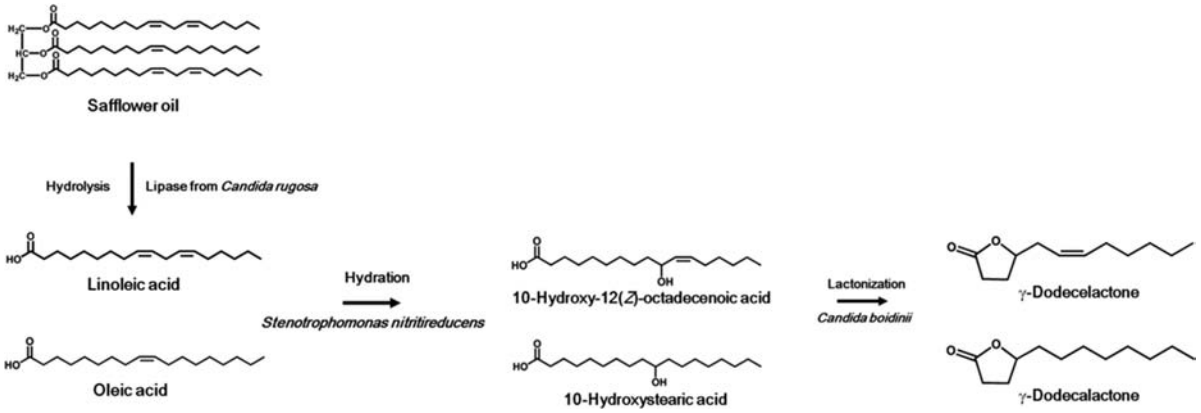

Figure 1. Production of γ-lactones from safflower oil by lipase and whole cells of *S. nitritireducens* and *C. boidinii* via fatty acids and hydroxy fatty acids.

MATERIALS AND METHODS

Materials. Safflower oil and γ-dodecelactone were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA) and Penta International (West Caldwell, NJ, USA), respectively. γ-Dodecalactone, lipase from *Candida rugosa*, and fatty acids, including linoleic acid, oleic acid, and palmitic acid, were purchased from Sigma (St. Louis, MO, USA).

Preparation of Hydroxy Fatty Acids. 10-Hydroxystearic acid was produced by the reaction of whole recombinant *Escherichia coli* cells expressing oleate hydratase from *Stenotrophomonas maltophilia*.[21] The reaction was performed in 50 mM citrate/phosphate buffer (pH 6.5) containing 50 g/L oleic acid, 10 g/L of *E. coli* cells, and 0.05% (w/v) Tween 40 at 35 °C for 4 h. 10-Hydroxy-12(*Z*)-octadecenoic acid was produced by the reaction of whole *S. nitritireducens* cells.[22] The reaction was performed in 50 mM Tris-HCl buffer (pH 7.5) containing 20 g/L linoleic acid, 20 g/L of *S. nitritireducens* cells, and 0.02% (w/v) Tween 80 at 30 °C for 2 h. 10-Hydroxystearic acid and 10-hydroxy-12(*Z*)-octadecenoic acid were prepared from the obtained reaction products by the following low-temperature solvent fractional crystallization.[9] An equal volume of ethyl acetate was added to the reaction products, and the ethyl acetate from the reaction mixture was removed using a rotary evaporator. The extract was mixed with 30% acetonitrile and 70% acetone at room temperature. The solution obtained was incubated at −80 °C for 24 h in a deep freezer. The liquid fraction containing the unsaturated fatty acid was separated at room temperature, and the remaining solid fraction containing hydroxy fatty acid was obtained. The acetonitrile and acetone in the solid fraction were removed using a rotary evaporator. This fractionation procedure was repeated three times, and the obtained products of 10-hydroxystearic acid and 10-hydroxy-12(*Z*)-octadecenoic acid with high purity (>99%) were identified by GC and GC-MS.[21,23] The two hydroxy fatty acids were used as the standard compounds for product analysis, and 10-hydroxy-12(*Z*)-octadecenoic acid was also used as a substrate for γ-dodecelactone production.

Microorganisms. The isolated strain *S. nitritireducens*[22] was used for 10-hydroxy-12(*Z*)-octadecenoic acid production from linoleic acid. *E. coli* ER2566 expressing oleate hydratase from *S. maltophilia* KCTC 1773 was used for the production of 10-hydroxystearic acid from oleic acid. *C. boidinii* KTCT 17776, *Candida palmioleophila* KTCT 17452, *Candida tropicalis* KTCT 7221, *Citeromyces matritensis* KTCT 17714, *Cryprococcus curvatus* KTCT 7225, *Saccharomyces cerevisiae* KTCT 7704, *Schizosaccharomyces pombe* KTCT 7167, *Sporobolomyces odorus* KTCT 17242, *Starmerella bombicola* KTCT 17652, *Waltomyces lipofer* KTCT 17657, and *Y. lipolytica* KTCT 17170 were used for γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid.

Media. *S. nitritireducens* was cultivated in nutrient broth containing 5 g/L peptone and 3 g/L beef extract. Recombinant *E. coli* cells were cultivated in Luria−Bertani (LB) agar. The growth medium was yeast malt (YM) broth containing 10 g/L glucose, 3 g/L malt extract, and 5 g/L peptone. The induction medium contained 5 g/L glucose, 7 g/L oleic acid, 0.1 g/L yeast extract, 2.1 g/L potassium phosphate monobasic, 4.51 g/L potassium phosphate dibasic, 0.1 g/L sodium chloride, 0.2 g/L magnesium sulfate, 9.14 mg/L iron sulfate heptahydrate, 0.5 mg/L zinc chloride, and 1.56 mg/L copper sulfate. The reaction medium contained 50 mM citrate/phosphate buffer (pH 5.5), 3.4 g/L yeast nitrogen base, 0.5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, and 0.05% (w/v) Tween 80.

Culture and Reaction Conditions. The cells were cultivated on the YM agar plate. After 1 day, a single colony in the plate was inoculated into 15 mL of the growth medium and cultivated at 30 °C with agitation at 200 rpm for 12 h. The seed culture was then transferred into a 2 L baffled flask containing 500 mL of the induction medium and was cultivated at 30 °C with agitation at 200 rpm for 15 h. The cells from the culture medium were harvested by centrifugation at 13000*g* for 20 min at 4 °C and then were washed twice with 50 mM citrate/phosphate buffer (pH 5.5). The harvest cells were used for γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid. Unless otherwise stated, the biotransformation reaction was performed in a 500 mL-baffled flask containing 100 mL of the reaction medium at pH 5.5 and 25 °C with agitation of 200 rpm for 3 h. For lactonization, the pH of the reaction solution was adjusted to 2.0 by adding 6M HCl and then incubated at 100 °C for 30 min.[9,10,14]

Selection of Inducer and Determination of Induction Process. Fatty acids and hydroxy fatty acids, including lauric acid, stearic acid, oleic acid, erucic acid, linoleic acid, 10-hydroxydecanoic acid, and 10-hydroxystearic acid, were used as inducers for the β-oxidation pathway. To select inducer, *C. boidinii* cells were cultivated in the induction medium supplemented with 7 g/L inducer. The effect of inducer on γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid was investigated using whole *C. boidinii* cells, and thus the best inducer oleic acid was selected. To determine the concentration of oleic acid for increased γ-dodecelactone production, the concentration of oleic acid was varied from 0 to 15 g/L in the induction medium containing 5 g/L glucose. To determine the optimal concentration of glucose, the concentration of glucose was varied from 1 to 15 g/L in the induction medium containing 7 g/L oleic acid. The cells were cultivated at 30 °C with agitation at 200 rpm for 15 h. To determine the induction time for the increased activity of β-oxidation, the cells were cultivated in the induction medium containing 5 g/L glucose and 7 g/L oleic acid at 30 °C with agitation at 200 rpm for 24 h. Samples were withdrawn at several intervals within 24 h. *C. boidinii* cells obtained from the cultures were harvested, and γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid using the harvested cells was conducted at 30 °C and pH 5.5 for 3 h.

Effects of pH and Temperature on γ-Dodecelactone Production. The effect of pH on γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid by whole *C. boidinii* cells was evaluated by varying the pH from 4.0 to 6.5 in 50 mM citrate/phosphate buffer while a constant temperature of 25 °C was maintained. To evaluate the effect of temperature, the temperature

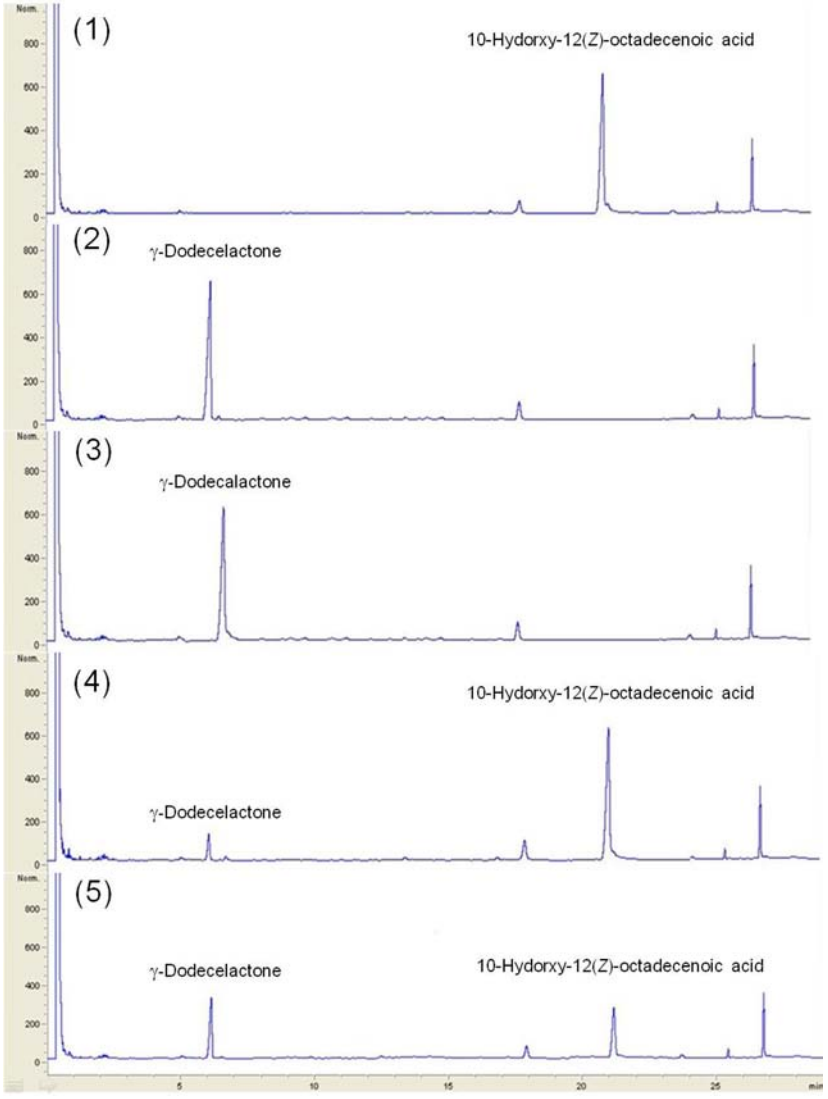

Figure 2. Gas chromatograms of 10-hydroxy-12(*Z*)-octadecenoic acid, γ-dodecelactone, and γ-dodecalactone. The reaction of whole *C. boidinii* cells was performed in 50 mM citrate/phosphate buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, 30 g/L cells, and 0.05% (w/v) Tween 80 at 25 °C with agitation of 200 rpm. (1) Gas chromatogram of 10-hydroxy-12(*Z*)-octadecenoic acid standard. The retention time of 10-hydroxy-12(*Z*)-octadecenoic acid was 21.1 min. (2) Gas chromatogram of γ-dodecelactone standard. The retention time of γ-dodecelactone was 6.1 min. (3) Gas chromatogram of γ-dodecalactone standard. The retention time of γ-dodecalactone was 6.7 min. (4) Gas chromatogram of the reaction solution at 3 h. (5) Gas chromatogram of the reaction solution at 6 h.

was varied from 15 to 35 °C while the pH was constantly maintained at 5.5. The reactions were performed under the above-described standard reaction conditions; only the pH and temperature were varied.

Effects of Cell and Substrate Concentrations on γ-Dodecelactone Production. The optimal concentrations of cells and substrate for the increased production of γ-dodecelactone from 10-hydroxy-12(*Z*)-octadecenoic acid by whole *C. boidinii* cells were determined by varying the cell concentration from 5 to 40 g/L at a constant 10-hydroxy-12(*Z*)-octadecenoic acid concentration of 5 g/L and by varying the substrate concentration from 2.5 to 15 g/L at a constant cell concentration of 30 g/L. The reactions were performed under the above-described standard reaction conditions; only the cell and substrate concentrations were varied.

Production of γ-Dodecelactone from 10-Hydroxy-12(*Z*)-octadecenoic Acid. γ-Dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acids by whole *C. boidinii* cells was performed in 50 mM citrate/phosphate buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, 30 g/L cells, and 0.05% (w/v) Tween 80 at 25 °C for 8 h.

Production of γ-Lactones from Safflower Oil. The hydrolysis of fatty acids from safflower oil by lipase from *C. rugosa* was carried out in 50 mM Tris-HCl buffer (pH 7.5) containing 7.5 g/L safflower oil, 1 g/L lipase, and 0.02% (w/v) Tween 80 at 37 °C for 30 min. To inactivate the lipase and arrest the reaction, the reaction solution was boiled at 100 °C for 50 min.[24] The production of hydroxy fatty acids by whole cells of *S. nitritireducens* was conducted in 50 mM Tris-HCl buffer (pH 7.5) containing the hydrolysate obtained from 7.5 g/L safflower oil, 20 g/L cells, and 0.02% (w/v) Tween 80 at 30 °C with agitation at 200 rpm for 90 min, under anaerobic conditions.[22] An equal volume of ethyl acetate was added to the cell reaction solution, the ethyl acetate from the reaction mixture was removed using a rotary evaporator, and the concentration of 10-hydroxy-12(*Z*)-octadecenoic acid in the reaction solution was adjusted to 5.0 g/L by dissolving the residue for the production of γ-lactones. The time course reactions for the production of γ-lactones by whole *C. boidinii* cells were carried out in 50 mM citrate/phosphate buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 5.0 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, 0.85 g/L 10-hydroxystearic acid, 0.27 g/L linoleic acid, 0.07 g/L oleic acid, 0.31

g/L palmitic acid, 30 g/L cells, and 0.05% (w/v) Tween 80 at 25 °C for 7 h.

Analytical Methods. The cell mass was determined by calibrating the optical density at 600 nm to the dry cell weight. The concentration of glucose in the medium was analyzed using a glucose assay kit (Asan Pharm, Seoul, South Korea). Heptadecanoic acid at 50 mM was used as an internal standard. The silylation of linoleic acid, oleic acid, palmitic acid, 10-hydroxy-12(*Z*)-octadecenoic acid, and 10-hydroxystearic acid was conducted by mixing pyridine and *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide with a ratio of 3:1. Silylated fatty acids, silylated hydroxy fatty acids, and γ-lactones were analyzed by a gas chromatography (Agilent 7890 N, Santa Clara, CA, USA) with a flame ionization detector and a Supelco SPB-1 capillary column. The column temperature was increased from 100 to 220 °C at the rate of 5 °C/min for 24 min, and then it was maintained at 220 °C. The injector and detector temperatures were maintained at 260 and 250 °C, respectively. γ-Dodecelactone (ring form), γ-dodecalactone, γ-dodecelactone (open form), palmitic acid, linoleic acid, oleic acid, 10-hydroxy-12(*Z*)-octadecenoic acid, and 10-hydroxystearic acid were detected on the basis of their retention times of 6.1, 6.7, 10.8, 14.3, 17.3, 17.9, 21.1, and 21.8 min, respectively. The γ-lactones, fatty acids, and hydroxy fatty acids in the reaction samples after hydrolysis of safflower oil and γ-dodecelactone and 10-hydroxy-12(*Z*)-octadecenoic acid in the reaction samples of whole *C. boidinii* cells containing 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid were identified to have the same retention times as those of their corresponding standards. The amounts of the products were calculated by calibrating the peak areas to the concentrations of γ-lactones, fatty acids, and hydroxy fatty acid standards.

RESULTS AND DISCUSSION

Selection of an Efficient γ-Dodecelactone-Producing Strain. In the GC profiles, the peaks for the substrate and the product obtained from the reaction solutions of whole *C. boidinii* cells were detected at the same retention times as those of the 10-hydroxy-12(*Z*)-octadecenoic acid and γ-dodecelactone standards, respectively (Figure 2). The open and ring forms of γ-dodecelactone in the reaction solutions of whole *C. boidinii* cells before and after acidification were analyzed by the GC. The open and ring forms of γ-dodecelactone before acidification were detected (Supporting Information Figure S1A). The open and ring forms of γ-dodecelactone were distinguishable from each other, showing different retention times in the GC profile. However, after acidification, the open form of γ-dodecelactone was converted to the ring form, and then it disappeared (Supporting Information Figure S1B).

The yeast *Sporobolomyces odorus*[25] and the fungi *Fusarium poae*[5,26] and *P. roqueforti*[20] have been reported to produce γ-dodecelactone. However, the yield of γ-dodecelactone produced by these microorganisms was very low. To obtain an efficient γ-dodecelactone-producing strain, 11 yeast strains were screened for γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid. Seven of the 11 yeast strains exhibited γ-dodecelactone-producing activity, and the efficiency of production was in the following order: *C. boidinii* > *C. curvatus* > *C. palmioleophila* > *S. bombicola* > *Y. lipolytica* > *S. odorus* > *S. cerevisiae*. However, *C. tropicalis*, *C. matritensis*, *S. pombe*, and *W. lipofer* did not produce γ-dodecelactone (Figure 3). The activity of *C. boidinii*, which was approximately 10-fold higher than that of the known γ-dodecelactone-producing stain *S. odorus*, was the highest among the 11 yeast strains. Thus, *C. boidinii* was selected as an efficient γ-dodecelactone-producing yeast and was used for γ-dodecelactone production. *C. boidinii* has been known to produce saturated lactones such as γ-dodecalactone and δ-dodecalactone.[27,28] However, the production of the monounsaturated lactone γ-dodecelactone by *C. boidinii* has not been reported yet.

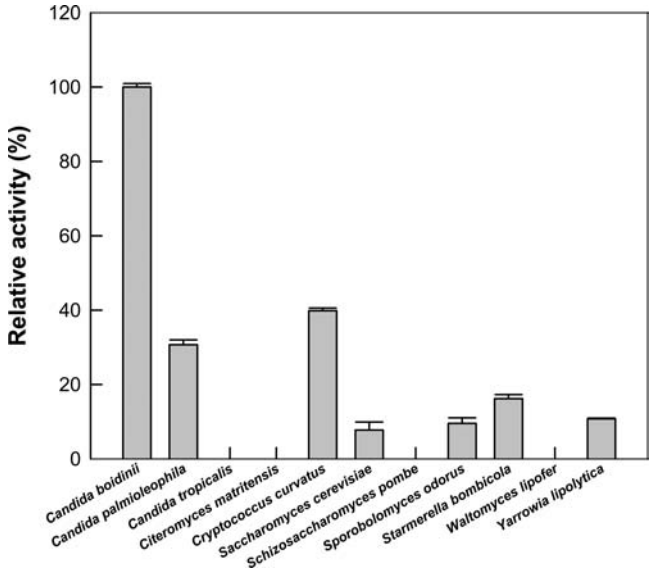

Figure 3. γ-Dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid by whole cells of the yeast strains. The reactions were performed in 50 mM citrate/phosphate buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 5 g/L cells, 0.5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, and 0.05% (w/v) Tween 80 at 25 °C with agitation at 200 rpm for 3 h. The data represent the means of three separate experiments, and error bars represent the standard deviation.

Induction of *C. boidinii* Cells for the Increased Production of γ-Dodecelactone from 10-Hydroxy-12(*Z*)-octadecenoic Acid. *C. boidinii* was cultivated in the induction medium supplemented with 7 g/L inducer, and then the induced whole cells were used in the reactions for γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid for 3 h. The inducers tested included lauric acid, stearic acid, oleic acid, linoleic acid, erucic acid, 10-hydroxydecanoic acid, and 10-hydroxystearic acid. The activity of *C. boidinii* cells for γ-dodecelactone production followed the order oleic acid > stearic acid > erucic acid > control (with no addition of inducer) > linoleic acid >10-hydroxystearic acid > 10-hydroxydecanoic acid (Figure 4A).

The maximum production of γ-lactones by *W. lipofer* was observed at 5 g/L oleic acid as an inducer.[9] Thus, the concentration of oleic acid was varied from 0 to 15 g/L for γ-dodecelactone production using *C. boidinii* cells. The γ-dodecelactone-producing activity was the highest when oleic acid was used as an inducer at a concentration of 7 g/L (Figure 4B). γ-Dodecelactone production by the cells induced with 7 g/L oleic acid was 2.2-fold higher than that by the noninduced cells. The concentration of glucose as an additional carbon source for the maximum production of γ-lactones by *W. lipofer* was 1 g/L,[9] and the growth medium of *C. boidinii*, which was yeast malt (YM) broth, contained 10 g/L glucose. Thus, glucose at various concentrations from 1 to 15 g/L was added to the induction medium containing 7 g/L oleic acid for increasing the activity for γ-dodecelactone production. The optimal concentration of glucose for γ-dodecelactone production was 5 g/L (Figure 4C). To decide the induction time, *C. boidinii* cells were cultivated in the induction medium for 24 h. A sample was withdrawn at regular time points, and γ-

dx.doi.org/10.1021/jf501081z | J. Agric. Food Chem. 2014, 62, 6736−6745

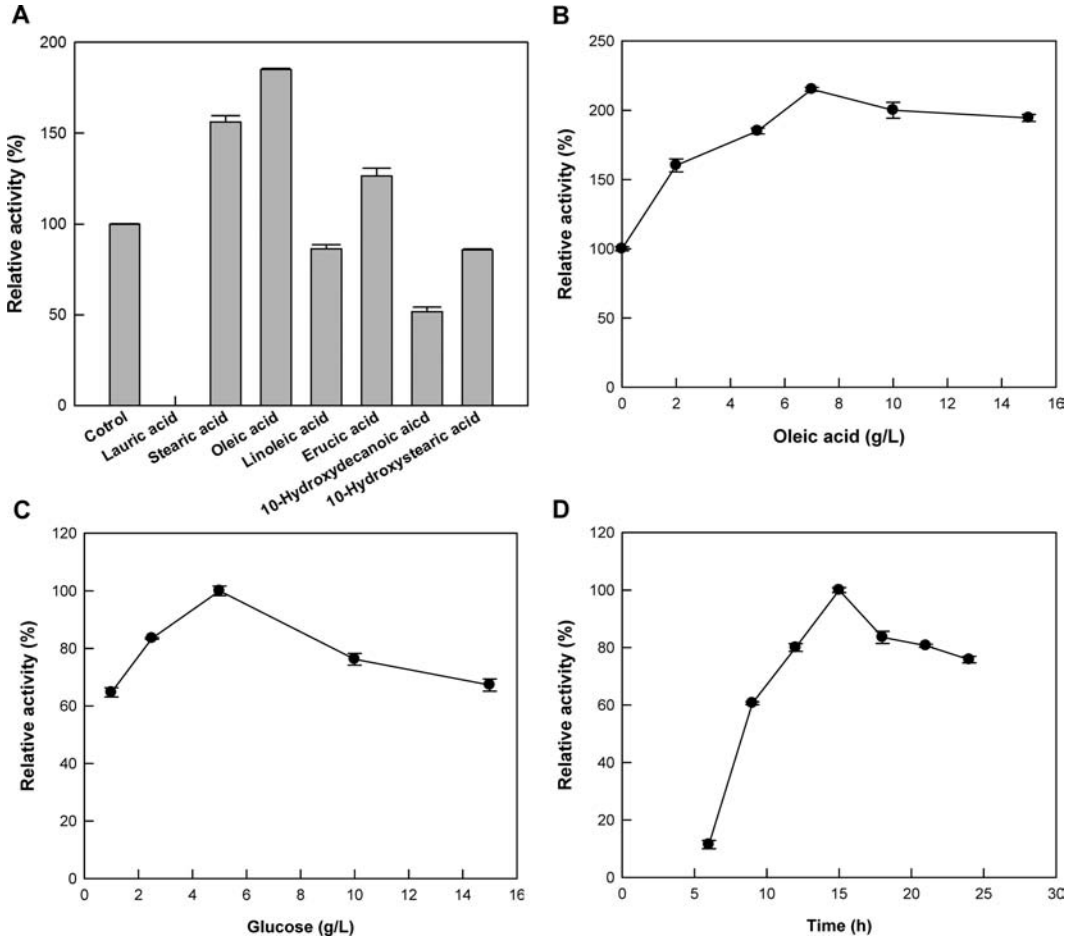

Figure 4. Induction of *C. boidinii* cells for increasing γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid. After induction, the reactions were performed in 50 mM citrate/phosphate buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 5 g/L cells, 0.5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, and 0.05% (w/v) Tween 80 at 25 °C with agitation at 200 rpm for 3 h. (A) Effect of inducer type. *C. boidinii* cells were grown on the induction medium containing 7 g/L inducer. The control reaction was γ-dodecelactone production by cells that were cultivated in the growth medium without the inducer. (B) Effect of oleic acid concentration. *C. boidinii* cells were cultivated in the induction medium by varying the concentration of oleic acid from 0 to 15 g/L. (C) Effect of glucose concentration. *C. boidinii* cells were cultivated in the induction medium by varying the concentration of glucose from 1 to 15 g/L. (D) Effect of induction time. *C. boidinii* cells were cultivated in the induction medium containing 7 g/L oleic acid and 5 g/L glucose for 24 h. Samples were withdrawn within 24 h at several intervals. The data represent the means of three separate experiments, and error bars represent the standard deviation.

dodecelactone-producing activity of *C. boidinii* was determined. The maximum γ-dodecelactone-producing activity was observed at 15 h of induction time (Figure 4D). Therefore, *C. boidinii* cells grown on the induction medium containing 7 g/L oleic acid and 5 g/L glucose for 15 h of induction time were used for γ-dodecelactone production. Under these induction conditions, γ-dodecelactone production by the induced cells was 14-fold higher than that by the noninduced cells.

Fatty acids have been used as inducers of the β-oxidation pathway.[29−31] Among the fatty acids, oleic acid has been determined to be the most effective inducer[9,32,33] of the enzymes related to the β-oxidation pathway of yeast.[34,35] High glucose concentrations repress the enzymes related to the β-oxidation pathway,[36,37] whereas low glucose concentrations stimulate the β-oxidation pathway.[9] When *W. lipoper* cells were induced, the induction time (12 h) in the medium containing oleic acid and glucose for the increased activity of β-oxidation was 4 h of progress time after glucose exhaustion (8 h).[9] In the induction of *C. boidinii* cells, glucose was exhausted at 12 h, and induction time for the increased activity of β-oxidation (15 h) was 3 h of progress time after glucose exhaustion. The activity of *C. boidinii* cells for γ-dodecelactone production appeared to be maximal at 3−4 h of progress time after glucose exhaustion.

Determination of the Reaction Conditions for the Increased Production of γ-Dodecelactone from 10-Hydroxy-12(*Z*)-octadecenoic Acid by Induced *C. boidinii* Cells. The reaction conditions for saturated γ-lactone production have been investigated.[9,14,38,39] However, to the best of our knowledge, the reaction conditions for unsaturated γ-lactone production have not been investigated. Therefore, the pH, temperature, and concentrations of cells and substrate for γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid were investigated using induced whole *C. boidinii* cells. The maximal activity for γ-dodecelactone production from 10-hydroxy-12(*Z*)-octadecenoic acid was observed at pH 5.5 and 25 °C (Figure 5). γ-Lactone production was performed at pH 6.5 and 35 °C by *W. lipofer*[40] and at pH 7.0 and 25 °C by baker's yeast.[41]

The concentrations of whole *W. lipofer* cells for the maximum production of γ-dodecalactone[14] and γ-lactones[9] were 30 and 20 g/L, respectively. To determine the concentration of whole *C. boidinii* cells for the maximal

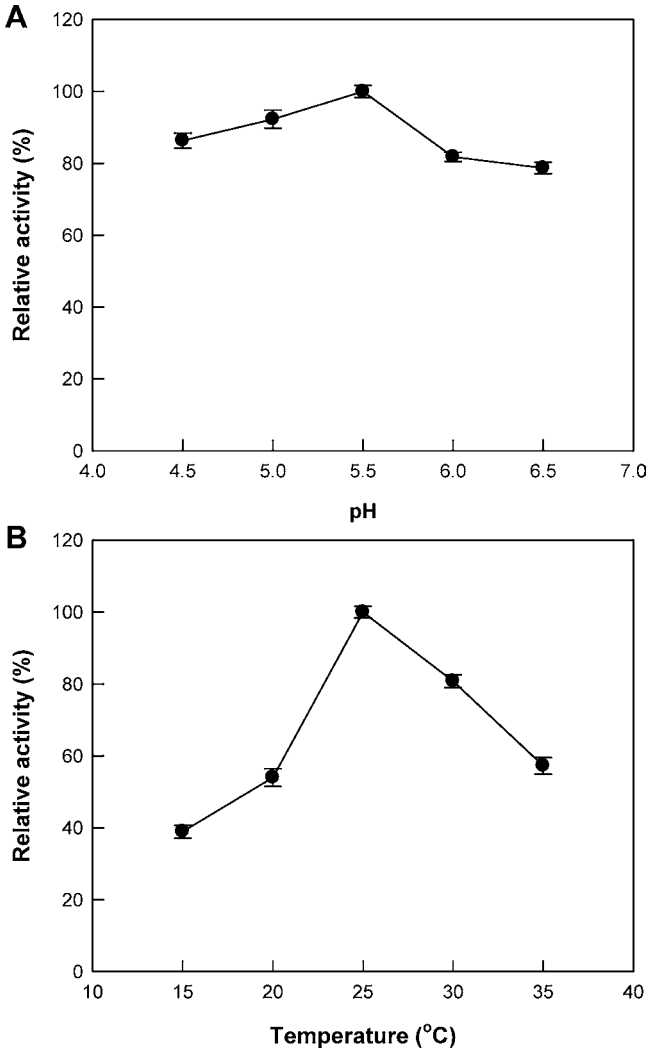

Figure 5. Effects of pH and temperature on the production of γ-dodecelactone from 10-hydroxy-12(*Z*)-octadecenoic acid by whole *C. boidinii* cells. The data represent the means of three separate experiments, and error bars represent the standard deviation. (A) Effect of pH. The reactions were performed by varying the pH from 4.0 to 6.5 in 50 mM citrate/phosphate buffer containing 3.4 g/L yeast nitrogen base, 5 g/L cells, 0.5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, and 0.05% (w/v) Tween 80 at 25 °C with agitation at 200 rpm for 3 h. (B) Effect of temperature. The reactions were performed by varying the temperature from 15 to 35 °C in 50 mM citrate/phosphate buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 5 g/L cells, 0.5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, and 0.05% (w/v) Tween 80 with agitation at 200 rpm for 3 h.

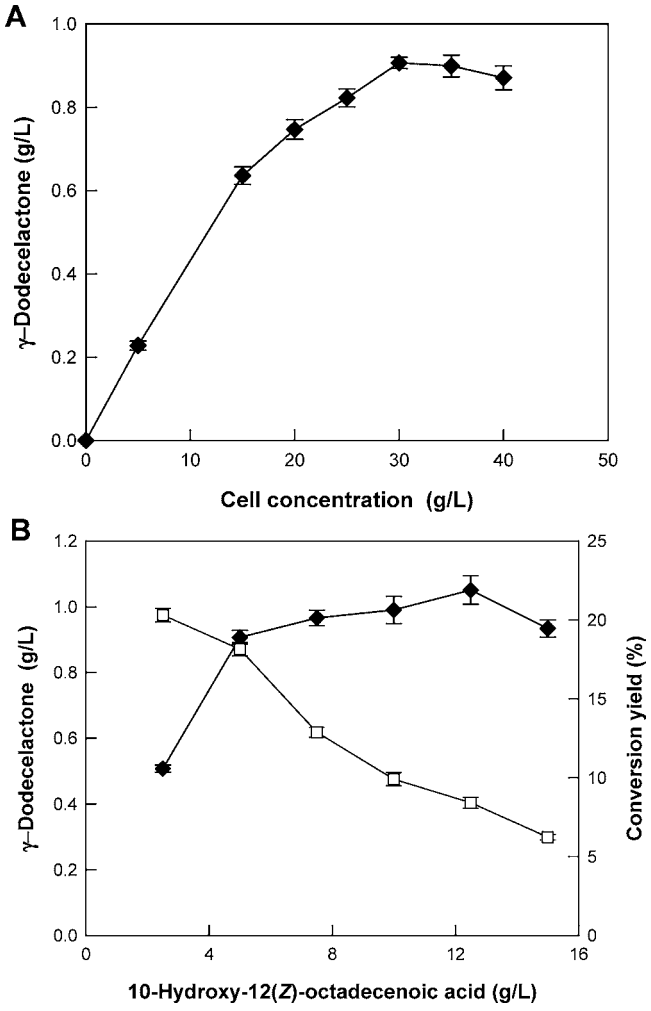

Figure 6. Effects of the concentrations of cells and substrate on the production of γ-dodecelactone from 10-hydroxy-12(*Z*)-octadecenoic acid. The data represent the means of three separate experiments, and error bars represent the standard deviation. (A) Effect of the concentration of cells. The reactions were performed by varying the cell concentration from 5 to 40 g/L in 50 mM citrate/phosphate buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, and 0.05% (w/v) Tween 80 at 25 °C with agitation at 200 rpm for 3 h. (B) Effect of substrate concentration: production (◆) and conversion yield (□) of γ-dodecelactone from 10-hydroxy-12(*Z*)-octadecenoic acid. The reactions were performed by varying the concentration of 10-hydroxy-12(*Z*)-octadecenoic acid from 2.5 to 15 g/L in 50 mM citrate/phosphate buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 30 g/L cells, and 0.05% (w/v) Tween 80 at 25 °C with agitation at 200 rpm for 3 h.

production of γ-dodecelactone, the concentration of the induced cells was varied from 5 to 40 g/L using 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid as a substrate for 3 h (Figure 6A). Below 30 g/L cells, 10-hydroxy-12(*Z*)-octadecenoic acid production increased with increasing cell concentration; however, above 30 g/L, it reached a plateau. As the cell concentration was higher than 30 g/L, the high viscosity of the reaction solution interfered with mass transfer in the aqueous phase, resulting in the conversion rate decreased. These results indicated that the cell concentration for the maximal production of γ-dodecelactone was 30 g/L.

The concentration of saturated hydroxy fatty acids, including 10-hydroxystearic acid, 12-hydroxystearic acid, and 12-hydroxydodecanoic acid, for the maximum production of saturated lactones, including γ-dodecalactone, γ-decalactone, and γ-butyrolactone, respectively, was 60 g/L.[9,14] The antimicrobial activities of monounsaturated hydroxy fatty acids were significantly higher than those of saturated hydroxy fatty acids.[42] Thus, the production of the monounsaturated lactone γ-dodecelactone was investigated with the range of low concentrations for 10-hydroxy-12(*Z*)-octadecenoic acid as a substrate from 2.5 to 15 g/L using 30 g/L cells for 3 h (Figure 6B). At concentrations below 12 g/L 10-hydroxy-12(*Z*)-octadecenoic acid, γ-dodecelactone production increased with increasing concentration of 10-hydroxy-12(*Z*)-octadecenoic acid. However, the conversion yield decreased as the concentration of substrate increased. This may be due to the

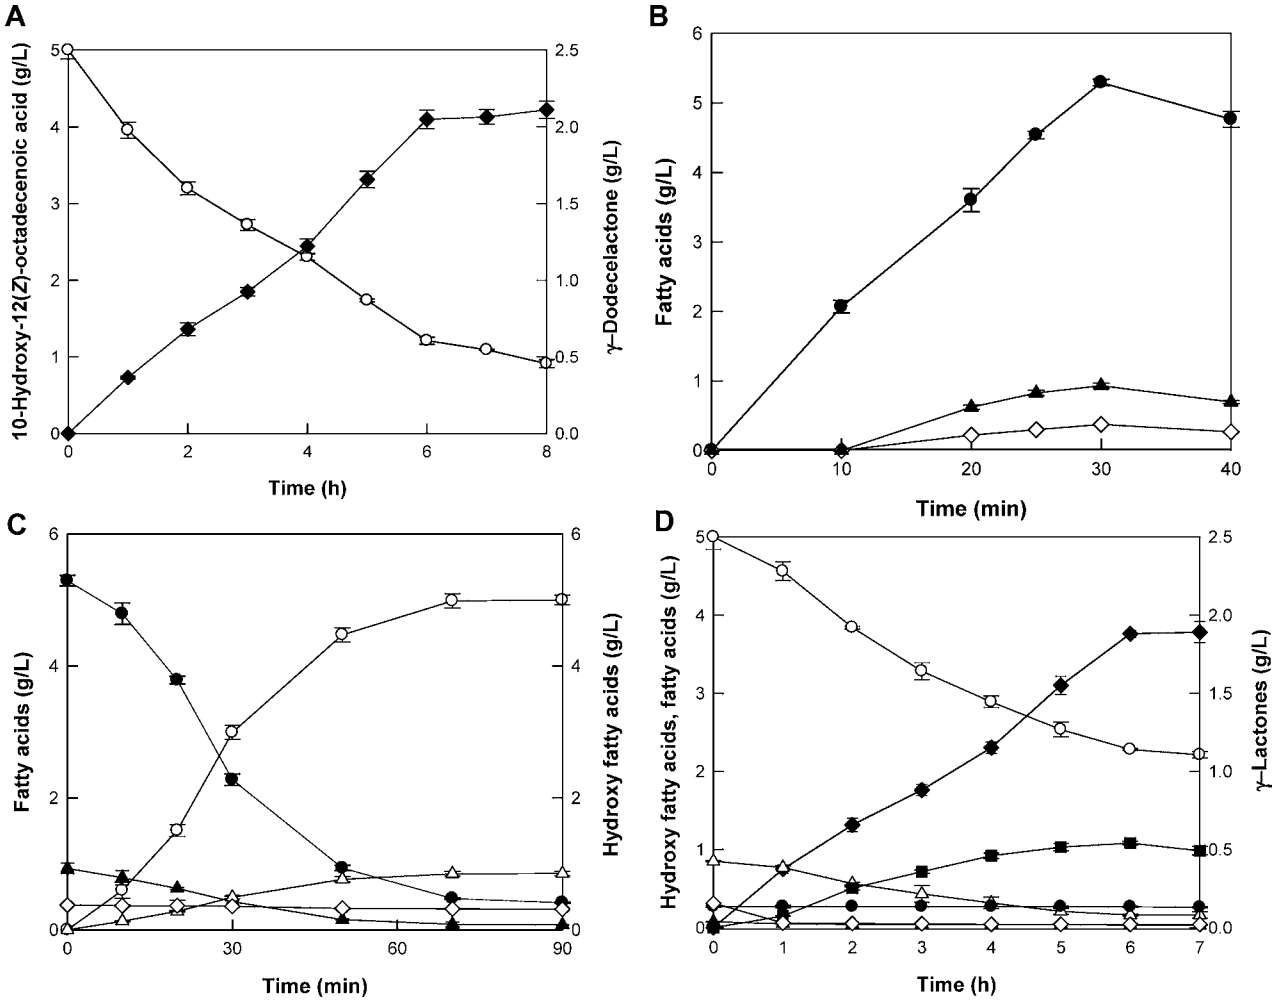

Figure 7. Time course reactions for the production of fatty acids, hydroxy fatty acids, and γ-lactones by lipase, *S. nitritireducens*, and *C. boidinii*, respectively. The data represent the means of three separate experiments, and error bars represent the standard deviation. (A) Production of γ-dodecelactone from 10-hydroxy-12(*Z*)-octadecenoic acid by whole *C. boidinii* cells. The reactions for the production of γ-dodecelactone (◆) were performed in 50 mM citrate/phosphate buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 30 g/L cells, 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid (○), and 0.05% (w/v) Tween 80 at 25 °C with agitation at 200 rpm for 8 h. (B) Production of fatty acids from safflower oil by lipase from *C. rugosa*. Fatty acids were linoleic acid (●), oleic acid (▲), and palmitic acid (◇). The reactions were performed in 50 mM Tris-HCl buffer (pH 7.5) containing 1 g/L lipase, 7.5 g/L safflower oil, and 0.02% (w/v) Tween 80 at 37 °C with agitation at 200 rpm for 40 min. (C) Production of hydroxy fatty acids from fatty acids by whole *S. nitritireducens* cells. Linoleic acid (●) and oleic acid (▲) were converted to 10-hydroxy-12(*Z*)-octadecenoic acid (○) and 10-hydroxystearic acid (△), respectively, by whole *S. nitritireducens* cells. However, palmitic acid (◇) was not converted. The reactions were performed in 50 mM Tris-HCl buffer (pH 7.5) containing safflower oil hydrolysate, 20 g/L cells, and 0.02% (w/v) Tween 80 at 30 °C with agitation at 200 rpm for 90 min under anaerobic conditions. (D) Production of γ-lactones from hydroxy fatty acids by whole *C. boidinii* cells. The cells well-consumed oleic acid (▲) and linoleic acid (●); however, they poorly consumed palmitic acid (◇). The reactions for the production of γ-dodecelactone (◆) and γ-dodecalactone (■) were performed in 50 mM Tris-HCl buffer (pH 5.5) containing 3.4 g/L yeast nitrogen base, 30 g/L cells, 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid (○), 0.85 g/L 10-hydroxystearic acid (△), and 0.05% (w/v) Tween 80 at 25 °C with agitation at 200 rpm for 7 h.

antimicrobial activity of 10-hydroxy-12(*Z*)-octadecenoic acid to cells.[42] Therefore, a substrate concentration of 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid for γ-dodecelactone production was selected as a suitable concentration to improve the performance in terms of both conversion yield and product concentration.

Production of γ-Dodecelactone from 10-Hydroxy-12(*Z*)-octadecenoic Acid by Induced *C. boidinii* Cells. The reaction conditions for the increased production of γ-dodecelactone by whole *C. boidinii* cells were pH 5.5 and 25 °C with 30 g/L cells and 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid. Under these conditions, induced *C. boidinii* cells produced 2.1 g/L (10.7 mM) γ-dodecelactone from 5 g/L (16.7 mM) 10-hydroxy-12(*Z*)-octadecenoic acid after 6 h, with a molar conversion yield of 64% (corresponding to 42%, w/w) and a volumetric productivity of 350 mg/L/h (Figure 7A). After 8 h, the production of γ-dodecelactone was observed to decrease, because γ-dodecelactone was degraded by the cells.[43] Yeast cells consume γ-lactones as carbon source by extensive β-oxidation degradation,[43] and γ-lactones are thus converted to viable biomass for longer cell maintenance.[44,45]

Production of γ-Dodecelactone from Lipase-Treated Safflower Oil by Two-Step Whole-Cell Biotransformation. γ-Dodecelactone production from safflower oil as a substrate via 10-hydroxy-12(*Z*)-octadecenoic acid intermediate was performed by an enzymatic hydrolysis reaction and a two-

[a]Productivity included the preparation time of whole cells.

step whole-cell biotransformation process. The conversion yield and productivity at each step during the conversion reactions are presented in Table 1. Natural safflower oil was hydrolyzed by lipase from *C. rugosa* because *S. nitritireducens* could not perform the hydroxylation of safflower oil. The reactions for the oil hydrolysis were performed using 7.5 g/L safflower oil and 1 g/L lipase at pH 7.5, 35 °C, and 200 rpm for 40 min (Figure 7B). At 30 min, safflower oil hydrolysate contained 5.3 g/L linoleic acid, 0.93 g/L oleic acid, and 0.37 g/L palmitic acid. After 30 min, the contents of these fatty acids decreased with increasing reaction time because lipase could catalyze the reverse reaction.[46] Therefore, the reactions were terminated at 30 min.

The first cell biotransformation step for γ-dodecelactone production from lipase-treated safflower oil hydrolysate was the conversion of unsaturated fatty acids into hydroxy fatty acids by hydrating the double bond in the unsaturated fatty acids from water.[47] The maximum production of hydroxy fatty acid by whole *S. nitritireducens* cells was observed at pH 7.5, 30 °C, and 20 g/L cells, under anaerobic conditions.[22] Under these conditions, *S. nitritireducens* cells converted 5.3 g/L linoleic acid and 0.93 g/L oleic acid in the hydrolysate obtained from 7.5 g/L safflower oil into 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid and 0.85 g/L 10-hydroxystearic acid after 90 min, respectively (Figure 7C), with molar conversion yields of 89 and 86% and volumetric productivities of 3333 and 567 mg/L/h, respectively (Table 1).

The second cell biotransformation step was the conversion of hydroxy fatty acids into γ-lactones by the induced whole *C. boidinii* cells. Under the conditions of pH 5.5 and 25 °C with 30 g/L cells and 5 g/L 10- hydroxy-12(*Z*)-octadecenoic acid, the induced *C. boidinii* cells produced 1.88 g/L γ-dodecelactone and 0.54 g/L γ-dodecalactone from 5 g/L 10-hydroxy-12(*Z*)-octadecenoic acid and 0.85 g/L 10-hydroxystearic acid after 6 h, respectively (Figure 7D), with conversion yields of 57 and 96% (mol/mol) and volumetric productivities of 313 and 90 mg/L/h, respectively (Table 1). The cells well-consumed oleic acid and linoleic acid; however, they poorly consumed palmitic acid. The total concentration of the two γ-lactones produced from 7.5 g/L safflower oil by an enzymatic hydrolysis reaction and a two-step whole-cell biotransformation process was 2.42 g/L for 8 h of the reaction time, with a volumetric productivity of 303 mg/L/h and a conversion yield of 32% (w/w). Several rounds of biotransformation reusing whole *S. nitritireducens* and *C. boidinii* cells were performed (Supporting Information Figure S2). The activities of the cells were decreased with increasing number of reuse and then showed 11 and 24% after the fourth batch, respectively. Thus, the hydration activity of *S. nitritireducens* and the β-oxidation activity *C. boidinii* cells are unstable.

The conversion yield and productivity of γ-lactones from oil are summarized in Table 2. The reported volumetric productivities of γ-decalactone from castor oil were 4 mg/L/h,[48] 10 mg/L/h,[15] and 6 mg/L/h.[16] The conversion yield and productivity of γ-dodecelactone using soybean oil were 0.00036% (w/w) and 0.025 mg/L/h, respectively, and those using copra oil were 0.0003% (w/w) and 0.0125 mg/L/h, respectively.[20] These yields and productivities were very low. In the present study, 1.88 g/L γ-dodecelactone was produced from 7.5 g/L safflower oil for 8 h of reaction time, with a conversion

dx.doi.org/10.1021/jf501081z | J. Agric. Food Chem. 2014, 62, 6736−6745

yield of 25% (w/w) and a volumetric productivity of 235 mg/L/h. The time to prepare whole *S. nitritireducens* and *C. boidinii* cells was 21 and 15 h, respectively. Thus, the total time to produce γ-dodecelactone from safflower oil, including the preparation time of whole cells, was 44 h. The volumetric productivity calculated from the total time was 43 mg/L/h. These conversion yield and productivity values of γ-dodecelactone from oil were 69400- and 4.3-fold higher than the previously reported highest conversion yield and productivity, respectively. These results indicate that the two-step whole cell biotransformation process via hydroxy fatty acid intermediate is an efficient method for increasing γ-lactone production from oil. A process developed in this study for the production of γ-dodecelactone from safflower oil contained an enzymatic reaction plus two-step biotransformation. The first step was the hydrolysis of safflower oil, the second step was the hydration of fatty acid, and the third step was the lactonization of hydroxy fatty acid. In the second step, the reaction was performed using oil hydrolysate obtained from the first step by adding *S. nitritreducens* cells without additional extraction or purification. In the third step, the reaction was performed using the extracted solution after the reaction solution obtained from the first step by adding *C. boidinii* cells with extraction to adjust the concentration of hydroxy fatty acid and without purification. In the industrial and large-scale production, this extraction can be omitted. The process containing an enzymatic reaction plus two-step biotransformation can be performed without extraction and purification by only adding enzyme and cells. Therefore, the process is not too complex for industrial and large-scale production.

In conclusion, the production of the flavor γ-dodecelactone from safflower oil was demonstrated via an enzymatic hydrolysis reaction and a two-step whole cell biotransformation process. Lipase-treated safflower oil hydrolysate containing linoleic acid was converted into 10-hydroxy-12(*Z*)-octadecenoic acid by whole *S. nitritireducens* cells and was subsequently converted to γ-dodecelactone by induced whole *C. boidinii* cells. To the best of our knowledge, our bioprocess exhibits the highest productivity and yield of γ-lactone produced from a natural oil reported to date. Thus, the two-step whole cell biotransformation process via the intermediate hydroxy fatty acid may be useful in lactone production from oils.

U.S. Food and Drug Administration (FDA). Sulfite-containing compounds including sodium sulfite (GRAS 182.3798), sodium bisulfite (GRAS 182.3739), and sodium metabisulfite (GRAS 182.3766) are on the FDA's GRAS list. Sulfites are multipurpose compounds commonly used as calcium, potassium, or sodium salts in the food and pharmaceutical industries as preservatives or antioxidants. They are also used to slow food oxidation and can sometimes affect the smell and taste of foods.[26] Sulfite-containing compounds occur naturally in foods, such as garlic, onions, cheeses, and eggs, and drinks, such as wine, beer, and some teas.

Although they are generally considered safe, sulfites can cause contact dermatitis and have been highlighted as a cause of cosmetic allergy.[27−29] However, allergies to preservatives such as sodium sulfite and its derivatives are considered rare.[30,31] The FDA requires labeling when sulfites are used as preservatives in a final product; however, when sulfites are used in food-processing steps, labeling is required only when the sulfite residual is ≥10 ppm.[32] The use of sulfite-containing compounds on fresh fruits and vegetables was banned in 1986 because of potential allergic reactions, and those suffering from asthma are at elevated risk of sulfite sensitivity.[33] Nevertheless, sodium metabisulfite is currently included as a preservative in therapeutic epinephrine,[34] and according to the prescription information for EpiPen, sodium metabisulfite is included as a preservative in the epinephrine shot used to counteract a severe food allergy reaction. Each 0.3 mL dose from an EpiPen autoinjector contains 0.5 mg of sodium metabisulfite. Individuals suffering from sulfide oxidase deficiency are also sulfite sensitive because of their inability to convert sulfites to sulfates.[35]

The development of new, cost-effective processing methods that can lower or eliminate the ability of tree nuts and peanuts to cause allergic reactions is important for the prevention of severe reactions. The reaction between sulfite and cysteine disulfides within proteins is reversible at alkaline pH and has been shown to disrupt disulfide bonds of several proteins.[36] Standard protocols using sodium sulfite to break disulfide bonds, referred to as sulfitolysis, can be used to introduce a negative charge on modified cysteines.[37] Here, using cashew extracts and purified Ana o 3, we evaluated the ability of sodium sulfite to target cashew allergens having structure and stability that are dependent upon cysteine disulfide bonds. We assessed the effect of sulfite addition on the structure of cashew allergens and their innate capacity to bind IgE from cashew allergic individuals.

EXPERIMENTAL PROCEDURES

Materials. "Ready to eat" cashews were purchased from Nuts Online (http://www.nuts.com, Cranford, NJ, USA). Roasted cashews were prepared by heating "ready to eat" cashews in an oven at 177 °C for 20 min. Sodium sulfite and dithiothreitol (DTT) were purchased from Sigma-Aldrich (St. Louis, MO, USA), spin columns from Millipore (Carrigtwohill, CO, USA), SDS-PAGE Any kD Mini-Protean TGX precast Tris-glycine gels from Bio-Rad (Hercules, CA, USA), and Novex 4−20% Tris−glycine gels from Life Technologies (Carlsbad, CA, USA). Sequencing-grade modified trypsin from Promega (Madison, WI, USA) was used for sample digestion prior to mass spectrometry. Biotinylated anti-human IgE antibody was purchased from Southern Biotech (Birmingham, AL, USA). IRdye-680-labeled streptavidin, IRdye-680, and IRdye-800 secondary antibodies were purchased from LI-COR (Lincoln, NE, USA). Nonsterile Maxisorp 96-well Nunc microtiter plates were purchased from Thermo Scientific (Rochester, NY, USA).

Cashew Extract Preparation. Raw and roasted cashews were ground with a coffee grinder and defatted with petroleum ether in a Soxhlet apparatus overnight. Defatted cashew flour (0.4 g) was placed in 10 mL of 0.2 M Tris, 0.2 M NaCl, pH 8.0, and vortexed for 30 s and then sonicated twice on ice for 15 s using a Sonic Dismembrator (Fisher Scientific Co., Orlando, FL, USA). Extract solutions were centrifuged for 30 min at 12000 rpm at 4 °C, and clarified cashew extracts were collected. Protein concentrations were determined using a NanoDrop (ThermoFisher, Pittsburgh, PA, USA), and samples were stored at −20 °C.

SDS-PAGE. Proteins were resolved by SDS-PAGE with either a Mini Protean system II (Bio-Rad) or a Novex Mini Cell gel rig (Life Technologies) and prestained Precision Plus molecular weight markers (Bio-Rad). Prior to electrophoresis, 4× NuPAGE LDS sample buffer (Life Technologies) was added to the protein samples using a 1:4 (v/v) ratio. Samples were heated at 65 °C for 15 min, and after electrophoresis, protein bands were visualized with Safe Stain (Invitrogen, Grand Island, NY, USA). Gel images were captured, and normalization of protein load in each lane was confirmed by quantifying the 680 nm channel signal on an Odyssey CLX infrared imaging system (LI-COR).

Cashew Extract Treatment. Cashew extract (125 μg) was incubated with various concentrations of sodium sulfite (0−100 mM) and at different temperatures (0−100 °C) for 15 min. Control samples were heated with or without added 5 mM DTT. Sample aliquots were removed and combined with SDS-PAGE sample buffer lacking reducing agent prior to analysis with SDS-PAGE or immunoblotting.

Rabbit Antibodies. Rabbit antibody production was performed by Pierce Biotechnology Inc. (Rockford, IL, USA). Briefly, prescreened rabbits were immunized with 1 mg of cashew extract made from "ready to eat" cashew nuts and then boosted at days 14, 28, and 42 with 0.5 mg of cashew extract at each injection. Test rabbits were phlebotomized, and sera were screened for antibodies against total cashew protein. Large-volume phlebotomies were collected from high-titer rabbits, and serum was stored at −80 °C for later use.

Human Sera. Clinically relevant sera from cashew-allergic patients (from >7 to 55 years of age) with a documented history of cashew allergy supported by in vivo (skin test) or in vitro (serum immunoassay) cashew-specific IgE were collected at Dallas-Allergy Immunology (Dallas, TX, USA). The study protocol was approved by the North Texas Institutional Review Board.

Immunoblotting. Cashew extract samples (25 μg) treated with DTT, water, or sodium sulfite were subjected to SDS-PAGE (with loading buffer lacking reducing agent) and transferred to a PVDF membrane for Western blot or spotted (5 μg) on to PVDF membrane for dot-blot. Blotted PVDF (Millipore, Billerica, MA, USA) was blocked for 1 h at room temperature in PBST with 2% (w/v) nonfat dry milk. Rabbit anti-cashew antibody was diluted 1:1000 in PBST and incubated overnight at 4 °C. The membranes were then washed three times for 5 min in PBST and incubated for 30 min with anti-rabbit IRdye-680 (1:10000 in PBST) at room temperature. The membranes were washed as above and visualized using an Odyssey CLx (LI-COR) infrared imaging system. Immunoblotting for IgE (Western blot and dot blot) was performed overnight using similar methods with sera pooled from six cashew allergic patients. Membranes were washed as above and incubated for 1 h at room temperature with biotinylated anti-IgE (1:1000 in PBST). Membranes were then washed and incubated for 30 min at room temperature with IRdye-680-labeled streptavidin (1:5000 in PBST) and visualized with an Odyssey CLx instrument.

Circular Dichroism (CD). Ana o 3 was purified as described in Mattison et al.[16] Purified native and chemically treated Ana o 3 samples were analyzed by far-UV CD (185−250 nm) on a Jasco-815 spectropolarimeter (JASCO, Oklahoma City, OK, USA) as described previously[16] with minor changes. Briefly, treated Ana o 3 samples were buffer exchanged into 5 mM sodium phosphate (pH 6.8) with a 3 kDa spin column and then diluted to a protein concentration of 0.1 mg/mL for analysis. CD spectra were acquired using a quartz cuvette with a 1 cm path length at 25 °C with a 2 nm bandwidth and a response time of 1 s. Three acquisitions were obtained for each sample, and background

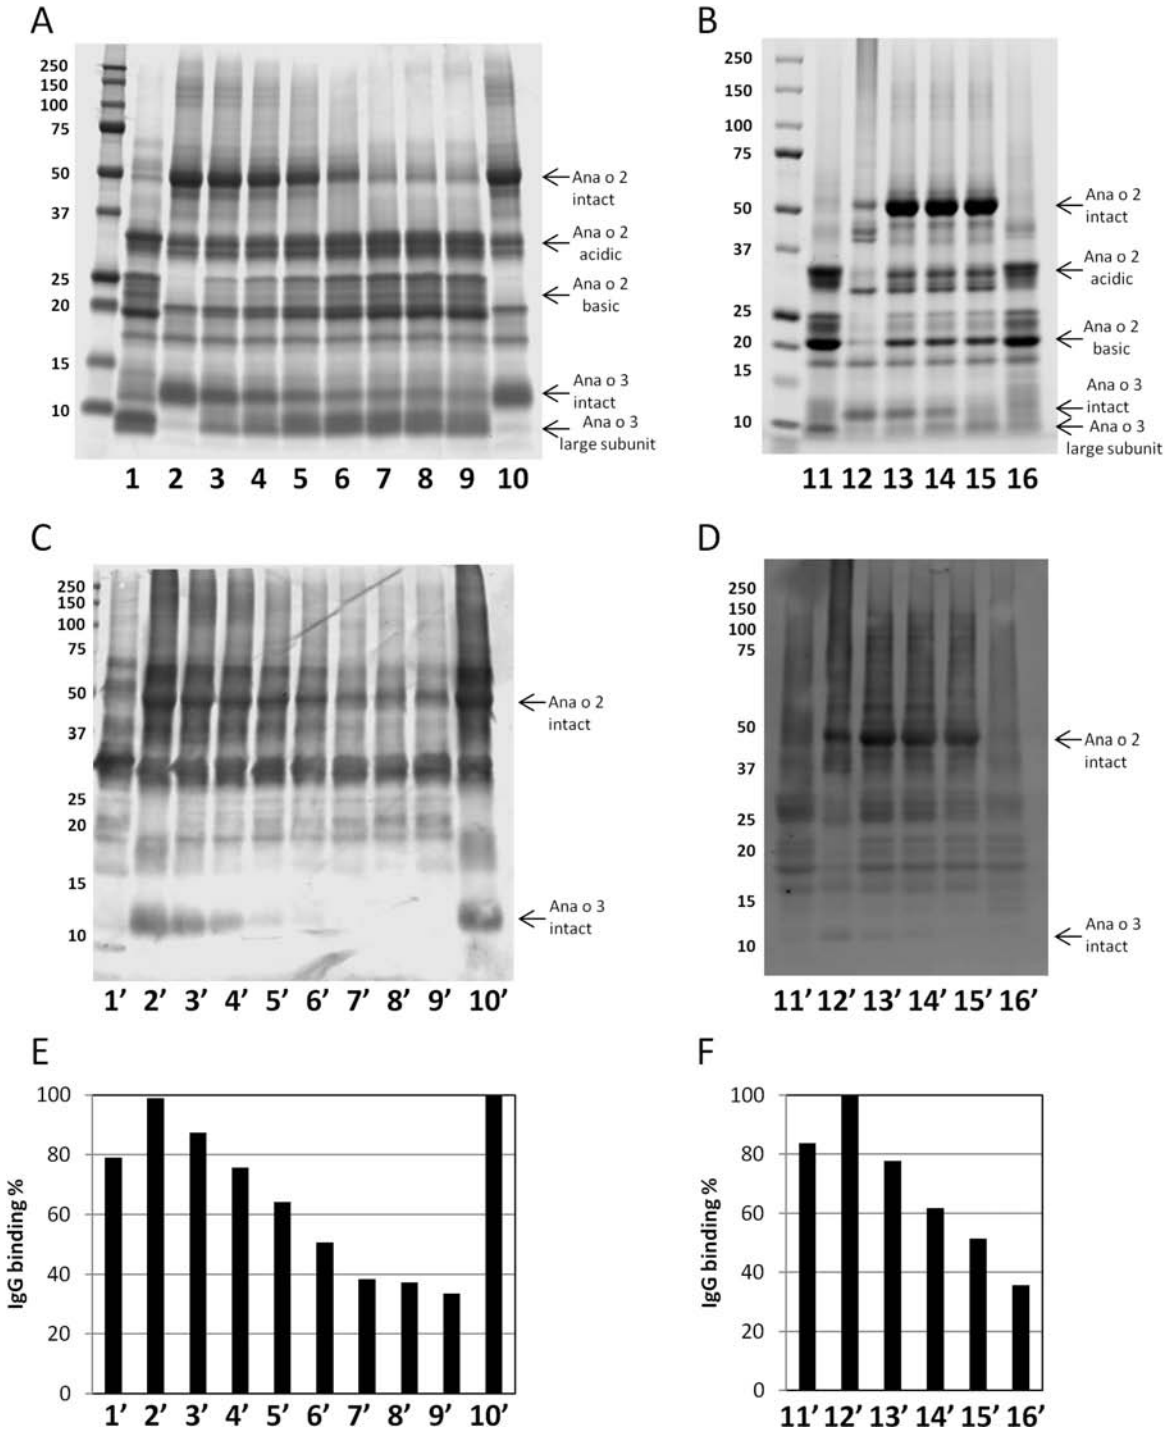

Figure 1. Sodium sulfite alters cashew protein migration and lowers antibody binding. Cashew nut extract (125 μg) subjected to treatment with various amounts of sodium sulfite and temperature was analyzed by nonreducing SDS-PAGE and rabbit anti-cashew antibodies. Cashew extract incubated for 15 min at 100 °C with sodium sulfite or 5 mM DTT was analyzed by SDS-PAGE (A) and immunoblot with rabbit anticashew antibodies (C). Lanes: (1, 1′) 5 mM DTT; (2, 2′, 10, 10′) buffer control, 100 °C; (3, 3′) 1 mM sodium sulfite; (4, 4′) 2.5 mM sodium sulfite; (5, 5′) 5 mM sodium sulfite; (6, 6′) 10 mM sodium sulfite; (7, 7′) 25 mM sodium sulfite; (8, 8′) 50 mM sodium sulfite; (9, 9′) 100 mM sodium sulfite. Sodium sulfite treatment of cashew extracts is temperature dependent. Cashew extract (125 μg) was subjected to treatment with 50 mM sodium sulfite at various temperatures and analyzed by SDS-PAGE (B) and immunoblot with rabbit anti-cashew antibodies (D). Lanes: (11, 11′) 5 mM DTT at 100 °C; (12, 12′) buffer control, 100 °C; (13, 13′) 50 mM sodium sulfite, 37 °C; (14, 14′) 50 mM sodium sulfite, 50 °C; (15, 15′) 50 mM sodium sulfite, 65 °C; (16, 16′) 50 mM sodium sulfite, 100 °C. Rabbit IgG binding was visualized with IRdye-680-labeled anti-rabbit IgG secondary antibody. Quantification of IgG antibody binding in each respective lane (C and D) is shown in panels E and F, and molecular weight markers are indicated on the left side of each gel or immunoblot.

measurements were subtracted. Mean residue ellipticity was calculated using a mean residue weight of 114.5 g/mol, and the K2D3 web server (http://www.ogic.ca/projects/k2d3/) was used to estimate secondary structure.[33]

dx.doi.org/10.1021/jf501117p | J. Agric. Food Chem. 2014, 62, 6746−6755

LC-MS/MS Mass Spectrometry. Following treatment with sodium sulfite, ammonium bicarbonate (100 mM) and calcium chloride (1 mM) were added to defatted cashew extracts made from "ready to eat" cashew nuts. Sequencing-grade modified trypsin (0.2 μg) was added, and samples were allowed to digest for 1 h at 37 °C with gentle mixing. Following acidification with formic acid, samples were analyzed via LC-MS/MS with an Agilent 1200 LC system, an Agilent Chip Cube interface, and an Agilent 6520 Q-TOF tandem mass spectrometer (Agilent Technologies, Santa Clara, CA, USA) as described previously.[16] Raw data files were extracted, sequenced, and searched against a custom food allergen database containing the Ana o 1, Ana o 2, and Ana o 3 sequences. Peptides were searched for sulfite (SO_3) cysteine modifications resulting in an 80 Da mass shift after incorporation of the corresponding mass change into the Spectrum Mill search algorithm.

Competetive ELISA. Microtiter plates were coated with 1 μg of raw cashew extract per well in coating buffer (15 mM Na_2CO_3, 35 mM $NaHCO_3$, pH 9.6) and incubated overnight at 4 °C. Cashew extract was discarded, and the plate was blocked with PBST containing 1% BSA (w/v) at room temperature for 1 h. Plates were washed three times with PBST following blocking and all experimental incubation steps to remove unbound proteins. Treated or untreated cashew extract was centrifuged with 3 kDa spin columns to remove unreacted sodium sulfite or DTT. Samples were then buffer exchanged in 100 mM Tris, pH 8.3, by 10-fold dilution and centrifugation four times using the spin columns to further dilute any remaining sodium sulfite or DTT. Samples were resuspended in 200 μL of buffer and serially diluted 10-fold with 100 mM Tris, pH 8.3. Competition samples, to evaluate IgE binding, were made using 12.5 μL of treated cashew sample, 12.5 μL of pooled sera, and 25 μL of 100 mM Tris, pH 8.3. Samples were added to the microtiter plates and incubated at 37 °C for 1 h. Plates were washed, and 50 μL of biotinylated anti-IgE (1:1000 in PBST) was added to each well and then incubated at 37 °C for 30 min. Plates were washed with PBST, and 50 μL of streptavidin-labeled IRdye-680 (1:5000 in PBST) was added to each well. Plates were incubated at 37 °C for 30 min, washed, and then imaged with the Odyssey CLx instrument. The data in the plot are presented as percent of IgE inhibition using the following formula: IR680 value of uninhibited control − IR680 value of inhibited sample/IR680 value of uninhibited control × 100.

RESULTS

Some nut allergens, including Ana o 2 and Ana o 3, contain disulfide bonds important for their structure; disruption of these bonds can result in lowered antibody binding. To determine if sulfite compounds could disrupt cashew nut IgE binding epitopes, we incubated cashew extracts with sodium sulfite. As shown in Figure 1A, addition of sodium sulfite and heating at 100 °C dissociated Ana o 2 and Ana o 3 and altered their SDS-PAGE migration patterns in cashew extracts. Concentrations as low as 1 mM sodium sulfite disrupted disulfide bonds and altered the migration pattern of at least a portion of the Ana o 2 and Ana o 3 proteins in the extract. Increasing the sodium sulfite concentration resulted in a gradient of dissociation and in the migration pattern of Ana o 2 and Ana o 3 proteins. Elevated sodium sulfite resulted in an increasing appearance of the Ana o 2 acidic (∼33 kDa) and basic (∼20−25 kDa) subunits and the large Ana o 3 subunit migrating just below the 10 kDa marker. At higher concentrations of sodium sulfite (25−100 mM), we observed a migration pattern very similar to that seen using 5 mM DTT (Figure 1A). Similar results were obtained when cashew extracts were incubated with 50 mM sodium bisulfite, sodium metabisulfite, and potassium sulfite, but not sodium thiosulfate (not shown).

Next, we altered the incubation temperature to determine if the dissociation and altered migration of the Ana o 2 and Ana o 3 allergens in cashew extracts treated with sodium sulfite were dependent upon temperature. Disruption of a small portion of Ana o 3 in the extract was observed at 37 °C in the presence of 50 mM sodium sulfite. More of the dissociated large subunit of Ana o 3 can be observed just below the 10 kDa marker as the temperature was increased to 50, 65, or 100 °C (Figure 1B). Extensive disruption of Ana o 2 and alteration in its migration pattern were not observed until the incubation temperature reached 100 °C (Figure 1B). These results indicated that Ana o 3 was more sensitive to sodium sulfite-induced disruption compared to Ana o 2 in the extracts. We did not observe a noticeable shift in the cashew extract protein migration pattern when samples were treated at temperatures below 37 °C in the presence of sodium sulfite.

To evaluate the immunological consequences of sodium sulfite treatment on cashew extracts, we raised antibodies against cashew proteins in rabbits. Western blots using these rabbit polyclonal antibodies indicated that there was a reduction in IgG binding to cashew proteins in sulfite-treated extracts (Figure 1C). We quantified the antibody binding signal and found that overall IgG binding was lowered by 60−70% at sodium sulfite concentrations of ≥25 mM and incubation at 100 °C (Figure 1E). In particular, we noticed a reduction in antibody binding to the slower migrating, higher molecular weight forms >75 kDa (Figure 1C,E). These forms have been associated with heating-induced cross-linking of peanut and other food allergens during processing and can alter IgE binding.[38−44] We also observed that binding to Ana o 3 was lowered at sodium sulfite concentrations as low as 1 mM and was undetectable at higher concentrations (Figure 1C,E). Similarly, antibody binding to Ana o 2 and other higher molecular weight proteins was lowered as sodium sulfite concentration increased. At ≥37 °C, we observed a reduction in antibody binding to cashew proteins treated with 50 mM sodium sulfite (Figure 1D,F). However, when extracts were incubated at 100 °C in the presence of 50 mM sodium sulfite, we observed the dissociation of Ana o 2 subunits and the largest reduction in overall binding to cashew proteins (Figure 1D,F).

Different food preparation methods have been shown to alter antibody binding, and nuts are commonly roasted before consumption. We next tested the effect of sodium sulfite on extracts made from roasted cashews. Extracts made from previously roasted cashews were treated with sodium sulfite, and we observed similar results. Figure 2A shows the disruption of Ana o 2 and Ana o 3 proteins into subunits from both the raw and roasted cashew samples after the sodium sulfite treatment. Whereas there was greater IgG binding to the roasted extracts, overall IgG binding was lowered in both raw and roasted sodium sulfite-treated extracts (Figure 2B). Although IgG binding to higher molecular weight cross-linked forms was lowered as it was to DTT-treated extracts, the reduction in IgG binding was not as great in the roasted extracts. We observed an approximate 50% reduction in binding to the extracts of roasted nuts after the IgG signal was normalized to the roasted nut control extract (Figure 2C). Notably, in each of our experiments, binding to the large subunit of Ana o 3 was markedly lowered in sodium sulfite-treated samples compared to control treated extracts.

Reducing agents have been shown to disrupt the structure of 2S albumins, including Ara h 2, Ber e 1, and Ana o 3, increasing their sensitivity to digestive proteases.[16,23,25] We compared the structure of purified Ana o 3 after treatment with water, DTT, or sodium sulfite using far-UV CD (Figure 3). The DTT-

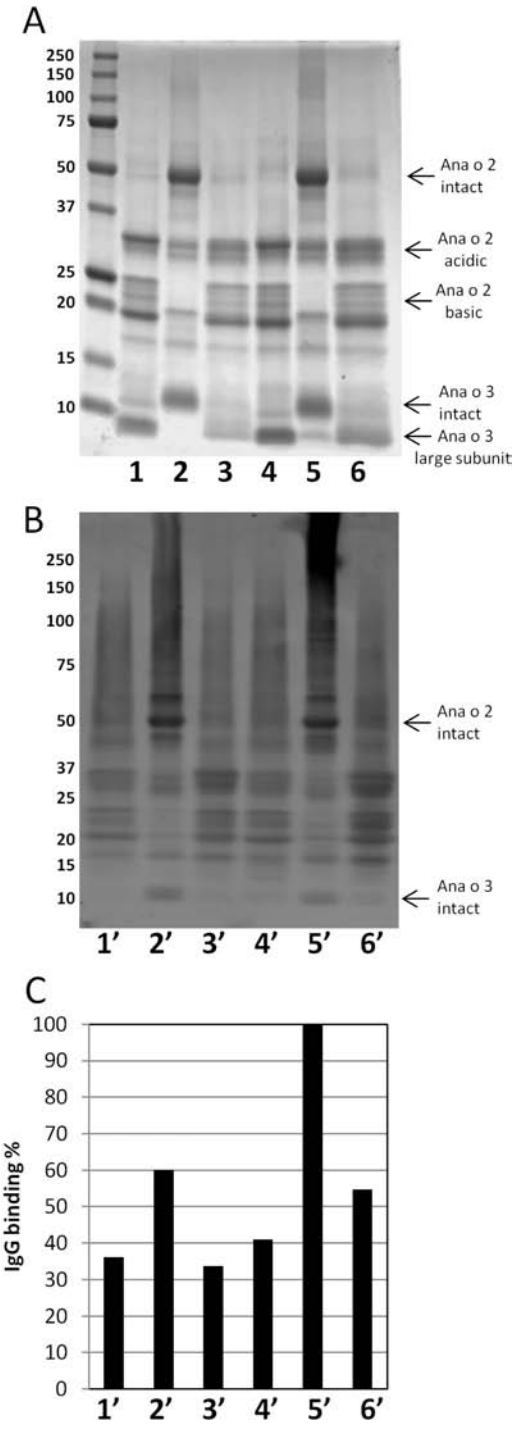

Figure 2. Sodium sulfite alters roasted cashew extract migration and lowers antibody binding. Raw or roasted cashew nut extract (125 μg), subjected to treatment with 5 mM DTT, buffer control, or 50 mM sodium sulfite at 100 °C, was analyzed by nonreducing SDS-PAGE (A) and rabbit anti-cashew antibodies (B). Lanes: (1, 1′) raw extract with 5 mM DTT; (2, 2′) raw extract buffer control; (3, 3′) raw extract 50 mM sodium sulfite; (4, 4′) roasted extract with 5 mM DTT; (5, 5′) roasted extract buffer control; (6, 6′) roasted extract 50 mM sodium sulfite. Rabbit IgG binding was visualized with IRdye-680-labeled anti-rabbit IgG secondary antibody (C). Quantification of rabbit anti-cashew IgG antibody binding in each respective lane is indicated in panel C, and molecular weight indicators are indicated on the side of each gel or immunoblot.

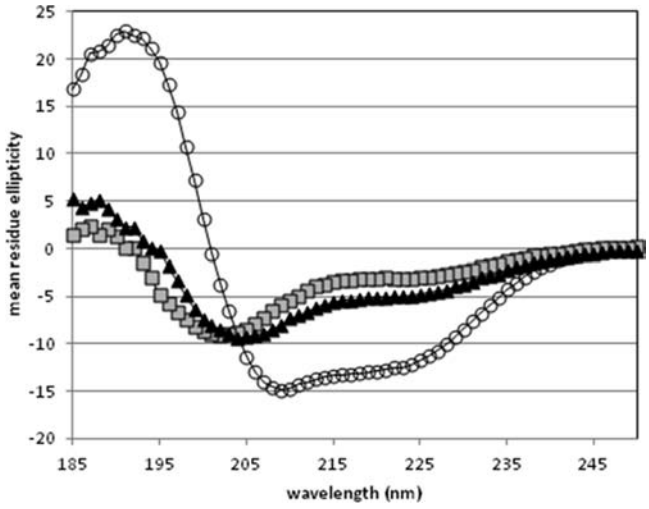

Figure 3. Ana o 3 protein structure is disrupted by sodium sulfite. Purified Ana o 3 was analyzed by circular dichroism from 185 to 250 nm in native form or after treatment with either DTT or sodium sulfite. Open circles represent native Ana o 3 after mock treatment at 65 °C, gray squares represent Ana o 3 after treatment with 5 mM DTT at 65 °C, and black triangles represent Ana o 3 after sodium sulfite treatment (50 mM) at 65 °C.

treated sample had an estimated 4% and the sodium sulfite-treated protein, 7%, α-helical content. The β-sheet content of the protein was also lowered slightly to 12% for DTT-treated and to 13% for sodium sulfite-treated extracts. Thus, sodium sulfite disrupts Ana o 3 structure to an extent similar to treatment of the protein with the reducing agent DTT.

Sodium sulfite is expected to attack the disulfide bond containing cysteine residues within the cashew allergens Ana o 2 and Ana o 3. To confirm that these bonds were targets of sodium sulfite, we digested treated extracts and analyzed the peptide mixture by mass spectrometry to find evidence of sulfite-modified cysteine-containing peptides. Indeed, tryptic peptide masses consistent with modification of Cys76 or Cys77 and Cys 89 in Ana o 3 were observed (Table 1). Peptides containing the expected modified cysteines were detected with an 80 Da shift, corresponding to the addition of sulfite ion (SO_3). These cysteine residues are expected to be part of the disulfide bond network important for Ana o 3 structure and stability. Importantly, the Cys76 and Cys77 residues in Ana o 3 lie within a previously mapped dominant IgE epitope.[14] We were unable to obtain confirmation of the precise location of the modified residue(s) within peptides because of the facile loss of the SO_3 modification prior to or during peptide fragmentation. A similar difficulty has been observed in attempts to specifically identify modified residues in insulin and BSA modified by sodium sulfite.[45] We also observed evidence of a SO_3 modification within several Ana o 2 cysteine-containing peptides (Table 1). The Cys25 and Cys101 SO_3 modified residues lie within or near previously mapped IgE epitopes that strongly react with Ana o 2.[13] Our mass spectrometry analysis further indicated that sodium sulfite disrupted cysteine disulfide bonds within Ana o 3 in cashew extracts.

It is evident from the analysis that sodium sulfite treatment can alter the structure of some cashew allergens, as well as the ability of rabbit IgG antibodies to bind these allergens. To determine if sodium sulfite treatment alters IgE binding to cashew allergens, we performed several IgE binding assays.

Figure 4 shows Western blot binding of IgE from a pool of six cashew-allergic patients' sera to sodium sulfite treated cashew extracts. Overall IgE binding to cashew proteins was lowered in both the DTT- and sodium sulfite-treated samples compared to the mock treated control. Quantification of the IgE signal indicated that binding to sodium sulfite- and DTT-treated extracts was lowered by 80−90% compared to mock treated extracts (Figure 4). In particular, reduction of Ana o 2 and Ana o 3 disulfide bonds with either DTT or sodium sulfite clearly lowered binding to both of these allergens. IgE binding to both of the faster migrating dissociated Ana o 2 subunits and the large subunit of Ana o 3 was markedly lowered (Figure 4).

Individual variation in IgE binding to nut allergens by allergy patients is well documented. We continued the IgE binding analysis by comparing IgE binding of individual cashew allergic sera to treated cashew extracts using dot-blots. Aliquots of treated or untreated cashew extract were spotted onto a PVDF membrane, allowed to dry, and extensively washed. We evaluated IgE binding to the bound material using six individual cashew-allergic patients' sera, and in every case IgE binding to the sodium sulfite-treated extract was lowered compared to the untreated control (Figure 5). When samples were incubated at 65 °C in the presence of sodium sulfite or DTT, the IgE signal was lowered to approximately half of the control sample with most of the sera samples we tested. Five of the six sodium sulfite-treated samples had IgE binding values ranging from 50 to 58% of the untreated control. The remaining sample was lowered to only 67% of the untreated control. IgE binding to the DTT-treated samples was also lowered to an extent equivalent to or greater than that of the sodium sulfite treatment for each of the sera. The DTT-treated samples had IgE binding values ranging from 16 to 53% of the untreated control. When extracts were incubated at 100 °C, the results were more dramatic. In both the sodium sulfite- and DTT-treated extracts, IgE binding was lowered to ≤10% of control treated extracts in five of six serum samples. In the remaining sample, IgE binding was lowered to 10% for sodium sulfite treatment and 16% for DTT. Our analysis of the cashew-allergic patients' serum samples indicated that treatment of cashew extracts with sodium sulfite could effectively lower IgE binding to cashew allergens.

To confirm these findings, IgE binding to the control and sodium sulfite-treated extracts was evaluated using competitive ELISA with the pooled cashew-allergic patients' sera. For these experiments, unreacted DTT or sodium sulfite was removed from extracts treated at 65 or 100 °C with centrifugation and buffer exchange over a course of 3 h using a 3 kDa cutoff spin filter to lower the remaining concentration to <0.01 mM following treatment. Representative plots from this analysis are shown in Figure 6, and both the DTT and sodium sulfite-treated extracts did not compete as well as control treated extract for IgE binding. Whereas the effect was more pronounced with DTT, sodium sulfite-treated extracts were a weaker competitor for IgE binding compared to untreated control extracts (Figure 6). Again, the reduction in IgE binding was greater when extracts were heated at 100 °C. Even at the highest protein concentration used, the sodium sulfite or DTT 100 °C treated extracts could not inhibit 50% of the IgE binding. These findings are consistent with the reduction of IgE binding we observed in the Western blot analysis (Figure 4).

DISCUSSION

Generation of hypoallergenic nuts via breeding, genetic engineering, or processing steps would provide a much-needed solution for those suffering from severe nut allergies. In addition, hypoallergenic nuts may be useful as immunotherapy reagents. Several studies have characterized the stability and allergenicity of cashew and other nut allergens to chemical, physical, mechanical, and enzymatic processing methods.[17,21,22,42,46−48] 2S albumins are common nut allergens, dependent upon cysteine disulfide bonds for their structure, and laboratory reducing agents have been used to decrease their potency as allergens. We hypothesized that there may be milder reducing agents that could have the same effect on these nut allergens. Our results with the GRAS compound sodium sulfite support our hypothesis. We observed clear changes in the migration pattern of redox-sensitive cashew allergens such as Ana o 2 and Ana o 3 following treatment of cashew extracts with sodium sulfite at elevated temperatures. This simple procedure was able to disrupt allergen structure and markedly lower in vitro IgE binding to cashew allergens in extracts.

The use of sulfating agents such as sodium sulfite could act at multiple levels to lower IgE binding to allergens. First, they target disulfide bonds and can destroy conformational IgE epitopes that require those bonds, thereby reducing IgE binding. This is supported by our SDS-PAGE and CD data showing that Ana o 2 and Ana o 3 structures were altered. Consistent with our results, experiments with purified peanut allergens Ara h 2 and Ara h 6 comparing reduced and native forms have demonstrated that conformational epitopes are of great significance for IgE binding to these 2S albumins.[46] Similar findings have been observed with soy protein,[49] and treatment of soy glycinin with sodium bisulfite has been shown to dissociate the acidic and basic subunits.[50,51] Second, sulfating agents covalently attach a large negatively charged sulfite ion to cysteine residues they have attacked,[37,45] and this charge is likely to repel IgE from linear epitopes harboring those residues, thereby reducing IgE binding. The decrease in IgE binding we observed in both immunoblot and ELISA assays supports our conclusion that both structural and linear epitopes are likely affected. Third, although not tested here, a sulfite attack of disulfide bonds and a loss of allergen structural integrity could lead to increased protease sensitivity in the stomach and a reduction in the amount of the protein available

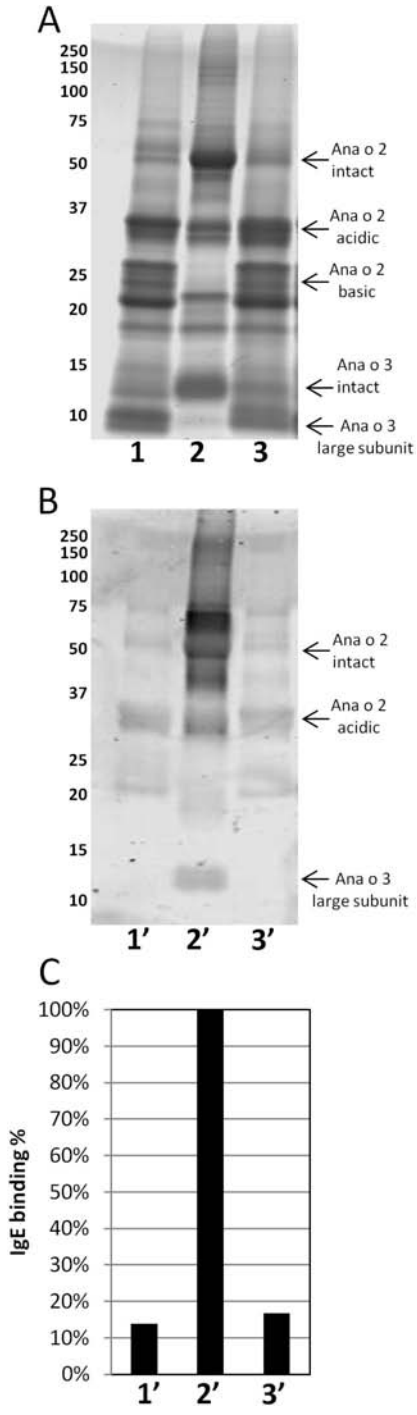

Figure 4. IgE binding to cashew extract is lowered following sodium sulfite treatment. Cashew extract (125 μg) was subjected to treatment with 5 mM DTT, buffer control, or 50 mM sodium sulfite at 100 °C and evaluated by SDS-PAGE (A) and IgE binding by Western blot (B). Lanes: (1, 1′) 5 mM DTT; (2, 2′) buffer control; (3, 3′) 50 mM sodium sulfite. Serum samples from a pool of six cashew-allergic patients were combined, diluted 1:10, and analyzed for IgE binding in control or sodium sulfite- or DTT-treated cashew extracts. IgE binding was visualized with IRdye-680-labeled streptavidin after incubation with biotinylated anti-human IgE secondary antibody. Quantification of IgE binding is shown in panel C, and molecular weight indicators are indicated.

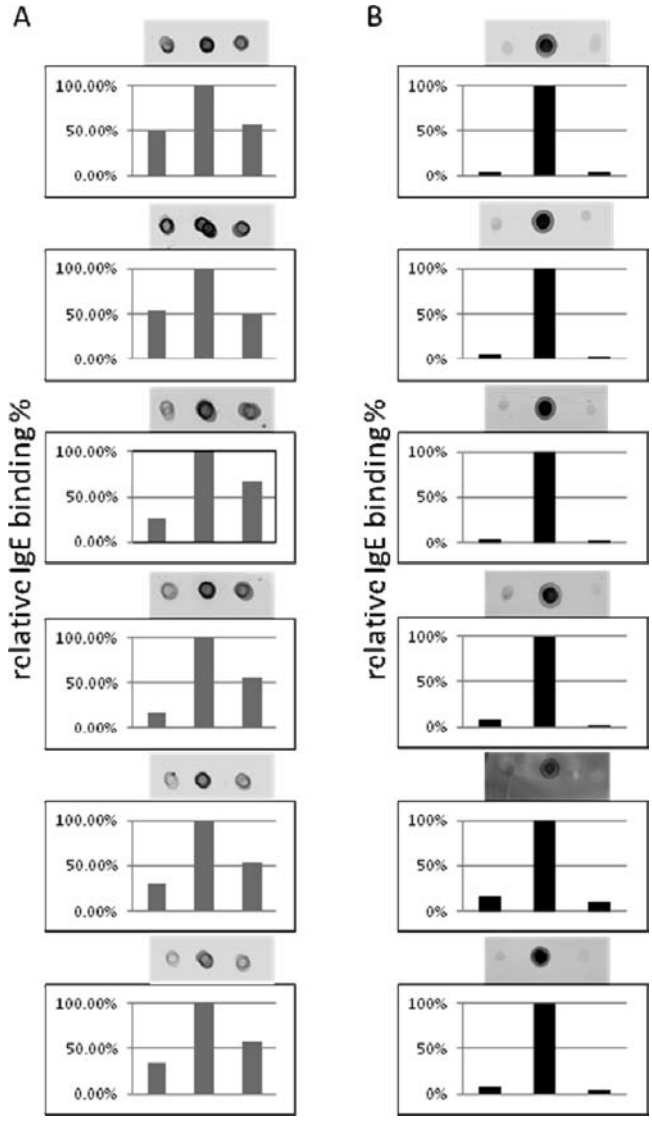

Figure 5. IgE binding to cashew extract is lowered following sodium sulfite treatment. Cashew extract (125 μg) was subjected to treatment with 50 mM sodium sulfite or 5 mM DTT at 65 °C (A) or 100 °C (B) and evaluated for IgE binding by dot-blot. For each panel the left column represents DTT treatment, the middle column the control, and the right column sodium sulfite treatment. Serum samples from individual cashew-allergic patients were diluted 1:5, and IgE binding was visualized with IRdye-680-labeled streptavidin after incubation with biotinylated anti-human IgE secondary antibody. Relative IRdye-680 units are indicated on the *y*-axis, and quantification of IgE binding is shown in the accompanying immunoblot.

for allergic response. Proteolyzed cashew extracts exhibit less IgE binding in vitro and a lowered allergenic response in mice.[16,47] Furthermore, proteolysis of sorghum protein can be increased by treatment with reducing agents including sodium sulfite compounds.[52,53] Finally, sulfite has been used to prevent browning, promote expenditure of reducing sugars and lysine in a reaction model, and act as an inhibitor of the Maillard reaction.[26,54] Studies have shown that Maillard reaction products can influence IgE binding to food allergens.[38−44] Our SDS-PAGE and immunoblot results also demonstrated that the addition of sodium sulfite to cashew nut extracts lowered the appearance of high molecular weight protein aggregates that are associated with Maillard reaction products in heated nut extracts.[43,48,55,56]

dx.doi.org/10.1021/jf501117p | J. Agric. Food Chem. 2014, 62, 6746−6755

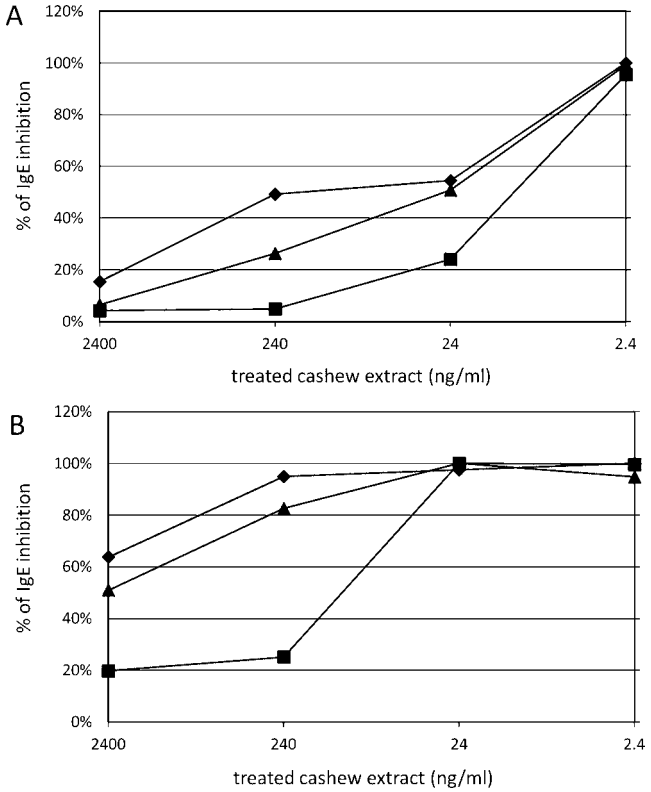

Figure 6. Sodium sulfite-treated cashew extract lowered IgE binding. Cashew extracts (squares) or cashew extracts pretreated with DTT (diamonds) or sodium sulfite (triangles) were evaluated for IgE binding in a competitive ELISA after incubation at 65 °C (A) or 100 °C (B). Cashew extract samples were serially diluted 10-fold, and IgE binding was evaluated in microtiter plates coated with 1 μg of cashew extract. Serum samples from a pool of six cashew-allergic patients were combined, diluted 1:4, and analyzed for IgE binding to sodium sulfite- or DTT-treated cashew extracts. Cashew extract concentration is indicated on the *x*-axis, and relative IgE binding in IRdye-680 units is indicated on the *y*-axis.

Our findings indicate that treatment of cashew extracts with sodium sulfite can be used to disrupt Ana o 3 structure and lower IgE binding. However, reductions in IgE binding do not always correlate with lowered basophil activation.[57] Basophil degranulation capacity has been shown to reside primarily with the 2S albumins of peanuts.[58−62] Several factors are likely to influence basophil degranulation by nut allergens, but if the same phenomenon is observed with cashew nut extracts, it would be expected that Ana o 3 may be the primary elicitor of basophil degranulation among cashew nut allergens. Further research that tests sulfite-treated cashew extracts in basophil activation assays or a mouse food allergy model or uses skin prick tests is necessary to determine the safety and efficacy of this method in attenuating cashew allergenicity.

Current FDA regulations require labeling at ≥10 ppm (10 mg/L) when sulfites are used in food processing. The current study used sodium sulfite at 50 mM or 6.302 g/L (6313 ppm) in the treatment step, which exceeds the labeling requirement. However, sulfite that has been incorporated into the nut proteins may no longer be biologically active, and any residual sulfite may be removed with additional steps. There are likely safe methods for removing or consuming residual sulfite or combining physical or mechanical steps with titrated amounts of sulfite during treatment. It may be that removal of excess sulfite in solution is easier using whole nuts compared to nut extracts, and sulfite absorbed into the nut may be expended if the treatment is performed early in the nut-processing procedure. Sulfite ions that have reacted with proteins, carbohydrates, or lipid components in foods may not be biologically active or accessible to cause allergy. The reversible nature and reactivity of sulfite adducts have been debated, and the current study did not address the long-term consequences to cashew allergen structure and IgE binding following removal of sulfite after treatment. We tested other sodium sulfite compounds and found that the addition of sodium bisulfite, sodium metabisulfite, or potassium sulfite also resulted in a similarly altered SDS-PAGE migration pattern of cashew proteins consistent with that observed with DTT. Further studies are necessary to extend these findings to whole nuts, as well as to determine the effects sulfite has on the sensory and quality characteristics of nuts.

surface display, bacterial spore surface display systems have been widely used for their resistance to heat, radiation, and chemicals in a harsh environment.[21] Moreover, *Bacillus subtilis* is classified as generally recognized as safe (GRAS) by the U.S. Food and Drug Administration, and its genetic information, spore structure, and mature genetic manipulation techniques are established, thus making it an excellent strain for a food-grade surface display system.[22−24]

In the present study, a surface display system was constructed based on *B. subtilis* 168 for the production of D-tagatose using CotX as an anchoring protein. After active L-AI was successfully observed on the spore surface of *B. subtilis* 168 and a higher efficiency to catalyze D-galactose to produce D-tagatose was exhibited, the potential of using a food-grade expression system to produce D-tagatose was confirmed. To the best of our knowledge, this is the first report for D-tagatose production using anchored L-AI on the spore surface of *B. subtilis* 168.

MATERIALS AND METHODS

Chemicals. D-Tagatose (≥99% purity) and D-galactose (≥98% purity) were purchased from Aladdin Industry Co., Ltd. (Shanghai, China). Ex-Taq DNA polymerase, restriction enzymes, T4 DNA ligase, ampicillin, and erythromycin were supplied by Takara Biotechnology Co., Ltd. (Dalian, China). Trypsin and proteinase K were purchased from Sigma. All other chemicals were analytical grade.

Plasmid and Strain Construction. To display L-AI on the surface of *B. subtilis* 168 spores, we constructed a genetic fusion: *cotX-araA*. The DNA fragment with the *cotX* (GenBank Accession No. NP_389058) promoter and structure gene from the genome of *B. subtilis* 168 was amplified by primers P1 and P2 (Table 1), digested with *Xba* I and *Kpn*I, and ligated into pJS700a cloning vector to generate the plasmid pJS700a-*cotX*.[25] The *araA* gene (GenBank Accession No. HM150718) was amplified from the genome of *L. fermentum* CGMCC2921 using primers P3 and P4 (Table 1), digested with *Kpn*I and *EcoR* I, and cloned into the same restriction endonuclease sites of plasmid pJS700a-*cotX* to obtain the plasmid pJS700a-*cotX-araA*.

Table 1. Oligonucleotides Used In This Study

oligonucleotides (forward, 5′ to 3′)	name
GCTCTAGATTACTTTGTCTGCCGACGAGA (*Xba* I underlined)	P1
CCGGTACCGAGGACAAGAGTGATAACTAGGATG (*Kpn*I underlined)	P2
AGAGGTACCATGCGTAAGATGCAAGATTAC (*Kpn*I underlined)	P3
CCGGAATTCCTACTTGATGTTGATAAAGT (*EcoR* I underlined)	P4

The competent cells of *B. subtilis* 168 were prepared as previously described.[26] The cells transformed by chemical transformation methods were cultured in 3 mL of Luria−Bertani (LB) medium at 37 °C and spread onto LB plates containing 4 μg/mL of erythromycin (Em). Plates were incubated at 37 °C overnight, and Em-resistant (Em^r) clones were selected and identified using the amylase activity assay.[27] To verify the amylase activity of colonies, we stained the colonies cultivated on LB plates containing 0.1% starch with iodine potassium iodide solution.

Culture Conditions of the Bacterial Strains and the Purification of Spores. For the formation of spores, *B. subtilis* 168 was cultivated in Difco-sporulation media (DSM) as described elsewhere.[28] After cultivation in DSM at 37 °C for 24 h, the spores and sporangial cells of *B. subtilis* 168 with recombinant plasmids were harvested by centrifugation and resuspended in 0.1 M sodium phosphate buffer (pH 6.5). The suspension was treated with 0.5% lysozyme for 1 h and then centrifuged at 5000 rpm (4470*g*) for 15 min. After the sediments were washed with 1 M NaCl, 1 M KCl, and phosphate buffer, the washed spores were obtained and resuspended in phosphate buffer at 4 °C without the addition of phenylmethylsulfonyl fluoride (PMSF).[16] The *E. coli* DH5α strain, used for the plasmid amplification for nucleotide cloning and sequencing, was grown in LB medium at 37 °C.

Activity Assays of the Anchored L-AI. Activity of spore surface-displayed L-AI was determined at 70 °C, pH 6.5, in 1 mL of 36 g/L of D-galactose and the washed spore suspension. After a 30 min reaction, the system was transferred to ice to terminate the reaction.

The generated D-tagatose was first examined using the cysteine-carbazol-sulfuric acid method, and the absorbance was measured at 560 nm.[29] Then, both D-tagatose and D-galactose were analyzed by high-performance liquid chromatograph (HPLC), using a Rezex RCM-Monosaccharide Ca^{2+} column at 80 °C with distilled water as the mobile phase at an elution rate of 0.5 mL/min. The components were analyzed with a refractive index detector RI-101.[30] The HPLC and Rezex RCM-Monosaccharide Ca^{2+} column were purchased from Agilent (Wilmington, DE) and Phenomenex (Guangzhou, China).

The standard linear graph prepared with different D-tagatose concentrations was used to calibrate the generated D-tagatose concentration from the reaction. One unit of enzyme activity is defined as the amount of displayed L-AI required to catalyze the production of 1 μmol D-tagatose per min.[30] The number of spores was calculated by direct counting with a Burker chamber under an optical microscope.[16]

Examination for the Properties of the Anchored L-AI. To examine the properties of the anchored L-AI, 30 mL of reaction mixture in a 250 mL Erlenmeyer flask was used with variations as follows. The optimization of temperature and pH were conducted with 36 g/L of D-galactose and the washed spore suspension from 10 mL of spore fermentation broth (containing about 8.4×10^8 spores) for 30 min. The optimal temperature of the anchored L-AI was analyzed over the range of 55−90 °C. The effect of the pH on enzyme activity was determined using the standard assay conditions at 70 °C with sodium acetate (pH 4.0−6.0), phosphate (pH 6.0−8.0), and Tris-HCl (pH 8.0−9.0). In addition, the thermal stabilities of spore surface-displayed L-AI were determined by incubating the reaction mixtures at 70, 75, and 80 °C for 90 min at pH 6.5, and the residual activities were determined using the standard activity assays every 15 min.

Production of D-Tagatose Using the Anchored L-AI. The optimization of substrate concentration was conducted with D-galactose at 25, 50, 100, 150, and 200 g/L for 24 h using the washed spore suspension from 10 mL of spore fermentation broth. The optimal cell dosage was determined by using the washed spore suspension prepared from 5, 10, 20, 30, 40, 50, 60, and 70 mL of spore fermentation broth for 24 h. Sufficient shaking was performed each time before samples were obtained from the spore fermentation broth. Finally, 100 mL of reaction mixture (containing about 1.4×10^{10} spores) in a 500 mL Erlenmeyer flask was used to determine the reusability of the spore surface-displayed L-AI in the production of D-tagatose. The reusability experiments were conducted by recycling the anchored L-AI for several cycles. The concentrations of D-tagatose and D-galactose were measured by HPLC. After each biotransformation batch, the amount of spores was counted, and the activity of the anchored L-AI was assayed. Subsequently, reaction mixtures were centrifuged and the sediment was reused for another batch.

RESULTS

Gene Clone and Construction of Recombinant Plasmid. To construct the recombinant plasmid, the *cotX* gene of the outer coat protein CotX (18.6 kDa) and the *araA* gene from *L. fermentum* CGMCC2921 were amplified successfully. Then, the *cotX* and *araA* genes were ligated into pJS700a to construct the recombinant plasmid pJS700a-*cotX-araA* (Figure 1), which was verified by the digestion method. DNA sequencing results also demonstrated that a correct recombinant plasmid pJS700a-*cotX-araA* was obtained.

Transformation of the Plasmid pJS700a-*cotX-araA* and Activity Assays of the Anchored L-AI. The

dx.doi.org/10.1021/jf501937j | J. Agric. Food Chem. 2014, 62, 6756−6762

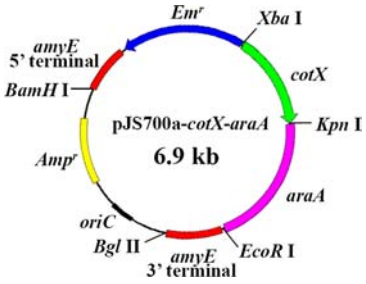

Figure 1. Construction of recombinant plasmid pJS700a-*cotX-araA*.

recombinant plasmid pJS700a-*cotX-araA* was transformed into *B. subtilis* 168, in which *cotX-araA* gene fusion was integrated into *B. subtilis*168 chromosome at *amyE* locus by double crossover events. As the integration of *cotX-araA* gene fusion at *amyE* locus disrupted the expression of amylase, colonies on starch-containing LB plate turned blue after staining by iodine potassium iodide solution, whereas *B. subtilis* 168 wild-type strain exhibited a distinctive yellow color due to the normal expression of amylase gene that resulted in hydrolysis of starch in the plate (Figure 2A).

A cotX-specific promoter was used in the surface display system to initiate expression of L-AI and sporulation of *B. subtilis* synchronously, whereas the outer coat protein CotX expressed at the coat of *B. subtilis* 168 was used as an anchoring motif for the display of L-AI. Assays of the surface-displayed L-AI revealed an activity value of 2.02×10^{-10} U/spore. The expression of L-AI on the external surface of *B. subtilis* 168 spores was verified by protease treatment. Purified spores of *B. subtilis* 168 (pJS700a-*cotX-araA*) were suspended in phosphate buffer containing 0.1% trypsin or 0.1% proteinase K for 1 h.[15] A control sample with the spores was also prepared in phosphate buffer without protease. As shown in Figure 2B, the activity of spores treated by protease was markedly lower than that of intact spores. This observation was due to the addition of protease to the outside environment of spores that cannot penetrate through the spore wall. This result indicated that the L-AI is located on the surface of spores.[31]

Properties of the Anchored L-AI. The optimal temperature and pH of the anchored L-AI were first examined in the present study. As shown in Figure 3, using D-galactose (36 g/L) as the substrate, the highest conversion efficiency of D-galactose was detected at 70 °C and pH 6.5. Enzyme stability is an important factor in the long-term commercial application of an enzymatic bioconversion.[32] In the temperature range of 65−80

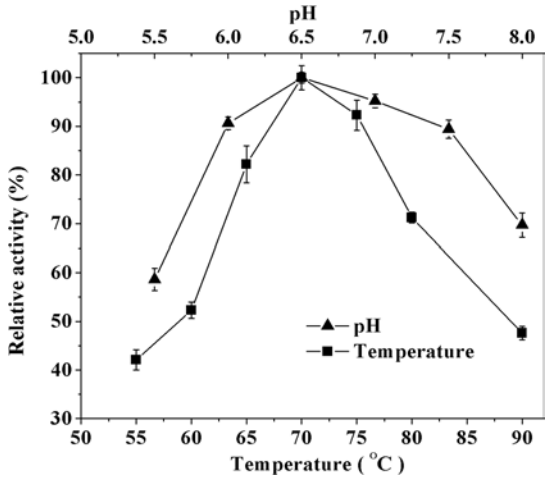

Figure 3. Effect of temperature (■) and pH (▲) on the displayed L-AI.

°C, the relative activity of the anchored L-AI remained >70% of the highest level, which suggested that the thermal stability was improved compared with the recombinant L-AI expressed in *E. coli*.[12] To verify this speculation, we examined the stability of the displayed L-AI treated at different temperatures. As shown in Figure 4, the activities of anchored L-AI incubated at 70 and

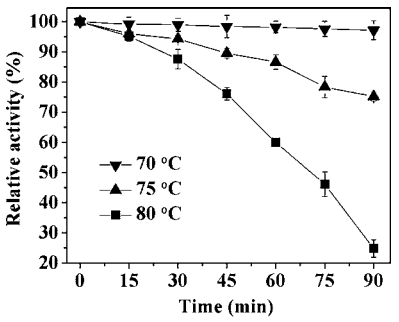

Figure 4. Thermostability of anchored L-AI incubated at (▼) 70 °C, (▲) 75 °C, and (■) 80 °C. The initial activity was defined as 100%.

75 °C for 30 min were not significantly decreased, and the relative activity even retained >75% of the highest level when incubated at 80 °C for 45 min. Moreover, within the pH range of 6.0−7.5, the relative activity of surface-displayed L-AI remained >90% of the highest level. These results indicated

that the spore surface-displayed L-AI exhibited high biotransformation capability toward D-galactose over wide ranges of temperature and pH.

Biocatalytic Production of D-Tagatose Using the Anchored L-AI. To obtain the maximum D-tagatose yield and efficiently utilize the substrate at the same time, we studied the concentration of D-galactose in the efficient production of D-tagatose using the washed spore suspension from 10 mL of spore fermentation broth. As shown in Figure 5A, an increase in D-galactose concentrations resulted in a decrease in conversion rate and an increase in D-tagatose yield. Although the conversion rate was 84% at the reaction system with 25 g/L of D-galactose, the D-tagatose yield was 0.85 g/L/h. On the contrary, the D-tagatose yield was improved to 2.78 g/L/h at the reaction system with 200 g/L of D-galactose, but the conversion rate decreased markedly (35%), which may lead to the low production efficiency and the waste of raw materials. On the basis of the above analysis, 100 g/L of D-galactose, with which the conversion rate was 51% and the D-tagatose yield was 2.01 g/L/h at the reaction system, was chosen as the optimal concentration for D-tagatose production.

Then, we analyzed the effect of the dosage of spore fermentation broth on this biotransformation. The different dosages of spore fermentation broth were added into the reaction mixture containing 100 g/L of D-galactose as the substrate. After the biotransformation at 70 °C for 24 h, the optimum dosage of spore fermentation broth was confirmed to be 50 mL (Figure 5B), corresponding to an ~75% yield of D-tagatose.

In investigating the reusability of spore surface-displayed L-AI, the reactions were conducted under the optimal transformation conditions (Figure 6). After each reaction cycle, spores with anchored L-AI were isolated by centrifugation and then washed with 0.1 M phosphate sodium buffer (pH 6.5). The anchored L-AI maintained high specific activities (1.72×10^{-10} U/spore, 85% of the initial activity) toward D-galactose within 5 reaction cycles. The conversion rate was maintained at 56% at the third cycle. However, the amount of spores decreased significantly after three cycles and only 20% of the initial amount was retained at the end of the fifth cycle. The biotransformation rate of the anchored L-AI was also gradually decreased from 75% to 19% at the end of the fifth cycle.

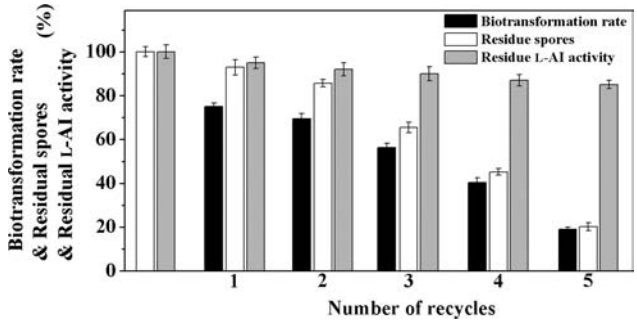

Figure 6. Recycling of spore surface-displayed L-AI for the production of D-tagatose. (■) Biotransformation rate of D-galactose; (□) residual amount of spores; (gray bar) residual activity of spore surface-displayed L-AI. The initial addition amount of spores and specific activity was defined as 100%.

■ DISCUSSION

Enzymatic synthesis of D-tagatose from D-galactose using L-AI has drawn wide attention. In previous studies, L-AI was always expressed in *E. coli* strains and used for D-tagatose production in the form of free enzyme or immobilized enzyme or contained in whole cells. However, the genetic background of *E. coli* remains controversial in application of the food industry, and the time-consuming purification processes restricted the use of an isolated enzyme. Therefore, it was important to explore the possibility of producing D-tagatose using L-AI carried by food-grade whole cells or a natural structure of cells, such as spores.

It is reported that bacterial spores may be good carriers of target proteins. Spores of *B. subtilis* are generally recognized as safe microbial resources and are used as additives in human and animal food. Moreover, *B. subtilis* draws considerable attention for its advantages of mature molecular genetic manipulation and detailed knowledge of its spore structure. All of these attributes make spores of *B. subtilis* an appealing medium for displaying heterogeneous proteins on its surface. In the present study, we introduced a novel system using the natural and robust spores of *B. subtilis* 168 with L-AI displayed on the surface for the enzymatic synthesis of D-tagatose.

The spores of *B. subtilis* are encased in a protective coat consisting of an inner and an outer layer, which are composed of >70 different proteins.[33] Most of the proteins successfully used in surface display were located in the outer layer, such as CotB, CotC, and CotG. Of these, CotB and CotC have always been used in the production of vaccines and antigens,[17,34] and CotG was reportedly used in biocatalysis with whole cells.[16,35] CotX, another outer spore coat protein, has not been documented in the application of displaying heterogeneous enzymes on the spore surface. CotX is synthesized inside the sporulating mother cells and deposited on the spore surface as spores emerge.[33] In the present study, we finally generated fusion protein CotX-AI, which was anchored on the spore surface of *B. subtilis* 168 successfully. According to the analysis of the biocatalytic reaction, the high conversion rate of the substrate and the stability during the recycling process

dx.doi.org/10.1021/jf501937j | J. Agric. Food Chem. 2014, 62, 6756−6762

demonstrate that this surface display system can be qualified for industry application. The confirmation of the availability of CotX also enriched the choice of spore coat proteins for use in surface display technology.

Existing L-AIs from wild or recombinant strains remain flawed in terms of being provided with appropriate biocatalytic temperature or pH for the industrial production of D-tagatose. For instance, L-AI from *Lactobacillus sakei* 23K was acid-tolerant, but the enzyme was rapidly inactivated at temperatures greater than 50 °C.[36] In another example, the optimal temperature of L-AI from *Geobacillus thermodenitrificans* was the expected result (70 °C), but its relative activity was markedly decreased at pH 7.0.[32] More examples are listed in Table 2. Conversely, Bacillus spores, which are formed in response to nutrient starvation, are robust and can withstand extreme heat, desiccation, and chemicals.[19] The thermal stability examined in the present study indicated that the incubation of the displayed L-AI at the temperature range of 65−80 °C within 30 min would not significantly decrease the relative activity of the enzyme. Moreover, the optimal catalytic temperature of anchored L-AI is 70 °C, whereas 92% activity was retained at 75 °C after 30 min. For the industrial production of D-tagatose from D-galactose, isomerization performed at the temperature range of 60−70 °C is the most suitable temperature condition, which is advantageous for the production, such as higher conversion yield, better sugar solubility, and lower risk of microbial contamination.[1,2] However, temperatures more than 75 °C also introduce undesirable consequences, such as browning and byproducts formation.[14] Furthermore, pH of 6.5, examined as the optimal pH of anchored L-AI, meet the industrial requirement for maintaining the pH within the range of 6.0−6.5. At this pH range, the browning changes can be controlled markedly,[14,39] and the production processes are simplified because the optimal pH of lactose hydrolase used for producing D-galactose from lactose is also in this range. Thus, the suitable temperature and pH make the anchored L-AI a desirable enzyme for the production of D-tagatose. The wide range of temperature available also offers elasticity during the industrial production.

Table 2. Optimal Temperature and pH of L-AI from Various Microorganisms for Industrial Production of D-Tagatose

organism	optimal temperature (°C)	optimal pH
Lactobacillus fermentum CGMCC2921(this work)	70	6.5
L. fermentum CGMCC2921[12]	65	6.5
Lactobacillus sakei 23K[36]	30−40	5.0−7.0
Bacillus licheniformis[37]	50	7.5
Alicyclobacillus acidocaldarius[38]	65	6.0−6.5
Thermoanaerobacter mathranii[2]	65	8.0
Geobacillus thermodenitrificans[31]	70	8.5
Thermotoga maritima[39]	90	7.0

After the optimization of the operating conditions, recombinant spores harboring the pJS700a-*cotX-araA* plasmid were able to catalyze 100 g/L of D-galactose into 75 g/L of D-tagatose in 24 h, and even yield 56 g/L of D-tagatose at the end of the third recycle. Compared with previous studies of L-AIs from various microorganisms with a different expression vector (Table 3), the conversion yield of the anchored L-AI is relatively higher. This result suggests that the anchored L-AI on the surface of the recombinant spores is a promising alternative for D-tagatose production. Moreover, it was expressed in a food-grade system and excludes the lengthy purification method. However, at the fifth batch, the conversion rate of D-galactose decreased to 25% of that of the first batch. It is worth noting that the amount of spores decreased to 41% of the first batch and the specific activity of anchored L-AI remained 86%, which indicates that the decrease in the conversion yield can be mostly attributed to the reduction of spore amount. Xu et al.[16] reported that the addition of nisin could inhibit the germination of *Bacillus* spores, which finally improved the conversion yield in the reaction by controlling the reduction of the spore amount. In addition, the reduction of spore amount may also be influenced by the environment with continuous vibrations and a high temperature solution, which is bound to damage the structure of spores to some extent. In our study, the reduction of spore amount could be mostly caused by the harsh environment. To overcome this difficulty, we are considering immobilized spores to adapt the mechanical strength during production.

The cost estimate is crucial to judge the significance of a new production method. In our study, the cost estimate mainly includes the medium for culturing bacteria and the substrate used in the catalytic reaction. For instance, cost comparison of different methods used to produce 10 kg of D-tagatose is shown in Table 4, and because the culture medium used for culturing spores in our study was poor nutrition, its cost saving reached 99.1%. However, the crucial factor of the cost saving was the higher conversion yield. To produce 10 kg of D-tagatose, the substrate (D-galactose) used in our study was much lower than the research conducted by Xu et al. Finally, the different culture medium and the lower amount of substrate made the cost savings achieve 45.4%.

To the best of our knowledge, this is the first report for the development of a food-grade spore surface display system for the production of D-tagatose from D-galactose by using recombinant spores. The reported system exhibited both a higher conversion yield rate and a cost-saving production

Table 3. Bioconversion of D-Galactose into D-Tagatose Using L-Arabinose Isomerases from Various Microorganisms with Different Expression Systems

source organism	expression system	conversion conditions	substrate (g/L)	conversion rate (%)	yield (g/L/h)
L. fermentum CGMCC2921(this work)	*B. subtilis* 168	70 °C, 24 h	100	75 ± 3.5	3.13 ± 0.15
L. fermentum CGMCC2921[12]	*E. coli* BL21	65 °C, 24 h	100	55	2.29
L. sakei 23K[36]	*E. coli* BL21	40 °C, 7 h	9	36	0.46

[a]Bold residues indicate the sites of mutation.

which may be formed by several subsites (+1,+2, +3, and so on).[15−18] The −1 subsite of various β-glycosidases have been studied,[16] and have shown that the glycone specificity is determined by a hydrogen network formed between glycone hydroxyls and amino acid residues of the subsite, and the amino acid residues close to the aglycone binding subsites +1 varied with various β-glucosidases in GH1 (Figure 1). Based on the sequence alignment of family 1 enzymes and analysis of the TmBglA structural model, three residues (F221, N223, and G224) in the active site pocket located on β-strand 5 close to sugar binding subsite +1 were selected for mutagenesis to investigate the influence on the enzyme kinetics (using the substrate *p*-nitrophenyl β-D-glucopyranoside (*p*NPG)), thermostability and pH profiles, and the hydrolysis of flavonoid glycosides (soy isoflavone glycosides and quercetin glucosides) in order to modulate the specificity of β-glucosidases that have valuable biotechnological applications.

MATERIALS AND METHODS

Strains, Plasmids, and Chemicals. The *p*-nitrophenyl (*p*NP) glycoside substrate *p*NPG as well as Isoflavone standards of daidzin (Din), daidzein, genistin (Gin), and genistein were purchased from Sigma Chemical Co. (St. Louis, MO, USA). High-performance liquid chromatography (HPLC) grade methanol and acetonitrile were purchased from Fisher Scientific (Hanover Park, IL, USA). Quercetin glucosides standards of quercetin-3,4′-*O*-glucose (Q3,4′), quercetin-3-*O*-glucose (Q3), quercetin-4′-*O*-glucose (Q4′), quercetin (Q) were purchased from Extrasynthese Chemical Co. (Genay, France). *Escherichia coli* (*E. coli*) JM109 (Promega, Madison, WI, USA) was used as host for the expression of β-glucosidase A gene from *T. maritima*, via plasmid pHsh.[19] DNA-modifying enzymes and polymerases were purchased from TAKARA (Dailian, China). All oligonucleotide primers were synthesized by Sangon (Shanghai, China). All other chemicals used were analytical grade reagents unless otherwise stated. Recombinant enzyme was induced by a temperature shift from 30 to 42 °C. *E. coli* was grown in Luria−Bertani (LB) supplemented with 100 μg of ampicillin mL^{-1}.

Sequence Alignment and Molecular Docking. The sequences of Tm-BglA and other GH1 β-glycosidases were aligned using ClustalW 2.0.12 and ESPript.[20] The structure of β-D-cellotetraose was docked into the active site of Tm-BglA (PDB code 2WC4) using AutoDock version 4.2.[21] The coordinate files of both protein and ligand required for docking calculation were prepared by AutoDockTools. The nonpolar hydrogens were deleted by the program, and the partial charges were merged to the carbon atoms. The sugar substrates were treated as rigid, and the rotatable bonds were set automatically by the program. The protein portion was set as flexible receptor by assigning the catalytic residues (E165 and E351) as flexible residues. AutoGrid was performed to precalculate the grid map of interaction energy prior to docking. The grid size was set at 60 × 60 × 60 with a grid point spacing of 0.258 Å at the center of protein. A Lamarckian genetic algorithm was used with a population size of 300, a maximum number of energy evaluations of 2500000, a maximum number of generations of 25000, and uniform crossover mode. Other parameters were set as default. The docked conformation was visualized using Accelrys DS Visualizer 3.0.[22]

Cloning and Site-Directed Mutagenesis. Plasmid constructions were carried out according to standard procedures.[23] The *T. maritima* β-glucosidase A gene, *Tm-bglA*, based upon that reported in Genbank entry X74163, was amplified with pET-20b-*Tm-bglA* as a template[7,8] and ligated at restriction sites XbaI and XhoI with pHsh;[19] the resulting recombinant plasmid was named as pHsh-*Tm-bglA*. Mutagenesis was performed in order to introduce the following designed changes F221L, N223L, G224T, F221L/N223L, F221L/G224T, N223L/G224T, and F221L/N223L/G224T, respectively. Eight oligonucleotides for each mutation were designed to contain the corresponding nucleotide changes (see Table 1). These oligonucleotides and pHsh-*Tm-bglA* as template were used to introduce mutations using polymerase chain reaction (PCR) under the following conditions: one cycle of denaturation at 95 °C for 5 min, 30 cycles of denaturation at 94 °C for 40 s, annealing at 55 °C for 40 s, extension at 72 °C for 4 min, and extra extension at 72 °C for 7 min. The PCR products were purified using the QIAquick PCR purification kit, phosphated with T4 polynucleotide kinase, and ligated into the expression vector pHsh,[19] resulting in the expression vectors containing exchange mutant Tm-BglA. The nucleotide changes were then sequenced by the Biological Services Unit of Shanghai.

Expression and Purification. To unambiguously characterize the activity of the mutational protein, the recombinant protein was purified to homogeneity as follows. *E. coli* JM109 containing pHsh-*Tm-bglA* and mutational plasmid were grown in LB media at 30 °C, pH 7.0 containing 100 μg of ampicillin mL^{-1} to an OD_{600} of 0.7−0.8, then transferred into a 42 °C shaking incubator, and grown for a further 9 h at 42 °C. The cells were harvested by centrifugation, washed twice with water, and then resuspended in binding buffer (5 mM imidazole, 0.5 M NaCl, and 20 mM Tris-HCl, pH 7.9). After sonication and centrifugation (30 min, 9600*g*, 4 °C), the supernatant was heated for 30 min at 70 °C to remove most of the host cell proteins by centrifugation. The resulting supernatants were purified by Ni-affinity chromatography (Novagen) to homogeneity as determined by the sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) using 12% polyacrylamide running gels with 4% polyacrylamide stacking gels. Protein concentration was determined by the Bradford method.[24]

Enzyme Assays. Enzyme activity was quantified by *p*NP release from *p*NPG. The reactions were performed in 50 mM potassium phthalate buffer (PPB, pH 6.2) containing 2 mM *p*NPG and 10 μL of suitably diluted enzyme for 5 min at 90 °C; the reaction was stopped by the addition of 600 μL of 1 M Na_2CO_3. The color that developed was read at 405 nm and translated to micromoles of *p*NP using a standard graph prepared under the same conditions. One unit was determined as the amount of enzyme producing 1 μmol of *p*NP/min under the preceding assay conditions. All reactions were done in triplicate.

Determiation of Kinetic Parameters. For determinations of the kinetic parameters (K_m, V_{max}, and k_{cat}/K_m) of *p*NPG, reaction was carried out at the optimum conditions using 0.2−2.0 mM *p*NPG. Kinetic parameters K_m and V_{max} were determined by the Lineweaver−Burk representation of the Michaelis−Menten model. Each experi-

dx.doi.org/10.1021/jf501932v | J. Agric. Food Chem. 2014, 62, 6763−6770

ment was done in duplicate, and measurements were made in triplicate. The standard error was recorded to be <2%.

The kinetic properties of the hydrolysis of Q4′ were determined by incubating the Q4′ at five concentrations in the range of 0.0215−0.215 mM. The standard reaction mixture (final volume, 50 μL) containing 5% dimethyl sulfoxide (DMSO) in 100 mM pH 5.0 PPB with 20 pmol of Tm-BglA and 10 pmol of G224T at 90 °C. The mixture without enzyme was preincubated at 90 °C for 5 min. After 5 min, the reactions were stopped by ice water cooling and freeze-dried and resuspended in 50 μL of methanol for HPLC analysis. The liberated Q was detected by measuring the absorbance at 260 nm; its amounts were calculated from standard curves of the Q peak areas over the 0.018−3.7 μmol range. The enzyme activity using Q4′ is expressed in units (U). A 1 U amount corresponds to the amount of enzyme required to release 1 μmol of Q/min under the described conditions. Each test was carried out with at least three replicates. The relative standard deviation was recorded to <2%. Obtained data were analyzed using graphpad prism 5.0, using a time range allowing the output of a Michaelis−Menten curve.

Hydrolysis of Isoflavone Glycosides and Quercetin Glucosides. First, onion extract from 10 g of onion skin was extracted for 40 min at 95 °C in 200 mL of 95% (w/v) ethanol, centrifuged (9600*g*, 4 °C, 30 min) and dried by speed vacuum, then resuspended in 25 mL of sterile double-distilled water (ddH_2O), and filtered through a 0.45 μm filter. To compare the hydrolysis of seven mutants toward flavone glycosides, 0.1 μmol of Din and 0.1 μmol of Gin were incubated with the purified Tm-BglA and mutant enzymes in 50 mM sodium phosphate buffer (SPB, pH 6.2) in a thermostatically controlled incubator at 90 °C, respectively. The flavone glycosides were where particular care was taken to ensure their complete solubility.[25,26] Equal molar concentrations of eight enzymes were assayed for their hydrolysis efficiencies toward the flavone glycosides. The reactions were stopped by ice water cooling before analysis, and 50 μL of methanol were then added to the hydrolyzed solutions. Aliquots of the methanol extract were spotted on thin layer chromatography plates using silica gel 60 F_{254} (Yantai Jiangyou Silica Gel Development Co., Ltd., China). The plate was developed with ethyl acetate/butanone/methanol/water (10:7:1:1, by vol) for the hydrolysis of daidzin and genistin, and with ethyl acetate/butanone/formic acid/water (5:3:1:1, by vol) and 2% aluminum trichloride methanol solution for quercetin glucosides; the products on the plate were visualized by absorbance under UV light at 254−365 nm.

Enzyme activity of the seven mutants and Tm-BglA for quercetin glucosides was determined using 20 μL of onion extracts, 20 pmol of enzymes, and 50 mM SPB (pH 6.2) in a 100 μL reaction volume at 90 °C for 10 min; then the hydrolyzed solutions were added into 300 μL of methanol. Samples of 20 μL were withdrawn and analyzed by HPLC to detect the hydrolysis of the quercetin glucosides. The analytical HPLC was carried out using the Agilent Zorbax SB-C18 column (4.6 × 250 mm, 5 μm). A gradient sequence using methanol (A) and 0.05% phosphoric acid solution (B) was utilized in the following proportions: 70% B (20 min), 30% B (5 min), 10% B (3 min), and 70% B (4 min) at a flow rate of 1 mL min^{-1}.

RESULTS

Structural Considerations and Mutation Strategy. The structure and the residues forming −1 subsite and the noncovalent interactions formed with the glycone of Tm-BglA have been reported; interacting residues included Gln20, His121, Asn165, Trp398, Glu405, and Trp406. In order to predict the interactions between Tm-BglA and the glycone substrate, cellotetraose was docked into the active site pocket of Tm-BglA to analyze putative interactions at the aglycone binding region. From the docked position of cellotetraose, 27 residues of Tm-BglA were predicted to be interacted with cellotetraose. Among these, the residues forming −1 subsite conforms to the report and the aglycone +1 subsite is formed by the residues V173, H180, N222, W324, and 407A (Figure 1). Inspection of residues surrounding the +1 subsite showed a nonconserved region at the "floor" of the active site, more precisely at the end of β-strand 5 (F221, N222, N223, G224, Y225, and F226). The nonconserved natures of these residues were shown by superimposition of known structures as well as analyzing a multiple sequence alignment. Superimposition of 3D structures of GH1 enzymes with diverse substrate specificities confirmed the variable area of β-strand 5 in the vicinity of the substrate pocket binding as well as variability in the loops. The variability at the end of β-strand 5 was also authenticated by the multiple sequence alignment of the Tm-BglA with other GH1 flavonoid-hydrolyzing enzymes (Figure 1). It was shown that the GH1 β-glucosidase (Te-BglA), from the *Th. ethanolicus* JW200, could more effectively hydrolyze isoflavone glucosides of soy flour to their aglycones than could Tm-BglA from *T. maritima*,[8] possibly due to the difference in amino acid residues around their glycone binding pockets. Therefore, the F221, N223, and G224 at the end of β-strand 5 were targeted for site-directed mutagenesis through replacement of the amino acid residues of Tm-BglA with the corresponding residues of Te-BglA, generating three single mutants, F221L, N223L, and G224T, as well as the corresponding three double mutants (F221L/N223L, F221L/G224T, and N223L/G224T) and one triple mutant (F221L/N223L/G224T).

Construction, Expression, and Purification of Mutant Enzymes. Seven expression vectors containing exchange mutant Tm-BglA were constructed as described in Materials and Methods. The nucleotide sequence of each mutant Tm-BglA was confirmed by DNA sequencing. These mutant and wild-type Tm-BglA (WT) were expressed in *E. coli*, purified by immobilized Ni-affinity chromatography after heat treatment and revealed by single bands on SDS-PAGE with apparent molecular masses of 52 kDa (Figure 2), which were in accordance with the theoretically calculated molecular mass.

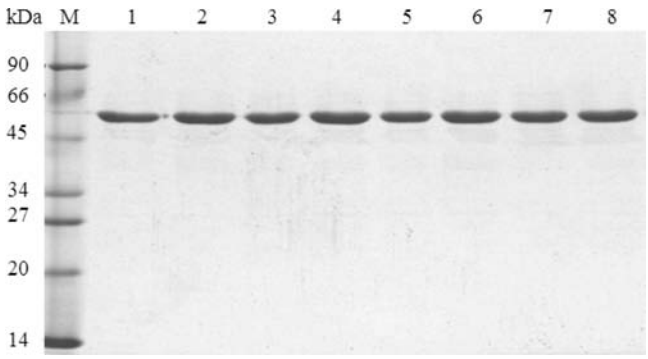

Figure 2. SDS-PAGE analysis of purified Tm-BglA and mutants: lane M, molecular mass standards; lane 1, Tm-BglA; lane 2, F221L; lane 3, N223L; lane 4, G224T; lane 5, F221/N223L; lane 6, F221L/G224T; lane 7, N223L/G224T; lane 8, F221L/N223L/G224T. Each lane except for the standards contained 2 μg of protein.

pH and Thermal Properties of Mutant and Wild-Type β-Glucosidases. The optimal temperatures and thermostabilities of seven variants were compared to those of WT in Figure 3A,B. All of the enzymes were optimally active at 90 °C except for G224T of which the optimal temperature was 95 °C. Nonetheless, the relative activity of seven mutants was lower than that of WT within the temperature range from 35 to 85

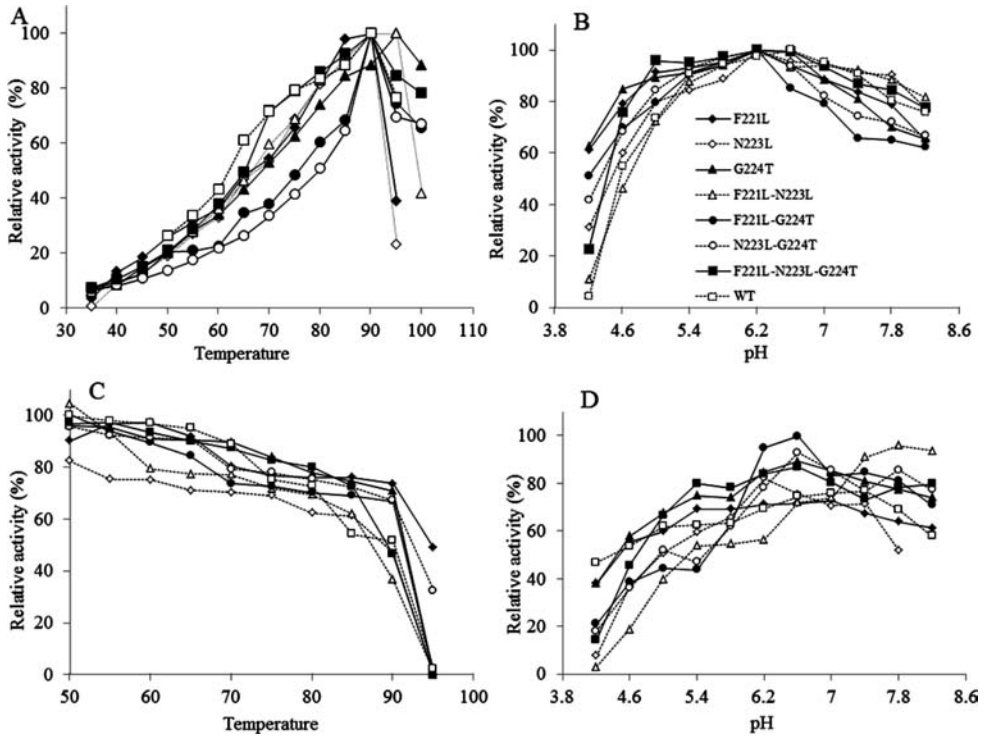

Figure 3. The optimal temperature (A), pH (B), heat stability (C), and pH stability (D) profiles of mutant and wild type β-glucosidases. Temperature dependence at pH 6.2 (A) and pH dependence at 90 °C (B) when a 5 min assay was used. The highest level of activity was defined as 100%. For heat stability (C), a 0.075 μg of purified enzyme in 50 mM PPB (pH 6.2) was perincubated for 1 h at a temperature range of 50−95 °C in the absence of substrate. For pH stability (D), 0.075 μg of purified enzyme in 50 mM PPB (pH 4.2 −8.2) was preincubated for 1 h at 37 °C in the absence of substrate. Full activity was determined at each pH value. The activity of the enzyme without preincubation was defined as 100%. Activity was determined at their optimal pH and temperature. Data are expressed as the means of three experiments, and the standard deviation for the mean was recorded to be <2%.

Table 2. Kinetic Parameters of the Tm-BglA and Seven Mutants[a]

enzyme	K_m (mM)	V_{max} (U·mg^{-1})	K_{cat} (s^{-1})	K_{cat}/K_m ($mM^{-1}·s^{-1}$)
		Hydrolysis of *p*NPG		
Tm-BglA	0.60 ± 0.01	299 ± 2	239 ± 4	398
F221L	0.80 ± 0.08	513 ± 22	448 ± 10	564
N223L	0.54 ± 0.04	257 ± 6	224 ± 5	414
G224T	0.87 ± 0.05	488 ± 12	426 ± 10	492
F221L/N223L	0.76 ± 0.03	415 ± 5	362 ± 4	474
F221L/G224T	0.72 ± 0.05	514 ± 13	448 ± 12	624
N223L/G224T	0.55 ± 0.03	467 ± 9	407 ± 8	740
F221L/N223L/G224T	0.78 ± 0.05	526 ± 9	459 ± 8	588
		Hydrolysis of Q4′		
Tm-BglA	0.066 ± 0.013	2.1 ± 0.29	17.6 ± 2.5	267
G224T	0.050 ± 0.002	3.5 ± 0.15	42.4 ± 1.8	848

[a]The kinetic parameters were determined at their optimal pH and temperature for the substrate concentrations ranging from 0.2 to 2.0 mM for *p*NPG and from 0.0215 to 0.215 mM for Q4′, using the standard assay as described in Materials and Methods.

°C. All seven mutants were stable up to 85 °C, which were the same as that of WT.

The pH properties of seven mutants and WT are shown in Figure 3C,D. The pH optima for the seven mutants were observed at pH 6.2 which are not altered from the pH optimum profile characteristic of WT. In contrast, seven mutants were found to decrease in stability within the pH below 5.0 compared to that of WT, whereas they displayed stability within the pH range from pH 6.5 to 8.3 and were even more stable than that of WT.

Kinetic Parameters of Mutant and Wild-Type Enzymes in pNPG Hydrolysis. The kinetic properties of WT and seven mutants for the hydrolysis of *p*NPG were determined at pH 6.2. The results are shown in Table 2. The K_m (mM) values of N223L and N223L/G224T calculated were 0.54 and 0.55, respectively, which were slightly lower than that for the WT (0.60), whereas the K_m (mM) for F221L, G224T, F221L/N223L, F221L/G224T, and F221L/N223L/G224T were 0.80, 0.87, 0.76, 0.72, and 0.78, respectively, which were slightly higher than that for the WT. Similarly, the k_{cat} (s^{-1}) value for N223L was 224, which was almost similar to the WT (239), whereas k_{cat} for F221L, G224T, F221L/N223L, F221L/G224T, N223L/G224T, and F221L/N223L/G224T were 448, 426, 362, 448, 407, and 459, respectively, which were increased

dx.doi.org/10.1021/jf501932v | J. Agric. Food Chem. 2014, 62, 6763−6770

about 1-fold compared to that of the WT. k_{cat}/K_m (s^{-1} mM^{-1}) values obtained for F221L, N223L, G224T, F221L/N223L, F221L/G224T, N223L/G224T, and F221L/N223L/G224T were 564, 414, 492, 474, 624, 740, and 588, respectively, and were obviously higher than that for the WT (398).

Hydrolysis of Isoflavone Glycosides and Quercetin Glucosides. The hydrolysis of isoflavonoid glycosides by WT and seven mutants were evaluated (Figure 4), and the hydrolysates were analyzed by thin-layer chromatography (TLC). The Gin were partially digested by the seven mutants and WT after 10 min reaction; the digested Gin by F221L, F221L/G224T, N223L/G224T, and F221L/N223L/G224T were less than that by the WT (Figure 4A). After 30 min of incubation, the hydrolysis of Gin by WT, N223L, and F221L/N223L were complete, but the reactions with other mutants (F221L, G224T, F223L/G224T, F221L/G224T, and F221L/N223L/G224T) retained a few Gin (Figure 4B). Meanwhile, Din were almost completely digested with WT after 10 min reaction, whereas after the reactions in the seven mutants some Din remained (Figure 4C). After 30 min of incubation, the Din was completely digested by G224T, N223L, F221L/G224T, and F221L/N223L/G224T; in the reactions with F221L, F221L/N223L, and N223L/G224T amounts of Din still remained (Figure 4D).

Subsequently, the hydrolysis of the quercetin glycosides and the free aglycones produced after reactions with or without enzyme were analyzed by TLC. As shown in Figure 4E, the Q4′ were almost completely digested by all of the variants carrying a mutation at position 224 (G224T, F221L/G224T, N223L/G224T, and F221L/N223L/G224T) after a 10 min reaction, whereas amounts of Q4′ remained in the reactions containing the WT and other mutants (F221L, N223L, and F221L/N223L). After 30 min of incubation, a little of Q4′ still remained in the reactions with N223L and F221L/N223L compared to almost complete digestion of the WT and F221L (Figure 4F). Therefore, the changes of components for hydrolyzing quercetin glucosides were further analyzed by HPLC (Figure 5). For the hydrolysis of Q3,4′, eight enzymes partially hydrolyzed the Q3,4′substrate to Q3 within the reaction time of 10 min except N223L and F221L/N223L (Figure 5A), which is consistent with that their increase of the component of Q3 (Figure 5B). The single, double, and triple mutants carrying a mutation at position 224 (G224T, F221L/G224T, N223L/G224T, and F221L/N223L/G224T) completely converted the Q4′ to Q after reactions for 10 min compared to the Q4′ that remained for the WT (Figure 5C) and had a higher yield of Q than WT (Figure 5D). The G224T resulted in a significant increase of 35.5% for conversion of Q4′ and 28.6% for conversion of Q3,4′ in accord with an increased turnover number (k_{cat}, 2.4×) and catalytic efficiency (k_{cat}/K_m,

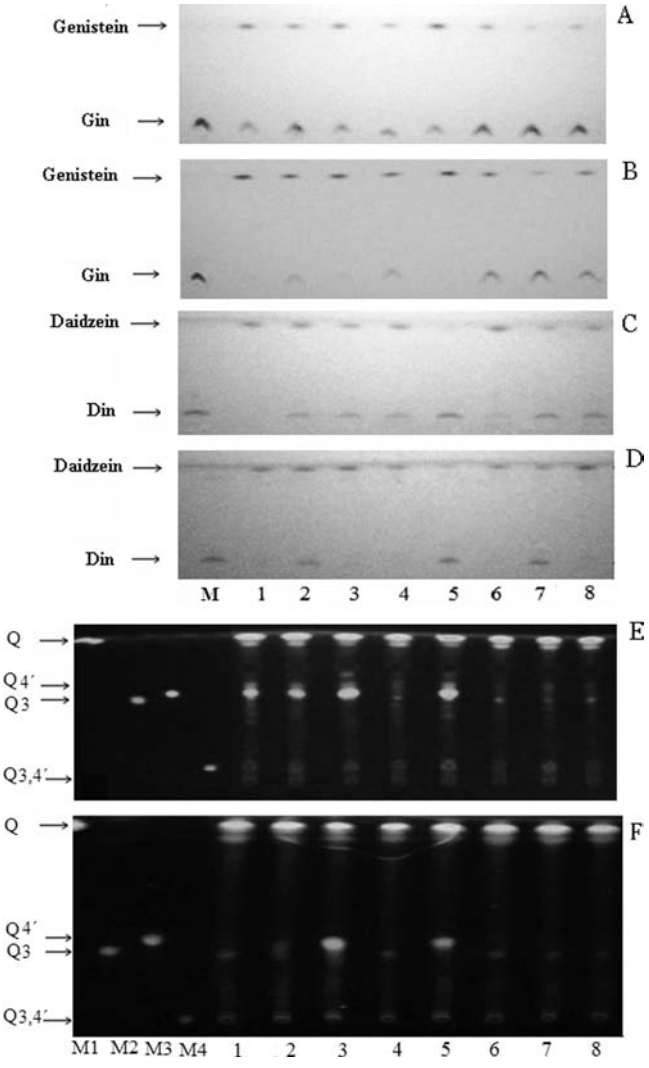

Figure 4. TLC analysis of the hydrolysis of isoflavonoid glycoside by mutants and WT. Hydrolysis of genistin (A and B), daidzin (C and D), and quercetin glycoside (E and F) in 50 mM SPB (pH 6.2) with mutants and WT for 10 min (A, C, and E) and 30 min (B, D, and F) at 70 °C. Lanes M, isoflavone glycosides (Din and Gin); lanes M1, quercetin; lanes M2, quercetin-3-*O*-glucose; lanes M3, quercetin-4′-*O*-glucose; lanes M4, quercetin-3,4′-*O*-glucose; lanes 1, reaction liquid with WT; lane 2, reaction liquid with F221L; lane 3, reaction liquid with N223L; lane 4, reaction liquid with G224T; lane 5, reaction liquid with F221/N223L; lane 6, reaction liquid with F221L/G224T; lane 7, reaction liquid with N223L/G224T; lane 8, reaction liquid with F221L/N223L/G224T.

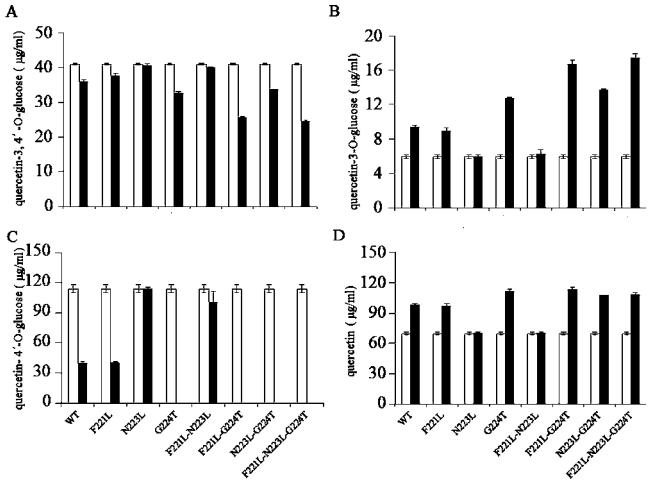

Figure 5. HPLC analysis of the hydrolysis of quercetin glycoside by mutant and wild type Tm-BglA (WT). Analysis of quercetin-3,4′-*O*-glucose (A), quercetin-3-*O*-glucose (B), quercetin-4′-*O*-glucose (C), and quercetin (D). White bars represent the quercetin glycoside concentration at time 0 min, and black bars are for the remaining quercetin glycoside concentration after 10 min incubation with the enzyme.

dx.doi.org/10.1021/jf501932v | J. Agric. Food Chem. 2014, 62, 6763−6770

3.2×) as indicated by a decrease of 24% in K_m for Q4′ (Table 2). However, 100% of Q4′, Q3, and Q3,4′ remained in the reactions containing N223L and F221L/N223L, indicating that the mutation at position 223 removed all hydrolytic activity on quercetin glucosides.

DISCUSSION

The *T. maritima* β-glucosidase A (Tm-BglA) effectively hydrolyzed isoflavone glucosides of soy flour to their aglycones and has demonstrated the great potential of a biocatalyst for food, medicine, and various agroindustrial processes. Pioneering studies suggested that GH 1 β-glucosidases have different capabilities of hydrolyzing flavone glycosides, reflecting that the amino acid residues located within the aglycone binding pocket varied with the enzymes. To investigate the role of the amino acid residues located within the aglycone binding pocket of Tm-BglA, the F221, N223, and G224 at the end of β-strand 5 were targeted for site-directed mutagenesis through replacement of the amino acid residues of Tm-BglA with the corresponding residues of Te-BglA from *T. ethanolicus* JW200. Seven mutants were constructed and expressed. All mutants prepared in this study were catalytically active, indicating that the selected amino acid residues were not an influence for active expression of Tm-BglA but resulted in slight shifts in optimum temperature and heat stability, and significant changes in hydrolysis activity of *p*NPG, isoflavone glycosides, and quercetin glucosides. All of the mutants showed pH-activity curves narrower on the basic side and wider on the acid side and had similar optimal pH and stability at pH 6.5−8.3 and were more stable up to 85 °C, but G224T displayed a higher optimal temperature (95 °C), indicating that the mutation at position G224 caused structural perturbation to change its thermal properties of Tm-BglA.

The enzyme kinetics (K_m, V_{max}, and k_{cat}/K_m) of Tm-BglA and the seven mutants for the hydrolysis of artificial substrate *p*NPG were studied in more detail. The seven mutants indicated an obvious increase in catalytic efficiency toward *p*NPG but an increase or no change in K_m, suggesting that F221, N223, and G224 were the key residues to determine *p*NPG binding of the substrate. All mutants did not have an increase in catalytic efficiency toward isoflavonoid glycosides. The F221L mutant showed a decrease in catalytic efficiency toward isoflavonoid glycosides whereas it did not affect the hydrolytic activity on quercetin-3,4′-*O*-glucose and quercetin-4′-*O*-glucose. In addition, the N223L mutation also decreased the catalytic efficiency on isoflavonoid glycosides but removed all hydrolytic activity of quercetin glucosides. These results indicate that the differences in catalytic efficiency between Tm-BglA and Te-BglA are not primarily due to differences in the residues that directly contact the substrate but rather drawn from differences in more remote residues in both aglycone and glycone binding pockets.[21] However, a mutation in the analogous position in *T. neapolita* TnBgl1 A, N221S, increased catalytic efficiency in both Q3 and Q4′ hydrolysis,[9] suggesting a preferred polar residue at this position toward quercetin glucosides hydrolysis.

Contrarily, the G224T mutant had a dramatic effect upon flavonoid-hydrolyzing activity, which decreased the catalytic efficiency in soy isoflavone glycosides, whereas G224T and corresponding double and triple mutants carrying G224T mutant increased the catalytic efficiency in Q3,4′ and Q4′. The G224 position has also shown significance in structural homologues of Tm-BglA. In this study, the k_{cat}/K_m (s^{-1} mM^{-1}) values obtained for G224T were obviously higher than that for the wild-type Tm-BglA, whereas G222F in TnBgl1A, corresponding to position G224, reduced catalytic efficiency (k_{cat}/K_m) for *p*NPG hydrolysis.[27] These results further support the influence of G224 on aglycone specificity. A close look at the binding interactions of G224 in the presence of Q4′ shows that the residue is interacting with residues in neighboring strands of the Tm-BglA (the backbone carbonyls of N222, N223, N246, and Y295; Figure 6), and G224 is

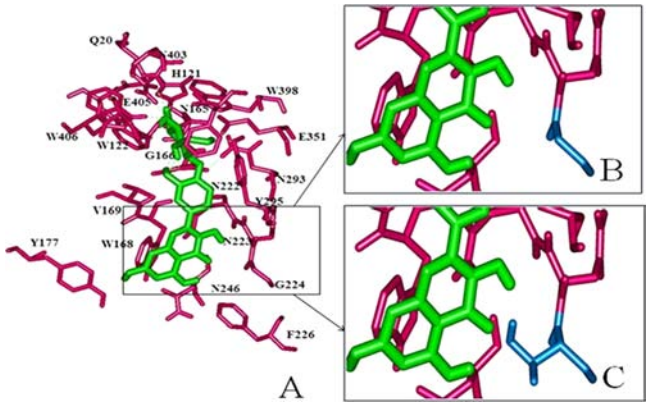

Figure 6. Model of Tm-BglA containing a docked structure of quercetin-4′-*O*-glucose. The quercetin-4′-*O*-glucose molecule is colored in green. In panel A, the residues of Tm-BglA interacted with quercetin-4′-*O*-glucose are labeled and depicted in red stick models. In panel B and panel C the amino acids at position 224 are colored by blue. The figure was drawn with Accelrys DS Visualizer 3.0.

located near the narrowest part of the active-site cleft, and previous finding suggest spatial hindrance is a mechanism for the reduced catalytic activity that occurs after insertion of a bulkier amino acid in this position.[12] In the present study, G224T increased the turnover number and catalytic efficiency for Q4′, and decreased the distance between the residue at position 224 and the C4 of the substrate Q4′ from 3.166 to 2.057 Å, likely because it is closer to the quercetin backbone of Q4′ to enhance the interaction between the enzyme and the substrate. Furthermore, the replacement G with T containing the OH side chain introduced structures similar to Q4′ (e.g., 5-OH and 3-OH on the quercetin backbone) accessible to an environment more suited for Q4′ in the aglycone binding pockets in accord with a decrease in K_m for Q4′.

In conclusion, F221, N223, and G224 at the end of β-strand 5 of Tm-BglA were selected for mutagenesis to investigate the influence on the kinetic properties and hydrolysis of glucosylated flavonoid. Our results suggest that three residues play an important role in determining the substrate specificity of Tm-BglA. G224T resulted in a dramatic increase conversion of Q4′ (35.5%) and Q3,4′ (28.6%) in accord with an increased turnover number (k_{cat}/K_m, 1.4×) and catalytic efficiency (k_{cat}/K_m, 2.2×) as well as a decrease in K_m (0.24) for Q4′, which we report herein have valuable biotechnological applications.

amphipathic termini, and is expressed by *Escherichia coli* as an insoluble recombinant protein. The insoluble fusion protein was mixed with triacylglycerol and phospholipid and reconstituted as AOBs, in which the lipophilic portion of oleosin is embedded in the triacylglycerol core and the amphipathic arms, fused with the target enzyme, are protruding on the surface[13] As illustrated in previous studies, the target enzyme tends to refold itself naturally and present itself in a biologically functional form on the surface of the AOB.[12,14] Therefore, AOB-based immobilization is an efficient way to achieve purification and immobilization of the recombinant enzyme in one step.

In this study, the CC-DPEase gene was constructed to allow *E. coli* to reveal the oleosin-fused protein. The purification, refolding, and immobilization of CC-DPEase were simultaneously accomplished upon reconstitution of the AOBs. To examine the alterations of enzyme characteristics due to the immobilization, central composite design (CCD) combined with response surface modeling (RSM) was employed for the planned statistical optimization of enzyme activity. The reusability and thermal stability of the AOB-immobilized CC-DPEase were also determined.

MATERIALS AND METHODS

Construction of CC-DPEase Expression Plasmid. The DNA fragments encoding CC-DPEase (GenBank accession no. ACL75304) were amplified by polymerase chain reaction (PCR) from the plasmid pET-21a-CC-DPEase[15] using the forward primer (5′ AGATCTATGAAACATGGTATATAC 3′) and reverse primer (5′ GGTACCGGAGTGTTTATG 3′). These two primers were designed to place a *Bgl*II site at the 5′ end and a *Kpn*I site at the 3′ end of the PCR products, respectively. The PCR fragments encoding CC-DPEase were digested with restriction endonucleases *Bgl*II and *Kpn*I. The fragments were then ligated with the *Bgl*II–*Kpn*I-digested plasmid pET29Ole,[16] generating pET29-DPEase-Ole, which was then sequenced to ensure that no errors were introduced during PCR. The resultant plasmids were used to transform *E. coli* BL21 (DE3) (Novagene, Madison, WI, USA) by standard techniques.[17] The *E. coli* BL21 (DE3) transformants were selectively grown at 37 °C on Luria–Bertani (LB) agar plates (Difco Laboratories, Detroit, MI, USA) containing kanamycin (50 μg/mL) (Sigma-Aldrich Co., St. Louis, MO, USA).

Expression of Recombinant Proteins. The *E. coli* BL21 (DE3) transformants were cultured in LB broth at 37 °C with shaking at 250 rpm for overnight. The overnight culture was subsequently seeded at a 1:100 dilution into 50 mL of fresh LB broth. The cell cultures were maintained at 37 °C with shaking at 250 rpm, and the cell proliferation was measured turbidimetrically at 600 nm (OD600). Once the cells reached an OD600 of 0.5, the cells were induced to express the recombinant protein with 100 μM isopropyl-D-1-thiogalactopyranoside (IPTG; Sigma-Aldrich Co.). After 4 h of induction, the *E. coli* cells were harvested by centrifugation at 5000*g* for 10 min at 4 °C.

Immobilization of CC-DPEase on AOB. The preparation of AOBs was carried out according to the method described by Chiang et al.[18] The *E. coli* cell pellet was resuspended in 1 mL of 50 mM sodium phosphate buffer (pH 7.4), ultrasonicated (Misonix, Farmingdale, NY, USA) for 10 min, and then fractionated into supernatant and pellet by centrifugation at 13000*g* for 10 min at 4 °C. To reconstitute the AOBs, the pellet fraction of the *E. coli* cell lysate containing 550 μg of oleosin-fused recombinant proteins was resuspended in 1 mL of 50 mM sodium phosphate buffer (pH 7.4) and then mixed with 15 mg of olive oil (Sigma-Aldrich Co.) and 150 μg of phospholipid (Sigma-Aldrich Co.). The mixture was subjected to ultrasonication for 10 min. The reconstituted AOBs were collected after centrifugation at 13000*g* for 10 min at 4 °C and were washed with 50 mM sodium phosphate buffer solution (pH 7.4). The results of each step of AOB reconstitution were monitored using sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE).[19] Confocal microscopic observation of the AOB-immobilized CC-DPEase was performed using a Leica TCS SP5 II spectral confocal microscope mounted on a Leica DMI 6000B inverted microscope (Leica Microsystems, Heidelberg, Germany) with a HCX PLAPO CS 63×/1.4-0.6 oil immersion objective.

CC-DPEase Activity Analysis. The enzyme activity of the AOB-immobilized CC-DPEase was determined using D-fructose (50 g/L; Sigma-Aldrich Co.) as the substrate in a reaction mixture containing sodium phosphate buffer (50 mM, pH 7.0), Co^{2+} (0.1 mM), and enzyme (0.5 μM) at 72 °C for 10 min. The reaction was stopped by boiling for 10 min, and then the amount of D-psicose epimerized from D-fructose was determined by using a high-performance liquid chromatography (HPLC) method.[10] The concentrations of D-psicose and D-fructose in the samples were determined by HPLC performed on a Shimadzu (Kyoto, Japan) LC-20 AT delivery system equipped with an RID-10A refractive index detector (Shimadzu), a Sugar-Pak I column (Waters Corp., Milford, MA, USA; 300 × 5 mm i.d.), and a Rheodyne injector (Rheodyne Inc., Cotati, CA, USA). The column was eluted at 80 °C with deionized water and a flow rate of 0.4 mL/min. One unit of enzyme activity was defined as that producing 1 μmol of D-psicose per minute from D-fructose under the assay conditions, with specific activity expressed as units per milligram of protein. The protein concentration was determined using the Lowry assay against a standard curve of bovine serum albumin, fraction V (Sigma-Aldrich Co.).[20]

The bioconversion rate of D-fructose to D-psicose by the AOB-immobilized CC-DPEase was determined using D-fructose (50 g/L; Sigma-Aldrich Co.) as substrate in a reaction mixture containing sodium phosphate buffer (50 mM, pH 7.0), Co^{2+} (0.1 mM), and enzyme (0.5 μM) at 72 °C for 30 min.

Optimal pH and Temperature of the AOB-Immobilized CC-DPEase. The pH and temperature are the key factors affecting enzyme activity of CC-DPEase;[10] therefore, we chose pH (denoted X_1) and temperature (denoted X_2) as the factors and CC-DPEase activity (denoted Y) as the response in the statistical experimental design. The optimal pH and temperature for the AOB-immobilized CC-DPEase were determined by applying CCD experimental design combined with RSM and regression analyses. On the basis of the CCD, a set of 13 experiments including 4 factorial points, 4 axial points, and 5 central points were performed. The experimental index numbers, scaled values, and actual values are shown in Table 1. The scaled values were defined as follows: $X_1 = (\mathrm{pH} - 7)$; $X_2 = (T - 72.5)/7.5$. The statistical experimental design, data, and regression analyses were carried out

Table 1. Process Variables Used in the CCD and Treatment Combinations and Mean Experimental Responses for AOB-Immobilized CC-DPEase

using Design Expert software (version 8.0.6, Stat-Ease Inc., Minneapolis, MN, USA). Regression analysis of the experimental data yielded linear, quadratic, and cubic polynomial models. Model analyses, lack-of-fit tests, and *R*-squared analyses were performed to validate the reliability of these models. A model with a significant *P* value ($P < 0.05$) in the model analyses, insignificant *P* value ($P > 0.05$) in lack-of-fit tests, maximum *R*-squared value, and smallest predicted residual sum of the squares (PRESS) was selected. Analysis of variance (ANOVA) was employed to determine the significance of the optimized model.

After the optimal pH and temperature for the AOB-immobilized CC-DPEase were predicted, the actual activity of the AOB-immobilized CC-DPEase was determined at the optimal conditions to compare the predicted values and experimental data and check the reliability of the RSM. Student's *t* test was used to detect the differences between the predicted and actual values.[21]

Thermal Stability of AOB-Immobilized CC-DPEase. The thermal stability of AOB-immobilized CC-DPEase was determined by incubation of the enzyme at 55 or 72 °C in sodium phosphate buffer (50 mM, pH 7.0) containing 0.1 mM Co^{2+}. Aliquots were withdrawn at intervals of 0, 10, 30, 60, and 120 min, and the residual enzyme activities were measured as specified.

Reusability of AOB-Immobilized CC-DPEase. The reusability of AOB-immobilized CC-DPEase was determined by incubation of the enzyme at 72 °C for 10 min in sodium phosphate buffer (50 mM, pH 7.0) containing 0.1 mM Co^{2+} and D-fructose (50 g/L). At the end of the reaction, the immobilized enzyme was recovered by centrifugation, and the supernatant was removed for analysis of the amount of D-psicose epimerized from D-fructose. The reaction was restarted by administration of the recovered enzymes in a fresh substrate solution.

RESULTS AND DISCUSSION

Simultaneous Refolding, Purification, and Immobilization of CC-DPEase on AOBs. The scheme of production of AOB-immobilized CC-DPEase is shown in Figure 1A. The DNA fragments encoding CC-DPEase were fused to the oleosin gene and overexpressed in *E. coli*. After induction with IPTG at 37 °C, a band of about 51 kDa corresponding to the CC-DPEase−oleosin fusion proteins was observed in the induced recombinant *E. coli* (Figure 1B, lane 2). The CC-DPEase−oleosin fusion proteins were generally found in the insoluble fraction of the cell lysate after centrifugation (Figure 1B, lane 4). After reconstitution into AOBs, most of the CC-DPEase−oleosin fusion proteins were present in the oil body fraction after centrifugation, and almost none of the CC-DPEase−oleosin fusion protein was found in the supernatant fraction (Figure 1B, lanes 5 and 6). According to the confocal microscopic observation (Figure 1C), the sizes of the AOBs ranged from 0.5 to 3.5 μm, with a mean size of 2.0 μm. The CC-DPEase activities of proteins obtained from each step of the AOB reconstitution were determined by HPLC using D-fructose as the substrate. Detectable levels of CC-DPEase activity were observed in the reconstituted AOBs but not in the insoluble fraction of the cell lysate of the induced recombinant bacteria, indicating that CC-DPEase was immobilized on the AOB surface and folded into the active structure. From 1.0 g (wet weight) of *E. coli* cells, we obtained 17.33 mg of CC-DPEase−oleosin fusion proteins and reconstituted 1.65 mL of

dx.doi.org/10.1021/jf502022w | J. Agric. Food Chem. 2014, 62, 6771−6776

AOBs. The protein concentration of the reconstituted AOBs was 10.5 mg/mL.

Optimization of Reaction Conditions for the AOB-Immobilized CC-DPEase. Mu et al. indicated that environmental pH and temperature were the key factors affecting the activity of CC-DPEase.[10] Therefore, we chose these two factors and employed a CCD experimental design and RSM analysis to determine the reaction conditions for optimal enzyme activity of the AOB-immobilized CC-DPEase. On the basis of the CCD experimental design, a set of 13 experiments were performed. The scaled and actual values of pH and temperature performed in the experiments and the results for enzyme activities are shown in Table 1. Regression analysis of the experimental data yielded linear, quadratic, and cubic polynomial models. In the analysis of the mathematical models, the quadratic model appeared to be the most accurate ($P < 0.05$), with insignificant lack-of-fit ($P > 0.05$) and the smallest PRESS value (Supporting Information Table S1). These results suggested that the quadratic model was more reliable and accurate than the other models.

The quadratic regression equation obtained was

$$Y = -4956.10 + 1038.45 \times \mathrm{pH} + 41.11 \times T - 75.93 \times \mathrm{pH}^2 - 0.30 \times T^2 + 0.35 \times \mathrm{pH} \times T \quad (1)$$

where Y is the predicted response for a specific activity (U/mg of total protein) of the AOB-immobilized CC-DPEase and pH and T are the actual values for pH and temperature (see Table 1).

The three-dimensional plot as functions of pH and temperature on the specific activities of the AOB-immobilized CC-DPEase is shown in Figure 2. The model predicted that the maximum specific activity of the AOB-immobilized CC-DPEase (162.13 ± 6.83 U/mg) would be observed at 72 °C and pH 7.0. To confirm the applicability of the model, the specific activity of AOB-immobilized CC-DPEase was determined at the suggested optimum conditions. The experimental activity of 166.22 ± 0.53 U/mg confirmed the accuracy of the model.

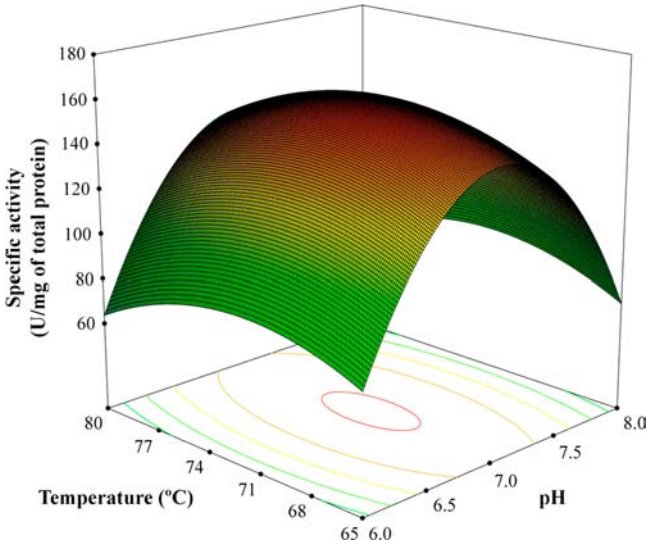

Figure 2. Response surface plot for the effects of pH and temperature on the specific activity of AOB-immobilized CC-DPEase.

Immobilization of enzymes can cause slight distortions in the enzyme structure, resulting in alterations in their activity, specificity, or stability.[22] Thus, we determined the optimal pH and temperature for the maximum enzyme activity of the AOB-immobilized CC-DPEase. We found that the maximum enzyme activity of the AOB-immobilized CC-DPEase occurred at pH 7.0 and 72 °C, which was different from that of the free-form CC-DPEase (pH 8.0 and 55 °C).[10] Therefore, we suggest that immobilization of CC-DPEase on AOB increased the optimal temperature but decreased the optimal pH of the enzyme activity. To compare the bioconversion rate of D-fructose to D-psicose by the AOB-immobilized CC-DPEase and by the free-form CC-DPEase, we performed epimerization reactions mediated by the AOB-immobilized CC-DPEase in the optimal reaction conditions for the free-form CC-DPEase (pH 8.0 and 55 °C) or for the AOB-immobilized CC-DPEase (pH 7.0 and 72 °C). The bioconversion rate of D-fructose to D-psicose by the AOB-immobilized CC-DPEase at pH 8.0 and 55 °C was 32.5%. This rate was similar to that of the free-form CC-DPEase reported by Mu et al.[10] In contrast, the bioconversion rate of D-fructose to D-psicose by the AOB-immobilized CC-DPEase at pH 7.0 and 72 °C was higher (45.8 vs 32.5%) than at the optimal reaction conditions for free-form CC-DPEase (pH 8.0 and 55 °C). In many cases, immobilization has an adverse effect upon enzyme activity because the interaction of the enzyme with carrier causes the distortion of the enzyme. To avoid degradation of enzyme properties, immobilization of the enzyme on a carrier via a linker is useful because the enzyme is flexible and reacts with the substrate more easily.[22] In this study, we introduced a linker polypeptide between the CC-DPEase and oleosin domains in the CC-DPEase−oleosin fusion protein. The AOB-immobilized CC-DPEase showed a bioconversion rate similar to that of the free-form enzyme, indicating that the CC-DPEase domain in the fusion protein was able to present its original conformation and maintain its functionality.

Thermal Stability of the AOB-Immobilized CC-DPEase. The thermal stability of AOB-immobilized CC-DPEase was evaluated by exposing the enzyme to 55 or 72 °C for 120 min. The residual activity of the AOB-immobilized CC-DPEase after incubation at 55 °C for 120 min was 85%, which was similar to that of the free-form CC-DPEase reported by Mu et al.[10] When the AOB-immobilized CC-DPEase was incubated at 72 °C for 120 min, the residual activity was 71% (Supporting Information Figure S1).

Thermal stability is an essential requirement for industrial enzymes because the reaction at higher temperatures can increase the bioconversion rate, reduce the reactants solubility, and reduce the risk of contamination during biocatalytic processes.[23] CC-DPEase has considerable potential in industrial practice because it possesses a remarkable thermal stability. Compared to *A. tumefaciens* DPEases, CC-DPEase has a similar bioconversion rate of 32%, but the half-life of CC-DPEase (9.5 h at 55 °C) is much longer than that of *A. tumefaciens* DPEase (8.9 min at 55 °C).[10,15] For the purpose of recovery and reuse, we immobilized CC-DPEases on AOBs and demonstrated that the bioconversion rate of D-fructose to D-psicose by the AOB-immobilized CC-DPEase was similar to that of the free-form enzyme. Thus, the AOB-immobilized CC-DPEase has potential application in the production of D-psicose at a lower cost than that of the free-form enzyme.

Reusability of the AOB-Immobilized CC-DPEase. To evaluate the feasibility of recovery and recycle of the AOB-immobilized CC-DPEase, the relative activity of the AOB-immobilized CC-DPEase was determined during five consec-

utive rounds of bioconversion of D-fructose to D-psicose at pH 7.0 and 72 °C. The AOB-immobilized CC-DPEase retained >50% of its initial activity after five cycles of enzyme use (Supporting Information Figure S2). Immobilized enzymes are preferred in biocatalytic processes for industrial applications because immobilized enzymes can be recycled and thus reduce the cost of production. AOB-immobilized enzymes can be easily and simply recovered from the surface of the reaction mixture by flotation centrifugation. Therefore, several enzymes, including D-hydantoinase, xylanase, and glucanase, have been immobilized on AOBs in previous studies.[12−14] Results in the previous and in our studies proved that, under optimal conditions, AOB-immobilized enzymes could be reused many times, thereby lowering the cost of enzymes for industrial application where the cost of enzymes is high.

In conclusion, the gene encoding CC-DPEase was cloned and expressed as an oleosin-fused protein in *E. coli*. Simultaneous refolding, purification, and immobilization of the active C-DPEase were accomplished as a result of reconstituting the AOBs. CCD experimental design combined with RSM and regression analyses were successfully applied to determine the optimal pH and temperature for the AOB-immobilized CC-DPEase. The optimum conditions for maximum enzyme activity of the AOB-immobilized CC-DPEase were observed at 72 °C and pH 7.0. Moreover, the AOB-immobilized CC-DPEase had a bioconversion rate and thermal stability similar to those of the free-form enzyme, but could be reused five times while retaining >50% of its activity. These results prove that the AOB-immobilized CC-DPEase has potential application in the production of D-psicose at a lower cost than the free-form enzyme does.

MATERIALS AND METHODS

Reagents and Solutions. Caffeine (CAS Registry No. 58-08-2), (+)-catechin (>99.0% (HPLC), CAS Registry No. 154-23-4) (C), (−)-epicatechin (>95.0% (HPLC), CAS Registry No. 490-46-0) (EC), (−)-epicatechin gallate (>98% (HPLC), CAS Registry No. 1257-08-5) (ECG), (−)-catechin gallate (>98% (HPLC), CAS Registry No. 130405-40-2) (CG), (−)-epigallocatechin (>95.0% (HPLC), CAS Registry No. 970-74-1) (EGC), (−)-gallocatechin (>98% (HPLC), CAS Registry No. 3371-27-5) (GC), (−)-gallocatechin gallate (>98% (HPLC), CAS Registry No. 4233-96-9) (GCG), (−)-epigallocatechin gallate (>95.0% (HPLC), CAS Registry No. 989-51-5) (EGCG), formic acid (>98%, CAS Registry No. 64-18-6), and acetic acid (>99%, CAS Registry No. 64-19-7) were all supplied by Sigma-Aldrich Química S.A. Methanol (high-performance liquid chromatography (HPLC) grade) CAS Registry No. 67-56-1 was provided by Scharlab (Mollet del Vallés, Spain). Ultrapure water was obtained from a Millipore Milli-Q_{PLUS} 185 system (Madrid, Spain).

An individual solution of each catechin and caffeine standard of 50 μg/g in methanol was used for the study. For building the calibration curve, a mixture of standards from caffeine and eight catechins with concentrations ranging between 1 ng/g and 75 μg/g in methanol was prepared. A 50 μg/g solution of green tea extract (GTE) was also prepared in methanol. The solution was filtered through a syringe filter of 0.22 μm pore size (KX Syringe Filter, 25 mm, 0.22 μm Nylon, Kinesis, UK) prior to injection.

Green Tea Extract and Polymeric Active Films. Green tea extract Sunphenon 90 MB (GTE) was supplied by TAIYO Europe (Filderstadt, Germany), and it contained around 75% total catechins (w/w), according to the HPLC determination provided by the supplier company.

The active packaging was manufactured and supplied by the Spanish company ARTIBAL S.A. (Sabiñánigo, Spain). It consisted of a solvent base coating layer (varnish) with a constant concentration of GTE (1% of green tea extract in the coating solution) applied on a plastic film of polyethylene terephthalate (PET). The system was under EU patent EP1477519-A1.[31] The coating varnish is approved for food contact. Active films contained the active substance expressed as percentage of active agent/weight active layer and the grammage of the material was 3.0 g/m^2. The PET film was 23 μm thick with a density of 18.73 ± 0.02 g/m^2. Coated films without GTE were used as blanks.

UPLC-MS/Q-TOF for the Analysis of Catechins and Caffeine Standards. Chromatography was carried out in an Acquity TM system using an Acquity UPLC BEH C18 column of 1.7 μm particle size (2.1 mm × 100 mm), both from Waters (Milford, MA, USA). Chromatography was carried out at 0.3 mL/min column flow, and the column temperature was 35 °C. The solvents used as mobile phase were water with 0.1% formic acid (eluent A) and methanol with 0.1% formic acid (eluent B). The gradient used was 0−6 min, 5% B; 6−8 min, 95% B; and 8−10 min, 5% B. The volume of sample injected was 5 μL.

Eluting compounds were detected by a time-of-flight mass spectrometer (TOF) LCT Premier XE from Waters with an electrospray probe in positive mode (ESI+) and in negative mode (ESI−) in W mode. Cone voltages were optimized between 20 and 50 V. Finally, 30 V was selected for the analysis because all catechin peaks were detected. Other MS parameters were as follows: desolvation gas flow, 600 L/h; desolvation gas temperature, 450 °C; source temperature, 120 °C. The MS range acquired was 50−1200 Da.

MassLynx (v. 4.1) software (Waters) was used to acquire and process the chromatographic and MS data.

UPLC-MS/TQ for the Analysis of GTE and for the Migration Tests. A system consisting of an Acquity Ultra Performance LC TQ detector (triple quadrupole; Waters) was used for the analysis. An ESI probe was used in positive (ESI+) and in negative (ESI−) mode as the ionization source, and MassLynx (v. 4.1) software (Waters) was used to acquire and process the chromatographic and MS data.

Chromatography was carried out in the Acquity system using an Acquity UPLC BEH C18 column of 1.7 μm particle size (100 mm × 2.1 mm) from Waters. Catechins and caffeine were separated under the following conditions: flow rate, 0.3 mL/min; injection volume, 10 μL; column temperature, 35 °C; solvents used as mobile phase were water with 0.1% formic acid (eluent A) and methanol with 0.1% formic acid (eluent B); and gradient used was 0−6 min, 5% B; 6−8 min, 95% B; and 8−10 min, 5% B.

Eluting compounds were detected and quantified by MS in both positive and negative modes under the following ionization conditions: capillary voltage, ±3.50 kV; source temperature, 120 °C; desolvation gas temperature, 450 °C; cone gas flow, 40 L/h; desolvation gas flow, 450 L/h. The cone voltage selected was 30 V. The compounds were detected in SIR mode, and the m/z ratios selected were 289.07 (C and EC, ESI−), 305.07 (EGC and GC, ESI−), 441.08 (ECG and CG, ESI−), 457.08 (EGCG and GCG, ESI−), and 195.08 (caffeine, ESI+).

Migration Tests. For migration experiments, a 6 cm × 12 cm piece of active plastic film was immersed in a 20 mL simulant solution. The simulants used for the migration test were Milli-Q water (simulant A from Directive 2002/72[32]) and 3% acetic acid in purified water (simulant B). The solutions were kept in an oven at 70 °C for 2 h. Finally, the solutions were analyzed by UPLC-MS/TQ using the same chromatographic method previously described. The concentration of GTE in the active plastic films was 1% in the coating solution. Plastic films without GTE were used as blanks. All of these samples were prepared in triplicate. The migration values were expressed as micrograms of compound per kilogram of food simulant. The migration values were corrected by taking into account the proportion of laminate/food simulant used in these experiments (72 cm^2 of laminate/20 mL of simulant) and those established in EU Regulation 10/2011 on plastic materials (6 dm^2 of laminate/1 kg of food simulant).[33]

Spectroscopic Analysis of Catechins and Caffeine Standards: The Continuous Variations Method (Job's Method). A 0.09 μM solution of catechin standard and 0.09 μM solution of epicatechin standard were prepared in methanol. A 0.13 μM solution of caffeine was also prepared in methanol. Five solutions were prepared and mixed to give solutions of mole fraction (X) of catechins solution varying from 0 to 1. Specifically, the different molar fraction solutions prepared were 0, 0.25, 0.5, 0.75, and 1. The measurements were carried out in a 1 cm quartz cell, and the volume of the final mixture was 3 mL. The absorbance of the mixtures was measured at 279 nm with a UV-1700 PharmaSpec UV−vis spectrophotometer (Shimadzu, Kyoto, Japan). All of the measurements were performed in triplicate.

Computer Simulation of Complexes between Caffeine and Catechins. Chem Draw and Chem 3D Pro 12.0 (Cambridge Soft Corp., Cambridge, MA, USA) were the softwares used to simulate the complexes between caffeine and catechins. These softwares are powerful tools for producing a nearly unlimited variety of biological and chemical drawings and can generate, operate, calculate, and predict realistic molecular structures and associated properties such as energies involved. Using Chem 3D Pro energy calculations with MM2 force field can be carried out.[34] MM2 methods include (1) "energy minimization" for locating stable conformation (global minimum), (2) "molecular dynamics" for studying molecular motion of atoms, and (3) "compute properties" for reporting the total steric energy (TSE) in a current conformation of a model.[35]

To optimize the model measurements, the minimum RMS gradient was fixed as 0.100, which was a reasonable compromise between accuracy and speed of calculations and afforded results close to a global minimum value of energy. The step interval, which determines the time between molecular dynamics steps, was fixed as 2 fs, and the frame interval value, which determines the interval at which frames and statistics are collected, was 10 fs. These values provided short periods of analysis. The heating/cooling rate was approximately 1.0 kcal/atom/ps because it minimally disturbed the trajectory of atoms. Finally, the target temperature was 300 K. The simulation is terminated when the target temperature is reached.

RESULTS AND DISCUSSION

Migration Test. Catechins and caffeine are the major ingredients in GTE. These compounds are known for their

antioxidant properties and can be incorporated into packaging materials to protect foodstuffs. In this work, active plastic films containing 1% green tea extract in the coating formula were evaluated. The migration values of catechins and caffeine were studied in two different food simulants. The most relevant analytical parameters for UPLC-MS/TQ are shown in Table 1.

Table 1. Analytical Features of the UPLC-MC/TQ Method

name	linear range (μg/kg)	LOD (μg/kg)	LOQ (μg/kg)	RSD (%, n = 3)
(+)-C	0.22−52.34	0.07	0.22	2.60
(−)-EC	0.09−52.34	0.03	0.09	3.37
(−)-GC	9.66−52.34	2.90	9.66	1.41
(−)-EGC	4.70−52.34	1.41	4.70	1.14
(−)-ECG	0.95−52.34	0.29	0.95	2.90
(−)-CG	0.44−52.34	0.13	0.44	1.25
(−)-EGCG	0.29−52.34	0.09	0.29	3.29
(−)-GCG	0.47−52.34	0.14	0.47	2.27
caffeine	0.07−24.56	0.02	0.07	1.05

Good results were obtained in terms of limit of detection (LOD), limit of quantification (LOQ), and reproducibility. The LOD values were between 0.02 μg/kg (caffeine) and 2.90 μg/kg (GC). In fact, the stereoisomers GC and EGC were the catechins with the lowest LODs. The RSD values were below 4%. The linear ranges obtained were calculated with at least five calibration points, and the results varied from 0.09 to 52.34 μg/kg for catechins. For caffeine, the linear range obtained was from 0.07 to 24.56 μg/kg.

Table 2 shows the migration values of catechins and caffeine found in the migration experiments for both simulants. The

Table 2. Migration Values of Catechins and Caffeine in Two Aqueous Simulants by UPLC-MS/TQ

name	simulant Milli-Q water (μg/kg)	simulant 3% acetic acid in water (μg/kg)
(+)-C	10.44 ± 0.76	22.52 ± 0.98
(−)-EC	18.76 ± 0.04	82.12 ± 0.87
(−)-GC	ND[a]	ND
(−)-EGC	ND	ND

caffeine	548.27 ± 4.33	1107.51 ± 5.65

[a]ND, not detected.

migration values were calculated for all catechins and caffeine except for GC and EGC, for which values were not detected in any simulant. Caffeine exhibited the highest migration value for simulants A and B, 548.27 ± 4.33 and 1107.51 ± 5.65 μg/kg, respectively. Approximately, the migration value of caffeine in simulant B was twice the migration value in simulant A. Catechins showed migration values from 3.94 ± 0.16 to 18.76 ± 0.04 μg/kg for simulant A and from 13.30 ± 2.34 to 213.80 ± 6.76 μg/kg for simulant B. It can be seen that the migration values for all green tea components took place in a major extension for simulant B. This fact can be related to the solubility of the catechins and caffeine in the different simulants. For simulant B, which was 3% acetic acid in purified water, the catechins and caffeine can be easily protonated, and therefore the solubility of these compounds from the plastic material is increased. However, for simulant A, which was Milli-Q water, the solubility was not so favorable, as the molecules are not protonated in water and therefore the migration values were lower than in simulant B.

On the other hand, the *cis* isomers (EC, ECG, and EGCG) exhibited higher migration values than the *trans* isomers (C, CG, and GCG). This fact can be related to the initial concentration of each catechin in the GTE (Table 3, column

Table 3. Concentration Values of Catechins and Caffeine of Green Tea Extract in the Absence (without H^+) and Presence (5% H^+) of Formic Acid

name	concn (μg/g), without H^+	%RSD (n = 3) without H^+	concn (μg/g), 5% H^+	%RSD (n = 3), 5% H^+	concn increase (%)

caffeine	4.10	4.74	4.88	4.87	15.95

2). For all *cis* isomers, the initial concentration was higher than the initial concentration of the *trans* isomers. As a consequence, the migration of the *cis* isomers such as EC, ECG, and EGCG from the material was higher than that for the *trans* isomers.

Migration values of catechins and caffeine were higher for the acidic food simulant (simulant B) than for water. To understand the behavior of green tea components, several experiments based on the influence of pH on the catechins and caffeine standards as well as on the green tea extract were investigated.

Influence of Acidic Media in Catechins and Caffeine Standards and in GTE. The high increase of caffeine is of concern, as this compound would be incorporated into the food. The migration tests showed a considerable influence of pH in the specific migration values of catechins and caffeine. To understand better the release of free caffeine and some catechins, an in-depth study was carried out. First, an acidic medium (formic acid) was added to several standard solutions of tea catechins and caffeine to evaluate the influence of the media in the tea components. Different stereoisomer mixtures of pure catechins were prepared, and caffeine was added to each catechin mixture. Specifically, the mixtures prepared in methanol were as follows: C, EC, and caffeine; GC, EGC, and caffeine; ECG, CG, and caffeine; EGCG, GCG, and caffeine. All of these mixtures were prepared in equimolecular concentrations of 50 μg/g each one (1:1:1). The samples were analyzed by UPLC-MS/Q-TOF in the absence of formic acid and after the addition of 5% formic acid. The area values were calculated in both cases, and the differences observed in the different mixtures were expressed as percent of area increase. Figure 1 shows the results obtained for these experiments. The combination of C, EC, and caffeine (1:1:1) was the mixture that showed the major change in the precent of area increase. After the addition of formic acid, the area of C increased 15.83%, the area of EC increased 13.41%, and the area of caffeine increased 14.45%. The proportions of C, EC, and caffeine increase were about the same, and it can be related to the concentration of each standard in the mixture. The percent

dx.doi.org/10.1021/jf5011287 | J. Agric. Food Chem. 2014, 62, 6777−6783

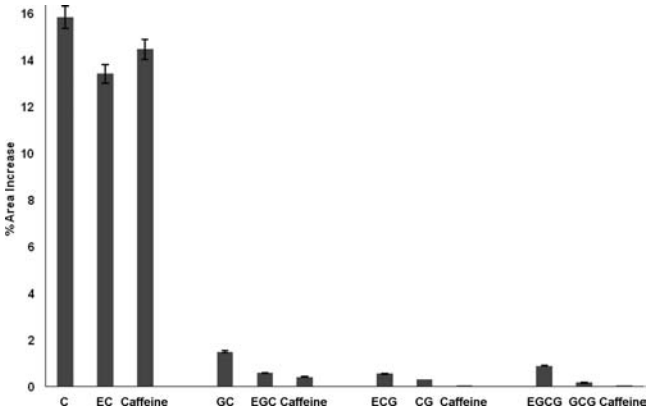

Figure 1. Percentage of area increase of different equimolecular mixtures of stereoisomers of catechins and caffeine (1:1:1) after addition of 5% formic acid.

area increase for the rest of the mixtures was almost unchanged. In fact, the percent area increase for the different mixtures was as follows: GC (1.89%), EGC (0.58%), and caffeine (0.41%); ECG (0.56%), CG (0.30%), and caffeine (0.06%); EGCG (0.89%), GCG (0.16)%, and caffeine (0.04%).

After the analysis of the different standard mixtures, the influence of the acidic media was evaluated in the GTE. GTE contains the eight catechins and caffeine previously studied as standards, but not as equimolecular proportions. A 50 μg/g solution of GTE in methanol was prepared in triplicate. The chromatographic analysis was carried out by UPLC-MS/TQ before and after the addition of 5% formic acid. This technique allowed us to quantify the variation of the different catechins and caffeine when formic acid was added. The results are shown in Table 3, where the second column lists the initial concentration of each green tea component before the addition of formic acid. Caffeine showed an initial concentration value of 4.10 μg/g. As can be seen, the proportion of catechins was not equimolecular, the *cis* isomers EC (3.13 μg/g), EGC (3.10 μg/g), ECG (2.35 μg/g), and EGCG (29.62 μg/g) being the most concentrated compounds in the GTE. The *trans* isomers showed initial concentration values below 2.18 μg/g (GC). The last column in Table 3 shows the concentration increase of the different catechins and caffeine after the addition of formic acid, expressed as percentage. Again, C (29.90%), EC (20.75%), and caffeine (44.93%) exhibited the major changes. The other catechins exhibited a variation below 2.39% (CG). In all cases the percentage of relative standard deviation was below 5%.

From the results obtained for the standards by UPLC-MS/Q-TOF and for GTE by UPLC-MS/TQ, it can be concluded that caffeine, C, and EC increased their concentration as a consequence of the addition of formic acid. According to the literature, C forms a 1:1 complex with caffeine by intermolecular hydrogen bonds[22] as well as EC, which forms also a 1:1 complex.[21] It is known that caffeine behaves as a very feeble base and reacts with acids. Experimental methods have explored the most stable protonated structure corresponding to the most basic site in the molecule, and the structure protonated from the N7 site (Figure 2), MH^+ (N7) was the most stable among the ions studied.[36] From this bibliography, it can be concluded that in the absence of formic acid, C and EC can exist as a C−caffeine complex anda an EC−caffeine complex, which present intermolecular interactions between molecules. However, in the presence of formic acid, the

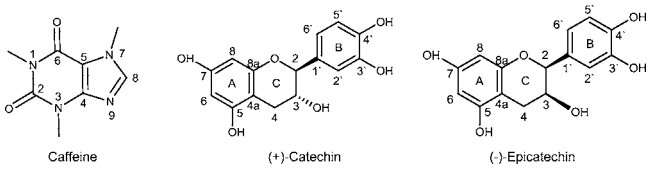

Figure 2. Structures of caffeine, (+)-catechin, and (−)-epicatechin.

molecules of caffeine can be protonated as quaternary ammonium salts and, consequently, the intermolecular interactions present in the complexes between C and caffeine and the complexes of EC and caffeine can be broken. As a result of this breakdown, molecules of C, EC, and caffeine can be released as individual free molecules and their concentrations increase. Furthermore, the sum of percent concentration increase for C and EC was approximately the same percentage value obtained for caffeine. These results suggest that for each molecule of caffeine liberated, one molecule of C or one molecule of EC will be liberated after the breakdown of the C−caffeine or EC−caffeine complex. This conclusion can be supported by the stoichiometry of the C−caffeine (1:1) or EC−caffeine (1:1) complexes proposed by Ishizu et al.[21,22] This fact is interesting and opens new ways to trap active compounds by chemical interaction with catechins.

Spectroscopic Analysis of Catechins and Caffeine Standards: The Continuous Variations Method (Job's Method). To confirm the formation of complexes between catechin and epicatechin with caffeine and their stoichiometry, a spectroscopic analysis based on the continuous variations method has been carried out. This method is often referred to as Job's method,[36] and it is an easy and common method for the determination of the reactant stoichiometry of chemical equilibrium. In this method, the measured concentration of the complex between catechin or epicatechin with caffeine (or a parameter that is proportional to its concentration such as its UV−vis maximum absorbance) is plotted against the mole fraction of the catechin or epicatechin solution reactant, whereas the sum of the reactant concentrations (catechin solution plus caffeine solution) is kept constant. This plot is referred to as Job's plot. Figure 3 shows the Job's plots of the C−caffeine system (dashed line) and the EC−caffeine system (continuous line). Five solutions of catechin derivate and caffeine were measured at different mole fractions, from 0 to 1, with a constant concentration of 0.03 μM. The maximum point of the curve, which corresponds to the maximum concentration

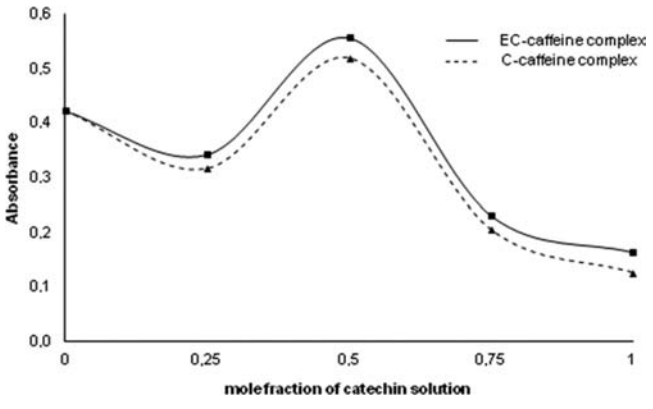

Figure 3. Job's plots of C−caffeine system (dashed line) and EC−caffeine system (continuous line).

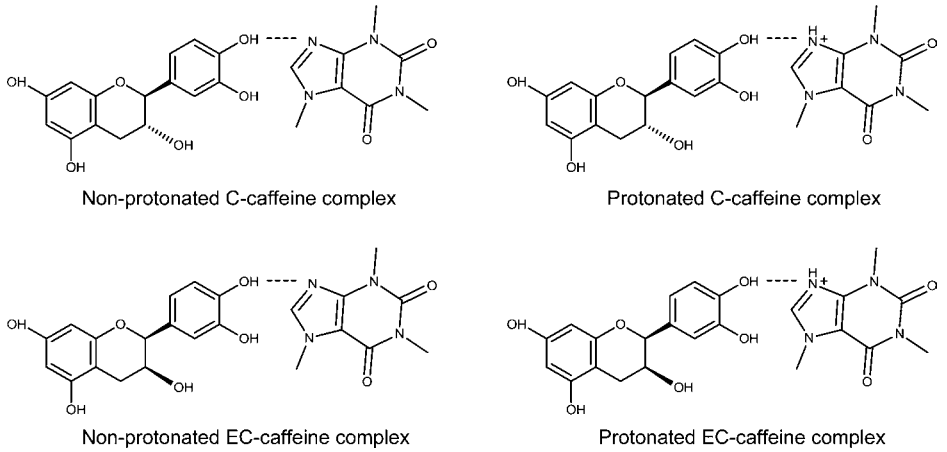

Figure 4. Structures of nonprotonated and protonated C−caffeine and EC−caffeine complexes.

of the catechin−caffeine complex, determined the stoichiometry of the equilibrium reaction. From this curve, the stoichiometry obtained for the C−caffeine complex was 1:1, and the absorbance value at this point was 0.518. In the case of the EC−caffeine complex, the stoichiometry of the complex was also 1:1 and the absorbance value was 0.556. Error bars show the relative standard deviation expressed as percentage (% RSD), and %RSD was below 2% for all measures.

The continuous variations method demonstrated that the complex between catechin and epicatechin with caffeine is formed in equimolecular proportions (1:1). These results confirm the conclusions given after the UPLC analysis of the green tea standards and the GTE. UPLC and spectrophotometric analyses confirm that catechin and epicatechin form complexes with caffeine by intermolecular interactions and these complexes are formed in 1:1 complex association.

An Approach: Simulation of Complexes of Tea Catechins with Caffeine. According to the results presented above, C and EC formed a complex with caffeine by intermolecular interactions, and this fact agrees with the previous bibliography.[21,22] Spectroscopic analysis also demonstrated that these complexes are formed in 1:1 complex association, catechin−caffeine complex and epicatechin−caffeine complex. The increase of the concentration value of free caffeine in the presence of formic acid means that caffeine was protonated as a quaternary ammonium salt. Consequently, the complexes between C and EC with caffeine can be broken and the different molecules can be liberated, thus increasing their concentrations. A molecular modeling approach was proposed to confirm the results experimentally obtained. Chem 3D Pro software was selected as the molecular modeling to perform this study.

The structures of C, EC, caffeine, protonated caffeine (Figure 2), and the complexes of C and EC with caffeine based on the structures determined by Ishazu et al.[21,22] (Figure 4) were drawn by Chem Draw. On the other hand, the protonated complexes of C and EC with caffeine were also drawn by Chem Draw software (Figure 4). The protonated site of caffeine was the N7 site according to the literature.[37] The hydrogen bond is represented by a dashed line in all structures (Figure 4).

