for each model system and resulted in coefficients of variation of <5%. All significance tests were performed by two-sample *t* test with a probability value of 99%. The Welch test was used alternatively in one case of differing standard deviations. The same probability value was selected. Confidence intervals were calculated with a probability value of 95%.

RESULTS AND DISCUSSION

Identification of β-Carotene Isomers. HPLC-UV analyses of spinach extracts led to the typical chromatograms shown in Figure 1. The identification was performed first by

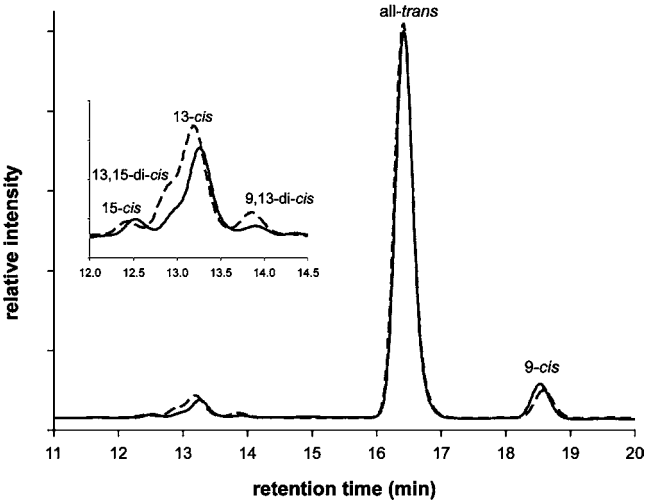

Figure 1. HPLC chromatograms of an authentic field-grown (solid line) and a greenhouse-grown (dashed line) spinach extract. Elution of β-carotene isomers (15-*cis*-β-carotene; 13,15-di-*cis*-β-carotene; 13-*cis*-β-carotene; 9,13-di-*cis*-β-carotene; all-*trans*-β-carotene; 9-*cis*-β-carotene) was monitored by UV detection at 450 nm.

LC/APCI-MS analyses. During negative ion APCI six peaks formed a pseudomolecular ion of *m/z* 536.7, thus verifying them as β-carotene isomers. Absolute configuration was verified by comparison of retention times using authentic references. Besides commercially available all-*trans*-β-carotene, independently synthesized 9-*cis*- and 15-*cis*-β-carotene were used. The remaining isomers were assigned on the basis of their spectral characteristics determined by HPLC-DAD analyses. *Q*-ratios (absorption at the subsidiary "*cis*-peak" divided by the absorption at λ_{max})[28,29] were formed and compared to the literature and thus allowed an identification of 13-*cis*-β-carotene.[30] As expected, our experiments gave the highest *Q*-ratio for 15-*cis*-β-carotene (0.61), followed by 13-*cis* (0.46), 9-*cis* (0.09), and all-*trans* (0.06). In addition, the HPLC elution pattern (Figure 1) was completely comparable to data of Strohschein et al., which identified the two remaining isomers as 13,15-di-*cis*- and 9,13-di-*cis*-β-carotene (exptl *Q*-ratio 0.42) using HPLC−NMR analyses.[31] The presented assignment using various approaches for the identification of β-carotene isomers allowed targeted analyses in the following studies.

Irradiation and Thermal Treatment Model Systems. Model system A simulated illumination conditions during field-grown cultivation. In this case a halogen lamp with a wavelength spectrum close to that of sunlight was used for irradiation (Figure 2A). All-*trans*-β-carotene underwent a strong degradation during the first 30 min of illumination, illustrated by a decrease starting from a concentration of 96.55 to 89.55%. After that, the degradation attenuated and almost reached equilibrium at 85.31%. 13-*cis*- and 15-*cis*-β-carotene showed opposite developments. Both isomers were formed in high yields during the first period of irradiation. 13-*cis*-β-Carotene rose from 2.39 to 6.96%, whereas 15-*cis* reached a concentration of 1.90% starting from 0.24%. Both isomers approximated equilibrium concentrations, too; however, a decrease was observed after full time of illumination (13-*cis*, 6.09%; and 15-*cis*, 1.66%). In contrast, an almost linear formation during the whole period of treatment was observed for 9-*cis*-β-carotene. Its concentration rose from 0.75 to 6.86% (ca. 1.5%/h); thus, 9-*cis* was the predominant *cis*-isomer after photoinduced isomerization. Interestingly, the formation of 9-*cis*-β-carotene was closely associated with degradation of 13-*cis*-β-carotene in the last period of irradiation, when all other isomers showed no appreciable changes anymore. Almost no change was observed for 9,13-di-*cis*-β-carotene, the concentration of which stayed unchanged at about 0.10%. Similar light-induced isomerization progress was observed by O'Neil et al. among others; that is, 13-*cis*- and dominantly 9-*cis*-β-carotene were formed after exposure to white light (24 h).[32] Further illumination yielded only a small increase of 9-*cis*, whereas 13-*cis* slightly decreased. Thus, the observed equilibrium for the 13-*cis* isomer is confirmed by the literature.[11,32]

In contrast, irradiation with limited-wavelength spectra using cutoff filters led to completely different isomerization progressions (Figure 2B,C). Model system B mimicked typical growing conditions under foils or plastic materials, which are impermeable for light under 400 nm. Thus, a 420 nm optical filter was interposed to simulate greenhouse-grown conditions. In comparison to model system A, the isomerization process was significantly suppressed, illustrated by a reduced decrease of all-*trans*-β-carotene to a concentration of just 90.08% (total loss of 6.91%). In the presence of energy-rich light a higher loss of 11.24% was observed before. Formations of 13-*cis*- and 15-*cis*-β-carotene were deferred, too. Their maximal concentrations of 6.00% (13-*cis*) and 1.50% (15-*cis*) were reached after 3 h to form equilibria. Slight decreases at the end of irradiation were detected as well. The concentration of 9-*cis*-β-carotene rose linearly to 2.47%, compared to 6.86% in model system A. Thus, the formation rate was almost 4 times higher in comparison to only 0.4%/h in model system B. The concentration of 9,13-di-*cis*-β-carotene showed no significant change during irradiation again. Although the degradation and formation of all isomers were extenuated, the pattern of isomerization was similar to that of model system A.

A 550 nm cutoff filter was used in model system C (Figure 2C) to simulate growing conditions under electric illumination. Commonly used sodium vapor lamps are designed especially for photosynthesis; that is, they emit only a wavelength range between 550 and 750 nm. Figure 2C illustrates that almost no isomerization occurred during this experiment. All-*trans*-β-carotene decreased to just 94.16%, that is, a total loss of 2.38% compared to 6.91% in model B or 11.24% in model A. 13-*cis*- and 15-*cis*-isomers were formed in only small amounts. Linear increases from 2.39 to 3.61% (13-*cis*) and from 0.24 to 0.60% (15-*cis*) were observed. Similar results were recorded for 9-*cis*-β-carotene, the concentration of which marginally rose to 1.27% starting at 0.75%. In contrast to both other models 9,13-di-*cis*-β-carotene was formed during this experiment. Here, its concentration increased significantly from 0.08 to 0.35%.

In addition, thermal treatment of β-carotene standard solutions was performed to exclude artifacts during extraction

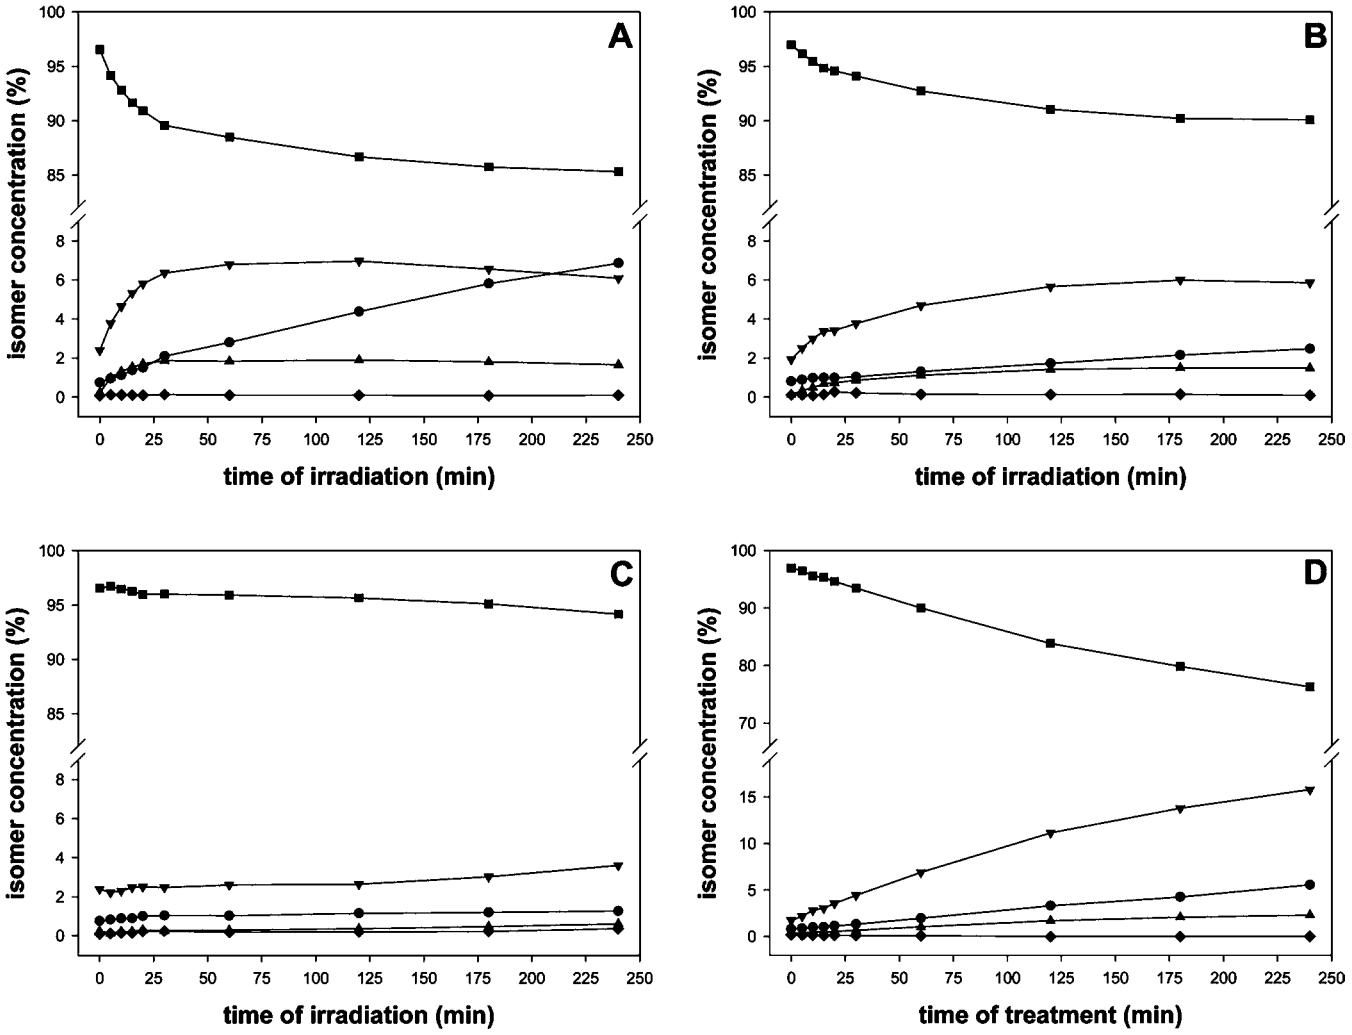

Figure 2. Concentrations of *β*-carotene isomers during irradiation with a halogen lamp over a period of 4 h using no filter (A), a 420 nm filter (B), a 550 nm filter (C), and thermal treatment at 65 °C (D), expressed as percentage of total *β*-carotene concentration (%): 15-*cis*-*β*-carotene (▲); 13-*cis*-*β*-carotene (▼); 9,13-di-*cis*-*β*-carotene (◆); all-*trans*-*β*-carotene (■); 9-*cis*-*β*-carotene (●).

and preparation for analyses. Simultaneous possible crossovers to photoinduced isomerization were clarified in this experiment. Thermal-triggered isomerization (Figure 2D) showed a similar pattern compared to model system B. All-*trans*-*β*-carotene was degraded from 96.97 to 76.31% and thus resulted in the highest decrease during all model systems (total loss of 20.66%). In parallel, 13-*cis*-*β*-carotene reached a concentration of 15.80% after 4 h of treatment at 65 °C, that is, nearly 3 times higher compared to model system A (6.09%). Furthermore, a linear increase was determined during heating with no equilibrium reached during the given time frame. Formation of 15-*cis*-*β*-carotene resulted in a similar progress. With a concentration of 2.31% the highest level of all systems was generated after thermal processing (compared to 1.66% in model A). 9-*cis*-*β*-Carotene was also formed during heating; however, its concentration rose to just 5.57% compared to 6.86% after irradiation in model system A. Interestingly, 9,13-di-*cis*-*β*-carotene was almost completely degraded after thermal treatment, when its concentration decreased to just 0.01%.

The results of all-*trans*-*β*-carotene model systems (Figure 2) were in line with theoretical studies on isomerization of *β*-carotene by Guo et al.[33] Compared to 13-*cis*- and 15-*cis*-*β*-carotene ($\Delta E^{\ddagger}$ = 9.1 and 9.7 kcal/mol (T_1)) the 9-*cis*-isomer has the highest barrier of activation energy ($\Delta E^{\ddagger}$ = 13.4 kcal/mol (T_1)). This means that its formation is preferred in the presence of energy-rich light.[33] Simultaneously, its high rotational barrier for reverse reaction leads to the highest stability within all *cis*-isomers and explains the linear formation during irradiation, whereas 13-*cis*-*β*-carotene was degraded after reaching a maximum (Figure 2A).[33] During irradiation in model systems B and C energy levels did not suffice to trigger the formation of hindered 9-*cis*-*β*-carotene up to that level. These studies provide an explanation for the curve progressions, too. On the one hand, 13-*cis*- and 15-*cis*-*β*-carotene represent the kinetically controlled products, because they were formed in high yields just at the beginning of irradiation. On the other hand, 9-*cis*-*β*-carotene was formed during the whole period of illumination associated with a decrease of 13-*cis* and 15-*cis* at the end of treatment, identifying 9-*cis*-*β*-carotene as the thermodynamically controlled product. Our experiments showed a formation of 9,13-di-*cis*-*β*-carotene during irradiation in model system C, whereas no formation was observed in model systems A and B. Accordingly, the barrier of activation energy has to be low to afford formation with energy-poor light. Otherwise, the isomer is characterized by a low rotational barrier for reisomerization processes, which

dx.doi.org/10.1021/jf501136g | J. Agric. Food Chem. 2014, 62, 4960−4967

explains constant concentrations during illumination with energy-rich light. During thermal processing the thermodynamic reaction product 9-*cis*-β-carotene was generated to a lesser extent compared to the daylight irradiation model, but higher than in model systems B and C. Similar observations were described in the literature; for example, Pott et al. showed increased levels of 9-*cis*-β-carotene in solar-dried mangoes, whereas conventionally dried mangoes contained high amounts of 13-*cis*-β-carotene.[10]

Thus, 9-*cis*-β-carotene and 9,13-di-*cis*-β-carotene were identified as potent markers for a possible differentiation of illumination conditions during cultivation of vegetables. In addition, 9,13-di-*cis* was not formed during thermal processing, which emphasizes its importance for a possible differentiation to photoinduced processes, whereas high levels of 13-*cis*- and 15-*cis*-isomers are useful parameters for the determination of thermal treatment of foods, as expected from the literature.[9−13] For example, Chandler et al. showed increased levels of 13-*cis*-β-carotene in various canned fruits and vegetables compared to fresh samples.[13]

Blanching of Fresh Spinach. Fresh spinach leafs were blanched in boiling water for defined periods of time. This experiment assigned the results of the above model systems to a complex matrix and was established to identify possible differences between untreated spinach and frozen commercial spinach, which is commonly blanched to inactivate enzymes and microorganisms.[34] Blanching of spinach resulted in a comparable pattern (Figure 3) to thermal incubation of all-

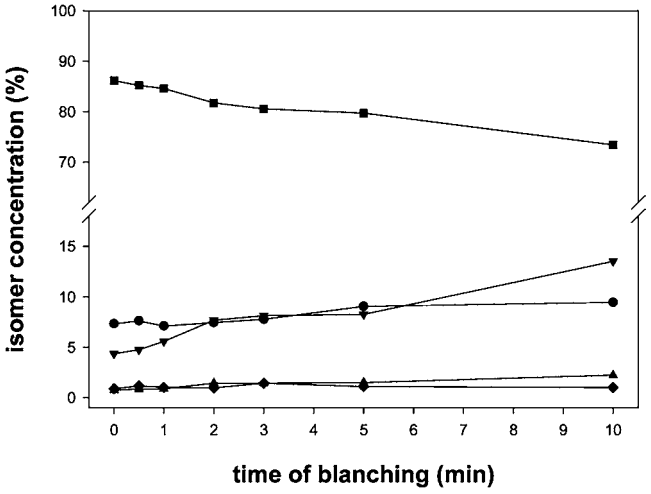

Figure 3. Concentrations of β-carotene isomers during blanching at 100 °C over a period of 10 min: 15-*cis*-β-carotene (▲); 13-*cis*-β-carotene (▼); 9,13-di-*cis*-β-carotene (◆); all-*trans*-β-carotene (■); 9-*cis*-β-carotene (●).

trans-β-carotene. The native all-*trans*-β-carotene concentration of 86.14% decreased to 73.43% during 10 min of blanching, whereas 13-*cis* (from 4.34 to 13.53%) was formed dominantly. A similar increase was found for 15-*cis*-β-carotene (from 0.71 to 2.22%) and 9-*cis*-β-carotene (from 7.32 to 9.44%), whereas 9,13-di-*cis*-β-carotene slightly rose from 0.87 to 0.99%. These results comply with observations in the thermal treatment model system and, thus, verify their validity for follow-up studies on authentic spinach samples. Lemmens et al. showed comparable results during the thermal processing of carrot puree, where 13-*cis* was dominantly formed and 9-*cis* resulted in a lower reaction rate constant.[11]

Isomeric Composition of Authentic and Commercial Spinach Samples. On the basis of the various model systems, four sets of spinach samples were analyzed with regard to their isomeric β-carotene pattern to identify possible differences caused by growing and processing conditions. All five β-carotene isomers showed significant differences compared to authentic field-grown and authentic greenhouse-grown spinach as depicted in Table 1 and Figure 4. In general, authentic field-grown spinach showed a higher *cis*-isomer concentration compared to authentic greenhouse-grown spinach, illustrated by a significantly lower concentration of all-*trans*-β-carotene (−1.28%). Simultaneously, significantly higher concentrations of 9-*cis*- (+1.03%), 13-*cis*- (+0.56%), and 15-*cis*-β-carotene (+0.27%) were determined. In contrast, 9,13-di-*cis*-β-carotene was the only isomer with a significantly lower concentration in field-grown spinach (0.25 ± 0.03%) compared to greenhouse-grown samples (0.76 ± 0.05%). Comparison of authentic field-grown and fresh commercial spinach led to two significant differences. Commercial spinach had a significantly lower concentration of all-*trans*-β-carotene (−1.10%) combined with a significantly higher level of 9-*cis*-β-carotene (+1.09%). A clear differentiation between authentic field-grown spinach and frozen commercial spinach was also possible; that is, five parameters with significant differences in the isomeric composition were observed. In this case 13-*cis*- and 15-*cis*-β-carotene showed significantly higher concentrations (13-*cis*, +0.98%; 15-*cis*, +0.22%), whereas all-*trans* (−0.49%), 9-*cis* (−0.48%), and 13,15-di-*cis* (−0.22%) resulted in significantly lower concentrations.

Table 1 shows that differences in the isomeric profile between authentic field- and greenhouse-grown spinach completely corresponded to model systems, where all relevant isomers (13-*cis*, 15-*cis*, 9-*cis*) reached higher concentrations during energy-rich irradiation. Additionally, 9,13-di-*cis*-β-carotene had a significantly lower concentration in authentic field-grown spinach (0.25 ± 0.03%) compared to authentic greenhouse-grown samples (0.76 ± 0.05%). This significant difference between both authentic groups is based on the limited stability of 9,13-di-*cis*-β-carotene in the presence of UV light as observed during the above model systems. On the basis of our experiments the most potent markers (9-*cis*- and 9,13-di-*cis*-β-carotene) were plotted in two dimensions in Figure 4 and led to a clear differentiation of authentic field- and greenhouse-grown spinach samples.

During analyses of both cultivated varieties 'Matador' and 'Bella' no significant differences were observed within the authentic groups; thus, no separation of samples was performed during plotting. Time of cultivation also led to no deviations within the groups.

A total of 37 fresh spinach samples available from local markets and food stores were then analyzed to prove the concept of differentiation of growing conditions for commercial spinach in open fields. Mean concentrations of the four above isomers showed no significant differences compared to authentic field-grown spinach, thus reflecting the typical cultivation of European spinach. In contrast, significant differences in all-*trans*- and 9-*cis*-β-carotene were determined compared to field-grown spinach. The mean concentration of all-*trans* was 1.10% lower, whereas 9-*cis* was 1.09% higher concentrated. This led to a separation in two subgroups of fresh spinach. One part indeed correlated to authentic field-grown spinach. The other set lay above the cluster of the authentic field-grown group, characterized by a strong increase in 9-*cis*-β-

Table 1. Mean Concentration (± Confidence Interval[a]) of All Analyzed β-Carotene Isomers Observed in Different Sets of Spinach Samples, Expressed as Percentage of Total β-Carotene

	authentic field-grown spinach (%) (n = 58)	authentic greenhouse-grown spinach (%) (n = 67)	fresh commercial spinach (%) (n = 37)	frozen commercial spinach (%) (n = 43)
15-*cis*	0.72 ± 0.04	0.45 ± 0.03#	0.64 ± 0.05	0.94 ± 0.05#
13,15-di-*cis*	0.80 ± 0.05	0.87 ± 0.05	0.75 ± 0.07	0.58 ± 0.06#
13-*cis*	4.37 ± 0.11	3.81 ± 0.11#	4.48 ± 0.12	5.35 ± 0.32*
9,13-di-*cis*	0.25 ± 0.03	0.76 ± 0.05#	0.28 ± 0.07	0.25 ± 0.04
all-*trans*	86.34 ± 0.21	87.62 ± 0.17#	85.24 ± 0.27#	85.85 ± 0.26#
9-*cis*	7.52 ± 0.14	6.49 ± 0.11#	8.61 ± 0.22#	7.04 ± 0.18#
μg/g FW (range)	41.90 (20.35−66.12)	64.55 (41.61−84.22)	44.93 (16.53−66.88)	34.00 (21.33−46.48)

[a]#, significant difference compared to authentic field-grown spinach calculated by t test (α = 0.01); *, significant difference compared to authentic field-grown spinach calculated by Welch test (α = 0.01).

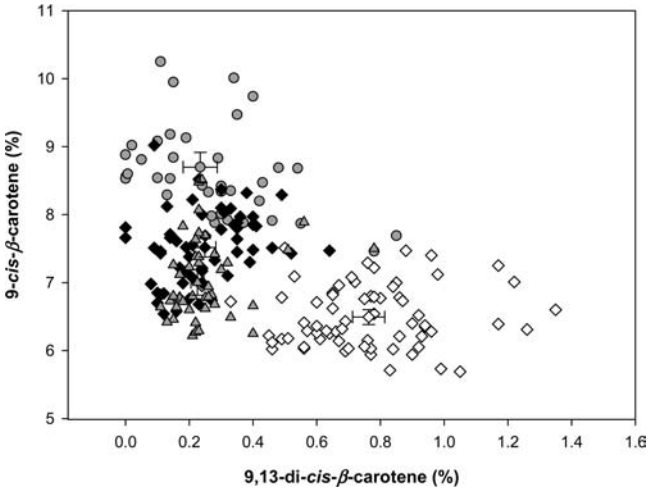

Figure 4. 9-*cis*- versus 9,13-di-*cis*-β-carotene concentrations of authentic field-grown (◆), authentic greenhouse-grown (◇), fresh commercial (gray circles), and frozen commercial (gray triangles) spinach samples, expressed as percentage of total β-carotene concentration (%).

carotene. These fresh spinach samples originated from Italy, where obviously not only higher sunlight intensity but also higher average temperatures lead to an increase of 9-*cis*. Moreover, 9-*cis* is known to be enzymatically formed from all-*trans* during biosynthesis of carlactones and strigolactones triggered by D27 isomerase.[35] This enzymatic activity might also be influenced by light conditions or the variety of spinach. Thus, 9,13-di-*cis*-β-carotene is clearly the stronger parameter for differentiation of field- and greenhouse-grown spinach as its concentration was just influenced by photoinduced processes, leading to 3 times lower concentrations in the presence of energy-rich UV light. Notably, three samples of fresh commercial spinach showed crossovers to authentic greenhouse-grown spinach caused by conspicuous 9,13-di-*cis*-β-carotene concentrations between 0.55 and 0.85%. This strongly suggested that these samples were cultivated in greenhouses. The purchase date (December 3, 2012; origin, Italy) further supported this hypothesis, because climatic conditions during November and December do not suffice for effective cultivation of spinach.

Furthermore, a total of 43 frozen spinach samples available from local food stores were analyzed for their isomeric composition. The mean concentration of 9,13-di-*cis*-β-carotene was in the same range compared to authentic field-grown and fresh commercial spinach. Unexpectedly, the concentration of 9-*cis*-β-carotene as a second marker for photoinduced isomerization was significantly lower than for the authentic field-grown set, but higher than for authentic greenhouse-grown samples. Still, two-dimensional plotting of 9-*cis*- and 9,13-di-*cis*-β-carotene allowed a clear assignment to authentic-field grown spinach, whereas almost no crossovers were observed to greenhouse-grown samples (Figure 4). This confirmed again that 9,13-di-*cis* is the stronger parameter for field-grown conditions and, in a broader sense, that commercial spinach is commonly cultivated under field-grown conditions in most European countries. Interestingly, three samples with unusually high concentrations of 9,13-di-*cis*-β-carotene (0.51−0.78%) compared to all other frozen samples overlapped to the greenhouse-grown set. According to the declaration, all three samples were produced in November 2012 with origin in Flanders, Belgium. In agreement with the literature, greenhouse cultivation is an intensive part of horticulture in the region of Flanders,[36] which for the present three samples was further supported by the date of production.

In addition, significantly higher concentrations of the identified thermal markers 13-*cis*- and 15-*cis*-β-carotene in parallel to a significantly lower concentration of all-*trans* were determined in frozen commercial spinach samples compared to both authentic-grown sets (Table 1). According to the above blanching model experiments and data from the literature, the increased concentrations must be attributed to thermal processing.[9,37] In general, frozen commercial spinach is blanched directly after harvest to inactivate enzymes and microorganisms that could influence quality or storage stability.[34] Obviously, the resulting isomeric composition allowed for a differentiation between frozen spinach and untreated fresh spinach samples based on two-dimensional plotting of 15-*cis*- and 13-*cis*-β-carotene concentrations (Figure 5). Although the mean concentration clearly differed from that of untreated fresh spinach samples, several crossovers were observed. This must be explained by considerable variations in temperature and duration of the industrial blanching processes. Nevertheless, this method seems to be applicable for a differentiation between blanched and untreated spinach. Comparable results were illustrated in the literature for blanched fruits and vegetables; for example, a 13-*cis*-β-carotene concentration of 15.3% was determined in canned spinach compared to just 8.8% in fresh samples by Chandler et al.[9,13]

In summary, on the basis of various model systems, 9-*cis*- and especially 9,13-di-*cis*-β-carotene were identified as potent markers for a differentiation of illumination conditions during cultivation, whereas 15-*cis*- and 13-*cis*-isomers were most characteristic for thermal processing as expected from the

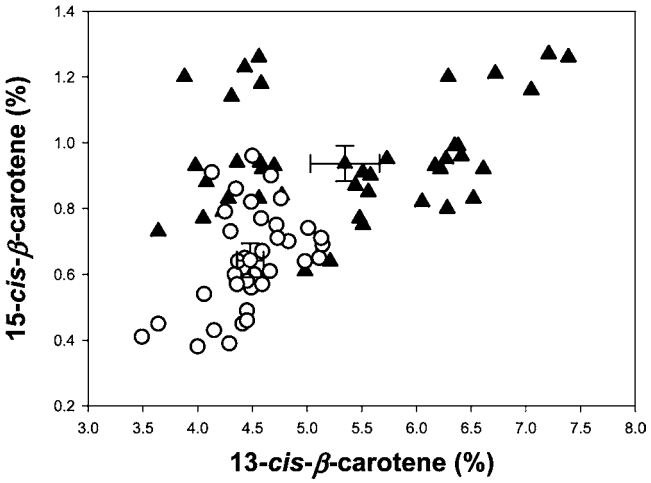

Figure 5. 15-*cis*- versus 13-*cis*-β-carotene concentrations of fresh (○) and frozen commercial (▲) spinach samples, expressed as percentage of total β-carotene concentration.

literature.[9−13] Results were successfully transferred to complex matrices and allowed a clear differentiation between authentic field- and greenhouse-grown spinach and additionally between blanched (frozen) and fresh spinach samples. The applicability to commercial spinach was proven and led to the putative identification of 6 greenhouse-grown samples of a total of 80 commercial samples. Further studies will show if the results on carotenoid isomerization can be transferred to other vegetables for authentication of growing and processing conditions.

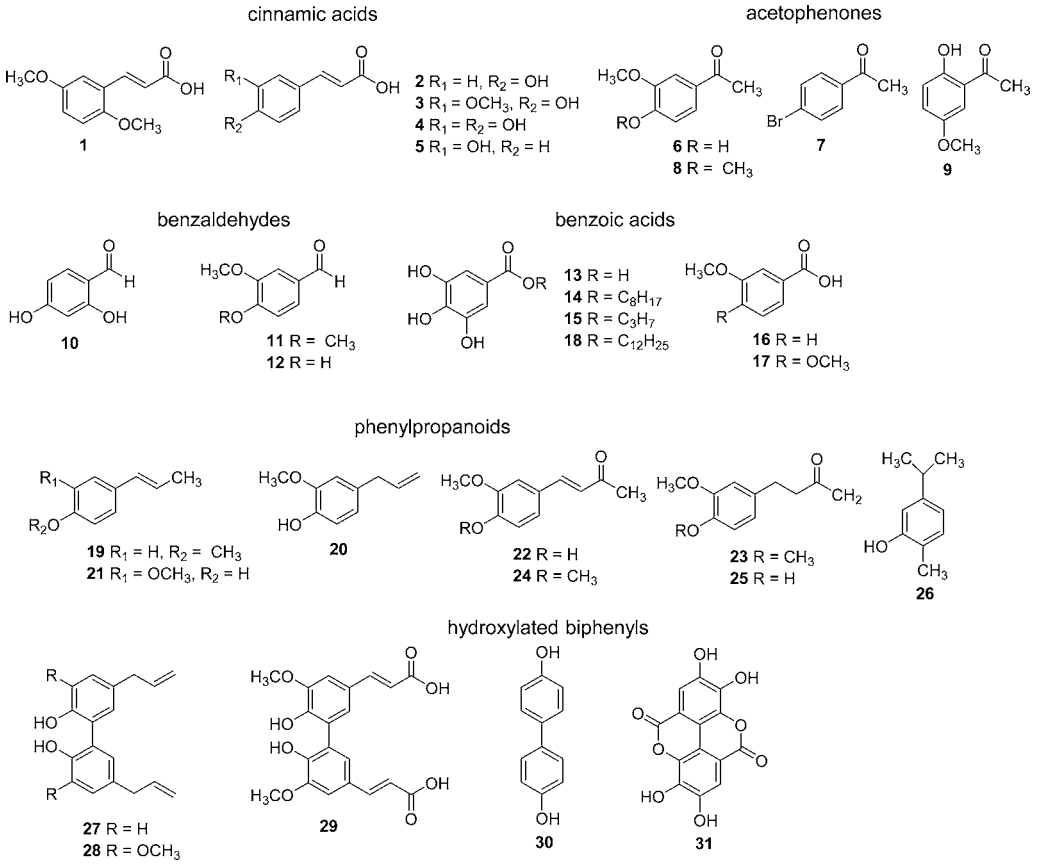

Figure 1. Chemical structures of studied compounds.

unsaturated chain are embedded in the aromatic ring.[15] Most of them are plant metabolites, generally present in food, spices, or food preservative or belonging to the generally recognized as safe (GRAS) list.[16]

The most abundant phenols extracted from maize grain pericarp and wheat bran are *trans*-ferulic acid and the corresponding dehydrodimers, namely, dehydrodiferulates.[13,14,17] Hydroxycinnamic acids are known to be major components of the primary cell wall of cereals.[13] The predominant feruloyl residues can also be dimerized under oxidative coupling mediated by peroxidases or form cross-links and/or dehydrodimers of ferulic acid that then lead to a reinforcement of the primary cell wall of the plant. Fungal esterases, which are overexpressed during growth on the host tissues, can release free forms of ferulic ester from cell wall tissues.[18] Once released, free ferulate may inhibit the ability of *Fusarium* to produce mycotoxins.

The objective of this study was to evaluate the inhibitory effect of a wide collection of natural and natural-like phenols and dimers on vegetative growth and mycotoxin *in vitro* production by a well-characterized 3-acetyl-4-deoxynivalenol producing strain of *F. culmorum*. We selected a series of compounds belonging to cinnamic acids, acetophenones, benzaldehydes, benzoic acids, phenylpropanoids, and hydroxylated biphenyls and compared their structural properties to the *in vitro* activity. A correlation between the inhibitory effect of the selected phenols and their lipophilicity, polarity, and antioxidant activity was also attempted.

MATERIALS AND METHODS

Fungal Strain and Culture Conditions. The highly virulent and well-characterized[1] strain ISPaVe MCf21 (synthetic strain INRA 117) of *F. culmorum* (W.G. Smith) Sacc., isolated in 1989 from triticale grown in Foggia, Apulia, southern Italy, was used in all of the experiments. Under *in vitro* conditions, *F. culmorum* MCf21 mainly produces 3-acetyl-4-deoxynivalenol (3-ADON) and, to a lesser extent, deoxynivalenol.[14,19] Strain cultures were set up on potato dextrose agar (PDA, at 25 °C in the dark). Short-term storage of PDA cultures was at 4 °C, while for long-term preservation, plugs of PDA cultures were stored in 50% aqueous glycerol at −80 °C.

For subsequent experiments, *F. culmorum* MCf 21 was grown in V8 vegetable juice for 7 days at 25 °C and 170 rpm. Cultures were filtered, and spores were collected by centrifugation, adjusted to 1×10^6 colony-forming units (CFU)/mL in sterile water, and used as inoculum for Vogel's liquid culture medium.[20]

All liquid and solid media were amended with streptomycin (50 μg/mL) and tetracycline (50 μg/mL), respectively, to prevent bacterial growth.

Tested Compounds (Figure 1 and Table 1). 2,5-Dimethoxycinnamic acid (**1**), 4-hydroxycinnamic acid (**2**), ferulic acid (**3**), caffeic acid (**4**), 3-hydroxycinnamic acid (**5**), apocynin (**6**), 4-bromoacetophenone (**7**), 3,4-dimethoxyacetophenone (**8**), 2-hydroxy-5-methoxyacetophenone (**9**), 2,4-dihydroxybenzaldehyde (**10**), veratraldehyde (**11**), vanillin (**12**), gallic acid (**13**), octyl gallate (**14**), propyl gallate (**15**), 3-methoxybenzoic acid (**16**), 3,4-dimethoxybenzoic acid (**17**), dodecyl gallate (**18**), *trans*-anethole (**19**), eugenol (**20**), isoeugenol (**21**), dehydrozingerone (**22**), Me-zingerone (**23**), Me-dehydrozingerone (**24**), zingerone (**25**), carvacrol (**26**), magnolol (**27**), dehydrodieugenol (eugenol dimer) (**28**), dehydrodiferulic acid (5,5′-diferulic acid dimer) (**29**), 4,4′-dihydroxybiphenyl (**30**), and ellagic acid (**31**) were selected and used with a purity >98%. Dehydrozingerone (**22**), Me-zingerone (**23**), Me-dehydrozingerone (**24**), dehydrodieugenol (**28**), and dehydrodiferulic acid (**29**) were prepared

[a]Log *P* = lipophilicity estimated by theoretical calculations, which express the partitioning of the phenols in a *n*-octanol/water system. [b]TE, Trolox equivalent; DPPH, 1,1′-diphenyl-2-picrylhydrazyl. [c]TEAC, Trolox equivalent antioxidant capacity; ABTS, 2,2-azinobis(3-ethylbenzothiazoline-6-sulfonic acid).

according to known procedures.[21−23] The other compounds were purchased from Sigma-Aldrich (Milan, Italy) and used as received. *β*-Cyclodextrin (*β*-CD, CAVAMAX W7 Pharma) was purchased from Wacker Chemie Italia (Peschiera Borromeo, Italy).

Amendment with Phenolic Inhibitors and Extraction of Type B Trichothecenes. Petri plates (60 mm diameter) containing 8 mL of Vogel's medium were amended with the compounds at different concentrations (ranging from 0.1 to 1.5 mM).

β-CD (3.0 mM) was added to the Vogel's medium to improve solubilization of phenolic compounds. The procedure was carried out in a way to exclude any stable inclusion of the compound into the *β*-CD cavity.

Each sample vial was sonicated at room temperature for 60 min and 60 Hz (Branson model 3510 OPTO-LAB). Sonicated media were inseminated with *F. culmorum* MCf 21 spore suspension to achieve a final concentration of 1×10^4 conidia/mL. Each compound was tested in triplicate, and cultures were incubated in the dark at 25 °C, without shaking. After 14 days of incubation, media and mycelia were collected for thin-layer chromatography (TLC) and liquid chromatography−mass spectrometry (LC−MS) analyses. Mycelia were separated from the medium by filtration through sterile filter paper, subsequently harvested from the filter papers with a sterile spatula, dried at 80 °C for 24 h, and weighed. Trichothecenes were extracted from 4 mL of harvested medium by adding 4 mL of ethyl acetate, followed by a shaking step at 150 rpm for 16−18 h at room temperature, and finally by recovering the organic phase. Each experiment was repeated at least 2 times.

LC−MS Analysis of Type B Trichothecenes. Quantitation was performed with reference to external calibration using type B trichothecene standards (Sigma-Aldrich, Milan, Italy). Quantitative determinations were carried out as described previously,[19] using a model HP 1100 liquid chromatography and mass spectrophotometric detector (Agilent Technologies, Palo Alto, CA).

Estimation of Lipophilicity and Polarity. Retention of a compound in reversed-phase liquid chromatography is governed by its lipophilicity and shows significant correlation with the *n*-octanol/water partition coefficient.[24] Lipophilicity of all phenols diluted in pure methanol was estimated by high-performance liquid chromatography (HPLC) on HP 1100 Agilent Technologies, Palo Alto, CA, using a 15 × 4.6 mm inner diameter, 3 μm, Luna RP-8 (Phenomenex, Torrance, CA), at temperature of 25 °C and with a flow of 0.4 mL/min, as reported in the literature.[25] Polarity of the compounds was estimated by TLC.

Radical Scavenging and Antioxidant Activity of Phenols. For each compound, a 5 mM stock solution was prepared in absolute ethanol. The radical scavenging activity of the compounds was determined *in vitro* [2,2-diphenyl-1-picrylhydrazyl (DPPH) and 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS)] by an electron paramagnetic resonance (EPR) spectrometer and ultraviolet/visible (UV/vis).

Table 2. *In Vitro* Effect of Different Phenolic Compounds (1.5 mM) on Vegetative Growth and 3-ADON Production by *F. culmorum* Strain ISPaVe MCf 21 (INRA 117)

zingerone (**25**)	83 ± 6	33 ± 10[c]

[a]Dry fungal biomass values are expressed as mean percent values (±standard error) relative to their level in the control culture (26.3 ± 1.3 mg). [b]3-ADON yields are expressed as mean percent values (±standard error) relative to their level in the control culture (242 692 ± 41 029 ng/g of dry biomass). [c]Values are significantly different ($p < 0.01$) from the untreated control based on ANOVA followed by the Dunnett test. [d]Values are significantly different ($p < 0.05$) from the untreated control based on ANOVA followed by the Dunnett test.

Radical scavenging activity was determined by the DPPH method,[26] with few modifications. Briefly, 100 μL of a solution of 1.0 mM DPPH was mixed with 1900 μL of the appropriately diluted sample solution. The mixture was incubated in the dark for 30 min and subsequently analyzed by an EPR spectrophotometer. The antioxidant activity determination was carried out as reported previously.[27]

Statistical Analysis. Data on mycelium growth (milligrams of dry weight per Petri plate) and 3-acetyl-4-deoxynivalenol production (ng/mL) obtained from separate experiments were expressed as percent values of the relative control treatment and pooled to perform a one-way analysis of variance (ANOVA), followed by multiple comparisons by Dunnett test, using Minitab for Windows, release 16.1.

RESULTS AND DISCUSSION

Screening of Type B Trichothecene Inhibitors. In a first screening, performed at the concentration of 1.5 mM, representatives of each class of compounds were selected according to their functional and structural features (Table 2). The results obtained from the initial screening were used to design further assays at the lower 1.0 mM concentration (Table 3). When their concentration in the medium was reduced, it was possible to test other phenolic compounds that were not soluble at higher concentrations. On the basis of the results achieved at 1.0 mM, a limited set of compounds were further assayed at the concentration of 0.5 mM (Table 4) and 0.25 mM (Table 5), respectively. The strategy allowed us to investigate the efficacy of compounds that are poorly soluble in water and may inhibit mycotoxin *in vitro* production at low concentrations without affecting fungal growth.

Cinnamic Acids. Vegetative growth was reduced to 59% compared to the untreated control, and 3-acetyl-4-deoxynivalenol production was almost completely inhibited when *F. culmorum* was grown in the presence of 1.5 mM 2,5-dimethoxycinnamic acid (**1**) (Table 2). At the concentration of 1.0 mM, the *in vitro* production of 3-acetyl-4-deoxynivalenol was reduced to 16−20% without affecting fungal growth by 4-hydroxycinnamic acid (**2**) and ferulic acid (**3**) (Table 3), with the latter maintaining a significant inhibitory activity also at 0.5 mM (Table 4), as reported previously.[14] When tested at 1.0 mM, caffeic acid (**4**) caused almost complete 3-acetyl-4-deoxynivalenol inhibition but did not significantly affect mycelial growth. On the contrary, 3-hydroxycinnamic acid (**5**) reduced fungal growth to 41% and 3-acetyl-4-deoxynivalenol production to 3% with respect to the untreated control (Table 3).

Table 5. *In Vitro* Effect of Different Phenolic Compounds (0.25 mM) on Vegetative Growth and 3-ADON Production by *F. culmorum* Strain ISPaVe MCf 21 (INRA 117)

treatment	dry fungal biomass (relative yield ± SE)[a]	3-ADON (relative yield ± SE)[b]
dodecyl gallate (**18**)	78 ± 0	11 ± 1[c]
Me-dehydrozingerone (**24**)	94 ± 5	344 ± 71[c]
carvacrol (**26**)	99 ± 32	11 ± 3[c]
magnolol (**27**)	21 ± 2[d]	0[c]
ferulic acid dimer (**29**)	73 ± 6	33 ± 8[d]

[a]Dry fungal biomass values are expressed as mean percent values (±standard error) relative to their level in the control culture (25.3 ± 2.4 mg). [b]3-ADON yields are expressed as mean percent values (±standard error) relative to their level in the control culture (202 873 ± 66 153 ng/g of dry biomass). [c]Values are significantly different ($p < 0.01$) from the untreated control based on ANOVA followed by the Dunnett test. [d]Values are significantly different ($p < 0.05$) from the untreated control based on ANOVA followed by the Dunnett test.

Acetophenones. Fungal growth was slightly, albeit not significantly, reduced to 67−70% compared to the untreated control upon treatment with apocynin (**6**) or 4-bromo-

dx.doi.org/10.1021/jf500647h | J. Agric. Food Chem. 2014, 62, 4969−4978

acetophenone (**7**), resulting in complete inhibition of 3-acetyl-4-deoxynivalenol *in vitro* production when tested at 1.5 and at 1.0 mM (Tables 2 and 3), respectively. Apocynin (**6**) maintained its ability to significantly reduce 3-acetyl-4-deoxynivalenol at the lower concentration of 0.5 mM without affecting fungal growth (Table 4). When tested at 1.0 mM compounds, 3,4-dimethoxyacetophenone (**8**) and 2-hydroxy-5-methoxyacetophenone (**9**) caused 67 and 48% vegetative growth, respectively, whereas only acetophenone (**9**) induced a significant inhibition (11% compared to the untreated control) of 3-acetyl-4-deoxynivalenol production (Table 3).

Benzaldehydes. Fungicide activity (25% vegetative growth compared to the control) and 3-acetyl-4-deoxynivalenol inhibition (20% trichothecene production) were observed when 1.5 mM 2,4-dihydroxybenzaldehyde (**10**) was added to *F. culmorum* growth medium, whereas at the same concentration, veratraldehyde (**11**), a benzaldehyde with two phenolic −OH groups protected by methylation, reduced 3-acetyl-4-deoxynivalenol production to 20%, with no significant inhibition of mycelium growth (Table 2). The same effects were observed with vanillin (**12**) tested at 1.0 mM (Table 3).

Benzoic Acids. Gallic acid (**13**) was selected as a prototype of benzoic acids. The production of 3-acetyl-4-deoxynivalenol was below the limit of detection (<LOD), while fungal growth was only slightly inhibited when 1.5 mM gallic acid (**13**) was added to *F. culmorum* liquid culture (Table 2). A strong fungicidal activity was observed with octyl gallate (**14**) at the concentration of 1.0 mM, whereas at 0.5 mM, this compound had no effect on mycotoxin production nor vegetative growth (Tables 3 and 4). On the contrary, propyl gallate (**15**) displayed a good inhibitory effect on mycotoxin production, while having no significant influence on mycelium growth at both 1.0 mM (Table 3) and 0.5 mM (Table 4). Dodecyl gallate (**18**) displayed a contrasting behavior, as a significant increase of vegetative growth with no effect on mycotoxin production was observed at 0.5 mM (Table 4), whereas at 0.25 mM, the same compound reduced 3-acetyl-4-deoxynivalenol production to 11% compared to the untreated control, with no significant inhibition of mycelium development (Table 5). When tested at the concentration of 0.5 mM, 3-methoxybenzoic acid (**16**) and 3,4-dimethoxybenzoic acid (**17**) did not exhibit any significant activity on fungal growth or 3-acetyl-4-deoxynivalenol production.

Phenylpropanoids. A significant inhibition of 3-acetyl-4-deoxynivalenol biosynthesis or a mycotoxin concentration of <LOD were observed upon amendment of the substrate with 1.5 mM *trans*-anethole (**19**), eugenol (**20**), and isoeugenol (**21**), three phenylpropanoids with an unsaturated side chain (Table 2). Complete inhibition of 3-acetyl-4-deoxynivalenol *in vitro* production was also achieved at 1.0 mM for eugenol (**20**) and isoeugenol (**21**) without affecting mycelium growth (Table 3).

Dehydrozingerone (**22**) and Me-zingerone (**23**) caused 100% 3-acetyl-4-deoxynivalenol inhibition and 54% mycelium growth inhibition at 1.5 mM (Table 2). Dehydrozingerone (**22**) retained almost the same inhibitory activities toward trichothecene *in vitro* production and mycelium growth at both 1.0 and 0.5 mM. When tested at 1.0 mM, Me-zingerone (**23**) retained 3-acetyl-4-deoxynivalenol inhibitory activity with an apparent, albeit not significant, stimulation of vegetative growth, while inducing 35% of 3-acetyl-4-deoxynivalenol production compared to the untreated control at 0.5 mM (Tables 3 and 4).

Almost no fungal growth and complete inhibition of trichothecene production were observed when Me-dehydrozingerone (**24**) was added at 1.0 mM to liquid culture (Table 3). When its concentration in the medium was reduced to 0.5 mM, Me-dehydrozingerone (**24**) had no significant effect on fungal growth, whereas 3-acetyl-4-deoxynivalenol was reduced to 22% of the untreated control (Table 4). When tested at 0.25 mM, this compound behaved as a strong inducer of 3-acetyl-4-deoxynivalenol *in vitro* production (Table 5).

Only 33% 3-acetyl-4-deoxynivalenol production was detected with zingerone (**25**) tested at 0.5 mM without significantly affecting fungal growth (Table 4).

Almost complete 3-acetyl-4-deoxynivalenol inhibition, with no significant inhibition of fungal growth, was observed when carvacrol (**26**), an alkyl phenol, was added at 1.0 mM in the liquid medium (Table 3). At 0.25 mM, carvacrol (**26**) reduced 3-acetyl-4-deoxynivalenol production to 11% without affecting vegetative growth (Table 5). In the present work, the trichothecene inhibitory activity of carvacrol (**26**) was not concentration-dependent.

Hydroxylated Biphenyls. Magnolol (**27**), a symmetrical hydroxylated biphenyl with two free phenolic −OH groups and two side chains *para* to each other, displayed a marked fungicide activity when tested at 1.5 mM (Table 2). Despite not being perceivable, the progressive decline in its inhibitory effect on fungal growth as the dosage decreased to 1.0, 0.5, and 0.25 mM, this compound retained the capacity to inhibit 3-acetyl-4-deoxynivalenol production by the fungus even at the lowest concentration (Tables 3 and 5). Dehydrodieugenol (**28**), structurally equivalent to magnolol (**27**) but having a methoxyl group *ortho* to each phenolic −OH group, strongly induced 3-acetyl-4-deoxynivalenol overproduction, with no reduction of fungal growth at both 1.0 and 0.5 mM (Tables 3 and 5).

No significant inhibitory activity on vegetative growth or trichothecene *in vitro* production were observed upon amendment of the substrate with ferulic acid dimer **29** at 0.5 mM, whereas at 0.25 mM, a significant reduction of 3-acetyl-4-deoxynivalenol production was detected (Tables 4 and 5). This effect might be due to a different pH of the environment, which would influence the interactions between inhibitor and enzyme. Amendment with 4,4′-dihydroxylbiphenyl (**30**) produced a 40% reduction of the fungal growth, with no significant effect on 3-acetyl-4-deoxynivalenol production when tested at 1.0 mM (Table 3). Almost complete 3-acetyl-4-deoxynivalenol inhibition with no significant reduction of vegetative growth was observed with ellagic acid (**31**) tested at 1.0 mM (Table 3), while no significant effect was detected when the substrate was amended with 0.5 mM ellagic acid (**31**) (Table 4).

Antioxidant Activity and Lipophilicity. The cinnamic acids (**2**−**4**), which display poor lipophilic properties, presented radical scavenging and antioxidant activity comparable to that of Trolox (Table 1). No radical scavenging activity nor antioxidant activity were detected for acetophenones and aldehydes, whose lipophilicity values, estimated by a computational program (log *P*) and HPLC, differ significantly only for 4-Br-acetophenone (**7**) (Table 1).

Lipophilicity values of all benzoic acids analyzed are well-distributed in the list of compounds, ranging between 0.47 and 5.27 log *P* according to the trend observed by reverse-phase (RP)-HPLC (**13** < **17** < **16** < **15** < **14** < **18**). High radical scavenging and antioxidant activities were detected for gallic acid (**13**) and its esters, compounds **18**, **14**, and **15**, with the

latter being the best antioxidant among all compounds studied (Table 1).

With the exclusion of zingerone (**25**), all phenylpropanoids had no significant or no antioxidant activity compared to the other phenols (Table 1), despite most representatives of this class of compounds demonstrating a remarkable inhibitory activity toward 3-acetyl-4-deoxynivalenol production while allowing normal vegetative growth. Lipophilicity of the compounds determined by HPLC decreased in the following order: **19** > **26** > **21** > **20** > **24** > **23** > **22** > **25**. Approximately, the same trend was maintained in the score of lipophilicity estimated by theoretical calculations that ranged between 3.37 and 1.27 log *P*.

Both radical scavenging and antioxidant activities increased in the hydroxylated biphenyls with the following trend: **31** > **28** > **29** > **27**. Ellagic acid (**31**) showed radical scavenging and antioxidant activities more than doubled and tripled compared to Trolox units (Table 1). Although ellagic acid (**31**) is conformationally hindered, a large electronic delocalization occurs in the rings, hence providing strong radical scavenging and antioxidant activities.

TLC Chromatography. Mycotoxins cannot be detected under UV at 254 nm and are poorly detectable in common TLC visualization reagents.[28] Although a *F. culmorum* strain producing mainly 3-acetyl-4-deoxynivalenol has been used, a fast and reliable TLC detection protocol was optimized for the identification of five trichothecene mycotoxins (3-acetyl-4-deoxynivalenol, 15-acetyl-4-deoxynivalenol, nivalenol, deoxynivalenol, and fusarenone X) by a single chromatographic run.

In vitro assays indicated that 31 of the tested compounds belonging to the classes of cinnamic acids, acetophenones, benzaldehydes, benzoic acids, phenylpropanoids, and hydroxylated biphenyls are inhibitors of mycotoxin type B trichothecene (3-acetyl-4-deoxynivalenol) *in vitro* production by *F. culmorum* MCf 21 without significant reduction of fungal growth. Four compounds showed effective fungicidal activity, hence providing new opportunities for application in crop protection. In an attempt to improve bioavailability of the tested compounds, *β*-CD was added to the growth medium. Although previous studies have demonstrated a synergistic effect of *β*-CD on the antimicrobial activity of plant-derived phenols,[29] no significant effect was observed in the present study.

It is worth doing further comments on results achieved with some compounds. Carvacrol (**26**), whose fungicidal activity at 1.0 mM was previously demonstrated[30] turned out to be a good type B trichothecene inhibitor, whereas inhibition of fungal growth was determined only at higher concentrations (data not shown).

Zingerone (**25**) and dehydrozingerone (**22**), both constituents of *Zingiber officinale* and *Curcuma longa*, are structurally and biologically related to curcumin. Both compounds possess antioxidant, anti-inflammatory, and anti-tumor-promoting activities.[31,32] Recently, the *in vitro* inhibitory effect and fungicide activity of some curcumin derivatives were observed in *F. proliferatum*, a fumonisin B1 producer.[33] Fungitoxic properties of dehydrozingerone (**22**) and zingerone (**25**) were reported toward *F. oxysporum* and *Aspergillus* sp., respectively.[34,35] In our study, dehydrozingerone (**22**), zingerone (**25**), and its natural-like Me-zingerone (**23**) tested at 1.0 and 0.5 mM showed a strong inhibitory effect on trichothecene production by *F. culmorum*, without significantly affecting its vegetative growth *in vitro*. Protection of the phenolic −OH group of dehydrozingerone (**22**) (e.g., compound **24**) caused at differing concentrations a fungicidal effect, inhibition, or even overproduction of 3-acetyl-4-deoxynivalenol.

Recently, ferulic acid dimers were evaluated in *F. culmorum* liquid culture[14] based on the assumption that the inhibitory activity of ferulic acid should be attributed to the dimeric forms (hydroxylated biphenyls) rather than the single monomer. In the present study, other natural hydroxylated biphenyls were evaluated, such as the dimers of eugenol (**28**) and magnolol (**27**), two compounds with antioxidant, anti-inflammatory, and antimicrobial activities.[36,37] Eugenol dimer (**28**) caused a significant increase in trichothecene production by *F. culmorum*. This effect could be attributed to the phenolic −OH groups that, near the methoxyl group, would be embedded in a five-membered ring hydrogen bond rather than a seven-membered ring involving the two phenolic −OH groups. This conformation excludes or restricts intermolecular hydrogen bond interactions, thereby hampering a likely key factor in fungicide activity. Interestingly, in magnolol (**27**), structurally similar to eugenol dimer (**28**) but lacking methoxy groups in the *ortho* position to phenolic −OH groups, a concentration-dependent fungicide-like activity was observed. The presence of a free phenolic −OH group seems to improve fungicidal activity. The moderate inhibition of fungal growth displayed by biphenol (**30**) at 1.0 mM may be attributed to the *para* orientation of the two phenolic −OH groups, which would promote quinone formation on oxidation.

Apocynin (**6**), known for its antioxidant, antimicrobial, and anti-inflammatory activities,[38] displayed a concentration-dependent inhibitory effect on trichothecene biosynthesis. A five-membered ring hydrogen bond in compound **6** would prevent strong intermolecular interactions with phenolic −OH group. Because a series of halide acetophenones were designed and prepared as potential fungicides against different phytopathogenic fungi,[39] we postulated that 4-bromo-acetophenone (**7**) would be a good candidate. No phenolic −OH group is present in the structure of acetophenone (**7**); nevertheless, an electron-withdrawing bromo group located in the *para* position to the methyl ketone function makes the aromatic ring sufficiently electron-deficient. As expected, complete mycotoxin inhibition was observed, with only moderate reduction of fungal growth.

Esters of gallic acid have already been studied for their antioxidant and antimicrobial/fungicide activities, which depend upon the length of the chain.[40] This feature was confirmed in the present study, because when a long aliphatic chain is present, the trichothecene inhibitory effect or the fungicidal activity depends upon the concentration. The effect is likely influenced by aggregation phenomena, especially in the case of compounds with a longer aliphatic chain, such as compounds **14** and **18**. When the length of the alcoholic chain is shorter, as in compound **15**, strong and comparable inhibitory activity on trichothecene *in vitro* production was detected at both 1.0 and 0.5 mM.

As a general rule, the 4-substituted 2-methoxy phenol (e.g., compounds **3**, **6**, **11**, **20**, **21**, **22**, **25**, **28**, and **29**) is the most representative structural skeleton present in the tested compounds; less representative are units where hydroxylation, demethylation, and demethoxylation occur in the aromatic ring or in different positions. The structural skeleton is present in both monomer and dimer forms and is characterized by different electronic and steric features according to substituents in the *para* position to the phenolic −OH group. Phenolic

compounds bearing a methoxy group in the *ortho* position to phenolic −OH, namely, a guaiacyl unit, usually form an intramolecular hydrogen bond, which is energetically favorable.[41] The guaiacyl unit exhibits antioxidant proprieties because it acts as a H donor to scavenge radicals.[42] It is well-acknowledged that antioxidant activity of the guaiacyl unit acts as a free radical scavenger by H atom transfer from the phenolic OH group.[43,44] Phenoxy radicals formed from a guaiacyl moiety do not favor quinone formation, as happens when radicals are generated by a catechol moiety (e.g., compound **4**).

When the corresponding phenoxy radical $ArO^{\bullet}$ formed in guaiacyl moiety is also delocalized in the side chain *para* to the phenolic −OH group, the radical is easier to form, e.g., in compounds **3**, **4**, **22**, **25**, **28**, and **29**, as compared to eugenol (**20**), isoeugenol (**21**), vanillin (**12**), veratraldehyde (**11**), and apocynin (**6**), all having a less extended electronic conjugation. As a result, the antioxidant activity of compounds **6**, **11**, **12**, **20**, and **21** is lower than in compounds **3**, **4**, **22**, **28**, and **29**. Except for biphenyl (**28**), all compounds bearing a guaiacyl moiety caused a significant inhibition of mycotoxin production without affecting fungal growth. It is therefore reasonable to assume that the presence of a guaiacyl unit with an electron-withdrawing substituent in the *para* position may be a key structure in trichothecene inhibition.

The inhibitory activity of a guaiacyl unit, with a phenolic −OH methyl protected, was not strictly associated with the antioxidant activity in the present work (e.g., compounds **11**, **23**, and **24**).

In solution, the guaiacyl unit presenting an extended conjugation is expected to be in plane or to deviate only marginally from the plane. Consequently, any difference in the activity of the molecules should be correlated to electronic phenomena rather than steric effects. On the contrary, in dimer form (e.g., hydroxylated biphenyls), steric effects would strongly influence the molecular properties (e.g., capacity to form stable radicals, interaction with proteins, increased lipophilicity, Lewis acidity enhancement, and polarizability), mainly when the two phenolic −OH groups are *ortho* to the C−C bond of the two aromatic rings. Nonplanar arrangement of the four groups along the C−C coupling bond occurs, providing steric influence, even when free rotation around the C−C single bond is expected.[45] Therefore, a steric effect may drive the ability of hydroxylated biphenyls to inhibit mycotoxin production. In 2,2′-dihydroxybiphenyls lacking a guaicyl unit and being conformationally more flexible, such as magnolol (**27**), marked antifungal activity was observed also at 0.1 mM (data not shown).

The relative order to partitioning in the organic phase (lipophilicity, determined by RP-HPLC) is in agreement with that determined for the polarity of each compound, as determined by HPLC. In principle, the least polar compound should present higher partitioning in the lipid phase, and this behavior should reflect an inhibitory property. Nonetheless, fungal matrices are multi-component systems, where the medium can be considered as both lipidic and emulsion systems. Thus, correlating theoretical calculations and experimental data is not a straightforward approach. The balance among lipophilicity, antioxidant activity, and capacity to activate weak interactions with enzymes is a key factor to estimate a good phenolic mycotoxin inhibitor.[46,47]

In addition to the known inhibitory activity of ferulic acid (**3**) and its derivatives, common natural compounds, such as compounds **6**, **15**, **20**, **22**, **25**, and **26**, exhibited a strong inhibitory activity within the range of the tested concentrations. Although some of these compounds have already been known for their fungicidal or antimicrobial activity on different fungi, this is the first time such molecules have been evaluated as mycotoxin inhibitors in *F. culmorum*. It has not escaped our notice that the remarkable fungicide activity detected for magnolol (**27**) is worth further application in different fields. The inhibitory activity of selected compounds is being tested *in planta* to evaluate potential application for the control of *Fusarium* affecting wheat and other small grain cereals.

polyphenols in tobacco leaves in 1977.[20] Snook et al.[21,22] made a good idea for improving above HPLC method and quantified seven polyphenols. In 1993, Achilli et al.[23] for the first time realized the separation of chlorogenic acid and rutin. The efforts of the separation of alkaloids and polyphenols are summarized in Table 1.

Table 1. Summarization of the Efforts on the Detection of Alkaloids and Polyphenols

year	author	target compound	separation mean
1962	Quin et al.[10]	alkaloids	GC with packed columns
1965	Massingill et al.[11]	alkaloids	GC with packed and capillary columns
2003	Cai et al.[12]	alkaloids	GC with megabore capillary column
1984	Sudan et al.[15]	alkaloids	reversed-phase HPLC
1985	Mousa et al.[13]	alkaloids	HPLC with electrochemical detection
1998	Sellergren et al.[14]	alkaloids	liquid−liquid extraction followed by reversed-phase HPLC using gradient elution
1999	Ciolino et al.[16−18]	alkaloids	reversed-phase ion-pair HPLC
1977	Court[20]	polyphenols	reversed-phase HPLC
1982	Snook et al.[21]	polyphenols	reversed-phase HPLC
1993	Achilli et al.[23]	polyphenols	reversed-phase HPLC

It is well recognized that chemical composition of tobacco is highly associated with the flavor of tobacco products and the risk of smoking.[24] Many methods have been developed to determine tobacco flavoring or harmful constitutions.[25−29] Currently, the chemical compositions of tobacco leaves have attracted a considerable amount of attention throughout the world.[30−33] In view of the fact that the unique combination of tobacco maturation stages and cultivation conditions result in unique secondary metabolites, comprehensive studies on the chemical constituents of tobacco sample of different origins harvested at different maturation stages might provide valuable information to identify superior cultivation condition and the appropriate time to harvest tobacco. However, to our knowledge, no such study was yet reported. In this study, a comprehensive high pressure liquid chromatography−photo-diode array-quadrupole time-of-flight mass spectrometry (HPLC−PDA-QTOF-MS) method was developed for the quantitative determination of the main polyphenols and alkaloids as well as qualitative profiling of other secondary metabolites in 12 batches of tobacco samples of three origins and four maturation stages. The reliability and adaptability of the method were verified by determination of linear range, recovery, and reproducibility with tobacco samples. We expect our work would provide a scientific basis and guidance for artificial cultivation and harvest of tobacco and, thereby, improve the quality of tobacco.

EXPERIMENTAL SECTION

Chemicals and Reagents. HPLC grade acetonitrile and methanol were purchased from Fisher Co. (Fisher Scientific, USA). Deionized water obtained from a Milli-Q water system (Milli-Pore Corp., Bedford, MA, USA) was used for sample preparation procedures and HPLC analyses. Other chemicals were of analytical grade. Eight reference compounds, namely nornicotine (**1**), neonicotine (**2**), anatabine (**3**), nicotine (**4**), myosmine (**5**), scopoletin (**6**), rutin (**7**), and quercetin (**8**) (Figure 1), were isolated and purified in our laboratory and were identified based on UV, IR, MS, ^{1}H NMR, and

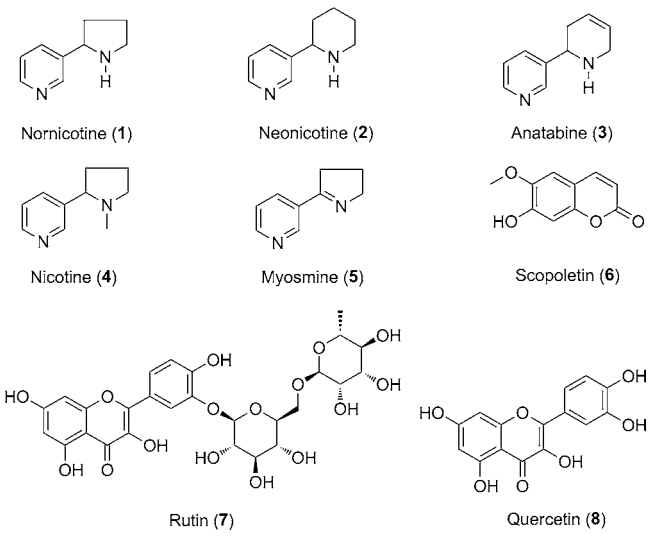

Figure 1. Chemical structures of reference compounds **1**−**8**.

^{13}C NMR analyses. The purity of these compounds was determined to be more than 98% by HPLC analysis. Among them, compounds **1**, **2**, **3**, **4**, and **5** are alkaloids, compounds **7** and **8** are polyphenols, and compound **6** is a coumarin.

Plant Material and Plantation Conditions. Seeds of a tobacco cultivar (*Nicotiana tabacum* "k326") were obtained from the Seed Center of Yunnan Academy of Tobacco (Yunnan, China). Seeds were planted and raised within a germination cabinet in 25 ± 1 °C. Thirty days after germination, the seedlings were transplanted into the pots (50 cm diameter × 50 cm deep). Soil for the potted plants was composed of the same red soil and humus (3:1). These plants were grown at three sites in China: Zhengzhou of Henan province (34°72′ N, 113°65′ E; elevation 110 m), Zunyi of Guizhou province (27°07′ N,106°88′ E; elevation 1000 m), and Jiangchuan of Yunnan province (24°17′ N,102°45′ E; elevation 1730 m). Each site had different temperature, humidity, and rainfall characteristics (Figure S-1 of the Supporting Information). Seedlings were transplanted between 23 April and 6 May of 2012. During the experiment, none of the plants experienced any water or nutrient stresses.

Tobacco leaf samples were collected from the three cultivation places at four maturities. The tobacco samples ZZ-T, ZZ-X, ZZ-C, and ZZ-C2 were collected from Zhengzhou, the samples ZY-T, ZY-X, ZY-C, and ZY-C2 were collected from Zunyi, and the JC-T, JC-X, JC-C, and JC-C2 samples were collected from Jiangchuan. Those sample names marked with -T, -X, -C, and -C2 suffixes represent they were harvested at 40 days (rosette stage), 60 days (squaring stage), 85 days (physiological maturation stage), and 100 days (harvest maturation stage) after transplantation, respectively.

Sample Preparation. The tobacco samples were sun dried on site right after collection and then fine-ground for further extraction. For HPLC analysis, an accurately weighted 1.0 g of the ground powder of each sample and 10 mL of methanol was added to a flask in an ultrasonic bath for 30 min. The extraction process was repeated three times. The extracted solutions were combined, filtered, and evaporated under vacuum. The residue was diluted to volume with methanol in a 25 mL volumetric flask. Then the solutions were filtered through a 0.22 μm PTFE syringe filter into HPLC vials for HPLC−PDA-MS analysis.

Trichloromethane was used to extract the fat-soluble components in the tobacco leaves. Then 1.0 g tobacco powder was introduced into a 25 mL flask, followed by the addition of 10 mL of trichloromethane. The extraction was performed under ultrasonication for 30 min. The mixture was filtered through a filter paper, and the solution was transferred to a 50 mL round-bottomed flask and evaporated to

dryness at 45 °C under reduced pressure. The residue in the round-bottomed flask was dissolved in 2 mL of cyclohexane with ultrasonication. The solution was then filtered through a 0.22 μm PTFE syringe filter before GC-MS analysis.

GC−MS Analysis. The fat-soluble components were analyzed on an Agilent 7890A gas chromatograph (Agilent Technologies, Santa Clara, CA) coupled to an Agilent 5975C mass spectrometer. Helium was used as the carrier gas at a flow rate of 1 mL/min. The GC analyses were performed on a capillary column (30 m × 0.22 mm inner diameter × 1.00 μm d_f). The split ratio was 1:10. The oven temperature was held at 50 °C for 4 min, followed by a ramp of 15 °C/min to 140 °C, then increased to 200 °C at 30 °C/min, followed by a ramp of 2 °C/min to 250 °C and held for 2 min, and then increased to the final temperature of 290 °C at 5 °C/min for 10 min and the inlet was set to a temperature of 240 °C. Temperature of the interface, ion source and quadrapole of the mass spectrometer were set at 280, 230, and 150 °C, respectively. The mass range of m/z 50−700 was set for all GC-MS analyses. Compound identification was based on comparisons to mass spectra of authentic reference compounds by reference to the National Institute of Standards and Technology (NIST) library and published data.

HPLC−PDA-QTOF-MS Analysis. The HPLC analysis was performed on a Waters ACQUITY UPLC I Class system (Waters Corp., MA, USA), equipped with a binary solvent delivery system, a 48-vial autosampler, and a photodiode array detector (PDA). The separation of the main components was achieved on a TSK gel ODS-100Z column (150 mm × 4.6 mm, 3 μm). The mobile phases consisted of solvent A (deionized water with 10 mM ammonium acetate) and solvent B (acetonitrile). The gradient elution was applied at a flow rate of 1.2 mL/min as follows: 3% B (0−4 min), 3−10% B (4−8 min), 10% B (8−12 min), 10−15% B (12−16 min), 15% B (16−18 min), 15%−60% B (18−34 min), 60%−99% B (34−35 min), and 99% (35−37 min). The column and autosampler temperature were maintained at 60 and 15 °C, respectively. The injection volume was 5 μL, and the UV wavelength was set at 254 nm for the detection of **1**−**5**, and **8**. While for the detection of **6**, the UV wavelength of 340 nm was used.

Stock solutions containing eight reference compounds were prepared and diluted to appropriate concentrations for construction of calibration curves. Resulting solutions were filtered through 0.22 μm nylon syringe filters, and aliquots of 5 μL were injected in the chromatographic system for analyses. The standard solutions were analyzed in triplicate, and peak areas were used as an analytical signal. The calibration curves were constructed by plotting the peak areas versus the concentrations of standards.

The method was validated for linearity, sensitivity, repeatability, and accuracy. The limits of detection (LOD) and limits of quantification (LOQ) under the present conditions were determined at an S/N (signal-to-noise) of about 3 and 10, respectively. Intra- and interday variations were chosen to determine the precision of the developed assay. For intraday variability test, three different amounts (high, middle, and low level) of reference compounds were analyzed for six replicates within 1 day, while for interday variability tests, the same mixed standards were examined in duplicates in consecutive 3 days. Variations were expressed by the relative standard deviation (RSD) of the data. Recovery was used to evaluate the accuracy of the method. Three different amounts of the standard solutions were added to sample ZY-C2, and the recovery was measured in triplicate. For comparison, unspiked ZY-C2 sample was concurrently prepared and analyzed. The recovery was calculated as follows: recovery (%) = (amount found − amount original)/amount spiked × 100%. For the stability test, the sample solution was analyzed using the established method at 0, 2, 4, 6, 8, 10, and 12 h, respectively, the peak areas of eight analytes were recorded, and the RSD of peak areas at different times were calculated.

Mass spectrometric analysis was performed on a Synapt G2 QTOF-MS (HDMS, Waters, USA) operating in electrospray ionization (ESI) positive mode. The HPLC elution was split 3:1 using a flow splitting tee, resulting in flow rate of 0.3 mL/min to MS analysis. The mass spectrometer was operated with the following parameters: capillary voltage of 2.5 kV, cone voltage of 40 V, source temperature of 110 °C, desolvation temperature of 300 °C, and desolvation gas (N_2) flow of 700 L/h. The mass range was set at m/z 50−1000 with a scan time of 0.25 s and an interscan time of 0.02 s. LC−MS/MS analysis was performed by a collision energy ramp from 15 to 35 eV in the mass range of m/z 50−1000 in MS^E mode. To ensure the accuracy of the measured mass, leucine−enkephalin (with a reference mass at m/z 556.2771 in positive mode) was used as the lock-mass compound at a concentration of 500 pg/μL and a flow rate of 5 μL/min. The UPLC and Synapt G2 system operations were carried out using MassLynx 4.1 software (Waters, Manchester).

Statistical Analysis. Cluster analysis is a common technique for statistical data analysis which provides means for classifying a given set of objects into groups (clusters) in such a way that the similarities between objects could easily be determined. In this study, hierarchical cluster analysis (HCA) was performed to reveal the similarities between tobacco samples of different origins and maturities according to their fat-soluble constituents. The fat-soluble constituents of the 12 tobacco samples were subject to hierarchical cluster analysis based on the 34 most abundant fat-soluble constituents in the samples obtained by GC-MS. The percentage peak areas (PPAs) of these peaks in 12 batches of tobacco samples were used as variables for the HCA calculation. HCA was performed using Euclidean distance and average linkage without standardizing the variables. Statistical analysis was performed by Minitab for Windows, release 12 (Minitab Inc., State College, PA, USA).

RESULTS AND DISCUSSION

Influence of Origin and Maturity on the Fat-Soluble Composition. The fat-soluble composition is one of the important parameters to understand the variation among tobacco samples of different origins and maturities. More than 100 compounds were detected in 12 batches of tobacco samples through GC−MS analyses, and the percentage compositions of 34 most abundant compounds were tentatively identified and summarized in Table 2. Obvious variation can be found in fat-soluble composition among all samples. For instance, higher contents of cyclohexanol, butyl citrate, vitamin E, and cyclotriacontane were found in the Zhengzhou and Zunyi tobacco samples in comparison to those from Jiangchuan. However, Zunyi and Jiangchuan samples showed higher contents of phytonadione, octadecane, and linolenic alcohol, while the Zhengzhou and Jiangchuan tobacco samples had higher contents of heptacosane, 1-triacontanol, 11-decylheneicosane, tetracosane, dihydropinene, 10-heptyl-10-octylicosane, tetradecanamide, and nonacosane. During maturity, the 10-heptyl-10-octylicosane contents in Zhengzhou tobacco samples were almost constant (6.26, 6.21, 6.29, and 5.31% for ZZ-T, ZZ-X, ZZ-C, and ZZ-C2, respectively), while that of Zunyi tobacco samples showed significant reduction (12.66, 8.86, 0, and 2.74% for ZY-T, ZY-X, ZY-C, and ZY-C2, respectively). However, the Jiangchuan tobacco sample showed an approximate increased 10-heptyl-10-octylicosane content (0.23, 10.09, 7.98, and 9.17 for JC-T, JC-X, JC-C, and JC-C2, respectively) during maturity. In contrast to 10-heptyl-10-octylicosane content, the Zunyi tobacco samples showed the highest methylcyclohexane content (ZY-T with 26.56%) among all the tobacco samples, while the Zhengzhou tobacco sample showed the lowest methylcyclohexane content (ZZ-T with 13.94%). These results clearly demonstrated the influences of different origins from the same region and different regions on fat-soluble compositions during maturity. The GC-MS profile clearly shows that tobacco samples of all three origins harvested at rosette stage exhibited more fat-soluble components, while those harvested at harvest maturation stage exhibited the least

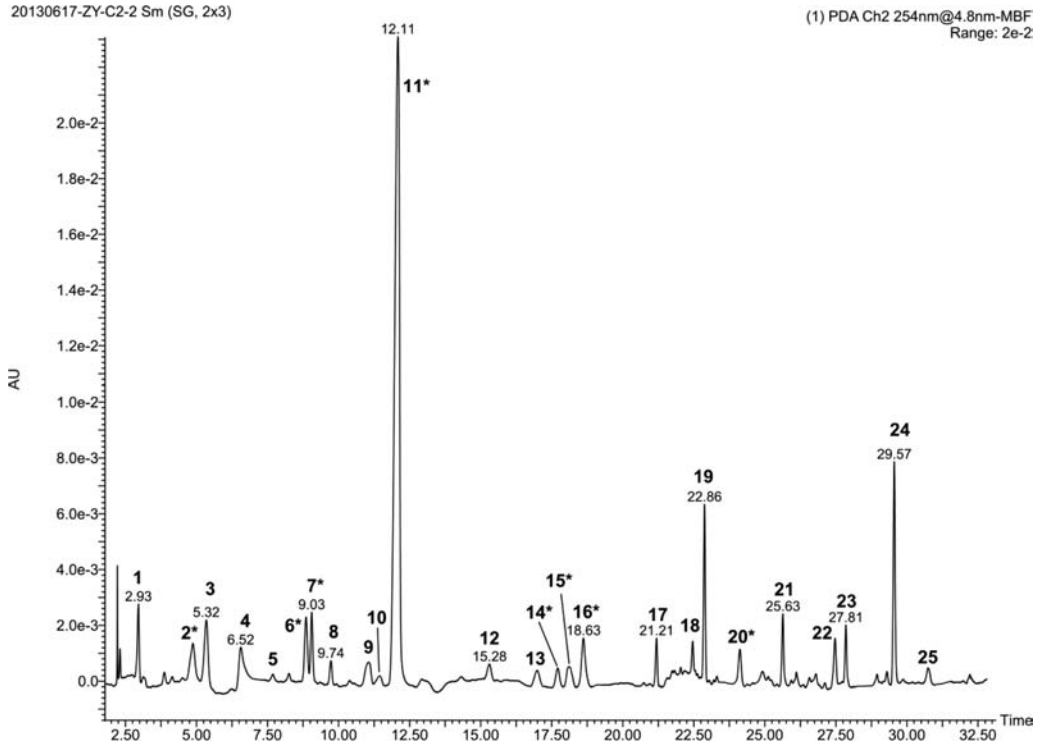

Figure 2. Chromatogram of a representative chromatogram of the tobacco samples (ZY-C2; detected at 254 nm). Peaks 2, 6, 7, 11, 14, 15, 16, and 20 were identified as reference standards **1**−**8**, and the tentative identification of the rest peaks can be found in Table 4.

fat-soluble components. The GC−MS profile of the fat-soluble components of the 12 batches of tobacco samples of three origins and four maturities is presented in Figures S-2−S-4 of the Supporting Information.

Validation of HPLC Method. All 12 batches of the tobacco sample were analyzed with the developed chromatographic condition, and the chromatogram of the eight standards and a representative chromatogram of the tobacco samples are illustrated in Figure 2. The chromatograms of the all the tobacco samples can be found in Figures S-4−S-6 of the Supporting Information.

The regression equation, correlation coefficient, linear range, LOD, LOQ, precision, repeatability, and recovery for the eight standards are summarized in Table 3. The correlation coefficient values (r^2 > 0.999) indicated appropriate correlations between the investigated compound concentrations and their peak area within the test ranges. The relative standard deviation (RSD) of peak area of each standard was within the range of 0.76−3.0% and 0.70−3.7% for intra- and interday repeatability and within 0.39−3.67% for stability. All the results demonstrated that the developed method is reproducible, precise, and stable. The spike recoveries were within the range of 98.8−102.7%, demonstrating superior performance of the method in both recovery and accuracy.

Variation in the Content of Alkaloids and Polyphenols between Samples of Different Origins during Maturity. Variation of the contents of nicotine and rutin in all tobacco samples is shown in Table 5. Of the five alkaloids and two polyphenols, nicotine and rutin showed the highest content in all tobacco samples, and thus nicotine and rutin were chosen as representative alkaloid and polyphenol compounds in the following discussion.

Affected by many factors such as growth conditions and leaf stalk position, the nicotine contents in tobacco varies from 1% to 3% of the total weight of tobacco.[34,35] Our results clearly showed that the nicotine content varied nearly 40-fold, ranging from 0.66 to 25.40 mg/g, in the tobacco samples of different origins and maturities (Table 5). As illustrated in Table 5,

among tobacco samples, the content of nicotine showed certain trend along the maturation stages. The content of nicotine in tobacco samples of each origin harvested at rosette stage was in a medium level (except for ZZ-T, which showed the highest nicotine level among all the tobacco samples) and in a dramatic decrease to reach the lowest level at squaring stage, reached the highest level at physiological maturation stage, and then fell sharply at harvest maturation stage. For the Zhengzhou tobacco samples, the nicotine contents ranged from 5655.62 ± 230.88 to 25399.39 ± 308.95 μg/g. The highest nicotine content of 25399.39 ± 308.95 μg/g was found in the rosette stage sample (ZZ-T) and in a dramatic decrease to reach the lowest level (ZZ-X with 5655.62 ± 230.88 μg/g) at squaring stage. Subsequently, the nicotine level showed an upward trend and reached a higher level at the physiological maturation stage and then decreased at the harvest maturation stage. The lowest nicotine level of 660.16 ± 24.78 μg/g was detected in a Zunyi tobacco sample (ZY-X). For the Zunyi tobacco samples, the highest nicotine content of 12215.15 ± 122.95 μg/g was detected in the sample harvested at physiological maturation stage. Similar to the Zunyi tobacco samples, the highest nicotine level (21409.02 ± 176.10 μg/g) in the Jiangchuan tobacco sample was also observed in the sample collected at physiological maturation stage.

The rutin contents of the tobacco samples harvested at different maturation stages varied greatly. At rosette stage, the rutin content ranged from 103.86 ± 8.57 to 201.87 ± 9.16 μg/g, while those ranged from 87.42 ± 2.78 to 734.66 ± 27.42 μg/g at squaring stage. The rutin contents at physiological maturation stage ranged from 90.30 ± 4.80 to 725.93 ± 40.70 μg/g, while those ranged from 164.00 ± 5.08 to 243.44 ± 6.79 μg/g at harvest maturation stage. The highest level of rutin of 734.66 ± 27.42 μg/g was found in the Jiangchuan tobacco sample harvested at squaring stage (JC-X), which was more

dx.doi.org/10.1021/jf5009204 | J. Agric. Food Chem. 2014, 62, 4979−4987

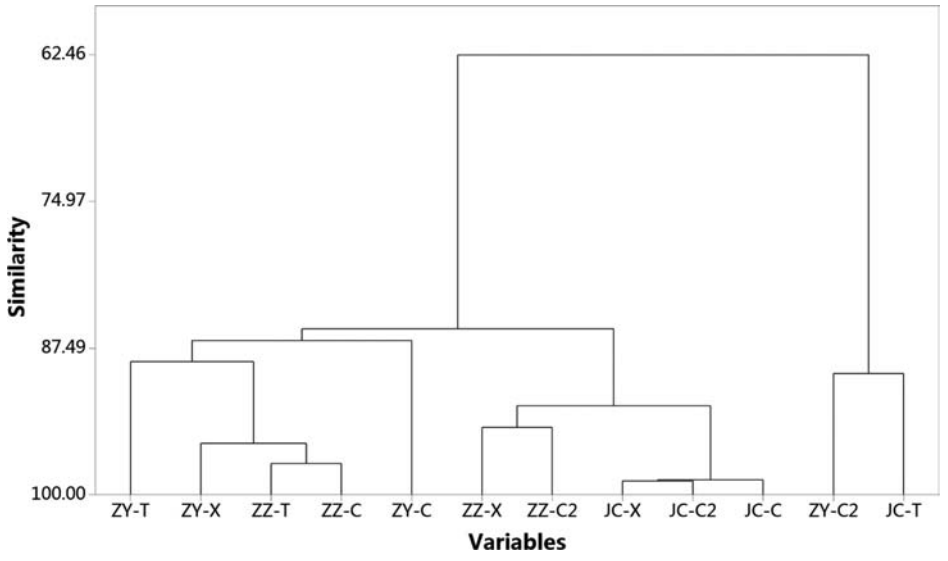

Figure 3. Dendrogram of hierarchical cluster analysis of 12 tobacco samples.

than 3-fold of that detected in the sample harvested at rosette stage (JC-T with 201.87 ± 9.16 μg/g). The lowest rutin content (ZY-X with 87.42 ± 2.78 μg/g) was detected in the Zunyi tobacco sample harvested at squaring stage, which was only approximately 70% amounts of that detected in the same origin harvest at harvest maturation stage (ZY-C2).

Among the Zhengzhou tobacco samples, the rutin content varied from 158.99 to 725.93 μg/g. The rutin content of the Zhengzhou tobacco samples harvested at physiological maturation stage was the highest (ZZ-C with 725.93 ± 40.70 μg/g) and was almost constant during rosette stage (ZZ-T with 186.28 ± 3.57 μg/g), squaring stage (ZZ-X with 158.99 ± 2.16 μg/g), and harvest maturation stage (ZZ-C2 with 164 ± 5.08 μg/g). For the Zunyi tobacco samples, the rutin contents varied from 87.42 ± 2.78 to 243.44 ± 6.79 μg/g. In the first three stages, the rutin contents did not vary with maturity (103.86 ± 8.57, 87.42 ± 2.78, 90.30 ± 4.80 μg/g for rosette stage, squaring stage, and physiological maturation stage, respectively). The maximum rutin content (ZY-C2 with 243.44 ± 6.79 μg/g) of the Zunyi tobacco samples was found at the harvest maturation stage. Compared to the tobacco samples from the other two origins, the Jiangchuan tobacco samples were found to have relatively high contents of rutin ranging from 201.87 ± 9.16 to 734.66 ± 27.42 μg/g. Generally, tobacco samples at the squaring stage had the highest level of rutin, which was about 3.5-fold over that measured in rosette stage.

Identification of the Main Constituents in Tobacco by HPLC-ESI-QTOF-MS. The difference of the chemical compositions is one of the important parameters to understand the variation among tobacco samples harvested from different origins and maturation stages. Unequivocal and tentative identification of the target compounds as well as the unknown constituents in the tobacco samples were performed by means of HPLC−ESI-QTOF-MS and MS/MS. Upon obtaining the data from MS and MS/MS analysis, a total of 25 compounds with relative high abundance were detected in 12 batches of the tobacco samples. Compounds at the retention times (t_R) of 5.0, 8.3, 9.1, 12.0, 17.9, 18.4, 18.8, and 24.9 min were unequivocally identified to be the reference compounds **1**−**8**, respectively. Other peaks were tentatively identified via searching for the precursor ion and fragmentation ions in MassBank Mass Spectral Database and literatures. We further performed empirical molecular formulas matching with those of the published compounds of tobacco in databases, such as PubMed of the U.S. National Library Medicine and the National Institutes of Health, SciFinder scholar of American Chemical Society, Chinese National Knowledge Infrastructure (CNKI) of Tsinghua University, and ChemSpider database when the precursor ion and fragmentation ions were not found in MassBank and literatures. When several empirical molecular formulas matched the same formula those isomeric compounds previously reported from tobacco would be preferentially selected as the putative ones. All the identified compounds in the tobacco samples were summarized in Table 4.

Statistical Analysis. To examine the change in similarity of fat-soluble compounds displayed in the 12 tobacco samples of different origins during maturity, a hierarchical cluster analysis based on the composition of major fat-soluble constituents was performed. The hierarchical cluster analysis is a multivariate procedure that allows the classification of variables into groups based on Euclidean distances between cases.[36] The dendogram of the 12 tobacco samples is shown in Figure 3. Two major clusters, viz., clusters 1 and 2, can be found in Figure 3. Cluster 1 was composed of 10 samples, while cluster 2 was composed of two samples. Cluster 1 formed two subclusters, viz., ZY-T, ZY-X, ZZ-T, and ZZ-C and ZZ-C2, JC-X, JC-C2, and JC-C. From the dendogram, it can be inferred that the tobacco samples of the same origin showed more similarity in the fat-soluble composition. The Jiangchuan tobacco sample showed more similarity during squaring stage, physiological maturation stage, and harvest maturation stage (i.e., JC-X, JC-C, and JC-C2). These clusters show that similarity mainly exists between samples of the same origin rather than different origins. In addition, it can be useful for farmers to choose the appropriate harvest stage of tobacco with desired content of components as well as to choose alternate origins with more similarity in the absence of a desired variety at the time of cultivation.

In conclusion, the presented study provided a comprehensive analysis in fat-soluble compositions as well as polar constituents in 12 batches of tobacco leaf samples of three origins at four maturations. The GC-MS analyses showed that tobacco samples harvested at rosette stage exhibited the most fat-

soluble components, while those harvested at harvest maturation stage exhibited the least fat-soluble components. In addition to GC-MS analysis, an HPLC-QTOF-MS method was developed for the quantitative analyses of eight main compounds in tobacco including five alkaloids and two polyphenols. The nicotine contents varied greatly in the 12 tobacco samples. The Zhengzhou tobacco sample harvested at rosette stage was found to have the highest nicotine content (ZZ-T), and the lowest nicotine level was detected in Zunyi tobacco samples harvested at squaring stage (ZY-X). The highest level of rutin was found in the Jiangchuan tobacco sample harvested at squaring stage (JC-X), and the lowest rutin content was detected in the Zunyi tobacco sample harvested at squaring stage (ZY-X). In addition to quantitative analyses, the main compounds in the tobacco samples were also unequivocally or tentatively identified. The developed method provided a convenient approach which might be applied for rapid maturity evaluation, tobacco flavor identification, and also holds the potential for analysis of compounds present in other plants.

pears produced low levels of the ester ethyl 2,4-decadienoate (0.11%), which has a pear note and is prominent in other pear varieties.[12] Despite its low content of ethyl 2,4-decadienoate, 'Comice' is considered by some to be the best dessert pear variety due to its juicy, buttery texture and well-balanced flavor.[13] Aroma volatile production is regulated by ethylene biosynthesis and action in many climacteric fruit, as demonstrated through the use of the ethylene action inhibitor 1-methylcyclopropene (1-MCP) and the study of transgenic apples with suppressed ethylene biosynthesis.[14,15]

Taste is also a key factor of sensory quality. The balance of sweet and sour taste affects consumer acceptance of fruit.[16] Sugars (fructose, sorbitol, glucose, and sucrose) and acids (malic acid) are the compounds most influencing sweet and sour/tart taste in pears.[5] Consumer tests have shown that the acceptable range of sweet/sour balance as measured by soluble solids content/titratable acidity (SSC/TA) ratio in pear fruit is 2−4.[16]

Sensory descriptive analysis is a primary approach to investigate the important attributes of a product that people perceive.[18] The sensory descriptive analysis of 'Comice' pears after cold storage and ripening was compared with that of unripe pears.[1] Ripe 'Comice' pears had high levels of sweetness, cooked pear odor and flavor, softness, and juiciness, but low levels of grassy/green odor.

Instrumental fruit quality measurements are sometimes well correlated with sensory attributes. In one study,[20] the best correlations and predictions of sensory texture attributes in apples were between the penetrometer puncture test and crispness (r = 0.8) or juiciness (r = 0.7). In another study, compressive force using a Sinclair iQ System and Güss Fruit Texture measurements had a significant correlation with sensory perception of hardness in both apples (r = 0.78−0.83) and pears (r = 0.83).[17]

The relationships between volatile compound concentrations, SSC or TA, and sensory attributes have not been reported for pears. For apples, relationships between the main volatile compounds and sensory attributes were determined by Karlsen et al.[18] Butyl acetate, 2-methylbutyl acetate, hexyl acetate, and ethyl acetate were related to fruity and sweet sensory attributes, whereas ethyl butanoate, 1-butanol, ethanol, and α-farnesene were related to sour, bitter, and grassy attributes.[18] To predict sensory perception of acidity, TA was the best instrumental measurement in apple fruit (r = 0.86)[19] compared to individual acids, SSC/TA, Brim A (SSC − 10 × TA) or suspension pH (the pH of the macerate before the start of the titration). On the other hand, sensory sweetness was difficult to predict by any instrumental measurement in apple.[19]

In this study, we compare the effect of ethylene conditioning and cold (0 °C) or intermediate (10 °C) temperature conditioning on the sensory quality of 'Comice' pears as evaluated by descriptive sensory analysis. We also describe the relationship between the sensory attributes and instrumental measures of fruit quality. These parameters were measured as a function of firmness level for the various conditioning treatments.

MATERIALS AND METHODS

Fruit Source. Mature-green 'Comice' (*Pyrus communis* L.) pears were harvested at the average firmness of 43 N from a commercial orchard in Lake County, California, in midseason (September 15, 2010). The fruits were transported to the Postharvest Pilot Plant at the University of California, Davis, on the same day and visually sorted to eliminate defective fruits and to obtain fruits of uniform size and color for use in the experiments. The fruits were stored at 20 °C and >90% relative humidity prior to the initiation of treatments on the following day.

Conditioning Treatments. The pears were randomly divided into six groups (five conditioning treatment groups and one control, nonconditioned group) with 200−350 fruits per group. Three groups were exposed to different storage temperatures and times; 0 °C (low temperature) for 15 or 25 days and 10 °C (intermediate temperature) for 10 days with >90% relative humidity (RH). Two groups were exposed to 100 μL L^{-1} ethylene gas at 20 °C in two 300 L stainless steel tanks for 1 or 3 days. Humidified air (95% RH) containing 100 μL L^{-1} ethylene was passed through the tank at 4 L min^{-1} to keep CO_2 concentration <0.3 kPa. An additional group was held at 20 °C as a nonconditioned control. After the initial conditioning treatments, all groups were transferred to 20 °C for ripening until they softened to the firmness of 9 N (±2.50 N). Four single fruit replicates were chosen from each treatment group when the average fruit firmness (15 fruits measured randomly from each treatment) reached 27, 18, and 9 N (±4.00 N), and the firmness of the four fruits selected for instrumental and sensory evaluation were as close to 27, 18, or 9 N as possible. Portions of each individual fruit were used for analysis of skin color, firmness, cell wall polyuronides, volatile content, SSC, TA, and sensory evaluation by a trained panel as described below.

Ethylene Production. Ethylene production was measured every day or every other day on a subset of fruits from each treatment after fruit transfer to 20 °C and until the fruit began senescence. Five fruits were placed into a 3.8 L jar as one replicate with three replicates for each treatment. The jars were sealed for 10−30 min before a 10 mL headspace gas sample was collected and analyzed for ethylene concentration using a gas chromatograph (AGC series 400; Hach-Carle Co., Loveland, CO, USA) fitted with a 1 mL sample loop, a flame ionization detector (FID), and an alumina column. The oven temperature was 80 °C, and the carrier gas was N_2 at a flow rate of 37 mL min^{-1}.

Flesh Firmness. Fruit firmness was determined at harvest and was measured every day or every other day after transfer to 20 °C for ripening until the fruit softened to 9 N. For analysis, the skin was removed from an area ∼20 mm in diameter on opposite sides of the equatorial region of each pear. Firmness was measured on each side of the pear using a Güss FTA Penetrometer (Guss, Strand, Western Cape, South Africa) fitted with an 8 mm probe. The four fruits per replicate for each treatment and firmness stage were selected when the average firmness for each treatment reached 27, 18, or 9 N.

Soluble Solids Content and Titratable Acidity. Two wedge-shaped slices were cut from stem to blossom end from opposite sides of each pear used for sensory evaluation and juiced for SSC and TA determination. A few drops of juice were used to measure SSC by refractometry (Reichert AR6 Series, Depew, NY, USA), and 4 g of juice diluted in 20 mL of deionized water was used for determination of TA (as malic acid equivalents; pH 8.2 end point), using an automatic titrater (Radiometer TitraLab; Tim850 titration manager and SAC80 sample changer).

Cell Wall Polyuronides. Samples for cell wall polyuronide analyses were collected from each fruit used for sensory evaluation by cutting a wedge from stem to blossom end and frozen at −80 °C for 14−16 weeks before analysis. About 10 g of frozen pear flesh tissue (without peel or core) was collected from each single pear replicate and used for cell wall polyuronide determination. The percentage of water-soluble polyuronides (water-soluble polyuronides/total polyuronides × 100) was determined following the method of Ahmed and Labavitch.[20]

Cell Wall Extraction. Tissue samples (10 g) were boiled in 95% ethanol for 20 min followed by homogenization for 1 min (Polytron PT 10/35; Brinkmann/Kinematica, Westbury, NY, USA). The pellet was collected, and the supernatant was decanted following centrifugation at 1000g for 10 min. The pellet was resuspended in 80% ethanol and recentrifuged at the same speed. This washing cycle was repeated twice to ensure that the pellet was colorless. The pellet was then washed with acetone and dried under a fume hood for 1 day, yielding a crude cell wall extract. Next, the crude cell wall was suspended in dimethyl sulfoxide

(DMSO)/H_2O (9:1 v/v) and shaken at room temperature for 24 h to remove starch. The slurry was centrifuged (1000*g* for 10 min) and the DMSO discarded; the pellet was washed twice in 95% ethanol to remove all trace of DMSO and then washed twice in acetone. The solids were dried under a fume hood for 2−3 days. The alcohol-insoluble and starch-free cell wall material (CWM) was stored in a desiccator for subsequent analysis.

Total Polyuronide Preparation. Cell wall material was weighed (2−3 mg) into a test tube containing a magnetic stir bar. The sample was cooled in an ice−water bath before 1 mL of chilled concentrated sulfuric acid was added. The mixture was stirred gently for 5 min before another 1 mL of chilled, concentrated sulfuric acid was added with an additional 5 min of stirring. Distilled water (0.5 mL) was added dropwise into the mixture and stirred for 5 min followed by another 0.5 mL of dH_2O, and stirring was continued until dissolution was complete (about 1 h). An additional 7 mL of dH_2O was added to a total volume of 10 mL. This solution was ready to assay for uronic acids to determine the total polyuronides.

Water-Soluble Polyuronide (WSP) Preparation. Cell wall material was weighed (30 mg) into a test tube containing a stir bar. Distilled water (10 mL) was added to dissolve WSP in the sample. The sample was stirred for 2 h and then centrifuged at 11840*g* for 25 min. The supernatant was collected for uronic acid assay to determine WSP content.

Uronic Acid Assay. An aliquot (400 μL) of the total polyuronide solution or the WSP supernatant was added to a test tube and cooled in an ice water bath. An aliquot (2.4 mL) of chilled uronic acid reagent (4.767 g sodium tetraborate decahydrate/L concentrated sulfuric acid) was added and mixed. The mixture was heated in a 100 °C water bath for exactly 5 min. The sample was cooled immediately in an ice−water bath. A 1.4 mL aliquot was transferred to another test tube. A 20 μL aliquot of meta-phenyl phenol solution [0.15% (w/v) meta-phenyl phenol in 0.5% (w/v) NaOH] was added to the test tube. A blank sample was included that contained only 20 μL of 0.5% sodium hydroxide (NaOH). The reaction was allowed to continue for about 1 h at room temperature to ensure color stabilization. The color intensity of the sample was determined at 520 nm by spectrophotometry (UV-1601 UV−vis; Shimadzu Co., Columbia, MD, USA). A standard curve was generated using 0, 0.05, 0.10, 0.15, and 0.2 mg mL^{-1} uronic acid and used to calculate sample uronic acid content.

Volatile Compounds. Pear tissue samples for measurement of volatile content were collected from each fruit used for sensory evaluation, cutting a wedge from the stem to the blossom end. Samples were frozen at −80 °C for 18−20 weeks prior to analysis. Frozen pear tissue flesh (10 g, without peel or core) was placed in a test tube, and 10 mL of a saturated $CaCl_2$ solution was added to prevent enzymatic reactions. The mixture was homogenized (Polytron PT 10/35; Brinkmann/Kinematica, Westbury, NY, USA) at speed 4 for 1 min after warming to room temperature. An 8 mL aliquot of the puree was transferred to each of two 20 mL amber glass vials (Supelco Analytical, St. Louis, MO, USA) as two technical replicates. An aliquot (7 μL of a 0.1 mM solution) of 2-methylbutyl isovalerate (Sigma-Aldrich Inc., St. Louis, MO, USA) in methanol was added to each vial as an internal standard.

The volatiles were collected by headspace sorptive extraction (HSSE) and then analyzed by GC-MS (Agilent 7890A GC/5975CMSD; Santa Clara, CA, USA) equipped with a thermal desorption unit (TDU) and a cooled injection system (CIS) (Gerstel, GmbH & Co. KG). The headspace was sampled using a 10 mm magnetic stir bar (also known as Twister; Gerstel GmbH & Co. KG), coated with 24 μL of polydimethylsiloxane (PDMS). The bar, suspended above the sample in the vial, was exposed to the headspace for 1 h at room temperature, while the sample was stirred at 270 rpm, using a 15-position stir-plate (Gerstel GmbH & Co. KG). After exposure, the bars were placed onto the autosampler. The volatile compounds sorbed onto the PDMS coating were thermally desorbed into the TDU and then cryofocused prior to GC-MS analysis for separation and detection. For the thermal desorption, the following parameters were used: initial TDU temperature of 30 °C, then heated to 250 at 720 °C min^{-1} and held for 5 min; transfer line temperature at 280 °C. Simultaneously, the analytes were transferred into the PVT-injector, where they were cryogenically focused at −80 °C, using liquid nitrogen. Initial injection temperature was programmed at −80 °C and then heated to 280 °C at 12 °C min^{-1}. The inlet was operated in split mode (5:1). The GC was equipped with a DB-5MS capillary column (30 m × 0.25 mm; film thickness = 0.25 μm) (Agilent Technologies), injector temperature at 220 °C, and helium carrier gas flow rate of 1.2 mL min^{-1}. The oven temperature started at 40 °C, increased to 80 °C at a rate of 3 °C min^{-1}, and then increased to 180 °C at a rate of 5 °C min^{-1}. MS parameters were as follows: transfer line temperature of 230 °C, source temperature of 230 °C, quadrupole temperature of 150 °C, continuous scan range from m/z 30 to 300. Spectral deconvolution was performed with AMDIS software (version 2.69; NIST, Gaithersburg, MD, USA), and spectra were aligned and analyzed with Mass Profiler Professional (version 2.0; Agilent Technologies). The identity of volatile compounds was confirmed by matching retention time and mass spectra with those of authentic standards whenever possible. When authentic standards were not available, identification was performed by comparing the calculated retention index with published values and matching their spectra with those present in the NIST library (NIST 0.8). Volatile concentrations were calculated by comparing the integrated peak area of each compound with that of the internal standard (15.13 μg L^{-1} 2-methylbutyl isovalerate, final concentration) and are reported as micrograms per kilogram of fruit fresh weight.

Descriptive Sensory Evaluation. The sensory descriptive analysis of fruit samples from each treatment at 27, 18, and 9 N firmness levels was performed by a trained panel. Panelists were recruited on the University of California, Davis, campus and 9 were selected on the basis of interest and availability and trained during six training sessions of 1 h per session per day. Descriptive attributes for aroma, texture, and taste of pear and their definitions were developed during the first session (Table 1). During the training sessions, reference standards for the attributes were presented in 60 mL plastic cups with lids or 1 mL glass vials with caps (aroma attribute references). Refinement of the attributes was discussed among the panelists in two subsequent training sessions. In the following sessions, the panelists were exposed to different ripening stages of pear samples (firm and soft) to practice evaluating the attributes using an unstructured 10 cm line scale on a score sheet and to achieve consensus for how to define and rate the attributes. During the last training session, panelists practiced evaluating pear samples in the actual sensory booths, using automated data collection (Compusense Five software, Ontario, Canada). The final attributes consisted of five aroma, five texture, and two taste attributes (Table 1).

Four individual fruit replicates of each firmness stage were selected from each treatment immediately after their firmness was measured. A slice from each pear fruit, cut as a wedge from the stem to blossom end, and without peel or core, was presented to each panelist. Therefore, there were 4 replicates per judge and 44 replicates (9 judges × 4 fruit reps) per treatment. Each slice was placed in a plastic cup (118 mL with lid) and labeled with a random three-digit code, up to 30 min before tasting began. Pear slices were served with a cup of water and some unsalted saltine crackers as palate cleansers. Panelists were not required to expectorate the samples, but the size of the pear samples and number of samples was small and did not result in satiation. With different ripening rates driven by each treatment, the panelists usually tasted four or eight samples each day using a randomized complete block design for assessing the samples. Evaluation was performed in individual sensory booths under red light at room temperature (20 °C). Descriptions and definitions of pear attributes were posted, and related reference standards for aroma (orthonasal) and taste, as shown in Table 1, were available as references during the tasting. The panelists were asked to evaluate the pear attributes for aromas, textures, and tastes on an unstructured 10 cm line scale using the software program Compusense Five (Compusense).

