For protein extraction, the fatty liver samples, stored frozen at −80 °C, were ground in liquid nitrogen to obtain a fine powder. Three hundred micrograms of this powder was then homogenized in a low ionic strength buffer (LIS), 40 mM Tris-HCl (pH 8), at 4 °C in a ratio of 1:4 (w/v) using a glass bead agitator MM400 (Retsch, Haan, Germany). The homogenate was centrifuged at 4 °C for 10 min at 10000g, and the fat cake supernatant was removed before a second homogenization was performed. After the second centrifugation, the supernatant containing the soluble protein fraction was collected and stored at −80 °C. The protein concentration was determined by using the Bradford[13] assay (Bio-Rad).

To perform bidimensional electrophoresis, 500 μg of proteins was incorporated in a buffer composed of 7 M urea, 2 M thiourea, 2% CHAPS (w/v), 0.4% carrier ampholyte (v/v), 1% DTT (w/v), and bromophenol blue. For the first dimension, samples were loaded onto immobilized pH gradient strips (pH 5−8, 17 cm, Bio-Rad), and isoelectric focusing (IEF) was performed using a Protean IEF cell system (Bio-Rad). Strips were first passively rehydrated for 16 h, after which a rapid voltage ramping was applied until a total of 86 kVh was reached. IEF was followed by successive incubation in an equilibration buffer containing 1% DTT and another containing 2.5% iodoacetamide and bromophenol blue. These buffers were both composed of 6 M urea, 30% glycerol, 2% SDS, and 50 mM Tris-HCl, pH 8.8. Equilibrated strips were loaded for the second dimension for a 12% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) using a Protean II XL system (Bio-Rad). After migration, gels were rinsed three times in permuted water and stained overnight with Coomassie Blue (Fermentas Page Blue). IEF was performed on 30 series of 12 samples and for each IEF series, SDS-PAGE was performed on 2 series of 6 samples, according to the capacities of our IEF and SDS-PAGE devices. Some damaged or unreadable gels were redone and a total of 360 gels made.

Two hundred and ninety-four stained gels were scanned using an Image Master 2D Platinum (GE Healthcare, Uppsala, Sweden), and the spots quantifications were done with Samespots software (TotalLab Ltd., Newcastle-upon-Tyne, UK). As the general aspect of a gel has an impact on the quality of the image analyses, problems concerning the aspect of the gels were recorded by annotating them in three categories: clear (no problem with the gel), blurred, and broken. Spot matching was performed across all 294 gels. Artifacts and spots detected by the software but not visible to the naked eye were removed from the analyses. The software calculated the intensity of each of the 326 remaining spots for each of the 294 samples.

Differentially expressed spots were manually excised from the gels using pipet tips and sent to the proteomics platform in Clermont-Ferrand (PFEMcp, INRA, Clermont-Ferrand Theix, France) for identification.

Spot Identification. *Protein Digestion.* The spots were destained with 100 μL of 25 mM NH_4HCO_3 with acetonitrile 95:5 (v/v) for 30 min and then washed twice in 100 μL of 25 mM NH_4HCO_3 with acetonitrile 50:50 (v/v) before dehydratation in 100% acetonitrile. Gel spots were completely dried using a Speed Vac, and trypsin digestion was performed at 37 °C over 5 h with 12 μL of trypsin (12.5 ng/μL; V5111, Promega) in 25 mM NH_4HCO_3. Peptide extraction was optimized by adding 9.6 μL of acetronitrile 100%, followed by 10 min of sonication. Then tryptic digests were concentrated for 5 min in a SpeedVac to eliminate acetronitrile and transferred to HPLC tubes, before LC-MS/MS analysis.

Nano-LC-MS/MS Analysis. For nano-LC-MS/MS analysis, peptide mixtures were analyzed by online nanoflow liquid chromatography using an Ultimate 3000 RSLC (Dionex, Voisins le Bretonneux, France). Eight microliters of peptide mixture was first preconcentrated at a flow rate of 20 μL/mn with a nano trap column of 5 cm length × 100 μm i.d., (Acclaim PepMap 100 C18, 5 μm, 100A nanoViper) equilibrated with trifluoroacetic acid 0.05% in water and then analyzed according to its hydrophobicity with a nanocapillary column of 15 cm length × 75 μm i.d., 2 μm, 100 Å (Acclaim PepMap 100 C18, Dionex) equilibrated with 0.5% formic acid in water. The solvent gradient increased linearly from 4 to 50% acetonitrile in 0.5% formic acid at a flow rate of 300 nL/mn for 45 mn. Identifications were attempted using an LTQ VELOS mass spectrometer (ThermoFisher Scientific, Courtaboeuf, France). The eluate was electrosprayed in positive-ion mode at 2.7 kV through a nanoelectrospray ion source that was operated in a CID top 10 mode (i.e., 1 full scan MS and the 10 major peaks in the full scan were selected for MS/MS). Full-enhanced-scan MS spectra were acquired with 1 microscan (m/z 400−1400), and dynamic exclusion was used with 2 repeat counts, 20 s repeat duration, and 120 s exclusion duration. For MS/MS, the isolation width for ion precursor was fixed at 1 m/z and single charged species were rejected; fragmentation used 35% normalized collision energy as the default activation of 0.25.

Database Search and Protein Identification. For raw data processing, Thermo Proteome Discoverer 1.4 (v: 1.4.0.288) was used with MASCOT (v 2.3) for database search (http://www.matrixscience.com). UniP_tax_Aves (150722 sequences) was used as database for protein identification, and the following parameters were considered for the searches: peptide mass tolerance was set to 1.5 Da, fragment mass tolerance was set to 0.5 Da, and a maximum of 2 missed cleavages was allowed. Moreover, variable modifications were methionine oxidation (M) and carbamidomethylation (C) of cysteine. Protein identifications were considered as valid if at least two peptides with a statistically significant Mascot score >48 were assigned. Ion score is $-10\log(P)$, where P is the probability that the observed match

is a random event. Individual ion scores >48 indicate identity or extensive homology at $p < 0.05$.

Identifications with only two unique peptides were manually validated with criteria of match fragment ions (occurrence of uninterrupted y- or b-ion series of at least three consecutive amino acids, preferred cleavages N-terminal to proline bonds, and mass occuracy).

The identification method was not able to annotate all of the analyzed spots of our set. For these spots, a manual annotation was performed on the basis of the peptide sequences given by the mass spectrometer. Alignments of the peptide sequences were done using BLASTP (http://blast.ncbi.nlm.nih.gov) on the nonredundant protein sequences database using all of the species. For each spot, alignment was done for the three longer peptides, and the validation of the spot annotation depended on three criteria. The e value had to be $<10^{-3}$ and the homology rate, 100%. The conservation between species was also checked. A spot was considered accurately identified as a protein when the cumulated percentage of this protein was >70%.

Statistical Analyses. Spot intensities were normalized using the GLM procedure of the SAS software to take simultaneously into account the technological effects of the bidimensional electrophoresis and the zootechnical effects. The sum of spot intensities of each gel was treated as a covariate, and six fixed effects were defined: (i) crammer effect (3 crammers); (ii) hatching batch effect (2 batches); (iii) general aspect of the gels (3 classes); (iv) first electrophoresis dimension effect (30 isoelectrofocusing series of 12 samples each); (v) second electrophoresis dimension effect (2 SDS-PAGE groups per isoelectrofocusing series); and (vi) interaction of both dimensions (60 levels corresponding to the chronological running order of the samples). Normalized spot intensities are the residual values of this model and will be used for all subsequent statistical analyses.

For each of the four traits considered (LW, MR, LprotCc, and LprotDc), foie gras samples were classified into four quartile groups (Q1, Q2, Q3, and Q4) according to their phenotypic values. For each of the 4 traits and each of the 326 normalized spot intensities, ANOVAs were performed using the GLM procedure of the SAS software across the 294 samples, taking 3 effects into account: the quartile group (4 levels), the F1 family group (3 levels), and the interaction between both, denoted quartile*family (12 levels). p values obtained were corrected by the Benjamini–Hochberg method. For each trait and each fixed effect, the 326 p values were sorted in descending order: the first value had the rank (k) 0 and the last had the rank 325. The corrected p value (q) was then defined as $q = p((326/(326 - k)))$. Effects for a spot were declared significant when $q < 0.1$. For each trait, quartile means were compared pairwise, that is, six tests. The significance threshold was then corrected using the Bonferroni method: the 5% threshold was divided by 6 (the number of tests performed). Spots were considered to be at significantly different levels between two quartiles when the p value was $p < 0.05/6$.

RESULTS

Association between Protein Abundance Levels and Phenotypic Traits. Quartiles of the phenotypic traits are represented in Table 1. For liver weight (LW), values range between 204 and 911 g and quartile means are 394 g for Q1, 531 g for Q2, 621 g for Q3, and 731 g for Q4. Quartiles 1 and 4 are more variable than the other two with values ranging over almost 300 g. For melting rate (MR), values range between 7.4 and 70.9% and quartile means are 18.7% for Q1, 34.8% for Q2, 46.5% for Q3, and 55.2% for Q4. The first quartile is the more variable with values ranging over 20%. For crude liver protein content (LprotCc) values go from 4.98 to 13.66%. Quartile means are 6.2, 7.1, 7.9, and 9.4% from the first to the fourth, respectively. Dry liver protein content (LprotDc) is almost twice higher than crude protein content with values going from 7.23 to 28.02%. Quartile means are 9, 10.7, 12.4, and 16.3% from the first to the fourth, respectively.

Table 1. Repartition in Quartiles of Phenotypic Values[a]

	Q1	Q2	Q3	Q4
LW (g)	394 ± 75	531 ± 27	621 ± 25	731 ± 59
MR (%)	18.7 ± 5.1	34.8 ± 5	46.5 ± 2.5	55.2 ± 3.9
LprotCc (%)	6.2 ± 0.4	7.1 ± 0.2	7.9 ± 0.2	9.4 ± 1.0
LprotDc (%)	9.0 ± 0.7	10.7 ± 0.4	12.4 ± 0.5	16.3 ± 2.9

[a]LW, liver weight; MR, melting rate expressed as a percentage of the liver quantity before cooking; LprotCc, crude liver protein content expressed as a percentage of the fresh liver weight; LprotDc, dry liver protein content expressed as a percentage of the dry liver weight.

For each of the four traits (LW, MR, LprotCc, and LprotDc), the number of spots found at different levels according to the quartile, family, or quartile*family interaction effects was tested by ANOVA, and 1304 statistical tests were performed altogether (4 phenotypic traits × 326 spots each). Thirty-five spots were found significantly affected by the quartile group after correction for multiple testing, only two by the F1 family affiliation of the individuals and one by the quartile*family interaction effect. It is noteworthy that the family affiliation affects the same two spots for each of the four traits and that LprotCc is the only trait for which no spot was affected by the quartile effect. Taken trait by trait, 17, 17, 0, and 16 spots are significantly affected by the LW, MR, LprotCc, and LprotDc quartile groups, respectively. However, some spots are common to several traits (Figure 1A): three spots are affected by the three traits LW, MR, and LprotDc, one spot is affected by both LW and MR, three spots are affected by both LW and LprotDc, and four spots are affected by both MR and LprotDc. Nine spots are affected by only LW, nine by MR, and six by LprotDc.

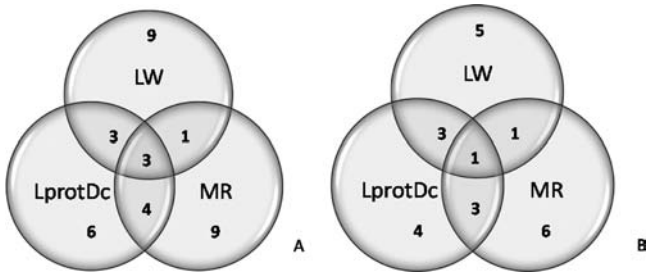

Figure 1. Venn diagram of the 35 differential proteins (A) and of the 23 identified proteins (B) affected by the phenotypic traits. Numbers correspond to the number of spots of protein affected by one, two, or three traits. LW, liver weight; MR, melting rate; LprotDc, dry liver protein rate.

Among the 35 spots affected by the phenotypic traits quartile groups, only 26 could be accurately identified. Three of them were attributed to keratin, which is considered as a contaminant in proteomics analyses, and the 23 remaining ones correspond to 20 unique proteins, 2 of which identified in several spots. α-Enolase was identified in three spots (spots 1403, 1414, and 1427) and annexin A5 in two spots (spots 1854 and 1914). For each protein, the spots were found at the same molecular weight but with different isoelectric points (Figure 2), suggesting different isoforms of the same protein. Among these 23 protein spots, 15 had a variation in abundance following a single trait only (LW, MR, or LprotDc), whereas the 8 remaining spots were differentially present following two or three traits simultaneously (Figure 1B). The 20 proteins showing variation in our data set represent several biological

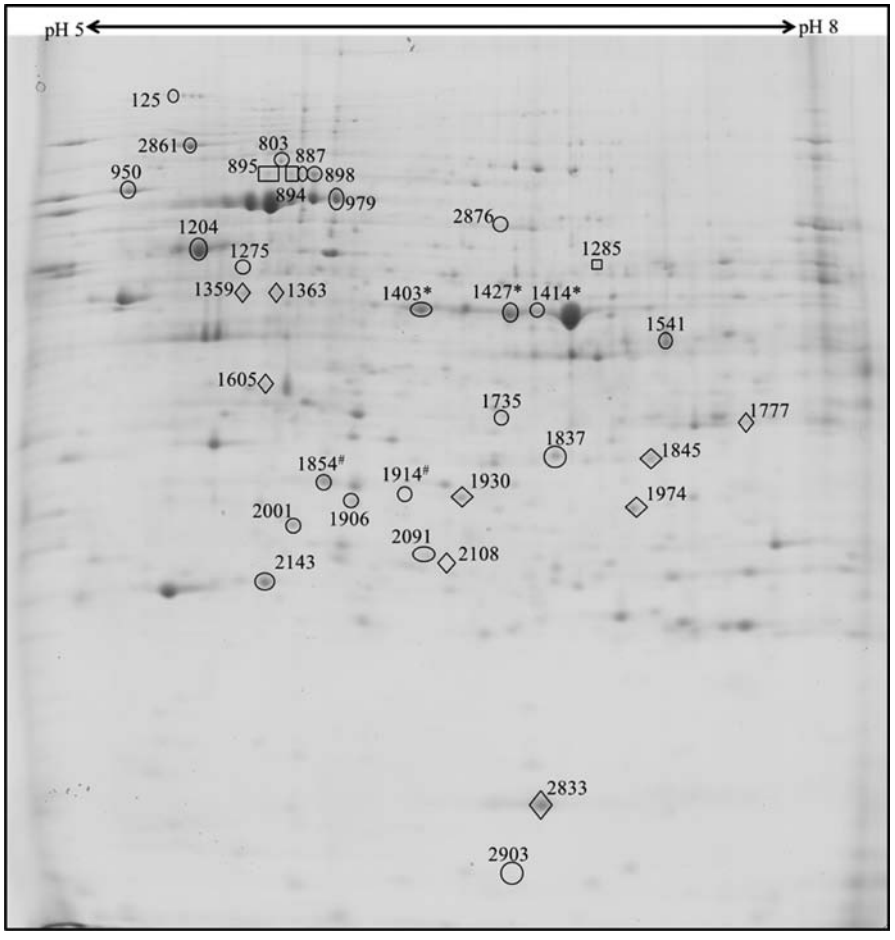

Figure 2. Two-dimensional gel electrophoresis representing a map of duck fatty liver soluble proteins. The first dimension separated the proteins according to their isoelectric point between pH 5 and 8. The second dimension separated the proteins according to their molecular weight in a 12% acrylamide gel. The 35 spots differentially expressed are represented. Spots surrounded by circles correspond to identified proteins, spots surrounded by squares correspond to keratin, and spots surrounded by diamonds correspond to nonaccurately identified spots. The star symbols or the hash symbols after spot numbers indicate that the spots correspond to the same protein.

pathways (Table 2) such as glycolysis, lipid metabolism, oxidative stress, transport, catabolism, and anabolism processes.

Variation of Protein Abundance Specific to a Single Trait. Five unique proteins were found at different levels according to LW values only (Appendix 1 in the Supporting Information). All showed significant differences between the lightest livers (Q1, LW < 486g) and the heaviest ones (Q4, LW > 661g). The hypoxia up-regulated protein 1 (HYOU1), annexin A5 (one of the two spots of ANXA5, spot 1854), and fatty acid binding protein 1 (FABP1) showed higher levels in the heaviest than in the lightest livers, whereas the glutamine synthetase (LOC100545435) and the malic enzyme (ME1) showed conversely lower levels in the heaviest than in the lightest. Of these five proteins, HYOU1 appeared to be particularly specific to LW values because the corrected p values for MR and LprotDc are >50%.

Six unique proteins corresponding to six identified spots were found to be at different levels according to MR values only (Appendix 2 in the Supporting Information). These proteins showed differences between low-melting livers (Q1, MR < 23%) and high-melting ones (Q3 or Q4, MR > 44%). The 70 kDa heat shock protein (HSPA5), the 60 kDa heat shock protein (HSPD1), and the *S*-formylglutathione hydrolase showed higher levels in the highest melting livers than in the lowest melting ones, whereas mitochondrial inner membrane protein-like (IMMT), dihydrolipoamide *S*-acetyltransferase (DLAT), and annexin A5 (the second spot of ANXA5, spot 1914) showed the inverse. With their corrected p value >50% for LW and LprotDc, HSPD1 and IMMT seemed to be specific to MR values.

Three unique proteins corresponding to four spots were found at different levels according to LprotDc values (Appendix 3 in the Supporting Information). Remarkably, all of these proteins show significant differences between the livers with the lowest overall protein content (Q1, LprotDc < 8.5%) and the ones with high content (Q4, Lprotdc >15.5%). α-Enolase was identified in two different spots (ENO1, spots 1414 and 1427), and both spots have lower levels in livers with the overall highest protein content. The two other proteins, trifunctional enzyme subunit α (HADHA) and prohibitin (PHB), showed higher levels in the protein-rich livers than in the protein-poor ones.

Variation of Protein Abundance Common to Two or Three Traits. Eight proteins corresponding to eight spots (Appendix 4 in the Supporting Information) showed different levels of abundance between the first quartile and the third or the fourth, for at least two traits. Among them, seven proteins were found expressed at different levels according to two traits simultaneously. FK506 binding protein 4 (FKBP4) was affected by LW and MR and showed a higher level in the heaviest and

highest melting livers. Ester hydrolase (C11orf54), peroxiredoxin 6 (PRDX6), and α-enolase (one of the three spots of ENO1, spot 1403) were affected by LW and LprotDc. The three proteins showed higher levels in the heaviest livers. Apolipoprotein A1 (APOA1), albumin (ALB), and transitional endoplasmic reticulum ATPase (VCP) were both affected by MR and LprotDc, but their variation profiles of abundance were different. Indeed, VCP showed higher levels both in the high protein content and the high-melting livers, whereas APOA1 and ALB showed similarly higher levels in the high protein content livers, but lower levels in the high-melting ones.

Fatty acid synthase (FASN) was the only protein for which the level of abundance varied with the three traits: it was present at a significantly higher level in the lightest weight and lowest melting livers (first quartile) than in the other ones (second, third, and fourth quartiles) and at a significantly lower expression level in protein-poor livers than in the other ones (first quartile versus second, third, and fourth quartiles).

Biological Pathways. For the eight protein profiles for which variation in protein abundance levels concerns two or three traits, a remarkable opposition appeared between the trend of protein expression with LW and MR levels, on the one hand, and LprotDc level, on the other hand. If the protein expression level increased with LW (FKBP4, C11orf54, PRDX6, ENO1), it also increased with MR or decreased with LprotDc. Inversely, if the protein expression level decreased with MR (APOA1, ALB, and FASN), it increased for LprotDc, with the notable exception of VCP. Using this information, the data set was split into two groups: group A was composed of proteins decreasing with MR or LW and/or increasing with LprotDc, and the "mirror" group B corresponded to proteins increasing with MR or LW and/or decreasing with LprotDc (Figure 3). The submission of the entire data set of proteins identified to IPA (Ingenuity Systems, www.ingenuity.com) helped in highlighting the relationships between protein through a network and in identifying the biological pathways. Proteins of group A represent pathways such as synthesis process (LOC100545435, FASN), anabolism process (DLAT, ME1), transcription regulation (PHB), and transport (APOA1, ALB). Proteins of group B represent biological pathways such as response to stress (HYOU, HSPA5, HSPD1, and PRDX6), transport (FABP1), glycolysis (ENO1), and catabolism process.

DISCUSSION

The aim of this work is to highlight possible differences in liver metabolic state, monitored by the analysis of the variation of protein levels in tissue samples, according to liver quality phenotypes. The primary focus is on four traits related to the quality of foie gras. However, contrary to what could have been expected, no significantly differential protein was identified for the trait LprotCc, whereas nine were found for LprotDc. The difference between the two traits comes from the way the predicted values of protein content are expressed. Indeed, it can be seen at the phenotypic level because values predicted by near-infrared spectroscopy (NIRS) on dry livers are almost twice higher than values predicted on crude livers. The expression of protein content related to the liver dry matter allows us to take partly into account the lipid content of the livers (51.6 ± 5.4%). As no significant result was found for LprotCc, we will therefore focus our discussion on the three other traits, namely, LW, MR, and LprotDc. The genetic correlations between LW and MR are strongly positive (+0.80), and LprotDc is negatively correlated to LW (−0.87) and to MR

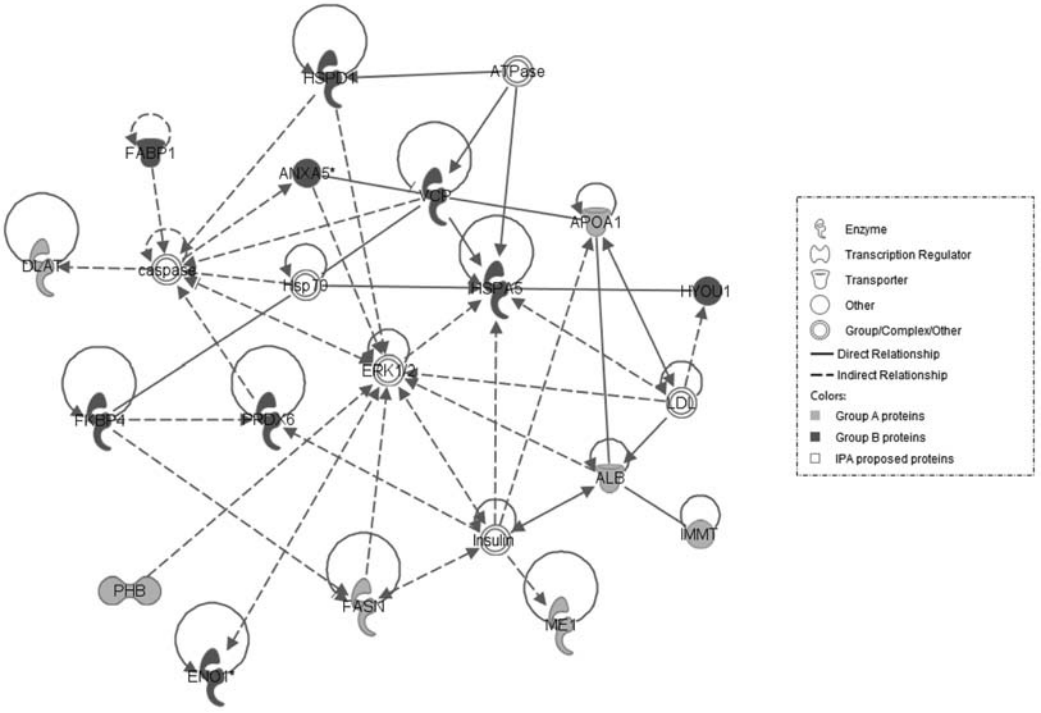

Figure 3. IPA network of hematological disease, immunological disease, and inflammatory disease associated functions representing a subset of 16 of our set of proteins (score of 46). Circled lines indicate self-regulating proteins. ALB, albumin; ANXA5, annexin A5; APOA1, apolipoprotein A1; ATPase, ATP synthase; DLAT, dihydrolipoamide *S*-acetyltransferase; ENO1, α-enolase; ERK1/2, extracellular signal-regulated kinase 1/2; FABP1, fatty acid binding protein 1; FASN, fatty acid synthase; FKBP4, FK506-binding protein 4; HSP70, 70 kDa heat shock protein; HSPA5, 70 kDa heat shock protein 5; HSPD1, 60 kDa heat shock protein; HYOU1, hypoxia up-regulated protein 1; IMMT, mitochondrial inner membrane protein-like; LDL, low-density lipoprotein; ME1, malic enzyme; PHB, prohibitin; PRDX6, peroxiredoxin 6. The proteins included in the network are the proteins included in IPA database.

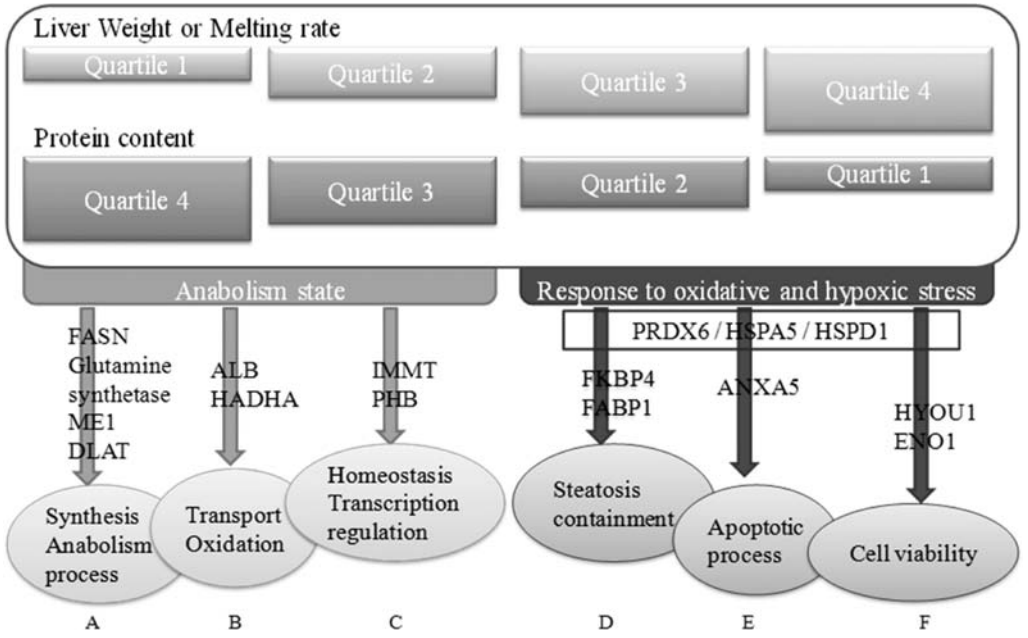

Figure 4. Summary diagram of the different liver protein profiles (from A to F) according to their phenotype. FASN, fatty acid synthase; ME1, malic enzyme; DLAT, dihydrolipoamide *S*-acetyltransferase; ALB, albumin; HADHA, trifunctional enzyme subunit α; APOA1, apolipoprotein A1; IMMT, mitochondrial inner membrane protein-like; PHB, prohibitin; PRDX6, peroxiredoxin 6; HSPA5, 70 kDa heat shock protein 5; HSPD1, 60 kDa heat shock protein; FKBP4, FK506-binding protein 4; FABP1, fatty acid binding protein 1; ANXA5, annexin A5; HYOU1, hypoxia up-regulated protein 1; ENO1, α-enolase.

(−0.87).[11] The phenotypic correlation between LW and MR is +0.67, and the phenotypic correlations between LprotDc and LW or MR are strongly negative (−0.78 or −0.79, respectively) (unpublished data).

dx.doi.org/10.1021/jf5006963 | J. Agric. Food Chem. 2014, 62, 7140−7150

Proteins of group A belong to six gene ontology (GO) processes (Table 2): transport (ALB, APOA1), oxidation (HADHA), transcription regulation (PHB), biosynthetic and metabolic processes (DLAT, glutamine synthase, ME1, FASN), mitochondria homeostasis (IMMT), and phospholipid binding (ANXA5). The biological functions of these proteins are summarized in Figure 4. During overfeeding, duck and geese develop an important steatosis due to an intense lipogenic activity and an insufficient exportation rate of triglycerides in the peripheral tissues. This activity was observed at an enzymatic level by Chartrin et al.,[14] who showed an increased activity of ME1 induced by overfeeding. At the transcriptomic level, studies showed an increased expression of FASN, ME1,[15,16] APOA1,[15] and DLAT[16] due to overfeeding. FASN is the enzyme synthetizing fatty acids. Both ME1 and DLAT are proteins involved in the malate and pyruvate metabolic processes, respectively. APOA1 is a lipid transporter from the liver to the peripheral tissues. Our results are consistent with the biological functions of these enzymes as they are present at higher levels, as well as glutamine synthase (LOC100545435) (proteins of the group A, Figure 4A). FASN, ME1, and glutamine synthase (LOC100545435) were indeed overexpressed in livers of low weight compared to heavy ones. Hérault et al.[15] also reported negative correlations between liver weight and APOA1, FASN, and ME1 gene expressions in duck. These results suggest that when liver weight increases, a negative regulation occurs to reduce lipogenesis. FASN, IMMT, DLAT, APOA1, and ALB were also overexpressed in livers of low melting rate (up to 26%). In a study aiming at determining the proteomic profile of low and high MR livers with the same weight and lipid content, Théron et al.[8] showed that enolase 1, triose phosphate isomerase, malate dehydrogenase, mitochondrial carrier homologue 2, and several ribosomal proteins are present at high levels in low MR livers. In the present study, we do not point out the same proteins. However, the biological functions of the proteins at differential levels are close in both studies. Taken together, these data suggest that livers with low MR are performing anabolic processes. ALB, HADHA, PHB, and FASN were overexpressed in livers with high protein content. To our knowledge, this is the first time that such a differential expression between different liver protein contents is reported. Finally, group A proteins were at high levels in light livers, low-melting ones, and livers rich in proteins; we can hypothesize that these livers were in a higher anabolic state, leading to a more intense lipid synthesis. They also showed a significantly decreased expression when liver weights increased, when melting rate increased, or when protein content decreased. In all three traits (LW, MR, and LprotDc), the significantly decreasing expression of these proteins was followed by the overexpression of proteins of group B (Figure 4).

Proteins of group B belong to six GO processes (Table 2): response to stress (HYOU, HSPA5, HSPD1, PRDX6), glycolysis (ENO1, three isoforms), transport (FABP1), hydrolase activity (C11Orf54), catabolic process (*S*-formylglutathione hydrolase), and steroid receptor (FKBP4). PRDX6 is an antioxidant enzyme induced by the increase of reactive oxygen species (ROS) levels and providing protection against oxidative injury;[17] its level was found higher both in heavy livers (>581 g) and in livers of low protein content (<10%). On the contrary, PRDX6 is underexpressed in simple steatosis compared to normal livers in rat.[18] Other cytoprotective proteins such as HSPA5 and HSPD1 were at higher levels in high-melting livers (>45%), assessing the development of cytoprotection mechanisms. Similarly, Théron et al.[8] reported a higher expression of heat shock protein 27 in high MR livers. Another kind of stress seems to occur only in heavy livers: hypoxia stress is suggested by the overexpression of HYOU1 (also named 150 kDa oxygen-regulated protein (ORP150)) in livers of weight >581 g. This protein seems to be specific to the high-weight livers, as for the two other traits it is highly nonsignificant (p value >50%). This hypoxia-induced protein was described as helping the cell to face stress induced by the lack of oxygen by its protective role to avoid apoptotic cell death.[19] If protein-poor and high-melting livers seem to develop protection against oxidative stress, heavy livers seem to accumulate stresses, with both oxidative and hypoxia stresses.

The proteomics results suggest that the livers are trying to cope with the high amount of lipid synthesized by using different pathways. The first one is by containing the steatosis development (Figure 4D), as suggested by the overexpression of FKBP4 and FABP1 in heavy livers (>581 g). FKBP4 (also known as FKBP52) belongs to the family of immunophilin and plays a role in immunoregulation and basic cellular processes involving protein folding and trafficking. It is also a regulator of glucocorticoid receptor activity. When deficient mice for FKBP52 are fed a high-fat diet, there was a high expression of lipogenic genes such as FASN and an underexpression of gluconeogenic genes in the liver. Finally, the livers of these mice exhibited high lipid content and a steatosis.[20] In our study, FKBP52 is overexpressed when the liver's weight and melting rate increased. On the contrary, FASN and ME expressions decreased. From this, we can speculate that the overexpression of FKBP52 could reduce lipogenesis and, thus, steatosis. FABP1 is the liver isoform of the fatty acid binding protein mainly implicated in lipid transport from liver to peripheral tissues. Results from the literature concerning this protein are inconsistent. Indeed, when comparing normal livers and livers with a simple steatosis by two-dimensional electrophoresis gels, Charlton et al.[21] found an overexpression of FABP1 in simple steatosis in humans, whereas Zhang et al.[18] pointed out an underexpression of the same protein in simple steatosis in rat. Moreover, Théron et al.[8] identified the adipocyte isoform, FABP4, as overexpressed in high melting rate livers. It was shown that FABP1 is a positive regulator of PPARα and of FASN,[22] but because our results do not show any overexpression of both FASN and FABP1 in the same group, we can only speculate that FABP1 has a cytoprotective role in exporting fatty acids.

The second pathway proposed to cope with the intense steatosis is apoptosis (Figure 4E). ANXA5 is a calcium-dependent phospholipid binding protein mainly known as a membrane apoptotic marker. In plasma or extracellular tissues, it also has anticoagulant and antithrombic properties.[23] It is a widely expressed protein in the liver[24] and was overexpressed in the soluble proteome of heavy livers but also in low-melting livers. Even if apoptosis is a common phenomenon for tissues to regenerate, it can be associated with disease such as steatosis in mammals. In the livers of patients suffering from nonalcoholic steatohepatitis (NASH), there is consistently an enhanced Fas expression, activation of caspase-3 and -7, and apoptosis, which positively correlated with biochemical and histopathological markers of liver injury.[23] However, in human livers with a simple steatosis, apoptosis evaluated by a Fas score is not different from normal livers.[25] In the present study, ANXA5 is overexpressed in the heaviest livers and in the lowest

MR ones. The network constructed by IPA (Figure 3) also shows that four proteins (FABP1, ANXA5, VPC, and HSPD1) are linked with caspases. It could emphasized that livers in which these proteins increased with MR or LW and/or decreased with LprotDc could be more prone to develop steatosis.

The third pathway proposed is the stress response to support cell viability (Figure 4F), suggested by both HYOU1 and α-enolase (ENO1). ENO1 is a gluconeogenesis enzyme implicated in growth control and hypoxia tolerance. Its implication in hepatocellular carcinoma (HCC) was described by Hamaguchi et al.:[26] in HCC, ENO1 activation by hypoxia-induced factor 1α (HIF-1α) implicated an increased HCC aggressiveness, whereas ENO1 knockdown inhibited HCC proliferation. ENO1 was overexpressed in livers of low protein content and in heavy livers like HYOU1, described as a suppressor of hypoxia-induced apoptotic cell death.[19] Both proteins promote cell survival and even cell proliferation, suggesting that, despite stress, cell viability is supported.

The high level of proteins of anabolism processes in livers with melting rates up to 26% and of stress response proteins in livers with melting rates >40% confirm what was found by Theron et al.:[8] with a fixed weight and fixed lipid content, livers of low melting rate were in anabolism, whereas livers of high melting rate developed protection mechanisms. Concerning liver weight, we were able to distinguish two different metabolic states according to the liver weight value: an anabolism state in light livers (<600 g) and a cytoprotection state in heavy livers (>600 g). In a kinetic study, Bax et al.[27] reported that during the first half of the overfeeding period, livers were in anabolism (overexpression of FASN), whereas they developed protection mechanisms during the second period. In the present study, similarly, the lightest livers, lowest melting livers, and livers rich in protein still exhibit higher levels of proteins involved in lipogenesis, whereas the heaviest ones show higher expression of stress response proteins. We can wonder if the first group of livers has a better control of steatosis or if steatosis is just delayed. On the contrary, the second group of livers showed a development of protection mechanisms and seemed to have reached an overphysiological point.

specific soy peptides are responsible for the LDLR modulation.[28−32] Nevertheless, the mechanism at the molecular level has not been investigated in detail yet. These bioactive peptides, initially encrypted in the soy protein sequences, are probably enzymatically released during digestion and absorbed.[33]

The majority of plasma cholesterol is transported by the LDL fraction, and the cellular uptake of LDL is mediated by the LDLR. The circulating level of LDL is determined in large part by its rate of uptake through the hepatic LDLR pathway.[34,35] Moreover, the LDLR plays a crucial role in Apo B turnover, being involved in determining the post-translation fate of apoB by increasing presecretory apoB degradation and mediating re-uptake of nascent lipoprotein particles.[36] In general, LDLR expression is finely tuned by changes in intracellular cholesterol.[37] A transcription factor known as the sterol-responsive element binding protein 2 (SREBP2) plays a critical role in LDLR mRNA expression.[38,39] Among SREBP2 gene targets, the 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase (HMGCoAR) is particularly important. This enzyme plays a key role in the intracellular cholesterol biosynthesis, because it is the rate-controlling enzyme in the mevalonate pathway. After synthesis, SREBP2 forms a complex with the SREBP cleavage-activating protein (SCAP) and is localized in the endoplasmic reticulum (ER) as an inactive precursor (pro-SREBP2). Sterol deficiency results in the release of SREBP2/SCAP complex from ER and transport to the Golgi, where pro-SREBP2 is processed further, allowing the N-terminal fragment (mature SREBP2) to enter the nucleus and up-regulate transcription of LDLR and HMGCoAR.[40] In addition to SREBP2, other transcription factors may be involved in a context-dependent fashion in regulating the LDLR expression.

Recent studies[41,42] identify a crucial signaling pathway, via phosphatidylinositol-3-kinase (PI3K)/Akt, as an important player in the regulation of cellular lipid metabolism. This pathway is the best known for its role in promoting cell growth, proliferation, and survival through increased glucose utilization and prevention of apoptosis.[43,44] In particular, Akt has recently been implicated in a novel form of lipid metabolism regulation, through the SREBPs.[45] The physiological coordination between Akt and SREBPs pathways is needed to produce the lipids for new membrane synthesis, which in turn is required for growing and proliferating cells.[41,42] Even though many studies have been focused on the SREBP-1c isoform,[45] new efforts are directed to explore and to investigate the link between Akt and SREBP2.[41,46]

The objective of the present study was to characterize in detail the molecular mechanism at the basis of the cholesterol-lowering properties of *L. albus* protein observed in experimental and clinical investigations. On the basis of the hypothesis that the activity may depend on specific peptides encrypted in the protein sequences, a total protein extract from lupin seed was hydrolyzed either with pepsin (P peptides) or with trypsin (T peptides). The HepG2 cell line was treated with both kinds of peptides, and molecular and functional investigations were performed on the LDLR-SREBP2 and PI3K/Akt pathways, using a combination of techniques.

MATERIALS AND METHODS

Chemicals. Dulbecco's modified Eagle's medium (DMEM), L-glutamine, fetal bovine serum (FBS), phosphate-buffered saline (PBS), penicillin/streptomycin, chemiluminescent reagent, and 96-well plates were purchased from Euroclone (Milan, Italy). Bovine serum albumin (BSA), RIPA buffer, HMGCoAR Assay Kit, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), and wortmannin were from Sigma-Aldrich (St. Louis, MO, USA). Antibodies against HMGCoAR were bought from Abcam (Cambridge, UK). Antibodies against β-actin, SREBP-2, rabbit Ig-HRP, and mouse Ig-HRP, PMSF, sodium orthovanadate inhibitors, and goat anti-rabbit Ig-HRP were purchased from Santa Cruz Biotechnology Inc. (Santa Cruz, CA, USA). Antibodies against the LDL receptor were from Pierce (Rockford, IL, USA). The inhibitor cocktail Complete Midi was from Roche (Basel, Switzerland). Mini protean TGX precast gel 7.5% and Mini nitrocellulose Transfer Packs were purchased from Bio-Rad (Hercules, CA, USA). LDL-DyLight 549 was from Cayman Chemical (Ann Arbor, MI, USA).

Preparation and Analysis of the Pepsin and Trypsin Peptide Mixtures. Lupin seeds of the species *L. albus* (cultivar Ares) were provided by Terrena (Matrignè-Ferchaud, France). The total protein extracts were obtained as previously reported.[47] Briefly, proteins were extracted from defatted flour with 100 mM Tris-HCl/0.5 M NaCl buffer, pH 8.2, for 2 h at 4 °C. The solid residue was eliminated by centrifugation at 6500*g*, for 20 min at 4 °C, and the supernatant was dialyzed against 100 mM Tris-HCl buffer, pH 8.2, for 24 h at 4 °C. The protein content was assessed according to the method of Bradford, using BSA as standard.

For the hydrolysis, the total protein extract was initially dissolved in Tris-HCl buffer 100 mM at pH 8, and then the pH was adjusted to the optimal hydrolysis conditions for each enzyme (pH 2 for pepsin and pH 8 for trypsin) by adding 1 M NaOH or 1 M HCl. The mixtures were incubated for 18 h, then the enzymes were inactivated, and the mixtures were purified by ultrafiltration through 3000 Da cutoff centrifuge filters (Amicon Ultra-0.5, Millipore, Billerica, MA, USA) at 12000*g* for 30 min at 4 °C. The peptide concentration in the permeates was measured according to a literature method,[48] based on chelating the peptide bonds by Cu(II) in alkaline media and monitoring the change of absorbance at 330 nm. Details are reported in a previous paper.[47]

The hydrolyzed mixtures were acidified with formic acid to a final 10% concentration. Eight microliters of tryptic digest for each band was injected in a nanochromatographic system, UltiMate 3000 RSLC nano-System (Thermo Scientific). The peptide mixtures were loaded on a reversed-phase trap column (Acclaim PepMap100, C18, 100 Å, 100 μm i.d. × 2 cm, Thermo Scientific) for the cleanup and preconcentration. After cleanup, the valve was switched to place the trap column in series with a fused silica reverse-phase column (picoFrit column, C18, 2.7 μm, New Objective). The peptides were eluted with a 30 min gradient from 4% buffer A (2% acetonitrile and 0.1% formic acid in water) to 60% buffer B (2% water and 0.1% formic acid in acetonitrile) at a constant flow rate of 300 nL/min. The chromatographic column was directly connected to an LTQ-XL mass spectrometer (Thermo Scientific) equipped with a nano spray ion source. Full scan mass spectra were acquired in the mass range from m/z 350 to 2000 Da, and the five most intense ions were automatically selected and fragmented in the ion trap. Target ions already selected for mass spectrometry (MS/MS) were dynamically excluded for 30 s. The MS data were analyzed separately by Mascot search engine (version 2.3.01) using Proteome Discover software (v. 1.2.0 Thermo) and consulting Uniprot_viridiplantae (30,264 sequences, 184,678,199 residues). Oxidation of methionine residues was set as variable modifications; two missed cleavages were allowed to trypsin; peptide mass tolerance was set to 1 Da and fragment mass tolerance to 0.8 Da; and an ion source cutoff of 20 was chosen. The false discovery rate obtained by Proteome Discoverer, consulting the Mascot decoy database, was <0.01. Tables 1S and 2S in the Supporting Information list the proteins and the unmatched peptides, with all relevant peptide signals, peptide sequences, ion score, variable modifications and mass errors.

Cell Culture Conditions. HepG2 cell line was bought from ATCC (HB-8065, ATCC from LGC Standards, Milan, Italy). The HepG2 cell line was cultured in DMEM high-glucose with stable L-glutamine supplemented with 10% FBS, 100 U/mL penicillin, and 100 μg/mL streptomycin (complete growth medium) and incubated at 37 °C under 5% CO_2 atmosphere. HepG2 cells were used for no more than 20 passages after thawing because the increase of the number of passages may change the cell characteristics and impair assay results.

MTT. HepG2 cells (3×10^4/well) were seeded in 96-well plates and treated with 0.3, 0.5, 1.0, 2.5, 5.0, and 10.0 mg/mL of P and T peptides, respectively, or vehicle (100 mM Tris) in complete growth media for 48 h. Subsequently, the treatment solvent was aspirated and 100 μL/well of MTT

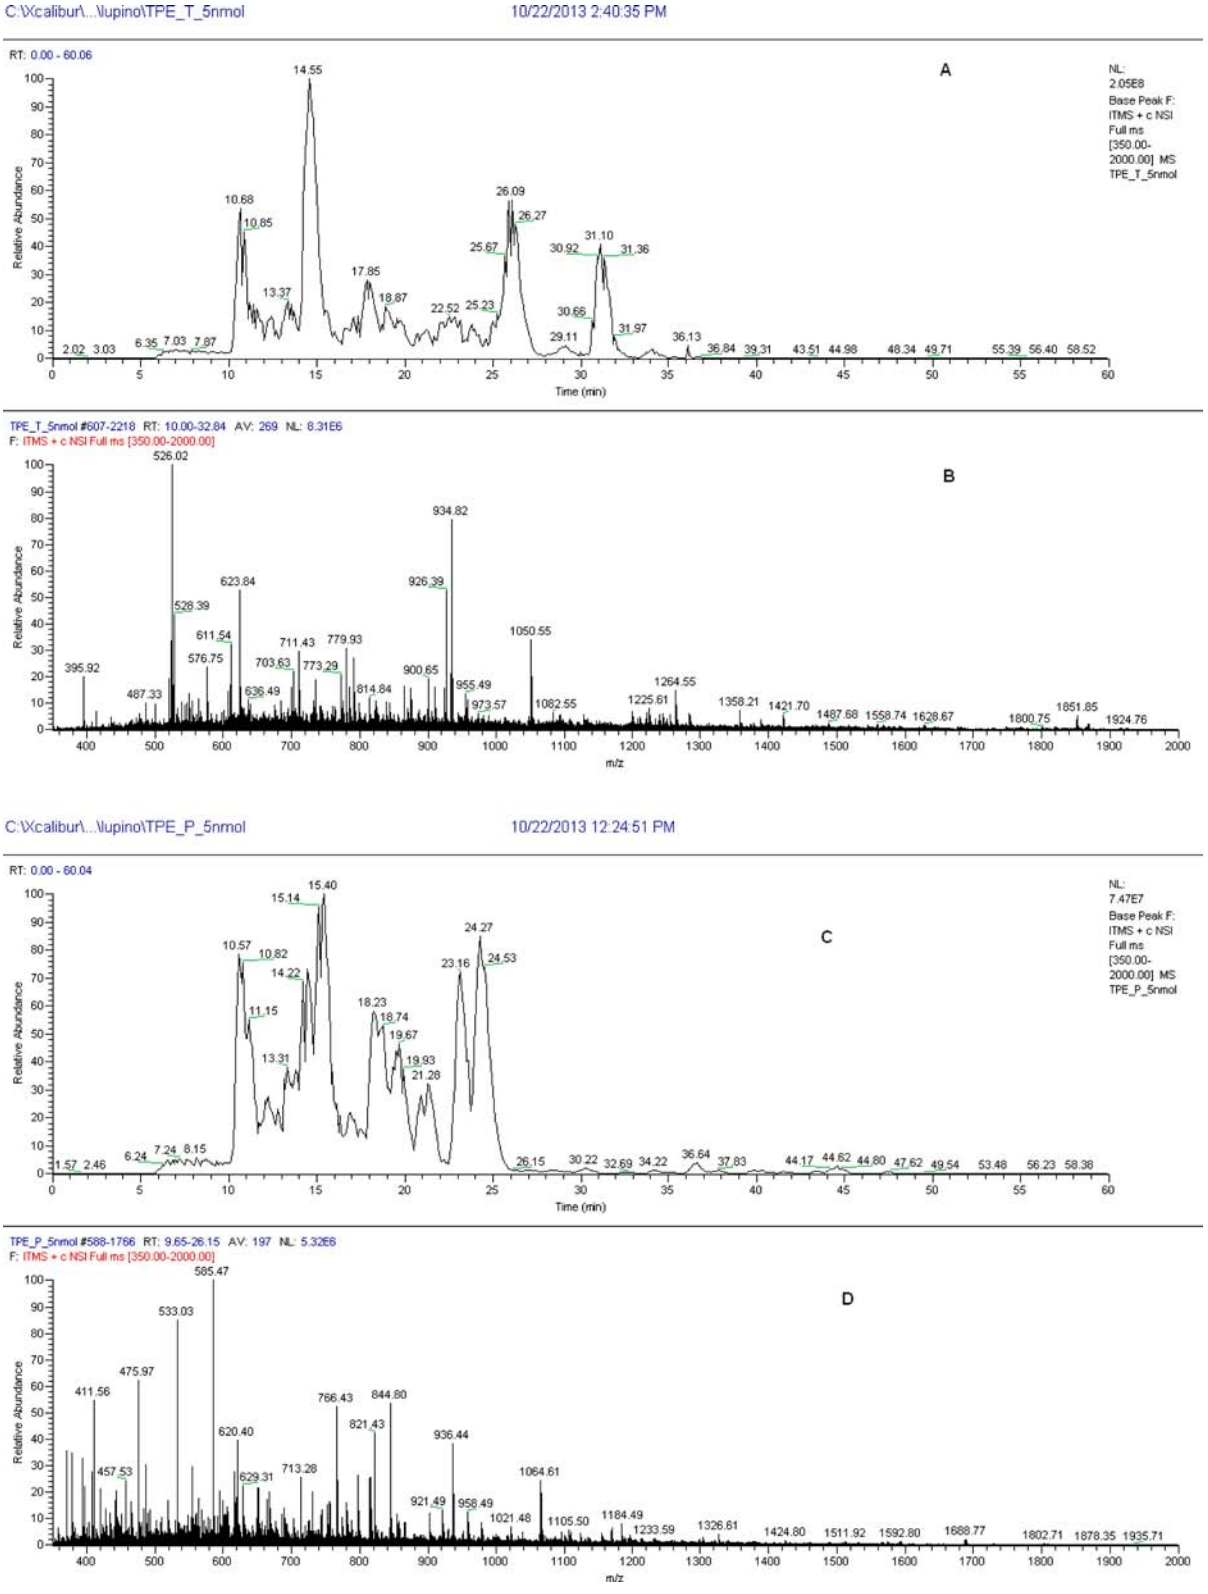

Figure 1. Nano-LC MS/MS of lupin peptide mixtures: (A, B) chromatogram and full scan mass spectrum of T peptides; (C, D) chromatogram and full scan mass spectrum of P peptides.

filtered solution added for 48 h. After the incubation time, 0.5 mg/mL MTT solution was aspirated and 100 μL/well of MTT lysis buffer (8 mM HCl + 0.5% NP-40 in DMSO) added. After 5 min of slow shaking, the absorbance at 575 nm was read on an LT 4000 spectrophotometer.

HMGCoAR Activity Assay. The assay buffer, the NADPH, the substrate solution, and the HMG-CoA reductase were provided in the HMGCoAR Assay Kit (Sigma). The experiments were carried out following the manufacturer's instructions at 37 °C. In particular, each reaction (200 μL) was prepared by adding the reagents in the following order: 1× assay buffer; 0.1, 0.25, 0.5, 1.0, and 2.5 mg/mL of T peptides or 0.5, 1.0, and 2.5 mg/mL of P peptides or vehicle (C); NADPH (4 μL); substrate solution (12 μL); and finally HMG-CoA reductase

(catalytic domain) (2 μL). Subsequently, the samples were mixed and the absorbance at 340 nm read by a Synergy H1 microplate reader from Biotek at times 0 and 10 min. The HMGC-CoA-dependent oxidation of NADPH and the inhibition properties of lupin peptides were measured by the absorbance reduction, which is directly proportional to the enzyme activity.

Western Blot Analysis. HepG2 cells (1.5×10^5/well, 24-well plate) were treated with 0.5, 1, and 2.5 mg/mL of P and T peptides for 24 h. For the experiments in the presence of wortmannin, cells were treated with 1 mg/mL P and 0.5 mg/mL T peptides in the presence or absence of 1 μM inhibitor for 24 h. After each treatment, cells were scraped in 40 μL of ice-cold lysis buffer (RIPA buffer + inhibitor cocktail + 1:100 PMSF + 1:100 sodium orthovanadate) and transferred in an ice-cold microcentrifuge tube. After centrifugation at 13300 rpm for 15 min at 4 °C, the supernatant was recovered and transferred into a new ice-cold tube. Total proteins were quantified according to the Bradford method, and 50 μg of total proteins was loaded on a precast 7.5% sodium dodecyl sulfate−polyacrylamide (SDS-PAGE) gel at 130 V for 45 min. Subsequently, the gel was pre-equilibrated with 0.04% SDS in H_2O for 15 min at room temperature and transferred to a nitrocellulose membrane (Mini nitrocellulose Transfer Packs,) using a Trans-blot Turbo at 1.3 A and 25 V for 7 min. Target proteins, on milk-blocked membrane, were detected by primary antibodies as follows: rabbit anti-SREBP2, rabbit anti-LDLR, anti-HMGCoAR, antipospho-Akt (ser473), antipospho-GSK3α/β (ser21/ser9), and anti-β-actin. Secondary antibodies conjugated with HRP and a chemiluminescent reagent were used to visualize target proteins, and their signal was quantified using ImageJ software. The internal control, β-actin, was used to normalize loading variations. In the case of SREBP2, the band at 70 kDa, corresponding to the N-terminal fragment (mature SREBP2 protein), was detected and quantified.

Fluorescent LDL Uptake Cell-Based Assay. HepG2 cells (3×10^4/well) were seeded in 96-well plates and kept in complete growth medium for 2 days before treatment. The third day, cells were treated with 1.0 mg/mL P peptides and 0.25 mg/mL T peptides, respectively, or vehicle (100 mM Tris) for 24 h. For the experiments in the presence of the PI3K inhibitor, HepG2 cells were treated with 1.0 mg/mL P peptides and 0.5 mg/mL T peptides in the presence or absence of 100 nM wortmannin and in the presence of the only inhibitor, as control, in DMEM without FBS for 24 h. At the end of the treatment periods, the culture medium was replaced with 75 μL/well LDL-DyLight 549 working solution. The cells were additionally incubated for 2 h at 37 °C, and then the culture medium was aspirated and replaced with PBS 100 μL/well. The degree of LDL uptake was measured using the Synergy H1 fluorescent plate reader from Biotek (excitation and emission wavelengths 540 and 570 nm, respectively).

Statistical Analysis. Statistical analyses were carried out by one-way ANOVA (Graphpad Prism 6) followed by Dunnett's test. Values were expressed as means ± SEM; P values <0.05 were considered to be significant.

RESULTS

Preparation and Analysis of the Peptide Mixtures. A total protein extract from lupin seed was hydrolyzed with pepsin and trypsin to produce P peptides and T peptides, respectively. The two samples were analyzed by nano-LC-MS/MS. The chromatograms (Figure 1) showed two diverse profiles due to the different peptide compositions of the digested samples. The number of potentially bioactive peptides is very high in both samples, because more than 2000 peptides were detected in the pepsin-digested mixture and about 3000 in the trypsin-digested one (Tables 1S and 2S in the Supporting Information).

It was possible to assign only a small number of peptides to known lupin proteins by Mascot software consulting the Uniprot_viridiplantae database. The other peptides were sequenced, but not assigned to protein hits, possibly due to the very incomplete sequencing of lupin proteins. The recognized peptides in the P sample belong to the main storage proteins in lupin seed: 21 peptides to the vicilins [*L. albus* vicilin-like protein (Q53HY0) and *L. albus* β-conglutin (Q6EBC1)]; 7 peptides to the legumins [*L. angustifolius* conglutin-α 3 (F5B8V8)], and 8 peptides to γ-conglutin [*L. albus* conglutin-γ (Q9FSH9)], a sulfur-rich basic protein typical of lupin (4−5%).

The identified peptides in the T sample are the following: 16 peptides belong to the vicilins [*L. albus* vicilin-like protein (Q53HY0), *L. albus* β-conglutin precursor (Q6EBC1), and *L. angustifolius* conglutin β (B0YJF8)]; 4 to the legumins [*L. angustifolius* legumin-like protein (Q53I55)], and 2 to δ-conglutin, a 2S protein [*L. albus* conglutin δ seed storage protein precursor (Q99235)]. Two peptides were assigned to other plant proteins, probably because the lupin sequences are not present in the database: *Zea mays* actin partial (ADF3).

HepG2 Cell Viability. MTT experiments were performed to exclude the peptide doses with potential toxic effects on the HepG2 cell line. No significant cell mortality was observed up to 2.5 mg/mL after a 48 h treatment versus vehicle (C, 100 mM Tris), suggesting that neither P nor T peptides induce cell mortality in this dose range, whereas about 20 and 80% cell mortalities were observed at 5.0 and 10 mg/mL, respectively (Figure 2). For this reason, all of the following experiments, aimed at investigating the molecular and functional effects of P and T peptides, were conducted using doses of ≤2.5 mg/mL.

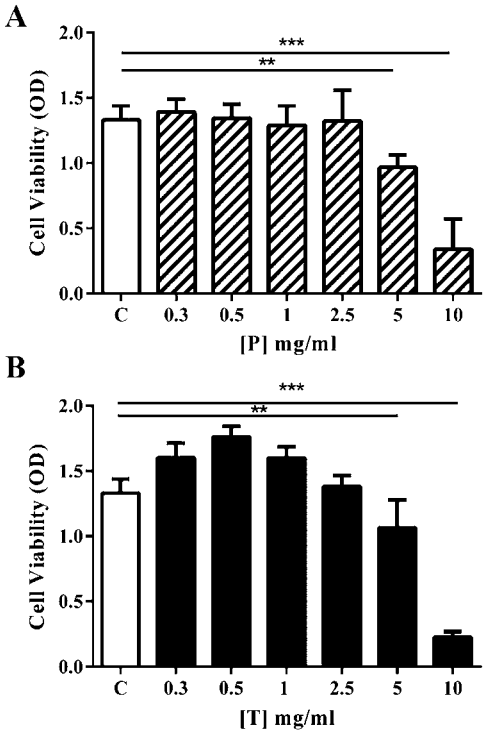

Figure 2. HepG2 cell viability after P and T peptide treatment. Bar graphs indicate the results of MTT cell viability assay of HepG2 cells after P and T peptide treatment for 48 h. Data points represent averages ± SEM of three independent experiments in triplicate. (**) $P < 0.001$ and (***) $P < 0.0001$ versus C. P, pepsin peptides; T, trypsin peptides; C, control.

Effects of P and T Peptides on the Catalytic Domain of HMGCoAR. To check the direct ability of P and T peptides to inhibit HMGCoAR, an in vitro assay was performed using the purified catalytic domain of this enzyme. Both P and T peptides

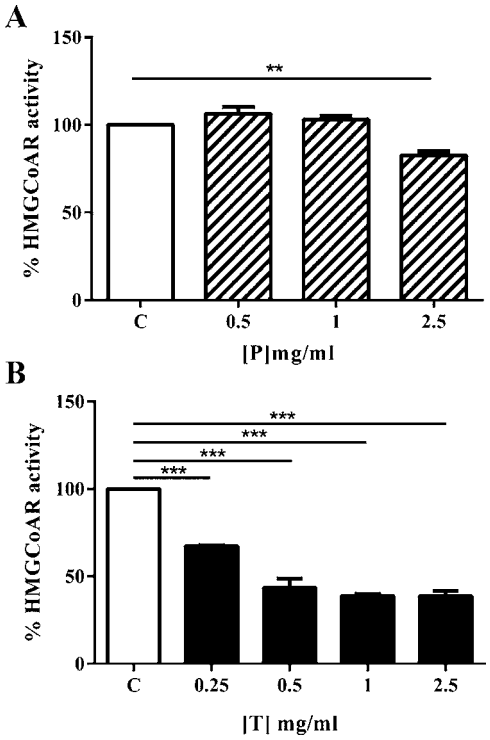

Figure 3. Lupin peptide effect on the catalytic domain of HMGCoAR. Bars indicate the effects of P peptides (0.5, 1.0, and 2.5 mg/mL) (A) and T peptides (0.25, 0.5, 1.0, and 2.5 mg/mL) (B) on HMGCoAR activity. HMGCoAR, physiologically, catalyzes the four-electron reduction of HMG-CoA to coenzyme A (CoA) and mevalonate (HMG-CoA + 2NADPH + $2H^+$ > mevalonate + $2NADP^+$ + CoA-SH). In this assay, the decrease in absorbance at 340 nm, which represents the oxidation of NADPH by the catalytic subunit of HMGCoAR in the presence of the substrate HMG-CoA, was measured spectrophotometrically. Data points represent averages ± SEM of three independent experiments in triplicate. (**) $P < 0.001$ and (***) $P < 0.0001$ versus C. P, pepsin peptides; T, trypsin peptides; C, control.

were capable of inhibiting HMGCoAR, but with very different activities and potencies (Figure 3). In fact, P peptides inhibited the enzyme with a statistical significance (−17%) only at the maximum tested dose (2.5 mg/mL), whereas they are ineffective at 0.5 and 1.0 mg/mL. On the contrary, T peptides showed a statistically significant reduction of the HMGCoAR activity at all tested doses: in fact, the enzyme activity was reduced by 37% at 0.25 mg/mL, by 57% at 0.5 mg/mL, and by 61% at 1.0 and 2.5 mg/mL.

Lupin Peptides Mediate the Up-regulation of LDLR-SREBP2 at HepG2 Cells. HepG2 cells were treated for 24 h with P and T peptides at concentrations of 0.5, 1.0, and 2.5 mg/mL. Immunoblotting experiments showed that the treatments with lupin peptides induce an up-regulation of the SREBP2 protein level. In particular, P peptides up-regulate the SREBP2 protein level by 100, 148, and 162% versus the control, whereas T peptides increase the SREBP2 protein level by 80, 73, and 44% versus the control, after 0.5, 1.0, and 2.5 mg/mL treatments, respectively (Figure 4B).

In the same experiments, also the LDLR and HMGCoAR protein levels were measured by immunoblotting. Figure 4C shows that both P and T peptides are able to induce a statistically significant up-regulation of LDLR protein in HepG2 cells versus the control, but with different behaviors. In particular, at 0.5, 1.0, and 2.5 mg/mL P peptides mediate 147, 136, and 120% inductions of the LDLR protein, whereas T peptides mediate a ∼85% up-regulation at 0.5 and 1.0 mg/mL and a 61% up-regulation at 2.5 mg/mL versus the control (Figure 4C). These results are in agreement with the up-regulation of SREBP2 protein level.

Both P and T peptides affect the HMGCoAR levels (Figure 4D), but with very different behaviors and activities. Precisely, P peptides increase the synthesis of HMGCoAR by 82% at 0.5 mg/mL, by 212% at 1.0 mg/mL, and by 340% at 2.5 mg/mL versus the control, that is, in a dose-dependent manner. On the contrary, treatment with T peptides enhances the production of HMGCoAR by 233% at 0.5 mg/mL and by only 97% at 1.0 mg/mL, whereas it is practically inactive at 2.5 mg/mL.

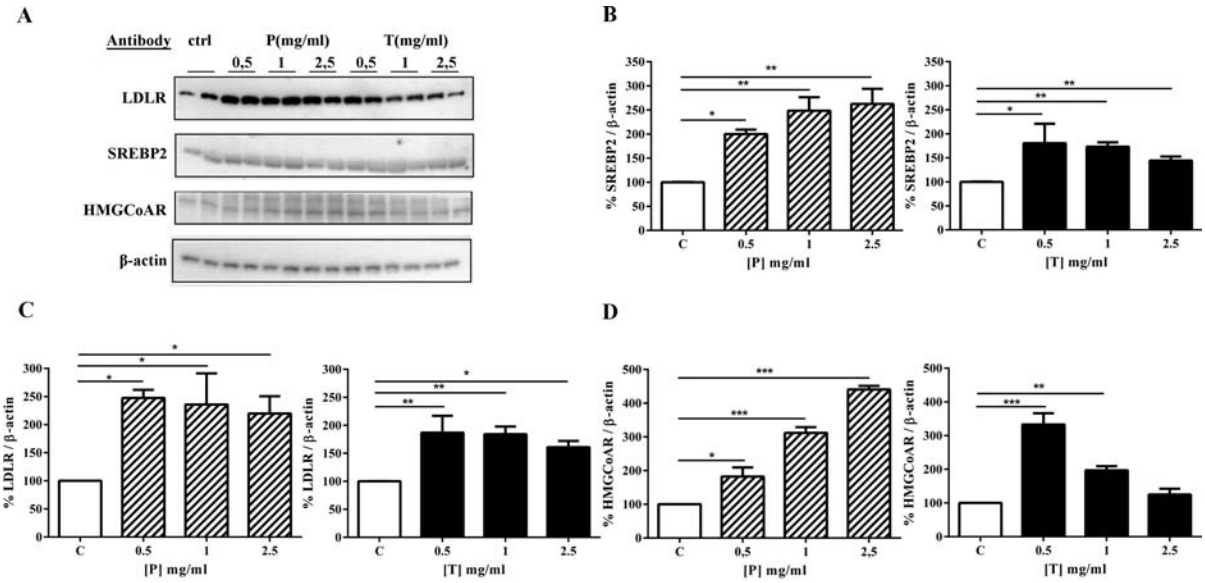

Figure 4. Effect of P and T peptides on the SREBP2, LDLR, and HMGCoAR protein levels. HepG2 cells (1.5×10^5) were treated with 0.5, 1.0, and 2.5 mg/mL of P and T peptides for 24 h, respectively. SREBP2, LDLR, HMGCoAR, and β-actin immunoblotting signals were detected using specific anti-SREBP2, anti-LDLR, anti-HMGCoAR, and anti-β-actin primary antibodies, respectively (A). SREBP2 (B), LDLR (C), and HMGCoAR (D) signals were quantified by ImageJ software and normalized with β-actin signals. Bars represent averages of duplicate samples ± SEM of three independent experiments. (*) $P < 0.05$ and (**) $P < 0.001$ versus C. P, pepsin peptides; T, trypsin peptides; C, control.

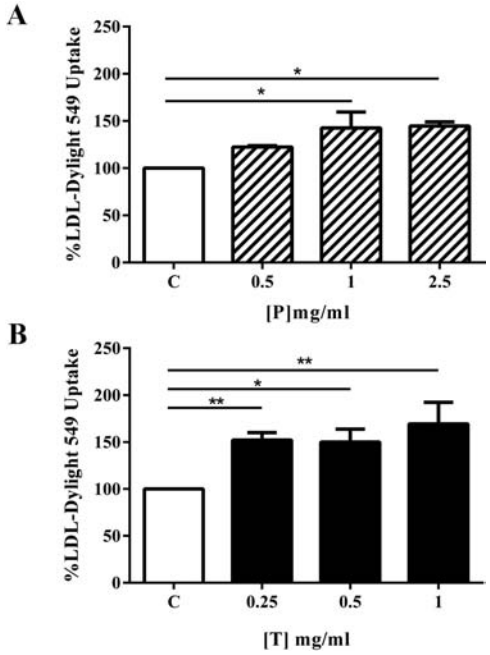

Figure 5. LDL uptake after P and T peptide treatments. HepG2 cells (3×10^4) were treated with P (0.5, 1.0, and 2.5 mg/mL) and T (0.25, 05, and 1.0 mg/mL) peptides for 24 h. LDL-Dylight 549 (10.0 μg/mL) was incubated for an additional 2 h. Excess LDL-Dylight 549 was removed, cells were washed two times with PBS, and specific fluorescent LDL uptake was analyzed by Synergy H1 (Biotek). Data points represent averages ± SEM of three independent experiments in triplicate. (∗) $P <$ 0.05 and (∗∗) $P <$ 0.001 versus C. P, pepsin peptides; T, trypsin peptides; C, control.

Lupin Peptides Increase LDL Uptake at the HepG2 Cell Line. Fluorescent LDL uptake experiments were performed for evaluating the cholesterol-lowering properties of lupin peptides from a functional point of view. Precisely, the fluorescent LDL uptake was examined in HepG2 cells following a 24 h incubation with P and T peptides. Figure 5 shows that both P and T peptides are able to increase the LDL uptake versus the control in a statistically significant way. In particular, treatment with P peptides at concentrations of 1.0 and 2.5 mg/mL increases the LDL uptake by 42 and 45%, respectively, versus the control, whereas the LDL uptake increase was not statistically significant at 0.5 mg/mL. On the other hand, at concentrations of 0.25, 0.5, and 1.0 mg/mL T peptides significantly raise the LDL uptake by 52, 50, and 70%, respectively, versus the control.

Lupin Peptides Mediate LDLR-SREBP2 Up-regulation through the Activation of PI3K/Akt/GSK3β Kinases. To examine the effect of lupin peptides on the activation of Akt and GSK3β (its direct substrate), immunoblot analyses were performed on lysates from treated HepG2 cells using antibodies, which are specific for Akt phosphorylated at serine residue 473 and for GSK3β phosphorylated at serine residue 9. In accordance with the preceding immunoblot experiments, HepG2 cells were treated with P and T peptides at concentrations of 1.0 and 0.5 mg/mL, and the variation of phosphorylated Akt and GSK3β levels was investigated. Figure 6B shows that the treatments with lupin peptides increased the Akt phosphorylation in a dose-dependent manner: by 92 and 125%, respectively, after treatment with P peptides at 0.5 and 1.0 mg/mL and by 144 and 196%, respectively, after treatment with T peptides at 0.5 and 1.0 mg/mL.

Additionally, P peptides mediate a 60% increase of the phosphorylation level of GSK3β at 0.5 mg/mL and a 74% increase at 1.0 mg/mL versus the control. After T peptide treatments, instead, the GSK3β phosphorylation level was increased by 133% at 0.5 mg/mL and by only 75% at 1.0 mg/mL (Figure 6D).

Treatment with 1 μM wortmannin, a PI3K inhibitor, inhibited the Akt phosphorylation either in the presence or in the absence of both lupin peptide mixtures. Figure 7A shows a representative immunoblot and the relative intensity of the phospho-Akt bands. The quantification and normalization against actin bands from

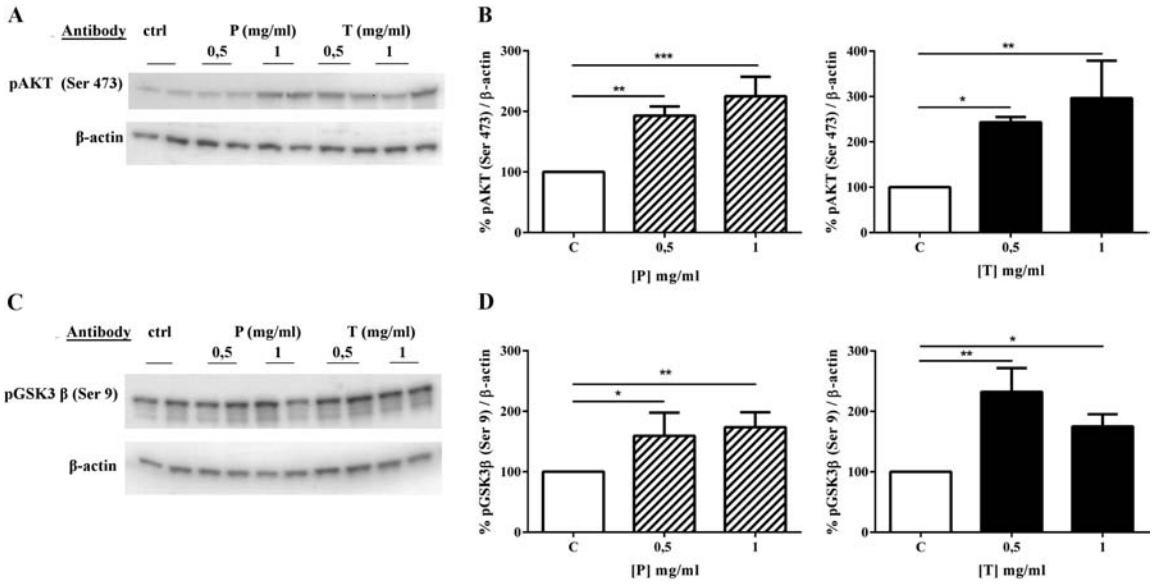

Figure 6. Effect of P and T peptides on the activation of Akt (Ser473) and GSK3 (Ser9). HepG2 cells (1.5×10^5) were treated with 0.5 and 1 mg/mL of P and T peptides for 24 h, respectively. The phosphorylation levels of Akt (Ser473) (A) and GSK3 (Ser9) (C) and β-actin immunoblotting signals were detected using specific anti-posphoAkt (Ser473), anti-posphoGSK3β (Ser9), and anti-β-actin primary antibodies, respectively. PosphoAkt signals (B) and posphoGSK3β (D) were quantified by ImageJ software and normalized with β-actin signals. Bars represent averages of duplicate samples ± SEM of three independent experiments. (∗) $P <$ 0.05, (∗∗) $P <$ 0.001, and (∗∗∗) $P <$ 0.0001 versus C. P, pepsin peptides; T, trypsin peptides; C, control; pAkt, posphoAkt; pGSK3β, posphoGSK3β.

dx.doi.org/10.1021/jf500795b | J. Agric. Food Chem. 2014, 62, 7151−7159

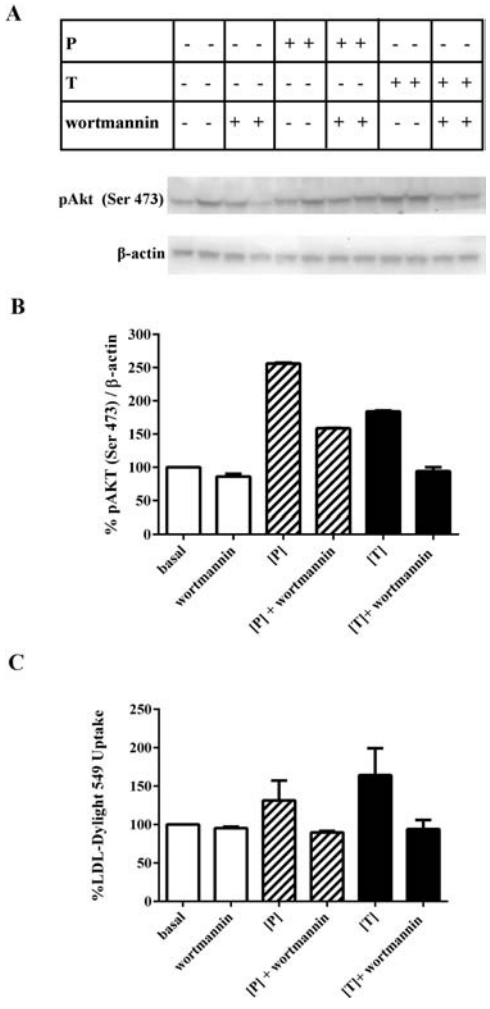

Figure 7. Involvement of PI3K/Akt pathway activation in the regulation of the LDLR−SREBP2 pathway through which lupin peptides mediate the cholesterol-lowering effects. HepG2 cells (1.5×10^5) were treated with 1.0 and 0.5 mg/mL of P and T peptides in the presence or absence of wortmannin for 24 h, respectively. The phosphorylation level of Akt (Ser473) (A) and β-actin immunoblotting signals were detected using specific anti-posphoAkt (Ser473) and anti-β-actin primary antibodies, respectively. Relative intensity of posphoAkt signals (B) was quantified by ImageJ software and normalized with β-actin signals. Panel C shows the LDL uptake after treatment with the PI3K inhibitor. HepG2 cells (3×10^4) were treated with P (1.0 mg/mL) and T (0.5 mg/mL) peptides in the presence or absence of wortmannin and inhibitor alone for 24 h. LDL-Dylight 549 (10.0 μg/mL) was incubated for additional 2 h. Excess LDL-Dylight 549 was removed, and cells were washed two times with PBS. Specific fluorescent LDL uptake was analyzed by Synergy H1 (Biotek). Bars represent averages of duplicate samples ± SEM of three independent experiments. pAkt, posphoAkt; P, pepsin peptides; T, trypsin peptides; C, control.

three different experiments, each performed in duplicate, is shown in Figure 7B. This figure clearly demonstrates that the wortmannin co-incubation with P and T peptides is able to reduce by about 40 and 50% the Akt phosphorylation level, abolishing the Akt phosphorylation induced by lupin peptides.

To confirm the involvement of the PI3K/Akt pathway activation in the regulation of the LDLR-SREBP2 pathway, functional LDL uptake experiments were performed in the presence of wortmannin. As Figure 7C shows, P peptides and T peptides are able to increase the LDL uptake with respect to the basal level, but these uptakes are blocked in the presence of wortmannin. Precisely, the LDL uptake is blocked at the basal level either in the presence of the inhibitor alone or in the co-incubation with P and T peptides, demonstrating that the LDL uptake induced by lupin peptides is abolished by treatment with this well-known PI3K inhibitor.

DISCUSSION

As already indicated in the Introduction, some experimental studies[11−14] and a few clinical trials[17−19] gave clear indications that lupin proteins are able to induce hypocholesterolemic effects in vivo. The present investigation at HepG2 cells was aimed at providing some further information on the mechanism through which the lupin peptides may be responsible of the observed activities.

The main findings of this study are the following: (i) T peptides are able to directly interfere with the HMGCoAR activity, whereas P peptides are much less effective. (ii) Both P and T peptides modulate the cholesterol metabolism at HepG2 cell line, through the up-regulation of the pathway involving the LDLR. (iii) Both P and T peptide treatments increase the LDL-uptake. (iv) Activation of the Akt/GSK3β pathway is involved in the up-regulation of the LDLR-SREBP2 pathway.

HMGCoAR is the rate-controlling enzyme of cellular cholesterol biosynthesis pathway, and therefore it constitutes the target of numerous investigations aimed at lowering the rate of cholesterol biosynthesis.[49] Therefore, initially in vitro experiments were performed using the purified catalytic domain of the enzyme with the objective of clarifying whether lupin peptides were able to directly inhibit the activity of HMGCoAR. As shown in Figure 3, T peptides but not P peptides act as enzyme inhibitors.

The LDLR expression and the receptor protein localization at cellular membranes are strictly correlated to the intracellular cholesterol biosynthesis pathway. In fact, the transcription of the LDLR and the genes required for cholesterol and fatty acid synthesis are controlled by membrane-bound transcription factors called SREBPs,[50] and the intracellular cholesterol acts with a negative feedback inhibition mechanism.[51] The SREBP2 isoform is responsible for the LDLR and HMGCoAR transcription, and the SREBP2 maturation is regulated by the intracellular cholesterol homeostasis. Thus, the up-regulation of LDLR represents a useful strategy to control plasma LDL cholesterol levels. Our findings demonstrate that both lupin peptide mixtures are able to up-regulate the LDLR protein levels through an increase of SREBP2 protein. However, a detailed investigation of the LDLR pathway revealed that lupin peptides produce different effects on the HMGCoAR level. In particular, whereas P peptides are able to increase the enzyme protein level in a dose-dependent manner, T peptides up-regulate the enzyme protein levels in a significant way versus the control at 0.5 mg/mL; the increase remains statistically significant, but it is smaller at 1.0 mg/mL, and it is finally completely abolished at 2.5 mg/mL (Figure 4D).

These pieces of evidence suggest that both peptide mixtures modulate the cholesterol metabolism pathway through the induction of LDLR protein levels due to an increase of SREBP2 protein, although their potencies of induction are different.

In agreement with immunoblotting results, the increase of LDLR protein levels leads to an increase of LDL uptake (Figure 5). Our findings suggest that both P and T peptides are able to significantly induce the LDL clearance, and this result is strictly correlated to an increase of LDLR protein level.

Recently, studies have indicated that there are links between the Akt and the SREBP pathways: in fact, emerging evidence

shows that Akt is implicated in the regulation of lipid metabolism through the activation of SREBPs.[45,52−55] Luu and co-workers[41] showed that insulin-like growth factor-1, an inducer of Akt signaling, acutely increases SREBP2 activation. This study provided evidence that Akt contributes to the regulation of cholesterol metabolism through activating SREBP2.

Even if the precise target or targets of Akt remain elusive and not clarified, part of our investigation was dedicated to evaluating the effects of lupin peptides on the PI3K/Akt pathway. Our study provides experimental evidence that either P or T peptides from lupin protein are able to induce increases of Akt and GSK3β phosphorylation levels, which are completely abolished by treatment with a well-known PI3K inhibitor, such as wortmannin. A constitutively active form of Akt activated the LDLR.[53] Our findings clearly support this study, because both P and T peptides increase the LDLR protein levels and induce an increased fluorescent LDL uptake at HepG2 cells. Moreover, after treatment with both lupin peptides in the presence of wortmannin, LDL uptake is blocked versus the P and T treatments alone, demonstrating that the inhibition of PI3K/Akt has general effects on cellular lipid homeostasis, although the precise Akt target or targets are not definitely assigned yet.

In conclusion, this is the first study providing evidence that peptide mixtures obtained by the hydrolysis of lupin proteins are able to modulate the LDLR/SREBP2 pathway with the final effect of an increased LDL uptake. Because, as indicated above, both P peptides and T peptides are complex mixtures, it appears very difficult to sort out which may be the peptides responsible for the observed activities. It is, however, possible to affirm that the diversity in the behaviors of the two peptide mixtures derives from their different compositions. Further work will be necessary to investigate these aspects in detail. This is also the first study to investigate in detail the mechanism of the hypocholesterolemic activity of peptides deriving from a plant protein, because, even in the case of soy, only partial information is available.[26−32]

soyasaponin B concentration is affected by specific environmental factors if soybeans are to be considered a source of saponins for the nutraceutical and functional food industries. Indeed a better understanding of factors affecting concentrations may help ensure the production of soybeans with a more stable and consistent saponin concentration. To our knowledge, the impact of specific environmental or crop management factors on soyasaponin B concentration in mature soybeans has never been researched. The objectives of this study were thus to determine the impact of specific crop management practices, environmental factors, and genotypes on soyasaponin B concentration of early maturing soybean. Three separate experiments, two field experiments and one growth chamber experiment, were conducted to meet these objectives.

MATERIALS AND METHODS

Field Experiment Description. Two distinct field experiments were conducted in 2007 and 2008 at multiple sites in Quebec, Canada to determine the impact of genotype selection and seeding dates on soybean soyasaponin B concentration. The experiments and treatments are only briefly presented here, as these experiments were part of a larger project investigating the impact of agronomic practices on soybean nutraceutical value.[26−28]

The first experiment (i.e., Exp. 1) evaluated 20 early maturing (i.e., maturity groups I to 00) soybean genotypes (AC Colibri, AC Orford, AC Proteina, Amasa, Arva, DH3604, Heron, Kamichis, KG41, Micron, OAC Wallace, Ohgata, Pronatto, S00147.40GB, S00147.40GN, S0022.67, S08-80, S14-P6, Toki, and Venus) in four environments: Saint-Mathieu-de-Beloeil in 2007 and 2008 (BEL; 45°36′N, 73°57′W), Sainte-Hyacinthe in 2007 (SHY; 45°37′ N, 72°58′ W), and Sainte-Martine in 2008 (SMA; 45°14′N, 73°48′ W). All genotypes were replicated twice in each environment. Seguin et al.[26] have previously characterized all genotypes evaluated herein. The second experiment (i.e., Exp. 2) evaluated the impact of four seeding dates (i.e., mid-May, early-June, mid-June, and late-June) of two cultivars (AC Proteina and OAC Vision) in Sainte-Anne-de-Bellevue in 2007 and 2008 (MTL; 45°24′ N, 73°57′ W). Each treatment was replicated four times in each environment.[26]

For both experiments, local recommendations for conventional soybean production were followed.[29] Description of specific management practices and sites used were previously provided in detail by Seguin et al.[26,27] The average plot size across all environments was 1.25 × 5 m. Plots in all experiments and environments were harvested when plants reached physiological maturity. At harvest, subsamples of 50 g were randomly selected from each plot and used for soyasaponin B extraction and quantification.

Growth Chamber Experiment Description. In this experiment (i.e., Exp. 3), two soybean cultivars (i.e., AC Proteina and OAC Champion), were grown in controlled environment growth chambers (model no. E15, Conviron, Winnipeg, MB, Canada). Details regarding growth conditions and seeding were previously described in detail by Chennupati et al.[30] Treatments consisted in the exposure of plants to high temperature at specific stages of development.[31] To generate the stress treatments, growth chambers were set at contrasting temperatures [i.e., stress (33/25 °C, day/night temperatures) and control conditions (23/15 °C)]. The treatments included (i) plants grown during all developmental stages under control conditions or plants grown under control conditions except for specific stages during which stress was imposed and which included (ii) pre-emergence, (iii) vegetative stages, (iv) reproductive stages R1−4 (flowering to early seed formation), (v) reproductive stages R5−8 (seed formation to maturity), and (vi) all stages. Each treatment was replicated four times. Depending on the treatments, the number of days varied for each cultivar to reach specific stage of development.[30] Plants were watered as needed, and a similar level of relative humidity was maintained in all growth chambers. Seeds of a specific treatment were harvested at maturity to determine soyasaponin B concentration.

Soyasaponin Extraction and Quantification. Upon harvest, seeds from all experiments were stored at room temperature for one month and were then finely ground (i.e., to pass through a 1 mm sieve) using a coffee grinder (Black & Decker, Towson, MD, USA)

immediately prior to the extraction of the soyasaponins. Extraction and analysis of soyasaponin B was performed using a modified version of the protocol of Hubert et al.[13] Five hundred milligrams of ground soybean seeds was dissolved in 5 mL of 80% aqueous methanol in a 20 mL vial. Extraction was further carried for 2 h at room temperature followed by vortexing. Then, 1.5 mL of solution was transferred into a 1.5 mL microcentrifuge tube, followed by centrifugation at 12,000*g* for 10 min. Filtration of the extract was done using 0.45 μm filters and 1 mL of clear supernatant was transferred to a HPLC (high performance liquid chromatography) vial. Fifty microliters of potassium hydroxide (5% w/v) was added and allowed to stand for 15 min at room temperature. Neutralization was achieved by the addition of 50 μL of acetic acid and also to maintain the pH of the solution in the range of 4–6.

Separation of soyasaponins was carried out using a Varian HPLC system (Walnut Creek, CA, USA) equipped with a ProStar 210 solvent delivery system, a Model 410 autosampler, and a ProStar 330 photo diode array detector. Twenty microliters of extract was used for each analysis. Separation was carried out on a C18 reversed-phase column (Luna, 5 μm, 4.6 × 250 mm, Phenomenex, Torrance, CA, USA) with a flow rate of 1.0 mL/min and with the column temperature maintained constant at 30 °C. Soyasaponins were detected at 205 nm. Mobile phase solvents, 0.05% trifluoroacetic acid in water (mobile phase A), and HPLC grade acetonitrile (mobile phase B) were used. Soyasaponin elution was carried out using a linear gradient system from 40% solvent B, with a 12 min hold time which then increased to 48% in 25 min followed by reaching up to 100% in 1 min and remaining at 100% for 2 min. The gradient program was recycled back to the initial state of 37% solvent B in 5 min.

Stock solutions of the individual soyasaponins were made by dissolving purified standards (ChromaDex, Irvine, CA, USA) in methanol, followed by serial dilutions. Standard curves were obtained by plotting the soyasaponin concentration as a function of peak area obtained from HPLC at 205 nm. Soyasaponin II standard was used as a reference for individual soyasaponin quantification. Total soyasaponin B concentration was calculated by the addition of the individual soyasaponins.

Statistical Analyses. Plots in each experiment were assigned to a randomized complete block design. The seeding date experiment (Exp. 2) had a split-plot restriction with cultivars as main-plots and seeding date as subplots. Data were analyzed using ANOVA (i.e., PROC GLM) in SAS (version 9.3, Cary, NC, USA) to identify significant model and treatment effects.[32] Data from the genotype evaluation and seeding date experiments (Exps. 1 and 2) were analyzed across environments.[33] Homoscedasticity among environments was confirmed using the chi-square test. Environments and replicates were considered random effects, and other factors were considered fixed. Comparisons between means in all experiments were made using least significant differences at a 0.05 probability level. For the genotype evaluation experiment (Exp. 1), analyses were also performed to determine the stability of genotypes across environments. Values for Francis and Kannenberg[34] mean-CV stability were computed using SAS.

RESULTS AND DISCUSSION

Experiment 1: Genotypes Grown in Multiple Environments. Genotype and environment main effects as well as a genotype × environment (G × E) interaction were observed for total soyasaponin B concentration ($P < 0.001$). Concentration averaged 3.92 μmol g^{-1} across genotypes and environments, ranging between 2.31 and 6.59 μmol g^{-1} (Table 1). This range is in accordance with values previously reported in whole soybean seeds by Hubert et al.[13] and Murphy et al.[14] The presence of a G × E interaction illustrates that the performance of specific genotypes varied across environments (Table 1). The G × E interaction, however, contributed to less than 1% of the total mean square, the environment and genotype contributing to 62 and 38% of the total mean square (data not shown). Ranking of specific genotypes was thus overall remarkably stable across 4 environments, Toki and Ohgata consistently having the highest and lowest concentration of total soyasaponin B, respectively (Table 1). However, these two genotypes also had a larger than average variation across environments (Figure 1). Genotypes with a higher

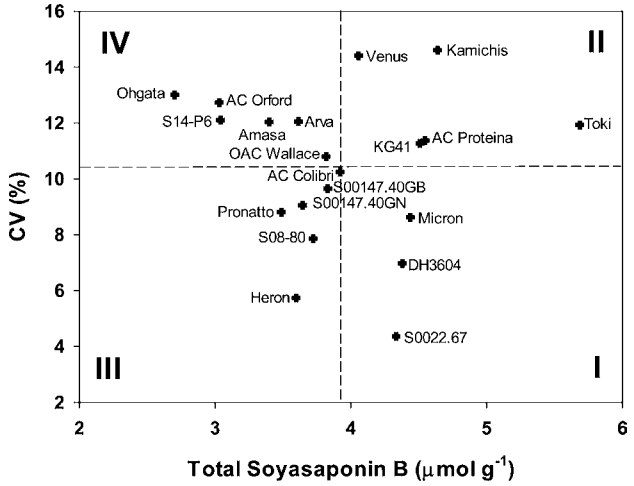

Figure 1. Plot of mean total soyasaponin B concentration versus coefficient of variation (CV) of 20 soybean genotypes grown in four environments in QC, Canada. Dotted lines intersecting the plot indicate the average performance (total soyasaponin B concentration) and average CV.

stability across environments are usually preferable. In Figure 1, genotypes located in quadrant I (i.e., Micron, DH3604, and S0022.67) are more desirable as they have both high concentration and high stability across environments.

Soyasaponin I represented 68% of the total soyasaponin B, the other forms contributing 17 to 2% of the total concentration (i.e., 17, 8, 5, and 2% for soyasaponins II, III, V, and IV, respectively); similar proportions were reported among 7 soybean cultivars from France and the USA.[13] Genotype and environment main effects were also significant ($P < 0.01$) for the concentration of all individual soyasaponin; however, G × E interactions were observed only for soyasaponin I and IV, indicating that the performance of genotypes was relatively stable across environments for the other soyasaponins (Tables S1 to S5, Supporting Information). The G × E interaction contributed to less than 5% of the total mean square for all individual soyasaponin, the environment contributing to more than 50% of the total mean square for soyasaponins II, III, and IV, the genotype contributing to more than 50% of the total mean square for soyasaponins I and V (data not shown). Ranking of genotypes across environments was thus relatively consistent, changes in ranking being minimal for all soyasaponins except for soyasaponin IV for which more variation was observed (Table S4, Supporting Information). Soyasaponin IV was, however, the form found in the lowest concentration. As for total soyasaponin B, genotypes DH3604, Micron, and S0022.67 consistently had high and stable concentrations of most individual soyasaponins with the exception of soyasaponin II (Figures S1 to S5, Supporting Information). Another group of genotypes had high and stable concentrations of soyasaponin II, namely, Toki, S00147.40GB, OAC Wallace, S00147.40GN, S08-80, and KG41.

Table 2. Analysis of Variance of Soyasaponin B Concentrations in Two Soybean Cultivars (AC Proteina and OAC Vision) Seeded at Four Seeding Dates (Mid-May, Early-June, Mid-June, and Late-June), in Two Years (2007 and 2008) in Sainte-Anne-de-Bellevue, QC, Canada

source of variation	soyasaponin I	soyasaponin II	soyasaponin III	soyasaponin IV	soyasaponin V	total
year (Y)	0.56	0.51	0.63	0.45	0.08	0.79
cultivar (C)	**<0.0001**	0.85	0.001	0.41	**<0.0001**	**<0.0001**
Y × C	0.14	0.88	0.32	0.65	**0.03**	0.21
seeding date (SD)	**<0.0001**	**<0.0001**	**0.0006**	**0.03**	0.28	**<0.0001**
SD × C	**0.006**	0.52	**0.04**	0.54	0.60	0.01
Y × SD	0.38	**0.04**	**<0.0001**	0.53	0.33	**0.33**
Y × SD × C	0.12	0.06	**0.02**	0.78	0.83	0.03
CV %	4.5	8.8	9.9	29.6	16.2	4.1
mean	3.15	0.73	0.30	0.06	0.27	4.51

Results thus suggest that the total soyasaponin B concentration, as well as that of most individual soyasaponins, of a given genotype relative to others is relatively stable across environments. The G × E interaction, however, often significantly contributed only minimally to the total variation observed. While this is a desirable characteristic, the large contribution of the environment to the total variation observed emphasizes that the actual soyasaponin B concentration observed at harvest can be greatly affected by environmental factors that remain to be identified.

Experiment 2: Seeding Dates. Seeding date affected total soyasaponin B concentration as well as concentrations of soyasaponins I, II, III, and IV (Table 2); in all cases, earlier seeding dates resulting in the highest concentrations (Figure 2 and Figure S6, Supporting Information). There was an 11% difference in total soyasaponin B concentration of soybeans seeded in mid-May compared to that in late-June, differences being of 9, 22, 11, and 26% for soyasaponins I, II, III, and IV, respectively. The presence of interactions between seeding date and other factors for individual soyasaponins illustrate that the response to seeding date depended on the year and/or the cultivar (Table 2). These interactions, however, only reflect differences in the magnitude of response especially between cultivars, response to seeding date being in some cases slightly greater for AC Proteina than OAC Vision (data not shown). This difference in response might be related to the overall greater concentration of soyasaponin B in AC Proteina, which had 26% more total soyasaponin B compared to that in OAC Vision.

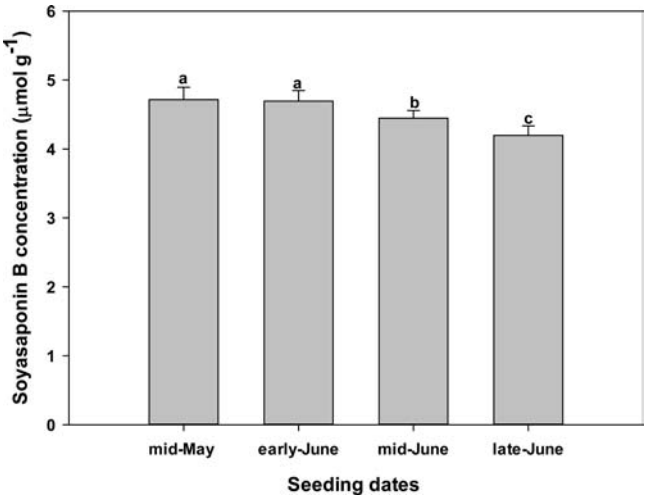

Figure 2. Total soyasaponin B concentrations in soybean seeded at four seeding dates (mid-May, early-June, mid-June, and late-June) in Sainte-Anne-de-Bellevue, QC, Canada. Results are the average for two cultivars (AC Proteina and OAC Vision) and two years (2007 and 2008). Means followed by different letters are significantly different ($P < 0.05$). Vertical bars indicate standard error.

The impact of seeding date on the concentration of other soybean health-beneficial compounds has previously been reported. The response observed herein for soyasaponin B is similar to that reported for α-tocopherol but opposite to that of isoflavones.[15,27,35,36] The response of soybean secondary metabolites to seeding date has often been associated with the impact of resulting temperatures at specific growth stages.[30,37] For example, earlier seeding dates (i.e., in May) compared to later dates (i.e., in June) are usually associated with higher air temperature during seed development. Higher air temperature during seed development has been demonstrated to increase α-tocopherol concentration but also decrease isoflavone concentration.[30,38] It is possible that the observed response of soyasaponin B to seeding date is mediated by a similar response to air temperature during specific growth stages, but this remains to be verified.

Experiment 3: High Temperature Stress at Specific Stages of Development. High temperature stress impacted the concentration of all individual soyasaponin B as well as total concentration ($P < 0.0001$); however, the response to specific treatments depended on the cultivar as illustrated by the presence of temperature stress treatment × cultivar interactions ($P < 0.01$) for all soyasaponin except soyasaponin III (Figure 3 and Figure S7, Supporting Information). High temperature stress restricted to the seed filling stages (i.e., R5−8)[31] increased total soyasaponin B concentration in AC Proteina by 28% when compared to that of control nonstressed plants. However, in OAC Champion, only high temperature applied during all growth stages had an impact reducing the total concentration by 27%.

The impact of specific stress treatments on individual soyasaponin was highly variable depending on the soyasaponin form and the cultivar (Figures 3 and S7, Supporting Information). High temperature stress applied during all growth stages resulted in large reductions (average of 60%) in soyasaponins II, III, and IV in both cultivars and of soyasaponin V in one cultivar (i.e., OAC Champion) when compared to that in the unstressed control. Stress restricted to stages R1−4 (flowering and early seed formation) reduced (average of 11%) the concentration of soyasaponins II, IV, and V of at least one cultivar but increased (average of 36%) that of soyasaponin III in both cultivars. Stress restricted to the R5−8

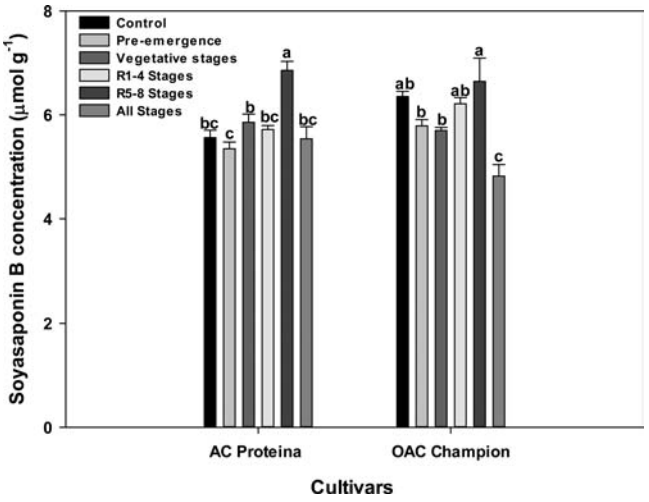

Figure 3. Total soyasaponin B concentrations in mature seeds of two soybean cultivars (AC Proteina and OAC Champion) after exposure to high temperature stress [i.e., 33/25 °C (day/night temperature)] at specific stages of development. Control conditions consisted of day/night temperatures of 23/15 °C. Means for a given cultivar followed by different letters are significantly different ($P < 0.05$). Vertical bars indicate standard error.

(seed filling to maturity stages) strongly reduced (average of 49%) the concentration of soyasaponins III and IV in both cultivars, increased slightly (average of 16%) that of soyasaponins I and II for one cultivar, while the response for soyasaponin V was opposite for the two cultivars. Finally, stress restricted to the pre-emergence stage did not impact any soyasaponin, while the response to stress restricted to vegetative stages postemergence was highly variable. Overall, the total saponin B concentration was comparable in both cultivars evaluated; however, AC Proteina had greater concentrations of soyasaponins I, III, and V, while the reverse was observed for soyasaponins II and IV (Figures 3 and S7, Supporting Information).

The response of soyasaponin B to high temperature is thus complex and appears to be cultivar specific. It is possible that the differential response of the two cultivars studied herein is attributable to differences in the expression of some of the multiple genes involved in the poorly studied saponin biosynthetic pathway in soybeans.[39] The difference in cultivar response might also be attributed to the differential profile of the individual soyasaponin observed between the two cultivars. Indeed, it is possible that the overall cultivar response is linked to its propensity to accumulate particular soyasaponin forms. If the impact of temperature at specific developmental stages has been correlated to the concentration of other heath beneficial compounds in soybean such as isoflavones and tocopherols, the evaluation of a larger number of cultivars will be required before definite conclusions can be made for soyasaponin B.[30,37]

In conclusion, soyasaponin concentration in mature soybeans is mostly determined by genotype and environment main effects. Specific environmental and crop management factors (i.e., air temperature and seeding date) were demonstrated to impact concentrations. The response to air temperature is, however, complex and cultivar specific. A study of soybean response to biotic and abiotic factors at the genetic and/or metabolomic level is now required to increase our understanding of factors determining soyasaponin concentrations in mature seeds. Such an understanding will increase our ability to minimize variation in soyasaponin concentration at harvest and ultimately produce soybeans with high and stable concentrations better suited for the nutraceutical and functional food markets.

phenolics in IADFP-CP and (ii) to explore the effects of ultrafine grinding on the antioxidant capacity and phenolic composition of IADFP-CP.

MATERIALS AND METHODS

Materials and Chemicals. Fresh citrus (*Citrus junos* Sieb. ex Tanak) pomace was gifted by the Citrus Research Institute of the Chinese Academy of Agricultural Sciences (Chongqing, China). Chlorogenic acid, ferulic acid, caffeic acid, sinapic acid, gallic acid, naringenin, hesperitin, naringin, hesperidin, and kaempferol (>98.0%) were purchased from Chengdu Biopurify Phytochemicals Co. Ltd. (Chengdu, China). (±)-6-Hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (trolox) and 2,4,6-tris(2-pyridyl)-1,3,5-triazine (TPTZ) were obtained from Sigma-Aldrich Co. Ltd. (Shanghai, China). 2,2-Diphenyl-1-picrylhydrazyl (DPPH) was purchased from Wako Pure Chemical Industries, Co. Ltd. (Tokyo, Japan). Methanol, acetonitrile, ammonium acetate, hexyl hydride, and ethyl acetate of HPLC grade were purchased from Merck Co. Ltd. (Darmstadt, Germany).

IADFP-CP Preparation. After the removal of seeds, fresh citrus pomace was shredded and immediately immersed in a water bath at 90 °C for 30 s to inactivate enzymes; then it was filtered, air-dried (65 °C, 48 h), and ground in a high-speed pulverizer (YS-103, Yongli Pharmaceutical Machinery Co. Ltd., Wenzhou, China) to pass through a 40-mesh sieve. After the resultant powder (350 g) had been defatted in 1.0 L of anhydrous ethanol at room temperature for 1 h, the solid part was recovered by filtering through four layers of cotton gauze. Then it was air-dried at 65 °C for 30 min to remove the solvent. The dried powder was subjected to the removal of soluble components by immersing it in 11.5 L of distilled water at 60 °C for 1 h with continuous stirring. The insoluble fraction was pelleted by centrifuging the suspension at 4000 rpm for 10 min. The pellet was air-dried (60 °C for 48 h) to achieve a moisture content below 6%, and the IADFP-CP was obtained. The dried IADFP-CP was subjected to ordinary grinding, which was performed with a YS-103 high-speed pulverizer. The pulverization process lasted for 3 min.

Ultrafine Grinding of IADFP-CP. The powder obtained by ordinary grinding was used as the starting material for ultrafine grinding (mechanical grinding and jet grinding). The mechanically ground IADFP-CP was prepared in a YSC-701 micronizer (Yanshanzhengde Co. Ltd., Beijing, China) for 8 min by operating the lapping wheel and fan at 4500 and 3500 rpm, respectively. To perform jet grinding, a CBF-250 jet mill (Chengdu, China) was applied and operated at the following parameters: compressor power, 210 kW; nozzle speed, 1 Mach; and rotational speed of classifier, 2100 rpm. The powders obtained by ordinary grinding, mechanical grinding, and jet grinding were denoted by OGP, MGP, and JGP, respectively. All powders were hermetically packaged in plastic bags and stored at room temperature in a brown desiccator with oxygen scavenger until analysis. The particle size was measured with a Mastersizer 2000 E laser particle size analyzer (Malvern Instruments Ltd., UK). In terms of average particle size ($D_{0.5}$), OGP, MGP, and JGP presented particle sizes of 347.25, 59.56, and 24.09 μm, respectively.

Determination of Proximate Composition. Ash, crude fat, and crude protein were determined using AOAC methods.[20] Total sugar was determined by anthrone colorimetry.[21]

HPLC Analysis of Phenolic Extracts. Free and bound phenolics in IADFP-CPs were extracted according to the method previously reported by Okarter et al.[22]

Free phenolics were extracted by blending the powder (1 g) with 50 mL of 80% chilled acetone for 10 min. After centrifugation at 4500 rpm for 10 min, the supernatant was removed. The residues were re-extracted as done for the powder. The supernatants were combined and evaporated at 45 °C to dryness. The remainder was made up to 25 mL with methanol, filtered through 0.45 μm nylon membrane, and frozen at −80 °C until analysis.

Bound phenolics were extracted with the residue from the free phenolic extraction as starting material. The residue was first digested with 2 mol/L sodium hydroxide at room temperature for 1 h while shaking under nitrogen. The mixture was then neutralized with concentrated hydrochloric acid. Hexanes were used to remove lipids in the mixture. The remaining mixture was then successively extracted with ethyl acetate (20 mL with 5 min) five times. The ethyl acetate fractions were combined and evaporated at 45 °C to dryness. The phenolics were reconstituted in 25 mL of methanol, filtered through 0.45 μm nylon membrane, and frozen at −80 °C until analysis.

The determination of phenolics in the extracts was conducted on an Agilent 1260 HPLC (Agilent Technologies, USA) equipped with a diode array detector (DAD). The UV−vis spectra of phenolics were recorded in the range 190−600 nm at an acquisition rate of 2.0 s (peak width = 0.1 min). The phenolics were separated by a reverse phase Thermo BDS Hypersil C18 column (250 × 4.6 mm i.d.; 5 μm) at 30 °C with the mobile phase consisting of A (0.1% ammonium acetate) and B (acetonitrile) at a flow rate of 0.8 mL/min. A linear gradient program was used: 0−3 min, 10% B; 3−15 min, 10−30% B; 15−35 min, 30−50% B; 35−45 min, 50−90% B; 45−48 min, 90−10% B; 48−55 min, 10% B. Each sample injection volume was 20 μL. Absorbance at 280 nm was applied to quantify the eluted phenolics. When a reference compound was not available, the calibration of a structurally related compound was employed with a molecular weight correction factor.[23] The HPLC method applied in the present study was validated and given acceptable values in the correlation coefficients of calibration curves ($R^2 \geqslant 0.9990$) and recovery (⩾80.6%) (Table S1 in the Supporting Information).

Identification of Phenolics by RP-HPLC-DAD/ESI-Q-TOF-MS/MS. To identify phenolics in the extracts, an Agilent 1290 HPLC (Agilent Technologies, Santa Clara, CA, USA) equipped with a binary pump (G4220A), a column compartment (G1316C), a DAD (G4212A), and an autosampler (CTCPAL) was coupled to an Agilent 6540 Q-TOF-MS/MS and applied in the present study. The RP-HPLC-DAD was operated with parameters as described above. The effluent from the column was split using a T-type phase separator before being introduced into the mass spectrometer (split ratio = 1:3). The dual electrospray ionization (ESI) source of the MS was operated in negative mode. Mass spectra were recorded across the m/z range of 100−1100 (scan rate, 1.00 spectra/s). The operating conditions of Q-TOF-MS were as follows: desolvation gas (N_2) temperature, 350 °C; desolvation gas flow rate, 480 L/h; nebulizer, 35 psig; capillary voltage, 3500 V; fragmentor voltage, 125 V; skimmer voltage, 65 V; Oct RFV, 750 V. The parameters of Q-TOF-MS/MS were the same as those for Q-TOF-MS except that the first quadrupole served as a mass filter and the sample injection volume was set as 10 μL. The mass spectra of all analytes were recorded at four collision energies: 10, 20, 30, and 40 V. The mass spectrum with a medium abundance for $[M - H]^-$ and high abundances for ionized fragments was selected and used to identify analytes. The whole system was controlled by MassHunter workstation software (B.05.00, Agilent Technologies).

Antioxidant Capacity of IADFP-CP. *DPPH Radical Scavenging Capacity (DPPH-RSC) Assay.* The DPPH-RSC of IADFP-CP was determined according to the method described by Gadow et al. with some modifications.[24] Briefly, 20 mg of IADFP-CP was weighed into a 10 mL centrifuge tube, and then 3.5 mL of methanol containing DPPH radicals (6×10^{-5} mol/L) was added. The tube was tightly capped and vortexed vigorously for 3 min and repeated twice with a 10 min interval. Then, it was subjected to centrifugation at 10000 rpm for 2 min. The control was prepared by replacing the phenolic extract with the same volume of methanol. The absorbance of the supernatant was recorded at 517 nm using a visible spectrophotometer (722, Shanghai Modern Science Spectral Instrument Co. Ltd., Shanghai, China) against the control. The measurement was performed in the dark and completed within 30 min. Results were expressed as micromoles of trolox equivalent (TE) per 100 g of dw of IADFP-CP.

Ferric Reducing Antioxidant Power (FRAP) Assay. The FRAP of IADFP-CP was determined with the procedure described by Benzie et al. with some modifications.[25] In detail, a fresh FRAP working solution was prepared by blending 25 mL of 300 mmol/L acetate buffer (pH 3.6), 2.5 mL of 10 mmol/L TPTZ in 40 mmol/L hydrochloric acid, and 2.5 mL of 20 mmol/L ferric chloride. To obtain an acceptable decoloring rate for FRAP assay, IADFP-CP was diluted with microcrystalline cellulose at a ratio of 1:4 (w/w). The diluted

Table 1. Proximate Composition and Phenolics in Insoluble Antioxidant Dietary Fiber Powders from Citrus Pomace[a]

component	OGP (g/100 g dw)	MGP (g/100 g dw)	JGP (g/100 g dw)
ash	3.07 ± 0.08b	3.15 ± 0.15b	3.10 ± 0.09b
crude fat	2.31 ± 0.10b	6.22 ± 0.27c	10.33 ± 0.97d
crude protein	5.28 ± 0.18c	4.99 ± 0.24bc	4.67 ± 0.18b

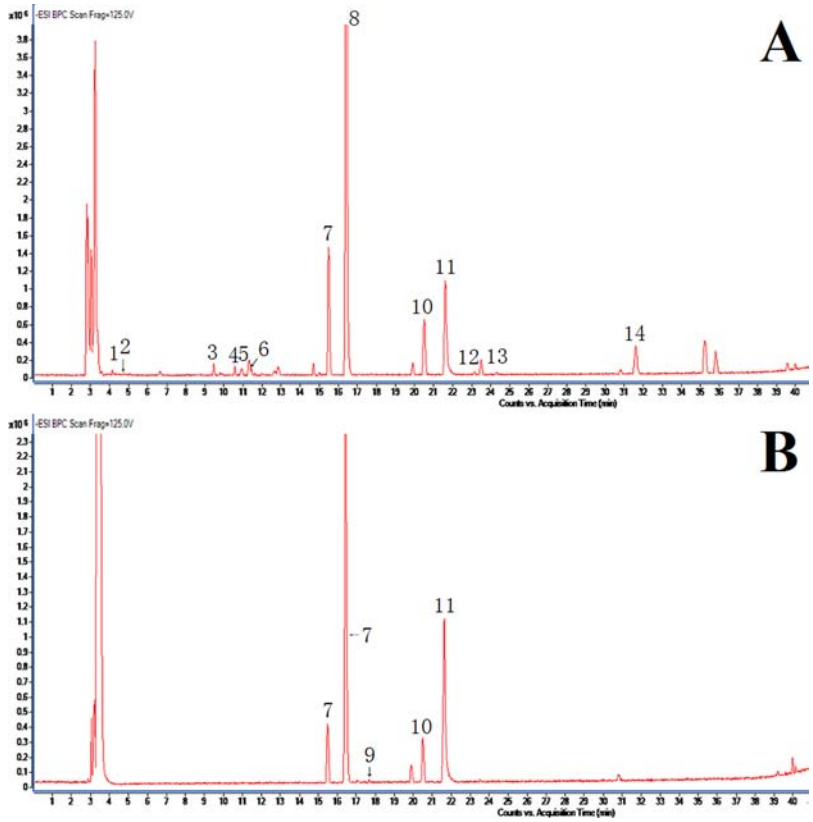

Figure 1. Base peak chromatograms of free (A, jet grinding) and bound (B, mechanical grinding) phenolics in insoluble antioxidant dietary fiber powders from citrus pomace.

IADFP-CP (20 mg) was weighed into a 10 mL centrifuge tube and then 3.5 mL of fresh FRAP working solution was added. The suspension was shaken and kept in a water bath at 37 °C for 5 min, followed by centrifugation at 10000 rpm for 5 min. The absorbance of the resultant supernatant was monitored at 593 nm using a 722 visible spectrophotometer against FRAP working solution. All solutions were used on the day of preparation. Results were expressed as micromoles of $FeSO_4{\cdot}7H_2O$ equivalent (FE) per 100 g of dw of IADFP-CP.

Antioxidant Capacity of Phenolic Extracts. The DPPH and FRAP assays of free and bound phenolic extracts were performed as done with IADFP-CP by omitting vortex and centrifugation treatments.

Statistical Analysis. Results were presented as the mean value ± standard deviation (SD) of triplicate determinations. ANOVA and LSD comparison tests were performed to identify differences between values using SPSS (version 19.0, SPSS Inc., Chicago, IL, USA). Significant differences were declared at $p < 0.05$.

RESULTS AND DISCUSSION

Proximate Composition of IADFP-CP. The proximate composition of IADFP-CP is presented in Table 1. In contrast to ordinary grinding, mechanical grinding generated significant effects only on the contents of crude fat and free, bound, and total phenolics ($p < 0.05$), but jet grinding presented significant changes in the contents of crude fat, crude protein, total sugar, and free and bound phenolics ($p < 0.05$). The contents of crude fat, total sugar, free, and bound and total phenolics in MGP and JGP were significantly different ($p < 0.05$). With regard to the increases in crude fat induced by MGP and JGP and in total sugar induced by JGP, the increases in their extraction efficiencies from micronized powders were assumed to be factual. Ultrafine grindings effectively disrupted the cell structure of the citrus pomace and substantially increased the specific surface of IADFP-CP.[18] The images of IADFP-CP recorded by scanning electron microscope confirmed this fact (Figure S1 in the Supporting Information). Furthermore, the

results implied that jet grinding was more effective in promoting extraction efficiencies than mechanical grinding, which can be explained by the smaller particle size of JGP (24.09 ± 0.67 μm) than of MGP (59.56 ± 0.66 μm).

Identification of Phenolics. The chromatographic profiles of free (jet grinding) and bound (mechanical grinding) phenolics in IADFP-CP are shown in Figure 1 (for the other four profiles see the Supporting Information, Figure S2). The RP-HPLC-Q-TOF-MS/MS in negative ionization mode allowed the separation and tentative identification of 14 phenolics (9 free, peaks 1−6 and 10−14; 1 bound, peak 9; and 4 free/bound, peaks 7, 8, 10, and 11) in IADFP-CP (Figure S3 in the Supporting Information). The retention time (t_R), molecular weight (MW), quasi-molecular ion $[M-H]^-$, and MS/MS fragment ions for each phenolic compound are summarized in Table 2. Among them, six phenolics including chlorogenic acid (peak 1), ferulic acid (peak 2), naringin (peak 7), hesperidin (peak 8), naringenin (peak 12), and hesperitin (peak 13) were identified using authentic reference compounds. Another eight detected phenolics were tentatively identified by comparing their UV−vis and mass spectra data with the literature data.

Peak 3 and 10, showing an $[M-H]^-$ ion at m/z 593.2 and MS/MS fragment ions at m/z 285.0, 309.0, 338.0, and 351.0, were observed at 9.5 and 20.5 min, respectively. The MS/MS fragment ion at m/z 309 could be assigned as a rutinosyl group.[26] However, fragment ions of glucosyl (−162 amu) or rhamnosyl (−146 amu) groups were absent in the MS/MS chart. In addition, the DAD profiles of peaks 3 and 10 were more similar to that of kaempferol than to that of luteolin. According to the evidence above, peaks 3 and 10 were assigned as kaempferol rutinoside isomers I and II, respectively.

For the identification of peak 4, the deprotonated molecule at m/z 649.4 was in agreement with the data of laggerstannin C (galloyl HHDP glucoside) reported in the literature.[26] Moreover, the MS/MS fragment ions at m/z 605.7 and 283.3 of the peak were in agreement with MS^3 fragment ion data of trisgalloyl HHDP glucoside.[26] Regrettably, the characteristic fragment ions of galloyl HHDP glucoside at m/z 301 and 497 have been not detected in the mass spectrum of peak 4. Thus, we tentatively characterized peak 4 as galloyl HHDP glucoside isomer.

Peak 5 at 11.2 min showed an $[M-H]^-$ ion at m/z 448.2 and MS/MS fragment ions at m/z 223.1, 162.0, and 385.2. According to the literature, the MS/MS fragment ion at m/z 223.1 resulted from the loss of a hexosyl unit (162.0 amu) from the sinapoyl hexoside moiety (385.2 amu).[27] Therefore, peak 5 was tentatively assigned as sinapoyl hexoside derivative.

Peak 6 at 11.5 min showed an $[M-H]^-$ ion at m/z 761.8. The MS/MS fragment ions at m/z 726, 487, and 290.9 were sinapic acid derivatives according to ref28. Moreover, the DAD profile of peak 6 was similar to that of sinapic acid. On the basis of their molecular ions, UV−vis spectra, and literature data, a sinapoyl unit was probably present in the compound, so peak 6 was assigned as a sinapic acid derivative.

Peak 9 at 17.7 min showed identical UV−vis spectra and identical $[M-H]^-$ ion (at m/z 609.0) and MS/MS fragment (at m/z 301.1, hesperitin) patterns to hesperidin. Because the retention time of peak 9 did not match the retention time of hesperidin (16.4 min), peak 9 was tentatively assigned as a hesperidin isomer.

Peak 11 (at 21.7 min), with an $[M-H]^-$ ion at m/z 293.2, was assigned as unknown. Although MS/MS fragments at m/z 236.1 (−57 amu, loss of $-C(CH_3)_3$) and m/z 221.1 (loss of a

methyl group from fragment at m/z 236.1) were observed, MS/MS fragments at m/z 236.1 and 221.1 were unclear. Therefore, peak 11 cannot be identified.

Peak 14 (at 31.6 min) showed an $[M - H]^-$ ion at m/z 529.2 and MS/MS fragments at m/z 154.9, 162, 204.9, 248.9, and 367, respectively. On the basis of the literature data, the fragment ion at m/z 367 resulted from the compound of peak 14 losing a caffeoyl moiety (−162 amu).[29,30] In addition, the MS/MS fragment ion at m/z 154.9 suggested the presence of a feruloyl moiety.[31] Therefore, the compound of peak 14 was assigned to feruloylquinic acid derivative.

Accordingly, phenolics in IADFP-CP mainly consisted of phenolic acids, flavonoids, and their derivatives. All phenolic acids were identified as hydroxycinnamic compounds, including chlorogenic acid (peak 1), ferulic acid (peak 2), sinapic acid derivative (peak 6), peak 11, and feruloylquinic acid derivative (peak 14). Two classes of flavonoids, including five flavanones (peaks 7−9, 12, and 13) and two flavonols (peak 3 and 10), have been characterized. Among the 14 phenolic compounds characterized in the present study, 7 (peaks 1, 2, 7−9, 12, and 13) identified phenolics were reported in citrus peel in the literature.[32−34]

Quantification of Phenolics. The quantitative results of free and bound phenolics in IADFP-CP are presented in Table 3. The free phenolic content (1022.01−1412.74 mg/100 g dw) was much higher than the bound phenolic content (483.46−680.01 mg/100 g dw) in IADFP-CP regardless of the grinding method. The study done by Oboh et al. revealed that the free phenolic content of citrus peels (6.5−13.1 mg/g) was significantly higher than the bound phenolic content (0.7−6.8 mg/g).[35] The total content of phenolic acids and their derivatives (328.95−290.84 mg/100 g) was much lower than that of flavonoids and their derivatives (1359.6−1600.42 mg/100 g). Among phenolic acids and their derivatives, peak 11 presented the highest abundance (257.29−208.78 mg/100 g) and was the unique bound phenolic acid derivative detected in all IADFP-CP samples. Meanwhile, in flavonoids and their derivatives, hesperidin (1048.11−1266.66 mg/100 g) was the most abundant monomer, which accounted for >70% (w/w) in both free and bound phenolics in all samples. It is well documented that flavonoids (mainly naringenin, hesperidin, naringin, and neohesperidin) were the predominant phenolics in citrus peels,[32] and their total content highly exceeded the content of phenolic acids by up to 10 times or more.[14,34] With regard to the effects of ultrafine grinding on free and bound phenolics in IADFP-CP, MGP and JGP presented a bound phenolic content comparable to that of OGP. Contrary to our expectations that the free phenolic content in IADFP-CP would be increased by ultrafine grinding, the free phenolic content in MGP was significantly lower than that in OGP. The possible

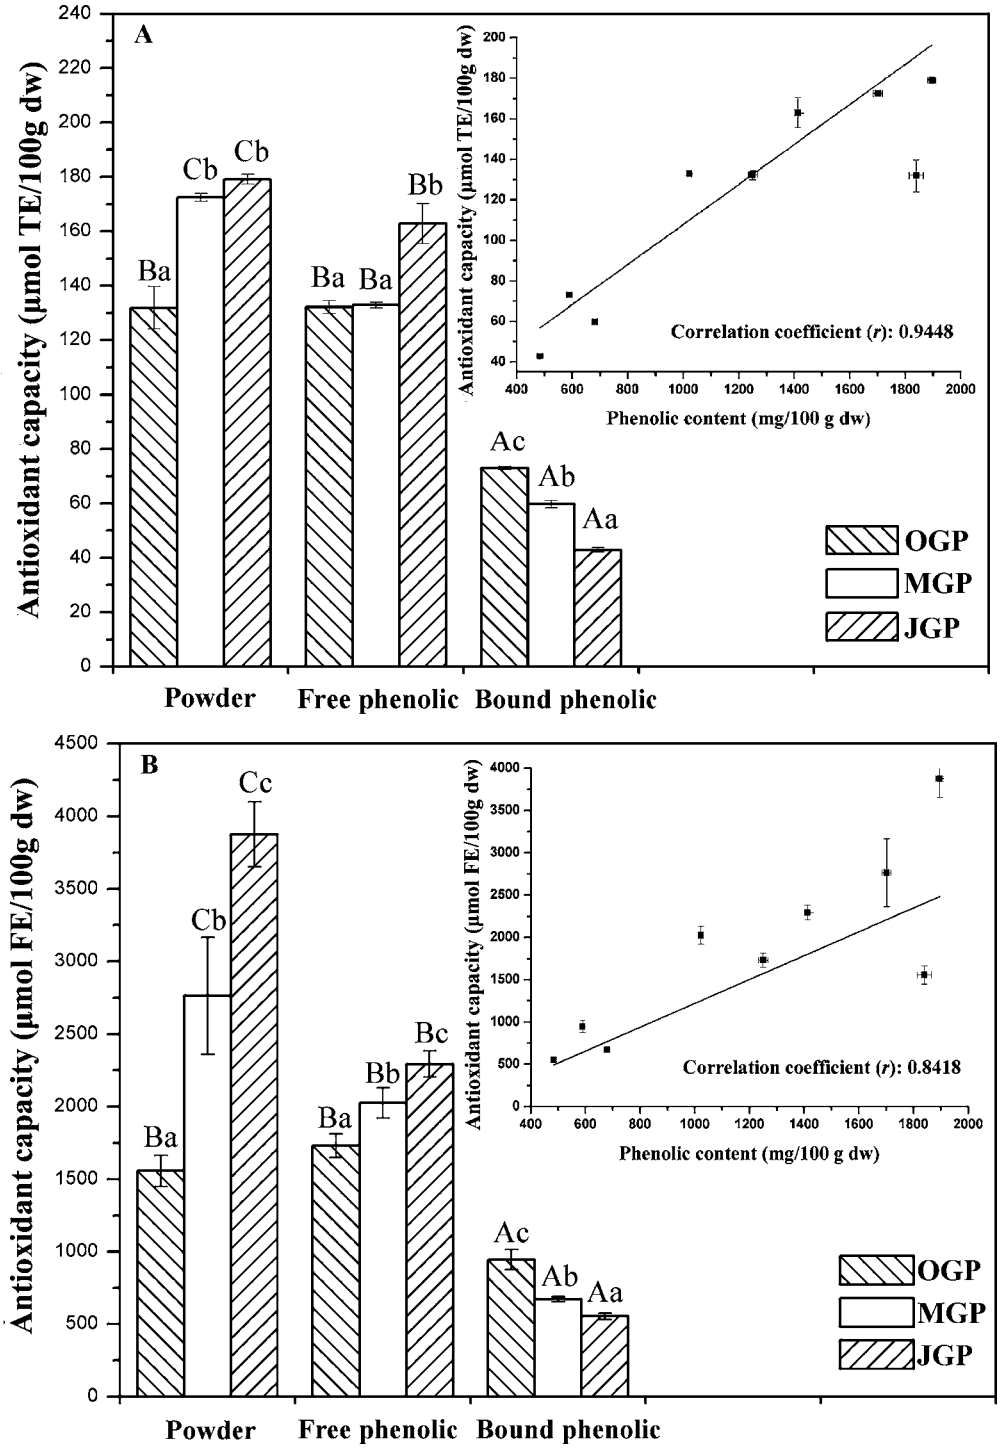

Figure 2. Antioxidant capacities (A, DPPH radical scavenging capacity; B, ferric reducing antioxidant power) of insoluble antioxidant dietary fiber powders from citrus pomace and their phenolic extracts as determined by the DPPH and FRAP assays. Columns bearing different lowercase letters (a–c) with the same sample form (powder, free and bound phenolic) were of significant differences ($p < 0.05$). Columns bearing different capital letters (A–C) with the same grinding method (ordinary (OG), mechanical (MG), and jet grindings (JG)) were of significant differences ($p < 0.05$).

explanation for the result would be the thermal damage of phenolics during mechanical grinding. This was evidenced by the fact that the free phenolic content in JGP was significantly greater than that in OGP. As reported, jet grinding is a good choice in producing thermally sensitive biomaterials. Jet grinding could produce impacting, colliding, and friction among materials by the energy of high-speed or steam and bring about less thermal energy (cavity temperature 32 °C in our study) compared with mechanical grinding.[18] Interestingly, the bound phenolic content in JGP was dramatically lower than that in OGP. Although the reasons for the result were not entirely understood, it is worthwhile noting that a redistribution of bound phenolics to free phenolics possibly happened during jet grinding.[33,36]

Antioxidant Capacity. Numerous studies demonstrated that the DPPH and FRAP assays are simple and cost-effective

dx.doi.org/10.1021/jf501646b | J. Agric. Food Chem. 2014, 62, 7166–7173

spectrophotometric methods to evaluate the potential antioxidant properties of biomaterials.[37,38] Therefore, they were applied in the present study to evaluate the antioxidant capacities of IADFP-CP and their phenolic extracts. The obtained results are presented in Figure 2.

With regard to DPPH-RSC (Figure 2A), in powder form, OGP, MGP, and JGP presented antioxidant values of 131.93, 172.44, and 179.12 μmol TE/100 g dw, respectively. By comparison, the DPPH-RSCs of MGP and JGP were significantly higher than the value of OGP, but no significant difference was observed between the values of MGP and JGP. Te effects of ultrafine grinding on the DPPH-RSC of free phenolics in IADFP-CP revealed that jet grinding significantly improved the antioxidant capacity, whereas mechanical grinding did not significantly change it. Commonly, the decrease in particle size of a powder could facilitate the extraction of antioxidants and increase their activity. This has been confirmed in numerous researche studies.[39,40] However, this law was not effective in comparing the DPPH-RSCs of OGP and MGP. MGP presented a significantly smaller particle size than OGP, but generated an antioxidant value equivalent to that of OGP. This discrepancy was possibly due to the thermal effects of mechanical grinding, which damaged the free phenolic components and thus deteriorated their antioxidant capacities.[18] Without exception, ultrafine grindings significantly decreased the antioxidant capacity of bound phenolics ($p < 0.05$). This should be related to the differences in total bound phenolics induced by the various grindings as mentioned above. With regard to FRAP (Figure 2B), similar results were obtained as with DPPH-RSC. Moreover, significant differences were observed between the antioxidant values of MGP and JGP powder and those from free phenolics in OGP and MGP.

The antioxidant capacity of OGP was lower than that of MGP and JGP, which may be due to the enhanced solubilization of antioxidants, including phenolic and nonphenolic substances, by the decrease in particle size.[19,41] The antioxidant capacities of both ultrafine grinding powders and their phenolic extracts followed the order of powder > free phenolic extract > bound phenolic extract. This sequence reflected that the antioxidant capacity of the powder came not only from its phenolic components but also from other nonphenolic components, such as carotenoids and Maillard compounds.[1] The differences in the antioxidant capacities of free and bound phenolic extracts could be explained by the higher phenolic content in free extracts than in bound extracts, which is reflected by the high correlation coefficients of the relationships between the antioxidant values and phenolic content ($r \geqslant 0.8418$) (Figure 2). Likewise, the DPPH-RSC ($r = 0.939$) and FRAP ($r = 0.906$) of 30 plant extracts were found highly dependent on their total phenolic contents.[42]

The free and bound phenolics in IADFP-CP and their changes induced by two kinds of ultrafine grindings (mechanical grinding and jet grinding) were first investigated in the present study. Fourteen phenolic compounds, mainly including phenolic acids, flavonoids, and their derivatives, were identified and quantified. The free phenolic content was much higher than the bound phenolic content in IADFP-CP. Hesperidin was identified as the component with the highest abundance, which accounted for >57% of total phenolics. As far as the protective effects on phenolics, the redistribution of bound phenolics to free phenolics, and the antioxidant capacity of powders were concerned, jet grinding was superior to mechanical grinding in producing IADFP-CP. For further research, the in vivo antioxidant activity of ultrafine ground IADFP-CP and their potential applications in food systems should be intensively addressed.

oil (HCO60). Uptake of CoQ in mixed micelles generated during digestion across the brush border membrane (i.e., apical uptake) by Caco-2 human intestinal cells and the extent of transport of CoQ across the monolayer into the basolateral compartment (i.e., basolateral secretion) also were determined. This coupled model has been used previously to compare the micellarization and cellular uptake of ubiquinone from various formulations.[24] The bioaccessibility of ubiquinone was greater for supplements containing solubilized CoQ.

CoQ exists primarily as ubiquinol in extra-mitochondrial cellular compartments and in plasma. Reduction of ubiquinone to ubiquinol has been proposed to be dependent on the activities of a number of enzymes located in various cellular compartments. These include glutathione (GSH) reductase,[25] thioredoxin (Trx) reductase,[26] and NAD(P)H quinone oxidoreductase 1 (NQO1, also commonly referred to as DT-diaphorase)[27] among others. As these enzymes are components of antioxidant systems, it is likely that a balanced redox status is essential for maintaining the elevated ratio of ubiquinol to ubiquinone. The second objective of this study was to examine the effect of disruption of the redox imbalance on the apical uptake and basolateral secretion of CoQ by Caco-2 cells. Cellular redox balance was altered by either decreasing the cellular concentration of GSH or inhibiting the activity of thioredoxin (Trx) reductase in Caco-2 cells.

MATERIALS AND METHODS

Reagents. Ubiquinone, ubiquinol, and polyethylene glycol 60-linked hydrogenated castor oil (HCO60) were provided by Kaneka Corp., Japan. Fetal bovine serum, fungizone, penicillin−streptomycin, L-glutamine, and nonessential amino acids were purchased from Life Technologies Corp. (Grand Island, NY, USA). Bile extract, pepsin, lipase, and pancreatin were purchased from Sigma-Aldrich (St. Louis, MO, USA). All other reagents were purchased from ThermoFisher Scientific (Pittsburgh, PA, USA) unless otherwise indicated.

Preparation of HCO60 Enriched with CoQ. Briefly, 1 g of HCO60 in a 50 mL glass tube was melted at 60 °C in a water bath before the addition of 0.2 g of ubiquinone or ubiquinol. After mixing well and incubating for 10 min at 60 °C, glycerol (0.6 g) was added, and tubes were mixed and incubated for an additional 10 min. Then 1.0 g of the stock solution was transferred to a glass tube (20 mL) containing 7 mL of DI water at 60 °C, mixed well, and incubated for 10 min. Finally, aqueous CoQ solution (1 g) was diluted with hot water to 10 mL to yield yellow and colorless clear solutions of ubiquinone and ubiquinol, respectively. Stock solutions were prepared fresh for each experiment.

Simulated Digestion of CoQ-Enriched HCO60. Details for simulated gastric and small intestinal digestion have been described previously.[28] Initial experiments showed that partitioning of ubiquinol in the filtered aqueous fraction of chyme (i.e., samples at termination of small intestinal phase of simulated digestion) markedly exceeded that of ubiquinone. Thus, the concentration of ubiquinol in 2 mL of HCO60 added to 14.2 g of fat-free yogurt was decreased to generate aqueous fractions of chyme containing similar concentrations of CoQ (sum of ubiquinone + ubiquinol) as that in the aqueous fraction after digestion of HCO60 containing ubiquinone. The total amounts of yogurt, HCO60, ubiquinone, and ubiquinol for in vitro digestion were 2.0 ± 0.1 g, 25 mg, 7.1 μmol, and 2.5 μmol, respectively. α-Tocopherol (50 μmol/L) and ascorbic acid (500 μmol/L) also were added to all tubes containing CoQ-rich yogurt to limit oxidation of ubiquinol during digestion. The efficiencies (%) of micellarization of CoQ during digestion of yogurt supplemented with 7.1 or 2.3 μmol of ubiquinol were similar (62.1 ± 1.8 vs 64.7 ± 3.1%, respectively, $p = 0.197$). Aliquots of the predigestion mixture of yogurt supplemented with CoQ-rich HCO60 (2 mL), after completion of the simulated small intestinal phase of digestion, and filtered (0.2 μm pores) aqueous fraction (2 mL) of chyme were transferred immediately to glass tubes containing 2 mL of 5% potassium hexacyanoferrate(III) in PBS and mixed. Sealed tubes were incubated in a shaking water bath for 10 min at 37 °C at 85 rpm before extraction as described below. Replicate aliquots of starting material, chyme, and its aqueous fraction were transferred to empty glass tubes and immediately extracted. Extracts were analyzed by HPLC with a diode array detector. Ubiquinol content was calculated by the difference in the amount of ubiquinone in tubes lacking potassium hexacyanoferrate and total CoQ in tubes containing potassium hexacyanoferrate. Recovery of CoQ after digestion was calculated as nanomoles of total CoQ in chyme divided by total CoQ in the starting material multiplied by 100%. The efficiency of micellarization was calculated as total CoQ in the aqueous fraction of chyme divided by nanomoles of total CoQ in yogurt matrix multiplied by 100%.

CoQ Uptake and Transport by Caco-2 Cells. Caco-2 HTB37 cells were obtained from American Type Culture Collection (ATCC, Rockville, MD, USA) at passage 19 and maintained as previously described.[28] Cells (2.5×10^5) were seeded on membrane insets (3.0 μm pore diameter; EMD Millipore, Billerica, MA, USA) in six-well dishes. Washed monolayers (passages 20−26) were used for experiments 21−24 days after monolayers became confluent.

Filtered aqueous fraction of chyme generated during in vitro digestion of yogurt containing ubiquinone or ubiquinol solubilized in HCO60 was diluted 1:3 with DMEM (pH 6.5) containing 500 μmol/L phenol red along with oleate (1 mmol/L): taurocholate (0.5 mmol/L) micelles to induce chylomicron assembly and secretion.[29,30] Phenol red-free DMEM (3 mL) containing 1% FBS and 1% NEAA was added to the basolateral compartment. Cultures were incubated for 4 h before apical and basolateral media were collected. Monolayers were washed once with cold PBS containing 2 g/L albumin followed by two additional washes with cold PBS. Cell pellets were collected in cold PBS and centrifuged at 400 × *g* for 5 min at 4 °C. Cell pellets and basolateral medium were stored frozen under nitrogen gas at −80 °C overnight. CoQ uptake was calculated as follows: [(ubiquinone + ubiquinol) in cells of CoQ supplemented cultures − (endogenous ubiquinone + ubiquinol)] + [CoQ] in basolateral compartment. Endogenous CoQ content in monolayers of Caco-2 cells grown on membrane inserts to 21 days postconfluency was 220 ± 12 pmol/mg protein ($n = 10$) with ubiquinol representing 65 ± 2.0% of total CoQ ($n = 10$). To determine possible differences in retrotransport of newly acquired CoQ from medium prepared after digestion of yogurt with ubiquinone or ubiquinol, 100 μmol/L verapamil was added to both apical and basolateral medium to block Pgp-mediated efflux into the apical compartment. The cell monolayer was not adversely affected during the 4 h of incubation with this concentration of verapamil as assessed by phenol red flux from the apical to basolateral compartment and cell protein content per membrane insert.

The effects of altered GSH status and inhibition of Trx reductase activity in Caco-2 cells on uptake and transport of CoQ across the monolayer of Caco-2 cells also were examined to determine the impact of redox imbalance on CoQ flux. For these experiments, cells were treated with inhibitors as described below. Control and treated cells were incubated in DMEM with 500 μmol/L phenol red and Tween-40 micelles containing ubiquinone (80 ± 5 μmol/L) or ubiquinol (65 ± 3 μmol/L) and 10 μmol/L α-tocopherol were prepared as described elsewhere.[28] Apical medium also contained oleate (1.0 mmol/L), sodium taurocholate (0.5 mmol/L), and glycerol (50 μmol/L) to induce chylomicron assembly and secretion into the basolateral compartment.[29] Phenol red-free DMEM containing 1% FBS and 1% NEAA was added to the basolateral compartment. After 4 h, basolateral medium and washed monolayers were collected and extracted immediately for CoQ analysis.

Alteration of Glutathione Status of Caco-2 Cells. The protocol described by Noda et al.[31] was used to decrease the ratio of GSH to GSSG in cells to induce cell redox imbalance without oxidative stress. This involves pretreatment of monolayers with apical medium containing 5 mmol/L DL-buthioninesulfoximine (BSO) for 12.5 h and 30 μmol/L 1,3-bis(2-chloroethyl)-1-nitrosourea (BCNU) for 30 min. Then fresh DMEM containing BSO, BCNU, diamide (30 μmol/L), phenol red (500 μmol/L), Tween-40 micelles containing either

dx.doi.org/10.1021/jf5017829 | J. Agric. Food Chem. 2014, 62, 7174−7182

ubiquinone or ubiquinol, and taurocholate-oleate micelles was added to the apical compartment of cultures. Basolateral medium and washed monolayers were collected after 4 h. To quantify intracellular reduced (GSH) and oxidized (GSSG) glutathione, cell pellets were immediately suspended in ice-cold PBS (0.25 mL) containing an equal volume of 10% PCA and 1 mmol/L DTPA and disrupted with a hand-held homogenizer. Homogenate was centrifuged at 16,000 × *g* at 4 °C for 5 min. Acidified supernatant was collected and stored at −80 °C for glutathione analysis by HPLC-EC using a boron-doped diamond electrode.[32] GSH and GSSG were separated on a Shiseido C_{18} column (5 μm, 250 × 3.0 mm; Phenomenex, Torrance, CA, USA) with a C_{18} guard column containing the identical solid phase. Mobile phase was 6% acetonitrile in 25 mM sodium dihydrogen phosphate containing 1.4 mM 1-octanesulfonic acid, pH 2.5, at a flow rate of 1.0 mL/min. Areas under the curve for cell GSH and GSSG were compared with six-point standard curves using pure GSH and GSSG. GSH reductase activity was measured in cell homogenates by monitoring reduction of GSSG by NADPH coupled to the reaction of GSH with 5,5′-dithiobis(2-nitrobenzoic acid).[25]

Inhibition of Trx Reductase Activity in Caco-2 Cells. Auranofin (10 μmol/L) was added to DMEM containing Tween-40 micelles with CoQ and taurocholate-oleate micelles. This medium (2 mL) was added to the apical compartment of Caco-2 cells grown on membrane inserts. After 4 h of incubation, basolateral medium was collected to quantify CoQ transport across the monolayer. Trx reductase activity and redox status of CoQ in washed monolayers were analyzed to compare with cells identically treated in the absence of auranofin. Trx reductase activity was determined by monitoring the reduction of DTNB substrate in the absence versus in the presence of inhibitor at 412 nm (Thioredoxin Reductase Kit, Abnova, Walnut, CA, USA).

Analysis of Coenzyme Q by HPLC-DAD. CoQ was analyzed by HPLC-DAD as described by Okamoto et al.[33] Briefly, aliquots (1 mL) of either medium or cell pellets resuspended in PBS were extracted in glass tubes with 2 mL of ethanol followed by 6 mL of hexane. The mixture was vortexed for 60 s and centrifuged at 800 × *g* for 10 min at 4 °C. Supernatant was transferred to clean glass vial, and samples were re-extracted. Combined supernatant was dried under a stream of nitrogen gas, the film was resolubilized with 0.4 mL of MeOH/hexane (75:25), and 20−60 μL was injected onto the HPLC column. Because this method lacked sufficient sensitivity for accurate quantification of ubiquinol in cells and basolateral medium, ubiquinol was oxidized by the addition of an equal volume of 5% potassium hexacyanoferrate-(III). After incubation at 37 °C with shaking (85 rpm) for 10 min, ubiquinone was extracted into ethanol and hexane. Ubiquinone was separated on a Sunfire C_{18} column (5 μm, 4.6 × 250 mm; Waters) following elution from a Sunfire C_{18} guard column. Mobile phase was a mixture of methanol and hexane (75:25) flowing at a rate of 1.0 mL/min. Peak area was monitored at 275 nm. A standard curve was prepared for quantification with the limit of detection (signal-to-noise ratio of 5:1) being 58 nmol/L. Ubiquinol was calculated as the difference between total CoQ in samples incubated with potassium hexacyanoferrate and the quantity of ubiquinone in the absence of the oxidant.

Miscellaneous. Cell protein was determined by the bicinchoninic acid assay (Pierce Chemical Co.) using bovine serum albumin as standard. Mean cell protein per insert was 1.2 ± 0.05 mg and independent of the presence or absence of ubiquinone and ubiquinol in the apical compartment. Flux of phenol red from the apical to the basolateral compartment was determined by measuring absorbance at 546 nm at 15 s after the addition of 20 μL of 1 mol/L NaOH to 150 μL of basolateral medium at room temperature.[34]

Analysis of Data. Results are expressed as means ± SD for the number (*n*) of observations indicated. Statistical analyses were performed using Student's paired *t* test and one-way analysis of variance and Tukey's HSD (honestly significant difference). A minimum *p* value of 0.05 was used to determine statistically significant differences among means for all tests.

RESULTS AND DISCUSSION

Bioaccessibility of Ubiquinol Exceeds That of Ubiquinone. We previously reported that the efficiency of micellarization of ubiquinone during simulated digestion was greater for commercial formulations in which the coenzyme was solubilized by incorporation into either γ-cyclodextrin or oils containing emulsifiers.[24] Here ubiquinone and ubiquinol were solubilized in HCO60 to directly compare their micellarization during simulated digestion. HCO60 is polyethylene glycol 60 linked to hydrogenated castor oil and is used as an emulsifier for cosmetic and pharmaceutical formulations.[35,36] Hydroxystearic acid, the most abundant fatty acid in this preparation, appears to have a relatively high affinity for CoQ and the PEG60 moiety facilitates emulsification in the water matrix. Also, PEGylated oils have low toxicity, teratogenicity, and mutagenicity. Preliminary studies showed that the efficiency of micellarization of ubiquinol during the small intestinal phase of digestion of HCO60 added to yogurt was 2−3 times greater than that of ubiquinone. Thus, the concentration of ubiquinone in HCO60 was increased to generate mixed micelles containing similar amounts of ubiquinone and ubiquinol for investigating uptake and transport of CoQ by monolayers of differentiated Caco-2 cells (Table 1).

Table 1. Effect of Redox State of CoQ on Stability and Efficiency of Micellarization during Simulated Digestion of Yogurt Supplemented with Ubiquinone or Ubiquinol in PEG60 Hydrogenated Castor Oil Vehicle[a]

		ubiquinone-rich yogurt	ubiquinol-rich yogurt
starting material (CoQ-enriched yogurt)			
μmol of CoQ	total CoQ[b]	7.1 ± 0.1[a]	2.34 ± 0.05[b]

[a]Data are the mean ± SD for four independent digestions. ND, not detected. Different letters in the same row indicate that means differ significantly ($p < 0.01$). [b]Total CoQ = ubiquinone + ubiquinol. [c]Percentage of total CoQ in chyme versus starting material. [d]Percentage of total CoQ in aqueous fraction of chyme versus starting material.

Recovery of ubiquinone after in vitro digestion of the yogurt containing the ubiquinone supplement was 82 ± 3.7% with 28% of the initial content of the coenzyme transferred to the aqueous fraction of chyme during the small intestinal phase of digestion (Table 1). All CoQ in the aqueous fraction, that is, the bioaccessibility, was ubiquinone. After digestion of the yogurt supplemented with ubiquinol, 84% of CoQ (ubiquinone + ubiquinol) in the food matrix was retained and 65% of initial content of CoQ partitioned in the bioaccessible fraction. Partial oxidation of ubiquinol occurred during both preparation of the ubiquinol-enriched yogurt and simulated digestion with

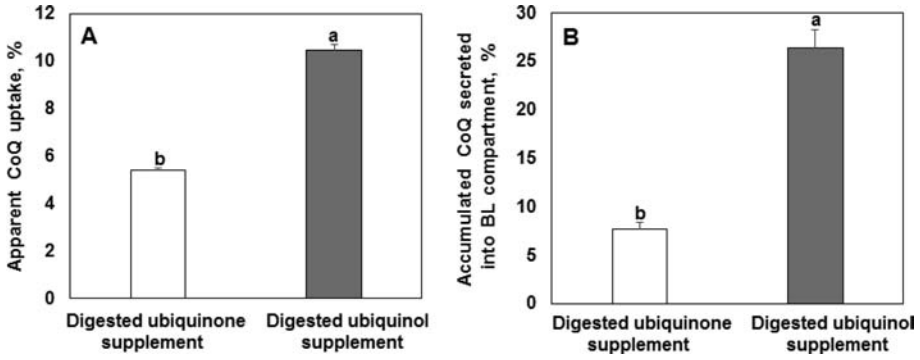

Figure 1. Apparent uptake of CoQ and secretion of the coenzyme into the basolateral compartment by Caco-2 cells incubated with aqueous fraction of chyme generated during digestion of yogurt containing either ubiquinone (20.0 nmol/well) or ubiquinol (15.2 nmol/well) supplement. Apparent uptake (A) represents the percentage of CoQ in the apical compartment present in cells (corrected for endogenous CoQ) and the basolateral compartment (B) of cultures of Caco-2 cells after 4 h of incubation. The percentage of CoQ accumulated by cells that was secreted into the basolateral medium was calculated by dividing the quantity of the coenzyme in the basolateral compartment by the corrected amount in cells plus the quantity in the basolateral compartment. Data are the mean ± SD, $n = 6$. Different letters above bars indicate that means differ significantly ($p < 0.01$).