Several dihedral angles of the catechin−caffeine complexes were calculated by Chem 3D Pro, and the values obtained are shown in Table 4. The dihedral angle values calculated for protonated and nonprotonated structures were the same. Therefore, Table 4 shows the dihedral angle values of nonprotonanted structures. The dihedral angle values obtained by the software were compared with the values determined by Ishazu et al.,[21,22] and they exhibited high similarity. Therefore, the results afforded by the software could be considered sufficiently reliable.

Table 4. Comparison of Chem 3D Pro Values and Ishazu et al.[21,22] Values of Several Dihedral Angles of the Complexes between C or EC and Caffeine

dihedral angle	Chem 3D Pro value	Ishazu et al. value
$H_2-C_2-C_3-H_3$ (C−caffeine)	173.1°	169.0°
$C_1'-C_2-C_3-O$ (C−caffeine)	52.4°	48.7°
$H_2-C_2-C_3-H_3$ (EC−caffeine)	66.1°	60.23°
$O_1-C_2-C_3-H_3$ (EC−caffeine)	176.0°	179.6°

Table 5 shows the computed properties of C, EC, caffeine, protonated caffeine, and the different complexes, nonprotonated and protonated, between C or EC and caffeine after the geometry optimization. For this, MM2 calculations were carried out by Chem 3D Pro software. The protocol of the procedure was as follows: (1) To calculate the computed properties of the structures proposed before the geometry optimization, different energy values were given such as stretch, bend, torsion, van der Waals, dipole−dipole, and charge−dipole. The energy values calculated for C, EC, caffeine, and protonated caffeine were the best energy values obtained after the MM2 job. However, the energy values obtained for all complexes were high TSE for the current conformation, and these results indicated that the geometry of these complexes was not optimized. The TSE values of complexes were approximately 2000 kcal/mol for all cases. (2) To obtain the geometry optimization, which corresponds to a minimum energy point, an energy minimization job was performed for each complex. For all structures evaluated, the TSE of the structures was much lower after geometry optimization. (3) A molecular dynamic job was performed to simulate the motion of the forces acting on the atoms. (4) Finally, a second computed properties job was performed after the energy minimization and molecular dynamic jobs. At this point, the total steric energy value was the best value obtained by running the MM2 methodology, which corresponded to the minimum energy value for the complex studied, and therefore the conformation that was more likely to exist.

These TSE values as well as the energy values of stretch, bend, torsion, van der Waals, dipole−dipole, and charge−dipole

Table 5. Energy Values of Several Parameters Calculated by Chem Pro 12.0 of Catechin, Epicatechin, Caffeine, Protonated Caffeine, and Nonprotonated and Protonated C−Caffeine and EC−Caffeine Complexes

energy (kcal/mol)	C	EC	caffeine	protonated caffeine	nonprotonated C−caffeine	protonated C−caffeine	nonprotonated EC−caffeine	protonated EC−caffeine
strech	1.0824	1.1529	0.8574	0.8763	2.2376	2.2405	2.2845	2.2357
bend	5.4820	6.6179	22.3571	21.5206	16.2340	29.4483	16.9875	29.8070
strech−bend	−0.0838	−0.0048	−0.0961	−0.0124	−0.0097	−0.0664	0.0271	−0.0321
torsion	−14.6109	−13.6778	1.9123	1.9651	−8.4744	−10.8780	−9.3759	−11.2062
non-1,4 VDW	−12.4550	−12.3518	0.3622	1.0650	−13.6243	−5.4612	−13.7413	−5.8387
1,4-VDW	12.6950	12.2932	9.2112	9.2406	25.3927	25.5631	25.2569	25.3394
charge−dipole				6.6489		−5.2226		−4.3414
dipole−dipole	0.0655	0.0616	−12.1210	−11.8936	−7.8468	−13.0465	−6.9793	−12.0958
total steric energy	−7.8248	−5.9089	22.4832	29.4105	13.9091	22.5772	14.4597	23.8679

are shown in Table 5 for the different structures. The aim of this simulation was to compare the main differences between nonprotonated and protonated complexes. For this purpose, the conclusions of this study were based on the total steric energy values. First, the sum of individual TSE values of C and caffeine (14.6584 kcal/mol) was compared to the TSE value of nonprotonated C−caffeine complex (13.9091 kcal/mol). Similarly, the sum of individual TSE values of EC and caffeine (16.5743 kcal/mol) was compared to the TSE value of the nonprotonated EC−caffeine complex (14.4597 kcal/mol). In both cases, the TSE values were lower for the C and EC complexes, and it was concluded that both C and EC were more likely to form caffeine complexes. With respect to the protonation of caffeine, the sum of the individual TSE values of C and protonated caffeine (21.5857 kcal/mol) was compared to the TSE value of protonated C−caffeine complex (22.5772 kcal/mol) and the sum of the individual TSE values of EC and protonated caffeine (23.5016 kcal/mol) was compared to the TSE value of protonated EC−caffeine complex (23.8679 kcal/mol). These differences showed that the protonated complexes of C and EC were less likely to exist than the molecules not arranged.

The differences of energy between nonprotonated and protonated complexes were also compared. The TSEs obtained for C−caffeine (13.9091 kcal/mol) and EC−caffeine (14.4597 kcal/mol) nonprotonated complexes were lower than the values obtained for C−caffeine (22.5772 kcal/mol) and EC−caffeine (23.8679 kcal/mol) protonated complexes. Once again, these results suggested that the nonprotonated complexes were more likely to exist compared to the protonated complexes.

The simulation data showed that protonated complexes were less stable than nonprotonated complexes, and these results consolidated the idea that the intermolecular hydrogen bond among catechins−caffeine complexes can be broken, giving individual molecules of C, EC, and the ammonium salt of caffeine, to establish the most stable conformation. Both the experimental work and the simulation studio concluded that C and EC form equimolecular complexes with caffeine in neutral media. However, the presence of an acidic media involves the breakdown of the intermolecular interactions between molecules, giving C, EC, and the ammonium salt of caffeine as free molecules.

This work recovers important information about the green tea components and their behavior depending on the pH of the media. The starting migration analysis of active packaging films containing GTE showed unexpected migration values for 3% acetic acid simulant. Specifically, the migration values in acidic simulant were more than double the migration values for aqueous simulant. To explain these results, a detailed UPLC analysis of green tea standards as well as green tea extract was performed. From the chromatographic results obtained and the previously reported literature, the formation of equimolecular complexes between catechins and caffeine through intermolecular interactions is proposed. The complexes can exist in neutral media but can be broken in acidic media as a consequence of the protonation of caffeine. A spectroscopic analysis based on the continuous variations method, also called Job's method, was carried out to verify the stoichiometry of the C-−affeine complex and EC−caffeine complex proposed. The results obtained for Job's method confirm that these complexes are formed in 1:1 complex association. Finally, a simulation studio based on the stabilization energies of the protonated and nonprotonated catechin complexes was performed to confirm

the conclusions achieved from the experimental work. The simulation showed that the total steric energies of the nonprotonated complexes are higher than the protonated complexes and therefore more stable and likely to exist. The conclusions reached from the simulation studio support the information given by the experimental analysis.

is performed, and due to the complexity of the yeast metabolome, there is a loss of information because the focus is not on the overall system. An untargeted approach allows the visualization of the process and reveals new insights by detecting as many metabolites as possible in a single step.[17,19] In an attempt to get as close as possible to this holistic metabolic view of a complex biological process, the aim of the present work is to build a metabolic profiling pipeline able to identify metabolites from a perturbed data set and latter validate them in their biochemical context. This newly developed methodology reproduces in a micro scale (5 mL) the same metabolic events that are usually monitored in a larger scale enabling the high throughput analysis of samples. The 5 mL fermentations were monitored online and noninvasively through the continuous sampling of the volatile fraction by headspace—solid phase microextraction (HS-SPME) analyzed by gas chromatography coupled to a mass spectrometry detection system (GC-MS) in order to capture as much information regarding the fermentation process as possible.

In order to evaluate the proposed pipeline a commercial stain of *Saccharomyces cerevisiae* fermented synthetic grape must containing the same concentration (200 mg/L) of different sources (ammonium and amino acids) of yeast assimilable nitrogen. These 5 mL fermentations were analyzed and the pipeline was validated by comparing them to a second set of fermentations performed on a larger scale (500 mL). The metabolic information was subjected to preprocessing through algebraic normalization (Pareto) using MarkerLynx, both in one dimension (1D), where the total ion chromatogram per sample was used and in two dimensions (2D), where the integrity time vs m/z per sample was used. Multivariate variable analysis (MVA) was used to evaluate the potential of a high throughput pipeline. This type of approach needs validation with the study of real time perturbations in a time course of some chemical compounds (targeted approach).

MATERIALS AND METHODS

Chemicals. The highest purity chemicals were used throughout the experiments. All chemicals were from Sigma-Aldrich (Germany) or Merck (Germany) unless otherwise stated.

Strain, Media, and Culture Conditions. The yeast strain used in this study was *Saccharomyces cerevisiae* VIN13 (Anchor yeast, Cape Town, South Africa). The yeast preculture was grown in the fermentation medium described below and containing NH_4Cl (1g/L) as nitrogen source. The yeast, precultured to the logarithmic growth phase, was centrifuged and resuspended in saline solution. Fermentation vessels were inoculated with the preculture to an OD_{600} of 0.1 (final cell density of approximately 10^6 cells/mL).

Fermentations were carried out in grape juice medium adapted from Jiranek et al.[20] The synthetic media was prepared by the combination of two aqueous solutions prepared and sterilized separately. The first solution contained glucose (100 g/L), fructose (100 g/L), citric acid (0.2 g/L), malic acid (3 g/L), K_2HPO_4 (1.14 g/L), $MgSO_4{\cdot}7H_2O$ (1.23 g/L), $CaCl_2{\cdot}2H_2O$ (0.44 g/L), KH tartrate (2.5 g/L). All the compounds were dissolved in distilled water, and the pH was set to 3.3 with KOH 10 M. This solution was autoclaved for sterilization. The second solution contained NH_4Cl and/or amino acids as described in Table 1, trace elements stock (final concentration in the synthetic grape must: $MnCl_2{\cdot}4H_2O$ 200 μg/L, $ZnCl_2$ 135 μg/L, $FeSO_4$ 36 μg/L, $CuCl_2$ 15 μg/L, H_3BO_3 5 μg/L, $Co(NO_3)_2.6H_2O$ 30 μg/L, $NaMoO_4.2H_2O$ 25 μg/L, and KIO_3 10 μ/L) and vitamin stock (final concentration in the synthetic grape must: myo-inositol 100 mg/L, pyridoxine HCl 2 mg/L, nicotinic acid 2 mg/L, Ca pantothenate 1 mg/L, thiamine HCl 0.5 mg/L, K para-aminobenzoate 0.2 mg/L, riboflavin 0.2 mg/L, biotin 0.125 mg/L, and folic acid 0.2 mg/L).[20]

Table 1. Different Fermentation Media (M1−5)

media	description
M1	without amino acids just 200 mg N/L of NH_4Cl (50 mg/L) (control)
M2	NH_4Cl (50 mg/L) and cysteine, alanine, arginine, asparagine, aspartic acid, glutamine, glutamic acid, glycine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, proline, serine, threonine, tryptophan, tyrosine, and valine (150 mg/L)
M3	NH_4Cl (50 mg/L) and the preferred amino acids (arginine, asparagine, aspartic acid, glutamine, glutamic acid) (150 mg/L)
M4	NH_4Cl (50 mg/L) and the amino acids precursors of "aroma compounds" (isoleucine, leucine, phenylalanine, tyrosine, valine) (150 mg/L)
M5	NH_4Cl (50 mg/L) and S-containing amino acids (cysteine and methionine) (150 mg/L)

This second solution was filter sterilized and added to the first solution.

Experimental Data Set. The synthetic grape must for each treatment (M1−5) contained 200 mg/L of a nitrogen source which varied in its composition (Table 1). For the evaluation of the scale effect each fermentation treatment was performed in two volumes, 5 and 500 mL. Each 5 mL sample (M1−5 × 3 replicates) was sampled and analyzed directly after one another nine times (intervals of almost 45 min). The 500 mL samples (M1−5 × 3 replicates) were sampled daily for volatile fraction analysis.

In order to monitor and synchronize all the fermentations, two additional sets of the 5 mL fermentations were carried out. One set was frequently sampled for optical density (OD) measurements at 600 nm. The second set of the 5 mL fermentation replicates was used only for weight measurements. The 500 mL fermentations were monitored frequently for both OD and weight measurements. For logistical reasons, the 5 mL fermentations were only monitored for the first 150 h after inoculation. The 500 mL were monitored to the end in order to evaluate whether the yeast was able to complete the fermentation process under the conditions tested.

Growth Measurement. Cell proliferation was determined with a spectrophotometer (Powerwave$_x$, Bio-Tek Instruments, Bedfordshire, U.K.) by measuring the optical density (600 nm) over the experimental period.

Volatile Analysis. A small-scale fermentation setup (5 mL) was designed using the 15 mL SPME vials for the CombiPAL auto sampler (CTC Analytics AG, Zwingen, Switzerland). Fermentations were carried out on the 32-sample tray and were left to ferment at ambient temperature (20 °C ± 2). In order to avoid the influence of any additional stress, such as heating and agitation, sampling took place directly out of the tray. A SPME (CAR/DVB Carboxen) fiber (Supelco, Bellefonte, PA) was used to collect headspace volatiles every 24 h from each sample. Elevated pressure due to CO_2 production was avoided by inserting a small piece of fused silica GC column in the septum of the vial-cap.

An automated system for the online process monitoring was used thus allowing the monitoring of the fermentation evolution over time. The 5 mL samples taken daily from the 500 mL fermentation were placed in identical vials and analyzed through the same procedure as the 5 mL fermentations. Sampling took place from the headspace of the fermentation vials with an extraction time of 10 min at ambient temperature (20 ± 2 °C) directly from the sample tray. Afterward the SPME fiber was thermally desorbed in the injection port of the GC-MS instrument (Agilent Technologies, Little Falls, Wilmington, U.S.A.) for 1 min at 240 °C in splitless mode and left for a further 9 min in the split mode to clean the fiber. The carrier gas used was helium, the split flow was 50 mL·min^{-1}, and the flow through the column was 1.2 mL·min^{-1}. The column used was a J&W FFAP (Free Fatty Acid phase, Agilent Technologies) of 60 m length, 0.25 mm inner diameter, with a film thickness of 0.5 um. The GC oven temperature program was as follows: 40 °C held for 2 min and then ramped to 240 °C at 10 °C·min^{-1} and held for 2 min. The transferline to the MS was heated to 250 °C, and the ion source temperature and the quadrupole temperature was set to 240 and 150 °C, respectively.

dx.doi.org/10.1021/jf502082z | J. Agric. Food Chem. 2014, 62, 6784−6793

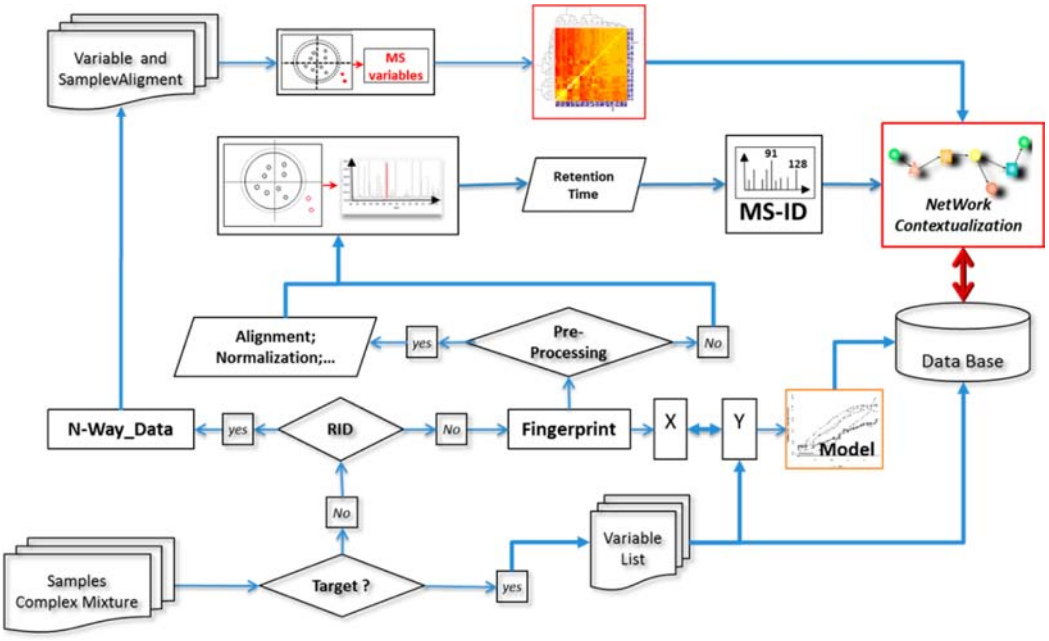

Figure 1. Metabolomic analysis pipeline.

The MS was operated in full-scan mode, scanning from 35 to 650 amu, with and ionization energy of 70 eV and an electron multiplier voltage of 1541 V.

Data Preprocessing. The ASCII file of chromatographic data obtained from each sample was extracted and a matrix created containing all the Total Ion Count features (TIC-Fingerprint). The normalized matrix was then imported into The UnscramblerX 10.1 (Camo, Norway) where baseline correction was performed and the first stage of the alignment of chromatograms done using correlation optimized warping. This algorithm aligns chromatograms by means of sectional linear stretching and compression, which shifts the peaks of one chromatogram to correlate with those of the other chromatograms in the data set.[21]

MarkerLynx XS (version 4.1, Waters, U.S.A.) was also used for peak deconvolution, peak integration (using apex track peak detection), and sample alignment. The peaks from different samples were aligned so that the same peaks (defined with retention time and m/z), most probably the same compound, are placed in the same row for all samples. The parameters used were XIC window 0.50 Da, peak width at 5% height 20 s, intensity threshold 1000 counts, mass window 0.45 Da, retention time window 0.10 min and noise elimination level 10. The list of features originated was then subjected to multivariate analysis. The matrix resulted from MarkerLynx underwent correlational analysis using Excel.

Normalization Methods. The fingerprint data (TIC) and the matrix generated in MarkerLynx were subjected to normalization: mean centering and Pareto normalization (dividing each feature by the square root of the standard deviation).

Statistical Analysis. The relative growth rates and CO_2 liberation in different volumes and different media were evaluated via two-way analysis of variance (ANOVA), using Microsoft Office Excel, version 2010.

Data was analyzed with PCA (principal component analysis), and OPLS-DA, using SIMCA-P+ (version 12.0.1, Umetrics, Sweden). Due to the large number of variables and few observations these methods highlight important information by correlating the variables.

PCA is an unsupervised technique that classifies samples according to their common spectral characteristics facilitating the observation of relationships between samples and highlighting the variables responsible for the variation (it projects the total variation on a plane, onto a smaller set of variables, called principal components (PCs), which are a linear combination of all the initial variables). The scores (the original data in the new system, a projection of the samples) and loadings (the weights applied, the original variables) plots may reveal clusters or outliers and the corresponding variables that have influence on the distribution of samples.

OPLS-DA is a modified version of PLS (partial least-squares), a supervised method, allowing the extraction of more information used for group classification/separation. The advantage is that the information about the discriminating classes is presented in its first component which makes easier to understand which variables are the responsible for this same separation due to the separation of systematic variation into a predictive and an orthogonal compound.[22] The sequence presented in this section is the metabolomics pipeline applied as represented in Figure 1.

RESULTS/DISCUSSION

Fermentation Kinetic Parameters. For logistical reasons, the 5 mL fermentations were only monitored for the first 150 h of the fermentation (Figure 2c, g). The 500 mL fermentations were monitored to the end in order to evaluate whether the yeast was able to complete the fermentation process under the nutrient conditions tested (Figure 2a, e). The percent weight loss (CO_2 production) was measured in order to evaluate the fermentation kinetics in both fermentation sets (Figure 2e, g). The relative rates of CO_2 production were calculated using the slope of CO_2 production vs time (Figure 2h). For the 500 mL fermentation, the slope was calculated for the 150 h period (Figure 2f). When the monitoring of the 5 mL fermentations cessed, they had lost 43% of the total CO_2 released by the 500 mL fermentations. Therefore, only this period is the focus of this study. A two-way analysis of variance (ANOVA) was applied to the relative rates of CO_2 production and the data showed that there were no significant differences between different media or different volumes ($p > 0.05$).

The yeast growth was also monitored for the entire fermentation process in 500 mL and until yeasts reached a quasi-stationary phase (OD of about 6) in 5 mL fermentations. The relative rates of cell growth were calculated using the slope of OD (600 nm) vs time in the exponential growth phase (Figure 2d). Once again for the 500 mL fermentations, only the data for the first 150 h was considered (Figure 2b). A two-way

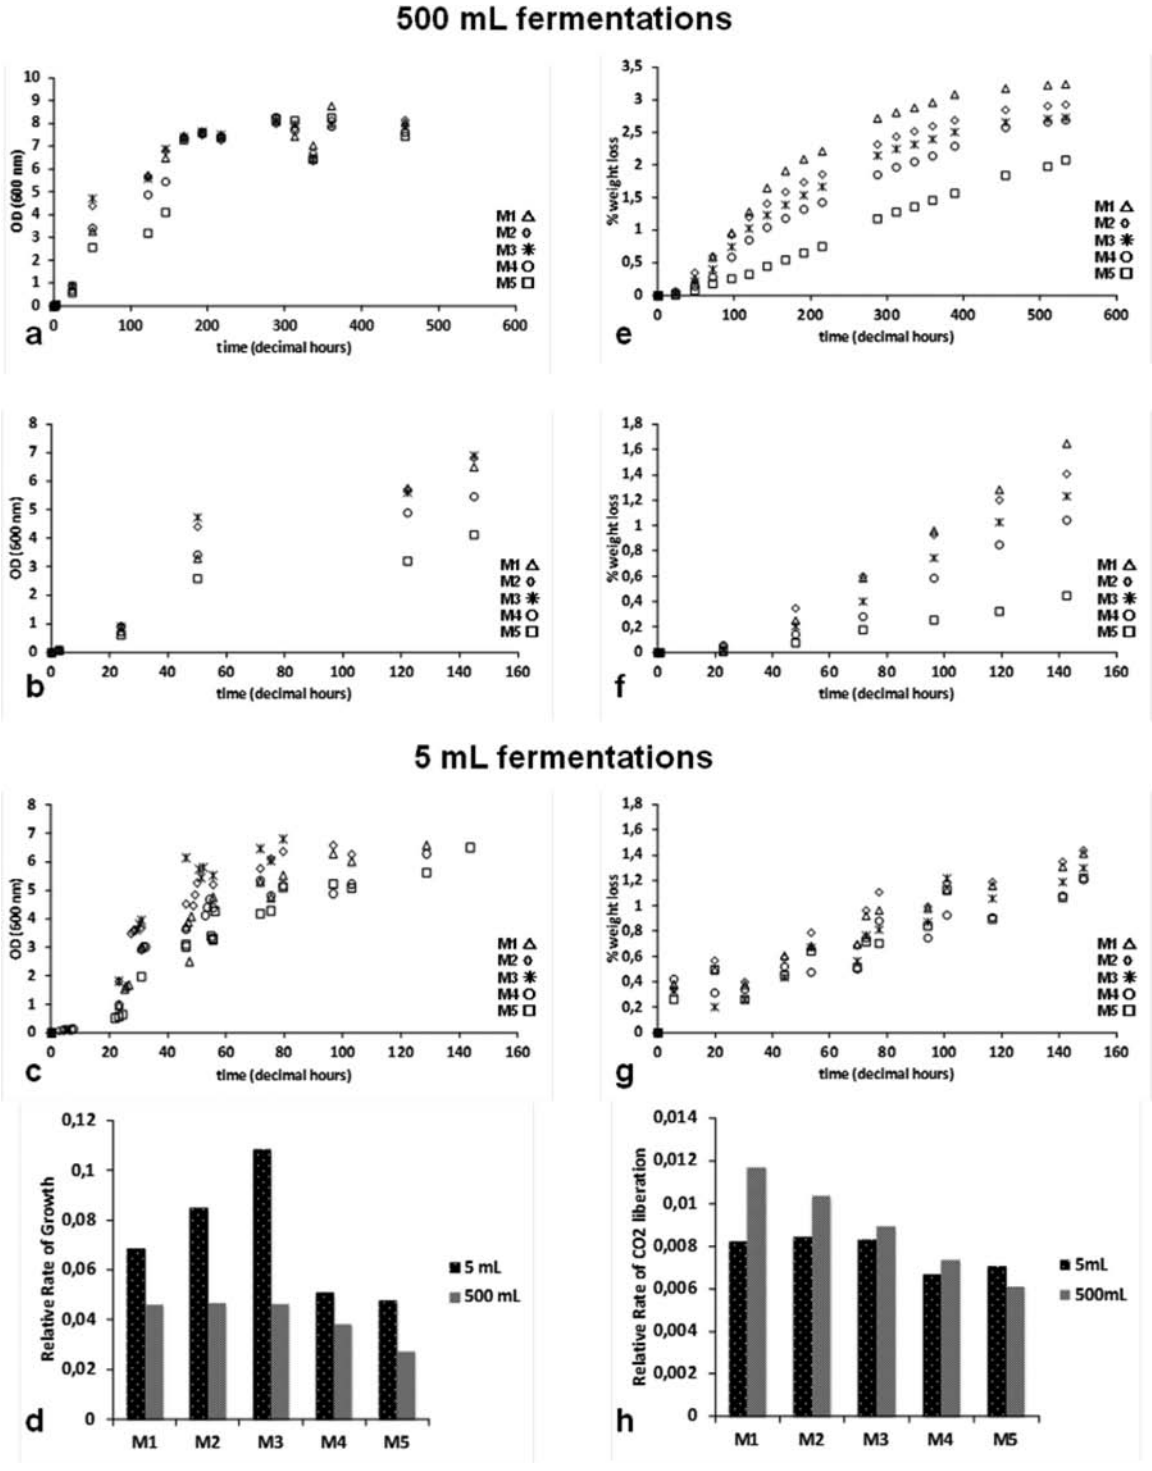

Figure 2. Profiles of yeast growth obtained through OD measurements at 600 nm in (a) 500 mL fermentations for the entire fermentation process and (b) for the first 150 h, (c) in 5 mL fermentations for 150 h and (d) relative rates of growth; % weight loss (CO_2 production) in 500 mL fermentations (e) for the entire fermentation process and (f) for the first 150 h (g) in 5 mL fermentations for 150 h and (h) relative rates of CO_2 production.

analysis of variance (ANOVA) was applied to this data, and it was concluded that although there were no significant differences between media ($p > 0.05$) there were significant differences between volumes ($p < 0.05$).

Data from the entire 500 mL fermentations process (Figure 2a, e) showed that despite the differences in the nitrogen composition of different media, *Saccharomyces cerevisiae* was able to perform the fermentation process in all media. In a media completely deficient in amino acids the yeast has the ability to use precursor metabolites, carbon skeletons originated from the central metabolic pathways, as starting substrates for the synthesis of amino acids. The tricarboxylic acid cycle is not functional during fermentation, so yeasts replace the cycle intermediates through anaplerotic reactions.[23,24]

Screening by TIC. Our initial goal with the fingerprint analysis (TIC) was to examine the intrinsic variation in both

(d) Biplot of the two first PC after preprocessing with MarkerLynx and normalized by Pareto (5 mL fermentations).

data sets to determine if the volatile fraction of the samples followed similar trends and/or media clustering prior to feature extraction techniques.

The raw data was first evaluated by PCA using the non-normalized data (data not shown) to verify the samples, and to detect outliers or trends within the different media applied in the TIC-Fingerprint matrix. For the 5 mL data set, the first three principal components showed 97% of the total variation and it was possible to observe a cluster with samples related to M4 (branch chain and aromatic amino acids). However, it was

dx.doi.org/10.1021/jf502082z | J. Agric. Food Chem. 2014, 62, 6784−6793

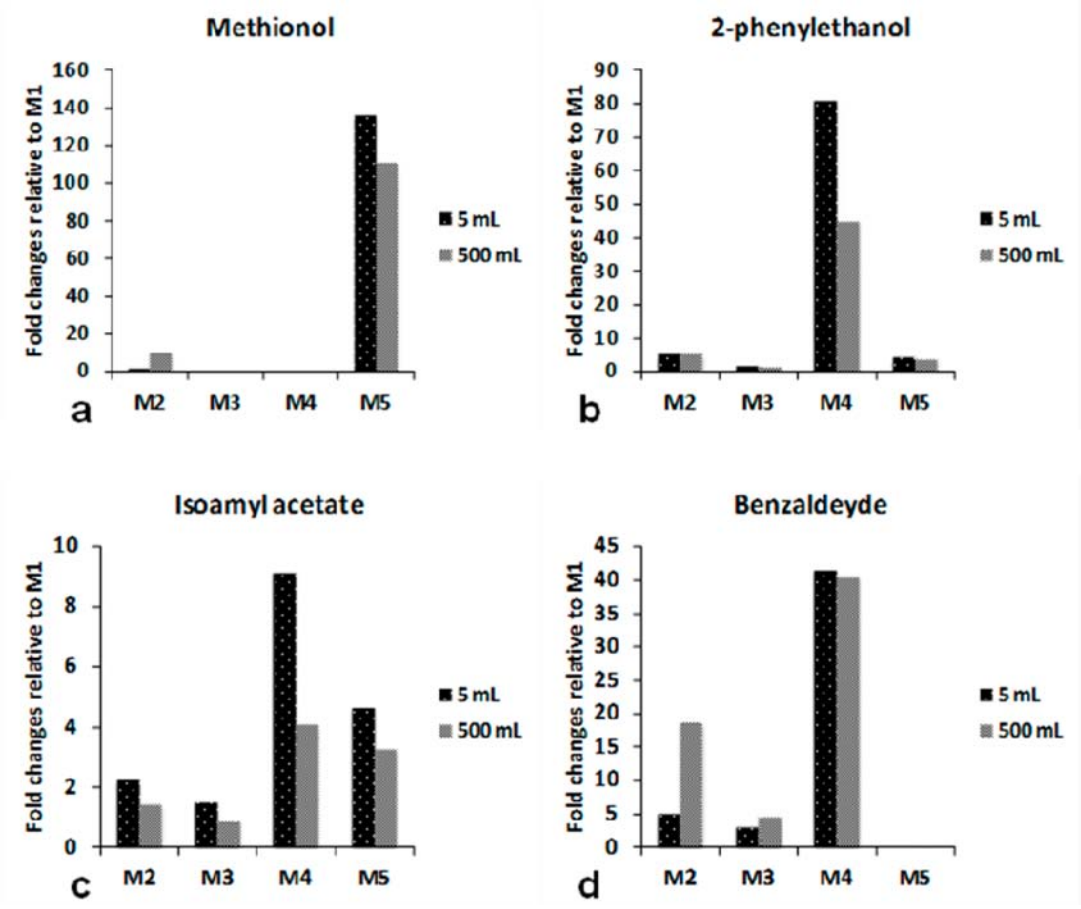

Figure 4. Fold changes relative to M1 (control) in 5 and 500 mL fermentations for (a) methionol, (b) 2- phenylethanol, (c) isoamyl acetate, and (d) benzaldehyde.

necessary to reach component 6 to visualize another cluster with the data of M5 (sulfur-containing amino acids) (just 0.37% of the variation was explained by this component). In the case of the 500 mL data set, the first three principal components showed 95% of the total variation, with M4 forming a cluster. To see another cluster it was necessary to reach component 4 (2% of variation explained). The second cluster found was for M5 as seen with the 5 mL fermentations. This suggests that metabolites, such as the volatile compounds produced in M4, may dominate and in so doing obscure others (such as the volatile compounds from S-containing amino acids medium). This may be overcome performing a mathematical normalization on data to minimize these differences. Pareto normalization is used to avoid problems such as baseline influence and variations in peak shapes, among others; the raw data was compared to this data set. The results confirmed that some metabolites hide others. The plots (Figure 3a, b) show that the second component separates the data from M4 and the third explains the medium containing sulfur amino acids (M5), while the first component is explained by fermentation products (with 79% and 88% (data not shown) of the total variation for the 5 and 500 mL samples, respectively).

2D "Landscape" Data Preprocessing. *Effect of Sample Discrimination.* In PCA, each chromatogram and all its information is compressed and projected onto a single point. Each point represents the entire exogenous volatile metabolome at a moment. PCA was performed to understand how samples cluster together (scores) (Figure 3c). These PCA score plots show that the metabolism of yeast is affected by the amino acids supplied in the media but not by the volume of media. In the case of the 5 mL data set, three principal components explained 67% of the total variation while in the 500 mL data set this explained 44%. For both fermentation volumes, the first component (x vector) describes the fermentations over time (kinetics). Indeed, at the beginning of fermentation (initial sampling point) there were no differences in the volatile metabolome, suggesting that the yeast is initiating metabolic pathways in response to the different fermentation media. In the second component, orthogonal to the first one, the result was, once again, similar for both 5 and 500 mL samples. It was possible to distinguish three clusters: M5 samples (cysteine and methionine), M4 samples (phenylalanine, tyrosine, valine, leucine, and isoleucine), and a cluster consisting of M1, M2, and M3. This suggests that it is possible to track the different metabolic pathways that yeast follows over time due to nutrient variation. When evaluating each medium (M) separately, a time dependent expression pattern emerged. For example, in the 5 mL fermentation score plot (Figure 3c(i)), medium M4 displays a time separation between sampling points 3, 4, and 5 whereas the last ones (6, 7, 8, and 9) are grouped in a shorter time range. These differences in volatile compound synthesis are potentially related to variations in gene expression between yeast subjected to different nutrient conditions. Differences in gene expression and consequent proteomic and metabolomic changes enable yeast to survive regardless the nutrient availability.[23,24]

dx.doi.org/10.1021/jf502082z | J. Agric. Food Chem. 2014, 62, 6784−6793

A biplot was constructed in order to understand and analyze how samples cluster together (scores) and identify which variables (metabolites) most contributed to their separation (loadings) (Figure 3d). This potentially allows metabolic discovery through the identification of possible biomarkers.[25] The biomarkers identified in each media were the same in both 5 and 500 mL samples. It was possible to identify ethyl acetate and ethanol for the cluster formed with M1, M2, and M3. Ethanol is one of main products of fermentation and ethyl acetate is formed from ethanol and acetyl-CoA by alcohol acyltransferase and is the most abundant ester produced during alcoholic fermentation.[13,26] This cluster contains media that placed fewer nutrient constraints on yeast growth as they contained glutamate and ammonia, which are the principal precursors for the synthesis of nitrogenous compounds.[24] This may somewhat contribute to the similarities in the volatile profiles detected. The compounds identified as being responsible for the clustering of M5 were sulfur containing compounds which originated from cysteine and methionine metabolism, such as methyl thioacetate, ethyl thiolacetate, dihydro-2-methyl-3(2H)-thiophenone, and methionol (a product of methionine degradation via Ehrlich pathway[27]) (Figure 4a). These may have a negative contribution to aroma due to the formation of thiols and sulfides.[28]

The clustering of M4 was due to the presence of some products resulting from the Ehrlich pathway, namely isoamyl alcohol and 2-phenylethanol (Figure 4b) together with hexanoic acid and benzyl alcohol. The higher alcohols isoamyl alcohol and 2-phenylethanol are formed by the decarboxylation and subsequent reduction of α-keto acids produced as intermediates of the amino acids leucine, isoleucine, and phenylalanine catabolism (Ehrlich pathway). Since their production from the corresponding amino acids is coupled to the oxidation of NADH, in anaerobic conditions yeasts use them as alternative electron acceptors.[29] These results are in agreement with literature.[30−32]

In order to gain more information and to contextualize each pathway in the global yeast metabolome an OPLS-DA between media was applied. The results generated with this approach corroborate the presence of the compounds identified in the PCA plots. Additionally, it was also possible to identify other compounds (with a correlation greater than 0.7) such as isoamyl acetate (Figure 4c), benzaldehyde (Figure 4d), and phenylethyl acetate in the case of M4 while for M5 was possible to observe isobutyl acetate and 3-methylsulfanylprop-1-ene. These were also confirmed by an OPLS with determined compounds (phenylethanol representing M4 and methionol representing M5) (data not shown). Phenylethyl acetate is the product of the esterification of phenylethanol and acetyl-CoA enzymatic by acetyltrasferase.[33,34] Isoamyl acetate is the enzymatic esterification product of acetyl-CoA with isoamyl alcohol. Isoamyl alcohol is produced from leucine, via the Ehrlich pathway or from α-ketoisocaproic acid through the anabolic pathway.[30,31] As expected, the production of both acetate esters increased dramatically in M4, as the amino acid precursors were present in great quantities.[35] The production of benzaldehyde (Figure 4e) by *Saccharomyces cerevisiae* was previously reported by Delfini et al.[36] Thereafter, several research groups have studied the mechanisms behind that process in different microorganisms and in vitro,[37] and several metabolic pathways have been proposed. While in some species this process is enzyme catalyzed,[37] in others it is also a chemical reaction involving metal ions and O_2.[38] Based on the fermentation conditions employed in this study (relatively low temperature, acidic pH, and anaerobic conditions), some of the possibilities referred in literature may be excluded; however, the data we possess does not allow the formation of a hypothesis regarding the mechanism behind benzaldehyde formation. However, the data shows that benzaldehyde production was favored in a medium containing phenylalanine (M4), which has been suggested as a possible precursor in several studies.[36−38] Further work should be done to confirm this observation. Benzaldehyde in turn can be reduced to benzyl alcohol, explaining its presence in the same medium.[38,39]

Isobutyl acetate results from the combination of acetyl-CoA with isobutyl alcohol produced from valine, via the Ehrlich pathway or from the anabolic pathway via α-ketoisovaleric acid.[40] This compound was significantly affected by sulfur containing amino acids, an effect that was also observed, although to a lesser extent, in isoamyl acetate. In M5 neither valine nor leucine was available, thus isobutyl and isoamyl alcohol were synthesized from the corresponding α-ketoacids generated through the de novo synthesis pathway from glucose.[23] According to the literature the production of acetate esters is more closely related to acetate than to higher alcohol production.[26] Therefore, the formation of high concentrations of acetates in media supplemented with sulfur containing amino acids may be due to the high production of acetyl-CoA from cysteine. Several pathways of cysteine degradation lead to pyruvate formation[41] that is converted to acetyl-CoA via cytosolic pyruvate dehydrogenase (PDH) bypass, which is an alternative route to the PDH reaction for the conversion of pyruvate to acetyl-CoA during fermentation.[29] Further work is needed to clarify this result. 3-methylsulfanylprop-1-ene is a sulfur compound resulting from the metabolism of cysteine or methionine, the only amino acids containing sulfur atoms. The compounds observed using a targeted strategy were the same ones described in the untargeted approach, which validates this untargeted approach. The results also show that although the fermentation performance is affected by the fermentation volume, there are no scale differences concerning the quality and formation kinetics of the volatile compounds identified using the applied workflow. It would be necessary to perform further work in order to validate its applicability in complex media. Additionally, the implications of these perturbations on a sensory level would need to be validated using greater volumes.

Since the scale effect seems not to affect the quality of the volatile fraction, this workflow may lead to the discovery of new compounds or the possible modification of known pathways and showing the systemic response to perturbations. To check this hypothesis, the correlation between the coexpression of metabolites were analyzed for the 5 mL data set in the matrix generated by MarkerLynx. In this study, these correlations did not identify the presence any new compounds. The highest correlations observed were between metabolically related volatile compounds, for example, ethyl hexanoate and ethyl octanoate (0.998), isobutyl acetate and ethyl octanoate (0.985), ethyl thiolacetate and ethyl octanoate (0.984). No negative correlations were found, which might be due to the duration of the period monitored. More alterations would have occurred over the time, changing the ultimate chemical profile.

Time Profile of Volatile Synthesis. The high throughput procedure presented in this study allowed the acquisition of snapshots of the biochemical events related to the fermentation process. The linking of the kinetic profile of each volatile

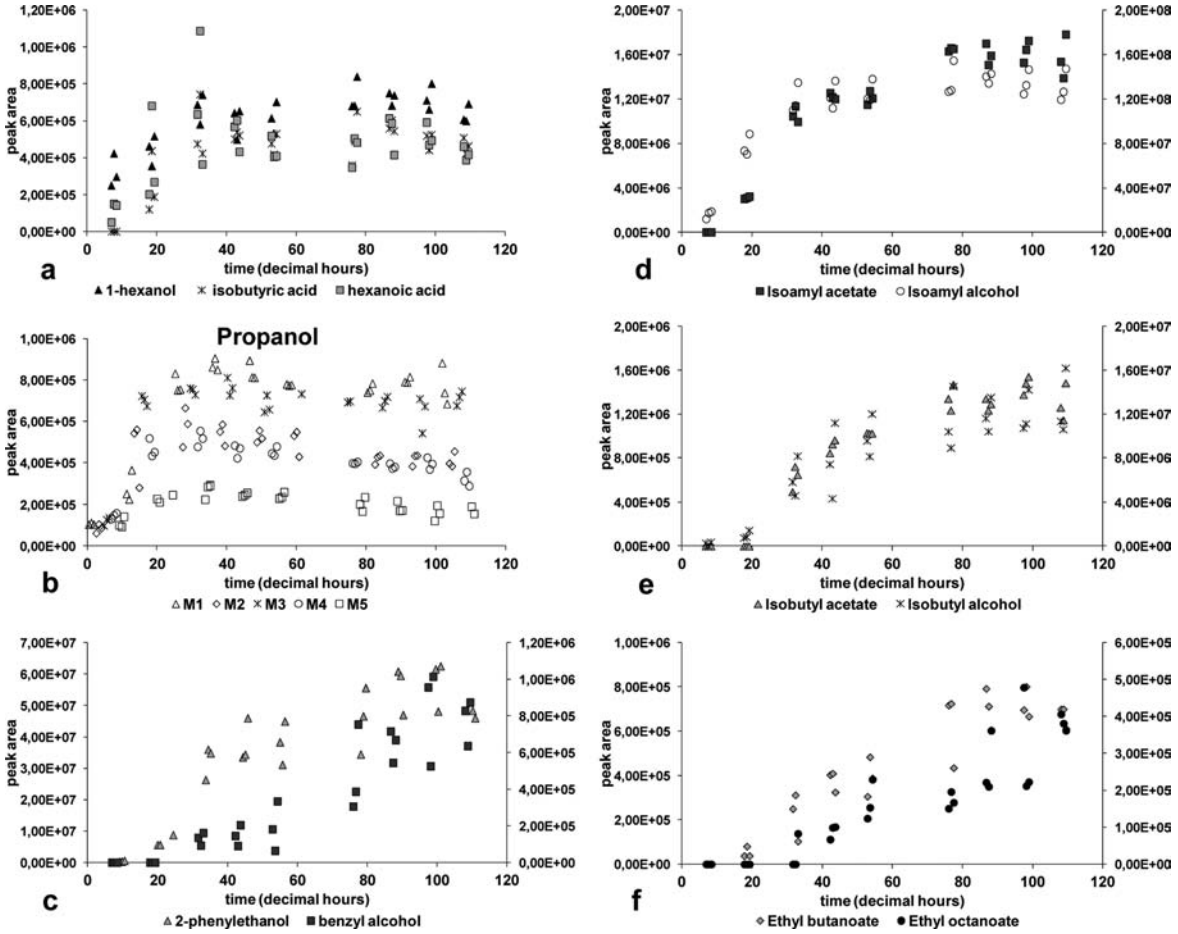

Figure 5. Kinetic profile of (a) 1-hexanol, isobutyric, and hexanoic acid in M4, (b) propanol in five media (M1−5), (c) 2-phenylethanol and benzyl alcohol in M4, (d) isoamyl acetate and isoamyl alcohol in M4, (e) isobutyl acetate and isobutyl alcohol in M4, (f) ethyl butanoate and ethyl octanoate in M4.

compound obtained in "real time" by GC-MS for 5 mL fermentations and the corresponding yeast growth curves obtained by OD measuring at 600 nm (Figure 2c) enabled the establishment of the metabolic time profile of the volatile fraction. A detailed description of the M4 data follows, but a similar approach could be done for each of the five media. During the first 20 h after the inoculation, during the lag phase, yeasts are adapting to the new media conditions, so there is no increase in the yeast population (OD remains unchanged). Although no growth occurs, yeast immediately begins to metabolize sugars and other nutrients present in media with consequent production of ethanol. There are several metabolites whose concentration start to increase during this phase namely hexanol, propanol, isobutyric, and hexanoic acids (Figure 5a). Hexanol is usually formed during the prefermentative stage of winemaking and is believed to be reductively formed by yeast from hexanal, which in turn is formed from linoleic acid.[42] Propanol reach maximum concentration few hours after inoculation and in agreement with the literature its increase was greater in the media without amino acids[43] and lower in the media containing only sulfur containing amino acids which may be related to the negative relationship between *n*-propanol production and H_2S formation from methionine and cysteine metabolism (Figure 5b).[44,45] After an adaptation period, yeast start growing. This exponential growth phase is influenced by several factors such as temperature, concentration of ammonia, amino acids, and other nutrients, and also by the oxygen level. During this phase yeasts use all the available nutrients to obtain energy and increase their population, which may reach 10^7−10^8 cells/mL. At the beginning of the exponential growth phase the concentration of higher alcohols and acids resulting either directly from sugars or from amino acid metabolism trough the Ehrlich pathway starts to increase or in some cases has already reached its maximum due to the yeast's high demand for new proteins needed for growth and reproduction. Isoamyl alcohol and isobutyric acid reached maximum concentrations about 24 h after inoculation and their concentrations remained constant (Figure 5a, d). The concentrations of isobutanol (Figure 5e), 2-phenylethanol, and benzyl alcohol (Figure 5c) started to increase at the beginning of this stage and their concentration continued increasing for the period monitored, indicating a possible continued increase in their production during the stationary phase.

During fermentation two groups of esters are synthesized: acetate esters and ethyl fatty acid esters. The synthesis of acetate esters isoamyl acetate and isobutyl acetate starts when their substrates, isoamyl alcohol, and isobutyl alcohol, are available in the media, and their time of expression is parallel to that of their precursor alcohols (Figures 5d, e).

The synthesis of ethyl fatty acid esters (ethyl hexanoate, ethyl octanoate, and ethyl decanoate) only started almost toward the end of the exponential growth phase (Figure 5f). According to literature the rate of ethyl ester formation is influenced by the

dx.doi.org/10.1021/jf502082z | J. Agric. Food Chem. 2014, 62, 6784−6793

concentrations of the two cosubstrates (acyl coenzyme A component and ethanol) and the activity of the enzymes involved in their synthesis and hydrolysis (e.g., acyl-CoA: ethanol *O*-acyltransferases, Eeb1 and Eht1). It has been suggested that the fatty acid precursor level rather than the activity of the biosynthetic enzymes is the major limiting factor for ethyl ester production.[46] Ethyl butanoate is formed from ethanol and propanoic acid derived from α-ketobutyrate,[47] an intermediate in the metabolism of several amino acids. Unlike other ethyl fatty acid esters, its concentration rises continuously from the beginning of the exponential growth period, probably due to the availability of both cosubstrates in the media since the beginning of the fermentation process (Figure 5f). After this period, yeast stops growing probably due to some nutrient deficiencies and the toxic effects of ethanol and other substances produced during alcoholic fermentation, resulting in a stationary phase. Finally yeast start dying and the population gradually decreases (decline phase).

The proposed methodology proved to be a useful tool capable of generating new insights concerning the implications of a given nutrient on the final product's volatile fraction. This knowledge can be quite useful for wine industry since it allows the possibility of modifying wine aroma by either increasing the desirable or eliminating the undesirable odors. This work culminates with the development a new metabolic profiling pipeline that relies on an unsupervised and untargeted approach applied to data acquired by a noninvasive methodology (HS-SPME/GC-MS) utilizing a small fermentation volume which allows the high throughput analyses that enables "real time" monitoring of the metabolic changes inherent to the biochemical dynamics of a perturbed complex biological system and the extraction of molecular candidates that are latter validated on its biochemical context. The pipeline proposed has several practical applications such as yeast phenotyping studies or exploring the impact of nutrient availability on yeast metabolism and subsequent volatile fraction quality. These results do require sensory validation on a larger scale.

In Vitro Fermentation. The fermentation medium used in this study was modified standard ileal efflux medium (SIEM) according to that of Ladirat et al.[12] Tween 80 was omitted from the fermentation medium because it influenced the analysis of polysaccharide degradation products. All medium components were purchased from Tritium Microbiology (Veldhoven, The Netherlands). The pH of the buffered fermentation medium was adjusted to 5.8, simulating the pH in the proximal colon; during fermentation the pH was maintained between 5.8 and 6.3. The inoculum was a standardized pool of adult fecal inoculum according to the validated protocol described by Minekus et al.[13] and prepared from eight healthy European adults (25−45 years old) who did not receive antibiotics during 2 months before donation. The inoculum (6 mL) was incubated in the modified SIEM (54 mL) for activation.[12]

CRP and ECRP (100 mg) were added to 9 mL of the modified SIEM in 25 mL bottles for each time point (0, 2, 6, 8, 12, and 24 h). The activated inoculum (1 mL) was added to the fermentation medium and flushed with CO_2. The bottles were immediately closed with rubber stoppers and sealed with aluminum caps. Fermentations were performed in duplicate for each substrate at 37 °C and shaken at 300 rpm until 24 h. A blank with only microbiota was taken as a control.

Fermentation digests were inactivated at 100 °C for 5 min and split into two parts. One part was reserved for direct analysis, and the other part of the fermentation digest was freeze-dried for further characterization.

Part of the dried fermentation digest was suspended in Millipore water (10 mg/mL) and centrifuged (10 min, 9000*g*, 4 °C) to obtain soluble and insoluble fractions. The insoluble fraction was freeze-dried and used along with the original dried fermentation digest for analyzing constituent monosaccharide content and composition. Constituent monosaccharide content in the soluble fraction was calculated from the difference in individual monosaccharide contents between the dried fermentation digest and the dried insoluble fraction of the fermentation digest. All samples were analyzed in duplicate.

Analytical Methods. *Constituent Monosaccharide Composition.* The constituent monosaccharide content and composition were determined using a prehydrolysis step with 72 (w/w%) sulfuric acid at 30 °C for 1 h followed by hydrolysis with 1 M sulfuric acid at 100 °C for 3 h. The monosaccharides formed upon hydrolysis were derivatized to alditol acetates and analyzed by gas chromatography using inositol as an internal standard.[14] The colorimetric *m*-hydroxydiphenyl assay[15] was used to determine the total uronic acid (UA) content.

Molecular Weight Distribution. Fermentation digests were centrifuged (10 min, 18000*g*, 24 °C) to obtain the soluble fraction, which was analyzed for molecular weight distribution using high-performance size exclusion chromatography (HPSEC) on an Ultimate 3000 HPLC (Dionex, Sunnyvale, CA, USA) as described before.[11] Three TSK-Gel columns in series (4000−3000−2500 SuperAW; 150 × 6 mm) were used for the analysis. They were preceded by a TSK Super AW-L guard column (35 × 4.6 mm). All columns were from Tosoh Bioscience (Tokyo, Japan). The molecular weight was estimated on the basis of a standard curve of pullulan standards.

Oligosaccharide Profiling. High-performance anion exchange chromatography (HPAEC) was performed on an ICS5000 system (Dionex), equipped with a Dionex CarboPac PA-1 column (2 × 250 mm) in combination with a Carbopac PA-1 guard column (2 × 50 mm). A volume of 10 μL of the soluble fraction of the fermentation digests (diluted twice with Millipore water) was injected into the system using a Dionex ICS5000 autosampler. The system was equipped with pulsed amperometric detection. The flow rate was 0.3 mL/min, and the gradient used was as described elsewhere.[16] The software used was Chromeleon version 7 (Dionex). Oligomers of galacturonic acid (DP 1−DP 5) were used as standards to identify and quantify galacturonic acid oligomers in the elution profile.

Analysis of Short-Chain Fatty Acids and Organic Acids. SCFAs and organic acids (lactate and succinate) were analyzed as described elsewhere.[17]

Microbiota Composition. Samples from a twin batch fermentation of CRP were analyzed for microbiota composition. The microbiota compositions for two independent duplicates of a 9 h fermentation digest of CRP (Supporting Information Figure S1) were similar, indicating reproducibility for fermentations of the cell wall material. The microbiota composition for ECRP fermentation was not performed due to limitations in the sample amount.

The molecular techniques used in isolation and amplification of DNA sequences followed by sequence processing and sequence analyses are as described previously.[18] In short, DNA was isolated from the fermentation digests using the AGOWA mag Mini kit (DNA Isolation Kit; AGOWA, Berlin, Germany), and a polymerase chain reaction (PCR) amplicon library was obtained by amplification of the V5−V7 hypervariable region of the small subunit rDNA gene (16S rDNA). The library was sequenced unidirectionally in the forward direction (A adapter) in one run in the 454 GS-FLX titanium sequencer (Roche, Branford, CT, USA) by Keygene (Wageningen, The Netherlands). Sequences extracted were processed using modules in the Mothur version 1.20.0 software platform module and aligned using the "align.seqs" command and an adaptation of the Bacterial SILVA SEED database as a template (http://www.mothur.org/wiki/Alignment_database). Aligned sequences were clustered into operation taxonomic units (OTUs; defined by 97% similarity) and were calculated by the average linkage clustering commando method.

RESULTS AND DISCUSSION

Characteristics of Fibers in Chicory Root Pulp and Ensiled Chicory Root Pulp. Table 1 shows the constituent monosaccharide composition of CRP and ECRP .[11] CRP is abundant in carbohydrates (64% w/w), of which 58% w/w represents CWPs and 6% w/w represents minor levels of the storage polysaccharide inulin with an average DP of 18.[11] The CWPs calculated from the mole percent monosaccharide composition and total sugar content (w/w %) (Table 1) contain 62% pectin (uronic acid + rhamnose + arabinose + galactose), 27% cellulose (arising from glucose not present in xyloglucan), and 11% hemicellulose (xylose + mannose + fucose + glucose in xyloglucan) as characterized earlier.[11] The carbohydrates present in the total soluble fraction represent only 12% of the CRP carbohydrates. As determined earlier for the dialyzed soluble fraction,[11] half is arabinose-rich pectin and

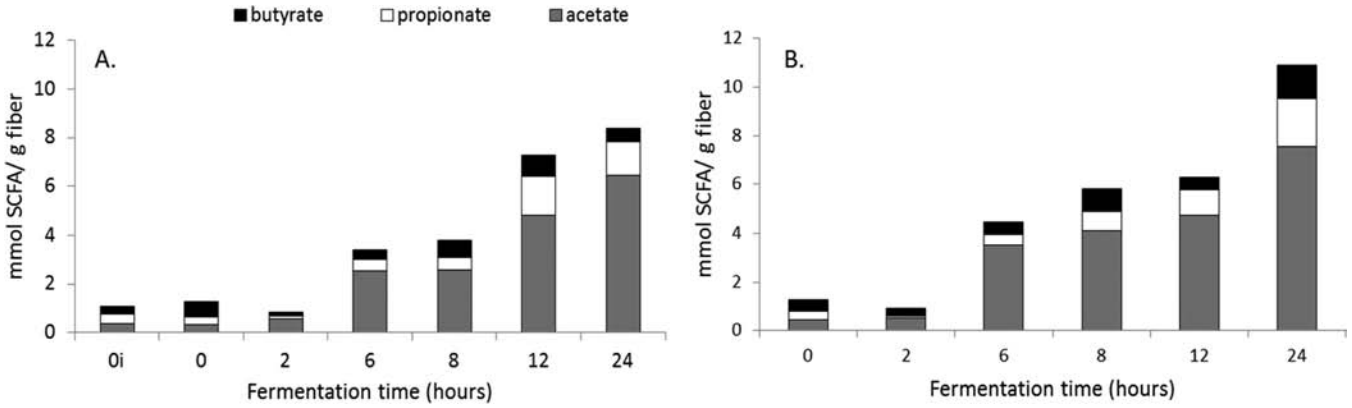

Figure 1. Short-chain fatty acid production during fermentation of (A) chicory root pulp (CRP) and (B) ensiled chicory root pulp (ECRP). Succinate and lactate levels are not shown due to low levels (<0.1 mmol/g fiber). 0i, inoculum + medium. Values present means of duplicate measurements. Values with corresponding standard deviations are presented in Table S1 of the Supporting Information.

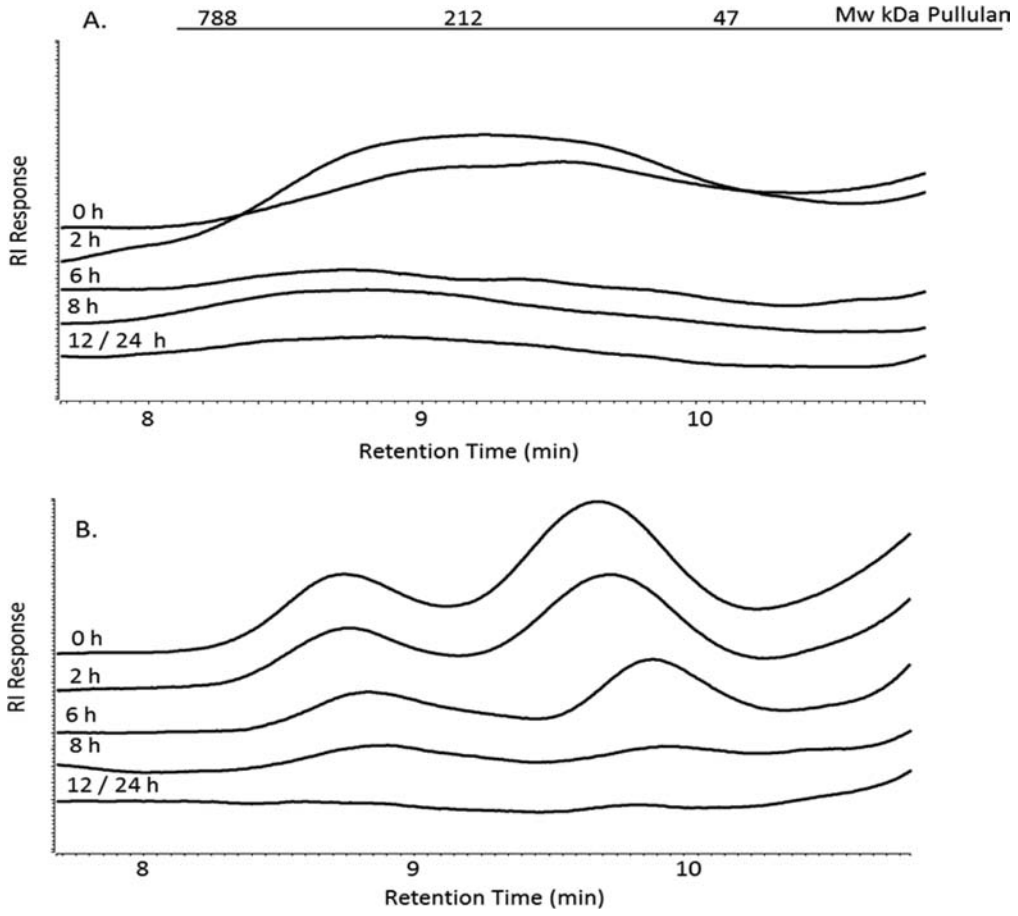

Figure 2. HPSEC elution patterns of fermentation digests during fermentation of (A) chicory root pulp (CRP) and (B) ensiled chicory root pulp (ECRP). Pullulan was used as a calibrant.

the other half is inulin, as is the case for the total soluble fraction. Almost 87% of the carbohydrates from CRP are insoluble and have a polysaccharide composition similar to that of the total CRP (Table 1).

The ECRP is rather similar in composition to CRP (Table 1), but contains no inulin.[11]

As indicated by the higher carbohydrate recovery (48%) in the soluble fraction from ECRP compared to that from CRP (12%) (Table 1), ECRP has more soluble fibers than CRP. Dominant among the sugars solubilized are the pectic sugars as seen from the sugar composition (Table 1). As determined from an earlier study for the dialyzed soluble fraction,[11] ECRP represents 4 times more pectic sugars than that from CRP as is the case for the total soluble fraction. The pectic sugars from the insoluble network of CRP are extractable only under severe conditions, such as chelating agents and alkali.[11] Apparently, they can be solubilized by ensiling. As a consequence, the insoluble fraction of ECRP represents a lower recovery of carbohydrates (55%) compared to CRP (87%) and is enriched in (hemi)cellulose (Table 1).

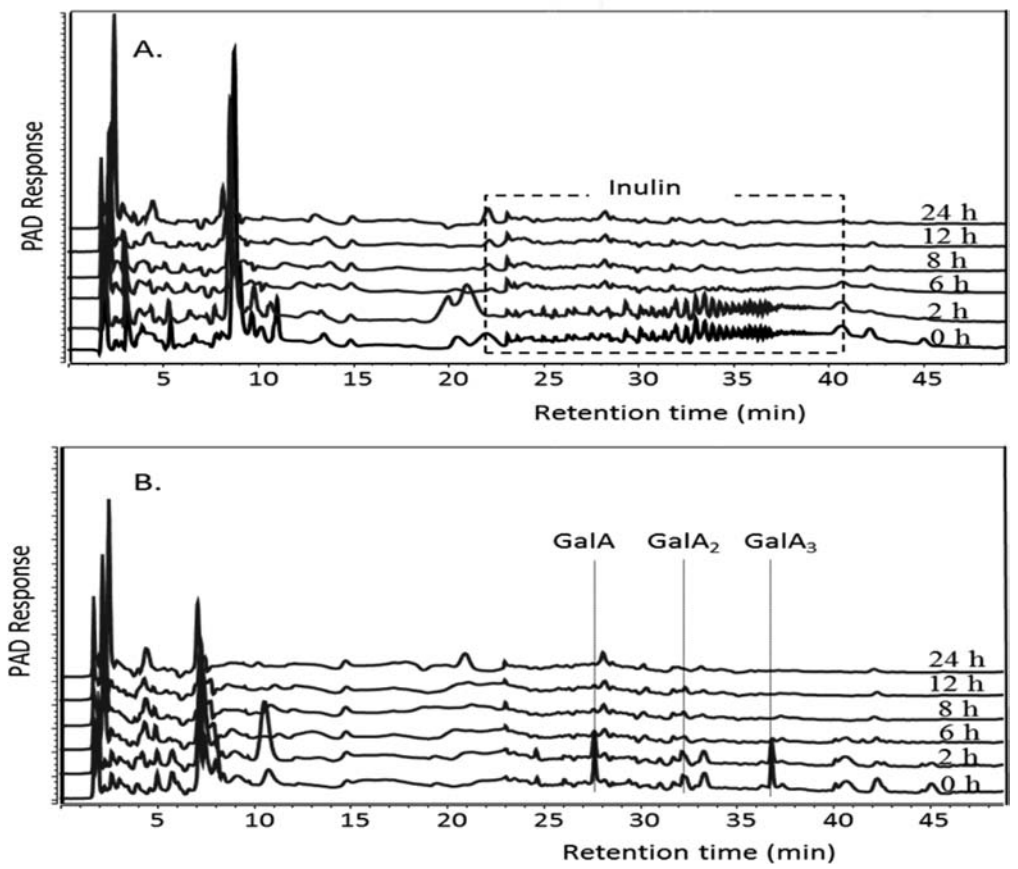

Figure 3. HPAEC elution profile of fermentation digests during fermentation of (A) chicory root pulp (CRP) and (B) ensiled chicory root pulp (ECRP). GalA, galacturonic acid; $GalA_2$, dimer of GalA.

Fermentation of CRP and ECRP: Short-Chain Fatty Acid Production. CRP and ECRP were well fermented as indicated by the increase in the levels of SCFAs produced (mmol/g substrate) in time (Figure 1) as well as from the decrease in CWP content discussed later in this study. The values including the corresponding standard deviation are presented in Supporting Information Table S1. The SCFA levels at the start of fermentation (0 h) for CRP and ECRP arose from the inoculum added to the medium as seen from similar levels between the inoculum blank (0i) and 0 h for CRP and ECRP fermentation. The initial SCFA levels (0 h) for both CRP and ECRP are higher than found for the digests after 2 h of fermentation, indicating utilization of SCFAs during the first 2 h. After 24 h of fermentation of CRP, 8.4 mmol SCFAs/g substrate was present.

Compared to CRP fermentation (Figure 1A), ECRP fermentation was quicker as high levels of SCFAs were produced within a short time period (6 h) of fermentation (Figure 1B). Besides a faster ECRP fermentation, a higher SCFA production (10.9 mmol/g after 24 h of ECRP fermentation) was seen compared to CRP fermentation (8.4 mmol/g). This indicated that the modified cell wall network of ECRP with a higher ratio of soluble/insoluble polysaccharides (0.8) (Table 3) compared to CRP (ratio 0.3) (Table 3) is more fermentable than that of CRP. The ratios of acetate/propionate/butyrate were similar between CRP (77:16:6) and ECRP (69:18:13) after 24 h of fermentation. Because the carbohydrate compositions of CRP and ECRP are similar, this suggested that fermentation of an open cell wall network has limited influence on utilization by the microbiota. This similarity in the SCFA ratio has also been observed for fermentations of sugar beet pulp and autoclaved beet pulp.[10]

Minor levels of intermediate fatty acids,[19] lactate and succinate (<0.1 mmol/g), were observed throughout the fermentation period. The fermentation of higher oligomers of inulin (discussed later) indeed resulted in very little butyrate and lactate formation. Fermentation of higher oligomers of inulin (DP >20) by the microbiota has been reported to more greatly hinder the production of butyrate and lactate than that of short oligomers of inulin (DP <10).[20,21]

Molecular Weight Distribution of Soluble Fibers. HPSEC elution profiles of solubles from CRP and ECRP fermentation digests are shown in Figure 2. For CRP fermentation, an increase in the amount of soluble material corresponding to high molecular weight (M_w) (8−10 min, 47−788 kDa) was seen after 2 h of inoculation. From 6 h onward, an almost complete disappearance in the high M_w fraction suggested degradation/utilization of the high M_w polysaccharide. This implies either rapid utilization of fibers solubilized during fermentation or direct utilization of insoluble fibers directly by the microbiota system.

Compared to the elution profile of CRP fermentation blank (0 h), the elution profile of the ECRP blank showed a 52% higher amount of high M_w material, as expected from the higher pectin solubility.[11] This material is present in two populations (8−9 min, 212−788 kDa; and 9−10 min, 47−212 kDa). After 6 h of fermentation, a decrease is seen in the intensity of both peaks, indicating degradation of both populations. These populations are almost completely utilized after 8 h of

fermentation. As for CRP fermentation, almost no high M_w solubles could be seen after 12 and 24 h of ECRP fermentation.

Oligomer Utilization. To determine oligomers formed/utilized during CRP and ECRP fermentation, soluble fractions from fermentation digests were analyzed using HPAEC (Figure 3). Before the start of CRP fermentation (0 h), higher oligomers of inulin (average DP of 18)[11] were observed. Because short oligomers of inulin were removed by the

industrial extraction from the root, the pulp contains only higher oligomers of inulin. Within 6 h, inulin is almost completely utilized.[11]

During fermentation, CWPs are degraded to lower M_w material, and in a previous study using sources other than CRP for CWPs, intermediate oligosaccharides could be clearly recognized.[16] However, in this study, no oligomers formed from CWPs were observed during CRP fermentation. *Bacteroides* sp., becoming dominant during CRP fermentation, as discussed later, are known to be motile and to possess "specialized polysaccharide utilization systems" in which cell surface proteins are involved in binding to different polysaccharides and transporting the oligomers that are formed directly over the bacterial membrane.[22,23] Such systems likely prevent diffusion of oligomers. Another possibility for the absence of oligomers could arise from rapid cross feeding of oligomers by other fermenting bacteria.[24]

Before the start of ECRP fermentation (0 h), a number of peaks can be identified as oligomers of galacturonic acid (GalA) on the basis of standards of GalA oligomers used (Figure 3B). These oligomers represent approximately 14% of total ECRP GalA and arose from ECRP after the process of ensiling. These oligomers are shown to decrease within the first 6 h of ECRP fermentation, pointing to their utilization. Similar to the CRP fermentation, no new oligomers are formed.

Changes in CRP Fiber Composition during Fermentation. Direct utilization of CWPs during CRP fermentation can be revealed from the decrease in the total carbohydrate content as well as from the constituent monosaccharides during fermentation. The constituent monosaccharide compositions of CRP fermentation digests are shown in Table 3. Low concentrations (w/w%) of carbohydrates in all of the fermentation digests are due to the presence of high concentrations of other fermentation media components, such as proteins and salts.[12,13] The constituent monosaccharide composition of the CRP fermentation blank (0 h) (Table 2) is similar to that of CRP (Table 1), indicating that the carbohydrates present in the medium before fermentation do not contain carbohydrates other than from CRP fibers. After 24 h of fermentation, 51% of CRP total carbohydrates were utilized (Figure 4A). This is rather similar to the degradability of sugar beet fiber showing 60% carbohydrate utilization after 24 h of fermentation with human fecal inoculum.[25]

Until 12 h of fermentation, the constituent monosaccharide composition remained similar, although 25% of all carbohydrates were utilized. This indicated unspecific utilization of CWPs in the first 12 h of fermentation. This is also seen in Figure 4A from 0 to 12 h of fermentation. As the fermentation continued from 12 to 24 h, the carbohydrate content was further reduced by another 25% and the constituent monosaccharide composition changed considerably. This suggests a more specific utilization of CWPs from 12 h onward. The calculated decrease in arabinose (Ara), galactose (Gal), and GalA by 86, 63, and 84%, respectively, after 24 h (Figure 4A), indicated enhanced utilization of arabinan, galactan, and homogalacturonan (HG) from CRP, respectively. The unexpected decrease in glucose utilization from 12 to 24 h (Figure 4A) might arise from an increase in bacterial cell walls containing glucose.[26]

The enzyme machinery from the fermenting bacteria seemed to be so efficient in degrading arabinan that the 14% level of resistant arabinan after 24 h of fermentation is only half of the arabinan remaining in the cell wall matrix after severe extraction by strong alkali.[11] This indicated that even part of the heavily entangled arabinan was utilized during fermentation.

Changes in Ensiled CRP Fiber Composition during Fermentation. The presence of more soluble fibers in a more open cell wall network in ECRP compared to CRP was hypothesized to have an effect on the fiber utilization during fermentation of the cell wall network. The constituent monosaccharide compositions of the fermentation digests obtained during fermentation of ECRP are shown in Table 2.

After 24 h of fermentation, 59% of all carbohydrates are utilized from ECRP (Figure 4B). The 8% higher carbohydrate utilization compared to CRP indicates a slightly higher fermentability of ECRP over CRP as has been seen from the higher SCFA production as discussed earlier. Unexpectedly, the increase in SCFA production (30%) is much higher than the 8% higher carbohydrate utilization. ECRP fermentation was also quicker as was indicated from the high level of carbohydrate utilization (36%) within a short time period of 12 h compared to only 25% carbohydrate utilization for 12 h of CRP fermentation (Table 2).

[a]Values are means of duplicate measurements with corresponding standard error. Rha, rhamnose; Fuc, fucose; Ara, arabinose; Xyl, xylose; Man, mannose; Gal, galactose; Glc, glucose; UA, uronic acid.

As for CRP fermentation, specific CWPs consisting of Ara, GalA, and Gal are favorably utilized the most during ECRP fermentation, but to a larger extent compared to CRP fermentation (Figure 4). As seen in Figure 4, the sugar utilization for ECRP is more pronounced than CRP fermentation after 12 h than after 24 h of fermentation. At 12 h, the sugar utilization was determined to be 31 and 74% Ara, 20 and 58% GalA, and 32 and 43% Gal for CRP and ECRP, respectively (Figure 4). This rapid increase in carbohydrate utilization coincides with the higher levels of soluble fibers composed of Ara, Gal, and GalA in ECRP. This indicated that processing of CRP, increasing the levels of soluble fibers and modifying the cell wall network, increased the degradability and the rate of fermentation of specific CWPs.

Utilization of Soluble/Insoluble Fibers from Cell Wall Materials during Fermentation. The presence of soluble fibers and/or more open CWP network of the remaining insoluble fibers in ECRP seems to enhance fermentation. To elaborate on this observation, carbohydrate levels in both soluble and insoluble fractions of digests from percent original carbohydrates are shown in Figure 5. Levels of individual carbohydrates in soluble and insoluble fractions of fermentation digests from percent original individual carbohydrates are shown in Table 3.

Utilization of Soluble/Insoluble Fibers from CRP. The insoluble fibers in CRP are utilized only after 12 h when all soluble fibers have been utilized. This is also in agreement with HPSEC in which no soluble fibers could be seen after 12 h of fermentation (Figure 2). Insoluble fibers are mostly utilized between 12 and 24 h of fermentation shown by the decrease from 73 to 48% of residual insoluble carbohydrates. Insoluble fiber utilization mostly involved pectic sugars of Ara, GalA, and Gal as indicated from Table 3. Only 18% of all insoluble pectin (GalA + Rha + Ara + Gal) (calculated from Table 3) remained unfermentable after 24 h, suggesting a high fermentability of insoluble pectin from the CRP plant cell wall.

For ECRP fermentation, utilization of soluble fibers can be seen from the decrease in the residual soluble carbohydrate levels from 45 to 4% from 0 to 24 h (Figure 5B). Utilization of insoluble fibers is slow and lower than found for the soluble fiber as shown by the decrease from 55 to 37% of residual insoluble carbohydrates (Figure 5B). Soluble fibers consisting of pectic sugars (Table 3) are thus preferentially utilized. This suggests that the increased rate and higher level (8%) of carbohydrate utilization in ECRP fermentation compared to CRP fermentation is due to fermentation of soluble pectin fibers that are present in high amounts in ECRP.

Compared to CRP, for ECRP, only 9% of all pectin (Rha + Gala + Ara + Gal) originally present remained unfermentable (calculated from Table 3). This suggested that pectin in the hypothesized more open structure of the ECRP cell wall was more degradable than the pectin in the CRP cell wall structure, contributing to an increased fermentability of ECRP. Other than pectin, the ECRP cell wall contained quite some cellulose + hemicellulose sugars (glucose + xylose + mannose) that were unfermentable (75%) (calculated from Table 3). This suggested that the fermentative degradation of the CWP network was selective for pectin fibers and preferably soluble pectin. This is in agreement with the limited degradation of (hemi)cellulose by the human gut microbiota in human subjects.[27]

Microbiota Composition during CRP Fermentation. The microbiota composition during the course of fermentation is expected to be modulated on the basis of the composition of the fiber added during fermentation.[28] The main genera present in the microbiota of the fermentation digest for CRP fermentation (Figure 6) are expressed as percent abundance of genera of the total microbiota in the fermentation digest. The highest increase was seen for *Bacteroides* sp. (8%), which remain the most dominant bacteria after 24 h of fermentation. In contrast, decreases were seen for *Dorea* sp. (1.5%), *Sutterella* sp. (5.7%), and *Clostridium* XIVa sp. (6%). The relative

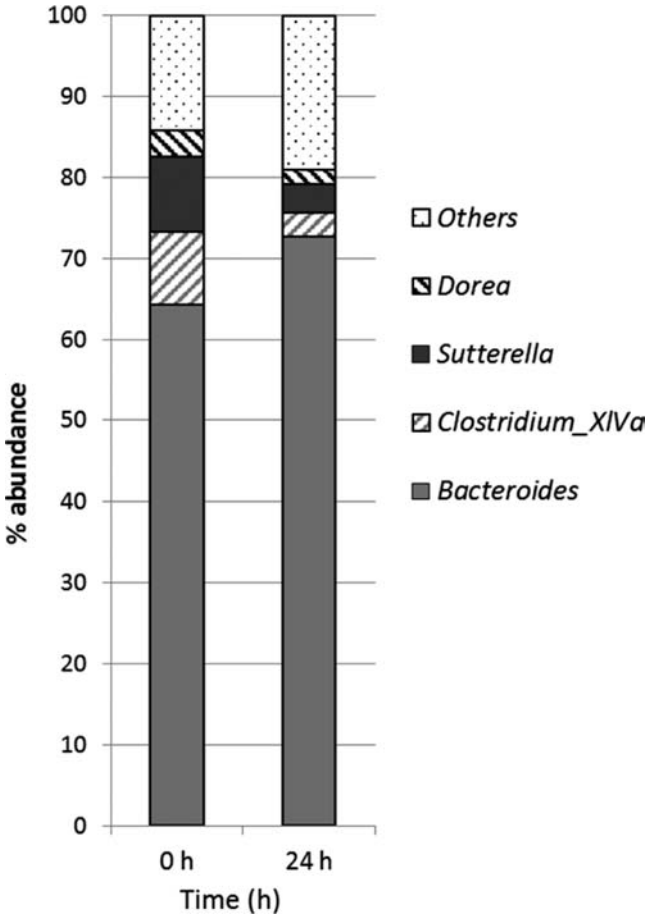

Figure 6. Microbiota composition during fermentation of chicory root pulp (CRP) expressed as percent abundance of genera of the total microbiota in the fermentation digest.

abundance of less dominant genera is presented in Table S2 in the Supporting Information.

The fermentation digest at 24 h of fermentation showed an increase in *Clostridium sensu stricto* sp. (1.34%) and *Lachnospiracea incertae sedis* sp. (1.21%) (Supporting Information Table S2).

Although *Lachnospiracea incertae sedis* sp. is a butyrate producer[29] and increased during fermentation, the observed lower butyrate/(acetate + propionate) ratio of 6:94 after 24 h compared to 50:50 at the start of fermentation (Figure 1) could be due to the decrease in butyrate producers,[30,31] such as *Clostridium* XIVa sp., *Faecalibacterium* sp. (0.94%), and *Butyricicoccus* sp. (0.57%) (Supporting Information Table S2).

Despite the presence of the bifidogenic inulin fraction,[32] no growth of *Bifidobacterium* sp. was seen after 24 h of fermentation, because inulin (6% of all CRP carbohydrates) was already utilized within 6 h of fermentation.

Although changes in the microbiota composition are seen during CRP fermentation, the significance of the change in the complex community of microbiota is hard to understand. Part of the significance may be understood when correlated to metabolite production, fiber degradation, and utilization. It is likely that *Bacteroides* sp., identified as the dominant bacteria in fermenting CRP, are responsible for the shown utilization of arabinan, galactan, and homogalacturonan and an increase in acetate and propionate. *B. thetaiotaomicron*, known to be highly abundant among *Bacteroides* sp.,[33] has been estimated to include 236 glycoside hydrolase genes.[34,35] Production of enzymes during the course of fermentation is up-regulated on the basis of the polysaccharides present during fermentation.[34]

Although it is not possible to include the microbiota composition for ECRP fermentation, measurements of different fiber degradations clearly point to differences in microbiota composition. As has been seen earlier,[36] differences in microbiota composition were found between soluble fibers (pullulan and soluble corn fiber) and insoluble fibers (resistant starch and cellulose). Because ECRP has more soluble fibers than CRP, it is probable that the soluble fiber degrading bacteria will be more dominant during ECRP fermentation than during CRP fermentation.

This study revealed that processing (ensiling) of chicory root pulp to open the cell wall network and solubilize pectin from the cell wall network will increase the fermentation rate of soluble pectin fibers as well as insoluble pectin fibers in the pulp. Processing an agricultural byproduct would thus be an option if an increased fermentation rate of cell wall polysaccharides is desired for the final dietary fiber product.

of whether allergic reactions can be elicited in allergic patients by residues of fining agents in wine is still unanswered. Kirschner et al.[14] investigated the tolerability of casein-, ovalbumin-, and isinglass-fined wines in 14 allergic patients by skin prick tests (SPT), as well as by double-blind, placebo-controlled food challenge (DBPCFC) with fined and filtered wines. The highly concentrated fining agents were allergenic in the SPT, but no patient reacted adversely to the oral challenge of the fined and filtered wines. However, in another study by Rolland et al.[12] after DBPCFC with fined and unfined wines, unspecific subjective, but no objective, symptoms occurred, which does not allow a clear interpretation. Because of this situation, since July 2, 2012, the application of fining agents such as casein and milk-derived products during wine processing has to be labeled if the final product contains 0.25 mg/L or more allergenic protein, which is a threshold given by Organisation Internationale de la Vigne et du Vin (OIV, Paris, France) regulations. This is a legal threshold under Regulation (EU) No. 579/2012 in conjunction with Regulation (EU) No. 1234/2007.

The method recommended by OIV for the detection of potentially allergenic residues of fining agents proteins in wine is ELISA with a limit of detection (LOD) of ≤0.25 mg/L and a limit of quantification (LOQ) of ≤0.5 mg/L. For this purpose various sensitive ELISA methods are described in the literature detecting ovalbumin, casein, and casein-derived products as well as dried hen's egg white.[2,15−18] Drawbacks of ELISA methods in this case are interfering compounds in the matrix such as polyphenols in red wine, as described by Weber et al.[15] and Monaci et al.[19] In recent years also a number of MS-based methods have been reported for the detection of residual allergenic fining agents in red and white wines.[19−24] With MS techniques LODs and LOQs in the lower milligrams per liter range up to 51 mg/L of fining agent residues in wine are achieved. A big benefit of MS analysis compared to ELISA is the possibility for simultaneous detection of, for example, casein and ovalbumin. However, a drawback of MS methods is that it is a nonimmunological method and the antigenicity of the target protein(s) is not considered, which might be important for allergen analysis.

The aim of the study was to develop very sensitive ELISA methods with detection limits in the micrograms per liter region to investigate possible casein fining agent residues in wine. These methods could then be used for risk assessment related to residues of allergenic wine fining agents and may avoid unnecessary labeling, which may lead to uncertainty and decreased quality of life in allergic consumers.[15,25]

For this purpose it is necessary to study the heterogeneity of different casein fining agents and get information on the influence of different standard substances as calibration reference on the results of the assay.

The characterization of different casein wine fining agents was done by lithium dodecyl sulfate−polyacrylamide gel electrophoresis (LDS-PAGE) with silver staining and immunoblot. For the quantification of these described possible fining agent residues in wine an indirect ELISA as well as an indirect sandwich ELISA were developed. Therefore, polyclonal antibodies raised against a casein fining agent were used for immunoblotting and ELISA development to achieve a higher specifity by considering all residual allergenic milk proteins remaining from the fining procedure with a casein-derived product.

The LODs and lower limits of quantification (LLOQ) depend on the type of ELISA, the calibrating substance, and the dilution of the analyzed wine and show the complexity of the wine matrix, especially for red wine.

The developed ELISA methods were used to investigate wines after using certain technological treatments to remove wine fining agents.

MATERIALS AND METHODS

Casein Standard and Fining Agents. Casein of analytical grade from Merck KGa (Darmstadt, Germany) was used as casein standard.

For matrix calibration the fining agent KalCasin was used, which is described as a potassium milk caseinate. It was obtained directly from the manufacturer, Erbslöh Geisenheim AG (Geisenheim, Germany), and had a protein content of approximately 76% by the Kjeldahl method.

Investigated and characterized fining agents were 12 casein products of different commercial European producers (Agrovin, Begerow, Enartis, Erbslöh, Laffort, Spindal, Vason) organized in OENOPPIA (International Association of Oenology Industrials for Oenological Products and Practice, Paris, France).

Antibodies. The capture antibodies for the sandwich ELISA, which were also used as primary antibodies for the indirect ELISA as well as for immunoblotting, were polyclonal antibodies raised against one fining agent, which is described as potassium caseinate. Antibody production was done by Eurogentec (Seraing, Belgium). For this three rabbits were immunized against this fining agent four times in four week intervals. The serum samples were taken 10 days after the second, third, and fourth immunizations and purified using affinity chromatography. Affinity chromatography was performed at CNBr Sepharose, and the antibodies were eluted with 100 mM glycine (pH 2.5). The antibodies were conserved with 0.01% thimerosal in phosphate-buffered saline (PBS), and the purity was >85%, determined by SDS-PAGE. The concentration of the purified antibodies was 1.1 mg/mL.

The primary antibodies for the indirect sandwich ELISA were produced by Immunology Consultants Laboratory (Newberg, OR, USA) against bovine casein in sheep. The concentration of the antibodies was 1.0 mg/L.

The secondary antibodies, used for the indirect ELISA as well as for the immunoblot, were HRP-conjugated goat anti-rabbit antibodies, obtained from Dako (Dako GmbH, Glostrup, Denmark). The concentration of the antibodies was 0.25 mg/L.

The secondary antibodies for the indirect sandwich-ELISA were produced by Immunology Consultants Laboratory against sheep, conjugated with HRP. The concentration of the antibodies was 1.0 mg/L.

Wine. Method development and validation were done with well-known experimental wines, produced by the Wine Research Institute Geisenheim in the context of project AiF 16330N, "Reducing the concentration of allergenic fining agents in the final wine by technological treatment". An unfined white wine of the grape variety Mueller Thurgau (vintage 2009) and an unfined red wine of the grape variety Regent (vintage 2009) were used as matrix for method development of the ELISAs. These wines were produced according to common winegrowers practice and finally bottled through a filter layer into 0.75 L bottles. The musts were inoculated with yeast (*Saccharomyces cereviseae*) and fermented at 16−18 °C. No fining procedure was done before filling.

Within the project different wine fining procedures were investigated concerning their effectiveness in reducing the content of certain allergenic wine fining agents in the final product wine. For that the described red wine and the described white wine were fined with the maximal permitted dose of wine fining agent as well as with double the maximal dose to demonstrate a worst-case scenario. This is to protect allergic consumers also from an accidental overdosage by the winegrower. These wines were produced according to common winegrower practice and finally bottled through a filter layer into 0.75 L bottles.

Eight processes to remove the fining agent were performed in 120 L flasks to simulate a wine tank. The wine was fined with 40 (A) and 80 g (B) KalCasin/hL wine.

To investigate whether there is a decrease of potential allergenic wine fining agent residues during the production process and how efficiently the different fining procedures work, two different production steps of every produced wine were analyzed by ELISAs. These two investigated production steps were the first after removal of the fining agent with different techniques (I) and the second after sterile filtration into commercially available bottles (II), respectively. The investigated red and white wines are presented in Table 1.

Table 1. Investigated White (WW) and Red (RW) Wines

wine		technique
WW1	RW1	I. 0.45 μm filtration
		II. sterile filtration
WW2	RW2	I. addition of bentonite
		II. sterile filtration

The following two filtration techniques and enological procedures used for wine production are discussed in this publication: (1) 0.45 μm filtration, using a Type 419A, grade B (beverage version) SEITZ-MEMBRAcart cartridge with 0.45 μm pore size from Pall Corp. (Port Washington, NY, USA); and (2) addition of bentonite, using Aktivit bentonite from Erbslöh. Immediately after these treatments, sterilizing filtration was performed on all wines, using SEITZ-EK 200 × 200 mm depth filter sheets from Pall Corp., and the wines were bottled into 0.75 L bottles. For example, the term WW1AII describes the white wine fined with 40 g/hL KalCasin, treated with process 1 to remove the fining agent, at processing step II, after sterile filtration.

Lithium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis. For electrophoretical separation, the casein standard and different fining agents were prepared in 10−13 mg/50 mL solutions with 10 mM carbonate solution under shaking on a horizontal shaker for at least 30 min.

All chemicals were of analytical grade. The proteins were separated as described by Steinhoff et al.[26] Precast NuPAGE Bis-Tris 12% gels (Invitrogen GmbH, Karlsruhe, Germany) were performed under denaturing conditions at 200 V using NuPAGE 3-(*N*-morpholino)-propansulfonic acid (MOPS) SDS running buffer (Invitrogen). For electrophoresis the protein solutions were diluted 1:2 with LDS sample buffer, which contained dithiothreitol (DDT) for reduction. Every lane was loaded with 20 μL of sample solution. The unpicked proteins were further silver stained or blotted on a nitrocellulose membrane.

Silver Staining. Detection of the separated proteins was done by a silver staining procedure according to Heukeshoven et al.[27] as described by Steinhoff et al.[26] At first, the proteins were fixed in the gel by treatment with 30% ethanol and 10% acetic acid in water for 30 min. Afterward, an incubation with a solution containing 0.1% sodium thiosulfate, 30% ethanol, and 6.8% sodium acetate in water occurred for 30 min. This was followed by a washing step with water. Then the gel was incubated in a silver nitrate solution (0.2% silver nitrate and 0.02% formaldehyde in water) for 20 min. Finally, development occurred with 2.5% sodium carbonate and 0.01% formaldehyde in water. Stop solution was prepared with 1.8% ethylendiaminetetraacetate (EDTA) in water.

Immunoblotting. All chemicals were of analytical grade. Immunoblotting was performed according to the method of Steinhoff et al.[26] By LDS-PAGE separated proteins were electrophoretically transferred onto a nitrocellulose membrane (Whatman, Maidstone, UK) via semidry western blotting. The dried membranes first were blocked with blocking solution (0.5% polyethylene-sorbitan monolaurate (Tween20), 0.9% sodium chloride, and 0.6% tris(hydroxymethyl)-aminomethane (Tris)) to inhibit nonspecific binding to the membrane. The membrane was incubated with the primary antibody, anti-potassium caseinate antibody (1/10000), followed by incubation with the secondary HRP conjugates anti-rabbit antibody (1/20000) at room temperature. Finally, staining was performed with staining solution containing 0.06% 3,3′,5,5′-tetramethylbenzidine (TMB), 0.2% dioctylsodium sulfosuccinate (DONS), 25% ethanol, 0.7% citric acid, and 1% Na_2HPO_4 in water. The protein weight marker was stained by adding Ponceau red solution.

Quantitative Indirect Sandwich and Indirect ELISA. Fining agent and protein standard solutions were prepared by dissolving about 12.5 mg of the respective substance in 50 mL of 10 mM carbonate solution under shaking on a horizontal shaker for at least 30 min. Depending on the ELISA to be undertaken, the calibration solutions were prepared by dilution with carbonate buffer (indirect ELISA) or PBS−Tween20 buffer (indirect sandwich ELISA).

All chemicals were of analytical grade. Buffer preparation was done according to the method of Weber et al.[15] Coating buffer (carbonate buffer, pH 9.6) contained 75 mM Na_2CO_3 and 175 mM $NaHCO_3$ in bidistilled water. Blocking solution (Tris−Tween20 buffer, pH 9.6) contained 50 mM Tris, 150 mM NaCl, and 0.5% Tween20 in bidistilled water. Washing solution (PBS−Tween20 buffer, pH 7.4) contained 10 mM $NaH_2PO_4 \cdot H_2O$, 70 mM Na_2HPO_4, 150 mM NaCl, and 0.5% Tween20 in bidistilled water. Citric buffer (pH 4.0) contained 210 mM citric acid monohydrate and 300 mM KOH in bidistilled water. The substrate solution was freshly prepared with 5 mg of TMB, dissolved in 125 μL of acetone filled to 1 mL with methanol, 19 mL of citric buffer, and 200 μL of H_2O_2 (1%). The stop solution was made of 2 M H_2SO_4 in bidistilled water.

An indirect ELISA procedure was modified according to the method of Weber et al.[2] Two hundred microliters per well sample solution in coating buffer was coated to a polystyrene microtiter plate (MaxiSorp F96, Nunc, Roskilde, Denmark) overnight at 8−9 °C. The plate was washed three times with 300 μL/well blocking solution. Subsequently, free binding sites of the wells were blocked with 250 μL/well blocking solution for 2 h at room temperature by horizontal shaking to inhibit unspecific bindings of the antibodies. Afterward, the plate was washed three times with 300 μL/well washing solution and incubated with 200 μL/well primary antibody in PBS−Tween20 (1:10000) for 1 h by shaking at room temperature. Then the plate was washed three times with 300 μL/well washing solution. Finally, 200 μL/well secondary antibody in washing solution (1:2000) was added and incubated for 1 h by shaking at room temperature. The plate was then washed three times with washing solution and three times with citric buffer. The enzymatic colorimetric reaction was performed by adding 200 μL/well substrate solution (TMB). By the HRP-catalyzed oxidation of the TMB, a blue compound is generated. The reaction was stopped after 5 min by adding 100 μL/well stop solution, which leads to a color change to yellow. The measurement occurs at 450 nm with 630 nm as reference wavelength.

For method validation the measurement occurs in 1/10 diluted white wine and 1/20 diluted red wine.

For the indirect sandwich ELISA method, the assay protocol of Weber et al.[2] was also used as guideline. The procedure started by coating a polystyrene microtiter plate (MaxiSorp F96, Nunc) with 200 μL/well capture antibody in coating buffer (1/20000) overnight at 8−9 °C. Afterward, the plate was washed three times with 300 μL/well blocking solution. Subsequently, free binding sites of the wells were blocked with 250 μL/well blocking solution for 2 h at room temperature by horizontal shaking to inhibit unspecific bindings. Then the plate was washed three times with 300 μL/well washing solution again and incubated with 200 μL/well sample solution in PBS−Tween20 for 1 h by shaking at room temperature. After a reapplied washing step, 200 μL/well primary antibody in washing solution (1/20000) was added. Then the plate was washed three times with 300 μL/well washing solution again and incubated with 200 μL/well secondary antibody in washing solution (1/20000) for 1 h by shaking at room temperature. Finally, the plate was washed three times with washing solution and three times with citric buffer. The colorimetric reaction was performed by adding 200 μL/well substrate solution as described for the indirect ELISA. The measurement occurs at 450 nm with 630 nm as reference wavelength.

For method validation the measurement occurs in 1/10 diluted white wine and 1/10 diluted red wine.

Washing of the microwell plates was done using an eight-channel automatic microplate washer ELx50 (BioTek, Winooski, VT, USA). Optical density (OD) was read using a MRX microplate reader

(Dynex Technologies, Chantilly, VA, USA) using the software Revelation G 3.2 (Dynex Technologies). Analysis of the measured data was done with SoftMax Pro 5.4 software (Molecular Devices, Sunnyvale, CA, USA).

Evaluation. The evaluation of the ELISAs occurred on the basis of a logistic four-parameter regression using the software SoftMax Pro 5.4 (Molecular Devices). The four-parameter curve is one of the most reliable and most flexible evaluations for immunoassays. The equation of a four-parameter curve is $y = [(A - D)/(1 + (x/c)^B] + D$ with y = extinction, A = lower asymptote, B = raising in the central point, D = upper asymptote, and x = concentration (Figure 1).

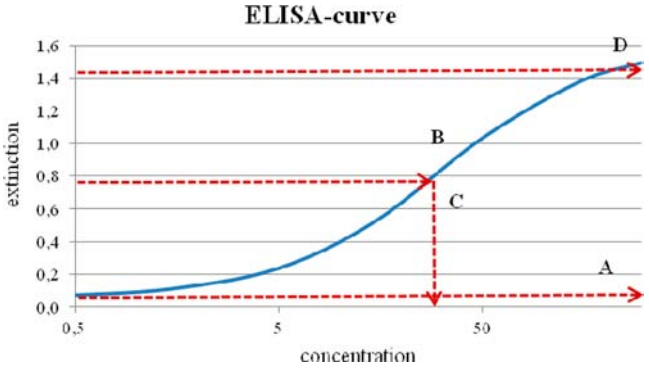

Figure 1. Sample diagram four-parameter regression.

The LOD was determined as the concentration of analyte for which the extinction of the blank value plus its standard deviation is lower than the extinction for the concentration of analyte minus its standard deviation. The LOD as well as the LLOQ are the most important statistical parameters for ELISA methods. A common practice is to use the signal-to-noise rate of the measured blank value for determination.[28,29] This is estimated as nonreliable because only the blank value is considered.

Additionally, a precision profile according to Ekins[30] was developed. This precision profile takes the variance of the nonconformance above the curve progression (heteroscedasticity) into account. In this way the relative nonconformance for every analyte concentration can be defined, and by incorporating a threshold for this relative nonconformance, the measurement range with LLOQ and upper limit of quantification (ULOQ) can be determined.[30−32] In this case the threshold for the relative nonconformance was defined with 20%.

Accuracy was checked by spiking unfined experimental wine samples with casein or KalCasin within the calibration range, respectively, and determining these recovery rates.

RESULTS AND DISCUSSION

Characterization of Different Casein Wine Fining Agents. A total of 12 commercially available casein wine fining agents of six European manufacturers were investigated by LDS-PAGE and silver staining as well as immunoblotting. These fining agents are denoted fining agents 1−12 in this publication, independent from their production and contained proteins.

The LDS-PAGE with silver staining (Figure 2) shows that every product contains not only casein (19−25 kDa) but also other milk allergens in different amounts, except for fining agent 7 (Figure 2, lane 7), which apparently mainly contains the whey proteins α-lactalbumin (ALA, 14.2 kDa) and β-lactoglobulin (BLG, 18.3 kDa). All other casein fining agents (Figure 2, lanes 1−6, 8−12) show similar protein band compositions, similar to the casein standard (Figure 2, lane Std), but with partially different band intensities. For electrophoresis, the fining agents, as well as the casein standard, were applied in concentrations from 200 to 250 mg/L. In two fining agents no bands were

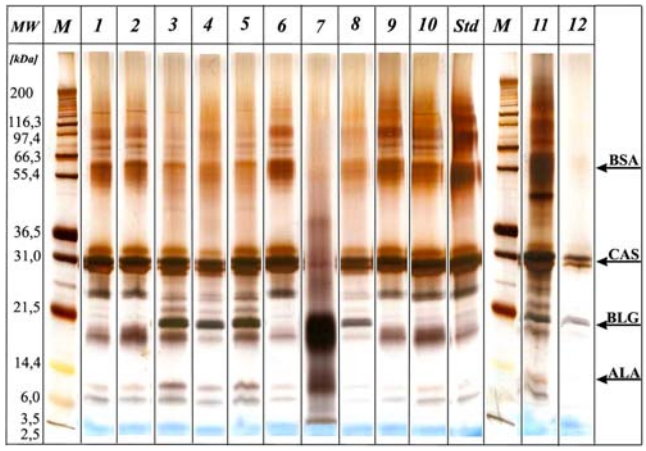

Figure 2. LDS-PAGE and silver-staining of the casein fining agents. MW, molecular weight (kDa); M, molecular weight marker; lanes 1−12, fining agents 1−12; Std, casein standard; BSA, bovine serum albumin (66.4 kDa); CAS, casein (19−25 kDa); BLG, β-lactoglobulin (18.3 kDa); ALA, α-lactalbumin (14.2 kDa).

detectable with this concentration; thus, the sample concentrations were increased to 2000 and 4000 mg/L. Degraded proteins were also detectable in the electropherogram of the casein products.

The described results of the unspecific silver staining are supported by specific immunochemical staining with an antibody raised against one commercially available fining agent. This antibody detects besides casein also the other milk proteins ALA, BLG, and bovine serum albumin (BSA, 66.4 kDa) as shown in Figure 3, whereas the antibody apparently has a low

affinity to the whey proteins ALA and BLG. Some of the degraded proteins are also detected with different intensity by the used antibody. With immunochemical staining the differences of the fining agents from one another as well as from the casein standard become more obvious. Most of the fining agents show more detectable protein bands than the casein standard (Figure 3, lane Std).

The demonstrated investigations of the different casein fining agents by LDS-PAGE and immunoblot show the necessity to

dx.doi.org/10.1021/jf5006098 | J. Agric. Food Chem. 2014, 62, 6803−6812

have analytical methods for determination of fining agent residues in wine, which are able to not only detect casein but also take into account the other milk allergens as well as the degraded proteins that are present in the fining agents and show detectable antigenicity as well.

ELISA Method Validation with a Casein Standard and a Casein Fining Agent. Validation of the developed ELISA methods was done in white wine as well as in red wine, although casein is mostly used for white wine, according to Lifrani et al.[17] Four calibration curves of four stock solutions with seven standard concentrations and a blank value were measured on one microtiter plate respectively (intra-assay validation). Every standard concentration for calibration was measured in triplicate on every plate. For testing the repeatability, every calibration was repeated on three different days. Thus, for every standard solution 36 measured data were acquired. Precision profiles according to Ekins[30] with percental normed data were determined for the different ELISAs. Furthermore, wine samples were spiked within the calibration range for measuring the recovery rates. Described validations were done with a casein standard (Merck), as well as a casein fining agent (KalCasin), to investigate the variance of the results depending on the used calibration standard and to get some information about the need for standardized calibration substances. This is particularly important if a threshold is given by law.

Casein has to be declared on a wine label if ≥0.25 mg/L allergenic protein remains in the final product, given by the OIV regulations. Furthermore, the OIV defines thresholds for LOD and LLOQ concerning ELISA methods developed for the analysis of wine. Thus, an accepted ELISA method for wine analysis needs to have a LOD of ≤0.25 mg/L casein or rather potentially allergenic residues of fining agent proteins, as well as a LLOQ of ≤0.5 mg/L casein or rather potentially allergenic residues of fining agent proteins. It is extremely important to have legally defined thresholds for potentially allergenic residues of wine fining agents in the final product to protect allergic consumers as well as to give research establishments, producers, and inspection agencies the possibility to control these potential residues. In this context it is necessary to give clear definitions concerning the potential residues. The threshold given by OIV is referred to "potentially allergenic residues of fining agent proteins in wine". It is problematic when an analytical method, for example, an ELISA, detects only caseins, although the fining agent contains beside caseins other milk proteins or degraded parts of the concerning proteins. This is also a problem for ovalbumin-specific ELISA methods and fining agents derived from hen's egg white.

The aim of this study was to develop methods for risk assessment of allergenic casein wine fining agent residues in wine to protect sensitive consumers. Thus, methods should be developed with as low as possible LOD and LLOQ by using calibration standards already taken in the processing of the wine samples and for production of antibodies.

Indirect ELISA versus Indirect Sandwich ELISA. At first, the indirect ELISA was developed for white wine. In agreement with previous publications[15,16] measuring casein in red wine by an indirect ELISA was unreliable. In unfined red wines, diluted 1/10 as the white wine, false-positive results were determined using the developed assay. Thus, an indirect sandwich ELISA was developed to investigate casein in red wine. Sandwich ELISA methods are supposed to be more specific because of the used capture antibody, which ideally binds only the target protein. Unfortunately, this assay also did not lead to satisfying results for red wine with regard to the LLOQ and recovery rates when used in 1/10 dilutions. Finally, the indirect ELISA could be identified as a reliable method for use when 1/20 diluted red wine was analyzed. However, both assays, indirect ELISA and indirect sandwich ELISA, are applicable for white wine. These investigations show that wine is a complex matrix and not easily handled. Some reasons for this are its low pH and the existence of much higher levels of phenolic compounds in red than in white wine.[15]

Statistical Data of the ELISA Methods. The precision profiles of the different calibrations including the mean calibration curve of all calibrations, respectively, are shown in Figures 4−11. The presented diagrams of the precision profiles show the standardized calibration curve of the three performed calibrations as a black continuous line. The tolerable failure was ascertained at 20% (gray line), and the curve of the precision profile is shown as a black dotted line. For validation LLOQ and ULOQ were determined, giving the measurement range of the ELISA, respectively, defined as intersections of the

precision profile curve with the tolerable failure line. All statistical data of the indirect and sandwich ELISA are mentioned in Tables 2−5.

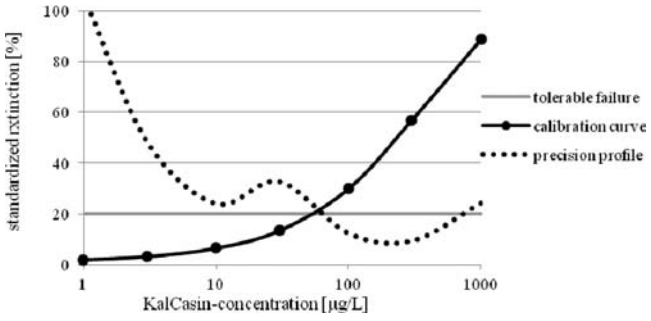

Figure 11. Precision profile of the sandwich ELISA matrix calibration with KalCasin in red wine.

In all developed assays, for white as well as red wine, the LOD of 0.25 mg/L (250 μg/L) accordingly requested by the OIV was reached for the detection of casein and the fining agent. The formerly described heteroskedasticity or the variance of the nonconformance is illustrated in the intra-assay coefficients of variation presented in Tables 2 − 5. The high data were determined for the standard solutions with the lower concentrations. For higher analyte concentration the intra-assay coefficients of variation are usually in the range of 10%. This discrepancy is caused through the sigmoidal curve progression. In the range of very low casein concentrations the curve reaches a plateau (see Figures 4−11). In this section small deviations in measured OD lead to comparatively huge deviations of the determined concentrations.

Accuracy was investigated by spiking the wine with casein and KalCasin at different amounts within the linear area of the calibration range and determining the recovery rates. Calibration curves were prepared with the same substance, which was used for wine spiking, respectively. For indirect ELISA the recovery rates ranged from 59 to 114% (casein) and from 64 to 84% (KalCasin) in white wine. Recovery rates determined with the indirect sandwich ELISA in white wine ranged between 66 and 78% for casein, whereas KalCasin showed no acceptable accuracy with recovery rates lower than 30%.

In red wine the recovery rates were achieved between 63 and 92% (casein) as well as 78 and 91% (KalCasin) for the indirect ELISA, determined in 1/20 diluted wine. In contrast, in 1/10 diluted red wine, for the indirect sandwich ELISA no satisfying recovery rates, <20% (casein) and <10% (KalCasin), could be achieved.

The concentration of casein in spiked wine with an OD significantly different from the blank value is defined as the LOD. For this, an unspiked and equally diluted wine was used for blank value. All presented assays were able to detect casein and KalCasin, respectively, according to the threshold of 250 μg/L allergenic protein, given by the OIV. For all developed ELISA methods the LODs are between 10 and 200 μg/L, usually just below the range of the first standard solution (Tables 2−5). The measurement range defined by the LLOQ and ULOQ can be determined from the precision profile (Figures 4−11). ELISA methods used for analysis of allergens in wine have to be able to quantify the allergen with a LLOQ of $\leq$500 μg/L. Looking at the statistical data, it can be seen that the indirect sandwich ELISA was not able to quantify casein as well as KalCasin in red wine under mentioned conditions with LLOQs around 730 μg/L. In contrast, the indirect ELISA is applicable for 1/20 diluted red wine with LLOQs of 491.20 μg/L (casein) and 414.56 μg/L (KalCasin). With both assays a quantification of casein and KalCasin in white wine is possible.

With the LLOQ of 100 μg/L (indirect) and 10 μg/L (sandwich) quantification of casein are more sensitive than for KalCasin with LLOQs of 146.26 μg/L (indirect) and 254.63 μg/L (sandwich). Qualitative analysis of casein in white wine is more sensitive using the indirect sandwich ELISA with a LOD of 10 μg/L, whereas for KalCasin in the indirect sandwich ELISA and casein as well as KalCasin using the indirect ELISA a LOD of 100 μg/L is achieved. Qualitative red wine analysis is more sensitive using the indirect sandwich ELISA with a LOD of 100 μg/L for casein as well as KalCasin in contrast to the indirect ELISA with a LOD of 200 μg/L for casein as well as for the fining agent. However, as previously mentioned, the recovery rates for red wine analysis are <20% using the sandwich method.

Analysis of Fined Wines. The results of the investigated wines treated with two different processing steps are given in Table 6. The white wines, diluted 1/10, were investigated using

the developed indirect ELISA. The red wines, diluted 1/10, were investigated using the developed indirect sandwich ELISA. The LOD of 100 μg/L of these ELISA methods is lower than the required LOD of 250 μg/L given by OIV.

The determined data show no detectable allergen content after the second processing step (sterilizing filtration) of the red wine as well as in the white wine using the developed ELISA methods. Thus, the value of 0.25 mg/L, given by the OIV, is complied with and labeling of the final wine is not necessary. An allergen content also is not detectable in the first processing step of the red wines. For the first processing step of the white wine, only WW2BI, with 80 g/hL KalCasin fined white wine after the addition of bentonite, shows a detectable amount of allergen between LOD and LLOQ (100 and 146.26 μg/L) using KalCasin for calibration.

This indicates the higher sensitivity using the fining agent in contrast to casein for calibration, because using casein for calibration leads to no detectable residues of the fining agent.

Concluding Remarks. Some formerly published studies fulfill the requirements for ELISA methods detecting potentially allergenic residues of fining agent proteins in wine. Weber et al.[2] developed an indirect ELISA for the detection of total casein and casein-derived fining agents with LOD of 5 μg/L casein, whereas a method for the quantification of caseinates in wine developed by Restani et al.[17] with a LOD of 280 μg/L and a LOQ of 760 μg/L no longer conforms with the criteria established by the OIV, which were given in 2012. In addition to these immunological-based methods many MS-based methods for the detection of residual allergenic wine fining agents were recently published. Matarozzi et al.[23] investigated red wines treated with α-casein, β-casein, and ovalbumin by liquid chromatography−electrospray−tandem mass spectrometry. In this case for caseinate a LOD of 200 μg/L was calculated. In 2013 Monaci et al.[22] published a MS-based multiallergen quantification of fining-related egg and milk proteins in white wines. With this method LODs between 400 and 900 μg/L are achieved for the detection of casein fining agent. A method published by Cereda et al.[33] is described to have a LOD of 1 μg/L casein in white wine, and 3.8 μg/L fining agent in red wine is described by D'Amato et al.[23] Summing up, ELISA as well as MS-based methods are very sensitive and able to detect residual allergenic wine fining agents. For this purpose it is beneficial that ELISA as an immunological-based method considers the antigenicity of the target proteins.

The method validation illustrates again that wine, especially red wine, is a complex matrix. This supports former publications and their results concerning allergen detection in wine.[15,21] Here the validation of a method for a risk assessment consideration in a very low area of concentration (μg/L and not mg/L) demonstrates very impressively these interferences by a complex matrix. Furthermore, it can be seen that results differ according to the standard used for calibration. Having homogeneous standard substances is important for the comparison of results acquired with different assays and in different laboratories. As shown by LDS-PAGE and immunoblot different casein fining agents also contain other milk allergens in different amounts, which might also be a problem for allergic consumers and have to be measured. As food allergy is very individual, people who are allergic to "milk" can be allergic to different milk proteins with variable intensity of allergic reactions.[25,34] Thus, a method that takes into account all milk proteins is necessary to have a reliable method and to implement the legal request for thresholds as discussed previously. Furthermore, possible different processings of the fining agents might result in different affinities of the contained proteins to the used antibody, and consequently this also might yield altered allergenic potency for allergic people. With regard to the described results an underestimation of residual allergenic fining agents in the analyzed final wine is possible if common ELISA methods commercially available are used for the detection of for example casein.

In conclusion, ELISA methods for the sensitive quantification of casein fining agents in white and red wines were developed, also taking into account other possible milk allergens in the

casein fining agents by antibodies developed against a commercial casein fining agent. These methods enable a risk assessment for fining agent residues in casein-fined wines to protect allergic consumers. Within the research project "Reducing the concentration of allergenic fining agents in final wine by technological treatment" (AiF 16330N), the development of technological procedures that reduce the concentration of allergenic substances used in wine treatment was aimed for. For the evaluation of these reductions and the risk assessment of well-defined wines and well-known fining agents used in wine processing these developed highly sensitive ELISA methods were needed.

fluorescence spectroscopy suitable for the study of HSA−keracyanin interaction. Besides, CD technique was utilized to quantitatively evaluate the secondary structure alterations of HSA upon binding to keracyanin chloride.

MATERIALS AND METHODS

Materials. HSA and keracyanin were purchased from Sigma-Aldrich Corp (St. Louis, MO). Mature mulberry fruits were bought from Nanjing, China, freeze-dried, and finally ground to powder. Organic solvents used for ESI-MS/MS and HPLC were chromatographic grade and were bought from Sinopharm Co., Ltd. (Beijing, China). All other chemicals (analytical grade) were bought from Sinopharm Co., Ltd. (Beijing, China). A 0.2 M stock solution of pH = 7.4 phosphate buffer was prepared by mixing NaH_2PO_4 and Na_2HPO_4 in ultrapure water. Ultrapure water was used throughout.

Methods. *Pigment Extraction Condition Screening and Identification.* In order to obtain the optimal extraction liquor, mulberry freeze-dried powder was weighed in the test tubes (0.05 g for each), and 10 mL of extraction solvent was added immediately to each tube. The ten extraction solvents were ethyl acetate, 1-butanol, acetone, alcohol, alcohol solution (70%), alcohol solution (50%), alcohol solution (30%), water, HCl solution (pH = 1), and alcohol (50%)−HCl mixture solution (pH = 3), respectively. The samples were processed using ultrasonic vibration with a water bath for 30 min to ensure a well mixed extraction. Then the supernatant was filtered through the filter paper and was diluted with water to a final volume of 50 mL. The absorbance spectrum of these solutions was recorded in the range of 200 to 800 nm. For extraction efficiency comparison, the method from Lee[13] was used to determinate the total anthocyanin content. We compared the extraction efficiencies of ten extraction solvents and chose the best one to do further analysis. We also weighed the dry residues of the extract using different liquors.

Mulberry freeze-dried powder (2 g) was added to 30 mL of petroleun ether (lipid-removal solvent). Then the mixture was stirred constantly with 60 °C water bath for half an hour. Supernatant was removed after centrifugation at 2000 rpm, and repeated extraction was done 5 times, after which the solvent was evaporated. The sample was then put into the optimal pigment extraction liquor (70% alcohol solution) and was processed using ultrasonic vibration with water bath for 30 min 4 times. All the extracts were transferred to a 300 mL round flask and evaporated by a rotary evaporator (30 rpm, 500 Pa, and 50 °C) to obtain solid substance (the crude mulberry anthocyanin extract). The pigment extract obtained here was utilized for separation and further analysis.

The TBE-300A HSCCC instrument was made by Shanghai Tongtian Co., Ltd. (Shanghai, China). For HSCCC experiment, a solvent system made up of methyl *tert*-butyl ether, 1-butanol, acetonitrile, water, and trifluoroacetic acid (10:30:10:50:0.05; %, v/v) was used. The two phases were separated and prepared for use after mixing of 1000 mL of solvent in a separating funnel. The instrument was then rotated at 850 rpm for equilibration of the solvent. 220 mg of anthocyanin mulberry extract was first dissolved in 5 mL of mobile phase, after which aqueous mobile phase was injected at 1.5 mL/min. The eluates at different time points were detected using a UV−vis detector at 280 nm.

HPLC analysis was performed on a Shimadzu LC-20AT liquid chromatography system (Shimadzu, Tokyo, Japan). The solvent system was composed of phase A (water:acetonitrile:formic acid = 96:3.3:0.55; %, v/v) and phase B (acetonitrile:water:formic acid = 55:44:0.55; %, v/v). Gradient conditions: 0−20 min, 6−20% A in B; 20−30 min, 20−40% A in B; 30−35 min, 40−60% A in B; 35−40 min 60−70% A in B. A reequilibration of 6 min was made afterward. The flow rate was 0.8 mL min^{-1}, and 20 μL aliquots were injected into the column. Diluted extracts were trasferred into the Kinetex PFP 100A column (Phenomenex Inc., Torrance, USA), and anthocyanins were detected at 280 nm. During the chromatography analysis UV−vis absorption spectra were recorded.

Samples separated from HSCCC were prepared for structural identification using a Thermo Fisher LCQ DecaXP MAX mass spectrometer (Thermo Fisher Scientific Inc., Waltham, MA). The MS/MS spectra were obtained using positive mode, and the ESI voltage was set at 5000 V. The sheath, aux, and sweep gas flow rates were adjusted at 9, 5, and 0 arb, respectively. All the spectra were collected within a scan range of 50−1200 m/z.

Spectroscopic Characterization of HSA−Keracyanin Interaction. Fluorescence experiments were carried out on a fluorimeter Hitachi F-4500 (Hitachi, Tokyo, Japan). Quartz cuvettes with a size of 1 × 1 × 4 cm were used in all the experiments. Voltage of the photomultiplier was set at 700 V. Excitation and emission slit widths were both set at 5 nm. All the spectra were recorded under the speed of 1200 nm min^{-1}.

The fluorescence spectra were corrected for the inner filter effects (IFEs) using the following formula:

$$F_{ideal}(\lambda_{ex}, \lambda_{em}) = F_{obs}(\lambda_{ex}, \lambda_{em})CF_p(\lambda_{ex})CF_s(\lambda_{em}) \approx F_{obs}(\lambda_{ex}, \lambda_{em})10^{(A_{em}+A_{ex})/2} \quad (1)$$

where CF_p and CF_s are the correction factors for excitation and emission light at λ_{ex} and λ_{em}, respectively. A_{ex} and A_{em} stand for the absorbance at λ_{ex} and λ_{em}, respectively. F_{obs} represents the observed fluorescence intensity.[14]

In quest of the fluorescence quenching mechanism, the well-known Stern−Volmer formula was applied to analyze and calculate the fluorescence data:

$$F_0/F = 1 + K_q\tau_0[Q] = 1 + K_{SV}[Q] \quad (2)$$

where F_0 and F represent the fluorescence intensities of a protein in the absence and presence of the ligand, and K_q and K_{SV} are the bimolecular quenching rate constant and the Stern−Volmer quenching constant, respectively. τ_0 is the average fluorescence lifetime of the fluorophore in the absence of quencher, and it is 10 ns for biomacromolecules. [Q] is the molar concentration of the quencher (keracyanin).

The binding information on the HSA−keracyanin system is determinated by the following formula:

$$\lg\frac{F_0 - F}{F} = \lg K_A + n \lg [Q] \quad (3)$$

K_A is the binding constant, and n is the average number of binding sites for one HSA molecule.

By utilizing the Van't Hoff equation, we calculated the corresponding thermodynamic parameters:

$$\ln\left(\frac{K_2}{K_1}\right) = \frac{\Delta H^\circ}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \quad (3)$$

where K is the binding constant calculated from the above step, R is the universal gas constant with a value of 8.314 J·mol^{-1}·K^{-1}, ΔH° and ΔS° are the changes in enthalpy and entropy. Gibbs free energy change (ΔG°) associated with the interaction of HSA and keracyanin can be calculated from

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ = -RT \ln K^\circ \quad (4)$$

The energy transfer efficiency E is defined by the following equation:

$$E = 1 - \frac{F}{F_0} = \frac{R_0^6}{R_0^6 + r^6} \quad (4)$$

where R_0 is the Förster critical distance and r is the average distance between the donor and the acceptor. R_0 is usually calculated from the following equation:

$$R_0^6 = 8.8 \times 10^{-25}k^2N^{-4}\Phi J \quad (6)$$

where k^2 is the orientation factor, N is the refractive index, and Φ is the quantum yield of the donor. The spectral overlap integral between the donor fluorescence spectrum and the acceptor absorbance spectrum is represented by J, and it is expressed as

dx.doi.org/10.1021/jf500705s | J. Agric. Food Chem. 2014, 62, 6813−6819

$$J = \frac{\sum F(\lambda)\,\varepsilon(\lambda)\,\lambda^4\,\Delta\lambda}{\sum F(\lambda)\,\Delta\lambda} \quad (7)$$

where $F(\lambda)$ stands for fluorescence intensity of the donor at wavelength λ, and $\varepsilon(\lambda)$ is the molar absorption coefficient of the acceptor at wavelength λ.

For synchronous fluorescence analysis, the spectra were collected by setting the differences of excitation and emission wavelengths at 15 or 60 nm ($\Delta\lambda = \lambda_{ex} - \lambda_{em}$ = 15 or 60 nm). The rest of the experimental conditions are the same with the steady-state fluorescence measurements.

CD measurements were performed on a JASCO-815 CD spectropolarimeter (Jasco Co. Ltd., Tokyo, Japan). CD spectra of 2 × 10^{-7} M HSA with or without pigment were measured between 190 and 260 nm using a 1 × 1 × 4 cm quartz cuvette. All the samples were prepared in pH 7.4 phosphate buffer, and the spectra were recorded at 25 °C. The contents of secondary conformation of the protein were analyzed using online SELCON3 program.

All the absorption spectra in this study were collected using a Shimadzu UV-2450 (Shimadzu, Tokyo, Japan) spectrophotometer equipped with a 1 × 1 × 4 cm quartz cell.

RESULTS AND DISCUSSION

Optimization of the Extraction Liquor. Absorption spectra of the extraction obtained using different solvents are shown in Figure S1 (Supporting Information). There are two typical peaks for anthocyanins, one at around 280 nm (corresponding to its aromatic ring structures) and the other at around 530 nm. The extraction obtained by alcohol solution (70%) tested by the two ways results in the highest weight of solid extract, showing the best yield of anthocyanins (Table S1, Supporting Information).

HSCCC Separation. The mobile phase flow rate and the revolution speed were optimized prior to the separation of anthocyanins. The results indicate that fast flow rate resulted in poor separation, and the chromatogram peaks easily huddled. Besides, when the revolution speed was set in the range of 800−900 rpm, the separation was not apparently influenced. Based on these facts, 1.5 mL/min flow rate and 850 rpm revolution speed were chosen as the experimental conditions. Separation of natural products using HSCCC depends on the suitability of solvent systems to a great extent. Figure 1 shows the HSCCC chromatogram for 220 mg of mulberry crude extract separation with 1000 mL of a solvent system comprising methyl *tert*-butyl ether, 1-butanol, acetonitrile, water, and trifluoroacetic acid (10:30:10:50:0.05; %, v/v) according to the literature. The HSCCC run yields four peaks that correspond to fractions I−IV (27.9%, 25.7%, 41.3%, and 5.1%), respectively. The shaded part of the peaks was obtained and concentrated. This isolation gives more than 95% purity for fractions II−IV based on HPLC analysis.

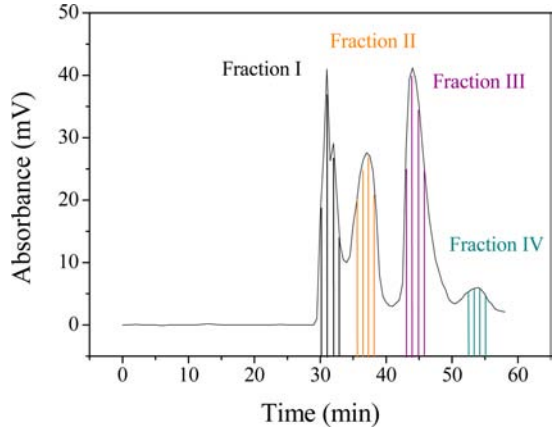

Figure 1. Chromatography of the crude ethanol solution extract of mulberry by preparative HSCCC using solvent system of methyl *tert*-butyl ether, 1-butanol, acetonitrile, water, and trifluoroacetic acid (10:30:10:50:0.05; %, v/v). Stationary phase: upper organic phase. Mobile phase: lower aqueous phase.

Solvent systems with high polarity are necessary for preparative separation of monomeric anthocyanin glycosides using HSCCC. For routine isolation, the aqueous solvent was usually employed as mobile phase, and 0.05% trifluoroacetic acid is required for stabilization of anthocyanins. In this way, the elution was in "head to tail" mode, and stable signals can be detected. Because anthocyanins are generally covalently bound with polymers and polysaccharides, the multiple peaks at the HPLC profile of fraction I are due to these complexes. Fraction I was also subjected to HPLC and represented a complicated mixture of components (Figure S2A, Supporting Information). Similar fractions were acquired from earlier isolation of anthocyanins using HSCCC in "head to tail" mode.[15−17]

Confirmation of Anthocyanin Structure. In order to elucidate the precise structure of the compounds, the fractions from HSCCC analysis were submitted to the ESI-MS/MS. Fraction II produced a molecular ion peak at *m*/*z* 595 (100) and MS^2 fragments with 287 (100) and 449 (37) U. The first fragment coincides with the cyanidin moiety, due to the loss of rutinose (308 U), and the second one at *m*/*z* 449 is due to the loss of the deoxyhexose (146 U) molecular fragment (Figure S3, Supporting Information). Fraction III reveals a molecular ion peak at *m*/*z* 595 (100) and fragment ions at *m*/*z* 287 (100) and 449 (26) U, indicating that it is a cyanidin derivative with similar structure of fraction II (Figure 2). Considering the elution order of the fractions from HSCCC, *m*/*z* values of the fragments, and previously published work,[18−20] fractions II and III should be identified as cyanidin 3-*O*-(6″-*O*-*α*-rhamnopyranosyl-*β*-glucopyranoside) and cyanidin 3-*O*-(6″-*O*-*α*-rhamnopyranosyl-*β*-galactopyranoside), respectively. Fraction IV shows a major molecular ion *m*/*z* 479 (100) confirmed probably as petunidin 3-*O*-*β*-glucopyranoside, however with other unknown ion peaks at *m*/*z* 385 (47), 499 (42), 249 (32) U, etc. as impurities (Figure S4, Supporting Information). HPLC analysis shows two major peaks for this fraction (Figure S2, Supporting Information). Comparisons were made for fractions II and III, both of which show fine purity.

HSA Fluorescence Quenching by Keracyanin and the Interaction Mechanism. HSA possesses three intrinsic fluorophores: Trp, Tyr, and Phe residues. However, most of the intrinsic fluorescence of HSA is contributed by Trp alone, taking up more than 95% of the fluorescence intensity.[21,22] Thus, alterations of HSA fluorescence intensity should be due to the change of Trp residue. Fluorescence measurements give information concerning the intermolecular distance, binding constants, binding sites, and binding mode for small molecule−protein interaction.[23−25] To elucidate the binding mechanism of keracyanin−HSA interaction, steady-state fluorescence spectra of HSA were recorded after addition of different amounts of keracyanin (Figure 3A). By exciting at 295 nm, the strong fluorescence emission band at 340 nm can be detected, which is due to the single Trp residue (No. 214 residue, shown in Figure S5, Supporting Information), which is located in the hydrophobic cavity.[26−28] The addition of keracyanin causes significant decrease in HSA fluorescence intensity, showing that

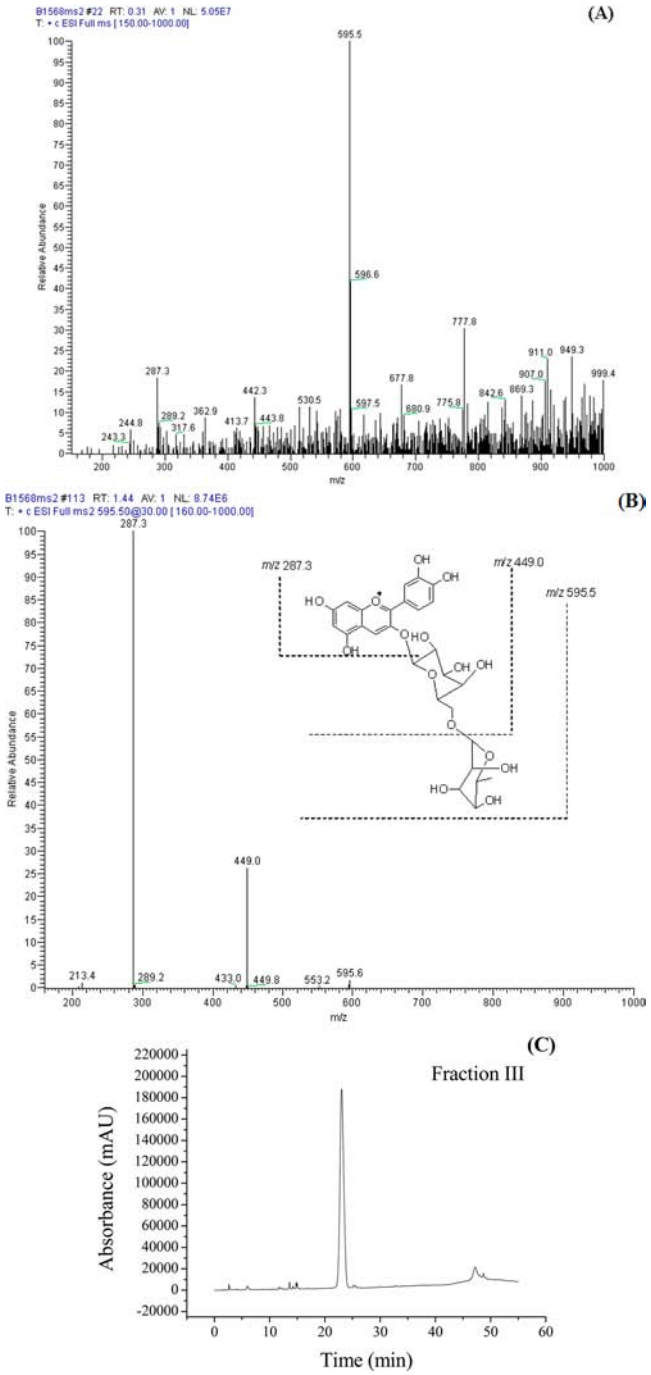

Figure 2. (A) MS and (B) MS/MS spectra of fraction III in mulberry separated from HSCCC. (C) HPLC chromatograms of fraction III separated from HSCCC (UV spectrum).

the intrinsic fluorescence of HSA was quenched upon keracyanin binding. It also implies that the microenvironment of Trp-214 was altered after interacting with keracyanin.

The quenching rate in the studied range shows good linearity after eliminating IFE (Figure 3B). In order to elucidate whether the quenching is dynamic or static, the Stern−Volmer quenching constant K_{SV} and the bimolecular quenching rate constant K_q were calculated. K_q was found to be larger than the maximum diffusion collision rate constant (2.0×10^{10} M^{-1} s^{-1}).[29] Besides, increment of the quenching constants is apparently observed with decreasing temperature, demonstrating that the fluorescence quenching of HSA was attributed to static mode in another way. Hence it can be safely considered that static quenching mechanism is dominant for HSA−keracyanin interaction.

Binding constants of HSA−keracyanin interaction were calculated using the fluorescence intensity at 340 nm. The results at different temperatures are shown in Table 1. Generally speaking, high binding constants for protein ligand interactions are within the range of 10^6−10^8 M^{-1}. The obtained binding constant of the HSA−keracyanin system is 2.49×10^4 M^{-1} at 298 K, which indicates a relatively weak interaction between keracyanin and HSA. The binding number for the interaction is about 1, suggesting that keracyanin binds the protein in 1 to 1 mode at 298 K. As lower (at 10^4 to 10^3 scales) binding constants and fewer binding sites are observed for high temperature, HSA may bind fewer keracyanin molecules at weaker forces at body temperature than room temperature, making keracyanin easier to be released from plasma protein to target organs.

In general, the binding forces between ligands and proteins involve electrostatic forces, H-bonding, van der Waals interaction, and hydrophobic forces. From the viewpoint of Ross,[30] if positive enthalpy change and entropy change implies hydrophobic interaction, then negative enthalpy change and positive entropy change suggests electrostatic force, and negative enthalpy change and entropy change reflects the van der Waals force or H-bonding. ΔS° can be treated as a constant since the temperature did not change too much, and the values of ΔH°, ΔS°, and ΔG° at 293 K, 298 K, and 303 K are listed in Table 1. ΔH° and ΔS° calculated in this work are all negative, suggesting that the dominating force is van der Waals force or hydrogen bonds.

Secondary Structure of HSA on Binding to Keracyanin. CD has been long used for evaluating conformational alterations of protein when binding ligands. The far-UV CD spectrum of HSA in the absence and presence of keracyanin was hence recorded for secondary structural evaluation. HSA was structurally dominated by α-helix, showing two negative peaks at 208 and 222 nm.[31,32] By adding keracyanin to HSA (Figure 4), the negative peaks decrease correspondingly, indicating decreased content of α-helix. However, the peak shape and position do not change with the ellipticity value, demonstrating that HSA managed to retain the overall structure. The decrease in β-sheet (from 7.4% to 6.7% to 5.9%) and α-helix (from 60.4% to 58.3% to 54.7%) contents and increase in random coil (from 23.4 to 24.5 to 25.6) structure are due to partial protein conformational changes in the HSA−keracyanin complexes. Loss of α-helical content also indicates destruction of H-bondings which maintain the special structure of α-helix. Combined with the fact that hydrogen bonds may form in the interaction, it can be concluded that keracyanin first perturbs the hydrogen bonds of HSA and then establishes new ones with the protein.

Energy Transfer from Trp of HSA to Keracyanin. Fluorescence resonance energy transfer (FRET) is a powerful and sensitive method to evaluate the possibility of energy trasfer from Trp residue of HSA to ligands and to estimate the binding distance between them. From Förster's nonradiative energy transfer theory, energy transfer occurs when the distance between the donor and the acceptor is less than 8 nm as calculated, and there is enough overlap area between the receptor's absorption spectrum and the fluorescence emission spectrum of donor.[33]

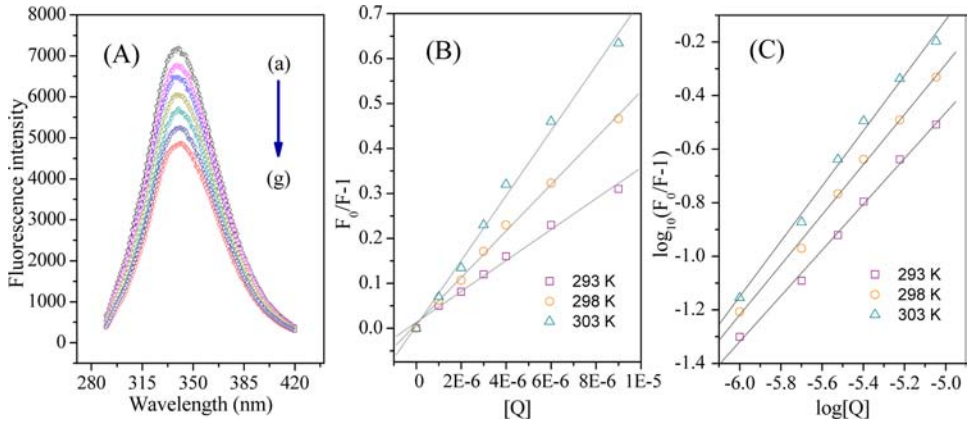

Figure 3. (A) Fluorescence emission spectra of HSA in the presence of keracyanin. C_{HSA}, 1×10^{-6} M; $C_{keracyanin}$ (a–g), 0, 1, 2, 3, 4, 6, and 9×10^{-6} M; pH 7.4, T = 298 K. (B) Stern–Volmer and (C) Hill plots of fluorescence data at different temperatures.

Table 1. Quenching, Binding, and Thermodynamic Parameters for HSA–Keracyanin System

	Stern–Volmer quenching constants			binding params			thermodynamic params		
T (K)	K_q (M^{-1} s^{-1})	K_{SV} (M^{-1})	R	K_A (M^{-1})	n	R	$\Delta G°$ (J·mol^{-1})	$\Delta S°$ (J·mol^{-1}·K^{-1})	$\Delta H°$ (J·mol^{-1})
293	7.23×10^{12}	7.23×10^{4}	0.9960	1.06×10^{5}	1.03	0.9969	-2.82×10^{4}	−621	
298	5.18×10^{12}	5.18×10^{4}	0.9986	2.49×10^{4}	0.936	0.9984	-2.51×10^{4}	−622	-2.10×10^{5}
303	3.44×10^{12}	3.44×10^{4}	0.9968	6.44×10^{3}	0.855	0.9981	-2.21×10^{4}	−621	

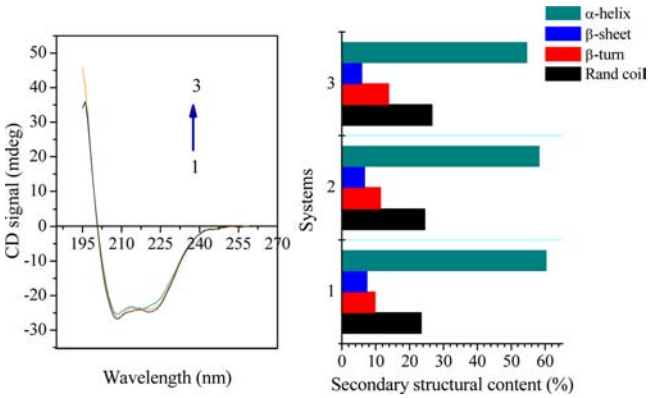

Figure 4. CD spectra of HSA–keracyanin system obtained at room temperature and pH 7.4 with secondary structural content shown. C_{HSA}: 2×10^{-7} M. $C_{keracyanin}$: 0, 5, and 10×10^{-7} M for 1–3.

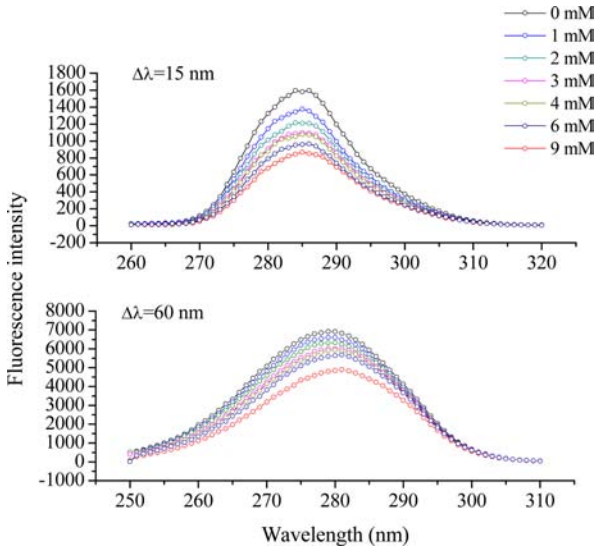

Figure 5. Synchronous fluorescence spectra of HSA in the presence of keracyanin at 298 K when $\Delta\lambda$ = 60 or 15 nm.

It has been reported for HSA that Φ = 0.118, N = 1.336, and k^2 = 2/3,[34,35] and J in eq 6 was the integration of the UV–vis absorption spectrum of keracyanin and the fluorescence emission spectrum of HSA, as shown in Figure S6 (Supporting Information). According to eqs 4–6, the values of J, E, r, and R_0 were calculated to be 2.43×10^{-15} cm^3 M^{-1}, 0.0967, 2.82, and 1.94 nm, respectively. These results show that the value for r is between 2 and 8 nm and is also on the $0.5R_0$–$1.5R_0$ scale, indicating the existence of energy transfer between HSA and keracyanin. Besides, 2.82 nm is near enough for microenvironmental alteration of Trp-214 by keracyanin.

Conformational Changes of HSA by Keracyanin. Characteristic information on the microenvironmental changes in the vicinity of fluorophores was investigated by synchronous fluorescence spectra. When $\Delta\lambda$ is set at 15 nm, the fluorescence spectra give information for Tyr, and 60 nm for Trp.[36] The synchronous fluorescence spectra of the HSA–keracyanin system are shown in Figure 5. While no obvious change is found when $\Delta\lambda$ is set at 15 nm, the emission maxima experienced a red shift from 279 to 281 nm when $\Delta\lambda$ = 60 nm. Thus, it can be concluded that the hydrophilicity around Trp-214 increases compared with that of Tyr. Water molecules are sufficient to perturb the vicinity of Trp-214 with the help of keracyanin binding, making the microenvironment from nonpolar to slightly polar.

The 3D fluorescence spectra for the HSA–keracyanin interaction system are presented in Figure 6 with peak information summarized in Table 2, where we can get the microenvironmental and conformational information on HSA upon keracyanin interaction. As we can seen in Figure 6, peak a results from the Rayleigh scattering of water (λ_{ex} = λ_{em}), whereas the strong peak b mainly reflects the characteristics of chromophores (mainly Trp residue) of HSA, and peak c is related to the polypeptide backbone structure of HSA.[37,38] As

dx.doi.org/10.1021/jf500705s | J. Agric. Food Chem. 2014, 62, 6813–6819

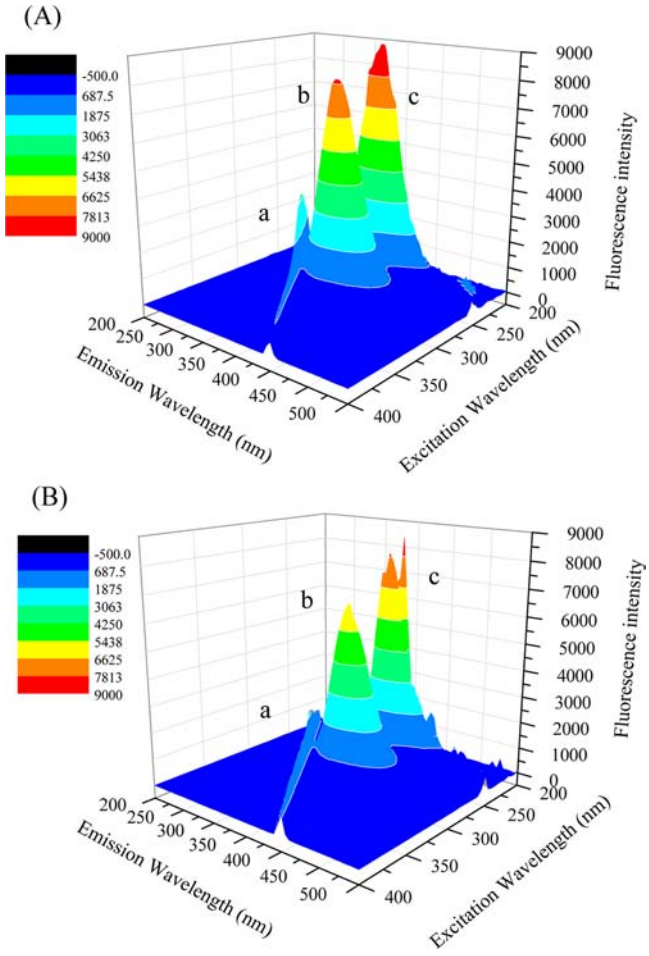

Figure 6. Three-dimensional fluorescence spectra of HSA without (A) and with keracyanin addition (B). C_{HSA}, 2×10^{-6} M; $C_{keracyanin}$, 5×10^{-6} M; pH 7.4, T = 298 K.

shown in Figure 6 and Table 2, with the addition of keracyanin the fluorescence of both peaks b and c is quenched and the fluorescence maximum of peak c red shifts slightly from 337 to 341 nm. These phenomena suggest that keracyanin perturbs the microenvironment of Trp-214 upon interaction with HSA, inducing slight unfolding or adaptive rearrangement of the polypeptide backbone of the protein.

Besides, the 3D structure of HSA is known to be composed of three homologous domains with two subdomains for each. The hydrophobic cavity, where Trp-214 locates, is in the center of the three domains. The binding site of keracyanin might be located in this pocket. The interaction of keracyanin causes changes of polarity of the hydrophobic microenvironment (also proved by synchronous fluorescence study), leading to protein conformational changes.

HSCCC technique makes it possible to separate anthocyanin-rich natural products and yield some pure anthocyanins on a semipreparative scale. Anthocyanins from mulberry most probably include cyanidin 3-*O*-(6″-*O*-*α*-rhamnopyranosyl-*β*-galactopyranoside) (keracyanin), cyanidin 3-*O*-(6″-*O*-*α*-rhamnopyranosyl-*β*-glucopyranoside), and petunidin 3-*O*-*β*-glucopyranoside. Details on the interaction between keracyanin and HSA were revealed using spectroscopy. Intrinsic fluorescence of HSA has been quenched by keracyanin following static mechanism, which is induced by the formation of a certain kind of new complex. The binding of keracyanin to HSA is moderate and equimolar. Thermodynamic parameters indicate that the reaction is spontaneous, with H-bonding and van der Waals forces playing the major role. Synchronous fluorescence spectroscopic results demonstrate that keracyanin gets close to Trp residues whereas the microenvironment around Tyr residues is almost unchanged. We have discovered and interpreted the structural changes of HSA by keracyanin complexation from CD and three-dimensional fluorescence analyses. Energy probably transfers from Trp to keracyanin in the binding process, and the binding distance between the two was estimated to be 2.82 nm at 298 K. The research results are expected to provide useful information for not only natural product separation and identification but the interactions of the carrier proteins with anthocyanin, which will be helpful for the development of food chemistry, clinical medicine, and life sciences.

[a]Letters within a row indicate significant difference using the Bonferroni family error rate $\alpha = 0.05$; if no letters are present, then no significant differences were observed for that compound. [b]RT = retention time in minutes. [c]Q ion = quantifier ion by GC-MS. [d]Measured using direct injection method.

used to study their formation in wine.[13] However, to yield detectable changes using a typical GC-MS system, stable isotope tracers must be added at a concentration of at least >0.5% (and generally higher) of the endogenous concentration,[14] which may be prohibitively expensive and, as mentioned above, create the risk of affecting fermentation physiology. Radioisotopes can be employed at lower concentrations due to their low natural abundance, with labeled compounds typically detected following off-line separation via a scintillation counter. In wine, [^{3}H]-malvidin glucoside has been used as a model to track the fate of anthocyanins before and after fermentation,[15] and [U-^{14}C]-glucose, -leucine, and -isoleucine have been used to follow volatile production in grain mash fermentations.[16] In practice, radioisotopes are rarely used as tracers in food chemistry studies because of associated hazards.

An alternative to conventional tracer experiments with GC-MS is high-precision isotope ratio measurement by gas chromatography combustion isotope ratio mass spectroscopy (GC-C-IRMS). In GC-C-IRMS, organic compounds are combusted to CO_2 following their elution from a GC, and the isotopomers of CO_2 (m/z 44, 45, 46) are measured by IRMS for each peak.[14] GC-C-IRMS has been used for natural abundance studies of wine, primarily for studies on authenticity and adulteration. For example, $^{13}C/^{12}C$ ratios can be used to detect illegal addition of cane sugar (derived from a C4 plant) to grape juice (derived from a C3 plant) prior to fermentation and, in combination with D/H and $^{18}O/^{16}O$ ratios, can serve as geographical fingerprints for wine provenance.[17] The major advantage of GC-C-IRMS for tracer studies is that it can achieve much higher precison than conventional GC-MS; in practice, ^{13}C enrichments as low as ~0.1 atom percent excess (APE) can be utilized for tracer studies.[18] GC-C-IRMS has been used for tracer studies in a number of disciplines where a sizable endogenous pool of a potential precursor exists and large degrees of enrichment are not possible for economic or other practical reasons.[14] For example, GC-C-IRMS has been used to monitor the fate and metabolism of dietary omega-3 fatty acids in animal studies.[19] GC-C-IRMS has also been used in conjunction with $^{13}CO_2$ labeling studies of chamber-grown grapevines to determine the timing of biosynthesis of glycoconjugate precursors,[20] but to our knowledge GC-C-IRMS has not been used for tracer studies of wine fermentations or in related areas of food processing.

In this work, we report the use of GC-C-IRMS as a novel approach to follow the path of a stable isotope tracer during the alcoholic fermentation of hexose. Uniformly labeled [U-^{13}C]-glucose was added to a grape must prior to fermentation at trace levels (0.01, 0.1, and 1 APE), and its contribution to a diverse range of fermentation volatiles (i.e., fusel alcohols, fatty acids, and their associated esters) was assessed. This technique can be used as a more general approach for studying the origin and fate of compounds in food systems while minimizing tracer concentration.

MATERIALS AND METHODS

Fermentations. Fermentations were conducted using Riesling juice sourced from the Cornell research vineyards in Lansing, NY, USA, during the 2010 harvest. Fruit (450 kg) was received by the Cornell Vinification and Brewing Technology Laboratory, where it was crushed, destemmed, basket pressed, and settled overnight at ambient conditions. Approximately 30 L was siphoned into two 20 L Nalgene containers (Thermo Fisher Scientific, Waltham, MA, USA) and frozen at −20 °C. Before use, the juice was thawed in a 40 °C water bath for 1 h and mixed by inversion. Glucose, fructose, and yeast assimilable nitrogen (YAN) were quantified by enzymatic colorimetric methods using a Chemwell 2910 Multianalyzer (Unitech Scientific, Hawaiian Gardens, CA, USA). To supplement the initial juice YAN content of 40 mg N/L, diammonium hydrogen phosphate (674 mg/L) and Fermaid K (Lallemand, Santa Rosa, CA, USA) (250 mg/L) were added to yield a final YAN concentration of 214 mg N/L. Yeast (EC1118, Lallemand) was rehydrated in 40 °C spring water (Crystal Rock, Watertown, CT, USA) with 40 g/L GoFerm (Scott Laboratories, Petaluma, CA, USA), and the juice (5 L) was inoculated at a rate of 0.3 g/L. Aliquots of 541 g (500 mL) of inoculated must were then added to 1 L Pyrex media bottles (Corning Inc., Tewksbury, MA, USA). One treatment served as a control (no [U-^{13}C]-glucose added), and uniformly labeled [U-^{13}C]-glucose (Cambridge Isotope Laboratories, Andover, MA, USA) was added at one of three levels: 1.0 APE (1.0150 g/500 mL), 0.1 APE (0.1015 g/500 mL), or 0.01 APE (0.0102 g/500 mL). Fermentations were carried out in triplicate for each of the four treatments (three tracer levels + one control). The fermenters were topped with a three-piece airlock with a floating bubbler (Buon Vino Manufacturing, Cambridge, ON, Canada). Fermentations were conducted over a 10 day period at ambient temperatures in a dark cabinet and were measured for residual sugar after all fermenters had stopped producing CO_2. At completion, all fermentations had residual sugar (glucose, fructose) values of <0.5 g/L. The wine was stabilized by the addition of 50 mg/L of SO_2 and then frozen and stored at −20 °C until needed for further analysis.

Sample Preparation. Volatile components were extracted from wine using the method described by Ortega and others.[21] To a 15 mL screw-capped borosilicate glass centrifuge tube were added 4.5 g of $(NH_4)_2SO_4$, 3 mL of wine, 7 mL of water, and 0.2 mL of dichloromethane (DCM). For GC-MS quantification 15 μL of a 140 μg/mL solution of 2-octanol was added to the sample as in internal sample; this step was omitted for the GC-C-IRMS analysis. The samples were mixed for 1 h using a carousel rotating at 20 rpm to invert the tubes and then centrifuged at 2500*g* for 10 min. Approximately 1.5 mL of the emulsified bottom layer was recovered with a glass Pasteur pipet, transferred to a 2.2 mL microfuge tube, and centrifuged for 4 min at 14000*g*. Finally, 100 μL of the DCM layer was transferred to an Agilent GC autosampler vial with a 250 μL microvolume insert.

Quantification and Identification of Volatiles by GC-MS. Compounds in the DCM extracts were identified and quantified by gas chromatography−mass spectrometry (GC-MS). An HP 6890 GC with a split/splitless inlet (Agilent Technologies, Palo Alto, CA, USA) and autoinjector was coupled to an Agilent 5795 quadrupole mass selective detector (MSD). A 60 m × 0.32 mm × 0.25 μm Aglient HP-INNOWax column (polyethylene glycol) was used. The GC conditions were as follows: initial head pressure at 8.57 psi with a column flow of 1.6 mL/min in constant flow mode, inlet at 250 °C, 2 μL splitless injection, and total flow through the injector of 84.8 mL/min. The oven parameters were as follows: initial temperature 35 °C (held for 2 min) ramped to 40 °C at 5 °C/min (held 5 for min), ramped to 200 °C at 3 °C/min (held for 5 min), and ramped to 250 °C at 25 °C/min (held for 20 min). The MSD was operated with an ionization energy of 70 eV with the electron multiplier voltage of 1700 V. The MSD was scanned over the mass range of m/z 33−300. Chemstation MSD (Agilent Technologies) was used for data processing. Compound identification was performed by matching retention times and mass spectra of peaks to authentic standards, and peak areas were normalized to that of the 2-octanol internal standard. Calibration curves were generated from the analysis of known concentrations of pure standards spiked into a model wine. Calibration curves for all 26 compounds had an $r^2 > 0.99$. Quantifier ions and retention times for each compound are listed in Table 1.

Due to its coelution with the extraction solvent DCM, ethanol was quantified separately via a direct injection method.[22] Wine was filtered through a 0.25 μm filter and 100 μL diluted with 900 μL of water; 1 μL of this sample was then injected at a 50:1 split into a 250 °C inlet. The oven parameters were as follows: initial 35 °C (held for 2 min) ramped to 40 °C at 5 °C/min (held for 5 min), ramped to 70 °C at 5 °C/min (held for 5 min), and ramped to 250 °C at 25 °C/min (held for 7 min).

Carbon Isotope Ratio Analysis of Wine Volatiles by GC-C-IRMS. The design and operation of the GC-C-IRMS system are described in more detail elsewhere.[23] Briefly, the HP 6890 GC-MS described above was coupled to a Thermo MAT 253 IRMS (Bremen, Germany) via a specially designed combustion interface. The IRMS was tuned for high linearity with the conduction limit open three full turns and operated at a source pressure of 9.3×10^{-7} Torr and an accelerating potential of 9.5 kV. The measured absolute sensitivity was ∼1600 molecules/ion. Data were collected and analyzed using ISODAT 3.0 (Thermo Scientific). The GC column was connected to an online microcombustion reactor via a four-way rotary valve, which permitted solvent diversion to the MSD and sample introduction into IRMS. The microcombustion reactor was constructed from a continuous fused silica capillary (50 cm × 0.53 mm i.d.) hand packed with three 15 cm × 0.1 mm wires (one Cu, one Pt, and one Ni wire) in the center of the capillary. The capillary portion containing the wires was mechanically retained in a 30 cm × 0.8 mm i.d. alumina tube with metal fittings (Valco Instruments, Houston, TX, USA) on both ends. The exposed ends of the capillary were connected to the interface with press-tight fittings. The alumina tube was maintained at 950 °C using a 30 cm Thermcraft tube furnace (Winston-Salem, NC, USA), which had a 15 cm heated zone. Water generated due to combustion was removed from the system using a Nafion water trap (dimensions = 10 cm × 0.8 mm i.d.) immediately following the combustion reactor. The open-split consisted of the 0.6 m × 0.075 mm capillary connected to the IRMS inlet at one end, with the other end directly inserted into the postwater trap transfer line. For analysis of wine volatiles, excluding ethanol, a 60 m × 0.32 mm × 0.25 μm Agilent HP-INNOWax column described above was used. The GC conditions were as follows: initial head pressure at 8.57 psi with a column flow of 1.6 mL/min in constant flow mode, inlet at 250 °C, 2 μL splitless injection, and total flow through the injector of 84.8 mL/min. The oven parameters were as follows: initial 35 °C (held for 2 min) ramped to 40 °C at 5 °C/min (held for 5 min), ramped to 200 °C at 3 °C/min (held for 5 min), and ramped to 250 °C at 25 °C/min (held for 20 min).

Because of ethanol's coelution with the extraction solvent, DCM, it was characterized by GC-C-IRMS separately from the other measured compounds. Sample preparation, injection technique, and GC conditions were the same as described for GC-MS.

ISODAT 3.0 was used to calculate isotope ratios in delta notation; ^{17}O corrections were made using the Santrock and Hayes method.[24] Background was determined using the individual background determination with a 5 s moving linear regression, whereas peak detection was set to a slope of 0.5 mV/s for peak start and 0.4 mV/s for peak end. For calibration, CO_2 gas pulses were admitted directly to the IRMS source from a Conflo III device (Thermo Scientific). CO_2 was supplied by a pressurized tank during each GC-C-IRMS run for isotope ratio standardization, with three 30 s pulses at the beginning and three at the end of each chromatogram. The isotope ratio of the CO_2 standard gas was traceable to the international standard Vienna Pee Dee Belemnite (VPDB) (R_{VPDB} = 0.011180) by running calibration standards containing fatty acid methyl ester (FAME) 17:0 and FAME 21:0 with known isotope ratios determined by off-line dual-inlet IRMS.[25] This FAME standard was run at the beginning and end of each day's runs to determine the "apparent" isotope ratio of the CO_2 gas pulses, which in turn could be used to calculate the isotope ratios of wine components during analytical runs. This calibration

approach addresses fractionation in the GC-C-IRMS system because the FAME standards go through the same path as the wine components (i.e., GC, online combustion, water trap, open split, IRMS).[25] Isotope ratios are reported as $\delta^{13}C_{VPDB}$ in units of "per mil" (‰) and based on the International System of Units (SI), where $\delta^{13}C_{VPDB}$ is defined as

$$\delta^{13}C_{VPDB} = \frac{R_X - R_{VPDB}}{R_{VPDB}} \quad (1)$$

R_X and R_{VPDB} represent the $^{13}C/^{12}C$ isotope ratio of an analyte compound X and the VPDB standard, respectively.

Bulk Analysis of Grape Must Carbon Isotope Ratio by Elemental Analyzer-IRMS (EA-IRMS). A 2 mL aliquot of the frozen Riesling juice (no [U-^{13}C]-glucose added) was submitted to the Cornell Stable Isotope Laboratory (COIL) for EA-IRMS analysis. Five microliters of juice taken from a 2 mL frozen aliquot was used for bulk stable isotope analysis using a continuous flow system.[26] The sample was combusted at 900 °C in a Carlo Erba NC2500 elemental analyzer, and resultant CO_2 was transferred via a Conflo IV interface (Thermo Scientific) to a Delta V isotope ratio mass spectrometer (Thermo Scientific) for carbon isotope analysis. Isotope ratios are reported in delta notation, as described above.

Statistical Analysis. All linear regression analysis and ANOVA calculations were carried out using MiniTab (Minitab, Reading, MA, USA) statistical analysis software.

Isotope Addition and APE Calculations. APE is defined in eq 2

$$APE = 100(F_{HEXe} - F_{HEXn}) \quad (2)$$

where F_{HEXe} is the atom fraction of the enriched hexose and F_{HEXn} is the atom fraction of the native hexose pool. F_{HEXe} is calculated by the amount of [U-^{13}C]-glucose added to the system. The mass balance equation (eq 3) can be rearranged to eq 4, where F_{ULG} is the atom fraction of uniformly labeled glucose and m_{ULG} is the mass.

$$F_{HEXe}m_{HEXe} = F_{ULG}m_{ULG} + F_{HEXn}m_{HEXn} \quad (3)$$

$$F_{HEXe} = \frac{F_{ULG}m_{ULG}}{m_{HEXe}} + \frac{F_{HEXn}m_{HEXn}}{m_{HEXe}} \quad (4)$$

For tracer level additions of [U-^{13}C]-glucose, the atom fraction of uniformly labeled glucose (F_{ULG}) = 1, the mass fraction (m_{HEXn}/m_{HEXe}) will be ~1, and eq 4 simplifies to

$$F_{HEXe} = \frac{m_{ULG}}{m_{HEXe}} + F_{HEXn} \quad (5)$$

Combining eqs 2 and 5 yields eq 6 and provides a good approximation for the APE of the enriched hexose pool (APE_{HEX}) as a function of the amount of [U-^{13}C]-glucose added to the fermentation and the original hexose concentration.

$$APE_{HEX} = 100\left(\frac{m_{ULG}}{m_{HEXe}}\right) \quad (6)$$

Calculating the Percentage of Carbon Derived from Hexose in Volatile Compounds. The observed APE of each volatile (APE_{obsd}) was calculated from experimental data for each volatile in each tracer fermentation, where R_E is the $^{13}C/^{12}C$ ratio in the enriched sample and R_N is the mean $^{13}C/^{12}C$ ratio of the corresponding compound in the natural abundance fermentations:[14]

$$APE_{obsd} = \frac{R_E - R_N}{1 + (R_E - R_N)} \quad (7)$$

To determine the percent of each volatile compound that originated from hexose substrate, (APE_{obsd}) was assumed to be related to the APE of the hexose pool (APE_{hex}) by eq 8.

$$APE_{obsd} = \alpha\ (\%\ \text{from hexose}) \times (APE_{HEX}) \quad (8)$$

APE_{hex} is a factor of the tracer level (eq 6). The apparent fractionation factor, α, can arise from kinetic isotope effects and can potentially vary among compounds. However, in most biochemical processes, α is expected to range from between 0.98 and 1.02, and assuming $\alpha = 1$ will introduce negligible error. Equation 8 can be simplified and rearranged to solve for the percent of carbon in a given volatile derived from hexose sugars (eq 9).

$$\%\ \text{fom hexose} = \frac{APE_{obsd}}{APE_{HEX}} \quad (9)$$

RESULTS AND DISCUSSION

Volatile Composition of Fermentations. A summary of the average concentration of volatile compounds by level of enrichment is given in Table 1. Mean concentrations of each compound were within the range of values reported previously in the analysis of wine samples.[21] Individual ANOVAs were calculated for each of the 28 compounds by level of enrichment. To account for potential type 1 error due to the number of comparisons, the Bonferroni correction was applied using a family error rate of $\alpha = 0.05$. Whereas most compounds did not show significant differences, ethyl lactate, ethyl decanoate, and decanoic acid show significant differences between the control fermentation and the enriched fermentations. These differences may have arisen because the control fermentation was conducted at a different time from the enriched fermentations, rather than as an effect of enrichment treatment. In particular, production of midchain fatty acids such as decanoic acid and their corresponding ethyl esters is known to be affected by variation in oxygen status during fermentation.[27] However, for all other compounds, the lack of difference indicates that labeling does not perturb the system.

Native $^{13}C/^{12}C$ Ratios. Table 2 reports the native isotope ratios of 19 volatile compounds in the experimental Riesling wine, expressed as $\delta^{13}C$ values. Literature reports on compound-specific isotope ratios of wine volatiles other than ethanol are relatively rare,[28] and to our knowledge our work represents the largest number reported to date. Significant

Table 2. $\delta^{13}C$ Values in Natural Abundance Control Fermentations[a]

compound	n	$\delta^{13}C_{VPDB}$ (‰)	SD (‰)	group[b]

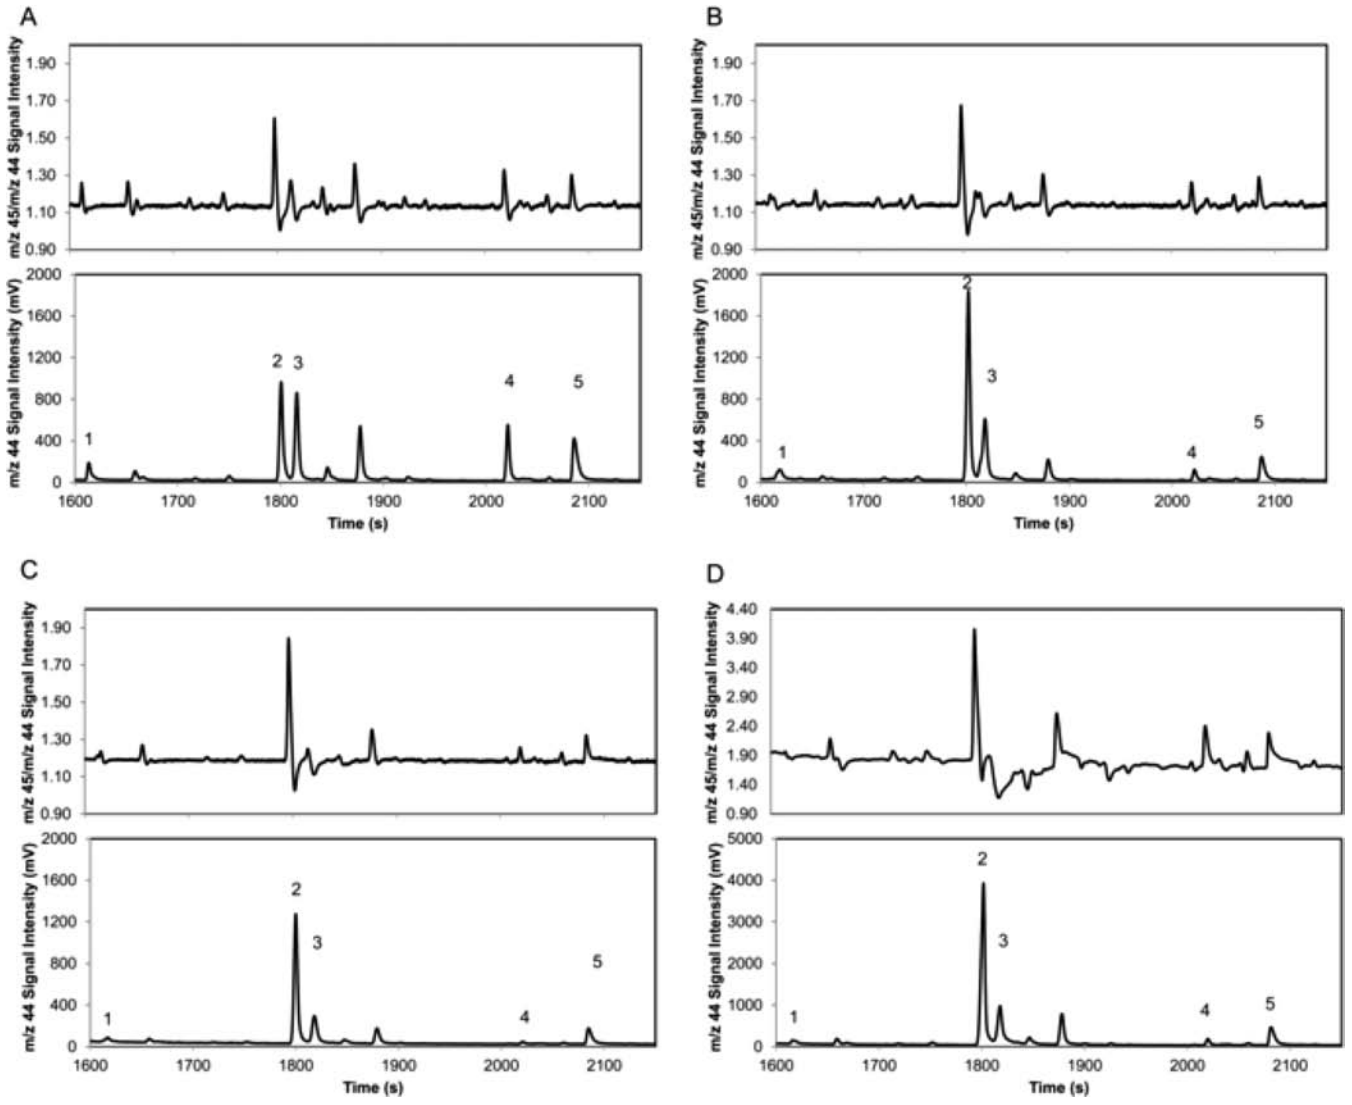

Figure 1. IRMS chromatograms of wine extract at different levels of ^{13}C enrichment: (A) control; (B) 0.01% [U-^{13}C]-glucose; (C) 0.1% [U-^{13}C]-glucose; (D) 1.0% [U-^{13}C]-glucose. The m/z 44 and 45 signals represent CO_2 ions containing ^{12}C and ^{13}C, respectively, from aroma compounds after separation and combustion. The top trace of each chromatogram depicts the 45/44 ratio. Peak identification: 1, hexyl acetate; 2, ethyl lactate; 3, hexanol; 4, ethyl octanoate; 5, acetic acid.

differences were observed in natural abundance isotope ratios among volatile compounds, and $\delta^{13}C$ values ranged from −13 to −35‰. Fewer compounds were characterized by GC-C-IRMS than were quantified by GC-MS because the combustion step of GC-C-IRMS converts all compounds to CO_2; thus, coeluting peaks cannot be resolved as they can be in GC-MS through use of a unique m/z ion to quantify each compound.[14] Precision, calculated as the standard deviation (SD) of $\delta^{13}C$ values (‰) from fermentation replicates, ranged from ±0.1‰ (ethanol) to ±7.5‰ (hexyl acetate), with a mean value of ±1.9‰. This precision is lower than that for benchmark values for high-precision GC-C-IRMS, SD ($\delta^{13}C$) < 0.4‰,[26] because it reflects biological variability among the fermentation replicates rather than analytical variability alone. We observed much better precision, SD ($\delta^{13}C$) < 1.4‰, for analytical replicates of the same fermentation samples. The higher precision observed for ethanol likely reflects the fact that it is the major fermentation product throughout alcoholic fermentation, and, thus, should be less prone to fractionation. Furthermore, the sample preparation did not require extraction. By comparison, many of the other volatiles in Table 2 account for <0.1% of the initial hexose substrate and thus may be more sensitive to changes in conditions among fermentation replicates.

The isotope ratio of ethanol ($\delta^{13}C$ = −27.47‰) was within the range typically observed for wine[29] and was depleted with respect to the isotope ratio for the bulk grape juice ($\delta^{13}C$ = −26.57‰). The depletion of ethanol and concurrent enrichment of CO_2 with respect to the sugar substrate has been previously reported and is believed to occur because ethanol is derived from the C-1, C-2, C-5, and C-6 positions of hexoses, which are depleted with respect to the C-3 and C-4 positions.[30] Several short- and mid-chain fatty acids (acetic, isobutyric, and decanoic) were enriched with respect to ethanol, as has been previously reported.[28] These volatile fatty acids are produced by yeast toward the end of fermentation.[31] Because lighter isotopes of sugars are metabolized preferentially during fermentation,[32] the observed effect may be due to enrichment of the hexose pool by the time the majority of these fatty acids are formed. However, as mentioned under Materials and

dx.doi.org/10.1021/jf500947x | J. Agric. Food Chem. 2014, 62, 6820−6827

Methods, this fractionation effect is small and constant and thus will not compromise results from labeling studies. Most other volatiles, including fusel alcohols, ethyl esters, and several acetate esters, did not differ significantly in isotope ratio from ethanol. The most depleted compound measured was 1-hexanol ($\delta^{13}C = -34.19‰$). As discussed in the next section, this is likely because hexanol is primarily derived from the ^{13}C-depleted grape lipid fraction[29] as opposed to being synthesized by yeast from sugars. Phenylethyl acetate was also significantly depleted with respect to ethanol, although the reason for this was unclear.

Determination of Hexose Contribution to Volatiles through Tracer Experiments. Typical chromatograms obtained at different levels of [U-^{13}C]-glucose enrichment are shown in Figure 1. With increasing enrichment of the hexose pool the m/z 45 trace increased relative to the m/z 44 trace for compounds such as ethyl lactate that derive most of their carbon from sugar. The 45/44 ratio for compounds that are derived primarily from grape compounds other than sugars, such as hexanol, did not change significantly. APE_{obsd} of volatile compounds in each fermentation experiment were calculated using eq 7, and the percent of carbon derived from the hexose pool was calculated by plotting APE_{obsd} versus APE_{hex} (eq 9). Representative plots are shown in Figure 2 for octanoic acid,

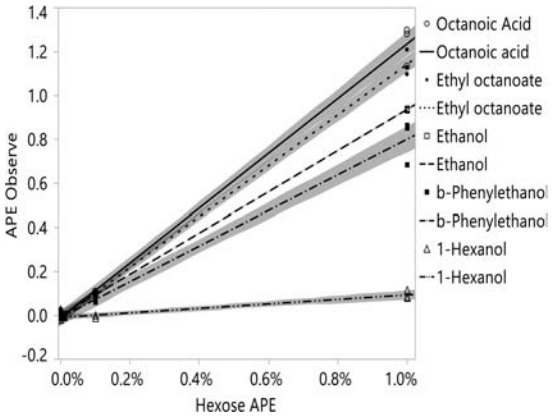

Figure 2. Linear regression of observed APE versus hexose APE. Shaded areas represent the 95% confidence interval.

ethyl octanoate, ethanol, β-phenylethanol, and 1-hexanol, where the slope represents the percent of carbon within a compound derived from the hexose pool. Figure 3 and Supplementary Table 1 in the Supporting Information report the fraction of carbon derived from hexose in each volatile compound. The error associated with measurements of percent hexose in individual compounds follows a similar pattern to what was observed in natural abundance studies.[16] The contribution of the hexose pool to ethanol, which is present in large quantities and represents a major fermentation product, can be determined with high confidence ($94 \pm 0.5\%$), whereas the error associated with low-concentration volatiles such as ethyl 3-hydroxybutyrate increases by an order of magnitude or greater.

The contribution of hexoses to ethanol (94%) was somewhat surprising, as it indicated that a small amount of non-hexose substrate contributed to ethanol formation. Excluding the possibility of impure standards or experimental error, one likely explanation is that fermentable sugars other than hexoses contributed to ethanol. In particular, sucrose is reported to be

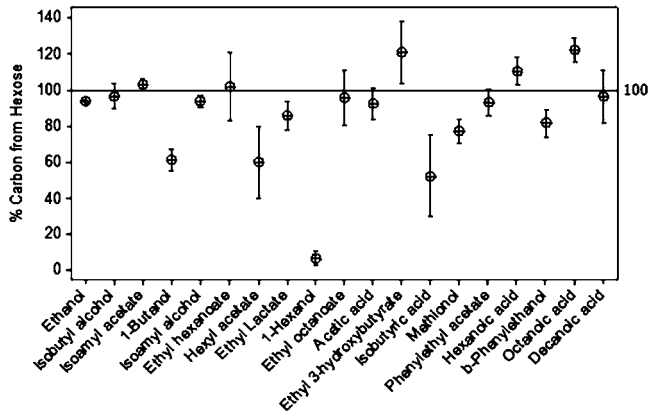

Figure 3. Contribution of hexose-derived carbon to each compound. The mean is indicated by the circles, and the error bars represent the 95% confidence interval.

present in musts at concentrations of 2−10 g/kg,[33] or up to 5% of the hexose concentration in our work. Unfortunately, sucrose was not measured, and it was not possible to evaluate this hypothesis.

Like ethanol, nearly all wine volatiles measured in our studies were derived primarily from hexoses (Figure 3 and Supporting Information Supplementary Table 1). Notably, fusel alcohols associated with amino acid metabolism (e.g., methionol, β-phenylethanol, isoamyl alcohol, isobutyl alcohol) were >75% hexose derived. The acetate esters (isoamyl acetate, phenylethyl acetate) are formed by acetylation of fusel alcohols and were also derived primarily from hexoses. This indicates that the major contributor to these fusel alcohols is the anabolic pathway, in which carbon skeletons are synthesized de novo from hexoses,[7] as opposed to catabolism of amino acids via the Ehrlich pathway.[8] A third potential source for β-phenylethanol is from juice in either a free or glycosylated form, although, based on data from a previous study, this could account for only 3% of the total β-phenylethanol observed.[34] To our knowledge, this is the first time that the relative contributions of different pathways to fusel alcohols in a wine fermentation have been evaluated. Whereas the values observed here are likely dependent on fermentation conditions such as yeast strain, our observation that the anabolic pathway is dominant is consistent with the amounts of fusel alcohols produced and the typical concentrations of amino acids in must available for Ehrlich degradation. For example, we observed ca. 100 mg/L of isoamyl alcohol in wine, whereas typical leucine concentrations in juice are reported to be <25 mg/L.[35] Although glucose labeling studies have not, to our knowledge, been previously performed on wine fermentations, [U-^{14}C]-glucose has been used to track production of fusel alcohols in grain mash fermentations.[16] In the earlier work, 25−45% of fusel alcohols were derived from glucose (no replicates), substantially less than in our current study. The discrepancy may be because the mash fermentation was performed at lower gravity, which would have decreased the relative importance of the anabolic pathway once amino acid sources were exhausted.

The high contribution (>90%) of the hexose pool to straight-chain fatty acids (hexanoic, octanoic, and decanoic) and their corresponding ethyl esters (ethyl hexanoate and ethyl octanoate) was as expected; these compounds are known to be produced by yeast fatty acid metabolism and, in the case of ethyl esters, through subsequent esterification with ethanol.[7]

Interestingly, two of the fatty acids (octanoic and hexanoic) and ethyl 3-hydroxybutyrate had apparent hexose contributions slightly but significantly greater than 100% (103−121%). Because these semipolar compounds demonstrated slight tailing and because GC-C-IRMS peak tails are ^{13}C depleted, hexose contributions of more than 100% may be an analytical artifact. Unlike the straight-chain fatty acids, only about half of the branched-chain isobutyric acid was derived from the hexose pool (Supporting Information Supplementary Table 1). Branched-chain fatty acids have been shown to decrease with supplementation of must with ammonia salts,[36] suggesting that they may arise from catabolism of amino acids.[37] This result may indicate that a significant portion of isobutyric acid arises from valine catabolism with the fermentation conditions employed.

Only one compound, 1-hexanol, was derived primarily from non-hexose sources. Although hexanol is generally present at concentrations of ≥1 mg/L in wine, alcoholic fermentation of juice-like media in the absence of non-sugar-grape derived compounds results in no detectable hexanol.[6] Hexanol is detectable in grape must and can also be produced during fermentation by the reduction of C_6 aldehydes and unsaturated C_6 alcohols.[38] These C_6 compounds are largely derived from enzymatic oxidation of unsaturated fatty acids during grape crushing.[39] Unsaturated fatty acids, along with other lipids, are known to be ^{13}C-depleted in plants,[40] a result which correlates with our previous observation that native hexanol is depleted as compared to other wine volatiles (Table 2). Hexyl acetate, formed by enzymatic esterification of hexanol,[41] is enriched to the level predicted by the mass balance of acetic acid and hexanol (Table 2).

Recommended Enrichment Levels for GC-C-IRMS Studies of Fermentations. The precision of GC-C-IRMS depends not only on the precision of the analytical instrumentation but also on the concentration of the compound of interest, the ^{13}C enrichment level, and the degree of biological variability. The fermentations were enriched with 0.01, 0.1, and 1.0% [U-^{13}C]-glucose, corresponding to roughly +11, +110, and +1100‰ maximal possible enrichments in volatiles, respectively. The average SD values for the three enrichment treatments were 1.7, 6.4, and 53.4‰ across increasing enrichment treatments. Defining the limit of detection as 3 times the noise, the smallest contribution of hexose to a volatile compound would be APE_{obsd} = 46, 17, and 15 for the 0.01, 0.1, and 1.0 APE treatments, although this will vary among compounds. Because of the marginal improvements associated with using 1.0 APE and the high costs of [U-^{13}C]-glucose, using 0.1 APE provides the best balance of cost and variability. For 500 mL fermentations containing 100 g of hexose per 500 mL of must, generating 0.1 APE requires 0.1 g of [U-^{13}C]-glucose, or $15 per fermentation at current prices of $150 per gram of [U-$^{13}C$]-glucose. Lower tracer levels may be possible, but will require limiting variability across replicates.

In conclusion, this study is the first evaluation of a method utilizing GC-C-IRMS to trace the origin of volatile compounds during the fermentation of grape juice into wine by enriching the hexose pool with ^{13}C. Under the conditions studied, the majority of fermentation volatiles studied, including most esters, fatty acids, and alcohols, derive at least 50% of their carbon from hexoses. Hexanol was the only compound observed to be majority (>90%) derived from grape compounds other than sugars. Using 0.1 APE of [U-^{13}C]-glucose provides the optimal balance between precision and cost. In future studies, the effects of varying physiological conditions, such as temperature, soluble solids concentration, and nutrient status, on the relative importance of different pathways could be quantified by this approach, assuming adequate analytical performance. This method could also be applied to other complex food systems, such as Maillard reactions, to clarify the contributions of different pathways while minimizing costs.

the oven. The resultant extracts (about 30 mL) were collected into glass vials. All aqueous SWE extracts were dried with the aid of a freeze-dryer for 24 h (Ilshin, Gyeonggi-do, Korea). The solid content of the SWE extracts was typically 0.3−0.4 g/g GTL. The pressure was maintained at around 10 MPa during SWE. The extraction time and temperature conditions were varied in separate experiments using only purified water as follows: extraction temperatures of 110, 130, 150, 170, and 190 °C and extraction times of 5, 10, and 15 min. A factorial design therefore produced 15 conditions for GTL. The temperature and time conditions giving the maximum extraction efficiency were selected as optimum conditions for several plants.

For the conventional extractions, 98% ethanol (Samchun Pure Chemicals, Seoul, Korea) and 99.8% methanol (Duksan Pure Chemicals, Ansan, Korea) were used at 60 °C for 2 h with 22 mL of solvent and 1 g of GTL in the water bath (C-WB1, Changshin Scientific, Seoul, Korea).

High-Performance Liquid Chromatography. The extracts were simply pretreated and then qualitatively and quantitatively analyzed by high-performance liquid chromatography (HPLC; 1260 series, Agilent Technologies, Waldbronn, Germany) with a Zorbax C18 column (4.6 mm × 150 mm, 5 μm pore size; Agilent Technologies), using a modified version of the method described by Choung and Lee.[13] For analysis of the six kinds of flavanols studied herein, the samples were pretreated with 0.1 g of freeze-dried extract with 20 mL of a purified water/ethanol (Duksan Pure Chemicals)/phosphoric acid (Samchun Pure Chemicals, Pyeongtaek, Korea) solution (48:50:2, v/v). The samples were then mixed well in a vortex mixer for 10 min prior to HPLC analysis. The HPLC mobile phase used for analysis comprised 0.1% phosphoric acid in water (solvent A) and methanol (solvent B) at a flow rate of 1.0 mL/min, with an initial A:B ratio of 80:20%. The proportion of solvent A was subsequently changed as follows: to 75% for 25 min, then to 65% for 25 min, and finally to 75% for 10 min in the analysis. Ten-microliter aliquots were injected into the HPLC system, and detection was performed at 280 nm. The resulting extracts were filtered through a 0.45 μm polyvinylidene filter (Whatman) and then analyzed by HPLC.

Data Analysis. The extraction yield (expressed in units of mg/g dried plant material) was calculated from the calibration curves of the standard flavanols. All peak chromatograms of the extracts were identified qualitatively by spiking experiments. The optimum SWE

conditions, in terms of the extraction temperature and extraction time, for GTL were chosen on the basis of the highest flavanol contents.

RESULTS AND DISCUSSION

HPLC Analysis for Flavanols from GTL. The obtained extracts were analyzed qualitatively and quantitatively by HPLC. The calibration indicated a highly linear regression of the peak areas versus concentrations of each standard (R^2 value of 1 for EC, ECG, EGCG, Ct, and CG, and of 0.998 for GCG). Figure 1 shows the chromatograms of the six different flavanol extracts from GTL.

Optimization of SWE Conditions for Extraction of the Six Flavanols. SWE was performed at temperatures between 110 and 190 °C and for processing times of 5−15 min to

dx.doi.org/10.1021/jf5012006 | J. Agric. Food Chem. 2014, 62, 6828−6833

determine the optimum temperature and time for the extraction of the precursor epicatechins (EC, ECG, and EGCG) and the epicatehin epimers (Ct, CG, and GCG) from GTL. The results obtained for the flavanols are presented in Figure 2. The SWE yields of the epicatechins were clearly time-dependent, being unstable at extraction times >5 min, whereas those of the epimers were both time- and temperature-dependent. The optimum SWE temperature/time conditions for EC, ECG, EGCG, Ct, CG, and GCG were 110 °C/5 min, 150 °C/5 min, 150 °C/5 min, 130 °C/15 min, 170 °C/10 min, and 130 °C/15 min, respectively. The extraction of total flavanols was notably degraded at temperatures >150 °C. These results are analogous to those of Yang and Hildebrand,[14] who found that temperatures >190 °C resulted in degradation, oxidation, and odorous extracts of flavonoids such as flavanols.

The efficiency of flavanol extraction depends upon factors such as the type of solvent, extraction temperature, extraction time, ratio of solvent to solute, and sample particle size. In the present study, the effects of SWE temperature and processing time on flavonol yields from GTL were investigated. The major flavanols extracted from GTL were EGCG and GCG. As shown in Figure 2, the concentration of EGCG extracted decreased dramatically for longer extraction times. The SWE yield of the other epicatechins, EC and ECG, was also time-dependent. However, the concentration of GCG first increased and then decreased with a 15 min extraction time. The SWE yields of the epimers Ct and CG were dependent upon both processing temperature and time. These results are similar to those of Vuong et al.,[15] who found that the epicatechin structure was more unstable than the epimer structure at temperatures >80 °C.

Effect of Epimerization of Flavanols on Subcritical Water. The epicatechins (EC, ECG, and EGCG) and epimers (Ct, CG, and GCG) can in part be converted back to their isomers via a process of epimerization. An epimerization change is likely to occur in a high-temperature environment, such as when using SWE, because heating results in the conversions of EGCG to GCG, ECG to CG, and EC to Ct.[16−18]

Table 2 lists the effects of extraction time and temperature on the epimerization of flavanols in subcritical water. The proportion of flavanol was calculated as follows:

$$\text{proportion of flavanol (\%)} = \text{compound concentration}/(\text{compound concentration} + \text{their isomer concentration}) \times 100$$

The conversion of flavanols to their isomers is reversible, but flavanols are usually only epimerized from ECs (2*R*,3*R*) to epimers (2*S*,3*R*) under high-temperature and high-pressure conditions with a long extraction time. As indicated by the results in Table 2, epimerization was accelerated over a long extraction time, thus reducing the proportions of ECs but gradually increasing those of epimers. In addition, ECs were epimerized more rapidly at higher extraction temperatures, thus again reducing the proportions of ECs and increasing those of epimers. However, at temperatures >170 °C there was very little epimerization, so that any remaining flavanols were destroyed.

Figure 3 shows a typical phase diagram for the SWE of flavanol at different temperatures (110−190 °C). The extraction of flavanols can be divided into three phases (I, II, and III) on the basis of the predominating effect of extraction efficiency, epimerization, and destruction. In phase I there was a significant increase in epimer extraction efficiency by 150 °C. Furthermore,

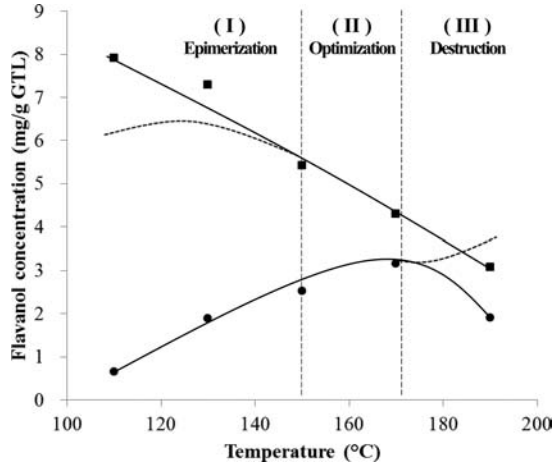

Figure 3. Typical phase diagram of ECs (■) and epimers (●) during SWE (solid line). The flavanol yield during a 5 min extraction time at various temperatures is shown (dotted-dashed line).

a few ECs were converted to epimers; in particular, the extraction efficiency of ECs for a short extraction time of 5 min (dotted-dashed line of phase I) was increased because the optimum extraction conditions had been reached and then subsequently decreased due to epimerization. In phase II there was an increase in the extraction efficiency of epimers continued to 170 °C, whereas that of ECs decreased. This means that most ECs were converted to epimers and the optimization of temperature for extracting epimers was attained, leading to some destruction at high temperature. In phase III, at extremely high temperatures the unstable flavanols, including both ECs and epimers, were destroyed. This is likely to have resulted in negligible epimerization of flavanols, with the exception of epimers at an extraction time of 5 min (dotted-dashed line of phase III), in which there was increased extraction due to epimerization of ECs. Therefore, extracting flavanols based on chemical structure is adequate for epimer structures such as Ct, CG, and GCG due to the epimerization of flavanols at high temperatures in subcritical water.

Comparison of Extraction Yields of Flavanols among Extraction Solvents. The adequacy of SWE relative to conventional extraction methods (using ethanol and methanol as solvents with extraction conditions of 60 °C and 2 h) was evaluated. As indicated in Figure 4, the maximum total yield of the six flavanols studied was 71.36 ± 4.23 mg/g GTL (mean ± SD) under extraction temperature/time conditions of 150 °C/5 min. The efficiency of SWE was slightly higher than that obtained using conventional extraction with either methanol (yield = 70.87 ± 0.57 mg/g GTL) or ethanol (yield = 60.43 ± 1.14 mg/g GTL).

The data presented in Figure 4 indicate that SWE is more effective at extracting epimers than epicatechins, which is due to the relatively high extraction temperature. The efficiency of SWE (yield = 21.69 ± 1.41 mg/g GTL) for epimers including Ct, CG, and GCG was higher than that of the conventional extraction solvents such as methanol (yield = 7.68 ± 0.09 mg/g GTL) and ethanol (yield = 6.98 ± 0.01 mg/g GTL). Therefore, the concentration of epimers greatly influences the efficiency of the total flavanols yield for optimize extraction conditions. GCG is an epimer of EGCG; an epimerization change is likely to occur in a high-temperature environment such as when using SWE, because heating results in the conversion of EGCG to GCG.[4] In the case of using organic solvents, small reductions were

dx.doi.org/10.1021/jf5012006 | J. Agric. Food Chem. 2014, 62, 6828−6833

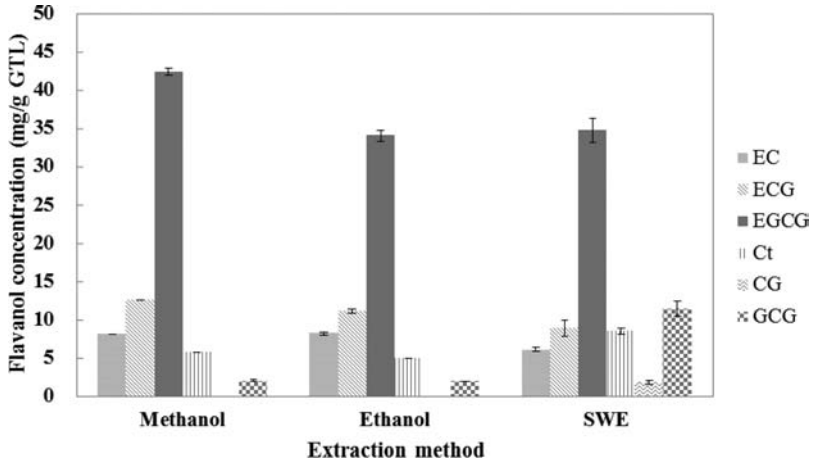

Figure 4. Comparison of yields of EC, ECG, EGCG, Ct, CG, and GCG obtained using conventional methanol and ethanol extraction methods (under temperature/time conditions of 60 °C/2 h) and SWE method (under temperature/time conditions of 150 °C/5 min). All experiments were conducted in triplicate. Data are the mean and SD values.

observed in the yield of unstable EGCG with long extraction times. The epimers Ct, CG, and GCG were poorly extracted with both methanol and ethanol. Because gallocatechin (GC) and epigallocatechin (EGC), which are known secondary major flavonols in green tea leaves, were very unstable at high operating temperatures (110−190 °C), the extraction yields by the SWE were not reproducible and those two compounds were excluded from consideration in this study. Wang and Helliwell[19] also reported that GC and EGC were taking place in other reactions such as oxidation or degradation for a given set of SWE conditions. Zhu et al.[20] and Yoshida et al.[5] demonstrated that flavanols in alkaline solutions were extremely unstable and degraded almost completely, whereas in acidic solutions they were stable. Although high extraction yields of other epicatechins could be obtained in SWE due to the relatively acidic character of subcritical water, GC and EGC were easily degraded at high temperature and the extraction yields of those two compounds did not influence the efficiency of the total flavanols yield.

Moreover, SWE has some excellent advantages: it is ecofriendly and nontoxic (using only purified water) and requires a shorter extraction time than conventional solvent-based methods, which make it an efficient recovery method.

Adequacy of Flavanol Extraction Based on Chemical Structure. The extraction of flavanols was affected by differences in physicochemical characteristics of the compounds, including their melting points and molecular weights. Flavanols have a lower melting point (at around 200 °C) than flavonoids.[16] Thus, EGCG, with the lowest melting point, has been considered too unstable to allow extraction.[21]

Flavanols including the gallates have large molecular weights and a stable structure. In addition, like gallate, gallic acid is soluble in alcohol, ether, acetone, and water (at 1.5 g/100 mL and 20 °C). Therefore, gallate catechins such as CG, GCG, ECG, and EGCG were extracted using subcritical water at higher optimum temperatures (i.e., >150 °C), indicating a relatively low dielectric constant.

The solubility in subcritical water is quantified by the solvent conditions and is influenced by the solute.[9] The polarity of the subcritical water solvent is determined by the dielectric constant (ε), which is lowered by increasing the temperature; less polar compounds can thus be extracted by subcritical water acting as an organic polar solvent.[22] Flavanols dissolve well in organic solvents such as ethanol;[23] however, flavanols with no oxygen molecule at position 4 were not adequate solutes at temperatures >170 °C in SWE. This finding is similar to that obtained with anthrone, whereby the presence of oxygen increases the solubility by 10 times over that of anthracene at SWE temperatures between 150 and 160 °C.[9] These results confirm that flavonols and flavanones that have an oxygen molecule at position 4 are more favorably extracted at higher temperatures than are flavanol catechins in SWE.[12] The yield of total flavanols from GTL was maximal under extraction temperature/time conditions of 150 °C/5 min. Pineiro et al.[24] also reported that the extraction of catechins and epicatechins from grape seeds was optimum under SWE conditions of 130 °C/10 min.