Statistical Analysis. The data for each sensory attribute were analyzed across treatments at each firmness level (27, 18, and 9 N). Three-way analysis of variance (three-way ANOVA) was conducted to test the effects of treatment, panelists, replicates, and all two-way interactions for each sensory attribute using a pseudomixed model with

Table 1. Pear Attributes, Definitions, and Reference Standards for Sensory Descriptive Analysis of 'Comice' Pears

attribute (general category)	definition	reference standards (intensity on 10 cm line scale)
fruity (aroma)	sweet aromatic, characteristic of ripe fruit	Del Monte canned mixed fruit (peaches, pears, and pineapple) in extra light syrup (10)
apple (aroma)	aroma associated with fresh apple	'Fuji' apple (10)
pear (aroma)	aroma note associated with fresh pears	hexyl acetate high: 3% (v/v) in water (10) medium: 1.5% (v/v) in water (5)
fermented (aroma)	aroma associated with fermented fruits (sweet + alcohol)	high: hard pear cider with 4% alcohol (10) medium: regular apple cider (5)
green stem (aroma)	aroma associated with green wood stems; twiggy	*cis*-3-hexen-1-ol in diluted apple juice in water high: 0.1% (v/v) in 35% apple juice (10) medium: 0.01% (v/v) in 3% apple juice (5)
firmness (texture)	force required to bite completely through the sample (first bite/chew)	firm: 'Fuji' apple (9) medium: flesh of peeled zucchini (5) soft: banana (0.5)
crunchiness (texture)	amount of noise generated when chewing with the back teeth	high: 'Fuji' apple (9) medium: cucumber (5) low: banana (0.5)
juiciness (texture)	amount of wetness or juiciness released from the sample during the first three chews	high: orange (9) medium: 'Fuji' apple (5) low: banana (0.5)
butteriness (texture)	degree of smooth texture of the flesh with an absence of detectable particles, like butter	high: butter (10), milk chocolate (medium quality) (9) medium: apple sauce (5) low: corn meal (0.5)
fibrousness (texture)	presence of fibers that are continuous filaments or are in discrete elongated pieces in the sample	high: 'Tommy Atkins' mango (9) medium: squash/pumpkin (5) low: banana (1)
sweetness (taste)	basic taste on the tongue stimulated by sugar and high-potency sweeteners	Kern's canned pear nectar high: 67% (v/v) in water + 25 g of sugar (9) low: 67% (v/v) in water (1)
tartness (taste)	sour taste stimulated by acids	Kern's canned pear nectar high: 67% (v/v) in water + 0.5 g of citric acid (9) medium: 67% (v/v) in water (5)

the panelist by treatment interaction as denominator (SAS version 9.0, Cary, NC, USA). The analysis of variance was also done across firmness levels for each treatment using a pseudomixed model. The multiple least-squares means comparisons were carried out using Tukey's Studentized range test at $p < 0.05$.

The effects of treatments on volatile compound concentrations, SSC, TA, sugars, and acids were analyzed by analysis of variance (one-way ANOVA) for each firmness level (27, 18, and 9 N) (SAS version 9.0). Multiple least-squares means comparisons were done using Tukey's Studentized range test at $p < 0.05$.

Partial least-squares (PLS) regression analysis was performed to evaluate the relationships between sensory attributes (Y-variables) that were significantly different among the treatments and compositional data (X-variables) that were significantly different among the treatments using Unscrambler (version 9.2., CAMO A/S, Trondheim, Norway). Compositional data included WSP, volatile compounds, SSC, and TA.

RESULTS

Physiochemical Analysis. Firmness changes were monitored during pear ripening at 20 °C after conditioning treatment. Fruit conditioned with ethylene for 3 days or held at 10 °C for 10 days softened to 9 N within 4 days, followed by fruit held at 0 °C for 25 or 15 days, which softened to 9 N within 6 days, and fruit conditioned with ethylene for 1 day, which softened to 9 N within 10 days (Figure 1). Fruit held at 20 °C (nonconditioned control) did not soften to any of the targeted firmness stages, 27, 18, or 9 N, within 31 days (data not shown). As a result, the nonconditioned control fruits were not included in any subsequent evaluations. During softening, pear ethylene production was highest from fruit conditioned with exogenous ethylene for 3 days or held at 0 °C for 25 and 15 days (Figure 2). Fruit conditioned at 10 °C for 10 days or conditioned with

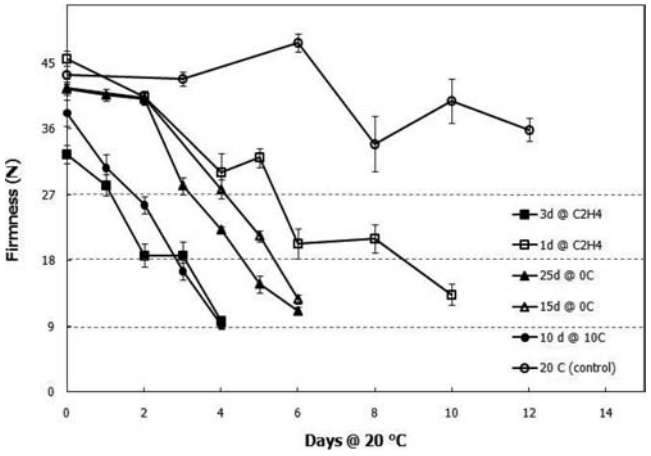

Figure 1. Changes in firmness (N) of 'Comice' pears at 20 °C after conditioning with C_2H_4 at 20 °C for 1 or 3 days or temperature conditioning at 0 °C for 15 or 25 days and at 10 °C for 10 days, and nonconditioned control at 20 °C. Vertical lines represent the standard error of the mean (n = 15).

ethylene for 1 days had similar levels of ethylene production, which were about half that of the highest level. The fruit from the control group had the lowest rate of ethylene production.

Sugar and acid content related to sweet and sour taste were estimated by SSC and TA, respectively. There were differences in SSC across treatments for fruit softened to 27 and 18 N ($p < 0.05$); there were no significant differences in SSC and TA among conditioning treatments when the fruit was softened to 9 N (data not shown). Fruit held at 0 °C for 15 days had the highest SSC at both 27 (15.4%) and 18 (14.0%) N firmness. Comparison of SSC across firmness levels revealed that fruit softened to 27 N had significantly higher SSC (14.2%) than fruit at 18 N (13.7%) and 9 N (13.6%). For TA, there were no significant differences across treatments within the same firmness levels or across firmness levels (data not shown). There were also no differences in the ratio of SSC/TA among treatments, but SSC/TA increased with fruit softening from 65.92 at 27 N to 71.57 at 9 N.

WSP content was not significantly different across conditioning treatments for each firmness level, but significantly increased with fruit softening from 27 to 18 to 9 N (from 17.9 to 26.2 to 38.1%) (data not shown).

Different conditioning treatments resulted in marked differences in pear aroma volatile profiles. Analysis of variance of 48 identified volatile compounds (Table 2) showed significant differences in the levels of 12 individual compounds, total alcohols, and total esters for the 27 N firmness stage; 18 compounds, total aldehydes, total alcohols, total esters, and total volatiles for the 18 N firmness stage; and 15 compounds, total aldehydes, total esters, and total volatiles for the 9 N firmness stage (Table 3). Within a conditioning treatment, the concentrations of many volatiles increased as firmness decreased. However, the magnitude of the increase in concentration of volatiles was dependent on the treatment (Table 3).

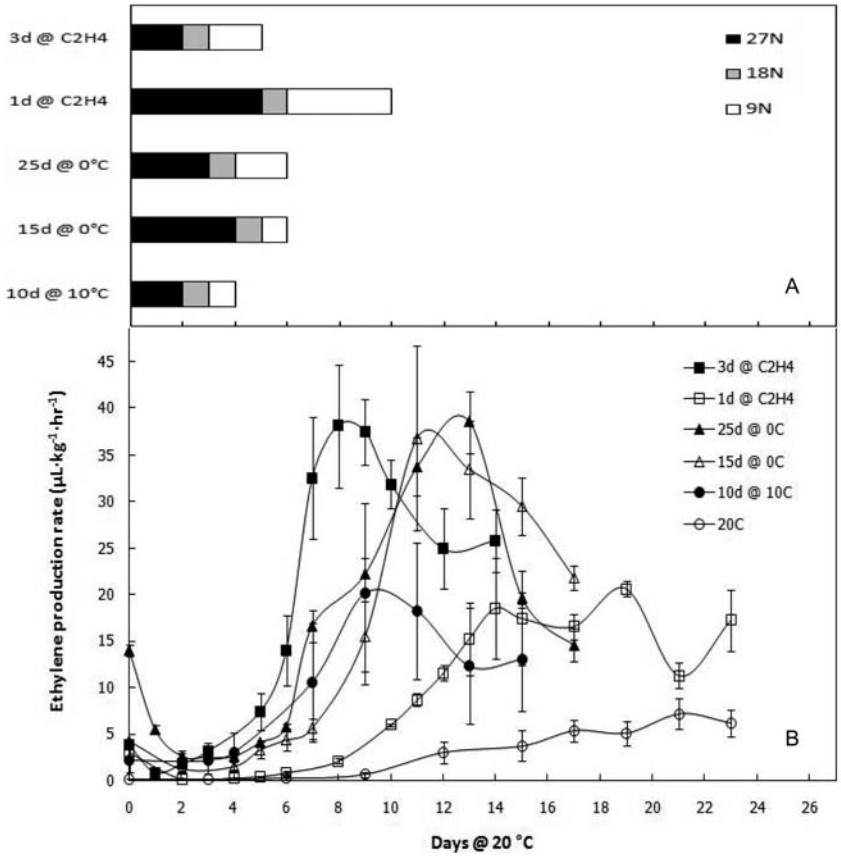

Figure 2. Days required to soften to 27, 18, and 9 N firmness (A) and changes in ethylene (C_2H_4) production (B) of 'Comice' pears at 20 °C after conditioning with C_2H_4 at 20 °C for 1 or 3 days or temperature conditioning at 0 °C for 15 or 25 days and at 10 °C for 10 days, and nonconditioned control at 20 °C. Vertical lines represent the standard error of the mean (n = 3).

[a]Within each row, values with the same lower case letter are not significantly different across treatments (Tukey: $p < 0.05$). Within each column, values with the same capital letter are not significantly different across firmness levels within each compound (Tukey: $p < 0.05$). [b]Not detected. [c]Total volatiles = sum of all compounds detected (all in Table 2). [d]Total aldehdyes = sum of all aldehydes shown in Table 2. [e]Total alcohols = sum of all alcohols shown in Table 2. [f]Total esters = sum of all esters shown in Table 2.

Descriptive Sensory Analysis. For fruit at the 27 N firmness level, an ANOVA using a pseudomixed model revealed that the sensory attributes of firmness, crunchiness, fibrousness, and tartness were significantly different across the different conditioning treatments ($p < 0.05$) (Table 4). The perception of firmness and crunchiness was highest for pears stored at 0 °C for 15 days, followed by pears stored at 0 °C for 25 days and pears stored at 10 °C for 10 days. Pears conditioned with ethylene for 3 and 1 days had the highest perceived fibrousness. Within the 27 N firmness group, pears conditioned with ethylene for 1 day also had the highest perceived tartness, whereas pears stored at 10 °C for 10 days were perceived as lowest in tartness (Table 4).

For fruit softened to 18 N firmness, crunchiness and fibrousness sensory attributes were significantly different across treatments as revealed by ANOVA ($p < 0.05$) (Table 4). Crunchiness was high in cold (0 °C) conditioned fruit, but low in ethylene conditioned fruit. However, ethylene conditioned fruits were perceived as the most fibrous.

For fruit softened to 9 N firmness, ANOVA showed significant differences among the treatments for fruity aroma, pear aroma, firmness, crunchiness, juiciness, and fibrousness sensory attributes ($p < 0.05$) (Table 4). Fruit conditioned at 10 °C for 10 days and at 0 °C for 25 days were highest in fruity aroma and pear aroma attributes. Fruit conditioned with ethylene for 1 day had the lowest perceived juiciness, but were not significantly different from fruit conditioned at 0 °C for 15 days. Fibrousness and firmness were highest in fruit conditioned with ethylene for 1 day, followed by fruit conditioned with ethylene for 3 days, and the latter were similar in fibrousness and firmness to fruit conditioned at 0 °C for 15 days (Table 4).

Relationship between Instrumental and Sensory Analysis. A partial least-squares (PLS) regression analysis showed the relationships and prediction of significant sensory attributes (*Y*-variable) by significant instrumental values (*X*-variable) at each firmness level. For pears with average firmness of 27 N, the first two latent vectors accounted for 95%

Table 4. Mean Sensory Score for Each Attribute in 'Comice' Pears during Softening after Temperature or Ethylene Conditioning[a]

[a]Within each row, values with the same lower case letter are not significantly different across treatments (Tukey: $p < 0.05$). Within each column, values with the same capital letter are not significantly different across firmness levels within each compound (Tukey: $p < 0.05$).

and 58% of the variance for the *X*- and *Y*-variables, respectively (Figure 3). The fibrousness sensory attribute characterized fruit conditioned with ethylene for 1 or 3 days and was negatively correlated with the volatile alcohols 1-octanol and 1-heptanol. Crunchiness and firmness sensory attributes had the strongest positive correlation with these alcohols, and these attributes were associated with fruit held at 0 °C for 25 days. In addition, 1-hexanol, 1-butanol, 1-pentanol, total alcohols, and SSC had the next strongest correlation with firmness and crunchiness, and this group of compounds was associated with fruit held at 0 °C for 25 and 15 days. The tartness sensory attribute was most strongly and positively associated with concentrations of 2-methyl-1-propanol; fruit conditioned with ethylene as well as fruit conditioned at 0 °C for 15 days were highest in both tartness perception and 2-methyl-1-propanol concentration. Fruit conditioned at 10 °C for 10 days had the highest levels of esters, but no sensory attributes were associated with these volatiles at this firmness stage.

dx.doi.org/10.1021/jf405047v | J. Agric. Food Chem. 2014, 62, 4988−5004

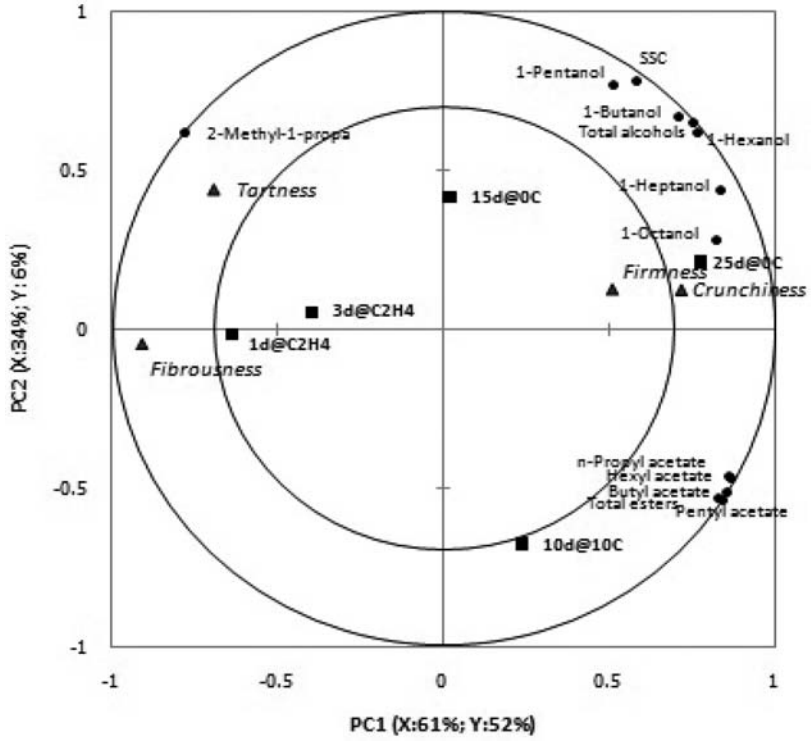

Figure 3. Partial least-squares (PLS) analysis of sensory attributes (*Y*-variable) and instrumental measurements (*X*-variable) of 'Comice' pears at 27 N on the conditioning treatments: (▲) sensory attributes; (●) chemical compounds; (■) conditioning treatments. 2-Methyl-1-propa = 2-methyl-1-propanol.

For pears with average firmness of 18 N, a PLS analysis showed that 92 and 97% of the variance for the *X*- and *Y*-variables was explained by the first two vectors, respectively (Figure 4). The crunchiness sensory attribute was strongly positively associated with high concentrations of 1-butanol, 1-hexanol, and total alcohols, followed by 1-pentanol. These volatiles and crunchiness perception were most associated with pears conditioned at 0 °C. On the opposite quadrant of the PLS map, fruits conditioned with ethylene were most closely associated with the fibrousness sensory attribute and with the concentration of 2-methyl-1-propanol. Pears conditioned with ethylene also had the highest levels of (*E*)-2-hexenal and total aldehydes and the lowest concentrations of esters. Esters, including propyl acetate, butyl acetate, 3-methylbutyl acetate, butyl propanoate, pentyl acetate, 5-hexenyl acetate, hexyl acetate, heptyl acetate, and total esters, as well as total volatiles were highest in pears conditioned at 10 °C.

For pears with average firmness of 9 N, the first two latent vectors accounted for 91 and 88% of the variance of the *X*- and *Y*-variables, respectively (Figure 5). Juiciness, pear aroma, and fruity aroma sensory attributes were negatively associated with fibrousness, firmness, and crunchiness attributes. Juiciness was most strongly correlated with concentrations of the alcohol 1-butanol and was associated with fruit held at 0 °C for 25 days. Pear aroma and fruity aroma were positively correlated with the acetate esters and the total ester concentration. Pentyl acetate had the strongest correlation with pear aroma, whereas butyl acetate had the strongest correlation with fruity aroma. These esters and aroma attributes were strongly positively associated with fruit held at 10 °C for 10 days and negatively associated with fruit held at 0 °C for 15 days. On the other hand, fibrousness and firmness had the strongest correlation with concentrations of 2-methyl-1-propanol, followed by (*E*)-2-hexenal. Crunchiness was highly associated with the concentration of hexanal and total aldehydes, followed by (*E*)-2-hexenal. These sensory attributes and volatile concentrations were most highly correlated with fruit conditioned with ethylene for 1 and 3 days.

Pearson correlation coefficients were also used to evaluate the relationships between sensory and instrumental measurements averaged across all treatments and firmness levels (Table 5). Many interesting correlations were found. For example, concentrations of hexanal and (*E*)-2-hexenal were positively correlated with green stem aroma and perception of fibrousness. Additionally, levels of (*E*)-2-hexenal were significantly negatively correlated with apple aroma intensity. Total aldehydes showed the same pattern of correlation as that of (*E*)-2-hexenal. The levels of the alcohols 1-propanol, 1-butanol, 1-hexanol, and 1-heptanol and the ester butyl acetate were positively correlated with fruity aroma, pear aroma, apple aroma, butteriness, juiciness, and sweetness perception. Propyl acetate, butyl acetate, pentyl acetate, and hexyl acetate were significantly and positively associated with fruity aroma, pear aroma, and butteriness. They were negatively correlated with firmness. Total esters and total volatiles displayed a correlation to sensory attributes similar to that of individual esters. For other analytical measurements, SSC was not significantly correlated with sweetness, whereas TA had a negative correlation with sweetness and a positive correlation with tartness. Moreover, the ratio of SSC/TA was negatively correlated with tartness. WSP levels displayed a very strong positive correlation with some texture (butteriness, juiciness) and some taste (sweetness) attributes, whereas WSP levels were negatively correlated with crunchiness and firmness. WSP levels were also positively correlated with fermented aroma, fruity aroma, and pear aroma (Table 5).

DISCUSSION

Conditioning treatments effectively enhanced ripening of 'Comice' pears as compared to the nonconditioned group. Whereas the control fruit did not soften below 33 N within 31 days at 20 °C, all of the conditioned fruit softened to 13 N within 10 days, and all conditioning treatments except ethylene for 1 day were nearly full ripe (full ripe = 9 N[21]) after 6 days. However, different conditioning methods resulted in different rates of softening. The softening rate of fruit conditioned with ethylene for 3 days, at 10 °C for

10 days, or at 0 °C for 25 days agrees with previously published results.[3]

The ability of the fruit to soften was related to their ethylene production rate, which varied by conditioning treatment. It was previously shown that treatments inducing a higher rate of ethylene biosynthesis resulted in more rapid and uniform softening.[22] In our study, the treatments that took less time to reach the climacteric peak produced more rapid softening. Fruit conditioned with ethylene for 3 days or conditioned at 10 °C for 10 days reached the climacteric peak and softened in the least amount of time, whereas fruit conditioned at 0 °C for 15 or 25 days or conditioned with ethylene for 1 day reached the climacteric peak later and softened more slowly.

The sensory profiles of 'Comice' pears within each firmness level evaluated were different for the various conditioning treatments. At 27 N, the fruits were still unripe and had fewer total volatiles, and the volatiles that were present were at low concentrations; however, once the fruit softened to 9 N firmness, the quantity and the number of different volatile compounds increased, causing many aroma attributes to become significantly different among the conditioning treatments.[23] Treatment at 10 °C for 10 days, followed closely by treatment at 0 °C for 25 days, produced fruit with the strongest fruity aroma and pear aroma, particularly once fruits softened to 9 N. As pears softened and ethylene production increased, the levels of many volatile compounds also increased, in particular, the major components of pear aroma, hexyl and butyl acetate, and total esters. This is consistent with previous studies highlighting a relationship between softening, ethylene production, and aroma volatile biosynthesis in climacteric fruit.[24−27] The volatile compound responsible for the characteristic aroma of 'Comice' pear, ethyl 2-methylbutanoate,[11] was detected in fruit from all treatments and softness stages, but no significant differences were found in ethyl 2-methylbutanoate levels among the conditioning treatments.

The five conditioning treatments resulted in marked differences in the aroma volatile profile. Regardless of the firmness level, the volatile composition of fruit conditioned at 10 °C for 10 days was dominated by esters, whereas ethylene treatments led to an aldehyde-rich volatile profile. The major esters of 'Comice' pear aroma (hexyl acetate and butyl acetate[12]) and other abundant esters that are found in most pear varieties (pentyl and propyl acetate) were highest in fruit conditioned at 10 °C for 10 days at all firmness levels. These compounds have sweet, fruity, floral, and pear notes (Table 6). In addition, other volatiles described as sweet and fruity were associated with fruit conditioned at 10 °C for 10 days, including heptyl acetate and 3-methylbutyl acetate in pears at both 18 and 9 N firmness and butyl propanoate in 9 N pears. Generally, many low boiling point esters increase when pear fruits ripen.[23] It is interesting that 5-hexenyl acetate, a less common fruit volatile previously detected only in 'La France' pear[23] and Chinese quince,[28] was found at significantly higher levels in fruit conditioned at 10 °C for 10 days. The odor of 5-hexenyl acetate is described as coarse, harsh, herbaceous, ketonic, estery, and reminiscent of blue cheese.[23] Similar to the results obtained in 'La France' pear,[23] its levels increased as the fruit softened.

Cold-temperature conditioning (0 °C) resulted in pears with relatively high levels of specific alcohols (1-butanol, 1-pentanol,

1-heptanol, 1-hexanol, 1-octanol) as compared to fruit from other conditioning treatments. These compounds have a sweet, green note except 1-butanol, which is described as fermented and fruity (Table 6). These alcohols described fruit conditioned at 0 °C and softened to 27 N; a reduced number of these compounds described fruit softened to 18 N, and only 1-butanol described fruit softened to 9 N firmness.

Our results showed that fruit conditioned at 10 °C for 10 days developed higher levels of volatiles in general and esters in particular at each ripeness stage evaluated, even though they had lower ethylene production at some firmness levels. The volatile composition of ripe fruit conditioned at 0 °C for 15 days was predominant in aldehydes, whereas fruits conditioned at 0 °C for 25 days were predominant in esters and alcohols. Fruit conditioned with ethylene for 1 or 3 days had high concentrations of aldehydes, but fruit conditioned with ethylene for 3 days also had high concentrations of esters. It appears that the longer treatments with ethylene or at 0 °C, both of which represent recommended treatments for maximum initiation of ripening, resulted in greater production of fruity esters. It will be interesting to further investigate gene expression and enzyme activities involved in alcohol formation (alcohol dehydrogenase, ADH) and ester formation (alcohol acyltransferase, ATT) in each conditioning treatment to determine how ADH and AAT are regulated in 'Comice' pears and the role of ethylene.

Most compounds detected in our study by headspace sorptive extraction (HSSE) have been previously detected in pears using other extraction techniques such as dynamic headspace concentration on carbon traps, simultaneous distillation and extraction, and solid phase microextraction (SPME). However, HSSE can be much more sensitive than those previous methods. Tienpont et al.[29] showed that HSSE was 100 times more sensitive than SPME, with high enrichment factors for highly volatile solutes. Limits of detection were on the order of 0.1 ppb in the full scan MS mode in Tienpont's study. Moreover, HSSE has a higher sensitivity than SPME for nonpolar and some medium polar compounds.[30,31] Using the dynamic headspace method, Lara et al.[32] detected ∼150 and ∼50 μg kg^{-1} butyl acetate and hexyl acetate, respectively, in 'Comice' pears after 2 months of storage at −1 °C and ripening. Suwanagul and Richardson[12] found butyl acetate and hexyl acetate in the amounts of ∼9 and ∼30 μg kg^{-1} 100 L^{-1}, respectively, after the fruits were stored at −1 °C for 3 months and softened. In our study using the HSSE technique, we detected much higher amounts of butyl acetate and hexyl acetate. Fruit conditioned at 0 °C for 25 days and softened to 9 N had 225 and 91 μg kg^{1-} of butyl acetate and hexyl acetate, respectively, whereas fruit conditioned at 10 °C for 10 days had more, with 404 and 412 μg kg^{-1}, respectively. Several compounds not previously identified in pears were detected in our samples, including four aldehydes (decanal, 2-decanal, tetrdecanal, and a tentative identification of pentadecanal), one ester (methyl benzoate), two ketones (2-pentanone, β-damascenone, and limonene) and nonanonic acid (tentative).

Even though the pears used in sensory testing were selected with an instrument (penetrometer) to have the same firmness, panelists perceived significant differences in firmness and crunchiness attributes among the various conditioning treatments. Crunchiness and firmness characterized cold-temperature treatments when the fruits were not fully ripe (27 and 18 N), whereas in 9 N fruit these attributes became prominent in fruit conditioned with ethylene. Juiciness was not significantly different among the various conditioning treatments in firmer fruit, but differences became apparent when the fruit softened to 9 N. At the softest firmness level, fruit that was cold conditioned at 0 °C for 25 days had the highest juiciness score. Fibrousness was consistently high in fruit conditioned with ethylene.

For sensory taste attributes, conditioning treatments did not differentially affect sweetness within any firmness level; however, differences in tartness could be perceived at 27 N, with fruits conditioned with ethylene for 1 day displaying the highest tartness score. Panelists perceived this difference in tartness of fruit conditioned with ethylene for 1 day, which the instrumental measurement (TA) did not detect. TA was significantly correlated to both sensory sweetness and tartness; however, SSC was not significantly related to either. The perception of tartness is influenced by the presence of both acids and sugars,[33] and there were significant differences in SSC in 27 N pears in our study. Aroma compounds can also affect perception of sweetness and sourness.

The instrumental parameters most significantly different (Tukey: $p < 0.05$) among the conditioning treatments were the volatile compounds. However, no significant differences in aroma attributes were perceived by the sensory panel in the firmest (27 N) pears, but differences were observed in 9 N pears. Pear aroma and fruity aroma sensory attributes were strongly correlated with esters, especially pentyl and butyl acetate. Butyl acetate is described as having sweet, vanilla, fruity, and pear notes, similar to pentyl acetate, which has sweet, floral, and banana notes (Table 6). The odor thresholds of these two compounds are low, and their odor units are among the highest of the statistically significant compounds in soft fruit conditioned at 10 °C for 10 days (Table 6). Therefore, butyl and pentyl acetate are likely important contributors to fruity aroma and pear aroma, which were predominant in fruit conditioned at 10 °C for 10 days. Hexyl acetate also exhibited a high odor unit value in soft (9 N) pears conditioned at 10 °C for 10 days; however, in our study, this compound showed weaker association with fruity aroma and pear aroma attributes than the other two compounds using both PLS and Pearson correlation analyses.

Ethyl 2-methylbutanoate has been reported as a characteristic aroma compound in 'Comice' pear.[11] Although the relative concentration of this compound detected in our pear samples was low, given its particularly low odor threshold, the odor unit was high and comparable to that of hexyl acetate in soft pears (9 N) conditioned at 10 °C for 10 days (Table 6). However, there were no significant differences in the concentrations of this compound across conditioning treatments or firmness levels tested. Interestingly, it also showed poor correlation to the sensory attributes in our study (Table 5), indicating that sensory evaluation may uncover additional predictors for characteristic aroma compounds in 'Comice' pears. Other compounds associated with the conditioning treatment at 10 °C for 10 days such as propyl acetate, heptyl acetate, octyl acetate, and 3-methylbutyl acetate may have less impact on aroma perception due to their very low odor units (Table 6). 5-Hexenyl acetate is not commonly found among fruit aroma volatiles; therefore, its odor threshold has not yet been evaluated, and we do not know how strong this compound's contribution is to aroma perception in pears.

Opposite to the sweet and fruity odor type compounds are the green-odor volatiles such as hexanal and (*E*)-2-hexenal. The concentration of these compounds was high in fruit conditioned with ethylene. Hexanal and (*E*)-2-hexenal may contribute to aroma perception in pears conditioned with ethylene at 9 N firmness due to their odor units >1 (Table 6).

Cold-temperature (0 °C) conditioning was associated with high concentrations of alcohols, including 1-butanol, 1-hexanol, 1-pentanol, 1-octanol, and 1-heptanol. These alcohols have a high odor threshold (Table 6), and their odor units in 9 N fruit held at 0 °C for 25 days (the conditioning treatment that resulted in the highest concentrations of these alcohols) were very low (<1). Therefore, these alcohols may be relatively small contributors to aroma in pear fruit conditioned at 0 °C. Esters may contribute more to the aroma of fruit held at 0 °C for 25 days, because this conditioning method also resulted in high production of esters, including butyl acetate and pentyl acetate, which have odor units >1. Hence, fruits conditioned at 0 °C for 25 days were predominant in fruity, pear aroma. However, each of the above assumptions is based on concentrations of volatile compounds calculated relative to the internal standard, and therefore more accurate quantification, along with aroma extract dilution analysis, and aroma reconstitution and omission experiments,[40] is needed to ascertain the precise contribution of each compound to pear aroma following each conditioning treatment.

Consumer studies have found that people like juicy and sweet pears with detectable pear flavor and aroma.[1,4,34] From the correlation table, the analytical variables (i.e., butyl acetate, pentyl acetate, hexyl acetate, propyl acetate, 3-methylbutyl acetate, 5-hexenyl acetate, heptyl acetate, 1-butanol, 1-hexanol, 1-hepatanol, 1-propanol, 1-octanol, total esters, total alcohols, total aroma, and WSP) all had similar positive correlations with sensory attributes including fruity aroma, pear aroma, apple aroma, fermented aroma, butteriness, juiciness, and sweetness; these compounds may therefore be indicators of ripeness associated with desired eating quality. The compounds having high correlation with fruity aroma ($r > 0.85$) and pear aroma ($r > 0.75$) were butyl acetate, pentyl acetate, and hexyl acetate. On the other hand, hexanal, (*E*)-2-hexenal, and pentanal were positively correlated with green stem aroma, an attribute that is generally undesirable in ripe pears.[1]

Water-soluble polyuronide content was the variable that best correlated with texture attributes generally associated with ripe fruit, such as butteriness ($r = 0.95$), juiciness ($r = 0.94$), and sweetness ($r = 0.95$), and was negatively correlated with firmness ($r = -0.93$) and crunchiness ($r = -0.92$). Our results are consistent with previous studies which showed that WSP levels increased as fruit softened[6] and that the fruits with higher WSP were more buttery and juicier than those with lower WSP.[6] Although there were significant differences in WSP among the firmness stages, the conditioning treatments did not affect WSP levels. This is interesting given the significant differences in perception of firmness, crunchiness, juiciness, and fibrousness that were detected among the conditioning treatments.

The present study found that SSC was not a good instrumental parameter for predicting sensory sweetness, confirming prior studies.[19,34,35] However, TA was a good parameter for predicting sensory sweetness and tartness, and SSC/TA was good for predicting sensory tartness. These results agree with previous studies.[19,36]

In conclusion, different conditioning treatments resulted in different sensory attributes of 'Comice' pears. The 10 °C for 10 day and 0 °C for 25 day treatments resulted in ripe fruit described as having fruity and pear aroma attributes that were associated with high ester content, especially butyl, pentyl, and hexyl acetate. These esters were much higher in fruit conditioned at 10 °C than at 0 °C. Fruity and pear aroma attributes were much lower in fruit conditioned at 0 °C for 15 days. Although treatment at 0 °C resulted in fruit with higher concentrations of alcohols, the odor units for these alcohols were low, and therefore their contribution to aroma perception is uncertain. Ester levels were also elevated in fruit conditioned at 0 °C for 25 days compared with other treatments, although not as high as in fruit conditioned at 10 °C. Ethylene treatments produced fruit described predominantly as fibrous in texture and having sweet, green aroma notes. The concentrations of hexanal and (*E*)-2-hexenal were high in fruit conditioned with ethylene for 1 day. When the same type of conditioning treatments were compared, fruit conditioned at 0 °C for 25 days had higher sweetness and juiciness scores than fruit conditioned at 0 °C for 15 days, and fruits conditioned with ethylene for 3 days were juicier than fruits conditioned with ethylene for 1 day. It is essential to determine whether the differences in sensory attributes observed among these conditioning treatments will influence consumer liking before the industry can determine the best conditioning treatment to use to maximize consumer satisfaction. This remains for a future study.

v/v). For aromatic reconstitutions, the various esters were added individually or blended together at the average concentrations found in red wines (Table 1),[32,33] to double-distilled ethanol and microfiltered water, to obtain an ethanol level of 12% (v/v) (pH adjusted to 3.5 with tartaric acid).[34]

Table 1. Composition of the Fruity Aromatic Reconstitutions Presented in the Olfactory Tests

compound	C (μg/L)
ethyl propanoate	150
ethyl butanoate	200
ethyl hexanoate	200
ethyl octanoate	200
ethyl 2-methylpropanoate	250
ethyl (2*R*)-2-hydroxy-4-methylpentanoate and ethyl (2*S*)-2-hydroxy-4-methylpentanoate (95:5, m/m)	400
ethyl 3-hydroxybutanoate	300
butyl acetate	10
hexyl acetate	2
methylpropyl acetate	50
methylbutyl acetate	250

GC-O Analysis of Reference Compounds. GC-O analyses were carried out to ensure that the high-purity reference compounds did not contain any odoriferous impurities and to ascertain that the compound considered was responsible for the odor properties identified. Olfactometry analyses were carried out using an HP-6890 gas chromatograph (Hewlett-Packard, Wilmington, DE, USA), equipped with a flame ionization detector (FID) and a sniffing port (ODO-I SGE, Ringwood, Australia), connected by a flow-splitter to the column exit. GC effluent was combined with humidified N_2 (Air Liquide, France) at the bottom of the glass-sniffing nose (SGE, Victoria, Australia) to avoid nasal dehydration. Samples containing <0.2 μL of each pure odorant were injected in splitless−split mode (injector temperature, 240 °C; splitless time, 30 s; split flow, 50 mL/min). The column was a BP20 (50 m × 0.22 mm i.d., film thickness = 0.25 μm, SGE, Ringwood, Australia). The oven was programmed at 40 °C for the first minute, and the temperature increased at a rate of 10 °C/min to a final isotherm at 220 °C for 10 min. The carrier gas was hydrogen 5.5 (Air Liquide, France) with a column head pressure of 15 psi.

1 Quantitation and Separation. Sample preparation was as optimized by Antalick et al.[33] The fiber (Supelco, Bellefonte, PA, USA) was coated with a 100 μm stationary phase polydimethylsiloxane film (PDMS-100). For the quantitative study, 20 μL of ethyl-d_5 butanoate, at about 200 mg/L in absolute ethanol, was added as an internal standard to 25 mL of the wine samples. A 10 mL sample of the mixture was placed in a 20 mL headspace vial, 3.5 g of sodium chloride was added, and the vial was tightly sealed with a PTFE-lined cap. The solution was homogenized in a vortex shaker and then loaded onto a Gerstel (Mülheim an der Ruhr, Germany) autosampling device. The program consisted of swirling the vial at 500 rpm at 40 °C for 2 min, then inserting the fiber into the headspace at 40 °C for 30 min as the solution was swirled again, and, finally, transferring the fiber to the injector for desorption at 250 °C for 15 min.

Gas chromatography analyses were carried out on an HP 6890N GC system coupled to an HP 5973 inert quadrupole mass spectrometer, equipped with a Gerstel MPS2 autosampler. Injections were in splitless mode, using a 2 mm i.d. nondeactivated direct linear (injector temperature, 200 °C; purge flow, 17.4 mL/min; interface temperature, 200 °C) and a Chiraldex B-DM column (40 m × 0.25 mm i.d., film thickness = 0.12 μm, Astec, Whippany, NJ, USA). Oven temperature was programmed at 30 °C for the first minute, raised to 60 °C at 2 °C/min, and, finally, increased at 4 °C/min to a final isotherm at 200 °C, maintained for 10 min. The carrier gas was helium Alphagaz 2 (Air Liquide, France) with a column head pressure of 15 psi. The mass spectrometer was operated in electron impact mode at 70 eV with selected ion monitoring (SIM), using seven characteristic ions: *m/z* 102 as quantifier and *m/z* 57, 85, 87, 74, 115, and 130 as qualifiers. **1a** and **1b** were characterized by comparing their linear retention indices and mass spectra with those of standards.

Calibration curves were evaluated in dilute alcohol solution (12%, v/v), using a representative range of average ester concentrations found in wines (linear range = 0.2−400 μg/L). The calibration curves were plotted as the relative peak areas (analyte versus the internal standard) as a function of the compound concentration. The functions are linear over the concentration range, presenting correlation coefficients of 0.9932 and 0.9955 for **1a** and **1b**, respectively. Repeatability was evaluated by relative standard deviation of 10 independent assays performed under the same analytical conditions over a short period of time. The relative standard deviation of the area ratios was <10% for both enantiomers, 7.6 and 6.8% for **1a** and **1b**, respectively. Detection and quantitation limits represent the average of 10 determinations at the lowest measurable peak area plus 3 and 10 times the standard deviation of this result, respectively. The limit of detection and limit of quantitation of both enantiomers were 0.2 and 0.6, respectively.

Recovery was also evaluated by adding **1a** and **1b** to a red wine with a low level of both enantiomers. Six different concentrations of **1a** and **1b** were spiked in the wine prior to extraction with dichloromethane (1, 5, 10, 50, 100, and 300 μg/L). The recovery was from 94 to 104% for both enantiomers.

Sensory Analyses. *General Conditions.* Sensory analyses were performed as described by Martin and de Revel.[35] Samples were evaluated at controlled room temperature (20 °C), in individual booths, using covered, black, ISO glasses (ISO 3591:1977),[36] containing about 50 mL of liquid, coded with three-digit random numbers. Sessions lasted approximately 5 min. Very recently Lytra et al.[34] evaluated the evolution of these 12 esters in dilute alcohol solution to assess the stability of the samples submitted to the panel. This evaluation demonstrated that the esters remained stable for the first 10 min. Consequently, the solutions presented to the panel were prepared every 10 min.

Sensory Panel. Panel 1 consisted of 22 judges, 10 males and 12 females, aged 28.4 ± 6.3 (mean ± SD) years. Panel 2 consisted of 8 judges, 2 males and 6 females, aged 27.3 ± 5.2 (mean ± SD) years. Panel 3 consisted of 18 judges, 8 males and 10 females, aged 29.3 ± 4.7 (mean ± SD) years. All panelists were research laboratory staff at ISVV, Bordeaux University, selected for their experience in assessing fruity aromas in red wines. They attended three sessions per week, for 4 weeks, each lasting 5 min. Fresh berry-fruit standards were presented (blueberry, blackberry, black currant, strawberry, cherry, and raspberry). Commercial jams, made from the same fruits, were presented directly as jammy fruit standards.

Discriminative Testing Methods. Olfactory thresholds were determined by panel 1 in dilute alcohol solution, using a three-alternative, forced-choice presentation (3-AFC) (NF ISO 13301:2002).[37] Each session consisted of 10 forced-choice tests. Each test contained one positive sample supplemented with increasing concentrations of the compound to be evaluated (Table 2). The olfactory thresholds of **1b** and the racemic mixture **1a** and **1b** (50:50, m/m) were measured.

The "olfactory thresholds" of specific mixtures were also established by panel 1. "Olfactory thresholds" of total aromatic reconstitution (TAR) excluding **1** were thus measured in two different matrices: dilute alcohol solution and dilute alcohol solution containing 50 μg/L **1b** (Table 2).

The results of all 3-AFC tests were statistically analyzed. The olfactory threshold was defined as the concentration at which the probability of detection was 50%. This statistical value was determined using an adaptation of the ASTM-E1432 method.[38] The concentration/response function is a psychometric function and fits a sigmoid curve ($y = 1/(1 + e^{(-\lambda x)})$). Detection probability was corrected using the chance factor ($P = (3p - 1)/2$, where p = proportion of correct responses for each concentration and P = proportion corrected by the chance effect, 1/3 for 3-AFC). Sigma Plot 8 (SYSTAT) software was used for graphic resolution and ANOVA transform for nonlinear regression.[39]

Table 2. Composition of Samples Subjected to Olfactory Threshold Determination in Different Matrices

compound tested	test concn (μg/L)	matrix
ethyl (2*R*)-2-methylbutanoate and ethyl (2*S*)-2-methylbutanoate (50/50, m/m)	0.5/1/2/4/8/16/32/64/128/256	dilute alcohol solution
ethyl (2*S*)-2-methylbutanoate	0.5/1/2/4/8/16/32/64/128/256	dilute alcohol solution
aromatic reconstitution	**aromatic reconstitution diluted in 50 mL of matrix (mL)**	**matrix**
fruity aromatic reconstitution excluding ethyl 2-methylbutanoate	0.1/0.2/0.4/0.8/1.6/3.1/6.3/12.5/25/50	dilute alcohol solution, dilute alcohol solution + 50 μg/L ethyl (2*S*)-2-methylbutanoate

A triangular test[40] was also performed, using two samples of aromatic reconstitutions in dilute alcohol solution. The first consisted of the fruity pool, consisting of all the esters excluding **1**, and the second contained the same fruity aromatic reconstitution supplemented with 50 μg/L **1b**. Three numbered samples were presented in random order, two identical and the third one different. Each judge had to identify the sample perceived as different in each test and give an answer, even if s/he was not sure. The results of this triangular test were statistically interpreted, according to the tables given in the literature,[35] on the basis of the binomial law corresponding to the distribution of answers in this type of test.

Descriptive Testing Methods. Descriptive analyses of the racemic mixture of **1** and the *S*-form alone were carried out by panel 2, using in both cases a concentration of 60 μg/L in dilute alcohol solution. Judges were asked to propose a maximum of three descriptors.

Panel 3 evaluated the sensory profiles of aromatic reconstitutions for overall aromatic intensity, red-berry-, black-berry-, fresh-, and jammy-fruit aroma intensity. Each sample was presented twice in each session. Two samples of aromatic reconstitutions in dilute alcohol solution were presented. The first consisted of the fruity pool, including all of the esters except **1**, and the second contained the same fruity aromatic reconstitution supplemented with 50 μg/L **1b**. For each sample, the subject rated the intensity of these descriptors on a 100 mm scale printed on paper, labeled "no odor perceived" on the left and "very intense" on the right.

Statistical data were analyzed using R analysis of variance (ANOVA) software: the homogeneity of variance was tested using Levene's test, and the normality of residuals was tested using the Shapiro–Wilk test. All descriptors were mean-centered per panelist and scaled to unit variance. The statistically significant level was 5% ($p < 0.05$).

RESULTS AND DISCUSSION

1 Enantiomer Distribution and Concentrations. The optical isomers of **1** were separated by chiral GC analysis on a β-cyclodextrin phase.

As previously observed, in the oldest wines, **1** levels were generally higher than those found in the youngest ones. The maximum concentration was 157 μg/L (Haut Médoc, 1988), and the minimum concentration was 3 μg/L (Pessac-Léognan, 2010), with an average concentration of about 50 μg/L. In light of these finding, it seems likely that only a few micrograms per liter of **1** was formed during alcoholic fermentation. Wine aging is marked by a gradual increase in **1** concentrations over time, stabilizing after about 5 years. These results corroborate those of Diaz-Maroto et al.,[41] who observed a tendency to **1** formation during wine aging. Other studies also reported that concentrations were higher in old red wines than in young red or white wines,[42] suggesting that it could be formed by esterification of the corresponding acid.

With regard to the enantiomeric distribution of **1**, the *S*-enantiomer was found almost exclusively in all wines studied. Generally, young red wines (2010) contained only the *S*-form, whereas very small amounts of the *R*-form were detected in aged red wines. The *R*-enantiomer is formed during storage, starting in the first year. Table 3 shows the enantiomeric distribution in the red wines studied. The highest **1a** levels were found in the oldest samples, with a maximum concentration of 1.3 μg/L (Médoc, 1985). The maximum enantiomeric ratio was 100% for the *S*-form (all 2010 vintage red wines). However, two wines (Pessac-Leognan) from young vintages contained particularly high **1a** ratios (2009 and 2008: 2.6 and 2.2%, respectively), but concentrations did not exceed 0.3 μg/L in either sample.

These findings are in agreement with data of previous studies on Dornfelder red wine, where analysis of **1**demonstrated that it occurred as its *S*-enantiomer in red wine, also identified as a key odorant.[29]

These results highlighted the importance of the *S*-enantiomeric form, in view of its relative abundance in red wines. According to Diaz-Maroto et al.,[41] ethyl esters of branched-chain fatty acids, such as **1b**, may be formed during alcoholic fermentation by *Saccharomyces cerevisiae* from the corresponding amino acid, L-isoleucine (2*S*,3*S*) in this case, through their transformation into α-oxo acids, which are decarboxylated to produce aldehydes, which are, in turn, oxidized to form the corresponding acids.

Our findings concerning the enantiomeric distribution of **1** are in agreement with previous investigations into its enantiomeric distribution in several fruits, which revealed that **1** occurred exclusively in the *S*-configuration.[6,10] More recent research found that the *S*-configuration represented at least 98% of **1**, with minute amounts of the *R*-form.[14,27,28]

Preliminary Verifications. GC-O analysis found parasite odors in some commercial odorant stimuli. These were eliminated, and new commercial products were purchased. Finally, all compounds used in this work were olfactively pure, as confirmed by the three judges who performed this analysis. Moreover, FID analysis confirmed the products' very high purity.

1b in dilute alcohol solution, determined by panel 1, was 2.60 μg/L, almost twice that of the *S*-form, which was 1.53 μg/L (confidence interval < 0.01) (Figure 1). These results match

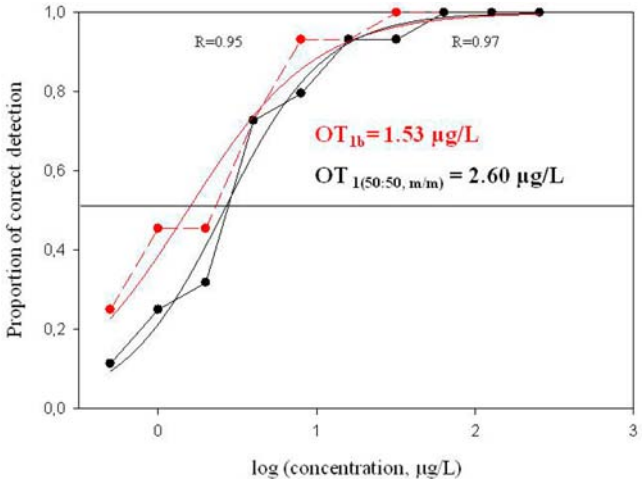

Figure 1. Detection probability of **1b** and the **1** racemic mixture (50:50, m/m) in dilute alcohol solution. OT, olfactory threshold. The curves are drawn according to a sigmoid function. **1**, ethyl 2-methylbutanoate; **1b**, ethyl (2*S*)-2-methylbutanoate.

those presented by Guth et al.,[27] who established the olfactory threshold of the racemic mixture in dilute alcohol solution (10%, v/v) at 1 μg/L. However, Ferreira et al.[43] referred to an olfactory threshold almost 7 times higher than our finding: 18 μg/L for **1** in synthetic wine model solution (11% v/v ethanol, 7 g/L glycerin, 5 g/L tartaric acid, pH adjusted to 3.4 with 1 M NaOH). In addition, both enantiomers have previously been studied in water: Amano et al.[44] mentioned an olfactory threshold of 10 μg/L for both enantiomers, whereas Takeoka et al.[6] referred to an olfactory threshold of 0.006 μg/L for the *S*-enantiomer, and, more recently, Buettner and Schieberle[14] determined the retronasal olfactory threshold of the *S*-enantiomer in water at 0.004 μg/L. The difference between our results and those found in the literature may be due to the fact that the olfactory threshold is extremely variable according to the matrix, experimental conditions (retronasal or orthonasal olfactory threshold, olfactory threshold determination method, etc.), and panel.[38,39,45]

As shown in Figure 2, the "olfactory threshold" of the fruity pool (excluding **1**), calculated by panel 1 in two different matrices, was 2.39 mL in dilute alcohol solution and 0.86 mL (diluted in 50 mL of each matrix) in dilute alcohol solution supplemented with 50 μg/L **1b** (confidence interval < 0.001).

These results, obtained using the average of the **1b** concentrations found in the red wines studied, detected by 98% of the panelists in dilute alcohol solution, confirmed the complexity of the matrix containing **1b**. Whereas a decrease in intensity is the most frequent effect of odor mixtures,[46] these data demonstrated that, despite the complexity of the matrix due to the suprathreshold concentration of **1b**, this compound enhanced the perception of fruity aromas. This effect may be explained by the fact that the fruity pool contained esters that were chemically and structurally similar to **1**.[47]

Organoleptic Impact of 1 on Qualitative Odor Perception. At concentrations perceived by the whole panel (60 μg/L), **1b** was mainly defined by fruity descriptors, such as green apple (Granny Smith) and strawberry, whereas a racemic

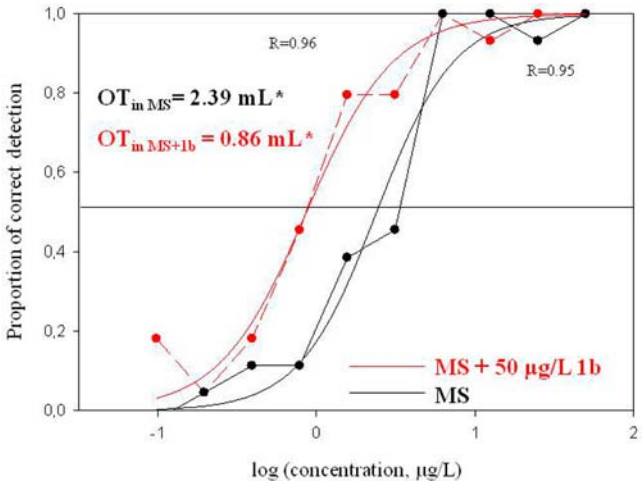

Figure 2. Effect of ethyl 2-methylbutanoate addition on the probability of detecting a fruity aromatic reconstitution. * Expressed in milliliters of fruity aromatic reconstitution diluted in 50 mL of matrix; **1**, ethyl 2-methylbutanoate; **1b**, ethyl (2*S*)-2-methylbutanoate; MS, model wine solution (dilute alcohol solution); OT, "olfactory threshold". The curves are drawn according to a sigmoid function.

mixture of **1a** and **1b** at the same concentration in dilute alcohol solution, also perceived by the whole panel (60 μg/L), was defined by an unspecific, irritating, fruity, solvent odor. Descriptors such us green apple for **1b** and an unspecific note for **1a** were previously mentioned in the literature by Amano et al.[44]

Before sensory analysis evaluation, the triangular test revealed that adding 50 μg/L **1b**, the average concentration found in red wines, to the fruity aromatic reconstitution, excluding **1**, was significantly perceived, confirming its impact in that fruity matrix. Later evaluations on a 100 mm scale of intensity revealed significant differences in black-berry-fruit intensity between the fruity aromatic reconstitution without **1** and that supplemented with 50 μg/L **1b** (Figure 3), whereas the average scores for red-berry-, fresh-, and jammy-fruit aroma descriptors were not modified by the addition of this ester. These results confirmed the sensory impact of 50 μg/L **1b**, suggesting that it contributed actively to the black-berry-fruit

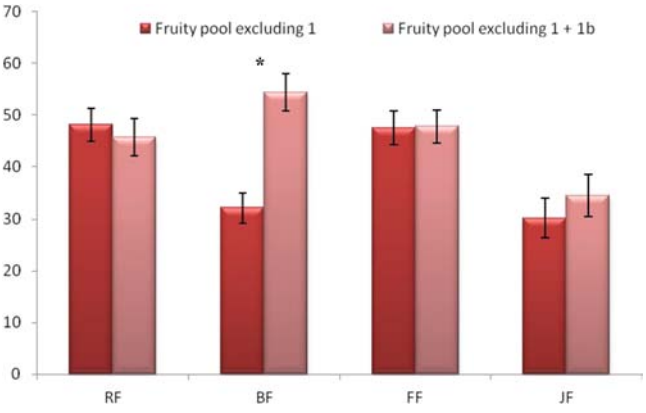

Figure 3. Mean intensities of aromatic descriptors of fruity aromatic reconstitutions prepared in dilute alcohol solution. *, $p < 0.05$; **1**, ethyl 2-methylbutanoate; **1b**, ethyl (2*S*)-2-methylbutanoate; RF, red-berry fruit; BF, black-berry fruit; FF, fresh fruit; JF, jammy fruit. nuances in the fruity matrix studied. The impact of **1** on qualitative odor perception was also demonstrated for complex mixtures of fruits, by Buettner and Schieberle[14] and Schieberle and Hofmann,[15] using omission tests, which revealed additive effects for the fruity aroma note. The qualitative contribution of **1b** was successfully demonstrated by Amano et al.,[44] who found that the *S*-enantiomer was an aroma-improving compound in food and drink, enhancing green and fresh notes.

Pineau et al.[32] demonstrated by addition tests that **1**, at a concentration of 40 μg/L, well below to its individual olfactory threshold in the wine matrices studied, contributed to black-berry-fruit aromas. The behavior of **1b** is similar to that of ethyl 2-hydroxy-4-methylpentanoate, as well as ethyl-3-hydroxybutanoate, ethyl propanoate, butyl acetate, and 2-methylpropyl acetate, compounds with similar chemical structures, recently described by Lytra et al.[34,48]

These experiments clarified current knowledge of this compound, particularly the relative abundance of its enantiomers. Taken together, these data revealed the importance of **1b**, due to its preponderance in all wines studied combined with its low olfactory threshold compared to that of the racemic mixture of **1a** and **1b**. In addition, the *S*-enantiomer, which was found almost exclusively in all wines studied, had a more pleasant, clearly fruity aroma than the racemic mixture of **1a** and **1b**, highlighting the real olfactory impact of this ester on the expression of fruity aroma.

Furthermore, the omission of **1b** from a complex matrix, such as an aromatic reconstitution of fruity esters, was clearly perceived. These findings also highlighted the indirect contribution of **1b** to red wine fruity esters aroma, showing that this ester enhanced perception of fruity character, particularly naturally enhancing black-berry-fruit aromas.

DCCD, to detect ceftiofur residues in animal tissues.[12−23] DCCD is one of the ceftiofur metabolites that contribute to the concentration of ceftiofur residues as measured by the HPLC-UV method. Because DFC (including naturally derivatized forms, measured as DCA and referred to as "total DFC" in the following context) is the official marker residue designated for regulatory testing, we hypothesized that DCCD may be used as a surrogate marker residue if a quantitative relationship between DCCD and total DFC can be established.

In the past two decades, liquid chromatography−tandem mass spectrometry (LC-MS/MS) has become a predominant tool in the analysis of small molecular weight drugs and metabolites in biological samples.[14,16,20,21,23−26] It offers superior specificity to the conventional HPLC. By using d_3-cysteine-DCCD, an internal standard (IS) synthesized in our laboratory, we developed[15] a simple and quantitative LC-MS/MS method for detecting DCCD in bovine kidney. The method was quantitative because the labeled IS corrects for the matrix effect. We observed, however, a small degree (up to 1.5%) of deuterium-to-hydrogen conversion when d_3-cysteine-DCCD was exposed to kidney tissue, which presumably was due to thiol−disulfide exchange with endogenous non-deuterated cysteine in the sample matrix. Therefore, d_3-cysteine-DCCD can be added only after the SPE cleanup, and matrix-based calibration must be used to achieve quantitative results. Recently, a new IS (d_3-methoxy-DCCD) has become commercially available (see Materials and Methods). When spiked into extracts, the concentration of this compound is expected to be unaffected by the unavoidable interchange with endogenous cysteine.

Besides the target kidney tissue, other edible tissues are sometimes analyzed as alternatives in regulatory testing, especially if tolerance levels have been established in those tissues. Therefore, in addition to kidney, we are also interested in investigating bovine liver and muscle.

In summary, the goals of the present study are to (1) further improve the method for detecting DCCD in bovine kidney using the new IS (d_3-methoxy-DCCD), (2) establish the correlation in kidney between the HPLC regulatory method and the improved LC-MS/MS method, and (3) develop a quantitative LC-MS/MS method for DCCD in bovine liver and muscle.

MATERIALS AND METHODS

Reagents and Supplies. Ultrapure water was generated using a Milli-Q water purification system from Millipore (Danvers, MA, USA) to give resistivity ≥18 MΩ·cm^{-1} and was used for all references to water. Methanol (MeOH) and acetonitrile (MeCN) were high-purity grade from Burdick & Jackson (Muskegon, MI, USA). Formic acid was Optima grade for LC-MS from Fisher Scientific (Pittsburgh, PA, USA). All other chemicals were ACS grade reagents from Fisher Scientific. Strata X SPE columns (33 μm, 60 mg, 3 mL) were purchased from Phenomenex (Torrance, CA, USA). Amber glass vials (12 × 32 mm) with preslit PTFE/silicone septa for a LC-MS/MS autosampler were purchased from Waters (Milford, MA, USA).

Reference Standards. Reference standard materials of DCCD (96% chemical purity) and d_3-methoxy-DCCD (98.9% isotopic purity and 96% chemical purity) were purchased from Toronto Research Chemicals (Toronto, Canada). Working solutions of DCCD at 0.1, 0.2, 0.4, 0.6, 1.0, 2.0, 4.0, and 8.0 μg/mL were prepared in water as described previously.[15] Stock solutions of IS were prepared in water at approximately 0.4 mg/mL and diluted to 3.0 μg/mL for use as working solution. All standard solutions were stored at −80 °C until analysis.

Ceftiofur hydrochloride reference materials of various potencies were supplied by Pfizer Animal Health (Kalamazoo, MI, USA) for the regulatory HPLC-UV analysis. Stock solutions at 100 μg/mL (ceftiofur free acid equivalent) were prepared in phosphate buffer (pH 7.0) and stored at < −10 °C for up to 6 months. Serial dilutions of the ceftiofur stock solution with buffer to 10.0 and 1.0 μg/mL were prepared on the day of the HPLC analysis.

Bovine Tissue Samples. This study was approved by the Institutional Animal Care and Use Committee (IACUC) of the Office of Research under FDA/CVM, in accordance with the *Guide for the Care and Use of Laboratory Animals* provided by the National Research Council. Experiment animals (Holstein steer) were housed in climate-controlled facilities accredited by the Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC). Control kidney, liver, and muscle samples were obtained from either a local grocery store (later screened negative for ceftiofur residues by the LC-MS/MS methods described herein) or in-house reared steers with tracked records certifying that they were never treated with ceftiofur.

Dosing was performed at the FDA/CVM animal facility. The animal study was divided into three phases. Phase 1 was the plasma depletion of the drug, phase 2 was the washout period, and phase 3 was the incursion of tissues. Animals were dosed in phases 1 and 3. The drug used in the study was Naxcel (ceftiofur sodium; PBS Animal Health, Massillon, OH, USA). The administration route was intramuscular injection. Dosage was 2.2 mg/kg body weight at 24 h intervals for 5 days in both phases 1 and 3.

During phase 1, eight healthy animals were dosed and plasma samples were taken before dosing and at various time points after the last dose. Because there are no previous data on DCCD depletion in bovine kidney, phase 1 was partially intended to provide some guidance for tissue harvesting time. The results for this part of the study will be published elsewhere. Following the completion of phase 1, these animals went through a 2 week minimum washout period (phase 2), and plasma samples were analyzed again to make sure the drug had been depleted completely before phase 3 started. Seven of the eight animals were dosed a second time in phase 3 to harvest incursion tissue and plasma samples. Samples were obtained at 24, 30, 36, 48, 60, 64, and 76 h, respectively, after the last dose to obtain different concentrations in kidney. We anticipated a wide range of concentrations from below the tolerance to several times the tolerance. After removal of the fat tissue and outer layer of membrane, the whole kidneys, ∼500 g of liver (approximately equal portions from four different lobes), 50 mL of plasma, ∼500 g of muscle at the injection site, and ∼500 g at other muscle sites located remotely from the injection site [diaphragm and hind limb muscles (semimembranosus and semitendinosus)] were collected in the necropsy room and transported to the laboratory with dry ice. Kidney (whole) and liver (mixture of four lobes: left, right, caudate, and quadrate) were cut into ∼$^1/_4$ in. sections that were ground into a semiliquid mixture with a blender. The homogenized kidney or liver samples were stored at −80 °C after grinding. Muscles were cut into ∼$^1/_8$ in. sections and ground into a powdery mixture using a 1:3 ratio with dry ice. The powder was first placed in a −20 °C freezer for 24−48 h to sublimate the carbon dioxide; then it was stored at −80 °C. Tissue samples obtained from a steer 12 h after the last dose, as described in our previous study,[15] were also included in the present analysis.

Analysis of DCCD. *Calibration Standards.* To prepare 1 mL of the individual solvent-based calibration standards, 100 μL of the IS working solution was transferred into eight amber autosampler vials. Then 100 μL of each of the DCCD working standard solutions was added to the autosampler vials followed by 800 μL of water and vortex-mixed.

Kidney Extraction. The kidney extraction procedure is modified on the basis of our previous paper.[15] Briefly, 100 μL of IS working solution was added to approximately 0.4 ± 0.008 g of test and control samples (thawed to room temperature first) in 10 mL Falcon round-bottom polypropylene (PP) tubes (Fisher Scientific). Then 3.5 mL of 1% phosphate buffer (pH 6.2) was added to all samples. The samples were homogenized for 30 s using an Omni Prep homogenizer with

disposable plastic probes (Omni International, Marietta, GA, USA), followed by centrifugation (Thermo IEC, Centra GP-8R) at 4140*g* (standard gravity) at room temperature for 20 min. The supernatant was subjected to SPE cleanup. The SPE cartridges were conditioned sequentially with 2 mL of MeOH and 2 × 2 mL of water. Raw extracts were loaded onto the SPE cartridges and eluted under gravity. Cartridges were washed with 2 mL of water before the analyte and IS were eluted with 2 mL of MeCN/water (50:50, v/v) into graduated 15 mL PP centrifuge tubes. The eluate was evaporated under N_2 at 40 °C to 1 mL or slightly less than 1 mL. If necessary, water was added to bring the volume to the 1 mL mark. The samples were centrifuged at 4140*g* at room temperature for 10 min, and the supernatant was transferred into prelabeled autosampler vials. For samples that remained turbid after centrifugation, the extracts were filtered directly into the autosampler vials through 13 mm, 0.2 μm, PVDF syringe filters using a 3 mL disposable syringe.

Liver and Muscle Extraction. After the samples were thawed to room temperature, approximately 0.2 ± 0.01 g of test and control samples was weighed into 10 mL Falcon round-bottom PP tubes. Samples were centrifuged for 2 min at 200*g* to bring tissue to the bottom of the tubes. The IS working solution (100 μL) was added to each sample followed by 3 mL of 1% phosphate buffer. The samples were homogenized for 30 s followed by the addition of 3.5 mL of MeCN. The mixture was vortexed on a multitube vortexer (VWR, Bridgeport, NJ, USA) for 2 min. Samples were centrifuged at 4140*g* at room temperature for 20 min. The supernatant was decanted into 15 mL PP centrifuge tubes. Three milliliters of hexane was added to each tube, and the tubes were vortexed for 2 min. The samples were centrifuged at 4140*g* for 5 min. The top hexane layer was removed using a disposable pipet. The MeCN was evaporated under N_2 at 40 °C to a volume of 1.5 mL or slightly less than 1.5 mL to ensure that MeCN had been sufficiently removed. To each sample was added water to the 3.5 mL mark. The tubes were centrifuged again at 4140*g* for 5 min at room temperature. The supernatant was subjected to SPE cleanup in the same manner as the kidney supernatant.

LC-MS/MS Conditions. The LC-MS/MS system consisted of a Waters Acquity ultraperformance liquid chromatography (UPLC) system coupled with a Micromass Quattro Micro mass spectrometer (Milford, MA, USA). MassLynx V4.1 software and TargetLynx V4.1 software (Waters) were used for data acquisition, processing, and reporting.

LC Parameters. The UPLC system consisted of a temperature-controlled sample manager, a binary solvent manager, and a heated column compartment. Sample vials were kept at 10 °C in the autosampler. Chromatographic separation was performed using a Phenomenex Kinetex C18 column (50 mm × 2.1 mm, 2.6 μm particle size, 100 Å pore size), coupled to a SecurityGuard Ultra C18 cartridge for 2.1 mm i.d. columns (both from Phenomenex, Torrance, CA, USA). The column compartment temperature was kept at 30 °C. The gradient mobile phases (A, 0.1% formic acid in water; B, 0.1% formic acid in MeCN) were as follows: 0−1 min, 0% B; 1−4 min, 30% B; 4−4.1 min, ramped to 95% B and held for 2 min; 6.1−6.2 min, back to 0% B and then held for 1.8 min (the total run time was 8 min). The flow rate was 0.3 mL/min. The mobile phases should be used within 1 week after preparation. The injection volume was 10 μL in the full-loop mode. The typical injection sequence follows: one to three water blanks; one midlevel standard for checking the system; calibration standards; negative controls; fortified quality control samples (QC); incurred samples; QC to bracket the incurred samples; and repeat injection of the midlevel standard.

Mass Spectrometry. The mass spectrometer was equipped with an electrospray ionization (ESI) source operated in positive ion mode. The source-dependent operating parameters have been reported previously. The $[M + H]^+$ ions at m/z 548.8 and 552.1 were identified as the precursors for collision-induced dissociation (CID) for DCCD and the IS, respectively. The multiple reaction monitoring (MRM) transitions were m/z 548.8 → 183.0 (for quantitation) and m/z 548.8 → 241.0 (for confirmation) for DCCD and m/z 552.1 → 244.1 for IS. The cone voltage was 33 and 32 V for DCCD and IS, respectively; the collision energy was 30 eV for m/z 548.8 → 183.0 and 20 eV for both m/z 548.8 → 241.0 and 552.1 → 244.1.

Internal Standard Calibration. The internal standard calibration curve with $1/x^2$ weighting was constructed using a linear regression model: $y = mx + b$, where y is the ratio of the DCCD peak area to the IS peak area and x is the concentration of the standard in ng/g.

HPLC-UV Analysis. We basically followed the method as described in the literature.[6] Briefly, 10 g of homogenized kidney tissue was incubated with a solution of DTE that cleaves ceftiofur and desfuroylceftiofur-related metabolites from proteins or other sulfur-containing compounds, yielding a common unstable DFC moiety. DFC was reacted with iodoacetamide to yield the stable DCA derivative. The derivative was first extracted onto a C-18 SPE column. Further purification was performed on a strong anion exchange (SAX) extraction column, followed by cleanup using a strong cation exchange (SCX) column. The derivatized residues were then analyzed via gradient HPLC using a C-18 column with UV detection. Because a reference standard of DCA was not available, a six-point standard curve equivalent to 0.075, 0.25, 0.5, 2.5, 7.5, and 12.5 μg/g of ceftiofur free acid in bovine kidney was prepared daily by fortifying a buffer solution with various ceftiofur stock solutions (the literature method used a six-point curve equivalent to 0.05, 0.25, 0.5, 1.0, 5.0, and 10.0 μg/g in tissue). Then, these solutions were processed by this method to obtain DCA calibration standards. Negative control and QC samples fortified with ceftiofur at 0.1, 1.0, and 10.0 μg/g were included for daily quality assurance. The procedure has a limit of quantitation (LOQ, the lowest fortified concentration at which accuracy and precision were found to be acceptable) of 0.1 μg/g. The average recovery of the fortified controls must be ≥80% to accept the batch.

RESULTS AND DISCUSSION

Kidney Analyses. *LC-MS/MS Method Validation.* Three major changes were made in the modified procedure compared to the previously reported regulatory procedure.[15] The changes streamline the method and improve its efficiency, thereby reducing the burden on testing laboratories. First, the new IS, d_3-methoxy-DCCD, was added in the beginning of the extraction. We found no deuterium-to-hydrogen exchange during the extraction procedure. Second, the calibration standards (equivalent to 25−2000 ng/g in 0.4 g of kidney sample) were prepared in solvent (water) instead of matrix extracts. This change reduced the number of samples in each run by eight. Third, the ion transition monitored for the IS changed to m/z 552.1 → 244.1 because of the different locations of deuterium.

Three minor changes were also implemented using the modified procedure: (1) the final volume of the extract was 1 mL instead of 2 mL to increase the intensity of the signal, (2) the final extract was centrifuged instead of filtered before LC-MS/MS analysis to simplify the procedure, and (3) the guard column was changed to a SecurityGuard Ultra C18 cartridge from an in-line filter to improve the lifespan of the analytical column. The modified procedure was revalidated by assessing interday accuracy and precision (n = 2 per day × 3 days for each fortification level); the results are shown in Table 1. Other validation parameters such as extraction efficiency, matrix effect,

Table 1. Revalidation of the Kidney Procedure: Fortified Samples

fortification level (ng/g)	N	found (ng/g)	SD	CV (%)	accuracy (%)
50	6	52.0	4.9	9.5	103.9
250	6	243.4	18.8	7.7	97.3
1000	6	1052.5	35.7	3.4	105.2

First (left) and second (left) rows are quantitation and confirmation ions in a control sample (A), respectively; third (left) and fourth (left) are quantitation and confirmation ions in a control sample fortified with DCCD at 50 ng/g (B), respectively. The chromatograms on the right side are quantitation ions for d_3-DCCD in control (A) and fortified sample (B), respectively. DCCD, desfuroylceftiofur cysteine disulfide.

and matrix stability were reported previously and are not expected to change. Because a different IS was used in the modified procedure, we verified the stability of the final extract and found that changes in concentration were <15% when stored for 3 days at 10 °C or for 7 weeks at −20 °C.

The calibration curve was linear between 25 and 2000 ng/g. The interday accuracy ranged from 97 to 105%, and the interday precision ranged from 3.4 to 9.5%. The LOQ was 50 ng/g. In addition, we also reanalyzed the samples at two concentration levels that were analyzed previously.[15] The high-level kidney sample was obtained from a steer (steer A) 12 h after the last dose, and the low-level sample was obtained by diluting the high-level sample with a control kidney sample in a 1:3 ratio. The concentrations were 1338.9 ± 111.1 (N = 9) and 387.2 ± 25.0 (N = 9) by using the modified procedure compared to the original results of 1323.5 ± 143.6 (N = 9) and 406.3 ± 18.4 ng/g (N = 9). There was no statistically significant difference between the new and original results (two-tailed t test, $p > 0.05$). Figure 1 shows the typical LC-MS/MS chromatograms of DCCD in kidney samples.

Correlation between DCCD and Total DFC (DCA). The concentrations of the incurred kidney samples were measured in at least five replicates by both the LC-MS/MS and HPLC-UV methods, and the results are listed in Table 2. Steer A was reported previously; however, the kidney DCCD concentration listed in Table 2 was measured by the modified LC-MS/MS procedure as discussed above. Because the violative kidney tissues are sometimes reported to have very high ceftiofur

Table 2. Analytical Results by the Two Methods (N = 6 Other than Those Noted)

		DCA (ppm)			DCCD (ppm)

[a] N = 9. [b] N = 5 due to sample loss during the extraction.

residue levels,[27] analysis of a wide range of concentrations was deemed necessary to establish the relationship between the two methods and to show that the new method is useful in practice. The actual extractable total DFC (measured as DCA) concentration ranged from just below the tolerance (0.391 ppm) to ~6 times the tolerance level (2.55 ppm). DCCD concentrations ranged from 0.0501 to 1.34 ppm. The coefficient of variation (CV%) was 3.4−13.1% for total DFC and 3.1−8.3% for DCCD.

The linear relationship between DCCD and total DFC was evaluated using a measurement error model, which accounts for the fact that both variables are measured with error. The analytical software, Functional Relationship Estimation by Maximum Likelihood (FREML), was developed by the Analytical Methods Committee of the Royal Society of Chemistry.[28] Figure 2 shows the observed values and predicted

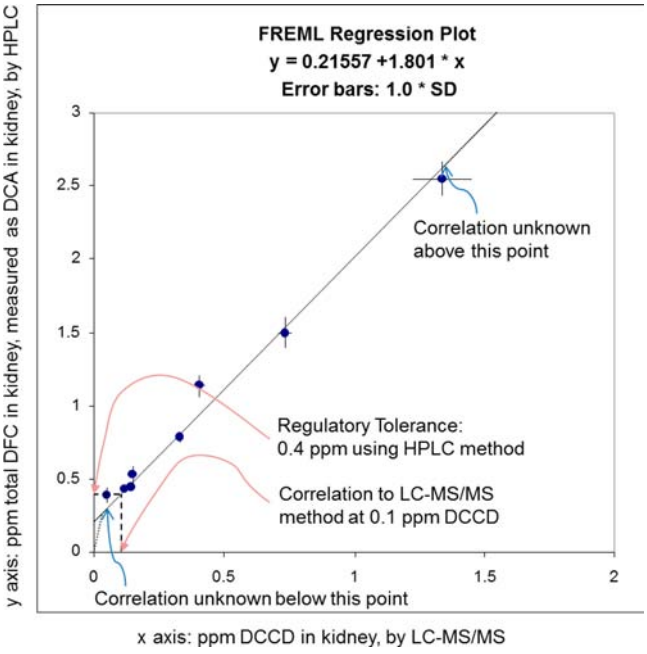

Figure 2. Correlation between the DCCD concentration by LC-MS/MS and the total DFC concentration measured as DCA by HPLC. DCCD, desfuroylceftiofur cysteine disulfide; DFC, desfuroylceftiofur; DCA, desfuroylceftiofur *S*-acetamide.

line with the DCCD concentrations on the *horizontal* axis and the total DFC concentrations on the *vertical* axis. The test for lack of fit is not significant ($p > 0.05$), and the model residuals did not display any pattern, an indication that the model is appropriate for describing the relationship between DCCD and total DFC. Figure 2 displays the linear relationship between DCCD and total DFC; for every unit increase in DCCD, there is a 1.8 unit increase in total DFC. On the basis of the relationship shown in Figure 2, when the kidney concentration of DCCD is 0.1 ppm, the predicted total DFC concentration would be around 0.4 ppm (tolerance level). Given adequate sample size at this level and establishment of a consistent correlation between the DCCD method and the official DFC method, a prediction interval for DCCD at the tolerance of 0.4 ppm can be estimated. Therefore, if a sample has a DCCD value below the lower prediction limit (or above the higher prediction limit), it can be confidently inferred that the corresponding total DFC level would be <0.4 ppm (or >0.4 ppm).

Figure 3 shows the relationship between the kidney concentration and sample harvesting time after the last dosing.

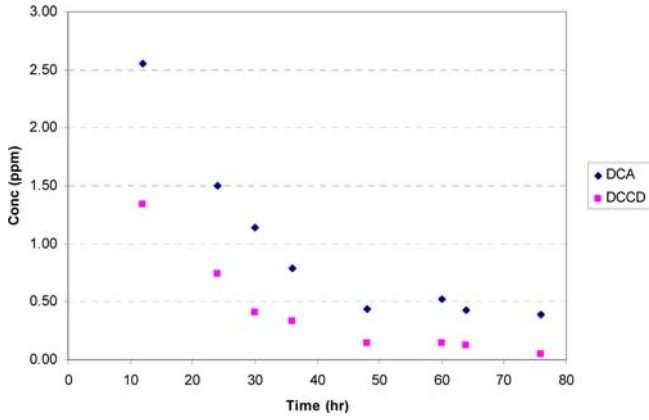

Figure 3. Kidney concentrations versus drug depletion time. DCCD, desfuroylceftiofur cysteine disulfide; DCA, desfuroylceftiofur *S*-acetamide.

From 12 to 48 h, the kidney concentrations were nearly inversely proportional to the harvesting time. By 48 h, the kidney total DFC concentration had already reached ~0.4 ppm. Therefore, we extended the harvesting time to achieve lower concentrations. Surprisingly, the next three animals harvested at 60, 64, and 76 h, respectively, showed a completely different depletion pattern for total DFC. The total DFC concentration first increased slightly at 60 h and then declined slowly. Even at 76 h, the total DFC concentration was still only slightly below 0.4 ppm. The DCCD depletion pattern paralleled total DFC except for the last time point, where it depleted more quickly (Figure 3). The total DFC depletion pattern observed in the present study is somewhat different from the data found in a residue depletion study reported in a Freedom of Information Act (FOIA) Summary[8] in support of a 4 day preslaughter withdrawal period for ceftiofur sodium. In this FOIA summary, cattle were dosed at the same dose level as in the present study, and total DFC was measured at 3, 24, 48, 72, 96, and 121 h after the last dose. Total DFC kidney concentrations showed a rapid decrease during the first 48 h and a nearly a 1-fold decrease every 24 h during the next 48 h. That study was specifically designed to investigate tissue depletion, and data were generated on the basis of multiple numbers of animals for each time point. Although our study was not designed as a tissue depletion study, similar depletion patterns between DCCD and total DFC support the use of DCCD as a surrogate for total DFC.

Berendsen et al.[12] summarized analytical methods for ceftiofur residues into three categories based on the targeted chemical entity: (1) ceftiofur, DFC (free form), or DCCD in biological matrices; (2) DCA derived from chemical conversion of all DFC derivatives, including protein-bound DFC; and (3) 2-amino-α-(methoxyamino)-4-thiazoleacetamide through ammonolysis. Although each of these approaches has its advantages and limitations, direct monitoring of the naturally occurring ceftiofur, DFC, or DCCD was considered inadequate for detecting ceftiofur's off-label use in poultry production. In poultry breast muscle, and possibly in bovine tissue as well, the combined yield of the three compounds listed above amounted

to only a small fraction of that acquired by either the DCA or the ammonolysis methods. Our result for DCCD in bovine kidney, however, shows that DCCD is present at a readily detectable concentration level compared to DCA (total DFC), and good correlation exists between the data generated by these two methods. For the regulatory application that this DCCD method was intended to address, the much simpler and higher throughput sample preparation procedure outweighs its weakness that not all DFC-related metabolites contribute to generating a single detection signal.

One of the advantages of a LC-MS/MS methodology is that the ion ratio can be used for structural confirmation along with the retention time and signal-to-noise ratio (S/N). For this study, we followed the confirmation criteria described in *FDA Guidance for Industry No. 118*[29] except we used a 2% acceptable range for retention time instead of 5% and an S/N ratio of 10 instead of 3. These changes made the confirmation process more stringent. The experimentally validated limit of confirmation (LOC) of the present LC-MS/MS procedure for DCCD in bovine kidney was 50 ng/g, the lowest fortified concentration at which all acceptance criteria were met. All incurred and fortified kidney samples passed confirmation. No false positives were observed. Therefore, the procedure described here for bovine kidney is valid for both determinative and confirmatory purposes.

Liver and Muscle Analyses. *Liver and Muscle Method Validation.* The procedure that worked well for kidney analysis was ineffective for liver and muscle. Liver showed more chemical interferences, and muscle formed a gel when homogenized in buffer. Therefore, we treated the initial buffer extract with acetonitrile and hexane to precipitate proteins and remove fats, respectively, as reported in previously published work.[16,20] After removal of the organic solvents by phase separation and evaporation, the aqueous extract was cleaned up by SPE. Because DCCD is very polar and hydrophilic, it is critical to remove all acetonitrile before the SPE to avoid loss of analyte due to weak retention of DCCD on the SPE sorbent. Extraction efficiency was measured by comparing the area ratio between prefortified and postfortified control samples. For liver, the overall extraction efficiencies of the sample preparation procedure were 81.7 ± 1.3% (N = 3), 74.4 ± 2.4% (N = 3), and 71.7 ± 8.3% (N = 3) at 100, 500, and 2000 ng/g, respectively. For muscle, the overall extraction efficiencies of the sample preparation procedure were 75.4 ± 5.8% (N = 3), 73.5 ± 7.3% (N = 3), and 71.8 ± 0.4% (N = 3) at 100, 500, and 2000 ng/g. The lower than 100% extraction efficiencies should not affect the quantitation because the labeled IS added in the beginning of the extraction was expected to track the analyte.

Despite extensive cleanup steps, significant matrix effects occurred for both liver and muscle extracts. The matrix effect was evaluated by the area ratio between the standards postfortified into the extracts of control samples and the standards in solvent (water) at 100, 500, and 2000 ng/g (N = 3 for each level). The average ratio was 1.23 for liver and 0.71 for muscle. This problem was again overcome by the use of the labeled IS, which provided satisfactory quantitation. Therefore, solvent-based calibration was used for quantitation. The curve was linear from 50 to 4000 ng/g. This range was chosen because of the much higher tolerances for cattle liver and muscle (2 and 1 ppm, respectively). The LOQ was 100 ng/g for both matrices. Tables 3 and 4 show the accuracy and precision in bovine liver and muscle. Figures 4 and 5 show the typical chromatograms in bovine liver and muscle matrices.

Table 3. Interday Accuracy and Precision in Bovine Liver

level (ng/g)	N	mean	SD	CV%	accuracy (%)
100	12	106.7	7.75	7.3	107
500	12	502.3	29.8	5.9	100
2000	12	2028.2	90.4	4.5	101

Table 4. Interday Accuracy and Precision in Bovine Muscle

level (ng/g)	N	mean	SD	CV%	accuracy (%)
100	12	97.3	10.7	11.0	97
500	12	499.1	28.9	5.8	100
2000	12	1984.9	98.3	5.0	99

Stability was also investigated during the method validation. The concentration of DCCD in bovine liver matrix decreased 16% after 12 months at −80 °C. An assessment of DCCD in incurred bovine muscle matrix was infeasible and unnecessary because concentrations are typically below the LOQ (see below). DCCD in the extract of bovine liver is stable for up to 48 h at 10 °C and for up to 19 days at −20 °C. DCCD in the extract of bovine muscle is stable for 72 h at 10 °C and for 35 days at −20 °C.

Liver and limb muscle samples were analyzed with validated methods except the limb muscle from steer G harvested at 64 h. Results are shown in Table 5. DCCD was found in all liver samples except the one collected at 76 h after the last dose. The liver DCCD concentrations peaked at 24 h at 573.2 ng/g, followed by a continuous decline in the next 24 h; increased at 60 h to 300.2 ng/g; and then decreased again rapidly. In contrast, the only muscle sample that contained a detectable but very low level of DCCD was the injection site muscle in steer A harvested at 12 h after the last dose.

In the aforementioned ceftiofur residue depletion study reported in the FOIA Summary,[8] ceftiofur marker residue (total DFC measured by the HPLC-UV method) in liver had a much lower concentration than the current tolerance level of 2 ppm set for bovine liver. The highest total DFC concentration in liver was 1.6 ppm at 3 h after the last dose. Total DFC concentration in liver showed a similar biphasic pattern to that of DCCD observed in our study, albeit the second peak was at 48 h, and the concentrations were below the LOQ (0.1 ppm) after 48 h. Total DFC at the injection site showed very high concentrations 3 h after the last dose, but the concentration fell below the 1 ppm tolerance level for bovine muscle quickly at approximately 24 h, although it remained detectable until 96 h. In muscle, total DFC was detectable 3 h after the last dose and diminished to below the LOQ within 24 h. In contrast to liver and muscle, the total DFC detection window in kidney was much wider (approximately 96 h), and the total DFC concentration was above the tolerance level of 0.4 ppm between 24 and 48 h. On the basis of these data and our own findings, we conclude that, although muscle is a common matrix for testing,[20,30−32] bovine muscle is unsuitable as the sole screening matrix for ceftiofur residues.

With regard to the confirmation of DCCD in liver samples, all fortified samples at 100, 500, and 2000 ng/g in acceptable batches were confirmed; 39 of a total of 45 replicates of incurred samples were confirmed. The six incurred samples that failed confirmation had concentrations between 100 and 150 ng/g. Therefore, the true LOC for the liver procedure is probably around 150 ng/g. We did not investigate this further, however, because we expect that the liver procedure will most

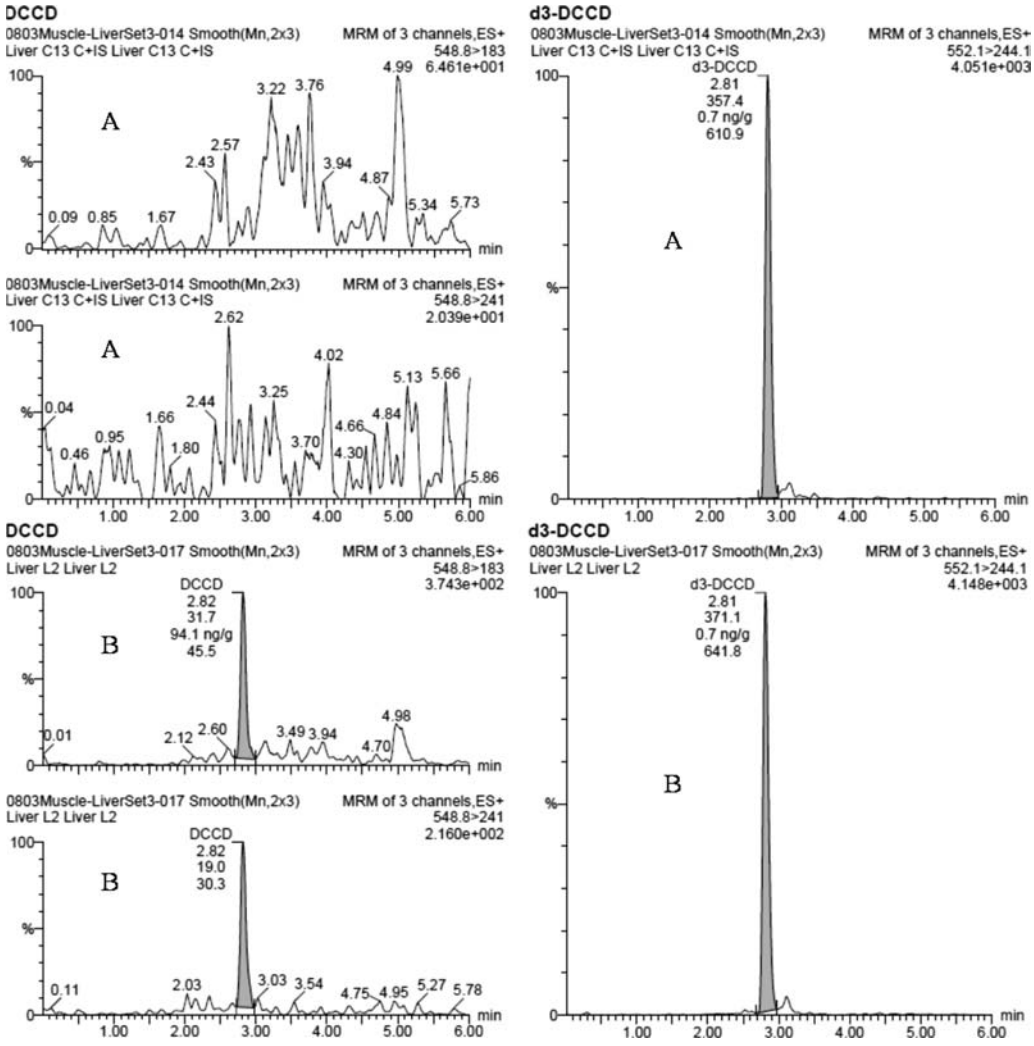

Figure 4. Typical LC-MS/MS chromatograms of DCCD and d_3-DCCD in bovine liver tissue. First (left) and second (left) rows are quantitation and confirmation ions in a control sample (A), respectively; third (left) and fourth (left) are quantitation and confirmation ions in a control sample fortified with DCCD at 100 ng/g (B), respectively. The chromatograms on the right side are quantitation ions for d_3-DCCD in control (A) and fortified sample (B), respectively. DCCD, desfuroylceftiofur cysteine disulfide.

likely be used for occasional ad hoc testing. Additionally, we did not investigate in detail confirmation of DCCD in bovine muscle because the procedure is unlikely to detect DCCD in bovine muscle samples.

Finally, because of the complex profile of ceftiofur's metabolites due to their chemically labile nature in the biological environment, proper selection of surrogate compounds in place of total DFC should match the specific animal species, the target tissue, and the intended regulatory purpose. In the work presented by Berendsen et al.,[12] DCCD was detectable (LOD 1 $\mu g/kg^{-1}$) in broiler breast muscle until at least 8 h postdosing, but at <24 h by extrapolation, with significant underestimation of total DFC. The ammonolysis approach was deemed more suitable for screening off-label use of cephalosporin antibiotics in poultry. Another ceftiofur in poultry study reported by Heinrich et al.,[33] however, reported that the parent compound, ceftiofur, could be detected for up to 28 days after a subcutaneous injection of Naxcel in the neck of a 1-day-old chicken (whole, including bones and feathers), but ceftiofur, DFC, and DCCD were undetectable in chicken muscle (20 days and older) or liver (16 days and older). Whether factors such as administration route and chicken age affect the relevance of a single metabolite's (or parent compound's) effectiveness as a surrogate marker or the applicability of particular analytical methods is unclear. Lastly, we noted a significant difference between the "DCFA method" (although no data were reported) and the "DCA method" used in the first example and the official method used in our work.

In conclusion, we report a simple and accurate LC-MS/MS method to detect and confirm DCCD in bovine kidney. DCCD may be used as a surrogate marker residue in regulatory testing on the basis of the quantitative relationship between DCCD and the official marker residue total DFC in bovine kidney. DCCD may also be used for ad hoc confirmatory analysis for bovine liver. Bovine muscle is not as suitable for screening or confirmation for ceftiofur residues if DCCD is the target analyte. As the two poultry studies mentioned above suggest, more work may be needed to substantiate the utility of DCCD for monitoring total DFC in targeted cattle tissues. Care must always be exercised when a correlation acquired under defined experimental conditions is extrapolated to other situations.

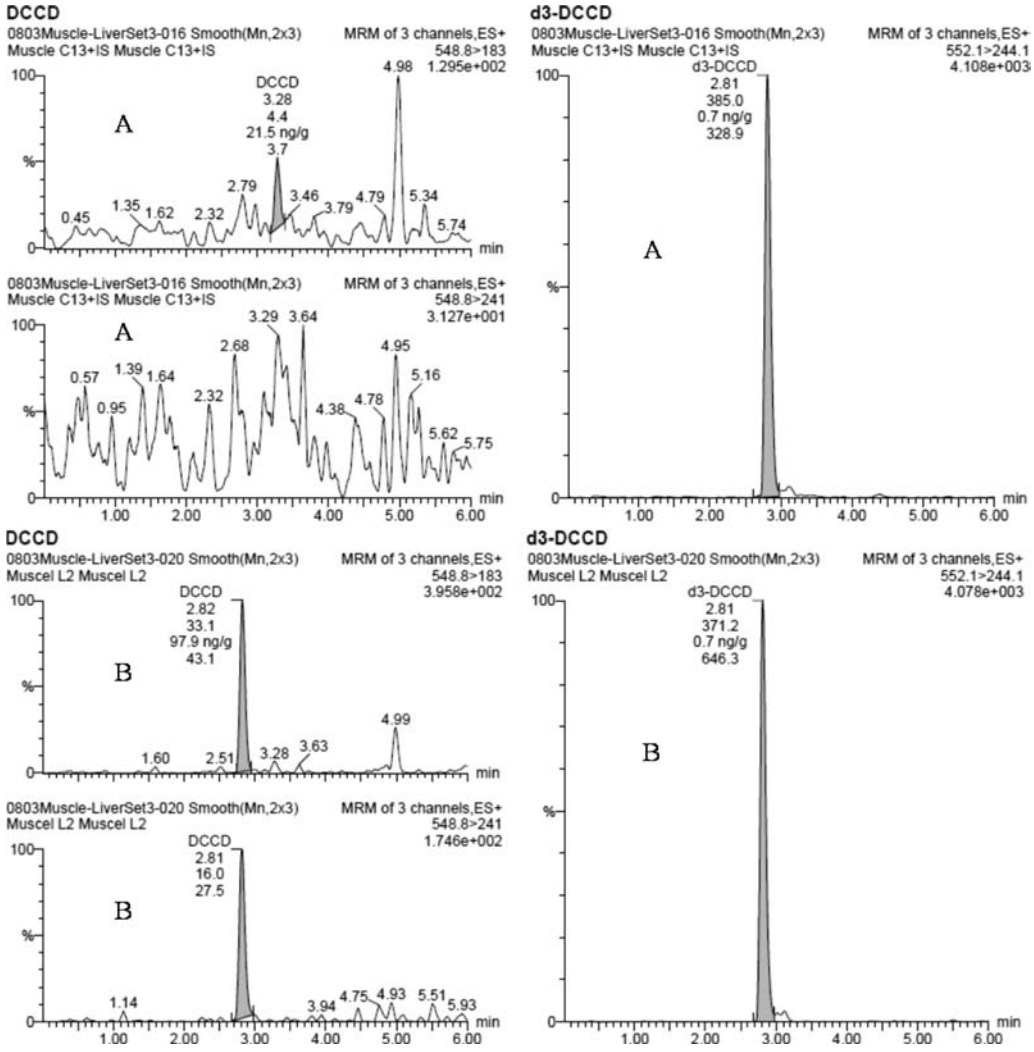

Figure 5. Typical LC-MS/MS chromatograms of DCCD and d3-DCCD in bovine muscle tissue. First (left) and second (left) rows are quantitation and confirmation ions in a control sample (A; peak at 3.28 min is incorrect assignment by software), respectively; third (left) and fourth (left) are quantitation and confirmation ions in a control sample fortified with DCCD at 100 ng/g (B), respectively. The chromatograms on the right side are quantitation ions for d_3-DCCD in control (A) and fortified sample (B), respectively. DCCD, desfuroylceftiofur cysteine disulfide.

as the stationary phase and a postcolumn reaction with 2,3,5-triphenyltetrazolium chloride. The resulting 1,3,5-triphenylformazans are detected photometrically at 480 nm, and in this case, free amino acids do not interfere with the quantitation.[6] Another approach follows the analysis of *N*-(2-furoylmethyl) amino acids formed by the controlled degradation of the Amadori products after acid hydrolysis, which can then be measured by either HPLC-UV or HPLC-MS, respectively.[7] High-performance cation or anion exchange chromatography in combination with either electrochemical detection[8] or tandem mass spectrometry[9] was recently used, but for electrochemical detection a special analytical equipment is required.

Most of the methods that have been developed so far use external calibration. However, quantitative data obtained by methods based on external calibration are difficult to correct for losses during extraction or degradation of the analyte, but such losses during workup can be completely compensated for by stable isotope dilution assays. There is only one study available on the quantitation of the Amadori product of lysine bound in a peptide using a stable isotope dilution assay.[10] Therefore, the aim of this study was to develop stable isotope dilution assays for seven Amadori compounds generated by a reaction of glucose with the amino acids valine, leucine, isoleucine, methionine, and phenylalanine as well as tyrosine and histidine. For this purpose, all seven unlabeled Amadori products as well as six carbon-13-labeled isotopologues were synthesized, and the new method was applied to the quantitation of the seven Amadori compounds in various food samples using LC-MS/MS.

MATERIALS AND METHODS

Materials. The following compounds were obtained from commercial sources: D-glucose (99.5%), malonic acid, *N*,*N*-dimethylformamide, and methanol (both Chromasolv) (Sigma-Aldrich, Steinheim, Germany); L-leucine, L-isoleucine, L-methionine, L-phenylalanine, L-valine, L-tyrosine, L-histidine (all for biochemistry), acetonitrile, and acetone (both Suprasolv) (Merck, Darmstadt, Germany); deuterium oxide (99.96% deuterium) (Euriso-top, Saint-Aubin Cedex, France); and [$^{13}C_6$]-D-glucose (99%) (Cambridge Isotope Laboratories, Andover, MA, USA).

Foods. Unroasted cocoa beans, 5 days fermented in wooden boxes, as well as roasted cocoa beans of the same batch (origin.. Sulawesi) were kindly provided by a food manufacturer. The green coffee beans (Arabica, Colombia) were supplied by Nestle PTC (Orbe, Switzerland). The beans were roasted in-house by means of a BRZ 4 drum roaster (Probat, Emmerich, Germany). The initial temperature of 185 °C was held for 3.5 min. Then, the air supply was opened, and the beans were roasted for another 2 min before cooling in the air stream of the collection chamber. Barley and wheat malt as well as wheat beer were obtained from a local brewery. The beer was produced from the same malt. Bell pepper and tomatoes were bought at a local market. The bell pepper powder was produced by drying of the vegetables in an oven at 50 °C for 7 days followed by grinding with a mill. Tomato powder was produced from fresh tomatoes by first shredding with a blender and then heating at 95 °C for 5 min followed by boiling for 3 h at 85−90 °C. The homogenized tomato paste was finally freeze-dried.

Syntheses of Amadori Rearrangement Products. D-Glucose (500 mg, 2.8 mmol) was dissolved in a 1:1 mixture of methanol/*N*,*N*-dimethylformamide (100 mL) and refluxed at 80 °C singly in the presence of each of the seven amino acids (3.8 mmol) with stirring for 3 h. Then, malonic acid (100 mg, 1.0 mmol) was added, and the mixture was refluxed for another 2 h at 90 °C until a light brownish color appeared. Undissolved components were filtered off, and the organic phase was concentrated to ∼5 mL by means of a rotary evaporator. The Amadori products were precipitated by the addition of cold acetone (45 mL) at −25 °C and, after centrifugation at 3500 rpm and 0 °C for 10 min, the precipitate was collected and the mother liquor was concentrated and treated again with cold acetone at −25 °C to gain a second portion of the target compound. The combined precipitates were dissolved in methanol (5 mL) at ∼45 °C and treated again with cold acetone (45 mL) at −25 °C before centrifugation. This step was repeated until the crystals were nearly white. The material was dried under vacuum in a desiccator overnight and then freeze-dried for 2 days. Yields varied between 8 and 40%. The products formed were assigned as 1-desoxyfructosyl amino acids using the following abbreviations, for example, Fru-Leu for the Amadori product from glucose and leucine, Fru-Phe for the Amadori product from glucose and phenylalanine, and so on.

Synthesis of the Carbon-13 [$^{13}C_6$]-Labeled Amadori Products. The respective carbon-13-labeled internal standards were synthesized using the same procedure but substituting glucose by [$^{13}C_6$]-glucose in the reaction with each of the amino acids. The assignment of the synthesized compounds was done by adding [$^{13}C_6$], for example, [$^{13}C_6$]-Fru-Phe for the carbon-13-labeled Amadori product synthesized from labeled glucose and phenylalanine.

HPLC-MS. The removal of glucose and the respective amino acid as well as byproducts was controlled by HPLC-MS using a combination of a P-4000 pump (Thermo Separation Products, Waltham, MA, USA), a 150 × 2 mm TSK Gel Amide-80 column (Tosoh Bioscience, Tokyo, Japan), and an ion trap MAT LCQ mass spectrometer (Finnigan, Bremen, Germany). Spectra were generated in the ESI$^+$ mode in parallel with UV detection at 210 nm.

Quantitative Nuclear Magnetic Resonance (qNMR) Spectroscopy. To cope with the amount of the remaining solvent and water in the labeled as well as unlabeled Amadori products, these were analyzed by quantitative NMR (qNMR).[11−13] Each analyte (100 mg) was dissolved in D_2O (Euriso-Top, Saarbrücken, Germany) in a 5 mL volumetric flask, and 600 μL of this stock solution was transferred into a 178 × 5 mm NMR tube (Norell, Landisville, NJ, USA) and analyzed using an AV III System (Bruker, Rheinstetten, Germany) at 400.13 MHz. The solutions were diluted with acetonitrile, placed in amber bottles, flushed with argon, and stored at −24 °C.

^{1}H NMR spectra were measured at 25 °C with a Bruker AV III system equipped with a 5 mm multinuclear observe probe head (BBFO, plus). The probe was tuned and matched with the sample in place, and the optimal 90° pulse width for the quantitation setup was investigated for every sample. The qNMR spectrum was determined by acquiring 16 scans with a relaxation delay of 40 s. Before Fourier transformation, the free induction decay was multiplied with a 0.3 Hz exponential line broadening factor and zero-filled. Phasing and integration of the peaks were done manually after automatic baseline correction. If necessary, the integrals were adjusted with the software functions SLOPE and BIAS. The concentration of each compound was calculated with the ERETIC 2 function of Topspin 3.0 (Bruker). Calibration of the qNMR was based on a solution of L-tyrosine of known concentration using the signal at 7.1 ppm (m, 2H). The signal of the methylene group at carbon-1 of the former glucose at 3.3 ppm (m, 2H) was used for the quantitation of the Amadori products Fru-Leu, Fru-Ile, Fru-Val, and Fru-Met. In the cases of Fru-Phe, Fru-Tyr, and Fru-His the aromatic protons were used for quantitation (Fru-Phe, 7.4 ppm, m; Fru-Tyr, 7.0 ppm, m; and Fru-His, 7.7 ppm, s) because the free amino acids were confirmed to be absent by HPLC measurements.

Isolation and Quantitation of Amadori Compounds in Foods. Either ground solid material (∼2 g) or beverages (∼20 mL) were exactly weighed in flasks and extracted with methanol (200 mL) after addition of the labeled internal standards. The mixtures were stirred for 1 h, then filtered and concentrated to ∼5 mL by means of a rotary evaporator. An extraction time of 1 h was needed for reproducible results, but a longer extraction did not change the results. To separate nonpolar substances, a 140 Å Strata C18-T SPE cartridge (1000 mg; volume, 6 mL) (Phenomenex, Aschaffenburg, Germany) was conditioned with methanol (10 mL). After application of the extract, the eluate (10 mL) was concentrated to dryness,

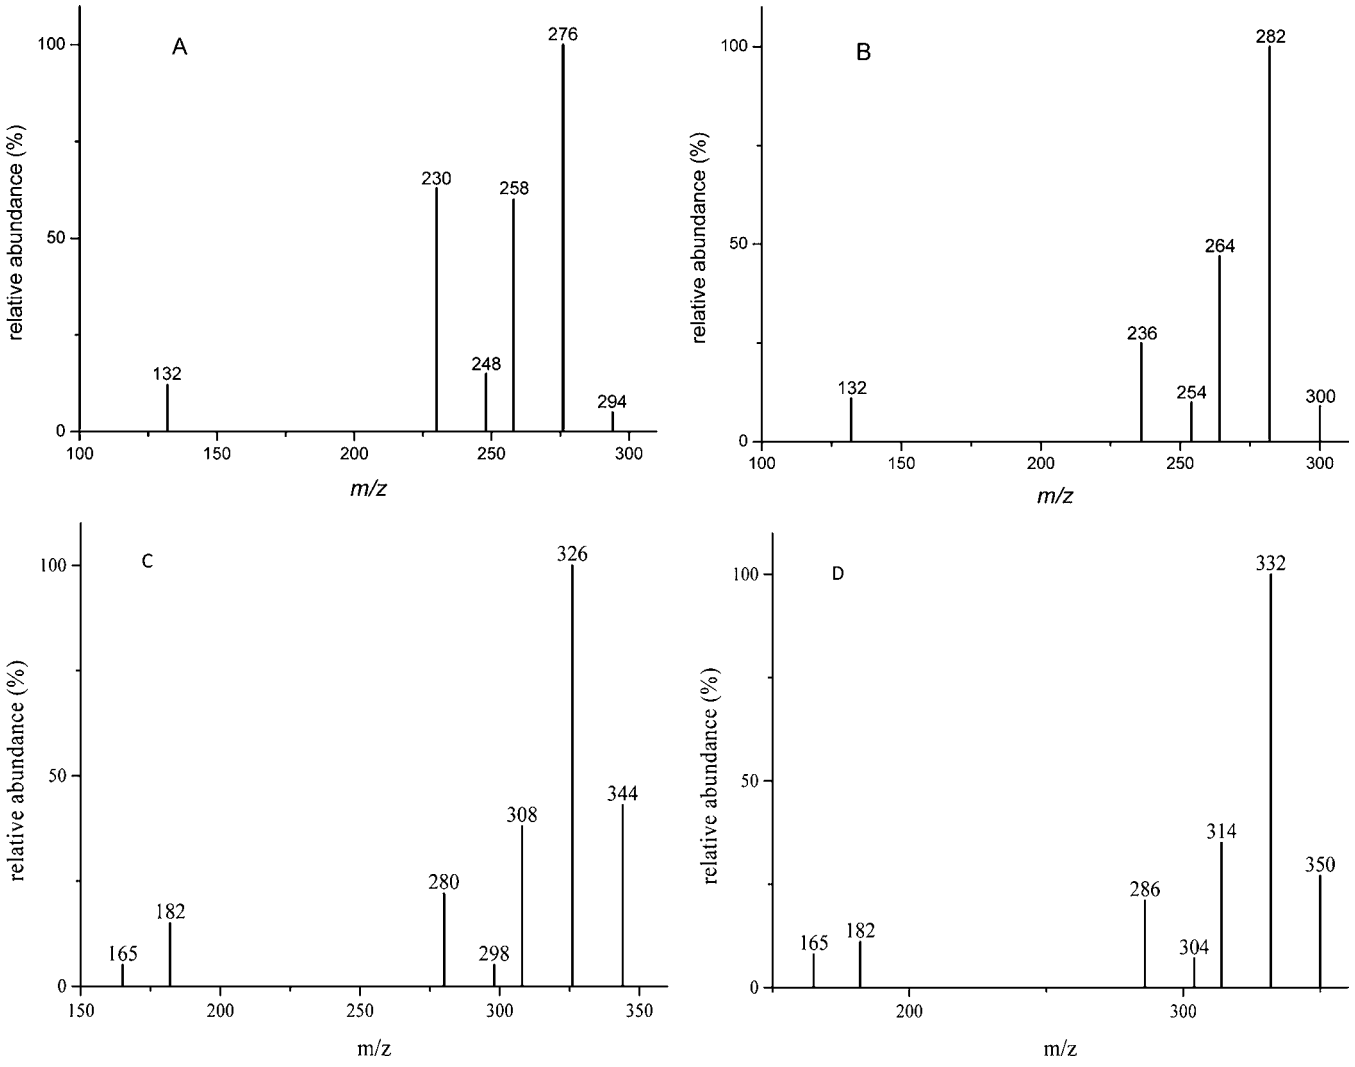

Figure 2. Mass spectra (ESI^+) of fructosyl leucine (Fru-Leu; A), [$^{13}C_6$]-fructosyl leucine (Fru-Leu; B), fructosyl tyrosine (Fru-Tyr; C), and [$^{13}C_6$]-fructosyl tyrosine (Fru-Tyr; D).

redissolved in acetonitrile (10 mL), and filtered through a Whatman Spartan 13/0.45 RC membrane filter (GE Healthcare, Wien, Austria).