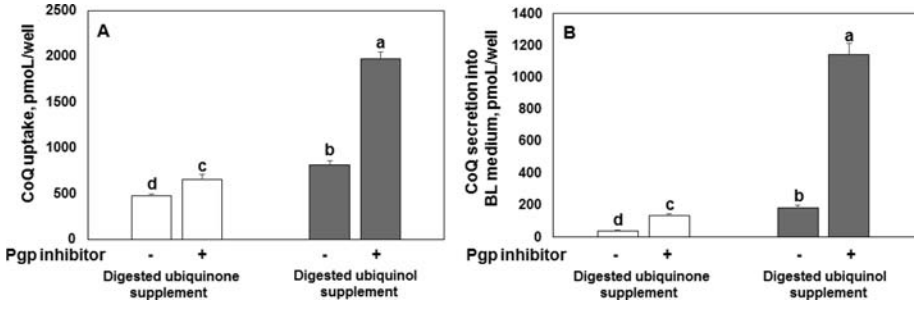

Figure 2. Inhibition of Pgp increases apparent uptake (A) and basolateral secretion (B) of ubiquinone and ubiquinol in apical medium. Caco-2 cells were treated with medium containing verapamil (100 μmol/L) in the apical and basolateral compartments for 30 min before addition of apical medium containing diluted aqueous fractions generated during digestion of yogurt supplemented with either ubiquinone. Apical medium contents of ubiquinone and ubiquinone were 12.8 and 12.3 nmol/well, respectively. Cultures were incubated for 4 h before collection of basolateral medium and washed cells. Data are the mean ± SD, $n = 3$. Different letters above bars indicate significantly ($p < 0.05$) different means.

ubiquinol, accounting for 59 and 56% of total CoQ in chyme and the filtered aqueous fraction, respectively. Nevertheless, the efficiency with which total CoQ partitioned in the aqueous fraction of chyme during digestion of the ubiquinol-supplemented yogurt was more than twice as great as that of CoQ after digestion of yogurt enriched with ubiquinone ($p < 0.001$). The similar recoveries of CoQ after digestion and its more efficient partitioning in the aqueous fraction of chyme demonstrated that solubilized ubiquinol has greater bioaccessibility than solubilized ubiquinone.

The extent of oxidation of ubiquinol during manual manipulations for solubilization in HCO, mixing in the yogurt food matrix, and simulated digestion likely exceeded that in standard commercial preparations of supplements and in situ digestion. The commercial form of ubiquinol is generally a soft-gel capsule. The content of the capsule is prepared in a deoxygenated environment under a blanket of inert gas before the soft-gel capsule shell is filled in the absence of air. These processes result in ≤2% oxidation of ubiquinol. Moreover, the shell of the soft-gel capsule has low oxygen permeability for ubiquinol to stabilize the reduced state until the capsule disintegrates in the stomach. Some oxidation of ubiquinol in the stomach and small intestine is possible as foods contain air and swallowing also introduces air into the stomach. However, oxygen diffuses from the gastrointestinal lumen into gut tissues, resulting in a decreasing oxygen gradient as chyme progresses from the stomach to the anaerobic environment in the colon.[37,38] Therefore, ubiquinol oxidation is expected to be lower in the commercial preparation of the delivery system and in situ environment than we observed in the laboratory.

Apical Uptake and Transepithelial Transport of CoQ by Caco-2 Cells from Micelles Generated during Digestion. Apical uptake of CoQ incorporated into mixed micelles during digestion of yogurt containing either ubiquinone or ubiquinol by Caco-2 cells and subsequent transfer of acquired CoQ to the basolateral compartment were determined. The quantities of CoQ in medium prepared with aqueous fraction of chyme after digestion of yogurt containing ubiquinone and ubiquinol were 20.0 ± 0.4 and 15.2 ± 0.4 nmol/well, respectively. Apparent uptake of CoQ from the apical compartment (%) was calculated as the corrected intracellular CoQ content (i.e., total CoQ minus endogenous CoQ) plus the quantity of CoQ in the basolateral compartment after 4 h of incubation. Apparent uptake of CoQ was twice as great for monolayers exposed to filtered aqueous fraction generated during digestion of yogurt enriched with ubiquinol as for cells incubated with aqueous fraction after digestion of yogurt supplemented with ubiquinone (Figure 1A). The corrected intracellular quantity of CoQ was 17% greater ($p < 0.001$) in cultures incubated with the filtered aqueous fraction of chyme after digestion of the ubiquinol supplement compared to the ubiquinone supplement (1.17 ± 0.02 vs 1.00 ± 0.04

dx.doi.org/10.1021/jf5017829 | J. Agric. Food Chem. 2014, 62, 7174−7182

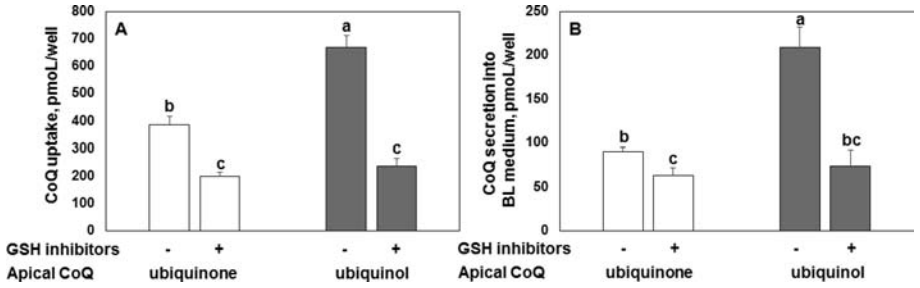

Figure 3. Altered cellular GSH status is associated with decreased apical uptake and basolateral secretion of CoQ. Caco-2 cells were incubated in the absence or presence of a cocktail of inhibitors of GSH synthesis and reduction as described under Materials and Methods. Apical medium containing ubiquinone (5.0 nmol/well) or ubiquinol (4.85 nmol/well) was added and cultures were incubated for 4 h. Data are the mean ± SD, $n = 6$. Different letters above bars indicate that means differ significantly ($p < 0.01$).

nmol/well, respectively). Ubiquinol accounted for 55% of intracellular pool of accumulated CoQ regardless of origin of the mixed micelles delivering CoQ. The quantity of CoQ secreted into basolateral medium was 5 times greater ($p < 0.0001$) in cultures incubated with micellar CoQ generated during digestion of ubiquinol-rich yogurt compared to CoQ incorporated into mixed micelles during digestion of ubiquinone-rich yogurt (0.42 ± 0.04 vs 0.08 ± 0.01 nmol CoQ/well). This represents 2.4-fold greater secretion of the quantity of the coenzyme apparently taken up by cells incubated with micelles generated during digestion of yogurt with ubiquinol compared to ubiquinone (Figure 1B). This difference was not associated with changes in barrier integrity of the monolayers as apical to basolateral flux of the paracellular marker phenol red was not significantly different for monolayers incubated with medium containing filtered aqueous fraction of chyme generated during digestion of yogurt enriched with either ubiquinone (86 ± 5 pmol/cm^2/h, $p = 0.4656$) or ubiquinol (87 ± 4 pmol/cm^2/h, $p = 0.3173$). These rates for paracellular transport of the dye were similar to that across monolayers of control cells, that is, 83.9 ± 8.1 pmol/cm^2/h.

Verapamil-mediated inhibition of the Pgp effluxer increased apparent uptake and basolateral secretion of CoQ from micelles generated during digestion of yogurt supplemented with either ubiquinone or ubiquinol (Figure 2). Apparent apical uptake of CoQ increased 38 and 140% when verapamil-treated Caco-2 cells were incubated with diluted aqueous fraction of chyme after digestion of ubiquinone and ubiquinol supplemented yogurt, respectively (Figure 2A). This change was associated with 19% ($p < 0.01$) and 31% ($p < 0.0001$) increases in intracellular CoQ in verapamil-treated cells incubated in medium containing diluted aqueous fraction from digested yogurt supplemented with ubiquinone and ubiquinol, respectively. Similarly, secretion of CoQ into the basolateral compartment increased 2.4- and 5.3-fold in Pgp-treated cells incubated with micelles generated during digestion of yogurt containing ubiquinone and ubiquinol, respectively (Figure 2B). These data suggest that apical uptake and secretion of CoQ into the basolateral compartment are more efficient for supplemented ubiquinol than for ubiquinone. It is unknown if the redox state of CoQ affects its transfer from mixed micelles to the apical surface of Caco-2 cells, transfer across or incorporation into the plasma membrane, or distribution to other subcellular compartments including the Golgi during chylomicron assembly.

CoQ content and redox status in medium containing the mixed micelles generated during digestion of yogurt with the supplements were stable during 4 h of incubation in cell-free wells. Recovery of total CoQ and ubiquinol exceeded 95 and 90%, respectively. Only ubiquinone was detected in the basolateral medium after collected samples were stored under nitrogen at −80 °C overnight, whereas both ubiquinone and ubiquinol were present in basolateral medium that was analyzed immediately upon termination of the incubation after 4 h. These data suggest that the presence of 19% oxygen (95% air, 5% CO_2) in the cell culture environment, the relative absence of other antioxidants in the basolateral compartment, and overnight storage of medium likely contributed to oxidation of ubiquinol after its transport across the basolateral membrane.

Effect of Altered Cellular Redox Status on Uptake and Basolateral Secretion of CoQ. Because uptake and basolateral secretion of CoQ from micelles generated during digestion of yogurt with ubiquinol exceeded that for micelles containing only ubiquinone, we hypothesized that efficient secretion of CoQ across the basolateral membrane required a reduced intracellular environment. Interactive redox systems are responsible for maintaining a reduced intracellular environment.[39] Reduced glutathione is the most abundant intracellular antioxidant in aerobic cells. Alterations in glutathione status previously have been shown to affect glucose uptake,[40] calcium absorption,[41] and the activity of organic solute transporters and ion channels.[42] The concentration of total glutathione and the high ratio of glutathione to glutathione disulfide are maintained by the activities of γ-glutamyl cysteine synthetase and NADPH-dependent GSH reductase, respectively. GSH reductase also has been reported to directly reduce ubiquinone to ubiquinol in tissue homogenates and cytosol.[25] The protocol of Noda et al.[31] was used to decrease GSH content of Caco-2 cells without inducing oxidative stress. GSH reductase activity and cellular GSH decreased 41 and 99%, respectively, and cell GSSG increased 23% in monolayers incubated with a cocktail. Despite this marked decrease in cellular GSH, there was no overt cytotoxicity as cellular morphology, mitochondrial activity as assessed by reduction of MTT, and cell protein content per well were not significantly different in control cultures and cultures exposed to the cocktail of inhibitors (data not shown). Similarly, there was no significant change in barrier integrity as apical to basolateral flux of phenol red was not significantly different in control in cultures with control and low glutathione status. Finally, the amounts of ubiquinone or ubiquinol in medium were not altered during co-incubation with the inhibitors in the absence of cells.

Apparent uptake of ubiquinone and ubiquinol from micelles in apical medium was decreased 48% ($p < 0.0001$) and 65% ($p < 0.0001$), respectively, in cells with low glutathione status

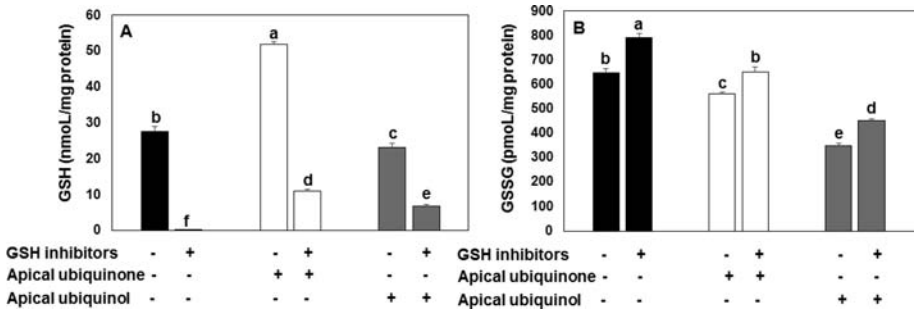

Figure 4. Intracellular GSH (A) and GSSG (B) are altered by exposure of Caco-2 cells to micellar CoQ and inhibitors of GSH status. Cultures were incubated in the absence (control) or presence of inhibitors of GSH status as described under Materials and Methods. Data are the mean ± SD, n = 6. Different letters above error bars indicate that means differ significantly ($p < 0.01$).

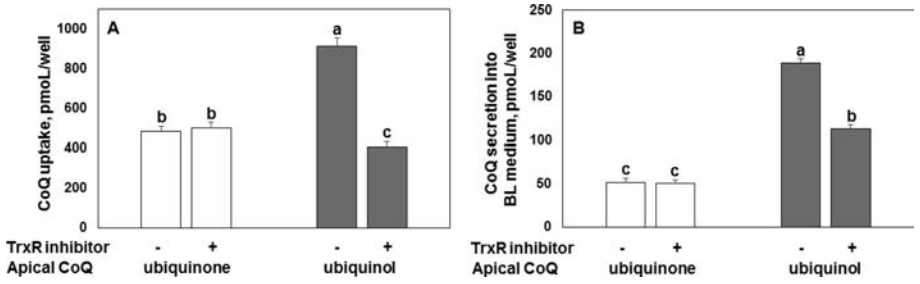

Figure 5. Inhibition of Trx reductase activity decreases apical uptake (A) of ubiquinol and basolateral secretion of CoQ (B) in cultures containing micellar ubiquinol or ubiquinone. Monolayers of Caco-2 grown were co-incubated in apical medium with auranofin (10 μmol/L) and either ubiquinone (6.3 nmol/well) or ubiquinol (6.1 nmol/well) for 4 h. Data are the mean ± SD, n = 6. Different letters above bars indicate significantly ($p < 0.001$) different means.

(Figure 3). Similarly, secretion of CoQ into the basolateral compartment decreased 30 and 65% in cultures incubated in medium with ubiquinone and ubiquinol, respectively. The quantities of CoQ in cells and in basolateral medium were not significantly different in cultures with low GSH status regardless of whether ubiquinone or ubiquinol was present in apical medium. Elucidation of the mechanism by which depletion of cell GSH adversely affects transport of both reduced and oxidized CoQ across the brush border and basolateral membranes of differentiated Caco-2 cells requires investigation.

There were additional interactions between CoQ and glutathione status. The endogenous ratio of ubiquinol to ubiquinone decreased by 20% ($p < 0.05$) in cells treated with the inhibitors of glutathione status in the absence of apical CoQ. The presence of 5.0 nmol of ubiquinone in apical medium was associated with a doubling of cellular GSH (Figure 4A) and a 14% reduction in GSSG (Figure 4B). Similarly, Wagner et al.[43] reported that treatment of C2C12 myotubes with 100 μmol/L ubiquinone plus 250 μmol/L lipoic acid increased expression of γ-glutamyl cysteine synthase and the activities of GSH reductase and glucose-6-phosphate dehydrogenase and phosphogluconate dehydrogenase, the latter two being key enzymes in the synthesis of NADPH. These changes resulted in a 4-fold increase in intracellular GSH. Hwang et al.[44] also reported that addition of 10 μmol/L ubiquinone to medium increased intracellular GSH concentration in UV-A irradiated keratinocytes. In contrast with the stimulatory effect of ubiquinone on cellular GSH content, incubation of cells in apical medium containing 4.85 nmol of ubiquinol per well decreased GSH and GSSG by 16 and 46%, respectively. The basis for the differential effects of ubiquinone and ubiquinol on glutathione status of Caco-2 cells in the present study is unknown. It is also noteworthy that apical medium containing ubiquinone and ubiquinol attenuated the extent of the reduction in cell GSH and increase in GSSG when cells were treated with BSO, BCNU, and diamide (Figure 4).

We next assessed whether the decreased uptake and transport of micellar CoQ in cells with low glutathione status was specific or reflected a more general effect of cell redox status on the greater bioavailability of ubiquinol than of ubiquinone. The thioredoxin/thioredoxin disulfide couple represents the other major intracellular redox system.[41] Trx reductase activity was 7.3−10.0 nmol/min/mg protein in cultures ± apical CoQ, but not detected in cells incubated with 10 μmol/L auranofin for 4 h. Loss of Trx reductase activity was associated with 50 and 40% decreases in the apical uptake (Figure 5A) and basolateral secretion (Figure 5B) of CoQ, respectively, in cultures incubated with apical medium containing ubiquinol. In contrast, cell uptake and basolateral secretion were not altered in auranofin-treated cultures incubated with apical medium containing ubiquinone. Similarly, the intracellular ratio of ubiquinol to ubiquinone also significantly decreased in auranofin-treated cells incubated with micelles containing ubiquinol, but not ubiquinone (Figure 6A). The discrepancy in the response of monolayers to auranofin led us to question whether the presence of the inhibitor in medium was associated with extracellular oxidation of ubiquinol. This interaction was confirmed by comparison of the stability of ubiquinol in Tween-40 micelles in the absence and presence of auranofin in cell-free medium. Ubiquinol decreased 31% during the 4 h of incubation in cell-free medium containing auranofin (Figure 6B). Oxidation of ubiquinol to ubiquinone accounted for only one-third of the total loss. The concentration of ubiquinone in medium ± auranofin incubated for 4 h in the absence of cells was not significantly altered after 4 h (Figure 6B). These results suggest the decreased uptake

dx.doi.org/10.1021/jf5017829 | J. Agric. Food Chem. 2014, 62, 7174−7182

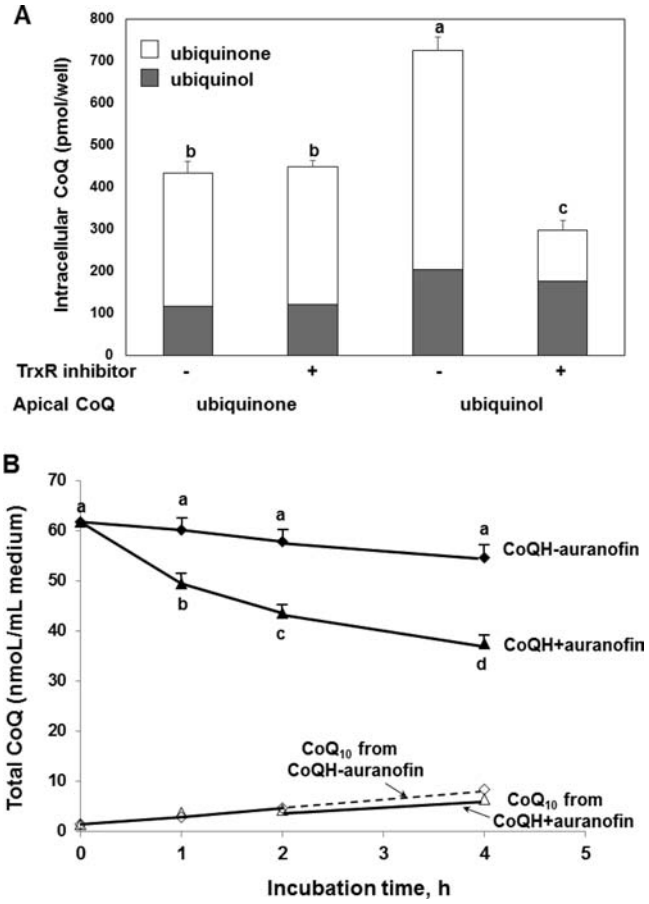

Figure 6. Decreased intracellular CoQ in monolayers co-incubated in apical medium containing 10 μmol/L auranofin and ubiquinol (A) is due to extracellular oxidation and degradation of the reduced coenzyme (B). The amounts of unbiquinone and ubiquinol in apical medium of Caco-2 cell cultures were 6.3 and 5.4 nmol/well, respectively. TrxR, thioredoxin reductase; CoQ_{10}, ubiquinone; CoQH, ubiquinol. Data are the mean ± SD for $n = 6$ and 4 in panels A and B, respectively. Different letters above error bars indicate that means differ significantly different ($p < 0.001$ for panel A and $p < 0.01$ for panel B).

and transport of ubiquinol in medium containing auranofin resulted from both oxidation and degradation of micellar ubiquinol in the apical compartment by an unknown chemical reaction.

NQO1 catalyzes the two-electron reduction of quinones in human tissues and has been suggested to participate in the reduction of ubiquinone.[27] Unlike normal intestinal epithelial cells, Caco-2 cells lack NQO1 activity because they express a mutant form of the enzyme that is rapidly eliminated by the proteosomal degradation pathway.[45−47] Therefore, we were not able to determine whether NQO1 activity affected CoQ uptake, transport, and the redox status of intracellular CoQ using this cell line. We did test the possibility that the enzyme might affect CoQ uptake and redox status using the HT-29 human colonic cell line that expresses wild-type protein. NQO1 activity was decreased by 25% in cells exposed to 10 μmol/L dicoumarol, a specific inhibitor of NQO1.[27] This change did not alter the intracellular content of CoQ or the ratio of ubiquinol to ubiquinone during incubation in medium supplemented with ubiquinone (80 μmol/L) (data not shown). In contrast, there was a 19% decline in intracellular cell CoQ content ($p < 0.05$) without alteration of the ratio of ubiquinol to ubiquinone when cultures were incubated in medium containing ubiquinol and dicoumarol. There was no extracellular interaction between dicoumarol and ubiquinol as recovery of ubiquinol during incubation in cell-free medium with dicoumarol for 6 h was 98%, with 95% of the coenzyme remaining in the reduced state. Together, these data suggest that partial loss of NQO1 activity minimally affected accumulation of ubiquinol by HT-29 cells. Clarity regarding the possible influence of NQO1 activity on the intestinal absorption of ubiquinol will require investigation in an animal model.

In summary, the present in vitro studies suggest that the greater bioavailability of ubiquinol compared to that of ubiquinone is the result of increased efficiency of several processes associated with the absorption of orally administered lipophilic compounds. These included partitioning into mixed micelles during simulated small intestinal digestion, apical uptake by Caco-2 cells, and subsequent secretion of the coenzyme across the basolateral membrane. The extent of the observed differences in these processes between ubiquinol and ubiquinone likely underestimate the situation in situ because oxygen tension in the laboratory exceeded that for commercial preparation of ubiquinol in soft gel capsules, exposure to compounds in the meal prior to ingestion, and during gastric and small intestinal phases of digestion. This led to the partial oxidation of ubiquinol to ubiquinone, resulting in the presence of both ubiquinol and ubiquinone in mixed micelles added to the apical compartment of Caco-2 cells. The present results also show that a reduced intracellular environment is necessary to maintain the elevated ratio of ubiquinol to ubiquinone within cells, which in turn facilitates both the apical uptake and basolateral secretion of CoQ. This was demonstrated by markedly decreasing cellular GSH and the activity of TrxR. Because the actual compartmentalization of the bolus of CoQ taken up by the cell is not known, it is unclear which flavoenzyme or combination of such enzymes shown to reduce extramitochondrial ubiquinone in cell homogenates and once purified are responsible for doing so in absorptive cells lining the gut.

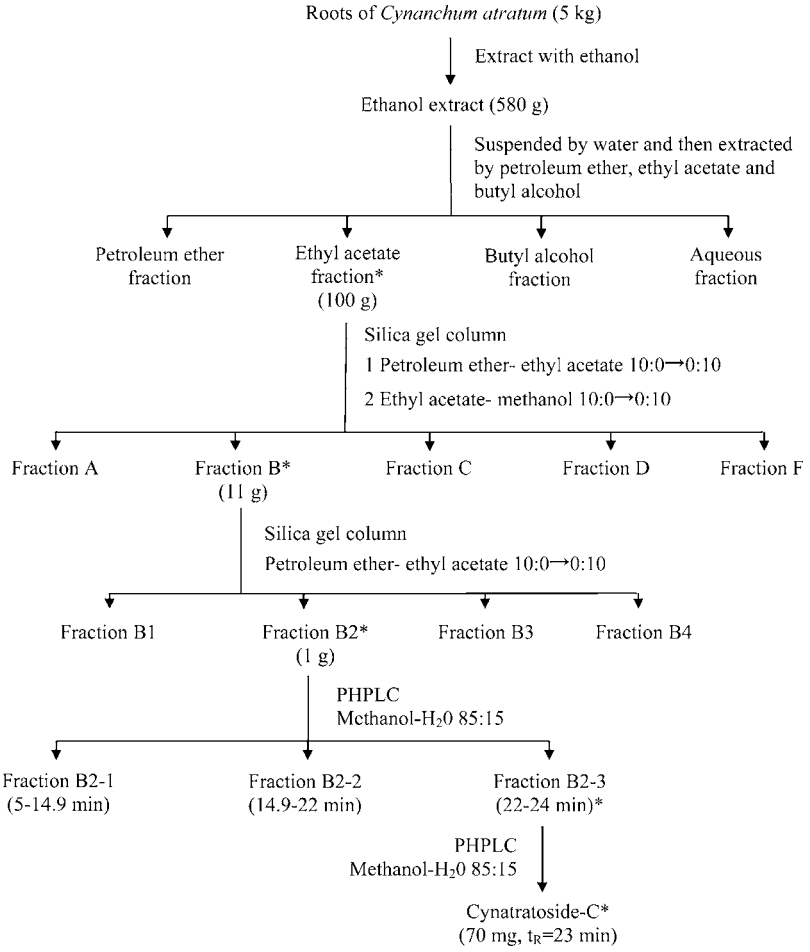

Figure 1. Bioassay-guided fractionation for identification of parasiticidal compound. *: Best antiparasitic activity from the same row.

(Agilent) equipped with a TC-C18 column (5 μm, 4.6 mm × 250 mm, Agilent) was used to analyze the purity of active compound. The thin layer chromatography (TLC) plate was used to identify the obtained semblable fractions with similar TLC patterns for further mixing the similar fractions before bioassay by means of visualizing the plate with a UV lamp (λ_{max} 254 and 365 nm) and anisaldehyde spray reagent (EtOH/anisaldehyde/sulfuricacid, 90:5:10, v/m/v). A Sartorius ME5 microelectronic balance (readability, 0.001 mg) (Sartorius, Niedersachsen, Germany) was used to weigh the fractions and active compound. An inverted microscope (Nikon, Tokyo, Japan) was used to observe and photograph the treated tomonts. Granule feed (Haid, Guangzhou, China) was used to feed grass carp daily to apparent satiation.

Extraction and Isolation of Bioactive Compound. The roots of *C. atratum* (5 kg) were purchased from the Chinese medicinal market at Guangzhou, China, and kept in an oven at 55 °C until completely dried. The dried plant materials were then powdered by a pulverizer with 50 mesh strainer. The root powder was extracted with 95% ethanol (3 × 20 L) at 50 °C. After removal of ethanol in vacuo at 50 °C by a rotary vacuum evaporator, the extract (580 g) was suspended in water (1 L) and partitioned with petroleum ether (3 × 1 L), ethyl acetate (3 × 1 L), and butanol (3 × 1 L).

A bioassay-guided fractionation was designed for the isolation and identification of compounds with anti-*I. multifiliis* effect as shown in Figure 1 and Table 1. Ethyl acetate fraction (100 g) was subjected to column chromatography and continuously eluted using a stepwise gradient of petroleum ether/ethyl acetate (10:0, 4:1, 1:1, and 0:10, v/v) and methanol to get five fractions (A−E). The most active fraction B was further fractionated on a silica gel column and eluted with petroleum ether/ethyl acetate (4:1, 1:1, 1:4, and 0:10, v/v) to obtain fractions B1−B4. The active fraction B2, acquired from the elution of a 1:1 petroleum ether/ethyl acetate, was separated by PHPLC to collect fraction B2-1, fraction B2-2, and fraction B2-3. The mobile phase used

[a]−: The fraction at the listed concentration could not kill 100% nonencysted tomonts after 4 h exposure. +: The fraction at the listed concentration killed 100% of nonencysted tomonts by 4 h exposure.

dx.doi.org/10.1021/jf5018675 | J. Agric. Food Chem. 2014, 62, 7183−7189

for PHPLC was methanol/H_2O (80:20, v/v), applied with a flow rate of 10 mL/min, and ultraviolet detection was a 210 nm. The active fraction B2-3 was further purified by PHPLC under the same condition to yield an active compound (70 mg, t_R = 23 min) at purity >98%. The active compound was recrystallized in methanol and identified by various spectroscopic analyses, including ESI−MS, HR-ESI−MS, and 1D NMR (^1H,^{13}C NMR, and DEPT), and characterized as cynatratoside-C. The other 256 mg of cynatratoside-C was purified from 15 kg of *C. atratum* roots by means of the same method mentioned above (showed in Figure 1) to meet the needs of trials, and stored at 4 °C in a refrigerator prior to use. The spectroscopic data of the active compound are as follows.

ESI−MS (positive) *m/z*: 801.7 $[M + Na]^+$. ESI−MS (negative) *m/z*: 813.8 $[M + Cl]^-$ and 777.9 $[M - H]^-$. HR-ESI−MS *m/z*: $[M + Na]^+$ 801.4039. ^1H NMR (500 MHz, MeOD) δ: 0.96 (3H, s, 19-CH_3), 1.24 (3H, d, *J* = 6.3 Hz, 6′-CH_3), 1.27 (3H, d, *J* = 6.2 Hz, 6″-CH_3), 1.29 (3H, d, *J* = 6.2 Hz, 6‴-CH_3), 1.49 (3H, s, 21-CH_3), 3.44 (3H, s, 3′-O CH_3), 3.45 (3H, s, 3‴-O CH_3), 3.91 (1H, dd, *J* = 9.6, 6.2 Hz, 15-CH_β), 4.13 (1H, dd, 3″-CH), 4.17 (1H, dd, *J* = 8.5, 7.0 Hz, 15-CH_α), 4.67 (1H, dd, *J* = 9.7, 1.8 Hz, 1′-CH), 5.01 (1H, br d, *J* = 3.4 Hz, 1‴-CH), 5.04 (1H, dd, *J* = 9.7, 1.9 Hz, 1″-CH), 5.32 (1H, ddd, *J* = 9.6, 7.5, 7.5 Hz, 16-CH), 5.45 (1H, d, *J* = 5.5 Hz, 6-CH), 6.33 (1H, br s, 18-CH). ^{13}C NMR (125 MHz, MeOD) δ: 18.1 (19-C), 18.4 (6″-C), 18.5 (6‴-C), 18.7 (6′-C), 24.6 (11-C), 24.9 (21-C), 29.1 (12-C), 30.6 (2-C), 30.8 (7-C), 36 (2‴-C), 37.5 (1-C), 38.1 (2′-C), 39.6 (2″-C), 39.7 (10-C), 39.9 (4-C), 41.7 (9-C), 54.5 (8-C), 57.1 (17-C), 57.4 (3‴-OMe), 57.7 (3′-OMe), 68.5 (5″-C), 68.7 (15-C), 69.9 (5‴-C), 69.8 (3″-C), 72.4 (5′-C), 76.5 (16-C), 77.5 (4‴-C), 79 (3-C), 79.2 (3‴-C), 80.1 (3′-C), 82.6 (4″-C), 84.2 (4′-C), 99 (1′-C), 99.6 (1″-C), 101.1 (1‴-C), 115.6 (20-C), 119.4 (13-C), 121.4 (6-C), 141.6 (5-C),144.5 (18-C), 177 (14-C).

Fish and Parasite. Healthy grass carp (*Ctenopharyngodon idellus*) weighing 22.6 ± 3.5 g was obtained from a commercial fish farm at Huadu, Guangzhou City, Guangdong Province. *I. multifiliis* was isolated from goldfish obtained from the ornamental fish market of Guangzhou. The infected goldfish were kept with five naïve grass carp in a 30 L opaque tank for 7 d to allow infection of the grass carp by *I. multifiliis*. The temperature of the water was controlled at 23.0 ± 0.3 °C, and the fish were fed daily with diets at 1% of fish weight. When grass carp were heavily infected with mature trophonts, the skin was gently scraped to dislodge the trophonts after the fish were anesthetized by 150 mg/L tricaine methanesulfonate (MS-222, Sigma). Mature trophonts were rinsed several times with dechlorinated water to wipe off fish mucus. Usage of grass carp was approved by the Animal Experimentation Ethics Committee of Jinan University.

Bioassay of Fractions against *I. multifiliis* Nonencysted Tomonts. Each fraction weighing 5 mg was dissolved in 2.5 mL of dechlorinated freshwater containing 1% (v/v) dimethyl sulfoxide (DMSO) to make a 2000 mg/L stock solution. The stock solution was diluted with dechlorinated freshwater in a 24-well issue culture plate to concentrations of 200, 100, and 50 mg/L. The control (0 mg/L) was made following the method described by Fu et al. (2014)[11] to avoid the influence of residual solvent in each fraction. Briefly, 50 mL of each solvent used in the different fraction was also concentrated under reduced pressure in a vacuum rotary evaporator until the solvent was invisible, and then 50 mL of dechlorinated freshwater containing 1% (v/v) DMSO was added to the evaporator to dissolve the residual solvent, and the solution was used as antitomont trial control.

Nonencysted tomonts came from trophonts obtained above. The average number of nonencysted tomonts per 100 μL of water was determined with the assistance of a microscope (4×) according to Zhang et al. (2013).[12] Approximately 80 nonencysted tomonts in 300 μL of dechlorinated freshwater were placed into each well of a 24-well tissue culture plate. Next, 300 μL of each fraction solution at different concentrations was added to each well in triplicate to make concentrations of 100, 50, 25, and 0 (control) mg/L, respectively. Survival or dead nonencysted tomonts were identified on the basis of movement (live) or no motion (paralysis or dead) of the parasite under a microscope at 4× magnification.

In Vitro Bioactivity of Cynatratoside-C on *I. multifiliis* Tomonts. The stock solution of cynatratoside-C (2000 mg/L) was prepared with the same method mentioned above. The stock solution was diluted with dechlorinated water in a 24-well plate to concentrations of 64, 32, 16, 8, 4, 2, 1, 0.5, 0.25, 0.125, 0.06, and 0.03 mg/L. Next, 300 μL of the cynatratoside-C solution at different concentrations was added to 300 μL of water including about 75 nonencysted tomonts in each well of a 24-well plate in triplicate, and the final concentrations of cynatratoside-C were 32, 16, 8, 4, 2, 1, 0.5, 0.25, 0.125, 0.06, 0.03, and 0.015 mg/L, respectively. The negative control (0 mg/L) was prepared with the method described above, and malachite green at 0.125 and 0.06 mg/L was used as positive control. The duration for killing all nonencysted tomonts was monitored at different time points for 5 h. The numbers of encysted tomonts and released theronts were determined at 6 and 22 h post exposure to cynatratoside-C, respectively. Theronts number in each well were determined under a microscope (10×) according to Zhang et al. (2013).[12]

To evaluate the effect of cynatratoside-C on encysted tomonts, a 300 μL solution that contained about 60 nonencysted tomonts was distributed to each well of a 24-well plate. The nonencysted tomonts were incubated for 6 h, and then encysted tomonts were enumerated in every well. The encysted tomonts were subsequently exposed to cynatratoside-C at concentrations of 32, 16, 8, 4, 2, 1, 0.5, 0.25, 0.125, 0.06, 0.03, 0.015, and 0 (negative control) mg/L, and positive controls (malachite green at 0.125 and 0.06 mg/L), respectively, and then maintained at 23 ± 0.3 °C for 16 h. After 22 h exposure, theronts in each well were counted as described above.

To monitor pathological changes in tomonts after exposure to cynatratoside-C, approximately 50 nonencysted tomonts with 200 μL of dechlorinated freshwater were placed in one well of a 24-well plate, and 200 μL of cynatratoside-C solution at 16 mg/L was added into the well to make a final concentration of 8 mg/L. Fifty nonencysted tomonts with 200 μL of water were put into another well and incubated for 18 h. Next, 200 μL of cynatratoside-C solution was added to the well to make a 0.25 mg/L final concentration. The treated nonencysted and encysted tomonts were observed and photographed under a Nikon ECLIPSE Ti−S inverted microscope at 10×, 20×, and 40× magnification, respectively.

Treatment of Ichthyophthiriasis with Cynatratoside-C. One hundred and twenty grass carp naturally infected with *I. multifiliis* (382 ± 35 trophonts on body surface per fish) were transferred to 12 20-L tanks with 10-L static dechlorinated water at 23 ± 0.3 °C, and randomly divided into four treatments: 0 (control), 0.5, 1, and 2 mg/L cynatratoside-C in triplicate (10 fish/tank). During the trial, water was aerated with air stones, and fish were fed every day. The dead fish were removed twice per day, and mortality was recorded daily. At 48 h post cynatratoside-C treatment, all test fish were moved from each tank, and numbers of trophont on the whole body surface were counted after the fish was anesthetized with 150 mg/L MS-222. Infection intensity was determined and expressed as total numbers of trophont on the fish body surface per infected fish.

Statistical Analysis. All experimental data were expressed as the mean ± SD (standard deviation). Statistical analysis was performed with Student-Newman-Keul's test using a statistical analysis system software package (SPSS 16.0). A probit procedure was used to determine median effective concentration (EC_{50}) with 95% confidence intervals (CI). *p*-values < 0.05 were considered of significant difference.

RESULTS

Isolation and Identification of the Anti-*I. multifiliis* Compound. The anti-*I. multifiliis* effects of different fractions are listed in Table 1. The active component (70 mg), a white amorphous powder, was isolated from fraction B2-3. The compound had a molecular weight of 778, which is consistent with a molecular formula of $C_{41}H_{62}O_{14}$. In the ^{13}C NMR and DEPT spectra, 41 carbons were displayed, including 10 methylene carbons and 5 quaternary carbons. After comparison

of its spectral data with the literature,[22] the compound was identified as cynatratoside-C (glaucogenin C 3-*O*-*α*-D-oleandropyranosyl-(1 → 4)-*β*-D-digitoxopyranosyl-(1 → 4)-*α*-D-oleandropyranoside) (Figure 2).

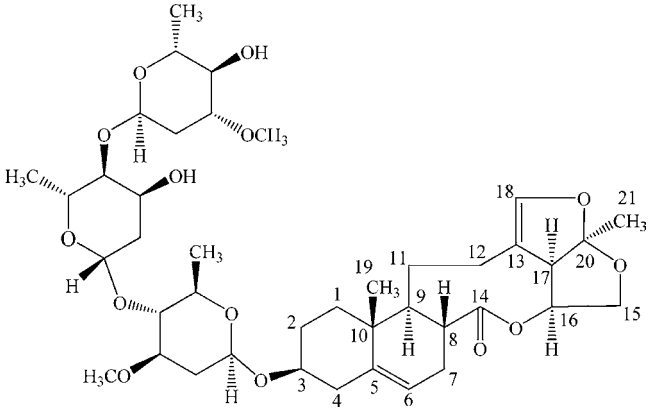

Figure 2. Chemical structure of cynatratoside-C.

In Vitro Bioactivity of Cynatratoside-C on *I. multifiliis* Tomonts. Nonencysted tomonts showed a clear dose−response to cynatratoside-C (Table 2). Mean death duration for killing all nonencysted tomonts ranged from 14.7 min at concentration of 32 mg/L to 270.0 min at concentration of 0.25 mg/L. The mortality of nonencysted tomonts ranged from 63.2% at concentration of 0.125 mg/L to 0% at concentration of 0.015 mg/L or lower (negative control) 5-h post exposure to cynatratoside-C. The 5-h EC_{50} of cynatratoside-C to nonencysted tomonts was 0.083 mg/L with a 95% confidence interval 0.014−0.365. Moreover, the number of theronts released from encysted tomonts sharply decreased from 223 in the negative control to 0 at a concentration of 0.125 mg/L 22 h post exposures. Even though 0.125 mg/L cynatratoside-C killed 63.2% nonencysted tomont 5-h post treatment, the survival nonencysted tomonts did not produce infective theronts. In positive control, malachite green at a concentration of 0.125 mg/L killed all nonencysted tomonts within 89 min and inhabited releasing infective theronts from all encysted tomonts.

Pathological changes of nonencysted tomonts are shown in Figure 3. After exposure to cynatratoside-C at 8 mg/L for 23 min, nonencysted tomonts changed their shape, formed transparent bubbles on plasma membrane, and cytoplasm spilled out from the tomonts (Figure 3b−d). Reproduction of encysted tomonts was significantly ($p < 0.05$) reduced after exposure to cynatratoside-C at concentration of 0.03 mg/L or higher as compared to that in negative control after 16 h treatment (Table 3). When encysted tomonts after incubation for 18 h were treated with 0.25 mg/L cynatratoside-C for about 60 min, the tomites (immature theronts) were released from

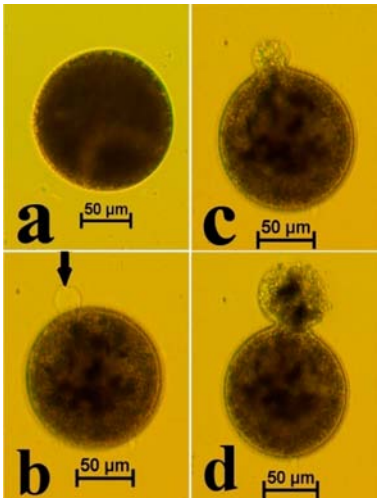

Figure 3. Morphology of nonencysted tomonts. Nonencysted tomont untreated with cynatratoside-C (a). The nonencysted tomont exposed to 8 mg/L cynatratoside-C for 23 min, showing a transparent bubble (black arrow) on plasma membrane (b). Cytoplasm spilled out of the nonencysted tomont from the bubble (c,d).

[a]Nonencysted tomonts were allowed to attach for 6 h, expose to cynatratoside-C for 16 h, and theronts were counted in every well. Values are expressed as mean ± SD of three replicated wells. Values with different letters in the same column are significant differences ($p < 0.05$). [b]Positive control.

the cyst and subsequently died (Figure 4a–d). The same phenomenon was also observed at concentrations of 0.06 and 0.125 mg/L after 22 h exposure.

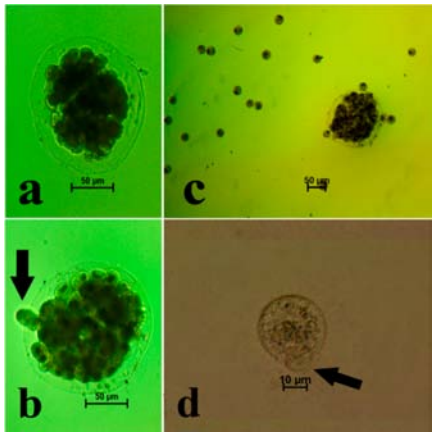

Figure 4. Morphology of encysted tomonts. A normal encysted tomont (a). Encysted tomont exposed to 0.25 mg/L cynatratoside-C for 60 min, showing the first tomite (black arrow) released from the cyst (b). More tomites were released from an encysted tomont (c). Subsequently, a tomite was dead and its cytoplasm (black arrow) was spilled out (d).

Treatment of Ichthyophthiriasis with Cynatratoside-C. Cynatratoside-C at concentration of 2 mg/L completely eliminated all trophonts and cured the infected grass carp within 48 h (100% survival) (Table 4). The infective intensity of grass carp treated with 1 mg/L cynatratoside-C was 184 trophonts/fish, significantly ($p < 0.05$) lower than that of the fish treated with 0.5 mg/L (406 trophonts/fish) and 0 mg/L (357 trophonts/fish).

Table 4. Treatment of Grass Carp Infected by *I. multifiliis* with Cynatratoside-C for 48 h[a]

DISCUSSION

Medical plants have provided an abundant source of natural products of new parasiticides to control *I. multifiliis*.[8,11,12] Since the crude extracts of *Allium sativum*,[23] *Mucuna pruriens*, and *Carica papaya*[7] were reported to be used to treat *I. multifiliis*, more studies have been conducted to discover new compounds from medical plants.[8−12,24] *C. atratum*, a perennial herb native to East Asia, showed significant parasiticidal effect to *I. multifiliis* in this study. An ethanol extract of *C. atratum* was partitioned with petroleum ether, ethyl acetate, butanol, and water. A bioassay-guided fractionation, a proven method for the discovery of active principles from natural products,[25−27] was used to isolate an anti-*I. multifiliis* compound from *C. atratum*. Finally, the anti-*I. multifiliis* compound was identified as cynatratoside-C by NMR, ESI−MS, and HR-ESI−MS. This is the first report on parasiticidal property of cynatratoside-C. Cynatratoside-C, one of the C-21 steroidal glycosides in *C. atratum*, has a 13,14:14,15-diseco-pregnane-type skeleton. Even though other structurally related analogues, such as cynatratoside-A, cynatratoside-B, cynatratoside-D, and cynatratoside-E, have the same skeleton of 13,14:14,15-diseco-pregnane-type,[22] only cynatratoside-C was isolated by bioassay-guided fractionation. This fact suggested that cynatratoside-C was the main ingredient and the principal compound in *C. atratum* responsible for killing *I. multifiliis*.

Glycosylation plays a key role in the activity of some natural compounds.[28,29] For example, rebeccamycin's inhibition of the topoisomerase I activity by the rebeccamycin analogues is more active than that of the corresponding aglycones lacking the sugar moiety.[28] Compound properties are affected if the glycosyl is changed.[30,31] For example, if the antitumor compound (25S)-ruscogenin 1-*O*-[*O*-*β*-D-glucopyranosyl-(1 → 3)-*O*-*α*-L-rhamnopyranosyl-(1 → 2)-*β*-D-glucopyranoside] from *Brodiaea californica* has a D-xylose added at the C-3 position of its inner glucose, the antitumor activity is significantly reduced.[30] Hence, we expect that the type of carbohydrate chain at C-3 position in the 13,14:14,15-diseco-pregnane-type skeleton of cynatratoside-C will influence the anti-*I. multifiliis* effect.

Once a tomont of *I. multifiliis* settles on a suitable substrate, it reproduces hundreds to thousands of infective theronts.[2,32] Once theronts penetrate into fish skin and gills, the control of the parasite becomes difficult.[33] Therefore, killing the parasite at the reproductive stage is an important way to prevent releasing of infective theronts and protect fish from infection.[12] On the basis of this consideration, trials were conducted to evaluate the parasiticidal effects of cynatratoside-C on nonencysted and encysted tomonts. The results indicated that cynatratoside-C at 0.125 mg/L markedly reduced nonencysted tomonts survival and at 0.06 mg/L completely inhibited encysted tomonts reproduction. Malachite green was used as a positive control, but its concentration of 0.06 mg/L could not completely stop theronts released from the encysted tomonts; the mean number of theronts released from each live tomont was 17. This suggested that cynatratoside-C was more toxic to encysted tomonts than malachite green. Previous studies demonstrated that pentagalloylglucose from *Galla chinensis* at a concentration of 40 mg/L was effective against nonencysted

dx.doi.org/10.1021/jf5018675 | J. Agric. Food Chem. 2014, 62, 7183−7189

tomonts,[12] and chelerythrine and chloroxylonine from *Toddalia asiatica* could be 100% effective against nonencysted tomonts at concentrations of 1.2 and 3.5 mg/L, respectively.[34] As for other chemicals used to treat parasites, potassium ferrate(VI) at a concentration of 19.2 mg/L demonstrated 100% mortality on both nonencysted and encysted tomonts,[35] and a mixture of hydrogen peroxide, peracetic, acetic, and peroctanoic acid at a concentration of 8 mg/L eliminates tomonts.[36] Thus, cynatratoside-C appears to be more effective against *I. multifiliis* than the reported parasiticides.

Published reports demonstrated that nonencysted tomonts were more sensitive to drugs than encysted tomonts, because an encysted tomont secreted a thick cyst wall that prevents drugs from permeating into encysted tomont.[10,35] The methanol extract from *Psoralea corylifolia* at a concentration of 5.00 mg/L kills 100% nonencysted tomonts, but killed only 88.89% encysted tomonts at the same concentration.[10] The acetone extract from *Morus alba* root bark at a dose of 25 and 50 mg/L causes 100% mortality of nonencysted tomonts and encysted tomonts, respectively.[11] However, the encysted tomonts were more susceptible to cynatratoside-C than nonencysted tomonts in this study. The reason for this phenomenon is unclear and needs further study.

The trophonts are more difficult to be killed than the parasite at the free-living stage,[12] because the trophonts are covered by a layer of host epidermis and a thick layer of mucus protects them from drugs in water.[32] In this study, cynatratoside-C at 2 mg/L completely kills all trophonts and cures the infected grass carp within 48 h. The infective intensity of grass carp exposed to 1 mg/L cynatratoside-C was significantly lower than those at 0.5 and 0 mg/L. Other studies on parasiticides, nitazoxanide at 1.5, 2, or 3 mg/L, showed reduction of approximately 98% in the number of trophonts on infected silver catfish (*Rhamdia quelen*) at 96 h exposure.[37] Bronopol utilized once a day for 27 days at concentrations of 2 and 5 mg/L significantly reduced the number of trophonts on juvenile rainbow trout (*Oncorhynchus mykiss*) by 90−98%.[38] The plant-active drugs dihydrosanguinarine and dihydrochelerythrine from *Macleaya microcarpa* were effective against *I. multifiliis* in barbel chub (*Squaliobarbus curriculus*) with median effective concentration (EC_{50}) values of 5.18 and 9.43 mg/L, respectively.[15] Pentagalloylglucose at 20 mg/L was effective for treating *I. multifiliis* infected catfish.[12] These data indicate that concentrations of the therapeutic agents against trophonts are much higher than that of cynatratoside-C. Therefore, cynatratoside-C could be a promising alternative parasiticide against *I. multifiliis*.

Pathological changes occurred after exposure to cynatratoside-C and the plasma membrane of nonencysted tomont was destroyed. This phenomenon was similar to the membrane of nonencysted tomont damaged by pentagalloylglucose.[12] When an encysted tomont was treated with cynatratoside-C, the tomont released abnormal tomites from the cyst. These abnormal tomites were immature theronts, could not infect fish, and finally died. Therefore, we postulate that cyantratoside-C permeates into an encysted tomont across the cyst wall and triggers pathological changes of tomites. Even though the exact mechanism of cynatratoside-C for killing nonencysted tomonts is unknown, it manifests itself microscopically through loss of membrane integrity.

In conclusion, cynatratoside-C isolated from *C. atratum* showed anti-*I. multifiliis* effects in vitro and in vivo. The compound at a very low concentration significantly decreased the survival of nonencysted tomonts and reproduction of encysted tomonts. In addition, the compound can cure the ichthyophthiriasis under laboratory conditions. Therefore, cynatratoside-C is a potential alternative parasiticide to control *I. multifiliis*, and deserves further studies to elucidate the anti-*I. multifiliis* mechanism and evaluate its effectiveness under fish farming conditions.

Table 1. Overview of the Composition and Structural Characteristics of the AXOS Used in This Article[a]

	HBFA-AXOS	HFFA-AXOS	MBFA-AXOS	MFFA-AXOS	LFFA-AXOS
AXOS content (% dm)	73 (±5)	73 (±1)	73 (±1)	74 (±3)	73 (±1)
free ara content (% dm)	<0.1	0.7 (±0.1)	0.1 (±0.1)	0.2 (±0.1)	0.2 (±0.1)
free xyl content (% dm)	<0.1	<0.1	0.7 (±0.1)	0.8 (±0.1)	1.2 (±0.1)
avDPxyl[b]	6.6 (±0.6)	6.6 (±0.1)	3.9 (±0.2)	3.9 (±0.2)	3.8 (±0.1)
avDAS[c]	0.38 (±0.05)	0.39 (±0.01)	0.22 (±0.01)	0.22 (±0.02)	0.19 (±0.01)
oligomeric glucose content (% dm)	12 (±2)	12 (±1)	12 (±1)	13 (±1)	13 (±1)
free FA content (% dm)	0.07 (±0.01)	6.00 (±0.21)	0.01 (±0.01)	1.44 (±0.02)	0.01 (±0.01)
bound FA content (% dm)	7.17 (±0.11)	1.10 (±0.29)	1.67 (±0.06)	0.21 (±0.09)	0.08 (±0.01)
total FA content (% dm)	7.24 (±0.11)	7.11 (±0.12)	1.68 (±0.06)	1.64 (±0.09)	0.09 (±0.01)

[a]Data are expressed as means and standard deviations of triplicate measurements. [b]avDPxyl, average degree of polymerization of the xylan backbone. [c]avDAS, average degree of arabinose substitution.

properties was investigated. Dough properties were studied using the Kieffer dough extensibility rig, and protein extractability was examined for the AXOS enriched breads. Dough pH evolution and the impact of additions on yeast during dough fermentation were studied as well. Furthermore, FA and AXOS recovery from bread and the Trolox Equivalent Antioxidant Capacity (TEAC) values for bread were determined.

MATERIALS AND METHODS

Materials. Commercial wheat flours TB9 (13.9% protein, 0.57% ash, 14.2% moisture content) and Julius (10.3% protein, 0.46% ash, 13.4% moisture content) were provided by Dossche Mills (Deinze, Belgium). All experiments were done using TB9 flour, unless mentioned otherwise. AXOS starting material (MBFA-AXOS) was produced by enzymatic treatment of wheat bran using the procedure described by Swennen et al.[2] with adaptations and obtained from Fugeia (Leuven, Belgium). Other AXOS samples were prepared and characterized as described in Snelders et al.[5] The composition of these samples is presented in Table 1. Throughout the remainder of this Article, AXOS samples are given a code based on their feruloylation. The code consists of "XYFA-AXOS" in which X stands for H, M, or L, indicating that the AXOS sample contained a high, medium, or low level of FA, respectively. The letter B or F at the Y position indicates that most FA was present in a bound or free form, respectively. HBFA-AXOS and HFFA-AXOS had similar carbohydrate structures and high FA level, but differed in the form in which FA was present (bound or free). Also, MBFA-AXOS, MFFA-AXOS, and LFFA-AXOS had similar carbohydrate structures, but specifically differed in the level and/or form in which FA was present. SDS and dithiothreitol were bought from Acros Organics (Geel, Belgium). All other solvents, chemicals, and reagents were of at least analytical grade and purchased from Sigma-Aldrich (Bornem, Belgium).

Methods. *Bread Making.* Bread was made according to a straight-dough method for 10 g of flour.[29] Wheat flour (10.0 g, 14.0% moisture), 0.53 g of compressed commercial yeast (AB Mauri, Merelbeke, Belgium), 0.60 g of sucrose, 0.15 g of NaCl, and 5.60 mL of water were mixed for 240 s in a 10 g pin mixer (National Manufacturing, Lincoln, NE) at 25 °C. Dough was transferred to a fermentation cabinet (National Manufacturing) and fermented for 90 min (30 °C, 90% relative humidity). Doughs were intermediately punched at 52, 77, and 90 min, using a dough sheeter (National Manufacturing). Following the third punch, doughs were molded and proofed (36 min at 30 °C, 90% relative humidity) before baking at 232 °C for 13 min in a rotary oven (Model Hearth, National Manufacturing). Immediately after baking, bread weight and height were measured. Bread volume was analyzed by use of a volumeter based on glass beads displacement.[30] Samples were frozen, freeze-dried, and ground with a laboratory mill (model A10, IKA-Werke GmbH and Co. KG, Staufen, Germany) for further analysis.

To study the effect of the AXOS addition on dough and bread properties, AXOS were added dissolved in the water for bread making. MBFA-AXOS and HBFA-AXOS were added to the bread recipe in different concentrations (1.0−8.0% and 0.25−2.00% AXOS (dm) on flour (dm) basis, respectively), based on their FA content, which corresponded to approximately 200−1800 ppm FA on flour (dm) basis. As the FA content of HBFA-AXOS was not exactly 4 times the FA content of MBFA-AXOS, indicated FA levels (in ppm) are an approximation of the FA levels over the entire range of AXOS additions. Breads were made in triplicate, and control breads were made as described above, without adding AXOS.

Analysis of Dough Extensibility. The Kieffer dough and gluten extensibility rig (Stable Micro Systems Ltd., Surrey, UK) was used for uniaxial dough extensibility measurements as described by Dunnewind et al.[31] Three separate dough samples were prepared by mixing flour (10.0 g, 14.0% moisture) with water (5.6 mL) for 240 s using the above-mentioned pin mixer. Each dough sample was punched, compressed between paraffin oil-coated Teflon plate molds, and rested for 30 min at 30 °C and 90% humidity. As the bottom Teflon plate had grooves, seven to eight dough strands were formed from one dough. For the actual measurement, these strands were clamped at both ends between two plates. The dough strand was pulled upward from the middle until breakage using the Kieffer rig dough extensibility fixture at 3.3 mm/s, attached to an Instron 3342 Single Column Testing System (Instron, Norwood, MA) with a 50 N load cell. From the load−displacement curve, dough extensibility (maximum extension until first point of breakage, mm), resistance to extension (maximum load until breakage, N), and total work needed for breakage (area under curve, mJ) were derived.

When AXOS were added, they were added solubilized in water, similar to described for bread making. Free FA was dissolved in ethanol, and 0.1 mL of this solution was added to flour, together with 5.6 mL of water. HBFA-AXOS and HFFA-AXOS were added in different concentrations ranging from 0.5% to 2.0% AXOS (dm) on flour (dm) basis, and MBFA-AXOS, MFFA-AXOS, and LFFA-AXOS in different concentrations ranging from 1.0% to 8.0% AXOS (dm) on flour (dm) basis, which in each case corresponds to approximately 200−1800 ppm FA on flour (dm) basis. Control samples without added AXOS or FA in the water or ethanol, respectively, were prepared in the same manner. Dough samples were prepared in triplicate, and for each dough, the averages of the above-mentioned rheological properties from 7 to 8 strands were determined.

Doughs with Julius flour were prepared by mixing flour (10.0 g, 14.0% moisture) with water (6.0 mL) for 165 s. Dough extensibility analyses were as described above. MBFA-AXOS was added directly, dissolved in water, and free FA was added in 0.1 mL of ethanol. In a separate experiment, MBFA-AXOS were added in different concentrations [0.0−8.0% AXOS (dm) on flour (dm) basis] together with different levels of free FA (0−1800 ppm FA) to achieve a constant total addition of 1800 ppm FA with varying concentrations of AXOS.

Analysis of Dough Protein Content Extractability and Extract Composition. Protein contents of dough samples, prepared as described above, rested for 30 min, freeze-dried, and ground, were determined by the Dumas method, an adaptation of the AOAC[32] to an automated protein analysis system (EAS Vario Max N/CN, Elt, Gouda, The Netherlands).

Ground freeze-dried dough samples were extracted with a 0.05 M sodium phosphate buffer (pH 6.8) containing 2.0% SDS (1.0 mg dough proteins/mL extraction buffer), centrifuged (10 min, 10 000*g*), and filtered (0.45 μm). Dough protein extractions were also performed under reducing conditions with the above-described buffer containing 1.0% (w/v) dithiothreitol and 2.0 M urea under nitrogen atmosphere to determine total extractability.

Size-exclusion high-performance liquid chromatography (SE-HPLC) on dough extracts was conducted using a LC-2010 system (Shimadzu, Kyoto, Japan) with automatic injection as described by Lagrain et al.[33] To this end, supernatants (60 μL) were loaded on a BioSep SECS4000 column (Phenomenex, Torrance, CA) and eluted with acetonitrile/water (50/50 v/v) containing 0.05% (v/v) TFA. The flow rate was 1.0 mL/min at a column temperature of 30 °C, and eluted proteins were detected at 214 nm. The elution profiles of nonreduced samples were divided into four fractions. First, the elution profile was separated using the lowest extinction value between the two major peaks as the cutoff point.[33] Peak 4 represents lower molecular weight proteins corresponding to SDS-extractable monomeric gluten proteins (mainly gliadins). The other major peak was subdivided into three other peaks based on reoccurring kinks in the profile. Resulting peaks most likely contain SDS-extractable high molecular weight polymeric gluten proteins (peak 1), low molecular weight polymeric gluten proteins (peak 2), and oligomeric gluten proteins (peak 3). SDS-extractability of proteins in the four distinct peaks of a sample in the absence of reducing conditions was expressed as the area under curve relative to the total area under curve of the SDS-extraction profile of the control sample under reducing conditions (100%).

Analysis of Carbon Dioxide Production by Yeast. The Risograph (National Manufacturing) was used to measure carbon dioxide production during 90 min in fermenting dough. Doughs were prepared as described above, with or without AXOS (added in the water phase) or FA (added in an additional 0.1 mL of ethanol).

Determination of pH of AXOS Solutions and Dough. The pH of AXOS solutions used was measured using HI 9126 pH probe (Hanna Instruments, Temse, Belgium). The pH of doughs prepared with and without yeast was measured before and after fermentation and after resting, respectively, by placing the above-mentioned pH probe directly in the dough.

Determination of WE-AX Content. WE-AX content of ground freeze-dried bread samples was determined to calculate the recovery of AXOS added to the bread recipe after baking. Extraction and quantification was done essentially as described by Loosveld et al.[34] Aqueous extracts of ground freeze-dried bread samples (2.00 g) were obtained by suspending them in water (1:10 w/v), shaking (30 min, room temperature), and centrifugation (3000*g*, 15 min, 7 °C). Monosaccharide composition was determined by gas chromatography after hydrolysis (60 min, 2.0 M TFA, 110 °C), reduction with $NaBH_4$, and acetylation of alditols. WE-AX content of one bread was determined in duplicate.

Determination of the FA and 4-Vinylguaiacol Content. Total FA and 4-vinylguaiacol (4-VG) content were analyzed after alkaline hydrolysis as described by Antoine et al.[35] with some modifications. Flour or bread sample (±100 mg) was suspended in 2.0 M sodium hydroxide (4.0 mL) and saponified under slow stirring for 2 h at 35 °C under nitrogen atmosphere and protected from light. Samples were acidified to pH 2.0 with 4.0 M hydrogen chloride, followed by addition of caffeic acid as internal standard. Phenolic acids were extracted twice with diethyl ether (2.0 mL). Ether was evaporated under a nitrogen flow, and phenolic acids were dissolved in methanol and filtered (0.45 μm). Monomeric FA and 4-VG were separated on a Luna Phenyl-Hexyl column (250 mm × 4.6 mm i.d., 5 μm particle size, plus 3 mm × 4.6 mm i.d. guard column; Phenomenex) in a LC-20AT modular high-performance liquid chromatography system (Shimadzu). After injection of 20 μL of sample, a ternary gradient system of 1 mM aqueous TFA (eluent A), acetonitrile/1 mM aqueous TFA [90/10 (v/v)] (eluent B) and methanol/1 mM aqueous TFA [90/10 (v/v)] (eluent C) at 45 °C was used according to Dobberstein and Bunzel[36] with some modifications (Table 2). UV-detection (Shimadzu, UV-10A detector) was carried out at 280 nm. The elution profile was also checked for additional peaks, possibly occurring due to the presence of di-FA in the tested sample.[36]

Table 2. Linear Elution Gradient for the Separation of FA and 4-Vinylguaiacol by Use of Reversed Phase HPLC on a Luna Phenyl-Hexyl Column[a]

time (min)	eluent A (%)	eluent B (%)	eluent C (%)
0.0	87	13	0
10.0	87	13	0
20.0	77	20	3
25.0	70	25	5
40.0	25	50	25
45.0	87	13	0
55.0	87	13	0

[a]Eluent A: 1.0 mM aqueous trifluoroacetic acid. Eluent B: acetonitrile/1.0 mM aqueous trifluoroacetic acid (90/10 v/v). Eluent C: methanol/1.0 mM aqueous trifluoroacetic acid (90/10 v/v).

Determination of Amino Acid Composition. The amino acid composition of flour and ground freeze-dried bread samples was determined after acid hydrolysis as described by Rombouts et al.[37] Samples (10.0 mg dm protein) were hydrolyzed by heating at 110 °C for 24 h in 1.0 mL of 6.0 M hydrogen chloride containing 1.5 mM norleucine (as internal standard) and 0.1% phenol, after the samples were flushed with nitrogen. Bread samples were brought under nitrogen atmosphere prior to hydrolysis by flushing the headspace during 10 s with nitrogen gas to prevent amino acid oxidation. After hydrolysis, samples were subsequently evaporated (110 °C, 180 min), resuspended in 5 mL of water, and diluted 40-fold. For determination of cysteine/cystine levels, cysteine/cystine residues were first converted to cysteic acids as described by Moore[38] with some modifications. Performic acid solution was prepared by mixing 30% hydrogen peroxide and 88% formic acid in a 1/9 volume ratio. This mixture was kept at room temperature for 60 min before cooling on ice (0 °C). Performic acid solution (4.0 mL) was added to flour or ground freeze-dried bread (10.0 mg dm protein), and the mixture was vortexed until the sample was completely dissolved. The reaction mixture was kept on ice for 16 h before reducing the excess of performic acid by adding 0.6 mL of hydrogen bromide (48%). After 5 min, the remaining bromine and formic acid were evaporated (60 °C, 1 mbar, 120 min) using a rotational vacuum concentrator (Q-Lab, Vilvoorde, Belgium).

Samples were filtered (0.22 μm) before separation on a Dionex BioLC system (Sunnyvale, CA) as described by Rombouts et al.[37] The system was equipped with a GS50 gradient pump with online degasser, an AS50 autosampler with a thermal compartment, and an ED50 electrochemical detector containing both a gold working electrode and a pH reference electrode. Separation of 25 μL samples was performed at 30 °C with an AminoPac PA10 guard (Dionex Benelux, 50 × 2 mm) and an analytical (Dionex Benelux, 250 × 2 mm) column at a flow rate of 0.25 mL/min. Chromeleon Version 6.70 software (Dionex Benelux) was used for chromatographic system control, data acquisition, and data analysis. Gradient conditions and pulsed amperometric detection waveform were described in Rombouts et al.[37]

Determination of the Antioxidant Capacity. Determination of the antioxidant capacity of bread samples was based on their ability to scavenge 2,2′-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt (ABTS) radicals. Prior to analysis, ABTS radicals were generated in McIlvaine buffer (pH 6.5, prepared by mixing appropriate amounts of 0.10 M citric acid and 0.20 M disodium phosphate) as described in Snelders et al.[5] The antioxidant reaction was started by adding 6.0 mL of radical solution to 5.0 mg of freeze-dried bread sample in a centrifuge test tube, as described by Serpen et al.[39] with some modifications. The tubes were vortexed (10 s) and shaken (20 min) to facilitate reaction between the solid particles and the ABTS radicals. When the shaking stopped, the solid particles spontaneously precipitated, and absorbance measurements at 734 nm

(Ultrospec III UV/vis spectrophotometer, GE Healthcare, Piscataway, NJ) were performed exactly 30 min after addition of the radical solution. ABTS radical solution was used as blank. A calibration curve was made between 0.5 and 25.0 μM Trolox (final concentration in cuvette). Therefore, Trolox was dissolved in ethanol and diluted in a range of concentrations. Antioxidant capacity measurements were performed by adding 5.9 mL of radical solution to 0.1 mL of Trolox solution. For the control of the calibration curve, 5.9 mL of radical solution was added to 0.1 mL of ethanol, while the control for the bread samples existed as 6.0 mL of radical solution. Analysis was done in duplicate for all produced breads and flour.

Statistics. Statistical analysis of the results was performed using SAS software 9.2 (SAS Institute, Inc., Cary, NC). Two-way analysis of variation (ANOVA) was performed to compare analysis results. A Tukey multiple comparison procedure was used with a 5% family significance level.

RESULTS AND DISCUSSION

The impact of addition of AXOS and associated FA to the bread recipe on dough and bread properties was investigated. To this end, on the one hand, feruloylated AXOS were produced and added to dough. On the other hand, free FA was added to dough in levels similar to FA levels present in AXOS fortified doughs. The impact of these additions on rheological dough properties, dough pH, gluten network formation, and yeast fermentation was studied. Impact of AXOS addition on (specific) volume of breads was determined. Conversely, the impact of bread making on the antioxidant capacity and extractability of AXOS and associated FA was assessed as well.

Impact of Addition of AXOS and FA on Dough Rheological Properties. Rheological properties of doughs were determined with the Kieffer dough and gluten extensibility rig. Both the level of the added AXOS as well as their FA content influenced the rheological properties of the resulting doughs. In Table 3, rheological properties of doughs with added AXOS with a high FA content (HBFA-AXOS), AXOS with a medium FA content (MBFA-AXOS), and free FA are summarized.

Addition of HBFA-AXOS to dough resulted in an increased dough extensibility and a decreased resistance to extension, already at a low dosage of 0.5%. At higher dosages, when up to 2% of these AXOS samples were added to dough, the extensibility almost doubled, while the resistance to extension was more than halved as compared to the control. The work needed for breakage of the dough was not influenced as the impact on dough extensibility and impact on dough resistance to extension counteracted each other. Only at the highest level of addition (2% in case of HBFA-AXOS), a significant but small decrease in total work needed for breakage was observed. The impact of free FA on dough properties was similar to that of HBFA-AXOS, suggesting that the effect of FA was predominant upon addition of AXOS. The results concerning the impact of free FA on rheological dough properties are in agreement with previous studies.[26−28] Previous research also showed that FA needs to be present in the soluble fraction of the dough to be reactive,[22−24] as is most probably the case for FA esterified to AXOS. HFFA-AXOS, which only differs from HBFA-AXOS in the appearance of FA (free vs bound), had the same effect on dough rheological properties as HBFA-AXOS (Table 4), indicating that the appearance of FA did not matter.

However, the FA-mediated impact on dough rheology as described above was not seen when AXOS with a low to medium FA content were added (MBFA-AXOS, MFFA-AXOS, and LFFA-AXOS) to dough (Table 3 and Table 5). Upon

[a]In each row, characteristics of doughs with approximately the same amount of added AXOS and FA, originating from different AXOS samples, are compared. Data are expressed as means and standard deviations. Values from the same sample at different doses differ significantly ($p < 0.05$) when not sharing the same uppercase letter. Values from different samples at the same dose did not differ significantly ($p > 0.05$). [b]Approximate levels of added FA due to addition of AXOS or free FA (FA/dm flour expressed in ppm). [c]Values obtained from Table 3.

addition of higher concentrations of these AXOS samples, the maximum extensibility of dough remained more or less constant, while the resistance to extension increased. As a consequence, total work needed for breakage increased as well when 8% of these AXOS was added. Although FA was present in the same levels as tested for free FA or FA-enriched AXOS when MBFA-AXOS or MFFA-AXOS were added, similar effects were hence not observed when also relatively high levels of carbohydrates in the form of AXOS were present. Therefore, addition of MBFA-AXOS, MFFA-AXOS, and LFFA-AXOS, with the latter having a lower FA content, had a similar impact on dough rheology. These observations were confirmed by comparing rheological properties of doughs with different levels of AXOS addition, combined with free FA addition, to obtain a constant combined high level of total FA (1800 ppm FA) (Table 6). Maximum extensibility upon addition of 1800 ppm FA only differed from the control when AXOS were added in concentrations lower than 2% (resulting in higher extensibility) or when 8% (resulting in lower extensibility) was added. Addition of 1800 ppm free FA also led to a reduced resistance to extension as compared to the control dough. However, upon addition of increasing levels of MBFA-AXOS, while keeping a constant total level of 1800 ppm FA addition, dough resistance to extension increased and was significantly higher than that of the control dough when 5% or more MBFA-AXOS were added. There was a trend of increased total work needed for breakage upon increasing levels of AXOS addition, which became significant at 6% and more addition. High levels of AXOS might compete for water or increase dough liquor viscosity. Indeed, maximum resistance to dough extension increases when less water is available for the gluten network[40] and/or when dough viscosity is increased.[41] This dough dehydration or stiffening effect was more dominant than the FA-mediated effect of feruloylated AXOS or free FA when the FA levels of the AXOS were not high.

Impact of Addition of AXOS and FA on Dough pH. As FA, and possibly also AXOS, have a weak acidic nature, they could affect dough pH. Dough pH can influence sulfhydryl−disulfide protein interchange reactions[40] and formation of other covalent bonds between gluten proteins.[42] In addition, charge repulsion of gluten strands and water binding, which influences dough stickiness, depends on dough pH.[40] Solutions with MBFA-AXOS and HBFA-AXOS used in dough and bread making had varying pH values (5.1−6.0), which were lower for the FA-enriched AXOS sample (HBFA-AXOS) and decreased when higher levels of AXOS were dissolved. Despite this, pH values of the obtained doughs were at every stage (before and after fermentation) not significantly different for the control doughs and doughs with added free FA, HBFA-AXOS, or MBFA-AXOS. Before fermentation, dough pH ranged from 5.2 to 5.3 for the different samples, and decreased to about 5.0 after dough fermentation (results not shown). As no significant differences in pH between doughs with different levels of AXOS or free FA were found, the observed differences in dough properties upon addition of AXOS or free FA cannot be explained by acidification.

Impact of Addition of AXOS and FA on Gluten Network Formation. SDS-extractability of dough proteins in the absence of reducing conditions was used to assess the impact of AXOS and FA on gluten network formation, as the extent of reducible disulfide bonds might be affected. The observed increase in SDS-extractability upon addition of higher levels of AXOS or free FA as compared to the SDS-extractability of the control (from approximately 61% to 66%, respectively) was not significant (results not shown). However, the level of SDS-extractable high molecular weight polymeric gluten proteins, as demonstrated by the area under the curve of the first peak, did increase upon increasing AXOS or free FA levels (Figure 1 and Table 7). When MBFA-AXOS, HBFA-AXOS, or free FA were added to the same level of FA, they had a similar effect on SDS-extractability. An increase in SDS-extractable high molecular weight polymeric gluten proteins upon addition of free FA was also observed in previous studies.[26,27]

Limited dough breakdown might be provoked due to reaction of FA (free or bound to AXOS) with thiyl radicals, formed upon disulfide bond breakage during mixing.[43] As a result, reinforcement of the gluten network through reformation of disulfide bonds is hindered.[22] However, the fate of the formed (AXOS esterified) FA radicals is less clear. Jackson and Hoseney[23] proposed the formation of an cysteine-FA adduct. This would explain the reducing effect of the addition of FA, which might act as a sulfhydryl blocking agent, and result in an increased SDS-extractability and formation of a more sticky dough.[44] Another possible fate of FA is the formation of di-FA resulting from FA radicals formed after reaction with thiyl radicals. However, a decrease in monomeric FA and formation of di-FA was not always observed, unless oxidizing conditions were present.[19,20]

The small increase in SDS-extractability of dough proteins might not be the only impact of AXOS or FA on gluten.

[a]Data are expressed as means and standard deviations. Values from the same sample at different doses differ significantly ($p < 0.05$) when not sharing the same uppercase letter. Values from different samples at the same AXOS dose differ significantly ($p < 0.05$) when not sharing the same lowercase letter. [b]Values obtained from Table 3.

The observed changes in rheological properties of doughs might be caused by changes in noncovalent interactions, such as hydrogen bonds or hydrophobic interactions, as well. The hydroxyl group of FA might interact with a carbonyl group of proteins.[45] FA and protein interactions can be further stabilized by hydrophobic interactions between the aromatic ring of FA and certain hydrophobic/aromatic amino acids.[45] Interactions between polyphenols and proline residues of proteins are well established.[46] In this way, AXOS and FA might disturb hydrophobic gluten interactions.

Impact of Addition of AXOS and FA on Yeast Fermentation. As yeast fermentation is a major factor determining bread volume, possible inhibition of yeast in dough by added AXOS and FA was determined using the Risograph. Although it is known that FA might inhibit yeast fermentation,[28,47] similar CO_2 production rates in the control doughs and doughs with AXOS or free FA up to FA levels of about 1800 ppm (corresponding to the addition of 8% MBFA-AXOS or 2% HBFA-AXOS) were observed (results not shown). Yeast inhibition might only occur in the presence of higher levels of FA, or when FA is not esterified.[28]

Impact of Addition of AXOS and FA on Bread Volume and Specific Volume. Because of the different impact of MBFA-AXOS and HBFA-AXOS on dough rheology, breads with different doses of these AXOS [up to 8% and 2% AXOS (dm)/flour (dm), respectively, yielding up to 1800 ppm FA in both cases] were prepared. Volumes of breads made with and without added AXOS varied around 49−50 cm^3 in all cases. The addition of AXOS up to a concentration of 1800 ppm FA equiv hence did not impact bread volume. On sight, there were no observational differences in crumb structure and crust of the produced breads. Doughs with high levels of MBFA-AXOS felt drier during bread making. The specific bread volumes when MBFA-AXOS was added in concentrations of 1−8% on flour dry matter basis decreased from 4.0 to 3.8 cm^3/g ($p < 0.05$), probably as the result of higher levels of dry matter in the AXOS enriched breads (Table 8). Doughs with 2% added HBFA-AXOS were sticky, and higher levels of HBFA-AXOS even led to unmanageable doughs. Nonetheless, neither the specific nor the regular bread volume changed upon addition of HBFA-AXOS up to 2% of flour dry matter. Previous research also showed that the impact of FA on bread volume is nonexistent or limited when less than 850 ppm FA is added to dough.[26,28] In contrast to these results and our results obtained with AXOS addition, lower bread volumes have been reported for doughs supplemented with 250 ppm FA in another study.[27]

A previous study also demonstrated that effects of additives on dough and bread properties can differ. Although glutathione had a weakening effect on the gluten network during the mixing phase, resulting breads did not necessarily have smaller volumes.[48] Glutathione, for example, increased the SDS-extractability of proteins during the mixing phase, which was here also observed to a small extent for FA and AXOS addition, but eventually resulted in the same SDS-extractability of proteins as the control after the fermentation and baking phase. Han and Koh[26] also demonstrated that SDS-extractabilities of proteins were similar for the control breads or breads with 850 ppm FA added to the recipe. If during the baking phase, the initial levels of sulfhydryl groups would be higher, this might facilitate sulfhydryl−disulfide exchange reactions and resulting gluten polymerization. This can only be the case if the sulfhydryl groups are free,[48] which would not be the case if cysteine-FA adducts had formed. However, no loss of cysteine

[a]SDS-extractability of dough proteins eluting in peak 1 of a sample in the absence of reducing conditions was expressed as the area under curve relative to total area under curve of SDS-extraction profile under reducing conditions of the control sample (100%). Data are expressed as means and standard deviations. Values from the same sample at different doses differ significantly ($p < 0.05$) when not sharing the same uppercase letter in the first column. Values from different samples at the same dose (FA content) did not differ significantly ($p > 0.05$). [b]Approximate levels of total added FA due to addition of AXOS or free FA (FA/dm flour expressed in ppm).

or monomeric FA during bread making was observed for any of the tested additions (data not shown).

Impact of the Bread Making Process on Antioxidant Properties and Extractability of AXOS and Associated FA. The antioxidant capacity of breads was measured by use of the TEAC assay. The results are summarized in Table 8. The antioxidant capacity of the control bread without added AXOS was 11.6 μmol Trolox/g dm, and it increased upon addition of AXOS. At the highest level of AXOS addition, that is, 8% of MBFA-AXOS or 2% of HBFA-AXOS on flour dm basis, the antioxidant capacity of bread almost doubled in comparison with that of the control. FA was, as previously demonstrated,[5] the major factor contributing to the antioxidant capacity of AXOS as antioxidant capacities of breads with added MBFA-AXOS were similar to those with added HBFA-AXOS when the level of FA added was similar. The increase in antioxidant capacity of breads due to AXOS addition was a bit lower than expected based on the antioxidant capacity of AXOS, as determined in Snelders et al.,[5] and the control bread. However, the conditions of the assay differed, and the presence of solid particles might influence the reaction between antioxidants and radicals. Cross-linking of FA would lower the antioxidant capacity as well.[5] However, this did not occur during bread making as the level of monomeric FA (sum of endogenous FA and FA from AXOS addition) was not altered after bread making and the areas of some small peaks (about 1% of peak area of monomeric FA) in RP-HPLC profiles, probably representing di-FA moieties, did not differ for breads with or

[a]In each row, TEAC values of breads with the same amount of total added FA are presented. Data are expressed as means and standard deviations of triplicate measurements. Values from the same sample at different doses differ significantly ($p < 0.05$) when not sharing the same uppercase letter. Values from different samples at the same dose did not differ significantly ($p > 0.05$). [b]Level of added FA due to addition of AXOS (FA/dm flour expressed in ppm).

without added AXOS (results not shown). Also, formation of 4-VG, which can result from thermal or microbial degradation of FA,[47] or altered levels of amino acids, in particular from cysteine and tyrosine, were not observed after baking (results not shown). Therefore, the bioavailability of FA esterified to AXOS in the obtained breads can be expected to be similar to the bioavailability of FA on feruloylated AXOS as such. FA esterified to AXOS will primarily be metabolized in the colon by means of microbial metabolism.[4] The fate and functionality of these microbial FA metabolites are, however, poorly studied up until now.

Furthermore, AXOS added to the bread recipe remained water-extractable after baking (results not shown). As also their impact on bread volume was limited, AXOS fortified breads can be a promising food product to deliver AXOS for human consumption. Previous research reported that a daily intake of 2.2 g of AXOS beneficially altered the bacterial metabolism in the large bowel of healthy humans.[49] As on average about 178 g, ranging from 90 to 329 g, of bread is consumed daily per capita in Western European countries,[50] breads should be supplemented with about 1.8% AXOS (dm)/flour (dm) to achieve the intake of this AXOS quantity exclusively via bread consumption. The here obtained data show that it is feasible to meet this criterion from a techno-functional point of view. Also, addition of high levels of FA to bread through supplementation with FA-rich AXOS was feasible.

In conclusion, AXOS addition impacted dough rheology probably by a FA-mediated effect. Indeed, the FA content of AXOS, but not the form in which it appeared (free or bound to AXOS), determined to a large extent the effect of AXOS addition on dough rheology. AXOS bound FA caused effects on dough rheology similar to those of free FA. When AXOS contained only low to medium levels of FA, the effects of FA on dough rheological properties were overshadowed by those of the carbohydrate moiety of AXOS. Indeed, addition of higher levels of AXOS might cause decreased hydration of the gluten network, causing dough stiffening, and/or might increase the viscosity of the dough liquor. The mechanism of the FA-mediated effect on dough rheology is not fully understood, as FA was not, or only to a minor extent, involved in cross-linking reactions. Furthermore, the impact on gluten was limited. The influence of added AXOS, and more specific of their esterified FA, on noncovalent interactions, such as hydrogen bonds and hydrophobic interactions, might contribute to their effect on dough rheology. Addition of FA-enriched AXOS was only possible up to 2% AXOS (dm)/flour (dm) as higher levels caused unmanageable doughs. The observed FA-mediated effect on dough rheology could also be involved in the strong impact of WE-AX and WU-AX on dough rheology. Native AX, however, contain only low to medium FA levels, and the effect of their presence might be overshadowed by the increased dough liquor viscosity due to the presence of WE-AX or decreased hydration of the dough gluten network in the presence of WU-AX. Despite the outspoken effects of AXOS addition on dough rheology, no impact on bread volumes was observed in the produced breads. It is hence techno-functionally feasible to provide the daily AXOS dose needed for a beneficial effect on colonic bacterial metabolism via the average consumption of breads supplemented with AXOS, poor or rich in FA. Furthermore, at these addition levels, AXOS associated FA also improved the antioxidant capacity of the produced breads.

[a]Source: Singh et al.[19] and CIAT[28] germplasm collection. [b]Phaseolin types (and subtypes) based on 1-DE banding patterns:[11,20,28] S, Sanilac (Sb, S Brazil; Sd, S Durango 222); M, Mesoamerica (M4, M11); B, Boyaca; A, Ayacucho; H, Huanchaco; T, Tendergreen. [c]Gene pool: M, Mesoamerican; A, Andean. [d]Race: M, Mesoamerica; NG, Nueva Granada; P, Peru; C, Chile.

seed weight across a broad range of genetic backgrounds and environments, tolerance to low soil pH, growth habit, early maturity, and resistance to parasites.[11,20,21] Moreover, the phaseolin is the major seed storage protein that may account for up to ca. 50% of the total seed proteome.[13] It is therefore largely responsible for the seed protein quality. In particular, the levels of phaseolin were found to be positively correlated with the nutritional availability of methionine in total bean seed protein.[22] It has been suggested, therefore, that an improvement of the seed protein quality of the present bean varieties might be accomplished by using types of phaseolin with differences in the number of methionine residues and molar ratio of methionine.[23]

So far, more than 40 different types of phaseolin have been found in domesticated and wild cultivars of beans by 1-DE.[4,5] Nevertheless, 1-DE phaseolin profiles typically have only two to six bands with molecular mass (M_r) ranging from 40 to 54 kDa.[4,24] More informative reference maps of the protein phaseolin have been obtained only recently using high-resolution two-dimensional electrophoresis (2-DE).[25,26] Application of high-resolution 2-DE provides characteristic and reproducible phaseolin profiles for each common bean population, each one constituted by a large number of spots containing differentially glycosylated and phosphorylated α- and β-type polypeptides (see Supporting Information Figures 1 and 2). This surge of information on the variation of the protein phaseolin enables one to obtain quantitative estimates of its degree of diversity across common bean populations based on measures of proteomic distance.[27]

The aim of the present work is to test whether high-resolution 2-DE phaseolin profiles can be useful as molecular markers of the degree of genetic divergence and/or the quality of seed protein in common bean populations. For this purpose, we performed a prospective study on the variation of 2-DE phaseolin profiles over domesticated and wild common bean populations belonging to the Mesoamerican and Andean gene pools. In addition, the quality of the total seed protein in these bean populations was estimated from the content of methionine, an essential amino acid deficient in bean seeds. From the results, we will try to determine whether proteomic distances based on 2-DE phaseolin profiles can efficiently identify populations belonging to each major gene pool, as well as the possible link between proteomic distances and seed protein quality. It might open the way of using the information contained in 2-DE phaseolin profiles for the genetic improvement of common bean populations.

MATERIALS AND METHODS

Plant Material. Dry mature seeds from 8 wild types and 10 cultivars of common bean (*P. vulgaris* L.) from Mesoamerican and Andean gene pools were screened for variability of phaseolin using 2-DE. The cultivars belong to the Mesoamerica, Nueva Granada, Peru, and Chile races. A complete list of the accessions used in this studied together with their passport information, which includes accession identifier, common name, phaseolin type assessed by 1-DE, race type, status (wild, landrace, or cultivar), origin (country and locality), seed

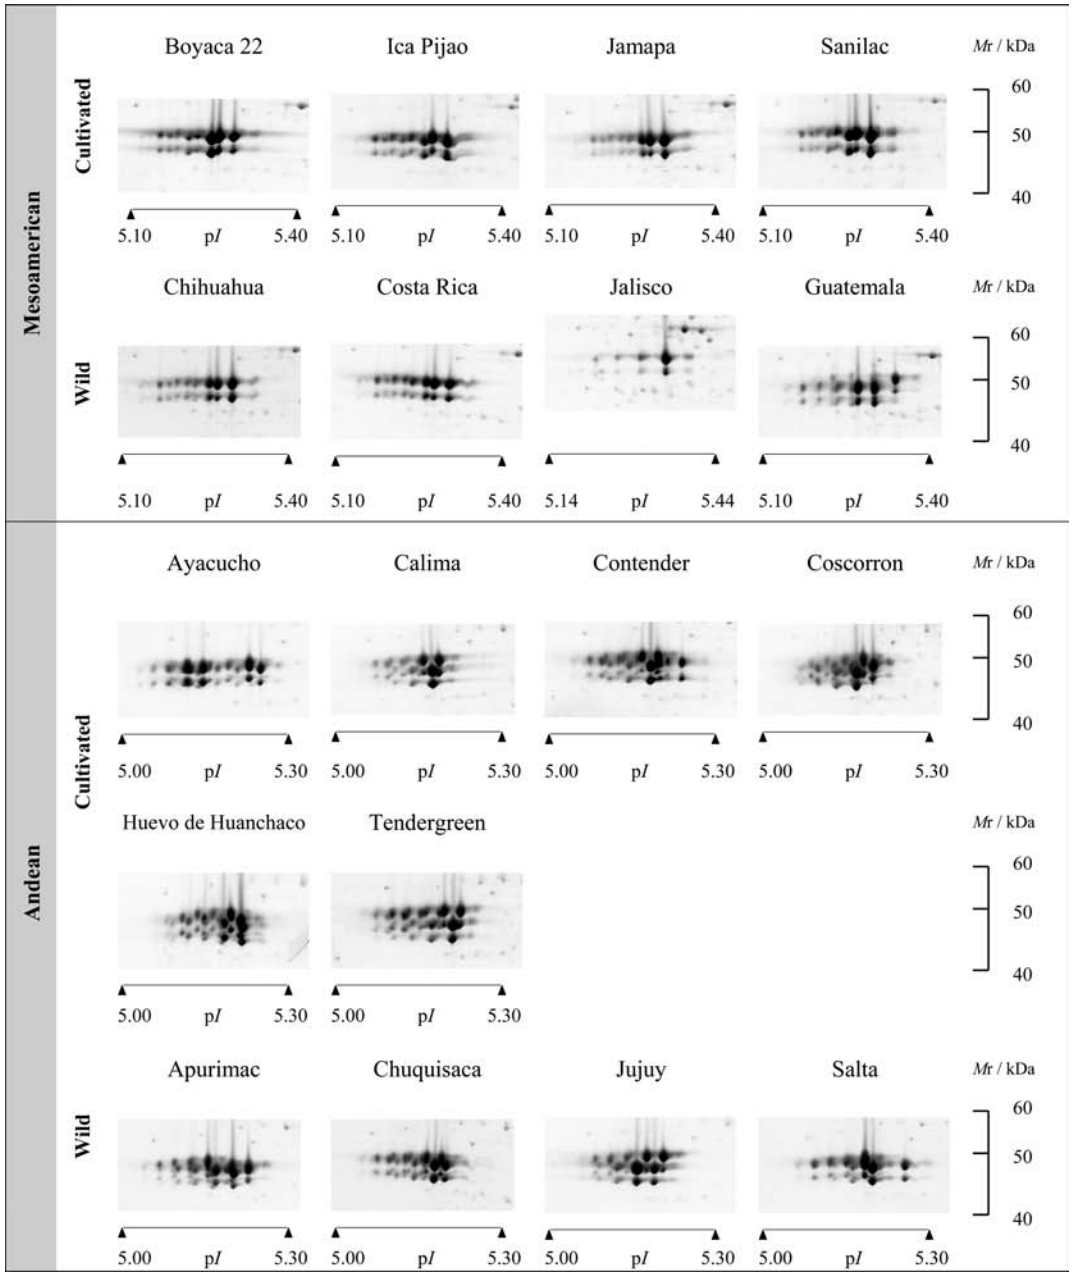

Figure 1. High-resolution 2-DE phaseolin profiles from seeds of 18 cultivated and wild accessions of common bean corresponding to the Mesomerican and Andean gene pools. Positions of the spots according to their isoelectric point (pI) and molecular mass (M_r) are shown.

weight, and seed color is given in Table 1. The seeds were provided by the United States Department of Agriculture (USDA). Ten bean seeds from each accession were lyophilized after previous grinding of the total seed tissue to a powder with liquid nitrogen using a precooled mortar and pestle. The samples were stored at −80 °C until protein extraction.

Seed Protein Extraction. Total seed protein was extracted by the phenol method, which has been proved to give highly satisfactory results for the separation of common bean seed proteins by 2-DE in comparison with other commonly used extraction methods.[29] The phenol method was performed from 100 mg of sample suspended in extraction buffer (500 mM Tris-HCl, 500 mM EDTA, 700 mM sacarose, 100 mM KCl pH = 8.0, 2% DTT, and 1 mM PMSF). Phenol saturated with Tris-HCl (pH 6.6−7.9) was added, and the phenolic phase was recovered after centrifuging (4500 rpm at 4 °C). Proteins were precipitated (0.1 M ammonium acetate in MeOH), and protein pellets were washed (0.1 M ammonium acetate, 10 mM DTT, 80% acetone, and 10 mM DTT) and resuspended in lysis buffer (7 M urea; 2 M thiourea; 4% CHAPS; 10 mM DTT, and 2% Pharmalyte pH 3−10, GE Healthcare, Uppsala, Sweden). Protein quantification was assessed for each extraction using the commercial CB-X protein assay kit (G-Biosciences, St. Louis, MO) following the instructions of the manufacturer for using a microplate reader.

2-DE Phaseolin Patterns. Optimized 2-DE protocol for high-resolution phaseolin patterns was used as previously described.[25,26] 2-DE was carried out from 50 μg of total seed protein extract dissolved in lysis and rehydration (7 M urea, 2 M thiourea, 4% CHAPS, 0,002% Bromophenol Blue) buffers. Protein extracts were loaded on 24 cm-long ReadyStrip IPG Strips with a pH linear gradient of 4.7−5.9 (Bio-Rad Laboratories, Inc., Hercules, CA), together with 0.6% dithiothreitol (DTT) and 1% IPG buffer (Bio-Rad Laboratories). First dimensional isoelectric focusing (IEF) was carried out until reaching 60 kVh after an initial rehydration step for 12 h at 50 V in a PROTEAN IEF cell (Bio-Rad Laboratories). Focused strips were incubated in the equilibration solution (50 mM Tris pH = 8.8, 6 M urea, 30% glycerol, and 2% SDS) with 1% DTT for 15 min at room

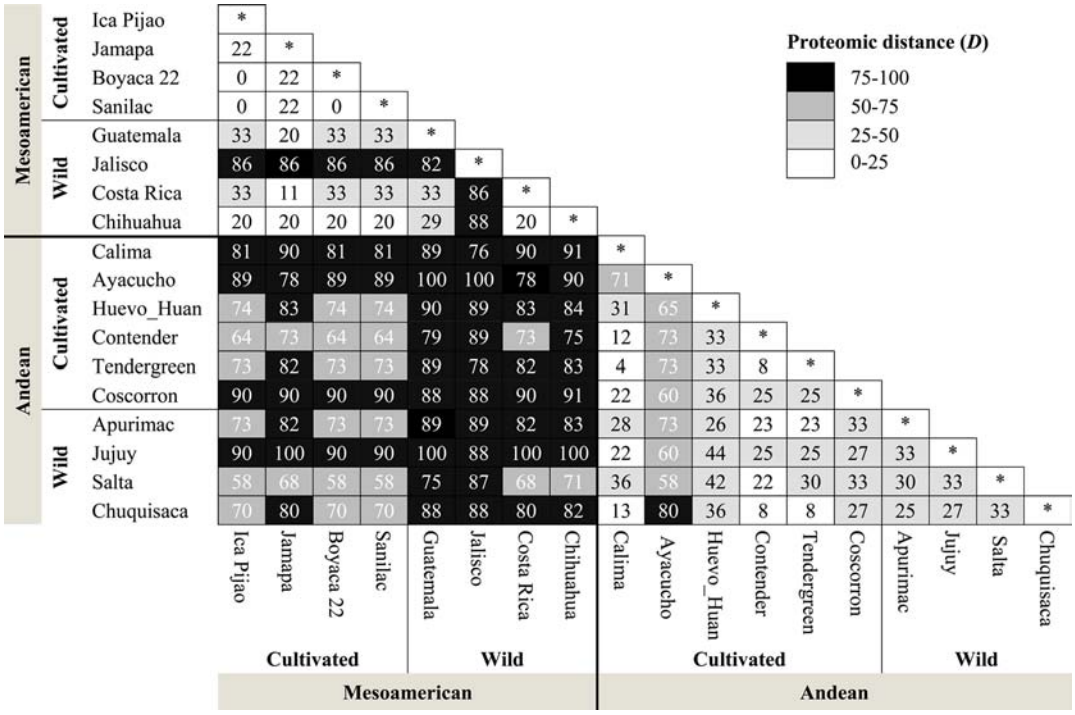

Figure 2. Pairwise proteomic distance (D), expressed as a percentage, based on high-resolution 2-DE phaseolin patterns from seeds of 18 cultivated and wild accessions of common bean.

temperature and then with 2.5% iodoacetamide under the same conditions. For the second dimension (SDS-PAGE), equilibrated strips were placed on 10% (w/v) gels, and they were run vertically in an Ettan DALTsix system (GE, Healthcare, Uppsala, Sweden) using Tris-glycine-SDS (50 mM Tris, 384 mM glycine and 0.2% SDS) as electrode buffer. SDS-PAGE was carried out at a constant current of 16 mA per gel over 15 h. After the run, gels were stained with Sypro Ruby stain (Lonza, Rockland, ME) following the manufacturer's indications.

The 2-DE gel images were acquired with a Gel Doc XR+ system (Bio-Rad Laboratories). Image analysis of digitalized gels was performed through PDQuest Advanced software v. 8.0.1 (Bio-Rad Laboratories). 2-DE gels were matched across wild and cultivated common bean accessions. Only qualitative (presence or absence) differences among spot patterns, detectable under a sensitivity of 1.1, were analyzed.

Seed Amino Acid Composition. Protein hydrolysis was carried out on 100 mg of bean flour (average moisture content 4.32%) with 5 mL of HCl (6 N) in an ampule glass sealed for 24 h at 110 °C. After hydrolysis, the solution was diluted with 200 mL of distilled water and filtered through a 0.45 μm filter (Filter-Lab, Barcelona, Spain). Tryptophan determination was not possible, because acidic hydrolysis transformed it into ammonium.

The derivatization conditions were as follows: 10 μL of sample was buffered to pH 8.8 (AccQFluor borate buffer; Waters, Milford, MA) to yield a total volume of 100 μL. Derivatization was initiated by the addition of 20 μL of AccQ-Fluor (Waters) reagent (3 mg/mL in acetonitrile).

The amino acid analyses were performed by high-performance liquid chromatography (HPLC). Chromatographic analysis conditions were as follows: separations were carried out in a Waters AccQ-Tag column (3.9 mm × 150 mm with a 4 μm of particle size); the pumps were fixed to maintain a flow rate of 1.0 mL/min; and the column heater was fixed to maintain a temperature of 37 °C. The gradient profile and composition of the mobile phase were adapted from methodology developed by Vandelen and Cohen[30] and Waters AccQ-Tag Instruction Manual. Separation and detection were carried out using Alliance model 2695 HPLC Module (Waters) and model 2475 scanning fluorescence detector (Waters). Empower 2 Advanced software (Waters) was used to control system operation and results management. Detection was accomplished by fluorescence with excitation at 250 nm and emission at 395 nm. Amino acids were identified by retention time and quantification using an external calibration, where amino acid standard solution (AA-S-18, Sigma-Aldrich, Saint Louis, MO) was prepared to obtain a calibration curve of five points. Two biological replicate samples were carried out per accession.

Data Analysis. The degree of similarity between 2-DE phaseolin profiles of common bean populations was estimated as the percentage of spots shared through the F (also described in the literature as S) coefficient[31] given by

$$F = 2n_{xy}/(n_x + n_y)$$

where n_{xy} is the number of phaseolin spots shared by populations x and y; and where n_x and n_y are the total numbers of phaseolin spots identified in populations x and y, respectively. Dissimilarity or proteomic distance (D) between pairwise populations was then estimated as

$$D = 1 - F$$

A hierarchical cluster analysis using the unweighted pair-group method with arithmetic averaging (UPGMA) was applied to the matrix of both pairwise proteomic distances and pairwise differences in methionine content. Nonmetric multidimensional scaling (MDS) algorithm was used to construct a two-dimensional plot on the basis of the pairwise proteomic distance matrix. The significance of the relationship between proteomic distance and difference in methionine content across pairs of accessions was assessed using Mantel's matrix-comparison test, which does not require that matrix elements be independent.[32] UPGMA, MDS, and the Mantel test were performed using NTSYSpc v. 2.1 software (Applied Biostatistics, Inc., Setauket, NY).

Standard statistical analyses were performed using the statistical software package IBM SPSS Statistics 20 (SPSS, Chicago, IL). Bootstrapping was used to calculate 95% and 99% confidence intervals (CIs) for the means of proteomic distance. For each set of N estimates of D, bootstrap samples of size N were obtained following a Monte Carlo algorithm putting mass $1/N$ at each one of the observed D

estimates. From distribution of 10 000 bootstrap mean replications of D, the bootstrap CIs (95% and 99%) were obtained by the bias-corrected percentile method.[33] A similar procedure was performed to obtain CIs for the means of methionine content across accessions. Random numbers were obtained using the standard multiplicative linear congruential generator implemented by Schrage,[34] which uses the multiplier 16 807 and prime modulus 2^{31}-1 to give long sequences that have appearance of randomness. Bootstrap CIs were obtained with the software DIANA (C. Zapata, unpublished).

RESULTS AND DISCUSSION

2-DE Phaseolin Patterns. 2-DE phaseolin patterns in 18 wild and cultivated accessions of common bean are shown in Figure 1. It can be seen that 2-DE phaseolin profiles were markedly diverse across accessions. Thus, the number of spots on 2-DE gels across the 18 phaseolin patterns ranged from 10 (Jalisco) to 28 (Huevo de Huanchaco) and averaged (±SE, standard error) 20.4 ± 1.1. Phaseolin patterns were found to be remarkably less complex in Mesoamerican gene pool (M) accessions than in Andean gene pool (A) ones: the mean number of spots for M and A accessions was 16.8 ± 1.4 and 23.4 ± 1.0, respectively (Mann–Whitney U test, $p < 0.01$). It is noteworthy that most of these variations were due to the presence/absence of spots in the first dimension (pI). Recent evidence has shown that differences in the pI of 2-DE phaseolin spots are largely due to differentially phosphorylated α- and β-type polypeptides.[26] The same study revealed that mobilization of the phaseolin in germinating seeds seems to occur through the degradation of highly phosphorylated isoforms. It suggests, therefore, that regulatory mechanisms responsible for the synthesis and subsequent degradation of phaseolin through phosphorylations might undergo variations over common bean populations.

Proteomic Distance. A quantitative estimation of the differences between 2-DE phaseolin profiles was obtained from the matrix of pairwise proteomic distances (D). The D-values (in percentage) between all possible pairwise comparisons of cultivated and wild common bean population are given in Figure 2. We found that proteomic distances were largely heterogeneous: values of D ranged from 0 (three M × M comparisons) to 100% (six M × A comparisons) and averaged 59.9 ± 2.4%. The mean proteomic distance (with 95% and 99% bootstrap CIs) within and between gene pools at different levels of comparison is shown in Table 2. Most of the heterogeneity in proteomic distance can be attributed to between gene pool differences. In fact, proteomic distance between gene pools was statistically significant higher than those proteomic distances within gene pools ($p < 0.01$). Within gene pools, proteomic distances were rather homogeneous over different levels of comparison with a single exception. The Mesoamerican cultivated (MC) populations exhibited indeed the lowest mean proteomic distance score (i.e., 11.0 ± 4.9), which was statistically significantly different from the remaining mean proteomic distances ($p < 0.01$), including Andean cultivated (AC) populations. Lower diversity for phaseolin types in the domesticated Mesoamerican gene pool than in the Andean one has also been reported on the basis of 1-DE analyses.[20] This evidence would support the interpretation that a single domestication event occurred in Mexico, whereas multiple domestication events occurred in the Andes,[20] but the domestication history of the common bean is still a controversial topic.[35]

On the basis of the matrix of pairwise proteomic distances, clustering analysis (UPGMA) and projection of the distances in two-dimensional space (MDS) were used to evaluate the efficiency of 2-DE phaseolin patterns in grouping the populations according to the classification by major gene pools. The UPGMA dendrogram generated from the matrix of pairwise D-values is shown in Figure 3. First, it must be highlighted that proteomic distances were able to reliably reproduce the known separation of the populations into the Mesoamerican and Andean gene pools. The only exception to the double-cluster pattern of Mesoamerican and Andean bean accessions was a well-separated branch containing the wild accession Jalisco. In addition, UPGMA dendrogram was also

able to unravel heterogeneity within the two gene pools. In particular, the accession of Ayacucho formed a clearly separated subcluster within Andean cluster. The projection of the proteomic distances between pairs of the 18 common bean accessions in two-dimensional space is shown in Figure 4. The

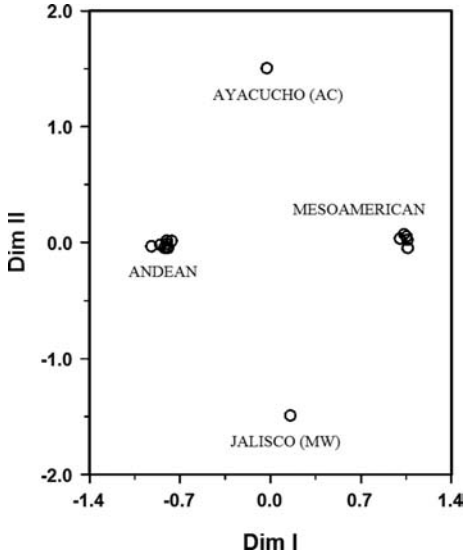

Figure 4. Multidimensional scaling (MDS) projection of the proteomic distance (D) between 18 cultivated and wild populations onto two-dimensional space based on high-resolution 2-DE phaseolin patterns.

stress function value was 0.074, which indicates a good goodness-of-fit of the projected distances in the configuration space to the monotone function of the original distances. The two-dimensional map obtained by MDS reflected essentially the same scenario obtained by the dendrogram. Thus, dimension I showed noticeable differences between two tight clusters of Mesoamerican and Andean gene pools, whereas dimension II separated clearly the bean accessions Ayacucho and Jalisco as two outliers strongly deviating from the two main clusters.

Previous investigations support the highest proteomic distance found for Ayacucho and Jalisco populations.[14,18,35−38] First, it is important to note that Ayacucho is a nuña, a type of cultivar currently restricted to certain parts of the highlands of Peru and Bolivia that exhibits the particular property of popping when exposed to heat. It is considered that nuña beans may represent ancient preceramic landraces descendents of the earliest Andean bean domesticates.[14,36] Second, Jalisco is a possible ancestral wild accession of *P. vulgaris*. Recent evidence using a variety of nuclear and chloroplast DNA markers suggests that the wild forms of *P. vulgaris* originated in Mesoamerica and the Andean gene pool originated through different migration events from central Mexico.[18,35,37] It also seems that Mesoamerican beans were domesticated in the region of Jalisco.[38] Accordingly, analysis of genetic diversity with microsatellite markers in a large number of wild and domesticated common bean accessions from Mesoamerican and Andean gene pools has shown than the race Jalisco constituted a single separated group together with the race Durango.[14] Taken together, our investigations show that proteomic distances obtained from 2-DE phaseolin patterns are a reliable marker of genetic differentiation among cultivated and wild bean populations.

Proteomic Distance and Seed Protein Quality. Essential and nonessential amino acid composition for the 18 cultivated and wild common bean seeds from the Mesoamerican and Andean gene pools is shown in Supporting Information Tables 1 and 2. Figure 5 shows that the values

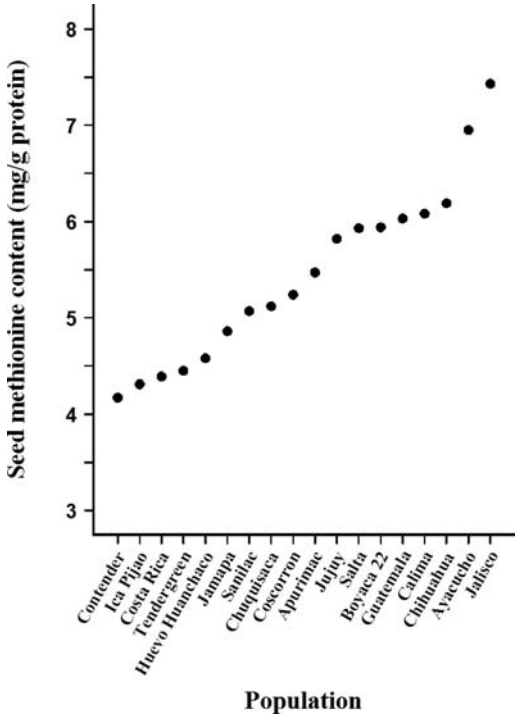

Figure 5. Mean methionine content (mg/g total seed protein) across 18 cultivated and wild populations of common bean.

of the seed methionine content varied markedly across the complete set of accessions: mean values ranged from 4.2 (Contender) to 7.4 mg/g (Jalisco) of protein sample. Despite these oscillations, all accessions contain methionine-cysteine poor proteins as compared to the reference amino acid FAO/WHO requirements recommended in human nutrition (see Supporting Information Figure 3).[7] On the other hand, no statistically significant differences in methionine content were detected between Mesoamerican and Andean gene pools by the Mann−Whitney U test ($p = 0.79$). However, we found a weak relationship between the degree of proteomic distance and the difference in methionine content in total seed protein over pairs of populations (see Supporting Information Figure 4). Specifically, a positive correlation was detected between both variables using both the Pearson product-moment correlation coefficient to assess the strength of association and the Mantel test to assess its probability ($r = 0.176$, $p < 0.05$, $n = 153$). This weak correlation can be understood taking into account that the phaseolin represents about 35−50% of the total seed protein.[6] It seems, therefore, that it is difficult to predict methionine content in total seed protein from individual proteomic distance scores based on 2-DE phaseolin profiles.

Cluster analysis offers a different perspective to the study of the diversity in the methionine content across bean accessions because their degree of similarity/dissimilarity can be analyzed jointly. Cluster analysis using UPGMA from differences in methionine content between pairs of accessions is shown in Figure 6. Interestingly, the accessions Jalisco and Ayacucho appear to be clear outliers distantly related to the rest of the

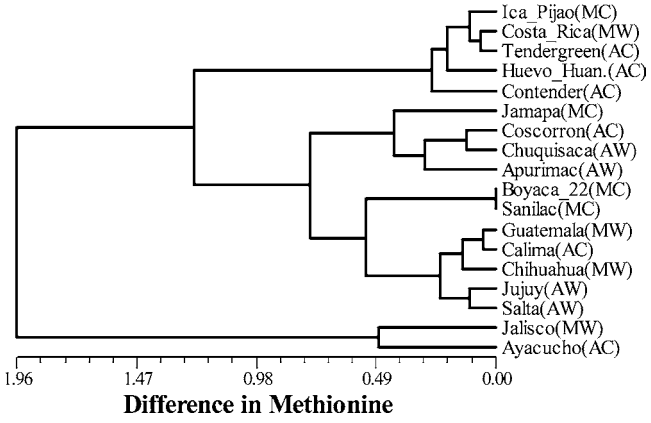

Figure 6. Unweighted pair-group method with arithmetic averaging (UPGMA) dendrogram based on pairwise differences in seed methionine content (mg/g total protein) from 18 cultivated and wild populations of common bean.

accessions in agreement with analyses based on proteomic distances. In addition, the levels of methionine were significantly higher in seeds of Jalisco and Ayacucho than in the remaining accessions used in this study ($p < 0.01$; Table 3),

Table 3. Methionine Content (mg/g protein) in Total Seed Protein of Ayacucho and Jalisco and Other Accessions

accessions	n^a	methionine content[b]	95% bootstrap CI (CL, CU)[c]	99% bootstrap CI (CL, CU)
Ayacucho	2	6.95 ± 0.15	6.94, 7.10	6.80, 7.10
Jalisco	2	7.44 ± 0.45	7.43, 7.88	6.99, 7.88
other accessions	32	5.22 ± 0.13	4.98, 5.47	4.91, 5.52

[a]Number of values. [b]Data are means ± standard error. [c]CI, confidence interval; CL, lower bound; CU, upper bound.

about 70% higher than in the Contender accession (Figure 5). These observations suggest, therefore, that proteomic distances based on 2-DE phaseolin profiles are an informative biomarker to identify outliers with distinct methionine content. Accordingly, phaseolin-based proteomic distances can establish a link between *P. vulgaris* genetic differentiation and methionine content in total seed protein, which has important implications for the genetic improvement of bean seeds with higher nutritional quality.[5,23,39]

The study of natural variation in the protein phaseolin from 2-DE-based patterns can provide additional valuable information to improve bean cultivars. Previous studies suggest that the existing natural variation in phaseolin types could be used for improving the digestibility of common bean. Thus, it is known that the nutritional value of common bean is affected by a high resistance of phaseolin to proteolysis by the digestive enzymes.[4,5,40−43] However, the degree of hydrolysis in vitro of phaseolin seems to be influenced more by the structural characteristics of the phaseolin type determined using 1-DE than by its amino acid composition.[4,5] A number of structural variations can alter the phaseolin susceptibility to proteolysis including differences in the proportion of α- and β-type polypeptides in the whole molecule and post-translational modifications such as glycosylations.[4,5,42,43] At this regard, 2-DE phaseolin profiles have the advantage that they provide more detailed information about the structural differences among phaseolin types than is available via 1-DE banding patterns. In particular, 2-DE profiles allow us to identify differentially glycosylated and phosphorylated α- and β-type phaseolin polypeptides (Supporting Information Figure 2).[25,26] It would be interesting to study as the natural variation in the levels of glycosylation and phosphorylation of α- and β-type polypeptides affects the susceptibility of phaseolin to in vitro and in vivo proteolysis. On the other hand, it is also probable that proteomic distances based on 2-DE phaseolin patterns can provide relevant information about other bean traits. It is well established that phaseolin diversity is associated with several important agronomic traits (seed weight, tolerance to low soil pH, resistance to parasites, etc.).[11,20,21] These associations are likely a byproduct of linkage disequilibrium between alleles at phaseolin coding genes and alleles at quantitative trait loci (QTLs) of agronomic relevance. Linkage disequilibria among functionally unrelated loci could have arisen at any given moment of the history of common bean populations by evolutionary mechanisms such as genetic drift, founder effects, and stratification (or admixture) of populations, and maintained by the self-pollinated nature of *P. vulgaris*.[11]

Overall, our results show that proteomic distances based on high-resolution 2-DE phaseolin profiles are a reliable marker of genetic differentiation of common bean populations. Our study also indicates that phaseolin-based proteomic distances can establish a link between *P. vulgaris* genetic differentiation and seed protein quality as evaluated by the content of the essential amino acid methionine. This link might conceivably include other bean traits of agronomic relevance. Therefore, 2-DE phaseolin patterns might be potentially exploited to speed the process of selection of common bean germplasm in follow-up breeding programs to the improvement of bean cultivars.

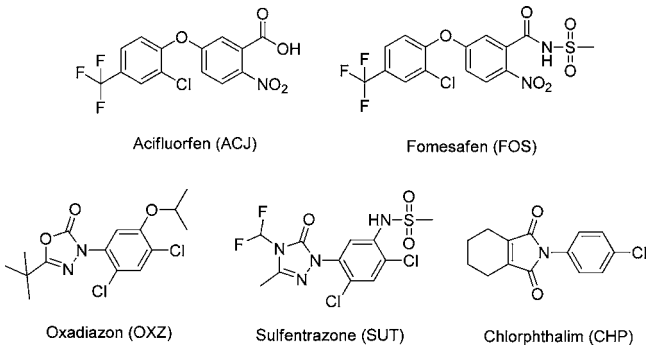
resistance.[26] Hence, it is of great importance to perform resistance prediction and understand the corresponding mechanism at the molecular level.[27]

In the present study, we have aimed to make a broad prediction of the resistance associated with target mutations in PPO and have acquired a detailed understanding of the resistance mechanisms of typical PPO-inhibiting herbicides by a newly developed computational protocol, computational mutation scanning (CMS).[3] We have computationally studied the resistance mechanism of five most frequently applied PPO-inhibiting herbicides, including acifluorfen (ACJ), fomesafen (FOS), oxadiazon (OXZ), sulfentrazone (SUT), and Chlorphthalim (CHP) (Scheme 1). The computationally determined

Scheme 1. Chemical Structures of PPO Inhibitors



shifts of the binding free energies caused by mutations correlated well with the corresponding experimental data, leading to valuable insights into the potential resistance mechanisms of PPO inhibitors, which will help to reduce the resistance risk of new inhibitors discovered by a structure-based design approach.

MATERIALS AND METHODS

Molecular Docking and Molecular Dynamics (MD) Simulation. The X-ray crystal structure of human PPO used for computation was downloaded from RCSB.[25] Docking calculations were performed on ACJ, FOS, OXZ, SUT, and CHP with AutoDock4.0.[28] Most of the parameters for the docking calculation were set to the default values. Each docked structure was scored by the built-in scoring function and was clustered by 0.8 Å of RMSD criterions. Finally, the enzyme-ligand complex structures were selected according to the criteria for Autodock Score, which were used as initial complex structures for subsequent MD simulations.

Ab initio quantum mechanics (QM) calculations were performed for inhibitor and FAD optimization at the HF/6-31+G* level to determine the electrostatic potential by using the restrained electrostatic potential (RESP) method according to the Merz−Singh−Kollman scheme.[29,30] The RESP charges of ligands (inhibitors and FAD) was produced by using the standard RESP protocol[31,32] implemented in the Antechamber module of the AMBER9 program.[33] To carry out the MD simulations, the topology and coordinate files of the complexes were built with the Leap module of the AMBER9 package. All molecules were solvated by a rectangular box of TIP3P waters extended at least 10 Å in each direction from the solute. Before the MD simulation, some energy minimization steps were applied to the system. First, the solute was kept fixed with a constraint of 500 kcal mol^{-1} $Å^{-2}$ and waters and counterions were minimized; the backbone atoms of the protein were then fixed with the ligand, side chains, and other atoms free to move; finally, the entire system was fully minimized without any constraint. In each step, energy minimization was first performed by using the steepest descent algorithm for 2000 steps and then the conjugated gradient algorithm for another 3000 steps.

The MD simulation was performed under periodic boundary conditions by using the Sander module of the AMBER9 program, as we have done for the same protein before.[27] First, the system was fixed to make the heating only for waters and counterions for 10 ps to make sure the solute was fully solvated; second, the whole system was gradually heated from 10 to 298 K by a weak-coupling method[34] and equilibrated for 100 ps with the protein backbone fixed; last, the system was switched to a constant pressure equilibration for 3 ns. During the MD simulation, the particle mesh Ewald (PME) algorithm[35,36] was used to deal with long-range electrostatic interactions with a cutoff distance of 10 Å, which was also used for the van der Waals (vdW) energy terms. All of the angles and bonds involving hydrogen atoms were constrained by using the SHAKE algorithm.[37] The time step used for the MD simulations was 2.0 fs and the coordinates were collected every 1 ps.

Computational Mutation Scanning. A free energy perturbation approach, computational alanine scanning (CAS), can be used to estimate the free energy shift caused by mutation to alanine, which has been widely used to study protein−protein/ligand interactions. The CMS method, as an extension of the CAS method, has been validated in our previous study and can be applied to all kinds of mutations with the entropy effects taken into account.[3] We saved a total of 100 snapshots from a stable MD trajectory of the last 1000 ps, that is, one structure in every 10 ps, for each MD-simulated complex. We performed mutation automatically on each snapshot with a modified MMTSB Tool Set package.[38] All force field parameters in the topology files for the residue to be mutated were replaced with the parameters of the corresponding new residue. Before the calculation of the binding free energy, the positions of side chain atoms of all residues were energy-minimized by using the Sander module of AMBER9 program via a combined use of the steepest descent/conjugate gradient algorithms, with a convergence criterion of 0.2 kcal mol^{-1} $Å^{-1}$. Then the Gibbs binding free energies between the protein and ligand for each snapshot were calculated by carrying out a modified molecular mechanics/Poisson−Boltzmann surface area (MM/PBSA) energy analysis.[27] The final binding free energy is the average of the calculated values associated with the 100 snapshots.

Kinetic Assays for PPO and Its Mutants. The recombinant plasmid (pHPPO-X) was a generous gift from Dr. Harry A. Dailey (University of Georgia, Athens, GA). *h*PPO (human PPO) mutations were generated from the recombinant plasmid (pHPPO-X) using the DpnI-mediated site-directed mutagenesis kit (Biocrest Manufacturing LP, Cedar Creek, TX), and mutations were confirmed by sequence analysis. Expression and purification methods of *h*PPO were the same as those used in our previous publication.[39,40] The *h*PPO activity was assayed by measuring the velocity of the formation of protoporphyrin from protoporphyrinogen on a 96-well plate using the continuous fluorometric method.[39]

The kinetic parameters were evaluated by Sigma Plot software 10.0 (SPSS, Chicago). IC_{50} was determined by

measuring *h*PPO activity over a range of inhibitor concentrations at a single substrate concentration. IC_{50} values were calculated by fitting v versus [I] data to a single binding site model described by eq 1

$$y = \min + \frac{\max - \min}{1 + 10^{\log IC_{50} - x}} \quad (1)$$

where y is the percentage of maximal rate, max and min are the y values at which the curve levels off, x is the logarithm of inhibitor concentration, and IC_{50} is the inhibitor concentration that elicits 50% of the total inhibition. Calculated K_i value is obtained by applying the following relationship, which exists for competitive inhibition among K_i, K_m, and IC_{50} at any saturating substrate concentration (S).

$$K_i = \frac{IC_{50}}{S/K_m + 1} \quad (2)$$

RESULTS AND DISCUSSION

Structures of PPO–Inhibitors Complexes. Our strategy for the prediction of PPO resistance to herbicides involved determining the binding models of the five inhibitors with PPO. We used molecular docking to examine their possible binding models. Due to docking, the method we used could not fully account for the flexibility of the protein and so the binding models from docking were further studied by molecular dynamics (MD) simulations. We selected the final structures of PPO–inhibitor complexes according to docking scores, the stability of the MD simulation, and geometric matching qualities with the known crystal structures of INH in a complex with tobacco PPO and ACJ in a complex with *Myxococcus xanthus* PPO and also with human PPO.[22,23,39] In addition, obtaining a stable MD trajectory is crucial for subsequent analysis, so the plot of root-mean-square deviation (RMSD) of the protein backbone and inhibitor atoms throughout the whole process of the MD simulation was examined for convergence. According to the RMSD values of the MD trajectories (Figure 1), the simulations have reached equilibrium states. The MD simulations were also repeated with different sets of parameters and force fields to further validate the convergence of the simulations (data not shown).

To further verify the reliability of the MD simulations, the binding free energies of the five inhibitors were calculated by using a modified MM/PBSA method.[27] The results included the overall binding free energy and each energy term (Table 1). The calculated binding affinities were also compared with the experimental data derived from inhibitions studies performed with the mutated PPO enzymes that we prepared. As listed in Table 1, the binding free energies (ΔG_{cal}) of the five inhibitors with respect to wild-type PPO obtained from the MM/PBSA calculations ranged from −11.7 to −23.80 kcal/mol. The corresponding experimentally derived free energies of binding (ΔG_{exp}) using wild-type PPO varied over the narrow range of −5.54 to −8.82 kcal/mol. These data show that the calculation largely overestimated the absolute values of the binding free energies by ∼2.0–2.7-fold. Nevertheless, the qualitative order of the calculated binding affinities for the inhibitors using computational methods was FOS > SUT > ACJ > OXZ > CHP, which is in accordance with the ranking of the binding determined experimentally. Quantitatively, the calculated binding free energies are precisely correlated with the corresponding experimental data, with a correlation coefficient

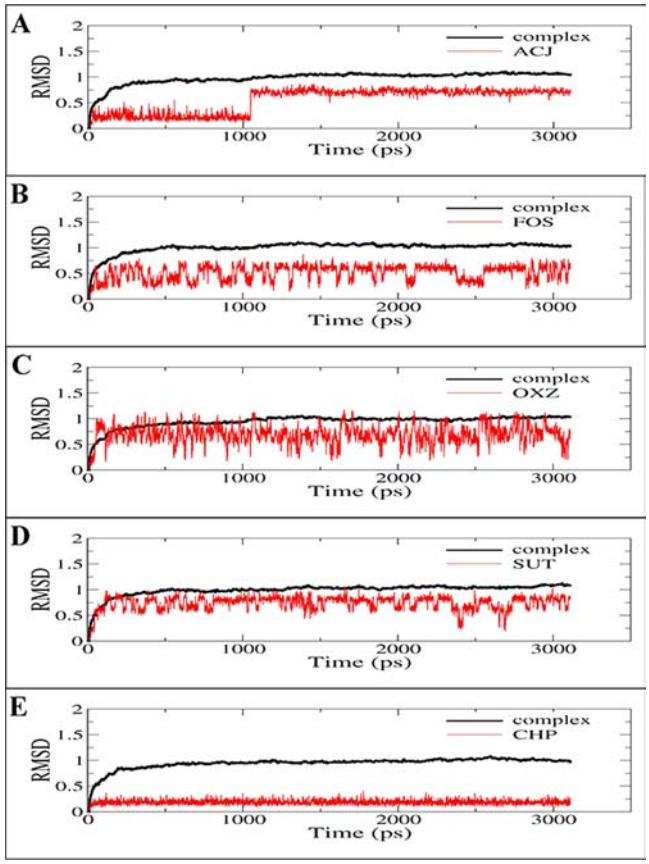


Figure 1. Time dependence of the RMSD of protein backbone atoms (color in black) and inhibitors (color in red). (A) PPO–ACJ, (B) PPO–FOS, (C) PPO–OXZ, (D) PPO–SUT, and (E) PPO–CHP.

r^2 = 0.88. The good agreement between the computational results and the experimental data further confirmed the computational models constructed and tested in this study are reliable.

In addition, the simulated binding models were also compared with available X-ray crystal structures and our previous studies.[27] The interaction between the inhibitor and PPO may occur in the binding pocket defined by seven residues. We have shown that most inhibitors interacted with PPO by establishing strong hydrogen bonds with the highly conserved Arg97 residue and a hydrophobic interaction with Met368, which is similar to that in the X-ray crystal structure of ACJ in a complex with *M. xanthus* PPO and the crystal structure of INH in a complex with tobacco PPO.[22,23] To make a clear view of the interacting pattern, MD simulated models of PPO inhibitors binding with residues in the pocket are shown in Figure 2. The five inhibitors have similar binding modes because they are thought to inhibit PPO activity by mimicking the same part of the substrate. So, the simulated three-dimensional structure of PPO inhibitor complexes obtained in the present investigation should be reasonable.

Selection of Residues for Mutation. The amino acids for mutation in PPO have been the subject of intensive resistance research in agriculture because of the tendency of this enzyme to lose efficacy toward a wide range of pesticides. To make reasonable selection of amino acid residues for mutation, we should compare the key residues interacting with substrate and inhibitors. In light of our earlier studies of both residue mutation experiments and in silico studies, we gained insights

[a]Results determined by the MM−PBSA calculations. The standard deviation (STD) values are included in the parentheses. [b]Experimental values ΔG_{exp} were derived from the experimental K_i values of *h*PPO according to $\Delta G_{exp} = -RT \ln K_i$.

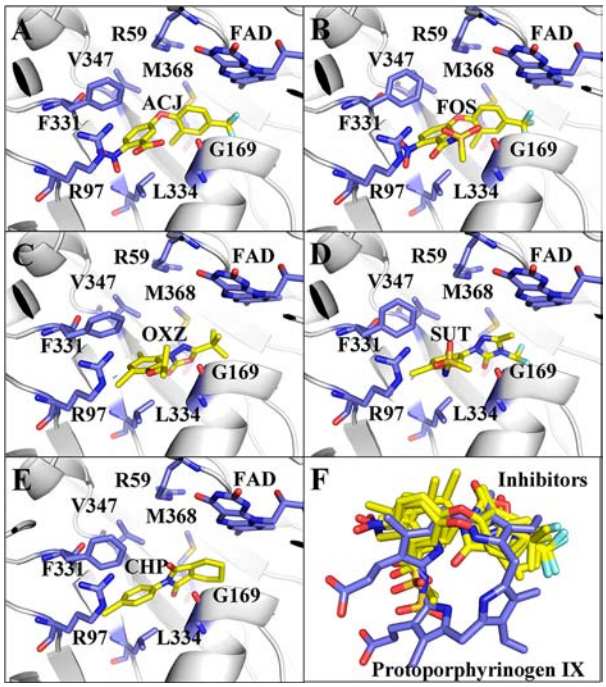

Figure 2. MD simulated models of human PPO in a complex with ACJ, FOS, OXZ, SUT, and CHP. (A) PPO−ACJ, (B) PPO−FOS, (C) PPO−OXZ, (D) PPO−SUT, (E) PPO−CHP, and (F) alignment of the binding conformation of five inhibitors and protoporphyrinogen IX.

into the binding modes of substrate and inhibitors in PPO.[40,41] The residues R59, R97, M368, G169, V347, L334, and F331 comprise the active site of PPO. On the basis of our previously determined binding model of the substrate[41] and site-directed mutagenesis studies of PPO, we identified three mutations, R59Q, R97G, and M368Q, that had no strong effect on the structure and catalytic activity of PPO. This result was at odds with our original idea that the R97G mutation would decrease the catalytic activity of the enzyme through loss of a key hydrogen bond interaction with the substrate. Indeed, the replacement of R97 with glycine improved the enzyme activity.[41] We therefore undertook further studies to understand the mechanism of binding of the five inhibitors to the R59Q, R97G, and M368Q mutants. Hence, site-directed mutagenesis and enzyme kinetic studies were performed on *h*PPO.

Computational Prediction of Resistance. To aid the course of pesticide discovery, the prediction of pesticide resistance by computational methods would be most valuable. Computational methods can provide information about the possible mechanisms of resistance that can be conferred by a target mutation. These mechanisms can be divided into six categories according to thermodynamic parameters: decrease of enthalpy, decrease of entropy, decrease of both the enthalpy and entropy, no significant change in enthalpy and entropy, decrease of enthalpy compensated by the increase of entropy, and decrease of entropy compensated by the increase of enthalpy.

Computational mutation scanning (CMS) calculations were performed to predict the resistance for the five inhibitors and to gain further insight into the contributions of the various energy terms to the differences in the binding free energy of R59Q, R97G, and M368Q, including the changes in the van der Waals and electrostatic interaction energies, as well as the electrostatic and nonpolar desolvation free energies upon mutation. The relative binding free energies calculated by CMS and the corresponding experimental values are given in Table 2. The $\Delta\Delta G$ value can be viewed as an indicator of the resistance level, with the negative and positive values of $\Delta\Delta G_{bind}$ ($\Delta G_{mutant} - \Delta G_{wild\text{-}type}$) indicating favorable and unfavorable outcomes, respectively. Thus, a positive $\Delta\Delta G$ value indicates resistance, whereas a negative $\Delta\Delta G$ value signifies lack of resistance. Most of the calculated relative binding free energies were positive, illustrating that the three mutants usually induced resistance in PPO with respect to the five inhibitors.

To gain further insight into the resistance mechanisms associated with the mutations, contributions of enthalpy and entropy to the binding free energy changes were analyzed by computational methods. As seen in Table 2, all of the mutations, except R97G for OXZ, R59Q for CHP, and R97G for CHP, should result in resistance due to the positive shift in binding free energy.

The resistance prediction results of PPO were validated in vivo, using site-directed mutagenesis and enzyme kinetic studies performed on PPO. We constructed mutant PPO genes, isolated the respective mutant proteins, determined their kinetic parameters via continuous fluorometric method, and compared the results with wild-type (WT) PPO. The three mutations could mostly induce resistance (uppermost 11.63-fold) for the five inhibitors with the exception of R59Q for CHP, R97G for OXZ, and R97G for CHP (Table 2). These outcomes were consistent with the computational studies.

CMS allowed us to further analyze the role of the individual thermodynamic parameters in the mechanism of resistance associated with the mutations. These data are presented as a histogram that compares the effect of the selected mutations in PPO on each parameter affecting the binding of the five inhibitors (Figure 3). R59Q and M368Q appear to function via the same resistance mechanism; they share the common characteristic that the decrease in the enthalpy contribution is mainly responsible for the decrease in binding affinity for the inhibitors. In contrast, R97G led to another mechanism, that the decrease in the enthalpy contribution was compensated by an increase in the entropic contribution. The replacement of

	M368Q	152.79	1.74	4.37	0.13	4.50	R

[a]Resistance fold (RF) = $K_{i,mutant}/K_{i,WT}$. RF > 1 means resistance, whereas RF ≤ 1 means no resistance. [b]$\Delta\Delta G = \Delta G_{MT} - \Delta G_{WT}$ calculated by CMS protocol. [c]Resistance prediction results. R means resistance, whereas N means no resistance.

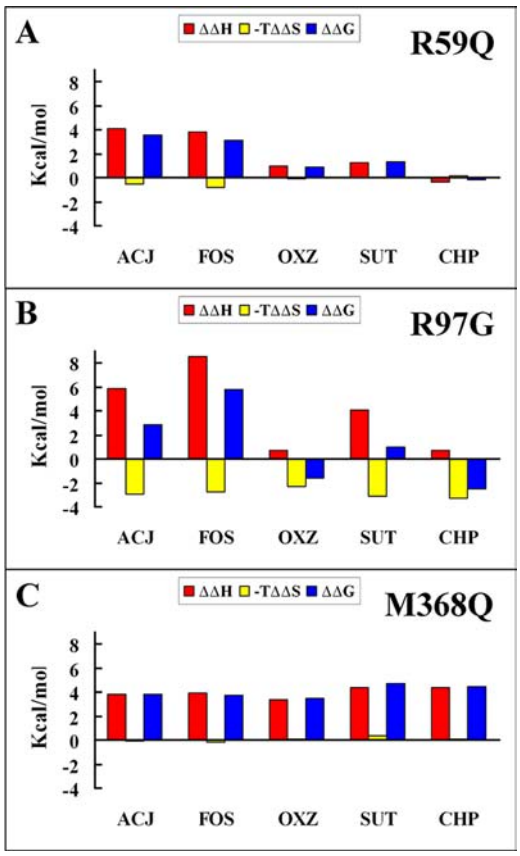

Figure 3. Thermodynamic representation of the resistance mechanism. The histogram means changes of enthalpy, entropy, and binding free energy of the five inhibitors in each mutant. Possible mechanisms of resistance were shown. (A) Resistance mechanism of R59Q. (B) Resistance mechanism of R97G. (C) Resistance mechanism of M368Q.

R97 with glycine could enlarge the mouth of the pocket and could improve the turnover of the inhibitors, which would favor the improvement in the conformational degrees of freedom of the inhibitors in the active site.[41] This structural change could cause an increase in conformational entropy, such that the loss of enthalpy would be offset.

However, R97G confers resistance for ACJ, FOS, and SUT, but not for OXZ and CHP. To explore why the R97G mutation could have such different effects, we further examined the binding models of the five inhibitors (Figure 2). According to a previous study, R97 was located in the pocket between the active site and the binding pathway of the substrate.[41] The inhibitors ACJ, FOS, and SUT can form important hydrogen-bonding interactions with R97 in WT PPO, but OXZ and CHP cannot. The replacement of the salt bridge functionality in R97 by a simple glycine caused ACJ, FOS, and SUT to lose more enthalpy contribution than did OXZ and CHP, which could induce resistance for ACJ, FOS, and SUT. But, the enthalpy loss was compensated by an increase in the entropy component of binding, thereby reducing the level of resistance. It is worth noting that R97G experienced a large enthalpy loss for FOS; such an enthalpy loss should result in over 100-fold rise in resistance if not for the entropic compensation. That is to say, the entropy increase due to the improvement of the conformational degrees of freedom can effectively reduce the resistance level.

The computational studies using the CMS protocol have led to a detailed understanding of the resistance mechanisms and the structure-resistance relation of PPO and five inhibitors associated with the target mutations. Computational simulations based on our developed 3D model of PPO−inhibitor binding structures, followed by resistance prediction, site-directed mutagenesis, and PPO activity assays, have led to a detailed understanding of PPO interaction with herbicides. The computationally determined mutation-caused shifts in the binding free energies are reflected by two resistance

dx.doi.org/10.1021/jf5018115 | J. Agric. Food Chem. 2014, 62, 7209−7215

mechanisms, which provide essential information for structure-based pesticide design. Our computational results demonstrated that the calculated entropy change seems to relate with the conformational degrees of freedom of the inhibitor in the binding pocket. That is to say, inhibitors designed to have more conformational flexibility in the binding site may inhibit both the WT and mutants of a targeted enzyme. The structural and mechanistic insights obtained from the present study provide a valuable base for rational design of novel PPO inhibitors.

fractionated using Sephadex LH-20 gel,[10] and the MW of each tannin fraction is determined based on depolymerization reactions. Estimating the MW of wine tannins using GPC requires the assumption that the hydrodynamic volumes of grape skin tannins equate to those of wine tannins at the same MW and that there is no interaction between the tannins and the gel media. The correlation between the results from GPC and mDP calculations can also be limited[14] as a consequence of low percent yield or differences in hydrodynamic volumes between the tannin sample and the grape tannins of the calibration curve.

Polymers can expand or contract in different solvents[16] and tannins in particular can be more condensed in water than in organic solvents and may change conformation in different hydroalcoholic solutions.[13] The hydrodynamic volumes of tannins in different wine-like conditions (pH 3.0−4.0, 10−15% aqueous ethanol) may therefore be very different to those measured using the GPC conditions. Given that wine tannin size can directly impact astringency,[2,3] it is important to determine if the relative tannin sizes determined using GPC, such as between aged and young wines tannins, are actually representative of relative tannin size in wine. For this reason, the MWs of a selection of tannins were measured using small-angle X-ray scattering (SAXS) with synchrotron radiation in a range of wine-like conditions and compared with those estimated using GPC and mDP. SAXS can be used to measure particle size and shape in a range of solutions[17,18] and has been previously used to measure tannins in aqueous ethanol solutions.[13] The size of macromolecules can be determined for a large range of particle sizes, from less than 1 kDa to several MDa and, although routinely used for model reconstruction from monodisperse systems of biomolecules (e.g., purified proteins),[17] the technique can be applied to the study of polydispersed systems. Previous experiments have measured changes in the MW of polydisperse grape and apple tannins with oxidation by comparing the SAXS forward scattering intensities with mDP,[6,12] highlighting the potential for using this technique for wine tannins. SAXS also provides information on the conformation of tannins in solutions,[19] providing an added advantage over GPC or mDP analysis.

Wine astringency is known to decrease in intensity with aging.[20,21] The underlying cause for this in unclear, and may relate to changes in tannin MW or conformation as no age-related trends have been observed in tannin concentration.[14] Studies that investigate tannin structure in aged wines have reported conflicting results, depending on the method used for analysis. Analyses comparing the mDP of tannins from younger and older wines have suggested that aged wine tannins are smaller than young wine tannins,[22,23] while GPC studies have reported that aged wine tannins are generally larger than younger wine tannins.[14,24] The difference in results produced from these two methods as well as the potential changes in the molecular dimensions of tannins with wine aging highlights the value in measuring aged and young wine tannins in wine-like conditions.

In this study, we determined the relative dimensions of wine tannin samples isolated from a 3 and a 7 year old Cabernet Sauvignon wine using SAXS in a range of wine-like matrixes, including different ethanol concentrations, pH, and ionic strengths. These results were then compared with those of the same wine tannin samples measured using GPC and mDP to assess the usefulness of each method for estimating the relative size of tannins in red wines. Results are also discussed with respect to the potential impact of tannin shape on wine astringency with aging.

MATERIALS AND METHODS

Chemicals. All solvents used were high-performance liquid chromatography (HPLC) grade, all chemicals were analytical reagent grade, and water was obtained from a Milli-Q purification system. Acetic acid (100%), acetonitrile, ethanol, formic acid (98−100%), and HCl (32%), were all purchased from Merck Australia (Kilsyth, VIC, Australia). Ascorbic acid, lithium chloride (LiCl), *N*,*N*-dimethylformamide (DMF), phloroglucinol, sodium acetate, tartaric acid, and sodium chloride (NaCl) were purchased from Sigma-Aldrich (Castle Hill, NSW, Australia).

Tannin Isolation and Fractionation. Tannins were isolated from two Australian Coonawarra Cabernet Sauvignon wines, aged 3 and 7 years, using Toyopearl HW-40F, as previously described.[4] Both isolated tannin samples were then fractionated using liquid−liquid separation with butanol and water as reported previously[4] to give six tannin samples: total tannin samples from each vintage (TT3 and TT7 for the 3 and 7 year old wine tannins, respectively), aqueous fractions from each vintage (Aq3 and Aq7) and butanol-soluble fractions from each vintage (Bu3 and Bu7). The aqueous fractions were more abundant than the butanol-soluble fractions for both vintages, with ratios of 3.6:1 (Aq/Bu) for the 3 year old tannin samples and 2.9:1 (Aq/Bu) for the7 year old tannin samples. Relative water-solubility of the tannin samples were determined using octanol/water assays as previously described.[14]

Tannin Molecular Weight Measurements Using Gel Permeation Chromatography and Depolymerization Reactions. Standard laboratory methods for determining average tannin molecular weight (MW) for each sample were performed using depolymerization reactions with phloroglucinol (phloroglucinolysis)[7] and gel permeation chromatography (GPC).[9] Briefly, for phloroglucinolysis, tannin solutions (25 μL, 10 g/L tannin in methanol) were added to phloroglucinol solution (25 μL, 100 g/L phloroglucinol in methanol with ascorbic acid (20 g/L) and 0.2 N HCl) to give final concentrations of 5 g/L tannin. Reactions were performed at 50 °C for 25 min, after which sodium acetate solution (70 mM, 150 μL) was added to neutralize the reaction. The cleaved subunits were analyzed using HPLC as previously described[7] to give the mean degree of polymerization (mDP, calculated from the proportion of extension to terminal subunits), percent yield (proportion of the tannin weight that was cleaved by acid hydrolysis), percent epigallocatechin subunits (% GC), and percent epicatechin gallate subunits (%ECG). The MW for each sample (MW_{mDP}) was calculated based on the mDP and subunit composition. GPC was performed as described previously[9] using a series of two PLgel columns (500 and 10^3 Å) with an isocratic solvent system of DMF solution (0.15 M LiCl, 1% v/v acetic acid, 5% v/v water in DMF). The retention time of 50% tannin elution of each sample (2 g/L tannin in 1:4 methanol/DMF) was compared with a calibration curve of preveraison grape skin tannins fractions[25] to give an average tannin MW (MW_{GPC}). Tannins are a mixture of polymers and thus the wine tannin samples were polydispersed with MW ranges within the 10−90 percentile range of 900 to 5900 g mol^{-1} for TT3 and from 1100 to 5800 g mol^{-1} for TT7, as measured using GPC.[9] The tannin subfractions were less polydispersed than the total tannin fractions with MW ranges from 1000 to 5000 g mol^{-1} for the butanol subfractions and from 1500 to 6000 g mol^{-1} for the aqueous subfractions.

Sample Preparation for SAXS Analysis. The tannin samples were prepared in 100% ethanol and in model wine solutions for small-angle X-ray scattering (SAXS) analysis. Model wine composition varied depending on the parameters investigated. For the experiments assessing the impacts of different ethanol concentrations, the model wine contained 2% v/v ethanol at pH 3.5 (adjusted with tartaric acid to a final concentration of 0.043 mM). The ethanol concentration was adjusted after tannin addition to give the final concentration range of 5, 10, 12, and 15% v/v ethanol in model wine. For experiments assessing the impacts of pH, the model wine contained 2% v/v ethanol

for a final concentration of 12% v/v ethanol after tannin addition. The pH was adjusted with tartaric acid at 0.08 mM and 0.01 mM for pH 3.0 and 4.0, respectively. For the ionic strength experiments, the model wine contained 2% v/v ethanol for a final concentration of 12% v/v ethanol after tannin addition. NaCl solution (0.5 M in model wine, pH 3.5) was added to give final concentrations of 25, 50, 100, or 200 mM NaCl. The ionic strength and pH experiments were performed only on the total tannin samples. Blank samples were prepared as the model wine solutions without tannins.

Wine tannin solutions were prepared in 100 μL volumes in 96-well plates at a range of concentrations (1, 2, 5, and 10 g/L). The plates were centrifuged (5 min, 2000 rpm), and the supernatant was transferred to clean 96-well plates prior to SAXS analysis. Tannin samples were first dissolved in ethanol to maximize solubility prior to addition into model wine solutions, however precipitation was observed in some solutions after centrifugation. The relative GPC peak areas of tannin solutions before and after centrifugation indicated that precipitation significantly impacted tannin concentration in Bu3, Aq3, and Aq7 in the 10g/L solutions at 5% ethanol, although there was no significant impact on the MW range of these samples. These samples were not included in the MW calculations as described in the next section.

SAXS Analysis and Data Processing. Small-angle X-ray scattering (SAXS) experiments were performed on the SAXS/WAXS beamline at the Australian Synchrotron (Melbourne, Australia).[26] The incident beam energy was 11.000 ± 0.005 keV (wavelength, λ = 1.0332 Å) with a corresponding scattering vector (q) ranged between 0.015 to 0.7 Å^{-1}, where $q = (4\pi \sin \theta)/\lambda$, and 2θ is the scattering angle. Experiments were performed at 25 °C using a Pilatus 1 M detector (DECTRIS, Switzerland). Samples were loaded using an automatic sample loader with a 2 × 96-well plate capacity (approximately 80 μL volume used per sample). Data collection involved recording successive frames (typically 10) of 2 s each per sample, and the multiple frames averaged as appropriate using ScatterBrain Analysis IDL v8.1 software (Australian Synchrotron) and subtracting the scattering recorded from the solvent blanks. Data were placed on absolute intensity scale using water as an intensity standard. The radiation exposure of the samples under these conditions did not result in sample degradation, as indicated by comparing scattering intensities of successive frames. The cleanliness of the capillary was periodically checked during system washing by monitoring intensity changes during water exposures.