In addition, the chemical compositions and flavanols concentration of the extract obtained by SWE were compared with the initial composition of the original material. The proximate analysis including carbohydrates, protein, lipids, ash, fiber, catechins, and caffeine contents is presented in Table 3. These results indicate that approximately 86.26% of flavanols was recovered from the original GTL material. Especially, epicatechin epimers (Ct, CG, and GCG) of approximately 95.43% were extracted by using the SWE method from the initial GTL.

Table 3. Chemical Composition of the GTL Used in This Study and the Extracts Yielded by SWE[a]

component	/g GTL	/g freeze-dried SWE extracts
total carbohydrate (%)	36.67 ± 0.76	33.72 ± 2.23
crude protein (%)	15.03 ± 0.82	24.18 ± 0.52
crude lipids (%)	1.54 ± 0.14	1.54 ± 0.35
crude ash (%)	5.82 ± 0.07	17.59 ± 0.15
crude fiber (%)	35.93 ± 0.25	17.97 ± 2.22
EC (mg)	7.16 ± 0.21	6.05 ± 0.02
ECG (mg)	9.93 ± 0.37	8.89 ± 0.85
EGCG (mg)	42.90 ± 3.67	34.74 ± 3.52

caffeine (mg)	24.23 ± 0.55	12.36 ± 0.56

[a]SWE was operated under optimum extraction temperature/time conditions of 150 °C/5 min. Data are the mean ± SD values of at least three measurements.

dx.doi.org/10.1021/jf5012006 | J. Agric. Food Chem. 2014, 62, 6828−6833

The ecofriendly SWE of flavanols is affected by both the subcritical-water solvent and the structure of the compounds. Flavanols lacking an oxygen molecule at position 4 are not adequate solutes at temperatures above 170 °C in SWE. However, the SWE was found to be slightly more efficient than extraction with two conventional solvents. SWE of the epicatechins EC, EGCG, and ECG was time-dependent, and SWE of the epimer catechins Ct, GCG, and CG was both temperature- and time-dependent. In addition, SWE appears to be a more effective solvent for extracting epimers compared to the precursor epicatechins. Thus, SWE appears to be an environmentally friendly, nontoxic, efficient, and selective extraction method that requires shorter extraction times than its conventional organic-solvent counterpart. SWE could have practical applications in the effective extraction of antioxidant polyphenolic compounds from various types of plant. Furthermore, this method can be easily implemented on an industrial scale.

mixtures of proteins and a biosurfactant *Quillaja* Bark Saponin at the air−water and oil−water interfaces have also been described in detail by Wojciechowski and co-workers.[22−24]

Recently, we reported that natural sweetener stevioside (STE), the most abundant component of steviol glycosides, exhibited a notable surface activity and could also be developed into a new type of biosurfactant.[25] The emulsions prepared by the mixtures of soy protein isolate (SPI) and STE showed a remarkable physical stability with small oil droplet size of ∼220 nm.[25] STE is a diterpene ent-kaurene glycoside, which consists of a hydrophobic headgroup, called diterpenoid or steviol backbone, with hydrophilic glucosyl and sophorosyl residues. The amphiphilic structure of STE molecules is similar to that of triterpenoid saponins, thus determining their potential capability as biosurfactants. Moreover, STE also exhibits many nontrivial biological activities, such as antitumor progression and antihyperglycemic and immunomodulatory effects.[26] In another recent work,[27] we further found that the soy protein−STE mixtures displayed interesting competition adsorption behavior by their mutual interactions at the interface, which were positively reflected in the corresponding emulsions with the long-term stability. All these present works to a large extent support the capability of STE as a new biosurfactant and further research on the mixed protein−STE systems due to their potential practical applications as foam/emulsion formulations.

Considering the fact that the behavior of adsorbed layers at the air−water interface obviously differs from that at the oil−water interface due to their different degrees of polarity and hydrophobicity,[3,5,12] which can strongly influence the properties of respective foams and emulsions, it is therefore of interest to further study the adsorption of soy protein−STE mixtures at the air−water interface and their relation to the corresponding foaming characteristics. Moreover, to the best of our knowledge, no report about the interactions between protein and STE in the bulk and at the air−water interface has been found to date. Thus, in this work, we focus on the adsorption of soy protein−STE mixtures at the air−water interface by using a combination of dynamic surface tension and dilational rheological studies. The soy glycinin (11S), the major and pure globulin of soybeans, is employed in this study because of its structural and functional properties extensively studied. The bulk 11S−STE interactions are first investigated by fluorescence spectroscopy and isothermal titration calorimetry (ITC) measurements to helpfully understand surface behavior of the mixtures. Subsequently, the foamability and foam stability in mixed 11S−STE systems are determined, and a possible stabilization mechanism is finally proposed to clarify the correlation between surface behavior and the actual foaming properties.

MATERIALS AND METHODS

Materials. STE (purity >95%) was purchased from Jining Aoxing Stevia Products Co., Ltd., China. Pyrene was purchased from Sigma-Aldrich (St. Louis, MO). Defatted soy flour was provided by Shandong Yuwang Industrial and Commercial Co., Ltd., China. The protein content of soy flour was 55.10% (determined by micro-Kjeldahl method, $N \times 6.25$, dry basis). 11S globulin was prepared as described by Yuan et al.[28] Protein content of 11S globulin was 96.29%, determined by Dumas method ($N \times 6.25$) in a Rapid N Cube (Elementar France, Villeurbanne, France). All other chemicals used were of analytical grade.

Sample Preparation. All samples were prepared in 10 mM phosphate buffer solution (pH 7.0) using ultrapure water (18.2 MΩ·cm) at room temperature (25 °C). The absence of surface active contaminants in the phosphate buffer was checked by surface tension measurements before sample preparation. No aqueous solutions with a surface tension other than that accepted in the literature (72−73 mN/m at 25 °C) were used. The 11S globulin solution was prepared by dispersing the freeze-dried protein in 10 mM phosphate buffer (pH 7.0) for 2 h under mild magnetic stirring and then was left overnight at 4 °C to allow complete hydration. All measurements were made at constant 11S concentration (0.1 wt %) and varying STE concentration (0−2 wt %) at pH 7.0. The mixed 11S−STE systems were obtained by mixing the appropriate volume of each double concentrated 11S and STE solutions up to the required concentration and stirring for a further 30 min before any measurements.

Fluorescence Spectroscopy Measurements. To investigate the effect of STE addition on the intrinsic fluorescence of 11S, fluorescence spectra of solutions containing a fixed 11S concentration (1 mg/mL) and different STE concentrations in 10 mM phosphate buffer (pH 7.0) were recorded using an F7000 fluorescence spectrophotometer (Hitachi Co., Japan) at 25 °C. The excitation wavelength was set at 295 nm, and the emission spectra were collected from 310 to 500 nm. Both the excitation and emission slit widths were set at 5 nm. The reference sample consisting of the phosphate buffer and STE was checked for fluorescence signals. The data on the tryptophan (Trp) fluorescence quenching were analyzed according to the Stern−Volmer equation (eq 1):

$$F_0/F = 1 + k_q\tau_0[Q] = 1 + K_{SV}[Q]$$

In this equation F_0 and F are the fluorescence intensities in the absence and presence of a quencher, respectively, $[Q]$ is the quencher concentration, K_{SV} is the Stern−Volmer quenching constant, k_q is the bimolecular quenching rate constant, and τ_0 is the lifetime of fluorescence in absence of a quencher. Hence, K_{SV} was determined by linear regression of a plot of F_0/F versus $[Q]$ according to eq 1.

Pyrene was used as the fluorescence probe to determine the micropolarity of STE with and without 11S solution (1 mg/mL). Each spectrum was measured in the wavelength range 350−500 nm with the excitation wavelength being 335 nm. The excitation and emission slit widths were set at 5 and 2.5 nm, respectively. The intensity ratio of I_{373} to I_{385} of the pyrene fluorescence spectrum shows the micropolarity where the probe exists. The final concentration of pyrene in each sample was 6.0×10^{-7} M.

Isothermal Titration Calorimetry (ITC). The ITC measurements were performed in a Nano ITC Low Volume instrument (TA Instruments, Newcastle, DE) at 25 °C. In a typical experiment, 250 μL 11S solution (1 mg/mL) was inserted into the sample cell, and the syringe was filled with 50 μL of STE solution (50 mg/mL). All solutions were prepared in phosphate buffer (10 mM, pH 7.0) and were degassed before each titration. After reaching equilibrium, STE solution was titrated into the sample cell as a sequence of 25 injections of 2 μL aliquots. The time delay between successive injections was 350 s. The contents of the sample cell were stirred throughout the experiment at 250 rpm to ensure thorough mixing. Control experiments included the titration of STE into buffer, buffer into protein, and buffer into buffer. The last two controls resulted in small and equal enthalpy changes for each successive injection of buffer and, therefore, were not further considered in the data analysis. Corrected raw data refer to experimental data after subtraction of the STE into buffer control data. The corrected data obtained as a plot of heat flow (μcal s^{-1}) against time (min) were then integrated peak-by-peak and normalized to obtain a plot of observed enthalpy change per mole of STE (ΔH, kcal mol^{-1}) against the STE concentration (mM). The experimental data were further fitted to the one-site independent binding model using the TA Nano Analyzer software, providing the thermodynamic parameters K_a (binding constant), ΔH (enthalpy change), ΔS (entropy change), and n (number of STE molecules bound per mole of 11S).

Dynamic Surface Properties Measurements. The dynamic surface properties of 11S, STE, and 11S−STE mixtures at the air−

water interface were monitored by recording temporal evolution of surface pressure and surface dilatational parameters using an optical contact angle meter (OCA-20, DataPhysics Instruments GmbH, Germany) equipped with oscillating drop accessory (ODG-20), as described elsewhere.[30] All the experiments were carried out at 25 °C. The solutions were placed in the syringe and were allowed to equilibrate for 30 min to reach the desired constant temperature before the measurements. The drop of sample solution was formed in a rectangular glass cuvette. The cuvette was sealed with a Parafilm M laboratory film (Pechiney Plastic Packaging Company, U.S.A.) and partially filled with the solution under test to saturate the air surrounding the drop and reduce the water evaporation, which could decrease the drop volume and thus falsify the test.

Dynamic Surface Tension. A drop of sample solution (12 μL) was delivered and allowed to stand for 180 min to achieve adsorption at the air−water interface. An image of the drop was continuously recorded by a CCD camera and digitalized. The surface tension (γ) was calculated through the shape analysis of a pendant drop according to the Young−Laplace equation analysis. The surface pressure is $\pi = \gamma_0 - \gamma$, where γ_0 is the surface tension of phosphate buffer (10 mM, pH 7.0) and γ is the time-dependent surface tension of the tested solutions. The average standard accuracy of the surface tension for at least three measurements with different drops was roughly 0.5 mN/m.

Dilatational Rheological Properties. To obtain surface dilatational parameters, sinusoidal interfacial compression and expansion were performed by decreasing and increasing the drop volume at 10% of deformation amplitude ($\Delta A/A$) and 0.1 Hz of angular frequency (ω). The drop was subjected to repeated measurements of five sinusoidal oscillation cycles followed by a time corresponding to 50 cycles without any oscillation up to 180 min required to complete adsorption. Details of this experiment are given elsewhere.[31,32] The surface viscoelastic parameters, i.e., surface dilatational modulus, E, its elastic, E_d, and viscous, E_v, components were derived from the change in surface tension (γ) (dilatational stress) resulting from a small change in surface area (dilatational strain). The surface dilatational modulus (E) is a complex quantity and composed of real and imaginary parts ($E = E_d + iE_v$). The real part of the dilatational modulus or storage component is the dilatational elasticity (E_d). The imaginary part of the dilatational modulus or loss component is the surface dilatational viscosity (E_v).

Foam Formation and Stability Measurements. The foaming properties of pure STE and 11S−STE mixtures were characterized through their foam formation and stability measured in a Foam Tester R2000 instrument (SITA Messtechnik, GmbH, Germany) at 25 °C, as described elsewhere.[33] In all experiments, the used volume of the foaming solutions was 300 mL. The same 11S and STE concentrations were used as in the surface properties study. Every foam test consisted of two cycles, namely, the foam generation and foam decay. Foams were generated by stirring the solutions at 1000 rpm and stopping every 10 s to measure the foam volume by the sensor unit. After 15 such cycles, the foam generation stopped and the foam was left to decay. During decaying, the foam volume was measured for every 1 min. The height of the foam column (mL) in a generation period is taken as a measure of the foamability. The stability of the foam is estimated by measuring the half-life ($t_{1/2}$, min) of the foam, the time taken for the height to decay to half of the maximum.

Statistical Analysis. Unless specified otherwise, three independent trials were performed, each with a new batch of sample preparation. All measurements were carried out in triplicate, and an analysis of variance (ANOVA) of the data was performed using the SPSS 19.0 statistical analysis system. Duncan Test was used for comparison of mean values among three treatments using a level of significance of 5%.

RESULTS AND DISCUSSION

Interactions between 11S and STE in Bulk Solution. The interaction between proteins and LMW surfactants in bulk solution is usually believed to influence the properties of surface layers and thus the formation and stability of foams.[12,13] Herein, to helpfully understand the adsorption behavior of the mixtures, the bulk 11S−STE interactions were thus studied by fluorescence spectroscopy and ITC, as shown in Figures 1 and 2.

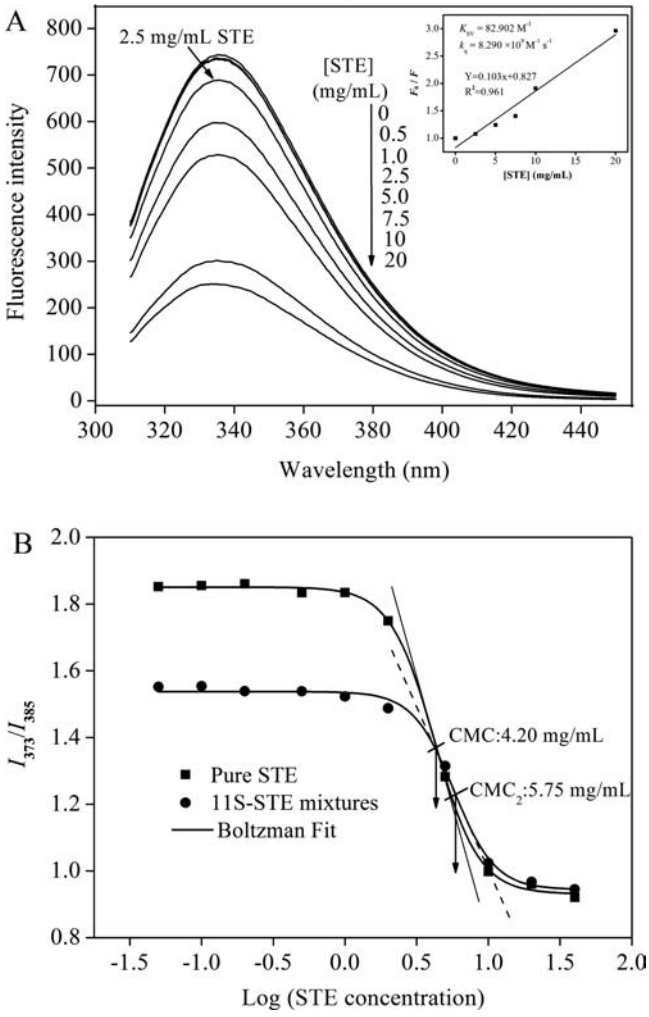

Figure 1. (A) Effect of STE on the intrinsic Trp fluorescence of 11S (1 mg/mL). The inset shows the Stern−Volmer plots describing fluorescence quenching of 11S in the presence of STE. (B) Pyrene fluorescence intensity ratios I_{373}/I_{385} in different STE concentrations with (CMC_2) and without (CMC) 11S. CMC: critical micelles concentration.

Effect of STE on Trp Intrinsic Fluorescence. Figure 1A shows the effect of STE on the Trp intrinsic fluorescence emission spectrum of 11S. The pure 11S exhibited an emission spectrum centered at around 335 nm. For STE concentrations below 1 mg/mL, there were no changes on the fluorescence intensity of 11S, indicating no obvious 11S−STE interactions. Addition of increasing STE concentrations from 2.5 mg/mL to 20 mg/mL gave rise to a progressive quenching of Trp fluorescence of 11S. Data fitting to eq 1 allowed determination of the Stern−Volmer quenching constant. As shown in the inset of Figure 1A, the value of k_q (8.29×10^9 M^{-1} s^{-1}) is much lower than the maximal dynamic quenching constant (2.0×10^{10} M^{-1} s^{-1}), indicating that the fluorescence quenching induced by STE is dynamic quenching.[29] This is in agreement with our previous study,[25] suggesting that STE cannot act as a direct Trp fluorescence quencher. Thus, this fluorescence attenuation should be the consequence of STE-induced protein

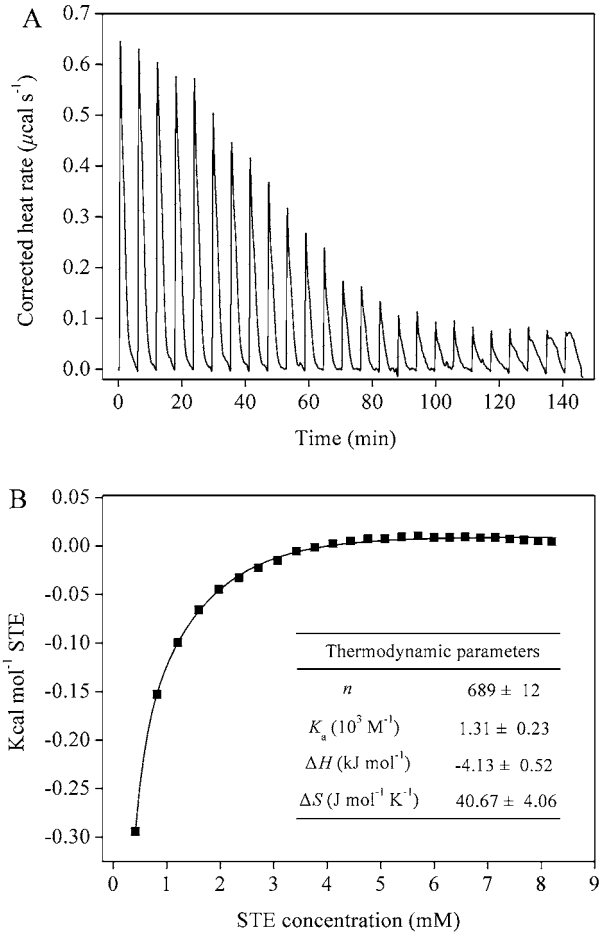

Figure 2. ITC determination of the binding of STE to 11S. (A) Heat flows recorded upon injection of STE solution (50 mg/mL) into 11S solution (1 mg/mL) at 25 °C. (B) Molar heat values obtained through integration of the individual heat flow signals as a function of the STE concentration. The solid line is the theoretical fit.

conformational changes. A similar behavior has been observed for the interaction of trehalose lipid biosurfactant with BSA.[34] In addition, as the concentration of STE was increasing from 7.5 mg/mL to 20 mg/mL (above the CMC of STE, see Figure 1B), the maximum emission wavelength underwent a moderate blue shift from 335 to 332 nm, revealing the movement of the Trp residues into a more hydrophobic environment, which was probably due to the interaction with hydrophobic portions of STE molecules (monomers and micelles).

Pyrene Fluorescence. The fluorescence emission of hydrophobic pyrene probe is sensitive to its microenvironmental polarity. A lower I_{373}/I_{385} value stands for higher hydrophobicity of the microenvironment. Upon micellization, pyrene partitions into or close to the hydrophobic interior of micelles, and consequently the intensity ratio I_{373}/I_{385} is changed.[35,36] The changes of the I_{373}/I_{385} values on the logarithm of STE concentrations with and without 11S were recorded and shown in Figure 1B. As can be seen, for STE concentrations below 1 mg/mL, compared to pure STE, 11S−STE mixtures showed lower I_{373}/I_{385} values, suggesting a higher hydrophobicity of the microenvironment, which was due to the hydrophobic domains in 11S. Moreover, no significant difference ($p > 0.05$) in the I_{373}/I_{385} values was observed when compared with that of pure 11S (1.54), indicating that there might be no obvious 11S−STE interactions when STE concentration was below 1 mg/mL. This result is in good agreement with the analysis of Trp intrinsic fluorescence (Figure 1A). The critical micelle concentration (CMC) of STE was determined from the threshold concentration, where the pyrene I_{373}/I_{385} begins to change markedly.[35,36] Therefore, the CMC values of STE in the absence and presence of 11S were determined as 4.20 mg/mL (CMC) and 5.75 mg/mL (CMC_2), respectively. The higher CMC value of STE in the presence of 11S revealed that there was interaction between 11S and STE, which sequestered STE molecules and reduced the concentration of free monomeric STE, thus increasing the STE concentration for formation of free micelles.[11] This result further supported previous analysis of Trp intrinsic fluorescence (Figure 1A).

ITC. The interaction between 11S and STE was further quantitatively studied by ITC, as shown in Figure 2. Upon injecting aliquots of STE solution (around 12 times above the CMC of STE) into 11S solution, the corrected heat trace peaks in Figure 2A demonstrated exothermic enthalpy released in the titration process, which should be caused by the binding of STE to 11S. On the basis of the fluorescence measurements (Figure 1), we can thus conclude that, upon the presence of STE micelles, STE could actually bind to the 11S cooperatively, forming the micelle-like clusters at the surface of 11S, thus resulting in the formation of exothermic peaks. Furthermore, with increasing STE addition, a decrease in exothermic peaks was observed (Figure 2A), suggesting the number of available binding sites on the 11S decreased. Once the protein became saturated with STE, the addition of more STE led to a plateau in the exothermic peaks (Figure 2A). The thermodynamic parameters were determined from the titration curve in Figure 2B. The binding ratio (n) was calculated to be 686 (±12), suggesting that 11S became saturated with 686 molecules of monomer STE bound per molecule of 11S. The binding ratio value was higher than those observed for the interactions between β-lactoglobulin and different types of LMW surfactants, such as SDS, alkyl trimethylammonium chlorides, or alkyl maltopyranosides.[11,37] This high binding ratio further supported the formation of STE clusters or micelles at the surface of 11S, in agreement with the Trp intrinsic fluorescence analysis (Figure 1A). Moreover, the larger molecular size of 11S (~360 kDa) could also provide a greater number of binding sites for STE. Interactions with binding constant $K_a > 10^4$ M^{-1} are considered to be of high affinity.[38] Thus, the binding constant ($K_a = 1.31 \times 10^3 \pm 0.23 \times 10^3$ M^{-1}) observed in this study indicated that binding of STE with 11S was much weaker, probably suggesting a nonspecific interaction.[34] In addition, the binding entropy was positive ($\Delta S = 40.67 \pm 4.06$ kJ mol^{-1} K^{-1}), indicating that the interaction was mostly driven by entropy. Since it is generally accepted that an entropy-driven reaction mainly involves hydrophobic interactions,[34,38] the present result suggested that STE binding to 11S should be mainly driven by interacting unspecifically with hydrophobic domains of 11S, which was again in line with the results of Trp intrinsic fluorescence (Figure 1A). Similar findings on the interaction of trehalose lipid biosurfactant with BSA were observed.[34]

Surface Behavior of 11S−STE Mixtures. *Dynamic Surface Tension.* The time evolution of surface tension (γ) for 11S−STE mixtures at the air−water interface is shown in Figure 3A. In all cases, the surface tension values gradually decreased with adsorption time, which can be associated with the surface-active substances adsorption at the interface. For pure 11S, it can be observed that the surface was already

dx.doi.org/10.1021/jf502027u | J. Agric. Food Chem. 2014, 62, 6834−6843

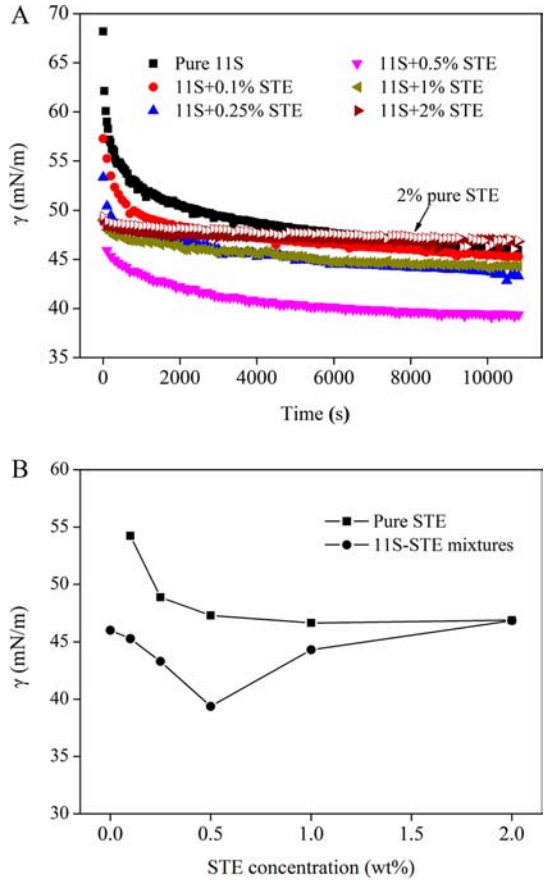

Figure 3. (A) Surface tension (γ) as a function of time for mixed solutions of 0.1% 11S with different STE concentrations (0–2%) at the air–water interface. (B) Surface tension versus the concentration of STE for solutions with and without 0.1% 11S. The values represent the surface tension after 180 min of adsorption.

saturated at the present bulk concentration (0.1%), in agreement with previous studies.[15,31,39] For 11S–STE mixtures, at low STE concentration (0.1%), the surface tension decay showed a very similar trend as compared to pure 11S, indicating that the surface layer was mainly dominated by 11S. However, with increasing STE concentrations to intermediate level (0.25 and 0.5%), especially at 0.5% STE, the surface tension decay curves started to differentiate markedly when compared to that of pure 11S, where a significant increase in the decay rate was observed. Upon the further increase of STE concentration (1 and 2%), an obvious slowing down of surface tension decay was found as compared with that of 0.5% STE. Moreover, the dynamic curve of the mixture (2%) started to resemble that for 2% pure STE (Figure 3A).

The surface tension after 180 min of adsorption from mixed 11S and STE systems is compared to the corresponding values for pure STE in Figure 3B. The surface tension value for pure 11S was 46.0 mN/m after 180 min, which is in consistent with previously reported results.[15,31] With increasing STE concentrations from 0.1% to 0.5%, an obvious decrease in surface tension values was found. Furthermore, it is noteworthy that the surface tension values of mixtures were always lower than those of pure 11S and STE, indicating mixed 11S–STE surface layers were formed. However, with increasing STE concentrations from 1% to 2%, the surface tension values of mixtures started to increase again, suggesting the decreased surface activity. Moreover, the surface tension value of the mixture (2%) coincided with that of pure 2% STE, which indicated that the interface was completely dominated by STE.

Surface Dilatational Rheology. The dynamic dilatational properties for pure and mixtures of 11S and STE are shown in Figure 4. The evolution of the dilatational modulus was

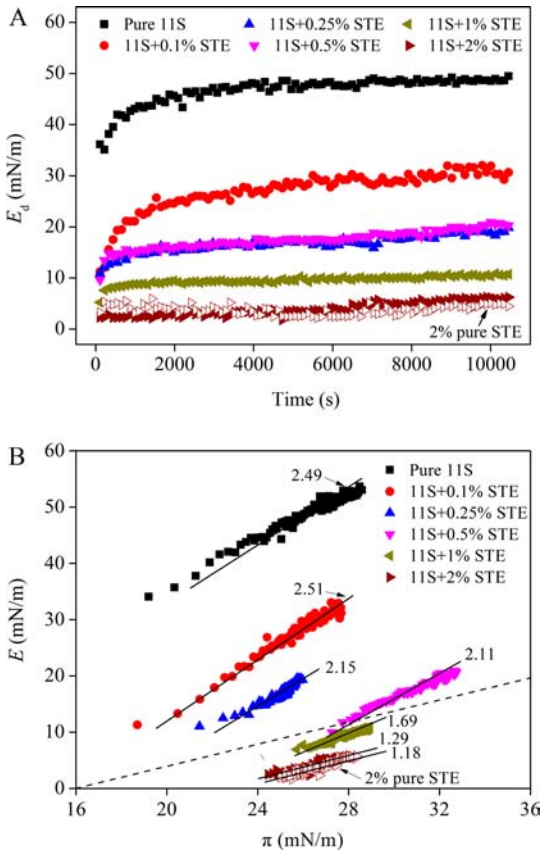

Figure 4. (A) Time-dependent dilatational elasticity (E_d) for adsorbed layers formed from mixed solutions of 0.1% 11S with various amounts of STE (0–2%) at the air–water interface. (B) Surface dilatational modulus (E) plotted as a function of surface pressure (π) for the above mixed solutions. Frequency: 0.1 Hz. Amplitude of deformation: 10%.

followed at the frequency of 0.1 Hz, which was tuned to give a good response for soy globulin, as it allows the collection of enough data points within the present adsorption time.[15,31,39] In all cases, it can be noticed that (data not shown) the values for surface dilatational modulus (E) were very similar to those for the dilatational elasticity (E_d), and the dilatational viscosity (E_v) values were low. Thus, from a rheological point of view, these results suggested the surface layers behaved as viscoelastic (primarily elastic) during the adsorption period studied here.[15]

Figure 4A presents the dynamic elastic modulus (E_d) of surface layers during the adsorption of 11S–STE mixtures. In all cases, the gradual increase in E_d with adsorption time should be associated with the adsorption of surface-active components at the interface. For pure 11S, the E_d increased gradually with time to reach 49.5 mN/m after 180 min, which is similar to those found by others,[15,31,39] implying that strong viscoelastic interfacial networks were formed mainly due to a combined effect of protein adsorption and development of strong intermolecular interactions and conformation changes at the interface.[1,15,31,40] With increasing amounts of STE in mixtures, even at low STE concentration (0.1%), the E_d clearly decreased as compared to that of pure 11S. This should be mainly due to

dx.doi.org/10.1021/jf502027u | J. Agric. Food Chem. 2014, 62, 6834–6843

the fact that the presence of STE could break down the protein intermolecular interactions, thus weakening the film and reducing the viscoelastic properties.[1,41] Similar findings were also reported for soy globulins/Tween 20 and hen egg-white lysozyme/C_{10}DMPO mixtures at the air−water interface.[14,15] Nevertheless, at intermediate STE concentrations (0.25 and 0.5%), it is very interesting to note that no marked difference in E_d values with increasing STE concentrations was observed. This result revealed that mixed 11S−STE surface layers showed a plateau in the elastic behavior within the STE concentration range. With the further increase in STE concentration (1 and 2%), the E_d values started to decrease again. At high STE concentration of 2%, the E_d value of the mixture was very close to that of 2% pure STE, which led to the conclusion that the interface was predominantly covered by STE. This result is in line with dynamic surface tension analysis (Figure 3). On the other hand, all pure STE samples (0.1−2%) showed very low E_d values (around 5.0−8.0 mN/m) (data not shown), indicating the interface stabilized by pure STE exhibited a low elasticity. Similar behaviors were also observed for many other LMW surfactants.[1,3,15,40]

The evolution of E with π in the surface layer for the adsorption of 11S−STE mixtures is shown in Figure 4B. The curve of E versus π generally reflects the surface equation of state of the adsorbed material at the interface, and if the E is only due to the amount of surface-active components adsorbed at the interface, all E data should be normalized in a single master curve of E versus π.[42] For pure 11S, it can be seen clearly that E increased almost immediately with increasing π value, and this dependence reflects the existence and the increase of interactions between the adsorbed protein residues. Moreover, E was higher at longer adsorption times, in line with the theory of Lucassen−Reynders.[43] The slope (2.49) of the $E-\pi$ plot was higher than 1 (represented by the dotted line in Figure 4B), which implied an important nonideal behavior for higher molecular interactions between the adsorbed proteins compared with those for an ideal behavior.[43] With increasing STE concentrations from 0.1% to 1%, all the slopes of $E-\pi$ plots were higher than 1, revealing an important nonideal behavior with higher molecular interactions between film-forming components. The low STE concentration (0.1%) showed a slope value of 2.51, which was similar to that of pure 11S (2.49), indicating that the interface was mainly dominated by 11S. This is consistent with the dynamic surface tension analysis (Figure 3). In addition, it is worth noting that, the mixtures with STE concentrations of 0.25% and 0.5% also exhibited high slope values of 2.15 and 2.11, respectively, which suggested the presence of high molecular interactions between the adsorbed 11S and STE at the interface. However, with further increasing STE concentrations (1 and 2%), the slope values started to decrease. At high STE concentration (2%), the $E-\pi$ plot partially overlapped with that of 2% pure STE, and the slope (1.29) was also very close to that of pure STE (1.18). These results indicated that the adsorption layer was formed mainly by STE, which again are in good agreement with previous analysis (Figures 3 and 4A). In addition, in all cases of pure STE (0.1−2%), the slope values of $E-\pi$ plots were around 1 (characteristic of the behavior of an ideal gas) (data not shown), thus revealing the E is only due to the amounts of STE adsorbed at the interface without apparent STE−STE interfacial interactions, in line with their behaviors at the oil−water interface.[27]

Foaming Properties of 11S−STE Mixtures. On the basis of the characterization of surface layers, we attempted to relate these findings to the properties of macroscopic foams formed from 11S−STE mixtures with the same compositions as used in the surface properties study. Thus, the foamability and foam stability of 11S−STE mixtures were measured, as shown in Figures 5 and 6, respectively.

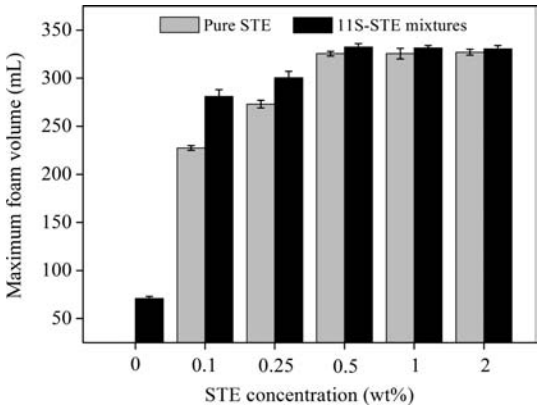

Figure 5. Maximum foam volume obtained from the solutions of pure STE (0.1−2%) and mixtures of 0.1% 11S with various amounts of STE (0−2%).

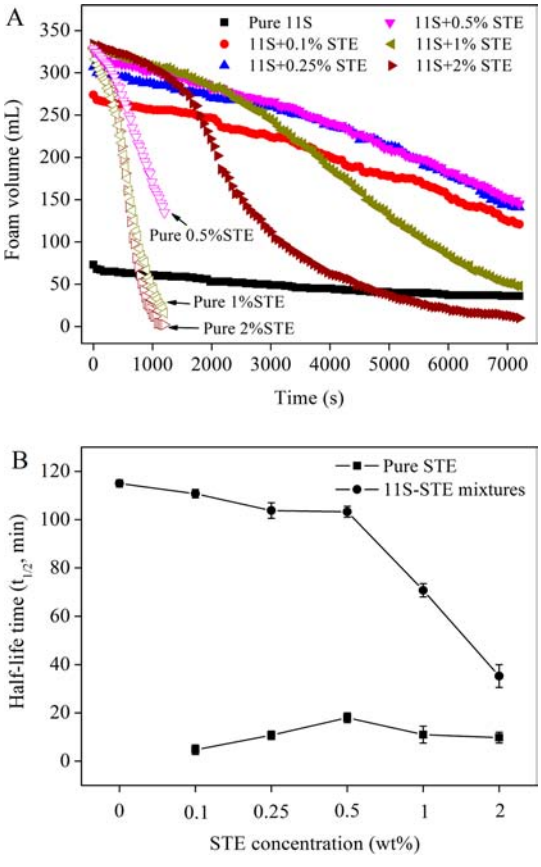

Figure 6. (A) Foam volume as a function of time for the solutions of pure STE (0.5−2%) and mixtures of 0.1% 11S with various amounts of STE (0−2%). (B) Half-life ($t_{1/2}$) of the foams formed by pure STE (0.1−2%) and the above mixed solutions.

Foamability. Foam formation is influenced by the adsorption of foaming agents at the air−water interface and their ability to reduce surface tension.[3,9,44,45] The maximum foam volume for different systems was measured to assess their foamability (Figure 5). As shown in Figure 5, pure 11S exhibited a low foam volume, suggesting a very poor foaming capacity. This might be due to the large size and close-packed globular conformation of 11S,[46] which hindered its rapid adsorption at the interface during foaming, thus impairing the foaming capacity. The high initial surface tension value of 11S supported this analysis (Figure S, Supporting Information [SI]). This is in line with previous study,[46] which suggested that high 11S concentration (2% or more) was required to make good foams. Compared to that of pure 11S, even at the addition of low STE concentration (0.1%), the maximal foam volume was significantly increased. Moreover, with increasing STE concentration from 0.1% to 0.5%, a gradual increase in the maximal foam volume was observed, suggesting the improved foaming capacity. This improving effect should be due to the greater ability for the mixtures to lower surface tension (Figure 3), hence, facilitating the foaming process. In the presence of high STE concentrations (1 and 2%), no significant difference ($p > 0.05$) in the maximal foam volume was observed when compared to that of the mixture containing 0.5% STE. This result should be mainly attributed to their similar initial surface tension values (Figure S, SI). On the other hand, at the same concentration (0.1%), the foamability of pure STE was better than that of pure 11S (Figure 5), which should be due to the fast adsorption of STE at the interface and thus the lower initial surface tension (Figure S, SI), which could contribute to foamability. Meanwhile, under STE concentration range from 0.1% to 0.5%, the 11S−STE mixtures exhibited a higher foaming capacity as compared to pure STE. However, at high STE concentrations (1 and 2%), the foamability results for pure STE and the mixed systems were very similar. These results perfectly matched the general trends seen in initial surface tension data (Figure S, SI), suggesting a strong relationship between the foamability and the initial surface tension of foaming agents.

Foam Stability. Foams are thermodynamically unstable, and their relative stability is governed by factors such as liquid drainage, coarsening, and coalescence.[47] To evaluate the foam stability, the foam volume versus time after foam generation and the half-life time ($t_{1/2}$) of foams were measured, as presented in A and B of Figure 6, respectively. In all cases, it can be clearly seen that, despite the poor foaming capacity (Figure 5), the foam formed by pure 11S exhibited the lowest foam decay rate (Figure 6A) and the maximum value of $t_{1/2}$ at 115 min (Figure 6B), indicating pure 11S-stabilized foam was very stable against bubble coarsening and coalescence. With increasing STE concentration from 0.1% to 0.5%, compared to those of pure 11S, the rate of foam decay was slightly increased (Figure 6A), and the formed foams also had slightly lower $t_{1/2}$ values (Figure 6B). These results suggested that, under the STE concentration range (0.1−0.5%) used, the 11S−STE mixtures could still make relatively stable foams. Moreover, it is worth noting that, despite increasing STE concentrations from 0.25% to 0.5%, no significant difference ($p > 0.05$) was observed in foam decay rates and $t_{1/2}$ values. Also, the decay curve of 0.25% practically overlapped with that of 0.5% (Figure 6A). These results indicated that the foams formed by 11S−STE mixtures (0.25 and 0.5%) showed very similar stability. However, at high STE concentrations (1 and 2%), with increasing STE concentration, the dramatic increase in decay rates and decrease in $t_{1/2}$ values were observed, respectively. Moreover, the decay curve and $t_{1/2}$ value started to be close to those of pure STE. These results completely reproduced the general trends observed in the data from surface properties (Figures 3 and 4); therefore, it can be concluded that interfacial results might be correlated to foam stability. On the other hand, despite the good foaming capacity of pure STE (Figure 5), the foams formed by pure STE in the studied concentration range (0.1−2%) showed very poor stability, as evidenced by high foam decay rates and low $t_{1/2}$ values (Figure 6). Similar behavior was observed in foams stabilized by many other LMW surfactants.[1,15]

General Discussion. Here, the results obtained at different scales, from the molecular to the macroscopic point of view, are discussed to try to provide understanding of the mechanism underlying the foamability and foam stability for 11S−STE mixed systems. On the basis of the results of surface tension (Figure 3), it is thus reasonable to speculate that, at intermediate STE concentrations (0.25 and 0.5%), a strong synergy in reducing the surface tension was observed in 11S−STE mixtures, in agreement with the previous study where similar behavior was seen at the oil−water interface.[27] This effect could be explained by the formation of 11S−STE complex at the adsorbed layer, which might possess higher surface activity than that of the individual components (Figure 3B). This speculation is supported by the results of fluorescence spectroscopy and ITC (Figures 1 and 2), which indicated that the 11S−STE complex was formed already in the bulk prior to its adsorption at the interface. The obvious binding of STE with 11S in bulk occurred mainly by nonspecific hydrophobic interactions when STE concentration was above 1 mg/mL (Figures 1 and 2). The binding is rather weak, as evidenced by ITC analysis (Figure 2), but appears to be sufficiently intense to result in the conformational changes of 11S (Figure 1A). Therefore, we can conclude that the complexation with STE might promote the partial dissociation of protein and loosen its rigid structure, which would facilitate further unfolding of 11S upon reaching the interface, thus increasing the surface tension decay rate (Figure 3A). Similar phenomena were reported in the mixtures of β-lactoglobulin/β-casein and *Quillaja* Bark Saponin.[23,24] On the other hand, at low STE concentration (0.1%), complexation of a small amount of STE could not change the protein conformation markedly (Figures 1 and 2). Despite the low initial surface tension (Figure S, SI) due to the fast adsorption of STE, the overall adsorption behavior of 11S−STE mixtures would be similar to that of pure 11S, as evidenced by the surface tension decay of the mixture (0.1%) (Figure 3A). Furthermore, at high STE concentrations (1 and 2%, above the CMC of STE, see Figure 1B), large amounts of STE micelles would exist in the bulk. Meanwhile, with increasing binding of STE, the formation of STE clusters or micelles at the surface of 11S (Figures 1 and 2) might make the complex more hydrophilic, thus leading to the decrease in its surface activity. Considering the initial surface tension of 11S−STE mixture was very close to that of pure STE (Figure S, SI), therefore, we can speculate that the preferential adsorption of small STE molecules over 11S−STE complex at the interface occurred, thus leading to the conclusion that the interface is predominantly covered by STE (Figures 3 and 4). Similar behavior was reported for conventional surfactants, e.g., Tween 20 or SDS, which could also remove proteins completely from the interface.[3,17,41]

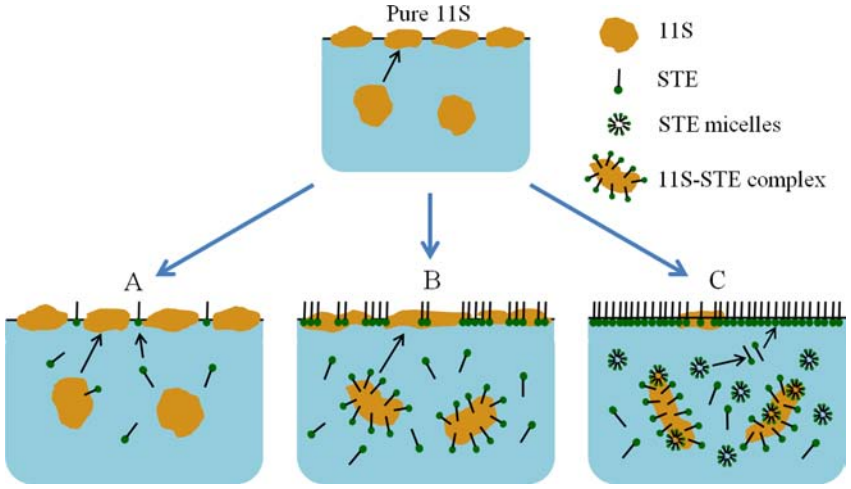

Figure 7. Schematic illustration of bulk behavior and adsorption at the air−water interface of 11S−STE mixtures with (A) low STE concentration (0.1%); (B) intermediate STE concentration (0.25−0.5%); (C) high STE concentration (1−2%).

The results of dynamic elastic modulus (E_d) and $E-\pi$ curves exhibited good correlation with each other (Figure 4). For 11S−STE mixtures, it is very interesting to note that, at intermediate STE concentrations (0.25 and 0.5%), a plateau in the elasticity for mixed surface layers was clearly seen (Figure 4A). This behavior could be explained with the partial dissociation and looseness of protein structure, induced by the binding of STE, which could promote further unfolding of 11S at the interface. The unfolding of 11S would facilitate enhancing protein−protein and protein−STE interactions at the surface layer, as evidenced by high slope values of $E-\pi$ plots (Figure 4B), thus increasing the E_d value.[15,41] This increase might offset the lost elastic modulus due to increasing STE concentration at the interface, and thus endowed the mixed surface layer with a plateau in the elasticity. These analyses were in line with surface tension analyses (Figure 3) and supported by fluorescence and ITC results (Figures 1 and 2).

On the basis of the above analysis, we can conclude that the synergy in surface tension decay and the plateau in surface elasticity appear to be crucial to the understanding of the dynamic surface properties for 11S−STE mixtures. Moreover, it is noteworthy to mention that no such behavior has been reported for protein/conventional surfactant mixtures. In general, for protein/nonionic surfactant mixtures, a monotonous decrease of the equilibrium surface tension and dilatational elasticity is observed, whereas for ionic surfactants, the surface tension exhibits a sharp decrease below the CMC, which is accompanied by a maximum of dilatational elasticity as the concentration of surfactant increases in the mixture.[3,12,14]

Considering the real foaming process, the link between surface characteristics and foaming properties is far from straightforward. However, in view of all of these present results, it could be speculated that there is a clear correlation between the surface behavior and the actual foaming properties for 11S−STE mixtures. As discussed previously, the foamability appeared to be affected strongly by the initial surface tension values of foaming agents (Figure 5 and Figure S in the SI). Furthermore, surface elasticity is generally believed to play an important role in foam stability.[1,3,40,47] Thus, despite poor foaming capacity of pure 11S (Figure 5), the formed foam remained very stable (Figure 6), which should be due to the formation of surface layers with high surface elasticity (Figure 4A) that protect the bubbles against coalescence.[1,3,7,40,47] Nevertheless, at intermediate STE concentrations (0.25 and 0.5%), surprisingly, although there was a dramatic decrease in surface elasticity (Figure 4A), no marked effect on the foam stability for the mixtures was observed (Figure 6). This suggested that the surface elasticity is not always the major factor influencing the stability of the mixed foams. Indeed, it is often stated and observed that protein−LMW surfactant mixtures could even give more stable foams than proteins alone.[1,45] The addition of the LMW surfactants will make the rather rigid protein layer more flexible and mobile, and the formed mixed surface layer might then be much better able to respond to deformations, which would prevent film rupture and thus have a positive effect on the foam stability.[1,45] This idea is consistent with the present observation on the stability of foams formed by 11S−STE mixtures (especially at 0.25 and 0.5%) (Figure 6) and is also supported by similar results on previous emulsion systems.[27] Accordingly, it might be speculated that the mixed surface layer stabilized by 11S and STE not only provided a relatively constant elasticity (Figure 4A) but also possessed a certain relaxation mechanism due to the existence of STE by the Gibbs−Marangoni effect,[1,3,4,6] thus endowing the foams with considerable stability (Figure 6). On the other hand, upon further increase of STE concentration (1 and 2%), the interface was gradually covered by STE (Figures 3 and 4) due to the preferential adsorption of STE molecules. Consequently the interface became weaker (low surface elasticity, see Figure 4A), and thus the resultant foams became less stable (Figure 6).

From these series of experiments and analysis, to better understand the correlation between the surface behavior and the actual foaming properties, a schematic illustration of bulk and surface behaviors of 11S−STE mixtures is proposed and shown in Figure 7. In the case of pure 11S, the slow adsorption at the interface impaired its foaming capacity (Figure 5 and Figure S in the SI); however, the formed surface layer with a high dilational elasticity (Figure 4) contributed to the generation of very stable foam (Figure 6). Upon the addition of low STE concentration (0.1%), the foamability of the mixture was obviously increased due to the fast adsorption of STE (Figure 5 and Figure S in the SI). Despite the marked effect on the surface dilational properties by STE, the interface was still mainly dominated by 11S (Figures 3 and 4). At intermediate STE concentrations (0.25 and 0.5%), the weak

dx.doi.org/10.1021/jf502027u | J. Agric. Food Chem. 2014, 62, 6834−6843

binding of STE with 11S in bulk occurred by nonspecific hydrophobic interactions (Figures 1 and 2). However, the binding was believed to be sufficiently intense to promote the partial dissociation and looseness of protein's rigid structure (Figure 1A). This would facilitate further unfolding of 11S upon adsorption and thus enhance the protein−protein and protein−STE interfacial interactions. These analyses were supported by the strong synergy in reducing surface tension and the plateau in surface elasticity for mixed layers (Figures 3 and 4), which endowed the corresponding foams with a fine foaming capacity, making the layer be better able to respond to applied stresses without rupturing and providing considerable foam stability against bubble coalescence (Figures 5 and 6). In addition, when high STE concentrations (1 and 2%) were added, large amounts of STE micelles formed in bulk. The preferential adsorption of STE molecules over the 11S−STE complex resulted in the formation of a surface layer covered mainly by STE (Figures 3 and 4), and thus the resultant foams became less stable due to low surface elasticity (Figures 4A and 6).

In conclusion, we have studied the adsorption of 11S−STE mixtures at the air−water interface by combining several approaches on different length scales. The obtained results showed clearly that the foaming properties of the mixtures were correlated with their surface behavior, which was found to be strongly influenced by 11S−STE interactions in the bulk. Compared to pure 11S, the surface dilational properties and foaming capacity were markedly affected even at low STE concentration (0.1%). When intermediate STE concentrations (0.25−0.5%) were added, the weak binding of STE with 11S in bulk occurred by nonspecific hydrophobic interactions, which appeared to be sufficiently intense to induce conformational changes of 11S, as evidenced by fluorescence and ITC. As a result, the strong synergy in reducing surface tension and the plateau in surface elasticity for mixed 11S−STE layers formed from the weakly interacting mixtures were clearly observed. This effect could be explained by the complexation with STE, which might facilitate the partial dissociation and further unfolding of 11S upon adsorption, thus enhancing the protein−protein and protein−STE interfacial interactions. These surface properties were positively reflected in foams produced by the weakly interacting system, which exhibited good foaming capacity and considerable stability probably due to better response to external deformations without film rupture. At high STE concentrations (1−2%, above its CMC), the preferential adsorption of STE molecules occurred, and thus the interface was predominantly covered by STE. Consequently, the resultant foams became less stable due to low surface elasticity.

Considering the conditions of practical foam formation and evolution, which mainly involve large deformation and high strain rates, the link between the present surface measurements and foaming properties is not straightforward. Further work is required on the study of the detailed microstructure and mechanical properties of adsorbed protein−STE layers under nonlinear conditions and large deformations using appropriate experimental techniques.[45,48] However, these results obtained in this work provide valuable information on the relation between the surface behavior and foaming properties of the 11S−STE mixtures. We expect that these findings would open up the potential of mixed protein−STE systems as foam/emulsion formulations in industrial applications.

Wine volatiles are huge in number because they derive from three factors: the grapes, the fermentation by yeast, and the storage of wine.[20] Moreover, grape variety and its cultivation, oenological practice, and aging influence the specific aroma profile of a wine.[11] Thus, an enormous natural and process-related variation is achieved. Untargeted MS data of wines underpin this complexity. Hence, a clearly defined sample collection and sufficient number of samples are of particular relevance for classification. Further, the appropriate procedure for data treatment that follows data conversion is of special interest. For example, a large amount of irrelevant variables occurs in GC−MS data and could mislead interpretation of data.[21] The appropriate sampling and treatment strategy is particularly important for serving the current demand for the validation of the resultant classification models.[22−25]

To face such a challenge, the present fingerprinting study of volatiles was conducted and its suitability for German white wine varietal authentication was explored. The analysis was carried out with commercially available white wine samples, and it is therefore assumed that the natural diversity and a wide range of biological and oenological effects on the wine composition were covered. After the HS−SPME−GC−MS analysis, the raw data were converted applying an available metabolomics tool. Then, the appropriateness of the proposed method, including data treatment and processing, was shown by investigating reliability and relevance. Finally, a validated multi-class model was achieved. Additionally, details of the resultant classification model were shown by visualizing the classification performance.

MATERIALS AND METHODS

Samples. A total of 272 commercial German dry white wine samples, obtained in 2011, with a varietal purity of 100% according to the producers, were transferred to 50 mL amber glass bottles and stored at 4 °C in the dark until analysis. A total of 198 wine samples of the botanical origin Riesling (56 samples), Müller-Thurgau (34 samples), Silvaner (44 samples), Pinot Gris (30 samples), and Pinot Blanc (34 samples) formed the main data set 1. Further, 74 additional wine samples, including Riesling (40 samples), Pinot Gris (20 samples), and Pinot Blanc (14 samples) origin, formed data set 2. Samples were of vintage 2009 and 2010 and diverse origin regarding vineyard location in Germany. The German wine quality categories employed were (a) quality wine from specific wine-growing regions and (b) Kabinett, a quality wine with special attributes. The distribution of vintage in data set 2 was of 2009 with 40 samples (all Riesling) and 2010 with 34 samples (all Pinot).

Chemicals. All reagents used were of analytical quality. To form the internal standard mix, 3,7-dimethyl-3-octanol (purity > 98%) and 2-hexyl-1-decanol (purity > 97%), both purchased from Sigma-Aldrich (Schnelldorf, Germany), were solved in ethanol absolute per analysi (p.A.), Merck (Darmstadt, Germany). The solution contained on average 30.9 $\mu g\ g^{-1}$ of 3,7-dimethyl-3-octanol and 1.5 $\mu g\ g^{-1}$ of 2-hexyl-1-decanol. The mix was stored at −20 °C until analysis and renewed each 5−7 days. The compounds were chosen because of their general absence in wine. They demonstrated stability within the wine matrix and were used to control the mass feature alignment in the pre-processing step. The repeatability of their main fragment areas was tested by successive injections of 17 independent aliquots of a wine sample, each 10 mL mixed with 20 μL of internal standard mix. This resulted in 7 and 8% relative standard deviation of the peak area for tetrahydrolinalool and 2-hexyl-1-decanol, respectively. The internal standard mix was equally prepared and used for data set 2 sample preparation.

Furthermore, butylhydroxytoluene (BHT), purchased from Sigma-Aldrich, was used for identification of a non-wine compound causing sample outliers. The reference standards (*R*)-(+)-limonene (purity = 97%), γ-terpinene (purity > 97%), and 2-phenylethyl acetate (purity > 99%) were provided by Sigma-Aldrich. α-Terpineol (purity = 95%) was purchased from ABCR (Karlsruhe, Germany), and 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN) (purity = 98%) was synthesized by VeZerf (Idar-Oberstein, Germany).

HS−SPME Sample Extraction and GC−MS Analysis. To extract samples, 10 mL of cooled wine (4 °C) and 20 μL of internal standard mix were filled in a 20 mL amber headspace vial, which was then immediately closed using headspace analysis screw caps with silicone/polytetrafluoroethylene (PTFE) septa of 1.3 mm thickness. Sample bottles were exclusively opened at the time of sample preparation. Samples of identical origin regarding grape variety were distributed equally across all sequences of measurement to ensure their comparability because of possibly biased analytical variation. For this purpose, the measurement order was chosen randomized along with a block design.

The HS−SPME of the wine volatiles was examined by full automation and online desorption of the analytes to the GC system using a MPS 2 device from Gerstel (Mülheim a. d. Ruhr, Germany). This ensured a steady throughput of samples and constant SPME parameters. The mono material fiber polydimethylsiloxane (PDMS), 100 μm thickness, 10 mm length (Supelco), purchased from Sigma-Aldrich, Germany, was chosen because of its low enrichment of ethanol, which avoided overload of the GC column. The extraction time for the PDMS fiber was 45 min at a temperature of 40 °C. The prior incubation time was 15 min at 40 °C, and the samples were agitated at 250 rpm during incubation and extraction. Immediately after the extraction, the desorption of analytes was carried out by hot injection at 260 °C, splitless for 2 min, in a narrow liner (0.75 mm internal diameter, Supelco). The split/splitless injector was equipped with a Merlin Microseal, Supelco, and, therefore, operated septumless. Bake-out of the SPME fiber was conducted for 10 min in a bake-out station at 250 °C immediately before every sample extraction. To check fiber intactness and detect possibly carry over of substances, fibers were desorbed without prior extraction twice a day and once every 10−15 samples (fiber blank). New SPME fibers and fibers not used for more than 1 day were conditioned at 250 °C for 30 min.

Analysis was carried out on an Agilent Technologies GC 6890 and MS detector 5973 inert (Böblingen, Germany). The desorbed sample analytes were separated on an Agilent J&W DB 1701 (30 m length, 0.25 μm film thickness, and 0.25 nm internal diameter). A helium flow of 1.1 mL min^{-1} was used. The initial oven temperature of 40 °C was held for 3 min and, after that, was first increased by 6 °C min^{-1} to 100 °C, with a hold time of 1 min, and second increased by 6 °C min^{-1} to 240 °C, with a hold time of 5 min. Finally, the temperature of 280 °C was held for 5 min to reduce contamination (total run time of 48 min). After transfer at 280 °C to the MS source with standard electron impact ionization at 230 °C, the quadrupole analysis (150 °C) was carried out in the range of mass/charge ratios of m/z 35−320, with 4.86 scans s^{-1}.

Another extraction device and GC−MS instrument was used for independent measurements; a different operator examined the similarly prepared samples of data set 2. The instrument used was of the same type and, therefore, identical in construction to the instrument described above. Identical analytical equipment, GC column type, and HS−SPME−GC−MS procedure were used.

Pre-processing and Data Treatment. The three-dimensional GC−MS raw data were converted to a matrix ($N \times M$) giving the intensity values for N samples of M extracted mass features or variables, which comprise the mass/charge ratio (m/z) per time unit (scan). On the basis of the original Agilent files, we performed this pre-processing step with the MetAlign software (http://www.wageningenur.nl, version 080311).[9,26,27] The result was stored as a CSV file.

After this, already extracted mass features, which could confound classification, were removed: (1) previously known and constant GC contaminants comprising cyclosiloxanes from SPME, siloxanes from sample vial septa (m/z 207, 281, etc.), and phthalates (m/z 149), (2) exceptionally disturbing mass features detected by exploratory data analysis with principal component analysis, and (3) mass features

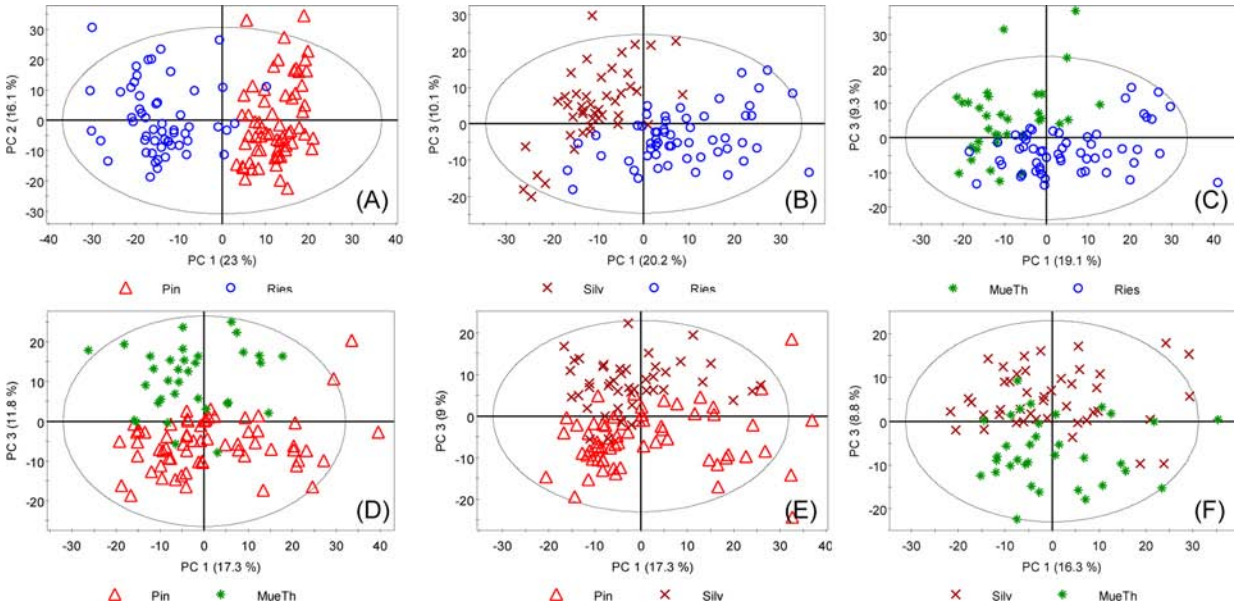

Figure 1. PCA score plots based on restricted numbers of white wine samples (data set 1): (A) Riesling and Pinot (N = 120), (B) Riesling and Silvaner (N = 100), (C) Riesling and Müller-Thurgau (N = 90), (D) Pinot and Müller-Thurgau (N = 98), (E) Pinot and Silvaner (N = 108), and (F) Müller-Thurgau and Silvaner (N = 78). Data set completely treated as proposed, $N \times M$ = 198 × 952. PC $n(x)$: n order number of PC and x explained variance in X [$R^2(X)$] regarding PC n. Ries (circles) = Riesling; Pin (triangles) = Pinot; Silv (crosses) = Silvaner; and MueTh (stars) = Müller-Thurgau.

associated with the internal standards after completion of controlling the alignment step of MetAlign.

Additional preliminary variable reduction to reduce noise[22] was carried out, so that the mass features with occurrence in less than 80% of samples in relation to each of the individual varietal classes used for modeling were removed. Thereby a mass feature with "no occurrence" in a sample was detectable by the constant low value set in the preprocessing step regarding intensities below the absolute threshold. A further step comprised the substitution of all retained mass feature intensities below the absolute threshold by zero to enhance usable signals of low signal-to-noise ratio.

Finally, three steps of common pretreatment methods were followed:[22,28,29] (1) square root transformation lowered heteroscedasticity typical for GC−MS data without changing the actual distribution (pseudo-scaling), (2) the row (sample-wise) scaling to constant total was used to compensate for the wide time range of measuring, and (3) directly prior to data analysis, the column scaling method autoscaling was used.

The variable reduction and pretreatment were examined using Excel (Microsoft Office, version 2010) and SIMCA-P+ (Umetrics, version 12.01.0).

Processing and Multivariate Data Analysis. Principal component analysis (PCA) was used for visualization of the analytical-derived connections among samples and between samples and mass features independent of the origin of samples (unsupervised analysis). It was performed for the purpose of exploratory data analysis. PLS-DA was used for the modeling of samples in relation to the settled classes Y (supervised analysis). A PLS-DA model was based on selected variables deriving from the variable importance in the projection (VIP) value of the variables of an orthogonal PLS-DA (OPLS-DA) model. VIP is the sum of all model dimensions of the contributions of variable influence. Variables with VIP values above 1 are supposed to be the most relevant for explaining Y in relation to the whole model[29] and were, therefore, exclusively used to build a PLS-DA model. OPLS-DA separates the modeled variation into the Y-predictive and Y-orthogonal (Y-unrelated) variation[30] and removes the latter from the model. This statistical technique was therefore most suitable to select the most contributing variables.

Four diagnostic parameters were considered to evaluate the performance of a classification model. First, the goodness of fit (R^2) of a model represents the explained variance used to extract the latent variables [principal components (PCs)] from the total data in relation to the class membership (Y). Second, the goodness of prediction of Y (Q^2) of a model gives an estimation of the result of internal cross-validation by leaving out $^1/_7$ of the data in turn.[29] Third, the classification power of classes was established by assigning test samples to a training model and revealing the percentage of accurately classified samples in relation to all predicted samples per class (% CC). Finally, the visual tool of receiver operating characteristic (ROC) curve analysis was employed, recently recommended to be used to evaluate the classification power of models.[22,24,25,31] A ROC curve is performed when plotting the proportion of true positives (TP) or the sensitivity against the proportion of false positives (FP)[22] or 1 minus the specificity under a varying decision threshold of classification. Thereby, the sensitivity is defined as TP/(TP + FN), and the specificity is defined as TN/(TN + FP), where FN values are false negatives and TN values are true negatives.

The optimization of each performed PLS-DA model was necessary, which means that the relevant number of PC was determined to avoid overoptimiztic modeling. This was carried out by considering (a) the gap between R^2 and Q^2, which should be as small as possible, and (b) Q^2, which should still be increasing.[29] Furthermore, for optimization, the results of a response permutation test, examined with 100 iterations and calculated by linear regression, in general, may not exceed 30% of the permuted R^2 of the random models; otherwise, overfitting of the original model was assumed.[29]

For the external validation of classification models, the OPLS-DA training models were made up of classes of equal size. At least 22 samples (two-class models) or 29 samples (four-class model) of each class were used to form representative training classes. To obtain these, the test samples were removed from the total set of class samples by a randomized selection per measuring block. This procedure was of advantage in comparison to a pure randomized selection because of the restricted number of possible iterations of the validation process. Thus, the chance of each sample to be a part of the test data was increased. At the same time, the analytical variation was considered. The variables were selected from an OPLS-DA training model to build a PLS-DA training model. The latter was optimized as described above, and the test samples were assigned to the PLS-DA training model, giving the prediction result % CC of each class. The

Table 1. Comparison of Two-Class PLS-DA Models Based on Independent Samples and Measurements (Selected Samples of Data Set 1 and Data Set 2)[a]

model	class	members (true class)	correct classification (%)	R^2 (%)	Q^2 (%)	RMSEP	selected variables (VIP > 1)	GC–MS peaks (VIP > 1)
1	Pinot	6	100	93	92	0.16	358	41
	Riesling	21	100					
2	Pinot	11	100	85	84	0.22	175	29
	Riesling	17	100

Training set of model 1: 22 samples per class (N = 44). Training set of model 2: 23 samples per class (N = 46). RMSEP = root mean square error of prediction.

procedure was repeated 3 times (two-class models) or 10 times (four-class model).

Excel (Microsoft Office, version 2010) was used for data set splitting. PCA, PLS-DA, OPLS-DA, response permutation, and VIP/variable selection were examined using SIMCA-P+ (Umetrics, version 12.01.0). ROC curve analysis was carried out with SPSS for Windows (IBM, version 12.0.2) based on the Y prediction values of the test samples assigned to the PLS-DA training models. The determination of associated signals or compounds based on mass features detected in exploratory analysis was examined by consulting the total ion chromatograms (TICs) of samples and a database match of their mass spectra with the National Institute of Standards and Technology (NIST) standard reference database (NIST, version 08).

RESULTS AND DISCUSSION

Exploratory Data Analysis. An untargeted approach was pursued for the classification of wine varietals, so that no GC peaks or mass features were *a priori* selected. Instead, the full information on 7290 scans (data set 1) was pre-processed. The time window of 10–36 min was used, and a data matrix was obtained, comprising 198 observations and the intensities of 6911 mass features for m/z 50 to 320 ($N \times M$ = 198 × 6911).

During exploratory analysis using PCA, we identified and then removed disturbing mass features. These were detected causing strikingly outer-lying samples by comparison of score plots (samples) with loading plots (variables). The TIC of samples were subsequently considered and followed by the examination of MS database match. Non-wine-related mass features comprised additional siloxane signals (m/z 73, 147, 207, 281, etc.) and m/z 205 and 220 deriving from butylhydroxytoluene (BHT), identified by standard addition. All of these mass signals are known to be frequently detected in GC–MS because they derive from common non-wine compounds widely used in technical applications.[32] Furthermore, wine-related mass features causing outer lying of samples were observed, among them the main fragments of ethyl-octanoate and ethyldecanoate. The disturbance was caused by the extreme detector saturation and the oversized width of these peaks, which could not be correctly aligned in the pre-processing step. Thus, the complete set of mass features in relation to these compounds was removed. Other observed alignment errors could be corrected by adjusting the user-defined parameters in the pre-processing step. Finally, the cleared data matrix of data set 1 was of size $N \times M$ = 198 × 5638.

The clustering ability of the data was also revealed by PCA, and the varietal classes used for classification were determined. Pinot Gris and Pinot Blanc wine samples showed identical centering and distributing tendencies and, therefore, formed a joint group "Pinot". This might be due to the fact that, from a botanical view, the two Pinot varietals are related. The similarity has been confirmed by a two-class PLS-DA model of Pinot Gris versus Pinot Blanc wine, which resulted in a model of zero PC, revealing the non-existence of a difference in variation between the two groups. Finally, the four disjoint groups Riesling, Müller-Thurgau, Silvaner, and Pinot are examined. The data display the most distinct variation between Pinot and Riesling wines. Figure 1A shows their grouping mainly along the axis of

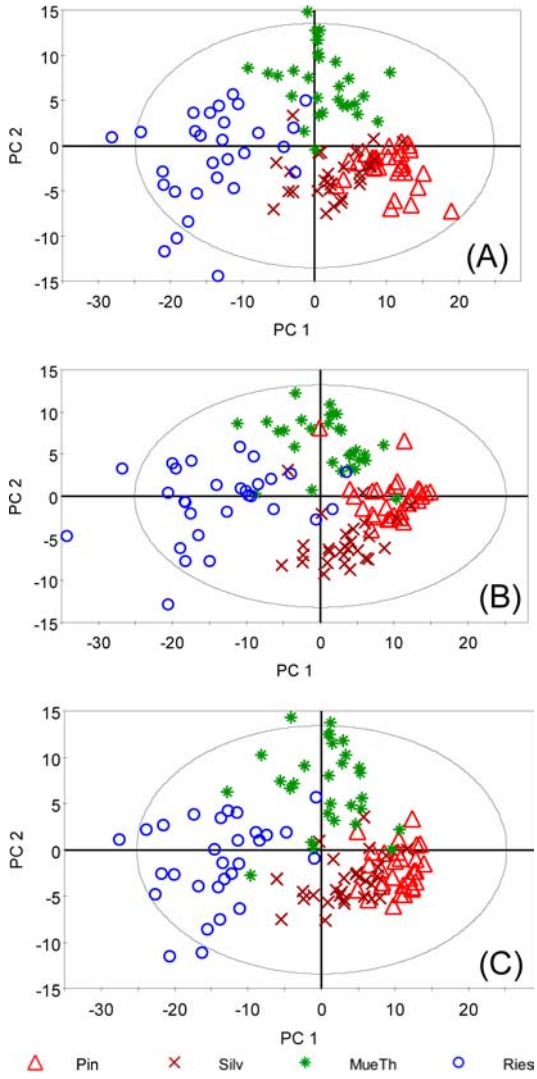

Figure 2. Score plots of example four-class PLS-DA training models (data set 1). Classification of Pinot (Pin, triangles; Pinot Gris and Pinot Blanc) versus Silvaner (Silv, crosses) versus Müller-Thurgau (MueTh, stars) versus Riesling (Ries, circles). A) Training model 2: $N \times M$ = 116 × 290, four PCs, 70.3% R^2; 65.3% Q^2. (B) Training model 7: $N \times M$ = 116 × 305, three PCs, 62.7% R^2; 57.7% Q^2. (C) Training model 10: $N \times M$ = 116 × 285, four PCs, 73.8% R^2; 66.6% Q^2.

Table 2. Test Sample Predictions to Four-Class PLS-DA Training Models (Data Set 1)[a]

class	members (true class)	correct classification (%)	Pinot (predicted)	Silvaner (predicted)	MueTh (predicted)	Riesling (predicted)	AUC
Pinot	35	91	31.8	2	1	0.2	0.97
Silvaner	15	97	0.2	14.5	0.2	0.1	0.98
MueTh	5	80	0.6	0.1	4	0.3	0.96
Riesling	27	93	0	0.8	1.2	25	0.99

[a]Classification of Riesling versus Müller-Thurgau (MueTh) versus Silvaner versus Pinot (Pinot Gris and Pinot Blanc), with correct classification and confusion matrix of the average of 10 iterations. Training data: $N \times M = 116 \times 289$ (average). Test data: $N = 82$. AUC = area under the ROC curve (average).

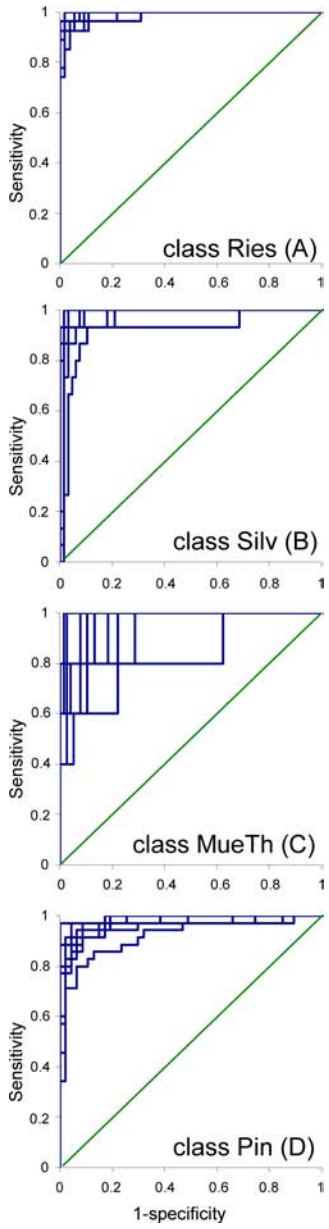

Figure 3. ROC curve analysis of four-class PLS-DA model (data set 1). Per class, all 10 ROC curves of test sample assignment to the training models are shown for classification of (A) Riesling (Ries) versus (B) Silvaner (Silv) versus (C) Müller-Thurgau (MueTh) versus (D) Pinot (Pin; Pinot Gris and Pinot Blanc).

the first PC with an explained variation of 23% $R^2(X)$. In contrast, more PCs are needed to achieve discrimination between other groups (panels B–F of Figure 1). Thus, these cases show sufficient but less variation regarding varietal differences.

Discrimination within the used sample set could not be demonstrated between the vintages 2009 and 2010, between the different quality categories, and between different German vineyard locations. A different study design might be necessary to prove any differences based on these factors. Accordingly, the found varietal classes appeared virtually homogeneous because no influence of the above factors could be detected. Therefore, multi-class varietal classification was examined on the basis of all samples. However, a few samples visually appeared slightly outside a varietal class. This was due to either natural variation or unknown reasons because no further information about samples was available.

Investigating Reliability of Classification. The two-class classification of Riesling versus Pinot using PLS-DA training models resulted in 100% CC for test samples of both classes. However, we could not be certain whether this excellent classification outcome is constant or varies depending upon other factors than the difference of the varietals. Thus, our objective was to conduct a simple approach to find out whether the classification ability was indeed of general validity.

Other factors of variation for a given method of analytics, data treatment, and statistical analysis are as follows: (a) the wine samples used, (b) the extraction by SPME, the GC separation, the MS ionization, and separation as well as detection, and finally, (c) the actual implementation of the given concept of feature extraction.

The present experiment was performed in varying all of these three factors. This comprised new samples (data set 2) measured on a second device. The obtained data were then pre-processed with newly established and appropriate parameters. Details on the MetAlign parameters applied are given with the Supporting Information. All equivalent samples of data set 1 were selected (71 samples). The proposed pre-processing and data treatment was equally applied to the two data sets (selected samples of data set 1 and data set 2). Then, PLS-DA training models based on selected variables were build. Model 1 was then related to the selected samples of data set 1, and model 2 was related to data set 2.

Table 1 shows the results of external validation for the two models. A 100% correct classification for Riesling and Pinot is always obtained, independent from the sample collection and the analytical device used. For modeling the classification question, in both cases, only one PC is necessary. The obtained difference between R^2 and Q^2 for each model was rather small, which demonstrates for both models their excellent prediction ability. However, the prediction of model 2 was based on a lower average percentage of explained variance (R^2). This could be due to a relatively higher degree of other variation sources constituting the data and the possible fact that the differences in relation to the varietals are less pronounced, respectively. Slight

differences in the data distribution of the two models could therefore be assumed. A difference in variable selections was shown in relation to the number resulting from the two data sets, which apply to a different number of peaks in the TIC. Nevertheless, both variable selections qualitatively provided a consistent prediction result. In contrast to the explained variance, the root-mean-square error of prediction (RMSEP) of the external validation is an absolute measure, with its use most suitable to compare models.[21] The average prediction error here was only slightly higher for model 2 and, on the whole, was fairly low pronounced.

Hence, such factors as samples, instrumental device, and feature extraction do not influence the classification result among Riesling and Pinot wine. The difference in the measuring results regarding the varietals was larger than the variation caused by the other factors. Therefore, a constant varietal prediction results from the proposed strategy. This suggests the applicability also to other laboratories. According to Esslinger et al., this kind of investigation is rare in the field of untargeted research but will be needed for future applications to meet control requirements.[4] When reliability is defined here as the frequency with which the classification results are within an allowable error, the experiment achieves 100% reliability for an example classification question. This is due to the fact that the two trials achieve identical results.

Multi-class Varietal Classification and Its Relevance. The present study focuses on the five most frequent German white wine varietals. These are cultivated in Germany on 77% of the white grape vineyard area (2012[33]). For classification, all samples of data set 1 were used, forming the four proposed classes. The PLS-DA training models on average were build with 289 selected variables. Three examples of score plots of the 10 training models are shown in panels A−C of Figure 2. Fairly good clustering of classes is observed. Four PCs on average were necessary to model the differences between the classes. All training models were on average explained by 70% of the variance (R^2). The goodness of prediction obtained was on average 64% (Q^2) which is a typical result achieved by metabolomics data.[29] Because the presented model additionally showed a low difference between R^2 and Q^2, its fairly good prediction ability is demonstrated.

In external validation, the test samples of Riesling, Silvaner, and Pinot classes achieved on average 91−97% CC (Table 2). We could not achieve such results for Müller-Thurgau samples. The small number of Müller-Thurgau test samples might be the reason for a less accurate classification.

Furthermore, we determined some of the substances here contributing to the classification among the four classes. This was examined considering the selected variables with occurrence in at least 8 of 10 PLS-DA training models. The concerned mass features were then related to peaks in the TIC of several example samples. Further, those were subjected to a MS database match. Identification was assumed for more than 90% compliance. It is to be noted that, from the results, no information was available on the absolute contribution of substances to the prediction because of the pretreatment applied. Further, the relation of compounds to a certain varietal class could not be revealed because of the complexity of the model. The monoterpenoids linalool, γ-terpinen*, α-terpineol*, and limonene*, the C_{13}-norisoprenoids 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN)* and vitispirane, and the esters 2-phenylethyl acetate*, methyloctanoate, and methyldecanoate were reliably identified. The marked substances (*) were additionally verified by retention time and mass spectral accordance to reference standards. These findings revealed some varietal-related compounds of monoterpenoids and C_{13}-norisoprenoids[11,34−36] contributing to the white wine classification. These are typical white-wine-related odorants.[34] For example, TDN is typical for Riesling and has a kerosene like odor.[11] Additionally, esters as alcoholic-fermentation-derived aroma compounds contributed, presumably indirectly, as previously reported, for example, regarding the classification of South African wines.[37] All of the contributing compounds were favorably extracted by the used PDMS SPME fibers. Polar compound groups, such as the aliphatic alcohols and acids, were not considered for classification because these were hardly extracted. This shows the volatiles "editing" character of the SPME technique.[1]

In the present study, a validated German white wine prediction based on untargeted data of volatile compounds is established for the first time. The most important German varieties are presented on the basis of commercial samples from all over Germany, comprising two vintages and two quality categories. Therefore, a broad variation of samples is considered. Moreover, the contributing variables are related to important odorants. It should be noted here that the developed method of data treatment, in particular, underpins the consideration of mass features with low signal-to-noise intensity in GC−MS, such as, e.g., linalool. Therefore, also compounds of low sensory threshold are considered for classification. On the whole, the significant relevance of the analytical method and data treatment for white wine is shown. Because the method also shows its ability to achieve reliable results, it is therefore highly adequate for German white wine varietal classification. The untargeted HS−SPME−GC−MS approach might be therefore considered along with other methods, which are used for verifying the botanical origin of white wine varietals, such as the determination of shikimic acid concentration or the application of NMR, to discriminate among a higher number of varietals. Godelmann et al.[38] successfully classified German white wine according to the botanical origin using untargeted NMR data. However, the NMR study equally joined Pinot Gris and Pinot Blanc samples for varietal classification because of their similarity. Therefore, further research on Pinot Gris and Pinot Blanc wine discrimination is of interest. Moreover, the current study could be extended regarding the number of Müller-Thurgau samples. To additionally meet the requirements of the global market, the extension to internationally cultivated white wine varietals would be useful.

Performance of Classification. The correct classification rate (% CC) is widely used to express the results of a classification model. However, this depends upon not only the model but also the decision that a sample belong to a certain class and not to the other nearest or overlapping class. Thus, the % CC normally does not give the full information about a class. ROC curve analysis overcomes the predefinition of a decision rule and visualizes the full performance of a class under varying thresholds. The area under the ROC curve (AUC) additionally gives a value to assess the classification quality of a class. Very good classification performance is discussed to be achieved for an AUC value of above 0.9 and good performance for a value of at least 0.8.[24] An AUC value of 0.5 indicates a full lack of discriminative power.

Thus, the here obtained model achieves very good performance for all classes. The AUC of all classes was above

0.95 (Table 2). However, to observe the differences of the classes in detail, we assessed the performance of each class by the shape of the curves. In a class with a high prediction performance, the ROC curve first rises vertically from the point (0/0) and then abruptly changes direction and continues horizontally toward the point (1/1). In cases of a lower predictive ability, the curve is flattened toward the diagonal line. This line represents pure random prediction. To compare the class performance, ROC curves of the 10 PLS-DA test data predictions were displayed overlapped per class (panels A–D of Figure 3).

First, of all classes, the Riesling class (Figure 3A) shows the best classification performance because all curves are close to the top left corner. In contrast, some of the Müller-Thurgau class curves (Figure 3C) are mostly flattened against the diagonal line and, therefore, show the lowest overall classification performance. This again could be due to a low test sample number. It can be seen that the height of a step in a curve is in relation to the sample number of the class. Furthermore, the Pinot and Silvaner classes show more cases of curves that are lowered at the horizontal part (panels B and D of Figure 3), meaning observed high FP rates.

These results of ROC curve analysis give a comprehensive impression of a class. For example, when considering a possible low FP rate, the Riesling class turns out to be the least sensitive because the test samples showed the maximum of about 30% FP. In contrast, the Pinot class proves to be the most sensitive class because up to about 90% FP was observed. Additionally, this technique could be of interest for future investigations, adjusting a model, for example, in relation to the requirement of a low outcome of FP.

[a]Phosphorylations are indicated after the peptide. [b]Q value was calculated according to Ney (1971) in cal mol^{-1}. Presence of peptides at different storage times is indicated by 'x'.

this time more than 90% of α- and β-CNs were hydrolyzed. The relatively low degree of β-lg denaturation in the UHT milk of 36.7 ± 3.2% indicated that the age gelation may be caused by a different mechanism than complexation of κ-CN with denatured β-lg. At this level of β-lg denaturation, only a very limited fraction of β-lg is associated with κ-CN.[22,23]

The aim of the present study was to analyze the peptide formation and specificity of PL in this UHT milk and to relate the peptides found with the previously observed bitter off-flavor and age gelation of the UHT milk during storage.

MATERIALS AND METHODS

Milk Processing. Three batches of 1 day old pasteurized (72 °C for 15 s) and homogenized milk (1.5% fat) were obtained from Arla Foods Stockholm Dairy (Sweden) during three consecutive weeks. The milk was preheat treated at 74 °C for 180 s in a tubular heat exchanger before being subjected to a direct steam infusion heat treatment at >150 °C for <0.2 s (UHT pilot plant, APV/SPX, Silkeborg, Denmark). After flash cooling to 67 °C, the milk was homogenized (pressure 160/40 bar), further cooled to 20 °C, and packed aseptically in 300 mL glass bottles. The UHT milk was stored in the dark at 20 °C in a climate chamber for 14 weeks. One bottle was used once every week of the storage period for analysis. The sterility of each batch of processed milk was tested according to ISO 4833.[24]

Sample Preparation. A volume of 15 mL of milk was taken from each bottle and adjusted to pH 4.6 with 1 M HCl followed by centrifugation at 11000*g* for 10 min at 4 °C. The clear supernatant was recovered and stored at −20 °C until further analysis. At the time of analysis, the samples were thawed for 60 min at room temperature. One mL of the sample was centrifuged at 13200*g* at 5 °C for 10 min and used for the analysis. Sample preparation was performed in duplicate.

Peptide Analysis. Ultra-high-performance liquid chromatography (uHPLC) was performed on an Agilent 1290 Infinity uHPLC (Agilent Technologies, Santa Clara, CA, USA) coupled to a quadrupole-time-of-flight mass spectrometer (Q-TOF MS, Agilent 6530 Accurate Mass Q-TOF LC/MS, Agilent Technologies) with a Jetstream interface.

Depending on the peptide concentration, 10 or 20 μL of the sample was injected to the uHPLC-Q-TOF-MS system. The column was an Xbridge BEH 300 (rp-C_{18}, 3.5 μm 2.1 mm × 250 mm) (Waters, Milford, MA, USA) operated at 45 °C. Buffer A was Milli-Q water with 0.05% trifluoroacetic acid (TFA) (v/v and buffer B acetonitrile with 0.1% (v/v) TFA. A linear gradient was applied with 100% buffer A from 3 min, 100% to 45% buffer A at 45 min at a flow rate of 0.3 mL min^{-1}. Peptides were monitored at 214 nm.

The Q-TOF MS was run in 4 GHz high resolution mode. The Jetstream interface added a sheath gas at 350 °C with a flow of 8 L min^{-1}. A nozzle voltage of 100 V was applied to improve the ionization. The drying gas temperature was set to 325 °C at a flow rate of 10 L min^{-1}. The capillary voltage was set to 2.5 kV in the first time segment (3.0−24.0 min) and to 4.0 kV in the second time segment (24.0−35.2 min) to achieve optimal ionization for both small and large peptides. Spectra in the mass range from 300 to 3200 m/z were recorded in positive mode with a resolution of 20000 in the Q-TOF. Tandem mass spectra of the two most abundant ions with a charge state of 1, 2, or 3 in each MS spectrum were obtained in collision-induced dissociation (CID) mode (collision gas nitrogen, isolation width 1.3 m/z (narrow) at 5 different fixed collision energies and flexible collision energies optimized for larger peptides. The fixed collision energies were 10, 20, 30, 50, and 100 V, and the flexible energy settings were based on charge state and m/z (singly charged: offset 18 V, slope 3 V m/z^{-1}; doubly charged: offset 2 V, slope 2.2 V m/z^{-1}; triply charged: offset 3.5 V, slope 1.5 V m/z^{-1}). Mass spectra and UV chromatograms were analyzed by MassHunter software (version B 6.01, Agilent Technologies).The MS spectra were investigated for potential peptides formed by plasmin, which were not identified by MS/MS, using the "Find by Formula" feature in MassHunter. Matching ions and isotopic patterns were further evaluated with regard to their retention time.

Database Search. The obtained tandem mass spectra were analyzed with Mascot v2.4 (Matrix Science, London, UK). Tandem mass spectra were searched against a custom database containing

known genetic and PTM (post translation modification) variants of major milk proteins. The following search parameters were applied: protease: unspecific; mass tolerance for precursor ions 15 ppm and 0.6 Da for product ions; variable modifications: phosphorylations serine, oxidation methionine. Only identified peptides (expect score <0.05) that were present in at least two of the three replicates were considered.

Relative Quantification of Identified Peptides. Peaks in the UV chromatogram were identified by their corresponding MS spectra and retention time of the identified peptides by MS/MS. The retention time shift between the UV and MS signal was approximately 0.25 min. Only peaks without or with only minor overlaps with other components in the MS spectra were considered. In order to compare the rate of peptide formation, the integrated UV peak area was divided by a calculated molar extinction coefficient (ε) for the peptide as described previously.[25] Phosphorylation of serine was not taken into account. Peak areas were further normalized for the initial casein distribution to correct for the differences in peptide concentration. The casein composition was based on the UV peak area corrected for the calculated ε (α_{S1}-CN: 30%, α_{S2}-CN: 13%, β-CN: 44%, κ-CN: 13%). Calculated ε in M^{-1} cm^{-1} were 346843 (α_{S1}-CN), 375032 (α_{S2}-CN), 331417 (β-CN) and 279859 (κ-CN).

Assessment of Bitterness. Bitterness of peptides was evaluated by applying Ney's Q-rule based on peptide hydrophobicity.[26] An average hydrophobicity Q of the peptide is calculated as the sum of the amino acids side chains hydrophobicity divided by the number of amino acid residues of the peptide. Peptides with a Q value >1400 cal/res^{-1} are considered bitter

RESULTS AND DISCUSSION

A total of 84 different casein-derived peptides were identified by the uHPLC-Q-TOF analysis (Tables 1−4). In the 1 day old milk (analyzed 1 day after processing), only 11 peptides could be identified by MS/MS. This number is small compared to other recent studies, which used more profound peptide extraction and concentration methods.[18,19] The main objective in this study, however, was to study the proteolysis and development of peptides during storage rather than the peptide profile of the milk used for the UHT treatment. The majority by number of the peptides identified were derived from α_{S2}-CN (36 peptides), followed by α_{S1}-CN (31) and β-CN (17). During the entire storage period, no peptides derived from κ-CN were detected, indicating that indigenous proteases other than PL, such as cathepsin D, were probably heat inactivated as could be expected due to their lower heat stability compared with PL and also that the raw material had not contained heat stable proteases from psychotrophic bacteria, which are known to be able to hydrolyze κ-CN.[27,28] More than 75% of the peptides (66 peptides out of 79) could be assigned to be the result of PL action solely (Table 4). In the remaining 18 identified peptides, PL was responsible for either the N- or C-terminal cleavage in 11 of the 18 identified peptides.

Identified Peptides Formed by Plasmin. Identified peptides derived from α_{S1}-CN and the storage time of their appearance is shown in Table 1. The position of the peptides within in the α_{S1}-CN sequence is shown in Figure 1. The only peptide present after 1 day of storage was α_{S1}-CN f(80−90), suggesting Lys_{79}-His_{80} and Arg_{90}-Tyr_{91} to be the initial sites cleaved by PL. After 4 weeks of storage, the peptides identified originated from the N-terminal region of α_{S1}-CN (Arg_{22}-Phe_{23} and Lys_7-His_8), from the central, lysine-rich region (Lys_{102}-Lys_{103}, Lys_{103}-Tyr_{104}, Lys_{105}-Val_{106}, and Lys_{124}-Glu_{125}) as well as the C-terminal end with cleavage at Lys_{193}-Thr_{194}. The peptides α_{S1}-CN f(91−102), α_{S1}-CN f(91−103), and α_{S1}-CN f(91−105) were not identified until after 8 or 14 weeks of storage,

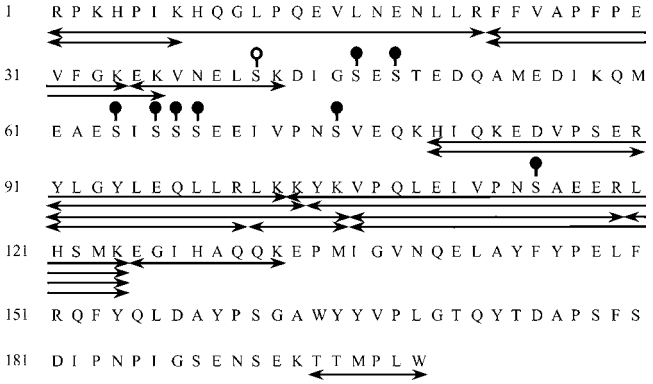

Figure 1. Primary structure of bovine α_{S1}-CN B-8P. Phosphoserine residues are indicated by circles. Open circle indicates a possible phosphorylation at Ser_{41}. Identified pH 4.6 soluble peptides formed by plasmin during storage at 20 °C are indicated by arrows.

indicating that Lys_{79}-His_{80} and Lys_{124}-Glu125 are the two major cleavage sites in the central region of α_{S1}-CN. The peptides α_{S1}-CN f(23−34), α_{S1}-CN f(23−36), and α_{S1}-CN f(35−42) appeared after 4−8 weeks of storage. This implies a sequential cleavage of the N-terminal region of α_{S1}-CN by PL beginning at Arg_{22}-Phe_{23} and subsequently Lys_{34}-Glu_{35} and Lys_{36}-Val_{37}. Peptides containing these cleavage sites Arg_{100}-Leu_{101}, Arg_{119}-Leu_{120}, and Lys_{132}-Glu_{133} occur only after 8 or 14 weeks of storage and seem not to be preferred by PL. The late or slow cleavage at these positions is most likely due to the preference of PL for cleaving after lysine rather than after arginine[29] and their close proximity to the major cleavage sites makes a further hydrolysis in the vicinity unlikely.

The identified cleavage sites of PL and the order of occurrence are in good agreement with previous studies using purified α_{S1}-CN[17,29] with the exception of the cleavage sites at Arg_{151}-Gln_{152}, a proposed major cleavage site by McSweeney et al.,[17] and at Lys_{58}-Gln_{59}. Relevant peptides and polypeptides containing the cleavage site Arg_{151}-Gln_{152} (α_{S1}-CN f(125−151), α_{S1}-CN f(133−151), α_{S1}-CN f(106−151), and α_{S1}-CN f(152−199)) were not detected. The cleavage site Arg_{151}-Gln_{152} is located in middle of the most hydrophobic region of α_{S1}-CN (Figure 4A), which has been identified as the main polymerization and interaction region of α_{S1}-CN via hydrophobic interactions.[30] In contrast to purified α_{S1}-CN, this region is likely to be inaccessible for PL and Arg_{151}-Gln_{152} and was also not hydrolyzed by trypsin in a micellar system.[31,32] The second not-present cleavage site, Lys_{58}-Gln_{59}, is placed between the two phosphoserine clusters of α_{S1}-CN (residues 41−51 and 61−70). The phosphoserine residues tightly bind to the calcium phosphate clusters in the casein micelle, which makes this region inaccessible for enzymatic hydrolysis.[31,33]

The largest numbers of peptides present as a result of PL activity derives from α_{S2}-CN (Table 2). After 1 day of storage, peptides originating from the N- and C-terminal region of α_{S2}-CN were present (Figure 2). The C-terminal region of α_{S2}-CN has previously been shown to be exposed and easily accessible for hydrolysis,[34] and the appearance of α_{S2}-CN f(182−188) and α_{S2}-CN f(174−181) after 4 weeks of storage suggests a sequential hydrolysis of the C-terminal region. Initial cleavage sites are Lys_{197}-Thr_{198} and Lys_{188}-Ala_{189}, followed by Lys_{181}-Thr_{182} and Lys_{173}-Phe_{174}. After the same storage time, peptides originating from the central region of α_{S2}-CN were formed by hydrolysis of Arg_{114}-Asn_{115}, Lys_{136}-Lys_{137}, Lys_{137}-Thr_{138}, Lys_{149}-

[a]Phosphorylations are indicated after the peptide. [b]Q value was calculated according to Ney (1971) in cal mol^{-1}. [c]Peptide was identified by MS only. [d]Intramolecular disulfide bond. Presence of peptides at different storage times is indicated by 'x'.

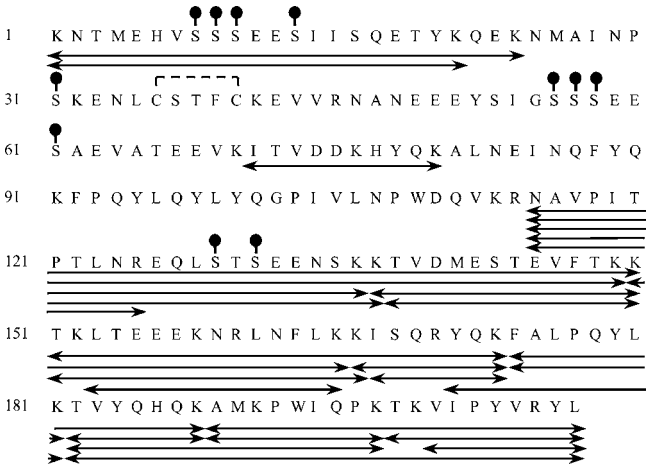

Figure 2. Primary structure of bovine α_{S2}-CN A-11P. Phosphoserine residues are indicated by circles. The dotted line between Cys_{36} and Cys_{40} indicates the intramolecular disulfide bridge. Identified pH 4.6 soluble peptides formed by plasmin during storage at 20 °C are indicated by arrows.

Lys_{150}, and Lys_{150}-Thr_{151}. Earlier studies suggest that the cleavage sites Lys_{149}-Lys_{150} and Lys_{150}-Thr_{151} are preferred over Arg_{114}-Asn115,[16] but the simultaneous appearance of α_{S2}-CN f(115−136), α_{S2}-CN f(137−149), and α_{S2}-CN f(138−150) indicate that PL readily hydrolyzed all of these cleavage sites. After 8 weeks of storage peptides originating from the region 151−173 in α_{S2}-CN were identified. The late appearance of these peptides indicates a sequential hydrolysis of this region from an N- and C-terminal direction after the preferred cleavage sites Lys_{150}-Thr_{151} and Lys_{173}-Phe_{174} are hydrolyzed. The least preferred cleavage sites in α_{S2}-CN seem to be Arg_{125}-Glu_{126} and Lys_{152}-Leu_{153}, which are either in close proximity to phosphoserine residues or to major cleavage sites (Figure 2). Although the region 25−114 contains eight potential cleavage sites for PL, only α_{S2}-CN f(71−80) and α_{S2}-CN f(25−45) could be identified. Masses corresponding to peptides including the cleavage site Lys_{91}-Phe_{92}, Lys_{32}-Glu_{33}, and Lys_{41}-Glu_{42} were not present in the milk. The not-present cleavage at Lys_{91}-Phe_{92} is located in a hydrophobic region of α_{S2}-CN (Figure 4B), which may be inaccessible for enzymatic hydrolysis.[35] Cleavage of this bond can be additionally hindered by Pro_{93} which induces a change in the secondary structure of α_{S2}-CN.[35] Lys_{32}-Glu_{33} and Lys_{41}-Glu_{42} are located in the proximity of the two

cysteine residues of α_{S2}-CN. The majority of the α_{S2}-CN molecules is present in a form with an intramolecular disulfide bond, which induces a tight loop in the protein[34,36] which may limit the accessibility of Lys_{41}-Glu_{42} and Lys_{32}-Glu_{33} for PL. To our knowledge, the cleavage of Arg_{45}-Asn_{46}, Lys_{70}-Ile_{71}, Lys_{80}-Ile_{81}, Arg_{125}-Glu_{126}, Lys_{166}-Ile_{167}, and Arg_{205}-Tyr_{206} has not been reported earlier for PL in either model studies or as part of the indigenous peptide profile in milk. This could be attributed to the low concentration of α_{S2}-CN in milk or a different conformation of α_{S2}-CN in model systems.[31,35]

In comparison to α_{S2}-CN, only a relatively small number of peptides was identified derived from β-CN (Table 3). The peptides β-CN f(1−28), β-CN f(1−29), β-CN f(29−48), and β-CN f(98−107) were present in the milk after 1 day of storage. After 4 weeks of storage, all the observed peptides except β-CN f(33−48) and β-CN f(1−25) were present. The identified peptides mainly derived from cleavage around the two major cleavage sites of PL in β-CN, Lys_{105}-His_{106}, and Lys_{107}-Glu_{108} (Figure 3). The peptide β-CN f(170−176) was the only identified peptide originating from the hydrophobic C-terminal part of β-CN and in contrast to earlier studies using trypsin,[31,37] no peptides were identified from hydrolysis of Arg_{183}-Asp_{184} and Arg_{202}-Gly_{203}.

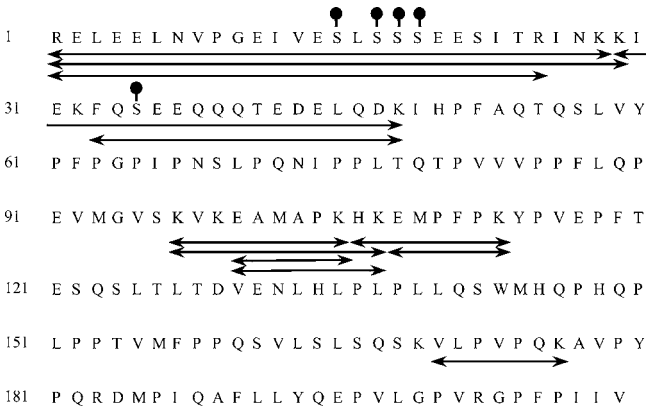

Figure 3. Primary structure of bovine β-CN A^2-5P. Phosphoserine residues are indicated by circles. Identified pH 4.6 soluble peptides formed by plasmin during storage at 20 °C are indicated by arrows.

Peptides Formed by Other Proteases. Peptides that were identified in the UHT milk samples and which cannot be assigned to be a result of PL activity alone are summarized in Table 4. Most peptides deriving from α_{S1}-CN or β-CN indicate activity of cathepsins alone or in combination with PL.[28,38,39] Peptides formed by cathepsins alone were identified after 1 day of storage or after 4 weeks of storage in the case of α_{S1}-CN f(1−14). Peptides formed by the combined activity of cathepsins and PL on the other hand appear after 4−8 weeks of storage. This indicates that cathepsins were active in the raw or pasteurized milk, but inactivated by the UHT treatment and that the polypeptides formed by cathepsins were further hydrolyzed by residual PL to smaller peptides. With the exception of cathepsin D, the heat stability of cathepsins is largely unknown. Although cathepsin D in its active form can partially survive HTST pasteurization,[40] it is unlikely that sufficient active cathepsins are present after the UHT treatment to significantly contribute to the observed proteolysis. The peptides deriving from α_{S2}-CN originate from the C-terminal of the protein. With the exception of α_{S2}-CN f(201−206), the peptides contained the PL cleavage site Lys_{197}-Thr_{198}. The apparently unspecific C-terminal cleavage site of the peptides suggests activity of carboxypeptidases in the raw milk or heat-induced hydrolysis.[41,42]

Peptide Development during Storage. The presence of identified peptides after different storage periods gives a good indication of preferred and uncleaved cleavage sites of PL in the UHT milk system, but only gives limited information on the actual concentration and development of the peptides. Semiquantitative analysis of the peptides using MS spectra was not possible because their response factors are unknown and their intensity might be affected by ion suppression of coeluting components. The UV chromatograms at 214 nm were therefore used for a relative quantification and comparison of the peptides. Due to substantial overlap of large areas in the chromatogram, only a limited number of peaks could be used for such relative quantification. Quantified peptides included α_{S1}-CN f(1−22), α_{S1}-CN f(106−124), α_{S2}-CN f(1−21), α_{S2}-CN f(1−24), α_{S2}-CN f(115−150), as well as β-CN f(1−28) and β-CN f(29−48). A comparison of the UV peaks and the extracted ion chromatograms are shown in the Supporting Information together with MS spectra of the peaks.

[a]Q value was calculated according to Ney (1971) in cal mol^{-1}. [b]Possible responsible proteases for N- and C-terminal cleavage are indicated: CB, cathepsin B; CD, cathepsin D; CG, cathepsin G; PL, plasmin; CP, carboxypeptidase; −, no cleavage; ?, unknown protease. Presence of peptides at different storage times is indicated by 'x'.

A comparison of peptides originating from the N-terminus of their parent proteins is shown in Figure 5. The peptide β-CN f(1−28) had the highest formation rate. During the first 4−5 weeks of storage, the relative concentration increased exponentially, reflecting the previously described increase in PL activity and rate of peptide formation. From 5 weeks of storage and further on, the relative concentration of β-CN f(1−28) increased almost linearly and then leveled out after 12 weeks of storage. The decrease in the rate of formation could be linked to changes in the matrix induced by the starting gelation of the milk after 11 weeks of storage. Further degradation of β-CN f(1−28) to β-CN f(1−25) may also reduce the concentration. Since the proteose peptones β-CN f(1−105) and β-CN f(1−107) were still present after 14 weeks of storage (data not shown), substrate depletion can be excluded as a cause for the reduced rate of formation. The peptide α_{S2}-CN f(1−24) showed the same initial rate of formation as β-CN f(1−28) and leveled off after 6 weeks of storage. The peptide α_{S2}-CN f(1−21) exhibited a lower rate of formation than α_{S2}-CN f(1−24), but in contrast to α_{S2}-CN f(1−24), continued to increase after 6 weeks of storage. This indicates a hydrolysis of α_{S2}-CN f(1−24) to α_{S2}-CN f(1−21) that may be caused by substrate depletion of the cleavage site Lys_{24}-Asn_{25}. The development of α_{S1}-CN f(1−22) differed from the other N-terminal peptides. The initial lag phase was not observable for α_{S1}-CN f(1−22), and the overall concentration was significantly lower compared to that of the N-terminal peptides derived from α_{S2}- and β-CN. The cleavage sites for these peptides in α_{S2}- and β-CN are in very hydrophilic domains of the proteins (Figure 4 A−C), while the cleavage site Arg_{22}-Phe_{23} in α_{S1}-CN is in a hydrophobic domain involved in casein−casein interactions.[43]

Peptides being present as the result of two proteolytic cleavages are shown in Figure 6. They exhibited an extended lag phase compared to the N-terminal peptides, due to the time needed to form their precursors. As discussed above, α_{S2}-CN f(115−150) originates from two of the most preferred cleavage sites in α_{S2}-CN and showed the highest formation rate. The peptide α_{S1}-CN f(106−124) developed almost in the same manner as α_{S1}-CN f(1−22) within the first 6 weeks of storage but showed a higher rate of formation from 7 weeks of storage on. These findings further highlight the preference of PL for cleavage sites located in the hydrophilic regions of the caseins. Gagnaire et al. (1998) found that the proteose peptones β-CN f(1−105/7) were retained in the casein micelle, while β-CN f(29−105/7) was released into the serum phase.[31] This release limits further hydrolysis of these proteose peptones by the casein-associated PL, which explains why β-CN f(29−48) was only formed in very small amounts.

Destabilization of Casein Micelles by Proteolysis. PL enters the milk from the blood[44] and associates itself with the casein micelle.[45] Whether PL is able to enter the micellar structure or is located entirely on the surface of the casein micelle is unknown. It becomes obvious from Figure 3 that the majority of the major cleavage sites of PL within the caseins, similar to those of trypsin,[31,32] are located at the most hydrophilic and serum-exposed regions of the proteins. β-CN is mainly present in the interior of the casein micelle[46] and is proposed to stabilize water or serum channels within the casein micelle.[47,48] α_{S2}-CN is involved in the binding to calcium phosphate clusters, regions that are hypothesized to be surrounded by hydrophobic domains[11] and likely to be inaccessible for PL. The rapid cleavage, within 4 weeks of storage, of the N-terminal regions of β-CN and α_{S2}-CN implies that PL is able to penetrate the casein micelle. In relation to a destabilization of the casein micelle by proteolysis, it is notable that the minor cleavage sites, together with some of the major cleavage sites, are located at the boundary between hydrophilic, hydrophobic, or phosphorylated regions of the caseins (Figure 4A−C). Thus, PL hydrolyses around the regions essential for the internal integrity and stabilization of the casein micelle, i.e. hydrophobic interaction between caseins, interactions of

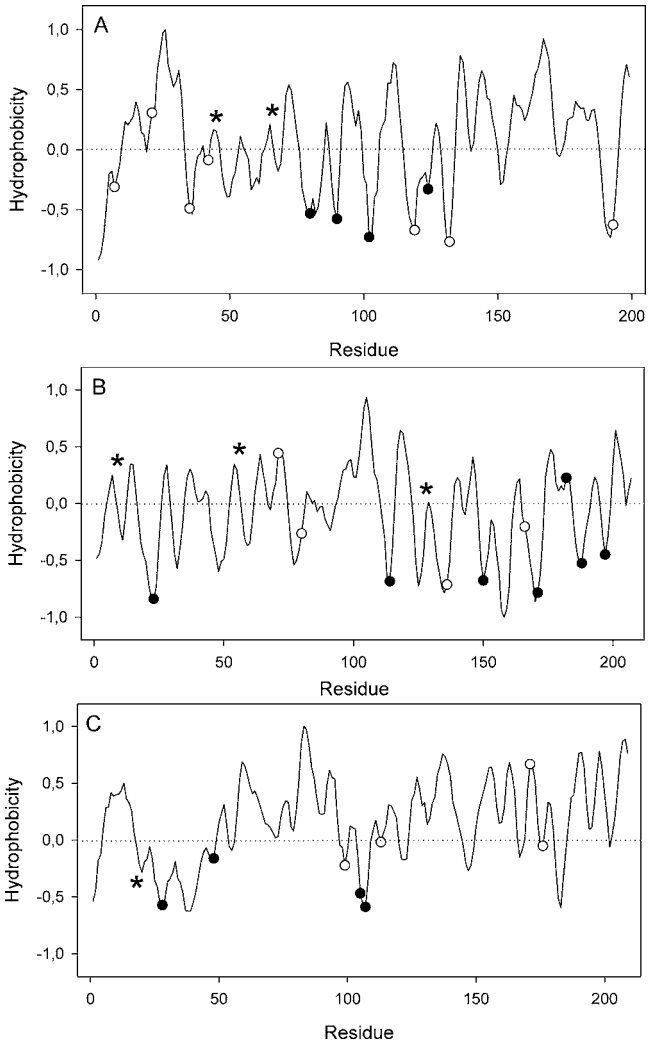

Figure 4. Hydrophobicity distribution in α_{S1}-CN (A), α_{S2}-CN (B), and β-CN (C) with major (●) and minor (○) cleavage sites of plasmin and phosphoserine clusters (*). Classification of major and minor cleavage sites is based on Tables 1−3. Hydrophobicity was calculated according to Tanford (1962) using an average of seven amino acids with a relative weight for the amino acid center being one and 0.75, 0.5, and 0.25 for the amino acids one, two, or three positions from the center amino acid. Positive values indicate hydrophobic and negative values, hydrophilic regions.

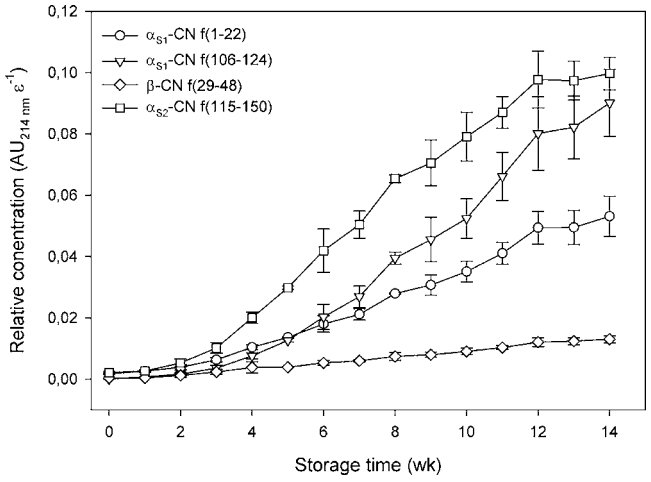

Figure 5. Development of casein-derived N-terminal peptides formed by plasmin in milk preheat treated at 72 °C for 180 s and subjected to direct steam infusion (>150 °C for <0.2 s) during storage at 20 °C. Relative concentration is based on peak area of UV absorbance at 214 nm corrected for the peptides theoretical molar extinction at 214 nm. Peptide concentration is normalized for α_{S2}-CN.

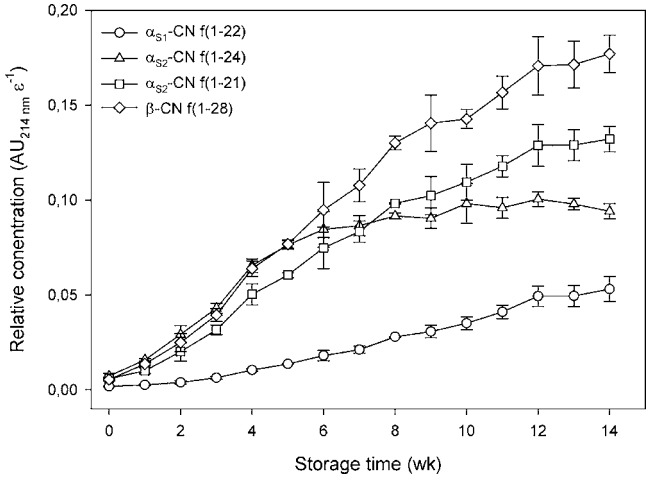

Figure 6. Development of casein-derived peptides formed by plasmin in milk preheat treated at 72 °C for 180 s and subjected to direct steam infusion (>150 °C for <0.2 s) during storage at 20 °C. caseins with calcium phosphate, and ionic or salt interactions between caseins. Cleavage of these regions in the casein micelle would lead to a loosening of the micelle structure, which correlates with the reported increase in micelle size after incubation with PL.[49] A looser structure is hypothesized to allow PL to reach previously inaccessible regions, which can explain the initial resistance of α_{S1}-CN to hydrolysis.

Age gelation of UHT milk has been proposed to be a two-stage process of proteolysis and physicochemical changes that lead to the gelation.[50] Proteolysis-induced age gelation of UHT milk by PL which does not involve the κ-CN−β-lg -complex, could occur after a critical number of the casein−casein and casein−calcium phosphate interaction sites have been hydrolyzed and the remaining interactions are not sufficient to maintain a micellar arrangement. While at the point of gelation, more than 95% of the α_S- and β-CN were hydrolyzed,[1] the peptide development showed that far from all cleavage sites were hydrolyzed completely. This indicates that a large number of amphiphilic and charged polypeptides were present in the milk system that could form and stabilize a gel network. While some proteolysis is needed for gelation, the extent of proteolysis has not yet been related with gelation. The lack of consistency in degree of proteolysis in relation to age gelation and PL activity described in previous studies could also be attributed to differences in processing conditions and levels of PL activity (direct or indirect UHT treatments, addition of PL to UHT milk).[2,50−53] Different processing conditions can greatly affect the protein matrix in milk, such as the degree of whey protein denaturation on casein micelles,[22] thereby influencing the substrate accessibility and the proteolytic pattern of PL in milk. A high PL activity could result in a fast breakdown of polypeptides to small peptides, which are unable to form a gel. Our results suggest that the proteolytic

pathway of caseins by PL is more important for the destabilization of the casein micelles than the overall decrease in the level of intact caseins.

Potential Bitter Peptides. Potential bitter peptides with a Q value >1400 cal mol^{-1} are highlighted in Table 1−4. Bitterness of peptides from β-CN was found in the γ-CN fraction after hydrolysis with PL,[3] and analysis of tryptic digests of β-CN have shown that β-CN f(203−209) is extremely bitter.[37] The potential bitter peptides found in the present study were β-CN f(108−113) and β-CN f(170−176), which have previously been described sensorially as tickling and burning.[37] The bitter peptide β-CN f(203−209) was not identified in the UHT milk or was only present in a very low concentration. Previously described bitter peptides deriving from α_{S1}-CN, that can be formed by PL, are α_{S1}-CN f(23−34) and α_{S1}-CN f(91−100).[54,55] Besides α_{S1}-CN f(91−100), all peptides from residue 91 to 100−105 found in the milk had Q values >1400, and were potentially bitter. The smaller peptides α_{S1}-CN f(1−7) and α_{S1}-CN f(194−199) were highly hydrophobic, and could have contributed to bitterness. The peptides α_{S2}-CN f(182−207), α_{S2}-CN f(189−207), and α_{S2}-CN f(198−207) have been correlated with bitterness and were also present early in the storage period in the UHT milk.[16] Besides α_{S2}-CN f(182−188), all peptides deriving from the C-terminal region of α_{S2}-CN from residue 171 and onward are potentially bitter. Cleavage of Arg_{205}-Tyr_{206} in α_{S2}-CN gives rise to the bitter dipeptide Tyr-Leu.[56] The identified potential bitter peptides indicate that the bitterness caused by PL might mainly be caused by hydrolysis of α_{S1}- and α_{S2}-CN, rather than β-CN as previously reported.[3] Several peptides formed by the combined action of PL and cathepsins were potentially bitter as well. Most of these peptides derive from the N-terminal region of α_{S1}-CN and the C-terminal region of α_{S2}-CN.

A bitter off-flavor was detected in the milk after 6 weeks of storage, which intensified rapidly within 1 week of storage.[1] The concentration and sensory thresholds of the potential bitter peptides in the UHT milk are unknown, and the bitterness cannot be attributed to a specific peptide. We suggest that either the overall concentration of bitter peptides reached the sensory threshold after 7 weeks of storage or that one or several bitter peptides with a lower sensory threshold were formed very rapidly in the storage period between 5 and 7 weeks. Similar to trypsin, PL has the capability to form a range of potential bitter peptides, but further studies are necessary to confirm the bitterness of these peptides and their sensory threshold.

In conclusion, the special UHT process used allowed the investigation of specificity and effect of PL in a sterile milk system, without causing substantial changes to the milk by the heat treatment. PL showed a different specificity in the milk system compared to previous model studies, and 6 new cleavage sites of PL in α_{S2}-CN could be identified. The relative quantification of peptides and time of their appearance allowed a direct comparison of formation rates of peptides to assess the affinity of plasmin to certain cleavage sites. We could show that PL is able to produce potentially bitter peptides and bitterness was most likely caused by peptides arising from α_{S1}- and α_{S2}-CN. The observed proteolytic pattern indicated that PL-mediated proteolysis can destabilize the casein micelle and explain proteolysis-induced age gelation of milk.

those measurements, we propose a toxicokinetic model for the absorption, distribution, and excretion of seven PFAAs in pigs. The behavior of PFAAs in pigs is also of interest because pigs are touted a biomedical model[26] of human physiology. Additionally, understanding the toxicokinetics in domestic pigs may help relate the body burden of wild boars (a related subspecies) to the environmental ubiquity of PFAAs. Our main focus is understanding PFAA kinetics from feed to porcine livestock and food products for consumer risk assessment and protection.

MATERIALS AND METHODS

Chemicals. Native and ^{13}C-labeled PFAAs were purchased from Wellington Laboratories, Guelph, ON, Canada. Methanol absolute, acetonitrile, formic acid (99%), and ammonium acetate (all ULC-MS) were purchased from Biosolve, Valkenswaard, The Netherlands. Sodium acetate anhydrous (p.a.), potassium hydroxide (p.a.), ammonia (25% p.a.), and acetic acid (100% p.a.) were obtained from Merck, Darmstadt, Germany. Pepsine (from porcine gastric mucosa), Lipase Type VII (L 1754), and Protease Type XIV (P 5147) were purchased from Sigma-Aldrich, Steinheim, Germany. Glycerol (99%) was obtained from ACROS Organics, Geel, Belgium. Water was double distilled using distillation unit 2001/2 of the Gesellschaft für Lebensmittel-Forschung.

Animals, Housing, and Feeding. Three groups of fattening pigs (German Landrace breed) consisting of 10 gilts (female pigs), 10 barrows (castrated male pigs), and 10 young boars (uncastrated prepubescent male pigs) were purchased from a commercial breeding farm (Agrargenossenschaft Groß Machnow, Germany) and transported to the experimental station of the Federal Institute for Risk Assessment (BfR). The animal experiment was authorized by the Landesamt für Gesundheit and Soziales in Berlin with approval G0043/10, complying with the German Animal Welfare Act (Tierschutzgesetz) and supervised by the BfR institutional animal welfare officer. The fattening pigs with initial body weight (BW) of 83 ± 12 kg (mean ± sample standard deviation) were separately housed in pens of eight experimental animals and two control animals with free access to water and restrictive feeding (2 kg/day and animal). Room temperature was 21 °C, and humidity was kept constant at approximately 68% throughout the entire feeding study. Health status of the fattening pigs was checked daily. The BW of each animal was recorded once a week. Upon arrival, all fattening pigs received a commercial cereal-based nonpelleted feed for 14 days, which was gradually exchanged during the first 7 days for the pelleted control diet with approximately 17% hay (adaption period). After the adaption period, fattening pigs were fed either PFAA-contaminated feed (3 × 8 experimental animals) or PFAA-free feed (3 × 2 control animals) for 21 days. Discussions refer to experimental animals, except where control animals are explicitly mentioned.

Contaminated Feed Cultivation and Preparation. PFAA-contaminated hay and barley were cultivated and harvested from a PFAA-contaminated region in Lower Saxony, Germany. The agricultural patch was polluted from the use of a soil improver provided by a recycling company that laced it with industrial waste containing high concentrations of PFAS.[27] To counteract an uneven contaminant distribution in the soil, the final feed was homogenized. PFAA-contaminated barley and hay used for the PFAA feed were determined to be substantially equivalent to PFAA-free varieties of barley and hay with regard to nutritional value. The control feed and the PFAA feed fulfilled the recommendations for nutrient and energy requirements of fattening pigs of the Society of Nutrition Physiology (GfE).[28] Nutrition data are shown in the Supporting Information (Table S1).

Sampling of Feed, Tissues, and Excretions. For PFAA analysis in feed, pooled samples were taken to obtain five representative feed samples for each week (2 weeks of adaption, 3 weeks of experimental feeding). Samples of blood plasma were taken of each experimental animal toward the end of the adaption period (day −4), twice a week during PFAA feeding (days 4, 8, 11, 15, and 18), and at the day of slaughter (22). Blood from control animals was taken at the end of the adaption period as well as at the day of slaughter. The blood was collected by puncturing the *vena jugularis* in a lithium−heparin monovette and centrifuged to obtain the plasma, pipetted off, and stored frozen (−20 °C) until analysis in PFAA-free polypropylene vessels. Urine was collected with varying regularity during feeding, weighing, or blood sampling. After the 21 days of the feeding period, the pigs had an average BW of 103 ± 11 kg and were fasted for 20 h before being slaughtered at the BfR slaughterhouse according to approved methods. Pigs were immediately killed by blood removal after stunning. To prevent cross-contamination between control and experimental animals, controls were slaughtered first. Liver and kidneys were carefully removed, weighed, and individually frozen in PFAA-free bags at −20 °C. The bladder was removed, and the urine it contained was emptied into polypropylene vessels. Samples of muscle tissue from the *musculus longissimus dorsi* (further termed dorsal muscle tissue), *musculus obliquus externus/internus abdominalis*, and *transversus abdominis* (further termed ventral muscle tissue) and the fat tissue covering the dorsal muscle tissue were frozen at −20 °C. Subsequent sample preparation and analysis were performed by the Chemical and Veterinary Analytical Institute Münsterland-Emscher-Lippe (CVUA-MEL). To avoid interferences between PFAA and biomolecules, matrix-specific sample preparations were performed. Plasma and urine was treated with half-concentrated formic acid.[29] Feed samples were extracted with methanol, and an aliquot was diluted with water (VDLUFA-Method). Liver, kidney, and muscle tissue meat samples were hydrolyzed with pepsine.[30] Sample solutions were purified and concentrated with solid phase extraction on an OasisWAX column[31] (60 mg/3 mL).

Analytical Determination. A total of 12 compounds was analyzed using high-performance liquid chromatography coupled with tandem mass spectrometry (HPLC-MS/MS). These included the following seven PFCAs, perfluorohexanoic acid (PFHxA), perfluoroheptanoic acid (PFHpA), PFOA, PFNA, perfluorodecanoic acid (PFDA), perfluoroundecanoic acid (PFUnA), and perfluorododecanoic acid (PFDoA); and the following five PFSAs, perfluorobutanesulfonic acid (PFBS), perfluorohexanesulfonic acid (PFHxS), perfluoroheptanesulfonic acid (PFHpS), PFOS, and perfluorodecanesulfonic acid (PFDS). The limit of detection (LOD) was 0.2 μg/kg for solid samples and 0.2 μg/L for liquid samples for all PFAAs except PFDS, with an LOD of 0.5 μg/kg for solid samples and 0.5 μg/L for liquid samples. It was not possible to identify perfluorobutanoic acid (PFBA) and perfluoropentanoic acid (PFPA) unequivocally because both substances show only one mass transition in multiple reaction monitoring mode (MRM) during HPLC-MS/MS analysis. Due to this fact, the substances were withdrawn from the substance spectra. PFPS, PFNS, PFUnS, and PFDoS were also excluded because standard substances were not commercially available. See Table S2 in the Supporting Information for a complete list of relevant substances for this study.

Analytical Measurement. The purified solutions were measured using HPLC-MS/MS, run in negative ion MRM mode. The separation was performed on an Agilent 1200 SL HPLC system. MS/MS detection was performed with an Agilent 6460 triple-quadrupole mass spectrometer equipped with an electrospray interface (ESI) operating in the negative ion mode. The MRM settings are published elsewhere.[32] The relative standard deviations were around 20% for concentrations near the limit of quantification (LOQ) and 10−15% for higher concentrations.

Quantification and Isomer Separation. Quantification was performed with isotope-labeled standards and a seven-point calibration curve. The LOD was defined as the signal-to-noise ratio of 3:1 of the qualifier ion. The LOQ is defined as the concentration at which a substance is identified unequivocally and quantified with a relative standard deviation of 20% or lower. In the case of PFOS, it could be ensured that only the linear isomer was quantified. Due to the fact that standard substances of branched PFHxA, PFHpA, PFBS, PFHpS, and PFHxS were not commercially available, it was not possible to ascertain that all of the branched substances are separated completely

from the linear ones. Only peaks with the same retention time as the respective linear substances were integrated. The ratios of the two most intense MRM transitions of the integrated PFHpS and PFHxS are the same as in the linear standard substance. Due to the finding that the transitions of the branched isomers differ from the transitions of the linear substances in the case of PFOS, this is an indication that the uncertainty caused by the branched isomers is small for PFHpS and PFHxS. The PFCA concentrations in the analyzed matrices were very low, so that a differentiation between the linear and the branched substances was not possible. It is described in the literature that 78% of the PFOA manufactured by the 3M Co. using electrochemical fluorination is linear.[33] The ratios of the two most intense MRM transitions of the integrated PFCA were the same as in the linear standard substances. Thus, it can be assumed that also in the case of PFCAs, the potential uncertainty caused by the branched isomers is small. The analytical method is described in more detail in the Supporting Information and by Ehlers.[30]

Body Weight of Pigs as a Function of Time. The pigs were weighed two times during the 14 day adaptation period, three times during the 21 day PFAA-contaminated diet experiment, and once more before being slaughtered on day 22 for a total of six BW measurements $M_k^{\text{exptl}}(t)$ per pig. To interpolate between those measurements, the BW function

$$M_k(t) = \omega_{A,k} + \omega_{B,k}(t + \theta)^{\omega_{C,k}} \quad (1)$$

was fitted to the experimental weights $M_k^{\text{exptl}}(t)$ using the nonlinear least-squares Levenberg–Marquardt algorithm[34] with fitted constants ω. Equation 1 is the empirical Janoschek growth equation,[35,36] valid only for the short experimental period of 35 days. Note that other growth equations should be used for longer periods of fattening time. The offset $\theta = 14$ days represents the adaptation period, so that $t = 1$, 2, 3, .., 21 days represent the experimental period in which PFAA-contaminated feed was fed. See Figure S1 and Table S3 in the Supporting Information for the three fitted ω constants for each individual pig (k).

Estimation of the Mass of Tissues. Several sources of data[37−40] were compounded to provide a consistent picture of the weight of each part of the pig (blood, edible and inedible tissues). Blood was estimated as $p_B = 6.5\%$ of BW.[40] Hematocrit (proportion of red blood cells and other cells to plasma) was taken[40] as 39%. From these two values, we calculate the mass of blood plasma (P) as $m_{P,k}(t) = 0.03965 M_k(t)$. The carcass is composed of edible parts of a slaughtered pig excluding blood, kidney, liver, and others deemed unfit for human consumption in some cultures. The weight of the carcass of pig k is then estimated as $(1 - p_B)M_k(t) - m_{L,k} - m_{K,k}$, where $m_{L,k}$ is the measured weight of liver (L) and $m_{K,k}$ is the measured weight of kidney (K). The amount of muscle tissue and fat tissue is calculated as a fraction of the weight of the carcass. From Table 6.2 of ref 37 we use the estimates valid for a pig between 90 and 100 kg, which indicate 62.6% of carcass is muscle tissue and 18.9% of carcass is fat tissue (F). Because we separately analyzed the PFAA content for samples of dorsal and ventral muscle tissues, we further differentiate between them. From Figure 6.1 of ref 37 we assign 51.5% of muscles as dorsal muscle tissues (D: chop, filet, and ham) and 48.5% of muscles as ventral muscle tissues (V: belly, jowl, blade shoulder, blade, knuckle, and dewlap). The mass of each tissue is given by

$$m_{X,k}(t) = p_X[(1 - p_B)M_k - m_{L,k} - m_{K,k}], \text{ with } X = \text{F, D, V} \quad (2)$$

and constants $p_F = 0.189$, $p_D = 0.626 \times 0.515$, and $p_V = 0.626 \times 0.485$. Other parts of the carcass not analyzed in this study represent 18.6% of its weight (bones, tendons, and skin, Table 6.2 of ref 37). Other parts of the body excluded from the carcass, such as the head, are neglected.

Urine Output. A pig urinates[39] between 5 and 30 mL/kg BW. The total urine output as a function of time is between $m_{U,k}(t) = 0.005 \times M_k(t)$ and $0.030 \times M_k(t)$ in L/day. We are forced to estimate the urine output per pig because it was not practicable to quantify the liquid volume per day in the experiment. The urine concentration $C_{U,j,k}^{\text{exptl}}(t)$ of each PFAA substance j in pig k was however experimentally determined every few days.

Mathematical Model of Toxicokinetics. We propose a two-compartment, first-order toxicokinetic model of the pig for each of the seven PFAA substances. The blood plasma represents the model's central compartment (compartment 1). The edible tissues taken together represent compartment 2 (Figure 1). To simplify notation,

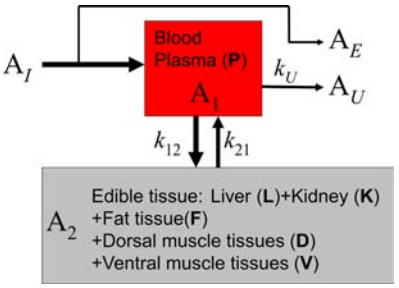

Figure 1. Graphical representation of the two-compartment model. The amount of PFAA in feed is designated as the intake A_I. The amount of PFAA in the central compartment is A_1, whereas the amount in edible tissue is designated A_2. The kinetic constants k_{12} and k_{21} quantify the speed of exchange. A_E is the amount found in feces, considered a fraction f_E of intake A_I, which bypasses A_1 unabsorbed. A_U is the amount excreted in urine, and k_U is the urinal elimination constant. Such a model is fitted independently for each substance and pig.

we will in most cases omit the subscripts for substance (j) and pig (k). The dynamic behavior of the amount of substance present A_1 and A_2 is described by two coupled ordinary differential equations:

$$\frac{dA_1(t)}{dt} = A_1(t) - A_E(t) - k_{12}A_1(t) + k_{21}A_2(t) - k_U A_1(t) \quad (3a)$$

$$\frac{dA_2(t)}{dt} = k_{12}A_1(t) - k_{21}A_2(t) \quad (3b)$$

The kinetic constants k_{12} and k_{21} quantify the speed of substance exchange between compartments 1 and 2, whereas k_u is the urinal excretion rate constant for each substance. These three kinetic constants are the fitted model parameters. $A_E(t)$ is the amount excreted in feces as a function of time t. $A_1(t)$ is the PFAA intake per unit of time or, in other words, the amount ingested by a pig, calculated from measurements

$$A_1(t) = C_I^{\text{exptl}}(t) m_I^{\text{exptl}}(t) \quad (4)$$

where $C_I^{\text{exptl}}(t)$ is the experimentally analyzed feed concentration of PFAA. The feed concentration was held nearly constant for each substance in the carry-over experiment. The second term, $m_I^{\text{exptl}}(t)$, is the average amount of feed intake per day for each pig. To provide estimates for the model parameters k_{12},k_{21}, and k_u, we integrate a form of eqs 3 to best fit the experimentally observed A_1^{exptl} and A_2^{exptl} as described under Numerical Method To Fit the Model to Experiment. Time series of seven data points were experimentally measured for the concentration of all seven PFAAs in blood plasma (P), from which we calculate the amount of each substance in compartment 1

$$A_1^{\text{exptl}}(t) = C_P^{\text{exptl}}(t) m_P(t) \quad (5)$$

where $C_P^{\text{exptl}}(t)$ is the experimental plasma concentration and $m_P(t)$ is the mass of the blood plasma. Because only one data point per pig and substance was measured after slaughter for each edible tissue, we group liver (L), kidney (K), fat (F), dorsal muscle tissues (D), and ventral muscle tissues (V) into the peripheral or edible tissue compartment (compartment 2). The total amount of PFAA in edible tissue compartment 2 at slaughter date $t_{\text{end}} = 22$ days is

dx.doi.org/10.1021/jf405827u | J. Agric. Food Chem. 2014, 62, 6861−6870

$$A_2^{\text{exptl}}(t_{\text{end}}) = \sum_{X=\text{L,K,F,D,V}} C_X^{\text{exptl}}(t_{\text{end}}) m_X(t_{\text{end}}) \quad (6)$$

The amount in edible tissues at the beginning of the experiment t_0 = 0 days is confirmed experimentally to be negligible, $A_2^{\text{exptl}}(t_0) = 0$. The amount excreted in feces is assumed proportional to the amount ingested, so $A_E(t) = f_E A_1(t)$, where the constant f_E for each substance is obtained from previously published experimental data for sheep[22] (Table 1). This simply means that the amount excreted in feces is estimated as an unabsorbed proportion (outer arrow A_E in Figure 1) of the ingested amount. The assumption was made that pigs behave like sheep just in this respect. The fractions in Table 1 are small, so they do not affect the mass balance greatly, but are used for completeness. Furthermore, the amount excreted in urine is a result of the model through the fitted k_U. We assume that there is no metabolic interaction between the substances, so that the models for each of the seven PFAAs are independent from each other. See Figure 1 for a graphical representation of the model.

Table 1. Fractions of Ingested PFAA Deemed Unabsorbed and Excreted in Feces of Sheep from Data in Reference 22 and Table 63 of Reference 30[a]

substance	fraction excreted in feces f_E (%)	substance	fraction excreted in feces f_E (%)
PFHpS	0.65	PFBS	4.30
PFHxS	1.35	PFHxA	4.35
PFHpA	3.20	PFOS	8.45
PFOA	3.95		

[a]These data were used to estimate the feces contribution in the mass balance for pigs of Figure 2.

Excretion in Urine. For each pig, the PFAA concentration of urine $C_U^{\text{exptl}}(t)$ was analyzed for up to four samples spread over the total 22 days. On average, 2.5 urine samples per pig were measured, plus 1 sample after slaughter (from bladder contents). These data were put on equal footing among pigs by performing a least-squares linear fit of the urinal PFAA concentration of the form $C_U^{\text{exptl}}(t) = \beta\, t$. This functional form was chosen by inspecting the apparent linear rise of the experimental blood plasma concentration $A_1^{\text{exptl}}(t)$ for most substances and pigs (Figure 3). Consistent with a linear rise in plasma concentration is a linear rise in urine concentration $C_U(t)$ for first-order kinetics, disregarding the variation in liquid amount. Using the linear fit for $C_U^{\text{exptl}}(t)$ above, the total cumulative urine excretion from experiment is integrated as

$$A_U^{\text{exptl, total}} = \int C_U^{\text{exptl}}(t) m_U(t)\, dt \quad (7)$$

Likewise, the cumulative amount excreted in urine for the model is obtained by integrating

$$A_U^{\text{total}} = \int k_U A_1(t)\, dt \quad (8)$$

Excretion via Feces. The PFAA amounts excreted in feces were not analyzed, because they were presumed to be relatively small with respect to the total cumulative PFAA dose. This assumption is confirmed by the mass balance, because most of the PFAA dose is accounted for by tissues and urine without resorting to the feces (Figure 2). It has been shown experimentally that anionic salts of PFOA and PFOS are secreted by the bile into the intestinal lumen.[41] It is hypothesized that PFOA and PFOS are recycled within enterohepatic circulation,[42] so that material already absorbed is not excreted into feces. Because we did not measure the PFAA content of feces but nevertheless wanted to have an estimate of the amounts excreted, we resorted to extrapolating the results obtained from measurements in sheep feces (ref 22 and Table 63 of ref 30). From the cumulative PFAA amounts that were ingested by sheep, we calculate the fractions of PFAA that remained unabsorbed and were excreted (Table 1).

Normalization of Mass Balance Equations. The mass balance performed using the pig physiological parameters, measured weights, and experimental PFAA concentration data is close to an average of 100% (Figure 2) of the cumulative ingested PFAA, calculated as the total amount of substance j ingested by pig k in the 22 days of the experiment. As suggested in ref 43, we opt for normalizing the data, so that the sum of accumulated and excreted PFAA mass becomes exactly

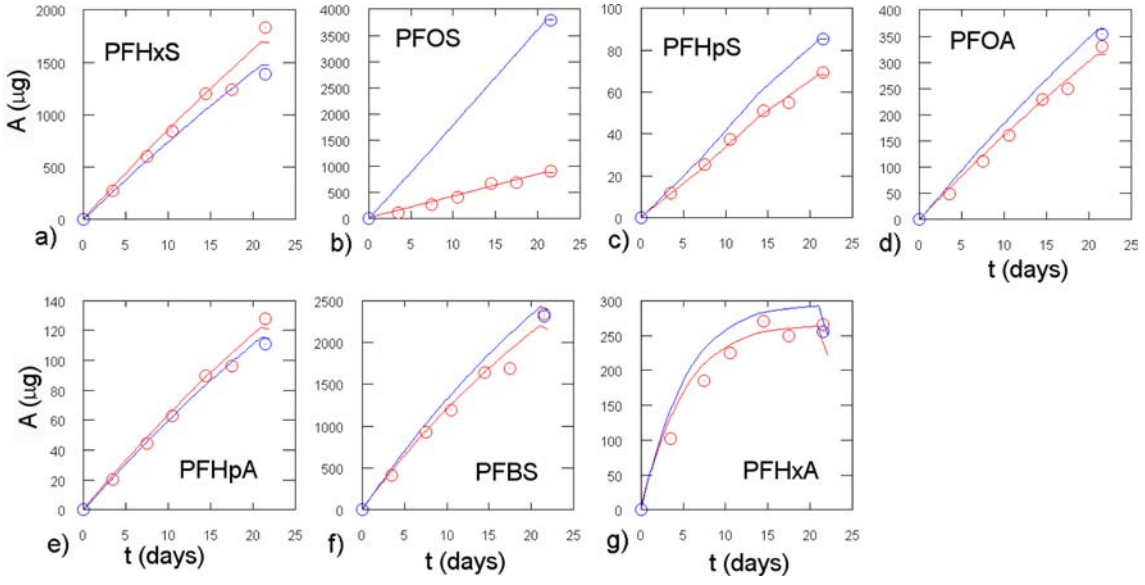

Figure 3. Dynamic behavior of the amount A of seven PFAA substances in an exemplary pig (gilt 8, one of 24 pigs, chosen for its similarity to the mean behavior). Circles correspond to experimental data (mediated by the pig physiological and growth estimates), and lines are the model solution of eq 10 using best-fit kinetic parameters. The substances are ordered from slowest (a) to fastest (g) urinary excretion k_U. The color red stands for the amount A_1 in blood plasma or central compartment. The color blue stands for the amount A_2 in the edible tissue compartment. Only the data for PFHxA suggest approach to steady state between days 1 and 21. Chart b stands out because most of the PFOS partitioned to edible tissue, in contrast to the rest of the PFAAs (panels a and c–g). On day 22, animals were fasted before slaughter (so the curves on that day show only excretion as a downward trend).

dx.doi.org/10.1021/jf405827u | J. Agric. Food Chem. 2014, 62, 6861–6870

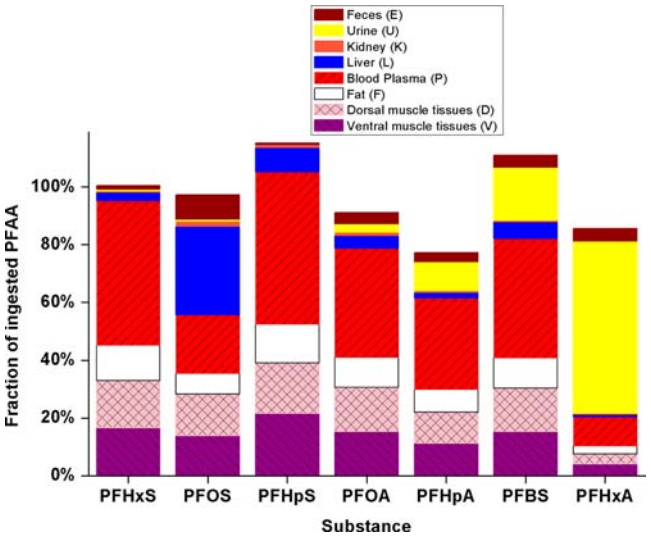

Figure 2. Mass balance for the seven PFAAs shows the ratio of substance in each tissue and excretion to the total cumulative PFAA ingested in feed. The substances are ordered from lowest percentage excreted (left) to highest percentage excreted in 21 days (right). By comparing the height of each bar, one gains insight into the relative affinity of each substance for the given matrices. The mass balance shown accounts on average for 97% of the PFAAs ingested and has not been normalized by eq 9.

equal to 100% of the total ingested and absorbed PFAA for each substance and each pig individually. The normalization factor for the mass balance equations is the ratio of PFAA found in tissues and excretions to PFAA ingested from feed, so that

$$\alpha = \frac{A_1^{\text{exptl}}(t_{\text{end}}) + A_2^{\text{exptl}}(t_{\text{end}}) + A_U^{\text{exptl, total}}}{\sum_{t=1}^{22} A_I^{\text{exptl}}}\left(\frac{1}{1-f_E}\right) \quad (9)$$

The normalization is performed by multiplying the first two terms of the right-hand side of eq 3a with the factor α in eq 9 and recognizing that $A_E(t) = f_E A_1(t)$. After rearranging, we obtain the set of differential equations

$$\frac{dA_1(t)}{dt} = \alpha(1-f_E)A_1(t) - k_{12}A_1(t) + k_{21}A_2(t) - k_U A_1(t) \quad (10a)$$

$$\frac{dA_2(t)}{dt} = k_{12}A_1(t) + k_{21}A_2(t) \quad (10b)$$

We thus fit the normalized model eqs 10 to self-consistent, mass-balanced data. Because of this normalization, the amount excreted in feces A_E (estimated from sheep data) is only relevant for the mass balance of Figure 2, but the terms A_E and f_E disappear from eqs 10 and do not have an effect on the fitted model constants k_{12}, k_{21}, and k_U for the pig. Physiologically this is due to the fact that A_E is an unabsorbed substance which bypasses distribution into the animal's tissues (Figure 1).

Numerical Method To Fit the Model to Experiment. To provide estimates for the model parameters k_{12},k_{21}, and k_u for each substance (j) and pig (k), we perform numerical integration of eqs 10 to best fit the experimentally observed A_1^{exptl} (7 data points, eq 5) and A_2^{exptl} (2 data points, eq 6). In some but not all cases, measurements for the PFAA concentrations in urine were available. In such cases, the best fit is performed as described before and simultaneously integrating eq 8 for the model A_U^{total} and fitting to $A_U^{\text{exptl, total}}$ (1 data point, eq 7). We are thus using 3 model fit parameters and a total of 9 (and in some cases 10) experimental data points. We have chosen to perform fixed effects modeling, meaning that we treat each pig and each substance separately. With this approach, we guarantee a best fit for each case and explore the intersubject variability a posteriori. An alternative approach not followed would have been to fit all pigs at the same time with one random effects model per substance, in a population pharmacokinetics fashion.[44] The MATLAB-compatible program code was written and run in the freely available GNU Octave 3.2.4 language. The dynamic behavior of the amount of substance in the compartments, eqs 10, is integrated using the explicit Runge–Kutta method of order (4,5) in Octave's ode45 algorithm. For the relevant cases, the cumulative amounts excreted in urine in experiment, eq 7, and in model, eq 8, are integrated using the trapezoidal rule. The feed intake $A_I(t)$ is calculated using eq 4. The best fit is performed by nonlinear least-squares minimization of the difference between model and experimental results using the Levenberg–Marquardt algorithm.[34]

Elimination Half-Life. From the fitted model constants, we may calculate the elimination half-life

$$\tau_{1/2} = \frac{\ln(2)}{k_U}(1 + k_{12}/k_{21}) \quad (11)$$

This equation is valid for a two-compartment model with fast equilibrium between compartments. The elimination half-life is thus valid for both compartments, blood plasma and edible tissue.

RESULTS AND DISCUSSION

Twelve PFAAs were analyzed[30] in every sample. Among those 12, 7 substances were detected well above the LOD of 0.2 μg/kg in feed and found in samples of most tissues, blood plasma, and urine: PFHxA, PFHpA, PFOA, PFBS, PFHxS, PFHpS, and PFOS. We present full results for these seven substances, as they were consistently found in amounts that allow for numerical analysis. A special case is PFNA, found in very small amounts in most plasma, liver, and kidney samples, but below the LOD of 0.2 μg/kg in feed and other tissues. Four further substances were below the LOD in all matrices except for the liver: PFDA, PFUnA, PFDoA (LOD = 0.2 μg/kg), and PFDS (LOD = 0.5 μg/kg).[30] The above five substances will not be further discussed, as the data preclude numerical analysis. See Table S2 in the Supporting Information for a complete list of relevant substances.

PFAA Concentration in Contaminated Feed. The mean concentration of each substance $\overline{C_I^{\text{exptl}}}$ in the PFAA-contaminated feed is listed in Table 2. The measured concentrations of PFAA varied slightly because of separate batch preparation for each of the three pig genders and for each of the 3 weeks (reflected as standard deviation in Table 2). These details are given in Table S4 of the Supporting

Table 2. Mean Concentration of Each PFAA $\overline{C_I^{\text{exptl}}}$ in Contaminated Intake (I) Feed on a Dry Basis (Arithmetic Mean ± Standard Deviation)[a]

substance	$\overline{C_I^{\text{exptl}}}$ (μg/kg)
PFOS	137 ± 13
PFBS	132 ± 11
PFHxS	91.3 ± 8.0
PFHxA	47.8 ± 4.4
PFOA	22.4 ± 2.6
PFHpA	10.2 ± 1.7
PFHpS	3.99 ± 0.50

[a]Averaging was performed for days 1–21 of the experiment and all 24 pigs. The LOD was 0.2 μg/kg. For the slightly variable individual measured values for each feed preparation by gender and week, see Table S4 in the Supporting Information.

dx.doi.org/10.1021/jf405827u | J. Agric. Food Chem. 2014, 62, 6861–6870

Inormation. The control feed was verified to have a PFAA concentration below the LOD.[30]

PFAA Partitioning to Blood and Edible Tissues. PFAAs distributed into all studied tissues of the pigs, blood plasma, muscle tissues, fat tissue, liver, and kidney (Figure 2), in line with the results in other species.[1] The mass balance of the PFAAs found in blood plasma and edible tissues accounts on average for 97% of the PFAA mass in the feed. The remaining 3% may be attributed to measurement errors and/or partitioning into tissues that were not measured, such as the brain and gastrointestinal tract. For most investigated substances (PFHxS, PFHpS, PFOA, PFHpA, PFBS, and PFHxA), blood plasma became the largest reservoir of unexcreted PFAAs by amount in the body of pigs. PFAAs are known to concentrate in the blood circulation of mammalian organisms, where they bind to proteins such as serum albumin.[45,46] The results show that PFAAs have an even higher affinity for blood plasma relative to other tissues in pigs than in cows and sheep.[21,22] PFAAs are not alone among persistent pollutants in their ability to bind to blood proteins. A study in pigs found that hydroxylated PCBs also accumulate in their blood.[47] This ability to strongly bind to blood proteins and the low clearance and slow excretion in the urine were recently proposed as the best predictors for a chemical's bioaccumulation potential and long half-life.[48] All three factors are present simultaneously in PFAAs, especially in long-chain PFSAs for pigs. After blood plasma, the next most important reservoirs for PFAAs were dorsal muscle, ventral muscle, and fat tissues. Considered together as meat, these three tissues account for between 40% (PFOS) and 49% (PFOA) of unexcreted, accumulated PFAAs. Note that the percentages in Figure 2 refer to both PFAA unexcreted and excreted during the time of the experiment. In contrast to exclusively lipophilic contaminants such as PCDD/Fs,[35] all seven PFAAs were found in similar amounts and concentrations in both fat as well as muscle tissues, in line with findings of PFAA in fat of mice[1] and rats.[49] This supports pooling of the results for muscle tissue and fat as "meat". Likewise, it contradicts the notion that PFAAs are always lipophobic and thus should be absent from fat tissue. This notion may stem from confusion between the (strongly lipophobic) perfluoroalkyl group, a protonated PFAA and its deprotonated version. A study using ion transfer cyclic voltammetry found deprotonated PFSAs and PFCAs to be around 100 times more lipophilic that their nonfluorinated alkyl counterparts,[50] for example, regular fatty acids. At physiological pH, PFSAs and PFCAs are predominantly deprotonated, lending credibility to our findings in fat tissue. Accumulated PFAA in the kidney accounted for under 2% of unexcreted substance. The liver accounted for under 7% of unexcreted PFAAs for all substances except PFOS. The substance PFOS showed a somewhat lower affinity for pig blood plasma and a markedly higher affinity for the liver (35% of unexcreted PFOS). This is likely related to specific protein binding. A study on the binding of several PFAS to human liver fatty acid binding protein (L-FABP)[51] showed that all studied PFAS bound to L-FABP but that PFOS had the strongest binding affinity. In this work, we have used a partitioning-type model, where the interaction with proteins is not an input of the model, as it was in ref 52. Our results may thus be compared a posteriori to in vitro protein binding affinities, because that information was not explicitly used in the model. Finally, because we were able to quantify all 12 PFAAs analyzed in liver samples, even the 5 PFAAs that we could not detect in other matrices, we support the use of liver samples in monitoring programs of farm animals and wild boars.

Baseline Levels of PFAAs in Control Pigs and Background Contamination. Even newborn animals may have body burdens, as maternal−fetal PFOA and PFOS transfer has been demonstrated in rats and humans.[17] Here, PFAA concentrations were found to be below LOD in the six control animals for all tissues and substances, except for PFOS in some liver samples. PFOS in the liver of control animals was always below 1 μg/kg BW, or >1000 times lower than in the experimental animals. PFAAs were also below LOD in drinking water and animal litter.[23]

Dynamic Behavior of PFAAs in Pigs. A very good fit was found for most pigs and substances between the dynamic model of eqs 10 and the experimental data. To exemplify the results, we chose gilt 8 for the plots in Figure 3, because this pig most closely resembles the average pig. The complete plots for all 24 pigs and the average pig are presented in the Supporting Information (Figures S2−S8) for all seven substances. The substances are ordered from slowest (PFHxS) to fastest (PFHxA) urinary excretion (Figure 3). On day 22, all curves display a slight to marked downward trend for both compartments. The curves do not mean a steady state was established, but rather reflect a short depuration period as the animals were fasted before slaughter. The numerical method to fit eqs 10 to experiment is not easily convergent when k_{12} and k_{21} (the rate of mass flow from compartment 1 to 2 and the rate between 2 and 1) are independently fitted. The physiological correlate for this lack of convergence is a fast equilibrium between the blood plasma and edible tissue compartments compared to the urinary excretion rate (so fast that it cannot be convergently calculated precisely). In mathematical language, this means that $k_{12} \gg k_U$ and $k_{21} \gg k_U$ simultaneously. Because we are not interested in the precise independent values of k_{12} and k_{21}, we opt for fitting only the partitioning ratio k_{21}/k_{12} with fast equilibrium between compartments 1 and 2. We thus reduce the number of fitted model constants to only two (k_{21}/k_{12} and k_U). In this way, the numerical method becomes convergent. Another validation of the model prediction of a fast equilibrium between blood plasma and edible tissue is the linear increase of the amount of PFAA in blood plasma for most substances. The red circles in Figure 3a−f display an increase that is almost linear with intercept zero (see also Figures S2−S8 in the Supporting Information). This experimental observation is only mediated by the pig growth functions and no further modeling. A linear increase in PFAA amounts can happen only if the excretion is very slow (compared to the 21 days of the experiment) and if k_{12} and k_{21} are large in comparison. PFHxA displayed nonlinear behavior approaching the steady state. However, the experimental red circles in Figure 3g also suggest a steady state curve shape consistent with fast equilibrium between compartments 1 and 2. We have de facto created a one-compartment model, not a priori, but as a result of the calculations. The Supporting Information section "Concise description of the toxicokinetic model and its constants" provides a compact implementation-ready overview.

Gender Differences in Elimination. This study with pigs found no statistically significant gender difference in elimination half-life between gilts, barrows, and young boars. The statistical insignificance result was obtained with the nonparametric Kruskal−Wallis test (p = 0.01) using the program SPSS 12.0.2G. This is in line with the lack of sex differences in renal elimination in many species, such as rabbits and mice,[53] and

differs from the marked testosterone-regulated difference in the renal elimination of PFCAs found in rats[49] and some fish.[54] The elimination half-life, eq 11, includes information from all model parameters. As no gender differences were found in pigs, averaging was performed using the results for all pigs.

Plasma Elimination Half-Life. From the fitted model constants, we may calculate the elimination half-life (Figure 4)

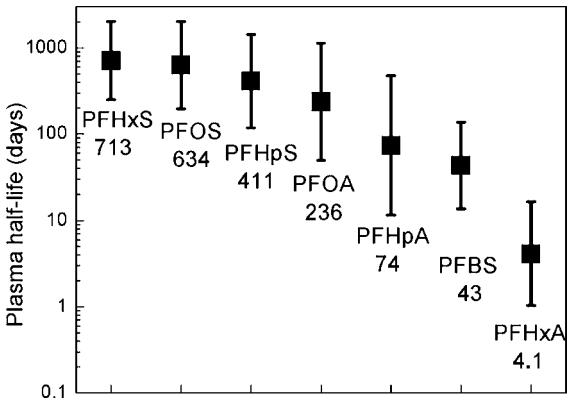

Figure 4. Elimination half-life $\tau_{1/2}$ of PFAAs in pigs. The squares denote the geometric average over up to 24 pigs, and the bars show 95% variability (Student's t statistics). These values reflect both the blood plasma and the edible tissue elimination half-lives, because plasma and edible tissue were found to be in fast equilibrium with each other.

from eq 11. The fast equilibrium between central (plasma) and peripheral (edible tissue) compartments is very advantageous for consumer risk management, because the values in Figure 4 are directly relevant to the elimination of PFAAs from edible tissues. The elimination half-life of PFAAs in pigs is mostly determined by the chemical end-group (sulfonic vs carboxylic acid); half-lives of PFSAs are much longer than for PFCAs. The chain length[10] plays a secondary role. The elimination half-lives are longer than those in trout,[55] rat,[1] Angus cattle,[56] mouse, and monkey[1] but shorter than those for humans.[1,14,17,25] PFHxS has a longer average half-life than PFOS, despite having a shorter chain, in agreement with results in humans.[1,14,17,25] Likewise, a study[14] in humans found a relatively large half-life variability using data from up to 66 individuals, similar to the large variability (vertical bars in Figure 4) in the current study with 24 pigs. It is impossible to separate the systematic from the stochastic variability, but these results may reflect an inherent variability in pig metabolism. Each PFAS may exist in several chain isomers (one linear and several branched). Other studies have found the half-life of each chain isomer to be different.[12,14] In this study, we were able to ensure that only linear PFOS was analytically quantified, without interference from branched isomers. By methodological analogy, although not with full certainty, the quantification of the rest of the substances was also only for the respective linear isomer. See Quantification and Isomer Separation for more details.

Biomagnification Factors. The biomagnification factor (BMF) (also called the bioconcentration factor) measures the ability of a substance to concentrate in an organism's living tissues in relation to the concentration in feed. The BMF is meaningful only in the steady state (ss) and is defined as

$$\mathrm{BMF}_X = \frac{C_X^{\mathrm{ss}}}{\overline{C_I^{\mathrm{exptl}}}} \tag{12}$$

for each substance, where X = plasma (P), liver (L), kidney (K), fat (F), dorsal muscle (D), ventral muscle (V), or whole pig. The concentration in feed $\overline{C_I^{\mathrm{exptl}}}$ is in Table 2. The steady state plasma concentration is obtained as $C_P^{ss} = A_1^{ss}/m_P$. To obtain the amount in blood plasma at steady state A_1^{ss}, one sets the differential eqs 3 to zero and algebraically solves for A_1. Likewise, we solve for the steady state total amount in edible tissue A_2^{ss}. If we assume fast equilibrium between edible tissues, we may use the experimental relative amounts in each tissue (cf. eq 8) to obtain

$$C_Y^{\mathrm{ss}} = \frac{A_Y^{\mathrm{exptl}}(t_{\mathrm{end}})}{A_2^{\mathrm{exptl}}(t_{\mathrm{end}})} \frac{A_2^{\mathrm{ss}}}{m_Y(t_{\mathrm{end}})} \tag{13}$$

where Y = liver (L), kidney (K), fat (F), dorsal muscle (D), ventral muscle (V), or whole pig, where $m_{\mathrm{whole}} = M(t)$, eq 1. Here we have presupposed that the tissues have reached their final weight at t_{end} = 22 days of the experiment. In this 3 week study, the steady state was only observed for PFHxA in some pigs (Figure 3g). The model predicts that the steady state is approached to 95% completion in $t_{95\%\mathrm{ss}} = 22 \pm 14$ days for PFHxA. We may use the model to numerically extrapolate and predict $t_{95\%\mathrm{ss}}$ for other substances. For PFBS, $t_{95\%\mathrm{ss}} = 217 \pm 120$ days and between 1 and 10 years for the rest of the compounds (Supporting Information Table S5). Both BMF and $t_{95\%\mathrm{ss}}$ depend only on the compound through the model constants and do not depend on $\overline{C_I^{\mathrm{exptl}}}$. The extrapolated steady state (eq 13) assumes a linear half-life behavior, which may be a flawed assumption if renal resorption saturation[57] is relevant for the concentrations considered (see section on Limitations). The computed BMF, eq 12, is listed in Table 3 by tissue groups, where meat is an average of D, V, and F.

Table 3. Biomagnification Factor, Dimensionless (Arithmetic Mean) from Equation 12[a]

substance	mean BMF whole pig	mean BMF meat	mean BMF liver
PFHxS	20.1	13.1	48
PFHpS	12.7	8.3	81
PFOS	17.9	9.7	503
PFOA	7.9	5.3	32.8
PFHpA	2.7	1.8	7.0
PFBS	1.2	0.8	6.
PFHxA	0.13	0.08	0.42

[a]Mean for all 24 pigs. For more detailed information on tissue-specific BMF, see Supporting Information Table S5.

Limitations. A drawback worth mentioning is the inability of this study to detect a possible interaction among substances regarding absorption, distribution, and excretion. Because we have chosen to study a mixture of PFAAs arising from a contaminated cultivation site, we cannot rule out that the specific pattern of substances (Table 2) results in a specific toxicokinetic profile. Likewise, we have not analyzed any PFAA precursors possibly present in the feed. The presence of precursors cannot be ruled out in the industrial waste that contaminated the soil.[27] The mass balance closes to 97% (Figure 2). Possible explanations for this good agreement in terms of PFAA precursors are (a) the feed did not contain precursors, (b) precursors were present, but the pigs' metabolic bioconversion is too slow to show up in 3 weeks, or (c) part of the PFAAs go into tissues not tested, such as the brain, whereas

the PFAAs from precursors balance this mechanism out. The two-compartment model includes no provision for saturation of binding,[52,57] but we know from experiments that blood proteins can bind much larger amounts than those observed here.[45,46] However, a mechanism known to be saturable in other organisms is renal PFAA resorption through organic anion transporters.[17] In our model, renal resorption is implicitly part of the renal excretion constant k_U and includes no saturable equations.[52,57] Saturable renal resorption may lead to nonlinear half-life, with faster elimination at higher plasma concentrations. The present experimental data are not designed for fitting renal resorption, so this caveat should be considered for half-life (Figure 4) and BMF (Table 3).

Consequences for Food Safety. The elimination half-lives are very long compared to the lifetime of a farm pig (~180 days) before slaughter, except for PFHxA. Even if contaminated animals are fed uncontaminated feed for weeks or months, it is not expected to see significant declines in PFAA levels. This has consequences for risk management. The EFSA has set a TDI limit of 0.15 μg/kg BW/day for PFOS and 1.5 μg/kg BW/day for PFOA.[8] No TDI is yet available for other PFAAs.[9] From the EFSA TDI and total exposure, including total diet studies, it is possible to derive exposure guidelines for pork. It is very important to produce consistent regulations for maximum content of PFAAs in animal feed and animal products, which is possible only when both a toxicokinetic model and a maximum exposure are available. This has been done for dioxins and other lipophilic pollutants in, for example, chicken feed/eggs.[58] Although lipophilic pollutants have different toxicokinetic properties from PFAAs, the general concepts needed to relate the maximum levels in feed and food are the same. The present toxicokinetic model enables such a quantitative connection between porcine feed and food product PFAA concentrations.

TiO_2 is considered to be an inert and poorly soluble matter. As a common additive in many foods, TiO_2 is used for whitening and brightening foods, particularly for confectionaries, white sauces and dressings, and certain powdered foods.[28] It has been estimated that in the UK the dietary intake of TiO_2 is 5 mg per person per day.[29] The quantity of TiO_2 cannot exceed 1% by weight of the food according to the federal regulations of the U.S. government. In 1969, WHO reported that the LD_{50} of TiO_2 for rats is greater than 12 g kg^{-1} BW after an oral administration. Therefore, a potential exposure route for the general population is oral ingestion. The studies of both longer exposure duration and the lower dose of TiO_2 are of interest for risk assessors. In view of the above, therefore, the aim of the present study was stated to be the investigation of whether the liver inflammation observed in the earlier studies is mediated by Th2 factors in mice for longer exposure duration and the lower dose.

MATERIALS AND METHODS

Chemicals. The preparation and characteristics of TiO_2 NPs particles including the anatase structure, size, surface area, mean hydrodynamic diameter, and ζ potential have been described in our previously work.[30,31] X-ray-diffraction (XRD) was used to detect the anatase structure and size with a charge-coupled device (CCD) diffractometer (Mercury 3 Versatile CCD detector; Rigaku Corporation, Tokyo, Japan) using Ni-filtered Cu Kα radiation. The NP size was determined using a TecnaiG220 transmission electron microscope (TEM) (FEI Co., USA). The surface area of NPs was determined by Brunauer−Emmett−Teller (BET) adsorption measurements on a Micromeritics ASCORBIC ACIDP 2020M+C instrument (Micromeritics Co., USA). The average aggregate or agglomerate size and ζ potential of NPs were measured by dynamic light scattering (DLS) using a Zeta PALS + BI-90 Plus (Brookhaven Instruments Corp., USA). XRD measurements suggested that TiO_2 NPs showed an anatase structure. The average particle size of powdered TiO_2 NPs suspended in 0.5% w/v HPMC solvent after 24 h (5 mg/mL) incubation ranged from 5 to 6 nm, and the surface area was 174.8 m^2/g. The mean hydrodynamic diameter of TiO_2 NPs in HPMC solvent (5 mg/mL) ranged from 208 to 330 nm (mainly 294 nm), and the ζ potential after 24 h incubation was 9.28 mV.[31] The anatase structure, size, surface area, mean hydrodynamic diameter, and ζ potential have been described in the Supporting Information.

Animals and Treatment. 160 CD-1 (ICR) male mice (20 ± 2 g body weight) were purchased from the Animal Center of Soochow University (China). All mice were housed in stainless steel cages in a ventilated animal room. Room temperature of the housing facility was maintained at 24 ± 2 °C with a relative humidity of 60 ± 10% and a 12 h light/dark cycle. Distilled water and sterilized food were available for mice *ad libitum*. Prior to dosing, the mice were acclimated to this environment for 5 days. All procedures used in animal experiments conformed to the U.S. National Institutes of Health Guide for the Care and Use of Laboratory Animals.

TiO_2 NP powder was dispersed onto the surface of 0.5% w/v HPMC, and the suspension containing TiO_2 NPs was treated ultrasonically for 30 min and mechanically vibrated for 5 min. The mice were randomly divided into four groups (n = 30 each), including a control group treated with 0.5% w/v HPMC and three experimental groups treated with 2.5, 5, or 10 mg/kg body weight (BW) TiO_2 NPs. The mice were weighed, the volume of TiO_2 NP suspensions was calculated for each mouse, and the fresh TiO_2 NP suspensions were gavaged to the mice by a gavage needle every day for six months. Any symptoms, growth state (weighing all animals every day), eating and drinking (quantitatively measuring food and water consumption every day), activity, and/or mortality were observed and recorded carefully daily during the six months.

Liver Indices. After six months, mice were weighed and then sacrificed after ether anesthesia. Blood samples were collected from the

eye vein by rapidly removing the eyeball, and serum was collected by centrifuging the blood samples at 1200*g* for 10 min. The livers of all animals were quickly removed and placed on ice. After weighing the body and livers, the liver indices were calculated as the ratio of liver (wet weight, mg) to body weight (g).

Titanium Content Analysis. The frozen liver tissues (n = 5 each) were thawed, and approximately 0.3 g samples were weighed, digested, and analyzed for titanium content. Prior to elemental analysis, the liver tissues were digested overnight with nitric acid (ultrapure grade), combined with 0.5 mL of H_2O_2, and incubated at 160 °C in high-pressure reaction containers in an oven until the samples were completely digested. The solutions were incubated at 120 °C to remove any remaining nitric acid until the solutions were clear. Finally, the remaining solutions were diluted to 3 mL with 2% nitric acid. Inductively coupled plasma-mass spectrometry (ICP-MS; Thermo Elemental X7; Thermo Electron Co., Waltham, MA, USA) was used to determine the titanium concentration in the samples. Indium (20 ng/mL) was chosen as an internal standard element. Elemental titanium (isotopes ^{48}Ti or ^{49}Ti) was quantified using ICP-MS against titanium standards, which also contained the internal standard.

Biochemical Analysis of Liver Functions. Serum biochemical functions including alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), and lactate dehydrogenase (LDH) concentrations (n = 5 each) were determined by ELISA (R&D Systems, Minneapolis, MN, USA). All biochemical assays were performed using a clinical automatic chemistry analyzer (type 7170A, Hitachi, Japan).

Histopathological Examination of the Liver. All histopathological examinations were performed using standard laboratory procedures. Five sets of liver tissues from each dose group were embedded in paraffin blocks, sliced to 5 μm thickness, and placed on separate glass slides (five slices from each kidney). After hematoxylin−eosin staining, the sections were evaluated by a histopathologist unaware of the treatments, using an optical microscope (U−III Multipoint Sensor System; Nikon, Tokyo, Japan).

Observation of Hepatocyte Ultrastructure. Livers (n = 5 each) were fixed in a fresh solution of 0.1 M sodium cacodylate buffer containing 2.5% glutaraldehyde and 2% formaldehyde followed by a 2 h fixation period at 4 °C with 1% osmium tetroxide in 50 mM sodium cacodylate (pH 7.2−7.4). Staining was performed overnight with 0.5% aqueous uranyl acetate. The specimens were dehydrated in a graded series of ethanol (75, 85, 95, and 100%) and embedded in Epon 812. Ultrathin sections were obtained, contrasted with uranyl acetate and lead citrate, and observed with a Hitachi H600 TEM (Hitachi Co., Japan). Liver apoptosis was determined based on the changes in nuclear morphology (e.g., chromatin condensation and fragmentation).

Assay of Cytokine Expression. The levels of mRNA expression of *IL-4*, *IL-5*, *IL-12*, *FN-γ*, *GATA3*, *GATA 4*, *T-bet*, *STAT1*, *STAt3*, *STAT6*, *eotaxin*, *MCP-1*, and *MIP-2* in the livers (n = 5 each) were determined using real-time quantitative (q)RT-PCR, as described previously.[32] Synthesized cDNA was generated by qRT-PCR with primers designed with Primer Express Software (Applied Biosystems, Foster City, CA, USA) according to the manufacturer's guidelines, and the sequences are listed in Table 1. The right livers from mice with or without TiO_2 NP treatment were homogenized using QIAzol lysis reagent with a TissueRuptor (Roche, USA). Total RNA from the homogenates was isolated using Tripure isolation reagent (Roche, USA) according to the manufacturer's instructions. The RT reagent (Shinegene, China) of 30 μL was prepared by mixing 15 μL of 2× RT buffer, 1 μL of random primer in a concentration of 100 pmol·μL^{-1}, 1 μL of RTase, 5 μL of RNA, and 8 μL of DEPC water together. The reaction condition was 25 °C for 10 min, 40 °C for 60 min, and 70 °C for 10 min. The internal reference gene was actin3. qRT-PCR was performed using the 7500 real-time PCR system (ABI) with SYBR Premix Ex Taq (Takara) according to the manufacturer's instructions. The gene expression analysis and experimental system evaluation were performed according to the standard curve and quantitation reports.

To determine IL-4, IL-5, IL-12, IFN-γ, GATA3, GATA4, T-bet, STAT1, STAt3, STAT6, eotaxin, MCP-1, and MIP-2 levels in the mouse liver tissues, ELISAs were performed using commercial kits specific for each protein (R&D Systems, Minneapolis, MN, USA), following the manufacturer's instructions. The absorbance was measured on a microplate reader at 450 nm (Varioskan Flash; Thermo Electron, Finland), and the concentrations of IL-4, IL-5, IL-12, IFN-γ, GATA3, GATA4, T-bet, STAT1, STAt3, STAT6, eotaxin, MCP-1, and MIP-2 were calculated from a standard curve for each sample.

Statistical Analysis. All results are expressed as means ± standard error (SE). One-way analysis of variance (ANOVA) was carried out to compare the differences of means among the multigroup data using SPSS 19 software (SPSS, Inc., Chicago, IL, USA). Dunnett's test was performed when each data set was compared with the solvent control data. Statistical significance for all tests was judged with a probability level of 0.05 (p < 0.05).

RESULTS

Body Weight, Liver Indices, and Titanium Accumulation. During the treatment, all mice were all at growth state. The daily behaviors such as food consumption, drinking, and activity in TiO_2 NP-treated groups were not significantly different from those of the control group. Figure 1 shows the net increase in body weight, liver weight, and liver indices caused by TiO_2 NP exposure. TiO_2 NP exposure resulted in significant reductions in the net increase of body weight and increases in liver indices as compared with the controls (p < 0.05), but liver weight did not exhibit differences among the four groups (p > 0.05). Furthermore, there was significant titanium accumulation with increased TiO_2 NP dose (Figure 2, p < 0.001). The decreased body weight and increased liver indices caused by TiO_2 NP exposure may be related to liver dysfunction and tissue injury, which were confirmed by the biochemical assays and histopathological observations of mouse livers.

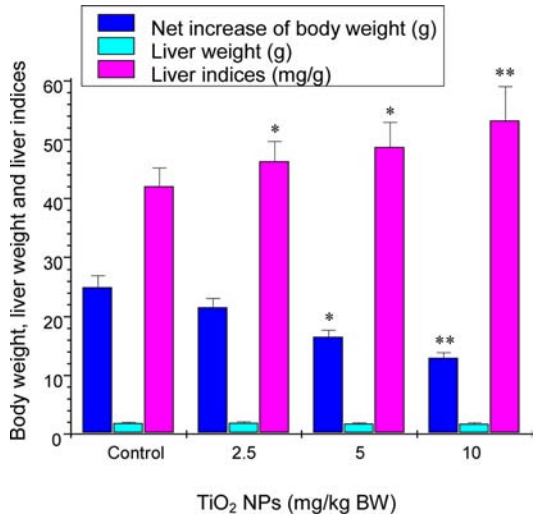

Figure 1. Net increase of body weight, liver weight, and liver indices of male mice after gavage administration of TiO_2 NPs for six consecutive months. *p < 0.05, and **p < 0.01. Values represent means ± SE (n = 40).

Histopathological Evaluation. The histological changes in the liver specimens are shown in Figure 3. Unexposed liver samples exhibited normal architecture including intact hepatic lobule and normal blood sinusoid opening (Figure 3), while those from five mice of each group exposed to increasing TiO_2 NP concentrations exhibited severe pathological changes,

dx.doi.org/10.1021/jf501428w | J. Agric. Food Chem. 2014, 62, 6871−6878

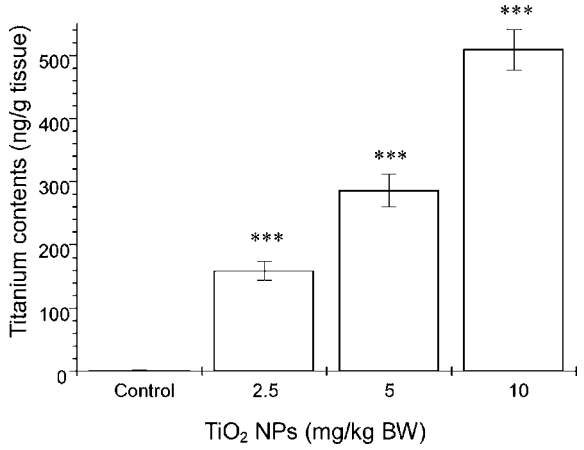

Figure 2. Titanium contents in mouse livers after gavage administration of TiO_2 NPs for six consecutive months. ***p < 0.001. Values represent means ± SE (n = 5).

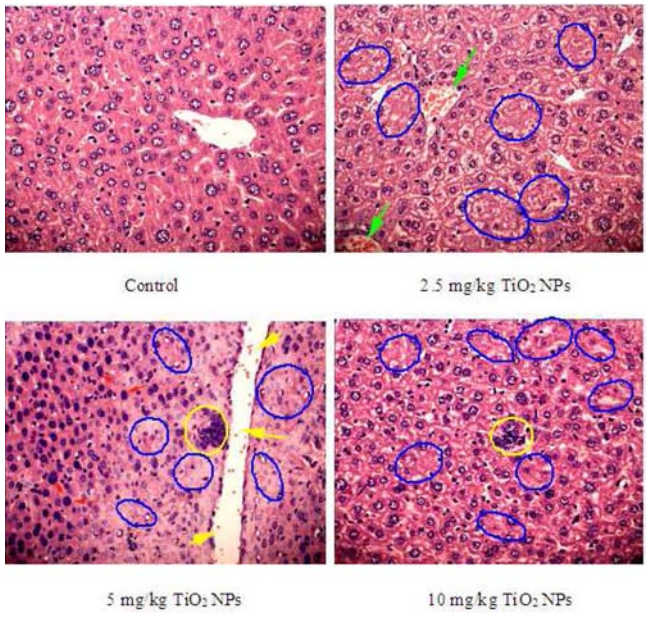

Figure 3. Histopathological observation of livers after gavage administration of TiO_2 NPs for six consecutive months (n = 5). The control group (unexposed mice) showed intact hepatic lobule and normal blood sinusoid opening (400×). The 2.5 mg/kg TiO_2 NP group presented with vein congestion (green arrows), angiectasis and hyperemia (white arrows), and neorobiosis of hepatocytes (blue circles) (400×). The 5 mg/kg TiO_2 NP group presented with inflammatory cell infiltration (yellow circle), macrophages (red arrows)), hepatic tissue crevice (yellow arrows), and neorobiosis of hepatocytes (blue circles) (400×). The 10 mg/kg TiO_2 NP group presented with inflammatory cell infiltration (yellow circle) and neorobiosis of hepatocytes (blue circles) (400×).

including angiectasis and hyperemia, infiltration of inflammatory cells, macrophage aggregation, hepatic tissue crevice, and hepatocyte necrosis (Figure 3). The results suggested that chronic exposure to TiO_2 NPs resulted in significant pathological changes in the livers, which may be related to cytokine expression.

Observation of Hepatocyte Ultrastructure. Changes to hepatocyte ultrastructure in the mouse liver samples are presented in Figure 4. As shown, hepatocytes of the control group contained elliptical nuclei with homogeneous chromatin

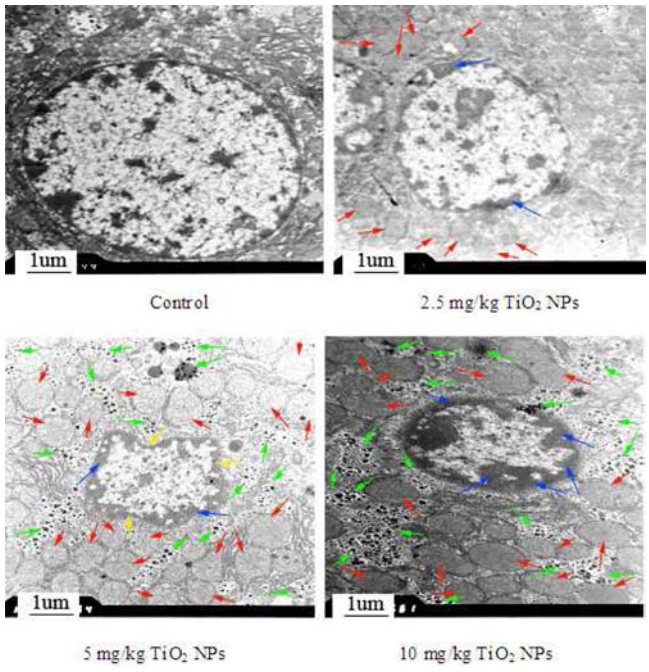

Figure 4. Ultrastructure observation of hepatocytes in mouse liver after gavage administration of TiO_2 NPs for six consecutive months (n = 5). The control showed elliptical nuclei with homogeneous chromatin (10,000×). The 2.5 mg/kg TiO_2 NP exposure group exhibited light mitochondrial swelling (red arrows) and chromatin marginalization (blue arrows) (10,000×). The 5 mg/kg TiO_2 NP exposure group exhibited mitochondrial swelling (red arrows), nuclear membrane collapse (yellow arrows), chromatin marginalization (blue arrows), and TiO_2 NP deposition in the cytoplasm (green arrows) and/or mitochondria (green arrows) (10,000×). (d) The 10 mg/kg TiO_2 NP exposure group exhibited severe mitochondrial swelling (red arrows), chromatin marginalization (blue arrows), and significant TiO_2 NP deposition in the cytoplasm and/or on nuclear membrane (green arrows) (10,000×).

(Figure 4); however, ultrastructure of hepatocytes in the liver treated with TiO_2 NPs indicated a typical apoptosis, including significant mitochondrial swelling, nuclear membrane collapse, and chromatin marginalization (Figure 4). In addition, we also significantly observed black particle agglomerates in the cytoplasm, in mitochondria, and/or on nuclear membranes in the TiO_2 NP-exposed hepatocytes (Figure 4), further confirming that TiO_2 NPs were deposited in the mouse liver.

Liver Function. The changes in the serum biochemical parameters induced by TiO_2 NP exposure are presented in Table 2. With increased TiO_2 NP dose, the levels of ALT, AST, ALP, and LDH were gradually increased, respectively (p < 0.05 or 0.01), suggesting that chronic exposure to TiO_2 NPs resulted in hepatic dysfunction.

Th2 Factor Expression. Mice with TiO_2 NP-induced hepatopathy presented with a significant, dose-dependent increase in Th2-type cytokines IL-4 and IL-5 and Th1-type cytokine IL-12 expression in the liver tissue (Tables 3, 4) (p < 0.05). This was associated with marked up-regulation of the measured IL-4 and IL-12 target genes, including IFN-γ, GATA3, GATA4, T-bet, STAt3, STAT6, eotaxin, MCP-1, and MIP-2, and significant down-regulation of STAT1 expression in the mouse liver under conditions of TiO_2 NP-induced hepatopathy (Tables 3, 4) (p < 0.05). These findings pointed to the promoted activation of the IL-4-mediated pathway in mice following exposure to TiO_2 NPs.

Table 2. Changes of Biochemical Parameters in the Blood Serum of Mice after Gavage Administration of TiO_2 NPs for Six Consecutive Months

	TiO_2 NPs (mg/kg BW)			
index	control	2.5	5	10
ALT (U/L)	27.44 ± 1.58	28.61 ± 1.63	38.95 ± 2.04[a]	41.43 ± 2.27[a]
AST (U/L)	103.26 ± 5.56	110.75 ± 5.78	142.81 ± 7.69[a]	175.96 ± 9.06[b]

DISCUSSION

The results of the present study indicate that gavage administration of 2.5, 5, or 10 mg/kg of TiO_2 NPs for six consecutive months led to body weight reduction, increased liver indices (Figure 1), and titanium accumulation (Figure 2). This resulted in an inflammatory response, macrophage aggregation, and hepatocyte necrosis in the livers (Figure 3) and ultrastructure damages of hepatocytes (Figure 4). Our previous studies observed that TiO_2 NP exposures with 10–250 mg/kg BW for 14, 60, or 90 consecutive days led to liver histopathological changes, including congestion of vascellum, wide-bound basophilia, focal ischemia,[2] large overall fatty

degeneration, inflammatory cell infiltration, necrosis,[3] congestion of interstitial vessels,[4] focal inflammatory cell infiltration and edema,[5] and apoptosis.[33] ALT, AST, ALP, and LDH are cellular enzymes that indicate the presence of injury in the liver. Under healthy circumstances, ALT, AST, ALP, and LDH are contained within the cell. When cellular injury occurs, the enzymes are released from the cytoplasm into the bloodstream, suggesting liver damage.[34] In the current study, TiO_2 NP exposure significantly elevated the serum ALT, AST, ALP, and LDH levels (Table 2), which is consistent with previous reports in our laboratory experiments[2−4] and may be cellular injury in the mouse liver (Figure 4). The liver injury and dysfunction caused by exposure to TiO_2 NPs may be involved in the impairment of immune-mediated function in mice, such as alteration in Th2-mediated gene expression in the liver.

Our previous studies had demonstrated that TiO_2 NP-induced hepatic inflammation was associated with overexpression of nucleic factor (NF)-κB, IκB kinase, NF-κBP52, NF-κBP65, NF-κB-inducible kinase (NIK), Toll-like receptor (TLR)-2 and -4, and proinflammatory cytokines including macrophage migration inhibitory factor, tumor necrosis factor-α, IL-6, IL-1β, cross-reaction protein, IL-4, IL-10, and IL-2 expression in mice.[2,3] In this study, however, a relationship between TiO_2 NP-induced liver injury and immunological factors was demonstrated (Tables 3 and 4). Elevated IL-4 has been reported in human liver diseases such as chronic hepatitis C[35] and primary biliary cirrhosis.[36] In the current study, increased IL-4 expression was also demonstrated to be involved in the TiO_2 NP-induced liver injury for longer exposure duration and lower dose. The administration of 2.5, 5, or 10 mg/kg of TiO_2 NPs for six consecutive months significantly increased the expression of hepatic IL-5, IL-12, STAT3, STAT6, and eotaxin-1, whereas TiO_2 NPs decreased STAT1 expression (Tables 3 and 4). These results suggested that Th2-mediated factors could be involved in the TiO_2 NP-induced liver injury for longer exposure duration and lower dose. It has been reported that IL-4 activates STAT6, which induces IL-5 and eotaxins-1,[25] and induces SOCS1 and SOCS3, which inhibit the STAT1 activity.[37] STAT3 is a transcription factor that participates in many biological processes, especially those of cell survival and proliferation.[38,39] IL-12 induces the tyrosine phosphorylation and DNA binding of STAT3 and STAT4.[40] Serine phosphorylation has been noted to increase transcriptional activation of STAT proteins.[41] On the other hand, STAT6 is necessary for the normal development of Th2 cells.[24] Therefore, the increased expression in the STAT3 and STAT6 due to exposure to TiO_2 NPs may indicate the protection of lymphocytes against apoptosis induction and development of Th2 cells.

T-bet and GATA play early roles in Th cell development to regulate IFN-γ and IL-4/IL-5 gene expression, respectively. The cytokines IL-12 and IL-4/IL-5 secondarily act via STATs to promote cell growth and extinguish expression of either GATA or T-bet.[42] GATA transcription factors belong to the family of zinc finger DNA-binding proteins and play critical roles in cell growth and differentiation.[43] Studies have shown that GATA1, GATA2, and GATA3 are involved in hematopoietic cell differentiation, whereas GATA4, GATA5, and GATA6 control specification and differentiation of mesoderm- and endoderm-derived cell types.[44,45] Our data demonstrated that TiO_2 NP exposure significantly up-regulated T-bet, IFN-γ, GATA3, and GATA4 expression in the liver (Tables 3 and 4), implying that these Th2-related factors may be associated with the TiO_2 NP-induced liver injury due to its hematogenic function for longer exposure duration and the lower dose.

A number of chemokines are responsible for the recruitment of inflammatory cells into the liver during the development of injury. MCP-1 is a CCL-type chemokine responsible for the recruitment of monocytes to sites of inflammation.[46] MIP-2 belongs to the CXC-type chemokine family and acts on CXC receptor 2. The chemokine is synthesized by activated tissue macrophages. MIP-2 performs similar functions to increase neutrophil egress from the bone marrow and mediate transmigration of these cells into the peripheral tissues.[47,48] Eotaxin-1/CCL11 is a chemokine belonging to the CC family and has been shown to be a potent chemoattractant for eosinophils both *in vitro* and *in vivo*.[49] Increased production of eotaxin-1 has been associated with allergic diseases.[50−52] It has also been shown that eotaxin-1 neutralization in mice substantially reduced eosinophil recruitment after Ag challenge. IL-5 is thought to be infiltrating T cells or eosinophils, and its overexpression exacerbates Th2 immune responses.[53] Kay also suggested that eotaxin-1 and IL-5 are involved in inflammation.[20] Therefore, the present study showed that the overexpression of MCP-1, MIP-2, eotaxin-1, and IL-5 (Tables 3 and 4) may be involved in the TiO_2 NP-induced hepatic inflammation such as infiltration of inflammatory cells and macrophage aggregation (Figure 3). However, possible direct evidence that Th2 factor expression is involved in the control of hepatic inflammation induced by chronic TiO_2 NP toxicity should be further confirmed in future experiments.

In conclusion, hepatotoxicity is closely associated with increased expression of IL-4, IL-5, IL-12, IFN-γ, GATA3, GATA4, T-bet, STAt3, STAT6, eotaxin, MCP-1, and MIP-2 and decreased STAT1 expression due to TiO_2 NP exposure in the mouse liver. Therefore, TiO_2 NP-induced liver injury may be via alteration of Th2 cytokine expression and/or a possible IL-4-mediated pathway in mice. The present study provides new insights into the mechanisms of TiO_2 NP-induced liver injury.

structural characterization after tedious compound isolation. Since its introduction for anthocyanin analysis,[10] HPLC has become the technique of choice for their qualitative and quantitative analysis. Further development in the mid-1980s of improved reversed-phase columns and coupling to photodiode array detectors represented a great advance, as a single analysis allowed separation and information for structural identification to be obtained on the basis of chromatographic retention and UV−vis spectra, which notably provides more clues for compound identification. Mass spectrometry atmospheric pressure ionization (API) interfaces, and especially electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) interfaces, led in the 1990s to hyphenation of HPLC and MS. This facilitated the identification of a plethora of compounds, including new anthocyanin families, such as pyranoanthocyanins, flavone/flavanol-linked anthocyanins or dimeric anthocyanins, as well as other related anthocyanin-like pigments such as oaklins resulting from the condensation of catechins and hydroxycinnamic acids.[11] Many of these new pigments were first identified in red wines to be further reported in plant tissues. According to Andersen and Jordheim,[12] by 2013 the number of anthocyanins identified in nature was 702, with about 200 additional structures proposed as tentative.

Nowadays the introduction of a new generation of HPLC as favored by the development of new column supports and smaller particle sizes has allowed further decreasing the analysis time and increasing peak capacity and sensitivity. Also, high-resolution mass spectrometers (HR-MS), such as time-of-flight (TOF), Fourier transform ion cyclotron resonance (FTICR-MS), and Orbitrap equipment, able to provide accurate masses have been developed, making possible the distinction between compounds differing in mass by around 20 mDa. The enhanced selectivity of these new instruments reduces interfering background ions, increasing sensitivity compared with triple-quadrupole and ion trap systems. Another advantage of these instruments is that compound signals may be used directly for compound tentative identification. Indeed, the combination of these high-resolution spectrometers coupled to the new high-capacity separation techniques and enhanced software platforms opens improved prospectives for qualitative (nontargeted compound identification) and quantitative analyses using single runs. Also, developments in mass spectrometry imaging (MSI) should be expected to help in visualizing the spatial distribution of compounds by their molecular masses, which should have an impact in determining tissue distributions and establishing biological targets of metabolites.

An interesting feature of LC-MS is that it provides another separation dimension to HPLC, through the use of selective detection modes, such as monitoring single ions, extracting particular ions, or recording characteristic transitions in the fragmentation of compounds. Selective detection increases sensitivity and the possibility of detecting and quantifying metabolites in biological samples, allowing important progress in understanding the processes of anthocyanin absorption and biotransformation in the human organism.

Hyphenation of liquid chromatography to NMR spectroscopy is another promising tool for the separation and structural elucidation of unknown compounds in mixtures. Even though it emerged in the mid-1990s this technique has not yet become popular, among others due to the existence of technical drawbacks that hamper its application. The technique is mostly restricted to H NMR, as low abundance of ^{13}C isotopes limits obtaining C NMR spectra to peaks of high concentration. In the particular case of anthocyanins, problems may also arise from their existence as different forms in equilibrium. Recent advances have been made concerning the improvement in NMR flow probe technology, introduction of new techniques for solvent suppression, or coupling to an online solid-phase extraction unit for concentrating the eluted peaks prior to spectra recording so as to increase the sensitivity (LC-SPE-NMR). This has contributed to improve the sensitivity, so that an increase in its applications should be expected in coming years, also favored by the introduction of cheaper equipment making the technique available to more laboratories.[13]

UNCOVERING FLOWER COLOR

It is well-known that anthocyanins are structurally dependent on the conditions and composition of the media where they are dissolved and suffer interactions among them and with other compounds that influence their chemical equilibria and modify their color. Kinetic and thermodynamic equilibria between colored and colorless anthocyanin forms as a function of the pH and temperature have been well established since the works performed by Brouillard and co-workers in the 1970s.[7,8] Anthocyanins are usually represented as their red flavylium cation, but in aqueous media this form undergoes rapid proton transfer reactions, leading to blue quinoidal bases, and hydration, generating colorless hemiketals in equilibrium with chalcone structures. The highly colored flavylium forms predominate only in very acidic solutions, whereas in weakly acidic aqueous media, even if they are kept in conditions (temperature, pH, light, oxygen) similar to those found in plant vacuoles, anthocyanins mostly occur as colorless species and tend further to degrade by irreversible cleavage of their molecules. Nevertheless, in their natural media, anthocyanins are able to express intense red, blue, or violet colors even at weakly acidic pH values, and, furthermore, the same anthocyanin can be found in different flowers providing distinct colorations.[14] This apparent paradox is explained by the existence of stabilizing mechanisms, among which the processes of copigmentation and metal complexation are prominent.[9,15] Nevertheless, although basic mechanisms involved in flower pigmentation have been clarified to a considerable extent, many unresolved questions remain. Further research has still to be undertaken to extend our understanding about the molecular and biological bases that control color expression and stability. Physicochemical studies are required to identify the most promising chromophores and to establish the influence of structural differences on the formation of metalloanthocyanins and the atomic structure of intra- and intermolecular stacking. Also, a better understanding is needed about charge transfer effects implicated in spectral shifts, mechanisms of metal and pigment transport into vacuoles, or the identification of transcriptional factors and the regulatory network controlling anthocyanin biosynthesis.[15] Expected advances in these fields in the coming years should offer plant breeders new options to produce flowers with the desired coloration.