HPLC-MS/MS. The samples were analyzed by LC-MS/MS using a Thermo Finnigan Quantum TSQ mass spectrometer (Finnigan, Bremen, Germany) connected to a 150 × 2 mm TSK Gel Amide 80 HPLC column (Tosoh Bioscience). Spectra were generated in the ESI-positive mode with selected reaction monitoring. The flow conditions were as follows: 0.2 mL/min acetonitrile/0.1% aqueous formic acid (9 + 1) for 3 min with a gradient to 0.1% aqueous formic acid/acetonitrile (9 + 1) within 12 min, then held for 5 min. The spray voltage was 3500 V, and the capillary temperature was 290 °C.

Determination of the Limit of Detection (LoD) and Limit of Quantitation (LoQ). Decreasing amounts of the synthesized, unlabeled Amadori products were added to either wheat starch or sunflower oil, respectively, and the mixtures were analyzed as described above for the food samples. The solutions were diluted until the analyte peaks were <3-fold the background noise (LoD) or 5-fold for LoQ.

Response Curves. Calibration curves were created from mixtures of each analyte and each labeled internal standard in ratios between 1:15 and 15:1 (by weight). To differentiate between Fru-Leu and Fru-Ile, first the sum of both was determined using [$^{13}C_6$]-Fru-Leu as the internal standard. Then, using a standard curve obtained by defined mixtures of Fru-Leu and Fru-Ile, the ratio of both isomers in the mixture was calculated by optimizing the collision energies for the intensities of the fragments m/z 88 and 144. At 31 eV, Fru-Leu showed an intensity of 94.7% for m/z 88 and only 5.3% intensity for m/z 144, whereas at 17 eV Fru-Ile showed an intensity of 5.9% for m/z 88 but 94.1% for m/z 144.[14] From these data, the ration of Fru-Leu and Fru-Ile in the total amount determined for both isomers could be determined.

RESULTS AND DISCUSSION

Syntheses. The general reaction route used in the synthesis of the 13 Amadori products from either glucose or [$^{13}C_6$]-glucose and the seven amino acids followed the formation pathway suggested for their formation in foods (Figure 1). Either glucose or labeled glucose, respectively, was singly reacted with each of the seven amino acids by refluxing in a mixture of methanol and dimethylformamide.[1] Smaller amounts of the educts were used, in particular because the expensive [$^{13}C_6$]-glucose was used to synthesize the isotopically labeled standards. For the analytes abbreviations were used to indicate the carbohydrate and the respective amino acid, for example, Fru-Leu to assign the Amadori reaction product from glucose and leucine, and [$^{13}C_6$]-Fru-Leu was used for the labeled isotopologue.

First, mass spectra in the ESI^+ mode were recorded. In panels A and B of Figure 2 the mass spectra of Fru-Leu and [$^{13}C_6$]-Fru-Leu are contrasted. The shift of the molecular ion m/z 294

[a]Numbering refers to Figure 3B.

for Fru-Leu to m/z 300 for [$^{13}C_6$]-Fru-Leu clearly indicated the successful incorporation of six carbon atoms. Further fragment pairs (m/z 276 and 258; m/z 282 and 264) indicated a sequential elimination of two molecules of water. The same type of fragmentation was found for Fru-Tyr (Figure 2C) and [$^{13}C_6$]-Fru-Tyr (Figure 2D) as well as for the other four Amadori products and their labeled homologues.

For quantitation, the synthesized analytes had to be weighed. However, neither the Amadori compounds nor the labeled homologues could totally be freed from the solvent, for example, water and methanol. Therefore, to determine the correct concentrations in the reaction products, quantitative NMR experiments were performed. As shown in the ^1H NMR spectrum of Fru-Leu (Figure 3A), the hydrogen atoms of the methylene group at carbon 1′ are appropriate for the quantitation because these were exclusively present in the Amadori products, but not in glucose or in leucine, respectively (data not shown). For the Amadori products of the aromatic amino acids, signals of the hydrogen atoms at carbon 1′ were at the same position as the methylene protons of the amino acid (data not shown). Therefore, as shown for Fru-Phe, the sum of the hydrogens in the aromatic ring was used for qNMR (Figure 3B). In any case the absence of the free amino acid was checked by HPLC.

To precisely characterize the structure of the analytes, also ^{13}C NMR and two-dimensional NMR experiments were performed. As examples, the ^{13}C NMR data obtained for Fru-Leu are summarized in Table 1 and those for Fru-Phe in Table 2.

Method Development. For HPLC separation of the seven analytes, a gel permeation chromatography column was chosen, because the matrix effects were low and the chromatographic separation was better than with other columns tested. Although a clear separation was not achieved for all analytes (Figure 4), each Amadori compound could separately be quantitated using its molecular ion in the selected reaction monitoring mode. For identification and quantitation two mass transitions were used for each analyte and the respective labeled internal standard, respectively (Table 3). Because the molecular masses of Fru-Leu and Fru-Ile are identical, first, the sum of the concentrations of both compounds was determined by using [$^{13}C_6$]-Fru-Leu as the internal standard. At higher collision energies (Table 3), Fru-Leu had a much better tendency to form m/z 88, whereas m/z 144 was exclusively formed from

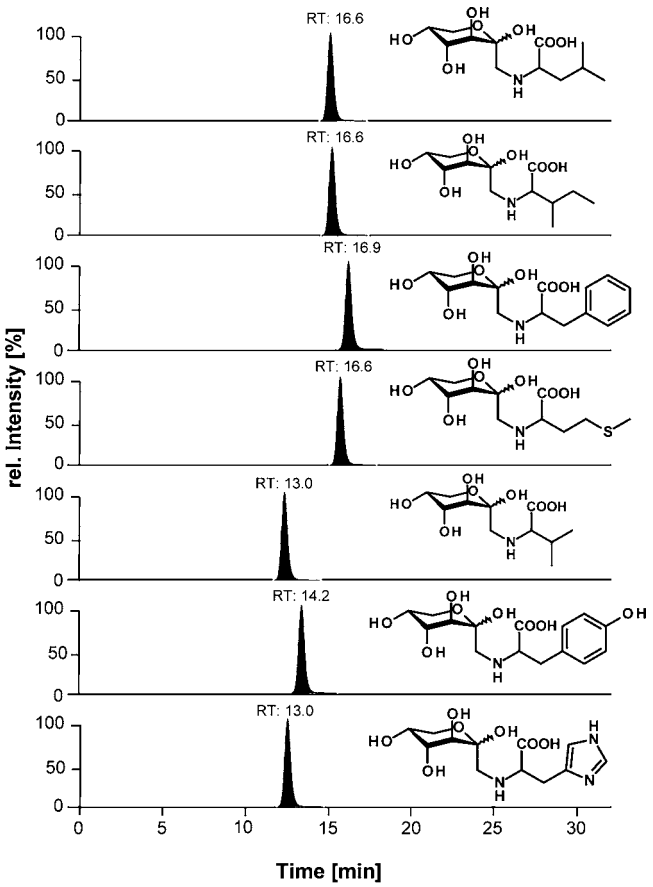

Figure 4. HPLC-MS/MS chromatograms obtained for the seven Amadori reaction products.

Fru-Ile.[14] By measuring defined mixtures of Fru-Leu and Fru-Ile, a calibration curve was created allowing the quantitation of both analytes by correlating the signal intensities m/z 88 and m/z 144 (Figure 5).

Method Validation. To determine the LoD and LoQ, mixtures of each analyte and the respective standard (1:1) were added in decreasing amounts to either wheat starch or sunflower oil as the matrix, respectively, and the samples were worked up as described for the food samples. Fru-Phe could be quantitated very sensitively down to 0.1 μg/kg in

[$^{13}C_6$]-Fru-His	8	324 → 306	16	324 → 195

[a]Conditions used to separately quantitate both Amadori compounds in a mixture.

wheat starch or 0.2 μg/kg in sunflower oil, respectively; the LoQs of the other Amadori products were at 2−35 μg/kg and that of Fru-Met was at 50 μg/kg (Table 4). The reproducibility of the method can be derived from the data for the food samples given below.

Application to Foods. The amounts of some of the Amadori compounds have previously been determined in several foods, and a thermal treatment at lower temperatures was found to favor their generation, whereas, for example, roasting conditions led to their degradation. The new stable isotope dilution assays were, therefore, applied on foods, in which some of the Amadori compounds had previously been analyzed for by other methods (Table 5). First, the reproducibility of the data can nicely be seen from the analysis of the beer sample (sample 7) (Table 5). For this experiment, three samples of the same beer were separately worked up. The data showed no standard deviation for Fru-Val in the triplicate, values below 5% for Fru-Ile, Fru-Phe, and Fru-Tyr, whereas a bit higher values were measured for Fru-Leu and Fru-His. Quantitations in unroasted and roasted cocoa from the same batch (samples 1 and 2) (Table 5) showed quite high amounts of most Amadori products in the unroasted cocoa, with Fru-Val being at 342 mg/kg. After roasting of the beans, however, all analytes were significantly degraded, except Fru-Met. Also in unroasted coffee beans (sample 3) (Table 5), all seven analytes were present, but these were also degraded during roasting, except Fru-His, which was higher in the roasted coffee (sample 4) (Table 5). Two cereal malts (samples 5 and 6) (Table 5) also contained high amounts of the Amadori products, with Fru-Val predominating in wheat malt. During beer production obviously the Amadori compounds are degraded, but still significant amounts were found in the wheat beer (sample 7) (Table 5).

To study the influence of a drying process, bell pepper as well as tomatoes were slowly dried at lower temperatures or cooked under laboratory conditions. Drying of bell pepper led

[a]Data are mean values of triplicates (three separate workups). Standard deviation is given in %.

to a significant increase, leading, for example, to ∼3.5 g of Fru-Val in the dried compared to 5.8 mg/kg in the fresh sample (based on dry weight). The amounts were similar to those also reported before for bell pepper powder.[6] Drying and cooking of tomatoes showed the same behavior (samples 10 and 11) (Table 5). In particular, Fru-Val and Fru-Tyr, which were not detectable in the fresh tomatoes, increased to 10.6 or 7.96 mg/kg, respectively, after cooking. However, the literature data[6] were much higher, which was probably due to the drum-drying process applied in the previous study. However, to the best of our knowledge our results present the first data on Fru-His and Fru-Tyr in all food samples analyzed.

In conclusion, the newly developed stable isotope dilution assays for the quantitation of seven Amadori compounds by means of LC-MS/MS showed a very good peak to noise ratio with low matrix interferences and a good reproducibility even for foods low in analytes, such as unprocessed tomatoes or bell pepper. Thus, LC-MS/MS analysis in combination with a stable isotope dilution assay is suggested as a reliable approach for the fast and accurate quantitation of Amadori compounds in foods. The results further corroborate that their formation is probably favored when slow heating is applied in food drying, whereas roasting leads to their degradation. The fact that quite high amounts were also found in unprocessed foods, such as cocoa and green coffee beans, might suggest a formation pathway other than that shown in Figure 1. This idea is supported by an experiment showing that unfermented cocoa beans, when stored for 7 days at 60 °C in an oven, did not generate any Amadori compound (Pammer and Schieberle, unpublished data), whereas the fermented beans contained quite high amounts after 7 days at nearly the same temperature. Therefore, one could conclude that Amadori compounds may be formed during fermentation of cocoa beans by an enzymatic reaction. This, however, has to be confirmed in further studies.

links and noncovalent links. Noncovalent interaction includes hydrogen bonding, hydrophobic bonding, and sometimes even ionic bonding. It occurs depending on the structure of polyphenols and various functional groups in proteins.[14−20] Noncovalent interaction could take place multisitely and multidentately due to the polarity of the polyphenol. Multisite interaction means that several phenolic compounds bound to one protein molecule, whereas multidentate interaction means that one phenolic compound bound to several protein sites or molecules. The type of interaction relies on the type and the molar ratio of both phenolic compound and protein.[21,22] Covalent interaction occurs through the interaction between oxidized phenolic substances and proteins.[23,24] Electrospray ionization (ESI) has been proven to be an effective tool to detect the weak associations of molecules in solutions such as receptor−ligand and protein−nucleic acid interaction.[25,26] A relatively well-developed way to determine the relative binding affinities of noncovalent complex has been established.[27,28] The mass spectrometry (MS) can reveal the noncovalent interaction strengths and qualitative information on the complex structure. Therefore, MS instrumentation was also used to detect and characterize soluble noncovalent complexes.[29]

In this study, the aim was to apply LC-ESI-MS to investigate the radical scavenging and other protein−phenolic interaction reactions between cloudberry ellagitannin and tryptic digests of β-Lg. Tryptic peptides of β-Lg have been used as a model to study protein−phenolic interactions. This simplified model enables the mechanistic investigations in more detail compared to those of a complicated protein. This model mimics possible reactions between proteins or peptides and plant phenolics during in vivo digestion but also in the food matrix as protein binding would affect polyphenol reactivity and influence its biological fate.

MATERIALS AND METHODS

Chromatographically purified and lyophilized β-Lg (variants A + B from bovine milk) was purchased from Sigma-Aldrich, Inc. (St. Louis, MO, U.S.A.). Sequencing-grade modified trypsin was obtained from Promega Corp./BioFellows (Madison, WI, U.S.A.). Of the reagents used in the analyses, ammonium bicarbonate, hydrogen peroxide (30% wt solution in water), and iron(III) chloride (reagent grade, 97%) were purchased from Sigma-Aldrich (Steinheim, Germany), whereas L(+)-ascorbic acid was a product of Merck (Darmstadt, Germany) and PIPES-buffer [piperazine-1,4-bis(2-ethanesulfonic acid)] from Fluka BioChemika (Buchs, Switzerland). Methanol, acetone, and acetonitrile were of HPLC grade and purchased from Rathburn (Walkerburn, Scotland). All other chemicals used in the analyses were supplied by J. T. Baker (Deventer, The Netherlands) or Sigma-Aldrich in either HPLC or reagent grade. The water used was always purified first by the Milli-Q system (Millipore Corp., Bedford, MA, U.S.A.). Fresh cloudberries (*Rubus chamaemorus*) were purchased from the local grocery.

Digestion and Fractionation of β-Lg Peptides. The in-liquid digestion of β-Lg was prepared using sequencing grade modified trypsin to obtain the cleavage to peptides which were later separated and collected using preparative HPLC according to the method described by Koivumäki et al.[8] In brief, 10 mg of β-Lg was dissolved in 50 mM ammonium bicarbonate buffer followed by addition of trypsin with a protease/protein ratio of 1:250. The protein digest was kept at 37 °C overnight, and thereafter the enzyme reaction was stopped by placing the digest in −20 °C. Isolation and fractionation of β-Lg peptides was carried out by using preparative HPLC and assigning the automated collection triggers for the corresponding m/z values of the theoretical peptides.

Isolation of Sanguiin H-6. Freeze-dried cloudberries (2 g, powder) were extracted with 70% acetone (2 × 20 mL) by accelerated solvent extraction (ASE) (Dionex, Sunnyvale, CA, U.S.A.). The extracts were evaporated to dryness and dissolved into Milli-Q water. Column (40 × 300 mm) chromatography with Amberlite XAD-7 was used for removal of sugars, organic acids, and phenolic acids eluting with 6% acetonitrile. A fraction containing flavonols, anthocyanins, and ellagitannins was collected using 100% acetonitrile. The dried polyphenol fraction dissolved into aq methanol (50%) was subject to further fractionation using a Sephadex LH-20 column (40 × 300 mm). The ellagitannin fraction was eluted with 70% acetone. An ellagitannin dimer, sanguiin H-6, was obtained from the ellagitannin fraction by using preparative-HPLC (Waters 2767 sample manager, Waters 2545 binary gradient module, and Waters system fluidic organizer) coupled with a Waters 2998 PDA and Waters ZQ single quadrupole mass spectrometer (Waters, Milford, MA, U.S.A.). The column was Develosil ODS-HG-5 column, 250 × 20 mm, 5 μm (Phenomenex, Torrance, CA, U.S.A.). The mobile phase consisted of 0.1% formic acid in water (solvent A) and 50% acetonitrile in water (solvent B). The elution condition was as follows: isocratic elution 0% B 0−2 min; linear gradient from 0% to 6% B, 2−8 min; from 6% to 10% B, 8−25 min; from 10% to 16% B, 25−40 min; isocratic 16% B 40−50 min; linear gradient from 16% to 64% B, 50−53 min; isocratic 64% B, 53−58 min; linear gradient from 64% to 0% B, 58−0 min. Injection volume was 1.0 mL. The flow (5.0 mL/min) was split 1:100 before the PDA and mass spectrometry (MS) detection. PDA scan range was 210−600 nm. Mass spectrometry (MS) was fitted with an ESI source and was operated in negative mode. The capillary voltage was 3.9 kV, cone 66.00 V, extractor 3.00, and RF lens 0.7 V. Source temperature was 120 °C, desolvation temperature 350 °C, cone gas flow 50 L/h, and desolvation gas flow 600 L/h. The scan range of the mass spectrometry was m/z 1200−2000. The m/z value 1869 (sanguiin H-6 $[M\text{-}H]^-$) was used as a trigger for the fraction collection. The system was controlled by Waters MassLynx software version 4.1 with FractionLynx (Waters).

The purity and identity of the isolated sanguiin H-6 was determined using the UHPLC-PDA-MS method outlined by Kähkönen et al.,[12] and the concentration was determined spectrophotometrically using the molar extinction coefficient $\varepsilon_{260\ nm}$ 72070 $M^{-1}cm^{-1}$ for sanguiin H-6 in methanol.[30] The concentration of isolated sanguiin H-6 was 254.3 μg/mL in methanol with a purity of 96%.

Oxidation of the Peptide Samples With and Without Sanguiin H-6. The three chosen peptides, LIVTQTMK, ALPMHIR and IPAVFK, were prepared into separate oxidation samples in triplicates, as well as both with and without the sanguiin H-6. The phenolic-to-peptide ratio was chosen to be 1000 μg of sanguiin H-6/g of peptide (molar ratio of 1:2000) according to pretesting done with LIVTQTMK, ALPMHIR, and IPAVFK. For further studies regarding the nature of the adduct between peptide and the ellagitannin, 162 mg sanguiin H-6/g of peptide (molar ratio of 1:12.5) was used with LIVTQTMK. After sanguiin H-6 was added to samples, H_2O_2 solution (final concentration 1 mM) was added into each sample just before the reaction in order to start the oxidation reactions. The samples were placed in an oven of +37 °C for 7 days with stirring on a magnetic tray. An aliquot of 200 μL of each sample was taken on

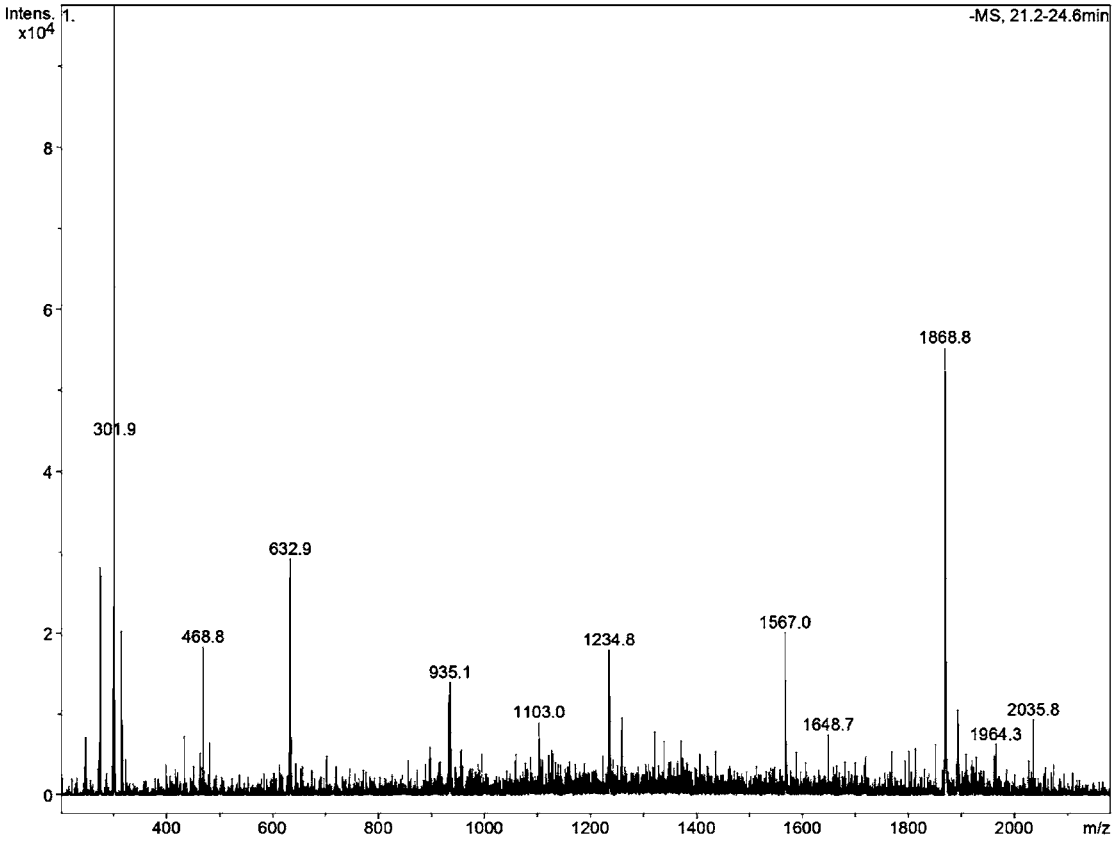

Figure 2. Full scan mass spectrum of isolated sanguiin H-6.

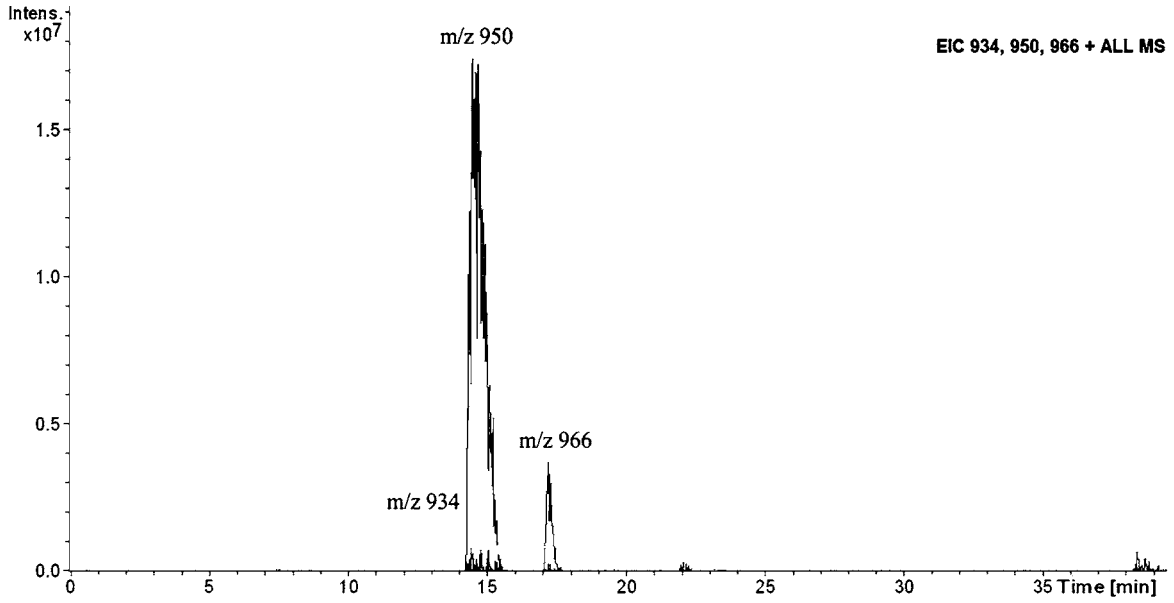

Figure 3. Extracted ion chromatograms (EIC) of the peptide LIVTQTMK ($[M + H]^+$ m/z 934), Met sulfoxide ([LIVTQTMK + O]) form of peptide LIVTQTMK, and Met sulfone ([LIVTQTMK + 2O]) form of peptide LIVTQTMK in positive mode by MS from day 0.

days 0, 1, 4, and 7 for analysis of reaction products. The sub samples were collected into Eppendorf tubes and immediately frozen at −20 °C until analysis.

Analysis of the Oxidation and Interaction Products by LC−MS. The LC−MS used in the analysis of all the oxidation samples was an Agilent 1100 HPLC including a binary pump, a degasser, an automated sample manager, a column heating unit and DAD, and fluorescence detectors (Agilent Technologies, Santa Clara, CA, U.S.A.), which were all connected to a Bruker Esquire quadrupole ion trap mass spectrometer (QIT-MS, Bremen, Germany) using ESI in both positive and negative mode. The column was a Waters XBridge BEH130 C18 (3.5 μm, 2.1 × 100 mm) together with a precolumn (both by Waters Corp., Wexford, Ireland). Injection volume was always 10 μL, and the column temperature was kept at +30 °C. Flow rate was 350 μL/min, and the eluents consisted of 0.1% formic acid in

dx.doi.org/10.1021/jf501190x | J. Agric. Food Chem. 2014, 62, 5028−5037

water (solvent A) and 0.1% formic acid in acetonitrile (solvent B). The diode array detector was set to record at 214 nm, and the fluorescence detector was set to 280 nm (Ex) and 350 nm (Em). The gradient used as well as all the MS-parameters for the positive mode were consistent with the method presented by Koivumäki et al.[8] Only in the negative mode the MS-parameters were optimized using peptides LIVTQTMK, ALPMHIR, and IPAVFK, and they were set to following: dry temperature +300 °C, dry gas 8.0 L/min, nebulizer 60.0 psi, capillary 3800 V, end plate offset −500, trap drive 102.5, capillary exit −178.5, lens-1 5.0, lens-2 60.0, and octopole rf amplitude 137.7 Vpp. For both positive and negative mode, the mass spectra were recorded in the full-scan mode over the m/z range of 200−2200 and analyzed by Bruker Daltonics Data Analysis software (Bremen, Germany).

Fragmentation of Sanguiin H-6 and Interaction Sample. Pure sanguiin H-6 sample and the sample with 162 mg of sanguiin H-6/g of peptide were also analyzed by LC-MS in negative mode. DAD and MS parameters were the same as mentioned previously, except that the nebulizer was changed to 70 psi. The m/z scan range of pure sanguiin H-6 sample was 200−2200, and it was 100−1200 for day 1 oxidation sample with 162 mg of sanguiin H-6/g of peptide.

Analysis of the Oxidation and Interaction Products by Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS-PAGE). Peptide and peptide-sanguiin H-6 complex (peptide-SH6) were analyzed with SDS-PAGE. Samples contained 10 μL of concentrated peptide or peptide-SH6 and 30 μL of sample buffer, which contained 12% SDS, 150 mM Tris/HCl pH 6.8, 0.05% bromophenol blue, and 30% glycerol, and they were incubated for 15 min at 37 °C and applied on gel wells.[30] The gels were Mini Protean Tris-Tricine Precast gels, 10−20% with 50 μL wells (Bio-Rad, Hercules, CA, U.S.A.). Molecular weight standard, 1.5 μL, was applied on two separate wells (Thermo Fisher, 10−170 kDa). Electrophoresis was performed using a Mini protean Electrophoresis system (Bio-Rad) at 20 °C as follows: maximum current throughout the run, 30 min at 30 V, 10 min at 60 and 100 V, until the electrophoresis was stopped. The anodic buffer was 1.0 M Tris and 0.225 M HCl at pH 8.9, and the cathodic buffer was 1.0 M Tris, 1.0 M Tricine, and 1.0% SDS at pH 8.25.[31] After the electrophoresis, the gel was fixed overnight in 30% ethanol, 0.5% acetic acid in deionized water and stained with silver.[32]

RESULTS AND DISCUSSION

MS Identification of Sanguiin H-6. A dimeric ellagitannin, sanguiin H-6, was isolated from cloudberry extracts and separated from the trimeric lambertianin C by using preparative HPLC. The isolated sanguiin H-6 was detected by MS in negative mode (Figure 2) with the fragmentation of m/z 1869. The fragment m/z 1869 of isolated sanguiin H-6 was further identified by MS/MS in negative mode. The retention time of m/z 1869 was around 23 min. These data are in accordance with earlier findings.[11,12] Hexahydroxydiphenoyl (HHDP), glucose, and galloyl groups are the basic functional groups contained in sanguiin H-6. The fragment ions of m/z 1567 (loss of HHDP), 1265 (loss of HHDP−HHDP), 1103 (loss of HHDP−HHDP-glu), and 933 (loss of HHDP−HHDP-glu-galloyl) are the characteristics for sanguiin H-6.[12] As the purity of isolated sanguiin H-6 was 96%, the rest of the extract contained peduculagin/casuarictin isomers because of the detection of m/z 1567, which was $[2M - H]^-$ of an ion m/z 783, potentillin/casuarictin due to $[M - H]^-$ at m/z 935, and its further fragmentation at m/z 633 was observed in the mass spectra of isolated sanguiin H-6 extracts (Figure 2).[33−35]

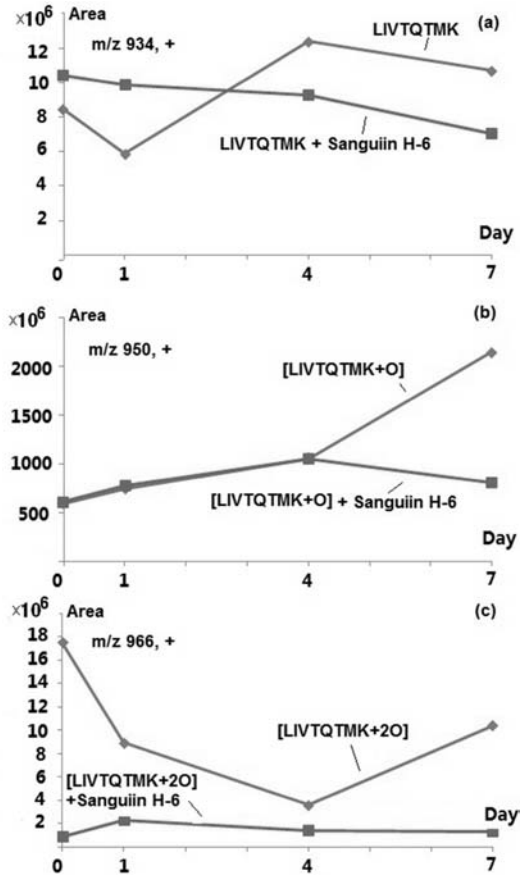

Figure 4. Changes of the amounts of peptide LIVTQTMK and its oxidation products in the samples with and without 1000 μg/g sanguiin H-6 and in positive mode detection (a) LIVTQTMK ($[M + H]^+$ m/z 934), (b) [LIVTQTMK + O] ($[M + H]^+$ m/z 950), and (c) [LIVTQTMK + 2O] ($[M + H]^+$ m/z 966).

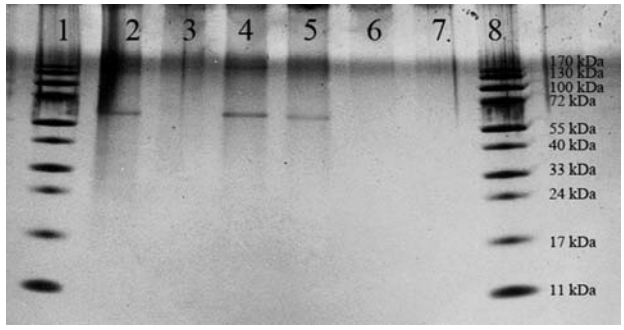

Figure 5. SDS PAGE gel with wells 1 and 8 for molar weight markers, well 2 with day 0 peptide LIVTQTMK, well 3 with day 7 peptide LIVTQTMK, wells 4 and 5 with replicate samples of day 7 peptide LIVTQTMK with high concentration (with 162 mg of sanguiin H-6/1 g of peptide) sanguiin H-6, and wells 6 and 7 empty.

Oxidation Products of Peptide LIVTQTMK and Its Interaction with Sanguiin H-6. Methionine sulfoxide (m/z 950) and methionine sulfone (m/z 966) forms of peptide LIVTQTMK were already observed in positive mode on day 0 (Figure 3), as previously reported by Koivumäki et al.[8] The amount of the unoxidized peptide LIVTQTMK (m/z 934) on day 0 was higher in the samples containing sanguiin H-6

dx.doi.org/10.1021/jf501190x | J. Agric. Food Chem. 2014, 62, 5028−5037

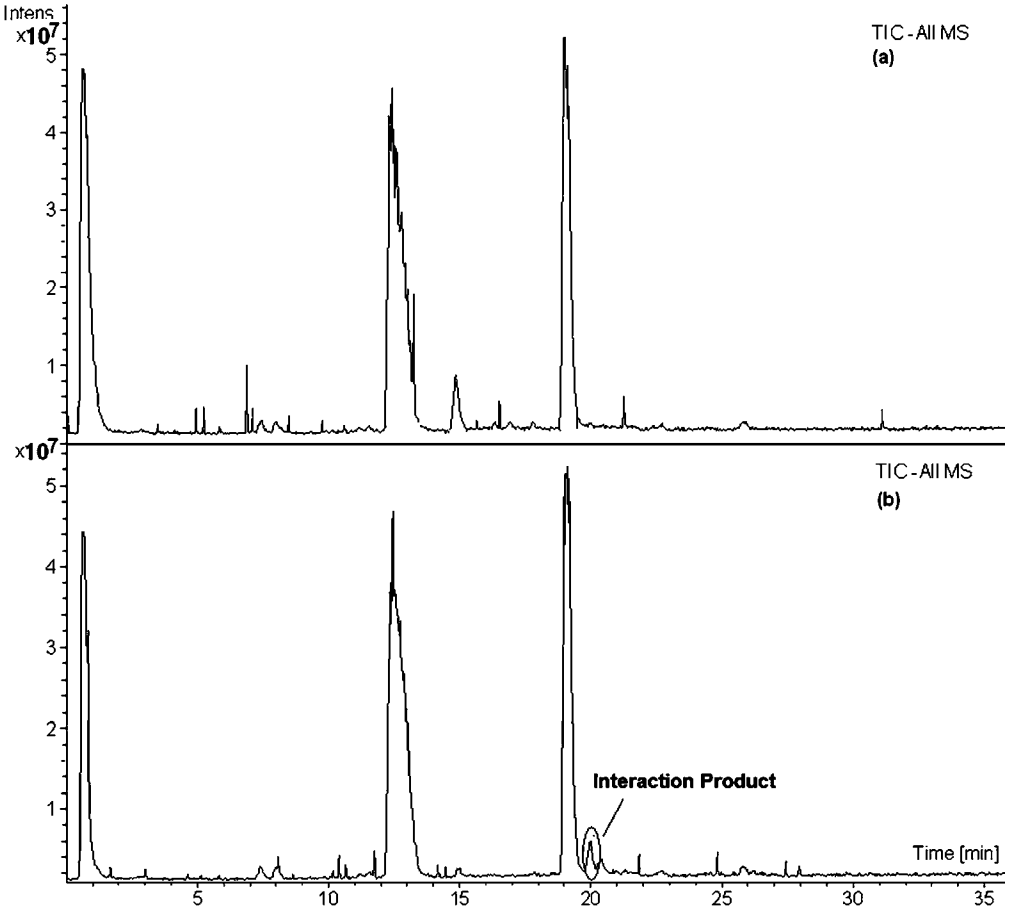

Figure 6. Day 0 LC-MS chromatograms in negative mode: (a) TIC of peptide LIVTQTMK without sanguiin H-6 and (b) TIC of peptide LIVTQTMK with 1000 μg/g of sanguiin H-6.

compared to the samples without sanguiin H-6 where the unoxidized peptide m/z 934 was not detectable (Figure 3). This may be due to the reduction of the methione sulfoxide form of peptide LIVTQTMK (by sanquiin H-6) back to the nonoxidized methionine residues in the peptide.[36] In the presence of sanquiin H-6, the unoxidized peptide m/z 934 continued to decrease (Figure 4a), which may be partly due to adduct formation as the amount of oxidized peptide forms did not increase (Figure 4 b, 4 c). In samples without sanguiin H-6 (Figure 4c), more of the methionine sulfone form of the peptide (m/z 966) was formed from methionine sulfoxide (m/z 950) because of further oxidation. For all the three ions (m/z 934, 950, 966), the trends of ion change were much less significant with sanguiin H-6 than for those without (Figure 4). This might indicate a significant slow scavenging step with sanguiin H-6 present, which maintained the stability of the sample system.[37] Rapid scavenging activity of sanguiin H-6 has earlier been seen toward lipid oxidation.[12] Sanguiin H-6 has been reported to donate an electron to highly reactive free radicals and to suppress the reactivity of the radical by delocalization of the unpaired electron on the phenolic ring.[38,39] Sanguiin H-6 might interact with protein through hydrogen bonding, hydrophobic bonding, or ionic bonding.[18−20,40,41] For example, for hydrogen bonding, the carbonyl functional groups of the amino acids or peptide backbone and the isolated phenolic hydroxyl group in the polyphenolic form a strong hydrogen bond during protein−polyphenol interaction.[15,42−45] It is postulated that when sanguiin H-6 interacts with ß-Lg with forming adducts this prevents the peptide from undergoing oxidation.

The gel electrophoresis showed the peptide LIVTQTMK on day 7 with replicate samples of sanguiin H-6 (well 4 and well 5), with two lines on both, one around 170 kDa and the other between 55 and 72 kDa (Figure 5). The peptide LIVTQTMK sample also displayed one line between 55 and 72 kDa on day 0 (well 2), but none was detected on day 7 with the oxidized peptide sample (well 3). Because the molar weight of peptide LIVTQTMK was less than 10 kDa (the cutoff of the gel), the peptide LIVTQTMK alone in the sample cannot be detected. It is assumed that the masses around 170 kDa and possibly also around 55−72 kDa might be due to the interaction products between sanguiin H-6 and peptide LIVTQTMK.

The interaction between peptide and sanguiin H-6 and the radical scavenging activity of sanguiin H-6 were observed by LC-MS in the negative mode. Normally, the peptide is detected in positive mode by LC-MS, whereas some of the phenolic compounds such as ellagitannins can only be perceived in negative mode.[12] The dimeric sanguiin H-6 with m/z of 1869 at $[M - H]^-$ in negative mode is shown in Figure 2. In the sample containing 1000 μg sanguiin H-6 per gram peptide LIVTQTMK, a new peak was found at retention time of 20 min compared with the sample without sanguiin H-6 on day 0 (Figure 6). The fragment ions m/z 1119 and m/z 997 that were detected on day 0 in negative mode may be the oxidation products of sanguiin H-6 fragments, which were m/z 1103 resulting in Δm = +16 amu (sanguiin H-6 loss of HHDP−HHDP-glu + O) and m/z 933

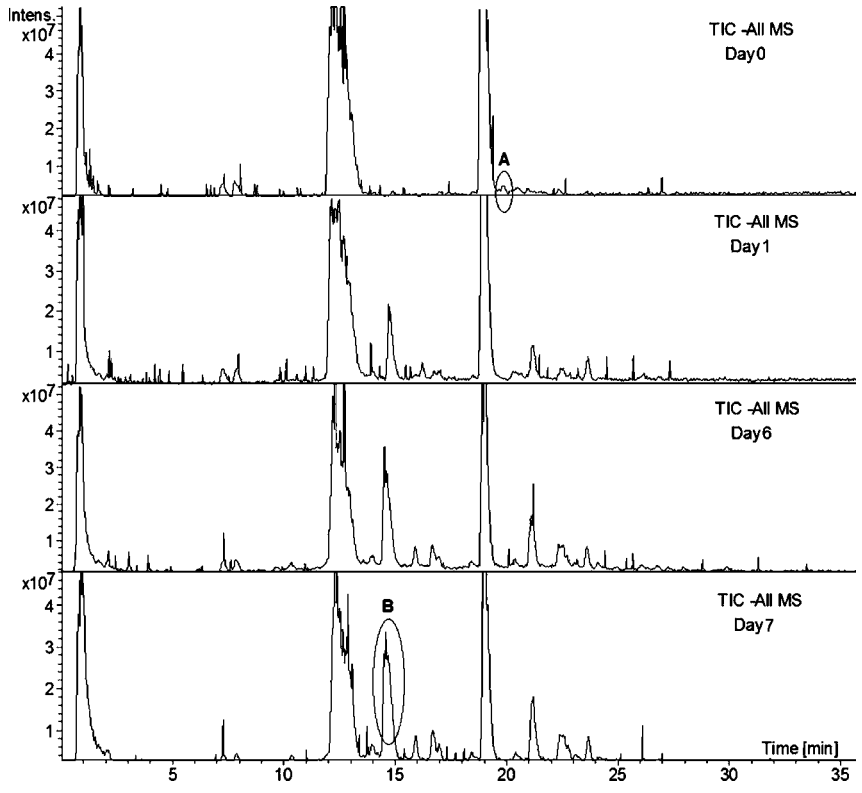

Figure 8. TIC of peptide LIVTQTMK with a high concentration (with 162 mg of sanguiin H-6/1 g of peptide) of sanguiin H-6 from days 0, 1, 6, and 7. Peaks A and B refer to interaction products.

dx.doi.org/10.1021/jf501190x | J. Agric. Food Chem. 2014, 62, 5028−5037

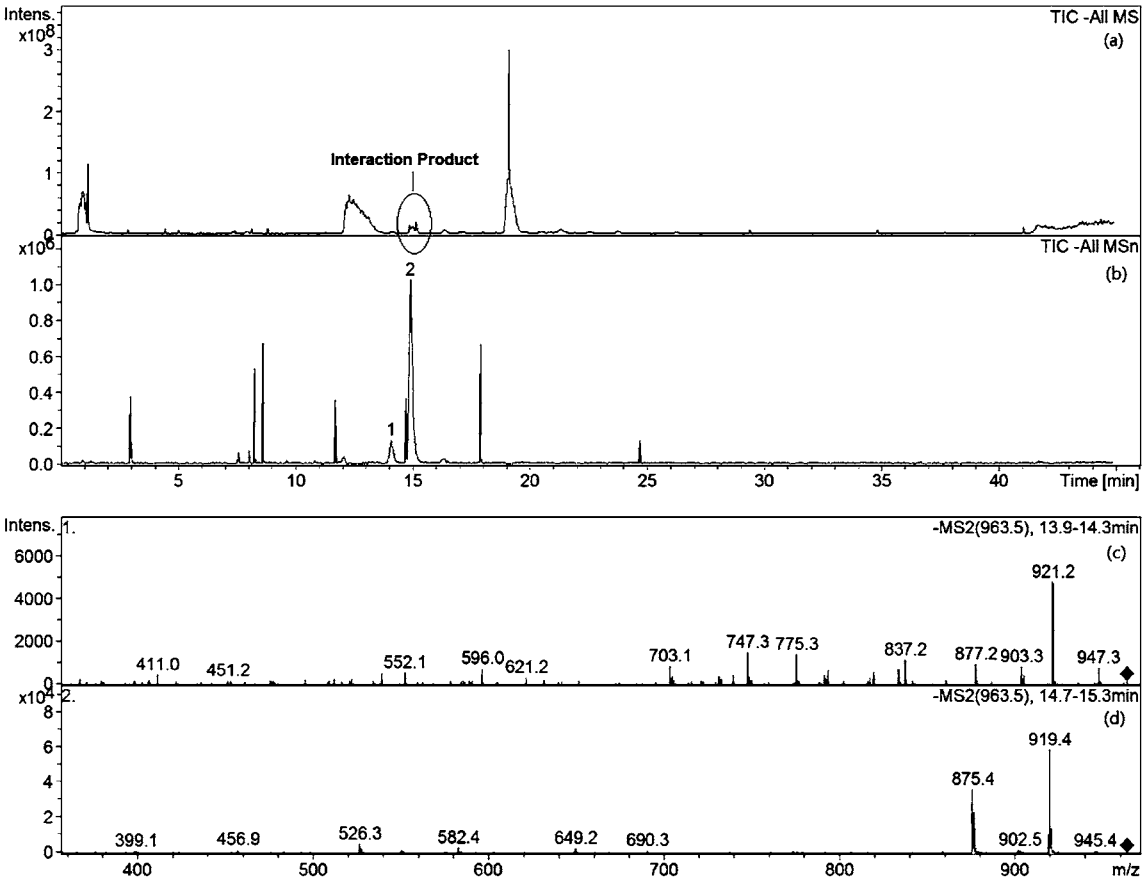

Figure 9. Peptide LIVTQTMK with a high concentration (with 162 mg of sanguiin H-6/1 g of peptide) from day 1 (a) TIC, (b) TIC of fragmentation of m/z 963.5, (c) MS/MS spectrum of peak 1, and (d) MS/MS spectrum of peak 2.

with +64 amu addition (sanguiin H-6 loss of HHDP−HHDP-glu-galloyl +4O). This suggests that the oxidation of sanguiin H-6 itself happened quite rapidly on day 0. The detection of ion m/z 963.5 and its extracted ion chromatogram reveal that the interaction product between oxidized peptide and oxidized ellagitannin monomer (casuarictin) with doubly charged ions was generated on day 0. Even though the intensity of m/z 963 was relatively low, m/z 963 is very likely to be the interaction product between peptide LIVTQTMK and sanguiin H-6.

The same peak indicating the formation of an interaction product was also detected at a retention time of 20 min (Figure 7d) in the samples containing a higher proportion of sanguiin H-6 to that of peptide (162 mg of sanguiin H-6/1 g of peptide). The peak of sanguiin H-6 (Figure 7a) was not detected on day 0 in the sample of sanguiin H-6 with peptide LIVTQTMK, whereas a new peak appearing at a retention time of 20 min (Figure 7d) was also detected both at 210 and 280 nm. This indicates the presence of both peptide bond and phenolic group, supporting the conclusion that the new peak is an interaction product of sanguiin H-6 and peptide LIVTQTMK. Other peaks (with retention times between 14 and 24 min, Figure 8) were found in the total ion chromatogram (TIC) in the samples with a higher concentration of sanguiin H-6 with peptide LIVTQTMK. The areas of these six peaks were increasing from day 0 to day 7. Peak A disappeared after day 1, which could indicate that further oxidation occurred. Peak B, around 15 min in Figure 8, seems to be the main interaction product with covalent bonding, as it was also identified in Figure 9. This figure also shows the $[M - H]^-$ m/z 963, which was further fragmented to m/z 919 and m/z 875. Compared to the MS/MS of peak 1 and 2 (Figure 10b), 877, 921, and m/z 947 in Figure 10c were 2 amu different compared with 875, 919, and m/z 945 in Figure 10d, which indicated there might be a double bond breakage. Furthermore, the 17 amu difference between m/z 921 and m/z 903 (Figure 9c), as well as m/z 902 and m/z 919 (Figure 9d), indicated that there might be an addition of ammonia. Lysine and methionine residues in peptide LIVTQTMK might be responsible for the interaction between peptide LIVTQTMK and sanguiin H-6. The interaction may occur owing to the hydrophoblic section in the side chain of lysine and methionine.[18,46−49] In addition, lysine has a positive charge near neutral pH, which makes it possible to interact with the carboxylate group or the aromatic ring of sanguiin H-6.

Oxidation Products of Peptide ALPMHIR and Its Interaction with Sanguiin H-6. Peptide ALPMHIR was detected with $[M + H]^+$ m/z 838 in positive mode and $[M - H]^-$ m/z 836 in negative mode by LC-MS. Met, His, and Pro present in peptide ALPMHIR are rather prone to be monoxidized, whereas Pro, Arg, and Met tend to be dioxidized.[2] [ALPMHIR + O] was observed to be the most prominent oxidation product formed during oxidation for 7 days, as earlier reported also by Koivumäki et al.[8] Similarly to peptide LIVTQTMK ($[M + H]^+$ m/z 934), during the oxidation process, the color of the peptide ALPMHIR ($[M + H]^+$ m/z 838) samples changed from transparent to lightly yellowish with tiny milky-white particles dissolving out from time to time. The precipitations were probably due to instable haze formed due to interaction between peptide and sanguiin H-6.

dx.doi.org/10.1021/jf501190x | J. Agric. Food Chem. 2014, 62, 5028−5037

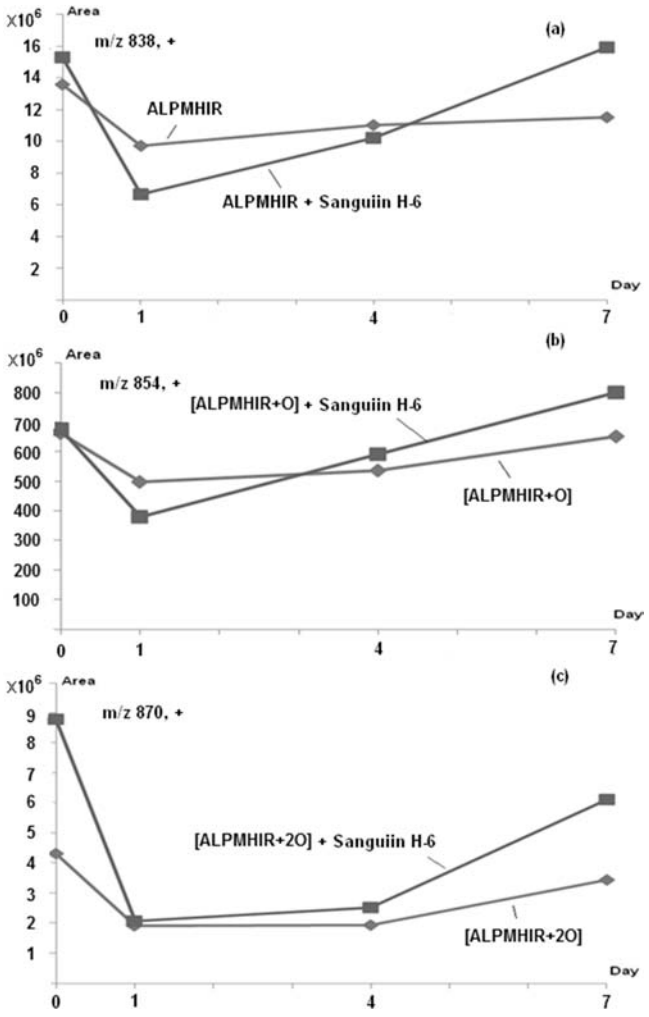

Figure 10. Changes in the amounts of peptide ALPMHIR and its oxidation products in the samples with and without 1000 μg/g sanguiin H-6 in positive mode detection in (a) ALPMHIR ($[M + H]^+$ m/z 838), (b) [ALPMHIR + O] ($[M + H]^+$ m/z 854), and (c) [ALPMHIR + 2O] ($[M + H]^+$ m/z 870).

The general trends of amounts for the peptide ALPMHIR ($[M + H]^+$ m/z 838) and its oxidation products ($[M + H]^+$ m/z 854 and $[M + H]^+$ m/z 870) were very analogous. They all decreased from day 0 to day 1 and increased through day 1 to day 7. The difference between the samples with and without sanguiin H-6 was that the changes of peptide and the amounts of its oxidation products were more stable without sanguiin H-6 than those with sanguiin H-6, thus contradicting the findings with peptide LIVTQTMK. Moreover, the rate of decline for the ion m/z 870 was faster than for the ions of m/z 838 and m/z 854 from day 0 to day 7 (Figure 10). On day 0, both monoxidized and dioxidized forms of peptide ALPMHIR (m/z 854 and m/z 870) were detected. The amount of unoxidized peptide ALPMHIR (m/z 838) was higher in the samples with sanguiin H-6 than without sanguiin H-6 because of the antioxidant or scavenging activity of sanguiin H-6 (Figure 10a). For [ALPMHIR + O], the amount in the sample with sanguiin H-6 was similar to that without sanguiin H-6 (Figure 10b). The reason might be that the oxidation of peptide ALPMHIR took place even more rapidly than the fast radical scavenging activity of sanguiin H-6. Therefore, the radical scavenging activity of sanguiin H-6 was not significant on day 0 for the very first oxidation step of peptide ALPMHIR. For the dioxidized form of peptide ALPMHIR (m/z 870), the amount of that in the samples with sanguiin H-6 was even higher (Figure 10c). This may be due to the dioxidation of proline, arginine, and methionine that occurred so rapidly and even faster than the scavenging activity of sanguiin H-6. Sanguiin H-6 may also have inhibited the further oxidation of dioxidized form of peptide ALPMHIR, and the amount of [ALPMHIR + 2O] was lower in the sample without sanguiin H-6, because many of them might be further oxidized. Contradictory to peptide LIVTQTMK, the sample without sanguiin H-6 was more stable than that with added sanguiin H-6 for peptide ALPMHIR. The reason might be the different amino acid composition of the peptides. Tannin presents both a fast and a significant slow scavenging step in the sample. Proline, methionine, histidine, lysine, and methionine are all capable to interact with sanguiin H-6. For example, proline residues could provide a hydrophobic binding site through pyrrolidine rings and may associate with aromatic rings in sanguiin H-6.[18,46−48] Therefore, besides oxidations on different residues, phenolic−protein interaction, antioxidant, and scavenging activity of sanguiin H-6 were occurring together in the sample with sanguiin H-6. Thus, the amount of interaction products was less stable. The tiny milky-white precipitation particles dissolved out from time to time were likely to be the haze due to the interaction between peptide ALPMHIR and sanguiin H-6 because the peptide ALPMHIR contains proline, which is usually rich in haze-forming proteins.[46] The haze was invisible to the eye until the formation of the polyphenol protein agglomeration precipitate. It was a less soluble entity most likely formed by the cross-linking of hydroxyl groups presented in polyphenol and protein molecules.[50] Therefore, the presence of haze also indicated the existence of unstable interaction products.

Oxidation Products of Peptide IPAVFK and Its Interaction with Sanguiin H-6. The peptide was detected at $[M + H]^+$ m/z 674 in positive mode and $[M - H]^-$ m/z 672 in negative mode by LC-MS. Phe (F) is known to be the most vulnerable residue to be oxidized due to its aromatic side chain.[51] However, peptide IPAVFK at $[M - H]^-$ m/z 672 was relatively stable and not easily and rapidly oxidized. There were no oxidation products significant enough to be quantified for peptide IPAVFK ($[M + H]^+$ m/z 674), as compared to the peptide LIVTQTMK ($[M + H]^+$ m/z 934) and the peptide ALPMHIR ($[M + H]^+$ m/z 838), in positive mode detection by MS.

Total ion chromatograms in Figure 11 were acquired from LC-ESI-MS in negative mode detection through oxidation day 0 to day 7. Two sets of samples were monitored, one is fractionated β-Lg peptide IPAVFK and the other is fractionated peptide IPAVFK with 1000 μg/g sanguiin H-6. When the peak integration was done by using the total ion chromatogram, several different analytes eluted simultaneously.

The amount of peptide IPAVFK did not change considerably in the samples with and without sanguiin H-6 on day 0. The same occurred also on day 7. Fewer peaks could be detected in the sample with sanguiin H-6 than without both on day 0 and day 7. The changes of peak areas of interaction products were not significant enough to be observed in the total ion chromatograms.

In negative mode, there were fewer peaks in the sample with sanguiin H-6 than that without. This may be because the scavenging activity of sanguiin H-6. Sanguiin H-6 interacted with other nontarget peptides and stabilized the reaction system. On day 7, unoxidized form of peptide IPAVFK ($[M - H]^-$ m/z 672) was still existing but slightly decreased as compared to day 0.

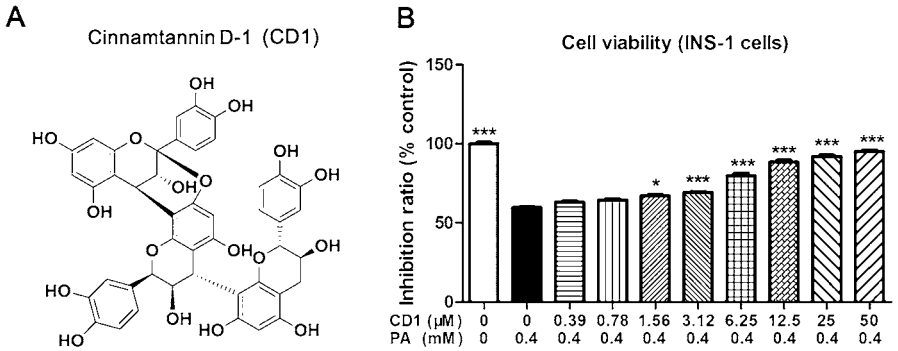

Figure 1. Cinnamtannin D-1 (CD1) protects INS-1 cells from PA-induced decrease in cell viability. (A) Chemical structure of CD1. (B) CD1 protection against PA-induced decreasing of cell viability in INS-1 cells. Cell viability was detected, and the results are shown as inhibition ratio (% of control). All data are expressed as the mean ± SE ($n = 6$). Asterisks denote significant difference versus the PA-treated alone group (∗, $p < 0.05$; ∗∗, $p < 0.01$; ∗∗∗, $p < 0.001$).

restoration of PA-injured insulin secretion in islets by CD1 was also observed.

MATERIALS AND METHODS

Materials and Reagents. All general reagents for cell culture were purchased from Hyclone, Shanghai, China; PA, bovine serum albumin (BSA), Hoechst 33342, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT), and chloromethyl-2′,7′-dichlorodihydrofluorescein diacetate acetyl ester (CM-H_2DCFDA) were purchased from Sigma-Aldrich, Shanghai, China. A Total Nitric Oxide Assay Kit was obtained from Beyotime, Shanghai, China.

Source of CD1. CD1 (Figure 1A) was isolated from the bark of *C. tamala* as previously described.[17] The structure of CD1 was confirmed by mass spectrometry (MS) and nuclear magnetic resonance (NMR). The compound purity was approved by high-performance liquid chromatography (HPLC: column, Agilent Extend C18 column, 5 μm, 4.6 mm × 250 mm; solvent system, acetonitrile−0.2% acetic acid with gradient elution; flow rate, 1 mL/min; UV detection, 280 nm; Agilent 1200, Agilent Technologies, Santa Clara, CA, USA). CD1 was >95% pure.

Cell Culture and Mouse Pancreatic Islets Isolation. The INS-1 rat insulinoma cell line was cultured in Roswell Park Memorial Institute (RPMI)-1640 medium supplemented with 10% fetal bovine serum (FBS) and 50 μM β-mercaptoethanol. The MIN6 mouse insulinoma cell line was maintained in Dulbecco's modified Eagle medium (DMEM) containing 25 mM glucose, 10% FBS, and 50 μM β-mercaptoethanol. All cells at passage 10−15 were kept at 37 °C and 5% CO_2 in humidified air.

Pancreatic islets were isolated from 6-week-old male C57BL/6J mice (Slac, Shanghai, China). Briefly, the mice were anesthetized by chloral hydrate, and collagenase V (1 mg/mL concentration, Sigma-Aldrich, Shanghai, China) was injected into the pancreas through the common bile duct. The pancreas was quickly removed for digestion at 37 °C for 15 min. The intact islets were handpicked from the digest solution after multiple washes and maintained in RPMI-1640 medium supplemented with 10% FBS, 10000 units/mL penicillin, and 10000 mg/mL streptomycin with 11.1 mM glucose in a sterile cell incubator at 37 °C with 5% CO_2 infusion and humidified 95% air. The islets were used in the following experiments after 24 h of culture. All animal care and experiments were permitted by Institutional Animal Care and Use Committees of Shanghai Institute of Materia Medica.

Cell Viability Assay and Hoechst 33342 Staining. First, to investigate the effect of CD1 on cell viability in PA-treated pancreatic β-cells, INS-1 and MIN6 cells were seeded in 96-well plates. PA/BSA solution was prepared as previously described.[18] The cells were treated with different doses of CD1 in the presence or absence of 0.4 mM PA and incubated for 48 h. Cell viability was determined by MTT assay. Briefly, the cells were incubated with MTT regent (0.5 mg/mL) at 37 °C for 4 h, and the absorbency at a wavelength of 492 nm was measured by FlexStation 3 (Molecular Devices, Sunnyvale, CA, USA). The inhibition rates were calculated by comparison with the control group (treated with 0.5% BSA alone, 100%). In the H_2O_2-treated β-cell model, INS-1 or MIN6 cells were preincubated with CD1 for 4 h and exposed to 500 μM H_2O_2 for 1, 2, and 4 h, respectively. Then the cell viability was measured by MTT assay.

Hoechst 33342 staining was performed to evaluate the proportion of apoptotic cells. INS-1 cells were seeded in a 24-well plate on cover glasses. After incubation with different concentrations of CD1 in the presence/absence of 0.4 mM PA for 48 h, the cells were fixed in 4% paraformaldehyde and stained with Hoechst 33342. The photos were taken by fluorescence microscopy (DP70, Olympus, Japan), and the apoptotic ratio in each group was analyzed.

Determination of Cellular ROS and NO Production. After the INS-1 cells were preincubated with different concentrations of CD1 for 4 h, 10 μM CM-H_2DCFDA was added into cells to load fluorogenic probes at 37 °C for 30 min. Then the cells were incubated with or without 500 μM H_2O_2 for another 20 min. After removal of H_2O_2 and multiple washes, the ROS levels were assessed by determination of 2′,7′-dichlorofluorescein (DCF), which was converted from CM-H_2DCFDA through oxidation. The formation of fluorescent DCF in each well was observed by fluorescence microscopy or quantified at an excitation wavelength 488 nm and emission wavelength of 525 nm by FlexStation 3. To detect the effect of CD1 on PA-induced ROS production, the cells were treated with different concentrations of CD1 in the presence/absence of 0.4 mM PA for 48 h; after washes, the probe was loaded, and the ROS level in each group was detect by the fluorescence.

For further investigation of the effect of CD1 on PA-induced NO generation, INS-1 cells were treated with PA and different concentrations of CD1 for 48 h, and then aliquots of media from each treated group were collected. NO production was then immediately assessed by measuring the amount of nitrite in the supernatant using the Total NO Assay Kit (Beyotime) according to its instructions.

Western Blot Analysis and Immunofluorescence Assay. After the INS-1 cells were treated with CD1 in the presence/absence of PA for 48 h, proteins from each group were collected and the expression levels of cleaved caspase-3 and iNOS were detected using Western blot analysis as described previously.[19] The following primary antibodies and dilutions were used: rabbit anticleaved caspase-3 (Asp175, 1:1000), rabbit antiphospho-Nuclear Factor Kappa B (NFκB, Ser536, 1:1000), rabbit anti-NFκB (1:1000), rabbit antiphospho-c-Jun N-terminal kinase (JNK, Thr183/Tyr185, 1:1000), rabbit anti-JNK (1:1000), rabbit antiphospho-p38 (Thr180/Tyr182, 1:1000), rabbit anti-p38 (1:1000; all from Cell Signaling Technology, Danvers, MA, USA); rabbit anti-NOS2 (iNOS, Santa Cruz Biotechnology, Dallas, TX, USA, 1:500); and mouse anti-β-actin (Sigma-Aldrich, St. Louis, MO, USA, 1:10000). The secondary antibodies were anti-mouse IgG and anti-rabbit IgG (Jackson Laboratory, USA, 1:10000). The expression of protein was measured by optical density using ImageJ (National Institutes of Health, Bethesda, MD, USA).

For double-immunofluorescence staining of insulin and iNOS, INS-1 cells or primary cultured islets were grown on coverslips in a six-well

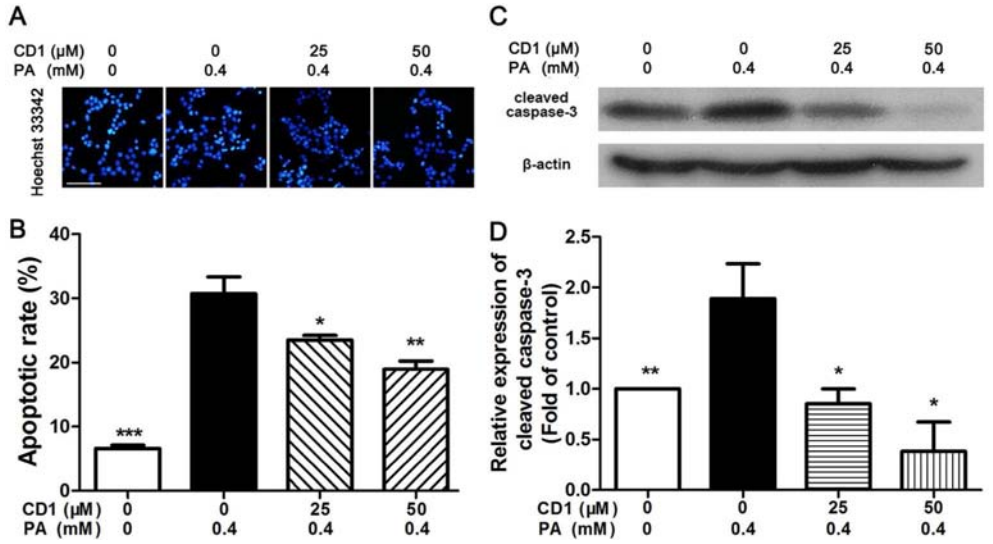

Figure 2. CD1 protects INS-1 β-cells from PA-induced apoptosis. (A) Representative fluorescent images of Hoechst 33342 staining in different treated INS-1 cells. Cells were treated with 0.5% BSA alone, 0.4 mM PA/0.5% BSA with or without 25 μM, and 50 μM CD1 for 48 h, and then Hoechst staining was performed. The brighter nuclei indicated Hoechst 33342-positive apoptotic cells. Scale bar = 50 μm and refers to all panels. (B) Statistical analysis of Hoechst 33342 staining showing the apoptotic rate in differently treated groups. The apoptotic rate was calculated as Hoechst 33342-positive nuclei divided by all nuclei ($n = 6$). (C) Western analysis of the effect of CD1 on the expression of cleaved caspase-3. (D) Histogram of the statistical results of Western blot analysis data. The optical density of each blot band of cleaved capsase-3 was determined and adjusted by the optical density of β-actin; the blots were performed for at least three independent experiments. All data are expressed as the mean ± SE. Asterisks denote significant difference versus the PA-treated alone group (*, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$).

plate and then incubated with 0.5% BSA alone or PA/BSA or PA/BSA mixed with different concentrations of CD1 for 48 h. The immunofluorescence was performed as previously described.[20] Briefly, INS-1 cells or islets were fixed in 4% paraformaldehyde and incubated with primary antibodies (rabbit anti-insulin, Cell Signaling Technology, dilution 1:100; mouse anti-NOS2, Santa Cruz, dilution 1:100) overnight followed with secondary antibodies (Alexafluor 488-conjugated goat anti-rabbit IgG and Alexafluor 546-conjugated goat anti-mouse IgG, Invitrogen, dilution 1:400). Then the nuclei were stained with Hoechst 33342, and the coverslips were mounted and observed by confocal microscope (FV1200, Olympus, Japan). A terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) assay was carried out to evaluate the apoptotic cells in islets. After islets were treated with different concentrations of CD1 in the presence/absence of 0.4 mM PA, the apoptotic cells in islets were detected by TUNEL kit (Roche, USA) according to the manufacturer's instructions. Hoechst 33342 was used for visualization of nuclei. The rate of apoptosis was calculated as the number of TUNEL-positive cells divided by the area of each islet.

Determination of Glucose-Stimulated Insulin Secretion (GSIS). Islets of approximately the same size were plated in 24-well plates (10 islets per well) for insulin secretion studies. Islets were incubated with CD1 in the presence/absence of 0.4 mM PA for 48 h. Then the culture medium was removed, and cells or islets were washed and preincubated in Krebs−Ringer buffer (KRB; 135 mM NaCl, 3.6 mM KCl, 0.5 mM NaH_2PO_4, 0.5 mM $MgSO_4$, 1.5 mM $CaCl_2$, 2 mM $NaHCO_3$, 10 mM HEPES, and 0.1% w/v BSA, pH 7.4) without glucose for 1 h at 37 °C. Thereafter, the cells/islets were incubated in KRB containing 5 mM glucose for 1 h at 37 °C and then in 25 mM glucose for another 1 h. The supernatant was collected, and the insulin level was measured by using an insulin ELISA kit (Millipore, Bedford, MA, USA) according to its protocol.

Statistical Analysis. All data were expressed as the mean ± SE. The comparison of different groups was assessed by t test or one-way ANOVA analysis followed by Dunnett's test. Differences were considered statistically significant at $p < 0.05$.

RESULTS

CD1 Protects INS-1 β-Cells from PA-Induced Apoptosis. There was no cytotoxic effect of CD1 on pancreatic β-cell lines (Supporting Information Supplementary Figure 1A). To evaluate the protective effect of CD1 on PA-induced β-cell apoptosis, we first examined the protective effect of CD1 on cell viability in PA-treated INS-1 cells. It was shown that CD1 could dose-dependently increase cell viability in the presence of 0.4 mM PA in INS-1 cells (inhibitory rates were 95.2 ± 2.2% at 50 μM, 92.1 ± 2.1% at 25 μM, 88.4 ± 2.9% at 12.5 μM, 79.9 ± 3.9% at 6.25 μM, 69.3 ± 1.2% at 3.12 μM, and 67.1 ± 2.1% at 1.56 μM vs 59.7 ± 1.5% for the PA-treated alone group, Figure 1B), which suggested that CD1 could protect pancreatic β-cells from PA-induced decrease in cell viability.

To further evaluate whether the protective effect of CD1 on cell viability was associated with apoptosis, Hoechst 33342 staining was then performed to detect the apoptotic rate. In Hoechst 33342 staining, the nuclei of apoptotic cells visualized by fluorescence microscopy displayed a high condensed chromatin compared with normal cells.[21] Cells treated with 0.4 mM PA showed brighter nuclei with highly condensed DNA and nuclei shrinkage, whereas an obviously reduced apoptotic rate was observed in CD1 (25/50 μM) and PA cotreated INS-1 cells (Figure 2A,B). The activation of caspase-3 was identified as a key role in the execution of cell apoptosis. In this study, it was found that CD1 significantly reduced cleaved caspase-3 level in PA-treated cells at doses of both 25 and 50 μM compared with PA-treated alone group (Figure 2C,D). All of these data suggested that CD1 could protect β-cells from PA-induced apoptosis.

CD1 Attenuates PA-Induced ROS, NO Production, and iNOS Expression in INS-1 β-cells. We then investigated the effects of CD1 on some oxidative stress-associated markers in PA-induced β-cell apoptosis. By detecting DCF fluorescence, ROS generation was significantly decreased in CD1 and PA cotreated cells compared with PA-treated alone INS-1 cells (Figure 3A). Moreover, as shown in Figure 3B, total NO synthesis was obviously inhibited by CD1 in a dose-dependent manner. Increased expression of iNOS can lead to sustained

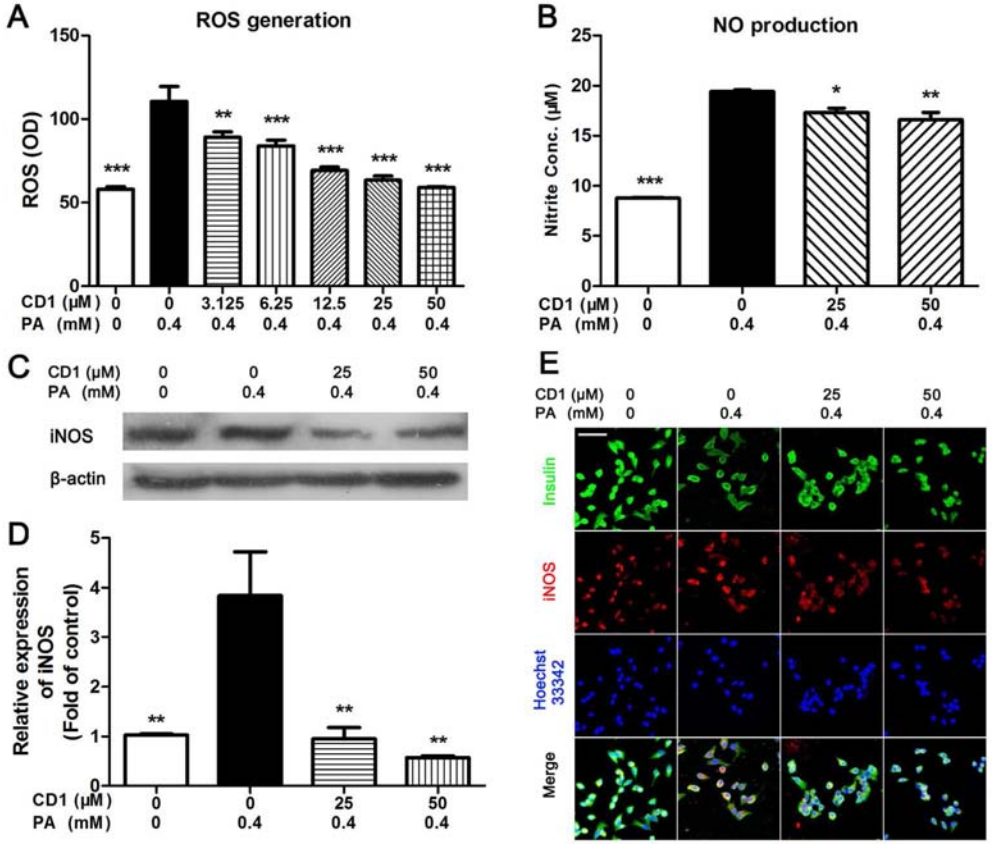

Figure 3. CD1 reduced PA-induced oxidative stress in INS-1 cells. (A) INS-1 cells were treated with different concentrations of CD1 in the presence/absence of 0.4 mM PA for 48 h. Quantified ROS production in the cells was detected ($n = 3$). (B) Cells were treated with different concentrations of CD1 in the presence/absence of 0.4 mM PA for 48 h. NO production was then detected ($n = 3$). (C) INS-1 cells were treated with 25 and 50 μM CD1 in the presence/absence of 0.4 mM PA for 48 h, and the expression levels of iNOS and β-actin were detected by Western blot analysis. (D) The optical density of each blot band of iNOS was determined and modified by the optical density of β-actin; the blots were performed for at least three independent experiments. (E) INS-1 cells were treated as above, and double immunofluorescence of insulin and iNOS was performed. Insulin was marked with green fluorescence, whereas iNOS was red; nuclei were stained by Hoechst 33342 (blue), and figures were merged. Scale bar = 50 μm and refers to all panels. This experiment was repeated at least three times. All data are expressed as the mean ± SE. Asterisks denote significant difference versus the PA-treated alone group (∗, $p < 0.05$; ∗∗, $p < 0.01$; ∗∗∗, $p < 0.001$).

elevation of NO, which was a major contributor in β-cell dysfunction and apoptosis.[22] Therefore, to investigate the expression level of iNOS in pancreatic β-cells, Western blot and immunofluorescence were performed in INS-1 β-cells and primary cultured islets. As expected, CD1 abolished the increasing expression level of iNOS induced by PA (Figure 3C,D). Double-immunofluorescence also showed that there were fewer iNOS-positive cells in CD1 and PA cotreated INS-1 cells than in PA-treated alone cells (Figure 3E), which was consistent with the results of Western blot analysis. Furthermore, to verify the effect of CD1 on iNOS expression in pancreatic β-cells, primary mouse islets were isolated and cultured for immunofluorescence staining. Compared with normal cultured islets, PA obviously increased iNOS expression. However, addition of 25 and 50 μM CD1 to culture medium could obviously suppress this deleterious effect (Figure 4A).

CD1 Decreases PA-Induced Apoptosis and Protects β-Cell Function against PA-Induced Impairment of GSIS in Isolated Mouse Islets. To further investigate whether CD1, an A-type proanthocyanidin trimer isolated from *C. tamala*, could reduce PA-induced apoptosis in primary cultured islets, TUNEL staining was carried out to detect the apoptotic cells by labeling DNA fragmentation.[23] After incubation with 0.4 mM PA for 48 h, the number of TUNEL-positive cells increased obviously in comparison with untreated islets. However, CD1 suppressed this pernicious effect significantly (Figure 4B,C).

It is known that chronic exposure to elevated levels of PA can induce β-cell apoptosis as well as impair β-cell insulin secretion. Therefore, the protective effect of CD1 against PA-induced impairment of insulin secretion in primary cultured islets was also investigated. It was found that PA-impaired GSIS function was partly restored by CD1 in a dose-dependent manner (Figure 4D). Together, results suggested that this compound could suppress PA-induced impairment of GSIS as it reduced the apoptosis of pancreatic β-cells.

CD1 Suppressed PA-Induced Phosphorylation of NFκB and JNK but Not p38 MAPKs. Multiple mechanisms are involved in PA-induced β-cell apoptosis, such as ER-stress, oxidative stress, and inflammatory effect. CD1 was involved as an antioxidant with the inhibitory activity against cyclooxygenase-2.[24] Therefore, in addition to iNOS, inhibition of other PA-activated pro-inflammatory gene expression in pancreatic β-cells might be associated with the protective effect of CD1. It was found that PA-induced phosphorylations of NFκB (Figure 5A,D) and JNK (Figure 5B,E) were significantly reduced in the presence of CD1. However, there was no obvious effect of CD1 on PA-activated p38 phosphorylation (Figure 5C,F).

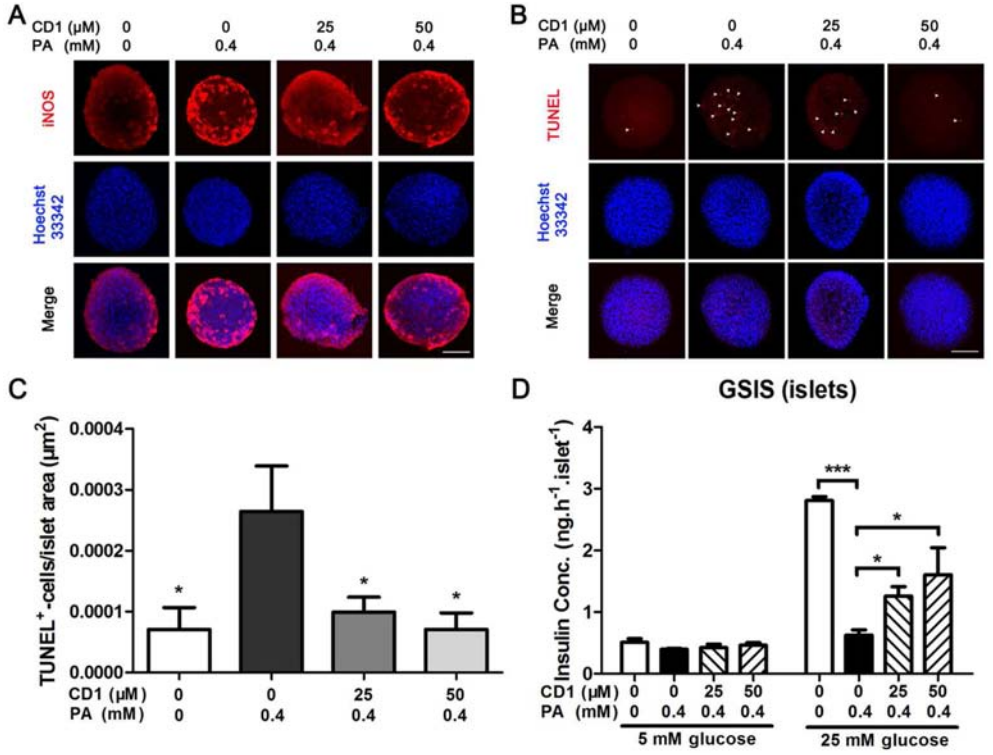

Figure 4. (A) CD1 affected iNOS expression in primary cultured islets. Islets were isolated and cultured with CD1 and PA for 48 h. Red fluorescence indicated iNOS expression, and Hoechst 33342 showed nuclei. The merged figures are shown in below. Scale bar = 50 μm and refers to all panels. (B) CD1 reduced cell apoptosis in PA-simulated primary cultured islets and restored PA-injured insulin secretion. After islets were treated with CD1 and PA, TUNEL staining was performed to investigate the apoptotic ratio of cells in primary cultured islets. TUNEL-positive nuclei were marked by red fluorescence. Representative TUNEL-positive cells are indicated by white arrows. All nuclei were stained with Hoechst 33342, which showed blue fluorescence. The merged figures are shown below. Scale bar = 50 μm and refers to all panels. (C) Histogram shows the number of TUNEL-positive cells modified by the area of each islet. At least 15 islets were analyzed in each group. (D) After treatment with CD1 and PA, isolated islets were incubated at 5 mM glucose and successive 25 mM. The supernatant was collected and used for insulin determination ($n = 3$). All data are shown as the mean ± SE. The statistics result showed significant difference versus the PA-treated alone group (*, $p < 0.05$; **, $p < 0.01$; ***, $p < 0.001$).

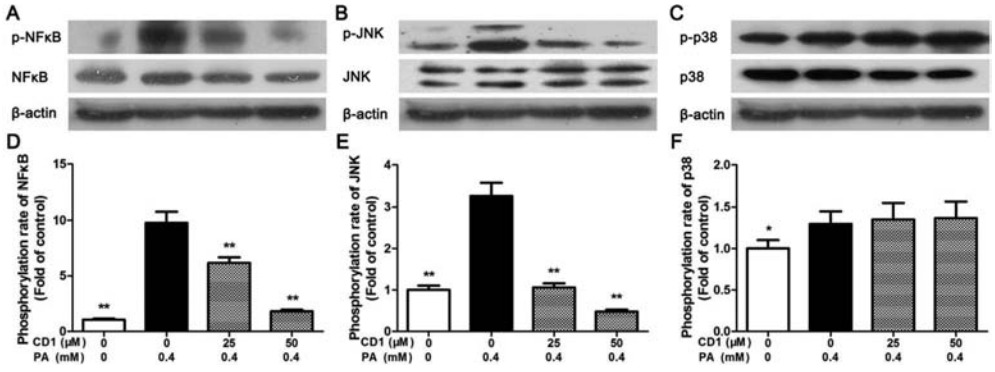

Figure 5. Western blot analysis of NFκB, JNK, and p38 phosphorylation. After the cells were treated with/without different concentrations of CD1 in the presence/absence of PA, the cell lysate was collected and followed phosphorylation proteins were detected. (A) The phosphorylation rate of NFκB was detected; β-actin was used as an internal. (B) The phosphorylation rate of JNK was detected; β-actin was used as an internal. (C) The phosphorylation rate of p38 was detected; β-actin was used as an internal. (D−F) The phosphorylation rate was measured by the expression of phosphorylated protein divided by total protein expression and adjusted by β-actin expression. All blots were repeated at least three times. The statistical data are expressed as the mean ± SE. Asterisks denote significant difference versus the PA-treated alone group (*, $p < 0.05$; **, $p < 0.01$).

DISCUSSION

Cinnamon exerts antidiabetic properties both in vitro and in vivo, and its antioxidative polyphenol components have been supposed to be the main contributor.[25,26] In a previous study, we have verified that *C. tamala* extracts exert antidiabetic effects and improve pancreas functions in a type 2 diabetic *db/db* mouse model.[17] As reported, the main components of extracts were A-type procyanidin trioligomers, including >43% CD1 and >23% CB1, one structural isomer of CD1.[17] A-type polymers were reported to reduce peroxide-induced pancreatic acinar cell injury,[27,28] generate insulin-like biological activity,[13] and improve insulin sensitivity in vivo.[29] However, as effective antioxidants[24] and the major components of antidiabetic natural products,[17] the effects of A-type polymers in *C. tamala* have not yet been

dx.doi.org/10.1021/jf500387d | J. Agric. Food Chem. 2014, 62, 5038−5045

explored on insulin-secreting β-cells. The present work focused on disclosing the mechanisms of the protective effects of CD1, one major A-type polymers in *C. tamala*. We demonstrated that CD1 could protect pancreatic β-cells from PA-induced apoptosis via attenuating oxidative stress in INS-1, MIN6 pancreatic β-cell line, and primary cultured murine islets. These findings also provide a new understanding of the mechanisms for the antidiabetic effects of procyanidin oligomers.

Many antioxidants have been reported to protect β-cells via their antioxidative activity.[30,31] Oxidative stress is involved in the pathobiology of T2D and its complications. During the development of T2D, high glucose and FFAs caused mitochondrial damage and overproduction of reactive species, such as ROS and RNS. These free radicals activate several stress-sensitive pathways including NF-κB, JNK/SAPK, and PKC, which lead to pancreatic β-cell death, insulin resistance, and impaired insulin secretion.[32] Combined with abnormal oxidation, oxidative stress leads to DNA damage, protein oxidationm and lipid peroxidation in various kinds of cells during T2D. We found that CD1 exhibited significant radical scavenging activity in INS-1 and MIN6 cells under oxidative stress condition induced by H_2O_2. Pretreatment with CD1 dose-dependently attenuated H_2O_2-induced decrease of cell viability in both INS-1 and MIN6 cells (Supporting Information Supplementary Figure 2A,B). The intracellular ROS level in each group was also detected. H_2O_2-induced ROS elevation was significantly reduced by pretreatment of CD1 in a dose-dependent manner (Supporting Information Supplementary Figure 2C,D). Therefore, CD1 might also reduce the elevated level of ROS and NO production induced by PA in β-cells.

Excessive and sustained generation of NO derived from iNOS plays a pivotal role in FFA-induced β-cell dysfunction and apoptosis.[33] Rachek et al. reported that elevated NO production induced by FFA could damage mitochondrial DNA and ultimately lead to apoptosis in INS-1 cells.[34] Meanwhile, evoked iNOS activity in pancreatic β-cells could lead to impairment of GSIS both in vivo and in vitro.[35,36] Therefore, inhibition of iNOS expression might reduce production of NO and exert a protective effect on β-cells. Hynes et al. demonstrated that inhibition of iNOS by lentiviral vector-based shRNA technology could protect β-cells from cytokine-induced apoptosis.[37] In this study, we found that CD1 could significantly suppress PA-induced ROS generation and NO production. PA-induced increase of iNOS expression level was also significantly inhibited by CD1 in both INS-1 cells and primary cultured islets. Similar results had also been confirmed on MIN6 β-cell line (Supporting Information Supplementary Figure 1C,D). Together the results suggested that the antioxidative activity might be one of the main mechanisms of the protective effect of CD1 on PA-injured β-cells.

Long-term exposure to FFAs results in increased β-oxidation and elevated reactive species levels in both islets[38] and β-cell lines.[39] Moreover, β-cell failure, including apoptosis and dysfunction, could be mediated obviously by oxidative stress in chronic exposure to elevated levels of FFAs in pancreatic islets.[40] Our experiments demonstrated that CD1 could significantly suppress PA-induced oxidative stress and subsequently reduced the apoptotic rate in PA-injured β-cells/islets. Together the results indicated that CD1 could protect pancreatic β-cells from PA-induced apoptosis.

As the compound showed great protective effect on cell viability and antiapoptosis in pancreatic β-cells cells, it was inferred that CD1 might have a protective effect on insulin secretion. In primary cultured islets, CD1 suppressed PA-induced impairment of GSIS. We speculated that the protective effect of CD1 on PA-treated islets could improve insulin secretion. Therefore, CD1 treatment may provide beneficial effects to the function of insulin secretion through its protective effect on pancreatic β-cells.

However, the underlying mechanism of the antioxidative effect of CD1 on pancreatic β-cells still needed further investigation. CD1 had been reported to act as an antioxidant with the inhibitory activity against cyclooxygenase-2,[24] and cyclooxygenase-2 could be regulated by an inflammatory-associated gene toll-like receptor-4 (TLR4).[41] Therefore, the expression of some downstream pro-inflammatory gene was detected in this study. We found that CD1 could significantly reduce PA-induced phosphorylation of NFκB and JNK. However, PA-activated p38 phosphorylation was not attenuated by CD1. Lee et al. had confirmed that JNK activation could be involved with TLR4 signaling pathway in palmitic acid-treated INS-1 cells and decrease inhibitory factor kappa B alpha (IκBα),[42] which was in accordance with our results. Therefore, the TLR4 pathway could at least associate with the protective effect of CD1 on pancreatic β-cells. In any case, further investigation on the effect mechanism of CD1 would still be necessary.

In conclusion, this study showed that CD1 protects pancreatic β-cells against PA-induced oxidative stress via its antioxidative properties. As the major component of *C. tamala*, CD1 could be the main active ingredient in *C. tamala* to possess antidiabetic activity and provide benefit for the protection of pancreatic β-cells during the development of T2D.

Japan). IR spectra were determined with a Nicolet 6700 FT-IR spectrophotometer (Madison, Wisconsin, USA). NMR spectra were obtained on Bruker Advance DRX-300, DRX-400 spectrometers (Rheinstetten, Germany) and the chemical shifts are given in δ (ppm) values with reference to TMS. The coupling constants (J values) are reported in Hz. HRMS were carried out on Waters Xevo G_2 Q-TOF mass spectrometer (Milford, Massachusetts, USA).

General Synthetic of Procedure CAPE Derivatives. *Method A for Compounds 1−4.* To a mixture of caffeic acid (1 mmol) in 10 mL anhydrous DME was added thionyl chloride (6 mmol) under nitrogen atmosphere. This mixture was heated to reflux for 12 h and then distilled under vacuum to remove the excess thionyl chloride completely. The intermediate was redissolved with 10 mL anhydrous DME, and to this solution was added alcohol (1 mmol). This mixture was heated to reflux for 4 h before evaporation. The residue was purified by column chromatography and/or recrystallization to give target compounds.

Modified Method A for Compounds 5−13. To a mixture of caffeic acid or its analogues (1 mmol) in 5−10 mL alcohol was added thionyl chloride (3−6 mmol) under nitrogen atmosphere. This mixture was heated slowly to 65 °C and stirred for 4 h. After distillation of most of alcohol under high vacuum the residue was purified by column chromatography and/or recrystallization to give target compounds.

Method B for Compounds 14 and 15. To a mixture of caffeic acid or its analogue (1 mmol), potassium carbonate (1.1 mmol) and 5 mL DMF was added benzyl bromide (1 mmol). This mixture was stirred at room temperature for 12 h. Fifteen mL water was added and the suspension was extracted with diethyl ether (10 mL × 3). The combined organic layer was washed with aqueous $NaHCO_3$ and brine, dried, evaporated and purified by recrystallization to give target compounds.

Method C for Compounds 16 and 17. A mixture of caffeic acid (1 mmol), phenethylamine/4-hydroxyphenethylamine (1 mmol), triethylamine (1.5 mmol) and 4 mL DMF were stirred at 0 °C for 10 min, to which was added a solution of BOP (1 mmol) in 4 mL DCM. After stirred for 30 min at 0 °C, the mixture was allowed to warm to room temperature and stirred for 20 h. Fifteen g crushed ice and 25 mL chloroform were added to the mixture, organic layer was separated and washed with 10% hydrochloric acid and brine, dried, evaporated and purified by column chromatography and recrystallization to give target compounds.

Method D for Compounds 18 and 19. A mixture of alcohol (10 mmol), meldrum's acid (12 mmol) and 40 mL 1, 4-dioxane was heated to reflux for 6 h before evaporation. The residue was purified by column chromatography to give the intermediate malonic acid mono ester. A mixture of malonic acid mono ester (5 mmol), 3,4-dihydroxybenzaldehyde/4-nitrobenzaldehyde (5 mmol), 5 mL pyridine and 0.5 mL piperidine was stirred for 15 h at room temperature before evaporation. The residue was redissolved with 50 mL ethyl acetate and washed with 5% hydrochloric acid, brine, dried, evaporated and purified column chromatography and recrystallization to give target compounds.

Caffeic Acid Cinnamyl Ester (1). The title compound was prepared according to method A as white powder (45 mg, 15.2% yield). mp 159−160 °C; IR (KBr) ν_{max} 3477, 3318, 1682, 1602, 1535, 1280, 1184 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.55 (1H, d, J = 16.0 Hz, H-β), 7.21−7.35 (5H, m, H-2′, 3′, 4′, 5′, 6′), 7.02 (1H, d, J = 1.2 Hz, H-2), 6.95 (1H, dd, J = 1.2, 8.0 Hz, H-6), 6.81 (1H, d, J = 8.0 Hz, H-5), 6.70 (1H, d, J = 16.0 Hz, H-γ'), 6.35 (1H, dt, J = 6.4, 16.0 Hz, H-β'), 6.31 (1H, d, J = 16.0 Hz, H-α), 4.79 (2H, d, J = 6.4 Hz, H-α'); HRESIMS $[M - H]^-$ m/z 295.0966 (Calcd for $C_{18}H_{15}O_4$, 295.0970).

Caffeic Acid Phenylpropyl Ester (2). The title compound was prepared according to method A as light yellow powder (47 mg, 15.8% yield). mp 121−123 °C; IR (KBr) ν_{max} 3491, 3338, 1683, 1603, 1535, 1278, 1183 cm^{-1}; ^1H NMR (300 MHz, DMSO-d_6) δ 9.56 (1H, s, −OH), 9.13 (1H, s, −OH), 7.45 (1H, d, J = 15.9 Hz, H-β), 7.15−7.30 (5H, m, H-2′, 3′, 4′, 5′, 6′), 7.03 (1H, d, J = 2.1 Hz, H-2), 6.98 (1H, dd, J = 2.1, 8.1 Hz, H-6), 6.75 (1H, d, J = 8.1 Hz, H-5), 6.24 (1H, d, J = 15.9 Hz, H-α), 4.09 (2H, t, J = 6.6 Hz, H-α'), 2.68 (2H, t, J = 6.6 Hz, H-γ'), 1.94 (2H, quintet, H-β'); HRESIMS $[M - H]^-$ m/z 297.1124 (Calcd for $C_{18}H_{17}O_4$, 297.1127).

Caffeic Acid 4-Hydroxyphenethyl Ester (3). The title compound was prepared according to method A as light yellow powder (60 mg, 20.0% yield). mp 153−155 °C; IR (KBr) ν_{max} 3495, 3266, 1698, 1605, 1513, 1283, 1204, 1170 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.89 (1H, d, J = 16.0 Hz, H-β), 7.46 (1H, d, J = 1.6 Hz, H-2), 7.40 (2H, d, J = 8.0 Hz, H-2′, 6′), 7.25 (2H, d, J = 8.0 Hz, H-3′, 5′), 7.16 (1H, dd, J = 1.6, 8.4 Hz, H-6), 7.00 (1H, d, J = 8.4 Hz, H-5), 6.55 (1H, d, J = 16.0 Hz, H-α), 3.87 (2H, t, J = 7.2 Hz, H-α'), 3.22 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 299.0916 (Calcd for $C_{17}H_{15}O_5$, 299.0919).

Caffeic Acid Nonyl Ester (4). The title compound was prepared according to method A as white powder (43 mg, 14.0% yield). mp 107−109 °C; IR (KBr) ν_{max} 3488, 3333, 1686, 1604, 1536, 1278, 1184 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.53 (1H, d, J = 16.0 Hz, H-β), 7.06 (1H, d, J = 2.0 Hz, H-2), 6.95 (1H, dd, J = 2.0, 8.0 Hz, H-6), 6.82 (1H, d, J = 8.0 Hz, H-5), 6.21 (1H, d, J = 16.0 Hz, H-α), 4.13 (2H, t, J = 6.8 Hz, H-1′), 1.63 (2H, m, H-2′), 1.20−1.32 (12H, m, H-3′-H-8′), 2.55 (3H, t, J = 6.8 Hz, H-9′); HRESIMS $[M - H]^-$ m/z 305.1739 (Calcd for $C_{18}H_{25}O_4$, 305.1753).

Ferulic Acid Phenethyl Ester (5). The title compound was prepared according to modified method A as light yellow gum (195 mg, 65.4% yield). IR (KBr) ν_{max} 3418, 1682, 1603, 1516, 1270, 1172 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.60 (1H, d, J = 16.0 Hz, H-β), 7.22−7.34 (5H, m, H-2′, 3′, 4′, 5′, 6′), 7.06 (1H, dd, J = 2.0, 8.4 Hz, H-6), 7.01 (1H, d, J = 2.0 Hz, H-2), 6.91 (1H, d, J = 8.4 Hz, H-5), 6.27 (1H, d, J = 16.0 Hz, H-α), 4.42 (2H, t, J = 7.2 Hz, H-α'), 3.91 (3H, s, 3−OCH_3), 3.02 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 297.1125 (Calcd for $C_{18}H_{17}O_4$, 297.1127).

Isoferulic Acid Phenethyl Ester (6). The title compound was prepared according to modified method A as white powder (202 mg, 67.7% yield). mp 79−81 °C; IR (KBr) ν_{max} 3384, 1686, 1600, 1262, 1184, 1165 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.58 (1H, d, J = 16.0 Hz, H-β), 7.22−7.34 (5H, m, H-2′, 3′, 4′, 5′, 6′), 7.13 (1H, d, J = 2.0 Hz, H-2), 7.01 (1H, dd, J = 2.0, 8.4 Hz, H-6), 6.83 (1H, d, J = 8.4 Hz, H-5), 6.27 (1H, d, J = 16.0 Hz, H-α), 4.41 (2H, t, J = 7.2 Hz, H-α'), 3.91 (3H, s, 3−OCH_3), 3.01 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 297.1120 (Calcd for $C_{18}H_{17}O_4$, 297.1127).

4-Methoxy Cinnamic Acid Phenethyl Ester (7). The title compound was prepared according to modified method A as light yellow gum (194 mg, 68.7% yield). IR (KBr) ν_{max} 2930, 1708, 1631, 1515, 1263, 1216, 1150 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.63 (1H, d, J = 16.0 Hz, H-β), 7.47 (2H, d, J = 8.8 Hz, H-2, 6), 7.24−7.32 (5H, m, H-2′, 3′, 4′, 5′, 6′), 6.90 (2H, d, J = 8.8 Hz, H-3, 5), 6.30 (1H, d, J = 16.0 Hz, H-α), 4.41 (2H, t, J = 7.2 Hz, H-α'), 3.83 (3H, s, 4−OCH_3), 3.02 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 281.1176 (Calcd for $C_{18}H_{17}O_3$, 281.1178)

3,4-Dimethoxycinnamic Acid Phenethyl Ester (8). The title compound was prepared according to modified method A as white powder (165 mg, 52.8% yield). mp 89−91 °C; IR (KBr) ν_{max} 2916, 2849, 1702, 1635, 1515, 1258, 1236, 1139 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.62 (1H, d, J = 16.0 Hz, H-β), 7.28 (5H, m, H-2′, 3′, 4′, 5′, 6′), 7.09 (1H, dd, J = 2.0, 8.4 Hz, H-6), 7.04 (1H, d, J = 2.0 Hz, H-2), 6.86 (1H, d, J = 8.4 Hz, H-5), 6.30 (1H, d, J = 16.0 Hz, H-α), 4.43 (2H, t, J = 7.2 Hz, H-α'), 3.90 (6H, s, 3, 4−OCH_3), 3.02 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 311.1300 (Calcd for $C_{19}H_{19}O_4$, 311.1283).

p-Coumaric Acid Phenethyl Ester (9). The title compound was prepared according to modified method A as white powder (157 mg, 58.5% yield). mp 90−92 °C; IR (KBr) ν_{max} 3279, 1681, 1631, 1582, 1515, 1278, 1206, 1170 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.62 (1H, d, J = 16.0 Hz, H-β), 7.39 (2H, d, J = 8.4 Hz, H-2, 6), 7.22−7.33 (5H, m, H-2′, 3′, 4′, 5′, 6′), 6.85 (2H, d, J = 8.8 Hz, H-3, 5), 6.27 (1H, d, J = 16.0 Hz, H-α), 4.42 (2H, t, J = 7.2 Hz, H-α'), 3.02 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 267.1016 (Calcd for $C_{17}H_{15}O_3$, 267.1021).

Cinnamic Acid Phenethyl Ester (10). The title compound was prepared according to modified method A as white powder (145 mg, 57.5% yield). mp 55−56 °C; IR (KBr) ν_{max} 1710, 1637, 1496, 1313,

1205, 1173 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.67 (1H, d, J = 16.0 Hz, H-β), 7.35−7.51 (5H, m, H-2, 3, 4, 5, 6), 7.21−7.33 (5H, m, H-2′, 3′, 4′, 5′, 6′), 6.42 (1H, d, J = 16.0 Hz, H-α), 4.42 (2H, t, J = 7.2 Hz, H-α'), 3.01 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 251.1067 (Calcd for $C_{17}H_{15}O_2$, 251.1072).

*Sinapic Acid Phenethyl Ester (**11**).* The title compound was prepared according to modified method A as light yellow oil (216 mg, 65.8% yield). IR (KBr) ν_{max} 3419, 1704, 1633, 1514, 1283, 1218, 1153 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.58 (1H, d, J = 16.0 Hz, H-β), 7.22−7.34 (5H, m, H-2′, 3′, 4′, 5′, 6′), 6.76 (2H, s, H-2, 6), 6.29 (1H, d, J = 16.0 Hz, H-α), 4.43 (2H, t, J = 7.2 Hz, H-α'), 3.91 (6H, s, 3, 5−OCH_3), 3.02 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 327.1228 (Calcd for $C_{19}H_{19}O_5$, 327.1232).

*Caffeic Acid 3-Bromophenethyl Ester (**12**).* The title compound was prepared according to modified method A as white powder (42 mg, 11.6% yield). mp 120−122 °C; IR (KBr) ν_{max} 3472, 3316, 1686, 1604, 1528, 1278, 1180 cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ 9.59 (1H, s), 9.12 (1H, s), 7.52 (1H, m, H-2′), 7.44 (1H, d, J = 16.0 Hz, H-β), 7.42 (1H, m, H-6′), 7.28 (2H, m, H-4′, 5′), 7.03 (1H, d, J = 2.0 Hz, H-2), 6.98 (1H, dd, J = 8.0, 2.0 Hz, H-6), 6.75 (1H, d, J = 8.0 Hz, H-5), 6.22 (1H, d, J = 16.0 Hz, H-α), 4.32 (2H, t, J = 6.8 Hz, H-α'), 2.95 (2H, t, J = 6.8 Hz, H-β'); ^{13}C NMR (100 MHz, DMSO-d_6) δ 166.4, 148.5, 145.6, 145.3, 141.1, 131.7, 130.5, 129.3, 128.1, 125.4, 121.6, 121.4, 115.7, 114.8, 113.7, 63.9, 34.0; HRESIMS $[M - H]^-$ m/z 361.0079 (Calcd for $C_{17}H_{14}O_4Br$, 361.0075).

*Caffeic Acid 2-Bromophenethyl Ester (**13**).* The title compound was prepared according to modified method A as white powder (68 mg, 18.7% yield). mp 137−139 °C; IR (KBr) ν_{max} 3465, 3301, 1694, 1607, 1529, 1280, 1188 cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ 9.59 (1H, s), 9.15 (1H, s), 7.61 (1H, dd, J = 7.6, 0.8 Hz, H-3′), 7.46 (1H, d, J = 16.0 Hz, H-β), 7.41 (1H, dd, J = 7.6, 1.6 Hz, H-6′), 7.34 (1H, dt, J = 7.6, 0.8 Hz, H-5′), 7.11 (1H, dt, J = 7.6, 1.6 Hz, H-4′), 7.04 (1H, d, J = 2.0 Hz, H-2), 6.98 (1H, dd, J = 8.0, 2.0 Hz, H-6), 6.76 (1H, d, J = 8.0 Hz, H-5), 6.22 (1H, d, J = 16.0 Hz, H-α), 4.34 (2H, t, J = 6.8 Hz, H-α'), 3.09 (2H, t, J = 6.8 Hz, H-β'); ^{13}C NMR (100 MHz, DMSO-d_6) δ 166.4, 148.5, 145.6, 145.3, 137.2, 132.6, 131.4, 128.8, 127.9, 125.4, 124.0, 121.4, 115.7, 114.8, 113.7, 62.7, 34.7; HRESIMS $[M - H]^-$ m/z 361.0073 (Calcd for $C_{17}H_{14}O_4Br$, 361.0075).

*Caffeic Acid Benzyl Ester (**14**).* The title compound was prepared according to method B as white powder (148 mg, 54.8% yield). mp 151−153 °C; IR (KBr) ν_{max} 3466, 3327, 1689, 1601, 1535, 1277, 1177 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.52 (1H, d, J = 16.0 Hz, H-β), 7.26−7.34 (5H, m, H-2′, 3′, 4′, 5′, 6′), 6.97 (1H, d, J = 1.2 Hz, H-2), 6.86 (1H, dd, J = 1.2, 8.0 Hz, H-6), 6.74 (1H, d, J = 8.0 Hz, H-5), 6.20 (1H, d, J = 16.0 Hz, H-α), 5.15 (2H, s, H-α'); HRESIMS $[M - H]^-$ m/z 269.0810 (Calcd for $C_{16}H_{13}O_4$, 269.0814).