SAXS data were analyzed using the ATSAS software package[27] to give forward scattering intensity, $I(0)$ and radius of gyration, R_g (using PRIMUS[28]), as well as the distance distribution function $P(r)$ (using GNOM[29]) for each tannin sample at each concentration. The $I(0)$ and R_g parameters were extracted from the data by the standard Guinier approach (where $qR_g < 1.3$ in all cases):[19]

$$I_{exp}(q) = I(0)\exp(-q^2 R_g{}^2/3) \quad (1)$$

The $I(0)$ values were normalized for tannin concentration, c, and subsequently averaged for the molecular weight (MW) calculations. Plots of $I(0)$ vs c (1, 2, 5, and 10 g/L tannin), were generally linear and indicated that the scattering results were concentration-independent since the correlation factor, R^2, was greater than 0.99 in most cases[30] (Supporting Information (SI) Table S1). R^2 values were less than 0.99 for Bu3, Aq3, and Aq7 at 10g/L in 5% ethanol (and at 10% ethanol for Aq7), and therefore these values were excluded from the MW calculations. The MW for each wine tannin sample was calculated by comparing the averaged $I(0)$ as a function of concentration ($I(0)/c$) at each ethanol concentration, pH, and ionic strength, with the ($I(0)/c$) values of a calibration curve of preveraison grape skin tannin fractions (MW range 1277 to 8996 g mol^{-1} as determined from depolymerization reactions) in wine-like conditions (12% v/v ethanol, pH 3.5). These were the same grape tannin samples as used in the GPC calibration.[25] This gave the calibration curve for the $I(0)/c$ values:

$$MW_{k.I/c}(\text{g mol}^{-1}) = 518\,396*(I(0)/c) \quad (2)$$

The averaged R_g values of the wine tannins were also compared with those of the grape tannin calibration curve to give a different MW measurement:

$$MW_{Rg}(\text{g mol}^{-1}) = 268.14*R_g \quad (3)$$

The MW of wine tannins was also calculated directly from the $I(0)/c$, independently of the calibration curve, using the equation as per Mylonas et al:[31]

$$MW_{\Delta\rho} = [N_A I(0)/c]/\Delta\rho_M{}^2 \quad (4)$$

where the Avogadro number, $N_A = 6.023 \times 10^{23}$ mol^{-1}. The scattering contrast per mass, $\Delta\rho_M = [\rho_{M.tannin} - (\rho_{solv}\, \upsilon)]r_0$, assumes that $\rho_{M.tannin}$ is similar to that of a flavan-3-ol monomer (3.19×10^{23} electrons/g calculated from the molecular formula and known molecular weight), and that the wine tannin density is 1.57 g/cm^3 as previously reported,[12,32] giving the tannin partial specific volume, υ = 0.637 cm^3/g. The solvent density for water, $\rho_{solv} = 3.34 \times 10^{23}$ e/cm^3 was used for tannins in aqueous solvents and that of ethanol, $\rho_{solv} = 2.68 \times 10^{23}$ e/cm^3 was used only for those samples in ethanol. The scattering length of an electron, $r_0 = 2.8179 \times 10^{-13}$ cm. Information on the conformation of the wine tannin samples was obtained from Kratky plot representations and from the distance distribution functions, $P(r)$, as calculated from the Fourier transformation of the scattering intensity.[19]

RESULTS AND DISCUSSION

Characteristics of Selected Wine Tannins. Wine tannins were isolated from a 3 and a 7 year old Cabernet Sauvignon wine and then separated into two fractions each, one water-soluble (aqueous fraction) and one butanol-soluble (butanol fraction) to give six wine tannin samples. The composition of each tannin sample was determined using phloroglucinolysis and subsequent HPLC analysis of the cleaved subunits (Table 1). This gave the mean degree of polymerization (mDP), proportion of epigallocatechin (%GC), and epicatechin gallate (%ECG) subunits, in addition to the percent yield (proportion of acid-labile interflavan bonds) of the reaction. The aqueous

fractions from both wines were larger (greater mDP) and contained more epigallocatechin subunits than the butanol fractions. The tannin samples isolated from the older wine contained fewer epicatechin gallate subunits and were less susceptible to the depolymerization reactions, with percent yields around half those of the tannin samples from the younger wine. This is likely to be a consequence of gradual oxidation and structural rearrangement reactions leading to intramolecular bond formation, as has been previously shown with grape and apple tannins,[6,12] as well as intermolecular interactions such as the incorporation of pigmented polymers.[4] The difference in water-solubility was demonstrated in the octanol/water partition coefficients (Log *P*) (Table 1). The tannins isolated from the older wine were more hydrophobic than those from the younger wine (−0.61 and −0.55 for TT3 and TT7, respectively), and the total tannin samples were more hydrophobic than the tannin fractions. This potentially suggested that some hydrophobic tannin species were removed from the fractionation process, however the benefit of fractionating the tannins was to enable the analysis of a range of chemically different wine tannins from the same starting wine. The aqueous fractions were more water-soluble than the butanol fractions, as expected.

Comparison of Relative Wine Tannin Sizes in Different Matrixes. Wines of different vintages (3 and 7 years old) were selected to compare wine tannin sizes from young and aged wines in different matrixes. Isolated tannins from each wine were separated into two fractions with distinctly different characteristics that were less polydispersed than the total wine tannins. This gave a range of tannin samples for molecular size analysis. Relative wine tannin sizes were determined using SAXS in 100% ethanol, which has been shown to be a good solvent for tannins,[16,32] and compared to more wine-like conditions: (5−15% ethanol, pH 3.0−4.0, and 2−200 mM NaCl). The forward scattering intensities of wine tannins in 100% ethanol indicated an absence of pronounced aggregation (Figure 1), which concurs with previous reports for grape and apple tannins.[16,32] It must also be noted that the greater $I(0)/c$ values for the tannins is 100% ethanol compared with in the hydroalcoholic solutions (Figure 1 and Table 1) is likely to be influenced by differences in solvent densities (ρ_{solv} = 3.34 × 10^{23} e/cm^3 for water and 2.68 × 10^{23} e/cm^3 for ethanol). This is corrected for in the MW calculations as noted in the next section. The aqueous tannin fractions were consistently larger than butanol fractions, and the aged wine tannins were generally larger than the younger wine tannins.

The major advantage of SAXS analysis over other techniques for tannin characterization is the potential to characterize macromolecules in a range of solvents. Polymer mixtures may expand or contract in different solvent conditions,[16] suggesting that the tannin characterization methods that calculate average MW from relative hydrodynamic volume, such as GPC, may be solvent-dependent. Wine astringency is known to decrease with increasing ethanol concentrations and with increasing wine pH[33] and this may relate to changes in tannin conformation in solution. The forward scattering plots for wine tannins in hydroalcoholic solutions showed aggregation, as indicated by large increases in the scattering intensities at low-*q* (Figure 1) for all measured tannin samples and at all concentrations. The extent of this scattering varied depending on solvent and sample, with tannin fractions from the older wine showing the greatest aggregation. The TT3 and Aq3 samples only aggregated at 5% ethanol, and the Bu3 sample showed some

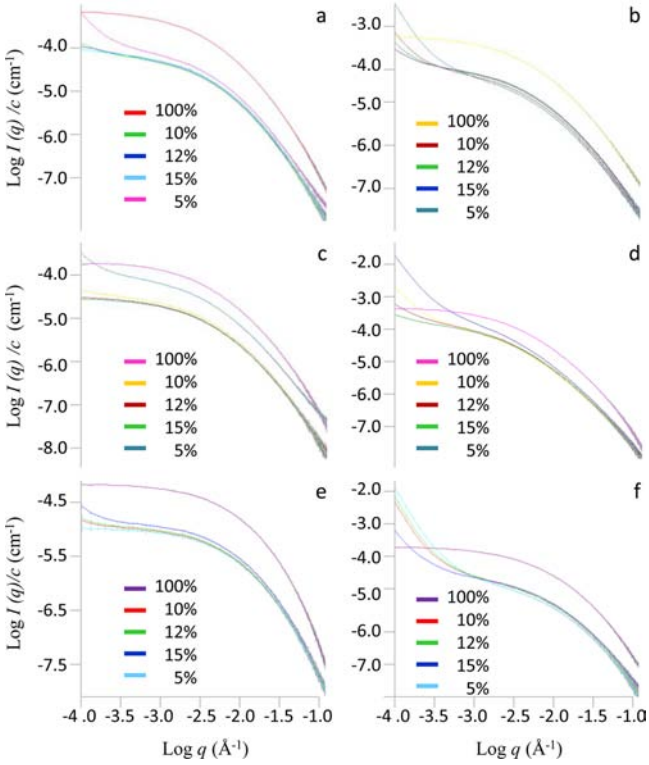

Figure 1. SAXS intensity plots, log $I(q)/c$ vs log q, at each ethanol concentration for (a) TT3; (b) TT7; (c) Aq3; (d) Aq7; (e) Bu3; and (f) Bu7.

aggregation at 15% ethanol. The TT7, Aq7, and Bu7 samples all aggregated in all hydroalcoholic solutions with increasing aggregation at decreasing ethanol concentration. In determining the R_g values for each sample, a shorter *q*-range was used to obtain a linear fit for the Guinier plots (within the qR_g < 1.3 limitation) to minimize the impact of aggregation on this measurement.[19] Some precipitation was observed at higher tannin concentrations (10 g/L) in 5% and 10% ethanol, and this was reflected in a decrease in linearity in the $I(0)$ vs c plots (SI Table S1). This was not the case in 12% ethanol, and these values were used for the MW comparisons as discussed in the next section.

The differences in aggregation between the aged and younger wine tannins are likely to be due to the greater oxidation of the tannins from the older wine, as observed from the comparatively lower percent yield in the phloroglucinol reactions (Table 1). Oxidized wine tannins reportedly have lower water solubility than "native" grape tannins, and are therefore more prone to aggregation in aqueous solutions.[12,32] This potentially contributes to the precipitation of tannins as wines age. The octanol/water partition coefficients (Table 1) also demonstrated that the tannin samples from the older wine were slightly more hydrophobic than the same fractions from the younger wine.

The R_g values were relatively consistent across the measured ethanol concentrations range for most tannin samples (Figure 2). Only the Aq7 fraction increased in R_g with a decrease in ethanol concentration which may relate to a change in tannin size, a change in the solvation layer around the tannin in more aqueous systems or, potentially, interference from aggregation.[13] Previous research has indicated that astringency intensity decreases with increasing ethanol (up to 15%) in

dx.doi.org/10.1021/jf405308m | J. Agric. Food Chem. 2014, 62, 7216−7224

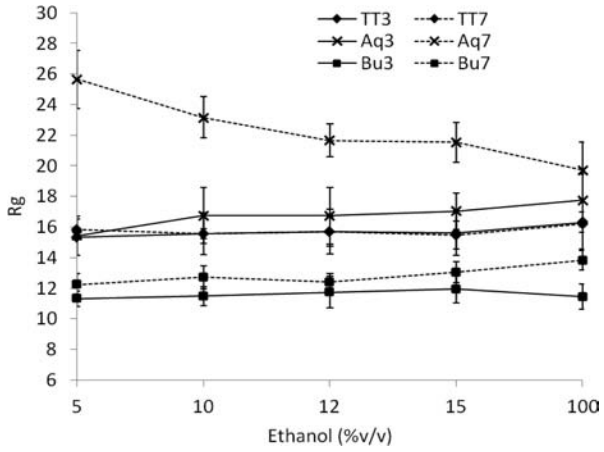

Figure 2. Impact of ethanol concentration on the radii of gyration (R_g, Å) for each tannin sample. Error bars represent the standard deviation of averaged replicates.

model wine solutions containing oliomeric tannins.[33] This study has shown that there is no change in tannin size over wine-like ethanol concentrations. The reported changes in astringency intensity with ethanol concentration may relate to changes in tannin aggregation rather than relative tannin size in solution. Wine pH and ionic strength have been shown to impact wine astringency and protein binding[33,34] and therefore the impact of these characteristics on the relative sizes of the total tannin fractions was also assessed. The $I(0)/c$ and R_g values of the total tannin samples showed no significant change in tannin dimensions across the ionic strength range from 0 to 200 mM NaCl (Figure 3a). Increases in ionic strength have been shown to augment the aggregation of grape and apple tannins[35] potentially due to changes in the solubility of tannins, since ionic strength did not directly alter the wine tannin molecular size. Wine pH also showed negligible impact on wine tannin dimensions with the R_g values remaining fairly consistent across the wine-like pH range (3.0 to 4.0) (Figure 3b). Wine pH has been previously correlated with model wine astringency, with solutions at pH 2.5 and 3.0 producing greater astringency intensity than model wines at 3.5 and 4.0,[33] and this is most likely to be a direct consequence of the wine matrix.

Comparison of Wine Tannin Molecular Weight Using Different Methods. The molecular weight of all wine tannin samples were compared using three different methods: SAXS analysis (from the forward scattering intensities ($I(0)/c$) and radii of gyration (R_g) values as compared to a standard curve, $MW_{k.I/c}$ and MW_{Rg}, respectively, and calculated directly from the $I(0)/c$, $MW_{\Delta\rho}$), GPC analysis (MW_{GPC}), and analysis of tannin subunits from depolymerization reactions (MW_{mDP}) (Table 2). The $I(0)/c$ and R_g of the tannin samples from the

[a]Depolymerization reactions (MW_{mDP}), gel permeation chromatography (MW_{GPC}) in methanol/DMF, and SAXS ($MW_{k.I/c}$ in 12% ethanol, $MW_{\Delta\rho}$ and MW_{Rg} in 12% and 100% ethanol). [b]Tannin MW calculated directly from $I(0)/c$: $MW_{\Delta\rho} = [N_A I(0)/c]/\Delta\rho_M^2$. [c]Tannin MW calculated from $I(0)/c$ using the calibration curve: $MW_{k.I/c} = 518\,396x$. [d]Tannin MW calculated from R_g using the calibration curve: $MW_{Rg} = 268.14x$.

SAXS analyses in 12% ethanol were compared with those of a calibration curve of fractionated preveraison grape skin tannins measured in 12% ethanol to give the average tannin MW values, $MW_{k.I/c}$ and MW_{Rg}, respectively. The MW_{Rg} values were also determined for the wine tannin samples in 100% ethanol for comparison, however differences in the scattering contrasts of ethanol and aqueous solutions prevented the same comparison for $MW_{k.I/c}$. Instead, MWs were calculated directly from the $I(0)/c$ values to give an independently determined MW of the wine tannins ($MW_{\Delta\rho}$) that corrected for the solvent contrast. For GPC, the retention times of the wine tannin samples (at 50% elution) in a methanol/DMF solvent system were compared to those of a calibration curve in the same solvent to give the average wine tannin MW (MW_{GPC}). The

	MW_{Rg}	0.7122	0.9084	0.9208	0.9255	0.9006	0.8894	

[a]Depolymerization reactions (MW_{mDP}), gel permeation chromatography (MW_{GPC}) in methanol/DMF, and SAXS ($MW_{k.I/c}$ in 12% ethanol, $MW_{\Delta\rho}$ and MW_{Rg} in 12% and 100% ethanol). [b]Tannin MW calculated directly from $I(0)/c$. [c]Tannin MW calculated from $I(0)/c$ using the calibration curve. [d]Tannin MW calculated from R_g using the calibration curve.

same grape-skin tannin fractions were used for the calibration curves in both the SAXS analysis and GPC, enabling a direct comparison between the results obtained in wine-like conditions with SAXS with those from the more widely used tannin characterization technique. The depolymerization reactions involved acid-catalysis of the tannin samples and HPLC analysis of the cleaved subunits to give the tannin subunit composition and mean degree of polymerization (mDP). These results were then used to calculate the average MW for each sample (MW_{mDP}).

The average MWs of all tannin samples as determined using GPC (MW_{GPC}), depolymerization reactions (MW_{mDp}), and with SAXS ($MW_{\Delta\rho}$, $MW_{k.I/c}$, and MW_{Rg}) are shown in Table 2. In all methods, the aqueous fractions (Aq3 and Aq7) were higher in MW than the total tannin fractions (TT3 and TT7), and the butanol-soluble fractions (Bu3 and Bu7) were much smaller. MWs derived from the SAXS data in 12% v/v ethanol were larger than those calculated from GPC analysis or depolymerization reactions (Table 2) indicating that the MWs of wine tannins in wine may be underestimated by the standard methods, particularly for aged-wine tannins. The solvation layer around the tannins in hydroalcoholic solutions would also have contributed to the relative tannin size as measured using SAXS, increasing the calculated MW.[13]

The SAXS-determined MWs and MW_{GPC} values indicated that the tannin samples from the older wine were larger or similar in size to the younger wine tannins. The MW_{mDP} values, however, suggested that the older wine tannins were smaller than the younger wine tannins. This may have be due to the lower percent yield of the older tannin samples (Table 1), which meant that only a very small proportion of the tannin was analyzed (≤15%) and this limited the number of extension subunits that could be cleaved by acid-catalysis. Furthermore, the preveraison grape skin tannin calibration curve used in the SAXS and GPC calculations may have also overestimated the average wine tannin MWs due to differences in spatial distribution between the grape tannin fractions and the wine tannins. The $MW_{\Delta\rho}$ values in 12% ethanol were larger than the MWs determined from the calibration curve ($MW_{k.I/c}$ and MW_{Rg}), suggesting that any differences in dimensions between the wine tannins and the grape tannins had only a limited impact on the determined wine tannin MWs. The calculations used for the $MW_{\Delta\rho}$ values presumed a tannin density of 1.57 g/cm^3 as previously reported for grape seed tannins;[12,32] however, the actual density of wine tannins may be greater given the disparity between these values and those determined with other methods. Further research is required to more accurately determine this value.

The extent to which the determined MWs from each method correlated for the wine tannin samples was measured as R^2 values from correlation plots (Table 3). The MW_{GPC} and MW_{mDP} were compared with the MWs determined using SAXS in 12% ethanol for an example of a wine-like solution and in 100% ethanol to ensure that the aggregation of tannins in hydroalcoholic solutions did not greatly interfere with the correlations. Correlations were strongest between the $MW_{\Delta\rho}$ and $MW_{k.I/c}$ in 12% ethanol (R^2 = 0.9998), providing good support for the MWs derived from the calibration curves, including the MW_{Rg} values in 12% ethanol, which also correlated well with the $MW_{\Delta\rho}$ values (R^2 = 0.9736). The MW_{GPC} values correlated most strongly with the $MW_{\Delta\rho}$ 100% ethanol (R^2 = 0.9866). The strong correlation between the GPC values and those in from both $MW_{\Delta\rho}$ and $MW_{k.I/c}$ in 12% ethanol (R^2 > 0.88) demonstrated that wine tannin MWs as determined with GPC do give a good indication of relative tannin molecular size in wine. The MW_{mDP} values had the weakest correlation with the SAXS methods ($R^2 \approx 0.6$ for MWs determined in 12% ethanol), further highlighting the differences produced from determining tannin MW from average polymer chain length and from relative tannin size.

Overall, there was no significant impact of different wine-like parameters on wine tannin dimensions across the measured ethanol concentration, ionic strength, and pH ranges. Further, the strong correlation between the determined tannin MW in wine-like matrixes as compared with GPC emphasizes that GPC is a useful method for comparing the relative MW of tannins in young and aged wines.

Estimation of Wine Tannin Conformation in Solution. One of the advantages of analyzing samples with SAXS over other techniques for characterizing wine tannins is the potential to obtain information on the conformation of macromolecules in solution. GPC has the advantage over mDP calculations by producing separation profiles, which indicate the proportions of the tannin broadly distributed around the nominal classes of "high", "medium", and "low" MW range, but this does not indicate the shape of the tannin polymer complex. Tannin conformations in solution were estimated for all samples in 100% ethanol, to ensure the complete dissolution of tannin molecules, using a Kratky plot ($q^2\ I(q)$ vs q) representation of the SAXS data and from the real-space distance distributions, $P(r)$. The Kratky plots (Figure 4) for each sample indicated that the tannins were compact but extended structures.[19] Distance distribution functions (Figure 5) indicated that the

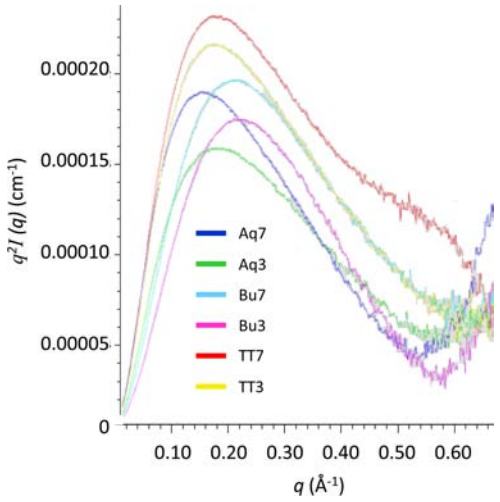

Figure 4. Kratky plots (q^2 $I(q)$ vs q) for each tannin sample in 100% ethanol.

wine tannin samples were not spherical and that the configuration more closely related to elongated ellipsoid structures.[19,36] The $P(r)$ for the wine tannin samples in all hydroalcoholic solutions (data not shown) resembled the elongated ellipsoid conformations that were observed in 100% ethanol.

In summary, the relative molecular dimensions of a range of wine tannins were measured in wine-like conditions using SAXS ($I(0)/c$ and R_g) and the calculated molecular weights (MWs) were compared to the more commonly used methods of GPC (MW_{GPC}) and depolymerization reactions (MW_{mDP}). The MWs determined with SAXS in 12% ethanol correlated well with the MW_{GPC} values, which suggests that GPC can be used to give a good indication of the average MWs of tannins in wines. Variations in wine-like solvent composition, including ethanol concentration, ionic strength, and pH, did not vary the measured tannin dimensions of all samples in solution, although tannin aggregation was influenced by ethanol concentration in the hydroalcoholic solutions. The conformations of the wine tannins resembled elongated ellipsoids in all tested solvent compositions. To our knowledge, SAXS measurements have not previously been attempted for wine tannins. Further research is needed to understand how tannin structures change with wine aging and how tannin aggregation may alter the perceived astringency of red wine.

[a]The corresponding gene expression levels in RPKM are provided for each enzyme. [b]Enzymes in bold represent ones that are not expressed at day 60 of lactation, but low expression of these genes has been detected at earlier stages of lactation (15 and 30 days). [c]Enzymes that do not show expression in milk, but expression data shows the presence of other enzymes that have a similar activity and are expressed.

occurs when samples are frozen. The stage of lactation of the first mother was 3 months and that of the second was 4 months. The mothers providing this milk were instructed to cleanse each breast with water and then use an electronic pump to collect a pool of milk from both breasts. The samples were then stored in the subjects' freezers and delivered to the laboratory on ice where they were stored at −80C.

Sample Preparation. Peptides were extracted from human milk according to the method of Dallas et al.[13] Briefly, 200 μL of each milk sample was thawed on ice and combined. To remove milk fat globules, the milk was centrifuged at 3000*g* for 10 min and the skim infranate was extracted. Centrifugation was repeated on the skim infranate to remove any remaining visible lipid layer. Proteins were then precipitated with the addition of 400 μL of 200 g/L trichloroacetic acid. Samples were vortexed briefly and then centrifuged at 3000*g* for 10 min, and the peptide-containing supernatant was collected, leaving the precipitated protein. This precipitation was repeated for a total of three times. Trichloroacetic acid, salts, oligosaccharides, and lactose were then removed from the peptides by C18 reverse-phase preparative chromatography. Contaminants were eluted with water, and peptides were then eluted with 80% acetonitrile (ACN)/0.1% trifluoroacetic acid (v/v). The peptide solution was then dried down in a vacuum centrifuge at 37 °C. After drying, the sample was rehydrated in 40 μL of nanopure water for MS analysis.

MS Analysis of Human Breast Milk Peptides. Peptides were analyzed via nanoliquid chromatography chip quadrupole time-of-flight tandem MS (Agilent, Santa Clara, CA, USA). Two microliters of sample was injected for each run onto the C18 reverse-phase nanochip. The nanopump flow was 0.3 μL/min, and the capillary pump flow rate was 3 μL/min. Peptides were eluted with the following gradient of solvent A (3% ACN/0.1% formic acid (FA) (v/v)) and solvent B (90% ACN/0.1% FA (v/v)): 0−8% B from 0 to 5 min, 8−26.5% B from 5 to 24 min, 26.5−100% B from 24 to 48 min, followed by 100% B for 2 min and 100% A for 10 min (to re-equilibrate the column). The instrument was run in positive ionization mode. Data collection thresholds were set at 200 ion counts or 0.01% relative intensity for MS spectra and at 5 ion counts or 0.01% relative intensity for MS/MS. Data were collected in centroid mode. The drying gas was 350 °C, and flow rate was 3 L/min. The required chip voltage for consistent spray varied from 1850 to 1920 V. Automated precursor selection based on abundance was employed to select peaks for tandem fragmentation with an exclusion list consisting of all peptides identified in previous analyses in this study. The acquisition rate employed was 3 spectra/s for both MS and MS/MS modes. The isolation width for tandem analysis was 1.3 m/z. The collision energy was set by the formula (slope) × $(m/z)/100$ + offset, with slope = 3.6 and offset = −4.8. Five tandem spectra were collected after each MS spectrum, with active exclusion after 5 MS/MS for 0.15 min. Precursor ions were selected only if they had at least 1000 ion counts or 0.01% of the relative intensity of the spectra. Mass calibration was performed during data acquisition based on an infused calibrant ion with a mass of 922.009789 Da.

Agilent Mass Hunter Qualitative Analysis Software (Santa Clara, CA, USA) was used to analyze the data obtained. Molecules identified in the spectral analysis were grouped into compounds by the Find by Molecular Feature algorithm, which groups together molecules across charge state and charge carrier. All tandem MS from each data file were exported as Mascot Generic Files (.mgf) with a peptide isotope model and a maximum charge state of +9.

Peptide identification was accomplished using both the MS-GFDB (via a command-line interface) and X!Tandem (using the downloadable graphical user interface). The human milk library used in both searches was constructed on the basis of a query to the Uniprot database. The query returned only proteins from *Homo sapiens* and at least one of the following: "tissue specificity" keyword "milk" or "mammary", "tissue" keyword "milk" or "mammary", or gene ontology "lactation". This query returned a list of 1472 proteins. These were exported to FASTA file format. For MS-GFDB, peptides were accepted if p values were ≤0.01 corresponding to confidence levels of 99%. No p values exist in X!Tandem, so a closely related statistic, e value, was used for the X!Tandem search. The e value thresholds selected were again 0.01, reflecting 99% confidence. In both programs, masses were allowed 20 ppm error. No complete (required) modifications were included but up to four potential modifications were allowed on each peptide. Potential modifications allowed were phosphorylation of serine, threonine, or tyrosine and oxidation of methionine. A nonspecific cleavage ([X]|[X]) (where "X" is any amino acid) was used to search against the protein sequences. For MS-GFDB, the fragmentation method selected in the search was collision-induced dissociation and the instrument selected was time-of-flight. For X!Tandem, there was no option for fragmentation type and instrument selection. Because the instrument did not always select the monoisotopic ion for tandem fragmentation, isotope errors were allowed (allowing up to one C13). No model refinement was employed in X!Tandem.

Enzyme Prediction. The web-based software EnzymePredictor[14] was employed to evaluate and predict which enzymes most likely contributed to cleavage of human breast milk proteins (http://bioware.ucd.ie/~enzpred/Enzpred.php). Enzymes were classified on the basis of their total number of performed cleavages, and they were evaluated on the basis of their odds ratio (OR; see Table 1), which is an indicator of their degree of participation in the hydrolysis of the proteins. The OR values indicate that certain enzymes are over-represented and others under-represented. The following information was also collected from EnzymePredictor: number of times an enzyme could have cleaved within the current peptides, total number of proteins cleaved by each enzyme, total number of cleavages performed by an enzyme on the C- and N-termini.

Expression Profiling of Human Milk. *Fresh Milk Sample Collection.* Fresh milk samples were obtained from three healthy females on days 4, 15, 30, and 60 postpartum who gave birth to a term infant (>37 weeks of gestation). In the early morning period, the donor manually pumped one breast until emptied into a collection bag, which was immediately delivered on cold-packs to the laboratory for processing. The Institutional Review Board of University of California, Davis, approved the project.

RNA Extraction for Gene Expression Studies. Somatic cells were pelleted by adding 50 μL of 0.5 M ethylenediaminetetraacetic acid to 20 mL of fresh milk and centrifuged at 2000*g* at 4 °C for 10 min.[15] The pellet of cells was washed with 10 mL of phosphate-buffered saline at pH 7.2 and 10 μL of 0.5 M ethylenediaminetetraacetic acid (final concentration = 0.5 mM) and filtered through sterile cheesecloth to remove any debris. The cells were then centrifuged again at 2000*g* at 4 °C for 10 min. The supernatant was decanted, and RNA was extracted from the milk somatic cell pellet using Trizol (Invitrogen, Carlsbad, CA, USA) according to the manufacturer's instructions. RNA was quantified by an ND-1000 spectrophotometer (Fisher Thermo, Wilmington, MA, USA), and the quality and integrity were assessed by the spectrophotometer 260/280 ratio, gel electrophoresis, and capillary electrophoresis with an Experion Bioanalyzer (Bio-Rad, Hercules, CA, USA).

RNA Sequencing and Data Analysis. Gene expression analysis was conducted on fresh milk samples collected on days 4, 15, 30, and 60 postpartum by RNA sequencing (RNA-Seq). Messenger RNA was isolated and purified using an RNA-Seq sample preparation kit (Illumina, San Diego, CA, USA). The fragments were purified and sequenced at the UC Davis Genome Center DNA Technologies Core Facility using the Illumina Genome Analyzer (GAII) and Illumina HiSeq 2000. Sequence reads were assembled and analyzed in RNA-Seq. Expression analysis was performed with the CLC Genomics Workbench 6.0 (CLC Bio, Aarhus, Denmark). Human genome, GRCh37.69 (ftp://ftp.ensembl.org/pub/release-69/genbank/homo_sapiens/), was utilized as the reference genome for the assembly. Data were normalized by calculating the "reads per kilobase per million mapped reads" (RPKM)[16] for each gene and annotated with ENSEMBL human genome assembly (55203 unique genes).

RESULTS AND DISCUSSION

This project aimed to determine the enzymes responsible for the cleavage patterns identified in milk, examine each enzyme's contribution to the hydrolyses of human milk proteins, and clarify whether these enzymes are expressed in milk or enter milk from other sources.

A novel MS-based peptide search platform using an iterative searching strategy detected a variety of peptides in minor abundances in pooled human breast milk samples.[13] The peptides extracted and identified for the present study were analyzed using EnzymePredictor.[14] The results of this analysis are presented in Table 1. The enzymes are ordered on the basis of their total number of cleavages, from those that have cleaved extensively to those that are predicted to have cleaved one residue. As discussed in the interpretation of EnzymePredictor,[14] the enzymes with a combined high number of total cleavages performed and a high odds ratio are the enzymes that are most likely active in the milk.

Expression profiles from samples of human breast milk were established as the means to investigate if the predicted enzymes originate from the mammary epithelial cells or they enter milk from other sources, such as blood. The samples that were obtained for analysis for peptide detection via MS were pooled from mature milk samples from two mothers, both 3 months postpartum, whereas that of expression data was of 2 month postpartum milk.

Major Cleavage of Proteins in Human Milk Is at Trypsin and Plasmin Target Sites. The natural cleavages of milk proteins showed a strong enrichment for cleavage after K or R, both consistent with plasmin and trypsin cleavage (Tables 1 and 4).

The presence of plasmin, an enzyme that plays a major role in the proteolytic breakdown of blood clots, has been previously reported in milk,[1] but its contribution to human milk proteolytic hydrolysis is unknown. This study found that plasmin potentially cleaved 320 peptides (Figure 1; Table 1)

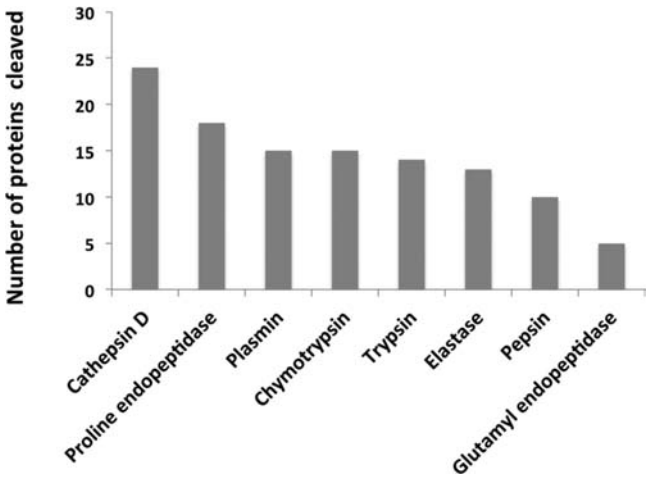

Figure 1. Representation of the total number of cleaved milk proteins per predicted enzyme. Each enzyme name on the *X*-axis is plotted against the total number of proteins it cleaves on the *Y*-axis.

derived from 15 milk proteins (Table 2). Anionic trypsin's presence in human milk was initially identified by Monti et al. and Borulf et al.[3,4] Borulf et al. showed that trypsin's presence in milk is likely in complex with IgA. Whether this enzyme contributes to the hydrolysis of human milk proteins remains unknown.

The two proteins most affected by potential plasmin or trypsin digestion were polymeric immunoglobulin receptor (32 cleavages of peptides) and β-casein (89). Other hydrolyzed proteins included α_{S1}-casein (11), osteopontin (18), butyrophilin subfamily 1 member A1 (15), and κ-casein (7). These analyses found that plasmin cleaves an androgen receptor that trypsin failed to cleave (Q9UN21; Tables 2 and 3). Butyrophilin subfamily 1 member A1 is part of the milk fat globule membrane. Thus, the low number of peptides detected from this protein might be due to the centrifugation for the removal of the milk fat globules. Trypsin can typically not cleave if the K or R is followed by a P, which makes the androgen receptor better fit the plasmin pattern (Table 4). This result would suggest that the cleavage tends to follow the specificity of plasmin more consistently than that of trypsin.

Table 4. Enzyme Specificity for Plasmin and Trypsin

	cleavage pattern						
enzyme	P4	P3	P2	P1	P1′	P2′	ref
trypsin	–	–	W	K	P	–	22
	–	–	M	R	P	–	22
plasmin	–	–	–	K or R	–	–	23

However, there are too few cleavages representing K or R followed by P (only one in our case) to disambiguate between plasmin and trypsin activities in the milk.

Enzymes Cleaving Hydrophobic Target Sites: Elastase, Cathepsin D, Pepsin, and Chymotrypsin. Whereas the active form of cathepsin D is found in bovine milk,[5] the major form of this enzyme in milk is the inactive zymogen, procathepsin D.[17] In this study, cathepsin D was found to be active in human milk (Table 1), cleaving 130 times. Cathepsin D hydrolyzed the highest number of milk proteins (24 milk proteins) compared to the other enzymes present in milk (Tables 1 and 5; Figure 1). Although the total number of times cathepsin D performed a cleavage is high (130 total cleavages), most of these are located in two proteins: β-casein with 78 cleavages and polymeric immunoglobulin receptor with 21 cleavages. Interestingly, both of these proteins have also been the most digested ones with all five top predicted enzymes.

A high number of potential cleavage sites was predicted for cathepsin D (846; Table 1), which were not observed in the peptide results, with an odds ratio below 1. This failure to produce predicted peptides could be due to the positioning of a subpopulation of these residues in regions difficult for the enzyme to access due to structural constraints. This structural inhibition is more likely for cathepsin D sites, because many potential cleavage sites are strongly hydrophobic, and hydrophobic regions are usually buried within the structured regions of proteins.

Elastase is another enzyme predicted to be active in human milk. Elastase is known to be a major proteinase in polymorphonuclear neutrophils (PMNs), which are phagocytic cells that destroy infectious agents in humans.[18] Elastase activity has been detected in PMNs recovered from milk during experimentally induced mastitis.[19] There is substantial overlap between the cleavage sites of elastase and cathepsin D, and again there are a large number of sites (563) interior to the peptides that were not cleaved. Elastase potentially performed 90 total cleavages of milk peptides (Table 6) over 13 proteins. The proteins that elastase cleaved the most are β-casein (41 cleavages of unique peptides) and polymeric immunoglobulin receptor (25 cleavages of unique peptides). No traces of elastase activity were observed on κ-casein (Table 6), and only one cleavage was observed for cathepsin D (Table 5). This reflects the similar, but not identical, cleavage patterns between elastase and cathepsin D. To resolve the specificity, the number of sites that were cleaved in common between both was determined (60 cleavages of unique peptides) or asa were those specific to only one (69 for cathepsin D of unique peptides, and 28 for elastase of unique peptides). This pattern suggests a role for both enzymes in human milk digestion prior to infant consumption.

Two other enzymes with hydrophobic targets, pepsin and chymotrypsin, are consistent with a number of digestion sites in addition to those digestible by cathepsin D and elastase. Only

Table 5. Human Milk Proteins Found To Have Been Digested by Cathepsin D[a]

protein name	Uniprot ID and access name	total no. of cleavages performed

[a]The proteins are ordered on the basis of the number of cleavages that trypsin has performed on each. Here we considered only the number of peptides that are unique; if a peptide was not unique, we considered only one copy of the peptide. Proteins exclusively found in milk are presented in bold.

21 of the 75 total peptide terminal cleavage sites of unique peptides that are predicted to be performed by chymotrypsin are common cleavages with elastase and cathepsin D. For pepsin, only 38 of the 72 cleavages sites predicted from the unique peptides are shared with elastase and cathepsin D. Furthermore, only 16 peptide terminal cleavage sites are shared between both pepsin and chymotryspin. These findings indicate the first support that pepsin- and chymotrypsin-like activities are present in human breast milk (Table 1).

Examination of Gene and Protein Expression Profile of Proteases in Human Milk. Previous work has suggested that plasmin is found in milk but that it originates from blood.[20] This study tested if the enzymes responsible for the observed peptide fragments are produced in the mammary gland or migrate into milk from other origins. Gene expression analysis was carried out for human milk according to the procedure used for bovine milk[15] (Table 1). The expression was analyzed for days 4, 15, 30, and 60 of lactation. For consistency purposes, day 60 gene expression was determined; however, we also took into account the expression levels for the other days of lactation to build Table 1, which shows the possibility of expression of an enzyme at different stages of lactation. The results show that very few of the proteolytic enzymes described in Table 1 are expressed in the mammary gland at these time points (Table 1). In agreement with previous literature, no gene expression of plasmin was detected in the milks. Moreover, no expression was observed for the intestinal enzyme trypsin.

Cathepsin D was highly expressed (365 RPKM, Table 1). Elastase, however, was not expressed in the mammary epithelial cells (Table 1). As mentioned above, the presence of active elastase in milk may be explained by its presence in PMNs. We would expect the vast majority of PMN cells to be pelleted by the centrifugation and, thus, would not participate in any degradation of the milk proteins after centrifugation (see Materials and Methods). However, PMN can secrete elastase

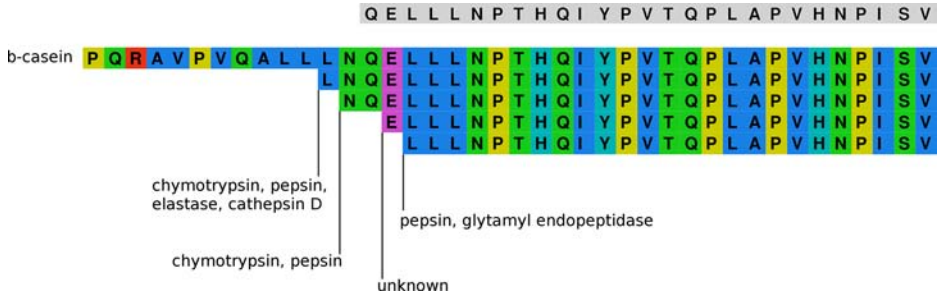

Figure 2. Illustration of antimicrobial-like peptides released in vivo from β-casein in human milk. The peptide QELLLNPTHQIYPVTQPLAPV-HNPISV shown at the top of the figure in gray has been discovered to be an antimicrobial peptide.[21] This peptide is found at the C-terminus of β-casein (positions 199−225). Four overlapping peptides found to be released in vivo in human milk are represented under the β-casein sequence. The in vivo cleavage positions are indicated with gray lines. The enzymes predicted to be responsible for these cleavages are presented beside the gray lines.

while still within the mammary gland, and the predicted elastase activity may derive from it.

Other Predicted Proteases That Were Also Expressed in Human Milk. Most of the other predicted enzymes have a low number of total cleavages, making it difficult to fully support their presence in milk (Table 1; total cleavages $\leq$ 44). Interestingly, some of these enzyme activities predicted in milk seem to be expressed in matching proteases. On the basis of a relatively specific cleavage site not shared by other proteases in these analyses (cleaves after E; with 76 cleavages in total), we predicted a glutamyl endopeptidase-like activity. Transcripts for glutamyl endopeptidase were, however, not detected in mammary epithelial cells. A glutamyl endopeptidase-like protease (proteasome subunit β type-3, PSMB3) is, however, highly expressed (75.9 RPKM; Table 1). This result may explain the high number of cleavage sites (930) predicted to be due to a glutamyl endopeptidase-like enzyme. Indeed, this glutamyl endopeptidase-like protease may have a more specific cleavage pattern explaining the many residues containing glutamic acid (E) that it did not cleave, as this cannot be accounted for by a structural bias, because the charged glutamic acids are not found buried in the core of the proteins. Although the gene expression of a glutamyl endopeptidase (called "a disintegrin and metalloproteinase with thrombospondin motifs 4" (ADAMTS4) was detected, its potential cleavage site, E'[AS], is cleaved only eight times in the data set. Thus, there is no indication for this enzyme playing a role as the major glutamyl endopeptidase activity in milk.

Proline-endopeptidase was found to be expressed in milk (5.52 RPKM; Table 1). Proline-endopeptidase is responsible for the cleavage of 45 residues covering a total of 18 milk proteins (Table 1; Figure 1).

In Vivo Release of Antimicrobial Peptides in Human Milk. Milk proteins may carry encrypted functional peptide sequences that, when released by enzymes from the intact protein, help in the protection and development of the neonate.[12] However, without in vivo results, these concepts remain unproven. This study identified four peptides that overlap (two extra or fewer amino acids on the N-terminus of the peptide) with a known antimicrobial peptide that has been reported previously in the literature.[21] This peptide is present at the C-terminus of β-casein (Figure 2). These four overlapping peptides are naturally released in human milk via the action of several enzymes, including cathepsin D and elastase (Figure 2). The overlapping peptides most likely carry the antibacterial activity, as the amino acid additions compared to the literature-defined sequence are unlikely to abolish the antimicrobial activity of these sequences.

Uneven Distribution of Enzyme Activity in Human Milk. To measure the enzyme activity, we considered the unique cleavages of each (i.e., if an enzyme cleaves out the same peptide from the parent protein multiple times, we will consider this to be only one unique cleavage). This measure highlights more the range of cleavages of an enzyme and makes it possible to compare it with other enzyme ranges rather than comparing its ability to cleave many times the same peptides. Consequently, this measure does not take the abundance of the proteins into account. Using this approach, we find that two proteins, β-casein and polymeric immunoglobulin receptor, show the highest susceptibility to the milk enzyme activity, as shown by the large number of fragments found from these two proteins. β-Casein is a milk-specific protein expressed during lactation. Interestingly, the other two milk-specific proteins, α_{S1}-casein and κ-casein, show little digestion susceptibly within the mammary gland. The possibility of protein structural disorder being the source of variability in degradation susceptibility among these proteins is not supported by these results, as κ-casein and α_{S1}-casein are also highly disordered proteins. The K and R residues are those that show the most susceptibility for the cleavages observed in human milk proteins. However, no enrichment of these amino acids was found in β-casein versus α_{S1}-casein or κ-casein (14 K and R sites in β-casein; 16 in α_{S1}-casein; and 13 in κ-casein). In fact, there are even fewer K and R in β-casein over the sequence length compared to α_{S1}-casein or κ-casein, arguing that this is not the driver behind β-casein susceptibility, nor is it for polymeric immunoglobulin receptor (6% in β-casein, 9% in α_{S1}-casein, 8% κ-casein, and 10% in polymeric immunoglobulin receptor). On the other hand, post-translational modifications may also explain these variations in susceptibility of proteins to degradation. Indeed, large modifications on proteins may prevent enzymes from reaching their target site. However, investigating the potential modification sites using Uniprot shows that all of the casein proteins are slightly/equivalently modified (in terms of numbers of glycosylations and phosphorylations).

The other major milk-specific proteins that have not been affected are α-lactalbumin and lactoferrin. No peptides from these proteins were detected despite the fact that plasmin, trypsin, cathepsin D, and elastase were all predicted to cleave both of these proteins. It is perhaps the particular structure and post-translational modifications of α-lactalbumin and lactoferrin that prevented the enzymes from cleaving them.

Although cathepsin D is highly expressed in milk (Table 1), it does not show a high effectiveness in cleaving milk proteins. This lower cleavage rate may be because cathepsin D is most effective at a more acidic pH (pH 5 for cathepsin D), which is different from the more neutral milk pH.

Independent studies have shown the existence and activity of some enzymes in milk, but the extent to which these enzymes are active relative to each other remained unknown. Likewise, whether or not these enzymes are created in the mammary epithelial cells was unclear. The enzymes that are active in human milk and responsible for protein digestion prior to entry into the infant's digestive system were determined. Using a combination of bioinformatics, peptidomics, transcriptomics, and literature results, we showed that milk begins to be digested even before infant consumption and that this digestion is mainly carried out by four proteolytic enzymes: plasmin, a trypsin-like enzyme, elastase, and cathepsin D (Tables 1−3, 5, and 6). Among these four enzymes, only cathepsin D and elastase are expressed in milk, with elastase showing only weak expression at days 15 and 30 and no expression after that (Table 1). Activity and expression of chymotrypsin and pepsin-like activity were also seen (Table 1). This finding is surprising, given that these enzymes have never been reported in human breast milk. Other enzymes that this analysis predicted from activity and expression are glutamyl endopeptidase and proline endopeptidase (Table 1).

Interestingly, plasmin, trypsin, elastase, and cathepsin D cleave the casein proteins (α_{S1}-, β-, and κ-casein) to various extents. Our novel MS-based peptide search platform using an iterative searching strategy to detect peptides in minor abundances did not detect peptides resulting from α-lactalbumin. Plasmin, a trypsin-like enzyme, elastase, and cathepsin are predicted to cleave this protein, yet none of the predicted peptides could be detected. The mechanism causing this protein selectivity of digestion remains unknown.

We know very little about proteolytic enzyme activity in human milk, which makes the problem of humanizing milk formulas even harder. The work we have carried out here sheds light on the different enzymes we find in human milk and the relative contribution of each of them, in terms of the release of unique peptides, to cleaving milk proteins. The example illustrated in Figure 2 of a known antimicrobial activity being released illustrates how enzyme activity in human milk may be playing a much greater role than previously anticipated, and fully clarifying this role is key to understanding infant needs.

ment and, especially, synthesize organic compounds via photosynthesis. However, the functional soybean sprouts should be germinated in artificial dark environment and without any external nutrients except their storage material.[3,4] Up to now, little information is available on the stress responses of soybeans germinating under dark conditions and their response at the proteome level in particular. Identification of distinct proteins has contributed to understanding of the molecular mechanism adopted by soybeans in response to stress, but the regulatory mechanisms of that operation in divergent organs are still unknown without comprehensive organ-specific proteome analyses.

Based on the aforementioned issues, in this study, proteomic responses of dark germinating soybean noncotyledons (hypocotyl and radicle) and cotyledons to NaCl stress, combined with NaCl and AG treatments, was investigated. The objective was to reveal the organ-specific defense strategy, the role of endogenous PAs, and the adaptive mechanisms of dark germinating soybeans against salt stress via identification of the differentially salt-induced endogenous PA-mediated and organ-specific proteins.

MATERIALS AND METHODS

Plant Growth Conditions. Dry soybean seeds (*Glycine max* L. cultivar *Yunhe*) were sterilized, washed, and steeped with distilled water at 30 ± 1 °C for 4 h. The soaked seeds were then placed in a bean sprouting machine to germinate in a dark incubator at 30 ± 1 °C with water containing the following additives: (A) CK, deionized water; (B) NaCl, 50 mM NaCl; (C) NaCl−AG, 50 mM NaCl and 2.5 mM AG. The culture solution was replaced every 1 day. Three independent biological experiments were performed, and 4 days after treatment, the cotyledons and noncotyledons (hypocotyl and radicle) were carefully collected and frozen in liquid nitrogen until analysis.

Malondialdehyde (MDA) Content Determination. The extent of lipid peroxidation in terms of MDA formation was measured following the method of Madhava and Sresty.[16]

GABA and Free PA (*f*PAs) Content Determination. GABA and *f*PA contents were analyzed as described by Yang et al.[11]

Protein Extraction and Two-Dimensional Polyacrylamide Gel Electrophoresis (2-DE). To minimize errors, 10 cotyledons and noncotyledons (hypocotyl and radicle) from ten germinated soybeans, respectively, were pooled for each biological repeat sample. Protein extraction was performed using trichloroacetic acid (TCA)/acetone precipitation with some modifications.[17] Briefly, sample powder was suspended in 10% (w/v) TCA in acetone containing 1 mM dithiothreitol (DTT), and held at −20 °C for 2 h. After centrifugation and rinsing, the pellets were air-dried at room temperature and dissolved at 4 °C in lysis buffer containing 7 M urea, 2 M thiourea, 4% (w/v) 3-[(3-cholamidopropyl)-dimethylammonio]-1-propane sulfonate, 40 mM DTT, and 2% (v/v) Pharmalyte. Insoluble residue was removed through centrifugation, and the protein content was determined according to the Bradford method.[18]

Cotyledon protein (800 μg) was applied onto a 24 cm pH 4−7 linear gradient immobilized pH gradient (IPG) strip (GE Healthcare, Buckinghamshire, UK) and was subjected to electrophoresis at 20 °C for a total of 94850 V·h. Similarly, 800 μg of noncotyledon (hypocotyl and radicle) protein was applied onto an 18 cm pH 4−7 linear gradient IPG strip and was subjected to electrophoresis for a total of 90850 V·h. Subsequently, the strips were equilibrated,[19] and the second electrophoretic dimension was performed by 12% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) and was run on the Ettan Six vertical set (GE Healthcare) in electrophoretic buffer at 15 °C with a cooling device (GE Healthcare). Finally, the gels were stained with Coomassie brilliant blue (CBB) G-250.

Gel Image Analysis. The stained 2-DE gels were digitized with a gel scanner (Imagescanner III, GE Healthcare), and analyzed with PDQuest software package (Version 7.2.0, BIO-RAD, California, USA). Spots were detected, matched, and normalized on the basis of total quantity of valid spots with the parameter of percent volume according to the software guide. For each protein spot, triplicate gels were used for each sample, and the mean relative volume was used to designate the significant and differentially expressed proteins (changed by more than 1.5-fold or less than 0.66-fold and statistically significant as calculated by one-way ANOVA, $P < 0.05$).

Peptide Preparation for Mass Spectrometry Analysis. Protein spots with differential expression patterns were excised from gels, washed with double-distilled water 3 times, destained with 25 mM NH_4HCO_3 for CBB G-250 staining spots, dehydrated with 50% (v/v) acetonitrile (ACN) in 25 mM NH_4HCO_3, reduced with 10 mM DTT in 50 mM NH_4HCO_3 for 1 h at 56 °C, alkylated with 55 mM iodoacetamide in 50 mM NH_4HCO_3 for 1 h at 25 °C, dried twice with 100% ACN, and digested overnight at 37 °C with sequencing grade modified trypsin (Promega, Madison, WI, USA) in 50 mM NH_4HCO_3. The peptides were extracted twice by washing the gel pieces with 0.1% trifluoroacetic acid (TFA) in 67% ACN. Extracts were pooled and lyophilized.

Protein Identification by Nano-Liquid Chromatography−Tandem Mass Spectrometry and Database Search. The lyophilized tryptic peptides were resuspended in 5 mg/mL α-cyano-4-hydroxy-trans-cinnamic acid containing 0.1% trifluoroacetic acid (TFA) and 50% ACN.[20] MALDI-TOF-TOF MS analyses were conducted using an ABI 4800 Plus MALDI-TOF-TOF analyzer (Applied Biosystems, Foster City, CA, USA). Both the MS and MS/MS data were integrated and search was performed using the GPS Explorer software V3.6 (Applied Biosystems, USA) over the NCBI database with the help of the MASCOT search engine V3.5 (Matrix Science Ltd., London, U.K.). The following parameters were used in the search: NCBInr Viridiplantae (Green Plants) database; trypsin as the digestion enzyme; one missed cleavage allowed; cysteine carbamidomethylation as a fixed modification and methionine oxidization as a variable modification; no fixed modifications; 50 ppm for peptide ion tolerance; 0.5 Da for fragment ion tolerance. Only significant hits, as defined by the MASCOT probability analysis ($P < 0.05$) or individual ion score > 49, were accepted.

Identified proteins were annotated to their biological function according to KEGG (http://www.kegg.jp/kegg/pathway.html) and literature. Information on these proteins was obtained from the Universal Protein Resource (http://www.uniprot.org/). Moreover, WOLF PSORT prediction (http://wolfpsort.org/) was used to predict subcellular localization of all identified proteins.

RESULTS

Growth Performance, Sprout Length, and MDA Content in Germinating Soybeans. To evaluate the effect of NaCl stress on germinating soybeans, the growth performance, sprout length, and MDA content in germinating soybeans were measured. Under NaCl stress, the sprouts were significantly shorter ($P < 0.05$) than those of the control at the same germination time, but there was no significant difference ($P > 0.05$) compared with those under NaCl−AG treatment (Figure 1A). The MDA content increased significantly ($P < 0.05$) after 4 days in both organs of the NaCl-stressed and NaCl−AG treated sprouts (Figure 1B). Figure 1C shows that the growth and development of untreated sprouts were better than those of sprouts under NaCl stress and NaCl−AG treatments. The growth was inhibited and membrane integrity was lost after 4 days in both the NaCl-stressed and the NaCl−AG-treated sprouts.

GABA and *f*PA Contents in Germinating Soybeans. The GABA and *f*PA contents in the cotyledons and noncotyledons (hypocotyl and radicle) of 4-day germinating soybeans under NaCl stress and NaCl−AG treatment were analyzed. After germinating for 4 days under NaCl stress,

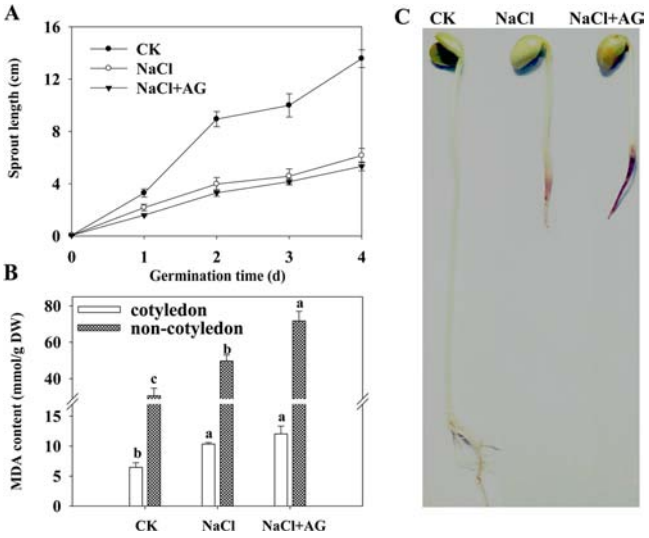

Figure 1. Effect of NaCl stress and NaCl−AG treatment on germinating soybean growth performance, sprout length, and MDA content. Noncotyledons: hypocotyl and radicle. Sprout length (A) and MDA content (B) of germinating soybeans were observed at 0, 1, 2, 3, and 4 days. The photograph of whole germinating soybeans was taken 4 days after treatment (C). Values are the mean ± SE (error bars). The lower case letters reflected the significance of differences in MDA content at germination for 4 days using the Duncan's test ($P < 0.05$).

GABA content was 1.54- and 1.70-fold higher than the control in the cotyledons and noncotyledons, respectively (Figure 2A). The GABA content in the noncotyledons of 4-day germinating soybeans treated with NaCl combined AG was not significantly ($P > 0.05$) different from that of the soybeans under NaCl stress, while the GABA content in cotyledons was significantly ($P < 0.05$) lower than in those under NaCl stress (Figure 2A). The *f*PA content decreased significantly in both organs of the 4-day germinating soybeans under NaCl stress compared with the control (Figure 2B). After treatment with AG, the DAO activity, as the rate limiting enzyme of PA catabolism, was completely inhibited (Supplementary Figure 1, Supporting Information), and the content of *f*PAs in 4-day germinating sprouts were all significantly ($P < 0.05$) higher than those of the sprouts under NaCl stress (Figure 2B).

Identification of Differentially Expressed Proteins Induced in Noncotyledons of 4-Day Germinating Soybeans under NaCl Stress and NaCl−AG Treatment. Comparative proteomic approach was used to determine the changes in protein abundance in noncotyledons of germinating soybeans exposed to NaCl stress and NaCl−AG treatment. The extracted proteins in the noncotyledons of 4-day germinating soybeans were separated using 2-DE and isoelectric focusing (IEF) on 18 cm linear IPG gels stained with CBB (Figure 3A). Three independent experiments were performed as biological replicates (Supplementary Figure 2, Supporting Information). The relative intensities of all the spots were analyzed using the PDQuest software. In total, more than 950 protein spots in germinating soybean noncotyledons were reproducibly detected on the 2-DE gels. A total of 67 proteins showed a less than 0.66-fold or more than 1.5-fold difference ($P < 0.05$) in relative volume in noncotyledons under different treatments. These proteins were excised from the gels for MALDI-TOF/TOF mass spectrometry. Finally, 63 proteins displayed in Table 1 were confidently identified according to the NCBI database (Supplementary Figure 3 and Supplementary Table 1, Supporting Information).

In the NaCl-treated group, 62 differentially expressed proteins were discovered compared with CK, including 37 (59.7%) up-regulated and 25 (40.3%) down-regulated (Figures 4A and 5A). These proteins were divided into 10 functional classes according to KEGG and the literature (Table 1, Figure 5A). Nine identified proteins were annotated as uncharacterized proteins, and six of them were searched for their homologues using BLAST (http://www.ncbi.nih.gov/BLAST/). At the amino acid level, the six proteins showed more than 65% positives, indicating that they might have similar functions (Table 2). All of the energy-related and synthesis-related proteins and most of the disease/defense-related noncotyledon proteins increased significantly under NaCl treatment, but all the transporter-related, signal transduction-related, and secondary metabolism-related and most uncharacterized noncotyledon proteins decreased under NaCl treatment (Figures 4A and 5A). The subcellular localization information of these identified proteins was also analyzed using WOLF PSORT prediction, which revealed that 36 (58%) differentially expressed proteins identified were predicted to be cytoplasmic proteins. All of the endoplasmic reticulum proteins, vacuole proteins, and mitochondrial proteins showed an increased abundance while half of the cytoplasmic proteins and chloroplast proteins showed a decreased abundance under NaCl treatment (Figure 5C).

A total of 51 noncotyledon proteins showed differential responses in the NaCl−AG treated group compared with the group under NaCl stress. Among these identified proteins, 22 were up-regulated proteins and 29 were down-regulated proteins (Figures 4A and 5B). For disease/defense-related

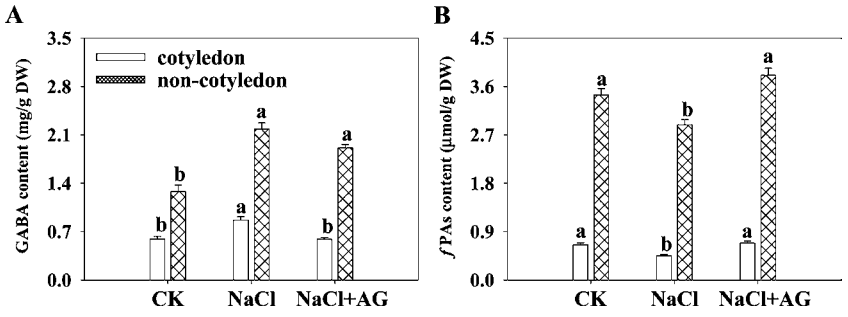

Figure 2. Changes in GABA and *f*PA content in 4-day germinating soybeans. The GABA content (A) and *f*PA content (B) in cotyledons and noncotyledons of germinating soybeans were determined. Noncotyledons: hypocotyl and radicle. Values are the mean ± SE (error bars). Data with the same letters were not significantly different compared with control as was determined using the Duncan's test ($P < 0.05$).

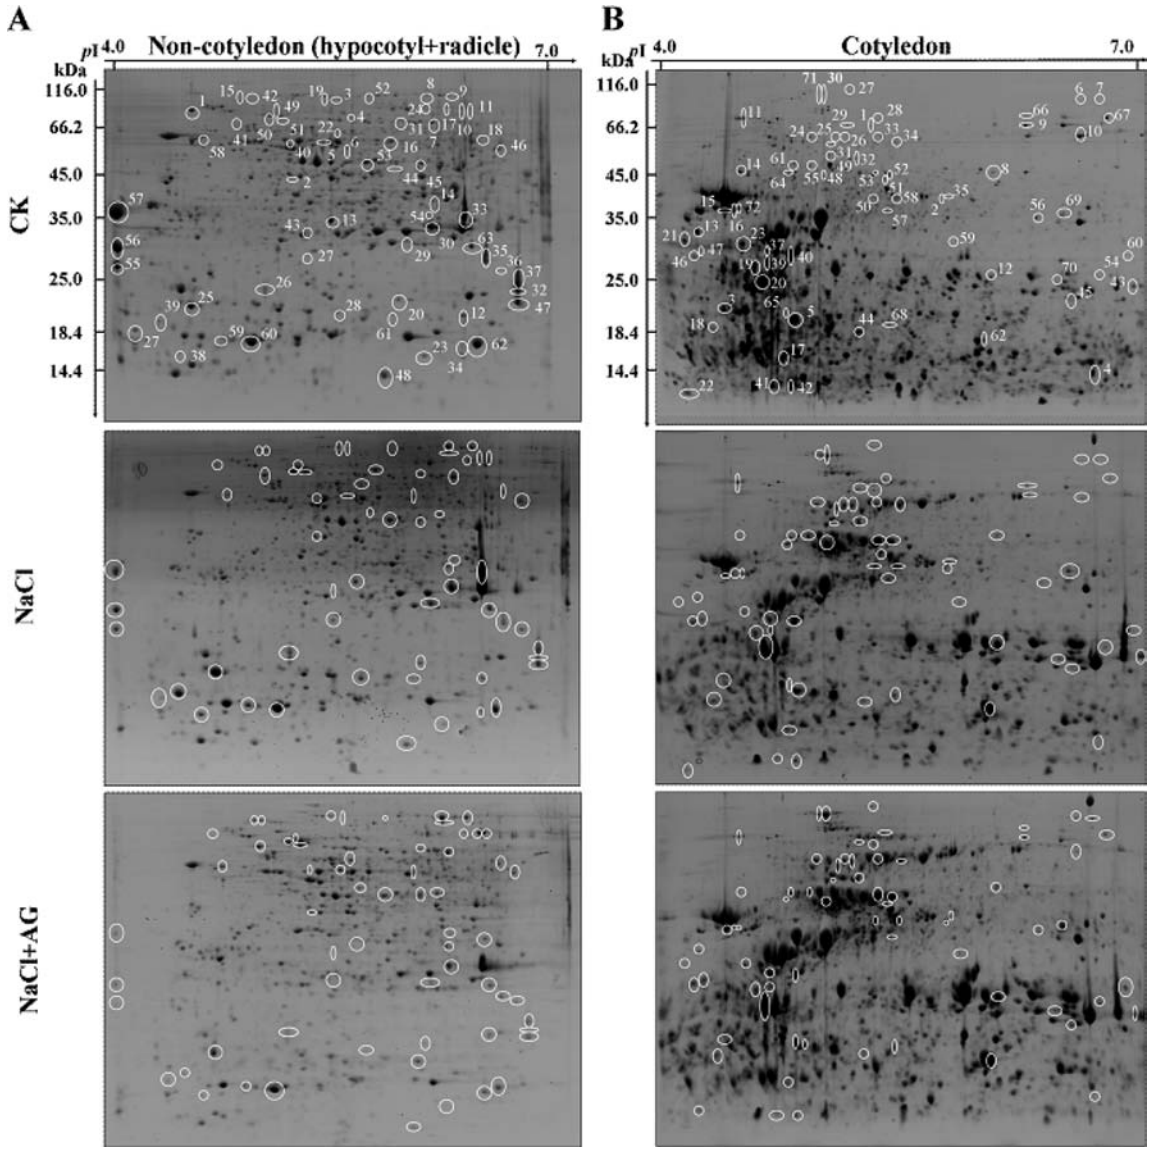

Figure 3. 2-DE pattern of 4-day germinating soybean noncotyledons and cotyledons proteins under NaCl stress or NaCl−AG treatment. Proteins extracted from noncotyledons (A) or cotyledons (B) were separated by 2-DE as described in the Materials and Methods and visualized with CBB staining. Noncotyledons: hypocotyl and radicle. Protein spot numbers are same as those shown in Tables 1 and 3.

proteins, the number of proteins that increased or decreased was equal. In addition, the majority of metabolism-related, energy-related, and protein synthesis-related proteins showed an increased abundance. However, the majority of the proteins involved in secondary metabolism, protein destination/storage, and metabolism showed a decreased abundance (Figures 4A and 5B). Most of the increased noncotyledon proteins were predicted to localize in the chloroplast, vacuole, and endoplasmic reticulum, while the cytoplasmic proteins and mitochondrial proteins were nearly equally increased or decreased (Figure 5D).

Identification of Differentially Expressed Proteins Induced in Cotyledons of 4-Day Germinating Soybeans under NaCl Stress and NaCl−AG Treatment. To analyze the extracted proteins in 4-day germinating soybean cotyledons, 24 cm linear IPG gels were used. Approximately 1150 protein spots were observed in all three biological replicates of stained gels (Supplementary Figure 4, Supporting Information). Among them, 72 protein spots that showed a more than 1.5-fold difference ($P < 0.05$) in abundance were successfully identified (Table 3; Supplementary Figure 4 and Supplementary Table 2, Supporting Information).

For the NaCl-treated group, a total of 72 proteins (45 up-regulated proteins and 27 down-regulated proteins) were significantly altered compared with CK (Figures 4B and 5E). Of these proteins, 45 (62.5%) were involved in the seed storage proteins (SSPs), and the remainder were divided into six functional classes, metabolism, energy, cell growth/division, proteolysis, transporters, and disease/defense (Table 3, Figure 5E). Most of the SSPs and metabolism-related proteins showed an increased abundance, while the energy-related, proteolysis-related, and disease/defense-related proteins showed a decreased abundance under NaCl stress. In total, different from the noncotyledon proteins, 55.5% of identified cotyledon proteins were predicted to localize in cytoplasm, and most of them were up-regulated under NaCl treatment (Figure 5G).

In cotyledons, 29 up-regulated and 13 down-regulated proteins were identified in response to NaCl−AG treatment

[j]Functional classification.

compared with NaCl stress (Figures 4B and 5F). Similarly, the majority of these cotyledon proteins were SSPs. Moreover, all of the metabolism-related and energy-related proteins were up-regulated ones, and most of SSPs were down-regulated ones (Figure 5F). The chloroplast proteins and vacuole proteins were equally increased or decreased while most proteins that localized in cytoplasm, nucleus, and mitochondria increased (Figure 5H).

Proteins Commonly Responsive to Stress in the Noncotyledons and Cotyledons. In the present study, five differentially expressed proteins responsive to NaCl stress were identified in both noncotyledons and cotyledons compared with CK (Tables 1 and 3; Supplementary Figure 6A, Supporting Information). Expansin-like B1 (E20 and C12), coatomer subunit β'-2 (E33 and C69), and endoplasmin (E41 and C71) all showed an increased abundance in noncotyledons and cotyledons under NaCl stress compared with CK. In addition, the embryonic protein DC-8 (E21, C9, and C10) and the soybean trypsin inhibitor (E25 and C20) showed an increased abundance in the noncotyledons but decreased in the cotyledons. Comparison of NaCl treatment with NaCl−AG treatment indicates that coatomer subunit β'-2 (E33 and C69) and endoplasmin (E41 and C71) increased in noncotyledons but decreased in cotyledons (Figure 4B).

DISCUSSION

In the present study, the GABA content was markedly higher in both organs in the NaCl-treated germinating soybeans than in the untreated ones (Figure 2A), which confirmed that soybeans could be good materials for producing functional sprouts. Consistent with previous reports,[11] the DAO activity was completely suppressed by AG, and the GABA content decreased (Figure 2). Additionally, identical negative effects such as inhibited growth of germinating soybeans and destroyed integrity of membrane under NaCl treatment were detected, since soybeans were considered as salt-sensitive plants (Figure 1). In response to NaCl stress, the identified proteins associated with metabolism were involved in amino acid, starch, fatty acid, nitrogen, and nucleotide metabolism pathways. In plant, GABA can be formed through the GABA shunt and the polyamine degradation pathway.[6,11] On the one hand, compared with the control, the abundance of the glutamine synthetase PR-2 (spot E2) and the glutamine synthetase precursor (spot E10) were much lower under NaCl treatment (Figure 6). The glutamine synthetase (GS) catalyzed the assimilation of ammonium to glutamine using glutamate as its substrate. Hence, down-regulated GS implied a higher glutamate content, which was further converted to GABA through the GABA shunt. On the other hand, higher abundance of methionine synthase (MS, spot E9), 5-methyltetrahydropteroyltriglutamate-homocysteine methyltransferase (spot E6), and aminoaldehyde dehydrogenase (spot E5) were observed in the NaCl-treated soybeans (Figure 6). MS and homocysteine methyltransferase, which are involved in the polyamine biosynthesis pathway, catalyze the transfer of a methyl group, resulting in the formation of methionine. Subsequently, the decreased *f*PA content was converted to GABA by the polyamine degradation pathway, since aminoaldehyde dehydrogenase, identified as the indispensable enzyme of polyamine degradation pathway was up-regulated under NaCl stress. The decreased abundance of GS and increased abundance of MS have also been documented on soybeans under other stresses.[19] Compared with NaCl treatment, application of AG decreased GS, and the three enzymes referred to above, which were involved in polyamine biosynthesis, further increased. These facts suggested that more glutamate as substrate was converted to GABA because the polyamine degradation pathway was suppressed. The significantly increased *f*PA content in both organs would in turn promote ion homeostasis and lower the ROS levels. Moreover, the remarkable expression of methionine synthase was an effect

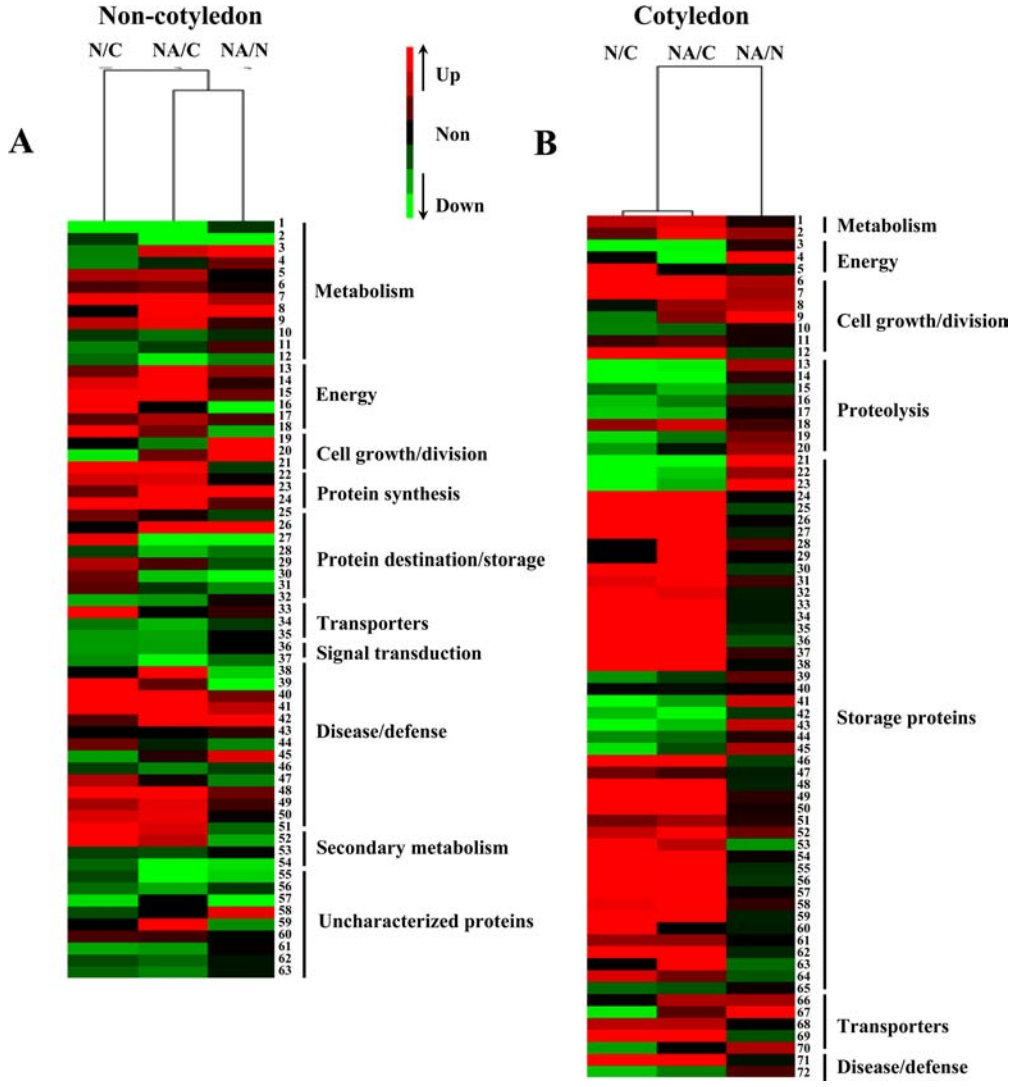

Figure 4. Proteins differentially expressed in response to NaCl stress or NaCl−AG treatment in noncotyledons and cotyledons. The expression change of noncotyledons (A) and cotyledons (B) based on the log2 transformed expression ratios of protein spots was performed using the Gene Cluster 3.0 software. The results were visualized using the JAVA TREEVIEW software. Noncotyledons: hypocotyl and radicle. C, CK; N, NaCl; NA, NaCl−AG treatment. Protein spot numbers are same as those shown in Tables 1 and 3.

of elevated activity of mechanisms that enhanced NaCl stress tolerance, since it was involved in detoxification of ROS.

In our proteome analysis, NaCl stress enhanced expression of all the identified proteins associated with energy metabolism. ATPases are membrane-bound enzymes, and they combine ATP synthesis with the transport of protons. The ATP synthase 24 kDa subunit (spot E13), the V-type proton ATPase subunit E (spot E14), the ATPase subunit 1 (spot E18), and two NADP-dependent malic enzymes (spots E16 and E17) are critical enzymes of glycolysis and the TCA cycle, which support plant growth. The V-type proton ATPase subunit E compartmentalizes Na^+ into the vacuole by generating a proton electrochemical gradient to supply a driving force utilized by the tonoplast Na^+/H^+ antiporter.[21] Studies have proven that increased expression in malate enzyme is an adaptive response to environmental stresses.[22] Up-regulated NADP-dependent malic enzyme in our soybean proteome analysis confirmed its key role in NaCl stress. Contrarily, the NADP-dependent malic enzyme (spot E16) and the ATPase subunit 1 (spot E18) decreased significantly while the other identified energy metabolism related proteins were not significantly different under NaCl−AG treatment compared with those under NaCl stress. This phenomenon suggested that NaCl stress dramatically enhanced energy metabolism in germinating soybeans while AG inhibited energy metabolism under NaCl stress.

Excess generation of reactive oxygen species (ROS), such as superoxide radical, hydroxyl radical, and hydrogen peroxide in plant cells, is an inevitable outcome of all abiotic stresses, especially NaCl stress. These ROS cause membrane damage and attack proteins and nucleic acids. Higher plants have developed an antioxidant enzymatic system to scavenge these toxic compounds. In addition, it has been proven that plant salt tolerance is positively associated with a more efficient antioxidant system. In the present study, Mn-superoxide dismutase (MnSOD, spot E44) increased significantly following its exposure to NaCl stress. This result indicated that MnSOD was the first line defense against the NaCl stress-induced ROS in germinating soybeans and suggested that the antioxidant defense mechanisms were more active in noncotyledons than in cotyledons under NaCl stress. Previous reports demonstrated that exogenous application of PAs improved the antioxidant enzyme system.[10] However, the expression of MnSOD and

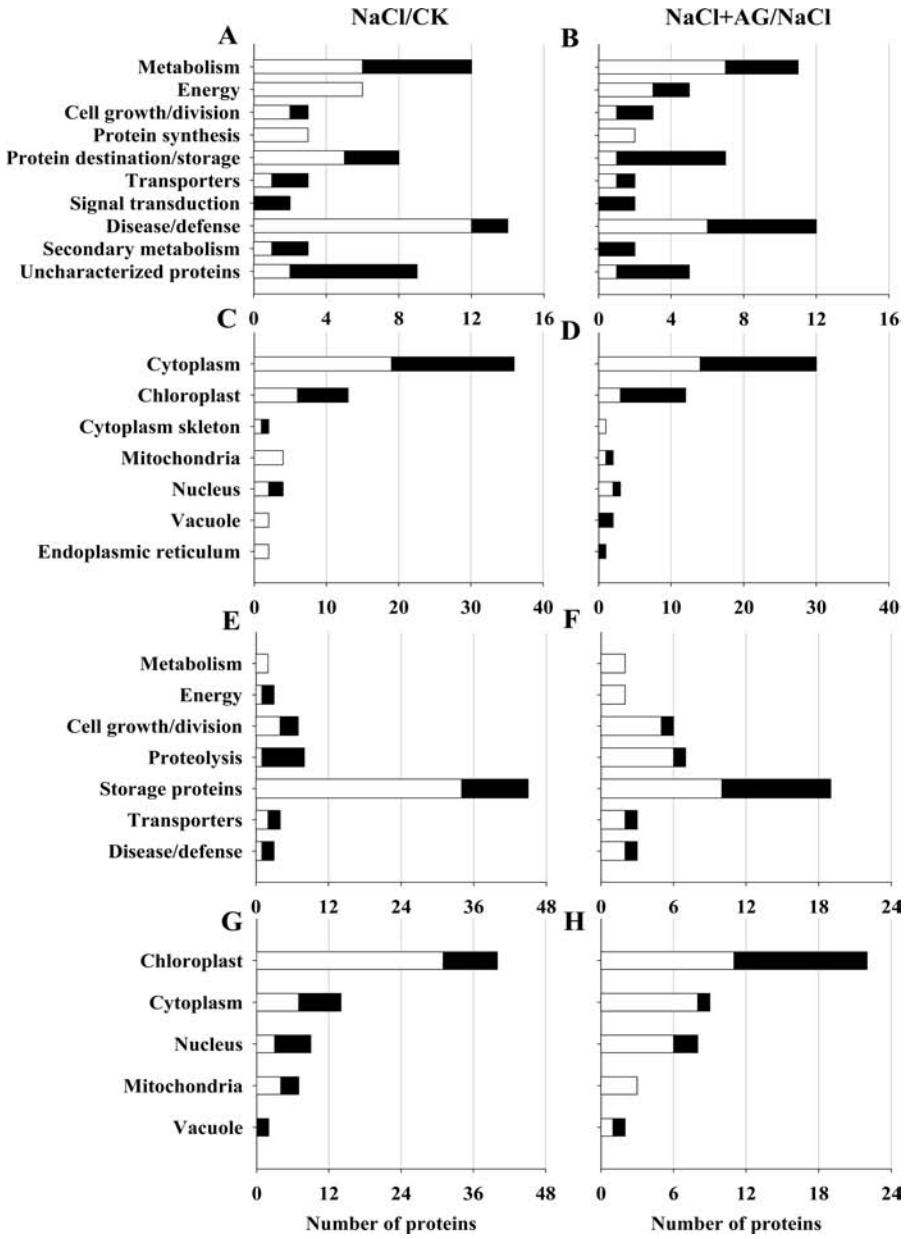

Figure 5. Classification of differentially expressed proteins in noncotyledons and cotyledons of 4-day germinating soybeans treated with NaCl or NaCl−AG. Noncotyledons: hypocotyl and radicle. The functions of differentially expressed proteins in noncotyledons (A, B), and cotyledons (E, F) treated with NaCl (A, E) and NaCl−AG (B, F) were assigned according to KEGG and literature. The localization-based classification of proteins in noncotyledons (C, D) and cotyledons (G, H) treated with NaCl (C, G) and NaCl−AG (D, H) is shown in the lower panels. Identified proteins were classified according to the subcellular localization predicted by WOLFPSORT prediction (http://wolfpsort.org). White and black columns represent increased and decreased proteins, respectively.

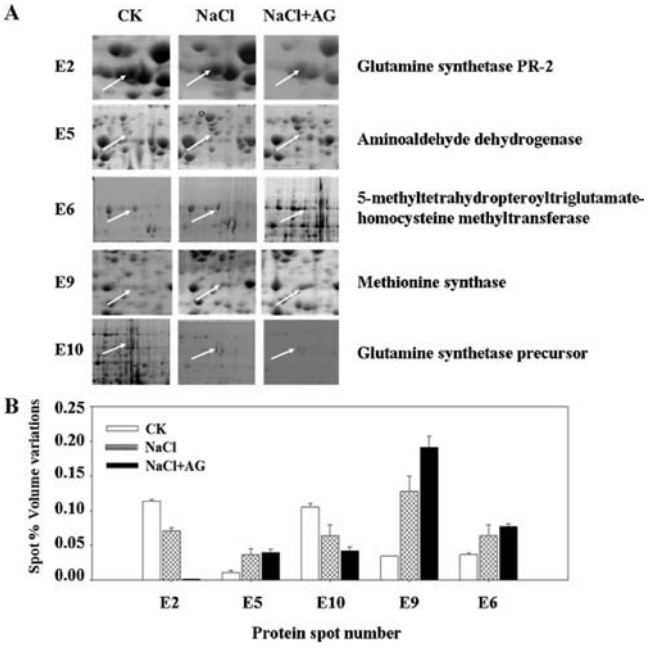

Figure 6. Differentially regulated proteins involved in GABA metabolism upon NaCl stress and NaCl−AG treatment in germinating soybeans. (A) Magnified views of differentially regulated proteins; (B) relative protein levels of differentia regulated proteins. Protein spot numbers are same as those shown in Tables 1 and 3.

processes of endogenous PAs would aggravate the negative effects of NaCl stress. It is noteworthy that nine differentially expressed proteins were associated with protein processing in endoplasmic reticulum, including four heat shock proteins (spots E42, E48, E49, and E51), two endoplasmins (spots E41 and C71), cell division cycle protein 48 (spot E19), luminal-binding protein 5 (spot E50), and calreticulin-1 precursor (spot C11). Almost all the proteins were up-regulated under NaCl stress except the cell division cycle protein 48. These results implied that promotion of protein processing in endoplasmic reticulum might be a very important strategy of germinating soybeans under NaCl stress.

Secondary metabolites play an important role in osmotic adjustment and ROS scavenging in response to environmental stressors.[23] Compared with CK, down-regulated caffeoyl-CoA-*O*-methyltransferase (CCoAOMT, spot E53) and isoflavone reductase (IFR, spot E54) and up-regulated polyphenol oxidase A1 (spot E52) in NaCl-stressed soybeans were detected in the present study. CCoAOMT plays a key role in the supply of substrates for the synthesis of lignin units.[24] Lignification of the cell wall may be one important strategy adopted by plants in response to NaCl stress. The down-regulated CCoAOMT might be linked to the reduced synthesis of monolignols, which was possibly due to stress-imposed growth suppression.[25] However, under NaCl−AG treatment, there was no significant difference in CCoAOMT abundance compared with NaCl treatment. IFR, associated with isoflavonoid biosynthesis pathways, was down-regulated under NaCl stress compared with CK and further significantly decreased under NaCl−AG

treatment. Additionally, polyphenol oxidase increased under NaCl stress but decreased after AG was added. It is well-known that isoflavonoids and polyphenol are potent antioxidants functioning as scavengers of ROS under stressful conditions. Accordingly, the accumulation of isoflavones and polyphenol could play an essential role in regulating the growth response. Taken together, these results indicated that the secondary metabolite synthesis pathways were targets for stress response, possibly altering the development of soybeans.

Auxin-binding protein ABP19a (spot E36 and E37), associated with auxin signaling pathway and mediating the action of auxins, was dramatically down-regulated under NaCl stress compared with the control. Furthermore, compared with NaCl treatment, its abundance decreased after AG was applied. It is known that auxins play a vital role in division and expansion of plant cells.[26] Therefore, the down-regulated auxin-binding protein ABP19a indicated that NaCl and NaCl−AG treatment inhibited plant growth of germinating soybeans, which was fully explained by the reduced sprout length and the inhibited growth performance.

In developing soybean seeds, the expression profiles of SSP are of a complex nature.[27] It has been displayed that SSP may not only function as seed storage reserves but also have additional roles.[28] Under stress conditions, SSP is mobilized and its composition and abundance is changed.[12,25,29,30] In the present study, 62.5% of the differentially expressed proteins (spots C21−C65) in the NaCl-stressed germinating soybean cotyledons represented various kinds of SSPs, almost all of which were assigned to β-conglycinin subunits and glycinin. β-conglycinin and glycinin are the hydrolysis products of globulin and are mobilized to provide carbon and nitrogen for seed germination and growth. GABA-enriched germinating soybeans were germinated in a dark artificial environment, so organic compounds could not be synthesized via photosynthesis. These storage materials were the major source of nutrients for the soybeans. Under NaCl stress, the growth of germinating soybeans was inhibited resulting in soybeans being unable to use SSPs for growth, and therefore they showed higher SSP abundance. However, the expression profiles of different types of subunits of β-conglycinin and glycinin were inconsistent in response to NaCl stress and NaCl−AG treatment. It remains to be seen whether these SSP changes could improve NaCl stress tolerance in germinating soybeans. Furthermore, only two up-regulated SSPs (spots E29 and E30) were detected and identified as 31 kD glycoprotein in noncotyledons. The 31 kD glycoprotein has been proven to accumulate during cell development and serve as a source of amino acids for the developing embryo. The up-regulated glutamine synthetase PR-2 (spot E1), aminoaldehyde dehydrogenase (spot E5), glutamine synthetase precursor (spot E6), methionine synthase (spot E9), and GABA content in the present study might also support the idea that 31 kD glycoprotein can be assumed from the paralleled uptake of amino acids.[25] In conclusion, these results might further indicate an additional role in plant defense of SSPs besides storage reserves.

A group of proteins such as eukaryotic initiation factor 4A-15 (elF, spot E22), eukaryotic translation initiation factor 5A3 (spot E23), and elongation factor 2 (spot E24), associated with protein biosynthesis pathways, were up-regulated by NaCl stress. Studies confirm that eukaryotic translation initiation factors play a key role in the cell division and cell death processes.[31] The elF was up-regulated under NaCl stress and further enhanced under NaCl−AG treatment. This could be caused by endogenous PAs, which were involved in the posttranslation activation of elF and increased significantly after application of AG under NaCl stress. Studies also show that protein synthesis can be enhanced by exogenous PAs.[32] However, our results indicated that increased endogenous PAs had a consistent stimulatory effect on the incorporation of amino acids into protein. The regulated expression response patterns of the three proteins indicated that the promotion of protein biosynthesis was required for germinating soybeans to respond to stress.

It is generally known that soybean seeds contain plenty of allergenic proteins, and thus their extensive usage was limited in the food industry. Gly m Bd 30K proteins (spots C13, C15, and C16) represent a major allergen because more than 65% of soybean-sensitive patients are allergic to the protein, although its content is lower than 1% in soybean seeds.[33] In the present study, Bd 30K protein showed a less than 0.42-fold or even 0.08-fold difference ($P < 0.05$) in abundance in germinating soybean cotyledons under NaCl stress or AG treatment, compared with CK.

The comparative proteomic and physiological analyses indicated that the molecular mechanisms that contributed to tolerance in germinating soybeans were complex. Based on the results of this study, the following conclusions could be drawn: (i) soybean germination under certain stressful conditions would be an effective way to accumulate functional ingredients and to decrease allergens; (ii) most of the differentially expressed proteins in soybean cotyledons were SSPs, and redistribution of SSPs is likely to play an important role in defense; (iii) down-regulated GS and up-regulated MS were responsible for accumulation of GABA and coping with NaCl stress; (iv) enhanced energy metabolism and accelerated protein processing in endoplasmic reticulum were very important strategies for germinating soybean response to NaCl stress; (v) the inhibition of polyamine degradation might further aggravate the negative effects of NaCl stress on germinating soybeans.

spectrometry (MS) have been established, facilitating our understanding of glycoconjugate structures.[19]

Electrospray ionization mass spectrometry (ESI-MS) is an ideal tool for structural characterization of various oligosaccharides, especially when coupled with ion trap instruments.[20] Ion trap mass spectrometry (IT-MS^n) allows selective fragmentation of target pseudoglycan ions and detailed elucidation of their sequence and branching and linkage types, but it is impractical for quantitative analysis of isomeric glycans. LC−MS and MS/MS, however, are available for glycan isomer separation and online identification. Hence, the LC−MS technique has been extensively employed as one of the most universal and successful methods for qualitative and quantitative glycan qualitation to date, although its resolving ability is not as powerful as that of MS^n in the analysis of complicated glycan isomer linkages.[21,22] Many researchers prefer online LC−ESI-MS, as it provides the possibility of peak integration, precise determination of retention times, and the principal ability to detect all types of glycans.[23−26]

Stable isotope reagents can be employed to assess rapidly and directly the qualitative and quantitative changes in different samples and to eliminate the variation in instrument response and ionization efficiency of the molecules with the same structures but from different resources. Accordingly, in comparative glycomic analysis, the stable isotopic labeling of glycans via reductive amination[27−29] or hydrazone formation[30] prior to HPLC separation and MS detection is usually involved. A glycan isotopic labeling approach using nondeuterated (d_0-) and deuterated (d_5-) aniline has been developed in our lab. This method is quite suitable for comparative glycomic analysis based on ultraviolet (UV) absorbance and relative ion abundance.[31]

In this article, ovotransferrin was purified from egg whites of chicken (domestic species) and pheasant (wild species), followed by composition profiling of their *N*-glycans released by PNGase F. Aniline stable isotopic labeling combined with ESI−MS analysis were utilized to compare quantitatively the *N*-glycan compositions of COT with those of POT. Online HILIC−MS and MS/MS were employed to identify *N*-glycan isomers and to quantify their relative abundance in COT and POT. This study is the first to reveal, comprehensively and in detail, the *N*-glycan patterns of COT and POT and to give a qualitative and quantitative comparison of COT and POT *N*-glycans.

MATERIALS AND METHODS

Materials. Chicken (*Gallus domesticus*) and pheasant (*Phasianus colchicus*) eggs were purchased from Luozhuang Farm (Xi'an, China). Molecular weight protein markers were purchased from Fermentas (Burlington, Canada). PNGase F was obtained from New England BioLabs (Ipswich, MA, USA). Nonporous graphitized carbon (Carbograph) solid-phase extraction (SPE) columns (150 mg/4 mL) were purchased from Alltech Associates (Deerfield, IL, USA). SepPak C18 SPE columns (100 mg/1 mL) were purchased from Waters (Milford, MA, USA). HPLC-grade methanol and acetonitrile were from Fisher Scientific (Fairlawn, NJ, USA). Other reagents used were of analytical grade.

Preparation of Ovotransferrin. On the basis of the work of Ko and Ahn,[32] the method of Fe^{3+} saturation and two-time ethanol precipitation was utilized to purify ovotransferrin from chicken and pheasant egg whites. Briefly, egg white was diluted with a 1-fold volume of distilled water, and then 2.5 mL of a 20 mM $FeCl_3 \cdot 6H_2O$ solution was added per 100 mL of diluted egg white solution to saturate the Fe^{3+}-bound sites. The obtained mixture was left standing for 1 h after homogenization. The majority of the egg white proteins were precipitated with 43% ethanol, leaving iron-bound ovotransferrin in the supernatant. Crude ovotransferrin was obtained when the ethanol concentration was increased to 59% (v/v). To obtain highly purified products, the crude was dissolved in 43% ethanol and treated again by an increase of the ethanol concentration to 59% (v/v). Finally, the highly purified ovotransferrin products were lyophilized for further use.

Identification of Ovotransferrin by Sodium Dodecyl Sulfate Polyacrylmide Gel Electrophoresis (SDS-PAGE). SDS-PAGE was performed according to the procedure developed by Laemmli,[33] using 4% acrylamide in stacking gels and 12% acrylamide in separating gels. Protein samples were dissolved in loading buffer (1% SDS, 40% glycerol, 0.1% dithiothreitol, and 0.05% bromophenol blue in 10 mM Tris-HCl buffer, pH 8.0) at the concentration of 2 mg/mL and then heated at 100 °C for 10 min. For a maximum visualization of egg white proteins, the amount of protein loaded was 10 μg for all samples. SDS-PAGE molecular weight standards ranging from of 3.4 to 250 kDa were used. Electrophoresis was carried out at 80 V in the stacking gel and 120 V in the separating gel using a Tris-Glycine electrophoretic buffer containing 0.1% SDS (pH 8.3). The gel was stained for 30 min with 1% Coomassie Blue R250 dissolved in a mixture containing 45% methanol, 45% water, and 10% acetic acid and destained with a mixture containing 87.5% water, 5% methanol, and 7.5% acetic acid. The gels were scanned using ImageQuant 350 (GE Healthcare, Milwaukee, WI, USA) and assessed by Gel-Pro Analyzer.

MALDI-TOF-MS Analysis. MALDI-TOF-MS was performed on an AXIMA Performance instrument (Shimadzu, Tokyo, Japan). The MS data acquisition was carried out in positive ion linear mode, using a nitrogen laser with the power level set at 98 and a matrix of 10 mg/mL α-cyano-4-hydroxy-cinnamic acid (CHCA) prepared in 50% acetonitrile containing 0.1% TFA. Two shots accumulated for each profile were acquired for each sample spot. Two milligrams of purified ovotransferrin was dissolved in 100 μL of deionized water, and 1 μL of the sample solution was mixed with 1 μL of matrix solution prior to spotting on a stainless steel target plate and drying at room temperature for analysis.

Release and Clean Up of *N*-Glycans from Ovotransferrin. Ovotransferrin (2 mg) was dissolved in 200 μL of protein denaturing solution (5% SDS, 0.4 M DTT) and denatured at 100 °C for 10 min. After the sample cooled, 20 μL of sodium phosphate buffer (0.5 M, pH 7.5), 20 μL of 10% NP-40, and 1 μL of PNGase F (500 units) were added prior to incubation at 37 °C for 24 h. The sample was boiled for 5 min to stop the reaction and then loaded onto a SepPak C18 SPE column. The released *N*-glycans were not retained on the column and eluted with 10 mL of water. The water fraction containing *N*-glycans was collected and desalted using a graphitized carbon SPE column. The salts were removed by washing with water, and the target *N*-glycans were eluted with 25% acetonitrile containing 0.01% TFA. The eluates were dried under a stream of nitrogen gas for further use.

Derivatization of *N*-Glycans with d_0-Aniline and d_5-Aniline. This procedure was based on a previously reported method.[31] Fifty microliters of d_0- or d_5-aniline, 50 μL of a 1 M $NaCNBH_3$ solution prepared in 30% acetic acid (v/v), and 50 μL of free *N*-glycan solution were mixed and sealed in a screw-capped tube, followed by incubation at 70 °C for 20 min. The resulting sample was purified using a graphitized carbon SPE column. After washing the column with 10−15 mL of distilled water, the target *N*-glycan derivatives were eluted with 30% acetonitrile, dried under a stream of nitrogen, and dissolved in 80% acetonitrile for chromatographic and MS analysis.

ESI−MS Conditions. MS analysis was carried out using an LTQ XL linear ion trap electrospray ionization mass spectrometer coupled with a HPLC system (Thermo Scientific, USA). The samples were injected via a Rheodyne loop with a volume of 2 μL and subsequently brought into the electrospray ion source by a stream of 50% methanol (v/v) at a flow rate of 200 μL/min. The spray voltage was set at 4 kV, with a sheath gas (nitrogen gas) flow rate of 30 arb., an auxiliary gas (nitrogen gas) flow rate of 5.0 arb., a capillary voltage of 37 V, a tube lens voltage of 250 V, and a capillary temperature of 375 °C. For MS/MS analysis, *N*-glycans were subjected to fragmentation by collision induced decomposition (CID), with helium (He) as the collision gas.

Collision parameters were left at default values with a normalized collision energy degree of 60 and an isotope width of m/z 3.00. Activation Q was set at 0.25, and activation time, at 30 ms. The MS and MS/MS data were recorded using LTQ Tune software (Thermo).

Online LC−MS Analysis. Online LC−MS analysis was performed using a Hypersil APS2 (NH_2) column (2.1 mm × 150 mm, 3 μm) (Thermo scientific, USA) on an HPLC system (Thermo) equipped with a photo diode array (PDA) detector and an LTQ XL linear ion trap ESI-MS system. The sample injection volume was 10 μL, and the mobile phase flow rate was 200 μL/min. The elution gradient was as follows: solvent A, acetonitrile; solvent B, water; solvent C, 10 mM ammonium acetate (pH 4.5); time = 0 min (t = 0), 80% A, 16% B, 4% C; t = 45, 27.5% A, 34% B, 38.5% C. The eluates from the chromatographic separation were directly introduced into the ESI-MS system for detection. The MS and MS/MS data were recorded using Xcalibur software (Thermo). The parameters used for LC−MS/MS analysis were the same as those described for ESI−MS/MS analysis in the above section. The obtained date were manually interpreted, and the proposed *N*-glycan compositions and sequences were checked using the software GlycoWorkbench.[34]

RESULTS AND DISCUSSION

Purification and Identification of Ovotransferrin. Highly purified glycoprotein is essential for glycomic analysis.

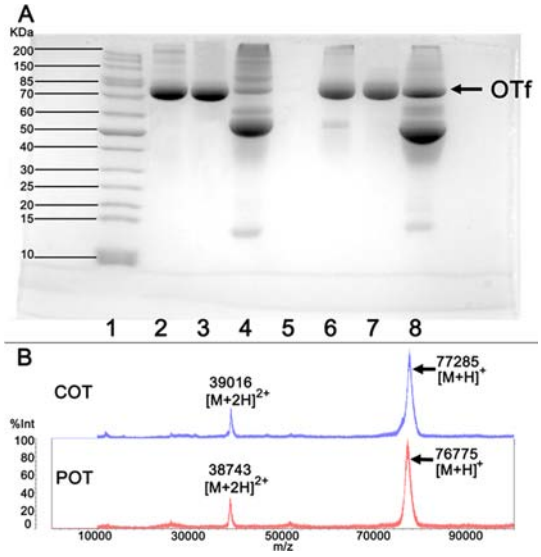

Figure 1. Profiling ovotransferrin (OTf) by SDS-PAGE and MALDI-TOF MS. (A) SDS-PAGE pattern. Lane 1: standard marker; lane 2: COT obtained after the first ethanol precipitation process; lane 3: COT obtained after the second ethanol precipitation process; lane 4: total protein of chicken egg white; lane 5: blank; lane 6: POT obtained after the first ethanol precipitation process; lane 7: POT prepared with a second ethanol precipitation; lane 8: total protein of pheasant egg white. (B) MALDI-TOF MS profiles of highly purified COT (blue mass spectrum) and POT (red mass spectrum).

However, some commercially available samples of egg white proteins such as ovotransferrin and ovalbumin are usually copurified with some other proteins, resulting in difficulties for precisely analyzing their glycosylation.[10,35,36] Thus, to compare the *N*-glycan patterns of COT and POT, a method for the efficient isolation of highly purified ovotransferrin from chicken and pheasant egg whites is needed. The ethanol method for ovotransferrin purification is simple in its operation and produces a high yield. Hence, in this article, we developed a method termed ethanol repeated precipitation to obtain highly purified ovotransferrin. Because iron-saturated ovotransferrin is more stable to chemicals such as ethanol than its iron-free form, the iron-free ovotransferrin in an egg white solution was converted to the iron-bound form by treatment with $FeCl_3$ solution. Almost all egg white proteins except for iron-bound ovotransferrin were denatured and precipitated in 43% ethanol. Iron-saturated ovotransferrin in the 43% ethanol solution started to precipitate as the ethanol concentration increased from 43%, and the optimal conditions for precipitating ovotransferrin occurred when the ethanol concentration reached 59%.[30] Therefore, using 43% ethanol to remove other egg white proteins and 59% ethanol to precipitate ovotransferrin, we obtained COT (lane 2 of Figure 1A) and POT (lane 6 of Figure 1A) with minor impurities. To obtain ovotransferrin that is pure enough for glycosylation analysis, the ethanol (increasing ethanol concentration from 43 to 59%) precipitation process was performed again using the crude COT and POT. As a result, a high purity of COT (lane 3 of Figure 1A) and POT (lane 7 of Figure 1A) was achieved. MALDI-TOF MS (Figure 1B) gave ion signals of COT at m/z 39 016 ($[M + 2H]^{2+}$) and m/z 77 285 ($[M + H]^+$) (blue mass spectrum in Figure 1B) and POT at m/z 38 743 ($[M + 2H]^{2+}$) and m/z 76 775 ($[M + H]^+$) (red mass spectrum in Figure 1B), indicating that the molecular weights of COT and POT are around 77 284 and 78 774 Da, respectively. These results are consistent with those of SDS-PAGE analysis as well as previous literature reports.[37−39]

Moreover, the results from the Gel-Pro Analyzer concerning the SDS-PAGE experiment suggested that the purities of COT and POT were both over 95%. Therefore, this approach proved to be an efficient and simple method for the purification of ovotransferrin. Considering that the variation between species-specific ovotransferrin proteins is related only to the attached glycan moieties,[14] the difference in molecular weights between COT and POT may validate this fact to a certain extent as well as facilitate an understanding of the following comparative glycomic analysis of COT and POT.

Composition Profiling of COT and POT *N*-Glycans. The *N*-glycan structures of COT have been investigated to a certain degree in previous reports.[15−18] However, there is no *N*-glycomic information on POT up to now. In this work, *N*-glycan compositions of COT and POT were analyzed by ESI−MS, where sodiated ions were predominantly produced. Figure 2 presents the MS profiles of the *N*-glycan compositions of COT (Figure 2A) and POT (Figure 2B). The double-sodiated COT glycan ions ($[M + 2Na]^{2+}$) at m/z 782.73 ($Man_3GlcNAc_5$), 884.27 ($Man_3GlcNAc_6$), and 1087.27 ($Man_3GlcNAc_7$) and POT ion of m/z 782.73 ($Man_3GlcNAc_5$) were not annotated here because the corresponding singly charged ions ($[M + Na]^+$) of these glycans were all observed. In total, 12 COT *N*-glycan compositions were observed as the $[M + Na]^+$ type ions at m/z 933.27 ($Man_3GlcNAc_2$), 1136.27 ($Man_3GlcNAc_3$), 1298.27 ($Hex_1Man_3GlcNAc_3$), 1339.27 ($Man_3GlcNAc_4$), 1501.18 ($Hex_1Man_3GlcNAc_4$), 1542.27 ($Man_3GlcNAc_5$), 1663.09 ($Hex_2Man_3GlcNAc_4$), 1704.27 ($Hex_1Man_3GlcNAc_5$), 1745.27 ($Man_3GlcNAc_6$), 1907.27 ($Hex_1Man_3GlcNAc_6$), 1948.09 ($Man_3GlcNAc_7$), and 2151.18 ($Man_3GlcNAc_8$). In contrast, 15 *N*-glycan compositions were found as $[M + Na]^+$ type ions at m/z 771.27 ($Man_2GlcNAc_2$), 933.27 ($Man_3GlcNAc_2$), 1095.27 ($Man_4GlcNAc_2$), 1136.27 ($Man_3GlcNAc_3$), 1257.27 ($Man_5GlcNAc_2$), 1298.27 ($Hex_1Man_3GlcNAc_3$), 1339.27 ($Man_3GlcNAc_4$), 1460.09 ($Man_5GlcNAc_3$), 1501.18 ($Hex_1Man_3GlcNAc_4$), 1542.27 ($Man_3GlcNAc_5$), 1663.09 ($Hex_2Man_3GlcNAc_4$), 1704.27

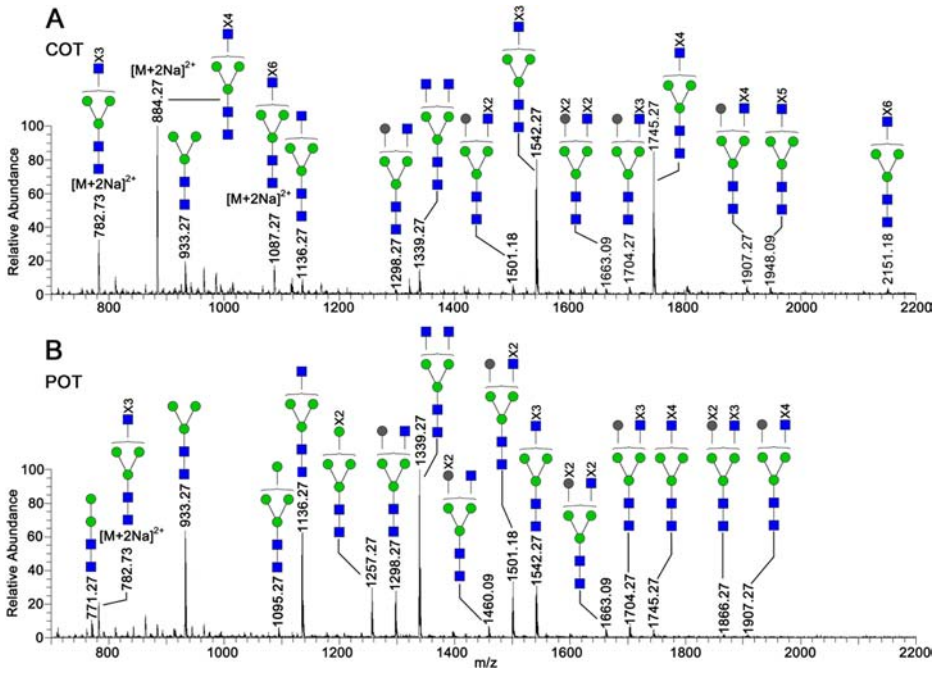

Figure 2. ESI−MS profiles of the *N*-glycans released from (A) COT and (B) POT. Sodiated ions are predominately produced. Putative glycan compositions are presented on the basis of the MS/MS analysis. Structural formulas: blue square, *N*-acetylglucosamine; green circle, mannose; gray circle, hexose.

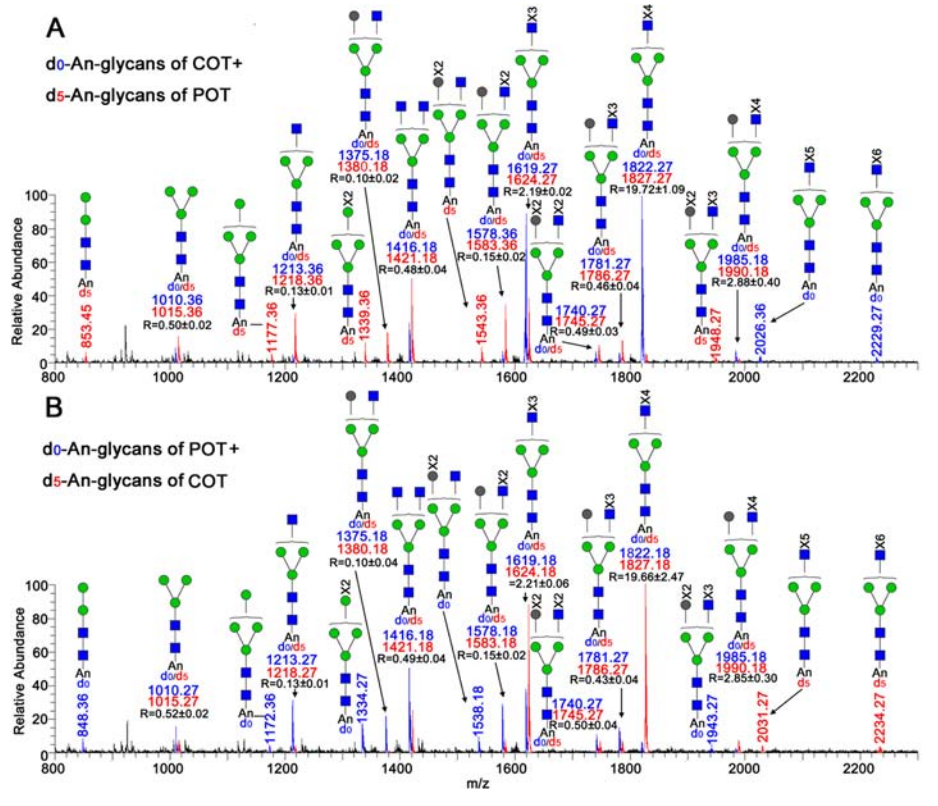

Figure 3. Quantitative comparison of COT and POT *N*-glycan compositions based on stable isotopic labeling using d_0- and d_5-aniline. (A) ESI−MS profile of an equimolar mixture of d_0-aniline derivatives of COT *N*-glycans (d_0-An-COT *N*-glycans) and d_5-aniline derivatives of POT *N*-glycans (d_5-An-POT *N*-glycans). (B) ESI−MS profile of an equimolar mixture of d_0-aniline derivatives of POT *N*-glycans (d_0-An-POT *N*-glycans) and d_5-aniline derivatives of COT *N*-glycans (d_5-An-COT *N*-glycans). The blue and red peaks are the signals of d_0-aniline and d_5-aniline derivatives, respectively. The intensity ratio between the d_0-aniline derivative of each glycan and its corresponding d_5-aniline derivative is shown as R, which consists of the mean value and standard deviation obtained from three repeated experiments. Sodiated ions are predominately produced. Structural formulas: blue square, *N*-acetylglucosamine; green circle, mannose; gray circle, hexose.

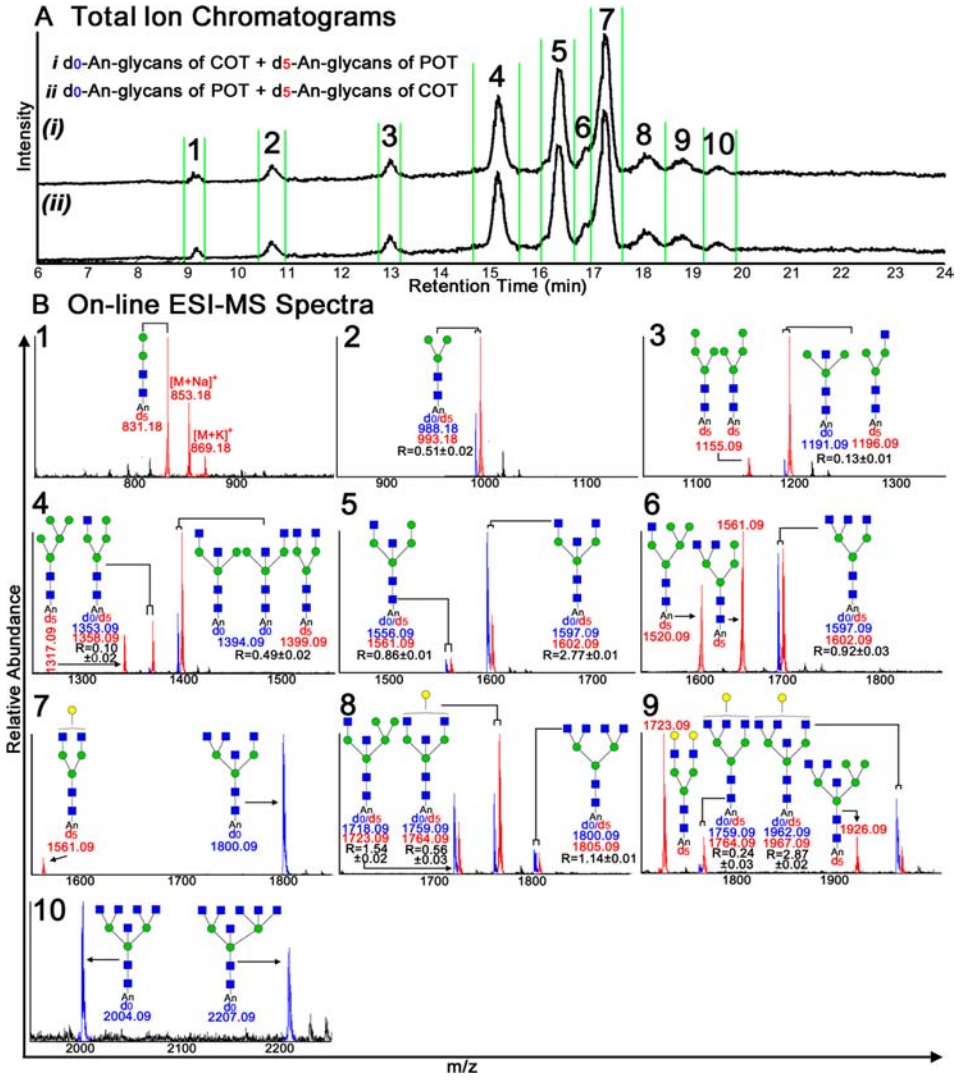

Figure 4. Qualitative and quantitative comparison of the COT and POT *N*-glycan isomers derivatized with d_0- or d_5-aniline via online HILIC−MS. (A) Total ion chromatograms (TICs) showing the elution profiles of (i) the equimolar mixture of d_0-An-COT *N*-glycans and d_5-An-POT *N*-glycans and (ii) the equimolar mixture of d_0-An-POT *N*-glycans and d_5-An-COT *N*-glycans. (B) Online MS spectra of an equimolar mixture of d_0-An-COT *N*-glycans and d_5-An-POT *N*-glycans. The blue and red ion peaks are the signals of d_0- and d_5-aniline derivatives, respectively. The intensity ratio of the d_0-aniline derivative of each glycan to its corresponding d_5-aniline derivative is shown as R, which consists of the mean value and standard deviation obtained from three repeated experiments. Protonated ions are predominately produced. Structural formulas: blue square, *N*-acetylglucosamine; green circle, mannose; yellow circle, galactose.

($Hex_1Man_3GlcNAc_5$), 1745.27 ($Man_3GlcNAc_6$), 1866.27 ($Hex_2Man_3GlcNAc_5$), and 1907.27 ($Hex_1Man_3GlcNAc_6$). Obviously, 10 of these *N*-glycans, at *m*/*z* 993.27, 1136.37, 1298.27, 1339.27, 1501.27, 1542.27, 1663.27, 1704.27, 1745.27, and 1907.27, exist in both COT and POT. All of these *N*-glycan compositions were identified via MS/MS (Supporting Information, Figures S1 and S2) and are supported by the literature.[18]

These results revealed that all of the *N*-glycans of COT and POT are neutral oligosaccharides and that no acidic oligosaccharide or fucosylated oligosaccharide was found in either sample. The *N*-glycan of $Hex_2Man_3GlcNAc_4$ corresponding to *m*/*z* 1663.27 was newly found in COT; however, the COT *N*-glycans including $Man_2GlcNAc_2$, $Man_1GlcNAc_3$, and $Hex_2Man_3GlcNAc_5$ reported in previous work[18] were not detected in our study, which may originate from other chicken egg white glycoproteins mixed in commercially obtained COT. Additionally, we are the first to demonstrate the *N*-glycan composition profile of ovotransferrin derived from wild bird species.

Quantitative Comparison of *N*-Glycan Compositions between COT and POT. For quantitative comparison of the *N*-glycan compositions between COT and POT, two aliquots of *N*-glycans released from COT or POT were separately derivatized with d_0- and d_5-aniline. The equimolar mixture of d_0-aniline-derivatized *N*-glycans of COT (d_0-An-glycans of COT) and d_5-aniline-derivatized *N*-glycans of POT (d_5-An-glycans of POT), as well as the equimolar mixture of d_0-aniline-derivatized *N*-glycans of POT (d_0-An-glycans of POT) and d_5-aniline-derivatized *N*-glycans of COT (d_5-An-glycans of COT), were analyzed by ESI−MS, and the compositions of these glycan derivatives were identified by MS/MS (Supporting Information, Figures S1 and S2).

As shown in Figure 3A, the equal-ratio mixture of d_0-An-glycans of COT and d_5-An-glycans of POT exhibits 12 peaks of d_0-An-glycans of COT and 15 peaks of d_5-An-glycans of POT

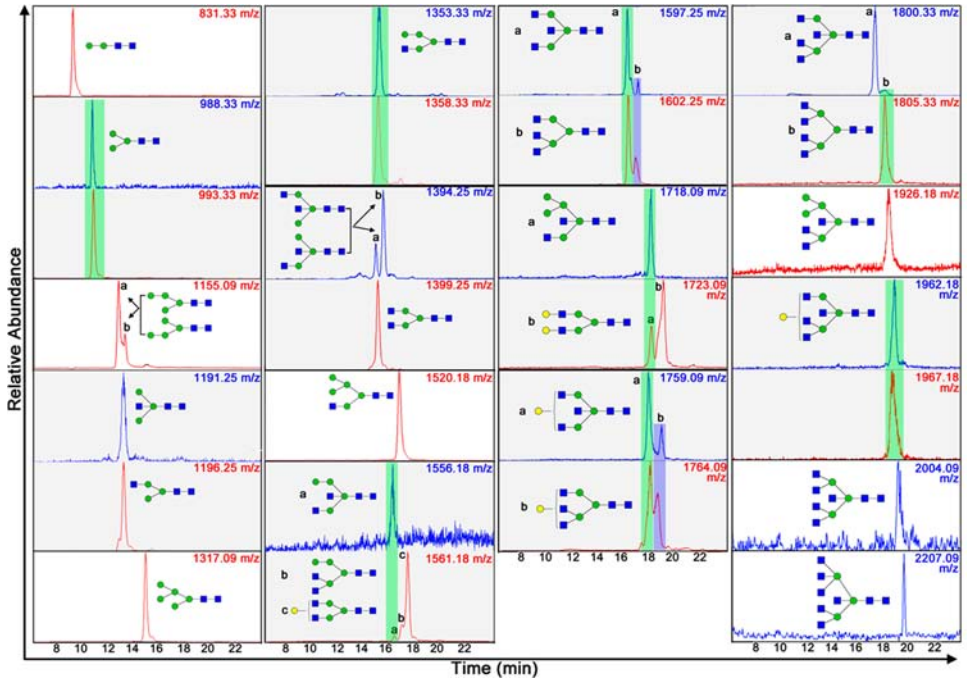

Figure 5. Extracted ion chromatograms (EICs) of d_0-aniline derivatives of COT *N*-glycans (d_0-An-COT *N*-glycans) and d_5-aniline derivatives of POT *N*-glycans (d_5-An-POT *N*-glycans). The blue and red chromatograms represent the EICs of d_0- and d_5-aniline derivatives, respectively. The EICs that share the same glycan compositions were covered with gray shadow. The paired blue (d_0-An-COT *N*-glycan) and red (d_5-An-POT *N*-glycan) EIC peaks that share the same glycan sequences were simultaneously covered with green or blue shadow. Structural formulas: blue square, *N*-acetylglucosamine; green circle, mannose; yellow circle, galactose.

in the ESI−MS profile, giving results that are consistent with those of the *N*-glycan composition profiling. All of those signals are assigned as $[M + Na]^+$ type ions, and their corresponding compositions are all displayed in the figure. In total, 10 pairs of peaks (m/z 1010.36/1015.36, 1213.36/1218.36, 1375.27/1380.27, 1416.18/1421.18, 1578.36/1583.36, 1619.27/1624.27, 1740.27/1745.27, 1781.27/1786.27, 1822.27/1827.27, and 1985.27/1990.27) and seven single peaks (m/z 853.45, 1177.36, 1339.36, 1543.36, and 1948.27 of d_5-aniline derivatives and m/z 2026.36 and 2229.27 of d_0-aniline derivatives) were clearly observed. The peak pairs indicate the coexistence of the corresponding *N*-glycans in both COT and POT, and the MS signal intensity ratio of d_0- to d_5-aniline derivatives of each glycan represents its abundance ratio, namely, the molar ratio between COT and POT. Meanwhile, the single peaks of the d_0- or d_5-aniline derivative indicates the existence of the corresponding *N*-glycans only in COT or POT, respectively. Clearly, 10 *N*-glycans exist in both COT and POT, of which $Man_3GlcNAc_2$, $Man_3GlcNAc_3$, $Hex_1Man_3GlcNAc_3$, $Man_3GlcNAc_4$, $Hex_1Man_3GlcNAc_4$, $Hex_2Man_3GlcNAc_4$, and $Hex_1Man_3GlcNAc_5$ are less abundant (by 0.51, 0.13, 0.10, 0.49, 0.15, 0.50, and 0.46 times, respectively) in COT than in POT, whereas $Man_3GlcNAc_5$, $Man_3GlcNAc_6$, and $Hex_1Man_3GlcNAc_6$ are more abundant (by 2.19, 19.69, and 2.87 times, respectively) in COT than in POT. Figure 3B shows the MS profile of the equal-ratio mixture of d_0-An-glycans of POT and d_5-An-glycans of COT. The results are well-consistent with the results of Figure 3A, confirming the correctness and excellent reproducibility of these results. Therefore, we conclude that the *N*-glycans of POT and COT exhibit conspicuous differences in both composition and abundance, although the two glycoproteins are encoded by identical genes and have the same amino acid sequence. Additionally, although POT possesses more *N*-glycan compositions than COT (15 vs 12), as Figure 3 demonstrates, the average size of oligosaccharides from COT is larger than the oligosaccharides from POT, consistent with the MALDI-TOF-MS analysis result (Figure 1) that demonstrated that the molecular weight of COT (77285 Da) is higher than that of POT (76774 Da).

Qualitative and Quantitative Comparison of COT and POT *N*-Glycan Isomers. Isomers exist extensively within the glycans released from glycoprotein. ESI−MS analysis of a mixture of glycans provides a rapid composition profile but gives little information regarding the isomers. HILIC affords a suitable means for the separation of aniline-labeled *N*-glycan isomers, and online MS/MS allows extensive fragmentation of separated glycan isomers, which provides rich information for differentiation and sequencing of diverse glycan isomers.[29] For the quantitative comparison of *N*-glycan isomers between COT and POT, an equimolar mixture of d_0-An-glycans of COT and d_5-An-glycans of POT and an equimolar mixture of d_0-An-glycans of POT and d_5-An-glycans of COT were separately analyzed by online HILIC−MS and online HILIC−MS/MS (Supporting Information, Figure S2).

The total ion chromatograms (TICs) (Figure 4A) of the two equal-ratio sample mixtures show parallel elution profiles, which exhibit of the derivatives of specific *N*-glycans. The equimolar mixture of d_0-An-glycans of COT and d_5-An-glycans of POT was selected as the example for quantitative comparison analysis. Figure 4B shows the online MS spectra corresponding to the major peaks of the TIC of the equimolar mixture of d_0-An-COT *N*-glycans and d_5-An-POT *N*-glycans. The isomeric sequences of the *N*-glycan derivatives presented in the spectra were proposed on the basis of the data in the extracted ion chromatogram (EIC) (Figure 5) and HILIC−

Table 1. Comprehensive List of COT and POT *N*-Glycans Detailing Monosaccharide Compositions, Proposed Structures, Glycan Types, Relative Quantity (%), and Abundance Ratios Found in Both COT and POT *N*-Glycan Compositions and Isomers

MS/MS (Suppporting Information, Figure S3). Protonated ions are predominately produced, and very few sodiated and potassiated ions are observed in the mass spectra. Twelve pairs of peaks (*m*/*z* 988.18/993.18, 1191.09/1196.09, 1353.09/1358.09, 1394.09/1399.09, 1556.09/1561.09, 1597.09/1602.09, 1597.09/1602.09, 1718.09/1723.09, 1759.09/1764.09, 1800.09/1805.09, 1759.09/1764.09, and 1962.09/1967.09) were clearly observed. The abundance ratios of the paired d_0-An-COT derivatives and d_5-An-POT derivatives at *m*/*z* 988.18/993.18, 1191.09/1196.09, 1353.09/1358.09, and 1962.09/1967.09 (by 0.51, 0.13, 0.10, and 2.87 times, respectively) are consistent with the results of the glycan composition comparison, and EICs (Figure 5) indicate that there is no isomer for these glycan compositions. Meanwhile, due to the existence of glycan isomers, several pairs of peaks give new molar ratios when compared with those obtained through the above-described *N*-glycan composition comparison analysis. Here, seven pairs of d_0-aniline derivatives and d_5-aniline derivatives at *m*/*z* 1556.09/1561.09, 1597.09/1602.09, 1597.09/1602.09, 1718.09/1723.09, 1759.09/1764.09, 1800.09/1805.09, and 1759.09/1764.09 give corresponding molar ratios of 0.86, 2.22, 0.28, 1.54, 0.56, 1.14, and 0.24, respectively, and each pair of peaks shares the same *N*-glycan sequence. Nevertheless, the pair of peaks at *m*/*z* 1353.09/1358.09 is an exception, as it shares the same composition but different glycan sequences. The molar ratio between the two peaks is 0.49, consistent with the ratio shown in Figure 3. The singly occurring *N*-glycan derivatives from COT or POT were also annotated in the spectra. Some of these *N*-glycans are the isomers of paired *N*-glycans, whereas the others that exist in either COT or POT have no corresponding isomeric structures in POT or COT. The results of HILIC−MS analysis are highly consistent with the data presented in Figure 3.

On the basis of ESI−MS and online HILIC−MS analysis, comprehensive analytical information on COT and POT *N*-glycans is summarized in Table 1, including monosaccharide compositions, proposed structures, glycan types, relative quantity (%) and abundance ratios of *N*-glycan compositions, and isomers found in both COT and POT. In total, 16 *N*-glycans of COT and 21 *N*-glycans of POT were found when glycan isomers were taken into account. Ten of these glycan structures exist in both COT and POT. Additionally, there is no acidic or fucosylated glycans observed in either COT or POT. The COT *N*-glycans with compositions of $Man_3GlcNAc_4$, $Man_3GlcNAc_5$, $Gal_1Man_3GlcNAc_5$, and $Man_3GlcNAc_5$ and POT *N*-glycans with compositions of $Man_4GlcNAc_2$, $Man_3GlcNAc_5$, $Hex_2Man_3GlcNAc_4$, and $Gal_1Man_3GlcNAc_5$ each have two isomers, and the COT *N*-glycan composition of $Hex_1Man_3GlcNAc_4$ has three isomers. The other *N*-glycan compositions have only single structures. As summarized in Table 2 and Figure 6, for COT *N*-glycans, 1 core structure (3.18%), 12 complex type (91.4%), 3 hybrid type (5.42%), and no high mannose type glycan were observed. In contrast, for POT *N*-glycan types, 1 core structure (6.26%), 3 high mannose type (5.20%), 10 complex type (67.52%), 6 hybrid type (19.14%), and 1 truncated structure (1.88%) ($Man_2GlcNAc_2$) were observed. COT contains five types of antennary complex-type structures described as follows: monoantennary (8.4%), biantennary (32.37%), triantennary (44.47%), tetra-antennary (3.56%), and penta-antennary (1.10%). However, POT contains four types of antennary structure including monoantennary (12.24%), biantennary (45.82%), triantennary (7.74%), and tetra-antennary (1.19%); no penta-antennary type structure was observed.

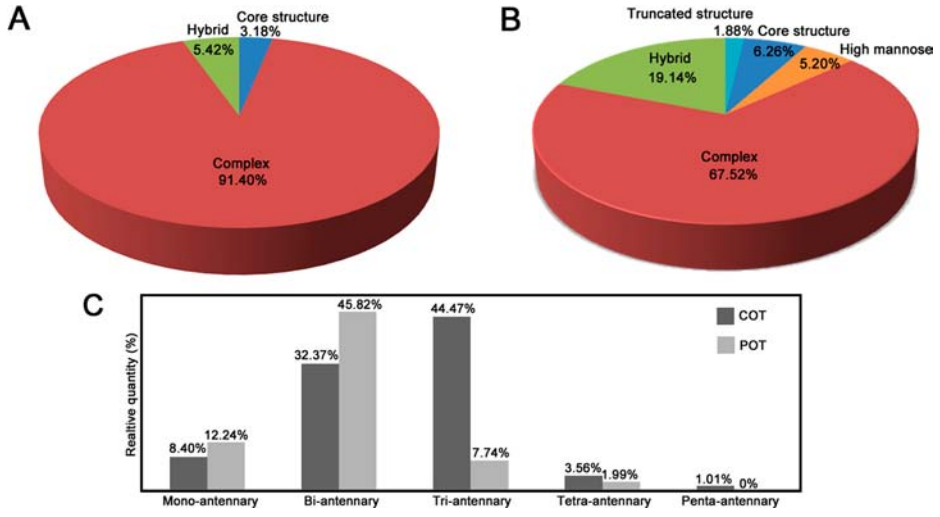

Figure 6. Charts showing the relative quantities of all *N*-glycan types in COT (A) and POT (B) as well as branched patterns of complex type *N*-glycans from COT and POT (C).

dx.doi.org/10.1021/jf501352j | J. Agric. Food Chem. 2014, 62, 7245−7254

This study, to our knowledge, is the first work that comparatively details COT and POT *N*-glycans, especially using qualitative and quantitative analysis of their *N*-glycan isomers through the combination of glycan isotopic aniline labeling, ESI−MS, HILIC−MS, and MS/MS. As the only variable component, attached *N*-glycans contribute to the primary structural differences between COT and POT and may influence the bioactivity of the two glycoproteins. This study provides a foundation for the further elucidation of the specific biofunctions of COT and POT, thereby stimulating, perhaps, their application in the food industry as a novel nutraceutical and functional food ingredient in the future.

temperature and assessing any sensory changes that developed after this storage. The primary aim of this study was to examine the relationship between bottle color and the development of a yellow-golden color, phenolic composition, and sensory characteristics in a Sauvignon Blanc wine after 8 months of storage.

MATERIALS AND METHODS

Reagents and Chemicals. Gallic acid (≥99%), caffeic acid (≥98%), *p*-coumaric acid (≥98%), caftaric acid (≥97%), quercetin (≥98%), and (+)-catechin (≥99%) standards were purchased from Sigma Chemical Co. (St. Louis, MO). Polyethylene membranes of a 0.22 μm pore size were acquired from EMD Millipore (Billerica, MA). Ethyl acetate (≥99.8%), diethyl ether (≥99.7%), anhydrous sodium sulfate (≥98%), glacial acetic acid (100%), ethanol (≥99.9%), hydrochloric acid (37%), and acetonitrile (HPLC-grade) (≥99.9%) were purchased from Merck (Darmstadt, Germany). All reagents were of analytical grade or higher. Ultrapure water was obtained from a Purelab Ultra MK2 purification system (Elga, St Albans, UK).

Wine Bottles. The bottles used (Bordeaux Punted model, 750 mL capacity) were provided by Cristalchile (Santiago, Chile). The bottles used in this study were designated by their trade names (Dead Leaf Green, Antique Green, Amber, and Flint) to describe their color. Groups of 25 bottles were used for each bottle color, for a total of 100 bottles. These colors were chosen because they represent the most commonly used bottles in the wine industry.

White Wine. A commercial Sauvignon Blanc wine (100 L) was provided from "Viña Veramonte" (Casablanca Valley [33°22′14″ S, 71°17′41″ W], Chile). The bottles were filled and capped with roll-on tamper-evident screw caps (Saran Tin liner) (Amcor, Hawthorn, Australia) at "Viña Veramonte". The basic chemical parameters for the wine were as follows: pH, 3.1; titratable acidity, 6.4 g/L (tartaric acid); free sulfur dioxide, 33 mg/L; total sulfur dioxide, 98.1 mg/L, reducing sugars, 1.2 g/L; ethanol, 13.9% (v/v).

Artificial Light Exposure Experiment. During the trial period (8 months), the bottles were stored in a dark room in which small temperature variations were observed (16.8 °C ± 2.9 °C) with a relative humidity of 40−50%, as registered using a VWR-4184 temperature/humidity meter (VMR International, Radnor, PA). Further details regarding the storage temperature will be given later. The bottles only received the light provided by the fluorescent tubes. The wine bottles were placed vertically inside three open cabinets, as shown in Figure 1 (height, 213 cm; width, 110 cm; depth, 52 cm). Each cabinet had four shelves, spaced at 40 cm, with two fluorescent tubes each (T10 40 W 54, standard daylight 6500 K, General Electric, Fairfield, CO), which were located 16 cm from the base of the shelf. The light emitted from the fluorescent tubes was measured using a HD9021 radiometer (Delta OHM, Padua, Italy), placing the radiometer's sensor at a distance of 20 cm from the fluorescent tubes. The incidental radiation at 20 cm from the fluorescent tubes was 68.0 ± 0.1 μmol/m^2·s. These measurements were used to delimit an area of the shelves in which radiation was uniform, to place all of the bottles within that area. The bottles were distributed at a distance of 20 cm from the light source and at a distance of 20 cm from each other. Subsequently, the light exposure regime was adjusted with a Tactic 111.0 timer (Grässlin, St. Georgen, Germany) to 16 h per day (from 8:00 to 24:00 h), with 8 h without light to simulate night-time conditions during the 8-month period of exposure. Furthermore, to assess the ability of each bottle type to limit the light radiation reaching the wine within the bottle, the radiometer recorded the incident radiation in the test room and the transmission inside the bottle. To measure the incident radiation and the transmission of light through the glass, a sensor was placed inside an empty bottle in the medium section, with the bottle located at 20 cm from the light source provided by the fluorescent tubes. All of the bottles were stored for 2 weeks to equilibrate them in the same dark room before the assay was initiated.

Figure 1. Photograph showing the open cabinets with the arrangement of the fluorescent tubes and bottles during the 8 months of storage.

Wine Chemical Analyses. The analyses were performed every month, but considering that the results did not vary much, only the results obtained every 2 months are presented. The chemical analyses at time zero (month 0) were performed after 2 weeks of storage without artificial light exposure. The wine's pH, titratable acidity (g tartaric acid/L), reduced sugar content (g glucose/L), ethanol content (% v/v), and free sulfur dioxide (mg/L) were measured according to OIV methods.[6] The total phenol content was determined by UV absorption at 280 nm using gallic acid as a standard and expressed as mg GAE (gallic acid equivalent)/L.[7] The total tannin content was measured using the method of Ribéreau-Gayon and Stonestreet.[8] Color intensity (CI) was estimated using the method described by Glories.[7] The color coordinates, lightness (L^*), chroma (C^*), hue (h^*), a^* (red-greenness), and b^* (yellow-blueness) were determined according to Ayala et al.[9] All absorbance measurements were taken with a UV−vis spectrophotometer, model UV/vis 1700 Pharmaspec (Shimadzu, Kyoto, Japan).

HPLC-DAD Analyses of Low Molecular Weight Phenolic Compounds. A 50 mL aliquot of white wine was extracted with diethyl ether (3 × 20 mL) and ethyl acetate (3 × 20 mL) to concentrate the phenolic compounds. The organics fractions were combined, dehydrated with 2.5 g of anhydrous sodium sulfate, and evaporated to dryness under a vacuum at 30 °C. The solid residue was dissolved in 2 mL of a methanol/water (1:1, v/v) solution and filtered through a 0.22 μm pore size membrane. A chromatographic system used for identification of individual phenolic compounds consisted of an Agilent Technologies 1100 series (Agilent Technologies, Santa Clara, U.S.) equipped with a diode-array detector (DAD) model G1315B, a quaternary pump model QuatPump G1311A, a degasser model G1379A, and an autosampler model G1329A. Aliquots (25 μL) of the final solution were subjected to reverse-phase chromatographic separation at 20 °C on a reverse-phase Nova Pack C_{18} column (4 μm, 3.9 mm i.d. × 300 mm; Waters Corp.). A photodiode array detector was set from 210 to 360 nm. Two mobile phases were used as follows: A, water/acetic acid (98:2 v/v); and B, water/acetonitrile/acetic acid (78:20:2 v/v/v). A gradient was applied at a flow rate of 1.0 mL/min from 0 to 55 min and 1.2 mL/min from 55 to 90 min as follows: 100−20% A, 20−10% A from 55 to 57 min, 10−0% A from 57 to 90 min. Each major peak in the HPLC chromatograms of the extracts was characterized by both the retention time and the absorption spectrum (from 210 to 360 nm), according to Peña-Neira et al.[10] Quantitative determinations were performed using the external standard method on commercial standards. The calibration curves were produced by injecting the standard solutions before an extraction, under the same conditions as for the samples analyzed, over the range of concentrations observed ($r^2 \geq 0.93$). Quercetin glycosides, for which no standards were available, were quantified using standard curves for quercetin. All of the qualitative and quantitative analyses of phenolic

composition (including their extraction step) were performed in triplicate.[11]

Sensory Evaluation. The sensory panel consisted of personnel (five females and seven males) from the Department of Agro-industry and Enology, ranging in age from 24 to 53 years. All of the judges had previous experience with sensory analysis in white wines. An initial training session was conducted for the recognition of aromatic references. The training consisted of a familiarization exercise with aromatic descriptors by using fresh and processed fruits and vegetables to exemplify the most common aromatic descriptors founded in Sauvignon Blanc wines. The evaluation sessions were performed in individual tasting booths, in a temperature-controlled room set at 20 °C. A total of 20 mL of wine was served at 10−11 °C in wine-tasting glasses (Arcoroc, Arques, France) after being labeled with a three-digit code using a completely randomized order. Each wine was evaluated with regard to two sensory attributes, color intensity, and aromatic intensity, on a 15 cm unstructured linear scale, anchored from "low" to "high" intensity. Furthermore, the judges analyzed the aromatic descriptors of each wine. The flavor descriptors appropriate for discriminating among wines are provided in Table 1. The judges chose a series of flavor descriptors, and the descriptors with the highest scores were chosen after the evaluation and expressed as a percentage. These terms were derived from previous studies of aromatic properties in Sauvignon Blanc wines.[12,13] All judges rated each wine in duplicate. The data were collected using the Fizz software (ver. 2.47b, Biosystemes, Couternon, France). The evaluation sessions lasted approximately 3 h each and were performed every 2 months.

Table 1. Flavor Descriptors and Reference Materials Used in Association with Each Descriptor

typicity	groups	aromas	reference material
vegetal	fresh vegetables	leaves/stems	green leaves
		grass	freshly cut grass
		green capsicum	green capsicum slice
		green pepper	green pepper slice
		tomato stalk	tomato stalks
		boxwood/cat urine	boxwood leaves
	canned/cooked	green beans	fresh green beans
		asparagus	canned asparagus
		green olives	canned green olives
		artichoke	canned artichoke
citric	citrus fruits	grapefruit	grapefruit slices
		lemon	lemon slices
		orange	orange slices
		lemon peel	lemon peel
tropical	tropical fruits	pineapple	pineapple slice
		melon	melon piece
		banana	banana piece
		cherimoya	cherimoya piece
others	stone fruits	apricot	fresh apricot slice
		peach	fresh peach slice
	pome fruits	green apple	fresh green apple slice

Statistical Analyses. Analysis of variance (ANOVA) and the Tukey's Honestly Significant Difference (HSD) test were used to separate the means at a significance level of 95% ($p < 0.05$). All of the chemical and physical analyses were performed in triplicate. The sensory data were analyzed by ANOVA and Least Significance Difference (LSD) test ($p < 0.05$). All statistical analyses were conducted using Statgraphics Centurion (ver. 15.2, Statpoint Technologies, Warranton, VA) and Excel 2007 version 12.0 (Microsoft Corp., Redmond, WA).

RESULTS AND DISCUSSION

Characterization of Bottle Type. To assess the ability of each bottle type to limit the light radiation reaching the wine within the bottle, a radiometer was used to record the incident radiation and the transmission inside the bottle. Table 2 compares the light transmission for the four types of bottles. The Flint bottles had the highest incident radiation with a value of 56.2 μmol/m^2·s. The colored bottles showed a range of incident radiation from 20.3 to 21.5 μmol/m^2·s with slight differences among them. The Flint bottles also had the highest value of transmittance. These results are corroborated by those in the study of Maury et al.,[1] who showed that the highest percentage of transmittance corresponded to the Flint bottles and that the lowest corresponded to the colored bottles. These authors showed that the Flint bottle is capable of transmitting all visible and some UV light; however, darker bottles reduce the amount of visible light reaching the sample and allow only a small amount of UV light to be transmitted.

Table 2. Radiation and Transmittance Percentages in Bottles[a]

bottles	incident radiation (μmol/m^2·s)	transmittance (%)
Dead Leaf Green	20.3 ± 0.2 c	29.9 ± 0.2 c
Antique Green	20.2 ± 0.1 c	29.8 ± 0.2 c
Amber	21.5 ± 0.2 b	31.7 ± 0.2 b
Flint	56.2 ± 0.3 a	82.7 ± 0.4 a

[a]All data are expressed as the mean ± standard deviation ($n = 3$). Different letters among bottle color indicate significant differences ($p < 0.05$) according to Tukey's HSD test.

Chemical Composition of the Wines. Table 3 shows the values of titratable acidity, pH, free sulfur dioxide, and phenolic composition of wine samples. The pH varied from 3.05 to 3.25. With regard to titratable acidity, the values varied from 6.1 to 6.6 g tartaric acid/L. The free SO_2 varied from 27.3 to 33.7 mg/L. These results were in agreement with data from white wines in previous studies.[14,15] No differences were observed in the concentration of total phenols at time 0.

From the second month onward, a slight increase in total phenol concentration was observed in all colored bottles as compared to the Flint ones. The increase in the content of total phenols in the first months could be due to a hydrolysis reaction and complex formation.[16,17] Moreover, the study of Maury et al.[1] on different colors of wine bottles showed a decrease in absorbance at 280 nm in Flint and Green bottles, coinciding with the lowest concentration of total phenols in the Flint bottle.

Regarding the analysis of the total tannins, there was an increase in the concentration across all treatments during wine storage, although an initial decrease was observed in the first month in the dark bottles; however, it is possible that this variation was due to experimental error. The Bate−Smith assay was utilized for the quantification of the total tannins and can be influenced by several variables that might affect the kinetics of color formation. For example, the incomplete transformation of proanthocyanidins into anthocyanidins has reaction yields that depend on both the structure and the polymerization degree of the proanthocyanidins.[18] The medium conditions and the presence of light may also have caused a depolymerization of the more polymerized tannins, leading to the consequent release of less polymerized tannins, procyanidins, and monomers, causing a greater reactivity of these compounds, specifically polymerized tannins and procyanidins in the acid-catalyzed oxidative depolymerization of these compounds.[19]

Table 3. Phenolic Composition and Chemical Parameters in Sauvignon Blanc Wines in Different Bottle Colors under Artificial Light Conditions during the 8 Months of Storage[a]

[a]All data are expressed as the mean ± standard deviation ($n = 3$). Different lowercase letters indicate significant differences ($p < 0.05$) between bottle colors in each month according to Tukey's HSD test. Different uppercase letters indicate significant difference ($p < 0.05$) for each bottle color during time storage according to Tukey's HSD test. GAE, gallic acid equivalent; CE, (+)-catechin equivalent.

These effects could have resulted in an increase in the value of total tannins quantified by this method.

Table 4 shows the content of some of the major low-molecular-weight phenols in Sauvignon Blanc white wines. The hydroxybenzoic acid quantified was gallic acid, and the hydroxycinnamic acids quantified were caftaric, *cis*-caffeic, *trans*-caffeic, and *p*-coumaric acids. The flavanol quantified was (+)-catechin, and the flavonols quantified were quercetin-3-glucoside, quercetin-3-galactoside, and quercetin. All of these compounds were detected in all of the wines used in this study.

The compounds exhibiting higher concentrations were *trans*-caffeic, caftaric, and *p*-coumaric acids. At time zero (month 0), the greatest differences in concentration were observed, with the highest concentrations of gallic acid, (+)-catechin, caftaric acid, *p*-coumaric acid, and quercetin-3-galactoside being noted in colored bottles, especially in Dead Leaf Green bottles. By contrast, Flint bottles presented a lower content of these compounds.

During storage under artificial light conditions, there was varying behavior in some of the phenolic compounds analyzed. With regards to phenolic acids, *cis*-caffeic acid, a slight increase in concentration during storage was observed, while instead caftaric acid showed a decrease in their concentration. On the other hand, gallic and *trans*-caffeic acids showed a more erratic behavior. The concentration of *p*-coumaric acid decreased substantially in Flint bottles, especially toward the end of the assay. During wine aging, both depolymerization and condensation occur. The storage conditions are expected to strongly affect the content of phenols, because they can undergo modifications during storage, mainly due to hydrolysis (enzymatic or not), oxidations, and complexations that are mainly responsible for the increase of simpler compounds, such as free phenolic acids, especially in colored bottles[16,17] that could support the behavior of some compounds in this assay. Cleavage of interflavan bonds of proanthocyanidins could happen at the pH of wine.[20] According to Schofield et al.,[19] the interflavan links in most condensed tannins may be broken under acid condition. In general, an increase in (+)-catechin concentration during wine storage was observed. This pattern may be due to the medium conditions, in which the combination of low pH (3.05−3.25) and the presence of light were able to cause a depolymerization of the higher molecular mass flavanols (i.e., condensed tannins) and the concomitant release of (+)-catechin monomers.[21] This hypothesis can be supported by the analysis of total tannins, wherein the presence of light and medium conditions could cause the depolymerization of more polymerized condensed tannins and consequent (+)-catechin release (Table 3).

Concerning the flavonols identified, there were different behaviors among them during storage under artificial light conditions. With respect to quercetin-3-glucoside, there were no differences between bottle colors and only minor, erratic differences throughout the time of storage. In contrast, quercetin-3-galactoside showed a clear decrease in concentration during storage that resulted in nondetectable values from the sixth month of storage onward; only in month 0 were differences among bottle color found to occur at a higher concentration in colored bottles. Moreover, quercetin was the predominant flavonol quantified in all samples, demonstrating an increased concentration throughout the wine storage period with no differences among bottle colors. This increase could be due to the hydrolysis reaction (enzymatic or not) that was mainly responsible for the increase in the number of simpler compounds,[16,17] such as quercetin, and was supported by the observed decrease in quercetin-3-galactoside throughout storage. These reactions may be accelerated by the presence of light.

Table 4. Mean and Standard Deviations Values (mg/L) for Wine Phenolic Compounds As a Result of the Exposition of Sauvignon Blanc Wines in Different Bottle Colors under Artificial Light Condition during 8 Months of Storage[a]

compounds	months	Dead Leaf Green	Antique Green	Amber	Flint

[a]All data are expressed as mean ± standard deviation ($n = 3$). Different lowercase letters in a row indicate significant differences ($p < 0.05$) between bottle colors in each month according to Tukey's HSD test. Different uppercase letters in a column indicate significant difference ($p < 0.05$) for each bottle color during time storage according to Tukey's HSD test. nd: not detected.

Regarding wine color, storage under artificial light conditions produced differences in the L^* parameter, which was significantly affected only in the treatments with a lower transmittance percentage, such as Antique Green and Dead Leaf Green bottles (Table 5). The Flint bottle showed a lower value of the parameter C^* throughout the 8 months of storage. This suggests that the higher value of C^* occurring in dark bottles may be linked to the production of pigments that contribute a higher color intensity and browning. The relationship between the loss of luminance (L^*) and the increase of chroma (C^*) is a characteristic of white wines stored for a certain time.[22] The hue values (h^*) differed among all bottle colors in their amounts, suggesting that most of the wines presented a medium yellow color, with a slight tendency toward green.[17,22] Regarding the color coordinates a^* and b^*, the Flint bottle presented the lowest values. The colored bottles showed a greater tendency toward red-greenness or yellow-blueness, especially the Amber bottle, which presented the highest value in coordinate b^*.

[a]All data are expressed as the mean ± standard deviation ($n = 3$). Different lowercase letters indicate significant differences ($p < 0.05$) between bottle colors in each month according to Tukey's HSD test. Different uppercase letters indicate significant difference ($p < 0.05$) for each bottle color during time storage according to Tukey's HSD test.