ENHANCING ANTHOCYANIN PRODUCTION

Anthocyanins are produced by a branch of the flavonoid pathway (i.e., shikimate/phenylpropanoid pathway), and their synthesis constitutes the most studied secondary metabolic pathway in plants. Actually, most of the knowledge about transcriptional regulation in plants has initially come from studies of the regulation of anthocyanin biosynthesis in the monocot maize, further extended to dicots, with *Arabidopsis* as a paradigm.[1]

The identification of transcription factors and a better understanding of the regulatory network controlling anthocyanin biosynthesis in plants are crucial prerequisites for the development of plants with enhanced or improved anthocyanin composition. By 1990, all of the enzymes involved in the early specific part of anthocyanin biosynthesis (from chalcone to anthocyanidin) had been solved, and cloning of the anthocyanin synthetic genes was nearly completed. Since that time, several genes coding for glycosyltransferases and acyltransferases in flower petals have been cloned, and several transcriptional factors regulating anthocyanin biosynthesis have been described.[15] Available findings indicate that transcription factors regulating anthocyanins share a great conservation of functional domains and that functional diversification in a species and among closely related species generally resides more in regulatory sequences than in coding regions. This high conservation may help in selecting the proper heterologous regulators to obtain anthocyanin-rich varieties through metabolic engineering.

The transcription factors controlling anthocyanin biosynthesis have been characterized for many species and an "MBW" regulatory complex consisting of a ternary complex of R2R3MYB, bHLH, and WD-Repeat proteins.[16] Thus, manipulating the anthocyanin pathway has often involved the overexpression of heterologous MYB and bHLH genes.[1] Various transgenic approaches have been taken to increase flavonoid levels in tomato fruit by overexpressing either the structural or regulatory genes involved in the biosynthetic pathway. Most of these attempts have exploited heterologous genes, and in only one case was an endogenous tomato regulatory gene (ANT1) overexpressed in tomato plants. Although a significant increase in the final content of some flavonoids (flavonols, in particular) was obtained, in tomato, the overexpression by activation tagging of the MYB ANT1 gene realized only a partial enhancement of anthocyanins,[1] which either were expressed in only the vegetative tissues of the plant or induced only a partial, spotted pigmentation, mostly limited to the peel of the fruit, which could be explained by the low availability of flavonoid biosynthetic precursors or the absence of other limiting regulatory factors (e.g., bHLH).[17] These constraints were overcome by Butelli et al.,[18] who produced a tomato highly enriched with anthocyanins throughout the fruit tissues, averaging ∼3 mg/g fresh weight, by the ectopic expression of two selected transcription factors (Del, a bHLH-type TF, and Ros1, an R2R3MYB-type TF) from the ornamental flower snapdragon (*Antirrhinum majus* L.). Interestingly, the high production of anthocyanins in these "purple" tomatoes was not obtained at the expense of other major classes of tomato fruit pigments, and the antioxidant activity attributable to the carotenoid fraction remained unchanged.[17]

Similar developments could be anticipated for the development of other anthocyanin-rich crops or ornamental plants. Furthermore, given that the biological properties of different anthocyanin compounds and of the other classes of flavonoids are often molecule-specific, a major objective of metabolic engineering approaches might be not only increasing but also optimizing their levels and composition in crops so that they could eventually be promoted as functional foods. Additionally, researchers could exploit natural genetic resources, either as an alternative to genetic engineering approaches or to strengthen them.[17]

■ ANTHOCYANINS IN FOOD

For years the main focus on anthocyanins in food has been put on their influence in color. In intact plant tissues (i.e., unprocessed fruits and vegetables), anthocyanins remain relatively stable. Nonetheless, tissue disruption during food processing affects anthocyanin extractability and stability. It has been suggested that anthocyanin extraction from berries into juice could be limited by their interaction with macromolecules from disrupted cell walls such as polysaccharides, tannins, and proteins. However, the factors that govern those interactions are still not well-defined and remain a promising research area. On the other hand, storage may also affect anthocyanin stability, leading to color changes. In food systems, in addition to be subjected to the equilibria among structural forms, anthocyanins can be involved in chemical and enzymatic reactions that may degrade them to colorless products or transform them into new structures. Indeed, the search for improved processing and storage methods to better control anthocyanin losses or to address anthocyanin reactions in the "right" direction to obtain more stable and desired colors constitutes a major challenge for the food industry.

Anthocyanin stability and reactions have been particularly studied in red wine, in which a variety of anthocyanin-derived products have been identified over the past two decades, such as pyranoanthocyanins and anthocyanin-flavanol condensed pigments, either directly linked or involving aldehydes, anthocyanin dimers, or xanthylium pigments.[11] Similar products have further been found in fruits and vegetables[19−22] and other plant-derived food.[23,24] Some of these compounds possess interesting chromatic properties, displaying a variety of colors from orange to blue and being more resistant to color bleaching by water or sulfur dioxide attack, so that they show more color capacity at weakly acidic and neutral pH values than original anthocyanins.[11] Anthocyanins are authorized as food additives both in the European Union (E-163) and the United States, where the Food and Drug Administration (FDA) includes them as natural "Colorants Exempt from Certification".[12] However, the applications of anthocyanins as food colorants are seriously limited due to their problems of stability. In these circumstances, the improved color properties that exhibit some anthocyanin-derived pigments make them potential candidates for their use as natural food colorants, which is particularly relevant taking into account the current concerns and restrictions for the use of synthetic dyes.

Owing to the current interest in the potential associations between anthocyanin consumption and health promotion, the estimation of the dietary intake of anthocyanins has also become a point of interest, so that adequate relationships with the incidence of chronic diseases can be established. It is, however, difficult to properly calculate anthocyanin consumption.[12] Accurate data on the qualitative and quantitative anthocyanin composition in foods and beverages are neither always available nor easy to obtain due to the structural diversity of anthocyanins and their stability problems. Anthocyanin contents can vary tremendously within a certain type of food depending on varietal, agronomic, and environmental conditions and, furthermore, both degradation and formation of derived products have great influence in the anthocyanin contents and profiles in processed foods and beverages. Indeed, stability is a very important (and challenging) element when considering the impact of dietary anthocyanins on the human organism. The common anthocyanins show instability toward a variety of chemical and physical parameters, including oxygen, high temperatures, light, pH

values, enzymes, and reactions with compounds in the food or body systems, which may vary anthocyanin properties.[12]

Estimations made by different researchers varied within a wide range, oscillating from 3 to 150 mg/day, depending on the country and nutrition habits. In a rough calculation, average adult intake of anthocyanins in Europe and the United States has been estimated on the scale of 10 mg/day.[12] Further studies are, nevertheless, required to increase our knowledge on anthocyanin composition in most consumed foods over different countries, taking into account that not only total intake is important but also qualitative profiles should have an influence on their putative health-promoting effects. Moreover, attention will also have to be paid to the increasing popularity of food supplements and the developing market for functional foods, as they may contribute substantially to a rise in the dietary intake levels.

BIOAVAILABILITY AND HEALTH ISSUES

Dietary anthocyanins have been related with health promotion, namely, relief of oxidative stress and protection against coronary heart disease, and also with antimicrobial anti-inflammatory and anticarcinogenic activities, control of obesity and diabetes, or improvement of vision.[2] The biological effects of anthocyanins have been classically associated with their antioxidant capacity, although the actual mechanisms involved at the physiological level are yet to be established, and a recent emerging view is that modulatory effects affecting signaling pathways in cells should also be important.[17]

For understanding of the exact impact of dietary anthocyanins on health and their underlying mechanisms, further knowledge is required about their bioavailability. Aspects such as absorption and biotransformation, the exact nature and amount of circulating metabolites, and their activity, tissue distribution, and accumulation or the forms able to reach particular cellular or molecular targets are still largely unknown. In these circumstances, the ability to detect, identify, and determine the metabolites at physiological concentrations is crucial. Furthermore, pure metabolites are required to be used in activity and mechanistic studies but are not always available as commercial standards. In this matter, chemical or enzymatic syntheses constitute different promising strategies to obtain some in vivo occurring anthocyanin metabolites.[25]

A fraction of anthocyanins could be absorbed both in the stomach and in the small intestine. The pH changes considerably in the human body from the stomach (1.5) to the intestine surface (5.3), urine (5.75), liver (7.0), and blood (7.40), and, therefore, anthocyanins will thus most probably under physiological conditions occur on different structural forms similar to those described in model systems.[12] Anthocyanin structure (e.g., type of aglycone, number and type of glycosyl and acyl moieties) would influence form distribution and stability, thus affecting their bioavailability, metabolism, or degradation mechanisms. Furthermore, a part of the anthocyanins in processed foods, and also in intact plants, may occur in the form of more complex structures (e.g., derived pigments), the equilibrium schemes, stability, and reactivity characteristics of which are not well elucidated and should differ from those of the simple anthocyanins.[12] Finally, the relevance of the food matrix and the interactions between anthocyanins and other food components, both macronutrients and bioactives, must also be considered. At present, most of this knowledge is to a large extent lacking.

Existing data indicate that the proportion of absorbed anthocyanins including their metabolized derivatives is very low. Actually, anthocyanins have been reported to have one of the lowest bioavailabilities of all of the dietary flavonoid subclasses,[26] with typical urinary excretion of the total amount of anthocyanins and their derivatives well below 1% of the ingested amount. Nevertheless, recent studies using ^{13}C-labeled anthocyanins carried out in humans by Czank et al.[27] have concluded that these compounds could be more bioavailable than previously reported. Thus, on the basis of the recovered ^{13}C dose, cyanidin-3-*O*-glucoside (Cy3G) was established to have a relative bioavailability in humans of 12.38 ± 1.38% on average, from which 0.18 ± 0.11% of the ^{13}C dose was recovered from blood, 5.37 ± 0.67% from urine, and 6.91 ± 1.59% from breath, whereas 32.13 ± 6.13% of the ^{13}C was found in feces. The fate of the remaining ingested ^{13}C remains unknown, although there was considerable interindividual variability in the recovery of the ^{13}C tracer that ranged from 15.1 to 99.3%, probably as a result of a high variation in gastric and intestinal transit times, composition, and catabolic activity of colonic flora and the ability to take up and excrete catabolites and metabolites.

The accumulation of multiple phenolic metabolites might ultimately be responsible for the reported bioactivity of anthocyanins, with the gut microflora apparently playing an important role in the biotransformation process. Although phase II conjugates of Cy3G and cyanidin (cyanidin-glucuronide, methyl cyanidin-glucuronide, and methyl Cy3G-glucuronide) were detected, the most important metabolites corresponded to products from the anthocyanin degradation (i.e., benzoic, phenylacetic and phenylpropenoic acids, phenolic aldehydes, and hippuric acid) and their phase II conjugates, which were found at 60- and 45-fold higher concentrations than their parent compounds in urine and plasma, respectively.[27] An interesting observation was the rapid appearance of Cy3G degradation products and their phase II conjugates within the serum, which suggested that some degradation likely occurred in the small intestine (either pre- or postabsorption) and, therefore, anthocyanin C-ring cleavage may not require the action of colonic microflora. Estimates made by Czank et al.[27] of the half-lives of elimination for ^{13}C-labeled metabolites were between 12.44 ± 4.22 and 51.62 ± 22.55 h, which suggested a relatively slow urinary clearance of some metabolites. Long elimination half-lives may be the result of a combination of hepatic recycling, enterohepatic circulation, and prolonged colonic production and absorption. All in all, these data suggested that anthocyanins would be as bioavailable as other flavonoid subclasses, such as flavan-3-ols and flavones, which have relative bioavailabilities between 2.5% and 18.5%.[26]

Further intervention studies using different anthocyanins and food matrices are, nevertheless, required to confirm these preliminary conclusions on anthocyanin absorption and bioavailability, as well as to establish their putative effects on human health. It is expected that the advances in analytical methodologies enabling the identification and quantification of metabolites, both in food and in body fluids and tissues, together with bioinformatic strategies should allow the characterization of changes produced in the human metabolome as a consequence of anthocyanin intake, so that possible biomarkers of consumption and effects can be identified and adequate relationships with the incidence of diseases established.

THE SEVENTH INTERNATIONAL WORKSHOP ON ANTHOCYANINS (IWA 2013)

Advances in anthocyanin research are revised every two years in the International Workshop on Anthocyanins (IWA), the last edition of which took place in the beautiful city of Porto (Portugal). The IWA is the only world congress that focuses exclusively on anthocyanins and represents an essential meeting point for all people working in these amazing molecules. Since the first IWA took place in Melbourne (Australia) back in 2000, five more IWA meetings have been held in Australia (Adelaide 2002 and Sydney 2004), New Zealand (Rotorua 2006), Japan (Nagoya 2009), and the United States (Charlotte, NC, 2011). In September 2013, the IWA came for the first time to Europe, with the goal of bringing together scientists from universities, institutes, and industries, from different research areas but with the common ground of working on anthocyanins and attracting European researchers who did not have the opportunity to join the previous workshops. The meeting was divided into six topics: (1) biosynthesis, trafficking, and functionality; (2) genetic and metabolic engineering; (3) horticultural and ornamental plants; (4) phytochemistry and analysis; (5) anthocyanin in health and nutrition; and (6) anthocyanins in foods and industry. Around 130 participants from 21 different countries attended the IWA 2013, presenting 16 invited lectures (6 plenary lectures and 10 invited keynotes), 21 regular oral communications, and 80 posters. In relation to previous IWAs, which were more focused on plant anthocyanins (physiological roles, biosynthesis, metabolic engineering, etc.), the Porto meeting was enlarged upon food anthocyanins, as related to sensory properties and health.

This highlights issue presents a selection of papers from IWA 2013 dealing with anthocyanin accumulation in plants, relationship with color expression and stability in plants and food, copigmentation effects, stability during food processing and storage, chemical applications, bioavailability and effects in model systems, properties of anthocyanin-related pigments, microbial degradation, or influence on allergenic properties of food components. Now the countdown to the 8th International Workshop on Anthocyanins, which will take place in Montpellier (France) in 2015 organized by Dr. Véronique Cheynier, is on.

We thank the Editor-in-Chief, Prof. Jim Seiber, and the *JAFC* editorial office for the opportunity to publish this special issue, as well as to all submitting authors and reviewers for their invaluable contributions.

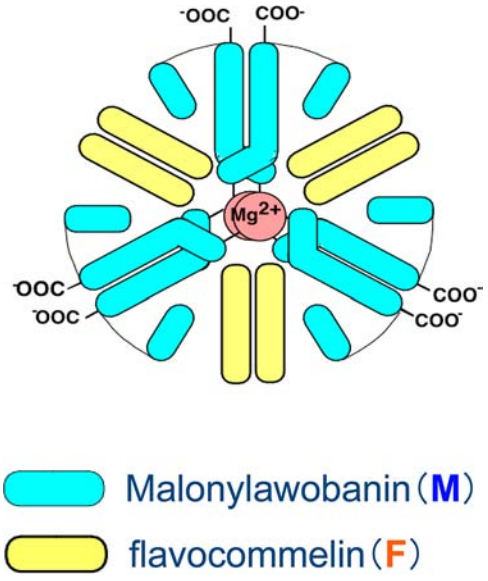

Figure 2. Self-assembly of malonylawobanin and flavocommelin (courtesy from Prof. Kumi Yoshida).

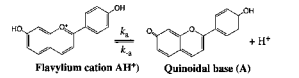
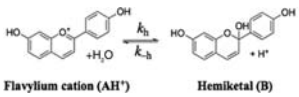
compound 4′,7-dihydroxyflavylium found in the Dragon's blood resins.[8]

The flavylium cation (AH^+) is stable only at very acidic pH values because the two reactions in which it is involved, deprotonation to give the quinoidal base (A), eq 1, and hydration leading to the hemiketal (B), eq 2, are pH dependent.



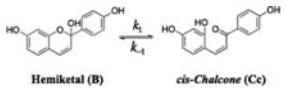
$K_a = k_a/k_{-a}$ (deprotonation) (1)



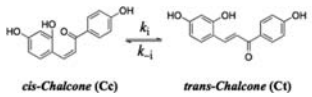
$K_h = k_h/k_{-h}$ (hydration) (2)

These two parallel reactions are in competition and occur on different scales of time: proton transfer in microseconds and hydration in minutes to subseconds, depending on pH. As a consequence upon a pH jump from very acid solutions (where AH^+ is the dominant species) to higher pH values, hereafter designated direct pH jump, A appears as a kinetic product that usually fades with time, because it is not the most stable species at the equilibrium. The hemiketal (chromene) is involved in a tautomeric process that leads to ring opening with the formation of a *cis*-chalcone form, eq 3. This reaction usually occurs on the subsecond time scale.

Finally, the *cis*-chalcone isomerizes and gives the *trans*-chalcone, eq 4, on the time scale of seconds or many days depending on the flavylium substitution pattern.



$K_t = k_t/k_{-t}$ (tautomerization) (3)



$K_i = k_i/k_{-i}$ (isomerization) (4)

The colored species of the network are the flavylium cation and the quinoidal base, the last one red-shifted in comparison with the former.

The analysis of the thermodynamic equilibria of the flavylium compounds becomes easier if eq 5 is considered.[9,10] Equation 5 is equivalent to a single acid−base equilibrium between flavylium cation and a conjugate base, CB, defined as the sum of the concentrations of the other species in the network, [CB] = [A] + [B] + [*Cc*] + [Ct]

$$AH^+ + H_2O \rightleftharpoons CB + H_3O^+$$

$$K'_a = K_a + K_h + K_hK_t + K_hK_tK_i \quad (5)$$

From the set of eqs 1−5 it is easy to obtain the pH-dependent mole fraction distribution of the network species.

$$\chi_{AH^+} = \frac{[H^+]}{[H^+] + K'_a}; \quad \chi_A = \frac{K_a}{[H^+] + K'_a};$$

$$\chi_B = \frac{K_h}{[H^+] + K'_a}; \quad \chi_{Cc} = \frac{K_hK_t}{[H^+] + K'_a};$$

$$\chi_{Ct} = \frac{K_hK_tK_i}{[H^+] + K'_a} \quad (6)$$

When a relatively high *cis*−*trans* isomerization barrier is present as in anthocyanins, it is very useful to define a pseudoequilibrium attained before formation of significant amounts of Ct.

$$AH^+ + H_2O \rightleftharpoons CB^\wedge + H_3O^+$$

$$K^\wedge_a = K_a + K_h + K_hK_t \quad (7)$$

$$[CB^\wedge] = [A] + [B] + [Cc]$$

The mole fraction distribution of the species at the pseudoequilibrium, AH^+, A, B, and Cc, can be obtained from the expressions of eq 6 by substituting K'_a by $K^\wedge_a$.

Equation 5 refers to the thermodynamic equilibrium and thus can be used for all of the systems independently of whether have a high or low *cis*−*trans* isomerization barrier. In Figure 4A the absorption spectra regarding the compound 4′,7-dihydroxyflavylium at the equilibrium are shown. Inspection of this figure identifies from the shape and position of the absorption spectra the flavylium cation at lower pH values and at higher pH values the quinoidal base (absorbing around 490 nm) and *trans*-

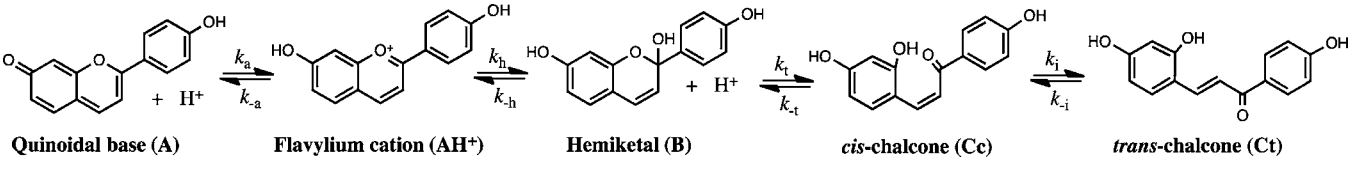


Figure 3. Network of chemical reactions of the natural compound 4′,7-dihydroxyflavylium. The equilibrium constants are defined as $K_n = k_n/k_{-n}$ (n = a, h, t, i).

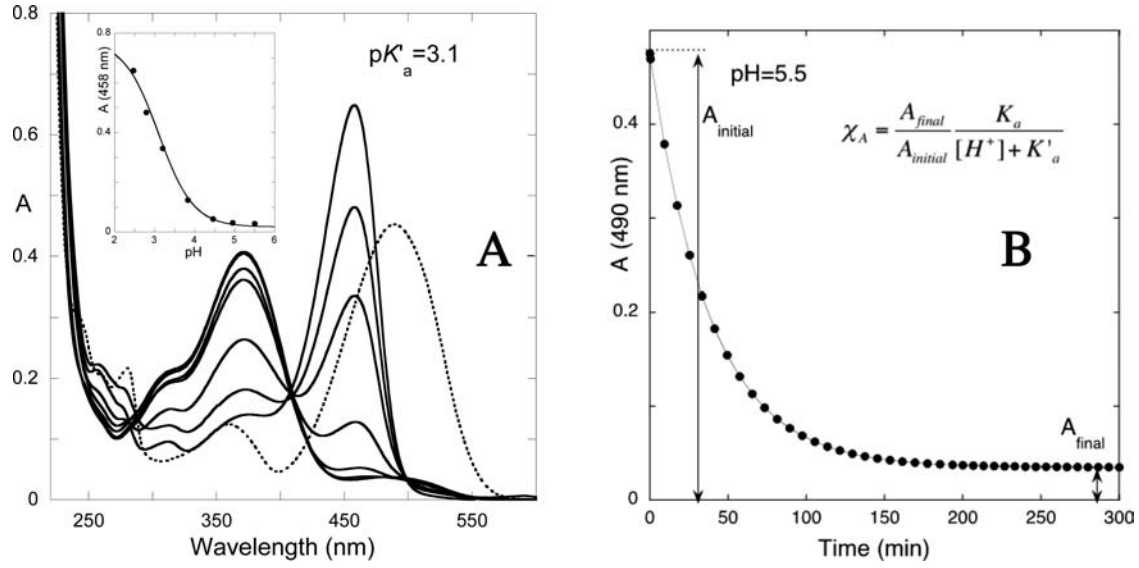

Figure 4. (A) Absorption spectra of equilibrated solutions of the compound 4′,7-dihydroxyflavylium (2.7×10^{-5} M) as a function of pH. Fitting was achieved through eq 5; for comparison purposes the absorption spectrum obtained immediately after the pH jump to 5.5 is shown (pointed line). Reprinted with permission from ref 19. (B) Trace of a direct pH jump from pH 1.0 to 5.5.

chalcone (absorbing around 360 nm), respectively minor and major products. In Figure 4B the trace corresponding to a pH jump from pH 1.0 to 5.5 taken at 490 nm is represented. The initial absorbance is due to the conversion of practically all flavylium cation into quinoidal base (absorption due to the total concentration C_0, see the respective absorption spectra Figure 4A, pointed line); at the equilibrium the absorbance corresponds to the remaining quinoidal base. The ratio $A_{final}/A_{initial}$ is equal to the mole fraction of quinoidal base at the equilibrium given by eq 6, permitting the calculation of the constant K_a from the previously known value of K'_a (Figure 4A).

One important breakthrough for the comprehension of the flavylium chemistry was the discovery of Brouillard and Dubois[9] that in acidic to neutral medium hemiketal is formed only through the hydration of flavylium cation and not from the quinoidal base.

The comprehension of the flavylium network of chemical reactions gains from the drawing of an energy level diagram easily achieved if the equilibrium constants of eqs 1−4 are known. The energy level diagram where all of the network species are positioned[11] is easily obtained from the relationship $\Delta G^0 = -RT \ln K$, where ΔG° is the standard Gibbs energy, R the gas constant, T the absolute temperature, and K the equilibrium constant for each process of the network.

The next discussion concerns flavylium networks exhibiting high *cis*−*trans* isomerization barriers, the paradigm of anthocyanins.

The relative position of each network species is very dependent on the substitution pattern of the flavylium core. The example of Figure 5 is representative of anthocyanins. In the case of a direct pH jump, for example, from pH 1.0, where the flavylium cation is the dominant species, to pH = pK_a, half of the flavylium cation is transformed in quinoidal base in a short time (less than the mixing time of a stopped-flow apparatus), according to eq 8:

$$k_1 = k_a + k_{-a}[H^+] \quad (8)$$

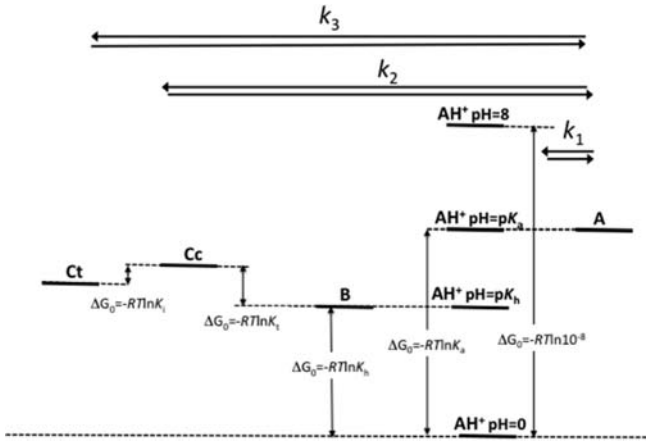

Figure 5. Energy level diagram of the flavylium network of chemical reactions, exhibiting a pattern representative of anthocyanins.

The base does not react in acidic to neutral pH values, and as a consequence the hydration of the flavylium cation (much slower than proton transfer in eq 1) is the next rate observed by stopped flow or in a common spectrophotometer (if it is slow enough). In the example of this pH jump, equal amounts of flavylium cation and quinoidal base disappear to give the more stable species. It must be emphasized that the interconversion between B and Cc is also very fast, and "once B is formed from the hydration of the flavylim cation" immediately it equilibrates with Cc. The last step (k_3, see below) is the formation of Ct, which is much slower. The second process with observed rate constant k_2 (eq 9) can thus be equivalent to a reversible first-order equilibrium involving two species: by one side AH^+ in fast equilibrium with A and by the other B in fast equilibrium with Cc. Without entering into a discussion of complex mathematical deductions,[12] the meaning of eq 9 can be extracted by considering that this observed rate constant is the sum of the direct process and the reverse one. The direct process is given by the rate constant k_h, which should be multiplied by the fraction of flavylium available to react $[H^+]/([H^+] + K_a)$ due to the discovery of Brouillard and Dubois that

dx.doi.org/10.1021/jf404869m | J. Agric. Food Chem. 2014, 62, 6885−6897

B in acidic medium is formed only through the reaction of AH^+. The reverse reaction is the formation of AH^+ from B accounted for by the term $k_{-h}[H^+]$. However, not all B is available to react, and thus the respective rate constant should be multiplied by its mole fraction resulting from the fast equilibrium between B and Cc, that is, $(1)/(1 + K_t)$.

$$k_2 = \frac{[H^+]}{[H^+] + K_a} k_h + \frac{1}{1 + K_t} k_{-h}[H^+] \quad (9)$$

At this stage of the kinetics, AH^+, A, B, and Cc are in pseudoequilibrium, $K^{\wedge}_a$.

The equilibrium is reached when Ct is formed; by a similar reasoning eq 10 can be written

$$k_3 = \frac{K_h K_t}{[H^+] + K^{\wedge}_a} k_i + k_{-i} = \frac{K_h K_t}{[H^+] + K_a + K_h + K_h K_t} k_i + k_{-i} \quad (10)$$

The first term corresponds to the formation of Ct from Cc given by k_i multiplied by the fraction of Cc available to give Ct (due to the formation of the pseudoequilibrium eq 7) plus the reverse isomerization reaction k_{-i}. Representation of this last process (in the case of the high *cis*−*trans* isomerization barrier) is shown in Figure 6.

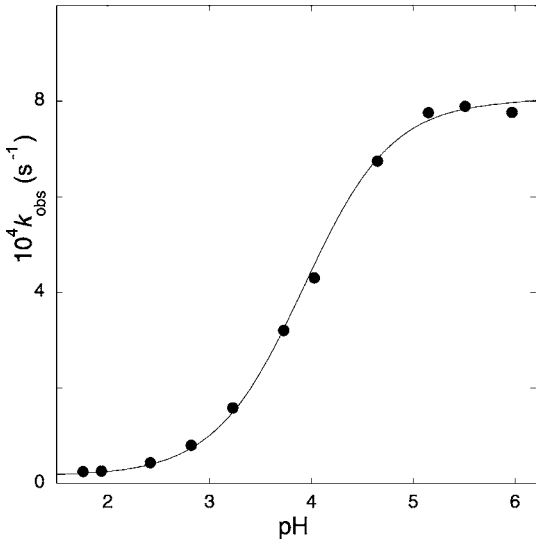

Figure 6. pH dependence of the rate constant of the slowest process upon a direct pH jump from solutions of 3′,4′-dihydroxy-7-*O*-*β*-D-glucopyranosyloxyflavylium at pH 1.0 to higher pH values: fitting was achieved with eq 10. Reprinted with permission from ref 18. Copyright 2013 Royal Society of Chemistry.

In the scheme shown in Figure 5, the data regarding the different kinetic process can be added, and in this way both thermodynamic and kinetic information of the system can be visualized.

In many other flavylium networks the *cis*−*trans* isomerization barrier is very small and the pseudoequilibrium is not formed; steps 2 and 3 above-described are transformed into one step.[13] Assuming that the equilibrium between AH^+ and A as well between B and Cc is reached during the kinetic process, the following equation can be deduced, again from simple reasoning without the use of more complex mathematical deductions.

$$A \underset{H^+}{\overset{K_a}{\rightleftharpoons}} AH^+ \underset{k_{-h}H^+}{\overset{k_h}{\rightleftharpoons}} B \overset{K_t}{\rightleftharpoons} Cc \underset{k_{-i}}{\overset{k_i}{\rightleftharpoons}} Ct \quad (11)$$

(equilibrium, equilibrium)

This is equivalent to the equilibrium

$$X \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Y \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Z \quad (12)$$

where the equilibrium between AH^+ and A is assigned to X, and the equilibrium between B and Cc to Y and Ct to Z.

Assuming the steady state for Y, the observed rate constant is given by eq 13

$$k_{obs} = \eta_{Y(direct)} k_2 + \eta_{Y(reverse)} k_{-1} \quad (13)$$

where $\eta_{Y(direct)} = (k_1)/(k_{-1} + k_2)$ is the formation efficiency of Y during the direct process and k_2 the rate of Z formation during the same process, $\eta_{Y(reverse)} = (k_{-2})/(k_{-1} + k_2)$ is the formation efficiency of Y in the reverse process, and k_{-1} is the rate of X formation in this last process.

In the scheme shown in eq 12 k_1 is equal to $([H^+])/([H^+] + K_a) \times k_h$ because k_h should be multiplied by the mole fraction of AH^+ available due to its equilibrium with A; k_2 is equal to $(K_t)/(1 + K_t)k_i$ due to the equilibrium between B and Cc. With regard to the reverse processes, k_{-2} is identified as k_{-i} and k_{-1} as $k_{-h}[H^+](1)/(1 + K_t)$, the last term also due to the equilibrium between B and Cc.

Substituting these constants in eq 13

$$k_4 = \frac{\frac{[H^+]}{[H^+] + K_a} k_h k_i \frac{K_t}{1 + K_t} + k_{-i} k_{-h}[H^+] \frac{1}{1 + K_t}}{\frac{k_{-h}[H^+]}{1 + K_t} + k_i \frac{K_t}{1 + K_t}} = \frac{\frac{[H^+]}{[H^+] + K_a} k_h k_i K_t + k_{-i} k_{-h}[H^+]}{k_{-h}[H^+] + k_i k_t} \quad (14)$$

dividing by k_{-h} gives the expression usually reported in the literature:

$$k_4 = \frac{\frac{[H^+]}{[H^+] + K_a} K_h K_t k_i + k_{-i}[H^+]}{[H^+] + k_i \frac{K_t}{k_{-h}}} \quad (15)$$

Now we have the kinetic equations to deal with flavylium derivatives exhibiting high or low *cis*−*trans* isomerization barriers.

In Figure 7, the bell-shaped curve is represented for the compound 3′,4′,7-trihydroxyflavylium (black circles).[14]

The same curve is obtained in the presence of *β*-cyclodextrin (see below the respective discussion).

The fitting of the bell-shaped curve permits us to obtain the following parameters that should be confirmed by other independent relationships based on different experimental data (see below):

$$K_a;\ K_h K_t k_i;\ k_{-i};\ \frac{k_i K_t}{k_{-h}}$$

Determination of the Rate and Equilibrium Constants of the Network. Two different strategies to calculate the rate and equilibrium constants of the network of flavylium compounds are used, depending on the existence or not of a thermal *cis*−*trans* isomerization barrier. In both cases, however, it is necessary the use of the so-called reverse pH jumps, which consist of the acidification of equilibrated or pseudoequilibrated

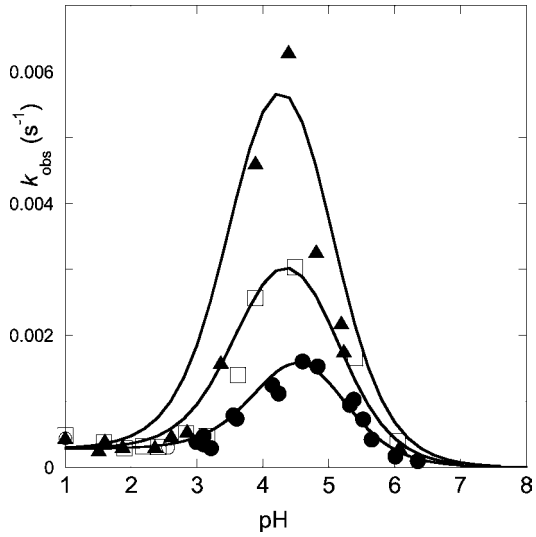

Figure 7. Representation of the rate constants regarding the formation of *trans*-chalcone upon a pH jump from equilibrated solutions of the compound 3′,4′,7-trihydroxyflavylium at pH 1.0 to higher pH values: (●) no *β*-cyclodextrin; (□) 4.8 mM; (▲) 8.3 mM. Fitting was achieved with eq 15. Reprinted with permission from ref 14. Copyright 2013 Royal Society of Chemistry.

solutions at moderate pH values. An example of a reverse pH jump is given in Figure 8.[15]

The ratio between the amplitude of the two exponentials Cc/B gives the equilibrium constant K_t. In the case of anthocyanins the mole fraction of Cc (and Ct) is very small, and thus this measurement should be repeated several times to find a value with statistical meaning.

In the case of the existence of a high *cis*−*trans* isomerization barrier as in anthocyanins, a step-by-step procedure to carry out this calculation was previously reported.[16] The constant K'_a is obtained from the fitting of the data as reported in Figure 4A. The constant K_a is obtained as shown in Figure 4B. Moreover, the fitting of k_2 (eq 9) allows us to determine k_h and k_{-h} and thus K_h, because the other constants are already known. The calculation of the hydration constant, K_h, should be coherent with the kinetic data of the reverse pH jumps as those represented in Figure 4B. The first process to be observed in the reverse pH jumps is the hydration reaction from all B present at the equilibrium (or even pseudoequilibrium). Taking into account that the final pH is very acidic, there is a change of regime in the sense that the hydration becomes faster than tautomerization. On this basis it can be considered that all B reacts to give AH^+ before significant changes in the Cc concentration take place. In other words, there is no equilibrium between B and Cc to consider and eq 16 is different from eq 9. (This difference is small if the constant K_t is small.)

$$k_5 = \frac{[H^+]}{[H^+] + K_a} k_h + k_{-h}[H^+] \tag{16}$$

$$k_6 = k_{-t} \tag{17}$$

A last much slower process leads to flavylium cation from Ct (not shown in Figure 4B). Due to the fact that no B is accumulated, the back reaction from B to Cc is not significant, and eq 17 can be used and k_{-t} obtained.

As shown above, once K_t, K_a, and K_h have been calculated and from the value of K'_a, the remaining equilibrium constant K_i is also found. With regard to the rate constants, $k_t = K_t k_{-t}$, k_i, and k_{-i} are achieved from the kinetics of the slowest process (eq 10) and the equilibrium constant K_i.

Summarizing the step-by-step procedure permits us to obtain all of the rate and equilibrium constants and, for example, to draw an energy level diagram such as the one reported in the scheme reported in Figure 5.

When the *cis*−*trans* isomerization barrier is small and the bell-shaped curve is followed, the strategy should be different, because the data acquired from the bell-shaped curve (eq 15) are not adequate to calculate all of the constants of the system.

Photochemistry: A Powerful Tool. As shown above, when the system possesses a high *cis*−*trans* isomerization barrier, it is possible to access all of the equilibrium and rate constants. However, when the barrier is very small, the species B and Cc are more or less elusive, and the only reliable data are

taken from the bell-shaped curve. Moreover, according to our experience there are multiple solutions of the bell-shaped curve, and as a consequence other relationships between equilibrium and rate constants should be achieved. When the compounds show photochemistry, the problem is easily solved.

Photochromism occurs in many flavylium derivatives including deoxyanthocyanins. A necessary requirement to observe this phenomenon is the existence of significant amounts of Ct at the equilibrium.

The photochromism arises from the formation of the flavylium cation (or quinoidal base) upon irradiation of the *trans*-chalcone (Figure 9).

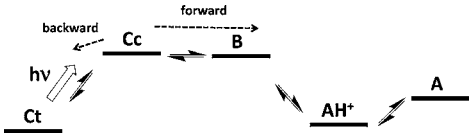

Figure 9. Photochromism in the flavylium network.

The irradiation of the *trans*-chalcone leads to the appearance of the *cis*-chalcone in a very fast process that takes 16 ns in the case of 4′,7-dihydroxyflavylium (not shown).[17] As presented in Figure 9 the *cis*-chalcone has two alternatives to react (because it is not thermodynamically stable): (i) backward to recover *trans*-chalcone and (ii) forward to give flavylium cation/quinoidal base. The last kinetic process is pH dependent, increasing with increasing proton concentration, and thus the photochromism can be modulated by the pH. One important aspect is the change of regime that takes place only at more acidic pH values (not assessed by direct pH jumps). At these pH values the hydration is faster than tautomerization and, as a consequence, the last one becomes the rate-determining step (see below).

The photochromism of flavylium compounds is a general phenomenon. In Figure 10 the spectral variations taking place upon steady state irradiation of the bioinspired compound 3′,4′-dihydroxy-7-*O*-*β*-D-glucopyranosyloxyflavylium (Figure 11) are shown.[18]

Flash photolysis is a powerful technique that can give further information regarding the flavylium-based photochromic systems. This technique was used, for example, to study the photochromism of the compound 4′,7-dihydroxyflavylium inside *β*-cyclodextrin, but it is a rather general technique (Figure 12).[19] When the absorption is followed at 371 nm, the bleaching immediately after the flash occurs because the *cis*-chalcone absorbs less than the *trans*-chalcone. The partial recovery corresponding to the first kinetic step is due to the backward reaction restoring part of the initial *trans*-chalcone. When the absorption is followed at the flavylium cation/quinoidal base (459 nm), the appearance of these species is observed (the relative fraction depending on the pH). The rate constants at both wavelengths follow a first-order kinetics and are equal within experimental error as expected from two parallel reactions. In a longer time scale the system reverts totally to the initial *trans*-chalcone, defining in this way a photochromic system.

Representation of the rate constants of Figure 12 as a function of pH (see Figure 13) is accounted for by eqs 9 and 18.

At higher pH jumps the rate-determining step is the hydration reaction and eq 9 ($(k_2 = ([H^+])/([H^+] + K_a)k_h +$

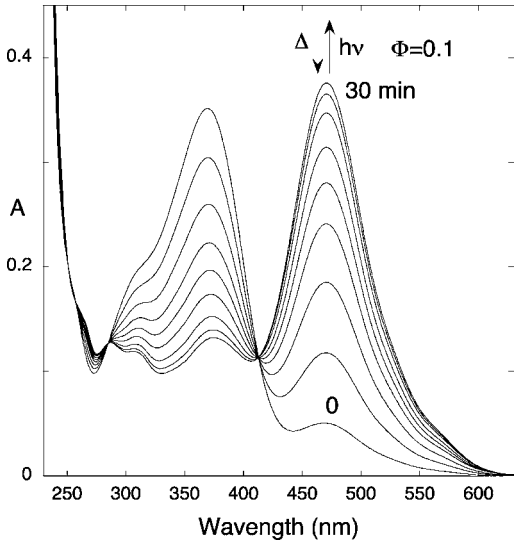

Figure 10. Spectral modifications as a function of irradiation time at 365 nm, pH 3.7, of the compound 3′,4′-dihydroxy-7-*O*-*β*-D-glucopyranosyloxyflavylium. Reprinted with permission from ref 18. Copyright 2013 Royal Society of Chemistry.

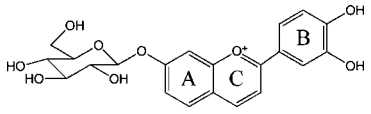

Figure 11. 3′,4′-Dihydroxy-7-*O*-*β*-D-glucopyranosyloxyflavylium.

$(1)/(1 + K_t)k_{-h}[H^+]))$ is followed. At lower pH values the hydration becomes faster than tautomerization (it is directly proportional to $[H^+]$) and eq 18 should be used.

$$k_7 = k_{-t} + k^H[H^+] + k^{OH}[OH^-] \quad (18)$$

In eq 18 the basic and acid catalysis of the tautomerization reaction as reported by McClelland and co-workers was considered.[20]

The reaction quantum yield is another source of kinetic information (Figure 14). When the hydration is the rate-determining step, the equilibrium between B and Cc is established, and the forward and backward reactions are respectively given by eqs 19 and 20:

$$k_{forward} = \frac{k_{-h}[H^+]}{1 + K_t} \quad (19)$$

$$k_{backward} = \frac{K_t}{1 + K_t}k_i \quad (20)$$

Neglecting the contribution of k_{-i} as well as $k_h[H^+]/([H^+] + K_a)$ (k_{-i} is relatively very small; on the other hand, the hydration is the rate-determining step at moderately acidic pH values, and this term has a negligible contribution), the pH dependence of the quantum yield is thus given by eq 21:

$$\Phi = \Phi_0 \frac{k_{forward}}{k_{forward} + k_{backward}} = \frac{[H^+]}{[H^+] + \frac{K_t k_i}{k_{-h}}} \quad (21)$$

The fitting from eq 21 should be coherent with the same parameter taken from the bell-shaped curve of eq 15.

dx.doi.org/10.1021/jf404869m | J. Agric. Food Chem. 2014, 62, 6885−6897

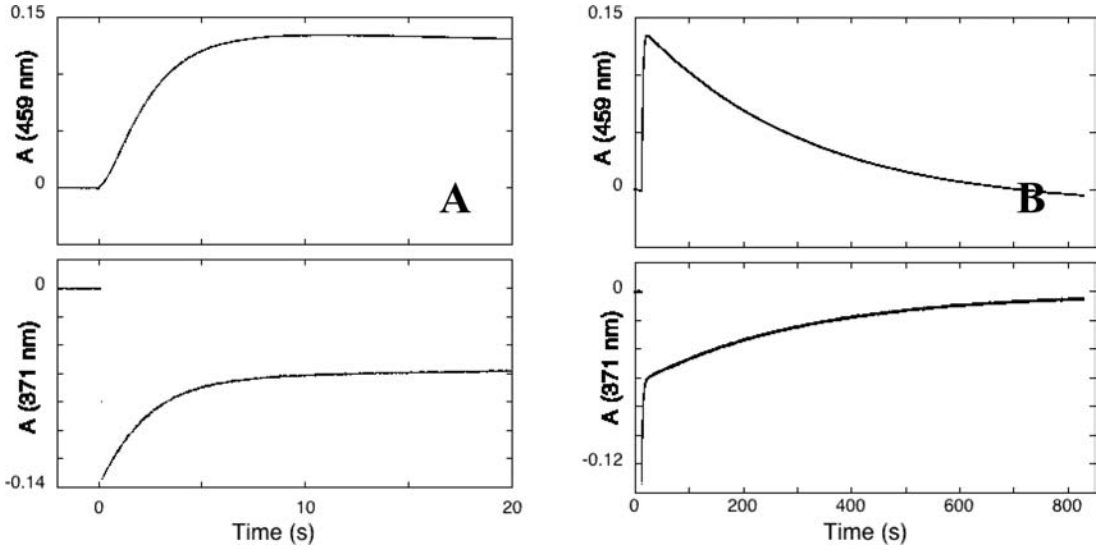

Figure 12. (A) Flash photolysis of the compound 4′,7-dihydroxyflavylium (2.7×10^{-5} M) in the presence of β-cyclodextrin (9 mM) at pH 3.6. The trace at 459 nm corresponds to the flavylium cation absorption, whereas that at 371 nm corresponds to the *trans*-chalcone. (B) The same observed in a larger time scale to evidence the reversibility of the photochromic system. Reprinted with permission from ref 18. Copyright 2013 Royal Society of Chemistry.

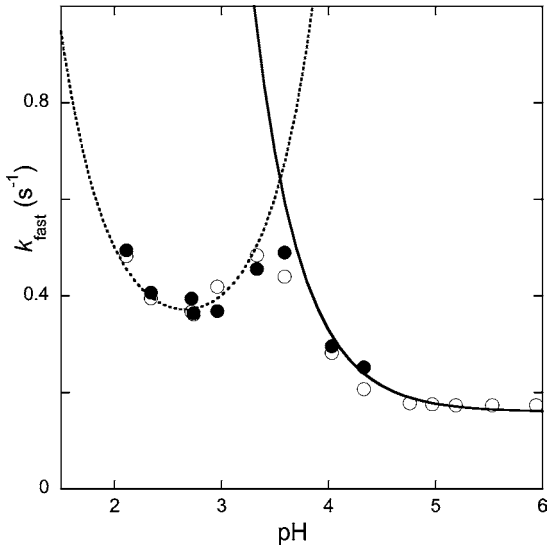

Figure 13. Typical dependence of the flash photolysis rate constants (faster process) as a function of pH: (●) monitored at the flavylium absorption maximum; (○) monitored at the *trans*-chalcone maximum. Full line fitting was achieved with eq 9 $k_{-h}/(1 + K_t) = 1700\ s^{-1}\ M^{-1}$; $k_i K_t//(1 + K_t) = 0.16\ s^{-1}$. Traced line fitting was achieved with eq 18 $k_{-t} = 0.28\ s^{-1}$; $k^H = 21\ s^{-1}\ M^{-1}$; $k^{OH} = 8 \times 10^9\ s^{-1}\ M^{-1}$. The experimental points correspond to the compound 3′,4′,7-trihydroxyflavylium in the presence of 4.8 mM β-cyclodextrin.

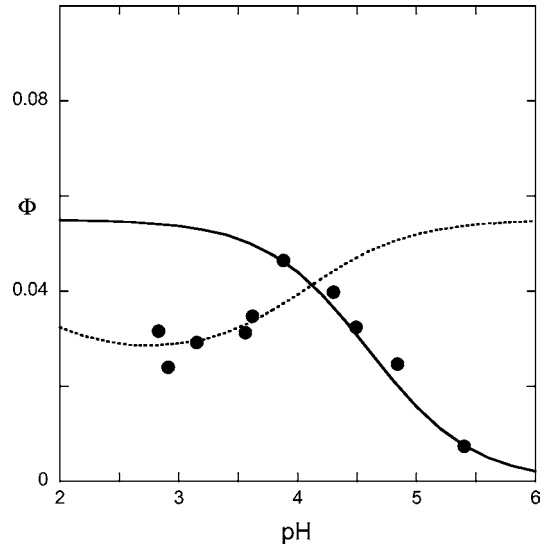

Figure 14. Quantum yields as a function of pH, fitted using eqs 21 and 22 for $K_t/k_i/k_{-h} = 2.5 \times 10^{-5}\ M^{-1}$; $k_{-t} = 0.45\ s^{-1}$; $k^H = 26\ M^{-1}\ s^{-1}$; $k^{OH} = 8 \times 10^9\ M^{-1}\ s^{-1}$; $k_i = 0.5\ s^{-1}$; $\Phi_0 = 0.055$. The experimental points correspond to the quantum yields of the compound 3′,4′,7-trihydroxyflavylium in the presence of 4.8 mM β-cyclodextrin.

When the rate-determining step is the tautomerization reaction, as observed in Figure 5 (change of regime), the pH dependence of the quantum yield follows eq 22:

$$\Phi = \Phi_0 \frac{k_{-t} + k^H[H^+] + k^{OH}[OH]^-}{k_{-t} + k^H[H^+] + k^{OH}[OH]^- + k_i} \quad (22)$$

To calculate all of the rate and equilibrium constants of the system, the more practical way is to carry out a global fitting of the bell-shaped curve (eq 15 together with eqs 9, 18, 21, and 22). In particular, eq 21 should be coherent with the values obtained from the bell-shaped curve. The procedure above-reported allows us to draw an energy level diagram also observed for the compound lacking a high *cis*−*trans* isomerization barrier. Such an example is reported in the scheme shown in Figure 15. Comparing the schemes shown in Figures 5 and 15 (respectively for compounds with and without the *cis*−*trans* isomerization barrier), the most interesting feature is the high energy level of species B and Cc, confirming our observation that they are more or less elusive species.

BIOINSPIRED APPLICATIONS

Flavylium Network in Confined Medium. Bioinspired application within the framework of flavylium chemistry includes compounds made by synthesis possessing some features of the anthocyanins and other natural related

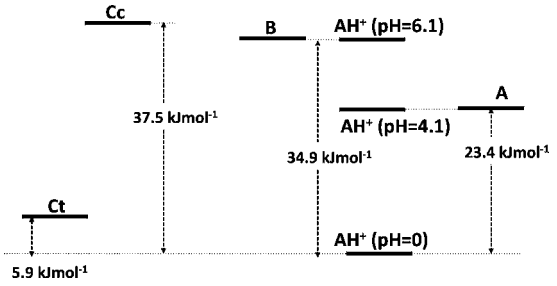

Figure 15. Energy level diagram of the compound 3′,4′,7-trihydroxyflavylium.

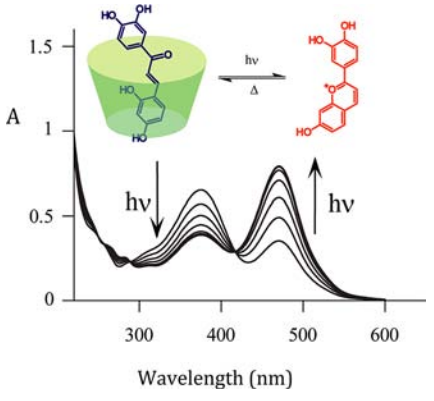

Figure 16. Representation of the compound 3′,4′,7-trihydroxyflavylium inside the cavity of the β-cyclodextrin according to the NMR data (ROESY). Irradiation at 365 nm gives rise to the formation of flavylium cation that migrates to the bulk solutions.

compounds, in particular following the same network of chemical reactions.

One question that can be posed is how the flavylium network behaves in different matrices. Recently the compounds 3′,4′,7-trihydroxyflavylium and 4′,7-dihydroxyflavylium were studied in the presence of β-cyclodextrin.[14,19] The main conclusion is that the *trans*-chalcone is preferentially stabilized by the β-cyclodextrin and that its interaction with flavylium cation is practically negligible (association constant ≈ 0). This is an interesting example of the so-called anticopigmentation effect,[21−23] because in the presence of β-cyclodextrin the rate to reach the equilibrium increases, favoring the colorless species (see Figure 7). According to the NMR data (ROESY) the position of the Ct inside the β-cyclodextrin can be determined (Figure 16). In addition, upon irradiation the formation of flavylium cation can be observed, and because this form does not interact with the host, it should migrate to the bulk solution, emptying in this way the cavity.

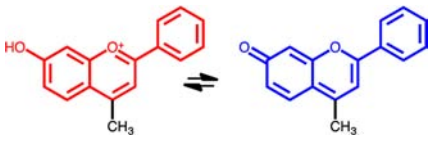

Figure 20. Chemical structure of 7-hydroxy-4-methylflavylium.

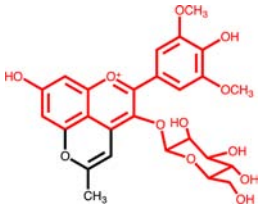

Figure 21. Chemical structure of methylpyranomalvidin-3-*O*-glucoside.

This example is in contrast with the behavior of 4′,7-dihydroxyflavylium in the presence of molecular clips as hosts. In that case the flavylium cation is stabilized to complexation with the host, whereas the *trans*-chalcone is poorly stabilized.[24]

Dragon's Blood. An Example of How Chemical Information Can Be Lost. Dragon's blood is a natural resin, presenting a rich deep red color, obtained from various trees, namely, *Dracaena draco* and *Dracaena cinnabaris* belonging to the Liliacae family. It is known that it appears in injured areas of the tree.[25] Dragon's blood has been used for centuries for medical and artistic purposes.[26] Despite the characterization of many compounds from Dragon's blood resins, with precise geographic origins and plant species, none could be responsible for the red color of the resins, except those reported in Table 1.[27]

Researchers familiar with the flavylium network of chemical reactions immediately recognized in these structures the quinoidal bases. However, the information that the red color of the resin named Dragon's blood is related to natural flavylium compounds has been misleading during the past decades, up to the description of dracofavylium.[27] Figure 17 shows a picture of the quinoidal base and flavylium cation colors.

More recently, the compound 4′,7-dihydroxyflavylium was also identified as one of the colorants of Dragon's blood.[8]

One interesting feature of dracoflavylium is its pH-dependent mole fraction distribution, which is very different from that of anthocyanins as well as from most of the synthetic flavylium compounds reported.[1] In dracoflavylium the more stable species at moderately acidic pH values is the quinoidal base (Figure 18). The color of Dragon's blood is given by the quinoidal base, which in these compounds is the major species at these pH values.

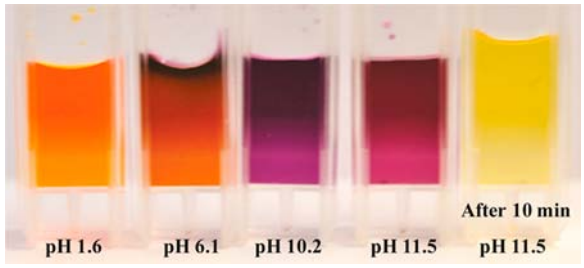

Figure 23. Formation of quinoidal base and ionized quinoidal bases from the flavylium cation of methylpyranomalvidin-3-*O*-glucoside and respective colors. Reprinted with permission from ref 29.

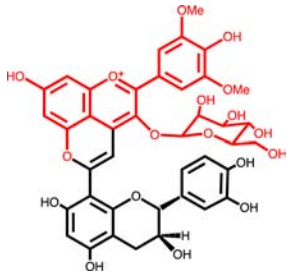

Figure 24. Chemical structure of pyranomalvidin-3-*O*-coumaroylglucoside-(+)-catechin.

Profit can be taken from the fact that these dyes belong to the family of flavylium network chemical reactions.[8] A simple and rapid liquid chromatographic method with diode array UV−vis spectrophotometric detection has been developed for the authentication of Dragon's blood resins from *Dracaena* and *Daemonorops* trees. The method uses an extract at pH 1.0 to have the flavylium cation of the different dyes. Using this method it was discovered that the flavylium chromophores differ among the species and could be used as markers to differentiate them. A study of parameters, such as time of extraction, proportion of methanol, and pH, was undertaken to optimize the extraction of the flavylium compounds. This method was then used to make extracts from samples of Dragon's blood resin obtained from material of known botanical origin. From the samples analyzed, 7-dihydroxy-5-methoxy-6-methylflavylium (dracorhodin), 4′,7-dihydroxy-5-methoxyflavylium (dracoflavylium), and 4′,7-dihydroxyflavylium were selected as species markers for *Daemonorops* spp., *Dracaena draco*, and *Dracaena cinnabari*, respectively. The chromatograms from these samples were used to build an HPLC-DAD database. The ability to discriminate among species of Dragon's blood using the single marker compounds was compared with a principal component analysis of the chromatograms in the HPLC-DAD database. The results from the HPLC-DAD method based on the presence of these flavylium markers was unequivocal. The HPLC-DAD method

was subsequently applied to 37 samples of Dragon's blood resins from the historical samples in the Economic Botany Collection, Royal Botanic Gardens, Kew, UK (Figure 19). The method identified anomalies in how samples in this collection had been labeled. It is clear that the method can be used to evaluate the provenance of samples used in different areas of cultural heritage. It also could be used to monitor the trade of endangered species of Dragon's blood and the species being used in complex formulations of traditional Chinese medicine.

Strategies To Avoid Hydration. The fact that 4-substituted flavylium compounds do not hydrate was previously described for the compound 7-hydroxy-4-methylflavylium (Figure 20).[28]

One family of compounds related to 4-methyl-7-hydroxyflavylium is pyranoanthocyanins. The pyranoanthocyanins are anthocyanin-derived pigments with a common structural feature: the presence of an additional pyranic ring between C-4 and the 5-hydroxyl group of anthocyanins. Different pyranoanthocyanin pigments have been identified in red wines over the years. Methylpyranomalvidin-3-*O*-glucoside (Figure 21) was obtained through the reaction of malvidin-3-glucoside with acetoacetic acid lithium salt.[29]

dx.doi.org/10.1021/jf404869m | *J. Agric. Food Chem.* 2014, 62, 6885–6897

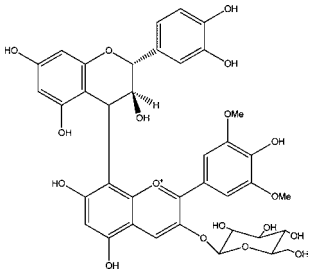

Figure 27. Chemical structure of catechin-(4,8)-malvidin-3-*O*-glucoside. The chiral carbons of catechin are 2*R*(+),3*S*(−), and from epicatechin both 2*R*,3*R* are (−).

As in the previous example the compound is very stable and the main reactions result from the deprotonation of flavylium cation at higher pH values to form the quinoidal base and the respective ionized quinoidal bases (Figure 22). These reactions are very fast, and only at very basic pH values does the last form take a few minutes to be formed (Figure 23). Another example concerns the compound pyranomalvidin-3-*O*-coumaroylglucoside-(+)-catechin (Figure 24).[30]

As in the previous example the equilibrium is established between flavylium cation and quinoidal base and respective ionized quinoidal bases (Figures 25 and 26).

Different is the behavior of the compound malvidin-3-*O*-glucoside-catechin-(4,8) (Figure 27).[31] This compound behaves like common anthocyanins (Figure 28). Figure 28 is given as an example of how all of the thermodynamic and kinetic information regarding a flavylium-derived network can be presented. At the left side the mole fraction distribution of the network species was calculated by means of eq 6, clearly indicating that at moderately acidic pH values the most stable species is the hemiketal. In the right part of Figure 28 an overview of the relative stability is given, together with the rates of interconversion between the different network species. The catechin in position 8 does not affect significantly the behavior of the anthocyanin malvidin-3-*O*-glucoside (oenin).

In conclusion, the substitution at position 4 seems to be a sufficient requirement to confer stability toward hydration. A possible explanation for this behavior is that the hydration starts from the attack at position 4 followed by a migration. This question is now under study.

Dye-Sensitized Solar Cells. Solar energy conversion is one of the most relevant questions of modern society. In particular,

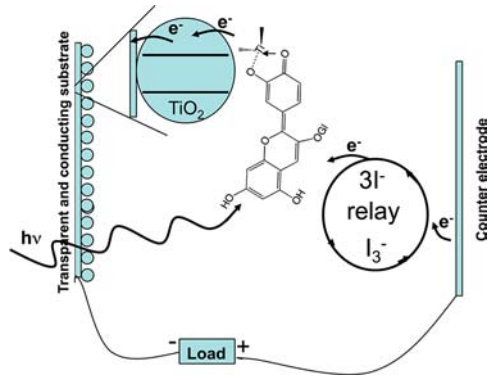

Figure 29. Scheme of a DSSC based on cyanidin. Reprinted with permission from ref 32.

dye-sensitized solar cells (DSSCs) are a very attractive solution because they are easy to fabricate, low in cost, and flexible in color, shape, and transparency.[32,33] The most efficient DSSCs are based on ruthenium and osmium complexes. These metals are toxic and expensive and, as a consequence, alternatives are needed. A very promising one is based on natural dyes. Grätzel[32] reported the first DSSC based on cyanidin (Figure 29). It is worth noting the fact that the flavylium species attached to the titanium dioxide is the quinoidal base. Light excitation of the quinoidal base leads to the injection of an electron into the titanium dioxide (radical cation). As a consequence, the quinoidal base becomes positively charged. The titanium dioxide is deposited into a conductive glass, and thus the electron is conducted through the device to the counter electrode (producing the electric current). In the counter electrode the electron is transferred to a relay, in this case I_3^-, which by itself transfers the electron to the oxidized form of the quinoidal base, closing the cycle. As mentioned in the Introduction, the base in moderately acidic conditions does not hydrate (the hydration takes place from the flavylium cation) and thus, in principle, could confer stability to the device. More recently, Calogero[34] used dyes of eggplant, arriving at a conversion of 0.7% that compares with 0.57% from the initial cyanidin-based Grätzel DSSC.

The DSCC can profit from the concept of bioinspiration.[35] Whereas the anthocyanins available are more or less reduced to six most common structures, there are many possibilities to synthesize new flavylium derivatives designed to obtain better

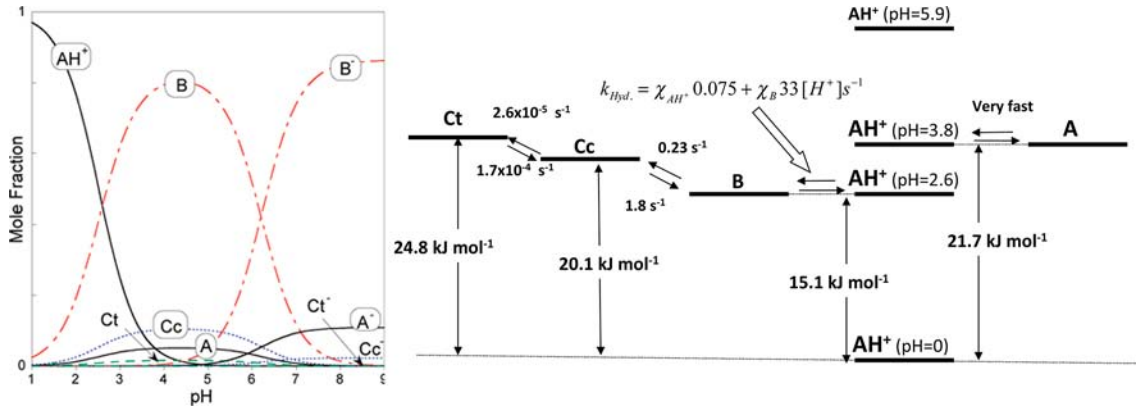

Figure 28. Complete characterization of the compound catechin-(4,8)-malvidin-3-*O*-glucoside, showing the respective mole fraction distribution, energy level of the species at the equilibriumm and rates of interconversion between the different networks of chemical reactions species.

performances of DSSC. For this purpose we have prepared the compounds reported in Figure 30.

The most efficient synthetic flavylium compounds are **d** and in particular **g**. In both cases there are donors in positions 7 and 4′. In the case of compound **g**, the reported efficiency was 2.1%, but recently a value of 3.5% was obtained (unpublished data).

Through this work we demonstrated that there are big advantages in looking at natural flavylium compounds and synthetic ones as components of the same reality, due to the existence of a common network of chemical reactions. Knowledge of the physical−chemical behavior of flavylium derivatives is indispensable in the study of the properties of these compounds. As an example, flavylium cation is stable only in very acidic media, which is not the most common situation in biological systems except in the stomach during part of the digestion. On the other hand, natural flavylium compounds are a source of inspiration for the synthesis of new (synthetic) flavylium compounds. With regard to the applications of the latter, it is not proved that they can substitute for the natural ones, for example, as food additives or antioxidants, but this is a possible field for future research. What seems to be unquestionable is the application of bioinspired flavylium compounds as interesting photochromic systems or light absorbers in dye-sensitized solar cells.

Figure 1. General structure of anthocyanidins (flavylium form).

they are biotransformed into their metabolites, which are absorbed. In the intestinal microbiota, anthocyanins are extensively metabolized, especially by genera and species with enzymes necessary to catalyze these reactions. Dietary polyphenols are substrates for several enzymes located in the small intestine and colon and in the liver (hydrolyzing and conjugating enzymes, phase I and phase II, respectively).[12−15] Therefore, the colon is being considered as an active site for metabolism rather than a simple excretion route and has been receiving much attention from the scientific community.[16] This conversion is often essential for absorption and modulates the biological activity of these dietary compounds, not only due to the direct bioactivity of the products of microbiota metabolism, which is different from that of the parent compounds, but also because of their prebiotic activity in modulating the microbiota composition.[17,18]

PRODUCTS OF COLONIC METABOLISM OF ANTHOCYANINS

Microbiota catabolism results in the production of new phenolic compounds, which may be absorbed and exhibit different bioactivity from that of the parents, and plays an important role in systemic and local health effects.[19] Information regarding the colonic metabolism of anthocyanins is scarce and diffuse, especially because the metabolism of the microbiota is often studied after an intervention with a whole food or beverage, which contains not only anthocyanins but also other phenolic compounds. In addition, animal and human studies comprise an underlying interindividual variability that can hardly be overcome.

Early in vitro studies on the metabolism of anthocyanins by gut microflora have concluded that bacterial metabolism involved the cleavage of glycosidic linkages and breakdown of anthocyanidin heterocycle.[20] Protocatechuic acid was indicated as the major metabolite of gut microflora, but the techniques employed did not allow the identification of other metabolites.[20] This phenolic acid was also the major human metabolite detected in feces after blood orange juice consumption as a cyanidin-3-glucoside source.[21] Keppler et al.[22] have also confirmed the cleavage of the 3-glycosidic linkage and the instability of the anthocyanidin, which is rapidly converted to phenolic acids. Furthermore, O-demethylation of phenolic acids was also shown.[22]

In vitro incubation of phenolic compounds with human gut fecal matter has been a first approach to determine the anthocyanin metabolites formed by microbiota catabolism. Incubation of a red wine extract with a batch of human fecal microbiota resulted in a rapid decline of malvidin-3-glucoside and its acylated forms, but complete degradation of anthocyanins was observed only after 30 h of incubation.[23] The fast catabolism of anthocyanins was attributed to the presence of β-glucosidase activity of the microbiota.[20] The acylation forms of anthocyanins also seem to be degraded easily.[23]

The breaking of the heterocyclic C-ring of anthocyanins and degradation into phloroglucinol derivatives (from A-ring) and benzoic acids (from B-ring) are usually the result of bacterial metabolism.[22] In Sanchez-Patan et al., phloroglucinol was not detected, but instead, the dihydroxylated benzene catechol/pyrocatechol were progressively formed with incubation time. Unlike other studies,[24,25] in the model used by Sanchez-Patan et al.,[23] only an increase in syringic acid was observed, but no changes in protocatechuic and vanillic acids. However, an increase in benzoic acid was observed, which could be indicative of O-demethylation metabolites being extensively dehydroxylated, giving rise to benzoic acid as the final degradation product.

Two phenolic acids and one aldehyde (3-*O*-methylgallic acid, syringic acid, and 2,4,6-trihydroxybenzaldehyde) have also been noted as colonic metabolites of anthocyanins from grapes.[26] The primary phenolic degradation product detected in the incubation of human gut microflora with malvidin-3-glucoside was syringic acid and transitorily gallic acid and pyrogallol.[27] Once again, syringic acid demethylation of the B-ring is proposed to account for gallic acid formation.[27] When other anthocyanins are incubated, the main metabolites found are gallic, syringic, and *p*-coumaric acids.[27]

Moreover, the supplementation of human volunteers with raspberry anthocyanins resulted in the increase of catechol, resorcinol, pyrogallol, 4-hydroxybenzoic acid, 3,4-dihydroxybenzoic acid (protocatechuic acid), tyrosol, 3-(3′-hydroxyphenyl)propionic acid, and 3-(3′,4′-dihydroxyphenyl)-propionic acid.[25] In this study, an in vivo approach was used, and as in other in vivo studies, with the advantage of being closer to what happens in regular human consumption of anthocyanins, but it also has the disadvantage of increasing the confounding factors that may affect and influence anthocyanin metabolism by colonic microflora.

An intervention study performed with red wine, which is a very good source of anthocyanins, revealed significant changes in eight metabolites: 3,5-dihydroxybenzoic acid, 3-*O*-methylgallic acid, *p*-coumaric acid, phenylpropionic acid, protocatechuic acid, vanillic acid, syringic acid, and 4-hydroxy-5-(phenyl)valeric acid.[28] It is important to highlight that red wine has several other phenolic compounds, other than anthocyanins, that can give rise to these products, but the *O*-methyl benzoic acids such as syringic and vanillic acids could arise from methoxylated anthocyanin catabolism[19,20] and protocatechuic acid from cyanidin. *p*-Coumaric acid may also be a product from *p*-coumaroyl-acylated anthocyanins.[29] In addition, alcohol does not seem to affect the performance of the microbial catabolism as there were no changes with red wine and dealcoholized red wine interventions.[28]

A recent paper described the metabolism of cyanidin-3-glucoside in human microbiota-associated rats and determined protocatechuic acid, 2,4,6-trihydroxybenzaldehyde, and 2,4,6-trihydroxybenzoic acid (gallic acid) as the main colonic metabolites.[24] Nevertheless, other metabolites were found but not identified.

In a very recent study that makes use of isotopically labeled cyanidin-3-glucoside (6,8,10,3′,5′-$^{13}C_5$-C3G), the human metabolism and pharmacokinetics of this anthocyanin were studied after an ingestion of 500 mg.[30] It is very interesting

dx.doi.org/10.1021/jf501808a | J. Agric. Food Chem. 2014, 62, 6898−6902

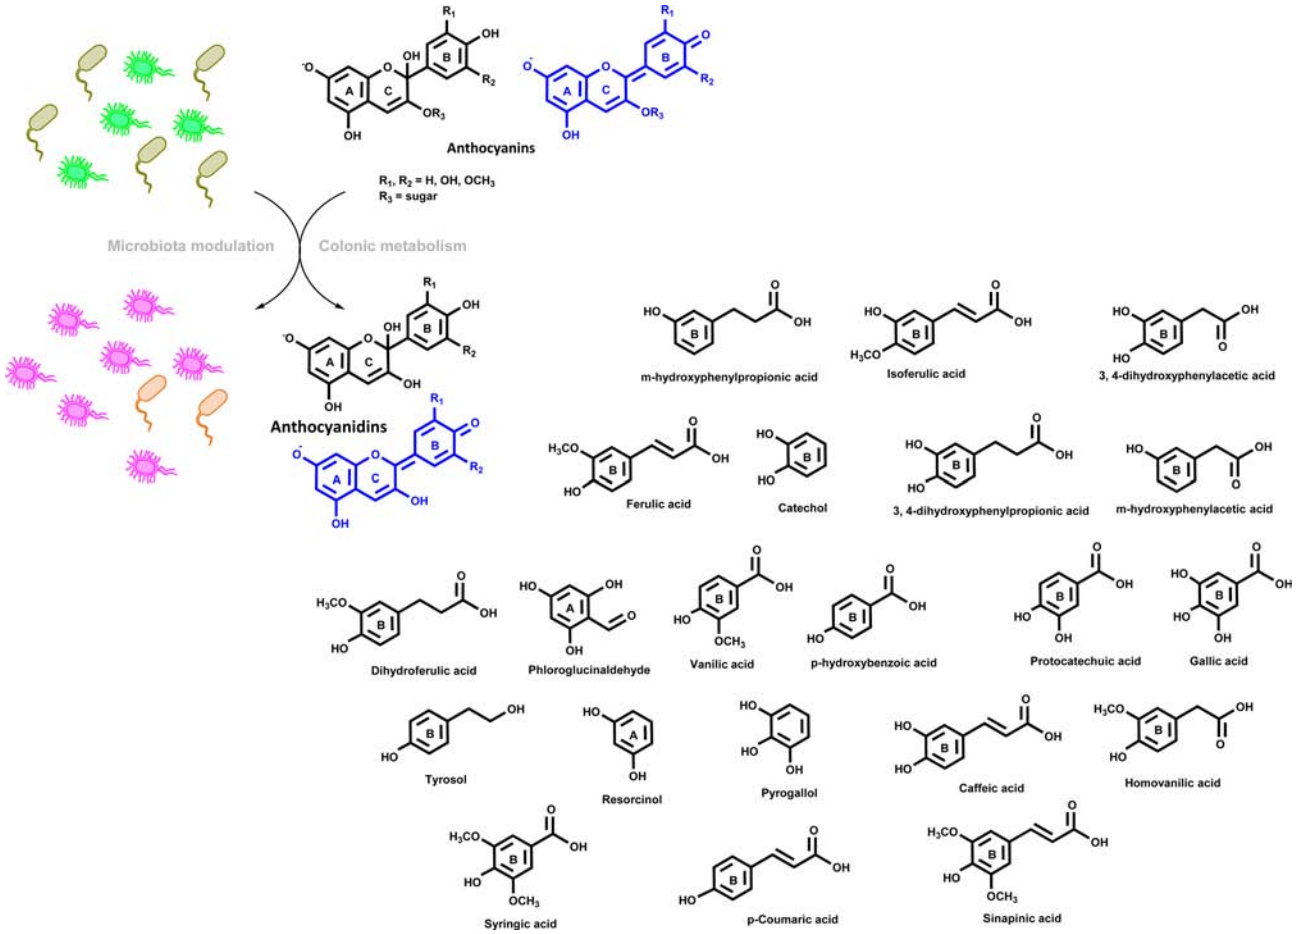

Figure 2. Schematic representation of anthocyanin microbiota modulation and most common detected colonic metabolites. On the one hand, interaction between the microbiota and anthocyanins results in a change of the abundance of certain bacterial groups (prebiotic activity), and, on the other hand, the microbiota is responsible for anthocyanin metabolization giving rise to anthocyanidins and a wide variety of simple phenolics. Anthocyanins are represented, according to the intestine pH range, in their carbinol anionic pseudobase and quinoidal anionic forms.

to observe that the higher ^{13}C-dose recovery was in feces and that the maximal concentration of total metabolites in feces was reached 24 h postconsumption,[30] highlighting the importance of colonic metabolization and degradation on the bioavailability and bioactivity of anthocyanins. A thorough analysis of these metabolites showed that B-ring derived ferulic acid was present at the highest concentrations within the feces, followed by the A-ring derived ferulic acid and protocatechuic acid.[31] Phase II metabolites of protocatechuic acid were also identified in feces by the presence of methyl-3,4-dihydroxybenzoate and methyl vanillate, suggesting that dimethylation is a product of microbial metabolism.[31] The detection of caffeic acid and its methyl metabolite, ferulic acid, within the feces supports the assumption that phenylpropenoic acids arise from cyanidin-3-glucoside as a result of bacterial cleavage of the C-ring in the colon,[31] as has already been proposed.[25,26]

It is worth noting that several factors differ within studies such as the microbiota origin species, the amount of anthocyanins tested in vitro and in vivo, the source of the anthocyanins, or the accuracy and sensitivity of the techniques used to identify the metabolites. Nevertheless, there is an interesting set of studies indicating that anthocyanins are metabolized in the colonic microflora, initially by deglycosylation and in a second phase by degradation into simple phenolic acids. Some of these acids appear to be consistent across studies, such as protocatechuic, vanillic, syringic, gallic, and *p*-coumaric, the latter as a product of acylated anthocyanins (Figure 2). These acidic metabolites are probably absorbed through monocarboxylic acids transporters (MCTs) by the epithelial cells.

■ ANTHOCYANIN MODULATION OF MICROBIOTA

No systematic reviews have been undertaken to assess the role of xenobiotic biotransformation in the colon, in particular with regard to anthocyanins. As described earlier, on the one hand, anthocyanins are subjected to metabolism by microbiota, and, on the other hand, they and/or their metabolites may modulate growth of specific bacteria from the microbiota (Figure 2).

There is evidence that the composition of the human intestinal microbiota has an influence on health and the incidence of disease and that gut health is largely determined by the complex interaction between host and gastrointestinal microbiota.[32]

Putatively beneficial bacteria such as *Bifidobaterium* spp. and *Lactobacillus* spp. are genera which include bacteria that have been observed to contribute to human health at different levels. They have been shown to enhance the gut barrier function, stimulate the host immune system, prevent diarrhea or allergies, participate in the activation of provitamins, and modulate lipid metabolism.[33,34] However, there are other bacterial species associated with negative implications, such as *Clostridium*

dx.doi.org/10.1021/jf501808a | J. Agric. Food Chem. 2014, 62, 6898−6902

difficile, which has been associated with inflammatory bowel disease.[35]

In vitro incubation of malvidin-3-glucoside with fecal slurry enhanced the growth of total bacteria including *Bifidobaterium* spp. and *Lactobacillus* spp.[27] with no effect observed on *Bacteroides* spp. growth. Interestingly, malvidin-3-glucoside mixed with other anthocyanins yielded a synergistic effect regarding the enhancement of growth of the beneficial bacterial group.[27] Gallic acid, one of the microbiota anthocyanin metabolites, was shown to reduce a group of potentially harmful bacteria such as *Clostridium histolyticum*, without negative effect on beneficial bacteria.[27] In addition, it significantly reduced *Bacteroides* spp. growth and enhanced total bacterial number and *Atopobium* spp.[27] Sanchez-Patan et al. also found decreased growth in the *C. histolyticum* group when incubating a red wine extract with human fecal bacteria, but no other changes were found. A similar result in the *C. histolyticum* group has also been described in human volunteers after red wine consumption.[36] It is noteworthy that red wine is a very complex polyphenolic mixture, so it is not possible to attribute these effects directly or solely to anthocyanins.[23]

Supplementation of mice with regular apples and genetically engineered apples for high biosynthesis of anthocyanins resulted in changes in the overall population of bacteria and in the number of some individual species.[37] Animals fed any of the apple-supplemented diet showed a greater number of bacteria than control mice. Moreover, a significant increase in *Bifidobaterium* spp. was observed.[37] Accordingly, a 6 week consumption of a blueberry drink by human volunteers significantly increased *Bifidobaterium* spp.[18]

The microbiota was also studied after an intervention in human volunteers with red wine and dealcoholized red wine. The distribution ratio of different genera within Bacteroidetes and Firmicutes phyla was different between baseline and intake periods,[36] with increased Firmicutes concentration after red wine consumption. At baseline, Bacteroides and Prevotellaceae frequencies were lower than those after the polyphenol intake periods, whereas the *Clostridium* frequency was similar. After the dealcoholized red wine and red wine periods, the Bacteroides, *Clostridium*, and Prevotellaceae frequencies were similar when analyzed by denaturing gradient gel electrophoresis (DGGE).[36]

Major groups of intestinal bacteria possess β-glucosidase activity, including *Bifidobaterium* spp. and *Lactobacillus* spp. They possess the ability to metabolize phenolic compounds during growth, supplying energy to cells and enriching the medium for bacterial growth with the release of glucose. These bacterial groups are associated with beneficial effects in the large intestine including the antimicrobial effect of pathogenic microorganisms by production of short-chain fatty acids, as well as by competition for growth substrate and adhesion sites.[38]

In vitro, animal and human intervention studies with the purpose of studying anthocyanin effect on gut microbiota are few and, due to the diversity of techniques to study microbiota, the different sources of anthocyanins, and the study designs, it is very difficult to relate them and reach a conclusion. In addition, whether anthocyanins exert a direct or indirect effect (mediated by their microbiota biotransformation products) on bacteria growth remains to be clarified. Nevertheless, there is broad agreement that polyphenols, and in particular anthocyanins, have the ability to modulate colonic bacteria growth.[7]

Several data from experimental models and human subjects support the fact that changing the gut microbiota by means of prebiotics and/or probiotics may participate in the control of several parameters involved in the development of metabolic diseases associated with obesity.[1] Further research is required to consolidate the prebiotic effects associated with the consumption of anthocyanin and to understand the mechanisms by which the gut microbiota interact with the host to provide new bases for putative dietary intervention.

The bioactivity of anthocyanins is significantly mediated through their several cellular pathways. With regard to all of the described bioactivities it must be assumed that they are absorbed (are bioavailable) and/or that they affect the microbiota, exerting in these ways their biological effects (as microbiota modulators). It is crucial to emphasize the benefits for bioavailability and/or bioactivity from anthocyanin metabolites that are synthesized by the colonic microbiota.

Finally, the present evidence supports the biotechnology applications of anthocyanins in the human diet and the interest of clinical trials to further assess their biokinetics.

clarified juice. Concentrated chokeberry juice was a gift from Artemis International (Fort Wayne, IN, USA). Concentration of ACN in chokeberry juice was normalized to 60 nmol Cy-3-glu equiv/mL by diluting with deionized (DI) water prior to storage in 20 mL aliquots at −20 °C until chemical analysis and use in the human trial. The qualitative and quantitative profile of ACNs was not altered during storage at −20 °C for 1 month.

Characterization of Juices. Content of monomeric anthocyanins of each juice was measured by pH differential method.[18] The total polyphenolic content of each juice was analyzed by using the Folin−Ciocalteu assay and reported as gallic acid equivalents.[19] Soluble sugar and pH were measured by portable refractometer (Fisher Scientific, 13-946-21, 0−32 °Brix) and by pH meter (Accument XL15, Fisher Scientific), respectively. The ACN profile of each juice was analyzed by HPLC as described below.

Experimental Design. The human study protocol was approved by the Institutional Review Board of The Ohio State University (IRB#20090058). Thirteen systemically and dentally healthy subjects (as evidenced by clinical attachment levels ≤2 mm and probing depths ≤3 mm and a low DMF (decayed, missing, filled teeth) index) over the age of 20 were recruited for the study. Subjects who had antibiotic therapy or professional cleaning within the previous 3 months, used immunosuppressant medications, bisphosphonates, or steroids, reported pregnancy, or a history of diabetes or HIV were excluded from this study to minimize variations in salivary secretion and oral bacterial profiles.[20,21]

A crossover study design with washout was used to investigate the role of oral microbiota on the metabolism of ACNs in the oral cavity. Subjects were instructed to refrain from consumption of ACN-containing foods, coffee, and tea for 24 h prior to the study. On the day of study, subjects brushed their teeth after awakening, avoided use of antibacterial mouthwash, and did not consume breakfast until arrival at the clinic. Control buccal cells were collected by brushing the left buccal mucosa 10 times with a toothbrush, followed by rinsing with 20 mL of phosphate-buffered saline (PBS), and used to determine baseline ACNs. Subsequently, chokeberry juice (20 mL in preweighed polypropylene tube) was retained and swished around the mouth for 5 min. Samples were not smelled to minimize the effects of smell on salivary production. Chokeberry juice remaining in the tube was measured gravimetrically. The retentate was expectorated and collected along with subsequent oral rinse (20 mL deionized water) in preweighed tubes to determine total amount of juice and saliva expectorated. A new toothbrush was used to collect buccal cells from the right buccal mucosal surface followed by saline rinse as for collection of control buccal cells. Tubes were reweighed to estimate the amount of saliva in retained juice and oral rinse. After a 1 week wash-out period, subjects were asked to follow the same procedures prior to arrival at the clinic, where they received professional oral cleaning to remove the oral bacterial biofilms, followed by rinsing with 15 mL of 0.12% chlorhexidine gluconate (Colgate-Palmolive, New York, NY, USA) for 1 min and followed by a 5 min wash-out period. Subjects retained chokeberry juice in their mouth using the same protocol of the previous week. Control buccal scrapings, retained chokeberry juice, and postjuice buccal scrapings were collected and processed using the same procedures as described above.

To determine the effect of ACN structure on stability and delivery to buccal tissue, juices from chokeberry and grape were assigned to subjects in a randomized crossover design with a 1 week wash-out period between juice treatments. Human subjects (n = 12) were instructed to abstain from consuming ACN-containing foods and beverages after 10 p.m. on the evening before testing. On the day of study, subjects brushed their teeth and consumed breakfast before arrival at clinic. Each subject served as their own internal control. Control buccal cells were collected prior to retention of juice, followed by postretention collection of buccal cells from the opposite cheek as described above. Data from one subject who reported accidental swallowing of a portion of the chokeberry juice were excluded.

Sample Processing. Retained juices and aqueous oral rinse were separately weighed and acidified with 88% formic acid (final concentration = 5% by adding 1.2:20 v/w) within 30 min after sample collection. Both solutions were combined, filtered (0.22 μm pore size), and stored at −20 °C until analysis. Buccal scrapings were centrifuged (130g, 5 min, 4 °C) to separate soluble mucus from buccal cells. Cell pellets were washed three times with 10 mL of cold sodium phosphate buffer (0.1 M, pH 6.0) and centrifuged to separate extracellular ACNs and mucin from buccal cells.[22] Washed cell pellets were resuspended in sodium phosphate buffer and stored at −20 °C. Pooled supernatant containing mucus from each subject also was stored at −20 °C), lyophilized to dryness, resolubilized in 15 mL of 1:1 (v/v) methanol/water for quantification of mucin, and filtered (0.22 μm pore size) for HPLC analysis of ACNs.

ACN Extraction from Buccal Epithelial Cells. Preliminary studies were performed to determine the efficiency of extraction of ACNs from buccal cell pellets. Extraction solvents tested were methanol, acetronitrile, acetone, and 70% acetone. All solvents were acidified with formic acid (5% final concentration) to stabilize ACNs. ACN-rich extracts (15 nmol of Cy-3-glu equivalents in 25 μL of 0.01% HCl solution) from chokeberry and red grape were added to 0.25 mL suspensions of control washed buccal cells isolated from two subjects. Suspensions were sonicated (30 s, ice−water bath) before addition of 0.75 mL of test solvents and frozen (−20 °C) overnight. Samples were thawed, sonicated for 20 min in an ice−water bath, and centrifuged (20800g, 5 min). Supernatant was collected, and the pellet was re-extracted twice. Supernatants for the three extractions were transferred to a preweighed tube, concentrated by evaporation under N_2 (30 min, 37 °C), weighed, and filtered (0.22 μm pore size) prior to HPLC analysis. Recovery was calculated as (amount ACNs extracted/amount ACNs added) × 100%. Recovery using 70% acetone solvent exceeded 84% for all ACNs in chokeberry and red grape juices (data not shown), which was considerably greater than recovery after extraction into the other solvents tested (i.e., 36−51%). The extent of recovery of each ACN was not significantly affected by type of monosaccharide. Therefore, ACNs in all test samples were extracted into acidified 70% acetone for analysis.

HPLC Analysis. The content of ACNs in juices, retentate, mucus, and cell extracts was analyzed by HPLC-PDA-ESI-MS according to previously published methods[17] and reported as Cy-3-glu equivalents. Identification of ACNs was based on retention time (t_R) and $\lambda_{max\text{-}vis}$ and matched molecular weights of parent compounds and daughter fragments with those of available anthocyanin standards, isolated chokeberry anthocyanins, and reported elution profiles for chokeberry[23,24] and red grape.[25−27] The cellular content of ACNs was normalized by DNA content in isolated cell pellets (Quantification of DNA in Buccal Cells). The quantity of ACNs in the mucus layer was normalized per milligram of mucin (Quantification of Mucin).

Separation, identification, and quantification of reported phenolic metabolites were performed using a HPLC-PDA-ESI-MS system[17] with the mobile phase consisting of (A) 0.1% formic acid in water and (B) 0.1% formic acid in acetonitrile. The gradient for the mobile phase was 0−30 min, 0−30% B; 30−31 min, 30−100% B; 31−32 min, 100−0% B; 32−37 min, 0% B. Partial flow from PDA detector was negatively ionized by the mass spectrometer with previously published parameters.[17] Mass spectra were obtained using scan mode (from m/z 50−800 with scan speed of 1000 amu/s) and selective ion monitoring (SIM) mode for PCA, PGA, gallic acid, syringic acid, vanillic acid, and 4-hydroxybenzoic acid at m/z 153, 153, 169, 197, 167, and 137, respectively.

Quantification of DNA in Buccal Cells. DNA in buccal cell aliquots was determined by diphenylamine (DPA) assay. The purpose of this test was to provide a basis for normalizing ACNs per unit buccal cells and allow for comparisons among the samples given that the number of cells collected for each buccal scrapping varies.

Briefly, 1 volume of cold acetaldehyde (0.16% in DI water) was mixed with 5 volumes of perchloric acid (20% v/v in DI water) to prepare the reagent. Cell suspensions were sonicated (20 min in ice bath) and aliquoted (40 μL) into a 96-well plate before addition of 60 μL of acetaldehyde solution. After mixing, 100 μL of DPA (4% in glacial acetic acid) was added to wells and the plate was incubated at 37 °C for 24 h. Absorbance was measured at 595 nm (corrected by subtraction of absorbance at a reference wavelength of 700 nm).

Corrected absorbance was compared to a five-point curve using DNA from herring sperm as standard.

Quantification of Mucin. Mucin concentrations in buccal washings were determined by using a modification of the previously described[29] Alcian Blue assay.[30] Aliquots of supernatant were incubated for 30 min in a 1:1 (v/v) of 1% solution of Alcian Blue in 50 mM sodium acetate buffer containing 25 mM $MgCl_2$, pH 5.8, under constant agitation at room temperature. Samples were centrifuged (705*g*, 20 min), and supernatant was discarded. The pellets were washed twice with 1 mL of 40% (v/v) ethanol in 50 mM sodium acetate buffer containing 25 mM $MgCl_2$, pH 5.8, briefly vortexed, and incubated for 5 min before centrifugation (705*g*, 20 min); supernatant was discarded. Mucin−dye complexes were dissociated by the addition of 1 mL of dioctyl sulfosuccinate solution (1:90 w/v in DI water) followed by brief mixing and ultrasonication at 40 W for 10 s with a VibraCellTM (Sonics & Materials, Danbury, CT, USA). Samples were centrifuged (705*g*, 1 min) to eliminate the foam generated during sonication. The absorbance of the dye was determined spectrophotometrically at 605 nm and compared to a five-point standard curve using known concentrations of mucin from bovine submaxillary glands as standard. This method does not distinguish larger (MG1) and smaller (MG2) mucins.

Statistical Analysis. Each sample (retained juices, oral washes, and washed buccal cells) collected and prepared from each subject was aliquoted for a minimum of three independent analyses. Statistical analysis was performed using SPSS release 19.0 for Windows (SPSS Inc., Chicago, IL, USA). Mixed-model analysis of ACN structure (fixed factor) and subject (random factor) with Bonferoni's adjustment of mean comparison was used. Pearson's product moment correlation analysis was used to determine correlation between salivary secretion and extent of degradation of ACNs. Repeated-measures ANOVA was used to evaluate the effect of inhibition of oral microbiota on reduction of ACN loss in the oral cavity. Independent-samples *t* test was used to compare (1) extent of ACN association with mucus and buccal cells between chokeberry and red grape juices and (2) abundance (%) of each ACN between samples, that is, juice, retained juice, mucus-bound, and buccal cell-associated fractions. Differences were considered significant at $P < 0.05$ unless indicated otherwise.

RESULTS

Characterization of Chokeberry and Red Grape Juices. Red grape and chokeberry were chosen because of their distinctive anthocyanin profiles, which were confirmed and monitored by HPLC-PDA-ESI-MS. Characteristics of each juice are listed in Table 1. Chokeberry juice contained four ACNs differing in the type of monosaccharides conjugated to the C3 position of the Cy aglycone. This material was chosen to allow for comparisons of anthocyanin structures with the same aglycone but different sugar substitutions. Red grape juice contained different anthocyanidins with each conjugated at the C3 position to glucose. This material was chosen to allow for evaluation of the impact of the type of aglycone, as it provides different aglycone structures, all with the same glycosylation pattern (just one glucose). ACN concentration in red grape juice was slightly less than that in chokeberry. Although the content of phenolic compounds and the pH for the two juices were comparable, red grape juice contained higher sugar content than chokeberry juice.

Metabolism of ACN in the Oral Cavity. Thirteen subjects (9 females, 4 males; ages 32.8 ± 9.5 years, range = 24−50 years; and body mass index (BMI) = 22.3 ± 3.1) were recruited for oral retention of chokeberry and red grape juices. Mean losses of total ACNs during the 5 min retention in the mouth were 12.5 ± 1.6% (range = 6.1−25.2%) and 15.3 ± 1.8% (range = 7.9−30.5%) for chokeberry and red grape juices, respectively. The loss of Cy-3-xyl was significantly ($P < 0.05$) greater than that of Cy-3-gal and Cy-3-arabinose in chokeberry juice (Figure 1A). Losses of Dp- and Pt-glucosides exceeded those of Cy-, Pn-, and Mv-glucosides during oral retention of red grape, although only the loss of Dp-3-glu was significantly greater than that of the other anthocyanidins ($P < 0.05$) (Figure 1B).

Table 1. Characteristics of Chokeberry and Red Grape Juices[a]

	chokeberry juice	red grape juice
monomeric ACN (nmol Cy-3-glu equiv/mL)	64.1 ± 1.4	52.9 ± 2.2
ACN composition (% of total ACN)	Cy-3-gal, 58.1 ± 1.1	Dp-3-glu, 9.3 ± 0.9
	Cy-3-glu, 3.8 ± 0.2	Cy-3-glu, 12.5 ± 0.1
	Cy-3-arab, 26.7 ± 0.2	Pt-3-glu, 8.0 ± 0.1
	Cy-3-xyl, 11.3 ± 1.0	Pn-3-glu, 42.2 ± 0.8
		Mv-3-glu, 28.1 ± 0.1
phenolic compounds (mg gallic acid equiv/mL)	272.4 ± 17.4	279.5 ± 7.8
pH	3.75	3.89
sugar (°Brix)	0.4 ± 0.2	19.6 ± 0.2

[a]Data are the mean ± SD of three independent analyses.

Microbial-Mediated Metabolism of ACN. Loss of ACNs during oral retention decreased in 8 of 10 individuals following treatment to reduce bacterial load (matched-pair analysis; Figure 2). The antimicrobial treatment also significantly decreased the mean loss of total ACNs in chokeberry juice from 9.57 ± 0.64 to 8.11 ± 0.77% ($P = 0.036$), supporting the likelihood that the observed loss was in part contributed by microbial activity during the 5 min retention. The extent of loss of ACNs was dependent on structure, with Cy-3-Glu and Cy-3-Gal demonstrating significantly greater loss in the presence of bacteria ($P < 0.01$, repeated-measured ANOVA, Figure 3).

Delivery of ACN to Mucus and Buccal Epithelium. Buccal scrapings were fractionated into mucus and epithelial cells to determine the relative distribution of ACNs delivered to the surface of this oral tissue. Greater than 97% of chokeberry ACNs in the buccal scraping were associated with mucus. The relative amounts of Cy-3-glu and Cy-3-arab in the mucus layer were significantly ($P < 0.01$) greater than that of Cy-3-xyl (Figure 4A). The relative amount of Cy-3-glu in washed buccal epithelial cells was significantly ($P < 0.05$) greater than those of the other Cy-3-monosaccharides (Figure 4B). The amount of red grape ACN associated with buccal mucus fraction was >98% of total scraping ACN after oral retention of the juice for 5 min. ACNs associated with mucus were significantly ($P < 0.001$) affected by anthocyanidin structure. Dp-3-glu was not detected in the mucus fraction, and the relative amount of Pt-3-glu was lower ($P < 0.05$) than those of Cy-, Pn-, and Mv-3-glucosides (Figure 5A). Dp- and Pt-3-glu were detected in the washed buccal cell fraction, although the relative amounts were lower than those of Cy-, Pn-, and Mv-3-glucosides ($P = 0.09$) (Figure 5B).

The amount of mucus-associated ACNs from red grape juice (Figure 5) was significantly less than that from chokeberry (Figure 4) (50.6 ± 11.1 vs 139.4 ± 18.5 μg ACN (mg mucin)$^{-1}$ (mg specific ACN intake)$^{-1}$, respectively; $P = 0.001$). Similarly, the total amount of ACNs from red grape juice that was present

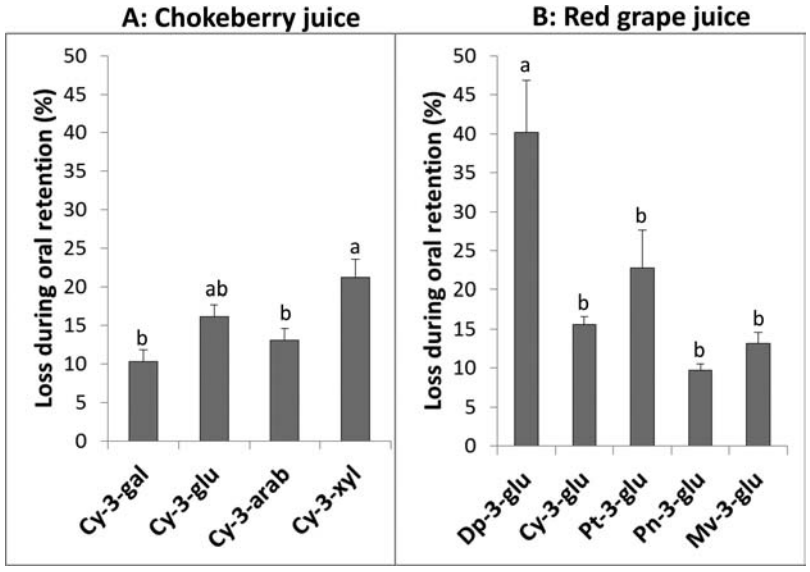

Figure 1. Loss of ACN during 5 min of retention of chokeberry (A) and red grape (B) juices in the oral cavity. Data are the mean ± SEM for 12 and 13 participants for chokeberry juice and red grape juice, respectively. Columns with different letters are significantly different ($P < 0.05$, two-sample t test).

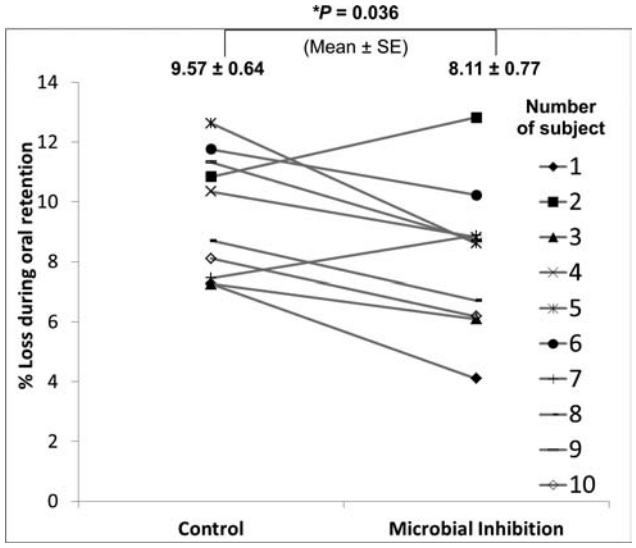

Figure 2. Extent of loss of total ACN in chokeberry juice during retention in the oral cavity was significantly decreased after removal of plaque and rinsing with antibacterial mouthwash. Matched-pair analysis and lines represent change in total chokeberry ACN in the oral cavity before and after removal of bacterial biofilms. The asterisk (∗) denotes significant ($P < 0.05$) difference between microbe-rich and microbe-depleted environments of 10 subjects.

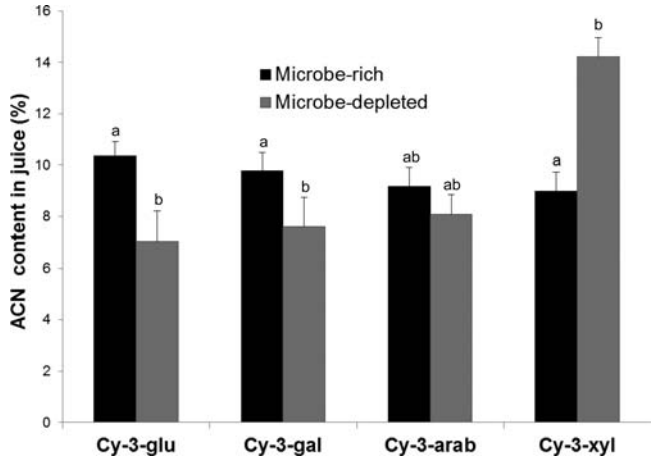

Figure 3. Degradation of ACN following treatment to reduce oral bacterial load. Data are the mean ± SEM for 10 subjects. Different letters above bars indicate that means differ significantly ($P < 0.05$).

in washed buccal cells was less than that after retention of chokeberry juice in the mouth for 5 min (2.16 ± 0.64 vs 13.5 ± 2.3 μg ACN (mg DNA)$^{-1}$ (mg specific ACN intake)$^{-1}$, respectively ($P = 0.001$). Moreover, comparison within the same subjects showed lesser relative amounts of red grape ACN in both mucus-associated and cellular fractions ($n = 5$ and 9, respectively).

To assess changes in the ACN profile of chokeberry and red grape juices during oral retention and delivery to the buccal surface, relative abundances of each ACN (i.e., percent area under curve at 520 nm) in juice, after retention in the mouth, and associated with buccal mucus and epithelium are compared in Figure 6. Notably, increases of relative abundance of Cy-3-arab (by 70%, $P < 0.001$) and Cy-3-glu (by 330%, $P < 0.001$), as well as decreases in Cy-3-gal (by 30%, $P < 0.001$) and Cy-3-xyl (by50%, $P < 0.005$), were observed in buccal cells compared to intact chokeberry juice (Figure 6A). Decreased relative amounts of Dp-3-glu (by 80%, $P < 0.001$) and Pt-3-glu (by 63%, $P < 0.005$) were coupled with increased relative amounts of Pn-3-glu (by 30%, $P < 0.001$) in buccal cells compared to red grape juice (Figure 6B).

Because protocatechuic acid (PCA) and cyanidin aglycone were recently reported to be present in the saliva of several subjects after oral retention of black raspberry juice for 3 min,[31] we examined the juice and cell extracts for the presence of possible metabolites before and after oral retention. HPLC chromatograms (250−600 nm) of juices and cell extract before and after retention were compared. Phloroglucinal aldehyde (PGA) was not found in any samples, which may be due to instability of aldehyde. PCA could not be quantified in retained chokeberry juice due to coelution with other compounds.

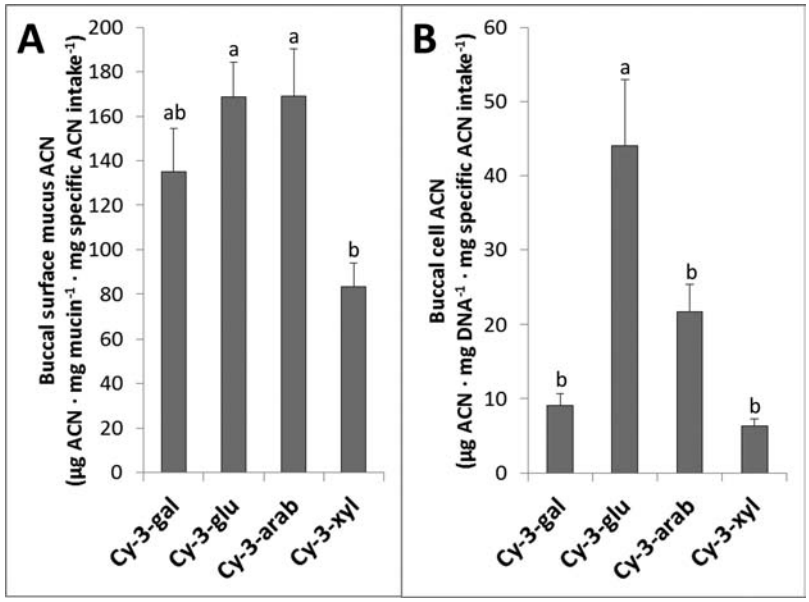

Figure 4. Adherence of chokeberry cyanidins to buccal surface mucus (A) and delivery to buccal epithelial cells (B). Data are the mean ± SEM for 8 subjects (A) and 12 subjects (B), respectively. Different letters above bars indicate that means differ significantly ($P < 0.05$).

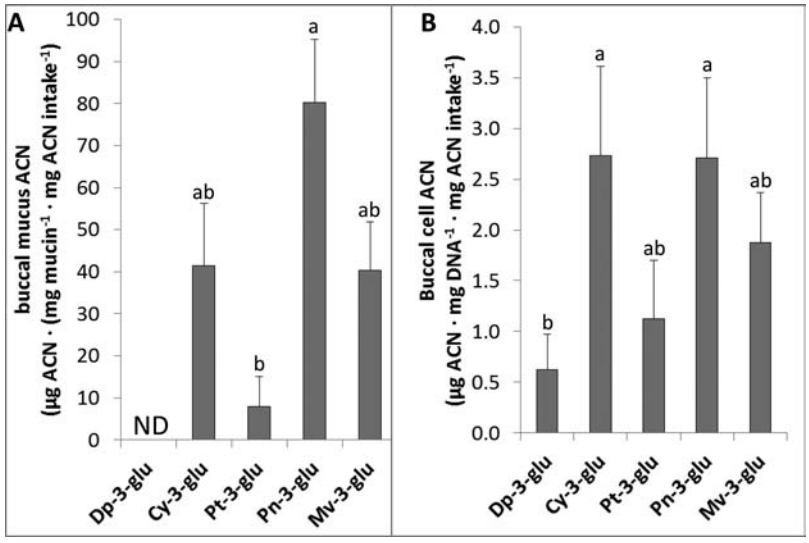

Figure 5. Adherence of ACN to buccal mucus (A) and delivery to epithelium (B) during retention of red grape juice in the oral cavity. Data are the means ± SEM for 8 subjects (A) and 12 subjects (B). Different letters above error bars indicate that means are significantly different ($P < 0.05$, A; $P = 0.09$, B). ND, not detected.

Cyanidin aglycone and PCA also were not detected in buccal cell extracts collected from 11 subjects after retention of chokeberry juice rinse (limits of detection for cyanidin aglycone and PCA are 2.0 and 3.6 ng/mL, respectively). Similarly, there was no detectable gallic acid, PCA, vanillic acid, or syringic acid, compounds that have been reported as products of cleaved B-ring of Dp, Cy, Pn, and Mv, respectively,[28,32−34,35] in either postrinse red grape juice or buccal cell extracts (limits of detection for gallic acid, vanillic acid, and syringic acid were 2.0, 2.5, and 3.3 ng/mL, respectively).

DISCUSSION

ACN-rich fruits and extracts have been shown to possess chemopreventive and chemotherapeutic activities in oral cell lines,[11,32] hamster buccal tissue,[10] rat esophagous,[36] and the human oral cavity.[13,14] This efficacy of ACN has been reported to be dependent on chemical structure.[37,38] It is also known that ACNs are degraded in the gastrointestinal (GI) tract[32,39,40] and the oral cavity.[17,31] An understanding on the effect of ACN structure on its relative stability, types of metabolites produced in the oral cavity, and availability to oral tissues is expected to provide insights for dietary recommendations and the strategic formulation of ACN-containing foods, beverages, confectionaries, and muco-adhesive gels for the promotion of oral health. We recently showed that the extent of biological and chemical degradation of ACNs in saliva is dependent in part on their chemical structure.[17] More specifically, Dp- and Pt-glycosides were degraded to a greater extent than Cy-, Pn-, and Mv-glycosides during ex vivo incubation in saliva. In the present study, we investigated the in vivo stability of ACN in the oral cavity and the levels of these compounds in buccal mucus and epithelial cells in the same human subjects who participated in

dx.doi.org/10.1021/jf405180k | J. Agric. Food Chem. 2014, 62, 6903−6910

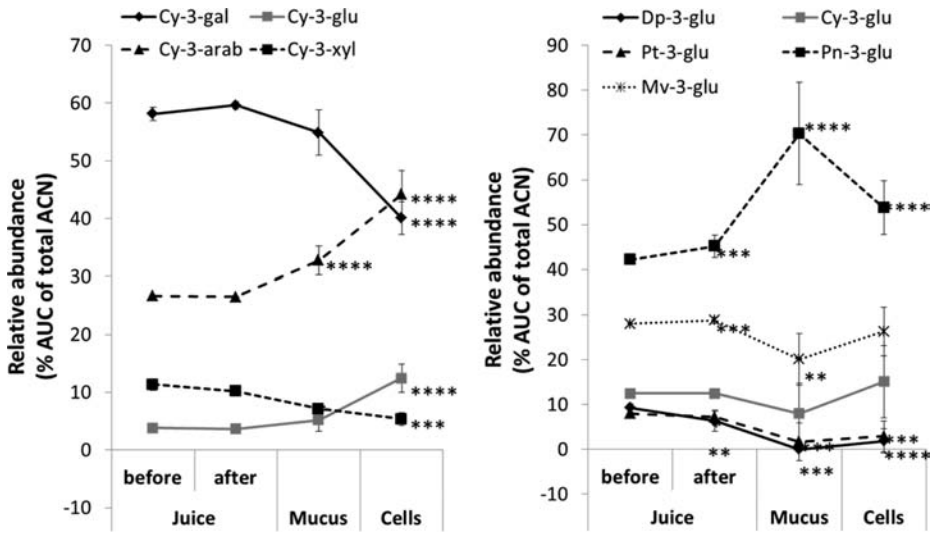

Figure 6. Change of ACN profile of ACN in chokeberry (A) and red grape (B) juices during oral retention and delivery to the buccal surface. Data are the mean ± SD for ≥8 subjects. Asterisks denote statistical difference compared to juice before retention at $P < 0.05$ (*), < 0.01 (**), < 0.005 (***), and <0.001 (****).

the earlier ex vivo study.[17] Loss of endogenous ACN from juice during brief retention in the oral cavity was used as a surrogate for metabolism in the present study. Because this loss may be attributable to spontaneous degradation, metabolism by oral microbiota,[17] adsorption to teeth and mucus,[41] and uptake by epithelial tissues,[31] the effect of each of these parameters was measured.

The extent of in vivo loss of chokeberry and red grape ACNs was affected by their structures (Figure 1B). The relative amount of Cy-3-xyl in chokeberry juice decreased during oral retention (Figure 1A), and this loss could not be attributable to selective binding to mucus (Figure 4A), metabolism by bacteria (Figure 3), or uptake by buccal epithelium (Figure 4B). Bermudez-Soto et al. reported that Cy-3-xyloside was less stable than the other Cy-3-glycosides during in vitro digestion of chokeberry juice.[42] Loss of Cy-3-gal, on the other hand, appeared to be due to microbial degradation and binding to mucus.

The preferential loss of Dp-3-glu from red grape juice during oral retention was similar to that during ex vivo incubation in saliva.[17] Our results are also in agreement with the report that glycosides of Dp, but not those of Pt, Cy, Pn, or Mv, in Concord grape juice were preferentially lost from the mouth to the ileum of ileostomy subjects.[43] However, the extent of loss could not be attributable to mucus binding (Figure 5A) or epithelial cell uptake (Figure 5B), leading us to speculate that microbial degradation or other causes may be responsible for this observation. The amount of saliva secreted during oral retention of red grape juice significantly exceeded that from subjects during retention of chokeberry juice (data not shown). We suspect that this was due to the higher concentration of simple sugars in the red grape juice (Table 1). Losses of Dp-3-glu and Pt-3-glu during 5 min of retention of red grape juice in the oral cavity were significantly ($P < 0.05$) correlated with amount of secreted saliva (data not shown). Enhanced salivary flow is associated with increased concentrations of sodium and bicarbonate ions in saliva.[44] We have shown that the presence of inorganic constituents, including bicarbonate, in artificial saliva resulted in the preferential degradation of Dp and Pt.[17]

We recently reported that microbial activity was a major contributor of ex vivo degradation of ACNs in saliva at 37 °C.[17] To evaluate whether oral microbiota contribute to the in vivo metabolism of ACNs in the oral cavity during a 5 min oral retention of chokeberry juice, the extent of loss of ACNs was compared in individual subjects before and after extensive oral disinfection (dental prophylaxis and antibacterial mouth rinse). This method has been shown to reduce the total bacterial load in the oral cavity significantly.[3] Because oral bacteria exhibit significant interindividual variability, a crossover study design was used to examine the effects of bacteria on loss of ACN during retention of juice in the oral cavity. The intervention resulted in a notable inhibition (ca. 15%) of ACN loss during the brief period of retention of juice in the oral cavity (Figure 3), suggesting that oral bacteria play a vital role in the metabolism of ACNs and may be a source of increasing availability of bioactive compounds to the host tissues.

We investigated whether there was preferential delivery of specific ACNs to buccal cells, because squamous cell carcinomas originate in this anatomical location[45] and because ACNs from black raspberries have been shown to inhibit oral cancer in hamsters[12] and human buccal lesions.[13,14] Chokeberry juice was used to investigate the effect of the type of conjugated monosaccharide on delivery of ACNs to the buccal epithelium. Strikingly, Cy-3-glu was preferentially enriched in the buccal epithelium (Figures 4B and 6A), suggesting preferential binding or uptake. When suspensions of buccal epithelial cells from two subjects were spiked with ACN-rich extract from chokeberry and incubated at 0 °C for 5 min, the relative amounts of the four Cy-glycosides were not significantly altered. This suggests that the increased bioavailability of Cy-3-glu compared to that of the other Cy-3-glycosides in chokeberry juice was temperature dependent and likely to be enzyme mediated. It has been reported that transport of Cy-3-glu by Caco-2 human intestinal cells exceeds that of Cy-3-gal.[46] The authors suggested that this difference was mediated by the specificity of the sodium-dependent glucose cotransporter-1 (SGLT1).[31] SGLT1 has also been detected in primary human buccal epithelial cells.[31,47] The possibility that Cy-3-glu is preferentially bound or taken up into

buccal epithelium during the brief retention of chokeberry juice in the oral cavity by SGLT1 and/or other unidentified transporters warrants further investigation.

Red grape juice allowed us to assess the effect of anthocyanidin structure on the bioavailability of ACNs to the buccal epithelium as it contains five distinct anthocyanidin-3-glucose compounds. Preferential loss of Dp-3-glu and Pt-3-glu in expectorated juice (Figure 1B) was coupled with lesser amounts of these ACN associated with both buccal mucus and buccal cells (Figure 5). These data suggest that the instability of Dp and Pt in the oral cavity lessens their accessibility to the buccal epithelial cells. Similarly, Stalmach et al. reported that loss of Dp-glycosides in Concord grape juice was greater than that of Pt-, Cy-, Pn-, and Mv-glycosides during passage from the mouth to the ileum of human ileostomists.[43] Delivery of ACNs to the washed buccal cell fraction during retention of red grape juice in the oral cavity was less than that for chokeberry juice (Figures 4 and 5). This difference appears to be due to the lower amount of ACN in the red grape juice (Table 1) and the greater instability of Dp-3-glu and Pt-3-glu.

Genistin (genistein-7-*O*-glucoside) is taken up by the SSC-9 human oral epithelial cell line and hydrolyzed to genistein aglycone.[48] It is possible that once ACNs are taken up by buccal epithelial cells, they are metabolized to anthocyanin aglycones that spontaneously degrade to phenolic compounds. Other investigators have reported that the degradation product PCA was detected in saliva from 2 of 10 subjects 4 h after an oral rinse with black raspberry for 3 min.[31] We did not detect ACN aglycone, PCA, PGA, or other phenolic products of ACN B-ring in the buccal cell extracts from 11 subjects immediately after the 5 min retention of chokeberry or red grape juices in the oral cavity. It appears that the generation of bioactive metabolites of ACNs may require increased duration of ACNs in the oral cavity. The possibility that there is time-dependent release of ACNs from mucin with some of the compounds becoming available to the buccal epithelium for uptake and metabolism merits investigation.

In summary, the present study provides novel insights on the effect of ACN structure on oral stability and delivery to the buccal mucosa. The results demonstrate that ACNs can be degraded in the human oral cavity and that the loss is partially due to microbial activity. These results also suggest that the structure of ACNs can affect oral stability and delivery to the buccal surface. Cy-3-glu appeared to be preferentially transferred to the buccal epithelium compared to other Cy-3-glycosides. Instability of Dp-3-glu and Pt-3-glu in the oral cavity resulted in association of lesser amounts of the ACNs with the buccal epithelium. The instability appeared to be associated with the amount of salivary secretion. These in vivo results with ACNs in a food matrix generally largely agree with the ex vivo stability and metabolism of ACNs in saliva.[17] The source of ACNs merits consideration for development of ACN-containing products for promoting oral health. The relationship between oral metabolism of ACNs and efficacy, for example, anti-inflammatory activity, as well as the role of metabolites of ACNs, warrants further investigation.

During ontogeny, plants live through different phases with distinct morphological and physiological features.[13] Although crop plants are often harvested before they have transitioned to the generative phase or completed reproduction, their development can be divided into growth stages with pronounced differences regarding morphology and physiology. The concentration of flavonoids and phenolic acids, for instance, is subject to variation throughout plant development.[14,15] Because it is commonly consumed as a leaf vegetable, lettuce is harvested before it enters generative growth. Nonetheless, there are distinguishable growth stages related to head formation as described by Krug et al.:[16] The process of head formation is based on reorientation of leaves from their primary horizontal rosette state toward an upright position, progressively bending inward to form a head, which will grow and become larger and denser with an increasing number of leaves. Obviously, this affects at least the distribution of radiation within the plant. In red leaf lettuce, young leaves have a lower quercetin aglycone concentration than older ones,[10] and the overall concentration of flavonol glycosides and caffeic acid derivatives of whole heads is higher in lettuce plants in early growth stages than in later growth stages.[12]

Although the light dependency of flavonoid biosynthesis in general is well-known, Kubasek et al.[17] additionally found the developmental stage to influence the induction of pivotal flavonoid biosynthesis genes in *Arabidopsis thaliana* (Brassicaceae) seedlings. When it comes to studying development-dependent effects of radiation on plants, many studies have focused on UV radiation.[10,17,18] Interestingly, Reifenrath and Müller[18] detected an interaction between UV radiation and leaf age regarding their effect on flavonol concentration in *Nasturtium officinale* (Brassicaceae). This indicates that the same elicitor could lead to a different response from the same plant, depending on the plant's growth stage. Indeed, flavonoid aglycones in red leaf lettuce display a development-dependent response to UV radiation.[10]

In the presented experiment, we studied the relationship between the concentration of several flavonoid glycosides as well as caffeic acid derivatives and low-level PPFD in three growth stages of two red leaf lettuce cultivars in a climate-controlled greenhouse. We wanted to examine the following hypotheses: (I) The concentrations of the major phenolic compounds of red leaf lettuce respond to PPFD levels below 225 μmol m^{-2} s^{-1}, as are common in Central European greenhouses in cool seasons. (II) Flavonoid glycosides and caffeic acid derivatives respond in a structure-dependent manner. (III) Their PPFD response is development-dependent.

MATERIALS AND METHODS

Plant Cultivation. We conducted the experiment in Grossbeeren (52°20′ N, 13°18′ E), Germany, in March−April 2012. The mean temperature in the greenhouse was 16.3 °C (minimum, 11.7 °C; maximum, 23.6 °C). Red oak leaf and red lollo lettuce (*Lactuca sativa* L. var. *crispa* L. cv. Eventai RZ and *L. sativa* L. var. *crispa* L. cv. Satine, respectively; RijkZwaan, De Lier, The Netherlands) was sown in rockwool cubes, kept at ca. 10 °C for 2 days for germination, and subsequently grown in a conventional greenhouse until the experiment started. When plants had developed four true leaves and a mean aboveground mass of 0.9 g 5 weeks after sowing, they were transferred into the experimental setting, where they were grown hydroponically, using nutrient film technique. The nutrient solution was prepared according to the method of Sonneveld and Straver[19] and checked for macronutrient concentration every week. The greenhouse area was divided into four blocks, according to differences in radiation intensity due to greenhouse construction elements. Additionally, half of each block was covered with a shading net, reducing the photosynthetic photon flux (PPFD) by 45%. This way, we obtained data on flavonoid glycoside and caffeic acid derivative concentrations in two cultivars of red leaf lettuce related to eight PPFD levels, ranging from 43 to 230 μmol m^{-2} s^{-1}. We followed the natural light cycle; no additional lighting was supplied. The PPFD was monitored permanently in each block with light meters LI 190SA Quantum (LI-COR Inc., Lincoln, NE, USA) and recorded by a data logger (DATATAKER, Victoria, Australia). Greenhouse glass has a very good transmissibility for visible and near-infrared wavebands but allows only 64% of UV-A and <1% of UV-B and UV-C radiation, respectively, to pass. Of the UV wavebands, UV-B is generally considered to be most bioactive.[10] We harvested the aboveground organs at three dates, obtaining data on different growth stages within the horticulturally interesting vegetative growth phase: Harvest 1 took place 12 days after planting (DAP), before head formation started. Harvest 2 took place shortly after head formation started (21 DAP), and at harvest 3, mature heads were formed (35 DAP). Harvest dates were set on the basis of experience gained in previous experiments.

Plant Growth Characteristics. At all harvest dates, the mean head weight of three plants per PPFD level and cultivar was used to obtain the mean head mass (n = 8). Values for head mass are given in grams of fresh matter (FM). To obtain dry matter (DM) content, weight before and after lyophilization was compared. Values for DM content are given as percent of FM.

Additionally, we counted the number of leaves (minimum length = 1.5 cm) and measured the maximum diameter of three lettuce heads for each PPFD level and cultivar (n = 8).

Light use efficiency was calculated for plants before and after the onset of head formation. This value displays how much dry matter plants accumulated per intercepted mole of PPFD. For each block and cultivar the intercepted PPFD was calculated separately, based on the measured head diameter. The PPFD absorbing surface area (m^2) was approximated by a circle. This area was multiplied with the PPFD integral (mol m^{-2}) for the intervals between the first and second and the second and third harvest dates, respectively. Light use efficiency (g mol^{-1}) was obtained as the ratio of the plants' dry matter gain (g) between the respective harvest dates and the corresponding intercepted PPFD.

Sample Preparation. A mixed sample from three plants was prepared for each cultivar, treatment, and replication. Only limp or deteriorated outer leaves were removed. Within 30 min after harvesting, the plants were cut in smaller pieces, mixed, frozen at −20 °C until lyophilized (Christ Beta 1-16, Osterode, Germany), and ground with an ultracentrifuge mill (hole size = 0.25 mm; ZM 200, Retsch, Haan, Germany).

Analyses of Phenolic Compounds. Flavonol and flavone glycosides as well as caffeic acid derivatives were analyzed via HPLC-DAD-ESI-MS according to the method of Becker, Kläring, Kroh, and Krumbein.[12] In short, 0.5 g of lyophilized, pulverized lettuce powder was extracted with 25 mL of aqueous methanol (50% MeOH) for 90 min at room temperature. The extract was centrifuged, and the supernatant was cleaned with PTFE filters and analyzed via HPLC-DAD-ESI-MS^2. The anthocyanin method was similar, except for a slightly different composition of the extraction agent and a shorter extraction time: The extraction agent was acidified aqueous methanol (40% MeOH, 10% acetic acid). Extraction of anthocyanin glycosides took 15 min.

The system used for analysis consists of an Agilent HPLC series 1100 Ion Trap (Agilent, Waldbronn, Germany). The compounds were separated on a Prodigy column (ODS 3, 150 × 3 mm, 5 μm, 100 Å; Phenomenex, Aschaffenburg, Germany) with a security guard C18 (ODS 3, 4 × 3 mm, 5 μm, 100 Å) at 30 °C using a water/acetonitrile gradient. DAD wavelength for quantification was 330 nm for caffeic acid derivatives, 350 nm for flavonol and flavone glycosides, and 520 nm for anthocyanidin glycosides.

Statistical Analyses. To study the effect of plant ontogeny, radiation intensity, cultivar, and their interactions on flavonoid glycosides and caffeic acid derivatives, multiple regression analysis

was performed. Representing plant growth stage, DAP was included to study the influence of ontogeny. Radiation intensity is included as PPFD (given in μmol m^{-2} s^{-1}). On the basis of previous experience[12] we considered the mean PPFD during the last 12 days before harvest to be an important factor influencing flavonoid biosynthesis. The two cultivars entered the analysis as cultivar 1 (red oak leaf) and cultivar 2 (lollo rosso), respectively. The resulting equations presented in this study contain only terms having an influence on the investigated variable that significantly differs from zero. A significance level of α = 0.01 was applied.

Growth characteristics were evaluated via two-way ANOVA (Fisher's F test).

Calculations were performed using STATISTICA (version 10, Statsoft Inc., Tulsa, OK, USA).

RESULTS AND DISCUSSION

Influence of Cultivar. Throughout ontogeny, red oak leaf lettuce had a higher number of leaves and greater diameter and head mass than lollo rosso (Table 1). The concentration of phenolic compounds in lettuce can be greatly influenced by genotype,[20] but lollo rosso and red oak leaf lettuce showed only quantitative and no qualitative differences. Concentrations were mostly higher in red lollo rosso, which is largely in line with results by DuPont et al.[21] Multiple regression analysis listed the cultivar as an influential factor on quercetin-3-*O*-(6″-*O*-malonyl)-glucoside, quercetin-3-*O*-glucoside, quercetin-3-*O*-glucuronide/luteolin-7-*O*-glucuronide, and chicoric acid concentrations (Table 2).

Table 1. Plant Growth Characteristics of Two Red Leaf Lettuce Cultivars, Grown in Low Mean Daytime PPFD (43−230 μmol m^{-2} s^{-1}) for 12, 21, and 35 Days after Planting (DAP), Respectively: Number of Leaves, Diameter, and Head Mass in Fresh Matter (FM) (Mean ± SD of the Eight PPFD Levels, n = 8)

DAP	cultivar	no. of leaves	diameter (cm)	head mass (g FM)
12	red oak leaf	10.3 ± 0.2	28.8 ± 2.8	9.2 ± 1.5
21	red oak leaf	18.6 ± 2.5	37.7 ± 3.7	52.6 ± 24.3
35	red oak leaf	30.7 ± 5.0	41.3 ± 2.1	199.7 ± 66.5
12	lollo rosso	7.3 ± 0.5	16.6 ± 1.2	7.5 ± 2.1
21	lollo rosso	11.5 ± 2.1	26.7 ± 0.3	33.8 ± 13.1
35	lollo rosso	21.0 ± 5.1	32.9 ± 0.6	137.0 ± 65.5

Plant Growth Characteristics. Table 1 presents the head mass, number of leaves, and head diameter per cultivar at the three harvest dates. As intended, the plants were in three distinct growth stages. Twelve days after planting, head mass and number of leaves of both cultivars were still low. The leaves formed an open rosette in which all leaves were exposed to radiation. From 12 to 21 DAP, head mass increased only moderately while there was a remarkable increase in diameter. The rosette was much denser at the second harvest date with leaves partly overlapping. From 21 to 35 DAP, there was a marked increase in head mass but not so much in diameter. Independent of cultivar, there was a significantly higher increase in head mass from 21 to 35 DAP compared to the earlier period, whereas the increase in diameter was higher from 12 to 21 DAP compared to the later period.

These results corroborate our visual assessment that plants had not yet developed a head 12 DAP, but that this process had begun at 21 DAP and continued until 35 DAP and is in agreement with the literature.[16] In the following, we named the three studied growth stages accordingly: preheading (harvest 12 DAP) and heading stages (harvest 21 DAP) and mature heads (harvest 35 DAP), respectively.

Table 2. Results of Multiple Regression Analysis: Equations Present the Significantly Influential Factors on the Single Phenolic Compounds of Red Leaf Lettuce (n = 48, α = 0.01)[a]

compound	equation	R^2
Cy3MG	= 1.075774 − 0.148608 × DAP + 0.019459 × PPFD − 0.000028 × PPFD^2 + 0.003040 × DAP^2 − 0.000077 × PPFD × DAP	0.88

[a]DAP, days after planting; PPFD, photosynthetic photon flux density in μmol m^{-2} s^{-1}; cultivar, red oak leaf (1) and lollo rosso (2); Cy3MG, cyanidin-3-*O*-(6″-*O*-malonyl)-glucoside; Q3G, quercetin-3-*O*-glucoside; Q3MG, quercetin-3-*O*-(6″-*O*-malonyl)-glucoside; Q3Gc/L7Gc, quercetin-3-*O*-glucuronide/luteolin-7-*O*-glucuronide. The value of R^2 displays the coefficient of determination.

The light use efficiency between the first and second harvests was significantly lower than that between the second and third harvest dates (0.3 and 0.7 g mol^{-1}, respectively). No significant differences between the cultivars were detected. This indicates that the photosynthetic capacity in the first interval was lower than in the second, as plants accumulated less biomass per intercepted mole of PPFD.

Phenolic Compounds. In our HPLC-DAD-ESI-MS^3 analyses of flavonol, flavone, and anthocyanidin glycosides as well as caffeic acid derivatives in red leaf lettuce, we identified three quercetin glycosides, one luteolin glycoside, one cyanidin glycoside, and several caffeic acid derivatives. The main phenolic compound was chicoric acid (di-*O*-caffeoyltartaric acid), followed by quercetin-3-*O*-(6″-*O*-malonyl)-glucoside, cyanidin-3-*O*-(6″-*O*-malonyl)-glucoside, quercetin-3-*O*-glucuronide, luteolin-7-*O*-glucuronide, chlorogenic acid (5-*O*-caffeoylquinic acid), caffeoylmalic acid, and quercetin-3-*O*-glucoside. These compounds were previously reported for red leaf lettuce.[8,21] Quercetin-3-*O*-glucuronide and luteolin-7-*O*-glucuronide coeluted and were quantified as sum. Mass spectrometric data suggested they on average contributed equal shares to the peak evaluated via DAD, which is in line with data obtained by DuPont, Mondin, Williamson, and Price.[21]

Flavonoid Glycosides. The results for flavonoid glycosides are presented in Figure 1 and Table 2. Generally, all flavonoid glycosides were present in higher concentrations in plants in earlier growth stages than in later ones, with the larger difference between preheading stage and heading stage than between heading stage and mature heads. Remarkably, the concentrations of all flavonoid glycosides increased with PPFD even in the very low levels studied. The response depended on structure and growth stage.

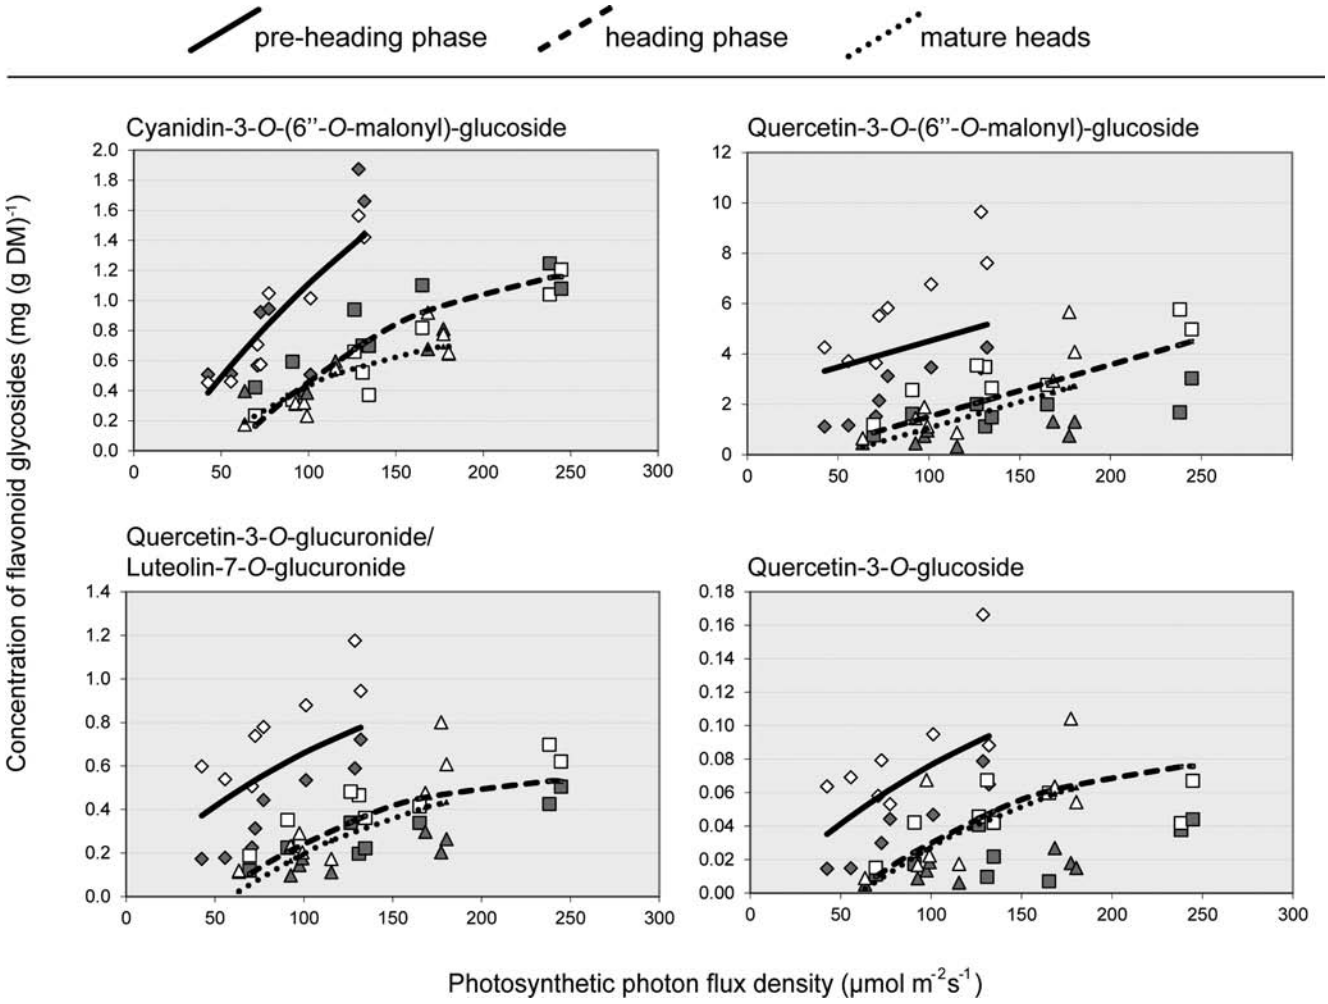

Figure 1. Concentration of flavonoid glycosides per gram dry matter (DM) of red leaf lettuce in three different growth stages in relation to photosynthetic photon flux density (in μmol m^{-2} s^{-1}). The relationship was evaluated via multiple regression analysis. Gray symbols represent values of red oak leaf lettuce; white symbols represent lollo rosso values. Diamonds represent values of preheading phase, squares represent values of heading phase, and triangles represent values of mature heads. The solid line is based on the values of preheading stage, the broken line is based on values of heading stage, and the dotted line is based on values of mature heads.

In detail, with regard to cyanidin-3-*O*-(6″-*O*-malonyl)-glucoside, the lettuce plants' response to radiation varied between the growth stages considered. Multiple regression analysis revealed an interaction between PPFD and plant age: Increasing PPFD had a stronger influence on smaller plants than larger ones. Furthermore, the increase of cyanidin-3-*O*-(6″-*O*-malonyl)-glucoside concentration with rising PPFD was becoming slower with rising PPFD (due to the negative influence of the square term of PPFD), suggesting the approach of a saturation level in PPFD ranges higher than those studied here. Due to the positive influence of the square term of DAP, the differences of cyanidin-3-*O*-(6″-*O*-malonyl)-glucoside concentration between growth stages were more pronounced between preheading and heading phases than between heading and mature heads.

The interaction between PPFD and plant age is most interesting and has not been reported this clearly before. With regard to UV radiation, Behn, Schurr, Ulbrich, and Noga[10] detected a similar age-dependent response when comparing leaves of different age. They cultivated red leaf lettuce for 21 days under UV-B exclusion and subsequently transferred the plants to an environment with ambient UV-B intensity for 2 days. Following this short-term exposure to UV-B radiation, the cyanidin concentration increased only in inner (= young) leaves of lettuce heads. Because responsiveness generally decreased with increasing leaf and plant age, they concluded that younger leaves have an increased requirement for cyanidin as photoprotectant as they have a lower capacity to utilize radiation energy compared to older ones. The light use efficiency of young lettuce was indeed much lower than that of older plants: Per intercepted mole of PPFD, older plants accumulated more than double the dry matter younger ones did. This increase during ontogeny is in line with the literature.[22] Concordantly, the PPFD required for maximum photosynthesis of lettuce plants increases with plant age.[23] This implies an imbalance between captured light energy and its utilization in carbon fixation in early growth stages as has been suggested for juvenile tree leaves by Hughes et al.[24] The surplus energy poses an oxidative threat to plant cells. This suggests that young plants were protecting themselves by anthocyanin accumulation and may explain the higher responsiveness of young plants, even to such low radiation intensities as we studied.

Although the role of anthocyanins in planta is to some degree still subject to discussion, their protective role against photoinhibition and photooxidation in leaves is widely accepted:[25] They absorb light in the green and yellow

dx.doi.org/10.1021/jf404782n | J. Agric. Food Chem. 2014, 62, 6911−6917

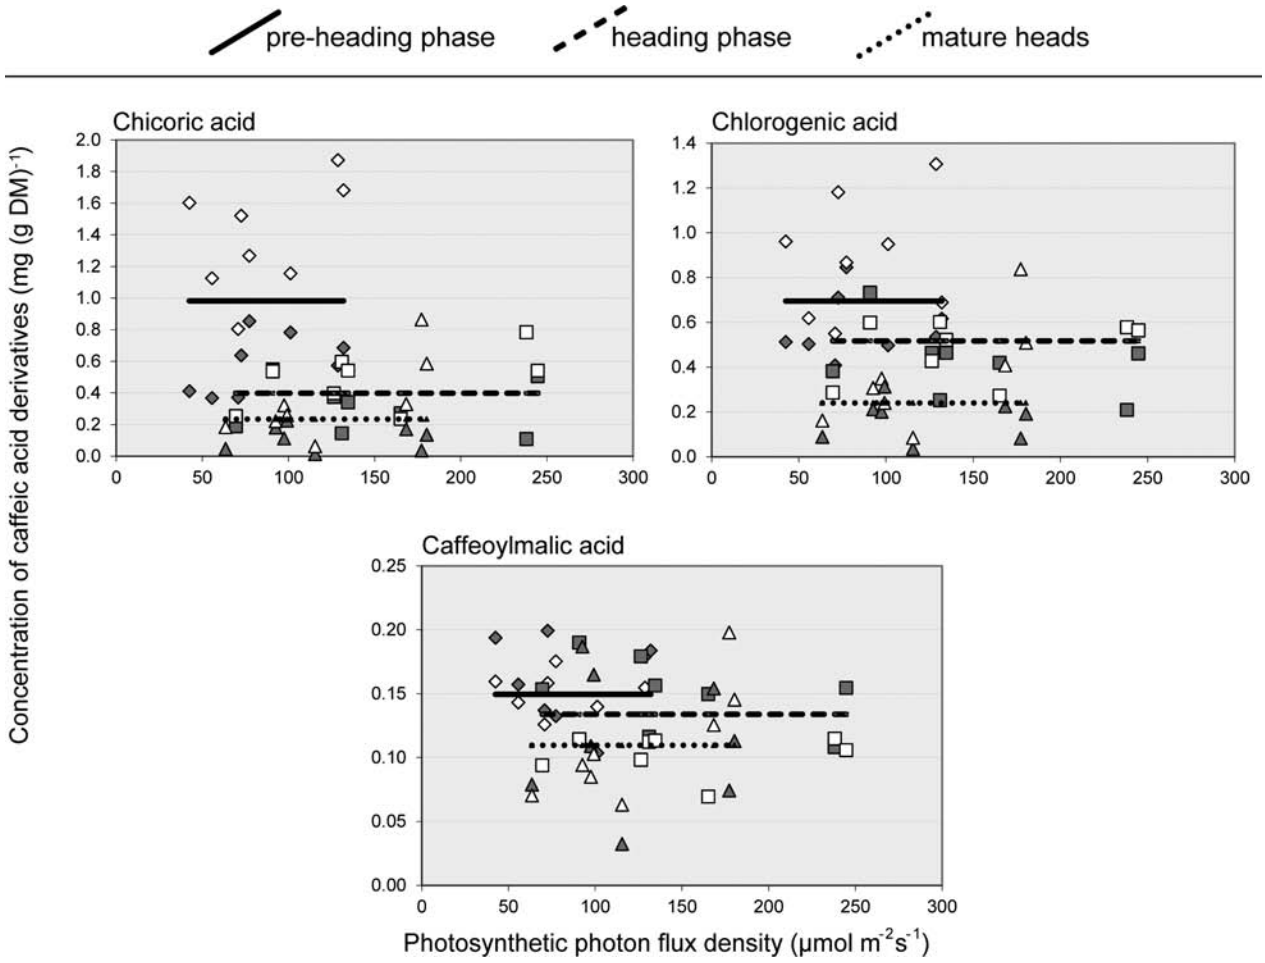

Figure 2. Concentration of caffeic acid derivatives per gram dry matter (DM) of red leaf lettuce in three different growth stages in relation to photosynthetic photon flux density (in μmol m^{-2} s^{-1}). The relationship was evaluated via multiple regression analysis. Gray symbols represent values of red oak leaf lettuce; white symbols represent lollo rosso values. Diamonds represent values of preheading phase, squares represent values of heading phase, and triangles represent values of mature heads. The solid line is based on the values of preheading stage, the broken line is based on values of heading stage, and the dotted line is based on values of mature heads.

wavebands (500−600 nm) and can, therefore, shield the photosynthetic apparatus against surplus radiation, which cannot be used for carbon assimilation and may therefore lead to oxidative damage of photosynthetic tissue.[26] On the other hand, they have a high antioxidant capacity[27] and can counteract reactive oxygen species formed, for example, by photochemistry.[28] Especially during light-sensitive ontogenetic stages, for example, in juvenile leaves in which the photosynthetic apparatus is not yet fully functional, these qualities become obvious.[24] Young leaves are more valuable to plants than old leaves and should, hence, be very effectively protected against harmful impacts.[18]

The concentrations of quercetin-3-*O*-(6″-*O*-malonyl)-glucoside, quercetin-3-*O*-glucoside, and quercetin-3-*O*-glucuronide/luteolin-7-*O*-glucuronide also increased with rising PPFD and decreased with plant age. Between preheading and heading plants the difference regarding concentration was very pronounced. Between heading plants and mature heads, on the other hand, there is hardly any detectable difference. The general increase of the concentration of quercetin glycosides with radiation is in line with previous results.[9,10] Yet, it has not been demonstrated before with regard to such low PPFD levels. Other than for cyanidin glycosides, we did not detect an interaction between PPFD and plant age with regard to quercetin glycoside concentration. Accordingly, Behn, Schurr, Ulbrich, and Noga[10] also found the UV-B response of cyanidin to be more strongly influenced by leaf age than the response of quercetin: Quercetin concentration increased in all of the studied leaf ages.

The effects we detected were clearly structure dependent. On the one hand, they were related to the aglycone: Cyanidin glycosides responded plant age-dependently, whereas quercetin glycosides did not. On the other hand, the glycosidic moiety appears to play a role, too. Otherwise, the three quercetin glycosides would have shown the same response. Yet, in the radiation levels we studied, quercetin-3-*O*-(6″-*O*-malonyl)-glucoside concentration increased linearly with PPFD ,whereas the quercetin-3-*O*-glucoside and quercetin-3-*O*-glucuronide/luteolin-7-*O*-glucuronide concentrations were negatively influenced by the square term of PPFD. Hence, the increase of their concentration was not linear but abated with rising PPFD. This implies that the latter compounds approached a saturation level at higher PPFD than we studied.

All of the presented results were related to dry matter. Yet, for consumers, the concentration-related fresh matter is also interesting. In our experiment dry matter content was not influenced by PPFD but decreased with increasing plant age (data not shown). Therefore, considering the concentration per

dx.doi.org/10.1021/jf404782n | J. Agric. Food Chem. 2014, 62, 6911−6917

100 g of fresh matter, the influence of PPFD corresponds to the results obtained for data related to dry matter, whereas the influence of plant age was even more pronounced.

All studied flavonoid glycosides displayed a remarkable, unexpectedly strong response to changes in PPFD level between approximately 50 and 150 μmol m^{-2} s^{-1}, which was independent of plant age. This demonstrates an impressive PAR sensitivity of the regulative mechanisms.

As mentioned earlier (Introduction and Influence of Cultivar), one major aspect of progressing plant age in the vegetative growth phase of lettuce is the increasing number of leaves accompanied by a change in plant architecture: the formation of a more or less dense head. As a result, the distribution of radiation within the plant is changed. With more leaves shading each other, less biomass per head is directly exposed to radiation. The light-dependent flavonoid biosynthesis, however, will only take place in the exposed tissue.[29] The relative decrease of light-exposed, flavonoid-synthesizing tissue per plant may explain the decrease of flavonoid glycosides we measured with progressing head formation.

Yet, according to Kubasek, Ausubel, and Shirley,[17] flavonoid biosynthesis regulation is influenced by environmental as well as developmental factors. When studying the mRNA level of four flavonoid biosynthesis genes in *Arabidopsis thaliana* seedlings, they found that mRNA levels were higher in 3-day-old than in 7-day-old seedlings, although plants were exposed to identical radiation conditions. They concluded that the gene expression potential was related to plant age. Despite obvious differences between the plants studied by Kubasek, Ausubel, and Shirley[17] and our experiment (different radiation conditions and different plant species), these results may at least be partly transferrable to lettuce in more advanced growth stages: The interaction between plant age and PPFD regarding cyanidin glycoside allows for the speculation that the decreasing concentration with plant age may not only be due to the mentioned dilution effect but also be influenced by growth-stage-dependent variation in the induction capacity of genes involved in biosynthesis. As we detected an interaction only between plant age and radiation concerning cyanidin glycosides, we suppose that the decrease of quercetin glycosides with plant age is due to the relative decrease of radiation-exposed tissue in more developed heads, whereas the decrease in cyanidin glycoside concentration is (additionally) mediated by decreasing biosynthetic capacity with increasing leaf age.

In further studies, it would therefore be interesting to take a closer look and compare the induction of genes at the junction leading to quercetin or cyanidin biosynthesis, for instance, the mRNA levels of flavonol synthase and dihydroflavonol 4-reductase, respectively.[15] Yet, considering the high number of levels at which regulatory processes can take place following transcription (stability of mRNA, translator effectivity, enzyme activation, and more), it might be additionally interesting to study the quantity and activity of the respective enzymes.

Caffeic Acid Derivatives. The results for caffeic acid derivatives are presented in Figure 2 and Table 2. Independent of growth stage, PPFD had no significant influence on the concentration of any of the caffeic acid derivatives. Unlike PPFD, progressing ontogeny had an influence on the concentrations of all three caffeic acid derivatives: They decreased with plant age, however to various degrees.

The decrease of chicoric acid concentration was counteracted by the positive influence of the square term of DAP. Hence, it was markedly higher in the preheading than in the heading stage, whereas the latter did not differ as much from the mature heads' concentration. We observed a significant influence of the cultivar on chicoric acid concentration. Chlorogenic and caffeoylmalic acid were only significantly influenced by DAP, that is, plant age.

The result that none of the three studied caffeic acid derivatives was influenced by PPFD is not in line with Oh, Carey, and Rajashekar,[9] who found an increase of caffeic acid derivatives with increased radiation. However, they exposed their small lettuce plants to 800 μmol m^{-2} s^{-1} for 1 day; this is much higher than the PPFD incident in our experiment (50–250 μmol m^{-2} s^{-1}). According to Fu et al.,[30] lettuce suffers no stress under 100–400 μmol m^{-2} s^{-1} but serious stress under 800 μmol m^{-2} s^{-1}. Furthermore, greenhouse glass absorbs UV radiation to a large degree and phenolic acids are discussed as UV protectants in red leaf lettuce.[31] Hence, incident radiation in this experiment may have lacked the intensity and UV wavelengths needed to trigger caffeic acid derivative biosynthesis.

In conclusion, we could partly confirm our first hypothesis: Quercetin and cyanidin glycosides responded to PPFD at low levels, whereas caffeic acid derivatives did not. Consequently, the measured responses were structure-dependent and the second hypothesis could be fully confirmed. The third hypothesis that the PPFD response is development dependent could be confirmed only for cyanidin-3-*O*-(6″-*O*-malonyl)-glucoside, which responded differently to increasing levels of PPFD depending on the plant's growth stage. Our results highlight how important it is to consider the plant's developmental stage when its physiology is studied.

For lettuce cultivation in greenhouses and the application of energy-saving screens, this implies that screen application during red leaf lettuce production is possible without reducing the concentration of chicoric, chlorogenic, or caffeoylmalic acid, no matter in which growth stage plants are shaded by the screen. Unfortunately, this is not true for cyanidin and quercetin glycosides. Yet, in mature heads losses due to reduced radiation were smaller than with younger plants with regard to three of four flavonoid glycosides.

The high concentration of polyphenols in preheading leaf lettuce and their response to shading may be especially interesting for producers of baby leaf lettuce. Furthermore, the selection of cultivars that are less sensitive to shading and maintain higher concentrations of phytonutrients under these conditions may represent interesting prospects for future studies.

calafate was delphinidin-3-glucoside, followed by petunidin-3-glucoside and malvidin-3-glucoside, with a total of 18 anthocyanins being detected.[12] Among them, five dihexoside derivatives, from delphinidin, cyanidin, petunidin, peonidin, and malvidin aglycones, were detected, characterized by two independent neutral losses of 162 amu in their respective MS/MS spectra. However, the identity and position of these sugars could not be determined by HPLC-DAD-MS/MS.[12]

On the other hand, identification and quantitation of hydroxycinnamic acid derivatives in calafate were recently determined. Twenty hydroxycinnamic acid derivatives were identified showing very high levels of these compounds, with a mean concentration of 4.19 μmol/g (n = 54), which is up to 1.5 times higher than those of other widely consumed berries.[15] Among these hydroxycinnamic acid derivatives, four isomeric caffeoyl-hexaric acids characterized by a neutral loss of 162 amu in their respective ESI-MS/MS spectra were detected. However, the identity of the hexaric acid moiety could not be established. These caffeoyl-hexaric acids accounted for a total proportion of 49.6 ± 10.9% among total hydroxycinnamic acid derivatives found in calafate berries, thus highlighting the importance of the contribution of these derivatives to the pool of hydroxycinnamic acids in calafate.

The high levels of anthocyanins and hydroxycinnamic acid derivatives in calafate berries made the unequivocal identification of each compound in the fruit relevant to demonstrate the nutraceutical value of this interesting fruit. In this context, the main aim of this research is the structural elucidation of anthocyanidin dihexosides and caffeoyl-hexaric acids in calafate berries. With this purpose, the isolation of these compounds using a combination of countercurrent chromatography (fast centrifugal partition chromatography, FCPC), solid phase extraction, and semipreparative HPLC was used, followed by structural elucidation by spectroscopic techniques, including online UV−vis, ESI-MS/MS, and ^{1}H and ^{13}C NMR.

MATERIALS AND METHODS

Chemicals. Ethyl acetate and hydrochloric acid of analytical grade were obtained from Fisher Scientific (Leicestershire, UK). 1-Butanol, trifluoroacetic acid (TFA) of synthesis grade, and methanol of HPLC grade were provided by Scharlab SL (Barcelona, Spain). Ammonia 20% of PRS grade, acetonitrile of HPLC grade, and formic acid 98% of PRS grade were purchased from Panreac Química SLU (Castellar del Vallès, Spain), and water was of Milli-Q quality. D-Saccharic acid potassium salt (standard for D-glucaric acid) and mucic acid (standard for D-galactaric acid) came from Sigma-Aldrich Química SL (Madrid, Spain). Malvidin-3,5-diglucoside and caffeoyl-tartaric acid used for optimization of MS working conditions were obtained from Phytolab (Vestenbergsgreuth, Germany).

Calafate Berry Samples. Mature calafate berries (*B. microphylla* G. Forst) were collected from the Magallanes and Aysén regions of the Chilean Patagonia, 42 samples in year 2011 and 26 samples in year 2012. A taxonomical identification, by comparison of the species with those from the University of Concepción Herbarium, was carried out to ensure the identity of the samples. Aliquots of 10 g of each berry sample were used for the analysis of the total content and distribution of hydroxycinnamic acid derivatives following a previously reported method.[15] A mix of all the samples from year 2012 was used for the isolation of anthocyanidin dihexosides and caffeoyl-hexaric acids.

Extraction Procedures. *Crude Calafate Extract.* Two kilograms of fresh calafate was extracted with 1000 mL of methanol/water (93:7). The extract was treated for 45 s with the ultrasonic bar, followed by 16 h of mechanical shaking under darkness. After centrifugation, the separated supernatant was transferred and the residual solid washed three times with the same solvent, using a total of 2000 mL, by mechanical shaking for 15 min. After elimination of excess methanol by rotatory evaporation at 35 °C, the extract was freeze-dried and stored at −20 °C until use for liquid−liquid extraction.

Liquid−Liquid Extraction. In a separation funnel, 100 mL of solvents A and B (A, ethyl acetate/1-butanol/water (77:15:8) + 0.1% TFA; B, ethyl acetate/1-butanol/water (40:46:14) + 0.1% TFA) were mixed together with approximately 1 g of whole calafate extract. After shaking, the two phases were separated: the aqueous phase contained the anthocyanidin dihexosides, whereas the organic phase held hydroxycinnamic acid derivatives and anthocyanidin 3-glucosides. The aqueous phase was concentrated by rotatory evaporation at 35 °C for further fractionation by FCPC, whereas the hydroxycinnamic acid derivatives in the organic phase were purified by SPE.

Isolation of Anthocyanidin Dihexosides. *Fast Centrifugal Partition Chromatography (FCPC).* To obtain a fraction enriched in anthocyanidin dihexosides, countercurrent chromatography was carried out using an FCPC system, model FCPC-200 (Kromatron, Sainte-Gemmes-sur-Loire, France), with a total rotor volume of 198 mL and 840 partition cells. The FCPC system was connected to a semipreparative ternary pump, model BETA-50 (ECOM, Czech Republic), a UV−vis detector, model Flash 06S DAD 600 (ECOM, Czech Republic), and a fraction collector. Samples were manually injected from a 10 mL loop through a 3725i valve (Rheodyne, Rohnert Park, CA, USA). The stationary phase was a mixture of ethyl acetate/1-butanol/water (4:5:91) with 0.1% TFA. Two mobile phases were required: A, ethyl acetate/1-butanol/water (77:15:8) with 0.1% TFA; and B, ethyl acetate/1-butanol/water (40:46:14) + 0.1% TFA. The separation was carried out by an elution−extrusion system, in ascending mode in the first case and in descending mode in the extrusion. The injection volume was 8 mL of aqueous calafate liquid−liquid extraction phase, previously freeze-dried and redissolved in 10 mL of a mixture of stationary phase and mobile phase A (50:50). The flow of the mobile phase was 5 mL/min with a linear gradient in ascending mode as follows: at 0 min, 75% mobile phase A and 25% B; at 65 min, 100% mobile phase B; at 122 min, 100% mobile phase B; from 122.001 to 142 min change to descending mode with 100% of stationary phase. Fraction collection was every 2 min from 22 to 142 min, and detection was performed at 520 nm.

Semipreparative HPLC. The FCPC fractions enriched in anthocyanidin dihexosides were purified by semipreparative chromatography using an HPLC system consisting of a U6K injector, a 510 pump, and a 996 DAD detector (Waters, Milford, MA, USA). The semipreparative column was a 250 × 10 mm i.d., 5 μm, Kromasil C18 (Análisis Vínicos, Tomelloso, Spain). The mobile phases and the elution gradient were based on the method described by the International Organization of Vine and Wine (OIV) for anthocyanin separation with modifications.[16] Acetonitrile was changed to methanol to reduce the analysis cost and the generation of toxic residues, whereas the formic acid proportions were modified to adapt to this change. Two solvent mixtures were used for the mobile phase: water/methanol/formic acid (92:3:5) (A) and water/methanol/formic acid (45:50:5) (B). The optimized gradient was as follows: at 0 min using 1 mL/min, 75% mobile phase A; at 2 min using 2 mL/min, 75% A; at 30 min, 75% A; at 40 min, 60% A; at 41 min, 0% A; at 44 min, 0% A; at 46 min, 75% A; at 50 min, 75% A; and at 52 min, 75% A and change to 1 mL/min. The injection volume was 250 μL, and detection was at 520 nm. After separation, the eluates were dried by rotatory evaporation at 35 °C, and they were redissolved in methanolic 0.1 M HCl to obtain the hydrochloride form of anthocyanins. A preconcentration by rotatory evaporation at 35 °C, followed by redissolution in water and freeze-drying, was required before NMR analysis.

Repurification of Malvidin Dihexoside by SPE. An additional purification step was necessary in the case of malvidin dihexoside because the semipreparative HPLC eluate contained nonanthocyanin compounds. SPE was carried out in 500 mg, 6 mL, Bond Elut Plexa PCX cartridges (Agilent, Waldbronn, Germany), which combine cationic exchange and reversed phase as retention mechanisms.[17] The process began with a preconditioning step using 5 mL of methanol and 5 mL of water. The malvidin dihexoside eluate was dried and

redissolved in 0.1 M HCl, then was loaded into the PCX cartridge, and cleaned up with 3 × 5 mL of methanol to remove nonanthocyanin compounds. After that, the malvidin dihexoside was eluted with 2% ammonia in 80% methanol until disappearance of blue-colored material from the cartridge, followed by neutralization with enough drops of 4 M HCl to restore the red-colored flavylium cationic form of the anthocyanin. This eluate was dried by rotatory evaporation at 35 °C, redissolved in 0.1 M HCl, and then loaded into an 820 mg, Sep-Pak Plus C18, SPE cartridge (Waters, Milford, MA, USA), which had been previously conditioned with 5 mL of methanol and 5 mL of water. After a cleanup step (6 × 5 mL of 0.1 M HCl) to remove excess ammonium chloride, the purified malvidin dihexoside was eluted with 3 × 5 mL of methanolic 0.1 M HCl, dried by rotatory evaporation at 35 °C, redissolved in water, frozen, and freeze-dried in the dark.

Isolation of Caffeoyl-hexaric Acids. *SPE.* A column filled with 10 g of PCX resin, recovered from PCX cartridges, was used for removing anthocyanins contained in the organic phase separated after liquid−liquid partition of calafate extracts, thus allowing a partial purification and enrichment of hydroxycinnamic acid derivatives. The process began with a preconditioning step using methanol and water (30 mL of each). The organic phase containing hydroxycinnamic acid derivatives was dried by rotatory evaporation at 35 °C, redissolved in 0.1 M HCl (20 mL), and loaded into the column followed by a cleanup step using 0.1 M HCl (2 × 30 mL) and, finally, the hydroxycinnamic acid derivatives were eluted using methanol (3 × 30 mL), the anthocyanins being retained by the stationary phase. The eluates were dried by rotatory evaporation at 35 °C and redissolved in 20 mL of phase A used for semipreparative HPLC and were ready for injection in the next step.

Semipreparative HPLC. The enriched fraction in hydroxycinnamic acid derivatives obtained by SPE was separated by using the semipreparative HPLC equipment described above. The separation conditions were based on a method previously described for hydroxycinnamic acid derivatives determination in calafate but with modification,[15] consisting of the substitution of acetonitrile with methanol. The mobile phases were 0.1% formic acid (A) and 100% methanol (B). The optimized gradient was as follows: at 0 min, using 1 mL/min, 85% mobile phase A; at 2 min, using 2 mL/min, 85% A; at 14 min, 75% A; at 25 min, 75% A; 26 min, 0% A; 35 min, 0% A; 36 min, 85% A; 45 min, 85% A; and at 46 min, 85% mobile phase A and change to 1 mL/min. The injection volume was 250 μL, and detection was performed at 320 nm. The isolated compounds were frozen and freeze-dried before NMR analysis.

Analysis by HPLC-DAD-ESI-MS/MS of Intermediate FCPC and Semipreparative HPLC Fractions and Isolated Compounds. The HPLC-DAD-ESI-MS/MS system was an Agilent 1100 series system coupled with a DAD, model G1315B, and an LC-MSD Trap VL, model G2445C VL, with electrospray ionization (ESI-MS/MS) detectors (Agilent, Waldbronn, Germany). Control and data analyses were carried out by an Agilent ChemStation (version B.01.03) data-processing station and Agilent LC-MS Trap software (version 5.3). The chromatographic separation was carried out in a 2.1 × 150 mm i.d., 3.5 μm, Zorbax Eclipse XDB-C18 (Agilent) column with a flow of 0.190 mL/min at 40 °C, and the injection volume was 10 μL. The mobile phases were: A, formic acid/acetonitrile/water (8.5:3:88.5); B, formic acid/acetonitrile/water (8.5:50:41.5); and C, formic acid/methanol/water (8.5:90:1.5). Anthocyanin analysis was carried out using a binary linear gradient between only solvents A and B as follows: at 0 min, 6% B; 10 min, 30% B; 30 min, 50% B; 34 min, 100% B; 36 min, 100% B; and 42 min, 6% B. The monitoring was at 520 nm, and the MS/MS conditions were positive ionization mode and ionization and fragmentation parameters optimized by direct infusion of a solution of malvidin-3,5-diglucoside in phase A. In the case of hydroxycinnamic acid derivatives, the linear gradient was as follows: at 0 min, 2% B and 0% C; 8 min, 4% B and 0% C; 37 min, 17% B and 13% C; 51 min, 30% B and 20% C; 51.5 min, 40% B and 30% C; 56 min, 50% B and 50% C; 57 min, 50% B and 50% C; and 64 min, 0% B and 0% C. In this case, the monitoring was at 320 nm and the MS/MS conditions were negative ionization mode and ionization and fragmentation parameters optimized by direct infusion of a solution of caffeoyltartaric acid in phase A.

Hydrolysis of Caffeoyl-hexaric Acids. Two of the caffeoyl-hexaric acids isolated in high purity were subjected to alkaline hydrolysis to release the hexaric acid moiety that was further compared to available standards of hexaric acids (D-glucaric and D-galactaric acids) by ^{1}H NMR. We followed a previously described hydrolysis method[18] that was combined with a further purification method by SPE. One milligram of caffeoyl-hexaric acid was dissolved in a 0.1 M solution of K_2CO_3 (8 mg) in D_2O (0.6 mL) and heated at 80 °C for 60 min in the oven. The ^{1}H NMR spectrum of this reaction mixture was very complex, and the identification of signals attributable to hexaric acid was not clear. Thus, a further cleanup step was carried out. Strongly acidic ion-exchange resin (Panreac Química S.L.U., Castellar del Vallès, Spain) was added (10 mg) to the hydrolysis mixture to remove excess carbonate ions by acidification of the medium. Then, the released hexaric acid was separated following an SPE method inspired by previous work on flavonol glycosides separation based on their acidity.[19] The acidified hydrolysis solution was loaded in a 500 mg, 6 mL, Oasis MAX SPE cartridge, filled with a stationary phase that combines reversed-phase and anionic exchange materials (Waters, Milford, MA, USA), previously conditioned with 5 mL of methanol and 5 mL of water. After washing with water (5 mL), the released hexaric acid was eluted by adding methanol (2 × 5 mL), and the retained compounds, including the released caffeic acid and other degradation products, were removed with 2% HCl in methanol (2 × 5 mL). After drying by rotatory evaporation at 35 °C, the eluate containing the hexaric acid was dissolved in D_2O (0.6 mL) and its ^{1}H NMR spectrum was recorded.

Structure Elucidation by Nuclear Magnetic Resonance (NMR) Spectroscopy. The NMR analyses were recorded in a Varian Inova NMR spectrometer (Agilent, Palo Alto, CA, USA), operating at 500 MHz for ^{1}H and at 125 MHz for ^{13}C. The samples of anthocyanins were dissolved in an acidic mixture of CD_3OD/CF_3COOD (95:5) to maintain the flavylium cation, whereas hydroxycinnamic acid derivatives were dissolved in CD_3OD. The identification of proton signals of hexoses was assisted by one-dimensional (1D)-TOCSY spectra. Two-dimensional (2D) spectra were recorded to help peak identification: gCOSY, gHMBC, gHSQC, and NOESY spectra in the case of anthocyanins and gCOSY, gHMBC, and gHSQC spectra for hydroxycinnamic acid derivatives. The spectrometer was equipped with a gradient amplifier and a four-nucleus 5 mm ^{1}H{^{15}N−^{31}P}PFG high-field indirect detection probe. All 1D and 2D experiments were performed at 298 K using standard pulse sequences from the Varian library.

RESULTS AND DISCUSSION

Isolation of Anthocyanidin Dihexosides and Caffeoyl-hexaric Acids from Calafate Berries. The liquid−liquid extraction of the whole calafate extract allowed the partition of main classes of occurring phenolic compounds into two phases.[12,15] The aqueous phase contained a mixture of calafate anthocyanins, mainly dihexosides, 3-rutinosides, and 3-glucosides. In contrast, the organic phase contained hydroxycinnamic acid derivatives and some anthocyanins, mainly 3-glucosides.

The aqueous phase was subjected to countercurrent chromatography by FCPC and resulted in the elution of anthocyanidin 3-glucosides (peak at 46−60 min) and anthocyanidin 3-rutinosides (peak at 70−82 min) following the order of increasing polarity. The more polar anthocyanidin dihexosides were retained by the stationary phase and did not elute after 125 min. Therefore, they were recovered in the further extrusion step (peak at 126−132 min). The extruded fraction mainly contained the dihexosides of B-ring trisubstituted anthocyanidins, namely, delphinidin, petunidin, and malvidin, together with minor amounts of the corresponding dihexosides of the B-ring disubstituted anthocyanidins, namely,

cyanidin and peonidin (Figure 1). All of these compounds exhibited MS and MS/MS spectra with signals at the expected

m/z values for their suggested structures.[12,20] The MS spectra showed molecular ions at 627, 611, 641, 625, and 655 for the respective dihexosides of delphinidin, cyanidin, petunidin, peonidin, and malvidin. The MS/MS spectra showed two fragment ions from each molecular ion, generated by independent and successive losses of two hexose units. The signal corresponding to the first hexose loss (m/z values of 465, 449, 479, 463 and 493, respectively) was always a little bit more intense than the second one, thus suggesting that both hexose units were linked separately to the anthocyanidin core.[20] The loss of the two hexose units led to their corresponding anthocyanidin aglycones at the expected m/z values of 303, 287, 317, 301, and 331, respectively. The further separation by semipreparative HPLC allowed the isolation of sufficient amounts of high-purity compounds for an NMR study, showing single peaks in their DAD chromatograms at 520 nm and no other signal in their MS spectra than that attributable to the expected molecular ions, in the cases of the major dihexoside anthocyanidins, consisting of delphinidin (5.9 mg), petunidin (12.5 mg), and malvidin (4.4 mg). Malvidin dihexoside coeluted with a nonanthocyanin compound, showing MS and MS/MS signals at m/z values of 490 and 328, respectively, and an extra purification step was necessary. The impurity was effectively removed by selective retention and further elution of the malvidin dihexoside in the SPE cartridge (PCX) filled with a stationary phase that combines reverse phase and cationic exchange materials.[17] The other two minor compounds were isolated in low amounts and were not pure enough to perform a complete NMR study. Hence, the dihexoside of peonidin (0.6 mg) was determined on the basis of its retention time and UV−vis, MS/MS, and ^{1}H NMR data, which matched those previously reported for this compound when isolated from Garnacha Tintorera grapes.[21] Finally, the occurrence of cyanidin dihexoside (1.6 mg) was suggested only on the basis of its congruent UV−vis and MS/MS data.

Caffeoyl-hexaric acids were first concentrated by SPE on C18 cartridges from the organic phase obtained by liquid−liquid extraction of whole calafate extract and then subjected to semipreparative HPLC. Three isomeric caffeoyl-hexaric acids were isolated showing common MS and MS/MS spectra, with signals at m/z values of 371 assigned to the pseudomolecular and fragment ions appearing at m/z values of 209 and 191.[15] Two of those isomers, eluting at 2.6 and 2.9 min, were stable and could be isolated in amounts of 2.3 and 4.1 mg, respectively, which were sufficient for further NMR study. In contrast, the third isomer, eluting at 3.2 min, was unstable and was partially degraded to a new chromatographic peak at 3.4 min, showing pseudomolecular and fragment ions at m/z values of 353 and 191, respectively, during the subsequent process of concentration of the HPLC fractions in which it was collected. The degradation product could likely be a δ-lactone, as has previously been reported for this kind of compound.[22]

Structure Elucidation of Anthocyanidin Dihexosides and Caffeoyl-hexaric Acids from Calafate Berries. In addition to matching of UV−vis and MS/MS data with those previously reported,[12,15] the structure elucidation of anthocyanidin dihexosides and caffeoyl-hexaric acids isolated from calafate was completed by NMR spectroscopy.

In the case of anthocyanidin dihexosides, the assignment of the anthocyanidin structures of delphinidin, petunidin, and malvidin was based on the agreement of ^{1}H and ^{13}C chemical shifts (Table 1) with those widely described in the literature[23] and was assisted by gHMBC and gHSQC 2D heteronuclear experiments. With regard to hexoses, two doublets assignable to sugar anomeric protons were always found in the ^{1}H NMR spectra: one of them resonated within the range of 5.38−5.43 ppm and the other within the range of 5.21−5.23 ppm, in accordance with previously reported data for the similar peonidin derivative.[21] The two sugars were determined as glucose on the basis of 1D-TOCSY experiments, because all homonuclear coupling constants between successive proton couples (J_{HH} from H-2″ to H-5″ and also from H-2‴ to H-5‴) ranged within 8−11 Hz, thus indicating their axial disposition in the cyclic sugar structure as expected for glucose. Moreover, the coupling constant between H-1 and H-2 for each glucose unit had values of 7−8 Hz, thus indicating a β-anomeric linkage between the sugar and the anthocyanidin core in all cases. The linkage position of the glucose units to the anthocyanidin core was achieved in two ways (Figure 2): long-range ^{1}H−^{13}C heteronuclear coupling between each anomeric proton and its respective carbon position of linkage in the anthocyanidin structure by gHMBC correlation experiments, and the nuclear Overhauser effect between each anomeric proton and the protons situated close to the respective linkage position by 2D-NOESY experiments. Thus, the glucose showing the resonance of the anomeric proton H-1″ at 5.38−5.43 ppm was linked to the C-3 position of the anthocyanidin because H-1″ correlated with C-3 (gHMBC) and also with H-4 (NOESY), and the glucose with the anomeric proton H-1‴ resonating at 5.21−

[a]Signals could be interchanged.

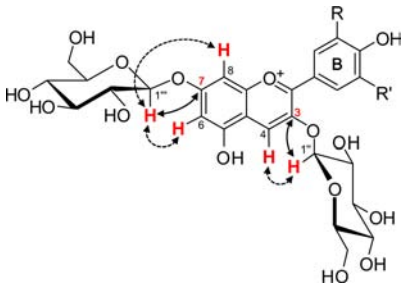

Figure 2. 2D homonuclear (NOESY, dotted arrows) and heteronuclear (gHMBC, solid arrows) correlations found in the NMR experiments of anthocyanidin 3,7-β-*O*-diglucosides that helped assignment of the glucose linkage positions (compound **1**, delphinidin 3,7-β-*O*-diglucoside, R = R′ = OH; compound **3**, petunidin 3,7-β-*O*-diglucoside, R = OH, R′ = OCH_3; compound **5**, malvidin 3,7-β-*O*-diglucoside, R = R′ = OCH_3).

5.23 ppm was linked to the C-7 position of the anthocyanidin, as H-1‴ correlated with C-7 (gHMBC) and protons H-6 and H-8 (NOESY). Therefore, the dihexosides of delphinidin, petunidin, and malvidin were unambiguously identified as delphinidin-3,7-β-*O*-diglucoside (**1**), petunidin-3,7-β-*O*-diglucoside (**3**), and malvidin-3,7-β-*O*-diglucoside (**5**), respectively. For peonidin dihexoside, it was not possible to record the ^{13}C NMR spectrum or to perform 2D-NMR experiments for the assignment of the type of hexoses and their linkage positions because of the low amount isolated. However, the matching of the retention time and the UV−vis, MS, MS/MS, and ^1H NMR spectroscopic data obtained for this peonidin dihexoside with those reported[21] for peonidin-3,7-β-*O*-diglucoside (**4**) provided strong evidence to suggest it would have the same structure. Finally, the NMR study was not possible for the cyanidin dihexoside because it was not pure and the purification attempts were unsuccessful. In this case, we can only suggest a tentative classification as cyanidin-3,7-β-*O*-diglucoside (**2**) that could complete the series of these kinds of derivatives in calafate, having also been found for 3-glucosides and 3-rutinosides derivatives.[12] This suggestion was supported by the following data: the congruent elution order for the series of anthocyanidin glycosides in reversed-phase C18 columns (e.g., anthocyanidin 3-glucosides and anthocyanidin 3,5-diglucosides elute in the order delphinidin < cyanidin < petunidin < peonidin < malvidin), because cyanidin dihexoside eluted

dx.doi.org/10.1021/jf5012825 | J. Agric. Food Chem. 2014, 62, 6918−6925

between delphinidin-3,7-β-*O*-diglucoside (**1**) and petunidin-3,7-β-*O*-diglucoside (**3**); the similarity of its UV−vis spectra, namely, wavelength of maximum absorbance and shape of the visible absorption band, when compared to that of the other B-ring disubstituted derivative, peonidin-3,7-β-*O*-diglucoside (**4**); and the *m*/*z* value of its molecular ion and the finding of the expected MS/MS fragmentation pattern.

Compounds **1**−**5** belong to a rare glycosylation substitution pattern that is seldom found among anthocyanins. Whereas 3,5-diglucosides are widely found in plant materials, 3,7-diglucosides have a more restrictive substitution pattern.[24] As far as we know, 3,7-diglucosides have been identified only in some flowers but not in fruits and berries, and they include the following structures: the nonacylated 3,7-diglucosides of cyanidin, delphinidin, and petunidin, and the (poly)acylated 3,7-diglucosides and 3,7-diglycosides of pelargonidin, cyanidin, delphinidin, petunidin, and malvidin.[24−32] Our group recently demonstrated the occurrence of peonidin 3,7-diglucoside as a very minor anthocyanin in Garnacha Tintorera grape and wine samples.[21] Therefore, compound **5** (malvidin 3,7-diglucoside) was never reported in plant materials. Moreover, the structure elucidation of compounds **1** and **3**, reported previously,[28,29] was based only on ^{1}H NMR and 2D homonuclear correlation (nuclear Overhauser effect) data. We are now reporting additional data on ^{13}C NMR and 2D heteronuclerar correlations (gHSQC and gHMBC) that reinforce the assignments of the 3,7-diglucosides of delphinidin and petunidin. Finally, we can conclude that a remarkable result of this work is that the complete series of five anthocyanidin 3,7-diglucosides has been found for the first time in a fruit, specifically a berry.

The unambiguous elucidation of the structures of caffeoyl-hexaric acids is a difficult challenge to overcome. The hexaric acid moiety exists in open form and has up to four possible linkage positions of the caffeoyl residue depending on the symmetry of the hexaric acid. Hence, we have to first determine the kind of hexaric acid involved in our compounds. The proposed strategies imply the hydrolysis of the ester and further analysis of the released hexaric acid moiety by GC after derivatization or directly by ^{1}H NMR.[8,18,22] After hydrolysis of the two pure caffeoyl-hexaric acids isolated from calafate, we isolated the released hexaric acid moiety by SPE, and its ^{1}H NMR spectrum matched that of a standard of D-glucaric acid (Figure 3). Each hexaric acid gives rise to characteristic and differentiated ^{1}H NMR spectra.[18] The identification of the linkage position of the caffeoyl residue to the hexaric acids is an additional challenge, as the pseudo symmetry of some of them (e.g., glucaric acid) does not allow for distinction between linkage positions 2 and 5, nor between 3 and 4, by NMR spectroscopy,[33] even when 2D homo- and heteronuclear correlation experiments (gCOSY, gHSQC, and gHMBC) are used.[18,34] The linkage of the caffeoyl residue causes an increase in the chemical shift of the corresponding attached proton[18,33] and helps the identification of the linkage position. Further analysis of the multiplicity of the poorly resolved proton signal of the linkage position allows distinguishing between "inner" (3 or 4; broad double doublet or triplet) or "outer" (2 or 5; broad doublet) positions (Table 2). On the basis of the aforementioned arguments, and in agreement with previously reported data for similar compounds,[8,18,33] the two analyzed caffeoyl-hexaric acid isomers were identified as 3-*trans*-caffeoyl-glucaric acid (**6**) and 4-*trans*-caffeoyl-glucaric acid (**7**), but it was not possible to determine which of the two positional

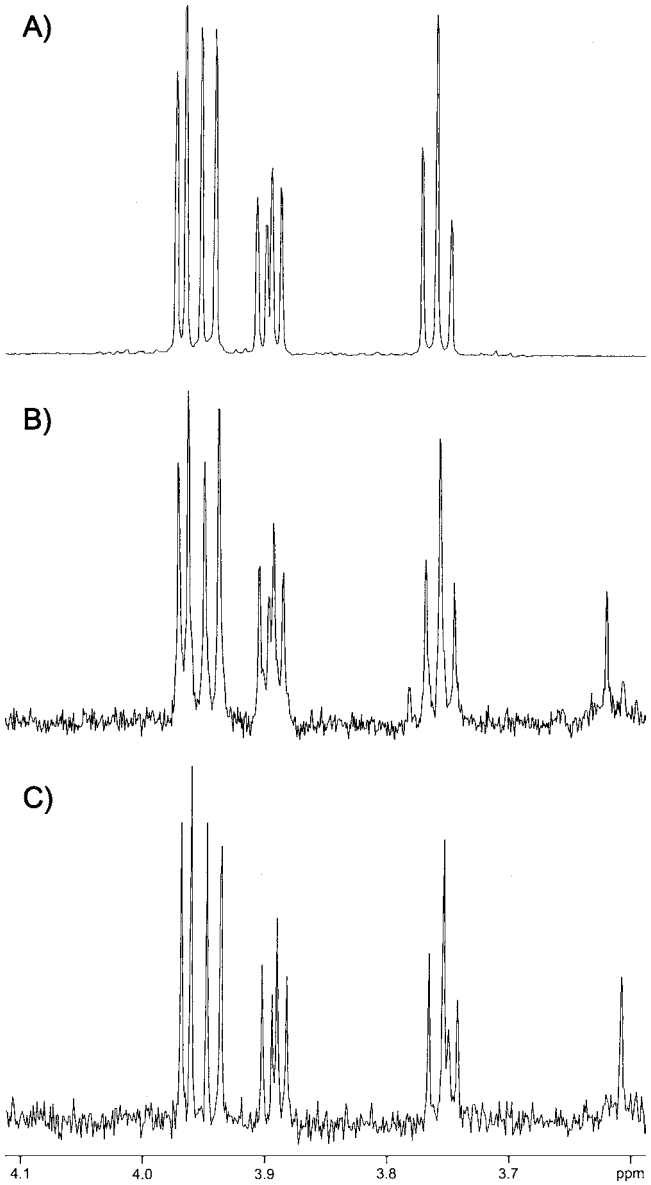

Figure 3. ^{1}H NMR spectra (500 MHz in D_2O) of the fractions containing the released hexaric acids in the hydrolysis experiments of isomeric caffeoyl hexaric acids isolated from calafate: (A) D-glucaric acid standard; (B) glucaric acid released from the first isomer; (C) glucaric acid released from the second isomer.

isomers corresponded to each compound. For one of these isomers, that eluting at 2.9 min, it was possible to record the ^{13}C NMR spectra (Table 2), and the results were in agreement with previously reported data.[22,34] The third detected isomer was degraded during the isolation process, and its structure was tentatively suggested to be 2- or 5-*trans*-caffeoyl-glucaric acid (**8**) on the basis of only UV−vis and MS/MS data.

The levels of caffeoyl-glucaric acids in 68 samples collected in years 2011 and 2012 were analyzed, showing high concentrations (Table 3) that corroborate previously reported data.[15] In addition, the total sum of caffeoyl-glucaric acid concentrations accounted for 42−43% of total hydroxycinnamic acid derivatives found in calafate berries, which reinforce the importance of these compounds within the pool of hydroxycinnamic acid derivatives of this Patagonian wild berry, in agreement with previous findings.[15]

[a]Differentiation between 3-*trans*-caffeoyl-glucaric acid (**6**) and 4-*trans*-caffeoyl-glucaric acid (**7**) is not possible. [b]2- or 5-*trans*-caffeoyl-glucaric acid (**8**). [c]Unidentified isomer.

In summary, the calafate berry contains unusual anthocyanins identified as the complete series of 3,7-β-*O*-diglucosides of the five anthocyanidins usually found in calafate, namely, delphinidin, cyanidin, petunidin, peonidin, and malvidin. Following separation and purification steps, it was possible to isolate the three major anthocyanins of this kind, and their structures were unambiguously determined as delphinidin-3,7-β-*O*-diglucoside (**1**), petunidin-3,7-β-*O*-diglucoside (**3**), and malvidin-3,7-β-*O*-diglucoside (**5**). Additionally, strong evidence suggested that peonidin-3,7-β-*O*-diglucoside (**4**) was another of these anthocyanins, whereas cyanidin-3,7-β-*O*-diglucoside (**2**) could be tentatively identified as the fifth anthocyanin completing the series of anthocyanidin 3,7-diglucosides of calafate, as found for other anthocyanin series of this berry, such as those of 3-glucosides and 3-rutinosides. Calafate also accounts for a high content of hydroxycinnamic acid derivatives with caffeoyl-hexaric acid isomers being important compounds. After isolation, two of these compounds were classified as 3- and 4-*trans*-caffeoyl-glucaric acids (**6** and **7**), although it was not possible to determine the linkage position for each isomer. A third isomer was also isolated, but it easily degraded; it is thought to be the 2- or 5-*trans*-caffeoyl-glucaric (**8**) acid, and more research needs to be developed to confirm this tentative determination.

[a] t_R, retention time. [b] M^+ (m/z) anthocyanins were obtained in the positive ion mode, other phenolics in the negative ion mode.

seasonal period of harvest, cultivar (early ripening cultivars were less affected by processing), and duration of long-term frozen storage (1 year). Late-ripening cultivars were characterized by a significant decrease in total anthocyanin content and particularly cyanidin 3-glucoside, which was most easily degraded during processing and the storage period.

In the available literature the impact of processing and storage on blackberry fruit metabolites (with emphasis on anthocyanins) was mostly studied on juice, puree, and canned fruit. Studies on freezing and frozen storage of fresh fruit are rare and limited to only a few compounds or total content levels of phenolic groups. Therefore, to increase the understanding of what is happening with nutraceuticals during prolonged storage in frozen blackberry fruit, more comprehensive studies are required. The objective of this study was to investigate the effect of slow and fast freezing of blackberry fruits followed by frozen storage of the fruit for 7 months on the composition of individual anthocyanins and other phenolics as well as sugars and organic acids in six blackberry cultivars.

MATERIALS AND METHODS

Plant Material and Juice Color and pH Analyses. Fully ripe blackberry fruits of 'Black Satin', 'Chester Thornless', 'Cacanska Bestrna', 'Thornless Evergreen', 'Loch Ness', and 'Thornfree' cultivars were harvested in the orchard of the Agricultural Institute (central Slovenia; latitude, 46°10′ N; longitude, 14°41′ E) from July 27 until August 6. After harvest, the blackberry fruits were immediately transferred into the laboratory on ice. The berries were randomly divided into three treatments: 1, harvest treatment, fresh fruits were immediately analyzed; 2, liquid N treatment, fruits were shock frozen in liquid nitrogen for 5 min and then stored in a deep freezer at −20

dx.doi.org/10.1021/jf405143w | J. Agric. Food Chem. 2014, 62, 6926−6935

°C; and 3, −20 treatment, fruits were stored in the freezer at −20 °C with no pretreatment of liquid nitrogen (slow freezing). Fruits were kept in the freezer for 7 months and immediately analyzed afterward. For each treatment six repetitions were performed, each repetition containing 100 g of blackberry fruit.

The fruits were crushed with a pestle and mortar, and the extracted blackberry juice was used for pH measurements (S20 SevenEasy pH meter, Mettler Toledo, Columbus, OH, USA) and spectrophotometric determination (Perkin-Elmer, UV−vis Lambda Bio 20 spectrophotometer, Waltham, MA, USA) of chromatic parameters. The chromatic parameters used to describe the color of blackberry juice were measured as color intensity (CI) and tonality (To) according to the method of Fragoso et al.[16] Color intensity represents the total amount of color and was calculated as the sum of the absorbances at 420, 520, and 620 nm measured in a 10 mm optical path quartz cuvette. Tonality indicates the relationship of the yellow-orange pigments (420 nm) over the red ones (520 nm):

$$\mathrm{CI} = A_{420} + A_{520} + A_{620}$$

$$\mathrm{To} = A_{420}/A_{520}$$

$$\%\ \mathrm{yellow} = (A_{420}/\mathrm{CI}) \times 100$$

$$\%\ \mathrm{red} = (A_{520}/\mathrm{CI}) \times 100$$

$$\%\ \mathrm{blue} = (A_{620}/\mathrm{CI}) \times 100$$

Extraction and Analysis of Individual Phenolics. Extraction was carried out as described by Mikulic-Petkovsek et al.[17] Fresh berries were ground to a fine paste in a mortar chilled with liquid nitrogen, and 5 g was extracted with 10 mL of methanol containing 3% (v/v) formic acid and 1% (w/v) 2,6-di-*tert*-butyl-4-methylphenol (BHT) in a cooled ultrasonic bath for 1 h. BHT was added to the samples to prevent oxidation during the extraction and formic acid for anthocyanin stabilization to the extraction solution. After extraction, samples were centrifuged at 12800*g* for 5 min at 4 °C, and the supernatants were filtered through Chromafil A0-20/25 polyamide filters (Macherey-Nagel, Düren, Germany). Frozen berries were extracted according to the same procedure as fresh blackberries. When taken out of the freezer, the frozen berries were left at room temperature for 20 min to thaw prior to extraction.

The HPLC analysis was performed on a Surveyor HPLC system with a PDA detector (Thermo Finnigan, San Jose, CA, USA). The column was a Gemini C18 (150 × 4.6 mm, 3 μm; Phenomenex, Torrance, CA, USA) operated at 25 °C. The elution solvents were aqueous 0.1% formic acid in double-distilled water (A) and 0.1% formic acid in acetonitrile (B). Samples were eluted using a linear gradient from 5 to 20% B in the first 15 min, followed by a linear gradient from 20 to 30% B for 5 min, then an isocratic mixture for 5 min, followed by a linear gradient from 30 to 90% B for 5 min, and then an isocratic mixture for 15 min before returning to the initial conditions[18] with some modifications, with an injection amount of 20 μL and a flow rate of 0.6 mL min^{-1}. Anthocyanins were detected and quantified at 530 nm, hydroxycinnamic acids at 310 nm, flavanols at 280 nm, and flavonols and ellagic acid derivatives 350 nm.

Phenolic compounds were identified on a Thermo Electron LCQ Deca XP MAX (Thermo Finnigan) mass spectrometer with electrospray ionization (ESI) operating in a positive (anthocyanins) or negative (all the other phenolics) ionization mode. Analyses were carried out using full scan, data-dependent MS^n scanning from m/z 100 to 1000. The MS data are presented in Table 1. The capillary temperature was 250 °C, the sheath gas and auxiliary gas were 60 and 15 units, respectively, and the source voltage was 3 kV for negative and 4 kV for positive ionization. The identification of compounds was confirmed by comparing retention times and their spectra as well as by adding the standard solution to the sample and by fragmentation and comparison to literature data. The concentrations of phenolics were calculated from peak areas of samples and corresponding standards. Concentrations were expressed in milligrams per kilogram FW (fresh weight). For compounds lacking standards, quantification was carried out using similar compounds as standards.

Sugar and Organic Acid Extraction and Analysis. Five grams of blackberry fruits was homogenized in 25 mL of double-distilled water using an Ultra-Turrax T-25 (Ika-Labortechnik, Staufen, Germany) and left for 30 min at room temperature as reported by Mikulic-Petkovsek et al.[17] The extracts for evaluation of vitamin C content were stabilized at low pH level with 3% metaphosphoric acid. After the extraction, the homogenate was centrifuged at 12800*g* for 7 min at 10 °C. The supernatant was filtered through a 0.20 μm cellulose ester filter (Macherey-Nagel) and transferred into a vial, and 20 μL of the sample was used for the analysis. The analysis of primary metabolites was carried out using a Surveyor HPLC system with a refractive index (RI) detector (Thermo Finnigan). The separation of sugars was carried out using a Rezex RCM-monosaccharide column from Phenomenex operated at 65 °C. The mobile phase was double-distilled water, and the flow rate was 0.6 mL/min; the run time was 30 min. Organic acids were analyzed with the same HPLC system, equipped with a UV detector set at 210 and 245 nm for ascorbic acid, using a Rezex ROA column from Phenomenex, as described by Mikulic-Petkovsek et al.[17] The column temperature was set at 65 °C. The elution solvent was 4 mM sulfuric acid at a flow rate of 0.6 mL min^{-1}. The duration of the analysis was 30 min. The concentration of an individual metabolite was calculated according to a calibration curve of corresponding standard solutions. The concentrations of sugars and organic acids were expressed as grams per kilogram or milligrams per kilogram FW.

Chemicals. The following standards were used for the determination of sugars and organic acids: sucrose, fructose, and glucose; ascorbic, citric, malic, and fumaric acid from Fluka Chemie (Buchs, Switzerland); tartaric and shikimic acid from Sigma-Aldrich Chemie GmbH (Steinheim, Germany). The following standards were used for the quantification of phenolic compounds: 3-caffeoylquinic acid, ellagic acid, rutin (quercetin-3-*O*-rutinoside), and pelargonidin-3-glucoside from Sigma-Aldrich Chemie GmbH; (−)-epicatechin, quercetin-3-galactoside, quercetin-3-glucoside, *p*-coumaric acid, procyanidin B1, cyanidin-3-galactoside, and kaempferol-3-glucoside from Fluka Chemie GmbH; quercetin-3-*O*-arabinofuranoside and quercetin-3-*O*-xyloside from Apin Chemicals (Abingdon, UK); isorhamnetin-3-*O*-glucoside from Extrasynthese (Genay Cedex, France); and (+)-catechin from Roth (Karlsruhe, Germany). Methanol for extraction of phenolics was acquired from Sigma. The chemicals for the mobile phases were HPLC-MS grade acetonitrile and formic acid from Fluka Chemie GmbH. Water for the mobile phase was twice distilled and purified with the Milli-Q system (Millipore, Bedford, MA, USA).

Statistical Analysis. The data were analyzed with the Statgraphics Plus 4.0 program (Manugistics Inc., Rockville, MD, USA) using two-way analysis of variance (ANOVA). Factorial analysis described the differences among treatments and cultivars and, additionally, their interaction. The differences between cultivars and cultivar × treatment interaction were tested using the Duncan test at a 0.05 significance level, whereas differences between treatments were tested using the LSD test at a 0.05 significance level. Means and standard errors of the parameters were calculated from six replicates ($n = 6$).

RESULTS AND DISCUSSION

Blackberry quality parameters and metabolic composition were evaluated and quantified at harvest and after 7 months of frozen storage at −20 °C. The storage treatments differed in the initial freezing of the berries; these were either shock frozen with liquid nitrogen or transferred to the freezer where the fruits were slowly frozen.

pH Value and Color Parameters. The average pH value of fruit juice at harvest was 3.01 and increased after 7 months of frozen storage to average values of 3.1 and 3.14 in liquid N pretreated fruit and slow freezing treatments, respectively (Table 2). The cultivars with the highest pH value were 'Thornfree' and 'Cacanska Bestrna' with pH 3.2. On the other

hand, the pH value of the juice extracted from fresh fruit of 'Loch Ness' cultivar was only 2.9. Blackberries are characterized by low pH values of the juice extracted from fresh fruit, and Wu et al.[10] measured pH values of two blackberry cultivars in the ranges of 3.2 and 4.3. Refrigerated storage at 2 °C caused an increase of fruit pH value, which could be associated with a lower content of titratable acidity. In their study during long-term frozen storage, the pH value remained rather constant.

Attractive color is one of the main visual features of fruit and berry products,[19] and blackberries are well-known for their intense dark color. Color intensity represents the total amount of color, and color composition indicates the contribution of blue, red, and yellow color to the overall color appearance (Table 2). Color intensity of blackberry fruit increased from harvest until the end of frozen storage in both freezing treatments. Similarly, frozen storage also altered the composition of red, yellow, and blue hues. The percent of red color decreased and the percent of yellow and blue hues increased during storage. It is well-known that anthocyanin properties (including their effect on color) are highly influenced by anthocyanin structure and the pH[20] value of cell sap. Therefore, the changes in monitored color parameters after 7 months of frozen storage could partly be explained with higher pH values of the juice of most analyzed cultivars. Anthocyanins are extremely pH sensitive, which results in different color expression depending on various pH values. Lower pH values stabilize their structure and lead to a darker appearance of the fruit. However, isolated anthocyanins and color hues remain quite stable during frozen storage if kept in low-pH solvents (pH values between 1.1 and 3). Higher pH values caused a shift to orange hues after frozen storage.[20] A similar trend has been detected for the tonality parameter, which indicates the relationship between yellow orange and red pigments and increased from harvest until the end of storage in both treatments.