*p-Coumaric Acid Benzyl Ester (**15**).* The title compound was prepared according to method B as white powder (213 mg, 83.8% yield). mp 90−92 °C; IR (KBr) ν_{max} 3401, 1691, 1599, 1517, 1279, 1203, 1170 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.60 (1H, d, J = 16.0 Hz, H-β), 7.34 (2H, d, J = 8.4 Hz, H-2, 6), 7.26−7.33 (5H, m, H-2′, 3′, 4′, 5′, 6′), 6.76 (2H, d, J = 8.4 Hz, H-3, 5), 6.27 (1H, d, J = 16.0 Hz, H-α), 5.18 (2H, s, H-α'); HRESIMS $[M - H]^-$ m/z 253.0860 (Calcd for $C_{16}H_{13}O_3$, 253.0865).

*Caffeic Acid Phenylacetamide (**16**).* The title compound was prepared according to method C as light yellow powder (81 mg, 28.6% yield). mp 153−155 °C; IR (KBr) ν_{max} 3488, 3346, 1649, 1602, 1551, 1326, 1287, 1189 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.34 (1H, d, J = 16.0 Hz, H-β), 7.13−7.24 (5H, m, H-2′, 3′, 4′, 5′, 6′), 6.93 (1H, d, J = 1.6 Hz, H-2), 6.82 (1H, dd, J = 1.6, 8.4 Hz, H-6), 6.71 (1H, d, J = 8.4 Hz, H-5), 6.16 (1H, d, J = 16.0 Hz, H-α), 3.48 (2H, t, J = 7.2 Hz, H-α'), 2.78 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 282.1125 (Calcd for $C_{17}H_{16}NO_3$, 282.1130).

*Caffeic Acid 4-Hydroxyphenylacetamide (**17**).* The title compound was prepared according to method C as light yellow powder (35 mg, 11.7% yield). mp 211−212 °C; IR (KBr) ν_{max} 3369, 1646, 1604, 1516, 1241 cm^{-1}; ^1H NMR (400 MHz, CD_3OD) δ 7.37 (1H, d, J = 15.6 Hz, H-β), 7.05 (2H, d, J = 8.4 Hz, H-2′, 6′), 6.99 (1H, d, J = 2.0 Hz, H-2), 6.89 (1H, dd, J = 2.0, 8.4 Hz, H-6), 6.75 (1H, d, J = 8.4 Hz, H-5), 6.70 (2H, d, J = 8.4 Hz, H-3′, 5′), 6.33 (1H, d, J = 15.6 Hz, H-α), 3.45 (2H, t, J = 7.2 Hz, H-α'), 2.74 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 298.1081 (Calcd for $C_{17}H_{16}NO_4$, 298.1079).

*Caffeic Acid 3,4-Dihydroxyphenethyl Ester (**18**).* The title compound was prepared according to method D as a white powder (648 mg, 41.0% yield for Knoevenagel condensation). mp 118−120 °C; IR (KBr) ν_{max} 3339, 1680, 1600, 1525, 1278, 1186 cm^{-1}; ^1H NMR (400 MHz, CD_3OD) δ 7.52 (1H, d, J = 16.0 Hz, H-β), 7.03 (1H, d, J = 2.0 Hz, H-2), 6.94 (1H, dd, J = 2.0, 8.0 Hz, H-6), 6.78 (1H, d, J = 8.0 Hz, H-5), 6.70 (1H, d, J = 2.0 Hz, H-2′), 6.70 (1H, d, J = 8.0 Hz, H-5′), 6.58 (1H, dd, J = 2.0, 8.0 Hz, H-6′), 4.29 (2H, t, J = 7.2 Hz, H-α'), 2.84 (2H, t, J = 7.2 Hz, H-β'); HRESIMS $[M - H]^-$ m/z 315.0862 (Calcd for $C_{17}H_{15}O_6$, 315.0869).

*Caffeic Acid 4-Nitrophenethyl Ester (**19**).* The title compound was prepared according to method D as a light yellow powder (305 mg, 18.5% yield for Knoevenagel condensation). mp 172−174 °C; IR (KBr) ν_{max} 3418, 1691, 1596, 1507, 1340, 1277, 1167 cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ 9.55 (1H, s), 9.11 (1H, s), 8.17 (2H, d, J = 8.8 Hz, H-2′, 6′), 7.58 (2H, d, J = 8.8 Hz, H-3′, 5′), 7.44 (1H, d, J = 16.0 Hz, H-β), 7.03 (1H, d, J = 2.0 Hz, H-2), 6.98 (1H, dd, J = 2.0, 8.0 Hz, H-6), 6.76 (1H, d, J = 8.0 Hz, H-5), 6.21 (1H, d, J = 16.0 Hz, H-α), 4.39 (2H, t, J = 6.4 Hz, H-α'), 3.11 (2H, t, J = 6.4 Hz, H-β'); ^{13}C NMR (100 MHz, DMSO-d_6) δ 166.4, 148.5, 146.7, 146.3, 145.6, 145.4, 130.2, 125.4, 123.4, 121.4, 115.7, 114.9, 113.6, 63.5, 34.2; HRESIMS $[M - H]^-$ m/z 328.0823 (Calcd for $C_{17}H_{14}NO_6$, 328.0821).

*Caffeic Acid 4-Aminophenethyl Ester (**20**).* A mixture of caffeic acid 4-nitrophenethyl ester (60 mg, 0.091 mmol), stannic chloride dihydrate (123 mg, 0.55 mmol) and 5 mL of ethanol was heated to reflux for 10 h before being cooled to room temperature. Ten milliliters of saturated Na_2CO_3 was added, and the suspension was extracted with ethyl acetate (10 mL × 3). The combined organic layer was dried, evaporated and purified by column chromatography to give the title compound as a light yellow powder (34 mg, 62.3% yield). mp 173−175 °C; IR (KBr) ν_{max} 3432, 1692, 1598, 1515, 1280, 1175 cm^{-1}; ^1H NMR (400 MHz, DMSO-d_6) δ 9.57 (1H, s), 9.12 (1H, s), 7.45 (1H, d, J = 16.0 Hz, H-β), 7.04 (1H, d, J = 2.0 Hz, H-2), 6.99 (1H, dd, J = 2.0, 8.0 Hz, H-6), 6.91 (2H, d, J = 8.4 Hz, H-2′, 6′), 6.76 (1H, d, J = 8.0 Hz, H-5), 6.50 (2H, d, J = 8.4 Hz, H-3′, 5′), 6.23 (1H, d, J = 16.0 Hz, H-α), 4.20 (2H, t, J = 7.2 Hz, H-α'), 2.75 (2H, t, J = 7.2 Hz, H-β'); ^{13}C NMR (100 MHz, DMSO-d_6) δ 167.0, 148.9, 147.5, 146.0, 145.5, 129.7, 126.0, 125.1, 121.8, 116.2, 115.3, 114.5, 65.4, 34.3; HRESIMS $[M - H]^-$ m/z 298.1075 (Calcd for $C_{17}H_{16}NO_4$, 298.1079).

*3,4-Dihydroxyphenyl Propionic Acid Phenethyl Ester (**21**).* To a solution of caffeic acid phenethyl ester (50 mg, 0.176 mmol) in 10 mL of ethyl acetate was added 10% Pd/C (5 mg) under nitrogen atmosphere. The reaction flask was vacuumed and backfilled with hydrogen and stirred at room temperature for 12 h. The mixture was filtered and evaporated to give the titled compound as yellow gum (50 mg, 99.4% yield). IR (KBr) ν_{max} 3400, 1709, 1605, 1519, 1352, 1282, 1192 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ 7.18−7.30 (5H, m, H-2′, 3′, 4′, 5′, 6′), 6.74 (1H, d, J = 8.0 Hz, H-5), 6.63 (1H, d, J = 2.0 Hz, H-2), 6.57 (1H, dd, J = 2.0, 8.0 Hz, H-6), 4.28 (2H, t, J = 7.2 Hz, H-α'), 2.91 (2H, t, J = 7.2 Hz, H-β'), 2.79 (2H, t, J = 7.8 Hz, H-α), 2.55 (2H, t, J = 7.8 Hz, H-β); HRESIMS $[M - H]^-$ m/z 285.1120 (Calcd for $C_{17}H_{17}O_4$, 285.1127).

*Cytotoxicities of CAPE and Its Derivatives **1**-**21** in PC12 Cells.* Differentiated PC12 cells were maintained in DMEM medium supplemented with 1% L-glutamine and 10% fetal bovine serum at 37 °C under a humidified 5% CO_2 atmosphere. Each test compound with appropriate concentration was dissolved in DMSO and diluted with serum-free media. Before treatment, cells were seeded on a 96 well plate at the density of 5 × 10^3 cells/well and cultured for 24 h. Then the medium was changed and cells were treated with CAPE and its derivatives at 4 and 40 nM for 24 h, respectively. Then, 20 μL of MTT solution (final concentration, 0.5 mg/mL) were added to each well, and cells were incubated for 4 h. The resultant formazan product was dissolved by the addition of 150 μL of DMSO. The absorbance was measured at the wavelength of 570 nm using a Thermo Scientific

[a]Reagents and conditions: Method A: (1) caffeic acid, $SOCl_2$, DME, reflux, 12 h, (2) acyl chloride of caffeic acid, alcohol, DME, reflux, 4 h; Modified method A: caffeic acid or its analogues, excess alcohol, $SOCl_2$, 65 °C, 4 h. Method B: caffeic acid or its analogues, benzyl bromide, K_2CO_3, DMF, RT, 12 h. Method C: caffeic acid, phenethylamines/4-hydroxyphenethylamine, triethylamine, BOP, DMF/DCM, 0 °C to RT, 20 h. Method D: (1) alcohol, meldrum's acid, 1,4-dioxane, reflux, 6 h; (2) malonic acid mono ester, 3,4-dihydroxybenzaldehyde/4-nitrobenzaldehyde, pyridine, piperidine, RT, 15 h. RT stands for ambient temperature.

Multiskan MK3 microplate reader (Waltham, MA, USA). Results were expressed as percentage of cell viability (%), assuming control cells as 100%. The cytotoxicities of CAPE and its derivatives in undifferentiated PC12 cells at 0.5, 5, 10, and 20 nM, respectively, were performed following a similar procedure, except that the culture media was changed to DMEM medium supplemented with 1% L-glutamine, 10% horse serum and 5% fetal bovine serum.

Cytoprotective Effects of CAPE and Its Derivatives 1–21 in PC12 Cells. Before treatment, differentiated PC12 cells were seeded on a 96 well plate at the density of 1×10^4 cells/well and cultured for 24 h. The medium was changed, and cells were pretreated for 6 h with 4 nM or 40 nM CAPE and its derivatives, respectively; then the cells were exposed to 200 μM H_2O_2 for another 24 h. Cell viability was determined using the MTT method as described above.

Neuritogenic Effects of CAPE and Its Derivatives 1–21 in PC12 Cells. Undifferentiated PC12 cells (5×10^4 cells/well) were seeded on poly-L-lysine-coated 12-well plates. NGF (Sigma-Aldrich, St. Louis, MO, USA) was dissolved in sterilized water and then diluted with serum-free media to the final concentration of 50 ng/mL. After 72 h of incubation with NGF, CAPE and its derivatives (0.5 nM or 10 nM), respectively, the neurite outgrowth of cells was observed by inverted microscope (OLYPUS IX71, Tokyo, Japan). Cells with one or more neurites whose lengths were greater than or equal to the length of one cell body were scored as positive. The number of neurite-bearing cells was counted in five randomly selected microscopic fields and expressed as a percentage of the total cells in the field. The neurite length was determined as the mean value for all identified neurite-bearing cells in a field (ImageJ software). At least 100 cells were selected for calculating the neurite length. Each experiment was conducted in triplicate.

Statistical Analysis. Data were reported as mean ± SD for triplicate determinations. Significant differences ($p < 0.05$ or $p < 0.01$) between the means of control and different treatment groups were analyzed by Dunnett's test using SPSS for Windows (version rel. 10.0.5, 1999, SPSS Inc., Chicago, IL).

RESULTS AND DISCUSSION

Synthesis of Caffeic Acid Phenethyl Ester Derivatives. Previous studies revealed that bioactivities of CAPE derivatives are mainly affected by the number of hydroxyl groups,[22,23] the methylation degree of the hydroxyl group,[24] the length of the ester moiety,[19] and the conjugate double bonds[25] in CAPE.

dx.doi.org/10.1021/jf500464k | J. Agric. Food Chem. 2014, 62, 5046–5053

These factors were the basis for designing the targeted compounds for the present study. In addition, selected electron-donating and -withdrawing groups were substituted on the benzene ring of the alcoholic moiety to alter the electronic density or provide additional binding sites.

As shown in Scheme 1, twenty-one CAPE derivatives (compounds **1**−**21**) were prepared, among which compounds **12**, **13** and **20** were first synthesized. Diverse methods were used for synthesis of these derivatives. We obtained caffeic acid esters (method A, compounds **1**−**4**) in 1,2-dichloroethane, which results in fewer side products compared to the frequently used 1,4-dioxane. Moreover, replacement of solvent with excess liquid alcohol lead to better yields of 50−70% in many cases (compounds **5**−**13**). Compounds **14** and **15** were conveniently obtained by alkylation (method B) with benzyl bromide in good yields and purities. Amide derivatives (compounds **16** and **17**) were synthesized by using a condensing agent such as BOP (method C). Some caffeate derivatives (compounds **18** and **19**) hardly unavailable by other methods were prepared by Knoevenagel condensation (method D). Reduction of compound **19** in the presence of stannous chloride gave compound **20** in high yield, and hydrogenation of CAPE afforded compound **21**.

Cytotoxicity of Caffeic Acid Phenethyl Ester Derivatives in PC12 Cells. CAPE and its derivatives were initially assayed for cytotoxic effects in differentiated PC12 cells (4 and 40 nM) and undifferentiated PC12 cells (0.5, 5, 10, and 20 nM), respectively. Differentiated and undifferentiated PC12 cells were incubated with these compounds for 24 h, respectively, and the extent of cell viability was determined using MTT assay. Cell viability less than 90% of control was considered toxic. The results demonstrated that CAPE and its derivatives were nontoxic in differentiated PC12 cells at 4 and 40 nM, respectively. While CAPE and its derivatives showed no toxicity at any tested concentrations except that compounds **4**, **12** and **13** have cytotoxicities at concentrations from 5 nM to 20 nM.

Caffeic Acid Phenethyl Ester Derivatives Protect PC12 Cells against H_2O_2-Induced Oxidative Stress. Reactive oxygen species (ROS) have been involved in the pathogenesis of many neurodegenerative diseases.[26] Hydroxyl radical is the most dangerous ROS and can be generated from H_2O_2 in the presence of transition metals including Fe and Cu. Hydroxyl radical can react rapidly with all types of intracellular biomolecules including lipids, DNA, and protein, eventually leading to cell death. Differentiated PC12 cells were reported to be more sensitive to oxidant stimulus than undifferentiated cells,[27] and be better for cytoprotective study. Thus, the cytoprotective activities of CAPE derivatives against H_2O_2-induced oxidative stress were evaluated on differentiated PC12 cells in the present study.

At the concentrations of 4 nM and 40 nM, all CAPE derivatives did not affect cell survival. Among the tested samples, 4 nM compounds **1** and **20** significantly increased the cell viability to 87.5% and 89.3%, respectively (Figure 1). Their cytoprotective activities were much better than those of the parent compound CAPE under the same concentrations. Compounds **3**, **4**, **12**, **13**, **15**, **16** and **19** showed similar protective capabilities to CAPE within the range of 62.9−81.1% at 4 nM, while compounds **1**−**4**, **6**, **7**, **9**, **10**, **12**, **13**, **16**, **19**, and **20** possessed equivalent protective effects as CAPE within the range 61.9−93.9% at 40 nM (Figure 1). Other CAPE derivatives demonstrated poorer activities against H_2O_2-indued cytotoxicity (data not shown).

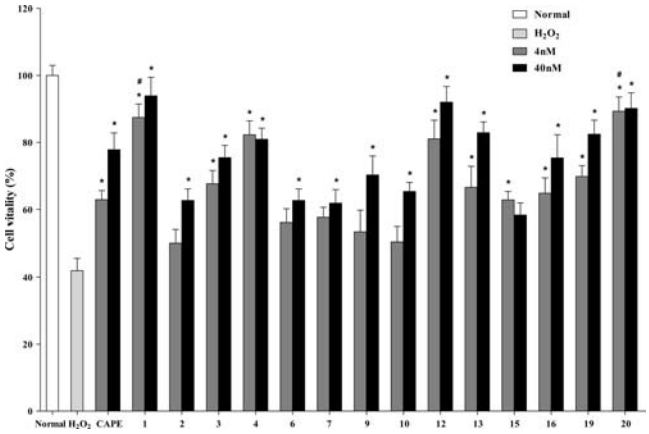

Figure 1. Cytoprotective effects of CAPE and selected CAPE derivatives in PC12 cells under H_2O_2-induced oxidative stress. Differentiated PC12 cells were treated with 4 nM, 40 nM CAPE and its derivatives for 6 h, respectively, and then the cells were exposed to 200 μM H_2O_2 for another 24 h. Cell viability was determined using the MTT method. The viability of normal cells was defined as 100%. Data are shown as mean ± SD (n = 3). (*) $p < 0.05$ compared to H_2O_2-treated group; (#) $p < 0.05$ compared to 4 nM CAPE group.

It is noteworthy that introduction of an amino group at C-4′ of the phenethyl ethanol moiety in CAPE could result in a more potent compound. Furthermore, a substitution of phenethyl ethanol with a cinnamyl group could more effectively suppress the toxicity induced by hydrogen peroxide. Our study also showed that the catechol group was not the crucial factor for the protective activities of CAPE derivatives on PC12 cells because compounds **14**, **17**, **18**, and **21** were inactive. Unexpectedly, caffeic acid 4-hydroxyphenethyl ester (**17**) and caffeic acid 3,4-dihydroxyphenethyl ester (**18**) poorly suppressed H_2O_2-induced cytotoxicity in PC12 cells. This phenomenon may be explained by their high hydrophilicities for additional phenolic hydroxyl on the phenethyl ethanol group, resulting in a poor permeability across the cellular membrane.

A series of catechol ring-fluorinated derivatives of CAPE and caffeic acid phenethyl amide (CAPA) were synthesized, respectively, and their cytoprotective effects were evaluated against menadione or H_2O_2-induced cytotoxicity in human umbilical vein endothelial cells (HUVEC).[24,28] One fluorinated derivative of CAPE and three fluorinated analogues of CAPA were found to possess similar cytoprotective activities with their parent compounds. Our results were well in accordance with these previous studies that CAPE derivatives could be considered as a new class of cytoprotective agents.

Caffeic Acid Phenethyl Ester Derivatives Induce Neurite Outgrowth of PC12 Cells. Nerve growth factor (NGF), showing benefits on the growth, differentiation and survival of neuronal cells, was expected to be a promising agent for the treatment of neurodegenerative diseases.[29] But the disadvantages of NGF such as inability to cross the blood−brain barrier and poor stability *in vivo*, drastically limited its application. As a result, discovery of small molecules from natural sources or their derivatives having neuritogenic ability is an alternative approach to prevent neurodegenerative diseases.[30,31]

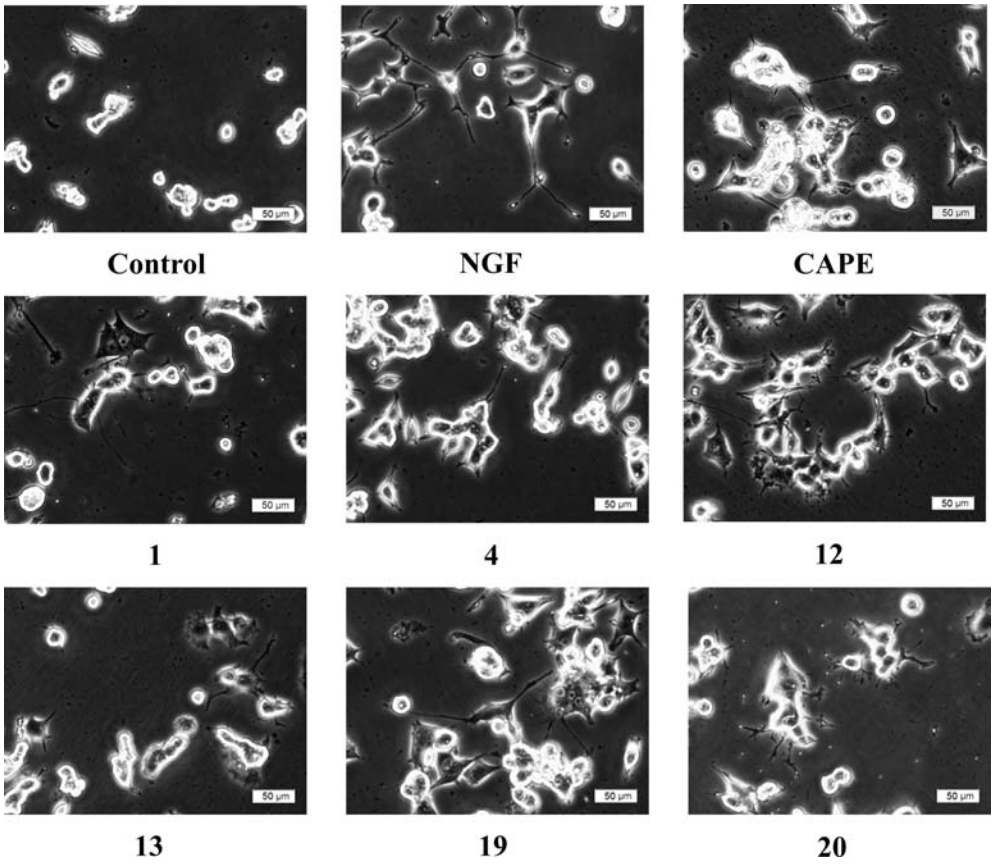

Figure 2. Morphology of PC12 cells treated with CAPE and its derivatives. Undifferentiated PC12 cells were seeded on poly-L-lysine-coated 12 well plates in DMEM medium (1% L-glutamine, 10% horse serum and 5% fetal bovine serum) for 24 h prior to treatment with NGF (50 ng/mL), CAPE (10 nM), and compounds **1** (0.5 nM), **4** (0.5 nM), **12** (0.5 nM), **13** (0.5 nM), **19** (10 nM), and **20** (10 nM) for an additional 72 h. Cell morphology was observed using inverted microscopy.

Undifferentiated PC12 cells are a useful model for the study of neuronal development *in vitro*, and they can be induced to differentiate into sympathetic-like neurons after exposure to NGF. The effects of CAPE derivatives **1**−**21** on the neurite outgrowth of undifferentiated PC12 cells were evaluated by morphological observations and a quantitative analysis of neurite-bearing cells and neurite length. Among the twenty-one CAPE derivatives, compounds **1**, **4**, **12** and **13** showed potential neuritogenic activities at 0.5 nM, while compounds **19** and **20** induced neurite outgrowth at 10 nM (Figure 2). As shown in Figure 3A, compounds **1**, **4**, **13**, **19** and **20** slightly increased the percent of neurite-bearing cells (<20%) and compound **12** modestly promoted the growth (>20%). The percent of neurite-bearing cells in groups treated with compounds **1**, **4**, **12**, **13**, **19** and **20** was significantly higher than the control. The average of neurite length for PC12 cells treated with compounds **1**, **4**, **12**, **13**, **19** and **20** was in the range of 25.1−37.0 μm, which was significantly higher than the control (18.4 μm) (Figure 3B). Specifically, 0.5 nM compound **12** markedly increased both the percentage of neurite bearing cells (21.5%) and the mean neurite length in those cells (37.0 μm) as compared with those in 10 nM CAPE (15.8% in numbers and 32.2 μm in length). Compounds **19** and **20** possessed similar neuritogenic activities as CAPE at 10 nM. These data suggested that the phenethyl alcohol group and its substitution were critical for maintaining or enhancing the neuritogenic activity of CAPE derivatives. Additional data are required for further structure−activity relationship analysis.

By comparison with the data from the literature,[30,31] the effective concentration of compounds **1**, **4**, **12** and **13** was much lower than that of natural products showing neuritogenic potential, and was comparable with that of tripchlorolide (10^{-10} M),[32] sargaquinoic acid (1.25−100 ng)[33] and catalpol (0.1−1 μg/mL),[34] geniposide (0.1−10 μg/mL),[34] and gardenoside (0.1−10 μg/mL).[34] Compounds **12** and **13** showed cytotoxicity against PC12 cells at 5 nM, which may be originated from the substitution of bromine atom on the aromatic ring. The cytotoxicity might be alleviated by the replacement of other halogen atoms such as fluorine (F) and chlorine (Cl) on the same position. Interestingly, we found that some compounds with significant cytoprotective activities also showed simulative effects on the neurite outgrowth of PC12 cells. These results indicated that the CAPE derivatives were promising candidates for reducing the risk of neurodegenerative diseases. To the best of our knowledge, this is the first report on neuritogenic activities of CAPE derivatives.

In conclusion, twenty-one CAPE derivatives with diverse substitution or carbon skeleton were synthesized. Among them, compounds **1** and **20** significantly protected the PC12 cells against H_2O_2-induced cytotoxicity. Meanwhile, compounds **1**, **4**, **12**, **13**, **19** and **20** remarkably induced the neurite outgrowth. Our study suggested that the presence of the caffeic acid group may be important for keeping the cytoprotective and neuritogenic activities, and the alcohol group and its substitution majorly affected the activities of CAPE derivatives. The results might promote the understanding of the health

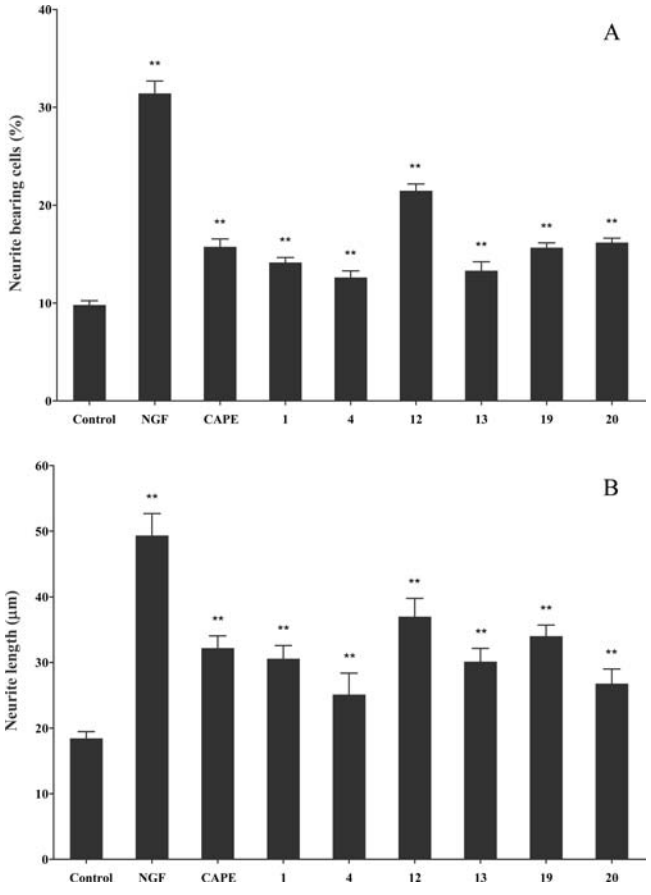

Figure 3. Effects of CAPE and its derivatives on neurite outgrowth in PC12 cells. Undifferentiated PC12 cells were treated with NGF (50 ng/mL), CAPE (10 nM), compounds **1** (0.5 nM), **4** (0.5 nM), **12** (0.5 nM), **13** (0.5 nM), **19** (10 nM) and **20** (10 nM) for 72 h to evaluate their neuritogenic effects, respectively. (A) Neurite bearing cells were counted under inverted microscopy in five random fields. (B) The average of neurite length for all identified neurite bearing cells was analyzed by ImageJ software. At least 100 cells were selected for calculating the neurite length. Data are expressed as mean ± SE (n = 3). (**) $p < 0.01$ represents significant differences compared with that of control.

benefits of CAPE and its derivatives, and may lead to the development of the functional food ingredients for the prevention of neurodegenerative diseases.

benefits in antiaging, as well as enhancements in vision and liver and kidney functions.[16,17] In recent years, goji has become increasingly popular in Europe and North America as a "superfruit" and botanical dietary supplement. The in vivo inhibitory activity of powdered *L. barbarum* (wolfberry) fruits when evaluated in an *N*-nitrosomethylbenzylamine-induced esophageal cancer model was reported recently in rats.[18] Other recent studies have indicated that goji berry extracts and *L. barbarum* polysaccharides possess a range of biological effects, including antiaging, antioxidant, antitumor, immunomodulatory, and cytoprotective activities.[17,19−21] The published chemical constituents of goji have been thoroughly reviewed, with the occurrence of pyrrole alkaloids well established.[16]

Due to the unexpected presence of the pyrrole alkaloids isolated, **1**−**4**, and their structural similarity to constituents found in goji berries,[12,13] as well as the recent report of contamination in commercial African mango samples,[9] the identity of the source material investigated came into question. The present study includes the bioactivity-guided isolation, identification, and biological evaluation of compounds **1**−**8** in addition to comparison of the commercial product with authentic African mango seeds and *L. barbarum* samples by chemotaxonomy using LC-MS and ^{1}H NMR fingerprinting as well as microscopic analysis.

MATERIALS AND METHODS

Instrumentation for Compound Isolation and Characterization. Optical rotations were measured using a PerkinElmer 343 automatic polarimeter (PerkinElmer, Waltham, MA, USA). UV spectra were collected on a Hitachi U-2910 spectrophotometer (Hitachi, Tokyo, Japan). IR spectra were obtained with a Nicolet 6700 FT-IR spectrometer (Thermo Scientific, Waltham, MA, USA). NMR spectroscopic data were recorded at room temperature on a Bruker Avance DRX-400 MHz spectrometer (Bruker, Billerica, MA, USA) using standard Bruker pulse sequences. High-resolution electrospray ionization mass spectra (HRESIMS) were obtained on a Micromass Q-Tof II (Micromass, Wythenshawe, UK) mass spectrometer operated in the positive-ion mode, with sodium iodide being used for mass calibration. Column chromatography was performed with Sephadex LH-20 (Supelco, Bellefonte, PA, USA) and 65 × 250 or 230 × 400 mesh silica gel (Sorbent Technologies, Atlanta, GA, USA). Analytical thin-layer chromatography (TLC) was conducted on precoated 250 μm thickness Partisil Si gel 60F_{254} glass plates. A 150 mm × 19 mm i.d., 5 μm, XBridge PrepC_{18} column with a 10 mm × 19 mm i.d. guard column of the same material (Waters, Milford, MA, USA) was used for semipreparative HPLC, along with a Hitachi system composed of an L-2130 prep pump, an L-2200 autosampler, and an L-2450 diode array detector (Hitachi, Tokyo, Japan).

Chemicals. All solvents used for chromatographic separations were purchased from Fisher Scientific (Fair Lawn, NJ, USA). 2′,7′-Dichlorodihydrofluorescein diacetate (H_2DCF-DA), esterase, ferrous sulfate ($FeSO_4$), hydrogen peroxide (H_2O_2), quercetin, dimethyl sulfoxide (DMSO), digitonin, EDTA, Trizma base, Tween 20, flavin adenine dinucleotide phosphate (FAD), glucose-6-phosphate (G-6-P), nicotinamide adenine dinucleotide phosphate (NADP), glucose-6-phosphate dehydrogenase (G-6-P-D), menadione, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), bovine serum albumin (BSA), L-sulforaphane, and deuterated NMR solvents were purchased from Sigma-Aldrich (St. Louis, MO, USA). Cell culture media and supplements were obtained from Life Technologies, Inc. (Grand Island, NY, USA). Gallic acid, methyl gallate, and ellagic acid that served as standards for HPLC-PDA analysis were authentic samples isolated in previous studies and stored in a compound library at The Ohio State University.

Plant Material. The commercial sample labeled as powdered seeds of African mango (*I. gabonensis*), used for isolation, was obtained by Nature's Sunshine Products, Inc., from a manufacturer in the People's Republic of China. A representative sample (code OSUADK-CCP0024) was deposited in the Division of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, The Ohio State University. An authentic sample of African mango seed powder, collected in Nigeria and imported by Nutralliance (Yorba Linda, CA, USA), was purchased by Nature's Sunshine Products, Inc. (code OSUADK-CCP0025; same repository). Three samples of authentic goji berries were obtained, two from the Ningxia province of People's Republic of China, by Nature's Sunshine, Inc., and another directly from a drug store in Chengdu, Sichuan, People's Republic of China (codes OSUADK-CCP0011, OSUADK-CCP0015, and OSUADK-CCP0026, respectively; same repository). The seeds of the last-mentioned product were separated manually from the fruit pulp. These five samples (OSUADK-CCP0024, OSUADK-CCP0026, OSUADK-CCP0015, OSUADK-CCP0011, and OSUADK-CCP0025) are referred to as products A−E, respectively, henceforth in this paper.

Extraction and Isolation. The commercial sample labeled as the powdered seeds of African mango (product A, 5 kg) was extracted by maceration with MeOH (3 × 10 L) at room temperature, for 3 days each. After filtration and evaporation of the solvent under reduced pressure, the combined crude methanol extract (ca. 1000 g) was suspended in H_2O (1 L) and then partitioned in turn with hexanes (3 × 1 L), $CHCl_3$ (3 × 1 L), EtOAc (3 × 1 L), and *n*-BuOH (3 × 1 L) to afford dried hexanes (40.1 g), $CHCl_3$ (5.0 g), EtOAc (6.5 g), *n*-BuOH (166.0 g), and H_2O-soluble (ca. 800 g) extracts. The $CHCl_3$-soluble extract showed activities in both hydroxyl radical-scavenging (ED_{50} 6.3 μg/mL) and QR induction (CD 12.4 μg/mL) assays and hence was selected for further fractionation. The $CHCl_3$-soluble extract was subjected initially to chromatography over a silica gel column, eluted with $CHCl_3$/MeOH (50:1 to pure MeOH, stepwise), to afford 12 fractions (fractions F01−F12). Fractions F01−F03 showed activity in either the hydroxyl radical-scavenging assay or the QR induction assay and were chosen for further purification.

Fraction F01 (ca. 890 mg) was chromatographed over an open C_{18} reversed-phase column, eluted with MeOH/H_2O (5:95 to pure MeOH, stepwise) to afford eight subfractions. Subfraction F0102 (ca. 400 mg, eluted by MeOH/H_2O 20:80) was subjected to passage over a Sephadex LH-20 column with MeOH/H_2O (20:80 to pure MeOH, stepwise) as the eluting solvent system to yield compound **8** (eluted by MeOH/H_2O 50:50; 3.0 mg) and a further subfraction F010211 (ca. 65 mg). Subfraction F010211 was separated by HPLC using a 150 mm × 19 mm i.d., 5 μm, XBridge PrepC_{18} column with a 10 mm × 19 mm i.d. guard column of the same material (Waters) and with CH_3CN/H_2O by isocratic elution (3:97; 8 mL/min) to afford compounds **5** (t_R 68.6 min; 5.7 mg) and **6** (t_R 55.0 min; 0.8 mg) and a further subfraction, F01021103 (ca. 40 mg, eluted with pure CH_3CN). F01021103 was purified further by HPLC on the same column with CH_3CN/H_2O (0.025% NH_4OH) isocratic elution (3:97; 8 mL/min) to obtain compound **2** (t_R 12.3 min; 4.5 mg).

Fractions F02 (ca. 180 mg) and F03 (ca. 120 mg) were subjected separately to Sephadex LH-20 column chromatography, eluted by MeOH/H_2O (50:50, 75:25, and pure MeOH) to remove pigments and afforded several subfractions. Subfraction F0203 (ca. 100 mg) was purified further by HPLC on the same XBridge PrepC_{18} column as above, by a gradient elution (A, CH_3CN; B, H_2O, 3−15% A over 70 min, 15−100% A from 70 to 85 min; 8 mL/min), to render the purification of compounds **1** (t_R 49.5 min; 4.8 mg), **3** (t_R 46.7 min; 1.3 mg), and **7** (t_R 16.5 min; 20.0 mg). Subfraction F0303 (ca. 80 mg) was also purified by HPLC on the same XBridge PrepC_{18} column, eluted by a CH_3CN/H_2O gradient (A, CH_3CN; B, H_2O, 3−15% A over 70 min, 15−100% A from 70 to 85 min; 8 mL/min), to yield compound **4** (t_R 22.7 min; 6.8 mg).

Methyl 2-[2-formyl-5-(hydroxymethyl)-1*H*-pyrrol-1-yl]-propanoate, 1, was isolated (ca. 0.0001% of dry weight) as a colorless resin: $[\alpha]^{20}_D$ +28.0 (*c* 0.1, MeOH); UV (MeOH) λ_{max} (log ε) 291 (4.09) nm; IR (film) ν_{max} 3424, 3120, 2946, 2850, 2803, 2727, 1749, 1655 cm^{-1}; ^{1}H NMR (400 MHz, CD_3OD) δ 9.31 (1H, s, CHO), 7.07 (1H, d, J = 4.0 Hz, H-3), 6.28 (1H, d, J = 4.0 Hz, H-4), 5.43 (1H, q, J = 7.0 Hz, H-1′), 4.63 (2H, ABq, $\Delta\nu$ = 8.1 Hz, J = 13.9 Hz, H-6), 3.67 (3H, s, OCH_3), 1.67 (3H, d, J = 7.0 Hz, CH_3); ^{13}C NMR (100 MHz,

CD_3OD) δ 180.5 (CHO), 172.5 (COO), 144.6 (C-5), 133.4 (C-2), 127.4 (C-3), 111.4 (C-4), 56.6 (C-6), 55.8 (C-1′), 52.8 (OCH_3), 18.0 (CH_3); HRESIMS m/z 234.0733 $[M + Na]^+$ (calcd for $C_{10}H_{13}NO_4Na$, 234.0742).

Evaluation of Hydroxyl Radical-Scavenging Activity. Hydroxyl radical-scavenging activity was tested according to the method previously reported.[22,23]

Evaluation of Quinone Reductase-Inducing Activity. The in vitro QR-inducing activity of the extracts, fractions, and pure isolates was assayed according to a previously published method.[24,25]

Microscopic Examination Procedure. The clean samples of products B−D were pulverized and passed through a no. 4 sieve to obtain fine granules. Products A and E were obtained as powders and thus passed through the sieve directly. The powdered materials of products A−E were each placed on a slide and stirred with a fine-pointed needle to distribute the powders evenly, followed by the application of 2 drops of clearing agent, Visikol (Phytosys LLC, New Brunswick, NJ, USA), and gentle heat until air bubbles moved to the edge of the slide. Two drops of diluted glycerin and a coverslip were added to the slide, followed by immediate observation under a Nikon Eclipse TE300 optical microscope (Nikon, Tokyo, Japan), along with an A01F881036 camera module (Roper Scientific, Trenton, NJ, USA) for digital imaging of the microscopic structures observed.

Sample Preparation and HPLC-PDA, LC-IT-MS, and ^{1}H NMR Fingerprinting Analysis. Each sample (3 g) was extracted with 10 mL of methanol by sonication at room temperature for 30 min. The methanol extracts were dried in vacuo (40 °C), followed by another ultrasonic extraction with 10 mL of chloroform at room temperature for 30 min, to obtain a chloroform-soluble extract of each sample, which was then dried in vacuo at 40 °C and stored at −20 °C before analysis. All analyses were completed within 24 h of extraction.

The HPLC-PDA analysis was performed using a 150 mm × 4.6 mm i.d., 5 μm, XBridge C_{18} analytical column (Waters), along with a Hitachi system composed of an L-2130 pump and an L-2450 diode array detector (Hitachi). The mobile phase consisted of 0.05% trifluoroacetic acid in water (A) and acetonitrile (B) using a gradient program of 3−20% B from 0 to 60 min and 20−100% B from 60 to 70 min. The mobile phase flow rate and the injection volume were 1 mL/min and 10 μL, respectively. The dried chloroform-soluble extract of each sample was dissolved in 1 mL of HPLC grade methanol, and filtered through a Fisher Scientific 13 mm syringe filter (0.2 μm) prior to injection. After comparison of the chromatograms of the chloroform-soluble extract solution recorded at wavelengths within 200−550 nm, it was found that 254 nm could best represent the profile of the analytes.

The LC-IT-MS analysis employed the same separation conditions and Xbridge C_{18} analytical column as used for the HPLC-PDA analysis mentioned above, on a Waters Alliance 2690 separation module. The injection volume was 10 μL. The mobile phase flow rate was maintained at 1 mL/min and was split approximately 50:1 postcolumn using a microsplitter valve (Upchurch Scientific, Oak Harbor, WA, USA) for the introduction to the ESI source. The electrospray ionization ion trap mass spectrometry (ESI-IT-MS) was performed on a Bruker dual funnel amaZon ETD ion trap mass spectrometer (Bremen, Germany) equipped with an orthogonal electrospray source operated in positive-ion mode. Sodium iodide was used for mass calibration for a calibration range of m/z 100−1000. Optimal ESI conditions were as follows: capillary voltage, 4500 V; source temperature, 250 °C; ESI drying gas (nitrogen), 4.0 L/min; and nebulizer, 10 psi. The ion trap was set to UltraScan mode with a target mass of m/z 500 pass ions from m/z 100 to 1000.

The ^{1}H NMR spectroscopic fingerprinting was conducted using the previously described chloroform-soluble extracts of products A−E. The samples were dissolved in 600 μL of $CDCl_3$, and spectra were measured at 300 K using a Bruker Avance-III HD400 spectrometer.

RESULTS AND DISCUSSION

Isolation, Structure Elucidation, and Biological Evaluation of the Constituents. The $CHCl_3$-soluble extract of product A (a commercial sample labeled as powdered seeds of African mango) was found to be the most potent among the hexanes-, $CHCl_3$-, EtOAc-, *n*-BuOH-, and H_2O-soluble extracts in the in vitro hydroxyl radical-scavenging (ED_{50}, concentration scavenging hydroxyl radical by 50%, 6.3 μg/mL) and QR induction (CD, concentration required to double QR activity, 12.4 μg/mL) assays. Therefore, it was selected for fractionation. Fractions F01−F03 of the $CHCl_3$-soluble extract showed hydroxyl radical-scavenging activity, with ED_{50} values of 3.3, 5.6, and 6.8 μg/mL, respectively. In addition, fractions F01 and F02 exhibited QR-inducing activity, with CD values of 6.9 and 10.2 μg/mL, respectively. Accordingly, fractions F01−F03 were used for further detailed purification. In this way, bioactivity-guided fractionation of product A led to the isolation of a new pyrrole alkaloid, **1**, and seven known compounds, **2**−**8**, as shown in Figure 1.

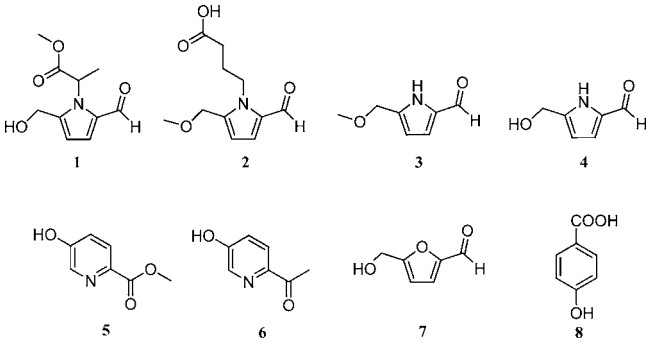

Figure 1. Structures of compounds isolated from a goji berry-contaminated commercial sample labeled African mango (*Irvingia gabonensis*).

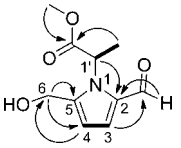

Figure 2. ^{1}H−^{1}H COSY (bold lines) and key HMBC (arrows) correlations of the new compound **1**.

Table 1. Hydroxyl Radical-Scavenging and Quinone Reductase-Inducing Activities of the Isolated Active Compounds 1, 2, and 6

	hydroxyl radical scavenging	QR induction		
compound[a]	ED_{50}[b] (μM)	CD[c] (μM)	IC_{50}[d] (μM)	CI[e]
1	16.7	43.1	>100	>2.3
2	11.9	2.4	>100	>42.6
6	>20	48.5	>100	>2.1
quercetin[f]	1.3			
L-sulforaphane[g]		0.77	16.7	21.7

[a]Compounds **3**−**5**, **7**, and **8** did not show hydroxyl radical-scavenging or QR-inducing activity at the concentrations tested. [b]ED_{50}, concentration scavenging hydroxyl radical by 50%. Compounds with ED_{50} values of <20 μM are considered active. [c]CD, concentration required to double QR activity. Compounds with CD values of <20, 20−100, and >100 μM are considered significantly active, weakly active, and inactive, respectively. [d]IC_{50}, concentration inhibiting cell growth by 50%. [e]CI, chemoprevention index (= IC_{50}/CD). [f]Positive control for hydroxyl radical-scavenging assay. [g]Positive control for QR induction assay.

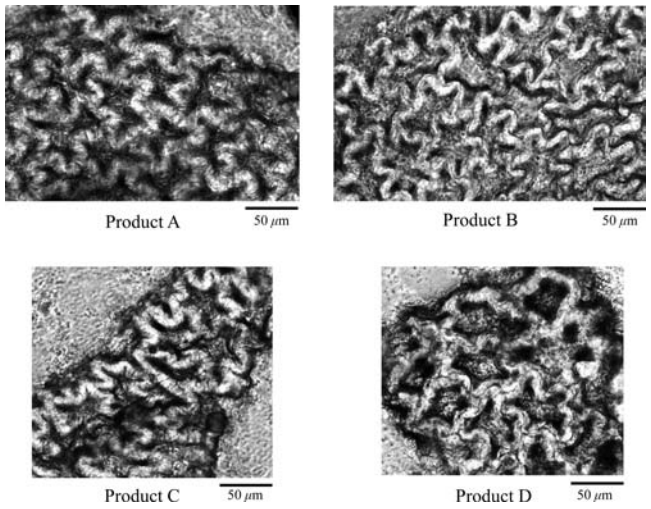

Figure 3. Microscopic structures of testa sclereids (stone cells) observed in products A–D.

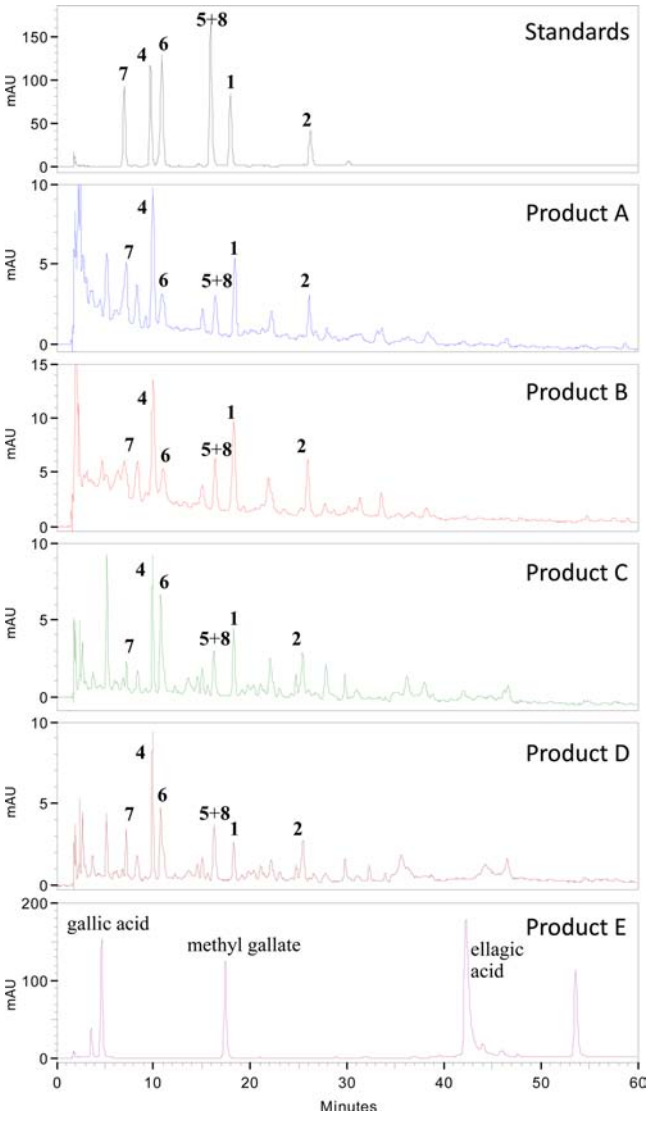

Figure 4. HPLC chromatograms (254 nm) of products A–E and standard compounds isolated from product A.

The new compound, **1**, was isolated as a colorless resin. The molecular formula was determined as $C_{10}H_{13}NO_4$ on the basis of the sodiated molecular ion peak in the HRESIMS. The IR spectrum showed absorptions of hydroxy (3424 cm^{-1}), ester carbonyl (1749 cm^{-1}), and conjugated aldehyde (2803, 2727, and 1655 cm^{-1}) groups. The UV spectrum of **1** exhibited a maximum absorption at 291 nm, which is characteristic of pyrrole 2-carbaldehyde.[13] The proton signal at δ_H 9.31 and the carbon signal at δ_C 180.5 correlated in the HSQC spectrum and indicated the presence of an aldehyde group. Two proton signals at δ_H 4.63 (2H, ABq, $\Delta\nu$ = 8.1 Hz, J = 13.9 Hz, H-6) resulted from a magnetically inequivalent oxygenated methylene group with geminal coupling. The HMBC correlation (Figure 2) of the methoxy group (δ_H 3.67, 3H, s, OCH_3) to the carbonyl at δ_C 172.5 revealed that this methoxy group forms an ester with this carbonyl. The quartet of H-1′ (δ_H 5.43, J = 7.0 Hz) and doublet of the methyl group (δ_H 1.67, J = 7.0 Hz), as well as their correlation in the COSY spectrum, clearly indicated the connection of the methyl group (δ_C 18.1) to C-1′ (δ_C 55.8). Furthermore, HMBC correlation of this methyl group (δ_H 1.67) to the ester carbonyl C-2′ (δ_C 172.5) suggested the connection of C-1′ (δ_C 55.8) to C-2′. The chemical shifts and coupling constants of the two protons at δ_H 7.07 (1H, d, J = 4.0 Hz, H-3) and δ_H 6.28 (1H, d, J = 4.0 Hz, H-4) implied the presence of a pyrrole ring. Moreover, the substitution pattern of the pyrrole ring should be 2,5- because a 2,3- or a 2,4-disubstituted pyrrole would have coupling constants of 1.3–2.9 or 2.3–3.2 Hz,[13] respectively. Also, the two carbons of the pyrrole ring at the lower field region (δ_C 144.6 and 133.4) were not present in the ^{13}C DEPT 135 spectrum, suggesting that C-2 and C-5 of this ring system are substituted (quaternary carbons). This was confirmed by the HMBC correlation of H-6 (δ_H 4.63) to C-4 (δ_C 111.4) and C-5 (δ_C 144.6), H-4 (δ_H 6.28) to C-6 (δ_C 56.6), H-3 (δ_H 7.07) to the aldehyde carbon (δ_C 180.5), and the aldehyde proton (δ_H 9.31) to C-2 (δ_C 133.4). In addition, the connection between C-1′ and N-1 was clearly indicated by the HMBC correlation of H-1′ (δ_H 5.43) to C-2 (δ_C 133.4). Therefore, the structure of **1** was established unambiguously as methyl 2-[2-formyl-5-(hydroxymethyl)-1*H*-pyrrol-1-yl]propanoate.

On the basis of the spectroscopic data measurements and the comparison of the data obtained with published values, the structures of the known compounds **2**–**8** were identified as 4-[formyl-5-(methoxymethyl)-1*H*-pyrrol-1-yl]butanoic acid, **2**,[13] 5-(methoxymethyl)-1*H*-pyrrole-2-carbaldehyde, **3**,[26] 5-(hydroxymethyl)-1*H*-pyrrole-2-carbaldehyde, **4**,[27,28] methyl-5-hydroxy-2-pyridinecarboxylate, **5**,[29] 5-hydroxy-2-pyridyl methyl ketone, **6**,[30] 5-hydroxymethyl-2-furancarbaldehyde, **7**,[31] and 4-hydroxybenzoic acid, **8**.[32]

In the present study, all of the isolates, **1**–**8**, were evaluated in vitro using the hydroxyl radical-scavenging and QR induction assays. The new compound, **1**, and the known pyrrole alkaloid, **2**, showed activities in both assays, as shown in Table 1. When the QR-inducing activities were compared among the structurally related pyrrole alkaloids, **1**–**4**, it was observed that **2**, containing a butanoic acid side chain at position N-1, exhibited the greatest potency (CD 2.4 μM); **1**, with a methyl propanoate substitution attached to N-1, showed much less potency (CD 43.1 μM), whereas **3** and **4**, each bearing no substituent to N-1, displayed no discernible activity (both CD >100 μM), suggesting that the length of the side chain at N-1 may significantly affect the QR-inducing activity of this type of compound.

Table 2. LC-MS Data of Constituents Identified in a Representative Authentic Goji Berry Sample (Product C)

t_R (min)	UV λ_{max} (nm)	molecular formula	$[M + H]^+$	$[M + Na]^+$	identification
7.0	230, 284	$C_6H_6O_3$	127.1	149.1	compound **7**
9.7	254, 299	$C_6H_7NO_2$	126.1	148.1	compound **4**
10.9	217, 261, 294	$C_7H_7NO_2$	138.1	160.0	compound **6**
15.9	254, 285	$C_7H_6O_3$, $C_7H_7NO_3$	139.1, 154.1	161.1, 176.0	compounds **5** and **8**
18.0	258, 296	$C_{10}H_{13}NO_4$	212.1	234.1	compound **1**
26.2	258, 296	$C_{11}H_{15}NO_4$	226.1	248.1	compound **2**

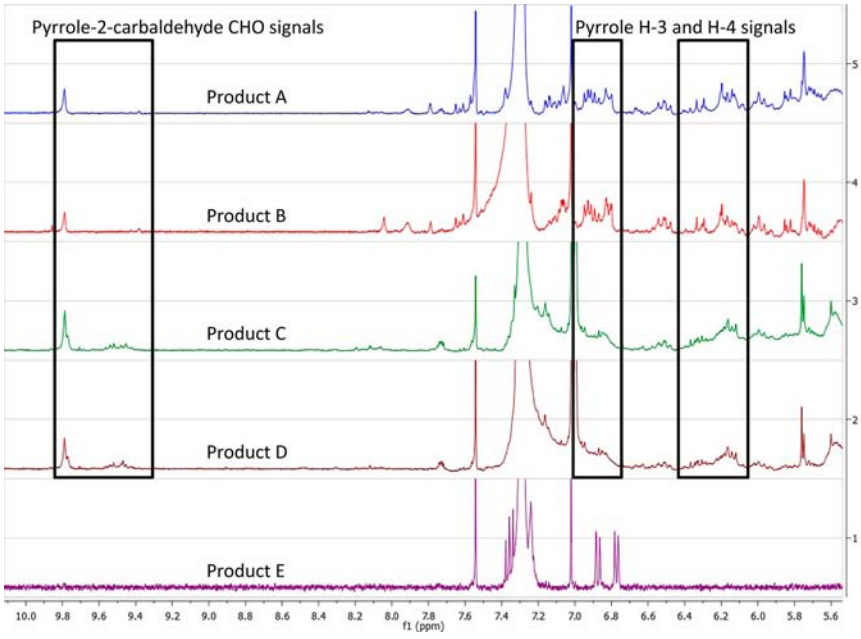

Figure 5. ^{1}H NMR fingerprinting (δ_H 5.5−10.1 ppm) of products A−E ($CDCl_3$, 400 MHz).

Pyrrole alkaloid **2** was initially isolated from goji berry (*L. chinense*).[13] Compounds **1**, **3**, and **4** are analogues of **2** and are also pyrrole alkaloids. In contrast, no alkaloid has been previously isolated or detected spectroscopically from African mango. In addition, both goji berry and African mango reportedly can be used as antiobesity medicinal plants.[33] Due to the unexpected presence of these pyrrole alkaloids and their structural similarity to and occurrence as constituents found in goji berries,[12,13] as well as the public concern and a recent report about frequent contamination in commercial African mango samples,[9] a comprehensive comparison of the commercial sample labeled as African mango seeds (product A) with authentic goji berry samples (products B−D) and African mango seeds (product E) was conducted via microscopic analysis as well as chemotaxonomy using LC-MS and ^{1}H NMR fingerprinting, as shown in the following sections.

Microscopic Examination. In the powders of products A−D, irregular polygonal testa sclereids (stone cells) were observed with thickened and curved walls as well as distinct striations in surface view (Figure 3), characteristic of the seeds of goji berry.[14] This microscopic feature was not found in the authentic sample of African mango seed powder (product E).

HPLC-PDA and LC-IT-MS Analysis. Products A−D shared very similar HPLC chromatograms, which differed significantly from that of product E (Figure 4). Compound **3** had been all consumed for bioassay and thus could not be used as a standard. However, compounds **1**, **2**, and **4**−**8** isolated from product A were present in the authentic goji berry samples (products B−D), as identified by comparison of the retention times, UV profiles, and mass spectra of the peaks with standard compounds that had been identified by NMR (Table 2). In contrast, the HPLC chromatogram of the authentic sample of African mango seeds (product E) was shown to be very different, containing gallic acid, methyl gallate, ellagic acid, and their derivatives as major constituents, as identified by the same analytical methods mentioned above. These substances have been previously detected in African mango.[8,9]

^{1}H NMR Fingerprinting. Visual inspection of the ^{1}H NMR spectra revealed that all samples tested contained triacylglycerols as major constituents. By comparison, however, products A−D each contained pyrrole alkaloids as minor constituents with characteristic signals at δ_H 6.0−6.4 ppm that were not observed in product E. The presence of signals in the region of δ_H 9.4−9.8 ppm can be attributed to the aldehyde functionality of the isolated pyrrole-2-carbaldehyde compounds and further distinguished the botanical identity of product A from product E. Additionally, the signals that were detected only in product E may be ascribed to the previously reported constituents of African mango, namely, methyl gallate, ellagic acid, or their derivatives.[8,9] The region of the NMR spectra pertinent to these comparisons is shown in Figure 5. The relative cleanness of the proton NMR spectrum of the authentic African mango seed extract suggests that ^{1}H NMR fingerprinting may be a useful tool for the future authentication and/or quality control of such samples.

Accordingly, chemotaxonomic examination by LC-IT-MS and ^{1}H NMR fingerprinting using authentic samples of goji berries and African mango suggested that there was evidence of

contamination, adulteration, and/or mislabeling of the commercial African mango sample evaluated (product A), in agreement with a concerning trend previously reported.[9] It is worth noting that goji berry from the same batch as product C was previously reported to exhibit in vivo inhibitory activity in a rat *N*-nitrosomethylbenzylamine (NMBA)-induced esophageal cancer model, and the detection of the in vitro active compounds **1**, **2**, and **6** in product C suggests that these compounds may possess potential in vivo cancer chemopreventive activity and hence merit further investigation.

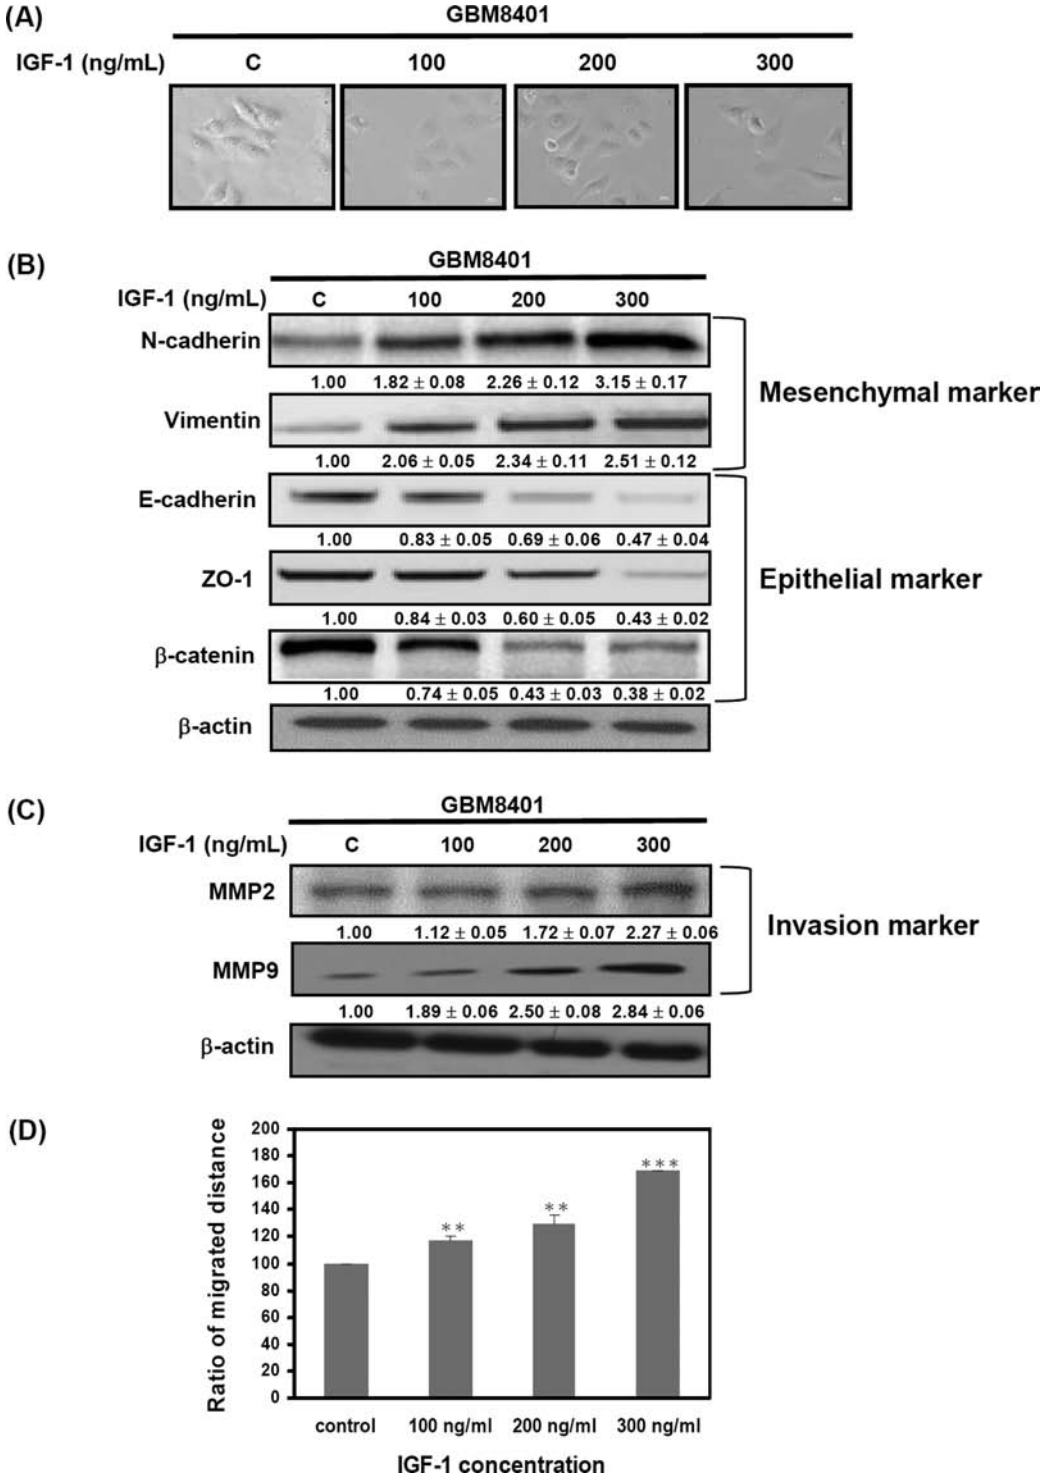

Figure 1. IGF-1-induced cell scattering and EMT in GBM8401 cells. GBM8401 cells were treated with DMSO (control) or increasing IGF-1 concentrations (100−300 ng/mL) for 24 h. (A) EMT was examined by phase contrast photomicrographs. (B) The cells were then harvested and lysed for the detection of N-cadherin, vimentin, E-cadherin, ZO-1, β-catenin, and β-actin. (C) The cells were then harvested and lysed for the detection of MMP-2, MMP-9, and β-actin. Western blot data presented are representative of those obtained in at least 3 separate experiments. Immunoblots were quantified, and the lower panel presents the average ± SD of three independent experiments. The value of the control cells was set to 1. (D) IGF-1-induced cell motility was determined by measuring the closure of wound. Data were plotted by mean ± SD ($n = 3$). The closure distance of the control cells was set to 100 (**, $p < 0.01$;***, $p < 0.001$).

Compared to normal brain tissue, IGF-1R is overexpressed in malignant GBM.[6] Recent studies suggested that IGF-1R activation, through autocrine or paracrine IGF-1 production, contributed to the proliferation and migration of GBM.[7]

Osthole, a coumarin derivative isolated from the fruit of *Cnidium monnieri* (L.) Cusson, has been widely used for the treatment of skin diseases and gynecopathy. Recently, osthole has taken considerable attention because of its broad spectrum of pharmacologic activities, including anti-inflammatory,[8,9] anti-

dx.doi.org/10.1021/jf501047g | J. Agric. Food Chem. 2014, 62, 5061−5071

allergic,[10] vasorelaxant,[11] antidiabetic,[12] and antitumor effects.[13] In addition, current studies demonstrated that osthole had neuroprotective effects on animal models of central nervous system (CNS) diseases, such as brain ischemia models,[14,15] and also in traumatic brain injury model.[16] However, the anti-GBM ability of osthole remains largely unknown.

A better understanding of the mechanisms behind the rapid growth of GBM may offer new therapeutic targets and improve outcome. IGF-1 activity has been closely examined in proliferative tissues for their relationship to change in cellular morphology associated with cancer progression. Therefore, the present study investigated whether IGF-1 could induce EMT in GBM cells. Since osthole has an ability to cross the blood−brain barrier and protect against brain injury, we further explore the potential of osthole in inhibiting the IGF-1-mediated EMT in GBM cells.

MATERIALS AND METHODS

Materials and Antibodies. Recombinant human IGF-1 was purchased from PeproTech, Inc. (Rocky Hill, NJ, USA). Osthole and PD98059 were purchased from Sigma Chemical Co. (St. Louis, MO, USA). LY294002 was purchased from Cayman Chemical Co. (Ann Arbor, Michigan, USA). Primary antibodies against IGF-1R, phospho-IGF-1R (Tyr 1135/1136), phospho-Akt (Ser 473), Akt, phospho-Erk1/2 (Thr 202/Tyr 204), Erk1/2, phospho-GSK3β (Ser 9), GSK3β, MMP-2, MMP-9, N-cadherin, vimentin, ZO-1, β-catenin, Snail, and E-cadherin were purchased from Cell Signaling Technology (Beverly, MA, USA). Antibody for β-actin was purchased from Sigma Chemical Co (St. Louis, MO, USA). Antibodies for ZEB1 and Twist were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Anti-mouse and anti-rabbit antibodies conjugated to horseradish peroxidase were also obtained from Santa Cruz Biotechnology, Inc.

Cell Culture. HEK-293T cells were obtained from the American Type Culture Collection (Rockville, MD, USA). GBM8401 cells were obtained from Bioresources Collection and Research Center (Hsinchu, Taiwan). GBM8401 cells were cultured in RPMI1640 supplemented with 10% fetal bovine serum (FBS) and 1% penicillin−streptomycin. Cell culture materials were obtained from Invitrogen (Burlington, Ontario, Canada).

Morphology Observation. GBM8401 cells (2×10^4) were seeded in a 24-well plate and pretreated with the indicated concentrations of osthole for the appropriate time. IGF-1 was added to each well with indicated concentrations, and cells were then incubated for 24 h. A Nikon TE2000-U inverted microscope was used to take representative photographs at 200× magnification.

Western Blot Analysis. Western blot was done as described previously.[17] Briefly, cells (2×10^6) were treated with various agents as indicated in figure legends. After treatment, cells were placed on ice, washed with cold PBS, and lysed in the lysis buffer. Fifty micrograms of protein extract was loaded into sodium dodecyl sulfate polyacrylamide gels, and the separated proteins were transferred to nitrocellulose filters. The filters were probed with the appropriate primary antibody.

Cell Viability Studies. To evaluate the cell viability of osthole in GBM8401 cells, MTT assay was employed. GBM8401 cells at a density of 1×10^4 cells per well were exposed to osthole for 24 h. MTT solution (stock concentration: 5 mg/mL in PBS) was diluted to 500 μg/mL. Each well was treated with 100 μL of MTT working solution and incubated at 37 °C for 2 h. The optical density was measured using an ELISA reader at 570 nm wavelength.

Confocal Microscopy. After treatment, GBM8401 cells were fixed for 40 min with 4% paraformaldehyde in PBS at room temperature, permeabilized and blocked with 5% nonfat dry milk, 1% BSA, and 0.5% Triton X-100, and incubated overnight with anti-vimentin monoclonal antibody and then FITC-conjugated anti-mouse IgG antibody. DAPI staining was used to determine the nuclei. Cells were imaged with a Leica TCS SP2 Spectral Confocal System (Leica, Wetzlar, Germany).

Wound Healing Assay. 4.5×10^5 GBM8401 cells were plated on a 6-well plate to form a confluent monolayer in serum-containing medium. Before being scratched, the confluent monolayer was pretreated with the indicated concentrations of osthole for 2 h. A sterile 200 μL pipet tip was used to scratch the monolayers, followed by washing with PBS to remove cell debris. RPMI1640 containing 0.5% FBS, indicated concentrations of osthole, and 200 ng/mL IGF-1 were then added to each well for 24 h. A Nikon TE2000-U inverted microscope was used to measure ten random fields at 200× magnification. Data from three independent experiments were analyzed by GraphPad Prism 5 software.

RNA Isolation and Quantitative Real-Time PCR. RNA isolation was performed as previously described.[18] Briefly, total RNA was extracted according to the manufacturer's protocol (Qiagen, Germantown, MD, USA). The extracted RNA was purified on an RNeasy purification column (Qiagen) and treated with DNase I according to the manufacturer's protocol. Reverse transcriptase reactions were performed using a first-strand cDNA synthesis kit (Fermentas, Hanover, MD, USA). Quantitative real-time PCR was performed using StepOnePlus real-time PCR system (Applied Biosystems Inc., Foster City, CA, USA) on an ABI Prism 7500HT sequence detection system following the manufacturer's instructions. In quantitative real-time PCR experiments, GAPDH (glyceraldehyde 3-phosphate dehydrogenase) was applied as an internal control. Primers used for E-cadherin were as follows: 5′-TGCTCTTCCAGGAACCTCTGTG-3′ (forward) and 5′-GGTGACCACACTGATGACTCCTG-3′ (reverse).

Reporter Construct Generation and Dual-Luciferase Reporter Assay. The reporter constructs were performed as previously described.[18] For dual-luciferase reporter assay, 1×10^5 GBM8401 cells were plated onto 24-well plates 1 day before transfection and then transfected with reporter constructs by using Lipofectamine 2000 (Invitrogen, Carlsbad, CA, USA). After transient transfection, the GBM8401 cells were treated with osthole at various concentrations with or without IGF-1-stimulation. GBM8401 cells were lysed in the lysis buffer (Promega, Madison, WI, USA) and detected with dual luciferase assay kits (Promega).

Tranfection. One day before transfection, 2×10^5 GBM8401 cells without serum were plated in a 6 cm dish. Cells were grown to 90% confluence and transfected on the following day by Lipofectamine 2000 (Invitrogen, Carlsbad, CA, USA) and premixed plasmid DNA with OPTI-MEM (GIBCO, Carlsbad, CA, USA) for 5 min and then added to the dish. The transfection was completed after 24 h of incubation.

Statistical Analysis. All values were expressed as mean ± SD. The independent Student's *t*-test was used to compare the continuous variables between two groups, and the chi-squared test was applied for comparison of dichotomous variables. Asterisk indicates that the values were significantly different from the control (*, $P < 0.05$; **, $P < 0.01$; ***, $P < 0.001$).

RESULTS

IGF-1-Induced GBM8401 Cells Undergo EMT. To determine whether IGF-1 could initiate cell morphology changes, GBM8401 cells were treated with various concentrations (100−300 ng/mL) of IGF-1 for 24 h. GBM8401 cells maintained a classic cobblestone epithelial morphology; after exposure of GBM8401 cells to IGF-1, morphology was changed to fibroblast-like and the cell−cell contact was reduced (Figure 1A). GBM8401 cells were treated with various concentrations of IGF-1 for 24 h, and IGF-1 decreased the expression of epithelial phenotype markers, E-cadherin, ZO-1, and β-catenin in a dose-dependent manner (Figure 1B). Inversely, IGF-1 increased the expression of mesenchymal markers N-cadherin and vimentin in a dose-dependent manner (Figure 1B). Our results indicated that IGF-1 induced EMT in GBM cells. We also determined whether IGF-1 regulated MMP-2 and MMP-9 expressions related to invasion and metastasis. The expression of MMP-2 and MMP-9 was increased after IGF-1 treatment for 24 h (Figure 1C). Moreover, IGF-1 induced an increase in cell migration (Figure 1D).

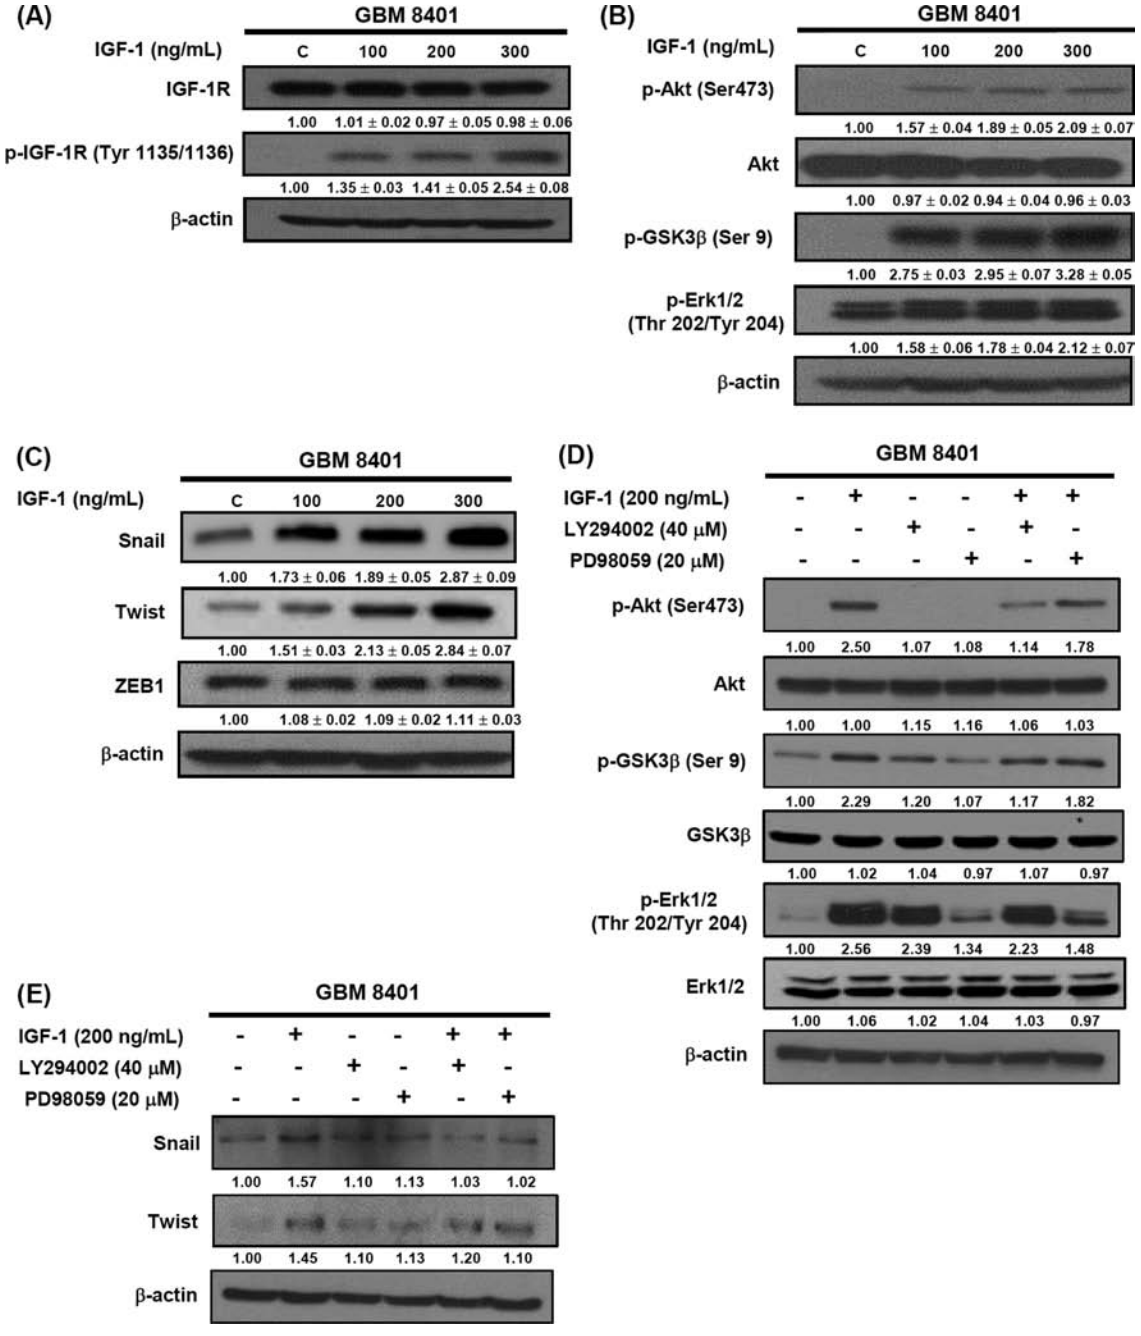

Figure 2. IGF-1 induced phosphorylation of Akt and Erk1/2 and Snail and Twist expression in GBM8401 cells. GBM8401 cells were treated with DMSO (control) or increasing IGF-1 concentrations (100−300 ng/mL) for 10 min. (A) The cells were then harvested and lysed for the detection of IGF-1R, p-IGF-1R, and β-actin. (B) The cells were then harvested and lysed for the detection of p-Akt, Akt, p-GSK3β, p-Erk1/2, and β-actin. (C) GBM8401 cells were treated with DMSO (control) or increasing IGF-1 concentrations (100−300 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of Snail, Twist, ZEB1, and β-actin. (D) GBM8401 cells were pretreated with 40 μM LY294002 or 20 μM PD98059 for 2 h prior to with or without IGF-1 stimulation (200 ng/mL) for 10 min. The cells were then harvested and lysed for the detection of p-Akt, Akt, p-GSK3β, p-Erk1/2, and β-actin. (E) BM8401 cells were pretreated with 40 μM LY294002 or 20 μM PD98059 for 2 h prior to with or without IGF-1 stimulation (200 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of Snail, Twist, and β-actin. Western blot data presented are representative of those obtained in at least 3 separate experiments. Immunoblots were quantified, and the value of the control cells was set to 1.

IGF-1-Induced EMT by Upregulating Snail and Twist in GBM8401 Cells. To investigate the ability of IGF-1-induced EMT through IGF-1R signaling, tyrosine phosphorylation of IGF-1R was examined in the presence of IGF-1. GBM8401 cells showed no detectable phosphorylation of IGF-1R when cells were cultured in a serum-free medium. In the presence of IGF-1, however, key tyrosine residues in the kinase domain of the β-subunit of IGF-1R became phosphorylated. There was no change in the amount of total IGF-1R as determined by immunoblotting (Figure 2A). We next determined the effect of IGF-1 on the key signaling molecules downstream of IGF-1R, Akt and Erk1/2. IGF-1 stimulation resulted in increased phosphorylation of Akt and Erk1/2 in comparison to serum-free condition (Figure 2B). Interestingly, IGF-1 stimulation also resulted in increased phosphorylation of GSK3β, the downstream of Akt, in a dose-dependent manner (Figure 2B). We next examined whether

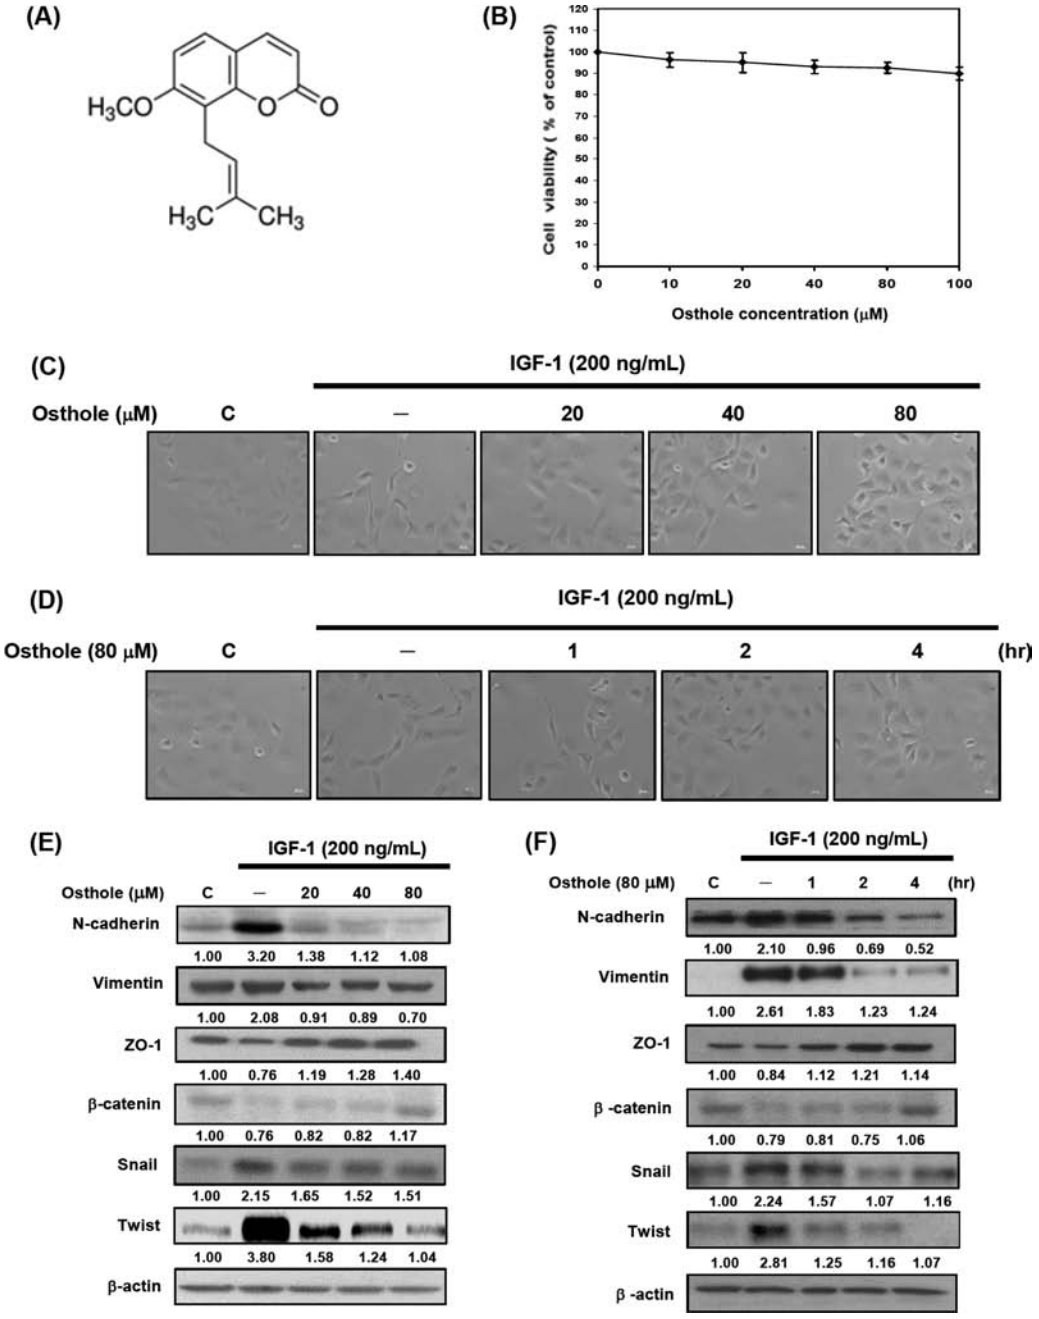

Figure 3. Osthole blocked IGF-1-induced cell scattering and EMT in GBM8401 cells. (A) Chemical structure of osthole. (B) GBM8401 cells were treated with increasing osthole concentrations (10−100 μM) for 24 h. The cell viability was then determined using MTT assay. This experiment was repeated three times. The data represented the mean ± SD. (C) GBM8401 cells were pretreated with DMSO (control) or increasing osthole concentrations (20−80 μM) for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. (D) GBM8401 cells were incubated with DMSO (control) or 80 μM osthole for 1, 2, or 4 h prior to IGF-1 stimulation (200 ng/mL). EMT was examined by phase contrast photomicrographs. (E) GBM8401 cells were pretreated with DMSO (control) or increasing osthole concentrations (20−80 μM) for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of N-cadherin, vimentin, E-cadherin, ZO-1, β-catenin, Snail, Twist, and β-actin. (F) GBM8401 cells were incubated with DMSO (control) or 80 μM osthole for 1, 2, or 4 h prior to IGF-1 stimulation (200 ng/mL). The cells were then harvested and lysed for the detection of N-cadherin, vimentin, E-cadherin, ZO-1, β-catenin, Snail, Twist, and β-actin. Western blot data presented are representative of those obtained in at least 3 separate experiments. Immunoblots were quantified, and the value of the control cells was set to 1.

EMT-inducing regulators, Snail, Twist, and Zeb1, were involved in IGF-1-induced EMT. GBM8401 cells were treated with different concentrations of IGF-1, and Western blotting analysis showed that IGF-1 increased both Snail and Twist expressions, but not the ZEB1 expression (Figure 2C). In order to further confirm whether Akt and Erk1/2 were involved in IGF-1-mediated EMT, LY294002, a specific inhibitor of PI3K, and PD98059, a specific inhibitor of MAPK, were used to inhibit IGF-1-induced phosphorylation of Akt and Erk1/2 in GBM8401 cells. The results showed that IGF-1-induced phosphorylation of Akt and Erk1/2 (Figure 2D) and upregulation of Snail and Twist (Figure 2E) were significantly inhibited by pretreatment with 40 μM LY294002 or 20 μM PD98059. Taken together, IGF-1

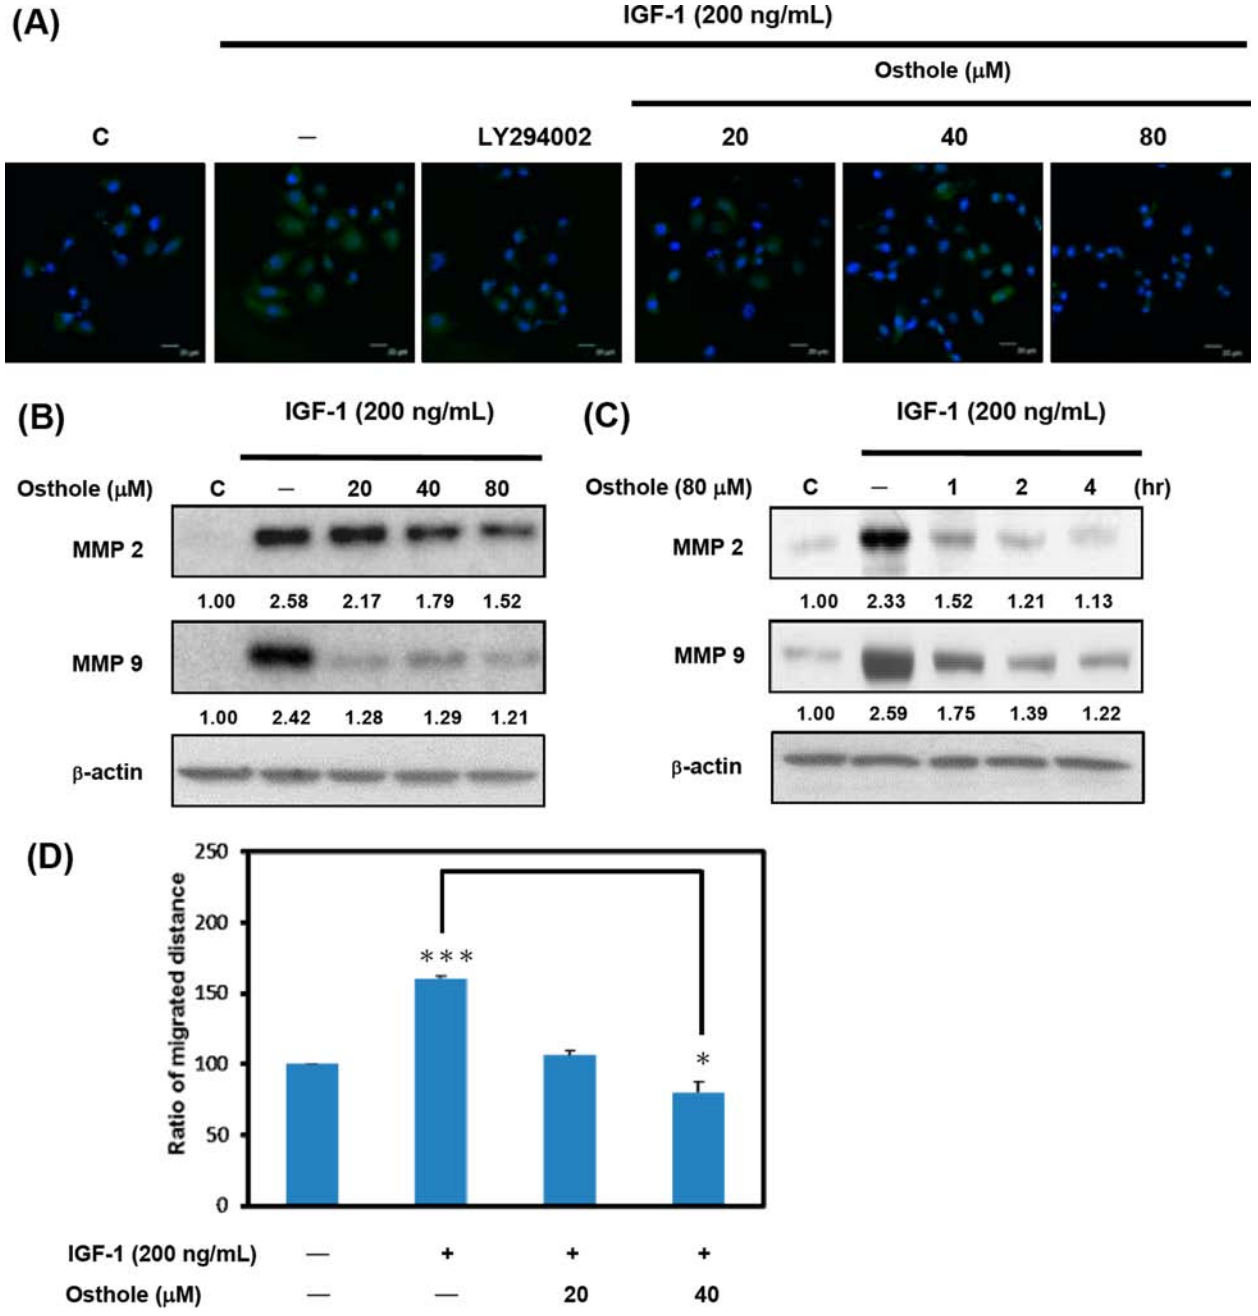

Figure 4. Osthole blocked IGF-1-induced cell migration in GBM8401 cells. (A) GBM8401 cells were pretreated with DMSO (control), 40 μM LY294002, or increasing osthole concentrations (20−80 μM) for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. Cells were fixed, permeabilized, and stained with anti-vimentin monoclonal antibody (green) and DAPI (blue). Cells were analyzed by confocal microscopy. (B) GBM8401 cells were pretreated with DMSO (control) or increasing osthole concentrations (20−80 μM) for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of MMP-2, MMP-9, and β-actin. (C) GBM8401 cells were pretreated with DMSO (control) or 80 μM osthole for 1, 2, and 4 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of MMP-2, MMP-9, and β-actin. Western blot data presented are representative of those obtained in at least 3 separate experiments. Immunoblots were quantified, and the value of the control cells was set to 1. (D) GBM8401 cells were pretreated with DMSO (control) or increasing osthole concentrations (20, 40 μM) for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. IGF-1-induced cell motility was determined by measuring the closure of wound. Data were plotted by mean ± SD (n = 3). The closure distance of the control cells was set to 100. Osthole significantly inhibited IGF-1-induced cell motility (*, $p < 0.05$).

induced phosphorylation of Akt and Erk1/2 and expression of Snail and Twist leading to EMT induction.

Osthole Blocked IGF-1-Induced EMT in GBM8401 Cells. The activation of IGF-1 signaling significantly caused fibroblast-like morphology in GBM8401 cells. We next determined whether osthole (Figure 3A) could affect the IGF-1-induced fibroblast-like morphology, and GBM8401 cells were pretreated with osthole prior to stimulation with IGF-1. To ensure that osthole blocked IGF-1-induced fibroblast-like morphology was not due to inhibition of proliferation, we tested the cytotoxicity of osthole on GBM8401 cells. As shown in Figure 3B, osthole had no significant cytotoxicity on GBM8401 cells. GBM8401 cells were pretreated with osthole (20−80 μM) for 2 h prior to stimulation with IGF-1 (200 ng/mL) for 24 h. Osthole blocked

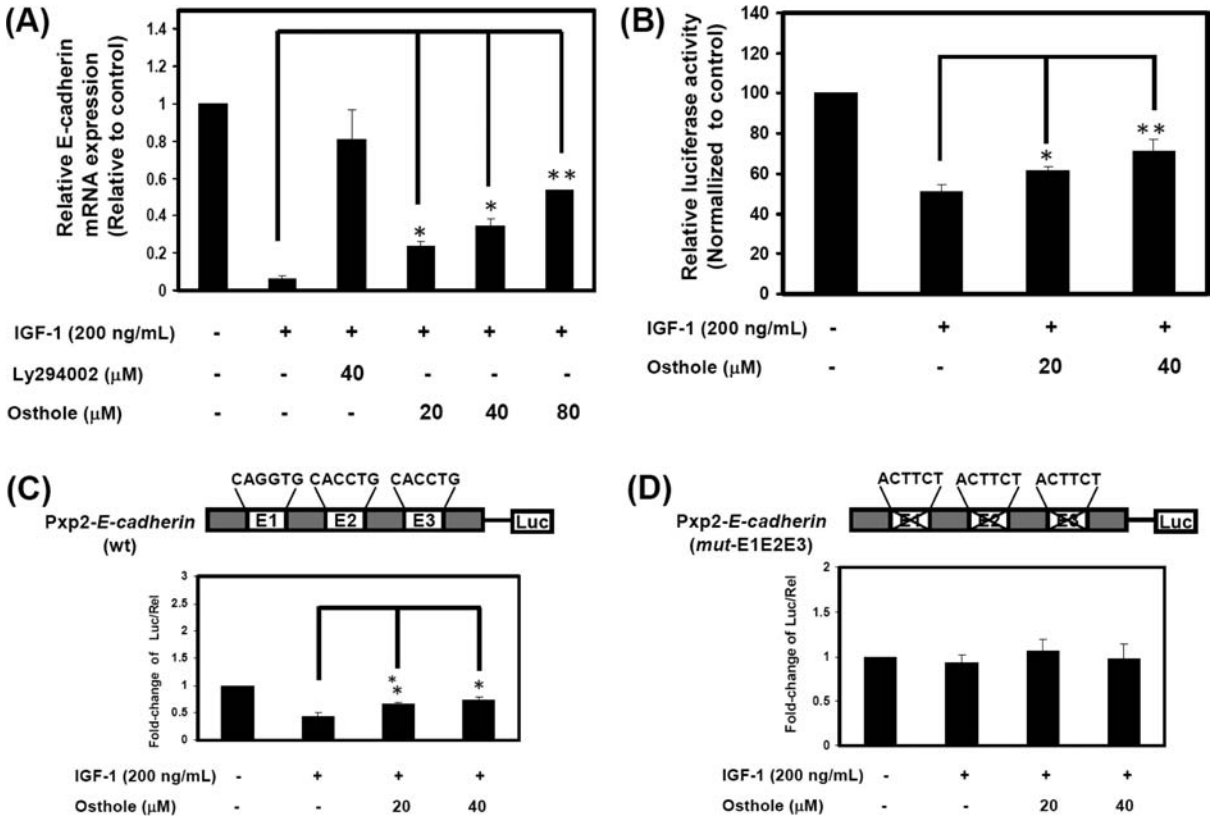

Figure 5. Osthole blocked IGF-1-induced EMT at transcriptional level. (A) GBM8401 cells were pretreated with DMSO (control), 40 μM LY294002, or increasing osthole concentrations (20−80 μM) for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. Quantitative real-time PCR was performed by the StepOnePlus real-time PCR system and GAPDH was applied as an internal control. Data were plotted by mean ± SD (n = 3). The value of control was set to 1. Asterisk, values significantly different from the IGF-1 stimulation. *, $p < 0.05$; **, $p < 0.01$. (B) After cotransfection with pRL-*CMV* and pXP2-*E-cadherin* in GBM8401 cells, cells were pretreated with DMSO (control) or increasing osthole concentrations (20, 40 μM) for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. *E-cadherin* promoter activity was analyzed by luciferase reporter assays. Data were plotted by mean ± SD (n = 3). The value of control was set to 1. Asterisk, values significantly different from the IGF-1 stimulation. *, $p < 0.05$; **, $p < 0.01$. (C) Top: schematic representation of the wild-type (pXP2-E-cadherin) *E-cadherin* promoter construct. E1, E2, and E3 indicate the E-boxes. Bottom: promoter-activity assay. HEK-293T cells were cotransfected with a promoter construct and the indicated vector. All cells were cotransfected with a plasmid that expressed *β-galactosidase,* and the luciferase activity values were normalized to the β-galactosidase activity. After cotransfection, the cells were pretreated with DMSO (control) or increasing osthole concentrations (20, 40 μM) for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. For each promoter, all values were standardized to the luciferase activity of the control; asterisks indicate $P < 0.05$, compared with the control cells. The data are shown as the means ± SD (n = 3). (D) Top: schematic representation of the mutated-E-boxes (pXP2-E-cadherin (*mut*-E1E2E3)) *E-cadherin* promoter construct. E1, E2, and E3 indicate the E-boxes. Bottom: promoter activity assay in HEK-293T cells under different transfection conditions. A vector expressing *β-galactosidase* was cotransfected to ensure the transfection efficiency and normalize the luciferase activity values. After cotransfection, the cells were pretreated with DMSO (control) or increasing osthole concentrations (20, 40 μM) for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. For each promoter, all values were standardized to the luciferase activity of the control. The data are shown as the means ± SD (n = 3).

IGF-1-induced fibroblast-like morphology in a dose-dependent fashion (Figure 3C). Moreover, we pretreated GBM8401 cells with 80 μM osthole for varying periods of time from 1 to 4 h prior to IGF-1 addition. An increase in inhibition of IGF-1-induced fibroblast-like morphology was observed beginning at 1 h of osthole pretreatment (Figure 3D). To further identify whether inhibition of IGF-1-induced fibroblast-like morphology in osthole treated GBM8401 cells resulted from inhibition of EMT, we examined the expression of EMT related proteins in GBM8401 cells. Pretreated GBM8401 cells with osthole significantly suppressed the IGF-1-induced upregulation of N-cadherin, vimentin, Snail, and Twist and downregulation of ZO-1 and β-catenin in a dose- and time-dependent manner (Figure 3E,F).

Osthole Blocked IGF-1-Induced Cell Migration by Downregulating MMP-2, and MMP-9 in GBM8401 Cells. To further examine that osthole suppressed the IGF-1-induced upregulation of vimentin, GBM8401 cells were imaged with confocal microscopy. As shown in Figure 4A, confocal microscopy with vimentin antibodies indicated that IGF-1 treatment resulted in upregulation of vimentin. Pretreatment with various concentrations of osthole for 2 h significantly suppressed the IGF-1-induced upregulation of vimentin in a dose-dependent manner (Figure 4A). IGF-1 has been shown previously to stimulate protease activity in many cell types.[19] To determine whether IGF-1 could stimulate metalloproteinase activity, GBM8401 cells were treated with 200 ng/mL IGF-1. IGF-1 stimulation resulted in increased expression of MMP-2 and MMP-9 compared to serum-free conditions (Figure 4B,C). Pretreatment with osthole significantly suppressed the IGF-1-induced upregulation of MMP-2 and MMP-9 in a dose- and time-dependent manner (Figure 4B,C). We next examined whether osthole inhibited IGF-1-induced cell migration by measuring the wound closure. Compared to GBM8401 cells treated with DMSO (control), IGF-1 significantly induced cell

dx.doi.org/10.1021/jf501047g | J. Agric. Food Chem. 2014, 62, 5061−5071

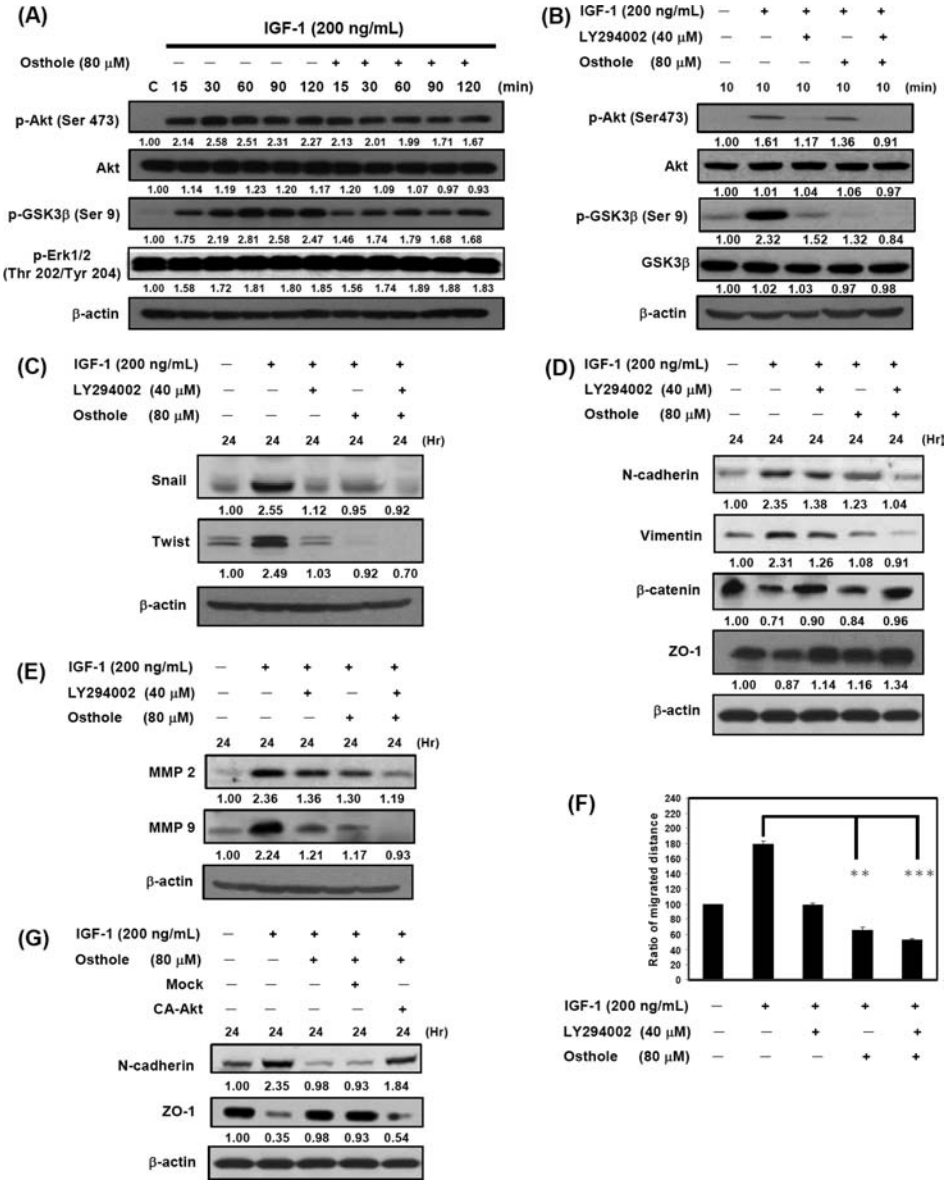

Figure 6. Osthole blocked IGF-1-induced Akt pathway in a time-dependent manner. (A) GBM8401 cells were preincubated in the presence or the absence of 80 μM osthole for 2 h prior to IGF-1 stimulation (200 ng/mL) for various times. The cells were then harvested and lysed for the detection of p-Akt, Akt, p-GSK3β, p-Erk1/2, and β-actin. (B) GBM8401 cells were pretreated with 80 μM osthole, or 40 μM LY294002, or a combination of 40 μM LY294002 and 80 μM osthole for 2 h and then treated with IGF-1 for 10 min. The cells were then harvested and lysed for the detection of p-Akt, p-GSK3β, and β-actin. GBM8401 cells were pretreated with 80 μM osthole, or 40 μM LY294002, or a combination of 40 μM LY294002 and 80 μM osthole for 2 h and then treated with IGF-1 for 24 h. (C) The cells were then harvested and lysed for the detection of Snail, Twist, and β-actin. (D) The cells were then harvested and lysed for the detection of N-cadherin, vimentin, β-catenin, ZO-1, and β-actin. (E) The cells were then harvested and lysed for the detection of MMP-2, MMP-9, and β-actin. (F) Cell motility was determined by measuring the closure of wound. Data were plotted by mean ± SD (n = 3). Osthole or a combination of LY294002 and osthole significantly inhibited IGF-1-induced cell motility (**, $p < 0.01$;***, $p < 0.001$). (G) GBM8401 cells were transfected with 50 nmol/L CA-Akt or mock. Twenty-four hours after transfection, preincubation was carried out in the presence or the absence of 80 μM osthole for 2 h prior to IGF-1 stimulation (200 ng/mL) for 24 h. The cells were then harvested and lysed for the detection of N-cadherin, ZO-1, and β-actin. Western blot data presented are representative of those obtained in at least three separate experiments. The values below the figures represent change in protein expression normalized to β-actin.

migration. Significantly, the IGF-1-induced cell migration was inhibited in the presence of osthole (Figure 4D).