Surprisingly, the color intensity of the Flint bottles presented values significantly lower ($p < 0.05$) than those of the colored bottles during the 8 months of storage (Figure 2), which is in agreement with the lowest value of C^* in Flint bottles (Table 5). Maury et al.[1] proposed that dark colored glass absorbs and retains more heat, driving pigmentation development in these bottles. Moreover, the higher retention of heat possibly occurring in dark bottle and the high composition of iron oxide[23,24] could result in a higher absorption of UV, visible, and infrared light and a higher production of pigments that increase the color intensity in dark bottles. In our study, the temperature of the dark room was registered at three points at 12:00 pm during the assay, as follows: March, min 17.0 °C, max 20.7 °C; July, min 12.6 °C, max 15.5 °C; October, min 16.0 °C, max 19.2 °C. At the same time, the thermometer probe was placed near of the surface of the bottles to register the temperature. Temperature recording near the bottles (5 cm) showed an average of 18 °C, which was quite variable depending on the temperature of the dark room. Because this experiment was performed with fluorescent tubes, the heat emission was predictably fairly low. In the study of Dias et al.,[4] the use of a mercury vapor lamp under controlled temperature conditions (38 ± 3 °C) produced increased coloration in Flint bottles, although uncontrolled temperature conditions led to the highest development of wine color in Antique Green bottles but the lowest development of wine color in Flint bottles. Moreover, in the study of Maury et al.,[1] a Sauvignon Blanc stored in bottles of different colors exposed to sunlight, with measurement of temperatures between 12.5 and 17.5 °C in the months of May, June, and July at the southeast of Australia, showed greater color development in darker bottles that are in agreement with the results of this work. In that case, the temperatures recorded outside of the bottles in this assay are similar to that exposed by Maury et al.[1] By observing the results of the low molecular weight phenolic compounds (Table 4), in some of them (e.g., caftaric, *p*-coumaric acids) there were a higher concentration in the wines bottled in darker color, especially during the first months of the assay. This slightly significant difference combined with the long storage of these bottles to artificial light conditions may explain the increase in yellow coloration found in the wines from colored bottles. Furthermore, another possibility is that the type of light transmitted by fluorescent tubes (e.g., small quantities of UV light) through the glass in the Flint bottles can degrade the pigments responsible for yellow coloration in white wines, as exposed by other authors.[1,4,25]

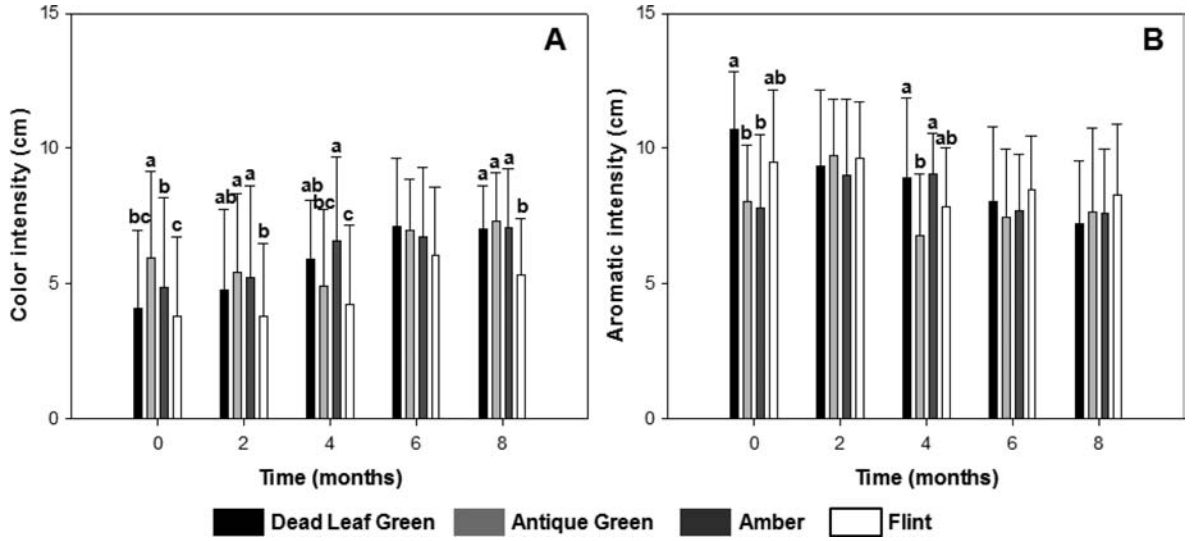

Figure 3. Sensory evaluation of the color intensity (cm) (A) and aromatic intensity (cm) (B) in Sauvignon Blanc wine in different bottle colors under artificial light conditions over 8 months of storage (n = 12). Different letters denote significant differences among bottle colors (p < 0.05, LSD test).

gustatory characteristics, such as bitterness, acidity, and taste intensity, these parameters did not show significant changes throughout the experiment; no differences were found among the treatments. Figure 3 shows the results of color and aromatic intensity. With regards to the perception of color, significant differences were observed among the treatments. The Flint bottles always had the lowest average values of color intensity, with varying differences across the sampling points. Still, only a trend reflecting an increasing color intensity during storage under artificial light conditions was observed. Furthermore, the color intensity by absorbance at 420 nm (Figure 1) and color coordinates (Table 5) correlated well with the sensory data. With regards to the aromatic intensity, only a trend of decreasing intensity was observed during the assay.

With regards to the aromatic descriptors analyzed, clear differences were observed among the treatments. The Sauvignon Blanc grapes are often described as producing wines that have a very distinctive varietal aroma, characterized by descriptors of fruity and vegetable flavors, including passion fruit, green capsicum, and boxwood.[12] In this study, the wines were grouped into four categories that represented the main aromatic characteristics of the Chilean Sauvignon Blanc, as follows: vegetal (e.g., grass, green capsicum, boxwood, asparagus), citric (e.g., lemon, orange), tropical (e.g., pineapple, cherimoya), and others aromas (e.g., apricot, peach, green apple) (Table 1). In general, the wines were described as having an important vegetal and citrus character, with lower notes of tropical fruits and other fruit aromas, specifically, peach and green apple. The analyses of the aromatic descriptors showed that there was a decrease in vegetal aromas in the darker bottles, especially in Antique Green bottles. In general, the storage time and exposure to artificial light produced an increase in citrus and tropical flavors. Clearly, storage under exposure to an artificial light produced significant changes in the aromatic descriptors that depended on the color of bottle used (Figure 4).

Although the principal aromatic descriptor of this cultivar is mainly due to the presence of volatile thiols, esters, and methoxypirazines,[2] further studies are needed to observe whether the use of different conditions of light and temperature

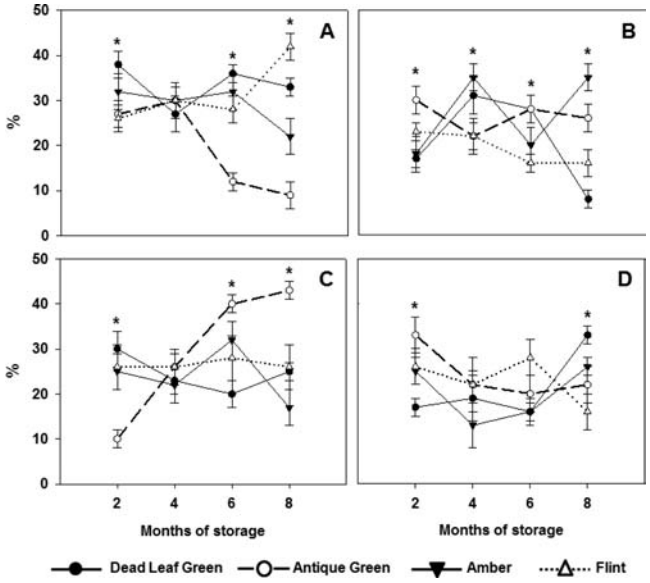

Figure 4. Evolution of the most important aromatic descriptors, such as vegetal (A), citric (B), tropical (C), and others (D), of Sauvignon Blanc wines in different bottle colors under artificial light conditions (n = 12). "*" denotes significant differences among bottle colors in each month (p < 0.05, LSD test).

can affect the concentrations of these compounds during wine storage.

In brief, this artificial light exposure experiment provided important data on the use of Flint and colored bottles and their effects on certain chemical and sensory features of wines. The implications of the results of this study are important to achieve a better comprehension of the principal factors affecting the chemical composition of the wines during storage. The color of the bottles, along with the light used, may affect the chemical composition of the wines. Furthermore, the exposure of the wines under artificial light after a long storage period may produce significant changes in the sensory properties of white wines, especially in the aromatic descriptors. This characteristic and the increase in the yellow coloration of the wines in darker

bottles should be taken into account by wineries and retail shops so that they may improve the safety of their wine storage.

characterized by not only resistance to dye leaching but also rapid color recovery in the presence of oxygen.

MATERIALS AND METHODS

Materials. MB, azure A (AA), thionine (Th), titanium(IV) oxide (TiO_2, AEROXIDE P25, nanopowder, 21 nm particle size), glycerol, zein from maize, and kappa (κ)- and iota (ι)-carrageenans were purchased from Sigma-Aldrich (St. Louis, MO) and used as received without further purification. The film for coating the oxygen indicator ink was a commercial nylon/polyethylene (PE) vacuum packaging film of 0.15 mm thickness (Pack4U, South Korea). All experiments were conducted in triplicate.

Carrageenan-Based Oxygen Indicator Film Preparation. Indicator ink consisted of 40 mg of MB, 1.2 g of TiO_2, and 1.2 g of glycerol. All of these components were added to 3.2 g of aqueous ethanol solution (90%) and then mixed thoroughly by a magnetic stirrer, followed by 5 min of ultrasonic dispersion (Vibra-Cell VCX-750, Sonics and Materials, Inc., Newtown, CT). The packaging film (4 × 4 cm) was spin-coated with the ink at 5000 rpm for 30 s using a spin coater (WS-400B-6NPP-LITE, Laurell Technologies Corporation, North Wales, PA) and dried. The resultant film was then dipped into ι-carrageenan solutions (0.2, 0.3, 0.4, and 0.5%, w/v) using a dip coater (KSV-DC, KSV Instruments, Bridgeport, CT) at an immersion and withdrawal speed of 85 mm/min and finally spun at 2000 rpm for 30 s.

The thickness of the carrageenan-based indicator films was measured using a thickness gauge (ID-S112B, Mitutoyo, Japan) and presented with an average of three samples with eight measurements along the edge of each film.

Zein-Based Oxygen Indicator Film Preparation. Zein (20%)-based indicator ink was prepared by adding 40 mg of MB, 1.2 g of TiO_2, 1.2 g of glycerol, and 0.8 g of zein to 3.2 g of ethanol solution (90%) and then mixing with ultrasonication. The packaging film (4 × 4 cm) was spin-coated with the ink at 5000 rpm for 30 s and then allowed to dry in the dark.

Dye Leaching of Oxygen Indicator Films into Water. The oxygen indicator films were submerged in a beaker filled with distilled water for 1 day, and leached dyes were quantified at 1, 3, 6, 12, and 24 h by measuring the absorbance at λ_{max} of each dye with a Varian Cary 50 UV−vis spectrophotometer. Dye leakage (%) was defined as a ratio of the amount of dye leaching into the water for a given time to the initial amount of dye on the film; thus, dye leakage of 100% indicates that all of the dye leached from the film into the water. The initial dye amounts were determined by measuring the absorbance after immersing the films in vigorously stirred solutions for 3 h: 70% ethanol for the zein-based films and HCl solution (2 M) for the carrageenan-based films.

Activation and Recovery of Oxygen Indicator Films. For bleaching of the oxygen indicator film, UV irradiation was carried out using a CL-1000 UV cross-linker (UVP, Upland, CA) equipped with five tubes of UVC lamps (8 W each). The irradiation intensity measured with a UVX digital radiometer (UVP, Upland, CA) was 5.5 mW/cm^2. For color recovery, the photobleached film was placed in ambient air, and its color change was monitored using a CM-2600d spectrophotometer (Konica Minolta, Tokyo, Japan).

Color Measurement. Several systems for expressing color numerically (i.e., color space) were developed by an international organization concerned with issues of lighting and color, the International Commission on Illumination (usually abbreviated CIE for its French name, Commission Internationale de l'Éclairage). The $L^*a^*b^*$ color space (also referred to as CIELAB) devised in 1976 is the most widely used, owing to the uniform distribution of colors.[25] In this space, L^* indicates lightness, ranging from 0 (black) to 100 (white), while a^* and b^* are the chromaticity coordinates that indicate color directions: $+a^*$ is the red direction; $-a^*$ is the green direction; $+b^*$ is the yellow direction; and $-b^*$ is the blue direction. Because the blue MB-based indicator loses its color during photobleaching and regains the color during recovery, the main color change happens in the b^* axis and can be defined as $-\Delta b^*$:

$$-\Delta b^* = b_0^* - b_t^*$$

where b_0^* is the initial b^* value of samples and b_t^* is their b^* value at a specific time t. The difference of the b^* value has been successfully used as a measure of the MB color.[19]

RESULTS AND DISCUSSION

Preparation of Carrageenan-Based Oxygen Indicator Films. To begin with, we examined whether carrageenans can interact with redox dyes. Two major classes of carrageenans were employed: κ- and ι-carrageenans. Carrageenans are linear, partially sulfated galactans that mainly consist of alternating 3-linked β-D-galactopyranose (G) and 4-linked 3,6-anhydro-α-D-galactopyranose (DA); κ-carrageenan (G4S-DA) has one sulfate group covalently coupled via ester linkage to the carbon atom C-4 of the G residue (G-4), while ι-carrageenan (G4S-DA2S) possesses two sulfate groups at the G-4 and DA-2.[22] Three types of thiazine dyes were used: MB, AA, and Th. When 0.2 mL of each aqueous dye solution (10 mg/mL) was added to 10 mL of ι-carrageenan solution (2.5 mg/mL), insoluble stringy aggregates were formed with all of the dyes tested; however, aggregation with κ-carrageenan was barely observed with the naked eye in all cases (data not shown). This can be explained by the difference in the sulfate content of the carrageenans; typically, commercial κ- and ι-carrageenans contain 22 and 32% (w/w) sulfate, respectively, although they vary considerably according to seaweed species and batches.[23] It was demonstrated that the sulfate moiety of carrageenans is essential for the interaction with cationic dyes, and the binding activity increases when the percentage of sulfate is increased.[26−28] In the present work, only ι-carrageenan was used for further study and carrageenan refers to ι-carrageenan unless otherwise mentioned.

We prepared UV-activated oxygen indicator films using carrageenan as the coating polymer; the packaging film was spin-coated with ink composed of redox dyes, glycerol, and TiO_2 and then dip-coated with carrageenan solutions (see the Materials and Methods). For comparison, the zein-based film was also fabricated in the same manner as the carrageenan-based film. However, little dye remained on the film because the dyes dissolved into the zein solution (90% ethanol) during the dip-coating step.[20] Therefore, the indicator films using zein as the encapsulation polymer were prepared by spin-coating the packaging film with the ink comprising redox dyes, glycerol, TiO_2, and zein, as described in the Materials and Methods. For reference, the carrageenan-based film could not be prepared in this manner because the addition of the dyes to the aqueous carrageenan solution led to the formation of insoluble aggregates as already mentioned.

Leakage Behaviors of Redox Dyes from the Films. Because MB is readily soluble in water, without proper protective polymers, the dye in the indicator film leaches out very quickly when immersed in water.[17] With the water-insoluble zein polymer (5%), the water resistance of the MB-coated indicator film was investigated by immersing the film in water for 24 h. As shown in Figure 1 (closed circles), after MB leached out quite quickly within the first hour of immersion, the dye leakage reached 48% and then remained nearly constant. The resultant MB/TiO_2/glycerol/zein (5%) film was so light-colored that it was not suitable for a colorimetric oxygen indicator. Although water-insoluble zein covered MB, it could not completely prevent the small water-soluble ionic

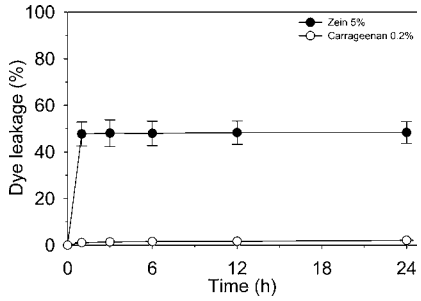

Figure 1. Dye leakage of zein (5%)-based and ι-carrageenan (0.2%)-based oxygen indicator films as a function of the water immersion time.

molecules (about 16.9 Å in length, 7.4 Å in breadth, and 3.8 Å in thickness) from leaking into the water.[29]

The same experiment was carried out using water-soluble carrageenan (0.2%) as the encapsulating polymer; surprisingly, only 2.1% of MB on the film leached into the water (open circles in Figure 1). This high resistance to dye leakage is believed to be attributed to the electrostatic interaction of the anionic polymer and the cationic dye.[26−28] Carrageenan is negatively charged because of the two sulfated groups on the repeating dimer, whereas MB, generally available as chloride salts, exists in cationic form in water.

The concentration effects of each polymer were examined for the protection ability against dye leakage: 5, 10, 15, and 20% for zein and 0.2, 0.3, 0.4, and 0.5% for carrageenan. When the zein concentration was increased from 5 to 20%, the dye leakage gradually declined to around 30% but it was still high (Figure 2a). The dye leakage of the carrageenan-based film slightly decreased from 2.1 to 1.8% when the concentration was increased from 0.2 to 0.5%, indicating that carrageenan is effective enough at as low a concentration as 0.2% (Figure 2b).

We examined whether carrageenan can also prevent dyes other than MB from leaching from the film into water. The carrageenan (0.2%)-based oxygen indicator films were prepared

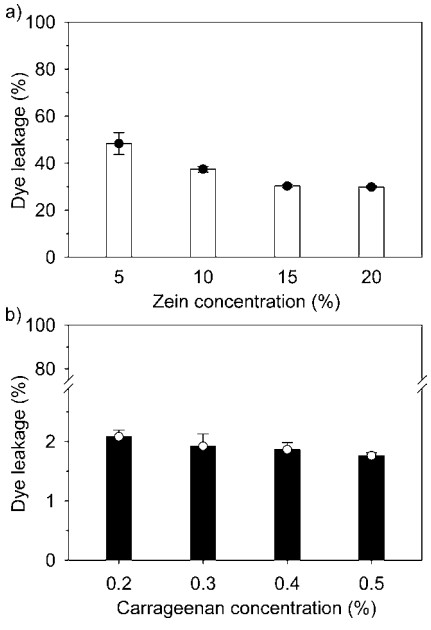

Figure 2. Effect of the polymer concentration on MB leakage after 24 h of (a) zein-based and (b) ι-carrageenan-based oxygen indicator films.

with AA and Th in the same way as with MB; for comparison, the zein (20%)-based films were also fabricated. The leakages of the three dyes after 24 h of immersion in water are shown in Figure 3: zein (open bars) and carrageenan (closed bars).

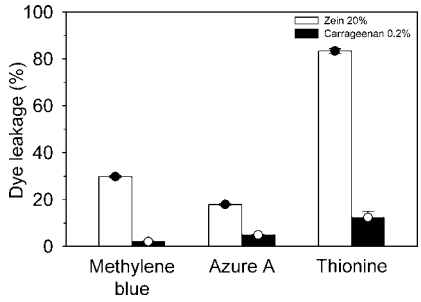

Figure 3. Leaching behaviors of MB, AA, and Th dyes on zein (20%)-based and ι-carrageenan (0.2%)-based oxygen indicator films.

Similar to MB, the leakages of AA and Th were considerable with the zein polymer, particularly Th. The reason why Th showed the highest leakage is not evident, but this could be due to the larger contact area of Th with water; Th (with no methyl group) is more hydrophilic than AA (with two methyl groups) and MB (with four methyl groups).[30] In comparison to zein, carrageenan diminished the leakage of AA and Th as well as MB to a greater degree because of the electrostatic interaction of the anionic carrageenan with the cationic dyes. In addition, the dye leakage might be further lowered by additional optimization (e.g., the employment of carrageenans with higher percentages of sulfate and/or with other molecular weights).[22,23]

Photobleaching and Recovery Process of Carrageenan-Based Indicator Film. An UV-activated indicator film should be bleached when exposed to UV light (photobleaching step) and regain its color in the presence of oxygen (recovery step). Because the strong interaction between carrageenans and dyes might impede the photobleaching and recovery processes of the carrageenan-based indicator film, we investigated this possibility. The oxygen indicator films were prepared using MB and carrageenan (0.2, 0.3, 0.4, and 0.5%) as the redox dye and the coating polymer, respectively. When the carrageenan-coated films were irradiated with UVC light (intensity = 5.5 mW/cm^2) for 4 min, all of the films were completely bleached (data not shown). The finely dispersed TiO_2 nanoparticles (photocatalyst) encapsulated in the polymer generate electron−hole pairs upon UV irradiation. The photogenerated holes oxidize glycerol (a sacrificial electron donor), and the photogenerated electrons reduce MB to its colorless reduced form.[12] The initial rate of photobleaching was also measured as a function of the carrageenan concentration. Figure 4a (circles) shows that the bleaching rate decreased as the polymer concentration increased. This may not be due to the increase in the thickness of the carrageenan film with the increasing concentration because the difference in the thickness was not significant, as shown in Figure 4a (bars); the reason is a question for future research.

Figure 4b shows the recovery behavior of the MB/TiO_2/glycerol/carrageenan (0.2%) indicator film in air under ambient conditions in which $-\Delta b^*$ was plotted against recovery time. The oxygen indicator film was recovered within about 8 h, The colorless reduced form of MB on the film was reoxidized by oxygen, and the original blue color of the indicator film was

dx.doi.org/10.1021/jf5014764 | J. Agric. Food Chem. 2014, 62, 7263−7267

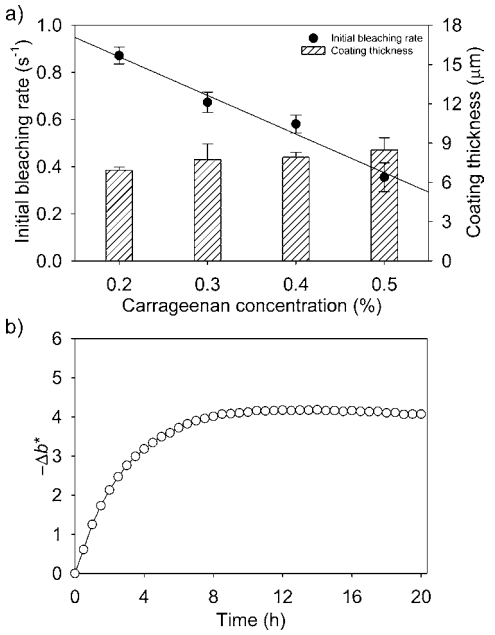

Figure 4. (a) Initial bleaching rate and coating thickness of MB/TiO_2/glycerol/*ι*-carrageenan oxygen indicator films as a function of the carrageenan concentration. (b) Recovery behavior of MB/TiO_2/glycerol/*ι*-carrageenan (0.2%) oxygen indicator film in air under ambient conditions with a sampling time of 30 min.

restored. This recovery time may not be satisfactory if compared to conventional water-susceptible indicator films (~6 min),[12] but it is appreciably short considering that the other waterproof films had recovery times of 5 days using sulfonated polystyrene[17] and 2.5 days using low-density PE.[19] The high recovery rate of the carrageenan-based film is probably attributed to the hydrophilic nature of carrageenans, because hydrophobic films hinder the formation of the charged species, MB^+ and OH^-, for color recovery.[17,19]

In conclusion, we have developed an UV-activated oxygen indicator film resistant to dye leaching by introducing carrageenans, which are natural sulfated polysaccharides. The dye-binding ability of carrageenans substantially lowered the leakage into water of all of the redox dyes tested (MB, AA, and Th). The MB/TiO_2/glycerol/carrageenan oxygen indicator film was successfully bleached upon UV irradiation and regained its color very rapidly in the presence of oxygen. This leaching-resistant colorimetric oxygen indicator film with in-pack activation and irreversibility can be applied to verify that all oxygen is removed using oxygen absorbers/oxygen scavengers, and it can also be used as a seal and leak detector with modified atmosphere packaging; it will be essential for intelligent food packaging.

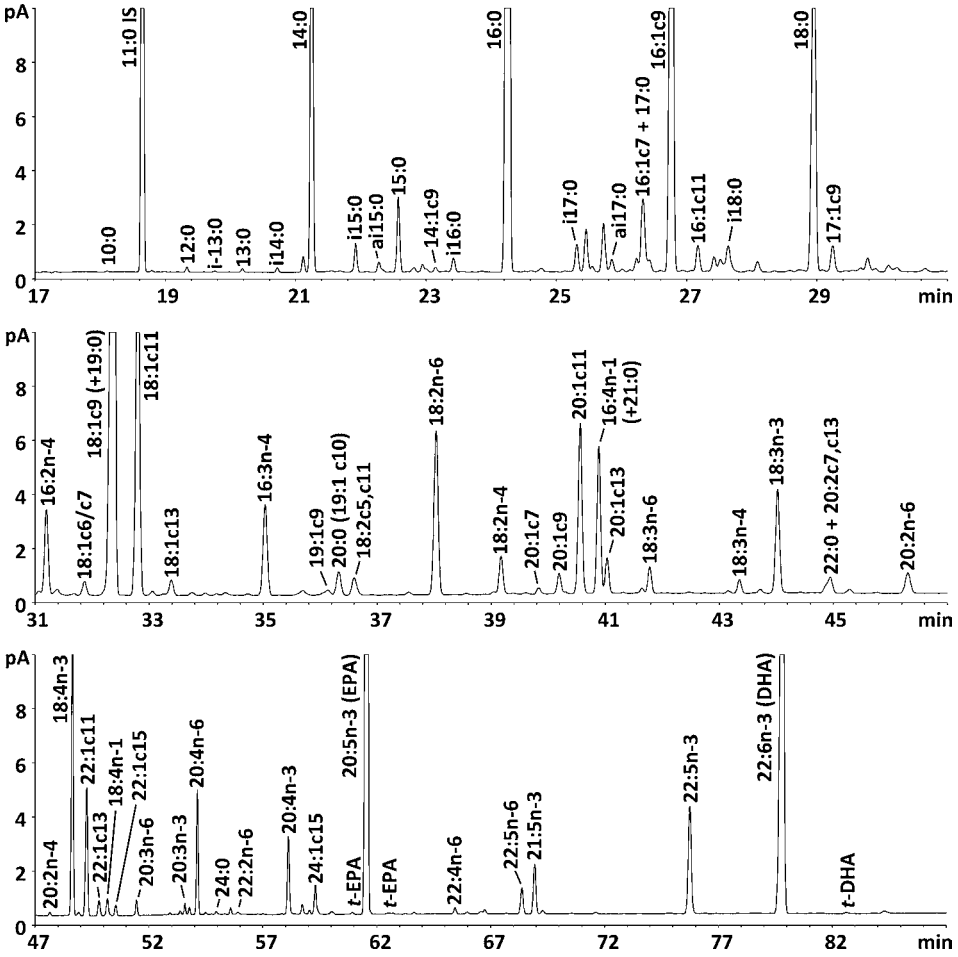

Figure 1. Gas chromatogram of FAME derived from an SO supplement.

conclusive research shows that consumption of EPA and DHA omega-3 fatty acids may reduce the risk of coronary heart disease".[21,22]

MATERIALS AND METHODS

Chemicals and Reagents. ACS reagent grade chemicals and solutions were purchased from Sigma-Aldrich (St. Louis, MO). HPLC grade solvents were purchased from Fisher Scientific (Pittsburgh, PA). FAME (EPA and DHA) and triacylglycerol (TAG; C11:0) standards were purchased from Nu-Chek Prep (Elysian, MN). Our choice of C11:0 TAG as internal standard (IS) was based on the fact that the content of C11:0 is negligible in FO and that the C11:0 FAME isomer is chromatographically resolved from other FAME on the 200 m SLB-IL111 column.[20]

SRM 3275. SRM 3275 was purchased from NIST (Gaithersburg, MD). This reference material consists of three fish oils: SRM 3275-1, a concentrate high in DHA; SRM 3275-2, an anchovy oil high in EPA and DHA; and SRM 3275-3, a concentrate containing nominally 60% omega-3 LCPUFA. The SRM was stored at 4 °C until analysis. Details of the development of SRM 3275 have been reported.[23]

Marine Oil Omega-3 Supplements. Marine oil omega-3 supplements were purchased online between May and July of 2012. Products were included in the study if their ingredient statements listed a source of marine oil and the Supplement Facts panel listed declarations for EPA and DHA. Eighteen of the products listed FO (e.g., anchovy, sardine, and mackerel) as the primary ingredient. Fifteen of the products listed FO concentrate (from anchovy, sardine, mackerel, or species undefined) as the primary ingredient. Nine of the supplements were marketed as salmon oil (SO) supplements. However, two of these products included an additional FO source in their ingredients lists (reportedly added for the purpose of increasing EPA and DHA potency, species undefined) and thus were classified as FO products. The remaining four supplements contained a combination of plant oil (e.g., borage, olive, and flax) and FO (i.e., plant/FO blends). Supplements were purchased in softgel (also referred to on product labels as capsule or minigel; $n = 40$) and liquid ($n = 6$) forms. Softgel products listed gelatin, glycerin, and water as ingredients. Forty-one of the products contained antioxidants (e.g., tocopherols, ascorbyl palmitate, and botanical extracts). Eleven of the products (24%) carried the qualified health claim for EPA and DHA. All products, which were collected for research purposes only, were stored at −80 °C until analysis and were analyzed prior to their expiration dates.

Methylation. Methylation was performed in duplicate according to AOCS Official Method Ce 2-66.[24] This method involves an alkali hydrolysis with 0.5 M NaOH in MeOH followed by methylation with fresh 14% BF_3 in MeOH.[24] For supplements, oil from 2−3 softgels was combined, then ∼50 mg was weighed into 16 × 150 mm glass extraction tubes for methylation. Following derivatization, FAMEs were solubilized in heptane (∼12.5 mg/mL) and stored in silanized, amber-colored autosampler vials.

Preparation of Isomerized EPA and DHA FAME. Standards for the *trans* isomers of EPA and DHA were prepared from all-*cis* EPA and DHA FAME, respectively, by isomerization with *p*-toluenesulfinic acid according to Snyder and Scholfield.[25] Samples were heated for a maximum of 3 min to limit the degree of isomerization. Isomerized EPA and DHA FAMEs were then fractionated by number of *trans* double bonds on silica gel plates impregnated with 10% silver nitrate (Analtech, Newark, DE). Plates were developed at −20 °C in toluene/MeOH (85:15, v/v) according to Fournier et al.[26] Individual bands

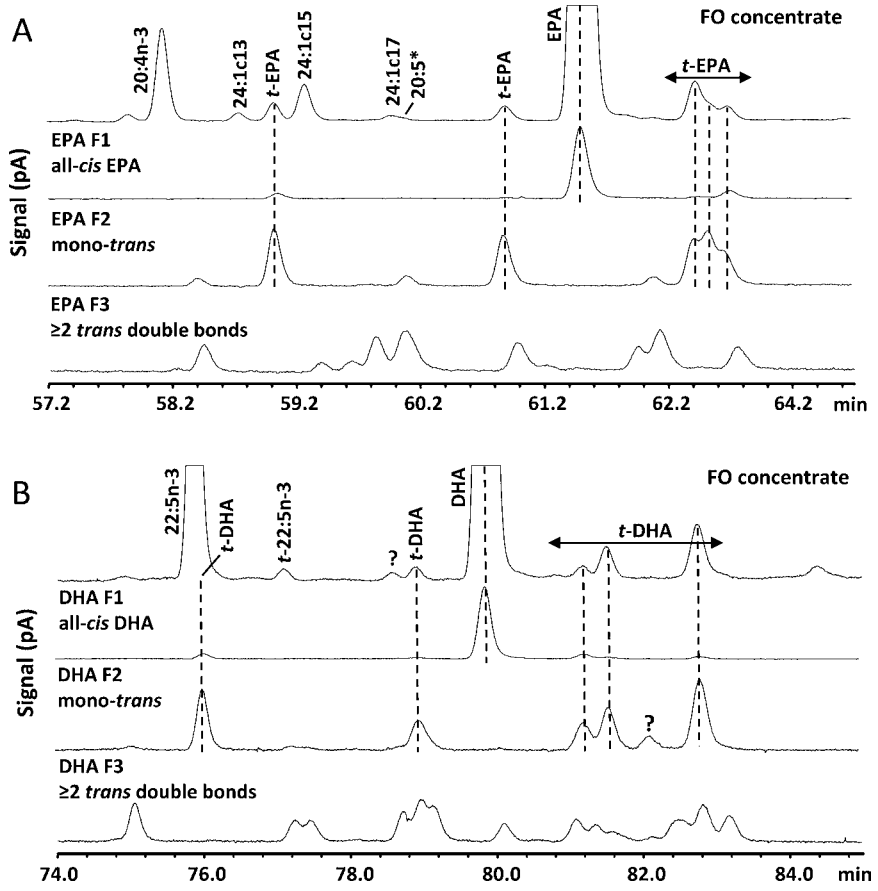

Figure 2. Partial gas chromatograms of FAME derived from an FO concentrate in the regions in which EPA (panel A) and DHA (panel B) elute. For each panel, the top partial gas chromatogram corresponds to FAME derived from the FO concentrate, while the lower partial gas chromatograms correspond to isomerized EPA and DHA FAME fractions (F1−F3). *20:5 contains C20:5n-4 plus *t*-EPA.

were identified by comparison with published thin layer chromatography (TLC) plate images.[27]

GC Instrumentation. Analysis by GC-FID was performed in split mode on a 6890N GC (Agilent Technologies, Wilmington, DE) equipped with a 200 m SLB-IL111 column, which was formed by connecting two 100 m SLB-IL111 columns (Supelco, Bellefonte, PA) using an Agilent press fit quartz column connector. The oven was maintained at 170 °C for 50 min, then ramped at 6 °C/min to 185 °C, held for 50 min, then ramped at 20 °C/min to 220 °C, and held for 5 min. The oven was maintained at 168 °C for the 5 min postrun. A single GC run time was 114.25 min. The flow program for the H_2 carrier gas was as follows: 1.6 mL/min for 35 min, ramped at 0.3 mL/min/min to 3.0 mL/min, and held for ∼70 min. The inlet and FID temperatures were 300 and 235 °C, respectively. The split ratio was 100:1, and the injection volume was 1 μL. A complementary analysis of FAME, which was performed to resolve FAME coeluting on the 200 m SLB-IL111 column, was carried out on the 30 m Supelcowax 10 column (Supelco, Bellefonte, PA) according to AOCS Official Method Ce 1i-07.[14] Calculations for fatty acid content were performed using theoretical correction factors.[14]

GC-mass spectrometry (MS) analysis was performed on a 7890A GC coupled to a 240 MS ion trap mass spectrometer (Agilent Technologies) and equipped with a 200 m SLB-IL111 column. The oven was maintained at 170 °C for 63 min, then ramped at 6 °C/min to 185 °C, held for 20 min, then ramped at 15 °C/min to 220 °C, and held for 22 min. The oven was maintained at 170 °C for a 5 min postrun. The flow of the He carrier gas was held at 1.6 mL/min for 45.5 min, then ramped at 0.3 mL/min/min to 2.0 mL/min, and held for 63 min. FAMEs were identified by covalent adduct chemical ionization (CACI) tandem MS using acetonitrile as the reagent gas.[28]

Calculations for Supplements. Single serving contents of individual fatty acids were calculated based on analyzed fatty acid contents (as % of total weight) and the weight of oil in a single serving. For products for which serving size was reported by volume (e.g., 5 mL), 10 servings were pipetted into tared weighing boats and weighed to the nearest 0.0001 g on an AE100 analytical balance (Mettler-Toledo, Columbus, OH). For products for which serving size was reported by quantity (e.g., two softgels), the weights of 20 servings or a minimum of 1/5 of the contents of the bottle were recorded. Softgel capsules were then punctured, rinsed with hexane, and the weights of the dry capsule shells recorded. The weight of oil in a single serving was calculated as the mean serving weight (capsule shell plus oil) minus the mean capsule shell weight.

Statistical Analysis. Statistical analysis was performed using JMP (version 9.0.0. 2010, SAS Institute, Cary, NC). One way analysis of variance was used to compare mean values, and Student's *t*-test was applied when significant differences were observed ($F < 0.05$). Values are reported as the means ± standard deviations (SD). Statistical outliers were determined using Grubbs' test.[29]

RESULTS

Chromatography. The chromatographic separation of FAME derived from an SO supplement is presented in Figure 1. Seventy-three FAME isomers, accounting for 91.9 ± 3.4% of total fat, were included in this analysis. Chromatographic conditions presented in this article are similar to those reported by Fardin-Kia et al.[20] but included a final temperature ramp to 220 °C, maintained for 5 min. The extended temperature program ensured complete elution of analytes in a single GC run and avoided the occurrence of ghost peaks in subsequent chromatograms due to analyte carryover.

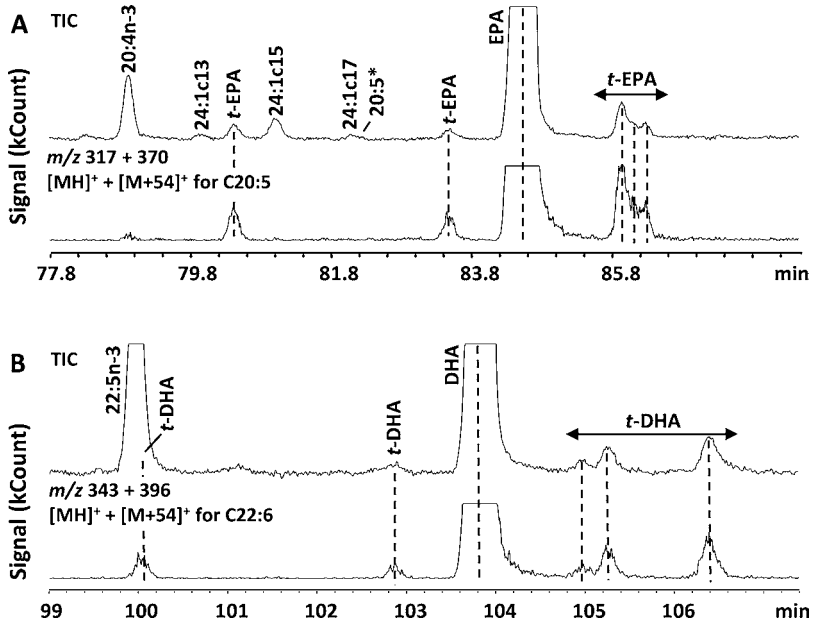

Figure 3. Partial GC-CACI-MS chromatograms of FAME derived from an FO concentrate product in the regions in which EPA (panel A) and DHA (panel B) elute. For each panel, the top partial GC-MS chromatogram corresponds to the TIC. The lower partial GC-MS chromatogram is a reconstructed ion chromatogram specific for ions attributed to C20:5 and C22:6 FAME (molecular ion, $[MH]^+$; m/z 54 adduct ion, $[M+54]^+$).[28]

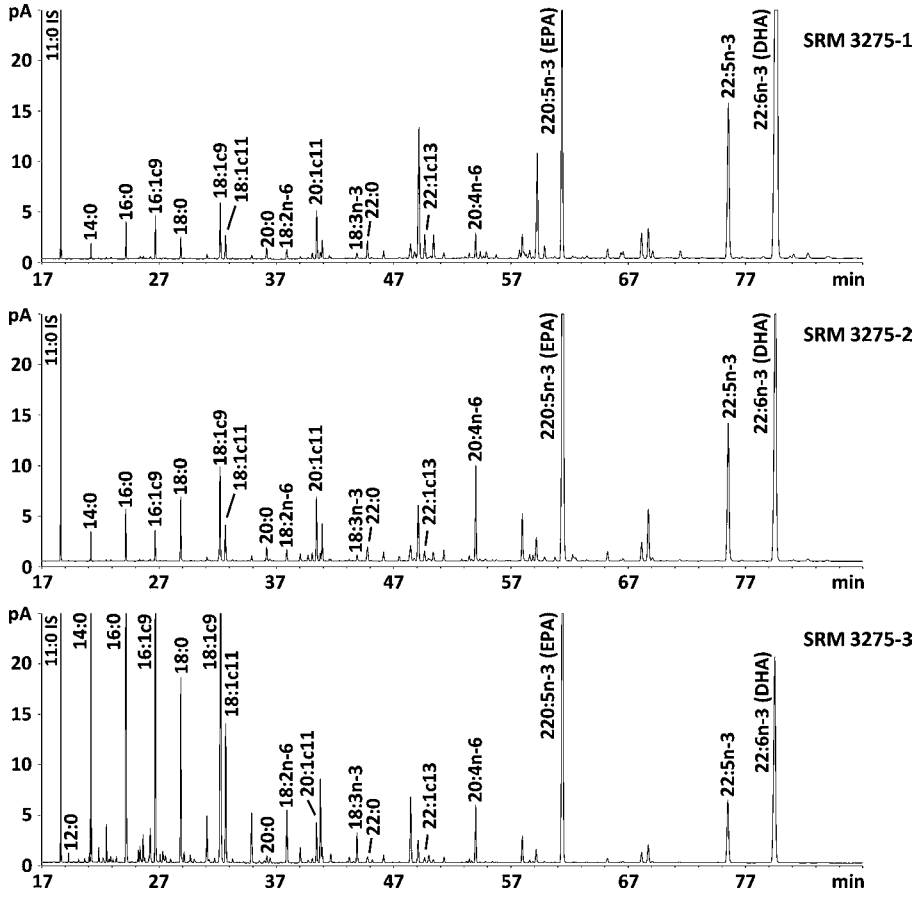

Figure 4. Gas chromatograms of FAME derived from the three fish oils of SRM 3275. FAME for which certified and reference mass fraction values are reported in the Certificate of Analysis are labeled.

[a]Mass fraction values for individual FAME are reported in the Certificate of Analysis for SRM 3275. Value assignments are based on two independent methods and the reported mean value represents the mean of the mean values from each method. Certified mass fraction values (bold font) are reported to represent the highest level of confidence in accuracy and account for all known or suspected sources of bias. The associated uncertainty is expressed at a 95% level of confidence and represents the combined standard uncertainty multiplied by a coverage factor *k*. Reference mass fraction values (not bold font) are reported to represent the best estimate of true value based on available data, and the associated uncertainties may reflect only measurement reproducibility. [b]Analyzed values represent the means ± SD of two independent determinations. [c]Recovery calculated as analyzed/certificate value × 100.

comparison with published TLC images.[27] Fractions corresponding to all-*cis* FAME, mono-*trans* FAME, and FAME with two or more *trans* double bonds were collected and analyzed by GC-FID for retention time. Figure 2 presents partial gas chromatograms for the *trans* EPA and DHA FAME standards and for FAME derived from an FO concentrate product. Peaks for five mono-*trans* EPA isomers were observed in both the mono-*trans* EPA standard and the marine oil omega-3 supplements (Figure 2A). The mono-*trans* DHA standard showed five mono-*trans* DHA peaks, but only four mono-*trans* DHA peaks were observed in the supplements (Figure 2B). The first eluting mono-*trans* DHA isomer coeluted with C22:5n-3 in the supplements (Figure 2B). FAMEs with two or more *trans* double bonds, if present in the supplements, were found at or near the level of detection.

The presence of *trans* isomers of EPA and DHA in the supplements was also verified by GC-CACI-MS analysis (Figure 3). The top chromatogram in Figure 3A corresponds to the total ion chromatogram (TIC) for FAMEs derived from an FO concentrate product. The lower chromatogram corresponds to the reconstructed ion chromatogram for *m/z* 317 ($[MH]^+$) and *m/z* 370 ($[M+54]^+$) ions, which are attributed to C20:5 FAME in the FO concentrate product. Peaks in the reconstructed ion chromatogram at 80.3, 82.3, and 85.8 min (Figure 3A) are consistent with those observed in the partial gas chromatogram for the mono-*trans* EPA standard (Figure 2A), providing further confirmation of the presence of mono-*trans* EPA in the supplements. Similarly, in Figure 3B, peaks in the reconstructed ion chromatogram, which correspond to *m/z* 343 ($[MH]^+$) and *m/z* 396 ($[M+54]^+$) ions that are specific to C22:6 FAME in the FO concentrate product, are consistent with those in the partial gas chromatogram for the mono-*trans* DHA FAME standard (Figure 2B). In addition, the first eluting mono-*trans* DHA FAME was found to coelute with C22:5n-3 (Figures 2B and 3B). GC-MS analysis indicated that the area of the first eluting mono-*trans* DHA isomer accounted for 20% of the total peak area for mono-*trans* DHA in the two products with the highest concentrations of *trans* DHA (Figure 3B). Therefore, for all samples, the quantitation of *trans* DHA included a correction factor (i.e., integrated area of mono-*trans* DHA/0.8) to account for the area of the mono-*trans* DHA FAME that coeluted with C22:5n-3.

Analysis of SRM 3275. GC-FID chromatograms for the separation of FAMEs derived from the three SRM fish oils are presented in Figure 4. Analyzed values for 21 FAMEs are presented in Table 1 along with corresponding values reported in the Certificate of Analysis. Recoveries for EPA and DHA, which were calculated as analyzed/certificate values × 100, varied from 99% to 106% and from 102% to 103%, respectively, among the three SRM fish oils. Analyzed values for EPA and DHA were all within the range of mass fraction values covered by the expanded uncertainty. For the remaining FAME, the majority of recoveries were within the range of 80% to 120%, whereas for a few FAMEs, recoveries varied from 49% to 1182%. Analyzed values for three FAMEs (C20:0, C20:1*cis*-11, and C22:0) were significantly greater than the corresponding certificate values, indicating the presence of coeluting peaks on the 200 m SLB-IL111 column.

[a]Values represent the means ± SD for all products within a group (FO, $n = 20$; FO concentrate, $n = 15$; plant/FO blend, $n = 4$; SO, $n = 7$). [b]Values within a row with different letters are significantly different ($P < 0.05$); NS, not significant.

Fatty Acid Composition of Omega-3 Supplements. The concentrations of EPA and DHA varied from 7.8% to 45.4% and from 5.5% to 44.1% of total fat, respectively, in the 46 marine oil omega-3 supplements (Table 2). EPA concentrations were highest in the FO concentrates (26.7 ± 11.4% of total fat) and lowest in the plant/FO blends (10.1 ± 3.8% of total fat) and SO supplements (9.3 ± 2.0% of total fat). DHA concentrations were significantly higher in the FO concentrates (17.2 ± 8.6% of total fat) than in the plant/FO blends (6.6 ± 2.0% of total fat) and SO supplements (9.3 ± 0.6% of total fat), while FO products provided intermediate concentrations. The concentration of total SFA, which varied from 0.2 to 26.6% of total fat among all products, was significantly higher in the SO supplements (23.0 ± 1.8%) than in the FO concentrates (11.7 ± 11.6%) and plant/FO blends (9.5 ± 1.2%). SO supplements had the highest mean concentration of MUFA. The plant/FO blends had the highest mean concentration of n-6 PUFA. The sum of the *trans* isomers of EPA plus DHA, which varied from 0.1% to 1.5% of total fat among all products, was significantly higher in the FO concentrates (0.6 ± 0.4%) than in the plant/FO blends (0.1 ± 0.0%) and SO supplements (0.2 ± 0.2%), while FO products provided intermediate concentrations. Concentrations of n-4 and n-1 PUFA, which varied from 0.2% to 3.1% and from 0.1% to 2.6% of total fat, respectively, among all products, were highly correlated ($R^2 = 0.9489$; Supporting Information, Figure 1).

Product Composition. Table 3 presents the contents of fatty acids in single servings within the four supplement groups. One of the FO products was excluded from this analysis because the content of total fat in a single serving of the product (9.2 g total fat) was nearly twice that of the next highest product (4.7 g), causing it to be a statistical outlier. For the remaining 45 products, the overall mean contents of EPA, DHA, and EPA plus DHA in a single serving were 354 ± 247 mg, 239 ± 133 mg, and 592 ± 354 mg, respectively. These values were not significantly different among the four product groups which could be attributed to the large variation in EPA and DHA contents within the FO and FO concentrate groups. Total MUFA were significantly greater in the SO supplements (741 ± 477 mg) than in the FO concentrates (210 ± 172 mg), while FO products and the plant/FO blends provided intermediate contents. Total n-6 PUFA and C18:3n-3 were highest in the plant/FO blends. The mean contents of the n-4 PUFA, n-1 PUFA, and total *trans* EPA plus DHA in a single serving, which were not significantly different among all groups, were 30 ± 31 mg, 23 ± 28 mg, and 8 ± 10 mg, respectively.

Comparison of Analyzed Values with Label Declarations. The measured contents of EPA and DHA (mg/serving) were within ±20% of the declared contents for 38 and 37, respectively, of the 46 products (Supporting Information, Figure 2). For the remaining products, three had EPA and/or DHA contents that exceeded 120% of the declared value, including one FO product that contained EPA at a content that

Table 3. Fatty Acids (mg) in Single Servings within the Marine Oil Omega-3 Supplement Groups

[a]Values represent the means ± SD for all products within a group (FO, n = 19; FO concentrate, n = 15; plant/FO blend, n = 4; SO, n = 7). [b]Values within a row with different letters are significantly different (P < 0.05); NS, not significant.

was three-times greater than its label declaration (i.e., 75 mg vs 24 mg). Six of the products (1 FO, 3 FO concentrates, 1 plant/FO blend, and 1 SO) had EPA and DHA contents that were less than 80% of the declared contents. Of these, one FO concentrate product contained EPA and DHA at 48% and 65%, respectively, of the declared values.

Estimated Intakes. Directions for use of the products, as declared on product labels (e.g., "As a dietary supplement, 1 softgel twice daily..."), varied from one to five servings per day. Half of the products (52%) suggested a daily intake of two or more servings per day. Therefore, products were evaluated on the basis of suggested daily use to facilitate comparisons of the amounts of EPA and DHA the products would be expected to provide (i.e., "estimated daily intake") in a single day. Calculations showed that FO and FO concentrate products provided higher mean estimated intakes of EPA plus DHA (1,036 ± 466 mg/d and 1,026 ± 621 mg/d, respectively) than the plant/FO blends and SO supplements (401 ± 164 mg/d and 533 ± 168 mg/d, respectively) (Figure 5; Supporting Information, Table 1). Estimated intakes of EPA plus DHA, which varied from 255 mg to 3,406 mg among all products, were ≥500 mg/d for 39 of the products, ≥1 g/d for 18 products (39%, 11 FO, 7 FO concentrates), and ≥2 g/d for four of the products (all FO products).

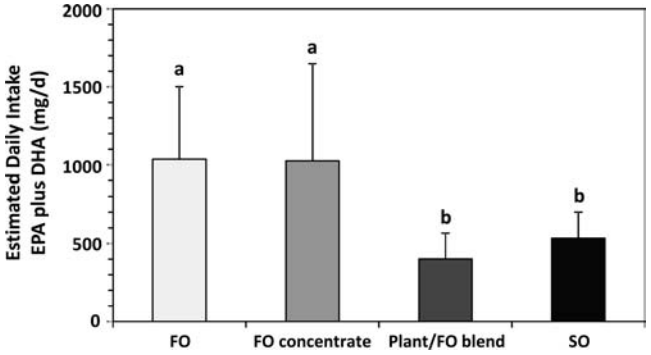

Figure 5. Estimated intakes of EPA plus DHA in the four marine oil omega-3 supplement groups (FO, n = 18; FO concentrate, n = 15; plant/FO blend, n = 4; SO, n = 7). Groups with different letters are significantly different (P < 0.05).

DISCUSSION

Chromatography. The analysis of oils derived from marine sources presents significant challenges due to their complex composition of fatty acids, susceptibility to oxidative changes, and potential for the presence of isomerized fatty acids that are formed during high temperature processing. In addition, many GC column stationary phases (e.g., PEG, cyanopropyl polysiloxane) offer a limited capacity to resolve FAMEs derived

from marine oil in a single-dimension GC run.[15] The present study applied a recently reported gas chromatographic method involving the 200 m SLB-IL111 ionic liquid column[19,20] to the analysis of the content and composition of fatty acids in marine oil omega-3 supplements. The accuracy of this method was confirmed using an SRM for omega-3 and omega-6 fatty acids in FO.

Analysis with the 200 m SLB-IL111 Column. The present study employed the 200 m SLB-IL111 column for the separation of FAME derived from marine oil. A complementary analysis using the 30 m PEG column was performed to resolve C16:1*cis*-7 and C17:0, which were known to coelute on the SLB-IL111 column.[19,20] In addition, Fardin-Kia et al.[20] demonstrated in a sample derived from menhaden oil that C20:0 coelutes with C19:1 FAME, C22:0 coelutes with C20:2*cis*-7,*cis*-13, and C20:1*cis*-11 partially coelutes with C21:0 and C16:4n-1 on the 200 m SLB-IL111 column. In the present study, data for C20:0, C22:0, and 20:1*cis*-11 were not adjusted to correct for coelutions on the SLB-IL111 column because of additional coelutions that were observed on the 30 m PEG column. In a recent study of FO fatty acids, Santercole et al.[15] reported that three GC separations, involving an analysis with the 30 m PEG column and two additional temperature programs using a 100 m cyanopropyl polysiloxane column, were necessary to separate most of the fatty acids derived from menhaden FO. Use of a 100 m cyanopropyl polysiloxane column in the present study may have provided a more appropriate complementary separation of FAMEs.

SRM 3275. The Certificate of Analysis for SRM 3275 reports certified and reference mass fraction values for individual FAMEs. Certified values represent the highest level of confidence in accuracy and account for all known or suspected sources of bias.[23] Reference values represent the best estimate of true value and may reflect only the variability in analytical measurement.[23] We observed recoveries for EPA and DHA FAME in the three SRM fish oils that varied from 99% to 106% and from 102% to 103%, respectively, compared with their respective certified and reference mass fraction values. On the basis of these findings, we determined that the chromatographic method used in the present study was appropriate for the analysis of EPA and DHA in marine oil. These findings are also consistent with those of Khoomrung et al.[30] who demonstrated, using selected FAMEs from SRM 3275-2, the accuracy of a microwave-assisted derivatization method for the preparation of FAME from yeast.

The Certificate of Analysis for SRM 3275 reports a total of 9 to 11 certified mass fraction values for FAMEs present in the three SRM fish oils. NIST selected these FAMEs based on the availability of pure reference standards that could be used to develop GC-MS calibration curves.[23] Our recoveries of FAMEs for which certified mass fraction values were reported were variable with some low abundance FAME having good recoveries (e.g., C18:2n-6 in SRM 3275-1; 103%) and some higher abundance FAMEs having poorer recoveries (e.g., C16:0 in SRM 3275-3; 83%). These discrepancies could be attributed to incomplete resolution of FAMEs with either our method or the NIST method. For example, coelutions on the 200 m SLB-IL111 column may explain the high recoveries that we observed for C20:0 (154%−1182%) and C20:1*cis*-11 (252%−302%). In contrast, NIST, in their characterization of SRM 3275,[23] reported using two cyanopropyl polysiloxane columns of slightly different selectivities for GC-FID and GC-MS analyses, and their conditions were optimized for the separation of 18-carbon omega-3 and omega-6 fatty acids. Representative chromatograms are not presented in the Certificate of Analysis, and it is possible that complementary separations, such as those reported by Santercole et al.,[15] were not performed.[23] Therefore, to our knowledge, chromatograms presented in this article are the first published chromatograms showing the separation of FAMEs derived from the three complex fish oils of SRM 3275.

Marine Oil Omega-3 Supplements. *trans-Isomers of EPA and DHA.* The presence of the *trans* isomers of EPA and DHA in marine oil occurs as the result of the geometrical isomerization of all-*cis* EPA and DHA during high-temperature processing designed to remove unpleasant odors (deodorization[16]) or produce concentrated EPA and DHA formulations (distillation[17]). Fournier et al.[16] demonstrated that deodorization temperature is directly related to the extent of thermal degradation of LCPUFA and the degree of isomerization. At a deodorization temperature of 180 °C, nearly 100% of the *trans* isomers of EPA and DHA were found as the mono-*trans* isomers. However, at a deodorization temperature of 250 °C, more than one-third of the *trans* isomers were present in the di-*trans* configuration.[16] Mono-*trans* isomers of EPA and DHA were the predominant form of the *trans* isomers observed in the marine oil omega-3 supplements analyzed in the present study (Figures 2 and 3). Isomers with two or more *trans* double bonds, if present, were found at or near the level of detection and therefore were not included in the quantitation.

Sciotto and Mjøs[31] reported concentrations for the *trans* isomers of EPA plus DHA that varied from 0.1% to 2.8% of total fat in 77 omega-3 products available in the European market. Products with the highest concentrations of *trans* isomers were those in the "33/23 concentrates" (i.e., products consisting of ∼33% EPA and ∼23% DHA), the "high DHA products", and the "high EPA products" groups.[31] In the present study, concentrations of the *trans* isomers of EPA plus DHA were significantly higher in the FO concentrates than in the plant/FO blends and SO supplements, while FO supplements had intermediate concentrations. Results of the present study are consistent with those of Sciotto and Mjøs,[31] indicating that FO concentrates tend to have higher concentrations of *trans* LCPUFA. However, Sciotto and Mjøs[31] note that because a large number of samples with low levels of *trans* EPA and *trans* DHA were observed in the concentrate groups, the process of deodorization was more likely to be a significant contributor of thermal isomerization than that of distillation.

Few studies of the bioactivity of the *trans* isomers of EPA and DHA can be found in the literature. In a study by Ferreri et al.,[32] six week old male Wistar rats were fed deodorized FO containing 0.1% *trans* EPA (as % of total fat) for 12 weeks. The authors found that the *trans* isomers of EPA were incorporated into liver microsomal membranes, with a *trans* isomeric profile reflecting that of the diet.[32] In the present study, the concentration of the *trans* isomers of EPA and DHA in the supplements varied from 0.1% to 1.5% of total fat, corresponding to a mean content of 8 ± 10 mg/serving (Table 3) and a mean estimated intake of 10 ± 11 mg/d (Supporting Information, Table 1). The nutritional significance of the *trans* EPA and DHA contents currently observed remains unclear.[31]

Significance of Other Fatty Acids. Analysis with the 200 m SLB-IL111 column permitted quantitation of rarely reported fatty acids such as C21:5n-3 and the n-4 and n-1 PUFA. We

observed concentrations of C21:5n-3 that were similar to those previously reported for FO ethyl esters (0.68−1.59% of total fatty acids).[33] Concentrations of n-4 and n-1 PUFA were comparable to those previously reported for FO supplements from Australia.[10] n-4 and n-1 PUFA have also been observed in marine microalgae[34,35] and marine invertebrates.[36,37] The correlation between the concentrations of n-4 and n-1 PUFA observed in the present study (R^2 = 0.9489) was unexpected.

Agreement with Label Declarations. FDA is tasked with, among others, ensuring that dietary supplement labels are truthful and not misleading. This mission is carried out in part through laboratory analysis of products for accuracy of label declarations. More than 80% of the products analyzed in the present study had EPA and DHA contents that were within ±20% of their label declarations. These findings are consistent with those of Ackman et al.[38] who found that the majority of 17 products from the US, Canada, and the United Kingdom had accurate label claims for EPA and DHA. Similarly, analyzed contents of EPA and DHA were within ±20% of label declarations in 15 of the 16 liquid FO products that were analyzed by Ritter et al.[39] In contrast, six of the products analyzed in the present study failed to meet label declarations for EPA and DHA. These findings are consistent with those of Chee et al.[9] who found that two of the nine marine oil capsules analyzed had EPA and DHA contents that were less than 80% of the declared values. Chee et al.[9] speculated that oxidative degradation was the cause of the low EPA and DHA contents. Oxidative degradation may have also been the cause of the low EPA and DHA contents observed in several samples in the present study, but we cannot confirm this.

Estimated Intakes. Half of the products analyzed in the present study had label recommendations for use that included the intake of two or more servings per day. In a similar study of nine marine oil omega-3 supplements from Austria and Germany, Tatarczyk et al.[12] reported that seven of the products had recommendations for daily use that included the intake of two or more servings per day. Only one of the products, a concentrated SO formulation, had a recommendation for intake of EPA plus DHA that exceeded 1 g/d.[12] In contrast, 18 of the products (39%) in the present study had estimated intakes of EPA plus DHA that exceeded 1 g/d. We observed a 13-fold variation in EPA and DHA estimated intakes (255 mg to 3,406 mg) that would be achieved if products were consumed according to their label directions for use.

Use of the Qualified Health Claim for EPA and DHA Omega-3 Fatty Acids. FDA uses its food labeling regulations in part to help consumers make healthful dietary choices. Daily values (% DV), which are used to characterize amounts of specific nutrients present in foods, have been established for many nutrients but remain to be determined for EPA and DHA because there is as yet no consensus among qualified experts regarding recommended daily allowances or dietary reference intakes for EPA and DHA.[1] FDA may also issue regulations authorizing health claims on conventional foods and dietary supplements when it determines that there is significant agreement among qualified experts that available scientific evidence supports such claims. In cases in which scientific evidence is considered supportive but not conclusive, FDA may authorize a "qualified" health claim. This is currently the case with claims regarding the contents of EPA and DHA in conventional foods and dietary supplements. FDA's qualified health claim states that "supportive but not conclusive research shows that consumption of EPA and DHA omega-3-fatty acids may reduce the risk of coronary heart disease".[21,22]

FDA has previously set recommendations for safety that are applicable to products bearing the qualified health claim for EPA and DHA.[21,22] These safety requirements are based on reports that intakes of EPA plus DHA greater than 3 g/d have been associated with adverse effects on bleeding time, glycemic control, and low density lipoprotein cholesterol concentrations.[40] FDA recommends that product labels bearing the qualified health claim suggest a daily intake of EPA plus DHA that is less than 2 g/d. In addition, FDA encourages manufacturers to limit the use of the qualified health claim to products recommending or suggesting daily intakes of 1 g or less of EPA and DHA.[40] In the present study, 11 of the 46 products analyzed (24%) carried the qualified health claim for EPA and DHA. All of these products followed FDA's recommendations, including listing the contents of EPA and DHA on product labels and recommending a daily intake of EPA plus DHA that was 2 g/d or less. In contrast, four of the products not bearing the qualified health claim had estimated intakes for EPA plus DHA that exceeded 2 g/d, including one product that would provide 3.4 g/d of EPA plus DHA if consumed according to label directions for use.

Overall, this study presents the content and composition of fatty acids, including the *trans* isomers of EPA and DHA, in 46 commercially available marine oil omega-3 supplements. We report, for the first time, the chromatographic separation of the *trans* isomers of EPA and DHA on the 200 m SLB-IL111 column and verify the accuracy of our method using an SRM for omega-3 and omega-6 fatty acids in FO. Of the 46 products analyzed, more than 80% had EPA and DHA contents that were consistent with values declared on product labels. In contrast, six of the products failed to meet label declarations for EPA and DHA, which could be attributed to thermal isomerization or oxidative degradation of the omega-3 LCPUFA. Results indicated that a wide range of estimated EPA and DHA intakes (255 mg to 3,406 mg) could be achieved if products are consumed according to label directions for use. However, all products bearing the FDA's qualified health claim for EPA and DHA (24% of analyzed products) met the agency's recommendations for such claims.

from the two protein mixtures, with 90% purity using hyaluronic acid.

As biodegradable, biocompatible, and environmentally friendly materials, anionic and cationic polysaccharides offer better methods of coacervation-based protein purification. Chitosan (Ch) is the deacetylated form of chitin and is considered to be the most widely distributed cationic biopolymer. Several complex coacervation pairs based on chitosan have been reported, including α-lactalbumin−chitosan and β-lactoglobulin−chitosan,[19] soy globulin−chitosan,[20] pea protein isolate−chitosan,[21] xanthan−chitosan,[22] caseinophosphopeptides−chitosan,[23] and gum arabic−chitosan.[24,25] However, relatively little is known about the interaction between soybean whey proteins and chitosan.

Three types of turbidity titrations had been reported by Dubin et al.[26] The experiment that led to the pH dependence of turbidity at constant ionic strength and protein and polymer concentration was called a "type 1" titration or pH titration. One may also follow the evolution of the turbidity upon addition of either protein to polymer ("type 2") or polymer to protein ("type 3"). In our experiment, type 1 titration was used to study SWP/Ch complexing behavior. Four critical pH values can be observed, which indicated the phase transitions upon changing pH of the system. An initial slight increase in turbidity occurred at pH_c, which corresponded to the soluble complex formation. A sharp elevation in turbidity was found at $pH_{\varphi 1}$, signifying the onset of phase separation. At pH_{max}, maximum turbidity was obtained, whereas at $pH_{\varphi 2}$ the coacervate or precipitate started to redissolove.[27−29]

The aim of this study is to obtain knowledge about the interaction between soybean whey protein and chitosan and to recover proteins from soybean whey. To achieve the goal, protein components in soybean whey were first re-examined. Then, soybean whey protein/chitosan mixtures were brought to complexing conditions by adding NaOH slowly, and effects of pH and protein/chitosan ratio on turbidity and protein recovery were investigated. Finally, protein composition and purity as affected by complexation conditions were studied.

MATERIALS AND METHODS

Materials. Hexane-defatted and flush-desolventized soy flake, provided by Shandong Wonderful Industrial and Commercial Co. Ltd., had a protein content of 52.4% (N × 6.25, dry basis) and a nitrogen solubility index (NSI) of 85%. Food grade chitosan (degree of deacetylation = 80−95%; viscosity average molecular weight = 620 kDa) was purchased from the Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). All other reagents were of analytical grade.

Preparation of SWP and Ch Stock Solutions. To obtain soybean whey, defatted soybean flake was extracted with distilled water (pH 7.0) with a water-to-meal ratio of 10:1 and blended at room temperature (25 ± 2 °C) for 30 min. After centrifugation of the suspension to remove insoluble precipitate, the supernatant was adjusted to pH 4.5 with hydrochloric acid to precipitate acid-insoluble soy proteins. The supernatant was adjusted to pH 8.0 with 1.0 M NaOH and centrifuged again. The solution was dialyzed for 48 h at 4 °C against water containing 0.02% sodium azide (to prevent microbial growth) and finally preserved at 4 °C. The protein concentration of the laboratory-prepared soybean whey was approximately 0.4% determined by Kjeldahl analysis.

The stock solution of 0.1% chitosan (w/v) was prepared by dispersing chitosan powder in 0.1% acetic acid solution (v/v) with magnetic stirring for 3 h at room temperature (25 ± 1 °C). As for the SWP stock solution, soybean whey was diluted with distilled water to a final concentration 0.1% (calculated by protein content).

Measurement of Turbidity. Both stock solutions were adjusted to a pH of 4.0 separately. Turbidity titration of the SWP/Ch mixture was conducted by first mixing two solutions at the desired ratio (from 100:1 to 1:1) and then adjusting the pH from 4.0 to 10.0. Turbidity was measured using an UV−vis spectrophotometer (Shimadzu, Kyoto, Japan) with a 1 cm cuvette at 600 nm. Turbidimetric titration was carried out by the addition of graded NaOH (1, 0.5, 0.1 M) in increments of ∼0.1 pH unit, to a final pH of 10.0, with gentle stirring and simultaneous monitoring of pH and turbidity. In this way, the added volume could be controlled in the range of 1.5−3% of total volume; thus, the dilution effect was not significant. Titrations were carried out at 25.0 ± 1.0 °C, and the pH (±0.01 pH unit) was monitored with a Mettler Toledo Delta 320 pH-meter that had been carefully calibrated. Homogenous SWP and Ch solutions were used as blanks at their respective concentrations. Homogenous SWP turbidity titration was conducted over the pH range from 3.5 to 7.5. Critical transition points, pH_c, $pH_{\varphi 1}$, pH_{max}, and $pH_{\varphi 2}$, were obtained according to methods reported by Mattison.[30] All measurements were made in triplicate, using separate stock solutions.

Zeta Potential Analyses. Both stock solutions were adjusted to a pH of 4.0 separately. The zeta-potentials (mV) of SWP (0.1%) and chitosan (0.1%) in solution at different pH values ranging from 4.0 to 10.0 were calculated separately from the electrophoretic mobility, at 25.0 ± 0.1 °C, using a Zetasizer Nano ZS instrument (Malvern, UK). All measurements were made in duplicate.

Protein Content Determination and SDS-PAGE Analysis. The phase-separated SWP/Ch mixtures were divided into precipitate and supernatant by centrifugation (4000 rpm, 15 min). Quantitation of protein in the supernatant was determined by using the bicinchoninic acid (BCA) method,[31] and the protein content of the precipitate was calculated by difference from that of the supernatant. BCA reagent was prepared by mixing 50 volumes reagent A (containing BCA (1%), Na_2CO_3 (2%), $Na_2C_4H_4O_6$ (0.16%), NaOH (0.4%), $NaHCO_3$ (0.95%), respectively) with 1 volume reagent B (4% $CuSO_4$) when it will be used. Then, 100 μL of the sample and 2 mL of BCA reagent were pipetted into a test tube and mixed thoroughly. After the mixture had stood for 30 min at 37 °C and then the temperature allowed to drop to room temperature, the change in absorbance was monitored at 562 nm, using 100 μL of water as a control. All measurements were made in triplicate.

Protein compositions of both parts were analyzed using a Tricine−SDS-PAGE method, according to the method of Schagger.[32] Concentrations of stacking and separating gels were 4 and 16%, respectively. 2-Mercaptoethanol was added into the samples to the concentration of 2% (v/v), and samples were heated for 5 min in a boiling water bath. Then 10 μL of each sample was loaded into a sample well, and the samples were electrophoresed at a constant voltage of 30 V until all of protein sample entered into the stacking gel and then at constant voltage of 100 V until the end. The gel was stained using Coomassie Brilliant Blue G-250.

SEC-HPLC Analysis. Contents of major protein component in the complex, supernatant, and soybean whey was determined by SEC-HPLC, using a TSK gel 2000 SWXL (300 mm × 7.8 mm, Tosoh, Tokyo, Japan) column on an Aglient Technologies (USA) 1260 Infinity system equipped with a UV detector, with 20 μL injections. The column was equilibrated and run with ultrapure water containing 45% (v/v) acetonitrile and 0.1% (v/v) trifluoroacetic acid (TFA). The flow rate was 0.5 mL/min, and the wavelength of the UV detector was at 214 nm. Initial sample solutions were directly analyzed after filtration (0.45 μm).

MALDI-TOF/TOF-MS. The verification of reported protein components and the identification of unknown proteins in soybean whey were conducted by the MALDI-TOF/TOF-MS analysis. The MALDI-TOF/TOF-MS analysis of sample was conducted according to the methods of Zhao.[33] The protein spots were excised from a Coomassie Brilliant Blue G-250 stained gel, washed in distilled water, and destained completely in a 30% acetonitrile (v/v) containing 100 mM NH_4HCO_3. After a 100% acetonitrile washing, the destained gel piece was placed into reducing solution (10 μL of 100 mM DTT, 90 μL of 100 mM NH_4HCO_3) for 30 min at 56 °C. After a 100%

acetonitrile washing, 70 μL of 100 mM NH_4HCO_3 and 30 μL of 200 mM iodoacetic acid were added, and the mixture was incubated for 20 min in the dark. After a 100% acetonitrile washing again, 5 μL (10 μg/mL) of trypsin (Promega, V5111) was added, and the mixture was put into a 4 °C refrigerator for 30 min. Then 25 mM NH_4HCO_3 solution was added. The peptides were generated after 20 h of incubation at 37 °C. The solution containing peptides was collected and concentrated at 30 °C to get a dry powder. Three microliters of 0.1% TFA (v/v) was used to dissolve the dry powder. In the final step before MALDI-TOF/TOF analysis, the sample was prepared by mixing 0.7 μL of the sample and 0.7 μL of 4-hydroxy-α-cyanocinnamic acid (used as a matrix) on a MALDI target and air-dried. All mass spectra were obtained with an ultrafleXtreme MALDI-TOF/TOF (Bruker Daltonics, Germany). All mass spectra were analyzed by flexAnalysis software provided by Bruker Daltonics Corp. Protein identification was performed by searching plant proteins in the latest version of the NCBInr database.

Trypsin and Chymotrypsin Inhibitor Activity Assays. Trypsin inhibitor activity (TIA) was measured with 0.04% (w/v) N^{α}-benzoyl-L-arginine 4-nitroanilide hydrochloride (BAPA) as the substrate, which dissolved in 0.05 M, pH 8.2, Tris-HCl buffer (1% dimethyl sulfoxide, v/v; 0.02 M $CaCl_2$). Assay solution was zeroed, and then 2 mL of 0.01% (w/v) trypsin in 0.04 mM HCl solution was added to begin the reaction.[34] Chymotrypsin inhibitor activity (CIA) was determined by using a method modified from that of Tan et al.[35] One milliliter of a diluted sample and 1 mL of deionization water were pipetted into a test tube. Then 4.2 mL of 0.05 M, pH 8.2, Tris-HCl buffer (0.01 M $CaCl_2$) and 2 mL of 0.02% (w/v) α-chymotrypsin in 0.002 M HCl solution were added, followed by 0.8 mL of 0.04% (w/v) *N*-benzoyl-L-tyrosine *p*-nitroanilide (BTpNA) in acetone solution and thorough mixing. Exactly 10 min later, the reaction was terminated by adding 1 mL of 30% (w/v) acetic acid. The change in absorbance was monitored at 410 nm for at least 3 min. Trypsin inhibitor units (TIU) or chymotrypsin inhibitor units (CIU) were calculated as the amount of inhibitor that reduced the absorbance per minute of the standard reaction by 0.01. For accuracy, the reaction was measured in the linear portion in the 40−60% inhibition range.

RESULTS AND DISCUSSION

Protein Components in Soybean Whey. The dialyzed soybean whey without further treatment to increase concentration was first analyzed by Tricine−SDS-PAGE, using 2% 2-ME as disulfide bond reductant, so as to gain an overview of the protein components in the sample. As shown in Figure 1a, five major bands, band 1−5, were obtained. From the molecular marker, it was known that bands 1 and 2 had molecular weights of 56 and 30 kDa, respectively, whereas twin bands 3 and 4 were centered around 20 kDa. Band 5 displayed as a broad smear at a molecular weight around 12 kDa.

To improve the electrophoretic resolution of bands 3, 4, and 5, proteins were enriched by mixing dialyzed soybean whey with chitosan at a ratio of 8:1 and alkalinized to pH 6 (at this condition, there were relatively high amounts of complex). The centrifuging precipitate was recovered and analyzed by Tricine−SDS-PAGE using DTT as disulfide bond reductant. As shown in Figure 1b, bands 1 and 2 were substantially eliminated, but proteins with molecular weight similar to those of bands 3, 4, and 5 were enriched by chitosan complexing. Only one band (4′) was found to correspond with the molecular weight of 20 kDa when using DTT as reductant. Therefore, bands 3 and 4 were actually the same protein showing different electrophoretic mobilities, possibly because of the insufficient reduction of disulfide bonds resulting in inhomogeneous molecular size. In Figure 1b, the original band 5 split in two bands (band 5′ and 5″), and the resolution further improved with the increase of DTT concentration.

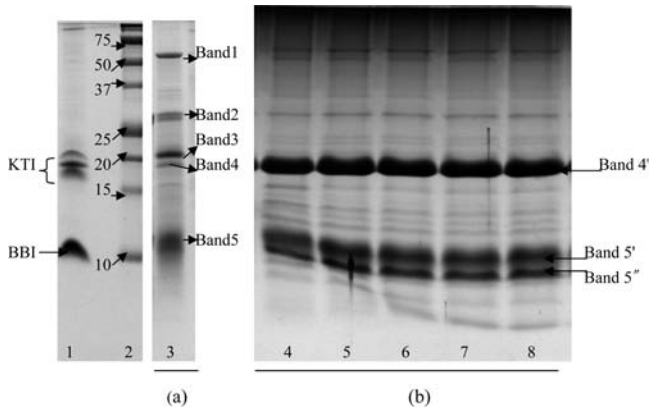

Figure 1. Tricine-SDS-PAGE for SWPs and precipitate proteins: (a) SWP treated with 2-mercaptoethanol (2.0%); (b) precipitate treated with DTT. Lanes 1 and 2 are standards of KTI and BBI; lanes 4−8 represent 200, 300, 600, 800, and 1000 mM DTT treatment, respectively. The DTT treatment samples were chosen as $R_{SWP/Ch}$ = 8:1, which contained the relatively higher content of bands 3−5; all DTT treatment samples were heated for 5 min in a boiling water bath. Band 4′ was derived from bands 3 and 4, and bands 5′ and 5″ were derived from band 5.

Major protein components in soybean whey as separated by Tricine−SDS-PAGE were identified by MALDI-TOF/TOF-MS. As shown in Table 1, bands 1 and 2 in Figure 1a were matched to β-amylase and soybean agglutinin, respectively. As expected, bands 3 and 4 in Figure 1a, as well as band 4′ in Figure 1b, were characterized as the same protein: soybean Kunitz trypsin inhibitor (KTI).

Bands 5′ and 5″, which derive from the 12 kDa protein, were matched to uncharacterized protein LOC100306176 precursor and unnamed protein product, respectively. The latter had a theoretical nominal mass (M_r) of 8807 and a theoretical calculated p*I* of 4.51. The amino acid sequence of the latter was further compared with that of Bowman−Birk protease inhibitor (BBI). It can be found in Table 2 that two specific binding domains existed in soybean BBI (IBBD1_SOYBN), which offers the binding sites for trypsin inhibitors,[36] that is, CTKSNPPQ and CALSYPAQ. Alfonso[37] reported another type of BBI: IBBD2_SOYBN. For this type, CTKSNP was replaced by CTRSMP. It was interesting to find that band 5″ showed a combination of the above: CTRSNP. In addition, there was an extra M residue at the N-terminal. Considering about 30% protein sequence coverage, band 5″ (BBI-U) could be a new member of the BBI family.

Trypsin and Chymotrypsin Inhibitor Activity of the 12 kDa Proteins. At $R_{SWP/Ch}$ = 4:1 and pH 6.39, the 12 kDa proteins distribute in both supernatant and precipitate, and the TIA and CIA activities in both parts (Figure 2) were investigated. It can be seen that there were 31.0% of TIA activity and 41.5% of CIA found in supernatants, due to three proteins in supernatants at the ratio of 4:1: SBA, β-amylase, and the 12 kDa proteins (illustrated under Protein Components of SWP/Ch Complexes). SBA and β-amylase showed no TIA activity; thus, the residual TIA was derived from 12 kDa proteins. As one of the 12 kDa proteins, BBI-U had a structure similar to that of BBI and should contribute part of the inhibitor activities.

SWP/Ch Complexing Behavior as a Function of pH and Mixing Ratio. *Critical Points of SWP/Ch Complexing.* pH affected the charge densities and thus the complexing

[a]Amino acid sequences of inhibitory domains are underlined. $P_1-P'_1$ are the reactive peptide bond sites, in bold text. Either K or R at position P1 determines specificity for trypsin, whereas L determines specificity against chymotrypsin. The peptides that contributed to protein identification are indicated in italics.

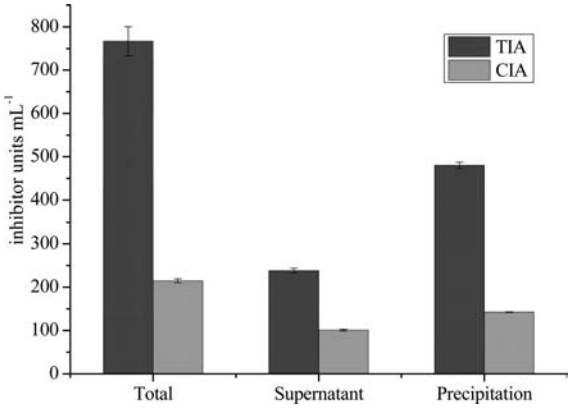

Figure 2. Trypsin and chymotrypsin inhibitor activity of SWP/Ch system at $R_{SWP/Ch}$ = 4:1. At $R_{SWP/Ch}$ = 4:1, the 12 kDa proteins distribute in both supernatant and precipitate. The activity is expressed as inhibitor units and presented as the mean ± SE (n = 3). Lanes: 1, total protein; 2, proteins remained in the supernatant; 3, precipitated proteins.

behavior of soybean whey proteins and chitosan, as shown in Figure 3. On addition of NaOH to SWP/Ch mixtures that had been adjusted to a pH lower than the isoelectric point of SWP (pH 4.3), we first observed the formation of a soluble complex at pH_c, below which electrostatic repulsive forces prohibited the formation of complexes, and the turbidity remained at the baseline. Upon further elevation in alkalinity to $pH_{\varphi 1}$, an abrupt increase in turbidity was observed, indicating the formation of insoluble complex particles. Turbidity rose to the maximum at pH_{max} and decreased rapidly as the pH continued to increase, and a turbidity level-off was found at $pH_{\varphi 2}$. As a control, chitosan was a primary aliphatic amine that can be protonated by selected acids (such as acetic acid), the pK of the chitosan

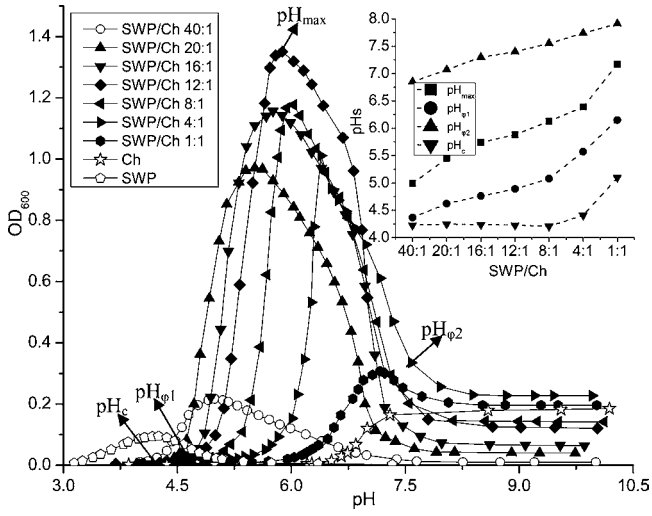

Figure 3. Turbidity curves for the SWP/Ch system (Cp = 0.10%) and homologous SWP solution as a function of $R_{SWP/Ch}$ in the absence of NaCl. The values of pH_c, $pH_{\varphi 1}$, and $pH_{\varphi 2}$ were determined graphically as the intersection point of two tangents to the curve, whereas pH_{max} corresponded to the maximum optical density at 600 nm. (Inset) pH values (pH_c, $pH_{\varphi 1}$, pH_{max}, and $pH_{\varphi 2}$) of SWP/Ch system for different ratios.

amine being 6.3. This made it soluble in acid solution, and deprotonation began at pH >6.3. Therefore, the turbidity curve (Figure 3) for chitosan displayed an abrupt increase in turbidity at pK_a and then reached a maximum at pH around 7.0, followed by the plateaus of turbidity, corresponding to the insolubility of chitosan.

Figure 3 shows that the complexing behavior of SWP/Ch was also substantially affected by the mixing ratio, and the shifts of pH values (pH_c, $pH_{\varphi 1}$, and $pH_{\varphi 2}$) for SWP/Ch system at different ratios are inset in this figure. It was found that a decrease in SWP/Ch ratio resulted in a shift of the turbidity curves to higher pH ranges. Another study done in our laboratory also found the shift of turbidity curves of soy protein−gum arabic mixtures when the mixing ratio changed.[38] The authors noted that, with the increase of soy protein/gum arabic ratio, critical pH values for the formation of insoluble complex shifted to higher values. At the same time, the pH value at which soy proteins and gum arabic carried equal amount but opposite charges also changed in the same way. Therefore, the movement of the turbidity curves seemed to be related to changes of conditions at which the protein/polysaccharide charge compensation was achieved.

To verify the above speculation, a more detailed analysis of electric charge relationships between two biomacromolecules

dx.doi.org/10.1021/jf501904g | J. Agric. Food Chem. 2014, 62, 7279−7286

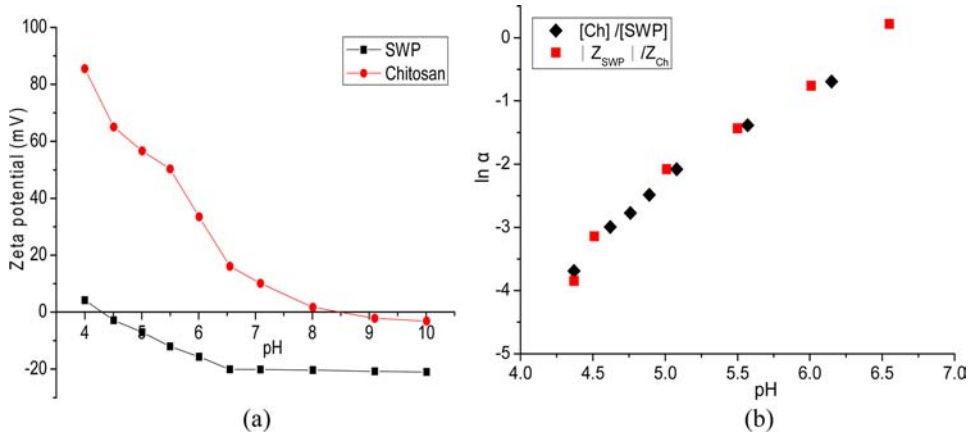

Figure 4. Zeta potential (mV) values for homogeneous SWP (0.1%) and chitosan (0.1%) in the absence of NaCl (a) as a function of pH (n = 2) and the relationship between [Ch]/[SWP] and $|Z_{SWP}|/Z_{Ch}$ as a function of pH (b).

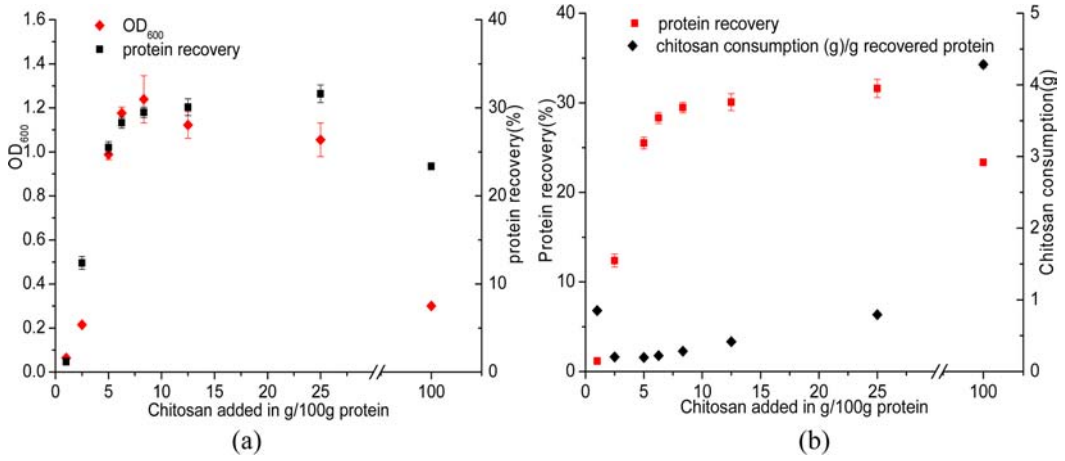

Figure 5. Relationship between turbidity (OD_{600}) and protein recovery (a) and between protein recovery and chitosan consumption (b) for the SWP/Ch (Cp = 0.10%) system. OD_{600} represented the maximum turbidity of given ratios; the protein recovery corresponded to maximum turbidity.

was conducted to get a more quantitative understanding of the effect of mixing ratio on the complexing behavior of SWP/chitosan mixtures. Figure 4a shows that chitosan gave positive zeta potential below about pH 8.3, whereas SWP presented negative zeta potential at pH >4.3. In addition to the nature of electric charges, the absolute value of zeta potentials revealed that the quantities of charges on SWP and Ch, respectively, were also pH dependent. Figure 4b shows the plot of $\ln(|Z_{SWP}|/Z_{Ch})$ as a function of pH. At the same time, $\ln([Ch]/[SWP])$ versus $pH_{\varphi 1}$ was also plotted in the same coordinate system. It was interesting to find that two sets of data can be described by essentially the same curve. We knew that a mixture with a given Ch/SWP ratio started phase separation at $pH_{\varphi 1}$. If we looked at the Ch/SWP mixing ratio of 1:8, or $\ln([Ch]/[SWP]) = -2$, the corresponding $pH_{\varphi 1}$ value was found to be 5.1. At around the same pH (5.05), the natural logarithm of $|Z_{SWP}|/Z_{Ch}$ had almost the same value. Thus, our study indicated that at $pH_{\varphi 1}$, $[SWP] \times |Z_{SWP}| = [Ch] \times Z_{Ch}$ or charge compensation was established. For other mixing ratios, the curve told us that charge compensations were also achieved.

In Figure 3, the maximum turbidity occurred at the pH higher than $pH_{\varphi 1}$, indicating that electric charges on soybean whey proteins and chitosan were not balanced. Most probably, the dissociation of carboxyl groups of proteins and the deprotonation of amino groups of chitosan proceeded more rapidly at higher pH and more complexes were formed in a limited period of time. Therefore, the position and height of maximum turbidity were affected both by thermodynamic and by kinetic factors.

Maximum Turbidity and Protein Recovery. Figure 5a shows the effect of chitosan level on maximum turbidity. It can be observed that turbidity increased rapidly when the amounts of chitosan, which was added into 100 g of soybean whey proteins, increased from 1 to 8.3 g. Further increase in chitosan level resulted in a decrease of turbidity. On the other hand, percent recovery of proteins from soybean whey by centrifugation precipitation of the SWP/Ch complex reflected not only the amount of complex formed but also the deposit ability of the complex. As shown in Figure 5a, protein recovery increased along with turbidity when the chitosan level increased from 1 to 8.33 g/100 g SWP. However, protein recovery kept increasing, although at a slower pace, at higher chitosan level and reached a maximum at 25 g/100 g SWP. A chitosan consumption was defined here as the amount of chitosan used to recover 1 g of proteins in soybean whey. Our experiment (Figure 5b) revealed that although the protein recovery was not very high at a SWP/Ch ratio of 20:1 and pH 5.5, chitosan consumption was lowest (0.196 g Ch/g recovered proteins) under this condition.

Protein Components of SWP/Ch Complexes. Dialyzed soybean whey was mixed at different mixing ratios, and SWP/

dx.doi.org/10.1021/jf501904g | J. Agric. Food Chem. 2014, 62, 7279−7286

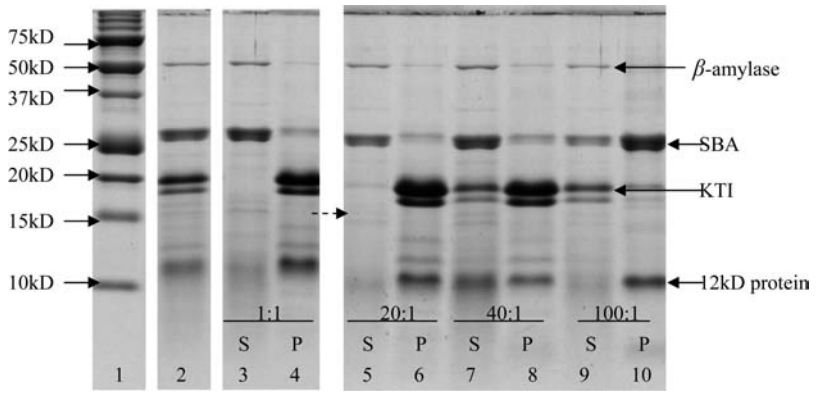

Figure 6. Tricine–SDS-PAGE for proteins in supernatant (S) and precipitate (P). Lanes: 1, marker; 2, SWP; 3, 5, 7, and 9, supernatants for $R_{SWP/Ch}$ 1:1, 20:1, 40:1, 100:1; 4, 6, 8, and 10, precipitates for the same ratios.

Ch complexes were formed by pH titrating to the maximum turbidity using NaOH solution, followed by centrifuging to obtain precipitates and supernatants. Protein compositions of complexes and supernatants were analyzed by SDS-PAGE, and the results are shown in Figure 6. In the case of the SWP/Ch ratio range from 1:1 to 20:1 (the other four ratios 16:1–4:1 are not shown in the figure), a negligible content of KTI in the supernatant and low contents of SBA and β-amylase in the precipitates were observed. For the mixture with a SWP/Ch ratio of 40:1, it was estimated that >80% of KTI transferred into the SWP–Ch complex, whereas >70% of SBA and β-amylase remained in the supernatants. The inability of SBA and β-amylase to form a complex with chitosan could partly be attributed to their higher isoelectric points (pH 5.8 and 5.6). Chitosan started to deprotonate at a pH higher than the pK_a (pH 6.3), at which point SBA and β-amylase were marginally negatively charged. Thus, the electric interaction between proteins and chitosan was weak. From the above, we knew that if the SWP/Ch mixing ratio was less than 20:1, all of the KTI of soybean whey would form a complex with chitosan.

Quite unexpectedly, the precipitate that was formed at very low chitosan level (SWP/Ch =100) and low pH (pH 4.8) displayed a very different protein composition, SBA and 12 kDa protein being the major proteins in addition to a small amount of KTI. The precipitate could not be formed by complexing because both SBA and Ch carried the same positive charge at this pH range. The precipitation of SBA in dialyzed soybean was also found at pH around 4.8. Most possibly, this precipitate was caused by the low solubility of SBA in very low salt concentration. Additionally, it was also remarkable to find that all precipitates seemed to contain essentially the same amount of 12 kDa proteins, regardless of the difference in pH and SWP/Ch ratio.

Selective Complexing of KTI. Protein separation had been achieved by Xu et al.[18] as a consequence of selective protein–polyelectrolyte complexation. This technique may afford the possibility of large-scale protein purification that is fast, efficient, and inexpensive compared to traditional protein separation methods such as chromatography, membrane separation, or centrifugation.[39] In this experiment, dialyzed soybean whey was adjusted to pH 4.0 and centrifuged at 4000 rpm to remove self-aggregated SBA and 12 kDa proteins to increase the selectivity of KTI. Protein content in the supernatant was determined and mixed with chitosan according to different SWP/Ch ratios.

Figure 7 shows that the protein composition of precipitates formed from 4:1 to 40:1. Soybean whey/chitosan mixtures

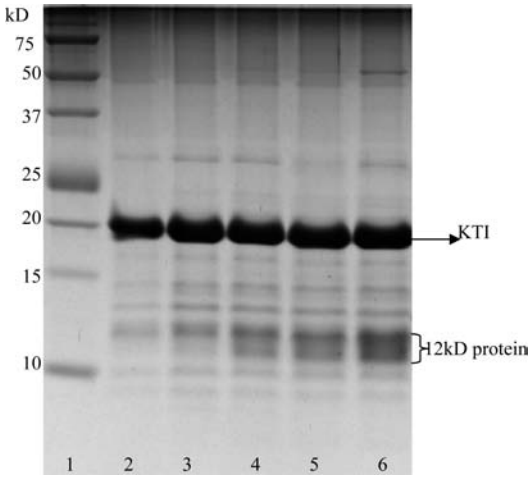

Figure 7. Tricine–SDS-PAGE for proteins in precipitates. Lanes: 1, marker; 2–6, precipitates for $R_{SWP/Ch}$ 100:1 (pH 4.86), 40:1 (pH 4.99), 20:1 (pH 5.52), 12:1 (pH 5.88), and 4:1 (pH 6.39).

were similar to the respective protein composition when soybean whey was not precentrifuged, KTI being the major component together with a small amount of 12 kDa proteins, whereas SBA and β-amylase showed only very faint bands. However, the protein composition for 100:1 precipitate was totally different from the above experiment: before precentrifugation, SBA and 12 kDa proteins were the main components, whereas after precentrifugation, KTI became the major protein. Therefore, the removal of self-aggregated SBA and 12 kDa proteins could increase the availability of chitosan for complexing with KTI. As a lectin, SBA is a nonenzyme, nonantibody, and carbohydrate-binding protein[40] and is well-known for its highly specific interactions with galactose/*N*-acetylgalactosamine.[41] On the other hand, chitosan is composed of randomly distributed β-(1–4)-linked D-glucosamine (deacetylated unit) and *N*-acetyl-D-glucosamine (acetylated unit), which can provide binding sites for SBA. In contrast to protein–polysaccharide complexing, the specific binding of SBA with chitosan at acidic pH range actually stabilized proteins against precipitation. This was confirmed by the fact that, when the isolated SBA was mixed with chitosan and the pH adjusted to the range of phase separation (pH >6.3), the

dx.doi.org/10.1021/jf501904g | J. Agric. Food Chem. 2014, 62, 7279–7286

obtained mixture gave turbidity lower than that of chitosan at the same condition. Therefore, by partly removing SBA through precentrifugation to reduce the consumption of chitosan, KTI was provided the opportunity to be complexed. As to the behavior of 12 kDa proteins, experimental results suggested that they displayed self-aggregating ability at the same pH as that for SBA and the complexing ability with chitosan under the same conditions for KTI complexing. However, it seemed that interaction between 12 kDa proteins and chitosan was weaker than that between KTI and chitosan, which was possibly because 12 kDa proteins had higher isoelectric points than that for KTI. This can explain why these proteins always coexisted with KTI in precipitates but were less enriched.

Kaibara et al.[42] reported that ionic strength, polyelectrolyte charge, and protein charge densities affected the protein purification. In their experiment, the selective coacervation of BSA from the BLG was achieved by the nonmonotonic control of ionic strength to enhance protein charge anisotropy. However, in our experiment, with an environment lacking ionic strength, the selectivity of coacervation depended on the charge of protein and chitosan pairs. The stronger binding affinity to chitosan of KTI than of the 12 kDa protein offered us the possibility to separate them by changing the ratio of protein/polysaccharide. As expected, in the low presence of chitosan, the two proteins showed a significant difference in binding ability, giving the priority of KTI to 12 kDa protein binding to chitosan, and a purified KTI was obtained.

This KTI−Ch complex obtained was adjusted to pH 10 to precipitate chitosan, followed by centrifugation (4000 rpm, 15 min) to collect the supernatant, which was rich in KTI. The purified KTI contained 95.89% protein, 2.02% polysaccharide, 0.87% ash, and 2.2% water. The TIA of the purified KTI was 5901.3 U/mg, higher than that of standard KTI (Sigma) with 5058.08 U/mg, showing that the presence of chitosan may have no effect on the natural activity of KTI.

The purifying effect of KTI by selective complexing with chitosan after precentrifugation was further verified by SEC-HPLC (Figure 8). Several peaks were observed in the dialyzed

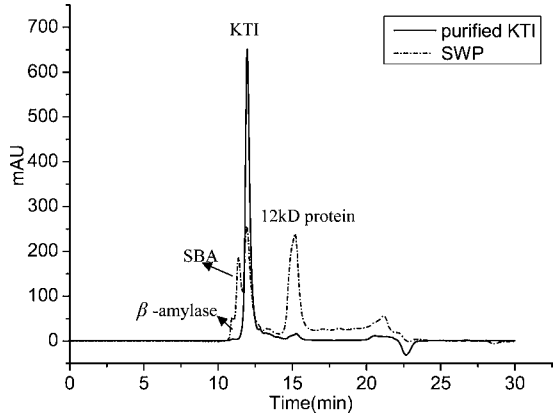

Figure 8. SEC-HPLC analysis for SWP and purified KTI.

soybean whey, and the content of KTI was 33.17% calculated from peak area. After complexing with chitosan, other proteins were substantially removed and the purity of KTI was 92.5%. The problem with the present result was the low (about 10%) recovery of KTI at one time. Two further experiments were also needed to extract the residual KTI in the supernatant, and the average purity of these three prepared samples was also >90%. Therefore, further studies will be conducted to consistently improve the KTI recovery.

In summary, a newly identified protein (12 kDa), which had a structure similar to that of BBI and showed CIA and TIA activities, was found in soybean whey by SDS-PAGE and MALDI-TOF/TOF-MS. The KTI and the 12 kDa protein were the main components to form complexes with chitosan. For different SWP/Ch ratios, charge compensation of system was found to be established at $pH_{\varphi 1}$, at which phase separation began to occur. Selective complexation between KTI and chitosan was observed only at the condition of SWP/Ch = 100:1, pH 4.8 and low ionic strength. After removing chitosan, a high purity KTI (more than 90%) could be obtained.

Data are means ± SDs (n = 3). The *, **, and *** indicate significant difference at 0.05, 0.01, and 0.001 level of Student's t-test between control and Mn soil in the given fraction.

impact of pH on Mn uptake in some crops did not match with known fact that "its bioavailability increases with decreasing pH" as for example, potato contained more Mn at less acidic pH.[3] Because control and Mn-soil we used differed in pH, a further solution test was done to verify its involvement in Mn uptake.

MATERIALS AND METHODS

Plant Cultured and Experimental Design. Selected crops were tested in the present study (provided by Josef Hedbavny), namely *Brassica napus* cv. Smaragd, *Hordeum vulgare* cv. Bojos, *Zea mays* cv. Korneli, *Triticum aestivum* cv. Tiguan. Seeds were surface sterilized and sown directly to pots containing 500 g of control or naturally contaminated soil (5 for *Zea*, 10 for cereals and 20 seeds for *Brassica* in order to achieve approximately similar biomass/soil ratio). Control soil, collected on the field (by Jozef Kováčik, western Slovakia, village Bošany), is widely distributed in the Slovak Republic—Eutric Cambisol (with sandy loamy texture) as reported previously.[18] Mn-contaminated soil was collected on the natural locality in the Krušné Hory Mountains (or Ore Mountains) as described in the previous paper.[19] We note that the origin of this soil is not clear, but is probably natural because the composition of plant species around and within this locality is similar (P. Švec, personal visitation). Soil moisture was maintained at 60% of water holding capacity with distilled water to prevent the impact on minerals. Cultivation was realized under laboratory conditions with ∼300 μmol m^{-2} s^{-1} PAR at leaf level supplied by cool white fluorescent tubes L36W/840 (Lumilux, Osram), 25/20 °C day/night temperature and relative humidity of ∼60%.[14] Whole shoots of plants were harvested after 21 days of cultivation because growth retardation was visible. In the subsequent experiment, crops were sown directly on filter paper placed on glass balls in plastic box and supplemented with 5 mM $MnCl_2{\cdot}4H_2O$ solution (deducted from Mn content in water-soluble fraction of Mn-contaminated soil, see discussion) with pH 6.5 or 3.7 (based on pH of water extracts from control and Mn-contaminated soil, see the Results section). Plants were harvested 10 days later because *Brassica* plants showed strong retardation of growth. For fresh mass-requiring parameters, individual plants were powdered using liquid N_2 and fresh material was extracted as described below. Dry samples (dried at 75 °C to constant weight) were analyzed for mineral nutrients including Mn.

Quantification of Mn and Mineral Nutrients. Samples were prepared by mineralization of dry plant material (10−20 mg) in the mixture of concentrated HNO_3 and water (5 + 5 mL) using microwave decomposition (Ethos Sel Microwave Extraction Labstation, Milestone Inc.) at 200 °C over 1 h (complete duration of the mineralization program). The resulting clear solution was placed to glass flasks and diluted to a final volume of 20 mL. Soil samples for total content of metals (more exactly it is pseudototal content because primary HNO_3 concentration in mineralizates is ca. 5 M and traces of metals may remained bound in silicates present in the soil) were prepared by the same way while water-soluble Mn and nutrients were extracted with deionized water as reported earlier.[18] All measurements were carried out using an atomic absorption spectrometer AA30 (Varian Ltd.; Mulgrave, Australia) and the air−acetylene flame. Measurements of mineral nutrients were done as described previously and Mn was quantified at λ_{max} = 279.5 nm, LOD of Mn was 2 μg/L.[14]

Fluorescence Microscopy. For microscopic analyses, cross sections were taken ca. 1 cm above the stem base and were immediately stained with respective reagents. General accumulation of ROS was monitored using two widely used reagents: 2′,7′-dichlorodihydrofluorescein diacetate (DCF-DA, $502_{Ex}/526_{Em}$ nm, Life Technologies, U.S.A.) and CellROX Deep Red Reagent ($644_{Ex}/665_{Em}$ nm, Life Technologies, U.S.A.). Staining procedure was conducted as previously reported.[20] Nitric oxide or reactive nitrogen species (RNS) were visualized with 2,3-diaminonaphthalene (DAN, $365_{Ex}/415_{Em}$ nm, Sigma-Aldrich, U.S.A.) using 250 μM DAN for 1 h at room temperature.[14] Lipid peroxidation was visualized by BODIPY 581/591 C11 lipid peroxidation sensor ($581_{Ex}/591_{Em}$ nm, Life Technologies, U.S.A.) and total thiols by monochlorobimane ($394_{Ex}/490_{Em}$ nm) according to previous protocols.[20,21] Staining solution was always removed by respective buffer and samples were observed using fluorescence microscope and appropriate set of filters (Axioscop 40, Zeiss, Germany).

Assay of Antioxidative Enzymes and Metabolites. For the assay of enzymatic activities, whole shoots were homogenized with inert sand in potassium phosphate buffer containing 1% insoluble PVPP (pH 7.0). Soluble proteins were quantified according to Bradford method[22] and bovine serum albumin as standard (595 nm). Ascorbate peroxidase (APX) and guaiacol peroxidase (GPX) activities were measured as the oxidation of ascorbate and guaiacol at 290 and 470 nm, respectively.[11,12,23] Glutathione reductase (GR) activity was assayed as the reduction of GSSG at 412 nm.[11] Catalase activity was measured as the reduction of H_2O_2 to water monitored at 240 nm.[23] Randomly selected supernatants were boiled and assayed in order to check that reactions were enzymatic.

Total soluble phenols were extracted with 80% methanol and quantified using the Folin−Ciocalteu method with gallic acid as standard and detection at 750 nm.[23]

Quantification of organic and inorganic anions was performed by an Ion-Exchange Chromatography system (DX 600, Dionex Corporation, Sun Valley, CA, U.S.A.) equipped with ED50 Electrochemical detector and conductivity cell installed in DS3 Detection Stabilizer and Anion Self-Regenerating Suppressor−Ultra II (2 mm, ASRS-ULTRA II) operating at 100 mA in AutoSuppression Recycle Mode. Samples were prepared in deionized water (0.1 g FW/1 mL) that was found to be more suitable in comparison with acidified water (data not shown).

Separation was carried out with an IonPac AS 11−HC (2 × 250 mm) analytical column and IonPac AS 11−HC (2 × 50 mm) guard column (Dionex Corporation, Sun Valley, CA, U.S.A.). The mobile phase consisted of deionized water (A) and 100 mM NaOH in deionized water (B). A linear gradient profile of the mobile phase from 1% B (0−4 min), 1−15% B (4−12 min), 15−25% B (12−17 min), 25−45% B (17−20 min), and 45−1% B (20−21 min) was applied at a flow rate 0.35 mL/min. The column was equilibrated for 15 min under initial conditions prior to injection of the next sample. The column temperature was 30 °C and injection loop was 10 μL. The peak identity was confirmed by comparing the retention times with retention time of standards and by spiking standard solutions to the samples. Calibration curves were linear (r^2 > 0.998) for each compound in the concentration range 1−100 μg mL^{-1}. Limit of detection was 0.2−0.9 μg mL^{-1}. Reagents (malic acid, citric acid, ammonium acetate, and ammonium formate) were purchased from Sigma-Aldrich (Chemie GmbH, Steinheim, Germany), sodium hydroxide solution 50%, sodium phosphate and sodium sulfate were supplied by Fluka Chemie (Buchs, Switzerland) and other chemicals (sodium chloride, oxalic acid, potassium nitrate, sodium nitrite) were obtained from Penta Chrudim (Czech Republic). All chemicals used were of analytical grade. Demineralized water with a specific resistance of 18.2 MΩ cm^{-1} (Mili-Q RG, Millipore, Bedford, MA, U.S.A.) was used to prepare all solutions and standards.

Statistical Analyses. Two independent repetitions of the whole experiment were performed in order to check reproducibility. At least six pots were used for each crop and soil. Data were evaluated using ANOVA followed by a Tukey's test (MINITAB Release 11, Minitab Inc.; State College, Pennsylvania) at $P < 0.05$. Additionally, Student's *t*-test was used to compare the difference between control and Mn-soil and biomass production. Number of replications (n) in tables/figures denotes individual soil samples or individual plants analyzed for each parameter. Only for Mn-exposed *Brassica*, several shoots were pooled to achieve enough biomass for measurements.

RESULTS AND DISCUSSION

Uptake of Mn, Alterations of Mineral Nutrients, and Growth of Plants Cultured in Mn-Contaminated Soil. Analysis of soil Mn content revealed ca. 10-times higher amount in Mn-contaminated soil than in control soil in the pseudototal fraction and much higher difference in water-soluble fraction (Table 1). Pseudototal Mn content in Mn-soil is within the range reported previously on the locality from which soil used in the present study originated.[19] Further assay of selected essential and nonessential metallic nutrients showed their higher pseudototal amount in control soil (except for Cd), although it was not observed for all metals in water-soluble fraction (Table 1). The control soil we used is widely distributed in the Slovak Republic−Eutric Cambisol (with sandy loamy texture) with higher Mg content as reported previously for the same soil type from other locality.[18] More acidic pH was the main difference between Mn-soil and control (Table 1) and we therefore subsequently studied the impact of pH on Mn uptake in solution culture (see last paragraph of discussion).

Uptake of Mn, such as in the case of other metals, is affected by soil conditions as well as by plant species. This variability has previously been observed in various plants collected from naturally Mn-contaminated locality.[19] As expected, plants showed similar amount of Mn in control soil because it is an essential micronutrient (Table 2). However, differences of Mn content in Mn-soil were more extensive and suggest species-specific uptake. To our knowledge, this is first laboratory-controlled study using naturally Mn-contaminated soil, and we therefore found no data exactly comparable with the present study. In terms of our crops, it has been reported that shoots of

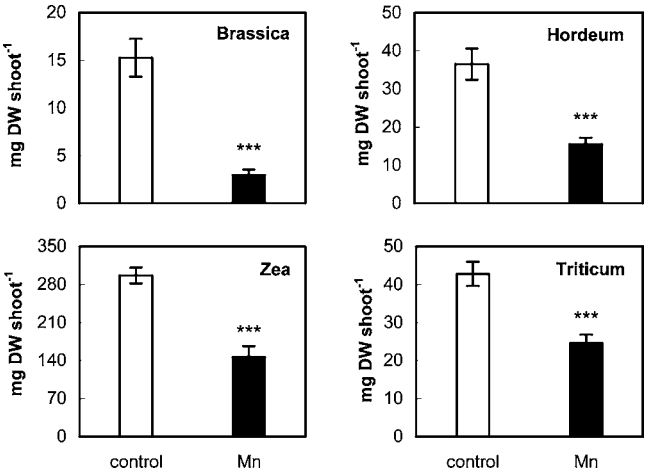

Figure 1. Dry biomass (milligrams per shoot) of four crops cultured in naturally Mn-contaminated soil (shown in Table 1) over 21 days. Data are means ± SDs (n = 10). *** indicates significant difference at 0.001 level of Student's t-test. Brassica, *Brassica napus* cv. Smaragd, Hordeum, *Hordeum vulgare* cv. Bojos, Zea, *Zea mays* cv. Korneli, and Triticum, *Triticum aestivum* cv. Tiguan.

Hordeum contained up to 3500 μg Mn g^{-1} in soil with total Mn concentration 500−2500 μg g^{-1} DW[2]; both these values are lower compared to our data (Tables 1 and 2), although growth depression by ca. 50% (Figure 1) is similar to mentioned study. Another theoretical comparison is possible with barley plants cultured in hydroponics with 1.83 mM Mn^{2+} where bioaccumulation (BAF) value was ca. 6.5:[8] considering that water-soluble Mn was ∼5 mM in our study (280.1 μg g^{-1} DW, Table 1), our BAF value is 21 and indicates similar extent of Mn uptake despite different culture conditions and Mn concentrations. However, BAF values for almost all species analyzed in the present study were calculated with respect to the pseudototal soil metal content, and this value is therefore lower in the case of *Hordeum* (0.92, Table 3). In this sense, only Mn-cultured *Brassica* had BAF higher than 1 but it does not confirm hyperaccumulation potential because growth was extremely suppressed (Figure 1).

Few studies also report Mn uptake in plants from natural localities and BAF can be calculated. For example, BAF in *Vaccinium myrtillus* was lower in the soil from polluted localities (3.6−14.4) in comparison with control localities (27.6−41.3).[10] In a similar study, species *Plantago lanceolata* and *Cardaminopsis arenosa* from a polluted locality (mining and metallurgic activity, where also higher soil Mn content was detected), revealed lower BAF if compared to control site (*P. lanceolata* 0.01−0.03 vs 0.09 in control; *C. arenosa* 0.02−0.1 vs 0.37 in control).[9] Above-mentioned data confirm that various plant species in natural populations do not elevate Mn content, although soil Mn content was higher on polluted localities. On the contrary, our plants had higher BAF values in Mn-soil: there is certainly a "break" of regulatory mechanisms and thus excessive Mn uptake damaged plants visibly in the present study.

Above-mentioned uptake of Mn was therefore reflected in the changes of growth. This was mainly visible in *Brassica* plants where the highest shoot Mn amount correlates with the most depleted growth (cf. Table 2 and Figure 1). Another aspect that certainly affected growth is depletion of some essential nutrients. Mainly Mg and Ca, being quantitatively important divalent cations that could compete with Mn uptake, decreased in plants from Mn-soil (Table 2). Although BAF for these metals was elevated in Mn-soil, indicating that plants effectively cope with their depleted amounts (compared to control, Tables 1 and 3), absolute quantities are probably not high enough for optimal growth (also visible by chlorosis of the leaves that appeared after several days of cultivation). In agreement with our data, Mn excess depleted macronutrients (Ca and Mg) more than the level of micronutrients (Fe, Zn, Cu) in cucumber plants and growth was also affected.[6] Besides, reduction of available Ca led to a dramatic increase in Mn content in *Phytolacca americana*.[24] However, our data also showed that the impact of Mn excess is species-specific and cannot be generalized because some metallic nutrients such as Zn or Fe even increased in Mn-cultured *Brassica* and *Zea*, but not in cereals (Table 2).

Another original aspect arising from the present study is the impact of Mn excess on the uptake of toxic metals. Amount of Cd and Ni was relatively similar in control and Mn-soil (Table 1). Accumulation of Ni was elevated in Mn-soil in *Brassica* and *Zea* plants but not in cereals. On the other hand Cd uptake strongly increased in Mn-cultured *Brassica* plants but was not detected in *Triticum* (Table 2). Owing to absence of similar literature, we are unable to compare these values deeply. Theoretical comparison is possible in relation to studies where polluted and nonpolluted localities in Poland were compared: although polluted localities contained more Mn, they also contained more Cd and therefore sharp increase in shoot Cd

[a]According to literature, BAF <1 and >1 indicate excluders and accumulators, respectively (see ref 18 for details).

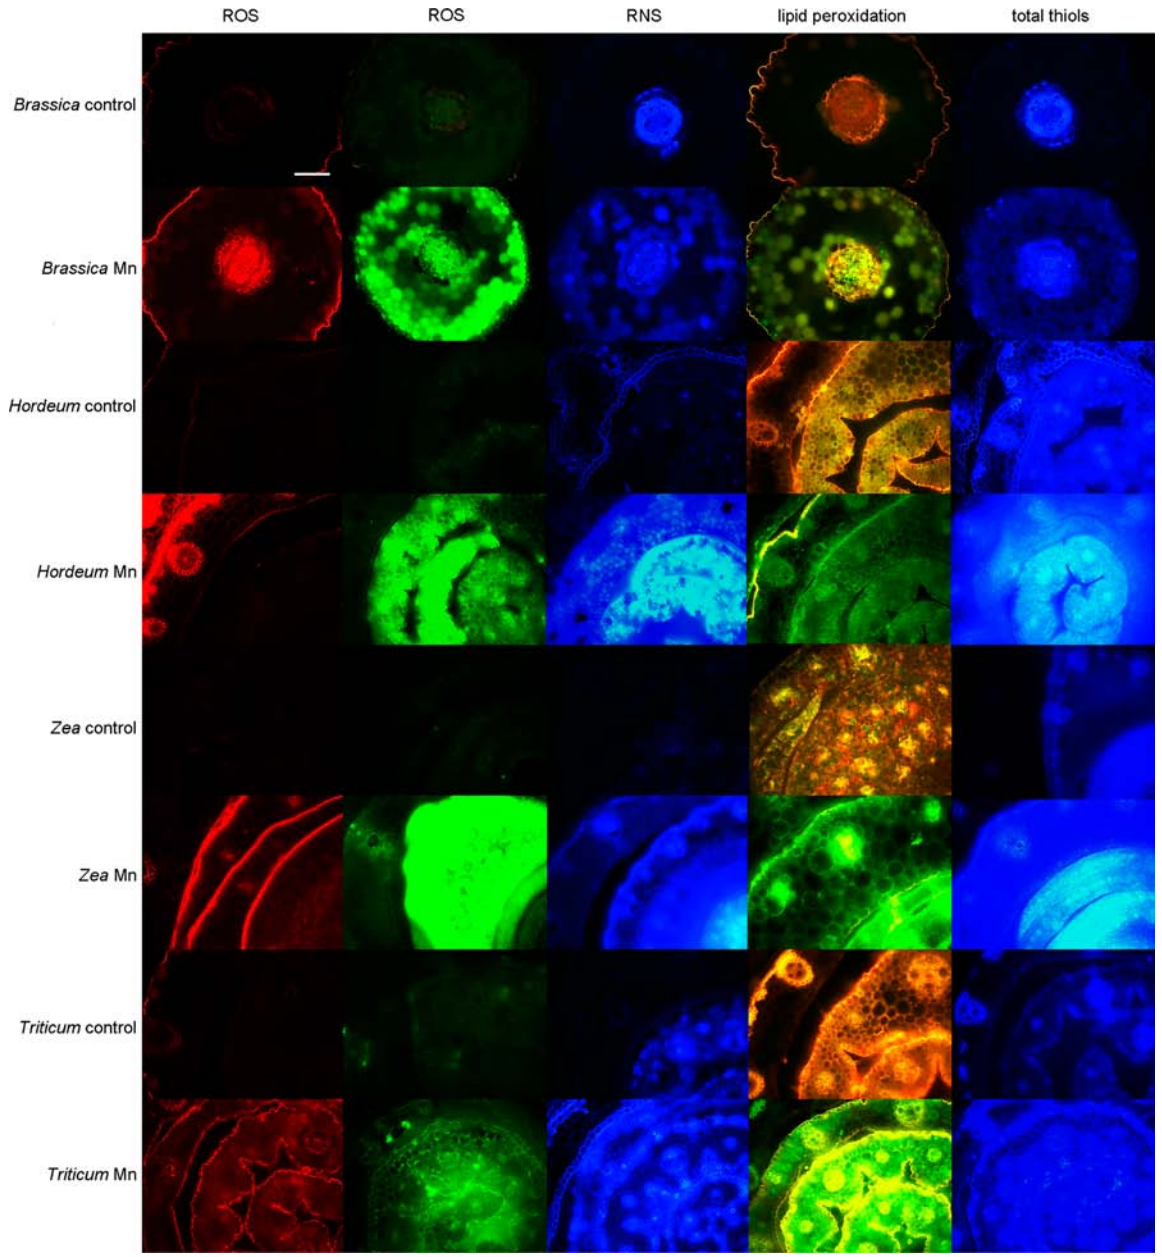

Figure 2. Fluorescence microscopy of selected oxidative stress-related parameters in the shoots of four crops cultured in naturally Mn-contaminated soil over 21 days. Species identity is the same as in Figure 1. Cross sections were taken ca. 1 cm above the stem base and were immediately stained. ROS (reactive oxygen species) were stained with CellROX Deep Red reagent (red signal) and 2′,7′-dichlorodihydrofluorescein diacetate (green signal), RNS (reactive nitrogen species) with 2,3-diaminonaphthalene, lipid peroxidation with BODIPY 581/591 C11 and total thiols with monochlorobimane. Bar indicates 200 μm.

content was found in three species.[9,10] However, our data again confirm that the uptake of toxic metals under Mn excess is not influenced only by pH or Mn itself and cereals (*Hordeum* and *Triticum*) seem to be less effective accumulators.

Oxidative Stress, Antioxidative Enzyme Activities and Metabolites in Plants Cultured in Mn-Contaminated Soil. Appearance of oxidative stress may be detected by various qualitative and quantitative methods. Fluorescence microscopy is sensitive qualitative method owing to use of specific reagents. In fact, visualization of ROS by two staining reagents confirmed that Mn excess evoked increase in ROS in all species investigated (Figure 2). Relatively less pronounced enhancement was observed in *Triticum*, a species with the lowest Mn amount (Table 2 and Figure 2).

Changes of nitric oxide (RNS, Figure 2) were also less extensive in *Triticum*, indicating that the lower level of oxidative stress does not evoke further elevation of nitric oxide. This fits well with our recent study where concentration-dependent stimulation of ROS in response to Mn excess was observed but nitric oxide presence differed in relation to ontogenetic stage; subsequent tests confirmed than exogenous NO ameliorated the appearance of ROS.[14] This is further evidence that NO plays an important role also under Mn excess, although this aspect is only poorly known.[15]

Higher ROS formation may also induce peroxidation of lipids. This peroxidation was confirmed by specific fluorescent reagent, shown as increase in green color within cross sections of tissue (Figure 2). This increase was detected in all species,

dx.doi.org/10.1021/jf5010176 | J. Agric. Food Chem. 2014, 62, 7287−7296

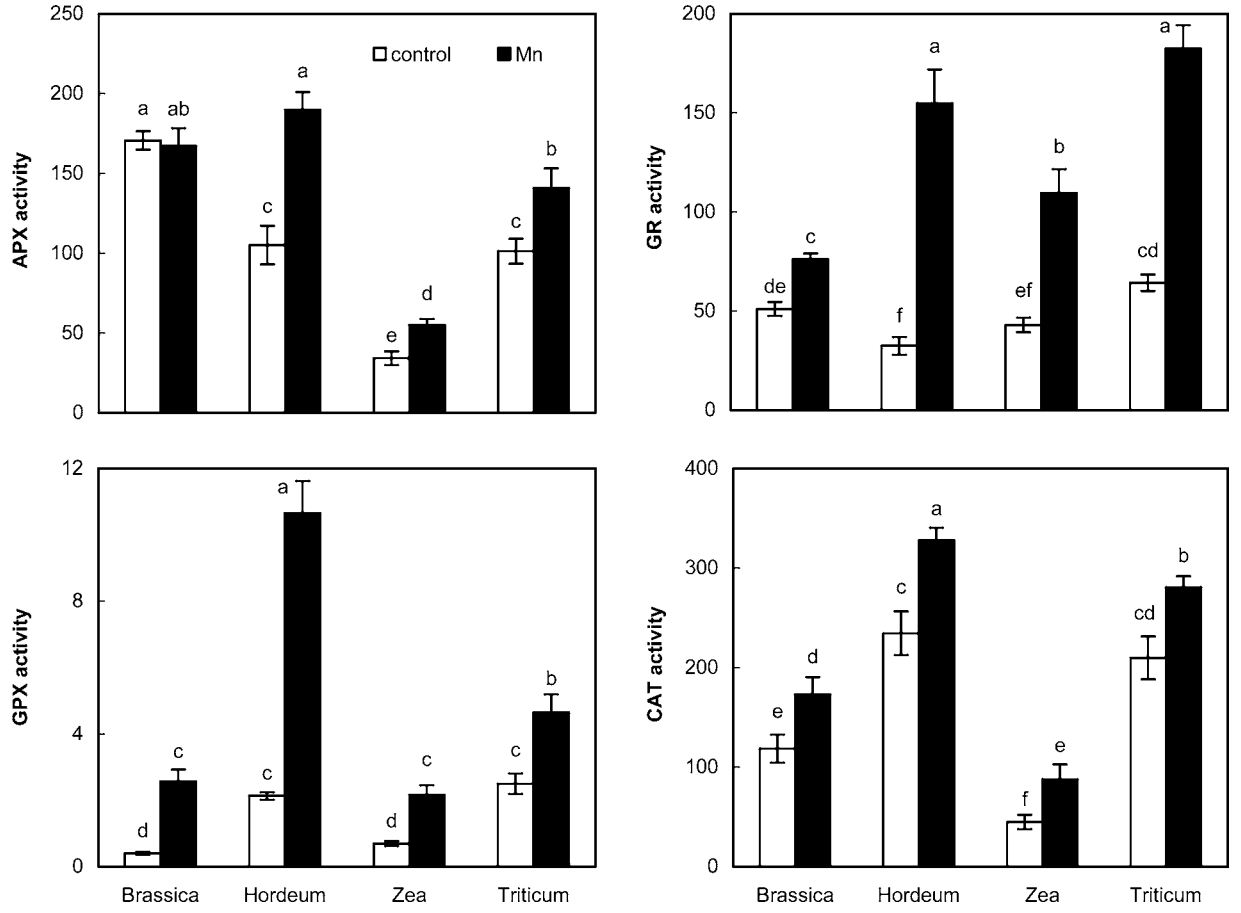

Figure 3. Activities of some antioxidative enzymes in the shoots of four crops cultured in naturally Mn-contaminated soil over 21 days. APX, ascorbate peroxidase, GPX, guaiacol peroxidase; GR, glutathione reductase; and CAT, catalase. Unit is μmol min^{-1} mg^{-1} protein for GPX and nmol min^{-1} mg^{-1} protein for other enzymes. Data are means ± SDs (n = 4). Values within each graph followed by the same letter(s) are not significantly different according to Tukey's test (P < 0.05). Species identity is the same as in Figure 1.

indicating oxidative damage from excessive Mn uptake. This may be explained by the fact that all species contained more Mn in shoots than chamomile plants in our previous study, where also concentration-dependent elevation of lipid peroxidation signal was visible.[14] Species-specific sensitivity is also known, e.g., low Mn excess had no impact on lipid peroxidation in mulberry plants,[25] while high Mn excess evoked only a slight elevation in rice seedlings after 20 days of cultivation.[7]

Antioxidative enzymes did not show any universal trend in relation to Mn amount in individual species (Figure 3). This was also observed in other species, e.g., in cucumber shoots[6] and no concentration dependency was found in pea[5] or chamomile seedlings.[14] In *Hordeum*, activity of enzymes was the most elevated. Peroxidases (APX and GPX) showed significantly enhanced activities in cereals (*Hordeum* and *Triticum*) in response to Mn excess (Figure 3). In agreement with our data, barley plants cultured under Mn excess had higher CAT and GPX activity[8] and rice seedlings showed elevation of GPX and APX activities in response to long-term presence of high Mn (3 and 6 mM)[7] that is similar to our water-soluble Mn fraction (Table 1). However, relatively slight impact of Mn on peroxidases in *Zea* observed in the present study has also been previously reported and even 1 mM of Mn^{2+} had negligible impact on oxidative or peroxidative activities in its roots.[16] Above-mentioned data confirm that antioxidative enzymes are involved in tolerance to Mn excess though responses differ in various species. Despite this increase, overall growth depression and appearance of oxidative damage were detected in all species (Figures 1 and 2). This is in accordance with other crops, e.g., tobacco plants cultured in vitro with 2 or 5 mM Mn contained similar amounts of Mn in leaves (up to 11 000 μg g^{-1} DW) as our plants (Table 2) but GPX and APX activities were considerably suppressed.[17] Glutathione reductase (GR) showed similar basic values in controls among plants and also strong increase in all species in Mn-soil with the exception of *Brassica* that could again indicate its sensitivity. Enhanced activity of GR was also reported in various crops where other antioxidative enzymes were depleted, such as rice,[7] cucumber,[6] and tobacco.[17] This fits well with visualization of total thiols though increase was less visible in some species (Figure 2). However, protein- and nonprotein thiols were variably affected by Mn excess in rice,[7] providing evidence that "total thiols" staining could not always match fully with individual parameters.

Phenolic metabolites are important stress-induced compounds including excess of metals.[26] In the case of Mn excess, it seems that their role is less important because we found significant increase only in *Brassica* plants that could be related to strong growth inhibition (Figure 4). Further studies are needed to analyze profile of phenols in plants under Mn excess. Soluble proteins are typically depleted by excess of metals depending on the given metal and applied concentration.[11] Mn excess in the present study evoked depletion in three species, but not in *Zea* (Figure 4). We assume this is related to high

dx.doi.org/10.1021/jf5010176 | J. Agric. Food Chem. 2014, 62, 7287−7296

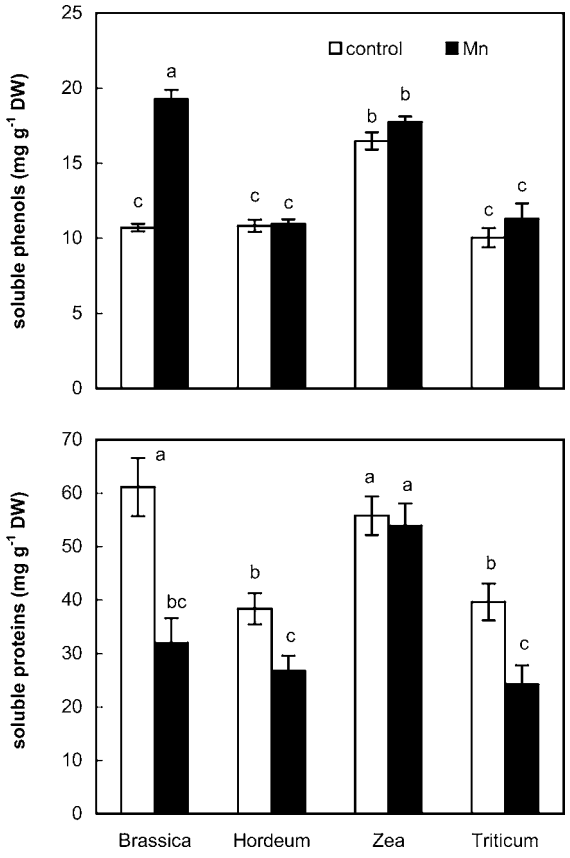

Figure 4. Quantitative changes of total soluble phenols and soluble proteins in the shoots of four crops cultured in naturally Mn-contaminated soil over 21 days. Data are means ± SDs (n = 4). Other details are the same as in Figure 3.

biomass production of *Zea* compared to other species and thus tissue-dilution impact on Mn translocation. Proteomic analyses will be carried out to study detailed changed at proteome level.

Quantitative Changes of Organic and Inorganic Anions in Plants Cultured in Mn-Contaminated Soil. Amount of malate was the highest among organic anions in control shoots of all plants (Table 4). This is in accordance with earlier report e.g. in *Zea*[27] while *Triticum turgidum* contained more oxalic and less malic acid[28] than our species (Table 4). Generally, organic acids such as oxalate, citrate and malate play an important role in the detoxification of various metals through chelation[27,28] or by modulation of rhizosphere pH.[29] In the case of Mn excess, oxalic acid is potentially involved in Mn detoxification in *Phytolacca americana*[30] and citrate enhanced Mn uptake in *Juncus effusus*.[31] Our present data showed decrease or unchanged contents of three above-mentioned acids and their role in the Mn uptake in any species is not expected. This could be related, the most probably, to observed growth depletion (and appearance of oxidative stress) leading to attenuated metabolism including Krebs cycle owing to high Mn excess in Mn-soil we used.

Increase in the nitrate amount in the majority of Mn-cultured species is in accordance with the depleted amount of proteins and indicates suppressed nitrate reduction and incorporation into the organic form. This was not observed in *Zea*, which probably has a higher potential to cope with Mn excess (Figure 4 and Table 4). The lower amount of sulfate in the majority of Mn-cultured crops may be related to elevated signal of thiols (Table 4 and Figure 2), suggesting its conversion into the

organic form under Mn excess. The phosphate quantity was lower in all Mn-exposed species, and its role in Mn uptake is not apparent, although Mn-containing crystals in some species may be formed with phosphate.[24]

Responses of Crops to Mn-Enriched Solution and Various pH. Because control and Mn-contaminated soil differed in pH (Table 1), we further investigated impact of pH on Mn toxicity in solution culture and crops were sown directly on filter paper with treatment solutions. Values of pH were selected based on water extracts (6.5 and 3.7 in control and Mn-soil) and Mn^{2+} concentration was based on water-soluble content in Mn-contaminated soil (Table 1; 280.1 $\mu g\ g^{-1}$ DW = ∼5 mM). Growth (both shoot and root biomass) in control treatments (deionized water only) was reduced only at pH 3.7 in *Zea* (data not shown). In Mn-enriched solutions, growth of *Hordeum* was reduced only by pH 3.7; both pH 3.7 and 6.5 reduced growth of *Zea*, *Triticum*, and *Brassica* (data not shown). Generally, impact of Mn excess on biomass was more negative at lower pH and in the case of *Brassica* it was pH-independent (only rudimentary roots ca. 1 mm long were developed). These are only slight differences in comparison with shoot biomass of plants cultured in Mn-contaminated soil where, e.g., *Triticum* was slightly more tolerant than *Hordeum* (Figure 1). This could be evoked by different exposure conditions and time (10 days in solutions vs 21 days in soil) and it may logically be expected that longer cultivation could lead to restoration of growth after adaptation to Mn excess. However, high sensitivity of *Brassica* to Mn excess (found in soil culture) was confirmed in solution culture and this sensitivity is not therefore pH-dependent but Mn-evoked. In agreement with our observations, growth of potato plants was more negatively affected by lower pH under Mn excess.[3]

Higher toxicity of Mn at lower pH could also be related to its higher solubility, as it is known that various metals are more readily absorbed at more acidic pH. Subsequent analyses of Mn content were therefore carried out to identify if Mn toxicity is related to its uptake in relation to pH. In control plants, decrease of pH depleted Mn content preferentially in the roots while such observation in Mn-exposed plants was only exceptional (Figure 5A). It has been reported that increasing pH increased Mn accumulation in the roots of barley[32] and Mn uptake by potato was also higher at pH 5.8 than at pH 4.0 depending on applied Mn dose.[3] This is partially in contradiction to our data because the Mn content in Mn-exposed plants was slightly higher or unaffected by lower pH in shoots (Figure 5A) but may be explained by concentration dependency of this process because potato treated with 5 mM (approximate concentration of water-soluble Mn in our Mn-soil as mentioned above) showed lower difference between various pH. However, impact of pH on Mn uptake was negligible in our Mn-exposed plants while more pronounced differences in control plants are rather evoked by translocation from seed during growth. This is in accordance with data from *Spiraea* plants where media pH did not affect foliar Mn.[4] It is also visible that shoot Mn content in Mn-treated plants was very similar to that observed in soil culture (cf. Figure 5 and Table 2) with *Brassica* and *Triticum* containing the highest and the lowest value, respectively.

The relatively negligible impact of pH in terms of Mn uptake was further verified at the level of oxidative stress induction. Fluorescence indicator of "general ROS" revealed no extensive or pH-dependent impact either in control or Mn-cultured roots (Figure 5B). It is clear that the appearance of oxidative damage is related to Mn presence, and the same was observed in shoot samples mentioned above (Figure 2).

CONCLUSIONS

Naturally contaminated manganese soil used in the present study had a clearly negative impact on the growth of four crops after prolonged cultivation. High shoot Mn accumulation and the overall trend of its uptake were similar in soil and solution culture, in which *Brassica* and *Triticum* contained the highest and the lowest amounts, respectively. Solution culture also confirmed that the low pH of Mn soil (3.7) is not the main factor affecting Mn uptake or ROS formation. The elevated fluorescent signal of nitric oxide and thiols together with typically enhanced activities of antioxidative enzymes could contribute to protection against Mn excess in soil culture, while the involvement of phenolic metabolites and aliphatic organic acids in this process was not observed. However, the sensitivity of the investigated plants to soil contamination by Mn urges for further selection of a cultivar tolerant to Mn excess, owing to its presence in acidic soils.

supplied by Varian (Agilent Technologies, Winnersh, U.K.), and 1-(heptafluorobutyryl)imidazole (HFBI, >98%) was purchased from Alfa Aesar England. 3-Chloro-1,2-propanediol (3-MCPD), sodium methoxide, filter papers (Whatman No. 4), and potassium bromide were purchased from Sigma-Aldrich (Gillingham, U.K.). MCPD-d_5 and 3-MCPD-palmitate-d_5 were obtained from CDN isotopes and Toronto Research Chemicals, respectively.

Refined wheat flour (standard T55/W150) was kindly supplied by Kraft Foods (Glattpark, Switzerland). Sucrose powder, sodium bicarbonate, ammonium bicarbonate, and sodium chloride were kindly supplied by Eti (Eskişehir, Turkey) and refined corn, canola, hazelnut, olive, and peanut oils by Zade (Konya, Turkey).

Preparation of Biscuits. The biscuits were prepared according to the American Association of Cereal Chemists Method 10-54 with some modifications.[22] The recipe contained 80.0 g of wheat flour, 35.0 g of sucrose powder, 20.0 g of corn oil, 1.0 g of sodium chloride, 0.4 g of ammonium bicarbonate, 0.8 g of sodium bicarbonate, and 17.6 mL of water. All ingredients were thoroughly mixed in accordance with the AACC Method 10-54 procedure using an Artisan Kitchen Aid 5KSM150 dough mixer. The dough was rolled to a 3 mm thickness and cut into three discs 5 cm in diameter and baked in a conventional oven (Memmert, UNE 400).

Two different recipes were prepared with corn oil, namely, a basic recipe and a basic recipe without sodium chloride. Biscuits having the basic recipe were baked at 180, 200, and 220 °C for different times for up to 19 min. The recipe without salt was baked at 220 °C for 7−11 min. Additionally, different refined oils, namely, canola, hazelnut, olive, and peanut, were also used to determine the effect of oil type on MCPD formation by replacing corn oil in the recipe. These sets of biscuits were baked at 220 °C for 10 min. All baking experiments were performed in duplicate. Regardless of the baking condition, all biscuits prepared contained <2% moisture.

Analysis of 3-MCPD and 2-MCPD. *Extraction.* The nonpolar part of the biscuits was isolated by extraction of 4.00 g of the ground biscuit twice with 40 mL of hexane. The combined extracts were kept for MCPD ester analysis; 100 μL of a 10 μg/mL internal standard solution, 3-MCPD-d_5, and 10 mL of 5 M NaCl were added to the defatted biscuits. Then, 7 g of diatomaceous earth sorbent, Hydromatrix, was added, mixed thoroughly, and transferred to a chromatography column (40 cm, 2 cm inside diameter, with a sintered glass disk and a tap at the lower end). Approximately 1 cm of sodium sulfate was added to the top of the column. 3-MCPD and 2-MCPD were eluted over 15 min with 100 mL of diethyl ether. One spatula of anhydrous sodium sulfate was added to the eluent. The extract was then filtered through Whatman No. 4 filter paper and the solvent removed by rotary evaporation to 1−5 mL. The concentrated extract was transferred to a 10 mL flask and made up to volume with diethyl ether.

Derivatization. Four milliliters of the final sample extract was transferred to a 4 mL septum-capped vial. The sample extracts were blown to dryness under a gentle stream of nitrogen before 1 mL of 2,2,4-trimethylpentane was added. A 50 μL aliquot of HFBI was added, and the vial was capped, shaken, and incubated at 70 °C for 20 min. One milliliter of distilled water was added to the cooled mixture; the vial was shaken, and the phases were allowed to separate. The upper 2,2,4-trimethylpentane phase was dried over anhydrous sodium sulfate and carefully transferred to a 2 mL gas chromatography−mass spectrometry vial.

For calibration, 1 mL of appropriate standard solutions was transferred to 4 mL septum cap vials and the same derivatization procedure was performed.

Quantitation. GC−MS determinations were made using an Agilent 6890 Series gas chromatograph with a Gerstel Multipurpose Sampler MPS2 injector interfaced with a 5973N mass selective detector (MSD). For chromatographic separation, a fused silica capillary column [Rxi-5 ms, 30 m × 0.25 mm (inside diameter), 0.25 μm film coated with Crossbond diphenyl dimethyl polysiloxane (Restek)] was used with a helium carrier at a constant flow of 1.1 mL min^{-1}. The following GC oven temperature program was used: 50 °C for 2 min, increase at rates of 2 °C min^{-1} to 80 °C and 50 °C min^{-1} to 270 °C, and hold for 2 min. The total run time was 22.8 min. Injections of 3 μL were made in the splitless mode. The MSD was operated in the selected ion monitoring mode (SIM) using electron impact ionization with an ionizing voltage of 70 eV. The MSD SIM acquisition parameters were m/z 253 (quantifier), 275, and 289 (qualifiers) for 2-MCPD, m/z 253 (quantifier), 275, 289, and 453 (qualifiers) for 3-MCPD, and m/z 257 (quantifier) for 3-MCPD-d_5 with a dwell time of 80 ms. The LOQ was 0.1 mg kg^{-1}. The retention times of 3-MCPD, 2-MCPD, and 3-MCPD-d_5 were 16.215, 16.338, and 16.010 min, respectively.

Analysis of Bound-MCPD. 3-MCPD bound as esters in biscuits was analyzed according to DGF Standard Method C-VI 18(10).[23] The nonpolar extracts of the biscuits, obtained by hexane extraction before 3-MCPD analysis, were evaporated until all the solvent phase was removed; 0.1 g of nonpolar fraction was transferred to a 4 mL vial. MCPD-dipalmitate-d_5 (100 μL) was added and the mixture dissolved in 100 μL of *tert*-butyl methyl ether. Then, 200 μL of CH_3ONa (25 g/L in methanol) was added and vortexed, and the mixture was left for 4 min at room temperature; 600 μL of an acidified chloride-free salt solution [600 g/L KBr, 35 mL of H_2SO_4 (25%) to 1 L of a KBr solution] was added and the aqueous phase was rinsed twice with 1 mL of *n*-hexane. The aqueous phase was extracted twice using 1 mL of a 60/40 ether/ethyl acetate mixture. The combined extract was vortexed, evaporated to dryness under a N_2 stream, dissolved in 2,2,4-trimethylpentane (1 mL), and derivatized as described for free MCPD.

Statistical Analysis. The 3-MCPD and 2-MCPD contents of the samples were statistically analyzed by Duncan and *t*-test (α = 0.05) using the statistical software SPSS.

RESULTS AND DISCUSSION

Kinetics of Formation of 3-MCPD, 2-MCPD, and Bound-MCPD. The corn oil used in the recipe was found to contain 8.7 × 10^{-4} mg of 3-MCPD kg^{-1} and 0.566 mg of bound-MCPD kg^{-1}. The kinetics of formation of 3-MCPD, 2-MCPD, and bound-MCPD were examined in biscuits with a basic formulation baked at 180, 200, and 220 °C for different baking times (Figure 1a−c). The free 3-MCPD content of biscuits was between 0.018 and 0.074 mg kg^{-1}, whereas the 2-MCPD content ranged from 0.002 to 0.008 mg kg^{-1}. From a food safety point of view, the results revealed that the amounts of 3-MCPD formed in biscuits during baking exceeded the maximal level of 20 μg kg^{-1} set for acid-HVP and soy sauce by the European Commission. As shown in panels a and b of Figure 1, both free 3-MCPD and 2-MCPD concentrations increased with an increasing baking time. 3-MCPD and 2-MCPD concentrations in biscuits baked at 220 °C increased by 4.1- and 3.7-fold, respectively, when the baking time increased from 7 to 11 min. Similarly, an increased baking temperature led to an increase in the 3-MCPD and 2-MCPD concentrations of biscuits. As the temperature increased from 200 to 220 °C, 3-MCPD and 2-MCPD concentrations increased 3.2- and 2.6-fold, respectively, in biscuits baked for 11 min. The effect of process parameters on the formation of 3-MCPD and 2-MCPD could be related to the increased thermal load. During the thermal process, water and steam hydrolyze triacylglycerols and phospholipids, producing diacylglycerols, monoacylglycerols, glycerol, and other products, which act as precursors of 3-MCPD and 2-MCPD.[24] Our results also show that the relative proportions of the major chloropropanols (3-MCPD and 2-MCPD) in biscuits were approximately in the ratio ranging from 6.24 to 13.57 in biscuits. The ratio of 10:1 has been reported in acid-HVPs.[21]

On the basis of the assumption that precursors, i.e., lipid and chloride, were present in excess, Hamlet and Sadd reported that formation of 3-MCPD was consistent with zero-order kinetics

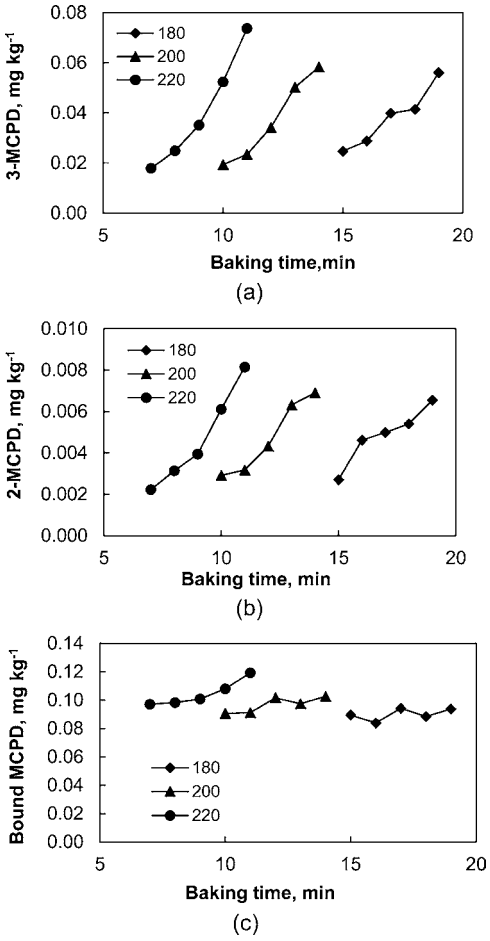

Figure 1. Effect of baking temperature and time on the formation of (a) 3-MCPD, (b) 2-MCPD, and (c) bound-MCPD (milligrams per kilogram of biscuit) in biscuits during baking.

during the baking of wheat flour dough.[16] As the food system studied, i.e., biscuit, suits the same case, the data successfully fit the zero-order kinetic equation. The kinetic rate constants are summarized in Table 1. An increase in temperature led to an increase in the reaction rate constants of both 3-MCPD and 2-MCPD, as the kinetic energy of the system increased. Each 20 °C increase in temperature increased the reaction rate constants of both 3-MCPD and 2-MCPD approximately 1.4-fold. The rate constant of 2-MCPD in biscuits during baking was found to be ~9.4 times lower than that of 3-MCPD. This confirms a previous study that reported that the rate of 2-MCPD formation is lower than rate of 3-MCPD in breads prepared with wheat flour dough.[16] The primary hydroxyl groups of glycerol were reported to be more reactive than the secondary group.[25] It is thought that this might be the reason for the formation of a quantity of 3-MCPD larger than that of 2-MCPD.