Sugars, Organic Acids, and Vitamin C. The composition and the amounts of sugars and organic acids as well as their relationship are a crucial quality index for blackberries,[1] determining their taste.

The principal sugars in blackberry fruits were glucose, fructose, and sucrose. Their content levels and proportions varied among cultivars, which is in accordance with previous results.[1,21] Generally, freezing conditions and long-term frozen storage resulted in better extraction of individual and total

sugars (Table 3). This could be due to cell wall degradation as well as disruption of different membranes during freezing, resulting in better extraction.[22] Similar results were recorded for blueberry in a study by Wu et al.,[10] where total soluble solids remained stable or even increased by 20% in specific cultivars during 6 months of frozen storage. Cultivar-specific response was also determined in our experiment. As shown by Kopjar et al.,[13] specific sugars such as glucose can have a positive effect on anthocyanin content in blackberry juice by preventing their degradation during storage.

The main organic acids detected in blackberry fruit were citric, malic, and tartaric acid. Citric and malic acids were the predominant organic acids,[1,23] depending on the cultivar analyzed. Several minor organic acids were identified in blackberry fruit such as fumaric and shikimic acid; however, their contribution to total organic acid content is not significant. Similar to total sugars, higher extraction of total organic acids was achieved after frozen storage compared to harvest treatment (Table 3). Wu et al.,[10] on the other hand, report stable or decreased levels in titratable acidity depending on analyzed cultivar after 6 months of frozen storage. Despite better extraction of total analyzed sugars and organic acids after frozen storage, their relationship remained constant and did not change among treatments. Consequently, blackberry fruits preserve their characteristic sour-sweet taste even after long-term frozen storage regardless of the initial freezing method or conditions. The relationship between sugars and organic acids was highest in the fruit of cultivar 'Thornless Evergreen'.

Another important organic acid, not counted in total organic acid content levels, is ascorbic acid (vitamin C). As expected, vitamin C content decreased during storage in both frozen treatments (Table 3). This has previously been determined for raspberry, blackberry, and blueberry fruits after long-term storage.[22,24] The reduction of vitamin C in our experiment was more pronounced in fast-frozen fruits compared to fruit subjected to slow freezing. The cultivars with low amounts of vitamin C at harvest such as 'Loch Ness' and 'Thornfree' lost about 50% or less during frozen storage. On the other hand, cultivars with initially higher content of vitamin C were characterized by an even higher loss (up to 80%).

Phenolics. Derivatives of hydroxycinnamic acids were not present in high amounts in blackberries (Table 4). Only two

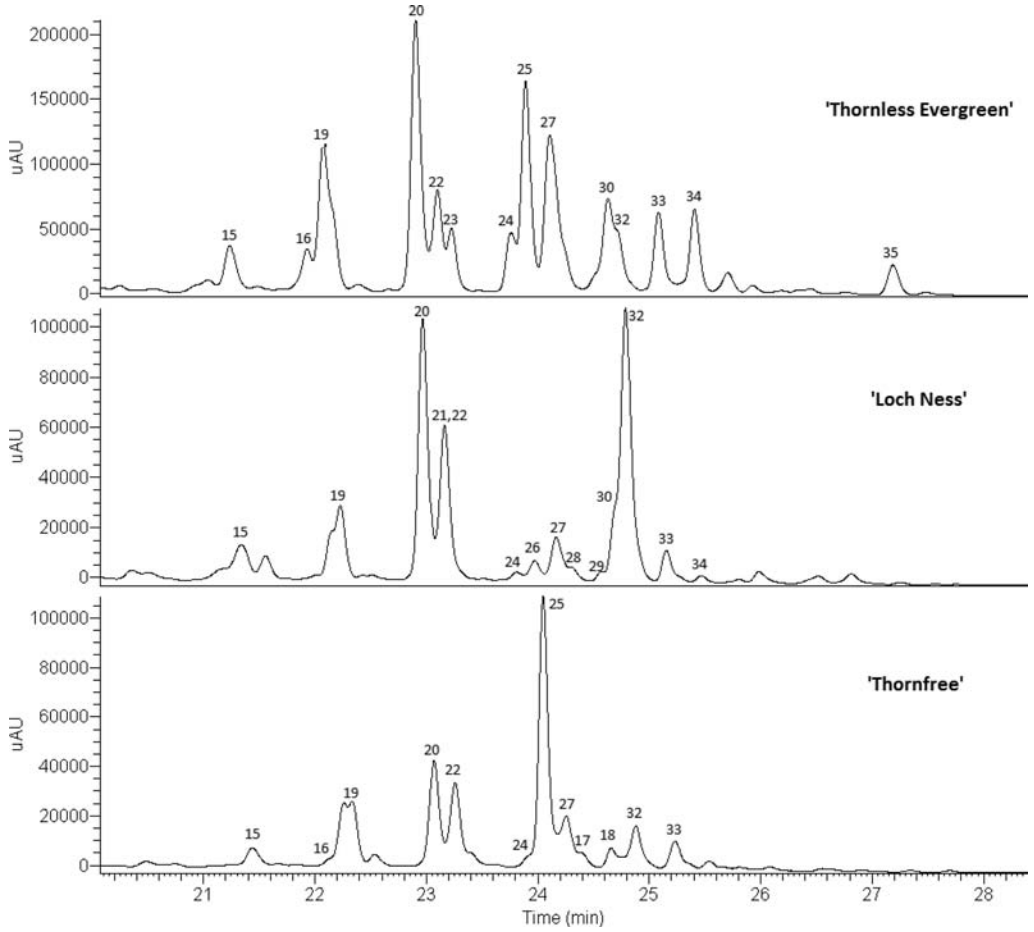

Figure 1. Flavonol profile of fresh blackberry fruit of 'Thornless Evergreen', 'Loch Ness', and 'Thornfree' cultivars. Peak numbers correspond to the compounds listed in Table 1

hydroxycinnamic acids were confirmed by MS analysis, namely, neochlorogenic acid in all cultivars and *p*-coumaric acid hexoside (not detected in 'Loch Ness' and 'Thornless Evergreen' cultivars). The 'Thornless Evergreen' cultivar contained the highest levels of neochlorogenic acid among the analyzed cultivars. Fast freezing followed by frozen storage did not affect the content of hydroxycinnamic acids in blackberry fruit; meanwhile, slow freezing resulted in higher extraction of this phenolic group compared to the harvest treatment. As shown by the study of Kopjar et al.,[13] hydroxycinnamic acids can be efficiently used as copigments stabilizing anthocyanins during storage of blackberry juice and preventing their degradation. This has also been described by Howard et al.,[8] who determined that anthocyanin acylation with cinnamic and organic acids greatly improves their stability and also the color of plant tissue and juice.

A great variety of flavonol glycosides has been determined in blackberry fruit. Three aglycones prevailed, namely, quercetin, kaempferol, and isorhamnetin, and details on their spectra and MS^n data of individual flavonol compounds are presented in Table 1. Quercetin glycosides were most abundant in fresh and frozen blackberry fruits as previously described by Mikulic Petkovsek et al.[3] Similar to the group of hydroxycinnamic acids, the extraction of flavonols was increased after long-term frozen storage, especially when slow freezing was applied levels Similarly, Türkben et al.[14] also measured higher levels of quercetin glycosides after long-term storage of the 'Chester Thornless' cultivar, whereas an opposite effect has been recorded in other blackberry cultivars analyzed. As mentioned previously, a better extraction of flavonols could be related to tissue damage by freezing, especially in the slow-freezing conditions. The effect of freezing damage can best be observed at thawing when a loss of turgor due to damaged cell walls and cell membranes results in permanent transfer of intracellular sap to the extracellular fluid, which cannot be reversed after thawing.[11] This can potentially be linked with a better extraction of various compounds compared to the harvest treatment when the cells are still intact. However, no significant differences have been recorded among treatments in 'Loch Ness' and 'Thornless Evergreen' cultivars. The latter was characterized by the highest content of total flavonols and a great abundance of individual flavonols compared to other cultivars analyzed (Figure 1).

Flavanols were the only group of phenolics that did not express any differences in the extracted amounts among different treatments (Table 4). Again, the highest total flavanol content was measured in 'Thornless Evergreen' and 'Loch Ness' cultivars. In fruit of both cultivars quantifiable amounts of catechin have be detected as opposed to other analyzed blackberry cultivars in which only epicatechin and different procyanidin units have been identified. Together with ellagic acid derivatives, flavanols present the tannin pool of blackberry fruits and, interestingly, cultivars with high flavanol content also contained high levels of ellagic acid derivatives (Table 4). The only exception was the 'Loch Ness' cultivar characterized by moderately high levels of flavanols and low contents of ellagic

acid derivatives. Most of these derivatives were better extracted after slow freezing and frozen storage. On the other hand, fast freezing and long-term frozen storage did not exhibit a similar effect. Considering that ellagic acid is a phenolic compound strongly linked to the cell walls,[14,25] damage due to slow freezing could result in better extraction of this specific compound. Blackberry ellagitannins were also reportedly stable during different processing procedures.[8] Contrary to our results, de Ancos et al.[25] reported a 14−21% decrease of extracted ellagic acid after acid hydrolysis in raspberry fruits stored for 12 months. The authors associated this with higher polyphenol oxidase activity linked to the cell wall.

In blackberries, the following anthocyanins yielding the aglycone cyanidin with glycosylation on the 3-position of the C ring have been identified: cyanidin 3-galactoside, cyanidin 3-glucoside, cyanidin 3-arabinoside, cyanidin 3-xyloside, cyanidin 3-(6″-malonylglucoside), and cyanidin 3-(6″-dioxalylglucoside). Additionally, an anthocyanin yielding pelargonidin aglycone and glucose has been confirmed with MS^n analysis in all cultivars, but the amount was rather small (Table 5). All of the quantified anthocyanins have previously been reported in fruita of different blackberry cultivars.[1] 'Loch Ness' and 'Thornless Evergreen' cultivars were the only cultivars in which cyanidin 3-rutinoside has been detected in small amounts, although this anthocyanin is reported as the major anthocyanin of Andean blackberry (*Rubus glaucus*) wines.[26] An additional minor anthocyanin, namely, cyanidin 3-arabinoside, could not be determined in 'Cacanska Bestrna' and 'Chester Thornless' cultivars. Cyanidin 3-glucoside was the prevalent anthocyanin in all analyzed cultivars, ranging from 74.3% of total analyzed blackberry anthocyanins in fruit of the 'Black Satin' cultivar to 92.3% in the 'Loch Ness' cultivar. Cyanidin 3-glucoside was most susceptible to degradation reactions occurring during processing and frozen storage of raspberries.[15] On the contrary, in our study cyanidin 3-glucoside remained relatively stable during blackberry long-term frozen storage or even increased if slow freezing was applied. An example is shown in Figure 2 for cultivar 'Thornfree'.

The amounts of total analyzed anthocyanins differed significantly among analyzed blackberry cultivars; 'Loch Ness' contained the highest and 'Thornless Evergreen' the lowest total anthocyanins levels (Table 4). In combination with a low juice pH value and high anthocyanin content, the juice of the 'Loch Ness' cultivar was characterized by the highest color intensity. Fast freezing with liquid nitrogen and long-term frozen storage did not influence the composition of anthocyanins. All compounds identified in berries at harvest were also present after 7 months of frozen storage. The slow-freezing treatment resulted in higher content of anthocyanins probably due to a better extraction of phenolics compared to the harvest treatment. Conversely, fast freezing did not exhibit an important influence on anthocyanin content. Poiana et al.[22] spectophotometrically analyzed total anthocyanin levels in blueberries and raspberries and reported decreases of 9% after 10 months and 3% after 6 months of storage compared to fresh fruit content. Similarly, Hager et al.[9] determined that quick freezing and frozen storage of intact blackberry fruits did not result in a loss of total analyzed anthocyanins or their polymerization. A cultivar-specific constant or moderately increased content of spectrophotometrically quantified total anthocyanins has been reported in a study of Wu et al.[10] after 6 months of blackberry storage. This is in accordance with our results suggesting that blackberry anthocyanins are protected from degradation when frozen and can be frozen-stored up to no less than 7 months. Ioannou et al.[27] determined that the flavonoid environment is important for understanding flavonoid behavior during food processing and storage. Positive or negative synergies can occur between flavonoids and other compounds in the food matrix, and therefore predictions are difficult to make.

The present study indicates that deep freezing (either fast or slow) is an appropriate way of preserving plant metabolites in blackberry fruits for at least 7 months of frozen storage. The fruit content of most compounds (such as individual anthocyanins) remained constant or even increased due to ice crystal damage of cell structures and better extraction, especially when slow freezing has been applied. The treatment is similar to the conditions consumers generate at home when deep freezing the fruit. However, a loss of vitamin C cannot be prevented during storage, and a fast use of thawed fruits is

necessary. Cultivar-specific composition and content of metabolites have also been demonstrated in the present study and may present an important factor in the choice of healthy fruit. Additional research should be conducted to predict ideal harvest maturity because high anthocyanin content levels cause the fruits to turn black before they are optimally ripe, and long-term experience is needed to select an appropriate picking time, especially because the fruits ripen subsequently.

For further research it is essential to know the composition of fresh fruit and the effect of deep freezing as one of the easiest methods for storing blackberries for off-season use. Therefore, our results can be useful for further studies on food processing and human metabolomic research.

MATERIALS AND METHODS

Chemicals and Reagents. Ascorbic acid, dehydroascorbic acid, and cetrimide (cetyltrimethylammonium bromide) were purchased from Sigma-Aldrich (Steinheim, Germany); formic acid, methanol, potassium dihydrogen phosphate, and sodium benzoate, all of analytical grade, were from Panreac Química S.A. (Barcelona, Spain). 1,2-Phenylenediamine dihydrochloride (OPDA) was from Fluka Chemika (Neu-Ulm, Germany). Cyanidin 3-glucoside was from Polyphenols (Sandnes, Norway). Milli-Q water used was produced using an Elix3Millipore water purification system coupled to a Milli-Q module (model Adventage10) (Molsheim, France).

Experimental Design. Pomegranate fruits from cv. Mollar de Elche (M) and cv. Wonderful (W), harvested in the Alicante region (southeastern Spain), were provided by "Cambayas Coop. V." (Elche, Alicante, Spain). Pomegranates were cut in halves, and the juices of each cultivar were obtained by pressure with a laboratory pilot press (Zumonat C-40; Somatic AMD, Valencia, Spain).[11,14]

Pomegranate varietal juices were mixed in different proportions: 75% M + 25% W, 50% M + 50% W, and 25% M + 75% W, keeping also two control juices of 100% 'Mollar de Elche' (100% M) and 100% 'Wonderful' (100% W), respectively. Homogenized blended and pure juices were centrifuged (3 min at 2754*g*), and sodium benzoate (200 mg/L) was added to prevent spoilage.[12] Juices were placed in screw-capped vials (10 mL) and stored in the dark at both 5 and 25 °C for 70 days. Triplicate solutions were prepared for each juice, and the mean values were reported in each case. Analyses were carried out at days 0, 6, 13, 20, 28, 42, 56, and 70.

Quality Parameters of Juices. pH, titratable acidity (TA), and total soluble solids (TSS) were evaluated as quality indices.[18] The pH values were measured using a pH-meter (GLP 21, Crison Ltd., Barcelona, Spain). The TA was determined by titrating 2 mL of juice (raised to a 20 mL final volume with Milli-Q water) with 0.1 N NaOH (pH 8.1). Results were expressed as grams of anhydrous citric acid per 100 mL. TSS contents were recorded in a hand refractometer (Atago N1, Atago, Tokyo, Japan) at 20 °C with values being expressed as °Brix. Measurements were repeated twice for each replicate. Ratio, also known as maturity index (MI), was calculated as the relationship between TSS and TA.

Identification and Quantification of Anthocyanins. The anthocyanin profile of pomegranate juices was assessed by liquid chromatography coupled to mass spectrophotometry (HPLC-ESI-MS^n), according to the method of Gironés-Vilaplana.[19] HPLC analyses for anthocyanin quantification were performed on a Merck-Hitachi liquid chromatograph (Tokyo, Japan), equipped with a diode array detector UV−vis L-7455, an autosampler L-7200, a pump L-7100, and an interface D-7000. Chromatograms were recorded and processed on a Merck-Hitachi D-7000 HSM PC-based chromatography data system. A 20 μL sample was analyzed on a Luna C_{18} column (25 cm × 0.46 cm, 5 μm particle size; Phenomenex, Macclesfield, UK) with a security guard C18-ODS (4.0 × 3.0 mm) cartridge system (Phenomenex), using a mobile phase of water/formic acid (95:5, v/v) (solvent A) and HPLC grade methanol (solvent B). Elution was performed at a flow rate of 1 mL/min. The linear gradient started with 1% B, remaining at isocratic conditions during 5 min, reaching 20% B at 20 min, 40% B at 30 min, 95% B at 35 min, and 1% B after 41 min. UV chromatograms were recorded at 520 nm. Anthocyanins were quantified by the absorbance of their corresponding peaks as cyanidin 3-glucoside.

Prior to injection, samples were centrifuged during 5 min at 10480*g* (model EBA 21, Hettich Zentrifugen, Tuttlingen, Germany) at room temperature. The supernatant was filtered through a 0.45 μm nylon membrane (Simplepure; Membrane Solutions, Plano, TX, USA) before HPLC analysis.

Extraction and Analysis of Vitamin C. Ascorbic acid (AA) and dehydroascorbic acid (DHAA) contents were determined by HPLC-UV as described elsewhere and fully detailed in González-Molina et al.[20] The vitamin C content was calculated by the addition of ascorbic acid and dehydroascorbic acid contents, and results were expressed as milligrams per 100 mL.

Color Measurement. Color measurement was determined as in Pérez-Vicente et al.[11] Samples were measured in glass cells of 2 mm path length (CT-A22) at 520 nm using a Minolta CM-508i tristimulus color spectrophotometer (Osaka, Japan) coupled with a CM-A760 transmittance adaptor, illuminant D65, and 10° observer according to the CIELAB 76 convention. Data (CIE L^*, CIE a^*, CIE b^*, chroma, and hue angle) were processed using the Minolta Software Chromacontrol S, PC-based colorimetric data system.

Statistical Analyses and Kinetics of Phytochemical Degradation. Analysis of variance (ANOVA) and multiple-range tests (Scheffé's test) were carried out using the IBM SPSS Statistics 19 software package (SPSS Inc., Chicago, IL, USA). Pearson correlation analyses were also performed.

The degradation kinetics of most phytochemicals follows the first-order eq 1 reaction[21,22]

$$C_t = C_0 \exp(\pm kt) \quad (1)$$

where C_t and C_0 are the concentration of bioactive compounds (anthocyanins and vitamin C) (mg/100 mL) at time t and t_0, respectively, k is the rate constant, and t is the storage time (days). Moreover, the half-life value ($t_{1/2}$) was calculated as $t_{1/2} = ((\ln 2)/k)$. D value (time required for 90% degradation of bioactive) was also calculated as $D = (1/k)$.

RESULTS AND DISCUSSION

Quality Parameters of Juices. No significant differences ($p > 0.05$) in the quality parameters (pH, TSS, TA, and MI) assayed during storage were noted and, hence, results are presented as mean values for all of the experiments (Table 1).

Table 1. Quality Parameters of Pure and Blended Varietal Pomegranate Juices through the Storage Period

juice	pH	TSS[a]	TA[b]	MI[c]
100% M	3.58 a[d]	16.75 e	0.27 e	63.2 a
75% M + 25% W	3.11 b	17.10 d	0.64 d	26.9 b
50% M + 50% W	2.92 c	17.50 c	1.09 c	16.1 c
25% M + 75% W	2.81d	17.85 b	1.39 b	12.9 cd
100% W	2.76 e	18.20 a	1.78 a	10.3 d
LSD[e]	0.01***	0.04***	0.01***	0.86***

[a]TSS, total soluble solids. [b]TA, titratable acidity (g citric acid/100 mL). [c]MI, maturity index (TSS/TA). Statistical treatment notes. [d]Means (n = 3) within a column followed by different letters are significantly different at $P < 0.05$ according to the Scheffé multiple range test. [e]LSD, least significant difference. Significant at (*) $P < 0.05$, (**) $P < 0.01$, and (***) $P < 0.001$.

The pH values in the juices decreased with the percentage of 'Wonderful' juice added, varying from ∼3.60 to ∼2.70 for 100% M and 100% W, respectively. TSS ranged between ∼16.7 for 100% M and ∼18.2 for 100% W, which cannot be considered an important difference despite its statistical significance. Otherwise, TA displayed severe differences among juices, oscillating between ∼0.30 and ∼1.80 g/100 mL for 100% M and 100% W, respectively. Acidity was augmented with increasing percentage of 'Wonderful' juice added in a dose−response effect, as expected. Consequently, the maturity index (MI), which is mainly influenced by TA for pomegranate juices,[14] was depleted as the 'Wonderful' juice proportion was increased in the blended juices.

The pomegranate cultivars chosen to develop the blended juices were widely distinct. 'Wonderful' is a worldwide variety rich in phytochemicals, with a deep red color, but too much acid. On the other hand, the Spanish 'Mollar de Elche' exhibits interesting organoleptical properties (high lightness and

elevated sweetness/sourness balance), although it is prone to suffer browning during processing and storage.[14] Both varietal juices might serve as complementary ones because the addition of 'Wonderful' to 'Mollar de Elche' juices could ameliorate the visual appearance of browning[10] as well as 'Mollar de Elche' addition to 'Wonderful' juices could improve their sensory properties by smoothing their high acidity. Moreover, a point worth mentioning is that pomegranate juices mixed at different percentages of each variety presented intermediate values of pH (Table 1). This fact turned these mixtures into valuable samples to study the degradation of anthocyanins at different pH conditions within a similar complex matrix, avoiding the oversimplification of common model systems.[23,24]

Evolution of Anthocyanins in Blended Varietal Pomegranate Juices. The anthocyanin profile of pomegranate juices was characterized by delphinidin, cyanidin, and pelargonidin 3-glucosides and 3,5-diglucosides (Table 2; Figures 1 and 2), in accordance with previous papers.[2,25] The amounts of these colored flavonoids were largely affected by the cultivar group, and total anthocyanin concentrations ranged from 23 to 171 mg/100 mL for 100% M and 100% W, respectively, in good agreement with those previously reported by Mena et al.[14] Varietal blends exhibited intermediate values according the proportion of varietal juices used, as expected. Major individual anthocyanins for all juices were cyanidin 3-glucoside, accounting for 31% of the total anthocyanin amount; delphinidin glycosides, both 3,5-diglucoside and 3-glucoside, 23% each one; and cyanidin 3,5-diglucoside, 20%. Pelargonidin glycosides accounted for only 3% of the total anthocyanins.

Table 2. Identification of Anthocyanins in Pomegranate Juice by HPLC-ESI-MS^n (Positive Mode)

ID	compound	RT (min)	$[M]^+$ (m/z)	MS^2 ion fragments (m/z)[a]	MS^3 ion fragments (m/z)
1	delphinidin 3,5-diglucoside	25.1	627	**465**,[b] 303	303
2	cyanidin 3,5-diglucoside	26.6	611	**449**, 287	287

Figure 1. Chemical structures of the anthocyanins found in pomegranate juices. Glc, glucose.

The loss of anthocyanins during storage (Figure 3) fitted well to exponential curves for the two selected temperatures (Table 3). These results indicated that pigment degradation at isothermal conditions followed first-order reaction kinetics, as usually reported for red juices.[4,10,21,22] The rate constant (k) increased at higher storage temperature, pointing out the notable influence of temperature on accelerated anthocyanin degradation.[8,22] Half-life values ($t_{1/2}$) ranged from 98 to 374 days at 5 °C and between 28 and 87 for 25 °C. D values pointing out the time required for the degradation of 90% of anthocyanins ranged between 141 and 539 days for juices stored at 5 °C and between 40 and 125 days at 25 °C. These differences of pigment shelf life between storage temperatures showed the role of the storage conditions in the preservation of the phytochemical composition of pomegranate juices. A point worth mentioning is that the shelf life values herein reported were considerably higher than those reported for thermally pasteurized pomegranate juices.[8−10] This fact emphasizes the need for developing novel approaches avoiding thermal treatments and limiting microbial load at fresh juice to preserve as much as possible the anthocyanin content of commercial pomegranate juices.

Kinetic parameters (Table 3) revealed a significant cultivar effect on the evolution of anthocyanins during storage at both 5 and 25 °C. The rate constant was clearly higher as the proportion of ;Mollar de Elche; juice was increased, the highest rate constants being recorded for 100% M. One hundred percent W juice registered rate constants 3.7- and 3.1-fold lower than those found for 100% M at 5 and 25 °C, respectively.

The blended juices used in the present work could be regarded as suitable samples to shed light on the factors behind the so-called cultivar effect. They displayed intermediate k values proving that drops in anthocyanins were diminished in the mixtures proportionally to the percentage of 'Wonderful' juice added (Table 3). Then, the blend containing merely 25% of 'Wonderful' juice (75% M + 25% W) could not only increase the anthocyanin content of 'Mollar de Elche'-based pomegranate juices but also preserve to a great extent the pigment composition through storage. In this sense, data herein obtained have shown that the higher pigment concentration, the lower degradation rate (Table 3). This phenomenon linking superior preservation to high anthocyanin concentrations could be attributed mainly to the formation of self-association complexes of copigmentation (the aggregation of different anthocyanin monomers in relatively concentrated matrixes).[26] Similarly, other complexes, adducts between flavan-3-ols and anthocyanins, have been found in fresh pomegranate juices.[27]

Another explanation behind the cultivar effect observed and the higher preservation of anthocyanins in those juices containing a higher percentage of 'Wonderful' varietal juice could be related to the effect of pH. Actually, a higher stability of anthocyanins is linked to lower pH values.[6] Differences of pH recorded for 50% M + 50% W, 25% M + 75% W, and 100% W (between 2.92 and 2.76, Table 1) were not so dramatic as the differences observed for anthocyanin shelf life in these same juices (Table 3). However, the stability of anthocyanins could be severely compromised at this restricted pH range

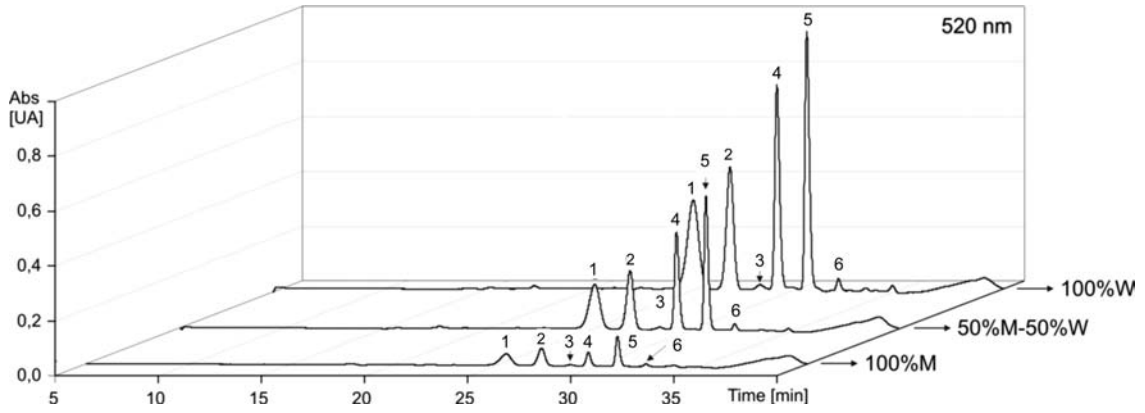

Figure 2. Chromatographic profile at 520 nm of anthocyanins registered in pomegranate juices. Peaks: (1) delphinidin 3,5-diglucoside; (2) cyanidin 3,5-diglucoside; (3) pelargonidin 3,5-diglucoside; (4) delphinidin 3-glucoside; (5) cyanidin 3-glucoside; (6) pelargonidin 3-glucoside.

considering how pH affects the equilibrium of anthocyanin structures (quinoidal base/flavylium cation) and pigment stability.[6] On the basis of these results, both pigment concentration and pH should be regarded as factors affecting anthocyanin stability and contributing to the cultivar effect. Finally, the superior content in citric acid of 'Wonderful' juice compared to 'Mollar de Elche'[14] may also contribute to the definition of the cultivar effect observed on anthocyanin stability.

Concerning structure stability, it could be pointed out that diglucosides were more stable than monoglucosides in those samples stored at 5 °C (5 and 24% of loss, respectively), as it is usually described attending to anthocyanin stability.[6,9,11,13,18] However, juices stored at 25 °C showed a different trend, and monoglucosides were revealed as the most stable anthocyanins (48% of loss for monoglucosides and 56% for diglucosides).

On the whole, decreases in the anthocyanin amounts could be explained attending to several processes taking part during storage: (1) polymerization reactions involving the condensa-

tion of anthocyanins with byproducts from the degradation of monosaccharides and organic acids, yielding furfurals and aldehyde compounds; (2) the occurrence of enzymes degrading anthocyanins; and (3) direct oxidation of anthocyanin with oxygen.[6,28,29]

Vitamin C Degradation and Its Relationship with Anthocyanins. Although pomegranate juice is not distinguished by possessing high vitamin C concentrations, it may play an important role in browning processes and anthocyanin degradation.[12]

Vitamin C was detected only in its oxidized form (dehydroascorbic acid). Its initial concentrations were 12.0 and 7.8 mg/100 mL for 100% M and 100% W, respectively. Vitamin C decreased following a first-order reaction kinetic at both selected temperatures through storage (Figure 4; Table 4). The rate constant (k) increased at higher storage temperature, the rate constant at 25 °C being up to 4-fold the rate constant recorded for the samples stored at 5 °C. This fact had a remarkable effect on the shelf life of vitamin C. Actually, whereas the half-life value ($t_{1/2}$) of juices stored at 5 °C ranged from 7 until 15 days, samples stored at 25 °C solely exhibited half-life values of 2.5 days. D values varied between 10 and 21 days for storage at 5 °C and were about 4 days at 25 °C. The degradation of vitamin C was not related to a certain cultivar pattern (Figure 4; Table 4).

The fast reduction in vitamin C content of pomegranate juices with added ascorbic acid has been attributed to pH and the presence of anthocyanins.[12] However, vitamin C has been preserved in juices combining lemon and pomegranate juices at different rates, where the influence of pH seemed to be negligible and, hence, this hypothesis should be ruled out.[18] On the other hand, whereas anthocyanins seem to play an essential role in vitamin C degradation,[7] decreases in vitamin C content were observed among all samples regardless of the kind of juice (Figure 4) and, thus, regardless of the anthocyanin content in the sample. Consequently, it is possible that endogenous vitamin C of pomegranate juices decreases without attending any contribution of external factors and due exclusively to its natural oxidative deterioration.

Color Parameters and the Role of Anthocyanins in Color Changes. Juice color varied significantly among varietal juices through storage (Figure 5). Lightness of pomegranate juices, represented as CIEL^* values, was in accordance with a previous study.[14] One hundred percent M showed the highest lightness, whereas 100% W displayed the lowest one. Significant differences were noted among varietal juices by the end of the storage period ($p < 0.001$) (Figure 5A,B). Whereas lightness of blended juices (75% M + 25% W, 50% M + 50% W, and 25% M + 75% W) and 100% W increased only slightly from day 42, a reduction was registered for 100% M for the first 42 days, prior to the final augment recorded (Figure 5A,B). General increases of lightness were in agreement with the trend followed by other unpasteurized pomegranate juices.[6,9,11,13,18]

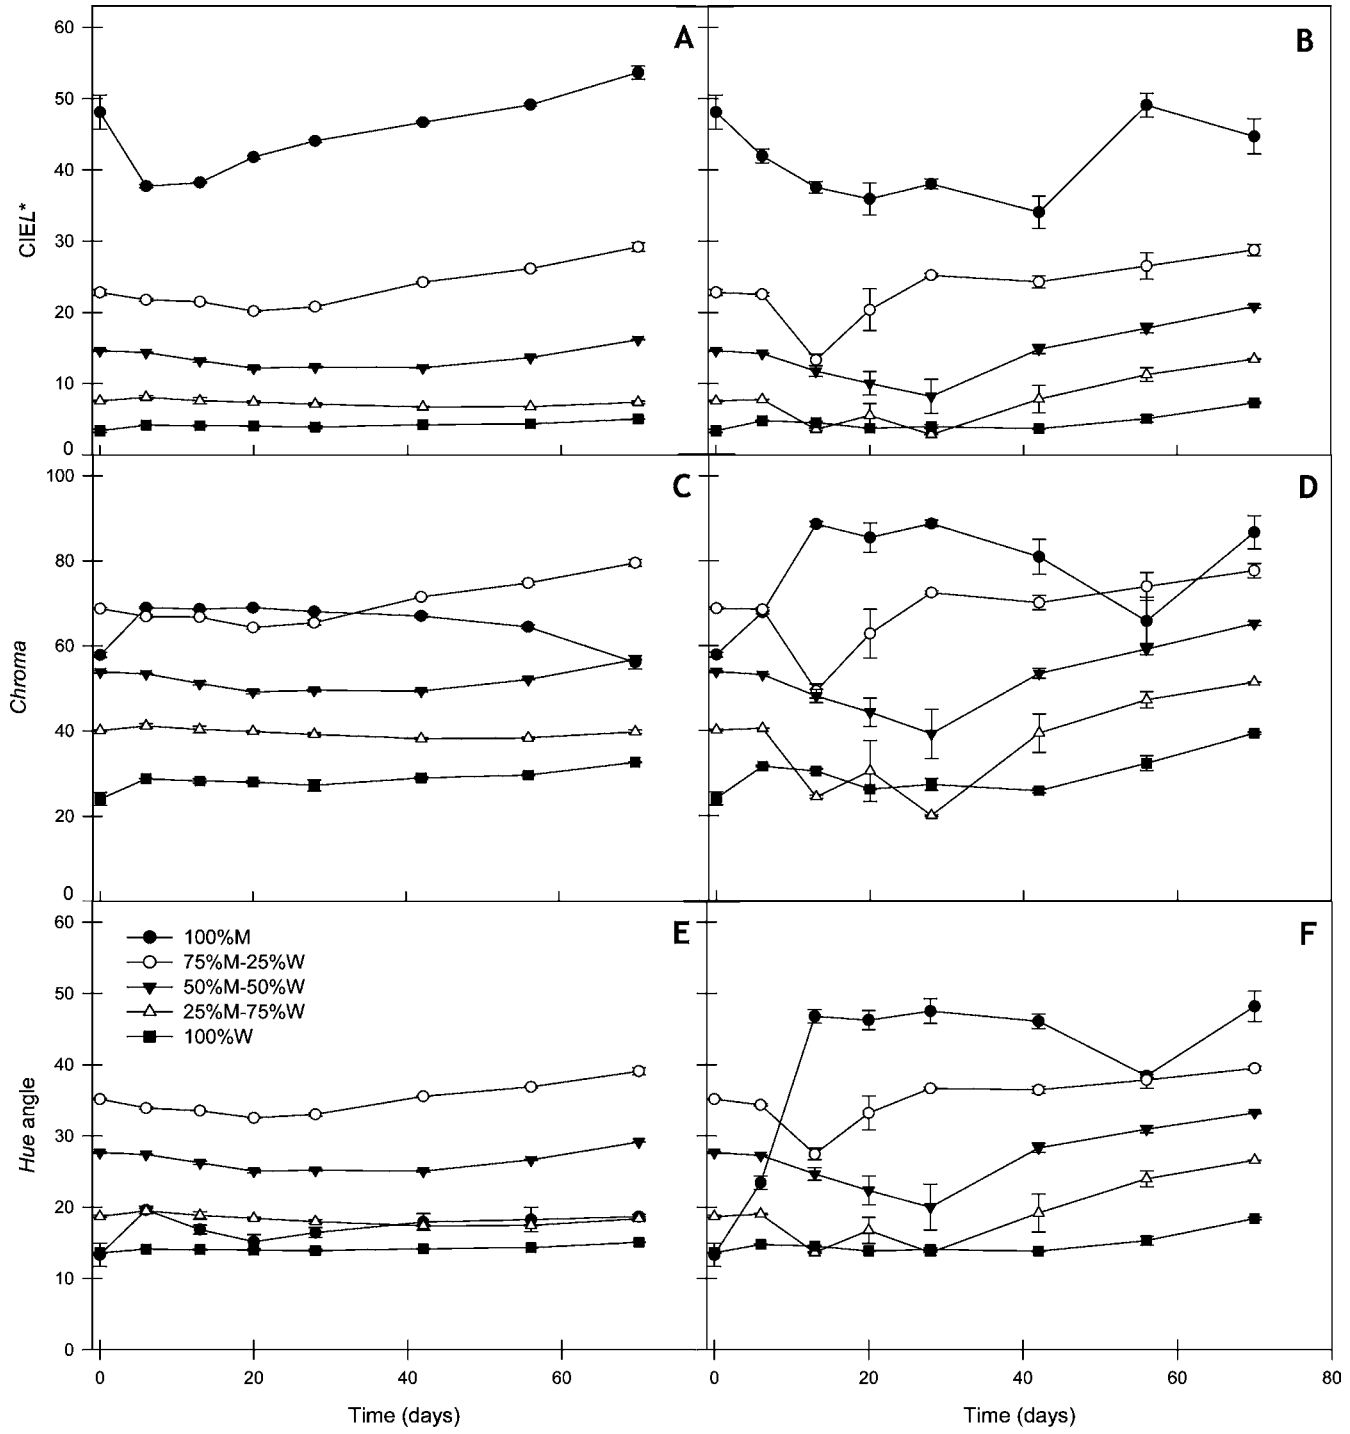

Figure 5. Evolution of color parameters in pure and blended varietal pomegranate juices through storage: CIE*L** in samples stored at (A) 5 °C and (B) 25 °C; chroma at (C) 5 °C and (D) 25 °C (D); hue angle at (E) 5 °C and (F) 25 °C. Error bars are presented as SEM.

Initial chroma values of blended juices were not the sum of their parts, and a different trend occurred among juices attending to their composition (Figure 5C,D). One hundred percent W and blended juices decreased and, then, increased during storage. On the contrary, 100% M was augmented and then decreased. These results stressed the significance of cultivar effect on the evolution of color intensity just as its influence on mixtures of different varietal juices. Similarly, a notable varietal effect was observed for hue angle (Figure 5E,F), especially in those samples stored at room temperature. Hue values of 100% W juice were preserved during storage at both temperatures, and they increased only slightly in blended juices. On the other hand, hue of 100% M juice was significantly increased during the first days, especially at 25 °C (Figure 5F), and then remained constant for the rest of the experiment. These color changes were consistent with the general increase of brownish hues reported for pomegranate juices.[9,11,12,18]

Changes oin CIE*L** and chroma values could be attributed to anthocyanins as a strong significant correlation was found among them ($r = -0.86$, $r = -0.89$, respectively; $p < 0.01$). However, anthocyanin degradation cannot fully account for the variations in hue angle values ($r = -0.66$; $p < 0.01$), so other

dx.doi.org/10.1021/jf405129q | J. Agric. Food Chem. 2014, 62, 6936−6943

compounds such as those formed as a consequence of browning processes (e.g., ascorbic acid degradation) or anthocyanin polymerization may contribute to hue variations.[8,12]

Color parameters as well as anthocyanin load in blended varietal pomegranate juices was mainly influenced by 'Wonderful' cultivar and not by 'Mollar de Elche'. In fact, despite the significant color variations in 100% M, a high stability of color parameters was observed in the blended juices, even for that juice containing merely 25% of 'Wonderful' juice (75% M + 25%W). This blend may also exhibit a great organoleptic potential as it preserves the genuine sensorial characteristics of the cultivar 'Mollar de Elche' (data not shown).[14] Consequently, blending different pomegranate juices could be regarded as an easy way to preserve juice color characteristics and pigment concentration of those varieties prone to color alterations such as 'Mollar de Elche'. These protective effects on the anthocyanin composition and color attributes of some of these blends could remain after realistic pasteurization treatments.[10] Therefore, the results herein presented may have direct implications for the pomegranate juice industry to solve browning problems during juice storage. Blending varietal pomegranate juices was useful not only to preserve the genuine characteristics of fresh juices but also to study different factors affecting anthocyanin stability while maintaining to the utmost the matrix studied. The role of anthocyanin concentration, pH, and the presence of ascorbic acid in pigment integrity was discussed, and it could contribute to the definition of cultivar effect in pomegranate juices. Finally, the present data could help to tackle anthocyanin degradation in other food matrices.

mercaptan.[12] In those conditions, interflavan linkages are disrupted and the flavanol units corresponding to extension and upper units of condensed tannins are liberated in the medium as flavanyl carbocations immediately converted into stable monomeric derivatives after trapping by the nucleophilic agent. At the same time, terminal flavanol units of condensed tannins are liberated as such in the reaction medium. Then, all of these reaction products can be easily separated and quantified by reversed phase HPLC.[13]

Apple flavonols are a series of quercetin (Q) glycosides namely: galactoside (hyperoside, generally the most concentrated), Q-3-*O*-glucoside (isoquercitrin), Q-3-*O*-rhamnoside (quercitrin), Q-3-*O*-rutinoside (rutin), Q-3-*O*-xyloside (reynoutrin), and Q-3-*O*-arabinoside (avicularin). Flavonols are yellow compounds mainly located in the peel of fruits and are poorly extractable. Therefore, juices and ciders are usually almost deprived of these components.[14] Among usually consumed fruits and fruit-derived foods, dihydrochalcones are the only group of flavonoids that can be considered specific for apples, although they can be present in low concentration in other species. One well-known compound of this class, namely, phloridzin (phloretin-2-glucoside), is present in apple tissues and apple juices and was also studied for its potential phytoestrogen activity.[15] In addition, phloridzin is considered as a feature compound for the adulteration of beverages with apple juice and hence used for quality control.[16] Phloridzin is also widely applied in the food, cosmetic, and pharmaceutical industries.[17]

Different from popular apple species, red-fleshed ones are characterized by high amounts of anthocyanins.[18,19] According to Sadilova et al.,[18] anthocyanins of the red-fleshed 'Weirouge' apples were mainly located in the peel at a concentration about 2.5 times higher than in the flesh. In both studies concerning 'Weirouge'[18] or 'Niedzwiedzkyana'[19] varieties, the anthocyanin class is mainly represented by cyanidin-3-*O*-galactoside (namely, ideain), although other cyanidin glycosides such as xyloside, arabinoside, rhamnoside, and glucoside have been also detected and quantified.[18] Interestingly, juices from red-fleshed varieties containing high levels of cyanidin-3-*O*-galactoside were generally the ones showing also a high antioxidant capacity.[19]

The fact that anthocyanins exist as several forms in equilibrium depending on the pH is well documented.[20,21] At low pH (~3), the colored flavylium cation form of anthocyanins is significantly present and is more stable. As the pH increases, colorless species (i.e., carbinol pseudobase and chalcones) may significantly contribute to this equilibrium.

Apple varieties strongly differ in quantitative content of each polyphenol.[7,9,22] The same was observed by comparing apples and juices made of them. According to Guyot et al.,[23] the extraction rates of hydroxycinnamic acids, dihydrochalcones, and flavanols during juice production differ according to variety. However, in general, apples with higher content of polyphenols gave juices with higher polyphenol concentrations in comparison to low-polyphenol-containing varieties. Interestingly, solid parts of the fruits act as selective barriers influencing the transfer of polyphenols from the fruits to the juices.[23] In particular, flavanol oligomers and polymers (i.e., condensed tannins) and especially those having a high degree of polymerization are largely adsorbed and retained on the apple pomace.

In the apple juice and cidermaking industries, enzymatic and nonenzymatic oxidations of polyphenols are important phenomena that contribute to the juice and cider quality.[3] Those reactions are responsible for the yellow-orange color of apple juices and ciders. After cell wall and cell membrane disruption, which occur when fruits are crushed and pressed, chlorogenic acid and, to a lower extent, catechins that contain a catechol group in their structure are enzymatically converted by the enzyme PPO into their corresponding *o*-quinones.[7] The quinones produced are very reactive species leading to the formation of neoformed polyphenolic structures involving most of the native polyphenols. As far as we know, there is no direct influence on anthocyanins, which are not considered as PPO substrates.[24] However, in a red wine model solution, it was found that anthocyanins can be indirectly involved by coupled oxidation reduction reaction with hydroxycinnamic acid *o*-quinones.[24] Furthermore, during juice or cider aging, there are series of nonenzymatic reactions involving polyphenol that potentially change the color. They may be favored at higher pH and in the presence of metal ions such as iron or copper.[18]

Among the different ways of inhibition or controlling of oxidation processes, the use of reducing agents is well documented. For instance, sulfites are highly effective and have been used in many products since antiquity.[7] In food technology, sulfite reagent doses are limited and banned for use in fresh fruits and vegetables because of their adverse effects on health.[25]

In the fermented beverages industry, concentrations of residual sulfites are generally not authorized above 350 and 200 mg/L for wines and ciders, respectively.[26,27] Ascorbic acid is also a widespread reducing agent. However, when it comes from the apple itself, it is rapidly consumed during crushing, as a consequence of cell wall disruption and oxidation reduction reaction with enzymatically produced *o*-quinones leading to the formation of dehydroascorbic acid. Then, dehydroascorbic acid may be degraded into a variety of products (aldehydes, ketones, carboxylic acids). A noticeable advantage of ascorbic acid is that there are fewer limitations for its use in food products (usually 50−150 mg/L in wines).

Food chemistry of anthocyanins[28] and in particular their sensitivity to oxidation have been well studied in the red wine model.[27] Then, pyranoanthocyanins appear as a class of very diverse anthocyanin derivatives that are largely involved in the evolution of wine color during aging.[29] In addition, anthocyanins and probably also their derivatives are known for their high antioxidant activity.

In this study, the qualitative and quantitative analyses of polyphenols of a red-fleshed apple cultivar and its clear and cloudy juices are presented. The transfer of polyphenols from fruits to juices, especially for anthocyanins responsible for red color, was measured. In a second part of the experiment, attention was paid to the stability of juice color depending on different parameters including oxygen presence, pH values, and addition of ascorbic acid, sulfites, and copper salt.

MATERIALS AND METHODS

Chemicals and Phenolic Standards. HPLC gradient grade methanol and acetonitrile were obtained from Carlo Erba reagents (Val de Reuil, France). Formic acid was purchased from NORMAPUR (VWR Prolabo, France). Ultrapure water was prepared with a Milli-Q water purification system (Millipore S.A., Molsheim, France). Ascorbic acid was from Fisher Scientific (Loughborough, UK). Copper(II) sulfate pentahydrate was from VWR (Fontenay Ss Bois, France). Sodium metabisulfite was from Merck (Darmstadt, Germany). Standards of (+)-catechin, (−)-epicatechin, 5-*O*-caffeoylquinic acid, *p*-coumaric acid, phloridzin, and avicularin (quercetin-3-*O*-arabinoside) were obtained from Sigma-Aldrich (Lyon, France). Hyperoside

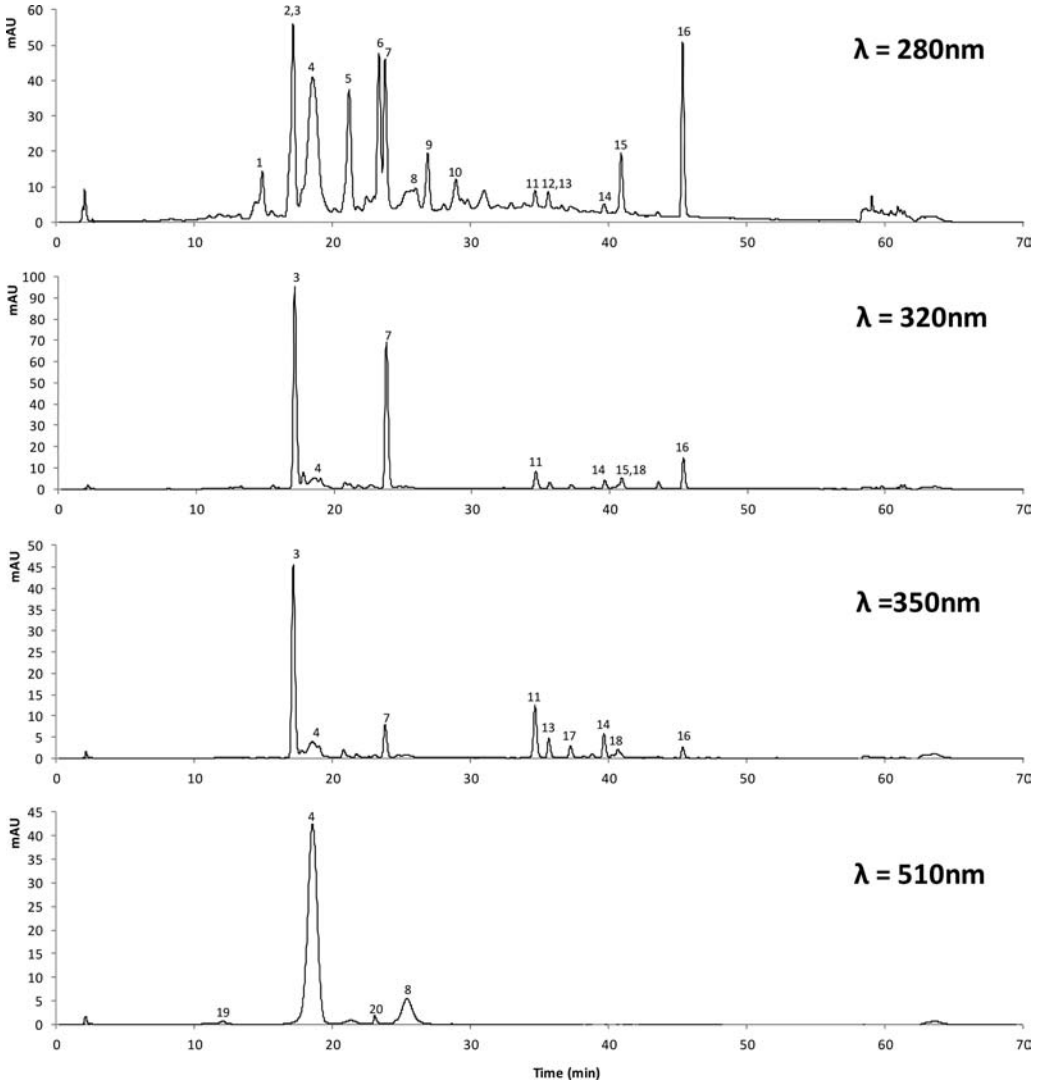

Figure 1. Reversed phase UV−visible chromatograms of the acidified methanol extract of the red-fleshed apple powder. Different wavelengths are used to optimize the detection of the phenolic compounds: (A) 280 nm, all phenolics are detected; (B) 320 nm, more specific for hydroxycinnamic; (C) 350 nm, more specific for flavonols; (D) 510 nm, more specific for anthocyanins.

(quercetin-3-*O*-galactoside), ideain chloride (cyanidin-3-*O*-galactoside chloride), procyanidin B1, and procyanidin B2 standards were purchased from Extrasynthese (Genay, France). (−)-Epicatechin-phloroglucinol, phloretin xyloglucoside, 4-*p*-coumaroylquinic acid, and procyanidin B5 were available standards purified in the laboratory from apple material by HPLC at the semipreparative scale.

Plant Material. A red-fleshed apple hybrid cultivar was selected at INRA Angers (code X4876). It was a cross between F2 parent *Malus pumila* varieties 'Jonathan' and 'Niedzwetzkyana'. Twenty kilograms of apples was harvested in late September 2012 at maturity stage "Starch 7"[30] in the experimental orchard of INRA Angers, Domaine de Beaucouzé.

Sample Preparation. *Fruit Sample Preparation.* Apples were sampled into three batches of 10 fruits. For each batch, fruits were mechanically cut and fruit pieces were randomly selected according to a systematic procedure.[42] This fresh material was immediately frozen in liquid nitrogen and freeze-dried. This dried material was crushed into a fine and homogeneous powder (Electrical Crusher Retsch, model YGG, Bioblock Scientific), which was stored at −30 °C until analysis.

Apple Juice Preparation. Apple juice was prepared in accordance with the internal procedure. Milling and pressing of the apples were performed in the same extraction instrument based on a modified hydropress 90 (Spiedel, Germany) modified by Demoisy (Baune, France). This instrument was specifically designed to limit oxidation during apple milling and pressing (3 bar) by keeping the atmosphere inert using carbon dioxide. The processed batch was approximately 15 kg of apples. A part of the juice was prevented from enzymatic oxidation by adding sodium fluoride (inhibitor of PPO, 0.2 g/L). The rest was left as nonprevented product. Juices were frozen and stored at −30 °C until use. Prevented juice was used for chromatographic characterization of the polyphenol profile, whereas nonprevented juice was used for the experimental design aiming to evaluate the stability of the color. Before analysis, the prevented apple juice was divided into two parts. The first part was centrifuged for 15 min at 3000 rpm on Beckman J2-21 floor model centrifuge. The supernatant, corresponding to "clear" juice, was recovered, whereas the second part was kept cloudy without any change and named "cloudy juice". Aliquots (0.5 mL) of both juices were freeze-dried overnight in 5 mL hemolysis tubes using a Lyovac GT2 freeze-drier (Leybold Vacuum, France). Freeze-dried samples were kept stored in a desiccator under vacuum at room temperature until analysis.

Analytical Procedures. *Determination of Simple Polyphenol Compounds in Fruits and Preserved Juice.* Simple polyphenols (i.e., hydroxycinnamic acids, monomeric flavanols, flavonols, dihydrochalcones, and anthocyanins) were extracted from freeze-dried apple powders using acidified methanol. About 50 mg of powder was precisely weighed in 5 mL hemolysis tubes and extracted using 1.2 mL

Table 1. LC-UV−Visible/MS Identification and Quantification[a] of the Main Phenolic Compounds in Red-Fleshed Apple Fruit and the Corresponding Clear Apple Juices

of pure methanol containing 5% v/v formic acid for 15 min in an ultrasonic bath containing ice (Brasson 2200, USA). Then, samples were filtered on 0.45 μm PTFE filters (Uptidisc, Interchim, France), and the filtrates were ready for HPLC analysis. This procedure was performed in triplicate.

For the cloudy and clear preserved juices, freeze-dried samples were extracted by 1.2 mL of acidic methanol in the ultrasonic bath according to the same procedure. This procedure was performed in triplicate.

Depolymerization of Procyanidins by Acidolysis in the Presence of the Phloroglucinol. The procedure was adapted from that of Kennedy and Jones.[31] Phloroglucinolysis reaction gives access to the subunit composition of procyanidins. The interflavan linkages of procyanidins can be easily disrupted by acidolysis in organic acid medium, leading to the formation of flavanyl carbocations corresponding to the extension units of the procyanidin structure, whereas the terminal units are released in the medium as catechin molecules. Flavanyl carbocations are immediately trapped by nucleophilic phloroglucinol in excess, leading to flavanyl-phloroglucinol adducts. In the case of apple procyanidins, phloroglucinolysis releases (+)-catechin and (−)-epicatechin from the terminal subunits and a (−)-epicatechin−phloroglucinol adduct from the extension subunits. Then, the HPLC analysis of the phloroglucinolysis media gives access to the concentration of each type of terminal and extension catechin unit that initially composed the procyanidin fraction. Therefore, it is possible to estimate the average degree of polymerization (DPn), the average distribution of the catechin units, and the total concentration of procyanidins in the fruit or juice samples.[32]

Apple powder samples (50 mg in 5 mL hemolysis tubes) or freeze-dried cloudy and clear preserved apple juices were dispersed in 0.8 mL of methanol containing phloroglucinol (75 g/L) and ascorbic acid (15 g/L). Then, the reaction was started by adding 0.4 mL of HCl (0.3 N in methanol), and media were immediately incubated at 50 °C for 30 min. The reaction was stopped by placing the tubes in an ice bath and by adding 1.2 mL of 0.2 M aqueous sodium acetate. Samples were filtered on 0.45 μm PTFE filters (Uptidisc, Interchim). The filtrates were ready for HPLC analysis. All phloroglucinolyses were performed in triplicate.

HPLC-UV−Vis and Mass Spectrometry Analysis. Analysis was carried out using a system composed of a thermostated autosampler (model Surveyor, Thermo Finnigan, San Jose, CA, USA), a binary high-pressure pump (model 1100, Agilent Technologies, Palo Alto, CA, USA), a UV−vis diode array detector (model UV6000 LP, Thermo Finnigan), and an ion trap mass spectrometer equipped with an electrospray source (model LCQ Deca, Thermo Finnigan). The column was a ZORBAX Eclipse XDB-C18 column (Agilent Technologies, 2.1 × 150 mm; 3.5 μm) equipped with a precolumn (2.1 × 12.5 mm) of the same material and thermostated at 30 °C. Solvents were (A) acidified pure water (0.1% formic acid) and (B) acidified acetonitrile (0.1% formic acid), both degassed by flushing with helium. The flow rate was 0.2 mL/min and the gradient was as follows: initial, 3% B; 0−40 min, 20% B, linear; 40−55 min, 35% B, linear followed by washing and equilibrating the column. The UV−vis detection was performed in the 240−600 nm range. The ESI source was used in the negative mode with the following parameters: spray voltage (−5 kV), capillary voltage (−70 V), sheath gas (67 arbitrary units), auxiliary gas (4 arbitrary units), and capillary temperature (240 °C). The MS detection was carried out with the following parameters: MS spectra were acquired in full scan negative ionization mode in the m/z 50−2000 range to obtain the signals corresponding to the deprotonated $[M-H]^-$ molecular ions. The method also included the MS/MS dependent scan mode, which was used to obtain the product ion spectrum of the main molecular ions detected on the chromatogram in the full scan mode. The collision energy was optimized in the range of 25−35% (arbitrary units) to clearly observe the production of both parent and main daughter ions. Data were collected and processed by XCalibur software (version 1.2, Thermo

Finnigan). By comparison with available standards, the retention times, UV−vis spectra, full MS spectra, and MS/MS spectra were used for complete identification. When the standard was not available, those criteria were used for only a partial identification. Quantifications were carried out by integration of the peaks on UV−vis chromatograms at 280 nm for flavanols and dihydrochalcones, at 320 nm for hydroxycinnamates, at 350 nm for flavonols, and at 510 nm for anthocyanins (Figure 1). (+)-Catechin, (−)-epicatechin, procyanidin B2, caffeoylquinic acid, phloridzin, hyperoside, and ideain were quantified according to their own calibration curves, whereas other compounds were quantified "as equivalent" according to a reference compound belonging to the same polyphenol class and showing a very similar UV−vis spectrum (see Table 1).

Experimental Design for Color Stability Evaluation. In addition to oxygen, four factors, namely, the pH of the juice (pH), ascorbic acid concentration (AA), sulfite concentration (SO_2), and cupric ion concentration (Cu), were considered as they were suspected to have an effect (main and quadratic) on color evolution with potential interactions between them. To evaluate these effects, a central composite design (fixed to be rotable and orthogonal) was chosen with factors pH, AA, SO_2, and Cu at five levels for each. The design matrix was defined using the tutorial of Stagraphics software: the factor levels were encoded −2, −1, 0, 1, and 2, and the center value was replicated 12-fold, giving 36 total experiments. The range of the factors was chosen to correspond to those encountered in cider and dessert apple juices (from pH 3.0 to 4.4) or usually added in apple juice or cider processing (from 0 to 200 mg/L for ascorbic acid and from 0 to 80 mg/L for SO_2) or measured in the juices and ciders (from 0 to 400 μg/L for copper). This design was applied to both conditions, with oxygen (under air saturation at the starting of the experiment) and without oxygen (under argon for the duration of the experiment), so that oxygen was considered as a two-level factor.

The crude juice (ca. 600 mL) was first thawed at 10 °C in the presence of CO_2 to prevent it from oxidation. Then, the juice was clarified by the addition of 80 μL/L of pectinase (Rapidase C80 Max, DSM, The Netherlands) to hydrolyze pectins and protect the juice from undesirable residues during experiment. After a whole night, the juice was centrifuged for 20 min (Beckman J2-21 floor model centrifuge), and the clear juice corresponding to the supernatant was used for the experimental design.

The initial pH of the juice was 3.4 (model 827 pH Lab pHmeter, Metrohm, France). The juice was divided into five equal volumes for which the acidity was modified by addition of malic acid or potassium hydroxide. Then, the juice was distributed into 10 mL aliquots in glass flasks and mixed with different doses of ascorbic acid (0, 50, 100, 150, or 200 mg/L final), sodium metabisulfite $Na_2S_2O_5$ (0, 20, 60, 40, and 80 mg/L in SO_2 equivalent), and $CuSO_4$ (0, 100, 200, 300, or 400 μg/L in Cu equivalent) according to the design matrix (Table 2). Finally, 36 flasks were placed under argon atmosphere, and another 36 flasks were prepared under air-saturated atmosphere. Preparation of those samples was carried out with appropriate microbiological conditions to maintain low contamination risk: Vessels were sterilized in steam (120 °C, 20 min), laboratory tools were kept in alcohol, and the additions were done in sterile conditions. All flasks were capped hermetically with inert caps.

The storage experiment was carried out for 2 weeks. Samples were stored in the absence of light for 10 days at 35 °C and for 4 days at 50 °C. Samples under air and argon atmospheres were analyzed by HPLC-coupled to UV−vis and mass spectrometry detection on the first and last days of the experiment.

Spectrophotometric Measurements of the Juices and Data Conversion. The native clear juice and the clear juices from the experimental design were analyzed using a spectrophotometer to collect the data necessary for the calculation of the colorimetric parameters. Aliquots (200 μL) of the juices stored under air atmosphere were taken daily from each flask to measure the absorbance corresponding to the visible spectrum in the 400−700 nm region at room temperature using a microplate spectrophotometer (model SPECTRAmax PLUS 384, Molecular Devices). Samples with argon were analyzed only at the last day of storage. Mathematical processing of the visible spectra was used to convert the absorbance data into colorimetric CIE *L*, *a*, and *b* parameters. Then, colorimetrical values including lightness (*L*), saturation (*C**), and hue (*h*) were used for color characterization. The correctness of conversion was checked before by comparison of data from colorimetrical measurement and spectrophotometric data conversion of the same samples.

Statistical Analysis. Statistical analyses were done by Statistical Analysis and Data Visualization software, Statgraphic (Sigma Plus, France). The experimental design was analyzed by the general linear model.

RESULTS AND DISCUSSION

Phenolic Compounds in the Red-Fleshed Apple Fruits. The polyphenol profile of the fruit and the juice of the red-fleshed apple variety 'Jonathan' × 'Niedzwetzkyana' were characterized by reversed phase HPLC coupled to UV−vis and MS detection. Figure 1 shows the chromatograms of the fruit methanol extract at four different wavelengths to have a better observation of the different polyphenol classes: all polyphenols including more or less polymerized procyanidins are detected at 280 nm. For this reason, the chromatogram appears very crowded with significant baseline deviation corresponding to coelution of several compounds. Hydroxycinnamates were more selectively detected at 320 nm, and flavonols are clearly observable at 350 nm between 34 and 42 min. Finally, the wavelength 520 nm was suitable for the specific detection of anthocyanins. Most of the compounds were numbered and unambiguously identified on the basis of their chromatographic (RT) and spectrometric (UV−vis, MS/

[a]Procyanidins. [b]5-Caffeoylquinic acid.

MS) features by comparison with authentic standards when they were available. In other cases, they were only partially identified on the basis of their UV−vis and MS/MS spectra and by comparison with previously published data.

Thus, considering the phenolic compounds usually found in common apple fruits, seven flavanols: ((+)-catechin (2), (−)-epicatechin (6), procyanidins B1 (1), B2 (5), and B5 (12), one trimer (9), and one tetramer (10)), five flavonols (avicularin (14), hyperoside (11), isoquercitrin (13), quercitrin (18), and reynoutrin (17)), two hydroxycinnamic acids (5-caffeoylquinic acid (3) and 4-*p*-coumaroylquinic acid (7)), and two dihydrochalcones (phloridzin (16) and phloretin-2-xyloglucoside (15)) were detected and identified in the fruit (Figure 1).

For the particular class of anthocyanins that are responsible for the red color, four peaks were clearly observable on chromatograms at 510 nm (Figure 1D). The main peak (4) was unambiguously identified as ideain (i.e., cyanidin-3-*O*-galactoside), and peak 8 was identified as cyanidin pentoside, likely corresponding to cyanidin-3-*O*-xyloside, already described as the second most concentrated anthocyanins after ideain in red-fleshed apples.[33] Two red-colored compounds corresponding to peaks 19 and 20 were also detected. Referring to a previously mentioned publication, compound **20** with $[M]^+$ ion at m/z 517 and a main product ion at m/z 355 could be 5-carboxy-pyrano-cyanidin-galactoside, but the information was not confirmed.[18] According to its MS and MS/MS spectra, compound corresponding to peak 19 ($[M]^+$ = 737, Table 1) likely corresponded to an (epi)catechin-cyanidin-hexoside.

Phloroglucinolysis reaction directly applied on apple powder followed by HPLC analysis was used to define the total content of procyanidins and the average degree of polymerization of flavanols.

The total concentration of polyphenols in fruits assayed by HPLC amounted to 490 mg/100 g of fresh weight (Table 3).

In accordance with previously published data for which thiolysis or phloroglucinolysis reaction was used to quantify condensed tannins in apple fruits also considering their polymerized forms,[34,35] major constituents present in samples were flavanols, with >70% content of procyanidins in apples. Among them, procyanidin B2 was the most abundant molecular form, whereas within monomers, (−)-epicatechin prevailed. As generally observed for apple condensed tannins, procyanidin extension subunits were only (−)-epicatechin, whereas (+)-catechin was found as a small proportion of the terminal units. The average degree of polymerization (DPn) of the flavanol class in the apples equaled about 3.6 (Table 4).

The second dominant group in apples was anthocyanins, with 9% of average total polyphenol content (Table 3). The major anthocyanin was ideain, namely, the cyanidin-3-*O*-galactoside (Figure 1D, peak 4) with a concentration close to 37 mg/100 g FW (Table 1) accounting for 85% of total anthocyanins in the fruit. This can be compared to other studies on red-fleshed apples. For instance, this concentration

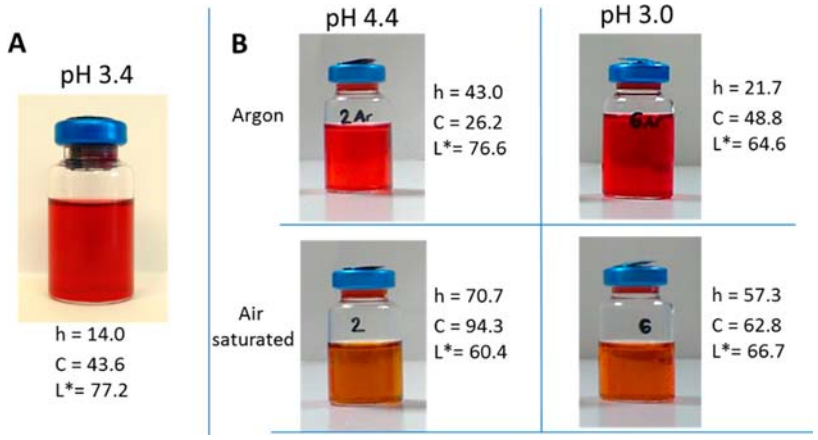

Figure 2. Pictures and colorimetric data of (A) the native clear red-fleshed apple juice without any additives and (B) four selected juices at the end (+14 days) of the color stability experiment: on the right, corrected pH 4.4; on the left, corrected pH 3.0; upper pictures, juices under argon atmosphere; lower pictures, juices under air-saturated atmosphere. All juices were diluted 4 times before spectrophotometric measurements.

of ideain in studied fruits was about 3 times higher than in 'Weirouge' apples studied by Sadilova et al., about 9.3 mg/100 g in unpeeled fruits.

Hydroxycinnamic acids, namely, 5-*O*-caffeoylquinic and 4-*p*-coumaroylquinic acid, represented >6% of total phenolic compounds (Table 3). These two compounds were present approximately at the same concentration, close to 15 mg/100 g FW (Table 1). Interestingly, in comparison to other apple varieties (Table 5), the red-fleshed cultivar was from 2 to 6 times less concentrated in 5-caffeoylquinic acid. Because this compound is the preferential substrate of PPO,[7] its presence at a very low concentration could be linked to a weak sensitivity of this apple variety to enzymatic oxidation.

Dihydrochalcones represented by phloridzin and phloretin-2-xyloglucoside accounted for only 3.8% of total phenolic compounds (Table 3), with phloridzin predominating at a concentration close to 13 mg/100 g FW, which is about 2 times higher than the level of phloretin-2-xyloglucoside (5.9 mg/100 g FW) (Table 1).

Flavonols accounted only for 1% of total phenolic compounds (Table 3), which represented 5.0 mg/100 g FW. They were represented by quercetin 3-*O*-galactoside (3.0 mg/100 g of fresh weight) and quercetin 3-*O*-arabinoside (1.3 mg/100 g of fresh weight). Other flavonols (quercetin glucoside, xyloside, and rhamnoside) were quantified in the range from 0.1 to 0.9 mg/100 g FW (Table 1). Quercetin 3-*O*-rutinoside (i.e., rutin), which is usually present in most apple varieties, was detected as only traces by mass spectrometry. Thus, it was not considered for UV–vis quantification in the present study.

The studied red-fleshed apples were rich in polyphenols. In comparison to other apple varieties, their phenolic quantity is included in the upper level (Table 5). They are characterized by a high concentration of procyanidins and a low amount of 5-caffeoylquinic acid. Red-colored apple juices are also rich in polyphenols but with a relatively low concentration of 5-CQA (Table 5).

Phenolic Compounds in the Juice and Their Extractability from the Fruits. The fruits for which polyphenol composition was described in the preceding paragraphs were used to produce a red-colored juice according to a standardized procedure. Distinction was made between the crude cloudy juice directly obtained after pressing and the clear juice obtained after centrifugation of the cloudy juice. Most of the simple phenolics found in the fruit were also found in the juice (Table 3). However, contrarily to what has been observed in some previous work,[14] no significant difference concerning the polyphenol composition was observed between the cloudy and centrifuged juices. For this reason, the following discussion will concern only the centrifuged clear juice.

Total polyphenol content in juice equaled 216 mg/100 mL (Table 3), which corresponds to an extraction rate of about 40%. This extraction rate was calculated by the ratio between the amount of polyphenol in the juice and the amount in the fruits that was processed to obtain this juice. As the juice yield has a high impact on this rate, we will use it only to compare the different phenols in a juice.

Total anthocyanins content was 12.3 mg/100 mL (Table 3), which corresponded to about 6% of the total polyphenol content and an extractability rate close to 26%. Logically, the main compound found in this class was cyanidin-3-*O*-galactoside, the one that is predominant in fruit flesh. Its extraction rate was close to 26%. Cyanidin pentoside was extractable in about 19%, whereas compound **19** (Table 1) corresponding to a putative anthocyanin–flavanol adduct and compound **20** corresponding to the tentatively identified 5-carboxy-pyrano-cyanidin-glucoside were both almost completely extracted in the juice.

As previously observed for apple juice when thiolysis or phloroglucinolysis coupled to HPLC was used for procyanidin oligomer and polymer characterization and quantification,[14,23] the main polyphenols found in red-fleshed apple juices were flavanols. Procyanidins were predominating with a concentration close to 135 mg/100 mL (Table 4). The extractability of flavanols in the juice was close to 42%, and their average degree of polymerization was close to 2.5.

Total content of hydroxycinnamic acids equaled 30.8 mg/100 mL in the clear juice. Interestingly, this value is very low in comparison to previously published data concerning apple juices. This fact can be mainly imputed to the very low concentration of 5-caffeoylquinic acid, which is almost at the same level of concentration as 4-*p*-coumaroylquinic acid (Table 1). Considering that 5-caffeoylquinic acid is the preferential substrate for PPO, this red-fleshed variety should not be sensitive to enzymatic oxidation and browning. Nevertheless, we noted that hydroxycinnamic acids were the most extractable polyphenol group with an extraction rate close to 100%.

Dihydrochalcones represented 3.5% of the phenolic content (Table 3) with an extraction rate close to 40%. Total dihydrochalcones were close to 7 mg/100 mL of juices (Table 3), with a predominance of phloretin-2-xyloglucoside compared to phloridzin (Table 1).

Flavonols were the least concentrated phenolic compounds in juices, with 0.4% of the total phenolic content (Table 3) and an extraction rate close to 16%. Quercetin 3-*O*-galactoside was the most concentrated flavanol, whereas the least abundant one was quercetin 3-*O*-arabinoside. Quercetin 3 -*O*-glucoside was not detected in the juices (Table 1).

Color of the Pure Juice. Figure 2A presents the picture of the pure, centrifuged juice at room temperature, directly before starting experimental design. Color was described in the CIE *Lab* scale by three orthogonal parameters, L^*, which represent the lightness, and a^* and b^*, which are related to redness and yellowness, respectively. It can be more convenient to express the two-dimensional coordinate system defined by a^* and b^* by the polar coordinates that are easier to understand in terms of color: the angle (h) in degrees representing the hue (0° for red and 90° for yellow) and the distance (C^*) from the center giving the saturation of the color (0° for gray, i.e., black to white depending on L^* and >60° for an intense color).

Figure 3 is used to indicate the hue position of different fruit juices or ciders in the CIE *Lab* representation. In comparison to

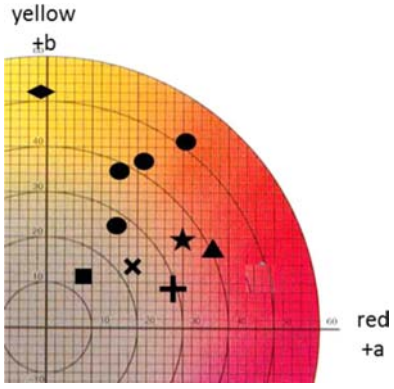

Figure 3. Position of different fruit juices in the CIE *Lab* color space: (▲) the studied red-fleshed apple juice; (●) four dessert apple juices;[37] (★) cranberry juice;[38] (×) raspberry juice;[38] (■) strawberry juice,[38] (+) grape juice;[39] (◆) French ciders.[36]

French ciders[36] or classical clear apple juices[37] made from dessert varieties, the studied red-fleshed juice was very different, characterized by a much higher a^* value (redness) and a lower b^* value (yellowness). Strawberry,[38] raspberry,[38] and grape[39] juices were slightly lower on the yellow scale, but showed about 2 times lower a^* values, giving a much paler red color than the red-fleshed apple juice. The closest juice on a color basis was cranberry juice[38] (Figure 3). When the juices were compared by using h and C^* values, the red-fleshed apple juice had the lowest hue (tend to pure red) and one of the highest saturation values, close to cranberry juice.[38]

Experimental Design Approach to Color Stability. Statistical analysis of the colorimetric data of 36 samples on the first day of the experiment ("start") and 72 samples on the last day ("finish") was performed to evaluate the stability of the juice color. The influences of oxygen (presence or absence of air in the flask), pH (3.0, 3.35, 3.7, 4.05, 4.4), ascorbic acid (from 0 to 200 mg/L), SO_2 (from 0 to 100 mg/L), and copper (from 0 to 400 μg/L) were tested for their effect (main and quadratic effects) on the color parameters: saturation (C^*), hue (h), and lightness (L^*). Furthermore, the effects of combinations of all these factors (interaction effect) were also estimated. For oxygen, only the main effect and interaction are available as only two modalities were used. Data were treated using the general linear model in Statgraphics software.

Figure 2B presents pictures of the samples under argon or air atmosphere at two different pH values (3.0 and 4.4) at the last day of the experimental design. For both pH values, oxygen-protected juices were redder and brighter. Samples that contained oxygen became brown-orange and less bright than those kept under argon atmosphere.

Figure 4 shows the value of the coefficients of the statistical model corresponding to the factors and interactions between factors that have a significant influence on the juice color parameters h, C, and L^*. A negative coefficient indicates a decreasing effect, whereas a positive one corresponds to an increasing effect. As all of the factors were coded from −2 to +2 corresponding to the range of encountered conditions, this

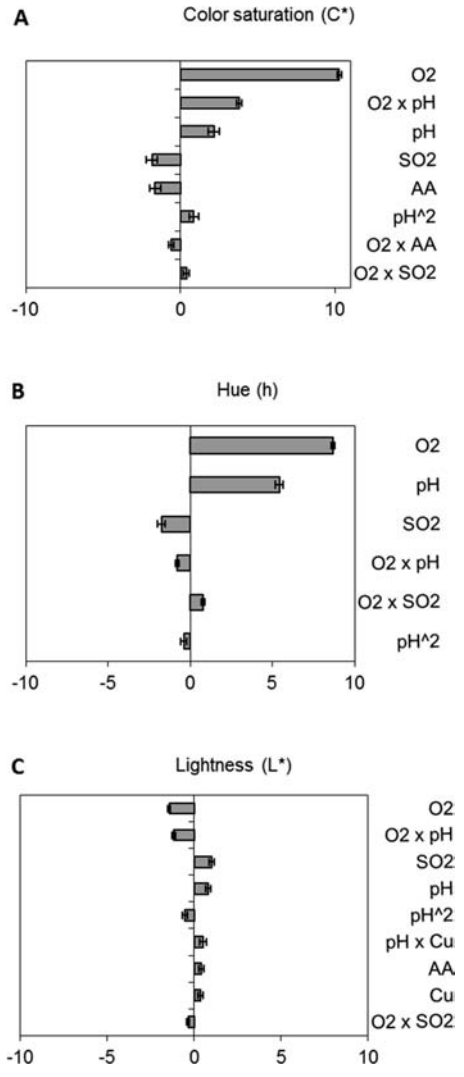

Figure 4. Coefficients of the statistical model describing the effect of the studied parameters (i.e., oxygen (O_2), pH, sulfites (SO_2), ascorbic acid (AA), and copper ions (Cu)) and their main interactions on the color saturation (A), hue (B), and lightness (C) of the clear red-fleshed apple juice.

dx.doi.org/10.1021/jf500336v | J. Agric. Food Chem. 2014, 62, 6944−6954

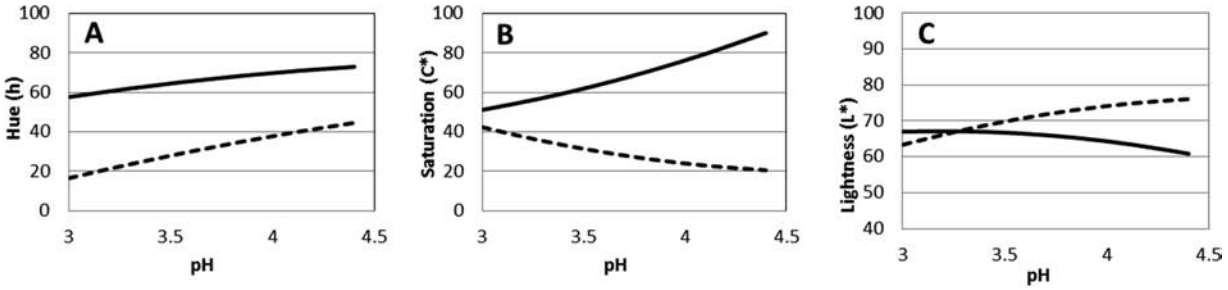

Figure 5. Effect of pH on the hue (A), saturation (B), and lightness (C) of the red-fleshed apple juice at the end of the storage period under air (solid line) or argon (dotted line) atmosphere.

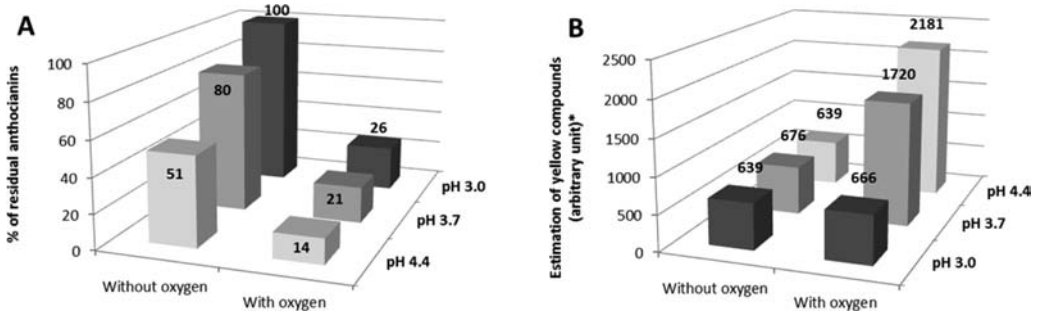

Figure 6. Impact of pH and oxygen on percentage of residual anthocyanins (A) and on formation of yellow compounds (B). * Corresponding to the total area of the chromatogram in the 400−460 nm region.

figure allows a comparison of the effects within the usual apple juice conditions. In general, the highest values of the coefficients were observed for saturation and hue, and only small values were observed for lightness. This indicated that lightness of the juice was not greatly modified during storage. In contrast, hue and saturation were strongly changed during the storage, and highest values were observed for the factors oxygen and pH, underlying the great impact of these factors on color change. Figure 5 gives a more detailed illustration of the effects of these two factors on the three color parameters. The presence of oxygen and the higher pH values always increased the hue angle (Figure 5A): when extreme conditions are accumulated (high pH in the presence of oxygen), the color of the initial juice changed from red (h = 20) to orange-yellow (h = 70), and the interaction that was observed between these factors was not high enough to change the sign of the global effect of each factor. These evolutions of the hue went together with changes of saturation and lightness. However, for these parameters, there were strong interactions between oxygen and pH so that the resulting effects of pH on saturation and lightness were inverted when oxygen was present (Figure 5B,C): in the oxygen-containing juices, an increase of pH from 3 to 4.4 led to an increase of saturation and a decrease of lightness. On the contrary, when the juice was under argon, an increase of pH reduced the saturation and enhanced the lightness. In addition, a quadratic effect of pH was observed for these three parameters, showing that the effect of pH is not linear. However, within the pH range that was tested, the quadratic effect was not high enough to give rise to a maximum or a minimum in the parameters.

The other factors also had significant effects on the color parameters, but their coefficients were lower: the effects of ascorbic acid and sulfites were in opposition to those of oxygen so that, as expected, these factors partially tend to prevent the evolution due to oxidation. A low effect of copper was observed on lightness (main effect P = 0.0296, interaction with pH P = 0.0120) but not on hue and saturation.

The high effect of oxygen on hue was not surprising because oxidation of anthocyanin is known to modify the color from pink/red toward yellow/orange, thus increasing the hue (Figures 4B and 5A). The concomitant increase of the saturation suggests that the new pigments that were produced by oxidation significantly contributed to the color saturation and, to a lesser extent, slightly reduced the lightness. The effect of pH was more complex due to the strong interactions with oxygen mainly observed for saturation (Figure 4A). However, those results were consistent with known mechanisms: On the one hand, a high pH favored autoxidation of anthocyanins that may produce new colored compounds such as pyranoanthocyanins[27] as already observed in wine models. Note that those neoformed colored compounds are not necessarily oxidation products of anthocyanins. For instance, they may result from nonenzymatic oxidation of flavanols leading to the formation of yellow compounds as previously observed in model solutions.[40,41] However, this oxidation occurs only when oxygen was present, which explains the interaction between the two factors pH and oxygen. On the other hand, a low pH is known to enhance red color due to a highest content of stable and red-colored flavylium cation forms of anthocyanins.[21] This effect reinforced the interaction (pH × oxygen) on saturation and lightness resulting in this inversion of the effect of pH depending of oxygen (Figure 5B,C). An effect of sulfites and ascorbic acid was expected, as these reagents are well-known reducing agents used in food industries. Their effect was actually in conflict with those of oxygen, which was consistent with their properties, but the reduction of the oxidation was rather low. This can be due to the small quantities of juice compared to an equivalent volume of air and also to the high diffusion rate of gases in such a small vial. The protective effect was probably limited by excessive oxygen availability in these

conditions. An effect of copper was also expected, but the results showed that, at the tested concentrations, the role of copper can be neglected compared to the other factors.

Taking advantage of the diode array UV−vis detection, HPLC analysis of selected juices at the end of the storage experiment allowed us to complete the information concerning color stability of the red-fleshed apple juice. As seen in Figure 6A, total anthocyanin content strongly changed during the storage. As observed for color stability, oxygen was the most important factor influencing the "red" compounds, so those two evolutions seem to be highly related. The level of decrease was clearly higher in oxygen-containing juices (from 75 to 86%), whereas under argon no more than 50% of the anthocyanins were degraded. The second factor influencing the stability of anthocyanins was the pH. The lowest amounts of anthocyanins were observed at pH 4.4 both at the beginning and at the end of the experiment, whereas at pH 3.0, more "red" compounds were detected on chromatograms. The decrease of anthocyanins in highly acidic conditions was around 74.5%, whereas at pH 4.4 it was up to 85.6%. This indicated that the level of decrease was highly related to the pH of the juice (Figure 6A).

The concentration of yellow compounds in the juices at the end of the storage period was estimated by measuring the global area between 5 and 45 min on the average chromatogram in the 400−460 nm range that reveals the absorbance due to yellow-orange (Figure 6B). For all pH values tested, the juices kept under argon atmosphere did not contain high amounts of yellow-orange compounds. In contrast, larger concentrations of yellow-orange compounds were found in the samples containing oxygen, and this concentration was much higher (close to 3.5 times more) for the juices at pH 4.4. Comparison with the 400−460 nm chromatograms of the juices at the beginning of the experiment (data not shown) revealed that most of the yellow-orange compounds found in the juices at the end of the storage period were not present in the fresh juices. These compounds likely corresponded to polyphenol oxidation products as already discussed, and further work is needed to characterize these neoformed yellow-orange compounds.

To conclude, the INRA red-fleshed X4876 apple cultivar was shown to be a raw fruit material producing an attractive red-colored clear apple juice. Interestingly, for several reasons, biochemical characteristics and in particular the polyphenol composition and distribution are favorable to red juice production with limitation of browning reactions during processing: (i) anthocyanins that are located in the flesh and responsible for the red color are highly extractable in the juice during pressing; (ii) compared to many other varieties, the juice is relatively acidic, which allows limiting the PPO activity and subsequent browning reactions; and (iii) the low concentration of chlorogenic acid, which is the preferential substrate of PPO, may also contribute to its low sensitivity to browning.

The study of the stability of the color revealed that the presence of oxygen in the juice was the main factor highly detrimental to color preservation, and this instability is enhanced when the pH increases. In those conditions, the juice turns orange-brown and HPLC analysis revealed as a consequence both anthocyanin degradation and the formation of yellow compounds likely corresponding to PPO products. In the conditions tested, the use of reducing compounds was only weakly effective for limiting the color degradation. In contrast, the reduction of oxygen level in the juice by using argon was highly effective. Further works would aim to identify those neoformed products responsible for color degradation. The present study was more particularly devoted to the color that happens during juice storage. However, it would also be essential to study the color degradation potentially occurring during fruit crushing and pressing when maximum PPO activity is available and also during apple juice fermentation for a particular use of this red juice in the cider industry.

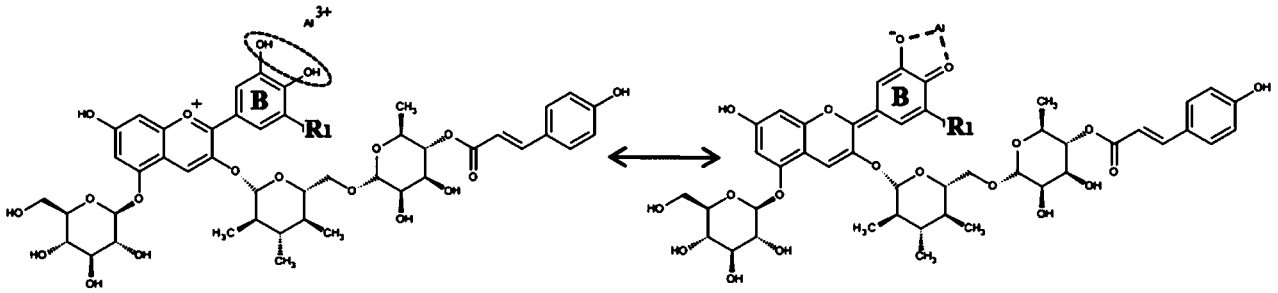

Figure 1. Al^{3+} chelation by cyanidin (B ring exhibiting catechol moiety) or delphinidin-3-*p*-coumaroyl-rutinoside-5-glucoside (B ring exhibiting pyrogallol moiety), where R_1 is H or R_1 is OH, respectively.

all being multivalent.[7] Al^{3+} anthocyanin complexes in ethanol have been reported to be relatively stable at pH 2−5 in reactions with delphinidin.[6] Cyanidin and delphinidin glucosides from berries had previously been found to develop blue-like hues with tin chelation, whereas iron chelates were more brown.[8] More recent publications emphasized the effects of B ring structure, acidic range pH, and buffer selection in anthocyanin complexation with trivalent metal ions (Fe^{3+} and Al^{3+}) in pectin and pectic fractions.[4] Unlike previous findings, ferric ion treated delphinidin-3-glucoside showed blue hues and farther bathochromic shifts than cyanidin and petunidin glucosides. These samples also showed highest stability over time.[4] The environment also can affect the stability of anthocyanin−metal chelates. In citrate and phosphate buffers, color shifts were not found to occur; however, metal chelation by anthocyanins seemed relatively unhindered in other buffers such as acetate and succinic acid.[4]

Aluminum has traditionally been considered innocuous to humans, but controversy has risen with links to neurotoxicity, dialysis encephalopathy, microcytic anemia, osteomalacia, and Alzheimer's disease.[9,10] However, no reports of dietary aluminum toxicity were found in the literature in healthy individuals.[11] The FDA considers aluminum sulfate as generally recognized as safe (GRAS) as a food additive with no usage limit, and aluminum salts may comprise 2% of the final product in synthetic lake type dyes.[12,13] Absorption from anthocyanin−aluminum colorants is likely low, based on anthocyanin chelating effects and aluminum's low bioavailability in water (0.3%).[9,11,14]

With still limited knowledge about the conditions supporting anthocyanin−metal chelation, the aim of this study was to explore factors conducive to blue color formation in acidic conditions typical of food products. This is one of the first known studies to evaluate the effects of food source anthocyanin structures, including acylated and nonacylated counterparts of delphinidin and cyanidin, with chelation of aluminum in varied conditions. The effects of differing anthocyanin concentrations and increasing concentrations of aluminum salt were evaluated to determine ideal conditions for complexation leading to most intense bathochromic and hyperchromic shifts in absorbance. These conditions were also carried out in the pH range 3−6 to better understand the role of pH in anthocyanin−metal chelation. Color stability was monitored by a 28 day study of delphinidin and acylated cyanidin chelates in different storage conditions.

MATERIALS AND METHODS

Materials. American eggplant (*Solanum melongena* L), Japanese eggplant (*Solanum melongena* L), red raspberry (*Rubus idaeus*), and red cabbage (*Brassica oleracea* var. *capitata* f. *rubra*) were purchased from a local grocery store in Columbus, OH, USA. Frozen whole black currants (*Ribes nigrum*) were purchased from CropPharms LLC (Staatsburg, NY, USA). A commercial black carrot (*Daucus carota* spp. *sativus*) anthocyanin powder was provided from D. D. Williamson (Louisville, KY, USA), and chokeberry (*Aronia melanocarpa*) juice concentrate was obtained from Artemis International (Fort Wayne, IN, USA). Aluminum chloride hexahydrate, USP 97.0−101.0% grade, was purchased and obtained from Sigma-Aldrich Co. (St. Louis, MO, USA). ACS grade sodium acetate anhydrous, 6 N hydrochloric acid (certified 5.95−6.05), trifluoroacetic acid, and sodium hydroxide N/10 (0.0995−0.1005) were purchased from Fisher Scientific (Fair Lawn, NJ, USA) as were all other standard ACS and HPLC grade reagents. For comparative purposes, powdered forms of brilliant blue or FD&C Blue No. 1 (certification no. AL9925) and indigotine or FD&C Blue No. 2 (certification no. AL2889), each having a color purity of 92%, were obtained from Noveon Hilton Davis, Inc. (Cincinnati, OH, USA). FD&C Blue No. 1 was diluted to 2.14×10^{-4} M with distilled water, whereas FD&C Blue No. 2 was diluted to 6.35×10^{-4} M.

Methods. *Extraction and Purification of Anthocyanins.* Extraction of anthocyanins from plant materials followed procedures described by Rodriguez-Saona and Wrolstad.[15] Whole plant samples (only peels from eggplant samples) were powdered with liquid nitrogen and treated with 0.01% HCl acidified 70% aqueous acetone before filtration, with repetition until plant material was discolored. Eggplant peels were instead treated with 3.0% trifluoroacetic acid acidified 70% aqueous acetone to reduce the brown discoloration, likely due to polyphenol oxidase, that occurred during extraction. After the filtrate was mixed with 1−2 volumes of chloroform, phase separation occurred overnight at 4 °C, except eggplant samples being limited to 4 h. The chloroform layer containing lipophilic compounds was appropriately discarded because chloroform is a mild carcinogen. Care should be taken to avoid introduction of bases to chloroform waste to avoid undue explosions. Aqueous layers were dried in a rotary evaporator at ∼37 °C under vacuum.

Anthocyanin Purification: Solid Phase Extraction. Crude anthocyanin extracts were purified by loading activated Waters Sep-pak C_{18} cartridges with samples. Loaded cartridges were washed with water acidified to 0.01% HCl to remove organic sugars and acids and then with ethyl acetate to remove phenolics. Anthocyanin pigments were recovered with 0.01% HCl acidulated methanol, which was removed in a rotary evaporator at 37 °C under vacuum. Pigments were stored in acidified water until further analysis.

Monomeric Anthocyanin Quantitation. Monomeric anthocyanins were quantitated by the pH differential method, described by Giusti and Wrolstad.[16] Briefly, anthocyanins were quantified by measuring the absorbance at 520 and 700 nm at pH 1 and 4.5 for each sample. On the basis of the difference of these absorbances, the concentration of monomeric anthocyanins of the solutions was determined. This information was then used to make dilution to known concentrations.

Monomeric anthocyanin pigments were quantitated using the formula ACN (mg/L) = $(A \times MW \times DF \times 1000)/(\varepsilon \times 1)$, with 1 cm path length. A was the absorbance, based on $(A_{\lambda 520} - A_{\lambda 700})_{pH\ 1} - (A_{\lambda 520} - A_{\lambda 700})_{pH\ 4.5}$. MW was the molecular weight of the sample's predominant anthocyanin, DF was the dilution factor used, and ε was

the molar absorptivity. Table 1 shows the values used for each sample's quantitation.

Table 1. Display of Anthocyanin, Associated Molecular Weight, and Molar Absorptivity Used for Monomeric Quantitation of Anthocyanins in Food Samples Evaluated

sample	anthocyanin	MW	molar absorptivity
American eggplant	delphinidin-3-rutinoside	647.0	26900[a]
Japanese eggplant	delphinidin-3-(*p*-coumaroylrutinoside)-5-glucoside	955.26	26900[a]
black currant	cyanidin-3-glucoside	484.8	26900[a]
red raspberry	cyanidin-3-glucorutinoside	757.0	26900[a]
chokeberry	cyanidin-3-glucoside	484.8	26900[a]
red cabbage	cyanidin-3- diglucoside-5-glucoside	773.0	30175
black carrot	cyanidin-3-xylosyl(feruloylglucosyl) galactoside	919.25	26900[a]

[a]Molar absorptivity of cyanidin-3-glucoside, used for monomeric quantitation.[16]

High-Pressure Liquid Chromatography (HPLC) Evaluation of Anthocyanins. Reverse phase HPLC was utilized to identify anthocyanins, with comparison to the literature. Samples were analyzed using a HPLC (Shimadzu, Columbia, MD, USA) system equipped with LC-20AD pumps and an SIL-20AC autosampler coupled to an LCMS-2010 mass spectrometer (Shimadzu) and an SPD-M20A photodiode array (PDA; Shimadzu) detector. LCMS Solution software (version 3, Shimadzu) was used to view results. Separation of anthocyanins was achieved on a reverse-phase Symmetry C_{18} column with 5 μm particle size and 4.6 × 150 mm column size (Waters Corp., Taunton, MA, USA), and a 4.6 × 22 mm Symmetry 2 micro guard column (Waters Corp., Bedford, MA, USA) was used. Samples were filtered through Phenomenex Phenex RC 0.2 μm, 15 mm membrane syringe filter (Torrance, CA, USA). The flow rate was set to 0.8 mL/min with a run time of 70 min, and PDA detection for 55 min. The solvents were phase A, 4.5% formic acid in LC-MS grade water, and phase B, LC-MS acetonitrile (Fisher Scientific Inc.). A binary gradient was used for solvent B: 0−35 min for 0−25% B, 35−40 min for 25−50% B, 40−45 min for 50−100% B, and returning B to 0% 50−55 min and maintained until 70 min. Spectral data were obtained from 250 to 700 nm, and elution of anthocyanins was monitored at 520 nm.

About 0.2 mL/min flow was diverted to a single-quadrupole ion-tunnel mass spectrometer equipped with an electrospray ionization (ESI) interface (Shimadzu). Mass spectrometry was performed under positive ion mode. Data were monitored using total ion scan (SCAN) (from m/z 200−1200) and selected ion monitoring at m/z 287 (cyanidin) and m/z 303 (delphinidin).

Formation of Complexes with Aluminum and Metal Salts in Acidulated Aqueous Solutions. (a) Evaluating Anthocyanin Structures, Concentrations, and Salt Ratios in Al^{3+} Complex Formation. To solutions of acidified water at pH 3 were added anthocyanin samples at three concentrations, based on monomeric quantitation: 25, 50, and 100 μM. Anthocyanin sources for this phase included American eggplant, black currant, red raspberry, chokeberry, red cabbage, and black carrot. $AlCl_3$ aqueous solutions were prepared to 0.057, 0.2288, and 0.4576 M. Salt solutions were added to anthocyanin solutions beginning at equal molar concentrations, then in factors of 10× to 100× molarity of anthocyanin content, then 500× and 1000×. Control samples for each concentration were maintained without salt addition for comparison. Three replicates were evaluated for each sample.

(b) Evaluating Color Stability over Time of Al^{3+} Complexed Anthocyanins. Anthocyanins from American eggplant and red cabbage were diluted in acidified water at pH 3 to 50 μM concentration. $AlCl_3$ salt solutions were added to anthocyanin solutions in factorial excesses of 0×, 1×, 100×, 500×, 1000×, and 2000× anthocyanin concentrations. Three replicates were evaluated for each sample in each storage condition, representing different product storages. Samples were stored for 28 days in each condition: dark storage at refrigeration temperatures (2−4 °C), dark storage at ambient temperatures (18−25 °C), and full light exposure from natural daylight ∼8 h and fluorescent lamps from above at ambient temperatures (18−25 °C).

(c) Evaluating the Effect of pH on Al^{3+} Complex Formation. Sodium acetate was used to prepare 1 M buffered solutions at pH 3, 4, 5, and 6. Anthocyanin samples from American eggplant, Japanese eggplant, chokeberry, and red cabbage were diluted to 50 μM solutions in each buffer. $AlCl_3$ solutions were added to achieve factorial excesses of 0×, 1×, 100×, 500×, 1000×, and 2000× over anthocyanin concentration. The pH of these and all samples was measured using a Mettler Toledo International Inc. S220 SevenCompact pH/ion meter (Schwerzenbach, Switzerland).

Spectrophotometry of Solutions with UV−Visible Transmission. Each sample from each phase of study was subjected to visible spectrophotometry and colorimetry. After 15 min of equilibration after salt addition, each sample was evaluated by visible transmittance (400−700 nm) spectrophotometry using 1 cm plastic cuvettes in a Shimadzu UV-2450 UV−visible spectrophotometer. Spectrograms were generated using UV Probe software, version 2.21 (Shimadzu) associated with this spectrophotometer model.

CIE-Lab Color of Solutions by Transmission. Samples were transferred to 2 mm path length plastic cells and read for CIE-*Lab*, chroma, and hue angle using a Hunter ColorQuest XE (Hunter Laboratories, Reston, VA, USA). The equipment was set for total transmittance, illuminant D65, and a 10° observer angle for all liquid samples.

Statistical Evaluation of Data. The mean and standard deviation of data replicates were calculated using Microsoft Office Excel 2010 (Office 14.0, Microsoft, Redmond, WA, USA). Data from evaluation of anthocyanin structures, concentrations, and salt ratios in Al^{3+} complex formation were conducted by one-way analysis of variance (ANOVA) (two-tailed, $\alpha = 0.05$) and Student's paired t test (two-tailed, $\alpha = 0.05$) of λ_{max} and associated absorbance comparing different anthocyanin concentration and increasing $AlCl_3$ concentration (0−1000× anthocyanin concentration) using Microsoft Office Excel 2010.

Stability over time of American eggplant and red cabbage anthocyanin−aluminum chelates was evaluated by the same testing on the λ_{max} and associated hue from the different salt treatments in differing storage conditions. Finally, the pH decreases likely caused by Al^{3+} chelation were also evaluated by one-way ANOVA (two-tailed, $\alpha = 0.05$). All other figures were also generated using this software.

RESULTS AND DISCUSSION

Evaluating Results from Reverse Phase HPLC-MS. Food samples used in this study represented two anthocyanin aglycone structures: delphinidin and cyanidin. American eggplant and black currant were chosen to represent glycosylated delphinidin. HPLC chromatograms are presented in Figure 2. The American eggplant showed delphinidin-3-rutinoside as the primary anthocyanin as indicated from its HPLC chromatogram and mass spectrometry and in agreement with previous literature.[17] Black currant chromatograms showed profiles similar to previous findings: delphinidin-3-rutinoside and cyanidin-3-rutinoside, each representing ∼40% of the anthocyanin profile.[18] Japanese and non-Japanese type eggplants share delphinidin as the primary anthocyanidin; however, the primary Japanese eggplant anthocyanin was acylated, delphinidin-3-(*p*-coumaroylrutinoside)-5-glucoside (or nasunin) (Figure 2).[17]

Sources and structures were more varied for cyanidin derivatives, being more prevalent in edible produce. Red raspberry and chokeberry were used as sources for glycosylated cyanidin. The main pigment in chokeberry was found to be

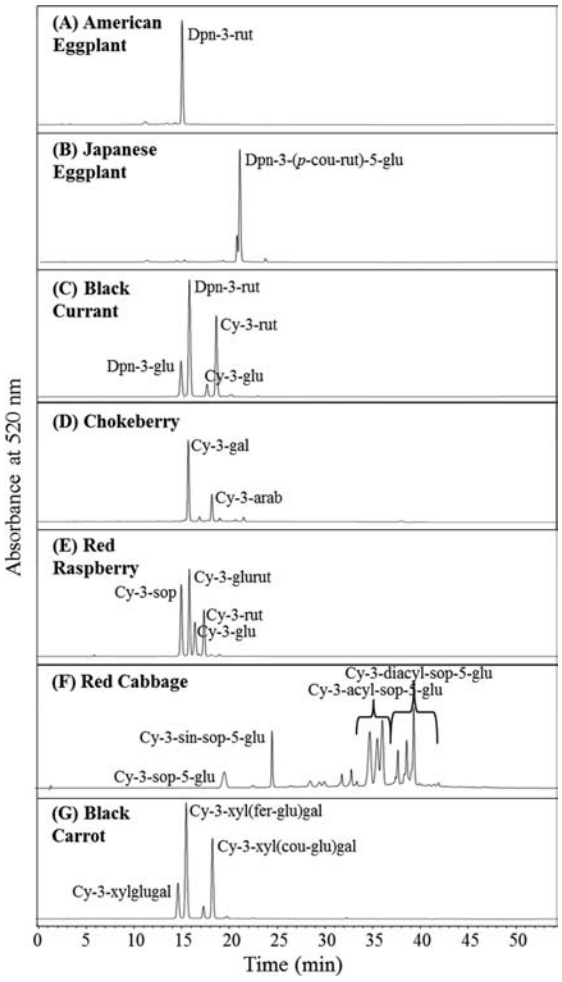

Figure 2. Reverse phase HPLC chromatograms of food sample anthocyanins: (A) American eggplant; (B) Japanese eggplant; (C) black currant; (D) chokeberry; (E) red raspberry; (F) red cabbage; (G) black carrot, with detection at 520 nm showing the main pigments identified.

cyanidin-3-galactoside, representing ~65% of the anthocyanin profile.[19] The chromatogram of red raspberries of this study showed four major pigments; most prevalent were cyanidin-3-sopohoroside and cyanidin-3-glucorutinoside.[20] Two sources of acylated cyanidin were also included in this study: red cabbage and black carrot. Several peaks for red cabbage were found, primarily various types and amounts of acylated of cyanidin-3-sopohoroside-5-glucoside.[21] Black carrot chromatograms showed five major peaks, resembling the profile of the 'Deep Purple' variety.[22] The major pigment of this variety was cyanidin-3-xylosyl(feruloylglucosyl)galactoside, agreeing with the literature.[22]

Evaluating Anthocyanin Structure, Concentrations, and Salt Ratios in Al^{3+} Complex Formation. In this portion of the study, samples were limited to sources of glycosylated delphinidin (American eggplant and black currant), glycosylated cyanidin (red raspberry and chokeberry), and acylated cyanidin (red cabbage and black carrot). This was intended to determine what role anthocyanin structure, concentration, and salt ratio played in metal complexation to induce bathochromic shifts toward blue colors.

All tested anthocyanins showed complexation to occur with aluminum, regardless of aglycon structure, type of glycosylation, or acylation. Each anthocyanin demonstrated both bathochromic and hyperchromic shifts when exposed to the metal ion. By comparison of B ring core structures, delphinidin-containing samples showed the farthest bathochromic shifts and become most blue-like at pH 3 (Table 2). Glycosylated delphinidin showed λ_{max} bathochromic shifts of 50 and 55 nm for American eggplant and black currant, respectively. Cyanidin samples showed lower bathochromic shifts ranging from 26 to 39 nm. These data indicate that increasing the number of free hydroxyl groups on the aglycone core structure leads to farther bathochromic shifts, agreeing with previous studies comparing petunidin, cyanidin, and delphinidin.[3]

Amount and type of common glycosylation do not seem to affect anthocyanin ability to chelate with metal ions but may mildly affect final solution color. When the two glycosylated cyanidin samples were compared, red raspberry anthocyanins demonstrated lower λ_{max} than chokeberry anthocyanins until high levels of Al^{3+} were achieved; Table 2 shows λ_{max} values of red raspberry anthocyanins to be about 10 nm less than those of chokeberry anthocyanins with $AlCl_3$ 100× anthocyanin content. However, both samples showed λ_{max} of 551−553 nm with $AlCl_3$ 500× anthocyanin content, with the exception of the chokeberry anthocyanins in 100 μM concentrations, which shifted to 567 nm but with constant final hue across all three anthocyanin concentrations. This occurrence did not follow the trend of other anthocyanin samples or concentrations. Perhaps due to the high anthocyanin content and high proportion of monoglycosylated cyanidin, additional intermolecular copigmentation could have occurred, leading to the shift in λ_{max}. This postulate does not explain why other anthocyanin samples did not exhibit the same trend, unless their individual complexes had already formed or were hindered related to additional structural components.

With acylation, cyanidin samples continued showing intense bathochromic and hyperchromic shifts in absorbance. The acylated samples did not seem to show larger hyperchromic shifts than nonacylated counterparts but did exhibit more intense chroma. The overall higher absorbances could be due to the proposed molecular stacking mechanisms of acylated anthocyanins, in which the acid groups are overlaid the anthocyanins.[23] This would increase the amount of electron density in that area, leading to intensification of signals found in spectrophotometry. Although the Al^{3+} complex colors of the two acylated cyanidin samples followed similar trends of absorbance increases, acylated cyanidin samples from red cabbage showed larger absorbance increases than acylated cyanidin pigments from black carrot (Table 2). Red cabbage anthocyanins also exhibited more blue-like colors, having a hue angle around ~298, whereas black carrot anthocyanin Al^{3+} chelates exhibited hue angles at ~316. These data suggest that the long sugar chain of black carrot anthocyanins may interfere with the molecular stacking arrangement, resulting in lower λ_{max} and fewer and less intense blue hues, as compared to red cabbage chelates.

Regardless of anthocyanin concentration (25−100 μM), all samples chelated Al^{3+}, showing bathochromic and hyperchromic shifts. However, the effects of increasing salt concentration (0−1000×) were less in lower anthocyanin concentration samples. At lower concentrations with the same factorial excesses of salt, samples demonstrated lesser bathochromic and hyperchromic shifts in absorbance compared to higher anthocyanin concentrations (Figures 3 and 4), until reaching optimum salt ratios where the same λ_{max} and hue angle

Table 2. Effects of Anthocyanin Concentration at pH 3 on Color Shifts, with λ_{max} and CIE-*Lab* Color Characteristics of Anthocyanins Complexed with $AlCl_3$ 100× Anthocyanin Concentration[a]

[a]In parentheses are the standard deviations, $n = 3$.

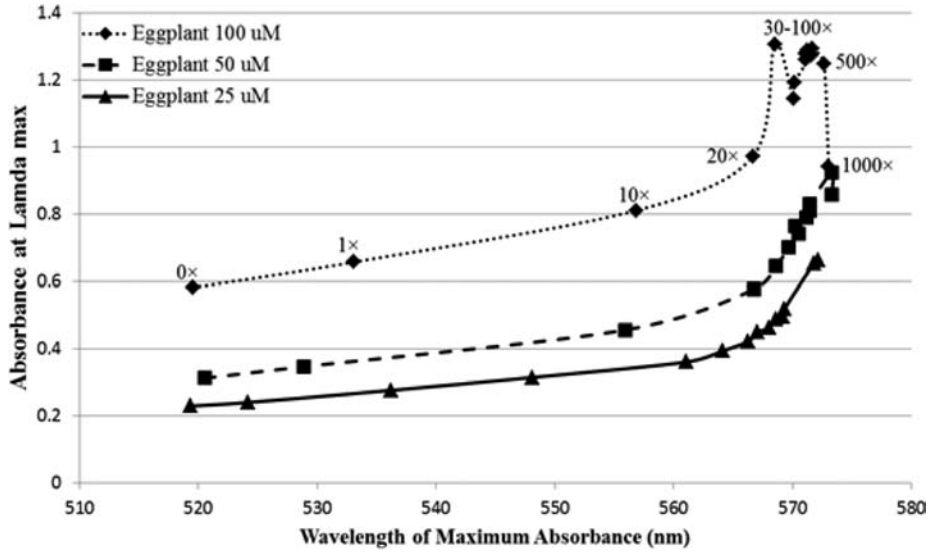

Figure 3. Visible absorbance (400−700 nm) of 25, 50, and 100 μM concentrations of American eggplant anthocyanins treated with factorial increases of $AlCl_3$ (0−1000×) over anthocyanin concentration at pH 3.

occurred. From the same anthocyanin source, the λ_{max} means resulting from each combination of salt treatment (0−1000×) and anthocyanin concentration were compared. *p* values of 6.64×10^{-8} or less were obtained from one-way ANOVA, indicating mean λ_{max} from each $AlCl_3$ treatment to be different from anthocyanins from the same sample.

Similar results were obtained from one-way ANOVA on absorbance of the same samples, giving *p* values of 1.82×10^{-6} or less, with the exception of 25 μM red raspberry anthocyanins. ANOVA resulted in *p* value of 0.05, for which the null hypothesis was still rejectable at 90% confidence. Typically, the increase in absorbance continued to rise with increasing anthocyanin content. Largest absorbance increases were found to occur with anthocyanins from black currants, which are roughly equal ratios of glycosylated delphinidin and cyanidin.[18] The hue reflects this anthocyanin profile, falling between the complex hues of either primarily delphinidin or cyanidin. With regard to the atypically high absorbance increases of black currant anthocyanins, responsibility could be attributed to intermolecular copigmentation between the

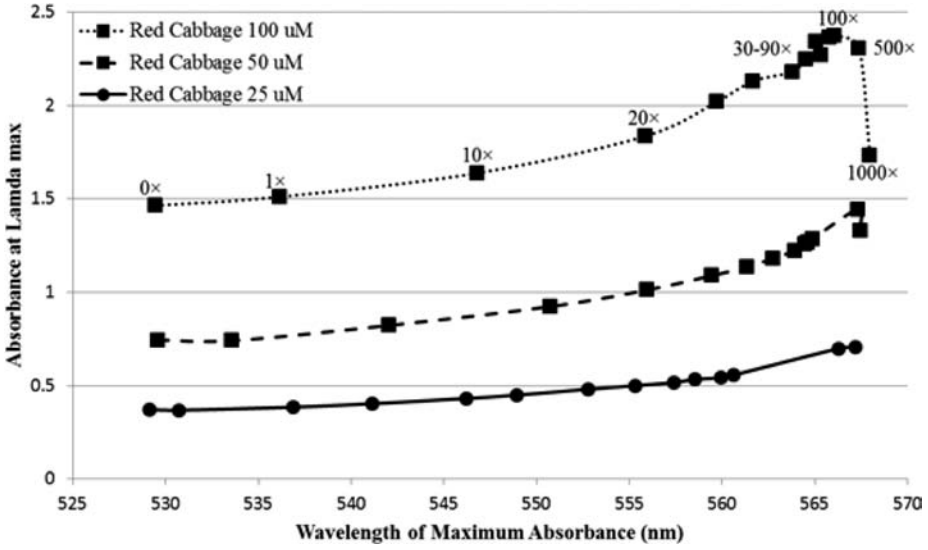

Figure 4. Visible absorbance (400−700 nm) of 25, 50, and 100 μM concentrations of red cabbage anthocyanins treated with factorial increases of $AlCl_3$ (0−1000×) over anthocyanin concentration at pH 3.

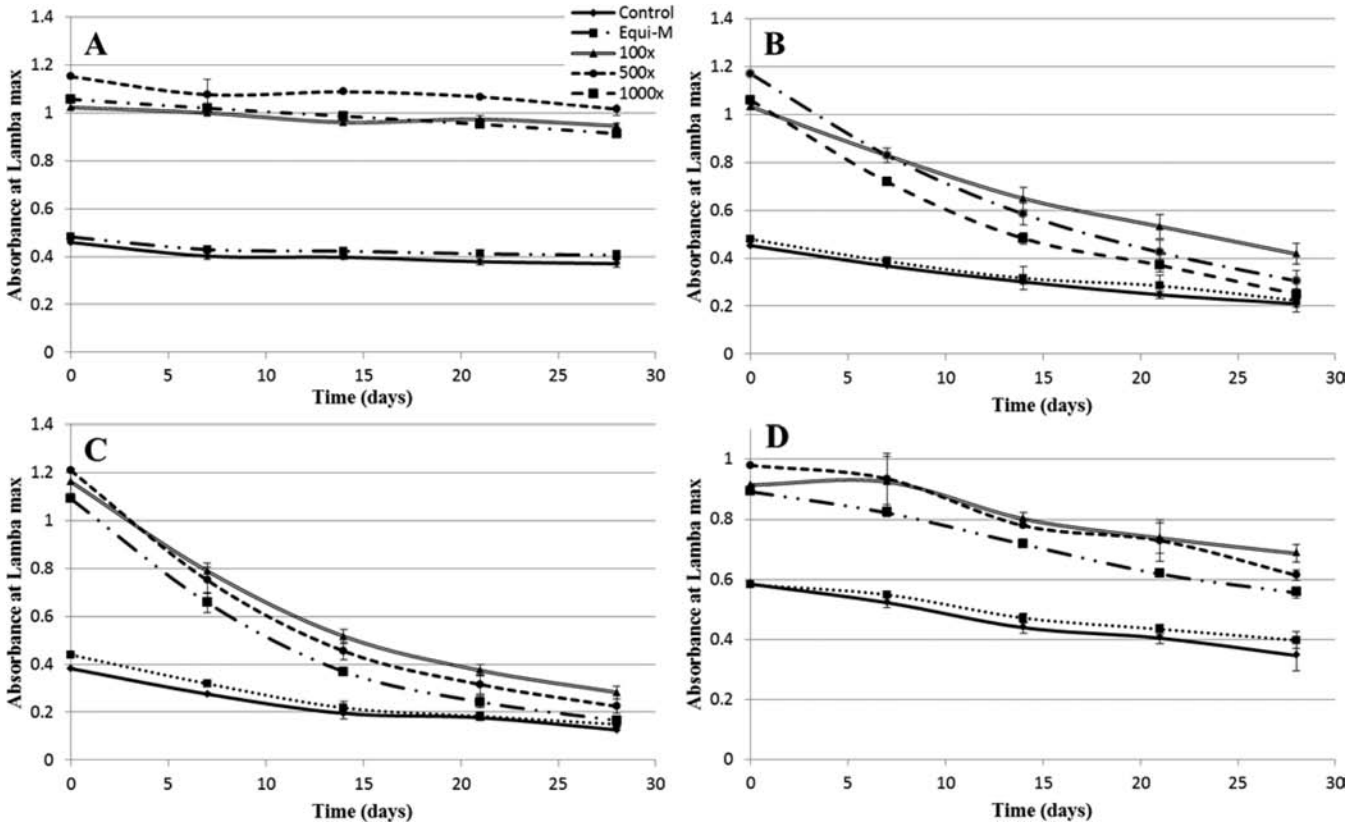

Figure 5. Changes in absorbance at λ_{max} of 50 μM anthocyanin solutions at pH 3 over 28 days of $AlCl_3$ (0−1000×) treated (A) delphinidin (American eggplant anthocyanins) with dark storage at 4 °C, (B) delphinidin with dark storage at ambient temperatures (19−25 °C), (C) delphinidin with light storage at ambient temperatures (19−25 °C), and (D) acylated cyanidin (red cabbage anthocyanins) with light storage at ambient temperatures (19−25 °C).

roughly equal ratios of cyanidin and delphinidin not found in other samples.

In addition to anthocyanin structure and concentration, $AlCl_3$ salt ratios were investigated to determine optimal ratios for preferred color development. Anthocyanin chelation with Al^{3+} was apparent essentially immediately with ion introduction to the system, causing visible color changes. Ideal $AlCl_3$ salt concentrations were found to be between 100× and 500× anthocyanin concentration, at which treated anthocyanins showed the highest intensity of absorbance and reached the farthest bathochromic shift (Figures 3 and 4). Comparing the λ_{max} means from $AlCl_3$ concentrations 100× and 500× anthocyanin content of 25 μM by Student's paired t test, p values of 0.02−0.09 were obtained. The λ_{max} values for these

dx.doi.org/10.1021/jf405145r | J. Agric. Food Chem. 2014, 62, 6955−6965

two salt concentration ratios on American eggplant, black currant, and red cabbage anthocyanins were found not to differ, having p values >0.06. The other samples were found not to differ with $AlCl_3$ concentrations 500× and 1000× anthocyanin content. The same results from t tests were obtained for 50 μM anthocyanin samples. For 100 μM anthocyanin samples, only chokeberry and red cabbage anthocyanin samples were similar with $AlCl_3$ concentrations 100−500×, and the remainder was similar with $AlCl_3$ concentrations 500−1000×.

In addition to λ_{max}, absorbance was evaluated by ANOVA and Student's paired t test for optimal salt ratios. A large excess of salt seemed to initiate some reversion of the color intensification achieved at lower ratios (Figures 3 and 4); a decrease in complex intensity can be noted at salt 1000× anthocyanin concentration in all anthocyanin concentrations (25−100 μM). This could be due to metal-induced pigment degradation or complex formation hindrance caused by the high salt concentration. By ANOVA, the absorbances of all anthocyanin concentrations with salt treatment were found different with p values of ≤0.005, except 25 μM red raspberry anthocyanin samples, which were still the same at 90%. From Student's t test, p values of ≤0.03 were found for all 50 and 100 μM anthocyanin samples with $AlCl_3$ concentrations 500× and 1000× anthocyanin content, except 100 μM chokeberry (p value = 0.09), supporting the observation that absorbance was decreasing with high $AlCl_3$ excesses of 1000×. Some slight decreases in absorbance were noted in 100 μM anthocyanins from American eggplant in the salt range of 30−90×, which did not follow general trends shown by other concentrations. On the basis of the largest absorbance and λ_{max} observed in these samples, optimal $AlCl_3$ concentration was found to be 100−500× anthocyanin concentration.

Evaluating Color Stability over Time (28 Days) of Al^{3+}-Complexed Anthocyanins. The mechanism for thermal degradation of anthocyanins has not been fully elucidated and therefore is still not understood (Schwartz and others, 2008). However, all three of the proposed pathways involve transformation of the flavylium cation to other forms more prevalent in higher pH, which then decompose into degradation products.[24] It has been proposed that chelation of metals by anthocyanins stabilizes the quinonoidal base form as well as protects it from nucleophilic attack by complexation coordination.[3,5] Metal chelation by anthocyanins has been shown to increase stability during storage as well as with thermal treatment.[3,25] Ferric chelates of cyanidin-3-glucoside showed improved stability to thermal treatment of 60 °C over 80 min, with intensity retention of ∼70%.[25] All chelates exhibited first-order kinetics of degradation, but those with delphinidin-3-glucoside in sugar beet pectin showed highest stability compared to glucosides of cyanidin and petunidin when stored at 20 ± 2 °C for 18−66 days.[3]

This study compared the stability of aluminum chelates of delphinidin-3-rutinoside (American eggplant) to that of acylated cyanidin glycosides (red cabbage), as the literature is limited about the stability of acylated anthocyanin−metal chelates. Highest stability for both samples was found in cold, dark storage as expected on the basis of ideal conditions for anthocyanin stability. For delphinidin chelates absorbance decreases were limited to ∼0.1 over 28 days, whereas almost no change was noted for acylated cyanidin samples (Figure 5). Much larger decreases in absorbance were noted for samples stored in ambient temperatures. Although those samples receiving light treatment showed slightly larger decreases, they did not differ significantly from dark storage samples, having p values of 0.1 and 0.5 from Student's paired t test for $AlCl_3$ levels 100× and 500× anthocyanin content. This indicates anthocyanin−metal complexes are more liable to heat treatment rather than light exposure. Degradation of delphinidin−Al chelates seems related to concentration with rate decreasing with time, in agreement with previous studies.[3] Acylated cyanidin chelates showed more linear degradation patterns (Figure 5). These samples also showed improved color stability, exhibiting lower changes in absorbance over time, likely resulting from the proposed molecular folding and stacking acylated anthocyanins can undergo protecting the chromophore.

Having used different ratios of salt to anthocyanin, it was possible to estimate concentrations for optimal anthocyanin chelate stability. Similarly to the decrease of absorbance noted with high excesses of $AlCl_3$, a large amount of salt also was found to diminish stability. From one-way ANOVA, all chelated sample means for λ_{max} were found to be different after 28 days, giving p values of ≤0.002 for each storage treatment. With salt 100−500× anthocyanin content, highest stability was noted on the basis of absorbance and hue angle. Those samples that received light and heat abuse showed $AlCl_3$ 100× to be slightly more stable than 500× based on hues, which differed by p value ≤0.02 from Student's paired t test. At this anthocyanin salt ratio (100×) perhaps the largest number of stabilized and protected complexes occurs.

Evaluating Effects of pH in Al^{3+} Complex Formation. Four samples were used in this phase of the study, American eggplant (glycosylated delphinidin), Japanese eggplant (acylated delphinidin), chokeberry (glycosylated cyanidin), and red cabbage (acylated cyanidin), to understand the effects of starting pH on final exhibited color. Decreases of overall solution pH were found to occur likely due to the release of hydrogen ions when anthocyanins chelate metals. At each of the starting pH levels tested (pH 3−6), all anthocyanins exhibited roughly equal decreases in pH in 1 M acetate buffer solutions (Figure 6). By one-way ANOVA, the pH decreases across each sample at starting pH levels were found not to differ by p values ≥0.23. These equivalent decreases in pH indicate the same concentration of H^+ ions being released from both aglycones. It is suggested that acidic pH may not limit the ability of these anthocyanins to chelate metals, despite the form

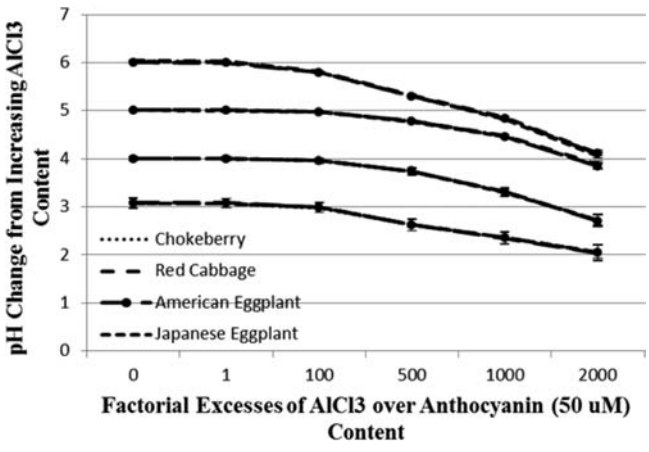

Figure 6. pH change of 50 μM anthocyanin sample solutions initiated by treatment with $AlCl_3$ (0−2000×) in 1 M sodium acetate buffers, pH 3, 4, 5, and 6.

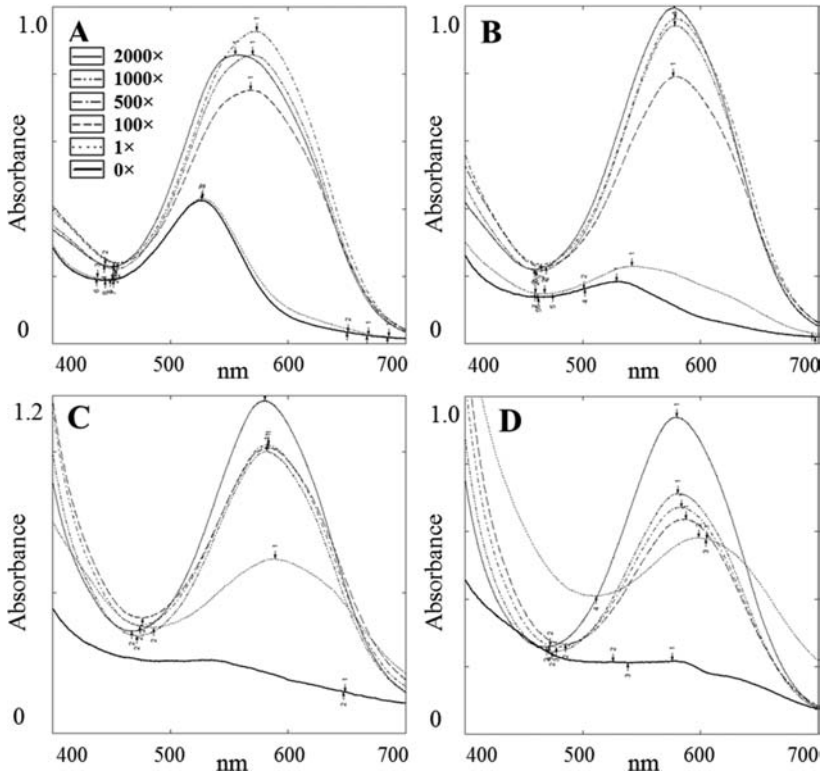

Figure 7. Visible (400−700 nm) absorbance of 50 μM acylated delphinidin (Japanese eggplant anthocyanins) treated with $AlCl_3$ 0−2000× anthocyanin concentration at (A) pH 3, (B) pH 4, (C) pH 5, and (D) pH 6.

equilibrium shifts. Addition of $AlCl_3$ to aqueous solutions can also cause pH decreases due to its ability to hydrolyze in water; however, using high-molarity buffer solutions helped to reduce these effects. In 1 M acetate buffers, pH decreases were minimized until after $AlCl_3$ salt concentrations exceeded 100× anthocyanin content (Figure 6), so color observations were due to complexation rather pH changes.

Even at more neutral pH, where anthocyanins tend to exhibit minimal color intensity, all Al^{3+}-treated samples showed bathochromic and hyperchromic shifts in visible spectrophotometry, becoming bluer than respective untreated anthocyanins. In agreement with previous studies, it was concluded that the predominant anthocyanin structure at said pH acts as the foundation against which the color of the anthocyanin complexes competes.[3] At low pH, where anthocyanins tend to appear in mostly red flavylium structures, those blue anthocyanin−metal complexes compete, giving the final solution a purple color. Conversely, at more neutral pH, where anthocyanins appear in colorless carbinol or yellow chalcone forms, the ultimate solution color is blue or blue-green with metal complex competition.

All samples, pH 3−6, followed the same general trend for Al^{3+} chelation depicted (Figure 7) for acylated delphindin (Japanese eggplant samples), showing hyperchromic shifts. In higher pH solutions, the absorbance of complexed solutions was not as intense as their respective counterparts in lower pH. Samples experienced only bathochromic shifts at low pH, until high levels of $AlCl_3$ 2000× anthocyanin concentration. The reverse was noted when the starting point was pH 6. With low salt concentrations (equimolar conditions), bathochromic shifts were first observed but became hypsochromic with increasing salt content. Across the tested pH range, the final λ_{max} terminated at similar wavelengths, within 10 nm, for pH 4−6 but were generally lower for samples starting at pH 3. Delphinidin samples showed greatest increases in λ_{max} versus cyanidin anthocyanins; interestingly, acylated anthocyanins tended to display lower increases in λ_{max} than nonacylated counterparts (Table 3). Despite similar λ_{max} values of Al^{3+} complexed anthocyanins, hue angles differed with changes in pH, as shown in Tab1e 3.

Starting at pH 3, no samples tested showed vivid blue hues. Acylated delphinidin (Japanese eggplant) demonstrated most blue-like hues, having a hue angle of 293 (Table 3). Other samples showed more purple-pink hues. Despite delphinidin having the pyrogallol moiety and exhibiting farthest bathochromic shifts upon Al^{3+} complexation, competition of H^+ ions from the acidic pH likely inhibited formation of pure blue colors. With inclusion of acylation on the molecule, the bathochromic shift was found to be no greater; however, there was a higher initial and terminating λ_{max} with metal chelation. Glycosylated cyanidin samples appeared much pinker than acylated counterparts upon complexation with Al^{3+}, which visually resembled delphinidin samples, although hue angles differed by about 10.

When increase in the starting pH to 4, anthocyanin−metal chelates began to approach blue hues. Results followed the same general trend for lower pH. Salt-treated glycosylated cyanidin samples were mostly pink, whereas acylated cyanidin from red cabbage exhibited similar hues to those of delphinidin. Both exhibited more blue-like color than at pH 3 with hues around 280−285; acylated cyanidin exhibited higher, more purple hue. Most interestingly, delphinidin acylated with coumaric acid (Japanese eggplant) showed pure blue color upon complexing with Al^{3+}. Hue of this sample treated with $AlCl_3$ 100× anthocyanin concentration was 265 and remained constant until reaching $AlCl_3$ 1000× and 2000×, becoming 269

Table 3. Effects of Acidic pH Change on Color Shifts, with λ_{max} and CIE-*Lab* Color Characteristics of 50 μM Anthocyanins (0×) and 50 μM Anthocyanins Complexed with $AlCl_3$ 100× Anthocyanin Concentration[a]

[a]In parentheses are the standard deviations, $n = 3$. [b]Values had to be estimated from spectrum due to low absorbance of untreated anthocyanins.

dx.doi.org/10.1021/jf405145r | J. Agric. Food Chem. 2014, 62, 6955−6965

and 274, respectively. As noted before, these high salt concentrations were also correlated with decreases in pH and increased H^+ competition against metal ions for the hydroxyl groups of the B ring.

Beginning at pH 5, more samples began to exhibit visibly blue colors. Delphinidin anthocyanins from American eggplant and acylated cyanidin from red cabbage showed hues of 272 with $AlCl_3$ concentrations 100× anthocyanin concentration. This hue was maintained until reaching $AlCl_3$ 2000×, where color reverted to higher hues. Salt-treated cyanidin samples formed unique purple-pink hues of 305−308, with hue increasing as salt concentration increased. Acylated delphinidin samples exhibited a wider range of hues than other samples from 230 to 263. The optimal pH for delphinidin-3-glucoside−ferric chelates was found to be 4.5 on the basis of formation and stabilization of the chelates.[3] Generally, absorbance of complexed solutions decreased as pH increased, except by comparing pH 3 and 4, where absorbance increased by about 0.1 except chokeberry anthocyanins, which were lower. Decreases in absorbance were highest by comparing pH 5 and 6, ranging from 0.9 to 0.25. From color and intensity evaluation, the ideal pH for blue color formation of anthocyanin−Al chelates likely lies in pH 4−5 range.

Similar trends were noted with starting pH 6; the highest amount of blue hues was exhibited from the most number of samples tested. Delphinidin and acylated cyanidin showed hues around 260, becoming more blue with the increasing pH. Cyanidin from chokeberry still did not exhibit blue colors at this pH, having hues around 300. It seems cyanidin, without acylation, lacks the necessary electron density and resonance to form blue colors in acidic pH with Al^{3+}. Acylated delphinidin exhibited a range of hues upon chelation with Al^{3+}, 216−260, depending on salt concentration and pH. These hues were found to be the most similar to the synthetic dyes FD&C Blue No. 1 and FD&C Blue No. 2, which were found to exhibit hues of 224.3 and 241.5, respectively. The colorant FD&C Blue No. 1 expressed a λ_{max} of 630, whereas Blue No. 2 showed λ_{max} of 610 nm, each of which easily correlated to their observed blue colors, in agreement with previous findings.[26] Despite the fact that these metalloanthocyanin complexes had much lower λ_{max} values, some were able to produce similar blue hues.

Unlike the findings from previous studies of anthocyanin−ferric chelates, precipitation of metalloanthocyanins was not observed until neutral or basic pH had been reached.[3] At pH 5, ferric anthocyanins were found to precipitate within 2 h of ion introduction, leaving the supernatant colorless after 24 h.[3] Data were not included, but anthocyanins were found to chelate to Al^{3+} in basic pH testing. However, when exposed to pH ≥7, the complexes almost immediately precipitated, leaving the supernatant mildly colored or colorless depending on salt concentration. Precipitates showed colors similar to their respective solution colors at pH 6.

Experiments revealed anthocyanins were able to interact with metals in wide concentration ranges, but salt ratio and pH determined final color and strength. Highest stability and color expression were found when catechol- or pyrogallol-bearing anthocyanins were mixed with $AlCl_3$ at ratios of 100−500× anthocyanin concentration. Anthocyanin color stability was also found to improve with metal chelation, exhibiting intense color for increased time. Three free hydroxyl groups on B rings of anthocyanins and acylation were found to further λ_{max} and blue color formation. Acylation proved critical to blue color development at low pH; acylated delphinidin exhibited blue hues at pH ≥2.5 when complexation occurred at pH 4. Nonacylated delphinidin−Al chelates did not express blue color until pH 5, and the same was noted for acylated cyanidin, in that red cabbage anthocyanins expressed blue hues at pH 5. Without acylation, cyanidin did not develop blue colors. This observation may be due to an effect of molecular folding occurring with acylated anthocyanins that increases electron density and resonance. With optimal anthocyanin−salt ratios, blue colors developed from metal−anthocyanins could be viable alternatives for synthetic blue colorants in food systems.

markedly relevant from ornamental and phytochemical perspectives.

Surprisingly, few studies have been carried out on ornamental pot plants, and little has been published regarding the response of these plants to saline fertirrigation, probably because they have been generally irrigated with high-quality water. Those studies that have appeared reported that the saline fertirrigation had a negative effect on yield and decreased the flower quality.[11,12] However, the positive or negative effects of salt stress will depend on the degree of tolerance of plants and stress saline conditions, so the mechanisms of salt stress action are not yet completely clear, especially the impact on the pigment composition and color expression of the flower organ.

Thus, the aim of this study was to assess the effect of salt stress on various physiological characteristics (flower biomass production, abscisic acid (ABA) content, ion leakage, and leaf photochemical efficiency) of *H. rosa-sinensis*, which has been described as a moderately salt-tolerant specie.[13] More importantly, the anthocyanin composition and content of *Hibiscus* petals were also studied to evaluate the influence of stress saline conditions on the color expression of the flower organ, objectively measured by digital image analysis.

Recent advances in image acquisition technology offer the possibility of using technically sophisticated apparatus available at relatively low cost and the ability to evaluate areas in terms of millions of pixels. In this way, more detailed evaluations of objects with heterogeneous color such as plant tissues are possible, because every different color present in the image can be accounted for one or more pixels. Thus, image analysis arises as a good option for satisfying the need of measuring color in this kind of sample. In addition, possible color−anthocyanin composition relationships were studied by applying multivariate statistical analysis.

MATERIALS AND METHODS

Chemicals and Standards. Folin−Ciocalteu reagent, gallic acid, and quercetin standards were purchased from Sigma (St. Louis, MO, USA). Cyanidin-3-glucoside was purchased from Extrasynthese (Genay, France). The solvents used in chromatography were of HPLC grade and purchased from Merck (Darmstadt, Germany). All other chemicals were of analytical grade and supplied by Panreac Química (Barcelona, Spain).

Plant Material, Growing Technique, and Treatments. *H. rosa-sinensis* L. (cv. Porto) plants were grown in a greenhouse located in Pisa, Italy (latitude, 43°43′ N; longitude, 10°23′ E), under natural environmental conditions (22−26 °C). The plants were grown in pots containing a soil/pumice mixture (3:1, v/v) and were irrigated twice a day with drip irrigation. Drip irrigation was carried out using a standard nutrient solution (120 g per plant) with an electrical conductivity (EC) of 2.6 dS m^{-1} and pH 6.5. The composition of the standard nutrient solution was as follows (concentrations are expressed in mol m^{-3}): 11 N-NO_3 h, 1.3 P-PO, 6.2 K^+, 3.1 Ca^{2+}, 1.2 Mg^{2+}, 9 Na^+, and 1.7 S-SO_4^{2-}. Micronutrients were added at Hoagland's concentration (in mmol m^{-3}: B 25, 88 Fe, 1 Cu, 5 Zn, and 10 Mn).

When the experiment started, 40 plants were subjected to salt-stress fertirrigation with NaCl at 200 mM, and another 40 to standard fertirrigation (as control plants). This saline condition was selected to achieve a clearly marked discoloration of the petals to be related with the qualitative and quantitative modification of flower pigments. Plants were daily irrigated during 28 days. Fresh leaf and flower samples with no apparent physical, insect, or microbial damage were collected from control and treated *Hibiscus* plants, during or at the end of the experiment, and carefully transported to the laboratory for the downstream analysis.

Flower Fresh Weight. Ten fresh flowers per treatment were collected to determine the fresh weight biomass production, expressed in grams per flower. Flowers were sampled from different *Hibiscus* plants just at the end of the experiment (after 28 days) and directly analyzed.

Abscisic Acid Content Determination, Electrolyte Leakage, and Chlorophyll *a* Fluorescence Measurements. Leaves, petals, style-stigma plus stamens, and ovary samples (100 mg fresh weight, FW) were collected, weighed, frozen in liquid nitrogen, and then stored at −80 °C until analysis. ABA was measured after extraction in distilled water (water/tissue ratio = 10:1 v/w) overnight at 4 °C. Then ABA was determined by an indirect enzyme-linked immunosorbent assay (ELISA) based on the use of DBPA1 monoclonal antibody, raised against S(+)-ABA[14] as described previously.[15]

For electrolyte leakage, the leaves were sampled every 7 days until the end of the experiment. Ten leaf disks were incubated by shaking in 5 mL of distilled water for 4 h at room temperature. After the incubation, the conductivity in the solution was determined by using an HI8733 conductivity meter (Hanna Instruments). Then, the samples were autoclaved and cooled, and the conductivity was read again in the solutions. Ion leakage was expressed as a percentage of the total conductivity after autoclaving.[16] Chlorophyll *a* fluorescence transients were determined on dark-adapted leaves kept for 30 min at room temperature, using a portable Handy PEA (Hansatech, UK). Leaf fluorescence detection was measured by fast-response PIN photodiode with RG9 long-pass filter and an excitation light intensity (ultrabright red LEDs with a peak at 650 nm) of 3000 μmol m^{-2} s^{-1} (600 W m^{-2}) (Hansatech, technical manual). The parameters measured were F_o, F_m, and F_v/F_m. JIP analysis was performed to determine the performance index (PI).

The chlorophyll fluorescence in plants adapted under ambient light conditions was measured using an FMS2 portable chlorophyll fluorometer (Hansatech, UK). The light was measured using a PAR sensor, and the parameters measured were the efficiency of the photosystem II (FPSII), maximum fluorescence under light conditions (F_m'), electron transport rate (ETR).

Anthocyanin Extracts from *Hibiscus* Petals. Anthocyanin extracts were obtained from red petals of *Hibiscus* flowers. Nine petals per treatment were carefully taken from fresh flowers just at the end of the experiment (after 28 days), and samples were frozen at −20 °C until the analysis.

The extraction of anthocyanin compounds was carried out as follows. Petals were manually divided in two pieces: the base (narrow basal portion) and the limb (cup-shaped upper portion). Each part was individually analyzed (petal bases n = 18; petal limbs n = 18). Samples were freeze-dried for 24 h (lyophilizer CRYODOS -80, Telstar Varian DS 102). The total amount of each homogeneous lyophilized powder obtained was separately extracted with methanol containing 5% of concentrated hydrochloric acid, for 12 h, with occasional agitation and sonication, in darkness at room temperature (18−20 °C). Then, supernatants were centrifuged (4190*g*, 10 min), and all of the methanolic extracts were evaporated to dryness in a rotary evaporator at temperatures below 30 °C. The residues were dissolved in 500−1000 μL of distilled water and centrifuged at 4190*g* for 3 min.

A total of 36 anthocyanin extracts were obtained for their identification and quantification by spectrophotometric and chromatographic (HPLC-DAD-MS) analysis. They corresponded to nine replicates per two treatments and two petal zones, as follows: nine petal bases from control plants; nine petal limbs from control plants; nine petal bases from salt-stress plants, and nine petal limbs from salt-stress plants. Moreover, each sample was analyzed in triplicate.

Total Anthocyanin, Flavonol, and Phenolic Contents. The spectrophotometric determinations of total anthocyanin, flavonol, and phenolic contents were performed with a Hewlett-Packard UV−vis HP8452 spectrophotometer (Palo Alto, CA, USA), using 10 mm path length glass cells and distilled water as reference.

Total anthocyanin content was determined according to the pH differential method.[17] Samples were diluted with aqueous pH 1.0 and 4.5 buffers (potassium chloride solution, 0.025 M, pH 1; sodium acetate buffer, 0.4 M, pH 4.5) and left standing for 10 min, after which

the absorbance measurements were taken at 520 and 700 nm. The method assumes that anthocyanin pigments show zero absorbance at pH 4.5. The molar extinction coefficient of cyanidin-3-glucoside was 26900, and its molecular weight was 449.2 Da. Results were expressed in milligrams of anthocyanins (as cyanidin-3-glucoside equivalent) per 100 g of petal dry weight (DW).

Total flavonol content was determined using a modification of the Glories method,[18,19] originally for wine phenols. Samples were diluted 1:10 with 10% ethanol. The method consisted of placing 0.25 mL of sample or standard in a test tube and adding 0.25 mL of 0.1% HCl in 95% ethanol and 4.55 mL of 2% HCl. The solution was mixed and allowed to sit for approximately 15 min before the absorbance was read at 360 nm. The standard used was quercetin in 95% ethanol, and the results were expressed as milligrams of flavonols (expressed as quercetin equivalents) per 100 g of petal DW.

Total phenolic content (TPC) was determined using a modification of the Folin−Ciocalteu method.[20] Absorbance was measured at 765 nm, and the results were expressed as milligrams of polyphenol (expressed as gallic acid equivalents) per 100 g of petal DW.

HPLC-DAD-ESI/MS Analysis. HPLC-DAD analysis was performed in a Hewlett-Packard 1200 series liquid chromatograph equipped with a quaternary pump, column heater, UV−vis diode array detector, automatic injector, and ChemStation software. A Zorbax SB C18 column (4.6 mm × 250 mm, 4.6 μm particle size) thermostated at 35 °C was used. All analyses were made in triplicate by direct injection of the samples, previously filtered through a 0.45 μm nylon filter (E0034, Analisis Vinicos, Spain).

Chromatographic analysis was carried out following a modification of the method described in Quijada-Morin et al.[21] The solvents used were (A) an aqueous solution (0.1%) of trifluoroacetic acid (TFA) and (B) 100% HPLC grade acetonitrile.

The elution profile was as follows: isocratic 10% B for 3.25 min, from 10 to 15% B for 12.37 min, isocratic 15% B for 5.21 min, from 15 to 18% B for 5.21 min, from 18 to 30% B for 20.84 min, and from 30 to 35% B for 5.20 min. The flow rate was 0.8 mL min^{-1}, and the injection volume was 50 μL. The UV−vis spectra were recorded from 220 to 600 nm with a bandwidth of 2.0 nm. Detection was carried out at 520 nm as the preferred wavelength.

For the anthocyanin identification, the mass spectrometer was connected to the HPLC system via the DAD cell outlet. MS detection was performed in an API 3200 Qtrap (Applied Biosystems, Darmstadt, Germany) equipped with an ESI source and a triple-quadrupole ion trap mass analyzer that was controlled by Analyst 5.1 software. Zero grade air served as nebulizer gas (GS1) and turbo gas (GS2) for solvent drying. Nitrogen served as curtain (CUR) and collision gas (CAD). MS analysis was carried out in positive mode (ESI+). The setting used was optimized by direct infusion of a malvidin 3-*O*-glucoside solution: declustering potential (DP), 41 V; entrance potential (EP), 7.5 V; ion spray voltage (IS), 5000 V; GS1, 40 psi; GS2, 50 psi (600 °C); CUR, 20 psi; and CAD, set as "high". Both quadrupoles were set at unit resolution. Mass method consisted of three mass experiments: full mass analysis (EMS mode, collision energy (CE) 10 V), MS2 analysis (EPI mode, CE 25 V), and MS3 analysis (CE 30 V, excitation energy (AF2) 50 V). Spectra were recorded between m/z 150 and 1100.

Anthocyanin compounds were identified by comparison of their retention time, UV−vis spectra, and mass spectra features with data reported in the literature. Quantification of anthocyanins was calculated from the peak areas recorded at 520 nm using a calibration curve purchase standard of cyanidin-3-glucoside. Results were expressed as milligrams per 100 g of petal DW.

Color Analysis of *Hibiscus* Petals by Digital Image Analysis. Prior to the frozen treatment, the same fresh petals considered for the anthocyanin determination (n = 9 per treatment) were used to analyze the color of *Hibiscus* flowers by digital image analysis.

The image acquisition was performed with a DigiEye imaging system[22] consisting of a calibrated digital camera connected to a controlled illumination cabinet and a computer with appropriate software (DigiPix). The digital camera used for image acquisition was a 10.2-megapixel Nikon D80 with Nikkor 35 mm f/2D objective. It was connected via USB to a computer with a Pentium IV processor at 3.00 GHz. The cabinet (VeriVide DigiEye, Leicester, UK) was equipped with two fluorescent tubes that emulate the standard illuminant D65 and offer stable lighting conditions. Lamps were switched on at least 10 min before being used, according to the manufacturer's indications, to stabilize them. The camera was calibrated with the Gretag Macbeth Color Checker DC Chart to characterize its response by relating the RGB signals to CIE specifications under the fixed lighting conditions in the cabinet. For the color measurements, fresh petal samples were appropriately placed into the cabinet using a white background that ensures an adequate segmentation of sample image.

For each image, a 625 × 625 pixel fixed area was taken and CIELAB color parameter data (L^*, a^*, b^*, C^*_{ab}, and h_{ab}) were estimated according to the method of Rodríguez-Pulido et al.,[23] with the software Matlab.[24] The color data obtained were averages of three measurements. In addition, the Euclidean distance between two points in the three-dimensional space define by L^*, a^*, and b^* was used to calculate the color difference between control and saline samples as follows: $\Delta E^*_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$.

Statistical Analysis. All statistical analyses were performed using Statistica v.8.0 software.[25] Univariate analysis of variance (ANOVA) was applied, using the general linear model procedure (GLM), to establish whether mean values of the phenological and physicochemical data obtained differed significantly as a function of the salinity treatment applied. The means values were compared by t test, Bonferroni test, or Tukey test at a significance level of $p < 0.05$. Correlations between color parameters and anthocyanin content were studied by forward stepwise multiple regression at a significance level of $p < 0.05$.

RESULTS AND DISCUSSION

Effect of Salt Stress on Abscisic Acid Content, Ion Leakage, and Photochemical Efficiency. The application of salt stress for a prolonged period influenced the morphology and physiology of *H. rosa-sinensis* plants.

In our conditions, the saline irrigation caused a significant decrease in flower fresh mass, which was about 60% after 28 days of treatment. The biomass reduction due to salt stress may be determined either by the decreased availability of water or by the NaCl toxicity.[26] Previous research on other ornamental flowers showed that quality parameters such as flower weight were unfavorably affected by salinity.[27] In fact, plants subjected to saline irrigation require additional energy in plant cells. This extra metabolic energy is likely to be consumed in processes related to osmotic adjustment within the cells, and hence less carbon is available for growth.[28] This is particularly relevant for plant visual quality, because the most decorative elements for ornamental plants are usually the flowers.

As reviewed by Ashraf and Harris,[29] salt-sensitive species showed an increase in electrolyte leakage in the leaves under saline conditions. Electrolyte leakage is an indicator for the extent of membrane damage under salt stress and was determined in the fully expanded leaves of salt-stressed *H. rosa-sinensis*. Low values of electrolyte leakage were recorded in the controls (0 mM). The presence of NaCl in the rooting medium induced a significant increase in electrolyte leakage in the leaves (Figure 1) and was greater as exposure time to saline treatment increased, reaching maximum values after 28 days.

The hormone ABA is well-known as a mediator in plant responses for both biotic and abiotic stresses. Endogenous ABA concentrations fluctuate in response to environmental conditions,[30] allowing plants to survive under adverse conditions, such as salt stress. In *H. rosa-sinensis* plants, salinity increased ABA content in leaves (Figure 2). This is consistent with other plant species that increase ABA production in response to salinity.[31] Moreover, ABA levels varied among the flower tissues

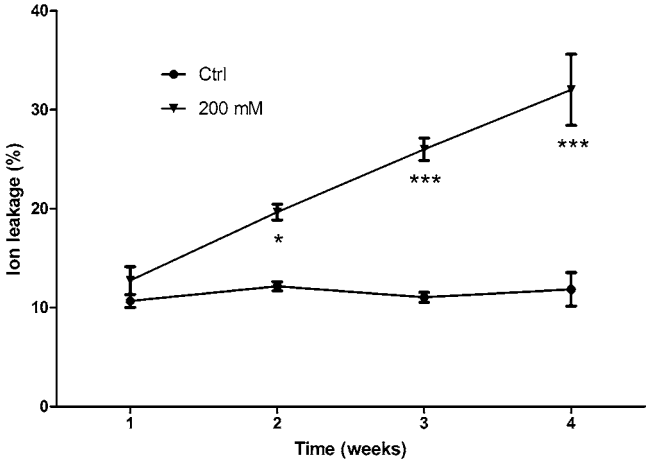

Figure 1. Cell damage trend over 28 days in *H. rosa-sinensis* leaves (means ± SD, $n = 3$). Asterisks indicate significant differences (Bonferroni post-test, $p < 0.05$) of ion leakage (%) after saline irrigation (related to the control).

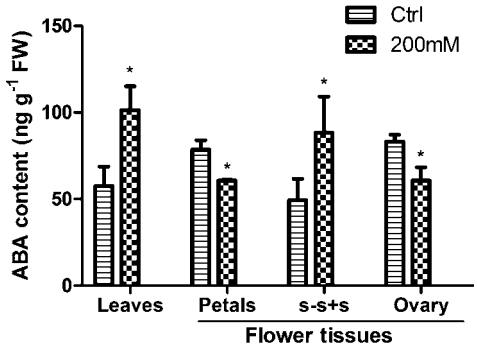

Figure 2. Effect of 200 mm NaCl on ABA content of *H. rosa-sinensis* tissues after 28 days of saline irrigation (means ± SD, $n = 4$). Asterisks indicate statistical differences (t test, $p < 0.05$) within the same tissue: s-s+s, style-stigma plus stamen.

examined, and as shown in Figure 2, its content enhanced in the style-stigma plus stamens, whereas in petals and ovary tissues it decreased. A possible relationship among the differential tissue rate of growth under salinity could explain the divergent trend of ABA levels in floral organs and needs to be further explored.

To better characterize the physiology of *Hibiscus*, the chlorophyll *a* fluorescence was measured. In dark-adapted leaves the PI declined drastically after 28 days of saline treatment, being 8.4 units in the control leaves, whereas in the treated plants it was 3.9 units. PI is an overall index that combines different fluorescence parameters and has been frequently employed to understand the responses of the photosynthetic apparatus to different physiological and environmental conditions.[10,32] Our results confirmed PI as a sensitive indicator of salt stress. Also, the chlorophyll *a* fluorescence measured from light-adapted leaves subjected to saline irrigation revealed a statistically relevant reduction in the relative quantum yield of PSII (0.7 in the control plants versus 0.4 under saline treatment), and these results are in agreement with the literature.[33]

To summarize, salinity promoted several physiological and biochemical changes in *Hibiscus* plant tissues including reduction of flower biomass and parameters associated with the functioning of the photosynthetic apparatus as well as fluctuation of ABA levels and increase in electrolyte leakage.

Effect of Salt Stress on Anthocyanin Composition and Color. Considering the heterogeneous color pattern of *H. rosa-sinensis* flowers with two red zones visually discernible, the base and the limb of petals were analyzed as separate groups to determine possible differences regarding their anthocyanin composition and content as well as to evaluate the influence of salt stress in each zone.

Results showed that the base and limb of flowers presented the same anthocyanin profile. The chromatographic analysis of the extracts, registered at 520 nm, shows the presence of five anthocyanins (Figure 3a), all of them identified as cyanidin derivatives according to their chromatographic and spectrometric features obtained in the HPLC-DAD-MS analysis (Table 1).

The major anthocyanin found in *H. rosa-sinensis* flowers was identified as cyanidin-3-sophoroside (peak 1), which accounted for 80% of total peak area. The mass spectrum of peak 1 (Figure 3b) obtained in the ESI positive mode exhibited an ion at m/z 611. MS/MS fragmentation of m/z 611 produced a daughter ion at m/z 287, which was indicative of the cyanidin moiety, as previously found in the literature.[34]

Peak 2 was identified as cyanidin-3-sambubidoside on the basis of its characteristic molecular ion at m/z 581 and a major fragment in MS^2 at m/z 287, which has been described as one of the most common anthocyanins in diverse *Hisbiscus* spp.[1] However, in our *H. rosa-sinensis* extracts, it was detected only in trace levels.

Peak 3 represented the second predominant anthocyanin in the analyzed extracts accounting for nearly 12% of total anthocyanins. Its fragmentation pattern showed a molecular ion at m/z 639, which produced two MS^2 daughter ions at m/z 449 ($M^+ - 190$), which corresponds to a cyanidin-hexose moiety, and m/z ratio at 287 ($M^+ - 190 - 162$), which corresponds to a cyanidin-aglycone moiety (Figure 3c). Although the MS^2 fragmentation pattern could not be confirmed with reported data, it indicated the sequential losses of an unidentified substituent (190 amu) and one hexose residue (162 amu, i.e., glucose as abundant sugar in plants) from aglycone. According to the literature, the glycoside moieties of anthocyanins are usually esterified with different organic or phenolic acids. Among them, the hibiscus acid has been described as a common compound of *Hibiscus* species showing a characteristic loss of 190 amu[35] when it appears as an esterification substituent. Moreover, the acylated nature of this compound is consistent with the relative retention time in the HPLC analysis, eluting before the corresponding 3-glycosides derivatives. Thus, peak 3 would tentatively correspond to a cyanidin-3-glucoside esterified by a hibiscus acid moiety.

In addition to the above-mentioned compounds, another two minor pigments were also detected (peaks 4 and 5), although their absorption or mass spectra were insufficient to allow speculation about their identity. Their structures still need to be elucidated by comparison of MS data with reference standards or using other spectroscopic techniques such as NMR.

The concentrations of the different anthocyanins detected by HPLC-DAD-MS together with the total content of anthocyanins, flavonols, and polyphenols assessed by rapid spectrophotometric methods are shown in Table 2, where the effect of saline fertirrigation can be observed.

Although there were five anthocyanins detected, quantitative differences for all of the individual compounds were observed

[a]tr, traces.

among the two distinct areas of the petals. Generally, the petal limb contained more anthocyanins and other phenolics than the base, which supports the heterogeneous color pattern exhibited by *H. rosa-sinensis* flowers. For the control sample, the average values of total anthocyanins, flavonols, and polyphenolic contents in the petal limb were found to be 821.5 ± 37.3, 23.0 ± 0.9, and 2252.4 ± 129.4 mg/100 g DW, whereas the global levels in the petal base were 228.0 ± 48.9, 12.9 ± 1.2, and 1077.9 ± 98.5 mg/100 g DW, respectively.

As can be observed, the saline treatment significantly ($p < 0.05$) affected the anthocyanin composition of *Hibiscus* flowers reducing its content (Figure 3a), but the magnitude of the effect was different in each zone of the petal (Table 2). The increase in the salinity of the nutrient solution was accompanied by a stronger decrease of the total anthocyanin content in the base than in the limb (30 vs 20%, approximately), which is mainly due to the cyanidin-3-sophoroside reduction in both cases. In particular, some of the individual anthocyanin compounds present in the limb were not affected by the saline treatment, which could explain the lower loss of pigments in this zone of the flower. As reported by other authors,[3] differences between the glycosyl units and acyl groups attached to the aglycone, and the site of their bonding, have a significant influence on the stability and reactivity of the anthocyanin molecule.

Furthermore, the saline fertirrigation caused a negative impact in the accumulation of other phenolic compounds because their total content was lower in flowers from plants grown with salinity stress conditions (25 and 15% lower for total flavonols and 29 and 10% lower for total polyphenols in the base and limb, respectively). There is considerable controversy in the literature concerning the positive and negative effects of salt stress on the phenolic composition of many plant species. Some authors have shown that the application of moderate salt stress stimulates anthocyanin synthesis.[7] However, our results are in agreement with those reported by Li et al.,[36] who observed that the anthocyanin content in grapes was negatively affected by high saline conditions (100−150 mM NaCl).

With regard to the color characteristics of *H. rosa-sinensis* flowers, Figure 4 shows the three-dimensional colorimetric representation of a petal sample (control plant) obtained by digital image analysis. It presents the L^*, C^*_{ab}, and h_{ab} CIELAB values assigned to each pixel of the petal image grouped with regard to the petal zone (base and limb; n = 100 pixels/petal zone), which provides a full characterization of the color variability of samples.[37] As can be seen, the color of the base

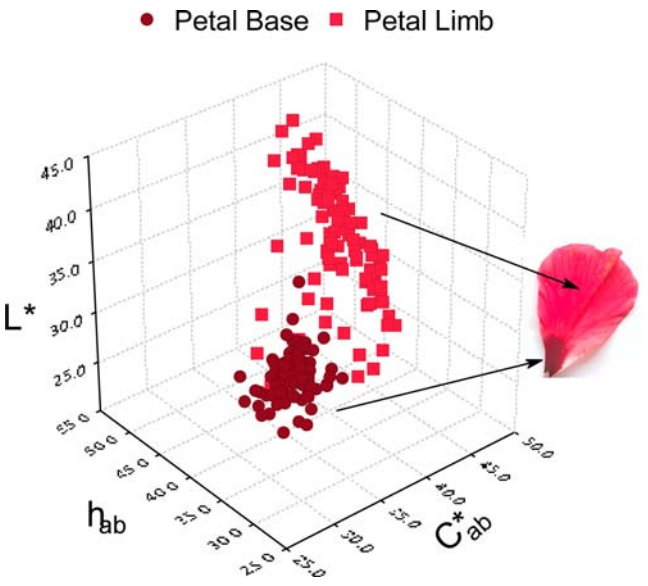

Figure 4. Tridimensional colorimetric representation (L^*, C^*_{ab}, h_{ab} CIELAB parameters) for a *H. rosa-sinensis* petal (base and limb; n = 100 pixels/flower zone) analyzed by digital image analysis.

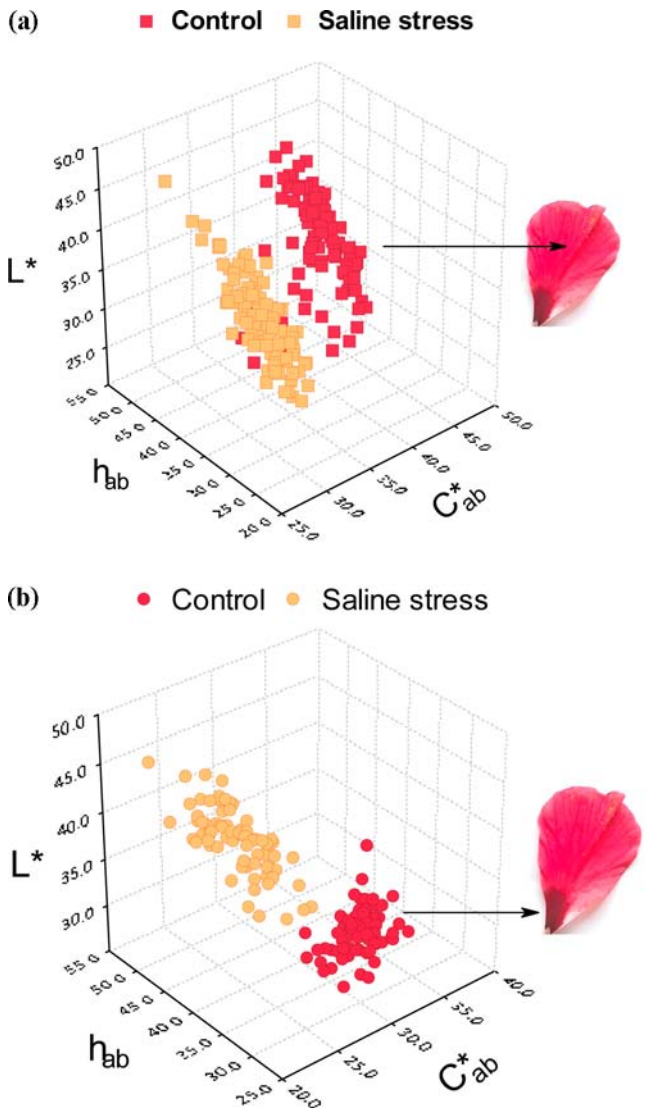

Figure 5. Changes in lightness (L^*), chroma (C^*_{ab}), and hue (h_{ab}) of an *H. rosa-sinensis* petal as a function of the fertirrigation treatment (control and 200 mM NaCl): (a) petal limb; (b) petal base (n = 100 pixels/flower zone, by digital images analysis).

could be easily distinguishable from the limb. Color points corresponding to the limb area appeared more disperse than those of the base and showed higher values of lightness (L^* ranging from 23 to 42 vs from 26 to 37 CIELAB units, respectively), chroma (C^*_{ab} ranging from 31 to 47 vs from 29 to 35 CIELAB units), and hue (h_{ab} ranging from 35° to 53° vs from 30° to 41°). This meant that the petal limb exhibits more vivid color with red-orange hues, which is consistent with the higher accumulation of red-orange forms of anthocyanins (cyanidin derivatives) in this flower zone.[38] On the contrary, the base of the petal corresponds to a more homogeneous redness area with darker and less saturated color, due to its lower concentration in cyanidin derivative pigments. Apart from the different amounts in pigments, the differences observed for the total content of flavonols and polyphenols in each petal zone (Table 2) may also account for the natural color variability of *Hibiscus* flowers because colorless phenolics are usually implied in the color expression of anthocyanins by means of copigmentation reactions contributing to color changes.[39]

For the whole set of samples, the mean color values for each petal zone regarding the fertirrigation treatment are summarized in Table 2, where p values for comparison among control and saline samples are shown. Results indicate that the color of *Hibiscus* flowers was significantly ($p < 0.05$) affected by salt treatment, which was in accordance with the effect induced in the pigment composition. The addition of 200 mM NaCl into nutrient solution resulted in quantitative (L^* and C^*_{ab}) and qualitative (h_{ab}) color variations both in the base and in the the limb of *Hibiscus* petals (Figure 5). Specifically, salt stress resulted in a general loss of color, as can be seen in Table 2. In each zone, L^* and h_{ab} values increased, whereas C^*_{ab} values decreased (L^* by 21 and 11%, h_{ab} by 20 and 5%, and C^*_{ab} by 12 and 3% in the base and limb, respectively), so *Hibiscus* flowers exhibited clearer and less vivid red color when they were fertirrigated under salt stress conditions, the effect being more marked in the base of the petals.

These results were also confirmed through the quantitative mean color difference (ΔE^*_{ab}) calculated among control and saline samples in each petal zone, which were 4.1 and 9.6 CIELAB units for the petal limb and base, respectively. Taking into account that ΔE^*_{ab} of up to 3 CIELAB units indicates color differences appreciable to the human eye,[40] it was confirmed that more important and hence more easily perceptible color loss was caused in the base of the *Hibiscus* petal, which is consistent with the higher reduction of the pigment concentration in this flower zone.

Apart from the assessment of color itself, the objective measurement of color can be harnessed for the rapid determination of pigments. In this regard, color measurements offer a series of advantages for this purpose, such as rapidity, nondestructiveness, and simplicity, among others. A forward stepwise multiple regression was performed for predicting the total anthocyanin content (mg/100 g DW) from the colorimetric data obtained by image analysis. In this respect, not only were conventional colorimetric coordinates (CIELAB) considered, but also other parameters related to heterogeneity of color that image analysis allows to be measured were evaluated. To quantify the heterogeneity of each sample, the

dx.doi.org/10.1021/jf502444u | J. Agric. Food Chem. 2014, 62, 6966−6974

point cloud produced when the color of all the pixels belonging to a sample was considered. These point clouds were fitted into an ellipsoid, and then the shape and orientation of these ellipsoids were included in the data set of the continuous predictors into the multiple regression. A deeper explanation of these parameters as well as the construction of ellipsoids can be found in Rodríguez-Pulido et al.[23] When both salt stress and control samples were used, the model included sequentially the variables chroma (C^*_{ab}), hue (h_{ab}), and the width of the ellipsoid that the pixels made up, and an $R^2 = 0.80$ was reached. However, the model improved when salt stress and control samples were used individually. For salt stress samples ($R^2 = 0.85$), the model included sequentially chroma (C^*_{ab}), hue (h_{ab}), and the orientation angle of the fitting ellipsoid. For control samples ($R^2 = 0.90$), the model included sequentially the length of the fitting ellipsoid, hue (h_{ab}), the orientation angle, and the mean color difference from the mean (MCDM).

As a summary, it was concluded that salt stress influences several physiological and biochemical changes in *Hibiscus* plant tissues including reduction of flower biomass and parameters associated with the functioning of the photosynthetic apparatus as well as fluctuation of ABA levels and increased electrolyte leakage. Results showed a higher preferential accumulation of pigments and other phenolics in the limb than in the base, which supports the heterogeneous color pattern exhibited by *H. rosa-sinensis* flowers. The increase in salinity was also accompanied by a decrease of the levels of most of the individual anthocyanin compounds present in *H. rosa-sinensis* flower, as well as of its total anthocyanin and phenolic contents, which was reflected in an important loss of color. Changes in the color as a result of salt stress occurred in different ways depending on the zone of the petal, being more marked at the basal portion of petals.

Due to the shape and heterogeneity of these samples, image analysis arises as a good alternative to measure their color as well as other features related to the appearance. Moreover, the anthocyanin content of petals could be estimated from their colorimetric data by applying multivariate statistical techniques. Although image analysis is not yet a substitute for conventional chemical analysis, it could be an attractive alternative due to its simplicity, versatility, and low cost, and thus it could become a useful way to assess the chemical characteristics and quality of biological samples of *Hibiscus* crops by controlling the variables.

oxidation. In fact, it has been recently reported that the addition of dehydrated waste grape skins during winemaking increased the concentration of some flavonoids in wines, preventing color loss during storage.[17,18]

Despite their potential use in enology, winemaking byproducts have received little attention in comparison to other wine additives (wood chips, enzymes, enological tannins, etc.), probably due to the difficulties related to the technical and legal concerns of its application. However, their application as natural wine additives could represent a sustainable alternative to maximize the exploitation of this valuable agricultural waste as well as to improve the quality of wines, making them more competitive. In this sense, further investigations are needed to advance the knowledge of the contribution of these agricultural byproducts to wine color and color stability.

Therefore, the main objective of this study was to compare the potential of different white winemaking byproducts (pomace, seeds, skins, and stems) as natural sources of antioxidants and copigments, in a model solution. The information reported in this work could be useful for high production winemaking areas.

MATERIALS AND METHODS

Standards and Reagents. Gallic acid, protocatechuic, caffeic, and caftaric acids, (+)-catechin (C), (−)-epicatechin (EC), quercetin, kaempferol, myricetin, sodium carbonate, potassium persulfate, and tartaric acid were purchased from Sigma-Aldrich (Madrid, Spain), and malvidin-3-glucoside was from Extrasynthese (Genay, France). Procyanidin dimer B1 standard was isolated in the laboratory by semipreparative HPLC.[19]

2,2-Azinobis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox) were purchased from Fluka (Madrid, Spain), and HPLC grade acetonitrile was from Carlo Erba (Rodano, Italy). Folin reagent, ethanol, and formic acid were obtained from Panreac (Barcelona, Spain).

Winemaking Byproducts and Sample Preparation. White winemaking byproducts from Zalema grapes (*Vitis vinifera* sp.) used in this study were pomace (PM), skins (SK), seeds (SD), and stems (ST). They were obtained from a winery located in Condado de Huelva Designation of Origin (southwestern Spain). The Zalema cultivar was selected because it is a high production variety rich in phenolic compounds that represents the main and more extensively white grape cultivated in the zone.

Pomace is the main organic winemaking byproduct generated from grape vinification, which is constituted by a mixture of skins and pulp rests, seeds, and stems. Three kilograms of pomace was collected the day of harvest after Zalema grapes were pressed for winemaking.

To be also individually used in the experiments, particles of stems, seeds, and skins were manually separated from the pomace. All winemaking byproducts were stored at −20 °C and further freeze-dried (lyophilizer Cryodos-80, Telstar Varian DS 102) until extracted. The moisture contents of byproducts were PM, 50%; ST, 40%; SD, 30%; and SK, 70% SK.

The extraction of the nonanthocyanin phenolic compounds from each winemaking byproduct was carried out in a wine-like medium containing 5 g/L tartaric acid in 12% ethanol, buffered with 1 M NaOH to pH 3.6, and ionic strength adjusted to 0.2 M by the addition of NaCl. For this purpose, 2 g of the homogeneous lyophilized powder of samples (PM, SD, SK, and ST) was individually macerated in 15 mL of wine-like medium for 12 h at room temperature (18−20 °C), with occasional agitation and sonication. The supernatants were centrifuged (4190*g*, 10 min) to separate out the liquid fraction containing the phenolic compounds extracted, which was filtered through 0.45 μm Millipore-AP20 filters (Bedford, MA, USA).

The crude phenolic solution obtained from each winemaking byproduct was analyzed for its phenolic composition (spectrophotometric and chromatographic analysis) and antioxidant activity. Also, they were used as a crude mixture of colorless phenolics (copigments) of wine anthocyanins in copigmentation experiments.

Total Phenolic Content. The spectrophotometric determination of the total phenolic content was performed with a Hewlett-Packard UV−vis HP8453 spectrophotometer (Palo Alto, CA, USA), using 10 mm path length glass cells and distilled water as reference.

The total phenolic content of the samples was determined using the Folin−Ciocalteu method.[20] Briefly, 0.25 mL of sample, 1.25 mL of Folin−Ciocalteu reagent, and 3.75 mL of a solution of sodium carbonate at 20% were mixed, and distilled water was added to make up a total volume of 25 mL. The solution was homogenized and left to stand for 120 min for the reaction to take place and stabilize. Absorbance was measured at 765 nm. Gallic acid was employed as a calibration standard, and results were expressed as gallic acid equivalents (mg GAE/L).

Phenolic Composition Analysis. Rapid-resolution liquid chromatography (RRLC) was performed on an Agilent 1260 system equipped with a diode array detector. Samples were filtered through a 0.45 μm pore size membrane filter, and 30 μL of sample was injected in a C18 Poroshell 120 column (2.7 μm particle size, 5 cm × 4.6 mm; Agilent, Palo Alto, CA, USA) maintained at 25 °C. Water/formic acid (99:1, v/v) as solvent A and acetonitrile as solvent B were used, setting the flow rate at 1.5 mL/min. The linear gradient elution was 0 min, 100% A; 5 min, 95% A and 5% B; 20 min, 50% A and 50% B; 22 min, 100% A; 25 min, 100% A. The wavelengths of detection were 280 nm (flavanols and benzoic acids), 320 nm (hydroxycinnamic acids and their tartaric esters), and 370 nm (flavonols).

Phenolic compounds were identified by their retention time, UV−vis spectra, and mass spectra data in an API 3200 Qtrap (Applied Biosystems, Darmstadt, Germany) equipped with an ESI source and a triple-quadrupole ion trap mass analyzer, as described by Jara-Palacios et al.[21] The identification of phenolic compounds was achieved by comparison of the retention times and mass spectra with those of the available pure standards and our data library.

The external calibration method was used for quantification by comparing the areas with standards of gallic, protocatechuic, caffeic, and *p*-coumaric acids, catechin, epicatechin, procyanidin B1, quercetin, and kaempferol. Caftaric and coutaric acids were quantified using the calibration curves of caffeic and *p*-coumaric acids, respectively. Procyanidin dimers B2, B3, and B4, procyanidin B2−3-*O*-gallate, trimers, and tetramer were quantified with the calibration curve of procyanidin B1. Quercetin and isorhamnetin derivatives were quantified as quercetin and kaempferol drivatives as kaempferol.

Total phenolic acids, total flavanols, total flavanol oligomers, and total flavonols were also calculated by the sum of individual phenolic acids, flavanols, flavanol oligomers, and flavonols identified, respectively. The samples were analyzed in triplicate and the results expressed as milligrams per liter.

Antioxidant Activity. The antioxidant activity was measured in vitro on the basis of the ability to scavenge the $ABTS^{\bullet+}$ radical.[22] The $ABTS^{\bullet+}$ radical was produced by the oxidation of 7 mM ABTS with potassium persulfate (2.45 mM) in water. The mixture was kept in the dark at room temperature for 16 h before using it, and then the $ABTS^{\bullet+}$ solution was diluted with phosphate-buffered saline (PBS) at pH 7.4 to give an absorbance of 0.70 ± 0.02 at 734 nm. Then, 50 μL of each sample was mixed with 2 mL of the $ABTS^{\bullet+}$ diluted solution and vortexed for 10 s, and the absorbance was measured at 734 nm after 4 min of reaction at 30 °C. Results were obtained by interpolating the absorbance of samples on a calibration curve obtained with Trolox (30−1000 μM). Three independent experiments in triplicate were performed for each sample, and the results were expressed as Trolox equivalent antioxidant activity (TEAC; μmol of Trolox equivalent (TE) with the same antioxidant activity of 1 L of sample).

Copigmentation Experiments. Copigmentation experiments were carried out in a wine-like medium using a crude anthocyanin solution prepared from Syrah red grapes and different crude phenolic solutions (colorless copigments) obtained from white winemaking byproducts.

The crude anthocyanin solution was obtained by macerating 1 g of homogeneous lyophilized powder of Syrah skins in 20 mL of wine-like medium (the same as previously described) for 12 h with occasional

agitation and sonication. Then, it was centrifuged (4190g, 10 min) and the supernatant filtered through 0.45 μm Millipore-AP20 filters (Bedford, MA, USA). The phenolic composition (anthocyanin pigments and other colorless monomeric phenols) of the crude anthocynin solution was analyzed by HPLC following the method described in Gordillo et al.[23]

Copigmented solutions were prepared by adding separately each crude phenolic solution from winemaking byproducts (PM, ST, SD, and SK) to the crude anthocyanin solution at seven levels (50, 100, 200, 300, 400, 500, and 600 mg/L). The final anthocyanin concentration was the same in all cases (200 mg/L). All of the solutions (2 mL) were prepared in triplicate and equilibrated to reach equilibrium for 2 h and stored closed in darkness at 25 °C, after which their absorption spectra were recorded.

Colorimetric Measurement. The absorption spectra (380−770 nm) of all solutions were recorded at constant intervals ($\Delta\lambda$ = 2 nm) with a Hewlett-Packard UV−vis HP8453 spectrophotometer (Palo Alto, CA, USA), using 2 mm path length glass cells and distilled water as a reference.

The CIELAB parameters (L^*, a^*, b^*, C^*_{ab}, and h_{ab}) were calculated from the absorption spectra by using the original software CromaLab,[24] following the recommendations of the Commission International de L'Eclariage:[25] the 10° Standard Observer and Standard Illuminant D65.

Color difference (ΔE^*_{ab}) was determined by applying the CIE76 color difference formula. It was calculated as the Euclidean distance between two points in the three-dimensional CIELAB space defined by L^*, a^*, and b^*: $\Delta E^*_{ab} = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$. It is assumed that color differences (ΔE^*_{ab}) >3−5 units can be perceived by an average observer.[26]

Copigmentation Measurements. The spectrophotometric determination of the magnitude of the copigmentation was made by comparing the absorbance at 520 nm of the crude anthocyanin solution (A_0) and the absorbance at 520 nm of the same solution containing different crude phenolic mixtures from white winemaking byproducts (A_c), at each concentration level and expressed as the percentage $[(A_c - A_0)/A_0] \times 100$.[27]

The color variation due to copigmentation was also evaluated by tristimulus colorimetry according to the methodology described in Gordillo et al.,[16] which offers an objective measurement of color because

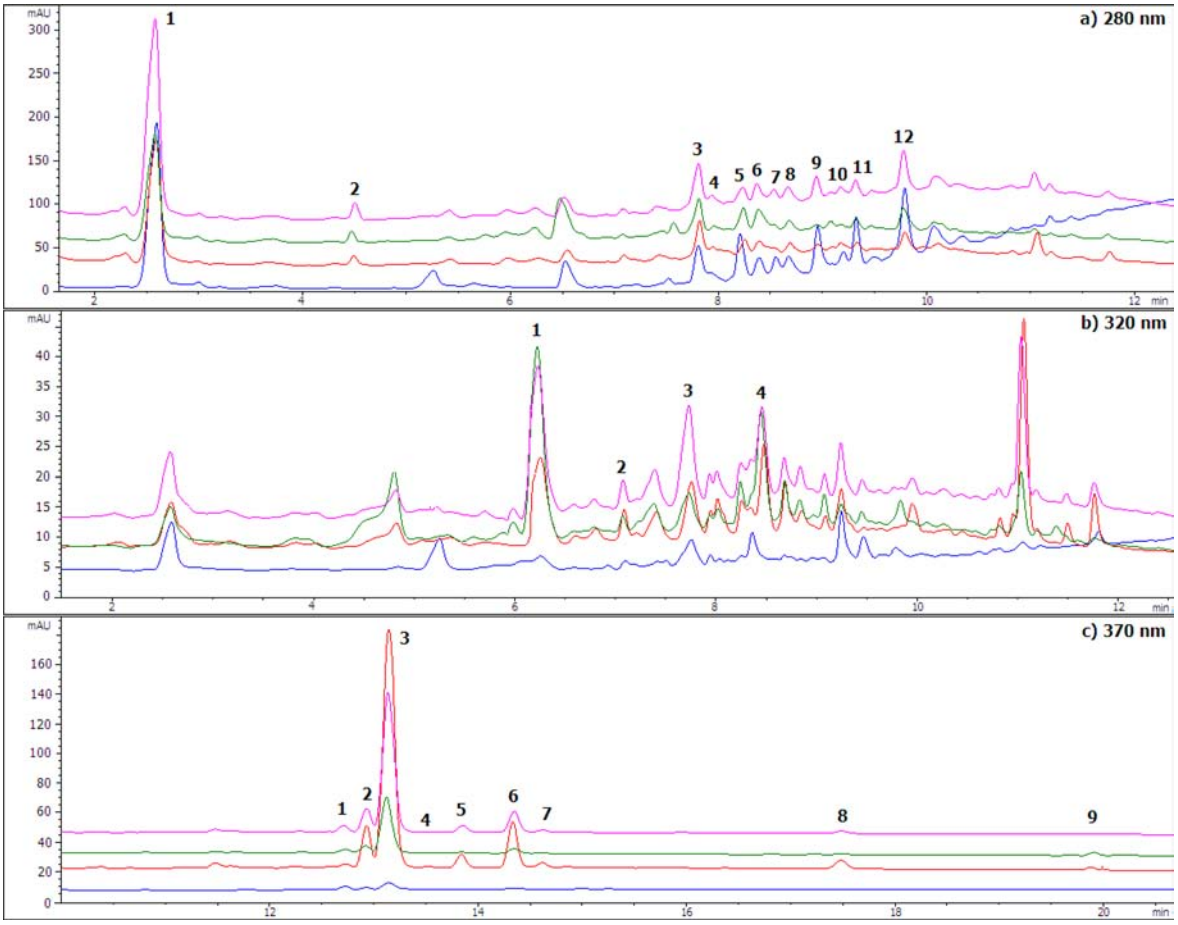

Figure 1. RRLC chromatograms recorded at 280, 320, and 370 nm of crude phenolic solution from seeds (blue), skins (red), stems (green), and pomace (magenta). Peaks: (a) 1, gallic acid; 2, protocatechuic acid; 3, procyanidin B1; 4, procyanidin B3; 5, catechin; 6, trimer C−C−EC; 7, tetramer; 8, procyanidin B4; 9, trimer C1; 10, procyanidin B2; 11, epicatechin; 12, procyanidin B2-*O*-gallate; (b) 1, caftaric acid; 2, *cis*-coutaric acid; 3, *trans*-coutaric acid; 4, caffeic acid; (c) 1, quercetin 3-*O*-rutinoside; 2, quercetin 3-*O*-glucuronide; 3, quercetin 3-*O*-glucoside; 4, quercetin pentose; 5, kaempferol hexoside; 6, kaempferol 3-*O*-glucoside; 7, isorhamnetin 3-*O*-glucoside; 8, quercetin; 9, kaempferol.

it is based on the consideration of the whole visible spectrum and allows the real assessment of color to be obtained. Following this methodology, diverse color difference formulas were applied in the CIELAB color space by using the scalar (L^*, a^*, b^*) and cylindrical (L^*, C^*_{ab}, h_{ab}) CIELAB color coordinates of samples. This provides a better evaluation of the quantitative and qualitative color implications of the copigmentation and their incidence on visual perception. The new colorimetric variables were determined as follows.

The total color of each sample was assessed as the CIELAB color difference (ΔE^*_{ab}) applied between its color (L^*, a^*, and b^*) with respect to distilled water ($L^* = 100$, $a^* = 0$, $b^* = 0$), as shown in eq 1. It represents a quantitative color attribute.

$$\text{total color: } \Delta E^*_{ab} = [(L^* - 0)^2 + (a^* - 0)^2 + (b^* - 0)^2]^{1/2} \quad (1)$$

The total color difference induced by copigmentation was assessed as the CIELAB color difference (ΔE^*_{ab}) applied between the color of the crude anthocyanin solution (L^*_0, a^*_0, and b^*_0) and the color of the same solution copigmented with each crude phenolic mixture from white winemaking byproducts (L^*_c, a^*_c, and b^*_c), as shown in eq 2:

$$\text{total color difference: } \Delta E^*_{ab(c-0)} = [(L^*_c - L^*_0)^2 + (a^*_c - a^*_0)^2 + (b^*_c - b^*_0)^2]^{1/2} \quad (2)$$

The relative contribution (%) of lightness, chroma, and hue to each total color difference induced by copigmentation was calculated by means of the color formulas shown in eqs 3, 4, and 5. They represent the weight of the three color attributes that make up the total color difference.

$$\text{relative contribution (\%) of lightness: } \%\Delta L = [(\Delta L_{c-0})^2/(\Delta E^*_{ab(c-0)})^2] \times 100 \quad (3)$$

$$\text{relative contribution (\%) of chroma: } \%\Delta C = [(\Delta C_{c-0})^2/(\Delta E^*_{ab(c-0)})^2] \times 100 \quad (4)$$

$$\text{relative contribution (\%) of hue: } \%\Delta h = [(\Delta h_{c-0})^2/(\Delta E^*_{ab(c-0)})^2] \times 100 \quad (5)$$

Δh_{c-0} being deduced as follows:

$$\Delta h_{c-0} = [(\Delta E^*_{ab(c-0)})^2 - ((\Delta L_{c-0})^2 + (\Delta C_{c-0}))^2]^{1/2}$$

Statistical Analysis. All statistical analyses were performed using Statistica v.8.0 software.[28] Univariate analysis of variance (Tukey test) was applied to establish differences for the phenolic composition, antioxidant activity, and copigmentation effects among the crude phenolic solutions from winemaking byproducts (GP, SD, SK, and ST). Moreover, correlations between the phenolic composition (main phenolic groups or individual phenolic compounds), and the antioxidant activity was studied by linear and multiple regressions. In all cases (differences or correlations), the statistically significant level was considered at $p < 0.05$.

RESULTS AND DISCUSSION

Phenolic Composition. A total of 24 phenolic compounds were identified and quantified in the crude phenolic solutions from winemaking byproducts by using the methodology and chromatographic conditions previously described. The phenolic profile of samples showed the presence of several types of monomeric and oligomeric colorless phenols belonging to diverse phenolic families. The benzoic acids, hydroxycinnamic acids, flavanols, and flavonols identified were the expected, well-known, compounds usually present in grapes. It included six phenolic acids (gallic, protocatechuic, caftaric, caffeic, *cis*-coutaric, and *trans*-coutaric acids); two monomeric flavanols (catechin and epicatechin), eight oligomeric flavanols (procyanidins B1, B2, B3, B4, and B2−3-*O*-gallate, two trimers, and one tetramer); and eight flavonols (quercetin and kaempferol aglycones, and 3-glycoside conjugated forms of quercetin, kaempferol, and isorhamnetin).

[a]Sum of individual anthocyanins, phenolic acids, or flavonols identified, respectively.

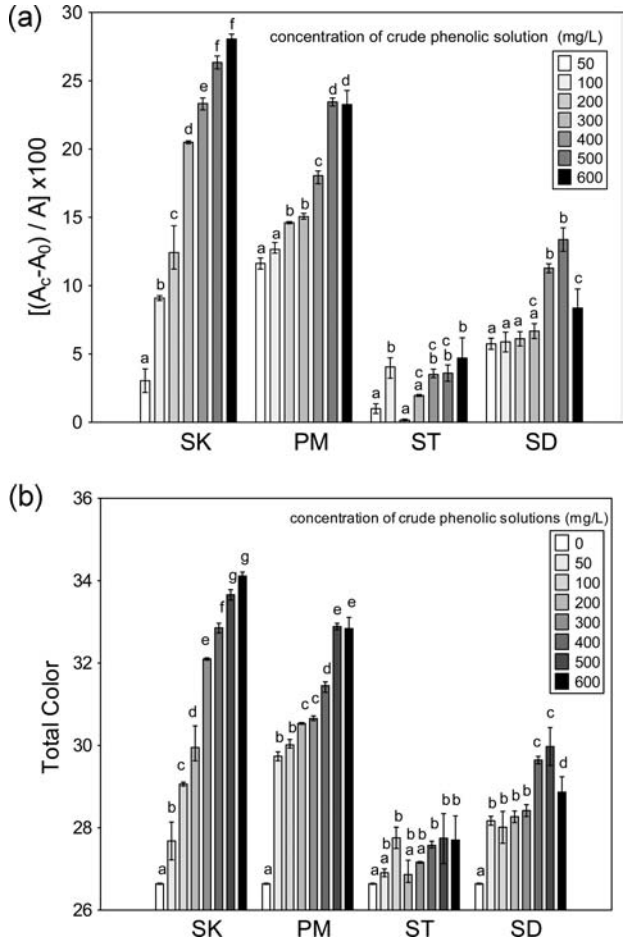

Figure 2. (a) Magnitude of copigmentation and (b) total color of the crude anthocyanin solution containing increasing concentrations of crude phenolic solutions from Zalema winemaking byproducts (SK, skins, PM, pomace; ST, stems; SD, seeds); mean ± SD, n = 3. Different letters in the same byproduct indicate significant differences (p < 0.05).

Table 1 summarizes the concentration for the mentioned phenolic compounds (mg/L) and the total phenolic content (mg GAE/L) of samples, showing the statistical differences found among them. In general terms, all samples presented important contents of total phenolics indicating that considerable amounts of bioactive compounds can be recovered from Zalema winemaking byproducts. As white wines are commonly elaborated by applying a shorter maceration time than used for red wines, the pomace obtained from white vinification is not as exhausted as that from red vinification, which increases its industrial value as a richer agricultural byproduct.[18] Nevertheless, significant differences (p < 0.05) were found for the total phenolic content among samples depending on the type of winemaking byproduct. The crude phenolic solution from SD showed the highest total phenolic content (around 2-fold the concentration of the other samples), which is consistent with previous studies.[29] The higher accumulation of phenolic compounds in seeds[30] but the lower extractability due to the solid cellular structure[31] could explain the greater phenolic potential of SD as winemaking byproduct. On the contrary, significantly (p < 0.05) lower contents of total phenolics were found in the crude phenolic solutions from SK and ST, indicating that they are comparatively poorer sources of phenolics.

The chromatographic analysis showed that crude phenolic solutions from PM, SK, SD, and ST had different qualitative and

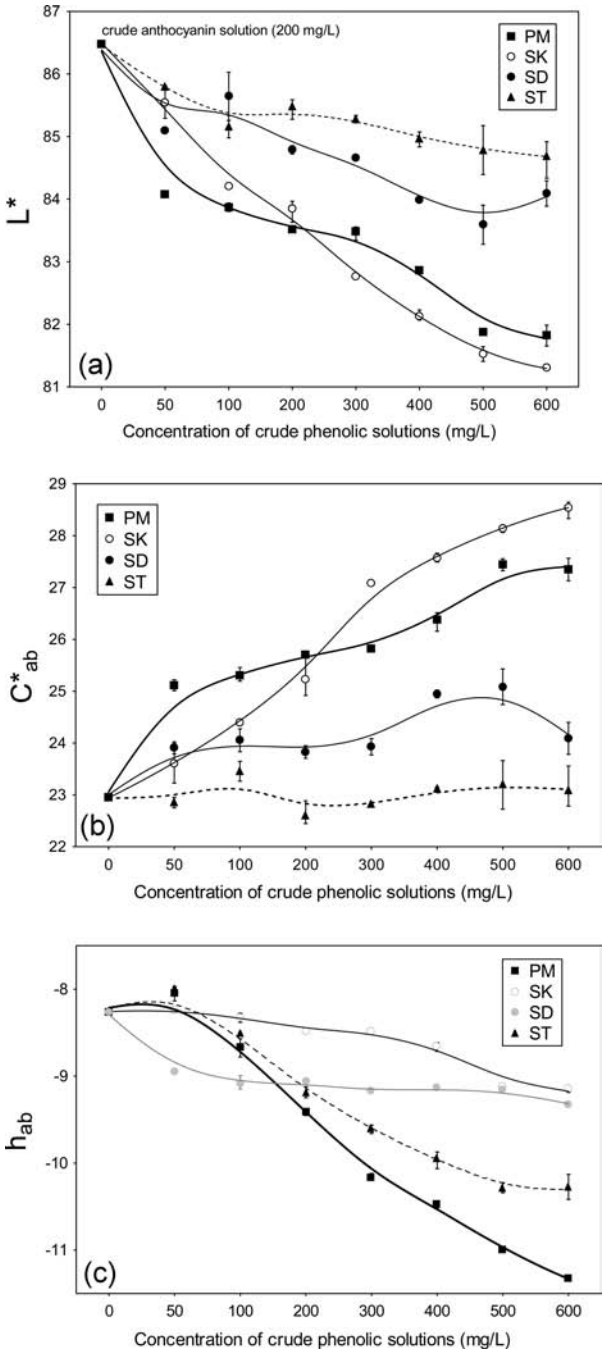

Figure 3. Changes in (a) lightness (L^*), (b) chroma (C^*_{ab}), and (c) hue (h_{ab}) of the crude anthocyanin solution after addition of increasing concentrations of crude phenolic solutions from Zalema winemaking byproducts (SK, skins; PM, pomace; ST, stems; SD, seeds); mean ± SD, $n = 3$.

quantitative phenolic profile (Figure 1), the differences being significant ($p < 0.05$) for most of the individual compounds identified (Table 1). These differences were also observed when compounds were grouped by phenolic families (phenolic acids, flavanols, and flavonols). Significantly higher contents of flavanols were found in the crude phenolic solutions from SD, which is in accordance with other studies.[8,32] The global level of flavanols was 35% higher than those found in the samples from PM and 64% higher than those from SK and ST. On the other hand, PM was the major source of phenolic acids, contributing to the crude phenolic solution at 34% higher than ST and SD and at 38% higher than SK. With regard to the flavonol contribution, SK represented the significantly richest source of these compounds in comparison with all other winemaking byproducts studied, as expected.