Osthole Suppressed IGF-1 Inducible E-Cadherin Transcriptional Downregulation. We next determined whether pretreatment with osthole could inhibit IGF-1-induced downregulation of E-cadherin through transcriptional level. Real-time PCR analysis was performed to assess the effect of osthole on E-cadherin mRNA expression. As shown in Figure 5A, IGF-1-induced downregulation of E-cadherin mRNA was restored by pretreatment with osthole. Our luciferase assay indicated that IGF-1 inhibited *E-cadherin* promoter activity, and pretreatment with osthole significantly restored the IGF-1-repressed *E-cadherin* promoter activity in a dose-dependent manner (Figure 5B). Figure 2C indicates that IGF-1 induced Snail and Twist expression. Interestingly, Snail and Twist bind to the same elements in the *E-cadherin* promoter: three *E-boxes* with a core 5′-CACCTG-3′ sequence. We next investigated whether osthole suppressed the binding of Snail and Twist to these *E-boxes* and

dx.doi.org/10.1021/jf501047g | J. Agric. Food Chem. 2014, 62, 5061−5071

repressed the *E-cadherin* promoter. Promoter activity was analyzed by transfection of *E-cadherin* promoter containing three *E-boxes* constructed into HEK-293T cells. Our promoter-activity assay showed that IGF-1 inhibited *E-cadherin* promoter activity. Pretreatment with various concentrations of osthole restored the IGF-1-repressed *E-cadherin* promoter activity (Figure 5C). As shown in Figure 5D, mutation of all three *E-boxes* abrogated repression by IGF-1. Pretreatment with various concentrations of osthole was not able to restore the *E-boxes*-mutated *E-cadherin* promoter activity. These data suggest that osthole inhibits IGF-1-mediated EMT through transcriptional level.

Osthole Inhibited IGF-1-Induced EMT through Inhibiting PI3K/Akt Signaling Pathway. To determine whether osthole inhibited the key signaling molecules downstream of IGF-1R, Akt and Erk1/2, the phosphorylation of Akt and Erk1/2 was examined at various time points after adding IGF-1 (200 ng/mL) to GBM8401 cells. The phosphorylation of Akt and Erk1/2 was increased at 15 min after stimulation, and this effect lasted for at least 120 min (Figure 6A). Pretreatment with osthole (80 μM) for 2 h significantly suppressed the IGF-β-induced phosphorylation of Akt and GSK3β (Figure 6A). However, pretreatment with osthole was not able to suppress the IGF-β-induced phosphorylation of Erk1/2 (Figure 6A). We next investigated whether Akt was involved in osthole inhibited IGF-1-mediated EMT; PI3K inhibitor LY294002 was used. Our study showed that IGF-1-induced phosphorylation of Akt and GSK3β (Figure 6B), upregulation of Snail and Twist (Figure 6C), upregulation of N-cadherin and vimentin and downregulation of β-catenin and ZO-1 (Figure 6D), and upregulation of MMP-2 and MMP-9 (Figure 6E) were significantly inhibited by pretreatment with 40 μM LY294002. Interestingly, in the cotreatment of LY294002 (40 μM) and osthole (80 μM), IGF-1-induced phosphorylation of Akt and GSK3β (Figure 6B), upregulation of Snail and Twist (Figure 6C), upregulation of N-cadherin and vimentin and downregulation of β-catenin and ZO-1 (Figure 6D), and upregulation of MMP-2 and MMP-9 (Figure 6E) were more potent than pretreatment with LY294002 or osthole alone. We further confirmed whether Akt was involved in osthole inhibited IGF-1-mediated cell migration. Figure 6F showed that IGF-1-induced cell migration was significantly inhibited by pretreatment with 40 μM LY294002. In the cotreatment of LY294002 (40 μM) and osthole (80 μM), IGF-1-induced cell migration was more potent than pretreatment with LY294002 or osthole alone (Figure 6F). To assess whether Akt was involved in osthole inhibited IGF-1-mediated EMT, we performed Akt-overexpression experiment using constitutively active Akt (CA-Akt). The result showed that CA-Akt abolished the ability of osthole to suppress IGF-1-induced EMT (Figure 6G). Taken together, our data suggest that the inhibition of PI3K/Akt signaling pathway is involved in osthole inhibited IGF-1-mediated EMT, and cell migration in GBM8401 cells.

DISCUSSION

Recent studies indicated an important role for the IGF signaling pathway in the proliferation, progression, and antiapoptosis of GBM cells. For example, treatment of glioblastoma cells with IGF-1 increased cellular proliferation and migration.[20] Inhibition of IGF-1R by tyrosine kinase inhibitor inhibited GBM cell growth.[21] IGF-1R inhibition contributed to the growth suppression of primary cell lines derived from human high-grade gliomas.[22]

The EMT is crucial for the migration and invasion of many epithelial tumors. IGF-1 stimulation has been shown to promote dramatic neomorphic effects of an EMT and enhanced cell migration and invasion. For example, Graham et al. have clearly shown that aberrant expression of ZEB1 occurs in part due to IGF-1, and the activated ZEB1 is then able to promote epithelial prostate cancer cells to exhibit a mesenchymal phenotype.[23] Kim et al. found that overexpression of a constitutively activated IGF-1R was sufficient to cause human mammary epithelial cells to undergo an EMT which was associated with dramatically increased migration and invasion.[24] Moreover, overexpression of IGFBP4 in U343 glioma cells resulted in upregulation of molecules involved in tumor growth, EMT, and invasion.[25] Herein, we showed that IGF-1 treatment caused GBM8401 cells to lose their polygonal appearance and cell−cell contacts leading to the acquisition of an elongated, spindle-shaped morphology, suggesting that GBM8401 cells underwent EMT. Taken together, these data indicate that IGF-1 can initiate EMT in cancer cells and promote tumor cell metastasis. Moreover, targeting IGF-1 signaling in GBM may be a promising anticancer strategy.

There are several zinc finger transcription factors, including Snail, Twist, and ZEB1, which have been described as E-cadherin repressors. Herein, our Western blotting analysis showed that IGF-1 increased both the expressions of Snail and Twist, but not the ZEB1 expression. Mikheeva et al. revealed that Twist promoted invasion through mesenchymal changes in GBM.[26] Zhang et al. indicated that Snail promoted the migratory and invasive properties of glioma cells.[27] Taken together, these data show that expression of Snail and Twist is characteristic of mesenchymal tumor areas of GBM, suggesting that similar mechanisms involved in the EMT in epithelial neoplasms played a role in mesenchymal differentiation in GBM.

Following binding of IGF-1 to the extracellular subunits of the IGF-1R, it leads to the activation of at least 2 main pathways: first via RAS, RAF, and Erk1/2, and second via the PI3K and Akt signaling pathway. Our data suggest that Erk1/2 and Akt are upstream factors of Snail and Twist activation in GBM cells. IGF-1 has been shown to activate the Erk1/2 and Akt signaling pathways in various cancer cells, and we showed in GBM8401 cells that Snail and Twist expressions were Erk1/2 and Akt dependent. Pharmacologic inhibition of Erk1/2 and Akt signaling has been shown to decrease invasion or inhibit specific biochemical changes consistent with EMT.[28,29] Our results are consistent with previous reports, suggesting that Erk1/2- and Akt-dependent pathways are sufficient to maintain the mesenchymal phenotype.

Recent studies showed that osthole regulates the proliferation, apoptosis, and invasion in many cancer cells via multiple signaling pathways.[30,31] Moreover, osthole has essential roles in brain functions by protecting neurons, suggesting that osthole could penetrate the blood−brain barrier for the chemotherapy drugs of brain tumors.[14−16] In the present study, we first evaluated the effects of osthole on IGF-1 induced EMT in GBM8401 cells. The present study showed that IGF-1 induced EMT in GBM8401 cells and this process could be effectively blocked by osthole. Pretreatment with osthole blocks IGF-1-induced EMT, however, how osthole affects these changes remain to be determined.

To further delineate the molecular mechanism of osthole blocking IGF-1-induced EMT, related pathways were investigated. In the study, both Erk1/2 and PI3K/Akt signaling pathways were investigated in osthole-treated GBM8401 cells.

GBM8401 cells were pretreated with osthole and showed significant decrease of phospho-Akt but no obvious decrease of phospho-Erk1/2. Our previous studies showed that osthole suppresses fatty acid synthase expression in HER2-overexpressing breast cancer cells through modulating the Akt/mTOR pathway[31] and suppresses the hepatocyte growth factor (HGF)-induced epithelial−mesenchymal transition via repression of the c-Met/Akt/mTOR pathway in human breast cancer cells.[13] Ding et al. revealed that osthole inhibited the proliferation, promoted apoptosis, and inhibited cell migration/invasion in vitro in glioma cells through inhibiting both PI3K/Akt and MAPK signaling pathways.[32] Xu et al. showed that osthole induced G2/M arrest and apoptosis in lung cancer A549 cells by modulating the PI3K/Akt pathway.[33] Based on these findings, osthole may be an ideal inhibitor for PI3K/Akt signaling pathway.

ance liquid chromatography coupled to photodiode array and mass spectrometry detectors (HPLC-DAD-MS^n).

MATERIALS AND METHODS

Chemicals. HPLC-grade methanol, methyl *tert*-butyl ether (MTBE), acetonitrile, and formic acid were obtained from Merck (Darmstadt, Germany). The other reagents were all analytical grade and obtained from Labsynth (Diadema, Brazil). The samples and solvents were filtered through Millipore (Billerica, MA, USA) membranes (0.22 and 0.45 μm) before the HPLC analyses. The standards for all-*trans*-β-carotene (99.5%), all-*trans*-β-cryptoxanthin (99.0%), all-*trans*-lutein (98.0%), cyanidin 3-glucoside (98.9%), cyanidin 3-rutinoside (98.0%), and gallic acid (99%) were purchased from Sigma-Aldrich (Darmstadt, Germany). Standards of 9-*cis*- (99%), 13-*cis*- (98%), and 15-*cis*-β-carotene (97%) were provided by DSM Nutritional Products (Basel, Switzerland). The cyanidin 3-rhamnoside chloride (98%), cyanidin 3-sambubioside chloride (97%), and pelargonidin 3-glucoside chloride (98%) standards were obtained from Extrasynthése (Genay, France). The purity of these standards was determined by HPLC-DAD, and they were used as received.

Samples. The fruits were collected from the Atlantic Forest (Figure 1S). The samples of grumixama (*Eugenia brasiliensis* Lam.), jussara (*Euterpe edulis* Mart.), araça (*Psidium cattleianum* Sabine), and uvaia (*Eugenia pyriformis* Cambess) were obtained from Bello's farm, located in Paraibuna (latitude 23°23′10″ S and longitude 45°39′44″ W) in São Paulo State, Brazil. The fruits were harvested at ripe stage. They were part of batches sent to the fresh fruit market and were also used to obtain frozen pulp (farm produced). The fruits endured a selection and washing process before being pulped to remove any seeds or other inedible parts. The pulps were immediately frozen in farm and sent to the laboratory. The samples were stored at −40 °C until analysis. The harvest and sampling of the fruits were conducted between April and November of 2011. The fruit pulps were analyzed from a 3.0 kg single batch.

Characterization and Proximate Composition of Pulp. Each fruit pulp was thawed, homogenized, and characterized regarding pH and total soluble solids. The analyses of the moisture, protein (nitrogen conversion factor of 6.25 total protein), lipids, fiber, and ash contents were performed according to the official methods of AOAC.[16] The carbohydrate content of the samples was obtained using the difference between the total percentage of moisture, protein, lipids, fiber, and ash. The energy value was expressed in kcal/100 g and was calculated using the conversion factors of nutrients into energy (1 g of protein = 4 kcal, 1 g carbohydrate = 4 kcal, and 1 g of fat = 9 kcal). All analyses were performed in triplicate.

HPLC-DAD-MS^n Analysis of the Carotenoids, Anthocyanins, and Other Phenolic Compounds. The carotenoids, anthocyanins, and phenolic compounds were determined with a Shimadzu HPLC (Kyoto, Japan) equipped with quaternary pumps (model LC-20AD), a DAD detector (Shimadzu, model SPD-M20A), a degasser unit (DGU-20A5), and a Rheodyne injection valve with a 20 μL loop. The equipment was also connected in series to a mass spectrometer (Esquire 4000 model) from Bruker Daltonics (Bremen, Germany) with an ion-trap analyzer (MS^n), as well as APCI (atmospheric pressure chemical ionization) and ESI (electrospray ionization) sources.

The carotenoids were exhaustively extracted with acetone from 15 g of fruit pulp and transferred to petroleum ether/diethyl ether (2:1); the solution was saponified overnight at room temperature with 10% methanolic KOH, washed until alkali free, and concentrated to dryness.[17,18] The experimental conditions for the separation, identification, and quantification by HPLC-DAD-APCI-MS^2 were the same as previously described.[17]

The following parameters were utilized to identify the carotenoids: elution order on a C_{30} reversed phase column, cochromatography with standards, UV/visible spectral features (λ_{max}, spectral fine structure (%III/II), and *cis* peak intensity (%A_B/A_{II})), and MS spectrum characteristics compared to standards analyzed under the same conditions and data available in the literature.[18−21] In addition, the protonated molecule ($[M + H]^+$) was assigned and confirmed using second-order MS fragmentation. The carotenoids were quantified by HPLC-DAD using five-point analytical curves of all-*trans*-lutein (1.0−50.0 μg/mL), all-*trans*-β-cryptoxanthin (1.0−60 μg/mL), and all-*trans*-β-carotene (1.0−50 μg/mL). The limit of detection (LOD) was calculated using the parameters of each standard curve: LOD = 3.3 × SD/S, where SD is the standard deviation of the response and S is the slope of the curve. For the three analytical curves of carotenoids, R^2 = 0.99, the limit of detection was 0.1 μg/mL, and the limit of quantification was 0.5 μg/mL. The carotenoid concentration was expressed in μg/100 g of fresh matter (f.m.). All analyses were performed in triplicate.

The anthocyanins were extracted from the grumixama and jussara pulps (20 g) using 100 mL of 0.5% HCl in methanol overnight at 5 °C under darkness. The slurry was filtered, and the solids were washed with an additional 100 mL of 0.5% HCl in methanol at room temperature three times. The acidic methanol extracts were combined and concentrated in a rotary evaporator (T < 38 °C) to yield the crude extract. The crude extract was diluted with water containing 5% formic acid/methanol (85:15, v/v) immediately before analysis by HPLC-DAD-MS^2. The anthocyanin separation was carried out as previously described.[22]

The anthocyanins were identified based on the combined information provided by elution order in the C_{18} reversed phase column and cochromatography with standards, as well as UV−visible and mass spectra in comparison with the literature data.[22−25] The anthocyanins were quantified using the percentage of the area obtained during the HPLC-DAD-ESI-MS^2 analysis and the monomeric anthocyanin content. The monomeric anthocyanin content was evaluated using the pH-differential method, as described by Lee et al.[26] The concentration was expressed in mg cyanidin 3-glucoside/100 g fresh matter or mg cyanidin 3-rutinoside/100 g fresh matter according to the major anthocyanin identified. All analyses were performed in triplicate.

The other phenolic compounds were extracted from 20 g of frozen pulp with 100 mL of methanol/water (8:2 v/v) by agitation provided by a magnetic homogenizer (Tecnal, Piracicaba, Brazil) for 20 min. The slurry was filtered, and the solids were washed with an additional 50 mL of methanol/water (8:2) two times more and concentrated in a rotary evaporator (T < 38 °C) until methanol evaporation. The extract was used to determine the phenolic compounds by HPLC-DAD-ESI-MS^n, as previously described.[27] The phenolic compounds were tentatively identified based on the following information: elution order, retention time, and UV−visible and mass spectral features compared to those of the standards analyzed under the same conditions and the available literature data.[27−29] The phenolic compounds were quantified using a seven-point analytical curve of gallic acid (0.5−60 mg/mL). The analytical curve was linear (r^2 = 0.99); the limit of detection was 0.2 μg/mL, and the limit of

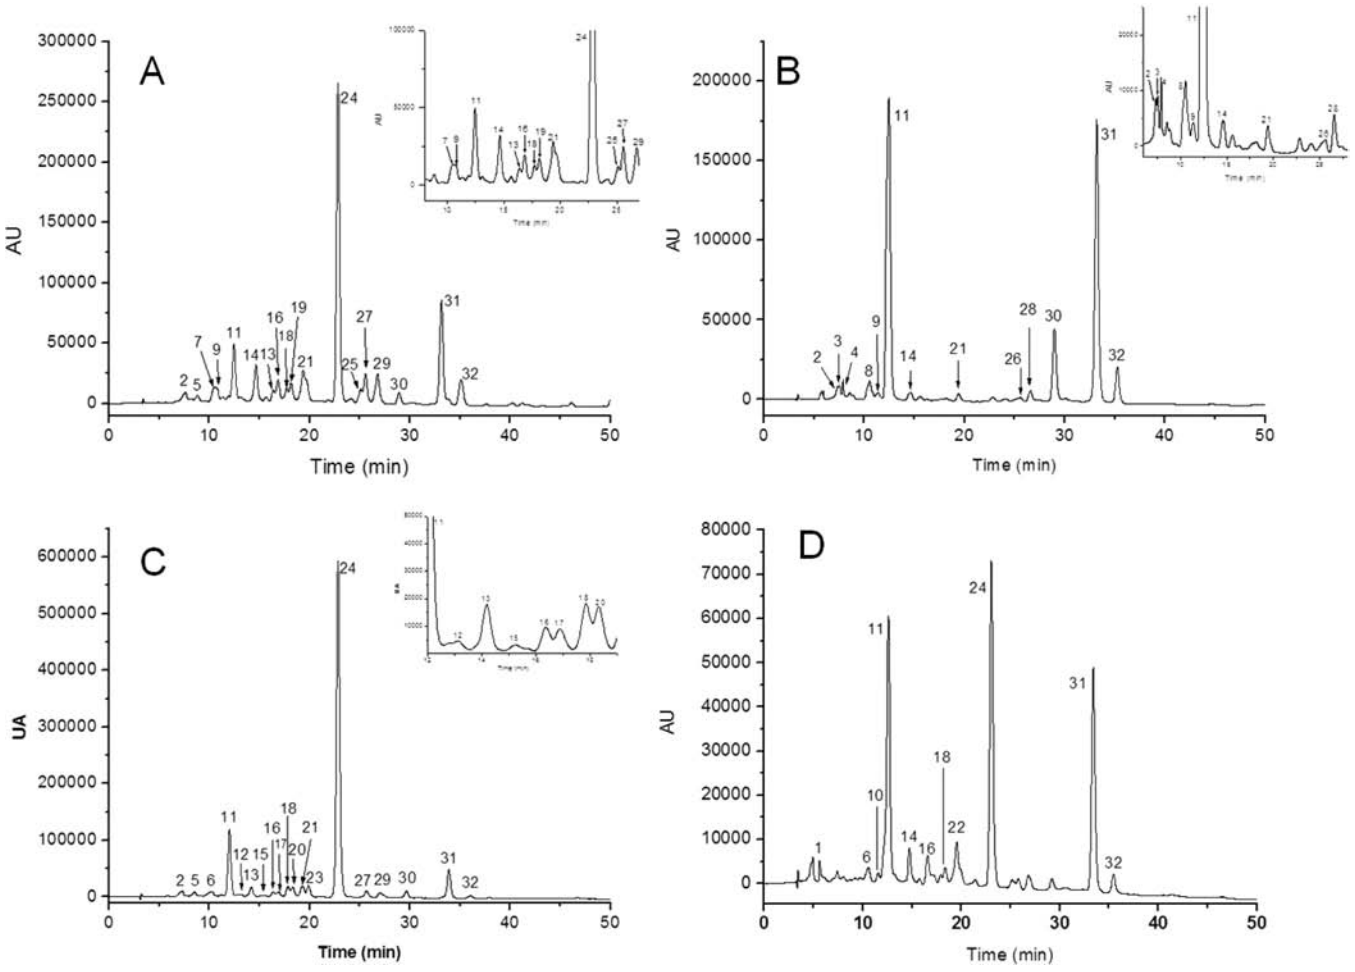

Figure 1. Chromatogram, obtained by HPLC-PDA-MS/MS, of the carotenoids from Atlantic Forest fruits: (A) uvaia, (B) jussara, (C) grumixama, and (D) araça. Chromatographic conditions: see text. Peak identification and characterization are given in Table 2. Processed at 450 nm.

quantification was 0.5 μg/mL as calculated using the parameters of the analytical curves (standard deviation and the slope). All analyses were performed in triplicate.

Statistical Analysis. The mean and standard deviation results related to the proximate composition and carotenoid and phenolic compound levels were calculated using the Microcal Origin 5.0 software.

RESULTS AND DISCUSSION

Characterization and Proximate Composition of the Fruit Pulp. The jussara fruit pulp had the highest pH (Table 1) and showed characteristics and chemical compositions similar to those of the established standards of identity and quality of açai.[30] Using the parameters of the Brazilian legislation, we might classify jussara as medium (type B) because the soluble solid content was between 11 and 14 degrees Brix. The levels of proteins, lipids, and carbohydrates of jussara, by dry weight, are consistent with the established legislation for açai pulp[30] (6.0 g protein/100 g; 20−60 g lipid/100 and 40 g total carbohydrates/100 g) since there is no current legislative regulation for jussara pulp. Moreover, our results show that the proximate composition of jussara from the state of São Paulo falls into the range of jussara samples obtained from five different regions in the state of Santa Catarina, Brazil.[11] However, the differences observed over the chemical composition of the pulp demonstrate that even jussara, which is native to the Atlantic Forest, is influenced by the soil, temperature, sunlight, and precipitation in the geographic location where the palms are grown.

The pulps under study were obtained from exotic fruits that have no current legislative regulation in Brazil, and only a few data for some fruits are available in the literature. The protein content of uvaia collected in the state of Rio Grande do Sul,[31] Brazil, was approximately 2.9 times higher than that measured in the present study, whereas soluble solid content (7.7°Bx)[11] was slightly lower than our results. In addition, the high fiber contents of these fruits are worth highlighting, particularly those from araça and jussara, because the consumption of a 100 g portion of fresh pulp of either fruit provides approximately 20% of the recommended daily intake of fiber, based on a 2000 kcal diet.

Carotenoid Composition. Figure 1 shows the chromatograms of the carotenoids from the four Atlantic Forest fruit pulps. The carotenoids separated from the jussara, grumixama, araça, and uvaia pulps were identified based on the combined information obtained from the chromatographic elution and UV−visible and mass spectral data (Table 2). Considering that a detailed description of carotenoid identification has already been reported,[18,22] only the most important aspects are discussed below.

As expected for the reversed phase columns, polar carotenoids with three and two hydroxyl groups, such as 9-*cis*-neoxanthin (peak 2) and all-*trans*-lutein (peak 11), eluted

[a]Numbered according to the chromatograms shown in Figure 1. [b]Tentative identification based on UV−vis and mass spectra as well as relative HPLC retention times and published data. [c]Linear gradient of methanol/MTBE. [d]n.d.: not detected. [e]n.c.: not calculated.

before the monohydroxy carotenoids (all-*trans*-β-cryptoxanthin, peak 24). The carotenes, including the all-*trans*-α-carotene (peak 30) and all-*trans*-β-carotene (peak 31), were the last to elute under these conditions. The carotenoids with 5,6-epoxide and/or 5,8-furanoid groups located on the 3- or 3′-hydroxy β-rings, 9-*cis*-neoxanthin (peak 2), 13-*cis*-violaxanthin (peak 4), and 9-*cis*-violaxanthin (peak 9) showed UV−vis and mass spectra features similar to those reported in the literature.[18−21]

Although the all-*trans*-lutein (peak 11) and all-*trans*-zeaxanthin (peak 14) have the same chemical formula ($C_{40}H_{56}O_2$) and therefore identical protonated molecule $[M + H]^+$ at m/z 569, zeaxanthin possesses two β-rings, while lutein has one β-ring and one ε-ring. Therefore, one of the lutein hydroxyl groups is allylic to the double bond in the ε-ring and not conjugated with the polyene chain, resulting in 10 conjugated double bonds (c.d.b.). However, zeaxanthin has both double bonds in the β-ring conjugated to the polyene chain; consequently, its chromophore displays 11 c.d.b. Therefore, it is possible to distinguish these two compounds using their UV−visible and mass spectra. As expected, zeaxanthin showed λ_{max} values (427, 450, 475 nm) higher than those of lutein (420, 444, 472 nm). The mass spectrum of zeaxanthin showed a more intense protonated molecule peak ($[M + H]^+$) at m/z 569 compared to the fragment at m/z 551 $[M + H - 18]^+$, while the opposite was observed for lutein.[18,21,22]

Peak 24 was identified as all-*trans*-β-cryptoxanthin; the protonated molecule was detected at m/z 553 along with less intense fragments at m/z 535 $[M + H - 18]^+$ and 461 $[M + H - 92]^+$, generated from the loss of a hydroxyl group and toluene, respectively. The isomers 15-*cis*-β-cryptoxanthin (peak 17), 13- or 13′-*cis*-β-cryptoxanthin (peaks 18 and 20), and 9- or 9′-*cis*-β-cryptoxanthin (peaks 27 and 29) were tentatively identified by comparing their elution order and UV−vis characteristics with the literature data.[22] The fine spectral structure (%III/II) decreases and the intensity of the *cis*-peak (%A_B/A_{II}) increases as the *cis*-double bond gets closer to the center of the molecule. However, it was not possible to differentiate between the 13-*cis* and 13′-*cis* or between the 9-*cis* and 9′-*cis* isomers of β-cryptoxanthin because there are no data available in the literature reporting their elution order on a C_{30} column after assignment of the *cis*-double bond positions in the β-cryptoxanthin structure using nuclear magnetic resonance. All-*trans*-β-carotene (peak 31) and its *cis* isomers (15-*cis*- (peak 26), 13-*cis*- (peak 28), and 9-*cis*-β-carotene (peak 32)) were confirmed via coelution with authentic standards, as well as comparison of the UV−vis and mass spectral features with standards and literature data.[18,21,22]

[a] n = 3 samples. n.d.: not detected. [b] The peaks were quantified as equivalent to all-*trans*-lutein. [c] The peaks were quantified as equivalent to all-*trans*-β-cryptoxanthin. [d] The peaks were quantified as equivalent to all-*trans*-β-carotene. [e] RAE: retinol activity equivalent.

According to Table 3, the total carotenoid content was highest in uvaia, followed by jussara and grumixama, and finally araça. The HPLC chromatogram separating the 18 carotenoids from uvaia is shown in Figure 1A. The all-*trans*-β-cryptoxanthin was the major carotenoid, representing 40% (m/m) of the total carotenoids content in this fruit pulp, followed by all-*trans*-β-carotene, which contributed 13% (m/m), in agreement with those reported in the literature for uvaia harvested in Rio Grande do Sul (South Brazil).[31] The levels of total carotenoids found in this study were lower than those previously reported (1700 μg/100 g fresh weight[32] for uvaia collected in Ceará (northwest region of Brazil)).

A typical HPLC-DAD chromatogram depicting the carotenoids from jussara is presented in Figure 1B, demonstrating the separation of 13 carotenoids on the C_{30} column. All-*trans*-lutein was the major carotenoid (39%, m/m) followed by all-*trans*-β-carotene (36%, m/m). The total carotenoid content found in the present study (737.5 μg/100 g) was 2.6 times lower than that found previously in jussara (1900 μg/100 g fresh matter) collected in Santa Catarina (South Brazil).[32] As far as we are concerned, this is the first report on the carotenoid profile of jussara.

Figure 1C shows the chromatogram of the carotenoids from grumixama, with 19 separated carotenoids, the principal ones being all-*trans*-β-cryptoxanthin (56%, m/m) and all-*trans*-lutein (11%). Studies regarding the carotenoid composition in grumixama were not found in the literature.

As observed in Figure 1D, 11 carotenoids from araça were separated on a C_{30} column, and nine were identified. The all-*trans*-β-cryptoxanthin was the major carotenoid, representing 34% of the total carotenoid content in this fruit, followed by all-*trans*-β-carotene and all-*trans*-lutein, corresponding to 26% and 20% of the total content, respectively. The other six minor carotenoids identified corresponded to 18.4% of the total content. This is the first report of the carotenoid composition of araça using mass spectrometry. In another study lutein has

[a]Peaks numbered according to Figure 2. [b]Linear gradient of water 5% v/v formic acid/methanol. C3G, cyanidin 3-glucoside; C3R, cyanidin 3-rutinoside. [c]Calculated using the percentage of the area and the content of monomeric anthocyanins. [d]n.d.: not detected. [e] n.i.: not identified.

been identified as the major carotenoid in araça (26.38 μg/g dry bases),[31] using only HPLC-DAD.

According to the classifications of good sources of carotenoids (low: 0−100 μg/100 g; moderate: 100−500 μg/100; high: 500−2000 μg/100 g; and very high: >2000 μg/100 g) proposed by Britton and Khachik,[33] uvaia and grumixama are high sources of carotenoids, particularly of β-cryptoxanthin (all-*trans* + *cis* isomers), while jussara is a moderate source of all-*trans*-lutein. However, araça is not a good source of carotenoids. Among the Atlantic Forest fruits evaluated in this study, the provitamin A activity value was higher in uvaia and jussara (Table 3). However, none of the fruits studied can be considered a good source of provitamin A compared with the Amazonian fruits[18] and acerola cultivar Olivier.[17]

Anthocyanin Composition. A typical chromatogram of the anthocyanins from grumixama is shown in Figure 2A, and their characteristics are presented in Table 4. The analysis performed by HPLC-DAD-MS/MS separated five anthocyanins. Peak 1 was identified as delphinidin 3-glucoside. This anthocyanin had a molecular ion at m/z 465 and a 303 u fragment related to the loss of a hexose; the identity of the hexose was assumed to be glucose according to the elution order.[24,25] Peaks 2 and 3 were identified as cyanidin 3-galactoside and cyanidin 3-glucoside, respectively. Both anthocyanins have a molecular ion at m/z 449 and a fragment at m/z 287 that is related to the loss of a hexose. This identification was confirmed using the elution order[24] and the coelution of peak 3 with a cyanidin 3-glucoside standard. The molecular ion and MS/MS fragments were not detected in peak 4, and thus this peak was not identified. Peak 5 exhibited a molecular ion at m/z 491, and in the MS/MS data, only a 287 u fragment ion was detected, indicating the presence of cyanidin after the loss of either an acetyl hexose or an oxalyl pentose moiety (204 u). Considering the occurrence of acylated anthocyanins in foods,[24,25] peak 5 was tentatively identified as cyanidin (acetyl)hexoside.

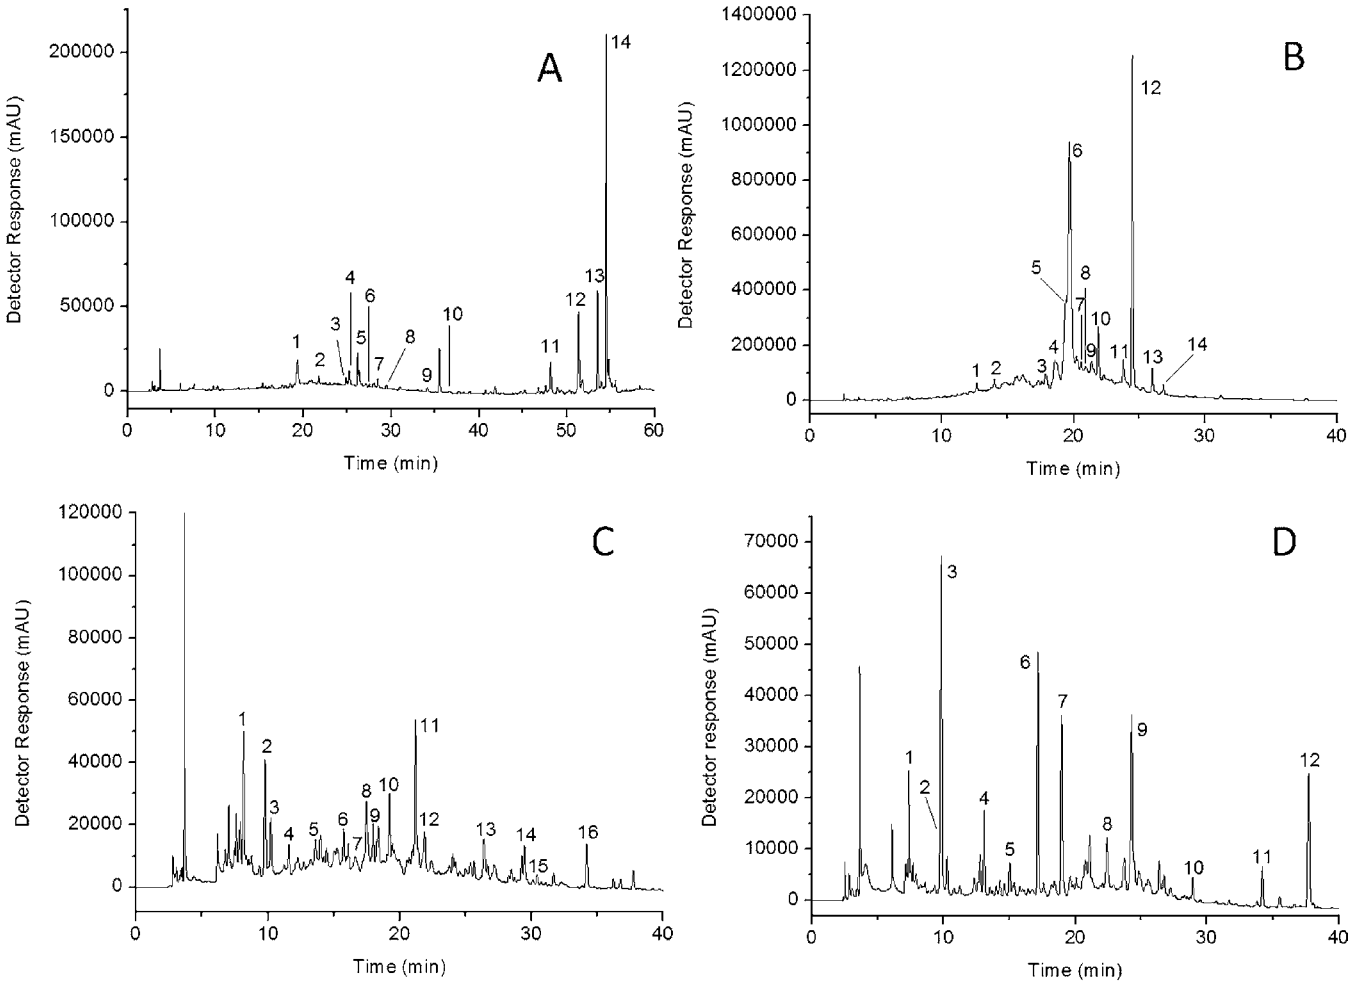

Figure 3. Chromatogram, obtained by HPLC-PDA-MS, of the phenolic compounds from Atlantic Forest fruits: (A) grumixama, (B) jussara, (C) araça, and (D) uvaia. Chromatographic conditions: see text. Peak identification and characterization are given in Tables 5 and 6. Processed at 280 nm.

The major anthocyanins found in grumixama were cyanidin 3-glucoside (94%) and delphinidin 3-glucoside (3.5%); the other anthocyanins (peaks 2, 4, and 5) were detected in amounts below 1.5%. These two major anthocyanins and cyanidin 3-galactoside are coincident with those reported in the literature;[13] however, cyanidin 3-acetylhexoside was not found by Flores et al.[13] and is therefore reported in grumixama for the first time. Cyanidin 3-arabinoside, delphinidin 3-pentoside, cyanidin 3-xiloside, malvidin 3-glucoside, and anthocyanidins delphinidin and cyanidin were detected in small amounts in grumixama by Flores et al.[13] but were not found in the present study. The monomeric anthocyanin level found in the present study was lower than that reported by Haminiuk et al.[14] for grumixama fruits collected in Brazil (266.34 ± 2.92 mg C3G/100 g).

The typical chromatogram of jussara shows the separation of seven anthocyanins (Figure 2B), and their characteristics are presented in Table 4. Peak 1 had a molecular ion peak at m/z 581, and two mass fragments were detected: one at m/z 449 related to the loss of one molecule of pentose ($[M - 132]^+$) and another at m/z 287 generated by elimination of one molecule of pentose plus one hexose ($[M - 132 - 162]^+$), furnishing a cyanidin aglycone with 287 u. Due to the presence of the fragment with 449 u, anthocyanin 1 was characterized as cyanidin 3,5-diglycosilated with a hexose and a pentose as the monosaccharides. However, the exact position of these two sugars could not be determined by MS. The identification as cyanidin 3-sambubioside could be excluded because two MS/MS fragments at m/z 287 and 449 were detected.[23]

In the mass spectrum of peak 2, the molecular ion was observed at m/z 449 with a fragment ion with 287 u ($[M - 162]^+$) by second-order MS, corresponding to the cyanidin moiety after hexose loss (162 u). The sugar moiety was confirmed to be glucose by coelution of peak 2 with the cyanidin 3-glucoside standard. Peak 3 showed a molecular ion at m/z 595 and two mass fragments with 287 and 449 u; the first corresponded to the cyanidin moiety after rutinose loss (308 u), and the fragment at m/z 449 resulted from the loss of deoxyhexose $[M - 146]^+$. The only disaccharide that showed fragmentation by MS/MS due to cleavage of the glycosidic bonds between the monosaccharides is rutinose, as previously described in the literature.[23−25] Cyanidin 3-rutinoside was definitively identified by coelution with a standard.

The mass spectrum of peak 4 showed a molecular ion at m/z 433 and an MS/MS fragment at m/z 271, corresponding to pelargonidin after the loss of a hexose. The identification of this anthocyanin was confirmed as pelargonidin 3-glucoside by coeluting peak 4 with the pelargonidin 3-glucoside standard. Peaks 5 and 6 were identified as pelargonidin 3-rutinoside and peonidin 3-rutinoside, respectively. The mass spectra of both

[a]Retention time on the C_{18} Synergi Hydro (4 μm) column. [b]Tentative identification based on UV–vis and mass spectra as well as relative HPLC retention times and published data. [c]Solvent: gradient of 0.5% formic acid in water and acetonitrile with 0.5% formic acid. [d]Peaks were quantified as equivalent to gallic acid.

anthocyanins showed the corresponding expected molecular ions (m/z 579 and 609, respectively) and two mass fragments after the loss of rhamnose and rutinose units, as verified in the MS/MS spectra. The molecular ion of peak 7 was found at m/z 433 with a fragment at m/z 287, indicating that the aglycone cyanidin was glycosylated with a deoxyhexose due to the loss of 146 u; this peak was identified as cyanidin 3-rhamnoside by coelution with the standard.

Cyanidin 3-glucoside (peak 2), cyanidin 3-rutinoside (peak 3), pelargonidin 3-glucoside (peak 4), pelargonidin 3-rutinoside (peak 5), and cyanidin 3-rhamnoside (peak 7) were also previously detected in jussara fruit.[12] In the present study cyanidin 3,5-diglycosilated with a hexose and a pentose was found instead of cyanidin 3-sambubioside;[12] our identification was confirmed by UV–vis and MS and the lack of coelution with the cyanidin 3-sambubioside standard. Peonidin 3-

dx.doi.org/10.1021/jf501211p | J. Agric. Food Chem. 2014, 62, 5072–5084

rutinoside (peak 6) was identified in jussara for the first time in the present study.

The monomeric anthocyanin content (239.16 ± 7.6 mg C3R/100 g) found in our jussara pulp was similar to the literature ranges for jussara pulps (192 mg/100 g f.m.[32] and 207 mg/100 g f.m. in jussara collected in region C in Santa Catarina State).[11] When compared to other fruits from the *Euterpe* genus, jussara showed a lower content of monomeric anthocyanins than those reported for açai (*Euterpe oleracea*) (282−303 mg C3G/100 g[23]). Similar to the results for jussara with 20% cyanidin 3-glucoside and 76% cyanidin 3-rutinoside, açai also shows large fractions of cyanidin 3-glucoside (12.5−13.2%) and cyanidin 3-rutinoside (86.8−87.5%).[23]

Profile of Phenolic Compounds. The HPLC-DAD-ESI$^-$-MS/MS method allowed for the separation and tentative identification of 14 phenolic compounds in the grumixama pulp (Figure 3A). Peak 1 was positively identified as cyanidin 3-glucoside based on coelution and comparison of the UV and mass spectral data with an authentic standard. Peaks 2−7, 9, and 10 belong to a series of quercetin derivatives (Table 5). All peaks exhibited λ_{max} values characteristic of flavonols, at 352−365 nm. Peaks 4, 5, 6, and 7 presented deprotonated molecules at m/z 447, 463, 433, and 433, respectively. In addition, the MS/MS fragmentation pattern obtained from these ions revealed the same fragment at m/z 301 corresponding to quercetin, suggesting neutral losses of the sugar moiety, deoxyhexose (loss of 146 u from $[M - H]^-$ in peak 4), hexose (loss of 162 u from $[M - H]^-$ in peak 5), and pentose (loss of 132 u from $[M - H]^-$ in peaks 6 and 7). Therefore, these peaks were identified as quercetin deoxyhexoside (peak 4), quercetin hexoside (peak 5), and quercetin pentoside (peaks 6 and 7). Peaks 2 and 3 show deprotonated molecules at m/z 477 and 615, respectively, and they showed MS/MS fragments at m/z 301 (loss of 176 u from $[M - H]^-$ in peak 2), as well as at m/z 463 and 301 (losses of 152 and 162 u from $[M - H]^-$ in peak 3). Consequently, these peaks were tentatively identified as quercetin glucuronide (peak 2) and quercetin galloylhexoside (peak 3). Due to the MS (m/z 609) and MS^2 (m/z 463, 301) data, quercetin deoxyhexosylhexose is presumptively identified as peak 9. Peak 10 was identified as quercetin (aglycone) based on coelution and comparison of the UV−vis and mass spectral data with an authentic standard. This peak presented a $[M - H]^-$ peak at m/z 301 and typical MS/MS fragmentation ions for quercetin at m/z 273 (loss of CO), 257 (loss of CO_2), and 229 (loss of CO + CO_2); the most interesting fragments concern the base peaks at m/z 179 and 151, due to a specific retro-Diels−Alder pathway leading to the $^{1,2}A^-$ and $^{1,3}A$ − CO.

Peaks 11, 13, and 14 were tentatively identified as sinapic acid derivatives, and peak 12 was not identified. Peak 11 was identified as sinapic acid dihexoside hydroxybenzoyl because of the deprotonated molecule at m/z 685 and MS/MS fragments at m/z 461 due to synapic acid loss (224 u) and at m/z 299 and 137 (loss of two hexose molecule). Peak 13 shows a $[M - H]^-$ peak at m/z 699 and MS/MS fragments at m/z 493, 331, and 169 after losing a sinapoyl group (206 u) and two hexose molecules, respectively. In addition the fragment at m/z 169 corresponded to gallic acid; consequently, these peaks were tentatively identified as gallic acid dihexoside sinapoyl. Sinapic acid dihexoside benzoyl (peak 14) was tentatively identified due to a deprotonated molecule at m/z 651 and MS/MS fragments at m/z 427, 265, and 103, suggesting losses of sinapic acid (224 u) and two hexose molecules.

The majority of the phenolic compounds in grumixama were sinapic acid derivatives (peaks 14 (43.2%) and 13 (13.5%)). The total phenolic compounds in grumixama comprised 145.2 ± 8.6 mg GAE/100 g fresh weight, while Haminuik et al.[14] reported a value of 25.98 ± 1.43 mg GAE/g dry basis. As far as we are concerned, this is the first report on the phenolic composition (except anthocyanins) from grumixama.

The HPLC chromatogram of the jussara extract is shown in Figure 3B. According to Table 5, 14 phenolic compounds were tentatively identified. The major phenolic compounds found in jussara include cyanidin 3-glucoside (peak 5), cyanidin 3-rutinoside (peak 6), and dihydrokaempferol hexoside (peak 12). Peaks 5 and 6 show their deprotonated molecule $[M - H]^-$ peaks at m/z 447 and 593, respectively. The MS/MS spectra of these compounds show fragments at m/z 285 for both peaks due to neutral hexose (peak 5) and rutinose losses (peak 6). This identification was confirmed in ESI positive mode during the anthocyanin analyses and by coelution with an authentic standard. Peak 12 was tentatively identified as dihydrokaempferol hexoside because the deprotonated molecule showed a $[M - H]^-$ peak at m/z 449 and MS/MS fragments at m/z 287 (loss of hexose molecule), corresponding to the dihydrokaempferol moiety, and at m/z 269 (loss of hexose molecule + H_2O). The fragment at m/z 269 (100%) was more intense than the fragment at m/z 287 (4%). The MS^3 spectra from the ion at m/z 287 showed typical flavanonol fragmentation. The fragments were detected at m/z 269 $[M - H - 18]^-$, m/z 243 $[M - H - 44]^-$, and m/z 215 $[M - H - 72]^-$, corresponding to the neutral losses of H_2O, CO_2, and CO + CO_2, respectively, and retro-Diels−Alder fragments were detected at m/z 151 ($^{1,3}A^-$) and 107 ($^{1,3}A^-$ − CO_2). Our MS data agree with those previously reported.[34,35]

Two other kaempferol derivatives are tentatively identified in jussara as peak 13 (kaempferol deoxyhexosylhexoside) and peak 14 (dihydrokaempferol acetylhexoside). Peak 13 shows a $[M - H]^-$ peak at m/z 593 and MS/MS fragments at m/z 447 and 285 after losing a deoxyhexose (146 u) and deoxyhexose + hexose unit (308 u), respectively. An MS^3-specific fragment (257, 243, 213, and 151) confirms the identity as kaempferol.[40] Peak 14 has a $[M - H]^-$ ion at m/z 491 and MS^2 ions at m/z 287 and 269, suggesting neutral losses of acetyl-hexose (204 u) and acetyl-hexose + H_2O (222 u). Peak 1 was tentatively identified as monogalloyl hexoside in jussara because of the deprotonated molecule at m/z 331, as well as the two MS^2 fragments at m/z 169, corresponding to the gallic acid moiety (loss of hexose) and m/z 125, corresponding to the consecutive losses of hexoside (162 u) and the CO_2 molecule (44 u). This fragmentation has been reported in *Caryocar villosum*[27] and jambolão.[36] Peak 2 was not identified; the deprotonated molecule had a m/z of 359, and the MS/MS fragment was at m/z 197, resulting from the loss of a hexose.

Five flavones were identified in jussara, three apigenin derivatives (peaks 3, 7, and 8), one luteolin derivative (peak 4), and one chrysoeriol derivative (peak 9). The flavones and their glycosides present two λ_{max} values at 320−370 and 250−280 nm due to their B-rings (cinnamoyl structure) and A-rings (benzoyl structure), respectively. The UV−vis spectra of the apigenin derivatives have λ_{max} values at 279 and 323−328 nm. Peaks 3, 7, and 8 were tentatively identified as apigenin dihexoside ($[M - H]^-$ at m/z 593), apigenin hexoside ($[M - H]^-$ at m/z 431), and apigenin deoxyhexosylhexoside ($[M - H]^-$ at m/z 577), respectively. All three compounds showed an MS^2 fragment at m/z 269 (apigenin moiety) as the most

[a]Retention time on the C_{18} Synergi Hydro (4 μm) column. [b]Tentative identification based on UV−vis and mass spectra as well as relative HPLC retention times and published data. [c]Solvent: gradient of 0.5% formic acid in water and acetonitrile with 0.5% formic acid. [d]Peaks were quantified as equivalent to gallic acid. [e]n.d.: not detected.

abundant ion, suggesting neutral losses of the sugar units. The MS^3 fragments from the ion at m/z 269 for peaks 3, 7, and 8 were not detected. Peak 4 was tentatively identified as luteolin deoxyhexosylhexoside according to the UV−vis spectra (λ_{max} at 273 nm (band II) and 323 nm (band I)) and MS fragmentation, leading to the luteolin aglycone at m/z 285 after loss of 146 u + 162 u (deoxyhexose and hexose moiety). The deprotonated molecule in peak 9 was observed at m/z 607, and the MS^2 fragment was detected at m/z 299, suggesting the loss of a rutinose unit. Chrysoeriol rutinoside (peak 9) and dihydroluteolin rutinoside (peak 11) were tentatively identified in jussara; both compounds showed a neutral loss of rutinose (308 u) from the deprotonated molecule at m/z 607 for peak 9 and at 595 for peak 11.

The three major phenolic compounds (peaks 5, 6, and 12) identified in jussara in this study were not reported in previous studies, but these compounds have been already identified in açai.[35,37] Previous studies have reported the presence of ferulic, gallic, protocatechuic, and coumaric acids, as well as catechin, epicatechin, and quercetin in jussara collected from the state of Santa Catarina, Brazil.[11] However, these compounds were not identified using mass spectrometry, which is currently the most suitable technique coupled to HPLC for identifying phenolic compounds in complex matrixes, such as fruit. Furthermore, we

dx.doi.org/10.1021/jf501211p | J. Agric. Food Chem. 2014, 62, 5072−5084

did not find the phenolic compounds reported by Da Silva Campelo Borges et al.[11] in our study.

The chromatograms of the phenolic compounds from araça and uvaia are shown in Figure 3C and D, respectively. Table 6 shows the chromatographic, UV−vis, and mass spectral data used to identify these compounds. Peak 2 from the phenolic compounds in araça (Figure 3C) and uvaia (Figure 3D) was identified as gallic acid because, in addition to presenting a maximum absorption in the UV−vis spectrum of 271 nm, the deprotonated molecule was detected at m/z 169 with a fragment in the MS^2 spectrum at m/z 125 due to neutral loss of 44 u (CO_2). The identification was confirmed by coelution with an authentic standard. Peaks 3 for araça and 1 and 3 of uvaia were identified as monogalloyl hexoside after they presented a deprotonated molecule at m/z 331 and three fragments in the MS^2 spectrum at m/z 271 after cross-ring fragmentation of the hexoside ring (M − H − 60) at m/z 169, corresponding to the gallic acid moiety, and at m/z 125 due to the decarboxylation of gallic acid (44 u). Notably, the existence and intensity of each fragment ion may be different for each galloyl hexoside peak, as well as for the other hydrolyzable tannins due to the presence of different isomeric forms in the same fruit.[15,38]

Peak 4 for araça showed a deprotonated molecule at m/z 483, as well as MS^2 fragments at m/z 331 due to loss of a galloyl group (152 u) and at m/z 313 due to loss of gallic acid (170 u). Furthermore, another isomer of digalloyl hexoside may have fragments at m/z 439 and 287; these signals are the result of the deprotonated molecule and the decarboxylation of a gallic acid linked to a hexoside (331 u). These fragmentation mechanisms were demonstrated by Meyers et al.[38] Peaks 5 and 6 for araça showed a UV−vis spectrum with a λ_{max} at 260 nm that is characteristic of dihexahydroxydiphenoyl hexoside (diHHDP-hexoside); furthermore, the two peaks showed a deprotonated molecule at m/z 783, yielding fragment ions at m/z 481 after the loss of a HHDP group, at m/z 301 after the loss of HHDP-hexoside group, and at m/z 257 after the decarboxylation of HHDP. Peaks 7 and 10 for araça showed UV−vis spectra with a λ_{max} at 280 nm and a deprotonated molecule at m/z 785, indicating the presence of HHDP-digalloyl-hexoside. In addition, the MS^2 spectra of these peaks showed fragments at m/z 633 after the loss of a galloyl residue (152 u), at m/z 615 after the loss of a gallic acid molecule, at m/z 483 due to loss of one HHDP group, and at m/z 301 after the loss of an HHDP hexoside molecule. Peak 12 for the araça sample was identified as HHDP-hexoside using the deprotonated molecule at m/z 481 and the MS^2 fragment at m/z 301, indicating the presence of HHDP. The gallic acid derivatives were identified based on literature data.[15,27,38]

In addition to the gallic acid derivatives, araça also contained quercetin hexoside (peak 13) and taxifolin hexoside (peak 11) in its phenolic fraction, presenting deprotonated molecules at m/z 463 and 465, respectively. The MS/MS spectra of these peaks showed fragments at m/z 301 (quercetin) and at m/z 303 (taxifolin), suggesting the loss of hexose units (162 u). Quercetin aglycone was identified and was confirmed using the MS^3 spectra: 273 $[M - H - CO]^-$, 257 $[M - H - CO_2]^-$, 229 $[M - H - CO - CO_2]^-$, 179 $[^{1,2}A]^-$, and 151 $[^{1,3}A]^-$. It was not possible to obtain an MS^3 spectrum from taxifolin, but the UV−vis absorption maxima at 291 and 347 nm helped to tentatively identify this compound. Peak 8 was tentatively identified as vanillic acid hexoside due to the presence of the deprotonated molecule at m/z 329 and the MS^2 fragment at m/z 167 after the loss of a neutral hexose. The UV−vis spectrum of this compound had λ_{max} at 260 and 296 nm, as well as the characteristic features of vanillic acid.

Peak 9 of araça was tentatively identified as the epicatechin−epicatechin dimer due to the protonated molecule at m/z 579 and the MS^2 fragment at m/z 289; the MS^3 spectrum of this fragment showed the characteristic configuration of an aglycone catechin with fragments at m/z 271 $[M - H - H_2O]^-$, 245 $[M - H - CO_2]^-$, 205 $[M - H - CO - CO_2]^-$, 179 $[^{1,2}A]^-$, and 151 $[^{1,3}A]^-$. Araça contained eriodictyol hexoside (peak 14) with a deprotonated molecular ion at m/z 449 and an MS^2 fragment at m/z 287 due to loss of a hexose. The MS^3 of the fragment at 287 was not obtained. Therefore, the identification of the aglycone was attempted. Peaks 15 and 16 were tentatively identified as ellagic acid derivatives (dimethyl ellagic acid hexoside and dimethyl ellagic acid pentoside) because both peaks showed characteristic fragments of methylated ellagic acid at m/z 315 and 313, respectively; at m/z 301, the ellagic acid was confirmed by the MS^3 spectrum of the fragment at 301 from peak 16.

Aside from peaks 1, 2, and 3, uvaia (Figure 3D) showed other derivatives of gallic acid in its phenolic composition. Peaks 6, 7, and 12 are gallic acid derivatives, but they have not been definitively identified. Peaks 7 and 9 were identified as lactonized trigalloyl acid and galloyl HHDP bis-hexoside, respectively. Peak 7 showed a deprotonated molecule at m/z 451 and MS^2 fragments at m/z 313, 282, and 169 that were attributed to galloyl and lactonized galloyl losses. Peak 9 was identified by the deprotonated molecule at m/z 935 and the MS^2 fragment at m/z 783 assigned to the loss of a galloyl group, as well as at m/z 633 due to loss of HHDP and at m/z 301 due to loss of HHDP-hexoside. The identification of this compound has already been reported in the phenolic composition of blackberries[39] and strawberries from Macedonia.[38]

Peak 5 in uvaia was identified as dicaffeic acid, with the deprotonated molecule at m/z 341 and an MS^2 fragment at m/z 179 due to the caffeoyl loss. Furthermore, the MS^3 spectrum at 179 u revealed fragments at m/z 161 and 135 attributed to water loss and decarboxylated caffeic acid, in accordance with the fragmentation pattern for dicaffeic acid proposed by Plazonić et al.[40] Peak 10 of uvaia presented a deprotonated molecule at m/z 447 and an MS^2 fragment at m/z 301 after the neutral loss of 146 u; this material was tentatively identified as quercetin deoxyhexoside. Peaks 4, 8, and 11 could not be identified.

The majority of the phenolic compounds in araça were gallic acid (peak 2, 12.24 ± 0.9 mg GAE/100 g fresh weight) and taxifolin hexoside (peak 12, 11.73 ± 0.8 mg GAE/100 g fresh weight). The total phenolic compounds in araça comprised 103.10 ± 6.5 mg GAE/100 g fresh weight, while Gordon et al.[15] reported a value of 754.4 ± 12.5 mg GAE/100 g dry weight. Although these authors have not quantified the compounds individually, the chromatogram revealed that the major compound was HHDP-digalloylglucoside.

Uvaia presented gallic acid (peak 2, 27.50 ± 1.2 mg GAE/100 g fresh weight) and galloyl HHDP-bis-hexoside (peak 7, 19.32 ± 1.5 mg GAE/100 g weight fresh) as the major phenolic compounds in the total 115.96 ± 7.15 mg GAE/100 g fresh weight. No data were found in the literature identifying the phenolic compounds in uvaia.

In conclusion, carotenoids and phenolic compounds were identified and quantified in four fruits from the Brazilian Atlantic Forest. In addition, jussara showed high levels of

phenolic compounds, primarily consisting of cyanidin 3-rutinoside, dihydrokaempferol hexoside, and cyanidin 3-glucoside. While the phenolic composition of jussara and grumixama was composed of several flavonoid glycosides, uvaia and araça presented mostly gallic acid derivatives. For the carotenoids, uvaia contained the highest concentrations. All-*trans*-β-Cryptoxanthin was the major carotenoid found in uvaia, grumixama, and araça, while all-*trans*-lutein was the major component in jussara. Therefore, these fruits are important as promising sources of bioactive compounds. Additionally, due to their nutritional value, high fiber content, and sweet taste, these four fruits from the Atlantic Forest can be used to supplement the diet of groups such as schoolchildren.

named teaghrelins in this study, were examined for the speculative biological activities via a food intake assay in rats as well as a biochemical assay detecting the stimulation of growth hormone secretion from rat primary anterior pituitary cells. Moreover, metabolites of teaghrelins were examined in bile of rats after intravenous (IV) injection.

MATERIALS AND METHODS

Chemicals and Materials. High-performance liquid chromatography (HPLC)-grade acetonitrile and methanol were purchased from Fisher Scientific (Fair Lawn, NJ). Acetic acid (99.7%) was obtained from J.T.Baker (Mallinckrodt Baker, Inc., Phillipsburg, NJ). Phosphoric acid (85%) was brought from Merck Millipore (Gibbstown, NJ). Purified water was afforded by a Millipore clear water purification system (Direct-Q, Millipore, Billerica, MA). Dulbecco's modified Eagle's medium (DMEM) and dialyzed fetal bovine serum were bought from Invitrogen (Carlsbad, CA). DNase I was obtained from Worthington Biochemical (Lakewood, NJ). GHRP-6 was purchased from GenWay Biotech, Inc. (San Diego, CA). Collagenase type I and [D-Arg^1,D-Phe^5,D-Trp^{7,9},Leu^{11}]-substance P were obtained from Sigma-Aldrich Co. (St. Louis, MO). Different oolong teas prepared from various cultivars (Tieguanyin, Chin-shin, Jin-xuan, Shy-jih-chuen, etc.) of tea plants (*Camellia sinensis*) were gifts or purchased from local manufacturers.

Preparation and HPLC Analysis of Tea Infusions. Tea infusions were prepared by adding 18 mL of boiling water to 1 g of various oolong teas. After 5 min, the brew was filtered through a 0.22 μm polyvinylidene difluoride (PVDF) membrane filter (Pall Corporation, Glen Cove, NY) and used for the following analysis. Chemical constituents in the tea infusions were analyzed on a liquid chromatography system coupled to a model 600E photodiode array detector (Waters Corporation, Milford, MA) and performed using a 250 × 4.6 mm inner diameter, 5 μm, C18 reversed-phase column (Waters Corporation, Milford, MA) as described previously.[19] The mobile phase consisted of (A) water containing 0.026% phosphoric acid and (B) acetonitrile. The gradient was as follows: 0−60 min, linearly gradient from 10 to 30% B; 61−70 min, 30% B; and 70−100 min, linear gradient from 30 to 10% B. The column was maintained at room temperature, and the injection volume was 5 μL at a flow rate of 1 mL/min. The ultraviolet (UV) absorbance detection wavelength was set at 280 nm.

Extraction and Isolation of Teaghrelins. Chin-shin oolong tea granules of 5 kg were powdered and extracted with 40 L of methanol 3 times (7 days for each time) at room temperature. Two unique acylated flavonoid tetraglycosides (termed teaghrelin-1 and teaghrelin-2 in this study), quercetin (3-*O*-[2^G-(*E*)-coumaroyl-3^G-*O*-β-D-glucosyl-3^R-*O*-β-D-glucosylrutinoside]) and kaempferol (3-*O*-[2^G-(*E*)-coumaroyl-3^G-*O*-β-D-glucosyl-3^R-*O*-β-D-glucosylrutinoside]), were first isolated from the methanol extract as a mixture preparation and then further separated to obtain their individual compounds according to the protocol as described previously.[20]

Animals. Male Sprague Dawley rats weighting 250−300 g were purchased from BioLASCO Taiwan Co., Ltd. (Taipei, Taiwan) and adapted for 1 week before use. Two animals were housed per cage and maintained in a controlled environment of 23 ± 2 °C, 60 ± 10% humidity, and 12 h light/dark cycle. The rats were fed with hard rodent chow pellets (Fwusow Industry Corporation, Taiwan) and purified water *ad libitum*. The animal experiments were approved by the Institutional Animal Care and Use Committee of the National Chung-Hsing University (IACUC Approval Number 102-92).

Food Intake Assay. The rats (n = 8) were fasted for 2 h with free access to drinking water and then orally administrated with aqueous solutions containing teaghrelins of 2.5 or 7.5 mg/kg. After oral administration for 2 h, rodent chow was supplied to rats and the net consumption (food intake) of each rat after feeding for 15 and 120 min was recorded to evaluate its appetite and total food consumption, respectively.

Primary Pituitary Cell Culture. Pituitary cells were isolated according to a modified enzymatic dispersion method developed by Yamazaki et al.[21] Briefly, Sprague Dawley male rats (n = 6) were anaesthetized with Zoletil 50 (40 mg/kg, IP; Virbac Laboratories, Carros, France), and the anterior pituitary glands were quickly removed after decapitation. The tissues were cut into small pieces and dispersed by incubations in DMEM containing 0.25% (w/v) collagenase type I for 60 min, 0.25% (w/v) trypsin for 15 min, and then DMEM containing 16 units of DNase I for 5 min. The dispersed anterior pituitary glands were passed through a 100 μm nylon cell strainer (BD Falcon, Franklin Lakes, NJ). Cells were finally suspended in DMEM containing 10% dialyzed fetal bovine serum. The yield of each anterior pituitary gland was approximately 1.5−2 × 10^6 cells.

Growth Hormone Secretion Assay. The anterior pituitary cells were seeded on a 96-well plate at a density of 4 × 10^4 cell/well and cultured at 37 °C under 5% CO_2 for 2 days prior to assay. The culture medium was removed, and cells were preincubated in serum-free DMEM for 90 min to stabilize basal hormone secretion. The medium was transferred to fresh DMEM containing teaghrelin-1 (from 10^{-9} to 10^{-4} M) or GHRP-6 (GHS-R1a agonist, 10^{-7} M), and cells were incubated for 15, 30, and 60 min at 37 °C under 5% CO_2. To test the effect of antagonist, the cells were incubated with a GHS-R1a antagonist, [D-Arg^1,D-Phe^5,D-Trp^{7,9},Leu^{11}]-substance P (0.5 μM), and then treated with DMEM containing teaghrelin-1 (10^{-5} M) or GHRP-6 (10^{-7} M) for 30 min. The medium was collected, and growth hormone secretion was assayed by a rat growth hormone enzyme-linked immunosorbent assay (ELISA) kit (EMD Millipore Corporation, Billerica, MA).

Bile Collection and Preparation. Male Sprague Dawley rats (n = 3) were fasted for 18 h and then anesthetized with Zoletil 50 (40 mg/kg, IP). The rats were kept alive at the period of surgery. All groups were treated with IV administration of normal saline containing teaghrelin-1 or teaghrelin-2 (30 mg/kg). Bile fistulas of the rats were cannulated with PE-20 polyethylene tubing for collection of bile. Bile was collected at 30 min intervals for 2.5 h after a single IV dosing. Bile samples of 200 μL were vortex-mixed with 2 volumes of methanol containing 0.1% phosphoric acid for 10 min and centrifuged at 10000g for 20 min at 4 °C. The supernatant was filtered by a 0.22 μm PVDF membrane filter (Pall Corporation) and used for the following analyses.

HPLC/UV and LC−MS^n Analyses of Bile Extraction. Bile metabolites were analyzed by a HPLC system (Waters Corp.) with a Syncronis C18 column (250 × 4.6 mm inner diameter, 5 μm) from Thermo Scientific (Waltham, MA). The HPLC mobile phase comprised (A) acetonitrile and (B) water containing 0.5% acetic acid. The gradient started at 5% solvent A and 95% solvent B, followed by a linearly increase of solvent A to 25% for 10 min, and raised to 30% for 30 min. Finally, the gradient was decreased to 5% A for 5 min. The sample injection volume was 20 μL with 1 mL/min flow rate at room temperature. The detection wavelength was set at 280 nm. Mass spectrometric analysis was performed on a LTQ linear ion trap tandem mass spectrometer (Thermo Electron, San Jose, CA) equipped with an electrospray ionization (ESI) interface and connected to a Surveyor LC system (Thermo Electron, San Jose, CA) with a 5 μL sample loop. The analytes were separated on a Waters Xterra-RP18 column (250 × 4.6 mm inner diameter, 5 μm). The tray temperature was set at 4 °C. The mobile phase comprised (A) acetonitrile and (B) water containing 0.5% acetic acid. The program for gradient elution started at 5% A, increased to 25% A in 10 min, and then changed to 30% A in 30 min. Subsequently, the gradient increased to 70% A in 1 min and was held for 8 min. Finally, the gradient went back to 5% A in 1 min and was held for 5 min. The flow rate was 1 mL/min. The mass spectra were obtained with negative ESI mode. The spray voltage was 4.5 kV, and the heated capillary temperature was at 300 °C. Flow rates of sheath gas, auxiliary gas, and sweep gas were 50, 13, and 3 arbitrary units, respectively. Data-dependent acquisition (DDA) was used to perform under automatic gain control conditions. The first scan was operated in full-scan mode ranging from m/z 150 to 1500. The other scans were set as the data-dependent MS^n scan using the high-purity helium (>99.99%) as the collision gas and the relative collision energy of 33−35%. Isolation width of the precursor ion was set to 2 Da. The MS/MS experiments of data-dependent acquisition were performed

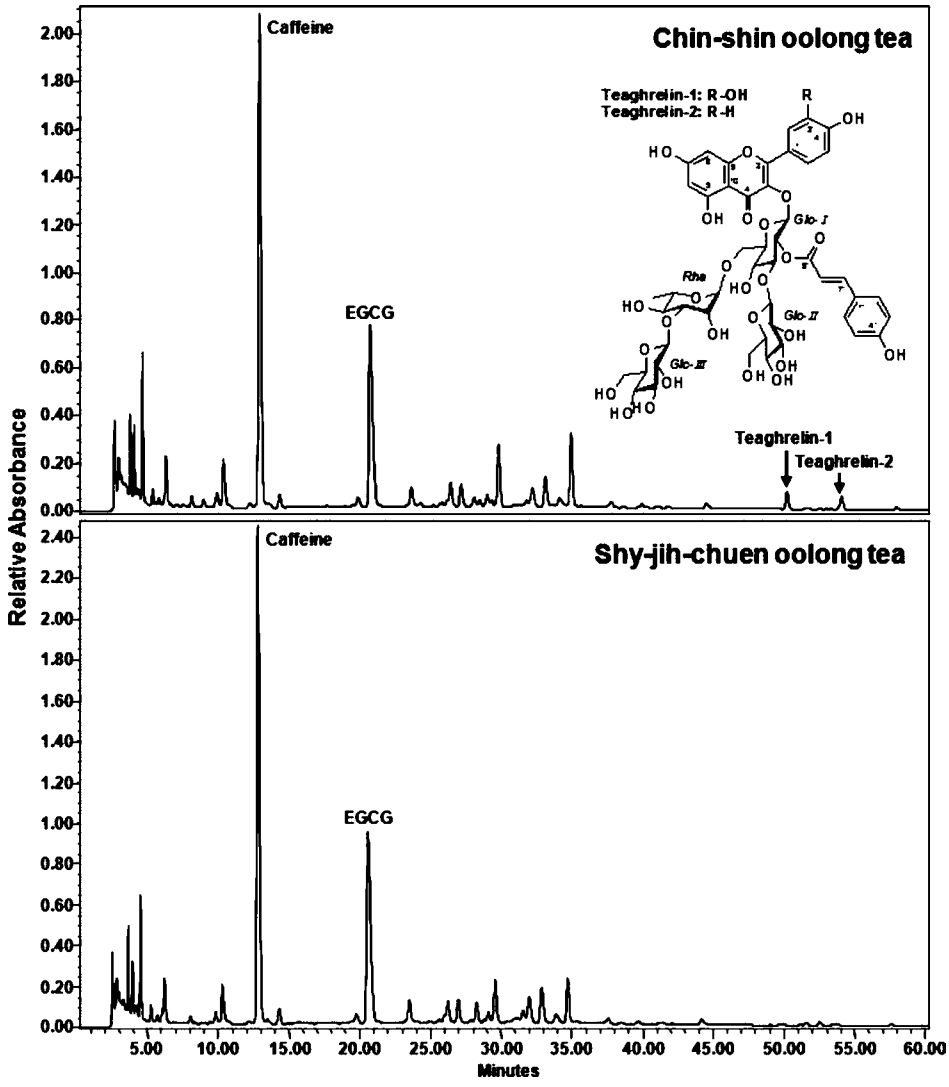

Figure 1. Comparison of the HPLC profiles of Chin-shin and Shy-jih-chuen oolong tea infusions. Two unique peaks, teaghrelin-1 and teaghrelin-2, in Chin-shin oolong tea were indicated by arrows, and their structures were shown on top of the peaks. Caffeine and the major catechin, epigallocatechin-3-gallate (EGCG), in both teas were labeled.

according to a previous scan. The highest intensity ion of the previous scan was chosen as the precursor ion for the successive MS/MS scans.

Statistical Analysis. The data were presented as mean values ± standard error of the mean (SEM). The differences were analyzed by one-way analysis of variance (ANOVA) followed by Duncan's post-hoc testing. Statistical calculations were performed by SigmaStat (version 3.5). A level of $p < 0.05$ was considered to be statistically significant.

RESULTS

Identification of Teaghrelins in Chin-shin Oolong Tea. To search for putative compounds responsible for the empirical effects (induction of hunger and acceleration of gastric emptying) of Chin-shin oolong tea, chemical compounds in the infusion of Chin-shin oolong tea were analyzed and compared to those of other oolong teas commonly found in Taiwan, as exemplified by Shy-jih-chuen oolong tea (Figure 1). Comparable patterns of chemical compounds, such as caffeine and catechins, were observed between Chin-shin oolong tea and Shy-jih-chuen oolong tea. Strikingly, two acylated flavonoid tetraglycosides whose structures were chemically determined by nuclear magnetic resonance (NMR) in our previous study were found relatively abundant in Chin-shin oolong tea.[20,22] Both compounds, tentatively named teaghrelin-1 and teaghrelin-2, were purified as a mixture or as their individual compounds and used for the following assays.

Effect of Teaghrelins on the Food Intake of Rats. In comparison to the control group, food intake of rats was significantly enhanced after ingestion with mixed teaghrelins (containing both teaghrelin-1 and teaghrelin-2) of 2.5 or 7.5 mg/kg (Figure 2A). The effect on the enhancement of food intake was more drastic after food supplied for 15 min than that after food supplied for 120 min. Apparently, ingestion of teaghrelins strongly induced the appetite of rats that ate relatively fast in the first 15 min, while the total food consumption accumulated for 120 min was only mildly increased in the long run. The appetite of rats induced by the ingestion with teaghrelins was also dose-dependent because a higher effect on the enhancement of food intake in the first 15 min was observed in rats ingested with 7.5 mg/kg of teaghrelins compared to those rats ingested with 2.5 mg/kg of teaghrelins. However, no statistical difference was observed for rats ingested with 2.5 and 7.5 mg/kg of teaghrelins with regard to their total food consumption accumulated for 120 min. Similar outcomes

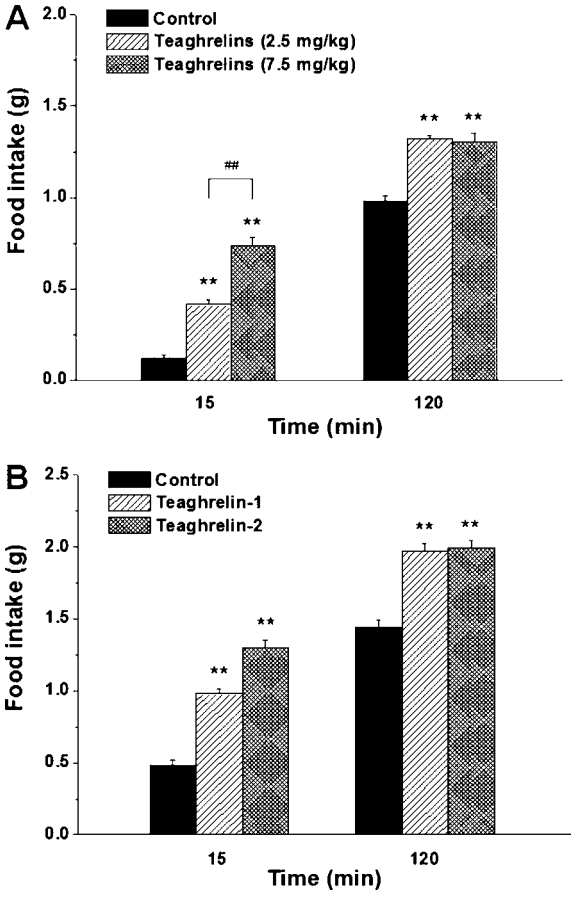

Figure 2. Effects of (A) mixed teaghrelins and (B) individual teaghrelin on food intake of rats. Mean cumulative values of food intake of rats 15 and 120 min after orally administration with mixed teaghrelins of 2.5 and 7.5 mg/kg as well as those with teaghrelin-1 or teaghrelin-2 of 7.5 mg/kg were recorded. Data were presented as means ± SEM with $n = 8$. Significance levels seen by one-way ANOVA were (**) $p < 0.001$ versus the control and (##) $p < 0.001$ significant differences between columns.

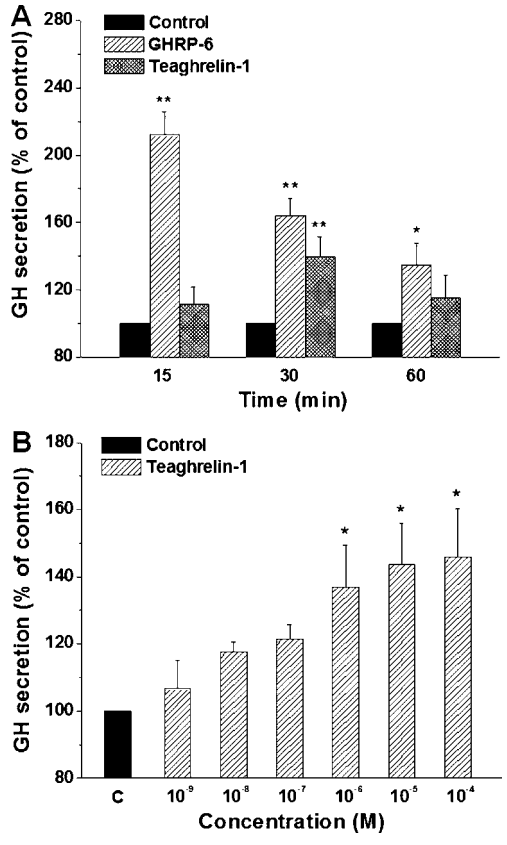

Figure 3. Effect of teaghrelin-1 administration on growth hormone (GH) secretion of pituitary cells. (A) GH secretion from rat primary pituitary cells was measured after incubation with medium (control), GHRP-6 (GHS-R1a agonist, 10^{-7} M), and teaghrelins-1 (10^{-5} M) for 15, 30, and 60 min. (B) GH secretion from rat primary anterior pituitary cells was observed by incubating with teaghrelin-1 of various concentrations for 30 min. Data were presented as means ± SEM with $n = 6$. Significance levels seen by one-way ANOVA were (*) $p < 0.05$ versus the control and (**) $p < 0.001$ versus the control.

and conclusion were obtained when 7.5 mg/kg of teaghrelin-1 and teaghrelin-2 were used in the same food intake assay, respectively (Figure 2B). Comparable effects on the enhancement of food intake were observed for both teaghrelins, and it was obvious that the minor structural difference in these two teaghrelins (one extra hydroxyl group at the 3′ position of teaghrelin-1) did not cause appreciable variation for their effects on hunger induction of rats.

Effect of Teaghrelin-1 on Growth Hormone Secretion of Rat Pituitary Cells. Stimulating growth hormone secretion of pituitary cells is a characteristic function of ghrelin. To evaluate if teaghrelins are also capable of stimulating the secretion of growth hormone, relatively abundant teaghrelin-1 is used to examine this characteristic function by incubating with primary rat anterior pituitary cells. Similar to GHRP-6, a synthetic analogue of ghrelin, teaghrelin-1 was able to stimulate the secretion of growth hormone from rat anterior pituitary cells (Figure 3A). In our assay conditions, the stimulatory effects of GHRP-6 and teaghrelin-1 on growth hormone secretion of rat pituitary cells were relatively high after treatment for 15 and 30 min, respectively. Treatment of teaghrelin-1 (from 10^{-9} to 10^{-4} M) for 30 min stimulated growth hormone secretion of the rat pituitary cells in a dose-

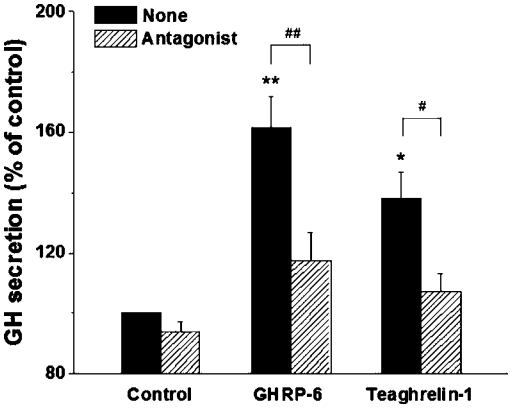

Figure 4. Effects of [D-Arg^1,D-Phe^5,D-Trp^{7,9},Leu^{11}]-substance P (GHS-R1a antagonist) on pituitary growth hormone (GH) secretion induced by GHRP-6 and teaghrelin-1. Rat primary anterior pituitary cells were incubated with GHRP-6 (10^{-7} M) and teaghrelin-1 (10^{-5} M) in the presence and absence of [D-Arg^1,D-Phe^5,D-Trp^{7,9},Leu^{11}]-substance P (0.5 μM) for 30 min. Data were presented as means ± SEM with $n = 6$. Significance levels seen by one-way ANOVA were (*) $p < 0.05$ versus the control, (**) $p < 0.001$ versus the control, (#) $p < 0.05$ significant differences between columns, and (##) $p < 0.001$ significant differences between columns.

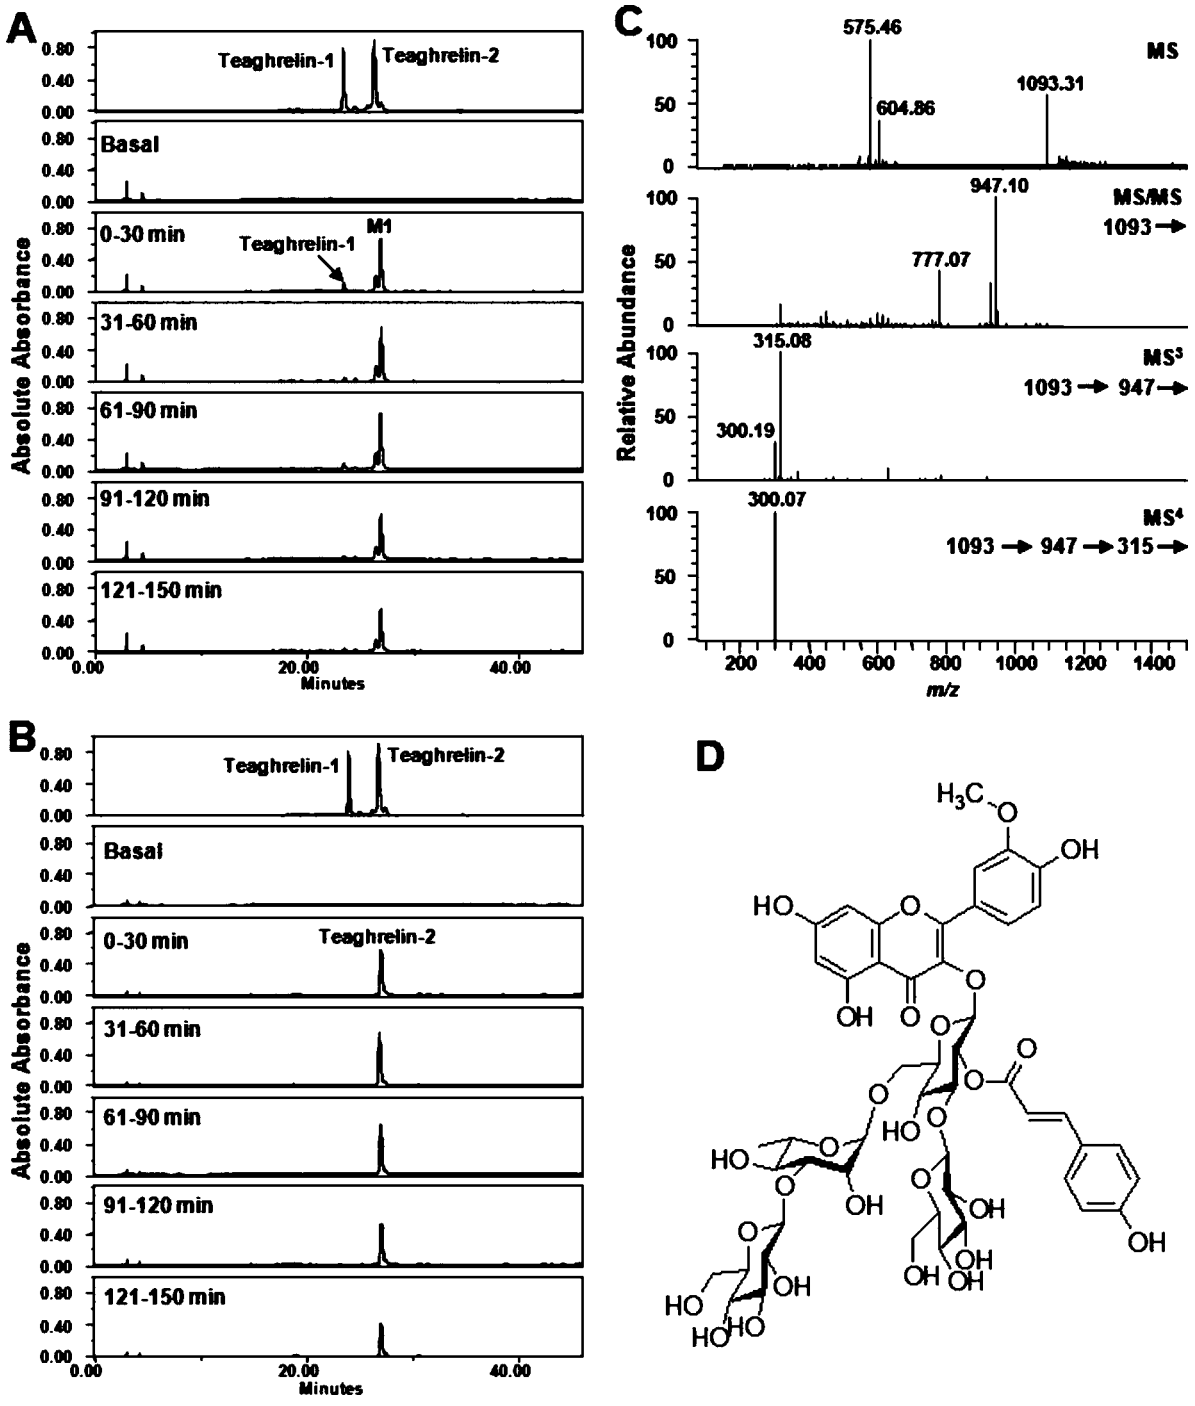

Figure 5. HPLC chromatograms of teaghrelins and bile metabolites in rats. Bile samples were collected from rats administrated with 30 mg/kg of (A) teaghrelin-1 and (B) teaghrelin-2 at different time intervals, basal, 0−30, 31−60, 61−90, 91−120, and 121−150 min. The samples were analyzed in a HPLC chromatogram by comparing to isolated teaghrelins as standards (teaghrelin-1 and teaghrelin-2 in the top panel). (C) Data-dependent MS^n spectra of teaghrelin-1 metabolite (M1). (D) Proposed chemical structure of M1.

dependent manner (Figure 3B). Moreover, both stimulatory effects of GHRP-6 and teaghrelin-1 on growth hormone secretion of the rat pituitary cells were inhibited by [D-Arg^1,D-Phe^5,D-$Trp^{7,9}$,Leu^{11}]-substance P, an antagonist of the ghrelin receptor (Figure 4). Taken together, teaghrelin-1 seems to be an agonist of the ghrelin receptor.

Identification of a Teaghrelin Metabolite in Rat Bile. To examine biliary metabolites, bile samples of three rats were collected every 30 min for 2.5 h after IV injection with 30 mg/kg of teaghrelin-1 and teaghrelin-2, respectively. Putative metabolites of teaghrelins were analyzed by LC−MS^n with data-dependent acquisition scan function. A major metabolite, M1, was detected after IV injection of teaghrelin-1 (Figure 5A). In contrast, teaghrelin-2 seemed to be unmodified in rat bile after IV injection (Figure 5B). The unmodified teaghrelin-2 in rat bile was also confirmed by mass spectroscopic analysis (data not shown). The structure of M1 was determined by multiple-stage mass spectra in the negative mode (Figure 5C). The deprotonated molecule of M1 at m/z 1093 was indicated in the full mass spectrum. The m/z 947 ion in the MS^2 spectrum was

dx.doi.org/10.1021/jf501425m | J. Agric. Food Chem. 2014, 62, 5085−5091

owing to the neutral loss of 146 Da identified as the *p*-coumaroyl moiety.[23] In the MS^3 spectrum, the fragment ion at *m*/*z* 315, produced from *m*/*z* 947 with the neutral loss of tetrasaccharide residue with 632 Da, was assigned as the monomethylated quercetin moiety of M1.[23] The fragment of *m*/*z* 300 was also found in the MS^3 spectrum and assigned as the $[M - H - CH_3^{\bullet}]^-$ fragment of the 3′-methyl quercetin.[24] The ion transition from *m*/*z* 315 to 300 observed in the MS^4 spectrum confirmed that the monomethylation occurred in the metabolite of teaghrelin-1. Altogether, M1 was proposed as 3′-methyl teaghrelin-1 (Figure 5D).

DISCUSSION

Two unique acylated flavonoid tetraglycosides (named teaghrelins in this study) previously identified in Chin-shin oolong tea were shown to be probably responsible for the empirical effects, such as hunger induction, of Chin-shin oolong tea presumably via the same molecular mechanism of the endogenous hunger hormone, ghrelin. Similar to ghrelin, teaghrelins are able to induce hunger sensation of rats as well as stimulate growth hormone secretion of rat primary anterior pituitary cells. The identification of teaghrelins in Chin-shin oolong tea seems to provide a scientific clue to resolve the mystery for the hunger experience strongly induced by Chin-shin oolong tea.

Several acylated flavonoid tetraglycosides with the same structural backbone but different hexosyl (at least, glucosyl, rhamnosyl, and arabinosyl) glycosides were detected in substantially low contents in various oolong teas, including Tieguanyin, Wuyi, Fenghuang, Gaoshan Shibi, Laocong Shuixian, and Baihao oolong teas, in our previous study.[23] These acylated flavonoid tetraglycosides are putatively regarded as different types of teaghrelins, and the presence of teaghrelins in variable oolong teas at a substantially low content presumably explains why many oolong teas are also able to induce hunger sensation, although not as strong as Chin-shin oolong tea. Moreover, it also explains why many green and black teas possess similar effects of hunger induction, because the same tea leaves, e.g., fresh leaves of Chin-shin tea plants, may be used to produce oolong tea as well as green and black teas.

Hepatic metabolism and biliary excretion mechanism are important for the pharmacological effects of drugs,[25] and thus, identification of drug metabolites in bile is helpful to realize the drug disposition for the preclinical study.[26] It has been shown that the most abundant compounds in tea, flavonoids, tend to be methylated in their *meta* (3′-*O*-) position of the catecholic moiety by catechol-*O*-methyltransferase, and the 3′-*O*-methyl derivatives are generally found as the major metabolites in bile.[27,28] Moreover, methylated flavonoids have been reported to possess better intestinal absorption and oral bioavailability than their unmethylated flavonoids.[29,30] Accordingly, a *meta*-O-methylated metabolite at the 3′ position of teaghrelin-1 was detected in rat bile after IV injection in this study. As expected, lacking a *meta* (3′-*O*-) position of the catecholic moiety, teaghrelin-2 was not methylated and remained unmodified in bile.

On the basis of the multiple biological activities of ghrelin, synthetic analogues (both peptidyl and non-peptidyl GHS-R1a agonists), such as GHRP-6, L-692,429, and MK-677, have been developed for the potential therapeutic applications of several diseases, e.g., gastrointestinal deficiency and anorexia.[31−34] In animal and human studies, ghrelin as well as its peptidyl analogues has a short biological half-life that limits its utility as a pharmacological agent.[35−37] In contrast, non-peptide oral ghrelin analogues have been found to possess better bioavailability.[31,34] However, oral ghrelin analogues, such as MK-677, lacked the efficacy for the treatment of gastrointestinal deficiency in elderly patients[38] and caused side effects in mild lower extremity edema and muscle pain, while the rise of appetite was maintained for a short period in healthy older people.[39] Moreover, TZP-101 and TZP-102, the macrocylic, peptidomimetic ghrelin receptor agonists, were reported to show no significant effect on diabetic gastroparesis treatment in the phase 2b program and caused minor adverse events, such as hyperglycemia, nausea, and diarrhea.[40−42] In a word, no synthetic oral agonists of the ghrelin receptor were satisfactory and approved for clinical application thus far. According to this study, teaghrelins extracted from oolong teas seem to be promising oral agonists of the ghrelin receptor, provided that they undergo necessary clinical trials.

p38 mitogen-activated protein are collectively known as stress-activated mitogen-activated protein kinases. JNK and p38 phosphorylate many known regulators of tumorigenesis, such as c-Jun, p53, Bax, Bcl-2, and Mcl-1. The activation of the p38 pathway has been shown to enhance the transcriptional activity of p53, leading to cell cycle arrest and apoptosis. JNK has also been shown to phosphorylate p53, activating transcription factor-2, c-Jun, and Elk-1 and regulating stability.[18,19] Activator protein 1 (AP-1) is a transcriptional factor which is composed of proteins belonging to the c-Fos, c-Jun, ATF, and ENDOG families, and it binds DNA at a site called a TRE and activates gene transcription. The regulation of c-Jun is complex and involves both increases in c-Jun protein levels and phosphorylation of JNK. Fos family proteins cannot form homodimers to bind a TRE in the absence of Jun.[20,21]

Polyphenol and anthocyanin-rich mulberry has been reported to have not only antiobesity, antidiabetic, antitumor, antioxidative, and anti-inflammatory effects but also neuro-, hepato-, and cardiovascular protective characteristics.[22−28] It has been reported that mulberry water extracts (MWEs) can inhibit the oxidation of low-density lipoprotein (LDL), thus preventing atherosclerosis.[29]

Our previous studies have shown that mulberry leaf extract (MLE) can inhibit atherosclerosis via effectively inhibiting proliferation and migration of VSMCs, and this inhibitory effect was attributed to the polyphenol component of MLE.[30,31] In the early stage of atherosclerosis, stimulating apoptosis of VSMCs and thus inhibiting VSMC proliferation and migration is an important process. To examine the effect of polyphenol-rich MWEs on the apoptosis of VSMCs and thus the prevention of atherosclerosis, we investigated the ability of MWEs to induce apoptosis and the underlying mechanism.

MATERIALS AND METHODS

Preparation of MWEs. MWEs were prepared from the fruit of *M. alba* L. (mulberry). Fresh mulberry fruit (500 g) was harvested and freeze-dried. Briefly, the dried fruit (100 g) was macerated, stirred with water (1000 mL), and centrifuged (6000 rpm, 10 min). The aqueous solution was lyophilized (−80 °C, 12 h) to obtain the MWEs and stored at −20 °C before use.

High-Performance Liquid Chromatography. The components of the MWEs were determined by high-performance liquid chromatography (HPLC) analysis using a Hewlett-Packard Vectra 436/33N system with a diode array detector.[32] The HPLC method employed a 5 μm RP-18 column (4.6 × 150 mm inner diameter). The MWEs were filtered through a 0.22 μm filter disk, and then 25 mg/mL of the MWEs was injected into the column. Chromatography was monitored at 280 nm, and UV spectra were collected to confirm peak purity. The mobile phase contained two solvents: A, 2% acetic acid/water; B, 0.5% acetic acid in water/acetonitrile. The total phenolic compound content in each extract was spectrophotometrically determined in accordance with the Folin−Ciocalteu procedure by reading the absorbance at 725 nm against a methanol blank. Briefly, samples (20 μL, with the addition of water to 1.6 mL) were introduced into test tubes, and then 100 μL of Folin−Ciocalteu reagent and 300 μL of sodium carbonate (20%) were added. The contents of the tubes were mixed and incubated at 40 °C for 40 min. Absorption at 725 nm was measured. The powders were then resuspended in distilled water and filtered through a 0.22 μm filter for use in cell cultures.

Animals and Diet. Thirty male New Zealand white rabbits (Da-Jung Animal Farm, Changhua, Taiwan), weighing 2000−2500 g were used. They were individually housed in metal cages in an air-conditioned room (22 ± 2 °C, 55 ± 5%, humidity), under a 12 h light/12 h dark cycle with free access to food and water. All experimental rabbits were randomly divided into five groups, each group containing six animals. Group I rabbits were fed with standard chow. Group II rabbits were fed with standard chow with 1% MWEs in the daily diet. Group III rabbits were fed with HCD diet (containing 95.7% standard Purina chow (Purina Mills, Inc.), 3% lard oil, and 1.3% cholesterol) for 10 weeks, to provoke an atherosclerotic process. Groups IV and V were fed with HCD plus 0.5% and 1.0% MWEs, respectively, in the daily diet. The selection of the MWEs dose was based on a suitable pharmacological dose for humans in a daily diet. During the 10 week feeding period, all of the animals were handled according to the guidelines of the Institutional Animal Care and Use Committee of Chung Shan Medical University for the care and use of laboratory animals. After 10 weeks, the rabbits were sacrificed by exsanguination after deep anesthesia with pentobarbital (30 mg/kg i.v.) via the marginal ear vein. Serum was stored at −80 °C prior to serum lipid analysis and measurement of serum values. The aortic arch and thoracic aortas were carefully removed to protect the endothelial lining, and the specimens were collected and freed of adhering soft tissue.

Evaluation of Atherosclerotic Lesions. Thoracic aortas were rapidly dissected, opened longitudinally, and stained with Sudan IV. Aortic arches were rapidly dissected and kept at −80 °C or in 10% neutral-buffer formalin. The sections of aortic arch were stained with hematoxylin and eosin or α-smooth muscle actin antibodies (Santa Cruz Biotechnology, Inc., CA). Immunohistochemistry was carried out to confirm the lesions. Experienced pathologists evaluated the presence of smooth muscle cells in the examined preparations.

Cell Cultures. Cell line A7r5, a rat thoracic aorta smooth muscle cell line, was obtained from ATCC (ATCC number: CRL-1444; Manassas, VA). The A7r5 cells were cultured in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum, 1% glutamine, 1% penicillin-streptomycin, and 1.5 g/L sodium bicarbonate (all from Gibco/BRL; Gaithersburg, MD). All cell cultures were maintained at 37 °C in a humidified atmosphere of 5% CO_2.

Cell-Cycle Analysis (Flow Cytometric Analysis). Cells synchronized at the G0 phase by serum starvation for 24 h were incubated in fresh serum-containing medium to allow for cell-cycle progression. At various time points after release from G0 arrest, the cells were analyzed by flow cytometry to determine cell-cycle distribution.[33] The cells were seeded in 10 cm dishes at a density of 10^7 cells/dish and cultured in normal or high glucose Dulbecco's modified Eagle's medium. The cells cultured in high glucose were treated with MWEs at various concentrations (0, 2.0, 4.0, 6.0, 8.0, and 10.0 mg/mL) at 37 °C for 48 h. At the end of treatment, they were collected, fixed in 1 mL of ice-cold 70% ethanol, incubated at −20 °C for at least 24 h, and centrifuged at 380 g for 5 min at room temperature. Cell pellets were treated with 1 mL of cold staining solution containing 20 μg/mL propidium iodide, 20 μg/mL RNase A, and 1% Triton X-100, and they were incubated for 15 min in darkness at room temperature. Subsequently, the samples were analyzed in a FACS Calibur system (version 2.0, BD Biosciences, Franklin Lakes, NJ) using CellQuest software. The extent of apoptosis was quantified by counting the fraction of

Table 1. Polyphenolic Compounds in the MWEs[a]

HPLC chromatogram assay	
polyphenolic compound	MWEs (%)
gallic acid	0.31 ± 0.05
protocatechuic acid	2.92 ± 0.45
catechin	0.54 ± 0.03
epigallocatechin gallate	2.68 ± 0.20
caffeic acid	1.10 ± 0.24
epicatechin	1.21 ± 0.17
p-coumaric acid	0.35 ± 0.04
rutin	3.22 ± 1.01
ferulic acid	0.27 ± 0.01
gossypin	0.26 ± 0.02
hesperetin	0.34 ± 0.10
resveratrol	0.35 ± 0.23
quercetin	0.50 ± 0.07
naringenin	0.52 ± 0.17
hydroxyflavin	0.58 ± 0.12
total	**15.13 ± 0.93**

[a]HPLC chromatograms of free polyphenols from MWEs (20 mg/mL). Quantitative assessment of the percentage of polyphenols in MWEs relative to the standards represents the average of three independent experiments.

cells with DNA content at the sub-G1 phase. The results were representative of at least three independent experiments.

DNA Fragmentation. A7r5 cells were pretreated with or without 20 nM pifithrin-α for 30 min before the addition of MWEs (1−5 mg/mL) for 48 h. The cells were detached by trypsin−EDTA, washed with phosphate buffered saline, and then subjected to genomic DNA extraction using a DNeasy Tissue Kit (QIAGEN) according to the manufacturer's instructions. DNA was separated by electrophoresis as previously described.[34]

P53, p38, JNK, ERK, PI3K, Caspase, and Fas-Ligand Inhibitor. Pifithrin-α, a p53 inhibitor, was purchased from Sigma (St. Louis, MO, U.S.A.), and diluted in dimethyl sulfoxide (DMSO). SB203580, a p38 inhibitor (Sigma, St. Louis, MO, U.S.A.), SP600125, a JNK inhibitor (Calbiochem-Novabiochem, San Diego, CA), PD98059, an ERK inhibitor (Sigma, St. Louis, MO, U.S.A.), wortmannin, a PI3K inhibitor (Sigma, St. Louis, MO, U.S.A.), and Z-VAD (OMe)-fluoromethyl ketone (FMK), a caspase inhibitor (Sigma, St. Louis, MO, U.S.A.) were diluted in DMSO. NOK-1 (sc-19681), a Fas-ligand (Fas-L) inhibitor (Santa Cruz Biotechnology, Santa Cruz, CA, U.S.A.), was diluted in phosphate-buffered saline. The cells were treated with different concentrations of the inhibitors (20 μM of SB203580, SP600125, or PD98059; 1 μM of wortmannin; 50 μM Z-VAD-FMK; or 5 μg/mL NOK-1) for 30 min followed by treatment with MWEs (3.0 mg/mL).

Transfection. A7r5 cells (3×10^5 cells/6-well dish) were pretransfected with dominant-negative (DN) JNK/p38 for 12 h. Liposome-mediated transfection was performed using LipofectAMINE Plus (Invitrogen).[35]

Extraction of Mitochondria Protein. Mitochondria were isolated with a mitochondria isolation kit according to the manufacturer's instructions by using a reagent-based method (cat. no. 89874; Pierce, Rockford).[36] After the indicated treatment of MWEs, we pelleted 2×10^7 cells by centrifuging the harvested cell suspension in a 2.0 mL microcentrifuge tube at ~850*g* for 2 min. Then, we carefully removed and discarded the supernatant. We added 800 μL of Mitochondria Isolation Reagent A, vortexed at medium speed for 5 s, and incubated the tube on ice for exactly 2 min. We added 10 μL of Mitochondria Isolation Reagent B and vortexed at maximum speed for 5 s. Then, we incubated the tube on ice for 5 min, vortexing at maximum speed every minute. We added 800 μL of Mitochondria Isolation Reagent C, and we centrifuged the tube at 700*g* for 10 min at 4 °C. We transferred the supernatant to a new, 2.0 mL tube and centrifuged at 12 000*g* for 15 min at 4 °C. Then, we transferred the supernatant (cytosol fraction) to a new tube. The pellet contained the isolated mitochondria.

Western Blot Analysis. For Western blot analysis,[37] we used specific antibodies to evaluate the expressions of p-JNK, p-p38, p-p53, p-Bad, Bad, Bcl-2, Mcl-1, p-Jun, Jun, Fos, activating transcription factor-2, cytochrome c, pro-caspase 3, cleavage-caspase 3, Fas-L, and C23 (all from Santa Cruz Biotechnology, Santa Cruz, CA, U.S.A.), p38, JNK, and p53 (Cell Signaling), and β-actin (Sigma, St. Louis, MO, U.S.A.). After the indicated treatment of MWEs (3.0 mg/mL) for 48 h, equal amounts of cell lysates (50 μg protein) were separated by electrophoresis on 8−12% SDS-PAGE and transferred to nitrocellulose membranes (Millipore, Bedford, MA, U.S.A.). The membranes were incubated with Tris-buffered saline containing 1% (W/V) nonfat-milk and 0.1% (V/V) Tween-20 for 1 h to block nonspecific binding, and they were then washed with Tween-20 for 30 min. Each membrane was incubated with the appropriate primary antibody for 2 h followed by horseradish peroxidase-conjugated second antibody (Sigma, St. Louis, MO, U.S.A.) for 1 h and developed by an ECL chemiluminescence kit (Millipore, Bedford, MA, U.S.A.), followed by analysis using AlphaImager Series 2200 software. The results were representative of at least three independent experiments.

4′, 6-Diamidino-2-phenylindole (DAPI) Staining. A7r5 cells (2×10^5 cells) were seeded in a 10 cm dish for 12 h and

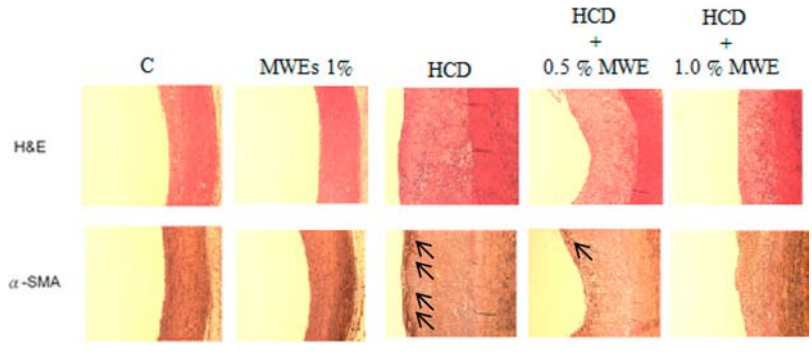

Figure 1. Histological analysis of a representative atherosclerotic lesion from HCD-fed rabbits treated for 10 weeks with MWEs.