Table 1. Calculated Reaction Rate Constants of Formation of 3-MCPD, 2-MCPD, and Bound-MCPD in Biscuits (basic recipe and basic recipe without NaCl) Baked at Different Temperatures According to the Zero-Order Kinetic Equation[a]

	rate constant k ($\times 10^5$ mmol kg^{-1} min^{-1})		
temp (°C)	3-MCPD	2-MCPD	bound-MCPD
	Basic Recipe		
180	6.81 ± 1.71 a	0.77 ± 0.17 a	1.18 ± 0.06 a
200	9.48 ± 0.65 b	1.01 ± 0.06 b	2.71 ± 0.14 b
220	12.59 ± 0.02 c	1.34 ± 0.00 c	4.88 ± 0.24 c
	Basic Recipe without NaCl		
220	5.35 ± 0.91	0.20 ± 0.08	not detected

[a]Values within columns having the same letter are not significantly different ($p > 0.05$).

The temperature dependence of simple chemical reactions was empirically described by Arrhenius' law, which is expressed as

$$k = A \exp\left(-\frac{E_a}{RT}\right) \quad (1)$$

where k (millimoles per kilogram per minute) is the reaction rate constant, A (millimoles per kilogram per minute) is a pre-exponential factor, E_a is the activation energy (joules per mole), R (8.314 J mol^{-1} K^{-1}) is the gas constant, and T (kelvin) is the absolute temperature. Rate constants obtained from both 3-MCPD and 2-MCPD kinetic data fit the Arhenius' equation well (R^2 = 0.999). Finally, the activation energies of both 3-MCPD and 2-MCPD reactions were found to be equal to 29 kJ mol^{-1}, which means that the reactants needed the same amount of energy to start the reaction and carry on spontaneously for both formation reactions.

The initial bound-MCPD concentration of the refined corn oil used in the biscuit formulations was 0.5664 mg (kg of oil)$^{-1}$. This was equivalent to 0.088 mg (kg of biscuit)$^{-1}$, considering that the oil was present at a level of 15% in the uncooked biscuit. Figure 1c shows the bound-MCPD content of the biscuits prepared, which ranged between 0.084 and 0.119 mg kg^{-1}. There was no significant difference between bound-MCPD concentrations of the uncooked biscuit doughs and biscuits baked for the minimal baking time, at all temperatures studied. The U.K. Food Standards Agency reported that both 2- and 3-MPCD could be released from MCPD esters, identified in bread crust and toasted bread.[8] This might lead to a decrease in bound-MCPD concentration. However, after a certain heat load, the concentration of bound-MCPD in biscuits started to increase. This increase could be related to the rate of formation being higher than the rate of degradation during baking. The reaction rate constants of bound-MCPD formation were also calculated. As given in Table 1, an increased baking temperature has an increasing effect on the bound-MCPD formation rate constant in biscuits, which was found to be statistically significant ($p < 0.05$).

Effect of Sodium Chloride on the Formation of 3-MCPD, 2-MCPD, and Bound-MCPD. It is known that chloride is one of the precursors of chloropropanols. Salt (sodium chloride) used in food formulations is the main source of chloride in most foods. The effect of the presence of chloride on the formation of 3-MCPD, 2-MCPD, and bound-MCPD in biscuits was tested. The biscuit recipe described earlier was used without the incorporation of sodium chloride. The results are shown in Figure 2a–c. It was found that eliminating salt had a statistically significant effect on the formation of 3-MCPD and 2-MCPD ($p < 0.05$). When the salt was removed from the recipe, the reaction rate constants of formation of 3-MCPD and 2-MCPD in biscuits decreased by 57.5 and 85.4%, respectively (Table 1). As discussed before, the bound-MCPD content of biscuits baked for 7 min was the same as that of refined corn oil, i.e., 0.088 mg (kg of biscuit)$^{-1}$. Without salt in the recipe, the

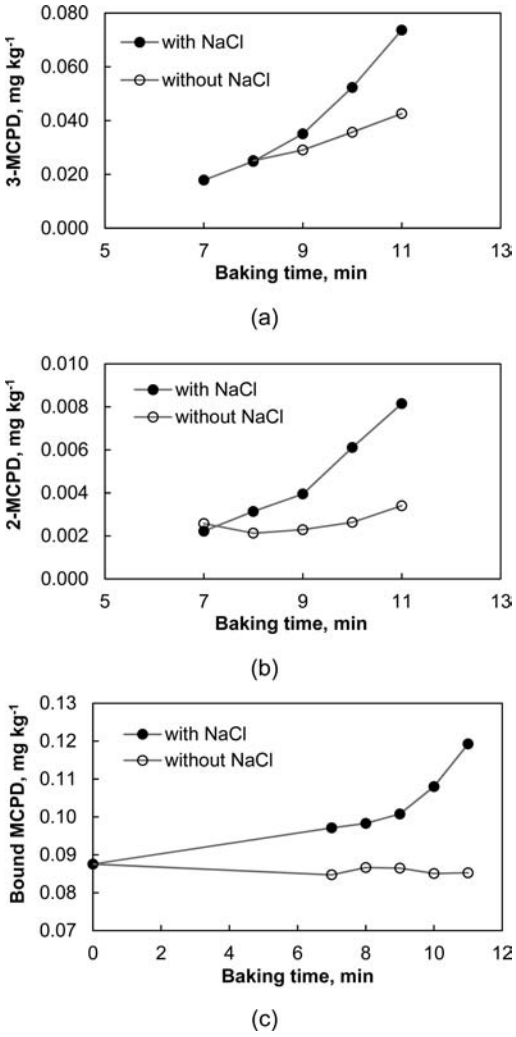

Figure 2. Effect of salt on the formation of (a) 3-MCPD, (b) 2-MCPD, and (c) bound-MCPD (milligrams per kilogram of biscuit) in biscuits during baking at 220 °C.

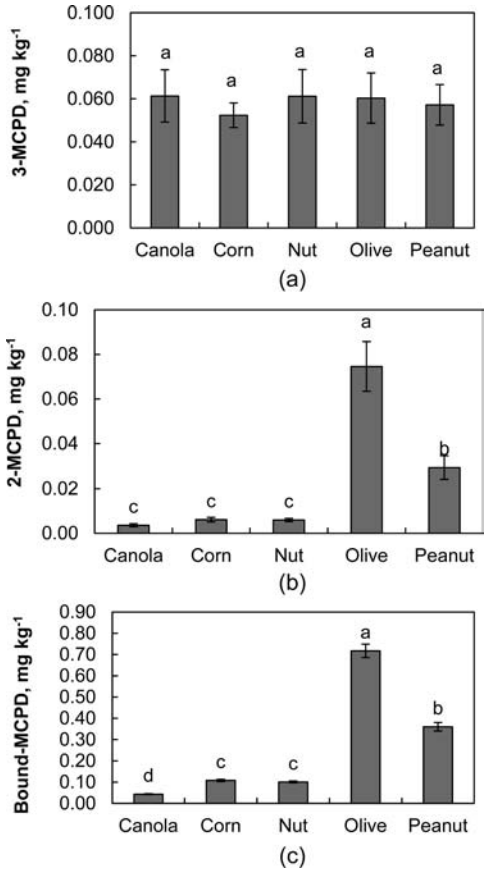

Figure 3. Effect of oil type on the formation of 3-MCPD (a), 2-MCPD (b), and bound-MCPD (c) (milligrams per kilogram of biscuit) in biscuits baked at 220 °C for 10 min. Values having the same letter are not significantly different ($p > 0.05$).

concentration of bound-MCPD in biscuits baked for 7 min was found to be 0.085 ± 0.003 mg (kg of biscuit)$^{-1}$. There was no significant increase in the bound-MCPD concentration during baking ($p < 0.05$). However, the presence of salt as a source of chloride caused an increase in the rate of formation of bound-MCPD in biscuits during baking. The mechanism behind this formation might be a possible reaction between di- and monoacylglycerols of oil and sodium chloride present in the biscuit recipe. In addition, it was reported that sodium chloride acts as a Lewis acid accelerating the hydrolysis of sucrose during heating.[26] In a similar way, it might break the ester bond of acylglycerols, giving available sites to chloride to bind.

Effect of Oil Type on the Formation of 3-MCPD, 2-MCPD, and Bound-MCPD in Biscuits. A range of different vegetable oils, namely, corn oil, canola, nut, olive, and peanut, were used in the biscuit formulation to determine their effect on the formation of 3-MCPD, 2-MCPD, and bound-MCPD (Figure 3a–c). The 3-MCPD content of all biscuits prepared with different oils was found to be ~0.06 mg kg^{-1}. Statistical analysis showed that there was no significant difference between the 3-MCPD contents of these biscuits ($p < 0.05$). Among the refined oils used in this study, 2-MCPD and bound-MCPD concentrations of the biscuit prepared with refined olive oil were found to be the highest, i.e., 0.075 and 0.717 mg kg^{-1}, respectively. Zelinková also reported that the bound-MCPD concentration with refined olive oil was higher than that with other refined edible oils, namely, soybean, sunflower, maize, and rapeseed.[27]

In conclusion, removal of chloride from biscuit formulations controlled the formation of 3-MCPD, 2-MCPD, and bound-MCPD, which could be an effective mitigation strategy in which there are no adverse effects on the biscuit flavor. Careful selection of the type of vegetable oil or shortening and testing for MCPD ester content prior to their use in baking could also reduce the content of these processing contaminants in bakery products.

significantly important to ascertain the validity of their use as substitutes for each other. In our previously published and unpublished work, we have found similarities and differences in metabolite profiles of plant species from same genus grown in China and India.[35−37] Furthermore, study of tissue distribution of metabolites paves a way to unravel the specific tissue sites for metabolic pathways of the plants.[38] Plants of the same species growing in different geographical regions exhibit varying morphological and genetic features, and also differences in the contents of their secondary metabolites are often observed. This is due to the effect of environmental conditions on their metabolic pathways and type of evolution in particular taxa. Evidences to these facts have been provided by various studies. For example, in a study involving broccoli, a variance in the glucosinolate profiles was observed in accessions grown in different environments.[38] In a report including *Brassica oleracea*, dissimilarities in glucosinolate−myrosinase system were found due to different climatic conditions.[39] Genetic diversity was reported in a study involving *Phyllanthus amarus* species grown in different geographical locations.[40,41]

Recently, laser microdissection (LMD) has been recognized as an important tool in isolation of specific plant and animal tissues due to its contamination-free tissue isolation procedures. Combined with hyphenated chromatography techniques like ultra-high-performance liquid chromatography−quadrupole time-of-flight mass spectrometry (UHPLC-QTOF MS) and gas chromatography−mass spectrometry (GC-MS), the LMD method can be exploited for application in tissue-specific metabolite analysis.[35,36]

In consideration of the significance of (+)-nootkatone as a biomarker for important human pathological conditions (like neurodegeneration) and its high demand in various industrial segments, it was selected as a marker for evaluation of the pharmaceutical quality of *C. rotundus* L. in the studied samples. The aim of the current study was to compare the tissue-specific metabolite profiles of *C. rotundus* L. rhizomes collected from various regions of China and India and evaluate the pharmaceutical quality of rhizomes based upon the content of the bioactive sesquiterpenoid (+)-nootkatone.

MATERIALS AND METHODS

Chemicals. For LC-MS analysis, acetonitrile (HPLC-grade) was obtained from E. Merck (Darmstadt, Germany). Formic acid (HPLC-grade, purity 96.0%) was used as a mobile phase modifier, and it was purchased from Tedia Company Inc. Ultrapure water used in various steps of the experiments was obtained from a Milli-Q water purification system (Millipore, Bedford, MA). Standard (+)-nootkatone (purity >95%) used as a reference compound, was procured from Extrasynthese, Genay cedex, France. For GC-MS analysis, *n*-hexane and ethyl acetate used in extraction were procured from ACI Lab Scan Ltd., Thailand.

Plant Material. Dried rhizome samples of *C. rotundus* L., comprising five sample sets from different regions of China and five sample sets from various locations in India, were used for analysis. The samples were authenticated by Professor ZhongZhen Zhao, and voucher specimens (voucher CM/005) were deposited in the Chinese Medicines Centre of Hong Kong Baptist University.

Microscopy Sample Preparation. The sampling of specific microscopic tissues from the *C. rotundus* rhizome samples was carried out as detailed in our previously published reports.[36] Prior to sectioning, the rhizome samples were wrapped in water-soaked noncellulose paper and kept under vacuum at 25 inHg pressure at room temperature for 24 h. After softening by application of vacuum, small sections of the rhizomes were cut and embedded in a cryogel matrix (Leica Microsystems, Germany). Rhizome sections of 25 μm thicknesses were cut with a cryotome and then placed on poly(ethylene terephthalate) (PET) slides at working temperature of −15 °C.

Laser Microdissection and Tissue Extraction. Sections of samples were prepared at −15 °C by use of a Thermo Shandon As620 cryotome. A Leica LMD 7000 system (Leica, Benshein, Germany) was used for laser dissection and investigation of microscopic features. At magnifications of 6.3× and 10×, the target tissues were dissected under a Leica LMD-BGR (blue−green−red) fluorescence filter system. A diode-pumped solid-state (DPSS) laser beam was used with an exposure time of 116.9 ms, aperture size of 1, gain of 2.3×, and speed of 3. The target tissues for investigation were excised by LMD, to obtain tissues with a total area of about 1×10^6 μm^2. The tissues were collected in Eppendorf tube caps, prefixed in the LMD collecting device, and used for further analysis.

For preparation of samples for UHPLC-QTOF MS analysis, the dissected rhizome tissues were centrifuged at 12 000 rpm for 5 min in a 5415Rcentrifuge (Eppendorf, Hamburg, Germany). Following centrifugation, 100 μL of HPLC-grade methanol was added into each sample tube, and the tubes were sonicated for 30 min (Crest 1875HTAG ultrasonic processor). After sonication, the tubes were subjected to centrifugation at 12 000 rpm for 10 min. The resultant supernatants were collected into amber-colored glass HPLC vials containing glass inserts with bottom springs (400 μL, Grace, HK) and stored at 4 °C until analysis.

For analysis of whole rhizome sections, each presoaked sample was sectioned with the cryotome. The sections were collected in Eppendorf tubes and subjected to extraction with 500 μL of methanol by the procedure described above for isolated tissues. The dissected whole sections were used for whole-rhizome metabolite profile analysis. For analysis of raw material, the rhizome samples were coarsely powdered (mesh size 2−8) and extracted as per the procedure used for whole sections.

For GC-MS analysis, the rhizomes were coarsely powdered (mesh size 2−8) and extracted for 1 h with hexane/ethyl acetate mixture (1:1).[39] The obtained extracts were then concentrated by use of a B-480 rotary evaporator from Buchi (Flawil, Switzerland).

Metabolite Profiling by UHPLC-QTOF MS. For ultra high performance liquid chromatography, an Agilent 6540 accurate−mass Q-TOF LC-MS system (Agilent Technologies, Santa Clara, CA) was used. A UPLC C_{18} analytical column [dimensions 2.1 mm × 100 mm, i.d. 1.7 μm, Acquity UPLC ethylene-bridged hybrid (BEH); Waters, Milford, MA] with a C_{18} precolumn (2.1 mm × 5 mm, i.d. 1.7 μm, VanGuard BEH, Waters), was used for separation. The analysis was carried out at room temperature of 20 °C. The operation parameters applied for UHPLC-ESI-MS analysis of adduct ion species generated by electrospray ionization (ESI) were as follows: dry gas temperature 300 °C, fragmentor voltage 150 V, dry gas (N_2) flow rate 6 L/min, Vcap 4500, nozzle voltage 500 V, and nebulizer pressure 40 psi. Mass spectra were acquired in both negative and positive modes. Scanning was carried out for adduct ions of mass to charge ratio (m/z) from 110 to 1700. A mixture of water (A) and acetonitrile (B), both containing 0.1% formic acid, was used as the mobile phase with an optimized linear gradient elution as follows: 0−8 min, 2−15% B; 8−18 min, 15−55% B; 18−23 min, 55−100% B; 23−26 min, 100% B; 26−26.1 min, 100−2% B, 26.1−30 min, 2% B. The injection volume was 2.0 μL. The flow rate was set at 0.4 mL/min. An ESI−low concentration tuning mix solution (Agilent Technologies) was used for accurate molecular mass analysis calibration. The accuracy error threshold of 10 ppm was applied for analysis.

GC-MS-Based Metabolite Profiling and (+)-Nootkatone Quantitation. GC-MS analysis was performed on a Shimadzu GCMS-QP2010 gas chromatograph−mass spectrometer, equipped with a DB-5 capillary column (dimensions 30 m length, 0.25 mm i.d., and film thickness 0.25 μm). An autoinjector (AOC-20i) was employed for sample injection. The oven temperature was programmed from 80 to 280 °C at the rate of 5 °C/min. A splitless injection mode was applied for analysis. The oven temperature was held at 80 °C at the start of the run, then increased to 110 °C at 8 °C/min and 180 °C at 3 °C/min, before being held at 280 °C for 10 min. Helium with a flow rate of 0.95 mL/min was used as a carrier gas. The ion source and interface temperatures were

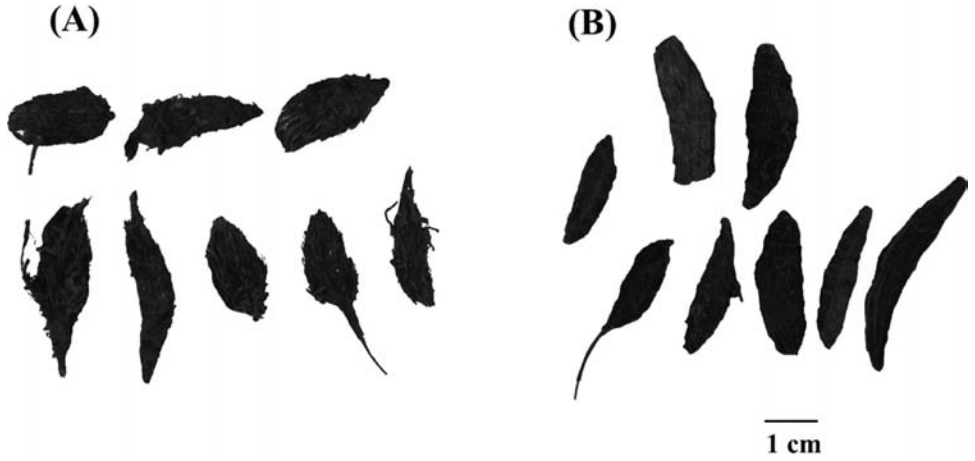

Figure 1. Pictorial representation of *C. rotundus* rhizome samples collected from (A) India and (B) China.

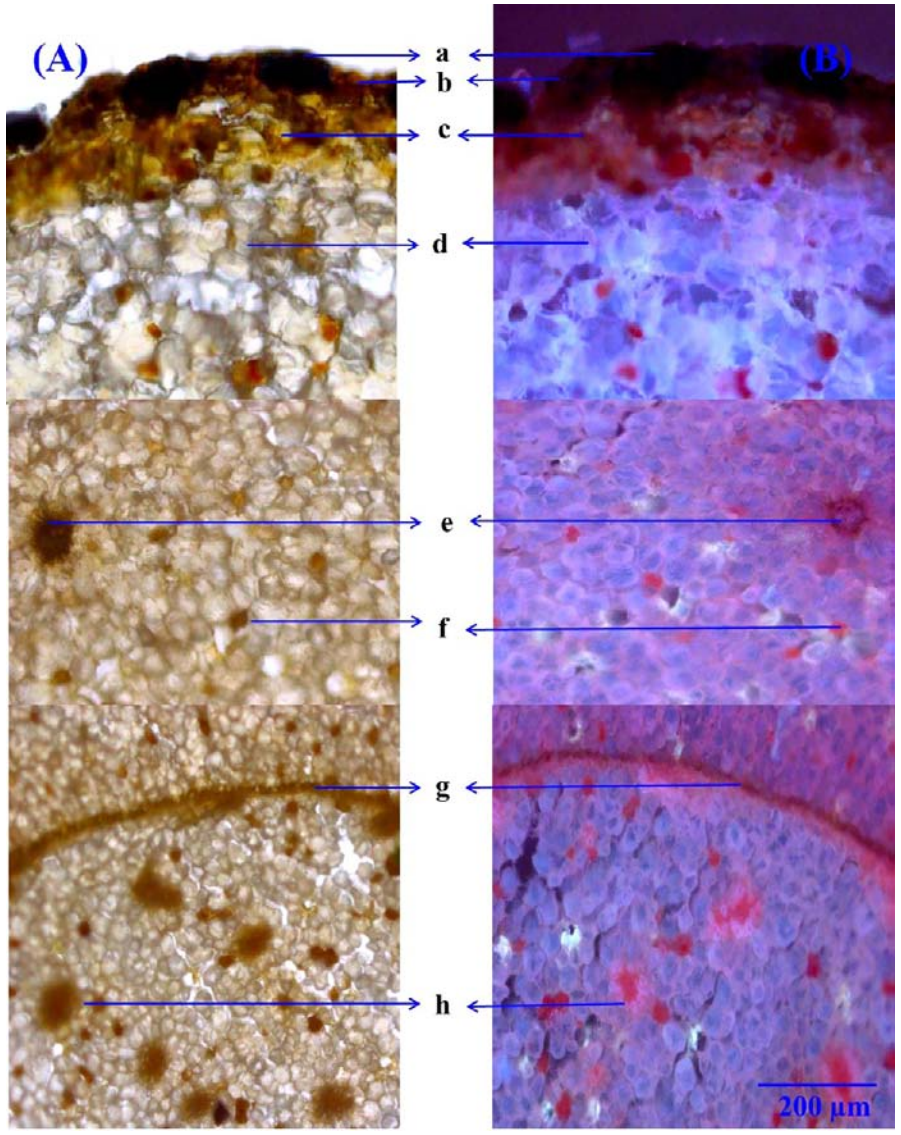

Figure 2. Microscopic characteristics of rhizomes of *C. rotundus*. Leica LMD 7000 system microscope was used with 10× magnification and a 200 μm scale bar. Images were observed under (A) normal light and (B) blue fluorescence. Tissues are denoted as (a) hypodermal fiber bundles, (b) epidermis, (c) hypodermis, (d) cortex, (e) leaf trace-type vascular bundles, (f) secretory cells, (g) endodermis, and (h) vascular bundles (amphivasal type).

held at 200 and 280 °C, respectively. The retention times and characteristic ions for the samples were studied by recording the electron ionization mass spectra of analytes in scan mode (range of m/z 35−425). For quantitative analysis, selected-ion monitoring (SIM)

Peak numbers indicating the identified constituents are listed in Table 1.

mode was used and the method was validated.[42] The characteristic ions selected for the analysis had m/z values 190 and 203 for (+)-nootkatone.

Working solutions of standard (+)-nootkatone were prepared by appropriate dilutions of stock of concentration 1.0 mg/mL. Hexane/ethyl acetate mixture (1:1) was used as the solvent for preparation of sample solutions.

Data Analysis. For analysis of LC-MS data, Agilent Mass Hunter Workstation software for qualitative analysis (version B 4.00, Build 4.0.479.5, Service Pack 3, Agilent Technologies, Inc., 2011) was used. Both positive and negative ion modes were applied for analysis with the following settings: peaks with height ≥2000 counts to be used, extraction restricted retention time of 1.0−30.0 min, and charge state of

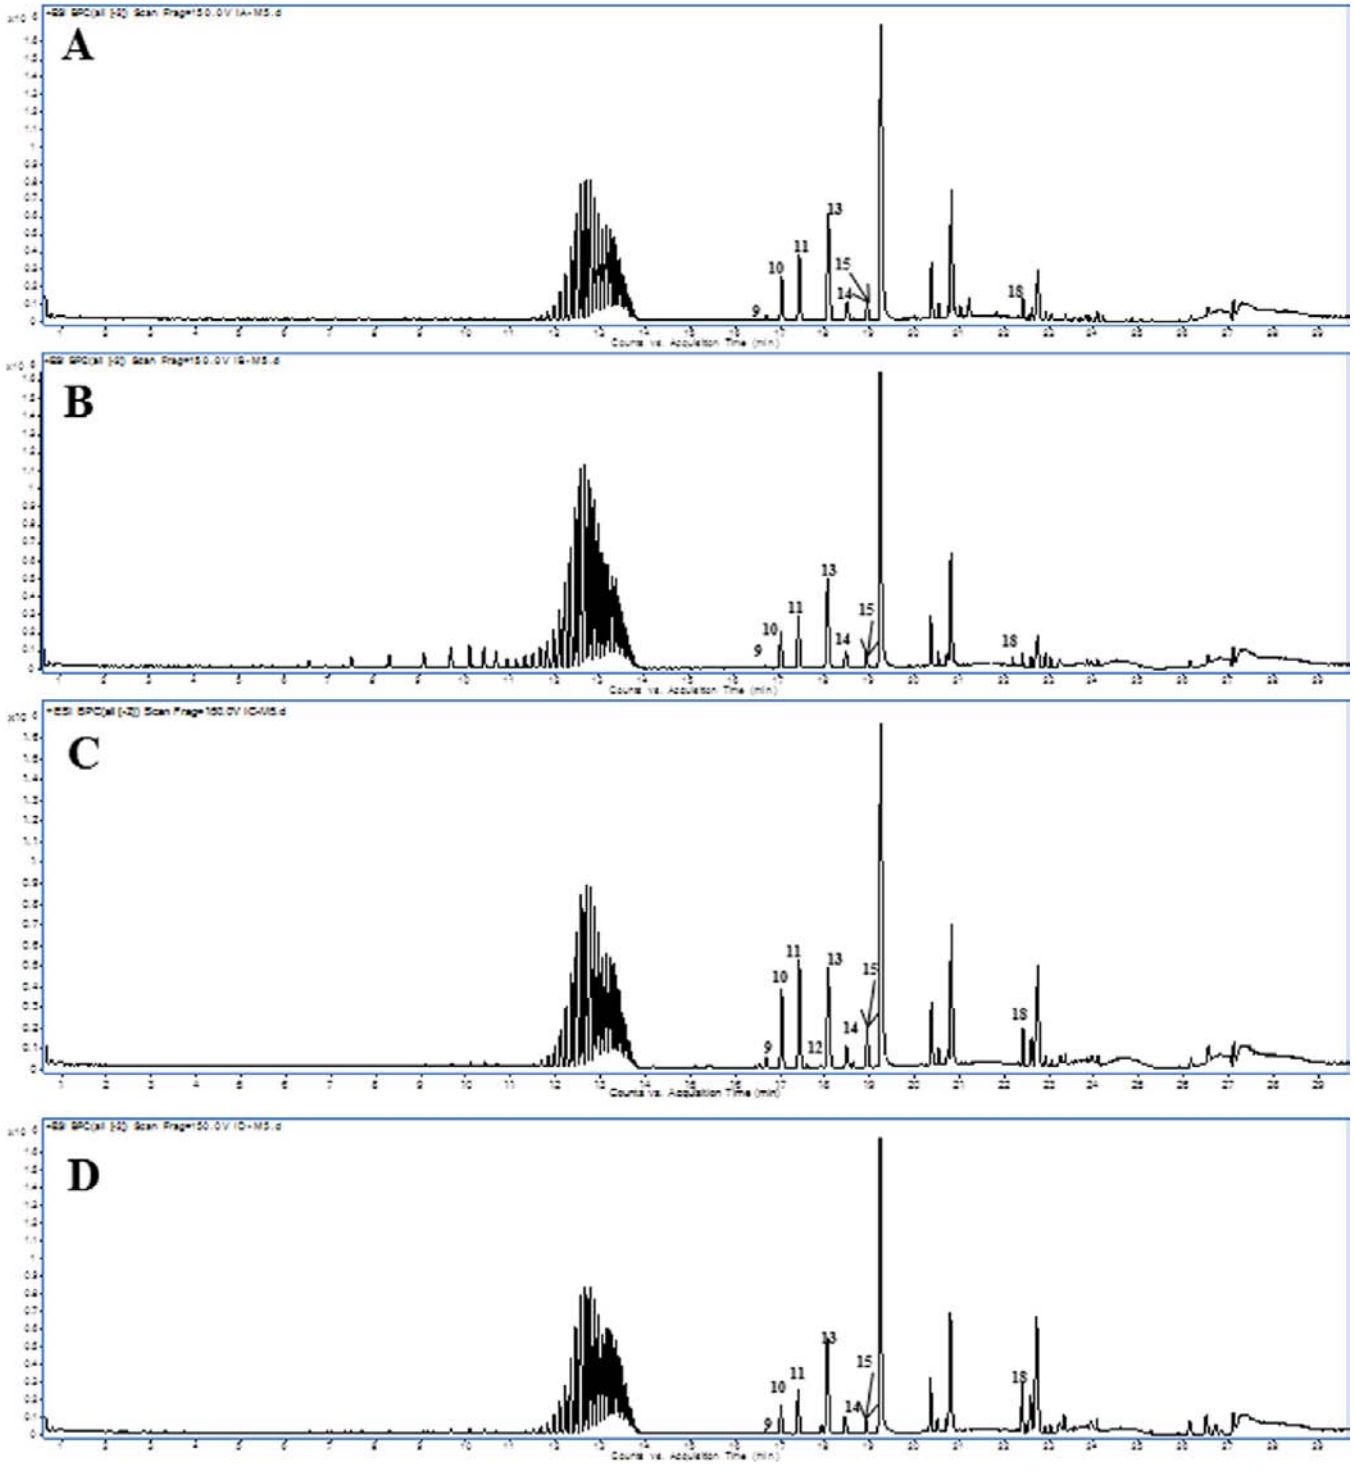

Figure 4. LC-MS base peak chromatograms of various laser-dissected tissues of rhizomes collected from India: (A) cortex, (B) hypodermal fiber bundles, (C) endodermis, and (D) amphivasal-type vascular bundles. Peak numbers indicating the identified constituents are listed in Table 1.

1 and −1 for positive and negative modes, respectively. The compound relative height was ≥2.5%, and absolute height was set to ≥5000 counts with elements of C, H, O, and N from 3−60, 0−120, 0−30, and 0−30, respectively, to generate formulas. The ranges 3−60, 0−120, 0−30, and 0−30 indicate the minimum and maximum limits for the number of elements C, H, O, and N for generation formulas. Peak spacing tolerance was set to 0.0025 m/z plus 7.0 ppm for analysis. The obtained results are depicted as base peak chromatograms (BPC with m/z range 150−950) for each dissected tissue and whole-rhizome tissue analysis. The resultant peak list for LC-MS analysis was processed through Mass Hunter Workstation software and Microsoft Excel software (Microsoft, Redmond, WA). GC-MS analysis data was processed by using the postrun analysis utility of GC-MS solution software (version 2.50 SU3). The results shown in the paper are average values of determinations performed in five sample sets collected from each of the selected countries.

RESULTS AND DISCUSSION

Macroscopic and Microscopic Studies. Pictorial representations of dried *C. rotundus* rhizomes collected from India and

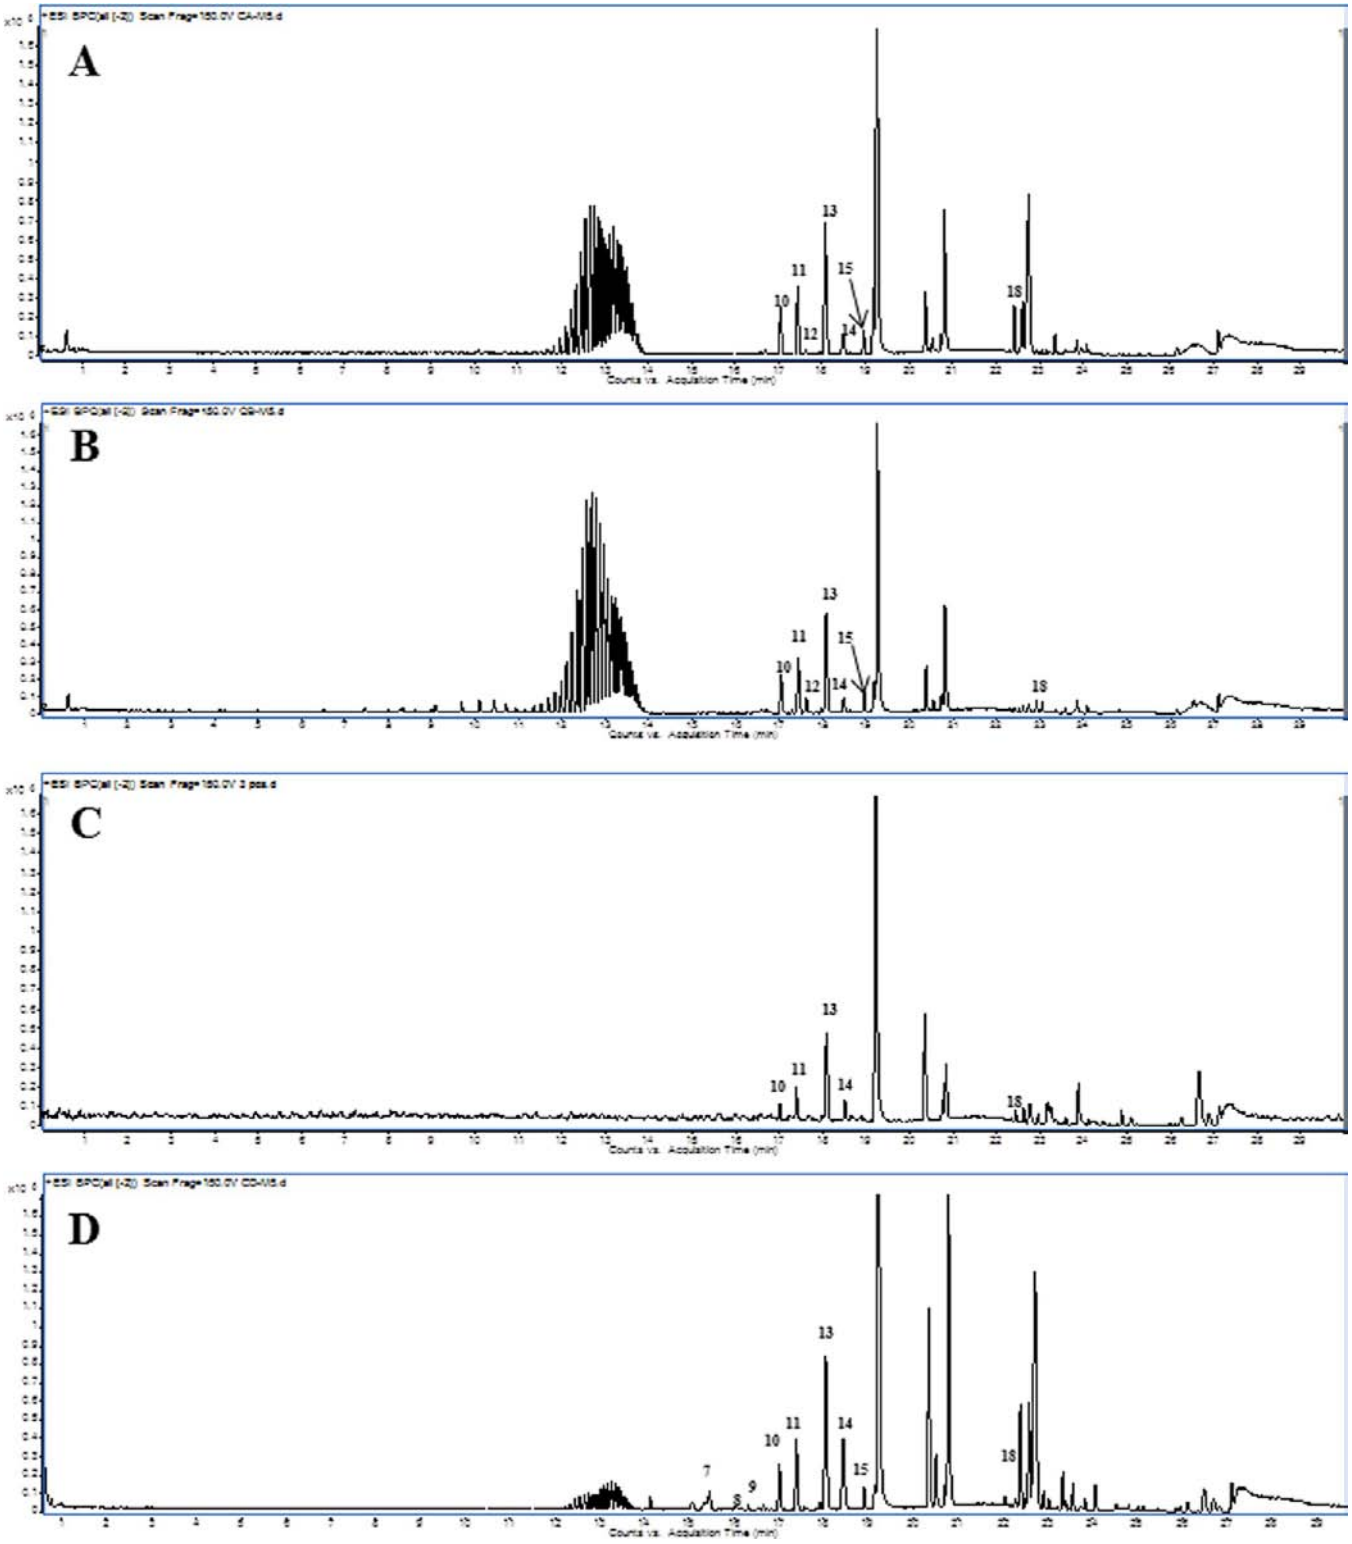

Figure 5. LC-MS base peak chromatograms of various laser-dissected tissues of rhizomes collected from China: (A) cortex, (B) hypodermal fiber bundles, (C) endodermis, and (D) amphivasal-type vascular bundles. Peak numbers indicating the identified constituents are listed in Table 1.

China are shown in Figure 1. The rhizomes of *C. rotundus* are usually spindle-shaped, 2.0−3.0 cm in length and 0.5−1.0 cm in diameter. The outer surface is dark brown or dull black in color. Longitudinal wrinkles are observed on the outer surface along with scars of fibrous roots. The internal surface appears pale cream or yellowish brown in color and has a pleasant odor.

Laser microdissection (LMD) was used to study the microscopic features of rhizomes; a UV laser beam was used to dissect tissues. In the present study, the cortex, hypodermal fiber bundles, endodermis, and amphivasal-type vascular bundles were isolated for analysis of constituents. The microscopic features of transverse sections of rhizomes observed under white light and blue fluorescence for samples from India and China were found

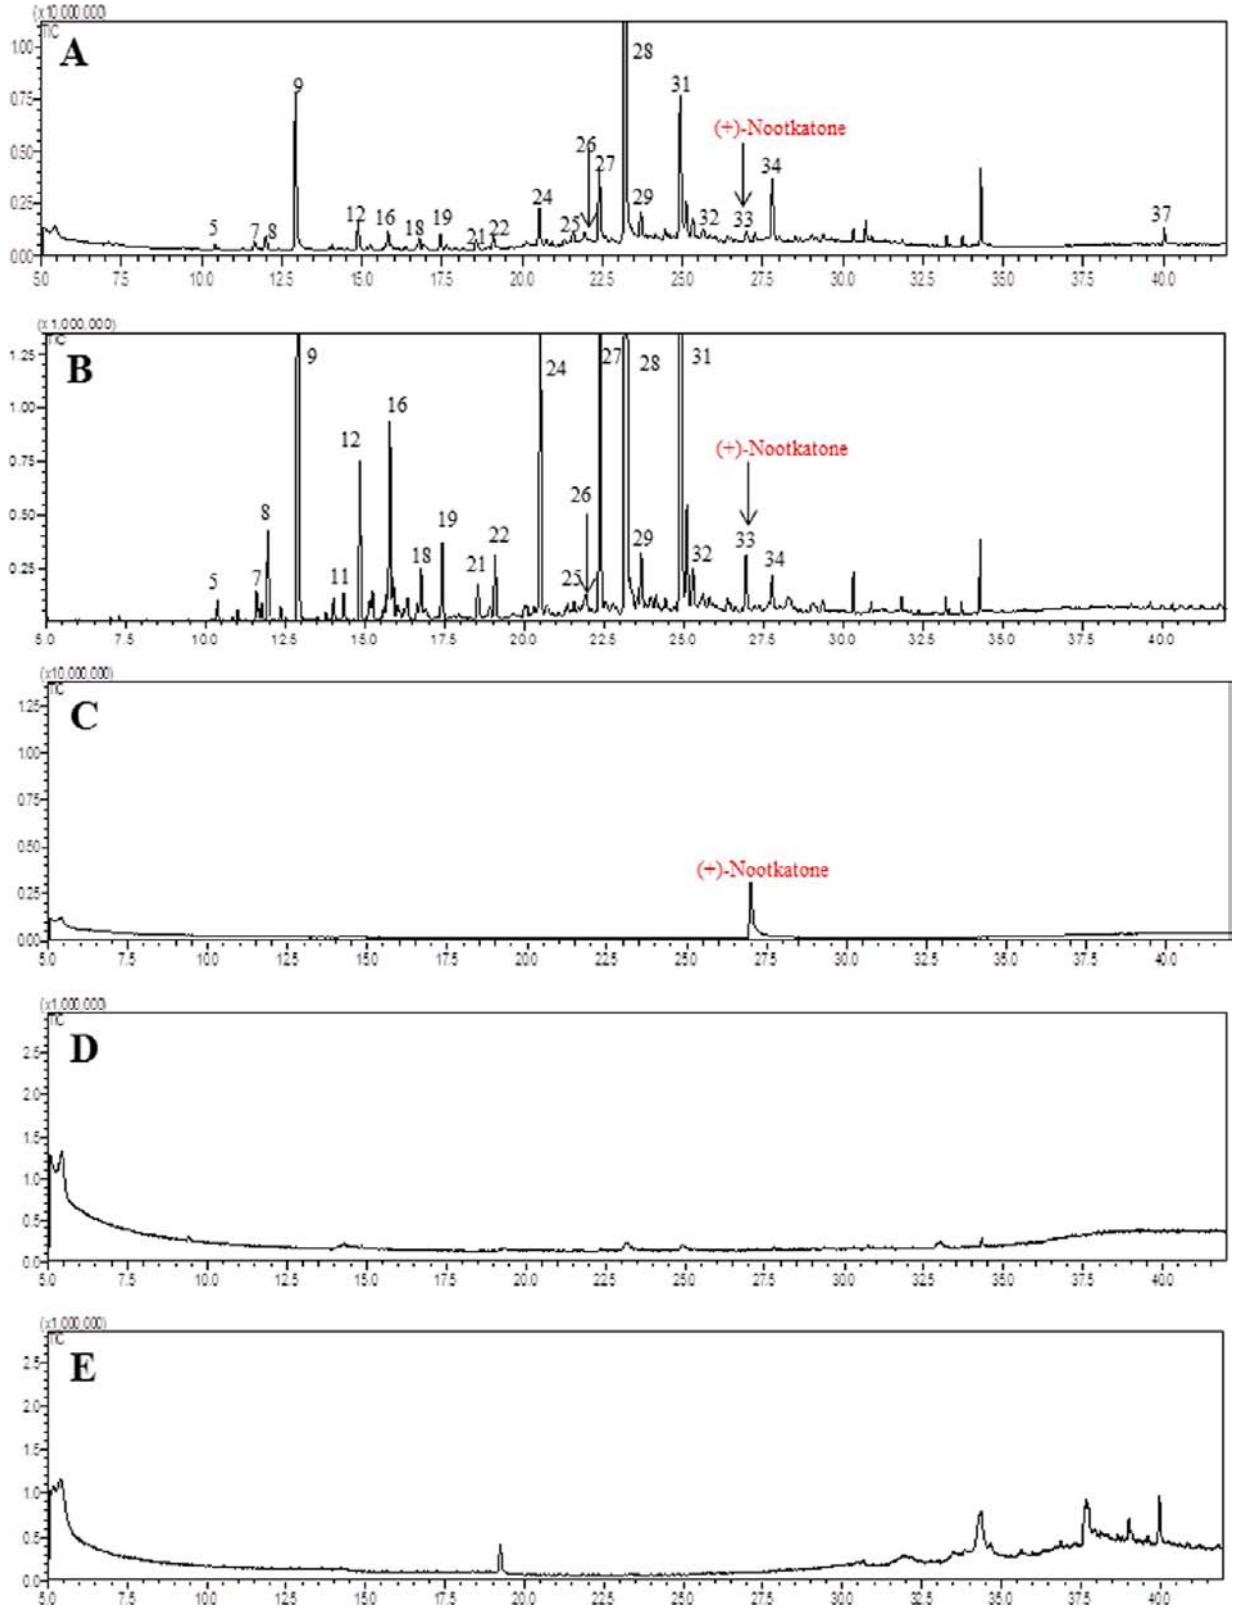

Figure 6. Representative GC-MS chromatograms of *C. rotundus* whole rhizomes: (A) extract of rhizomes collected from India; (B) extract of rhizomes collected from China; (C) (+)-nootkatone standard; (D) blank solvent (hexane/ethyl acetate); (E) cryogenic gel. The peak numbers indicating the identified constituents are listed in Table 2.

to be similar. A representative image indicating various tissues of rhizomes is shown in Figure 2.

A single layer of yellowish-brown epidermis is found to occur with scattered hypodermal fiber bundles (as indicated in Figure 2A). Under blue fluorescence, the epidermis appears blackish-brown (see Figure 2B). Followed by the epidermis, the hypodermis consists of 2−3 layers of fibers filled with dark brownish contents. Under fluorescence, the fibers appear reddish

[a]CW, extract of sections of whole rhizomes collected from China; CA, CB, CC, and CD represent cortex, hypodermal fiber bundle, endodermis, and amphivisal-type vascular bundle tissues isolated from *C. rotundus* rhizomes collected from China; IW, extract of sections of whole rhizomes collected from India; IA, IB, IC, and ID represent cortex, hypodermal fiber bundle, endodermis, and amphivisal-type vascular bundle tissues isolated from *C. rotundus* rhizomes collected from India. (+) denotes presence of constituents in respective samples. [b]Calculated Kovats retention indices.

brown. The cortex consists of numerous layers of parenchymatous cells with intercellular spaces. In the cortex, there are numerous secretory cells scattered, and a few leaf trace vascular bundles are also found. When observed under blue fluorescent light, the parenchymatous cells of cortex appear pale blue and secretory cells and endodermis appear reddish brown. An endodermis made of subrectangular cells forming a distinct ring is observed. The stele shows the occurrence of several amphivasal vascular bundles and secretory cells. The samples collected from both India and China belong to the same species, and in the microscopic and morphological investigations carried out in this study, these features were found to be similar between them.

Metabolite Profiling by UHPLC-QTOF MS. *Cyperus* rhizomes are well-known for their terpenoidal constituents.[43] The sesquiterpenoids are a particular class of terpenoids found in this plant. For metabolite profiling of the whole-rhizome tissue sections and the target isolated tissues of *C. rotundus* rhizomes, a database of 86 phytoconstituents reported for *Cyperus* species in scientific publications and mass banks was prepared.[43−48] The constituents found in LC-MS spectra were deduced on the basis of extracted fragment groups and losses in molecular masses of fragment ions.

Representative LC-MS base peak chromatograms of the rhizomes of both Indian and Chinese samples and controls of cryogenic gel and methanol are shown in Figure 3. Retention times, molecular fragment ions, m/z values of measured adduct ions, and calculated molecular masses of all the secondary metabolites detected in samples of *C. rotundus* rhizomes by LC-MS analysis are listed in Table 1. The database of 86 reported constituents was prepared through literature survey and used for identification of components (see Table S1 of Supporting Information). The cryogel used in preparation of tissue sections

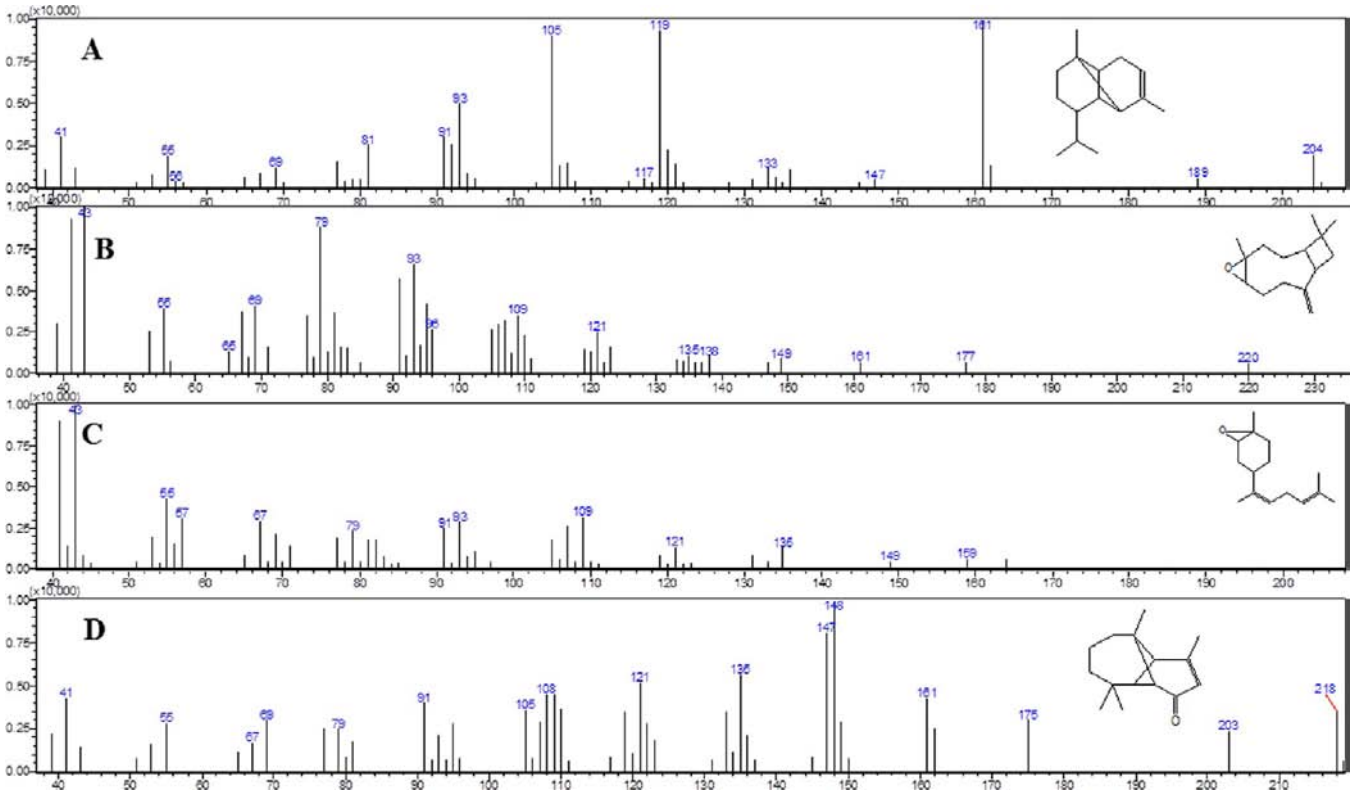

Figure 7. GC-MS mass spectra of some abundant constituents found in whole rhizome samples collected from India: (A) copaene, (B) caryophyllene oxide, (C) *trans-Z-α*-bisabolene epoxide, and (D) longiverbenone.

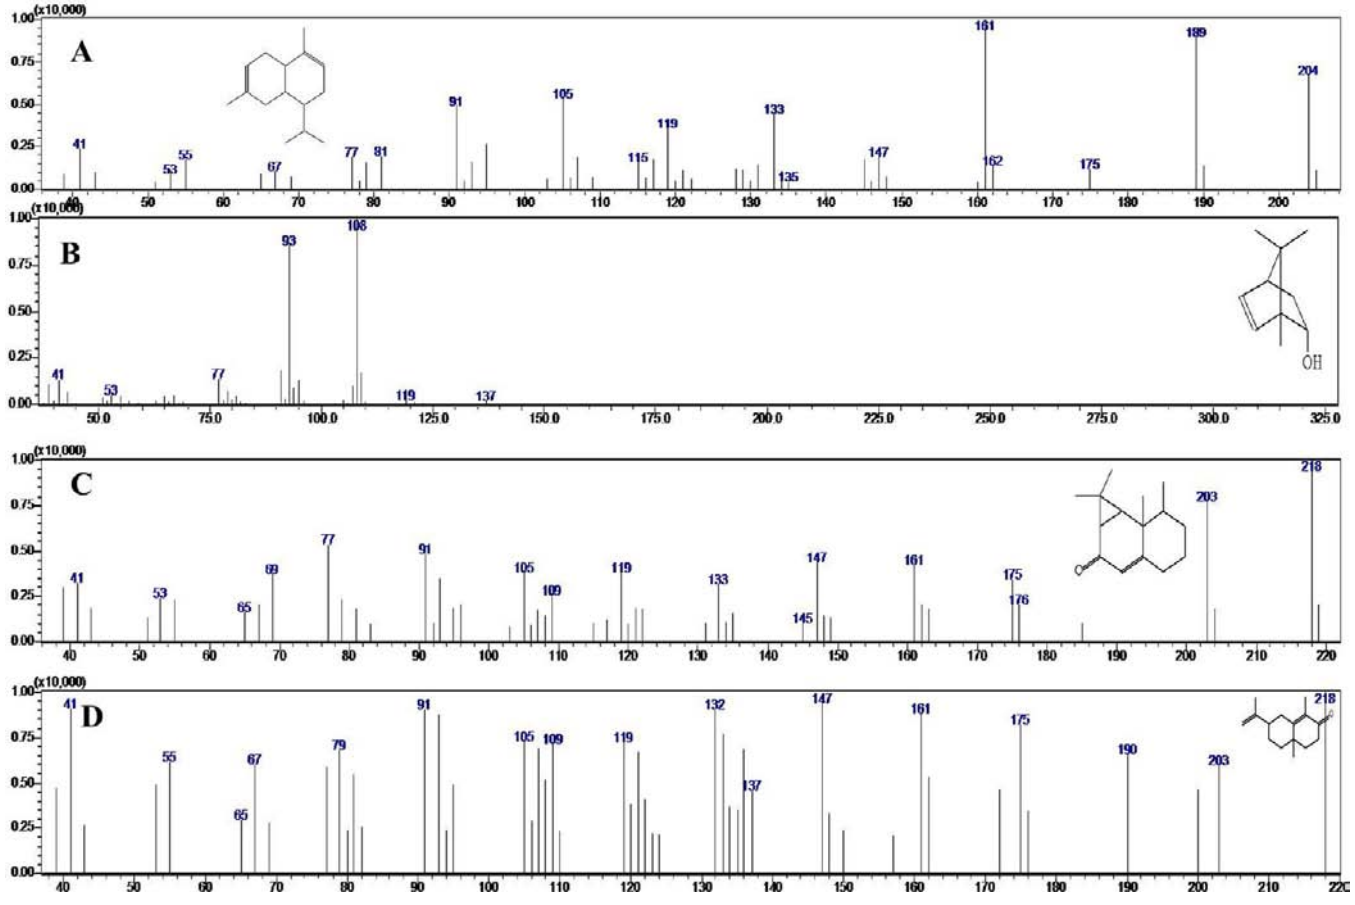

Figure 8. GC-MS mass spectra of some abundant constituents found in whole rhizome samples collected from China: (A) *β*-cadinene, (B) *α*-fenchone, (C) aristolone, and (D) *α*-cyperone.

dx.doi.org/10.1021/jf502494z | J. Agric. Food Chem. 2014, 62, 7302−7316

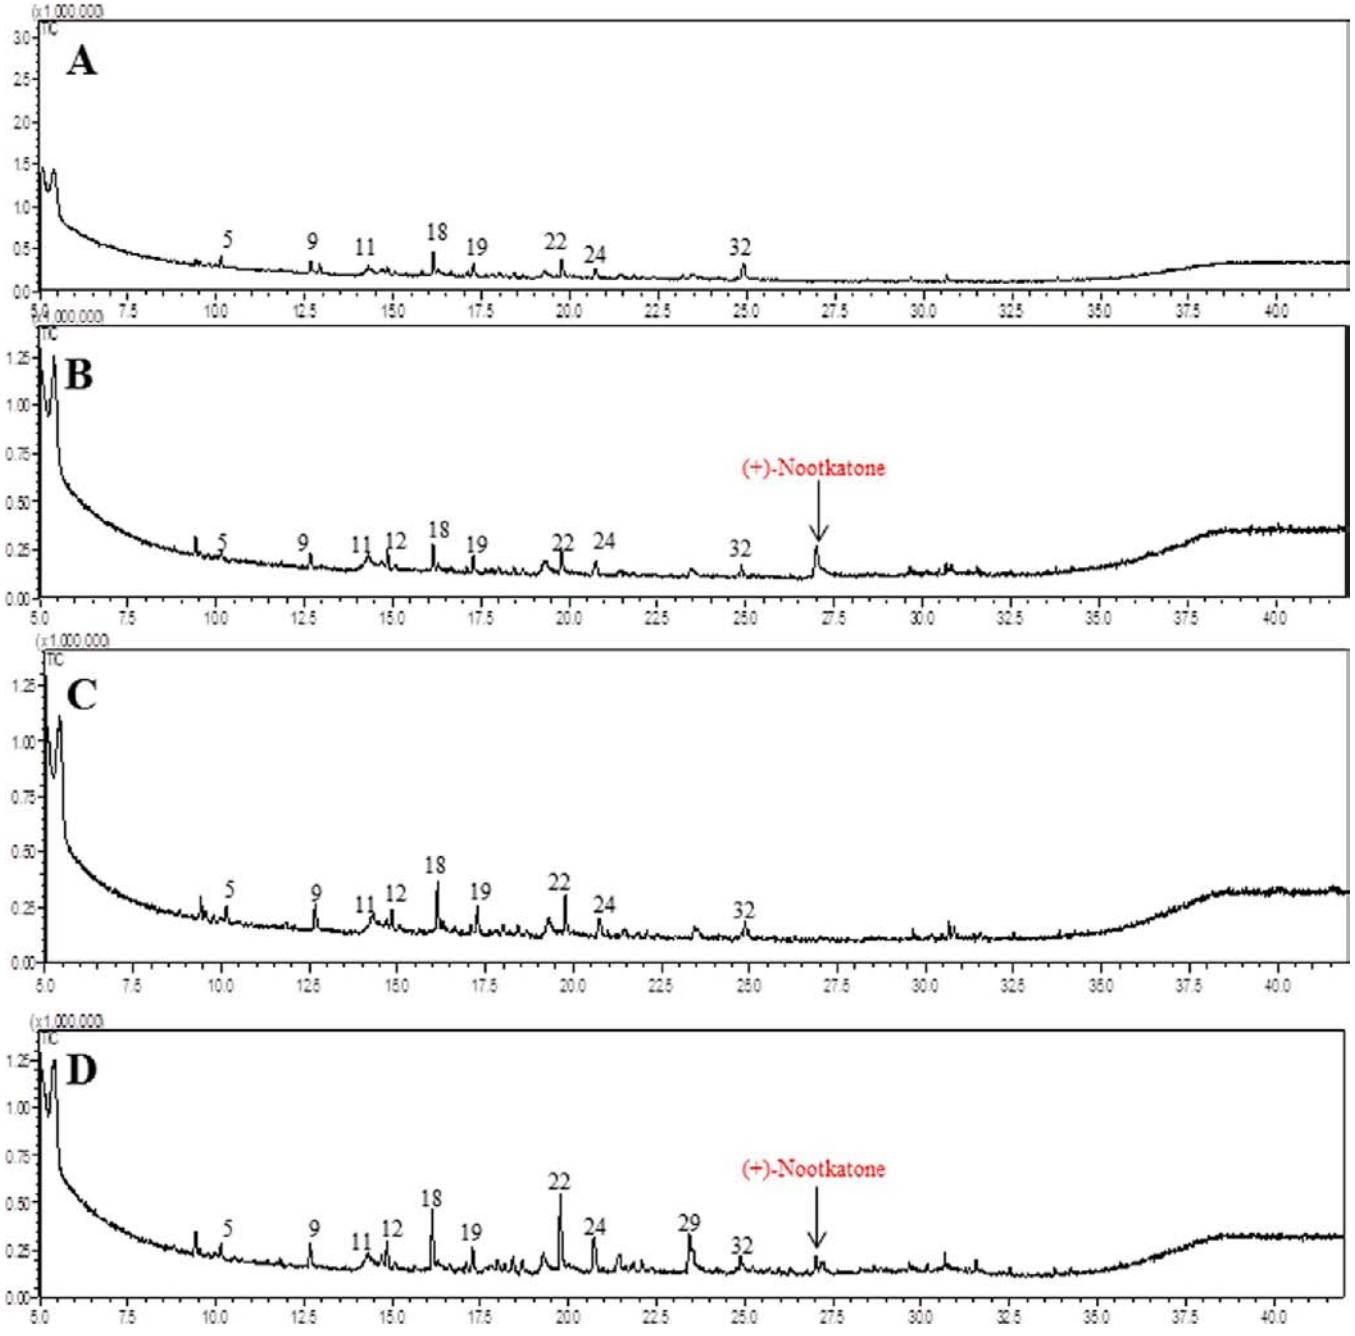

Figure 9. GC-MS base peak chromatograms of various laser-dissected tissues of rhizomes collected from India: (A) cortex, (B) hypodermal fiber bundles, (C) endodermis, and (D) amphivasal-type vascular bundles. Peak numbers indicating the identified constituents are listed in Table 2.

exhibits sharp peaks of glycols and poly(vinyl alcohol) polymers between 11 and 14 min of retention time. Methanol, used as solvent, exhibits few peaks from 18 to 21 min. The positive mode in comparison to negative mode exhibited a better response for profiling of constituents; hence the positive mode was used for analysis.

As seen in the chromatograms of Figure 3, there are several constituents that occur in common between the samples collected from India and China. There were also some constituents that occurred exclusively in each of the samples from India and China. The components cyperanic acid, 7-methoxy-2-tetralone, sobrerol, sugetriol, and (−)-epoxycaryophyllene were found only in samples from India. The common constituents for samples from India and China were ligucyperonol, calamenene, mandassidione, 4-cymene, sugeonol, cyperusol B1 and B2, sitosterol, myrcetin, cyperotundone, isolongifolanone, and valerenal.

Tissue-Specific Metabolite Analysis by UHPLC-QTOF MS. The metabolites present in the selected target tissues were identified by LC-MS analysis. The tissues isolated for analysis were cortex, hypodermal fiber bundles, endodermis, and amphivasal-type vascular bundles. The base peak chromatograms obtained after LC-MS analysis of these tissues of samples from India and China are shown in Figures 4 and 5 respectively. The peak numbers assigned to all the identified secondary metabolites and their occurrence in various tissues is indicated in Table 1, along with the details of their molecular characteristics in LC-MS analysis. Table S1 of Supporting Information lists all the constituents used for profiling.

dx.doi.org/10.1021/jf502494z | J. Agric. Food Chem. 2014, 62, 7302−7316

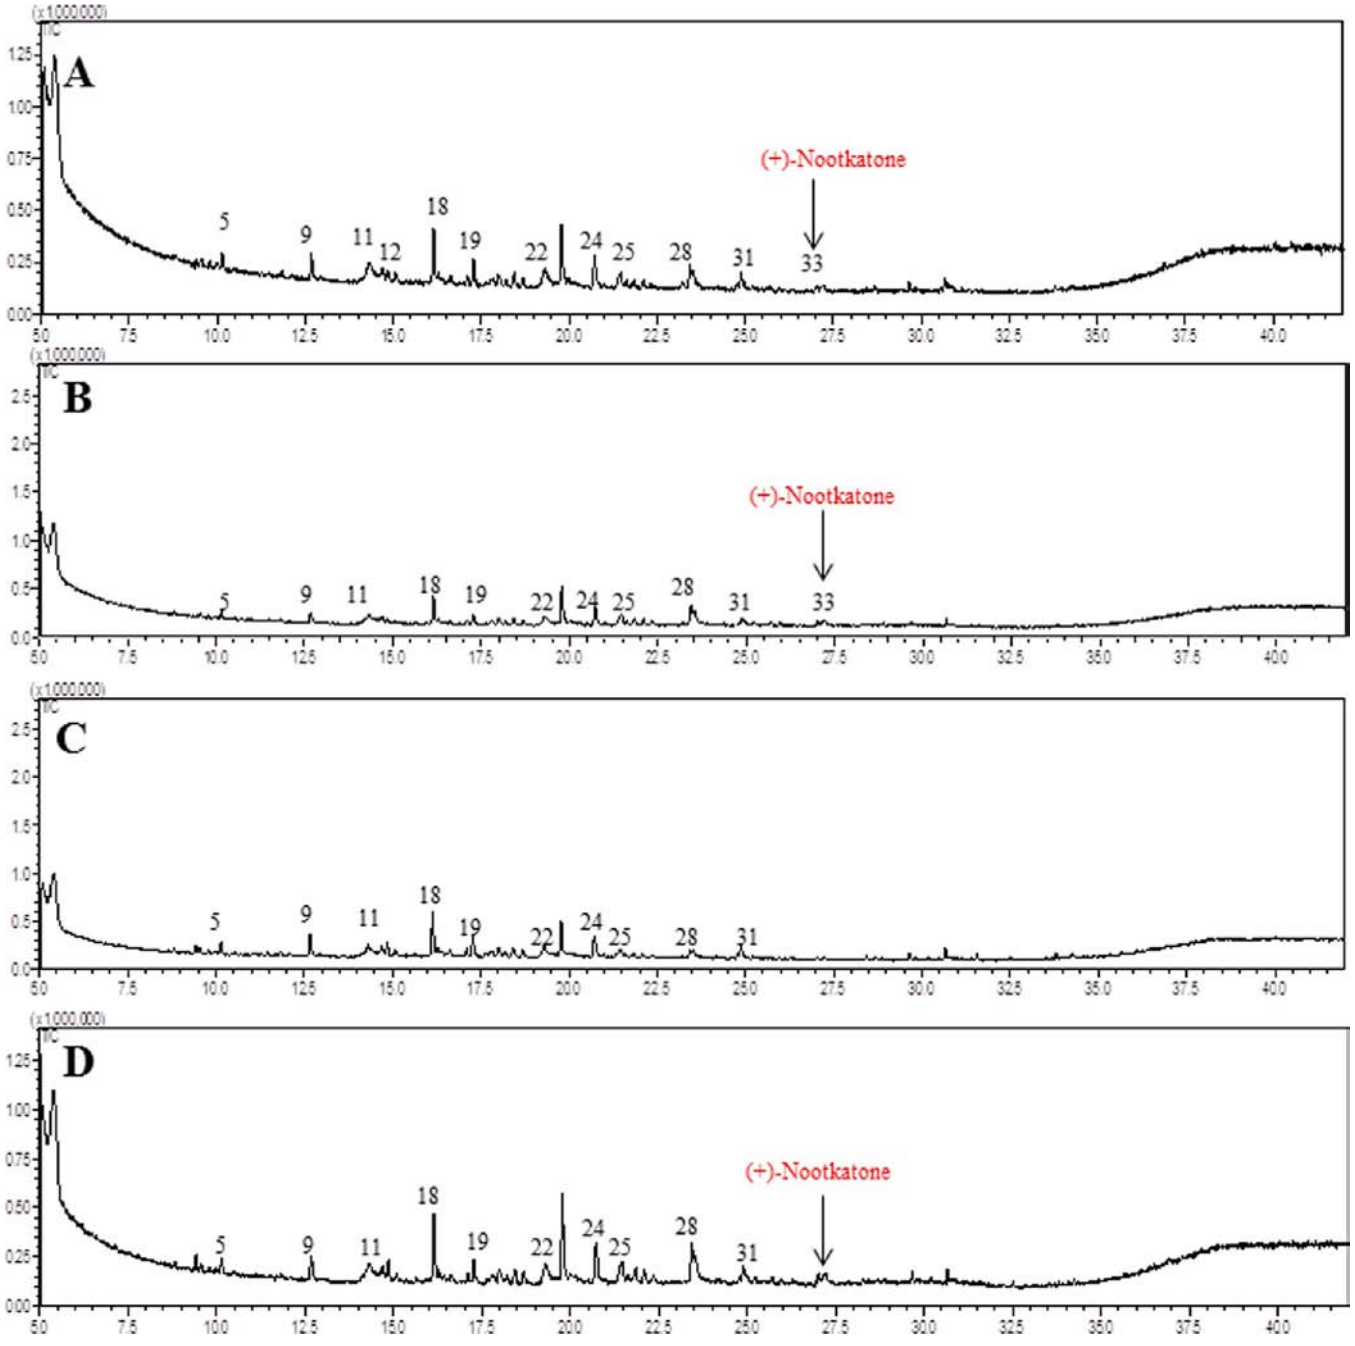

Figure 10. GC-MS base peak chromatograms of various laser-dissected tissues of rhizomes collected from China: (A) cortex, (B) hypodermal fiber bundles, (C) endodermis, and (D) amphivasal-type vascular bundles. Peak numbers indicating the identified constituents are listed in Table 2.

As indicated in Figure 4 and Table 1, the tissues of rhizomes collected from India contained 4-cymene, sugeonol, cyperusol B1, sitosterol, myrcetin, cyperotundone, and myristic acid. The cortex, hypodermal fiber bundles, endodermis, and amphivasal vascular bundles did not differ significantly in constituents except for the endodermis, which contained cyperusol B2 in addition to the common constituents.

With regard to samples collected from China, some differences were observed in the type of constituents in the selected tissues (see Figure 5). The common constituents in all tissues were sugeonol, cyperusol B1, sitosterol, myrcetin, and myristic acid. The cortex and hypodermal fiber bundles also contained cyperusol B2 and cyperotundone in addition to the common constituents. The endodermis contained all the common constituents listed above. The amphivasal vascular bundles, in addition to the common constituents, also had calamenene, mandassidione, 4-cymene, and cyperotundone. On the basis of comparative profiling of tissue metabolites, we infer that the *C. rotundus* rhizome samples collected from both India and China can be used as qualitative substitutes for each other.

GC-MS-Based Metabolite Profiling. As mentioned earlier, several reports indicate the presence of terpenoids, alkaloids, flavonoids, and steroids in rhizomes of *C. rotundus*. In this study, various essential oil constituents present in *C. rotundus* were characterized and the content of the sesquiterpenoid constituent (+)-nootkatone was quantified by GC-MS analysis. Representative chromatograms of extracts of whole rhizome samples from India and China, with hexane/ethyl acetate (1:1) used as blank

dx.doi.org/10.1021/jf502494z | *J. Agric. Food Chem.* 2014, 62, 7302−7316

solvent and (+)-nootkatone standard, are presented in Figure 6. The 37 constituents identified in the study samples through GC-MS analysis are listed in Table 2, along with their retention times and calculated Kovats retention indices. (+)-Nootkatone was found to have a retention time of 26.99 min. The constituents found in common between the samples from India and China are *trans-Z-α*-bisabolene epoxide, longiverbenone, and (+)-nootkatone. From percentage areas it was found that the most abundant constituents in samples from India were copaene (6.96%), *trans-Z-α*-bisabolene epoxide (9.75%), caryophyllene oxide (9.01%), and longiverbenone (8.50%). In samples collected from China, the abundant constituents found were *β*-cadinene (33.45%), *α*-fenchone (7.44%), aristolone (23.31%), and *α*-cyperone (23.31%). Overall, in the optimized experimental conditions used for this study, 23 constituents were detected in samples from India and 20 constituents were detected in samples from China.

Representative mass spectra of some major constituents in samples from India and China are indicated in Figures 7 and 8, respectively, and their occurrence or absence is indicated in Table 2.

GC-MS-Based Tissue-Specific Metabolite Profiling. The presence of nonpolar metabolites in cortex, hypodermal fiber bundle, endodermis, and amphivasal-type vascular bundle tissues of rhizomes was estimated by GC-MS analysis. The base peak chromatograms for tissues of rhizome samples from India and China are shown in Figures 9 and 10, respectively. The peak numbers for all the identified constituents are indicated in the chromatograms are listed in Table 2.

In the rhizome samples collected from India, all the tissues contained ionone, *β*-cadinene, methyl isoeugenol, cycloisolongifolene, alloaromadendrene oxide-(1), *trans-Z-α*-bisabolene epoxide, 9*H*-cycloisolongifolene, and isoaromadendrene epoxide. All these metabolites were found to occur in the cortex. In addition to these common metabolites, the hypodermal fiber bundles and endodermis indicated the presence of *α*-fenchone. The amphivasal-type vascular bundle tissues contained longipinocarvone in addition to *α*-fenchone and the above-mentioned common constituents.

In the rhizome samples collected from China, the common metabolites among all the target tissues were ionone, *β*-cadinene, methyl isoeugenol, cycloisolongifolene, (−)-neoclovene-(II), aristolone, and *α*-cyperone. The cortex, hypodermal fiber bundles and amphivasal-type vascular bundle tissues in addition to the common metabolites contained (+)-nootkatone; however, it was not detected in the endodermis tissues.

Quantitation of (+)-Nootkatone and Method Validation. The content of (+)-nootkatone was determined in the rhizome samples of *C. rotundus* through GC-MS analysis. SIM mode was used for quantitative analysis and the peak areas obtained for the standard analyte in the calibration curve were used for calculation of (+)-nootkatone content in the samples. The content of (+)-nootkatone in samples from India was found to be higher than in samples from China (see Table 3).

The method was validated as per International Conference on Harmonisation (ICH) guidelines (Q2 R1).[42] The results obtained for recovery studies and other parameters of validation are reported in Table 4.

The sesquiterpenoid component (+)-nootkatone has significant insecticidal, anticancer, and antiplatelet activity, and it is an important flavoring agent used in biotechnology, pesticide, and perfume industries.[46−50] Finding sources of rich (+)-nootkatone content like *C. rotundus*, which is an easily available weed and an agricultural waste product, would be of significant importance for the relevant industries.

Table 3. Content of (+)-Nootkatone in *C. rotundus* Rhizome Samples

sample[a]	(+)-nootkatone[b] (μg/10 g)
CW	21.72 ± 0.572
IW	30.47 ± 0.716

[a]CW, extract of whole rhizome samples collected from China; IW, extract of whole rhizome samples collected from India. [b]Contents were calculated on the basis of dry weight of the rhizomes (n = 3) and are presented as mean ± relative standard deviation (RSD).

Table 4. Results of Various Parameters of Validation Studies

parameter	value for (+)-nootkatone
calibration curve equation	y = 109 851x + 56 174
correlation coefficient (r^2)	0.9887
LOD (ng/mL)	0.303
LOQ (ng/mL)	1.0
calibration range (ng)	1.0−100.0
intraday precision (% RSD, n = 5)	0.239
interday precision (% RSD, n = 3)	0.645
repeatability (RSD, n = 5)	0.423
recovery (n = 3)	
low-level spike (50% ± RSD)	56.15 ± 0.203
intermediate-level spike (100% ± RSD)	99.78 ± 0.019
high-level spike (150% ± RSD)	125.73 ± 0.372

In conclusion, our study is the first to compare tissue-specific metabolites and (+)-nootkatone content in *C. rotundus*, which is a common plant species found in China and India. Quantitatively, the samples from both these geographical regions have a difference in their percentage contents of (+)-nootkatone. However, qualitatively they have considerable similarities, which suggests their validity of being used as substitutes for each other.

The plant *C. rotundus* is important not only due to its therapeutic utility in traditional medicine and its applications in food industry but also due to its use as an economic and easily available source of (+)-nootkatone. Thus, its (+)-nootkatone-rich content adds to its beneficial values despite its reputation of being a notorious weed in the agricultural sector.

The experimental approach was designed with a perspective of evaluating the quality of *C. rotundus* rhizome from two different countries in terms of differences in their metabolites and (+)-nootkatone content. Such studies can help in identification of geographical locations for obtaining herbal material of superior quality. Our study provides information that can be utilized for quality control and standardization of *C. rotundus* rhizomes and its products. Furthermore, our study provides a perspective for advantageous utilization of the notorious weed *C. rotundus*, which has been a major concern for the agricultural sector.

that several kinds of soy sauce are assessed. However, this technique is expensive and time-consuming due to the preparation of a huge amount of fraction of soy sauce. Thus, it is difficult to use this technique for several soy sauce samples.

Meanwhile, metabolomics concerning as many metabolites as possible has become an important tool over a wide research area. Specifically, metabolic or compound profiling based on metabolomics technology has recently been receiving much attention for application in the research of the relationship between compounds and food quality.[12,13] Research on metabolic profiling and its relationship to the taste of food has been reported before such as in green tea,[14] tomato,[15] cheese,[16] sake,[17] and soy sauce.[18]

In a previous study[18] about profiling between the compounds and taste of soy sauce, hydrophilic compounds were measured by gas chromatography−mass spectrometry (GC-MS), and its correlation with sensory attribute was assessed. The study focused on the construction of a prediction model of sensory attributes by metabolic profiling that was able to predict the umami taste intensity using metabolite data obtained by GC-MS. In addition, it was reported that glutamic acid, glucose, and sucrose had strong correlation with the umami taste intensity and were suggested as the significant compounds for umami taste. However, the study did not confirm the effect of these compounds on the umami taste of actual soy sauce. Moreover, the compounds' data measured by GC-MS were not likely enough for the aim of the study due to the limitation of measurable compounds by GC-MS.

The aim of the present study was to explore the compounds that affect the umami taste intensity in actual soy sauce by using metabolic profiling and sensory evaluation. We employed two analytical platforms, GC-MS and liquid chromatography−mass spectrometry (LC-MS), for the measurement of compounds. For selection of the candidate compounds related to the umami taste intensity, projection to latent structure (PLS) regression analysis (also known as partial least-squares) was conducted with both the metabolite data and the umami taste intensity data. Additionally, the effect of the candidate compound on the umami taste intensity in soy sauce by sensory evaluation was assessed. On the basis of a metabolic profiling approach, we show that the compound found to be statistically significant to umami taste intensity indeed affects the umami taste of soy sauce.

MATERIALS AND METHODS

Soy Sauce. Twenty-five soy sauce samples were used in this study. The countries of origin of the samples were China (samples 1−6 and 20−22), the United States (samples 7−9), and Japan (samples 10−19 and 23−25). The samples were preserved in a freezer at −30 °C prior to chemical analysis and sensory evaluation.

Chemicals. All chemicals used in this study were of analytical grade. Ribitol was used as internal standard, and pyridine was used as solvent; both were purchased from Wako Pure Chemical Industries (Osaka, Japan). The derivatization reagents methoxyamine hydrochloride and *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide (MSTFA) were purchased from Sigma-Aldrich (Milwaukee, WI, USA) and GL Science, Inc. (Tokyo, Japan), respectively.

N-(1-Deoxyfructos-1-yl)glutamic acid (Fru-Glu) for compound identification and sensory evaluation was synthesized from food grade glucose and glutamic acid following the literature.[19] Briefly, a mixture of D-glucose (Sanei Sucrochemical Co., Ltd., Aichi, Japan) and L-glutamic acid in a molar ratio of 40:1 in 50 mM phosphate buffer was heated at 60 °C for 3 days under reflux with vigorous stirring. The reaction mixture was purified by passage through a column of cation-exchange resin (DOWEX 50Wx8 200−400 mesh (H) cation exchange resin, Wako Pure Chemical Industries, Osaka, Japan) and ODS-type resin (Daisogel SP-120-40/60-ODS-B, DAISO Co., Ltd., Osaka, Japan). The purity of Fru-Glu (>90%) was confirmed by LC-MS using the same conditions as given below.

Sample Preparation of Soy Sauce for GC-MS Analysis. A previously reported method of sample preparation and derivatization for GC-MS analysis[18] was used with modifications. Soy sauce samples were diluted 10 times, and 20 μL of the diluted sample in a microtube was extracted with 1000 μL of $MeOH/H_2O/CHCl_3$ (5:2:2, v/v/v). Sixty microliters of 0.2 mg/mL ribitol was added to the mixture. The sample was centrifuged at 16000*g*, for 3 min at 4 °C, and then 900 μL of the supernatant was transferred to another microtube. Four hundred microliters of distilled water was added to the sample before mixing. Following centrifugation (16000*g*, 3 min at 4 °C), 900 μL of supernatant was transferred to another microtube and capped. The cap was subsequently pierced and the extract was evaporated, to remove methanol, in a centrifuge vacuum concentrator at room temperature for approximately 2 h. After evaporation, the extract was freeze-dried at room temperature overnight.

Sample Derivatization for GC-MS Analysis. For derivatization, 100 μL of methoxyamine hydrochloride in pyridine (20 mg/mL) was added to the above freeze-dried sample, and the mixture was incubated in a Thermomixer comfort (Eppendorf Ltd., Hamburg, Germany) at 30 °C for 90 min to induce the methoxylation reaction. Fifty microliters of *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide, the second derivatization agent, was added, and the mixture was incubated at 37 °C for 90 min to induce the silylation reaction. The samples were then used for GC-MS analysis. One microliter of sample was injected in split mode (25:1, v/v).

GC-MS Analysis. A previously reported GC-MS condition[18] was used with modifications. The GC-MS used in this study was a Shimadzu GCMSQP2010 Ultra (Shimadzu, Kyoto, Japan) equipped with a 30 m × 0.25 mm i.d. fused silica capillary column coated with 0.25 μm CP-SIL 8 CB low bleed/MS (Agilent Technologies, Palo Alto, CA, USA). The injection temperature was 230 °C. The carrier gas was helium at a linear velocity of 39 cm/s. The column temperature was held at 80 °C for 2 min isothermally and then raised at 15 °C/min to 330 °C and held for 6 min. The MS conditions were as follows: transfer line temperature, 250 °C; ion source temperature, 200 °C. Ions were generated at 70 eV with electron ionization and were recorded at 20 scan/s over the mass range m/z 85−500. Each sample was measured three times. A standard alkane mixture (C_8−C_{40}) was injected at the beginning and end of the analysis for tentative identification.

Sample Preparation of Soy Sauce for LC-MS Analysis. The sodium chloride (NaCl) level in soy sauce was reduced to below 1.0% by electrodialysis with a Micro Acilyzer S1 (Asahi Chemical Industry, Tokyo, Japan). One hundred microliters of soy sauce sample and 200 μL of methanol were mixed, and 10 μL of the mixed sample was diluted 10 times with distilled water. The sample was filtered before it was placed in a glass vial.

LC-MS Analysis. LC experiments were conducted using an HPLC system (Shimadzu, Japan) consisting of an LC-20AB binary pump, an SIL-20AC autosampler, and a CTO-20AC column oven. Chromatographic separation was achieved using a reversed-phase column (Discovery HS-F5 column, 150 mm × 2.1 mm, 3.5 μm, Sigma-Aldrich, Milwaukee, WI, USA) with a gradient elution with a mobile phase composed of eluents A (0.1% acetic acid in water, v/v) and B (0.1% acetic acid in acetonitrile, v/v). The mobile phase was consecutively programmed as follows: an isocratic elution of 2% B for the first 3 min, followed by linear gradient elutions of 2−50% B from 3 to 16 min and 50−100% B from 16 to 18 min. After the solvent composition of 100% B had been held from 18 to 24 min and then changed to 2% B for the next 10 min, the column was returned to its starting conditions. A 1 μL aliquot of the sample solution was injected onto the column. The flow rate was 0.2 mL/min, and the column temperature was maintained at 40 °C throughout the analysis. The compounds were detected by Shimadzu ion trap/time-of-flight hybrid mass spectrometry (IT-TOF/MS) equipped with an electrospray ionization source (ESI). The MS conditions were as follows: positive ion mode; electrospray voltage, 1.7

kB; CDL temperature, 200 °C; block heater temperature, 200 °C; nebulizing gas (N_2), 1.5 L/min; drying gas (N_2) pressure, 0.1 MPa. Mass spectra were acquired in the range of m/z 100−1000, and ion accumulation time was 200 ms. The calibration of mass accuracy was conducted every 24 h with standard. For quality control, the mixture of all samples was measured every 24 h during the measurement period. Each sample was measured three times.

In MS/MS analysis, MS/MS spectra were acquired in the m/z range of 80−500 under the following conditions: precursor ion isolation in the m/z range of 100−1000 (width, 3 Da); ion accumulation time, 50 ms; tolerance m/z, 0.05; repeat = 2; and CID energy, 50%.

In quantitative analysis, we used synthesized Fru-Glu for external standard and the LC-MS system under the same conditions as above.

Data Processing. A previously reported method for data processing concluding tentative peak identification[18] was used with modifications. MS data obtained by GC-MS were exported in the netCDF format. Peak detection and alignment were performed by MetAlign software (Wageningen UR, The Netherlands; freely available at http://www.pri.wur.nl/UK/products/MetAlign/).[20] The resulting data were exported in the CSV-format file. Then, the CSV-format file was imported by the AIoutput software[21] for tentative peak identification and construction of a data matrix. In tentative peak identification, retention indices of the eluted compounds were calculated on the basis of the standard alkane mixture. Then, by comparing the retention indices and unique mass spectra with our in-house reference library, tentative identifications were obtained. In the construction of the data matrix, spectra were normalized manually by adjusting the peak intensity against the ribitol internal standard before an organized data matrix was generated.

The peak detection and alignment of MS data obtained by LC-MS were performed by Profile solution version 1.0 (Shimadzu). The peak integration parameters were set as default, and the peak alignment parameters were as follows: ion m/z tolerance, 5 mDa; retention time tolerance, 0.5 min; peak intensity threshold, 5000. The resulting data were exported in the CSV-format file. To reduce the risk of ghost peaks, peaks having maximum intensity and minimum relative standard deviation among samples of >300,000 and <15% (n = 3), respectively, were selected for statistics.

Sensory Evaluation of the Umami Taste Intensity of Soy Sauce. Quantitative data of the umami taste intensity were acquired by 13 external panelists who had previous experience in quantity description analysis.[18] Twenty milliliters of each sample in randomized numbered cups covered with a plastic lid were presented to the panelists in random order. Panelists tasted 0.2 mL of the sample and marked the umami taste intensity on a 12 cm line scale. Each sample was evaluated three times.

To assess the influence of Fru-Glu on the umami taste intensity of soy sauce, we evaluated soy sauce samples with or without additional Fru-Glu using 10 in-house panelists who could discriminate between 11.8 and 14.3 mM MSG solutions. In case of the comparison between the two samples, the order effect may be the bias for panelists when the control and test sample are fixed. To remove the order effect, the 10 panelists were randomly divided into two groups of five. In group 1, the Japanese *koikuchi* soy sauce (sample 10) with additional Fru-Glu (5 or 10 mM) was designated as the test sample and the same soy sauce without additional Fru-Glu acted as the control. In group 2, the designation was reversed in which the test sample and control used were the soy sauce without additional Fru-Glu and soy sauce with additional Fru-Glu, respectively. Panelists were not informed which sample was the control.

For both groups, the sensory evaluation for the relative intensity of umami taste was carried out by using a nine-point rating scale (from −4, "very weak compared to the control", to 4, "very strong compared to the control"). Each sample was evaluated three times. In the case of group 2, assuming that a higher umami taste intensity in samples with additional Fru-Glu was observed compared to that without additional Fru-Glu, the sample was rated as "−2, weak". Also, the rating was reversed (i.e., −2 becomes +2,) when counting results.

The same evaluation method was used for the addition of glutamic acid.

Statistics. Multivariate analysis was performed. One-way analysis of variance (ANOVA) and PLS regression analysis were carried out with Excel 2007 and SIMCA-P software (version 12.0, Umetrics, Umeå, Sweden), respectively. For data pretreatment, autoscaling was used so that each variable had a unit variance and zero mean. The number of latent factors (PLS components) in the PLS model was determined by computing the optimum number at the balance between R^2 and Q^2 with the SIMCA-P software algorithm. After fitting the model, R^2 and Q^2 were calculated as the index of model quality. R^2 is the correlation coefficient between actual response variable and predictive value obtained from PLS. Q^2 is an index that reflects the predictive ability of the model.

After construction of the PLS model, the variable importance in the projection (VIP) of each explanatory variable was calculated to select the candidate umami compound. The VIP_{Ak} value of the kth explanatory variable in K variables of PLS with component A was calculated using the equation[22]

$$\mathrm{VIP}_{Ak} = \sqrt{\left(\sum_{A}^{a=1} (w_{ak}^2 \times (\mathrm{SSY}_{a-1} - \mathrm{SSY}_a)) \times \frac{K}{(\mathrm{SSY}_0 - \mathrm{SSY}_A)}\right)}$$

w_{ak} is the PLS weight of the kth variable. SSY_a indicates the amount of Y variance explained by each PLS component, a. The VIP value indicates the contribution of each explanatory variable to the model.[23] The "VIP scores >1" rule is generally used as the criterion for important variable selection.[24]

RESULTS AND DISCUSSION

Metabolite Data Obtained by GC-MS and LC-MS. We employed two analytical platforms, GC-MS and LC-MS, for the measurement of compounds in 25 samples of soy sauce. GC-MS was used to measure low hydrophilic nonvolatiles such as sugar or amino acid with sample derivatization, whereas LC-MS was expected to detect the compounds that are difficult to volatilize with derivatization such as peptides and Maillard compounds. Using the two platforms made it possible to detect a broad range of physical and chemical characteristics of compounds in soy sauce. From the 122 peaks detected in the GC-MS analysis, 68 peaks were tentatively identified by comparing the retention indices and unique mass spectra with our in-house reference library using AIoutput 2.0. The tentatively identified compounds included 26 kinds of amino acids, 23 kinds of sugars or sugar alcohols, 8 kinds of organic acids, 4 kinds of amines, and 7 kinds of other compounds (Supporting Information Table S1). On the other hand, 305 peaks were detected with the positive mode of LC-MS. The m/z range of these peaks was from 110.008 to 671.200. These results suggested that a wide range of compounds were detected by GC-MS and LC-MS analyses. We used the data obtained from LC-MS for explanatory variables of PLS regression analysis before peak identification because identification of all peaks was difficult using only accurate mass. Then, the selected peaks based on VIP values obtained via PLS (described in the succeeding section) were identified by comparison with the MS/MS spectrum and retention time of authentic standard.

Umami Intensity of Soy Sauce by Sensory Evaluation. The umami taste intensity of each soy sauce sample was obtained using sensory evaluation (Figure 1). The highest umami taste intensity was 4.01, and the lowest was 2.79. For evaluation of the significant differences among samples, we conducted one-way ANOVA. The F value was 1.53, and p value was <0.001. Because the data of the umami taste intensity had highly significant differences, we concluded that it is appropriate for the response variable of PLS regression analysis.

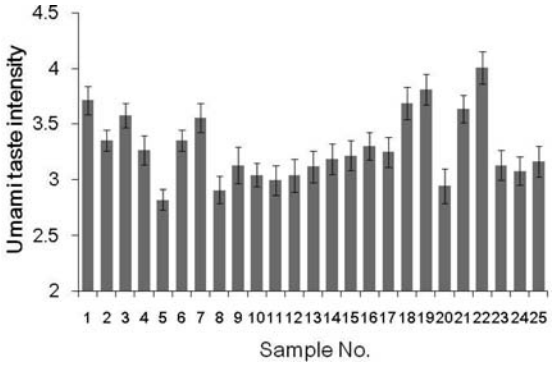

Figure 1. Umami taste intensities of each soy sauce sample. Sensory evaluation was performed by 12 experts using a line scale. Samples 5 and 22 exhibit the weakest and strongest umami taste intensities, respectively, among 25 tested samples. Values are the mean ± standard error.

Metabolic Profiling with PLS Regression Analysis. PLS regression analysis, a supervised multivariate data analysis, summarizes the explanatory variables of the multivariate data into new variables (PLS factors) that maximally correlate with response variables.[25] PLS is often used in metabolomics research due to its ability to cope with a large number of variables and multicollinearity.[26] In addition, the VIP value obtained via PLS is used for the estimation of the relevant explanatory variables to the response variable.[20] To find the relationship between the metabolites data and the umami taste intensity, we conducted PLS regression analysis using the metabolite data obtained from GC-MS and LC-MS as the explanatory variables and the umami taste intensity obtained the sensory evaluation as the response variable. The predicted versus measured figures of the umami taste intensity are shown in Figure 2. R^2 (proportion of explained variance) and Q^2

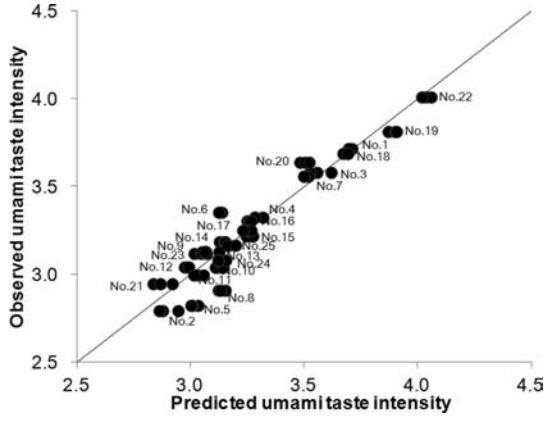

Figure 2. Relationships between predicted and measured umami taste intensity based on projection to latent structure (PLS) model. The numbers of explatanory variables and response variables were 427 and 1, respectively. PLS component was 4. R^2 and Q^2 were 0.914 and 0.877, respectively.

(proportion of predicted variance), which are the diagnostic indices of model quality, were 0.914 and 0.877, respectively. Previously, it has been reported that the accuracy of the prediction model of PLS constructed with only GC-MS is enough.[18] When GC-MS data obtained in this study were used for PLS, R^2 and Q^2 were 0.899 and 0.821, respectively. On the other hand, R^2 and Q^2 from the LC-MS data were 0.909 and 0.816, respectively. Thus, this indicated that the model using both sets of data had the highest quality. In the VIP analysis, the higher quality PLS model was preferred for the relevant variable selection.

Selection of Candidates of Umami Compound Using VIP Value. The explanatory variables were assessed by VIP values for the inference of the compounds that are likely relevant to the umami taste intensity. VIP is an index of the effect of every explanatory variable on the response variable in the model and is used to select the important metabolites in various metabolomics-based research.[26] Whether the effect on response variable is positive or negative was judged by the regression coefficient of each explanatory variable. The compounds with positive coefficients having larger VIP values than glutamic acid (2.14) are shown in Table 1. In the PLS

Table 1. Compounds Selected by Variable Importance in the Projection (VIP) Analysis

RT[a] (min)	m/z	compound	VIP	coefficient[b]	platform
2.20	310.113	*N*-(1-deoxyfructos-1-yl)glutamic acid	2.35	0.045	LC-MS
9.85	174[c]	unknown	2.25	0.036	GC-MS
2.07	349.053	inosinic acid	2.23	0.047	LC-MS
9.47	174[c]	4-aminobutyric acid	2.15	0.044	GC-MS
10.15	246[c]	glutamic acid	2.14	0.038	GC-MS

[a]RT, retention time. [b]Regression coefficient of each compound. [c]The highest fragment mass of peak detected by GC-MS.

model construction, compounds with VIP values >1 were considered to be significant.[24] These compounds in Table 1 have VIP values >1; thus, these compounds are significant explanatory variables for the prediction of the response variable. In the following discussion, we focused on four compounds that had VIP values larger than that of glutamic acid.

In Table 1, both Fru-Glu and inosinic acid were identified using information on both the retention time and MS/MS spectra of authentic standards obtained by LC-MS. Fru-Glu was detected as m/z 310.113 ion and a retention time of 2.20 min. Figure 3 shows the MS/MS spectrum of Fru-Glu obtained by IT-TOF/MS. The m/z 148.06 product ion contained in the mass spectrum corresponded to glutamic acid H^+ adduct. The neutral loss from precursor ion (m/z 310.113) is m/z 162.05 and corresponds to the molecular weight of glucose without one water molecule. Inosinic acid was detected as the m/z

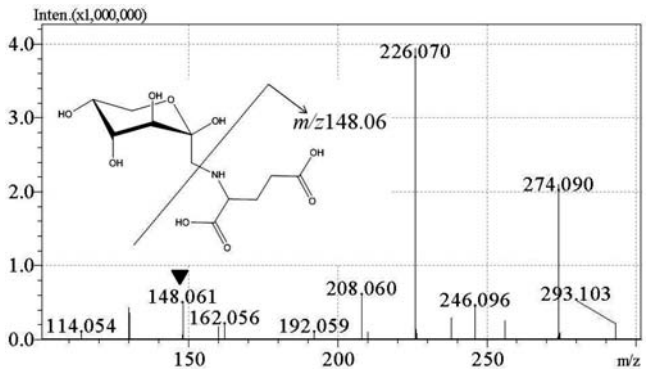

Figure 3. MS/MS spectrum of *N*-(1-deoxyfructos-1-yl)glutamic acid obtained in the positive ionization mode. Triangle symbols indicate m/z 148.061 corresponding to glutamic acid H^+ adduct.

349.053 ion and retention time of 2.07 min by LC-MS via MS/MS analysis (data not shown).

The compound with the largest VIP value was Fru-Glu. It was reported that the umami taste intensity of Fru-Glu was similar to that of MSG in water or NaCl solution,[27] and Fru-Glu was detected in the wheat gluten hydrolysate.[28] However, there has been no report of the umami of Fru-Glu and its taste property in soy sauce.

The compound with the second largest VIP detected by GC-MS could not be identified using our in-house library.

The third largest VIP value was 2.23 for inosinic acid, known as a umami enhancer of MSG.[29] In naturally fermented soy sauce, inosinic acid is not detected because the phosphatase enzymes made by *kouji* mold degrade the inosinic acid in natural soy sauce.[30] Also, some soy sauce products have inosinic acid added as a food additive for umami enhancement after fermentation.[31]

The compound with the fourth largest VIP detected by GC-MS was 4-aminobutyric acid. 4-Aminobutyric acid, which has a VIP value was close to that of glutamic acid, has been reported to give a weak sour taste and a mouth-drying sensation in aqueous solution.[32] It is unclear whether 4-aminobutyric acid has an effect on the umami taste intensity of soy sauce.

This metabolic profiling approach helps in the selection of candidate compounds from a huge number of variables. However, this approach could not substantiate the effect for the umami taste intensity of "actual" soy sauce. We therefore evaluated the effect of Fru-Glu addition, the compound with the highest VIP value, on the umami taste intensity of soy sauce.

Effect of Fru-Glu on the Umami Taste Intensity of Soy Sauce. Using sensory evaluation, we assessed the effect of Fru-Glu addition, the compound with the largest VIP value, on the umami taste intensity of soy sauce. In sensory evaluation, panelists compared the control sample (Japanese *koikuchi* soy sauce (sample 10) without additional Fru-Glu) with the test sample containing the same soy sauce with additional Fru-Glu.

Before sensory analysis, the concentration of Fru-Glu was measured in all samples. We found that the concentration of Fru-Glu in sample 10 was 0.7 mM, and the highest concentration among the samples was 5.5 mM (Figure 4). The additional Fru-Glu concentrations were 5 and 10 mM. The same evaluation method was conducted using glutamic acid. The result of sensory evaluation is shown in Figure 5. The

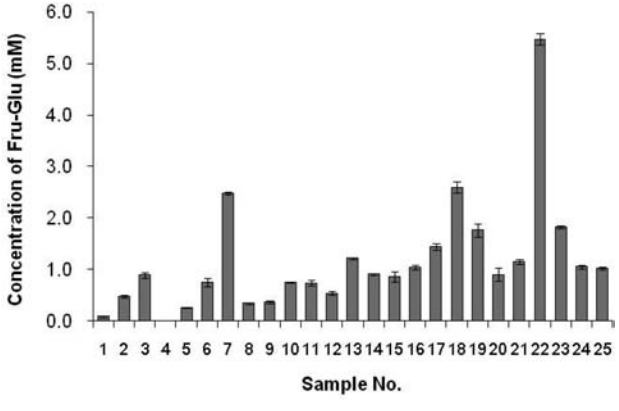

Figure 4. Concentration of *N*-(1-deoxyfructos-1-yl)glutamic acid in each soy sauce sample. Values are the mean ± standard deviation in three replications.

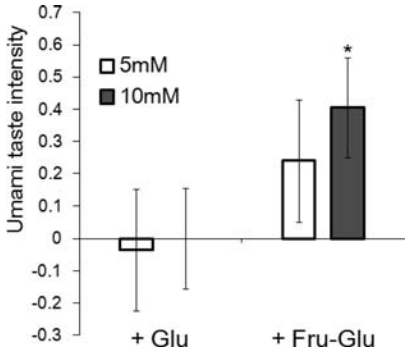

Figure 5. Results of the sensory evaluation of *N*-(1-deoxyfructos-1-yl)glutamic acid (Fru-Glu) in soy sauce. The umami taste intensity was evaluated by comparison between soy sauce with the addition of Fru-Glu and without the addition (control) of Fru-Glu. Sample 10 was used for the evaluation. The 9-point relative categorical scale (comparing control sample −4, "very weak", to 4, "very strong") was used. Intensity was evaluated by 10 selected panelists. The same evaluation method was used for the addition of glutamic acid (Glu). Values are the mean ± standard error. (∗) $p < 0.05$ (sample t test against 0).

umami taste intensity tended to increase with higher Fru-Glu concentration, and there was a significant difference between the sample with added 10 mM Fru-Glu and control sample (one-sample t test $p < 0.05$). On the other hand, there was no significant difference in the umami taste intensity in samples with added 5 and 10 mM glutamic acid. These results indicated that Fru-Glu increased the umami taste intensity of soy sauce at a lower concentration than glutamic acid even though the taste threshold of both compounds in aqueous solutions is the same.[24] Consequently, the evaluation of the taste property of compounds in complex systems such as food may differ from that of model experiment due to the effect of taste interactions such as a synergy effect. Furthermore, these results suggested that Fru-Glu has a stronger synergistic effect than glutamic acid in soy sauce. Glutamic acid did not affect the umami taste intensity at this concentration even though it had a high VIP value. Considering the discrimination threshold of MSG in *koikuchi* soy sauce,[6] a concentration >10 mM is needed for increasing the umami taste intensity of soy sauce. We therefore conclude that to enhance umami taste, at low concentration, Fru-Glu is more essential than glutamic acid in soy sauce. To the best our knowledge, there is no report on the relationship between Fru-Glu and umami in soy sauce.

In summary, the present study explored the compounds related to the umami taste intensity by a metabolic profiling approach. Using this approach, Fru-Glu was found to increase the umami taste intensity of soy sauce more effectively than glutamic acid, the key umami compound. The advantages of the metabolic profiling approach over traditional methods such as sensory-guided fractionation are as follows: (1) metabolic profiling is able to cover a wide variety samples because it is not necessary to prepare fractions; (2) compounds that are difficult to separate from other compounds can also be evaluated. However, the result of statistical analysis such as PLS does not directly substantiate the contribution of each compound to taste; thus, validation of the effect of compounds on taste using sensory evaluation is necessary. The combination of metabolic profiling and sensory evaluation is a useful tool for exploring the compounds that affect taste and may contribute to the

quality assessment or improvement of soy sauce and other foods.

and Alan Seawright. Recognizing many of the commonalities between the two countries in livestock poisoning problems, he proposed a Joint U.S.–Australian Symposium on Poisonous Plants, which was held in Logan, Utah, in 1977. A reciprocal meeting took place in Brisbane, Australia, in 1984. At this meeting it was noted that a number of participants were from countries other than the United States or Australia, and a subsequent meeting, held once again in Logan in 1989, was titled the 3rd International Symposium on Poisonous Plants. The fourth such meeting was held in Fremantle, Western Australia, in 1993, and the Chair of that meeting, Dr. Peter Dorling, proposed that the meetings henceforth adopt the name of International Symposium on Poisonous Plants, codified as ISOPP, followed by the meeting number. Subsequent meetings have been held in San Angelo, Texas, in 1997 (ISOPP5); Glasgow, Scotland, in 2001 (ISOPP6); Logan, Utah, in 2005 (ISOPP7); and João Pessoa, Brazil, in 2009 (ISOPP8). The broadening international scope of these symposia has shown that other countries have gone or are going through a progression of poisonous plant research analogous to that experienced by the United States and Australia, albeit at a much more rapid pace. This consists of documentation of poisoning occurrences, identification of the plant and animal species involved, syndromes of toxicity, and ultimately isolation and structural identification of the specific toxins. It is noteworthy that the ISOPP meetings have led to international collaborations, such as that between the research group of Dr. Franklin Riet Correa in Brazil and chemists at the PPRL in Logan, Utah, currently leading to the identification of new plant toxins.

In July 2013, the 9th International Symposium on Poisonous Plants (ISOPP9) was held under the sponsorship of Inner Mongolia Agricultural University and the USDA/ARS Poisonous Plant Research Laboratory at the West Campus of Inner Mongolia Agricultural University in Hohhot, the capital of the Inner Mongolia Autonomous Region of China. After a series of symposia held on the continents of North and South America, Australia, and Europe over more than 30 years, this was the first time that an ISOPP meeting had been held in Asia, a very appropriate venue because the history of poisonous plants in China is well established. It is estimated that there are more than 900 such plant species, belonging to about 100 plant families, affecting livestock. It is noteworthy that many of these species are used in traditional Chinese medicine (TCM). In Inner Mongolia alone, where livestock production is a major economic enterprise, 270 poisonous plant species encompassing 57 plant families have been identified on the extensive grasslands characteristic of the region. The major hazards to grazing livestock are the widespread species *Oxytropis glabra*, *Stellera chamaejasme*, and *Datura stramonium*. *O. glabra* is a member of one of the two plant genera (*Astragalus* and *Oxytropis*) of which certain species have been identified as responsible for locoweed toxicity in the United States, illustrating the common interests in poisonous plant species in disparate parts of the world. In fact, the endophytic toxin, swainsonine, first isolated from *Swainsona* spp. in Australia[15] and subsequently shown to be present in *Astragalus* and *Oxytropis* locoweeds in the United States,[16,17] has recently been identified in *O. glabra* and other Chinese *Astragalus* and *Oxytropis* species.[18] In some areas of western Inner Mongolia 15–30% of the grassland is contaminated by *O. glabra*, and the direct economic loss due to this plant alone has been estimated at RMB 3 million per year (U.S. $0.5 million/year). Its effect on livestock in the region is regarded as being on a par with sandstorms and soil salinization, all three of which can be catastrophic to producers.

Other poisonous plant species, such as *Stellera chamaejasme* (Thymelaeaceae) are unique to China and surrounding regions, or specifically Inner Mongolia. These species have been extensively described and their effects on livestock defined. On the other hand, the role of chemistry in isolating the toxins, elucidating their structures, and determining their mode of action has not become fully integrated into poisonous plant research process. This collection of papers from the ISOPP9 meeting focuses on research that has taken advantage of modern chemistry techniques to fully understand the deleterious nature of plant toxins on animals and perhaps provide structural leads in areas such as pest control, invasive plant management, and new pharmaceuticals. It is anticipated that the presentations at the very successful Hohhot meeting will provide opportunities for collaboration not only within China but also internationally, so that subsequent ISOPP meetings will reveal novel chemistry. A return to Brisbane, Australia, in 2016 is planned for the ISOPP10 meeting, 32 years after the previous meeting there.

the presence of swainsonine without this verification as the other methods are preliminary and not definitive.

Swainsonine concentrations in locoweeds vary among species, varieties, and populations, often ranging from not detected to >0.2%.[16,24] For example, in *Astragalus amphioxys* mean swainsonine concentrations were <0.001%, whereas in species such as *Astragalus mollissimus* var. *mollissimus* mean concentrations were >0.1%.[16] Additionally, in some varieties of *Oxytropis lambertii* and *A. mollissimus*, such as *O. lambertii* var. *articulata*, *O. lambertii* var. *lambertii*, and *A. mollissimus* var. *thompsonii*, mean swainsonine concentrations were <0.001% in all populations, yet in other varieties within these species mean concentrations were >0.01%.[16,24]

The purpose of this review is to highlight past and current research investigating (1) other swainsonine-containing plants besides those in the Fabaceae family; (2) fungi that produce swainsonine; (3) the plant, endophyte, and swainsonine relationship; (4) environmental factors that influence swainsonine concentrations; and (5) areas for future research.

OTHER SWAINSONINE-CONTAINING PLANTS

In addition to the Fabaceae family, swainsonine has been documented in two other plant families: the Convolvulaceae (Solanales) and the Malvaceae (Malvales) (Figure 2; Table 3). Swainsonine was identified in these plant families after numerous episodes of livestock poisoning by these plants and subsequent economic impact. Many of the species within these families are nontoxic and are important forages. Clinical signs and pathology of animals poisoned by these plants are similar to those of animals poisoned by swainsonine-containing legumes.[6,26−31] Two genera in the morning glory family, *Ipomoea* and *Turbina*, contain swainsonine. Seven taxa among these two genera, *Ipomoea carnea*, *Ipomoea polpha*, *Ipomoea riedelii*, *Ipomoea sericophylla*, *Ipomoea* sp. Q6 (aff. *calobra*), *Ipomoea verbascoidea*, and *Turbina cordata*, contain swainsonine (Table 2).[26−30] Swainsonine concentrations also vary considerably in some of these species.[30] These species are found in South America or Australia with the exception of *I. carnea* and *I. verbascoidea*. *I. carnea* can be found throughout the tropics

worldwide, whereas *I. verbascoidea* is an African species by herbarium record,[32] although the report of its containing swainsonine comes from Brazil.[29] Only a single species of the Malvaceae, *Sida carpinifolia*, contains swainsonine (Table 2).[31]

SWAINSONINE-PRODUCING FUNGI

For many years it was thought that swainsonine was a plant-derived secondary metabolite; however, recent research suggests otherwise. A swainsonine-producing ascomycete, *Undifilum oxytropis* (Pleosporales), an endophyte associated with *O. lambertii*, *Oxytropis kansuensis*, and *Oxytropis sericea*, is reported to produce swainsonine (Table 1; Figure 2).[33,34] Initial studies described this endophyte as an *Embellisia* species.[35] The *Undifilum* genus (Pleosporales) is phylogenetically related to the genera *Alternaria*, *Embellisia*, and *Ulocladium*.[34] On the basis of molecular and morphological characteristics, three unique *Undifilum* species, *Undifilum cinerum*, *Undifilum fulvum*, and *Undifilum oxytropis*, have been found and identified among the three North American locoweed taxa *A. mollissimus*, *A. lentiginosus*, and *O. sericea*, respectively (Table 1).[34,36] This is in contrast to the swainsonine-containing *Astragalus* and *Oxytropis* species examined to date in China, which all have the same endophyte species, *U. oxytropis* (Table 1).[22] A swainsonine-producing *Undifilum* sp. has also been identified in the Australian species *S. canescens* (Table 1); molecular and morphological data suggest it is a novel species as well.[37] To date, the swainsonine-containing *Astragalus*, *Oxytropis*, and *Swainsona* spp. evaluated for the presence of an *Undifilum* spp. by PCR are associated with an *Undifilum* spp. (Table 1).[16,22,37] *Undifilum* spp. can be cultured from seeds and above-ground plant tissues; however, they have not been cultured from below-ground tissues.[33] *Undifilum* spp. are primarily found in the seed coat as they can be cultured from the seed coat but not the embryo.[38] As a result, plants derived from the embryo where the seed coat has been removed contain little or no swainsonine.[38] Using microscopy, *U. oxytropis* was detected growing between cells in vegetative tissues of *O. sericea*, providing further support that it is an endophyte.[39]

Recently, a swainsonine-producing endosymbiont in the ascomycete order Chaetothyriales was isolated from *I. carnea* (Table 1).[40] This endosymbiont was cultured from seeds and

plants and detected by PCR in plants containing swainsonine. Unlike the locoweed endophyte, this endosymbiont grows as an epiphyte on the leaf surface of plants containing swainsonine (Figure 3). The epiphyte/endosymbiont was not observed on

Figure 3. Photograph of *Ipomoea carnea* leaf showing the Chaetothyriales fungal endosymbiont that produces swainsonine.

the surface of leaves from plants lacking swainsonine that were derived from fungicide-treated seeds. Plants derived from fungicide-treated seeds did not contain swainsonine but rather contained calystegines, nortropane alkaloids that are also glycosidase inhibitors. The calystegines are also found at similar concentrations in the control non-fungicide-treated plants.[40]

Swainsonine has been detected in other phylogentically disjunct groups of Basidiomycetes and/or Ascomycetes. *Rhizoctonia leguminicola* (Cantharellales), a basidiomycete, is a fungal pathogen of red clover (*Trifolium pratense*) that causes black patch disease.[41] *R. leguminicola* produces swainsonine as well as the indolizidine alkaloid slaframine, which is responsible for the slobbers syndrome in horses.[41,42] Recent data suggest that this fungus is misclassified and is actually an ascomycete (R. Creamer, personal communication). *Metarhizium anisopliae* (Hypocreales), an ascomycete, produces swainsonine and is an entomopathogen that attaches to the outside of an insect, grows internally, and causes death.[43] Lastly, a preliminary study suggests two ascomycetes, *Fusarium trinctum* and a *Schizophyllum* sp., may also produce swainsonine.[44] These fungi were isolated from Chinese swainsonine-containing *Astragalus* and *Oxytropis* species and their rhizosphere soils. More research is needed to determine if *F. trinctum* and the *Schizophyllum* sp. produce swainsonine as there was no detailed analytical work performed such as mass spectrometry coupled to liquid or gas chromatography.

PLANT/ENDOPHYTE RELATIONSHIP

Multiple factors may influence the interaction of plant and endophyte and ultimately determine swainsonine concentrations in planta. Some considerations include, but are not limited to, different plant parts and the phenological stages of the plant. Other factors include, but are not limited to, different plant species, varieties, and populations as well as the respective endophyte associated with each.

Secondary metabolites often differ among plant parts and as a function of plant phenology. Swainsonine is found in all plant parts with greater concentrations in above-ground parts than in below-ground parts in *Astragalus* spp. and *O. sericea* (Figure 4A).[45,46] Furthermore, swainsonine concentrations vary season-

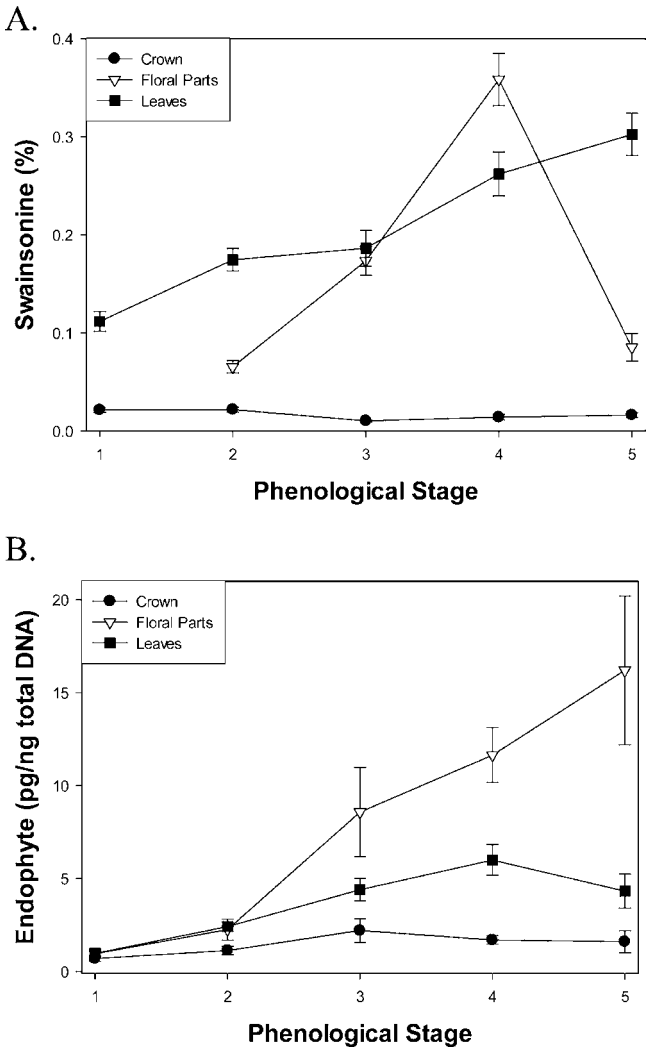

Figure 4. (A) Swainsonine concentrations (%) and (B) endophyte amounts (pg/ng total DNA) in different plant parts of *Oxytropis sericea* from Cuchara, CO, USA, as a function of phenological stage. Mean swainsonine concentrations and endophyte amounts ± the standard error at the different phenological stages (stage 1, vegetative; stage 2, early flower; stage 3, late flower/early pod; stage 4, full pod/mature seed; stage 5, senesced) are shown. Adapted from data presented in Cook et al.[47]

ally or as a function of phenology.[47,48] In *O. sericea*, swainsonine concentrations increase in above-ground tissues throughout the growing season until the plant reaches maturity (Figure 4A).[47] Young newly developing tissues have the least amount of swainsonine, whereas more mature tissues have more swainsonine.[47] As plants senesce, swainsonine concentrations decrease significantly.[47] Likewise, the endophyte *Undifilum* spp. is found in all plant parts, again with greater concentrations in above-ground parts than below-ground parts with the exception

dx.doi.org/10.1021/jf501674r | J. Agric. Food Chem. 2014, 62, 7326−7334

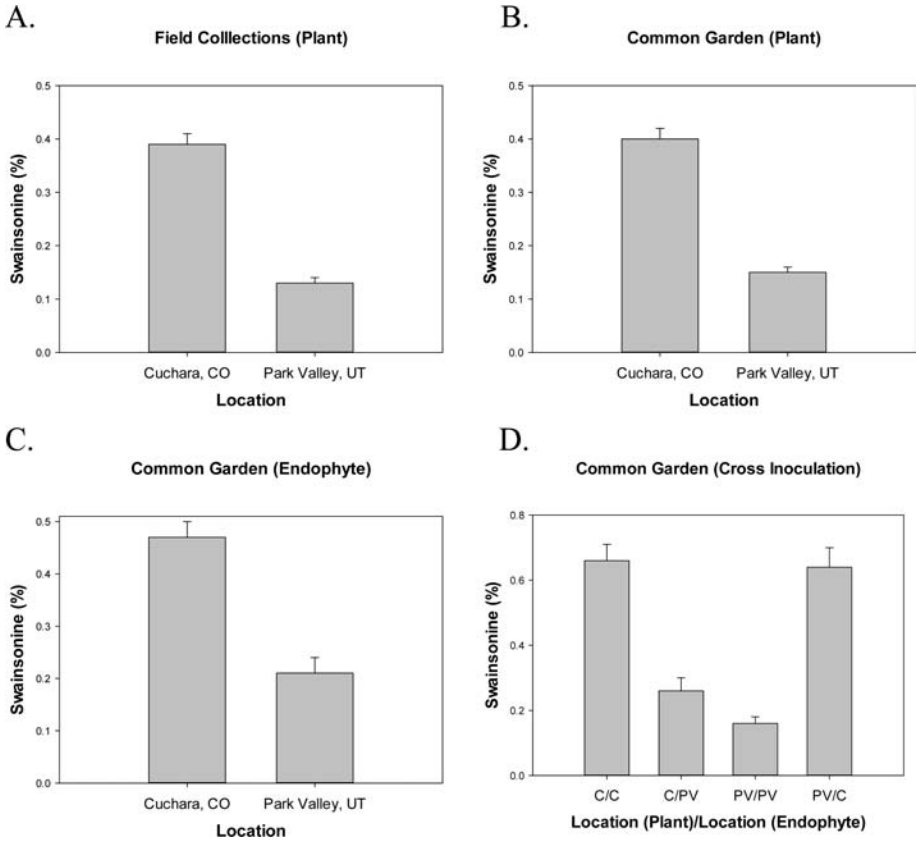

Figure 5. Swainsonine concentrations (%): (A) field collections from two populations, Cuchara, CO, USA (C), and Park Valley, UT, USA (PV), of *Oxytropis sericea*; (B) common garden performed in greenhouse of two *O. sericea* populations; (C) common garden of fungal endophyte isolated from two *O. sericea* populations; (D) common garden of cross inoculation experiment (location: plant/endophyte). Figure adapted from data presented in Cook et al.[49]

of the root crown (Figure 4B).[45,46] The root crown has endophyte amounts more similar to those of above-ground parts, and because many locoweeds are perennial plants, this may serve as a reservoir for the endophyte for the following year's growth.[45,46] In *O. sericea*, endophyte amounts increase in above-ground parts throughout the growing season until the plant reaches maturity (Figure 4B).[47] Swainsonine and endophyte amounts are highly correlated over the growing season in *O. sericea*, indicating that endophyte amount plays a critical role in determining swainsonine concentration in the plant.[47,48]

Environment and genotype of the plant and/or endophyte or an interaction of these factors may influence swainsonine concentrations. Swainsonine concentrations differ spatially among populations of *O. sericea*; for example, mean concentrations were approximately 3 times greater in plants from Cuchara, CO, USA (0.40%), compared to plants from Park Valley, UT, USA (0.15%) (Figure 5A).[47] The following observations suggest that concentration differences between these populations are due to the genotype of the endophyte. First, differences in swainsonine concentrations between populations persisted when plants from these two locations were grown in a common garden (Figure 5B).[49] Second, the respective endophyte, *U. oxytropis*, from each population produced different amounts of swainsonine in vitro when grown under common culture conditions (Figure 5C).[49] Third, a cross inoculation experiment, wherein the endophyte from one population was inoculated onto the embryo from the other location, demonstrated that the endophyte genotype, not the plant genotype nor differences in endophyte amount, were responsible for differences in swainsonine concentration between the two populations (Figure 5D).[49] Although no differences were observed in the internal transcribed spacer sequence between endophyte isolates from the two populations,[49] other genotypic differences may be present that explain the difference in swainsonine production.

Data suggest that the interaction of the plant species and endophyte genotype is a key factor in determining swainsonine concentrations in planta. First, different *Astragalus* and *Oxytropis* species had similar rank order swainsonine concentrations in field collections and greenhouse-grown plants. For example, *Astragalus wootoni* had the highest mean swainsonine concentration followed by similar concentrations in *A. lentiginosus* and *A. mollissimus* var. *mollissimus*, and the lowest concentrations were noted in *O. sericea*.[16,50] Second, similar trends in rank order swainsonine concentrations between field collections and greenhouse-grown plants were observed from the highest to lowest, respectively, in *A. mollissimus* var. *mollissimus*, *O. sericea*, *A. mollissimus* var. *bigelovii*, and *A. mollissimus* var. *matthewsii* or var. *thompsonii*.[51,52] In the latter example the trends in rank order swainsonine concentrations remained the same whether or not the plants were grown under optimum conditions, under water stress, or with a deficiency in nitrogen.[51,52] It is not known if the respective endophyte from each of above species produces different amounts of swainsonine; however, results observed for swainsonine production between the *U. oxytropis* isolates found in the Cuchara, CO, USA, and Park Valley, UT, USA, *O. sericea*

populations suggest this may be the case.[49] Caution should be used not to extrapolate beyond the populations of the highlighted taxa because other populations of these same taxa may have different mean swainsonine concentrations.

Swainsonine concentrations differ among individuals within toxic populations of *Astragalus* and *Oxytropis* spp.[16,24] Swainsonine concentrations segregate into two groups, namely, chemotype 1 plants, which have swainsonine concentrations >0.01%, and chemotype 2 plants, which have concentrations much <0.01% (generally near 0.001% or not detected).[45,46] Initial observations showed a correlation between swainsonine concentrations and the presence of the endophyte, *Undifilum*, as it could be cultured from chemotype 1 plants and was not cultured from chemotype 2 plants.[53] Further studies confirmed these culturing results and demonstrated that the endophyte could be detected by PCR in both groups.[16] These two chemotypes differed significantly in the amount of endophyte they had, further supporting the differences in swainsonine concentrations of the respective host plants.[45,46] Additional studies demonstrated that seeds collected from each corresponding chemotype also differed significantly in swainsonine and endophyte amounts as well.[54]

Endophytes can be horizontally and vertically transmitted.[55] The following observations support the hypothesis that *Undifilum* spp. are vertically transmitted from seed to progeny. Progeny derived from seeds of *Astragalus* and *Oxytropis* chemotype 1 plants had variable swainsonine and endophyte amounts consistent with both chemotype 1 and chemotype 2 plants.[50] Progeny derived from seeds of a chemotype 2 plant had swainsonine and endophyte amounts consistent with chemotype 2 plants.[50] Chemotype 1 seeds and their resulting progeny, with variable amounts of both swainsonine and endophyte, suggest that there is imperfect transmission of the endophyte, resulting in both chemotypes. Chemotype 2 seeds and their resulting progeny suggest that these seeds lack some critical amount of endophyte necessary to produce sufficient swainsonine to be classified as a chemotype 1 plant.[50]

Seed endophyte amounts and/or a plant endophyte by genotype interaction may be important factors in determining swainsonine concentrations in chemotype 1 and 2 plants. The following observations suggest that seed endophyte amounts at germination are a major determinant in the production of swainsonine and thus the classification of a plant as chemotype 1 or 2. First, plants derived from chemotype 1 seeds, in which the amount of endophyte was reduced by seed coat removal or fungicide treatment, had swainsonine and endophyte amounts consistent with those of chemotype 2 plants.[54] Results from the seed coat removal experiment were consistent with previous results reported by Oldrup et al.[38] Second, plants derived from *Undifilum*-inoculated chemotype 1 and chemotype 2 embryos had swainsonine and endophyte amounts consistent with those of chemotype 1 plants.[54] Similar results were observed for both *Astragalus* and *Oxytropis* species. If a plant endophyte by genotype interaction was a key determinant, one would have expected that plants derived from an inoculated chemotype 2 embryo would have had swainsonine and endophyte amounts similar to those of a chemotype 2 plant.[54]

INFLUENCE OF ENVIRONMENTAL FACTORS ON SWAINSONINE CONCENTRATIONS

As swainsonine is an alkaloid, one may suspect that nitrogen availability could influence its production. *Astragalus* and *Oxytropis* species are legumes and are known for forming symbioses with nitrogen-fixing bacteria, thus altering the nitrogen status of plants.[56] Swainsonine concentrations increased in plants inoculated with one strain of *Rhizobium* but not others, suggesting an interaction between the two classes of symbionts.[56] The *Rhizobium*-inoculated plants with the positive swainsonine response had more leaves, more clusters, and greater leaf biomass. These changes in swainsonine and plant physiological measures likely resulted from increased nitrogen availability to the plant and endophyte.[56] However, others have shown that when nitrogen was supplied through fertilizer to locoweed species with different mean swainsonine concentrations, there were no consistent differences in swainsonine concentrations across locoweed taxa either at deficient or optimum nitrogen amounts.[51] All species regardless of mean swainsonine concentration responded positively to nitrogen in terms of biomass and leaf photosynthesis and pigments.[51] Additionally, other experiments showed no differences in swainsonine concentrations in *O. sericea* or *U. oxytropis* when grown under optimum or deficient nitrogen conditions.[38] These results suggest that a given endophyte may produce a defined conentration of swainsonine per unit biomass notwithstanding nitrogen availability. It is critical to note that the total pool of available swainsonine is higher in plants under optimum nitrogen conditions because plant biomass is increased.

Water status of the plant may influence swainsonine concentrations. Swainsonine concentrations were reported to be significantly greater compared to controls in *O. sericea* plants and *U. oxytropis* isolates cultured from these plants that were water-stressed.[38] Further studies by Vallotton et al.[52] demonstrated that swainsonine concentrations increased in some species in response to water deficit but not in others such as *O. sericea*. Swainsonine concentrations increased only in taxa with medium and high swainsonine concentrations. In the species where swainsonine concentrations did change, concentrations changed only after the third water deficit period. Furthermore, in the various plant species there was little evidence for a growth trade-off in physiological measures such as shoot and root biomass, relative growth rate, or photosynthetic rate from taxa differing in mean swainsonine concentrations. The differential effect of water stress in *O. sericea* may be a result of plants being grown in tissue culture on artificial media in one experiment, whereas in the other experiment the plants were grown in soil in pots.[38,52]

It is unclear if herbivory from insects or large ungulates influences swainsonine production. Swainsonine concentrations did not change in response to clipping used to simulate herbivory.[57] There are no reports investigating the bioactivity of swainsonine against insects, fungi, or bacteria, with the exception of one preliminary study that suggested swainsonine had no effect on a native weevil herbivore of locoweeds.[58] Lastly, swainsonine appears not to deter grazing by large ungulates, as animals take 2−3 weeks to show clinical signs and continue grazing locoweeds after becoming intoxicated.[59]

FUTURE DIRECTIONS

In the past 15 years, knowledge concerning swainsonine and fungal relationships has changed dramatically. In summary, the following observations support the assertion that swainsonine is a fungal-endophyte-derived secondary metabolite and is not produced by the host plant in the legume genera and *I. carnea*: (1) Legume species and *I. carnea* that contain swainsonine are infected with *Undifilum* species[22,33−37] or a Chaetothyriales

endosymbiont,[40] respectively. (2) Plants derived from fungicide-treated swainsonine-containing legume and *I. carnea* seeds have no detectable swainsonine or have concentrations <0.001%.[40,54] (3) *Undifilum* species and the Chaetothyriales isolate that were isolated from their respective hosts produce swainsonine in vitro.[22,33,34,37,49] Additional studies on native legumes demonstrate further that swainsonine is a fungal-endophyte-derived secondary metabolite. First, plants derived from *Astragalus* and *Oxytropis* embryos where the seed coat was removed have no detectable swainsonine or have concentrations <0.001%.[38,54] Second, plants derived from *Undifilum*-inoculated embryos have swainsonine concentrations >0.01%.[54]

There are yet unanswered questions that would be important to solving poisoning problems worldwide. The identification of plant taxa containing swainsonine defined to date are primarily a result of episodes of livestock poisoning that result in the plant screening for swainsonine. A systematic examination for swainsonine in taxa from the six plant genera that contain swainsonine, namely, *Astragalus*, *Oxytropis*, *Swainsona*, *Ipomoea*, *Turbina*, and *Sida*, would be valuable to assess future risk. A modified swainsonine extraction method that was recently published[60] allows for the rapid extraction of hundreds of samples simultaneously and could be used to accomplish this objective. Additionally, herbarium specimens in which a small amount of material is removed from a voucher specimen could be screened rather than using field collections. This would facilitate the LC-MS screening of hundreds of taxa in a short amount of time, as verified by a recent paper that shows swainsonine can be detected in herbarium samples.[23] This same material could be screened for the presence of the corresponding fungal endophyte. Furthermore, the presence or absence of swainsonine could be validated in the legumes listed in Table 1. This approach would strengthen the foundation for future work on genetic and environmental factors related to swainsonine and endophyte concentrations.

The biosynthesis of swainsonine should be investigated to identify and characterize the genes that encode the proteins in the swainsonine biosynthetic pathway. To facilitate this work, the biochemical pathway for swainsonine biosynthesis has been investigated in the fungi *R. leguminicola* and *M. anisopliae*.[61,62] Swainsonine is derived from lysine, which is converted into pipecolic acid. Two precursors of swainsonine in the *R. leguminicola* biosynthetic pathway were also detected in the shoots of Diablo locoweed (*Astragalus oxyphysus*).[61,63] As a result, the investigators proposed that the biosynthetic pathway of swainsonine in *R. leguminicola* is similar to the pathway in locoweeds.[63] Subsequently, in *Astragalus* and *Oxytropis* species, swainsonine has been shown to be produced by *Undifilum* species,[33,34,37] which supports the presence of a common pathway in fungi. Investigators have recently developed a transformation system to genetically manipulate *U. oxytropis* that will facilitate this work.[64] These same investigators also knocked out the saccharopine reductase gene from *U. oxytropis*, a protein involved in lysine metabolism, and showed that the fungus had increased swainsonine amounts.[65]

A seed-transmitted endophyte is responsible for the biosynthesis of swainsonine in the legume and morning glory families; thus, methods may be developed to disrupt the transmission of this endophyte to seeds. The swainsonine-containing locoweed and morning glory species are native plants, so following the grass model by developing germplasm that lacks the endophyte or has a nontoxic version of the endophyte is not an option, as these native range plants are not planted in a pasture system like tall fescue and perennial ryegrass.

The preponderance of evidence to date indicates that swainsonine is found in plants due to an interaction between the host and a fungal endosymbiont. Additional research could be performed demonstrating that *Chaetothyriales* spp. are associated with other swainsonine-containing morning glory species as this has been demonstrated only for *I. carnea*. Research could also be performed to determine if the presence of swainsonine in *Sida carpinifolia* is due to a fungal endosymbiont. We anticipate that a fungal endosymbiont will be found in association with other swainsonine-containing morning glory species and *S. carpinifolia*. Lastly, we anticipate that whenever swainsonine is found in a given plant taxa, swainsonine will be associated with a fungal endosymbiont responsible for its production.

explore how secondary compounds isolated from nectar and/or pollen affect the behavior, reproduction, and/or survival of pollinators. Second, because pollinators are often able to survive the consumption of secondary compounds in nectar or pollen, we review the biochemical, physiological, and behavioral mechanisms by which pollinators cope with their consumption. Given that bees are the dominant pollinators globally, we focus most of our review on how bees cope with secondary compound consumption and only touch on other types of pollinators, such as Lepidoptera and birds. Finally, we propose avenues for future research on the chemistry, biochemistry, and ecology of secondary compounds in floral rewards from the plant's and the pollinator's perspectives.

SECONDARY COMPOUNDS IN NECTAR AND POLLEN: CASE STUDIES AND THEIR EFFECTS ON POLLINATORS

Several genera of poisonous plants are found in rangelands throughout the world and the western United States. These plants are typically visited by a suite of generalist pollinators or, more rarely, by select specialists. Here we highlight eight genera of plants (Figure 1), including their pollinators, secondary compounds, and relevant literature describing the presence and concentrations of these secondary compounds in floral rewards as well as their effects on pollinators (Table 1). We focus on alkaloid-containing plants as estimates suggest that 10−25% of angiosperm species contain alkaloids, and alkaloids are well-known to mediate plant−animal interactions.[21]

Figure 1. Floral images of select genera of poisonous plants found in rangelands throughout the world and the western United States: (A) *Zigadenus elegans* (= syn. *Anticlea elegans*); (B) *Veratrum californicum* (= syn *V. tenuipetalum*); (C) *Delphinium barbeyi*; (D) *Aconitum columbianum*; (E) *Nicotiana attenuata*; (F) *Lupinus prunophilus* (= syn. *L. polyphyllus*); (G) *Senecio serra*. Photographs provided courtesy and copyright of Al Schneider (www.swcoloradowildflowers.com).

***Zigadenus* spp. (= syn. *Amianthium*, *Anticlea*, *Stanthium*, and *Toxicoscordion*;[22] Death Camas; Melanthiaceae).** Reports show that several *Zigadenus* species, including *Zigadenus nuttallii* and *Zigadenus paniculatus*, are visited by a single bee, *Andrena astragali*, or a subset of the bee community in the family Halictidae, whereas others such as *Zigadenus elegans* are visited by flies.[23−25] *Zigadenus* spp. contain a group of cevanine-type steroidal alkaloids (Table 1) including esters of germine, protoverine, and zygadenine.[26−28] Zygacine, **1** (Figure 2), an ester of zygadenine, is the major alkaloid in *Z. paniculatus* and *Zigadenus venenosus*.[27,28] These neurotoxic alkaloids bind open voltage-sensitive calcium channels[29] and are toxic to mice, sheep, and cattle.[30,31] Humans have also been poisoned accidentally via consumption of death camas bulbs.[30] Zygacine and related alkaloids can be detected in all above-ground vegetative parts.[28] Moreover, preliminary data suggest that zygacine can be detected in floral rewards, including nectar and pollen of *Z. paniculatus*.[32] In an experiment, adults of the generalist bee *Osmia lignaria* were paralyzed and died soon after feeding on biologically relevant doses of zygacine,[32] matching results suggesting toxicity of nectar and pollen of *Z. venenosus* to honey bees (*Apis mellifera*).[33] Larval progeny of *O. lignaria* also died when they were fed provisions with zygacine.[32] The authors suggest that the presence of zygacine in nectar and pollen may explain the absence of generalist pollinators visiting this plant and that *A. astragali* and pollinating flies may have adaptations to cope with consumption of zygacine.

***Veratrum* spp. (Corn Lily; Melanthiaceae).** The dominant floral visitors of *Veratrum* spp., such as *Veratrum album*, are ants, flies, and beetles.[34] In *V. album* there was also a single record of a bee belonging to the Halictidae visiting the flowers.[34] *Veratrum* spp. contain a series of steroid alkaloids termed azasteroids (Table 1), such as cyclopamine, **2** (Figure 2), of which there are different groups, including veratranine, jervanine, and cevanine; the cevanine types are similar to those found in *Zigadenus* spp.[35] These alkaloids are found in roots as well as vegetative parts and, like zygacine, are also neurotoxins that bind open voltage-sensitive calcium channels.[29] Consuming alkaloids from *V. album* suppresses larval growth in house flies (*Musca vicina*), an effect that dwindles as larvae mature and has been reported in a number of nonpollinating insect species,[36] suggesting negative post-ingestive consequences for

Table 1. Ecology and Secondary Chemistry of Select Poisonous Plants of the Western United States and Impacts on Floral Visitors

plant genus	secondary chemistry	primary pollinators	effects on floral visitors
Zigadenus	cevanine-type steroidal alkaloids	flies, specialized bee *Andrena astragali*, some bees in the Halictidae	zygacine causes mortality in *Osmia lignaria*[32]
Veratrum	azasteroid-type steroidal alkaloids	ants, flies, beetles, rarely bees	induces mortality in house flies and honey bees[36,38,39]
Delphinium	lycoctonine-type C_{19} norditerpene alkaloids	bees (especially bumble bees), hummingbirds	dose-dependent deterrence and reductions in bee activity[4,7]
Aconitum	aconitine-type C_{19} diterpene alkaloids	bees (especially bumble bees), hummingbirds	detected at trace concentrations in bumble bee tissues but effects on bees unknown[48]
Nicotiana	piperidine and pyridine alkaloids	bees, hawkmoths, hummingbirds	dose-dependent deterrence and reductions in bee health and survival[9,15,19]
Lupinus	piperidine and quinolizidine alkaloids	solitary and social bees	sparteine has both deterrent and toxic effects on honey bees[9]

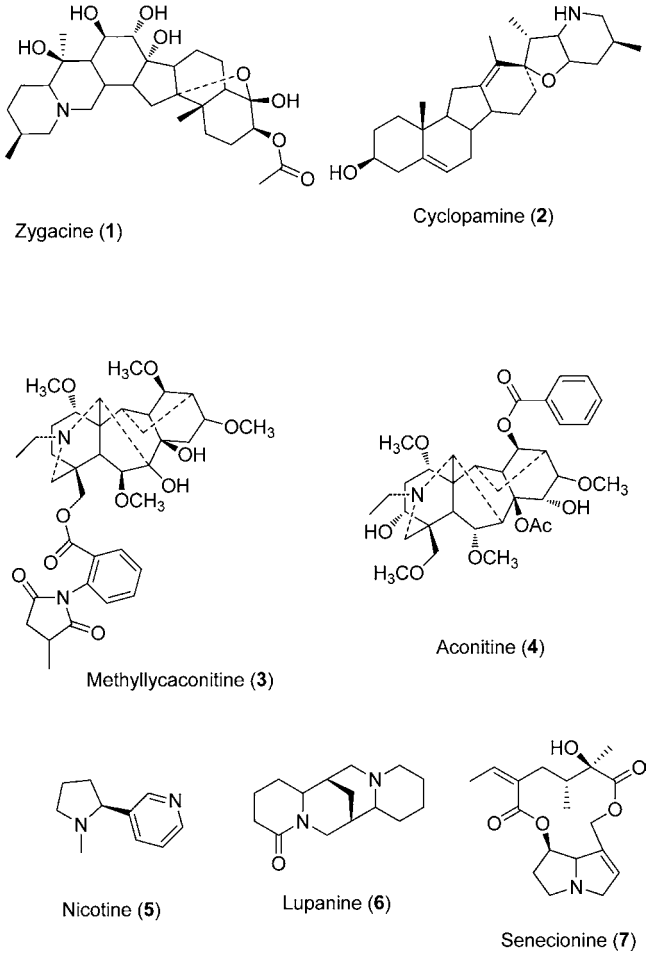

Figure 2. Chemical structures of zygacine, **1**, a steroidal alkaloid from *Zigadenus* spp.; cyclopamine, **2**, a steroidal alkaloid from *Veratrum* spp.; methyllycaconitine, **3**, a norditerpene alkaloid from *Delphinium* spp.; aconitine, **4**, a diterpene alkaloid from *Aconitum* spp.; nicotine, **5**, a pyridine alkaloid from *Nicotiana* spp.; lupanine, **6**, a quinolizidine alkaloid from *Lupinus* spp.; and senecionine, **7**, a pyrrolizidine alkaloid from *Senecio* spp.

pollinator development. Moreover, alkaloids of *V. album* are sequestered by the specialist sawfly *Rhadinoceraea nodicornis*, reducing predation by ants, spiders, and bush crickets.[37] However, no studies to our knowledge have documented the identities and concentrations of alkaloids in *Veratrum* spp. floral rewards, although reports exist of *Veratrum californicum* toxicity to honey bees foraging in the field.[38,39] The structural similarity between some of the *Veratrum* spp. alkaloids and those found in *Zigadenus* spp. leads to speculation of the possibility that these compounds may deter generalist bee pollinators from visiting these plants, as has also been speculated in *Zigadenus* spp. This hypothesis warrants further investigation.

***Delphinium* spp. (Larkspur; Ranunculaceae).** The dominant floral visitors of *Delphinium* spp. are generalists, including a variety of bees, especially bumble bees, as well as hummingbirds.[40,41] The nectar of *Delphinium* flowers is recessed within a nectar spur, so only bees and hummingbirds with a long proboscis or bill can reach the nectar rewards. *Delphinium* spp. contain a series of C_{19} norditerpene alkaloids mainly of the lycoctonine type (Table 1); several of these alkaloids are usually found in any given species. These lycoctonine C_{19} norditerpene alkaloids are divided in two structural classes, the *N*-(methylsuccinimido)anthranoyllycoctonine (MSAL) type, **3** (Figure 2), and the 7,8-methylenedioxylycoctonine (MDL) type, the former being more toxic and the latter less toxic.[42] These alkaloids bind to acetylcholine receptors and are toxic to mammals and insects.[43−45] Consumption of these plants causes significant cattle losses on an annual basis throughout the western United States.[42] *Delphinium barbeyi* and *Delphinium nuttallianum* contain alkaloids in vegetative and floral parts as well as the floral rewards, including nectar and pollen.[4] Alkaloid concentrations differ between floral rewards, vegetative, and floral parts (Figure 3), with alkaloid concentrations in the nectar being at

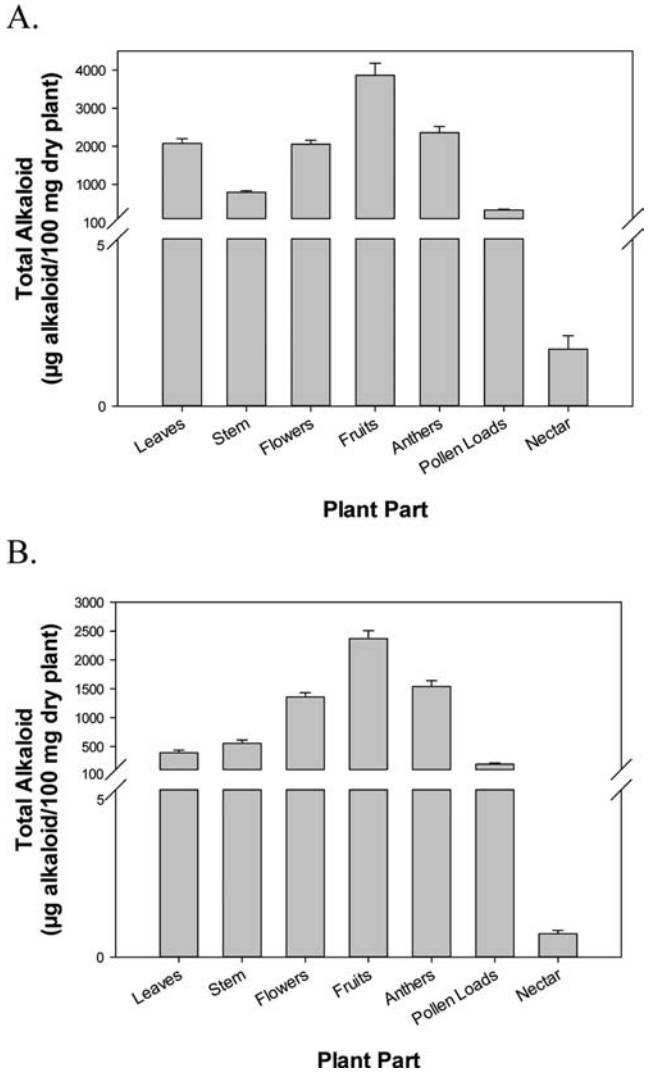

Figure 3. Total alkaloid amounts in different plant parts of (A) *Delphinium barbeyi* and (B) *Delphinium nuttallianum*. Bars are means + SE.

least 450 times less than any vegetative or floral part in both species. Alkaloid concentrations in *Delphinium* pollen are likely to be intermediate to concentrations in pollen loads and anthers as anthers contain other tissues that may overestimate actual pollen concentrations, whereas pollen loads contain nectar that may underestimate pollen concentrations.[4] The alkaloid profile observed in floral rewards is qualitatively similar to the profile found in vegetative parts in both species. Bees fed sugar water supplemented with *Delphinium* alkaloids exhibited

dx.doi.org/10.1021/jf500521w | J. Agric. Food Chem. 2014, 62, 7335−7344

reduced activity, but only at concentrations at least 50 times higher than those detected in floral nectar.[4,7] *D. barbeyi* flowers supplemented with alkaloids had fewer visits by bee pollinators, and bees spent less time per visit, but the effect was concentration dependent.[7] Whereas *D. barbeyi* nectar alkaloid concentrations within the natural range had no effect on bee behavior, alkaloid concentrations higher than reported in nature strongly deterred pollinators, suggesting an adaptive benefit to low nectar alkaloid concentrations to encourage pollination.[7]

***Aconitum* spp. (Monkshood; Ranunculaceae).** *Aconitum* spp. are typically visited by generalist pollinators, including bumble bees and hummingbirds, and in rare instances by specialists.[46−48] The flowers of *Aconitum* spp. are characterized by one of their petaloid sepals forming a hood that holds two nectar spurs on stalks; thus, like *Delphinium* spp., nectar is only accessible to visitors with a long proboscis. *Aconitum* spp. contain a series of C_{19} diterpene alkaloids mainly of the aconitine type, **4** (Table 1; Figure 2). Aconitine-type alkaloids are neurotoxic and cardiotoxic to insects and mammals,[30,49] including livestock; however, there are few livestock morbidity reports from consumption of *Aconitum* as it is seldom eaten in sufficient quantity to cause mortality.[30] Gosselin et al.[48] reported alkaloid concentrations in different plant parts as well as floral rewards in *Aconitum septentrionale*. Alkaloid concentrations in pollen were similar to leaf and flower concentrations, whereas concentrations in nectar were significantly lower. Lappaconitine was the dominant alkaloid in all plant parts investigated including the floral rewards, although some differences were observed in the rank order of abundance of other alkaloids between other tissues and floral rewards. *A. septentrionale* pollen contains alkaloids in concentrations above the LD_{50} concentrations for most alkaloids tested by Detzel and Wink[9] on honey bees, suggesting the potential for post-consumptive effects on pollinator performance. However, effects of *A. septentrionale* alkaloids on bumble bee pollinator larval survival and performance remain unknown. Additionally, Gosselin et al.[48] detected the alkaloid lappaconitine in the tissues of the specialist bumble bee *Bombus consobrinus* but not the generalist *Bombus wurflenii*. Whether this observation has any biological significance or results in a fitness benefit is not known.