As far as individual compounds are concerned, great variability has been described in the literature about the distribution of phenolic acids in different types of winemaking byproducts, which is attributable to the influence of several factors such as grape variety, cultivation and climatic conditions, or the enological processes applied during winemaking.[33−35] However, the qualitative profile of phenolic acids did not differ much among samples. In particular, gallic acid was the main phenolic acid found in the samples being transferred in significantly ($p < 0.05$) higher quantity by PM. Caftaric acid was the second most abundant phenolic acid, ST and PM being the better sources.

In contrast, the group of flavonoids (flavanols and flavonols) varied considerably among samples. In the case of flavanols, significantly higher levels of monomeric compounds were obtained from SD, mainly due to a more important contribution in catechin and epicatechin. Nevertheless, Zalema winemaking byproducts contributed with greater quantities of oligomers than monomers to the total flavanol content (PM, 84%; SK, 80%; ST, 75%; and SD, 70%). Among them, procyanidins B1, B4, and B2−3-*O*-gallate were the most representative oligomers in all samples. Specifically, SD and PM were the significantly richest sources in oligomeric flavanols (98.9 and 77.3 mg/L in samples, respectively), contributing to the crude phenolic solution about 2.5-fold higher than SK and ST. With regard to flavonols, quercetin-3-glucoside was the predominant compound in all samples. The crude phenolic solution from SK was noteworthy for having significantly higher levels of all flavonols compared to those from PM, ST, and SD (6.6% of the total phenolic contribution versus 2.3, 1.7, and 0.3%, respectively).

The individual phenolic compounds present in the crude phenolic solution have critical importance because each compound can have different antiradical and copigmentation powers.[36,37] Thus, on the basis of the results obtained, differences on the antioxidant and copigmentation properties of samples were expected as well, because different heterogeneous phenolic mixtures coexisting in competing equilibria might result in additive or suppressive effects.[8,15]

Antioxidant Activity. Results showed that the antioxidant activity was in accordance with the total phenolic content of each sample (Table 1). Thus, the crude phenolic solution from SD, with the highest phenolic content, showed the greatest antioxidant activity (888.7 μmol TE/L) followed in decreasing order by those from GP, ST, and SK (463.3, 305.6, and 297.5 μmol TE/L, respectively).

Univariate linear regression was applied to these data to explore relationships between the total phenolic content and the antioxidant activity, and very strong and significant correlations ($R^2 = 0.98$, $p < 0.05$) were found, which indicate that Zalema winemaking byproducts represent good sources of natural antioxidants with high added value.

Also, a multiple regression analysis was performed to check the more influential phenolic groups (independent variables: total phenolic acids, total flavanols, and total flavonols) on the antioxidant activity (dependent variable). High multiple correlation coefficient ($R^2 = 0.99$) and significant correlation ($p < 0.05$) were obtained for the total flavanols ($\beta = 0.98$) followed by the total phenolic acids ($\beta = -0.18$).

On the other hand, two multiple regression analyses were carried out to determine the relative importance of individual

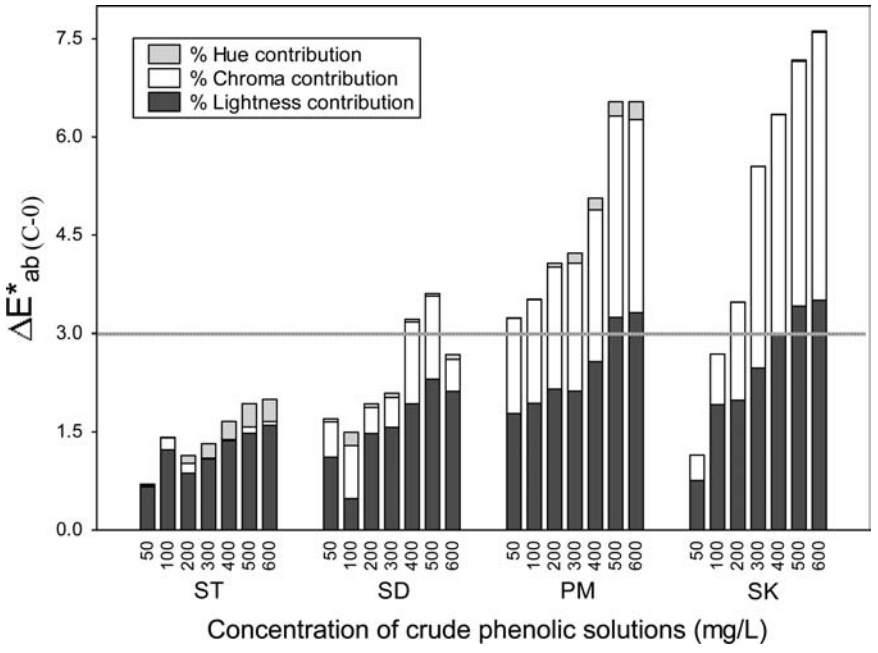

Figure 4. Total color difference induced by copigmentation ($\Delta E^*_{ab(c-0)}$) with the relative contribution of lightness, chroma, and hue (%ΔL, %ΔC, %Δh), calculated between the color of the crude anthocyanin solution and after addition of increasing concentrations of the crude phenolic solution from Zalema winemaking byproducts (SK, skins; PM, pomace; ST, stems; SD, seeds).

phenolic compounds on the antioxidant activity. First, a regression analysis between antioxidant activity (dependent variable) and individual flavanols (independent variables) was performed to assess the influence of these phenolic compounds. Results indicated good correlation ($R^2 = 0.98$) having catechin ($\beta = 0.83$), epicatechin ($\beta = 1.01$), trimer C1 ($\beta = 1.28$), and procyanidins B2 ($\beta = 0.54$) and B4 ($\beta = 0.68$) with significant influence ($p < 0.05$). Multiple regression analysis considering phenolic acids showed also a high multiple correlation coefficient ($R^2 = 0.99$) having caffeic acid ($\beta = -2.20$), caftaric acid ($\beta = 1.33$), *trans*-coutaric acid ($\beta = -1.20$), and gallic acid ($\beta = 1.22$) more influential than *cis*-coutaric and protocatechuic acids.

Copigmentation Effect. The crude anthocyanin solution obtained from Syrah skins was analyzed for its phenolic composition. Eleven anthocyans including nonacylated, acetylated, and *p*-coumaroylated forms of the five expected anthocyanidins (delphinidin, cyanidin, petunidin, peonidin, and malvidin) were identified by HPLC, which accounted for 95.8% of the total phenolic content. Also, the presence of other minor nonanthocyanin phenolic compounds was confirmed. They were mainly flavonols and phenolic acids, which accounted for <5% of the total phenolic compounds identified. The relative proportion of each identified compound is presented in Table 2.

Figure 2 shows the magnitude of copigmentation (a) and the total color (b) of the crude anthocyanin solution containing increasing concentrations of crude phenolic solutions from Zalema winemaking byproducts (PM, SK, SD, and SK). Immediate intermolecular copigmentation was observed in the mixtures, which are evidenced by the hyperchromic shift of the λ_{max} of the crude anthocyanin solution (520 nm) and also by an increase of its initial total color (26.6 CIELAB u). As observed, the magnitude of copigmentation differed depending on the type of winemaking byproduct and the phenolic concentration applied. Stronger copigmentation effects were produced by the crude phenolic solutions from SK and PM, which induced the highest hyperchromic shifts (from 2 to 28% and from 11 to 24%, respectively) and increases of the total color (from 26.6 to 34.4 and 32.5 CIELAB u, respectively). The effect was significantly ($p < 0.05$) more pronounced with increasing copigment concentration. In contrast, SD and ST appeared as the less effective sources of copigments because the addition of the crude phenolics solutions at increasing levels did not always result in progressive increases of the magnitude of copigmentation in the total color.

Our results indicate that the quantitative and qualitative profile of phenolic mixtures used as colorless copigments determined distinctive effects on the extent of multiple copigmentations, as previously reported by Gonzalez-Manzano et al.[15] Higher relative proportions of more effective copigments as flavonols (mainly quercetin derivatives), oligomeric flavanols (mainly B-type procyanidins), or some phenolic acids in SK and PM samples could explain their greater copigmentation effect observed.[36]

Also, it was confirmed that the color of the crude anthocyanin solution was improved by the crude phenolic solution from winemaking byproducts, which was manifested through positive changes in the CIELAB parameters (L^*, C^*_{ab}, and h_{ab}), shown in Figure 3). The progressive enrichment in colorless copigments resulted in decreasing lightness and hue values (L^* and h_{ab}) and increasing chroma (C^*_{ab}), which means a progressively darker and more saturated bluish color. However, important differences existed for the quantitative and qualitative color effects induced depending on the type of winemaking byproduct. In this sense, crude phenolic solutions from PM and SK decrease the initial values of lightness approximately by 6% (from 86.5 to 81.3 and 81.8 CIELAB u, respectively) and increase the chroma value by 24 and 19% (from 22.9 to 28.5 and 27.4 CIELAB u). For the qualitative attribute of color (h_{ab}), the effect was more important with crude phenolic solution from PM and ST, which decreases the initial hue value approximately in three grades (from −8.26° to −11.33° and −10.29°)

The total color differences, $\Delta E^*_{ab(c-0)}$ between the crude anthocyanin solution and those containing crude phenolic solution from winemaking byproducts at increasing concentration were calculated (Figure 4), which provide relevant color information related to visual perception. Moreover, the relative contribution of lightness (%ΔL), chroma (%ΔC), and hue (%Δh) to each color difference calculated permits us an objective comparison of the colorimetric effect among the samples. Results showed that the color changes were visually perceptible ($\Delta E^*_{ab} > 3$, according to Martínez et al.[26]) for the crude phenolic solution from PM at all the assayed concentrations, as well as for most of those from SK. In contrast, samples from SD and ST resulted in color differences of <3 CIELAB u (not clearly perceptible). This fact confirms again their poorer efficiency as copigments sources, which is consistent with the results obtained for the magnitude of copigmentation and total color.

With regard to winemanking byproducts causing perceptible color changes (SK and PM), it can be observed that both samples induced similar effects independent of the concentration tested. In general, the weight of the lightness and chroma modifications were more marked than in hue (%ΔL = 54 and 52%; %ΔC = 45 and 45.5; %Δh = 0.1 and 2%, as mean values, respectively, in SK and PM). This meant that for the same concentration of the SK and PM crude phenolic solutions, comparable darkening and greater quantity of color were induced without substantially modifying the original hue.

In summary, white winemaking byproducts from Zalema grape are rich sources of phenolic compounds consisting of mainly flavanoids and phenolic acids. The antioxidant activity of these compounds is related to the total phenolic content and particularly to the flavanol and phenolic acid contents. The copigmentation effects in model solution indicate that white winemaking byproducts could improve the anthocyanin color quality depending on the type of byproduct used as copigment source (PM, SK, SD, and ST) and the phenolic concentration applied, causing perceptible color changes. Therefore, the exploitation for their potential reuse in the wine industry could be of great interest, considering either the Zalema pomace or its individual components (seeds, stems, and skins).

stabilize wines. This technique causes the precipitation of tartrates and unstable colloidal substances and aims at avoiding further undesirable precipitations and wine turbidity.[3] Nevertheless, cold can also precipitate coloring matter either by adsorption on the tartrate crystals or by the instability of colloidal coloring matter. The role of wine polysaccharides in preventing those phenomena has been proposed. The mannoproteins are considered to be protective colloids that can hinder tartrate crystallization,[3] avoiding the growth of the crystals. Furthermore, they play an important part in protein haze stabilization.[19] They are glycoproteins of the *Saccharomyces cerevisiae* cell wall that can be excreted to the wine during alcoholic fermentation or be released to the wine during yeast autolysis.[20] Although the compositions of these two types of mannoproteins are quite similar, only the mannoproteins released from cell walls seem to exert the stabilizing effects.[21] Recently, it has been reported that mannoproteins can also influence tannin aggregation by adsorption of the mannoproteins on the tannin molecule, preventing the growth of the tannin particles.[22,23] Nevertheless, Poncet-Legrand and co-workers[24] showed that the tannin-stabilizing effect depends on the molecular weight of the mannoprotein and also on other factors such as ethanol content or ionic strength. The results of that study confirmed that mannoproteins seem to act as steric stabilizers. Taking into account that mannoproteins were able to stabilize tannins, it was hypothesized that they might also act as stabilizers of the colloidal coloring matter. In fact, different mannoprotein-rich commercial preparations are now available,[25] and among the benefits claimed by manufacturers is the increase of color stabilization. However, studies on the effects of mannoproteins on wine color and pigment composition are scarce. Escot and co-workers[26] reported that the presence of mannoproteins released by yeast to the wine during alcoholic fermentation improved color stability. Guadalupe and co-workers, on the contrary, reported that the mannoproteins released by mannoprotein-overproducing yeasts affected neither wine color nor monomeric anthocyanin content,[27] whereas the addition of commercial mannoproteins during the prefermentation stage even caused a loss of stable wine color.[27,28] These differences in the behavior of mannoproteins might be related to differences in their composition. Fernández and co-workers[29] observed greater color intensity and a slight tendency to red tones when the wine was treated with lysated lees obtained by acidification and enzymatic treatment instead of those obtained only by acidification. Nevertheless, none of these works study the influence that mannoproteins can exert on the colloidal stability of anthocyanin-derived pigments, the influence of which on wine color cannot be neglected in aged wines. Furthermore, the usefulness of these products on preventing color loss by cold treatment has to be studied.

The objective of the present study was to assess the chemical and colloidal stabilization of wine color and pigment composition as a consequence of the addition during alcoholic fermentation of either an enological tannin containing hydrolyzable and condensed tannins or a mannoprotein obtained from yeast by enzymatic treatment. The effect of these two enological products on preventing the loss of coloring matter has also been studied after wines had been submitted to cold stabilization treatment. Samples were analyzed after malolactic fermentation and 10 weeks later to verify if the effects were maintained over time. CIELAB parameters were used to evaluate color modifications, whereas changes in pigment composition were assessed by HPLC-DAD-MS^n analysis.

MATERIALS AND METHODS

Samples. Three different wines (100 L of each) were made from *Vitis vinifera* L. cv. Tempranillo grapes. The first wine served as control (C), whereas the second and third wines were treated with an enological tannin and with a mannoprotein (product M), respectively (wines T and M). All of the wines were made in duplicate. Following the manufacturer's advice these enological products (100% soluble in wine) were added in equal amounts during alcoholic fermentation at densities 1100, 1060, and 1020 g/L, reaching a final concentration of 35 g/hL (dose recommended by manufacturer). Further details of these enological products are given below. Maceration−alcoholic fermentation lasted 12 days. Then, the wines were inoculated with *Oenococcus oeni* and malolactic fermentation (MLF) took place, lasting 20 days. After MLF, two aliquots of 10 L from each wine were separated from the rest of the sample. One aliquot was cold-treated, whereas the other was not subjected to this treatment. Cold treatment consisted in cooling samples at 4 °C during 48 h followed by centrifugation during 10 min at 3000 rpm. Both aliquots were filtered (2 μm) and then bottled (bottles of 750 mL). Furthermore, the precipitate was recovered and dissolved in model wine solution (5 g/L of tartaric acid in 12% aqueous ethanol adjusted to pH 3.6). The CIELAB color parameters and the pigment composition of the wines not subjected to cold treatment (C1, T1, and M1) and of those cold-treated (C1*, T1*, and M1*) as well as of the redissolved precipitates (C1p, T1p, and M1p) were then determined. Another bottle of each fraction (subjected and not subjected to cold) was kept in the dark and at 15 °C and analyzed 10 weeks after the first analysis (wines C2, T2, M2, C2*, T2*, and M2*).

Enological Tannin. The enological tannin (Tanin VR Color) was supplied by Laffort España (Rentería, Spain) and consisted of an extract from natural sources mainly constituted by catechins and proanthocyanidins (58.8%), oak ellagitannins (11.2%), and hydroxybenzoic acids (7.5%). The composition of the enological tannin was determined in our laboratory by means of HPLC-DAD-MS employing the conditions described by Ferrer-Gallego and co-workers[30] for the analysis of catechins and proanthocyanidins.

Yeast Mannoproteins (Product M). In a preliminary study two commercial mannoproteins and four different mannoproteins obtained by Laffort from *S. cerevisiae* by either enzymatic or thermal treatments were tested to evaluate their potential protective effect on the colloidal unstable coloring matter of the wines. Among all of the tested mannoproteins only one (product M, obtained by enzymatic treatment) showed a statistically significant protective effect, and for this reason it was selected for the present study. Other tested mannoproteins, on the contrary, even provoked additional precipitation, which is in accordance with the results of previous studies that did not find a protective effect of mannoproteins on coloring matter.[27,28] Gel permeation chromatography revealed that all of the tested mannoproteins contained three main peaks that were present in different percentages. In relation to the other mannoproteins, product M showed a higher percentage (50%) of the heaviest peak (70 kDa).

Colorimetric Measurements. Because wine color is dependent on pH, it was standardized in all of the samples to 3.6 with 0.1 N HCl (Panreac, Castellar del Vallès, Spain) prior to the spectrophotometric measurements. Absorption spectra (190−1100 nm) were recorded in a Hewlett-Packard UV−vis HP 8453 (Agilent Technologies, Waldbronn, Germany) spectrophotometer in 2 mm path length quartz cells. The analysis of color was made only from the visible spectra (380−770 nm) data, using the CIE 1964 standard observer (10° visual field) and the CIE standard illuminant D65 as references. CIELAB color parameters (L^*, a^*, b^*, C_{ab}^*, and h_{ab}) were calculated using the software CromaLab.[31] Color differences between different wine samples were determined by means of the CIELAB color difference formula:

$$\Delta E_{ab}^* = ((\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2)^{1/2}$$

[a]Differences due to the addition of the enological products, to cold treatment and time are also shown. Letters a−c following entries show the significance of the differences among the samples of the first sampling point (C1, T1, M1, C1*, T1*, and M1*). Letters α, β, and χ following entries show the significance of the differences due to time in non-cold-treated samples (C1, T1, M1, C2, T2, and M2). Numbers 1−3 following entries show the significance of the differences due to time in cold-treated samples (C1*, T1*, M1*, C2*, T2*, and M2*). $p < 0.05$ in all cases.

HPLC-DAD-ESI/MS^n Analyses. The anthocyanins and derivative pigments were analyzed by HPLC-DAD-MS^n in all of the wine samples (cold-treated and non-cold-treated) as well as in the precipitates of the cold-treated samples. Wine samples were diluted (1/5) with acidified water (pH 1.3, HCl) and filtered through a 0.45 μm Millex syringe-driven filter unit (Millipore Corp., Bedford, MA, USA) before HPLC-DAD-MS analysis. The precipitates that had been redissolved in model wine solution were also acidified (0.25 mL acidified water/mL sample) and filtered prior to the HPLC-DAD-MS analysis. Analyses were performed in a Hewlett-Packard 1100 series liquid chromatograph (Agilent Technologies, Waldbronn, Germany). An AQUA C18 reversed-phase, 5 μm, 150 mm × 4.6 mm column (Phenomenex, Torrance, CA, USA) thermostated at 35 °C was used. The HPLC-DAD conditions have been previously employed with satisfactory results in our laboratory in the analysis of wine samples.[32] Detection was carried out at 520 nm as the preferred wavelength. Spectra were recorded from 220 to 600 nm. The mass spectrometer was connected to the HPLC system via the DAD cell outlet. MS detection was performed in an API 3200 Qtrap (Applied Biosystems, Darmstadt, Germany) equipped with an ESI source and a triple-quadrupole ion trap mass analyzer that was controlled by Analyst 5.1 software. MS analysis was carried out in positive mode (ESI$^+$). Zero grade air served as nebulizer gas (GS1) and turbo gas (GS2) for solvent drying. Nitrogen served as curtain (CUR) and collision gas (CAD). Settings used were optimized by direct infusion of a malvidin 3-*O*-glucoside solution: declustering potential (DP), 41 V; entrance potential (EP), 7.5 V; ion spray voltage (IS), 5000 V; GS1, 40 psi; GS2, 50 psi (600 °C); CUR, 20 psi; and CAD, set as "high". Both quadrupoles were set at unit resolution. Mass method consisted of three mass experiments: full mass analysis (EMS mode, collision energy (CE) 10 V), MS^2 analysis (EPI mode, CE 25 V), and MS^3 analysis (CE 30 V, excitation energy (AF2) 50 V). Spectra were recorded between m/z 150 and 1300.

Compounds were identified from the data supplied by the HPLC-DAD-MS^n analyses of the samples (retention time, UV−vis spectra, m/z ratio, and fragmentation patterns) and by comparison to the data previously obtained in our laboratory for wine samples analyzed in the same conditions.[32] Thirty-one anthocyanins and derivative pigments were determined: 5 anthocyanin 3-*O*-glucosides, 5 anthocyanin 3-*O*-acetylglucosides, 8 anthocyanin 3-*O*-coumaroylglucosides (5 *trans*

dx.doi.org/10.1021/jf4055825 | J. Agric. Food Chem. 2014, 62, 6984−6994

isomers and 3 *cis* isomers), 2 anthocyanin 3-*O*-caffeoylglucosides, 7 flavanol–anthocyanin direct condensation products (F-A^+ dimers), 2 A-type vitisins, a B-type vitisin of malvidin 3-*O*-glucoside, and the vinylphenol–malvidin 3-*O*-glucoside pyranoanthocyanin. All of these compounds were considered for the quantitative analysis. As it usually happens in the analysis of wine samples by HPLC, an elevation of the baseline was observed at the end of the chromatogram corresponding to difficult resolution pigments, such as dimeric anthocyanins.[33] Although it is difficult to know the exact composition of these unresolved peaks, it is important to know their percentage over the total coloring matter because they show absorbance at 520 nm and can, therefore, contribute to the final color of the wine. Their contribution was assessed as the absorbance of the "hump" formed above the theoretical baseline. Because the final color of a wine depends both on the total pigment content and on the proportions of the different types of pigments, the percentage of each compound over the total area was calculated.

Total pigment content of each sample was also calculated and expressed as malvidin 3-*O*-glucoside (Extrasynthèse, Genay, France).

Statistical Analysis. The CIELAB parameters, the percentages of the different pigments, and their modifications with cold treatment and with time were analyzed by means of one-way analysis of variance (ANOVA) and Tukey's honestly significant difference test to assess the significance of the differences observed among samples ($p < 0.05$). An unsupervised pattern recognition method, principal components analysis (PCA), was used for data analysis. PCA was applied from the correlation matrix of the original variables (mean percentages of the 31 identified pigments and that of the difficult resolution pigments).

Student's *t* test was employed to evaluate the statistical significance between pairs of samples (95% confidence levels). The IBM-SPSS Statistics 21 for Windows software package (IBM, Armonk, NY, USA) was used to carry out the statistical analysis.

RESULTS AND DISCUSSION

Chromatic Analysis. It is relevant to first analyze the color modifications that are a direct consequence of the addition of these two enological products to the wine. It has been observed that the addition of either the enological tannin or product M causes a decrease in lightness (L^*) and an increase in a^* and b^* coordinates and consequently an increase in chroma (C_{ab}^*) and in hue (h_{ab}) in relation to those observed in nontreated samples (Table 1). Nevertheless, only the changes in b^* coordinate and in hue were statistically significant. Although the changes were more noticeable in the samples to which product M was added than in those treated with enological tannin, the differences among tannin and M-treated samples were not statistically significant (Table 1). Color differences between control and tannin- or M-treated wines were assessed by ΔE_{ab}^*. In both cases ΔE_{ab}^* was >3, which means that the color modifications induced by the treatments are visible to the human eye.[34] Previous studies on mannoproteins and their influence on wine color[27,28] reported that in the tested conditions the mannoproteins did not modify wine color in relation to control samples, and they even observed the precipitation of stable color when the mannoprotein was added to the wine as an extract but not when mannoprotein-overproducing yeast strains were used. This was not observed in the present study. Differences might be related to the type of mannoprotein employed. As previously indicated, the molecular weight, the source from which they are obtained, or the methodology employed to obtain them[21,24,29] can modify the effect of the mannoproteins. Nevertheless, as in our study, Guadalupe and co-workers[27] observed an increase in the b^* coordinate in wines fermented with a mannoprotein-overproducing yeast strain either in the absence or in the presence of a commercial mannoprotein.

Thus, from these first results it can be concluded that the addition of the enological tannin or product M to the wines modifies the values of the CIELAB color parameters observed in control wines.

Modification of the CIELAB Parameters after Cold Treatment. In relation to lightness, it was observed that the samples that underwent cold stabilization increased their L^* value in relation to those not subjected to cold treatment (see "Sampling Point 1" and "Differences Due to Cold Treatment" in Table 1). This fact can be related to the precipitation of compounds after cold treatment, either directly due to their own instability or indirectly by adsorption to compounds such as tartrates, which easily precipitate with cold. Differences have been observed among the different samples. In control samples L^* increased ca. 14 units after cold treatment. However, in the cases of either tannin- or M-treated wines the values of L^* determined in the samples not subjected to cold treatment (T1 and M1) and in those subjected to cold treatment (T1* and M1*, respectively) were not statistically different. Furthermore, ΔL^* due to cold treatment was not statistically different in tannin- or M-treated wines. This is indicative of a stabilizing effect of both types of compounds against cold precipitation.

As can be observed in Table 1 (see "Sampling Point 1" and "Differences Due to Cold Treatment"), cold treatment caused a significant increase in the b^* coordinate only in the case of control wines. On the contrary, the a^* coordinate decreased in all samples, although it was only statistically significant in the case of control wines. This might be pointing to a color stabilization effect toward cold treatment caused by the addition of these two enological products. From these two parameters (a^* and b^*), chroma (C_{ab}^*) and hue (h_{ab}) parameters can be calculated. Although chroma decreased in all of the samples after cold treatment, only the changes observed in control wines were significant. Thus, wines treated with the enological tannin or with product M were able to better maintain their own quantity of color after cold treatment. With respect to hue, after cold treatment, it significantly increased in control wines, shifting color toward more orange hues. On the contrary, hue remained quite stable after cold stabilization in tannin- or M-treated wines (Table 1).

From these results it seems that the addition of these two products to the wine allows a stabilization of the coloring matter against cold treatment. In fact, whereas cold treatment caused a color difference (ΔE_{ab}^*) of 23 units in control samples, in treated samples it hardly exceeded the human eye threshold of 3 units. The main initial drawback might be the slight shift of the wine color toward red-orange hues observed after the addition of these two enological products. However, after cold treatment, the color in the wines treated with these two products (T1* and M1*) is redder than that of cold-treated control wines (C1*) and darker and with higher chroma than that of control wines even before cold treatment (C1).

Modification of the CIELAB Parameters over Time. The color parameters of these samples were studied 10 weeks after cold treatment to determine if the effect of the addition of either the enological tannin or product M is maintained over time.

In all samples, the modification in lightness (ΔL^*) caused by time (between sampling points 2 and 1) is much lower than that caused by cold treatment (Table 1). This might indicate that there has not been an important quantitative change in pigment composition such as additional pigment precipitation.

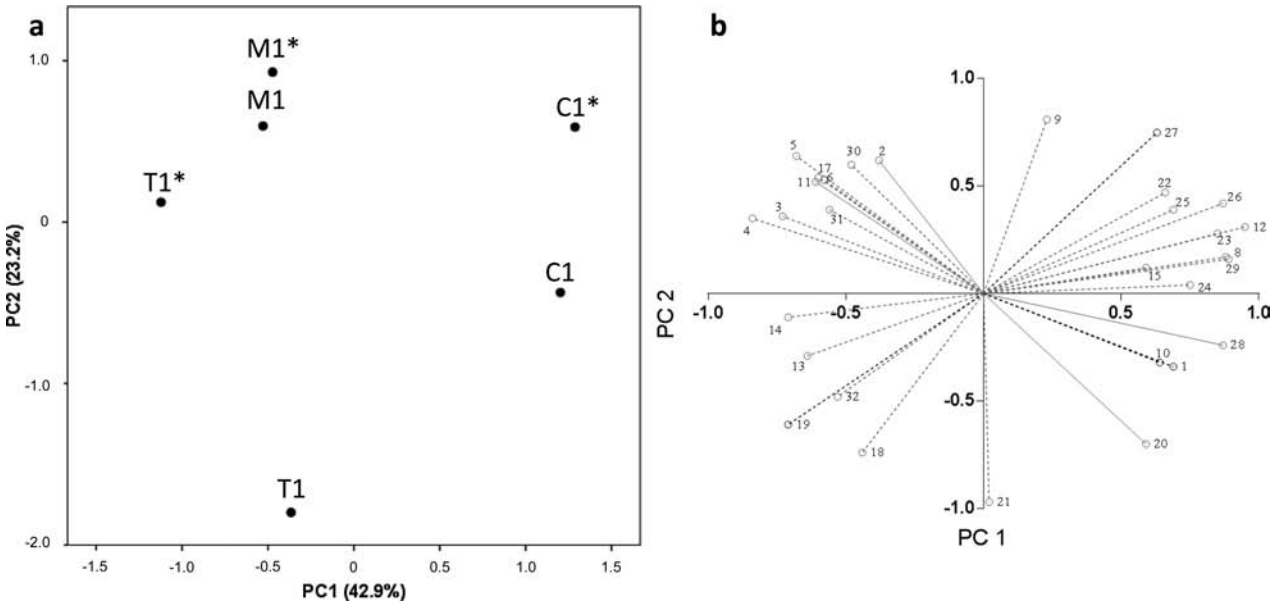

Figure 1. (a) Projection of the wine samples on the plane defined by the first and second principal components (PC2 vs PC1). These samples correspond to all wines (control, tannin- and M-treated wines) in the first sampling point either subjected to cold treatment (samples C1*, T1*, and M1*) or not (samples C1, T1, and M1). (b) Loading plot of the PCA. The identities of the original variables are indicated in Table 2.

Furthermore, the modifications in L^* (ΔL^*) produced by time were not significantly different among the different kinds of samples (control, tannin- or M-treated samples).

With respect to a^* and b^* parameters and their modification over time (Δa^* and Δb^* between sampling points 2 and 1, Table 1, "Differences Due to Time"), it can be seen that, in most cases, time produced a decrease in both parameters. In addition, no significant differences can be observed in the values of Δa^* and Δb^* among samples, which indicates that time affects a^* and b^* in a similar way in all of the samples, independently of the initial treatment. Because chroma and hue depend on a^* and b^* parameters, they also decreased over time in most of the samples (see ΔC_{ab}^* and Δh_{ab} in Table 1). As in the case of Δa^* and Δb^*, no significant differences were observed in the evolution of chroma and hue (ΔC_{ab}^* and Δh_{ab}) over time among the different treatments either in the samples not subjected to cold treatment or in the samples cold-treated (compare C2−C1, T2−T1, M2−M1, C2*−C1*, T2*−T1*, and M2*−M2). It has to kept in mind that, on the contrary, cold treatment did affect differently the samples treated either with the enological tannin or with product M, observing significant differences in the values of ΔL^*, ΔC_{ab}^*, and Δh_{ab} between control samples and the samples treated with any of these enological products. As indicated in the previous section, their addition has been proven to produce a stabilization of the initial color of the samples against cold treatment in relation to the samples to which these products were not added (compare C1*−C1 to T1*−T1 and M1−M1* in Table 1). This might indicate that the addition of these two types of enological products might be useful to prevent color loss due to cold but not to prevent changes in color due to age. Cold treatment mainly affects pigment composition by precipitation (reflected in the changes in L^* and C_{ab}^*, above all), whereas pigment evolution over time involves chemical modifications of the pigments initially present (reflected in the changes in h_{ab}), which can be accompanied or not by precipitation. Nevertheless, the time range between sampling points 1 and 2 is too low (10 weeks) to draw conclusions about the possible long-term effect in pigment composition. In fact, slight differences in the behavior of the color parameters over time have been observed among the different types of cold-treated samples. Although not statistically significant, they might be pointing out differences in the mechanisms of both types of products. Furthermore, although the magnitude of the modifications over time in chroma and hue (ΔC_{ab}^* and Δh_{ab}) has been the same in all types of samples, the final colors of the tannin- or M-treated samples not subjected to cold after 10 weeks show a hue similar to that of control wine before cold treatment at point 1 (compare T2−C1 and M2−C1, Table 1). This means that although these products have not been able to avoid the decrease in hue observed from point 1 to point 2, the initial increase caused in this parameter by their addition has made up for this decrease. In other words, they have also "stabilized" the hue of the nontreated wine. Furthermore, treated wines (T2 and M2) were darker and possessed higher chroma than control wine at the first sampling point (C1).

Pigment Analysis. Because the addition of the enological tannin or product M to the wine modified the initial color of the samples, it seems interesting to first analyze the modification induced in the pigment composition by these additions (compare C1, T1, and M1). In relation to total pigment content, the samples to which the enological tannin was added (T1) showed the highest pigment content (630.3 mg/L) followed by those treated with product M (M1, 582.6 mg/L). Control samples (C1) showed the lowest total content (541.3 mg/L). This lower pigment content explains the higher L^* value of control samples in relation to treated samples. The higher total pigment content observed in T1 samples might be related to a higher extraction of native grape pigments favored by the addition of the enological tannin as previously observed in our laboratory.[18] T1 samples also showed the highest contents for each group of pigments in relation to the other types of samples. For this reason, the differences among types of wines were lower when the percentages of the different groups of pigments were considered. To evaluate the relevance of the different wine pigments on the differences observed

among samples, a principal component analysis (PCA) was performed from the percentages of the individual pigments over the total pigment content. The three first principal components (PC1, PC2, and PC3) explained 85% of the total system variability. Figure 1a shows the projection of the wine samples on the plane defined by the first and second principal components (PC2 vs PC1). In the PCA plot the samples treated with any of these products (T1 or M1) are well separated from control samples (C1) along the PC1 factor. In fact, control samples have a positive value, whereas the two others are negative. Taking into account the loadings (Figure 1b and Table 2, for the identity of the variables), positive values are mainly correlated with grape native anthocyanins and negative values with F-A$^+$ derivative pigments and with A-type vitisins. This means that these types of derivative pigments are more represented in the samples treated with enological tannin or with product M than in control wines, whereas the weight of native anthocyanins is higher in control wines than in treated ones. In previous studies carried out in our laboratory not only in model solutions (data not shown) but also in wines,[18] it has been observed that the synthesis of these types of derivative pigments is favored by the presence of the enological tannin. With respect to the synthesis of A-type vitisins, it has been demonstrated that it requires the presence not only of anthocyanins and pyruvic acid but also of oxidants to complete the last step of the synthesis.[35] Ellagitannins, which are present in the enological tannin employed in the present study, can promote the conversion of oxygen into reactive oxygen species which, in turn, might take part in the last step of the A-type vitisin synthesis. On the other hand, the enological tannin employed in this study also contained oligomeric proanthocyanidins having interflavanic linkages that can be cleaved at the pH of the wine, releasing carbocations which, in turn, can react with anthocyanins and originate F-A$^+$ dimers.[32] Furthermore, this condensation reaction may be favored by the ellagitannins present in the enological tannin.[32,36]

With regard to wines treated with product M, no evidence supporting the higher formation of anthocyanin-derived pigments was clearly found. In a recent work, Andújar-Ortiz and co-workers[37] reported higher levels of vitisin B and of one isomer of malvidin 3-glucoside-ethyl-epicatechin in wines treated with glutathione-enriched inactive dry yeast (G-IDY) preparations than in control wines. Although no explanation is given, the higher contents of these two types of anthocyanin-

derived pigments might be related to a higher availability of acetaldehyde in the G-IDY wines, which can be, in turn, related to the glutathione content. Thus, in that study, the addition of the G-IDY preparations caused a chemical transformation of the grape native anthocyanins into derivative pigments in which formation acetaldehyde is involved. This was not the case in the present work, and the higher percentages of A-type vitisins and F-A$^+$ derivative pigments in M-treated samples may be related to a colloidal stabilization of the coloring matter. In fact, some polysaccharides are traditionally considered as "protective" colloids, macromolecular colloids that coat other colloids present in the wine, thus preventing their agglomeration.[3] Riou and co-workers[22] demonstrated the different ability of different wine polysaccharides to prevent the aggregation of tannin colloids. Among them and at their usual concentration in wines, only mannoproteins were able to prevent the growth of tannin particles and, therefore, their flocculation and precipitation. These authors proposed that this protective effect was due to the adsorption of the mannoprotein on the particles formed by tannins. Further studies carried out by the same research group[24] confirmed that the mechanism involved was steric stabilization and that the molecular weight of the polysaccharide conditioned the activity of the mannoprotein. Medium (∼62 kDa) and low (∼51 kDa) molecular weight polymers were more efficient than high molecular weight polymers (∼337 kDa). Because F-A$^+$ dimers are originated from the direct condensation of a flavanol and an anthocyanin, a similar protective mechanism can be proposed for them. Product M, containing medium and low molecular weight polymers, might have prevented the aggregation of F-A$^+$ dimers or even the aggregation of these colored dimers with other proanthocyanidins that probably occurred in control samples.

The higher percentages of A-type vitisins found in M-treated samples might be also related to their colloidal stabilization. The additional pyran ring confers hydrophobicity to the molecules, making them less polar and less soluble in hydroalcoholic solutions (wine) than the original anthocyanins from which they are synthesized. Furthermore, unlike anthocyanins, the main species of which at wine pH is the colorless hemiketal form, the main species of the A-type vitisins is the orange quinonoidal base,[38] which can also be responsible for the lower solubility of these anthocyanin derivatives. The lower solubility might favor interactions (hydrophobic and/or $\pi-\pi$ interactions) between molecules that might induce their aggregation and cause their precipitation. Mannoproteins might have acted as steric stabilizers, being adsorbed on the pigment and thus lowering the possibility of aggregation.

Although along PC1 the samples treated with product M (M1) and those treated with the enological tannin (T1) showed similar values, they were well separated along PC2. In general, the positive values of PC2 correlate with most of the F-A$^+$ dimers and with all of the *trans*-isomers of the anthocyanin coumaroylglucosides, and the negative values correlate above all with acetylglucosides and with the *cis*-isomers of the coumaroylglucosides. M-treated samples showed positive values and tannin-treated samples showed negative values. In fact, although the percentages of coumaroyl derivatives were quite similar in both types of samples, the percentage represented by the *cis*-isomers was higher in the case of tannin-treated wines than in M-treated samples. This was also the case for acetyl derivatives, which represented higher percentages in the former than in the latter ones. On the contrary, the *trans*-isomers of the coumaroyl derivatives and the A-type vitisins were more represented in M-treated samples. Control wines showed percentages of *cis*-coumaroyl derivatives that were similar to those of tannin-treated wines and percentages of acetyl derivatives between those of treated wines. As a result, control wines showed a negative value of PC2.

Thus, the addition of either the enological tannin or product M to the wines causes some modifications in the pigment composition. The main composition differences between control and treated wines shown by PCA are the higher proportion of anthocyanin-derived pigments (A-type vitisins and F-A$^+$ dimers, above all) in treated samples in relation to control wines and between treated wines, the different proportions of *cis*- and *trans*-isomers of the coumaroyl derivatives, the different percentages of acetyl derivatives, and the different proportions of A-type vitisins. The changes in the color parameters observed in the treated wines (M1 and T1) in relation to control (C1) wine can be, therefore, explained by these changes in the composition. The decrease in lightness might be due to the higher pigment content observed in both types of treated samples in relation to control ones. In the case of tannin-treated wines, the decrease in L^* might be also due to other phenolic compounds supplied by the enological tannin such as proanthocyanidins. In the case of M-treated wines, L^* might partly decrease as a consequence of the polysaccharidic nature of the enological product tested. The increase in the hue observed in the treated samples in relation to control wines might be due to the increase in the percentage of the derivative

pigments that are redder or more orange (above all, A-type vitisins and F-A$^+$ dimers) at wine pH.

Modification of the Pigment Composition after Cold Treatment. Figure 1a also shows the location of the samples along PC1 and PC2 after cold treatment (C1*, T1*, and M1*). Cold treatment barely modified PC1 in control and M-treated wines, whereas it caused a decrease in PC1 in the samples to which enological tannin was added. This decrease correlates with an increase in the percentage represented by some anthocyanin derivatives (F-A$^+$ dimers and A-type vitisins) and with a decrease in the percentage of native grape anthocyanins. On the contrary, all types of samples increased the values of PC2 in relation to those of the samples not subjected to cold treatment. Taking into account the loadings of this PCA (Figure 1b), an increase in PC2 correlates with a decrease in acetyl and *cis*-coumaroyl derivatives and with an increase of the percentages of F-A$^+$ dimers, *trans*-coumaroyl derivatives, and some A-type vitisins. It has to be noted that M-treated samples showed the lowest change along PC2 after cold treatment. Thus, taking into account that these samples barely changed along PC1, the addition of product M to the samples seems to stabilize the pigment composition against cold treatment. To determine the compound groups that are mostly benefited by these enological practices, the percentages of the main pigments in the sample before cold treatment were compared to those determined in the precipitates (see Table 2 for the percentages of the individual compounds and Table 3 for the percentages of the main groups of pigments). It was first observed that in all types of wine the total percentage of the F-A$^+$ dimers was lower in the precipitates than in the sample not subjected to cold treatment. This means that independent of the addition of one or other enological product F-A$^+$ dimers are quite unaffected by cold treatment. In fact, some of these dimers that were present in the samples not subjected to cold treatment were not detected in the precipitates (Table 2). Although for most of the F-A$^+$ dimers the lowest percentages were found in the precipitates of the M-treated samples, differences among treatments were not significant. On the contrary, the difficult resolution pigments responsible for the hump observed at the last part of the chromatogram were more represented in the precipitates than in the samples before being cooled. This is indicative of certain instability of this type of pigment against cold treatment. The lowest increase in the percentages was found in M-treated wines, pointing to a stabilizing effect of this product in this type of compound. Although the exact nature of these difficult resolution pigments is not well established, they are supposed to be polymeric pigments, and, in fact, dimeric anthocyanins have been reported to be a part of this group of pigments.[33] Product M probably caused their colloidal stabilization. The enological tannin employed in this study, on the contrary, caused a higher precipitation of these compounds, which is probably related to the higher content (data not shown) detected in this type of sample. However, from a statistical point of view, the percentages of this group of compounds in the precipitates were not statistically different in the different wines. In all of the samples, the percentage of anthocyanin monoglucosides decreased in the precipitates in relation to the samples before cold treatment. However, M-treated samples were those for which the percentages changed less. With respect to acyl derivatives, it was observed that, in general, the percentages of the acetylglucosides were lower in the precipitates than in the samples not subjected to cold treatment, whereas coumaroyl and caffeoyl glucosides increased their percentages in the precipitates (Tables 2 and 3). This is indicative of a higher instability of coumaroyl and caffeoyl glucosides toward cold in relation to acetyl derivatives. However, differences were observed among treatments. In the case of the coumaroylglucosides, the percentages found in the precipitates of control and tannin-treated samples were statistically higher than those determined in the samples not subjected to cold treatment. In the case of the samples treated with product M, the percentages of most of the coumaroylglucosides were not statistically different from those determined in the sample before cold treatment (Table 2). This fact points to a protective effect of product M toward the precipitation of this group of compounds caused by cold treatment. Gonçalves and co-workers[39] reported higher retention of malvidin 3-*O*-*p*-coumaroylglucoside by wine polymeric material in relation to other acetylated and nonacylated anthocyanins, which was attributed to the higher hydrophobicity of the coumaroylglucosides, which can increase the hydrophobic interactions between them and the polymeric material. The studies of Morata and co-workers[40,41] on the adsorption of anthocyanins on yeast cell walls also demonstrated that coumaroyl derivatives were the most adsorbed compounds, even in different yeast strains. Taking into account that the structure of the mannoproteins present in the cell wall of *S. cerevisiae* is similar to that of the mannoproteins released by the yeast to the wines and that they can represent up to 50% of the cell wall[20] and 80% of the exocellular polysaccharides released by yeast to the wines,[3] it can be assumed that coumaroyl derivatives are more retained by product M than other anthocyanins, thus being protected from precipitation by cold treatment. In the case of caffeoyl derivatives, the increase of the percentage in the precipitate was significant only in control samples, thus indicating differences between control samples and tannin- or M-treated samples. The percentage of the A-type vitisins also increased in the precipitates of all types of samples, but again, M-treated samples were those that changed less (Tables 2 and 3). Cold treatment reduces the solubility of the pigments and, as previously indicated, the solubility of A-type vitisins seems to be lower than that of the anthocyanins from which they are synthesized. For this reason, A-type vitisins were more affected by cold treatment than anthocyanins and their percentages increased in the precipitates in relation to those found in non-cold-treated samples. Cold might have favored the hydrophobic interactions between molecules and caused their precipitation. The addition of product M might have reduced this precipitation by adsorption of the mannoprotein on the pigment molecule, hindering the hydrophobic interactions. The malvidin 3-*O*-glucoside vinylphenol pyranoanthocyanin seemed to be quite stable against cold treatment because its percentage in the precipitates was similar to that detected in the samples before cold treatment (Tables 2 and 3). Although differences between treatments were not significant, the precipitates from M-treated samples were those that showed the lowest percentages in relation to the initial percentages, which might be indicative of the possible protective effect of product M against the precipitation of this pyranoanthocyanin by cold. Thus, it can be seen that the most relevant changes in the percentages of the pigments between control samples and their precipitates (decrease of anthocyanin monoglucosides and their acetyl derivatives, increase of A-type vitisins and coumaroyl derivatives) were lowered with the use of product M. The addition of the enological tannin also

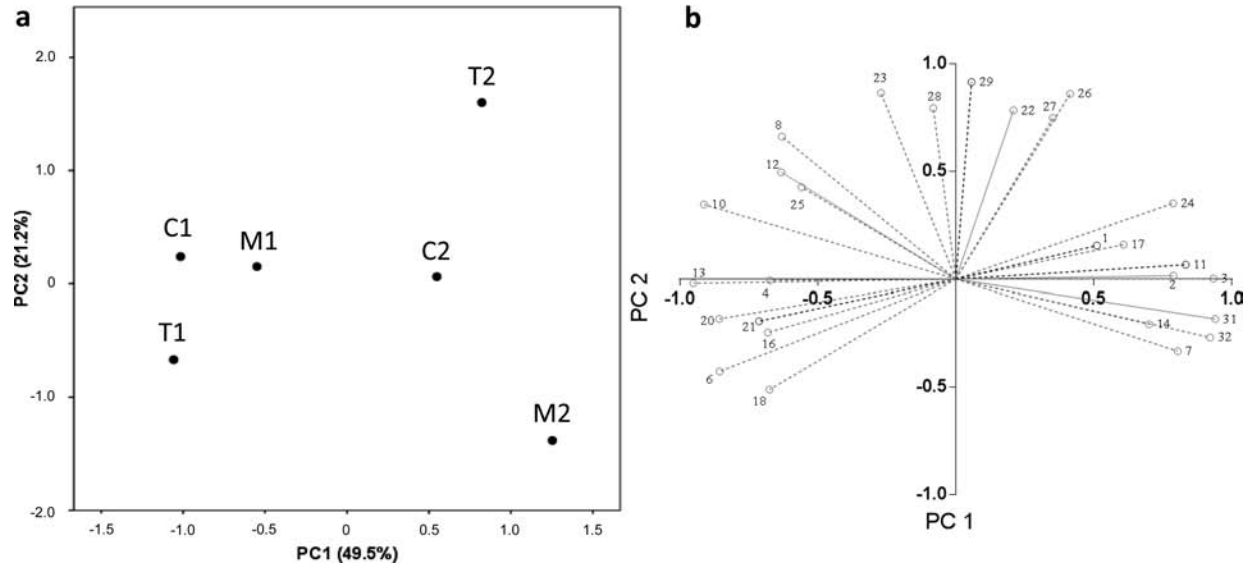

Figure 2. (a) Projection of the wine samples on the plane defined by the first and second principal components (PC2 vs PC1). These samples correspond to all wines (control, tannin- and M-treated wines) not subjected to cold in the first (samples C1, T1, or M1) and second sampling points (samples C2, T2, or M2). (b) Loadings of the original variables. The identities of the original variables are indicated in Table 2.

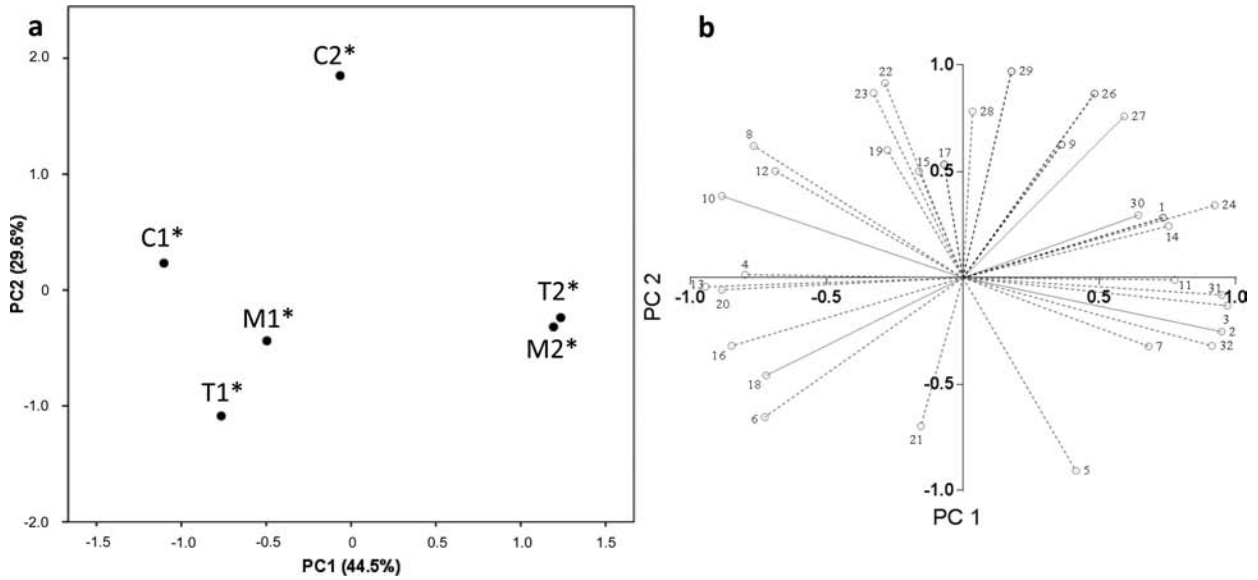

Figure 3. (a) Projection of the wine samples on the plane defined by the first and second principal components (PC2 vs PC1). These samples correspond to all wines (control, tannin- and M-treated wines) subjected to cold in the first (samples C1*, T1*, or M1*) and second sampling points (samples C2*, T2*, or M2*). (b) Loadings of the original variables. The identities of the original variables are indicated in Table 2.

preserved the samples from some of these changes, but the effect was lower than in M-treated samples.

Modification of the Pigment Composition over Time. Figures 2 and 3 show the score plots for the samples not subjected to cold treatment in both sampling points (C1, T1, M1, C2, T2, and M2, Figure 2) and for the samples subjected to cold treatment (C1*, T1*, M1*, C2*, T2*, and M2*, Figure 3). In both cases it can be seen that all of the samples are separated along PC1 according to sampling point, with the younger samples showing negative scores and the older ones, positive. According to the loadings (Figure 2b and 3b), this change from negative to positive scores with age is related to a decrease in anthocyanin monoglucosides, acetylglucosides, and B-type vitisin and to an increase in derivative pigments (F-A^+ dimers, A-type vitisins, malvidin 3-*O*-glucoside vinylphenol pyranoanthocyanin, and difficult resolution pigments). This is in accordance with what might be expected because as wine ages native anthocyanins react with other wine constituents, giving rise to anthocyanin-derived pigments. Nevertheless, some differences could be observed among treatments in both sample series (subjected and not subjected to cold treatment). In general, in sampling point 2, control samples were those that showed the lowest positive values of PC1. Tannin- or M-treated samples, on the contrary, showed the highest positive values. This means that independent of being cold-treated or not, tannin and M-treated wines still show higher percentages of derivative pigments than control wines after 10 weeks. In the series of wines not subjected to cold treatment (C2, T2, and M2), tannin- and M-treated samples were further separated along PC2, mainly due to higher percentages of derivative

dx.doi.org/10.1021/jf4055825 | J. Agric. Food Chem. 2014, 62, 6984−6994

pigments in M-treated samples and higher percentages of anthocyanin coumaroylglucosides in tannin-treated samples. However, these changes in the composition hardly cause differences in the CIELAB parameters because differences between T2 and M2 were not significant (Table 1). In the series of samples subjected to cold treatment (C2*, T2*, and M2*), there were no differences along PC2 between T2* and M2*. However, important differences along PC1 and PC2 could be observed between C2* and the treated samples (T2* and M2*) that were higher than in the case of the samples not subjected to cold. C2* shows a PC1 value next to zero and a PC2 positive value distant from the PC2 value of treated samples. This is related in both coordinates to lower percentages of derivative pigments. It has to be borne in mind that C2* samples come from C1*, control samples subjected to cold, that had already lost a part of the anthocyanin derivatives due to cold treatment. For this reason, differences between control and treated wines were higher in the cold-treated series than in the non-cold-treated ones. As previously indicated, C2* samples showed significantly higher values of lightness and lower values of chroma than treated wines (T2* and M2*). This means that even after 10 weeks from cold treatment, wines treated either with the enological tannin or with product M still show higher percentages of derivative pigments in relation to control wines.

In conclusion, the usefulness of the addition of either an enological tannin containing condensed and hydrolyzable tannins or a mannoprotein with medium−low molecular weight (product M) in stabilizing wine color against cold treatment has been demonstrated. Both enological treatments have been proven to slightly increase the hue of the wines to which they are added and to better maintain the color (L^*, C_{ab}^*, h_{ab}) of those samples after cold treatment than control samples. Furthermore, although time affected similarly all types of samples, after 10 weeks from malolactic fermentation (sampling point 2) tannin- and M-treated samples, either subjected to cold or not, still showed CIELAB color parameters more similar to those shown by control wines before cold treatment than those shown by control wines at sampling point 2. The pigment analysis has revealed that both enological treatments increased the percentages of anthocyanin-derived pigments in relation to control wines not only in wines not subjected to cold treatment but above all in cold-treated wines. In the case of the enological tannin, the higher percentages observed for these derivatives is probably due to a higher synthesis because the addition of the enological tannin can favor the extraction of anthocyanins from grapes during the maceration/alcoholic fermentation step and supplies substrates and/or oxidants to complete the synthesis reactions. Thus, the addition of the enological tannin leads to a chemical stabilization of the coloring matter of the wines, because grape native anthocyanins are transformed into anthocyanin-derived pigments that are chemically more resistant than anthocyanins toward hydration and/or SO_2 bleaching. In the case of the mannoprotein, it seems that the stabilization of the coloring matter consists of a colloidal stabilization. Cold treatment forced the precipitation of unstable coloring matter, revealing the unexpected colloidal instability of some chemically stable anthocyanin-derived pigments, such as A-type vitisins. However, the mannoprotein employed in the present study has been able to reduce the cold-induced precipitation of A-type vitisins and other derivative pigments and the spontaneous precipitation of these compounds in non-cold-treated samples. To our knowledge, this is the first report on the stabilizing effect of mannoproteins on anthocyanin derivative pigments. Further studies aim at evaluating the effect of the addition of both enological products to the same wine to attain a chemical and colloidal stability of the coloring matter.

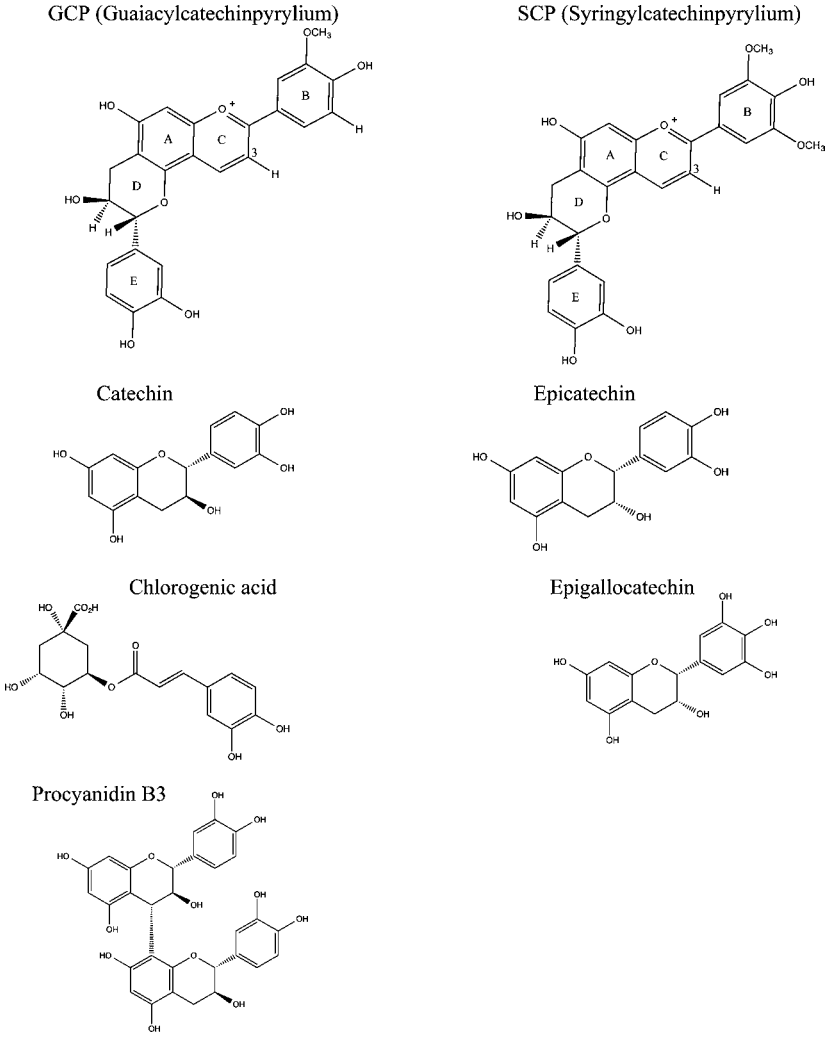

Figure 1. Chemical structures of the deoxyanthocyanidin derivatives, oaklins (GCP and SCP), and the copigments investigated in this work.

pigment/copigment solution was prepared by mixing a volume of pigment (10^{-4} M) solution with an aliquot of copigment solution to give the required pigment/copigment molar ratios of 1:0, 1:1, 1:5, 1:10, 1:20, 1:30, and 1:40. Each experiment was performed in triplicate. All of the solutions were left to equilibrate for 30 min before spectroscopic measurements. For GCP with the copigment epigallocatechin, the absorbance values were collected at the wavelength (λ_{max} 498 nm) of the isosbestic point of the flavylium cation (10^{-4} M) and its copigmentation complex (GCP/copigment molar ratio = 1:40). This parameter was determined in strongly acidic solutions (1 M aqueous HCl, pH ≈0) in which the flavylium ion is the sole anthocyanin form. However, for the rest of the copigments and for the pigment SCP, an isosbestic point was not observed; hence, the absorbance values were collected at the maximum absorption wavelength of free pigment (GCP/SCP) at pH 3.5 (λ_{max} 485 nm for GCP and 500 nm for SCP).

UV−Visible Spectroscopy. UV−visible spectra were recorded on a Bio-Tek Power Wave XS spectrophotometer at a constant temperature of 25 °C from 360 to 830 nm (1 nm sampling interval) using a 1 cm path length cell.

Data Analysis. The curve fittings were carried out using the software program MicroMath (Salt Lake City, UT, USA). Curve fittings were achieved through a least-squares regression method. Statistical analysis reported standard deviations and correlation coefficients.

Molecular Dynamic Simulations. The initial geometries of the pigments (GCP and SCP) and copigments (catechin, epicatechin, epigallocatechin, B3, and chlorogenic acid) molecules were built with GaussView software.[14] To calculate the optimized geometries and electronic properties for the subsequent parametrization of these compounds, the Gaussian 09 suite of programs[15] was used to perform restricted Hartree−Fock calculations (RHF), with the 6-31G(d) basis set. Atomic charges were further recalculated using the RESP algorithm.[16] This methodology was chosen for its consistency with that adopted in the parametrization process of the AMBER 10.0 simulation package.[17] Molecular dynamics (MD) simulations were performed with generalized Amber force field for small organic molecules (GAFF)[18] and the TIP3P model for the solute and water, respectively. Explicit solvation was included as a rectangular box with a 12 Å distance between the box faces and any atom of the compounds. One counterion (Cl^-) was employed to neutralize the positive charge of each system, which has a size of approximately 5700 atoms. All complex geometries were minimized in two stages: first, the solute was kept fixed and only the position of the counterion and water molecules was minimized (500 steps using the steepest descent algorithm and 1500 steps carried out using conjugate gradient); second, the full system was minimized (1000 steps using the steepest descent algorithm and 2000 steps carried out using conjugate gradient). Subsequently, an MD simulation of 100 ps at constant volume and temperature, and considering periodic boundaries conditions, was run, followed by 30 ns MD simulation with the NPT ensemble, in which Langevin dynamics was used (collision frequency of 1.0 ps^{-1}) to control the temperature at 303.15 K.[19] All simulations were carried out using the PMEMD module, implemented in the AMBER 10.0 simulation package.[17] Bond lengths involving a hydrogen atom were constrained using the SHAKE algorithm, and the equations of motion were integrated with a 2 fs time step using the Verlet leapfrog algorithm.[20] The particle-mesh Ewald (PME) method[21] was used to include the long-range interactions,

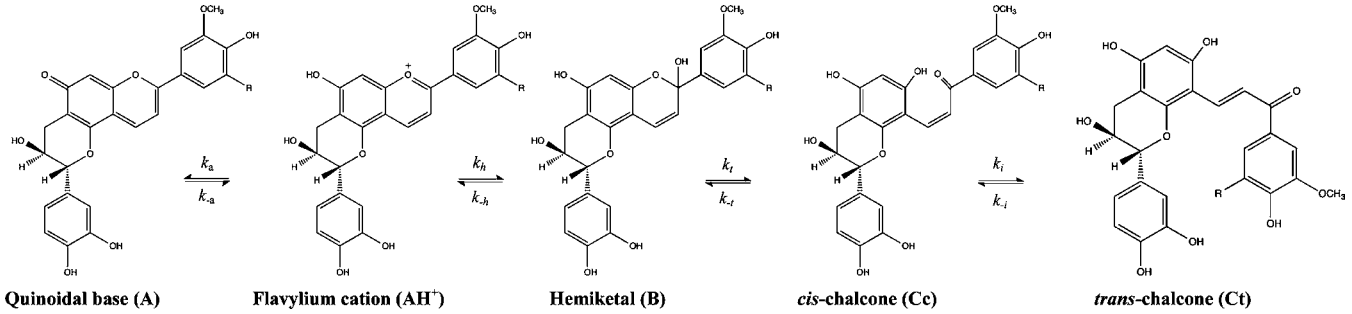

Figure 2. Network of chemical reactions of oaklins (R = OCH_3, SCP; R = H, GCP).

and the nonbonded interactions were truncated with a 10 Å cutoff. The MD trajectory was saved every 2 ps, and the MD results were analyzed with the PTRAJ module of AMBER 10.0.[17]

Calculation of Relative Binding Free Energies ($\Delta\Delta G_{binding}$). The molecular mechanics–Poisson–Boltzmann surface area (MM-PBSA) script[22−24] as implemented in the AMBER 10.0 simulations package[17] was used to calculate the binding free energies ($\Delta G_{binding}$) for all complexes. A series of 150 geometries was extracted every 100 steps of each simulation. The internal energy (bond, angle, and dihedral) and the electrostatic and van der Waals interactions were calculated using the Cornell et al. force field[25] with no cutoffs. The electrostatic solvation free energy was calculated by solving the Poisson–Boltzmann equation with the PBSA program. The nonpolar contribution to the solvation free energy due to van der Waals interactions between the solute and the solvent and cavity formation was modeled as a term that is dependent on the solvent-accessible surface area of the molecule. As these compounds possess similar structures and binding modes, the relative binding energies ($\Delta\Delta G_{binding}$) were calculated with respect to the most stable complex.

RESULTS AND DISCUSSION

The association of the oaklins GCP (guaiacylcatechin-pyrylium) and SCP (syringylcatechin-pyrylium) with the copigments selected (Figure 1) was quantitatively evaluated through the determination of the copigmentation binding constants (K_{CP}) for each pigment–copigment pair.

To minimize self-association effects in the intermolecular copigmentation studies, a low concentration of pigment (1×10^{-4} M) was used. Although ethanol largely reduces the copigmentation effect,[26] its inclusion in the experimental conditions was crucial to prevent precipitation during the spectroscopic analysis of the pigment and copigment compounds due to their low solubility in water.

Copigmentation Interactions Occurring in Oaklins. In a very acidic medium, only the flavylium cation is present, and the visible absorbance is

$$A_0 = \varepsilon_{AH^+} C$$

where C is the total pigment concentration and can be approximated to $C = [AH^+]$.

In contrast to anthocyanins, in which the contribution of quinonoidal bases (A) is negligible in mildly acidic medium (pH 3.5) and the hemiketal is the predominant species, in deoxyanthocyanidins, particularly oaklins, the equilibrium plateau occurs between the flavylium cation, the neutral quinoidal base, and the *trans*-chalcone, with the hemiketal and the *cis*-chalcone being transient species.[7] Copigmentation of the quinoidal bases could make a contribution, as those forms are also prone to stacking interactions with copigments. However, as the quinoidal bases and their copigmentation complexes absorb the visible light at higher wavelengths than their flavylium counterparts, no specific contribution is expected in the measured wavelength range (480–500 nm).[27] Copigmentation of quinoidal bases also promotes a high bathochromic shift (which is not observed in our case), especially with purine copigments such as caffeine and theophylline.[28]

With this in mind, the total concentration of the pigment for deoxyanthocyanidins at mildly acidic solutions can be represented by[11,29]

$$C = [AH^+] + [A] + [B] + [C_c] + [C_t]$$
$$= [AH^+] + [A] + [B']$$

where B′ is the pool of colorless forms in equilibrium.

The *apparent* thermodynamic constant for the overall reactions (Figure 2) taking place is thus given by

$$K'_a = K_a + K_h + K_h K_t + K_h K_t K_i$$

Being so, one can also write

$$C = \frac{[AH^+]}{1 + \frac{K'_a}{[H_3O^+]}}$$

In contrast to common anthocyanins in which $A_0 = ((\varepsilon_{AH^+}[AH^+])/(1 + (K_h/([H_3O^+]))))$, from the equations above and in the absence of the copigment one easily obtains

$$A_0 = \frac{\varepsilon_{AH^+} C}{1 + \frac{K'_a}{[H_3O^+]}} \quad (1)$$

In the presence of the copigment, and assuming a 1:1 stoichiometry for the complex, the visible absorbance at pH 3.5 becomes

$$A = \varepsilon_{AH^+} C + \varepsilon_{AHCP^+}[AHCP^+]$$

We thus have

$$A = \frac{\varepsilon_{AH^+} C(1 + rK_{CP}[CP])}{1 + \frac{K'_a}{[H_3O^+]} + K_{CP}[CP]} \quad (2)$$

with $r = (\varepsilon_{AHCP^+}/\varepsilon_{AH^+})$.

By combining eqs 1 and 2, A can also be expressed as[13,30]

$$A = \frac{\varepsilon_{AH^+} C(1 + rK_{CP}[CP])}{\frac{a}{r-a} + \frac{1}{(r-a)K_{CP}} \times \frac{1}{[CP]}} + A_0 \quad (3)$$

where $[CP]$ is the total concentration of the pigment, $a = (1/(1 + (K'_a/10^{-pH})))$, A and A_0 represent the visible absorbance of the pigment in the presence and absence of copigment, respectively, and r is the ratio of the molar absorption coefficient of the complex to that of the free flavylium ion. Because r is the ratio

between the molar absorption coefficient of the copigmentation complex and the free flavylium ion, r = 1 by definition at the isosbestic point (determined at pH ≈0 to ensure total conversion of the pigment into the flavylium form). Surprisingly, it was only possible to determine the isosbestic point with the pair GCP/epigallocatechin. Indeed, for the rest of the compounds, at pH ≈0, an unexpected hyperchromic effect of the pigment−copigment complex was observed instead of a bathochromic shift, which is typical of copigmentation interactions. In these cases, the maximum absorption wavelength of the complex was selected for the calculations and parameter r was estimated to be the ratio between the absorbance of the copigmentation complex and the free flavylium form at this wavelength (Tables 1 and 2).

An absorbance increase with the copigment concentration is observed, which reflects a preferential association of the copigment to the flavylium cation and the subsequent shift of the hydration toward the colored forms.

For each copigment, a plot of absorbance as a function of wavelength was presented, and the typical behavior of copigmentation phenomena was perceived: increase of absorbance (hyperchromic effect) and a slight bathochromatic shift of λ_{max} as the copigment concentration increased. Figure 3 presents the absorption spectra of free GCP and GCP/epigallocatechin complex obtained at several molar ratios (Figure 3A) and the corresponding mathematical treatment to determine K_{CP} according to eq 3 (Figure 3B).

Equation 3 was used for the curve fitting of the experimental data $A = f([CP])$ to achieve the optimized values for K_{CP} as the sole adjustable parameter. Statistical analysis gave good correlation coefficients and standard deviations for the copigmentation constants (K_{CP}) (Table 3).

The highest copigmentation binding constants were observed for the complexes with the copigment epicatechin with both pigments (GCP and SCP). The two pigments also followed a similar copigmentation pattern, with the following highest copigmentation constants observed in decreasing order for epigallocatechin and procyanidin B3. For GCP, the lowest two were observed in decreasing order for chlorogenic acid and catechin, whereas for SCP the decreasing order was catechin and chlorogenic acid.

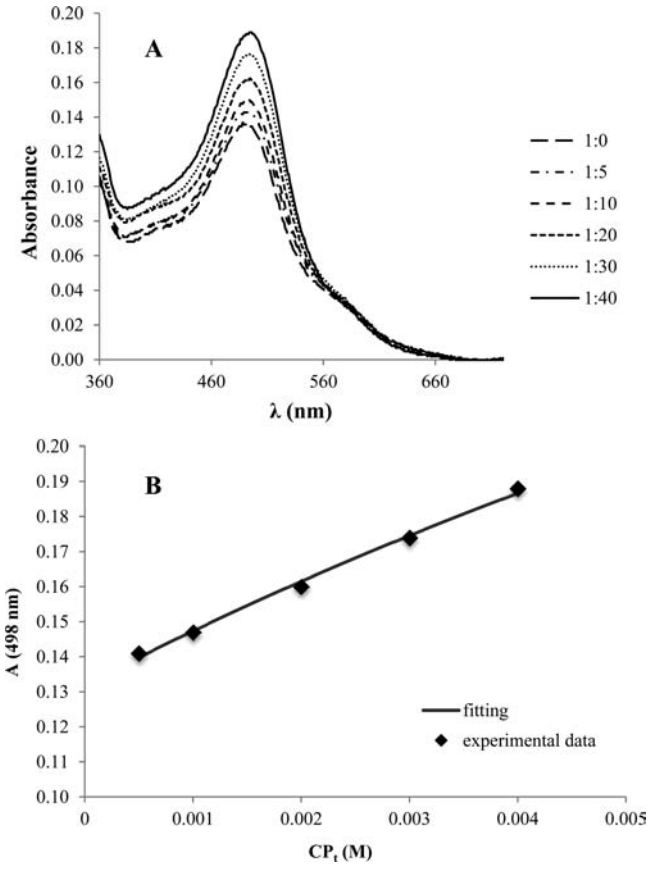

Figure 3. (A) Absorption spectra of GCP (0.1 mM) in the presence of epigallocatechin in a pH 3.5 phosphate buffer with 10% ethanol at 25 °C. Pigment/copigment molar ratios: 1:0, 1:5, 1:10, 1:20, 1:30, 1:40. (B) Plot of the visible absorbance at 498 nm as a function of copigment concentration; experimental points (◆) and theoretical curve (−) from a curve fitting according to eq 3 (pK'_a set at 3.05).

When comparing the copigmentation constants obtained for these deoxyanthocyanidin derivatives with the ones reported for anthocyanins, we observed similar results regarding their order of

Table 3. Copigmentation Constants for the Oaklin/Copigment Complexes

	GCP		SCP		oenin	malvin
copigment	K_{CP}	R^2	K_{CP}	R^2	K_{CP}	K_{CP}
catechin	101 (±2)	0.997	96 (±3)	0.998	136 (±4)[13]	
epicatechin	176 (±5)	0.999	165 (±4)	0.998	99 (±2)[13]	
chlorogenic acid	125 (±4)	0.995	90 (±2)	0.998		350[32]
epigallocatechin	165 (±3)	0.998	152 (±4)	0.995	177 (±7)[13]	
procyanidin B3	130 (±4)	0.998	117 (±5)	0.996	48 (±2)[13]	

magnitude. However, we found some interesting results for some copigments, such as epicatechin and procyanidin B3, which presented higher binding constants than what was expected for anthocyanins.[13,31,32]

Computational Studies of Pigment−Copigment Complexes. To better characterize the copigmentation behavior of each complex, computational studies were performed on copigment molecules (catechin, epicatechin, epigallocatechin, B3, and chlorogenic acid) complexed with both GCP and SCP pigments. Molecular dynamics simulations of 30 ns were carried out for these 10 distinct complexes, which allowed the respective conformational space to be sampled to identify several conformations for each copigmentation complex studied. A similar protocol was used in previous studies in the literature.[5,13,33] The relative binding free energies obtained by the MM-PBSA approach[22−24] are in total agreement with the experimental results (Table 4), which suggests that the MD simulations provide an accurate portrait for conformational analysis. Although the theoretical $\Delta\Delta G_{binding}$ values fit qualitatively with the experimental values, the quantitative differences are 10 times higher, which could be due to some approximations within the computational method. These results suggest that both GCP and SCP pigments have the ability to interact with the copigment compounds tested. Considering the copigmentation group with the GCP as pigment, the $\Delta G_{binding}$ energy of the GCP−epicatechin complex is the most negative value, followed by GCP−epigallocatechin, GCP−B3, GCP−cholorogenic acid, and GCP−catechin. In relation to the group with the SCP as pigment, the ranking obtained for the binding free energies is SCP−epicatechin > SCP−epigallocatechin > SCP−B3 > SCP−catechin > SCP−cholorogenic acid. In fact, these data indicate that the GCP/SCP−epicatechin and GCP/SCP−epigallocatechin complexes display higher stability and their formation is thermodynamically favored when compared to the other complexes. However, the maximum experimental and theoretical $\Delta\Delta G$ binding values (0.36 and 2.73 kcal/mol, respectively) reveal a higher stability for all copigmentation complexes.

Table 4. Relative Binding Free Energies of the Copigmentation Complexes

		$\Delta\Delta G_{binding}$ (kcal/mol)	
pigment	copigment	theor	exptl[a]
GCP	epicatechin	0.00	0.00
	epigallocatechin	0.65	0.04
	procyanidin B3	1.39	0.18
	chlorogenic acid	1.77	0.20
	catechin	3.19	0.33
SCP	epicatechin	0.00	0.00
	epigallocatechin	0.36	0.05
	procyanidin B3	1.10	0.20
	catechin	1.77	0.32
	chlorogenic acid	2.73	0.36

[a]Experimental values calculated from Table 2 using $\Delta\Delta G = RT \ln(K_{pigment:epicatechin}/K_{pigment:X})$.

Figure 4 shows the closest geometries to the average structures for the 10 GCP−copigment and SCP−copigment complexes. As expected, the formation and stabilization of each complex is ensured by the establishment of hydrophobic interactions between the polyphenolic rings, as well as hydrogen bonds with the hydrophilic hydroxyl polar groups of both compounds. According to the literature, the formation of copigmentation complexes is driven by van der Waals interactions between the large planar surfaces of the pigment and copigment and the concomitant release of high-energy water molecules from the solvation shells (hydrophobic effect). Although the copigmentation systems studied here have large numbers of degrees of

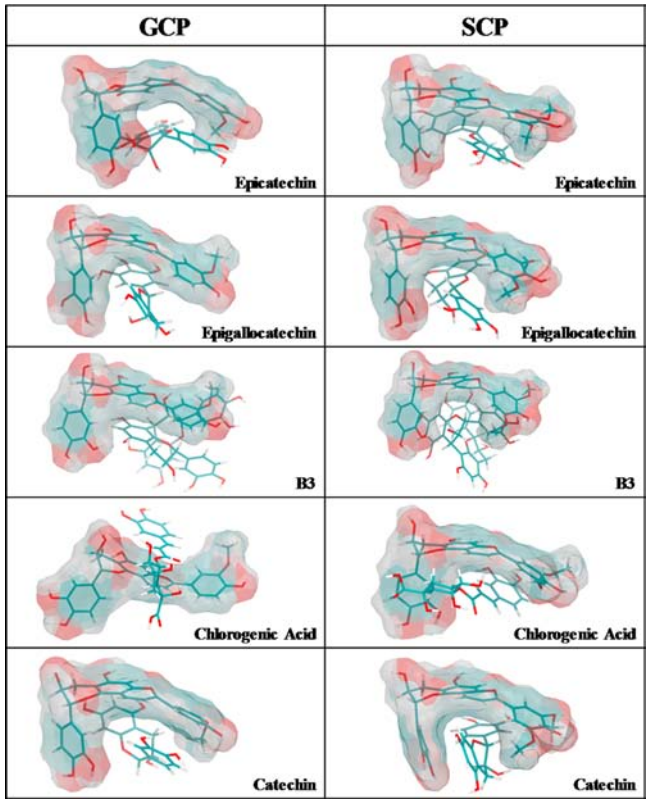

Figure 4. Closest geometries to the average structures of the GCP/SCP−epicatechin, GCP/SCP−epigallocatechin, GCP/SCP−procyanidin B3, GCP/SCP−cholorogenic acid, and GCP/SCP−catechin complexes. Carbon, oxygen, and hydrogen atoms are colored blue, red, and white, respectively. The charged pigment is depicted in a surface representation.

dx.doi.org/10.1021/jf404640m | J. Agric. Food Chem. 2014, 62, 6995−7001

freedom, the geometries displayed in Figure 4 show several optimized π-stacking arrangements. Hence, the proximity between aromatic planar surfaces of the pigment and copigment molecules should reflect the stability of each complex. The interplanar distances between the CAD nucleus, B and E rings of GCP/SCP, and the aromatic and benzopyrylium rings of each copigment were calculated along each MD simulation. Table 5

Table 5. Average Minimal Distances between Approximately Planar Surfaces of the GCP/SCP Pigments and Copigment Molecules in Each Copigmentation Complex

		average minimal distance (Å)		
pigment	copigment	CAD	B	E
GCP	epicatechin	4.95 (AC)	4.82 (B)	7.11 (AC)
	epigallocatechin	5.77 (AC)	5.97 (AC)	7.94 (B)
	procyanidin B3	5.81 (AC′)	5.52 (B′)	8.35 (AC′)
	chlorogenic acid	4.65 (B)	6.11 (B)	9.21 (B)
	catechin	5.31 (B)	6.56 (B)	8.44 (B)
SCP	epicatechin	5.28 (B)	6.37 (B)	6.60 (AC)
	epigallocatechin	5.65 (AC)	5.71 (AC)	7.18 (B)
	procyanidin B3	5.37 (AC)	4.87 (B)	6.83 (AC)
	catechin	5.48 (AC)	5.69 (B)	5.84 (AC)
	chlorogenic acid	5.78 (B)	5.11 (B)	7.59 (A)

shows the minimal distances obtained. The results show that the benzopyrylium and B rings of epicatechin and cholorogenic acid molecules are the closest planes to the CAD nucleous of GCP (4.95 and 4.65 Å, respectively). In addition, epicatechin is the copigment that has the nearest planes to the B and E rings of GCP (4.82 and 7.11 Å, respectively). Relative to the copigmentation complexes with SCP, epicatechin, B3, and catechin show minimal distances to the CAD, B, and E planes of this pigment (5.48, 4.87, and 5.84 Å, respectively). Because intermolecular distances of about 4 Å are consistent with van der Waals contacts, these data reveal that the shortest copigment−pigment distances were obtained for the complexes with the epicatechin copigment, which agrees with their highest stability constants (K).

According to the structures of the 10 complexes shown in Figure 4, it was observed that in both complexes (with GCP and SCP), the copigment epicatechin has its planar surfaces (AC and B) in an optimized position to establish a direct $\pi-\pi$ stacking and strong van der Waals contacts with CAD and B pigment planes. In both GCP and SCP complexes with epigallocatechin, the benzopyrylium provides a huge roughly planar polarizable surface that is strategically positioned in the middle of the pigment structure, establishing an accessible face and a closer contact with the B and E planes of both pigments. These facts contribute to a great association of epicatechin and epigallocatechin molecules to GCP/SCP pigments and thus to the also higher K values obtained for their complexes. For GCP/SCP-B3, it was observed that the AC′ nucleus of the copigment is located perpendicularly to the CAD plane of both pigments, which hampers the establishment of nonpolar contacts between both molecules. In relation to GCP/SCP−chlorogenic acid and GCP/SCP−catechin complexes, it was noted that there are several aromatic planes of these copigments facing solvent molecules, which prevents a simultaneous interaction of both moieties (A and B in chlorogenic acid; AC and B in catechin) with the CAD, B, and E nucleus of each pigment. Subsequently, because the hydrophobic contacts with the aromatic nucleus of oaklins are the major contributions to the copigmentation driving force, it is expected that chlorogenic acid and catechin have the smallest copigmentation binding contants. All of these structural data show that epicatechin and epigallocatechin copigments are closer to GCP and SCP pigments than B3, chlorogenic acid, and catechin molecules, which is in accordance with the first two copigments having the highest copigmentation binding constants for both pigments.

Furthermore, the copigmentation process could also be strengthened by H bonds involving the numerous hydroxyl groups from phenolic units. Table 6 shows the most important

Table 6. Most Important Hydrogen Bonds Established between Both Pigments (GCP and SCP) and Several Copigments during the MD Simulation of Each Complex

interaction	H bond	% of occurrence
OH-E ring (GCP)−OH-AC nucleus (epicatechin)	2.8 ± 0.1	5.8
OH-E ring (GCP)−OH-AC nucleus (epigallocatechin)	2.7 ± 0.1	5.8
OH-CAD nucleus (GCP)−OH-AC nucleus (procyanidin B3)	2.7 ± 0.1	12.7
OH-CAD nucleus (GCP)−OH-B ring (chlorogenic acid)	2.8 ± 0.1	14.0
OH-E ring (SCP)−OH-AC nucleus (epicatechin)	2.7 ± 0.1	5.3
OH-E ring (SCP)−OH-AC nucleus (epigallocatechin)	2.7 ± 0.1	5.1
OH-E ring (SCP)−OH-AC nucleus (procyanidin B3)	2.7 ± 0.1	22.7
OH-CAD nucleus (SCP)−OH-A ring (chlorogenic acid)	2.7 ± 0.1	14.0

hydrogen bond (H bond) interactions established within each copigmentation complex studied. As seen, with the exception of catechin, all copigments make one important H bond with each pigment, which contributes to the copigmentation complex formation.

The deoxyanthocyanidin derivatives studied (oaklins) presented intermolecular copigmentation interactions. Despite the loss of color in solution being already greatly diminished in oaklin compounds when compared to anthocyanins, not only because the pK'_a is greater but also because the mole fraction of the base is substantially higher at higher pH values, they also demonstrated that they were capable of presenting copigmentation interactions with some wine copigments that further stabilize the flavylium cation in hydroalcoholic solutions, with higher binding constants than the ones reported for anthocyanins in some cases.

Due to their higher stability in aqueous solutions and copigment interactions, oaklins continue to be regarded as potential food colorants. Further studies are still required to test their chromatic properties at different conditions (temperature, sulfites, etc.) as well as their antioxidant capabilities.

anthocyanin-derived pigments. The molecular basis for the antioxidant properties mainly occurs by two different pathways: a hydrogen atom transfer or a single-electron transfer. These two mechanisms are described by eqs 1 and 2, respectively:[22−25]

$$ArOH + R^{\bullet} \rightarrow ArO^{\bullet} + RH \quad (1)$$

$$ArOH + R^{\bullet} \rightarrow ArOH^{\bullet+} + R^{-} \quad (2)$$

Previous computational studies have been performed on flavonoids and pyranoanthocyanins,[22−29] in which the bond dissociation energy (BDE) of their hydroxyl groups and the ionization potential (IP) were determined as the better representative descriptors for the radical scavenging ability. Lower BDE and IP values favor both H abstraction and the electron-transfer reactions and, in general, the gas phase computed values of BDE and IP for flavonoids fall in the ranges of 70−90 and 160−190 kcal/mol, respectively.[25]

In this paper, the geometrical features and the BDE and IP thermodynamic parameters of one anthocyanin and seven pyranoanthocyanins from aged wine have been computed to corroborate the experimentally determined antioxidant capability of these compounds.

MATERIALS AND METHODS

Chemicals. Dimethyl sulfoxide (DMSO) was purchased from Euriso-top; Trolox, 2,2-diphenyl-1-picrylhydrazyl, 2,2′-azobis[2-methylpropionamidine] dihydrochloride (AAPH), Hepes, NaCl, soybean L-α-phosphatidylcholine, iron(III) chloride ($FeCl_3$), and 2,4,6-tripyridyl-*s*-triazine (TPTZ) were purchased from Sigma-Aldrich.

TSK Toyopearl gel HW-40(S)-Tosoh (Tokyo, Japan), polyamide resin (100−120 mesh, SINOPEC, Hunan, China), acetonitrile (HPLC grade), and ethanol (absolute) were purchased from Carlo Erba (France); formic acid (98%, PA-ACS) and methanol (99.5%) were purchased from Panreac Química Sau (Spain); hydrochloridric acid (37% v/v), sodium hydroxide, and ethyl acetate were purchased from José M. Vaz Pereira, S.A. (Portugal).

Extraction of Anthocyanins. Anthocyanins were extracted from *Vitis vinifera* red grapes of Touriga Nacional variety by the addition of an acidulated solution of methanol/water (50% v/v) as described elsewhere.[30] The obtained anthocyanin extract was concentrated using a nanofiltration system (membrane Desal 5 model DK 150−300 Da). Methanol was evaporated by rotary evaporation under vacuum at 30 °C, and the solution was frozen in water and freeze-dried.

The anthocyanin extract, dissolved in water, was purified by column chromatography using a polyamide resin. The fraction recovered with a solution of 10% (v/v) aqueous methanol was analyzed by HPLC and found to contain anthocyanin-3-glucosides; another fraction recovered with a solution of water/methanol 40% (v/v) was shown to contain acylated anthocyanins. The fractions were concentrated in a rotary evaporator under vacuum and frozen in water for later lyophilization.[31] The pigments were purified by preparative HPLC (Knauer K-1001) fitted with a Purospher C-18 reversed-phase column, 250 mm × 25 mm i.d., at 520 nm using a UV−vis L-2420 Elite LaChrom detector. The injection volume was 2 mL. The solvents were (A) H_2O/HCOOH (9:1) and (B) HCOOH/MeOH/H_2O (1:5:4). The gradient consisted of a linear gradient from 60 to 0% A in 70 min at a flow rate of 5 mL/min for the isolation of malvidin-3-coumaroylglucoside and from 65 to 15% A in 70 min at a flow rate of 10 mL/min for the isolation of malvidin-3-glucoside. The column was washed with 100% B during 20 min and then stabilized at the initial conditions for another 20 min. The isolated compounds were frozen in water and freeze-dried. The purity of the compounds was confirmed by HPLC/DAD-ESI/MS and NMR.

Hemisynthesis and Purification of Pyranoanthocyanins. Oxovitisin (**9**) and the coumaroyl derivative of oxovitisin (**10**) were synthesized and purified according to the procedure described elsewhere;[32] vitisin B (**7**) and the coumaroyl derivative of vitisin B (**8**) were synthesized from the reaction of malvidin-3-glucoside and malvidin-3-coumaroylglucoside, respectively, with vinyloxytrimethylsilane as previously reported;[33] vitisin A (**6**) was obtained from the reaction of malvidin-3-glucoside with pyruvic acid in water at pH 2.6 and at 35 °C with a molar ratio 50:1 (pyruvic acid/malvidin-3-glucoside) over 5 days as previously reported;[32,34] methylpyranomalvidin-3-glucoside (MethylPyMv3gluc) (**11**) was synthesized and purified according to the literature;[7] PyMv3gluc-(+)-catechin (**4**), PyMv3coumgluc-(+)-catechin (**5**), PyMv3gluc-catechol (**2**), and PyMv3coumgluc-catechol (**3**) pigments were obtained according the procedures described elsewhere.[11,35,36] Briefly, solutions containing Mv3glc or Mv3coumglc (2.5 mM) were incubated with 8-vinyl-(+)-catechin, 8-vinyl-(−)-epicatechin, or 4-vinylcatechol (2−3 equiv) in 5−10% ethanol/water at pH 3.5 (adjusted with dilute HCl or NaOH) at 30 °C.

Purity Evaluation of the Compounds. The purity of all pigments obtained was confirmed by MS and NMR analysis by using a ^{1}H NMR (600.13 MHz) and ^{13}C NMR (150.90 MHz) in DMSO/TFA (9:1) on a Bruker Avance III 600 spectrometer with a TCI CryoProbe at 293 K using TMS as internal standard.

Radical Scavenging Assay (DPPH). The tested compound reacts with DPPH (2,2-diphenyl-1-picrylhydrazyl) and induces a decrease of the absorbance measured at 515 nm, which indicates the scavenging potential of the compounds. Because all tested pigments also absorb at 515 nm, their initial absorbance ($t = 0$) was subtracted. The reaction for scavenging DPPH radicals was performed in a microplate reader of 96-well plates (Biotek Powerwave XS with software KC4). The reaction was carried out on the plate wells with a temperature of 25 °C. A solution of 60 μM DPPH was prepared in methanol, and 297 μL of this latter solution was added in each well together with 3 μL of antioxidant. The compounds to be tested were previously dissolved in methanol and used in a final concentration of 10 μM. The decrease in absorbance was measured at 515 nm, at $t = 0$ and every 10 min, during 30 min. For the final results, the 0−20 min reaction time window was used. Antiradical activity was expressed as micromolar Trolox equivalents. The antiradical activity was calculated from the equation determined from linear regression after plotting standard solutions of Trolox with different concentrations.

Lipid Peroxidation Assay. Liposomes were prepared as described elsewhere.[19] Lipid peroxidation of L-α-phosphatidylcholine soybean lipid unilamellar vesicles (LUVs) was induced by peroxyl radicals generated at a constant rate, by thermal degradation of the azo compound AAPH in the presence or absence of antioxidants, and followed by measuring the oxygen consumption.

The rate of oxygen consumption was measured continuously with a Clark-type oxygen electrode (Hansatech) provided with an automatic recording apparatus. The reaction mixture containing 1220 μL of Hepes buffer (pH 7.4), 256 μL of liposomes (340 μM final concentration), and 2 μL of the antioxidant (1 mM initial concentration) tested, dissolved in methanol, was left in a 37 °C thermostated bath for 1 h. This mixture was introduced in a closed glass vessel, protected from light, thermostated at 37 °C, and provided with a stirrer, and the reaction was started by the addition of 22 μL of AAPH (10 mM final concentration).[37] The induction periods (Ti) in the presence of antioxidants were determined graphically from the profiles of oxygen consumption by the coordinates of the interception of tangents to the inhibited and uninhibited rates of oxidation.[19] In addition to the analysis of the anthocyanin-derived pigments, the antioxidant activity of Trolox (water-soluble analogue of vitamin E) was evaluated. The results were expressed in terms of ratio between these pigments and Trolox antioxidant capacities.

Theoretical and Computational Studies. The energies of all geometries of anthocyanin-derived pigments and their respective radicals were calculated in vacuum with the density functional theory (DFT) approach, at the unrestricted B3LYP[38−40] hybrid density functional level (Becke−Slater−HF exchange with Lee−Yang−Parr correlation functional) using the 6-311+G(d) basis set as implemented in the Gaussian 09 package.[41] The inclusion of polarization functions correctly takes into account intramolecular H bonds. The optimized structures were confirmed as true minima by vibrational analysis performed at the same level of theory. A temperature of 298.15 K and a pressure of 1 atm were used for vibrational frequency and thermal energy correction calculations. Single-point energy calculations using

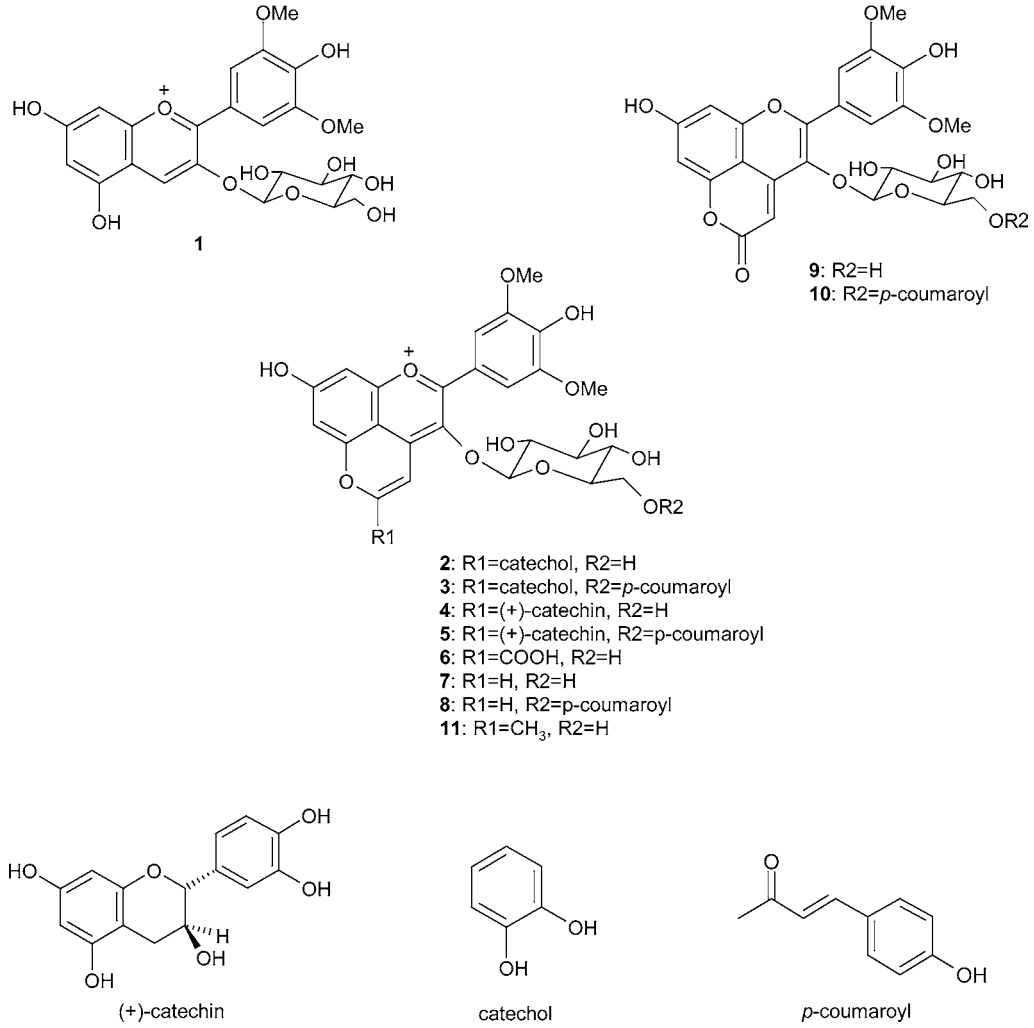

Figure 1. Structures of the pigments studied: malvidin-3-glucoside (**1**), PyMv3gluc-catechol (**2**), PyMv3coumgluc-catechol (**3**), PyMv3gluc-(+)-catechin (**4**), PyMv3coumgluc-(+)-catechin (**5**), vitisin A (**6**), vitisin B (**7**), coumaroyl derivative of vitisin B (**8**), oxovitisin (**9**), coumaroyl derivative of oxovitisin (**10**), and MethylpyMv3gluc (**11**).

the 6-311++G(d,p) basis set were performed at the B3LYP level of theory. This basis set was specifically used because it provided very reliable results in other studies performed for polyphenolic antioxidants.[22,23,27,29] The unrestricted open-shell approach was used for radical species. No spin contamination was found for radicals; values were 0.750 in all cases. To evaluate the effect of the solvent environment, the energy of all optimized geometries (using a dielectric constant (ε) of 78.35 to mimic the water solution) was recalculated. Solvation energies

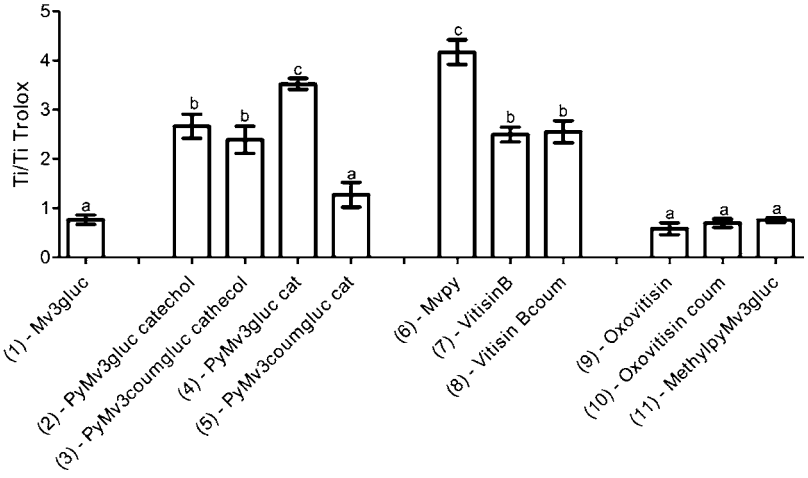

Figure 3. Inhibition of AAPH-initiated oxidation of soybean PC liposome by a 1.25 μM concentration of compound by monitoring oxygen consumption. Results are inhibition times in ratio to Trolox. Columns represent mean ± standard deviation (SD) $p < 0.05$. Columns with the same letter do not differ statistically.

were computed with the polarizable continuum method (PCM) using a polarizable conductor calculation model.[42] Gas-phase corrections were employed to calculate enthalpy values in the aqueous and alcoholic phases, as thermal corrections are expected to be similar in both gas and solvated phases.

Both BDE and IP values were computed at 298.15 K. The former is the sum of the enthalpy of the radical resulting from the hydrogen atom abstraction and that of the hydrogen atom minus the enthalpy of the parent molecule, whereas the latter is the enthalpy difference between the radical cation and the parent molecule.

Statistical Analysis. All tests were conducted at least in triplicate. Values are expressed as means ± standard deviation. Statistical significance was evaluated by one-way ANOVA, followed by the Bonferroni test. Differences were considered significant when $p < 0.05$. Columns with the same letter in the figures are not statistically different.

RESULTS AND DISCUSSION

This work aimed at studying some antioxidant features of pigments derived from malvidin-3-glucoside (the major anthocyanin present in *Vitis vinifera* red grapes). For this, 10 malvidin-3-glucoside derivatives belonging to different classes of pyranoanthocyanins were obtained by hemisynthesis (Figure 1). All of these pigments have already been detected in red wines, especially Port red wines, although in very low amounts.

The antioxidant features of these compounds were tested by assessing their antiradical potential (using the DPPH method) and their capacity to prevent lipid peroxidation using soybean L-α-phosphatidylcholine (PC) LUVs as lipid substrate. The protection against lipid peroxidation was assayed by monitoring oxygen consumption during oxidation of soybean PC liposomes. The antioxidant features of all the pyranoanthocyanins tested were compared to that of malvidin-3-glucoside.

DPPH. Following the method described in the literature[43] with some modifications, radical activities were determined by using DPPH as a free radical. Overall, the results indicate that all classes of pyranoanthocyanins tested displayed antiradical properties, as seen from Figure 2. The structural transformations of malvidin-3-glucoside into new pigments did not compromise its antiradical capacity, having even increased it in certain cases. Indeed, the three vitisin-like pigments tested were found to display a higher antiradical capacity. On the other hand, the oxovitisins tested and methylpyranomalvidin-3-glucoside were found to maintain an antiradical capacity similar to that of malvidin-3-glucoside (Figure 2). As to the pyranoanthocyanin-catechols and pyranoanthocyanin-catechins, the results are similar to those obtained with the vitisin-like pigments except for PyMv3gluc-catechol (also known as pinotin A) that displayed a 2-fold higher antiradical capacity than malvidin-3-glucoside (Figure 2). This outcome is likely to be related to the presence of an additional *o*-dihydroxyl group in its structure (catechol) combined with the extended conjugation of π electrons that could readily stabilize the radical scavenged. This structural feature is often associated with a higher radical scavenging capacity.[15,16,44,45] However, this outcome was not obtained in the case of the two pyranoanthocyanin-catechins tested (PyMv3-gluc-catechin and PyMv3coumgluc-catechin). Other structural features such as steric hindrances may partly impair the antiradical capacity of the compounds.

Altogether, the general tendency of the antiradical capacity observed in this study agrees with some data already reported in the literature, although only a marginal effect of the catechol moiety was observed in another work using a different lipid substrate.[46]

Monitoring Oxygen Consumption during the Oxidation of Liposomes. The protection afforded by these malvidin derivatives toward lipid peroxidation was assayed by monitoring oxygen consumption during oxidation of soybean PC liposomes (Figure 3). Liposomes were used as they are usually employed to mimic biological targets (e.g., cellular membranes). The evaluation of the antioxidant capacity of the anthocyanin pigments, against oxidation of soybean PC liposomes, was performed using AAPH as a peroxidation initiator, as commonly used in this kind of study. The generation of peroxyl radicals from AAPH induces a significant oxidation of phosphatidylcholine, because they are able to remove hydrogen atoms from polyunsaturated acyl chains, yielding radicals that lead to the propagation chain.[47] The data yielded from the oxygen consumption assays showed that all of the anthocyanin pigments scavenged efficiently the peroxyl radicals generated in the aqueous phase compared to the control assay (without any compound) (data not shown).

The results are presented in the form of a ratio between the induction time (Ti) of the compound tested and that of Trolox. This induction time is representative of the delayed time of oxygen consumption, which remains practically constant prior to the initiation of lipid peroxidation.[37]

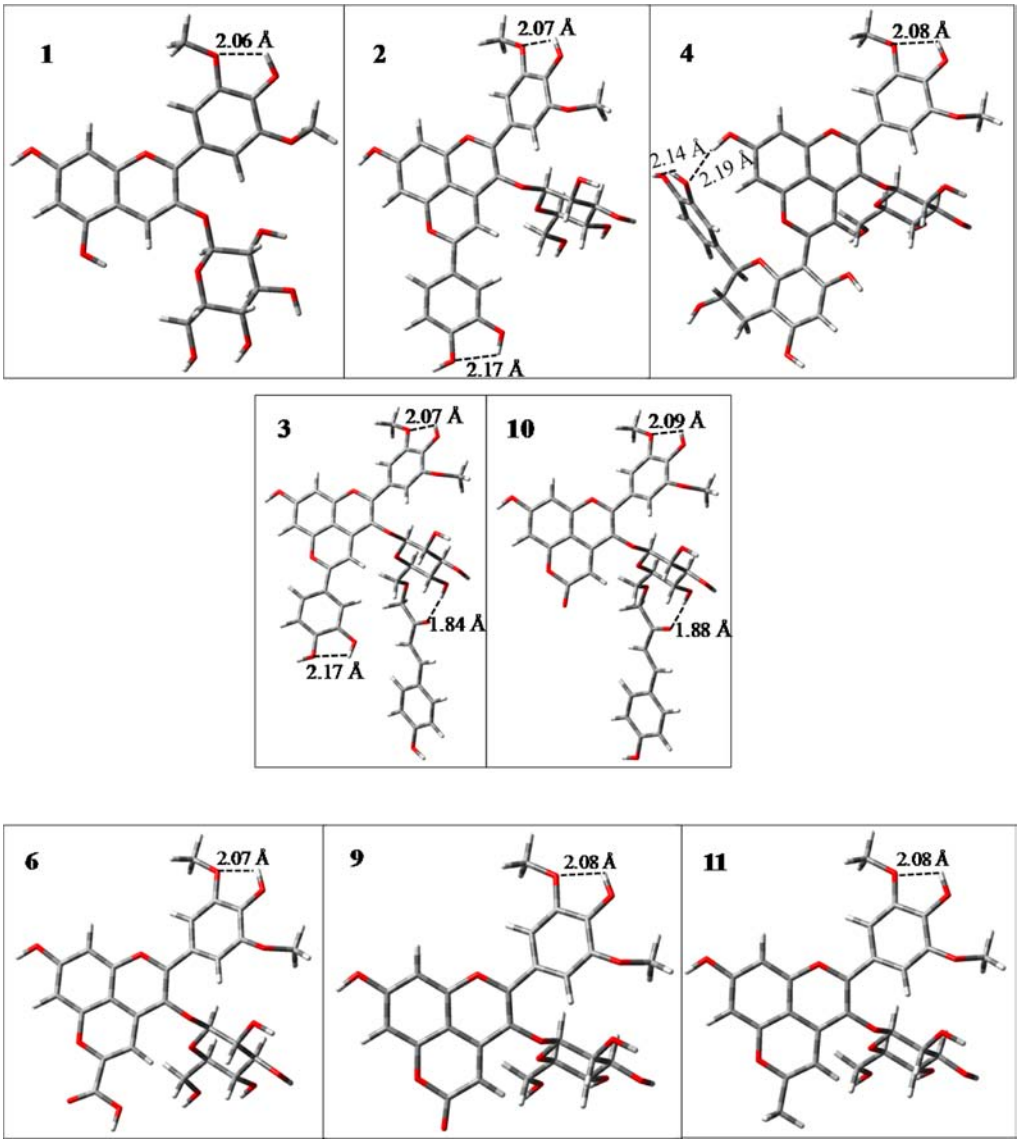

Figure 4. Optimized geometry of pigments **1**, **2**, **3**, **4**, **6**, **9**, **10**, and **11**. Oxygen, carbon, and hydrogen atoms are colored in red, gray, and white, respectively.

In the presence of any antioxidant, lipid peroxidation is delayed during a certain period of time that varies with the antioxidant capacity of the tested compound. The anthocyanin pigments are thought to trap AAPH-derived peroxyl radicals, inhibiting the initiation of lipid peroxidation. On the other hand, if located at the surface of the liposome, they may also quench liposome-derived peroxyl radicals, inhibiting the chain propagation.[48]

Bearing in mind the results obtained from the DPPH assay, one could assume that a similar trend was expected for the lipid peroxidation assay. However, some slight differences were observed.

The oxovitisins tested and methylpyranomalvidin-3-glucoside were found to maintain an antioxidant potential similar to that of malvidin-3-glucoside (Figure 3), as also observed in the DPPH assay (Figure 2). Furthermore, the vitisin-like pigments, the pyranoanthocyanin-catechols and pyranoanthocyanin-catechins, were found to delay the peroxidation of the PC liposomes more than malvidin-3-glucoside (Figure 3). These results also agree with those yielded from the DPPH assay. The only differences are related to PyMv3gluc-catechin and the pyruvic adduct of malvidin-3-glucoside Mv-py, also known as vitisin A. These two latter pigments were shown to be the most effective in delaying lipid peroxidation. The available data allow only speculation that this feature may be due to the proximity/affinity of the molecules toward the lipid layer, thereby promoting a higher protection through a more efficient radical scavenging capacity. This feature is closely related to the polarity of part of or the whole molecule.

Theoretical and Computational Studies. The pigments studied here were **1**, **2**, **3**, **4**, **6**, **9**, **10**, and **11**. and their optimized geometries are shown in Figure 4. All pyranoanthocyanins possess an intense π electron delocalization and conjugation that involve the rigid core composed by A−C−D rings and a less rigid B ring. In pigments **2** and **3**, the presence of the E ring draws electron flow that enhances the possibility of delocalization and conjugation in this part of the molecule. A similar behavior was observed in compound **4** that possesses a catechin group and allows a major delocalization and conjugation in this moiety.

Furthermore, all minimum energy structures are specially arranged to maximize the number of intramolecular H bonds

10	0.0	5.9							4.6
11	0.0		9.9						

within the B, E, and sugar rings. It was observed that in all molecules, the HO-4′ establishes a H bond to the adjacent 3′-OCH_3 group, whereas an additional H bond is established between the 3′-OH and 4′-OH groups of pigments **2** and **3**. Pigments **3** and **10** possess another H bridge established between the carbonyl group of the *p*-coumaroyl moiety and the 4-OH of glucose unit. Compound **4** shows two more specific H bonds, one within the catechin unit and another between an OH group of the catechin B ring and the OH group of the pyranoanthocyanin A ring. Furthermore, there are several H bonds established between the various hydroxyl groups of the pyranoanthocyanin sugar ring. However, they should not influence the reactivity of the polyphenol molecules, although these energetic H bonds can stabilize the whole systems.

Radicals from Hydrogen Abstraction. By abstracting an H atom from every HO group present on the eight molecules studied, two (for **6**, **9**, and **11**), three (for **1** and **10**), four (for **2**), five (for **3**), and seven (for **4**) radical species are obtained. The relative energies of all radicals are presented in Table 1, and the optimized geometries of all radicals are given in Figure SI-1 in the Supporting Information (SI). As observed, the HO-4′ radicals of pigments **1**, **6**, **9**, **10**, and **11** are the most stable, probably due to resonance effects around the radical center. For pigments **2**, **3**, and **4**, the absolute minimum of radical species is the HO-4″. Radical species **2** and **3** are particularly stabilized by the presence of the previously mentioned intramolecular H bond within the OH groups of catechol moiety, whereas the radical of compound **4** is also stabilized by the intermolecular H bond in the B ring of its catechin group.

Figure SI-1 also shows the highest values (colored in green) of atomic spin density distribution of the most stable radicals of all eight pigments. As seen, radical species of pigments **1**, **6**, **9**, **10**, and **11** have the spin density distribution more concentrated at O-4′, suggesting that the unpaired electron remains on the radical oxygen atom and that there is some involvement of the adjacent $-OCH_3$ groups and atoms of pyranoanthocyanin B ring due to the possibility of resonance effects. Similarly, the atomic spin density of pigments **2** and **3** shows that the unpaired electrons are located mostly on the O4″ atoms at E rings, as well as the unpaired electron of radical 4-O4″ is mainly placed on the O4″ atom. It was also observed that a certain delocalization around all atoms of the B ring of catechin group exists.

Radicals from Electron Abstraction. The optimized geometries of the eight radical cations are shown in Figure SI-2 in the SI. All cation radical species retain the intermolecular H bonds established in the parent stable molecule. Figure SI-2 also indicates that the atomic spin density of all cation radicals is mainly found at the pyranoanthocyanin B ring. Both cation radicals of **9** and **10** have a high atomic spin density concentrated at the oxygen atom of ring D, due to the high capacity of the carbonyl group to retain the unpaired electron.

Bond Dissociation Energy (BDE) and Ionization Potential (IP) Values. Table 2 shows the BDE and IP computed values for the eight pigments in the gas and aqueous media. The BDE gas phase values ranged between 64.6 and 73.3 kcal/mol, which slightly decrease in a water environment. Pigment **2** shows the lowest value of BDE in both vacuum and condensed phases. This pigment possesses two hydroxyl groups at rings B and E, and the high electron delocalization involving both aromatic rings causes a stabilization of radicals formed upon H abstraction, which affects and decreases the BDE value. In addition, the presence of two *O*-methyl groups around the OH group at the B ring favors the radical formation and allows low BDE values. Compared with pigments **2** and **3**, the addition of the bulky cathechin and *p*-coumaroyl groups increases the BDE value by approximately 4 and 6 kcal/mol (BDE values of 68.8 and 71.2 kcal/mol in vacuum, as well as 67.0 and 70.0 kcal/mol in water, respectively). Although pigments **6**, **9**, and **11** differ in the substituent group at C12 (COOH, CO, and CH_3 groups, respectively), their BDE values are very similar, which indicates the absence of specificity of this carbon position to BDE values. The addition of an extra *p*-coumaroyl group in pigment **10** increases the BDE value by approximately 2 kcal/mol, in relation to pigment **9**. According to the IP values computed for the eight anthocyanin/pyranoanthocyanins studied, the condensed media also decrease the energy required to extract a single electron. However, the drop in condensed IP values is more highlighted due to the occurrence of electrostatic interactions with the double-charged radicals. The lowest IP values (159 and 147 kcal/mol in the gas phase; 131 and 123 kcal/mol in water) exhibited by pigments **9** and **10**, respectively, indicate that they are better in donating a single electron to oxidant molecules in solution. These pigments are followed by pigments **2**, **4**, and **3**, in which their extra E rings/B catechin ring contribute to the lowering of

Table 2. Bond Dissociation Energies (BDE) and Ionization Potentials (IP) in the Gas Phase and Water Environment

	BDE		IP	
pigment	gas phase	water	gas phase	water
1	73.3	70.5	228	142
2	64.6	62.7	210	134
3	71.2	70.0	204	139
4	68.8	67.0	208	138
6	72.9	70.3	226	142
9	68.9	67.6	159	131
10	72.9	69.6	147	123
11	72.9	69.8	222	140

dx.doi.org/10.1021/jf404735j | J. Agric. Food Chem. 2014, 62, 7002−7009

the IP values because it allows a better distribution of the unpaired electron. The Mv-3-gluc molecule has the highest BDE and IP values in both gas and condensed phases, revealing a lesser ability of this molecule to act as a good antioxidant. Therefore, all of these results are in agreement with previous computational studies that suggested that the presence of D and E rings in pyranoanthocyanins contributes to the lowering of BDE values compared to anthocyanin molecules. In addition, an extended delocalization and conjugation of the π-electrons and the resonance phenomena greatly contributes to the mechanism of the electron transfer, decreasing the IP values.[23] Gas phase BDE values of the HO-4′ group in malvidin (96.0 kcal/mol)[49] and malvidin-3-*O*-β-glucoside (88.9 kcal/mol)[50] were computed at B3LYP/6-31G(d,p) and B3LYP/6-31G(d)//6-311G(2d,2p) levels. More recently, the gas and condensed phase BDE values of pigments **2** (78.5 and 89.9 kcal/mol), **6** (81.7 and 94.2 kcal/mol), and **9** (78.2 and 94.5 kcal/mol) were also computed at the B3LYP/6-311+G(d)//6-311++G(d,p) level.[26−29] The BDE values for these three molecules presented in this work are not exactly equal to the previous computational studies because the latter have substituted the glucose unit by a methyl group to reduce the computational effort. However, the ranking of the relative BDE and IP values of these molecules is similar, validating all of the other values.

In conclusion, the present experimental and computational data suggest that all classes of pyranoanthocyanins displayed antiradical properties, in particular the pigments **2**, **9**, **3**, **6**, and **11**. The only exceptions are the higher antiradical potential and antioxidant ability observed computationally for pigments **9**, **10**, and **11** when compared with experimental values. This unexpected result may be due to some approximations within the DFT method to describe BDE and IP values of uncharged molecules or some experimental conditions such as solubility problems associated with these specific molecules that can influence their antiradical potential. The antioxidant potential of anthocyanin derivatives, especially pigments derived from Mv-3-gluc, maintains the same level or is even increased. It was verified that the inclusion of a catechol or catechin moiety increases the antioxidant potential of the anthocyanin derivatives, which agrees with the key role of catechol proposed previously for the antioxidant capacity.[28,50]

cell functions in an allergic immune response, leading to an alleviation of allergy symptoms.[15] Polyphenols are also known to have significant binding affinity for proteins, which can lead to the formation of soluble and insoluble (precipitated) protein−polyphenol complexes.[16] Protein−polyphenol interactions can either be through hydrogen bonding or hydrophobic interactions, or polyphenols may cross-link between proteins.[17,18] Several studies were conducted in which phenolic acids such as caffeic, chlorogenic, ferulic, gallic, and recently tannic acid were bound to peanut proteins to form insoluble complexes, which rendered the remaining soluble portion of peanut and peanut butter extracts less allergenic.[19−22] However, a practical means for efficient modification of allergenic peanut proteins with natural plant-derived polyphenols to form a hypoallergenic peanut ingredient suitable for OIT has not previously been accomplished.

Recently, we described a novel tactic for stably binding plant polyphenols to high-protein flours or protein isolates (soy, hemp, peanut, or pea) to create low-calorie, dry, health-protective matrices (granular or powdered ingredients) with improved bioavailability, efficacy, and shelf stability of the fruit-derived components.[23−27] In the present work, we describe a novel approach to bind selected polyphenols to peanut flour, the current active ingredient for OIT, with the goal of masking IgE binding epitopes and attenuating allergenicity. A series of fruit juices and plant extracts with different characteristic polyphenol profiles were stably complexed with peanut flour, and the modified peanut protein−polyphenol chimeric matrices were screened for qualitative changes in IgE binding capacity, secondary protein structure, basophil activation capability (ex vivo), and mast cell degranulation (in vivo), to gauge the potential for various polyphenol moieties to modulate allergenicity. The ultimate goal of this research is to create dry, edible peanut matrices (peanut flour stably complexed with polyphenols) with reduced allergic potential and associated side effects that retain properties integral for modulating the allergic response of patients as a highly controlled, hypoallergenic edible OIT ingredient.

MATERIALS AND METHODS

Materials and Reagents. Lipophilic Sephadex LH-20, Amberlite XAD-7, Folin−Ciocalteu reagent (FCR), 4-(dimethylamino)-cinnamaldehyde (DMAC), catechin, epicatechin, gallic acid, and pepsin from porcine gastric mucosa (3802 U mg^{-1} protein, 92% purity) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Procyanidin A2 and procyanidin B1 were obtained from Chromadex (Irvine, CA, USA). Procyanidin trimer [epi-(4β → 6, 2β → O→7)-epi-(4β → 8, 2β → O→7)-cat] and tetramer [epi-(4β → 8, 2β → O→7)-epi-(4α → 6)-epi-(4β → 8, 2β → O→7)-cat] were obtained from Planta Analytica (Danbury, CT, USA). NuPAGE LDS sample buffer (4×) and Tris/glycine/SDS running buffer were purchased from Invitrogen (Carlsbad, CA, USA). Novex 16% Tricine gel, Novex Tricine SDS running buffer (10×), Novex Tricine SDS sample buffer (2×), NuPAGE reducing agent (10×), SeeBlue Plus2 prestained protein standard, MagicMark XP Western protein standard, SimplyBlue SafeStain, and bovine serum albumin (BSA) were purchased from Life Technologies (Grand Island, NY, USA). Criterion Precast Tris-HCl gel (10−20% polyacrylamide), Laemmli sample buffer, Bio-Safe Coomassie G-250 stain, and Precision Plus Protein Unstained standard were obtained from Bio-Rad (Hercules, CA, USA). Biotinylated goat IgG−anti-human-IgE was obtained from Kirkegaard & Perry Laboratory, Inc. (Gaithersburg, MD, USA). NeutrAvidin HRP (horseradish peroxidase), Super Signal West Pico Chemiluminescent Substrate, and Pierce BCA protein assay kit were purchased from Thermo Scientific (Rockford, IL, USA). Fluorescence-activated cell sorting (FACS) lysing solution was obtained from BD Biosciences (San Jose, CA, USA). Ethylenediaminetetraacetic acid (EDTA) and Roswell Park Memorial Institute medium (RPMI) were purchased from Cellgro (Manassas, VA, USA). Human rIL-3 was obtained from Miltenyi Biotec (Auburn, CA, USA). Cholera toxin was purchased from List Biologicals Laboratories, Inc. (Campbell, CA, USA).

Plant Materials. A series of fruit juice concentrates and plant extracts, representing different characteristic phytochemical profiles, was chosen to evaluate the relative efficacy of different polyphenolic groups to modulate the allergenicity of peanut flour. Elderberry (*Sambuccus nigra* L.) and aronia (*Aronia melanocarpa*) juice concentrates (65 °Brix) were provided by Artemis International (Fort Wayne, IN, USA). Muscadine grape (*Vitis rotundifolia*) juice concentrate from the Noble variety (65 °Brix) was obtained from Muscadine Products Corp. (Wray, GA, USA), and black currant (*Ribes nigrum*) juice concentrate (65 °Brix) was provided by The New Zealand Blackcurrant Co-operative Ltd. (Nelson, New Zealand). Cranberry (*Vaccinium macrocarpon* Ait.) juice concentrate (50 °Brix) was obtained from Urban Processing LLC (Wisconsin Rapids, WI, USA). Cinnamon powder (*Cinnamomum burmannii*, A grade, 3% oil) was purchased from Frontier Co-op (Norway, IA, USA), and organic green tea leaves (*Camellia sinensis*) from Sri Lanka were provided by QTrade Teas & Herbs (Cerritos, CA, USA). Light roast 12% fat peanut (PN) flour (*Arachis hypogaea* L.) was obtained from Golden Peanut Co. LLC (Alpharetta, GA, USA).

Preparation of Juices and Extracts. Dried green tea leaves were ground into a fine powder prior to extraction. Cinnamon or green tea powders were extracted with 50% ethanol (1:5; w/v). The mixtures were heated in a water bath at 60 °C for 1 h. Because the cinnamon powder extract was very viscous, it was subsequently diluted 1:1 (v/v) with 50% ethanol to obtain a final 1:10 (v/v) dilution. The solutions were centrifuged at 7000 rpm for 20 min (Sorvall RC-5B refrigerated centrifuge, DuPont Instruments, Wilmington, DE, USA) and filtered, and the ethanol was evaporated. The extracts were then reconstituted with water to original volume. Any precipitated material was separated by centrifugation, and the supernatant was filtered before treatment with PN flour. Juice concentrates required dilution prior to mixing with the PN flour because high viscosity otherwise interfered with effective mixing and separation of the flours. Aronia, Noble muscadine grape, and elderberry juice concentrates were diluted 2 times (1:1; v/v) with water. Black currant juice concentrate was diluted 4 times with water (1:3; v/v). Cranberry juice concentrate was diluted to both 2 times (1:1; v/v) and 4 times (1:3; v/v) with water. Degrees Brix was determined by measuring refractive index using an Abbemat 550 refractometer to estimate total sugar content (Anton Paar, Ashland, VA, USA).

Quantification of Polyphenols. Polyphenols were quantified in the original juices and extracts (Table 1). Total phenolics (TP) were determined using the Folin−Ciocalteu assay according to the method of Herald et al.[28] Results were expressed as milligrams per milliliter gallic acid equivalents (GAE) based on a gallic acid standard curve. Total proanthocyanidins (PAC) were determined using the 4-(dimethylamino)cinnamaldehyde (DMAC) assay with modifications.[29] Briefly, samples were diluted in 80% ethanol (v/v) when necessary. Fifty microliters of diluted or undiluted sample, blank (80% ethanol), or standard (procyanidin A2) was added to a 96-well plate. Subsequently, 150 μL of a 0.1% DMAC solution dissolved in acidified ethanol (ethanol, water, HCl; 75:12.5:12.5; v/v/v) was added to the plate and mixed using a multichannel pipet. Absorbance was measured using a Tecan Safire^2 plate reader (Tecan Group Ltd., Männedorf, Switzerland) at 640 nm for 30 min in 1 min intervals at 25 °C. Quantification of total PAC was performed from the maximum absorbance observed and expressed as micrograms per milliliter procyanidin A2 equivalents.

HPLC analysis of total monomeric anthocyanins (ANC) was performed using an Agilent Technologies 1200 series HPLC (Santa Clara, CA, USA) with a photodiode array (PDA) detector.[30] Samples were filtered through 0.2 μm cellulose syringe filters, and 5 μL was injected onto a Supelcosil-LC-18 column (250 mm × 4.6 mm × 5 μm,

Table 1. Total Phenolics (TP), Total Proanthocyanidins (PAC), and Total Monomeric Anthocyanins (ANC) Concentrations and °Brix Values in Juices and Extracts[a]

source	TP[b] (mg mL^{-1})	PAC[c] (mg mL^{-1})	ANC[d] (mg mL^{-1})	°Brix
cranberry juice 1:1 dilution	5.0 e	1.6	1.1	27.5 d
cranberry juice 1:3 dilution	2.1 de	0.7	0.5	14.1 f
cinnamon powder extract	0.9 f	0.4	NA[e]	2.5 h
green tea leaves extract	31.7 ab	59.5	NA	6.5 g
aronia juice	15.3 b	2.9	3.7	37.0 c
muscadine juice	8.8 d	0.4	3.3	39.6 a
black currant juice	12.9 c	2.0	2.5	19.9 e
elderberry juice	39.9 a	1.9	22.5	37.1 b

[a]Values within each column with different letters are significantly different at $p < 0.05$. [b]Determined by Folin−Ciocalteu assay and expressed as mg mL^{-1} gallic acid equiv. [c]Determined by DMAC assay as mg mL^{-1} procyanidin A2 equiv. [d]Determined by HPLC as mg mL^{-1} cyanidin-3-*O*-glucoside equiv. [e]NA, not applicable.

Supelco, Bellefonte, PA, USA) column, which was maintained at 30 °C. The mobile phase consisted of 5% formic acid in distilled H_2O (A) and 100% MeOH (B). Flow rate was set at 1 mL min^{-1} with a gradient as follows: 0−5 min, 10% B; 5−15 min, 15% B; 15−20 min, 20% B; 20−25 min, 25% B; 25−45 min, 30% B; 45−47 min, 60% B; 47−60 min, 10% B. Cyanidin-3-*O*-glucoside (0.25−1.0 mg mL^{-1}) was used as an external standard. ANC were detected at 520 nm and expressed as cyanidin-3-*O*-glycoside equivalents.

Preparation of Polyphenol-Fortified PN Matrices. PN flour was combined with diluted juice concentrates or extracts (30 g L^{-1}), mixed for 15 min at room temperature to allow sorption of polyphenols to PN proteins, and centrifuged for 20 min at 4000 rpm. A blank treatment (PN flour mixed with water only) was also prepared. The supernatant was decanted and filtered prior to analysis. The pellet was freeze-dried to afford the polyphenol-fortified PN matrix or blank (treated with water only) PN matrix. Polyphenols that were bound to PN matrices were extracted using the method described by Grace et al.[26] and quantified as described above in terms of milligrams of polyphenol per gram of polyphenol-fortified PN matrix.

Characterization of Polyphenol-Fortified or Blank PN Matrices and PN Flour. Moisture (percent) was determined gravimetrically by drying polyphenol-fortified PN matrices or unmodified PN flour in an oven for 6 h at 130 °C.[31] Percent fat was estimated using a Bruker minispec Plus mq$_{one}$ seed analyzer (Billerica, MA, USA). Water activity (a_w) was measured using an Aqua Lab 4TE device (DecagonDevices, Pullman, WA, USA). To determine protein solubility, 10% dispersions of polyphenol-fortified PN matrices or unmodified PN flour in phosphate-buffered saline (PBS, pH 7.5) were prepared. Total nitrogen content of the soluble fractions was determined using a 2400 CHN Elemental Analyzer (PerkinElmer, Norwalk, CT, USA).

PN Protein Distribution and PN-Specific IgE Binding. SDS-PAGE was used to observe protein distribution in polyphenol-fortified PN matrices and unmodified PN flour. PBS soluble fractions (from 10% dispersions; w/v) were added 1:1 to Laemmli buffer containing 5% mercaptoethanol. Samples were also solubilized in NuPAGE LDS sample buffer (10%; w/v) and centrifuged. Resulting LDS soluble fractions were added 1:1 to Laemmli buffer containing 5% mercaptoethanol. All samples were heated for 5 min at 95 °C. For PBS soluble fractions, equivalent protein (5.4 μg) was loaded per lane, whereas for LDS soluble fractions, equivalent volume (10 μL) was loaded per lane. Loaded samples were subjected to SDS-PAGE (55 min, 200 V) and stained with Bio-Safe Coomassie G-250 stain.

For the detection of PN-specific IgE binding by PN proteins, Western blotting was performed with pooled plasma from two PN-allergic individuals obtained from PlasmaLab (Everett, WA, USA). Both individuals had PN-specific IgE > 100 kU/L as determined via ImmunoCAP (Phadia, Uppsula, Sweden). SDS-PAGE resolved proteins were transferred to a polyvinylidene fluoride (PVDF) membrane (iBlot, Invitrogen, Carlsbad, CA, USA). The membrane was allowed to dry (30 min), rehydrated in MeOH (10−15 s), and washed with PBS containing 0.5% Tween20 (PBST, 1×) for 5 min. The membrane was then blocked in PBST containing 2% BSA for 1−2 h at room temperature. The membrane was incubated overnight with a 1:40 dilution (v/v) of pooled human plasma in PBST containing 2% BSA (primary antibody), then washed in PBST four times for 5−10 min, and subsequently incubated with biotinylated goat IgG−anti-human IgE (secondary antibody, 1:4000; v/v in PBST with 2% BSA) for 1 h. The membrane was again washed four times for 5−10 min and incubated with NeutrAvidin−horseradish peroxidase (HRP) conjugate (NA-HRP, 1:10000; v/v in PBST with 2% BSA) for 30 min. Finally, the membrane was washed for 5−10 min, incubated with Super Signal West Pico Chemiluminescent Substrate for 8 min, and developed on a ChemiDoc MP system (Bio-Rad).

Attenuated Total Reflectance−Fourier Transform Infrared Spectroscopy (ATR-FTIR). ATR-FTIR spectra of polyphenol-fortified PN matrices and unmodified PN flour were recorded using an IRPrestige-21 FTIR spectrometer (Shimadzu, Norcross, GA, USA) equipped with a MIRacle ATR accessory (Pike Technologies, Madison, WI, USA). Samples were pressed onto the surface of a ZnSe crystal using a micrometer pressure clamp. Spectra were collected in triplicate between the wavenumbers 600 and 4000 cm^{-1} and displayed between 1475 and 1800 cm^{-1}.

PN-Specific IgE Binding Capacity of PAC or ANC-Fortified PN Matrices. An Amberlite XAD-7 resin and acidified water (0.3% TFA; v/v) were used to remove free sugars, pectins, and organic acids from the cranberry juice concentrate to ultimately obtain a polyphenol-rich fraction. The fraction was freeze-dried, and the sugar-free polyphenol-rich extract was applied to a Sephadex LH-20 column (20 × 2 cm) and eluted with acidified (0.3% TFA) 80% MeOH (v/v) to collect the ANC-rich fraction. The column was then washed with 70% acetone (v/v) to elute the PAC-rich fraction. Organic solvents were evaporated and aqueous fractions were freeze-dried. The ANC or PAC fractions were dissolved in water and used to prepare ANC- or PAC-fortified PN matrices. IgE binding capacity of water-soluble or insoluble fractions of fortified PN matrices was evaluated by Western blotting as described above.

Specific Binding Capacity of Cranberry PAC to PN Flour. To investigate the specific binding capacity of individual PAC, HPLC analysis of cranberry juice before and after treatments with PN flour was performed. Prior to analysis, a cleanup step using Sephadex LH-20 was conducted to eliminate interfering compounds according to the method of Gu et al.[32] The PAC fraction was collected, and solvent was evaporated using a rotary evaporator system (Büchi, Flawil, Switzerland) and a SpeedVac concentrator (Thermo Fisher Scientific, Waltham, MA, USA). The dried residue was then resuspended in 2 mL of acetone/water/acetic acid (AWA, 70:29.5:0.5; v/v/v) and subsequently filtered through a 0.2 μm cellulose filter prior to HPLC analysis.

PAC were analyzed with a Dionex Summit HPLC system (Sunnyvale, CA, USA) consisting of a model P680 quaternary pump, an ASI-100 autosampler, a TCC-100 column oven, and an RF2000 fluorescence detector according to the method of Hammerstone et al.[33] with modifications described by Constanza et al.[34] Compounds were separated on a 5 μm, 250 × 4.6 mm, Luna silica column (Phenomenex, Torrence, CA, USA). The binary gradient consisted of dichloromethane, MeOH, water, and acetic acid (A, 82:14:2:2; v/v/v/v) and MeOH, water, and acetic acid (B, 96:2:2; v/v/v). The flow rate was set at 1 mL min^{-1} with a gradient as follows: 0−20 min, 0−11.7% B; 20−50 min, 11.7−25.6% B; 50−55 min, 25.6−87.7% B; 55−65 min, 87.7% B, isocratic; 65−70 min, 87.7−0% B. The peaks were monitored by fluorescence detection with excitation at 276 nm and emission at 316 nm. Quantification of compounds was performed by means of external calibration curves using monomer

(DP1) through tetramer (DP4) commercial standards. PAC with DP ≥5 including polymers were expressed as DP4 equivalents.

Basophil Degranulation Assay. Because the PN protein polyphenol-fortified matrices were largely insoluble, an existing basophil activation assay was modified to evaluate solid-phase PN flours.[35] For this assay, 1 mg of cranberry polyphenol-fortified PN matrix (prepared with 1:1 and 1:3 dilutions of cranberry juice concentrate) or unmodified PN flour was added to 200 μL of basophil media (RPMI-10 plus 2 ng mL^{-1} human rIL-3) and subsequently added to 200 μL of whole blood from PN-allergic children (PN-allergic subjects were enrolled in an IRB-approved protocol at UNC-Chapel Hill). Antigen and whole blood were mixed by pipetting up and down several times, and then samples were placed in a 37 °C humidified CO_2 incubator for 30 min. Reactions were stopped by addition of 50 μL of PBS plus 2 mM EDTA. Cells were stained for expression of CD123, CD203c, and CD63 at 4 °C in the dark for 30 min and then washed with staining buffer (PBS plus 0.5% BSA plus 2 mM EDTA). Red blood cells were lysed and white blood cells fixed with 4 mL of FACS lysing solution for 15 min at room temperature. Samples were centrifuged and pellets resuspended in staining buffer for flow cytometry. Samples were analyzed on a Canto II flow cytometer (BD, San Jose, CA, USA) with data processing on FlowJo software (TreeStar, Ashland, OR, USA). Basophils were identified as $CD123^+$ $CD203c^+$ lymphocytes, and degranulation was monitored by CD63 expression. Results are expressed as the percentage of basophils that were $CD63^+$.

Simulated Gastric Digestion Assay and IgE Binding Capacity of Digestive Products. To investigate the stability of PN proteins within unmodified PN flour or cranberry polyphenol-fortified PN matrix to pepsin digestion, a simulated gastric digestion assay was used. Simulated gastric fluid (SGF) was prepared as reported in the United States Pharmacopeia with minor changes.[36] A 0.2% solution of NaCl in water (w/v) was prepared and adjusted to a pH of 2.0 using 6 N or 1 N HCl. A 10 mL dispersion of either unmodified PN flour or cranberry polyphenol-fortified PN matrix was prepared in SGF (1.1%; w/v) and stirred on a stir plate for 5 min, the pH was subsequently adjusted with a few microliters of 1 N HCl (because adding PN flour or cranberry polyphenol-fortified PN matrix to SGF results in a slight pH increase), and the dispersions were completed to equal volume in two separate 15 mL centrifuge tubes using SGF. A 1 mL aliquot from each of the well-mixed dispersions was taken and added to two separate 2 mL centrifuge tubes (controls, no pepsin added). Dispersions, in tubes, were subsequently placed into a 37 °C water bath and prewarmed for 15 min while a 0.2 mg mL^{-1} pepsin solution in SGF (w/v) was prepared and also prewarmed (for only 5−10 min to prevent a possible loss of enzyme activity due to autodigestion). One milliliter of pepsin solution was subsequently added to each tube containing the dispersions (resulting in a total volume of 10 mL and a 1% dispersion per tube). One milliliter digestive aliquots were taken after 0.5, 2, 8, and 30 min, added to separate 2 mL centrifuge tubes, and immediately subjected to a 90 °C water bath for 15 min to inactivate pepsin. Each control (a 1 mL aliquot of each dispersion without pepsin) underwent the same heat treatment. Throughout the digestion period samples were inverted several times to secure proper mixing of dispersion and enzyme. Pepsin-inactivated digestive samples and control samples were subsequently centrifuged, and resulting supernatants were used for further analysis. SDS-PAGE and Western blotting were used to evaluate digestive samples and their respective controls for protein distribution and IgE binding capacity. For SDS-PAGE 40 μL of undiluted sample was added to 50 μL of Novex Tricine SDS sample buffer (2×) and 10 μL of NuPAGE reducing agent (10×), resulting in a final volume of 100 μL (according to the manufacturer's instructions). Samples were heated for 2 min at 85 °C. Ten microliters of each sample was loaded onto the gel, subsequently subjected to SDS-PAGE (90 min, 125 V), and stained with SimplyBlue SafeStain. Western blotting was performed as stated earlier in this paper.

Oral Challenges in PN Allergic Mice. Three-week-old C3H/HeJ female mice were purchased from Jackson Laboratories (Bar Harbor, ME, USA). Mice were allowed to acclimate to their new environment for 2 weeks before being used in protocols. Mice were housed under pathogen-free conditions with free access to water and food while being kept on a PN-free diet the entire study. All studies were approved by the IACUC at UNC Chapel Hill. To sensitize mice to PN, a PN extract from unmodified PN flour was prepared using PBS with NaCl. Briefly, unmodified PN flour was mixed with PBS (1:4; w/v) and stirred for 1 h while a constant pH of ∼8.5 was maintained using 12 M NaOH. The mixture was subsequently centrifuged at 30000*g* at 4 °C for 30 min and the resulting supernatant (PN extract) filtered using 0.8 and 0.2 μm membranes. The protein concentration in the PN extract was determined (Pierce BCA protein assay) and diluted to 10 mg mL^{-1} in PBS (v/v). The protein solution was stored frozen until needed. Mice were sensitized to PN proteins by oral gavage using PN extract plus cholera toxin as an adjuvant.[37] On days 1, 8, and 15 mice received 2 mg of PN proteins plus 10 μg of cholera toxin and on day 22 received 5 mg of PN proteins plus 10 μg of cholera toxin. Mice were challenged on day 36 with either unmodified PN flour (50 mg) or polyphenol-fortified PN matrix made with 1:1 dilution of cranberry juice (50 mg) suspended in PBS. Mice were bled 45 min after challenge by submandibular bleeding using a 4 mm lancet, and serum was subsequently assayed for mouse mast cell protease-1 (MMCP-1) as a marker of intestinal mucosal mast cell degranulation. MMCP-1 was quantified by ELISA according to the manufacturer's instructions (eBiosciences, San Diego, CA, USA). UNC IACUC approval number was 12-176.

Statistical Analysis. All flours and polyphenol-fortified PN matrices were prepared in triplicate, and analysis of variance was performed using JMP 10.0 (SAS, Cary, NC, USA). When significant ($p < 0.05$), means were separated using Student's t test. Basophil data were analyzed on GraphPad version 5 (La Jolla, CA, USA), and the data were compared by the Wilcoxon test, and the MMCP-1 data were compared by the Mann−Whitney test (one-tailed).

RESULTS AND DISCUSSION

Characterization of Polyphenol Sources. Although the polyphenolic sources chosen for this study have some overlapping chemical characteristics, we divided them into three main groups. Cranberry and cinnamon contain high levels of A-type PAC.[38,39] B-type PAC, on the other hand, can be found in aronia and green tea with the latter being also a rich source of PAC monomers such as catechin, epicatechin, or epigallocatechin gallate.[40,41] Noble muscadine grape, black currant, and elderberry feature high ANC concentrations and different characteristic ANC profiles.[42−44] Concentrations of total phenolics (TP), total proanthocyanidins (PAC), total monomeric anthocyanins (ANC), and °Brix values of the diluted juices and extracts before complexing with PN flour are provided in Table 1. TP concentration ranged from 0.9 mg mL^{-1} (cinnamon powder extract) to 39.9 mg mL^{-1} (elderberry juice). Green tea leaves extract showed the highest concentration of PAC (59.5 mg mL^{-1}), whereas the PAC content of cinnamon powder extract and muscadine juice was low (0.4 mg mL^{-1} for each). It should be noted that the DMAC assay has limitations when estimating total PAC levels, as the DMAC reagent reacts only with the terminal monomer of the PAC molecule, regardless of the size of the oligomer or polymer.[45] Therefore, plant sources rich in oligomeric/polymeric proanthocyanidins, such as cinnamon and aronia,[46] are usually underestimated when assayed with the DMAC reagent compared to those rich in monomeric proanthocyanidins such as green tea. The highest amount of ANC was observed in elderberry juice (22.5 mg mL^{-1}). Degrees Brix ranged from 2.5 (cinnamon powder extract) to 39.6 (Noble muscadine grape juice).

Characterization of Polyphenol-Fortified Matrices. Moisture (%), fat (%), water activity (a_w), and soluble nitrogen

(SN) are shown in Table 2. Degrees Brix (soluble sugar) values of juices and extracts were positively correlated with the

Table 2. Moisture, Fat, Water Activity (a_w), and Soluble Nitrogen (SN) of Unmodified Commercial Light Roast 12% Fat Peanut (PN) Flour and Polyphenol-Fortified PN Matrices[a]

source	moisture (%)	fat (%)	a_w	SN[b] (g L^{-1})
PN flour	2.0 i	11.7 b	0.3	0.59 a
blank[c]	3.4 h	13.9 a	0.3	0.16 d
cranberry juice 1:1 dilution	16.9 b	6.9 g	0.2	0.05 f
cranberry juice 1:3 dilution	10.4 e	10.9 d	0.1	0.06 f
cinnamon powder extract	5.0 g	11.2 c	0.3	0.11 e
green tea leaves extract	6.5 f	8.4 f	0.4	0.20 d
aronia juice	15.9 b	6.0 i	0.3	0.10 ef
muscadine juice	21.1 a	6.4 h	0.3	0.17 d
black currant juice	11.7 d	8.8 e	0.1	0.26 c
elderberry juice	13.2 c	5.9 i	0.2	0.45 b

[a]Values within each column with different letters are significantly different at $p < 0.05$. [b]SN concentrations were determined by preparing 10% (w/v) phosphate-buffered saline (PBS) solutions. [c]PN flour modified with water only.

moisture content of the prepared PN matrices ($r^2 = 0.82$). This is attributed to the hygroscopicity of residual sugar in the matrices prepared with juices with high sugar content. Additionally, fat content, which ranged from 5.9% (elderberry juice polyphenol-fortified PN matrix) to 13.9% (blank, flour modified with water only), was negatively correlated with moisture content ($r^2 = 0.71$). The a_w of all polyphenol-fortified PN matrices was ≤0.4, which is well below the limit for microbial growth. SN concentrations ranged from 0.1 g L^{-1} (both 1:1 and 1:3 dilutions of cranberry polyphenol-fortified PN matrices, cinnamon polyphenol-fortified PN matrix, and aronia polyphenol-fortified PN matrix) to 0.6 g L^{-1} (unmodified PN flour) (Table 2). Protein solubility decreased in all polyphenol-fortified PN matrices compared with unmodified flour, suggesting that polyphenols bound to PN proteins, rendering them less soluble. Whereas polyphenols in general have exhibited significant binding affinity for proteins, which can lead to the formation of soluble and insoluble protein−polyphenol complexes,[16] in particular, PAC are known to have a strong affinity for proteins, which likely explains the low SN of cranberry-, cinnamon-, and aronia-modified matrices.[47]

The concentrations of TP, total PAC, and total monomeric ANC bound to PN flours after complexation with the various diluted juices and extracts are shown in Table 3. The highest amount of total PAC was captured from green tea leaves extract (429.7 mg g^{-1}), whereas the lowest concentration of total PAC was observed in aronia polyphenol-fortified PN matrix (0.7 mg g^{-1}). As noted previously, the DMAC assay tends to underestimate total PAC for plants such as aronia, which feature oligomeric and polymeric PAC. Elderberry, which has inherently high ANC content (Table 1), resulted in the highest concentration of total ANC when complexed in the PN protein−polyphenol matrix (44.9 mg g^{-1}).

PN Protein Distribution and PN-Specific IgE Binding. To understand the potential for IgE binding modification, polyphenol-fortified PN matrices were screened using SDS-PAGE and subsequent Western blots using PN-specific IgE.

For this approach, samples must first be solubilized, and two buffers were chosen for this purpose. LDS sample buffer, which is an anionic detergent that can disrupt hydrophobic and electrostatic interactions among macromolecular complexes, led to greater solubilization of PN proteins and resolution by SDS-PAGE than PBS, which is an isotonic buffer solution (Figure 1A,C). The major PN seed storage proteins and allergens, Ara h 1, Ara h 2, Ara h 3, and Ara h 6, were observed in the SDS-PAGE from LDS samples; however, Ara h 1 was not detected in the SDS-PAGE from PBS samples at these concentrations. Of the major seed storage proteins, Ara h 1 solubility is most affected by thermal processing (roasting), whereas Ara h 2 solubility is less affected.[48,49]

Although equal amounts of protein were loaded (5.4 μg), for several samples solubilized in PBS, no protein was resolved by SDS-PAGE, and this corresponded to reduced IgE binding on the Western blot (Figure 1A,B). This may be due to bound polyphenols interfering with protein staining and IgE binding or protein−polyphenol complexes, if present, being too large to be resolved on the gel. All major PN allergens from polyphenol-fortified PN matrices were more soluble in LDS than compared with PBS (Figure 1C). Whereas IgE binding was generally enhanced by solubilizing in LDS compared to PBS, IgE binding to several PN proteins in select LDS-solubilized samples, notably cranberry (1:1 dilution) and green tea, was reduced (Figure 1D). Whereas several LDS-solubilized samples showed reduced IgE binding in the middle and lower part of the membrane (medium to small molecular weight region), some, such as cranberry, green tea, or aronia, showed increased IgE binding in the upper part of the membrane (high molecular weight region). Changes in IgE binding behavior and pattern compared to untreated PN flour could be attributed to polyphenol interference with PN-specific IgE binding. In terms of hypoallergenicity, reduction of allergic potential of Ara h 1, Ara h 2, and Ara h 6 in particular is highly sought. Initially it was thought that Ara h 1 was the major PN allergen of concern;[50] however, studies have shown that Ara h 2 and Ara h 6 have a far more pronounced ability to release histamine from human basophils containing PN-specific IgE and have a higher reactivity in skin tests in PN-sensitive individuals compared to Ara h 1.[51−55] Thus, preventing IgE binding to

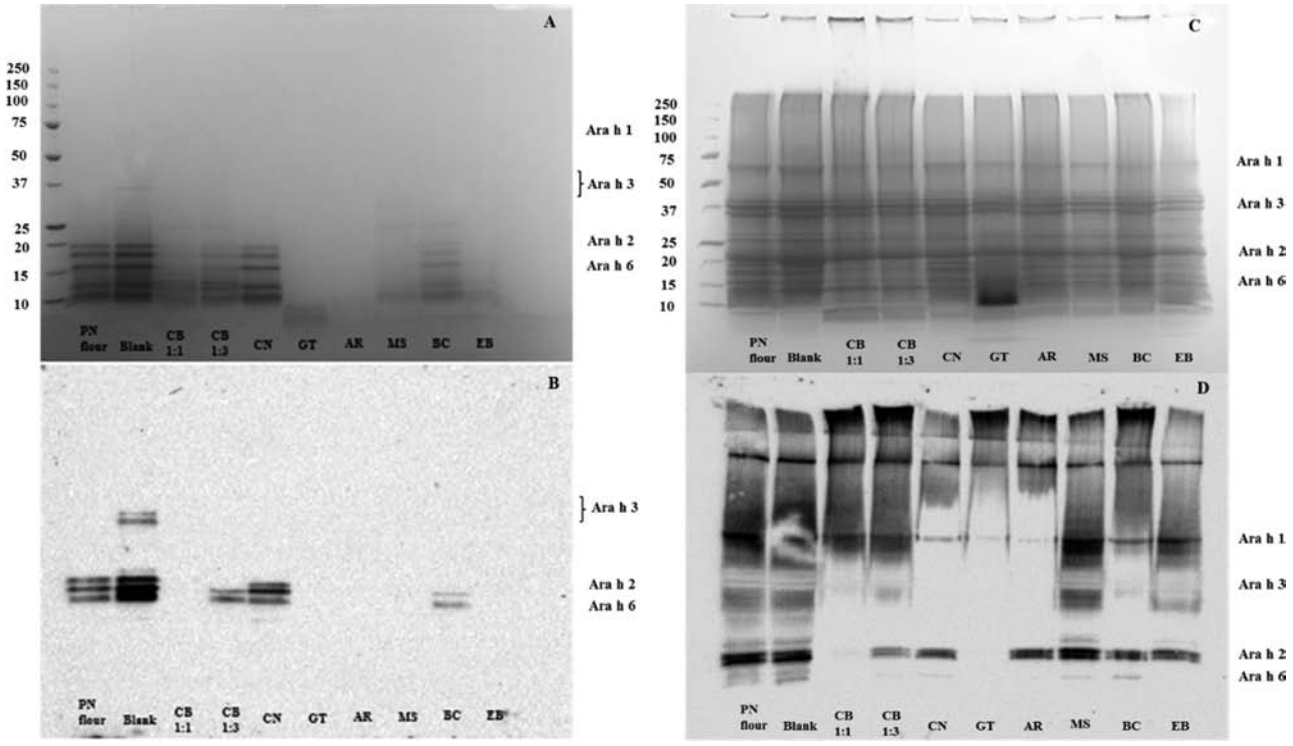

Figure 1. SDS-PAGE (A, C) and corresponding Western blot (B, D) of unmodified light roast 12% fat peanut (PN) flour and polyphenol-fortified peanut matrices (blank, peanut flour modified with water only; CB, cranberry juice (1:1 and 1:3 dilutions); CN, cinnamon powder extract; GT, green tea leaves extract; AR, aronia juice; MS, Noble muscadine grape juice; BC, black currant juice; EB, elderberry juice) solubilized in either PBS (A, B) or LDS (C, D), respectively. An equal amount of protein was loaded (5.4 μg) for PBS samples and an equal volume (10 μL) was loaded for LDS samples. Approximate locations for peanut allergens are shown. Gray scale was used for SDS-PAGE and contrast was optimized for both SDS-PAGE and Western blot.

Ara h 2 and Ara h 6, as observed in cranberry and green tea samples, may significantly reduce allergenicity.

In general, reduced IgE binding to one or more PN proteins in LDS extracts was observed particularly in the PAC-rich samples (cranberry, cinnamon, green tea, and aronia) and also in the ANC-rich black currant sample. In a separate experiment, PN flours were treated with fractions enriched in ANC and PAC (originally isolated and purified from cranberry juice concentrate) and tested for their polyphenol-class specific contributions to PN-specific IgE binding. Western blotting demonstrated that the PAC-rich fraction was more effective in reducing IgE binding than the ANC-rich fraction in both the soluble and insoluble fractions, but both reduced IgE binding compared to the blank, water-treated PN flour (Figure 2). This supports what we observed in the polyphenol-fortified PN matrices and is likely attributable to the natural affinity of PAC to proteins.[47] Additional experiments are needed to understand the mechanism of reduced IgE binding observed here; however, data suggest that some polyphenol-fortified PN matrices, particularly those prepared with cranberry juice and green tea extract, may potentially be hypoallergenic. Whereas proteins are denatured and bound to a PVDF membrane in this approach (i.e., conformational epitopes are disrupted), SDS-PAGE and Western blots were shown to be a reproducible screen for IgE binding modifications.

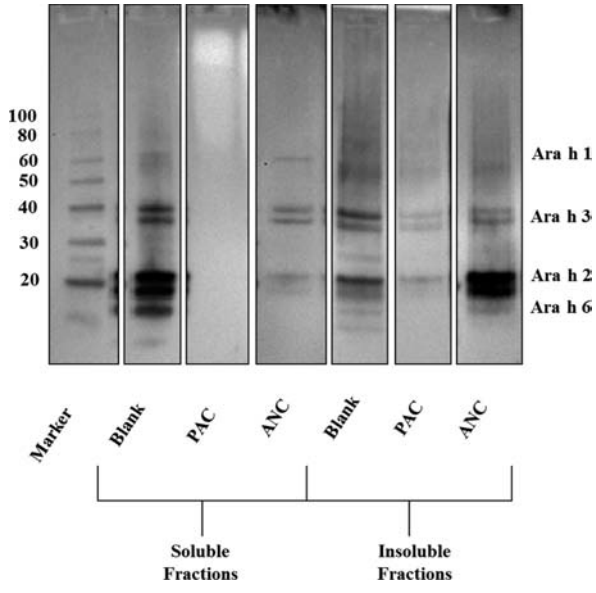

Figure 2. Western blots demonstrating peanut-specific IgE binding in protein extracted from peanut flour modified with water (blank), cranberry proanthocyanidin-fortified (PAC) peanut matrix, or cranberry anthocyanin-fortified (ANC) peanut matrix. Western blot individual lanes were combined from two separately conducted blots under the same conditions. Approximate locations for peanut allergens are shown.

ATR-FTIR Spectra. ATR-FTIR spectra of the polyphenol-fortified PN matrices were recorded to evaluate modification to protein secondary structure. This technique allows for evaluation of the modified flours in their natural insoluble powdered state. The most prominent bands were the amide I (1600−1700 cm^{-1}) and amide II (1480−1575 cm^{-1}) bands, which result from vibrations of the protein backbones (Figure

dx.doi.org/10.1021/jf405773b | J. Agric. Food Chem. 2014, 62, 7010−7021

3). Because a mixture of crude proteins was examined as opposed to a single purified PN protein, only qualitative

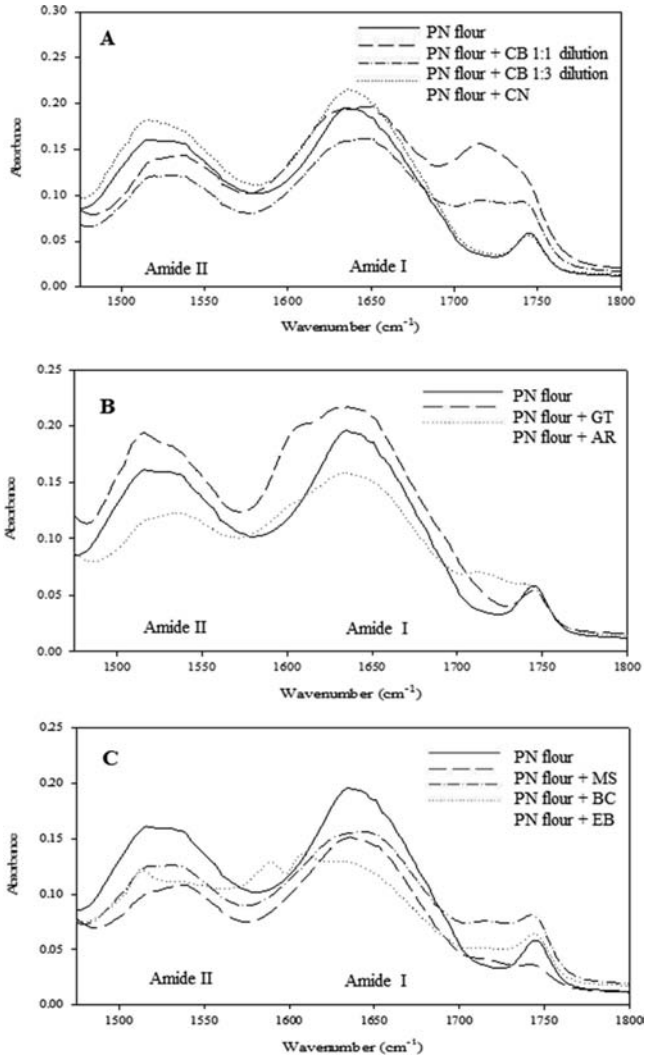

Figure 3. ATR-FTIR spectra (amide I and II bands) of unmodified light roast 12% fat peanut (PN) flour and peanut matrix modified with (A) proanthocyanidin A-type, (B) proanthocyanidin B-type, and (C) predominately anthocyanin-rich juices and extracts. CB, cranberry juice (1:1 and 1:3 dilutions); CN, cinnamon powder extract; GT, green tea leaves extract; AR, aronia juice, MS, Noble muscadine grape juice; BC, black currant juice; EB, elderberry juice.

indications of conformational changes in PN proteins were gained. Amide I and amide II bands were altered to some extent in all polyphenol-fortified PN matrices compared to unmodified PN flour. Generally, polyphenol-fortified PN matrices that displayed significantly altered IgE binding, including cranberry, aronia, elderberry, and green tea, also displayed altered FTIR profiles in the form of increased or decreased band intensities, band shifting or width changes, and/or appearance of additional peaks compared to the unmodified PN flour. Band shifting can indicate that hydrogen bonds were affected.[56] Because some of the polyphenol-fortified peanut matrices had a relatively high moisture content (up to 21.1% for muscadine modified matrix), it should be taken into account that water absorbs within the amide I region (1645 cm^{-1}, H−O−H bending vibration) and could, besides protein-bound polyphenols, contribute to observed spectrum changes.[57] Width changes are linked to the conformational freedom of a structure. Molecules that bind to proteins can lead to conformational restriction, thus reducing bandwidth.[56] These findings suggest that the decreased IgE binding observed in polyphenol-fortified PN matrices may be partly due to changes in protein secondary structure. However, because modified matrices were screened on a qualitative level, a water reference spectrum as well as further IR spectral data analysis methods would be needed to evaluate water interference and to break down and analyze overlapping bands in amide regions in a more qualitative and quantitative manner, respectively.

Characterization of Cranberry PAC Bound to PN Matrices. On the basis of decreased IgE binding specifically to Ara h 2 and Ara h 6 (Figure 1) and significantly altered FTIR spectra (Figure 3), the cranberry polyphenol-fortified PN matrix (rich in A-type PAC) was selected for further experiments. PAC isolated from cranberry juice (1:1 dilution) and from supernatants (spent juice) obtained after complexation with PN flour were analyzed to evaluate the capacity of individual PAC to bind to PN flour. HPLC chromatograms of PAC in the cranberry juice before (A) and after (B) treatment with PN flour are shown in Figure 4. PAC that were more highly polymerized showed a higher level of binding to PN flour (Figure 4B). Table 4 shows the amount of individual PAC bound to PN flour (mg g^{-1}). Polymerized PAC have a stronger binding capacity to proteins than PAC monomers or oligomers. Because noncovalent interactions between proteins and monomeric phenolic compounds such as catechins require relatively high molecular ratios of phenolic compounds to proteins (>100) to affect the functional properties of proteins, it is more likely that PAC and particularly polymerized PAC interacted with PN proteins.[47,58,59] Further experiments must investigate the binding nature of polyphenols to PN proteins.

Basophil Degranulation Assay. A modified basophil assay provided an ex vivo assessment of the ability of antigens to trigger degranulation of human basophils found in peripheral blood and allowed for testing the nonsoluble matrices in a whole blood basophil assay. The basophil activation test augments the IgE binding and FTIR data described above, as it allows for a functional assessment of the polyphenol-fortified PN matrices' capacity to cross-link IgE on basophils, leading to degranulation. PN protein−polyphenol matrices created with cranberry juice triggered significantly less basophil degranulation (median = 37.2% and range = 5.2−70.5% for the 1:1 dilution; median = 45.5% and range = 8.0−78.4% for the 1:3 dilution) than the unmodified PN flour (median = 66.1%, range = 15.5−94.0%) in the seven PN-allergic subjects studied with the basophil assay (Figure 5). Statistically significant reduction in activation level was found by comparing the cranberry polyphenol-fortified PN matrices to the unmodified PN flour (p = 0.015). Although basophil activation was not completely abrogated by cranberry modification of PN flour, the significant decrease in IgE cross-linking suggested enhanced hypoallergenicity.

The basophil assay results indicate that PN proteins complexed with cranberry phytochemicals have a decreased capacity to cross-link IgE, although there are important limitations to this finding. For example, the assay is conducted using edible PN matrices that are not exposed to acidic pH or digestive enzymes, which would be encountered following oral ingestion. Exposure to a low pH, such as that found in the stomach, as well as exposure to various digestive enzymes such as pepsin (stomach) may disrupt the PN protein−polyphenol

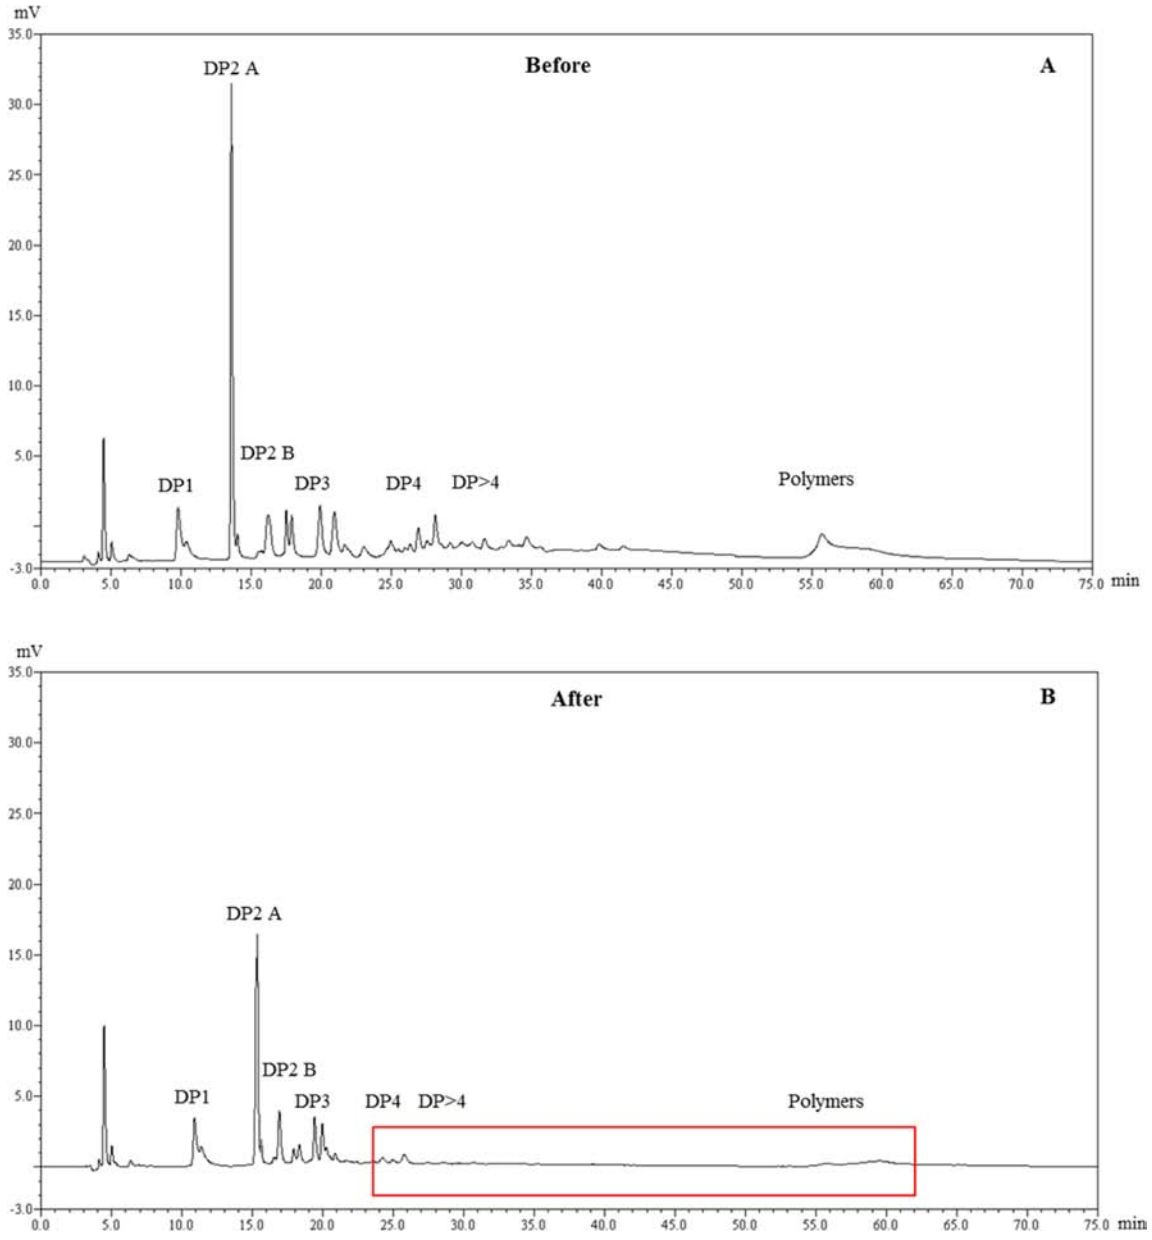

Figure 4. HPLC chromatogram of proanthocyanidin monomers and oligomers in cranberry (A) untreated 1:1 diluted juice (before) and (B) after complexation with commercial light roast 12% fat peanut (PN) flour (supernatant) with fluorescence excitation and emission wavelengths 276 and 316 nm. interactions and lead to the release of allergens that can cause reactions.

Simulated Gastric Digestion Assay. An in vitro digestion method was used to mimic the gastric digestion of unmodified PN flour or cranberry polyphenol-fortified PN matrix by pepsin in an acidic environment at a physiological temperature. This assay was used to evaluate and mimic protein stability and digestibility under harsh conditions such as those present in the stomach. Pepsin was obtained with the highest specific enzyme activity commercially available (3802 U mg^{-1} protein), whereas enzyme concentration (0.2 mg mL^{-1}) was optimized for a more gradual digestion of proteins. The digestibility of proteins can be evaluated by keeping track of the disappearance of intact protein bands on SDS-PAGE. PN proteins in unmodified PN flour as well as in cranberry polyphenol-fortified PN matrix were rapidly digested into smaller molecular weight digestive fragments (Figure 6A). In particular, Ara h 1 and Ara h 3 (acidic subunits) as indicated in the figure were significantly digested by pepsin in both unmodified PN flour and cranberry polyphenol-fortified PN matrix after 0.5 min. However, as expected, Ara h 2 and Ara h 6 in both unmodified PN flour and cranberry polyphenol-fortified PN matrix were highly resistant to enzymatic proteolysis. In addition, digestive fragments at ~10 and ~4 kDa were observed that likely correspond to pepsin-resistant fragments of Ara h 2 and Ara h 6 as previously observed in studies working with purified individual peanut allergens.[60,61] In fact, similar findings for Ara h 2 and Ara h 6 are not surprising, because both, although independent allergens, belong to the 2S albumin family and are 59% homologous with respect to their amino acid sequence.[62] Even

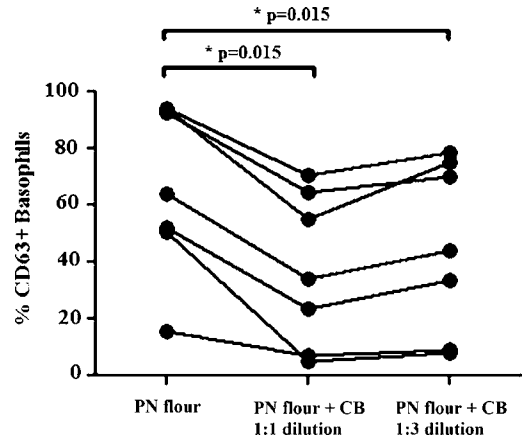

Figure 5. Basophil activation assay of unmodified light roast 12% fat peanut (PN) flour and polyphenol-fortified peanut matrices modified with 1:1 and 1:3 dilutions of cranberry juice (CB). Data shown are percentage of basophils that are degranulated on the basis of CD63$^+$ expression from seven peanut allergic subjects. Individual data are shown with significant differences indicated.

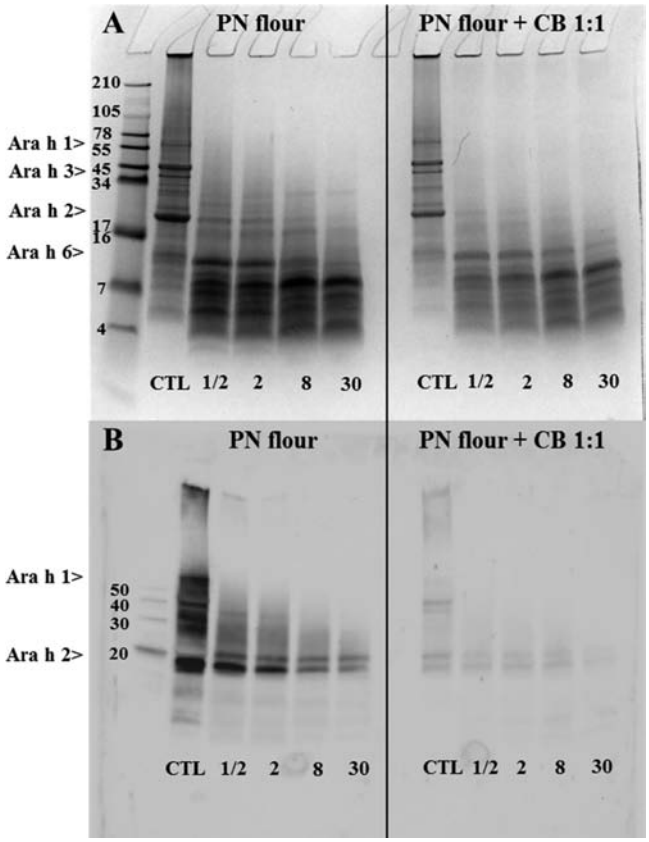

Figure 6. Pepsin simulated gastric digestion of unmodified light roast 12% fat peanut (PN) flour, cranberry polyphenol-fortified peanut matrix (PN flour + CB 1:1 dilution), and their respective controls (CTL; unmodified peanut flour or cranberry peanut matrix in simulated gastric fluid at pH 2 and no pepsin added) at time points 0.5, 2, 8, and 30 min: (A) SDS-PAGE under reducing conditions; (B) associated Western blot. Approximate locations for peanut allergens are shown.

though our findings were observed in both unmodified PN flour and cranberry modified PN matrix, more conclusive interpretations of resulting digestive fragments cannot be made on the basis of a mixture of various allergenic and nonallergenic peanut proteins present in our samples. Whereas digestion of PN proteins resulted in digestive fragments with various molecular weights, not all showed IgE binding on the respective Western blots (Figure 6B). Pepsin-resistant allergens Ara h 2 and Ara h 6 (see Figure 6A) both retained their IgE-binding capacity over the digestion period when unmodified PN flour was used, however, Ara h 6 to a much lesser extent. Ara h 2 remained immunoreactive throughout the digestion of cranberry polyphenol-fortified PN matrix, whereas IgE binding to Ara h 6 could barely be observed. Other studies also have shown that extensive digestion of peanut allergens by gastrointestinal enzymes can result in the survival or formation of peptide fragments that remain immunoreactive (intact and accessible IgE binding epitopes).[60,63,64] SDS-PAGE provided us with general information about how or to what extent PN proteins present in unmodified PN flour or cranberry polyphenol-fortified peanut matrix were broken down by pepsin, but only limited data could be obtained as to which digestive fragment (band) belongs to which intact allergenic or nonallergenic PN protein. Additionally, results gained from Western blots do not determine if digestive fragments remain or do not remain immunoreactive in vivo. Pepsin, trypsin, and chymotrypsin are all important enzymes that could influence the allergenicity of these cranberry–PN complexes in vivo. Thus, we next investigated the cranberry polyphenol-fortified PN matrix's allergenicity in an oral challenge in PN-allergic mice.

Oral Challenges in PN-Allergic Mice. To further evaluate the allergenic potential of the cranberry-fortified PN matrix in vivo, C3H/HeJ mice (n = 4 per group) were made allergic to PN proteins and challenged orally with either unmodified PN flour (control) or polyphenol-fortified PN matrix modified with 1:1 dilution of cranberry juice. No difference was observed in groups of mice for PN-specific IgE levels prior to oral challenge (data not shown). Levels of MMCP-1 were measured in sera of mice to gauge the ability of the cranberry polyphenol-fortified PN matrix to attenuate intestinal mucosal mast cell degranulation. Results showed that mice challenged with cranberry polyphenol-fortified PN matrix had significantly lower levels (using the Mann–Whitney test (one-tailed), we find a p value = 0.041) of MMCP-1 in their sera than mice challenged with unmodified PN flour (Figure 7). These results demonstrate that the cranberry–PN complexes are hypoallergenic in vivo because mast cells are degranulated to a lesser

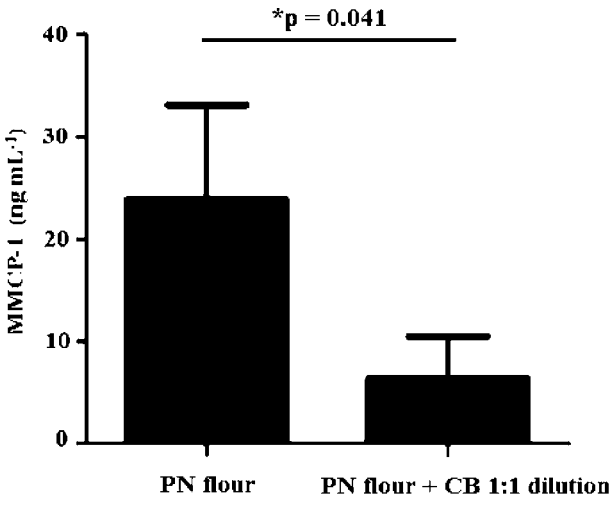

Figure 7. MMCP-1 levels in serum 45 min following oral challenge with unmodified light roast 12% fat peanut (PN) flour or polyphenol-fortified peanut matrix modified with 1:1 dilution of cranberry juice (CB) in peanut-allergic mice (n = 4 per group). Data shown are means plus standard deviation and showed significant difference when using the Mann−Whitney test (one-tailed) at p = 0.041.

extent than in mice challenged with the unmodified PN flour. Together, our data showing decreased IgE binding to the major PN allergens, decreased capacity to degranulate human basophils, and decreased allergic response in vivo in a mouse model led us to conclude that the cranberry polyphenol-fortified PN matrix is hypoallergenic.

To our knowledge, no other modified PN materials have been assessed for allergenicity in an oral challenge mouse model. However, similar assays were utilized to study egg allergens and the effects of heat-induced modifications.[65] The authors found that heating egg allergens caused reduced IgE binding and reduced responses in basophil assays, as well as reduced allergic symptoms following an oral challenge. The research suggests that structural modifications following heating may eliminate conformational IgE-binding epitopes. It is interesting that in our work, we also observed structural changes in proteins upon complexation of PN flour with cranberry polyphenols, without heating, as evidenced by ATR-FTIR.

Collectively, these results suggest that the cranberry polyphenol-fortified PN matrix is hypoallergenic and may have potential to serve as a safer second-generation ingredient for oral immunotherapy trials. Future trials with the other promising polyphenol sources are warranted to validate their efficacy as well. Although other technologies for producing hypoallergenic PN proteins have been described, including genetic engineering,[66] high-pressure processing,[67] enzymatic hydrolysis,[68] and controlled Maillard type modifications,[69] among others, there are challenging regulatory barriers, costs, and negative public perceptions associated with many of these approaches. In contrast, the technology we describe here is of food grade, is economical, and could be readily adapted to produce sufficient quantities of polyphenol-fortified PN matrices necessary for clinical applications. Importantly, this technology has also been demonstrated for a range of food grade plant and animal proteins, suggesting it could be readily adapted to treat other food allergies.

*(M.A.L.) Mail: 600 Laureate Way, North Carolina Research Campus, Kannapolis, NC 28081, USA. E-mail: mlila@ncsu.edu. Phone: (704) 250-5400. Fax: (704) 250-5409.

Funding

This study was funded through the Everett W. Byrd Endowment and NC State appropriations for North Carolina State University at Kannapolis.

Notes

The authors declare no competing financial interest.

ACKNOWLEDGMENTS

We gratefully acknowledge the kind assistance of Kristin M. Price with Western blotting. We thank the Muscadine Products Corp. (Wray, GA, USA), The Super Grape (Magnolia, NC, USA), the New Zealand Blackcurrant Co-operative Ltd. (Nelson, New Zealand), Artemis International (Fort Wayne, IN, USA), and QTrade Teas & Herbs (Cerritos, CA, USA) for providing plant material. We also thank the Golden Peanut Co. LLC (Alpharetta, GA, USA) for providing the light roast 12% fat PN flour.

ABBREVIATIONS USED

PN, peanut; PN flour, light roast 12% fat peanut flour; ATR-FTIR, attenuated total reflectance−Fourier transform infrared spectroscopy; OIT, oral immunotherapy; a_w, water activity; SN, soluble nitrogen; LDS, lithium dodecyl sulfate; TP, total phenolics; GAE, gallic acid equivalents; PAC, proanthocyanidin; DMAC, 4-(dimethylamino)cinnamaldehyde; ANC, anthocyanin; DP, degree of polymerization; SGF, simulated gastric fluid

Table 1. Concentrations of Anthocyanins, Proanthocyanidins, and Chlorogenic Acid in Wild Blueberry Crude Extract and Semipurified Fractions

blueberry sample	anthocyanins,[a] mg/g	proanthocyanidins,[b] mg/g	chlorogenic acid,[c] mg/g (mmol/g)
crude extract (CE)	28.20 ± 0.9	10.44 ± 0.7	6.18 ± 0.2 (0.02)
polyphenol-rich (PPR)	424.37 ± 5.7	78.05 ± 3.1	35.6 ± 1.4 (0.10)
anthocyanin-rich (ANC)	830.18 ± 26.7	2.76 ± 0.2	25.84 ± 0.6 (0.07)
proanthocyanidin-rich (PAC)	10.09 ± 0.4	299.17 ± 10.6	5.04 ± 0.2 (0.01)
ethyl acetate (EA)	18.70 ± 0.6	15.13 ± 0.5	82.26 ± 1.6 (0.23)

[a]Anthocyanins were quantified by RP-HPLC as cyanidin-3-glucoside equivalents. [b]Proanthocyanidins were quantified by NP-HPLC as procyandin A-2 dimer. [c]Chlorogenic acid was quantified by RP-HPLC using a reference standard.

Maine. The composite was made in the fall of 2011, frozen by Cherryfield Foods at −15 °C (Cherryfield, ME, USA), and subsequently stored at −80 °C until extraction.

Extraction and Preparation of the Polyphenol-Rich Extract. The whole frozen blueberry fruits (100 g) were blended (Waring, Torrington, CT, USA) with methanol, acidified with 0.3% TFA (200 mL), and filtered first through multiple layers of muslin sheets and then on Whatman's filter paper no. 4 (Florham Park, NJ, USA) with the aid of suction. The collected hydroalcoholic extract was evaporated to about 50 mL using a rotary evaporator at a temperature not exceeding 40 °C. The obtained aqueous concentrated extract was partitioned against ethyl acetate (4 × 50 mL), and the organic solvent was evaporated to afford the ethyl acetate (EA) extract (0.25 g). The aqueous layer was loaded onto an Amberlite XAD-7 column (15 × 10 cm), preconditioned with acidified water (0.3% TFA). The resin was washed thoroughly with acidified water (0.3% TFA, ∼1 L) to remove free sugars, pectins, and organic acids. The polyphenol-rich mixture was then eluted with 0.5 L of methanol. The eluate was evaporated to remove the organic solvent and freeze-dried to yield 0.75 g of polyphenol-rich (PPR) extract.

Fractionation of the Polyphenol-Rich Extract. The PPR extract (0.5 g), obtained from the Amberlite XAD-7 column, was applied to a column packed with Sephadex LH-20 (20 × 2 cm) and preconditioned with H_2O/MeOH 80:20 (0.3% TFA), with an isocratic elution using the same solvent ratio. Four fractions (1−4), each of 80 mL, were collected starting when the colored material began to elute from the column. The column was then washed with 70% acetone (fraction 5) to elute oligomeric and polymeric proanthocyanidins. Solvents were evaporated (<40 °C) and immediately freeze-dried to afford 0.21, 0.06, 0.02, 0.1, and 0.18 g, respectively. Fraction 1 contained the highest anthocyanin concentration; thus, it was designated the anthocyanin-rich (ANC) fraction. Fraction 5 contained the oligomeric and polymeric proanthocyandins; thus, it was designated the proanthocyanidin-rich (PAC) fraction. Three samples from each extract/fraction were run for HPLC analysis.

HPLC-PDA Analysis. The HPLC analyses were conducted using an Agilent 1200 HPLC (Agilent Technologies, Santa Clara, CA, USA) with a photodiode array (PDA) detector and an autosampler with Chemstation software as a controller and for data processing.

Anthocyanin separation was performed using a reversed phase Supelcosil-LC-18 column, 25 mm × 4.6 mm × 5 μm (Supelco, Bellefonte, PA, USA). The mobile phase consisted of 5% formic acid in H_2O (A) and 100% methanol (B). The flow rate was constant during HPLC analysis at 1 mL/min with a step gradient of 10, 15, 20, 25, 30, 60, 10, and 10% of solvent B at 0, 5, 15, 20, 25, 45, 47, and 60 min, respectively. Samples were prepared by dissolving 5 mg in 1 mL of methanol and filtering through 0.2 μm nylon filters (Fisher Scientific, Pittsburgh, PA, USA) before 15 μL was injected onto the HPLC column with a constant temperature of 30 °C. Three concentrations of cyanidin-3-*O*-glucoside were prepared at 1.0, 0.5, and 0.25 μg/mL, where 15 μL was injected as an external standard. Quantification of anthocyanins was performed from the peak areas recorded at 520 nm with reference to the calibration curve obtained with cyanidin-3-*O*-glycoside. Blueberry extracts were analyzed in triplicate.

HPLC for chlorogenic acid was performed using a Synergi 4 μm Hydro-RP 80A column (250 mm × 4.6 mm × 5 μm, Phenomenex, Torrance, CA, USA). The mobile phase consisted of 2% acetic acid in distilled H_2O (solvent A) and 0.5% acetic acid in 50% acetonitrile in water (solvent B). The flow rate was set at 1 mL/min with a step gradient of 10, 15, 25, 55, 100, and 10% of solvent B at 0, 13, 20, 50, 54, and 60 min, respectively. Quantification was performed from the peak areas recorded at 280 nm to the calibration curve obtained with reference standards.

PAC separation was performed according to the method of Wallace and Giusti[16] using a normal phase Develosil Diol column, 250 mm × 4.6 mm × 5 μm (Phenomenex). The binary mobile phase consisted of (A) acetonitrile/acetic acid (98:2, v/v) and (B) methanol/water/acetic acid (95:3:2, v/v/v). Separation was accomplished using a linear gradient at 35 °C with 0.8 mL/min flow rate as follows: 0−35 min, 0−40% B; 35−40 min, 40−100% B; isocratic 100% B, 45 min; 100−0% B, 50 min; and 0% B to 55 min. The column was re-equilibrated for 5 min between samples. Eluate was monitored by fluorescence detection with excitation at 230 nm and emission at 321 nm as well as at 280 nm with the DAD detector. Proanthocyanidins were identified by comparison with available standards, reported in the literature,[16] and LC-ESI-MS.

Macrophage Cell Culture. The mouse macrophage cell line RAW 264.7 (ATCC TIB-71, obtained from American Type Culture Collection, Livingstone, MT, USA) was maintained in Dulbecco's modified Eagle's medium (DMEM, Life Technologies, NY, USA), supplemented with 100 IU/mL penicillin/100 μg/mL streptomycin (Fisher) and 10% fetal bovine serum (Life Technologies) at a density not exceeding 5×10^5 cells/mL and maintained at 37 °C in a humidified incubator with 5% CO_2. Unless otherwise specified, extracts and pure compounds for cell culture use were prepared in DMSO as 1000× stocks and stored at −20 °C until use.

Cell Viability Assay and Dose Range Determination Studies. RAW 264.7 cells were seeded in a 96-well plate (5×10^4 cells/well) for the viability assay. Cell viability was measured after 24 h of exposure by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay in triplicate and quantified spectrophotometrically at 550 nm[17] using a Synergy H1 microplate reader (BioTek). The concentrations of test reagents that showed no changes in cell viability compared with that vehicle (DMSO at a final concentration of 0.1%) were selected for further studies.

Anti-inflammatory in Vitro Assay. Cells were seeded in 24-well plates (5×10^5 cells/well) 24 h prior to treatment. The cells were pretreated for 1 h with blueberry extracts and fractions at 50, 100, or 150 μg/mL, or pure bioactive components malvidin-3-glucoside, epicatechin, and chlorogenic acid at 1 μM, the upper range of physiologically available doses reported for malvidin in portal circulation.[18] Cells were then elicited with lipopolysaccharide (LPS) at 1 μg/mL for an additional 6 h. For every experiment, one positive control (dexamethasone at 10 μM) and one negative control (DMSO at a final concentration of 0.1%) were included. Three replicates were made for both the treatments and the controls.

Total RNA Extraction, Purification, and cDNA Synthesis. The total RNA was isolated from RAW macrophages using TRIzol reagent (Life Technologies) following the manufacturer's instructions. RNA was quantified using the Synergy H1/Take 3 spectrophotometer (BioTek, Winooski, VT, USA). The cDNAs were synthesized using 2 μg of RNA for each sample using a commercially available high-capacity cDNA Reverse Transcription kit (Life Technologies), following

dx.doi.org/10.1021/jf4051599 | J. Agric. Food Chem. 2014, 62, 7022−7028

the manufacturer's protocol on an ABI GeneAMP 9700 (Life Technologies).

Quantitative PCR Analysis. The resulting cDNA was amplified in duplicate by real-time quantitative PCR using SYBR green PCR Master Mix (Life Technologies). To avoid interference due to genomic DNA contamination, only intron-overlapping primers were selected using Primer Express version 2.0 software (Applied Biosystems, Foster City, CA, USA) as follows: β-actin, forward primer 5′-AAC CGT GAA AAG ATG ACC CAG AT-3′, reverse primer 5′-CAC AGC CTG GAT GGC TAC GT-3′; COX2, forward primer 5′-TGG TGC CTG GTC TGA TGA TG-3′, reverse primer 5′-GTG GTA ACC GCT CAG GTG TTG-3′; iNOS, forward primer 5′-CCC TCC TGA TCT TGT GTT GGA-3′, reverse primer 5′-TCA ACC CGA GCT CCT GGA A-3′; IL6, forward primer 5′-TAG TCC TTC CTA CCC CAA TTT CC-3′, reverse primer 5′-TTG GTC CTT AGC CAC TCC TTC-3′; IL1β, forward primer 5′-CAA CCA ACA AGT GAT ATT CTC CAT G-3′, reverse primer 5′-GAT CCA CAC TCT CCA GCT GCA-3′; and Mcp1, forward primer 5′-CTT CTG GGC CTG CTG TTC A-3′, reverse primer 5′-GCA GCC TAC TCA TTG GGA TCA-3′. Quantitative PCR (qPCR) amplifications were performed on an ABI 7500 Fast real-time PCR (Life Technologies) using 1 cycle at 50 °C for 2 min and 1 cycle of 95 °C for 10 min, followed by 40 cycles of 15 s at 95 °C and 1 min at 60 °C. The dissociation curve was completed with 1 cycle of 1 min at 95 °C, 30 s at 55 °C, and 30 s at 95 °C. mRNA expression was analyzed using the ΔΔCT method and normalized with respect to the expression of the β-actin housekeeping genes using 7500 Fast System SDS software v1.3.0 (Life Technologies). A value of <1 indicates transcriptional down-regulation (inhibition of gene expression) compared with LPS, which shows maximum genetic induction. Values >1 imply overexpression of the particular gene in excess of LPS stimulation. Amplification of specific transcripts was further confirmed by obtaining melting curve profiles.

Statistical Analysis. Statistical analyses were performed using Prism 4.0 (GraphPad Software, San Diego, CA, USA). Data were analyzed by one-way ANOVA with treatment as a factor. Post hoc analyses of differences between individual experimental groups were made using Dunnett's multiple-comparison tests. Significance was set at $p < 0.05$. Values are reported as means ± SEM.

RESULTS AND DISCUSSION

Phenolic Compounds. Crude methanolic extract (CE) of wild lowbush blueberries contained anthocyanins (28.20 ± 0.9 mg/g extract), proanthocyanidins (16.85 ± 0.7 mg/g), and chlorogenic acid (6.18 ±0.2 mg/g) as major phenolic components (Table 1). In close agreement with previously published data,[19] anthocyanins comprised the highest content of total phenolic compounds, whereas chlorogenic acid was the major hydroxycinnamic acid found in blueberries (Figure 1). Polyphenol enrichment procedure over Amberlite resin resulted in 15- and 10-fold increases in anthocyanins and proanthocyanidins, respectively, in the polyphenol-rich (PRR) extract (Table 1). Partition of CE with ethyl acetate resulted in a phenolic acid-enriched fraction (EA) (Table 1; Figure 1C). Furthermore, Sephadex fractionation of the PRR extract afforded two semi-purified fractions: an anthocyanin-rich fraction (ANC) containing 830.18 ± 26.7 mg/g anthocyanins (Figure 1A) and a proanthocyanidin-rich fraction (PAC) containing 299.17 ± 10.6 mg/g oligomeric and polymeric proanthocyanidins (Figure 1B), a 30-fold increase over polyphenolic content of the original CE extract.

Malvidin glycosides were the most abundant anthocyainins present in the ANC fraction (324 mg/g), followed closely by delphinidin glycosides (250.5 mg/g), for a combined total of 67% (w/w) of the fraction (Table 2). Therefore, anthocyanin composition of blueberries was dominated by malvidin glycosides similar to that of grapes[20] but different from delphinidin- and cyanidin-dominated black currants[21] and bilberries,[22] cyanidin-dominated blackberries[23] and cranberries,[24] or pelargonidin-dominated strawberries.[25]

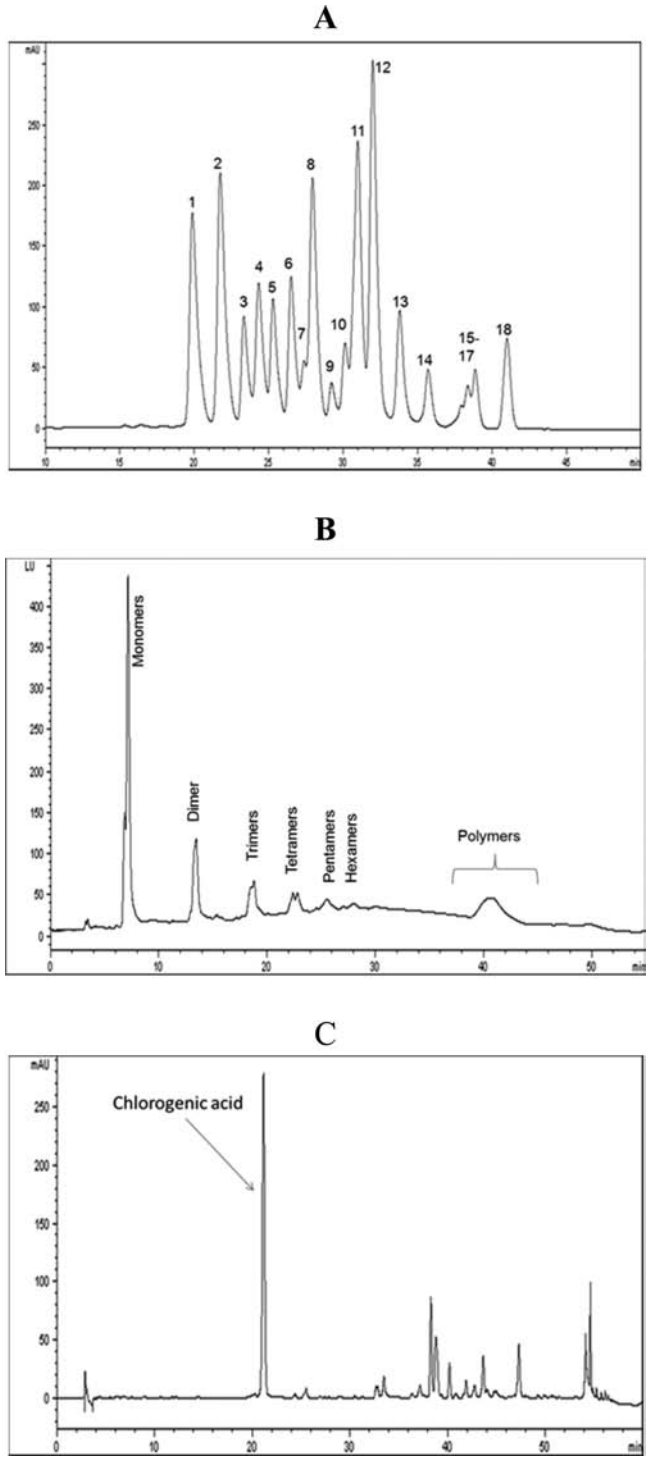

Figure 1. Analytical profiles of wild blueberry (*V. angustifolium*) fractions: (A) reversed phase HPLC-UV chromatograms for anthocyanins (A_{520}) in the anthocyanin-rich fraction (ANC) (refer to Table 2 for anthocyanin identification); (B) normal phase HPLC-FLD chromatogram for proanthocyanidins in the proanthocyanidin-rich fraction (PAC); (C) RP-HPLC-DAD chromatogram for the ethyl acetate fraction (EA) (280 nm).