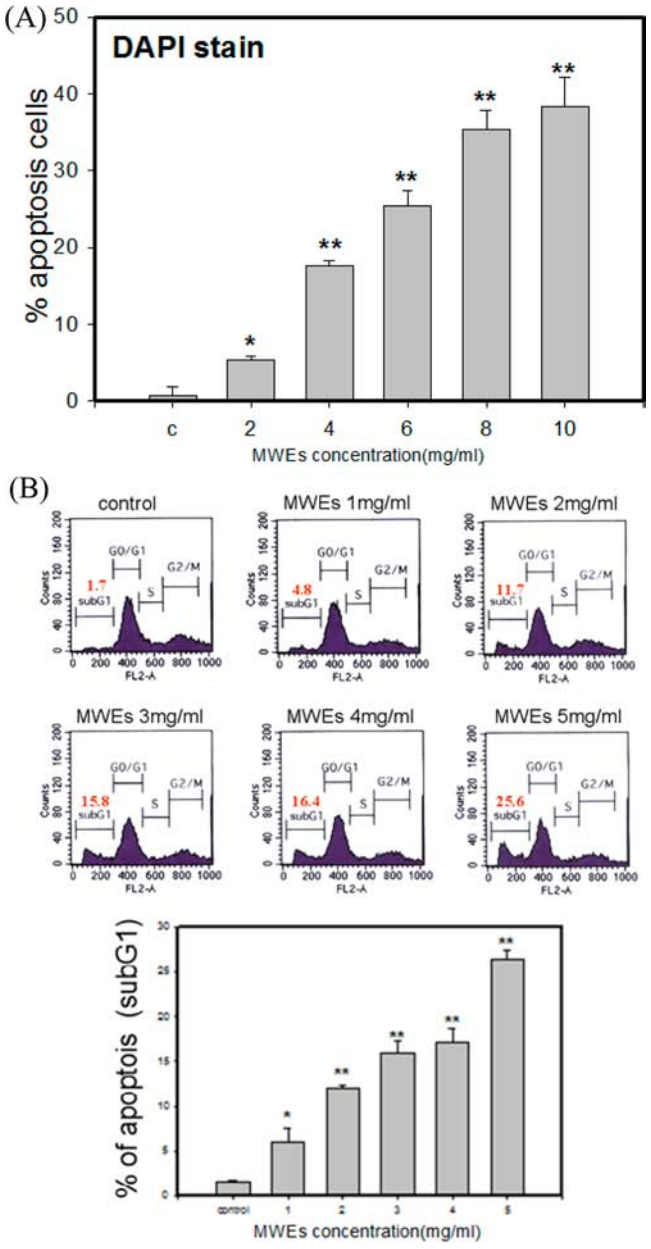

Figure 2. Effect of MWEs on the apoptosis of A7r5 cells. Cells were treated with or without MWEs (0−10 mg/mL) for 48 h, and then the apoptotic cells were stained by DAPI solution. (A) Apoptotic values were calculated as the percentage of apoptotic cells relative to the total number of cells in each random field (>100 cells). (B) Genomic DNA was analyzed by electrophoresis on 0.75% agarose gel and staining with ethidium bromide and then photographed under UV light. (C) Propidium-iodide-stained DNA histograms of the A7r5 cells were analyzed by flow cytometric analysis. Quantitative assessment of the percentage of cells in four phases represents the average of three independent experiments ± SD. *p < 0.001, **p < 0.0001 compared with the control.

then treated with MWEs (3 mg/mL) for 48 h. The A7r5 cells were fixed in 2−4% formaldehyde in phosphate-buffered saline for 30 min and then stained with DAPI (Sigma, St. Louis, MO, U.S.A.) to visualize nuclei.[38]

Statistical Analysis. The results are reported as the means and standard deviations of three independent experiments, and statistical comparisons were evaluated by one-way analysis of

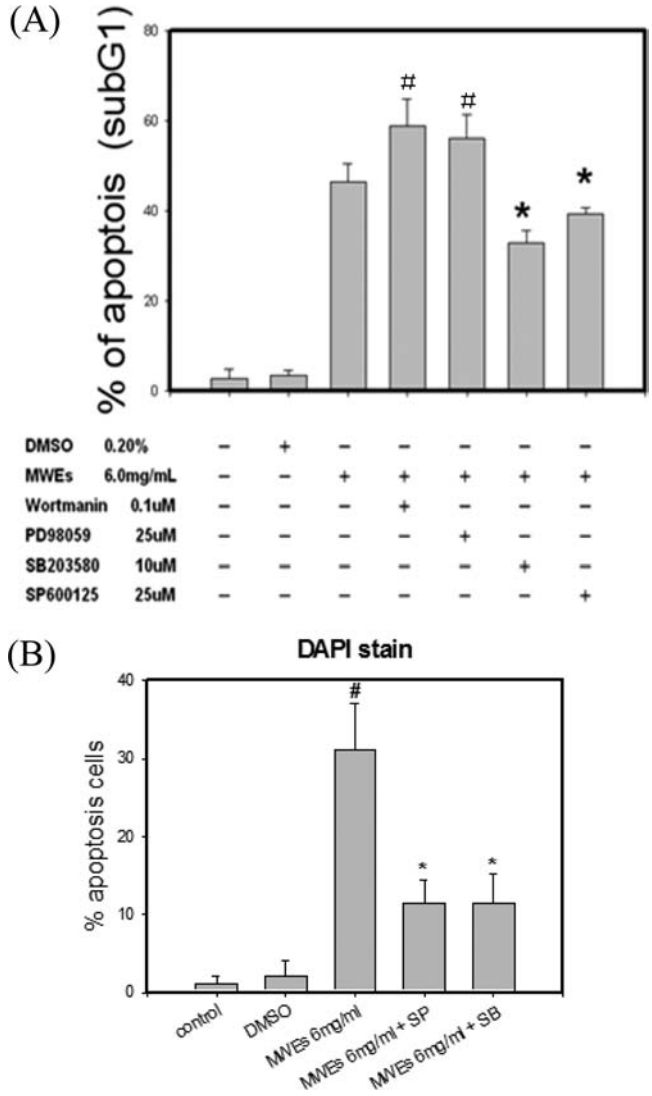

Figure 3. Effect of MAPK inhibitors on MWEs-induced apoptosis in A7r5 cells. Cultured cells were treated with or without 6.0 mg/mL of MWEs for 48 h and then treated in the absence or presence of various concentrations of wortmannin, PD98059, SP600125, and SB203580 for 30 min. Apoptosis was analyzed by (A) flow cytometry and (B) DAPI stain. Quantitative assessment of the percentage of A7r5 cells represents the average of three independent experiments. #p < 0.05, *p < 0.005 compared with MWEs only.

variance (ANOVA). A p-value less than 0.05 was considered to be statistically significant.

RESULTS

Polyphenolic Compounds of MWEs. The main constituents of MWEs have been identified as gallic acid (0.31%), protocatechuic acid (2.92%), catechin (0.54%), epigallocatechin gallate (2.68%), caffeic acid (1.10%), epicatechin (1.21%), p-coumaric acid (0.35%), rutin (3.22%), ferulic acid (0.27%), gossypin (0.26%), hesperetin (0.34%), resveratrol (0.35%), quercetin (0.50%), naringenin (0.52%), hydroxyflavin (0.58%), and unknown components without standards (Table 1).

MWEs Inhibited Proliferation of VSMCs via Stimulating Apoptosis. Histological analysis was performed on a representative atherosclerotic lesion from HCD-fed rabbits after treatment with MWEs for 10 weeks. Figure 1 shows that the MWEs dose-dependently inhibited HCD-fed-induced

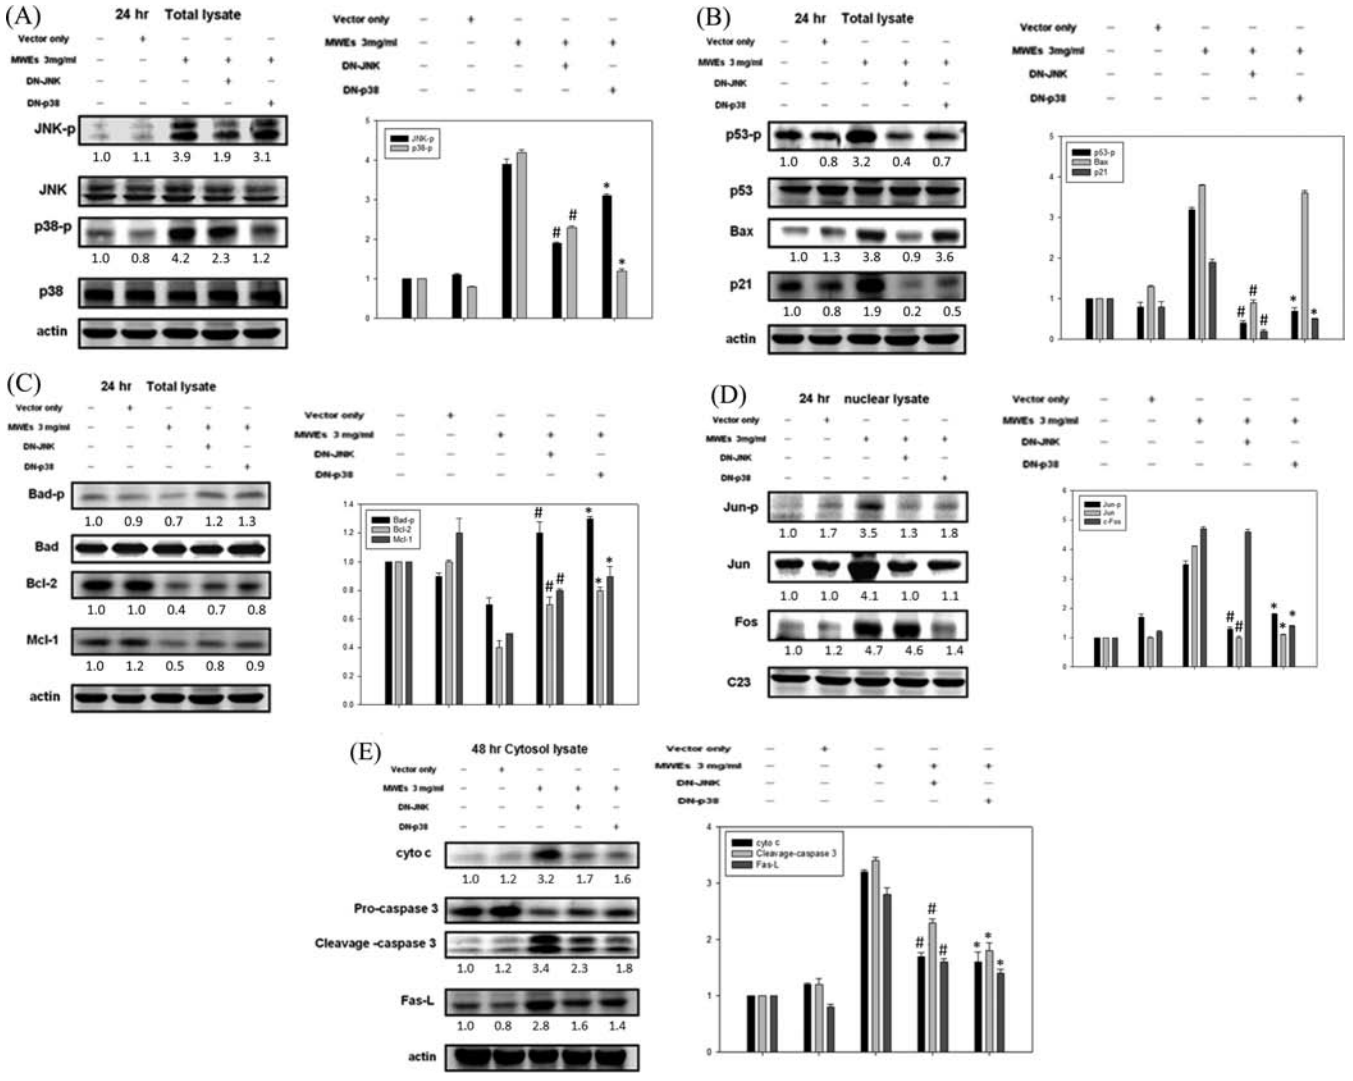

Figure 4. Effect of dominant-negative JNK/p38 on the related proteins of MWEs-induced apoptosis. A7r5 cells (5×10^5 cells/6-well dish) were pretransfected with dominant-negative JNK/p38 for 12 h and then were treated with MWEs (3.0 mg/mL) for 24 or 48 h. Cell lysates (50 μg) were prepared and subjected to Western blot analysis. Proteins were detected by (A) MAPK activation, (B) p53-signaling protein, (C) Bcl-2 family proteins, (D) nuclear transcriptional factors, and (E) caspase 3, FasL, and cytochrome c. β-actin was used for equal loading. $^{\#}p < 0.05$ compared with MWEs only, $^{*}p < 0.05$ compared with MWEs only. Beta-actin and C23 were used as internal standards.

intimal hyperplasia of vessel walls. In Figure 2, A7r5 cells were treated with or without MWEs (0−10 mg/mL) for the indicated times, and the apoptotic cells were stained by DAPI solution. As shown in Figure 2A, from the dose of 2 mg/mL, the MWEs effectively induced apoptosis of A7r5 VSMCs in a dose-dependent manner. DNA fragments in the A7r5 cells were then analyzed by electrophoresis on 0.75% agarose gel and staining with ethidium bromide. Propidium-iodide-stained DNA histograms of the A7r5 cells were analyzed by flow cytometry assay. DNA fragmentation of the A7r5 cells was increased as the dose of MWEs increased from 4 mg/mL (data not show). Flow cytometric analysis showed that the MWEs dose-dependently increased the percentage of apoptosis cells in the sub-G1 phase from the dose of 1 mg/mL (Figure 2B).

MWEs Induced Apoptosis via JNK/p38 Signaling Pathways. The A7r5 cultured cells were treated with or without 6.0 mg/mL of MWEs for 48 h in the absence or presence of wortmannin (PI3K inhibitor), PD98059 (ERK inhibitor), SB203580 (p38 inhibitor), and SP600125 (JNK inhibitor) for 30 min, and then the percentage of apoptotic cells in the sub-G1 phase was analyzed by flow cytometry and DAPI staining (Figure 3). The A7r5 cells (5×10^5 cells/6-well dish) were pretransfected with dominant-negative JNK/p38 (DN-JNK/DN-p38) for 12 h and then treated with MWEs (3.0 mg/mL) for 24 h. Total cell lysates (50 μg), nuclear lysates, and cytosol lysate were prepared and subjected to Western blot analysis. Proteins were detected by specific antibodies. In Figure 3A, the MWEs-induced apoptosis was significantly increased after treatment with inhibitors of PI3K and ERK. After inhibition of JNK and p38 with DN-JNK and DN-p38, the stimulatory effect of MWEs on apoptosis was reduced, and the MWE-induced increased DNA fragmentation was also reduced (data not show). As shown in Figure 4A, after treatment with the MWEs, the expressions of phosphorylation of JNK and p38 were significantly increased. However, these increased expressions decreased after treatment with DN-JNK and DN-p38. After treatment with the MWEs, the expressions of phosphorylation of p53, Bax, and p21 were increased (Figure 4B). The increased expressions of phosphorylated p53 and p21 after treatment with MWEs were significantly reduced

after treatment with the DN-JNK and DN-p38. The MWEs-induced increased expression of Bax was significantly reduced after inhibition of JNK but not changed after inhibition of p38. After treatment with the MWEs, the expressions of antiapoptosis proteins Bcl-2 and Mcl-1 were significantly decreased (Figure 4C). The decreased expressions of Bcl-2 and Mcl-1 after treatment with the MWEs were only partially recovered after treatment with the DN-JNK and DN-p38. After treatment with the MWEs, the expressions of Jun-p (phosphorylated Jun) and Fos in nuclei were increased (Figure 4D). Only the enhanced expression of Jun-p, but not Fos, was decreased after treatment with the DN-JNK. However, the enhanced expressions of Jun-p and Fos were decreased after treatment with the DN-p38. After treatment with the MWEs, the expressions of cytochrome c (cyto c), cleavage caspase-3 (activated caspase-3) and Fas-L in cytosol were all increased, and these increased expressions were all significantly reduced after treatment with the DN-JNK and DN-p38.

MWEs Induced Intrinsic and Extrinsic Pathways via the Up-Regulation of p53. The A7r5 cells were treated with or without 6.0 mg/mL of MWEs for 48 h in the absence or presence of 20 nM pifithrin-α (p53 inhibitor) for 30 min (Figure 5). After treatment with the MWEs, the percentage of apoptotic cells in the sub-G1 phase increased significantly (Figure 5A). After treatment with the p53 inhibitor, the percentage of apoptotic cells in the sub-G1 phase decreased significantly. The increase in DNA fragmentation after MWEs treatment was reduced after treatment with the p53 inhibitor (Figure 5B). The A7r5 cells were pretreated with or without 20 nM pifithrin-α for 30 min before the addition of the MWEs (3 mg/mL) for 24 h (Figure 6). Phospho-p53, p53, and Bax expressions were determined using a specific monoclonal antibody. After treatment with the MWEs, the expressions of phosphorylated p53 and Bax were enhanced, and these increased expressions of p53 and Bax were decreased after treatment with the p53 inhibitor (Figure 6A). After MWEs treatment, the expressions of p53 in the nuclei and mitochondria were all enhanced, and these increased expressions were reduced after treatment with the p53 inhibitor (Figure 6B). The MWEs-induced increased expression of phosphorylated JNK was decreased significantly after treatment with the p53 inhibitor (Figure 6C). However, the MWEs-induced increased expression of phosphorylated p38 was not affected after p53 inhibitor treatment. We then investigated the relationship between p53 and the downstream transcription factors of JNK and p38, including Jun, Fos, AIF, and ENDOG. The MWEs-induced increased expressions of p-Jun, AIF, and ENDOG were reduced significantly after treatment with the p53 inhibitor; however, the MWEs-induced increased expression of Fos was not affected after treatment with the p53 inhibitor (Figure 6D). The MWEs-induced decreased expressions of the antiapoptotic proteins Bcl-2 and Mcl-1 were recovered after treatment with the p53 inhibitor; however, the MWEs-induced decreased expression of phosphorylated Bad was not affected by treatment with the p53 inhibitor (Figure 6E). The MWEs-induced increased expressions of cytochrome c and activated caspase 3 from the mitochondria were decreased after treatment with the p53 inhibitor (Figure 6F). The MWEs-induced increased expression of Fas-L was also decreased after p53 inhibitor treatment.

Effect of Caspase Inhibitors on MWEs-Induced Apoptosis. A7r5 cultured cells were treated with or without 3.0 mg/mL of the MWEs for 48 h in the absence or presence of 5 μg/mL NOK-1 (Fas-L inhibitor) or 50 μM Z-VAD-FMK (caspase inhibitor) for 30 min (Figure 7). Apoptosis was analyzed by flow cytometry, and quantitative assessment of the percentage of A7r5 cells in the sub-G1 phase was completed. The increased number of MWEs-induced apoptotic cells in the sub-G1 phase were reduced after treatment with the inhibitors of Fas-L and caspase, and especially with the caspase inhibitor.

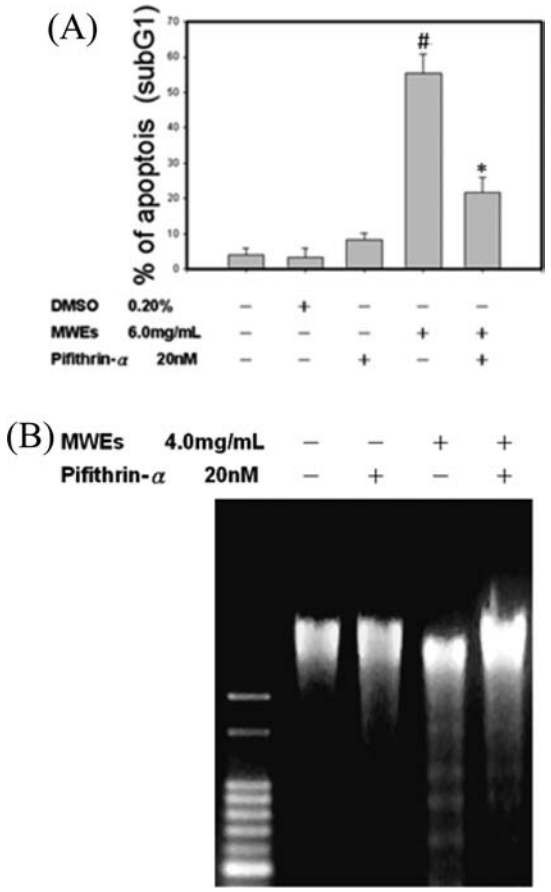

Figure 5. Effect of a p53 inhibitor on MWEs-induced apoptosis in A7r5 cells. Cultured cells were treated with or without MWEs (6.0 mg/mL) for 48 h in the absence or presence of 20 nM pifithrin-α for 30 min. (A) Apoptosis was analyzed by flow cytometry. (B) Genomic DNA was analyzed by electrophoresis on 0.75% agarose gel and staining with ethidium bromide and then photographed under UV light. The results are representative of the average of three independent experiments. $^{\#}p < 0.005$ compared with the control, $^{*}p < 0.005$ compared with MWEs only.

DISCUSSION

It has been reported that polyphenols have many biochemical activities. A previous study showed that MLE can inhibit the oxidation of LDL in rabbits and humans.[39] In addition, mulberry leaf polyphenols have been shown to possess an antiatherogenesis effect via inhibiting LDL oxidation and foam cell formation.[40] Our previous in vitro studies revealed the underlying mechanisms of polyphenol-rich MLE in the prevention of atherosclerosis via inhibiting proliferation and migration of VSMCs by way of up-regulating p53, inhibiting cyclin-dependent kinase, and blocking small GTPase, Akt/NF-κB signals. The inhibitory effect of MLE on the proliferation and migration of VSMCs has been attributed to the polyphenol component of MLE.[30,31] MWEs are rich in phenolic acids and

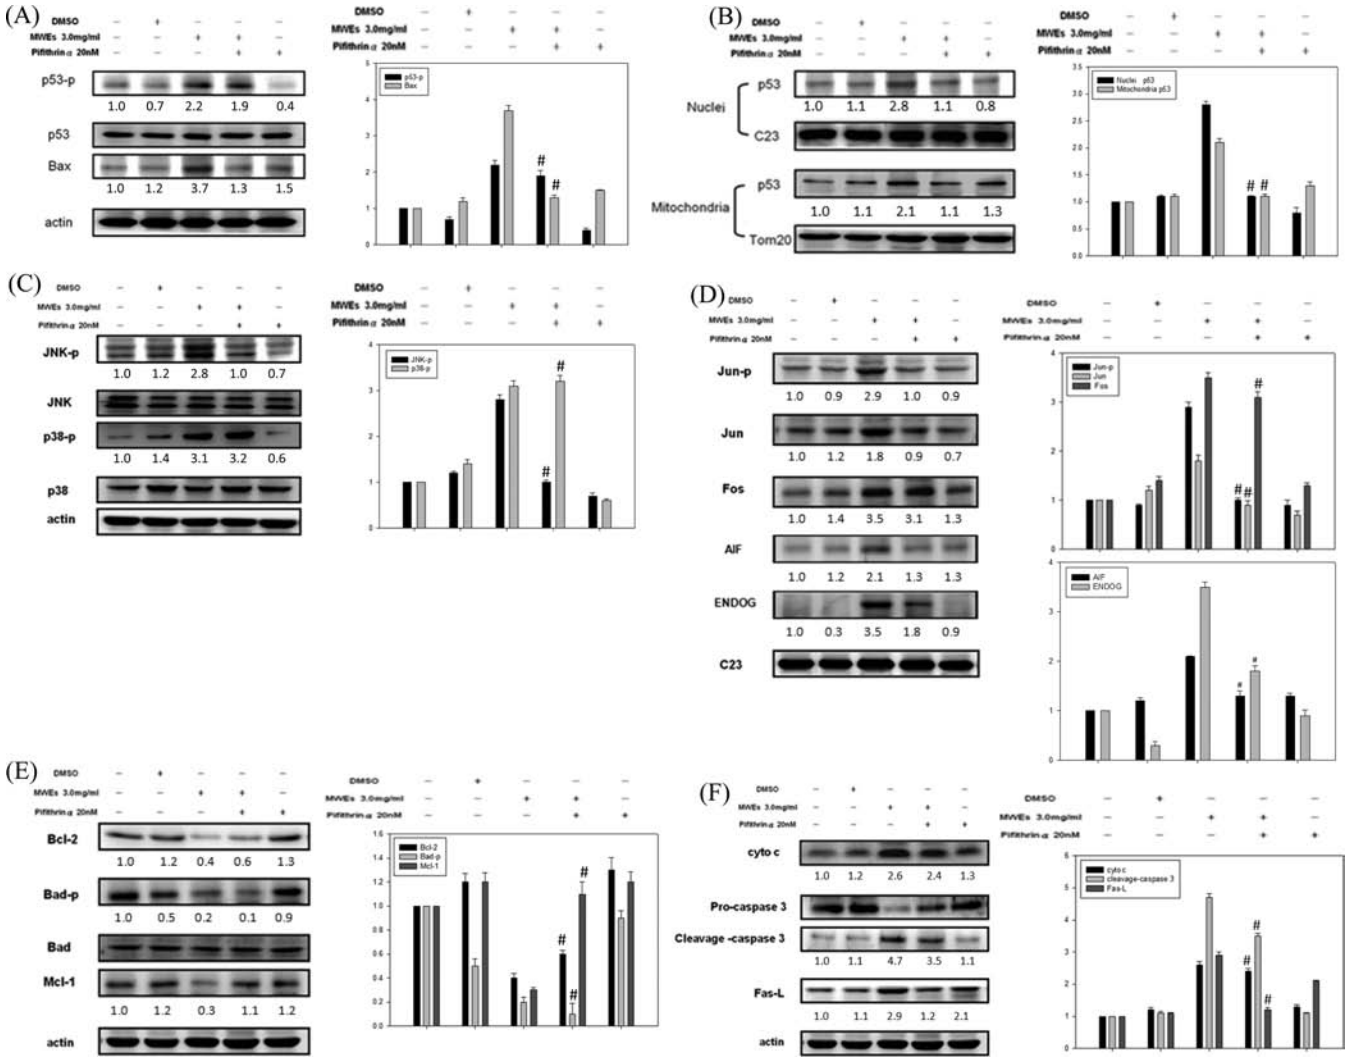

Figure 6. Effect of a p53 inhibitor on MWEs-induced p53 activation and expressions of related proteins in A7r5 cells. A7r5 cells were pretreated with or without 20 nM pifithrin-α for 30 min before the addition of MWEs at the indicated concentrations for 24 h. Fifty micrograms of total cell extracts was loaded per lane onto a 10% SDS-polyacrylamide gel and electro-blotted onto a nitrocellulose membrane. (A) p53 and Bax (B) p53 in nuclei and mitochondria extracts, (C) MAPK activation, (D) nuclear proteins, (E) Bcl-2 family protein, and (F) caspase 3, Fas-L, and cytochrome c. β-actin, C23, and Tom20 were used as internal controls. $^{\#}p < 0.05$ compared MWEs only and MWEs with pifithrin-α.

flavonoids, including gallic acid, caffeic acid, protocatechuic acid, catechin, epigallocatechin gallate, epicatechin, rutin, quercetin, and naringenin. Gallic acid has been reported to have a potential hypolipidemic effect on mice fed with a high-fat diet, as well as an ability to intervene in platelet−leukocyte interactions, thereby preventing atherosclerosis. Protocatechuic acid has also been reported to have an anti-inflammatory effect by inhibiting LDL oxidation. Flavones and catechins are the most powerful flavonoids that can protect against free radicals. Quercetin has been reported to inhibit the activity of xanthine oxidase, thereby reducing oxidative injury. Similarly, catechin, epicatechin, and epigallocatechin gallate have also been reported to have inhibitory effects on free radical production by inhibiting xanthine oxidase.[31] The supplementation of rutin was reported to promote the excretion of fecal sterols, thereby leading to a decreased absorption of dietary cholesterol as well as lower plasma and hepatic cholesterol.[41] Caffeic acid has been reported to inhibit PDGF-induced proliferation of vascular smooth muscle cells, thus to prevent atherosclerosis and restenosis.[42]

In the present in vivo and in vitro studies, we found that MWEs could effectively induce apoptosis of A7r5 VSMCs in a dose-dependent manner. As shown in Figure 3A, the MWEs-induced apoptosis was significantly increased after treatment with inhibitors of PI3K and ERK. This indicated that the mechanism of MWEs-induced apoptosis was less related to PI3K and ERK signaling. MWEs may inhibit VSMCs proliferation by way of inhibiting PI3K and ERK signaling with another unknown mechanism but not apoptosis. After treatment with inhibitors of p38 and JNK, the MWEs-induced increase in apoptosis was reduced, indicating that MWEs induce apoptosis via these two pathways. After treatment with DN-JNK and DN-p38, the increased expressions of JNK-p and p38-p by MWEs were reduced, which confirmed MWEs stimulate apoptosis via the JNK and p38 pathways. The increased expressions of phosphorylated-p53 and p21 after treatment with MWEs were significantly reduced after treatment with DN-JNK and DN-p38, indicating that JNK and p38 affect p53. The MWEs-induced increased expression of Bax was significantly reduced after treatment with DN-JNK but not changed after treatment with DN-p38, which indicates that JNK but not p38 affects the expression of Bax. The decreased expressions of the antiapoptosis proteins Bcl-2 and Mcl-1 after

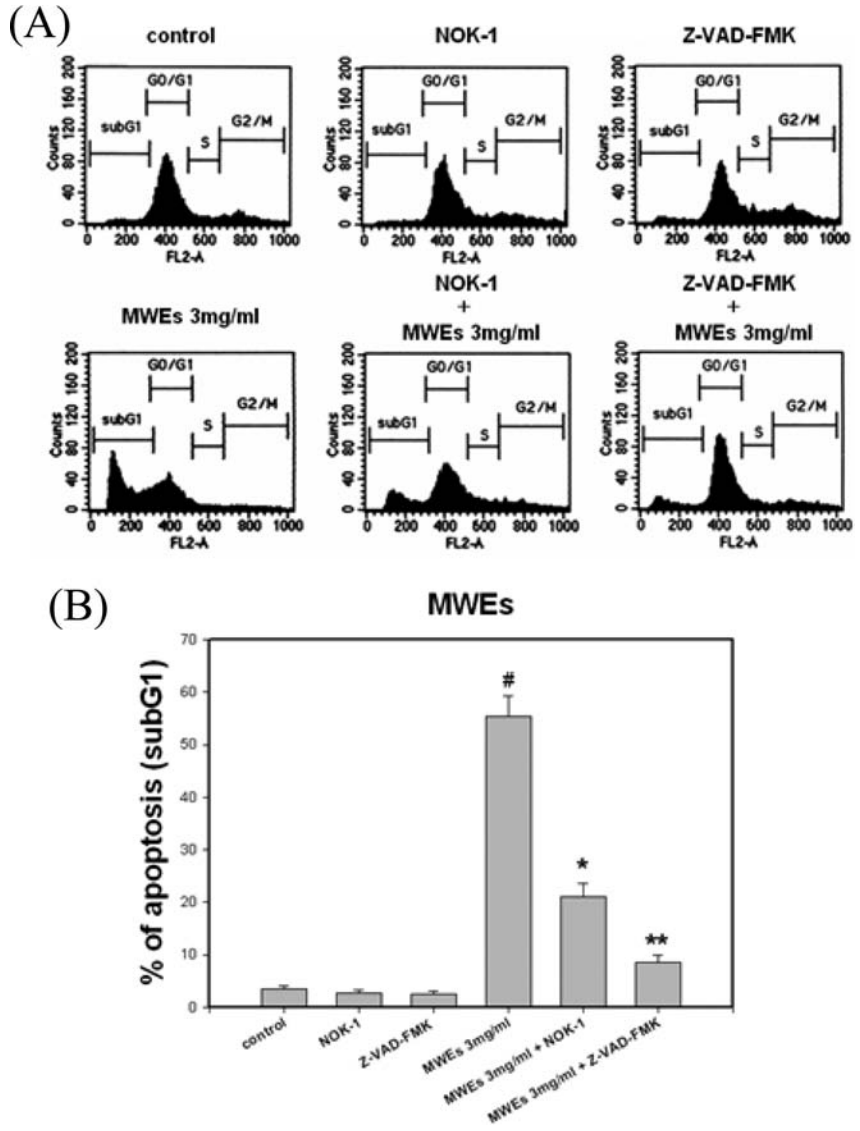

Figure 7. Effect of caspase inhibitors on MWEs-induced apoptosis in A7r5 cells. Cultured cells were treated with or without MWEs (3.0 mg/mL) for 48 h in the absence or presence of 5 μg/mL NOK-1 or 50 μM Z-VAD-FMK for 30 min. (A) Apoptosis was analyzed by flow cytometry. (B) Quantitative assessment of the percentage of A7r5 cells in the sub-G1 phase was done as indicated by propidium iodide (PI) and represents the average of three independent experiments. #p < 0.00001 compared with control, *p < 0.005, and **p < 0.0005 compared with MWEs only.

treatment with MWEs were only partially recovered after treatment with DN-JNK and DN-p38, suggesting that JNK and p38 affect the expressions of Bcl-2 and Mcl-1, but that there may still be other pathways regulating Bcl-2 and Mcl-1. Only the MWEs-induced enhanced expression of Jun-p, but not Fos, was decreased after treatment with DN-JNK. However, the MWEs-induced enhanced expressions of Jun-p and Fos were decreased after treatment with DN-p38, indicating that p38 is the key factor affecting transcription factors Jun and Fos and that JNK affects Jun. The MWEs-induced increased expressions of cytochrome c, cleavage caspase-3, and Fas-L in cytosol were all significantly reduced after treatment with DN-JNK and DN-p38, which confirmed the pathway by which MWEs activate p38 and JNK and then affect Fas-L and apoptosis. After treatment with a p53 inhibitor, the MWEs-induced increased apoptosis decreased significantly, indicating that MWEs induce apoptosis by way of p53. The MWEs-induced increased expression of Bax was decreased after treatment with a p53 inhibitor, indicating that the MWEs-induced apoptosis in mitochondria is related to p53. As shown in Figure 6B, after treatment with MWEs, the expressions of p53 in nuclei and mitochondria were enhanced, and these increased expressions were reduced again after treatment with a p53 inhibitor, indicating that MWEs affect the expressions of p53 in both nuclei and mitochondria. The MWEs-induced increased expression of phosphorylated JNK was decreased significantly after treatment with a p53 inhibitor. However, the MWEs-induced increased expression of phosphorylated p38 was not affected by treatment with a p53 inhibitor. These results indicate that p53 also affects MWEs-induced phosphorylation of JNK but not p38 phosphorylation. The MWEs-induced increased expressions of p-Jun, AIF, and ENDOG were reduced significantly after treatment with a p53 inhibitor; however, the MWEs-induced increased expression of Fos was not affected after treatment with a p53 inhibitor, indicating that p53 is upstream of Jun, AIF, and ENDOG but not Fos. The MWEs-induced decreased expressions of the antiapoptotic proteins Bcl-2 and Mcl-1 were recovered after treatment with a p53 inhibitor, however the MWEs-induced

dx.doi.org/10.1021/jf501466t | J. Agric. Food Chem. 2014, 62, 5092−5101

decreased expression of phosphorylated Bad was not affected by treatment with a p53 inhibitor. The MWEs-induced increased expressions of cytochrome c and activated caspase 3 from mitochondria were decreased after treatment with a p53 inhibitor. The MWEs-induced increased expression of Fas-L was also decreased after treatment with a p53 inhibitor. This indicates that MWEs affect apoptosis both in intrinsic mitochondria and extrinsic Fas-L pathways by way of p53. The increased number of apoptotic cells in the sub-G1 phase induced by the MWEs was reduced after treatment with the inhibitors of Fas ligand and caspase, indicating that MWEs induce apoptosis by way of both Fas-L and caspase pathways. In summary, MWEs first activate JNK/p38 and p53, which in turn activate the Fas-L and mitochondria pathways. This then causes mitochondria translocation of Bax as well as the reduction of Bcl-2, which triggers the cleavage of procaspases and finally results in apoptosis of VSMCs.

It is known that intimal hyperplasia is the main cause of restenosis after PCI. Stimulating apoptosis of VSMCs and thereby inhibiting VSMCs proliferation and migration is important for the prevention of atherosclerosis in the early stage, and this may be able to reduce the restenosis rate of PCI. The present study shows that MWEs can effectively stimulate the apoptosis of VSMCs by regulating both extrinsic and intrinsic pathways, thereby preventing atherosclerosis and intimal hyperplasia with restenosis after PCI. Our findings show that 0.5−1.0% of MWEs is effective to reduce HCD-fed-induced intimal hyperplasia in rabbits. Therefore, 2.5−5.0 g/day of MWEs for humans may be enough to prevent atherosclerosis.

*bm*5 phenotype (five plants collected) and F2 × U740*bm*5 plants displaying a normal phenotype (five plants collected).

Samples were first roughly chopped, dried at 65 °C (ventilated oven) for 72 h and then ground with a hammer mill to pass through a 1 mm screen for further analyses. The milled samples were subjected to exhaustive extraction with water, then with ethanol in a Soxhlet apparatus. The recovered extractive-free samples were dried (65 °C) and used for the analyses of lignins and of cell-wall-linked ferulic and *p*-coumaric acids.

Dioxan lignin fractions were isolated from extractive-free U740 and U740*bm*5 stem samples according to a published procedure.[10]

Determination of Klason Lignin (KL). Extractive-free sample (approximately 300 mg weighed to the nearest 0.1 mg) was transferred to a 25 mL beaker, and a 72% (w/w) H_2SO_4 solution, which was prepared from concentrated 96% H_2SO_4 according to a published procedure,[11] was added (3 mL) while stirring with a small glass rod. The mixture was allowed to stand for 2 h at 20 ± 3 °C with rod stirring every 30 min. The content of the beaker was carefully transferred to a 250 mL round flask, and additional water was used to rinse the beaker and to dilute the acid to a final concentration of 5%. The solution was refluxed (sand bath) for 3 h and with occasional shaking. The cooled reaction mixture was quantitatively vacuum-filtered through a preweighed 60 mL porosity 1 filtering Pyrex crucible (Fischer Scientific, Illkirch, France) fitted with a type GF/A glass microfiber filter (Whatman-Fisher, Illkirch, France). The insoluble residue was washed free of acid with water and dried at 105 °C overnight. The KL content was calculated from the oven-dry weight of the residue. The crucible with residue was put in a muffle furnace at 550 °C overnight and then cooled before weighting to the nearest 0.1 mg. The KL content was corrected for the presence of acid-insoluble ash. All samples were assayed at least in triplicate.

Thioacidolysis and Subsequent Gas Chromatography−Mass Spectrometry (GC-MS) Analyses of the Lignin-Derived Monomers. The thioacidolysis reagent was prepared by adding 10 mL of ethanethiol and 2.5 mL of BF_3 etherate to a 100 mL volumetric flask containing 20 mL dioxane and then adjusting the final volume to 100 mL with dioxane. For each sample, 10 mg of extractive-free ground material was put into a 30 mL glass tube fitted with a Teflonlined screwcap, together with 7 mL of freshly prepared thioacidolysis reagent and 0.1 mL of internal standard solution (heinecosane C21, 2.5 mg/mL in CH_2Cl_2). The closed tubes were then heated for 4 h and at 100 °C (oil bath), with occasional gentle shaking. After tube cooling in ice water, 7 mL of 0.2 M $NaHCO_3$ was put into each tube to quench the excess BF_3 etherate. Then, 0.1 mL of HCl (6 M) solution was added to ensure that the pH of the reaction mixture was less than 3, before addition of 7 mL of dichloromethane extraction solvent and tube mixing. About half of the lower organic phase was carefully removed with a Pasteur pipet and dried over anhydrous sodium sulfate. The dried organic extract was then concentrated under reduced pressure to a final volume of about 1 mL. An aliquot of this solution (5 μL) was trimethylsilylated (TMS) with 100 μL of *N,O*-bis(trimethylsilyl)trifluoroacetamide and 10 μL of ACS-grade pyridine for 1 h at room temperature. The TMS sample was injected (1 μL) onto a GC-MS Varian 4000 instrument (Varian, Les Ulis, France) fitted with an autosampler, a splitless injector (280 °C), and an ion trap mass spectrometer operating in the electronic impact mode with a source at 220 °C, an interface at 280 °C, and a 50 to 650 *m*/*z* scanning range. The column used was a VF-1 ms 15 m × 0.25 mm i.d. polydimethylsiloxane capillary column (0.25 μm film thickness) (Agilent Technologies, Les Ulis, France) operated in the temperature program mode (from 45 to 180 °C at +30 °C/min, then 180 to 260 °C at +3 °C/min), with helium carrier gas at a 1.5 mL/min flow rate. The GC-MS determinations of the H, G, and S lignin-derived monomers were carried out on ion chromatograms respectively reconstructed at *m*/*z* 239, 269, and 299, as compared to the internal standard hydrocarbon evaluated on the ion chromatogram reconstructed at *m*/*z* (57 + 71 + 85).[12] In addition, the marker compound diagnostic for ferulic acid incorporation in lignins, referred to as the A_G marker,[13] was evaluated from ion chromatograms reconstructed at *m*/*z* 269. The evaluation of the frequency of free phenolic groups within the H, G, and S units was performed by the same thioacidolysis method applied to samples comprehensively permethylated according to a published procedure.[14]

Analysis of *p*-Coumaric Acid and Ferulic Acid Ester-Linked to the Cell Walls. *p*-Coumaric and ferulic acids linked to the cell walls by ester bonds were released by mild alkaline hydrolysis and then analyzed by high-performance liquid chromatography (HPLC) combined with photodiode array (PDA) detection, as previously described.[12,15]

Analysis of Arabinoxylan-Bound *p*-Coumaric and Ferulic Acids. The evaluation of *p*-coumaric and ferulic acids ester-linked to arabinose units was made according to a recently published mild acidolysis method[16] adapted from the trifluoroacetic acid hydrolysis developed earlier.[17,18] The 5-*O*-*p*-coumaroyl-L-arabinofuranose, **1**, and 5-*O*-feruloyl-L-arabinofuranose, **2**, compounds (α and β anomer mixture) (Figure 1) were analyzed by GC-MS of their TMS derivatives, as previously described.[16]

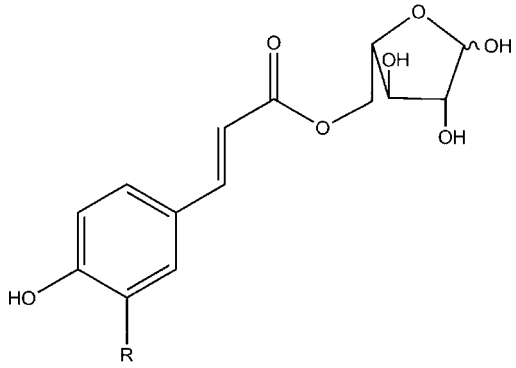

Figure 1. 5-*O*-*p*-coumaroyl-L-arabinofuranose, **1** (R = H), and 5-*O*-feruloyl-L-arabinofuranose, **2** (R = OMe), compounds (α and β anomer mixture) released by mild acidolysis of extractive-free maize samples.

RESULTS AND DISCUSSION

In the present work, we studied the cell wall phenolics (lignins and ester-linked *p*-hydroxycinnamic acids) in three different maize genetic backgrounds in order to reliably ascertain the effect of the *bm*5 mutation on these components. We thus analyzed mature stems from two inbred lines provided with the *bm*5 mutation (5803H*bm*5 and U740*bm*5) as compared to the corresponding controls (5803H and U740). In addition, we crossed the U740*bm*5 isogenic line with the INRA F2 line in

dx.doi.org/10.1021/jf5019998 | J. Agric. Food Chem. 2014, 62, 5102−5107

order to comparatively analyze F2 × U740*bm5* plants with the *bm* phenotype and F2 × U740*bm5* plants with a normal phenotype. Similar to other maize *bm* mutants,[1,2] the *bm5* plants analyzed herein displayed the brown-midrib phenotype together with the reduced Klason lignin (KL) (Table 1). In the three genetic backgrounds provided with the *bm5* mutation, the KL levels were reduced by 10−20% as compared to the corresponding controls.

Effect of the *bm5* Mutation on Levels of *p*-Coumarate Esters and Ferulate Esters in Lignified Cell Walls. The *bm5* mutation was found to significantly reduce the level of *p*-coumarate esters in the three *bm5* samples analyzed, which were decreased by 20−30% relative to the control values (Table 1). A reduced level of *p*-coumarate esters has also been found in *bm1* and *bm3* stems, whereas the level of *p*-coumarate esters is not affected by the *bm2* and *bm4* mutation.[1,19] The accretion of *p*-coumaric acid in maize cell walls has long been reported to parallel lignification because most maize *p*-coumarate esters are incorporated into lignins.[20,21] However, the fact that *p*-coumarate reduction by 20−30% exceeds the 10−20% reduction in lignin in *bm5* samples (Table 1) suggests that lignin *p*-coumaroylation is also affected by the *bm5* mutation. This hypothesis was confirmed by the analysis of purified dioxan lignin fractions isolated by acidolysis in refluxing dioxane/H_2O (9/1, v/v) containing 0.2 mol/L HCl for 30 min under nitrogen, a method which essentially preserves the *p*-coumarate esters linked to lignins. Although dioxan lignin fractions were recovered with a similarly high isolation yield from *bm5* and control extractive-free U740 stems (60% of the KL lignin level), the *bm5* dioxan lignin fraction contained about 10% less *p*-coumaric acid than the control dioxane lignin. *p*-Coumaric acid released by duplicate mild alkaline hydrolyses was 127.1 ± 1.5 mg/g from U740*bm5* dioxan lignin versus 140.9 ± 2.4 from U740 dioxan lignin. By contrast, the *p*-coumaroylation of maize arabinoxylans was not reduced by the *bm5* mutation as revealed by similar levels of 5-*O*-*p*-coumaroyl-L-arabinofuranose released by mild acidolysis of control and *bm5* samples (Table 2). It is noteworthy that the mild acidolysis method, run according to a recently published protocol,[16] provided the evidence that a weak but measurable amount of *p*-coumaric acid acylates maize arabinoxylans, whereas previous studies based on trifluoroacetic acid hydrolysis failed to provide such quantitation.[19,22] Taken together, these results suggest that the *bm5* mutation affects the content of *p*-coumarate esters linked to the cell walls by reducing both lignin level and lignin *p*-coumaroylation. According to literature,[23,24] both reductions could favorably affect the degradability of maize cell walls.

Table 2. Analyses of 5-*O*-*p*-Coumaroyl-L-Arabinofuranose, 1, and of 5-*O*- Feruloyl-L-Arabinofuranose, 2, Released by Mild Acidolysis of Control (Ctrl) and *bm5* Extractive-Free Maize Samples[a]

[a]Data are means ± SD (n = 3). [b]Stems of greenhouse-grown plants collected at the grain maturity stage. [c]Significantly different from control at $p < 0.05$ (Anova test). [d]Greenhouse-grown plants collected without ears and at the grain maturity stage.

As compared to control levels, mild alkaline hydrolysis released more ferulic acid from U740*bm5* and F2 × U740*bm5* samples provided with the *bm5* mutation (Table 1). Mild acidolysis consistently released more 5-*O*-feruloyl-L-arabinofuranose from the same *bm5* samples and relative to the controls (Table 2). It has been shown that measurable ferulate is reduced by lignification[1,25,26] as ferulate cross-links lignins to arabinoxylans not only at its *O*-4 position[27] but also in other bonding modes that resist alkaline hydrolysis.[25] Accordingly, the higher level of measurable ferulate esters observed for two *bm5* samples could originate from a higher ferulic acid incorporation into their arabinoxylans and/or from their reduced lignin content. The analysis of cell wall polysaccharides in control and *bm5* samples did not reveal any substantial change of the arabinose-to-xylose ratio, which suggests that the arabinoxylan substitution degree is not affected by the *bm5* mutation.

Unusually High Incorporation of Free Ferulic Acid in *bm5* Lignins as Revealed by Thioacidolysis. We then evaluated the impact of the *bm5* mutation on lignin structure by thioacidolysis. This method provides lignin-specific H, G, and S thioethylated monomers without any interference from ferulate and *p*-coumarate esters. In addition, the identification of minor, but diagnostic, unusual thioacidolysis monomers has provided major clues to the identification of lignin structural alterations induced by the mutation target gene.[5,28−30] On this basis, we performed an in-depth investigation of lignin-derived compounds released by thioacidolysis of extractive-free maize samples provided with the *bm5* mutation and as compared to control samples.

When calculated in μmol/gram of Klason lignin, the total yield of thioacidolysis monomers is a reflection of the frequency of lignin units only involved in 8-*O*-4 ether bonds.[4] This frequency is reduced by the *bm5* mutation as shown by lower thioacidolysis yield relative to the corresponding controls (Table 3). In addition, the relative percentage of H, G, and S thioacidolysis monomers was found to be strongly altered by

the *bm*5 mutation, with a lower level of G monomers and a higher one of S or H monomers (Table 3). Beside these changes in conventional lignin-derived thioacidolysis monomers, we looked for the occurrence of unusual minor monomers. Not unexpectedly, there were neither increased 5-OH G monomers nor increased *p*-hydroxycinnamaldehyde-derived compounds, corroborating the fact that *bm*5 mutation does not affect the genes encoding the lignin-specific COMT or CAD enzymes. By contrast, 1,2,2-trithioethyl ethylguaiacol, the thioacidolysis A_G molecular marker reported to be diagnostic of the incorporation of free ferulic acid in the lignins from various cinnamoyl CoA reductase (CCR)-deficient angiosperms,[13,30,31] was systematically observed in noticeable amounts for the three genotypes provided with the *bm*5 mutation while detectable as a trace component on the GC-MS traces of control samples (Figure 2). This component could be unambiguously identified from the mass spectrum of its TMS derivative (Figure 3). It was released from samples provided with the *bm*5 mutation, with a yield accounting for 0.5−1% of the yield of the main (H + G + S) monomers, a level 5- to 20-fold higher than that from control samples (Table 3). Such an increase indicates that free ferulic acid has been incorporated into lignins at its 8 position and by *bis* 8-*O*-4 cross-coupling that induces the loss of its carboxylic group and the formation of an unusual acetal interunit bond.[9,13] This cross-coupling mode drastically contrasts with the more conventional cross-couplings of grass ferulate esters and lignin units involving mainly the ferulate *O*-4 position.[32] When subjected to thioacidolysis, ferulate esters with free or etherified *O*-4 positions only provide free ferulic acid together with its thioethylated addition products, but no A_G.[13] By contrast, A_G was released from CCR-deficient poplar, *Arabidopsis* or tobacco plants in 5- to 50-fold higher yield than from corresponding controls, a phenomenon diagnostic of ferulic acid incorporation into lignins.[13] From the three maize genotypes under examination that are provided with the *bm*5 mutation, A_G was recovered with similarly increased yields as compared to the control level.

Higher Frequency of Free-Phenolic G Units in the Lignins of Maize Provided with the *bm*5 Mutation. In addition to conventional thioacidolysis, we performed thioacidolysis following an exhaustive cell wall methylation.[4,14,33] In these conditions, thioacidolysis monomers methylated at C4 (HOMe, GOMe, and SOMe) originate from originally free-phenolic and methylatable H, G, or S parent structures, whereas monomers trimethylsilylated at C4 (HOTMS, GOTMS, and SOTMS) originate from originally etherified H, G, and S parent

[e]Greenhouse-grown plants collected without ears and at the grain maturity stage.

structures. As shown in Table 4 and in agreement with previously published results,[4,33] the 8-*O*-4 linked H units were essentially free-phenolic units (i.e., 80−90% of H monomers were methylated at C4), whereas S units were prominently internal units etherified at C4 (only 6−8% could be methylated). G units displayed an intermediate behavior and, more importantly, the percentage of free-phenolic G units was substantially increased in the samples provided with the *bm*5 mutation. As already reported for maize samples,[4] the percentage of free-phenolic G units among the 8-*O*-4 linked G units was in the 50−55% range for the controls, whereas this percentage was in the 60−64% range for the samples with the *bm*5 mutation (Table 4). The same trend was observed for S units (Table 4). An increased frequency of free-phenolic G units relative to G units involved in 8-*O*-4 bonds has been already shown in the lignins of various CAD-deficient[4] and CCR-deficient plants.[13,30] Not unexpectedly, the thioacidolysis A_G molecular marker for ferulic acid incorporation into lignins was observed both as C4-OMe and C4-OTMS derivatives on the GC-MS traces of the TMS thioacidolysis reaction mixture obtained from permethylated samples provided with the *bm*5 mutation.

Introduction of Readily Cleavable Acetal Linkages into the Lignin Backbone by the *bm*5 Natural Mutation. In addition to the moderately reduced lignin content, the *bm*5 mutation induces substantial alterations in the structure of the lignins from the three maize *bm*5 genotypes analyzed herein. The most remarkable alteration, which is common to *bm*5 maize lignins and to the lignins from CCR-deficient plants,[13,30,31] is the increased frequency of *bis* 8-*O*-4 acetal linkages in the lignin polymers as revealed by the higher yield of the thioacidolysis-derived A_G marker. According to recent studies, these acetal bonds are produced by the incorporation of free ferulic acid into the lignin polymers through readily cleavable acetal linkages.[9,13] In recent years, research efforts have focused on redesigning lignin structure to make lignins more amenable to the chemical delignification pretreatments which are necessary for cost-effective production of cellulosic ethanol.[8,9,34] Such a structural redesigning can not only rely on elegant transgenic strategies as recently reported[35] but can also profit from spontaneous mutations like the *bm*5 maize mutation.

■ ACKNOWLEDGMENTS

We very sincerely thank Dr. Paul Scott (Iowa State University), Dr. Thomas Lübberstedt (Iowa State University), and Dr. Marty Sachs (MGCSC, University of Illinois) for kindly providing the *bm*5 seeds in the U740 and 5803H genetic backgrounds. We thank Richard Chazal for performing the analysis of the composition of cell wall polysaccharides. This research was partially funded by the ANR Biomass for the Future program (BFF 2012−2019; http://www.biomassforthefuture.org/en/) and by the ANR MAGIC 2008−2012 program for financial support to A.L.

■ ABBREVIATIONS USED

CAD, cinnamyl alcohol dehydrogenase; COMT, caffeoyl-*O*-methyltransferase; CCR, cinnamoyl CoA reductase; G, guaiacyl; H, *p*-hydroxyphenyl; KL, Klason lignin; 5-OH G, 5-hydroxyguaiacyl; S, syringyl; TMS, trimethylsilylated

[a]DM = dry matter; OM = organic matter; EE = ether extract; NDF = neutral detergent fiber; ADF = acid detergent fiber; ADL= acid detergent lignin; CHO = carbohydrate. Carbohydrate was calculated as CHO = 100 − EE − CP − Ash (NRC-2001). Hemicellulose = NDF − ADF (NRC-2001); cellulose = ADF − ADL (NRC-2001). R_DDM = in situ rumen digestibility od DM. C_DDGS = corn DDGS; B_DDGS = barley DDGS. SEM = pooled standard error of the mean. Means with the different letters in the same row are significantly different ($p < 0.05$).

dx.doi.org/10.1021/jf500711p | J. Agric. Food Chem. 2014, 62, 5108−5117

hypothesized that the changes in carbohydrate molecular structures were sensitive to different processing methods and interactively affect bioavailability in animals.

MATERIALS AND METHODS

Coproducts from Different Manufactures in China and Chemical Analysis. In this study, five kinds of corn DDGS and two kinds of barley DDGS were collected from 2012 to 2013 in China. They were numbered as "1, 2, 3, 4, 5, 6, and 7". Dry matter, ash, organic matter (OM), and ether extract (EE) were determined by using the procedure of AOAC (1990) method.[1] Neutral (NDF) and acid detergent fibers (ADF) and lignin (ADL) were determined using the filtration method.[11] For the starch content analysis, the samples were ground to 0.5 mm and measured using the Megazyme method.[12] The hemicellulose, cellulose, and carbohydrate (CHO) were calculated.[5,11]

Partitioning Carbohydrate Subfractions and Predict Values for Energy in Animals. The carbohydrate subfractions were partitioned by Cornell fraction system (CNCPS),[13,14] into CA fraction (CA = fast degradable), CB1 fraction (CB1 = medium degradable), CB2 fraction (CB2 = available cell wall), and CC fraction (CC = unfermentable fiber fraction).

Truly digestible fatty acid (tdFA), tdNDF, tdNFC, TDN, digestible ($DE_{1\times}$), metabolizable ($ME_{p3\times}$), net lactation ($NE_{lp3\times}$), net maintenance (NE_m), and net growth energy values (NE_g) were modeled[5,15,16]

In Situ Rumen Incubation. In situ nylon bag technique was used to estimate rumen digestibility of dry matter at 16 h with two nonlactating Holstein dairy cattle with a rumen cannula, housed at dairy research station in University of Saskatchewan (Saskatoon, Canada).[20,21] The detailed procedure was conducted according to previous published literature.[17−19] The animals were cared by following guidelines of the Canadian Council of Animal Care (CACC).[22]

Molecular Spectroscopy and Analyses on Carbohydrate Structure. The carbohydrate spectral features were studied at Professor Dr. Yu's molecular spectroscopy lab with JASCO FT/IR-4200 (Tokyo, Japan) in the University of Saskatchewan (Canada) following standard lab procedures.[23]

OMNIC 7.3 (Thermo-Nicolet, Madison, Wisconsin) software was used to analyze CHO molecular spectral data. The following chemical functional groups centered differently which are related to the CHO molecular structure were focused on (1) structural CHO (STCHO), (2) cellulosic compounds (CELC), and (3) total carbohydrate (CHO). The CHO spectral parameters (in terms of STCHO, CELC, and CHO peak intensity and their ratio) were obtained from publications.[24−28]

The univariate molecular spectral analysis was performed with OMNIC 7.3 (Thermo-Nicolet, Madison, Wisconsin) software. The STCHO peak, related to hemicellulose and cellulose, were in the region ca. 1507−1186 cm^{-1}, and three subpeaks in this region with peak height centering at ca. 1456, 1374, and 1240 cm^{-1}, respectively. The peak area region mainly associated with cellulose compounds was at ca. 1304−1186 cm^{-1}, and the cellulose compounds peak height centered at ca. 1240 cm^{-1}. For the CHO, the peak area region was at ca. 1217−907 cm^{-1}, and three subpeaks were also found in this region, with peak heights centered at ca. 1150, 1093, and 1037 cm^{-1}, respectively.

For multivariate molecular spectral analysis for CHO molecular structure, the CHO IR fingerprint data of different corn DDGS and barley DDGS were analyzed by cluster and principal component analyses using Statistics 8.0 software (StatSoft Inc., Tulsa, OK, U. S. A.) according to previous study.[24] These analyses were used to clarify and distinguish inherent carbohydrate structural difference and relationships among these kinds of DDGS samples within the regions of STCHO (ca. 1507−1186 cm^{-1}), cellulose compounds (ca. 1304−1186 cm^{-1}), and CHO (ca. 1217−907 cm^{-1}).

Statistical Analysis. *Basic Carbohydrate Chemical Profiles, Carbohydrate Subfractions, and Estimated Energy Studies.* All chemical composition, carbohydrate subfractions partitioned by CNCPS and estimated energy values data were analyzed by using the PROC MIXED procedure of Statistical Analysis System (SAS version 9.3, SAS Institute Inc., Cary, NC, U. S. A.).[29] The model was $Y_{ij} = \mu + F_i + e_{ij}$, where, Y_{ij} was measures ij; F_i was the feed source (i = 1−7). The comparison of corn based DDGS with barley based DDGS was carried out using Contrast statement in SAS.

In Situ Degradation. The model for the analysis was $Y_{ijk} = \mu + F_i + R_j + e_{ijk}$, where Y_{ijk} was an measure; F_i was the feed source (i = 1−7), as a fixed effect, R_j was the in situ experiment with two cows as a random effect. The comparison between corn DDGS and barley DDGS was carried out using Contrast statement in SAS.

Carbohydrate Molecular Structure Spectral Data Analysis. The FT/IR spectroscopic data were analyzed using a completely randomized design model $Y_{ij} = \mu + T_i + e_{ij}$, where Y_{ij} was measrue (STCHO peak area and three subpeak height and area, cellulose compounds peak area and peak height, CHO peak area and three subpeak height and area); T_i was the feed source (i = 1−7), as a fixed effect. The comparison between corn DDGS and barley DDGS was carried out using Contrast statement in SAS.

Correlation Analysis of CHO Molecular Spectral Profile with CHO Nutritional Profiles. The relationship between changes in CHO molecular structure spectral profile or functional groups and in CHO chemical and nutrients profiles (chemical composition, CHO fractions partitioned by CNCPS, in situ rumen degradation of DM) in the different types of Chinese DDGS were analyzed by using the PROC CORR procedure of SAS 9.2.[29] The assumption for correlation analysis was checked using Shapiro-Wilk method.

Significance was declared at $p < 0.5$. Differences among treatments were evaluated using Tukey-Karmer method; means with different letters were obtained with "pdmix800 SAS macro".[29]

RESULTS AND DISCUSSION

Difference in CHO Chemical Profiles and CHO Fractions among All DDGS Samples. The detailed CHO chemical profiles are presented in Table 1. Chemical feature differ among the DDGS samples. Our results showed that DM content in five kinds of corn DDGS and two kinds of barley DDGS was different ($p < 0.05$), and ash content in all DDGS samples also was different ($p < 0.05$). It might be explained by different plant location of original cereal grains, which produce the coproductions. Organic matter content in corn DDGS was similar (949 vs 956 g/kg DM) with previous study.[30] The content of EE showed differences ($p < 0.05$) among all DDGS samples. Corn DDGS was lower ($p < 0.05$) in NDF than barley DDGS (454 vs 545 g/kg DM), lower ($p < 0.05$) in ADF than

dx.doi.org/10.1021/jf500711p | J. Agric. Food Chem. 2014, 62, 5108−5117

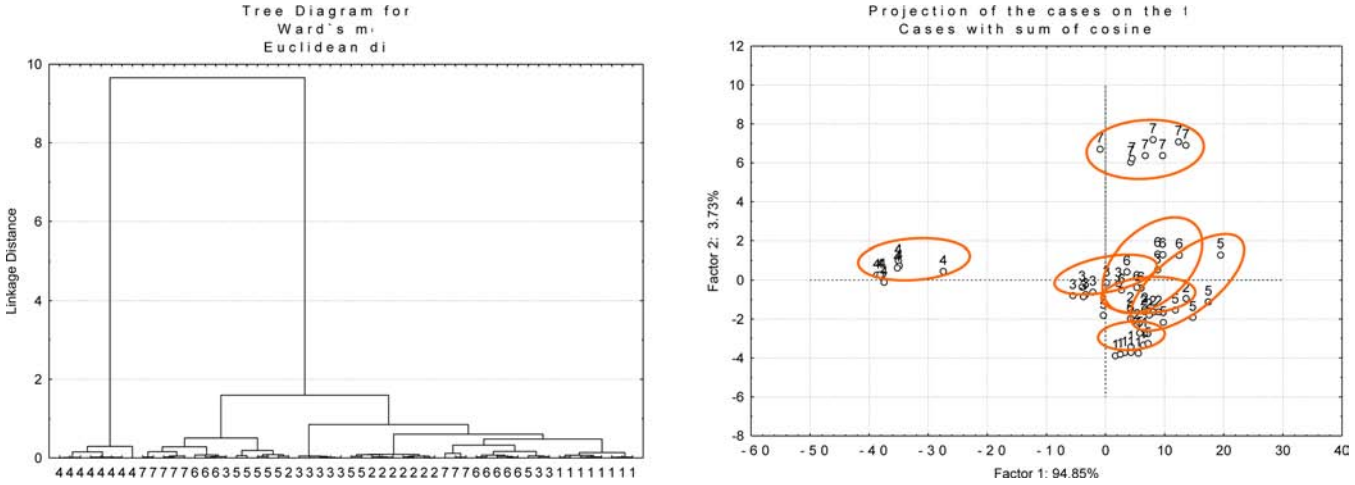

Figure 1. Multivariate molecular spectral analysis of STCHO (region: 1507−1186 cm^{-1}) CLA and PCA analysis.

barley DDGS (160 vs 184 g/kg DM), and lower ($p < 0.05$) in ADL than barley DDGS (25 vs 52 g/kg DM). Some residual starch in the Chinese DDGS samples indicated incompleted fermentation. However, the residual starch in the sample was not significantly different between two types of DDGS (37 vs 39 g/kg DM). The residual starch content in all seven DDGS samples was different ($p < 0.05$); cereal grain fermentation efficiency may account for the difference, which is associated with grain particle size, liquids temperature, and fermentation time in processing.

Carbohydrate subfractions, which were partitioned by CNCPS and included CA, CB1, CB2, and CC, are shown in Table 2. Compared with barley DDGS, corn DDGS was higher ($p < 0.05$) in the CA subfraction, lower ($p < 0.05$) in the CB2 subfraction and CC subfraction, similar in the CB1 subfraction. The CA subfraction content in corn DDGS in our result is much higher than the previous reported,[30] and the CA content in barley DDGS in our study is lower than previous study.[31]

Difference in Predicted Value for Energy in Animal from Corn DDGS and Barley DDGS. The NRC models are applied to predict the coproduct value of energy in animals, the results are presented in Table 2. Compared to barley DDGS, corn DDGS was lower ($p < 0.05$) in truly digestible FA and truly digestible NDF. Corn DDGS in our study was lower ($p < 0.05$) in TDN (806 vs 898 g/kg DM), lower ($p < 0.05$) in tdNDF (190 vs 221 g/kg DM), and higher ($p < 0.05$) in tdNFC (199 vs 85 g/kg DM) than corn DDGS in previous literature.[30] This may indicate that corn DDGS in our study is superior to those previous reported. In this study, the $DE_{1\times}$, $ME_{p3\times}$, $NE_{lp3\times}$, and NE_g in barley DDGS were not different from corn DDGS ($p > 0.05$).

Difference in In Situ Rumen Degradation. The effects of the DDGS types on in situ rumen degradability of DM (R_DDM) after 16 h rumen incubation are presented in Table 1. There are significant different ($p < 0.05$) in D_DM at 16 h incubation between corn DDGS and barley DDGS (R_DDM: 47.9−51.5%). Rumen degradability of DM at 24 and 48 h in the previous study were 65.8% and 81.8%, respectively.[30] There were no large quantities left after 24 h fermentation for the coproducts. In the lactating cow with typical levels of intake, little DM remains for 48 h. The samples were often stay in rumen for 12 to 18 h, and then the residue flows into the small intestine.[32]

Carbohydrate Molecular Structure Features in Different Type and Sources of DDGS. Absorbed IR intensity of carbohydrate and their spectral ratios in different type of DDGS are presented in Table 3. The carbohydrate-related molecular spectral groups or functional groups in our study are involved structural carbohydrate (STCHO), cellulose compounds (CELC), and total carbohydrate (CHO). For STCHO fraction, such as hemicellulose, cellulose and nonstructural carbohydrate, there were significantly different ($p < 0.05$) between corn DDGS and barley DDGS with regard to most of spectral profiles. The STCHO first and third peak heights as well as area absorbed intensities for corn DDGS were 0.062, 0.015, and 3.529 IR units and 0.018, 0.015, and 3.929 IR units for barley DDGS, respectively. The difference between the two type of DDGS may imply that the hemicellulose and cellulose compounds were higher ($p < 0.05$) in corn DDGS than in barley DDGS. However, no difference ($p > 0.05$) was observed between those two types of DDGS in STCHO second peak height. For CELC fraction, corn DDGS was significantly ($p < 0.05$) higher than barley DDGS in cellulose compound peak area (0.866 vs 0.573 IR unit). The absorption peak concentrate at ca. 1240 cm^{-1} within STCHO region (ca. 1507−1186 cm^{-1}), which was associated with CELC (baseline ca. 1304−1186 cm^{-1}), Compared to SCHO spectral parameters, corn DDGS was similar to barley DDGS in CELC peak height absorption intensities. These results are in good accordance with cellulose data showed in Table 1. CHO spectral intensities in terms of peak intensity area and three-subpeak area and height were significantly different ($p < 0.05$) in those two type of DDGS with regard to most of CHO spectral parameters. The above carbohydrate functional group ratios are associated with feed quality and nutritive values.[33,34]

In our study, parameters of ratio in terms of peak height and peak area showed significant difference ($p < 0.05$) between these two types of DDGS samples with regards to most of carbohydrate spectra. Corn DDGS had higher ($p < 0.05$) ratio values of CHO first peak to second and third peak area than barley DDGS (0.238 vs 0.196 IR unit). The ratio values of CHO first peak to third peak height in corn DDGS was higher ($p < 0.05$) than barley DDGS (0.359 vs 0.217 IR unit). The ratio of STCHO to CHO peak intensity area and amide I to CHO peak intensity area ratio were significantly different ($p < 0.05$) between corn DDGS and barley DDGS, the value of the peak area ratio was 0.203, 0.230, 0.305, and 0.263 IR unit,

dx.doi.org/10.1021/jf500711p | J. Agric. Food Chem. 2014, 62, 5108−5117

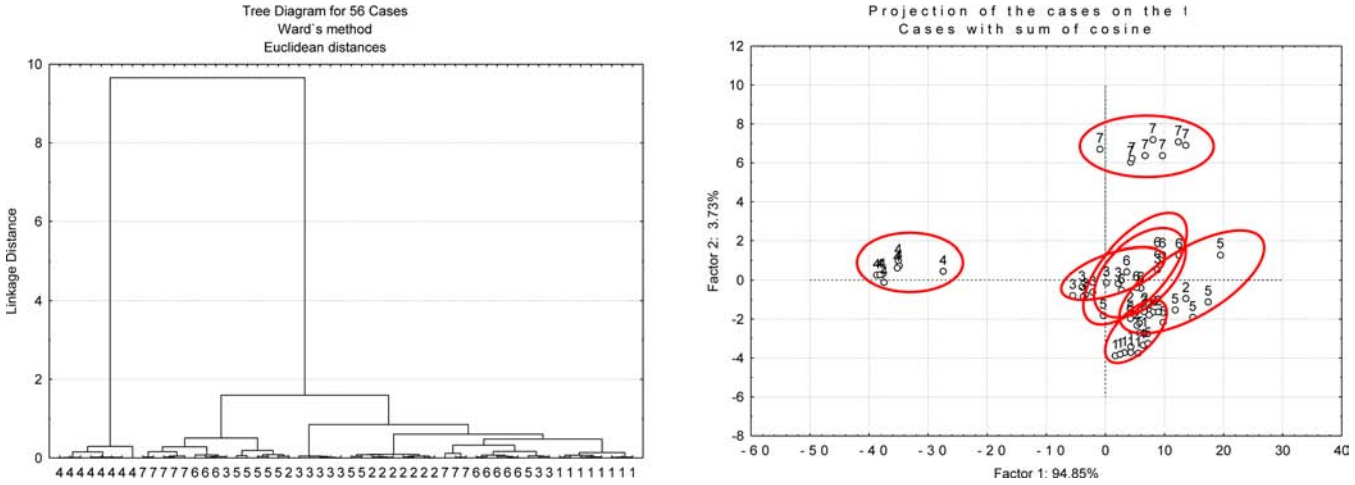

Figure 2. Multivariate molecular spectral analysis of cellulosic compounds (region: 1304−1186 cm^{-1}) CLA and PCA analysis.

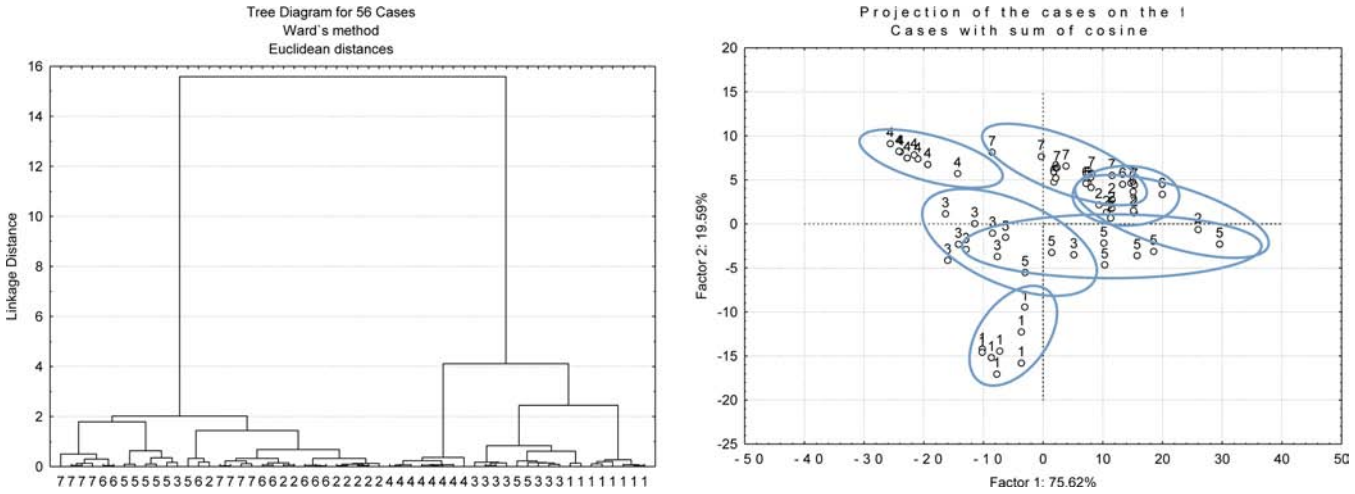

Figure 3. Multivariate molecular spectral analysis of total carbohydrate (region: 1217−907 cm^{-1}) CLA and PCA analysis.

respectively. This showed that the advanced molecular spectroscopic could reveal the real inherent molecular structure spectral profile. There was no published study of carbohydrate molecular structure in corn DDGS and barley DDGS, so the comparison of carbohydrate molecular spectral parameters between them could not be made. However, a previous study reported that the carbohydrate molecular (in terms of different component peaks and their ratio) ratio parameters were related to degradation rate and extend.[35] These molecular spectral profiles in those two types of DDGS are believed to highly relate feed quality.

Multivariate Molecular Spectral Analysis in the Fingerprint Region in Corn DDGS and Barley DDGS. The CLA and PCA analysis[23] were conducted on the entire spectral information within STCHO, CELC, and CHO region. The analysis results are showed in Figures 1−3. Figure 1 shows the result of CLA and PCA of carbohydrate molecular spectral in the fingerprint region ca. 1507−1184 cm^{-1}. The CLA indicated that the structures of carbohydrate (STCHO) were not fully separated except for the number 1 and 4 samples. Also, it was not distinguished from themselves except for the number 4 and 7 samples. The first and second principal components explained 94.85% and 3.73% of the total variance, respectively. Figure 2 shows the results of CLA and PCA analysis of cellulose compounds (CELC) molecular spectral in the fingerprint region ca. 1305−1184 cm^{-1}. The CLA showed that inherent structure makeup of five corn DDGS and two barley DDGS was not distinguished. The result of PCA analysis was similar to STCHO. Figure 3 showed the result of CLA and PCA analysis of total carbohydrate (CHO) molecular spectral in the fingerprint region ca. 1217−907 cm^{-1}. Carbohydrate structure makeup of five corn DDGS and two barley DDGS were not distinguished. The PCA showed that the first and second principal component were 75.62% and 19.59% of the total variance, respectively. These results illustrated that those DDGS samples were related to each other, although the molecular spectral structure of some DDGS samples were different.

Correlations between Carbohydrate Spectral Characteristics and Carbohydrate Nutritive Properties among Different Types and Sources of DDGS. The correlation results are presented in Table 4. The result showed that the molecular spectral intensity of STCHO and CELC peak area had no correlation ($p > 0.05$) with nutritive parameters in corn DDGS and barley DDGS, except for ADF. Negative correlation between STCHO peak area and ADF content with $R = -0.63$ ($p < 0.05$). CELC peak area had a negative correlation with ADF ($p < 0.05$) with $R = -0.57$. These results indicated that higher STCHO and CELC peak area are associated with lower ADF content in the corn DDGS and barley DDGS sample. It

also indicated that STCHO and CELC could not be used as an indicator to predict nutrient profiles except for ADF in DDGS samples.

For the total CHO part, it also found that ADF had negative correlation with CHO first, second, and total peak area ($p < 0.05$) with $R = -0.54$, -0.78, and -0.65, respectively. However, there is no correlation ($p > 0.05$) with CHO third peak area. CHO first and total peak area had a negative correlation with truly digestible NDF (tdNDF) ($p < 0.05$) with $R = -0.55$ and -0.57, respectively. DM content in original corn DDGS and barley DDGS also had a negative with CHO second and total peak area ($p < 0.05$) with $R = -0.75$ and -0.71, respectively. However, no correlation ($p > 0.05$) was found between in situ digestibility of DM (R_DDM) and CHO second and total peak area. No correlation was found between all carbohydrate spectral parameters and energy values and carbohydrate subfractions partitioned by CNCPS. Our data of correlation between CHO spectral parameters and carbohydrate basic chemical profile and in situ digestible of DM were not consistent with a previous study; however, the results of relationship between all spectral intensities of CHO and energy values and carbohydrate subfractions were to some extent consistent with the previous report.[36] Further study with large range sample size is necessary to confirm whether carbohydrate structure spectral profiles could be used as a fast predictor of the nutritional values and to find which spectral of functional groups of carbohydrate are much more sensitive to the coproduct samples after the different processing.

In summary, different types and sources of DDGS from China in this study have different carbohydrate nutritional profiles and carbohydrate inherent structural makeup. According to the result of correlation analysis, ADF showed negative correlation with most of carbohydrate peak area (e.g., structural carbohydrate peak area, cellulose compounds peak area, and total carbohydrate first, second, and total peak area). CHO spectral parameters have no correlation with carbohydrate subfractions and energy values. Spectral intensities of CHO also showed no correlation with truly digestible nutrients except for truly digestible NDF (tdNDF). The results indicate that carbohydrate spectral profiles are highly associated with carbohydrate utilization in coproducts from biofuel and biobrewing processing. The results indicate that carbohydrate spectral profiles are highly associated with carbohydrate utilization in coproducts from biofuel and biobrewing processing.

Funding

The current study was supported by the Thousand-Talent-People Program in Tianjin, the Ministry of Agriculture Strategic Feed Research Chair Program at the University of Saskatchewan, and the Natural Sciences and Engineering Research Council of Canada (NSERC- Individual Discovery). The scholarship was provided to L.C. for overseas training and research through the Thousand-Talent-People Program in Tianjin.

Notes

The authors declare no competing financial interest.

■ ACKNOWLEDGMENTS

The authors also thank the Department of Animal and Poultry Science at the University of Saskatchewan (Canada) for providing lab and animal research facilities to do this international collaborative feed research project, Jifei Ma for his support at Tianjin Agricultural University, Zhiyuan Niu, Hangshu Xin and Manji Sun for research and laboratory assistance.

MATERIALS AND METHODS

Bacterial Strains, Plasmids, Enzymes, and Reagents. *L. plantarum* WCFS1 was kindly provided by M. Kleerebezem (NIZO Food Research, The Netherlands). *Escherichia coli* DH10B and *E. coli* BL21 (DE3) were used as transformation and expression hosts in the pURI3-Cter vector.[28] Plasmid pGro7 (TaKaRa) was used to overexpress GroES/GroEL chaperones. The *L. plantarum* strain was grown in MRS medium (Pronadisa, Spain) adjusted to pH 6.5 and incubated at 30 °C. The *E. coli* strains were cultured in Luria−Bertani (LB) medium at 37 °C with shaking at 200 rpm. When required, ampicillin, chloramphenicol, or arabinose were added to the medium at a concentration of 100 or 20 μg/mL or 2 mg/mL, respectively.

Plasmid DNA was extracted with a High Pure plasmid isolation kit (Roche). PCR product was purified with a QIAquick gel extraction kit (Quiagen). Oligonucleotides were purchased from Eurofins MWG Operon (Ebersberg, Germany). *Dpn*I and HS Prime Star DNA polymerase were obtained from TaKaRa. His-tagged protein was purified by a Talon Superflow resin (Clontech). All the *p*-nitrophenyl esters, isopropyl-β-D-thiogalactopyranoside (IPTG), ampicillin, chloramphenicol, and arabinose were obtained from Sigma (Madrid, Spain). All other chemicals were obtained from commercial suppliers.

Cloning of lp_1002 from *L. plantarum*. The gene encoding for a putative lipase/esterase (*lp_1002*) (gene ID 1063602) in *L. plantarum* WCFS1 was PCR-amplified by Prime Star HS DNA polymerase (TaKaRa) by using the primers 959 (5′-*TAACTTTAAGAAGGAGATATACATatg*caagttattaagcaaaaattaa) and 960 (5′-*GCTATTAATGATGATGATGATGATG*acgattatcagctagccattcaag) (the nucleotides pairing the expression vector sequence are indicated in italics, and the nucleotides pairing the *lp_1002* gene sequence are written in lowercase letters). The 795-bp purified PCR product was inserted into the pURI3-Cter vector using a restriction enzyme- and ligation-free cloning strategy.[28] The vector produced recombinant proteins having a six-histidine affinity tag in their C-termini. *E. coli* DH10B cells were transformed, recombinant plasmids were isolated, and those containing the correct insert were identified by restriction enzyme analysis, verified by DNA sequencing, and then transformed into *E. coli* BL21 (DE3) cells for expression.

Expression and Purification of Recombinant Lp_1002 Esterase. *E. coli* BL21(DE3) harboring pGro7 (TaKaRa), a vector overexpressing GroES/GroEL chaperones, was transformed with the recombinant plasmid pURI3-Cter-1002. *E. coli* was grown in LB medium containing 100 μg/mL ampicillin, 20 μg/mL chloramphenicol, and 2 mg/mL arabinose until an optical density at 600 nm of 0.4 was reached and then induced by adding isopropyl-β-D-thiogalactopyranoside (IPTG) at 0.4 mM final concentration. Following induction, the cells were grown at 22 °C for 20 h and collected by centrifugation (8000*g*, 15 min, 4 °C). The cells were resuspended in phosphate buffer (50 mM, pH 7) containing 300 mM NaCl. Crude extracts were prepared by French press lysis of the cell suspension (three times at 1,100 psi). The insoluble fraction of the lysate was removed by centrifugation at 47,000*g* for 30 min at 4 °C, and the supernatant was filtered through a 0.2 μm pore-size filter and then applied to a Talon Superflow resin (Clontech) equilibrated in phosphate buffer (50 mM, pH 7) containing 300 mM NaCl and 10 mM imidazole to improve the interaction specificity in the affinity chromatography step. The bound enzyme was eluted using 150 mM imidazole in the same buffer. The purity of the enzymes was determined by SDS-PAGE in Tris-glycine buffer. Protein concentration was measured according to the method of Bradford using a protein assay kit (Bio-Rad) with bovine serum albumin as the standard. Fractions containing the His6-tagged protein were pooled and analyzed for esterase activity.

Enzyme Assay. Esterase activity was determined by a spectrophotometric method described previously using *p*-nitrophenyl acetate (Sigma-Aldrich) as the substrate.[26] The rate of hydrolysis of *p*-nitrophenyl acetate for 10 min at 37 °C was measured in 50 mM sodium phosphate buffer pH 7.0 at 348 nm in a spectrophotometer (UVmini-1240 Shimadzu). The reaction was stopped by chilling on ice.

In order to carry out the reaction (1 mL), a stock solution of 25 mM of *p*-nitrophenyl acetate was prepared in acetonitrile/isopropanol (1:4, v/v)[29] and mixed with 50 mM sodium phosphate buffer (pH 7.0) to obtain a 1 mM substrate final concentration. Control reactions containing no enzyme were utilized to account for any spontaneous hydrolysis of the substrates tested. Enzyme assays were performed in triplicate. One unit of esterase activity was defined as the amount of enzyme required to release 1 μmol of *p*-nitrophenol per minute under standard reaction conditions

Substrate Specificity. The substrate specificity of Lp_1002 was determined by using different *p*-nitrophenyl esters of various chain lengths (Sigma-Aldrich) [*p*-nitrophenyl acetate (C2), *p*-nitrophenyl butyrate (C4), *p*-nitrophenyl caprylate (C8), *p*-nitrophenyl laurate (C12), *p*-nitrophenyl myristate (C14), and *p*-nitrophenyl palmitate (C16)] as substrates, as described previously.[22,26] A stock solution of each *p*-nitrophenyl ester was prepared in acetonitrile/isopropanol (1/4, v/v). Substrates were emulsified to a final concentration of 0.5 mM in 50 mM sodium phosphate buffer, pH 7.0, containing 1.1 mg/mL Arabic gum, and 4.4 mg/mL Triton X-100. The reaction mix consisted of 990 μL of emulsified substrate and 10 μL of enzyme solution (10 μg protein). Reactions were carried out at 37 °C in a spectrophotometer (UVmini-1240 Shimadzu) as described above.

The enzymatic substrate profile of purified protein was determined by using an ester library described previously.[30] *p*-Nitrophenol was used as pH indicator to monitor ester hydrolysis colorimetrically. The screening was performed in a 96-well Flat Bottom plate (Sarstedt) where each well contains a different substrate (1 mM) in acetonitrile (1%). A buffer/indicator solution containing 0.44 mM of *p*-nitrophenol in 1 mM sodium phosphate buffer pH 7.2 was used as pH indicator. Esterase solution (10 μg, 20 μL in 1 mM sodium phosphate buffer pH 7.2) was added to each well, and reactions were followed by measuring the decrease in absorbance at 410 nm for 2 h at 37 °C in a Synergy HT BioTek microplate spectrophotometer. Blanks without enzyme were carried out for each substrate, data were collected in triplicate, and the average activities were quantified. Results are shown as means ± standard deviations.

Effects of Temperature, pH, and Additives on Lp_1002 Esterase Activity. The effects of pH and temperature on the esterase activity of Lp_1002 were studied by using buffers of different pH ranging from 3 to 9. The buffers (100 mM) used were acetic acid−sodium acetate (pH 3−5), sodium phosphate (pH 6 to 7), Tris-HCl (pH 8), and glycine-NaOH (pH 9). The optimal temperature was assayed by incubating purified Lp_1002 esterase in 50 mM phosphate buffer (pH 7) at different temperatures (5, 20, 30, 37, 40, 45, 55, and 65 °C). For temperature stability measurements, the recombinant esterase was incubated in 50 mM phosphate buffer pH 7 at 20, 30, 37, 45, 55, and 65 °C for 5, 15, and 30 min and 1, 2, 4, 6, and 20 h. Aliquots were withdrawn at these incubation times to test the remaining activity at standard conditions. The nonheated enzyme was considered as control (100%). The analyses were performed in triplicate.

To study the effect of metals and ions on Lp_1002 esterase activity, the enzyme was incubated in the presence of the different additives at a final concentration of 1 mM for 5 min at room temperature. Then, the substrate was added, and the reaction mixture was incubated at 37 °C. The residual esterase activity was measured after the incubation of the purified enzyme with each additive. The additives analyzed were $MgCl_2$, KCl, $CaCl_2$, $HgCl_2$, $ZnCl_2$, $CuCl_2$, $NiCl_2$, $MnCl_2$, Triton-X-100, Tween 20, Tween 80, SDS, urea, EDTA, DMSO, cysteine, DTT, PMSF, DEPC, and β-mercaptoethanol. Esterase activity measured in the absence of any additive was taken as control (100%). Experiments were done in triplicate.

Effect of Wine Compounds on Lp_1002 Activity. The effect of the presence of compounds present during winemaking was assayed. The effect of ethanol on esterase activity was studied at ethanol concentrations ranging from 0 to 20% (v/v). Reaction mixtures were prepared as described for the temperature optimum experiments, but different volumes of ethanol were added, and the volume of the buffer was adjusted accordingly to maintain the final reaction volume. The reactions were preincubated for 5 min at room temperature, and the substrate (*p*-nitrophenyl acetate) was added. The effect of the presence of several organic acids was also studied. L-Malic, L-tartaric, DL-citric, and DL-lactic acids were assayed at concentrations ranging from 0 to 5 g/L.

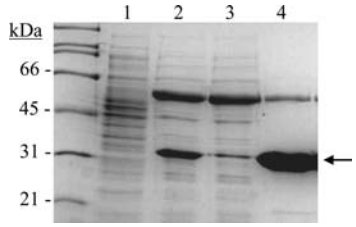

Figure 1. Purification of Lp_1002 esterase. SDS-PAGE analysis of the expression and purification of the His_6-Lp_1002 esterase. Analysis of soluble cell extracts of IPTG-induced *E. coli* BL21(DE3) (pURI3-Cter) (pGro7) (1) or *E. coli* BL21(DE3) (pURI3-Cter-1002) (pGro7) (2), flowthrough (3), or eluted protein after His affinity resin (4). The arrow indicated the overproduced and purified protein. The gel was stained with Coomassie blue. Molecular mass markers are located at the left (SDS-PAGE Standards, Bio-Rad).

Reaction mixtures were prepared by adding different volumes of the corresponding stock solution (25 g/L). Finally, the effect of sulfite was determined by adding sodium metabisulfite at concentrations ranging from 0 to 1 g/L. The reactions were done by adding different volumes of a 25 g/L stock solution. Reaction mixtures were preincubated for 5 min at room temperature before the enzyme was added. After the reaction, the absorbance was measured.

Statistical Analyses. The two-tailed Student́s *t* test performed using GraphPad InStat version 3.0 (GraphPad Software, San Diego, CA) was used to determine the differences between means. The data are representative means of at least three independent experiments.

RESULTS AND DISCUSSION

Production and Purification of Recombinant Lp_1002 Protein. Numerous open reading frames (ORF) encoding putative lipase/esterase proteins can be identified from the genomic information on complete *L. plantarum* genome sequences. Considering the *L. plantarum* WCFS1 genome (accession NC_004567), more than 20 ORF were annotated as putative esterases. The first two ORFs lipase/esterase have been already biochemically characterized, the feruloyl esterase Lp_0796[13,26] and the esterase Lp_0973.[22] The next ORF, annotated as putative esterase/lipase, is Lp_1002, present in all the available *L. plantarum* genome sequences, and predicted to

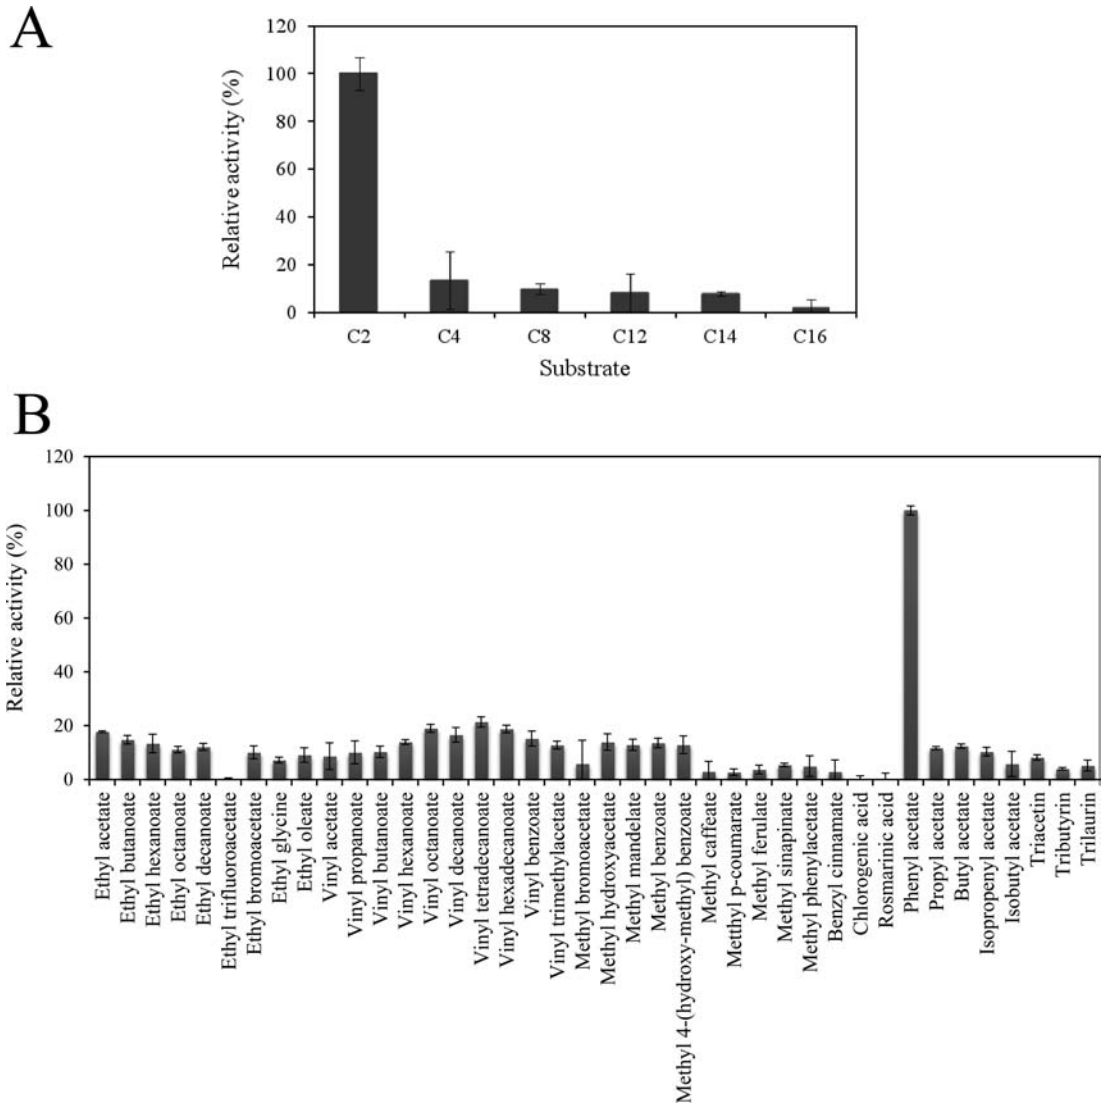

Figure 2. Substrate profile of Lp_1002 against chromogenic substrates (*p*-nitrophenyl esters) with different acyl chain lengths (C2, acetate; C4, butyrate; C8, caprylate; C12, laurate; C14, myristate; C16, palmitate) (A) or toward a general ester library (B). The relative activities obtained toward different substrates are shown. The error bars represent the standard deviation estimated from the three independent assays. The observed maximum activity was defined as 100%.

Figure 3. Comparison of amino acid sequences of bacterial arylesterases from *Lactobacillus casei* (LCA), *Gluconobacter oxidans* (GOX), *Lactobacillus plantarum* (LPL), and *Pseudomonas fluorescens* (PFL). Multiple alignments were done using the program ClustalW2 after retrieval of sequences from BLAST homology searches. Residues that are identical (*), conserved (:), or semiconserved (.) in all sequences are indicated. Dashes indicated gaps introduced to maximize similarities.

encode a 260 amino acid sequence protein with a theoretical molecular mass of 28.7 kDa. The deduced amino acid sequence of Lp_1002 lacked a N-terminal secretion signal sequence, suggesting that this enzyme is located intracellularly. The amino acid sequence of Lp_1002 showed a 53% identity to *Lactobacillus brevis* and *Lactobacillus coryniformis* proteins, which are annotated as putative lipases/esterases (data not shown). The presence of the sequence conserved motif Gly-X-Ser-X-Gly, typical of serine hydrolases, suggests they belong to the α/β hydrolase superfamily of enzymes, which has been confirmed structurally since the atomic coordinates of Lp_1002 have been deposited at the Protein Data Bank by the Joint Center for Structural Genomics (PDB entry: 3bjr).

The *lp_1002* gene was cloned into the pURI3-Cter expression vector by a ligation-free cloning strategy described previously.[28] The vector incorporates the DNA sequence encoding a C-terminal hexa-histidine tail to create a His-tagged fusion enzyme for a further purification step. The integrity of the construct was confirmed by DNA sequencing. The *lp_1002* gene was expressed in *E. coli* under the control of an IPTG inducible promoter. Cell extracts were used to detect the presence of overproduced proteins by SDS-PAGE analysis. Whereas control cells containing the pURI3-Cter vector did not show protein overexpression, an overproduced protein with an apparent molecular mass around 28 kDa was present as inclusion bodies in the insoluble fraction. In order to produce Lp_1002 in a soluble form, plasmid pGro7, producing GroES/GroEL chaperones, was used. When pURI3-Cter-1002 and pGro7 plasmids were used simultaneously, Lp_1002 appeared in the intracellular soluble fraction of the cells (Figure 1). Since the cloning strategy would yield a His-tagged protein, *L. plantarum* Lp_1002 could be purified on an immobilized metal affinity chromatography (IMAC) resin. The recombinant protein was eluted from the resin at 150 mM imidazole and observed as a single band on SDS-PAGE (Figure 1), although some overproduced GroEL proteins were retained in the resin and eluted along Lp_1002. The eluted protein was dialyzed against 50 mM phosphate buffer (pH 7) containing 300 mM NaCl. Routinely about 20 mg of purified protein from 1-L culture was obtained. The calculated specific activity for the esterase Lp_1002 was 170 U/mg for *p*-nitrophenyl acetate.

As esterases and lipases could not be distinguished by sequence comparison, the activity of Lp_1002 against *p*-nitrophenyl esters possessing different acyl chain lengths was assayed. Lp_1002 showed activity only on short-acyl chain esters, exhibiting a clear preference for *p*-nitrophenyl acetate (Figure 2A), therefore confirming that Lp_1002 is a true esterase.

Substrate Profile and Biochemical Characterization of Lp_1002. Once the esterase activity of Lp_1002 was confirmed, it was biochemically characterized in further detail. To test the substrate range of esterases, an ester library was used.[30] This ester library consisted of esters that were chosen to identify acyl chain length preferences of the esterase and also the ability to hydrolyze charged substrates. From Figure 2B it

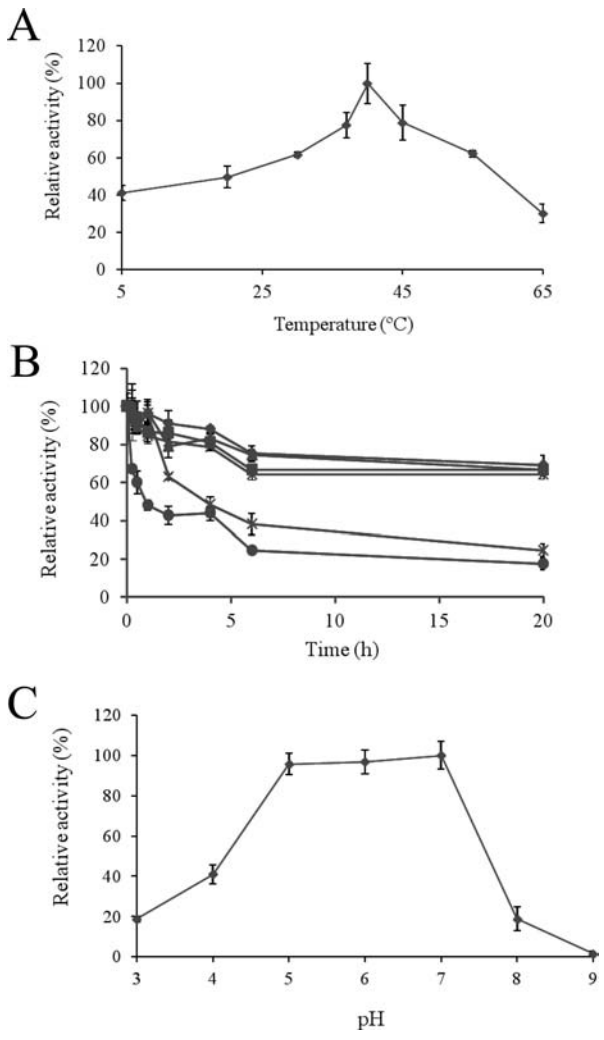

Figure 4. Biochemical properties of Lp_1002 esterase. (A) Relative activity of Lp_1002 versus temperature. (B) Thermal stability of Lp_1002 after preincubation at 22 °C (filled diamond), 30 °C (filled square), 37 °C (filled triangle), 45 °C (cross), 55 °C (star), and 65 °C (filled circle) in phosphate buffer (50 mM, pH 7); at indicated times, aliquots were withdrawn and analyzed as described in the Materials and Methods section. (C) Relative activity versus pH. The experiments were done in triplicate. The mean value and the standard error are shown. The observed maximum activity was defined as 100%.

Table 1. Effect of Additives on Lp_1002 Esterase Activity

additions (1 mM)	relative activity (%)
control	100
KCl	105
$HgCl_2$	14
$CaCl_2$	125
$MgCl_2$	80
$ZnCl_2$	58
$CuCl_2$	13
$NiCl_2$	23
$MnCl_2$	129
Tween 20	116
Tween 80	115
Triton-X-100	122
SDS	32
urea	97
DMSO	106
cysteine	117
DTT	92
β-mercaptoethanol	16
EDTA	98
PMSF	65
DEPC	105

can be deduced that Lp_1002 shows higher hydrolytic activity on phenyl acetate. Phenyl acetate is a commonly used substrate to identify bacterial arylesterases.[6] Among esterases, arylesterases are of biotechnological interest, since they are active not only toward aliphatic esters but also toward aromatic ones, modulating the ester profile of food substrates. Arylesterases were less understood that other esterases, especially carboxylesterases or lipases.[31] Until recently, most of the arylesterases reported were from mammalian sources, playing an important role in detoxification of organophosphorous compounds. In contrast, there are few reports on bacterial arylesterases, whose physiological function remains largely unknown. In addition, little is known about the genetic and biochemistry of bacterial arylesterases. Bacterial arylesterases have only been described from *Vibrio mimicus*,[32] *Agrobacterium radiobacter*,[33] *Acinetobacter* sp.,[34] *Pseudomonas fluorescens*,[35] and *Sulfolobus solfataricus*.[31] Among LAB, only arylesterases from *Lactobacillus helveticus*[9] and *Lactobacillus casei*[10] have been described. Finally, regarding wine-related bacteria, an arylesterase from *Gluconobacter oxidans* has been recently described.[36] As far as we know, Lp_1002 is the first arylesterase described in *L. plantarum* and in a wine LAB. Amino acid sequences of bacterial arylesterases showed less than 20% identity among them. The highest sequence identities detected were between Lp_1002 and *G. oxidans* (16% identity), *P. fluorescens* (16%), and *L. casei* (14%) arylesterases (Figure 3).

Bacterial arylesterases may be used for industrial purposes, especially considering the fact that they have broad substrate specificities.[32] In this regard, although to a lesser extent than phenyl acetate, Lp_1002 also hydrolyzes most of the substrates assayed (Figure 2B). Thus, Lp_1002 catalyzed the hydrolysis of small activated and small nonactivated esters with similar rates regardless of their size. Larger activated esters (e.g., vinyl decanoate) reacted similarly compared to larger nonactivated esters (e.g., ethyl decanoate). Regarding the acyl chain selectivity, Lp_1002 exhibited hydrolytic activity toward all the ethyl esters, vinyl esters, and methyl esters assayed, possessing varied chain length as well as an electron-withdrawing group (e.g., ethyl bromoacetate and ethyl glycine) or an hindered group (e.g., vinyl benzoate and vinyl trimethyl acetate). Considering the alcohol moiety selectivity, both acetates and butyrates were also hydrolyzed. From the 40 potential substrates assayed, only ethyl trifluoroacetate, chlorogenic acid, and rosmarinic acid were not hydrolyzed by Lp_1002.

The broad substrate range exhibited by Lp_1002 indicated its potential utility in wine fermentations. From the substrates included in the ester library, relevant aroma compounds such as ethyl acetate (pineapple aroma), ethyl butanoate (floral, fruity), ethyl hexanoate (green apple), ethyl octanoate (sweet soap), and ethyl decanoate (floral, soap) were hydrolyzed by Lp_1002.[3]

Other important biochemical properties of Lp_1002 have been characterized. Figure 4A shows that the optimal temperature for Lp_1002 activity against phenyl acetate is 40 °C, retaining 50% of its maximal activity at winemaking temperatures (15−25 °C). Moreover, Lp_1002 showed thermal stability since 70% of its maximal activity was observed after 20 h of incubation at 45 °C or below (Figure 4B).

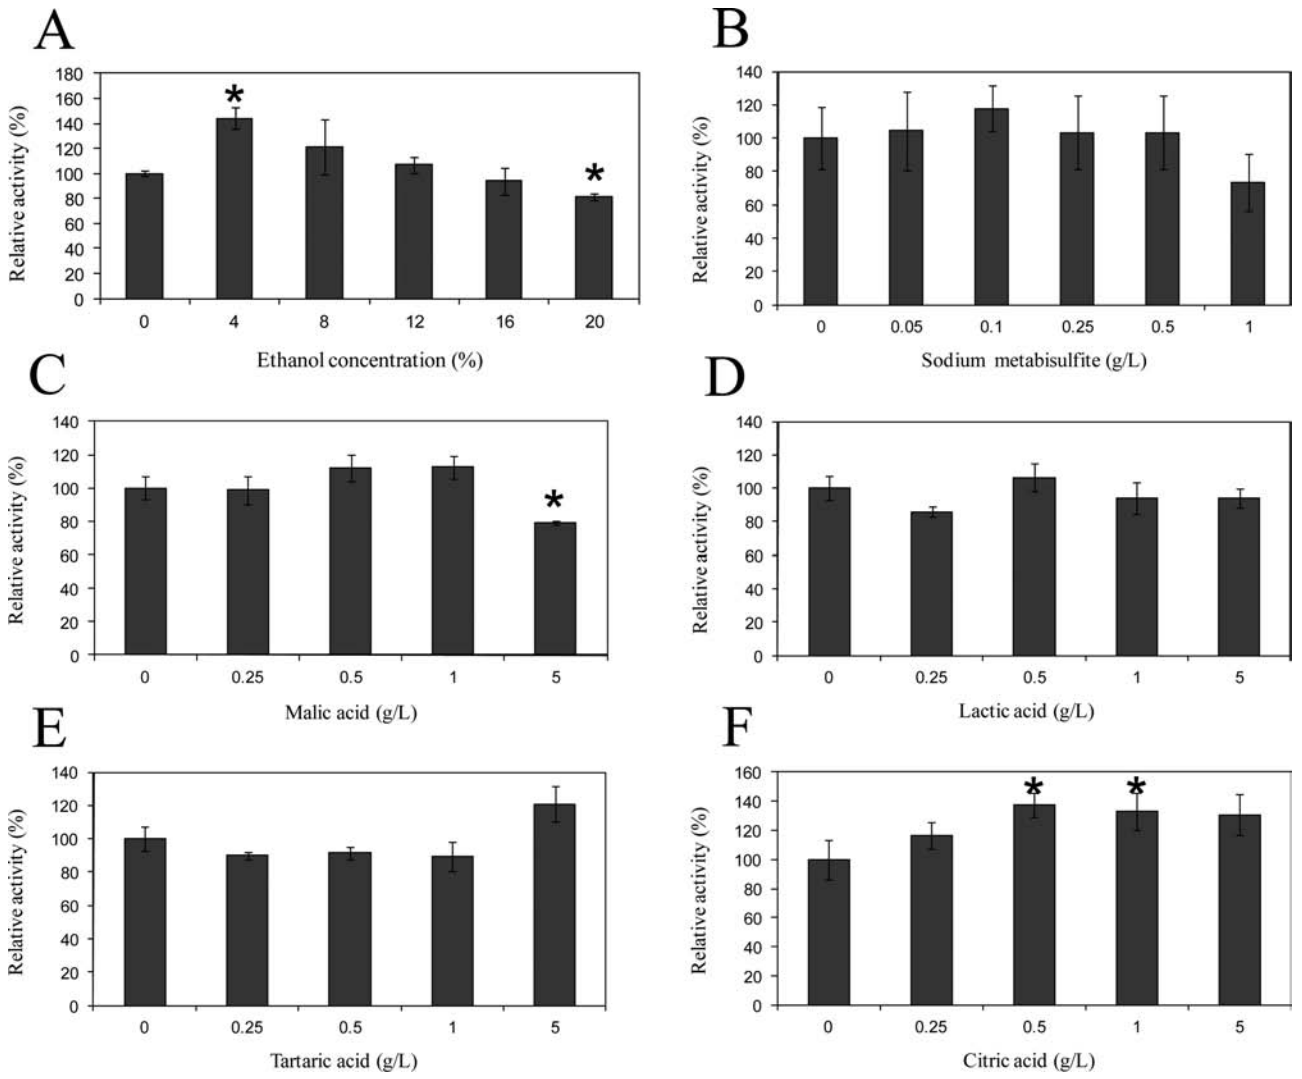

Figure 5. Activity of Lp_1002 esterase in the presence of compounds frequently found in wine. Relative activity of Lp_1002 after incubation in the presence of ethanol (A), sodium metabisulfite (B), malic acid (C), lactic acid (D), tartaric acid (E), and citric acid (F) at the concentrations indicated. The activity of the enzyme in the absence of the compound was defined as 100%. The experiments were done in triplicate. The mean value and the standard error are shown. Asterisks indicate a P value <0.05.