***Nicotiana* spp. (Tobacco; Solanaceae).** *Nicotiana* spp. are visited by a suite of generalist pollinators, including bees, hawkmoths, and hummingbirds. *Nicotiana* spp. contain several piperidine and pyridine alkaloids (Table 1), including nicotine, **5** (Figure 2), that can be toxic to insects and mammals.[50,51] Nicotine acts as a stimulant and binds as an agonist to nicotinic acetylcholine receptors. Nicotine is synthesized in the root and transported to all above-ground plant parts, including floral rewards,[50,52,53] with nicotine concentrations in leaves and flowers being greater than that in nectar. In general, species that contain greater concentrations of nicotine in leaves have greater amounts of nicotine in their nectar.[53] Nicotine can reduce the amount of time spent per flower, as well as the amount of nectar removed per visit, by hawkmoth and hummingbird pollinators.[8,54] However, the deterrent effects of nicotine in nectar can be dose-dependent[15,55] and dependent on nectar-sugar concentration,[15] and even at the highest concentrations of nicotine in artificial nectar, there is not complete deterrence.[15] Moreover, Singaravelan et al.[19] found that nectar with low nicotine concentrations is preferred by honey bees over nectar that contains no nicotine, suggesting that low nicotine concentrations may act as attractants or feeding cues. Nicotine consumption also has dose-dependent effects on honey bee health and survival.[9,14,15]

***Lupinus* spp. (Lupine; Fabaceae).** The pea-like flowers of *Lupinus* spp. have an upper banner petal and two lower petals fused into a keel. Pollinators must be strong enough to push down the keel to gain access to the pollen, and in some cases nectar, with bees being the most common pollinators. *Lupinus* spp. contain piperidine and quinolizidine alkaloids (Table 1), such as lupanine, **6** (Figure 2), that bind to nicotinic and muscarinic acetylcholine receptors. These alkaloids are toxic to livestock and are thought to provide protection against natural enemies, including insects.[56−58] Detzel and Wink[9] documented alkaloids in the pollen of *Lupinus polyphyllus*, with pollen alkaloid concentrations being 5 times less than that in flowers and 27 times less than that in leaves. Sparteine, identified in *L. polyphyllus* pollen, has both deterrent and toxic effects on honey bees in the laboratory.[9]

Other Genera. There are several other toxic rangeland plant genera of the western United States, including *Senecio* spp. (Asteraceae) and *Echium* spp. (Boraginaceae). *Senecio* spp. are visited by a suite of generalist pollinators; *Echium* spp. such as *Echium vulgare* can be visited by generalist species of bumble bees in their introduced range in North America but are also the host plants of several oligolectic bees in their native range.[59] *Senecio* and *Echium* spp. both contain pyrrolizidine alkaloids.[30,60] Pyrrolizidine alkaloids, such as senecionine, **7** (Figure 2), are hepatotoxic to livestock and are thought to provide protection to the plants against natural enemies, including insects.[61] These alkaloids have been detected in the pollen and/or flowers (or florets) of different species within each genus.[62] Moreover, pyrrolizidine alkaloids have been detected in honey from *Echium*[62−65] and *Senecio*;[66] whether these alkaloids in honey come from pollen, nectar, or both reward sources remains to be determined. 1,2-Unsaturated tertiary pyrrolizidine alkaloids of *Senecio vernalis* were toxic to honey bees at a concentration of 2% in the laboratory, and honey bees were deterred by pyrrolizidine-*N*-oxides at concentrations >0.2%.[17] How common these effects are on the preference and performance of other pollinators remains to be investigated.

Synthesis. Three general patterns emerge from examination of the case studies. First, secondary compound concentrations in nectar tend to be lower than in pollen or leaves. Second, pollen secondary compound concentrations can, in some cases, be equal to or even higher than those concentrations found in leaves. Third, secondary compounds in floral rewards can act as filters on the community of species visiting flowers, sometimes discouraging visitation by nonspecialist pollinators or nectar robbers or thieves, which could increase the chance of pollen transfer for plants. The ecological and evolutionary implications of these patterns for both plants and pollinators remain to be explored in most cases, and the biochemical and physiological mechanisms behind secondary compounds in nectar are an active area of research.[3]

HOW DO POLLINATORS COPE WITH PLANT SECONDARY COMPOUNDS?

Given that pollinators are exposed to secondary compounds in their diet and frequently survive after consuming these compounds, pollinators, like herbivores, may have mechanisms to cope with the consumption of secondary compounds. Indeed, pollinators and herbivores likely use some of the same biochemical, physiological, and behavioral mechanisms. We focus our review primarily on how bee pollinators survive the

consumption of secondary compounds, but we note that the frugivory literature[67] may also provide testable predictions for how vertebrate pollinators cope with the consumption of not only fruit but also nectar or pollen with secondary compounds. Moreover, we broaden this portion of the review beyond alkaloids to include other classes of secondary compounds that can occur in floral rewards and how pollinators cope with their consumption, including phenolics and terpenoids.

Biochemical and Physiological Mechanisms. There are a variety of biochemical and physiological mechanisms that may help bees survive the consumption of secondary compounds, including detoxification, conjugation, target-site insensitivity, sequestration, rapid excretion, and endosymbionts. Although these mechanisms have been studied in greater depth in herbivores, there is some evidence that bees and/or other pollinators also use some of the same types of mechanisms, with the most literature documenting detoxification.

Detoxification. A common way that animals cope with a variety of potentially toxic compounds is through enzymatic conversion to less toxic forms that can then be eliminated. One of the most prominent superfamilies of enzymes is the cytochrome P450 superfamily of monooxygenases that catalyze the oxidation of organic substances. P450s are present in a wide diversity of prokaryotic and eukaryotic taxa, including pollinating bees. For bees, the diversity and activity of P450s have been studied in the most depth in honey bees and to a lesser extent in bumble bees. Honey and bumble bees contain significantly fewer P450 genes than other insect genomes, such as flies;[68] for example, the honey bee genome contains only 46 P450 genes, almost half that contained in other insect genomes.[69] Why bee genomes are relatively depauperate in detoxification genes relative to other insects remains an active area of research, especially given the generalized foraging strategy of most solitary and social bees. However, one relevant hypothesis is that because nectar and sometimes pollen have lower concentrations of secondary compounds than leaves,[4,6,9] natural selection for detoxification genes in bees may be weaker than that in phytophagous insects,[68] the adults of which may nectar-feed but larvae feed on leaf material.

Nonetheless, a number of P450s in bees have been implicated in the metabolism of secondary compounds found in nectar and pollen as well as xenobiotics, such as acaricides used to control *Varroa* mites,[70] and the CYP6 family of P450s has shown expansion relative to other insect genomes and may be involved in the metabolism of phytochemicals found in nectar, pollen, and honey.[69,71] For example, quercetin, a flavonoid found in honey and pollen, is metabolized by five enzymes in the CYP6AS and CYP9Q subfamilies of P450s.[70,71] In a similar vein, phytochemicals found in pollen and honey, such as *p*-coumaric acid, result in the up-regulation of detoxification genes.[72] *p*-Coumaric acid is ubiquitous in pollen and nonfiltered honey and, although unlikely to be toxic to bees, it may serve as a predictable cue for the up-regulation of detoxification genes against a wide variety of secondary compounds. Honey bees are also exposed to plant secondary compounds when they gather resins from vegetation to produce propolis, a sticky substance used in hive maintenance and architecture.[73] A set of propolis-derived phenolic compounds, such as pinocembrin and pinobanksin, are present in most honeys, where they are considered minor contaminants.[74] These compounds have also been shown to up-regulate P450 detoxification genes.[72]

Along with P450s, other enzyme systems may also play a role in metabolic detoxification, including the carboxylesterases (COEs). COEs catalyze the hydrolysis of esters into amino acids and alcohol. For example, albeit to a lesser extent than P450s, COEs may also be responsible for the detoxification of pyrethroids,[75] insecticides derived from pyrethrins naturally occurring in *Tanacetum* spp. daisies. Like the P450s, there are only about half as many COE protein-coding genes compared to other insect genomes.[69] Additionally, the expression and thus activity of the various detoxification genes may vary as a function of bee sex and/or exposure at a particular life history stage.[68]

Conjugation. Conjugation, another form of detoxification, involves the production of a compound that binds to the secondary compound, which is thus rendered harmless and excreted.[76,77] For example, the superfamily of glutathione *S*-transferases (GSTs) can catalyze the conjugation of exogeneous toxins, including pyrethroids (originally derived from plants) and other xenobiotics.[78,79] Treatment with the pyrethroid flumethrin increased GST activity in larvae, pupae, and nurse honey bees.[80] However, in another study exploring honey bee tolerance to pyrethroids, Johnson et al.[75] found that GSTs did not contribute significantly to honey bee pyrethroid tolerance. To our knowledge, the role of conjugation as a countermeasure for secondary compound consumption is not well explored in bees and warrants further research.

Target-Site Insensitivity. Target-site insensitivity occurs when there is a change at a neuroreceptor site for a particular secondary compound that subsequently inhibits or excludes binding, or when there is a change in the number of receptors for a particular compound, and is a primary mechanism by which herbivores can become resistant to pesticides.[81,82] Although the role of target-site insensitivity to secondary compounds is relatively unexplored in bees, it may play a role in other types of pollinators consuming secondary compounds. For example, target-site insensitivity to milkweed (*Asclepias* spp.) cardenolides occurs in a number of herbivores, including the monarch butterfly (*Danus plexippus*; Lepidoptera) and four other insect orders (Heteroptera, Orthoptera, Coleoptera, and Diptera).[83] Because *D. plexippus* adults can also act as pollinators of milkweed and milkweed nectar can contain toxic cardenolides,[84] it is plausible that target-site insensitivity may also play a role in allowing adults to cope with the consumption of secondary compounds. We should note, however, that target-site insensitivity is not universal in herbivores that feed on cardenolides; for example, arctiid moths feeding on cardenolides may use the perineurium surrounding the nervous tissue as a barrier, preventing cardenolides from reaching the Na^+/K^+-ATPase in the central nerve cord.[85] Nonetheless, adults sometimes nectar feed on the same host plants as their folivorous larvae. These cases may provide insights into the biochemical and physiological mechanisms that adult pollinators use to cope with these compounds.[86]

Sequestration. Some foliar herbivores concentrate and retain secondary compounds from their diets, a phenomenon known as sequestration.[87] As most pollinators consume plant material, it is possible that they too sequester secondary metabolites, but this has been studied for only a few pollination systems. Several species of male ithomiine butterflies (Nymphalidae: Danainae) avidly seek and consume floral nectars containing pyrrolizidine alkaloids, which they sequester.[88] These alkaloids deter predators,[89,90] serve as pheromone

precursors, and operate in a sexual selection mating system.[91] In another example, Southeast Asian *Bulbophyllum* orchids attract their fruit fly (Tephritidae) pollinators with phenylpropanoid secretions including zingerone and methyleugenol; male flies sequester these compounds, converting them to sex pheromones.[92−94]

It is possible that bees might also sequester secondary compounds, because their diet consists almost entirely of nectar and pollen that often contain those compounds, and other herbivorous Hymenoptera such as sawflies commonly sequester compounds such as iridoid glycosides and glucosinolates.[87] In the only study to our knowledge that has investigated sequestration by bees, Gosselin et al.[48] reported trace amounts of six alkaloids in the tissues of a bumble bee species foraging on *Aconitum septentrionale*, including the aconitine-type alkaloid lappaconitine, the major alkaloid in pollen and nectar; however, there was no evidence that bees concentrated the alkaloids. Sequestration is most often found in insects with specialized diets, and given that ∼20% of bees specialize in their pollen collections, the possibility of sequestration of secondary compounds by bees is a research avenue that deserves further attention.

Rapid Excretion. Rapid excretion of secondary compounds either with or without detoxification may serve as another mechanism by which pollinators cope with the consumption of these compounds. One striking example is the reduced gut retention time following consumption of secondary compounds involving Palestine sunbirds (*Nectarinia osea*) feeding on the nectar of tree tobacco (*Nicotiana glauca*). The nectar of *N. glauca* contains the pyridine alkaloids anabasine and nicotine. Gut transit time of a sugar solution containing either of the pyridine alkaloids was significantly lower when compared to that of birds fed a sugar solution without the alkaloids.[55] The authors suggest that consuming pyridine alkaloids may induce a laxative effect, as is observed in mammals that consume plant material containing pyridine alkaloids, which results in accelerated gut transit time due to increased tone and activity of the intestinal smooth muscles.[95] A laxative effect of secondary compounds may be common in other plant-pollinator systems as well but remains to be tested widely.

Endosymbionts. Many species of invertebrates harbor endosymbiotic microbes in their guts, which may play a role in the detoxification of secondary compounds.[96,97] Bees interact with specific suites of horizontally transmitted bacteria[98,99] that mediate immune responses to gut pathogens[100] and may play a role in digestion of plant foods.[101] Some phytophagous beetles interact with endosymbiotic gut fungi that assimilate carbon from their hosts' diets, sometimes detoxifying alkaloids and other potentially toxic compounds to do so.[96,102] Although a detoxifying effect has not been demonstrated for endosymbiotic fungi of pollinators such as bees, the possibility is worth exploring given that bees harbor a diversity of gut fungi.[103]

Behavioral Mechanisms. Behavioral mechanisms may also help pollinators cope with secondary compounds. Here we highlight three strategies: avoidance, diet mixing, and storage.

Avoidance. Biochemical and physiological mechanisms to cope with secondary compounds usually occur or are induced following compound ingestion. In contrast, behavioral mechanisms such as avoidance (or deterrence) can prevent pollinators from consuming or collecting nectar or pollen with secondary compounds prior to tasting their food (i.e., via olfactory or visual cues) as well as reduce feeding once a foraging choice has been made (i.e., via reduced per-flower visit length or the number of flowers visited per plant). For example, the darkly colored nectar of the South African aloe *Aloe vryheidensis* may serve as a warning to some floral visitors of the bitter-tasting phenolic nectar, albeit other visitors might find such coloration attractive.[104] In comparison, high concentrations of nectar alkaloids in *Gelsemium sempervirens* have no effect on whether or not a plant is visited, but do affect floral visitor behavior once pollinators have tasted the nectar, reducing the proportion of flowers visited per plant and the time spent per flower.[6]

Secondary compounds in floral rewards may not only affect adult foragers but also their offspring when bees collect nectar and pollen to provision to their larvae. Just as adult phytophagous insects can avoid exposing their larvae to toxic plants by not ovipositing on them,[105] adult bees could similarly limit larval exposure to secondary compounds by reduced nectar and pollen gathering from sources with floral secondary compounds. In Lepidoptera, the link between oviposition preference and offspring performance can be genetically controlled.[106] The degree to which such preference−performance matches occur and are genetically determined in bees is less explored. One strong difference, however, between phytophagous insects and bees is that, in some cases, adult phytophagous insects are unable to determine which plants are suitable for their larval offspring,[107] but larvae can move between plant species if poor oviposition choices are made.[108] In contrast, bee larvae typically cannot use movement as a behavior to avoid feeding on unsuitable provisions, including those that may have secondary compounds, and thus are forced to eat provisions that may be distasteful and/or toxic.

Diet Mixing. Like many mammalian herbivores, most bees are dietary generalists and are thus exposed to a great diversity of plant secondary compounds. Mixing the products of many plants could dilute the negative effects of any one compound, thereby allowing generalists to exploit a food base that includes nectar and pollen containing secondary compounds.[109] Research with solitary bees (*Osmia* spp.: Megachilidae) demonstrates that foragers will incur greater energetic costs than necessary to assemble pollen loads from a variety of plant species, rather than a single species near the nest,[110] and that bees may develop normally on pollen mixtures that contain up to 50% of a toxic pollen that is lethal when consumed alone.[111] This increased energy expenditure to collect pollen from a variety of plant species may be a mechanism to prevent larval toxicity and/or to balance nutrient acquisition, although such hypotheses warrant further investigation.

Storage. There is evidence that pollinators can avoid negative consequences of secondary compound consumption through social behaviors such as honey production and storage. Honey is the product of enzymatic conversion and dehydration of floral nectar by honey bees and related Apidae.[112] Glucose oxidase, a product of the hypopharyngeal gland of nurse honey bees, may deactivate (or suppress induction of) alkaloids[113] and lower the secondary compound content of plant nectar within the hive.[14,114] Moreover, honey bees maintain a nest homeostasis that is high in temperature and low in CO_2 relative to the environment, which promotes the modification and/or degradation of phenolic compounds.[114] However, toxic honeys have long been known[115] and may also contain unadulterated secondary compounds such as the grayanotoxins of *Rhododendron* (Ericaceae).[116] Although there are reports of nectars that are toxic to bees[117] and some honey is toxic to humans, we do not know whether such "toxic honeys" are toxic to the bees that

produce them. Future research should examine the role of apparently toxic honey in the ecology of social bees.

FUTURE DIRECTIONS

Exciting challenges remain in the study of secondary compounds in floral rewards. Throughout this review we have highlighted a diversity of topics warranting further investigation. Here we highlight three areas that we believe are particularly promising for future research.

Chemistry and Biochemistry of Secondary Compounds in Floral Rewards. Plant secondary compounds have been quintessential in the study of plant−herbivore interactions, and there is growing recognition that these compounds occur in floral rewards.[1,3] A historical survey of plants suggests the commonality of secondary compounds in nectar,[2] with 55% of plants surveyed containing nonprotein amino acids in their nectar, 36% containing phenolics, and 9% containing alkaloids. However, few studies have identified and measured actual concentrations of secondary compounds in nectar and/or pollen rewards and how they relate to secondary compound expression in a whole-plant context.[4,9,48,53,84,118,119] Measuring secondary compounds in floral rewards within a whole-plant context provides an ideal opportunity to test predictions about compound expression related to optimal defense theory.[84,120] A variety of analytical tools are now available to measure both within-species and among-species variation in floral reward chemistry, including large-scale, nontargeted metabolomics approaches.

There is a dearth of information not only on the identities and concentrations of secondary compounds in floral rewards but also of the origin of these reward components. Especially within the context of nectar, where nectar secondary compounds are produced and how they are added to the nectar remain mysteries in most cases. Studies that measure nectar secondary compounds within a whole-plant context should also consider measuring their identities and concentrations in the phloem sap. Doing so may help to identify those compounds that are manufactured by the nectary itself versus those that come from the phloem sap and thus may be a pleiotropic consequence of plant defense against herbivores. Physiological and molecular research into the secretion mechanisms of secondary compounds may also help to identify compounds that serve an adaptive function.

Costs and Benefits of Secondary Compound Consumption for Pollinators. Studies that have focused on the costs and benefits of secondary compounds in floral rewards have in many cases been phytocentric, measuring their effect on plant fitness via changes in pollinator behavior.[6,119] However, as consumers of nectar and pollen, pollinators such as bees are exposed to a diverse array of secondary compounds in their diet. Thus, there is nearly unlimited opportunity to assess how secondary compounds in a pollinator's diet affect performance and fitness and to assess the mechanisms involved. Since the 1800s, there has been recognition that honeys can become contaminated with floral products from nectar and pollen that are harmful to human health, and so it is logical to extend these effects to natural consumers of nectar and pollen. The handful of studies conducted thus far show variable effects of secondary compounds on pollinator performance, even when the same compound is explored. For example, the nectar alkaloid gelsemine reduced oocyte width in subordinate but not dominant bumble bees of *Bombus impatiens*,[13] whereas the same nectar alkaloid had no effect on larval survival or weight of the solitary bee *Osmia lignaria*.[121] Future research should consider that secondary compounds in floral rewards may have not only costs for pollinator preference, performance, and fitness but also potentially benefits and that the relative costs versus benefits may be dependent on the identify and concentration of secondary compound consumed. Moreover, more mechanistic studies are needed from a diversity of approaches, including molecular, biochemical, physiological, and behavioral, that explore how pollinators cope with and benefit from secondary compound consumption and the potential consequences for interactions with other factors, including xenobiotics and parasites. Given widespread concerns over pollinator declines, a mechanistic exploration into how pollinators survive secondary compound consumption may provide insights into how pollinators handle chemical exposure in rangeland and agricultural habitats.

Role of Secondary Compounds in Pollen. Whereas the costs and benefits of nectar secondary compounds are becoming more widely explored,[1,3] research on secondary compounds in pollen has lagged behind. One challenge with the study of pollen is its dual role, both as a gamete for plants and as a reward for pollen-harvesting bees. Nonetheless, research to date suggests that pollen secondary compound concentrations can sometimes mirror or even be higher than those in flowers or leaves, albeit sometimes less chemically diverse.[4,48,118] Whether pollen secondary compounds are simply a pleiotropic consequence of plant defense and development or whether they serve an adaptive function remains to be tested in most cases. Studies that explore pollen secondary compounds using a comparative phylogenetic approach and that incorporate research both from the plant's and the floral visitor's perspective will provide important scientific insights.

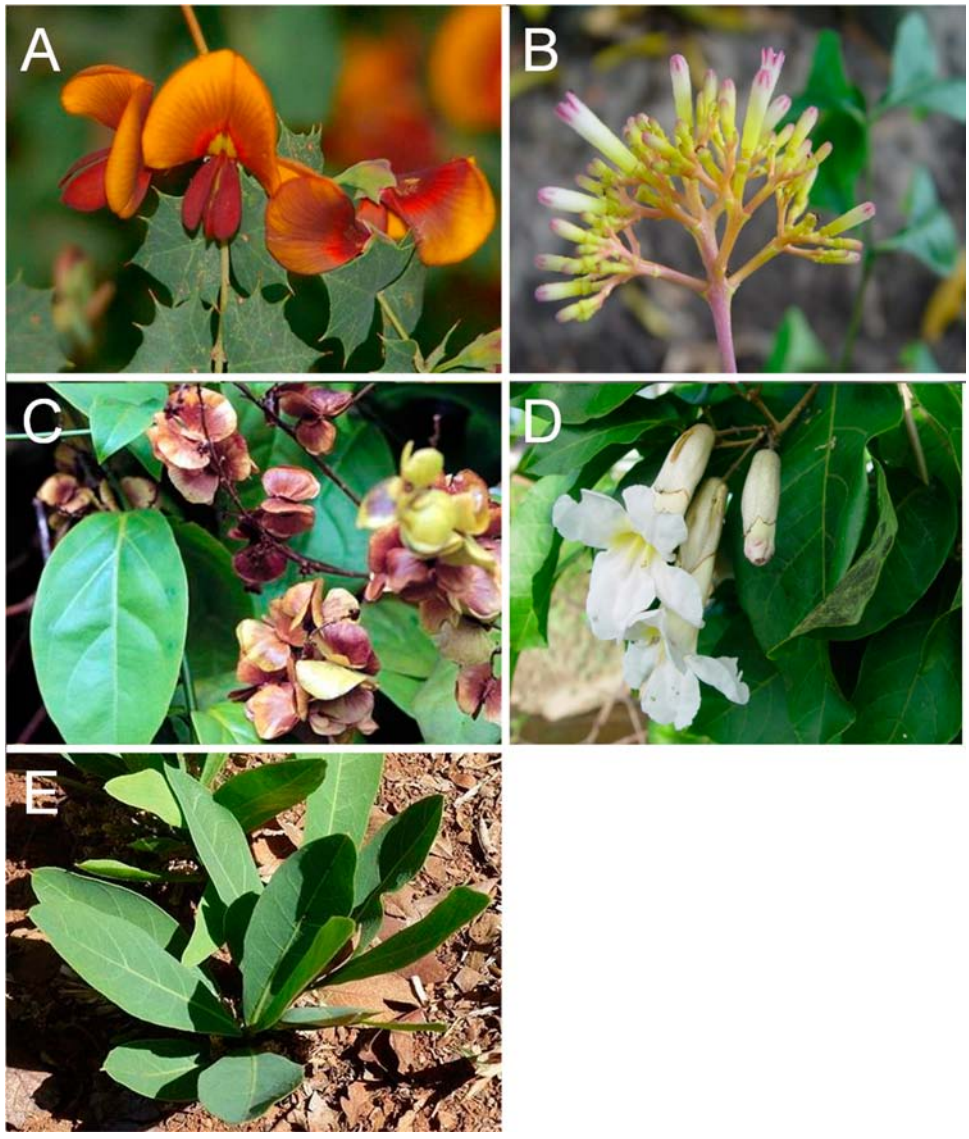

Figure 1. Photographs of representative plants containing monofluoroacetate: (A) *Gastrolobium spinosum*, image courtesy of John E. McLennan; (B) *Palicourea marcgravii*; (C) *Amorimia septentrionalis*; (D) *Arrabidaea bilabiata*; and (E) *Dichapetalum cymosum*, image provided courtesy of JMK (http://commons.wikimedia.org).

concentrations of up to 0.26% in *G. bilobum*, 0.040% in *G. spinosum*, 0.13% in *G. floribundum*, 0.13% in *G. bennettsianum*, and 0.25% in *O. parviflorum*. However, the report warned against extrapolating too much from these values because of the large variation in monofluoroacetate content that was observed within a species. Nonetheless, it was reported that monofluoroacetate concentrations were highest in the reproductive tissues, such as pods, flowers, and young leaves, and much lower in mature leaves and wood.[11−14] Table 1 lists 31 species of *Gastrolobium* and one species of *Acacia* (*A. georginae*) that have been reported to contain monofluoroacetate.[11,13−21] Not listed in Table 1 are five *Gastrolobium* species, *G. appressum*,[11,16] *G. densifolium*,[11,16,17] *G. heterophyllum*,[11,16] *G. ovalifolium*,[9,16] and *G. trilobum*,[16] that have been reported to be toxic but have not been demonstrated to contain monofluoroacetate.

The variability of monofluoroacetate content is documented throughout the *Gastrolobium*/*Acacia* literature. Some of this variation may be due to differences in analysis including the method, the place of analysis, and sampling procedures. However, it is clear that some variation is due to intrinsic biology of the plants. This variation is illustrated by the monofluoroacetate concentration in individual plants within stands of *G. brevipes* (0.0017−0.0099% in leaves and 0.0056−0.030% in pods, expressed as percent dry weight here and all subsequent occurences)[14] and between populations of *G. bilobum* with 0.0010% in leaves and 0.0073% in flowers from one location compared to 0.017% in leaves and 0.11% in flowers from another location.[13] There can be considerable intrastand variability between individual plants growing within meters of each other. For example, the monofluoroacetate concentrations in the leaves of different *G. bilobum* and *G. calycinum* plants within stands ranged from 0.023 to 0.39% and from 0.0029 to 0.058%, respectively.[13] In addition, reports of the presence of high concentrations of monofluoroacetate in leaves of *A. georginae*, *G. bilobum*, *G. calycinum*, *G. oxylobioides*, *G. villosum*, and *G. spinosum* were not confirmed by a ^{19}F NMR analysis. ^{19}F NMR failed to detect monofluoroacetate in leaves from each of these species except *G. bilobum*, for which a concentration 10 times less than reports was measured.[18]

Table 1. Monofluoroacetate-Containing Genera of the Fabaceae (*Acacia*, *Gastrolobium*), Rubiaceae (*Palicourea*), Bignoniaceae (*Arrabidaea*), Malpighiaceae (*Amorimia*), and Dichapetalaceae (*Dichapetalum*, *Tapura*)

[a] *Tanaecium bilabiatum* was previously known as *Arrabidaea bilabiata*.

A recent re-examination of some *Gastrolobium* spp. from Western Australia using a HPLC-APCI-MS method of analysis again documented variability reported in the literature with respect to their monofluoroacetate content (Table 1).[20] The presence of monofluoroacetate was confirmed in *G. bilobum*, *G. calycinum*, *G. parviflorum*, and *G. villosum*. However, none was detected in *G. spinosum*, *G. laytonii*, or a sample of *G. calycinum* that was collected from the Murdoch University Toxic Plant Garden (Perth, Australia), removed from its native environment over two decades ago.[20]

Rubiaceae. *Palicourea* is a genus composed of approximately 200 species, which range in growth habit from small shrubs to trees. The genus is distributed throughout the tropics of the New World.[22,23] *Palicourea marcgravii* was the first poisonous plant studied in Brazil and is the single most important toxic plant in Brazil due to its acute toxicity, palatability, and broad geographical distribution.[2,24] Three other *Palicourea* species, *P. aeneofusca*, *P. grandiflora*, and *P. juruana*, are also reported to cause sudden death. These plants have less impact due to their restricted distribution.

P. marcgravii is documented to contain monofluoroacetate,[25−27] and a recent report demonstrated that *P. aeneofusca* contains monofluoroacetate.[27,28] A systematic screening of *Palicourea* taxa was recently initiated wherein herbarium specimens were tested for monofluoroacetate (Table 1).[25−28] Monofluoroacetate was confirmed in *P. marcgravii* and *P. aeneofusca* and was detected in *P. grandiflora* and *P.* aff. *juruana*, which is consistent with these species causing sudden death.[29−31] *P.* aff. *juruana* likely corresponds to *P. juruana* as described by Tokarnia,[24] but the identity of *P. juruana* is problematic as this name has been used variously for several different species. Additionally, monofluoroacetate was detected in several other species including *P. amapaensis*, *P. macarthurorum*, and *P. nigricans*[27] (taxonomically similar to *P. grandiflora*[32]), and *P. longiflora*, *P.* aff. *longiflora*, and *P. vacillans*[27] (taxonomically similar to *P. marcgravii* and *P. aeneofusca*[32]).

There are limited data on monofluoroacetate concentrations from *Palicourea* field collections. Studies suggest that monofluoroacetate concentrations in mature leaves are highly variable within populations of *P. marcgravii* and *P. aeneofusca*, ranging from 0.03 to 0.58% and from 0.03 to 0.18%, respectively.[28] Mean concentrations of monofluoroacetate within field collections of mature leaves of *P. marcgravii* and *P. aeneofusca* were approximately 0.20 and 0.10%, respectively.[28] Young leaves from one population of *P. marcgravii* contained monofluoroacetate at concentrations of 0.88 ± 0.08%, in contrast to that in mature leaves at 0.21 ± 0.17%.[28]

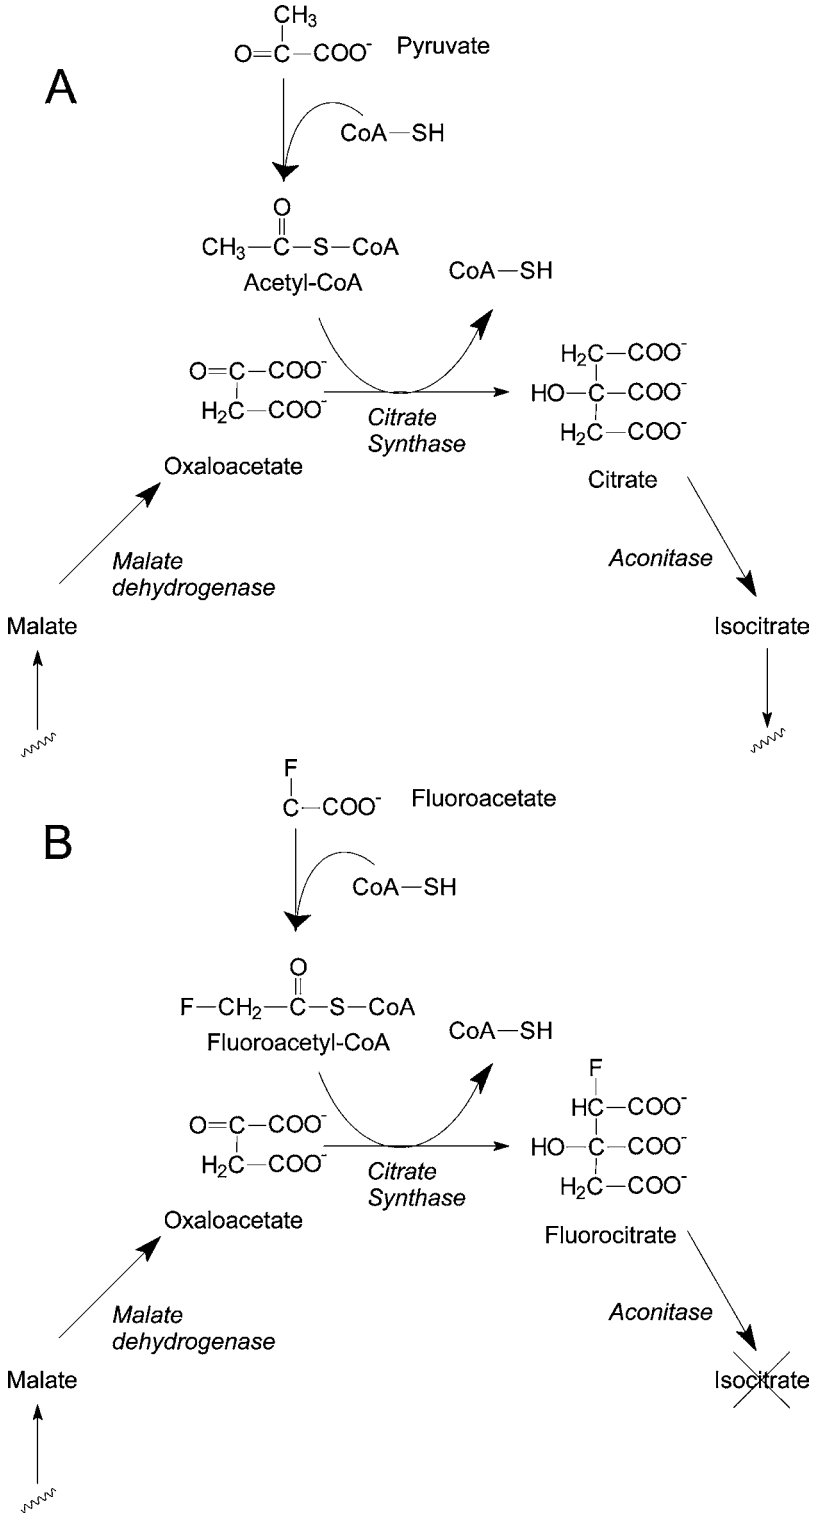

Figure 2. (A) Partial tricarboxylic acid cycle illustrating the incorporation of acetyl-CoA into the cycle. (B) Partial tricarboxylic acid cycle illustrating the incorporation of fluoroacetyl-CoA into the cycle resulting in the formation of fluorocitrate and subsequent inhibition of aconitase.

Bignoniaceae. Several lianas in the family Bignoniaceae, previously classified as *Arrabidaea* and *Pseudocalymma*, are reported to cause sudden death. A recent taxonomic study using molecular and morphological characters has changed the generic circumscriptions in this group.[33] Currently, most *Arrabidaea* and *Pseudocalymma* are now included in *Fridericia* and *Mansoa*, respectively. However, some species such as *Arrabidaea bilabiata* and *Pseudocalymma elgans* were incorrectly classified as to genus and are known as *Tanaecium bilabiatum* and *Fridericia elegans*, respectively. *Fridericia* comprises approximately 70 species that typically grow as high-climbing woody vines or occasionally as small shrubs and trees and is distributed throughout the Neotropics from Mexico and the West Indies to Argentina. *Tanaecium* comprises about 20 species of similar habit found across the same range.[33] Three species of Bignoniaceae have been reported to cause sudden

dx.doi.org/10.1021/jf500563h | J. Agric. Food Chem. 2014, 62, 7345−7354

death, *Arrabidaea bilabiata* (= *Tanaecium bilabiatum*), *A. japurensis* (also sometimes called *Scobinaria japurensis*, = *Fridericia japurensis*), and *Pseudocalymma elgans* (*Fridericia elegans*).[24,34] One species, *A. bilabiata*, has been reported to contain monofluoroacetate (Table 1).[35] Similar concentrations of monofluoroacetate were found in *A. bilabiata* and *P. marcgravii*.[35] The other species have not been confirmed to contain monofluoroacetate, but likely contain this toxin because livestock poisoned with these plants exhibit similar clinical signs.

Malpighiaceae. *Amorimia* is a genus composed of 10 species, which are found in tropical South America and grow as woody vines or sometimes shrubs.[36] *Amorimia* spp. are among the more important poisonous plants of Brazil due to their widespread distribution[24,28] throughout South America from southern Brazil northward.[36] *Amorimia* species were previously included in *Mascagnia*; however, recent taxonomic research using morphological and molecular studies resulted in the separation of the new genus, *Amorimia*.[36,37] Five *Mascagnia* species, *M. elegans*, *M. exotropica*, *M. pubiflora*, *M. rigida*, and *M.* aff. *rigida* have been reported to cause sudden death in livestock.[24,34,38] The latter four are now included in *Amorimia*, whereas *M. elegans* remains in *Mascagnia*.[36,37]

Field collections and a systematic screening of herbarium specimens across these Malpighiaceae were performed to test for monofluoroacetate. Monofluoroacetate was detected in *A. amazonica*, *A. camporum*, *A. exotropica*, *A. pubiflora*, *A. rigida*, and *A. septentrionalis* (Table 1).[28] However, monofluoroacetate was not detected in *A. kariniana*, *A. maritima*, *A. velutina*, and *M. divaricata* (*M. elegans*).[28] This may be due to the limited number of specimens that were available for sampling in some taxa; some of these species have not been reported to be toxic[24] and may not contain monofluoroacetate.

Monofluoroacetate was not detected in *M. elegans*,[28] also known under the synonym *M. divaricata*. This species is reported to have caused sudden death syndrome in Pernambuco state in northeastern Brazil;[38] however, no herbarium collections of *M. divaricata* are known from any of the states of the semiarid area of northeastern Brazil. The plant reported to have caused the sudden death syndrome may have been *A. septentrionalis* or another species that was identified as *M. divaricata*. Another *Mascagnia* sp., *M. sepium*, was reported to cause sudden death syndrome in Rondônia, a state of northwestern Brazil.[39] However, *M. sepium* does not occur in this region of Brazil, but is found in southeastern Brazil. A photograph of the plant responsible for the livestock poisoning was included in the paper and was identified as an *Amorimia* species (W. Anderson, University of Michigan) on the basis of the fruits (i.e., samaras). Because of the location of the case report it is likely that the plant responsible for causing sudden death in this paper was *A. amazonica*; however, this cannot be verified without a voucher specimen.[28] These two examples highlight the need for voucher specimens in plant poisonings and correct identification of plants suspected of toxicity.

Monofluoroacetate was detected in the field collections of *A. septentrionalis* but only in 60% of the plants surveyed.[28] Monofluoroacetate concentrations varied among plant parts with concentrations ranging from approximately 0.001 ± 0.0003% in stems to 0.008 ± 0.004% in flowers and other parts falling within the range reported above.[28] Concentrations of monofluoroacetate in *A. septentrionalis* were significantly less than those reported for *P. marcgravii* and *P. aeneofusca*, which is consistent with the incidence of poisoning and the amount of plant material required to cause sudden death with *Palicourea* and *Mascagnia* species.[40−42]

Dichapetalaceae. *Dichapetalum* spp. occur as trees or shrubs throughout the lowland tropical regions of the world, with more than 80 species reported from Africa.[3] *Dichapetalum cymosum* (Gifblaar) causes sudden death or "Gifblaar poisoning" and is the third most important toxic plant in South Africa.[3] Seven *Dichapetalum* spp., *D. barteri*,[43] *D. braunii*,[44] *D. cymosum*,[45] *D. edule*,[44] *D. heudelotii*,[46] *D. michelsonii*[44,47] (possibly the same as *D. stuhlmanii*), and *D. toxicarium*,[48] have been documented to contain monofluoroacetate (Table 1), and three of these, *D. cymosum*, *D. barteri*, and *D. toxicarium*, are reported to be lethally toxic to livestock.[3] *D. ruhlandii* has also been reported to be lethally toxic, but, apparently, has not been shown to contain monofluoroacetate.[3] Similar to the other species thus far described herein, monofluoroacetate concentrations have been shown to vary between species and plant parts in that young leaves contain greater amounts of monofluoroacetate than do mature leaves. For example, O'Hagan et al.[44] analyzed leaves of three *Dichapetalum* spp. and found concentrations of monofluoroacetate to be 0.72 ± 0.02% in the young leaves of *D. braunii*, 0.012 ± 0.002 and 0.007 ± 0.002% in the young leaves of *D. edule*, and 0.004 ± 0.002% in the young leaves of *D. stuhlmanni*; however, the concentrations in the mature leaves from these three plants were all <0.002%. In addition, *Tapura fischeri*, an African tree of the Dichapetalaceae family, is also reported to contain monofluoroacetate but has not been reported to be involved in livestock poisoning (Table 1).[3]

■ TOXICOLOGY OF MONOFLUOROACETATE

Monofluoroacetate is not toxic per se but requires intracellular metabolism to fluorocitrate that then inhibits aconitase and thereby blocks the cellular respiration tricarboxylic acid cycle (Figure 2).[3] Clinical signs usually take 4−24 h to appear. This is a time-dependent process because the plant material has to be digested in the rumen and the monofluoroacetate absorbed into the bloodstream, transported to the target cells, and then converted to monofluorocitrate, which disrupts cellular respiration.[3] Clinical signs of livestock poisoned by monofluoroacetate-containing plants can include loss of balance, ataxia, tachycardia, and labored breathing.[34] Livestock may attempt to rise after collapsing but immediately fall, sometimes staying in lateral recumbence and pedaling in an attempt to stand up.[34] Death usually occurs shortly after these clinical effects.[34] In sublethal cases, a reluctance to walk or slow movements, lying down frequently, heart palpitations, and a visibly pulsing jugular vein are often observed.[34,38] Clinical signs are usually exacerbated by exercise but, due to the rapidity of death, are rarely seen under field conditions.[3]

Monofluoroacetate poisoning of livestock usually results in no significant gross lesions. Most animals that die of sudden death do not show lesions of any diagnostic significance, although some histological lesions have been observed. Approximately two-thirds of the cattle poisoned by *P. marcgravii* had necrosis and hydropic degeneration of the epithelium of the renal tubules.[38] In some cases of Gifblaar poisoning, myocardial fibrosis and necrosis have been observed.[49] Cardiac fibrosis has also been observed in *Amorimia* spp. from repeated sublethal doses.[39,50]

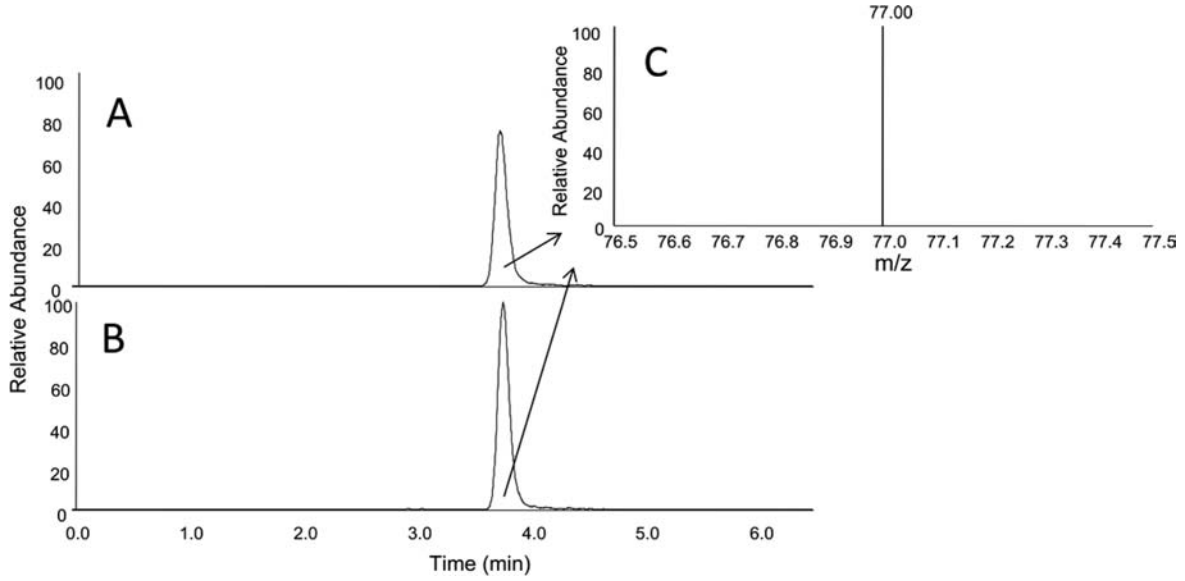

Figure 3. Selected ion monitoring (SIM) at m/z 77 from (A) 2.5 μg/mL standard of sodium monofluoroacetate and (B) water extract of *Palicourea marcgravii* leaves diluted 1:5. (C) Mass spectrum of the peaks.

METHODS OF ANALYSIS FOR MONOFLUOROACETATE

Several methods exist to measure monofluoroacetate in various matrices. Many of these methods require derivatization prior to final analysis by GC,[51−53] GC-MS,[54−56] or HPLC with UV−vis or fluorescence detection.[57,58] A GC method without prior derivatization of monofluoroacetate was developed; however, preparation and frequent replacement of a guard column and intermittent injections of phosphoric acid were required to maintain chromatographic integrity.[59] In addition, capillary zone electrophoresis with UV detection has also been reported for fluoroacetate analysis.[60] Analysis of monofluoroacetate in plant extracts has been accomplished by ^{19}F NMR spectroscopy,[18] ion chromatography with conductivity detection,[44] and HPLC with UV detection at 210 nm.[61] A HPLC-APCI-MS method was developed to measure monofluoroacetate in foods,[62] and this has recently been modified for the analysis of monofluoroacetate in plant samples. Thus, an aliquot of dried, milled plant (10−100 mg) was extracted with water, filtered, appropriately diluted, and analyzed using HPLC-APCI-MS in the selected ion monitoring (SIM) mode at m/z 77 for the $(M - H)^-$ ion of monofluoroacetate. The total HPLC run time was 7.0 min, with monofluoroacetate eluting at 3.8 min (Figure 3).[28]

COEVOLUTION OF NATIVE FLORA AND FAUNA IN SOUTHWESTERN AUSTRALIA

With so many plants containing monofluoroacetate in a small and isolated region of Australia, it might be expected that the fauna that coevolved in the area would develop some tolerance to this poison. Indeed, early settlers in Western Australia were misled about the safety of these plants for their livestock because they observed native animals grazing *Gastrolobium* spp. with impunity.[1] However, it was not until the late 1970s that tolerance to monofluoroacetate was demonstrated in some species of native mammals in Western Australia.[63,64] Subsequently, varying degrees of tolerance has been demonstrated in many insects, reptiles, birds, and mammals that are native to this region.[4,65−72] Within the mammals in particular, this tolerance has been demonstrated by comparing the susceptibility to monofluoroacetate of different populations of the same species, or of closely related species, that live inside and outside the region with these plants. The difference in tolerance can be remarkable, as has been demonstrated in different populations of the bush rat, *Rattus fuscipes*. Populations in eastern Australia are 20−80 times more susceptible to monofluoroacetate poisoning than populations in southwestern Australia.[4,72] Generally, tolerance to monofluoroacetate is greatest in herbivorous species, moderate in omnivores, and least developed in native carnivores.[4] Birds are generally the least sensitive of endothermic vertebrates, and ectotherms are relatively insensitive to monofluoroacetate.[4,73,74]

The high concentration of monofluoroacetate in many *Gastrolobium* spp. seems excessive when it is recognized that most unadapted mammals are fatally poisoned by <2 mg/kg.[74] It is believed that these very high concentrations are the result of a coevolutionary event in which the plants produced monofluoroacetate as a protection against herbivory at the same time as the herbivores developed a resistance to the poison in order to use these plants in their diet.[69] This hypothesis also explains the variation in the levels of tolerance to monofluoroacetate that have been demonstrated. The degree to which the population of any species of animal is tolerant depends on their diet and habitat specialization, the size of their home range, and the length of their evolutionary exposure to the toxic vegetation.[4,64,69,75]

The evolutionary development of tolerance to monofluoroacetate is supported by the development of resistance under artificial situations. The LD_{50} of monofluoroacetate in laboratory rats, *Rattus* sp., was increased from 2.0 to 3.5 mg/kg by dosing the poison over five generations,[76] and in house flies, *Musca domestica*, it was increased from 0.6 to 4.2 μg fly^{-1} by dosing over 25 generations.[77] More recently, Twigg et al.[78] demonstrated a significant reduction in susceptibility to monofluoroacetate in populations of wild rabbits, *Oryctolagus cuniculus*, in Australia that had been subjected to intensive baiting with sodium monofluoroacetate (1080) over a 25 year period.

dx.doi.org/10.1021/jf500563h | J. Agric. Food Chem. 2014, 62, 7345−7354

Several possible mechanisms have been suggested for the tolerance that has developed in native animals in southwestern Western Australia,[4] but none have been proven. In recent times attention has been directed to the aconitase gene *ACO2*, responsible for the aconitate hydratase enzyme. However, the sequencing of the full length *ACO2* transcript has failed to identify a sequence variant between susceptible and tolerant subspecies of the tammar wallaby, *Macropus eugenii*, which would result in an amino acid change in the active site of the enzyme.[79]

METHODS TO MITIGATE LIVESTOCK POISONING FROM MONOFLUOROACETATE

Although the mechanism of toxicity due to monofluoracetate has been known for over 50 years, there is not currently a proven therapy or antidote to reverse or prevent acute intoxication.[5] Remedies such as ethanol, monoacetin (glycerol monoacetate), acetamide, and sodium succinate have been tried with various degrees of success.[5,80] Supportive care for intoxicated animals is important if they survive the initial toxic insult.[5,81]

There are various aspects of animal or pasture management that may prove useful to reduce the incidence of poisoning by monofluoroacetate-containing plants. The most critical aspect is to prevent animal access to the plants. In Australia, Brazil, and southern Africa, fencing is considered the most reliable method to prevent livestock deaths.[34,82] Other possible means of reducing exposure include hand-grubbing to remove the plants, herbicidal control, or grazing management to reduce plant−animal interactions in pastures. Fencing is both expensive and impractical in expansive rangeland settings, but has been used on smaller scales to fence localized patches of monofluoroacetate-containing plants.[3,34,82] Herbicidal control is possible, but is often impractical and expensive.[3,82] Furthermore, many monofluoroacetate-containing plants have extensive underground root systems (e.g., *D. cymosum*), which makes long-term herbicidal control much more difficult.

Reducing grazing livestock selection of monofluoroacetate-containing plants involves both animal and rangeland management. *Palicourea* species are very palatable to livestock,[2] but no studies have documented relative consumption by livestock of *Palicourea* species in overgrazed versus well-managed rangeland situations. In parts of southern Africa, populations of *D. cymosum* are most problematic on overgrazed or degraded rangelands because alternate forage sources are often limited, particularly during the dry season.[3] Livestock losses to *D. cymosum* increase during drought as other nontoxic forage may be scarce;[82] similarly, livestock losses to monofluoroacetate-containing plants in Brazil also increase during drought, particularly in drought-prone northeastern Brazil.[24]

Livestock that consume lethal amounts of monofluoroacetate-containing plants often die suddenly after drinking water or exercising.[3] One critical aspect of management when animals have been exposed to monofluoroacetate-containing plants, particularly plant species with sometimes lower (i.e., less lethal) concentrations of monofluoroacetate, is movement (i.e., exercise) of the animal. Animals that have been consuming nonlethal amounts of monofluoroacetate-containing plants may die suddenly from exercise-induced exacerbation of the intoxication.[38] In Brazil, livestock intoxicated by *Palicourea* or *Arrabidaea* species rarely recover, and many animals are found dead even without exercise.[38] However, livestock intoxicated by monofluoroacetate-containing *Amorimia* species frequently recover if the animals do not exert themselves.[34] The current recommendation is to allow exposed, potentially intoxicated animals in pastures about 7−14 days without access to the plant to allow complete detoxification before moving them to another area.[34] Similarly, if actively grazing animals must be moved during a poisoning episode to prevent further deaths within a herd, the survivors must be moved very cautiously so as to not trigger additional deaths.[3,34]

Managing water intake may attenuate livestock losses. In southern Africa, small holders grazing livestock in communal areas water their animals late in the day to allow increased time for any toxin ingested during the day to be metabolized, thus reducing potentially fatal absorption when animals drink water (I. Zimmermann, Polytechnic of Namibia, personal communication). In South Africa it is recommended that animals that have been exposed to *D. cymosum* be kept from drinking water for 48 h to reduce mortality.[3]

Anecdotal accounts from southern Africa suggest that about 50% of naïve livestock exposed to *D. cymposum* are fatally poisoned, in contrast to a mortality rate of 5% in experienced animals that are raised on rangelands with the toxic plant (I. Zimmermann, personal communication). Furthermore, weaned calves are more likely to be fatally poisoned than are nursing calves grazing alongside their experienced mothers, suggesting that when calves are with mothers who avoid the plant, the calves also avoid the plant.[83] When ruminants consume monofluoroacetate-containing plants such as *A. septentrionalis* or *D. cymosum* and are not fatally poisoned, they appear to acquire a natural aversion to the plant (I. Zimmermann, personal communication).[84] Monofluoroacetate has been used experimentally to induce strong taste aversion learning in rats.[85] Conditioned taste aversion may be a cost-effective way to prevent livestock deaths from some monofluoroacetate-containing plants. Some initial success has been reported in using conditioned taste aversion to reduce consumption of a monofluoroacetate-containing plant, *Mascagnia rigida*.[84,86] It will likely be more difficult to condition livestock to avoid highly toxic monofluoroacetate-containing plants such as *Palicourea* species, because of the difficulty in administering a nonlethal dose to condition the aversion.

It is well documented that some animal species in Australia have evolved resistance to monofluoroacetate.[63,64] In addition to this Australian phenomenon, in South America it appears that water buffalo (*Bubalus bubalis*) are more resistant to monofluoroacetate poisoning than are cattle (*Bos taurus* or *B. indicus*).[87−89] Studies indicate that the lethal dose of monofluoroacetate-containing plants is 4−8 times higher in water buffalo compared to cattle.[87,88] Furthermore, the clinical time course for signs to appear in intoxicated water buffalo is much longer than for cattle.[87] The reason for the difference in susceptibility between bovines and water buffalo is not clear but may involve absorption, ruminal detoxification, or other mechanisms of resistance at the cellular level.[90] For example, in the classic studies on mimosine (3-hydroxy 4(1*H*)-pyridone) toxicity, Jones and Lowry[91] were able to document the bacterial detoxification of mimosine by some ruminants. Furthermore, Jones and Megarrity[92] showed that this detoxification could be transferred from animal to animal in pasture situations, thus alleviating the toxic effects of mimosine.

Recent research has shown that repeated ingestion of nontoxic doses of the monofluoroacetate-containing plants *Amorimia septentrionalis* and *Palicourea aeneofusca* increased the resistance of goats to monofluoroacetate poisoning.[88,93] The

increased resistance was transferred to naïve goats by transfaunation of ruminal fluid. Interestingly, unlike resistance to potentially toxic mimosine in *Leucaena leucocephala*,[92] cohabitation of resistant goats with naïve goats for 6 months did not result in increased resistance in the naïve animals.[93] The increased resistance of subchronically intoxicated ruminants may result from the proliferation of monofluoroacetate-degrading microbes when sufficient substrate is available.[88]

Australian investigators have successfully genetically modified the ruminal bacteria *Butyrivibrio fibrisolvens* by introducing a gene that codes for a dehalogenase, thus rendering the bacteria capable of hydrolyzing monofluoroacetate.[94] The stability of that modified organism has been demonstrated by its retention in the rumen of sheep for over 5 months in vivo.[95] If this modified bacterium could be successfully transferred and maintained in the rumen of grazing animals consuming monofluoroacetate-containing plants, this may provide a method to greatly reduce or eliminate livestock losses.[96]

PERSPECTIVE

Many methods and remedies to mitigate monofluoroacetate plant poisoning have been tried with various degrees of success. Currently, there is no one accepted practice or antidote to eliminate poisoning by monofluoroacetate-containing plants in livestock; however, research in this area is promising, and the solution may be a combination of management strategies and new information or biotechnology. The coevolution of monofluoroacetate-containing plants and fauna in Western Australia may provide some clues to the development of resistance in livestock.

There have been cases when humans have been poisoned by accidental ingestion of monofluoroacetate (1080).[5] However, because monofluoroacetate is highly soluble in water and has a short half-life in livestock, the risk of secondary poisoning by monofluoroacetate in meat intended for human consumption is low.[97] Accidental poisoning of pets by monofluoroacetate (1080) has also been reported.[98−100] Livestock-associated research in poisoning by monofluoroacetate may provide insight into possible treatments for poisoned humans and pets.

dendricles resembling a hedgehog, resulting in its being named the hedgehog (*Hh*) gene. In 1993 three mammalian *Hh* counterparts, Desert hedgehog (*Dhh*), Indian hedgehog (*Ihh*), and Sonic hedgehog (*Shh*), were identified in a mouse[14] and named after two hedgehog species and the video game character, Sonic the Hedgehog. In 1995 human *Ihh* and *Shh* genes were identified and their chromosomal locations determined.[15] In 1999 the human *Dhh* gene was identified and its location determined.[16,17] *Shh* is the most broadly expressed and has been the most investigated of the mammalian *Hh* signaling genes. In mammals, *Shh* is responsible for embryonic development of symmetry along the sagittal plane, the central nervous system, skeleton, limbs, eyes, teeth, intestines, lungs, skin, muscles, cartilage, and sperm. Mouse embryos that lacked a *Shh* gene resulted in early embryonic death, holoprosencephaly (failure of the forebrain to develop into hemispheres), cyclopia at the base of an external proboscis, limb mispatterning, and foregut abnormalities, among numer-

Figure 3. ous other malformations.[18,19] Loss of *Shh* functioning in embryonic human development has also resulted in holoprosencephaly, cyclopia, and proboscis above the eye (Figure 2C).[20] In less severe human cases, flat nose absent of nasal cartilage, decreased distance between the eyes, and underdevelopment of the midface have been observed (Figure 2D).[20]

CYCLOPAMINE AND THE SONIC HEDGEHOG GENE

In 1996 while actively conducting research on the *Shh* gene pathway, Dr. Philip Beachy recalled images of the cyclopic lambs reported in Idaho in 1950−1960s and hypothesized that cyclopamine, **1**, could be used to probe the *Shh* pathway. In 1998 Beachy and co-workers[21] and Incardona et al.[22] established that cyclopamine inhibits the *Shh* signaling pathway. A simplified characterization of the *Shh* signaling pathway is presented in Figure 4. In most adult cells the *Shh* receptor Patched interacts with Smoothened, in effect acting as a molecular brake and inhibiting Smoothened (Figure 4A). During embryonic development, when *Shh* is present, *Shh* binds to Patched and Smoothened is then released from Patched. Smoothened then initiates downstream signaling that results in the binding of *Gli* transcription factors to DNA and subsequent activation of gene expression (Figure 4B). Cyclop-

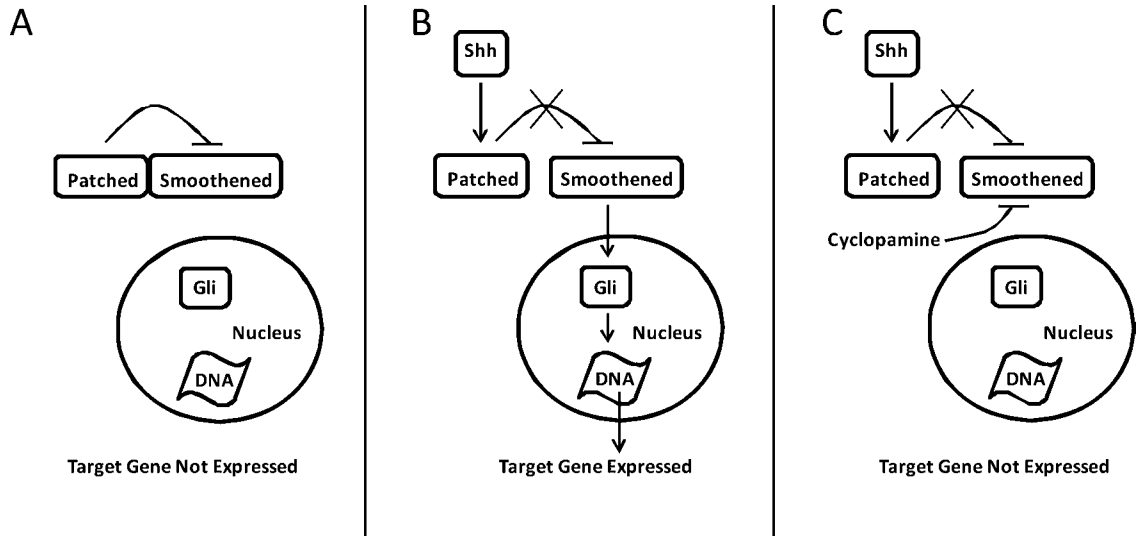

Figure 4. *Shh* signaling pathway. (A) Patched interacts and inactivates Smoothened. (B) When *Shh* is present, *Shh* binds to Patched, Smoothened is released from Patched, and Smoothened leads to downstream signaling via binding of the *Gli* transcription factors to DNA and activation of gene expression. (C) Cyclopamine binds to Smoothened and inhibits the *Shh* pathway downstream from Patched.

amine binds to Smoothened and inhibits the *Shh* pathway downstream from Patched and upstream from *Gli* (Figure 4C).[23,24] Modifications of cyclopamine to improve solubility as well as other pharmacokinetic characteristics have resulted in compounds with enhanced *Shh* signaling pathway inhibitor activity. For example, 3-keto-*N*-(aminoethyl-aminocaproyl-dihydrocinnamoyl)cyclopamine, **2** (KAAD-cyclopamine), a semisynthetic derivative of cyclopamine, was shown to have a 10−20-fold increase in potency compared to cyclopamine.[23]

CYCLOPAMINE DERIVATIVES AND CANCER TREATMENT

In addition to playing a key role in embryonic development, inappropriate activation of the *Shh* signaling pathway in mature cells has been associated with nevoid basal cell carcinoma (Gorlins syndrome) and several cancers, such as basal cell carcinoma, medullablastoma, and rhabdomyosarcoma, that are often driven by inherited mutations in Patched and, less frequently, Smoothened.[24,25] Nevoid basal cell carcinoma is an inherited condition characterized by multiple basal cell carcinomas, other malignant and benign tumors, and malformations.[26] Basal cell carcinoma is the most common type of skin cancer, medulloablastoma is the most common brain tumor in children, and rhabdomyosarcoma is a relatively rare cancer that is most commonly observed in children.[25,27] Other cancers such as colon, glioma, breast, esophageal, gastric, pancreatic, prostate, small cell lung, biliary tract, bladder, ovarian, liver, myeloma, leukemia, and oral cancers have been associated with autocrine- and paracrine-secreted hedgehog protein signaling.[27,28]

The *Shh* signaling pathway plays a critical role in embryonic development and appears to play an important role in a number of cancers in mouse models, because it no longer has a normal biological function in most mature cells. Consequently, inhibition of the *Shh* signaling pathway may be a promising cancer treatment method as it could stop tumor growth without many of the common side effects of traditional cancer therapeutics. Cyclopamine, **1**, has been shown to inhibit tumor growth in a genetic mouse medulloblastoma model,[29] a mouse medulloblastoma allograph model,[30] and mouse xenograft models with human glioma,[31] melanoma,[32] colon cancer,[33] pancreatic cancer,[34−36] prostate cancer,[37] and small cell lung cancer[38] without noticeable side effects in the cyclopamine-treated adult mice.[29−32,34,36] Tumor regression in human patients with basal cell carcinomas was reported after administration of a topical cream containing cyclopamine was applied directly onto the tumors, with no adverse effects to the patient, including the skin surrounding the treated tumors.[39] These results highlight the potential of using cyclopamine and other inhibitors of the *Shh* signaling pathway as therapies for human cancers promoted by aberrant *Shh* signaling and argue for initiation of human clinical trials using inhibitors of the *Shh* signaling pathway for lethal cancers.

Although cyclopamine, **1**, shows promise as a human chemotherapy agent, cyclopamine per se does have some inherent limitations. Cyclopamine has low solubility in water, normal saline, and other physiological solutions. In addition, cyclopamine is not stable under acidic conditions, as would be encountered in the stomach of humans and other monogastric animals. Under acidic conditions, the ether bond in ring E is readily hydrolyzed followed by aromatization of ring D, resulting in veratramine, **3**,[40,41] which is inactive in the *Shh* signaling pathway. These characteristics limit the bioavailability and delivery options of cyclopamine. Previous success in increasing the potency of the *Shh* pathway inhibition with KAAD-cyclopamine, **2**, suggests that other semisynthetic cyclopamine, **1**, compounds could be developed, which would overcome the pharmacokinetic limitations of cyclopamine, **1**, and may even have increased potency as anticancer therapies. In this regard, several different approaches have been undertaken to address the limitations of cyclopamine as a chemotherapeutic agent.

One simple solution to increase the solubility of cyclopamine, **1**, in physiological solutions has been achieved by the creation of a cyclopamine-tartrate salt. The solubility of cyclopamine was increased to approximately 2 mg/mL as cyclopamine-tartrate salt and up to 5 mg/mL with the addition of 1.5 mg of tartaric acid to the solution, as reported by the inventors.[42] Cyclopamine-tartrate salt was used to characterize the pharmacokinetic profile of cyclopamine in sheep[43] and

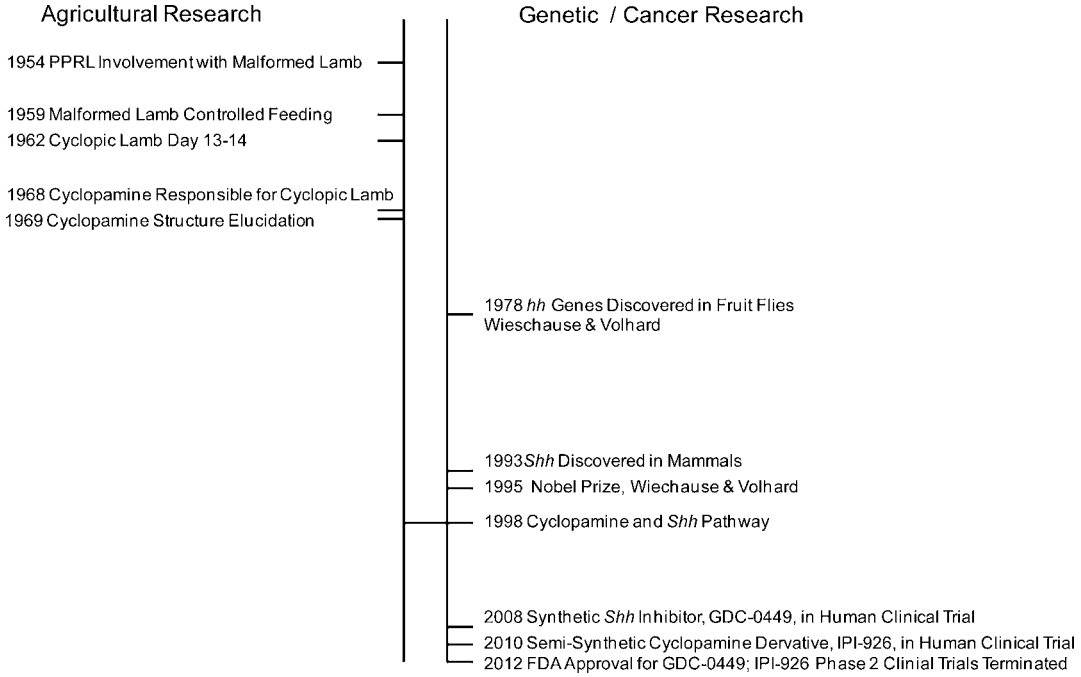

Figure 5. Agricultural, cell biology, and cancer research time line.

induced tumor shrinkage in two mouse basal cell carcinoma models.[44]

Chemists at Utah State University in collaboration with scientists at the PPRL investigated increasing the solubility of cyclopamine, **1**, while retaining or improving its potency by using "click" chemistry to form a series of 11 carbohydrate−cyclopamine conjugates. Most of the conjugates were less potent than cyclopamine; however, the *N*-(4-L-rhamnopyranosyl-1*H*-1,2,3-triazol-1-yl)-methylcyclopamine, **4**, conjugate showed higher potency than cyclopamine in a cytotoxicity assay with lung cancer cells.[45]

Although the *Shh* signaling pathway is inactive in most mature cells, there are select mature cells in which *Shh* signaling is required, such as the gonads, gastrointestinal tract, and bone marrow. To circumvent any possibility of toxicity in these cells, two cyclopamine, **1**, based pro-drugs were developed to target only prostate cancer cells. High levels of enzymatically active prostate specific antigen (PSA) exist in the immediate vicinity of both normal and tumorigenic prostate cells. Enzymatically active PSAs are inactivated by serum protease inhibitors in circulation. Peptide carriers were synthesized that serve as substrates to PSA. Amino acid sequences of His-Ser-Ser-Lys-Leu-Gln (HSSKLQ) and Ser-Ser-Lys-Leu-Gln (SSKLQ) that could be selectively cleaved from cyclopamine in the presence of PSA were conjugated to cyclopamine. The PSA substrate pro-drugs, morpholino (Mu), Mu-HSSKLQ-cyclopamine, and Mu-SSKLQ-cyclopamine, **5**, were evaluated in the presence of enzymatically active PSA, with Mu-SSKLQ-cyclopamine being more efficiently hydrolyzed. In addition, whereas the pro-drugs were minimally effective when cultured in a non-PSA-expressing prostate cancer cell line, the addition of PSA to the culture led to a dramatic 7-fold increase in the efficacy of the pro-drug.[46]

Several pharmaceutical companies have developed *Shh* signaling pathway inhibitors. For example, IPI-926, **6**, is a compound with a number of synthetic modifications to cyclopamine, **1**, which result in improved stability, kinetic profile, and potency. Enlargement of ring D from a six- to a seven-member ring dramatically improved the acid stability and aqueous solubility compared to cyclopamine.[47] The addition of the sulfonamide at the C-3 position further increased the metabolic stability of IPI-926 compared to cyclopamine.[47] IPI-926 was shown to have a longer pharmacokinetic half-life in multiple mammalian species and was more potent in a cellular *Hh* inhibition assay than other semisynthetic lead compounds.[47] Daily oral administration of IPI-926 in a mouse medulloblastoma allograph model led to complete tumor regression during the treatment phase, and tumor regrowth was not observed 21 days post treatment.[47] IPI-926 was also effective in inhibiting tumor growth in lung and pancreatic cancer xenograft models.[47]

A phase I clinical study of IPI-926, **6**, was commenced in 2010 in adult patients with solid tumors. The objectives of this first in-human study were to determine maximum tolerated oral dose and to characterize the pharmacokinetic profile of IPI-926. In addition, an expanded portion of the study evaluated the efficacy of IPI-926 at the maximum tolerated dose in patients with advanced or metastatic basal cell carcinomas. A well-tolerated dose was determined, and IPI-926 showed antitumor activity in patients with basal cell carcinomas.[48]

IPI-926, **6**, was further evaluated in a phase 1b/2 clinical study in patients with previously untreated metastatic pancreatic cancer in 2011. In the phase 1b portion of the study, patients were orally treated with IPI-926 in combination with intravenously administered gemcitabine. This trial evaluated the safety and pharmacokinetics and determined the recommended dose of IPI-926 for phase 2 clinical trials. In this study, a partial response to the therapy was observed in 31% of the patients. The combination of IPI-926 and gemcitabine was well tolerated, and no pharmacokinetic interactions were observed between the two drugs.[49] The phase 2 portion of the study compared IPI-926 in combination with gemcitabine to placebo with gemcitabine in patients with previously untreated metastatic pancreatic cancer with the

dx.doi.org/10.1021/jf5005622 | J. Agric. Food Chem. 2014, 62, 7355−7362

primary end point being overall survival. However, this study was terminated after an interim analysis found that the median survival of patients on the IPI-926 plus gemcitabine arm of the study was <6 months, whereas the median survival of the placebo plus gemcitabine arm was >6 months.[50]

Phase 2 clinical studies were also conducted with IPI-926, **6**, as a single agent in patients with myelofibrosis, an incurable cancer of the bone, and chondrosarcoma, a cancer of the cartilage, with primary end points of progression-free survival. Interim analysis of the chondrosarcoma study concluded that treatment with IPI-926 was similar to placebo and the study was terminated. At the same time, the phase 2 exploratory study with myelofibrosis was discontinued due to unsatisfactory clinical activity in initial patients.[51]

Other small molecules that act as hedgehog pathway inhibitors are currently being studied as anticancer therapies. However, many of these compounds are not based on the steroidal alkaloid structure of cyclopamine, **1**. The most successful of these compounds to date is the synthetically derived GDC-0449, **7**.[52,53] GDC-0449 has completed phase 2 clinical studies in patients with basal cell carcinoma, ovarian, and colorectal cancers and received FDA approval in January 2012 for treatment of adults with metastatic and/or locally advanced basal cell carcinoma.[54−56] In addition, clinical studies with GDC-0449 are active or are recruiting patients with basal cell nevus syndrome, basal cell carcinoma, myeloma, pancreatic, small cell lung, chondrosarcoma, medullablastoma, glioblastoma, prostate, glioma, leukemia, sarcoma, breast, and other solid cancers.[57]

PERSPECTIVE

Dr. Philip Beachy's recollection in 1996 of the research and images of the cyclopic lambs reported in the 1960s led to the correct hypothesis that cyclopamine, **1**, could be used to probe the *Shh* pathway. This observation and hypothesis connected agricultural-based research that had taken place 30 years earlier to current cell biology research. Since this discovery, cyclopamine has served as a valuable tool in elucidating and understanding the *Hh* signaling pathway in embryonic development and in the investigation of the role of the *Hh* pathway in various cancers. In addition, cyclopamine has served as a model compound for new cancer therapy drugs. Figure 5 is a timeline that shows the relationship between agricultural research, cell biology research, and cancer research and the major advances in the research areas that relate to cyclopamine. This long timeline is reminiscent of that involved in the development of Taxol (paclitaxel), which began in 1964 with the discovery that extracts of Pacific yew (*Taxus brevifolia*) bark were cytotoxic.[58] The Taxol time line continued with the identification of Taxol as the active principle in 1971 and the approval by the FDA of Taxol as a treatment for ovarian cancer and breast cancer, respectively, in 1992 and 1994. The use of Taxol has continued to increase and, along with its semisynthetic analogue, Taxotere, has become the best-selling anticancer drug in history.[58] We anticipate that cyclopamine will continue to be an important research tool in the future and additional advances in cancer therapies and the *Hh* pathway will be forthcoming. In addition, other poisonous plants should be investigated as sources for anticancer agents, new drugs, and other biomedical applications.[59]

This review highlights the importance of agricultural/poisonous plant research and the rapid advances that can be made by an interdisciplinary and nonlinear approach to solving important research problems.

behavior is one of the most common results of drug−drug interactions.[7]

Interactions involving drug metabolism can have profound effects on the concentration of active drugs by affecting the rate at which the drug is either bioactivated or detoxified. Many drugs inhibit, or induce, key drug-metabolizing enzymes including cytochrome P450s (CYP). For example, dietary substances such as grapefruit juice will inhibit CYP 3A4, a ubiquitous drug-metabolizing enzyme, whereas some herbal remedies such as St. John's wort will induce CYP3A.[6,8] Thus, cotreatment with dietary, herbal, or additional drugs can result in altered metabolism of the drugs and subsequently alter the concentration of the bioactive drugs. In this regard, studies have shown the potential for negative effects from concomitant use of certain herbs and drugs.[9] For example, St. John's wort, by inducing CYPs, may affect the bioavailability of many conventional drugs[10] including the efficacy of drugs such as warfarin.[11] Clinical studies have suggested the risk for adverse reactions increases when herbal and conventional drugs are taken at the same time.[12] For example, rutaecarpine, an alkaloid found in *Evodia rutaecarpa*, a plant used in traditional Chinese medicine, affects CYP-mediated metabolism, glucuronidation, and transport pathways, which results in altered metabolism and elimination of caffeine, theophylline, and acetaminophen.[13−15] Similarly, the furanocoumarins in grapefruit juice, which inhibit CYP3A4, are known to interact with at least 85 drugs, resulting in adverse effects in many instances.[16] Although this phenomenon is most commonly associated with grapefruit juice, furanocoumarin derivatives have been found in numerous other plants.[17] In this regard, the furanocoumarins that are known to inhibit CYP3A4 have also been detected in eight other citrus fruits.[18] Consequently, the ingestion of many citrus fruits and/or other plants may adversely affect drug therapies by altering CYP3A4-mediated metabolism.

■ CHEMICAL MIXTURES OF PLANT TOXINS

In most cases where livestock are poisoned by plants in a range setting, there is more than one potential poisonous plant in that area. Additionally, many poisonous plants contain more than one toxin. Often, much is known regarding the toxicity of the individual plants and their toxins; however, little is known regarding the effect of coexposure to multiple toxic plants or even multiple toxins from an individual plant. For the remainder of this review, we will focus on the effect of chemical mixtures of plant toxins. We will discuss results from experiments in which we investigated the role of two different types of alkaloids from larkspur (*Delphinium* species) plants on the overall toxicity of the larkspur plant. We will also consider results from experiments characterizing the effect of coexposure to two different plants, each containing different classes of toxins. These experiments provide examples of the mixture effects that result from exposure to multiple toxins, either from an individual plant species or from two different plant species.

■ LARKSPUR: MDL- AND MSAL-TYPE ALKALOIDS

Larkspurs are placed into one of three categories based upon the mature plant height and distribution: low, tall, and plains larkspurs.[19] Larkspurs contain numerous (>18) norditerpenoid alkaloids, which are structurally delineated as 7,8-methylenedioxylycoctonine (MDL)-type alkaloids, such as deltaline, **1**, and 14-*O*-acetyldictyocarpine (14-OAD), **2**, and *N*-(methylsuccinimido)anthranoyllycoctonine (MSAL)-type alkaloids, such as methyllycaconitine (MLA), **3** (Figure 1).[19] Each of the different larkspur classes and species contains the

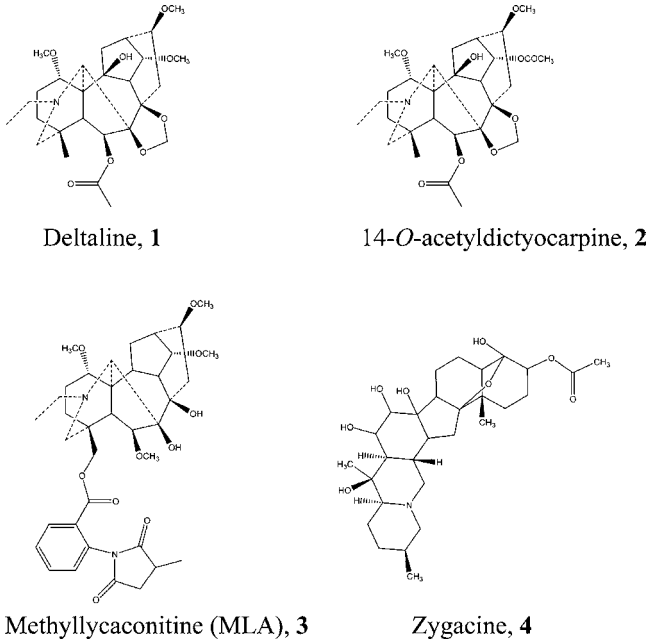

Figure 1. Chemical structures of selected norditerpenoid alkaloids in larkspur (*Delphinium* spp.) plants and zygacine, the main toxic alkaloid in death camas (*Zigadenus paniculatus*). Larkspurs contain numerous (>18) norditerpenoid alkaloids, which are structurally delineated as 7,8-methylenedioxylycoctonine (MDL), including deltaline and 14-*O*-acetyldictyocarpine (14-OAD), and *N*-(methylsuccinimido)anthranoyllycoctonine (MSAL)-type alkaloids, including methyllycaconitine (MLA).

norditerpenoid alkaloids, with MLA occurring to some degree in most larkspurs.[19] Although the MSAL-type alkaloids are more toxic (typically >20 times) than the MDL-type alkaloids,[20,21] the MDL-type alkaloids are generally more abundant in the tall larkspur *Delphinium barbeyi* and *Delphinium occidentale* populations.[19,22,23] If a risk analysis of tall larkspur species is performed on the basis of the MSAL-type alkaloid content only, then *Delphinium glaucum* is considered the most toxic tall larkspur species followed by *D. barbeyi* and *Delphinium glaucescens*, with *D. occidentale* being the least toxic tall larkspur species.[24] In this regard, current management recommendations for grazing cattle on larkspur-infested ranges are in fact based primarily on the concentration of the MSAL-type alkaloids,[25,26] in part because research has demonstrated that tall larkspur populations with only MDL-type alkaloids are of low risk to cattle.[27]

D. barbeyi is one of the more problematic species of tall larkspur plants due to its high concentration of MLA. However, the most abundant norditerpenoid alkaloids in most *D. barbeyi* populations are the less toxic MDL-type alkaloids, either deltaline or 14-OAD.[19,21,23] Although the toxicities of MLA, 14-OAD, and deltaline have been determined individually,[28] it is not known what effects the proportionally higher concentration of deltaline or 14-OAD in these plants have on the toxicity of MLA. To understand what contributions MDL-type alkaloids make to the overall toxicity of larkspurs, the effects of deltaline and 14-OAD on the toxicity of MLA were assessed by comparing the lethality, in mice, of these alkaloids administered individually and in combination. Both deltaline and 14-OAD

caused an increase in toxicity when co-administered with MLA (Figure 2). The effect of these two MDL-type alkaloids on the

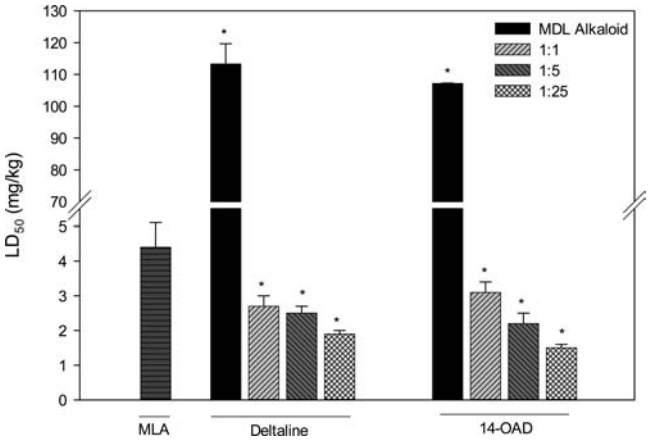

Figure 2. Effect of co-administration of various 7,8-methylenedioxylycoctonine (MDL)-type alkaloids on the toxicity of methyllycaconitine (MLA) in mice. The data represent the LD_{50} of MLA alone, MDL-type alkaloids alone, and MLA plus MDL-type alkaloids at ratios of 1:1, 1:5, and 1:25 MLA to MDL-type alkaloids. Results represent the mean ± SD of 24−86 mice per group; ∗, $P < 0.05$ as compared to the MLA group. (Adapted from Welch et al.[29])

toxicity of MLA was greater than additive, as their co-administration with MLA at 1:1, 1:5, and 1:25 ratios resulted in decreases in the LD_{50} (more toxic) by approximately 25, 50, and 60%, respectively, versus that of MLA alone. Solutions containing both MLA- and a MDL-type alkaloid showed increased toxicity compared to MLA alone, suggesting that MDL-type alkaloids exacerbate MSAL toxicity and therefore play an important part in the toxicity of larkspur plants.[29]

We examined the role of MDL-type alkaloids in the overall toxicity of larkspur plants to cattle with the hypothesis that if the MDL-type alkaloids affect the toxicity of the larkspur plant material in an additive manner, then a larkspur population with a high MDL-type alkaloid concentration would be more toxic than a larkspur population with a low MDL-type alkaloid concentration when both have a similar MSAL-type alkaloid content.[30] The results of that study (Table 1) clearly demonstrate that as the ratio of MDL- to MSAL-type alkaloids

Table 1. Effects of Single Doses of Three Tall Larkspur Populations on Heart Rate in Steers

	dose (mg alkaloid/kg)			heart rate[a] (beats/min)	
tall larkspur population (MDL:MSAL)	MSAL-type	MDL-type	total alkaloid	baseline	24 h
D. barbeyi (3:1)	8	25	33	75 ± 9	102 ± 16*
D. barbeyi (1:1)	12	12	24	70 ± 5	82 ± 12

decreased, the amount of plant material required to raise heart rate, a clinical sign of poisoning in larkspur-poisoned cattle, increased.[31] A decrease in the MDL- to MSAL-type alkaloid ratio from 3.1:1 to 0.6:1 required the dose to be increased from 8 to 18 mg MSAL/kg to achieve an elevated heart rate. Coincidentally, the dose that was observed to elevate heart rate was >26 mg total alkaloid/kg for each population. Consequently, it could be argued that surpassing a threshold of total alkaloid is all that is required to elevate heart rate. However, we found a correlation between the increase in heart rate associated with larkspur intoxication and serum MLA concentrations ($P = 0.0001$) but not deltaline ($P = 0.2$).[32] Additionally, we observed that cattle dosed at 37.6 mg total alkaloid/kg with a tall larkspur population that contains almost exclusively MDL-type alkaloids showed no elevation in heart rate.[27] These results are in agreement with the mouse experiments[29] and demonstrate that MDL-type alkaloids increase the toxicity of MSAL-containing larkspur plants.

In the study using cattle, animals were dosed with different populations of tall larkspur that naturally have different ratios of MDL- to MSAL-type alkaloids.[30] A drawback with that study was that as the ratio of MDL- to MSAL-type alkaloids changed, so did the amount of MSAL-type alkaloids dosed, which made it difficult to differentiate the role of the MDL-type alkaloids from that of the MSAL-type alkaloids. Therefore, we also examined the role of MDL-type alkaloids on the overall toxicity of tall larkspur plants to cattle while controlling for the exact dose of MSAL-type alkaloids.[33] Cattle were dosed with plant material from two different populations of tall larkspur containing either almost exclusively MDL- or MSAL-type alkaloids (Figure 3). A more detailed description of the alkaloids in *Delphinium* species is provided by Gardner et al.[34] These two plant populations were combined to create mixtures with ratios of 0.3:1, 1:1, 5:1, and 10:1 MDL- to MSAL-type alkaloids. The dose that elicited similar clinical signs of poisoning was determined for each mixture based on the MSAL-type alkaloid content (Figure 4). As the ratio of MDL- to MSAL-type alkaloids increased, the amount of MSAL-type alkaloids required to elicit clinical signs decreased.

The results from these studies indicate that MDL-type alkaloids exacerbate the overall toxicity of the MSAL-type alkaloids and should be considered when predicting potential toxicity of larkspur populations. Therefore, when chemical analyses are performed on larkspur plants to assess their toxic potential, the concentration of both the MSAL- and MDL-type alkaloids should be determined, with more weight given to the effect of the MSAL-type alkaloids. Finally, the results from this study indicate that larkspur plants containing large amounts of MDL-type alkaloids, in addition to high MSAL-type alkaloid content, should be considered potentially more dangerous to cattle than plants with only high MSAL-type alkaloids.

■ DEATH CAMAS AND LOW LARKSPUR

There are many species of death camas (*Zigadenus* spp.) located in North America.[35,36] Death camas is one of the first plant species to emerge in the spring. Poisonings generally occur during the spring when death camas is abundant and while other forage species show little growth. Poisonings also occur on overgrazed ranges where better quality forage has been depleted or when management errors result in hungry animals being moved into death camas-infested areas.[37] Livestock losses due to death camas have been reported in numerous species, with the largest losses generally occurring in

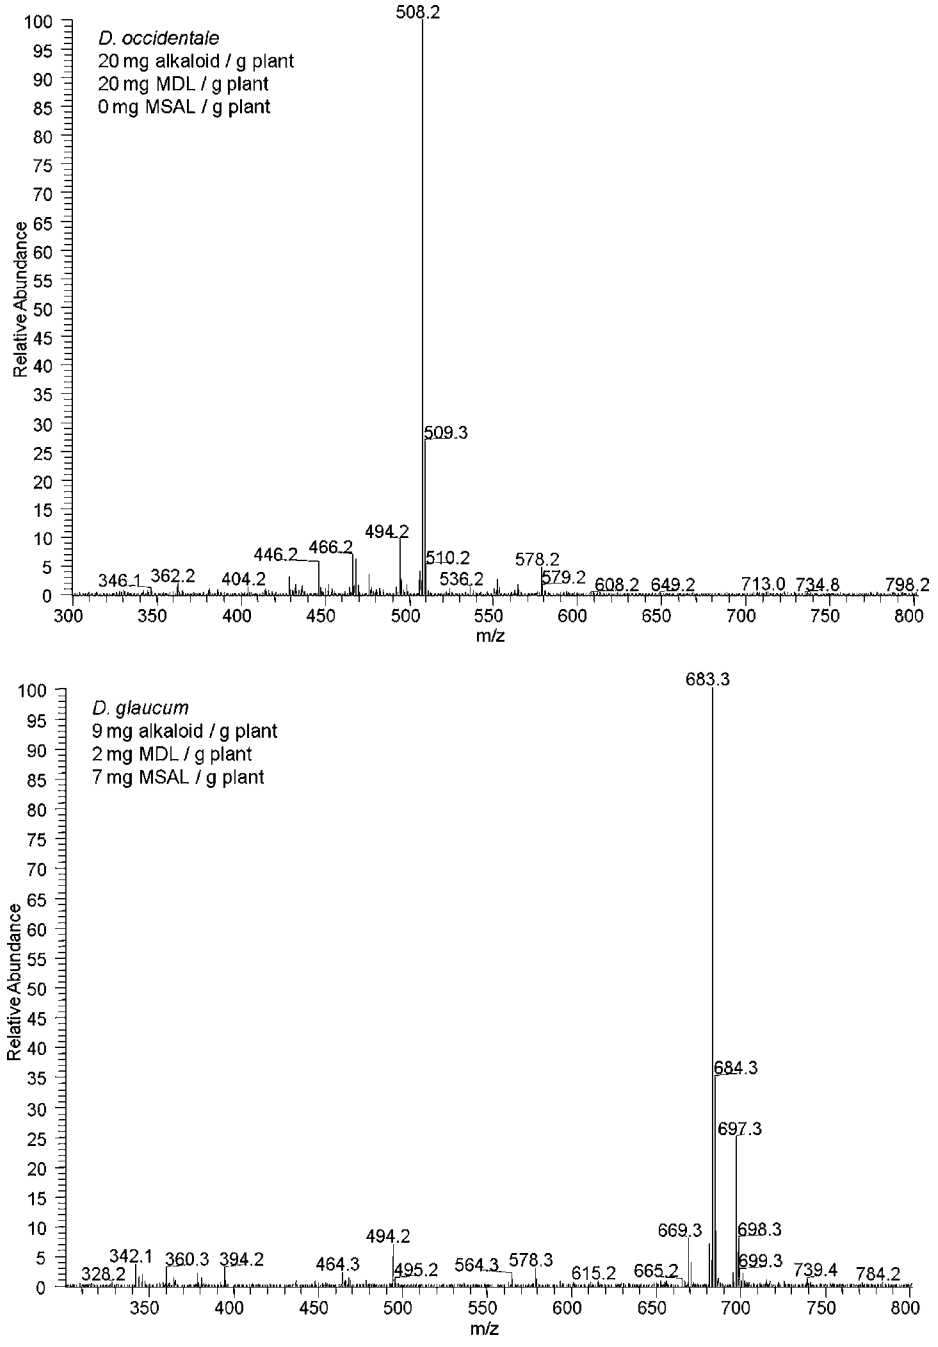

Figure 3. Mass spectra of alkaloids from the *Delphinium occidentale* and *Delphinium glaucum* plant populations used for these experiments. Spectra include protonated molecules (MH^+) for the different alkaloids in the plants. The major alkaloid in the *D. occidentale* population was deltaline (*m*/*z* 508), whereas the major alkaloid in the *D. glaucum* population was methyllycaconitine (MLA; *m*/*z* 683). (Adapted from Welch et al.[33])

sheep[38] and some reported losses in cattle.[39] Sheep are primarily affected because of their tendency to select forbs, particularly in the early spring when there is little other plant growth. Clinical signs of poisoning are similar for all animal species studied, including excessive salivation, with foamy froth around the nose and muzzle that persists, followed by nausea and occasionally vomition in ruminants. Intestinal peristalsis is dramatically increased, accompanied by frequent defecation and urination, muscular weakness with accompanying ataxia, muscular fasciculations, prostration, and eventual death.[37,40] Zygacine, **4** (Figure 1), is often the most abundant alkaloid in death camas and is consequently believed to be the primary toxic component.[41,42]

One common poisonous plant found growing simultaneously in the same area as death camas is low larkspur (*Delphinium nuttallianum*). *D. nuttallianum* is known to contain a high concentration of MLA.[43,44] In fact, MLA is one the more abundant alkaloids in many low larkspur species.[45,46] Additionally, the kinetic profile of MLA and the other toxic alkaloids in low larkspur have been shown to be similar when the alkaloids are dosed to cattle as either tall or low larkspur.[32,47,48] Consequently, the objective of our studies was to determine if co-administration of low larkspur will exacerbate the toxicity of death camas. We first characterized the effects of coexposure of the primary toxin from each of these plants in a mouse model.[42] The LD_{50} values of purified zygacine and MLA in mice were 2.0

dx.doi.org/10.1021/jf500086u | J. Agric. Food Chem. 2014, 62, 7363−7369

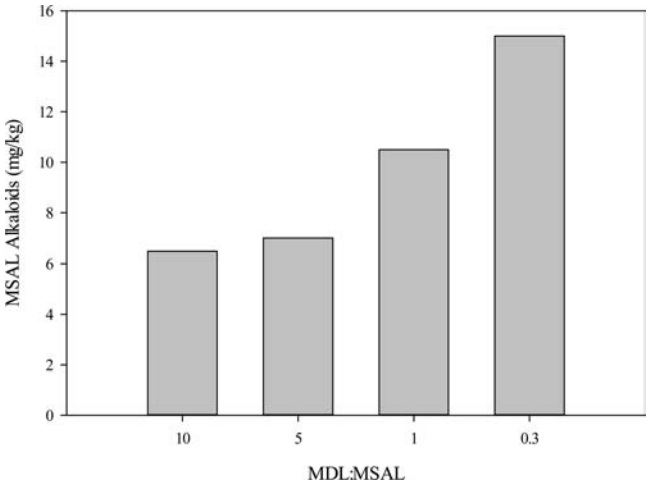

Figure 4. Effect of ratios of 7,8-methylenedioxylycoctonine (MDL)- to *N*-(methylsuccinimido)anthranoyllycoctonine (MSAL)-type alkaloids on lethal dose determination. Data represent the amount of MSAL-type alkaloids required to kill at least one steer per group; n = 2−4 steers per group. (Adapted from Welch et al.[33])

± 0.2 and 4.6 ± 0.5 mg/kg, respectively (Figure 5).[42] In comparison, the LD_{50} of a 1:1 mixture of MLA to zygacine was

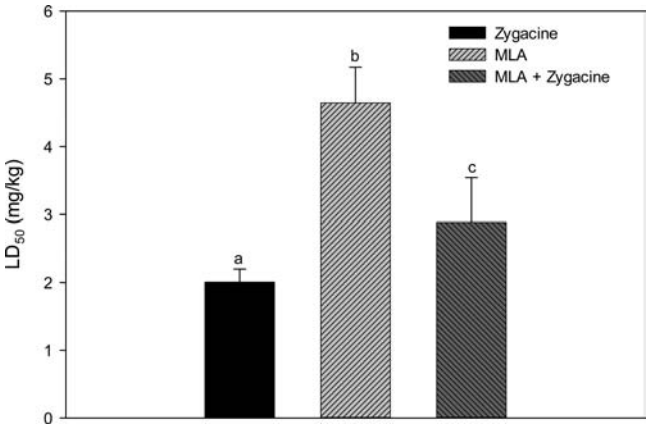

Figure 5. Comparison of the acute toxicity of zygacine, MLA, and a 1:1 mixture of zygacine and MLA. The data represent the median lethal doses (LD_{50}) of zygacine, methyllycaconitine (MLA), and a 1:1 mixture of zygacine and MLA. Results represent the mean ± SD of 28−39 mice per group. Different letters above bars designate significant difference between groups, $P < 0.05$. Each group was significantly different from the other two groups. (Adapted from Welch et al.[42])

2.9 ± 0.7 mg/kg. The LD_{50} value for the mixture is almost halfway between the LD_{50} values for the individual compounds, suggesting that both alkaloids contributed to the toxicity. Similar results were observed when the toxicity of a 1:1 mixture of a death camas total alkaloid extract and a low larkspur total alkaloid extract was compared to the toxicities of the individual total alkaloid extracts.[42]

The alkaloids in low larkspur inhibit normal neuromuscular function, causing muscle weakness and collapse in poisoned animals. This muscle weakness can be exacerbated by physically stressing the animals. Consequently, we evaluated the effect of low larkspur and death camas coexposure on exercise-induced muscle weakness and fatigue in sheep.[49] For this experiment, four groups of four sheep each were used, including control (alfalfa), death camas alone, death camas plus low larkspur, and low larkspur alone. The sheep were exercised by walking them back and forth across a 100 m alley at approximately 3 km/h for 10 min at 4, 8, and 24 h postdosing. The number of sheep in each group that were physically unable to maintain this pace was noted (Table 2). Statistically there was no difference in the

Table 2. Effect of Death Camas and Low Larkspur Cotreatment on Exercise-Induced Muscle Weakness[a] in Sheep

	4 h		8 h		24 h	
group	yes	no	yes	no	yes	no
control	0	4	0	4	0	4
death camas	1	3	1	3	0	4
death camas + low larkspur	0	4	2	2	1	3
low larkspur	0	4	0	4	0	4

[a]Data represent the number of sheep that collapsed due to muscle weakness (yes) or did not collapse (no) at each time point. Statistical comparisons were performed using Fisher's exact test, using a 2 × 2 contingency table; none of the comparisons of treated and control animals were significantly different ($P > 0.05$). (Adapted from Welch et al.[49])

number of sheep that collapsed in each group at each time point. An important note was that no sheep receiving low larkspur alone demonstrated any clinical signs of poisoning, which supports previous findings that sheep are very resistant to larkspur poisoning. Consequently, the results from this study suggest that low larkspur does not potentiate the toxicity of death camas in sheep. However, due to the fact that there was an additive effect in mice, future experiments will be conducted to determine what effect coexposure of low larkspur and death camas has in cattle, a livestock species known to be susceptible to both death camas and low larkspur poisoning.

■ ISOBOLOGRAMS OF MULTIPLE PLANT TOXINS

The isobologram, introduced by Loewe and Muischnek,[50] provides a convenient graphical method to visually characterize the effect of co-administration of two compounds in relation to their individual effects.[51] The isobologram consists of a set of discrete, experimentally determined points, the location of which allows a classification of the interaction. Points on the isobologram that are significantly below the additivity line indicate synergistic, or potentiating, combinations (sometimes referred to as greater than additive), whereas those significantly above this line are antagonistic (sometimes referred to as less than additive). We evaluated the interaction of multiple plant toxins in mice by performing an isobolographic analysis for the different combinations. For characterization of the co-administration of MDL- and MSAL-type alkaloids, the isobologram was constructed by connecting the mouse LD_{50} of the corresponding MDL-type alkaloid deltaline, plotted on the x-axis, with the mouse LD_{50} of the MSAL-type alkaloid MLA, plotted on the y-axis, to obtain the additivity line. The corresponding values for mixtures of the two types of alkaloids were also plotted, and their location was compared to the additivity line (Figure 6A). It is very evident that co-administration of these two types of alkaloid has a greater than additive effect.

For characterization of the co-administration of zygacine and MLA to mice, an isobologram was constructed by connecting the LD_{50} of the zygacine plotted on the x-axis with the LD_{50} of

dx.doi.org/10.1021/jf500086u | J. Agric. Food Chem. 2014, 62, 7363−7369

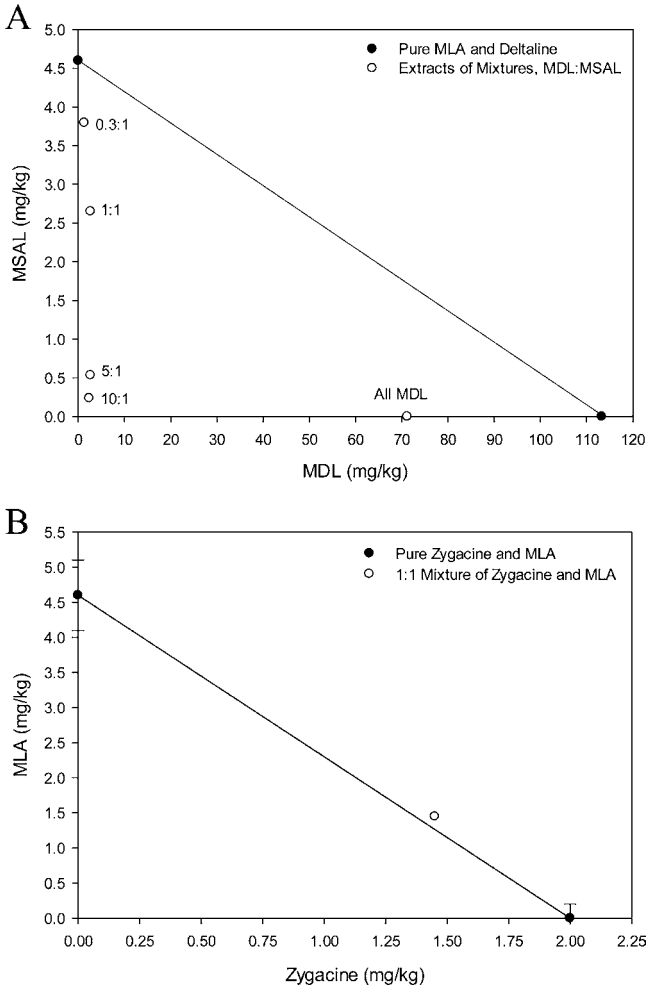

Figure 6. Isobologram analysis for the effect of simultaneous administration of multiple toxins. Panel A represents the effect of simultaneous administration MSAL- and MDL-type alkaloids in mice. Solid circles correspond to the LD_{50} of pure MDL- and MSAL-type alkaloids dosed individually. The line connecting the two points represents the additivity line. Open circles correspond to the LD_{50} of mixtures of MDL- and MSAL-type alkaloids at the indicated ratios. Panel B represents the effect of simultaneous administration of MLA and zygacine in mice. Solid circles correspond to the LD_{50} of zygacine and MLA dosed individually. The line connecting the two points represents the additivity line. The open circle corresponds to the LD_{50} of the 1:1 mixture of zygacine and MLA.

the MLA plotted on the *y*-axis to obtain the additivity line. The corresponding value for the 1:1 mixture of zygacine and MLA was also plotted and its location compared to the additivity line (Figure 6B). The close proximity of the value for the 1:1 mixture to the additivity line suggests that co-administration of these two alkaloids to mice has an additive effect.

In conclusion, the results from our experiments dosing animals with multiple plant toxins demonstrate that there can be a mixture effect. The experiments with tall larkspur indicate that MDL-type alkaloids exacerbate the overall toxicity of the MSAL-type alkaloids and should be accounted for in the prediction of potential toxicity of larkspur populations. The results from the experiments with mice using MLA and zygacine suggest that there could be an additive effect with death camas and low larkspur. However, low larkspur cotreatment does not potentiate the toxicity of death camas in sheep. This information will be useful in further developing livestock management recommendations for ranchers and in designing additional experiments to study the toxicity of multiple plant toxins in livestock species.

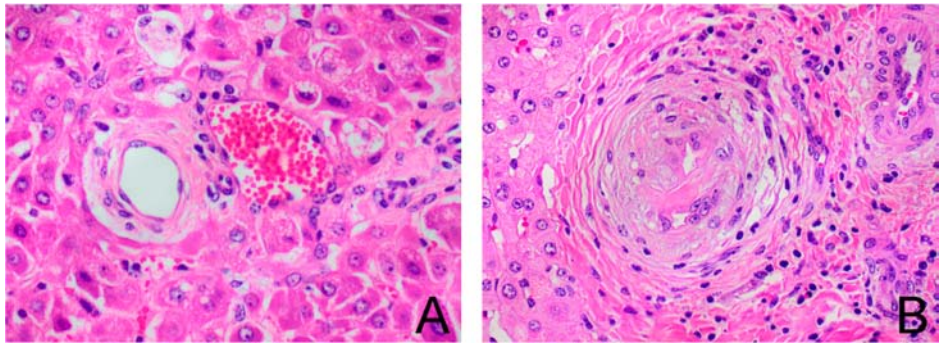

Figure 1. (A) Photomicrograph of the liver of a cow that had grazed a turnip crop and that had been photosensitive for 9 days. The dilated small bile duct (left of center) is lined by an abnormally thin, attenuated epithelium and surrounded by a thin band of concentric fibrosis. A normal portal vein (right of center) and a small arteriole between the vein and bile duct are also visible. (B) Photomicrograph of the liver of another cow that had grazed a turnip crop and that had been photosensitive for 16 days. Two small bile ducts are present in the center, and both are surrounded by a moderately thick band of concentric fibrosis. A normal arteriole is visible top right. H&E 40×.

GLUCOSINOLATES (GSLS) AND THEIR DEGRADATION PRODUCTS

GSLs (mustard oil glucosides) are biosynthesized from certain amino acids and are composed of a β-D-thioglucose group linked to a sulfonated aldoxime. Nearly 130 unique glucosinolates with elongated and modified amino acid-derived side chains[4] have been described. GSLs are classified as aliphatic, aromatic, or indolic depending on whether the derived amino acids are aliphatic (methionine, alanine, valine, leucine, isoleucine), aromatic (tyrosine, phenylalanine), or indolic (tryptophan).[5] There are a large number of GSLs in turnip and rape varieties grown around the world, but the six that occur in the highest concentrations are (i) progoitrin (2-hydroxy-3-butenyl GSL), (ii) gluconapin (3-butenyl GSL), and (iii) glucobrassicanapin (4-pentenyl GSL), all three of which are in the alkenyl (terminally unsaturated carbon in the side-chain) subgroup of the aliphatic GSL, plus (iv) gluconasturtiin (2-phenylethyl), an aromatic GSL, as well as the indolic GSLs (v) glucobrassicin and (iv) neoglucobrassicin.[6−11] In New Zealand, progoitrin would appear to be the dominant GSL,[12] whereas gluconapin, glucobrassicanapin, and gluconasturtiin tend to be more dominant elsewhere.[8,10] Another aliphatic GSL worth mentioning is sinigrin (2-propenyl GSL), which is found in high concentrations in *Brassica oleracea* (kale, cabbage, cauliflower, broccoli, Brussels sprouts) and *Brassica nigra* (black mustard), and in small amounts in turnips and rape.[9]

Intact GSLs are stable, nontoxic compounds found in all plant tissues in *Brassica* spp. When plant cells are crushed during cutting or chewing, the GSLs come in contact with the myrosinase enzyme system, leading to rapid generation of unstable thiohydroximate-*O*-sulfonate intermediates and spontaneous Lossen rearrangement of the core structure to form the isothiocyanate and, in the case of progoitrin GSL, the oxazolidine-2-thione (goitrin). This process is sometimes called the "mustard oil bomb".[4] In vitro experiments have shown that the interaction of nitrile-specifier protein, epithiospecifier protein, and epithiospecifier-modifier protein act as non-enzymic cofactors that, in the presence of ferrous ions, drive the hydrolysis of specific GSLs toward the production of nitriles (organic cyanides) and epithionitriles.[13−16] As far as is known, however, no in vivo work has yet been done to establish whether these proteins are functional in the rumen. Low pH (4−6) also favors nitrile formation.[17,18] Conceivably, it is also possible that microbiota with myrosinase activity, such as lactic acid bacteria, could further contribute to heightened nitrile/epithionitrile production in the rumen.[19] Other hydrolysis derivatives include thiocyanates, glucose, elemental sulfur, and ascorbigens.[18,20−22] Isothiocyanates are regarded as the most active GSL derivatives but are often volatile, highly reactive, and unstable; nitriles, on the other hand, are less reactive but more stable.[23] A diagrammatic representation of this process is shown in Figure 2.

The majority of the degradation products that result from the presence of intact GSLs in the rumen under weakly acid pH conditions are nitriles.[24] Furthermore, nitriles can be produced from GSLs by the action of Fe^{2+} under similar pH conditions.[23] Epithionitriles, characterized by the cyclic thiirane (episulfide)

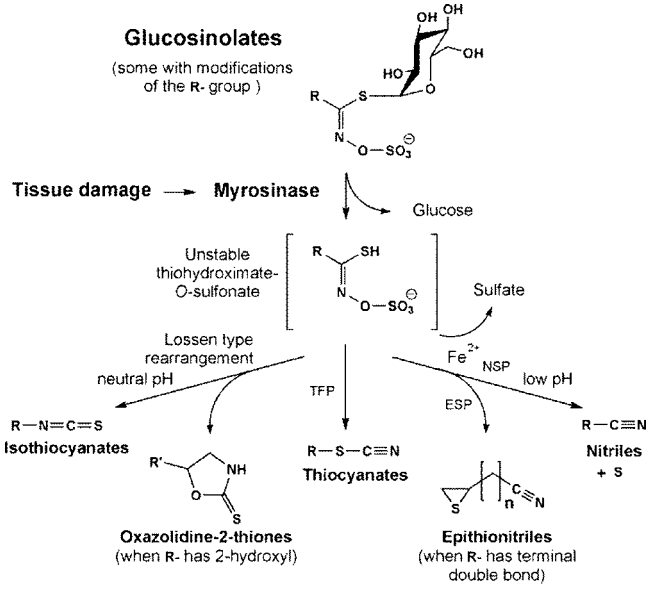

Figure 2. Generic diagram of glucosinolate (GSL) hydrolysis following tissue damage and myrosinase enzyme activity ("the mustard oil bomb") with the respective derivatives (based on Wittstock and Halkier).[5] At neutral pH the unstable thiohydroximate-*O*-sulfonate rearranges to form the isothiocyanate or the oxazolidine-2-thione (goitrin) if the R-group is hydroxylated at carbon 3. In some GSL, a thiocyanate-forming protein (TFP) drives the formation of thiocyanate. Nitriles and epithionitriles tend to be derived when certain cofactors, such as nitrile-specifier protein (NSP), epithiospecifier protein (ESP), and ferrous ions, plus low pH, are present.

Table 1. Parent Glucosinolates, Together with Their Nitrile and Epithionitrile Derivatives[a]

Glucosinolate R-group	Glucosinolate name, synonym(s), formula and structure	Nitrile name, synonym(s), formula and structure	Epithionitrile name, synonym(s), formula and structure
Alkenyl	Progoitrin, (Glucorapiferin, 2(R)-hydroxy-3-butenyl GSL) $C_{11}H_{19}NO_{10}S_2$ 	3-hydroxy-4-pentenenitrile, (1-cyano-2-hydroxy-3-butene, crambene) C_5H_7NO 	β-hydroxy-thiiranepropanenitrile, ((2R)-1-cyano-2-hydroxy-3,4-epithiobutane, (2R)-3-hydroxy-3-(thiiran-2-yl)-propanenitrile) C_5H_7NOS [diastereoisomers] 	Sinigrin, (2-propenyl GSL, allyl GSL) $C_{10}H_{17}NO_9S$ 	3-butenenitrile, (allyl cyanide) C_4H_5N 	thiiraneacetonitrile, (3,4-epithiobutanenitrile, 1-cyano-2,3-epithiopropane) C_4H_5NS (3(R,S)-isomers) 	Gluconapin, (3-butenyl GSL) $C_{11}H_{18}NO_9S_2$ 	4-pentenenitrile, (1-cyano-3-butene) C_5H_7N 	thiiranepropanenitrile, (1-cyano-3,4-epithiobutane, 4,5-epithiovaleronitrile) C_5H_7NS (4(R,S)-isomers) 	Glucobrassicanapin, (4-pentenyl GSL) $C_{12}H_{20}NO_9S_2$ 	5-hexenenitrile, (1-cyano-4-pentene) C_6H_9N 	thiiranebutanenitrile, (5,6-epithiohexylnitrile, 1-cyano-4,5-epithiopentane) C_6H_9NS (5(R,S)-isomers) Aromatic	Gluconasturtiin, (2-phenylethyl GSL) $C_{15}H_{21}NO_9S_2$ 	phenyl-3-propanenitrile (2-phenylethyl cyanide) C_9H_9N 	
Indolic	Glucobrassicin (indol-3-ylmethyl GSL) $C_{16}H_{20}N_2O_9S_2$ 	indole-3-acetonitrile $C_{10}H_8N_2$ 	

[a]The first name for each compound is the systematic name[26] and the one used in the text. One or more synonyms, sometimes used in references, for each compound, together with the chemical formula and structure are also shown.

moiety, can be derived only from the alkenyl subgroup of the aliphatic GSLs.[16,25] The following nitriles and epithionitriles, using systematic nomenclature,[26] are potentially derived: (*R*)-3-hydroxy-4-pentenenitrile plus two diastereomeric (2*R*)-*β*-hydroxy-thiiranepropanenitriles from progoitrin; 4-pentenenitrile and thiiranepropanenitrile from gluconapin; and 5-hexenenitrile and thiiranebutanenitrile from glucobrassicanapin.[21,27−30] Additional nitrile derivatives potentially derived from turnips and rape include phenyl-3-propanenitrile from gluconasturtiin and indole-3-acetonitrile from glucobrassicin.[31−33] Of these nitriles, the most stable is 3-hydroxy-4-pentenenitrile from progoitrin.[21] The class, trivial name, synonym(s), and formula of the GSLs in turnips and rape, as well as the systematic names, synonyms, formulas, and structures of their respective nitrile and epithionitrile derivatives are shown in Table 1.

NITRILE AND EPITHIONITRILE TOXICITY STUDIES IN RATS AND MICE

In mice, the nitrile derivatives of progoitrin GSL are about 8 times as toxic as the oxazolidinethione derivative, goitrin.[34] Rats fed diets containing mixed nitriles developed liver lesions (bile duct hyperplasia, fibrosis, megalocytosis, and zonal necrosis) and kidney lesions (megalocytosis of renal tubular epithelial cells).[35] Similar dose-dependent lesions, associated with serum biochemical alterations indicative of hepatocellular damage and cholestasis, were induced in rats that were fed diets containing the diastereoisomers of (2*S*)-*β*-hydroxy-thiiranepropanenitrile for 3 months.[36] The authors in this study described hepatic changes similar to those seen after ingestion of aflatoxin or pyrrolizidine alkaloids, as well as biliary hyperplastia with "flattened epithelium and dilated lumina"[36] of affected bile ducts. The latter changes are reminiscent of the microscopic cholangiectasis seen in a turnip-poisoned cow (Figure 1A).

dx.doi.org/10.1021/jf500526u | J. Agric. Food Chem. 2014, 62, 7370−7375

The derivatives responsible for the nephrotoxicity in rats were identified as (2*S*)-*β*-hydroxy-thiiranepropanenitrile and thiiranepropanenitrile.[37−39] It is not clear whether the renal lesions are due to released cyanide, terminal hypoxia, the epithio group, the nitrile itself, or oxidation products of the aliphatic moiety.[38−40] In another experiment, administration of thiiranepropanenitrile to rats caused severe toxicity, characterized by periacinar hepatic necrosis and renal tubular degeneration.[40] Degeneration and necrosis of the forestomach epithelium of rats dosed with thiiranepropanenitrile have also been described.[39]

Another less potent nitrile derived from progoitrin, 3-hydroxy-4-pentenenitrile, is a selective pancreatotoxin, causing apoptosis and necrosis in individual exocrine acinar cells in rats treated for 4 days.[41] This may be related to the duration and route of exposure as subcutaneous injections of this nitrile into pregnant rats induced liver necrosis and bile duct hyperplasia after 12 days.[37] In contrast, the closely related 4-pentenenitrile derivative from gluconapin GSL appears to be nontoxic in rats.[40]

A large number of aliphatic nitrile compounds are utilized in industrial applications and manufacturing, and some of these products produce central nervous system, hepatic, cardiovascular, renal, or gastrointestinal toxicity. Acrylonitrile, for example, is a known mutagen, animal carcinogen, and suspected human carcinogen. It and the structurally similar methacrylonitrile are eliminated unchanged in expired air, as well as via a variety of urinary metabolites. The principal metabolites in bile are glutathione conjugates, whereas oxidation by cytochrome P450 enzymes to an epoxide intermediate could lead to the release of cyanide.[42]

With regard to nitrile compounds that could potentially be hepato- or cholangiotoxic in cattle, attention is drawn to the epithionitrile derivatives. The latter are thiirane molecules (1,2-episulfides) that are rarely encountered in nature.[43] Chemically, they are similar to epoxides and would be expected to bind covalently to proteins and to DNA and thus could act as alkylating agents with cytotoxic, mutagenic, and carcinogenic effects.[40,44−46] In addition, they could react with a wide variety of electrophilic and nucleophilic compounds, as well as undergo polymerization.[40,47] Polymerized thiiranepropanenitrile appeared to be relatively nontoxic when administered in high doses to rats.[40] In the rat, thiiranepropanenitrile is rapidly absorbed irrespective of route of administration. It is bioactivated following conjugation to glutathione and excreted predominantly as a mercapturic acid in urine with smaller amounts in bile.[46,48,49] It has been suggested that the three-membered thiirane ring is partially responsible for the toxicity of the epithionitriles.[50]

In addition, it is possible that the slow liberation of hydrogen cyanide may make some contribution to the toxicity of epithionitriles.[46] In humans, there are reports of convulsions and fatalities following respiratory arrest ascribed to a variety of aliphatic nitriles that are structurally similar to 3-hydroxy-4-pentenenitrile.[51] Experiments with mice inoculated intraperitoneally show that these nitriles release free cyanide after hepatic microsomal biotransformation of the cyano group.[51] It has been suggested that cyanide levels in the brain play an important role in mortality.[52] For aliphatic nitriles, the length of the carbon chain, the position of a double bond, and the presence of an *α*-hydrogen atom are determinants of the extent of metabolism of nitriles to CN^-.[53,54]

NITRILE AND EPITHIONITRILE STUDIES IN RUMINANTS

3-Butenenitrile, a derivative of the glucosinolate sinigrin, has been shown to cause minor liver damage as indicated by slightly raised GGT activities when given orally to sheep. The liver lesions were not characterized histologically.[55,56]

The analysis of samples of fat, liver, kidney, and muscle from slaughtered beef cattle that had been fed a ration containing up to 10% crambe (*Crambe abyssinica*) seed meal, which would be expected to contain high levels of crambene (3-hydroxy-4-pentenenitrile),[57] failed to detect any GSL derivatives.[58]

In ruminants grazing brassica crops, the dose of derived nitriles and epithionitriles will depend both on the amount produced via enzymatic hydrolysis during chewing and rumination and on the amount produced nonenzymatically in the presence of low rumen pH and ferrous ions. Certainly, additional metabolism including microbial degradation in the rumen and the nature, concentration, and reactivity of, and host tolerance to, the respective compounds will influence disease development.[23,24] Further work on the mechanism by which nitriles and epithionitriles exert potentially noxious effects on hepatocytes and biliary epithelium is needed. An aspect that will also need investigation in future cases is whether a lowered rumen pH, associated with subacute ruminal acidosis induced by the low neutral detergent fiber and high water-soluble carbohydrate content of forage brassica, contributes to greater nitrile or epithionitrile elaboration in the rumen.[12,59]

In conclusion, distinctive bile duct lesions can occur in cattle that develop photosensitization following grazing on turnip or rape forage crops. To date, the identity of the hepato- or cholangiotoxic phytochemical(s) in such toxic forage brassica remains undiscovered. Various nitrile and epithionitrile derivatives of GSL found in crop plants have been shown to be hepatic, renal, pancreatic, and/or gastric toxins in rats. Because of this, it is hypothesized that one or more of these GSL derivatives, in particular those with the thiirane episulfide moiety (the epithionitriles), could be toxic to the livers of cattle under certain circumstances, such as when rumen pH is acidic. Research on the potential toxicity of these compounds, either through the dosing of pure compounds or through the creation of rumen conditions conducive to their formation in high concentrations (low pH, ferrous ions) from ingested brassica forage, is warranted.

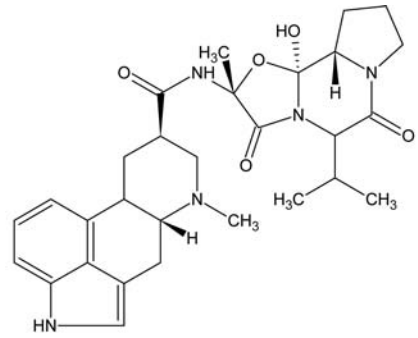
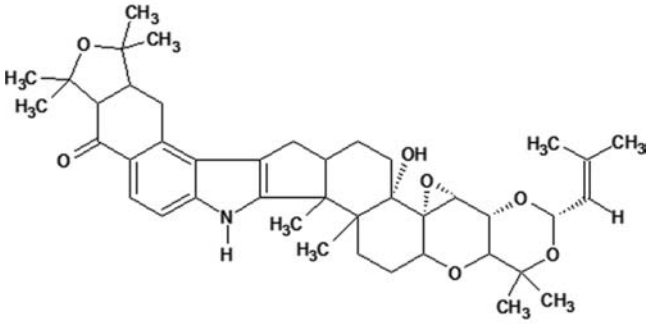
NOTE ADDED AFTER ASAP PUBLICATION

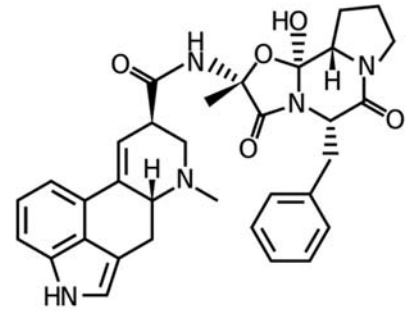
The structures in Table 1 have been revised from the original posting of April 11, 2014. The correct version was posted July 8, 2014.



Ergovaline = **1**



Lolitrem B = **2**



Ergotamine = **3**

Figure 1. Chemical structures of the compounds ergovaline (**1**), lolitrem B (**2**), and ergotamine (**3**).

and perennial ryegrass straw, with particular attention paid to replicating the environmental conditions in which these animals exist; such a study has been conducted for camelids.[6]

The OSU Endophyte Service Laboratory[13] receives an average of 3497 test requests per year (years 2005−2013) to test feed material for the alkaloids discussed above. During 2005−2013, an average of 226 accessions/year were clinical cases submitted principally by veterinarians who suspected feed material was causing vasoconstrictive disease, reproductive problems, or ryegrass staggers. The remaining majority of the samples were submitted by the Ag-Fiber industry with the goal of ensuring "safe feed". A summary of the extraction and HPLC detection methodologies currently in use and six examples of clinical cases follow.

EXTRACTION AND DETECTION METHODOLOGY

Extraction of Endophyte Mycotoxins from Plant Material. *Ergovaline and the Ergot Alkaloids.* A method for the extraction of ergot alkaloids from plant material was developed on the basis of previous studies for subsequent analysis by HPLC-fluorescence.[2,3,10,14] As "neat" standard is expensive and difficult to synthesize, ground seed or straw is mixed in large batches at four target concentrations to generate reference material for use in a calibration curve, which is validated using >98% pure ergovaline, **1**, provided by Forrest Smith, Auburn University. Seed and straw samples are ground in a Cyclotec 1093 sample mill and passed through a 0.5 mm screen. To each tube containing 1 g of sample, control, or reference material are added 10 mL of chloroform plus 1 mL of internal standard (0.661 mg/L ergotamine, **3**, in chloroform) and 1 mL of 0.001 M NaOH; the tubes are capped and mixed for 18−24 h in the dark and then centrifuged at 650*g*. Five milliliters of organic supernatant is applied to a 500 mg/6 mL solid phase extraction (SPE) column containing 0.5 g of Ergosil and 0.5 g of anhydrous sodium sulfate. Ergovaline, **1**, and the ergot alkaloids are extracted by adding 5 mL of sample eluent to the SPE contained in a positive pressure manifold, followed by a 2 mL 4:1 acetone/chloroform (v/v) wash and elution with 2.5 mL of methanol. The eluent is dried under nitrogen at 50 °C and then reconstituted in 0.5 mL of methanol. Samples are mixed for 10 s, sonicated for 10 s, and centrifuged at 650*g* for 5 min. Samples are transferred to amber HPLC vials and sealed for analysis. The percent recovery for this method is 91% for seed and plant material; inter- and intra-assay variations are 5.7 and 3.8%, respectively.

Extraction of Lolitrem B. Lolitrem B, **2**, quantitation involves solvent extraction and filtering before HPLC analysis.[4,10] Plant material is ground as described above, and then 3 mL of a 2:1 chloroform/methanol (v/v) mixture is added to 0.200 g of sample, control or reference material, capped, and mixed for 18−24 h in the dark. Due to the same cost and availability circumstances described above, the Endophyte Service Laboratory uses straw or seed reference material mixed in large batches at four concentrations that is validated using purified lolitrem B, **2**, provided by Ag Research, Ltd., New Zealand, to establish a calibration curve. Next, the samples are centrifuged at 650*g* for 10 min, and 1.6 mL of supernatant is dried under nitrogen at ambient temperature. One milliliter of dichloromethane (CH_2Cl_2) is added to the evaporated supernatant, capped, and sonicated for 10 s, followed by vortexing for 10 s. An additional 1 mL of CH_2Cl_2 is added, and the sample is again sonicated and vortexed for 20 s each to ensure the entire sample is dissolved. CUSIL 500 mg/6 mL SPE cartridges are loaded onto a positive pressure manifold and preconditioned with 2 mL of CH_2Cl_2. The samples are loaded onto the SPE, followed by a 2 mL CH_2Cl_2 wash. A 0.5 mL wash of elution solution (4:1 CH_2Cl_2/acetonitrile (CH_3CN) (v/v)) is added to the cartridges, and positive pressure is applied. The sample is then eluted with 3 mL of elution solution; SPE columns are dried to force all remaining liquid out of the columns. The eluent is mixed, and 1.5 mL is transferred to amber HPLC vials and sealed for analysis. The percent recovery for this method is 91.5% for plant material. Inter- and intra-assay variations are 8.1/8.5 and 6.2/6.8% for straw/seed, respectively.

HPLC-Fluorescence Analysis for Ergot Alkaloids. *Ergovaline, 1.* The current protocol in our laboratory for HPLC analysis of ergovaline, **1**, involves reversed-phase chromatography with fluorescence detection (excitation and emission wavelengths of 250 and 420 nm, respectively) and a gradient pump program run at a flow rate of 1.8 mL/min with 35% CH_3CN and 2 mM ammonium carbonate in purified water as mobile phase A and CH_3CN as mobile phase B, as follows:

dx.doi.org/10.1021/jf5027229 | J. Agric. Food Chem. 2014, 62, 7376−7381

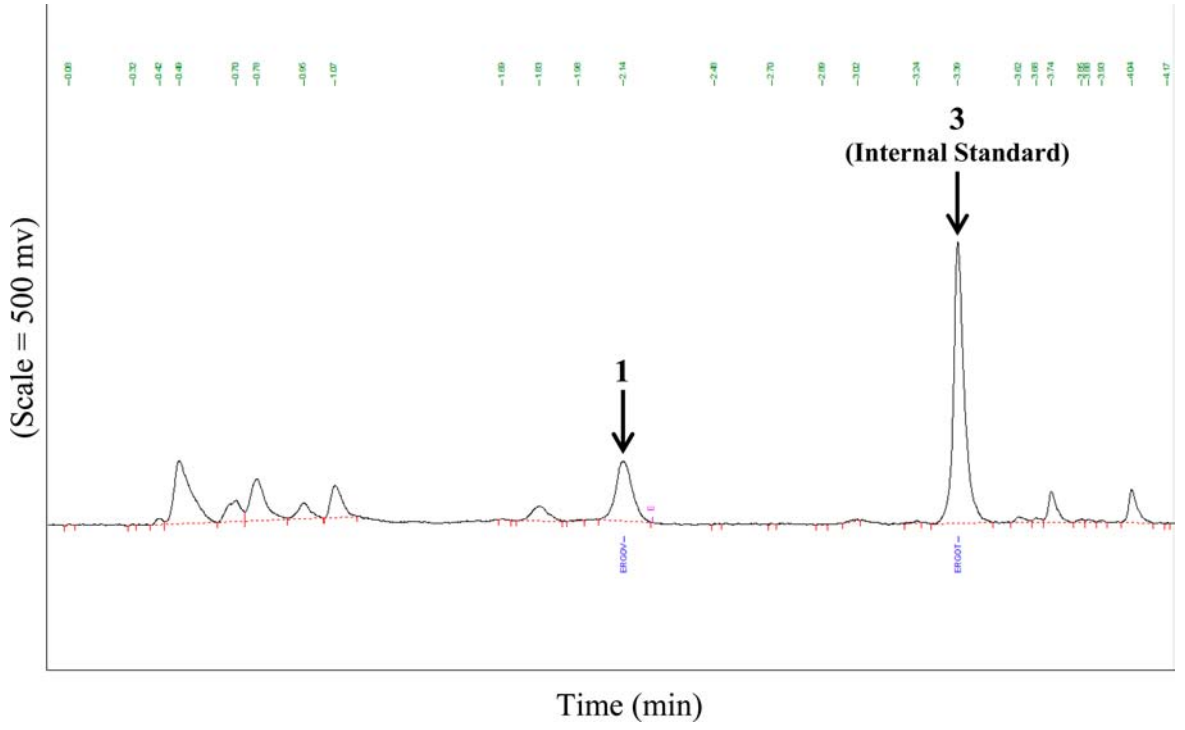


Figure 2. HPLC-fluorescence chromatogram of tall fescue seed (500 ppb) extracted for ergovaline, **1**, by the Endophyte Service Laboratory, Oregon State University. Ergotamine, **3**, is added as an internal standard to all materials being tested.

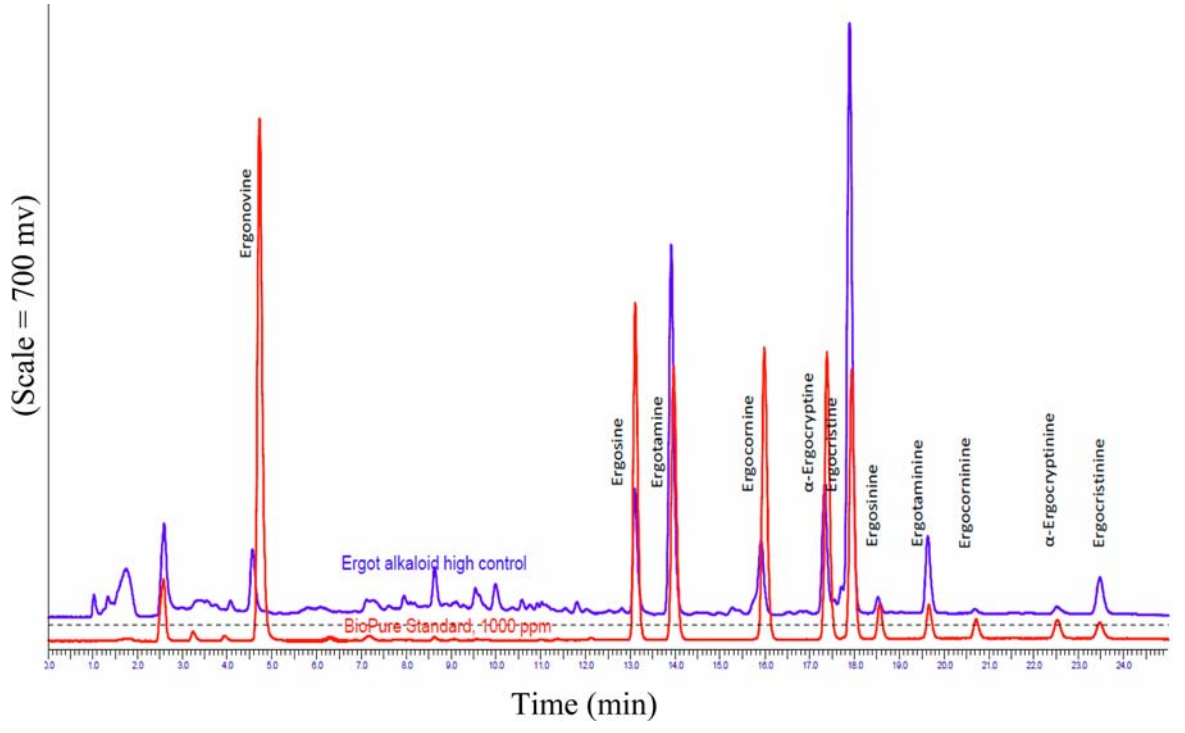

Figure 3. HPLC-fluorescence chromatogram of pure standard (red trace) and tall fescue high control seed (blue trace) extracted for the five ergot alkaloids associated with ergot (ergosine, ergotamine, **3**, ergocornine, α-ergocryptine, and ergocristine) by the Endophyte Service Laboratory, Oregon State University. (The -inine epimers for these five alkaloids elute subsequent to the main compounds.)

equilibrate from 0 to 0.5 min at 99% A, hold at 99% A for 1.0 min, then decrease linearly from 1.5 to 2.3 min to 35% A, hold at 35% A from 2.3 to 3.1 min, then raise linearly to 99% A from 3.1 to 3.4 min, and hold for another 1.3 min before cycling to the next sample. A column (either 100 mm × 4.6 mm i.d., 2.6 μm, Kinetex C18 or 100 mm × 4.6 mm i.d., 2.7 μm, Brownlee SPP C18) is used in conjunction with a guard column cartridge of similar packing. The retention time for ergovaline, **1**, is 2 min, whereas that for ergotamine, **3**, is 3 min. The limit of detection (LOD) of ergovaline, **1**, is 31 ppb, whereas the limit of quantitation (LOQ) is 100 ppb. Figure 2 shows an example of a HPLC-fluorescence chromatogram for ergovaline, **1**, produced using this assay.

dx.doi.org/10.1021/jf5027229 | *J. Agric. Food Chem.* 2014, 62, 7376−7381

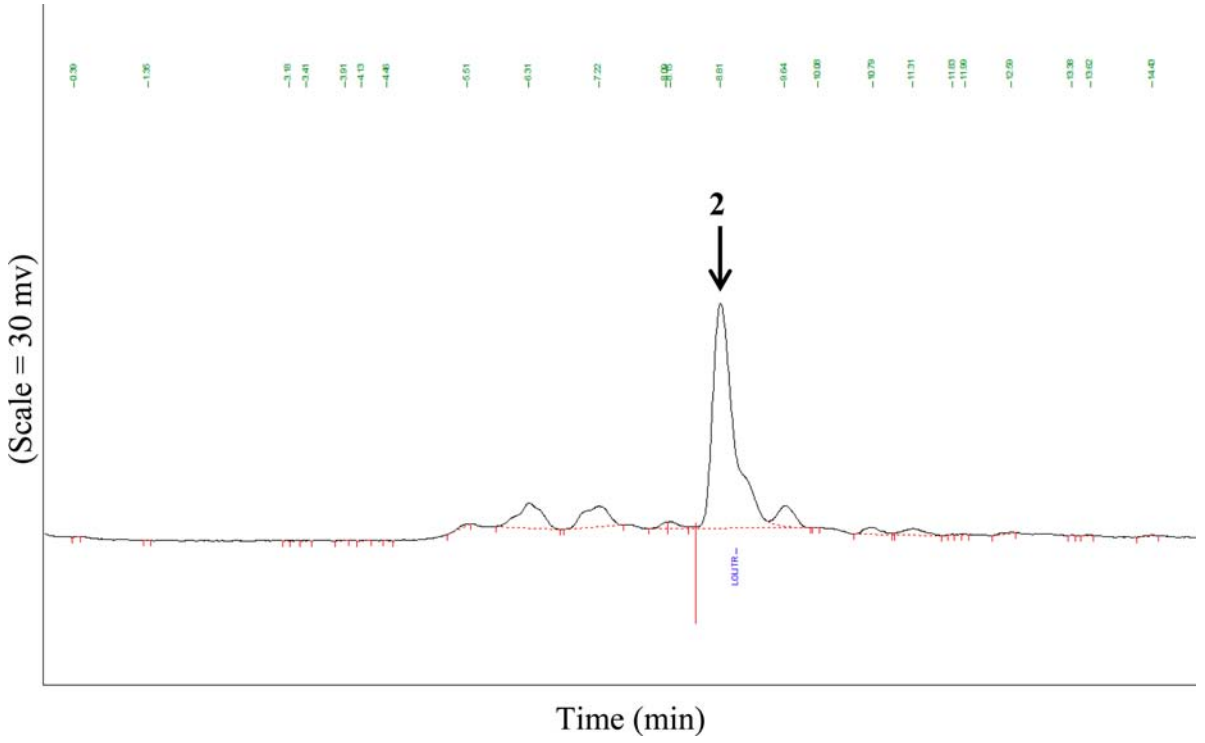

Figure 4. HPLC-fluorescence chromatogram of perennial ryegrass straw (2500 ppb) extracted for lolitrem B, **2**, by the Endophyte Service Laboratory, Oregon State University.

Ergot Alkaloids. For ergot analysis, fluorescence detection is the same as above but a different chromatography configuration is used. At a flow rate of 0.9 mL/min, mobile phases of 1 mM ammonium carbonate (A) and CH_3CN (B) are run through a gradient pump program as follows: equilibrate from 0 to 5 min at 75% A, then decrease linearly to 65% A from 5 to 15 min, hold at 65% A from 15 to 20 min, and then decrease linearly to 25% A from 20 to 25 min. Compounds analyzed in this assay and their LOD/LOQ values are ergosine, ergotamine, **3** (11/38 ppb), ergocristine (14/50 ppb), ergocornine (11/41 ppb), and α-ergocryptine (13/49 ppb). Figure 3 illustrates an example of a HPLC-fluorescence chromatogram for the ergot alkaloids examined for cases of ergot using this assay.

HPLC Analysis Protocol for Lolitrem B, 2. The Endophyte Service Laboratory performs lolitrem B, **2**, quantitation by HPLC-fluorescence detection using normal phase separation and an isocratic mobile phase ($CH_2Cl_2/CH_3CN/H_2O$ 4:1:0.02 (v/v)) run at 0.5 mL/min for 15 min.[15−17] Lolitrem B, **2**, is detected using a fluorescence detector set with an excitation wavelength of 268 nm and an emission wavelength of 440 nm. A 250 mm × 4.6 mm i.d., 5 μm, Zorbax RX-SIL analytical column is used in conjunction with a hand-packed silica guard column. The retention time of lolitrem B, **2**, is 8.3 min. The LOD is 30 ng/mL and the LOQ, 100 ng/mL, for plant material. Figure 4 shows an example HPLC-fluorescence chromatogram of straw reference material extracted for lolitrem B, **2**, using this method.

CASE REPORTS

The following documents six clinical cases of endophyte toxicoses in herds of cattle in the Pacific Northwest, USA and Canada, coupled with toxin levels analyzed by the Endophyte Service Laboratory. Often, these values were confirmatory of the tentative diagnosis. In addition, these values helped validate the threshold levels that had been determined by experimental feeding trials.

Case 1. A crossbred beef cow/calf operation of 1800 head from Harney County, eastern Oregon, was supplemented in January with endophyte-infected tall fescue straw in addition to their winter range. They were owned by the same family but were kept divided into three herds, A, B, and C. Two of the three herds with 1040 animals (herd A) and 260 cows (herd B) were fed from common stacks of tall fescue straw. Tall fescue straw was fed initially as the sole source of fiber, supplemented with residual fall pasture grazing starting November 25. Herd A had added alfalfa hay at 20% of the ration to their younger cows and at a 50:50 ratio to the older cows from December 1 to January 17. Herd B had free access to a protein supplement (28%), and both herds A and B had access to mineral salts. On January 17, all feeding of the tall fescue stopped. Herd C with 500 cows was fed 100% fine fescue straw until November 27 and then changed on December 10 to 50% meadow hay and 50% fine fescue. This herd returned to a full ration of fine fescue from December 31 to January 15. Clinical signs of lameness and swollen feet were first noted by the owners in cows from herds A and B on December 25, but the cause was not yet understood. These signs progressed to dry gangrene of the feet, often with subsequent fracture of the necrotic toes or lower limbs. By March 5 in herd A, 449 animals had died or were euthanized due to fescue foot, 56 were lame, and 12 had uterine prolapses. In herd B, 36 were dead or destroyed, 49 were lame, and 3 had uterine prolapses. Abortions and birth of weak or dead calves occurred in the majority of the pregnant cows that were affected. Herd C had no clinical problems. The minimum environmental temperatures from November 25 to December 25 ranged from 1 to 30 °F, with 16 days of minimum temperatures below 10 °F. Core samples of the remaining tall fescue were taken on January 17, with subsequent analyses for ergovaline, **1**, concentration. The mean of 10 core

dx.doi.org/10.1021/jf5027229 | J. Agric. Food Chem. 2014, 62, 7376−7381

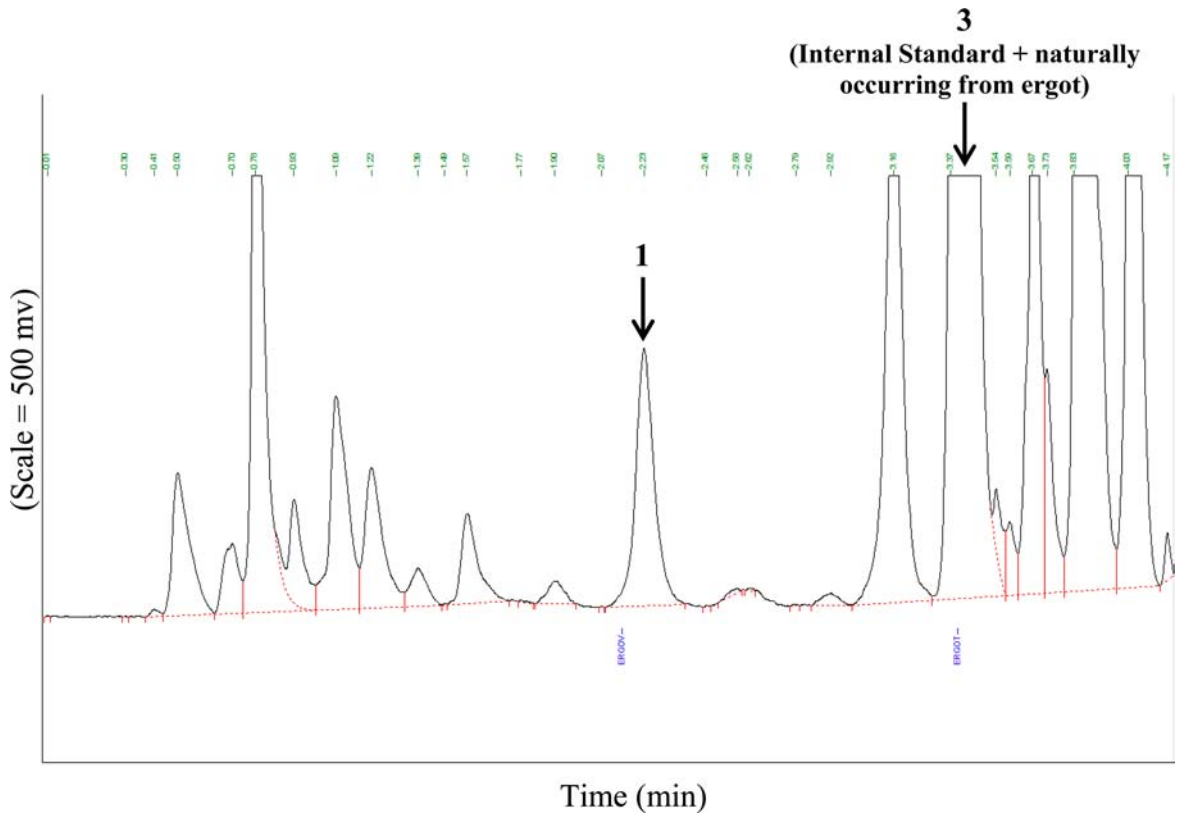

Figure 5. HPLC-fluorescence chromatogram of pellets associated with loss of 13/40 cattle (case 4). Sample was flagged for suspected ergot contamination by the Endophyte Service Laboratory, Oregon State University, due to the large ergotamine, **3**, peak eluting in the ergovaline, **1**, assay.

samples was 329.7 ppb, with a standard deviation of 90.7 ppb. Whereas some core samples had low levels of 116 and 222 ppb, eight samples had values from 340 ppb to a high of 406 ppb. Forty tons of tall fescue straw had been consumed in November and December, prior to testing. Within a month, a total of 600 cows had died, were humanely euthanized, or aborted.

Case 2. During January, 1500 steers in Lethbridge, Alberta, Canada, were supplemented with silage and wheat and barley grain. Clinical signs of dry gangrene of the ears and feet were evident, with sloughing of the hooves being the most serious. In sum, 45 steers were euthanized or died. The grain was infected with *C. purpurea* and contained 3473 ppb total ergot alkaloids. This total was derived from peaks of 262 ppb of ergosine, 545 ppb of ergotamine, **3**, 753 ppb of ergocornine, 613 ppb of α-ergocryptine, and 1299 ppb of ergocristine.

Case 3. In January, 330 steers, bulls, and pregnant beef cows, on frozen pastureland in Coburg, OR, USA, were supplemented with tall fescue straw plus pellets. The pellets were said to be made from perennial ryegrass screenings combined with steamed corn. Five bins of pellets were tested, as well as the straw bales. The straw bales had <100 ppb of ergovaline, **1**, which is below the LOD for our method. It was determined that the five bins of pellets had more than ryegrass screenings, as evidenced by chromatographic analyses, which showed ergovaline, **1**, concentrations ranging from 800 to 1100 ppb; these values are more consistent with tall fescue screenings. One bin of pellets underwent an ergot analysis, which had a value of 820 ppb of ergotamine, **3**. Initial examination of the lameness by a local veterinarian was mistaken for wire cuts on the lower limbs. Within days, multiple cows were affected with vasoconstrictive dry gangrene. Eventually, 44 animals lost hooves, ears, and tails, resulting in their deaths.

Case 4. Forty cattle in a cow/calf operation were housed in a pen in rural Oregon in early January. They were being fed pellets, seed screenings, and haylage. Thirteen of these developed lameness and dry gangrene of their distal limbs and were euthanized. It was determined that the vasoconstrictive lesions were due to ergot toxicosis caused by *C. purpurea*. Pellets were contaminated with 54916 ppb total ergot alkaloids. These included ergotamine, **3** (36858 ppb), ergocristine (8016 ppb), α-ergocryptine (3494 ppb), and ergosine (4684 ppb) (Figure 5).