Procyanidin monomers (catechin and epicatechin) represented 32% of the PAC fraction. Both of these flavanols have already been detected in blueberries in previous studies.[26]

Table 2. Concentrations of Individual Anthocyanin in the Anthocyanin-Rich (ANC) Fraction of Wild Blueberry

peak[a]	anthocyanins	mg/g[b]	mmol/g
1	delphinidin-3-galactoside	83.37 ± 1.2	0.18
2	delphinidin-3-glucoside	94.81 ± 1.5	0.20
3	cyanidin-3-galactoside	35.31 ± 1.2	0.08
4	delphinidin-3-arabinoside	50.93 ± 2.9	0.12
5	cyanidin-3-glucoside	43.06 ± 3.5	0.10
6	petunidin-3-galactoside	49.47 ± 1.8	0.10
7	cyanidin-3-arabinoside	14.61 ± 0.9	0.03
8	petunidin-3-glucoside	88.63 ± 1.4	0.19
9	peonidin-3-galactoside	14.83 ± 0.3	0.03
10	petunidin-3-arabinoside	23.76 ± 0.4	0.05
11	malvidin-3-galactoside	107.65 ± 1.8	0.22
12	malvidin-3-glucoside	125.10 ± 5.9	0.25
13	malvidin-3-arabinoside	42.71 ± 2.3	0.09
14	delphinidin-3-(6″-acetoyl)-glucoside	21.42 ± 1.1	0.04
15	cyanidin-3-(6″-acetoyl)-glucoside	6.81 ± 0.2	0.01
16	malvidin-3-(6″-acetoyl)-galactoside	11.30 ± 0.3	0.02
17	petunidin-3-(6″-acetoyl)-glucoside	16.40 ± 0.5	0.03
18	malvidin-3-(6″-acetoyl)-glucoside	28.93 ± 1.8	0.05

[a]For peak number, refer to the chromatogram in Figure 1. [b]Concentrations were measured by HPLC and calculated as cyanidin-3-glucoside.

Table 3. Proanthocyanidin Content of the Proanthocyanidin-Rich (PAC) Fraction of Wild Blueberry

proanthocyanidin	mg/g[a]	mmol/g
monomers	96.23 ± 3.8	0.33
dimers	43.74 ± 1.2	0.07
trimers	35.34 ± 0.6	0.04
tetramers	36.45 ± 1.3	0.03
pentamers	28.45 ± 1.7	0.02
hexamers	8.96 ± 0.5	0.01
polymers	49.98 ± 1.8	NA

[a]Concentrations were measured by HPLC and calculated as procyanidin A2.

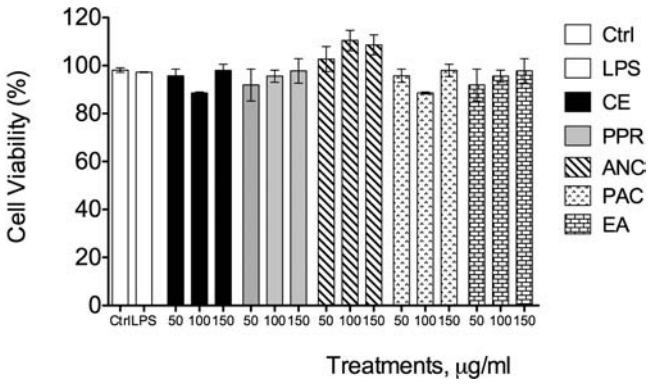

Figure 2. Effects of crude wild blueberry extract and its fractions on cell viability of murine RAW 264.7 macrophages. Cells were treated with crude extract (CE), polyphenol-rich (PPR), anthocyanin-rich (ANC), proanthocyanidin-rich (PAC), and ethyl acetate (EA) fractions for 24 h and cell viability was quantified spectrophotometrically by the MTT assay. Cell viability is reported as the mean ± SEM for three independent experiments.

The rest of the fraction contained proanthocyanidins with various degrees of polymerization (Table 3; Figure 1B). The predominant phenolic acid in blueberries was chlorogenic acid, and it was the predominant component of the EA fraction (82.26 ± 1.6 μg/mg, Figure 1C). The presence of chlorogenic acid in many berries including blueberries has been reported in a number of previous studies.[26,27] Which phenolic compound, either alone or interactively with others, contributes the most to biological effects of blueberries is still an open question.

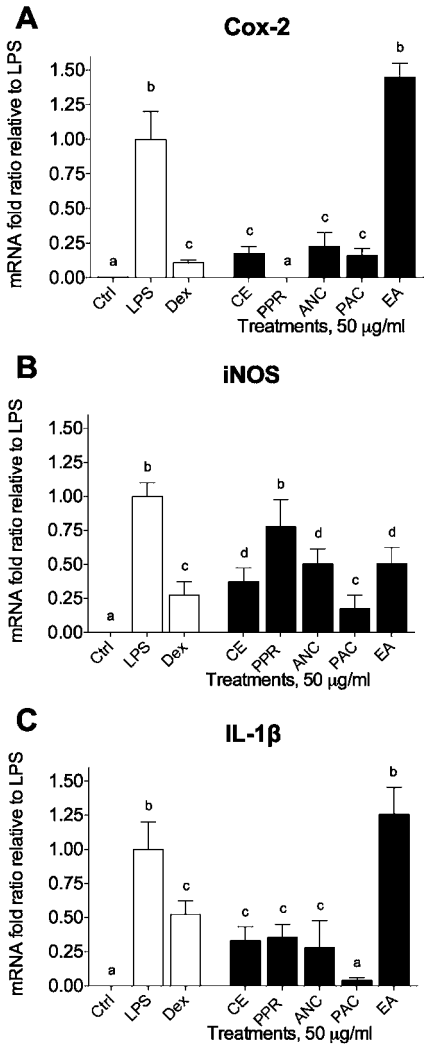

Figure 3. Effects of crude wild blueberry extract and its fractions on pro-inflammatory gene expression profiles associated with acute inflammatory response: (A) cyclooxygenase-2; (B) inducible nitric oxide synthase (iNOS); (C) cytokine IL-1β. Macrophages were pretreated with crude extract (CE), polyphenol-rich (PPR), anthocyanin-rich (ANC), proanthocyanidin-rich (PAC) and ethyl acetate (EA) fractions, and inflammatory response was induced with 1 μg/mL LPS for 6 h. Dexamethasone at 10 μM was used as a positive control. Fold changes in gene expression are reported as the mean ± SEM relative to LPS controls. Means not sharing the same letter are significantly different (one-way ANOVA, Tukey's post hoc test, $p < 0.05$ was considered significant).

Effect of Phenolic Fractions on Cell Viability. The cytotoxic effects of the phenolic fraction were evaluated by measuring RAW 264.7 macrophage viability by the MTT assay after 24 h of exposure (Figure 2). PPR, ANC, and EA fractions did not affect cell viability in the 50−150 μg/mL dose range used in the subsequent studies. CE and PAC fraction at 100 μg/mL reduced cell viability to 90%, but this result did not reach statistical significance and was not observed at a higher dose.

dx.doi.org/10.1021/jf4051599 | J. Agric. Food Chem. 2014, 62, 7022−7028

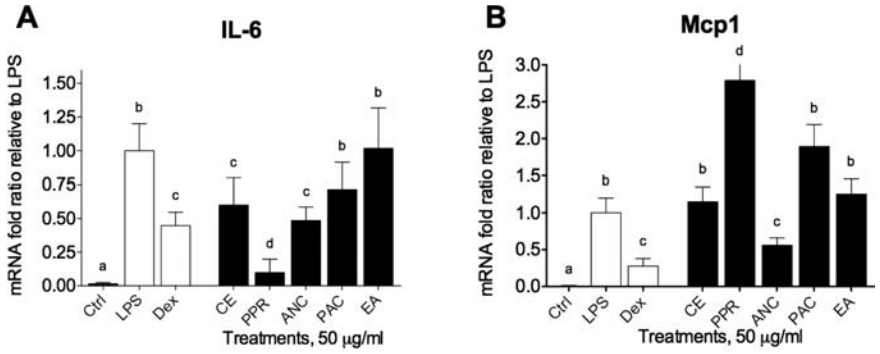

Figure 4. Effects of crude wild blueberry extract and its fractions on pro-inflammatory gene expression profiles associated with chronic inflammatory response: (A) cytokine IL-6; (B) monocyte chemotactic protein 1 (Mcp1/CCL2). Macrophages were pretreated with crude extract (CE), polyphenol-rich (PPR), anthocyanin-rich (ANC), proanthocyanidin-rich (PAC), and ethyl acetate (EA) fractions, and inflammatory response was induced with 1 μg/mL LPS for 6 h. Dexamethasone at 10 μM was used as a positive control. Fold changes in gene expression are reported as the mean ± SEM relative to LPS controls. Means not sharing the same letter are significantly different (one-way ANOVA, Tukey's post hoc test, $p < 0.05$ was considered significant).

Effect of Phenolic Fractions on Inflammatory Markers. Cell viability assays showed that none of the blueberry fractions were cytotoxic to RAW 264.7 macrophages at 50 μg/mL, an amount that is easily achievable in the gastrointestinal tract after consumption of berries or juices.[28] We then investigated the ability of blueberry phenolic fractions to modulate gene expression profiles for acute and chronic inflammation in the LPS-stimulated RAW 264.7 macrophages. For each assay, a negative control (vehicle alone), an induction control (1 μg/mL LPS), and a positive control (1 μg/mL LPS and 10 μM dexamethasone) were used to establish a reference baseline, maximum induction of marker genes, and assay effectiveness, respectively. The use of LPS as a systemic inducer of inflammatory response is warranted by its dual role in inducing both acute inflammatory response and endothelial cell injury[29] as well as low-level chronic inflammation associated with gastrointestinal dysfunction and increased flux of endotoxins.[30]

All blueberry fractions suppressed at least one biomarker of inflammation (Figures 3 and 4). Cox-2 expression was most strongly affected by all treatments with the exception of the EA fraction, which showed no activity ($p < 0.05$). Whereas the PAC fraction was most effective at suppressing the expression of acute pro-inflammatory genes iNOS and IL-1β ($p < 0.01$), it showed no significant effect for attenuation of the LPS-induced IL-6 or Mcp1 expression (Figure 4). On the contrary, ANC was the only fraction that showed borderline inhibition of both IL-6 and Mcp1 markers at 50 μg/mL ($p = 0.08$) and significant inhibition of Cox-2, iNOS, and IL-1β markers of acute inflammatory response ($p < 0.05$). The effect of ANC on IL-6 or Mcp1 markers may be potentiated in the presence of PAC components (Figure 4), as the PPR fraction that contains both ANC and PAC was the most effective at suppressing IL-6 expression ($p < 0.01$). Similar ANC and PAC fractions from blueberry–blackberry fermented beverages inhibited nitric oxide production, iNOS expression, and NF-κB activation as reported earlier.[7]

Comparative Effects of Major Phenolic Constituents. Treatment with three major phenolic compounds found in blueberries showed various levels of activity, ranging from no inhibition to substantial inhibition of expression (Figure 5). All pure compounds were tested at the concentration of 1 μM, the upper range of physiologically available doses reported for malvidin in portal circulation.[18] This concentration, however, is unlikely to be achieved in plasma following phase II liver metabolism, as studies performed in healthy volunteers receiving red wine[31] or grape juice[32] anthocyanins showed low detectable quantities of both 3-*O*-glucoside and *O*-glucuronide conjugates with C_{max} values in the 10 nmol/L range. Low systemic availability of anthocyanins may therefore suggest that their anti-inflammatory effects will be more pronounced in the gastrointestinal and mesenteric adipose tissues exposed to portal circulation.[30] These in vitro observations may not also be directly transferable to a postprandial in vivo situation in humans as shown for antioxidant effects of black currant anthocyanins.[33]

Malvidin-3-glucoside showed the highest anti-inflammatory activity ($p < 0.05$), whereas epicatechin and chlorogenic acid were largely ineffective at reducing mRNA expression of pro-inflammatory genes at this concentration with the exception of iNOS (Figure 5). A trend to inhibit iNOS expression was evident when macrophages were pretreated with chlorogenic acid. Other studies using higher concentrations of chlorogenic acid (>5 μM) reported reduction in nitric oxide production and iNOS and Cox-2 expression in RAW 264.7 macrophages and BV2 microglial cells treated with LPS.[34] Epicatechin at 1 μM also significantly reduced iNOS expression (Figure 5B). Similar effects were reported for epicatechin and related compounds at doses exceeding 8–20 μM.[35] Previous studies have also noted anti-inflammatory effects of malvidin glycosides in vitro, at supraphysiological concentrations that exceeded 10 μM in macrophages[36] and 25 μM in bovine aortic endothelial cells.[37] iNOS was the only marker showing some responsiveness to the three pure compounds when tested separately (Figure 5), but not when grouped together in the PPR fraction (Figure 3B). It is possible that the biological effects will depend on specific concentrations and molar ratios of bioactive compounds in a particular plant extract or fraction or the yet unknown interactions among the dietary bioactive compounds and the extract matrix itself.

It is also interesting to note that only anthocyanins and not other polyphenolic compounds used in this study (Figures 4 and 5) showed a profound inhibitory effect against monocyte chemoattractant protein (Mcp1) production in macrophages. A similar protective effect of red wine anthocyanins in primary human endothelial cells was reported previously.[38]

In summary, the anti-inflammatory activity of the blueberry extract was most prominent in the ANC fraction. The obtained results demonstrate that malvidin-3-glucoside, at concentrations that are attainable in the gastrointestinal tract and portal

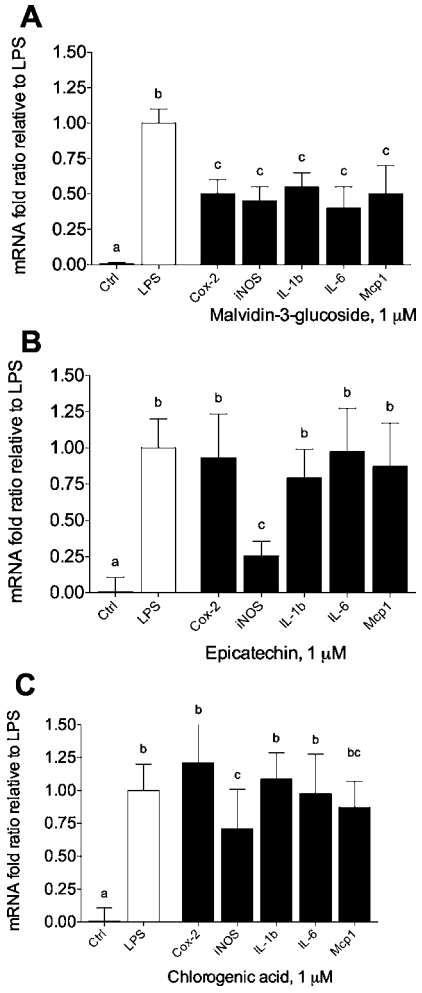

Figure 5. Effects of major phenolic constituents from wild blueberry extract on pro-inflammatory gene expression profiles: (A) malvidin-3-glucoside; (B) epicatechin; (C) chlorogenic acid. Macrophages were pretreated with 1 μM levels of individual compounds as specified, and inflammatory response was induced with 1 μg/mL LPS for 6 h. Dexamethasone at 10 μM was used as a positive control. Fold changes in gene expression are reported as the mean ± SEM relative to LPS controls. Means not sharing the same letter are significantly different (one-way ANOVA, Tukey's post hoc test, $p < 0.05$ was considered significant).

circulation, suppressed activation of key pro-inflammatory genes triggered by an inflammatory stimulus. These genes are central to the regulation of, among others, transcriptional regulation and cytokine-mediated acute and chronic inflammation. Thus, the obtained results suggest that malvidin-3-glucoside-containing diets could improve outcomes from immune and metabolic disorders linked to sustained inflammation.

anatomical components the starchy endosperm, germ, and bran are present in the same relative proportions as they exist in the intact caryopsis". In April 2013, the AACCI further characterized a whole-grain product as being one that must contain 8 g or more of whole grain per 30 g of product.[27] The U.S. Food and Drug Administration (FDA) adopted the AACCI definition of whole grain; however, to qualify for the FDA whole-grain health claim at least 51% of the total weight of the product must be whole grain. The main whole-grain cereals consumed across the world are wheat, rice, and corn, followed by oats, rye, barley, triticale, millet, and sorghum.[18]

Carbohydrates. Starch is the main storage polysaccharide of cereal grains and is an important source of energy in the human diet. The endosperm of cereal grains contains mostly starch. In wheat, for example, starch comprises approximately 80−85% of the grain.[18] Starch is composed of amylose, a linear glucan with few branches, and amylopectin, which is a larger and more highly branched molecule. The ratios and molecular weights of the starch polymers vary widely among the cereals and help account for wide variations in functionality. Amylose comprises approximately 15−30% of total starch, and its content varies from one cereal to another.[28]

Dietary fiber includes macromolecules that resist digestion by human endogenous enzymes and is essentially composed of plant cell wall components.[19] These macromolecules are nonstarch polysaccharides, or structural carbohydrates.[29] Dietary fiber as defined by the AACCI is the edible part of plants and analogous carbohydrates that is resistant to digestion and absorption in the human small intestine with complete or partial fermentation in the large intestine. Dietary fiber includes polysaccharides, oligosaccharides, lignin, and associated plant substances.[27] Thus, the AACCI definition also includes resistant starch, which is starch that resists digestion in the small intestine, but is later fermented by the colonic microflora. There are several definitions of dietary fiber; some include resistant starch, whereas others do not include starch polysaccharides.[30] For labeling, dietary fiber is defined by a number of analytical methods that are accepted by the Association of Official Analytical Chemists International (AOAC). Thus, labeling and defining dietary fiber in the United States rely on analytical methods rather than an accurate definition that includes its role in health.[31]

Dietary fiber may be soluble or insoluble on the basis of its solubility in water and buffer solutions. Soluble fibers are easily fermented by the microflora of the large intestine. They consist of pectins, gums, inulin-type fructans, and some hemicelluloses. Insoluble fiber is poorly fermented, but it contributes to fecal bulk, thereby promoting laxation, and includes cellulose, some hemicelluloses, lignin, and arabinoxylan.[19]

Whole grains are an abundant source of dietary fiber and other bioactive components, with the bran and germ fractions containing higher proportions than the endosperm. For example, approximately 63% of the fiber component of wheat is found in the bran and germ.[18] During the refining process the bran and germ fractions are removed. Thus, most refined cereal products have lost the protective components.[18] Whole grains contain approximately 80% more dietary fiber than refined cereal products.[32] A product that contains the original components of a whole grain recombined to deliver the relative proportion that naturally occurs in the grain kernel is referred to as a reconstituted whole-grain product. The bulk of the whole-grain food products available on store shelves would be considered reconstituted whole-grain products.[32] In the United States, approximately 90% of the whole grains consumed are provided by ready-to-eat-cereals (28.7%), yeast breads (25.3%), hot cereals (13.75%), popcorn (12.4%), and crackers (6.4%).[33]

In a summary of the American Society for Nutrition Symposium on the health benefits of whole grains, Jonalagadda et al. determined that observational studies have consistently shown an association between whole-grain consumption and disease risk reduction; however, the evidence from interventional studies offered less support.[32] In an evaluation of studies using foods that conformed to the AACCI definition of whole grains, no effect of whole-grain consumption on cardiovascular disease (CVD) risk reduction was found. When the analysis was expanded to studies that included bran, germ, and fiber along with whole grains, the results of 14 observational studies suggested a protective effect of whole-grain consumption on CVD risk. In the expanded analysis, intervention studies for the most part supported a beneficial effect.[26] Similar associations have been determined for cereal fiber and whole grains on risk factors for obesity, diabetes, and CVD,[34] suggesting that the fiber component of whole grain may be the determining factor in the physiological responses. However, the mechanisms involved in eliciting the positive effect have not been clearly elucidated. The possibility of the synergistic actions of the other bioactive components cannot be excluded.[18]

It has been suggested that dietary fiber may be protective against colorectal cancer on the basis of the finding of a low incidence of colorectal cancer in rural, black Africans, whose diet contained large amounts of unprocessed food plants, especially cereals.[35] However, incontrovertible evidence from human studies of a protective role for dietary fiber in colorectal cancer is unavailable at this time. Large randomized controlled trials found no effect of supplementation of wheat bran[36] or dietary fiber[37] on the recurrence of colorectal adenomas.

In the large multicenter European Prospective Investigation into Cancer and Nutrition (EPIC) observational study, dietary fiber from foods was inversely related to incidence of large bowel cancer.[38] However, another large-scale epidemiological study showed no correlation between fiber intake and the risk of colorectal cancer.[39] Furthermore, in a pooled analysis of 13 prospective cohort studies it was found that high dietary fiber intake was not associated with a reduced risk of colorectal cancer when adjusted for other risk factors, but the study did find an increased risk among people with a low intake of dietary fiber (<10 g/day).[40] In a large prospective cohort of men and women in the NIH-AARP Diet and Health Study[41] that assessed dietary intake through self-administered food frequency questionnaires, although no association was found between fiber intake and colorectal cancer, a statistically significant inverse association between whole-grain consumption and colorectal cancer was observed. The authors suggested that whole-grain components other than fiber such as vitamins, minerals, phenols, and phytoestrogens may have an effect on colorectal carcinogenesis.

Starch is generally considered to be completely digestible; however, starches can contain significant amounts of resistant starch depending on the nature of the starch and the processing. The digestibility of starch and thereby the resistant starch content are influenced by several factors that affect its accessibility to enzymes such as the structure of the starch granule and whether it is disrupted or intact. Greater hydrolysis is achieved with hydration and heat treatments that cause gelatinization. The polymers in starches with high amylose

content can reassociate on cooling in a process called retrogradation, which is then poorly digested by amylases. Interactions with other food components such as the formation of lipid complexes may also reduce the rate of amylosis.[42]

In addition, grains also contain significant amounts of oligosaccharides such as oligofructose and inulin. These carbohydrates, which have a low level of polymerization, are nonviscous but have some effects similar to those of soluble fiber in the gastrointestinal tract.[43] Further dietary fiber, oligosaccharides, and resistant starch entering the large bowel can alter the gut microbiome and confer protective effects on health. The fiber and resistant starches are fermented to short-chain fatty acids (SCFAs), which may play an important role in the prevention and treatment of chronic disease. The molecular mechanisms by which SCFAs induce their effects are being actively investigated. Nevertheless, they have been shown to play an important role in the prevention and treatment of the metabolic syndrome, bowel disorders, and certain cancers.[44]

Proteins. A large proportion of the world supply of dietary protein, approximately 65%, is met by plant proteins with cereal grains (47%) and pulses, nuts, and oil seeds (8%) accounting for most of it.[45] In Western diets, protein from plant sources constitutes a lower proportion of protein intake compared to developing nations. The digestibility, amino acid composition, and presence of factors that influence digestibility are the major differences between plant and animal protein sources. However, contrary to popular belief, protein from plant sources can meet human protein needs. Whole grains are rich sources of protein, albeit low in the amino acid lysine. Diets that comprise plant sources of protein abundant in lysine such as pulses can complement whole-grain components. A lower protein to energy ratio may be the outcome compared to diets high in animal protein and more closely resembles the recommended intakes for protein.[46] Moreover, high intakes of animal protein are associated with obesity.[47] Plant sources of protein being lower in fat provide less energy.

Vitamins and Minerals. Whole-grain cereals are significant sources of the B-vitamins thiamin, niacin, pantothenic acid, and biotin. Wheat germ is rich in pyridoxine. However, whole-grain cereal products are not a particularly good source of folate. Moreover, the bioavailability in whole grains varies greatly and is far less than 100%. Of the B-vitamins, thiamin and pyridoxine have the greatest bioavailability.[18] Thiamin diphosphate functions as a coenzyme necessary for the oxidative decarboxylation of pyruvate, α-ketoglutarate, and the branched-chain amino acids. These reactions are necessary for generating energy. As a coenzyme it is involved in the synthesis of pentoses and NADPH. In addition, thiamin has a non-coenzyme role in membrane and nerve conduction.[48] Pyridoxal phosphate, the coenzyme form of vitamin B_6, is necessary for amino acid, lipid, and homocysteine metabolism as well as the synthesis of heme. It plays a role in the synthesis of serotonin from tryptophan and other neurotransmitters. A pyridoxine-dependent enzyme is also involved in homocysteine metabolism.[48]

Vitamin E functions as an antioxidant protecting the integrity of cellular membranes by preventing the oxidation of polyunsaturated lipids by free radicals.[49] In vivo studies among animals[50] and in human aortic endothelial cells[51] have shown that vitamin E prevents oxidative stress. The vitamin E content of whole-grain cereals is variable. Corn and rye are the richest sources, whereas wheat, barley, and oats have lesser amounts.[49] Vitamin E may also function to maintain selenium in the reduced state. Selenium is a cofactor for gluthathione peroxidase, an enzyme that protects against oxidative damage to tissues; however, the selenium content of cereals depends upon the soil in which the grain is grown.[52]

Whole grains and pulses are among the richest sources of magnesium, which may in part explain their favorable effects on insulin sensitivity and diabetes. In cardiac and vascular smooth muscle, magnesium has a role in the regulation of contractile proteins and sarcoplasmic reticular membrane transport of calcium ions (Ca^{2+}). It is a cofactor in ATPase activities and is involved in the metabolic regulation of energy-dependent cytoplasmic and mitochondrial pathways. Magnesium is found associated with calcium and phosphate in hydroxyapatite, the major component of bone. Additionally, magnesium is found on the surface of bone in an amorphous form that is thought to maintain serum levels through an exchangeable pool.[48] Intracellular magnesium concentration has also been shown to be effective in increasing insulin secretion and the rate at which glucose is cleared from the blood. It offsets calcium-related excitation−contraction coupling and decreases smooth cell responsiveness to depolarizing stimuli. Thus, magnesium may play a key role in modulating insulin-mediated glucose uptake and vascular tone.[53] However, calcium from whole-grain cereals may not contribute significantly to bone health because the calcium to potassium ratio in cereals is below the recommendation for effective calcium use by the body. More than 85% of the potassium content of cereals is supplied by phytic acid, which has a high affinity for hydroxyapatite. Thus, grain consumption may have a role in dental health through the cariostatic effect of phytic acid.[18]

Other minerals such as iron, zinc, copper, and manganese are cofactors of antioxidant enzymes and have other regulatory and metabolic functions. The physiological functions of zinc include bone formation, skin integrity, carbohydrate metabolism, and taste acuity.[48,54] Iron has an important role in respiration and energy metabolism, immune function, and cognitive development. Plant foods are primarily sources of nonheme iron. The absorption of nonheme iron is approximately 2−3%, which can be enhanced to 8% if it is ingested along with a source of vitamin C and meat, fish, or poultry.[48] Furthermore, whole grains have a high concentration of phytic acid, and chelation of minerals may reduce their bioavailability.

Phytonutrients. Phytochemicals are non-nutrient bioactive compounds in fruits, vegetables, grains, and other plant foods that may reduce the risk of chronic disease.[55] Phenolics are phytochemicals that form part of the plant defense mechanism and include phenolic acid, which contributes approximately two-thirds of the phenolics in our diets, the remaining being supplied by flavonoids.[55] The phenolic compounds in grains include derivatives of benzoic and cinnamic acids, anthocyanidins, quinones, flavonols, chalones, amino phenolic compounds, tocotrienols, tocopherols, and carotenoids.[56] Whole grains are a major source of phenolic acids such as ferulic, vanillic, caffeic, syringic, sinapic, and *p*-coumaric acids.[49] Whole grains have been associated with antioxidant activity, which may be attributed to their phytochemical content.

Phenolic acids are mostly found esterified or bound to plant cell wall polymers. These complexes can evade digestion to reach the colon intact, where they may be digested by organisms in the microbiome, thereby releasing the bound phenolic compounds to exert their physiological effects. Thus, unlike fruits and vegetables where the antioxidant polyphenols are either free or in the form of soluble conjugates and available

in the small intestine, in whole grains their site of action may be the colon.[49] This may in part be the reason why whole grains have been associated with reduced risk of colon cancer.

The antioxidant capacity of breads, ready-to-eat breakfast cereals, and uncooked cereals ranges from 13.18 to 24.79 Trolox equivalents (TE)/g, which is higher than that of most vegetables but far less than that of dry beans, which ranges from 80.4 to 149.21/g.[57] In vivo, the antioxidant potential may be higher than that derived from in vitro assays because fiber-associated compounds are generally not included.[49] The bound fractions make a significant contribution and are generally much higher than the free and soluble fractions.[58,59]

Carotenoids are a group of pigments synthesized by plants and select species of algae and fungi.[60] Approximately 90% of the carotenoids in the human diet consist of β-carotene, α-carotene, lycopene, cryptoxanthin, and lutein.[61] One of the characteristic features of carotenoids is a long series of alternating double and single bonds. Carotenoids scavenge free radicals and become free radicals themselves, but they can remain stable compounds because the free radical can be delocalized among the alternating single and double bonds. Thus, carotenoids make good antioxidants.[62] Despite a vast amount of research, a disease-preventing role is hard to ascribe to carotenoids,[60,63] which may be because the experimental designs have used an all or none approach more conducive to trials of drug efficacy, whereas the populations may not have been completely naïve to carotenoids. Carotenoids are ubiquitous components of food and may have small effects that aggregate over decades, working in synergy with other dietary components and lifestyle factors.[60]

Phytic acid present in whole grains chelates minerals such as zinc, iron, calcium, and magnesium, which reduces their bioavailability. On the positive side, phytic acid has been shown to reduce oxidative damage by suppressing iron-catalyzed oxidative reactions.[18] Phytic acid may also reduce oxidative damage to the intestinal epithelium associated with oxygen radicals produced by colonic bacteria.[52] However, the antioxidant effect of phytic acid from whole grains has not been evaluated.

Lignins are components of whole-grain cereals that may comprise 3−7% of the bran fraction. Structurally, lignins are related to lignans but differ from them by their polymeric nature and distribution in plants. Lignans are phytoestrogens present in whole grains such as corn, oats, wheat, and rye. Rats can metabolize lignins and lignans from cereal sources to mammalian lignans.[64] Lignans and their metabolites, the mammalian lignans enterodiol and enterolactone, have antioxidant potential due to their polyphenolic structure.[49] Lignins, because of their polymeric nature and their embedding in the cell wall, are usually considered inert in the digestive tract.[64] Lignans have been shown to be protective against certain cancers;[65] hence, if lignins are metabolized to lignans in humans as they are in rats, whole-grain cereal consumption might confer added anticancer effects.[18]

Plant sterols and stanols are found in grains, as well as pulses. These compounds are structurally similar to cholesterol. The mechanisms by which they are clinically beneficial include reduction in cholesterol absorption and transintestinal cholesterol synthesis, both of which result in increased fecal neutral sterol excretion to explain the low-density lipoprotein (LDL) cholesterol lowering effect of plant sterols and stanols.[66] The vast amount of evidence to support a cholesterol-lowering effect led to the recommendation for the inclusion of plant sterols and stanols in the diet because humans are unable to synthesize these compounds. However, the recommended level of 2 g/day is difficult to meet and the average consumption in the Western diet ranges from 0.2 to 0.4 g/day.[67] Thus, whole-grain consumption may help to meet the recommendation and potentially confer a cardioprotective effect.

COMPOSITION OF PULSES

Legumes are plants belonging to the Leguminosae family. They are second to cereals in providing food crops for the world.[68] Legumes include alfalfa, clover, lupin, green beans and peas, peanuts, soybeans, dry beans, broad beans, dry peas, chickpeas, and lentils. Pulses are annual leguminous crops yielding from 1 to 12 grains or seeds within a pod. The Food and Agriculture Organization (FAO) limits its definition of pulses to crops harvested solely for dry grain, thereby excluding crops harvested green for food such as green peas and green beans, and classifies these as vegetable crops. Also excluded are those crops used mainly for oil extraction, such as soybean and peanuts, and leguminous crops such as seeds of clover and alfalfa that are used exclusively for sowing purposes. Pulses contain approximately 55−65% of their total weight as carbohydrates, mainly starches.[69] The protein content of pulses ranges from about 20% (dry weight) in peas and beans to 38−40% in lupin.[68] A serving of pulses (half cup of cooked dried pulses) contains 2−4 g of fiber and 7−8 g of protein. Most beans are very low in fat, generally containing <5% of energy as fat except for chickpeas, lupin seeds, and soybeans, which contain from <15 to 47% fat.[70] Pulses contain substantial amounts of the B-vitamins and minerals important for human health, such as iron, calcium, and potassium, as well as phytochemicals: bioactive compounds, including enzyme inhibitors, lectins, oligosaccharides, and phenolic compounds.[71]

Carbohydrates. Starch digestibility affects the glycemic response and compared to cereal foods such as whole-grain breads, spaghetti, rice, breakfast cereals, and oatmeal, legumes elicit the lowest postprandial glucose responses.[72,73] The digestibility of starch from legumes is much lower than that ofcereal starch.[74−77] The rate at which legume starches are digested is approximately 45% lower than that of cereal starches.[75] Starch digestion is slowed in the small intestine if access to pancreatic amylase is hindered by the presence of other plant materials. Pulses have a rigid cell wall, which inhibits swelling and dispersion of the starch. Moreover, the crystallinity of starch in pulses as determined by the ordered arrangements of adjacent double-helix amylopectin is the B and C type, which is more resistant to digestion than the A type found in cereals.[19] Pulses contain 30−40% of amylose starch, which is 5−10% more amylose starch than cereals.[78] Higher amylose than amylopectin starch content correlates with higher resistant starch content.[19] Although it is difficult to quantify resistant starch because of a lack of standardized methods of analysis,[79] cooked pulses are prone to retrograde more quickly than cereals, which slows the process of digestion. Moreover, pulses are high in protein, and protein−starch interactions further hinder digestibility. Additionally, the presence of high amounts of dietary fiber in pulses may greatly lower the rate and extent of starch digestibility.[19]

Pulses are high in fiber even without including the resistant starch fraction, ranging from 4 to 19 g and averaging approximately 13 g per cup of mature dry seeds, cooked (boiled without salt).[80] Along with cereals, pulses are a primary source of phytates in the human diet. Phytates may reduce the

rate of starch digestion and delay the postprandial glycemic response.[81] Furthermore, α-amylase inhibitors found in pulses, particularly dry beans, in amounts ranging from 2 to 4 g/kg may also reduce starch availability.[82] Bean extracts containing α-amylase inhibitors have been shown to reduce starch digestion in vitro and cause weight loss in humans,[83] but the lack of consistent results[83−86] and the fact that residual phytohemagglutinin present in beans may cause adverse gastrointestinal events[87] warrant further investigation. Thus, pulses are known as slow-release carbohydrates because of their reduced digestibility.

The oligosaccharides raffinose, stachyose, and verbascose are present in pulses in amounts ranging from 1 to 12% of the dry weight of pulses. Humans lack α-galactosidases in the upper regions of the gastrointestinal tract; hence, the oligosaccharides enter the lower gut, where they are fermented by bacteria to produce carbon dioxide and hydrogen.[88] The flatulence and bloating associated with pulse consumption has been attributed to these nondigestible but rapidly fermentable oligosaccharides. The discomfort of possible gastrointestinal disturbances may deter pulse consumption,[89] although evidence suggests that flatulence or other gastrointestinal symptoms associated with the consumption of pulses may progress into tolerance.[90,91]

The amount and type of dietary fiber have major influences on the composition of intestinal microbiota and thereby the production of SCFAs.[44] However, it is likely that the diet-induced effects depend on pre-existent gut microbial composition, in interaction with the host phenotype. Changes in the diet such as increased nondigestible food ingredients can also result in shifts in microbiota distribution.[92] Nevertheless, the high oligosaccharide and resistant starch components of pulses are potentially good sources of substrates for SCFA production.

Humans share a mutual relationship with their gut microbiota marked by symbiosis, wherein one partner benefits without harming the other, or commensalism, wherein partners coexist without detriment but without any noticeable benefit.[93] The mucosal immune system selectively and actively tolerates the gut microbiota during steady-state conditions and will mount an inflammatory response once there is a threat of disease or infection. Once microbiota are under immune attack, a more pathogenic profile will emerge and the peaceful coexistence will cease. Commensal bacteria maintain a stable environment by inducing and modulating host innate immunity.[94] Thus, manipulations of the gut microbiome through the diet are therapeutic interventions that are not unthinkable; however, it is only long-term diets that appear to effect the desired changes.[95] Because α-galactosides, more commonly known as oligosaccharides, comprise 25−65% of the sugar fraction of legumes,[96] their prebiotic potential is worthy of exploration.

Proteins. Pulses accumulate large amounts of proteins during their development and are among the richest sources of dietary proteins. The proteins in pulses are largely storage proteins with globulins forming the largest component. Pulse storage proteins are relatively low in sulfur-containing amino acids, methionine and cysteine, as well as the aromatic amino acid tryptophan. However, they contain significant amounts of lysine, which is the limiting amino acid in cereals, making the two plant sources of proteins nutritionally complementary. The degree of complementation may also depend on the content of the second limiting amino acid, namely, threonine in cereals and tryptophan in pulses.[68] Meat consumption in the United States averages 212 g/day. High meat consumption is associated with higher intakes of energy and fat compared to lower meat intake and a greater likelihood of obesity.[47] High red meat intake is associated with less desirable levels of the biomarkers of inflammation and glucose metabolism (C-reactive protein, fasting insulin, and HbA1C), and a high body mass index (BMI) accounts for a significant proportion of this association.[97] Therefore, although protein needs in the United States are largely met by meat consumption, substitution with plant proteins provides a healthier option.

Pulse seeds contain several comparatively minor proteins called antinutrients, including enzymes, enzyme inhibitors, and lectins. The inhibition of various digestive enzymes, including trypsin, chymotrypsin, and amylase, reduces the bioavailability of nutrients, but their effect is usually manifest only if the seed or the flour is consumed uncooked, because cooking normally denatures the antinutrients.[68] The term antinutrient appears to be a misnomer as their extracts have beneficial effects on human health and the nutraceutical potential is worth noting.

Lectins account for 2.4−5% of the protein content of kidney beans. They directly inhibit HIV reverse transcriptase, an enzyme critical for replication of the human immunodeficiency virus, and β-glucosidase, which is required for processing of viral proteins.[82] Thus, lectins from kidney beans form an important component of antiretroviral therapy. Including raw kidney beans in the diet of obese rats reduces lipid accumulation, which may be due to reduced insulin levels caused by lectins.[98] Lectins can resist gastric digestion, yet they can be absorbed into the bloodstream while remaining biologically active, and these properties may contribute to their antitumor effects. Lectins may bind to cell membranes or receptors to cause cytotoxicity, apoptosis, and inhibition of tumor growth. They may also penetrate the cell to cause agglutination of cancer cells.[99] Lectins may have a role in weight management by increasing the shedding of brush border membranes to interfere with gastric secretion and nutrient absorption, but reports of lectin toxicity are conflicting.[100] Thus, further research on a safe and effective dose is needed before its therapeutic role in the treatment of obesity is promoted.

Protease inhibitors of the Bowman−Birk inhibitor family, from peas, have been shown to have antiproliferative effects in human colon cancer cells. These inhibitors also inhibit protease-mediated inflammation. However, the beneficial effects require the protein to be in the biologically active form. Although cooking deactivates these proteins, denaturation may not always be complete; thus, regular consumption may contribute to the beneficial effect.[68] Angiotensin-1 converting enzyme (ACE) raises blood pressure when it converts angiotensin-1 to a potent vasoconstrictor angiotensin-2, and ACE inhibitor drugs are used to treat hypertension. Chickpeas and peas contain ACE inhibitor peptides. In vitro digestion studies indicate that pea protein and red lentil isolates have antihypertensive activity.[101,102] Therefore, pulses and their extracts may possess the potential for anticarcinogenic, anti-inflammatory, and antihypertensive effects, but further research is needed.

Vitamins and Minerals. Pulses are also a good source of B-vitamins, namely, riboflavin, thiamin, niacin, pyridoxine, and folic acid. These vitamins have important functions in energy metabolism and fatty acid metabolic pathways. Niacin is a coenzyme in energy metabolism and fatty acid metabolic pathways. It is involved in the modification of chromosomal

Table 1. Energy, Macronutrient, and Fiber Contents of Common Legumes and Cereals[a]

	serving size	energy (kcal)	carbohydrate (g)	protein (g)	fat (g)	fiber[b] (g)
legumes						
pinto beans	1/2 cup	122	22.42	7.70	0.56	7.7
great northern beans	1/2 cup	104	18.66	7.37	0.40	6.2

proteins that function in the nucleus in DNA repair and regulation as well as cell differentiation. Niacin is also required for mobilization of calcium from intracellular stores.[48] In societies where the chief dietary staple consists of cereals such as corn or sorghum, niacin deficiency is likely to occur because it is covalently bound to complex carbohydrates, although chemical treatment with bases such as limewater can improve availability.[48]

Beans are an excellent source of folate, and two or more servings of some pulses can provide approximately 400 μg, which represents 100% of the daily requirements.[71] Global DNA hypomethylation and targeted hypermethylation are considered deviant patterns of DNA methylation found in many human diseases, such as cancer, imprinting disorders, and developmental disabilities.[103−105] Reductions in global DNA methylation may be precipitated by a low folate status.[106]

Minerals are essential micronutrients in human health. Iron is essential for respiration and energy metabolism. Zinc is a component of numerous metalloenzymes having catalytic activity or structural integrity that are zinc-dependent.[48] Although the bioavailability of iron from pulses is relatively low, approximately 20−25% of zinc is bioavailable.[107] Zinc deficiency has been associated with cardiovascular and renal diseases.[108] Calcium is an important component of the structure of bones and teeth. It is involved in blood clotting, enzyme regulation, nerve transmission, and muscle contraction.[48] Calcium bioavailability from pulses is half that of milk; nevertheless, approximately 20% of the calcium content of beans is bioavailable.[109]

Pulses are high in potassium and low in sodium. The effects of potassium on blood pressure are intertwined with sodium. The kidneys are genetically predisposed to conserve sodium and excrete potassium. This adaptation is linked to prehistoric humans who consumed a diet rich in potassium and low in sodium. The linkage of modern diets rich in sodium and low in potassium to the pathogenesis of hypertension is supported very strongly by reductions in blood pressure with diets that reverse this cationic composition.[110,111]

Retained sodium not only replaces potassium, which is then excreted in the urine, but it is also stored extracellularly in skin, cartilage, and bone. It is readily mobilized to increase its level in body fluids. Thus, in the absence of conservation, a low-potassium diet leads to a potassium deficit in the body. Sodium retention and potassium depletion have direct effects on arterial wall endothelium and nitric oxide synthesis to promote vasoconstriction. Sodium restriction and a high-potassium diet reverse these effects.[111] Moreover, potassium deficiency is associated with glucose intolerance and impaired insulin secretion, whereas potassium infusion increases insulin secretion. Membrane depolarization induced by potassium may be the trigger for insulin secretion by pancreatic β cells.[112,113]

Phytonutrients. The major phenolic compounds in pulses are tannins, phenolic acids, and flavonoids. Phenolics have at

least one aromatic ring with one or more hydroxyl groups. They can transfer electrons to remove free radicals, chelate metal catalysts, activate enzymes, and inhibit oxidases.[114] These compounds are known to have antioxidant, anti-inflammatory, and antimicrobial properties[115] that protect body tissues against oxidative stress.[116] Flavonoids limit free radicals, free radical mediated cellular signaling, and inflammation.[117] They improve endothelial dysfunction and platelet aggregation.[118] Enhanced reactive oxygen species release from the vascular wall can affect the platelet activity cascade by scavenging nitric oxide and thereby decreasing the antiplatelet activity of the endothelium.[119]

Polyphenols reduce the expression of NADPH oxidase, an enzyme that generates superoxide anions in arterial cells, and increase the expression of antioxidant enzymes such as catalase and superoxide dismutase. Their antioxidant effects extend to inflammation-related proteins such as nuclear factor κB and cyclooxygenase-2. Thus, polyphenols reduce vasoconstriction and pro-inflammatory responses and promote vascular health by reducing oxidative stress induced degradation of nitric oxide.[120,121] Anthocyanins are present in pulses such as black beans,[82] red kidney beans, and pinto beans.[116] They have been shown to increase phase II antioxidant and detoxifying enzymes in human gastric adenocarcinoma cells[122] and breast epithelial cell lines exposed to a carcinogen.[123] Phenolic compounds have the potential to prevent tumor development. Lentils have the highest phenolic content, followed by red kidney beans and black beans.[82] The high pigmentation in dark-colored beans such as red kidney beans and black beans appears to increase their phenolic content.

Pulses contain other minor constituents such as phytic acid and saponins that promote human health. Phytic acid induces differentiation and maturation of malignant cells, often reverting cells to the normal phenotype. It can regulate the cell cycle to impede uncontrolled cell division, forcing malignant cells to either differentiate or go into apoptosis.[124] Saponins suppress the metastatic potential of tumors by regulation of enzymes involved in the apoptosis pathway, leading to programmed cell death.[82] Saponins form an insoluble complex with cholesterol to inhibit its intestinal absorption. By increasing the excretion of bile acids some saponins indirectly decrease cholesterol.[71,125] The energy, macronutrient, and fiber composition of select pulses and cereal products are presented in Table 1. The vitamin and mineral components are presented in Tables 2 and 3, respectively.

HEALTH BENEFITS OF WHOLE GRAINS

The evidence for an association between whole-grain consumption and health is largely supported by observational

studies, which precludes the establishment of causality.[126] Epidemiological data collected among a predominantly Caucasian population suggest that the consumption of three or more servings (3 oz equivalents) of whole grains is associated with a positive impact on body mass index (BMI), abdominal obesity, CVD risk reduction, and glucose homeostasis.[32] A comprehensive meta-analysis showed that compared with those who rarely or never consume whole grains, 48−80 g of whole grains or three to five servings of whole grains per day reduces the risk for type 2 diabetes and CVD by 26 and 21%, respectively. An inverse association between whole-grain intake and weight gain was also observed.[127]

Observational studies that reported an inverse association between whole grains and chronic disease investigated mixtures of whole grains and ≥25% of bran rather than whole grains alone.[128] However, there is a paucity of randomized controlled trials (RCTs) assessing the health effects of whole-grain consumption. Moreover, they are of short duration (≤1 year), measured biomarkers rather than end points of disease, and used a specific fiber, whole grain, or bran in doses that do not represent daily consumption. The existing evidence from RCTs suggests that whole grains alone are insufficient to exert a beneficial effect on disease risk reduction.[128,129]

Cardiovascular Disease. There is fairly consistent evidence to support an association between whole-grain consumption and a reduction in blood pressure.[130,131] Four or more servings of whole grains are associated with a 23% lower risk of hypertension.[130] The evidence from RCTs is less consistent. In one study substitution of three servings of refined cereals foods with whole-grain foods (100−120 g of whole-wheat foods or whole-wheat foods and oats) for 12 weeks lowered blood pressure.[132] In another study among 14 normal-weight healthy individuals, 48 g/day of whole-grain consumption for 3 weeks reduced blood pressure.[133] Replacement of 20% of the energy content of the Step 1 diet of the American Heart Association with whole grains reduced blood pressure in mildly hypercholesterolemic individuals.[134] However, 3 months of high-fiber cereal foods did not improve blood pressure in 23 diabetic individuals.[135]

A positive association between whole-grain consumption and improvements in coronary artery intima media thickness has been observed,[136,137] but the effect of whole-grain consumption on blood lipids is not clear. The effect of β-glucan, a soluble fiber found in oats and barley, on reducing low-density lipoprotein cholesterol is well documented,[138−142] but, apart from the quantity, other properties such as the molecular weight and solubility of β-glucan influence its physiological effects.[143] These properties, which determine the cholesterol-lowering effects, may be altered during processing. Thus, it is difficult to draw any definite conclusions as to the effects of these extracts compared to consumption of the whole grain. Furthermore, the effect of whole-grain foods prepared from

other cereal grains in lowering blood lipids is not consistent.[144−146]

Whole-grain consumption has been shown to decrease C-reactive protein, a marker of inflammation, in overweight adults with the metabolic syndrome consuming a hypocaloric diet for 4 weeks.[147] However, in the WHOLEheart study the addition of up to 120 g of whole grains to the diet over 8 and 16 weeks did not significantly improve markers of CVD risk, including C-reactive protein, among 316 overweight individuals.[144] A majority of the studies evaluating the effect of whole-grain consumption on cardiovascular risk included the fiber-rich bran and the germ as well as the whole grain in the definition of whole grain. When only studies that meet the FDA definition of whole grain are analyzed, it appears that there is insufficient evidence to support a claim that whole grains reduce the risk of CVD, suggesting that the fiber content of whole grains may to a large extent mediate its cardiovascular effects.[26] On conducting a systematic review of the scientific evidence including controlled clinical trials and prospective cohort studies in healthy individuals, Health Canada concluded that the current evidence may not be sufficient to support a health claim about whole grains and coronary heart disease.[148]

Diabetes and the Metabolic Syndrome. Epidemiological evidence indicates an inverse association between whole-grain consumption and type 2 diabetes.[10,149] A meta-analysis showed that a two serving per day increase in whole-grain consumption is associated with a 21% reduction in the risk for type 2 diabetes.[10] In a randomized crossover trial among 30 overweight individuals, markers of insulin sensitivity and inflammation were not significantly affected by the inclusion of whole grains in the diet for 6 weeks compared to refined grains intake. Insulin sensitivity was measured using the euglycemic hyperinsulinemic glucose clamp, which is considered the gold standard for measurement of insulin sensitivity.[150] However, in a smaller randomized crossover study among 11 overweight or obese hyperinsulinemic individuals, consumption of whole grains for 6 weeks improved insulin sensitivity measured using the glucose clamp.[151] Whole-grain consumption for 12 weeks had no effect on insulin sensitivity, compared to consumption of refined cereals assessed by the frequently sampled intravenous glucose tolerance test.[152] In other studies, consumption of high-fiber cereal foods for 3 months did not improve markers of glycemic control or risk factors for coronary heart disease in 23 subjects with type 2 diabetes.[135] However, in 61 subjects with the metabolic syndrome, a 12 week diet based on whole grains reduced postprandial insulin and triglyceride responses compared to a diet based on refined grains.[153] In a review of studies evaluating the effects of oat and barley products on blood glucose, it was determined that at least 4 g of β-glucan is needed to lower the glycemic response.[154] The FDA concurred with The 2010 Dietary Guidelines Advisory Committee and concluded that there is limited evidence for an association between whole-grain intake and reduced risk of type 2 diabetes.[155] The Grains for Health Foundation Summit 2012 arrived at a similar conclusion[156]

Obesity. Whole-grain products from rye, oats, barley, and wheat have been shown to increase satiety. Whole-grain rye is a good source of soluble and insoluble dietary fiber.[157] Arabinoxylan is the dominant fiber, and the water extractable component of arabinoxylan is highly viscous when dispersed in water.[158] Similarly, oats and barley contain the soluble fiber β-glucan in significant amounts, which exhibits a high viscosity at relatively low concentrations.[159] Viscous soluble dietary fiber delays gastric emptying and slows intestinal transit to reduce the absorption rate of nutrients, thereby increasing the possibility of interaction between nutrients and the cells that release satiety hormones.[160]

Whole-grain rye products have consistently been shown to increase satiety, compared to wheat bread.[161−168] The results of studies investigating the effect of β-glucan from oats and barley on satiety are inconsistent. Using β-glucan in doses ranging from 2.2 to 9 g, several studies found that satiety or satiety hormones increased,[143,169−174] whereas others found no effect of β-glucan on satiety.[175−177] The insoluble fiber found in breakfast cereals made with whole-grain wheat in amounts ranging from 26 to 33 g/meal also increased satiety compared to cornflakes of equal weight,[178] or equal energy content,[179] as well as compared with a breakfast of bacon and eggs.[180] However, subjective satiety and food intake following consumption of whole-grain bread providing 10.5 g of fiber per day for 3 weeks was not significantly different compared to refined grain bread providing 5.8 g of fiber per day.[133] Thus, the fiber component of whole grains through its effects on bulking and viscosity may help to keep consumers full for a prolonged period.

Observational studies have consistently shown that whole-grain consumption of approximately three servings (≥3 oz equivalents of whole-grain foods) per day is associated with lower BMI compared to refined grain intake.[11,181,182] Reductions in weight gain and abdominal obesity have also been observed with whole-grain consumption.[34,183] In the Health Professionals follow-up study, a prospective study assessing 8 year weight gain among health professionals, a 40 g per day increase in whole-grain intake from all foods reduced body weight by 0.49 kg. The addition of bran was found to further reduce the risk of weight gain. Every 20 g per day increase in bran intake reduced weight gain by 0.36 kg.[183]

The results of intervention trials have been less consistent. In studies evaluating the effect of whole-grain consumption over 4−12 weeks, no differences in weight loss were found when compared with control diets,[146,147,184−186] although one study found a reduction in fat mass[146] and another found a decrease in waist circumference[186] compared to refined grain consumption. In a meta-analysis including 21 RCTs, whole-grain intake reduced weight gain compared to control diets. However, heterogeneity among the studies, short intervention periods, and relatively small sample sizes limit the results of this analysis.[127]

More recently, a meta-analysis[187] evaluating the evidence from 26 RCTs investigating the effect of whole-grain consumption on body weight and body composition compared to non-whole-grain and refined-grain controls found no effect on body weight but a small beneficial effect on body fat. The average duration of the studies included in this analysis was 4−6 weeks, and to compensate for the short duration, the doses used in the studies represented whole-grain consumption that exceeded the highest level of intake among population groups that consume whole grains. Nevertheless, a meta-regression showed no dose−response relationship between whole-grain intake and differences in body weight.

Observational studies show reductions in weight gain of approximately 0.5 kg,[187] rather than weight loss, between consumers and nonconsumers of whole grains, which raises the possibility that the differences are a marker of a healthy lifestyle rather than the effect of whole grain intake per se. These subtle differences may be difficult to capture in relatively short-term

intervention trials, but longer-term trials may be fraught with the possibility of nonadherence to the diet. Thus, although there is some evidence to indicate that whole-grain consumption may lead to a reduction in fat mass, weight loss that is clinically significant remains to be established.

HEALTH BENEFITS OF PULSES

Cardiovascular Disease. Epidemiological evidence shows a 22% reduction in coronary heart disease and an 11% reduction in cardiovascular disease with consumption of legumes four times or more per week compared with once a week.[15] Intake of one serving of beans per day is associated with a reduced risk of myocardial infarction by 38% compared to no or less than one serving per day, after adjustment for factors such as smoking, diabetes, hypertension, abdominal obesity, and physical activity.[188] The evidence is not as strong as the evidence for a similar association from whole grain consumption; however, intervention trials, which permit the establishment of causality, show fairly consistently that legume consumption lowers total cholesterol and LDL-C, which is the most atherogenic lipoprotein.[71] Total cholesterol LDL-C levels were significantly improved by a high-pulse diet, compared to a high-protein diet, a fatty fish diet, and a control diet.[189] In hypercholesterolemic individuals, consumption of half a cup of baked beans per day as part of the usual diet for 8 weeks reduced total cholesterol by 5.6% and LDL-C by 5.4% compared to a control treatment consisting of half a cup of carrots.[190] Among individuals 50 years or older a pulse-based diet for 2 months reduced total cholesterol and LDL-C.[191] In other studies, chickpea supplementation significantly reduced total cholesterol and LDL-C.[192−194]

In the Legume Inflammation Feeding Experiment, a legume-rich, high-fermentable fiber diet designed to include foods that have a low glycemic index (GI), 21 g fiber/1000 kcal with a GI = 38 led, to greater reductions in total cholesterol and LDL-C compared to an American diet (9 g fiber/1000 kcal having a GI = 69, no legumes).[195] In diabetic participants, a pulse-rich low-GI diet consumed for 3 months lowered total cholesterol and triglycerides.[196] Meta-analyses of RCTs assessing the effect of pulses on blood lipids have shown that legume consumption lowers total and LDL-C levels.[197,198]

The hypocholesterolemic effects of pulses appear to be related to their soluble fiber component, which binds bile acid and decreases the reabsorption of bile acids. Furthermore, fermentation of soluble fiber in the colon and the production of SCFAs contribute to decreased hepatic cholesterol synthesis.[198] Pulse proteins containing the 7S globulin fraction also appear to lower plasma cholesterol and triglyceride levels.[199] Moreover, diets containing vegetable sources of fat and protein may reduce the risk factors for CVD.[200] Other components such as phospholipids and saponins may also contribute to the cholesterol-lowering effects.[198]

Consistent results from RCTs suggest that diets containing pulses may positively affect blood pressure. Consumption of four servings of pulses per week for 8 weeks within an energy-restricted diet reduced total cholesterol, LDL-C, and systolic blood pressure compared to an energy-restricted control diet without pulses.[201] In patients without diabetes, the consumption of pulses as part of energy-restricted diets reduced blood pressure.[189,201−203] A low-GI diet containing pulses reduced blood pressure and heart rate among diabetic individuals, compared to a high wheat fiber diet.[196] Isocalorically replacing foods with pulses significantly lowered the systolic and mean arterial blood pressure in individuals with and without hypertension.[204]

The reduction in cardiometabolic risk factors associated with pulse consumption may also be attributed to their antioxidant components. Besides, pulses have other components such as folic acid that reduce homocysteine levels to reduce the risk of stroke.[205] Markers of systemic inflammation such as interleukin-6 and tumor necrosis factor-α receptor-2,[206] as well as C-reactive protein[207] are inversely associated with intake of dietary fiber, which may contribute to the beneficial effect of pulse consumption on risk factors for cardiometabolic disease. Four servings of pulses per week within an energy-restricted diet reduced pro-inflammatory markers and markers of oxidative stress, after adjustment for weight loss, compared to an energy-restricted control diet without pulses.[201]

Diabetes and the Metabolic Syndrome. Besides being high in protein, pulses are a low-GI food. In a comparison of 24 common foods including grains, cereals and pasta, breakfast cereals, biscuits, and tuberous vegetables, legumes lowered the glycemic response by 45% when eaten by healthy individuals.[74] Compared to eight cereal foods, legumes have been shown to release 56% less sugars and oligosaccharides over a period of 5 h in healthy individuals.[208] When compared to isoenergetic meals containing potato flakes and meat, meals containing bean flakes and meat produced a significantly lower glycemic response.[209,210] In a meta-analysis of 20 randomized controlled trials, it was concluded that low-carbohydrate, low-GI, Mediterranean, and high-protein diets lead to greater improvements in glycemic control compared to control diets.[211]

Epidemiological as well as randomized controlled trials have demonstrated a beneficial effect of pulse consumption on the prevention and management of diabetes as well as the metabolic syndrome. Among middle-aged Chinese women, followed for approximately 5 years, a high intake of legumes, particularly soybeans, was associated with a decreased risk for diabetes.[212] In short-term experimental studies pulse consumption lowered blood glucose and insulin responses[74,213,214] and increased insulin sensitivity[214] when compared with white bread or pasta. A meta-analysis of RCTs evaluating the effects of pulse consumption on markers of glycemic control showed that pulses alone, or as part of a low-GI or high-fiber diet, improved glycosylated hemoglobin (HbA_{1c}) and fructosamine, both markers of glycemic control.[215] A low-GI pulse diet consumed by 121 diabetic individuals for 3 months, led to a fall in levels of HbA_{1c} by a mean of 0.5% compared to the wheat fiber diet. Participants were encouraged to increase pulse intake by 1 cup of cooked pulses/day or to increase insoluble fiber by consumption of whole-wheat products.[196] In subjects with diabetes, pinto, dark red kidney, and black beans each served with rice lowered the glycemic load (product of the GI and the available carbohydrate) of the meal and attenuated the blood glucose response compared to white rice alone.[216]

Pulses have also been shown to have a second-meal effect, whereby postprandial blood glucose response to a meal eaten a period of time after consumption of a particular food is lowered. Chickpeas and lentils have been shown to have a second-meal effect.[217−220] Although yellow peas did not have a second-meal effect,[217] 20 g of isolated yellow pea protein served in a tomato soup manifested a first-meal as well as a second-meal effect to lower the postprandial blood glucose response on both occasions.[221]

Central to the metabolic syndrome is insulin resistance and a cluster of associated cardiovascular risk factors such as

abdominal obesity, elevated blood pressure, and dyslipidemia. A significant association between legume intake and decreases in mean systolic blood pressure, fasting blood glucose, and increase in high-density lipoprotein cholesterol (HDL-C) levels was observed in 80 subjects diagnosed with the metabolic syndrome.[222] Consumption of 5 cups per week of pulses (yellow peas, chickpeas, navy beans, and lentils) over 8 weeks in an ad libitum diet reduced the risk factors of the metabolic syndrome, and these effects were equivalent to, or greater than, those precipitated by an energy-restricted diet.[17]

Obesity. Lentils have been shown to increase satiation (termination of a meal) compared to a meal consisting of pasta and sauce, but showed no effect on energy intake at a subsequent pizza meal served 4 h later.[213] Lentils as well as yellow peas reduced appetite and energy intake at a subsequent meal compared to a meal consisting of macaroni and cheese.[217] In other studies, daily energy intake decreased by 380 kcal in the subjects consuming 5 cups of pulses per week, which was similar to the reduction in intake of subjects placed on an energy-restricted diet.[17] A meal containing bean purée increased satiety over 4 h compared to the same meal substituted with potato purée.[209] The acute effect of chickpea breakfasts on satiety and energy intake was not significantly different,[223] but chickpea supplementation of approximately 104 g/day for 12 weeks increased satiety.[224] Bread in which 40% of wheat flour was replaced with lupin kernel produced greater satiety and lower energy intake at lunch compared to white bread.[225] Furthermore, a lupin-kernel fiber-enriched sausage patty produced greater effects on satiety than a conventional patty and an inulin fiber-enriched patty.[226] However, in another study consumption of bread produced by replacing of 10% of wheat flour with lupin flour had no effect on satiety or energy intake.[227] Thus, pulse consumption may have an effect on satiety, which can help consumers overcome environmental cues to eat or help them to adhere to calorie restriction.[71]

Epidemiological evidence shows an inverse association between bean consumption and body weight.[14] In intervention trials, rice and bean meals consumed twice daily increased weight loss at 1 month compared to meals consisting of lean meat; however, the effects did not persist over 2 months, possibly as a result of subjects dropping out of the study.[228] In a comparison of a high-pulse diet, a high-protein diet, a fatty fish diet, and a control diet excluding pulses and fish, for 8 weeks, the high-protein and high-pulse diets produced similar effects on weight loss. Furthermore, both diets increased weight loss compared to the control diet.[189] Four servings of pulses per week for 8 weeks within a 30% energy-restricted diet produced greater weight loss than an energy-restricted control diet that excluded pulses.[201]

A diet high in legumes including beans and peas for 3 weeks had no significant effect on body weight, but this duration may have been too short to assess weight change.[229] A high-pulse–low-GI diet reduced body weight after 3 months.[196] However, subjects provided pulses and whole grains for incorporation into their diets did not show significantly different weight loss after 6 or 18 months, compared to a control group provided refined cereals and high glycemic index foods, although waist circumference reduced at 18 months in subjects on the high-legume diet.[230] The endosperm of lupin seeds is used to produce flour that contains 40–45% protein and 25–30% fiber with negligible amounts of sugar and starch.[225] Although bread made with lupin flour has been shown to increase satiety,[225,231] it had no effect on weight loss, weight maintenance, or body composition in studies lasting for 12 months.[202,232] Thus, the consumption of pulses and other legumes may enhance weight loss, but its effects on long-term weight management have yet to be convincingly demonstrated.

WHOLE GRAINS AND PULSES

Dietary recommendations emphasize increasing intakes of foods that are nutrient dense and contain fiber while achieving and maintaining a healthy body weight.[22] The challenge lies in meeting these goals, especially, because grains, which are a major component of most diets, provide a substantial amount of energy. Whole grains provide approximately 2.4 g of fiber per serving (1 oz equivalent), whereas refined grains provide 0.7 g per serving.[233] According to the National Health Interview Survey 2000,[234] the average American consumes only half the intakes of dietary fiber (25–38 g/day) recommended by the Institute of Medicine.[235] A shift from low-fiber refined grains to whole-grain foods will help to meet dietary recommendations while lowering the metabolizable energy. Three servings of whole grains would provide approximately 7.5 g of fiber or one-fourth of the recommendation. Moreover, essential vitamins, minerals, and phytonutrients are lost in the milling process, making whole grains nutritionally dense compared to refined grains.[62,236]

Epidemiological data provide consistent evidence for the health benefits of whole-grain consumption; however, the same cannot be said for the results from RCTs. Part of the reason for the inconsistent results may be the grain structure. An intact botanical structure may delay or preclude starch absorption. Milling of wheat, for instance, separates the bran, germ, and endosperm. Reconstitution of the separated parts produces wholemeal flour, which elicits the same glycemic response as refined flour when incorporated into bread.[237] Nevertheless, the nutritional benefits of whole-grain foods are without doubt, and their consumption can make a fairly significant contribution to meeting dietary fiber recommendations, the health benefits of which have long been appreciated.[238] The consumption of cereal fiber, or mixtures of whole grains and bran, is modestly associated with reducing the risk of chronic disease including obesity, type 2 diabetes, and cardiovascular disease.[128]

Pulses are a rich source of protein, slow-release carbohydrates, dietary fiber, micronutrients, and other bioactive components associated with health benefits.[19] One serving of pulses contains approximately 7.6 g of fiber.[239] Unlike the evidence for whole-grain cereal foods, both epidemiological and experimental results provide substantial evidence for a protective effect against chronic disease. A diet that includes pulses meets the recommendations of the Dietary Guidelines for Americans 2010[22] and could contribute to increasing the fiber and lowering the energy density of a diet. Diets high in pulses may be recommended in the prevention and management of obesity and chronic diseases including diabetes, cancer, and cardiovascular disease. Vegetables, fruits, lean meats, and whole grains are among the other recommendations of the Dietary Guidelines. However, some of these products are expensive sources of energy,[240] which may in part explain their substitution with less expensive, energy-dense, nutrient-poor foods. Legumes, dried beans and peas in particular are relatively less costly than animal sources of protein, which can help to overcome the cost constraints of nutritious diets while providing a host of benefits in terms of improving the

Table 4. Impact of Whole Grain Intake on Obesity and Related Co-morbidities Based on Experimental Trials Reviewed

whole grain type	impact on disease		
	obesity	cardiovascular disease	metabolic syndrome/eiabetes
whole grains/ wheat bran	reduced cumulative energy intake (from breakfast and lunch);[178] reduced appetite and energy intake[179,180]	reduced blood pressure;[132−134] decreased C-reactive protein;[147] benefcial effect on total cholesterol and LDL-C[146]	improved insulin sensitivity;[151,185] reduced postprandial insulin and triglyceride responses;[153] improved postprandial glucose response[178,179]
	no effect on subjective satiety and/or energy intake[174,176]	no effect on blood pressure;[135] no effect on cardiometabolic risk factors;[144] no effect on total cholesterol and LDL-C[147]	no effect on postprandial blood glucose;[176] no effect on markers of insulin sensitivity and inflammation[150,152,135]
	no effect on body weight[146,147,184,185] but fat mass[146] and abdominal obesity reduced[147]		
barley and oats/ β-glucan	increased subjective satiety and reduced energy intake;[169,170,173] increased subjective satiety but no effect on energy intake[174]	reduced total cholesterol and/or LDL-C[138−142,186]	decreased insulin response response;[173] reduced postprandial glucose response;[175] at least 4 g of β-glucan needed to reduce postprandial glucose response[154]
	positively affected satiety hormones[169,172,173]		no effect on postprandial blood glucose[176]
	no effect on subjective satiety[175,177]		
	no effect on body weight but waist circumference reduced[186]		
rye	increased subjective satiety;[161,163,165,166,168] increased colonic fermentation and reduced energy intake at a subsequent meal but no effect on subjective satiety[167]	not assessed as a single component of the diet	improved glycemic/insulinemic response[161]
	no effect on energy intake[165,166]		

nutritional quality of the diets, lowering the energy density, and aiding in the prevention and management of chronic disease.

The emphasis on increasing intakes of whole grains has been consistent since the first Dietary Guidelines for Americans was released in 1980, yet, according to the NHANES 1999−2004, daily consumption of whole-grain servings was less than one-third of the recommended intakes.[20] In the absence of a universal definition of whole grains, part of the reason for the limited consumption of whole grains may be that consumers are confused as to what constitutes a whole-grain product.[129] Furthermore, in foods that are partially whole grain the relative proportions of whole-grain ingredients is unknown. Hence, a product that does not have whole grains as the first ingredient listed on the product package may contain anywhere from 1 to 49% whole-grain ingredients.[32] Ironically, among the USDA's top 20 food sources of fiber, whole-wheat bread, the most commonly consumed whole-grain component of the U.S. diet, is not present. On the other hand, 12 varieties of pulses are among the top 20 fiber sources.[239]

All refined grains are not completely devoid of nutrition. The enrichment process returns to the grains the nutrients lost in processing. Enriched grain products are required to have iron, thiamin, riboflavin, niacin, and folic acid added at specified minimum and maximum levels, according to the U.S. Code of Federal Regulations.[241] Nationwide fortification of enriched uncooked cereal grains with folic acid became mandatory in the United States in 1998.[242] Refined grain foods remain a major component of the diet in the United States, the United Kingdom, and Australia, which may be due to traditional preferences for refined grain products or unfamiliarity with cooking techniques. However, consumption of half the recommended grain intakes as refined grains is not associated with an increase in disease risk.[243] The inclusion of pulses in a meal containing refined grains provides a means of lowering the energy density of the meal and the postprandial glycemic response while helping to substantially meet dietary fiber recommendations. A meal containing pinto beans, dark red kidney beans, or black beans served with approximately half a cup of white rice has been shown to reduce the glycemic response compared to a meal containing only white rice.[216]

Pulses and whole grains contain a host of macronutrients, micronutrients, and other bioactive components essential for health, some of which are greater in one food group compared to the other. For instance, 1 cup (two servings) of beans and peas contains 15.2 g of fiber compared to 5 g contained in two servings of whole grains.[233] Pulses provide approximately 230 μg of folate per cup of cooked dried pulses (two servings) compared to 26 μg in two slices (two servings) of whole-wheat bread. Bread made with enriched flour has 90 μg of folate in two servings. Magnesium intake is often below the recommendations, and whole grains are a good source of magnesium.[244] However, the bran component has a higher content at 89 mg per one-fourth cup of wheat bran compared to 86 mg per cup of cooked brown rice. The content of magnesium in a cup of cooked pinto beans is 86 mg. The vitamin E content of two servings of whole-wheat bread is 1.70 mg, whereas in 1 cup of pulses it is 0.58 mg.[80]

Together, pulses and grains provide all of the indispensable amino acids to meet human requirements for growth and health. They are a rich source of nondigestible carbohydrates, which may strategically alter the balance of gut microbiota to promote health.[44] In a study among Korean adults, a dietary pattern consisting of whole grains and legumes was found to be

Table 5. Impact of Legume Intake on Obesity and Related Co-morbidities Based on Experimental Trials Reviewed[a]

legume type	impact on disease		
	obesity	cardiovascular disease	metabolic syndrome/diabetes
legumes	increased mitochondrial oxidation[189] reduced appetite and/or energy intake;[17,217] reduced body weight over 4−8 weeks[189,201,228] and over 3 months[196] no effect on body weight but waist circumference reduced at 18 months[230]	reduced total cholesterol[196] and LDL-C[189,195,201] but reduced HDL-C[189,195,201] reduced blood pressure[189,196,201]	reduced risk factors for metabolic syndrome;[17] reduced HbA1C[196] and blood glucose[74,213,216]
chickpeas	increased satiation[224] no effect on satiety and energy intake[223]	lowered total cholesterol and LDL-C[192−194]	lowered blood glucose;[74,213] reduced single-meal blood glucose but no effect over 6 weeks;[214] produced second-meal effect on blood glucose[217]
lentils	reduced appetite and/or energy intake[17,213,217]	not assessed as a single component of diet	lowered blood glucose;[74,213] produced second-meal effect on blood glucose;[217] produced first- and second-meal effects on blood glucose[218,219]
navy beans	no effect on appetite or energy intake compared to control	reduced total cholesterol and LDL-C[190]	lowered blood glucose[213]
yellow split peas	reduced appetite and energy intake[217]	not assessed as a single component of diet	lowered blood glucose[213]
lupin seeds	increased satiety and/or reduced energy intake[225,226,231] no effect on satiety or energy intake;[227] no effect on body weight[202,232]	reduced blood pressure;[202,203] no effect on blood lipids[232]	inconsistent effects on blood glucose[202,225,231,232]
Swedish brown beans	reduced hunger and positively affected satiety hormones following a subsequent meal[220]	lowered inflammatory markers and increased short-chain fatty acid concentrations following a second meal[220]	produced a second-meal effect on blood glucose and insulin responses[220]

inversely associated with insulin resistance.[245] In a cross-sectional study among subjects participating in the Tehran Lipid and Glucose study, an inverse association was found between intake of fiber from cereal and legume sources and risk for the metabolic syndrome.[246] In participants with coronary artery disease, the replacement of refined grains at breakfast with a whole-grain and legume powder for 16 weeks had a positive impact on glucose, insulin, and homocysteine concentrations as well as lipid peroxidation.[247] The inclusion of whole-grain barley and legumes in a diet reduced cardiometabolic risk factors in 46 overweight women compared to a diet with a similar nutrient composition but lacking whole-grain barley and legumes.[248] Thus, a synergistic effect of legumes and whole grains on promoting human health is not entirely unfounded and bears further investigation. The impacts of whole-grain and legume consumption on obesity, cardiovascular disease, and diabetes, based on the experimental trials reviewed, are presented in Tables 4 and 5 respectively.

In conclusion, plant-based diets that include pulses and cereals, although associated with lower socioeconomic status[249] and fraught with difficulty in incorporating into the diet due to a bland taste, lack of knowledge of cooking techniques, and perceptions of flatulence from pulse consumption, can be a dietary strategy with significant implications on health. The evidence for the health benefits of pulse consumption is fairly robust from observational as well experimental studies. Whether the incorporation of pulses in the diet can be sustained in the long term is an important consideration that warrants investigation. Nevertheless, there is a need to establish more convenient delivery systems for pulses in familiar food forms to lower the energy density of these foods and provide health benefits. Federally mandated funding to promote consumption of pulses and the incorporation of pulse foods into the National School Lunch Program, which is presently being considered, will help to increase consumption.

Despite strong evidence from epidemiological studies assessing the health effects of whole-grain consumption, causality is difficult to establish mainly due to the dearth of RCTs. The assessment of biomarkers rather than disease end-points, variability in the definition of whole grains, and, especially, differences in grain structure are some of the factors associated with the lack of consistency in the results from RCTs. Although this should not undermine the potential health benefits of whole grains, it may be worthwhile to promote incorporating pulses into the diet along with traditionally preferred enriched grains to derive some of the benefits of whole-grain consumption. Finally, the host of nutrients and bioactive components contained in whole grains and pulses suggests the potential for a synergistic effect that could provide significant health benefits when these food groups are included in the diet.

Table 2. Total Phosphorus and Nitrate Nitrogen of Seawater in Gangwei, Zhao'an, Jiuzhen, and Fotan (mg/L, Mean ± SD; n = 3)

	GW	ZA	JZ	FT
total phosphorus	0.015 ± 0.004	0.035 ± 0.006	0.034 ± 0.008	0.043 ± 0.010
nitrate nitrogen	0.164 ± 0.032	0.182 ± 0.040	0.280 ± 0.042	0.419 ± 0.046

Young small size oysters were transplanted to these four bays (FT, JZ, GW, and ZA) and a 4-month experiment was conducted from last December, 2012 to March, 2013. A batch of oysters (30 individuals) about 5 cm were collected and brought to the laboratory immediately and thoroughly cleaned again to eliminate organic materials and appendiculate sediments. The soft tissues were isolated from the shell, dried, and ground as a powder by an agate mortar.

Preparation of Digestive Juices and Incubation of Gut Microbiota. The preparation of digestive juice and the incubation of gut microbiota were based on the reference.[15] According to human physiology, the process and time of digestion were designed.[16] The gastrointestinal inorganics, organics, bioenzyme, and gut microbiota were added to prepare the digestive juices.

Oyster (1.0 g) powder was digested successively in the bionic mouth, stomach, and intestine at 37 °C on a gentle oscillation as follows. The bionic gastrointestinal digestion process was initiated with the addition of 5 mL of saliva and oscillated for 5 min to simulate chewing. Then, 30 mL of gastric juice was added to the above sample and incubated for 3 h to simulate bionic gastric digestion. After gastric digestion, the pH value of the chyme was adjusted to 7.8 ± 0.2 with 1 mol/L NaOH, and then the chyme was mixed with 30 mL of duodenal juice, 15 mL of bile, and 15 mL of gut microbiota, and incubated on a gently rocking shaker for 7 h to simulate for intestinal digestion. All chymes were filtered with a 0.45 μm membrane.

Egg-derived (0.1 g) lecithin was dissolved in chloroform and then transferred into a rotatory evaporator to evaporate chloroform. Chyme (25 mL) was mixed with liposome to form a homogeneous liposome suspension, frozen at −71 °C in a super low freezer for 30 min, and then thawed at 37 °C. Such a freeze−thaw process was repeated 5 times to promote the metal speciation distribution in a liposome−water system. Affinity-liposome metals could be separated from water-soluble metals by 0.22 μm membrane.

Determination of Metal Concentration in Seawater, Oysters, and Affinity-Liposome Metal in the Chyme. Oysters (0.1 g, powder) were added to concentrated HNO_3 (4.0 mL) and Milli-Q water (4.0 mL), heated in a water bath at 80 °C until no smoke arose. Then, they were digested by concentrated HNO_3 (2.0 mL) and H_2O_2 (1.0 mL, 30%) in closed Teflon tubes for 10 min, using a microwave technique. Seawater which has been filtered by a 0.22 μm membrane, all of the affinity-liposome metal, or water-soluble metal was directly decomposed by concentrated HNO_3 (2.0 mL) and H_2O_2 (1.0 mL, 30%) in a microwave oven at the same conditions. After digestion, a dilution by water to 50 mL was carried out for metal determination by ICP-MS.

Statistical Analysis. SPSS 19.0 was used for the statistical analysis. Possible relationships between trophic status (nitrate N or total P) and metal content (or metal BAF or metal OBA) were examined by partial correlation analysis and quantified by the coefficient of determination, r. A significance level of $p < 0.05$ was adopted for all comparisons. The regressions were quantified by the coefficient of determination, R^2. The plots and regression lines were drawn in SigmaPlot for Windows, version 10.0.

Accuracy of the Method. The validity of the proposed method was checked by analyzing standard reference materials, and the results are shown in Table 1. The recoveries were reasonable for the analysis of Fe, Cu, As, Cd, and Pb in oysters, ranging from 99.3.−105.2%. Metal values were in good agreement with certified concentrations in both standard reference materials. The RSD was within 9.3%. Therefore, the described method can be applicable to the determination of low levels (mg/kg or mg/L) of metals (Fe, Cu, As, Cd, and Pb) in oysters, affinity-liposome metals, and those that are water-soluble in chyme.

RESULT

Trophic Status of Four Bays. Total phosphorus and nitrate nitrogen as trophic indicators of the bays in GW, ZA, JZ, and FT were determined and shown in Table 2. The bays of GW, ZA, JZ, and FT were semiclosed, the field experiment was done in winter (from December, 2012 to March, 2013), the seawater exchange rates were poor, and the concentration of N and P in the seawater was stable during our field experiment. These results were similar to those in the database from the Department of Ocean and Fisheries in Zhangzhou City, Fujian Province, China. Similar results were also reported for other semienclosed bays.[17,18] Total phosphorus and nitrate nitrogen in these four bays were varied from 0.016 to 0.043 mg/L and from 0.164 to 0.419 mg/L, respectively. On the basis of the seawater quality standard of China, except for GW, the trophic status of the other three bays was eutrophication in some ways.

Metal Bioaccumulation in Oysters and the Correlation of BAF and Trophic Status in Four Bays. Metal bioaccumulation in oysters under different trophic status is shown in Table 3. In seawater, the concentrations of these trace metals, except for Fe, were in the range of 0.11−6.53 μg/L; however, Fe content was from 0.26 to 2.11 mg/L. All metal contents in the seawater met the standard of clean bays. Fe contents in oysters ranged from 1.22 mg/g to 2.54 mg/g, and the other metals (Cu, As, Cd, and Pb) in oysters were enriched at the level of microgram per gram. Trace metals (Fe, Cu, As, Cd, and Pb) were largely bioaccumulated in oysters. BAF was used to evaluate metal bioaccumulation in oysters, which was significantly different ($p < 0.001$). Compared to the clean bay of GW, BAF in oysters was largely increased by 5.5 and 7.3 times for Fe in the trophic bays of JZ and FT, deceased by 0.5 times for Fe in trophic ZA, and 0.5−0.9 times for Cu in trophic ZA, JZ, and FT. However, the BAF of As was irregularly fluctuant, which did not relate to trophic status in seawater. The

As	4.05 ± 0.44	17.48 ± 0.72	4212	4.52 ± 0.41	16.71 ± 0.66	3609	1.47 ± 0.45	9.50 ± 0.35	6291	1.29 ± 0.33	5.79 ± 0.28	4386
Cd	0.13 ± 0.03	6.39 ± 0.32	49535	0.28 ± 0.05	2.34 ± 0.21	7996	0.14 ± 0.03	3.39 ± 0.26	24926	0.11 ± 0.03	3.00 ± 0.24	27778
Pb	4.03 ± 0.21	2.46 ± 0.11	596	6.13 ± 0.33	2.21 ± 0.09	352	5.00 ± 0.30	3.09 ± 0.16	602	3.82 ± 0.20	2.42 ± 0.10	617

[a]Note: the density of seawater (ρ_w) was 1.025 g·cm^{-3}. Metal bioaccumulation factor (BAF) was estimated by proportion of the oysters' and water's mass concentration. BAF = $Conc_o \times (Conc_w \times \rho_w)^{-1}$; $Conc_o$ and $Conc_w$ stand for the concentrations of seawater and oyster, respectively.

BAF of Pb did not vary significantly. Compared with the clean GW bay, the BAF of Cd in trophic bays (ZA, JZ, and FT) was decreased by 0.4−0.8 times. Furthermore, the BAF of Cd was increased as the trophic status, and the effect of trophic status on metal bioaccumulation could be discussed by partial correlation.

Partial correlation between BAF of Cd and total P (or nitrate N) was highly significant (r = 0.999, p = 0.024 for total P; and r = 0.998, p = 0.035 for nitrate N). The BAFs of Cu and Pb in oysters were not significantly correlated (p > 0.05) with total P (r = −0.98, r = −0.93) or nitrate N (r = 0.96, r = 0.95). The BAF of Fe in oysters was not significantly correlated with nitrate N (r = 0.90, p > 0.05) and show no correlation with total P (r = −0.277). The bioaccumulation in oysters in four bays was significantly different (P < 0.01), but it was not correlated with total P or nitrate N.

Relationship between Trophic Status of Seawater and Metal Oral Bioavailability. Only metal bioaccumulation in oysters could not fully reflect the potential toxicity or nutrition of metals in oysters. Therefore, metal oral bioavailability in oysters was studied by bionic digestion and liposome extraction. After bionic digestion, metal complexes in oysters could be released and entered into the gastrointestinal tract, transformed into their final coordinated complexes by the functions of bioemzymes and gut microbiota. The affinity-liposome metals in the chyme were available for gastrointestinal absorption. Correlations of metal oral bioavailability in oysters and total P (or nitrate N) are shown in Figures 1 and 2, respectively. Oral bioavailability of trace metals (Fe, Cu, As, Cd, and Pb) in oysters was all below 24%, i.e., metal species distribution in the chyme of oysters was mainly water-soluble metals. Metal OBA in oysters was not beyond 3.9% for Cu, 8.0%−17.4% for Fe, and 7.7%−18.6% for Cd. Only a small fraction of Cu in oysters was absorbed by the bionic membrane. OBA of As in oysters under different trophic status ranged from 2.5% to 23.5%. OBA of Pb in oysters were ranged from 12.1% to 14.0%, which was not significant variation (two way analysis of variance, p = 0.15).

With the aggravation of eutrophication, As OBA in oysters was largely increased. The OBA of As was significantly positively correlated to nitrate N (R^2 = 0.973, P = 0.007) and total P (R^2 = 0.904, P = 0.049). The OBA of Fe was negative correlated to nitrate N (R^2 = 0.882, p = 0.061). However, the OBA of other metals did not show any correlation with total P or nitrate N (correlation significant at P > 0.05).

Safety Assessment of Oysters for Consumption Based on Metal Oral Bioavailability. Deficiency of essential metals or metal overload is harmful for human health. Oysters are a kind of widespread seafood. Hence, safe dosage and maximum consumption of oysters are important for people. The impact of coastal trophic status on the metal safety of oysters should be assessed. Maximum consumption value for oysters was calculated by the ratio of tolerable upper intake levels (or maximum level of daily intake)[19,20] to affinity-liposome metal content, and the results are shown in Table 4. The result demonstrated that the maximum level of daily intake of oysters was mainly controlled by affinity-metal content of As. The oyster's maximum levels of daily intake ranged from 132.3 g/d to 197.4 g/d. As the N and P content increased, the maximum consumption of oysters was significantly decreased. Metal safety assessment of oysters demonstrated that an oyster's quality was significantly influenced by coastal trophic status. Consequently, the contents of N, P, and metals in the coastal

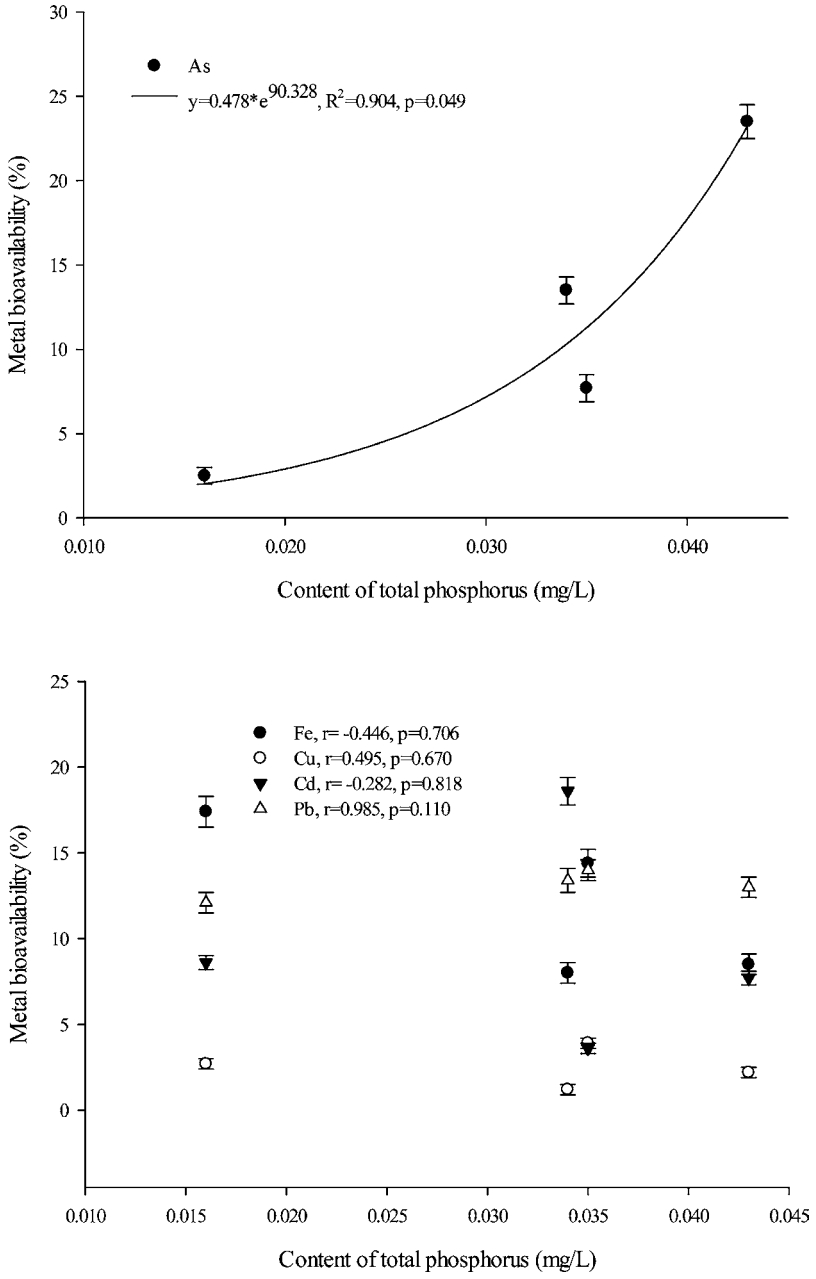

Figure 1. Relationship between the content of total phosphorus in seawater and metal oral bioavailability in oysters (two-tailed, partial correlation, $n = 3$).

seawater should be monitored simultaneously to avoid metal toxicity in oysters for consumption.

DISCUSSION

In coastal ecosystems, eutrophication has become a serious environmental problem.[21,22] The effect of trophic status on the metal bioaccumulation of an aquatic organism, such as crayfish[23] and fish,[24,25] has been reported. The input of macronutrients can not only change the concentration and ratio of marine nutrients but also affect algal structure (including species composition and abundance),[26] growth, cell shape, surface basic function groups, and biochemical compositions.[4] Coastal eutrophication also affected metal uptake and assimilation by marine algae and metal transfer in coastal food webs.[3,27] Oysters, as suspension-feeding bivalves, could assimilate metals from two sources, food particulates (e.g., algae and their debris) and dissolved metals in seawater.[28,29] The increase of N and P concentration was associated with increasing algal abundance and debris.[27] Because the bioconcentration factors of metals by marine algae were different for different metal species and nutrient regimes,[4] the influence of trophic status on metal BAF in oysters was also different with metal species. Increase of algal biomass or metal sedimentation in the debris in trophic bays may promote the ingestion of marine alga and debris. In our study, a significant positive effect of the trophic status of the seawater on the concentration of Cd in oysters (i.e., BAF) was observed. Consequently, the dominating assimilation pathway for Cd in oysters may be particulate ingestion.

After gastrointestinal digestion and gut metabolism of oysters, the affinity-liposome metals in the chyme were bioaccessible to the gastrointestinal tract, so they could be

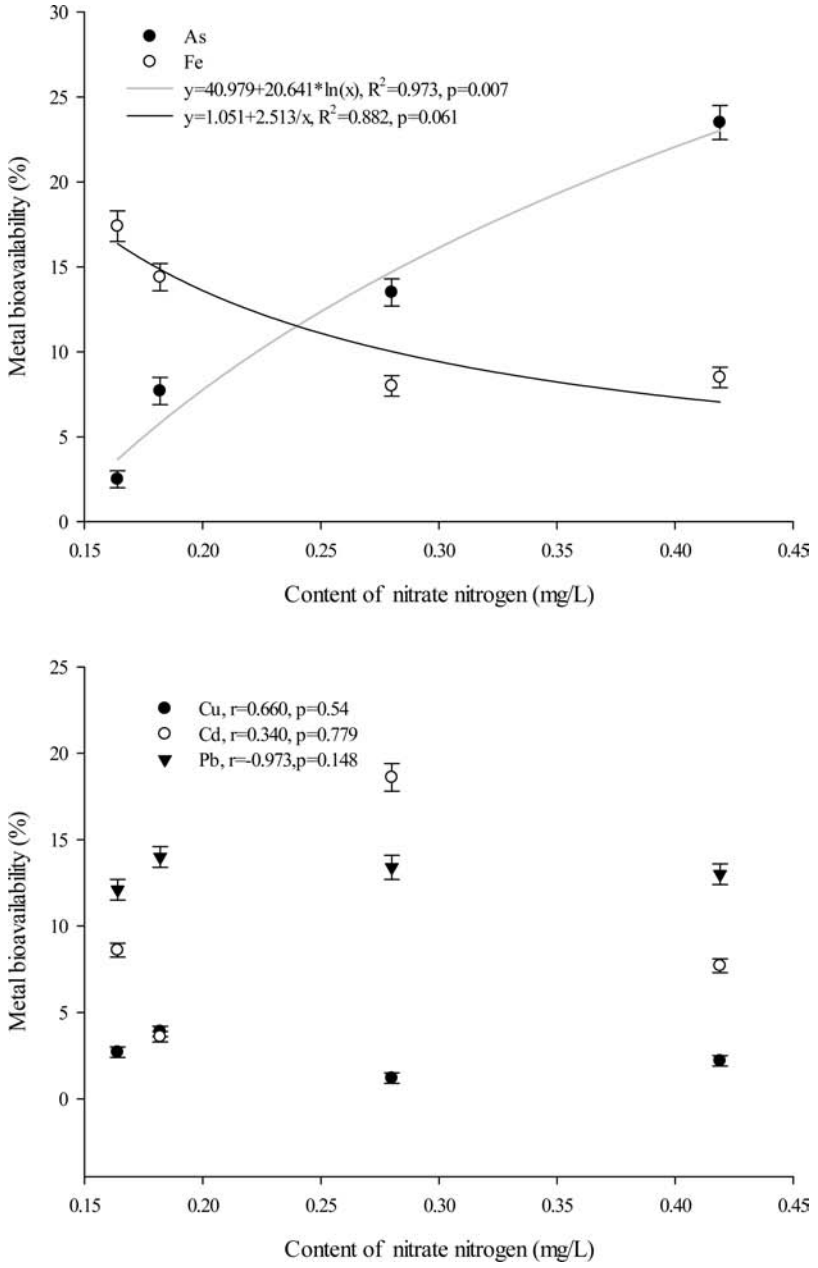

Figure 2. Relationship between the content of nitrate nitrogen in seawater and metal oral bioavailability in oysters (two-tailed, partial correlation, n = 3).

Table 4. Maximum Level of Daily Intake for Oysters[a]

		maximum consumption of oysters			
	Uls/ML value (mg/d)	GW (g/d)	ZA (g/d)	JZ (g/d)	FT (g/d)
Fe	45	197.4	256.1	221.5	210.1
Cu	10	954.0	3390.3	7628.5	2917.3
As	0.18[b]	411.9	139.9	140.4	132.3
Cd	0.3	545.9	3561.3	475.8	1298.7
Pb	0.3	1007.9	969.6	724.5	953.6

[a]Note: Uls, tolerable upper intake levels; ML, maximum level of daily intake without detriment to health. [b]UIs of inorganic arsenic BMDL was computed to be 0.18 mg/d for 60 kg weight people (3.0 μg/kg body weight per day) by WHO.

refined as the metals which were orally bioavailable to humans. Metal oral bioavailability was controlled by organic ligands.[30] Furthermore, the interaction of nitrogen and the food web may influence the metal speciation in organisms. In natural waters, the biosynthesis of organoarsenicals was enhanced by eutrophication, and arsenic speciation would be influenced by the balance of biological processes.[31] Metal ligands were closely related to metal oral bioavailability.[32] As and Fe were mainly distributed in heat-stable protein and granules, respectively, in marine molluscs (including oysters).[33] Subcellular distribution (including heat-stable protein and granules) of metal in marine oysters could be affected by the trophic status of seawater.[34] In our experience, the OBA of As was positively related to the trophic status of seawater, i.e., the OBA of As in oyster was increased as the aggravation of eutrophication in seawater and the OBA of Fe in oyster was negatively correlated to nitrate N. Metal bioaccumulation and oral bioavailability in oysters were significantly different. Through the Pearson correlation analysis,

dx.doi.org/10.1021/jf5001953 | J. Agric. Food Chem. 2014, 62, 7050−7056

only BAF of Fe was not significantly negative correlated to oral bioavailability (r = −0.992, P = 0.078). Consequently, this study suggested that As OBA in oysters could be used as a predictor of eutrophication in seawater and the potential toxicity of oysters for consumption.

In previous studies, metal bioaccessibility was indicated as the metal fraction of seafood which was released from seafood into the digestive tracts. Only the fraction of bioaccessible metals which could be absorbed by the biomembrane of the gastrointestinal tract was oral bioavailable metals. The concentration of bioaccessible metal was more than that of oral bioavailable metal and metal exposure via the consumption of seafood could be overestimated by this difference.

Table 1. Descriptors of the Five Hot Pepper Cultivars Used in This Experiment

cultivar	*Capsicum* species	pungency category[a]	leaf characteristics	fruit characteristics	growth habit[b]	source
Yuyi	*annuum*	low	big leaf, ovate shape	bell, campanulate, blunt end	annual	Japan
Keenoo-Pama	*annuum*	medium	small leaf, lanceolate shape	short, slim, elongated, pointed end	perennial	Myanmar
Huay-Siiton	*annuum*	medium	small leaf, lanceolate shape	Thai chilli, elongated, pointed end	perennial	KKU, Thailand
BGH 1719	*chinense*	high	small leaf, deltoid shape	short, slim, elongated, pointed end	perennial	USDA, Brazil
Perennial	*annuum*	high	small leaf, deltoid shape	short, slim, campanulate, blunt end	perennial	USDA, Mexico

[a]High = >100,000 Scoville heat units (SHU); medium = 50,000−100,000 SHU; low = <50,000 SHU. [b]All cultivars were grown and harvested within one season. (Plant growth habits of these cultivars are typically perennial type, but actually grown and harvested as annual type.).

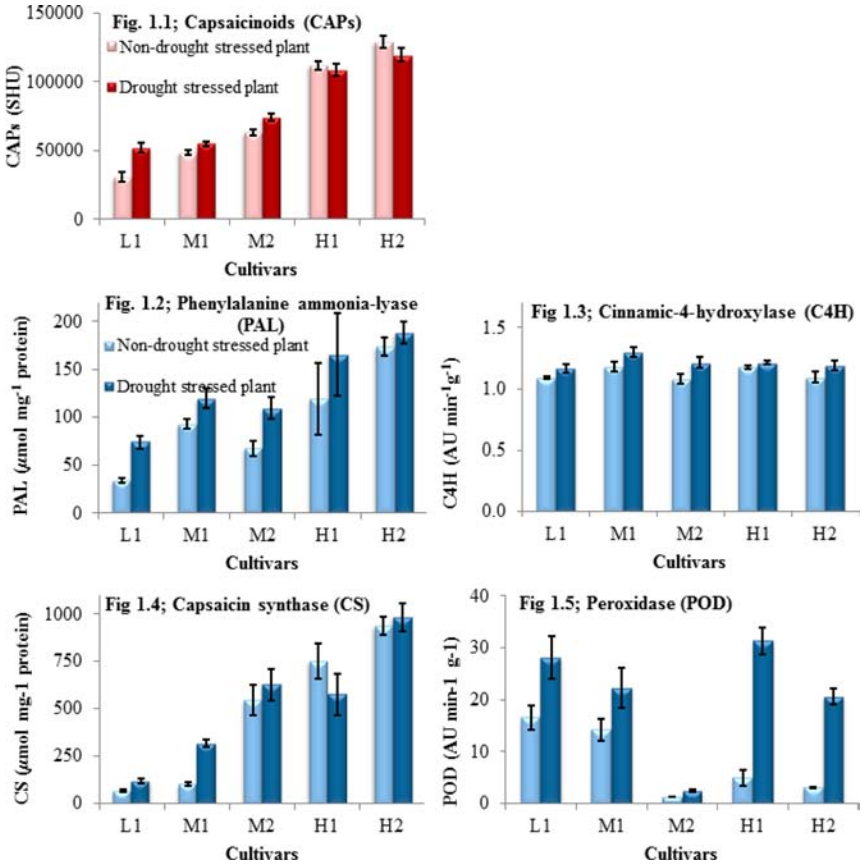

Figure 1. Sum of capsaicin and dihydrocapsaicin (CAPs) (redrawn from Phimchan et al.[7] (with permission from *HortScience*)) and activities of PAL, C4H, CS, and POD between non-drought-stressed and drought-stressed plants in the fruits of five hot pepper cultivars: one low pungent cultivar (L1, Yuyi), two medium pungent cultivars (M1, Huay-Siiton; M2, Keenoo-Pama), and two high pungent cultivars (H1, BGH 1719; H2, Perennial).

Phenylalanine Ammonia-lyase Activity. PAL activity was measured following the method of Koç et al.[11] with some modification from Ochoa-Alejo and Gómez-Peralta.[12] In this procedure, 0.5 g of fresh frozen fruit tissue was ground under 4 °C with 1.5 mL of 50 mM Tris-HCl buffer (pH 8.8) containing 1 mM EDTA, 15 mM β-mercaptoethanol, and 50 mM ascorbic acid. Then the mixture was centrifuged at 15,000 rpm for 30 min by using a Hettich Zentrifugen Universal 30RF model (Hettich GmbH & Co. KG, Kirchlengern, Germany), and after that, the supernatant was collected. The amount of protein was calculated by comparing the sample to the calibration curve obtained with bovine serum albumin (BSA) following the method of Bradford.[13] The absorbance at 595 nm was determined with a spectrophotometer using a Spectro SC-model (LaboMed, Inc., Los Angeles, CA, USA).

The assay mixture contained 0.1 mL of the enzyme extract, 1 mL of 100 mM Tris-HCl buffer (pH 8.8), 0.5 mL of 10 mM L-phenylalanine, and 0.4 mL of deionized water. The mixture was incubated for 1 h at 37 °C, and the reaction was terminated by adding 0.5 mL of 6 M HCl. Then the sample absorbance was measured at 290 nm with a spectrophotometer by using a GENESYS 10S UV−vis model (Thermo Scientific, Waltham, MA, USA). The calibration curve was constructed using cinnamic acid. The blank had the same constituent mixture as the sample.

Cinnamic-4-hydroxylase Activity. C4H activity was measured according to the method of Ochoa-Alejo and Gómez-Peralta[12] with some modification. One gram of fresh frozen fruit tissue was ground under 4 °C with 6 mL of 100 mM Tris-HCl buffer (pH 7.5). The extract was centrifuged at 15,000 rpm for 30 min at 4 °C, and the supernatant was collected as the enzyme extract.

The reaction mixture consisted of 1.5 mL of 100 mM Tris-HCl buffer (pH 7.5), 0.05 mL each of 20 mM glucose-6-phosphate, 12 mM β-mercaptoethanol, 8 mM cinnamic acid, and 8 mM NADP, 1000 units per 12.5 mL of G6P dehydrogenase, and 1 mL of the extract solution. The absorbance of the extracted solution at 340 nm was measured for 5 min by using an Agilent 8453 UV−visible model (Agilent Technologies, Inc., Santa Clara, CA, USA) with the time course method.

Capsaicin Synthase Activity. The procedure for the measurement of CS activity followed that of Ochoa-Alejo and Gómez-Peralta[12] with some modification. The extract was prepared by grinding 0.5 g of

fresh fruit tissue with 6 mL of 100 mM Tris-HCl buffer (pH 6.8). The homogenate was centrifuged at 15,000 rpm for 30 min at 4 °C and the supernatant collected for enzyme source.

The reaction mixture contained 0.1 mL of 0.4 M Tris-HCl (pH 6.8), 10 μL of 0.2 M vanillylamine, 5 μL each of 40 mM ATP, 40 mM $MgCl_2$, and 40 mM 8-methyl-6-nonenoic acid, and 0.3 mL of extracted enzyme. The reaction was performed at 37 °C for 1 h and terminated with 0.1 mL of 1 M HCl. The assay mixture was extracted with 0.5 mL of chloroform and evaporated to dryness at 50 °C in vacuo. Then, 1 mL of acetone was added, and the mixture was placed on a shaker for 1 h. The mixture was filtered with 0.45 μm PVDF Millipore; 10 μL of filtered solution was used for each HPLC assay using a Shimadzu VP series model (Shimadzu Co., Kyoto, Japan).

Peroxidase Activity. POD activity was measured through adaptation of the method of Arnnok et al.[14] All steps of enzyme extraction were carried out at 4 °C. A total of 1 g of homogenized hot pepper tissue was extracted with 0.1 M phosphate buffer (pH 7) containing 5 g of polyvinylpyrolidone using a magnetic stirrer for 15 min. The homogenate was filtered through Whatman no. 41 filter paper and then centrifuged at 2500 rpm for 20 min. The supernatant was filtered through Whatman no. 42 filter paper and collected as an enzyme extract. The activity of POD was assayed at 470 nm. The reaction mixture contained 0.15 mL of 40% (v/v) guaiacol, 0.15 mL of 1% (v/v) H_2O_2, 2.66 mL of 0.1 M phosphate buffer (pH 7), and 40 μL of the enzyme extract. The blank sample contained the same mixture solution without the enzyme extract.

Statistical Analyses. Statistical analyses were conducted following the procedure of Gomez and Gomez.[15] Analysis of variances (ANOVA) in a randomized complete block design was used with LSD to compare the significant differences among cultivars within treatment, and a *t* test compared the significant differences between control and drought stress treatments within a cultivar. A percentage increase of enzyme activities was calculated by using the equation [(drought − control)/control] × 100. In addition, the sum of capsaicin and dihydrocapsaicin (CAPs) of the five hot peppers cultivars used in this experiment was redrawn from a previous experiment[7] to estimate the relationship between the responses of enzyme activities and capsaicinoid content to drought stress (Figure 1).

RESULTS

All enzyme activities, PAL, C4H, CS, and POD, differed significantly among cultivars within a treatment (Table 2). The cultivars grown under the control treatment gave enzyme activities significantly lower than those under drought stress, except for PAL within cv. BGH 1719 and Perennial and CS within cv. Keenoo-Pama, BGH 1719, and Perennial.

Phenylalanine Ammonia-lyase Activity. For both control and drought-stressed plants, the activities of PAL differed significantly among cultivars (Table 2). As expected, the values of PAL activity under both treatments of the high-pungent cultivars were high, followed by medium-pungent ones, and PAL activity was low in the low-pungent cultivar. The high-pungent cv. Perennial exhibited the highest value of PAL activity under drought stress and control treatments (188.32 and 173.54 μmol mg^{-1} protein, respectively). Even though the PAL activity of cv. BGH 1719 under control treatment (148.91 μmol mg^{-1} protein) was significantly lower than that of cv. Perennial, its value under drought stress (165.23 μmol mg^{-1} protein) was not significantly different from that of cv. Perennial. The PAL activities of the medium-pungent cv. Huay-Siiton under control and drought stress treatments (92.59 and 135.59 μmol mg^{-1} protein, respectively) were not significantly different from those of cv. Keenoo-Pama (67.68 and 109.16 μmol mg^{-1} protein, respectively) within treatment. Yuyi, the low-pungent cultivar, showed the lowest values of PAL activities under control and drought stress treatments (33.99 and 74.02 μmol mg^{-1} protein, respectively). Moreover, the increase percentages of this enzyme activity in the drought-stressed plants related to control ones were large and highly significant for the low-pungent cv. Yuyi (117.75%), followed by those of the medium-pungent cv. Keenoo-Pama (61.26%) and Huay-Siiton (28.44%). However, they were small and not significantly different for the high-pungent cv. BGH 1719 (39.0%) and Perennial (8.52%).

dx.doi.org/10.1021/jf4051717 | J. Agric. Food Chem. 2014, 62, 7057−7062

Cinnamic-4-hydroxylase Activity. Under control and drought stress treatments, the activities of C4H differed significantly among cultivars (Table 2). The significant difference of this enzyme's activity between the control and the treatment were found in all cultivars studied. For the control treatment, the value of medium-pungent cv. Huay-Siiton and the high-pungent cv. BGH 1719 exhibited high values of 1.181 and 1.177 AU min^{-1} g^{-1}, respectively. Under drought stress treatment, cv. Huay-Siiton presented the highest C4H value (1.298 AU min^{-1} g^{-1}), which was significantly higher than those of the other cultivars (1.167−1.215 AU min^{-1} g^{-1}). The low-pungent cv. Yuyi gave a low C4H value. Although the increase percentages of the drought-stressed plants related to the controls were not as large as those of PAL activities, a significant difference between control and drought-stressed plants was observed in all cultivars studied.

Capsaicin Synthase Activity. The activity of the CS enzyme was significantly different among cultivars under both the control and drought stress treatments (Table 2). Similarly to PAL activity, the responses of CS activities in cultivars with different pungency levels were elevated in the high-pungent cultivars, followed by medium-pungent, and lowest in the low-pungent cultivars under both treatments. However, the responses among cultivars were different within a treatment. The high-pungent cv. Perennial presented the highest values of CS under control and drought stress treatments (936.4 and 982.7 μmol mg^{-1} protein, respectively). The value of CS activity in the other high-pungent cultivar, cv. BGH 1719, in the control treatment (752.4 μmol mg^{-1} protein) was not significantly lower than that in cv. Perennial. However, its value in stress conditions (578.3 μmol mg^{-1} protein) was not as high as that of cv. Perennial. Of the medium-pungent cultivars, cv. Keenoo-Pama gave higher CS values under control and stress treatments (546.8 and 628.5 μmol mg^{-1} protein, respectively) compared to cv. Huay-Siiton (104.9 and 316.7 μmol mg^{-1} protein, respectively). As expected, the low-pungent cv. Yuyi had the lowest values of CS activities under control and drought stress treatments (67.6 and 119.6 μmol mg^{-1} protein, respectively). In addition, the increase in this enzyme's activity in the drought-stressed plants related to the control was large (201.96%). In addition, it was significantly different in the medium-pungent cv. Huay-Siiton and the low-pungent cv. Yuyi (76.90%), whereas it was not different for the other cultivars.

Peroxidase Activity. POD activities in all cultivars studied under drought stress treatment were significantly different among cultivars within a treatment and higher than those under the control treatment. The POD activity in the control treatment was contradictory to the other three enzyme activities (Table 2 and Figure 1). The POD enzyme activities were low in both of the high-pungent cultivars, BGH 1719 and Perennial, under control treatment (5.06 and 3.13 AU min^{-1} g^{-1}, respectively), but they were high under drought stress treatment (31.31 and 20.63 AU min^{-1} g^{-1}, respectively) and highly significantly different from those of the controls. For the medium-pungent cultivars, their POD activities in both treatments were not consistent. For example, cv. Huay-Siiton gave high values of POD activity under both control and drought stress treatments (14.25 and 22.26 AU min^{-1} g^{-1}, respectively), which were significantly higher than those of cv. Keenoo-Pama (1.26 and 2.46 AU min^{-1} g^{-1}, respectively). Moreover, the low-pungent cv. Yuyi gave high POD activity (16.50 and 28.13 AU min^{-1} g^{-1}, respectively); however, these values were not significantly different from those of cv. Huay-Siiton within a treatment. The increase of this enzyme's activity in the drought-stressed plants related to the control plants was large and highly significantly different for the high-pungent cv. BGH 1719 and Perennial (518.8 and 559.1%, respectively). A small increase of this enzyme activity was observed for the medium-pungent cv. Huay-Siiton and Keenoo-Pama and for the low-pungent cv. Yuyi (56.21, 95.24, and 70.48%, respectively), but they were all significantly different.

Relationship between Enzyme Activities and Capsaicinoid Responses to Drought Stress. The low- and medium-pungent cultivars under drought stress produced significantly higher amounts of capsaicin and dihydrocapsaicin (CAPs) than the control plants. The high-pungent cultivars did not significantly differ in capsaicinoid amount when subjected to drought stress conditions (Figure 1.1). The responses of PAL activity showed a trend similar to the responses of the capsaicinoid amounts under both treatments, with the values for PAL activities and capsaicinoid content low in the low- and medium-pungent cultivars and high in the high-pungent cultivars under both treatments (Figure 1.2). Moreover, the significant increase of PAL values in the low- and medium-pungent cultivars and the nonsignificant increase in the high-pungent cultivars were exactly the same responses of CAPs of those cultivars with different pungency levels under drought stress. The enzyme C4H activities did not show any association with the capsaicinoid responses, where C4H values in all cultivars with different pungency levels were all significantly increased compared to their control ones (Figure 1.3). The responses of CS activities and capsaicinoid amount in the low- and high-pungent cultivars showed a similar trend under drought stress; that is, both traits were increased for the low-pungent cultivar and not increased for the high-pungent ones (Figure 1.4). However, those values of both traits in the medium-pungent cultivars were inconsistent and not associated with capsaicinoid responses. Meanwhile, values of both traits in cv. Huay-Siiton were increased, but they were not for cv. Keenoo-Pama. In contrast to the other enzyme activities, POD values showed a negative trend for capsaicinoid amount under control treatment, where POD value was high in the low-pungent cultivar and low in the high-pungent cultivars (Figure 1.5). Nevertheless, these enzyme activities in all cultivars with different pungency levels were all significantly increased compared to their control plants.

DISCUSSION

PAL, C4H, CS, and POD are reported as the important enzymes in capsaicinoid biosynthesis.[9,16] In addition, they are the key enzymes involved for capsaicinoid changes under drought stress.[6] In this study, PAL activity showed an obvious trend associated with the capsaicinoids among hot pepper cultivars with different pungency levels. The three other enzyme activities, C4H, CS, and POD, had an inconsistent relationship to capsaicinoid content.

The different levels of enzyme activity among cultivars within a treatment and between treatments within a cultivar illustrated the significant interaction of the environments on the enzymes. These observations confirm previous studies that different pepper cultivars vary in their enzymatic responses.[10,14,18] Hot pepper cultivars with high capsaicinoid levels were less sensitive to drought stress as compared to the low- and medium-pungent cultivars. This indicates the stability of high-pungent cultivars under stress conditions to produce capsaicinoids. Our results concur with the finding by Gurung et al.[19] that capsaicinoid

amounts in high-pungent cultivars do not fluctuate as compared to low-pungent cultivars in the different environmental conditions. On the other hand, genotype by environment interaction does affect capsaicinoid production;[3] however, a genotype is the major factor compared to the environmental effect.[19]

It has been reported that capsaicinoid content increases under drought stress,[4] and the increase is related to four key enzymes of the capsaicinoid biosynthesis pathway.[6] The changes of these enzyme activities under drought imply that these enzymes were strongly influenced by the drought stress effects.[7] The enzymatic activities in the phenylpropanoid pathway starting from lignin and free phenolic compounds,[20] which are the products of the shikimate pathway, were increased by stress. Subsequently, they resulted in the increase of phenylalanine, the precursor of the capsaicinoid.[21] Thereafter, phenylalanine enters and converts to cinnamic acid, thus increasing this precursor under drought stress, which affects further enzyme activity in the capsaicinoid synsthesis pathway, including C4H, CS, and POD.[16] Our results showed increases of activity for the four enzymes for all of the cultivars under drought stress. Among these four enzymes, PAL changes under drought stress showed a complete association with capsaicinoids, in all five hot pepper cultivars examined. The changes of PAL and CAPs between the control and drought-stressed plants in the low- and medium-pungent cultivars were all significantly different, but they were not for the high-pungent cultivars. Moreover, the responses of PAL in the five cultivars concur with the results of Estrada et al.,[4] in which the PAL activities increased with water stress.

It is important to note that the C4H activities were significantly increased under drought stress, but those changes were not associated with an increase of capsaicinoids among the cultivars. CS activities showed a similar trend to PAL in that there was an unchanging amount in the stressed plants of high-pungent cultivars. PAL activity between the two medium-pungent cultivars was not associated with the capsaicinoid responses. The increase of CS activity was found in cv. Huay-Siiton and was not found in cv. Keenoo-Pama, whereas capsaicinoids in these two cultivars did increase. Furthermore, POD activity had a negative association with capsaicinoid amounts, which is similar to the observations reported by Contreras-Padilla and Yahia[22] and Di et al.[23] This adverse relationship might be attributed to the fact that POD activity is closely related to the oxidization of the capsaicinoid metabolism,[17] resulting in a decrease in POD activity, with an increase in the capsaicinoid amount. The significant increase in POD activity under drought stress observed for all cultivars studied was not associated with their capsaicinoid content. The increase in POD activity under drought stress in all cultivars studied clearly indicated a negative relationship between the evolution of capsaicinoids and POD activities due to its involvement in capsaicinoid degradation.[22,23] The increase in POD activity in our results contradicted the results of Sung et al.,[6] who found a decrease in POD activity under drought stress. The difference could be attributed to the fact that our stressed plants received a level of stress to alter the physiological metabolism,[24] for example, capsaicinoid biosynthesis, and resulted in an increase of this enzyme under the stress.

In conclusion, PAL, C4H, CS, and POD activities were found to differ due to drought stress induction. Under drought stress, the activities of the enzymes increased as compared to the optimum water application treatment. A novel discovery was that under drought stress the PAL enzyme was the only one to affect the capsaicinoid biosynthesis.

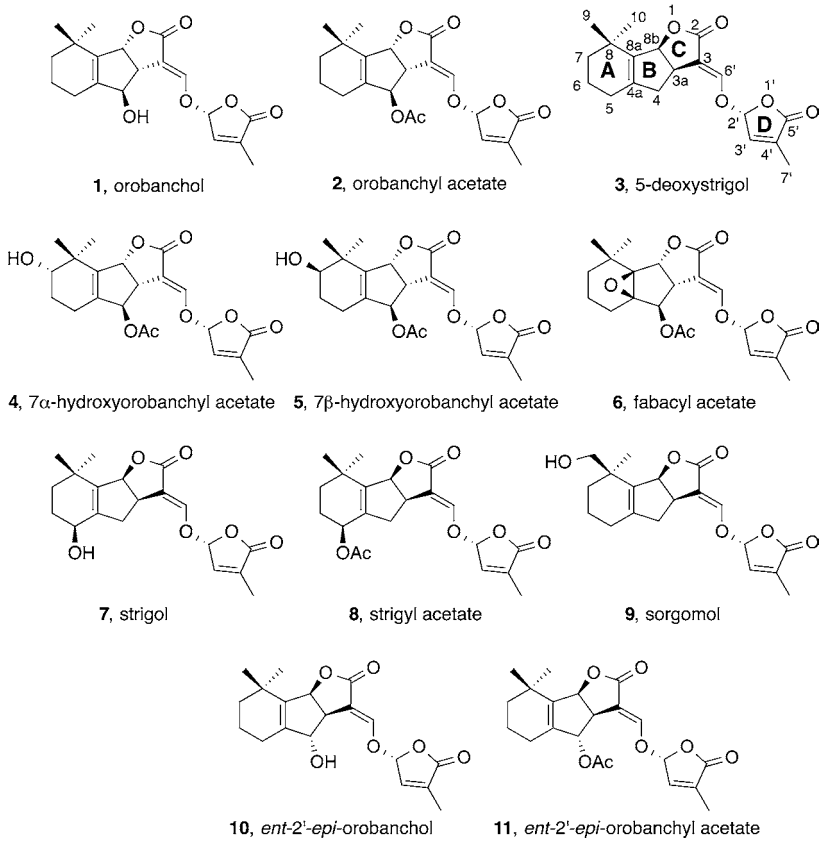

Figure 1. Structures of strigolactones used in this work: orobanchol (**1**), orobanchyl acetate (**2**), 5-deoxystrigol (**3**), 7α-hydroxyorobanchyl acetate (**4**), 7β-hydroxyorobanchyl acetate (**5**), fabacyl acetate (**6**), strigol (**7**), strigyl acetate (**8**), sorgomol (**9**), ent-2′-epi-orobanchol (**10**), and ent-2′-epi-orobanchyl acetate (**11**).

The parasitic plant species used were *O. crenata* (population collected on faba bean in Spain), *O. foetida* (collected on faba bean in Tunisia), and *P. aegyptiaca* (collected on faba bean in Israel). Parasitic seeds were collected from dry inflorescences using a 0.6 mm mesh-size sieve (Filtra, Barcelona, Spain) and stored dry in the dark at 4 °C until use.

Faba Bean Root Exudate Collection. Faba bean seeds were surface sterilized with 4% sodium hypochlorite containing 0.02% Tween 20. Then, they were rinsed three times with sterile distilled water and placed on moistened filter paper inside Petri dishes to allow imbibition and germination. Four days after imbibition, germinated faba been seeds (radicle from 0.5 to 3 cm long) were transferred to pots filled with sterile Perlite in a growth chamber (22 °C, 12/12 h d/night regime and 200 μmol/m^2/s irradiance). Plants were always watered with tap water and therefore suffering from nutrient starvation. Seven days after imbibition faba bean plant epicotyls emerged from Perlite, and 12 d after imbibition the first two leaves were expanded. Two, three, and four weeks after imbibition, faba bean plants were removed from the perlite and the roots were carefully washed with sterile distilled water. Faba bean plants were individually placed in tubes by immersing the roots for 24 h in sterile distilled water, allowing them to release the root exudates. The root solutions containing the faba bean root exudate were collected, and the total faba bean root contained in each tube was weighed. As exudation might vary accordingly with the amount of faba bean roots in each tube, which varied with faba bean plants and harvesting times, root solution per each individual plant was adjusted with sterile distilled water to achieve equivalent concentration of faba bean fresh root weight/mL of root solution across treatments. Three final concentrations were tested for all treatments in broomrape germination: 0.02 g of faba bean root (fresh weight)/mL of hydroponic media (root solution) and, in order to be sure that broomrape seeds could recognize any germination factor present in the root exudates from the resistant cultivars, we used two additional highly concentrated root exudate solutions: 0.04 and 0.1 g/mL. Those concentrations are higher than those normally used for faba bean—broomrape seed germination bioassays.[36]

Parasitic Seed Surface Sterilization and Conditioning. *Orobanche* and *Phelipanche* seeds were surface sterilized with 0.2% (w/v) formaldehyde containing 0.02% (v/v) Tween 20, rinsed with sterile distilled water, and dried for 60 min in a laminar airflow cabinet. Approximately 100 seeds of each broomrape species were placed separately on glass fiber filter paper (GFFP) discs of 1.5 cm diameter moistened with 120 μL of sterile distilled water and conditioned in a 10 cm sterile Petri dish in the dark at 20 °C for 10 d.

Root Exudate Bioassay on Broomrape Germination. GFFP discs containing 10 d-conditioned seeds of each species as described above were transferred onto a sterile sheet of paper to remove the excess of water used during seed conditioning and dry discs transferred to new 10 cm sterile Petri dishes. Differences in the ability displayed by each faba bean accession to induce broomrape germination was studied by applying triplicated aliquots of 100 μL of root exudate collected from each faba bean plant (four plants per faba bean line) at each harvesting time. Sterile distilled water was used as negative control. GR24 (10^{-6} M) was used as a second positive control in addition to the susceptible cultivar Prothabon. Distilled water and GR24 were applied on three additional discs of each *Orobanche* and *Phelipanche* species. Seeds were stored in the dark at 20 °C for 7 d to allow germination. The germination was scored for each disc by determining the number of germinated seeds on 100 seeds using a stereoscopic microscope. Seeds were considered germinated when radicle was visible through the seed coat.

Strigolactone Analysis and Quantitation. *Root Exudate Collection and Purification Using Ethyl Acetate.* Root exudates were collected as described previously.[40] Faba bean lines used were Prothabon as susceptible line and Navio and Quijote as resistant lines. Faba bean seeds were surface-sterilized in 70% ethanol and then with 1% NaClO. After being thoroughly rinsed with sterile distilled water, seeds were imbibed in water to allow germination for 2 d. Five seedlings were

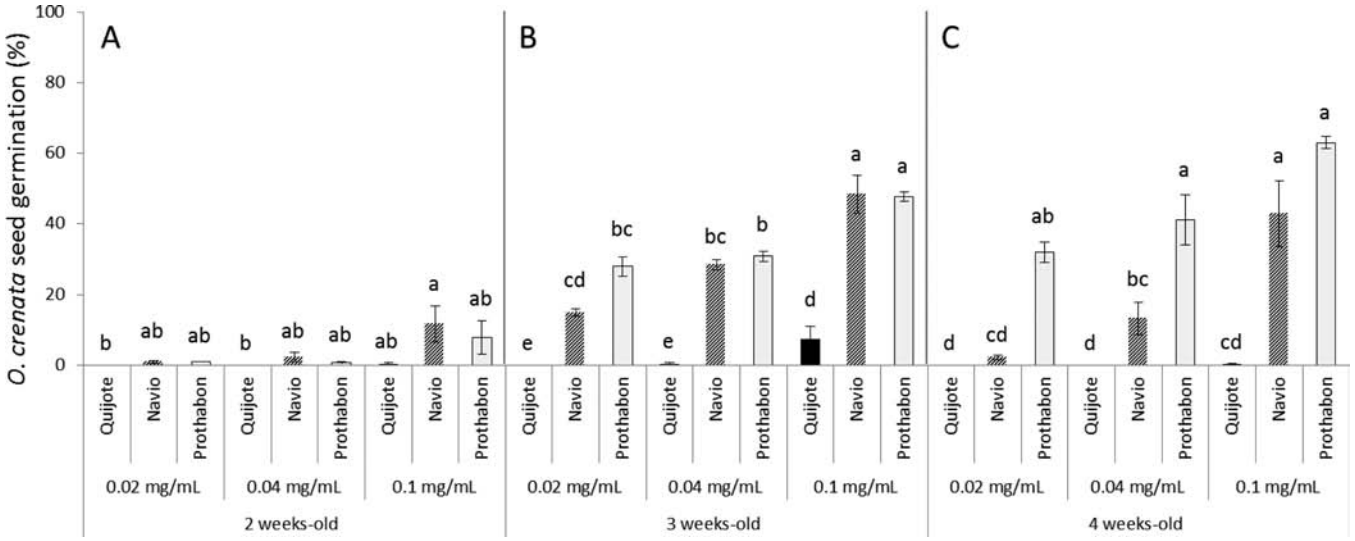

Figure 2. Effect of plant age, accession, and concentration of root exudates on germination of seeds of *Orobanche crenata*. Vertical bars represent standard error for $n = 4$. Analysis of variance was applied to transformed replicate data. For each plant age, bars with different letters are significantly different according to the Tukey test ($p = 0.05$). Negative control (distilled water) = 0%. Positive control (GR24, 10^{-6} M) = 61%.

transferred to a plastic cup (9 cm in diameter at top, 7.5 cm in diameter at the bottom, 8 cm deep, with 7 mm diameter holes on the bottom) placed in a larger plastic cup (8 cm in diameter at top, bottom 5.7 cm in diameter at the bottom, 13.5 cm deep, approximately 500 mL in volume) containing 400 mL of tap water as the culture medium. The culture medium (tap water) was frequently refreshed to allow aeration. The plants were grown in a growth chamber with a 14/10 h photoperiod at 23 °C. At 1, 2, 4, 6, 8, and 10 weeks after seed imbibition, the culture medium (tap water) was refreshed, allowing faba bean plants to release their root exudates in fresh tap water for 24 h before collection. One plastic cup was used for each faba bean line and stage of development. The tap water root exudates were extracted twice with ethyl acetate. Ethyl acetate solutions were combined, washed with 0.2 M K_2HPO_4 (pH 8.3), dried over anhydrous $MgSO_4$, and concentrated in vacuo.

Root Exudate Collection and Purification Using C18 SEPAK Cartridge. Faba bean seeds from cultivars Prothabon, Navio, and Quijote were surface sterilized and placed on sterile moistened filter paper inside Petri dishes to promote germination. Four-days-old faba been seedlings were individually transferred from the Petri dish to pots filled with sterile perlite in a growth chamber with a 14/10 h photoperiod at 23 °C. Plants were watered with tap water. After 2 weeks of cultivation in the pots, faba bean plants were removed from the Perlite and roots carefully washed with tap water. Faba bean plants were individually placed in 50 mL flasks containing sterile distilled water. Faba bean plants released in the tap water their root exudates during 24 h. Individually collected root exudate of four replicated plants per cultivar was individually loaded and purified in pre-equilibrated C18 SEPAK cartridges according with previous protocols.[36]

Strigolactone Analysis and Quantitation Using Liquid Chromatography−Tandem Mass Spectrometry. Identification of strigolactones was performed using a tandem mass spectrometer (Quattro LC Mass Spectrometer, Micromass, Manchester, U.K.) equipped with an electrospray ionization (ESI) source and coupled to a UPLC system (HITACHI Lachrom Ultra HPLC system, Hitachi, Japan). Chromatographic separation was achieved on a 2.1 mm × 50 mm, 2.0 μm, L-Column2 ODS column (CERI, Japan) by applying a methanol−water (MeOH-H_2O) gradient as follows: 0−3 min, 30−45% methanol; 3−8 min, 45−50% methanol; 8−12 min, 50−70% methanol; 12−15 min, 70−100% methanol, maintained for 3 min, then returning to 30% methanol over 1 min. Finally, the column was re-equilibrated under these conditions for 3 min, prior to the next run. The column was operated at 40 °C with a flow rate of 0.2 mL/min. The drying and nebulizing gas was nitrogen generated from pressurized air in an N2G nitrogen generator (Parker-Hanifin Japan, Tokyo, Japan). The nebulizer gas flow was set to approximately 100 L/h and the desolvation gas flow to 500 L/h. The interface temperature was set to 400 °C and the source temperature to 150 °C. The capillary and cone voltages were adjusted to orobanchol (**1**) and to the positive ionization mode. MS/MS experiments were conducted using argon as the collision gas, and the collision energy was set to 16 eV. The collision gas pressure was 0.15 Pa. The mass spectrometer was operated in positive ESI mode. Sample injection volume was 5 μL. Multiple reaction monitoring (MRM) was used for identification of strigolactones in root exudates and extracts by comparing retention times with 10 synthetic and natural strigolactone standards at 1 μM solution: orobanchol (**1**), orobanchyl acetate (**2**), 5-deoxystrigol (**3**), 7α-hydroxyorobanchyl acetate (**4**), 7β-hydroxyorobanhyl acetate (**5**), fabacyl acetate (**6**), strigol (**7**), strigyl acetate (**8**), sorgomol (**9**), *ent*-2′-epi-orobanchol (**10**), and *ent*-2′-epi-orobanchyl acetate (**11**) (Figure 1).[40,41]

Strigolactone Assays on Broomrape Germination. The effects of three major strigolactones in legume crops were tested on germination of broomrape species. The strigolactones detected in root exudates of faba bean lines Prothabon, Quijote, and Navio (i.e., orobanchol (**1**) and orobanchyl acetate (**2**)) were used in germination assays of seeds of *O. crenata*, *O. foetida*, and *P. aegyptiaca*. Although not detected in faba bean in the present work, 5-deoxystrigol (**3**) was also studied as it is known as a major strigolactonein Fabaceae.[40] These three strigolactones were tested at 10^{-6}, 10^{-7}, and 10^{-8} M on GFFP discs containing 10-d conditioned seeds of each parasitic species. GFFP discs containing the parasitic seeds conditioned as described above were transferred into a sterile sheet of paper to remove the excess of water and transferred to new 10 cm sterile Petri dishes. Each strigolactone was dissolved in acetone and diluted with sterile Milli-Q water to a final concentration of 0.7% of acetone. Aliquots of 100 μL of orobanchol (**1**), orobanchyl acetate (**2**), or 5-deoxystrigol (**3**) at each concentration were applied to triplicated GFFP discs containing parasitic seeds. This was done for each broomrape species separately. Petri dishes were sealed with Parafilm and incubated in the dark at 20 °C for 7 d. Milli-Q water containing 0.7% acetone was used as negative control. The germination was scored as described above.

Statistical Analysis. Experiments were performed using a completely randomized design. Percentage data were approximated to normal frequency distribution by means of angular transformation (180/Π × arcsine (sqrt[%/100])) and subjected to analysis of variance (ANOVA) using SPSS software for Windows, version 21.0 (SPSS Inc., Chicago, Illinois, USA). The significance of mean differences among treatments was evaluated by Tukey HSD test. Null hypothesis was rejected at the level of 0.05.

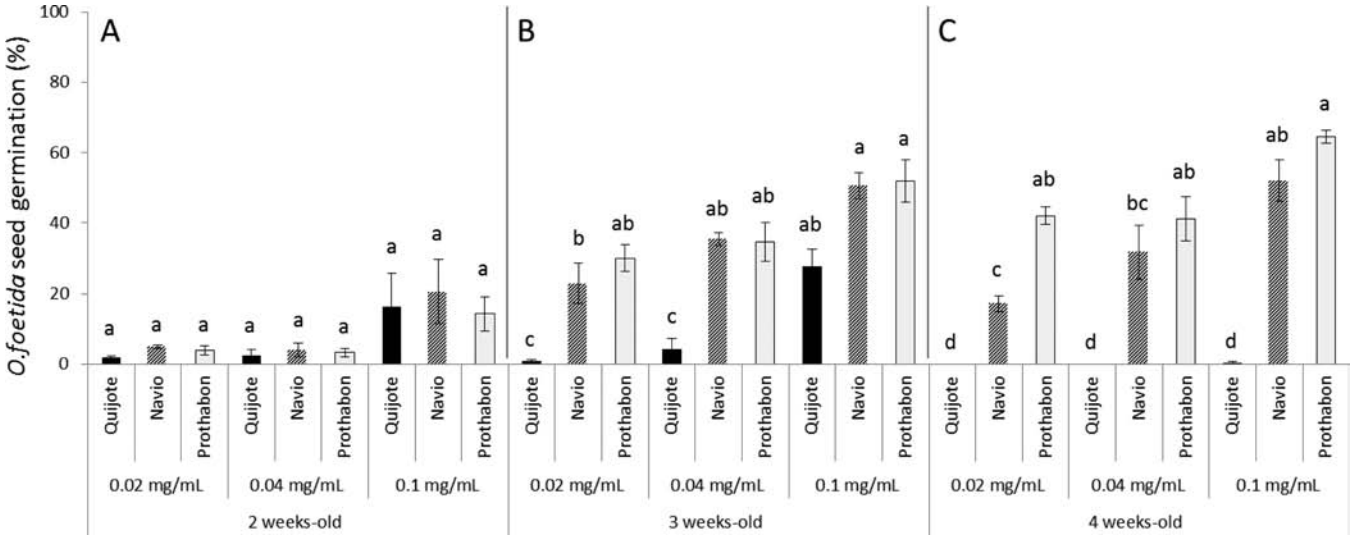

Figure 3. Effect of plant age, accession, and concentration of root exudates on germination of seeds of *Orobanche foetida*. Vertical bars represent standard error for $n = 4$. Analysis of variance was applied to transformed replicate data. For each plant age, bars with different letters are significantly different according to the Tukey test ($p = 0.05$). Negative control (distilled water) = 0%. Positive control (GR24, 10^{-6} M) = 0%.

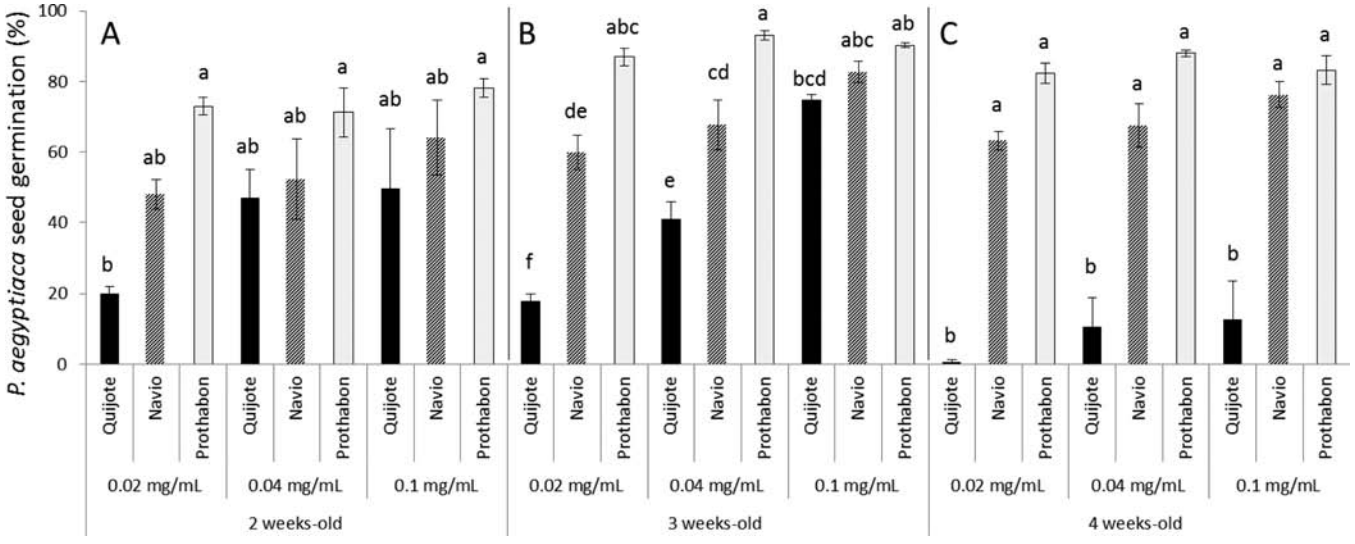

Figure 4. Effect of plant age, accession and concentration of root exudates on germination of seeds of *Phelipanche aegyptiaca*. Vertical bars represent standard error for $n = 4$. Analysis of variance was applied to transformed replicate data. For each plant age, bars with different letters are significantly different according to the Tukey test ($p = 0.05$). Negative control (distilled water) = 0%. Positive control (GR24, 10^{-6} M) = 91%.

RESULTS AND DISCUSSION

Time Course Analysis on Stimulatory Effect of Faba Bean Root Exudates on *Orobanche* and *Phelipanche* Seed Germination. The effects of faba bean cultivar (resistant cultivars: Quijote and Navio; and susceptible cultivar: Prothabon), plant age (2, 3 and 4 weeks old), and root exudate concentration (0.02, 0.04, and 0.1 g of faba bean root/mL of root solution) on germination of seeds of *O. crenata*, *O. foetida*, and *P. aegyptiaca* are shown in Figures 2, 3 and 4, respectively. In all cases, null germination was observed when broomrape seeds were treated with negative control (distilled water).

Significant effect in broomrape germination was observed for cultivar, (ANOVA, $p < 0.001$). Root exudates of the highly resistant cultivar Quijote induced the lowest levels of parasitic germination on all the broomrape species tested at all harvesting times (11.3% ± 2.1) followed by the moderately resistant cultivar Navio (35% ± 2.5). The susceptible cultivar Prothabon used as a positive control showed the highest stimulatory activity on germination of broomrape species (48% ± 3.1).

Significant effects in broomrape germination were observed both for plant age and the interaction plant age × cultivar (ANOVA, $p < 0.001$, $p < 0.001$ respectively). The effect of plant age was different in the different faba bean cultivars tested. The induction potential of parasitic germination by Quijote root exudate was not significantly different across life stages; however, root exudates collected from older Navio and Prothabon plants induced higher germination levels on *O. crenata* and *O. foetida* seeds.

Significant effect in broomrape germination was observed for broomrape species (ANOVA, $p < 0.001$). *P. aegyptiaca* was the parasitic species more responsive when exposed to faba bean root exudates. The germination average induced to *P. aegyptiaca* seeds by all faba bean cultivars at all harvesting times and root exudate concentrations was 59.4% ± 2.8, being significantly higher than

dx.doi.org/10.1021/jf5027235 | J. Agric. Food Chem. 2014, 62, 7063−7071

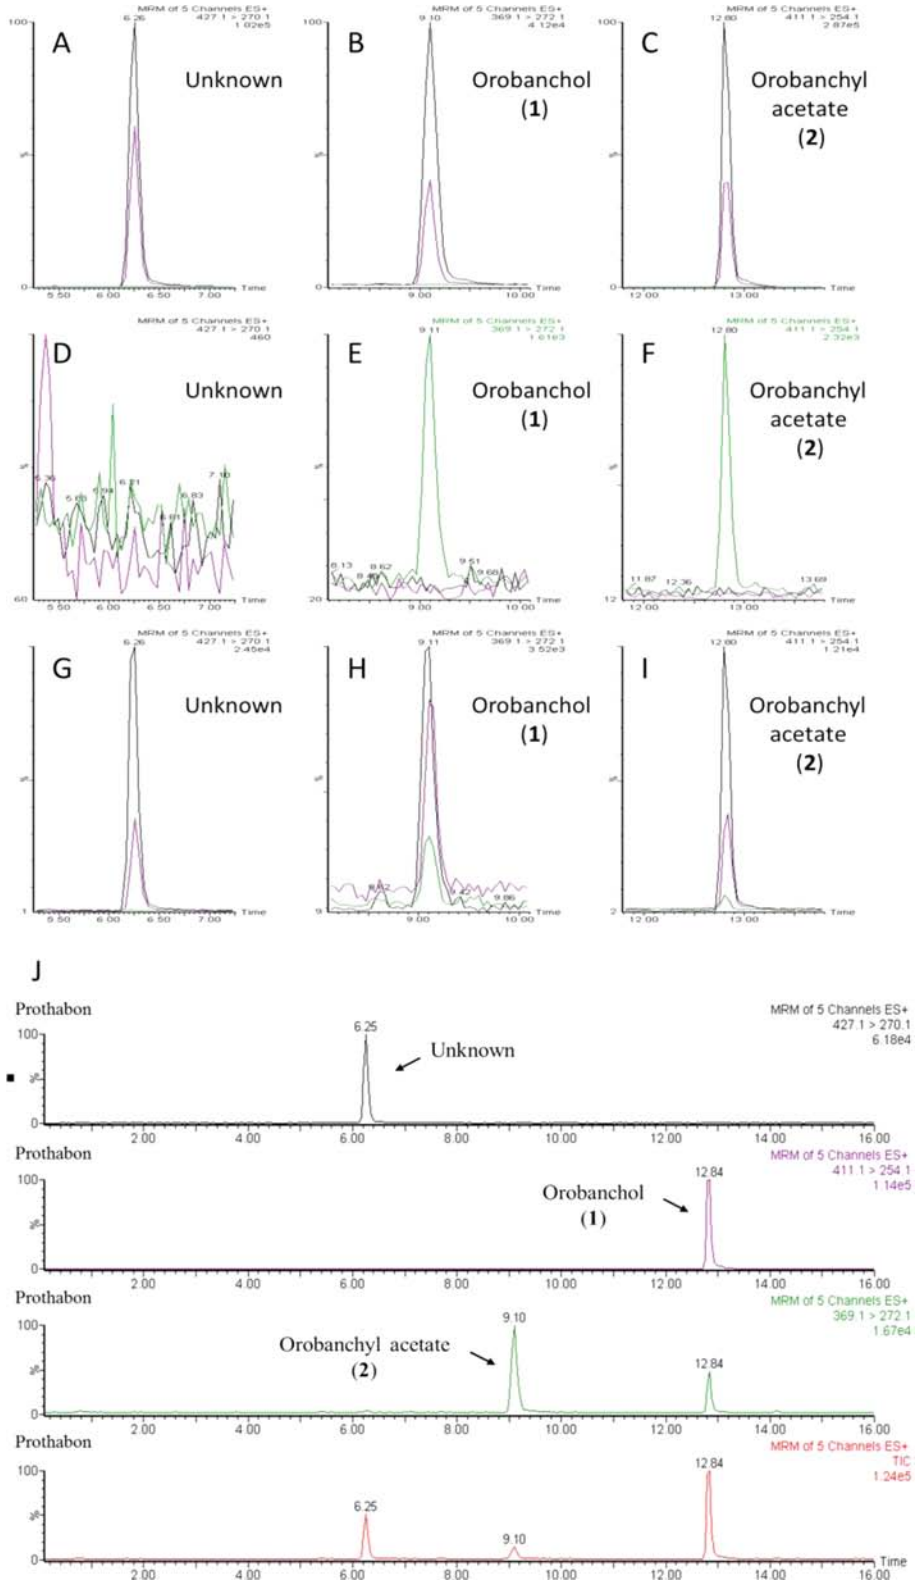

Figure 5. Liquid chromatography tandem mass spectrometry analysis of (A, B, C) faba bean susceptible line (Prothabon), (D, E, F) faba bean moderately resistant line (Navio), and (G, H, I) faba bean resistant line (Quijote). Root exudates were analyzed on 2-week-old faba bean plants (green line), 4-week-old faba bean plants (purple line), and 8-week-old faba bean plants (black line). (J) Representative UPLC chromatogram from a 4-week-old Prothabon root exudate sample.

the average induced to *O. crenata* (15.4% ± 2.0) and to *O. foetida* (22.2% ± 2.1).

For each broomrape species tested, significant effects in germination were observed for root exudate concentration (ANOVA, $p < 0.001$). Germination of broomrape species was not significantly affected by the interaction concentration × cultivar. Thus, we rule out the hypothesis that the resistance to broomrape in cultivars Quijote and Navio based on low levels of

Table 1. Quantitation (According to the Peak Area) of the Strigolactones Orobanchol (1) and Orobanchyl Acetate (2) in the Root Exudates of Resistant Cultivars Quijote and Navio and Susceptible Cultivar Prothabon[a]

	amount of strigolactones and unknown germination stimulant (peak area)								
	2-week-old			4-week-old			8-week-old		
	Quijote	Navio	Prothabon	Quijote	Navio	Prothabon	Quijote	Navio	Prothabon
orobanchol (1)	26.0	32.2	0.0	65.8	0.0	407.6	97.2	0.0	1200.6
orobanchyl acetate (2)	12.6	39.0	0.0	84.2	0.0	2467.0	221.8	0.0	5280.8
unknown	0.0	0.0	0.0	170.6	0.0	1264.6	566.6	0.0	2352.8

[a] Quantitation was also performed on the unknown germination stimulant.

broomrape seed germination is due to presence of germination inhibitors at the concentrations tested in this work.

Root exudates of the resistant faba bean cultivar Quijote induced negligible levels of seed germination of *O. crenata* at all concentrations and harvesting times tested. They showed also a negligible activity on germination of *O. foetida* at 0.02 g/mL (1.0% ± 0.3) and at 0.04 g/mL (2.0% ± 1.2) at all harvesting times tested. Only at the highest root exudate concentration (0.1 g/mL), Quijote root exudates stimulated some *O. foetida* germination, that although low was significant at 3 weeks (27.7% ± 6.7) but not at 2 and 4 weeks of plant cultivation. *P. aegyptiaca* germination was induced by 2- and 3-week-old Quijote plants (39.1% ± 6.9 and 38.1% ± 8.8), but this activity significantly decreased at 4-week-old to 7.4% ± 4.4. Quijote root exudate concentration had significant effect on *P. aegyptiaca* germination only when seeds were exposed to root exudates collected from 3-week-old Quijote plants.

As described before, root exudates of Navio induced higher germination than Quijote although still much lower than Prothabon. Root exudates of Navio plants showed activity on the three tested species, but this was higher on *P. aegyptiaca* seeds (64.1% ± 2.7) than on *O. crenata* (18.3% ± 3.1) and *O. foetida* (26.7% ± 3.1) seeds.

Prothabon root exudates induced germination of the three parasitic species tested. The average germination at all harvesting times and root exudate concentration for *P. aegyptiaca*, *O. crenata*, and *O. foetida* was 81.9% ± 1.5; 25.9% ± 3.7; and 32.3% ± 3.8, respectively. The Prothabon stimulation of broomrape seeds increased with harvesting time reaching maximum levels of germination for each broomrape species when Prothabon plants were 4 weeks old.

LC-MS/MS Analysis for Strigolactone Identification and Quantitation in Faba Bean Root Exudate. Root exudates collected from each faba bean cultivar were screened for the presence of strigolactones by LC-MS/MS. This analysis was repeated across faba bean development, 6 times at 1, 2, 4, 6, 8, and 10 weeks of cultivation. Strigolactone profiles of root exudates from 1- and 2-week-old plants were similar for each faba bean cultivar. Strigolactone profiles for 6-, 8-, and 10-week-old plants were similar for each faba bean cultivar.

LC-MS/MS analysis indicated that the same strigolactones were present in root exudates of all faba bean cultivars studied (Figure 5, Table 1). However, there were differences between cultivars in the pattern of strigolactone exudation. We observed a link between the low amounts of strigolactones exuded by Quijote and Navio, the low level of broomrape germination observed in vitro in this work and in previous reports,[36] and the high level of broomrape resistance observed in the field in these resistant cultivars.[36] For all faba bean cultivars the LC-MS/MS chromatograms showed two peaks at retention times 9.10 and 12.84 min, and they were identified as orobanchol (1) and orobanchyl acetate (2), using comparisons with 11 strigolactone standards (Figure 1). In addition, a peak at retention time 6.25 was collected and proved for germination stimulatory activity. This peak corresponds to an unknown germination stimulant and is currently under characterization. The susceptible cultivar Prothabon was the cultivar that exuded relatively larger amounts of strigolactones followed by Navio. The highly resistant cultivar Quijote was the cultivar whose root exudates contained the lowest amount of strigolactones.

There were also differences between cultivars in the timing of strigolactone detection along the faba bean development. Table 1 shows the pattern of strigolactone exudation at 2, 4, and 8 weeks. At early growth stages (1 and 2 weeks old), none or negligible amounts of strigolactones were detected in root exudates of any of the faba bean lines tested. These contents remained low as time increased in Navio but increased markedly in Prothabon. Strigolactones levels in Quijote were under detection limits in young plants. As Quijote plants grew, orobanchol (1) and orobanchyl acetate (2) were detected in their root exudates but their levels were very low across all life stages studied. Quijote plants exuded 83.8% less orobanchol (1), 96.6% less orobanchyl acetate (2), and 86.6% less of the unknown germination stimulant than Prothabon plants when compared at 4 weeks old and 91.9% less orobanchol (1), 95.8% less orobanchyl acetate (2), and 75.9% less unknown germination stimulant than Prothabon plants when compared at 8 weeks old.

In order to further confirm low exudation of strigolactones in Quijote plants, we analyzed by LC-MS/MS the root exudates individually collected from four replicated plants of Quijote, Navio, and Prothabon growing in 50 mL tubes. Previous to root exudate purification and LC-MS/MS analysis, aliquots of root exudate (at concentration 0.02 g/mL) of each plant and cultivar were tested on *P. aegyptiaca* and *O. crenata* germination. Differences in activity of the root exudates between susceptible control and resistant cultivars were confirmed, Prothabon root exudates being highly active on broomrape germination and Navio showing low activity, and very low or negligible levels of broomrape germination were induced by Quijote (data not shown). Our LC-MS/MS analysis showed that strigolactone levels, if any, were under detection limits for Quijote samples, while a peak corresponding to orobanchyl acetate (2) was detected in all Navio samples. In all Prothabon samples the peak corresponding to the unknown germination stimulant was always observed. This peak was collected and probed actively for germination stimulatory activity. This novel germination stimulant is currently under characterization.

Differential Effect of Pure Strigolactones on *Orobanche* and *Phelipanche* Seed Germination. Figure 6 shows the effects of strigolactone (orobanchol (1), orobanchyl acetate (2), and 5-deoxystrigol (3)) and strigolactone concentration (10^{-6} M, 10^{-7} M, and 10^{-8} M) on germination of seeds of

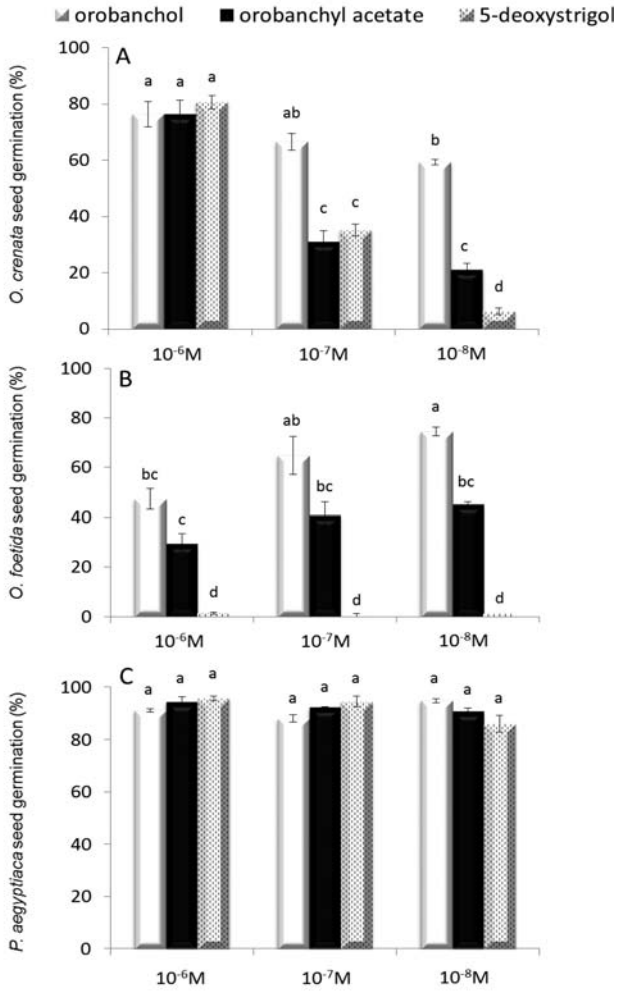

Figure 6. Effects of orobanchol (**1**), orobanchyl acetate (**2**), and 5-deoxystrigol (**3**) at decreasing concentrations on seed germination of *O. crenata* (A), *O. foetida* (B), and *P. aegyptiaca* (C). Vertical bars represent standard error for $n = 3$. The same letter per broomrape species indicates that differences are not statistically significant between SL and SL concentrations (Tukey test, $p < 0.05$). Negative controls (distilled water) = 0%, for *O. crenata*, *O. foetida*, and *P. aegyptiaca*.

O. crenata, *O. foetida*, and *P. aegyptiaca*. In all cases, null germination was observed when broomrape seeds were treated with distilled water (negative control). We observed significant differences in parasitic seed germination depending on the strigolactone tested ($p < 0.001$), the concentration applied ($p < 0.001$), the parasitic species tested ($p < 0.001$), and their interactions ($p < 0.001$).

Seeds belonging to *O. crenata* and *O. foetida* were more sensitive to orobanchol (**1**) and orobanchyl acetate (**2**) than to 5-deoxystrigol (**3**). The effect of strigolactone and strigolactone concentration was highly significant (ANOVA, $p < 0.001$ and $p < 0.001$ respectively for *O. crenata* seeds and $p < 0.001$ and $p = 0.007$ respectively for *O. foetida* seeds). Germination of *P. aegyptiaca* seeds was very sensitive to all strigolactones and strigolactone concentrations tested. The effect of strigolactone and strigolactone concentration was not significant (ANOVA, $p = 0.543$ and $p = 0.077$ respectively) showing a germination rate close to 90% in all cases.

The interaction between broomrape species × strigolactone × strigolactone concentration was highly significant (ANOVA, $p < 0.001$). The stimulatory effects of strigolactones on *O. crenata* seed germination increased at increased concentrations, being maximum (77.7% ± 2.2) at 10^{-6} M. This decrease was more marked for 5-deoxystrigol (**3**), which induced 6.3% ± 1.3% of *O. crenata* germination at 10^{-8} M, and moderate for orobanchyl acetate (**2**) (21.3% ± 2.2). On the contrary orobanchol (**1**) and orobanchyl acetate (**2**) effects on *O. foetida* germination increased as the strigolactone concentration decreases, showing a maximum germination rate of 74.5% ± 1.8 at 10^{-8} M. Remarkably, 5-deoxystrigol (**3**) was not effective inducing the germination of *O. foetida* seeds at the concentrations tested. High germination rates were observed on *P. aegyptiaca* seeds with all strigolactones and strigolactone concentrations.

Several measures are available for broomrape management; however, they are not fully applicable in a low input crop such as faba bean.[37,42] Therefore, development of resistant cultivars is the most desirable strategy.[42] Resistance in faba bean against broomrape has been based on mechanisms hampering the parasitic penetration and development in the host.[39] Only recently, resistance due to reduced parasitic seed germination has been discovered in faba bean against *O. crenata*, *O. foetida*, and *P. aegyptiaca*.[36,43] In the later study we have shown that the reduced susceptibility observed in the field by the cultivar Quijote was correlated with reduced stimulatory activity of broomrape in the *in vitro* germination test, but the underlying mechanisms were not determined.

Our LC-MS/MS analysis of root exudates from three faba bean cultivars has detected orobanchol (**1**) and orobanchyl acetate (**2**) both in susceptible and resistant cultivars. We have not detected 5-deoxystrigol (**3**), in spite that this strigolactone is common in the Fabaceae, as well as orobanchol (**1**) and orobanchyl acetate (**2**).[40] In addition to these known strigolactones, a third unknown germination stimulant was found.

A time course quantitation of strigolactone according to the peak area in LC-MS/MS[44] showed that the pattern of strigolactone exudation differs within faba bean cultivars and directly related with low levels of broomrape germination observed in vitro. As the roots of the susceptible cultivar Prothabon developed, strigolactone exudation increased greatly, this fact being in agreement with previous findings that production and exudation of strigolactones vary significantly with plant growth conditions and growth stages.[1] On the contrary, the resistant faba bean lines Quijote and Navio exuded low or undetected levels of strigolactones at all plant ages studied. Reduced broomrape infestation in the resistant lines might depend on a combination of low concentration of strigolactones in root exudate and their exudation pattern along the life stages that could avoid the correct timed encounter between parasites and host.

According with the results of strigolactone quantitation by LC-MS/MS, the germination tests carried out on seeds of three broomrape species showed that parasitic germination increased with the age of Prothabon plants from which root exudates were collected. Small differences between LC-MS/MS and the germination test were observed for the resistant varieties. As described before, LC-MS/MS analysis detected low or undetected amount of strigolactones in root exudates of Quijote and Navio at all life stages but their relative quantitation across the life cycle showed a small increase with age in Quijote but a small decrease in Navio plants. However, broomrape seed germination increased as Navio plants grew older and in Quijote plants the broomrape germination decreased when exposed to 4-

dx.doi.org/10.1021/jf5027235 | J. Agric. Food Chem. 2014, 62, 7063−7071

week-old plants. It is important to remark that Quijote root exudates induced low germination of *P. aegyptiaca*, a broomrape species highly sensitive to strigolactones. Also, they induced germination of *O. crenata* and *O. foetida* seeds only observed when applied at the highest concentrations, which was much higher than those commonly used in germination tests until now. Several factors may determine the observation of low but still significant broomrape germination when low or negligible levels of strigolactones were detected by LC-MS/MS. First, plant growth and root exudate collection for germination bioassays and strigolactone quantitation were carried out in independent laboratories. Activity of root exudates may change from experiment to experiment as production and exudation of strigolactones vary significantly with different environmental conditions.[1] These variations may be more remarkable when the production of germination stimulants is low as is the case for Quijote and Navio cultivars. Second, germination tests when carried out on seeds of the highly strigolactone-sensitive broomrape species such as *P. aegyptiaca* and *O. minor* are considered more sensitive for strigolactone detection than LC-MS/MS analysis. Third, LC-MS/MS analysis only detects major strigolactones from the myriad of compounds exuded by plant roots. Non-strigolactone-like molecules of unknown nature present in host root exudate can induce germination of the broomrape species tested in this work.[45,46] And last, faba bean samples analyzed by LC-MS/MS were obtained by ethyl acetate extraction washed with 0.2 M K_2HPO_4 to remove acidic substances. This procedure was done in order to facilitate direct comparisons between crude samples from different plants and cultivars by removing interference of acidic substances with electrospray ionization of strigolactones. This procedure may lead to removal of additional substances other than strigolactones in the faba bean root exudates with potential for broomrape germination.[45,46]

We have studied the effect of three major strigolactones typically found in legumes (orobanchol (**1**), orobanchyl acetate (**2**), and 5-deoxystrigol (**3**)), on three broomrape species that parasitize legumes but differ in their host ranges. *P. aegyptiaca* seeds highly germinated when exposed to all strigolactones, at all concentrations tested, confirming the sensitive nature of this broomrape species to strigolactones that correlates with the broad host range of this species.[47] Intriguing results were found for the more host-specific species *O. crenata* and *O. foetida*. First, in both broomrape species, orobanchol (**1**) induced much higher germination than orobanchyl acetate (**2**). Orobanchyl acetate (**2**) with less activity on *O. foetida* and *O. crenata* was found to be more abundant in root exudates of faba bean. This fact could point to a germination tuning between parasitic and host species through strigolactone concentration. In addition, 5-deoxystrigol (**3**) was not found in the faba bean root exudate tested in this work and was not active in inducing germination of *O. fetida,* a broomrape species with a very narrow host range for few legumes.[47] However, 5-deoxystrigol (**3**) was active inducing germination of *O. crenata*, a species that, although still being rather host-specific, expands its host range to other host families with different strigolactone exudation profiles, confirming previous observations.[48]

Results presented here show that low strigolactone exudation does exist within faba bean germplasm, contributing to resistance to broomrape. Therefore, selection for this trait is feasible in a breeding program. Inheritance of this trait should be studied, and it seems feasible that it might be simple inheritance, as was the case for low induction of *Striga* germination in sorghum.[49,50] This would be a great advantage as the resistances available before were of complex inheritance and, therefore, more difficult to breed for.[37] The use of molecular markers tightly linked to specific resistance mechanisms will allow their tracking in segregating populations, facilitating their pyramiding with other genes. The remarkable fact that low induction of germination is similarly operative against *O. crenata*, *O. foetida*, and *P. aegyptiaca* reinforces the value of this resistance.

To the best of our knowledge, there is no study reporting the exposure and risk assessment of chlorpyrifos in a maize field under different heights of maize. Although pesticide exposure assessments should be considered before and after the spraying process, the major objective of this study was to compare the potential dermal exposure (PDE) and internal dermal exposure (IDE) of various parts of the body and analyze potential inhalation exposure (PIE) with lever-operated knapsacks during spraying processes in a maize field at different maize plant heights. The margin of safety (MOS) was also calculated using the data obtained from the exposure evaluation to help estimate the status of the chlorpyrifos exposure of the applicators during the spraying process in maize fields year round.

MATERIALS AND METHODS

Chemicals and Reagents. The test item used in this study was a commercial insecticide, chlorpyrifos (EC, 48% w/v, Dow AgroSciences LLC, USA). Analytical standard chlorpyrifos was purchased from Sigma (St. Louis, MO, USA). Ethyl acetate, acetonitrile, and acetone were of analytical grade.

Study Site. Applicator exposure experiments were conducted in a maize (Sweet Jane169) field located in the city of ShaoXing, Zhejiang province, China, between May and June 2012. The maize field chosen was 100 m long and 100 m wide. The planting density of the maize field was 0.4 m × 0.2 m. The chosen field was divided into 10 plots. Each area of the plot was 8.0 m × 100 m with 20 rows of maize. Two rows of maize between two plots served as a neutral buffer zone, which was not treated with chlorpyrifos. Three types of pesticide exposure spraying environments (different growth or height of the maize field) were designed to analyze the potential exposure of chlorpyrifos during the application, namely, an average of 61.8 cm (A1), 108 cm (A2), or 212 cm (A3) height of the maize. Temperature, humidity, and wind speed were recorded before field trials were conducted. All exposure experiments were conducted under temperatures ranging between 29 and 33 °C, relative humidity of 56−79%, and a wind speed between 0.2 and 2.9 m s^{-1} (Supporting Information Table S1). Near the field, a warehouse was set for the pesticides and application equipment storage.

Workforce and Application Process. Four groups of personnel were divided in this study: (1) Two engineers who had been engaged in pesticide toxicology research for >5 years were in charge of the pesticides and spray equipment storage, and they also supervised the whole application process. (2) Five laboratory technicians mixed/loaded test pesticides, and they also collected samples from applicators after each field trial. (3) Eight farmers who had experience planting maize for more than 3 years, and they participated in the field application process. (4) Two agricultural technicians who had been engaged in agriculture for >5 years and had previously participated in other similar field trials also participated in the field application process. According to the "basic healthy check-up project directory"[17] issued by China Health Ministry, application personnel (totally 10 people) performed ordinary routine physical examination, and they were all healthy and disease-free. The height of applicators was 165−175 cm and their weights were 57.4−69.2 kg, with an average of 63.1 kg (Supporting Information Table S1).

All applicators used lever-operated knapsacks (SX-LK16 ShiXia; single-cone nozzle), which were calibrated at the beginning of the field study by the two engineers. According to the recommended dose of chlorpyrifos, the laboratory technician prepared a concentration of 960 ai mg L^{-1} chlorpyrifos liquid without any additives. The total spray volume for each applicator was 45 L. Because the capacity of each spray tank was only 15 L, laboratory technicians were responsible for refilling each applicator's tank three times (Supporting Information Table S1), but the time spent on the refilling was not included in the application time. All applicators followed their usual technique (right-hand operation, moving forward while spraying) without further instructions during the spraying process.

Dermal Exposure and Inhalation Exposure Assessments. According to OECD/GD (97) guidelines,[18] dermal exposure is measured by using the whole body dosimetry technique to collect samples from the applicators.[19] To measure the PDE and the IDE, each applicator wore 100% cotton inner (Hongdou underwear, Hongdou Home Apparel Co.) and outer protective garments (Xtep Sportswear, Xtep (China) Co., Ltd.), an inner hat wound with eight layers of gauze (20 cm × 40 cm), a hat with a brim, two layers of cotton gloves, and single-layer knee-high socks (Supporting Information Figure S1). The application personnel also wore 30 cm high rubber boots and protective masks.

PIE was measured using a personal air monitor equipped with an air pump (BUCK Libra plus LP-5) and solid sorbent (ORBO TM 609 Amberlite XAD-2 400/200 mg, Supelco), which traps pesticides in the air. The flow rate was 2 L min^{-1} during the application process.

Sample Collection. After each field trail was done, five laboratory technicians collected samples on site. The tubes with XAD-2 resins inside were cut and capped at both ends. Hats, gloves, and socks were carefully removed. The face, the surface of the protective mask, and the neck were wiped with eight layers of gauze (10 cm × 10 cm) containing 5 mL of 0.01% aerosol OT (Sinopharm Chemical Reagent Co., Ltd., China). Bare hands were washed with 0.01% aerosol OT for the mass balance. The inner and outer protective garments were cut into different sections as indicated in Figure 1. Clean sets of gloves were exchanged during the cutting of different sections of the protective garments. All samples were put into individual polyvinyl chloride bags, and they were transported to the laboratory within 6 h after the sampling, where they kept in refrigerators at −20 °C for later analysis.

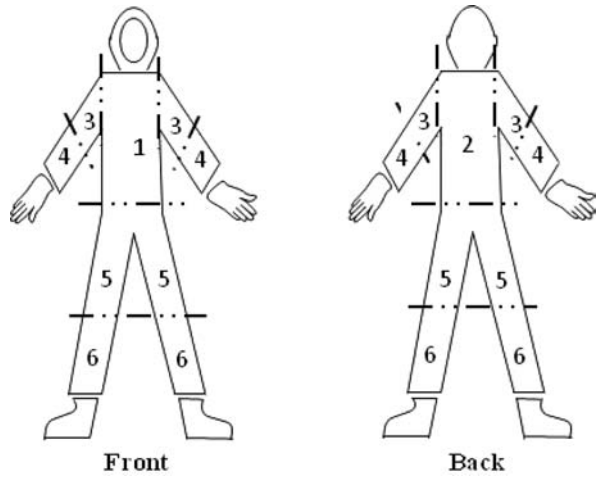

Figure 1. Protective garment segmentation maps (front and back).

Sample Analysis. Different sections of the inner and outer cotton protective garments and hats were all cut into pieces (less than 1 cm × 1 cm) by laboratory technicians with clean disposable gloves. The above treated samples were individually put into customized bottles, ethyl acetate (2 cm above the level of samples) was added, and then bottles were sealed and oscillated at 200 rpm for 1 h. Selection of extraction vessels and volume of extract added depended on sample types, such as a chest part placed in a 1000 mL bottle with a diameter of 12 cm, and then 800 mL of extraction reagent was added; a glove was placed in a 500 mL bottle with a diameter of 10 cm, and then 150 mL of extraction reagent was added; the gauze was placed in a 100 mL bottle, and then 50 mL of extraction reagent was added; XAD-2 resins were placed in a 50 mL bottle, and then 10 mL of extraction reagent was added. In addition, 100 mL of aerosol OT liquid (0.01%) for hand washing was accurately pipetted into a 500 mL bottle, 250 mL of acetonitrile was added, and then the above sample was shaken for 1 h. All extracts were concentrated to dryness and made to 2 mL volume with acetone. Finally, aliquots (2 mL) were passed through a 0.22 μm

filter (nylon filter, Target) and analyzed with a gas chromatograph. All samples were extracted and analyzed within 20 days after sampling.

Previously, analytical method validation verified the reliability of the above sample analysis methods. Chlorpyrifos was found stable within exposure matrices (e.g., cotton cloth, gloves, socks, XAD-2 resins, and gauze containing 5 mL of 0.01% aerosols OT and 0.01% aerosol OT), and it also showed stabilization during −20 °C refrigeration for 20 days of storage (Supporting Information Tables S1 and S2).

Analytical Conditions. All chromatographic analyses were performed on a Thermo Finnigan Trace (Thermo Electron Corp., USA) gas chromatograph equipped with a flame photometric detector (FPD) and a fused silica capillary column (DB-17, 30 m × 320 μm × 0.25 μm). The GC-FPD operating conditions for sample analysis were as follows: injector temperature, 250 °C; FPD temperature, 150 °C; oven temperature programmed from 220 °C (1 min isothermal) to 260 °C (held for 3 min at final temperature) at 20 °C min^{-1}; injection volume, 1 μL; carrier gas, N_2, flow rate, 2.0 mL min^{-1}; H_2, 90 mL min^{-1}; air; 115 mL min^{-1}.

Calculation of PDE, IDE, and PIE. Concentrations of the pesticide in each extract and the extraction reagent volume were used to calculate the amount of pesticide deposited on each coverall part. Then the PDE or IDE was calculated either with the amount of pesticide deposited and the derma exposure time (application time) (in mg h^{-1}) or with the amount of pesticide deposited, the concentration of pesticide formulation, and the derma exposure time (in mL h^{-1}).

XAD-2 resin pesticide adsorption amount (mg) was calculated with the XAD-2 resin pesticide extraction volume, the respiration rate (light work, 1740 L h^{-1}),[20] and the flow rate of the air pump, and then the PIE was calculated either with the amount of XAD-2 resin for pesticide adsorption and the dermal exposure time (in mg h^{-1}) or with the amount of XAD-2 resins for pesticide adsorption, the concentration of pesticide formulation, and the dermal exposure time (in mL h^{-1}).

Risk Assessment. PDE values by themselves do not define whether pesticide applications result in levels of exposure that could be considered to be safe or unsafe. Therefore, the margin of safety (MOS) was used to evaluate the safety of applicators' exposure to pesticides because it allows comparisons under very different field situations, such as different application techniques or different plant heights.[21]

When an MOS value was ≥1, it would mean safe working conditions for the operators. Conversely, it would mean unsafe working conditions if the MOS value was <1.[19] In this study, MOS was calculated to consider any risk in the spraying process. The MOS is defined as

$$\mathrm{MOS} = \mathrm{AE}/(\mathrm{DE} \times \mathrm{AF} \times \mathrm{SF})$$

where AE = acceptable exposure, DE = dermal exposure, AF = absorption factor, and SF = safety factor. The values considered in the present experiments are shown here. AE values are calculated on the basis of appropriate toxicological end-points according to the following expression: AE = AOEL × average body weight, as for chlorpyrifos, AOEL (acceptable operator exposure level) = 0.01 mg kg^{-1} day^{-1});[22] and an average body weight of 61.26 kg.

DE = (PDE or IDE + PIE) × EWT (exposure work time, 4 h day^{-1}) (as mg day^{-1} chlorpyrifos).[15,23]

AF = 0.11, considering an effective dermal absorption of 10%,[24] with an additional 1% added to include the inhaled fraction.[25]

SF = 1 as by definition the AOEL includes a safety factor.

Thus, the actual formula used was

$$\mathrm{MOS} = 5.569/\mathrm{DE}$$

RESULTS AND DISCUSSION

Dermal Exposure and Inhalation Exposure Assessments. The PDE and IDE results for applicators during the application of chlorpyrifos in the maize field are presented in Table 1. PDE refers to the potential dermal exposure under no personal protective equipment (PPE) circumstance; IDE refers to the internal dermal exposure under single -layer garment and gloves protection circumstance. Three spraying environments (A1, A2, and A3) were designed for this study: A1, the average maize height (61.8 cm) was below the applicators' waist; A2, the average maize height (108 cm) was close to the applicators' chest; and A3, the average maize height (212 cm) was above the applicators' head. As shown in Table 1, the total PDE values were 27.8, 90.6, and 462.1 mL h^{-1} for the applicators under A1, A2, and A3 spraying environments, respectively. In similar studies, Hughes et al.[19,26] reported that the total PDE value for applicators was 78.2 mL h^{-1} in a chard field with 40−50 cm plant height; in broccoli fields with an average 40−70 cm broccoli height, the total PDE value was 140 mL h^{-1}, and Choi

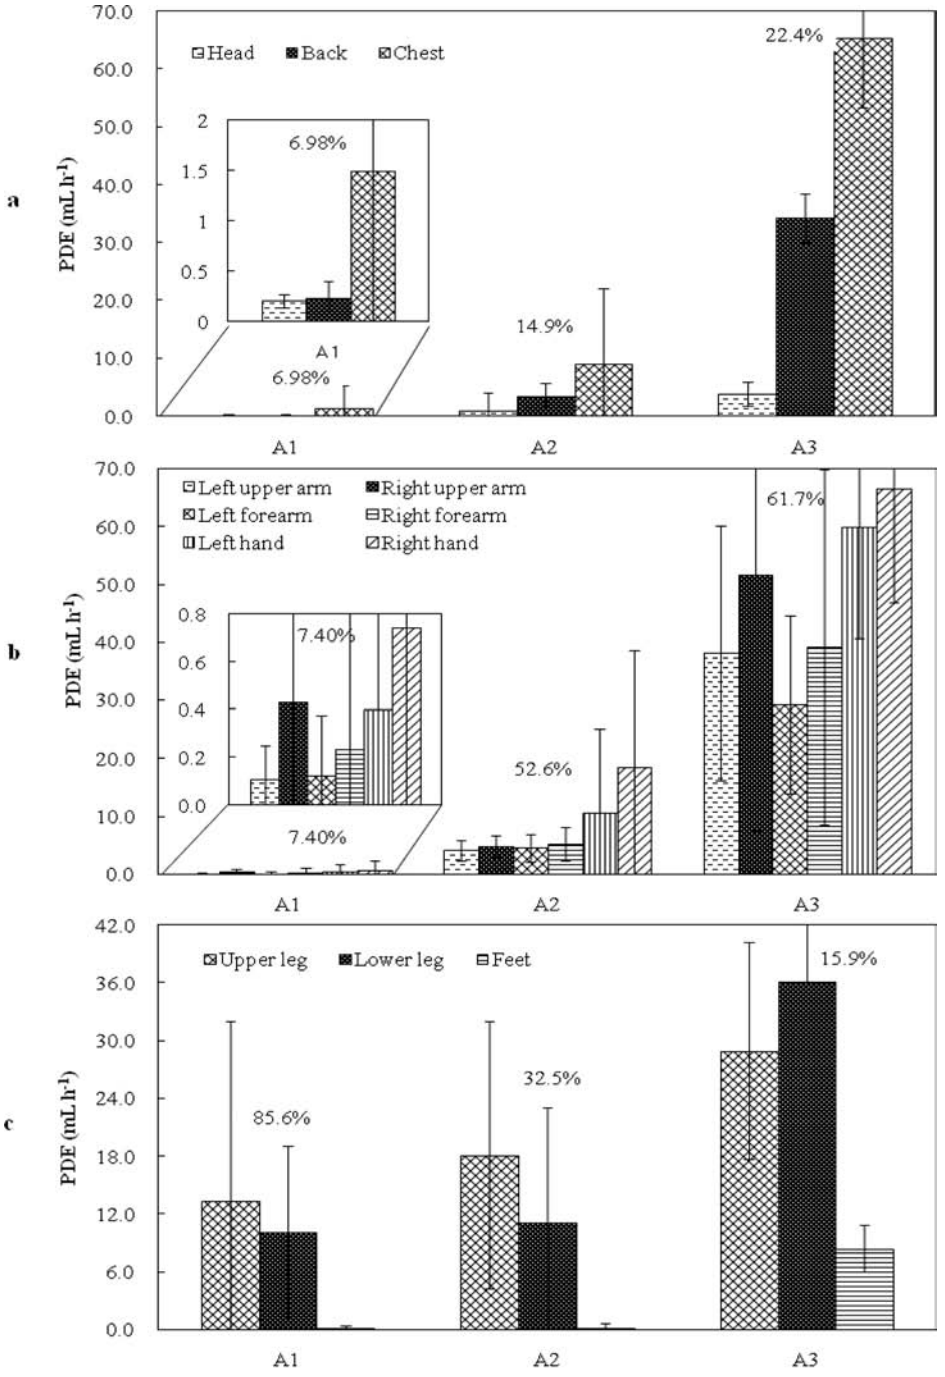

Figure 2. Potential dermal exposure (PDE) distribution on the head, back, and chest (a), the arms, forearms, and hands (b), and the legs and feet (c) in three spraying environments.

et al.[15] reported that the PDE measured reached 550−1180 mL h^{-1} in mandarin fields. Under experimental conditions similar to those of A3, Hughes et al.[27] reported that the total PDE value was 258 mL h^{-1} in a maize field with a maize planting density of 0.4 m × 0.8 m, which was slightly different from the results obtained in our study. The above difference of the PDE values could be related to maize planting density because the maize planting density was 0.4 m × 0.2 m in our present study, which was denser than that used in Hughes et al.[27] Generally, applicators would have more contact with plants if plant cultivation density was high in fields. Therefore, the degree of direct contact with plants could directly affect human pesticide exposure level.[28]

Evaluating pesticide exposure to applicators also considers clothing/protective garment penetration rate. In this study, the applicators wore double protective garments (100% cotton). The internal dermal exposure (IDE) was 3.37 mL h^{-1} for A1, 4.28 mL h^{-1} for A2, and 18.32 mL h^{-1} for A3, which accounted for 12.1, 4.7, and 4.0% of the total PDE under A1, A2, and A3 spraying environments, respectively (Table 1). Ten percent clothing penetration was assumed by many studies.[15,29,30] An average of 6.9% clothing penetration was obtained in our present study. The growth stage of crops and crop density could also affect the clothing penetration rate.[31] In addition, the clothing penetration rate is affected by many other factors, such as fabric thickness, yarn twist and wicking, the viscosity of

dx.doi.org/10.1021/jf501027s | J. Agric. Food Chem. 2014, 62, 7072−7077

pesticide mixtures, and the surface tension of pesticide mixtures.

PIE below the LOD was observed under A1 and A2 spraying conditions, respectively, but the PIE detected for A3 was 0.0121 mL h^{-1}, which accounted for 2.6×10^{-3}% of the total PDE and 3.6×10^{-5}% of the total spray volume in the study. Choi et al.[15] reported that the potential inhalation exposure for applicators was not observed in the mandarin fields; Kim et al.[29] observed the minimal amount of inhalation exposure for applicators in the paddy fields, accounting for 1.96×10^{-6}% of the total amount of pesticide applied. The results of our present study were similar to the results mentioned for the above research studies.

A characteristic distribution pattern of exposure was found on the applicators' bodies during spraying process, indicating nonuniformity of dermal exposure as suggested by previous studies.[14,23,32] As shown in Figure 2a, for the upper body (head, back, and chest), the exposure accounted for 6.98, 14.9, and 22.4% of the total PDE under A1, A2, and A3 spraying environments, respectively. It is noted that the chest under A2 and A3 spraying environments demonstrated relatively higher exposure than the head and back, which could be explained by the fact that the chests of the applicators had easy direct contact with the maize plants while moving forward during the application.

As shown in Figure 2b, the exposure of the arms and hands accounted for 7.4, 52.6, and 61.7% of the total PDE under A1, A2, and A3, respectively. The high exposure of pesticide under A2 and A3 could result from the spraying manner of the applicators. With an increase in the maize plant height, the applicators had to spray upward and downward; in addition, the upper leaves of the maize plants were denser than the lower parts of the maize plants. Therefore, the applicators' arms and hands were subsequently more exposed to the spray cloud or pesticide drift. It must be noted that there was far greater exposure on the hands than the section of the arms. Additionally, the right hand showed more exposure than the left hand (Figure 2b) in the three spraying environments. This difference could be explained by applicators using the right-hand to hold the spray lance during the application and the fact that large and fine spray droplets were more likely formed on the right hand. Hands can come into contact with many parts during the application, such as the spray instrument, clothes, or plants. Therefore, it is important to put great protection on hands during the application[33,34] to strengthen self-protection.

As shown in Figure 2c, the exposure of legs and feet accounted for 85.6% of the total PDE under A1 spraying environment. Under A1, the maize plant height was about 60 cm, so the lower half of the body of the applicators had higher PDE resulting from more contact with spray droplets during application. However, similar studies reported that legs and feet were usually the highest exposed body pars because of easy contact with spray droplets.[19,21,35,36] In the present study, the exposure of legs and feet only accounted for 32.5 and 15.9% of the total PDE under A2 (maize height = 108 cm) and A3 (maize height = 212 cm), respectively.

Risk Assessment. The PDE value provides quantitative information on a chemical substance loaded on uncovered body regions and clothing worn by pesticide applicators, but it cannot define whether the exposure level of pesticides to applicators is safe or not.[28,37] As shown in Table 2, under no PPE circumstance, the estimated MOS value for applicators ranged from 0.003 to 0.052 under the three exposure environments, which were ≪1. Under single-layer garment and gloves protection circumstance, the MOS value was also <1. By assuming A 10% clothing penetration rate, with double protective garments and double gloves protection circumstance, the MOS value reached only 0.8 under the A3 spraying environment, which still implied a risky spraying environment for the applicators. On the basis of the above results, we could conclude that the selected spraying environments were unsafe for the applicators under the present study conditions.

Table 2. Estimates of Dermal Exposure (DE), Margin of Safety (MOS), Exposure Control Need (ECN), and Safe Work Time (SWT) for Applicators at Different Plant Heights[a]

protective measures	application[b]	DE (mg day^{-1})	MOS	ECN (%)	SWT (h)
none	A1	106.8[c]	0.052	94.8	0.209
	A2	347.9[c]	0.016	98.6	0.064
	A3	1774.6[c]	0.003	99.7	0.013
single-layer garment and gloves	A1	12.9[d]	0.43	57.0	1.7
	A2	16.4[d]	0.34	66.0	1.4
	A3	70.4[d]	0.08	92.1	0.3
double-layer garment and gloves	A1	1.3[e]	4.3		
	A2	1.6[e]	3.4		
	A3	7.0[e]	0.8	45.7	3.2

[a]PDE (potential dermal exposure), IDE(internal dermal exposure) and PIE (potential inhalation exposures) unit as mg h^{-1}. [b]A1, average maize height of 62 cm; A2, average maize height of 108 cm; A3, average maize height of 212 cm. [c]DE = (PDE + PIE) × 4 h day^{-1}. [d]DE = (IDE + PIE) × 4 h day^{-1}. [e]DE = (IDE + PIE + feet PDE + PIE) × 10% of penetration through clothes ×4 h day^{-1}.

When an MOS value is <1, Machado-Neto[25] proposed to calculate ECN (exposure control need) value and SWT (safe work time) value to inform operators when to strengthen their personal protection and how long to continue the spraying process. The ECN value is calculated as follows: ECN = (1 − MOS) × 100.[25] The SWT value was calculated on the basis of the following formula: SWT = MOS × EWT (4 h day^{-1}).[15,24] In the present study, the ECN values calculated under no PPE were extremely high, and the SWT was only 0.013−0.209 h. Even with single-layer garment and gloves protection, the ECN values were still relatively high, and the SWT was not more than 2 h. Even if wearing double protective garments and double gloves in the A3 spraying environment, applicators should not work for more than 3.2 h.

To estimate the risk associated with similar pesticides used in maize fields, an interesting extrapolation was made. It was hypothesized that 10% imidacloprid diluted to 2000-fold (AOEL = 0.08 mg kg^{-1} day^{-1})[22] was applied in the present study condition, and the same PDE as measured for chlorpyrifos was assumed. The MOS values calculated would be >1 under A1 and A2 spraying environments without PPE circumstance. However, with single-layer garment and gloves protection circumstance, the MOS value was 8.3 for the A3 spraying environment, which was <1 under no PPE circumstance. Therefore, the risk associated with the pesticide application is also affected by the type of pesticide used and the concentration applied.

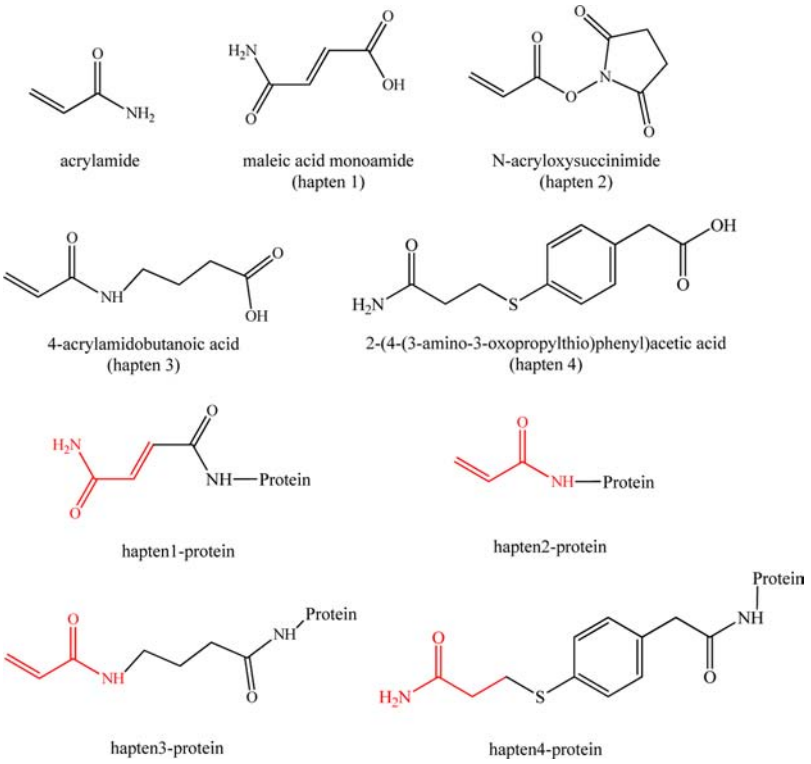

Figure 1. Chemical structures of acrylamide, its haptens, and the hapten−protein conjugates.

cakes.[14] These two methods have been reported to detect acrylamide directly; however, repeatability of these assays has been very poor because attempts using the same strategy to produce specific acrylamide antibodies have failed twice in our group. Preston et al. have designed a novel hapten by derivatizing acrylamide with 3-mercaptobenzoic acid and obtained a polyclonal antibody with high binding affinity for acrylamide derivative.[15] They proposed a competitive indirect enzyme-linked immunosorbent assay (ciELISA) for the indirect detection of acrylamide, necessitating a derivatization of extracted acrylamide with 3-mercaptobenzoic acid. This strategy appears helpful for the rapid determination of acrylamide, but its sensitivity is insufficient, with a LOD of 65.7 μg/kg.

In this study, several haptens against acrylamide were designed in attempts to obtain a specific acrylamide-affinity antibody. Although no antibodies with binding ability to free acrylamide were obtained, a polyclonal antibody was produced against 4-mercaptophenylacetic acid (4-MPA)-derivatized acrylamide (acrylamide-4-MPA) that showed high binding affinity to the derivative. A ciELISA for acrylamide via preanalysis derivatization was then developed, as acrylamide easily reacted at high yield with 4-MPA. The assay conditions were then optimized, and the assay was applied to detect acrylamide in several food samples.

MATERIALS AND METHODS

Materials and Reagents. Acrylamide (99%), methacrylamide, methyl acrylate, acrylic acid, acrolein, maleic acid monoamide, *N*-acryloxysuccinimide (NAS), and aminobutyric acid were purchased from J&K Scientific (Beijing, China). 4-MPA was obtained from Meryer Chemical Technology Co., Ltd. (Shanghai, China). Horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG was obtained from Boster Biotech Co., Ltd. (Wuhan, China). Keyhole limpet hemocyanin (KLH), dicyclohexyl carbodiimide (DCC), ovalbumin (OVA), *N*-hydroxysuccinimide (NHS), 3,3′,5,5′-tetramethylbenzidine (TMB), and complete and incomplete Freund's adjuvants were purchased from Sigma (St. Louis, MO, USA). Chromatographically pure methanol and acetonitrile were purchased from Guangzhou FanHong Trade Co., Ltd. Polystyrene ELISA plates were from Guangzhou Jiete Biotech Co. All other reagents were of analytical grade and obtained from a local chemical supplier (Yunhui Trade Co., Ltd., Guangzhou, China). Strata-X-C cartridge solid phase extraction cartridges were purchased from Phenomenex Science Apparatus Co. (Guangzhou, China).

Instruments. Plates were washed in a Multiskan MK2 microplate washer (Thermo Scientific, Hudson, NH, USA). ELISA values were read with a Multiskan MK3 microplate reader (Thermo Scientific). Ultraviolet−visible (UV−vis) spectra were recorded on a UV-160A Shimadzu spectrophotometer (Kyoto, Japan). Nuclear magnetic resonance (NMR) spectra were obtained with both DRX-400 and DRX-600 NMR spectrometers (Bruker, Rheinstetten, Germany). HPLC-MS/MS analysis was carried out by using the 1200 series HPLC system (Agilent Technologies, Santa Clara, CA, USA) equipped with the Triple Quad 5500 HPLC-MS/MS System (AB SCIEX, Framningham, MA, USA). HPLC-ECD analysis was carried out on the SPD-20A HPLC system (Shimadzu, Kyoto, Japan).

Buffers. The following buffers were used in this study: (1) 0.1 mol/L phosphate-buffered saline (PBS, pH 7.4) containing 0.05% Tween-20 for antibody dilution; (2) 0.05 mmol/L carbonate-buffered solution (pH 9.6) for coating; (3) 0.01 mmol/L PBS containing 0.05% Tween-20 (PBST, pH 7.4) for washing; (4) 0.1 mol/L citrate and sodium phosphate for substrate buffer (pH 5.5); (5) 10 mL of substrate buffer, 150 μL of 1% (w/v) solution of TMB in DMF, and 2.5 μL of 6% (w/v) H_2O_2 mixed for substrate solution; (6) 2.0 mol/L H_2SO_4 used for stopping reagent.

Synthesis and Characterization of Haptens. Haptens were synthesized as follows (Figure 1).

Hapten 1. Maleic acid monoamide was used directly as hapten 1.

Hapten 2, NAS was used directly as hapten 2.