The optimal temperature shown by Lp_1002 is similar to the optimal temperatures exhibited by arylesterases from *P. fluorescens*,[30] *G. oxidans*,[23] and *L. helveticus*,[9] which are the arylesterases with the highest sequence similarity to Lp_1002. In addition, EstB28 and EstCOo8 esterases from a wine LAB, *O. oeni*, also showed optimal activity at 40 °C.[13,14]

Regarding the dependence on pH for Lp_1002 activity, Figure 4C showed that the protein was active between 3 and 8, exhibiting a broad optimal pH range (5 to 7). This result indicates that Lp_1002 shows a marked preference for acidic conditions when compared to other known bacterial arylesterases, which exhibited optimum pH values ranging from 7 to 9. However, acidic esterases were previously described for esterases from wine bacteria; thus, optimal pH around 5 was described for EstB28 and EstCOo8 from *O. oeni* and EstC34 from *L. hilgardii*.[13,14] At pH values commonly found in wines (pH 3−4), Lp_1002 still retained activity (20−40%), confirming its potential activity during winemaking.

The effect of some metal ions and additives on Lp_1002 activity was studied and is shown in Table 1. Esterase activity was significantly inhibited by Hg^{2+}, Cu^{2+}, and Ni^{2+} ions, as well as by β-mercaptoethanol. The enzymatic activity was increased by Mn^{2+} ion and by the detergents Tween-20 and Tween-80; contrarily, SDS inhibited 68% Lp_1002 activity. The increase in enzyme activity observed by nonionic detergents, and the decrease by an ionic detergent were previously described in an arylesterase isolated from goat rumen[37] and in a feruloyl esterase from *L. plantarum*.[26]

Effect of Wine Compounds on Lp_1002 Arylesterase Activity. The biochemical properties showed by Lp_1002 indicated that the enzyme could be defined as an arylesterase, potentially active at wine conditions. The observation that Lp_1002 is an intracellular protein indicates that cell lysis may be important for its release and the subsequent flavor formation during winemaking. Therefore, special attention should be paid to the effect of compounds that could affect Lp_1002 activity once it has been released to the media. With this aim, the influence of several compounds naturally present in wine fermentations, such as ethanol, sodium metabisulfite, and several organic acids, such as malic, lactic, tartaric, and citric acids, was studied.

Ethanol concentration is an important parameter during winemaking, since malolactic fermentation is often conducted

dx.doi.org/10.1021/jf500991m | J. Agric. Food Chem. 2014, 62, 5118−5125

after the completion of alcoholic fermentation, when the concentration of this compound in wine can exceed 12%.[38] For this reason, the influence of ethanol on the Lp_1002 arylesterase activity has been analyzed. Experiments were conducted with concentrations higher than those found in wines (up to 20%). Ethanol concentration up to 16% seem to increase Lp_1002 activity. The highest esterase activity was observed at the ethanol concentration 4% (Figure 5A). The activity of an esterase from the wine bacterium *O. oeni* was stimulated by 14% ethanol.[13]

In addition, sodium metabisulfite, a powerful antimicrobial commonly used in wine, did not inhibit the enzyme when present at concentrations commonly found in wine. Final levels of 0.1−0.2 g/L of metabisulfite are found in wines.[38] At wine concentrations, metabisulfite did not significantly affect Lp_1002 arylesterase activity (Figure 5B). In grape must there are several organic acids, such as malic acid (up to 8.6 g/L) or tartaric acid (up to 7.4 g/L). During vinification the concentration of these acids varies, and as a consequence of LAB metabolism, lactic acid appeared. In wines, concentrations of 5, 4, and 4 g/L (w/v) of malic, tartaric or lactic acid, respectively, could be found.[38] Esterase Lp_1002 retained high activity at wine concentrations of these organic acids (Figure 5C−F). Only 5 g/L malic acid concentrations inhibited 20% Lp_1002 activity (Figure 5C). The activity shown by Lp_1002 in the presence of wine compounds suggests that this arylesterase could play a role in modulating ester profiles during winemaking. The International Organization of Vine and Wine (OIV) recommends that side enzymatic activities which have a potential negative effect on wine should not be present in commercial enzyme preparations.[39] Therefore, the use of recombinant, pure, and widely biochemical characterized enzymes will avoid the negative side activities present on commercial preparations

In conclusion, in this work it is shown that Lp_1002 is the first arylesterase described in *L. plantarum* and in a wine LAB. This arylesterase showed a broad substrate range, being able to modify relevant compounds for wine aroma. Lp_1002 arylesterase showed high activity under conditions commonly found during winemaking, such as cold temperature, acid pH, the presence of ethanol, malic acid, tartaric acid, or sulphites. The biochemical characteristics shown by Lp_1002 from *L. plantarum* suggest that this arylesterase is a very promising enzyme during vinification

MATERIALS AND METHODS

Strains, Plasmids, Media, and Materials. *L. plantarum* WCFS1, kindly provided by M. Kleerebezem (NIZO Food Research, Netherlands), was grown in MRS medium (Pronadisa, Spain) adjusted to pH 6.5, and incubated at 30 °C. This strain is a colony isolate of *L. plantarum* NCIMB 8826, which was isolated from human saliva. *Escherichia coli* DH10B was used as the host strain for all DNA manipulations. *E. coli* BL21 (DE3) was used for heterologous expression in the pURI3-TEV vector.[21] *E. coli* strains were cultured in Luria−Bertani (LB) medium at 37 °C with shaking at 200 rpm. When required, ampicillin and chloramphenicol were added to the medium at a concentration of 100 or 20 μg/mL, respectively.

Plasmid DNA was extracted by a High Pure Plasmid Isolation Kit (Roche). The polymerase chain reaction (PCR) product was purified with a QIAquick Gel Extraction Kit (Qiagen). Oligonucelotides were purchased from Eurofins MWG Operon (Ebersberg, Germany). *Dpn*I and HS Prime Star DNA polymerase were obtained from TaKaRa. His-tagged protein was purified by a Talon Superflow resin (Clontech).

Cloning of Lp_2631 Esterase Encoding Gene. Genomic DNA from *L. plantarum* WCFS1 was extracted. The gene encoding a putative lipase/esterase (*lp_2631*) in *L. plantarum* WCFS1 was amplified by PCR using the primers 569 (5′-*GGTGAAAACCTG-TATTTCCAGGGCat*ggtgcggacgaccaaatttggtg) and 570 (5′-*ATCGA-TAAGCTTAGTTAGCTATTATTA*tttaagaatgttggtctccaag) (the nucleotides pairing the expression vector sequence are indicated in italics, and the nucleotides pairing the *lp_2631* gene sequence are written in lowercase letters). Prime Star HS DNA polymerase (TaKaRa) was used for the PCR amplification. The 786 bp purified PCR product was inserted into the pURI3-TEV vector using a restriction enzyme- and ligation-free cloning strategy.[21] The vector produces recombinant proteins having a six-histidine affinity tag in their N termini. *E. coli* DH10B cells were transformed; recombinant plasmids were isolated; and those containing the correct insert were identified by size, verified by DNA sequencing, and then transformed into *E. coli* BL21 (DE3) cells for expression.

Expression and Purification of Lp_2631 Esterase. *E. coli* BL21 (DE3) harboring pGro7 (TaKaRa), a vector overexpressing GroES/GroEL chaperones, was transformed with the recombinant plasmid pURI3-TEV-2631. *E. coli* was grown in LB medium containing 100 μg/mL ampicillin, 20 μg/mL chloramphenicol, and 2 mg/mL arabinose, on a rotary shaker (200 rpm) at 37 °C until an optical density (OD) at 600 nm of 0.4 was reached. Isopropyl-β-D-thiogalactopyranoside (IPTG) was added to a final concentration of 0.4 mM, and protein induction was continued at 22 °C for 18 h.

The induced cells were harvested by centrifugation (8000*g* for 15 min at 4 °C), resuspended in phosphate buffer (50 mM, pH 7) containing 300 mM NaCl, and disrupted by French Press passages (3 times at 1100 psi). The insoluble fraction of the lysate was removed by centrifugation at 47000*g* for 30 min at 4 °C, and the supernatant was filtered through a 0.2 μm pore-size filter and then loaded onto a Talon Superflow resin (Clontech) equilibrated in phosphate buffer (50 mM, pH 7) containing 300 mM NaCl and 10 mM imidazole to improve the interaction specificity in the affinity chromatography step. The bound enzyme was eluted using McIlvaine buffer (100 mM, pH 5).[22] The purity of the enzyme was determined by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) in Tris−glycine buffer. Fractions containing the His_6-tagged protein were pooled and analyzed for esterase activity.

Enzyme Assay. Esterase activity was determined by a spectrophotometric method as described previously using *p*-nitrophenyl acetate (Sigma-Aldrich) as the substrate.[18]

Substrate Specificity. To investigate the substrate specificity of Lp_2631, activity was determined using different *p*-nitrophenyl esters of various chain lengths (Sigma-Aldrich), *p*-nitrophenyl acetate (C_2), *p*-nitrophenyl butyrate (C_4), *p*-nitrophenyl caprylate (C_8), *p*-nitrophenyl laurate (C_{12}), *p*-nitrophenyl myristate (C_{14}), and *p*-nitrophenyl palmitate (C_{16}), as substrates as described previously.[18,23]

Determination of Optimum pH, Temperature, and Thermostability. The effect of pH was studied by assaying esterase activity in a range of pH values from 3.0 to 9.0 as described previously.[18] The temperature effect was assayed in 50 mM sodium phosphate buffer (pH 7.0) at 5, 20, 30, 37, 40, 45, 55, and 65 °C for 10 min. For temperature stability measurements, the esterase was incubated in 50 mM sodium phosphate buffer (pH 7.0) at 22, 30, 37, 45, 55, and 65 °C for 5 min, 15 min, 30 min, 1 h, 2 h, 4 h, 6 h, and 20 h. After incubation, the residual activity was measured as described above.

Effects of Additives on Lp_2631 Esterase Activity. The effect of metal ions, surfactants, reductants, and inhibitors on the activity of the esterase was assayed by incubation of the enzyme in the presence of different additives at a final concentration of 1 mM for 5 min at room temperature. Then, the substrate was added, and the reaction was incubated at 20 °C.[18] The compounds analyzed were $MgCl_2$, KCl, $MnCl_2$, $CuCl_2$, $NiCl_2$, $CaCl_2$, $HgCl_2$, $ZnCl_2$, diethylpyrocarbonate (DEPC), cysteine, SDS, dithiothreitol (DTT), Triton X-100, urea, Tween 80, Tween 20, ethylenediaminetetracetic acid (EDTA), dimethyl sulfoxide (DMSO), phenylmethanesulfonyl fluoride (PMSF), and β-mercaptoethanol.

In addition, the effect of several compounds present in food fermentation was assayed. The effect of ethanol on esterase activity was studied at ethanol concentrations ranging from 0 to 20% (v/v). Reaction mixtures were prepared as described for the temperature optimum experiments; however, different volumes of ethanol were added, and the volume of the buffer was adjusted accordingly to maintain the final reaction volume (1 mL). The reactions were preincubated 5 min at room temperature, and the substrate (*p*-nitrophenyl acetate) was added. The effect of the presence of several organic acids was also studied. Malic, tartaric, citric, and lactic acids were assayed at concentrations ranging from 0 to 5 g/L. Reaction mixtures were prepared by adding different volumes of the corresponding stock solution (25 g/L) prepared in phosphate buffer (50 mM, pH 7.0). The effect of sulfite was determined by adding sodium metabisulfite at concentrations ranging from 0 to 1 g/L. The reactions were performed by adding different volumes of a 25 g/L stock solution. Finally, the effect of NaCl was determined by adding NaCl at concentrations ranging from 0 to 25% (v/v). Reaction mixtures were prepared as described for the temperature optimum experiments; however, different volumes of 25% NaCl solution were added, and the volume of the buffer was adjusted accordingly to maintain the final reaction volume. Reaction mixtures were preincubated for 5 min at room temperature before the enzyme was added. After the reaction, the absorbance was measured at 348 nm.

Statistical Analyses. Two-tailed Student's *t* test preformed using GraphPad InStat, version 3.0 (GraphPad Software, San Diego, CA), was used to determine the differences between means. The data are representative means of at least three independent experiments.

RESULTS AND DISCUSSION

Production and Characterization of Lp_2631 Esterase. LAB are used for the preservation of food raw materials, such as milk, meat, and vegetable or other plant materials. *L. plantarum* is a flexible and versatile species that is encountered in a variety of environmental niches, including some dairy, meat, and many vegetable or plant fermentations. The ecological flexibility of *L. plantarum* is reflected by the observation that this species has one of the largest genomes known among LAB.[10] This large genome codifies enzymatic activities, which could develop a fundamental role in food fermentations, such as cold-active esterases (also known as cold-adapted). When the published sequence of *L. plantarum* WCFS1 was analyzed, numerous open reading frames (ORFs) encoding putative esterases/lipases were found. Because it is not possible predict the biochemical function encoded by these *L. plantarum* ORFs, features found in cold-active esterases were searched. According to previous studies,[24−26] in comparison to mesophilic or themophilic esterases, cold-adapted enzymes

dx.doi.org/10.1021/jf501493z | J. Agric. Food Chem. 2014, 62, 5126−5132

revealed structural traits, such as a low ratio or Arg/(Arg + Lys), a low proportion of proline residues, or a high proportion of small residues (Gly and Ala). Among the putative esterases encoded by the *L. plantarum* WCFS1 genome, *lp_2631* encodes a protein that exhibits some of these structural features. Thus, when the amino acid composition of Lp_2631 was analyzed, the ratio of Arg/(Arg + Lys) was found to be 0.45, lower than that of other cold-adapted esterases: 0.50 in Est10 from *Psychrobacter pacifiensis*,[27] or 0.56 in rESt97 from a metagenomic library.[28] Also, the total percentage (20.31%) of small residues Gly (7.28%) and Ala (13.03%) is relatively high compared to the low proportion of Arg (3.45%) and Pro (5.75%). These characteristics of the primary structure may suggest that Lp_2631 could be a cold-active esterase.

Lp_2631 is predicted to encode a 261 amino acid protein, 42% identical to a putative esterase/lipase from *Lactobacillus sakei* and 35% identical to uncharacterized proteins from *Lactobacillus salivarius* or *Lactobacillus ruminis* (data not shown).

The *lp_2631* gene was cloned into the pURI3-TEV expression vector, and the recombinant plasmid obtained was transformed into *E. coli* BL21 (DE3). Cell extracts were used to detect the presence of overproduced proteins. SDS−PAGE analysis showed that there was one major band of protein, approximately 28 kDa, present as inclusion bodies in the insoluble fraction. To obtain Lp_2631 soluble, plasmid pGro7, producing GroES/GroEL chaperones, was used. When pURI3-TEV-2631 and pGro7 plasmids were used simultaneously, Lp_2631 appeared in the intracellular soluble fraction of the cells (Figure 1). The molecular weight of the overproduced

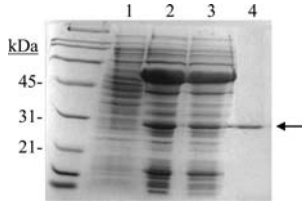

Figure 1. SDS−PAGE analysis of the purification of Lp_2631 esterase from *L. plantarum* WCFS1. Analysis by SDS−PAGE of soluble cell extracts of IPTG-induced *E. coli* BL21 (DE3) (pGro7) (pURI3-TEV) (1) or *E. coli* BL21 (DE3) (pGro7) (pURI3-TEV-2631) (2), flowthrough (3), or protein eluted after His affinity resin (4). The gel was stained with Coomassie blue. Molecular mass markers are located on the left (SDS−PAGE Standards, Bio-Rad).

protein was consistent with the theoretical one expected for Lp_2631. The recombinant protein was observed as a single band on SDS−PAGE (Figure 1). Routinely, about 8 mg of purified protein from a 1 L culture was obtained.

Lp_2631 protein purified by the affinity resin was biochemically characterized. Substrate specificity was determined using *p*-nitrophenyl-linked esters of various acyl chain lengths (C_2−C_{16}) at 20 °C (Figure 2). The enzyme was only active on substrates with a chain length up to C_4, with minimal activity detected with the longer chain lengths. This result indicated that Lp_2631 is an esterase and not a true lipase. This narrow substrate range displayed by Lp_2631 is similar to the substrate range described for a *L. plantarum* esterase described previously.[23]

The influence of pH, in the range of 3.0−9.0, on esterase activity was studied at 20 °C (Figure 3A). Although the enzyme showed activity at pH from 3.0 to 8.0, the highest activity was

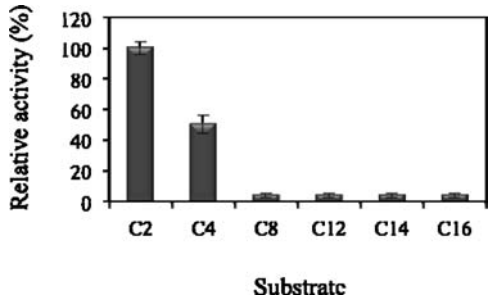

Figure 2. Substrate profile of Lp_2631 against chromogenic substrates (*p*-nitrophenyl esters) with different acyl chain lengths (C_2, acetate; C_4, butyrate; C_8, caprylate; C_{12}, laurate; C_{14}, myristate; and C_{16}, palmitate). The figure displays the relative specificities obtained toward different substrates, and lines on top of each bar represent the standard deviations estimated from three independent assays. The observed maximum activity was defined as 100%.

observed at pH 6.5. Similar to the substrate range, only the esterase described previously by Brod et al. exhibited an optimal pH range of 6.0−6.5. Apart from both of these esterases, the *L. plantarum* esterases described thus far showed higher optimum pH, pH 7 for Lp_2923[29] and a feruloyl esterase[18] and pH 8 for Lp_0796.[30] LAB-fermented food products are characterized by a low pH. For example, a final pH around 5.5 could be found in meat fermentations; at this pH, Lp_2631 still exhibited 40% of its maximal activity.

The influence of the temperature on enzymatic activity was determined (Figure 3B). Maximal activity was observed at 20 °C, confirming previous structural data of Lp_2631, suggesting that this esterase could be a cold-adapted protein. As far as we know, Lp_2631 is the first esterase from *L. plantarum* exhibiting such functional features. In fact, other *L. plantarum* esterases show higher optimal temperatures, such as 30 °C for Lp_2923,[29] 35 °C for Lp_0796,[30] or 40 °C for Lp_0973.[31] More interestingly, Lp_2631 showed more than 90% activity at 5 °C and decreases to 30% at 30 °C. A similar behavior has been described in cold-active esterases described from non-LAB or metagenomic libraries.[31−35] Lp_2631 is the first esterase described from LAB that shows higher activity at refrigeration temperatures. This is an important property in food fermentations; e.g., during the ripening of a fermented meat product in the traditional manufacturing process, temperatures can be as low as 15 °C. Moreover, esterase activity could be important even at meat storage temperatures (3 and 7.5 °C).[33]

The available data regarding psychrophilic enzymes pointed out that the high specific activity at low temperatures is often associated with a low thermostability, which make them inclined to lose their activity at moderate and even high temperatures.[24] Low-temperature activity has been generally associated with low conformational stability. To assess the thermostability of Lp_2631, the enzyme was preincubated at different temperatures for different time intervals, before assaying the residual activity. Figure 3C shows that Lp_2631 was fairly stable under room temperatures. The enzyme retained up to 80% activity after incubation for 20 h at 20 °C. The enzyme showed 50% of its maximal activity after 4 h of incubation at 30 or 37 °C or 40% after 2 h at 45−65 °C. Therefore, esterase Lp_2631 not only showed high activity levels at low temperature but also exhibited higher thermostability when compared to other cold-active enzymes, e.g., the low-temperature lipase from psychrotopic *Pseudomonas* sp. strain KB700A.[36] In fact, other cold-adapted esterases are also

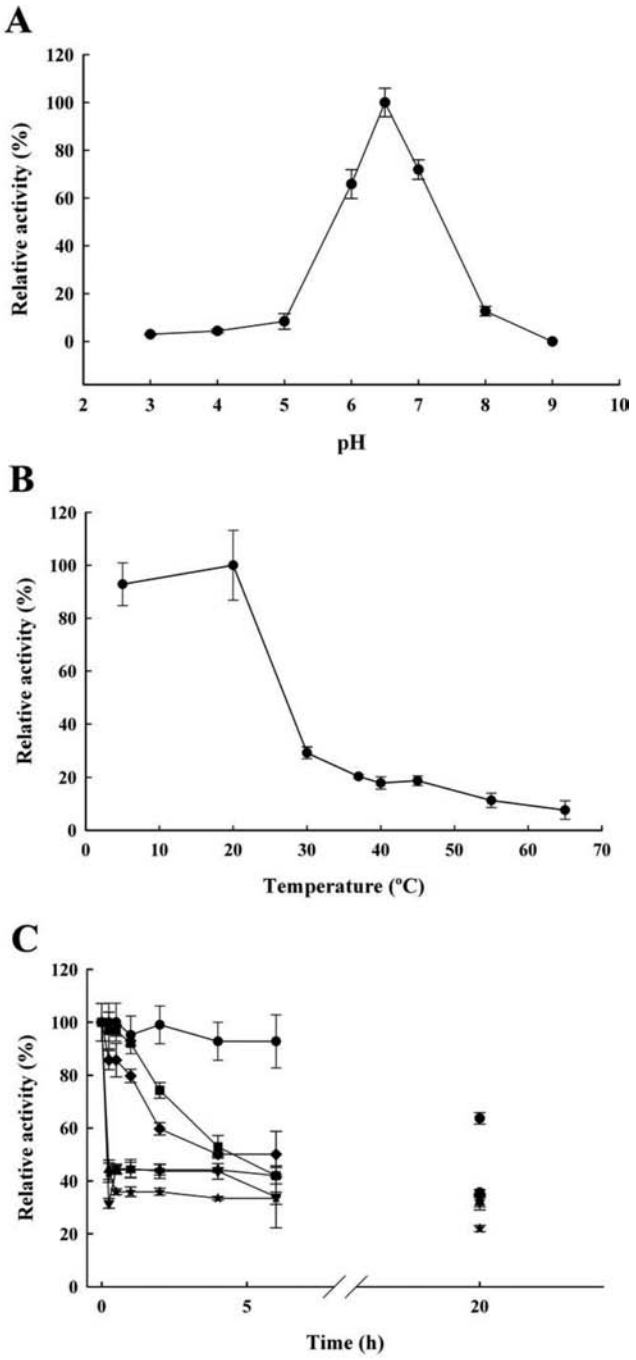

Figure 3. Biochemical properties of Lp_2631 esterase. (A) pH activity profile of Lp_2631. (B) Temperature–activity profile of Lp_2631. (C) Thermal stability profile for Lp_2631 after preincubation at 22 °C (●), 30 °C (■), 37 °C (◆), 45 °C (▲), 55 °C (▼), and 65 °C (★) in phosphate buffer (50 mM, pH 7) at indicated times. Aliquots were withdrawn and analyzed as described in the Materials and Methods. The experiments were performed in triplicate. The mean value and standard error are shown. The percentage of residual activity was calculated by comparing to unincubated enzyme.

fairly stable.[37] Although high catalytic activity at a low temperature tends to be associated with thermosensitivity, directed evolution studies to improve the thermostability of cold-adapted enzymes revealed that, as in Lp_2631, there is not a strict correlation.[19]

The effects of several ions, surfactants, reductants, and inhibitors on Lp_2631 activity are shown in Figure 4. In

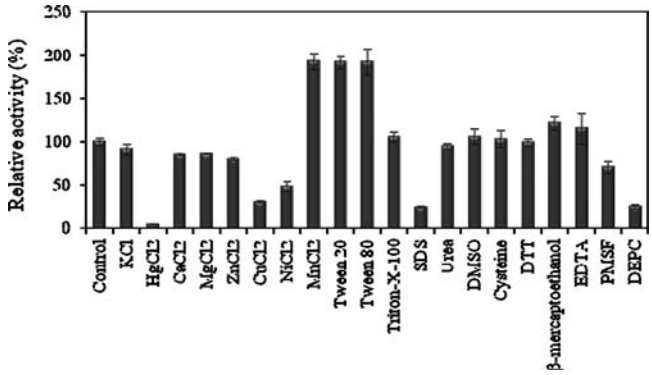

Figure 4. Effects of additives on Lp_2631 esterase activity. Relative activity of Lp_2631 after incubation with 1 mM concentration of different additives. The activity of the enzyme in the absence of additives was defined as 100%. The experiments were performed in triplicate. The mean value and standard error are shown.

comparison to the enzyme incubated in 50 mM phosphate buffer at pH 7, the enzymatic activity was increased 2-fold by the detergents Tween 20 and Tween 80, and in contrast, SDS greatly inhibited Lp_2631. The increase in enzyme activity observed by non-ionic detergents and the decrease by ionic detergent were previously described in a feruloyl esterase from *L. plantarum*[16] and in the cold-active lipase EML1 from a deep-sea sediment metagenome.[38] With regard to metal ions, only Mn^{2+} increases activity, while Ni^{2+}, Cu^{2+}, and Hg^{2+} significantly inhibited esterase activity. Inactivation by Hg^{2+} ions has previously been described in other *L. plantarum* esterases, such a feruloyl esterase[18] and a lipase purified from *L. plantarum* 2739.[14] Normally, the esterase activity of hydrolases does not require cofactors, such as metals. On the contrary, the inhibitory effects of some of then are observed and explained in terms of covalent modification of catalytic residues (such as the covalent modification of thiol groups by Hg^{2+}). The effects of other metals on esterase activity (either activating or inhibiting the enzyme) have also been reported;[29] however, the molecular mechanisms underlying these effects have not been determined, and most likely, they are unspecific. The enzyme was also partially inactivated by PMSF and DEPC, confirming the involvement of a serine and a histidine at the active site of the enzyme.

Activity of Lp_2631 in the Presence of Compounds Found in Food Fermentations. Also important, to understand the role of Lp_2631 esterase activity during food processing is the study of compounds present in food fermentation media that could affect its activity. Food processing subjects microorganisms and their enzymes to adverse environmental conditions (such as osmotic stress, toxic compounds, and ethanol), which affect their survival and technological performances. Because of its industrial relevance, a better understanding of the influence of compounds present in food fermentations is important. The influence on Lp_2631 activity of several compounds naturally present in food fermentations, such as ethanol, malic acid, tartaric acid, and sodium metabisulfite in winemaking, NaCl in cheese and meat fermentations, and lactic acid as a main product resulting for LAB fermentation, was also studied.

The ethanol concentration is an important compound during winemaking, because malolactic fermentation is often conducted after the completion of alcoholic fermentation, when the ethanol concentration of wine can exceed 12%.[39] For this

dx.doi.org/10.1021/jf501493z | J. Agric. Food Chem. 2014, 62, 5126–5132

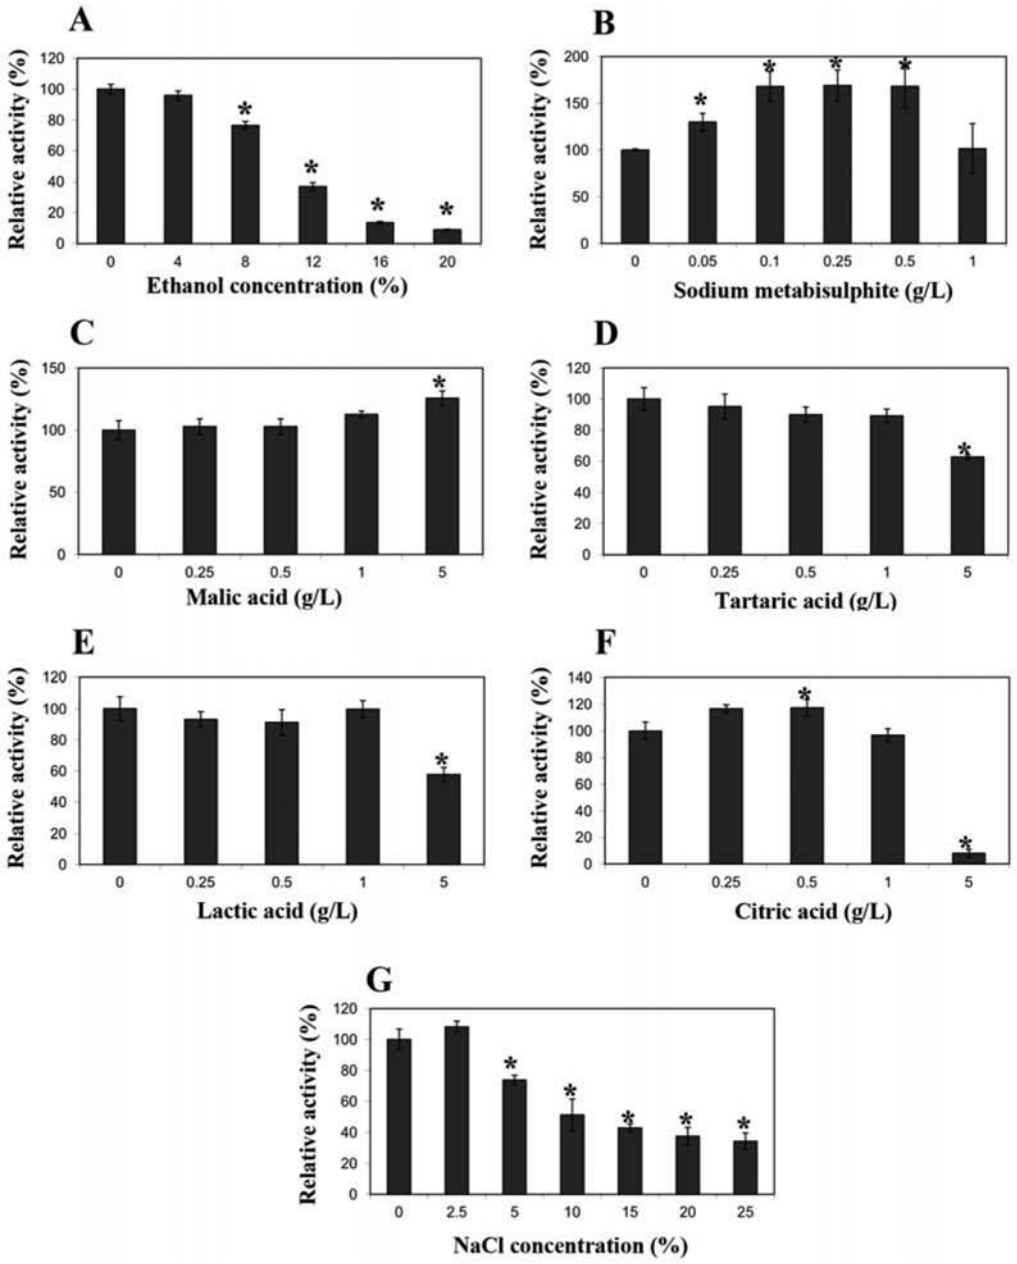

Figure 5. Activity of Lp_2631 esterase in the presence of compounds found in food fermentations. Relative activity of Lp_2631 after incubation in the presence of compounds present in food fermentation media, such ethanol (A), sodium metabisulfite (B), malic acid (C), tartaric acid (D), lactic acid (E), citric acid (F), and NaCl (G) at the concentrations indicated. The activity of the enzyme in the absence of the compound was defined as 100%. The experiments were performed in triplicate. The mean value and standard error are shown. Asterisks indicate a p value < 0.05.

reason, the influence of ethanol on the Lp_2631 esterase activity has been analyzed. Experiments were conducted with concentrations higher than those found in wines (up to 20%). The highest esterase activity was observed in the absence of ethanol; however, at wine ethanol concentrations (12%), Lp_2631 exhibited 40% of its maximal activity (Figure 5A). A different ethanol effect was observed in an esterase from the wine bacterium *Oenococcus oeni* because it was stimulated by 14% ethanol, producing a 49% activity increase.[22]

In addition, sodium metabisulfite, a powerful antimicrobial commonly used in wine, did not inhibit the enzyme when present at concentrations commonly found in wine. Final levels of 0.1−0.2 g/L of metabisulfite are found in wines.[39] At wine concentrations, metabisulfite increases up to 70% esterase activity (Figure 5B). Again, Lp_2631 esterase showed a different behavior than *O. oeni* esterase, which was partially inhibted in the presence of metabisulfite.[22] In grape must, there are several organic acids, such as malic acid (up to 8.6 g/L) or tartaric acid (up to 7.4 g/L). During vinification, the concentration of these acids varies, and as a consequence of LAB metabolism, lactic acid appeared. In wines, concentrations of 5, 4, and 4 g/L malic, tartaric, or lactic acid, respectively, could be found.[39] Esterase Lp_2631 showed activity at wine concentrations of these organic acids. Malic acid concentrations up to 5 g/L increased esterase activity (Figure 5C); however, esterase was partially inhibited by tartaric and lactic acids at wine concentrations (panels D and E of Figure 5). Lp_2631 activity was not affected by concentrations of citric acid usually

dx.doi.org/10.1021/jf501493z | J. Agric. Food Chem. 2014, 62, 5126−5132

found in grape musts or wines, with a maximum of 0.90 and 0.88 g/L, respectively.[37]

L. plantarum strains are active in fermented foods, such as milk or meat fermentations, in which salt or citric or lactic acid are present.[40] Under cheese-ripening conditions (4% NaCl), Lp_2631 was only partially inhibited, retaining 74% of its maximal activity at 5% (Figure 5G). Citric and lactic acids showed a similar behavior, with both acids inhibiting Lp_2631 activity at 5 g/L, whereas at 1 g/L, the enzyme keeps full activity. At cheese concentrations (50 mg/100 g),[41] citric acid did not inhibit Lp_2631 activity. The activity shown by Lp_2631 suggests that this esterase could play a role in modulating ester profiles during cheese ripening.

The obtained results indicated that Lp_2631 is an esterase, which retains activity under conditions commonly found in food fermentations, such as cold temperature and the presence of salt, ethanol, organic acids, or antimicrobials. The main disadvantage for the use of Lp_2631 in food fermentations is its narrow pH profile under standard reaction conditions. Further assays need to be performed under combined conditions to know the effect of the simultaneous presence of different factors on Lp_2631 activity.

In conclusion, in the present study, the cold-active esterase, namely, Lp_2631 from *L. plantarum*, an industrially important LAB species, which can be found in numerous fermented foods, was purified and biochemically characterized. Lp_2631 is a cold-active esterase that exhibited maximum activity at 20 °C and, more importantly, retains more than 90% activity at refrigeration temperatures. In addition, esterase Lp_2631 not only showed good activity at low temperatures but also had good thermostability compared to other cold-active enzymes. On the basis of the findings reported in this study, it appears that Lp_2631 will retain adequate activity under food fermentation conditions.

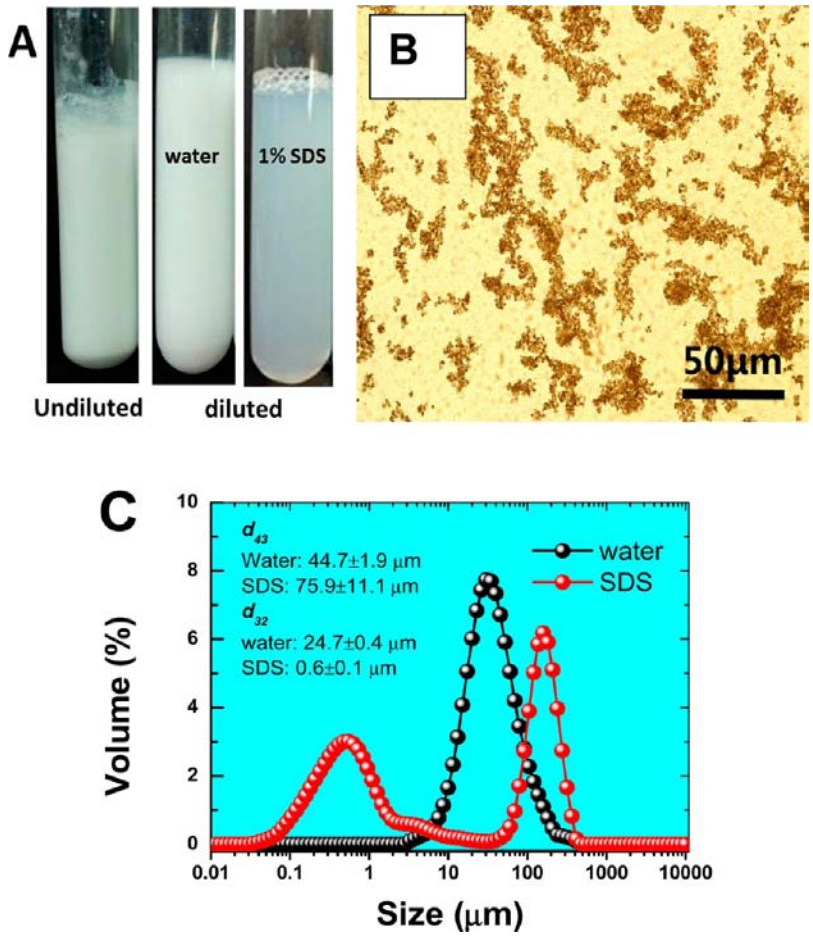

Figure 1. (A) Visual observations of undiluted and diluted phytosterol colloidal dispersions, obtained at a protein concentration of 0.05% (w/v) and organic phase fraction of 0.5. The dispersion was diluted by 5-fold volume of water or 1% SDS. (B) Typical light microscopic image of the phytosterol colloidal dispersion. (C) Volume-average droplet size distribution profiles of the corresponding dispersion, with water or SDS solution as the dispersing solvent.

Thus, the present work was undertaken to develop phytosterol into a kind of Pickering-like stabilizer. To achieve this, we first successfully prepared a kinetically stable phytosterol colloidal dispersion, using an emulsification process using whey protein as the emulsifier, followed by a solvent displacement/or evaporation. Instead of Tween series (e.g., Tween 20), whey protein was applied as the emulsifier, because of the safety consideration. Then, the obtained colloidal dispersion was applied to form emulsions, at varying solid concentrations (in the phytosterol dispersion; in the range of 0.1−3.0%, w/v) and oil fractions (ø; 0.2−0.6). The emulsion characterization was carried out by visual and confocal laser scanning microscopy (CLSM) observations. Interestingly, we found that, at high solid concentrations and/or ø values, gel-like emulsions using the phytosterol-based particles as the Pickering stabilizers could be formulated.

MATERIALS AND METHODS

Materials. Phytosterol with a total content of >95% (dry basis), consisting of β-sitosterol (~40%), compsterol (15−30%), stigmasterol (15−30%), and brassicasterol (<10%), was obtained from Xi'an Healthful Biotechnology Co., Ltd. (China). A commercial whey protein concentrate (WPC80) was purchased from New Zealand Milk Products (NZMP, Fonterra Co-operative Group Limited, New Zealand), whose composition was 78.1% protein, 6.67% fat, 4.83% moisture, and less than 3% ash (dry basis). Soy oil was purchased from a local supermarket in Guangzhou (China). Nile Red was obtained from Sigma-Aldrich (Sigma Chemical Co., St. Louis, MO). All other chemicals used were of analytical grade.

Preparation of Phytosterol Colloidal Dispersion. The phytosterol colloidal particles were synthesized on the basis of an anti-solvent precipitation method.[21,22] The synthesis process basically consisted of two steps: first, phytosterols are fully dissolved in organic solvent (100% ethanol in the present work), and then, the organic phase was dispersed in an aqueous phase with an emulsifier; and second, the organic phase in the resultant dispersion was removed by rotary evaporation. Phytosterol (1.2%, w/v) in 100% ethanol was applied as the organic solvent, while a concentration (0.05%, w/v) of WPC solution in 10 mM phosphate buffer (pH 7.0) was applied as the aqueous phase. Sodium azide (0.02%, w/v) was applied as an antimicrobial agent for the aqueous phase. The organic phase (100 mL) was fast (added using a syringe without a needle within 2 min) and mixed with the aqueous phase (100 mL), under vigorous mixing conditions (at a rate of 8000 rpm) using a high-speed dispersing unit (model IKA Ultra-Turrax T25 basic, IKA 190 Works, Inc., Wilmington, NC). After complete mixing of the organic phase with the aqueous phase, the dispersion was further stirred at the same rate for an additional 2 min. Then, a turbid dispersion with a milky color was formed. At last, the ethanol in the resultant dispersion was removed, until the dispersion was concentrated by approximately 4-fold. The total solid concentration (c) of the final dispersion containing colloidal particles was precisely adjusted to 3% (w/v), with the same phosphate buffer.

Phytosterol Colloidal Particle Characterization. *Particle Size Distribution and Volume- and Surface-Averaged Size ($d_{4,3}$ and $d_{3,2}$).*

dx.doi.org/10.1021/jf404930c | J. Agric. Food Chem. 2014, 62, 5133−5141

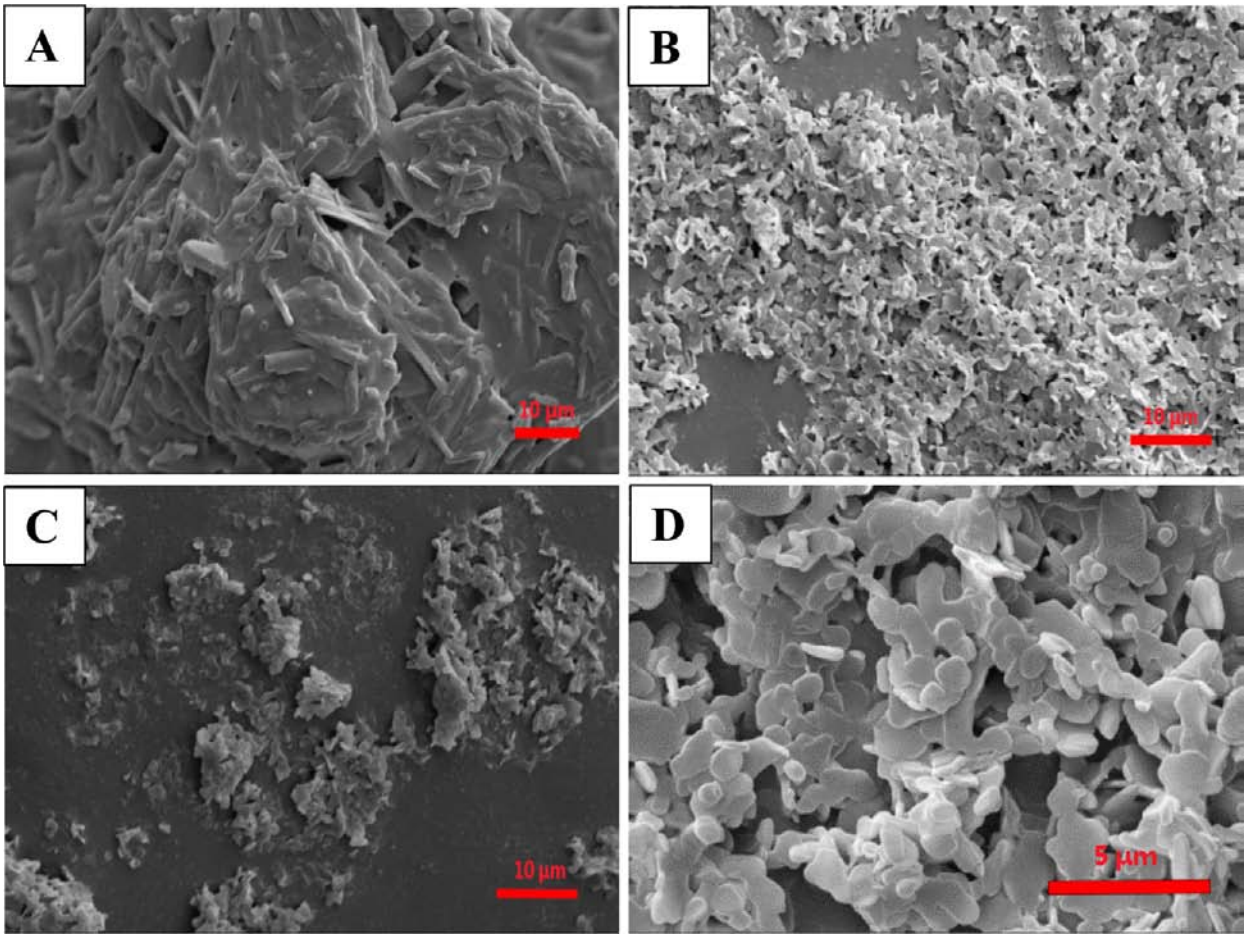

Figure 2. SEM micrographs of (A) original phytosterol and phytosterol colloidal dispersion (B and D) untreated or (C) treated by homogenization. The dispersion was prepared according to the same process as described in the caption of Figure 1.

The size distribution and $d_{4,3}$ (or $d_{3,2}$) of particles in fresh phytosterol preparations (see the above) were measured using a Malvern MasterSizer 2000 (Malvern Instruments, Ltd., Malvern, Worcestershire, U.K.). The pH 7.0 phosphate buffer was used as the diluting solvent. The relative refractive index was taken as the value of 1.095, which was calculated by the refractive index of the phytosterol particle (1.456) dividing by that of the continuous phases (1.33). The determinations were performed on separate samples at least in duplicate, with the means and standard deviation reported.

Microstructure. Light microscopy (LM) and scanning electron microscopy (SEM) were used to characterize the morphology of colloidal particles in the phytosterol preparation. For the LM observation, a drop of the dispersion was directly deposited on a microscope slide. The specimens for the SEM observation were prepared by drying a drop of the dispersion on the SEM stub using conductive double-side adhesive tape. After drying, the specimens were coated with gold and examined using a Zeiss EVO 18 scanning electron microscope (Carl Zeiss SMT, Oberkochen, Germany) at an accelerating voltage of 10 kV.

Preparation of Phytosterol Colloidal Particle-Stabilized Emulsions. For all emulsions, the phytosterol colloidal particle dispersion with a c of 3.0% (w/v) was applied. If necessary, the dispersion was diluted with the same phosphate buffer (pH 7.0) to an appropriate solid concentration up to 0.1% (w/v). To prepare an emulsion (with a constant total volume of 6 mL), a certain volume of the phytosterol preparation (dependent upon ϕ) was poured into a glass vial and a predetermined volume of soybean oil was slowly added to the dispersion while mixing with an Ultra Turrax homogenizer with a dispersing head operating at 13 500 rpm for 2 min. After all of the oil was added, the emulsion was further homogenized at the same rate for an additional 1 min. The last obtained emulsions were stored at 4 °C.

Emulsion Characterization. *Microstructure.* The microstructure of the emulsions was examined by CLSM, using the same microscope and process as described in our previous work.[23]

Drop Test and Conductivity Measurement. The type of the emulsions, formed at ϕ = 0.3−0.6, was evaluated by the dropt test and conductivity, immediately after the preparation. The droplet test was performed by dispersing a small portion of emulsions into either 10 mM phosphate buffer (pH 7.0) or pure oil, under the conditions with or without vortexing for 10 s. The conductivity measurement was conducted using a DDS-307 conductivity meter (Leici Co., China) at 25 °C, with means and standard deviations of two replicates on separate samples reported.

Droplet Size Analysis from Microscopy. The emulsion droplet size was manually measured over 100 droplets from the CLSM image using the microscopic image analysis software (Nano Measurer 1.2.5, Fudan University, China). The average droplet size was presented in terms of the volume mean diameter, $d_{4,3}$ $(=\sum n_i d_i^4 / \sum n_i d_i^3$, where i is the number of droplets with diameter d_i).[24]

Rheological Property. The flow behavior and dynamic oscillatory measurement of the formed gel-like emulsions were performed at 25 °C using a HAAKE RS600 rheometer (Thermo Electron Co., Waltham, MA) between two parallel plates (d = 27.83 mm) with a gap of 1.0 mm. The equipment was driven through the RheoWin 3 data manager (Thermo Electron Co., Waltham, MA). For the steady shear measurement, the shear rate was increased in the range of 0.1−100 s^{-1}, and apparent viscosity (η) was recorded with the shear rate increasing. For dynamic oscillation measurement, the frequency sweep was performed at 25 °C with the frequency ranging from 1 to 100 rad/s (all of the measurements were conducted within the linear viscoelastic region). The elastic (G') and loss (G'') moduli as a

function of the frequency were recorded. All determinations were conducted on separate samples at least in duplicate.

RESULTS AND DISCUSSION

Characterization of Phytosterol Colloidal Dispersions. The obtained phytosterol colloidal dispersion at c = 3.0% (w/v), with a WPC concentration of 0.12% (w/v) and a phytosterol concentration of 2.88% (w/v), was milky and turbid, and aggregation could be observed on the wall of the container (Figure 1A, undiluted). The aggregated state of phytosterol colloidal particles could be well-observed in the LM observation (Figure 1B). When the dispersion was diluted with water by 5-fold, the aggregation seemed to be greatly reduced and the diluted dispersion was still milky but homogeneous. When the dispersion was diluted with 1% sodium dodecyl sulfate (SDS) by 5-fold, the turbidity of the dispersion considerably decreased, as compared to that with water, and in this case, the dispersion even became a bit translucent (Figure 1A). The observations indicated that most of the phytosterol colloidal particles in the dispersion were in the aggregated form and the weak interparticle hydrophobic interactions seemed to play a role in the aggregation.

The detailed morphology of the colloidal particles in the dispersion was further evaluated by SEM. The untreated phytosterol sample exhibited a typical needle-like crystal morphology (Figure 2A), which well agrees with the previous observations.[16,18] In contrast, most of the phytosterol colloidal particles in the dispersion exhibited morphology of stacked platelet-like sheets (panels B and D of Figure 2). The morphology of these colloidal particles is completely different from that of phytosterol nanodispersions, formed with small-molecular-weight emulsifiers (e.g., Tween 20) using a similar preparation process,[20,25] where the particles were basically present in the regularly spherical form. The morphology is also completely different from that of phytosterol crystals in an emulsion stabilized by a series of Tween group emulsifiers,[16] where the corresponding crystals exhibited a needle-like morphology. The differences in morphology might be due to the differences in the extent of crystallization of phytosterols that occurred during the evaporation of organic solvents as well as the amount of crystals per particle. The application of whey proteins to coat the phytosterol particles might to a certain extent inhibit the crystallization of the free phytosterol molecules. Taking the particle size data together (Figure 1), it can be reasonably proposed that the phytosterol colloidal particles were the flocs of platelet-like phytosterol crystals, with a kind of fractal network.

Phytosterol Colloidal Particle-Stabilized Emulsions. *Visual Observation and Phase Diagram.* Figure 3 shows the photographs of all of the emulsions, formed at varying c (0–3.0%, w/v) and $ø$ (0–0.6) values, after storage periods of 1 and 3 days. In the absence of the oil phase, the homogenization process caused instability of the aqueous dispersions and there were sediments at the bottom of the vessel as well as some kind of sticky "creams" at the top of the vessel (Figure 3, first column). The extent of instability seemed to increase with increasing c from 0.1 to 3.0%. The observations are in accordance with the SEM observations at c = 3.0% (w/v), showing that, after the homogenization, most of the colloidal particles became more clustered (panels B and C of Figure 2). Thus, the colloidal particle structure in the dispersion could be disrupted by the mechanical agitation during the homogenization.

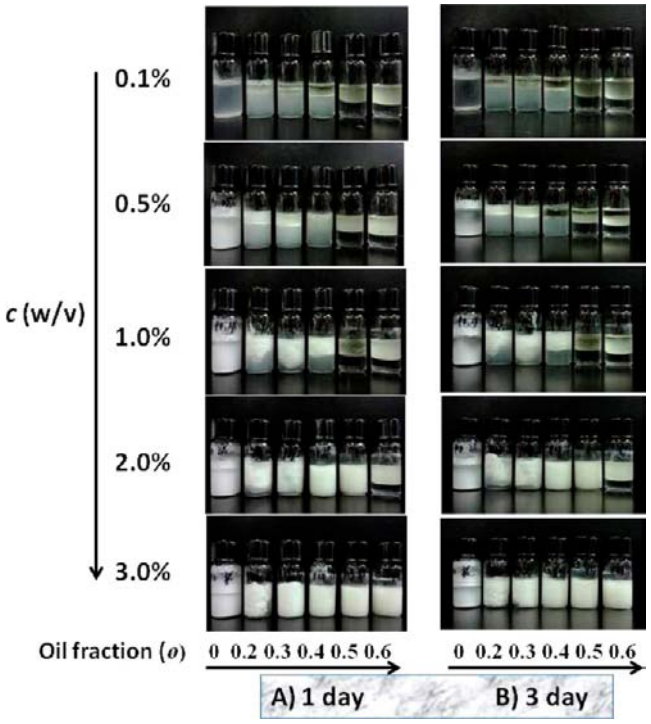

Figure 3. Photographs of emulsions stabilized with different solid concentrations (0.1–3.0%, w/v) of phytosterol colloidal particles at various oil fractions of 0–0.6. The photographs were taken 1 or 3 days after the preparation.

As expected, the morphology of the emulsions stabilized by the colloidal particles changed with the applied c and $ø$ (Figure 3). At c = 0.1 or 0.5%, the formed emulsions fast phase-separated over the whole test $ø$ range and a macroscopic oil phase was observed after longer storage periods and at higher $ø$, indicating that the amount of colloidal particles was not enough to stabilize the emulsions. However, it can still be observed that, at high $ø$ values above 0.4, most of the colloidal particles were absent from the aqueous phase (because the bottom layer was transparent), suggesting that the phytosterol colloidal particles were hydrophobic in nature and tended to be dispersed in the organic phase. When c was increased up to 1.0%, some "cotton fiber"-like aggregates were formed in the top phase for the emulsions at low $ø$ values of <0.4, while at higher $ø$ values, a phase separation with a macroscopic oil phase was still observed (Figure 3). In this case, a strong emulsion-gel material for the top phase was interestingly obtained at $ø$ = 0.4, which could be put upside down without leaking out the aqueous phase (Figure 4A, left). When c was further increased up to 3%, a homogeneous and turbid emulsion-gel-phase material, without phase separation, could be formed at appropriate $ø$ values. For example, at c = 2.0%, a homogeneous emulsion gel was formed at $ø$ = 0.4 or 0.5, while at $ø$ = 0.6, the emulsion-gel material was formed in the top phase. Whereas in the situation at c = 3.0%, the emulsion-gel structure could be observed over a much larger $ø$ range (0.3–0.6) and a typical morphology of the formed emulsion gel at $ø$ = 0.6 is illustrated in Figure 4A (right).

Figure 4B summarizes the phase diagram of all of the emulsions after 1 day of storage. At a low $ø$ value of 0.2, a serious aggregation occurred at c values of 1.0–3.0%, with a higher extent observed at higher c values, while at c values of <1.0%, a macroscopic oil phase could be observed (Figure 3A).

dx.doi.org/10.1021/jf404930c | J. Agric. Food Chem. 2014, 62, 5133–5141

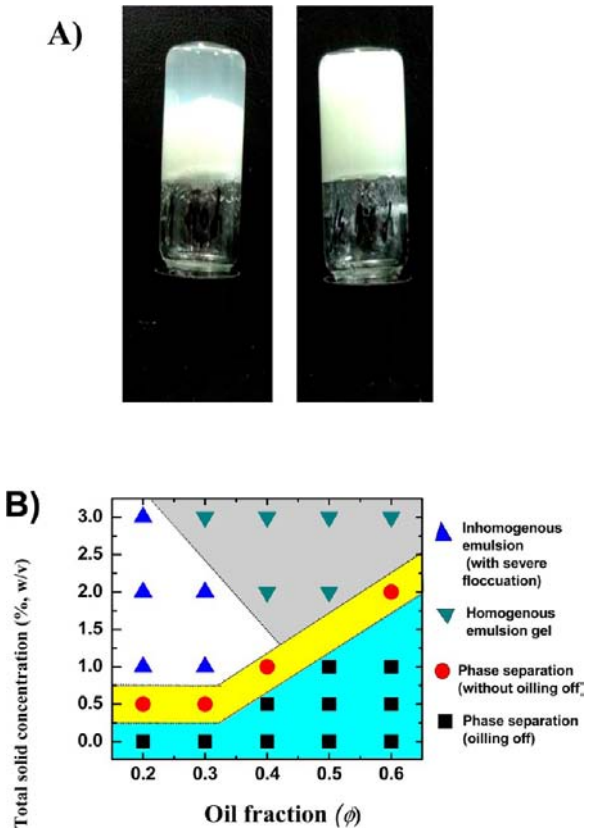

Figure 4. (A) Photograms of the emulsions formed at c = 1.0% and ϕ = 0.4 (left) or at c = 3.0% and ϕ = 0.6 (right), which were put upside down. (B) Phase diagram of the emulsions stabilized by the phytosterol colloidal particles at different solid concentrations of 0.0−3.0% (w/v) and oil fractions of 0.2−0.6.

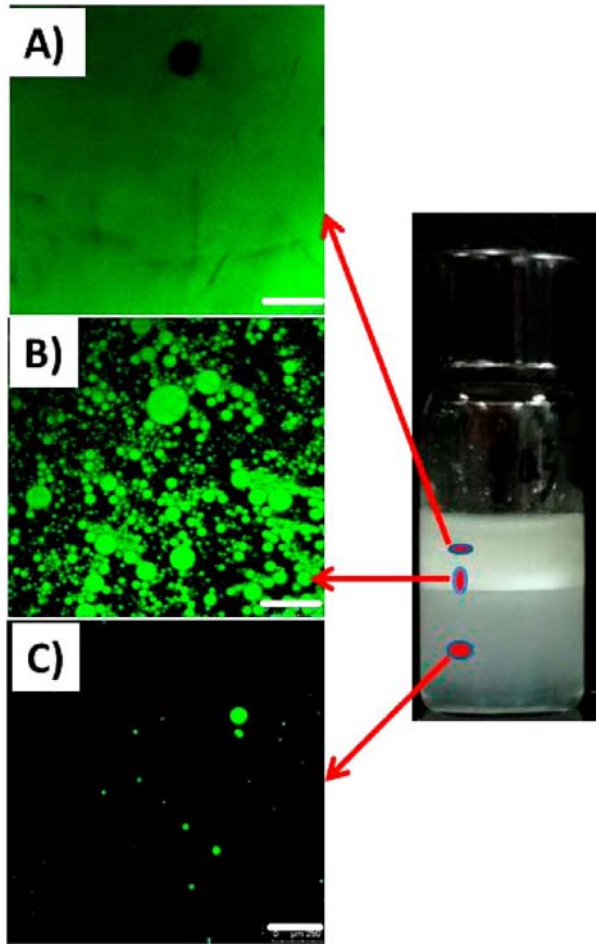

Figure 5. CLSM images of the different parts of the phytosterol colloid particle-stabilized emulsion at c = 0.5% and ϕ = 0.3 after a storage of 3 days: (A) macroscopic oil phase (upper layer), (B) middle emulsion phase, and (C) bottom aqueous phase. The bars represent 250 μm in scale.

In this case, the colloidal particle-coated oil droplets seriously flocculated to exhibit a "cotton fiber"-like morphology. The flocculated droplets remained on the top of the aqueous phase. On the other hand, at a high ϕ value of 0.6, it can be observed that a macroscopic separation occurred at c values up to 2.0% (w/v), with all of the colloidal particles incorporated in the upper phase (oil phase) (Figure 3A, last column). Interestingly, within the upper phase, a new phase separation occurred, with the extent decreasing upon the increase in c. In this situation, when c was increased up to 3.0% (w/v), no distinct phase separation was observed and, instead, a homogeneous emulsion-gel network was formed throughout the whole emulsion (Figures 3A and 4B). A similar emulsion-gel material could be observed at higher c (e.g., 2.0% or above) and ϕ (at least 0.3) values (Figure 4B).

Microstructure of the Emulsions [Inversion from O/W to Water-in-Oil (W/O) Type]. The microstructure of the phytosterol colloidal particle-stabilized emulsions, formed at different c or ϕ values, was evaluated using the CLSM technique in combination with light microscopic observation. The oil phase was dyed using Nile Blue A, which shows a green color in the CLSM images. In the emulsions, where the amount of the colloidal particles was distinctly not enough to stabilize the droplet interface, e.g., at low c values of <1.0% (w/v), a phase separation with a macroscopic oil phase occurred (Figure 3). Figure 5 shows typical CLSM observations for the emulsion at c = 0.5% and ϕ = 0.3 after 3 days of storage. In this case, the CLSM images of different parts of the emulsion (upper or bottom phase) were provided. The CLSM image for the bulk part of the upper phase of the emulsion was basically green, while that for the bottom part was black (panels A and C of Figure 5), confirming the occurrence of phase separation (with a macroscopic oil phase). However, in the vicinity of the border of the two phases, a droplet-flocculated microstructure of an O/W emulsion could be still observed (Figure 5B). This observation suggests that, at a low c value and a relatively high ϕ value (e.g., 0.3), an O/W type of emulsion stabilized by the phytosterol colloidal particles was formed, although the emulsion was unstable against coalescence, flocculation, and even creaming.

When c was increased up to 3.0%, a homogeneous emulsion-gel material with no phase separation was formed at ϕ values of 0.3−0.6 (Figure 3A). Accordingly, in the CLSM images of these gel-like emulsions, the oil phase (with green color) became the continuous phase, while the aqueous phase with black color (undyed) was relatively even dispersed in the system (Figure 6, upper row). This observation indicated that all of these emulsions were basically W/O type in nature. In this case, it can be still observed that the microstructure of the dispersed phase considerably changed with the applied ϕ (Figure 6, upper row). For the emulsion at ϕ = 0.3, the aqueous phase with a homogeneous and globular droplet morphology was relatively

dx.doi.org/10.1021/jf404930c | J. Agric. Food Chem. 2014, 62, 5133−5141

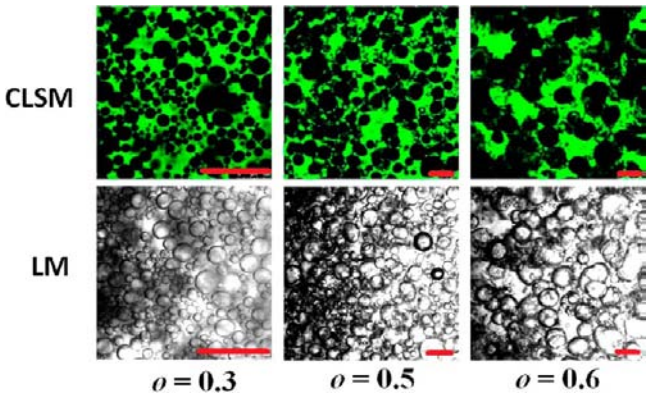

Figure 6. CLSM (upper row) and LM (bottom row) images of the phytosterol colloidal particle-stabilized emulsions at a constant c of 3.0% (w/v) and different ø values of 0.3−0.6 after a storage of 3 days. The bars represent 200 μm in scale.

dispersed in the continuous oil phase, while in the cases at ø = 0.5 or 0.6, the morphology of the dispersed phase became more uneven and irregular with greater droplet flocculation and the emulsions were more like the oil-in-water-in-oil (O/W/O) type in nature (relative to that at ø = 0.3; Figure 6, upper row). The formation of the complex O/W/O colloidal structure led to a distinct increase for the volume of dispersed droplets, thus strengthening the gel network. On the other hand, the CLSM and LM observations also interestingly showed that, in the emulsions at ø = 0.5 or 0.6, there were plenty of emulsified oil droplets with much smaller sizes stabilizing the colloidal structure of dispersed droplets (Figure 6). In a recent work, Ye and others[26] reported that nanoemulsion droplets stabilized by micellar casein could be applied as an emulsifier to stabilize W/O emulsions, through being adsorbed at the interface. This interesting finding implies that, in the present work, a small portion of oil droplets coated with the phytosterol colloidal particles or whey proteins, initially formed during the emulsification, might stabilize the dispersed aqueous droplets in the system.

To ascertain the transition of the emulsion type, we visually evaluated the dispersion of the formed gel-like emulsions at a constant c value of 3.0% (w/v) and varying ø values of 0.3−0.6 in water or oil, as displayed in Figure 7. All of the emulsions remained at the top of the water and could not be dispersed in water, while they could be well-dispersed in oil, under vortexing conditions. After vortexing, a turbid and homogeneous dispersion was formed for each case, confirming that the gel-like emulsions were the W/O type in nature. This can be further confirmed by the conductivity measurement of the emulsions, where the conductivity of the gel-like emulsions progressively decreased from 6.7 ± 1.5 to 1.5 ± 0.7 μs/cm, as ø increased from 0.3 to 0.6 (data not shown). The magnitude of conductivity values for these emulsions was considerably lower than that of the aqueous phase (~2270 μs/cm), with the latter basically comparable to those previously reported.[27]

Emulsion Size. In the present work, the droplet size of the emulsions, especially for those formed at low c values, was difficult to measure, because of their instability, e.g., against flocculation, creaming, and phase separation. In contrast, the gel-like emulsions formed in the present work (Figure 4) were relatively stable against creaming and phase separation, thus providing a possibility to evaluate the c dependence of the droplet size of the emulsions (although the emulsions were the

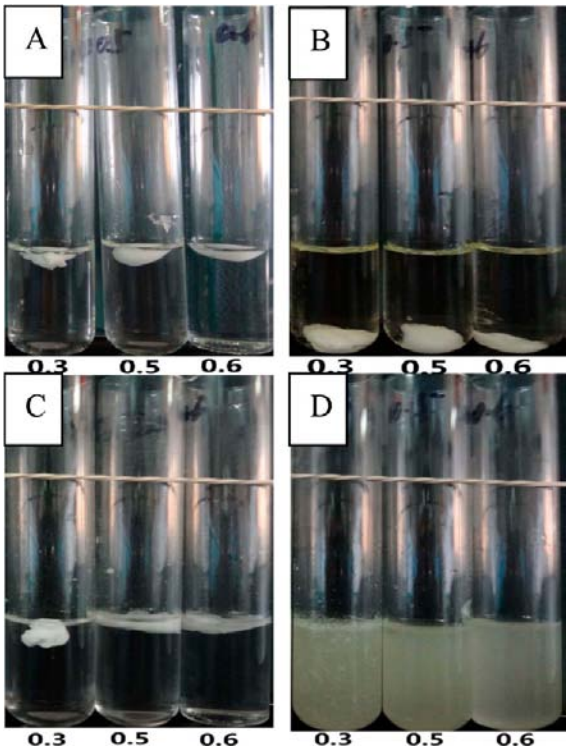

Figure 7. Visual observations for the dispersion of the phytosterol colloidal particle-stabilized emulsions (at c = 3%, w/v, and ø = 0.3−0.6) in (A and C) 10 mM phosphate buffer (pH 7.0) or (B and D) oil under conditions (A and B) without and (C and D) with vortexing for 10 s.

W/O type in nature). Figure 8 shows the influence of the solid content/oil ratio on the droplet size of these gel-like emulsions,

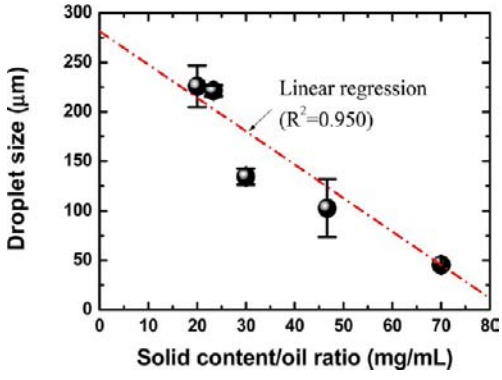

Figure 8. Droplet size values of the gel-like emulsions formed at varying c values and at ø = 0.3−0.6, as a function of the total solid content/oil ratios (mg/mL). The droplet size ($d_{4,3}$) of droplets was obtained by analyzing the CLSM images of the emulsions using an image analysis software. Each data is the mean and standard deviation of duplicate measurements on separate samples.

formed at varying c values and at ø = 0.3−0.6, by analyzing their CLSM images using the Nanomeasurer software. As expected, the approximately calculated droplet diameter progressively reduced from around 230 to 50 μm as the solid content/oil ratio increased from 20 to 70 mg/mL (Figure 8). This observation basically reconciles with the general consensus that the droplet size of Pickering emulsions stabilized by solid particles is negatively related to the particle concentration,

because at higher particle concentrations, more particles help to stabilize the smaller oil droplets produced during the emulsification.[28−30]

Rheological Characterization of Gel-like Emulsions. All of the gel-like emulsions, formed at c = 3.0% and three specific $ø$ values of 0.3, 0.5, and 0.6, exhibited a distinct shear-thinning behavior at high shear rates above 0.1 s^{-1}, with η progressively decreasing with increasing shear rate (Figure 9A). This

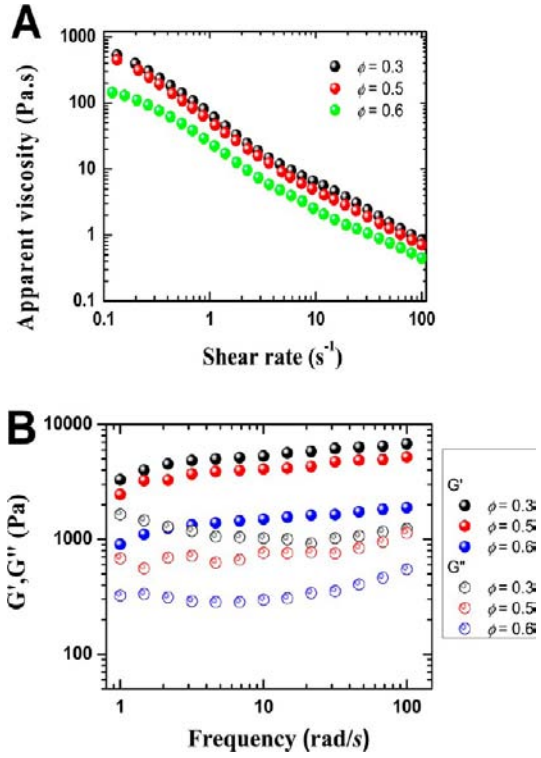

Figure 9. Dependence of (A) apparent viscosity (η) and (B) storage moduli upon the shear rate and frequency, respectively, of the gel-like emulsions stabilized by the phytosterol colloidal particles at c = 3.0% and $ø$ values of 0.3−0.6. G', storage modulus; G'', loss modulus.

phenomenon is a typical flow behavior of weakly flocculated colloidal dispersions, including oil-in-water emulsions,[31−33] which corresponds to the deflocculation of droplets in the system upon shearing. Among all of the emulsions, G' at any test frequency was considerably higher than G'' (Figure 9B), indicating a predominantly elastic gel-like behavior. Furthermore, G' persistently increased with the frequency, while G'' was relatively less dependent upon the applied frequency at low frequencies (e.g., <20 rad/s) (Figure 9B). A similar observation was reported in gel-like O/W emulsions stabilized by proteins.[33−35] Similar to the situation in heat-induced gels of proteins,[36] the present observations suggest that the gel-like network might be maintained through non-covalent "physical" cross-links in nature.

For these emulsions, η (or the moduli) at any test point progressively decreased with increasing $ø$ from 0.3 to 0.6 (panels A and B of Figure 9), indicating weakening in the gel strength or stiffness. The observation is well in accordance with the fact that the volume of the dispersed aqueous phase progressively declined upon the increase in $ø$, further confirming that these gel-like emulsions were mainly the W/O type in nature. The weakening effect of decreasing the volume of the dispersed phase on the gel stiffness has also been observed in the gel-like O/W emulsions stabilized by the proteins.[33,34]

Supposed Mechanism for the Formation of Phytosterol Colloidal Particle-Stabilized Emulsions. Besides the whey proteins, free phytosterol molecules, such as stigmasterol and β-sitosterol, have been confirmed to have a high ability to reduce interfacial tension.[37] This allows these colloidal particles to migrate to the interface of the droplets in the emulsions, and as a consequence, a kind of phytosterol colloidal particle-stabilized emulsion can be formed. Because a small portion of WPC [e.g., approximately 0.12% (w/v) at the maximal c of 3.0%, w/v] was applied to coat and stabilize the phytosterol particles, the possibility should be excluded that the applied WPC rather than the colloidal particles might largely contribute to the stabilization of the emulsions. To exclude this possibility, we evaluated and compared the stability of the emulsions stabilized by the phytosterol colloidal particles or WPC alone (in both cases, the WPC concentration was comparable), according to the method by Timgren et al.[30] Sudan III was applied to indicate the stability of the emulsions stabilized by WPC alone. If the emulsions are not stable, e.g., against coalescence and oiling off, they will exhibit a bright red color or would still exhibit a milky morphology. The results indicated that, at a constant concentration of WPC (0.125%), increasing the oil fraction from 0.2 to 0.6 progressively decreased the stability of the emulsions stabilized by WPC alone, while at a fixed oil fraction (0.3), increasing the concentration of WPC progressively increased the stability (see Figure S1 of the Supporting Information, upper row). In contrast, the situation for the emulsions stabilized by the colloidal particles (at a comparable concentration of WPC) is completely different. In this situation, at a fixed total solid content of 3% (w/v), increasing the oil fraction (increasing the solid content at a fixed oil fraction) progressively favored the formation of more homogeneous and stable (against creaming and phase separation) emulsions (see Figure S1 of the Supporting Information, bottom row). The observations clearly confirmed that the amount of WPC alone up to 0.12% (w/v) was not enough to fully stabilize the emulsions and the stabilization of the emulsions was thus mainly due to the action of the WPC-coated phytosterol particles.

Another point is worth mentioning that these phytosterol colloidal particles, especially after the homogenization, were mainly hydrophobic in nature, which is consistent with the fact that the phytosterols are much more soluble in the oil phase than in the water phase.[38,39] During emulsification together with the oil phase, these colloidal particles would be preferentially adsorbed to the oil−water interface, stabilizing the emulsions. The colloidal particles, initially adsorbed at the interface, might locate in a close proximity and associate with one another. Besides the strong lateral interactions between individual adsorbed colloidal particles, the interdroplet interactions between the adsorbed particles on different oil droplets were also strong, which might greatly facilitate the droplet flocculation in the emulsions. Furthermore, these adsorbed colloidal particles would further migrate toward the oil phase, upon storage of the emulsions, because of their high insolubility in water and much better solubility in oil.[16] As result, the extent of adsorption at the interface and migration between the different phases as well as the interdroplet attractive interactions, which were largely dependent upon the applied c and/or $ø$, would produce a significant influence on the

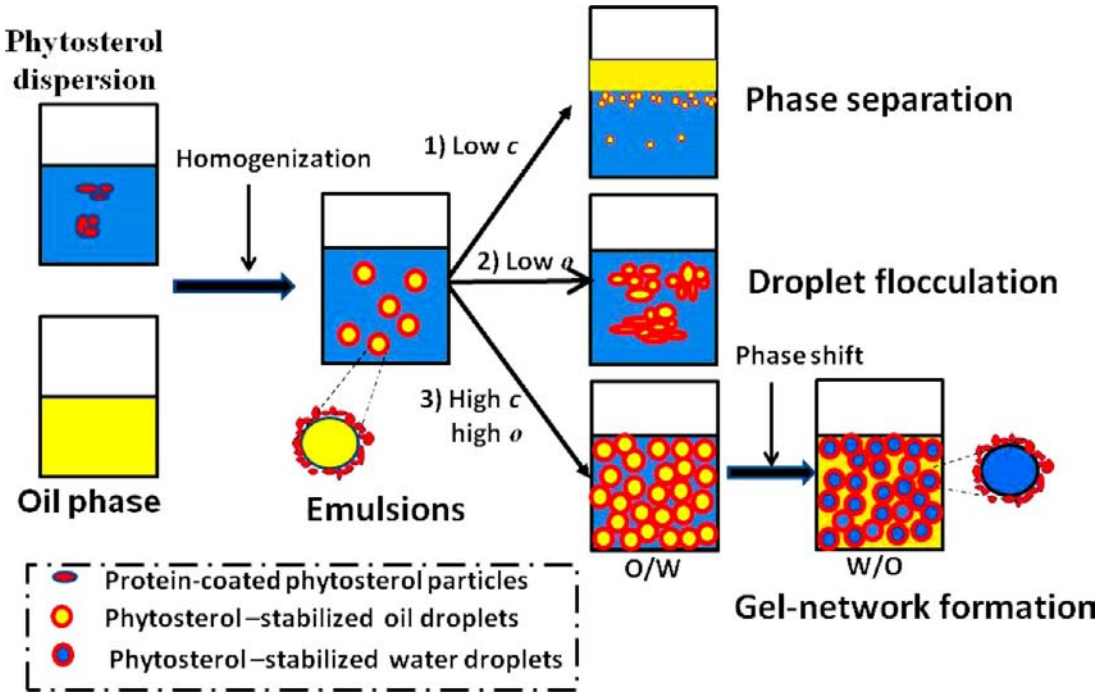

Figure 10. Supposed mechanism for the formation and instability of the emulsions stabilized by the phytosterol colloidal particles.

type, properties, and stability of the correspondingly formed emulsions.

If the droplet flocculation in the emulsions that is favored by increasing the volume of dispersed phase aand the enhancement of interdroplet attractive interactions are high enough, the instability of the emulsions will happen fast. In the present work, what kinds of instability of the emulsions occurred highly depended upon the magnitude of c and/or ϕ values. Thus, there were approximately several situations of instability of the emulsions occurring, depending upon the applied c and/or ϕ values. For example, at low c values (e.g., 0.1−0.5%, w/v), the emulsions were easily susceptible to severe coalescence and even oiling off, when the ϕ was above 0.3 (Figure 3), because of the shortage of colloidal particles to stabilize the emulsions. Once the amount of colloidal particles was enough to fully cover the interface newly created during the emulsification, the droplet flocculation might dominate the whole instability of the emulsions (rather than the instability against coalescence and phase separation). Especially when both the c and ϕ values are high enough, the droplet flocculation will lead to formation of a kind of self-supporting gel-like emulsion, such as at c = 3.0% and ϕ above 0.2 (Figure 3). The flocculation-induced gel network formation has been similarly proposed for the emulsions stabilized by denatured whey protein or soy proteins.[34,35]

At c = 3.0% (w/v), it can be interestingly observed that the type of emulsions changed from the O/W (at ϕ < 0.3) to W/O (ϕ = 0.3 or above) type (Figures 3 and 6), implying that the emulsions at high ϕ values might suffer a phase inversion from the O/W to W/O type. In this case, we tend to hypothesize that the initially formed emulsions were basically the O/W type in nature. The initially adsorbed colloidal particles at the oil−water interface are kinetically unstable, and they may gradually migrate from the aqueous side of the interface to the other side (oil phase), upon the storage of these emulsions. When the migration of the colloidal particles occurs to a certain extent, the interface between initially individual oil droplets fuses and, concomitantly, the initially coated oil droplets are released. As a result, a phase inversion occurs for these emulsions. A schematic representation for the formation and instability of the phytosterol colloidal particle-stabilized emulsions is illustrated in Figure 10.

In conclusion, water-insoluble phytosterols have been successfully developed into a kind of colloidal particle stabilizer for the emulsions. The properties and stability of the emulsions stabilized by these colloidal particles were highly dependent upon the applied c and ϕ. If both c and ϕ were appropriately high, a kind of self-supporting gel-like emulsion could be formulated. The emulsions could change from the O/W to W/O type, with ϕ increasing from 0.2 to 0.6 (especially at high c values, e.g., 3.0%, w/v). The elaborated Pickering emulsions with a gel-like structure could be applied as a novel delivery system for the unmodified phytosterol and other water- or lipid-soluble active ingredients. However, further research is needed to elaborate a kind of phytosterol colloidal particle at the nanoscale to be effective Pickering emulsion stabilizers.

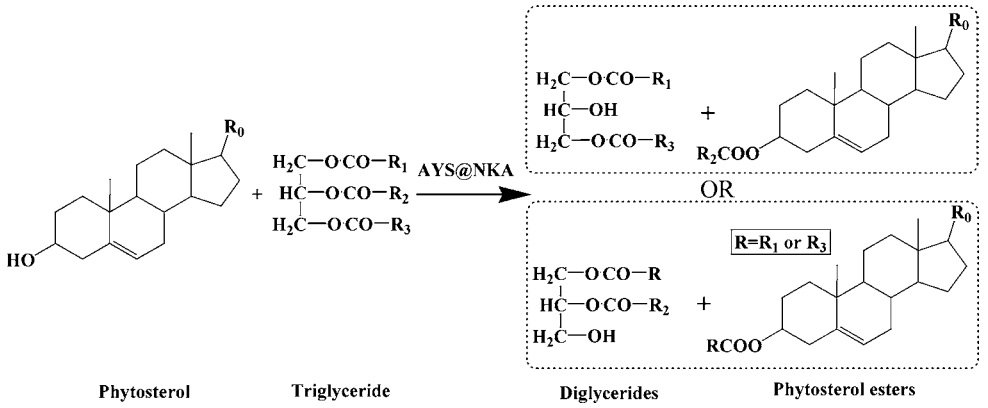

Figure 1. Preparation scheme of functional oil rich in both phytosterol esters and diglycerides using AYS@NKA as the biocatalyst.

the intermediate chemical compounds would save time and resources.[21] The main objective of this study is to develop a novel functional oil rich in both phytosterol esters and diglycerides with one-pot enzymatic esterification. Lipase immobilized on porous cross-linked polystyrene resin beads (NKA) was prepared, characterized, and used as the biocatalyst. The transesterification activity of immobilized lipase was compared with that of the free lipase. Then, a rapid and convenient method was proposed for the enzymatic transesterification of phytosterols with different vegetable oils to produce functional oils in one pot. The physiochemical properties of four kinds of functional oils with phytosterol esters and diglycerides as well as the different fatty acid (FA) compositions were also determined. As far as we are aware, a method related to producing functional oils containing both phytosterol esters and diglycerides with controllable FA composition has not been reported yet.

EXPERIMENTAL PROCEDURES

Reagents and Chemicals. The porous cross-linked polystyrene resin beads (NKA, 200−220 Å) used for preparing the immobilized lipase were obtained from the Chemical Plant of NanKai University (Tianjin, China). Ethanol, 2-propanol, acetonitrile, iso-octane, *n*-hexane, *tert*-amyl alcohol, cyclohexane, anhydrous disodium phosphate, molecular sieves (3 Å), and other solvents were all purchased from Sinopharm Chemical Reagent (Shanghai, China). 2-Propanol and acetonitrile were of chromatographic pure grade, and other reagents were of analytical reagent grade. Purified water was obtained with a Millipore water purification equipment (Boston, MA, USA). Thin layer chromatography (TLC) silica gel 60 glass plates were purchased from Merck (Darmstadt, Germany).

Lipase PS (*Burkholderia cepacia* lyophilized powder) and AYS (*Candida rugsa*, lyophilized powder) was purchased from Amano Enzyme Inc. (Tokyo, Japan). Novozym 435 (*Candida antarctica*), Lipozyme TL IM (*Thermomyces lanuginosus*), and Lipozyme RM IM (*Rhizomucor miehei*) were purchased from Novozymes A/S (Bagsværd, Denmark). Phytosterols (*β*-sitosterol (89.0%), campesterol (8.9%), stigmasterol (2.1%)) were purchased from Vita-Solar Biotechnology Co., Ltd. (Xi'an, China). Refined and bleached sunflower oil, rapeseed oil, corn oil, and linseed oil, which were used as the source of triglycerides, were purchased from the supermarket. Diglyceride and monoglyceride standards were purchased from Larodan Fine Chemicals (Malmö, Sweden). Phytosterol ester standard (97%) was purchased from BASF (China) Co., Ltd. (Shanghai, China).

Immobilization of Lipase AYS on the NKA Beads. The immobilized lipase AYS was prepared as proposed by Yan et al. with some modification.[22] First, 20.0 g of NKA beads was prewetted with 40 mL of ethanol. Then immobilization of lipase AYS on the NKA beads via adsorption was studied in phosphate buffer (400 mL, 100 mM, pH 7.0). The initial concentration of lipase was kept at 0.5−7.0 mg/mL in buffer solution. The immobilization experiment was conducted at 30 °C for 8 h with continuous stirring. After immobilization, the NKA beads were separated from the lipase solution and then washed with buffer solution three times and then washed with acetone twice. The resulting immobilized lipase (designated AYS@NKA) was lyophilized and stored at 4 °C prior to use. The amount of immobilized lipase was obtained by using the equation

$$Q = [(C_0 - C)V]/M \quad (1)$$

where Q is the amount of lipase immobilized onto NKA (mg/g), C_0 and C are the concentrations of the lipase in the solutions before and after immobilization, respectively (mg/mL), V is the volume of the aqueous solution (mL), and M is the mass of the beads (g). The amounts of protein in the medium and wash solutions were determined according to the Bradford method.[23] Nitrogen sorption experiments were carried out at 77 K using Gemini V2380 surface area and pore size analyzer (Micromeritics, Norcross, GA, USA).

One-Pot Enzymatic Synthesis of Functional Oil. The following esterification conditions were used: phytosterols (50−150 mmol/L), triglycerides such as sunflower oil, corn oil, rapeseed oil, or linseed oil (80−640 mmol/L), lipase (free AYS, AYS@NKA, 10−40 mg/mL), and solvent (hexane, iso-octane, etc., 10 mL) were added into an Erlenmeyer flask. The solvent had, in advance, been dehydrated with 15% (w/w) molecular sieves 3 Å for at least 24 h.

The vial was placed in a shaking incubator at 45−60 °C with a shaking speed of 180 rpm for a certain time. The reaction bioconversion was monitored periodically by HPLC to confirm production. The bioconversion was calculated from the ratio between the measured concentration of phytosterol esters and the expected concentration assuming complete reaction. Standard solution calibration curves were used to quantify target analytes, as it was found that no matrix effect was present. Calibration curves for phytosterol esters and diglycerides were obtained by dissolving standard substances with mobile phase in different concentrations, and results were detected and recorded on the HPLC-PDA detection. The reaction lasted for a certain time, and the relevant samples (50 μL) were withdrawn from the reaction mixture at relevant time intervals and diluted to 1 mL with the mobile phase for the analytical monitoring of the reaction. The transesterification of phytosterols might occur at either sn-1,3 or sn-2 position of triglyceride; thus, the products including diglycerides and phytosterol esters might be several possibilities (see Figure 1).

Following the lipase-catalyzed esterification, immobilized lipase and molecular sieves were filtered from the mixture. Functional oil was prepared after rotary evaporation to remove reaction solvent.

Isolation and Analysis of Functional Ingredients in the Functional Oil. High-performance liquid chromatography (HPLC) analysis was performed on an LC-6A Prominence instrument (Shimadzu, Japan) equipped with a photodiode array (PDA) detector. An Inertsil ODS-SP column (5 μm, 250 mm × 4.6 mm) purchased

dx.doi.org/10.1021/jf500744n | J. Agric. Food Chem. 2014, 62, 5142−5148

from GL Science Inc. (Tokyo, Japan) was adopted to separate and detect the targeted products. Injection volume was 10 μL. The mobile phase was acetonitrile/2-propanol (65:35, v/v). Column temperature was 40 °C, and flow rate was 1.0 mL/min. Detection was carried out by PDA at 205 nm.

A 50 μL aliquot of the reaction product was taken from the reaction system and isolated by thin layer chromatography (TLC) plates with hexane/acetic ether/acetic acid (88:12:1, v/v/v) as the developing solvent.[24,25] First, products were diluted with the developing solvent and spotted on TLC plates repeatedly (>10 times), with standard substances of phytosterol ester and diglyceride as references. Then development was carried out in the developing solvent, and the spots were visualized by iodine vapor and exposure in an oven set at 60 °C for 5 min. Ten bands corresponding to diglycerides and phytosterol esters were scraped off and collected, respectively.

Fatty Acid Composition Analysis. The fatty acid compositions of the triglycerides, diglycerides, and phytosterol esters were further confirmed by gas chromatography (GC) analysis. First, the fatty acid methyl esters (FAMEs) were prepared from diglycerides, triglycerides, and phytosterol esters according to "Animal and Vegetable Fats and Oils Preparation of FAMEs" (GB/T 17376, ISO 5509:2000, IDT) with some modification. Briefly, 100 μL of sodium methylate solution (0.5 M in methanol) and 2.5 mL of hexane were added to 0.2 g of triglyceride or a certain amount of other targets (diglycerides or phytosterol esters; each needs 10 bands collected from TLC) and then reacted for 10 min in the shaker at 55 °C. The FAMEs were extracted twice with 20 mL of hexane, and after 10 min of centrifugation, the supernatant FAMEs were concentrated with nitrogen before being preserved for GC analysis.

The fatty acid compositions of the diglycerides, triglycerides, and phytosterol esters in the products were analyzed by GC. An Agilent 7890 series gas chromatograph (Hewlett-Packard Co., Avondale, PA, USA), equipped with a flame ionization detector (FID) and a fused silica capillary column (DB-5 HT, 30.0 m × 320 μm × 0.25 μm, Agilent Technologies, Palo Alto, CA, USA) was used. The injection volume was 1 μL at a split ratio of 80:1. The carrier gas was nitrogen, and the nitrogen flow rate was 1.5 mL/min in constant flow rate mode. The flow rates of hydrogen and air were 40 and 400 mL/min, respectively, and the makeup gas was also nitrogen at a flow rate of 41.5 mL/min. The injector and detector temperatures were maintained at 250 and 300 °C, respectively. The oven temperature was held at 210 °C for 9.0 min, then increased to 250 °C at a rate of 20 °C/min, and held at 250 °C for 5 min. The fatty acid compositions of the diglycerides, triglycerides, and phytosterol esters in the products were compared with the standard substances of different fatty acids and confirmed by the retention time. The proportion of each fatty acid could be calculated by the ratio of peak area assigned to corresponding fatty acid in the GC profile.

Physiochemical Properties of Functional Oils from Different Triglyceride Sources. The peroxide value (PV) and acid value (AV) were determined according to the National Standard of the People's Republic of China (PRC) (GB/T 5538, ISO 3960:2001, IDT; GB/T 5530, ISO 660:1996, IDT).[26]

The conjugated diene (CD) value was determined as reported previously.[27] Briefly, the sample was dissolved in 50 mL of cyclohexane and the optical density (1 cm light path) recorded at 234 nm against a cyclohexane blank. The conjugated diene value was calculated according to the equation

$$\mathrm{CD\ (mmol/kg\ of\ oil)} = \frac{AV}{\varepsilon bm} \times 100 \quad (2)$$

where A is the absorbance at 234 nm of the test sample, V is the constant volume, ε is the molar absorption coefficient, 26000 L/(mol·cm), b is the thickness of the absorption cell, and m is the sample mass.

RESULTS AND DISCUSSION

Preparation and Characterization of the AYS@NKA. Five enzymes including lipase PS, lipase AYS, Novozym 435, Lipozyme TL IM, and Lipozyme RM IM were selected as the biocatalyst for transesterification of phytosterol with triglyceride. Lipase AYS was the most effective among the enzymes tested (conversion >52%). Thus, lipase AYS was selected for the following experiments. To take advantage of high specific surface area and ideal porous structure, NKA beads were used as a support matrix to immobilize lipase AYS.

However, it is difficult for the enzyme solution to access the inner surface of the NKA bead pores because of the highly hydrophobic nature of these surfaces. When prewetted with ethanol, the NKA beads were perfectly suspended in the enzyme solution, which could help the lipase reach the internal of the hydrophobic pores. The presence of ethanol may also contribute to a rearrangement of the secondary structure involving a higher accessibility of some hydrophobic side chains, which could increase the activity of noncovalently immobilized lipase.[28] Furthermore, the catalytic activity of soluble lipase in the presence of 10% ethanol concentrations could not have been negatively affected.[28] Thus, ethanol (10%, v/v) was added and acted as an intermediate between the lipase solution and the NKA beads in this experiment.

The AYS@NKA was characterized by measuring the texture parameters of samples using a Brunauer−Emmett−Teller (BET) treatment of the N_2 sorption isotherm data. It can be found that the surface area and pore volume of NKA are 562 m^2/g and 0.66 cm^3/g, respectively. After lipase absorption, the NKA beads have a lower surface area (501 m^2/g) and a lower pore volume (0.63 cm^3/g). The decrease of surface area and pore volume values of NKA after absorption indicated that the lipase AYS has been absorbed on the NKA surface and partly occupied the NKA surface pores.

To evaluate the loading capacity of the carrier, 20 g of NKA beads was loaded with 400 mL of different initial lipase concentrations ranging from 0.5 to 7.0 mg/mL. The adsorbed AYS amount increased with increasing initial AYS amount until 6.5 mg/mL and reached a maximum value of 51.2 mg/g, which was higher than that of lipase immobilized on magnetic microspheres (48.1 mg/g) and a fibrous polymer (44.7 mg/g).[23,29] The result shows that the macroporous resin NKA beads have excellent adsorption properties and allow the adsorption of a high amount of AYS with high activity.

Activity and Thermal Stability of Free AYS and AYS@NKA. The catalytic activity and thermal stability of free AYS and AYS@NKA during the transesterification reaction were evaluated. As shown in Figure 2, almost no formation of phytosterol esters occurred in the absence of AYS. Under the temperature of 50 °C, the conversion of phytosterol esters increased rapidly during the first 12 h and reached a relatively high conversion (92.4%) with AYS@NKA, whereas the conversions of phytosterol esters reached only 68.6% after 24 h of reaction using free AYS as the catalyst. These facts indicated that the immobilized AYS@NKA showed much higher catalytic activity than that of free AYS, especially at the first 12 h. The high catalytic activity of the immobilized AYS@NKA might be ascribed to the better dispersion effect as well as the higher mass transfer rate of the immobilized AYS@NKA in the reaction system compared with that of the free AYS, which might easily become aggregated in the reaction system.

The conversion of phytosterol esters catalyzed by free AYS in 60 °C showed a sharp decrease compared with that in 50 °C, which might be because the higher temperature would inhibit the activity of lipase AYS. In contrast, AYS@NKA retained most of its initial activity, and the conversion was 87.2% under the same conditions, proving enhanced thermostability for this

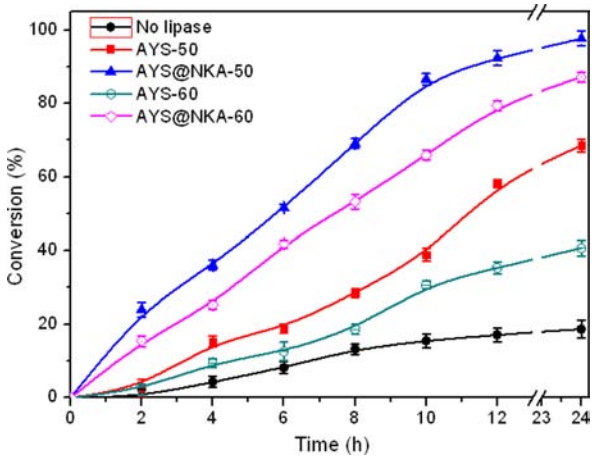

Figure 2. Activity and thermal stability of AYS@NKA and free AYS. Each experiment from Figures 2−6 was duplicated three times. The standard deviations are shown as error bars in each figure.

composite material. This is attributed to the stabilizing effect of the AYS immobilized on the NKA surface, which prevents extensive structural changes typical of thermal denaturation. The ability to retain enzyme activity at high temperatures provides several processing advantages, such as improved substrate solubility.

Optimization of Enzymatic Transesterification Conditions. Generally speaking, the kind of organic solvent is a key factor for enzymatic transesterification, because it affects not only the activity and stability of enzymes but also the solubility of substrates. The more hydrophobic solvent used, the greater activity and stability the lipase exhibited. Taking the whole into consideration, *n*-hexane, iso-octane, cyclohexane, and *tert*-amyl alcohol, which show different log *P* values, were chosen as solvents for the esterification reaction. As shown in Table 1, the

Table 1. Effects of Organic Solvents on Conversion of Enzymatic Transesterification[a]

solvent	log *P*	conversion (%)
n-hexane	3.2	95.2
iso-octane	4.5	89.7
cyclohexane	3.5	75.4
tert-amyl alcohol	1.2	80.6

[a]Reaction conditions: 80 mmol/mL phytosterols, 1:2 molar ratio of phytosterols to sunflower oil, 25 mg/mL AYS@NKA in solvent, 180 rpm, and 50 °C.

reaction in hexane exhibits the highest conversion after 12 h among the four solvents. As is known to all, the conversion is affected by both the solubility of substrates and solvent polarity. The highest conversion in hexane might ascribed to the compromise of the solubility of substrates and solvent polarity.

The effect of the substrate concentration on the conversion of phytosterol esters was evaluated. The molar ratio of phytosterols to sunflower oil was 1:2. As shown in Figure 3, it was observed that increasing the concentration of phytosterols from 50 to 150 mmol/L led to a continued decrease in the conversion. Some of the phytosterols were not soluble in the solvent at higher concentration, which was responsible for the lower conversion. In addition, an increase in phytosterols and triglyceride concentration may change the catalytic environment and the active site of AYS@NKA to some

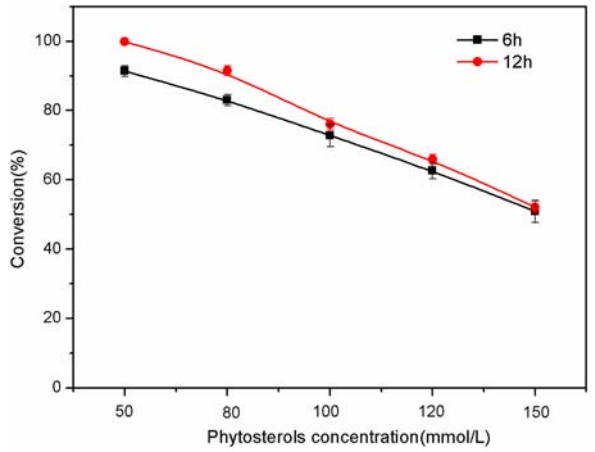

Figure 3. Effect of phytosterol concentration on the conversion of phytosterol esters in lipase-catalyzed reaction. Reaction conditions: 1:2 molar ratio of phytosterols to sunflower oil, 25 mg/mL AYS@NKA in hexane, 180 rpm, and 50 °C.

extent.[29] With phytosterol concentrations of 50 and 80 mmol/L, the phytosterol esters reached relatively high conversions, 99.8 and 91.5% after 12 h, respectively. Considering both the conversion and the economical aspect of the process, a relatively higher phytosterol concentration of 80 mmol/L was selected for the subsequent experiment.

The effect of the molar ratio of phytosterols to triglycerides on the conversion of phytosterol esters was evaluated. The molar ratio of phytosterols to sunflower oil was 1:1−1:8. With the molar ratio of phytosterols to sunflower oil increasing from 1:1 to 1:8, as shown in Figure 4, the conversions increased from

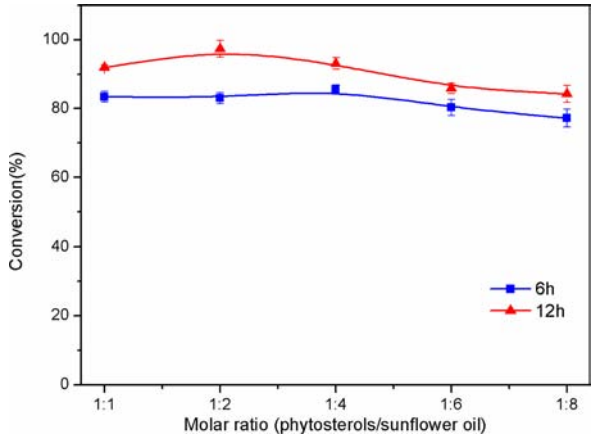

Figure 4. Effect of molar ratio of phytosterols to triglycerides on the conversion of phytosterol esters in lipase-catalyzed reaction. The phytosterol concentration was 80 mmol/L. Other conditions were the same as described in Figure 3.

91.8 to 97.4% and then decreased to 84.3%. This might due to the fact that an increase in triglyceride molar ratio may not only change the catalytic environment and the active site of AYS@NKA but also increase the viscosity of the reaction solvent and thus decrease the mass transfer rate.[30] Considering the extent of esterification and economical aspect of the process, the mole ratio of 1:2 was selected for the subsequent experiment.

The influence of the AYS@NKA load on the conversion of phytosterol esters was evaluated with a 1:2 phytosterols to sunflower oil molar ratio and an 80 mmol/L phytosterol

dx.doi.org/10.1021/jf500744n | J. Agric. Food Chem. 2014, 62, 5142−5148

concentration using various amounts of AYS@NKA from 0 to 40 mg/mL. The content of phytosterol esters was very low (18.7%) in the absence of AYS@NKA (See Figure 2). From Figure 5, it observed that with the amount of AYS@NKA

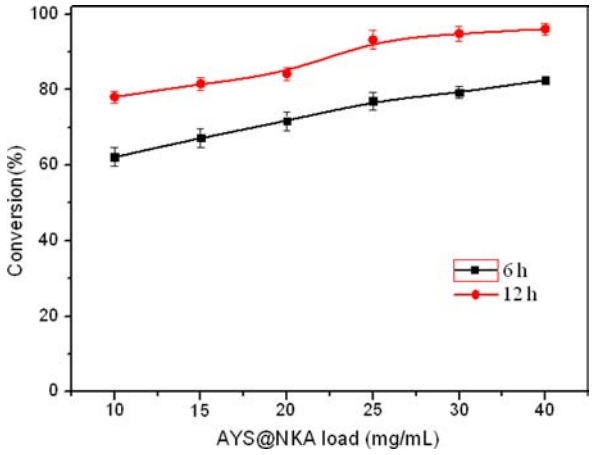

Figure 5. Effect of AYS@NKA load on the conversion of phytosterol esters in lipase-catalyzed reaction. Reaction conditions: 80 mmol/L phytosterols, 1:4 of the molar ratio of phytosterols to sunflower oil, hexane, 180 rpm, and 50 °C.

loaded increasing from 10 mg/mL to 40 mg/mL, the conversion increased from 78.1 to 96.1%. A good synthesis method should consider the conversion and economical interest of the reaction, in other words, use less AYS@NKA to obtain a satisfactory transesterification ratio. Using a minimal amount of AYS@NKA such as 10 mg/mL would be economically attractive, but conversion of phytosterols reached only 78.1% after 12 h. Increasing the amount of AYS@NKA loaded led to better production of phytosterol esters. The formation of the phytosterol esters was much higher with a 25 mg/mL AYS@NKA load and reached a 93.2% conversion after 12 h of reaction. Considering both the conversion and the economical aspects of the process, 25 mg/mL AYS@NKA was selected for the subsequent experiment.

The effect of temperature on the conversion of phytosterol esters was evaluated. The temperature ranged from 40 to 60 °C. As the reaction temperature increased from 40 to 60 °C, as shown in Figure 6, the conversion of phytosterol esters increased from 78.7 to 97.4% and then decreased to 79.2%. The highest conversion was achieved when the temperature was 50 °C. As the temperature was up to 60 °C, the conversion showed an obvious decrease (79.2%), and the energy consumption was high as well. Thus, 50 °C was selected as the reaction temperature for the subsequent experiment, which yielded an excellent conversion as well as energy savings.

Synthesis of Functional Oils with Different Vegetable Oils. Under the optimized conditions, the transesterification of phytosterols with four vegetable oils including sunflower oil, corn oil, rapeseed oil, and linseed oil was investigated. As listed in Table 2, the transesterification ratios of phytosterols with four vegetables oils were between 92.1 and 100.2%. The results suggest that AYS@NKA could be used to catalyze the transesterification of phytosterols with different acyl donors with relatively high conversion. This might be ascribed to the fact that lipases prefer to adsorb on hydrophobic supports, involving the adsorption of the hydrophobic areas surrounding the active center and leaving the active site fully exposed to the

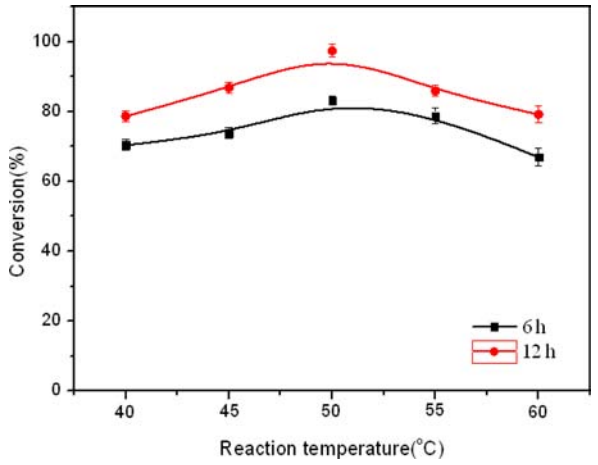

Figure 6. Effect of reaction temperature on the conversion of phytosterol esters in lipase-catalyzed reaction. Reaction conditions: 80 mmol/L phytosterols, 1:4 molar ratio of phytosterols to sunflower oil, hexane, and 180 rpm.

reaction medium.[31] HPLC analysis results showed that the peaks of two functional ingredients including phytosterol esters and diglycerides were observed in two functional oils obviously (Figuer 7). The peaks of phytosterol in functional oils were almost disappeared, which prove that the enzymatic transesterification ratio was quite high (>92.1%). As listed in Table 2, the contents of functional ingredients in four different functional oils were in the ranges of 10.4−12.5% for diglycerides and 20.2−25.1% for phytosterol esters, respectively.