Case 5. Thirty pregnant cows in their second trimester were on grass seed fields in late December. Pellets made of tall fescue grass seed screenings were spread in piles over the field. After 2 weeks of ingestion, two animals aborted and three animals had open bleeding from their distal limbs and were in extreme pain. Feeding of the pellets was stopped and samples were sent to the Endophyte Service Laboratory for analysis. The affected animals also developed vasoconstrictive lesions in their feet; five were euthanized, four lost their tails, two became lame, and two aborted. Analysis of the screenings detected ergovaline, **1**, at 2096 ppb.

Case 6. Seventeen Hereford × Red Angus male and female calves weighing between 136 and 181 kg had been weaned and moved into confinement in the Willamette Valley, Oregon. They were fed free-choice perennial ryegrass straw and started on a grain ration, the amount of which was gradually increased over a 1.5 week period to 1.82 kg/calf/day. After 1 week, some of the calves developed head tremors and a staggering, stiff gait. The owner incorrectly suspected grain overload and treated them with a mineral oil drench, procaine penicillin G (IM), and dexamethasone (20 mg IM). Response to this treatment was minimal. The calves were not removed from the perennial ryegrass straw until day 23 following the initiation of feeding and

dx.doi.org/10.1021/jf5027229 | *J. Agric. Food Chem.* 2014, 62, 7376−7381

the death of one of the calves. Samples of the turf-quality perennial ryegrass straw being fed contained 3711 ± 243 ppb of lolitrem B, **2** (the threshold of toxicity in cattle is between 1800 and 2000 ppb of lolitrem B, **2**). The ruminal contents of the necropsied calf had a lolitrem B, **2**, concentration of 185 ppb, as compared to a clinically normal calf from the same herd with 25 ppb of lolitrem B, **2**, in its ruminal fluid. Eight of 17 of the calves developed concurrent acute pulmonary emphysema, which had not been reported. An experimental study with four healthy calves fed perennial ryegrass straw with a similar lolitrem B, **2**, concentration showed ryegrass staggers in all animals after 5 days of the feeding trial, but no lung lesions.[18]

SUMMARY

The overriding importance of the Endophyte Service Laboratory is to ensure "safe feed" is exported throughout the world, as well as to local markets. The clinical cases presented here of lameness, dry gangrene, sloughing of ears and tails, and abortions in livestock highlight the fact that, only through feed analysis, can the causative agent of disease be determined. In a similar manner, definitive diagnosis of ryegrass staggers requires analysis of feed even though cessation of feeding does result in remission of clinical signs. For tall fescue toxicosis, levels of ergovaline, **1**, at 300−350 ppb are the threshold for development of clinical disease in horses and cattle.[5] With extreme low environmental temperatures during winter months, these values may be lower. Care should be taken not to feed endophyte-infected tall fescue straw or seed screenings in the winter months unless they have been analyzed for ergot alkaloid toxins. Threshold values for cattle of lolitrem B, **2**, in feed are between 1500 and 2000 ppb;[8] camels have shown clinical signs in experimental feeding trials at 1000 ppb when fed continuously for 60 days.[6] Table 1 details current threshold levels for livestock species for these two endophyte toxicoses. In addition, in the Pacific Northwest, cases of ergotism due to *C. purpurea* contamination of feed have been increasing. Feeding trials need to be conducted to establish threshold of toxicity levels in livestock species for the collection of ergot alkaloids that cause this disease.

Table 1. Threshold Levels for Fescue Toxicosis (Ergovaline, 1) and Perennial Ryegrass Staggers (Lolitrem B, 2)

	ergovaline, **1**	lolitrem B, **2**
camels	not determined	500 ppb
cattle	300−500 ppb[a]	1800−2000 ppb
horses	300−500 ppb[b]	not determined
sheep	500−800 ppb[a]	1800−2000 ppb

[a]Depending on weather. [b]Brood mares should have no detectable ergovaline, **1**, in their feed.

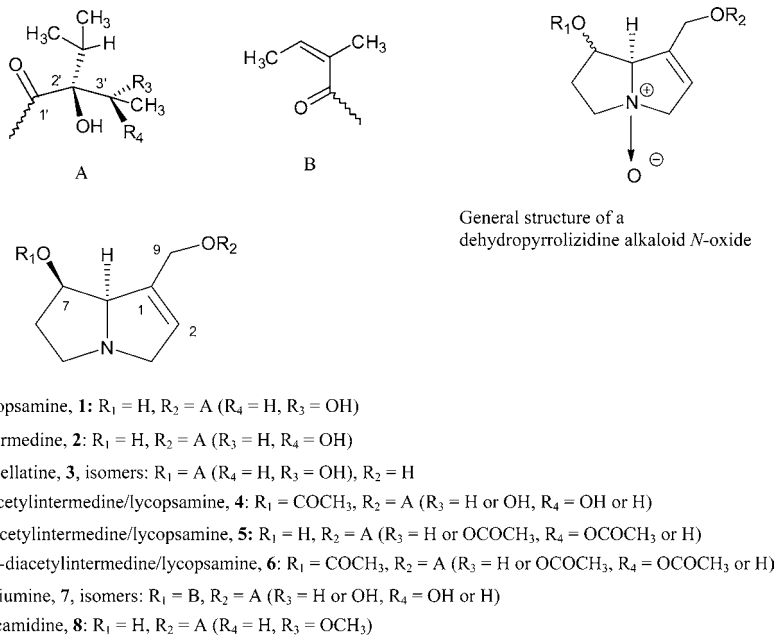

Figure 1. Structures of dehydropyrrolizidine alkaloids detected in *Amsinckia* species or discussed in the text.

and a putative deoxylycopsamine-*N*-oxide. The latter has also been observed in *Cryptantha crassipes*[13] and may correspond to the monoester dehydropyrrolizidine alkaloid amabiline previously identified in some *Amsinckia* species.[7] Also described in the same study of collections of *Amsinckia intermedia* from Arizona and Washington states were some pan-seasonal changes in dehydropyrrolizidine alkaloid levels and, in contrast to Johnson et al.,[3] the presence of **1** as its free base in the seeds of plants collected in Arizona and a significant increase in the quantity and diversity of alkaloids produced by the plants collected in Washington relative to the Arizona plants.[5] This difference once again raises the issue of potential taxonomic misassignment based upon very similar morphologic features.

A continued concern about taxonomic differentiation based on subtle morphologic features, combined with the HPLC-esi(+)MS capacity to directly detect and quantitate both the free base and *N*-oxide forms of the dehydropyrrolizidine alkaloids, prompted this current investigation of annotated herbarium specimens of *Amsinckia*. The objectives included a more accurate profiling of the free base/*N*-oxide ratios, a correlation of the alkaloid profiles with the species, and a determination of the potential usefulness of herbarium-preserved specimens with respect to detection of dehydropyrrolizidine alkaloids and their *N*-oxides.

MATERIALS AND METHODS

Chemicals and Reagents. Methanol was reagent ACS/USP/NF grade (Pharmaco Products; Brookfield, CT). Acetonitrile was the HPLC-certified solvent (Honeywell Burdick and Jackson; Muskegon, MI), and water was Milli-Q-purified (18.2 MΩ/cm) (Millipore; USA). Formic acid, was "For Analysis" grade (>99%) (Acros Organics/Thermo Fisher Scientific; NJ). Lycopsamine, **1**, and intermedine, **2**, and their *N*-oxides (Figure 1) and lasiocarpine (all >99% pure based on HPLC-esi(+)MS and NMR analysis) were sourced from the stocks of extracted and purified pyrrolizidine alkaloids kept by the USDA/ARS Poisonous Plant Research Laboratory.

Plant Specimens. One or two leaves from geographically- and/or temporally differentiated specimens of annotated *Amsinckia douglasiana*, *A. tessellata*, *Amsinckia retrorsa*, *A. menziesii*, *Amsinckia lycopsoides*, *Amskinckia eastwoodiae*, and *A. intermedia* were harvested from the Stanley L. Welsh Herbarium, Brigham Young University. Additionally, leaf samples of similarly differentiated specimens of *A. eastwoodiae*, *A. douglasiana*, *A. lunaris*, and *A. vernicosa* were obtained from the Botany Herbarium and the Agronomy Herbarium of the University of California, Davis. Samples of specimens of *A. menziesii* var. *intermedia*, *A. intermedia* and *A. retrorsa* were harvested from the USDA/ARS Poisonous Plant Research Laboratory Herbarium. Finally, five samples each of *A. eastwoodiae*, *Amsinckia lunaris*, and *Amsinckia vernicosa*, and four samples each of *Amsinckia grandiflora* and *A. douglasiana* were supplied by the Jepson Herbarium at the University of California, Berkeley (Table 1).

Sample Preparation and Extraction. The entire sample for each specimen was transferred to a weighed microcentrifuge tube (2 mL Graduated Free Standing) (Fisherbrand, Pittsburgh, PA) to which was added a 4.5 mm Copperhead copper-coated steel pellet (Crosman Corporation, Bloomfield, NY). The capped tubes were then shaken using a MM301 Retsch shaker (Retsch Inc., Newtown, PA) for 5 min at 17 cps. The grinding pellet was carefully removed from the centrifuge tube that was then recapped and weighed to afford the residual plant weight (ca. 7−70 mg). Methanol (0.5 mL) was added to each tube and the powdered plant gently extracted by inversion mixing at room temperature for 16 h. After centrifugation (15000*g*, 5 min), analytical samples were prepared by adding a 10 μL aliquot of the supernatant to 90 μL of a solution of 0.1% formic acid/methanol (1:1, v/v) containing lasiocarpine (ca. 10 μg/mL) as an internal standard. In some cases, a more concentrated sample was prepared by dilution of 50 μL of the supernatant with 50 μL of the formic acid/methanol solution.

HPLC-esi(+)MS and MS/MS Analysis. Analytical samples (5 μL) were injected using a model 1260 Infinity HPLC system (Agilent Technologies, CA) onto a 150 mm × 2 mm i.d., 4 μm, Synergi Hydro RP column (Phenomenex, Torrence, CA) fitted with a 2 mm × 4 mm i.d. AC C18 guard column (Security Guard cartridge system, Phenomenex, Torrence, CA). A gradient flow (400 μL/min) of 0.1% formic acid in water (mobile phase A) and acetonitrile (mobile phase B) was used to elute sample components from the column. Mobile phase B was held at 3% for 2 min before linearly increasing to 70% by 10 min. After holding at 70% for another 5 min, the column was re-equilibrated to 3% mobile phase B over 2 min and held for a further 7 min before the next injection.

Eluate from the column was monitored using a Velos Pro LTQ mass spectrometer (Thermo Scientific, USA) in a two-scan, positive ion mode and equipped with a heated electrospray ionization (HESI)

source. The first full scan (m/z 200−800) was followed by a data dependent, collision-induced dissociation (CID) scan using a generic CID energy of 32%, activation Q of 0.25, and an activation time of 10.0 ms. The capillary temperature was set at 275 °C, the ionization spray voltage at 3.45 kV, the HESI source heater temperature at 305 °C, and the sheath gas flow was 40 units with an auxiliary flow of 5 units.

Identification and Quantitation of Dehydropyrrolizidine Alkaloids. Reconstructed ion chromatograms (RICs) displaying the mass to charge ratio (m/z) of the protonated molecule (MH^+) for dehydropyrrolizidine alkaloids previously identified in *Amsinckia* spp. were used in the first instance to identify potential alkaloids (Figure 2). The retention times and MS/MS data of significant peaks thereby observed were compared to standards where available. Otherwise, the MS/MS data were examined for fragment ions characteristic of dehydropyrrolizidine alkaloids or their *N*-oxides and, further, compared to literature reports of the suspected alkaloids.[12,14]

To account for intrinsic inconsistencies between analytical ion chromatograms, the peak area for a dehydropyrrolizidine alkaloid or its *N*-oxide was divided by the peak area of the internal standard, lasiocarpine, to afford an "adjusted area". Every HPLC sample was analyzed twice to provide an average "adjusted area". This process immediately highlighted any machine or user errors that could be

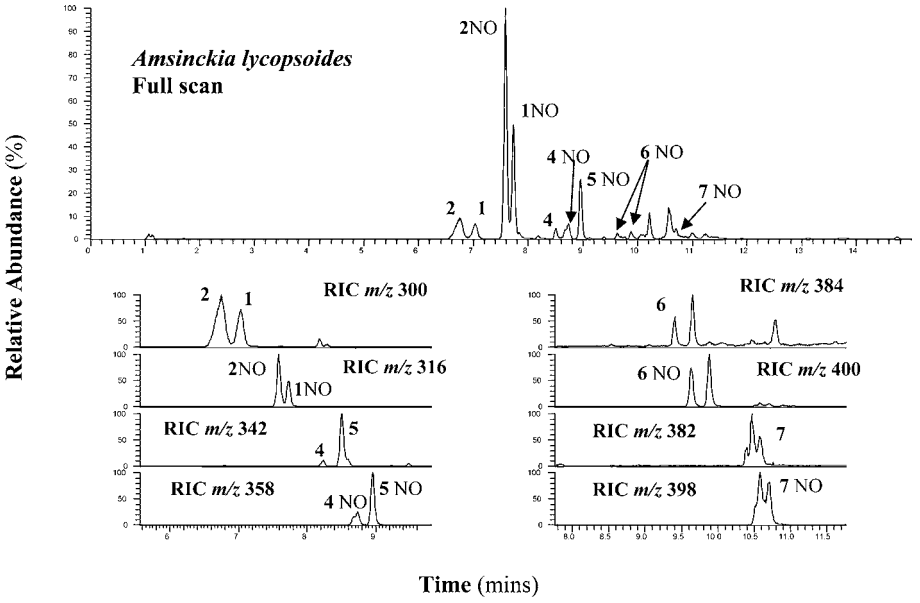

Figure 2. HPLC-esi(+)MS base ion (m/z 200−1000) and reconstructed ion chromatograms for specimen 5 of *Amsinckia lycopsoides* (Table 1). Peaks are annotated with the structure numbers (bold) (Figure 1).

corrected. Relative quantitative estimates of the dehydropyrrolizidine alkaloid and *N*-oxide content of most samples were then based on an eight-point calibration curve (adjusted area = 1.35 × concentration in μg/mL: R^2 = 0.9983) generated using seven 1:1 serial dilutions of intermedine, **2**, from 14.15 to 0.12 μg/mL. In more dilute samples, the quantitative estimate was completed using an eight-point calibration curve (adjusted area = 0.0023 × concentration in μg/mL: R^2 = 0.9993) generated using seven 1:1 serial dilutions of **2** from 2.2 to 0.016 μg/mL). Therefore, concentrations of alkaloids and their *N*-oxides are expressed as "μg equivalents of intermedine/g plant material".

RESULTS AND DISCUSSION

CalFlora recognizes 11 species and five additional varieties of *Amsinckia*,[10] while the USDA plants database describes 10 species with six varieties and many synonyms.[11] It appears that of those, only *A. intermedia*, *A. lycopsoides*, *A. menziesii*, and *A. tessellata* are widely distributed and have been carried from their historical ranges, mainly in the states of California, Oregon, and Washington, with lesser representation east onto the Columbia Plateau and Great Basin regions. The remaining species and varieties are distributed mainly in coastal California and nearby desertic ranges, some into the Great Valley, and others along the U.S. coast northward as far as Skagway, Alaska. The weedy representatives of this genus have been spread, by whatever means (feed, autos, planes, people, etc.), widely within the U.S. and to other parts of the world including Europe and Australia.

However, the taxonomic differentiation within the genus *Amsinckia* (Boraginaceae) is somewhat suspect in many cases, due mainly to the minor morphological distinctions upon which such differentiation is based. Therefore, in an attempt to discover any useful chemotaxonomic indicators, the dehydropyrrolizidine alkaloid profiles of leaf samples collected from herbarium specimens of *Amsinckia* species, including some of doubtful assignation, were acquired from crude methanolic extracts of the samples. Because only small samples of leaves from herbarium specimens could be taken for analysis, detection of only the major dehydropyrrolizidine alkaloids present in each sample was expected. For similar reasons, replicate analyses of the same specimen were not possible and thus potential intraspecimen variation could not be accounted for or addressed.

Dehydropyrrolizidine alkaloids, usually present mainly as their *N*-oxides, were detected in every sample analyzed (Figure 1). The efficiencies of recovery of dehydropyrrolizidine alkaloids and their *N*-oxides from these small samples were not determined. However, because all samples were treated the same way, it is assumed that the relative profiles determined for each specimen will be an accurate reflection of alkaloid content. Estimated total levels of dehydropyrrolizidine alkaloids were usually quite variable within and between species and varied from about 1 to 4500 μg equivalents of intermedine/g plant material (Table 2). The predominant dehydropyrrolizidine alkaloids observed were the *N*-oxides of lycopsamine, **1**, and

Table 2. Total Dehydropyrrolizidine Alkaloid Content Summary

		total dehydropyrrolizidine alkaloid content (μg equivalents intermedine/g dry weight plant)			
Amsinckia species	no. of specimens	median	average	range	standard deviation

intermedine, **2**, in varying relative amounts from almost exclusively **1** in specimen 2 of *A. tessellata* to almost exclusively **2** in specimen 2 of *A. lunaris* (Figure 3). In extracts that

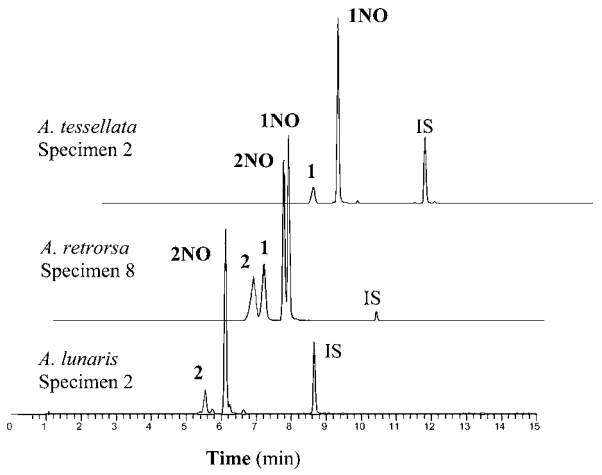

Figure 3. HPLC-esi(+)MS reconstructed base ion chromatograms showing differences in the production of lycopsamine, **1**, intermedine, **2**, and their *N*-oxides in samples of three species of *Amsinckia*. Peaks are annotated with the structure numbers (bold) (Figure 1). "IS" is the internal standard lasiocarpine.

contained larger amounts of alkaloids several trace to minor levels of components were observed that revealed MS/MS profiles strongly indicative of dehydropyrrolizidine alkaloids. However, their contribution to the overall dehydropyrrolizidine alkaloid content and profile was considered negligible. Additionally, minor amounts of the 1,2-dihydro analogues of the dehydropyrrolizidine alkaloids were observed that displayed very similar MS/MS profiles, albeit with fragment ions 2 Da greater than their dehydro counterparts.

The relative abundance profile of dehydropyrrolizidine alkaloids could be quite different between species and even within a designated species (Table 3). It remains to be determined whether these differences represent natural diversity or whether taxonomic misassignments have occurred. For example, specimen 1 of *A. retrorsa*, collected in 2005 from Cache County, Utah (Tables 1 and 3), was an intermedine chemotype with about 95% (of total dehydropyrrolizidine alkaloids identified) intermedine-*N*-oxide, **2**NO, (Figure 4A), whereas the other seven specimens of the same species collected in neighboring counties in Utah, or from sites in the states of Nevada and Washington, all showed a more even ratio of **1NO** and **2NO** (Figure 4B–H). Also noted are the relative differences in the *N*-oxides of the two 3′-monoacetylated derivatives, **5**NO(1) and **5**NO(2), described in detail later in the text, between the specimens of this species (Figure 4).

When comparing the specimens annotated as *A. menziesii*, *A. intermedia*, or *A. menziesii* var. *intermedia* (Table 3) it appears as though four out of five specimens of *A. menziesii* and seven out of 10 of the *A. intermedia* specimens produce both **1**NO and **2**NO in various relative amounts (from predominantly **1**NO, through approximately equal amounts, to predominantly **2**NO), whereas *A. menziesii* specimen 3 and *A. intermedia* specimens 4, 9, and 10, and both samples annotated *A. menziesii* var. *intermedia*, only produce **1**NO. Therefore, it is possible that the sole production of **1** and its *N*-oxide can characterize *A. menziesii* var. *intermedia* and that the *A. menziesii* and *A. intermedia* specimens with the inconsistent profiles may be misassigned.

Three minor abundance ions, isobaric with lycopsamine, **1**, and intermedine, **2**, were deduced, on the basis of the MS/MS data, to be tessellatine, **3**, and related isomers (Table 4). In particular, the base ion peak at m/z 156 in the MS/MS profile for the putative tessellatine isomers is in contrast to the base peak at m/z 138 that is observed with the C9 monoesters **1** and **2** and is consistent with a C7 monoester dehydropyrrolizidine alkaloid analyzed under these esi(+)MS conditions.[15] A corresponding *N*-oxide was only observed for the putative tessellatine peak that eluted earlier than the other two isomers. The putative tessellatine (as its *N*-oxide) is only a major contributor in one specimen analyzed, i.e., *A. eastwoodiae* specimen 1 (Tables 1 and 3). Similar to the lack of tessellatine detected in the preparative chromatography work by Cooper et al.,[8] no significant amount of the putative tessellatine, its isobaric isomers or any other peak that might be assigned to tessellatine on the basis of its MS/MS data were observed for any of the other samples analyzed. This included *A. grandiflora*, *A. douglasiana*, and *A. tessellata* in the section Tessellatae and which were previously reported to contain significant amounts of tessellatine, **3**.[7]

Echiumine, **7**, an open chain diester dehydropyrrolizidine alkaloid more commonly observed in *Echium* species,[12] has been previously reported to be restricted to the section Muricatae and has been detected in one of three specimens of *A. eastwoodiae* and four of 14 specimens of *A. menziesii* var. *intermedia* examined using GC-MS.[7] In this present HPLC-esi(+)MS/MS examination, up to three closely eluting echiumine-*N*-oxide isomers (Figure 2) with identical MS/MS profiles were observed to occur in various relative abundances. In addition to both specimens of *A. menziesii* var. *intermedia* and one of 13 specimens of *A. eastwoodiae*, echiumine (as its *N*-oxide)[12] has also been detected in one of eight specimens of *A. retrorsa*, one of five specimens of *A. menziesii*, three of six specimens of *A. lycopsoides* and five of 10 specimens of *A. intermedia*, all in the section Muricatae, but also in three of five specimens of *A. tessellata* in the section Tessellatae.

Within some specimens examined in this study, four monoacetylated derivatives of lycopsamine-*N*-oxide isomers (i.e., MH^+ m/z 358) were detected in various relative abundances ranging from one, two, three, or through to all four being present in a specimen. The characters of the four isomers are illustrated by comparison of the MS/MS profiles (Table 4) for m/z 358 in *A. intermedia* specimen 2 and specimen 5 (Figure 5). In *A. intermedia* specimen 2, two major monoacetylation peaks are observed at ca. 8.70 and 8.92 min. They have near identical MS/MS profiles (peaks 3 and 4, Figure 5) that include a strong loss of 60 Da (m/z 358 → m/z 298) indicative of a 3′-acetyl derivative. In *A. intermedia* specimen 5, three major monoacetylation peaks are observed at ca. 8.68, 8.73, and 8.92 min. While the third, later eluting peak is the same as described for specimen 2, the early eluting peaks (peaks 1 and 2, Figure 5) again have near identical MS/MS profiles that include a minor ion at m/z 298, a base ion peak at m/z 214, and an ion at m/z 180 indicative of a C7 acetylated derivative.[14] Because of the near coelution of the peaks at ca. 8.68, 8.7, and 8.73 min, there is some mixing of the MS/MS data when all three are present, but scans at the beginning, middle, and end of the coeluting peak envelope help distinguish the three eluants. It is suggested that the four isomers represent 3′- and 7-acetyl derivatives of lycopsamine-*N*-oxide and intermedine-*N*-oxide. The largest

[a]Concentration shown as μg intermedine equivalents/g plant material. [b]Structures shown in Figure 1: **1**, lycopsamine; **2**, intermedine; **3**, tessellatine; **4**, 7-acetyllycopsamine and/or 7-acetylintermedine; **5**, 3′-acetyllycopsamine and/or 3′-acetylintermedine; **6**, 3′,7-diacetyllycopsamine and/or 3′,7-diacetylintermedine; **7**, echiumine and isomers. [c]isomers with the same MS/MS profiles and eluting close together. [d]"+" indicates nonquantitated, low level detection of alkaloid.

effect of acetylation might be expected at the epimeric C3′ position and thus have more effect on retention time of the lycopsamine- and intermedine-based compounds as observed in this HPLC system.

Even though the first five specimens annotated as *A. intermedia* were all collected in Washington County, Utah, between 1983 and 1987 (Table 1), they displayed somewhat different *N*-oxide profiles for lycopsamine isomers and acetyllycopsamine isomers (Figure 6). This may serve as a further example of the variation observed in the HPLC-esi(+)MS profiles of some of the *Amsinckia* species examined or an indication of possible misassignment on morphologic grounds. Specimens 2, 3, and 5 (Table 1) contained similar amounts and ratios of **1**NO and **2**NO. However, specimen 2 was found to produce both of the 3′-acetyl isomers, **5**NO, whereas specimens 3 and 5 produced both of the 7-acetyl isomers, **4**NO, and only the **5**NO isomer 2 (Rt ca. 8.9 min). Specimen 1 produced mainly **1**NO relative to **2**NO, whereas specimen 4 was a lycopsamine chemotype similar to *A. intermedia* specimens 9 and 10.[5]

In accord with an earlier observation,[9] diacetylation of **1** and/or **2** was sometimes evident as two well resolved peaks (Figure 7) with MS/MS profiles (Table 4) that included the presence of ions at *m*/*z* 180 and 214 as well as a loss of 60 Da (*m*/*z* 400 → *m*/*z* 340), consistent with acetylation at both C7 and C3′. The data did not allow specific assignment of the peaks to either diacetyllycopsamine-*N*-oxide or its epimer diacetylintermedine-*N*-oxide. For example, no relative abundance correlation was observed between the similar relative abundances of **1**NO and **2**NO in specimen 9 of *A. douglasiana* and specimen 5 of *A. retrorsa* and their C3′ and C7 monoacetylated derivatives or the two diacetylated derivatives (Figure 7).

Four of the specimens of *A. lunaris* were collected (in 1899, 1938, 1976, and 1986) from Contra Costa County in California while the fifth was collected (in 2008) from San Mateo County in the same state. Similar to four of six specimens of *A. vernicosa*, four of the five *A. lunaris* specimens were also intermedine, **2**, chemotypes with the *N*-oxide predominating except for the oldest specimen collected in 1899. In contrast, *A. lunaris* specimen 4, despite being collected in the same county, produced equal amounts of intermedine and lycopsamine, and their *N*-oxides, in addition to significant levels of the putative tessellatine-*N*-oxide, **3**NO. Another source of contrast between the *A. lunaris* specimens was the production of the monoacetylated derivatives. The oldest two specimens (3 and 4) showed unquantified traces (confirmed by the MS/MS profiles) of the 3′-acetyllycopsamine/intermedine isomer 2,

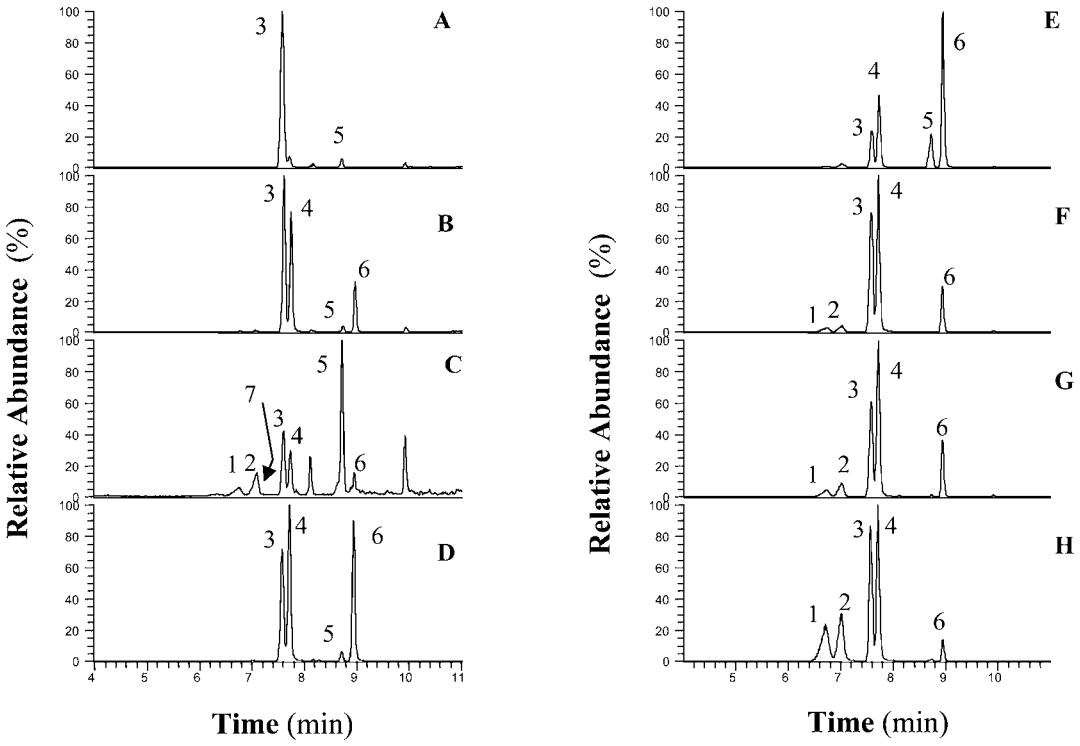

Figure 4. Comparison of HPLC-esi(+)MS reconstructed ion chromatograms displaying (A–H) the major ions *m/z* 300, 316, and 358 for the specimens 1–8, respectively, of *Amsinckia retrorsa* (Table 1). Peak 1 = intermedine, **2**; peak 2 = lycopsamine, **1**; peak 3 = intermedine-*N*-oxide, **2**NO; peak 4 = lycopsamine-*N*-oxide, **1**NO; peak 5 = 3′-acetyllycopsamine-*N*-oxide isomer 1, **5**NO(1); peak 6 = 3′-acetyllycopsamine-*N*-oxide isomer 2, **5**NO(2); peak 7 = putative tessellatine-*N*-oxide, **3**NO.

Table 4. MS and MS/MS Data for Pyrrolizidine Alkaloids Detected in Methanol Extracts of Various *Amsinckia* Species[a]

pyrrolizidine alkaloid	retention time (min)	$MH^+/(2M + H)^+$ *m/z* (% relative abundance)[b]	MS/MS *m/z* (% relative abundance)
lycopsamine (**1**) and intermedine (**2**)	7.0 and 6.7	300	282(0.5), 256(3), 210(2) 156(6), 138(100), 120(22), 94(48),
lycopsamine-*N*-oxide and intermedine-*N*-oxide	7.7 and 7.6	316(100)/631(17)	298(8), 272(19), 254(3), 226(28), 210(4), 172(100), 155(8), 154(7), 138(27), 137(6), 136(12), 120(2), 112(2), 108(2), 94(7)
putative tessellatine (**3**) or isomer	6.4	300	282(1), 256(5), 238(1), 210(1), 192(1), 156(100), 139(1), 138(3), 120(1), 108(2),
putative tessellatine-*N*-oxide or isomer	6.8	316(100)/631(2)	298(3), 272(5), 238(3), 226(3), 172(100), 171(8), 170(6), 154(5), 153(2), 138(1), 137(3), 136(2), 111(1), 106(3)
unidentified tessellatine (**3**)-like isomers (no corresponding *N*-oxides observed)	8.18 and 8.3	300	300(2), 282(9), 256(23), 238(2), 210(36), 194(5), 184(2), 156(100), 139(16), 138(9), 122(8), 120(14), 110(3), 108(2), 94(3)
3′-acetyllycopsamine and/or 3′-acetylintermedine (**5**)	8.22	342	324(2), 297(20), 282(80), 187(3), 156(1), 138(100), 136(3), 120(14)
3′-acetyllycopsamine and/or 3′-acetylintermedine (**5**) isomer	8.5	342	324(2), 282(40), 187(3), 156(1), 138(100), 136(3), 120(14)
3′-acetyllycopsamine-*N*-oxide and/or 3′-acetylintermedine-*N*-oxide	8.7 and 8.9	358 (100)/715(10)	340(10), 316(9), 298(100), 280(2), 172(15), 154(2), 138(5), 137(1), 136(3)
7-acetyllycopsamine and/or 7-acetylintermedine (**4**)	8.6	342	324(1), 282(5), 198(3), 180(57), 162(4), 138(13), 136(1), 124(1), 120(100), 118(2)
7-acetyllycopsamine-*N*-oxide and/or 7-acetylintermedine-*N*-oxide	8.67 and 8.72	358(100)/715(5)	340(12), 314(25), 298(6), 268(23), 252(4), 242(3), 214(100), 197(4), 180(11), 178(5), 154(3), 137(6), 136(3), 120(3)
3′,7-diacetyllycopsamine and/or 3′,7-diacetylintermedine (**6**)	9.4 and 9.65	384	366(6), 352(1), 342(2), 338(1), 324(100), 240(1), 198(2), 180(79), 162(5), 120(90), 118(2)
3′,7-diacetyllycopsamine-*N*-oxide and/or 3′,7-diacetylintermedine-*N*-oxide	9.63 and 9.88	400(100)/799(5)	382(12), 358(11,) 340(100), 322(4), 214(9), 197(2), 180(3), 137(2), 136(1), 120(1)
echiumine (**7**)	10.4, 10.47, and 10.58	382	364(2), 338(1), 300(1), 238(2), 220(27), 138(1), 120(100), 118(2)
echiumine-*N*-oxide	10.53, 10.58, and 10.71	398(100)/795(5)	380(10), 354(22), 308(18), 298(6), 292(4), 282(2), 254(100), 238(2), 237(5), 236(1), 220(12), 218(4), 154(2), 137(4), 136(2), 120(3)

[a]Where indicated by bold numbers, structures are shown in Figure 1. [b]Depending upon the intensity of the protonated molecule (MH^+), weak to moderate dimer ions $(2M + H)^+$ were observed for *N*-oxides

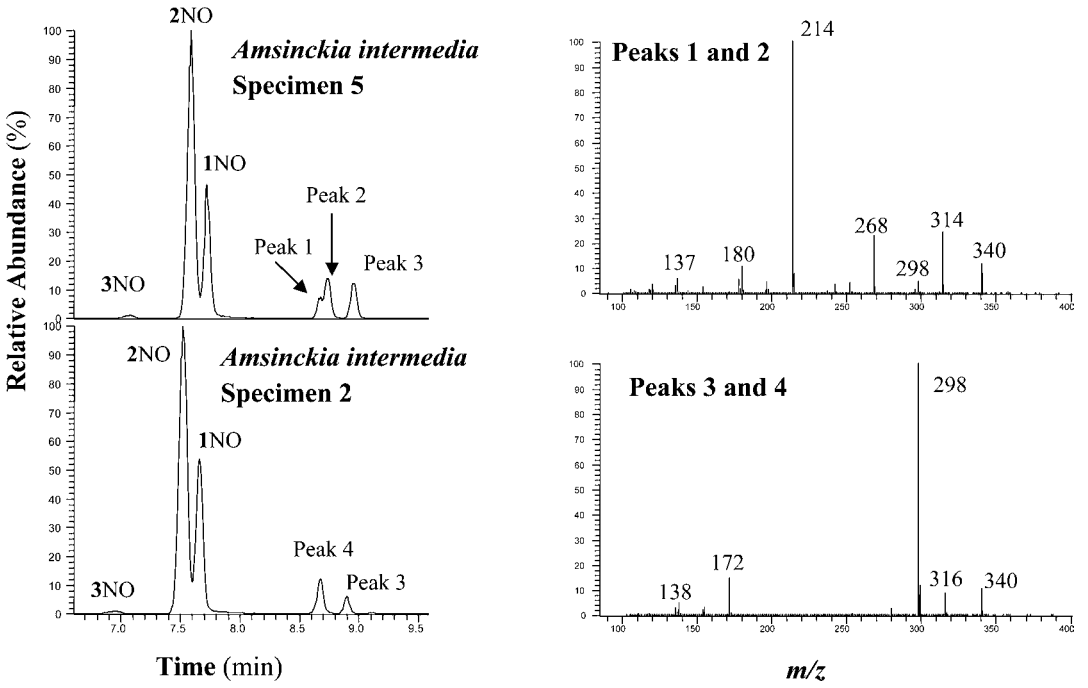

Figure 5. MS/MS differentiation of four monoacetyllycopsamine isomers detected at varying relative amounts in the *Amsinckia* species analyzed. Shown, for example, are the HPLC-esi(+)MS reconstructed ion chromatograms (displaying *m*/*z* 316 and 358) for *Amsinckia intermedia* specimens 5 and 2 (Table 1) and the MS/MS spectra for each pair of monoacetylated *N*-oxide derivatives (peaks 1 and 2 = C7 acetylation (**4**), and peaks 3 and 4 = C3′ acetylation (**5**)). Also annotated are the peaks for lycopsamine-*N*-oxide, **1**NO; intermedine-*N*-oxide, **2**NO; and the putative tessellatine-*N*-oxide, **3**NO.

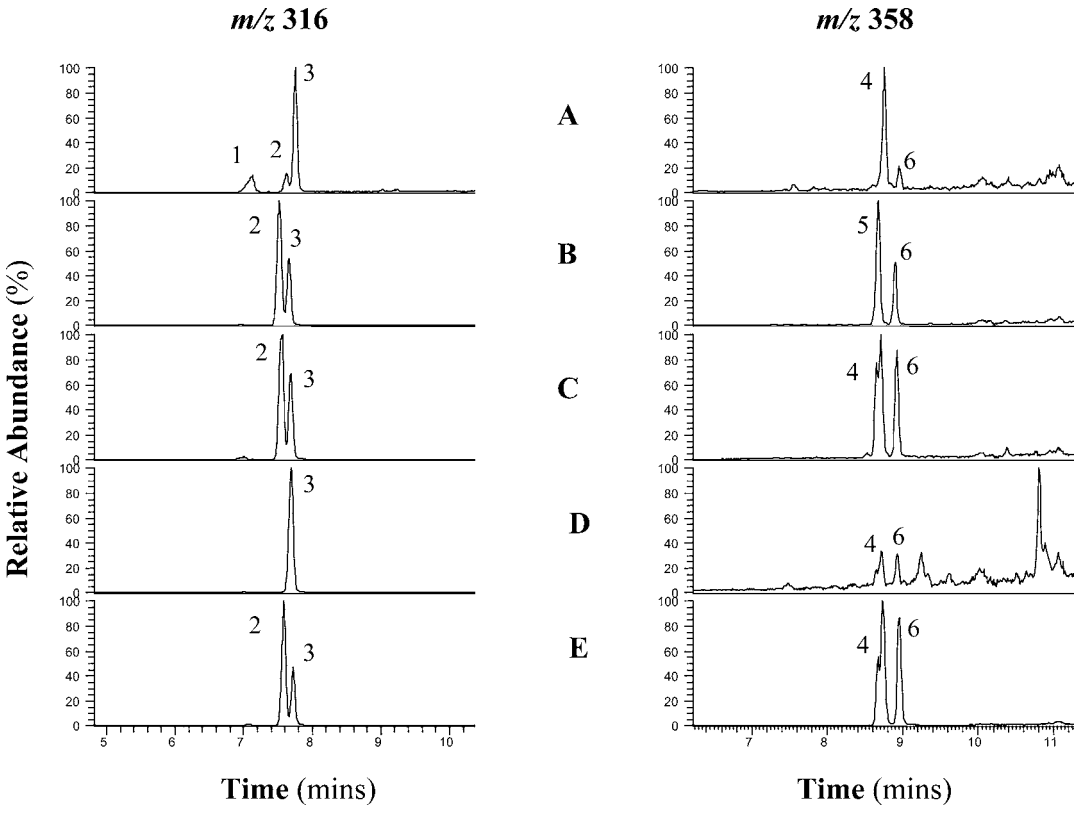

Figure 6. HPLC-esi(+)MS comparison of *N*-oxide profiles of the lycopsamine isomers (*m*/*z* 316) and acetylated isomers (*m*/*z* 358) produced by: (A–E) specimens 1–5 (Table 1) identified as *Amsinckia intermedia*, all collected in Washington County, Utah, between 1983 and 1987. Peak 1 = putative tessellatine-*N*-oxide, **3**NO; peak 2 = intermedine-*N*-oxide, **2**NO; peak 3 = lycopsamine-*N*-oxide, **1**NO; peak 4 = two 7-acetyllycopsamine-*N*-oxide isomers, **4**NO; peak 5 = a 3′-acetyllycopsamine-*N*-oxide isomer, **5**NO (1); and peak 6 = a 3′-acetyllycopsamine-*N*-oxide isomer, **5**NO (2).

dx.doi.org/10.1021/jf500425v | J. Agric. Food Chem. 2014, 62, 7382–7392

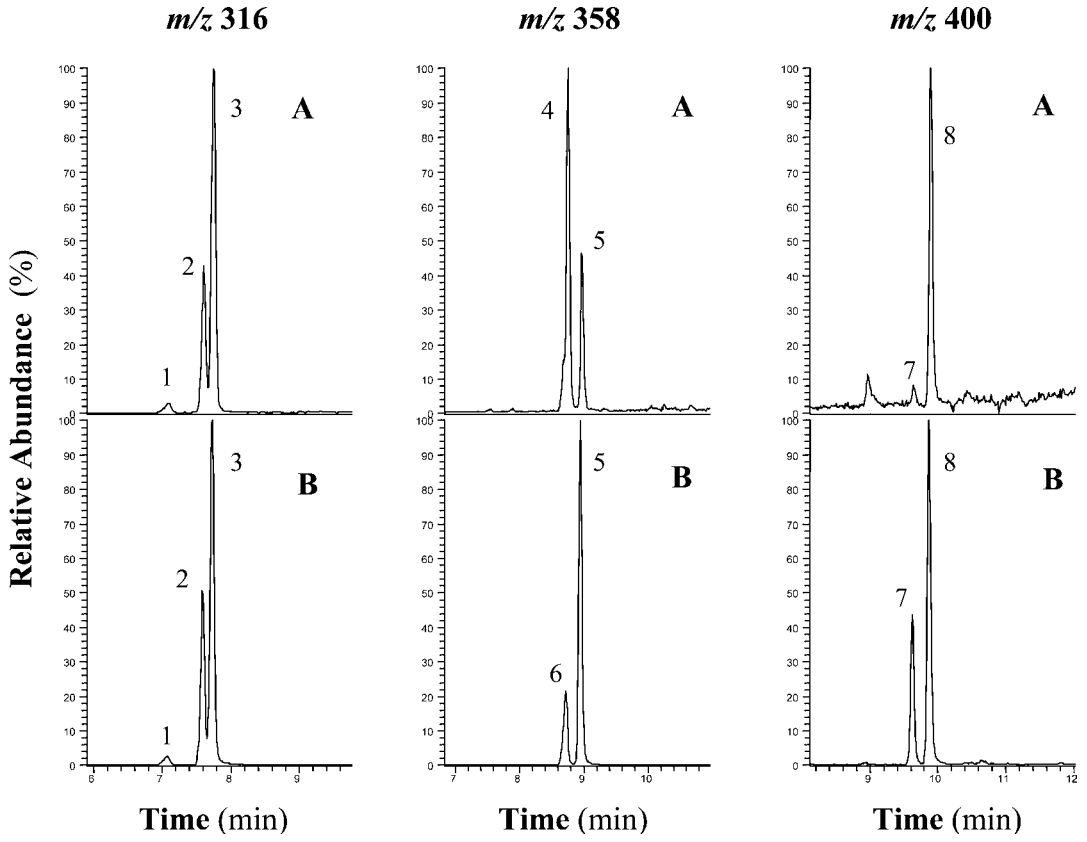

Figure 7. HPLC-esi(+)MS reconstructed ion chromatogram comparison of lycopsamine-*N*-oxide and intermedine-*N*-oxide (*m*/*z* 316) with their mono- (*m*/*z* 358) and diacetylated (*m*/*z* 400) derivatives detected in specimen 9 of *Amsinckia douglasiana* (A) and specimen 5 of *Amsinckia retrorsa* (B). Peak 1 = putative tessellatine-*N*-oxide, **3**NO; peak 2 = intermedine-*N*-oxide, **2**NO; peak 3 = lycopsamine-*N*-oxide, **1**NO; peak 4 = two 7-acetyllycopsamine-*N*-oxide isomers, **4**NO; peak 5 = a 3′-acetyllycopsamine-*N*-oxide isomer, **5**NO (2); peak 6 = mainly 3′-acetyllycopsamine-*N*-oxide isomer, **5**NO (1), with minor presence of 7-acetyllycopsamine-*N*-oxide isomers, **4**NO; peaks 7 and 8 = 3′,7-diacetyl derivatives of lycopsamine and intermedine *N*-oxides, **6**NO.

5NO (2). Specimen 1 produced a single 7-acetyl derivative, presumably of intermedine, while specimen 2 produced both the 7-acetyl derivative, **4**NO, and the second 3′- acetyl derivative, **5**NO (2). In stark contrast, the specimen collected in San Mateo County, although still an intermedine chemotype, only produced the first 3′- acetyl derivative, **5**NO (1).

The levels of dehydropyrrolizidine alkaloids in the six specimens of *A. vernicosa* were all quite low, ranging from 2−26 μg equivalents intermedine/g plant. In contrast to most of the other species examined the level of free base exceeded the level of corresponding *N*-oxide. Three of the *A. grandiflora* specimens were clearly lycopsamine/lycopsamine-*N*-oxide chemotypes, with the fourth presenting with a significant level of intermedine and its *N*-oxide.

The levels of dehydropyrrolizidine alkaloids observed did not uniquely reflect the date of specimen collection and herbarium-mounting. There were some consistencies within a species collected in the same area but decades apart, for example *A. eastwoodiae* specimens 4 and 11 collected in 1938 and 2013 in Tulare County, California both returned very low (ca. 1−2 μg equivalents intermedine/g plant material) total levels of dehydropyrrolizidine alkaloids. However, there were also some inconsistencies such as *A. douglasiana* specimens 2, 5, and 7 collected from San Louis Obispo County, California, in 2011, 1938, and 1962, respectively, that showed total alkaloid levels of about 3, 3, and 1412 μg equivalents intermedine/g plant material. Of these, only specimen 2 produced about equal levels of the *N*-oxides of **1**, **2**, and the monoacetyl derivative(s) of **1** and/or **2**. The other two only showed **1** (about 33% total dehydropyrrolizidine alkaloid content) and its *N*-oxide (ca. 61%). Of the 12 specimens annotated as *A. douglasiana*, six were lycopsamine/lycopsamine-*N*-oxide chemotypes, whereas the other six produced both lycopsamine-*N*-oxide and its epimer, intermedine-*N*-oxide, in various relative levels.

It is clear that the application of HPLC-esi(+)MS and MS/MS to the analysis of mass-limited samples harvested from herbarium-preserved specimens is a useful approach to simultaneous profiling of the dehydropyrrolizidine alkaloids and their *N*-oxides. It is important to consider that intraspecies (as designated in this study by the herbaria) variations in profiles may reflect differences in degradation of the alkaloids and their *N*-oxides that were influenced by different collection, storage, and preservation processes. Notwithstanding this caveat, and although the dehydropyrrolizidine alkaloid data have not yet been correlated to an in-depth examination of morphology for the species examined, it seems evident that there are either: (1) few, robustly unambiguous differences in the dehydropyrrolizidine alkaloid profiles that would facilitate or support species differentiation or (2) that the observed, inconsistent profiles of dehydropyrrolizidine alkaloids within a species may reflect taxonomic misassignment. For example, it is possible that the lack of significant, or any, intermedine-*N*-oxide in samples annotated as *A. menziesii* var. *intermedia*, compared to four of the five *A. menziesii* samples and eight of the 10 *A. intermedia* samples

dx.doi.org/10.1021/jf500425v | *J. Agric. Food Chem.* 2014, 62, 7382−7392

may well support a differentiation between the three and indicate possible taxonomic misassignment of the samples with inconsistent profiles. Future work should also attempt to correlate the dehydropyrrolizidine alkaloid profiles of the herbarium-preserved specimens with profiles determined for collections of fresh plant from the same sites to determine any significant changes of profile with age of the preserved specimen or the potential for specimen collection and storage artifacts.

the tube but not tightened completely. The tube was placed on the heat block (90 °C) for a minimum of 2 h or until all of the hair sample was digested. Following digestion the contents of the tube were transferred to a clean 10 mL graduated cylinder, and the sample volume was increased to 1 mL using nitric acid. Then 0.5 mL of digested sample was transferred to a 15 mL polypropylene, colorless, metal-free centrifuge tube containing 9.5 mL of ultrapure water. Appropriate dilutions were made when necessary, and after vortexing, the samples were analyzed using an ELAN 6000 inductively coupled plasma mass spectrometer (ICP-MS) (PerkinElmer, Shelton, CT, USA) at the Utah Veterinary Diagnostic laboratory at Utah State University. Quantification of Se was performed by the standard addition method, using a four-point standard curve. A quality control sample (in similar matrix) was analyzed after every five samples, and analysis was considered acceptable if the Se concentration of the quality control sample fell within ±5% of the standard/reference value for the quality control.

Plant Digests. Plant samples of aster (*Symphyotrichum ascendens*), sedge (*Cyperaceae* spp.), and water cress (*Nasturtium* spp.) as well as a mixture of grasses were collected from various locations in the pasture, dried, and ground with a Wiley mill to pass through a 0.5 mm screen. The ground plant material (0.50 g) was placed into a labeled 30 mL Oak Ridge Teflon digestion tube (Nalge Nunc International). Trace metal grade nitric acid (9.0 mL) (Fisher Scientific) was added to the digestion tubes. The tubes were then heated at 90 °C for 2 h with the caps loose on the tubes. After digestion, tubes were allowed to cool and contents were quantum satis to 10 mL and then transferred to another trace metal-free tube. Five hundred microliters of sample was transferred into another trace metal-free tube containing 9.5 mL of ultrapure water, to make up a 5% nitric acid matrix. After vortexing, the samples were analyzed using an ELAN 6000 ICP-MS (PerkinElmer) at the Utah Veterinary Diagnostic Laboratory at Utah State University. Quantitation and quality control were performed as described above.

RESULTS

Three of the four horses that grazed on a Se-contaminated pasture were chronically poisoned by Se. The diagnosis of chronic Se poisoning was made in May, 6 months after the horses were removed from the pasture. ICP-MS analysis of forage samples from various locations in the pasture, collected during the following year, demonstrated that the forages which contained >5 μg/g Se were found within 7 m of the stream in the pasture. None of the six mixed forages that were collected from other locations in the pasture, that were >7 m from the stream, contained >1.31 μg/g Se. Some of the forages growing in the stream and in the meadow portion of the pasture contained up to 127.4 μg/g Se (dry weight) and are reported in Table 1. Water samples were also collected from the stream at various times the following year. On May 18 the Se concentration in the stream was 0.82 μg/L and by August 30 the Se concentrations had dropped to 0.06 μg/L (Table 1).

None of the horses had alopecia of mane, tail, or body hair. The predominant lesions in the three horses that grazed the pasture for the entire previous grazing season were hoof lesions (Figure 1). Mane and tail samples were collected approximately 6 months after the horses were removed from the pasture, the ends were aligned, and the samples were segmented into 2.5 cm segments and analyzed for Se content. The lengths of the mane and tail samples collected from each horse are reported in Table 2. The Se concentrations in mane samples ranged from 0.7 to 27.6 μg/g Se and showed an increase and decrease in Se concentrations for each of the horses sampled (Figure 2A). The Se concentrations in the tail samples ranged from 0.6 to 47.6 μg/g Se, and for each of the longer tail samples the Se concentrations followed a cyclic pattern (Figure 2B).

Table 1. Selenium Concentrations of Forages and Water in the Selenium-Contaminated Pasture Where Horses Were Poisoned[a]

plants in pasture	collection date	Se (μg/g)
sedge from meadow	May 18	60.82
watercress from meadow	May 18	127.40
sedge from meadow	June 10	30.64
watercress from meadow	June 10	91.13
aster, 7 m from stream	June 10	14.29
grass, >7 m from stream	June 10	<1.31
water in pasture	collection date	Se (μg/L)
stream	May 18	0.82
stream	June 10	0.33
stream	July 29	0.09
stream	Aug 30	0.06
stream	Sept 29	0.04
stream	Oct 28	0.04

[a]All plant values are the Se concentration in μg/g on a dry weight basis of a composite sample of 5−7 plants.

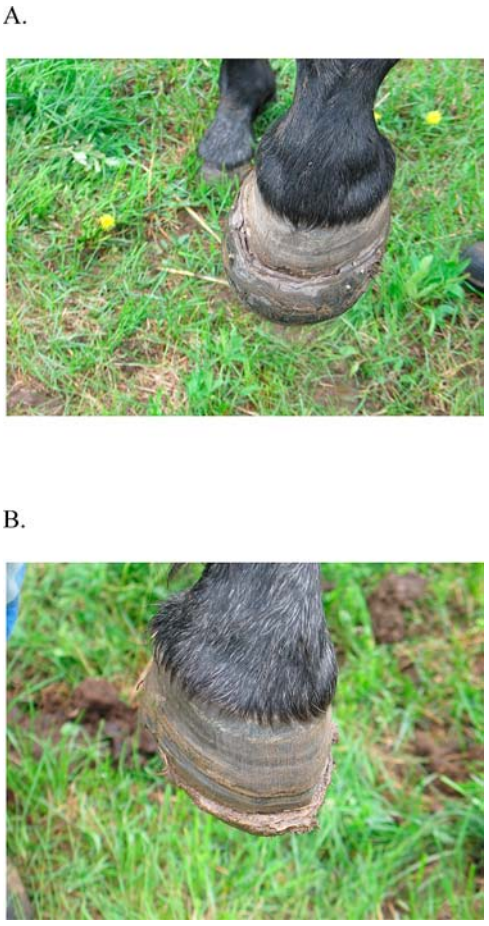

Figure 1. Photographs of (A) left front and (B) right front hooves of a horse chronically poisoned on selenium 7 months after being removed from the pasture containing high-selenium forage and water. The horse had been shod 6 weeks previously and had sloughed part of the right front hoof 1 day prior to this photograph being taken.

Horse 1 developed severe hoof lesions (Figure 1). Clinically his condition deteriorated and he became lame and was fitted with pads to help relieve the pain. However, within 4 months of his last exposure he became reluctant to bear weight on both

Table 2. Description of Horses Chronically Poisoned on Selenium and the Length of Their Mane and Tail Samples Collected and Analyzed for Selenium Content

			first sampling (May 15)		second sampling (Oct 15)	
horse	description	time in contaminated pasture	length of mane (cm)	length of tail (cm)	length of mane (cm)	length of tail (cm)
1	5-year-old gelding	~May 15 to Nov 15 for 3 years	24.5	68.5	NA	NA
2	9-year-old mare	~May 15 to Nov 15 for 3 years	35.5	87.6	35.5	101.6
3	11-year-old mare	~May 15 to Nov 15 for 3 years	20.3	33.0	38.1	91.4
4	15-year-old gelding	Sept 1 to Nov 15 for 1 year	30.4	69.8	NA	NA

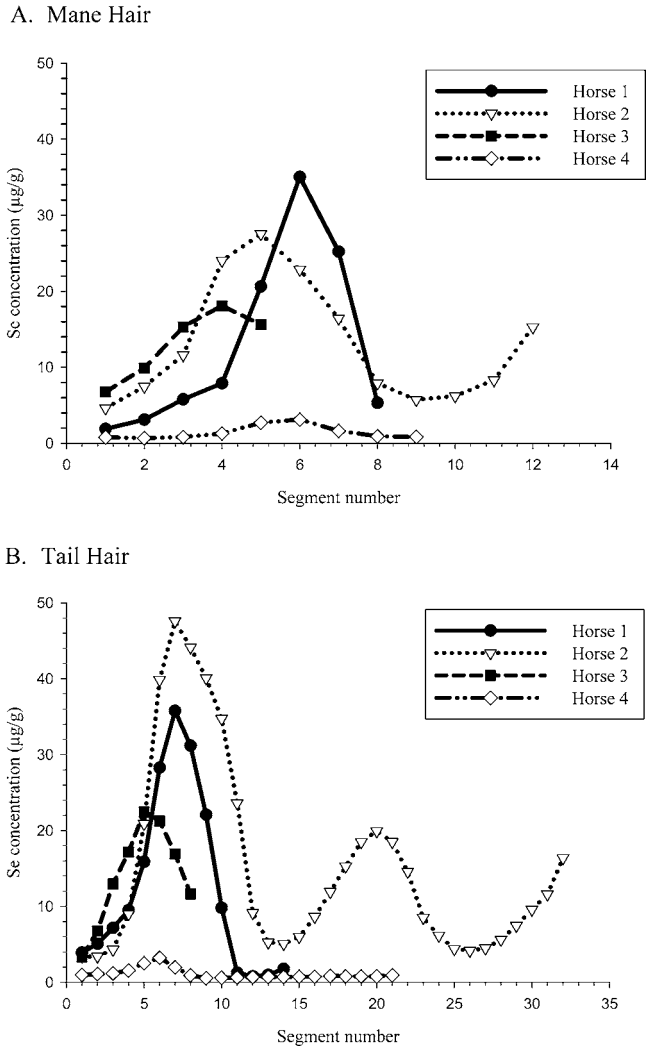

Figure 2. Selenium (Se) concentrations in (A) mane segments (2.5 cm) and (B) tail segments (2.5 cm) from four horses that grazed in a pasture with high-Se forages and water. The hair segments were numbered sequentially with the most recent growth (closest to skin) being number 1. Horses 1−3 grazed the pasture from May 15 to November 15 for three consecutive years. Horse 4 was in the pasture for 1.5 months during the third year only.

front feet. Seven months postexposure there was severe necrosis of the laminae of both front feet and the hoof wall sloughed away from underlying laminae up to the hyperplastic circular band of new growth that had developed around the hooves postexposure. The peak Se concentrations in the tail of horse 1 were from segment seven and were 35.8 μg/g Se. The mane of horse 1 was only 24.5 cm long, and the peak Se concentration in his mane was in segment six and contained 34.2 μg/g Se. Horse 1 required nearly 18 months to recover as he was rested as the hoof laminae healed and regrew. He was returned to normal work, although the prognosis of complete recovery with normal hoof strength and growth is questionable.

Horse 2 had hoof lesions that included vertical cracks in the hoof walls and prominent circular bands below the coronary band. The horse periodically exhibited minor signs of lameness but was able to be used for light ranch work. The mane of horse 2 was divided into 12 segments that could be analyzed, and the Se concentration of each segment plotted as a curve showed the complete increase and decrease of Se concentrations over one grazing season and the decrease of Se from a second grazing season (Figure 2A). The tail of horse 2 was 87.6 cm long and had increased Se concentrations during two grazing seasons that were flanked by lower Se concentrations marking the growth during months without high-Se exposure (Figure 2B). Horse 2 also had the highest peak Se concentration found in any of the hair from the horses with segment seven of the tail containing 47.6 μg/g Se.

Horse 3 had the shortest mane and tail samples but the cyclic pattern was the same as observed in horses 1 and 2. The peak Se concentrations in the mane and tail were both in segment five and were 18.1 and 22.5 μg/g Se, respectively. Horse 3 had minor vertical hoof wall cracks with some circular laminae disruption below the coronary band. She did not become lame at any time and was therefore able to be used for normal work on the ranch.

Horse 4 was in the pasture for approximately 45 days during one grazing season from the first of October until the middle of November. The horse did not develop hoof lesions, nor did it become lame at any time. The peak Se concentrations in the mane and tail of horse 4 were both in segments six and were 3.1 and 3.2 μg/g Se, respectively.

A second collection of tail and mane samples was made from horses 2 and 3 at 5 months after the first hair collections. The hair samples were segmented in the same manner as the hair from the first collection, and the Se concentrations were determined and are shown in Figures 3 and 4, respectively.

DISCUSSION

The horses were diagnosed with chronic Se poisoning on the basis of hoof lesions and mane and tail Se concentrations. On the basis of the cyclic pattern that was observed in the longer tail samples and forage and water analysis, it was determined that the forage and water during 6 months of each year were likely the toxic sources of Se. Mineral supplements were eliminated as a possible source of excessive Se because the horses were on the same mineral supplement on a year-round basis. The Se concentrations in streams contaminated by Se in the mining area are generally elevated during the spring months when runoff is high; thus, forages growing in or near the water source can also contain elevated Se concentrations.

The lesions observed in this case are typical of those reported for chronic selenosis in horses.[4,6] Horses that lose hair will eventually grow their mane and tail to normal lengths over a

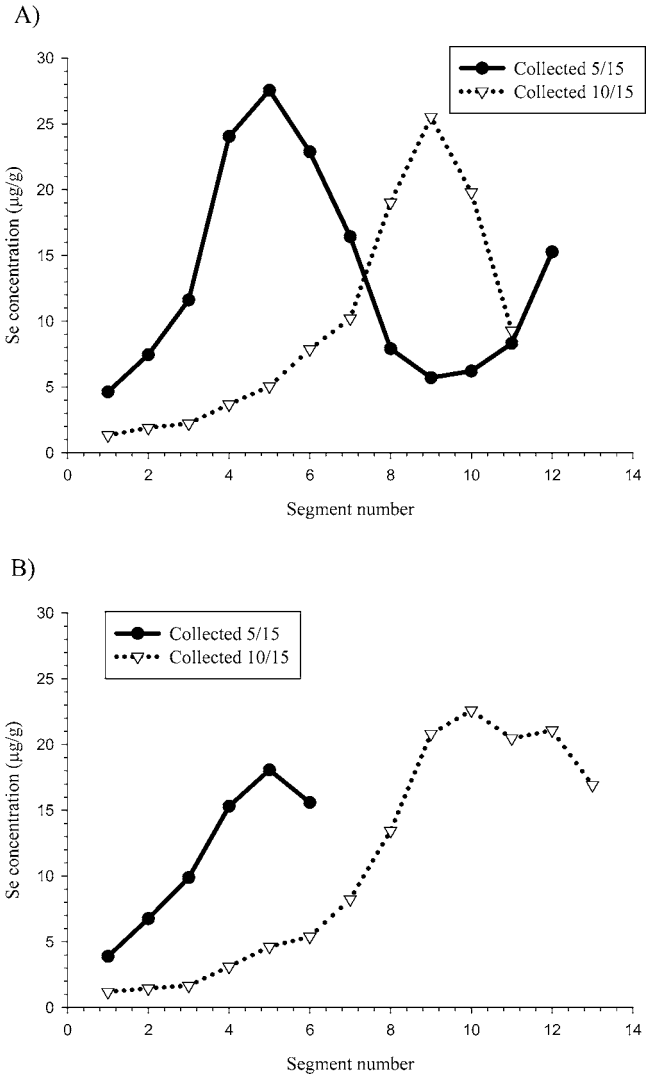

Figure 3. Selenium (Se) concentrations in mane segments (2.5 cm) from horse 2 (A) and horse 3 (B) that grazed in a pasture with high-Se forages and water. The hair segments were numbered sequentially with the most recent growth (closest to the skin) being number 1. The samples were collected 6 and 11 months postremoval from the pasture.

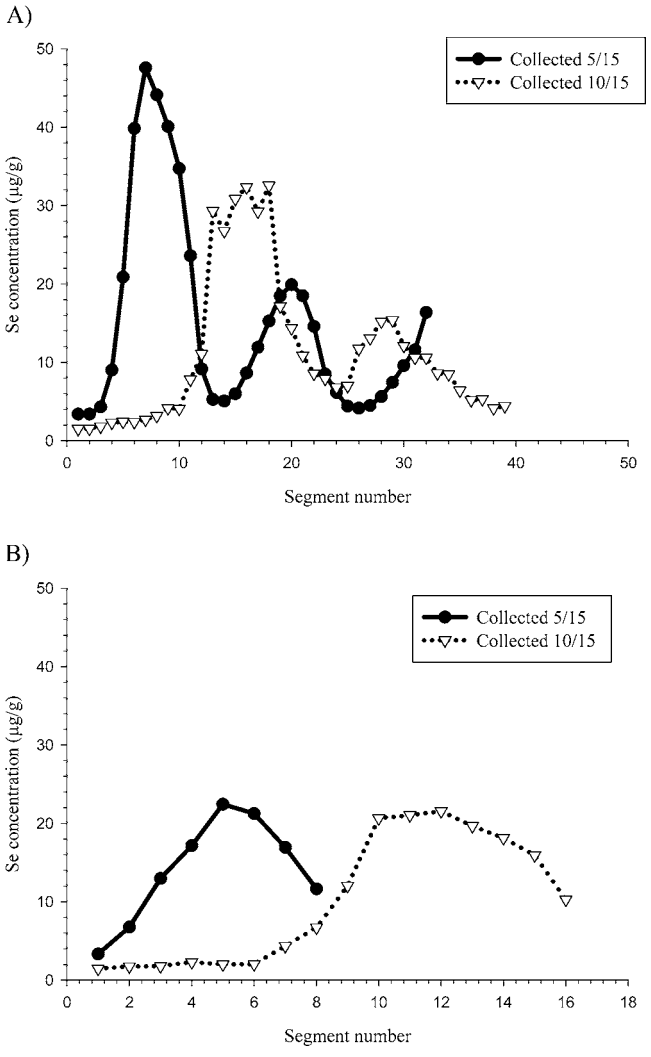

Figure 4. Selenium (Se) concentrations in tail segments (2.5 cm) from horse 2 (A) and horse 3 (B) that grazed in a pasture with high-Se forages and water. The hair segments were numbered sequentially with the most recent growth (closest to the skin) being number 1. The samples were collected 6 and 11 months postremoval from the pasture.

period of 1−2 years. However, horses that suffer severe hoof lesions and slough their hoofs often suffer from severe laminitis and may need to be euthanized to alleviate their suffering.

To avoid similar problems in the future the recommendation was made to use the pasture as a holding pasture for yearling steers for durations of 1−3 days when steers are received and shipped. The ranchers were told to avoid using the pasture for horses for any length of time because horses are more susceptible to Se toxicosis than many other livestock species.

Selenium accumulates in the hair of horses when exposed to forage with high Se content, and the concentrations of Se in the forage have been previously correlated with Se concentration in the mane and tail.[4] Hair analysis has been used to track human exposure to toxic metals.[10] Previous studies have demonstrated that there is a continual growth in the permanent hair of equine mane and tail. These studies indicate a relatively constant rate of growth of manes and tails over periods of time up to 12 months.[11,12] Dunnet and Lees[12] reported that tail and mane (medial) grew at 0.792 and 0.746 mm/day, respectively. In our study the horses were in the contaminated pasture for approximately 6 months each year. The distance between the peak Se concentrations and lowest Se concentration in each hair sample was very symmetrical, indicating that the growth rate of the hair was relatively the same over the time period during which the hair grew. Our data also support previous studies[12] that tail hair grows more rapidly than mane hair as the distance between the peak Se concentrations and the closest low Se concentration before concentration increased again was generally one segment less.

Often horses chronically poisoned on Se will have alopecia of the mane and tail. The reason for alopecia in some cases and not others is unknown. However, we speculate that it may be due to the forms and amounts of Se to which the horses are exposed. It may also be due to the Se and nutritional status of the horse at the time of the exposure.

In cases in which Se-exposed horses do not have mane and tail alopecia, the data from this study demonstrate that hair samples can be taken 1−3 years postexposure to document exposure to seleniferous forages, diets, or contaminated water.

dx.doi.org/10.1021/jf500861p | J. Agric. Food Chem. 2014, 62, 7393−7397

Additionally, the data presented in Figures 3 and 4 in which two of the horses were sampled a second time, 5 months after the first sampling, demonstrate that the concentrations of the Se in the mane and tail are relatively stable. The plotted curves of Se concentration in the mane and tail from the second sampling of horses 2 and 3 contain the same pattern with nearly the same Se concentrations as the hair contained when the final samples were collected. However, the curves are shifted to the right as the hair has grown longer and the high Se-containing segments have moved farther down the hair samples. The sampling is repeatable because the Se has been incorporated into the hair.

Cases of chronic selenosis in horses continue to occur in horses grazing seleniferous forages or when forage produced on soils with high concentrations of available Se is harvested and fed to horses. The cost of poisoning can be high because some trained horses are very valuable and are often treated as companion animals. Some animals may need to be euthanized. However, in some cases such as this one, even though the animal is not functional for an extended period of time because of lameness, the poisoned horse may be able to recover and be used for normal work.

In conclusion, sampling and segmenting of equine tail and mane can be a valuable tool to document or determine exposure to excessive Se in the diet for up to 3 years postexposure in some cases. Additionally, this study demonstrates that the concentrations of Se in mane and tail hair remain relatively stable over time.

10% *M. tenuiflora* plant material or the components therefrom, extracted or synthesized, during gestation days 6–21. Rats were humanely euthanized (CO_2 asphyxiation) on gestation day 21, and pups were examined for cranial–facial defects including cleft palate and cleft lip and skeletal malformations. Nine different experimental diets were tested including *M. tenuiflora* leaf and seed material, crude methanol extracts of leaf and seed, crude alkaloid extracts of leaf and seed, and the purified alkaloids *N*-methyltryptamine (**2**) and *N,N*-dimethyltryptamine (**1**). The concentrations of **1** and **2** in each of the different diets were measured and reported in Table 1. The use of all animals was approved by the Institutional Animal Care and Use Committee (Utah State University, IACUC approval 1527) and conducted under veterinary supervision.

Preparation of Methanol and Crude Alkaloid Extracts. For an experimental group of 10 animals approximately 4 kg of feed was needed over a period of 15 days (gestation days 6–21). Therefore, for a 10% concentration in the feed, 400 g of *M. tenuiflora* leaf, seed, or extract from the equivalent amount of plant material was used in the formulation of the experimental group ration. Thus, 400 g of plant material was extracted with methanol (3 L) by Soxhlet extraction for 48 h. The methanol extracts were concentrated by rotoevaporation and transferred to a glass storage vessel by dilution in methanol at a concentration of 50 g of plant material equivalents per 100 mL. For preparation of the rations, 44 g of plant or the equivalent extract (88 mL) was combined with 360 g of rat chow (the methanol was removed by evaporation) and 36 g of corn starch and formulated as previously described.[3]

To obtain a crude base (alkaloid) fraction, an 88 mL aliquot of the methanol extract (equivalent to 44 g of plant material) was evaporated by rotoevaporation, the flask rinsed twice with 1% H_2SO_4 (50 and 25 mL), and the acid solution saved. The flask was then rinsed three times with dichloromethane (3 × 50 mL), the dichloromethane was subsequently extracted with 1% H_2SO_4 (2 × 100 mL), and all acid extracts were combined. The acid solution was applied to a Strata XC solid phase extraction column (5 g) (Phenomenex, Torrance, CA, USA) prerinsed with methanol (50 mL) and water (50 mL). The SPE column was then rinsed with water (150 mL) and methanol (150 mL). The crude alkaloid fraction was then eluted with ammoniated methanol (150 mL; methanol saturated with ammonia then diluted with methanol 1:10). The ammoniated methanol was removed by rotoevaporation and the residue then dissolved in methanol (50 mL) and stored at 2 °C until used in rat chow formulation. This procedure was repeated approximately nine times to provide the total alkaloid fraction to formulate the rat chow for one experimental group of 10 rats.

Synthesis of *N,N*-Dimethyltryptamine (1). *N,N*-Dimethyltryptamine (**1**) was prepared by synthesis from tryptamine using reductive amination,[4] with modifications, followed by cleanup with flash chromatography. Tryptamine (4.7 mmol, 750 mg) was combined with sodium triacetoxyborohydride (18.4 mmol, 3.9 g) and glacial acetic acid (9 mmol; 0.54 mL) in 40 mL of THF. The solution was stirred at room temperature, and 1.89 mL of formaldehyde (37%) (~23 mmol) was added dropwise; the reaction continued with stirring for 2 h. The reaction solution was transferred to a round-bottom flask and the THF solvent removed by rotoevaporation at 40 °C. The flask was then rinsed with 1 N HCl (2 × 40 mL) and the acid solution extracted with ethyl acetate (2 × 50 mL). The ethyl acetate extract was discarded, and the pH of the acid solution was increased to a pH value of 10 with a 20% KOH solution and the basic solution extracted with ethyl acetate (2 × 70 mL). The ethyl acetate extract was dried over anhydrous sodium sulfate and filtered, and the solvent was removed by rotoevaporation to give crude **1**. The crude reaction mixture was purified by flash chromatography over silica gel (50 g) (Biotage) using a solvent gradient of ethyl acetate (A) and methanol (B) at a flow rate of 50 mL/min. Solvent gradient was 5% B (4 min), 5–40% linear gradient (26 min), 40% B (5 min). Fractions (20 mL) were collected throughout the run, and fractions selected on the basis of the UV detection at 280 nm were further analyzed by HPLC-UV-MS. The purest fractions were combined to give the final product (**1**) (380 mg; 43% yield). The reaction was repeated as needed to supply sufficient product for rat chow formulations. The final product was characterized by NMR and MS analyses and purity estimated to be >95%. UV (acetonitrile/water with 0.5% acetic acid/0.05% TFA) 233, 273, 279 nm; MS (LC-APCI-MS) 189 (100%; MH^+), 144 (20), 130 (40); ^{1}H NMR (300 MHz, $CDCl_3$) δ 8.05 (br s, NH), 7.62 (d, 1H, J = 7.5 Hz, H-1), 7.34 (d, 1H, J = 8.2 Hz, H-4), 7.16 (dt, 1H, J = 7.9, 1.0 Hz, H-2 or H-3), 7.12 (dt, 1H, J = 7.9, 1.0 Hz, H-2 or H-3), 7.02 (br s, 1H, H-8), 2.95 (m, 2H, H-11), 2.64 (m, 2H, H-10), 2.34 (s, 6H, $N(CH_3)_2$) in agreement with previously reported ^{1}H NMR data.[1]

Quantitative Analysis of *N*-Methyl- and *N,N*-Dimethyltryptamine by LC-MS in Formulated Rat Chow Pellets. Samples of the formulated rat chow were analyzed for the concentrations of **1** and **2** by LC-MS. Six random pellets from each formulation were ground separately with a mortar and pestle. A 100 mg aliquot of each pellet was placed into a 15 mL screw-cap test tube and extracted with 4 mL of dichloromethane and 4 mL of 1% H_2SO_4 for 3 h by mechanical rotation. The samples were centrifuged and the upper aqueous layer removed and saved. The samples were then extracted a second time with 2 mL of 1% H_2SO_4 for 5 min and centrifuged and the upper aqueous layer removed and combined with first extraction. The total aqueous acid extract (~6 mL) was added to a prepared 200 mg Strata SCX SPE cartridge, prerinsed with 2 mL of methanol and 2 mL of water. The SPE column was rinsed with 2 mL of water and 2 mL of methanol. The analytes were eluted with 4 mL of an ammoniated methanol solution. The samples were evaporated to dryness under a flow of nitrogen at 60 °C and then dissolved in 1.0 mL of 50%

dx.doi.org/10.1021/jf5005176 | J. Agric. Food Chem. 2014, 62, 7398–7401

methanol/0.1% TFA, and 5 μL injections were analyzed by LC-APCI-MS using a Betasil C18 column, 100 mm × 2.1 mm i.d. (Thermo Fisher, Waltham, MA, USA) and a linear gradient of acetonitrile (A) and water (0.05% TFA/0.5% acetic acid) (B). Flow rate was 0.300 mL/min with a gradient of 10% A (0−3 min), 10−70% A (3−10 min), and 70% A (10−15 min). Detection was by APCI-MS, and peak areas were measured from reconstructed ion chromatograms of the protonated molecules (*m*/*z* 175 and 189). Calibration curves were composed of a set of five standards prepared from the *N*-methyltryptamine and *N*,*N*-dimethyltryptamine at concentration levels of 40, 30, 20, 10, and 2 μg/mL.

RESULTS AND DISCUSSION

In the original work, Medeiros[3] clearly demonstrated the acceptable characteristics of the rat model for testing of teratogenic effects of *M. tenuiflora*. Data were presented showing no adverse effects on animals receiving the ration containing 10% *M. tenuiflora* seed as to feed consumption, weight gain, clinical signs of sickness, abnormal behavior, and organ weights, and no significant histological lesions were produced in the treated pregnant rats. However, significant fetal malformations were observed, clearly demonstrating the teratogenic effects of the *M. tenuiflora* seed. In the most recent experiments presented here, the *M. tenuiflora* seed formulation was repeated, but the investigation extended to leaf material and then to chemical extracts and purified compounds found in *M. tenuiflora* in an attempt to identify and further understand the active chemical components in the plant material responsible for the teratogenic effects.

As in the prior work, rats accepted the prepared diets and showed no significant differences between control and treated animals as to feed consumption, weight gain, and overall health (data not presented). For the analysis of the current experiments fetal malformations were assessed in three categories: (1) soft tissue cleft palate; (2) hard palate anomalies; and (3) skeletal deformities. The skeletal deformities were grouped together and included analysis of spinal column alignment (scoliosis) and development of the sternebrae, the caudal, lumbar, sacral, and thoracic vertebrae, metacarpals, ribs, and parietal bones.

From the current experiment groups, rat pups from mothers who received *M. tenuiflora* plant material, methanol extracts, alkaloid extracts, and purified *N*-methyltryptamines had a higher incidence of soft tissue cleft palate in all treatments (Table 1). The soft tissue cleft palate was the most consistent and significant observed deformity in pups from treated dams. This soft tissue cleft palate was characterized by incomplete closure or overlap of the tissue (Figure 1). Deformities of the hard palate were observed only in the combined dose of **1** and **2**.

Skeletal deformities, including missing, extra, or misaligned bones, were observed in all treatment groups to some degree (Table 1). An extreme example was a pup with missing vertebrae (Figure 2). Minor skeletal aberrations were noted in a few control animals and were considered in the treatment evaluations. In general, the skeletal deformities were highly random in type and frequency, but when added together were considerably higher in frequency in comparison to the control group.

Specifically noted was the frequency of observed scoliosis in Table 1 to highlight an observed difference in the results of the rat pups from mothers receiving the mixed *N*-methyl- and *N*,*N*-dimethyltryptamine treatments. The frequency of induced scoliosis was higher at 13.4 ± 5.5% in pups from the *N*-methyl- and *N*,*N*-dimethyltryptamine group compared to all other treatments (2.1 ± 1.7%).

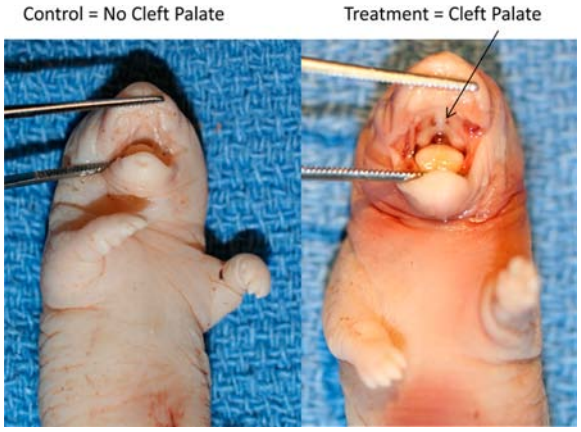

Figure 1. Observed induced soft-tissue cleft palate in a rat pup from a dam treated with *Mimosa tenuiflora* leaf and a control.

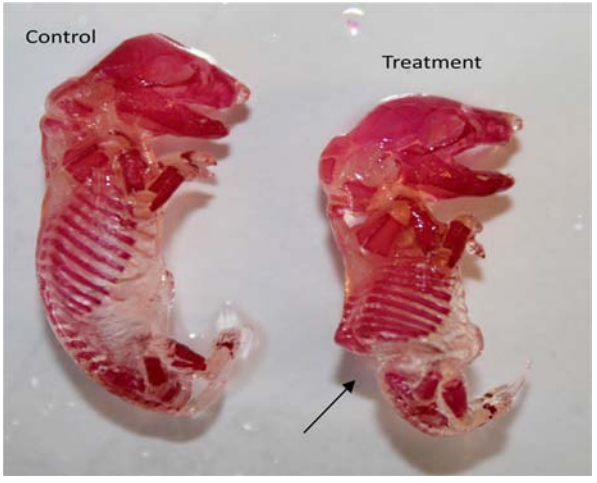

Figure 2. Observed skeletal malformation in a rat pup from a dam receiving a ration containing 10% *Mimosa tenuiflora* leaf and a control. Note complete lack of lower vertebrae.

In using the rat model, the teratogenic compounds were found to be extractable in methanol and not lost during further cation ion exchange solid phase procedures giving a teratogenic active crude base fraction. In previous work[5] the alkaloid content of *M. tenuiflora* was examined, and the major alkaloid fraction was found to be composed of *N*,*N*-dimethyltryptamine (**1**), 2-methyltetrahydro-β-carboline (**3**), and an unidentified alkaloid with a proposed molecular weight of 174. The unknown alkaloid has since been identified as *N*-methyltryptamine (**2**) (Figure 3). It was thus followed here with experimental diets using the two major alkaloids (**1** and **2**) in purified form, first in separate formulations and then in a combined (**1** and **2**) fortified ration.

Dams receiving **1** or **2** only rations resulted in pups with a slightly lower frequency of induced cleft palate compared to the original plant material or even the methanol or crude base extracts; however, skeletal deformities were of similar frequency (Table 1). In the final experiment using a combined **1** and **2** fortified ration, an increase in cleft palate and skeletal deformities was expected. Cleft palate induction frequency indeed increased (58.6%), and in a few cases there was even observed hard palate damage. An unexpected finding was the

dx.doi.org/10.1021/jf5005176 | J. Agric. Food Chem. 2014, 62, 7398−7401

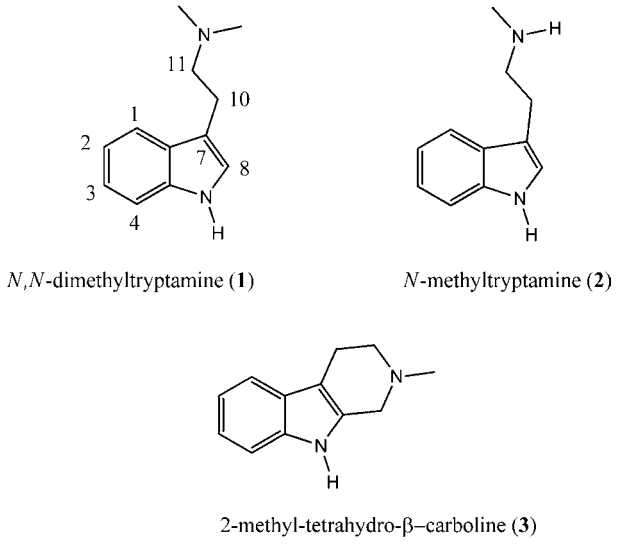

Figure 3. Structures of alkaloids in *Mimosa tenuiflora*.

total lack of skeletal deformities such as missing or misaligned or extra bones in this series of pups, although the frequency of induced scoliosis increased. There are no prior reports of any teratogenic effects of **1** or **2**. They are best known for their psychoactive properties.[6−8] There is currently insufficient information to allow speculation on the possible teratogenic mechanism of action at this time.

In summary, the use of the pregnant rat model for the testing of crude chemical extracts, semipurified extracts, and even purified compounds for teratogenic effects of *M. tenuiflora* seems plausible. The results confirmed that the active principles could be extracted from the plant with methanol and were carried through an ion exchange procedure to what would be considered a crude alkaloid fraction. However, other compounds of basic characteristics, for example, basic amino acids, would also be present in this crude alkaloid fraction. Both **1** and **2** were found to be teratogenic in the rat model as they induced cleft palates and skeletal malformations. Future work should include confirmation of the teratogenic activity of *N*-methyl- and *N,N*-dimethyltryptamine in a small ruminant model.

onset of clinical signs, initially manifest as severe diarrhea. Appropriate analytical technology was not then available, and plant toxin levels were not reported for any of these feeding trials.

Analysis of simplexin levels in *Pimelea* plant material by liquid chromatography−tandem mass spectrometry (LC-MS/MS) has demonstrated that toxin levels are dependent on *Pimelea* species, growth stage, weathering, and the particular plant parts utilized.[2,3] In previous feeding trials it was common to utilize material collected from a number of different sites, but this now causes complications in the interpretation of data due to subsequent reclassification of *Pimelea* species.[2] For instance, Clark[8] dosed cattle with *Pimelea* material from multiple field collections from different locations, with no record of whether individual collections were combined or administered separately. Herbarium voucher specimens lodged for these individual collections have now been re-examined and determined to represent multiple different *Pimelea* species.[2] Given the composite nature of these collections, it is now not possible to make any realistic estimate of the dosage of toxin in plant material administered in these previous trials. Our present study utilizes a single collection of *P. trichostachya* of measured simplexin content and was undertaken to ascertain the minimum toxin intake required to induce *Pimelea* poisoning in cattle. Animal tissues arising from the feeding trial were also analyzed for simplexin to determine whether this toxin intake results in detectable simplexin residues in animal tissues.

MATERIALS AND METHODS

Plant Material. Young flowering *P. trichostachya* plants (Queensland Herbarium voucher AQ751764) were collected from a single location 40 km south of Roma (Queensland). The composite aerial portion (seeds, flower heads, small stems, and leaves) of the air-dried plant material was milled and kept frozen at −20 °C until required. Simplexin levels of the composite sample (6 kg) were determined by LC-MS/MS analysis.[2]

Calf Feeding Trial. Four weaned, ruminating calves (130−180 kg) with no previous exposure to *Pimelea* were housed in individual enclosed, low-security cattle pens at the Animal Research Institute, Yeerongpilly (Queensland), and fed a base diet of Rhodes grass (*Chloris gayana*) and lucerne (*Medicago sativa*). Thawed *Pimelea* plant material was mixed with molasses (approximately 50 mL) and added to a small amount of Rhodes grass and lucerne, which was consumed by the calves prior to provision of their basic daily feed of lucerne/Rhodes grass. *Pimelea* plant material was introduced incrementally over the initial 4 days (days 1−4; 25, 50, 75, and 100% of the daily dose, respectively) to an initial dose of 7.5 mg dried *Pimelea* plant/kg bw/day. This daily dose was maintained until day 14, when the dose was incremented to 10.0 mg dried *Pimelea* plant/kg bw/day, and increased thereafter in 2.5 mg increments every 14 days. This feeding trial was conducted taking full account of the welfare of the calves under DAFF Animal Ethics Committee Approval SA 2008/03/239. The health of the animals was monitored daily throughout the trial, with feed intake, demeanor, scours, rectal temperature, and heart and respiratory rates recorded daily. Scouring by animals was assessed and scored (1−5): 1 = regular dung pat; 2 = moist pat; 3 = wet pat; 4 = scour; 5 = watery scour.

Jugular blood samples (3 × 10 mL) were obtained weekly and immediately before euthanasia. Blood for hematology was collected into EDTA anticoagulant; that for clinical biochemistry testing and toxin assay was collected into lithium heparin and frozen (−40 °C) for toxin analysis. Hematological values measured by ABX VET ABC Hematology Analyzer (ABX Diagnostics, Montpellier, France) were hemoglobin concentration, packed cell volume, erythrocyte count, total leucocyte counts, and erythrocyte indices; enzyme activities and chemical concentrations measured in plasma using an Olympus AU400 (Olympus, Tokyo, Japan) were aspartate aminotransferase, creatine phosphokinase, glutamate dehydrogenase, γ-glutamyl transferase, total protein, albumin, globulin, calcium, sodium, magnesium, potassium, chloride, β-hydroxybutyrate, total bilirubin, urea, and creatinine. At 2-week intervals, muscle biopsy samples were excised from the rump muscle as previously described[12] and frozen (−40 °C) for assay.

Animals were killed at day 125 by stunning with a captive bolt pistol and exsanguination and immediately necropsied. At necropsy, samples of liver, kidney, heart, skeletal muscle, and renal fat were collected, frozen, and stored at −40 °C before assay. Tissues were also collected at necropsy into 10% buffered neutral formalin for histopathology.

Extraction of Lyophilized Blood. Freeze-dried blood (0.5 g) was shaken with chloroform/methanol (2:1, 15 mL) for 30 min and centrifuged at 3200*g* for 10 min; the supernatant was decanted, and the residue was re-extracted by the same process. The combined decanted supernatant was washed once with brine (6 mL) and then with methanol/brine (1:1, 6 mL). The organic layer was dried (Na_2SO_4) and evaporated under reduced pressure. The residue was partitioned between hexane (4 mL) and acetonitrile (4 mL). The hexane layer was extracted with further acetontrile (2 × 2 mL), and the combined acetonitrile extract was evaporated.

Extraction of Adipose Tissue. Adipose tissue (1.0 g) was homogenized by IKA T25 Ultra Turrax (In Vitro, Brisbane, Australia) in chloroform/methanol (2:1, 15 mL) and the resultant solution filtered, washed with brine (0.73%, 4.5 mL), dried (Na_2SO_4); the solvent was removed under reduced pressure. The oily residue was redissolved in hexane (20 mL) and extracted with acetonitrile (3 × 5 mL), and the combined acetonitrile extract was evaporated.

Extraction of Other Tissues. Methanol (10 mL) was added to other animal tissues (1.0 g), cooled in ice (5 min), and homogenized by Ultra Turrax. Chloroform (20 mL) was added and the suspension shaken for 30 min and centrifuged at 3200*g* for 20 min. The filtered supernatant was washed with brine (6 mL) and then with methanol/brine (1:1, 6 mL). The organic layer was dried (Na_2SO_4) and evaporated under reduced pressure. The residue was partitioned between hexane (5 mL), acetonitrile (2 mL), and methanol (1 mL). The hexane layer was extracted with further acetontrile (2 × 2 mL), and the combined acetonitrile extract was evaporated.

LC-MS/MS Analysis. For each tissue, the evaporated residue was taken up in methanol (0.5 mL) and filtered (0.22 μm PVDF), and the simplexin content was determined by LC-MS/MS analysis as previously described.[2]

RESULTS AND DISCUSSION

LC-MS/MS quantification of simplexin in positive-ion atmospheric pressure chemical ionization (APCI) mode comprises multiple reaction monitoring (MRM) transitions 533 → 253 (for quantification) and 533 → 267 (for verification),[2] which represent the two most dominant daughter ions from the fragmentation of the protonated molecular ion (Figure 2). LC-MS/MS analysis of the milled dried *P.*

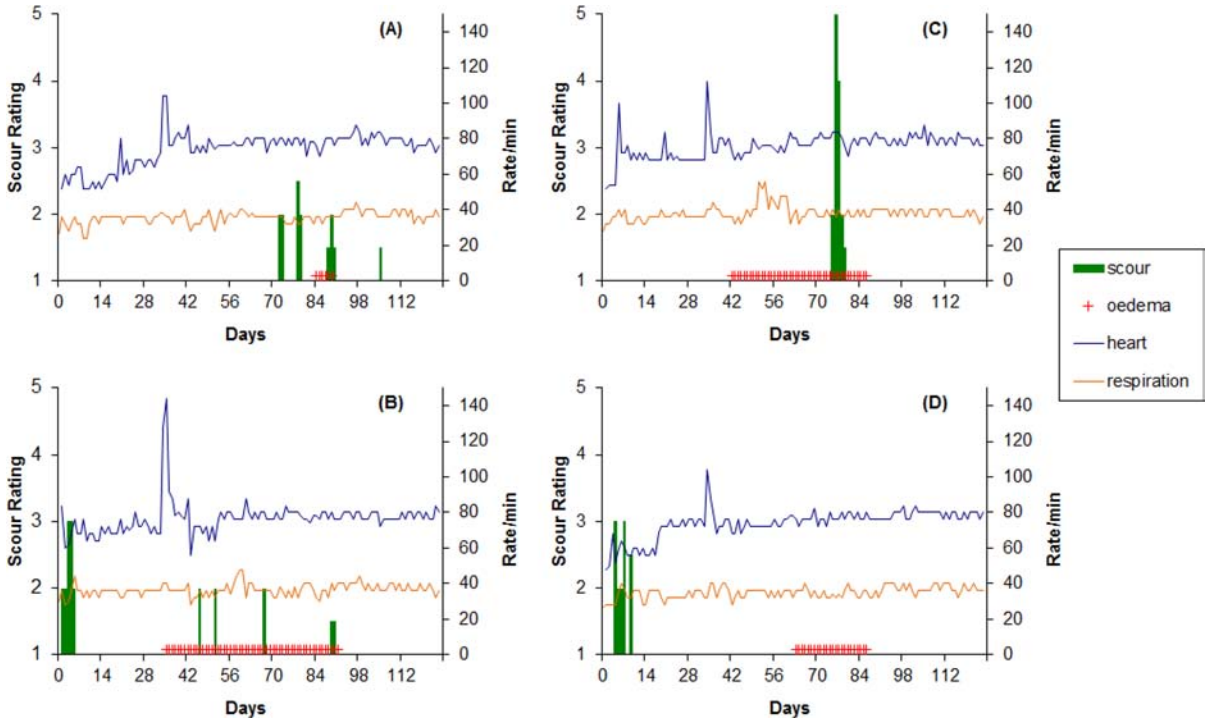

Figure 3. Plots for calves (A–D) showing days during the *Pimelea* feeding trial on which edema was recorded, scour rating (1–5), and heart and respiration rates (per minute).

trichostachya plant material used in this feeding trial provided a simplexin content of 227 mg simplexin/kg plant, comparable to average simplexin concentrations measured in flowering *P. trichostachya* or *P. elongata* of 225 and 239 mg simplexin/kg plant, respectively.[3] By comparison, the simplexin content of *P. simplex* flowering foliage is generally lower, with an average concentration of only 116 mg simplexin/kg plant.[3] Simplexin is a quite stable molecule, and the simplexin levels in the milled plant material were relatively unchanged during the feeding trial, with 195 mg simplexin/kg determined after 4 months at −20 °C.

Previous feeding trials by Clark[8] have shown that a high oral dose rate of 50–100 mg/kg bw/day dried *Pimelea* caused acute intoxication characterized by profuse watery diarrhea, emaciation, and jugular vein distension within 1 week but without edema. Kelly[9] induced similar subacute symptoms without jugular distension with dried *Pimelea* stems at 40–80 mg/kg bw/day for 6–14 days. Lower feeding dose rates over extended periods produced a more chronic syndrome with "subcutaneous edema, hydrothorax and jugular pulsation in addition to the features of subacute intoxication".[9] In his work, Clark[8] demonstrated that intravenous injection of plant extracts caused pulmonary venule constriction and proposed that prolonged constriction of these vessels is the basic cause of the classic *Pimelea* poisoning edema through increased pulmonary vascular resistance. The *Pimelea* toxin simplexin was later isolated[13] and subsequently demonstrated to constrict bovine pulmonary venules in vitro,[14] consistent with the proposed cause of the disease.

In previous *Pimelea* feeding trials,[6−11] the simplexin content of plant material employed was not known, and the toxin dosage rate is therefore unknown. Without this prior knowledge, the dosing regimen employed in our feeding trial erred on the side of caution with 2-week dose increments to avoid unintended adverse effects. The initial daily dose of 7.5 mg dried *Pimelea* plant/kg bw (equal to only 1.7 μg simplexin/kg bw) was incremented by 2.5 mg dried *Pimelea* plant/kg bw (or 0.57 μg simplexin/kg bw) every 14 days to a final dose of 27.5 mg dried *Pimelea* plant/kg bw (or 6.2 μg simplexin/kg bw) at day 125. The calves tolerated the daily intake of *P. trichostachya* with no adverse effects, other than initial mild diarrhea in two of four animals, until day 35, when increased heart rates were noted and one animal had mild subcutaneous edema under the jaw. In the remaining calves similar fluid accumulation under the jaw developed at days 42, 63, and 84, respectively (Figure 3). Although still being fed *P. trichostachya*, the subcutaneous edema progressively diminished, and all four animals appeared normal from day 91 until the end of the experiment at 125 days. All four calves developed diarrhea on at least one occasion for up to 5 days, and all showed a trend to elevated heart rates after a few weeks, which were sustained for the duration of the feeding (Figure 3).

Previous *Pimelea* feeding trials have reported falls in white cell count and reduction in packed cell volume and hemoglobin concentration preceding the onset of acute diarrhea.[9] A full range of biochemical and clinical parameters were studied during the current trial. The mean corpuscular volume increased in three of the four animals during the trial period (Figure 4i), whereas the red cell counts (Figure 4ii) tended to decline initially with a trough around days 35–42, followed by a mild to moderate increase over the next 7–14 days and then a gradual recovery during the remainder of the trial.

Similar to the mild clinical and hematological effects of *Pimelea* seen in the feeding trial animals, necropsy examinations showed little pathology. Subjectively, all four animals appeared to have a mild increased volume of pericardial fluid. Histopathology of lung tissues did not show convincing evidence of constriction of pulmonary venules, the primary pathological effect of the toxin simplexin. The lack of inclusion of a control animal in the experiment meant comparisons could

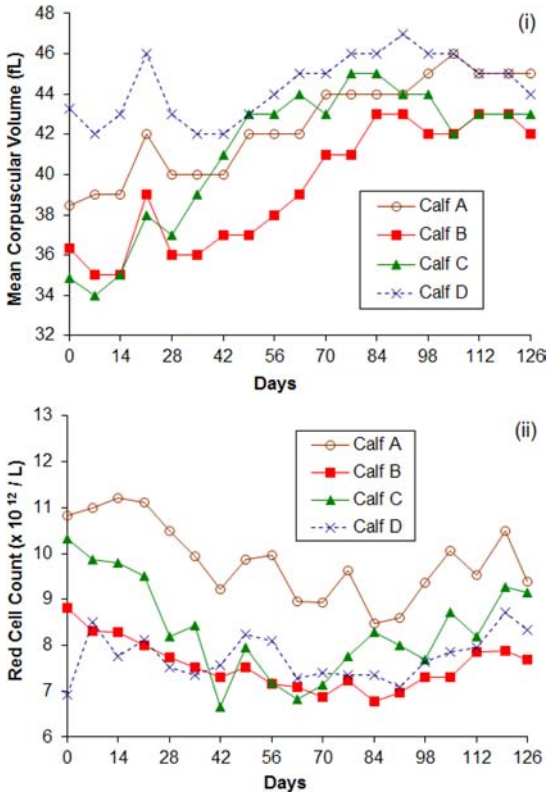

Figure 4. (i) Mean corpuscular volume (fL) and (ii) red cell count ($\times 10^{12}$/L) in each of the four calves (A–D) measured during the *Pimelea* feeding trial.

not be made, therefore reducing the chance of recognizing any very subtle changes. However, there was no evidence of significant gross pulmonary or subcutaneous edema, cardiac dilation, or liver changes (namely, peliosis hepatis) as seen in severely affected natural cases of *Pimelea* poisoning.[15]

Due to its hydrophobic nature, the potential for simplexin to form tissue residues in animals consuming this plant has also been considered. Our LC-MS/MS method for simplexin was adapted to analyze the toxin in animal tissues with good recoveries from a range of tissues spiked at 0.028 and 0.055 mg/kg (skeletal muscle, 90–104%; heart, 88–97%; liver, 63–81%; kidney, 76–93%) and at 0.055 and 0.088 mg/kg in dried blood (60–84%), with a limit of detection (LOD) of 17 μg/kg in dried blood and 8 μg/kg in other tissues. Tissues (heart, muscle, liver, kidney, fat, and blood) collected at necropsy together with weekly blood samples collected throughout the trial were analyzed by using this method. The simplexin concentration in all samples was below the LOD. Fortnightly rump muscle biopsy samples were also collected throughout the trial, but the sample quantity proved insufficient to provide a reliable simplexin result.

Earlier experimental work postulated that cattle exposed to the *Pimelea* toxin predominantly through inhalation of plant debris developed the circulatory failure and edema signs, whereas those ingesting plant material (and toxin) developed diarrhea.[6−8] Current knowledge, however, suggests that most inhaled particles are likely to be trapped in the mucosa of the upper respiratory tract and ultimately swallowed. Hence, regardless of the mode of exposure (ingestion or inhalation), we consider the digestive tract as the major route of toxin absorption from *Pimelea* plant material. In the present study, incorporation of the *Pimelea* plant material in molasses excluded inhalation as a means of exposure, and cattle developed both circulatory signs and diarrhea, consistent with the digestive system as the major route of toxin absorption.

At day 35 when the initial signs of edema were evident, the calves were each consuming 12.5 mg *Pimelea*/kg bw/day (equivalent to 2.8 μg simplexin/kg bw/day). For 160 kg calves this equates to a daily intake of approximately 2 g *Pimelea* per day (approximately 0.07% of their daily ration), and a total intake at that point of only 55 g *Pimelea* (12.5 mg simplexin) from the commencement of the feeding trial. This relatively small dose of plant material required to induce signs of mild *Pimelea* poisoning demonstrates the potent toxicity of these plant species and is consistent with field observations where only minor, inadvertent consumption of *Pimelea* plant material by cattle seems sufficient to result in poisoning. The time required to induce visible symptoms in this trial is also consistent with producer observations, which indicate that naive animals introduced into a *Pimelea*-infested pasture do not develop poisoning symptoms rapidly and generally noticeable symptoms take several weeks to appear.

It is particularly noteworthy that edema effects in all four calves diminished as the feeding trial progressed, despite being fed increasing doses of *Pimelea* plant material of the same simplexin content and, hence, corresponding increasing simplexin doses. These calves were sourced from south east Queensland, which is geographically distant from the arid inland regions where *Pimelea* occurs, and these animals would not previously have encountered these plant species or toxin. It was concluded that these calves, when exposed to prolonged low simplexin doses, developed mechanisms within a matter of 5–12 weeks for detoxifying or metabolizing simplexin, possibly through rumen microbial adaptation or activation of liver enzymes. The exact mechanism by which the observed tolerance is induced has not yet been determined, but it is noted that structurally similar phorbol esters are not degraded by rumenal microbes[16] but are metabolized by carboxylesterase and other microsomal liver enzymes.[17] Possibly such enzymes would be induced by prolonged low toxin doses. Regardless of the mechanism for the induced tolerance of simplexin, if similar low simplexin doses could be artificially maintained in field animals, then this could possibly provide an effective protective mechanism to prevent significant stock losses from *Pimelea* poisoning.

shady place after air-drying and grinding. Swainsonine was analyzed by TLC and GC-MS methods.[9] Swainsonine content was determined by gas chromatography as 0.021% by weight of the total plant. The plant was identified by the Institute of Botany (College of Life Science, Northwest A&F University).

Animals and Animal Feed. The animals and protocols used in this study were approved by the Animal Care Committee of Xi'an Jiaotong University. Sprague−Dawley rats were purchased from the Experimental Animal Center of College of Medicine, Xi'an Jiaotong University (Xi'an, China). The aerial portion of *O. kansuensis* was ground completely and sifted through a 200 mesh screen. The resulting *O. kansuensis* meal was mixed with whole feed (25% flour, 28% cornmeal, 20% soybean cake, 10% wheat bran, 10% fish meal, 1% vegetable oil, 1% yeast powder, 2% bone meal, 1% cooking salt, 1% cod-liver oil, 0.9% mineral additive, 0.1% vitamin additive)[10] to reach 15, 30, and 45% plant content (0.003, 0.006, and 0.009% swainsonine, respectively).[11] Water was then added to this mixture and stirred into 1−3 cm^3 diced mixed rations, dried for preservation.

Chemical Reagents and Apparatuses. NRNAiso Plus Total RNA Extraction kit, RT-PCR kit, and Real-Time PCR Kit were obtained from TaKaRa Bio Inc. (Dalian, China). DNA marker (Topsun, Jiangmen, China), PCR-mix (TransGen, Beijing, China), PCR primers (GenScript, Nanjing, China), EB (RUNDE, Sichuan, China), APES (Boster, Wuhan, China), DAB (Boster, Wuhan, China), IHC Antibody Diluent (Beyotime, Shanghai, China), S-P Ultra-Sensitive SAP kit (Maixin, Fuzhou, China),and primary antibody (MAN2A1, Abcam, London, UK) were obtained as noted.

Establishment of a Chronic Poisoning Model of *O. kansuensis* in SD Rats. Experiments were performed on male and female SD rats (200−220 g total body weight). After a week-long adaptation period in a room with controlled temperature (21 ± 1 °C) and lighting (12 h light/12 h dark), 24 SD rats were assigned to either a control group (complete feed) or experimental groups I (15% *O. kansuensis* containing 0.003% swainsonine), II (30% *O. kansuensis* containing 0.006% swainsonine), or III (45% *O. kansuensis* containing 0.009% swainsonine), and the 6 SD rats of each group were fed in three cages separately. All treated rats were fed for 119 days and showed neurological disorders to different degrees, which was considered to be successful establishment of a chronic poisoning model of *O. kansuensis*. All SD rats were anesthetized with ether vapor and sacrificed by decapitation. The cerebrum and cerebellum were collected and divided into two parts: one was preserved in liquid nitrogen, whereas the other was fixed in 4% paraformaldehyde.

Immunohistochemistry. Immunohistochemistry was performed according to instructions of the S-P UltraSensitive SAP kit (Maixin, Fuzhou, China). Paraformaldehyde fixed brain tissues were paraffin-embedded and sliced at 6 μm thickness onto slides. Tissue slices were deparaffinized, rehydrated, treated using microwave heat-induced epitope retrieval, and incubated in 3% hydrogen peroxide to block endogenous peroxidases with healthy nonimmune goat serum to block endogenous biotin. Subsequently, tissues were incubated in a 1:100 dilution of primary antibody for 12 h at 4 °C. A negative control slice was incubated with antibody diluent alone. Tissues were then incubated with a biotin-labeled secondary antibody for 10 min at room temperature, followed by treatment with streptavidin−peroxidase and staining by DAB. The stained tissues were observed through a light microscope, and the resulting images were analyzed using Image-Pro Plus 6.0 (Media Cybernetics).

Real-Time Quantitative PCR. PCR primers were designed by Primer 5.0. The primer sequences for MAN2A1 were as follows: forward primer, 5′-TCAGCTACCCTTCCCTCCTC-3′; reverse primer, 5′-TGCCCACCTTTGACTGTATTG-3′. The length of the PCR amplicon was 189 bp. β-Actin was used as an internal reference with primer sequences as follows: forward primer, 5′-GACAGGATG-CAGAAGGAGATTACT-3′; reverse primer, 5′-ATAGAGCCACCA-ATCCACACAG-3′. The length of the PCR amplicon was 104 bp. All primers were synthesized by GenScript Co. (Nanjing, China).

The tissues preserved in liquid nitrogen were prepared as tissue homogenate for total RNA extraction according to the manufacturer's instructions for the NRNAiso Plus kit. RT-PCR was performed following the manufacturer's instructions for the PrimeScript RT Reagent Kit with gDNA Eraser; the resulting cDNA was then used as input for real-time PCR performed as described by the manufacturer's protocol for SYBR Premix Ex *Taq*II. The reaction mixture was 1 μL of cDNA, 0.3 μL of forward primer (10 μM), 0.3 μL of reverse primer (10 μM), 7.5 μL of SYBR, premix *Ex Taq*II (2×), and ddH_2O up to 15 μL. The reaction conditions were as follows: initial denaturation for 3 min at 95 °C, followed by 40 cycles of denaturation at 94 °C for 3 s, annealing at 58 °C for 30 s, and extension at 72 °C for 30 s. After cycling, a final step was performed at 72 °C for 10 min.

Statistical Analysis. Results are expressed as the mean ± standard deviation. All data were analyzed in SPASS 18.0 using one-way analysis of variance (ANOVA) followed by Duncan's test for multiple comparisons. $P < 0.05$ was considered statistically significant.

RESULTS AND DISCUSSION

Effects of *O. kansuensis* on the Distribution and Expression of MAN2A1 in Brain Tissues of SD Rats. MAN2A1 was expressed in all areas of the brain except the molecular layer of the cerebral cortex and certain hippocampal layers (the stratum radiatum, the stratum oriens, and the molecular layer of the gyrus dentatus). The strongest expression levels were observed in the pyramidal cell layer of the cerebral cortex, the mesencephalon, the mesocephalon, the cerebellar nuclei or nerve cells of the medulla oblongata, and the Purkinje cells. The expression level of MAN2A1 in neurons is higher when compared to other cell types. Among neurons, MAN2A1 expression was strongest in cells located in the nucleus of the facial nerve and the pyramidal cell layer of the cerebral cortex, followed by Purkinje cells. The lowest expression was in the hippocampus cells. The expression of MAN2A1 decreased proportionally with increasing doses of

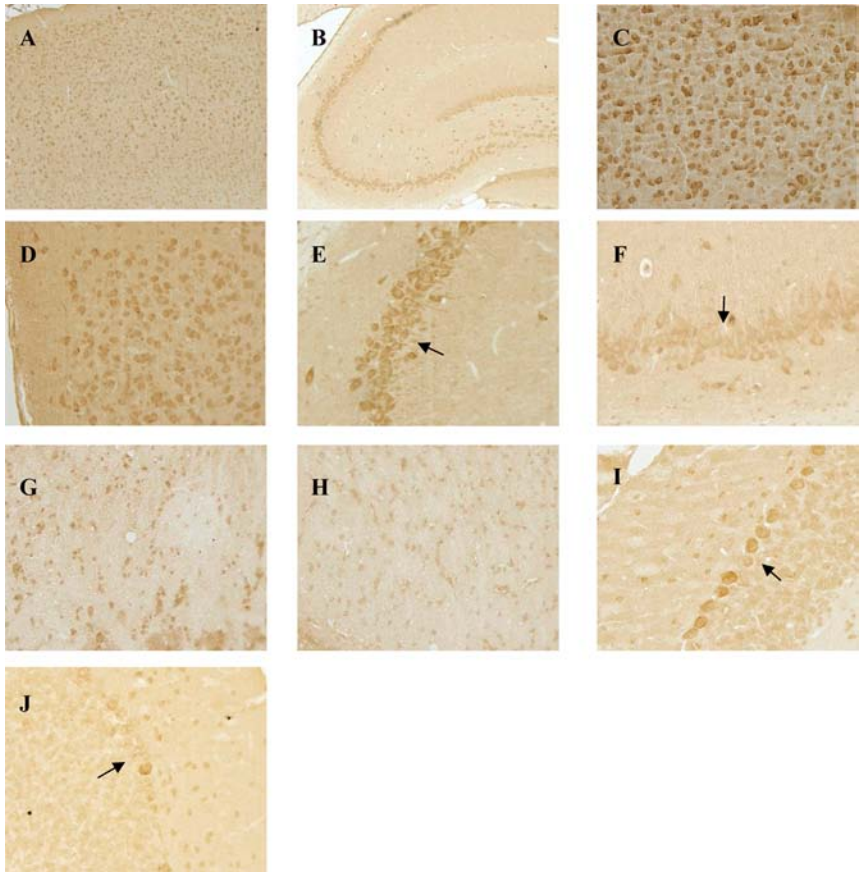

Figure 3. MAN2A1 expression in different areas of the cerebrum and cerebellum: (A) cerebral cortex in the control group (IHC × 100); (B) hippocampal formation in the control group (IHC × 100); (C) external granular cells in the control group (IHC × 400); (D) external granular cells in experimental group III (IHC × 400); (E) hippocampus of the control group (IHC × 400); (F) hippocampus of experimental group III (the arrow indicates pyramidal cells) (IHC × 400); (G) corpus callosum of the control group (IHC × 400); (H) corpus callosum of experimental group III (IHC × 400); (I) cerebellar cortex of the control group (the arrow indicates Purkinje's layer) (IHC × 400); (J) cerebellar cortex of experimental group III (some of the Purkinje cells turned pale) (IHC × 400).

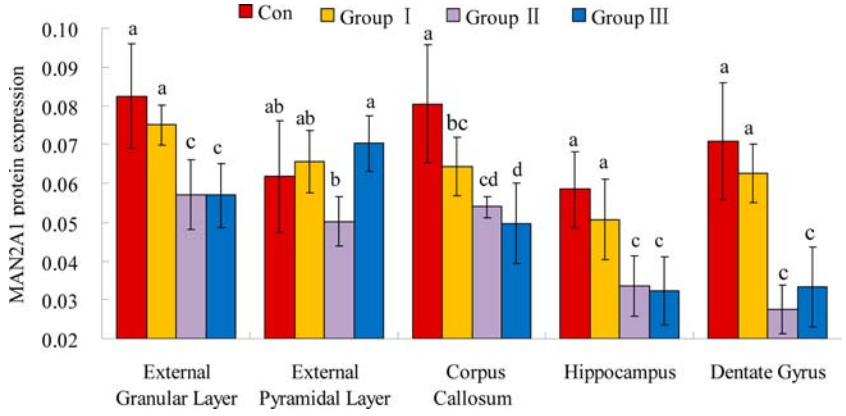

Figure 4. MAN2A1 expression in different areas of the cerebrum. MAN2A1 expression was detected in the cerebrum of SD rats by immunohistochemistry. The stained tissues were observed through a light microscope, and the resulting images were analyzed using Image-Pro Plus 6.0. Results are the mean ± SD. Identical letters denote nonsignificant deviation ($P > 0.05$); adjacents denote significant deviation ($P < 0.05$), and alternates denote extreme significance ($P < 0.01$) versus the control group.

swainsonine, and it significantly decreased in the external granular layer of the cerebral cortex, nerve cells in the hippocampus, cerebellar medulla, and molecular layer.

Expression of MAN2A1 in Different Areas of the Cerebrum. We found MAN2A1 was widely distributed in the cerebral cortex, with expression in all regions except the molecular layer (Figure 3A). It was most strongly expressed in the granular layer and the external pyramidal layer, whereas its expression was relatively weaker in the polymorphic layer. In the hippocampus, MAN2A1 was expressed most strongly in the stratum pyramidale, followed by the molecular layer; however, there was almost no expression in the hippocampal medulla, and the expression level was even lower in the dentate gyrus (Figure 3B). When the poisoning dose was increased, the

dx.doi.org/10.1021/jf501299d | J. Agric. Food Chem. 2014, 62, 7407−7412

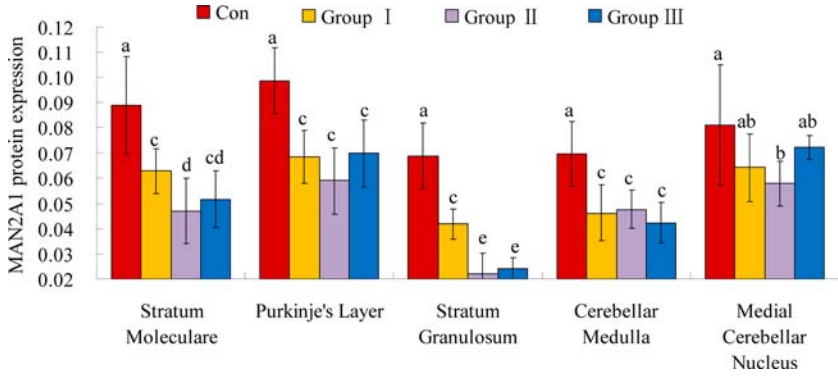

Figure 5. MAN2A1 expression in different areas of the cerebellum. MAN2A1 expression was detected in the cerebellum of SD rats by immunohistochemistry. The stained tissues were observed through a light microscope, and the resulting images were analyzed using Image-Pro Plus 6.0. Results are the mean ± SD. Identical letters denote nonsignificant deviation ($P > 0.05$); adjacents denote significant deviation ($P < 0.05$), and alternates denote extreme significance ($P < 0.01$) versus the control group.

expression of MAN2A1 decreased in the cerebrum; the decrease in expression was more obvious in the external granular layer of the cerebral cortex than in either the external pyramidal layer, ganglion cell layer, or polymorphic layer. Furthermore, the difference in expression in the polymorphic layer was more significant than that in the ganglion cell layer (Figure 3C,D). MAN2A1 was expressed at much lower levels in the hippocampus of experimental groups when compared to the control group (Figure 3E,F). MAN2A1 was more strongly and widely expressed in the corpus callosum (Figure 3G), and its expression in this region was much weaker in experimental groups when compared to the control group (Figure 3G,H).

The expression of MAN2A1 in different groups is shown in Figure 4. When compared with the control group, the expression of MAN2A1 showed a tendency to decrease in the external granular layer of the cerebral cortex in the experimental groups. The expression levels of experimental groups II and III decreased by 30.8 and 31.0%, respectively, and this difference was found to be extremely significant ($P < 0.01$). When compared with the control group, the expression of MAN2A1 in the external pyramidal layer of the cerebral cortex was 18.7% lower in experimental group II and 5.9 and 13.6% higher in experimental groups I and III, respectively. However, these differences were not significant ($P > 0.05$). The expression of MAN2A1 fell by 13.1, 42.4, and 44.8% in the hippocampus and by 11.7, 61.1, and 52.9% in the gyrus dentatus in the experimental groups, respectively. The differences between the control group and experimental groups II and III were extremely significant ($P < 0.01$), as were those between experimental group I and experimental groups II and III ($P < 0.01$). In the corpus callosum, the expression of MAN2A1 decreased by 20.1, 33.0, and 38.2% in experimental groups, respectively, and these differences were either significant or extremely significant when compared with the control group ($P < 0.05$ or $P < 0.01$) (Figure 3G,H).

Expression of MAN2A1 in Different Areas of the Cerebellum. The Purkinje cell layer had the highest expression, whereas the molecular layer and the granular layer had the lowest (Figure 3I). With increasing locoweed doses, the expression of MAN2A1 in the cerebellum decreased clearly and uniformly in the cerebellar medulla and the molecular layer, whereas in the Purkinje cell layer, parts of Purkinje cells showed decreased or complete loss of expression, but in some cells the expression level tended to increase (Figure 3I,J).

The expression of MAN2A1 of the different groups is shown in Figure 5. Upon increasing the locoweed dose, MAN2A1 expression tended to decrease in the molecular layer of the cerebellum, the Purkinje cell layer, the granular layer, and the medulla. When compared with the control group, the expression in groups I, II, and III, respectively, decreased by 30.7, 40.3, and 29.3% in the molecular layer; by 29.4, 47.2, and 42.0% in the Purkinje cell layer; by 38.9, 67.8, and 64.9% in the granular layer; and by 33.7, 31.5, and 39.0% in the medulla, and all differences were extremely significant with respect to the control group ($P < 0.01$); however, differences between experimental groups were either significant or nonsignificant ($P < 0.05$ or $P > 0.05$). The expression in the medial cerebellar nucleus of experimental groups I, II, and III dropped by 20.8, 29.9, and 10.8%, respectively, when compared with the control group; these differences were either significant or extremely significant ($P < 0.05$ or $P < 0.01$).

Effects of *O. kansuensis* on the Expression of MAN2A1 mRNA in Brain Tissues of SD Rats. *Expression of MAN2A1 mRNA in the Cerebrum.* The MAN2A1 mRNA expression showed a decreasing trend in the cerebrum of SD rats as the poisoning dose increased in experimental groups (Figure 6). When compared with the control group, MAN2A1 mRNA expression was reduced by 8.1, 11.8, and 21.3% in the cerebrum of experimental groups I, II, and III, respectively. However, these differences were not significant ($P > 0.05$).

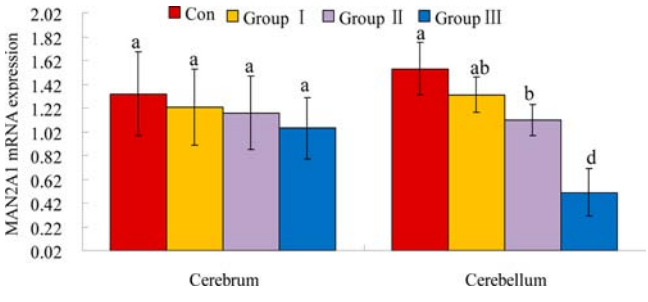

Figure 6. MAN2A1 mRNA expression in the cerebrum and cerebellum. MAN2A1 mRNA expression was measured using real-time quantitative PCR. Swainsonine treatment decreased the expression of MAN2A1 at mRNA levels. Results are the mean ± SD. Identical letters denote nonsignificant deviation ($P > 0.05$); adjacents denote significant deviation ($P < 0.05$), and alternates denote extreme significance ($P < 0.01$) versus the control group.

Expression of MAN2A1 mRNA in the Cerebellum. Expressions of MAN2A1 mRNA also had a decreasing trend in the cerebellum of SD rats as the poisoning dose increased in experimental groups (Figure 6). When compared with the control group, MAN2A1 mRNA expression was reduced by 14.2, 27.7, and 67.1% in the cerebellum of experimental groups, respectively. The difference was not significant for experimental group I ($P > 0.05$), whereas differences were either significant or extremely significant in experimental groups II and III ($P < 0.05$ or $P < 0.01$).

MAN2A1 contains an amino acid sequence from family 38 of the glycoside hydrolases that distributes it to the Golgi apparatus, but its location within the Golgi apparatus can vary in different cell types.[12] It plays a key catalytic role during the N-glycosylation process of proteins, specifically cleaving mannose α-1,3 and α-1,6 glycosidic bonds.[13,14] Immunohistochemical staining showed that MAN2A1 is widely distributed throughout brain of SD rats, consistent with reports that N-linked glycoprotein is also widely distributed throughout the brain.[8] The expression level of MAN2A1 is variable in different kinds of cells: it is high in cells involved in information transmission and low in cells that do not participate in information transmission. These differences may due to the important role of N-linked glycoprotein in mediating signal transduction and intracellular communication.[4]

Swainsonine can specifically inhibit MAN2A1;[14] therefore, it can interfere with the glycosylation pathway, leading to abnormal N-glycosylation of proteins and effects on the processing, modification, and transport of proteins, which subsequently affect cell functions.[7,15] The results from this study clearly showed that swainsonine can inhibit the expression of MAN2A1 in external granular layer cells, stratum pyramidale cells, granular cells of the dentate gyrus, Purkinje cells in the cerebellum, and cerebellar granular cells. The hippocampus plays an important role in the process of memory formation and, when damaged, may cause dysmnesia. The Purkinje cell, originating from the cerebellar cortex, is the only neuron that can transmit the efferent impulses from the cerebellum. Its axon goes through the granular layer and white substance, reaching the cerebellar central nuclei, and plays a significant role in the motor coordination of animals.[16] Abnormal N-glycosylation may affect signal transmission and, as a result, produce clinical symptoms such as ataxia in animals. MAN2A1 mRNA levels decreased in the cerebrum and cerebellum of SD rats from experimental groups, but the absence of significant differences when compared to the control group shows that swainsonine can weakly inhibit the expression of MAN2A1 at the transcriptional level.

Swainsonine inhibited the expression of MAN2A1 in many areas of the cerebrum and cerebellum of rats, potentially causing abnormal N-glycosylation that would decrease the synthesis of complex N-linked oligosaccharides while increasing the synthesis of hybrid N-linked oligosaccharides.[17] Proteins that undergo N-glycosylation include receptors, secreted proteins, hormones, and intracellular proteins, and abnormal N-glycosylation can affect the bioactivity, folding, and location of these proteins. The complex N-linked oligosaccharide chain of glycoproteins participates in the posttranslational modification of intracellular and secreted proteins, and their inhibition can cause cellular dysfunction.[17−19] Tomoya et al.[20] found that rats that are deficient in Golgi α-mannosidase II genes die quickly during the postnatal period due to dyspnea, proving that complex N-linked oligosaccharide chains play an important role in the respiratory system of newborn animals. The effects of MAN2A1 on the CNS of animals have not been reported.

Researchers have also shown that the development and metastasis of cancer cells are related to abnormal N-glycosylation of glycoprotein on the surface of these cells. Finding an inhibitor of the key enzyme in this process has clinical significance, and MAN2A1 is one of the key enzymes in catalyzing N-glycosylation.[15] It has been reported that giving terminal cancer patients a specific inhibitor of MAN2A1, swainsonine, could inhibit tumor growth and metastasis with relatively minor side effects.[21−24] At the same time, ongoing research highlighted the search for a MAN2A1inhibitor with lower toxicity.[25,26]

mRNA is translated into polypeptide chains in the ribosome; these polypeptide chains are then folded and modified by processes such as acylation and hydroxylation in the endoplasmic reticulum. Subsequently, these chains undergo further processing, such as glycosylation and are packaged into the Golgi apparatus, before mature proteins are finally transported to the lysosome and cytomembrane or secreted as extracellular proteins.[27] If a protein is folded incorrectly, it will be degraded through the ubiquitin pathway. When compared with the control group, differences in MAN2A1 expression of the experimental group at mRNA level were not as significant as differences at the protein level. This may be due to the abnormal metabolism and processing of glycoproteins after swainsonine poisoning, which can affect the translation and posttranslational modification of MAN2A1, ultimately leading to MAN2A1 being degraded because it cannot mature or is incorrectly folded. Furthermore, the differences could also be due to how much swainsonine each cell type is exposed to.

In this study, the influence of swainsonine on the expression of MAN2A1 in the cerebrum is not as significant as in the cerebellum. These data are consistent with the fact that clinical signs in poisoned rats are characterized by dyskinesia. Our results further demonstrate the inhibition of MAN2A1 by swainsonine in SD rats and provide experimental evidence for the underlying neurotoxicological mechanism of swainsonine.

Gross and Histopathology. SHNW1−3 and SHNW7−10 were subjected to necropsy within 12 h of death at the Veterinary Diagnostic Laboratory, University of Adelaide. Representative tissues were collected and fixed in 10% neutral buffered formalin or frozen for storage and future analysis. Tissues fixed in 10% neutral buffered formalin were routinely processed for examination by light microscopy.[5]

Haematology, Serum Biochemistry, and Urinalysis. Blood samples were analyzed within 24 h of collection. Hematological analysis was conducted on EDTA whole blood, using a Cell Dyne 3500 automated analyzer (Abbott Diagnostics, Abbott Park, IL, USA). Blood films were made from EDTA-preserved whole blood, stained with a Wright−Giemsa stain using a Hema-tek Slide Stainer (Ames Division of Miles Laboratories, Elkhart, IN, USA), and examined under light microscopy for WBC differential counts and morphological evaluation. Biochemical analysis was performed using extracted serum samples in a Beckman Coulter AU480 (Beckman Coulter, Brea, CA, USA) analyzer.

Plant Material for Analysis. *Heliotropium europaeum* samples were collected from a paddock where affected wombats had been found approximately 10 km southwest of Blanchetown in South Australia. Field-collected plant material was transported to the laboratory, where the material was freeze-dried, milled, and stored frozen at −20 °C prior to analysis. A separate pressed mature plant sample was submitted for species identification by the State Herbarium of South Australia and confirmed as *H. europaeum* (Voucher AD255584).

Plant, Gastrointestinal, and Fecal Toxicology. Milled plant material (2 g) was extracted to provide both a free pyrrolizidine alkaloid extract and a total alkaloid extract (after Zn reduction of pyrrolizidine alkaloid *N*-oxides) as previously described.[6] Pyrrolizidine alkaloid analysis was conducted by GC-MS on a 30 m × 0.25 mm i.d. HP-5MS column (Agilent Technologies) with retrorsine added as an internal standard. Retention indices for each alkaloid were calculated with respect to co-injected standard hydrocarbons[6] and are slightly greater than those measured on a similar DB-5MS column, but with similar relative retention order. Individual alkaloids were identified by comparison of mass spectra and retention index with a laboratory mass spectra database and literature data.

Fecal and gastrointestinal contents from SHNW7−10 were collected during necropsy examinations. Samples were also freeze-dried, milled, and similarly analyzed by GC-MS for pyrrolizidine alkaloids. Initial analysis indicated negligible alkaloids were present, and sample extracts were concentrated 20-fold and reanalyzed.

RESULTS AND DISCUSSION

Gross Pathology and Histopathology. Most significant pathological findings were identified in the three juvenile female wombats (SHNW1−3). Wombats were jaundiced, in poor to emaciated body condition, and had extensive patchy to diffuse hair loss over the dorsal and lateral body walls and head. Elevation of total bilirubin in either the blood or urine was present in two wombats. Grossly, the livers of all animals were decreased in size with scalloped lobar borders, orange-yellow, and firm on palpation and had an enhanced lobular pattern, and one liver (SHNW1) had multifocal white foci <2 mm in diameter over the capsular and cut surfaces. In SHNW3, the gall bladder walls were thickened and inflamed. SHNW7−10 were adult female wombats in poor to emaciated body condition with extensive bilaterally symmetrical patchy alopecia and dermatitis.

Histologically, a spectrum of changes was observed in the livers of juvenile female wombats (SHNW1−3) including marked and often atypical ductular proliferation and disrupted sinusoidal architecture (Figure 1A), hepatocellular megalocytosis and multinucleation (Figure 1B), cholestasis, periportal and bridging hepatic fibrosis, nodular regeneration, multifocal

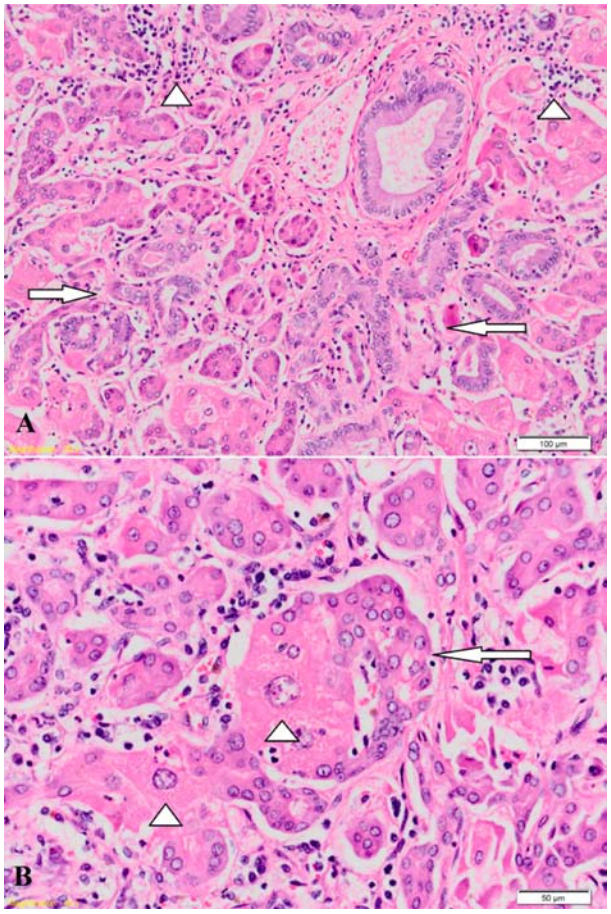

Figure 1. (A) Atypical ductular proliferation (arrows) and markedly disrupted sinusoidal architecture observed in the livers of affected wombats (SHNW1). Lymphomonocytic infiltrates (arrowheads) were seen in periportal regions in some sections. (B) Hepatocellular multinucleation (arrow), megalocytosis (arrowheads), anisocytosis (variation in cell size), and anisokaryosis (variation in nuclear size), frequent abnormalities in wombat livers (SHNW1).

necrosuppurative hepatitis, and lymphomononuclear infiltrates. Hepatocellular degeneration and necrosis, megalocytosis, bile ductile proliferation, nodular regeneration, and portal fibrosis are features of pyrrolizidine alkaloid toxicity.[7−10] Toxic hepatopathies associated with the grazing of toxic weeds have not been reported in wombats previously; however, they are well characterized in domestic grazing species such as the cow, sheep, and horse.[4,8,11,12] Both acute and chronic forms of pyrrolizidine alkaloid toxicosis can occur in animals, often reflecting variation in species susceptibility to toxic effects[8,13] as well as chemotype of plant ingested. Cattle, horses, pigs, chickens, ducks, rats, and mice are susceptible to pyrrolizidine alkaloid intoxication, whereas sheep, goats, rabbits, and guinea pigs are relatively resistant to toxicity.[12,14−17] The susceptibility of the wombat to toxic alkaloids relative to other species is uncertain. In other marsupial species, hepatic lesions typical of pyrrolizidine alkaloid toxicity have been reported in red kangaroos from free-ranging regions in which pyrrolizidine alkaloid-containing plants occur, and hepatotoxicity and secondary photosensitization have been reported in captive red kangaroos following ingestion of *Lantana camara*.[18,19] Hepatosis in pygmy possums has circumstantially been related to the feeding of honey from regions with heavy ragwort (*Senecio jacobea*) infestations.[20]

In SHNW1 and SHNW2 there was severe bilaterally symmetrical exudative and necrohemorrhagic dermatitis of facial extremities and sun-exposed alopecic dorsal and lateral body skin. Histologically, skin lesions were characterized by vascular degeneration, hemorrhage, thrombosis, and infarction in the superficial layers of sun-exposed skin. Eyelid and ear lesions were characterized by locally extensive exudative necrosuppurative and hemorrhagic dermatitis with superficial vascular degeneration, thrombosis, and infarction. Features that support hepatogenous photosensitization as the underlying cause of these skin lesions include the distribution of lesions (dorsal and lateral body wall, eyelids, and ears, with sparing of ventral abdomen and medial aspects of legs), superficial vascular degeneration, hemorrhage, thrombosis, infarction restricted to superficial layers of sun-exposed skin, and the presence of a severe cholestatic hepatopathy in both wombats.[21−24] Significant hair loss and pigmentary incontinence in skin from these animals in conjunction with unusual diurnal grazing habits may have rendered them more susceptible to photosensitization and solar skin damage (superficial dermal sclerosis).

Clinical Pathology. Clinicopathological data were available for two live juvenile and one adult female wombats (SHNW4−6) and from antemortem samples collected from a juvenile wombat subjected to necropsy examination (SHNW3). SHNW4−6 were in thin or emaciated body condition with patchy bilaterally symmetrical noninflammatory alopecia. Serum biochemical analysis in SHNW3−6 identified elevated hepatocellular leakage enzymes (GLDH, AST) and/or hepatobiliary enzymes (GGT, ALP). Elevations in hepatic leakage (cytosolic) enzymes GLDH and AST suggest either sublethal or lethal hepatocyte damage, and elevations in hepatobillary liver enzymes GGT and ALP are induced enzymes suggestive of inflammation or irritation within the hepatobiliary tree and/or intra- or extrahepatic cholestasis.[25,26] Similar patterns of hepatic enzyme elevations are observed in horses and ruminants with pyrrolizidine alkaloid toxicity.[12,13,27] Elevated total bilirubin was seen in antemortem blood samples collected from SHNW3, consistent with jaundice and intrahepatic cholestasis observed post-mortem.

Hematological analysis identified a moderate poorly regenerative (normocytic normochromic) anemia in the three juvenile wombats (SHNW3−5) and leukocytosis characterized by a mature neutrophilia in SHNW3. The normocytic normochromic nonregenerative anemia observed was typical of findings seen in malnourished free-ranging wombats during drought conditions[28,29] and with starvation or malnutrition in domestic animal species.[30]

Habitat Botanical Survey. Botanical surveys of habitat from where affected wombats were found revealed a scarcity of native grasses and invasion by introduced weed species with a dominance of and sometimes monoculture of onion weed (*Asphodelus fistulosus*), with lesser Wards weed (*Carrichtera annua*) and horehound (*Marrubium vulgare*). *Echium* spp. and *Heliotropium europaeum* were also present, sometimes in close proximity to wombat warrens. Southern hairy-nosed wombats are herbivorous, feeding mostly on native grasses (*Austrastipa*, *Poa* spp.), fresh shoots, and bulbs when available[31,32] and will also graze introduced grasses and sedges.[33] They will dig up grass and plant roots and eat bulbs if vegetative sources are not available, particularly during drought. A scarcity of wombat-preferred herbivory and predominance of poorly palatable introduced weed species in areas of the Murraylands in which affected wombats were found likely contributed to their poor body condition and health status, as well as their tendency toward consumption of toxic weeds.

Plant, Gastrointestinal, and Fecal Toxicology. Toxicological analysis performed on scats and gastrointestinal contents from wombats from habitat in which affected wombats were found (SHNW7−10) identified a number of toxic alkaloids consistent with ingestion of *H. europaeum*. Plant material collected in March 2012 (autumn) at the site from which affected wombats were identified was confirmed as *H. europaeum* by State Herbarium of South Australia Voucher AD255584. The plant sample was freeze-dried, milled, and analyzed for pyrrolizidine alkaloids by GC-MS with individual alkaloids, **1**−**5** (Figure 2), identified by comparison of retention index (RI) and mass spectra.[34−36] Pyrrolizidine alkaloids can occur as either the free alkaloids or the *N*-oxides, with the latter not detected by GC-MS analysis unless chemically reduced to the free alkaloid prior to analysis. GC-MS analysis of the plant extract with and without zinc reduction thus enables the alkaloid content of both free alkaloids and total alkaloids to be determined.[6]

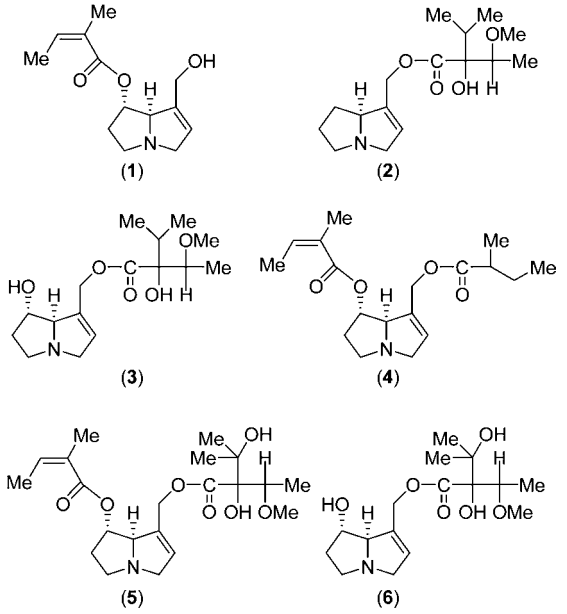

Figure 2. Pyrrolizidine alkaloids identified in plant and animal extracts: 7-angeloylheliotridine (**1**), heleurine (**2**), heliotrine (**3**), 7-angeloyl-9-(2-methylbutyryl)heliotridine (**4**), lasiocarpine (**5**), and europine (**6**).

Alkaloids present were identified as lasiocarpine, **5** (RI 2652, M^+ 411), and 7-angeloyl-9-(2-methylbutyryl)heliotridine, **4** (RI 2258, M^+ 321), with lesser amounts of 7-angeloylheliotridine, **1** (RI 1888, M^+ 237), heleurine, **2** (RI 2036, M^+ 297), heliotrine, **3** (RI 2198, M^+ 313), and three further components tentatively identified as heliotridine diesters, with all alkaloids present predominantly as free alkaloids. Mass spectra were consistent with depicted structures and with previously reported data for 7-angeloylheliotridine, **1**,[34,36] heliotrine, **3**,[35,36] 7-angeloyl-9-(2-methylbutyryl)heliotridine, **4**,[34] and lasiocarpine, **5**.[35,36] It is not possible to definitively distinguish between retronecine/heliotridine isomers from mass spectra,[36] but on biosynthetic grounds alkaloids **1** and **4** are assumed to be heliotridine alkaloids. This analysis contrasts with previous analysis of *H. europaeum* in which europine, heliotrine, and lasiocarpine were major alkaloids with lesser amounts of heleurine and supinine,

with all alkaloids present primarily as *N*-oxides.[37] These authors noted wide variations in this species between site, sampling periods, and following rainfall, but none as markedly different as seen in AD255584, which may represent a different chemotype of this plant species. Neither 7-angeloylheliotridine, **1**, nor 7-angeloyl-9-(2-methylbutyryl)heliotridine, **4**, has previously been reported in *H. europaeum*. Both alkaloids, **1** and **4**, have however been reported as components of *Cynoglossum officinale* and *Cynoglossum amabile* within the same family, Boraginaceae.[34] Trace amounts of lasiocarpine, **5**, and 7-angeloyl-9-(2-methylbutyryl)heliotridine, **4**, were also detected in three of four wombat fecal samples collected from the same location as *H. europeaum* AD255584.

Stomach, small intestinal, colonic, and/or fecal contents collected from four wombats (SHNW7−10) from a different site, euthanized in April 2012 (autumn), were also analyzed for pyrrolizidine alkaloids (Table 1). Concentrated extracts of the stomach contents from two wombats (SHNW8 and SHNW9) showed lasiocarpine, **5**, heliotrine, **3**, europine, **6**, and heleurine, **2**. Levels of alkaloids were too low to be quantitated (LOQ = 1 μg/g), but relative amounts are shown in Table 1. Alkaloids were identified from background-subtracted mass spectra and retention index, which provided good matches with mass spectra from plant extracts, match quality 90 or better. Europine, **6** (RI 2327, M^+ 329), was identified by comparison with literature mass spectra.[35] In each of SHNW8 and SHNW9, alkaloids were predominantly present in the zinc-reduced extracts, indicating the presence of *N*-oxides rather than free alkaloids in these stomach contents. This alkaloid profile is more consistent with previously reported analyses of *H. europaeum* plant material[37] and with previous unpublished analysis of this species in our laboratory. Intestinal and colonic contents from SHNW10 contained europine, **6**, with lesser amounts of other alkaloids. Feces from this animal contained europine, **6**, with negligible amounts of other alkaloids. Europine, **6**, was present in both free and reduced extracts, indicating the presence of the free alkaloid in the fecal sample. Alkaloids **1**−**6** are all 1,2-dehydropyrrolizidine ester alkaloids (dehydroPAs) and as such have the requisite structure to be metabolized to hepatotoxic intermediates.[38] Only alkaloids with this 1,2-dehydro bond are hepatotoxic.

Table 1. Relative Presence of Heleurine, Heliotrine, Europine, and Lasiocarpine as Free and Total Alkaloids As Measured by GC-MS Analysis of Wombat Gastrointestinal Samples[a]

Managing the Risk to Wombat Populations. *H. europaeum* (also known as common heliotrope or potato weed) is a summer-growing annual with widespread prevalence in southeastern Australia. Through this study and additional work we have observed a distinct bias toward hepatotoxicity occurring more frequently in juvenile wombats. Although this weed is generally unpalatable, ingestion may have occurred in these juvenile animals due to decreased availability of preferred forages in the severely degraded habitat in which these animals were found and due to the emergence of weeds around the time of weaning of naive animals. Furthermore, it has been shown elsewhere that young of other animal species exhibit higher susceptibility to the toxic effects of pyrrolizidine alkaloids than do adults;[10,12] therefore, similar mechanisms for susceptibility may also exist in wombats.

There is clear evidence that the wombats are consuming *H. europaeum*. There is wide variation in the alkaloid profile of this introduced heliotrope species, but whether the alkaloid profile looks like that reported here in AD255584 or that detected in the stomach contents of SHNW8 and SHNW9, it would make little difference to toxicity. Both free alkaloids and *N*-oxides are hepatotoxic if consumed, with *N*-oxides reduced to free alkaloids in the gut. Individual alkaloids have differing toxicity with lasioscarpine > heliotrine > europine,[37] but, regardless, all are hepatotoxic; consequently, if wombats are consuming this plant species, it may well be responsible for the observed toxicosis.

Hepatotoxicity due to ingestion of a pyrrolizidine alkaloid-containing plant in juvenile Murraylands wombats is supported by characteristic histopathological changes in the liver, detection of pyrrolizidine alkaloid-containing plants during botanical surveys, and gastrointestinal toxicology performed on wombats from the same habitat. Habitat degradation leading to malnutrition and ingestion of weed species is a significant welfare issue in the Murraylands southern hairy-nosed wombats. It appears that ingestion of *H. europaeum* is the most likely cause of the observed hepatotoxicity in juvenile wombats; however, the contribution of other weeds with known or proposed hepatotoxicity such as *Carrichtera annua* and *Echium* spp. is presently unknown. It is not known whether wombats will graze *Echium*, and although found during botanical surveys of affected habitat, it was noted to be less prevalent than *H. europaeum*. However, as toxic *Echium* spp. contain pyrrolizidine alkaloids and therefore have a similar mechanism of action to *H. europaeum*,[4] it cannot be excluded as a contributor to hepatotoxicity in wombats. The toxic principles in *C. annua*, or Wards weed, are unknown, but thought to be glucosinolates.[4] Hepatic lesions have been observed in cattle thought to have died following ingestion of *C. annua*;[39] therefore, contribution of this plant to hepatotoxicity in wombats cannot be definitely excluded either. Exposure to such a number of weeds containing toxic principles (*H. europaeum*, *Echium* spp., *C. annua*, and also *Asphodelus* spp.) has significant welfare implications for the animals that inhabit this degraded habitat, and the full spectrum of adverse effects in wombats due to ingestion of toxic plants may be broader than currently appreciated.

Due to the often close interaction between agricultural enterprises and wildlife, the findings of this study have implications for the management of both conservation areas and agricultural land. The habitat described in this study was previously a livestock grazing enterprise, in which wombats had coexisted with livestock. Loss of preferred forage, weed overgrowth, and health problems in wombats attributable to habitat degradation arose soon after the land was destocked and land management practices abandoned, highlighting the need for consideration of the impact that changes in agricultural

management may have on native species that coexist in the region. Future research directions focus on the clarification of underlying ecological and land management factors that have led to these problems in Murraylands southern hairy-nosed wombats, as well as the best methods to manage and prevent this problem becoming more widespread.

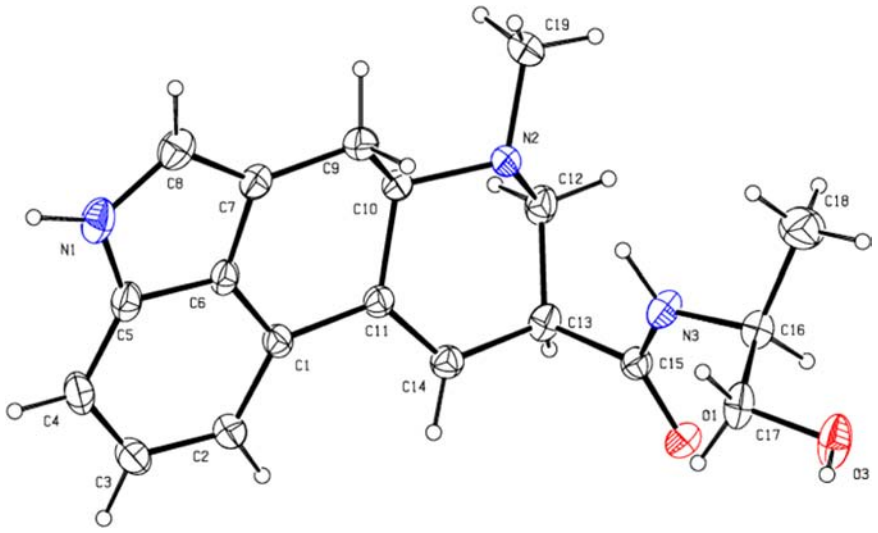

Figure 1. Single-crystal X-ray diffraction analysis for ergonovinine.

TLC. The chloroform extract (fraction 4) was further purified by silica gel column chromatography (CC; ⌀ 46 × 630 mm, 200−300 mesh, 270 g) and eluted with a step gradient of chloroform/methanol (100:1, 50:1, 30:1, 20:1, 10:1, 5:1, 2:1, 1:1, 9.7 L), followed by repeated CC ($CHCl_3$/MeOH, 3:1) on silica gel, Sephadex LH-20, and preparative TLC. Compound **1** (ergonovinine, 23.2 mg) was produced by recrystallization and further Sephadex LH-20 CC ($CHCl_3$/MeOH, 1:1). Compound **2** (ergonovine, 17.8 mg) was fully purified and obtained by repeated CC on silica gel eluted with a step gradient of chloroform/methanol (20:1, 10:1).