Hapten 3. A 1 mL volume of acrylic acid was added to 1 mL of thionyl chloride and the mixture stirred at 50 °C for 3 h and then filtered to yield solution A. A 500 mg quantity of aminobutyric acid

[a]Antiserum dilution considered suitable while $A_{490\ nm}$ value approximately 1.0 at coating concentration of 1.0 mg/L. [b]Percentage inhibition calculated by following equation: inhibition (%) = $(A_{ck} - A_{analyte})/A_{ck}$. A_{ck} is the $A_{490\ nm}$ in the absence of analyte and $A_{analyte}$ is the $A_{490\ nm}$ in the presence of analyte (100 mg/L acrylamide).

was added to 2 mL of double-distilled H_2O, followed by the addition of 500 μL of 2 M NaOH and 2 mL of butylene oxide to obtain solution B. Next, solution A was slowly introduced dropwise into solution B and stirred overnight at room temperature. The mixture was then extracted with ethyl acetate and evaporated to obtain 4-acrylamidobutanoic acid (hapten 3). ESI-MS analysis (negative) m/z 156 $[M - H]^-$; ^1H NMR ($CDCl_3$, TMS, 300 MHz) δ 11.0 (s, 1H), 8.03 (brs, 1H), 6.48 (d, J = 10.2 Hz, 1H), 6.04−5.98 (m, 1H), 5.52−5.48 (m, 1H), 3.20−3.13 (m, 2H), 2.33−2.28 (m, 2H), and 1.94−1.89 (m, 2H).

Hapten 4. With stirring, 1.0 mmol of 4-MPA in 1.6 mL of methanol was added to a solution of 5 mmol of acrylamide in 0.8 mL of coating buffer. The mixture was left to stand at 37 °C in darkness for 1 h. Subsequent precipitation of the product was enhanced by the addition of 2 mL of deionized water and then dried under light vacuum in darkness for 0.5 h to obtain 2-(4-(3-amino-3-oxopropylthio)phenyl)-acetic acid (hapten 4). ESI-MS analysis (negative) m/z 238 $[M - H]^-$; ^1H NMR (CD_3OD, 400 MHz) δ 7.335−7.349 (d, J = 5.6 Hz, 2H), 7.233−7.247 (d, J = 5.6 Hz, 2H), 3.579 (s, 2H), 3.144−3.168 (m, 2H), and 2.488−2.513 (m, 2H).

Preparation of Hapten−Protein Conjugates. All four haptens were coupled to KLH for immunogens and to OVA for coating antigens. Haptens 1, 3, and 4 were conjugated to carrier proteins by the active ester method, as described by Sheng et al.[16] Hapten 2 was coupled to carrier proteins according to the method of Zhou et al.[13] The hapten−protein conjugates were then dialyzed against 0.01 M PBS at 4 °C for 24 h with six changes of PBS. UV−vis spectral data were used to confirm the structures of the final conjugates and the ratios of hapten to carrier protein determined using the 2,4,6-trinitrobenzenesulfonic acid method.[17]

Preparation of Polyclonal Antibodies. For each immunogen, intramuscular injections were given to two New Zealand white rabbits and a total of eight rabbits used to raise antibodies. The prepared immunogen (0.5 mg of coupled protein in 1 mL of PBS) was emulsified with 1 mL of Freund's complete adjuvant (1:1, v/v) for the first injection into a New Zealand rabbit weighing 1.2−2.2 kg, provided by Guangdong Medical Laboratory Animal Center. Then, Freund's incomplete adjuvant was used as the booster muscle injection, at intervals of 4 weeks. Bleed samples were collected 10 days after the fourth immunization, and the obtained antiserum was purified by the caprylic acid−ammonium sulfate method and separated into 1 mL aliquots held at −20 °C until use. Negative (control) serum was obtained from an unimmunized rabbit. All animal experiments were performed in compliance with the relevant protective and administrative laws for laboratory animals of China and conducted with the approval of the Institutional Authority for Laboratory Animal Care.

Competitive Indirect ELISA. Serum samples were screened for antibodies specific to the analyte (acrylamide or its derivative acrylamide-4-MPA) via a ciELISA. The 96-well plates were coated with coating antigens (1 mg/L, 100 μL/well) in carbonate buffer at 4 °C overnight. The wells were next washed two times with PBS Tween-20 (PBST) and blocked with 120 μL/well of 5% skimmed milk in PBST at 37 °C for 3 h, and the plates were dried at 37 °C for 1 h. The wells were then incubated with 50 μL of diluted acrylamide or its derivative standards in PBS, and 50 μL of diluted antibody in PBST was added. After 40 min in a water bath at 37 °C, the wells were washed five times with PBST and HRP-conjugated goat anti-rabbit IgG (diluted 1:5000) added with 100 μL/well. Finally, TMB solution (400 μL of 0.6% TMB−dimethyl sulfoxide and 100 μL of 1% H_2O_2 diluted with 25 mL of citrate−acetate buffer, pH 5.5) was added to the wells and incubated for 10 min. The reaction was quenched by the addition of 50 μL of 2 M H_2SO_4 and the absorbance recorded at 450 nm.

Optimization of Immunoassay. Experimental parameters, such as coating concentration, antibody dilution, and working buffer, were optimized to improve the optimal sensitivity of this immunoassay. The criteria used to evaluate immunoassay performance were maximal absorbance (A_{max}) and IC_{50} (50% inhibition of antibody binding) values, with the A_{max}/IC_{50} ratio being a convenient estimate of an influence on ELISA sensitivity and higher ratios indicating higher sensitivity.[18] Competitive curves were created in working buffer containing a concentration series of PO_4^{3-} (from 0.1 to 0.4 M), Tween-20 (from 0.08 to 0.5 M), or methanol (from 0 to 15%, v/v) to evaluate the effects of ELISA conditions on assay sensitivity.

Cross-Reactivity (CR). CR was studied using the standard acrylamide solution or its derivative and some of its analogues. CR values were calculated as follows: CR% = (IC_{50} of analyte/IC_{50} of analogue) × 100.

Data Analysis. Competitive curves were obtained by plotting absorbance against the logarithm of the analyte concentration. Sigmoid curves were generated using OriginPro 7.5 software (OriginLab Corp., Northampton, MA, USA): $Y = (A - D)/[1 + (x/C)^B] + D$, where A and D are the maximal and minimal Abs (A_{max} and A_{min}, respectively), B is the slope of the sigmoidal curve, and C is the concentration of acrylamide or its derivative that causes IC_{50}. The LOD was defined as the standard concentration of acrylamide or its derivative that inhibited 10% of antibody binding, and the detectable concentration range was defined as the standard concentration that inhibited 20−80% of acrylamide's or its derivative's standard antibody binding.[19]

Preparation of Samples. Samples of potato chips, cookies, and coffee were bought from a local supermarket. Samples of 4.0 g and 20.0 mL of water were placed in 50 mL centrifuge tubes and subjected to ultrasound for 1 min, followed by a defatting step using 20 mL of *n*-hexane and then centrifugation at 8200*g* at 15 °C for 10 min. The 10 mL supernatant was cleaned by solid phase extraction on a strata-X-C cartridge (Phenomenex Inc., Torrance, CA, USA). The eluate was subjected to HPLC-MS/MS analysis and derivatized to obtain acrylamide-4-MPA for ciELISA analysis. For derivatization, 1 mL of eluate was adjusted to pH 10 by adding aqueous NaOH and then 10 μg of 4-MPA. This reaction mixture was stirred in darkness at 70 °C for 30 min and then acidified to pH 2.0 with HCl. The resulting mixture was then extracted using ethyl acetate and the organic phase blown dry under a nitrogen stream. Finally, the residue was dissolved in 1 mL of PBS and diluted at least 4-fold with optimized working buffer to remove matrix effects prior to ciELISA analysis.

HPLC Conditions. The yield of acrylamide-4-MPA was characterized by HPLC-ECD. A 20 μL portion of sample was resolved at a 0.8 mL/min flow rate and 40 °C using an acetonitrile/acetic acid (plus 1 g of H_2O/L) gradient. A linear gradient was programmed over 15 min using 30−60% (acetonitrile content, by vol). The initial acetonitrile proportion (30%) was then pumped for 5 min before

the next injection was applied. The ECD quantitation channel was selected at 254 nm.

HPLC-MS/MS was used for acrylamide detection, with the spectra recorded by a mass spectrometer (AB SCIEX Triple Quad 5500, AB SCIEX) coupled to a spectra series HPLC (Shimadzu-20A) equipped with a SunFire HPLC column (250 × 4.6 mm, 5 μm; Waters Corp., Milford, MA, USA). A 20 μL portion of sample was separated at a 1.0 mL/min flow rate using an isocratic eluent (methanol/diluted acetic acid, 10:90, v/v, plus 1 g of H_2O/L). Analytes were determined using the above mass spectrometer equipped with a turbo-spray ion source. Quantitation was performed in multiple reaction monitoring (MRM) analysis mode. The respective MS parameters were as follows: curtain gas at 40 psi; collision gas at 6 psi; ion spray voltage at 5500 V; temperature at 650 °C for both; ion source gases 1 and 2 both at 55 psi; declustering potential at 57 V; and entrance potential at 12 V. The analyte indentities were confirmed with product/precursor ions as well as on the basis of the peak retention times corresponding to the standard. The $[M + H]^+$ (m/z 72.0) was selected as the parent acrylamide ion. Qualitative ions were selected at m/z 43 and quantitative ions at m/z 55. The mass spectrometer was controlled and quantitation performed using Analyst 1.5.1 software from AB SCIEX.

RESULTS AND DISCUSSION

Hapten Design and Antibody Production. The key step during the production of an immunoassay is to consider the design and synthesis of an optimal immunizing hapten. In the beginning, the goal was to produce an antibody with specificity against acrylamide, and for this purpose three haptens were designed. Maleic acid monoamide shares the common structure of acrylamide as well as a carboxyl group, which can be directly attached to carrier protein; therefore, it was first selected as a hapten (H1, Figure 1). After coupling to protein, the acrylamide amino linkage could be exposed. NAS (H2) was also employed as a hapten because it has been reported to be able to produce antibodies specific to free acrylamide.[13] After reaction with protein, the conjugate preserved the intact acrylamide structure, and the double bond could be exposed. However, the H2 spacer arm might have been too short, which might have resulted in embedding the hapten in the protein surface. Therefore, another hapten, 4-acrylamidobutanoic acid (H3), was synthesized through the reaction of acrylic acid and aminobutyric acid. These haptens were coupled to KLH and used to immunize rabbits, but the resulting antisera against the three haptens proved not to contain antibodies specific for free acrylamide (Table 1). The inability of the above immunogens to stimulate antibody production possessing the desired specificity for acrylamide was probably because of their diminutive mass of 71.08 Da and the lack of sufficient epitope for virgin B or T helper cell binding.

The double bond of acrylamide can easily react with sulfhydryl groups by Michael addition. Preston et al. have designed a hapten by reacting acrylamide with 3-mercaptobenzoic acid (3-MBA).[15] The corresponding antiserum showed specific binding to acrylamide-3-MBA in a ciELISA; however, the sensitivity of this ciELISA was unsatisfactory. In that study, immunogens were generated by coupling the hapten to carrier proteins via a carboxylic acid spacer. However, in relation to hapten design for small molecular weight compounds, a suitable spacer length between the hapten and the carrier protein should be beneficial for producing desired antibodies.[20] A previous study has indicated that hapten conformation can be altered when too short a spacer is employed for its conjugation

to carrier protein.[21] Therefore, in this study, 4-MPA instead of 3-MBA was reacted with acrylamide to obtain a novel hapten, which was then coupled to KLH to form an immunogen.

Table 5. Recoveries of Acrylamide from Spiked Food Samples by HPLC-MS/MS and Recoveries of Acrylamide Derivative from Spiked Food Samples by ciELISA

			recovery ± SD (%)

Although the corresponding antiserum produced here showed no binding affinity for acrylamide (Table 1), it demonstrated significant binding to acrylamide-4-MPA (Table 2). As acrylamide can easily react with 4-MPA to yield acrylamide-4-MPA, an ELISA based on antiserum 4 could be developed to detect acrylamide by including a rapid preanalysis derivatization.

Development and Optimization of ciELISA. Antiserum 4 and hapten 4-OVA were used to develop a ciELISA for acrylamide-4-MPA. Several physicochemical parameters, including coating concentration, antibody dilution, ionic strength, and Tween-20 concentration, which are important in assay performance, were evaluated to improve ELISA performance. For each condition, standard curves for acrylamide-4-MPA were established (n = 3), and the maximum value of the inhibition curve (A_{max}) as well as the analyte concentration that produced 50% decreased inhibition in A_{max} (IC_{50}) was obtained from these curves. The results of these physicochemical parameter effects on ELISA performance are summarized in Figure 2.

For coating concentration and antibody dilution, a preliminary checkerboard titration was applied to choose several combinations of coating concentration and antibody dilution, under which the A_{450} was ∼1.0. The results indicated that the combination of coating concentration and antibody dilution at 125 μg/L and 1:256000, respectively, were optimal for the highest sensitivity (Figure 2A). For the working system, three solutions (PBST, PBS, 100 mmol/L, pH 7.4, and H_2O) were examined, and it was found that the A_{max}/IC_{50} ratio was highest with PBST (Figure 2B). Further study of Tween-20 concentration and ionic strength effects indicated that the

optimal Tween-20 concentration and ionic strength were 0.08 and 0.1 mol/L, respectively (Figure 2C,D).

Sensitivity and Specificity. Using the optimized reaction conditions, dose−response and inhibition curves for acrylamide-4-MPA in assay buffer were constructed (Figure 3, panels A and B, respectively). The method exhibited an IC_{50} of 9.61 μg/kg and an LOD of 0.12 μg/kg for acrylamide-4-MPA (239 Da), whereas the detection linear range was 0.85−81.2 μg/kg, which was equivalent for acrylamide (71.08 Da) to an IC_{50} of 2.86 μg/kg, an LOD of 0.036 μg/kg, and a linear range of 0.25−24.15 μg/kg. The sensitivity of this assay was significantly improved compared to that of Preston et al.,[15] which might be attributed to the introduction of a suitable length spacer arm between the hapten and carrier protein. A similar conclusion, that the introduction of longer spacer arm rather than a monocarboxylic acid on benzene ring could led to antibody production with higher affinity to analyte, was also obtained by our group in antibody production and ELISA development for furaltadone metabolite 3-amino-5-morpholinomethyl-2-oxazolidinone.[22]

The selectivity of the present antibody and its applicability in actual acrylamide screening were investigated by examining the CRs of the antibody to a series of structural analogues and their derivatives. Acrylamide-4-MPA, 4-MPA, acrylamide, methacrylamide, methyl acrylate, acrylic acid, acrolein, maleic acid monoamide, NAS, and 4-acrylamidobutanoic acid were tested, and the results are summarized in Table 3. No CR was observed to any of the test compounds except acrylamide-4-MPA, suggesting that the antibody possessed high specificity for acrylamide-4MPA. As no CR to 4-MPA was detected, there was no need to remove unreacted 4-MPA after the derivatization step.

Optimization of Acrylamide-4-MPA Derivatization. The derivatization yield of acrylamide-4-MPA was improved by studying several derivatization conditions, such as the reaction's molar ratio of acrylamide/4-MPA, temperature, pH, and time, with the acrylamide-4-MPA content determined by HPLC-ECD. An $L_9(3^4)$ orthogonal experiment was performed after a series of preliminary single-factor experiments. As seen in Table 4, the influences on the mean compound extraction yields by these factors were found to decrease in the order molar ratio of acrylamide/4-MPA (D) > temperature (A) > time (B) > pH (C), according to the related R^a values. The reaction temperature was found to be an important yield determinant. The highest acrylamide-4-MPA derivatization yield was $A_3B_2C_3D_2$ (70 °C reaction temperature, 30 min reaction time, pH 10, 1:5 acrylamide/4-MPA molar ratio). Under the best conditions, the acrylamide-4-MPA derivatization yield was 93.2%.

Sample Preparation and Recovery Test. A standard HPLC-MS/MS method was developed here for acrylamide analysis. The acrylamide limit of detection by HPLC-MS/MS was 0.2 μg/L, and good linearity was observed over the acrylamide range of 0.9−1000 μg/L in each calibration, with a correlation coefficient of 0.9995.

Potato chips, cookies, and coffee samples were first analyzed for their acrylamide content by HPLC-MS/MS and then spiked with three different concentrations (50, 200, and 1000 μg/kg) of acrylamide standards. The samples were extracted by water and then derivatized with 4-MPA to form acrylamide-4-MPA. Next, the acrylamide-4-MPA content was analyzed using the optimized ciELISA procedure. Recoveries were tested from 81.9 to 107.7% for cookies, from 88.7 to 104.9% for potato chips, and from 73.7 to 112.3% for coffee (Table 5). Good correlations were observed between the results from ciELISA and standard HPLC-MS/MS (Table 5).

As a 20-fold dilution of the three samples was performed and good recoveries were observed from ciELISA, the IC_{50} of the proposed ciELISA for acrylamide in cookie, potato, and coffee samples was concluded to be 57.2 μg/L. The LOD and linear range here were 0.7 and 5.0−483 μg/kg for acrylamide, respectively, and the sensitivity almost the same as that of HPLC-MS/MS.

ciELISA Screening and HPLC-MS/MS Analysis of Blind Samples. Four different kinds of cookie samples, five potato chip samples, and four coffee samples were obtained from a local supermarket. The content of acrylamide in these samples was then determined by both ciELISA and HPLC-MS/MS; the results are shown in Table 6. A correlation coefficient of 0.9828 was obtained between the results of ciELISA and HPLC-MS/MS, indicating good reliability and accuracy for the proposed ciELISA. In acrylamide content, higher average concentrations were observed in potato samples. The results were equal to the typical concentration[4] and mean concentration[23] of acrylamide in these foods.

In conclusion, a ciELISA was developed for acrylamide detection via the determination of 4-MPA-derivatized acrylamide. For acrylamide, the IC_{50} was 2.86 μg/kg, the LOD 0.036

μg/kg, and the linear range 0.25−24.15 μg/kg in the chosen assay buffer. The recoveries from acrylamide-spiked potato chips, cookies, and coffee samples were tested from 73.7 to 112.3%, and good correlations were obtained between the results of ciELISA and standard HPLC-MS/MS. Although the sample pretreatment was not simple enough, it was more inexpensive than HPLC-MS/MS analysis. Additionally, the ciELISA was easy to apply with professorial training and suitable for routine acrylamide screening in a large number of food samples.

To perform complete analyses of both OP and pyrethoid insecticide degradation, methods for the extraction and analysis of both parent insecticide compounds and their degradates are required. A suitable method for the extraction of insecticides from foods and the subsequent analysis of these analytes by gas chromatography (GC) with electron capture detection has previously been developed.[20] However, few methods have been developed to analyze insecticide degradates in food.[9,12,14,21] None of the previously reported extraction methods combine analysis of pyrethroid and OP insecticide degradation products. Because both classes of insecticides may be used on a single crop, it is possible for degradates of both classes to be present in food.

As recognized in the Food Quality Protection Act of 1996,[22] risk factors unique to children make understanding their insecticide exposure particularly important. Children's physiological traits put them at higher risk for long-term damage from insecticide exposure.[9] For example, their high metabolic rate causes them to eat more food per kilogram of body weight than adults, and their lower detoxifying enzymatic activity and immature neurological system make this potentially heightened pesticide exposure even more hazardous.[9,23] Their behavioral tendencies, such as preference for foods that tend to contain higher amounts of insecticides and greater tendency to place fingers and objects in their mouths, also put them at risk for higher insecticide exposure.[9,24] Assuming insecticide degradates are present in food and other environmental matrices such as dust, the same risk factors that make children more likely to be exposed to insecticides also make them likely to be exposed to degradates. Hence, it is particularly important to understand children's exposure to insecticide degradates, especially in the case when measurement of such compounds as biomarkers of exposure is anticipated.

There are currently few data on the adsorption, further metabolism, and potential toxicity of many insecticide degradates.[9,12] Consequently, it is difficult to separate the health effects of insecticide degradates from those of the parent compounds. The ability to extract these compounds from food would allow research separating the health effects of the parent and degradate compounds.

For these reasons, a method for the extraction of insecticide degradates in baby food was developed. Degradates analyzed include malathion dicarboxylic acid (MDA), a hydrolysis degradation product of the OP insecticide malathion; 3,5,6-trichloro-2-pyridinol (TCPy), a hydrolysis degradate of the OP insecticides chlorpyrifos and chlorpyrifos-methyl; *cis*/*trans*-2,2-(dichloro)-2-dimethylvinylcyclopropane carboxylic acid (DCCA), a hydrolysis product of several pyrethroid insecticides; and 3-phenoxybenzoic acid (3-PBA), a nonspecific hydrolysis/oxidation product of several pyrethroid insecticides resulting from the hydrolysis of the insecticide and then subsequent oxidation of the degradate.

MATERIALS AND METHODS

Reagents and Materials. Methanol (HPLC grade), acetonitrile (HPLC grade), and glacial acetic acid were purchased from Sigma-Aldrich, Inc. (St. Louis, MO, USA). Water was purified in-house to 18.2 MΩ·cm with a Milli-Q water system (Millipore, Billerica, MA, USA). Oasis HLB mixed phase extraction sorbent extraction cartridges (200 mg, 6 mL) were purchased from Waters Corp. (Milford, MA, USA). Bond Elut reservoir cartridges were purchased from Agilent Technologies (Santa Clara, CA, USA).

Standards. MDA was purchased from Crescent Chemical Co. (Islandia, NY, USA). TCPy was purchased from Sigma-Aldrich (St. Louis, MO, USA). DCCA was purchased from Cambridge Isotope Laboratories (Tewksbury, MA, USA), and 3-PBA was purchased from Acros Organics (Pittsburgh, PA, USA). All standard purities were >95%. A stock solution containing 10 μg/g MDA, TCPy, DCCA, and 3-PBA in acetonitrile (ACN) was used to create standard dilutions from 5 to 2000 ng/mL. These dilutions were used to create matrix-based calibration curves ranging from 0.25 to 100 ng/g of matrix. This range was based on amounts of insecticide degradation products found previously in foods and juices.[9,12]

Isotopically labeled standards (MDA-D_6, DCCA-$^{13}C_3$, and 3-PBA-$^{13}C_6$) were purchased from Cambridge Isotope Laboratories. These standards were diluted to 1000 ng/mL made in ACN and used as internal standards (ISTDs).

Baby Foods. We have elected to use baby food in this work to avoid the typical heterogeneity associated with standard food samples. Numerous methods can be found in the literature to produce homogeneous food samples. The use of baby food, which has been processed into a uniform consistency, eliminates most of the heterogeneity associated with processing raw samples.

Baby foods were purchased from local grocery stores in Atlanta, GA, USA. Green beans, carrots, peas, apples, bananas, and pears were chosen on the basis of the vegetable and fruit baby foods most frequently purchased in the United States.[25] Two popular conventional brands of each were chosen, as well as an organic version of one of these conventional brands. Only organic baby food was used for method validation to minimize degradate contamination from the food itself.

Sample Preparation. The method developed here was based on an extraction of urinary insecticide metabolites previously reported but with substantial modification.[11,26] One gram (1.0 g) of baby food, 50 μL of labeled ISTD, and 2 mL of water were added to a trace-cleaned conical centrifuge tube. The tube was vortex mixed for 4 min at 1000 rpm and centrifuged for 7 min at 150*g*. An Oasis HLB cartridge was placed on a vacuum manifold and preconditioned with 3 mL of methanol (MeOH) and 3 mL of 1% acetic acid in water. The water extract (supernatant) was filtered through a Bond Elut Reservoir cartridge and then loaded onto the OASIS cartridge. After the cartridge was loaded, it was washed twice with 2 mL of 1:5:94 (v/v/v) acetic acid/MeOH/water. The cartridge was then dried under vacuum. A test tube was placed under the cartridge in the vacuum manifold, and the sample was eluted twice with 2.5 mL of methanol. Because the cartridge had been dried completely, vacuum was required to start the elution process. Once the eluate began to flow through the cartridge, the vacuum was broken and the eluate was allowed to flow out using gravity only. The eluate was evaporated to dryness using a Turbovap LV evaporator (Zymark Corp., Hopkinton, MA, USA) under air at 15 psi and 45 °C and was then reconstituted with 100 μL of 30:70 (v/v) MeOH/water. The sample was then vortex mixed briefly and centrifuged for 3 min before being transferred to an HPLC vial for analysis. Any residual particulate matter was left behind.

Analysis by LC-MS/MS. An Agilent 6460 triple-quadrupole HPLC-MS/MS (Agilent, Santa Clara, CA, USA) equipped with a negative mode electrospray ionization (ESI) interface was used to analyze samples. A Zorbax Eclipse Plus Phenyl-hexyl column (3.0 × 100 mm, 3.5 μm particle size, Agilent) was used for separation and kept at 45 °C. Solvent A was water with 1% acetic acid, and solvent B was MeOH with 1% acetic acid. The following parameters were used: the source temperature was 250 °C, the vaporizer gas flow (N_2) was 5 L/min, the nebulizer gas flow pressure was set to 35 psi, and the corona voltage was 3500 V. Each metabolite was matched to its own isotopically labeled internal standard with the exception of TCPy, for which no isotopically labeled standard was available. The best results were found when isotopically labeled DCCA was used as an internal standard for TCPy. Ions were analyzed in selected reaction monitoring (SRM) mode; their optimized precursor and product ions along with their optimized fragmentation and collision energies are shown in Table 1. Mass Hunter Quantitative software (Agilent Technologies) and Microsoft Excel (Redmond, WA, USA) were used for data analysis.

Table 1. Instrument Parameters for Optimized Quantification and Confirmation Ions of Insecticide Degradation Products with Fragmention Energies (FE), Collision Energies (CE), and Retention Times (RT)[a]

compound	precursor ion	product ion	FE (V)	CE (V)	RT (min)
MDA-ISTD	280	147	80	1	3.3
MDA	273	141	80	1	3.9
MDA	273	157	80	12	3.9

DCCA	209	209	90	0	8.2
3-PBA-ISTD	219	99	98	20	7.4
3-PBA	213	93	122	16	9.0
3-PBA	213	169	122	8	9.0

[a]ISTD, internal standard; MDA, malathion dicarboxylic acid; TCPy, 3,5,6-trichloro-2-pyridinol; DCCA, *cis/trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane-1-carboxylic acid; 3-PBA, 3-phenoxybenzoic acid.

During compound identification and optimization, by infusing the solution containing standard chemicals into the LC-MS/MS system, a number of precursor/product ion pairs were identified for each analyte according to their fragmentation patterns. A multiple time segment containing a specific multiple reaction monitoring (MRM) experiment was created and used during MS/MS acquisition. We selected both the quantification and confirmation ions by monitoring the intensity, peak shape, background level, and potential interferences in different urine samples. The same procedure was also applied to the isotopically labeled internal standard.

Method Validation. *Limits of Detection (LODs).* LODs were calculated using replicates of blanks and low-spike (10 ng/g) samples as the lowest analyte concentration at which reliable detection was feasible. If analyte was detected in the blank samples, the following procedure was used to determine the LOD. Ten replicate samples were injected, and the mean blank concentration was determined. The standard deviation (SD_{blank}) of the blank concentrations was also determined. The LOD, defined here as the lowest concentration acceptable as a measured quantity, was defined by the equation

$$LOD = mean_{blank} + 3(SD_{blank})$$

If no analyte was detected in the sample, a different procedure was used to determine the LOD. MassHunter software afforded an estimate of the signal-to-noise ratio (S/N) for each sample taken. The reported LOD was determined by noting when S/N drops below 3 among the standards. If the S/N for the lowest standard was >3, we reported the LOD as the concentration that would have produced S/N = 3 based on extrapolation. If the extrapolated LOD falls below the lowest standard, the lowest standard was used as the LOD instead.

Accuracy and Precision. Method accuracy and precision were determined by measurements of spiked samples at two concentrations (10 and 25 ng/g). For each matrix, 1.0 g of each type of food was fortified with either parent or metabolite compounds to either 10 or 25 ng/g. These quality control (QC) samples were then extracted and analyzed alongside other samples. Percent spiked recovery (relative recovery; Table 2) was calculated on the basis of the percentage of observed concentrations of the nominal spiked concentrations. Within-run precision, presented as relative standard deviation (RSD), was also calculated for fruits and vegetables on the basis of these fortified samples.

Test for Analytic Degradation. To test for analytic degradation in baby food fruits and vegetables, six samples of 1.0 g of carrots and six samples of 1.0 g of apples were obtained. For each matrix, three of the samples were fortified with 25 ng/g parent insecticide (malathion, permethrin, and chlorpyrifos) per sample, and all samples were fortified with degradate ISTD at a final concentration of 50 ng/g. The samples were then immediately extracted and analyzed according to the insecticide metabolite procedure. To test for analytic degradation, we examined the concentration of analytes from fortified and unfortified samples. A two-tailed t test ($p = 0.05$) was used as the test criterion to ascertain that the degradate concentrations were identical regardless of parent insecticide spiking.

Table 2. Relative Recoveries for Degradation Products in Baby Food Expressed as Percentages[a]

	MDA	TCPy	DCCA	3-PBA
green beans				
QCL	85.8	119.5	100.0	94.5

QCL	92.0	123.5	93.2	98.9
QCH	109.1	132.3	100.5	101.5

[a]QCL, low (10 ng/(g) quality control sample; QCH, high (25 ng/(g) quality control sample; MDA, malathion dicarboxylic acid; TCPy, 3,5,6-trichloro-2-pyridinol; DCCA, *cis/trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane-1-carboxylic acid; 3-PBA, 3-phenoxybenzoic acid. $N = 1$ in all cases.

Matrix Effects. Matrix effects were accounted for by developing calibration curves in a surrogate matrix. The surrogate matrices included one for vegetables and one for fruits consisting of an equal contribution of each individual food for the two classes.

Method Implementation. The method was used to measure pesticide degradates in several baby food samples on the basis of the most frequently purchased baby foods in the United States: green beans, carrots, peas, apples, bananas, and pears.[25] For each food, there were three samples: two different conventional brands and one organic brand.

RESULTS

Method Performance. The extraction and cleanup method produced mass chromatograms free of interfering peaks. A typical QC mass chromatogram is shown in Figure 1. Two sets of matrix-based calibration curves were created, one in vegetables and one in fruits. Calibration curves were linear and resulted in $R^2 > 0.98$ for all compounds. A typical matrix calibration plot is shown in Figure 2. Calibration curves for the other analytes can be found in the Supporting Information.

As shown in Table 3, relative recoveries were between 80 and 120% for all analyte/matrix combinations except TCPy in fruit. Table 3 summarizes method performance by showing average relative recovery, RSD, and LODs stratified by fruits and vegetables. All RSDs were under 15% with the exception of MDA.

Test for Analytic Degradation. Using a two-tailed t test ($p = 0.05$), we determined that there was no significant difference between insecticide degradate concentrations between identical food samples regardless of parent compound

dx.doi.org/10.1021/jf500779a | J. Agric. Food Chem. 2014, 62, 7085−7091

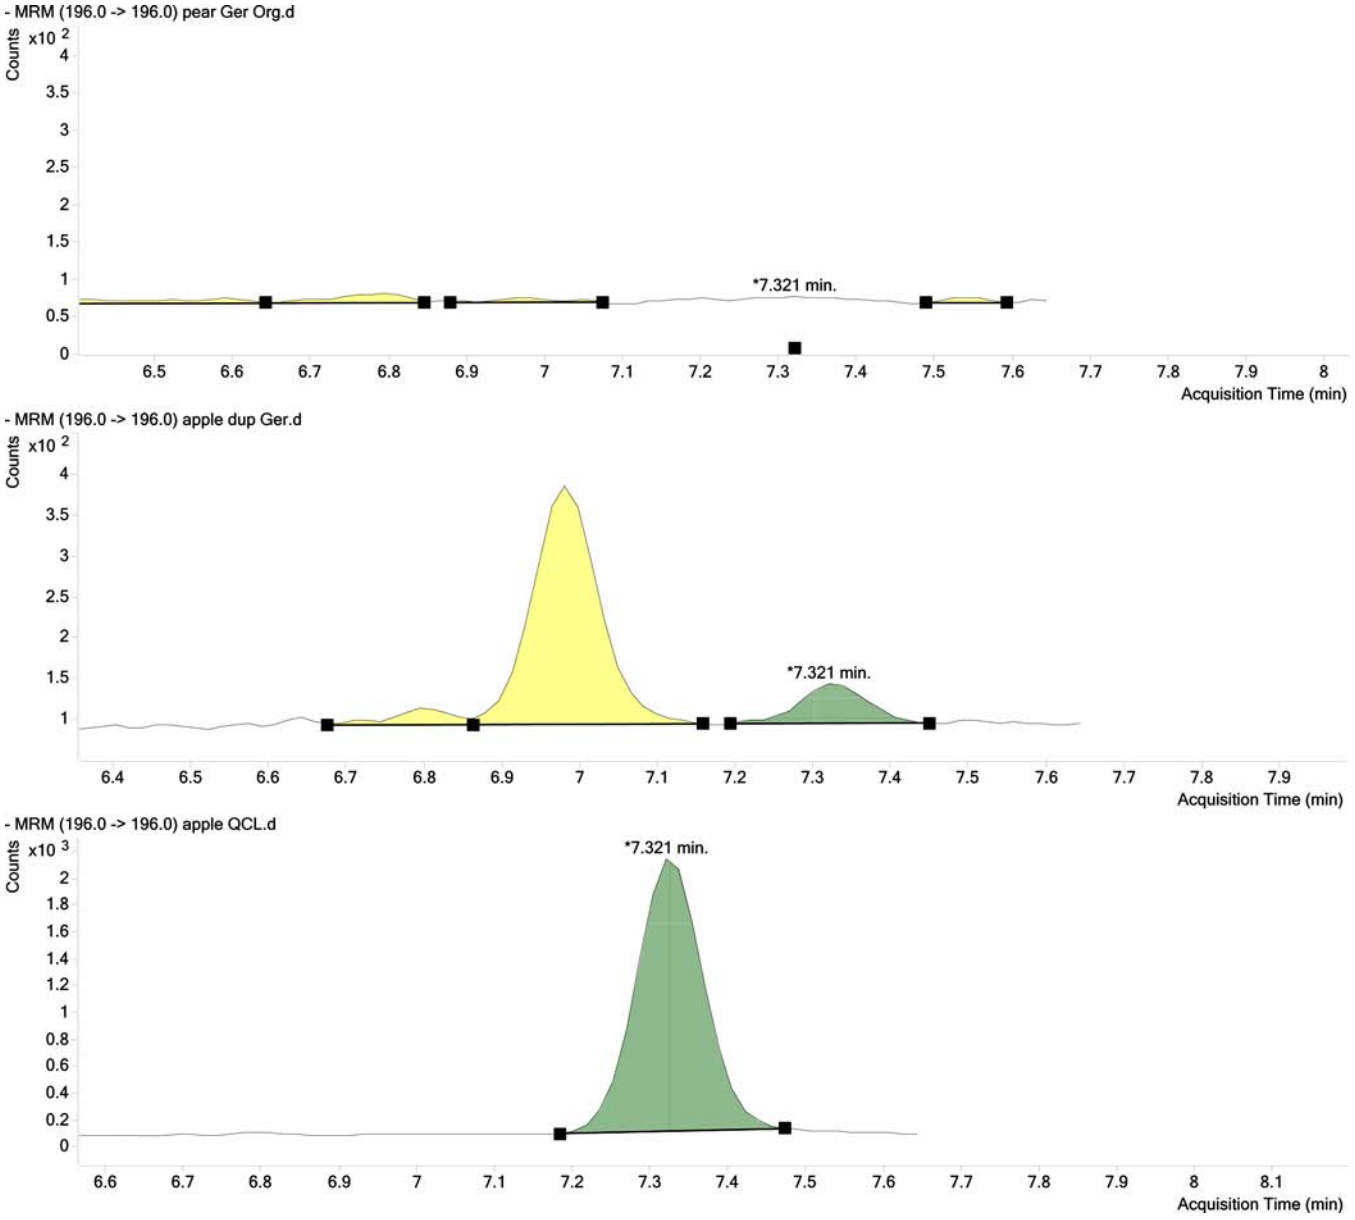

Figure 1. Comparison of chromatographic peaks for chromatogram of TCPy: (top) sample with no detection; (middle) peak detected at 7.321 min in an apple juice sample with a concentration below the LOQ (scale identical to top); (bottom) spiked quality control materials at 10 ng/g equivalent (note factor of 10 change in scale).

fortification. Table 4 presents average concentrations and standard deviations for spiked and nonspiked samples.

Method Implementation. Degradates were found in three samples. One conventional sample of pears contained TCPy at a concentration of 1.81 ng/g, the organic banana sample contained DCCA at a concentration of 1.64 ng/g, and the organic pea sample contained MDA at 3.63 ng/g. 3-PBA was not detected in any samples.

DISCUSSION

Method Performance. All degradate recoveries were between 80 and 120% except TCPy in fruit (122%), which is likely the result of the lack of an isotopically labeled analogue for TCPy. If DCCA, the labeled standard used as a surrogate standard for TCPy, was preferentially adsorbed by proteins or other matrix surfaces or interacted differently with the matrix from TCPy, falsely high recoveries (from calculations) could have resulted. Ion abundances in the mass spectrometer may have changed because of solvent and eluted matrix component composition changes resulting from retention time shifts. Such changes that are not matched by ISTD may also have led to less accurate recoveries.

Blanks were developed from matrix-matched samples with no detectable concentration of degradate under most circumstances. Each type of sample had numerous "blank" values associated with it. For example, blank "vegetable" samples included a measure of organic peas that displayed no measurable concentration of degradate. We choose foods labeled "organic" for our blank samples under the supposition that they would likely contain lower levels of any parent pesticide or degradate. This supposition was borne out as measurable concentrations of degradate in such systems were <LOD. For a small number of cases, we detected the presence of degradate in these "blank" samples. Under such a scenario,

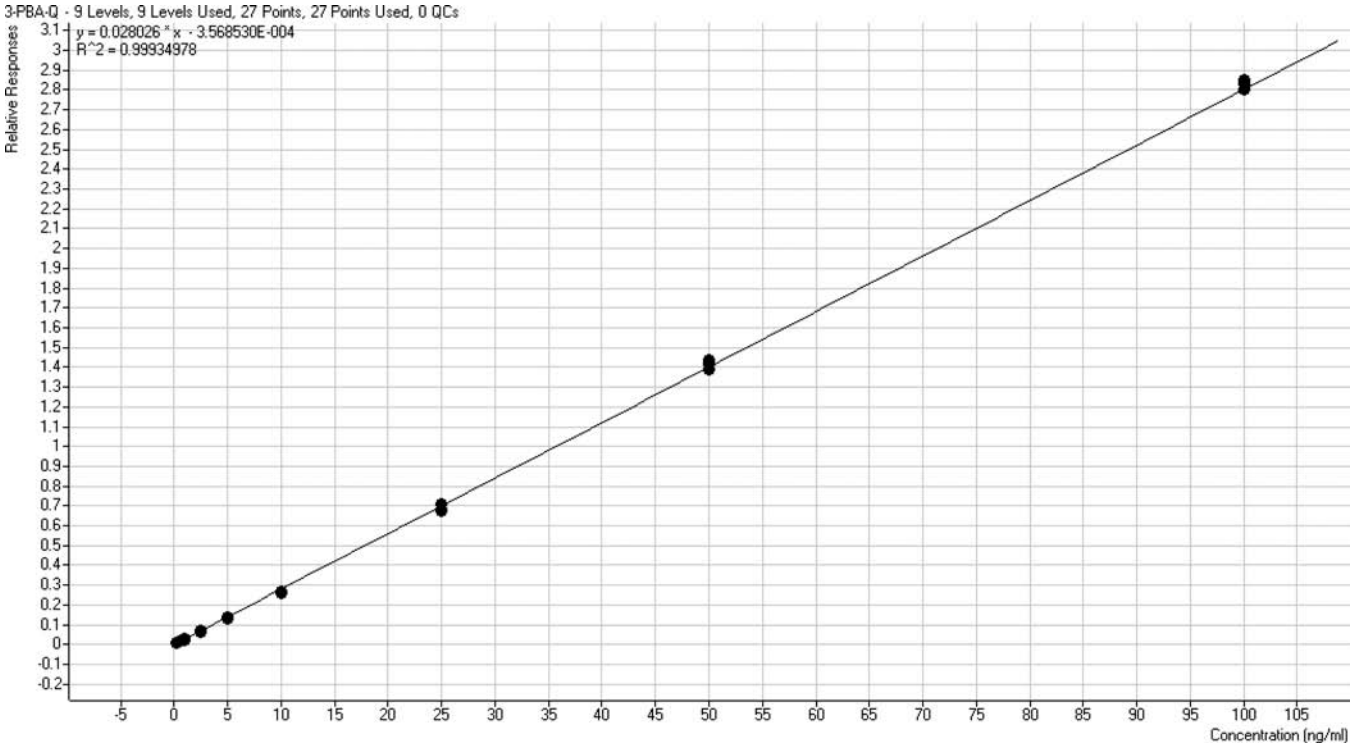

Figure 2. Calibration curve for 3-phenoxybenzoic acid, a degradate of many pyrethroid insecticides, in vegetables. All calibration points were injected in triplicate, and all points are present on the graph.

Table 3. Results for Recovery of Degradates from Fruits and Vegetables[a]

	QCL	QCH	LOD (ng/g)
vegetables			
MDA	91.7 ± 15.9	93.4 ± 13.3	2.3
TCPy	109.7 ± 14.5	96.0 ± 11.9	2.7
DCCA	102.9 ± 2.6	100.4 ± 8.7	0.87
3-PBA	92.8 ± 1.7	93.3 ± 4.9	0.25
fruits			
MDA	92.0 ± 15.4	107.5 ± 20.6	0.18
TCPy	122.0 ± 12.0	122.1 ± 11.1	0.76
DCCA	102.0 ± 8.3	102.0 ± 8.3	0.87
3-PBA	103.9 ± 9.2	102.5 ± 9.7	0.25

[a]Relative recoveries (±SDs) and limits of detection (LODs) are presented. QCL, low quality control material fortified to 10 ng/g; QCH, high quality control material fortified to 25 ng/g; MDA, malathion dicarboxylic acid; TCPy, 3,5,6-trichloro-2-pyridinol; DCCA, *cis/trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane-1-carboxylic acid; 3-PBA, 3-phenoxybenzoic acid. $N = 3$ in all cases.

Table 4. Test for Analytic Degradation in Vegetables and Fruits[a]

	spiked samples	nonspiked samples
carrots		
MDA	1.44 ± 0.01	1.43 ± 0.02
TCPy	0.26 ± 0.38	0.31 ± 0.12
DCCA	0.22 ± 0.38	nd
3-PBA	0.09 ± 0.01	0.08 ± 0.01
apples		
MDA	nd	nd
TCPy	nd	nd
DCCA	1.05 ± 0.26	0.46 ± 0.42
3-PBA	0.14 ± 0.01	0.13 ± 0.01

[a]Spiked samples were fortified with 25 ng/g malathion, chlorpyrifos, and permethrin, precursors to the four analytes. There was no significant difference found between sample concentrations using a two-tailed *t* test ($p = 0.05$). MDA, malathion dicarboxylic acid; TCPy, 3,5,6-trichloro-2-pyridinol; DCCA, *cis/trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane-1-carboxylic acid; 3-PBA, 3-phenoxybenzoic acid; nd, not detected. $N = 3$ in all cases.

the reported concentration after spiking had to be greater than the mean blank value plus 3 times the standard deviation of the blank value (mean + 3σ(blank)) to be considered as >LOD.

RSDs were <15% for all analytes except MDA. RSDs under 15% are preferred for analytical analyses.[27] MDA may have had less precise results because a deuterated MDA was used for an ISTD. Deuterium may have been exchanged much more easily during solvent interactions than ^{13}C or other isotopes, causing greater imprecision. Alternatively, the fact that MDA has two ionizable groups, thereby causing the possibility of four forms to be present at a given time, may contribute to its high RSD.

During compound optimization, no fragmentation was observed for both TCPY and DCCA. Although we could induce the "loss of chlorine" and use m/z of 35 as a product ion, it could come with higher background noises due to its low mass value. We thus decided to employ pseudotransitions for these compounds, which means the same m/z was detected in both Q1 and Q3 of the mass spectrometer.

Analytic Degradation. High concentrations of insecticides that could degrade into the target analytes were spiked into baby foods before extraction of degradates to test for analytic degradation. Even when using as much as 25 ng insecticide/g matrix, which is 100 times the lowest degradate calibration point used, statistically significant amounts of degradation products were not produced. This observation suggests that the use of this method to analyze the degradation of insecticides in

dx.doi.org/10.1021/jf500779a | J. Agric. Food Chem. 2014, 62, 7085−7091

food without creating false-positive detection of insecticide degradate is acceptable.

Although not statistically significant, there was a larger difference in DCCA concentrations in spiked versus unspiked samples of apples than of carrots. There is the potential that the lower pH of apples (pH 3.0−4.0) versus carrots (pH 4.5−6.0) contributes to the degradation of permethrin, the parent of DCCA, during extraction, thereby causing the larger analyte difference in spiked versus unspiked samples.[28]

Matrix Effects. Matrix effects are common in analyses of food samples and should be accounted for. In principle, there may well be a different matrix effect for each food analyzed. For single food analyses, this presents only minor problems as a matrix calibration curve can easily be constructed. However, for more complex samples, such as a duplicate diet sample, establishing separate calibration curves for each food is not practical. We made the compromise in our analysis to construct calibration curves separately for vegetables and fruits. These two food groups are likely to have different matrix characteristics with, for example, fruits being more acidic. We have included all foods of these two classes for which we performed analysis into two matrices and developed curves using these mixtures. All vegetable samples were analyzed using the curve developed using the vegetable mixture with similar protocols followed for fruit samples. We offer this as a compromise solution to the likely matrix effects problem.

Method Implementation. MDA, TCPy, and DCCA were all found in baby food, including some organic foods. 3-PBA was not found in any baby food. It is not certain whether 3-PBA, 3-phenoxybenzyl alcohol (3-PBAlc), or both compounds would be produced from the degradation of pyrethroids. Hydrolysis of these compounds should lead to 3-PBAlc, not 3-PBA. However, in the mammalian body, the alcohol moiety is transformed to the acid by an oxidase.[29] This oxidation may not happen in fruits and vegetables. Previous studies have demonstrated that the presence of antioxidants, such as those found in fruits and fruit juices, suppresses the production of pesticide oxidation degradates, so perhaps oxidation of 3-PBAlc to 3-PBA is suppressed by these compounds.[16,17]

Although the detection frequency of these three compounds may not seem very high (17% for MDA, TCPy, and DCCA) compared to insecticide degradate concentrations found in other studies, there are a few possible explanations. First of all, other studies in which pesticide degradate concentrations were found in food observed DAPs,[12,14,15] which are nonspecific degradates formed from 75% of the EPA-registered OP insecticides.[30] However, MDA is formed from only malathion, TCPy is formed from only chlorpyrifos and chlorpyrifos-methyl, and DCCA is formed from the three pyrethroids permethrin, cypermethrin, and cyfluthrin.[31] Because DAPs are formed by so many more insecticides than these three compounds, it makes sense that their detection frequency was higher than that of MDA, TCPy, and DCCA. Furthermore, two of the studies cited analyzed for DAPs and/or 3-PBA only in produce already known to contain the parent insecticide.[14,15] This sample preselection likely led to a larger degradate detection frequency than would happen if produce was analyzed regardless of parent insecticide content. Although 3-PBA, which is also a broad-range insecticide degradate, was not found in any of our baby food samples, this is possibly due to suppression of 3-PBAlc oxidation.

One may inquire as to the optimization of the final elution program of the SPE by comparing our work with normal-phase SPE or ion exchange SPE. However, in the case of a reversed phase SPE, a generic method provided by the manufacturer can be followed with minimum optimization process, as long as the isotopic analogues are used as internal standards and the target analytes are polar compounds. Our analytes are quite polar, and on the basis of their Log *P* values they can be dissolved in polar solvents such as acetonitrile, methanol, ethyl acetate, and acetone. We chose not to use acetonitrile to reduce the laboratory cost, and acetone is not recommended for use due to high chemical backgrounds. Using the same elution solvent, Olsson et al.[26] reported their extraction recoveries of >80% for all analytes except MDA. Although we are satisfied with our method LODs for most of the compound measured, we do recommend further optimization to increase the LOD of MDA if such analysis is deemed critical for a given study.

This method could be expanded to analyze produce or other foods for insecticide degradation products. If other foods were analyzed, prehomogenization using a blender, food processor, or other homogenization system before the extraction step would be required to ensure a true understanding of analyte content in the sample.

This method is suitable for the analysis of insecticide degradates in baby food. The presence of degradates in baby food discovered during method implementation supports the need for this method. Furthermore, the widespread measurement of these urinary metabolites for exposure assessment purposes highlights the need for a better understanding of the contribution of preformed environmental metabolites to urinary concentrations. Use of this method in food samples will allow a more complete understanding of insecticide degradation product concentrations in such samples, and this knowledge in turn will allow more accurate estimation of human insecticide exposure.

In this study, a rapid, efficient, and sensitive method for the simultaneous determination of 31 OCPs and 19 PYs in Chinese teas by GC-NCI-MS and GC-MS/MS were developed. The established methods were validated according to the criteria by EU Commission Decision 2002/657/EC,[20] and a survey of 101 tea samples was conducted by the established method.

MATERIALS AND METHODS

Materials and Reagents. The Florisil cartridges (2 mg, 12 mL) were purchased from Agilent (Santa Clara, CA, USA); primary−secondary amine (PSA) powder with the size of 40−60 μm was also obtained from Agilent.

Acetone, hexane, and ethyl acetate (P.R. grade) were purchased from J. T. Baker (Deventer, The Netherlands); anhydrous sodium sulfate (P.R. grade) purchased from Sigma Co. (Beijing, China) was heated at 250 °C for 4 h and kept in a desiccator; sodium chloride (analytical reagent grade) was purchased from Beijing Chemical Industry (Beijing, China); deionized water was obtained from a Milli-Q water purification system (Millipore, Bedford, MA, USA).

Analytical Standards. Analytical reference standards of PYs and OCPs (listed in Table 1), d_6-*trans*-cypermethrin, d_6-*trans*-permethrin, d_5-bifenthrin, and 24 ^{13}C-labeled OCPs were all purchased from Dr. Ehrenstorfer GmbH (Augsburg, Germany), with purity of not less than 96.0%.

Standard Solution. The stock solution for all of the standards and the internal standards (IS) were prepared by accurately weighing a certain amount of the standard powder and then quantitatively dissolving by ethyl acetate at the concentration of 1000 mg/L, respectively. The mixed intermediate standard and internal standard solution were quantitatively diluted from the stock standard solutions with hexane, and the final concentrations of all the individual standards and the internal standards were 2 and 1 mg/L, respectively. All of the standard solutions were stored at −20 °C in amber glass bottles.

Tea Samples and Pretreatment. All 101 tea samples were purchased from local supermarkets (Beijing, China) in 2013, including green tea (n = 44), scented tea (n = 23), dark tea (n = 8), black tea (n = 13), and oolong tea (n = 13). The tea samples were ground by a homogenizer and filtered through a 40 mesh sieve. The grinding program was conducted as follows: ground for 3 s and halted for 5 s; 5−10 cycles were enough for each sample.

A negative green tea sample was selected as the blank for the recovery studies.

Sample Extraction. 2.0 g of ground tea powder was weighed by a balance with the precision of 1 mg; 40 μL of the mixed IS solution (1 mg/L) was spiked, and then the mixture was soaked by 10 mL of hot water (90−100 °C) for 30 min. 20 mL of acetone was added, and the mixture was vortexed for 1 min and then ultrasonicated for 30 min, and then centrifugation was performed at 7000 rpm for 5 min at 4 °C. The extracted solution was transferred and partitioned by 20 mL of hexane with the addition of 1.0 g of NaCl. Two partitions were performed, and the organic solutions were combined and evaporated to near dryness at 30 °C by rotary evaporation. The residues were redissolved with 3 mL of hexane.

Sample Cleanup. The Florisil cartridge (2 mg, 12 mL) with a layer (ca. 1 cm) of PSA on the sieve plate was prepared and preconditioned with 5.0 mL of acetone/hexane (1:9, v/v) and 5.0 mL of hexane. The extract was applied to the conditioned cartridge and eluted with 10 mL of acetone/hexane (1:9, v/v). The loading and eluting fluid were both collected and evaporated to dryness by a gentle nitrogen stream in a water bath at 30 °C. The residue was redissolved with 200 μL of hexane and filtered through a 0.22 μm PTFE filter for GC-NCI-MS analysis.

GC-NCI-MS Analysis. The analysis of the target analytes was performed on a DB-5 ms column (30 m × 0.25 mm i.d. × 0.25 μm) by Bruker 450 GC and 320 MS (triple-quadrupole mass spectrometry, MS workstation version 7.0 software) with the 8400 autosampler (Bruker, USA), operated under NCI for screening. Helium with a purity of not less than 99.999% was used as carrier gas at a constant flow of 1 mL/min. Methane gas was used as the reaction gas for NCI analysis, and the filament current was set to the default value. The GC oven temperature program was as follows: 80 °C kept for 1 min, raised to 200 °C at a rate of 20 °C/min, then raised to 240 °C at a rate of 15 °C/min, then raised to 286 °C at a rate of 5 °C/min, held for 5 min, and finally raised to 300 °C at a rate of 20 °C/min and held for 5 min. The temperature of the injection port and transform line were 250 °C. The splitless injection volume was 1 μL with a solvent delay time of 5 min.

The ion source temperature of 230 °C, MS quadrupole temperature of 40 °C, electron multiplier voltage of 1400 V, and ion source energy of 70 eV were used. Analysis was performed in the selected ion monitoring

Table 2. Linearity Curves, Limits of Detection (LODs), and Limits of Quantitation (LOQs) of 50 Standard Pesticides in Blank Tea Matrix

mode (SIM). Pesticides were identified according to retention times, the quantitative ions and three qualitative ions (Table 1), and the chromatogram is shown in the Supporting Information. Four ions were selected following the EU regulation (EEC657/2002). Pesticides were monitored in different time segments, and the dwell time for each ion was fixed by the instrument.

Calibration and Quantification. Three deuterium PYs and 24 ^{13}C-labled OCPs were used as IS as shown in Table 1. For the quantification of the OCPs, quantitative values were calculated using isotope dilution technique through a relative response factor (RRF) calculation.

GC-NCI-MS/MS Identification. GC-MS/MS identification was also conducted on a 450GC-320MS under NCI mode. The other parameters were the same as for the GC-NCI-MS method except for the ion source energy. With the ion source energy of 20 eV, ions with larger mass were more easily acquired, which is helpful for MS/MS detection. The mass

[a]Interday recovery RSDs. [b]Intraday recovery RSDs.

parameters are provided in Table 1. The positive samples of pyrethroids were verified by the established GC-NCI-MS/MS method for the limited isotope-labeled IS. For OCPs, one-to-one IS were used leading to more reliable quantitation and qualitative analysis by GC-NCI-MS. Identification of the target compounds in the tea matrix was based on criteria set by Commission Decision 2002/657/EC.[20]

Quality Control. A positive sample containing bifenthrin and cypermethrin and a positive sample with 4,4′-DDE and dicfol were chosen as quality control samples. The quality control samples were both tested and quantified in every batch. A procedural blank, a matrix blank, and QC samples must be run in each batch to check for contamination, peak identification, and accurate quantification.

RESULTS AND DISCUSSION

Sample Preparation. In this research, tea samples were soaked in hot water for 30 min and then extracted with acetone and hexane, which can effectively extract the target compounds and remove water-soluble impurities such as caffeine and tea polyphenols.[18] Considering the nonpolar or semipolar properties of OCPs and PYs, cartridges of Florisil, Carb-NH_2, diatomite, and neutral aluminum oxide were used to check the cleanup effect for tea extracts. The results showed that most of the pesticides could not be eluted from the neutral aluminum oxide cartridge, and the recoveries of some pesticides were not satisfied with the diatomite column. The Florisil and Carb-NH_2 cartridges were much more preferred. Considering the low cleanup ability to the lutein in tea matrix and the lower recoveries for *o,p′*-DDT (62.1%) and acrinathrin (65.8%) with Carb-NH_2 cartridge, the Florisil cartridge was selected. To sufficiently remove the pigments and other impurities such as fatty acids, organic acids, sugars,[11,21,22] and extra water from the matrix, the mixture of 150 mg of PSA powder and 500 mg of anhydrous sodium sulfate was placed on the sieve plate of the Florisil cartridge for better cleanup.

GC-NCI-MS and GC-NCI-MS/MS Detection. Although GC-MS provides qualitative and quantitative information on pesticide residues in foods, there were still some potential difficulties for the accurate qualitation because of the complicated matrix effect. For more accurate qualitation and higher sensitivity, a GC-MS/MS method under NCI mode for PYs analysis in tea samples was established for the first time. All of the positive samples were verified by the GC-MS/MS method.

Method Validation. Validation parameters for quantification of 31 OCPs and 19 PYs were obtained under the optimal conditions. Good linearity regression for all of the pesticides were in the range of 0.05−1.00 mg/L with correlation coefficients (r) of not less than 0.995 as shown in Table 2.

The LOD and LOQ are determined, following IUPAC recommendation, as the minimum detectable amount of analytes from blank sample spiked extract with signal-to-noise ratios (S/N) of 3:1 and 10:1, respectively. The LODs and LOQs were 0.02−4.5 and 0.1−15 μg/kg for GC-NCI-MS determination, respectively (Table 2). The LODs for GC-MS/MS determination ranged from 0.1 to 5.0 μg/kg.

The accuracy and precision of the method were examined by the interday and intraday reproducibility of the spiked blank tea samples at levels of 10, 20, and 100 μg/kg. The recoveries, as shown in Table 3, ranged from 61.4 to 119.9% with relative standard deviations (RSDs) of 0.5−17.7% for interday recovery and 1.2−18.8% for intraday recovery.

To evaluate the matrix effect, six-point (0.05, 0.1, 0.2, 0.4, 0.8, and 1.0 μg/mL with IS 0.2 μg/mL for each) neat solution calibration curves and matrix-matched calibration curves were constructed. The responses of most pesticides were slightly enhanced compared with that in the solvent; however, with the internal standards calibration, the matrix enhancement did not have much influence on the quantitation results.

Therefore, considering easy performance, the calibration curve by solvent was preferred.

Quality Control Results. The results of the quality control samples were relatively stable with the RSD of less than 3% for 12 batch analysis, indicating the reliable analysis results of all tea samples.

Contamination Levels of PYs in Chinese Tea. As shown in Tables 4 and 5, the most frequently detected PY in Chinese tea was bifenthrin, with the detection rate (DR) of 63.4% at concentrations of ND−3.848 mg/kg, followed by λ-cyhalothrin (55.4%, ND−3.244 mg/kg), cypermethrin (46.5%, ND−0.499 mg/kg), and fenvalerate (24.8%, ND−0.217 mg/kg). It was reported (Table 6) that the residues of bifenthrin, cyhalothrin, cypermethrin, and fenvalerate in Chinese tea during the years of 2006−2008 were 0.020−7.020 mg/kg (543 samples), 0.010−0.490 mg/kg (423 samples), 0.020−1.370 mg/kg (2321 samples), and 0.010−2.320 mg/kg (7095 samples), respectively.[23,24] It was obvious that PYs were still the major pesticides commonly used in tea plantations in China.

Interestingly, residues of PYs in teas differed with tea type. For example, fenvalerate, a pesticide restricted on tea plantation in China from 1999, was detected only in green tea samples and scented tea samples with a violation rate (VR) of 3.0%. A study in 2007[23] reported that the concentration of fenvalerate in Chinese tea samples was in the range of 0.050−0.250 mg/kg, with VR of 73.4% in oolong tea and 52.3% in scented tea. It could be inferred that the usage of fenvalerate on tea plantation was decreased after strict management by the government. In addition, there were two scented tea samples containing phenothrin and λ-cyhalothrin with the VR of 1.0%.

Contamination Levels of OCPs in Chinese Tea. Although the use of most OCPs has been banned or restricted in China, some OCPs were still detected in Chinese tea, such as endosulfan with a DR of 63.4% and the concentration range of ND−1.802 mg/kg, DDTs (56.4%, ND−0.411 mg/kg), HCHs (24.8%, ND−0.377 mg/kg), and heptachlor (15.8%, ND−0.102 mg/kg). Only three scented tea samples with concentrations of 0.411, 0.390, and 0.260 mg/kg, respectively, exceeded the MRL for DDTs (0.20 mg/kg). The major DDT residues in Chinese tea were 2,4′-DDD and 2,4′-DDE. As OCPs have been banned for decades in China, it was presumed that the DDTs were mainly from the soil or water through the ecological cycle. Moreover, DDTs were used as intermediates in the production of the pesticides dicofol and may occur as a major impurity in the final products.

In all, most of the OCPs and PYs were in compliance with the MRLs established in China and Europe, and thus Chinese tea was safe enough for human consumption and exportation in terms of OCP and PY residues.

nidin-rich extracts were degraded under acidic conditions. These formed carbocations (upper units) react in the presence of flavan-3-ols as nucleophile agents to dimeric proanthocyanidins.

In a previous study, 57 samples with regard to the occurrence of dimeric procyanidins B1−B8 were analyzed.[14] In this context, dimeric procyanidins B1−B4, B6, and B7 in hazelnut skins were detected in low amounts.[14] According to Gu et al.,[2] hazelnut polymers are composed of 41.9% (−)-epicatechin, 39.5% (+)-catechin, 10.8% (epi)gallocatechin, and 0.5% epicatechin-3-*O*-gallate in their extension units. The conditions are appropriate for the use of semisynthesis to produce all eight dimeric procyanidins B1−B8 in higher amounts. Therefore, the aim of the present study is the isolation of B-type dimeric procyanidins in high amounts (i.e., 500 mg) after semisynthesis of hazelnut skins for the first time. Furthermore, the proanthocyanidin composition of hazelnut skins is not well-characterized in the literature until now. Here, we characterize for the first time various proanthocyanidins, that is, flavan-3-ol (epi)afzelechin, B-type dimeric propelargonidins, and different A- and B-type dimeric prodelphinidins, which occur naturally in hazelnut skins by LC-MS/MS and/or NMR spectroscopy.

MATERIALS AND METHODS

Chemicals. Water (deionized, Nanopure, Werner, Leverkusen, Germany), acetonitrile of HPLC quality (Fisher Scientific, Loughborough, UK), *tert*-butyl methyl ether (distilled, industrial quality), methanol (distilled, industrial quality), *n*-hexane (distilled, industrial quality), *n*-butanol, p.a. (Fisher Scientific), ethyl acetate, p.a. (Fisher Scientific), 2-propanol, p.a. (Sigma, Steinheim, Germany), (+)-catechin hydrate, ≥98% (Sigma), (−)-epicatechin, p.a. (Sigma), hydrochloric acid, 37% (Riedel-de-Haën, Seelze, Germany), ethanol, p.a. (Riedel-de-Haën), sodium hydrogen carbonate, p.a. (Merck, Darmstadt, Germany), and acetone-d_6 (Deutero GmbH, Kastellaun, Germany) were used.

High-Performance Liquid Chromatography Photodiode Array (HPLC-PDA) and HPLC−Electrospray Ionization Multiple Mass Spectrometry (HPLC-ESI-MS^n) Analysis. HPLC-PDA and HPLC-ESI-MS^n conditions were the same as described earlier.[12]

Optimization of the Reaction Conditions for Semisynthesis of Dimeric Procyanidins. The reaction conditions, such as ratio of substrates, reaction time, and reaction temperature, were described in Esatbeyoglu and Winterhalter.[12]

Sample Preparation for High-Speed (HSCCC) and Low-Speed Rotary Countercurrent Chromatography (LSRCCC) Separation. Hazelnut skin precipitate was obtained from 70% aqueous acetone extract of hazelnut skins after ethanol/*n*-hexane (5:13, v/v) precipitation as described earlier.[15] The precipitate, received after filtration, was used for semisynthesis.

For HSCCC. Amounts of 1 g of (+)-catechin or (−)-epicatechin and 500 mg of hazelnut skin precipitate were dissolved in 50 mL of 0.1 N methanolic HCl and kept at 40 °C for 30 min in a water bath. The reaction mixture was neutralized with about 10 mL of 0.5 N sodium hydrogen carbonate solution and evaporated, and the residue was lyophilized. About 1 g of the reaction mixture was applied for HSCCC separation.

For LSRCCC. For semisynthesis of dimeric procyanidins B1, B3, B6, and B7, 10 g of (+)-catechin and 10 g of hazelnut skin precipitate were used, and 10 g of (−)-epicatechin and 10 g of hazelnut skin precipitate were applied to semisynthesize dimeric procyanidins B2, B4, B5, and B8. Further conditions for sample preparation are given in Esatbeyoglu et al.[15] About 10 g of the reaction mixture was used for LSRCCC separation.

HSCCC. A high-speed countercurrent chromatograph model CCC-1000 (Pharma-Tech Research Corp., Baltimore, MD, USA) was equipped with three preparative coils of PTFE tubing, connected in series (total volume, 800 mL; 2.6 mm i.d.; 160 m length). A Biotronik HPLC pump BT 3020 pumped the two-phase solvent systems. The aqueous lower phase was used as mobile phase (elution mode, head to tail). All samples were dissolved in 10 mL upper and 10 mL lower phases and loaded into the system by loop injection. The amount of loaded sample, revolution speed of the apparatus, flow rate, and solvent systems are given in the discussions for the respective runs. The HSCCC separation was monitored at λ = 280 nm with a Knauer UV−vis detector (Berlin, Germany) and recorded on a plotter (BBC Goerz SE 120, Vienna, Austria; 3 cm/h). Fractions of 12 mL were collected using a Super Frac fraction collector (Pharmacia LKB, Bromma, Sweden).

LSRCCC. LSRCCC separation of dimeric procyanidins B1, B3, B6, and B7 was carried out according to the method of Esatbeyoglu et al.[15] For the LSRCCC separation (single coil, total volume, 5500 mL; 8.2 mm i.d.) of dimeric procyanidins B2, B4, B5, and B8, 12.4 g of the lyophilized filtrate of the semisynthetic process with (−)-epicatechin was dissolved in 100 mL upper and 100 mL lower phases and was loaded into the system via a sample loop. *tert*-Butyl methyl ether/*n*-butanol/water (4.5:0.5:5, v/v/v) was used as the two-phase solvent system. The flow rate was set at 4 mL/min, and the revolution speed at 50 rpm. The upper organic phase represented the mobile phase. LSRCCC separation was carried out in the "head-to-tail" elution mode. After an elution time of 39 h, the elution mode was switched to extrusion. In this case, the aqueous lower phase was pumped into the LSRCCC column. UV absorbance of the effluent was monitored at λ = 280 nm with a Knauer UV−vis detector. The elution was recorded on a Servogor 120 plotter (BBC Goerz Metrawatt SE 120, Vienna, Austria). About 50 mL fractions were collected by a fraction collector (Pharmacia LKB Super Frac).

Semipreparative HPLC. CCC fractions were purified on a preparative HPLC system from Knauer (Smartline 1000 HPLC pump, Smartline Manager 5000 solvent organizer and degasser, Wellchrom K-2600 UV detector). A Hypersil ODS C-18, 5 μm, 250 × 16 mm i.d. (M&W Chromatographietechnik GmbH, Berlin, Germany) semipreparative HPLC column was used for the isolation of proanthocyanidins. Water (solvent A) and acetonitrile (solvent B) were used as solvent systems. The flow rate was 6 mL/min. The following gradients were used for the isolation of proanthocyanidins: Gradient 1 for dimeric procyanidins B1 and B3 and dimeric prodelphinidin B2, 0 min, 8% B; 40 min, 25% B; 42 min, 100% B; 47 min, 100% B; 49 min, 8% B; 54 min, 8% B. Gradient 2 for dimeric procyanidins B2, B4, B5, and B7, 0 min, 10% B; 30 min, 30% B; 32 min, 100% B; 37 min, 100% B; 39 min, 10% B; 44 min, 10% B. Gradient 3 for dimeric procyanidin B6 and trimeric procyanidin C1, 0 min, 10% B; 40 min, 30% B; 42 min, 100% B; 47 min, 100% B; 49 min, 10%; 54 min, 10% B. Gradient 4 for dimeric procyanidin B8, 0 min, 10% B; 50 min, 35% B; 52 min, 100% B; 57 min, 100% B; 59 min, 10%; 64 min, 10% B. Gradient 5 for dimeric prodelphinidin B1, 0 min, 6% B; 50 min, 27% B; 52 min, 100% B; 57 min, 100% B; 59 min, 6% B; 65 min, 6% B. Gradient 6 for dimeric prodelphinidin B3, 0 min, 6% B; 40 min, 15% B; 42 min, 100% B; 47 min, 100% B; 49 min, 6% B; 54 min, 6% B. The fractions were monitored at λ = 280 nm. The purity of all compounds was confirmed by HPLC-PDA (>95%) at λ = 280 nm.

Phloroglucinolysis. Analysis was carried out according to the methods of Esatbeyoglu et al.[13] and Kennedy and Jones.[16] Phloroglucinol adducts (+)-catechin-(4α → 2)-phloroglucinol and (−)-epicatechin-(4β → 2)-phloroglucinol as reference compounds were obtained by HSCCC according to the method of Köhler and Winterhalter.[17]

Circular Dichroism. CD spectra were measured according to the method of Esatbeyoglu et al.[15]

Nuclear Magnetic Resonance (NMR) Spectroscopy. ^{1}H and ^{13}C NMR, ^{1}H−^{1}H correlated spectroscopy (COSY), ^{1}H−^{1}H phase-sensitive nuclear Overhauser enhancement spectroscopy (NOESY), heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC) experiments were performed at 300 or 240 K on a Bruker Avance ARX 400 NMR spectrometer equipped with a variable-temperature unit B VT-2000 (Rheinstetten, Germany). Samples were dissolved in acetone-d_6. Chemical shifts were

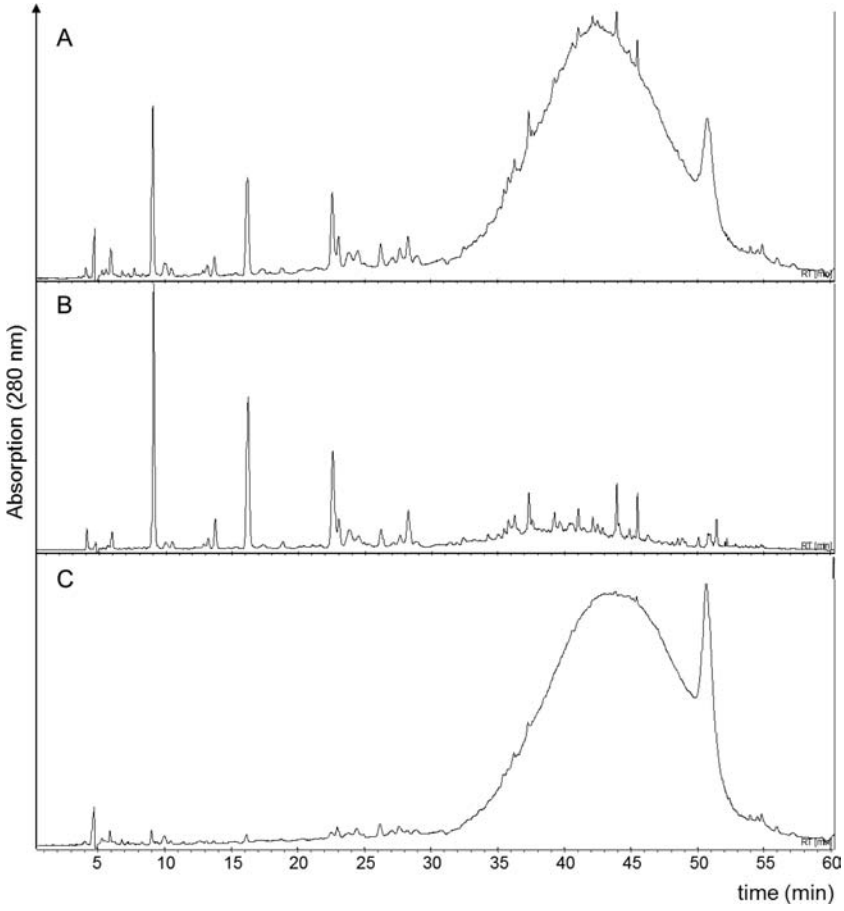

Figure 1. HPLC-PDA chromatograms at λ = 280 nm of the 70% acetone extract of hazelnut skins before (A) and after ethanol/*n*-hexane precipitation (B, filtrate; C, precipitate). Modified from Esatbeyoglu.[38]

referenced to the residual solvent signals and are reported in parts per million and coupling constants in hertz.

(−)-Epigallocatechin-4β → 8-(+)-catechin (dimeric prodelphinidin B1): amorphous white powder; λ_{max} = 228 and 276 nm; ESI-MS/MS *m/z* 593 $[M - H]^-$; MS/MS fragments *m/z* 575, 467, 425, 407, 303, 289, 245; CD (0.17 mmol/L in methanol) $[\theta]_{207}$ −84791, $[\theta]_{218}$ 84795, $[\theta]_{235}$ 35278, $[\theta]_{281}$ −5207.

■ RESULTS AND DISCUSSION

Initially, the defatted 70% acetone extract of hazelnut skins was precipitated with ethanol and *n*-hexane in a ratio of 5:13 (v/v). This allows an enrichment of higher oligomeric and polymeric proanthocyanidins in the precipitate and an enrichment of lower oligomeric proanthocyanidins in the filtrate. Figure 1 shows the HPLC-PDA chromatograms of 70% acetone extract of hazelnut skins before and after precipitation. The proportion of flavan-3-ol constituents in the upper and terminal units of the hazelnut skin precipitate was determined by phloroglucinolysis, as published earlier.[4,14] The analysis showed that 30.7 ± 0.55% (+)-catechin-(4α → 2)-phloroglucinol and 62.9 ± 1.45% (−)-epicatechin-(4β → 2)-phloroglucinol are present in the upper units of the polymeric proanthocyanidin fraction of hazelnut skins. Also, 3.67 ± 0.15% (−)-epigallocatechin and 2.97 ± 0.11% (+)-gallocatechin as part of the upper unit were detected.

To find the optimal reaction conditions for semisynthesis of dimeric procyanidins, the influence of the reaction time, temperature, and ratio of reagents such as nucleophile agent, that is, (+)-catechin and (−)-epicatechin, as well as the polymeric procyanidin fraction (hazelnut precipitate) was determined (data not shown). The optimal reaction conditions for semisynthetic studies were 30 min at 40 °C with a ratio of substrates of 1:2 (hazelnut precipitate and nucleophile agent). For LSRCCC separation a ratio of 1:1, because of the cost of (−)-epicatechin as nucleophile agent, was chosen. Under these conditions a maximum formation of dimeric procyanidins and a minimum formation of byproducts, that is, gambiriins (chalcan-flavan-3-ol derivatives) are observed. It is possible to semisynthesize all eight dimeric procyanidins B1−B8 (Figure 2). This is due to the flavan-3-ol compositions of the polymeric procyanidin fraction of the hazelnut skin precipitate, which is composed of 30.7% (+)-catechin and 62.9% (−)-epicatechin. After reaction with (+)-catechin, the amount of dimeric procyanidins B1, B3, B6, and B7 increased. With (−)-epicatechin as nucleophile agent dimeric procyanidins B2, B4, B5, and B8 are formed.

Fractionation of the Semisynthetic Reaction Mixture by HSCCC. The fractionation of the semisynthetic reaction mixture, carried out with (+)-catechin as a nucleophile agent, was performed by HSCCC using the solvent system ethyl acetate/*n*-butanol/water (14:1:15, v/v/v).[11] Figure 3A shows the results of the HSCCC separation. Fraction I contained mainly A-type dimeric prodelphinidin (−)-EGC-(2β → O7, 4β → 8)-(+)-C[15] and an unknown B-type dimeric prodelphinidin. Further unknown A- and B-type dimeric prodelphinidins were found in fraction II. About 50 mg of B1 (purity = 95.5%) was obtained from fraction III. Fraction IV was composed of two B-type trimeric procyanidins EC-4β → 8-EC-4β → 8-C and EC-4β → 6-EC-4β → 8-C.[13] Dimeric procyanidin B3 was enriched in fraction V (37.1 mg; 87.6%). For compounds with partition coefficients (*K* values) >2, which remained on the CCC coil, the more apolar two-phase solvent system was used for fractionation. The chromatogram of the CCC separation acquired at 280 nm is shown in Figure 3B. Fraction I did not

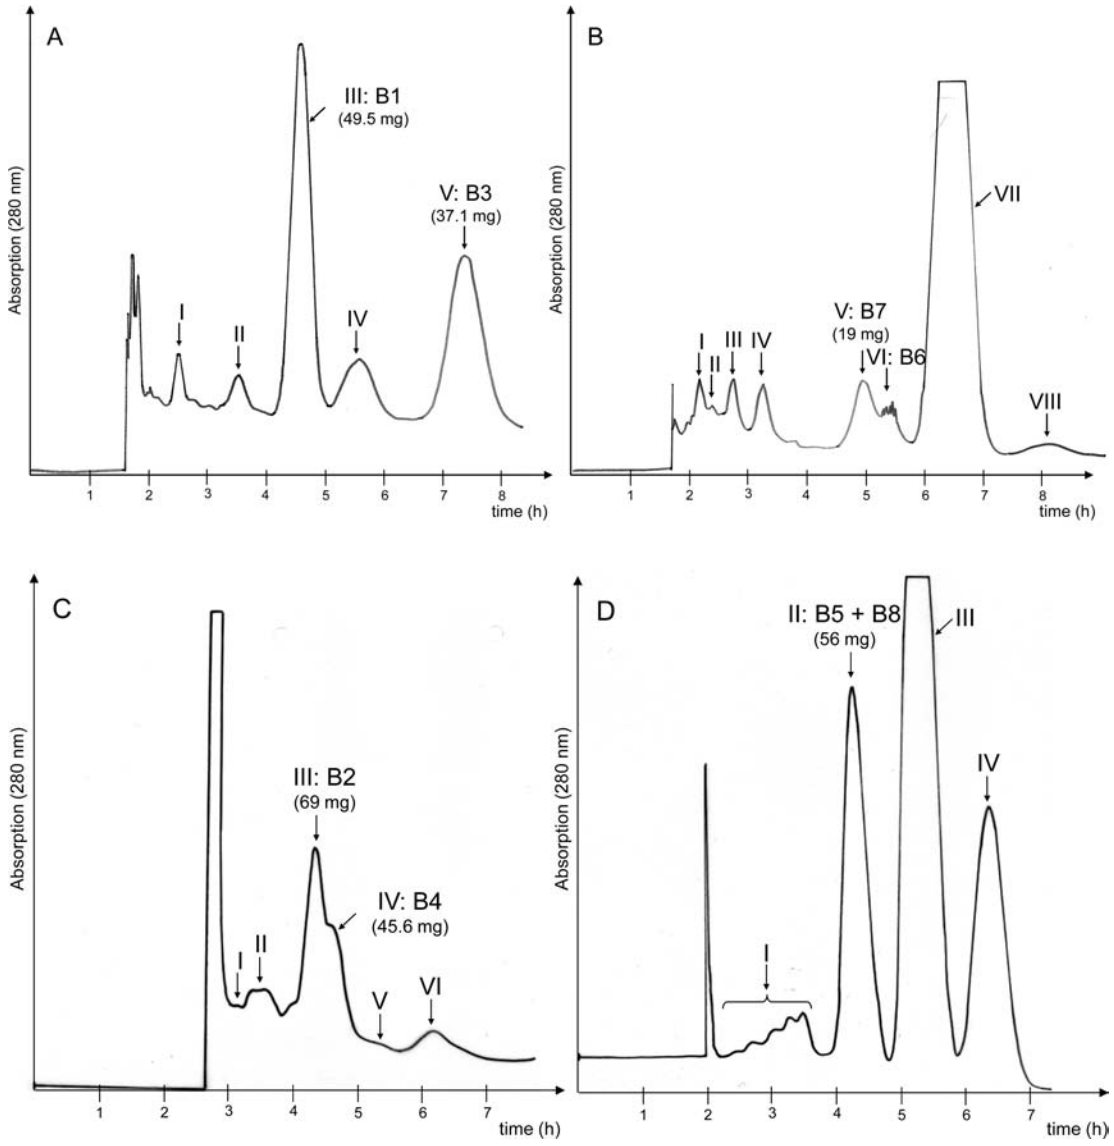

Figure 3. (A) HSCCC chromatogram of the reaction mixture of hazelnut skin precipitate and (+)-catechin. Sample load, 928 mg; solvent system, ethyl acetate/*n*-butanol/water (14:1:15, v/v/v); flow rate, 2.7 mL/min; revolution speed, 900 rpm. (B) HSCCC chromatogram of the coil (A). Sample load, 550 mg; solvent system, *n*-hexane/ethyl acetate/methanol/water (1:10:1:10, v/v/v/v); flow rate, 3 mL/min; revolution speed, 1000 rpm. (C) HSCCC chromatogram of the reaction mixture of hazelnut skin precipitate and (−)-epicatechin. Sample load, 1000 mg; solvent system, ethyl acetate/isopropanol/water (20:1:20, v/v/v); flow rate, 3 mL/min; revolution speed, 1000 rpm. (D) HSCCC chromatogram of the coil (C). Sample load, 395 mg; solvent system, *n*-hexane/ethyl acetate/methanol/water (1.2:10:1.2:10, v/v/v/v); flow rate, 2.7 mL/min; revolution speed, 1000 rpm. Modified from Esatbeyoglu.[38]

contain any relevant compounds. Fraction II contained mainly trimeric procyanidin C1. In fraction III unknown compounds, that is, galloylated dimeric procyanidins (m/z 729 $[M - H]^-$),[8] A-type trimeric procyanidin (m/z 863 $[M - H]^-$), B-type dimeric propelargonidin (m/z 561 $[M - H]^-$), and an A-type dimeric prodelphinidin (m/z 591 $[M - H]^-$) were enriched. The byproduct gambiriin A1 was found in fraction IV. Fraction V consisted of dimeric procyanidin B7 (18.8 mg, purity = 82.6%). B6 was enriched in fraction VI (10.8 mg, purity = 26.1%). Unreacted (+)-catechin was obtained from fraction VII (purity = 99.0%). The last fraction contained the second byproduct gambiriin A3.

To isolate dimeric procyanidins B2, B4, B5, and B8 the reaction mixture of the semisynthesis carried out with (−)-epicatechin was separated with the solvent system ethyl acetate/isopropanol/water (20:1:20, v/v/v) (Figure 3C). Fraction I contained several compounds, that is, B-type trimeric procyanidin, two B-type dimeric prodelphinidins, and two A-type dimeric prodelphinidins. One dimeric prodelphinidin was identified as EGC-4β → 8-EC (see below) and one A-type dimeric prodelphinidin as EGC-(2β → O5, 4β → 6)-C.[15] Fraction II contained compounds similar to those of fraction I. Two B-type trimeric procyanidins were identified as EC-4β → 6-EC-4β → 8-EC and trimer C1 (EC-4β → 8-EC-4β → 8-EC).[13] B2 was enriched (69 mg; purity = 88.7%) in fraction III and B4 in fraction IV (45.6 mg, purity = 70.5%). Fraction V consisted of A- and B-type dimeric prodelphinidins, an A-type dimeric procyanidin, and a trimeric procyanidin. A galloylated dimeric procyanidin (m/z 729 $[M - H]^-$)[8] was enriched in fraction VI. This CCC separation was repeated twice. Coil fractions of two CCC separations were divided into five fractions, and fraction II and III were combined to isolate B5

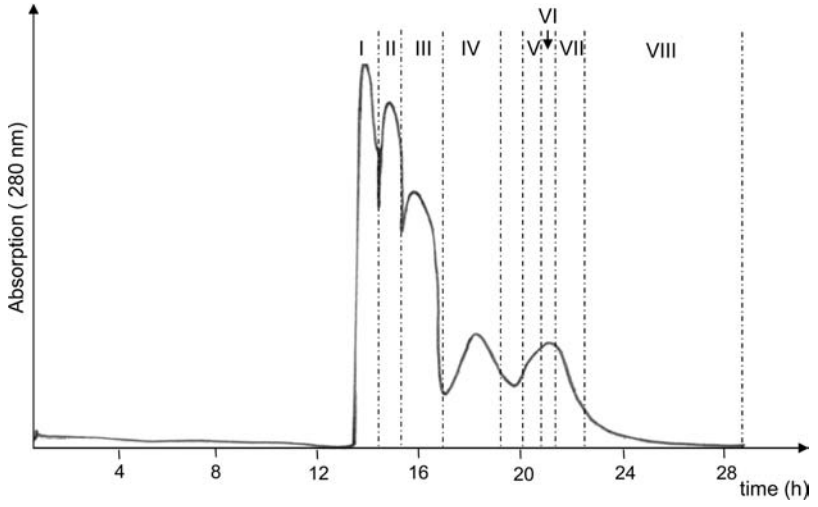

Figure 4. LSRCCC chromatogram of the filtrate of the reaction mixture of hazelnut skin precipitate and (+)-catechin after ethanol/*n*-hexane precipitation (5:13, v/v) (LSRCCC-1). Sample load, 9.58 g; solvent system, *tert*-butyl methyl ether/*n*-butanol/water (4.3:0.7:5, v/v/v); flow rate, 5 mL/min; revolution speed, 50 rpm; elution mode, U−H (upper organic phase as mobile phase; head to tail). Modified from Esatbeyoglu.[38]

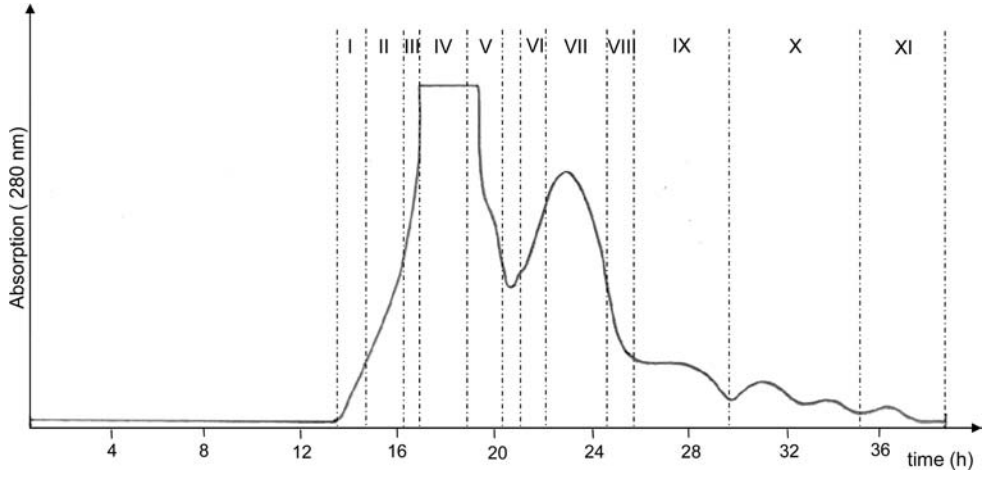

Figure 5. LSRCCC chromatogram of the reaction mixture of hazelnut skin precipitate and (−)-epicatechin (LSRCCC-2). Sample load, 12.4 g; solvent system, *tert*-butyl methyl ether/*n*-butanol/water (4.5:0.5:5, v/v/v); flow rate, 4 mL/min; revolution speed, 50 rpm; elution mode, U−H (upper organic phase as mobile phase; head to tail). Modified from Esatbeyoglu.[38]

and B8 (Figure 3D). The solvent system *n*-hexane/ethyl acetate/methanol/water (1.2:10:1.2:10, v/v/v/v) was selected for this separation. Fraction I was composed of polymeric procyanidins. Dimeric procyanidins B5 and B8 were found in fraction II (56 mg). High-purity (−)-epicatechin (98.4%) was recovered from fraction III, whereas fraction IV contained (+)-catechin (purity = 93.9%).

In summary, hazelnut skins are suitable substrates for semisynthesis of all eight B-type dimeric procyanidins B1−B8. To achieve a higher yield of dimeric procyanidins and enrichment of minor compounds, the separation of semisynthetic reaction mixture was carried out on a large scale by LSRCCC.

Fractionation of the Semisynthetic Reaction Mixture by LSRCCC. The reaction mixture, after semisynthesis with (+)-catechin, was precipitated with ethanol/*n*-hexane in a ratio of 5:13 (v/v). After filtration of this solution, the resulting filtrate (9.58 g) after evaporation and lyophilization was fractionated with the solvent system *tert*-butyl methyl ether/*n*-butanol/water (4.3:0.7:5, v/v/v) by LSRCCC. The first LSRCCC separation of procyanidins, from a semisynthetic reaction mixture of a commercial grape seed extract with (+)-catechin, has been described by Köhler.[18] In the current study, the isolation of proanthocyanidins from hazelnut skins after semisynthetic preparation was described for the first time. Figure 4 shows the LSRCCC separation of the filtrate of the reaction mixture of hazelnut skin precipitate and (+)-catechin after ethanol/*n*-hexane precipitation. The collected fractions were analyzed by HPLC-PDA at λ = 280 nm and combined to eight fractions. The coil fraction, which was obtained by extrusion, was divided into three fractions. Figure S1 in the Supporting Information shows the composition of some selected LSRCCC fractions. Due to the similar *K* values of dimeric procyanidins B6 and B7, (+)-catechin, and (−)-epicatechin, all compounds eluted in fractions I−III. Fraction I was composed of various proanthocyanidins, that is, 65.7% (+)-catechin, 7.6% (−)-epicatechingallate, 7.1% dimeric procyanidin B7 (coelution with gambiriin A3), and 2.0% dimeric procyanidin B6. Smaller amounts of A-type dimeric prodelphinidins, A-type trimeric proanthocyanidins (*m*/*z* 879 $[M - H]^-$ (Epi)C-(Epi)C-(Epi)GC, tentatively), B-type dimeric propelargonidins, and prodelphinidins [(Epi)GC-

dx.doi.org/10.1021/jf501312a | J. Agric. Food Chem. 2014, 62, 7101−7110

(Epi)GC (m/z 609 [M − H]$^-$)] as well as galloylated dimeric procyanidins (m/z 729 [M − H]$^-$) were found. From this fraction EGC-(2β → O5, 4β → 6)-C[15] and dimeric procyanidin B6 were isolated with the solvent system *n*-hexane/ethyl acetate/methanol/water (1.4:10:1.4:10, v/v/v/v) by HSCCC (data not shown). Fraction II was composed of 88.8% (+)-catechin, 4.2% dimeric procyanidin B7, 1.4% (−)-epicatechin, and 1.1% dimeric procyanidin B6. About 90% (+)-catechin, 3.9% (−)-epicatechin, and 2.0% dimeric procyanidin B7 were enriched in fraction III. Fraction IV contained dimeric procyanidin B3 (560 mg; purity = 76.9%). Fraction V consisted of 67.0% dimeric procyanidin B1 (168 mg) and the trimeric procyanidins EC-4β → 8-EC-4β → 8-C and EC-4β → 6-EC-4β → 8-C.[13] About 600 mg of dimeric procyanidin B1 was obtained from fractions VI and VII (purity = 81.1 and 90.1%, respectively). In fraction VIII dimeric procyanidin B1, A- and B-type dimeric prodelphinidins, B-type trimeric procyanidin, and a further A-type trimeric proanthocyanidin (m/z 879 [M − H]$^-$ (Epi)C-(Epi)C-(Epi)GC) were enriched. GC-4α → 8-C was isolated from this fraction by preparative HPLC. EGC-4β → 8-C and EGC-(2β → O7, 4β → 8)-C were obtained from coil fractions I and II. The structures of these B-type dimeric prodelphinidins are elucidated by NMR spectroscopy (see below). Trimeric procyanidin EC-4β → 8-C-4α → 8-C was enriched (276 mg; purity = 62.0%) in coil fraction III.[13]

Dimeric procyanidins B2, B4, B5, and B8 were isolated from the reaction mixture of the semisynthesis carried out with (−)-epicatechin and hazelnut skin precipitate by LSRCCC. To eliminate the polymeric compounds, the reaction mixture was treated with ethanol/*n*-hexane (5:13, v/v). This solution was filtered, and the obtained filtrate after evaporation and lyophilization was fractionated with the solvent system *tert*-butyl methyl ether/*n*-butanol/water (4.5:0.5:5, v/v/v). The LSRCCC separation is shown in Figure 5. After separation by elution as well as extrusion and analysis of selected samples by HPLC-PDA, 11 fractions from the elution and five coil fractions from the extrusion were obtained. Selected fractions are depicted in Figure S2 in the Supporting Information. Fraction I contained the more apolar compounds gambiriin A5, (−)-epicatechingallate, galloylated dimeric procyanidin, and (epi)afzelechin. (Epi)afzelechin is until now unknown for hazelnut skins.[2,8,9,19] Besides the compounds found in fraction I, fraction II contained dimeric procyanidins B5 and B8, (+)-catechin, and (−)-epicatechin. Fraction III was composed mainly of (−)-epicatechin (37.5%), (+)-catechin (28.1%), dimeric procyanidins B5 (13.0%), and B8 (3.7%). Besides these dimeric procyanidins, 83.4% (−)-epicatechin was obtained from fraction IV. Compounds in fractions I− IV show similar *K* values. For further isolation of compounds in fractions I−IV, separation was performed with HSCCC (data not shown). The main compound in fraction V was (−)-epicatechin (82.5%), and one B-type galloylated dimeric procyanidin was detected in minor amounts, as well. Fraction VI consisted of target compounds B2 (23.5%) and B4 (33.6%) as well as EC-4β → 8-EC-4β → 6-EC (5.1%).[13] Fraction VII contained dimeric procyanidins B2 and B4 in large amounts of 740 and 350 mg, respectively (calculated at λ = 280 nm by HPLC-PDA). Fraction VIII was composed of 44.3% dimeric procyanidin B2 and 10.9% B-type trimeric procyanidin C1, whereas fraction IX contained about 70% trimeric procyanidin C1. Up to 110 mg of procyanidin trimer C1 was isolated from this fraction. One B-type galloylated dimeric prodelphinidin (m/z 745 [M − H]$^-$) was also detected in smaller amounts. The main compound in fraction X was EC-4β → 6-EC-4β → 8-EC,[13] together with dimeric procyanidin B1 and A-type trimeric proanthocyanidin (m/z 879 [M − H]$^-$ (Epi)C-(Epi)C-(Epi)GC). The last fraction was composed of A- and B-type dimeric prodelphinidins as well as two B-type trimeric proanthocyanidins (m/z 881 [M − H]$^-$, according to ref 2 tentatively (Epi)GC-(Epi)C-(Epi)C). B-type dimeric prodelphinidin (−)-EGC-4β → 8-(−)-EC was isolated from coil fraction I, and its structure was elucidated by NMR spectroscopy (see below). This minor compound occurred naturally in hazelnut skins, confirmed by LC-MS/MS, and is described for the first time in this study. Smaller amounts of A- and B-type dimeric prodelphinidins (with (epi)gallocatechin as upper unit), trimeric proanthocyanidins, and trimeric proanthocyanidins (Epi)GC-(Epi)C-(Epi)C and (Epi)C-(Epi)GC-(Epi)C were identified by LC-MS/MS. Similar compounds were found in coil fractions II−IV. The last coil fraction contained EC-4β → 8-C-4α → 8-EC[13] and small amounts of a B-type trimeric proanthocyanidin (m/z 897 [M − H]$^-$, according to ref 20 tentatively (Epi)GC-(Epi)GC-(Epi)C).

C4 → C8 linked dimeric procyanidins B1 and B3 (about 600 mg; purity = 76.9−90.1%) as well as dimeric procyanidins B2 and B4 (740 and 350 mg) were isolated in large amounts for the first time. Dimeric procyanidins B5−B8 are formed in lower amounts because of steric hindrance.[21−23] Moreover, the semisynthesis of different B-type trimeric procyanidins (EC-4β → 8-EC-4β → 8-C, EC-4β → 6-EC-4β → 8-C, EC-4β → 6-EC-4β → 8-EC, trimer C1 (EC-4β → 8-EC-4β → 8-EC), EC-4β → 8-C-4α → 8-C, EC-4β → 8-EC-4β → 6-EC and EC-4β → 8-C-4α → 8-EC) was shown.

The structure of the minor compounds such as A- and B-type dimeric prodelphinidins EGC-4β → 8-EC, EGC-4β → 8-C, GC-4α → 8-C, EGC-(2β → O7, 4β → 8)-C, and EGC-(2β → O5, 4β → 6)-C are elucidated by NMR spectroscopy[13,15] and were described in hazelnut skins for the first time as well as dimeric prodelphinidins composed of (Epi)GC-(Epi)GC (m/z 609 [M − H]$^-$). Further unknown A- and B-type dimeric prodelphinidins (m/z 591 and 593 [M − H]$^-$) and B-type galloylated dimeric prodelphinidins (m/z 745 [M − H]$^-$) were detected. To date, the occurrence of prodelphinidins in hazelnuts was known, but not their exact structures and their galloylated forms.[2,4,8] The detection of the flavan-3-ol (epi)-afzelechin, B-type dimeric propelargonidins (m/z 561 [M − H]$^-$) and A-type dimeric procyanidin (m/z 575 [M − H]$^-$) were detected for the first time in hazelnut skins. Recently, the occurrence of A- and B-type trimeric proanthocyanidins consisting of (epi)catechin, (epi)gallocatechin, and (epi)-catechingallate units was described in roasted hazelnut skins.[8,9] In the present study, different types of proanthocyanidins such as an A-type trimeric procyanidin (m/z 863 [M − H]$^-$), A-type trimeric proanthocyanidins (m/z 879 [M − H]$^-$ tentatively (Epi)C-(Epi)C-(Epi)GC), and B-type trimeric proanthocyanidins (m/z 881 [M − H]$^-$ tentatively (Epi)GC-(Epi)C-(Epi)C and (Epi)C-(Epi)GC-(Epi)C; m/z 897 [M − H]$^-$ tentatively (Epi)GC-(Epi)GC-(Epi)C) were identified in hazelnut skins. The natural occurrence of these compounds in hazelnut skins was confirmed by LC-MS/MS by analyzing the hazelnut skin filtrate, which was obtained after precipitation of the 70% acetone extract.

Structure Elucidation of B-Type Dimeric Prodelphinidins. B-type dimeric prodelphinidins (−)-EGC-4β → 8-(+)-C, (−)-EGC-4β → 8-(−)-EC, and (+)-GC-4α → 8-(+)-C were

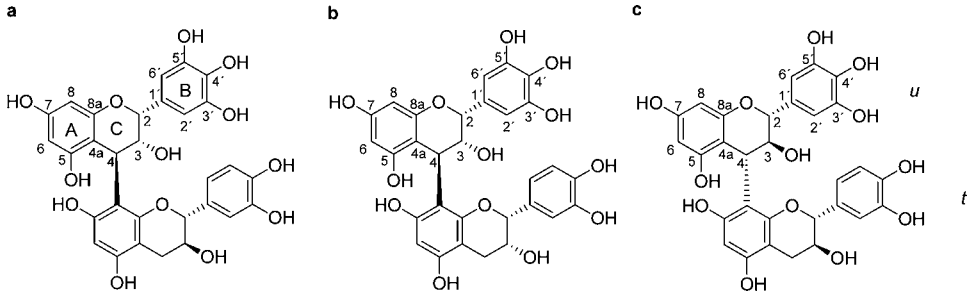

Figure 6. Chemical structures of the dimeric prodelphinidins B1 (a), B2 (b), and B3 (c). *u*, upper; *t*, terminal.

isolated as white amorphous solids from coil fraction I (LSRCCC-1 and LSRCCC-2) and fraction VIII (LSRCCC-1) of the LSRCCC separation after purification by preparative HPLC. Their chemical structures are shown in Figure 6. The structure of these compounds was determined on the basis of electrospray ionization mass spectrometry as well as by 1D and 2D ^{1}H NMR spectroscopic analysis that included COSY and NOESY. 1D and 2D ^{13}C NMR spectroscopy (HSQC, HMBC) were used for structure determination of (+)-GC-4α → 8-(+)-C, as well. All ^{1}H NMR spectra for (−)-EGC-4β → 8-(+)-C and (−)-EGC-4β → 8-(−)-EC were recorded at 240 K (400 MHz, acetone-d_6), and all ^{1}H and ^{13}C NMR spectra (400 and 100 MHz, respectively) of (+)-GC-4α → 8-(+)-C were recorded in acetone-d_6 at 300 K. Chemical shifts and coupling constants are given under Materials and Methods.

LC-MS/MS analysis yielded a molecular ion of $[M - H]^-$ m/z 593 with fragment ions m/z 575, 467, 425, 407, 303, 289, and 245, which indicated the presence of a B-type prodelphinidin (Supporting Information Figure S3). On the basis of the fragment ions m/z 425 and 289 derived from the quinone-methide cleavage and absence of m/z 305, it was concluded that (epi)gallocatechin was the upper unit and (epi)catechin the terminal unit.[2,20,24]

NMR spectra of dimeric prodelphinidins are similar to those of dimeric procyanidins.[25,26] Structure elucidation was performed as in refs 13 and 15, and only relevant data are shown here.

The relative configuration of both units was determined from the magnitude of the coupling constants $J_{2,3}$ and $J_{3,4}$ of the heterocyclic protons (C-ring).[27−32] EGC-4β → 8-C showed a 2,3-*cis*-3,4-*trans*- and 2,3-*trans*-configuration, EGC-4β → 8-EC a 2,3-*cis*-3,4-*trans*- and 2,3-*cis*-configuration, and GC-4α → 8-C a 2,3-*trans*-3,4-*trans*- and 2,3-*trans*-configuration.

Proton singlets at about δ 6.41, 6.45, and 6.55 (H2′ and H6′ are chemically equivalent) are evidence of trihydroxylated B-rings (pyrogallol ring: 3′,4′,5′-substitution) of the upper unit. All C-ring protons were assigned from inspection of COSY spectra. Long-range correlations between H2′ and H6′ (B-ring) as well as H2 (C-ring) allowed the identification of B- and C-rings of both units. Only one proton for H4 of the upper unit was determined. This observation confirmed (epi)gallocatechin as the upper unit.

NOE correlations of H2′ and H6′ of the terminal unit with H4 of the upper unit were characteristic of a 4 → 8 interflavanoid linkage. All compounds are linked C4 → C8. Due to the absence of NOE correlations between H2 and H4, the terminal unit is bound quasi-axially in EGC-4β → 8-EC and EGC-4β → 8-C. Detection of NOE correlations between H2 and H4 indicated that the terminal unit of GC-4α → 8-C is bound quasi-equatorially.

Compound EGC-4β → 8-EC showed a major rotamer (90%) and a minor rotamer (10%), whereas no rotamers were detected for EGC-4β → 8-C. The presence of (+)-gallocatechin in the upper unit leads to hindered rotation around the interflavanoid linkage, producing two major rotational isomers in a ratio of about 1:1 (55 to 45%). This leads to signal duplication in ^{1}H and ^{13}C NMR spectra at 300 K. In addition to EGC-4β → 8-EC and EGC-4β → 8-C, one- and two-dimensional ^{13}C NMR spectra were recorded for GC-4α → 8-C. H2′ and H6′ protons of the trihydroxylated B-ring C atoms ((epi)gallocatechin) showed a signal at about δ_C 108.0. Inspection of the region δ_C 115−120 show the signals of H2′, H5′, and H6′ of the dihydroxylated B-ring C atoms ((epi)catechins).[33−35] Signals at δ_C 83.0 and 84.0 suggested the 2,3-*trans* configuration of both units.[27] The observed data were in accordance with literature data.[34] The presence of two rotamers (25 °C, 500 MHz, acetone-d_6) was described later by Karonen et al.[26]

Structure Elucidation by Phloroglucinolysis and CD. The flavan-3-ol units and the interflavanoid bond of these compounds were confirmed by phloroglucinolysis. Degradation of >70% indicated a 4 → 8 interflavanoid linkage of these B-type dimeric prodelphinidins. Mild degradation yielded for compound EGC-4β → 8-EC 20.1% EGC-phloroglucinol for the upper unit and 54% EC for the terminal unit. EGC-4β → 8-C gave 18.2% EGC-phloroglucinol and 53.9% C and GC-4α → 8-C, 26.0% GC-phloroglucinol and 64.9% C. Moreover, these results indicated that 4 → 8-linked B-type dimeric prodelphinidins with (+)-gallocatechin in the upper unit were cleaved more quickly than those with (−)-epigallocatechin in the upper unit.

The absolute configuration at positions C2 and C4 was determined by CD spectra. All compounds ((−)-EGC-4β → 8-(+)-C, (−)-EGC-4β → 8-(−)-EC, (+)-GC-4α → 8-(+)-C) with 2*R* absolute stereochemistry showed a negative Cotton effect at 280 nm. Compounds (−)-EGC-4β → 8-(+)-C and (−)-EGC-4β → 8-(−)-EC showed a positive Cotton effect at 220−240 nm, indicating the 2β-4β-orientation (4*R* configuration).[36] However, the 2α−4α orientation (4*S* configuration) in (+)-GC-4α → 8-(+)-C was confirmed by the negative Cotton effect at 220−240 nm.

To date, the structure elucidation of these three dimeric prodelphinidins was done by ^{13}C NMR spectroscopy and acid-catalyzed degradation or ^{1}H NMR spectroscopy after derivatization (i.e., peracetylation), whereas Malik et al.[37] elucidated only the structure of EGC-4β → 8-EC by ^{1}H NMR spectroscopy without derivatization or degradation. Here, we describe to the best of our knowledge the NMR and assignment of the interflavanoid bond from ROESY spectra of B-type dimeric prodelphinidins for the first time in detail.

Structure elucidation was performed without the necessity of derivatization and degradation (i.e., phloroglucinolysis), ^{1}H NMR spectroscopy was sufficient.

oxidation of phenolic hydroxyls leading to the formation of *O*-quinone via semiquinone form. Therefore, it may be argued whether these four easily oxidized phenolic acids are true representatives of "total phenolic acids" having diverse oxidation potentials.

There is very limited study about the usage of GC electrodes as electrochemical TAC sensors. Milardović et al. developed an amperometric antioxidant activity method, based on the reduction of 2,2′-diphenyl-1-picrylhydrazyl radical ($DPPH^{\bullet}$) at the GC electrode; because the cyclic voltammograms of a number of water- and ethanol-soluble common antioxidants gave either irreversible or undefined oxidation peaks, electrochemical reduction of $DPPH^{\bullet}$ was conducted in the presence and absence of antioxidants, but potential selection was critical due to the electrochemical interferences of caffeic acid and trolox.[9] The electrochemical $ABTS^{\bullet+}$ assay is based on measuring catalytic voltammetric currents caused by antioxidants acting as reductant toward the electrochemically generated $ABTS^{2+}$ (thereby enabling reoxidation of $ABTS^{\bullet+}$ on the electrode) in edible oils; this method produced rather high blank values in the trolox calibration curve, and trolox addition to sunflower oil matrices did not yield perfectly linear responses.[10]

It may be argued that novel electrochemical TAC methods should be based on indirect determinations, that is, on the redox behavior of a single electroactive species capable of reacting with antioxidants with a definite stoichiometry and kinetics, because, otherwise, irreversible or undefined peaks of phenolics oxidation may emerge within a range of potentials, making an evaluation of the results obtained with complex samples very difficult and sometimes inaccurate. Although an electrochemical CUPRAC method (based on CV and chronoamperometry) of antioxidant analysis has very recently been published,[11] it does not cover a wide range of antioxidant compounds, and there is no DPV method in the literature for the determination of cupric reducing antioxidant capacity of complex samples. Therefore, the aims of this study are to develop a new electrochemical technique using DPV–CUPRAC methodology for pure phenolic antioxidants, ascorbic acid, and their complex matrices such as herbal teas and to compare the results obtained by the proposed assay with those obtained by spectrophotometric CUPRAC assay. Compared to other chromogenic reagents of similar properties (i.e., $DPPH^{\bullet}$ and $ABTS^{\bullet+}$), the CUPRAC reagent has been shown to be much less dependent on phenolic lipophilicity, steric effects of accessibility, solvent composition, pH, dissolved oxygen, and daylight.[12]

MATERIALS AND METHODS

Chemicals. The following chemicals of analytical reagent grade were supplied from the corresponding sources: copper(II) chloride, ammonium acetate, hydrochloric acid, sodium hydroxide, potassium chloride, ascorbic acid, and syringic acid were purchased from Merck Chemicals (Darmstadt, Germany); gallic acid, neocuproine, chlorogenic acid, (−)epicatechin, *p*-coumaric acid, quercetin, ferulic acid, vanillic acid, trolox, acetic acid, nitric acid, methanol, and absolute ethanol were supplied from Sigma-Aldrich Chemicals (Steinheim, Germany); (−)-catechin and kaempferol were obtained from Fluka (Buchs, Switzerland).

Samples and Standards. The herbal tea samples (green tea, marjoram, sage, and alchemilla) were obtained from local markets (Istanbul, Turkey). The fine dried herbal tea samples were extracted with the aid of a microwave-assisted extraction (MAE) system (Milestone ETHOS ONE, Shelton, CT, USA). MAE was utilized in 12 Teflon closed vessels with an automatic fiber optic temperature control system; dried sample (0.5 g) was extracted with 10 mL of $EtOH/H_2O$ (4:1, v/v) mixtures at 80 °C for 3 min after 3 min of temperature balancing time, and the microwave power (0−1500 W) was adjusted automatically according to temperature (5 min). The obtained ethanolic extracts were filtered through a filter paper, then through 0.45 μm PTFE syringe filters (Whatman), and kept at 4 °C until use. All standard solutions of antioxidant polyphenols were initially prepared in absolute EtOH at a concentration of 10 mM and diluted (to 1 mM) using bidistilled water (Millipore Synergy UV, Molsheim, France). Thus, the polyphenol working solutions were finally in 10% EtOH medium, except quercetin, which was finally prepared in 50% EtOH due to the aqueous solubility limitation. All standard solutions were stored at −20 °C prior to analysis. For spectrophotometric measurements, $CuCl_2$ solution (10 mM) and ammonium acetate buffer solution (1 M, pH 7.0) were prepared in bidistilled water, and neocuproine solution (7.5 mM) was prepared in EtOH. For electrochemical measurements, $CuCl_2$ solution (2 mM) and acetic acid/acetate buffer solution (supporting electrolyte, 0.1 M, pH 4.76) were prepared in bidistilled water, and neocuproine solution (4 mM) was prepared in EtOH.

DPV–CUPRAC Assay (Proposed Method). DPV was performed using a potentiostat model Reference 600 (Potentiostat/Galvanostat/ZRA, Gamry) in a three-electrode configuration, employing a GC electrode (Gamry, 3 mm disk, 7 mM OD) as the working electrode, platinum wire as the counter electrode, and Ag/AgCl (∼5 mol/L KCl) as the reference electrode. The GC electrode was polished before electrochemical measurements; that is, the electrode surface was manually polished with an alumina suspension (Baikowski Int. Corp.; 0.05 μm) on polishing cloth for 2 min and rinsed with distilled water; then, the electrode was immersed in $EtOH/H_2O$ (1:1, v/v) mixture, transferred to an ultrasonication bath for 3−4 min, and rinsed with ultrapure water. Finally, the electrode was immersed in distilled water and ultrasonication was repeated.

The required volume of antioxidant standards and samples (herbal tea extracts) was added by micropipet into a mixture solution of the supporting electrolyte and Cu(II)−Nc chelate in the electrochemical cell. The reaction mixture was left to react for ∼1 min on a stirrer at room temperature. The voltammograms were recorded immediately to minimize adsorption of polyphenols (or other electroactive species) onto the GC electrode surface. DPV conditions were as follows: scan range, from +0.6 to −0.25 V; pulse size, 50 mV; step size, 4 mV; pulse time, 0.1 s; and sample period, 0.5 s. The cyclic voltammograms were recorded on a freshly polished GC electrode by scanning the potential from +0.8 to −0.2 V at a scanning rate of 40 mV/s.

The TAC values of herbal teas were determined by DPV experiments, and the results were expressed as millimoles of trolox equivalents per gram of tea (mmol TE/g tea). The standard calibration curves of trolox and other phenolics were obtained by measuring the currents (I_p) at the cathodic reduction peak potential of the $Cu(Nc)_2^{2+}/Cu(Nc)_2^{+}$ redox couple before and after reaction with antioxidants, taking the difference (ΔI_p), and plotting this difference versus concentration of antioxidant standard.

Spectrophotometric CUPRAC Assay. The spectrophotometric CUPRAC method described by Apak et al. is based on the reduction of a cupric neocuproine complex (Cu(II)−Nc) by antioxidants to the highly colored cuprous form (Cu(I)−Nc).[12] One milliliter of $CuCl_2$, 1 mL of Nc solution, and 1 mL of NH_4Ac solution were added to x mL of the analyte, followed by $(1.1-x)$ mL of H_2O. The absorbance of the final solution (of 4.1 mL total volume) at 450 nm was read against a reagent blank after 30 min of standing at room temperature. The absorption measurements were recorded in matched quartz cuvettes using a Varian CARY Bio 100 UV−vis spectrophotometer (Mulgrave, Victoria, Australia) having a spectral resolution of ≈1 nm. The calibration curves (absorbance versus concentration graphs) of each antioxidant were constructed under the described conditions, and their TEAC coefficients, found as the ratio of the molar absorptivity of the concerned compound to that of trolox in the CUPRAC assay, were calculated. All spectrophotometric analyses were carried out in triplicate and performed at room temperature.

Statistical Analysis. Statistical analyses were realized using Excel software (Microsoft Office 2002) for calculating the means and the standard errors of the means. Results were expressed within 95% confidence interval as mean ± ($t_{0.05}s/n^{1/2}$), where $t_{0.05}$ is the Student's table t value for 4 degrees of freedom and s is the standard deviation of n = 5 measurements. Using SPSS software for Windows (version 13), the data were interpreted by two-way analysis of variance (ANOVA).[13]

RESULTS AND DISCUSSION

Electrochemical Behavior of $Cu(Nc)_2^{2+}$ Reagent. The cyclic voltammogram of $Cu(Nc)_2^{2+}$ reagent (prepared in 1:2 molar ratio of metal to ligand, i.e., 2 mL of 2 mM Cu(II) + 2 mL of 4 mM Nc) in 6 mL of 0.1 M acetic acid/acetate buffer solution (supporting electrolyte, pH 4.76) at a glassy carbon electrode shows the existence of $Cu(Nc)_2^{2+}/Cu(Nc)_2^{+}$ redox couple (Figure 1). An oxidation (anodic) peak appeared at

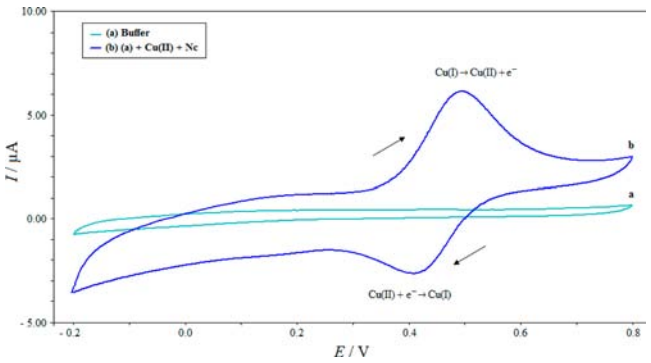

Figure 1. Cyclic voltammogram of $Cu(Nc)_2^{2+}$ reagent (scan rate = 40 mV/s): (a) acetic acid/acetate buffer solution (0.1 M, pH 4.76) (supporting electrolyte); (b) acetic acid/acetate buffer solution + 0.4 mM Cu(II) + 0.8 mM Nc. CV scan was made negatively from +0.8 to −0.2 V (one cycle) and at a rate of 40 mV/s.

approximately 0.5 V and a reduction (cathodic) peak at approximately 0.41 V. Compared to the electrochemical CUPRAC method of Cárdenas et al. carried out in pH 7 ammonium acetate buffer,[11] it can be clearly seen from the voltammogram in Figure 1 that pH 4.76 acetate buffer produced better electrochemical reversibility.

Figure 2 shows the DPVs of copper(II), cupric−neocuproine complex, and trolox in acetic acid/acetate buffer medium and under identical conditions. It is apparent from this figure that the presence of 2 equiv of neocuproine per 1 equiv of copper(II) leads to a substantial change (of about 0.43 V) in the potential of the Cu(II)/Cu(I) redox couple due to the selective stabilization of tetrahedral cuprous state by neocuproine (i.e., the logarithmic stability constants of the concerned copper chelates, $Cu(Nc)_2^{2+}$ and $Cu(Nc)_2^{+}$, have been reported as 12 and 19, respectively).[14] The reduction potential of the cupric−neocuproine complex was found at approximately 0.41 V with DPV. The peak current of cupric−neocuproine (Figure 2d) decreased as a result of reaction with trolox (Figure 2e) without a significant shift in reduction potential.

Electrochemistry of $Cu(Nc)_2^{2+}$ Reagent in the Presence of Trolox. Concentrations of trolox >0.001 mM led to a corresponding decrease of the cathodic peak currents (see Figure 3A,B). When trolox is added in the electrochemical cell containing $Cu(Nc)_2^{2+}$, it is easily oxidized to the quinone form, whereas Cu(II)−Nc is reduced to the highly colored Cu(I)−Nc chelate. As the concentration of trolox increases, the

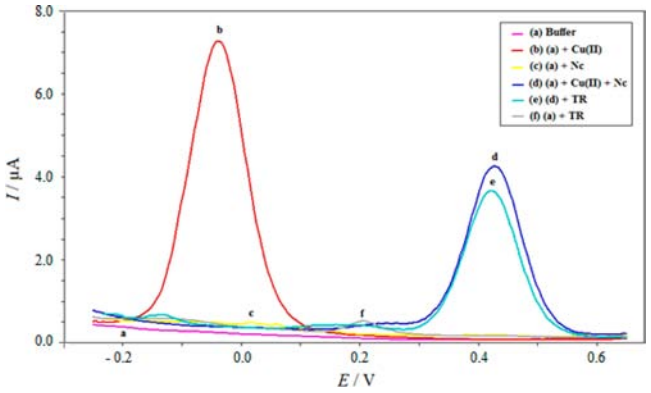

Figure 2. Differential pulse voltammograms of (a) acetic acid/acetate buffer solution (0.1 M, pH 4.76) (supporting electrolyte), (b) acetic acid/acetate buffer solution + 0.4 mM Cu(II), (c) acetic acid/acetate buffer solution + 0.8 mM Nc, (d) acetic acid/acetate buffer solution + Cu(II) + Nc, (e) acetic acid/acetate buffer solution + Cu(II) + Nc + 0.08 mM TR, and (f) acetic acid/acetate buffer solution + 0.08 mM TR. Scans range from +0.7 to −0.25 V; pulse size, 50 mV; step size, 4 mV; pulse time, 0.1 s, and sample period, 0.5 s.

cathodic voltammetric currents decrease further, because the $Cu(Nc)_2^{2+}$ complex in the media is reduced to the $Cu(Nc)_2^{+}$ form in proportion to trolox. Thus, the initial amount of $Cu(Nc)_2^{2+}$ cannot be maintained upon trolox addition, causing a pronounced decrease in cathodic currents (Figure 3A,B). On the other hand, with increasing trolox concentrations, more $Cu(Nc)_2^{+}$ will be produced, and its electrochemical oxidation (anodic peak) currents at approximately 0.5 V show a slight increase (Figure 3A). The decrease in cathodic peak current upon trolox addition is taken as a measure of trolox concentration (Figure 3C). The dependence of ΔI_p on trolox concentration (C_{TR}) is presented in Figure 3C, where ΔI_p is defined as the difference between the measured DPV peak currents in the absence of trolox ($I_{p,0}$) and in the presence of corresponding trolox concentrations ($I_{p,x}$), that is, $\Delta I_p = I_{p,0} - I_{p,x}$. The calibration equation corresponding to the regression line as ΔI_p versus C_{trolox} using the DPV method was $\Delta I_p/\mu A = 46.66 C_{TR}/\text{mmol L}^{-1} + 0.019$. This equation was also used for TAC determination of herbal teas, reported as trolox equivalents.

The linear concentration range for trolox in the proposed method was 0.001−0.005 mM (correlation coefficient r = 0.9995, N = 5), within which the relative standard deviation (RSD) was 3.1%. The limit of detection (LOD) and the limit of quantification (LOQ) were calculated using the equations LOD = $3s_{bl}/m$ and LOQ = $10s_{bl}/m$, respectively, where s_{bl} is the standard deviation of a blank and m is the slope of the calibration line. The LOD and LOQ for trolox were found as 0.18 and 0.61 μM, respectively.

Determination of Polyphenols by Voltammetric and Spectrophotometric Methods. The chromogenic oxidizing reagent of the spectrophotometric CUPRAC method, that is, (Cu(II)−Nc) chelate, reacts with n-electron reductant antioxidants (AO) in the following reaction:[12,15]

$$n\text{Cu(Nc)}_2^{2+} + n\text{-electron reductant (AO)} \rightarrow n\text{Cu(Nc)}_2^{+} + n\text{-electron oxidized product} + n\text{H}^{+} \quad (1)$$

In this reaction, the reactive Ar−OH groups of polyphenolic antioxidants are oxidized to the corresponding quinones (e.g.,

dx.doi.org/10.1021/jf5017797 | J. Agric. Food Chem. 2014, 62, 7111−7117

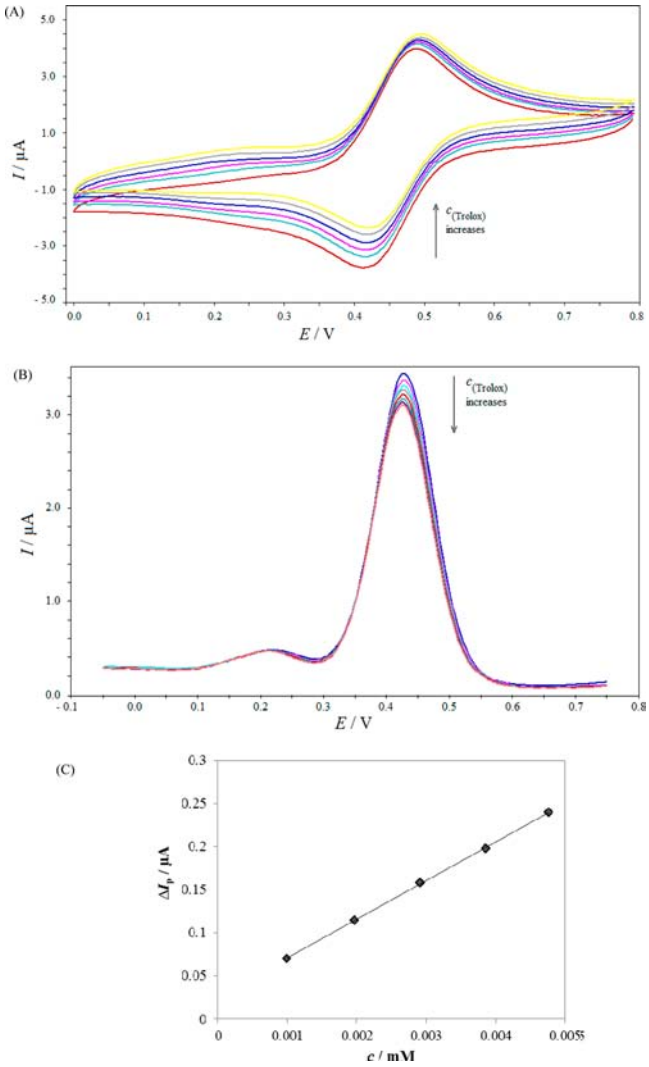

Figure 3. Cyclic (A) and differential pulse (B) voltammograms of $Cu(Nc)_2^{2+}$ reagent, showing the effect of increasing trolox concentration in the range of 0.001−0.005 mM; (C) dependence of ΔI_p on trolox concentration. ΔI_p is defined as the difference between the measured DPV peak currents in the absence of trolox ($I_{p,0}$) and in the presence of corresponding trolox concentrations ($I_{p,x}$), that is, $\Delta I_p = I_{p,0} - I_{p,x}$. Supporting electrolyte was acetic acid/acetate buffer solution (0.1 M, pH 4.76), and other conditions were the same as in Figure 2.

ascorbic acid is 2e-oxidized to dehydroascorbic acid, and trolox is 2e-oxidized to the corresponding quinone), whereas Cu(II)−Nc is reduced to the highly colored Cu(I)−Nc chelate showing maximum absorption at 450 nm. Spectrophotometric CUPRAC is a relatively fast assay, where most of the tested antioxidants reach ≥80% of their maximal molar absorptivities within ≥1 min and do not show a distinct capacity change within 30 min. However, slow-reacting antioxidants (i.e., naringenin, hesperetin) may show a dramatic capacity change within 30 min.[12,16] Therefore, the relatively short measurement time of the electrochemical CUPRAC method does not pose major problems in electron-transfer kinetics of most antioxidants.

The recommended voltammetric method for TAC assay is based on the electrochemical reduction of $Cu(Nc)_2^{2+}$ at the GC electrode polarized at a potential lower than the reduction potential of $Cu^{II,I}(Nc)_2$ redox couple (which is about 0.6 V). Antioxidant capacities of 12 antioxidant compounds, namely, hydroxybenzoic acids (vanillic acid, gallic acid, syringic acid), hydroxycinnamic acids (*p*-coumaric acid, ferulic acid, chlorogenic acid), flavonols (kaempferol and quercetin), flavon-3-ols (epicatechin and catechin), and others (trolox and ascorbic acid), were electrochemically determined.

Table 1 summarizes the related linear equations, correlation coefficients, linear ranges, and LOD and LOQ values of the antioxidant compounds tested by the DPV−CUPRAC method (for comparison, the corresponding values found by the conventional spectrophotometric−CUPRAC method are also listed in Table 1). The electrochemical determination of the antioxidant capacity of these phenolic groups (except for *p*-coumaric and ferulic acids) was performed under the same experimental conditions used for quantifying trolox (Table 1). A linear response of the peak current as a function of concentration was observed for phenolic compounds over the concentration ranges studied.

The LOD values of the phenolics found with the DPV−CUPRAC method were lower than those found with spectrophotometric−CUPRAC. The LOD (0.18 μM) found by the recommended DPV method was much lower than that of the electrochemical CUPRAC method of Cárdenas et al.[11] It is also noteworthy that the LOD values for CT and CGA found with the proposed DPV procedure (0.15 and 0.24 μM, respectively) are lower than the corresponding LODs of 1.03 and 0.28 μM, reported by Blasco et al., who used a flow injection system with a glassy carbon electrode.[17]

The voltammetric trolox equivalent antioxidant capacity ($TEAC_{voltammetric}$, defined as mM trolox equivalents of 1.0 mM antioxidant solution under investigation) was simply calculated by dividing the slope of the linear calibration equations of phenolics under investigation by that of trolox under corresponding conditions (i.e., the slope of trolox was 46.66 μA/mM) using eq 2.

$$TEAC_{voltammetric} = \frac{slope_{AO}}{slope_{TR}} \text{ (AO, antioxidant; TR, trolox)} \quad (2)$$

The spectrophotometric trolox equivalent antioxidant capacity ($TEAC_{spectrophotometric}$) values of the phenolics in 10% ethanol were likewise calculated by dividing the molar absorptivity (ε) of each antioxidant by the molar absorptivity of trolox (ε_{trolox} was 15.36 L $mmol^{-1}$ cm^{-1} under the specified conditions) using eq 3.

$$TEAC_{spectrophotometric} = \frac{\varepsilon_{AO}}{\varepsilon_{TR}} \quad (3)$$

The $TEAC_{voltammetric}$ and $TEAC_{spectrophotometric}$ values were compared (Table 2) to yield compatible results. For the tested phenolic antioxidants, the voltammetric method correlated linearly with spectrophotometric method (r = 0.9791, N = 5) (Figure 4). A similar investigation on the interrelationship of spectrophotometric and DPV[10] modification of ABTS/persulfate assay gave slightly different results for the TEAC coefficients of gallic and ascorbic acids (unreported data), naturally requiring more measurements on antioxidant varieties to reach any conclusion. It should be remembered here that spectrophotometric−CUPRAC measures the absorbance of the $Cu(Nc)_2^{+}$ formed at pH 7.0, whereas voltammetric−CUPRAC measures the reduction current of the remaining $Cu(Nc)_2^{2+}$ at pH 4.76, after reaction with antioxidants; therefore, this

correlation is highly satisfactory. The slight discrepancies of the spectrophotometric TEAC values obtained by the CUPRAC method shown in Table 2 from those available in the literature[15] may have arisen from the differences in solvent composition (i.e., measurements in this work were performed in 10% EtOH-containing aqueous media).

TAC Measurements of Herbal Teas. Addition of certain amounts of herbal tea extracts to the electrochemical cell containing $Cu(Nc)_2^{2+}$ reagent caused a successive decrease of the DPV peak currents (Figure 5A). Apparently, the antioxidants present in herbal teas exerted an electrochemical effect similar to that of trolox, as represented by eq 1. The decrease in DPV current intensities of $Cu(Nc)_2^{2+}$ reagent as a result of increasing herbal tea extract volume ratio ($V_{herbal\ teas}/V_{total}$, %) is shown for the tested herbal tea extracts in Figure 5B. The good linearity between these two parameters confirms that the voltammetric–CUPRAC method can be used for the determination of TAC of herbal teas and similar complex antioxidant samples. The TAC values of herbal teas were calculated with the use of eq 4, where ΔI_p is the difference in current intensity, m is the mass of dry herbal tea sample, V is volume, and DF is dilution factor.

dx.doi.org/10.1021/jf5017797 | J. Agric. Food Chem. 2014, 62, 7111–7117

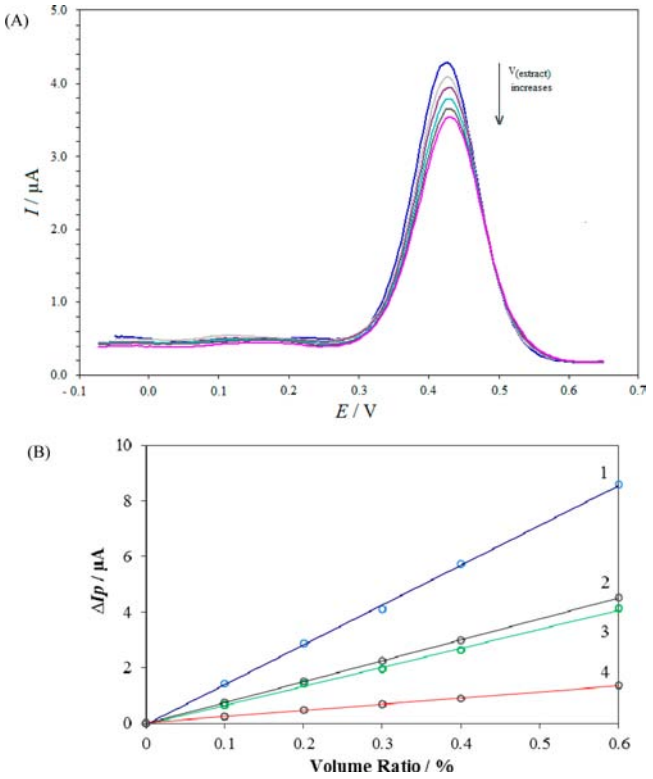

Figure 5. (A) Differential pulse voltammograms of $Cu(Nc)_2^{2+}$ reagent showing the effect of increasing herbal tea extract volume parts; (B) dependence of ΔI_p on the volume ratio ($V_{herbal\ teas}/V_{total}$, %) of green tea (1), marjoram (2), sage (3), and alchemilla (4) herbal teas. The calibration lines were found $y = 14.276x - 0.022$ $r = 0.9997$; $y = 7.512x - 0.002$, $r = 0.9999$; $y = 6.825x + 0.023$, $r = 0.9990$; and $y = 2.231x + 0.018$, $r = 0.9995$, respectively ($N = 5$). Supporting electrolyte was acetic acid/acetate buffer solution (0.1 M, pH 4.76), and other conditions were the same as in Figure 2.

$$\mathrm{TAC_{voltammetric}\ (mmol/g)} = \frac{\Delta I_p \pm \text{intercept}}{(\Delta I_p/c)_{TR}} \times \frac{V_{total}}{V_{sample}} \times \frac{V_{extract}\ (mL)}{m\ (g)} \times DF \times 10^{-3} \quad (4)$$

The analytical results for total antioxidant capacity (expressed in mmol trolox equivalents per g of dry herbal tea sample) by voltammetric method were found to be 1.23 ± 0.06, 0.80 ± 0.11, 0.68 ± 0.02, and 0.40 ± 0.03 mmol/g for green tea, sage, marjoram, and alchemilla, respectively. The corresponding spectrophotometric findings with the conventional CUPRAC method were 1.19 ± 0.11, 0.70 ± 0.02, 0.66 ± 0.01, and 0.38 ± 0.02 mmol/g for green tea, marjoram, sage, and alchemilla, respectively.

The TAC values of tested herbal tea samples measured by the developed voltammetric method were in good agreement with those of spectrophotometric–CUPRAC (Figure 6). The two-way analysis of variance (ANOVA) comparison by the aid of F test of the mean-squares of "between treatments" and of residuals[13] for a number of real samples (herbal teas) enabled the conclusion that there was no significant difference between the population means for a given sample. In other words, calculated total antioxidant contents were alike at a 95% confidence level ($F_{exptl} = 1.875$, $F_{crit(table)} = 6.608$, $F_{exptl} < F_{crit(table)}$ at $P = 0.05$). Thus, the proposed methodology was

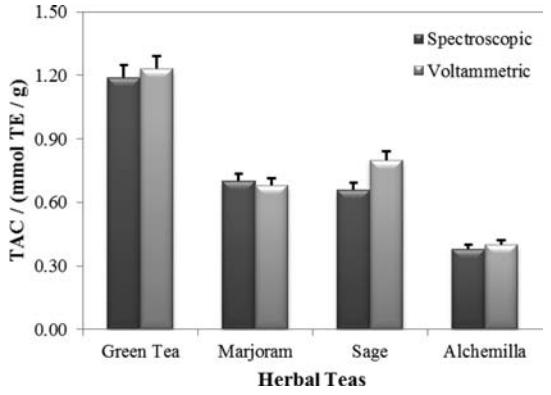

Figure 6. Total antioxidant capacities (mmol TE/g) of herbal teas (green tea, marjoram, sage, and alchemilla) determined by differential pulse voltammetric and spectrophotometric CUPRAC methods. Data are presented as mean ± ($t_{0.05}s/n^{1/2}$), $N = 5$. ($P = 0.05$, F_{exptl} =1.875, $F_{crit(table)} = 6.608$, $F_{exptl} < F_{crit(table)}$.)

validated. The proposed voltammetric method correlated linearly with the spectrophotometric method ($r = 0.9803$, $N = 5$), and the TAC values found with the two methods for herbal teas were compatible by ±3.2%.

Performance and Prospects of the DPV–CUPRAC Method. The developed DPV–CUPRAC method has been demonstrated for a variety of antioxidant compounds and validated against the well-documented spectrophotometric–CUPRAC procedure and can be an interesting alternative to spectrophotometric methods for determining the TAC of phenolic compounds in some herbal teas. The voltammetric method may be potentially useful for turbid and colored samples in which plant pigments may obscure the color of cuprous–neocuproine chromophore in spectrophotometry. The proposed method is easy and fast and showed better sensitivity (lower detection limits) than similar electrochemical assays. The electrochemical results showed that TACs of herbal teas were in the order green tea > sage > marjoram > alchemilla, in compliance with the results of the spectrophotometric–CUPRAC assay.

A separate turbidity investigation was undertaken in which TACs of filtered and unfiltered orange and peach nectars were assayed by DPV–and spectrophotometric–CUPRAC methods. The DPV–CUPRAC assay results (for both filtered and unfiltered samples) were close or comparable to those (for filtered sample) found by the spectrophotometric–CUPRAC method (Table 3). However, the unfiltered nectars gave high CUPRAC absorbances and therefore yielded positive errors in spectrophotometry. All spectrophotometric measurements, by nature, require the elimination of particulate matter (by filtration) before absorbance measurement. As a result, the proposed electrochemical assay proved to be efficient for turbid

Table 3. TACs of Some Nectars As Assayed by DPV – and Spectrophotometric– CUPRAC Methods[a]

sample	$TAC_{DPV-CUPRAC}$ (mmol trolox equiv/L nectar)	$TAC_{spect-CUPRAC}$ (mmol trolox equiv/L nectar)
orange nectar	1.96 ± 0.03 (2.04 ± 0.09)	1.82 ± 0.01 (4.5 ± 0.21)
peach nectar	1.57 ± 0.08 (1.53 ± 0.08)	1.51 ± 0.03 (3.5 ± 0.17)

[a]Data presented as mean ± ($t_{0.05}s/n^{1/2}$), $N = 5$. TAC values in parentheses represent turbid sample results.

dx.doi.org/10.1021/jf5017797 | J. Agric. Food Chem. 2014, 62, 7111–7117

samples for which the widely used spectrophotometric TAC assays are not accurately responsive.

Table 2. Verification of Results for Specificity of Targets on Prespotted Plate[a]

| | test samples | targets | | |

DNA Extraction. Genomic DNA was isolated from 100 to 200 mg of homogenized seed powder or planting material using DNeasy Plant Mini kit (Qiagen Gmbh, Hilden, Germany), as per manufacturer's instructions. The integrity and purity of genomic DNA were determined by agarose gel electrophoresis. Intact DNA of high molecular weight was obtained (Figure 1). DNA samples were quantified by measuring UV absorption at 260 nm, while DNA purity was evaluated on the basis of the UV absorption ratio at 260 nm/280 nm ranging from 1.6 to 1.9 using a Quawell UV−vis spectrophotometer Q5000 (Quawell, CA, USA). DNA samples were diluted to a concentration of 25 ng/μL for specificity experiments and tested for the absence of PCR inhibitors.[14] To determine limit of detection (LOD) of the targets, working solutions with 1.0, 0.1, 0.05, 0.025, 0.01, and 0.005% GM content were prepared by mixing the DNA samples of particular GM events positive for specific targets with the corresponding non-GM counterpart.

Selection of Targets and Methods. The multitarget RTi-PCR based screening system developed in the present study aims to detect 21 GM events of five crops, namely, maize (12 events), cotton (6 events), one GM event each of eggplant, rice and soybean, 5 construct regions (junction regions of two transgenic elements), 15 commonly employed transgenic elements (11 transgenes, 2 promoters and 2 terminators) along with 6 taxon-specific targets as shown in Figure 2. Taxon-specific assays for six crops (cotton, eggplant, maize, potato, rice, and soybean) were included as internal control for corresponding GM event-specific/element-specific assays. TaqMan probes and primers for *cry1C*, modified *cry3A*, *AmA1*, *P35S-cry1C* were designed using the primer design software Primer3 (version 0.4.0) (http://bioinfo.ut.ee/primer3-0.4.0/). Primers and probes for event-specific detection of *Bt* eggplant event EE1, for *cry1Ac* and *cry2Ab* transgenes, *P35S-cry1Ac* and *P35S-uidA* construct regions were previously reported by our laboratory.[8,15−17] Details of other oligonucleotides used are listed in Table 1. Prior to development of prespotted plates, primers and probes were tested and verified using respective RTi-PCR assays.

The RTi-PCR plate includes 47 targets along with a negative amplification control in duplicate, allowing the simultaneous analysis of two test samples per plate (Figure 2). Primers and probes were prespotted in each well in lyophilized format at a final concentration of 900 nM primers/250 nM probes. Primer and probe synthesis and automatic spotting were outsourced (Applied Biosystems, Foster City, CA, USA). All probes were labeled with 6-carboxyfluorescein (FAM) and 6-carboxytetramethylrhodamin (TAMRA) at the 5′ and 3′ ends, respectively.

Real-Time PCR Assay. RTi-PCR assays were performed using 96-well prespotted plates on a 7500 Real-Time PCR system (Applied Biosystems, Foster City, CA, USA) in 25 μL reactions containing 100 ng of template DNA, 1× TaqMan Universal PCR Master Mix (Applied Biosystems). Thermal profile used was 30 °C for 5 min for allowing the dissolution of lyophilized primers and probes, 95 °C for 1 min, followed by 45 cycles of 95 °C for 15 s and 60 °C for 60 s.

Experimental Design. The specificity of each method spotted on the plate was tested against the DNA samples obtained from wild-type plant species and most of the GM events/crops, as shown in Table 2. The expected results for each target have been compiled in Table 2, based on the information from publicly available databases, namely, http://www.igmoris.nic.in, http://www.cera-gmc.org, http://www.gmo-compass.org, http://gmdd.shgmo.org/, http://www.envfor.nic.in/divisions/csurv/geac/geac_home.html, and from *in silico* analysis (http://gmo-crl.jrc.ec.europa.eu/jrcgmomatrix/). Prior to conducting specificity experiments, one of the plates was tested with test samples positive for each target in one set I of the plate (1−48 wells), and the second set II (49−96 wells) with water (nontemplate control) as negative control was run simultaneously, to check the false positive results.

To test sensitivity of all 47 target-specific assays included in the multitarget system, LOD was determined by testing each DNA test sample for GM content up to 1.0, 0.1, 0.05, 0.025, 0.01, and 0.005%, in 16 PCR replicates, for each target. Sensitivity of the system in terms of copy number (LOD_{copies}) was also calculated using the 1C value corresponding to the weight in picograms per haploid host plant genome.[18]

Repeatability and intermediate-repeatability of developed multitarget system was confirmed by single-laboratory experiments performed by four operators. Each operator ran two plates in duplicate, accounting for a total of four replications per operator, hence 16 replications per assay.

For assessing the practical utility and applicability of developed system:

(i) A sample of stacked GM cotton event MON15985 × MON88913 was tested. DNA of stacked GM cotton event was loaded in each well of the plate to check for the presence or absence of specific targets, and hence analyzed in duplicate (Sets S1 and S2 of the plate).

(ii) Two powdered samples, labeled as A and B, unknown to the operators, were also tested. Sample A comprised of homogenized seed powder of non-GM wheat, whereas sample B comprised homogenized seed powder from reference material of GM event TC1507.

(iii) Samples of the Proficiency Program organized by the United States Department of Agriculture and the Grain Inspection, Packers and Stockyards Administration (USDA-GIPSA) in 2013 were tested for specific GM maize events and corresponding transgenic elements, included in the prespotted plate.

RESULTS AND DISCUSSION

In the present "RTi-PCR-based multitarget screening system", element-, construct-, and event-specific assays have been combined so as to facilitate preliminary screening of an unknown sample for its GM status. The 47 targets included in the system may facilitate event-specific detection of 21 GM events and further screening of more than 140 GM events under field trials in India.[13]

Specificity and Sensitivity of Developed Multitarget System. The present work describes multitarget TaqMan RTi-PCR-based screening system consisting of a 96-well plate coated with lyophilized primers and probes, in which a sample can be tested in duplicate for 47 targets. Five *Bt* cotton events, i.e., MON531, MON15985, GFM-*cry1A*, Event 1, and MLS-9124 are authorized for commercial cultivation in India. These events can be efficiently detected on developed multitarget system using event-specific assays for MON531 and MON15985 and construct-specific assays, i.e., *P35S-cry1Ac*, *P35S-uidA*, *P35S-cry1C*, and *ctp2-cry2Ab*. The outcomes of the applicability of event- and construct-specific assays included in the system to detect commercially authorized Indian GM events may be interpreted as follows: (i) If sample contains MON531 event, then MON531 event- and *P35S-cry1Ac* construct-specific targets would amplify; (ii) If sample contains MON15985 event, then MON531 and MON15985 event-specific along with *P35S-cry1Ac*, *P35S-uidA*, *ctp2-cry2Ab* construct-specific targets would amplify; (iii) If sample contains Event1, then only *P35S-cry1Ac* construct-specific target would amplify; (iv) If sample contains GFM-*cry1A* event, then both the *P35S-cry1Ac* and *P35S-uidA* specific targets would amplify; and (v) If sample contains MLS-9124 event, then only *P35S-cry1C* specific target would amplify.

The *ctp2-epsps* construct-specific assay detects the imported wheat GM event MON71800 for herbicide tolerance. As the adventitious presence of this event was reported in the Oregon fields in the United States in June 2013 (http://westernfarmpress.com/blog/oregon-gmo-mystery-wheat-whodunit), so we used the DNA of imported sample of the same event (imported for research purposes) just to check whether the developed system is capable of tracing this event, and further confirmation can be done with the respective event-

[a]Number of replications per assays was 16 (as indicated in ISO 5725-3-1994, estimates of repeatability should be obtained on sufficient number of test results, at least 15 replicates[50]). [b]Positive amplification was considered below Ct value of 40.

specific assay. Other selected targets include 11 transgenes, 2 promoters (*P-35S*, *P-nos*), and 2 terminators (*T-35S*, *T-nos*) (Figure 2), facilitating further screening of more than 140 GM events under field trials which were indigenously developed or imported for research purposes.[13]

Prior to conducting specificity experiments, one of the plates was tested with test samples positive for each target in one set I of the plate, and the second set II with water (nontemplate control) was run simultaneously. All the targets were amplified in set I, whereas no amplification was observed in set II as expected, thus eliminating the possibility of false positives in the reactions. Specificity of each method was assessed and further confirmed by testing with wild-type plant species and most of the GM events/crops, against the whole set of methods. All 47 assays successfully amplified the targets (event-, construct-, element-specific) only in the corresponding GM events/crops (Table 3), and taxon-specific targets in the corresponding plant

Figure 3. Practical applicability of developed multitarget screening system for simultaneous analysis of two unknown samples (Samples A and B) per plate; (a) targets amplified in the system are encircled; (b) amplification profile of the targets amplified in the test samples. Details of samples unknown to the operators: Sample A: Homogenized seed powder of non-GM wheat. Sample B: Homogenized seed powder of GM maize event TC1507.

species. The amplification results were in line with the information from theoretical data, as shown in Table 2.

Plate performance was determined by the Ct values of each target from the amplification data of 16 replications. Mean Ct values for the targets ranged from 24.35 ± 0.87 to 38.12 ± 0.40 as shown in Table 3. Results were consistent in terms of Ct values, and the mean standard deviation ranged from 0.05 to 2.82.

To determine LOD of different RTi-PCR assays, DNA dilutions with GM content of 1.0, 0.1, 0.05, 0.025, 0.01, and 0.005% were analyzed. LOD is the lowest amount or concentration of analyte in a sample, which can be reliably detected, but not necessarily quantified, as demonstrated by single-laboratory validation. Since the analytical method should detect the presence of the analyte at least 95% of the times at the LOD, ensuring ≤5% false negative results (Codex Alimentarious Commission CAC-GL 74-2010,[19] http://gmo-crl.jrc.ec.europa.eu/doc/Min_Perf_Requirements_Analytical_methods.pdf), 16 replicates were tested for each target. Most of the assays detected the target sequence in respective DNA samples up to 0.1% of GM target; however, assays for detection of NK603 event and *P35S-cry1Ac* construct region detected up to 0.025%. LOD of GM events, namely, 3272, 59122, MON531, MIR604, *Bt*11, Event 3006 and genes *Adh1*, *cry1Ab*, *T-nos*, *pat*, *AmA1* was found to be 0.01% (Table 3, Figure S1 of the Supporting Information). Sensitivity in terms of LOD_{copies} was also estimated, and the results are in agreement with different genome sizes[18] of the individual plant species selected for testing of respective targets. Each assay was found sensitive enough to detect the respective target, with the LOD_{copies} ranging from 4 to 222. Fourteen of the targets, namely, *Adh1*, *Bt*11, NK603, MIR604, 3272, 59122, MON531, Event 3006, *P35S-cry1Ac*, *ctp2-epsps*, *cry1Ab*, *AmA1*, *bar*, *pat* demonstrated LOD_{copies} up to 10 copies, and the sensitivity of most of these targets in the multitarget system was also in line with that of EU-validated protocols.

Overall LOD of present multitarget system was established up to 0.1%, revealing that it can efficiently detect samples with GM content as low as 0.1% of each of the 47 targets in a single run. However, the developed system can be efficiently used for qualitative testing for checking the presence/absence of 47 targets in an unknown sample, if 0.1% content of particular target is present (for some targets, detection limit was up to 0.01%, as mentioned earlier). Twenty-one GM events can be efficiently checked for their presence in an unknown sample using this system. In the case of presence of particular GM event(s) in the sample, further quantification can be done to determine the content of a particular event by running separate RTi-PCR using the reference materials to generate the standard curve.

Applicability of the Multitarget System. Practical applicability of developed system was tested using DNA sample of stacked GM cotton event, MON15985 × MON88913. RTi-PCR analysis was performed in duplicate for each target. Detection of a stacked GM event is based on the use of event-specific detection assays developed for the parental GM events contributing the stack. In both the replicates S1 and S2, amplification signal was detected only for specific targets

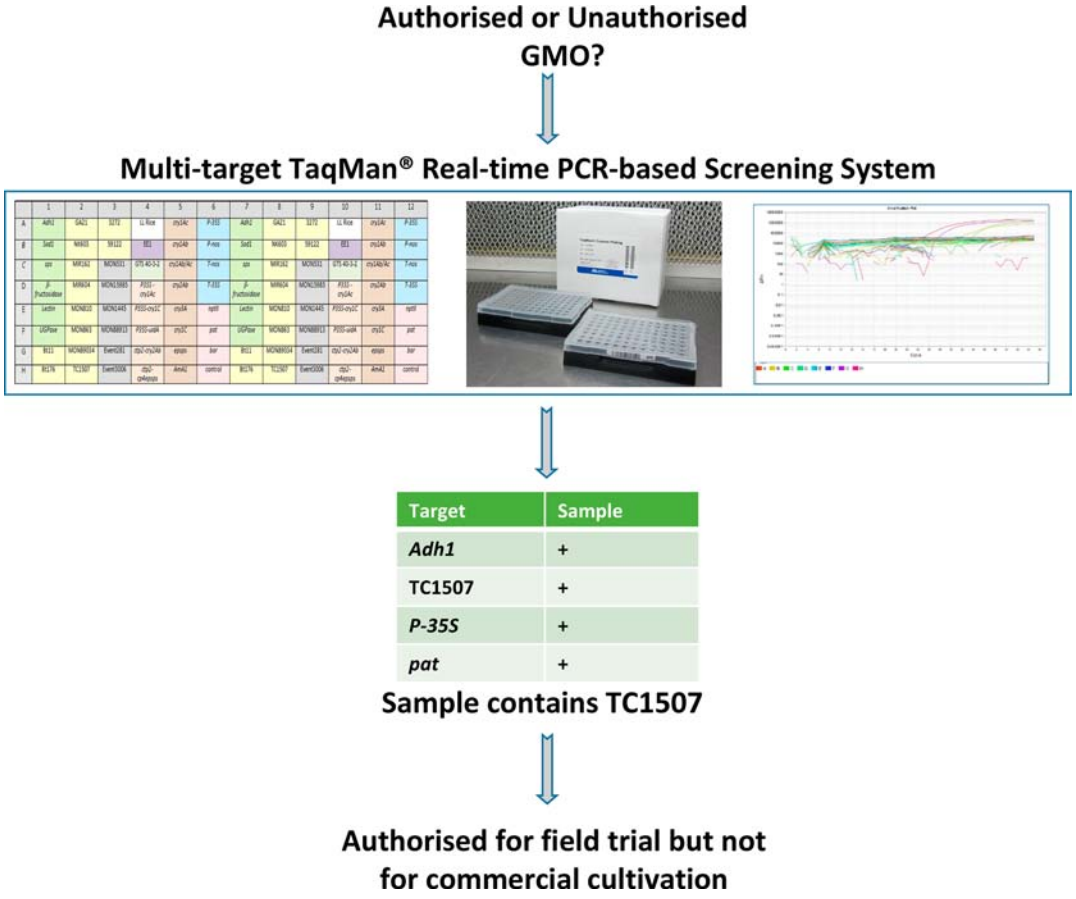

Figure 4. Workflow of developed multitarget RTi-PCR-based screening system to check for unauthorized GM events.

Table 4. Screening Pattern obtained on Pre-spotted Plate using Maize Samples of Proficiency Testing[a]

| test samples | targets | | |

tested for specific GM maize events and their respective transgenic elements. The results obtained were as expected; for example, in the Sample 1, five of the GM maize events, namely, MON810, *Bt*176, *Bt*11, NK603, Event 3272 along with the respective transgenic elements were detected, as shown in Table 4. The results of proficiency test samples were satisfactory and in agreement with the final results of the USDA-GIPSA Proficiency Program-2013.

With only a few simple steps involved, the present multitarget GMO screening tool offers efficient and rapid testing of GM status of a sample while significantly reducing both workload and chances of contamination. The approximate cost of the prespotted plate for testing a DNA sample for presence/absence of 47 targets would be INR 20000 to 26000. This multitarget approach is user-friendly and flexible which may facilitate detection of all the commercialized GM events of India and screening of more than 140 GM events that were under field trials (2006-2012), the scope of which may further be enhanced by including more transgenic elements of upcoming authorized GM events in Indian context, as per the availability of RTi-PCR methods.

were approved by the Committee on Animal Research at Ajou Medical Center, Ajou University.

Experimental Treatment. For in vitro experiments, AITC and ASA were dissolved in 70% PEG−saline. The final concentration of 70% PEG−saline never exceeded 0.1%. For ex vivo and in vivo experiments, AITC and ASA were dissolved in 70% PEG−saline. Seventy percent PEG−saline solution did not influence platelet aggregation. All agents were prepared just before use.

Preparation of Platelet-Rich Plasma (PRP) from Rat and Human Blood. PRP from rat blood was prepared as described previously.[15,16] Briefly, SD rats weighing 200−240 g were lightly anesthetized with diethyl ether. A volume of 8−10 mL of blood was collected from the abdominal aorta into a syringe containing 3.8% sodium citrate. The ratio of blood to 3.8% sodium citrate was adjusted to 1:9 v/v. After centrifugation at 150*g* for 10 min at room temperature, supernatants (PRP) were used for the aggregation study. To prepare washed platelets (WP), blood was collected into a syringe containing acid citrate dextrose (ACD; 2.5% trisodium citrate, 2% dextrose, and 1.5% citric acid) and adjusted to a ratio of 1:9 v/v. After centrifugation at 150*g* for 10 min at room temperature, the platelets were isolated and then centrifuged again at 150*g* for 10 min in washing buffer (Tyrode's solution containing 10% ACD buffer and 0.3% BSA). Platelets were diluted with Tyrode's solution (11.9 mM NaCl, 2.7 mM KCl, 2.1 mM $MgCl_2$, 0.4 mM NaH_2PO_4, 11.9 mM $NaHCO_3$, 11.1 mM glucose, and 3.5 mg/mL bovine serum albumin, pH 7.2). To make platelet-poor plasma (PPP) from rat blood, PRP was centrifuged at 1200*g* for 10 min at room temperature, and supernatants were obtained as PPP. For PRP from human blood, human platelet suspensions were supplied from the Red Cross (Suwon, Korea). Human blood was collected from healthy human volunteers who had not taken medicine as indicated by the Red Cross guide.

In Vitro Platelet Aggregation and Shape Change in Rat PRP. The platelet aggregation study was performed as previously described.[17,18] Briefly, PRP was diluted with Tyrode's solution containing 0.3% BSA and adjusted to about 2×10^8 platelets/mL. PRP was stimulated to aggregate by using different aggregating agents at the following final concentrations: collagen, 2 μg/mL; thrombin, 0.2 U/mL; ADP, 2.5 μM; AA, 100 μM; and U46619, 1 μM. We decided the concentrations of agonists on the basis of the results from preliminary experiments (data not shown). Platelet aggregation was recorded for 5 min after stimulation by using whole blood/optical Lumi-Aggregometer (Chrono-Log). Aggregations were measured and expressed as percent changes in light transmission with respect to PPP. Data of light transmission assay were calculated to percent change by using Chrono-Log software. In the in vitro study, PRP was preincubated with AITC or ASA at 37 °C for 3 min before being stimulated with the aggregating agents. To monitor shape change, a platelet shape change study was performed as previously described.[19] Platelets (2×10^8 platelets/mL) were preincubated with apyrase (2 U/mL), indomethacin (10 μM), and EGTA (1 mM) before the addition of collagen.

Determination of Cytotoxicity in Rat PRP. To determine the cytotoxicity of AITC, lactate dehydrogenase (LDH) release from platelets was measured as previously described.[20] After incubation of PRP (2×10^8 platelets/mL) with 70% PEG−saline or different concentrations of AITC for 3 min at 37 °C, PRP was centrifuged at room temperature at 10000*g* for 1 min. A 25 μL aliquot of the supernatant was mixed with 100 μL of NADH solution (0.03% β-NAD, reduced form of the disodium salt in phosphate buffer) and 25 μL of pyruvate solution (22.7 mM pyruvic acid in phosphate buffer) at room temperature. Reductions in absorbance at 340 nm because of conversion of NADH to NAD^+ were measured to determine LDH activity in supernatants. LDH release is expressed as the percentage of the total enzyme activity in platelets completely lysed with 0.2% Triton X-100.

Measurement of TXA_2 Production and ATP Release in Rat and Human PRP. Measurement of TXA_2 production was conducted using a TXB_2 EIA kit (Cayman Chemical Co, Ann Arbor, MI, USA) as previously described.[21] PRP (2×10^8 platelets/mL) was incubated for 3 min in the presence or absence of samples, and then collagen (2 μg/mL) was added and PRP was incubated at 37 °C for 5 min with stirring. EDTA (10 mM) was added to stop TXA_2 production. After centrifugation at 12000*g* for 3 min, the amount of TXB_2 was measured according to the manufacturer's instructions.

Detection of ATP release was determined as previously described.[22] PRP (2×10^8 platelets/mL) was incubated at 37 °C with stirring at 1200 rpm. After addition of the luciferin−luciferase reagent, collagen (2 μg/mL) was added to initiate the reaction. PRP was incubated with AITC (30, 100, or 300 μM) for 3 min before the addition of luciferin−luciferase reagent.

Determining the $[Ca^{2+}]_i$ in Rat PRP. The intracellular Ca^{2+} was determined with Fura-2/AM as described previously.[23] Briefly, the PRP was incubated with 6 μM Fura-2/AM for 60 min at 37 °C. The Fura-2-loaded washed platelets (10^8 mL^{-1}) were then preincubated with AITC for 3 min with 1 mM $CaCl_2$. Next, WPs were stimulated with collagen (2 μg/mL) for 5 min. Fura-2 fluorescence was measured in a spectrofluorometer with an excitation wavelength that ranged from 340 to 380 nm, changing every 0.5 s, and an emission wavelength of 510 nm. The $[Ca^{2+}]_i$ was calculated as[24]

$$[Ca^{2+}]_i \text{ in cytosol} = 224 \text{ nM} \times (F - F_{min})/(F_{max} - F)$$

where 224 nM is the dissociation constant of the Fura-2−Ca^{2+} complex and F_{min} and F_{max} represent the fluorescence intensity levels at very low and very high Ca^{2+} concentrations, respectively. F_{min} is the fluorescence intensity of the Fura-2−Ca^{2+} complex at 510 nm, after the platelet suspension containing 20 mM Tris/10 mM EGTA had been solubilized by 0.1% Triton X-100. F_{max} is the fluorescence intensity of the Fura-2−Ca^{2+} complex at 510 nm, after the platelet suspension containing 1 mM $CaCl_2$ had been solubilized by 0.1% Triton X-100. F indicates the fluorescence intensity of the Fura-2 complex at 510 nm after WPs were stimulated by collagen, with 1 mM $CaCl_2$ and AITC or vehicle.

Western Blotting. The immunoassay was performed as previously described.[4] The WPs (2×10^8 platelets/mL) were stimulated by collagen (2 μg/mL) in the presence or absence of AITC (300 μM). Reactions were terminated by adding 10 mM EDTA and centrifuged at 12000*g* for 3 min. After the addition of ice-cold platelet lysis buffer (1% NP40, 15 mM HEPES, 75 mM NaCl, 1 mM EDTA, 1 mM phenylmethanesulfonyl fluoride (PMSF), 1 mM sodium fluoride (NAF), 1 mM Na_3VO_4, 1 μg/mL leupeptin, and 1 μg/mL aprotinin; pH 7.4), lysates were centrifuged at 13000*g* for 10 min at 4 °C. The supernatants were collected, and protein concentration was determined using a BCA protein assay (Thermo Scientific, Vernon Hills IL, USA). Equal volumes of protein were resolved using SDS-PAGE (10%) and transferred to PVDF membranes. The PVDF membranes were blocked with 5% nonfat dry milk in TBS and incubated with the primary antibody diluted in TBS buffer (1:1000 ratio, 4 °C overnight). Immunoblots were then incubated again with a horseradish peroxidase (HRP)-conjugated secondary antibody, and then the immune-reactive bands were visualized with a LAS 4000 (Fuji, Honshu, Japan) using a Western blot detection system (WestZol, Intron, Seoul, Korea).

Ex Vivo Platelet Aggregation Study in Rat. Two hours before experiments, SD rats were orally administered 70% PEG−saline, AITC (0.3, 1, 3 mg/kg), or ASA (50 mg/kg). Rat blood samples were collected, and the platelet aggregation study was performed as described above.

In Vivo Acute Pulmonary Thromboembolism Study in Mouse. Acute pulmonary thromboembolism model was performed as previously described.[25] Male ICR mice weighing 35−40 g were fasted for 6 h before experiments. AITC and ASA were dissolved in 70% PEG−saline. Mice were orally administered AITC or ASA 2 h before experiments were performed. Collagen (500 μg/kg) plus epinephrine (25 μg/mL) was injected to the tail vein to induce thrombosis. Each mouse was watched for 15 min to determine whether the mouse was paralyzed, dead, or recovered from the acute thrombotic challenge.

In Vivo Mouse Tail Bleeding Time Assay. Mouse tail bleeding times were recorded as previously described.[26,27] Male ICR mice

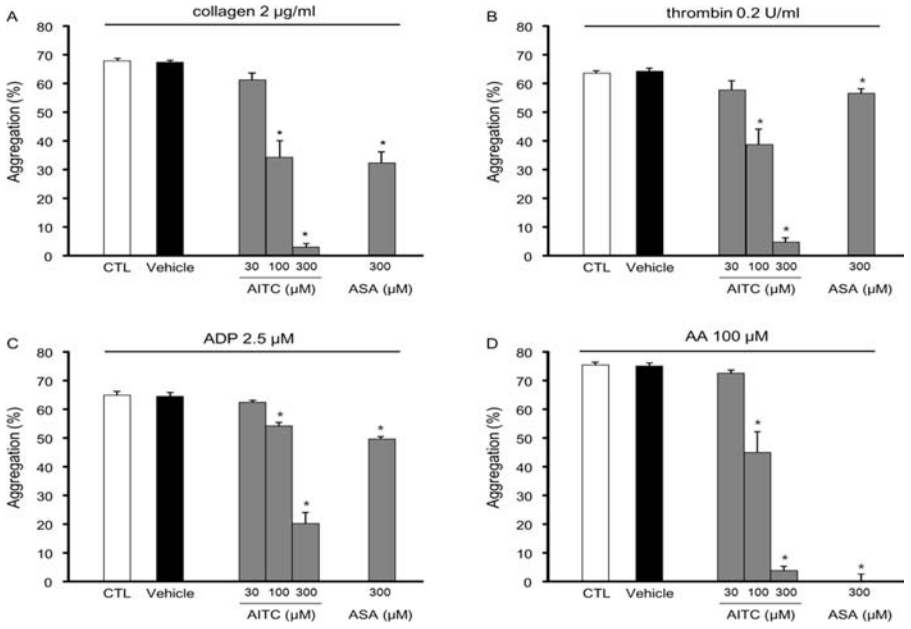

Figure 1. Concentration-dependent inhibitory effect of AITC on in vitro platelet aggregation. Platelets were preincubated with 70% PEG−saline (vehicle group), ASA (300 μM), or AITC (30, 100, or 300 μM) or not (control group) for 3 min at 37 °C. After preincubation, platelets were stimulated by the following agonists: collagen, 2 μg/mL (A); thrombin, 0.2 U/mL (B); ADP, 2.5 μM (C); or arachidonic acid (AA), 100 μM (D). Data are expressed as means ± SEMs (n = 5). (*) P < 0.05 versus vehicle.

weighing 35−40 g were fasted for 16 h before experiments. Two hours after the oral administration of AITC (0.3, 1, or 3 mg/kg) or ASA (50 mg/kg), the mice were anesthetized with ketamine (100 mg/kg) and xylazine (10 mg/kg). Thereafter, the mice were individually placed on a hot plate to control body temperature, and tails were transected 3 mm from the tips by using a razor blade. The tail was then immersed in a 15 mL clear conical tube containing warmed saline (37 °C). The time until the cessation of blood flow was then measured. Bleeding time was defined as the time taken for bleeding to stop for 15 s.

Statistical Analysis. In the thromboembolism experiment, the chi-square test was used to determine significant differences between the vehicle and treated groups. Statistical significance was considered at P < 0.05. In other experiments, data were expressed as means ± SEMs of at least three experiments. One-way ANOVA followed by Dunnett's test or the paired t test by using Sigma Stat statistical software (San Rafael, CA, USA) was used for the analysis. Significance was accepted for P values of <0.05.

RESULTS AND DISCUSSION

Effect of AITC on Rat Platelet Aggregation in Vitro. To evaluate the antiplatelet effect of AITC, we first examined its effect on rat platelet aggregation induced by various agonists. During pathological thrombogenesis, platelets are activated after binding to collagen on a vascular lesion. Activated platelets initiate intrinsic pathways, such as arachidonic acid (AA) liberation, to release secondary agonists including ADP, which in turn activate other platelets.[28] Thrombin initiates platelet activation through cleavage of the N-terminal exodomain of the protease-activated receptor.[29] Thrombus formation is induced by multiple physiological ligands and, thus, an antiplatelet agent that affects only one type of ligand-platelet interaction is likely to have a limited preventive effect against thrombogenesis.[27] Therefore, an antiplatelet agent that acts on multiple platelet activation pathways has been suggested to be a more effective compound for treating platelet-involved cardiovascular disease. Indeed, dual antiplatelet therapy, such as a combination of clopidogrel and ASA, has been shown to be more effective in inhibiting pathogenic thrombi.[30] ASA inhibits platelet aggregation through inhibition of cyclooxygenase, and clopidogrel inhibits platelet activation through irreversible binding to the $P2Y_{12}$ ADP receptor on platelet membrane.

In this study, PRP was stimulated by collagen (2 μg/mL), thrombin (0.2 U/mL), ADP (2.5 μM), or AA (100 μM) to induce platelet aggregation. The platelet aggregations induced by collagen, thrombin, ADP, and AA (68, 64, 62, and 74%, respectively) were significantly inhibited by either 100 or 300 μM AITC (6, 8, 18, and 5%, respectively) (Figure 1). In addition, AITC showed lower IC_{50} values than ASA in collagen, thrombin or ADP-induced platelet aggregation (Table 1). Taken together, these results indicate that AITC inhibits platelet aggregations induced by multiple agonists, and thus it may have beneficial potential for the prevention of platelet-related disorders.

Table 1. IC_{50} of AITC and ASA for Platelet Aggregation in Vitro[a]

agonist[b]	AITC IC_{50} (μM)	ASA IC_{50} (μM)
collagen	112.8 ± 16.3	312.7 ± 30.6
thrombin	100.6 ± 10.7	1314.7 ± 76.4
ADP	149.7 ± 17.7	1422.6 ± 129.1
AA	167.2 ± 22.6	27.3 ± 0.9

[a]Results are expressed as means ± SDs. [b]Concentration of agonists were as follows: collagen (2 μg/mL), thrombin (0.2 U/mL), ADP (2.5 μM), and AA (100 μM).

Effect of AITC on Platelet Cytotoxicity. To examine the cytotoxicity of AITC, LDH release from platelets was measured. LDH release is used as an index of cellular injury, including injury to platelets.[31] There was no significant LDH release from platelets treated with either vehicle (70% PEG−saline) or AITC (30, 100, or 300 μM) (Table 2). These findings suggest that the antiplatelet effect of AITC was not the result of cytotoxic effects, such as platelet membrane disruption.

dx.doi.org/10.1021/jf4041518 | J. Agric. Food Chem. 2014, 62, 7131−7139

Table 2. Effect of AITC on LDH Release by Platelets[a]

treatment	LDH release[b]
CTL	11.2 ± 1.6
vehicle	13.1 ± 1.7
AITC 300 μM	11.5 ± 1.6
AITC 100 μM	11.8 ± 2.2
AITC 30 μM	10.1 ± 2.0

[a]Data are expressed as means ± SEMs (n = 5). [b]LDH release was measured after rat platelet-rich plasma was treated with either vehicle or AITC (30, 100, or 300 μM) for 3 min. P < 0.05 versus vehicle.

Effects of AITC on TXA_2 Production, ATP Release, and Ca^{2+} Increase in Rat PRP. Platelets are activated by various agonists including collagen. Activated platelets recruit other platelets to form aggregation. To recruit other platelets, activated platelets secrete TXA_2 and granules containing ATP and ADP, which act as paracrine activators.[22,32] Through interaction with the T_P receptor on the platelet membrane, TXA_2 plays a key role in platelet shape change and fibrinogen receptor (GPIIb/IIIa) activation, subsequently leading to platelet aggregation.[33,34] A parallel process involves release of ATP and ADP, which then bind to $P2X_1$ and $P2Y_1/P2Y_{12}$ receptors, respectively, leading to Ca^{2+} entry and amplification of platelet activation and shape change.[35]

Because TXA_2 production and ATP release follow platelet activation, they are well-known indicators of platelet activation.[36] To evaluate the mechanism of the antiplatelet effect of AITC, TXA_2 production and ATP release were examined in this study. Because TXA_2 is unstable and quickly converted to its stable form, TXB_2, the production of TXB_2 was measured instead. Collagen-induced TXB_2 production (4022 pg/mL) was significantly inhibited by AITC at a concentration of 300 μM (1320 pg/mL), but not by 100 μM (3812 pg/mL) (Figure 2A). Consistently, AITC significantly inhibited platelet aggregation induced by U46619 (77%), a thromboxane A_2 receptor agonist, only at the concentration of 300 μM (11%) (Supporting Information file 1). These findings suggest that the antiplatelet effect of 100 μM AITC (Figure 1) may be attributed to a mechanism other than the TXA_2 inhibition pathway. To investigate the mechanism underlying the effect of 100 μM AITC, the effect of AITC on granule secretion was examined by measuring ATP release, which reflects the release of ADP, because ATP/ADP release from granules is known to be activated independently of TXA_2 pathway.[22,37] AITC, at the concentrations of both 100 and 300 μM, significantly inhibited collagen-induced ATP release by 48 and 84%, respectively (Figure 2B). From these results, it is suggested that the antiplatelet effect of AITC at 100 μM is likely to be attributed to inhibition of ATP/ADP release rather than TXA_2 inhibition, whereas the antiplatelet effect of 300 μM AITC is attributed to inhibition of both ATP/ADP release and TXA_2.

Another biomarker of platelet activation is intracellular Ca^{2+} increase. After collagen binds platelet membrane receptor, intracellular Ca^{2+} increases and plays a key role in TXA_2, ATP/ADP secretion, and shape change.[38] In addition, increasing

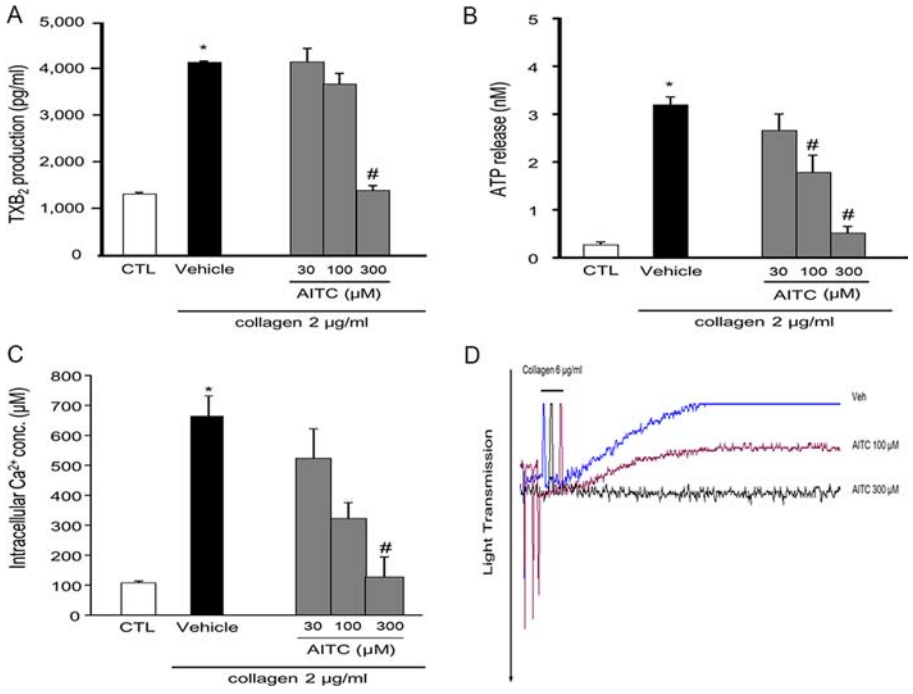

Figure 2. Inhibitory effect of AITC on collagen-induced TXA_2 production (A), ATP release (B), intracellular Ca^{2+} increase (C), and platelet shape change (D). For the TXA_2 assay, platelets were preincubated with AITC (30, 100, or 300 μM) for 3 min, and then platelets were stimulated with collagen (2 μg/mL) for 6 min. The amount of TXA_2 was determined by measuring TXB_2 concentrations using an EIA kit (n = 8). For ATP measurement, platelets were preincubated with AITC (30, 100, or 300 μM) for 3 min before the addition of a luciferin−luciferase reagent. After the luciferin−luciferase reagent was added, platelets were stimulated with collagen (2 μg/mL) for 6 min. ATP release was measured using a lumi-aggregometer (n = 8). For measurement of intracellular Ca^{2+} increase, platelets were loaded with Fura-2/AM. The platelets were preincubated with or without AITC (30, 100, or 300 μM) for 3 min and stimulated with collagen 2 μg/mL (n = 5). For measurement of platelet shape change, platelets were preincubated with apyrase (2 U/mL), indomethacin (10 μM), EGTA (1 mM), and with or without AITC (30, 100, or 300 μM) for 3 min followed by stimulation with collagen (6 μg/mL) and traces recorded. Data are expressed as means ± SEMs (n = 5). (*) P < 0.05 versus control. (#) P < 0.05 versus vehicle.

dx.doi.org/10.1021/jf4041518 | J. Agric. Food Chem. 2014, 62, 7131−7139

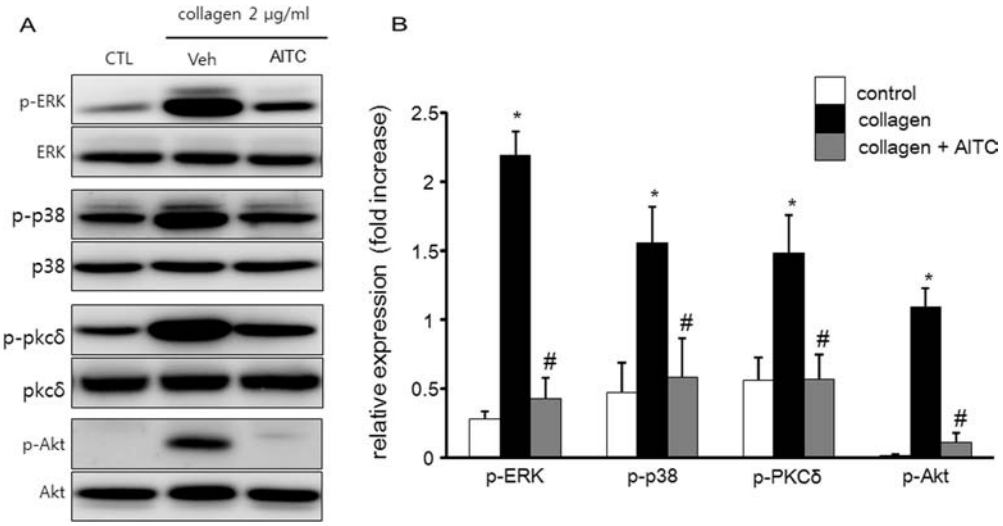

Figure 3. Effect of AITC on protein phosphorylation. (A) AITC attenuated collagen-activated platelet Akt, PKCδ, ERK, and p38 phosphorylation. Washed platelets were preincubated with either vehicle or AITC (300 μM) for 3 min with stirring. After preincubation, washed platelets were stimulated with collagen (2 μg/mL) for 5 min. Platelet lysates were analyzed by a Western blot immunoassay. (B) Relative expression was compared between total expression and phosphorylated expression. Values in bar graphs are means ± SEMs (n = 4). (∗)P < 0.05 versus control. (#) P < 0.05 versus vehicle.

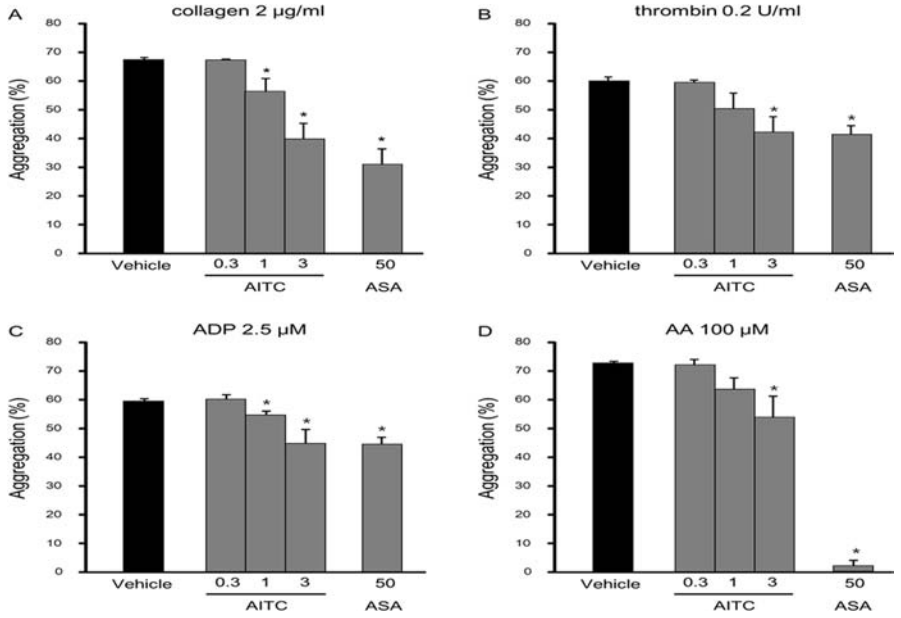

Figure 4. AITC inhibits ex vivo platelet aggregation after oral administration in a dose-dependent manner. AITC (0.3, 1, or 3 mg/kg) or ASA (50 mg/kg) was administered 2 h before blood collection. Platelet aggregation was induced by the following agonists: collagen, 2 μg/mL (A); thrombin, 0.2 U/mL (B); ADP, 2.5 μM (C); AA, 100 μM (D). Data are expressed as means ± SEMs (n = 6). (∗) P < 0.05 versus vehicle.

Ca^{2+} contributes to platelet aggregation through transformation of fibrinogen binding receptor GPIIb/IIIa. Transformed GPIIb/IIIa has high affinity with fibrinogen to aggregate platelets through fibrinogen binding. Furthermore, high intracellular Ca^{2+} contributes to platelet shape change through dissociation of actin−profilin complexes.[39] In this study, the effects of AITC on intracellular Ca^{2+} increase and shape change were examined to elicit its inhibitory mechanism on platelet aggregation. Collagen-induced intracellular Ca^{2+} increase (612 μM) was significantly inhibited by AITC at 100 and 300 μM (350 and 181 μM, respectively) (Figure 2C). In addition, collagen-induced platelet shape change was also inhibited by 100 and 300 μM AITC. These results suggest that the antiplatelet mechanisms of AITC at 100 and 300 μM may involve its inhibition of intracellular Ca^{2+} increase and shape change.

Effects of AITC on Phosphorylation of PLCγ, p38, ERK, PKCδ, and Akt. At the sites of atherosclerotic lesion, collagen is the most important thrombogenic component of the subendothelial matrix. Collagen binds to receptors on the platelet membrane, including the glycoprotein VI (GPVI) receptor, which has recently been considered as a new therapeutic target to prevent platelet aggregation with fewer side effects.[40,41] Recent studies have shown that inhibition of GPVI contributes to protection from thrombi with mild side effects, such as minor bleeding.[42,43] In the process of platelet

dx.doi.org/10.1021/jf4041518 | J. Agric. Food Chem. 2014, 62, 7131−7139

aggregation, collagen binding to GPVI receptor triggers activation of PLCγ/protein kinase C delta (PKCδ)/extracellular signal-regulated kinases (ERK) and/or p38 mitogen-activated protein kinases (p38) signaling pathway and phosphoinositide 3-kinase (PI3K)/protein kinase B (Akt) signaling.[44] PLCγ is a specific signaling molecule for the collagen-induced platelet activation pathway, whereas Akt, PKCδ, ERK, and p38 are common molecules for all of the collagen-, thrombin- and ADP-induced signaling pathways for platelet activation.[45,46] The phosphorylation of Akt, PKCδ, ERK, and p38 is known to contribute to platelet activation, which can lead to thrombogenesis.[44,46−48] In this context, phosphorylation of proteins in the collagen-activated pathway was examined in this study to investigate the underlying action of signaling pathway mechanism of AITC. AITC was shown to markedly inhibit the phosphorylation of Akt, PKCδ, ERK, and p38 induced by collagen (2 μg/mL) (Figure 3), but not PLCγ phosphorylation (Supporting Information file 2). From these results, it is suggested that the inhibitory effect of AITC on collagen-induced platelet aggregation is, at least partially, mediated through Akt, PKCδ, ERK, and p38 inhibition rather than PLCγ suppression.

Effect of AITC on ex Vivo Platelet Aggregation in Rat. To investigate the ex vivo effect of AITC in rat, AITC was orally administered at 0.1, 0.3, 1, 3, or 10 mg/kg. Compared to vehicle treatment, AITC at 3 mg/kg po significantly inhibited platelet aggregation induced by collagen (2 μg/mL), thrombin (0.2 U/mL), ADP (2.5 μM), and AA (100 μM) (Figure 4).

Table 3. ID_{50} of AITC and ASA for Platelet Aggregation ex Vivo[a]

agonist[b]	AITC ID_{50} (mg/kg)	ASA ID_{50} (mg/kg)
collagen	6.2 ± 0.6	84.0 ± 8.9
thrombin	13.3 ± 0.9	837.0 ± 28.3
ADP	27.9 ± 0.7	450.0 ± 14.1
AA	24.1 ± 1.3	27.3 ± 5.5

[a]Results are expressed as means ± SDs. [b]Concentration of agonists were as follows: collagen (2 μg/mL), thrombin (0.2 U/mL), ADP (2.5 μM), and AA (100 μM).

Also, IC_{50} values of AITC and ASA were suggested at Table 3. ASA at 50 mg/kg was used as positive control. There was no antiplatelet effect of AITC at 0.1 and 0.3 mg/kg, and there was no significant difference in antiplatelet effect between 3 and 10 mg/kg AITC (data not shown). These results indicate that per orally treated AITC has a significant antiplatelet effect in rat, although further information such as pharmacokinetic data may be needed to link in vitro concentrations to in vivo doses of AITC.

Protective Effect of AITC on Pulmonary Thromboembolism Attack in Mouse. The goal of antiplatelet agents is prevention of thrombosis such as venous thromboembolism, which is the third most common vascular disease after heart attack and stroke.[49] The acute pulmonary thromboembolism mouse model, widely used to investigate antithrombotic therapeutic compounds, was evaluated to determine the protective effect of AITC against thromboembolism attack.[50] In the present study, oral administration of 3 mg/kg AITC had a protective effect against mortality (63%) caused by pulmonary thromboembolism (Table 4). This means that the antiplatelet effect of AITC is maintained in vivo.

Table 4. Effect of AITC on Acute Pulmonary Thromboembolism in Mice[a]

treatment	paralyzed or dead animals/total	protection (%)
CTL	8/8	0
vehicle	14/15	7
AITC		
0.3 mg/kg	11/13	15[b]
1 mg/kg	9/15	40[b]
3 mg/kg	6/16	63[b]
ASA		
50 mg/kg	3/15	80[b]

[a]The chi-square test used to examine the difference between the vehicle and treated group. [b]$P < 0.05$ versus vehicle.

Effect of AITC on Mouse Tail Bleeding Times. We investigated whether AITC has a prolonging effect on mouse tail bleeding time. Because the bleeding time reflects normal platelet function during physiologic hemostasis,[26] a prolongation effect of bleeding time has been used as an indicator for the side effect.[20] Because 3 mg/kg AITC and 50 mg/kg ASA showed similar inhibitory effects on collagen-induced platelet aggregation, we estimated bleeding time at those concentrations (3 mg/kg AITC and 50 mg/kg ASA). As shown in Figure 5, the prolonged bleeding time by 3 mg/kg AITC was

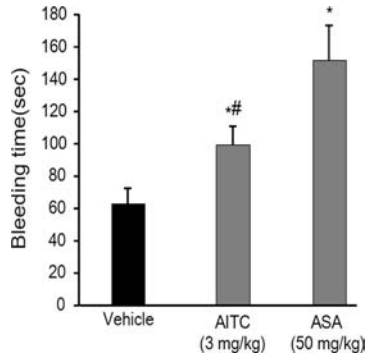

Figure 5. Effect of AITC on mouse tail bleeding time. AITC (3 mg/kg) or ASA (50 mg/kg) was given orally to mice 2 h before experiments. Data are expressed as means ± SEMs ($n = 10$). (*) $P < 0.05$ versus vehicle. (#) $P < 0.05$ versus ASA.

significantly less (40% less) than that by 50 mg/kg ASA, even though AITC still induced prolongation ($P < 0.05$). These results imply that AITC elicits an antiplatelet effect with less bleeding adverse effect.

Antiplatelet Effect of AITC in PRP from Human Blood. To investigate the effect of AITC on human blood, a platelet aggregation experiment was performed with PRP from human blood. Similar to the inhibitory effect of AITC on rat PRP, 100 and 300 μM AITC significantly inhibited platelet aggregation of human PRP induced by collagen, thrombin, ADP, and AA (Figure 6). AITC also inhibited TXB_2 production and ATP release in human platelets.

In conclusion, the present study is the first to demonstrate the antiplatelet activity of AITC in vitro, ex vivo, and in vivo. These effects of AITC seem to be mediated, at least partially, through inhibition of TXA_2 production, ATP/ADP release, and intracellular Ca^{2+} increase. AITC also showed protective effect against thromboembolism attack. These findings suggest that AITC may have therapeutic potential for the prevention of

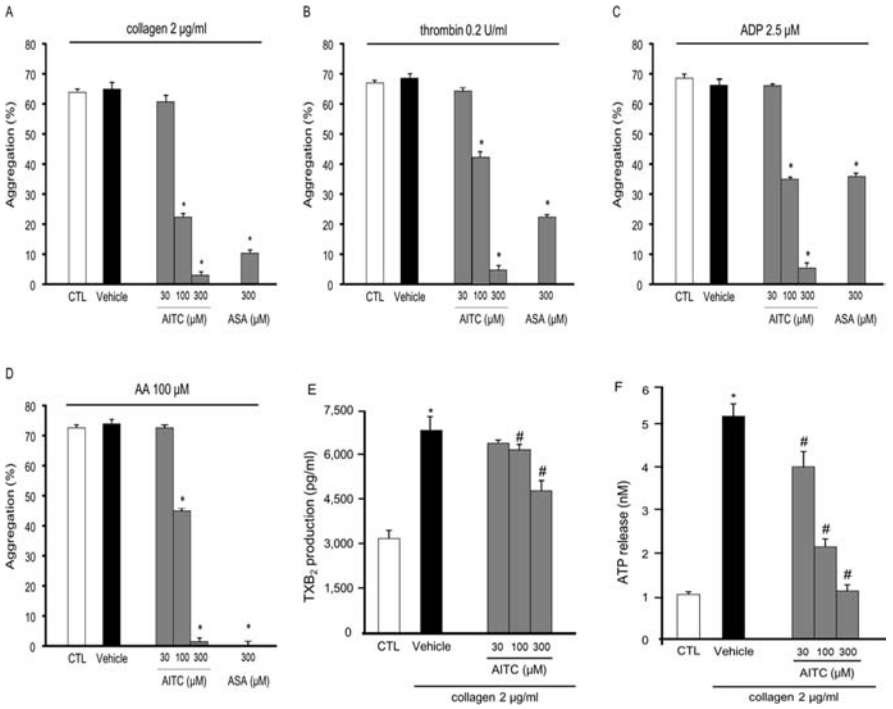

Figure 6. Effect of AITC on human platelet. Platelets were preincubated with 70% PEG−saline (vehicle group), ASA (300 μM), or AITC (30, 100, or 300 μM) or not (control group) for 3 min at 37 °C. After preincubation, platelets were stimulated by the following agonists: collagen, 2 μg/mL (A); thrombin, 0.2 U/mL (B); ADP, 2.5 μM (C); or arachidonic acid (AA), 100 μM (D) (n = 5). For the TXA_2 assay (E), platelets were preincubated with AITC (30, 100, or 300 μM) for 3 min, and then platelets were stimulated with collagen (2 μg/mL) for 6 min. The amount of TXA_2 was determined by measuring TXB_2 concentrations using an EIA kit (n = 4). For ATP measurement (F), platelets were preincubated with AITC (30, 100, or 300 μM) for 3 min before the addition of a luciferin−luciferase reagent. After the luciferin−luciferase reagent was added, platelets were stimulated with collagen (2 μg/mL) for 6 min. ATP release was measured using a lumi-aggregometer (n = 4). Data are expressed as means ± SEMs (n = 6). (*) $P < 0.05$ versus vehicle.

aberrant platelet activation, although further study remains to be performed for the potential of clinical application.

of the livers in relation to their phenotypes and allows us to better understand the biological mechanisms underlying the variations of foie gras technological quality. This could in turn suggest new and more adapted farming practices aimed at reducing variability.

MATERIALS AND METHODS

Experimental procedures were performed in accordance with French National Guidelines for the care and use of animals for research purposes (Certificate of Authorization to Experiment on Living Animals no. 7740, Ministry of Agriculture and Fish Products).

Animal Design. The animals studied here are male mule ducks, produced within the framework of a QTL detection experiment based on a grandson design,[9] in which they are measured to estimate the value of their common duck (*Anas platyrhynchos*) mothers. Two common duck parental lines were crossed: the heavy Pekin INRA37 and the Kaiya INRA444 to produce 7 F1 males, of which 3 were mated to 20 INRA444 female common ducks to produce 98 backcross (BC) female common ducks in 3 F1 half-sib families. These BC ducks were then crossed with 23 Muscovy (*Cairina moschata*) drakes to produce a total of 294 mule ducks in two hatching batches. The mule ducks were bred from 0 to 12 weeks of age in growing batches of 50 animals.[11] At 12 weeks of age, ducks were overfed in two successive series for a period of 12 days. Each overfeeding series was performed by two different crammers (one for the morning and one for the evening and a total of three crammers for all batches). Animals were slaughtered at the end of the overfeeding period. Livers were sampled at 20 min post-mortem by a small slit in the animal abdomen and frozen in liquid nitrogen for biochemical analyzes. Carcasses were refrigerated for 24 h at 4 °C. Then, they were eviscerated and livers collected for foie gras preparation.

Data Recording. *Liver Quality Traits.* Phenotypic measures were collected on mule ducks. Liver weights (LW) were collected just after evisceration at 24 h post-mortem. The liver melting rate (MR), corresponding to fat loss during cooking, is measured by sterilizing 60 g of refrigerated liver for 50 min at 105 °C. It is expressed as a percentage of the liver quantity before cooking. Protein contents were estimated using a near-infrared spectrophotometer (FOSS NIRSystem) on ground liver.[12] The results are expressed as a percentage of fresh liver weight (crude liver protein content, LprotCc, %) or as a percentage of dry liver weight (dry liver protein content, LprotDc, %) to limit the impact of liver lipid contents on the trait.

Analyses of Soluble Proteins by Bidimensional Electrophoresis. The bidimensional electrophoresis method for foie gras analyses was described by Theron et al.[8] and was performed here on the foie gras samples of all 294 mule ducks taken at 20 min post-mortem.