Table 2 also lists the FA profile of the original vegetable oils (four kinds of triglycerides) and phytosterol esters and diglycerides produced. Four vegetable oils, which cover a wide range of oleic, linoleic, and linolenic acid values, were used as the sources of different acyl donors. Analysis of the FA composition of vegetable oils, phytosterol esters, and diglycerides by GC showed that almost all of the FAs present in the vegetable oils were incorporated into the corresponding phytosterol esters and diglycerides. In other words, the developed method could produce functional oils rich in both phytosterol esters and diglycerides with controllable FA composition by modulating the initial acyl donors with the wanted FA composition.

Physiochemical Properties of Functional Oils Prepared from Different Vegetable Oils. The physiochemical properties of functional oils prepared from different vegetable oils are shown in Table 3. The PV and CD values were low, which showed that few products of peroxidation were produced, a benefit of the mild reaction conditions. The AV and PV values were less than 1.0 mg KOH/g and 2.1 mmol/kg, respectively, which agree with the standards of sunflower oil, rapeseed oil, corn oil, and linseed oil of China (GB10464-2003, GB1536-2004, GB19111-2003, GB8235-2008) as well as the cold pressed oils standards of the Codex Alimentarius Commission (CAC) and thus could be used as the functional lipid alone or as the fat-soluble additive in vegetable oils.

Conclusion. In conclusion, a rapid and convenient esterification method using immobilized AYS@NKA as catalyst was developed to synthesize novel functional oils rich in both phytosterol esters and diglycerides in high yield under mild conditions. Furthermore, the developed method could produce phytosterol esters and diglycerides with controllable FA

Table 2. Fatty Acid Profile of the Phytosterol Esters (PE) and Diglycerides (DG) in Functional Oils Corresponding to Different Vegetable Oils as the Acyl Donors[a]

			fatty acid composition (%, w/w)					
product		content (%)	C16:0	C18:0	C18:1	C18:2	C18:3	conversion (%)
sunflower oil			6.4	3.4	30.4	59.8	0	
functional oil 1	PE	25.1	6.9	2.4	29.4	61.3	0	98.9
	DG	12.3	5.3	5.4	32.4	56.9	0	
corn oil			13.0	1.7	31.1	54.2	0	
functional oil 2	PE	20.2	13.5	2.6	24.8	59.1	0	96.5
	DG	10.4	12.0	0	42.7	45.3	0	
rapeseed oil			4.9	1.9	64.9	20.9	7.4	
functional oil 3	PE	24.1	4.2	2.6	64.8	20.3	8.1	92.1
	DG	12.5	6.9	0	65.2	22.5	5.5	
linseed oil			5.2	3.2	18.1	16.3	57.2	
functional oil 4	PE	22.3	7.4	4.5	14.5	15.3	58.3	100.2
	DG	11.2	0	0	26.8	18.7	54.6	

[a]Values are the average of analysis from triplicate sets. Functional oils 1−4 were obtained by transesterification of phytosterols with triglycerides from sunflower oil, corn oil, rapeseed oil, and linseed oil, respectively. Contents of PE and DG were short for the content of phytosterol esters and diglycerides in different kinds of functional oils. Reaction conditions: 80 mmol/L phytosterols, 1:2 molar ratio of phytosterols to triglycerides, *n*-hexane, 180 rpm, and 50 °C.

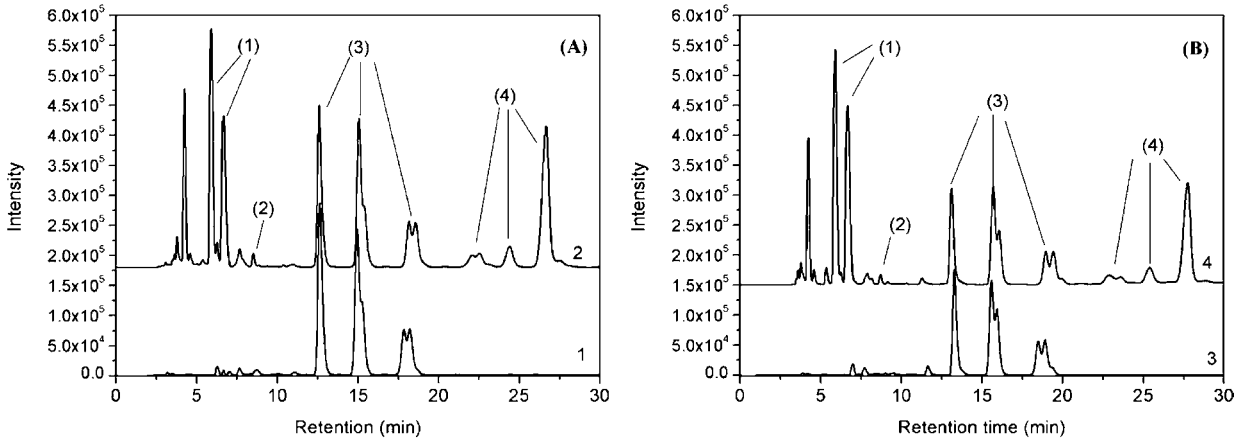

Figure 7. Liquid chromatograms of sunflower oil (A1), corn oil (B3), and responding functional oils (A2, B4). Peaks: (1) diglycerides; (2) phytosterols; (3) triglycerides; (4) phytosterol esters.

Table 3. Physiochemical Properties of Four Vegetables and Corresponding Functional Oils

product	PV[a] (mmol/kg)	AV[a] (mg of KOH/g)	CD[a] (mmol/kg)
sunflower oil	1.6	0.8	1.93
functional oil 1	1.6	0.9	1.87
corn oil	1.5	0.5	1.47
functional oil 2	1.8	0.7	1.62
rapeseed oil	1.5	0.6	1.96
functional oil 3	1.7	0.8	1.95
linseed oil	1.8	0.7	1.72
functional oil 4	2.1	1.0	1.69

[a]PV, AV, and CD are abbreviations for peroxide value, acid value, and conjugated diene value, respectively. Functional oils 1−4 are the same as those described in Table 2.

composition by modulating the initial acyl donors with the wanted FA composition. The physiochemical properties of four prepared functional oils were found to be closely related to the FA composition of the corresponding triglycerides. These findings could promote the wide application of the novel functional oils produced by the food grade process in different formulations of functional foods.

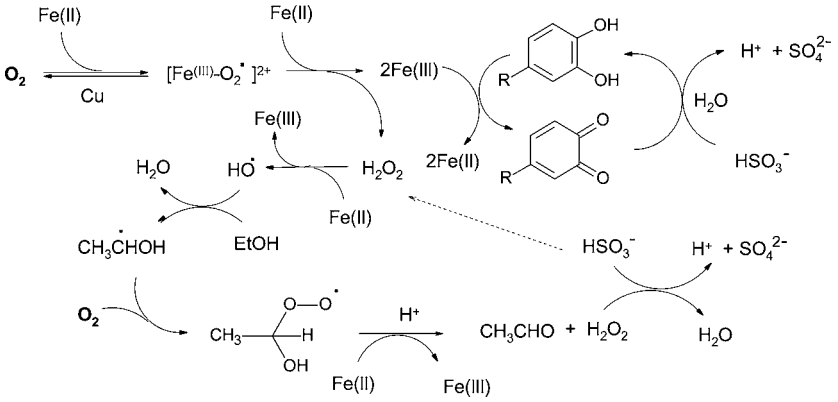
Scheme 2. Revised Mechanism of Oxygen Reduction Coupled to Catechol Oxidation Mediated by Fe Redox Cycling; Participation of Sulfite in Regenerating the Catechol and Removing Hydrogen Peroxide



which is presumably formed in very small amounts.[16,20] Importantly, sulfite also reacts rapidly with hydrogen peroxide and so prevents ethanol oxidation.[15]

For some time it was accepted that sulfite simply reacted with oxygen, but it is now apparent that its action is far more complex. As with polyphenols, oxygen cannot react directly with sulfite. It requires the catalytic intervention of Fe. Sulfite is first oxidized by Fe(III) to the sulfite radical ($SO_3^{\bullet-}$), which then reacts rapidly with oxygen to produce the peroxomonosulfate radical ($SO_5^{\bullet-}$). This radical is a stronger oxidant capable of oxidizing sulfite directly to generate further sulfite radicals and so continue the chain reaction.[21−23] Sulfate radicals ($SO_4^{\bullet-}$) are also produced. These radicals are very powerful oxidants of similar oxidizing capability to hydroxyl radicals and so will also oxidize ethanol to acetaldehyde.[15] Far from being a reductant, sulfite alone will generate a highly oxidizing system in the presence of oxygen. Similarly, polyphenols alone produce a powerful oxidant by generating hydrogen peroxide. It has been proposed that polyphenols and sulfite complement each other, in that polyphenols would prevent sulfite oxidation by intercepting peroxomonosulfate radicals, whereas sulfite reduces quinones back to polyphenols and removes any hydrogen peroxide that is produced.[16] However, more recent results have confirmed that sulfite autoxidation is so slow that it is unlikely to occur in wine conditions.[18] In any event, under ideal conditions when a catechol is oxidized in model wine, the SO_2:O_2 molar reaction ratio is 2:1, one mole of SO_2 reacting with the quinone and the other with the hydrogen peroxide. However, in real wine the ratio may be less than 2:1, and this has been ascribed to substances that compete with sulfite for quinones.[20]

In addition to the above reactions, sulfite forms nonvolatile adducts with carbonyl compounds,[24] such as acetaldehyde, phenylacetaldehyde, and methional, produced during the winemaking process, which otherwise would produce unpleasant (oxidized) aromas.[25] Importantly, SO_2 also prevents microbial growth both directly as molecular SO_2 and indirectly as sulfite,[24,26] by preventing the growth of aerobic bacteria by facilitating polyphenol oxidation, so removing oxygen.[18]

A detailed examination of wine oxidation, therefore, reveals the key involvement of iron throughout the process. It is proposed that the ability of Fe to redox cycle is made possible by its co-ordination to tartaric and malic acids, which determine the reduction potential of the Fe(III)/Fe(II) couple in relation to that of the oxygen and catechol couples.[18,27] In this paper the importance of tartaric and malic acids is demonstrated by comparing the mechanism of catechol oxidation in tartrate, malate, and acetate model wines at pH 3.6. Acetic acid coordinates less strongly with Fe(III) than the diacids and so should raise the reduction potential of the Fe couple.

MATERIALS AND METHODS

Materials. Water (Emsure, Fe ≤ 1 μg/L, Cu ≤ 0.4 μg/L; E. Merck, Darmstadt, Germany), Cu(II) sulfate pentahydrate, Fe(III) chloride hexahydrate, sodium hydroxide, L-(+)-tartaric acid (BDH AnalaR grade), L-(−)-malic acid, acetic acid (BDH, GPR), and ethanol (96% GPR grade) were obtained from VWR International (Lutherworth, UK). 4-Methylcatechol (4-MeC, 95+%) and Fe(II) sulfate heptahydrate (99+% ACS reagent) were obtained from Sigma-Aldrich (Poole, Dorset, UK), and potassium metabisulfite (Kadifit) was from Erbslöh Geisenheim AG (Geisenheim, Germany). UV−vis spectra were taken with a Jenway 7315 spectrometer (Keison Products, Chelmsford, UK)

Preparation of Model Wine Solutions. L-(+)-Tartaric acid (5.0 g, 3.33×10^{-2} mol/L), L-(−)-malic acid (4.46 g, 3.33×10^{-2} mol/L), and acetic acid (3.81 mL, 6.66×10^{-2} mol/L) were each dissolved in water (∼800 mL) in a 1 L volumetric flask. Ethanol was added to give a 12% (v/v) final concentration, and the pH was increased to 3.60 with 2.5 N sodium hydroxide; also, water was added progressively to the mark as the required pH was approached.

Solutions of $FeSO_4$, $FeCl_3$, 4-MeC, and $K_2S_2O_5$ were freshly made up in water and (+)-catechin in 1:1 H_2O/EtOH by volume before use and added in small volumes (25−200 μL) to the model wines as required.

Reaction of Fe(II) with Oxygen in Tartrate and Acetate Model Wine. Fe(II) (20 mg/L) was added to the model wine (3 × 20 mL) containing Cu(II) (0.3 mg/L). The resulting solutions were immediately transferred to three 100 mL bottles fitted with screw caps, stored in the dark, and shaken periodically to maintain air saturation. Fe(III) concentration was determined from the absorbance at 334 nm in triplicate.

Oxidation of 4-MeC in Model Wines. 4-MeC (1.0 g/L) was added to model wines (500 mL) containing Cu(II) (0.15 mg/L), followed by SO_2 (∼60 mg/L) and Fe(II) (5.0 mg/L). Initial free SO_2 concentration was determined in duplicate, and the resulting solution was immediately divided between three 500 mL stoppered flasks, stored in the dark with periodic shaking to maintain air saturation. Oxidation was followed by measuring SO_2 concentration in triplicate on the basis of a 2:1 SO_2/O_2 molar reaction ratio.

Spectroscopic Measurements. Spectra were taken using 10 mm quartz cuvettes against a model wine blank. The small notch that was observed in spectra at ∼248 nm coincided with a sharp increase in absorbance of the model wine. It was, therefore, assumed that it was due to a large decrease in light transmission through the instrument, and spectra at lower wavelengths were not taken to be reliable. Fe(III) calibration curves were obtained by dissolving $FeCl_3$ hexahydrate (48.4 mg) in 10 mL of model wine; 50−400 μL of this solution was then

dx.doi.org/10.1021/jf5007402 | J. Agric. Food Chem. 2014, 62, 5149−5155

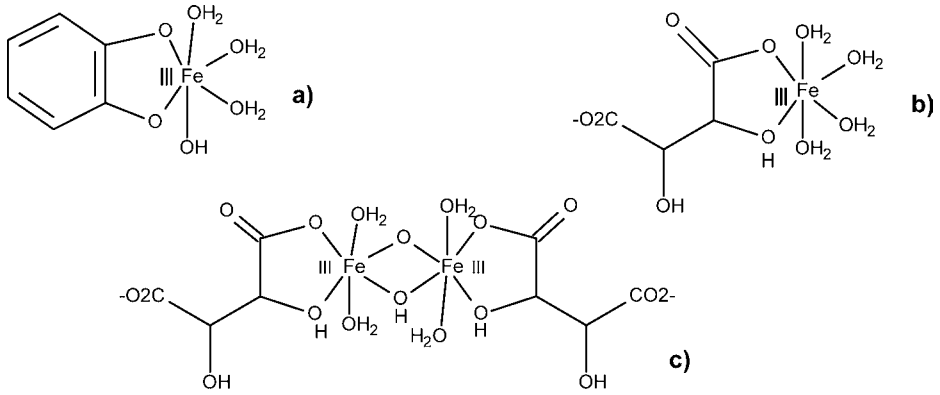


Figure 1. Proposed structures Fe complexes: (a) Fe(III)−catecholate complex;[29,30] (b) Fe(III)−tartrate monomer; (c) Fe(III)−tartrate dimer at wine pH.[31,32]

diluted to 20 mL with model wine to give the calibration standards. Such solutions were stable for at least 9 h when stored in the dark.

Measurement of SO_2. Free SO_2 concentration was measured with the modified Ripper procedure, using potassium iodate and starch−KI.[28]

When measurements were taken in triplicate, mean values (±SD) were calculated and figures drawn using Excel software (Microsoft, Redmond, WA, USA). Where error bars denoting ± SD are not shown, they were smaller than the data point symbol dimensions. Experiments were conducted at ambient temperature (18.5−20.5 °C).

RESULTS AND DISCUSSION

In the absence of stronger competing ligands such as tartaric acid, catechol forms a 1:1 complex, $[Fe(L^{2-})(H_2O)_4]^+$, with Fe(III) at pH 2−3, which exhibits two broad absorption bands at 429 and 700 nm, ε_{max} = 880 and 1000, respectively.[29,30] Bound water molecules in the complex are rendered more acidic, and one is likely to deprotonate to give $[Fe(L^{2-})(OH^-)(H_2O)_3]$ at wine pH, where LH_2 stands for the catechol (Figure 1a).[30] However, the complex is unstable and decomposes over ∼24 h to a mixture of Fe(II) and quinone,[29] which in turn decomposes further.[27] Fe(II) does not form a catecholate complex below pH ∼7.[29] Fe(III) coordinates strongly with tartaric acid, forming a monomeric complex $Fe(L^{2-})^+$ at low pH (Figure 1b), with an absorption maximum at 346 nm, where LH_2 is tartaric acid and L^{2-} is where both carboxyl groups are ionized. Above pH 2 the dimeric complex, $[Fe_2(L^{2-})_2(-3H^+)]^-$, is formed, becoming the dominant species at pH ∼3.5 (Figure 1c), which has a less pronounced absorption maximum that is shifted to 335 nm. At pH 5 the analogous trimer, $[Fe_3(L^{2-})_3(-6H^+)]^{3-}$ is produced, which displays no clear maximum but a flat shoulder at ∼300 nm.[31,32] The exact structure of these complexes has not been established. However, the water molecules attached to two Fe(III) are the most acidic, and the dioxygen olate bridge system is drawn here to explain the loss of the three protons on dimerization (Figure 1c).[33] Fe(II) binds much more weakly with tartaric acid to form a monomeric complex.[31] The greater affinity of tartaric acid for Fe(III) displaces the redox equilibrium toward Fe(III), making it a weaker oxidant and hence Fe(II) a stronger reductant.[18] Consequently, the reduction potential of the Fe(III)/Fe(II) couple was found to be lowered to 385 mV by cyclic voltammetry in model wine pH 3.3.[18] This value was the same as found in aqueous tartaric acid.[34] Because the reduction potential was found to decrease by 130 mV per pH unit increase in the wine pH range,[34] it should be 345 mV at pH 3.6, which places it well below that of the O_2/H_2O_2 couple ($E_{3.6}$ = 565 mV).[18,27] As a result, Fe(II) is rapidly oxidized to Fe(III) in air-saturated model wine containing a small amount of Cu(II) (Figure 2). In contrast,

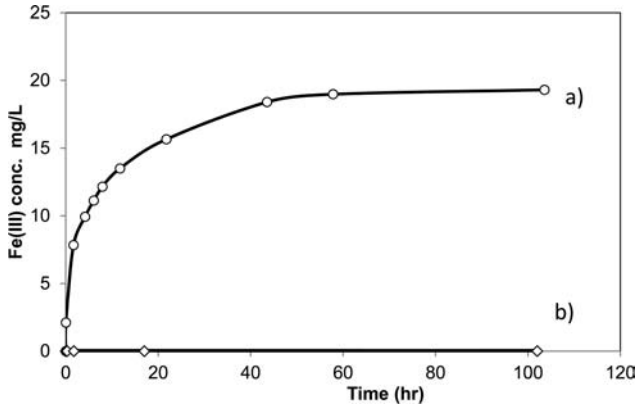

Figure 2. Oxidation of Fe(II) (20 mg/L, 3.58 × 10^{-4} mol/L) at pH 3.6 in model wines saturated with aerial oxygen in the presence of Cu(II) (0.3 mg/L): (a) tartrate model wine; (b) acetate model wine.

under the same conditions, Fe(II) failed to reduce oxygen in the acetate model wine (Figure 2), which is consistent with an increase in the reduction potential of the Fe(III)/Fe(II) couple. The reduction potential of the Fe(III)/Fe(II) couple in aqueous $NaClO_4/H_2SO_4$, where Fe(III) and Fe(II) exist as the hexaaquo complexes, $[Fe(H_2O)_6]^{3+}$ and $[Fe(H_2O)_6]^{2+}$, was found to be 687 mV at pH 3.3 by cyclic voltammetry, which also places it above that of the oxygen couple. Consequently, Fe(II) was also found not to reduce oxygen in this system.[18] Raising the reduction potential even further by adding 2,2′-bipyridyl to tartrate model wine has the same effect.[18] Inhibition of oxidation has also been demonstrated by electron paramagnetic resonance spectroscopy, where addition of 2,2′-bipyridyl as well as FerroZine to the tartrate model wine and real wine prevented the production of 1-hydroxyethyl radicals.[35]

It is also apparent that the reduction potential of the Fe couple is lowered to well below that of the quinone/4-MeC couple ($E_{3.6}$ = 577 mV) and, as observed previously at higher tartaric acid concentration,[18] Fe(III) is no longer able to oxidize 4-MeC at wine pH. When Fe(III) is added as $FeCl_3$ to tartrate model wine, a weak absorption band (λ_{max} = 335 nm, ε_{max} = 2050) (Figure 3, curve a) is observed, which can be ascribed to the dimer (Figure 1c). When 4-MeC is added, the resulting

dx.doi.org/10.1021/jf5007402 | J. Agric. Food Chem. 2014, 62, 5149−5155

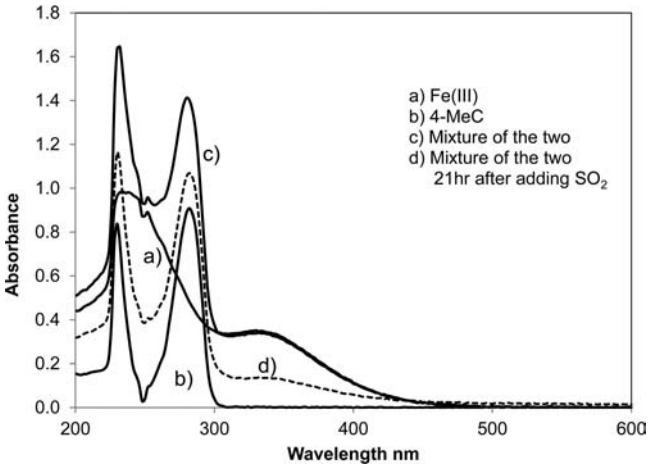

Figure 3. UV−vis spectra in tartrate model wine: (a) Fe(III) (10 mg/L, 1.79×10^{-4} mol/L); (b) 4-MeC (44.5 mg/L, 3.58×10^{-4} mol/L); (c) spectrum taken immediately after mixing the two; (d) spectrum 21 h after mixing the two with the addition of SO_2 (32 mg/L, 5.0×10^{-4} mol/L).

spectrum is the sum of the two individual spectra (curve a plus b) and remains unchanged for at least 4 days (curve c). Not only is the catechol unable to reduce Fe(III), but it is also too weak a ligand to compete with tartaric acid for Fe(III) at the relative concentration used in this experiment, as the absorbance due to the Fe(III)−tartrate dimer at 335 nm remains unchanged over many days. (+)-Catechin and gallic acid behaved similarly and were not oxidized by Fe(III) in the same system (Supporting Information Figures SI 1 and SI 2). However, with pyrogallol, which is a stronger reductant, addition of Fe(III) caused a steady increase in absorbance in the 300−350 nm range, presumably due to oxidation products as the reaction mixture progressively yellowed. This spectral change overlapped with the Fe(III) absorption band, and it was not possible to follow the extent of reduction (Supporting Information Figure SI 3). Previously, it had been shown by monitoring oxygen uptake that, in contrast to (+)-catechin, pyrogallol is oxidized in model wine without sulfite assistance.[17] The importance of reduction potentials in polyphenol oxidation is illustrated by the addition of FerroZine to model wine. This Fe(II) selective ligand raises the reduction potential of the Fe couple to such an extent that Fe(III) is then able very rapidly to oxidize catechols.[18,19]

It has been shown that when (+)-catechin is exposed to oxygen in tartrate model wine, enough oxygen is taken up to oxidize the initial Fe(II) that is present but oxidation proceeds no further. However, oxygen uptake continues when sulfite is added.[17] The rate of oxidation in model systems containing sulfite increases with increasing Fe and catechol concentration, and it is, therefore, concluded that sulfite functions by promoting catechol oxidation, drawing forward the thermodynamically unfavorable reaction by reacting with the quinone.[16,20] It has also been shown that, although 4-MeC does not reduce Fe(III) in tartrate model wine, it does so in the presence of sulfite.[18] This is a key reaction as it allows the metal to redox-cycle, and the effect is also seen in the above experiment. Addition of sulfite to a nonreacting mixture of 4-MeC and Fe(III) results in the reduction of Fe(III); the concentration of Fe(III) stabilizes from 10 to 3.4 mg/L after 21 h (Figure 3, curve d). It has been found that sulfite alone does not reduce Fe(III) in tartrate model wine, or at least the reaction is extremely slow.[18]

Fe(III) is reported to form a trimeric complex in acetate buffer at pH 1.9−3.31,[31] and addition of Fe(III) as $FeCl_3$ to acetate model wine gave a similar absorbance curve as in the tartrate model wine (Figure 4, curve a; λ_{max} = 334−338 nm,

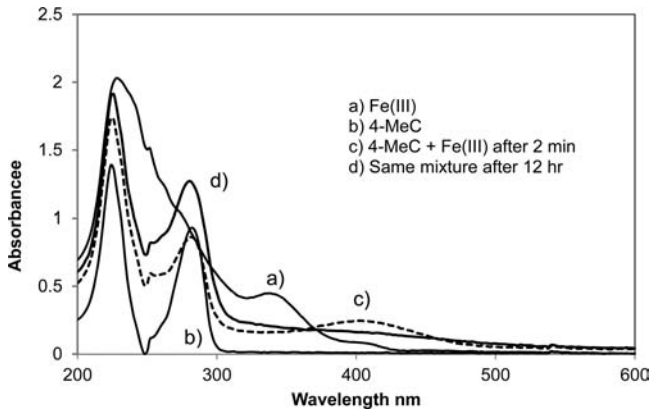

Figure 4. UV−vis spectra in acetate model wine: (a) Fe(III) (20 mg/L, 3.58×10^{-4} mol/L); (b) 4-MeC (44.5 mg/L, 3.58×10^{-4} mol/L); (c) spectrum taken 2 min after mixing the two; (d) spectrum of the same mixture taken after 12 h.

ε_{max} = 1273) but with a slight shoulder at ∼400 nm. However, catechols interacted very differently with Fe(III) in the acetate system. Addition of 4-MeC (Figure 4, curve b) resulted in an immediate loss of absorption at ∼335 nm and formation of a new broad absorption band at ∼400 nm, ε_{max} = 690 (curve c). It is proposed that this absorption is due to the formation of the catecholate complex (Figure 1a) discussed above, as the catechol is now capable of competing with the weaker monodentate acetate ligand. As previously reported, this absorption band faded over 12 h, and it is concluded that electron transfer within the complex results in the reduction of Fe(III) by the catechol.[29,30] (+)-Catechin was found to behave similarly in this system. Addition of (+)-catechin (3.58×10^{-4} mol/L) to Fe(III) (1.79×10^{-4} mol/L) in acetate model wine instantly abolished the absorption band at 334 nm due to the Fe(III)−acetate complex with the formation of a blue-green Fe(III)−(+)-catechin complex, with broad absorption maxima at ∼426 and ∼700 nm. The color progressively changed to green over 1.3 h, with intensification of the broad absorption band at ∼426 nm, which shifted to ∼392 nm over 31 h, as the catechin is oxidized (Supporting Information Figure SI 4).

Sulfite was also found to affect oxidation in the acetate model wine but in a different manner. Although Fe(II) does not react with oxygen in this system (Figure 2), it does so on addition of sulfite. Addition of an equimolar amount of sulfite to a solution of Fe(II) (20 mg/L, 3.58×10^{-4} mol/L) in air-saturated acetate model wine resulted in a steady increase in absorbance at 336 nm as Fe(III) was produced, 8.6 mg/L after 106 min (Figure 5). Under the same conditions sulfite alone did not reduce Fe(III) over 17.5 h. These results were unexpected as sulfite is generally viewed as a reductant rather than facilitating Fe(II) oxidation. Perhaps sulfite is able to coordinate with Fe(III)/Fe(II) in the presence of acetate and lower the reduction potential of the couple so that it may reduce oxygen. However, as in tartrate model wine, Fe(II) is very rapidly oxidized by H_2O_2. From the absorbance at 338 nm it was shown that all of the Fe(II) (3.58×10^{-4} mol/L) was oxidized within 1 min in

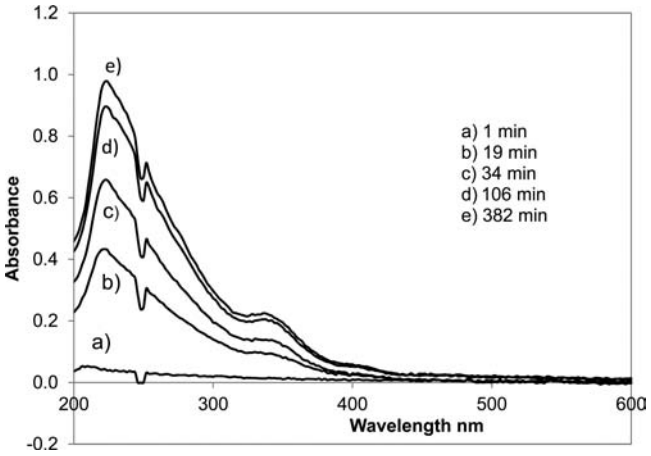

Figure 5. UV−vis spectra in air-saturated acetate model wine: oxidation of Fe(II) (20 mg/L, 3.58×10^{-4} mol/L) at times indicated after addition of SO_2 (22.9 mg/L, 3.58×10^{-4} mol/L).

acetate model wine upon the addition of H_2O_2 (5.1×10^{-4} mol/L). It is concluded, therefore, that the Fenton reaction would proceed in this as in the tartrate model system.

Malic acid has a similar chelating ability with Fe(III) as tartaric acid, forming similar polynuclear complexes at wine pH.[36] Below pH 2.6 the mononuclear complex, $[(Fe\ (L^{2-})]^{+}$, is formed, which exhibits a weak absorption maximum at 241 nm, similar to that of the corresponding tartrate complex. However, in the wine pH range the dinuclear, $[Fe_2\ (L^{2-})_3(-H^{+})_2]^{2-}$, and trinuclear, $[Fe_3(L^{2-})_5(-H^{+})_4]^{5-}$, complexes are both formed, which differ from the tartrate complexes in that the Fe(III)/ligand ratios are no longer 1:1.[36] No absorption maximum is observed in the 330−350 nm range, absorbance increasing steadily without inflection (Figure 6, curve a). Like tartaric acid,

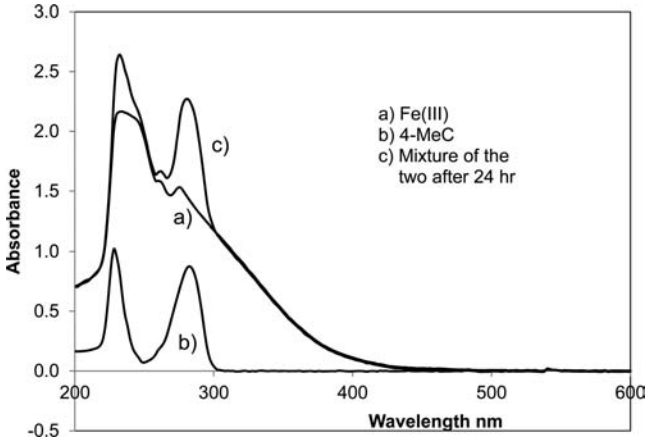

Figure 6. UV−vis spectra in malate model wine: (a) Fe(III) (20 mg/L, 3.58×10^{-4} mol/L); (b) 4-MeC (44.5 mg/L, 3.58×10^{-4} mol/L); (c) spectrum taken 24 h after mixing the two.

malic acid coordinates only weakly with Fe(II), both acids being hard ligands that bind preferentially to Fe(III). Consequently, they should modify the catalytic activity of the Fe(III)/Fe(II) couple in a similar manner.

When $FeCl_3$ was added to 4-MeC in malate model wine, the same result is obtained as in the tartrate system. The resultant spectrum (Figure 6, curve c) was the sum of that for Fe(III) and 4-MeC, and no change was discernible for 24 h. As in the tartrate system, Fe(III) did not oxidize the model catechol nor was the catechol able to coordinate with Fe(III) to a detectable extent. Furthermore, when Fe(II) was added to air-saturated malate model wine containing a small amount of Cu(II), Fe(II) was rapidly oxidized. From the absorbance measured at 350 nm it was estimated that 94% had been oxidized to Fe(III) over 15 h (Figure 7).

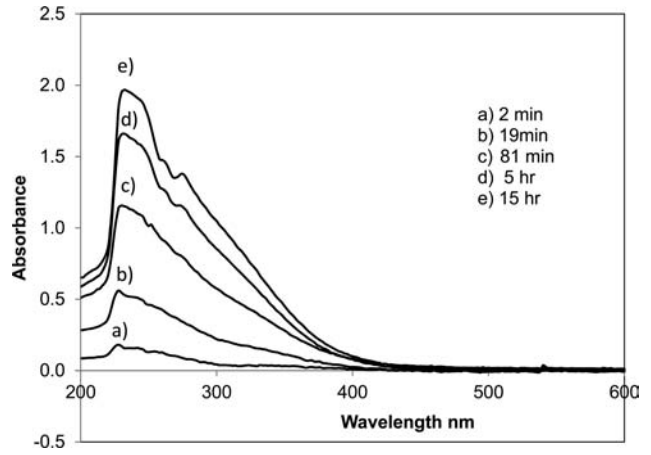

Figure 7. UV−vis spectra in air-saturated malate model wine: spectra at times indicated after adding Fe(II) (20 mg/L, 3.58×10^{-4} mol/L) to model wine containing Cu(II) (0.3 mg/L).

As discussed above, the oxidation of catechols is dependent on the ability of Fe to redox cycle, that is, the reaction of Fe(II) with oxygen to generate Fe(III) and the ability of Fe(III) in turn to oxidize catechols to regenerate Fe(II). Having compared both halves of the cycle in tartrate and acetate model wines, the overall rates of 4-MeC oxidation were compared in the two systems in the presence of sulfite (Figure 8). In the tartrate model system sulfite reacts with the hydrogen

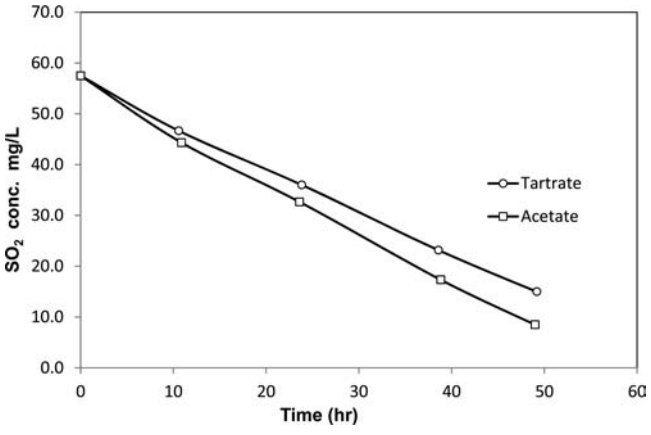

Figure 8. Free SO_2 concentration during the oxidation of 4-MeC (1.0 g/L) in acetate and tartrate model wine maintained at air saturation containing Fe(II) (5.0 mg/L) and Cu(II) (0.15 mg/L).

peroxide that is generated as oxygen is reduced and the quinone as the catechol is oxidized, resulting in a 2:1 molar reaction ratio as discussed in the Introduction.[15,16,20] The rate of reaction was found to be independent of SO_2 concentration, as it remained constant over a wide SO_2 concentration range. It is concluded that its rate of reaction with the above oxidation products is fast relative to that of oxidation, which is dependent on oxygen and catechol concentrations. Oxygen concentration

dx.doi.org/10.1021/jf5007402 | J. Agric. Food Chem. 2014, 62, 5149−5155

was held constant as the model wines were maintained at air saturation, and catechol concentration changes little as it is in substantial molar excess and is in part regenerated as oxidation proceeds. In the above studies it was shown that Fe(II) is oxidized in acetate model wine, which presumably generates hydrogen peroxide. It was also demonstrated that the catechol/Fe(III) complex is unstable, spectral changes being consistent with formation of the quinone.[29] It is, therefore, assumed that SO_2 will react with the hydrogen peroxide and quinone as in the tartrate system, also resulting in a 2:1 molar reaction ratio in acetate model wine. As can be seen, the rates of reaction are both linear, with rate in the tartrate model system a little slower. However, on the basis of the above results, it would have been a mistake to assume that the underlying mechanisms are the same. In the tartrate case, Fe(II) reacts directly with oxygen, but the oxidation of the catechol requires sulfite assistance. In the acetate system the reverse operates. Fe(III) reacts unaided with the catechol; it is Fe(II) oxidation that requires sulfite assistance.

Previous studies have provided strong evidence that polyphenol oxidation in wine is dependent on Fe catalysis, in which electrons are transferred from the polyphenol to oxygen by the intermediate redox cycling of the Fe(III)/Fe(II) couple.[15,16] The overall rate of reaction will be dependent on either the rate of reaction of Fe(II) with oxygen or the rate of reduction of Fe(III) by the polyphenol, whichever is slower. As discussed above, the rates of these reactions should depend on the reduction potential of the Fe(III)/Fe(II) couple relative to that of the oxygen and polyphenol couples.[18] Therefore, tartaric and malic acids do not just provide an acidic environment but also determine the catalytic activity of the Fe redox couple. It would not be valid to base mechanistic arguments on standard reduction potentials, which are determined at pH 0. The reduction potential of the oxygen and polyphenol couples is pH dependent, decreasing linearly by 59 mV per unit increase in pH, one proton adding to neutralize the negative charge as each electron is introduced in the reduction step.[27] Both Fe(III) and Fe(II) form octahedral complexes, and the reduction potential of the couple will depend on the relative affinity of ligands for the two oxidation states. The structure of the complexes may also be pH dependent, such as in the case of Fe, by determining the degree of "polymerization". The pH will also determine the extent to which ligands forming the complex are protonated, so altering the charge surrounding metal ions. Therefore, the reduction potential of the metal couple may not be simply deduced. These findings should apply to other model systems designed to study oxidation in foods and other beverages. Consequently, not only should pH be considered, but metal ligands mimicking those present in the system being studied should be incorporated.

Studies in model wine have proved very helpful for exploring the catalytic function of Fe and Cu and the mechanism of action of sulfite in real wine. These present model wine studies should be no less relevant. In white wine tartaric and malic acids are present in very large molar excess compared to any polyphenol that might coordinate with Fe and so will be the dominant Fe ligands. In red wines, with higher polyphenol and lower acid concentrations, it is possible that polyphenols could compete effectively with tartaric acid for Fe(III). However, as hard ligands, which also favor co-ordination to Fe(III) relative to Fe(II), polyphenols would lower the reduction potential of the Fe(III)/Fe(II) couple in a similar manner to the acid.[18] Such co-ordination would, therefore, also facilitate Fe(II) autoxidation and, by binding directly to Fe(III), could facilitate polyphenol oxidation. It is possible, therefore, that the mechanisms of oxidation of white and red wines may differ slightly. As concluded in the present study, the ligand would determine the catalytic activity of the metal.

centrifuged to remove insoluble substances and was adjusted to pH 8.0 by 1 M Tris-HCl (pH 8.0) and 1 N HCl. The solution was then run through a DEAE-Sepharose FF column (buffered with 20 mM Tris-HCl buffer, pH 8.0, ⌀ 2.6 × 30 cm) and eluted with the same buffer followed by 0.14 M NaCl in the same buffer and a linear NaCl concentration gradient of 0.14−0.5 M, again in the same buffer. The eluted fraction was subjected to 55% saturated ammonium sulfate fractionation. The precipitate fraction was separated from the supernatant fraction, desalted by dialysis against deionized water, and lyophilized to obtain purified emu TENP.

Deglycosylation of TENP. Specific cleavage of *N*-glycan moieties (*N*-acetylglucosamine−asparagine bonds) present in TENP was carried out using glycopeptidase F (Takara-Bio Inc., Otsu, Japan). After denaturation by boiling for 3 min in buffer containing 0.5% SDS and 0.75% β-mercaptoethanol, the sample was subjected to digestion with glycopeptidase F at 37 °C overnight.

SDS-PAGE. SDS-PAGE was performed using 12.5 or 15% polyacrylamide gel according to the method of Laemmli.[10] The sample solution was mixed with an equal volume of loading buffer prior to heat treatment. The resulting sample was run on a SDS-PAGE gel. After electrophoresis, the gels were stained with 0.025% Coomassie Brilliant Blue R-250 (CBB) in an aqueous solution of 50% methanol and 10% acetic acid. The stained gels were washed using an aqueous solution of 25% methanol and 10% acetic acid, followed by water.

cDNA Cloning of Emu TENP. Total RNA was extracted from emu tissues using the TRI Reagent (Molecular Research Center, Inc., Cincinnati, OH, USA), and first-strand cDNA was synthesized using SuperScript III First-Strand Synthesis SuperMix and oligo-dT (20) primer (Invitrogen Co., Carlsbad, CA, USA). The first-strand cDNA was used for subsequent PCR amplifications of emu TENP cDNA with Ex *Taq* DNA polymerase (Takara Bio Inc., Shiga, Japan). For the cloning of emu TENP cDNA, primers were designed on the basis of the nucleotide sequence of chicken TENP (GenBank ID NM_205026). Sequences of the primers are listed in Table 1.

Table 1. Primers Used in This Study

name	sequence (5′ → 3′)	use
TENP-7F	CCTGGCTTTGTCCGAGCA	cloning
TENP-5R	CCCACATTGGAGGCAGCCA	cloning
TENP-8F	CTACTACACCAGCCTCTTCCTC	cloning
TENP-16R	GTTACAATCCATCCTCCTTC	cloning
TENP-10F	ACAGCAAACAGAAAAGGCAG	cloning
TENP-12R	GACGGTGAGGAAGAGCTTCA	RT-PCR
TENP-15F	CGGACAAGGAGATTGATGTCG	RT-PCR
bact-13F	GTGACCTGACAGACTACCT	RT-PCR
bact-14R	CAGGAAGGATGGCTGGAAGAG	RT-PCR

At first, emu TENP cDNA fragment was amplified from magnum cDNA using the primers TENP-7F and TENP-5R. Next, the primers TENP-8F based on the emu TENP cDNA fragment and TENP-16 based on the chicken TENP were used for amplification of the fragment containing a start codon of emu TENP cDNA. Also, the reverse primer TENP-12R based on the emu TENP cDNA fragment and the forward primer TENP-10F based on the sequence of chicken TENP cDNA were used for amplification of the fragment containing a stop codon of emu TENP cDNA. All amplified fragments were cloned into pCR2.1-TOPO (Invitrogen) and sequenced.

DNA Sequencing. Nucleotide sequences of cloned DNAs in pCR2.1-TOPO were analyzed by Macrogen Japan Co. (Tokyo, Japan). T7 promoter primer and M13 reverse primer (Invitrogen) were used as sequencing primers. The resultant nucleotide sequence data were assembled using the ATGC program (Genetyx Corp., Tokyo, Japan) and analyzed by using the NCBI nucleotide BLAST program.

Reverse Transcription Polymerase Chain Reaction (RT-PCR). For tissue expression profiling of emu TENP mRNA, the primer set composed of TENP-15F/TENP-12R and emu magnum cDNA were used for RT-PCR analysis. Sequences of the primers are listed in Table 1. PCR amplification was performed with Ex *Taq* DNA polymerase (Takara Bio) at 94 °C for 30 s followed by 35 cycles at 94 °C for 30 s, 55 °C for 30 s, and 72 °C for 45 s. To calibrate the cDNA concentration between samples, the β-actin gene was amplified as a housekeeping gene using a primer set of bact-13F/bact-14R, as determined by the same program. Amplicon sizes were confirmed by agarose gel electrophoresis with ethidium bromide staining.

Phylogenetic Tree Analysis. The amino acid sequences of TENP and other BPI superfamily proteins were obtained from the NCBI GenBank database as indicated in Figure 3. The ClustalW 1.81 multiple sequence alignment program was used for the alignments of protein sequences of various BPI superfamily proteins and emu ovotransferrin (DDBJ ID AB455549), determination of amino acid substitution, and construction of the neighbor-joining phylogenetic tree. Bootstrap analysis was replicated 1000 times to evaluate the phylogenetic tree topology.[11]

Antibacterial Assay. *Escherichia coli* TOP10, *Salmonella* Typhimurium TA1535/pSK1002, *Micrococcus luteus* NRIC1094, and *Bacillus subtilis* NRIC1016 were used for antibacterial assay. The antibacterial activity of TENP was measured using the method described by Wellman-Labadie et al.[12] with some modifications. Overnight bacterial cultures were grown to the log phase in nutrient broth (for all bacteria except *E. coli*) or in LB broth (for *E. coli*), then centrifuged, washed, and resuspended in 10 mM sodium phosphate buffer (pH 7.4). TENP dissolved in the same buffer or in homogenized egg white samples was added to an equal volume of bacterial suspension diluted to 0.02 at $OD_{675\ nm}$ to give 5−200 μM final TENP concentration and then incubated for 1 h at 37 °C. After incubation, a serial dilution of the sample was plated onto nutrient agar or LB agar and incubated at 37 °C until distinct colonies could be counted (18−36 h). All assays were performed in triplicate, and the antibacterial activity was represented as the percentage of reduced bacterial cell (colony) number compared with controls consisting of microbes incubated alone.

RESULTS AND DISCUSSION

Primary Structure of TENP. In a previous study, we detected and identified TENP by amino acid sequencing of its N-terminus and found that TENP was one of the major proteins in emu egg white.[2] Here we designed a gene-specific primer set for emu TENP based on the sequence of chicken TENP and successfully cloned and sequenced the 1356 bp sequence of TENP precursor cDNA, containing an ORF encoding for a 46 kDa mature protein (Figure 1). A signal peptide cleavage site of emu TENP (indicated in Figure 1) was previously identified by N-terminal amino acid sequencing of the purified protein.[4] The results were in accordance with the prediction obtained from the SignalP program using the emu TENP precursor sequence. They were also in agreement with that of the chicken TENP (HG007958) proposed by Whenham et al.,[8] but different from that published by Yan and Wang[7] (AF029841), as shown in Figure 2. Our results indicate that the emu TENP sequence is 6 amino acids longer than that of chicken TENP (HG007958) at the C-terminus and has 1 amino acid insertion at position 123 (Figure 2). The predicted N-glycosylation site and the number of cysteine residues were conserved features of both TENPs of emu and chicken. A consensus proline-rich region was found in the midsection (amino acid position 209−220 in emu) of both sequences. It was previously reported that human BPI consists of two domains of similar size that are connected by a proline-rich linker of 21 residues including 6 prolines.[13] Upon phylogenetic analysis of the inferred amino acid sequence, results showed that emu TENP belongs to the BPI/LBP/PLUNC superfamily together with other avian TENPs but distinct from other BPI-related proteins[14] such as BPI-like 1

dx.doi.org/10.1021/jf5008117 | J. Agric. Food Chem. 2014, 62, 5156−5162

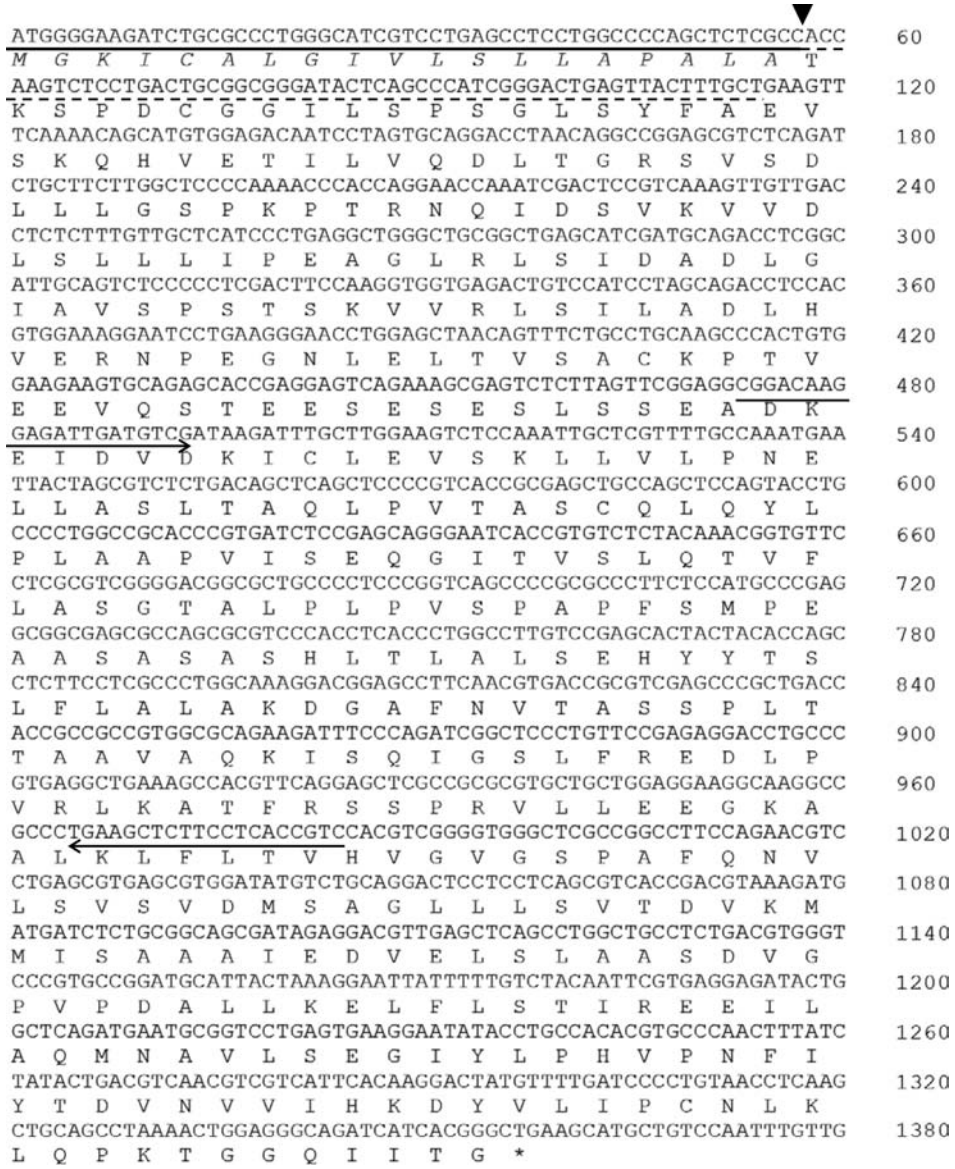

Figure 1. Nucleotide and deduced amino acid sequences of emu TENP. Signal peptide sequence is indicated by a bold underline. The amino acids determined by direct sequencing in a previous paper[2] are indicated by a dashed line. A signal cleavage site is indicated by an inverted triangle. This sequence will appear in the DDBJ database under the accession number AB556937. Arrows indicate locations of the primers for RT-PCR.

(BPIL1) and ovocalyxin-36 (OCX-36) (Figure 3). OCX-36 is an eggshell protein that is secreted during shell formation and found in the basal shell and associated membranes[15] and also eggshell cuticle.[16] Upon BLAST search for emu TENP, chicken TENP sequence was found to be identical to the protein previously known as chicken ovoglobulin G2 (sequence ID AB219158). Ovoglobulin G2 has three different polymorphic forms, AA, AB, and BB, with the majority being of the BB type.[17] Although ovoglobulin G2 is well documented for its presence in chicken egg white,[18] its biological function in egg white remains unknown. On the basis of amino acid sequence similarity with BPI and in relation to its bactericidal domain, chicken TENP was predicted to exert bactericidal activity similar to that of BPI protein. It is well established that BPI is an essential component of the innate immune system repertoire against Gram-negative bacterial infections.[19] Antibacterial activity and LPS-binding capacity of chicken OCX-36 were recently reported.[20] The phylogeny represented in Figure 3 suggests that avian TENPs, including emu TENP, are orthologous to mammalian BPIL1s, as previously suggested by Gautron et al.[14]

Gene Expression of TENP in Emu Tissues. The chicken egg is formed in the reproductive system composed of the ovary and the oviduct, and the egg white is produced in the magnum, a specific region of the oviduct.[21] To confirm whether TENP mRNA is expressed in the magnum, RT-PCR analysis of the magnum and the ovary of female egg-laying emus was performed. As expected, the TENP gene was highly amplified from the emu magnum, but was hardly detected in the ovary, as shown in Figure 4. Yan and Wang[7] reported the transient expression of chicken TENP gene in embryonic retina and brain tissues during the early developmental stages. Recently, a strong expression of the TENP gene was reported in the chicken magnum.[22] Whenham et al.[8] revealed that the expression of TENP gene is largely confined to the magnum of the oviduct of adult chicken and is controlled by gonadal steroids as a typically egg-specific gene. It is predicted that the emu TENP gene is also specifically expressed in the magnum of

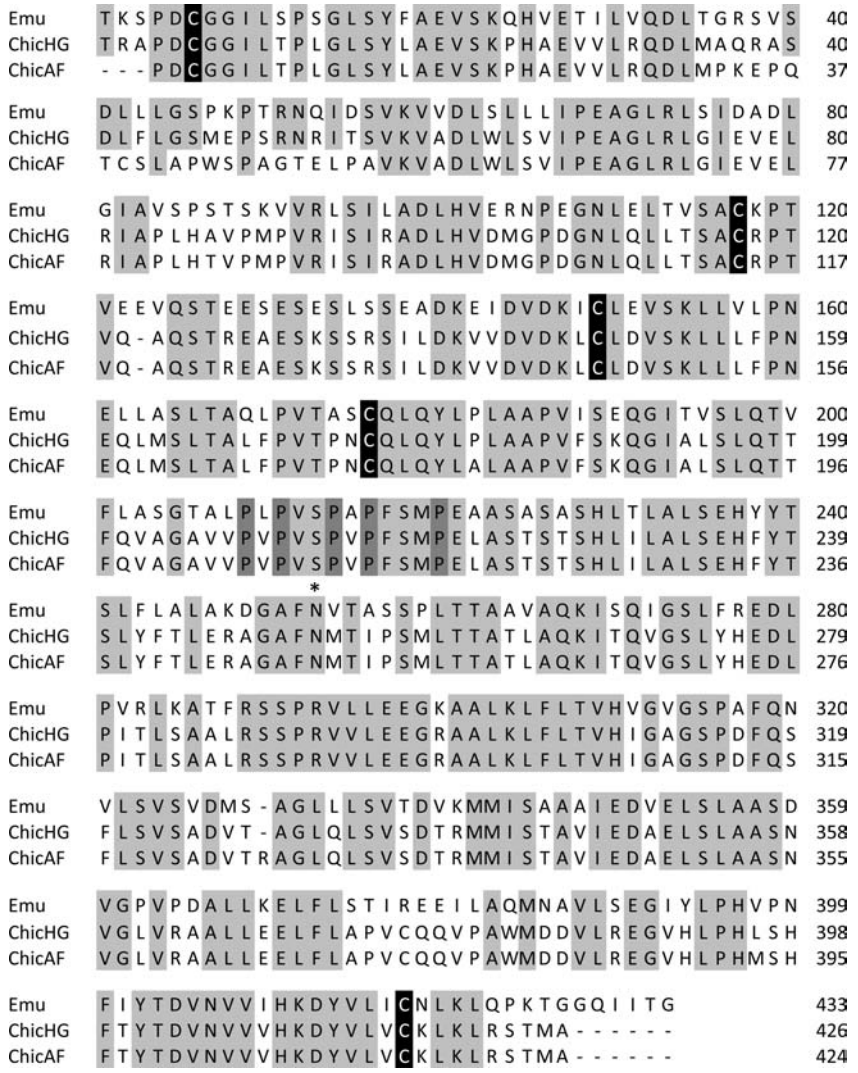

Figure 2. Alignment of amino acid sequences of emu and chicken TENPs [GenBank ID HG007958 (ChicHG) and AF029841 (ChicAF)]. Consensus sequences are highlighted in gray. Consensus cysteine residues are highlighted in black, whereas proline-rich regions are indicated by a dark gray background. The asterisk indicates a potential N-glycosylation site.

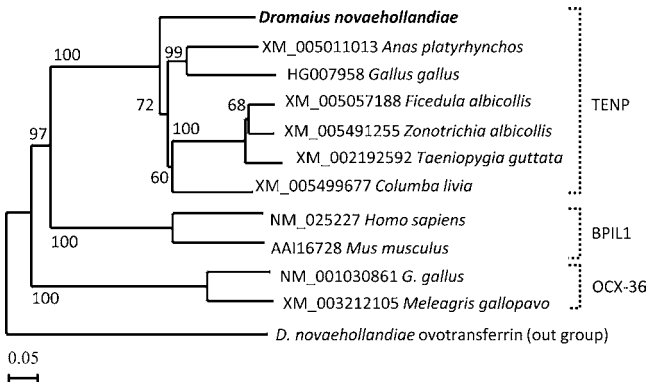

Figure 3. Phylogenetic analysis of TENPs and BPI/LBP/PLUNC-related proteins based on amino acid sequences. The accession numbers of the proteins used in this analysis are indicated. Numbers at the nodes represent bootstrap proportions (%) from 1000 replicates.

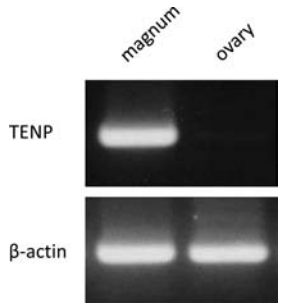

Figure 4. RT-PCR analysis of expression of TENP gene in emu magnum and ovary.

laying emus, as is the case in chickens. It would thus be of great interest to investigate the tissue distribution and regulation of TENP gene expression in each region of the emu oviduct including the magnum, the white isthmus, and the uterus, to further understand the abundance of TENP in the emu egg white in relation to its gene expression profiles.

Purification and Identification of TENP from Emu Egg White. Emu egg white preparation was separated into three peaks on DEAE-Sepharose FF column with NaCl elution. As determined by SDS-PAGE analysis, peaks P1 and P2 contained mainly an 80 kDa protein and a 100 kDa protein, respectively (Figure 5B). These peaks were further characterized by

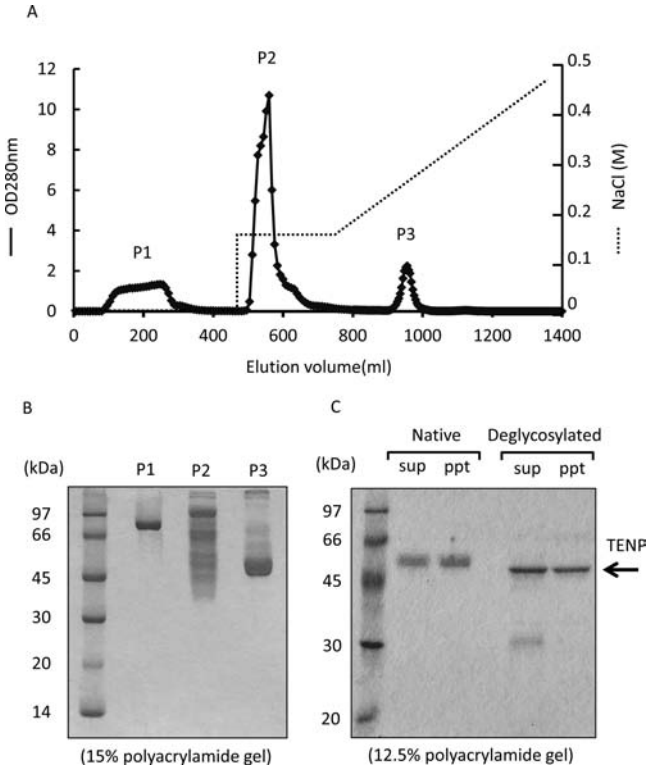

Figure 5. (A) Separation of emu egg white on DEAE-Sepharose column. (B) SDS-PAGE of DEAE peaks. (C) SDS-PAGE of deglycosylated samples from ammonium sulfate fractions (sup, supernatant; ppt, precipitate) of P3. Deglycosylation was carried out using glycopeptidase F.

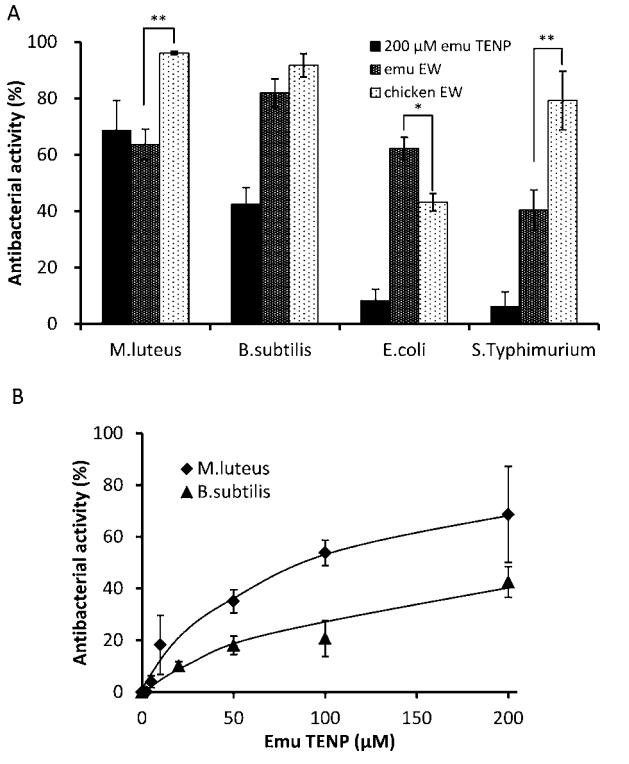

Figure 6. (A) Antibacterial activity of emu and chicken egg whites (EW) versus emu TENP. (B) Antibacterial activity of emu TENP against *M. luteus* and *B. subtilis*. M. luteus, *Micrococcus luteus* NRIC1094; B. subtilis, *Bacillus subtilis* NRIC1016; *E. coli*, *Escherichia coli* TOP10; S. Typhimurium, *Salmonella* Typhimurium TA1535/pSK1002. The results are represented as the average values obtained from three independent experiments. (∗) $p < 0.05$; (∗∗)$p < 0.01$.

separation (data not shown) and identified as ovotransferrin and ovalbumin, respectively, as previously described in our studies.[4] P3 contained mainly a 50 kDa protein, which was further separated by a 55% saturated ammonium sulfate fractionation. Resultant supernatant (sup) and precipitate (ppt) fractions both showed a single band on SDS-PAGE, as indicated in Figure 5C. However, after deglycosylation the sup fraction revealed another protein of 30 kDa. We reported in our previous study that emu egg albumen contained a riboflavin-binding protein of 50 kDa, which showed a 30 kDa band after deglycosylation.[23] A 50 kDa protein, reduced in size after deglycosylation, of the ppt fraction was identified as TENP by protein sequencing and we thereby concluded that emu TENP is an N-glycosylated protein as predicted from its amino acid sequence. The deglycosylation also confirmed that the ppt fraction was not contaminated with RBP. Thus, purified TENP migrating as a single band on SDS-PAGE was obtained from the ppt fraction and used for further testing on antimicrobial activity.

Antimicrobial Activity of Emu TENP. It is well-known that chicken egg white significantly reduces growth of bacteria;[12] more particularly, Gram-positive bacteria are sensitive to a bacteriolytic enzyme, lysozyme, in the egg white. As represented in Figure 6A, chicken egg white exhibited antibacterial activity against Gram-positive bacteria including *M. luteus* and *B. subtilis*. Similarly, emu egg white exhibited antibacterial activity against Gram-positive bacteria. However, it has been reported that emu egg white hardly contains lysozyme, so lytic activity is not detected in emu egg white.[5] It is now widely recognized that the avian egg holds a number of antimicrobial proteins, not only ovotransferrin and lysozyme, but also defensin peptides, protease inhibitors, and novel unidentified proteins.[2] Therefore, the existence of bactericidal proteins against Gram-positive bacteria, other than well-established substances, was expected in emu egg white. Emu TENP (0.2 mM) purified from emu egg white reduced the growth of Gram-positive bacteria, especially *M. luteus*, but substantively failed to affect the growth of Gram-negative bacteria including *E. coli* and *S.* Typhimurium. The final concentration of TENP present in the bacterial suspension mixed with emu egg white was estimated to be approximately 0.15 mM on the basis of the 16% estimated level of TENP[4] present in 8.9% of total protein in egg white.[1] The antibacterial activities of emu TENP against *M. luteus* and *B. subtilis* increased as a function of TENP concentration, as shown in Figure 6B. The protein purity of the TENP sample was evaluated by SDS-PAGE; however, further confirmation is required to rule out any concern with contaminants that may affect its antibacterial activity. Human[24] and oyster[25] BPIs exert antimicrobial activities against *Pseudomonas aeruginosa* and *E. coli*, respectively. On the basis of its structural similarity with BPI, it was expected that TENP would exhibit a bactericidal activity spectrum similar to that of BPI against Gram-negative bacteria. Surprisingly, emu TENP was found not to affect Gram-negative bacteria but caused bactericidal effects against Gram-positive bacteria. These results suggest a contribution of TENP to the antibacterial activity of emu egg white against Gram-positive bacteria such as *M. luteus* and *B. subtilis*. OCX-36, a member of the BPI superfamily, which is an abundant

dx.doi.org/10.1021/jf5008117 | J. Agric. Food Chem. 2014, 62, 5156−5162

component of chicken egg shell membrane, was recently investigated for its antimicrobial activity and was found to be effective against *Staphylococcus aureus* but not against Gram-negative bacteria such as *P. aeruginosa*, *E. coli* and *S.* Typhimurium.[21] The avian eggshell protects the embryo against entry of micro-organisms.[26] OCX-36 was suggested to play an innate role in the protection of the egg.[21] Defensins constitute a large number of cationic antibacterial peptides.[27] Avian β-defensin 11 was purified from chicken egg vitelline membrane and exhibited antimicrobial activity toward both Gram-positive and Gram-negative bacteria.[28] In emu egg, an ovocalyxin-17 (OC-17)-like protein, a member of the C-type lectin-like proteins, was named dromaiocalcin and represents a dominant protein in the eggshell matrix.[29] Because chicken OC-17 is a bactericidal protein,[30] dromaiocalcin is also expected to play an important role in the protection of the emu egg. In a previous study by Wellman-Labadie et al., species differences in the antibacterial activity of egg albumen were observed between Galliformes and Anseriformies and were attributed to the concentrations of ovotransferrin and lysozyme.[12] Because ovotransferrin is present in emu egg white[4] in a remarkably abundant amount, it was suggested that ovotransferrin was the main contributor to the antibacterial activity of emu egg white, whereas TENP was only partially involved, for example, against *M. luteus*.

In this study, we examined for the first time the bioactivity of TENP and found that emu TENP is a novel antibacterial protein but exerts a different spectrum of action compared to BPI, despite their structural similarity. Because TENP is contained abundantly in emu egg white, emu TENP might play a role, even partially, in the defense system against bacterial infection of the egg white. Further investigations on the antimicrobial action of TENP is required to elucidate the natural defense system present in emu egg white, with a particular focus on the role of ovotransferrin, the most abundant protein in emu egg white.

electrospun fibers after heat treatment. Thermal processing will generally reduce the α-helix structure, and increase the intermolecular antiparallel β-sheet form of protein secondary structure, which induces protein conformational changes.[12] Hence, the protein secondary structure of the heat-cured electrospun fibers was investigated using a vibrational spectroscopy technique such as ATR-FTIR. Overall, the objectives of this work were to evaluate the effect of heat treatment on the physicochemical properties of the electrospun fibers, and to characterize the extent of denaturation along with the degree of cross-linking on heat-cured Ze and Ze-GA electrospun fibers using ATR-FTIR, SS-NMR, and gel permeation chromatography (GPC). Other physicochemical properties, namely, the color properties, surface hydrophobicity, morphology, and release performance of the heat-cured electrospun fibers, were also determined in this work.

MATERIALS AND METHODS

Materials. Zein (Z 3625) and *N*-methyl-2-pyrrolidone (NMP, HPLC grade) were purchased from Sigma-Aldrich (St. Louis, MO, USA). The zein powder was used without further purification. Ethanol (ACS grade) was purchased from ECP Ltd. (Auckland, New Zealand). Milli-Q water (18 MΩ cm, Millipore, Bedford, MA, USA) was used for preparation of all solutions.

Electrospinning Process. The zein and gallic acid incorporated zein solutions were prepared and electrospun as described in our previous studies.[10,11] Briefly, zein solution was prepared at a concentration of 25 wt % by dissolving zein powder in 80 wt % ethanol aqueous solutions under constant stirring using a magnetic stirrer at room temperature (approximately 21 to 24 °C). Zein electrospun fibers containing various amounts of gallic acid in the solid fibers were prepared by first dissolving gallic acid in 80 wt % ethanol aqueous solutions, followed by dissolving zein powder to obtain 25 wt % zein solutions. The final content for the gallic acid in the solid fibers was 5 and 10 wt %, meaning gallic acid to zein weight ratio of 1:19 and 1:9 in the final dry electrospun fibers, respectively. These electrospun fibers were designated as Ze (for pure zein with no gallic acid incorporation), Ze-GA 5%, and Ze-GA 10%, respectively. The solutions were placed in 5 mL syringes that were driven by a syringe pump (Cole Parmer 74900 series, Vernon Hills, IL, USA) to give a solution feed rate of 0.8 mL h^{-1}. The positive electrode of a direct current power supply (high voltage power supply series 230, Bertan, Hicksville, NY, USA) was connected to a 20 gauge needle (i.d. of 0.61 mm) of a syringe and the negative terminal to a grounded collector. The applied voltage was 16 kV with a distance between needle tip and collector of 13 cm. Finally, the as-spun electrospun fibers were heat-cured in a laboratory oven at 150 °C for 24 h.

Scanning Electron Microscopy (SEM). The morphology of the fibers was examined using a Philips XL 30S FEG (Philips, Eindhoven, The Netherlands) scanning electron microscope, after sputter coating the samples with platinum under vacuum for 5 min at 5 to 10 mA using a Quorum Q150R-S sputter coater (Quorum Technologies Ltd., Ashford, Kent, U.K.) to reduce electron charging effects. The fiber diameter was measured as the average diameter with UTHSCSA image tool (IT) for windows, version 3.00 (University of Texas Health Science Center, San Antonio, TX, USA) from over 60 randomly selected fibers.

Color Measurement. Instrumental color analyses of the heat-cured Ze and Ze-GA fiber mats after heat curing were determined using a CR300 colorimeter (Minolta, Osaka, Japan) to provide background information on their optical properties. L^* value describes lightness, where $L^* = 0$ is black and $L^* = 100$ is close to white; a negative a^* represents greenness, and a positive a^* is redness; a negative b^* indicates blueness, while a positive b^* is yellowness. Measurements were made directly on the fiber mats after calibrating the instrument using a standard white calibration plate ($L^* = 96.86$, $a^* = -0.02$, and $b^* = 1.99$). The measurements were carried out in triplicate.

Water Contact Angle. The wettability of the electrospun fibers was determined by using the sessile drop method. Each of the electrospun fiber mats (thickness was approximately 77 μm) was carefully peeled off from the aluminum foil and was mounted on the lifting stage connected to a KSV CAM 100 contact angle goniometer (KSV Instrument Ltd., Finland). A droplet (approximately 5 μL) of distilled water was placed on the fiber surface with a microsyringe. The tangent line at the point of contact of the water droplet with the fiber surface was captured and measured immediately using the CAM 100 computer simulation software at room temperature (approximately 22 °C). The contact angle for each sample was taken as the average of 10 different measurements in order to get a reliable value.

Release Assay. The release characteristics of gallic acid from the heat-cured Ze-GA electrospun fibers were determined by a modification of total immersion method by Tungprapa et al.[13] in Milli-Q water. Briefly, 20 mg of the electrospun fiber mat was submerged in 40 mL of Milli-Q water at 23 °C under gentle stirring. An aliquot of 50 μL of the solution was withdrawn at specified time intervals, ranging between 0 and 360 min and diluted with 450 μL of Milli-Q water. The sample solutions were filtered through a cellulose acetate 0.45 μm (Phenomenex, Torrance, CA, USA) syringe filter before analysis by high performance liquid chromatography (HPLC). The amount of the released gallic acid was quantified by HPLC using a Phenomenex Luna C18 column (250 mm × i.d. 4.6 mm, 5 μm particle size) according to the previously published method by Neo et al.[14] Briefly, isocratic elution was carried out with a mobile phase consisting of water/methanol (82:18 v/v) containing 2% (v/v) acetic acid, at a flow rate of 1 mL min^{-1}. A diode array detector was used for the detection of gallic acid, and the HPLC profiles were obtained at 280 nm. The injection volume for all samples was 20 μL. Identification of gallic acid was based on retention times in comparison with standards. The concentration of the gallic acid was calculated using peak area and the calibration curves obtained from the gallic acid standard solutions. The morphology of heat-cured electrospun fibers after the release assay was determined using SEM, as described in the aforementioned section.

Gel Permeation Chromatography (GPC). The molecular characteristics of the electrospun fiber mats were investigated using gel permeation chromatography (GPC). The GPC system consisted of a Waters 515 HPLC pump (Waters Inc., Milford, MA, USA), a Rheodyne manual injector (Rheodyne, Cotati, CA, USA) fitted with 200 μL injection loop, a Phenomenex Degassex DG-4400 online degasser (Phenomenex, Torrance, CA, USA), two PolyPore columns (300 mm × 7.5 mm with mixed pore sizes) from Polymer Laboratories/Varian Inc. (Amherst, MA, USA) with a PolyPore guard, a multiangle laser light scattering (MALLS) detector (632.8 nm, DAWN DSP, Wyatt Technology, Santa Barbara, CA, USA), and a Shimadzu RID-10A refractive index (RI) detector (Shimadzu, Kyoto, Japan), and the columns were thermostated at 40 °C using a Waters column oven (Waters Inc., Milford, MA, USA). The electrospun fiber mats were dissolved in 5 mL of *N*-methyl-2-pyrrolidone (NMP) separately after constant stirring using a magnetic stirrer until complete solubility. The prepared concentration for each sample was 5 mg mL^{-1}. The samples were filtered through 13 mm 0.45 μm polytetrafluoroethylene (PTFE) syringe filters (Grace, Deerfield, IL, USA) before injection onto the column set. A 100% NMP was used as the mobile phase, which had been filtered by 0.2 μm PTFE membrane filter (Supelco, Bellefonte, PA, USA). The flow rate was 0.2 mL min^{-1}, and the pump pressure was approximately 950 psi. Six poly(methyl methacrylate) (PMMA) standards (EasyCal Kit, Polymer Laboratories, U.K.) were dissolved in the same mobile phase at 2 mg mL^{-1}. The 29960 g mol^{-1} standard peak was used to normalize the light scattering detectors. Data acquisition and processing were performed using the ASTRA 4.0 software (Wyatt Technology, Santa Barbara, CA, USA). The specific RI increment value (dn/dc) was determined by assuming 100% mass recovery for non-heat-cured Ze solution of accurately known concentration in NMP, and was found to be 0.056 mL g^{-1}. The molecular weight and root-mean-square radius of gyration for each electrospun fiber mat were calculated with a first-

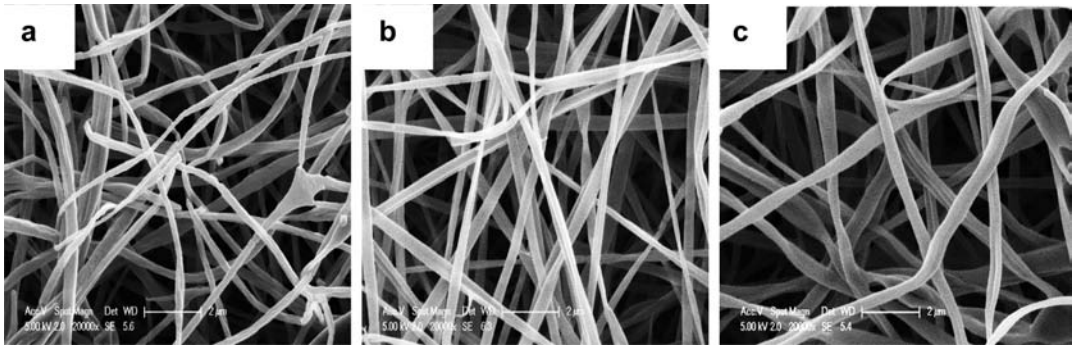

Figure 1. SEM images of heat-cured Ze and Ze-GA electrospun fibers at 2 μm scale bar: (a) Ze, (b) Ze-GA 5%, (c) Ze-GA 10%.

order Debye fit. Four of the 18 detector signals were excluded for the data processing due to poor signal-to-noise ratio.

Attenuated Total Reflectance Fourier Transform Infrared (ATR-FTIR) Spectroscopy. The chemical interaction and compositional analysis of the electrospun fiber mats were examined using ATR-FTIR spectroscopy. The ATR-FTIR spectra were recorded on a Thermo Electron NICOLET 8700 FTIR spectrophotometer using the Smart Orbit ATR accessory with diamond crystal, single bounce at 45° (Thermo Electron Corporation, Waltham, MA, USA) over the wavenumber region of 700 to 3600 cm^{-1}. Interferograms were averaged for 32 scans at 4 cm^{-1} resolution. The measurements were carried out in triplicate. Second derivative spectra (Savitsky−Golay derivative) were obtained using the OMNIC 5.0 spectroscopic software (Nicolet Instrument Corp., Madison, WI) to determine the component peak positions. Next, fitting of the component bands was carried out for the 1300 to 1730 cm^{-1} region using the OMNIC 5.0 spectroscopic software, and a Gaussian/Lorentzian function was used for the fitted curves. The composition of the protein secondary components was determined semiquantitatively through the relative peak heights of each component. Fitting was not limited to the amide I region (1600 to 1700 cm^{-1}) in order to overcome the possible errors due to overlapping components from the other regions. All the given fits converged with the original spectra.

^{13}C Solid State Nuclear Magnetic Resonance (SS-NMR). Structural analysis of the electrospun fiber mats was conducted using SS-NMR. CPMAS NMR experiments were performed at a ^{13}C frequency of 75.47 MHz using a Bruker Avance 300 spectrometer (Bruker BioSpin GmbH, Germany). The magic angle was adjusted by maximizing the sidebands of ^{79}Br signal of a KBr sample. The electrospun fiber mats were packed in zirconium oxide 7 mm rotors with airtight Kel-F caps. The sample rotation frequency was 7000 ± 1 Hz, and the free induction decays were acquired with a spectral width of 40 kHz. The ^{1}H 90° pulse was 4.2 μs, 1 ms contact time, using a recycle delay of 2 s to avoid signal loss through saturation. The number of scans for the CPMAS experiments was 4000 to 5000. The spectra were externally referenced using polycrystalline adamantane (38.48 ppm relative to tetramethylsilane (TMS, 0 ppm)) as suggested by Morcombe and Zilm.[15] All experiments are performed at room temperature (approximately 21 to 24 °C).

Statistical Analysis. Statistical analysis was performed using MINITAB 13.0 software (Minitab Inc., State College, PA, USA). The data were compared using analysis of variance (ANOVA) at 5% significance level. All values are reported as means of three determinations, and the results were expressed as mean values ± standard deviation.

RESULTS AND DISCUSSION

Morphological and Color Properties of the Fiber Mats. The microstructures of the heat-cured Ze and Ze-GA electrospun fibers using SEM are shown in Figure 1. The heat-cured fibers exhibited distorted and flattened structures. They generally retained their morphological integrity as continuous randomly oriented cylindrical fibers, and the average diameter of the heat-cured electrospun fibers was in the range from 357 to 519 nm.

Color values of the electrospun fiber mats are presented as L^*, a^*, and b^* values as shown in Table 1. The average color values of heat-cured Ze and Ze-GA electrospun fiber mats were found to be between 91.31 and 94.68 for L^*, 0.25 and 1.32 for a^*, and 8.64 and 10.28 for b^*. The heat-cured electrospun fibers became significantly darker, redder, and more yellowish with the increasing amount of gallic acid loaded, as evidenced by their lower L^* and greater a^* and b^* values as shown in Table 1. Interestingly, the heat-cured electrospun fibers were also found to be more yellowish than the non-heat-cured electrospun fibers. The average color values of non-heat-cured Ze and Ze-GA electrospun fiber mats were reported to be between 0.90 and 2.51 for b^* in our previous study (Table 1).[11] These observations are in agreement with other reported studies on heat-treated protein films.[2,8,16] Overall, the color values of the heat-cured Ze-GA electrospun fibers mats were significantly different ($P < 0.05$) from those of the non-heat-cured fiber mats in terms of lightness, yellowness, and redness. The browning reaction of zein protein during high temperature processing is suggested to be due to isopeptide bond formation between the amine, $-NH_2$ side chain of lysine or arginine with the carboxyl −COOH containing side chains or amide group of glutamic acid, aspartic acid, glutamine, and asparagine, through the liberation of water and ammonia.[17,18] These reactions are also reported to be responsible for the formation of cross-linking bonds. Other than that, Reddy et al.[19] also reported that

Table 1. Reflectance (Hunter L^*, a^*, b^*) Values of Heat-Cured Ze and Ze-GA Electrospun Fibers

GA content (wt % in solid fibers)	L^*	a^*	b^*
	Non-Heat-Cured[a]		
0	96.488 ± 0.55 a	0.034 ± 0.08 d	1.368 ± 0.99 h
5	94.805 ± 1.32 b	0.178 ± 0.06 de	0.895 ± 0.25 h
10	95.680 ± 0.80 ab	0.187 ± 0.12 de	2.512 ± 0.59 i
	Heat-Cured		
0	94.683 ± 0.48 b	0.253 ± 0.06 e	8.643 ± 0.57 j
5	92.850 ± 0.54 c	0.663 ± 0.17 f	8.883 ± 0.58 jk
10	91.310 ± 0.28 c	1.315 ± 0.05 g	10.282 ± 0.05 k

[a]The reflectance values for non-heat-cured electrospun fibers were extracted from the previously published data (Neo et al., 2013).[11] Data are displayed as means ± standard deviation of three replications. Means in each column bearing different letters are significantly different ($P < 0.05$).

dx.doi.org/10.1021/jf500841m | J. Agric. Food Chem. 2014, 62, 5163−5172

the dehydration of the carboxylic acids at high temperature that forms an unsaturated acid would cause yellowness of the cross-linked material. Hence, the greater yellowness of Ze-GA electrospun fiber mats suggested the potential chemical interactions of the carboxylic group of gallic acid with the zein amino acids.

Water Contact Angle of the Heat-Cured Electrospun Fiber Mats. The wettability of the heat-cured electrospun fiber was determined using the water contact angle upon the surface of the fiber mats. A large contact angle ($\theta > 65°$) generally implies a hydrophobic surface, while a small contact angle ($\theta < 65°$) suggests a hydrophilic surface.[20] The wettability of the non-heat-cured Ze and Ze-GA electrospun fibers was very high, judging by the fact that the water droplets spread instantly into the non-heat-cured fiber matrices. Hence, no contact angle value could be measured for the non-heat-cured fibers during the experiments. All heat-cured Ze and Ze-GA electrospun fiber mats exhibited a contact angle of approximately 110° in the first 10 s, indicating the variation of the surface properties after the heat-curing process (Figure 2). The contact angle gradually

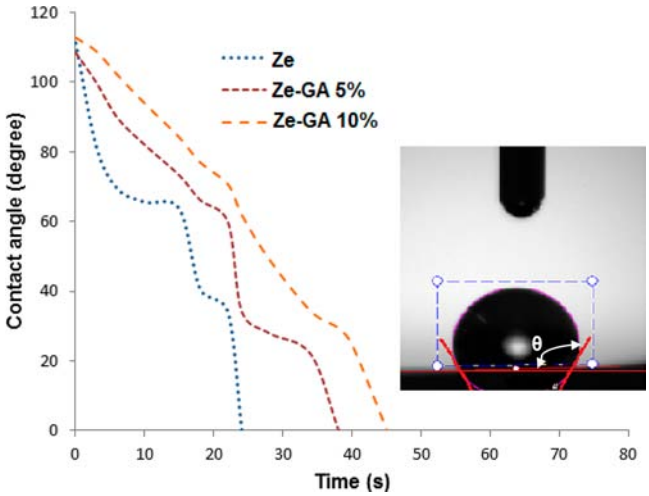

Figure 2. Plot of contact angle of heat-cured electrospun fiber mats as a function of time.

decreases with time, and a complete spreading of the water droplets is observed for all the heat-cured fiber mats within 50 s. Tang et al.[21] suggested that heat treatment will induce the unfolding of proteins, which consequently will uncover some of the hydrophobic functional groups of the protein that were originally buried in the interior of the molecules. Hence, the differences in the wettability among the electrospun fiber mats might be due to the alterations in the protein structure after the heat-curing process. Interestingly, the wettability of the heat-cured electrospun fiber mats decreased with the increase in gallic acid content. Thus, it is prudent to assume there was significant chemical bonding between gallic acid and zein protein after the heat-curing process, which have modified the chemical properties of zein.

Release Performance of the Loaded Gallic Acid. The release curves of gallic acid from the heat-cured Ze-GA electrospun fiber mats in water at 23 °C for 6 h are shown in Figure 3. The electrospun fibers with different gallic acid loadings displayed comparable gradual release trends. In our previous study,[11] we showed a rapid release performance of the loaded gallic acid from the non-heat-cured Ze-GA fiber mats that increased with an increase in gallic acid content. However, it was obvious in this study that the release performance of gallic acid was inhibited after the heat-curing process as compared to the non-heat-cured Ze-GA fibers reported in our previous studies. Figure 3 shows that, in heat-cured fiber mats, only approximately 60% release of gallic acid was detected after 6 h of immersion in water at 23 °C, while in the non-heat-cured sample the release was over 80% within 1 h. Interestingly, it was noticed that the release rate of the gallic acid decreased with the increasing content of loaded gallic acid. Heat-cured Ze-GA 5% and Ze-GA 10% demonstrated gallic acid release percentages of 53% and 48%, respectively, at the end of 2 h of immersion in water.

The zein electrospun fibers normally demonstrate excessive swelling in aqueous medium due to hydrophobic interactions among the zein molecules.[22] The morphology of the heat-cured electrospun fibers was examined after the release assay, in order to determine the effect of soaking in water. Figure 4 shows the Ze electrospun fibers after immersion in water for 6 h. The number of junction pores of the soaked Ze fiber mat was reduced, and the high surface area-to-mass ratios of the electrospun fiber mats were compromised. Figure 4b,c indicates a swollen fiber network of heat-cured Ze-GA electrospun fiber mats. The fiber diameter was found to range from 531 to 657 nm for the heat-cured and soaked Ze-GA fibers. In contrast to Ze electrospun fibers that lost the fiber structure, heat-cured Ze-GA fiber mats retained their fibrous structure after immersion in water. Figure 4c evidently shows that Ze-GA 10% maintains better fiber morphology and greater water stability as compared to Ze-GA 5%. It could be deduced that cross-linking reactions have occurred between the gallic acid reactive sites and zein protein to form linkages during the heat-curing process. The rapid release performance of gallic acid seen in non-heat-cured Ze-GA electrospun fiber mats had been decelerated in the heat-cured fibers, which might be due to the chemical bonding between gallic acid and zein after heating.

Molecular Characteristics of the Electrospun Fibers Using Gel Permeation Chromatography (GPC). Figure 5 shows the elution profile of the electrospun fiber mats in the GPC from the RI detector. The non-heat-cured electrospun fiber mats eluted from the column in one peak with a maxima at around 9 mL. A progressive shift toward smaller elution volumes was observed for the heat-cured electrospun fiber mats. These results suggest the formation of higher molecular weight components with non-heat-cured electrospun fiber mats. The relevant molecular parameters for the electrospun fiber mats are tabulated in Table 2 and include molecular mass averages, polydispersity indices (weight-average molecular weight/number-average molecular weight, M_w/M_n), and molecular radii (expressed as the root-mean-squared radius of gyration, R_g). All the electrospun fiber mats are showing polydispersity indices greater than 1.0, indicating a broad range of molecular masses. The polydispersity of the non-heat-cured electrospun fiber mats decreased with increasing gallic acid content, but variations were noted among the heat-cured electrospun fiber mats. It is important to note that both the heat-cured and non-heat-cured Ze-GA 5% fiber mats generally exhibited higher radii of gyration and molecular weight compared with the other electrospun fiber mats studied. Figure 5 shows a small peak (indicated by an arrow) eluting before the primary component of heat-cured Ze-GA 5% fiber mats, suggesting the possible formation of higher molecular weight aggregates after the heat-curing process. As a result, the heat-

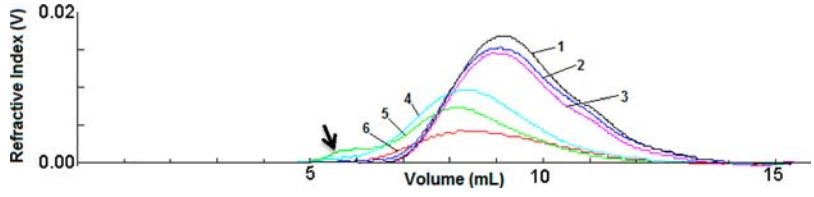

Figure 5. GPC elution profile of the electrospun fiber mats: (1) Ze, (2) Ze-GA 5%, (3) Ze-GA 10%, (4) heat-cured Ze, (5) heat-cured Ze-GA 5%, (6) heat-cured Ze-GA 10%. Arrow indicates a small peak eluting before the primary component of heat-cured Ze-GA 5% fiber mats.

cured Ze-GA 5% fiber mats exhibited the highest polydispersity and molecular weight among the electrospun fiber mats, with number-average (M_n), weight-average (M_w), and *z*-average (M_z) molecular weight of 1.497×10^6 g mol^{-1}, 6.586×10^6 g mol^{-1}, and 4.451×10^7g mol^{-1}, respectively and a polydispersity of 4.40. Interestingly, the heat-cured Ze-GA 10% shows the lowest molecular weight and also the lowest polydispersity compared with the other heat-cured fibers. This might be due to the nonstoichiometry in mixing that occurs in the Ze-GA 10% system that requires further investigation. Also shown in Table 2 are the R_g values (R_n, R_w, R_z) of the electrospun fiber mats. The radii of gyration for the non-heat-cured electrospun fiber mats ranged from 51.3 to 63.5 nm, whereas the radii of gyration for the heat-cured-electrospun fiber mats ranged from 62.6 to 67.5 nm as shown in Table 2. The nonmajor change in radii of gyration between heat-cured and non-heat-cured fibers suggested that the zein protein still exists in the globular form after the heat-curing process. Yet, the generally larger hydrodynamic radius observed in heat-cured electrospun fiber mats implies the formation of larger

aggregates or extended protein conformation by cross-linking after the heat-curing process. The chemical nature of the cross-linking process might be inferred as the formation of amide cross-links between amine and carboxyl groups as suggested by

dx.doi.org/10.1021/jf500841m | J. Agric. Food Chem. 2014, 62, 5163−5172

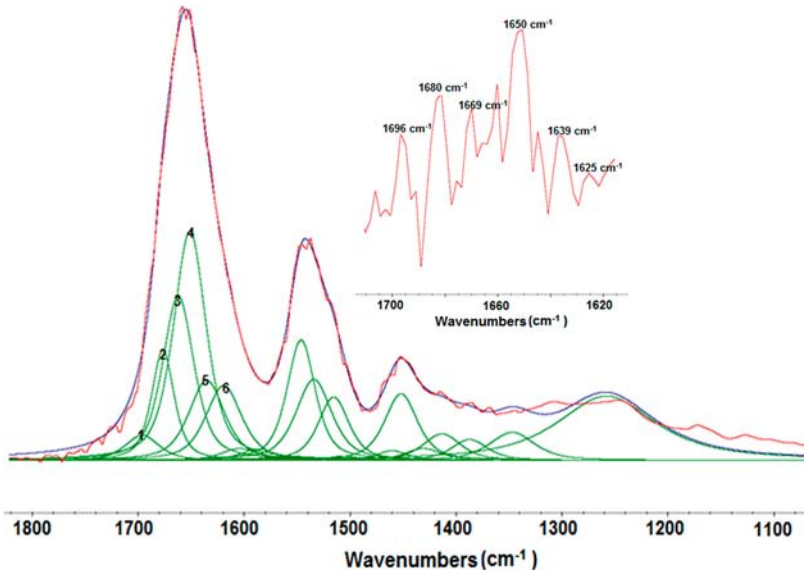

Figure 7. Curve-fitted ATR-FTIR spectra for the 1300 to 1730 cm^{-1} region for non-heat-cured Ze electrospun fiber mats. The original spectra were curve fitted based on the number of peak components and positions identified from the second derivatives. Components are numbered (1−6) for the amide I region and are given in green. Inset is the second-derivative spectrum showing the bands associated with the secondary structure of zein protein. Peaks (1) inter/anti parallel β-sheet (1696 cm^{-1}), (2) β-sheet (1680 cm^{-1}), (3) β-turn (1669 cm^{-1}), (4) α-helix (1650 cm^{-1}), (5) random coil (1639 cm^{-1}), (6) β-sheet (1625 cm^{-1}). The fits (blue) overlay the original spectra.

Gorham et al.[1] and Rombouts et al.[23] in collagen and wheat gluten. Overall, all the electrospun fiber mats have shown high molecular weight after the heat-curing process, which may imply thermal polymerization of the zein protein.

Compositional Analysis of the Electrospun Fiber Mats. Figure 6 shows the normalized ATR-FTIR spectra of the electrospun fiber mats. Compared with the Ze electrospun fibers (spectra 1 and 4), all the Ze-GA fibers (spectra 2, 3, 5, and 6) demonstrated new peaks at 1336 cm^{-1}, 1197 cm^{-1}, 1037 cm^{-1}, 876 cm^{-1}, and 777 cm^{-1}, which confirms the presence of gallic acid.[10] The heat-cured Ze-GA fibers demonstrated similar ATR-FTIR spectra to their non-heat-cured counterparts as shown in Figure 6a. However, differences in intensity for the bands of heat-cured and non-heat-cured fibers were observed in the amide II band at 1530 cm^{-1} (Figure 6a) and the CH_2 stretch modes at bands 2927 and 2850 cm^{-1} (Figure 6b). The heat-cured electrospun fibers generally showed peak shifting to near 1525 cm^{-1} from approximately 1530 cm^{-1} for the non-heat-cured fibers. Figure 6a indicates broadening of the amide II bands and the presence of a shoulder at approximately 1510 cm^{-1} (indicated by an arrow in Figure 6a). The amide II mode is predominantly an −NH bending vibration coupled to −CN stretching vibration.[24] Pelton and McLean[25] suggested that bands between 1510 and 1530 cm^{-1} indicate the presence of β-sheet structures; the shoulder at 1510 cm^{-1} in this study is thus evidence of the presence of new intermolecular bonding in the heat-cured electrospun fibers. On the other hand, significant reductions in the bands at 2927 and 2850 cm^{-1} were observed for all the heat-cured fibers as shown in Figure 6b, which are attributed to the CH_2 stretching vibrations. These results show the substantial influence of the heat-curing process on the aliphatic group of zein protein, especially the methylene groups as shown in Figure 6b. Overall, the broadening of amide II band and the loss of methylene groups implies the potential formation of new isopeptide bonding in the zein electrospun fiber mats due to heat curing.

The correlation between protein secondary structure and the frequency in the ATR-FTIR spectra for the amide II band is proposed to be less straightforward than those for the amide I vibrations.[24] Hence, analysis of the amide I region was used to further investigate the secondary structural changes upon the heat-curing process. The amide I band is mainly due to stretching vibrations of the carbonyl group, and hence represents the secondary structure of the proteins well.[3] To study the structural changes of zein, the band positions of the overlapping components corresponding to different secondary structures were determined from the secondary derivative spectra, and then fitted to the amide I band using curve fitting. The band positions of six major bands thus determined in the amide I band are shown in the inset in Figure 7. Resolution of the amide I peak into these six bands was performed using the Peak resolve curve fitting function of the OMNIC 5.0 spectroscopic software, following the method of Forato et al.[26] and Georget et al.[27] The six band components thus identified in this study were the inter/antiparallel β-sheet at 1696 cm^{-1}, β-sheet at 1680 cm^{-1}, β-turn at 1669 cm^{-1}, α-helix at 1650 cm^{-1}, random coil at 1639 cm^{-1}, and intermolecular β-sheets at 1625 cm^{-1}. Estimation of the secondary structural content was based on the band component areas as shown in Figure 7. The assigned component areas are tabulated in Table 3. All the electrospun fiber mats exhibited characteristics of α-helix rich protein that shows a strong vibrational mode at around 1650 cm^{-1}. The amount of α-helix content calculated from the ATR-FTIR spectra ranged from 34.3 to 45.1% for all the electrospun fibers. This result is in agreement with the observations of other studies that suggested α-helix content of approximately 43% in solid state zein.[26] The high content of α-helix structure in zein is generally associated with α-zein that accounts for more than 80% of total zein. Nevertheless, Table 3 shows that non-heat-cured Ze-GA fibers have higher β-turn content (22.9% and 24.6% for Ze-GA 5% and Ze-GA 10%, respectively) as compared to non-heat-cured Ze fibers (18.7%). The secondary structure content of the heat-cured Ze

random coil (1639 cm^{-1})	15.30	17.69	13.80	20.06	9.31	8.74
β-sheet (1625 cm^{-1})	12.10	10.11	12.31	9.10	13.17	13.29
total β-sheet content	26.87	24.86	25.74	23.16	27.71	28.53

[a]The amide I peak deconvolution using OMNIC 5.0 spectroscopic software was carried out according to Forato et al.[26] and Georget et al.[27]

electrospun fibers was 34.3% α-helix, 23.2% of total β-sheets, 22.5% of β-turn, and 20.1% of random coil as shown Table 3. The results exhibited a slight decrease in α-helix and β-sheet content, and a slight increase in β-turn and random coil content for heat-cured Ze compared with the non-heat-cured Ze electrospun fibers. These results suggest an increase of the "disordered phase (or lack of defined structure)" of zein protein after heat treatment, as α-helix and β-sheets are generally considered as "ordered phases", while β-turns and random coil are "disordered phases" as suggested by Oliviero et al.[28] The reduction of α-helix content after heating has also been observed in other protein films such as gelatin and wheat gluten,[12] yet it is important to note that α-helix structure in zein protein is linked by rigid structures that are generally stable.[29] The considerable changes in the α-helix content between the heat-cured and non-heat-cured fibers support this statement. Interestingly, the heat-cured Ze-GA fibers have exhibited higher α-helix content and total β-sheets content at the expense of β-turn and random coil as shown in Table 3. The random coil content of heat-cured Ze-GA fibers is 9.3% and 8.7% for Ze-GA 5% and Ze-GA 10%, respectively. The increase in β-sheet content of heat-cured Ze-GA fibers at 1696 cm^{-1}, 1680 cm^{-1}, and 1625 cm^{-1} (Table 3 and Figure 7 inset) indicates an extensive inter- and intramolecular bonding after the heat-curing process. This result corresponds well with the observation of amide II band broadening as demonstrated previously. The secondary structural component changes of the protein as determined for the electrospun fiber mats indicate the covalent cross-linking of protein during heat treatment. The results also suggest the potential of the heat-curing as a post-electrospinning treatment of proteinaceous materials as a method to modify their functional properties.

Assignment of ^{13}C Peaks. Solid-state NMR has been used to generate information related to molecules of proteins using $^{13}C-^{1}H$ cross-polarization.[30] SS-NMR chemical shifts can be used to elucidate the protein conformation since the internal rotation around the peptide bonds is usually fixed.[31] In zein, glutamine, glutamic acid, tyrosine, histidine, arginine, aspartic acid, asparagine, threonine, serine, and cysteine are the amino acids which contain potential reactive side groups.[32] It is a challenge to assign specific amino acid sites in the zein ^{13}C NMR spectrum due to line broadening and the considerable overlap of peaks. Nevertheless, the ^{13}C NMR resonances can be assigned on the basis of previous reports.[26,32,33] The solid state CPMAS spectra of the electrospun fiber mats are presented in Figure 8. Zein shows resonance signals of the carbonyl carbons,

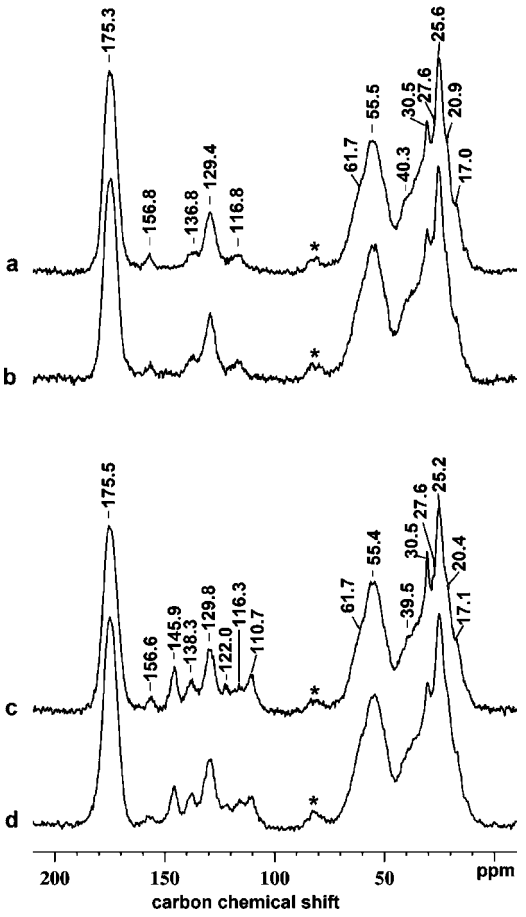

Figure 8. ^{13}C CPMAS NMR spectra of the electrospun fiber mats: (a) non-heat-cured Ze, (b) heat-cured Ze, (c) non-heat-cured Ze-GA 10%, and (d) heat-cured Ze-GA 10%. The asterisks denote spinning sidebands.

aromatic side chains, α-carbons, and carbons of the amino acid aliphatic side chains at about 175, 100 to 140, 45 to 70, and 15 to 45 ppm, respectively (Figure 8a,b), which is in accordance with the findings of Forato et al.[26] Out of the potential reactive side groups in zein suggested by Wu et al.,[32] only those from tyrosine at 156.8, 129.4, and 116.8 ppm and histidine at 136.8 ppm show relatively resolved peaks (Figure 8a,b). Figure 8c,d demonstrates that the ^{13}C NMR spectra of Ze-GA 10% fibers have exhibited new resonance signals in the aromatic carbon region between 100 to 140 ppm. This observation is in agreement with the literature that suggested ^{13}C NMR chemical shifts for gallic acid between 110 and 169 ppm.[34] The carbonyl chemical shifts at the resonance 170 to 178 ppm region are generally sensitive to the protein conformations.[26,35] The SS-NMR characteristics obtained from this region should represent the protein behavior. Figure 8 shows that all the electrospun

dx.doi.org/10.1021/jf500841m | J. Agric. Food Chem. 2014, 62, 5163−5172

fiber mats have exhibited strong resonance at 175 ppm, indicating high α-helix content that is in accordance with the ATR-FTIR peak assignments. Other than the presence of new resonance signals at the aromatic carbon region, ^{13}C NMR spectrum for non-heat-cured Ze-GA 10% also revealed changes in resonance intensity at 30.5 ppm, which indicates the resonance for amino acid aliphatic side chains (Figure 8c,d). Even though the ^{13}C NMR chemical shift spectra of the heat-cured and non-heat-cured electrospun fiber mats look similar, the relative differences observed on the resonance intensities of the electrospun fibers implied possible structural changes after the heat-curing process, which is in line with ATR-FTIR data. Specifically, the cross-polarization experiment relies on magnetization transfer from abundant (^1H) to the rare spin system (^{13}C). This process is dependent on dipolar interactions between nuclear spins making it very sensitive to structural and dynamic aspects of the local environment. Further studies using relaxation and spin-diffusion experiments will need to be conducted in the future, in order to provide information on the rigidity and the spatial distribution of microscopic domain sizes for various components in the electrospun fiber systems.

In summary, the heat-curing process has shown prominent modification on the physicochemical properties of the Ze and Ze-GA electrospun fibers. Thermal treatments had also induced color changes on the electrospun fiber mats. Interestingly, the changes increased with the increase in gallic acid content, which implied that chemical interactions had taken place between zein and gallic acid. The morphology of the heat-cured fibers was found to be flattened and the fiber diameters were enlarged and the hydrophobicity of the electrospun fiber surface was found to have increased after the heat-curing process. In addition, Ze-GA fibers showed slow but constant release of gallic acid in water over time. An improved morphological stability of Ze-GA fibers was observed after immersion in water at 23 °C for 6 h. It was also found that the molecular weight of Ze and Ze-GA fiber mats increased tremendously after the heat-curing process. Changes in the amide II bands and CH_2 stretch modes were observed in the heat-cured electrospun fiber mats as indicated by the ATR-FTIR spectra. All the electrospun fiber mats exhibited characteristic of α-helix rich protein. The α-helix and β-sheet contents of Ze-GA fibers were found to increase at the expense of β-turn and random coil after the heat-curing process. No major chemical shifts were observed among the ^{13}C NMR spectra, yet the difference in the resonance intensities among the electrospun fibers implied the presence of different chemical environment between the electrospun fiber systems before and after heat curing. Current studies provide a base for further assessment of the thermal treatment of protein based electrospun fibers. Further studies on the elucidation of Ze and Ze-GA structure are essential to complement the investigation. The new properties exhibited by the heat-cured gallic acid loaded zein electrospun fibers will offer potential to develop new protein based nanostructured electrospun fibers for food packaging or food-contact materials with enhanced properties.