Cytotoxicity Assay of the Ergot Alkaloids. The 96-well nanoculture plates with a microsquare pattern [NCP-L-MS (96)] were provided by NUNC Corp. (Roskilde, Denmark).

Vascular smooth muscle cells (VSMC) from cattle (*Bos taurus*) were purchased from the Shanghai cell bank of the Chinese Academy of Sciences and maintained at 35 °C under an atmosphere of 95% air and 5% CO_2 in Dulbecco's modified Eagle's medium (DMEM; Mediatech, Herndon, VA, USA) containing 10% fetal bovine serum (FBS), 100 IU/mL penicillin, and 100 μg/mL streptomycin.

The cytotoxicity of the ergot alkaloids was determined by measuring the cell viability of cultured cells after exposure to different concentrations of extract from the grass. The cytotoxicity of ergot alkaloids was assessed according to the methyl thiazolyl tetrazolium assay (MTT) method.[23] To initiate cell culture, VSMC cells were seeded at a density of 1×10^4 cells/well on a conventional monolayer 96-well plate for expanding propagation. Each of the two ergot alkaloids (1 mg) was dissolved in 0.1% dimethyl sulfoxide (DMSO) (10 μL) and then diluted to concentrations of 125, 100, 75, 50, 12.5, 6.25, and 3.175 μg/mL with the medium and filtered using 0.22 μm syringe filters. These were then added to 24 h cultured cells in 96-well tissue culture plates. Logarithmic phase VSMC cells with a density of 1×10^5 cells/well were inoculated into 96-well plates for 18 h, and then the various concentrations of ergot alkaloids were added as the treatments. Media with 0.1% DMSO in DMEM was used as the blank group, and the cell cultures without added ergot served as the control, each treatment being repeated eight times, independently. The cells were then exposed to different concentrations of the above alkaloids. The cells in the control wells received medium containing the same volume of DMSO (0.1%). Twenty-four hours after the incubation, 20 μL of MTT reagent (5 mg/mL in PBS) was added and cells were incubated for an additional 4 h. The formazan produced by the viable cells was solubilized by the addition of 100 μL of DMSO. The suspension was placed on a microvibrator for 15 min, and absorbance at 490 and 570 nm was quantitated after subsequent addition of MTT solution and DMSO and was also read using a Versamax + Multiwash III ELISA reader (Molecular Devices, Sunnyvale, CA, USA). The experiment was performed three times for each alkaloid concentration treatment. The percentage of growth inhibition was calculated with respect to vehicle control using the following formula:

$$\text{inhibition rate } (\%) = (A_{\text{control}} - A_{\text{test}})/A_{\text{control}} - A_{\text{blank}} \times 100\%$$

Statistical Analysis. All values are expressed as the mean ± SE. Analysis of variance (ANOVA) using SPSS software (SPSS 13.0 Inc., Chicago, IL, USA) was conducted for the cell inhibition rate that resulted from various concentrations of the two ergot alkaloids. Analysis of regression was also carried out between the cell inhibition rate and concentrations of the ergot alkaloids.

RESULTS AND DISCUSSION

Isolation and Identification of the Alkaloids from E+ Plant Compounds. Single-crystal X-ray diffraction for ergonovinine is shown in Figure 1, and ^1H and ^{13}C NMR spectral data for ergonovine and ergonovinine are shown in the Supporting Information. Two ergot alkaloids, ergonovinine and ergonovine, were identified (Figure 2).

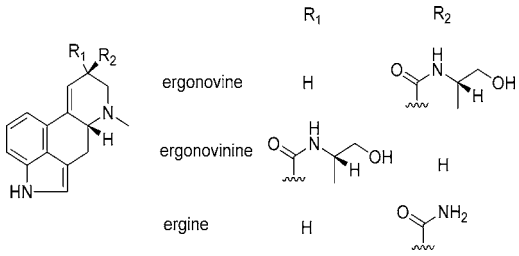

Figure 2. Structures of ergonovinine, ergonovine, and ergine and their C-8 epimers.

Ergonovine (25 mg from 2 kg) and ergonovinine (30 mg from 7 kg) were first isolated from dry powdered drunken horse grass, but without studying the biological activity.[24] Ergonovine and ergine (i.e., lysergic acid amide) were the major ergot alkaloids in drunken horse grass from Xinjiang province.[18] Previous research also investigated the ergonovine and ergine levels and their temporal variation within E+ and E− drunken horse grass grown in Gansu province.[19] Furthermore, seven alkaloids were also detected from drunken horse grass growing naturally near the Jinqiang River, Tianzhu county, Gansu province.[25] Ergine was reported as the main alkaloid, but we did not isolate it during this experiment because of its instability

dx.doi.org/10.1021/jf502264j | J. Agric. Food Chem. 2014, 62, 7419−7422

under high temperature. Ren[26] first reported that animals produced symptoms of intoxication after grazing on drunken horse grass. However, sheep were not significantly intoxicated[27,28] when gavaged with drunken horse grass powder, contrary to equines and rabbits (*Oryctolagus cuniculus*).[29] Research showed that the *Neotyphodium* endophyte was the cause of drunken horse grass toxicity in rabbits.[20] Recently, it was also reported that the *Neotyphodium* endophyte was apparently responsible for the toxicity of drunken horse grass on sheep (*Ovis aries*), which was especially harmful to kidney and liver function.[30]

Cytotoxicity of the Two Ergot Alkaloids. Each of the two ergot alkaloids exhibits cytotoxicity on animal smooth muscle cells, the cell inhibition rate increasing with alkaloid concentration in a significantly ($P < 0.05$) positive correlation (Figure 3). The regression equations for these two alkaloids

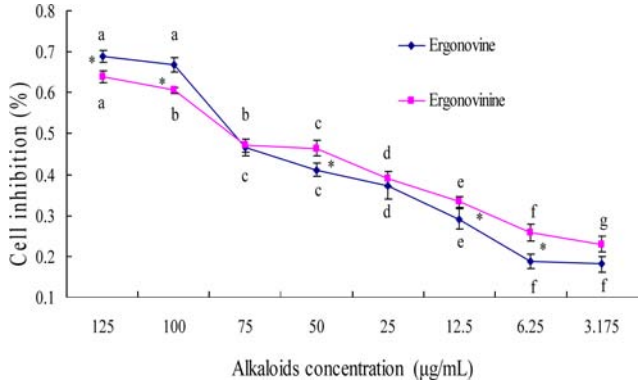

Figure 3. Cytotoxicity of the two ergot alkaloids on VSMC.

were $Y_{ergonovine} = 0.0041x + 0.205$ ($R^2 = 0.945$, $P < 0.05$) and $Y_{ergonovinine} = 0.0032x + 0.2672$ ($R^2 = 0.9411$, $P < 0.05$). The median inhibitory concentrations (IC_{50}) for ergonovine and ergonovinine were 71.95 and 72.75 μg/mL, respectively.

In conclusion, to the best of our knowledge, the present work represents the first study on the cytotoxic effect on animal smooth muscle cells of the pure ergot alkaloids isolated from E+ drunken horse grass. These alkaloids may be the cause of E+ drunken horse grass poisoning and elicit its clinical symptoms. The absence of detection of these chemicals could indicate plants that are safe for grazing animals.

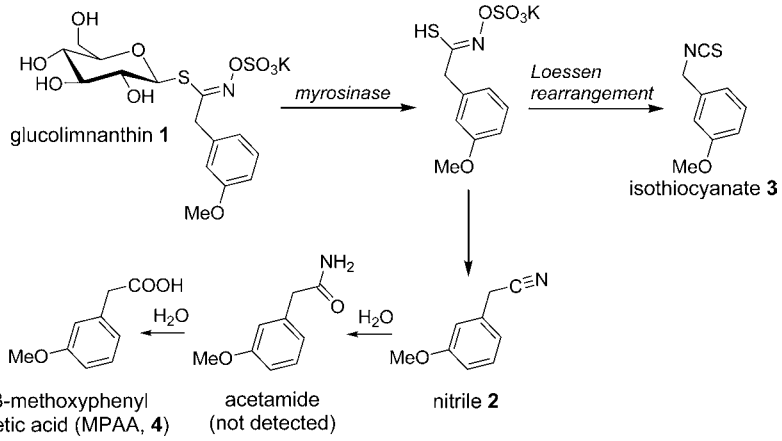

Figure 1. Production of glucolimnanthin breakdown products in soil amendment with meadowfoam seed meal.

another glucolimnanthin **1**-related compound and evaluated the phytotoxicity of soil amended with either nonactivated or activated MSM on seed emergence and growth.

MATERIALS AND METHODS

Chemicals. Glucolimnanthin **1** (1-*S*-(2-(3-methoxyphenyl)-*N*-(sulfonatooxy)ethanimidoyl)-1-thio-β-D-glucopyranose) was extracted from MSM.[11] 3-Methoxyphenylacetonitrile (nitrile **2**) (Sigma-Aldrich Chemicals, St. Louis, MO), 3-methoxybenzyl isothiocyanate (isothiocyanate **3**) (Oakwood Products, West Columbia, SC), and 3-methoxyphenylacetic acid (MPAA **4**) (TCI America, Portland, OR) were purchased from the indicated commercial sources.

Materials. MSM (Natural Plant Products, Salem, OR) was processed using a coffee grinder (Proctor Silex E160B, Southern Pines, NC) and sieved through 1 mm mesh before use. MSM was used at 3:100 MSM/dry soil. Activated MSM was produced by adding 1:100 freshly ground meadowfoam seed/MSM to provide active myrosinase.[11] Nonactivated MSM contained only ground MSM.

Soil was collected at 0−20 cm in 2010 from a site near Sweet Home, Oregon, USA (44°25′5″ N, 122°42′43″ W), where no herbicide application had been made for at least 4 years. The soil was a Newburg sandy loam (coarse-loamy, mesic Fluventic Haploxerolls) with an organic matter content of 3.2% and pH of 6.1. The soil was ground, passed through a 2 mm sieve, air-dried for 7 days, and kept in a closed container until use.

Isolation and Identification of a Compound 4. Compound **4** was detected in soil amended with MSM and activated MSM and was not found in the untreated control during the analyses of glucolimnanthin **1** and its breakdown products. Isolation and identification of compound **4** were performed using the following procedures. Soil amended with 3% by weight of MSM was mixed thoroughly in an 11 cm × 11 cm × 3.5 cm plastic box, and H_2O was added to reach 30% moisture content. The MSM amended soil was incubated in the sealed box at room temperature for 4 days before extraction. The moist soil was transferred into a glass centrifuge tube, and CH_2Cl_2 was added (1.5 mL/g of moist soil). The tube was shaken, sonicated for 3 min, and allowed to stand for 15 min. The supernatant was transferred to a glass tube, and the extraction was repeated for two more cycles. The supernatants were combined and then dried using a rotary evaporator. The resultant residue was redissolved in MeOH (2 mL/g dry soil). The methanolic resuspension was extracted with hexane three times to remove nonpolar compounds. The remaining MeOH suspension was evaporated using a rotary evaporator, and resuspended in MeOH before purification using a 2.5 cm × 50 cm column of Sephadex LH-20 (Sigma-Aldrich Chemicals, St. Louis, MO) eluted with 100% degassed MeOH at a flow rate of 1.6 mL/min. Elution was monitored using high performance liquid chromatography (HPLC) as previously described.[11]

The fractions containing compound **4** were collected and concentrated using a rotary evaporator. The fractions were redissolved in acetonitrile and separated on a 250 mm × 4.6 mm Phenomenex Luna 5 μm C18 column (Phenomenex, Torrance, CA) eluted with a linear gradient of 35−40% of 0.1% formic acid in acetonitrile and aqueous 0.1% formic acid in H_2O at 1 mL/min. The eluted compound **4** was identified using LC-UV at λ 274 nm (SPD-10Avp UV−vis detector, Shimadzu Scientific Instruments, Columbia, MD) and high resolution LC-MS/MS (Triple TOF 5600, AB SCIEX, Framingham, MA). Mass spectrometric analysis utilized negative full scan and product ion scan modes. A DuoSpray source was operated at 550 °C and −4.5 kV using a declustering potential of −80 V and a collision energy of 20 eV. The commercial standard was analyzed using LC-UV and high resolution LC-MS/MS under the same conditions as the suspension extract. The retention times and mass spectra of the standard and compound **4** were compared.

Glucolimnanthin and Its Breakdown Products in Soil. Soil incubations were conducted in 15 mL centrifuge tubes using a completely randomized design with three replications. Dry soil (1.94 g) was incubated with either 0.06 g of MSM or activated MSM in a tube. After addition of 750 μL of deionized H_2O to thoroughly hydrate the seed meal amended soil, the tubes were laid horizontally. Nonamended soil was used as a control. The extraction method for glucolimnanthin **1** and its breakdown products from the soil was developed by modifying the method of Stevens et al.[11]

Each incubated soil tube received 6 mL of 70% MeOH. The tube was shaken, sonicated for 10 min, and allowed to stand for 60 min. The mixture was centrifuged for 5 min at 3000 rpm. The supernatant was centrifuged for 10 min at 13 000 rpm. The MeOH concentration in the supernatant was increased to 90% to prevent further enzymatic degradation of glucolimnanthin **1**. The analyses of glucolimnanthin **1** and GBPs were performed using HPLC.[11] The injection volume was 30 μL. A Waters 2996 photodiode array detector (Waters Corporation, Milford, MA) at λ 274 nm was used to calculate peak areas for all compounds. Analyte concentrations were determined from calibration curves constructed for each analyte using the external standard method. The glucolimnanthin **1** and GBPs were quantified on 0, 1, 2, 3, 6, 12, and 18 DAI. The experiment was repeated.

Petri Plate Bioassay. In a comparative assay of relative toxicity, each GBP was used to test the response of lettuce germination and growth. A 10 cm diameter Petri plate (VWR International, Visalia, CA) served as a bioassay study chamber. Test compounds were dissolved in EtOH and diluted in various concentrations. Test solutions (480 μL) were added on top of an 8.3 cm diameter germination blotter paper. Based on preliminary testing, the following concentrations were chosen for dose−response study of the test compounds. Concentrations of test compounds were adjusted by considering the potential losses during the evaporative period. Nitrile **2** solutions were prepared to give 0, 0.38, 3.77, 7.54, 15.1, 22.6, 30.1, 37.7, and 75.4 μmol/plate. Isothiocyanate **3** was prepared to deliver 0, 0.033, 0.33, 0.67, 1.33, 2, 2.66, and 3.33 μmol/plate, and MPAA **4** was prepared at 0, 0.048, 0.48, 4.8, 9.6, 19.2, 28.8, 38.4, and 48 μmol/plate.

dx.doi.org/10.1021/jf5018687 | J. Agric. Food Chem. 2014, 62, 7423−7429

Control plates received EtOH only. Plates were placed in a fume hood for a 3-h evaporative period to remove EtOH.

After 3 h, each plate received 6 mL of deionized H_2O. Sixteen lettuce seeds (*Lactuca sativa* L. "Black Seeded Simpson", Plantation Products, Norton, MA) were placed in a 4 × 4 grid on top of a germination blotter paper. The Petri plate was sealed with a layer of Parafilm (American National Can, Menasha, WI). Lettuce seeds were grown in the incubator at 20/15 °C day/night temperature with a 14 h photoperiod. Seeds were counted as germinated when the hypocotyl, radicle, or hypocotyl plus radicle measured 2 mm, and seedling growth was evaluated by measuring radicle and hypocotyl length on day 7. The experiment was performed in a completely randomized design with three replications of each test compound and was repeated.

Phytotoxicity of Meadowfoam Seed Meal. Filter paper was placed at the bottom of a 132 mL pot to prevent soil loss. Pots were filled with 116.4 g of soil and amended with 3.6 g of either MSM or activated MSM. The untreated control was 120 g of soil without amendment. Lettuce seeds were sown nine seeds per pot at an approximate depth of 0.4 cm on 0, 6, and 12 days after MSM incorporation (DAI). Each pot was watered daily. Soil moisture in each pot was maintained at 37.5% by weighing the pots. The experiments were conducted in the greenhouse with 25/20 °C day/night temperature and a 14 h photoperiod. Seedling emergence was counted, and shoot biomass was harvested 21 days after planting. The biomass was dried at 60 °C for 72 h and weighed. The experiment was structured in a randomized complete block design with three replications and was repeated.

Statistical Analyses. Concentrations of glucolimnanthin **1** and GBPs and lettuce germination, emergence, hypocotyl and radicle growth, and biomass were analyzed using analysis of variance (ANOVA) with means separated using a least significant difference (LSD) test at a 0.05 level. For the phytotoxicity of GBPs in the lettuce germination study, dose−response curves were obtained by a nonlinear regression using a log−logistic equation (eq 1),[26,27]

$$y = C + (D - C)/[1 + (x/I_{50})^b] \quad (1)$$

where y represents germination (percent of untreated control) at GBP concentration x, C is the mean response at the greatest GBP concentration (lower limit), D is the mean response when the GBP concentration is zero (upper limit), b is the slope of the line at I_{50}, and I_{50} is the GBP concentration required for 50% germination reduction.

The regression parameters, 95% confidence interval for each GBP, and lack of fit test were obtained using the package drc in the statistical program R.[28] The relative I_{50} level was calculated by the ratio of one GBP to another GBP. The statistical program R v. 3.0.2 was used for all the statistical analyses.[29]

RESULTS AND DISCUSSION

Glucolimnanthin 1 and Its Breakdown Products. The analytical data of the composition of MSM and activated MSM are provided in Supporting Information, Figure S1. When MSM was incubated with soil, a previously unknown metabolite **4** of glucolimnanthin **1** was observed (Figure 1). Its identity was confirmed by LC-UV and by high resolution LC-MS/MS with a 4.2 ppm error compared with the exact mass of MPAA **4** (Figure 2). The observed spectrum of an MPAA **4** standard had 2.4 ppm error compared with the calculated mass of MPAA **4** (Supporting Information, Figure S2).

Glucolimnanthin **1** was converted into isothiocyanate **3** by active myrosinase from freshly ground meadowfoam seed (Figure 3B). The production of isothiocyanate **3** occurred quickly within 30 min after soil incorporation with activated MSM. Maximal concentrations of isothiocyanate **3** were observed at 1 DAI, after which they decreased >90% of the maximum by 2 DAI. Within 6 days, glucolimnanthin **1** in MSM (Figure 3A) degraded slower to trace amounts compared with activated MSM (Figure 3B), and isothiocyanate **3** was not detected. Isothiocyanate **3** was the major degradation product and was produced rapidly. Similar findings were observed in soil incorporation of Brassicaceous plants. Brown et al.[30]

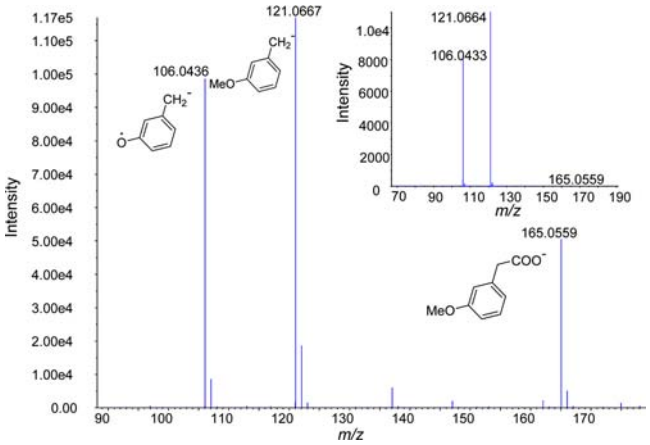

Figure 2. Time-of-flight (TOF) mass spectrum of 3-methoxyphenylacetic acid (MPAA) produced from soil amended with 3% by weight of meadowfoam seed meal, showing the molecular ion (observed m/z 165.0559, calculated m/z 165.0552, 4.2 ppm error). The inset shows an MS−MS fragmentation of the parent peak at m/z 165.

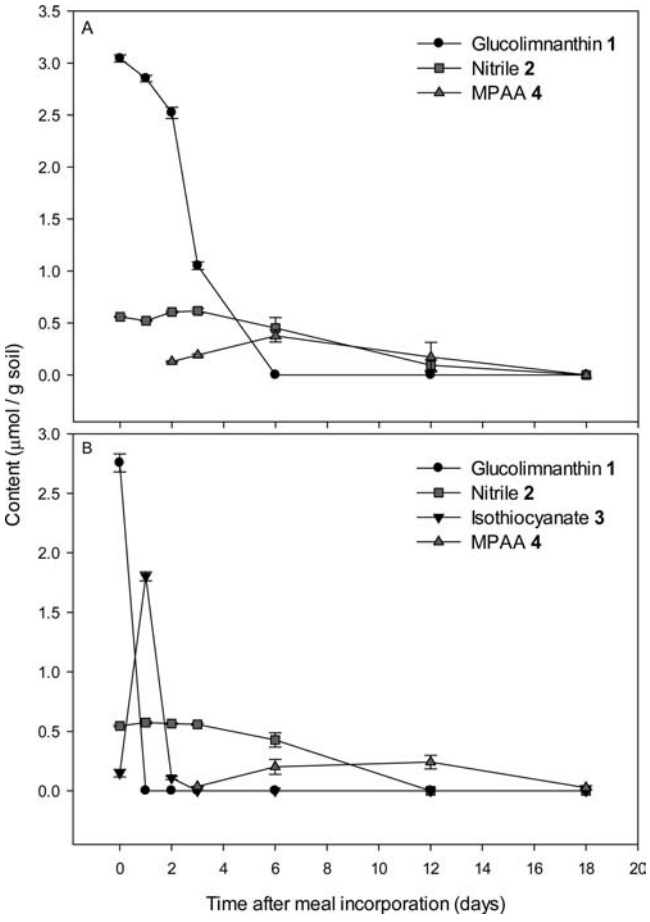

Figure 3. Concentrations of glucolimnanthin and its breakdown products in soil amended with meadowfoam seed meal (A) and activated meadowfoam seed meal (B). On day 0, the extraction started 30 min after meal incorporation. Symbols and bars represent means and standard errors of two studies (n = 6).

dx.doi.org/10.1021/jf5018687 | J. Agric. Food Chem. 2014, 62, 7423−7429

reported the isothiocyanate degradation from soil amended with rapeseed (*Brassica napus* L.) meal, which was detected in 2 h but decreased to trace amounts at 2 DAI. The maximum concentrations of detected meadowfoam isothiocyanate **3** were similar to allyl isothiocyanate from sinigrin decomposition in soil.[31] Allyl isothiocyanate reached maximum levels within 1 DAI and remained detectable until 7 DAI. Morra and Kirkegaard[32] suggested that greater isothiocyanate production and its retention could occur by disruption of glucosinolate-containing tissue to provide greater contact between glucosinolate-containing tissue and myrosinase. However, isothiocyanate disappeared rapidly, possibly because it easily binds with free amino acids and proteins.[13]

Nitrile **2** occurs in MSM because of the heat involved in the commercial process, but it is minimally produced by enzymatic degradation of glucolimnanthin **1**.[11] From 0 to 3 DAI, nitrile **2** concentrations with MSM or activated MSM were not different ($p > 0.05$) (Figure 3). Nitrile **2** concentrations decreased from 3 to 18 DAI in MSM and from 3 to 12 DAI in activated MSM. Vaughn et al.[22] reported that the large amount of nitrile **2** in MSM was possibly a driving factor for its phytotoxicity.

MPAA **4** appeared on 2 DAI of MSM and 3 DAI of activated MSM (Figure 3). While nitrile **2** decreased after 3 DAI, MPAA **4** increased. MPAA **4** occurred last and remained detectable at 12 DAI. Soil was amended with nitrile **2** alone to determine whether nitrile **2** was the parent compound of MPAA **4**. The metabolite mass was consistent with the calculated mass of standard MPAA **4** (mass error 4.8 ppm; Supporting Information, Figure S3). A possible pathway for MPAA **4** formation from glucolimnanthin **1** via nitrile **2** involves hydrolytic conversion of nitrile **2** to its corresponding amide followed by hydrolysis of the amide into its corresponding carboxylic acid, MPAA **4** (Figure 1). However, MPAA **4** was detected when soil was incubated with either MSM or activated MSM within 3 DAI, when nitrile **2** concentration had not decreased. A potential explanation is that the MPAA **4** formation may not have been only from nitrile **2** degradation but also derived from glucolimnanthin **1** through nitrile **2**. MPAA **4** was not detected in incubation of MSM in the absence of soil. It was also possible that MPAA **4** was not present as a simultaneous metabolite but occurred through enzymatic activity mediated by soil microbes. MPAA **4** production may have been facilitated by nitrilases from soil microorganisms, which are known to catalyze nitriles into their corresponding carboxylic acids.[33]

Petri Plate Bioassay. Herbicidal efficacy of each GBP was of interest. Commercially available GBPs were used to evaluate their phytotoxicity. The required concentrations of GBPs for suppression of seed germination and growth are important for developing MSM as a bioherbicide. Nitrile **2**, isothiocyanate **3**, and MPAA **4** showed potent inhibition of lettuce germination and growth (Figures 4 and 5). Isothiocyanate **3** had the most effective herbicidal activity followed by MPAA **4** and nitrile **2**. The amounts required to reduce germination by 50% (I_{50}) were 1.4 μmol/plate for isothiocyanate **3**, 11.9 μmol/plate for MPAA **4**, and 20.2 μmol/plate for nitrile **2**. I_{50} values for the GBPs were different from each other ($p < 0.05$). The relative potency of isothiocyanate **3** was 8.5- and 14.4-fold greater than MPAA **4** and nitrile **2**, respectively. The relative potency of MPAA **4** was 1.7-fold greater than nitrile **2**. Both hypocotyl and radicle length decreased with increasing concentrations of GBPs (Figure 5). Isothiocyanate **3** provided the greatest inhibition of hypocotyl and radicle length followed by MPAA **4** and nitrile **2**,

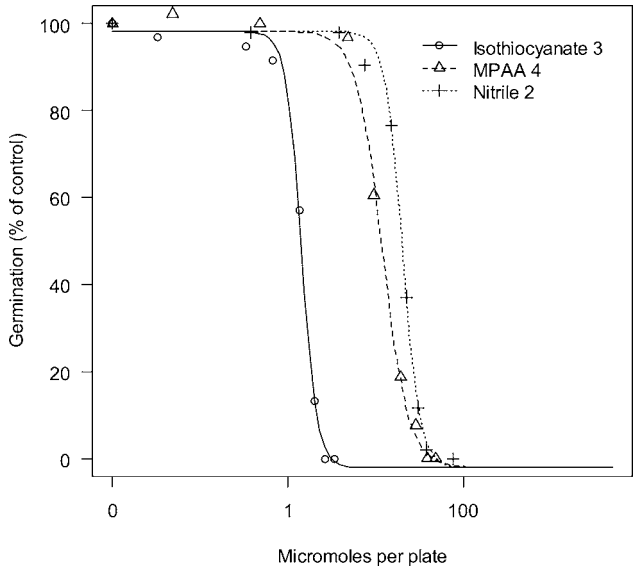

Figure 4. Phytotoxicity of glucolimnanthin breakdown products on lettuce germination. Symbols represent means of samples of two studies ($n = 6$).

respectively ($p < 0.05$), which was the same as for germination inhibition.

Several published studies of Brassicaceae glucosinolates[9,32] and meadowfoam glucolimnanthin **1**[23−25] have shown

dx.doi.org/10.1021/jf5018687 | J. Agric. Food Chem. 2014, 62, 7423−7429

isothiocyanates to be the major phytotoxic metabolites. Vaughn et al.[22] reported that meadowfoam isothiocyanate **3** had phytotoxic effects on velvetleaf and wheat (*Triticum aestivum* L.) radicle growth, but they were unable to detect isothiocyanate **3** in nonactivated MSM. However, Stevens et al.[11] reported that meadowfoam nitrile **2** had greater activity than the isothiocyanate **3** in preventing coleoptile emergence of downy brome. The difference between the studies may have been due to experimental conditions and target species. In our study, isothiocyanate **3** had the greatest phytotoxic effects on lettuce germination and growth. It is possible that phytotoxicity does not depend on a single chemical compound. A combination of all GBPs may result in phytotoxicity. A synergistic or antagonistic response of GBP combinations for herbicidal activity may exist.

Phytotoxicity of Meadowfoam Seed Meal in Soil. Greenhouse studies were conducted to evaluate the direct use of MSM as a soil amendment material for inhibition of seed emergence and growth. Lettuce emergence and growth were different among amendment materials and planting times (Table 1). Activated MSM had greater phytotoxicity on lettuce

Table 1. Greenhouse Studies on Lettuce Emergence and Growth in Soil Amended with 3% by Weight of Meadowfoam Seed Meal (MSM) or Activated MSM

treatments	lettuce emergence[a] (% of sown seeds)	lettuce biomass (mg/plant)
	Planted on 0 DAI[b]	
unamended	57.4 ± 5.30 a	9.7 ± 1.30 a
MSM	50.0 ± 10.24 a	4.1 ± 0.87 b
activated MSM[c]	25.9 ± 4.68 b	2.7 ± 1.00 b
	Planted on 6 DAI	
unamended	79.6 ± 5.30 ns[d]	9.4 ± 0.89 ns[d]
MSM	70.4 ± 9.37	13.9 ± 3.29
activated MSM[c]	77.8 ± 2.87	8.5 ± 2.61
	Planted on 12 DAI	
unamended	81.5 ± 8.45 ns[d]	10.0 ± 0.65 b
MSM	77.8 ± 7.03	19.3 ± 2.44 a
activated MSM[c]	75.9 ± 3.41	10.9 ± 1.83 b

[a]Data are from two experiments, with each value representing the mean of six replicates ± the standard error of the mean. Different letters within a column indicate significant differences at the 0.05 level within a planting date. [b]Planting dates after meal incorporation (DAI). [c]1:100 freshly ground meadowfoam seed/total meadowfoam seed meal. [d]Not significant.

emergence than MSM when lettuce seeds were sown on 0 DAI ($p < 0.05$). Lettuce emergence was reduced by 55% in activated MSM compared with the untreated control. On the 0 DAI planting date, the lettuce seedling biomass was reduced by 58% in MSM and 72% in activated MSM treatments compared with the untreated control. Adding active myrosinase from freshly ground meadowfoam seed to MSM increased phytotoxicity and suppression of lettuce growth. Similar results were reported in another study where activated MSM with 18-h incubation or addition of iron provided greater inhibition on coleoptile emergence of downy brome compared with MSM.[11] Other glucosinolate-containing seed meals such as brown mustard (*Brassica juncea* (L.) Czern.)[18,34,35] and white mustard (*Sinapis alba* L.)[35,36] have been reported to have potential uses as bioherbicides without requiring activation.

No differences in lettuce emergence and biomass were found among treatments when lettuce seeds were planted 6 days after seed meal incorporation so waiting before planting into MSM treatments was necessary to prevent crop injury. A study conducted by Rice et al.[18] suggested that lettuce sown into 3% white mustard seed meal-amended soil required approximately 35 DAI for crop safety. The length of phytotoxicity varied depending on glucosinolate-containing species, application methods, and environmental conditions such as soil moisture and soil temperature.[37]

On the 12 DAI planting date, there was no difference in lettuce emergence but there was a difference in lettuce biomass. The lettuce biomass was greater in MSM compared with untreated control and activated MSM. These results were possibly due to the protein and fiber content in MSM,[6] which may be utilized as N and C sources by soil microorganisms. Similar fertilizer effects were found after other Brassicaceae seed meal applications.[18] However, the reduced lettuce biomass in activated MSM compared with MSM was potentially due to greater phytotoxicity and nonselective inhibition of soil microorganisms. When the concentration of the remaining phytotoxic compounds was no longer toxic to lettuce seeds, it still may have inhibited soil microbial activity. Snyder et al.[38] suggested the mixed effects of different glucosinolate-containing Brassicaceae seed meals on plants and soil microbes involved with the N cycle. The soil microbes may not have completely recovered and utilized the C and N sources provided by the activated MSM application. Intanon[37] reported that between 0 and 7 days after activated MSM incorporation, microbial biomass C and N increased. Microorganisms immobilized C and N sources, and then C and N became available to plants during microbial turnover.[39] The harvest time at 21 days after seeding may not be long enough to observe the fertilizer effect from the activated MSM application.[37]

The low number of emerged lettuce seedlings in all treatments on the 0 DAI planting date possibly was due to seeds being buried during the initial irrigation. When seeds were planted 6 and 12 days later, the soil was more settled so seeds were not buried as deep. Other possible reasons were a CO_2 flush or microbial respiration. Andalo et al.[40] suggested that the response on seed germination to elevated CO_2 as a result of wetting dry soil is species specific. Lettuce seed germination was inhibited with increasing the concentration of CO_2 to 6.4% and 12.8%.[41] The increase of CO_2 concentration during germination had no effect on seed germination in mouse-ear cress (*Arabidopsis thaliana* (L.) Heynh.).[40] After wetting of the soil, the moisture can induce metabolic processes such as respiration by seeds and microbes. During the respiration process, heat was released, which possibly reduced germination.[42]

Although isothiocyanate **3** was shown to have the greatest toxicity, its presence in the soil amended with activated MSM was very short-lived (Figure 3B). The rapid degradation of this bioactive compound in the soil should allow the use of activated MSM for weed control preplant. After the loss of MSM phytotoxicity, subsequent fertilizer effects were observed. Thus, planting crops in the field at least 6 days after MSM application may protect the crop from allelochemicals and increase competitiveness against emerging weeds.

The results of this study improve the current knowledge that activated MSM has greater herbicidal activity compared with nonactivated MSM. The temporal change in biodegradation of glucolimnanthin **1** and GBPs under soil conditions were evaluated. In addition, the newly identified metabolite, MPAA **4**, was discovered as a breakdown product of glucolimnanthin

1, and it has phytotoxic activity. The study benefits meadowfoam growers as well as provides an alternative bioherbicide for use on organic farms and other high value crops for which reduced synthetic herbicide applications are desired.

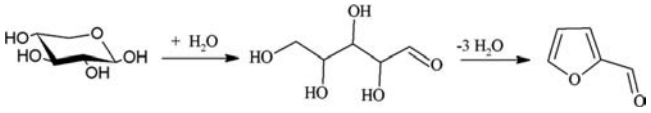
Scheme 2. Illustration for the Production of Furfural from Xylose in [BMIM]Cl



xylose in IL has received much attention.[6,27,28] The aim of this work was to perform the conversion of xylose using IL ([BMIM]Cl) as a pertinent solvent and LS as catalyst. The combination of using biomass-based feedstock and catalyst as well as green solvent presents a pathway to realize the green conversion of xylose into high value-added chemicals.

MATERIALS AND METHODS

Chemicals and Reagents. *Dendrocalamus membranaceus* (*Dm*M) was obtained from Kunming, China. The composition (%, w/w) of *Dm*M was 45.68% cellulose, 25.60% hemicelluloses, 26.33% lignin, 1.53% ash, and 1.40% wax on a dry weight basis. Xylose was supplied by J&K Scientific Ltd. Furfural standard, *N*,*N*-dimethylformamide (DMF), *N*,*N*-dimethylacetamide (DMA), dimethyl sulfoxide (DMSO), tetrahydrofuran (THF), and *N*-methylpyrrolidone (NMP) were purchased from Aladdin Reagent Co., Ltd. [BMIM]Cl (99%) was purchased from Zhongke Kate Industry & Trade Co., Ltd. Acidic ion-exchange resin, acetonitrile, and 1,4-dioxane were purchased from Shanghai Chemical Reagent co., Ltd. Toluene and methanol were supplied by National Medicine Group Chemical Reagent Co., Ltd. Lignosulfonate was prepared by sulfonating the lignin according to the former literature;[29] lignin was obtained by bamboo kraft pulping process and purified from black liquor as reported.[29,30] The M_w of the obtained lignosulfonate was about 534 g/mol determined by gel permeation chromatography (GPC). THF was used as eluent with the flow rate of 1.0 mL/min. The lignosulfonate concentration was 1.0 g/L. Distilled and deionized water was obtained in-house from a Heal Force Smart ultrapure water system.

Catalyst Preparation. The synthesis of LS was prepared according to the literature[23] with slight modifications. The acidic resin was activated in a saturated aqueous solution of NaCl for 1 day, followed by the treatment of 2.5 wt % NaOH aqueous solution for 80 min, and then washed with distilled water until pH 7.0, and finally it was treated with 5.0 wt % HCl aqueous solution for 12 h. Afterward, the resin was transferred to a column and washed with deionized water until the eluent reached pH 7.0. The sodium salt of LS (3.0 g) was dissolved in water (50 mL), and the solution was allowed to flow through the acidic resin column at a speed of 20 drops per minute. The acidic eluent was collected and then freeze-dried for 12 h to obtain LS product.

Catalyst Characterizations. Fourier transform infrared (FT-IR) spectra was conducted on a Vector-33 FT-IR spectrometer in the wavenumber range of 400–4000 cm^{-1}. The thermal stability of lignosulfonate and LS was determined by using an SDT-Q500 thermogravimetric analyzer (TGA) with temperature varying from room temperature to 700 °C in a nitrogen atmosphere and at a heating rate of 20 °C/min. A Zeiss EVO 18 (Jena, Germany) scanning electron microscope (SEM) was also used to investigate the morphology of lignosulfonate and LS. An Agilent 1100 (Santa Clara, CA, USA) high-performance liquid chromatograph (HPLC) was used to determine the yields of furfural.

Titration of −SO3H in LS. LS (100 mg) was added into a NaCl (2.00 mol/L, 20 mL) aqueous solution, sonicated for 1 h, and then centrifuged. The solution was titrated by standard NaOH solution (0.05 mol/L) with phenophthalein as indicator. The average value of $-SO_3H$ content was determined to be 1.87 mmol/g. The sulfur content in LS was determined to be 1.93 mmol/g by elemental analysis, which was very similar to the result of titration. These results showed that sulfur species on the sample were mainly in the form of sulfonic acids.[31]

Catalyst Reactions. In a typical procedure, LS (50 mg) was added into [BMIM]Cl (2 g) to obtain a well-proportioned and stable LS–IL solution in 15 min at 80 °C. Then xylose (200 mg) was added into the mixture and oil-bathed at 120 °C for 1 h. The reaction mixture was diluted with deionized water/methanol (1:4 by volume) to a certain concentration for HPLC detection range.

Identification and Quantitation with HPLC. Furfural was quantified by external standard calibration curve method, which was performed on an Agilent 100 HPLC system. The sample was separated by using a reversed-phase C_{18} column (200 × 4.6) at 40 °C with a detection wavelength of 283.40 nm. The optimized mobile phase consisted of methanol and deionized water with a volume ratio of 30:70. The flow rate was fixed at 1.0 mL/min. The seven concentrations of furfural (0.005, 0.0025, 0.001, 0.0005, 0.00025, 0.0001, and 0.00005 mol/L) were selected for HPLC analysis to determine the standard calibration curve. The content of furfural was obtained directly by calibration curves.

RESULTS AND DISCUSSION

Characterization of LS Catalyst. The FT-IR spectrum of LS is shown in Figure 1. Three new bands appeared at 1200–

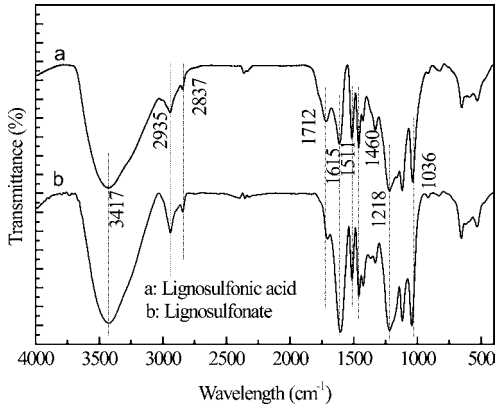


Figure 1. FT-IR spectrum for the lignosulfonic acid and lignosulfonate.

1250, 1010–1100, and 650 cm^{-1}, which were attributed to the O═S═O asymmetric and symmetric stretching vibration and S–O stretching vibration of sulfonic groups ($-SO_3H$), respectively.[32] The peak at 1712 cm^{-1} is attributed to −COOH. The absorbance at 3200–3500 cm^{-1} can be assigned to the O–H stretching vibration of LS, which is consistent with the former literature.[31] The peaks at 2837 and 2935 cm^{-1} belonged to the extensional vibration of −CH−, indicating that the phenol structure of LS is connected by methylene of the aldehyde structure.[33] The absorptions at 1460, 1511, and 1615 cm^{-1} are characteristic peaks of benzene rings.

The results of TGA are illustrated in Figures 2 and 3. Because of the evaporation of water, when the temperature was >100 °C, the TG curves of LS and lignosulfate fell slowly. LS began to pyrolyze when the temperature was >140 °C and decomposed quickly at higher temperature. The thermal stability of lignosulfonate was much better when the temperature was <170 °C.

Figures 4 and 5 show the SEM images of the lignosulfate and lignosulfonic acid. It was indicated that lignosulfonate exhibited spheres, which was different from fragmentary LS. The particle size of LS was much finer than that of lignosulfonate. It was found that LS was easier to dissolve in [BMIM]Cl than lignosulfonate.

Influence of Reaction Conditions on Catalytic Conversion of Xylose into Furfural. The influence of solvents on the formation of furfural is shown in Table 1 and Figure 6. It was found that it was easy to prepare a 2.5 wt % solution of LS in [BMIM]Cl at 80 °C for 15 min, and a brown-red solution was obtained. In this study, conversion of xylose into furfural catalyzed by LS was carried out in [BMIM]Cl and various organic solvents to investigate the influence of solvent. As shown in Table 1 and Figure 6, furfural yields were 3.4% in 1,4-dioxane, 3.2% in DMSO, 2.8% in toluene, and 10.3% in [BMIM]Cl, indicating that [BMIM]Cl was a better reaction solvent for furfural conversion catalyzed by LS. Clearly, DMF, DMA, and NMP were less effective reaction media in this study, with furfural yields of 0.7, 0.7, and 0.6%, respectively. The results demonstrated that the homogeneous catalysis of LS in [BMIM]Cl accelerated the conversion of xylose into furfural.[23] Furthermore, [BMIM]Cl could suppress the formation of humins during the conversion of xylose into furfural catalyzed by LS.

The effect of reaction temperature on the conversion of xylose into furfural was also studied. The conversion of xylose in [BMIM]Cl catalyzed by LS was carried out at 80, 100, 120, and 140 °C to study the influence of reaction temperature on furfural formation. The effect of reaction temperature on the hydrolysis of xylose is shown in Figure 7. It was found that the reaction temperature had a significant influence on the conversion of xylose.[6] Furfural yield (1 h) first increased from 8.7 to 15.0% as the temperature increased from 80 to 100 °C and then decreased to 12.4% when the temperature rose to 120 °C. The results indicated that high temperature not only facilitated the conversion of xylose into furfural but also facilitated the formation of humins.[16,28,34] Additionally, when the temperature increased to, or above, 100 °C, the thermal stability of LS was not so good. Therefore, 100 °C was the optimal temperature for the conversion of xylose into furfural catalyzed by LS.

To illustrate the relationship between reaction time and the yield of furfural, the experiments were carried out for 0.5, 1.0, 1.5, 2.0, and 2.5 h at 100 °C, respectively. As can be seen from Figure 8, the furfural yield increased from 8.2 to 18.3% as the reaction time increased from 0.5 to 2.5 h. With the increase of reaction time, the furfural yield increased first significantly, and then the increasing trend became slow. The reason may be ascribed to the decrease of furfural selectivity. Zhang and Lima[11,28] reported that the formation of humins led to low furfural selectivity, especially at high pentose conversions. The side reactions (dehydration of furfural, condensation between furfural and intermediates, and resinification of furfural) at longer reaction time formed undesired byproducts and decreased furfural yield. Therefore, the suitable reaction time was 1.5 h.

Besides solvents, reaction temperature, and time, the effect of catalyst loading on the conversion of xylose was also investigated. The reactions were carried out at 100 °C with LS loadings of 50, 100, 150, 200, 250, and 300 mg, respectively. As shown in Figure 9, the catalyst loading displayed a remarkable effect. A general trend was that the furfural yield increased with the increase of LS loading during the time course of reaction process. It was noted that with the increase of LS dosage from 50 to 250 mg, the yield of furfural increased from 10.3 to 18.1%. This improvement can be attributed to more active sites at higher catalyst loading. However, further increase in the catalyst loading to 300 mg did not result in a significant increase in furfural yield, which implied that the catalytic active sites available for the substrate in the system under the experimental condition were saturated, and a higher catalyst concentration could also facilitate both the dehydration

of xylose and the dehydration of furfural. Further increasing the loading of LS could not facilitate the conversion. According to the results discussed above, the optimum reaction conditions were 250 mg of LS, 100 °C, and 1.5 h.

Recycling of LS Catalyst. The humins can be precipitated from the IL phase by ethanol. Therefore, the lifetime of LS was studied for the conversion of xylose into furfural by extracting furfural with ethyl acetate and then the precipitated humins were filtered and the catalytic system was used for the next

dx.doi.org/10.1021/jf502404g | J. Agric. Food Chem. 2014, 62, 7430−7435

process. The furfural yields for each reaction run are shown in Figure 10. It was found that the furfural yield decreased from

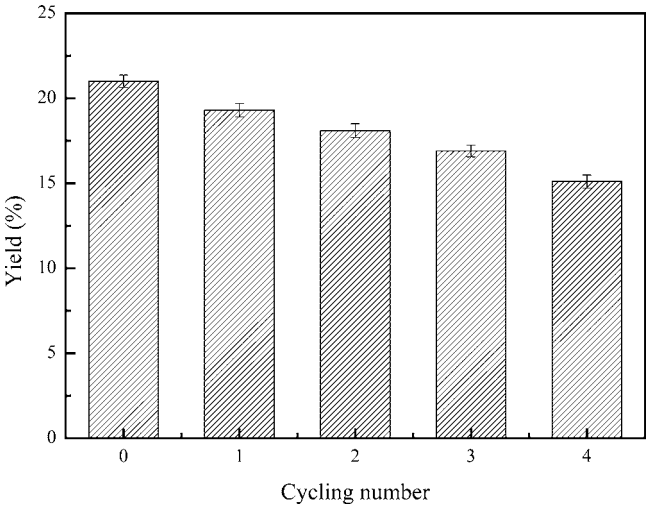

Figure 10. Reusability of LS in conversion of xylose into furfural. Experimental conditions: 2 g of [BMIM]Cl, 200 mg of xylose, 250 mg of LS, 100 °C, 1.5 h.

21.0% for the first time to 15.1% for the fifth time. This demonstrated that the humins may form and accumulate during the reaction, which affected the catalytic activity of LS in IL.

In summary, the homogeneous catalysis of LS in IL was successfully utilized as an efficient and environmentally friendly system for the conversion of xylose to furfural. The conversion yield of furfural from xylose was up to 21.0% for 1.5 h under mild conditions. LS was stable in the reaction process. The reusability study of the LS−IL catalytic system illustrated that the furfural yield decreased from 21.0 to 15.1% after five cycles, and the catalytic activity could be recovered after removal of the accumulated humins. For the integration of using sustainable lignocelluloses, renewable catalyst, and environmentally friendly solvent, this study shows a promising furfural production process that followed the concept of green chemistry.

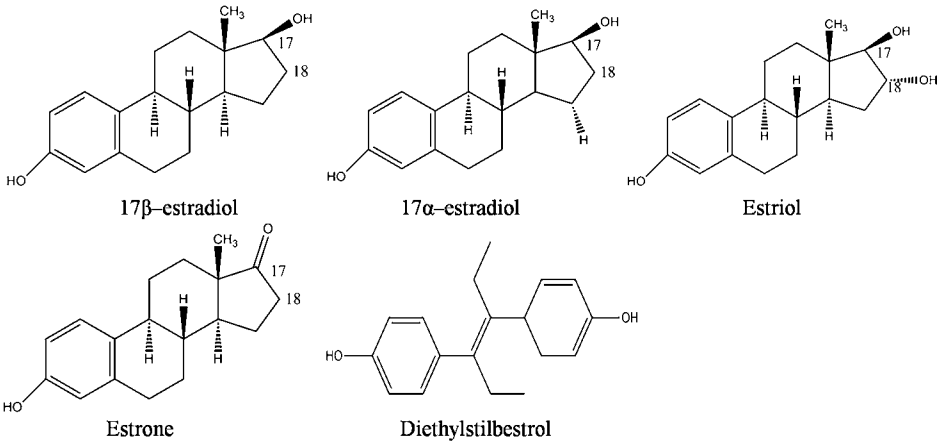

Figure 1. Chemical structures of 17β-estradiol, 17α-estradiol, estriol, estrone, and diethylstilbestrol.

(GO) has an extremely large specific surface area and small dimension,[19] and these characteristics make GO an excellent candidate as a support material for preparing surface MIPs.[20] Using MIPs on GO surface (MIPs-GO) has been proposed with high loading capacity and short binding time for the template molecule.[20,21] However, MIPs-GO homogeneously disperses in solution and is difficult to separate via traditional centrifugation and filtration methods, which restricted the application of MIPs-GO to some extent. Magnetic nanoparticles (Fe_3O_4) have properties of superparamagnetic and magnetic susceptibility, which means Fe_3O_4 can easily be separated from solutions by an external magnetic field.[22,23] On the basis of the advantages of GO and Fe_3O_4, the GO-Fe_3O_4 composites have been developed and widely applied in MIPs fields.[24,25] However, information is lacking on the development of 17β-E_2-based MIPs by using GO-Fe_3O_4 composites as the supporting material.

In the present paper, 17β-E_2-based MIPs were coated on the GO-Fe_3O_4 surface to achieve high imprinting efficiency and binding capacity. This study was the first demonstration for the preconcentration of 17β-E_2 in a food matrix using MIPs-GO-Fe_3O_4. The characteristics and binding capacity of 17β-E_2-based MIPs-GO-Fe_3O_4 were investigated in detail. The efficacy of MIPs-GO-Fe_3O_4 in extracting 17β-E_2 from food samples was also evaluated.

EXPERIMENTAL PROCEDURES

Reagents and Materials. 17β-Estradiol (17β-E_2), 17α-estradiol (17α-E_2), estrone (E_1), estriol (E_3), and diethylstilbestrol (DES) were purchased from Aladdin (Shanghai, China), and Figure 1 shows their chemical structures. Graphite powder, hexahydrate ferric chloride ($FeCl_3{\cdot}6H_2O$), sodium acetate, and ethylene glycol were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). Acrylic acid (AA) and 2,2′-azobis(isobutyronitrile) (AIBN) were purchased from Aladdin. Acrylamide (AM) and ethylene glycol dimethacrylate (EGDMA) were obtained from Sigma-Aldrich (Shanghai, China). Other reagents were analytically pure and used without further purification.

Synthesis of Graphene Oxide. GO was prepared using natural graphite powders according to the modified Hummers method.[26] Five grams of graphite powders and 2.5 g of $NaNO_3$ were added into a flask containing 120 mL of H_2SO_4 (95%) and cooled in an ice bath with stirring. After the graphite powders dispersed, 15 g of $KMnO_4$ was added gradually under stirring, and the temperature of the mixture was kept at 35 °C for 60 min. H_2O_2 (3 mL, 30%) and deionized water (100 mL) were added slowly into the above reaction mixture at 90 °C with vigorous agitation for 30 min. Finally, the resultant yellow-brown GO was washed with a 10% HCl aqueous solution and distilled water until the pH was 7.0 and then was dried at 40 °C for 24 h.

Synthesis of Magnetic Graphene Oxide (GO-Fe_3O_4). The GO-Fe_3O_4 nanocomposites were synthesized according to the solvothermal method as follows:[27] 0.45 g of GO was completely dispersed in 70 mL of ethylene glycol via ultrasound for more than 3 h; then 1.4 g of $FeCl_3{\cdot}6H_2O$ and 2.8 g of NaOAc were added into the above mixture. After stirring for about 30 min, the mixture was transferred into a 100 mL Teflon stainless steel autoclave and reacted at 200 °C for 8 h. The obtained GO-Fe_3O_4 nanocomposites were thoroughly washed with distilled water and ethanol and then freeze-dried.

Modification of GO-Fe_3O_4 Nanocomposites. The surface of GO-Fe_3O_4 nanocomposites was grafted with AA by the following procedures:[28] Briefly, 5 mL of the suspension containing 100 mg of GO-Fe_3O_4 nanocomposites was added into 15 mL of ethanol with ultrasonication, and 1 mL of AA was then added into the above mixture with shaking at a rate of 300 rpm for 2 h.

Preparation of MIPs-GO-Fe_3O_4. The 17β-E_2-based MIPs-GO-Fe_3O_4 was prepared using AM as functional monomer, EGDMA as cross-linker, and AIBN as initiator in acetonitrile containing surface supporting materials of GO-Fe_3O_4-AA. 17β-E_2 (0.272 g, 1 mmoL), AM (0.517 g, 6 mmoL), EGDMA (170 μL, 0.90 mmoL), and AIBN (0.062 g, 0.381 mmoL) were added into 60 mL of acetonitrile containing GO-Fe_3O_4-AA (80 mg) in a 250 mL thick-walled glass tube. The prepolymerization mixture was degassed by using an ultrasonic bath for 10 min, then purged with nitrogen for 15 min to remove oxygen, and polymerized at 60 °C for 24 h. The MIPs-GO-Fe_3O_4 particles were washed with methanol/acetic acid solution (9:1, v/v) to remove completely the template molecules and residual monomers. Finally, the particles were dried to constant weight under vacuum at 55 °C. As control, non-imprinted polymers (NIPs-GO-Fe_3O_4) were synthesized simultaneously under identical conditions but omitting the template in the reaction system.

Characterization. Fourier transform infrared (FT-IR) spectra were recorded by using a FT-IR spectrophotometer (Nicolet 5700, Thermo Electron Corp., Waltham, MA, USA). The X-ray diffractometer (XRD) patterns were recorded using an XRD analyzer (D8-FOCUS, Bruker, Karlsruhe, Germany). Transmission electron microscopy (TEM) images were obtained on a JEOL (JEM-2010HR, Japan) transmission electron microscope. The magnetic properties were examined by vibrating specimen magnetometer (VSM) (7407; Lake Shore Cryotronics, Westerville, OH, USA). Raman spectra were collected using INVIA spectrophotometer (Renishaw, UK).

Adsorption Experiments. To investigate the binding capacity of MIPs-GO-Fe_3O_4 particles, a static adsorption test was conducted in acetonitrile solutions as follows:[15] 20 mg of MIPs-GO-Fe_3O_4 particles was dispersed in a 10 mL flask containing 2.0 mL of 17β-E_2 solutions of various concentrations within 0.1−1.0 mmol L^{-1}, respectively. After shaking for 12 h at room temperature, the samples were separated by

dx.doi.org/10.1021/jf501845w | J. Agric. Food Chem. 2014, 62, 7436−7443

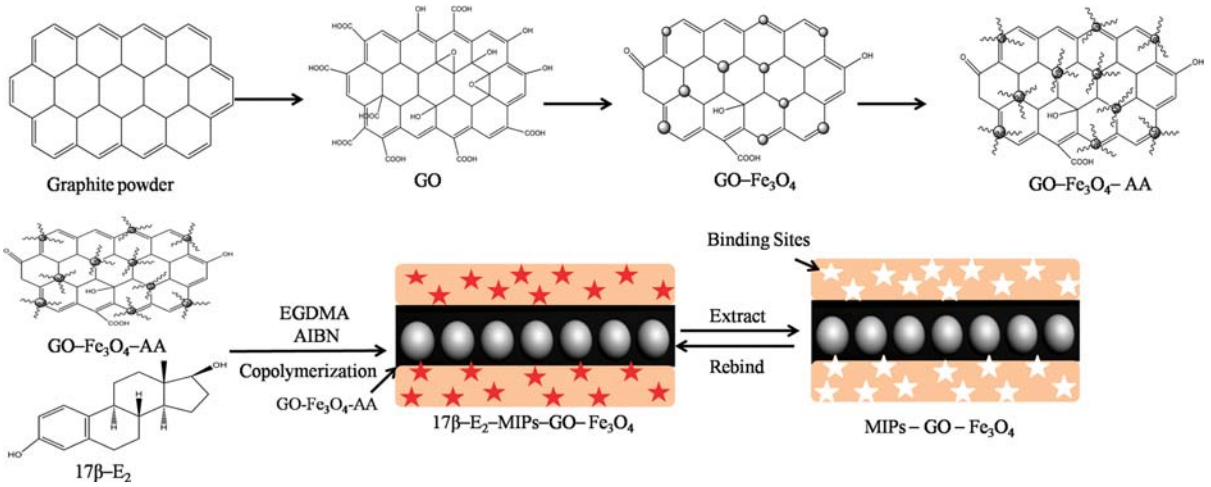

Figure 2. Schematic illustration of the preparation processes of MIPs-GO-Fe_3O_4.

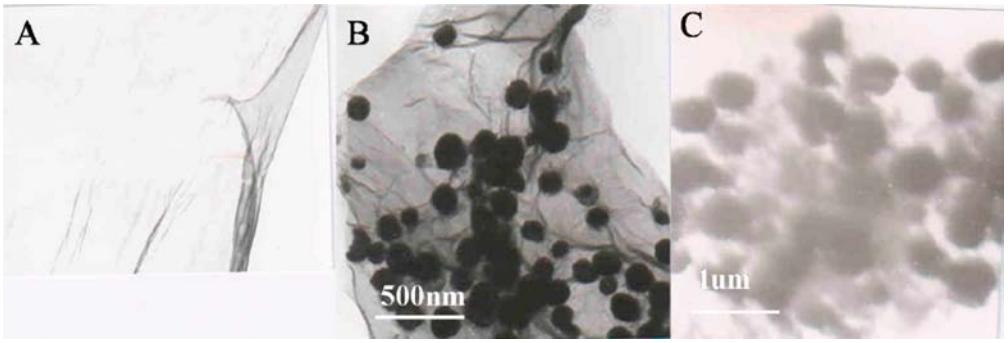

Figure 3. TEM images of GO (A), GO-Fe_3O_4 (B), and MIPs-GO-Fe_3O_4 (C).

an external magnet. The free concentration of 17β-E_2 in the supernatant solutions was determined using a UV spectrometer at 280.0 nm (TU-1810; Beijing Purkinje General Instrument Co., Ltd.). The adsorption amount of 17β-E_2 on MIPs-GO-Fe_3O_4 particles (Q) was calculated according to the following equation; Q tests were performed in triplicate with data reported as the mean values:

$$Q = (C_0 - C_F)V/M$$

C_0 (mg mL^{-1}) and C_F (mg mL^{-1}) are the initial and final 17β-E_2 solution concentrations, respectively. V (mL) is the sample volume, and M (g) is the mass of MIPs-GO-Fe_3O_4 particles.

Dynamic adsorption experiments were also performed. MIPs-GO-Fe_3O_4 (20 mg) or NIPs-GO-Fe_3O_4 (20 mg) were dispersed into 2.0 mL acetonitrile solutions containing 17β-E_2 (0.5 mmol L^{-1}), respectively. The solution was separated, and the free concentration of 17β-E_2 in the supernatant solutions was determined using UV spectrometry at 280.0 nm after 5, 10, 15, 20, 25, 30, 35, and 40 min of stirring, respectively.

Selectivity experiments were conducted using 17α-E_2, E_1, E_3, and DES as structural analogues. MIPs-GO-Fe_3O_4 (20 mg) or NIPs-GO-Fe_3O_4 (20 mg) were dispersed into 2.0 mL acetonitrile solutions containing 0.5 mmol L^{-1} of 17β-E_2, 17α-E_2, E_1, E_3, and DES, respectively. The amount of 17β-E_2, 17α-E_2, E_1, E_3, and DES in the supernatant was determined by UV after shaking for 12 h at room temperature. The recognition ability of MIPs-GO-Fe_3O_4 was evaluated by imprinting factor (α), which is defined in the equation

$$\alpha = Q_{MIP}/Q_{NIP}$$

where Q_{MIP} and Q_{NIP} are the adsorption amounts of the template or analogues on MIPs-GO-Fe_3O_4 and NIPs-GO-Fe_3O_4, respectively.

Analysis of 17β-E_2 in Real Samples. Milk powder samples were purchased from a local market. The milk powder samples (2 g) without spiking or spiked with 17β-E_2 standard solutions (2 mL; 0.2, 0.5, or 1.0 μmol L^{-1}) were first extracted using acetonitrile (20 mL) for 30 min. Then the solutions were centrifuged and filtered, and the extract solutions were obtained. MIPs-GO-Fe_3O_4 particles (20 mg) were added to the extract solution. The solution was shaken at room temperature for 1 h. A magnet (N_{35} model) was used to separate MIPs-GO-Fe_3O_4 particles from the solution, and the supernatant was measured by UV to determine the amounts of 17β-E_2. Simultaneously, the 17β-E_2 adsorbed onto MIPs-GO-Fe_3O_4 sorbent was subsequently eluted with 2 mL of methanol/acetic acid (9:1, v/v). After desorption for 2 h, the template molecule 17β-E_2 and adsorbent were easily rapidly separated by the magnet. The solution containing template molecule 17β-E_2 was dissolved in 2 mL of acetonitrile solvent, and the recovery amount of 17β-E_2 was determined by UV at 280.0 nm. All tests were performed in triplicate with data reported as the mean values. It should be noted that matrix interferences could be excluded by using the selective MIPs-GO-Fe_3O_4 as extracting agent. Moreover, the absorbance values were measured by deducting the blank values.

RESULTS AND DISCUSSION

Fabrication of MIPs-GO-Fe_3O_4. Figure 2 illustrates the synthesis route of MIPs-GO-Fe_3O_4. GO was prepared according to the classic Hummers method using graphite powders as starting material. GO-Fe_3O_4 nanocomposites were fabricated by a solvothermal method, GO was dissolved in ethylene glycol solution, and $FeCl_3 \cdot 6H_2O$ and NaOAC were used as the iron source and reductant, respectively. The Fe^{3+} could be absorbed by oxygen-containing functional groups of GO, and the Fe^{3+} was reduced to Fe_3O_4 by NaOAC during the reaction. GO-Fe_3O_4 nanocomposites were functionalized by a simple coordination reaction of the carboxyl group of AA with

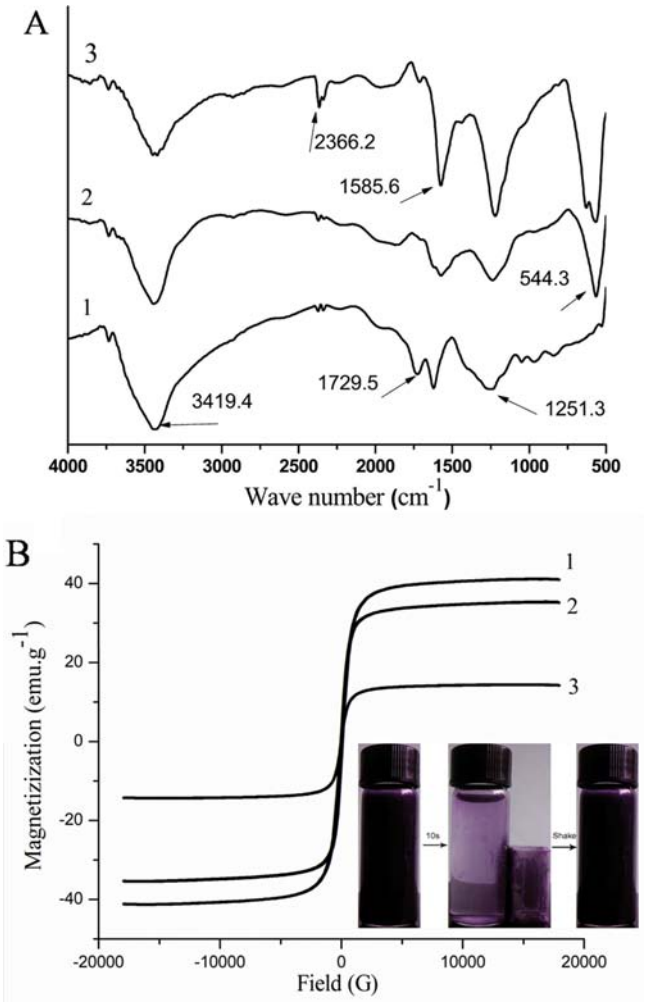

Figure 4. FT-IR spectra (A) of GO, GO-Fe_3O_4, and MIPs-GO-Fe_3O_4 (1, GO; 2, GO-Fe_3O_4; 3, MIPs-GO-Fe_3O_4) and VSM (B) (1, Fe_3O_4; 2, GO-Fe_3O_4; 3, MIPs-GO-Fe_3O_4).

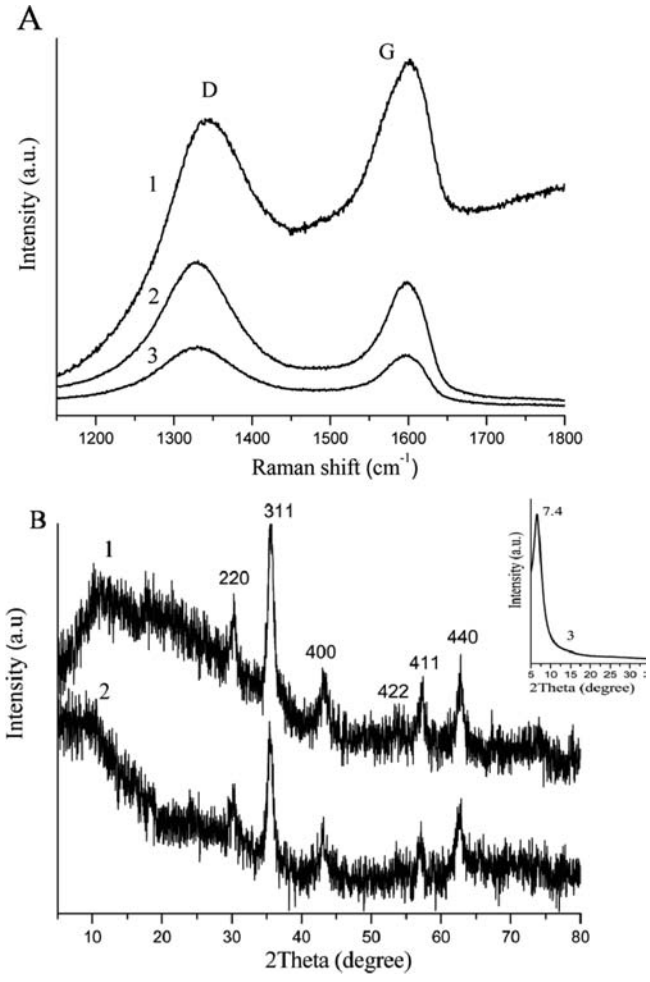

Figure 5. Raman (A) (1, GO; 2, GO-Fe_3O_4; 3, MIPs-GO-Fe_3O_4) and XRD (1, GO-Fe_3O_4; 2, MIPs-GO-Fe_3O_4; 3, GO).

the oxygen-containing functional groups of GO and particle surface residual Fe^{3+}. AA monomer grafted to GO-Fe_3O_4 surfaces and formed GO-Fe_3O_4-AA with vinyl end groups.[29,30] The 17β-E_2-based MIPs-GO-Fe_3O_4 was developed at 60 °C for 24 h in the presence of nanosized supporting materials (GO-Fe_3O_4-AA), template molecule (17β-E_2), functional monomer (AM), and cross-linking agent (EGDMA). The imprinted monolayer will polymerize at the GO-Fe_3O_4 surface by the reaction between AA and AM.[31,32] Finally, MIPs-GO-Fe_3O_4 was fabricated after washing with methanol/acetic acid (9:1, v/v) to remove the template molecule of 17β-E_2.

Characterization of MIPs-GO-Fe_3O_4. The prepared samples were characterized by TEM, FT-IR, Raman, XRD, and VSM. Figure 3 shows the morphologies of GO, GO-Fe_3O_4, and MIPs-GO-Fe_3O_4, respectively. GO displays a thin and irregular paper-like morphology with some wrinkles (Figure 3A). Fe_3O_4 nanoparticles were formed and homogeneously anchored onto the GO sheet (Figure 3B). As shown in Figure 3C, the MIPs were firmly attached on the surface of GO-Fe_3O_4 after polymerization.

Figure 4A shows the FT-IR spectra results of GO, GO-Fe_3O_4, and MIPs-GO-Fe_3O_4. The three samples have the same adsorption peak at 3419.4 cm^{-1} because of the O−H stretching vibration. For the FT-IR spectra of GO, the peak at 1251.3 cm^{-1} characterized C−O stretching vibration of the epoxy groups. A strong Fe−O characteristic stretching vibration peak of 544.0 cm^{-1} appeared for GO-Fe_3O_4, which indicated that Fe_3O_4 nanoparticles were successfully anchored onto the GO sheets. For the FT-IR spectra of MIPs-GO-Fe_3O_4, the absorption peaks of 2366.2 and 1585.6 cm^{-1} were attributed to C═O stretching vibration of AA monomer.[28] The intensity of C═O stretching (1728.0 cm^{-1}) was remarkably increased when Fe_3O_4 particles were covered with MIPs containing a large number of C═O groups in polyacrylamide units, which indicated the formation of imprinted polymers on the GO-Fe_3O_4 surface.

Figure 4B shows the magnetic property of Fe_3O_4, GO-Fe_3O_4, and MIPs-GO-Fe_3O_4, and the inset illustrates the dispersion and agglomeration processes of MIPs-GO-Fe_3O_4. The remanence and coercivity of samples almost disappeared, indicating that Fe_3O_4, GO-Fe_3O_4, and MIPs-GO-Fe_3O_4 have superparamagnetic characteristics. The saturation magnetization of Fe_3O_4, GO-Fe_3O_4, and MIPs-GO-Fe_3O_4 gradually decreased 41.14, 35.37, and 11.11 emu g^{-1}, respectively. Saturation magnetization decreased for MIPs-GO-Fe_3O_4 because of the presence of the GO and MIPs polymers on the Fe_3O_4 surface. Fortunately, the saturation magnetization value of MIPs-GO-Fe_3O_4 (11.11 emu g^{-1}) was sufficient to ensure the easy and quick separation of the compounds from solutions. As shown in the inset of Figure 4B, the MIPs-GO-

dx.doi.org/10.1021/jf501845w | J. Agric. Food Chem. 2014, 62, 7436−7443

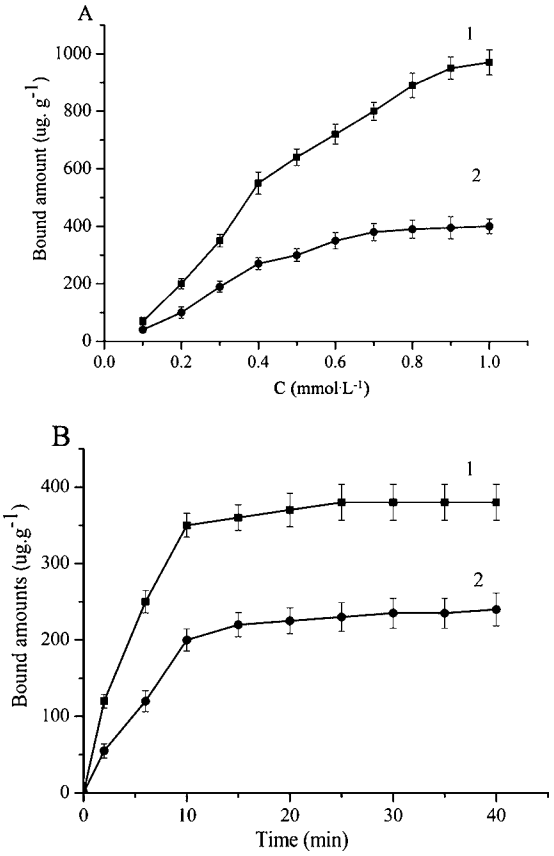

Figure 6. Static adsorption isotherms (A) and kinetic binding curves (B) of 17β-E_2 onto MIPs-GO-Fe_3O_4 (1) and NIPs-GO-Fe_3O_4 (2). Data are represented as the mean ± standard deviation (SD) (n = 3).

Fe_3O_4 can homogeneously disperse in aqueous solutions and is also sensitive to the magnetic field, showing MIPs-GO-Fe_3O_4 can be separated easily by the external magnet.

Figure 5A shows the Raman spectra of GO, GO-Fe_3O_4, and MIPs-GO-Fe_3O_4. All Raman spectra showed that three samples had G (approximately 1580 cm^{-1}) and D bands (approximately 1340 cm^{-1}), which agreed with the usual features of carbon materials in the Raman spectra. The valued of I_D/I_G wrtr approximately 0.923, 1.24, and 1.38 for GO, GO-Fe_3O_4, and MIPs-GO-Fe_3O_4, respectively.[33] The average size of the in-plane graphitic crystallite sp^2 domains increased, and such increase may be due to the small partial reduction of GO during synthesis.

The corresponding (XRD) patterns of GO, GO-Fe_3O_4, and MIPs-GO-Fe_3O_4 are presented in Figure 5B. GO showed a very sharp diffraction peak at 2θ = 7.40 corresponding to a d-spacing of 12.45 nm. However, the sharp peak of 2θ = 7.40 decreased for GO-Fe_3O_4 and MIPs-GO-Fe_3O_4, showing that GO was reduced to some extent by NaOAC during preparation. Typical XRD pattern peaks of Fe_3O_4 were observed at 2θ values of 30.0, 35.7, 42.9, 53.6, 56.8, and 62.7 for GO-Fe_3O_4 and MIPs-GO-Fe_3O_4, which are consistent with the standard XRD data of Fe_3O_4 (JCPDS Card 019-0629). The XRD pattern results showed that MIPs-GO-Fe_3O_4 comprised Fe_3O_4 nanoparticles, and the synthesized processes did not change the XRD phase of Fe_3O_4.

Binding Studies of MIPs-GO-Fe_3O_4. The static, dynamic, and selective binding abilities of MIPs-GO-Fe_3O_4 were investigated. Figure 6A shows the static binding isotherms of 17β-E_2 on MIPs-GO-Fe_3O_4. The adsorption capacity of MIPs-GO-Fe_3O_4 for 17β-E_2 increased quickly with increasing concentration. When the equilibrium concentration reached 0.9 mmol L^{-1}, the adsorption amounts of MIPs-GO-Fe_3O_4 appeared stable, and such stability may be due to the recognition sites, which were almost completely occupied by 17β-E_2. Figure 6A also shows that the NIPs-GO-Fe_3O_4 had lower saturated adsorption amounts than MIPs-GO-Fe_3O_4 because of the nonspecific recognition sites in NIPs-GO-Fe_3O_4. Moreover, the equilibrium dissociation constant (k_d) and maximum adsorption capacity (q_{max}) of the Scatchard equation were calculated, as follows: 12.68 μg mL^{-1} and 5.44 μmol g^{-1} for MIPs-GO-Fe_3O_4 and 7.65 μg mL^{-1} and 1.42 μmol g^{-1} for NIPs-GO-Fe_3O_4, respectively. The obtained q_{max} well

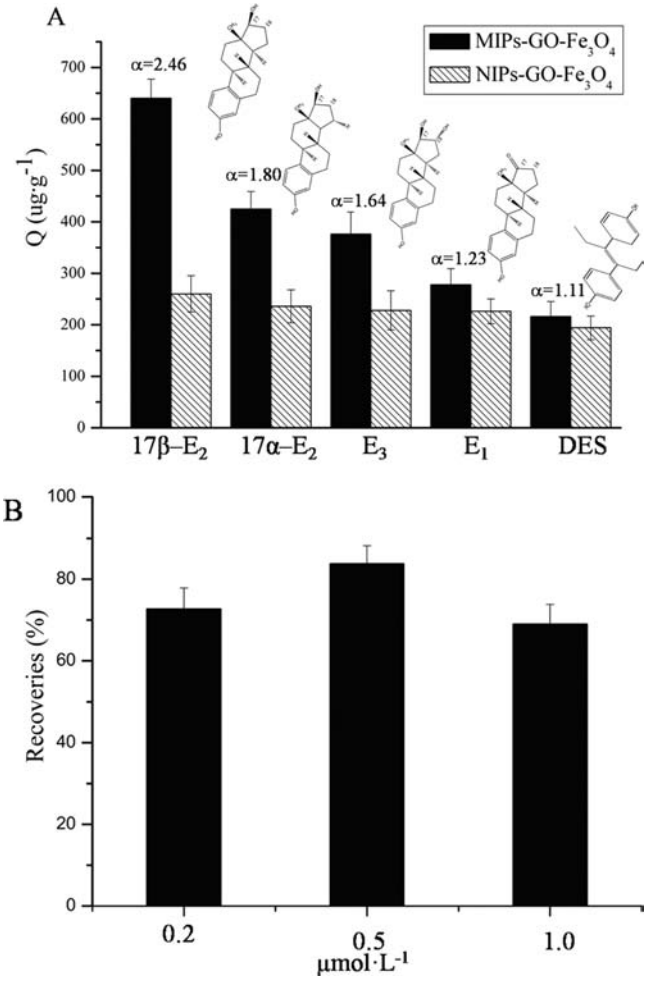

Figure 7. Competitive binding of 17β-E_2, 17α-E_2, E_3, E_1, and DES on MIPs-GO-Fe_3O_4 and NIPs-GO-Fe_3O_4 (A), and recoveries (%) and RSD (%) of MIPs-GO-Fe_3O_4 obtained from analysis of milk powder samples spiked with different concentrations (0.2, 0.5, and 1.0 mmol L^{-1}) 17β-E_2 (B). Data are represented as the mean ± SD (n = 3).

agreed with the experimental result (3.95 μmol g^{-1}). The results suggested that the MIPs-GO-Fe_3O_4 had excellent binding capacity for the template molecule.

Moreover, the adsorption process was further studied by four classical isotherm models including Langmuir, Freundlich, Scatchard, and Langmuir–Freundlich.[34] The corresponding equations and parameters of these models for adsorption of 17β-E_2 onto the MIPs-GO-Fe_3O_4 and NIPs-GO-Fe_3O_4 are listed in Table 1. The best fit was obtained from the Langmuir–Freundlich model, which resulted in a correlation coefficient of 0.9872. The parameters N_t, α, and m were 59.28, 0.038, and 0.682 for MIPs-GO-Fe_3O_4 and 6.365, 0.034, and 0.825 for NIPs-GO-Fe_3O_4, respectively. An excellent imprinting effect was observed from the presence of a number of specific binding sites on the MIPs-GO-Fe_3O_4 surface.

Dynamic binding experiments were performed to investigate the mass transfer properties of MIPs-GO-Fe_3O_4, and the results are shown in Figure 6B. The adsorption amounts of MIPs-GO-Fe_3O_4 for 17β-E_2 increased and reached equilibrium within 10 min. The rapid adsorption and high equilibrium binding capacity (381.2 μg g^{-1}) were due to the high ratio of surface-imprinted sites and large surface-to-volume ratio of MIPs-GO-Fe_3O_4, which allow high binding capacity and fast mass transfer. To investigate the mechanism underlying the biosorption process, such as mass transfer and chemical reaction, the pseudo-first-order and pseudo-second-order kinetic models were used to test the experimental data of MIPs-GO-Fe_3O_4 and NIPs-GO-Fe_3O_4.[35] The results are shown in Table 2. The pseudo-second-order model could better fit the time effect on the adsorption system than other kinetic models. The pseudo-second-order model provided the most suitable correlation for the adsorption, with the highest correlation coefficient of 0.9912. The obtained rate constant (k_2) was 0.0062 g (mg·min)$^{-1}$, and the equilibrium adsorption capacity (Q_e) was 4.378 μmol g^{-1}. Therefore, the adsorption could be deduced to follow the pseudo-second-order kinetic model.

To investigate the binding specificity of the MIPs-GO-Fe_3O_4, a selectivity test was conducted using structural analogues of 17β-E_2, being 17α-E_2, E_3, E_1, and DES, as control compounds. As shown in Figure 7A, the adsorption capacity of NIPs-GO-Fe_3O_4 is very close and nonselective for the five compounds because selective recognition sites are absent in NIPs-GO-Fe_3O_4. However, MIPs-GO-Fe_3O_4 showed a significantly higher binding capacity for 17β-E_2 than for these competitive analogues. The binding capacities of MIPs-GO-Fe_3O_4 for 17β-E_2, 17α-E_2, E_3, E_1, and DES were 640, 425, 376, 278, and 216 μg g^{-1}, respectively. Accordingly, the imprinting factor values (α) of MIPs-GO-Fe_3O_4 for 17β-E_2, 17α-E_2, E_3, E_1, and DES were 2.46, 1.80, 1.64, 1.23, and 1.11, respectively. These results indicated that MIPs-GO-Fe_3O_4 has highly specific recognition ability for 17β-E_2. The high selectivity for 17β-E_2 may be based on two factors. The first factor is the difference in chemical structures between 17β-E_2, 17α-E_2, E_3, E_1, and DES. The second factor is that only 17β-E_2 can specifically match the binding sites with the template in terms of size and shape.

Method Validation and Application to Analysis of 17β-E_2 in Food Samples. To further assess the practical applicability of MIPs-GO-Fe_3O_4, milk powder samples were

dx.doi.org/10.1021/jf501845w | J. Agric. Food Chem. 2014, 62, 7436–7443

used as real sample in the analysis. Figure 7B shows the extraction recoveries of MIPs-GO-Fe_3O_4 at three spiked 17β-E_2 concentrations of 0.2, 0.5, and 1.0 μmol L^{-1}, that is, 72.63, 84.20, and 68.93% with relative standard deviations (RSDs) of 5.26, 4.67, and 4.92%, respectively. The limits of detection and quantification were determined to be 0.035 and 0.10 μmol L^{-1} on the basis of signal-to-noise ratios of 3 and 10, respectively, and the regression equation was attained, $y = 0.0933x + 0.2152$ ($R^2 = 0.9928$) within 0.1−1.0 mmol L^{-1}. It is noted that the separation process was finished quickly within 10 s when a magnet was used. Compared to conventional MIPs extraction, a simpler, faster, and more economical magnetic separation procedure was provided, dispensing with pretreatment such as filtration or centrifugation. Thus, MIPs-GO-Fe_3O_4 can be used for preconcentration, separation, extraction, and removal of 17β-E_2 in real food samples.

In conclusion, a new type of molecularly imprinted nanomaterial (MIPs-GO-Fe_3O_4) was developed for the specific recognition and highly effective removal of 17β-E_2 in complicated matrices. MIPs-GO-Fe_3O_4 was prepared using GO-Fe_3O_4, AM, and 17β-E_2 as the supporting material, monomer, and template molecule, respectively. The magnetic property of MIPs-GO-Fe_3O_4 allowed the simple, rapid, and efficient separation of 17β-E_2 from matrices. Owing to the extremely large area of GO-Fe_3O_4, MIPs-GO-Fe_3O_4 has faster desorption and adsorption dynamics and higher selectivity than other traditional MIPs. MIPs-GO-Fe_3O_4 also showed excellent selectivity toward template molecules. In addition, MIPs-GO-Fe_3O_4 displayed satisfactory 17β-E_2 recovery when used for enrichment and removal of 17β-E_2 from food samples. We have provided an excellent platform for pretreatment and removal of 17β-E_2 from contaminated environmental and food samples.

evidence of toxicity to GT has been reported. Patients have shown tolerance to drug complaints of gastrointestinal distress, even at high doses (72 g/kg body weight).[14] GT derivatives may thus be useful as additional or adjuvant preventive and therapeutic agents for hypercholesterolemia. The lipid-lowering effect of GT derivatives is considered to be associated with the increased excretion of bile acids.[13] However, the metabolic effects of 1,4-GL in hypercholesterolemia are yet to be reported.

Metabonomics, an emerging subject of the postgenome era, deals with the quantitative understanding of metabolites in biological fluids and their dynamic responses to changes in endogenous and exogenous factors. Metabonomics can thus provide the information on what is actually happening. Furthermore, this technology adopts a "top-down" strategy to determine the function of organisms from the terminal symptoms of the metabolic network and to elucidate the metabolic changes in a complete system caused by interventions in a holistic context.[15] Therefore, metabonomics provides important information on the possible model of action of nutritional agents.[16,17] The present study reveals that 1,4-GL significantly prevents or delays the onset and development of hypercholesterolemia when rats were coadministered with a high-fat, high-cholesterol (HFHC) emulsion. The metabolic mechanism of 1,4-GL in hypercholesterolemia prevention was quantitatively investigated via nuclear magnetic resonance (^{1}H NMR)-based metabonomic analysis and colonic flora tests.

MATERIALS AND METHODS

Chemicals. 1,4-GL and the sodium salt of (trimethylsilyl)-propionic-2,2,3,3-d_4 acid (TSP) were purchased from Sigma (USA). All chemicals used were of analytical reagent grade. The HFHC emulsion was prepared as previously described,[18] and it was composed of 20% lard, 10% cholesterol, and 2% sodium cholate.

Animal Experiment. Forty female Sprague–Dawley (SD) rats weighing 180–200 g were randomly divided into five groups (n = 8 each) after acclimating to the environment for 7 d. The control group received water via oral gavage for 12 d once daily. Rats in the HFHC group were administered with 1.0 mL of HFHC for 12 d once daily to induce hypercholesterolemia. The 1,4-GL treatment group received 1,4-GL (30.0 mg/kg) via oral gavage for 12 d once daily. The HFHC +1,4-GL1 and HFHC+1,4-GL2 groups were treated with HFHC (1.0 mL) in combination with 30.0 or 10.0 mg/kg 1,4-GL, respectively, via oral gavage daily for 12 d. All animals were housed in approved facilities by group at a controlled relative humidity (50–70%) and temperature (22 ± 2 °C). Water and regular rodent chow were available ad libitum. On the 13th day, all rats were placed in individual metabolism cages and fasted for 12 h. Urine and blood samples were collected after 24 h. The rats were immediately sacrificed following the treatment. Rat livers were removed and stored at −20 °C. All urine samples were immediately diluted after collection with H_2O to 15.0 mL. About 1.2 mL of the aliquots of the solution were centrifuged at 8000 rpm for 10 min. The obtained supernatant was stored at −20 °C until analysis.

Animal experiments were carried out in accordance with the Guidelines for Animal Experiments at Nanchang University (Nanchang, China). The protocol was approved by the Animal Ethics Committee at Nanchang University.

Measurement of Lipids in Serum and Extraction of Liver. In this experiment, 0.2 g of liver tissue was homogenized. The lipid was extracted by 4.0 mL of 2-propanol. The lipid levels in the serum and liver extracts, which include total cholesterol, triglyceride, and high- and low-density lipoprotein cholesterol, were measured in duplicate by using commercial kits from Jiancheng Biotechnology Institute (Nanjian, China).

^{1}H NMR Spectroscopy of Urine Samples. Urine samples were prepared for NMR spectroscopy by diluting 300 μL of rat urine with 200 μL of 0.2 M sodium phosphate buffer (pH 7.4) and 50 μL of TSP in D_2O to a final concentration of 0.1 mM to calibrate the chemical shift. NMR spectroscopy was carried out using a Bruker AvanceII-600 MHz spectrometer (Germany). All spectra were recorded at 298 K. 1D proton spectra were obtained from 32 scans over a spectral width of 14 ppm. The presaturation method was used to suppress the proton signal of the solvent.

All ^{1}H NMR spectra were processed using Topspin 2.1 (Bruker Biospin GmbH, Rheinstetten, Germany). The spectra were processed to a size of 64 k after multiplying with an exponential window function. The spectra were phase and baseline corrected manually. The chemical shifts were referenced to the TSP signal. Full-resolution spectra from 0.2 to 9.5 ppm were saved. Data from 4.5 to 6.5 ppm were excluded to eliminate the effects of imperfect water suppression and cross-saturation of urea. Each spectral intensity data set was normalized to the total spectral intensity over the whole spectrum.

The metabolites were identified in the ^{1}H NMR spectra by comparing their chemical shifts and coupling patterns with the corresponding values from the literature and publicly accessible databases (http://www.bmrb.wisc.edu, http://www.hmdb.ca). Total correlation spectroscopy (TOCSY), ^{13}C-heteronuclear single-quantum correlation (^{13}C-HSQC), statistical total correlation spectroscopy (STOCSY), and some standard compounds were also utilized to identify the metabolites.

Data Processing. Principal component analysis (PCA) and orthogonal partial least-squares discriminant analysis (OPLS-DA) were performed using SIMCA-P (version 12.0, Umetrics, Umeå, Sweden). The quality of OPLS-DA models was described by R^2X, R^2Y, and Q^2. The parameters were calculated using the default leave 1/7 out cross validation. R^2X and R^2Y represent the fraction of the sum of squares for the selected component. Q^2 represents the predictive ability of the model. To investigate model predictability and data overfitting, a 200-iteration permutation test was performed in the PLS-DA model with the same number of components as that in the OPLS-DA model.[19] Score and loading plots combined with variable importance in the projection (VIP) were used to interpret the model.

Gut Microflora Cultivation. After thawing at room temperature, the samples taken from colonic contents were accurately weighed and immediately homogenized using glass beads into a sterile saline solution (1.0 g/10.0 mL). The solution was serially diluted in 10-fold steps. Then 0.1 mL of the aliquots of the diluents (10- and 100-fold) was inoculated in the middle of agar plates containing eosin methylene blue agar, *Enterococcus* selective agar, *Lactobacillus* selective agar, and BBL agar media. The sample was spread over the surface of the plate by using an L-rod. Each diluent was inoculated in duplicate. *Escherichia coli* was aerobically incubated at 37 °C for 48 h. *Lactobacillus* and *Enterococcus* were incubated at 37 °C for 48 h in a microaerophilic environment; *Bifidobacterium* was incubated in an anaerobic glovebox at 37 °C for 72 h. Bacterial colonies were counted after incubation.

Quantification of Significant Metabolites in Urine and Serum. The contents of lactate, acetate, formate, creatinine, and bile acid in urine samples were quantified based on their individual ^{1}H NMR spectra. At least six concentrations of the standard solutions were analyzed. The calibration curves were constructed by plotting the ratio of the analyte peak area to TSP area against each analyte. The contents of lactate and creatinine in serum were quantified using commercial kits from the Jiancheng Biotechnology Institute (Nanjian, China). The acetate in serum was measured using commercial kits from R-Biopharm (Germany).

Creatinine clearance (CC) was calculated using the formula given as follows: CC = Urine creatinine concentration × Urine volume (24 h)/Serum creatinine concentration.

RESULTS

HFHC-Induced Hypercholesterolemia in Rats. Animal models have provided fundamental contributions to the analysis of the onset and progression of complex multifactorial

Table 1. Serum (and/or Liver) Lipid Levels for Various Treatments[a]

biochemical indexes	control	1,4-GL1 treatment	HFHC group	HFHC coadministered with 1,4-GL1	HFHC coadministered with 1,4-GL2
LDL-C (mmol/L)	0.70 ± 0.09	0.94 ± 0.16	5.45 ± 0.74[b]	1.78 ± 0.39[c]	2.58 ± 0.33[c]
HDL-C (mmol/L)	1.76 ± 0.08	1.73 ± 0.10	1.68 ± 0.14	1.45 ± 0.15	1.68 ± 0.13
TC (mmol/L)	3.06 ± 0.26	3.08 ± 0.18	6.51 ± 0.09[b]	3.44 ± 0.29[c]	4.32 ± 0.32[c]
(liver, μmol/g)	6.04 ± 1.21	6.34 ± 2.11	15.3 ± 2.41[b]	7.42 ± 2.12[c]	10.6 ± 1.33[c]
TG (mmol/L)	0.82 ± 0.08	0.93 ± 0.10	1.58 ± 0.56	1.04 ± 0.15	0.95 ± 0.17
(liver, μmol/g)	0.21 ± 0.02	0.18 ± 0.04	0.78 ± 0.04[b]	0.38 ± 0.01[c]	0.53 ± 0.04[c]

[a]1,4-GL1 and 1,4-GL2 respectively denote the doses of 1,4-GL, which are 30.0 and 10.0 mg/kg. The values are expressed by mean ± SEM, $n = 8$. Abbreviations: LDL-C: low-density lipoprotein cholesterol; HDL-C: high-density lipoprotein cholesterol; TC: total cholesterol; TG: triglyceride. [b]Significant difference from the control group ($p < 0.05$, one-way ANOVA). [c]Significant difference from the HFHC group ($p < 0.05$, one-way ANOVA).

(a) PCA score plot; the variables were scaled by unit variance (UV). ●: HFHC group; ■: HFHC coadministered with 1,4-GL (30.0 mg/kg); ○: control group; ▲: 1,4-GL treatment (30.0 mg/kg). ★: Mean score of $t[1]$ (or $t[2]$) for each group. (b) Statistical validation of the OPLS-DA model by PLS-DA for the HFHC group and the control group. (c) Statistical validation of the OPLS-DA model by PLS-DA for the 1,4-GL treatment group and the control group.

diseases, such as cardiovascular diseases.[20] Animal models have smaller interindividual variation in their genetic and metabolic factors in each strain than in humans. In addition, experiments can be carried out at the same environmental and feeding conditions. In this study, the rats were administered with HFHC[18] or coadministered with 1,4-GL for 12 successive days. Table 1 reveals that the biochemical indicators of hypercholesterolemia, particularly serum LDL-c and total cholesterol (TC), significantly increase in the HFHC group compared with those in the control group. Furthermore, notable increases in TC and triglyceride (TG) in the liver are observed in the HFHC group. The dose-dependent decreases in LDL-c, TC, and TG in the serum are detected upon coadministration of HFHC with 1,4-GL (10.0 and 30.0 mg/kg), which suggests strongly that 1,4-GL prevents or delays the onset and development of HFHC-induced hypercholesterolemia.

^{1}H NMR-Based Metabonomic Analysis for Rat Urine. A ^{1}H NMR-based metabonomic experiment was carried out to explore the possible mechanisms of 1,4-GL in preventing the development of HFHC-induced hypercholesterolemia at metabolic levels. PCA is a statistical approach to facilitate an understanding of the relationships of a number of complex objects in a multivariate data set. The resulting data were displayed as "score plots", which represent the distribution of samples in multivariate space. The score plots of the first two principal components allowed visualization of the data and to establish whether there was any intrinsic difference in the ^{1}H NMR-based metabolic profiling of rat urine. The PCA score plot (Figure 2a) shows that the HFHC group is isolated from other groups; however, the group of HFHC coadministered with 1,4-GL is closer to the normal groups. The result indicates that 1,4-GL restores the urinary ^{1}H NMR phenotype that is disturbed by HFHC-induced hypercholesterolemia.

OPLS-DA, a supervised model, can be considered as a modification of the traditional PLS-DA, particularly in extracting information on changes in the metabolic profiling of samples. Thus, in this study, the ^{1}H NMR data of rat urine were employed to establish pairwise OPLS-DA models of the

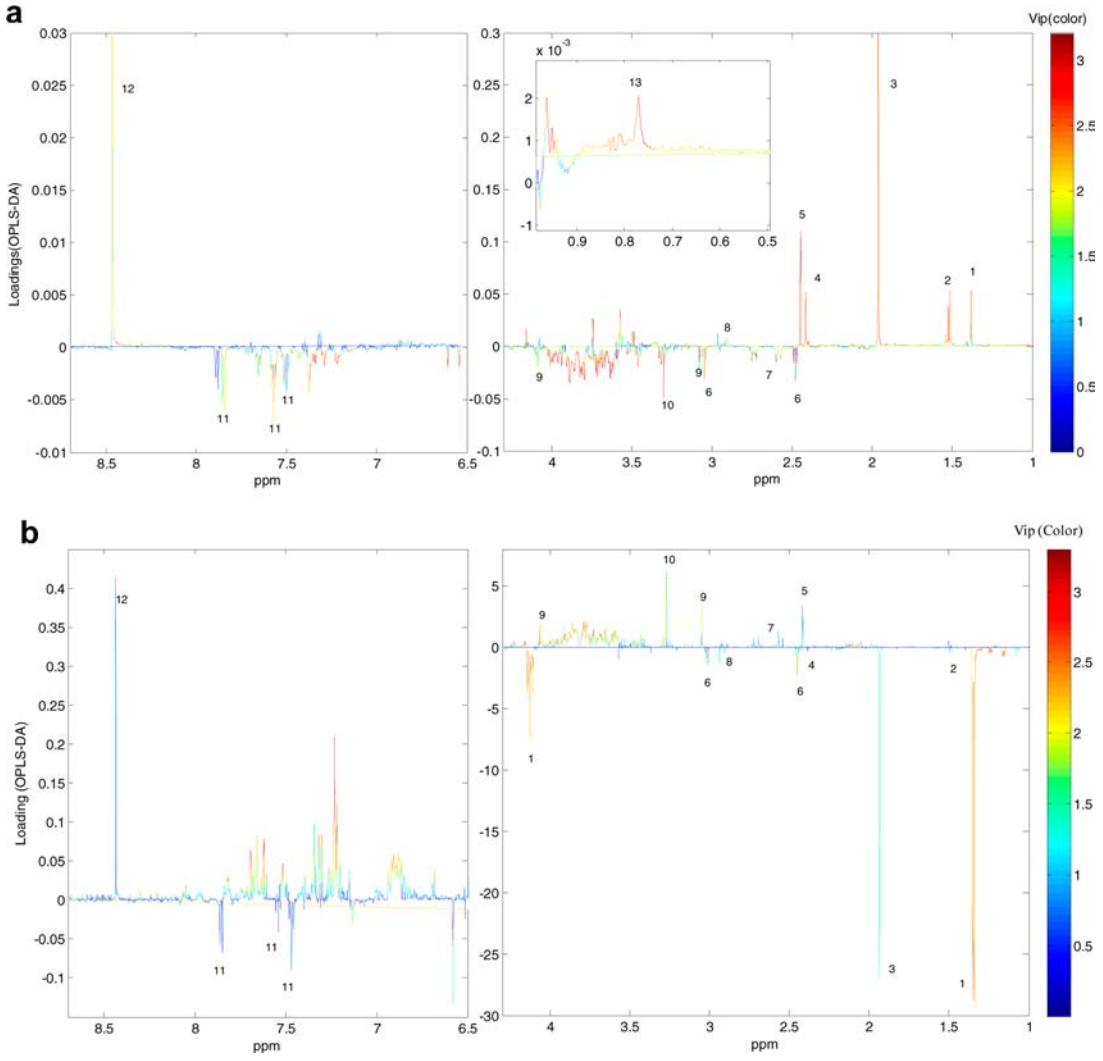

Figure 3. VIP-coded loadings plot. The color scales (VIP values) show variable importance in the OPLS-DA projection generated by the urinary ^{1}H NMR data of the HFHC and the control group (a: R^2X, 0.878, R^2Y, 1.0; Q^2, 0.89) or the 1,4-GL treatment and the control group (b: R^2X, 0.72, R^2Y, 0.97; Q^2, 0.73). Metabolite keys: 1, lactate; 2, alanine; 3, acetate; 4, pyruvate; 5, succinate; 6, 2-oxoglutarate; 7, citrate; 8, TMA; 9, creatinine; 10, TMAO; 11, hippurate; 12, formate; 13, cholate.

HFHC group (and the 1,4-GL treatment group) to the control group, aiming to single out statistically and potentially significant variables (metabolites) responsible for the difference between the HFHC group (and 1,4-GL treatment group) and the control group. Successful discrimination is achieved with a goodness-of-prediction Q^2 of more than 0.70. The OPLS-DA models reveal that the HFHC and 1,4-GL treatment groups are statistically distinguishable from the control group (p = 0.031 and p = 0.018, respectively; CV-ANOVA). The validation plot from the PLS-DA model (Figure 2b and c) demonstrates that the original OPLS-DA model is not random and overfitted because the permutated R^2 and Q^2 values are significantly lower than the corresponding original values; hence, the OPLS-DA model is robust.

A bivariate plot, which combines the loading coefficients and VIP, was generated based on the OPLS-DA model[21] (Figure 3). The plot characterizes the variation of a peak with changes in intensity and its importance to classification (color code). Upward- and downward-oriented peaks in the bivariate plot reflect the increased and decreased intensities from the intervention of HFHC or 1,4-GL, respectively. Figure 3 lists the important metabolites for classification.

1,4-GL Modifies Gut Flora Intervened by HFHC. Figure 3 reveals the significant downregulation and upregulation of trimethylamine-*N*-oxide (TMAO) in the HFHC and 1,4-GL groups, respectively, upon comparison with the control group. The excretion of trimethylamine (TMA) is also found to be opposite the alteration by HFHC compared with the 1,4-GL treatment. Metabolites (e.g., TMAO and TMA) are directly related to the statuses of gut microbiota and are urinary biomarkers of the alteration of gut flora.[22,23] We therefore presume the differences between the effects of 1,4-GL treatment and HFHC on gut flora. To clarify the hypothesis, the contents in rat colon underwent aseptic manipulation to culture the enterobacteria. The results show that the levels of gut bacteria, such as *Bifidobacterium*, *Lactobacillus*, and *Enterococcus*, markedly decrease in the HFHC group compared with the control group (Figure 4). Similar results to *Bifidobacterium* species in high-fat-feeding mice have been previously reported.[24,25] However, the quantities of *Bifidobacterium*, *Lactobacillus*, and *Enterococcus* significantly increase when the rats with hypercholesterolemia were coadministered with 1,4-GL. 1,4-GL significantly increases the quantities of *Bifidobacterium* (1.7-fold) and *Lactobacillus* (4.2-fold) but

dx.doi.org/10.1021/jf501744d | J. Agric. Food Chem. 2014, 62, 7444−7451

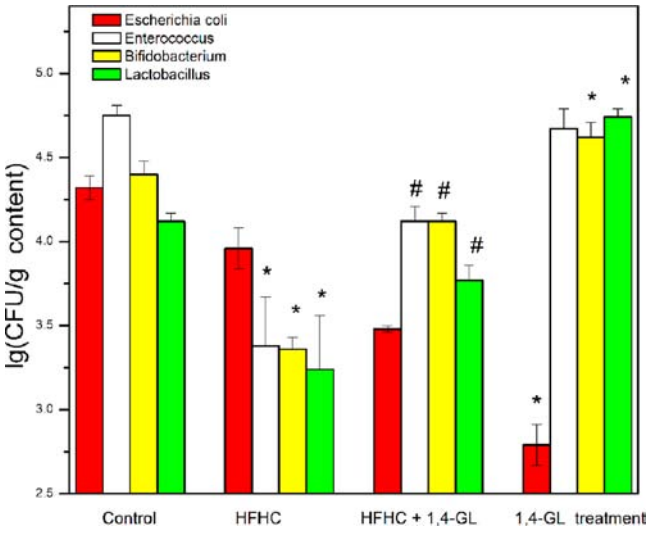

Figure 4. Levels of bacterial flora in rat colon after various interventions. CFU: colony forming units. The bar graph represents the mean ± SE for samples derived from five rats in each group. *Significant difference from the control group ($p < 0.05$, one-way ANOVA). #Significant difference from the HFHC group ($p < 0.05$, one-way ANOVA).

reduces that of *E. coli* (31.2-fold) in 1,4-GL-treated rats (Figure 4). The findings indicate that 1,4-GL restores the HFHC-induced imbalance of gut flora and affects their conversion to probiotics (e.g., *Bifidobacterium* and *Lactobacillus*).

Elevation of Serum Lactate and Acetate in Hypercholesterolemic Rats. NMR-based metabonomic results (Figure 3) indicate that the alterations of particular metabolites (e.g., lactate, creatinine, acetate, and formate) in urine were significantly opposite the direction of regulation caused by HFHC intervention compared with 1,4-GL treatment. To comprehend the possible biological effects of 1,4-GL in preventing hypercholesterolemia, the contents of the key metabolites were determined in the urine and serum samples (Table 2). The HFHC group exhibits higher serum (lactate: 1.77-fold, $p < 0.01$; acetate: 1.50-fold, $p < 0.01$) and urinary excretion (lactate: 1.47-fold, $p > 0.05$; acetate: 4.87-fold, $p < 0.01$) of lactate and acetate than the control group.

The quantitative results (Table 2) also show that the concentrations of lactate and acetate in serum fall to normal levels when the rats were coadministered with HFHC and 1,4-GL. Meanwhile, urinary excretions of lactate and acetate after rats were treated with HFHC and 1,4-GL were found to be about 2 to 3 times higher than those treated with HFHC alone. Kidneys excrete waste products from the body through urine and regulate the concentration of metabolites in the blood. The data indicate that the increased urinary excretion of lactate and acetate by 1,4-GL treatment contributes to the prevention of hypercholesterolemia.

Increased Creatinine Clearance after 1,4-GL Treatment. Metabonomic and quantitative results likewise reveal that 1,4-GL treatment significantly increases the urinary excretion of creatinine. Creatinine is constantly produced at a rate proportional to the muscle mass; this substance is then filtered from the blood by the kidneys. In this study, no statistical differences were observed in rat weight between different groups during the experiment. This result suggests that the increased urinary excretion of creatinine during 1,4-GL treatment is not attributed to changes in muscle mass. The excretion of creatinine is primarily determined by glomerular filtration and proximal tubular secretion. Therefore, creatinine levels in blood and urine can be used to calculate the creatinine clearance, which reflects renal function.[26] Our results show that the creatinine clearance of 1,4-GL treatment exceeds that of the control group by 77.4%. Creatinine clearance was reduced by 33.6% in the HFHC group and was not statistically significant in the group coadministered with HFHC and 1,4-GL compared with that of the control group (Table 2). The increased creatinine clearance after 1,4-GL treatment increases the urinary elimination of metabolites (e.g., lactate and acetate) and maintains the concentration of metabolites in the blood.

DISCUSSION

Mammals are "superorganisms" with karyomes, chondriomes, and microbiomes. Research has suggested that the microbiome–host relationship contributes to diabetes, obesity, and increased blood pressure.[27,28] The results from metabonomic analysis show that particular urinary biomarkers (e.g., hippurate, TMAO, and TMA) of the changes in gut microbiota are significantly altered after 1,4-GL treatment. Thus, counts of some general gut bacteria in rat colonic contents were

Table 2. Quantitative Results of Particular Metabolites in the Urine (from 0 to 24 h) and Serum of Rats (n = 6–8 in Each Group, Mean ± SE)[a]

metabolite	control	HFHC group	HFHC coadministered with 1,4-GL	1,4-GL treatment
lactate (U, μmol)	271 ± 48.3	397 ± 79.5	750 ± 126[c]	146 ± 37.2[b]
acetate (U, μmol)	299 ± 40.6	1461 ± 292[c]	4384 ± 608[c]	179 ± 50.7[b]
formate (U, μmol)	81.2 ± 8.90	540 ± 135[c]	2158 ± 431[c]	72.4 ± 25.5
creatinine (U, μmol)	13.5 ± 1.30	12.5 ± 2.30	13.9 ± 3.20	22.2 ± 2.10[b]
cholate (U, μmol)	not detected	19.4 ± 1.70	28.5 ± 3.60[d]	not detected
lactate (S, μmol/L)	189 ± 20.9	335 ± 47.1[c]	219 ± 31.5	167 ± 18.7
acetate (S, μmol/L)	15.1 ± 1.40	23.8 ± 1.20[c]	15.5 ± 1.50	15.3 ± 1.50
creatinine (S, μmol/L)	30.5 ± 2.90	40.4 ± 5.70	30.7 ± 3.45	26.7 ± 2.70
CC (mL/h)	20.8 ± 3.30	13.8 ± 3.0[b]	19.8 ± 2.20	36.9 ± 3.40[c]

[a]Abbreviations: U, urine; S, serum; CC, creatinine clearance; control, rats were administered with water; HFHC, rats were administered with high-fat, high-cholesterol emulsion; HFHC coadministered with 1,4-GL, rats were administered with 1,4-GL (30.0 mg/kg) and administered with high-fat, high-cholesterol emulsion afterward; 1,4-GL treatment, rats were administered with 1,4-GL (30.0 mg/kg). [b]Significant difference from the control group by $p < 0.05$ (one-way ANOVA). [c]significant differences from the control group by <0.01 (one-way ANOVA). [d]Significant difference from the HFHC group ($p < 0.05$, one-way ANOVA).

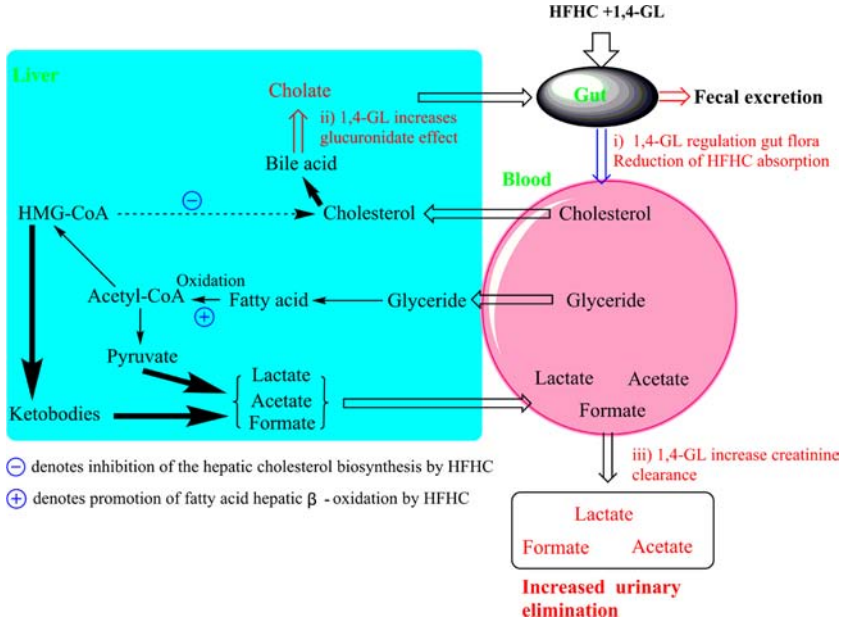

Figure 5. Putative mechanism of 1,4-GL in preventing HFHC-induced hypercholesterolemia.

measured. The results reveal that 1,4-GL treatment regulates gut flora by notably decreasing the colonic quantity of *E. coli* but increases the quantities of probiotics *Bifidobacterium* and *Lactobacillus*, which contribute to reduction in cholesterol in vivo. The probiotics bind cholesterol in the small intestines and decrease the absorption of dietary cholesterol absorption.[29,30] Indeed, since *β*-glucuronidase is mainly produced by *E. coli* in the gastrointestinal tract,[31,32] part of the reason for the reduction in colonic quantity of *E. coli* after 1.4-GL treatment lies in the inhibitory effect of 1,4-GL on the enzyme. The decreasing of *E. coli* could affect gut microbiota balance and lead to an elevated colonic quantity of probiotics. Our results imply that there exists a high correlation between prevention of hypercholesterolemia by 1,4-GL and gut microbial community.

The amount of particular metabolites (e.g., lactate, pyruvate, and acetate) in urine and blood samples increases in the HFHC group. A previous study in mice has suggested that the increase in serum lactate and pyruvate is strongly associated with a high fat diet,[33] which is in agreement with our results. During absorption of dietary fat, fatty acids and monoglycerides that are enzymatically digested in the intestines are transported into the endoplasmic reticulum. These substances are used to synthesize triglycerides. The provision of dietary triglyceride in the blood promotes fatty acid hepatic *β*-oxidation.[34] Lactate and acetate are also produced when acetyl-CoA derived from lipid *β*-oxidation exceeds the capacity of the TCA cycle.[35] Furthermore, the biosynthesis of hepatic cholesterol is inhibited by high dietary cholesterol.[36] As a result, HMG-CoA may produce ketobodies and then convert into lactate *in vivo*.[37] Given these processes, the metabolites such as lactate and acetate after the administration of HFHC are, at least in part, the breakdown products from dietary fat/cholesterol catabolism.

The products are accumulated in the blood if the production rate from successive administration of HFHC exceeds the removal rate by tissues or urinary excretion. The increase in metabolites in the blood yields a new equilibrium in the synthesis. Catabolism of fat and cholesterol is established from the interconversion among lactate, glucose, cholesterol, and fatty acid.[34,38] The high correlation of increased urinary excretions of lactate and acetate with prevention of hypercholesterolemia by 1,4-GL treatment suggests that the increased urinary excretion of the breakdown products of fat/cholesterol from the increase in creatinine clearance after 1,4-GL treatment prevents hypercholesterolemia.

Bile acids are water-soluble end products synthesized by cholesterol in the liver and conjugate with glucuronic acid (glucuronidation), are excreted through the biliary tract, and are transported to the intestine for the enterohepatic cycle. The inhibition of *β*-glucuronidase by 1,4-GL increases the glucuronidation and catabolism of cholesterol in the liver.[7] The results show that the urinary excretion of cholate increases (Table 2), which supports the hypothesis.

We propose the putative mode of action of 1,4-GL in preventing HFHC-induced hypercholesterolemia on metabolic levels based on the results (Figure 5), which involve the following: (i) increased gut bacteria (e.g., *Bifidobacterium* and *Lactobacillus*), which reduces the absorption of cholesterol;[29,30] (ii) increased bile acid glucuronidate to inhibit *β*-glucuronidase, thereby enhancing the conversion of cholesterol into bile acid; (iii) increased urinary elimination of breakdown products (e.g., lactate and acetate) from fat catabolism because of increased creatinine clearance. One limitation of this study is the limited information on enzymes related to the production of lactate and acetate after HFHC administration and 1,4-GL treatment. This work will be performed by combining molecular biology and metabonomics.

In conclusion, we demonstrate that 1,4-GL significantly prevents HFHC-induced hypercholesterolemia in rats, which supports the benefits of the use of 1,4-GL in treating cardiovascular diseases. Metabonomic analysis and colonic flora test results reveal the increased quantities of probiotics (e.g., *Bifidobacterium* and *Lactobacillus*) and urinary excretion of breakdown products of fat/cholesterol because of increased creatinine clearance after 1,4-GL treatment. This procedure contributes to the cholesterol-lowering effects. We first reported on the direct link between the development of HFHC-induced hypercholesterolemia and gut flora as well as

the breakdown products of fat/cholesterol, which provides insights in the treatment and prevention of hypercholesterolemia based on systemic considerations.

MATERIAL AND METHODS

Chemicals. DMSO (dimethyl sulfoxide), MtBE (methyl-*tert*-butyl ether), and all other solvents used were of HPLC grade. Pure DL-α-tocopherol (100% analytical grade) was used from Calbiochem (Darmstadt, Germany). All carotenoids (97−99% analytical grade) were purchased from CaroNature (Ostermundigen, Switzerland). HPLC grade water (18 MΩ) was prepared using a Millipore Milli-Q purification system (Millipore GmbH, Schwalbach, Germany). Carbonate buffer, polar aprotic mixture, photosensitizer, and all other chemicals were of analytical grade. Special reagent was 2.2-azinobis-(3-ethylbenzothiazoline-6-sulfonic acid)diammonium salt (ABTS) (Sigma-Aldrich, Taufkirchen, Germany).

Standard Preparation. Stock solutions of each carotenoid standard were prepared in the specific solvent and stored at −30 °C. The exact concentrations of the stock solutions were determined spectrophotometrically at their specific absorption maxima as described in ref 10.

Food Samples. Fresh tomatoes, tomato ketchup, tomato passata, tomato pesto, and tomato puree were bought in a local supermarket and stored in the refrigerator until analysis.

Food Extraction. All examinations were performed under subdued light conditions. All products were each weighed into an Erlenmeyer flask and extracted with methanol/tetrahydrofuran (1/1, v/v) by homogenization using an ultra turrax (type T25, IKA-Werke, Staufen, Germany) for 30 s on ice. The extract was filtered under vacuum through filter paper no. 390 (Filtrak, Niederschlag, Germany) on a Büchner funnel with magnesium hydroxide carbonate. This extraction was repeated until colorlessness. The combined extracts were rotary-evaporated under reduced pressure at 30 °C to a small volume. The dried residues were dissolved in a defined volume of MeOH/THF (50/50, v/v) using an ultrasonic bath. After centrifugation (18407 rcf, 5 min), the samples were used for PCL and HPLC measurement. For the α-TEAC assay the samples were extracted with *n*-hexane.

PCL. Carotenoid stock solutions and food extracts were dried under nitrogen and dissolved in MtBE/DMSO (1/4, v/v). The carotenoid concentrations were prepared to 25, 50, and 75 μmol/L, and the food samples were diluted in different concentrations. α-Tocopherol (dissolved in methanol) at concentrations of 2.5−125 μmol/L was used for calibration. Hence, AOA and AOC were expressed as α-tocopherol equivalents (α-TE). The measurement was performed in a special cuvette apparatus (Analytik Jena AG, Jena, Germany). A polar aprotic mixture, carbonate buffer, photosensitizer and sample were pipetted in a quartz glass cuvette (Hellma GmbH, Müllheim, Germany). Methanol and MtBE/DMSO (1/4, v/v), were used as blank.

α-TEAC Assay. The lipophilic α-TEAC assay was performed according to (ref 10) by using a V-530 spectrophotometer (Jasco, Gross-Umstadt, Germany). The α-TEAC procedure is based on the decolorization of the $ABTS^{\bullet+}$ to determine the lipophilic antioxidant properties of the samples. The method was described by Miller et al.[11] and was modified slightly by numerous researchers. Briefly, the radical cation $ABTS^{\bullet+}$ was prepared by filtering an ABTS solution (tip of a spatula ABTS dissolved in PBS) covered with manganese dioxide powder. Afterward, the particles of manganese dioxide were removed by 0.2 μm membrane filtration. The stable radical cation $ABTS^{\bullet+}$ was produced daily by diluting with 75 mM phosphate buffer (pH 7.4) to an absorbance of 0.70 ± 0.05 at 730 nm in a cuvette spectral photometer and preincubated at room temperature for 2 h. For the measurement, 100 μL of lipophilic extract of the antioxidants and 1000 μL of the adjusted $ABTS^{\bullet+}$ solution were shaken for 30 s in reaction tubes. Following, the solution was transferred completely in half-micro cuvettes and was centrifuged for 30 s at 200 rcf to separate the phases. Exactly 2 min after initiation of mixing, the absorbance of the lower phase was measured at 734 nm. The lipophilic antioxidant potential was expressed in mmol α-tocopherol equivalents per 100 g.

Analysis of Carotenoids and Vitamin E. The analysis of carotenoid compounds was performed on an HPLC apparatus with diode array detection at 450 nm (Merck Hitachi, Darmstadt, Germany). The chromatographic separation was performed at 13 °C on a Develosil RP-Aqueous (250 mm × 4.6 mm, 5 μm) C_{30}-column (Phenomenex, Aschaffenburg, Germany) by using the following gradient procedure of MeOH (solvent A) and MtBE (solvent B): initial conditions 90% solvent A and 10% solvent B; 40 min linear gradient to 50% solvent B; 2 min linear gradient to 60% solvent B, 40% solvent A and 60% solvent B for 23 min; 5 min linear gradient to 10% solvent B; and 90% solvent A and 10% solvent B for 5 min. The flow rate was 1 mL/min. The carotenoid standards were diluted daily 1:50 with MeOH/THF (50/50, v/v) modified to Werner et al.[12]

Tocopherols and tocotrienols were analyzed with a fluorescence detector (excitation: 292 nm, emission: 330 nm) (Merck Hitachi, Darmstadt, Germany) according to the method of Franke et al.[13] The column was a normal-phase Eurospher 100 Diol (250 mm × 4.0 mm, 7 μm, Knauer, Berlin, Germany) and was heated to 35 °C. Elution was carried out using a mixture of *n*-hexane/MtBE (98/2, v/m) at a flow rate of 1.5 mL/min, and the run time was 45 min. Calibration curves were done for α-, δ-, γ-tocopherol, and γ-tocotrienol in the range 0.1−3 μg/mL, for β-tocopherol 0.1−1 μg/mL, for α- and β-tocotrienol 0.1−2 μg/mL, and for δ-tocotrienol 0.3−6 μg/mL.

Carotenoids and tocopherols as well as tocotrienols were identified and quantified by comparison with external standards.

Statistical Analysis. All experiments were done in triplicate. The data are expressed as means ± SD (n = 3). The data were analyzed with ANOVA using SPSS statistical software (version 19.0; SPSS, Chicago, USA). The homogeneity of variances for all data was assumed by Levene's test. The antioxidant activities of carotenoids and the antioxidant capacities of tomato products were tested with Student−Newmann−Keuls procedure. Differences were considered statistically significant at $p < 0.05$. Tests on correlation between the carotenoid content and the antioxidant capacity were made using the Pearson procedure $p < 0.01$.

RESULTS AND DISCUSSION

AOA of Carotenes and Xanthophylls. The antioxidant activities of 6 carotenes and 11 xanthophylls were measured in three different concentrations on three different days. Table 1 shows the results of the antioxidant activity of α-carotene. The highest concentration (75 μmol/L) resulted in reproducible values. In contrast, the variation in results of the smaller concentrations was higher. This trend was observed for all carotenes and xanthophylls used. One reason for this phenomenon could be adsorption effects of carotenoids at the surface of the quartz glass cuvettes. Therefore, we did experiments to check adsorption effects by using photometric spectra and measured different concentrations. However, there were no results indicating absorption effects. We looked also for the solubility of the carotenoids in MtBE/DMSO (1/4, v/v) and for α-tocopherol in MeOH. The concentrations of capsanthin, antheraxanthin, and α-tocopherol were measured in stock solutions and in MtBE/DMSO (1/4, v/v) respectively MeOH. All carotenoids investigated were completely dissolved in the solvent mixture for PCL as well as α-tocopherol in MeOH.

Table 1. Antioxidant Activity (mol α-TE/mol) of Different Concentrations of α-Carotene, Measured on Three Different Days by Using PCL; Different Letters within Columns Indicate Significant Differences between Days, Determined by ANOVA with *post hoc* S−N−K ($p < 0.05$)

	antioxidant activity [mol α-TE/mol] of α-carotene

Concentration-dependent effects, which were described in the literature[14−16] for hydrophilic substances, could be one reason for the different values of 25, 50, and 75 μmol/L. The AOA of pure substances and food extracts was dependent on their concentration and dilution.

The antioxidant activities of all carotenoids investigated were calculated by using the highest concentrations (75 μmol/L) (Figure 2). α-Tocopherol, used as calibration standard, expressed

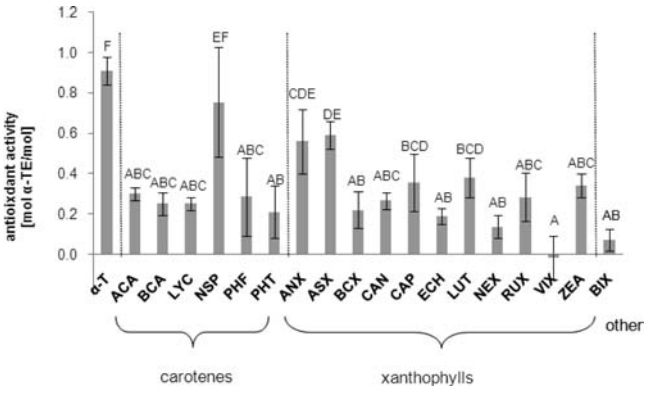

Figure 2. Antioxidant activities (mol α-TE/mol) of carotenoids ((all-E)-isomers), measured by PCL on three different days at 75 μmol/L. Bars with different letters differ significantly (ANOVA, $n = 3$, *post hoc* S−N−K, $p < 0.05$). α-T = α-tocopherol; ACA = α-carotene; ANX = antheraxanthin; ASX = astaxanthin; BCA = β-carotene; BCX = β-cryptoxanthin; BIX = bixin; CAN = canthaxanthin; CAP = capsanthin; ECH = echinenone, LUT = lutein; LYC = lycopene; NEX = neoxanthin; NSP = neurosporene; PHT = phytoene; PHF = phytofluene; RUX = rubixanthin; VIX = violaxanthin; ZEA = zeaxanthin.

the highest antioxidant power compared to all analyzed carotenoids. Within the carotenes, neurosporene (0.76 ± 0.27 mol α-TE/mol) presented the highest and phytoene (0.21 ± 0.13 mol α-TE/mol) the lowest activity. β-Carotene (0.25 ± 0.06 mol α-TE/mol) and lycopene (0.25 ± 0.03 mol α-TE/mol) were similar as well α-carotene (0.30 ± 0.03 mol α-TE/mol) and phytofluene (0.29 ± 0.19 mol α-TE/mol). Astaxanthin (0.59 ± 0.07 mol α-TE/mol) showed the maximum antioxidant activity of all xanthophylls investigated followed by antheraxanthin (0.56 ± 0.16 mol α-TE/mol), lutein (0.38 ± 0.10 mol α-TE/mol), capsanthin (0.36 ± 0.14 mol α-TE/mol), and zeaxanthin (0.34 ± 0.06 mol α-TE/mol). The AOA of rubixanthin (0.28 ± 0.12 mol α-TE/mol) and canthaxanthin (0.27 ± 0.04 mol α-TE/mol) did not differ significantly. Echinenone (0.19 ± 0.04 mol α-TE/mol) showed a small activity as well as neoxanthin (0.14 ± 0.06 mol α-TE/mol), which showed only 15% of the activity of that of α-tocopherol. Bixin was just as little (0.07 ± 0.05 mol α-TE/mol) and violaxanthin (−0.02 ± 0.11 mol α-TE/mol) did not show any activity using the PCL method.

Comparison of PCL Data with Results of FRAP, α-TEAC, DPPH, and LPSC Assay. The AOA values of the PCL method were compared to the results of Müller et al. (2011) (Table 2).[10] Generally, the AOAs of PCL were lower than the results of FRAP, LPSC, and α-TEAC for most of the investigated carotenoids. Neither carotenes nor xanthophylls demonstrated any DPPH scavenging activity. Only α-tocopherol showed an activity (1.0 mol α-TE/mol). In FRAP assay, rubixanthin (3.3 mol α-TE/mol) indicated the highest antioxidant activity. β-Cryptoxanthin, capsanthin, lutein, and lycopene had the second highest activity (2.1 mol α-TE/mol) with no differences between these compounds. However, all carotenes, excluding lycopene, did not show remarkable ferric reducing activity. In the α-TEAC assay, the highest $ABTS^{\bullet+}$ reducing activity was observed for lycopene (3.9 mol α-TE/mol) followed by β-cryptoxanthin (3.2 mol α-TE/mol), rubixanthin (3.3 mol α-TE/mol), α-carotene (3.3 mol α-TE/mol), and β-carotene (3.1 mol α-TE/mol). Phytoene and phytofluene showed the same reducing potential as α-tocopherol (1.0 mol α-TE/mol). The lowest values in the α-TEAC assay with no differences were shown for astaxanthin and canthaxanthin (0.8 mol α-TE/mol).

Table 2. Comparison of Antioxidant Activities of Carotenoids ((all-*E*)-Isomers) and α-Tocopherol in PCL to Other AOA Assays (Data from Müller et al. 2011[10]); Different Letters Indicate a Significant Difference within the Column, Determined by ANOVA ($p < 0.05$) with *post hoc* S−N−K

[a]All results presented are calculated by taking the dilution factors and means (± SD) of three independent analyzes. Values with different capital letters within rows differ significantly (ANOVA, $n = 3$, *post hoc* S−H−K, $p > 0.05$). ^{X}concentration-dependent effect.

The AOA measured by LPSC showed 10 times higher values than using the PCL method. The highest luminol-chemiluminescence peroxyl radical scavenging capacity was measured for bixin (29.1 mol α-TE/mol). All xanthophylls, excluding rubixanthin, showed comparable LPSC values, ranging between 19.3 and 26.3 mol α-TE/mol. Astaxanthin and echinenone demonstrated the same activity with 26.3 mol α-TE/mol. The carotenes phytoene, phytofluene, and neurosporene did not react in the LPSC assay.

The AOAs of β-cryptoxanthin, lutein, capsanthin, zeaxanthin, rubixanthin, and violoxanthin analyzed by PCL differed significantly compared to the LPSC assay. β-Cryptoxanthin had 10 times higher antioxidant activity in FRAP and 100 times higher in LPSC than in PCL. Using FRAP and α-TEAC assay, lutein, capsanthin, zeaxanthin as well as rubixanthin and violaxanthin did not show significant differences in the antioxidant activity. These xanthophylls showed considerably higher values compared to the measured activity in PCL assay (five times for lutein, capsanthin and zeaxanthin, 12−15 times for rubixanthin and violaxanthin). No statistically significant differences were observed for astaxanthin, antheraxanthin, neoxanthin, canthaxanthin, or bixin in PCL, FRAP, and α-TEAC. In the carotene group neurosporene indicated the highest activity in PCL but in α-TEAC, FRAP, and LPSC was among the lowest activities. Phytofluene and phytoene differed only in α-TEAC, whereas the values for FRAP, LPSC, and PCL were similarly low. Lycopene had significantly different values in all AOA assays.

Relationship of AOA of Carotenoids and Their Structure. The chemical structures of some carotenes are illustrated in Figure 3. The antioxidant activity of the carotenes increased with the number of conjugated double bonds with the exclusion of lycopene. A relationship could be established between the AOA of the carotenes and their structure. Consequently, the following order can be presented, depending on the antioxidant activity and the number of conjugated double bonds: phytoene < phytofluene < neurosporene. Additionally,

dx.doi.org/10.1021/jf502019r | J. Agric. Food Chem. 2014, 62, 7452−7459

the presence of functional groups, e.g. carbonyl-, hydroxyl-, epoxy-groups also affect the AOA of xanthophylls. The antioxidant activities of carotenoids are based on their singlet oxygen ($^1O_2$) quenching properties and their ability to trap peroxyl radicals.[17] The quenching ability is based on the number of conjugated double bonds and is influenced to a lesser extent by carotenoid end groups (cyclic or acyclic) or the nature of substituents in carotenoids containing cyclic end groups.[17] Carotenoids that contain more than seven conjugated double bonds were reported to have stronger antioxidant activity.[18] The conjugated system delocalizes the electrons along the chromophore.[19] This property gives the carotenoids their distinctive molecular shape, chemical reactivity, and light-absorption properties.[20] Carotenoids lose their color when exposed to radicals or to oxidizing species. This process involves interruption of the conjugated double bond system either by cleavage or by addition to one of the double bonds.[1] Lycopene, which has 11 conjugated and two nonconjugated double bonds and gives tomatoes their red color, had the highest singlet oxygen quenchers activity of the natural carotenoids.[17,21−23] Hence, we expected that lycopene had the highest AOA compared to the other carotenes measured by PCL. But lycopene is very susceptible to oxidation because of the high unsaturated chemical structure.[24] Furthermore, lycopene is also very sensitive to light, heat, oxygen, and acids in degradation, and some metallic ions such as Cu^{2+}, Fe^{3+} catalyze its oxidation.[25] In nature, lycopene exists in all-*trans*- form and seven of these bonds can isomerize from the *trans*-form ((all-*E*)-lycopene) to the mono- or poly *cis*-form ((*Z*)-isomers) under the influence of heat, light, or certain chemical reactions.[25] Traces of metallic ions in solvents as well as the influence of the pH of the carbonate buffer (10.6) could be reasons for the low AOA of lycopene.

AOC, Carotenoid and Vitamin E Contents of Various Tomato Food Products. Fresh tomatoes, tomato ketchup, tomato passata, tomato pesto, and tomato puree were investigated on their lipophilic antioxidant capacity by photochemiluminescence and α-TEAC assay. All extracted samples were analyzed in different concentrations and in triplicate. To quantify the carotenoid and vitamin E contents, HPLC methods were used (Table 3). The results measured for the tomato samples depended on the assay used, but in general the AOC of fresh tomatoes was lower than that of other tomato product samples in PCL and α-TEAC assay as well as in the carotenoid content. In PCL assay fresh tomatoes and tomato passata did not differ significantly as well as tomato pesto and tomato puree. The highest value was shown for tomato ketchup followed by tomato pesto, tomato puree, tomato passata, and fresh tomatoes. The contained herbs and spices could explain the highest antioxidant potential of tomato ketchup. The composition of the tomato pesto was basil, garlic, pine nut, different oils (e.g. sunflower oil and olive oil), hard cheese and ascorbic acid which also had a positive influence on the antioxidant capacity. In contrast to tomato passata, tomato puree is a more concentrated tomato product, and the order of the antioxidant potential, which was assumed, could be demonstrated. The raw material fresh tomato was estimated to have the smallest AOA of the measured tomato products. Because the fresh tomato is a raw material without concentration steps, and no substances like herbs or spices and no oils were added, which can have positive influence on the AOC. To date, it is very difficult to compare our results because publications about the lipophilic antioxidant capacity of tomato products measured by PCL are scare in the literature.

The theoretically calculated antioxidant capacity in μmol α-TE/100 g for PCL could be generated with measured single substances measured by PCL. The lowest antioxidant potential was expected for fresh tomatoes and the highest for tomato pesto. Noticeably, the experimental values were higher than the calculated values. For example, the experimental AOC of tomato ketchup was much higher than calculated (2592%). Reasons could be interaction between single substances which was described in the literature. Researchers observed synergistic effects between lycopene and α-tocopherol,[26,27] lycopene and β-carotene,[26,28] lycopene and lutein,[27,28] lutein and β-carotene,[27] α-tocopherol and β-carotene.[28,29] However, Zanfini et al. described that significant synergistic acts do not take place when compounds are combined.[27] All four substances (lycopene, β-carotene, lutein, and α-tocopherol) which have the ability to make synergism were detected in our tomato samples. Synergistic effects were dependent on the type of antioxidant and on their concentration.[30] Mixtures of carotenoids could be more effective than single substances.[31] Matrix effects (for example interactions between antioxidants and polysaccharides) should not be disregarded.

To check if the water content of samples had an influence on the antioxidant capacity, we calculated the dry weight-based antioxidant capacity. The differences between the fresh tomatoes and the tomato products were mainly due to the water content. In the PCL as well as in the α-TEAC assay the antioxidant capacities were dependent on the water content.

For all results in the PCL assay and α-TEAC, concentration-dependent effects on the measured AOC were detected. Hengst et al.[14] described first the influence of the sample concentration on determination of the hydrophilic antioxidant capacity. The hydrophilic PCL assay was investigated as well as TEAC, FRAP, ORAC, and total phenolics assays. The measured antioxidant activities/capacities of pure substances (gallic acid, uric acid, Trolox, ascorbic acid) and food extracts (strawberry nectar, tomato extract, white tea) decreased or increased with increasing sample concentration. Hence, the values depended significantly on the applied sample concentration. The basic causes of these dilution effects are hardly unknown.[14−16] The AOC of tomato pesto and tomato puree measured by PCL increased with increasing dilutions (Figure 4). The opposite was shown for tomato ketchup, having the highest polysaccharide content, the values decreased with decreasing concentrations. For fresh tomatoes and tomato passata not any relation between their concentration and their results was observed. In addition, for the three samples with high antioxidant capacity, a good linear

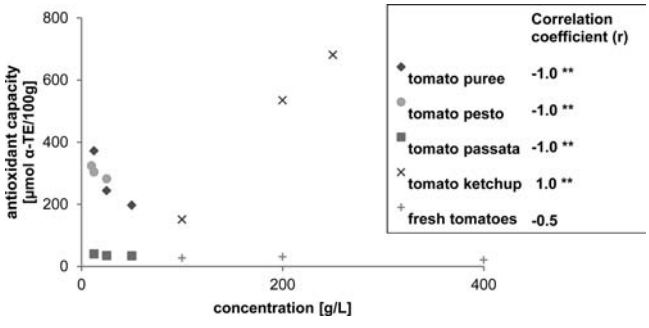

Figure 4. Correlation between the concentration of the tomato samples and their antioxidant capacity. Data were statistically analyzed using the Spearman correlation coefficient test. ** Indicates a significant correlation at the level of $p < 0.01$.

correlation between concentrations and antioxidant capacity was registered. On the basis of the concentration-dependent effects it is suggested to measure different sample dilution factors/concentrations, for the analysis to detect and to discuss the influence of concentrations.

It is assumed that the range in the α-tocopherol calibration (2.5−125 μmol/L) had also an influence on the results. If the values were smaller than 25 μmol/L, the standard deviation of the determined tomato products became higher. For example the tomato pesto dilutions were measured in an α-tocopherol concentration range between 50 μmol/L and 75 μmol/L. Therefore, the variation and the concentration-dependent effects were smaller. In contrast, for the tomato passata, the concentration area analyzed was <25 μmol/L α-tocopherol, and the variation was higher. Consequentially, the sample concentration should not be smaller than 25 μmol/L α-tocopherol calibration.

According to Navas et al.,[32] chemiluminescence not only has advantages such as superior sensitivity, safety, and controllable emission rate but also has some disadvantages such as poor reproducibility. Furthermore, Barni et al.[33] described that photosensitizer solutions can be sensitive to light and the presence of metal cations (e.g., iron and copper). In addition, the light-producing pathway for the oxidation of photosensitizers is a complex multiple process and depends on several factors, including pH, temperature, and ionic strength of the reaction medium and reactive species that can be present in solution and interact with photosensitizer metal catalyst or hydroxide ions.

The lipophilic extract of the tomato puree, characterized by a high carotenoid and vitamin E content, showed the highest antioxidant capacity (2562 ± 238 μmol α-TE/100 g) measured using ABTS radical cation decolorization assay. Tomato passata (594 ± 65 μmol α-TE/100 g) and tomato ketchup (414 ± 19 μmol α-TE/100 g) were significantly different from tomato pesto (344 ± 20 μmol α-TE/100 g). Fresh tomatoes had significantly the lowest lipophilic antioxidant capacity in the TEAC assay.

A significantly linear correlation between the antioxidant potential measured by α-TEAC and the contents of carotenoids could be observed (R = 0.939). An increase of the carotenoid content led to an increase of the lipophilic antioxidant capacity using the α-TEAC. Only a low correlation between the PCL values and the carotenoid contents was observed (R = 0.333).

The PCL and the α-TEAC assays are based on different reaction mechanisms. The pH value can also have an influence. While the PCL reaction is in an alkaline the α-TEAC is in a neutral milieu. Matrix effects should not be disregarded.

The antioxidant capacity of all tested tomato products showed different results. All methods to determine the antioxidant capacity are based on different principles. The α-TEAC assay is based on the single electron transfer reaction (SET).[9,34] The mechanism of PCL is still unclear.[35] The antioxidant capacity is being measured by individual, different methods and reflects only the chemical reactivity under the specific conditions applied in that assay. It is inappropriate and misleading to generalize the data as indicators of "total antioxidant activity". No single assay will reflect the "total antioxidant capacity" of the samples. Diverse methods which are based on different reaction mechanisms as well as the lipophilic and hydrophilic capacities should be used.[10,14,34]

Our results have shown that lycopene is the main carotenoid in tomatoes, which was expected from the literature. The total lycopene contents in the tomato samples investigated ranged between 16.7 mg/100 g (tomato fresh) and 81.3 mg/100 g (tomato puree). The total lycopene content in processed tomatoes was higher than that in the raw tomatoes. The content of carotenoids measured in this study is in good agreement with the results of Baranska et al. (2006)[36] who measured lycopene and β-carotene in tomatoes, ketchup, and puree. On the other hand, the lycopene values, determined by Fröhlich et al.[37] are about 45−23% lower for tomatoes, ketchup, and tomato passata. Sass-Kiss et al.[38] recorded that lycopene represented 90−95% of the total carotenoid content in tomatoes. Our lycopene contents also ranged between 91 and 98% of the total carotenoid composition in the variety of tomato products. Lower abundance for lycopene was determined by Kotíková et al.[39] with 67% and Burns et al.[40] with 58%. Otherwise, a much higher contribution was detected for lutein in fresh tomatoes and ketchup by Gama et al.[41] Total β-carotene in fresh tomatoes and in tomato products amounted 0.36−2.17 mg/100 g and was comparable with the results of Fröhlich et al.[37] and Baranska et al.[36] Differences between the carotenoids contents can be affected by many factors such as variety, growing conditions and time of harvest, climatic conditions, and geographical locations. Warmer and south-oriented areas may promote the production of lycopene at the expense of other carotenoids.[37,39]

Tomato pesto has shown the highest total tocopherol content of all samples, because of containing olive and sunflower oils, which have a high α-tocopherol concentration.[42] Tomato puree had the highest β-tocotrienol content (3.11 ± 0.11 mg/100 g) compared to the other samples. Tomato passata, tomato ketchup, and fresh tomatoes did not differ significantly in their vitamin E content. δ-Tocotrienol was not found in the analyzed samples. Only β-tocopherol and α-tocotrienol were determined in tomato pesto as well as δ-tocopherol and γ-tocotrienol in fresh tomatoes. In comparison to the data of Pinela et al.,[43] the α-tocopherol content of fresh tomatoes was similar to our results. However, β- and γ-tocopherol were not detected in our fresh tomatoes, and Pinela et al. did not determine the content of tocotrienols. The main form of vitamin E determined in the tomato samples was α-tocopherol with relative contents between 31% for fresh tomatoes and 86% for tomato pesto. A much higher contribution of α-tocopherol for raw tomatoes (78%), ketchup (92%) and puree (94%) was measured by Chun et al.[44] A reason for the high content of α-tocopherol could be that only α-tocotrienol was found in trace amounts in raw tomatoes and no other tocotrienols were found in ketchup and puree.

that CO_2 enriched atmospheres, which are used widely to reduce the incidence of decay of strawberries, resulted in the degradation of fruit internal color, which is manifested in a remarkable decrease in the anthocyanin content.[15] In another study, it was found that arils of pomegranates, which were stored in air enriched with 10 kPa CO_2, had a lower anthocyanin concentration than air-stored fruit.[16] In addition, Harb et al.[10] reported a dramatic loss in ascorbic acid and lower antioxidative capacity of water-soluble antioxidants in blueberries stored under CA conditions. In another study that addressed superatmospheric O_2 treatments with 'Duke' blueberries, researchers found significant increases in the antioxidant levels of blueberries that were stored at 60−100% O_2.[17]

Despite the above-mentioned findings, detailed studies that address quantitative and qualitative changes of polyphenols during storage of blueberries, as well as changes in the expression levels of selected genes that have roles in the biosynthesis of polyphenols, are limited. Accordingly, this study aims to quantify changes in polyphenols in blueberries in addition to the relative quantification of expression levels of some related genes. The findings of this study provide new insights into the postharvest biology of blueberries which may have implications on storage technologies for these fruits.

MATERIALS AND METHODS

Plant Material, Storage Conditions, and Determination of Quality Parameters. Blueberries (cultivar: Duke) were obtained from a private orchard located at Lake of Constance region, Germany. Directly after picking, fruits were stored at 1 °C (±0.3 °C) under the following CA-storage conditions (kPa O_2 + kPa CO_2): 21 + 0.03 (air-storage = control), 3 + 6, 3 + 12, 3 + 18, 10 + 6, 10 + 12, and 10 + 18. Storage containers were 26.4 L hermitic jars that were continuously monitored by gas analyzers. After 4 and 8 weeks of storage, portions of the stored blueberries were assessed for firmness, total soluble solids, and titratable acidity. For each treatment and sampling date, there were three biological replicates, each with 250 g (125 fruits) of berries. All measurements were conducted on the same sampling day after 2 h conditioning period at room temperature. Firmness of 20 fruits for each replicate was measured using a nondestructive device (FirmTech2, BioWorks, Wamego, KS) designed for soft fruits. Readings obtained are expressed in g mm^{-1}. The same fruits used for firmness measurements plus another 30 fruits (a total of 50 fruit per each biological replicate) were used for total soluble solids (TSS) and titratable acidity (TA) measurements. TSS of the juice was determined using a digital refractometer (PR-1; Atago Co. Ltd., Tokyo, Japan) and expressed as °Brix. TA was determined through titration of 10 mL juice plus 50 mL distilled water with 0.1 N NaOH to pH 8.1 using a fully automatic titration robot (Metrohm 702 SM Titrino, Filderstadt, Germany). TA was expressed in meq

Extraction and Determination of Individual Polyphenols Using LC−MS. Twenty fruits per biological replicate (60 fruits for each treatment with three biological replicates) were obtained after a storage period of 8 weeks to be rapidly frozen in liquid nitrogen. The samples were freeze-dried to powder, and 100 mg of the lyophilized tissue (from each biological replicate) was added to 500 μL of absolute methanol and 250 μL of the internal standard solution (50 mg biochanin A in 250 mL absolute methanol). After vortexing for 1 min and sonicating for 5 min, the mixed solutions were centrifuged at 13 200 rpm for 10 min. Supernatants were collected in fresh tubes, and pellets were extracted, vortexed, sonicated, and centrifuged once again as mentioned above. Supernatants were pooled and placed in a Speed-Vac for 2 h. The dried residue from each replicate was dissolved in 35 μL of water, sonicated for 10 min, and finally centrifuged at 13 200 rpm for 10 min. For each replicate, 20 μL of the clear supernatant was placed in a HPLC vial for final analysis using an LC−MS instrument (Agilent HPLC 1100; MS: Bruker Daltonics esquire3000plus, Santa Clara, CA) which was equipped with a Phenomenex column (Luna 3u C18 (2) 100A″, 150 mm × 2.0 mm (Part-Nr. 00F-4251-B0); Aschaffenburg, Germany). The analysis conditions were as follows: column temperature, 28 °C; injection volume, 5 μL; flow rate, 0.2 $mL.min^{-1}$. Solvents were as follows: A, 0.1% formic acid in water; B, 0.1% formic acid in methanol; gradient 0−30 min, 0−50% B; 30−35 min, 50−100% B; 35−50 min, 100% B; 50−55 min, 100−0% B; 55−65 min, 0% B; detection wavelength, 280 nm. MS details are as follows: dry gas, nitrogen at 330 °C; flow rate of 10 L min^{-1}; capillary, −4000 V; end plate offset, −500 V. The electrospray ionization voltage of the capillary was set to −4000 V and the end plate to −500 V. The full scan mass spectra were measured in a scan range from m/z 100 to 800. Tandem mass spectrometry was carried out using helium as collision gas (3.5−6 mbar) with the collision voltage set at 1 V. Spectra were acquired in both positive and negative ionization modes. Data analysis was performed using the DataAnalysis 5.1 software (Bruker Daltonics, Bremen, Germany). Relative concentrations of polyphenols were calculated on the basis of the values of the internal standard (Biochanin A; Sigma-Aldrich, Seelze, Germany).

Gene Expression Analysis. Samples were taken from berries that were stored for 8 weeks at the designated conditions. The gene expression analyses were conducted according to Harb et al.[18] with minor modifications. Ten berries per each biological replicate were randomly selected after 2 h conditioning period at room temperature, shock-frozen in liquid nitrogen, and ground to powder. RNA extraction was conducted according to the protocol of Chang[19] with modifications. Eight grams of powdered tissue were added to 20 mL prewarmed (65.0 °C) CTAB-based extraction buffer and incubated for 15 min at 65.0 °C. After centrifugation at 7740*g* for 10 min at room temperature, 15 mL from the clear supernatant was added to an equal volume of chloroform/isoamylalcohol (24:1), vortexed, and centrifuged at 7740*g* for 20 min at room temperature. This step was repeated twice, and RNA was precipitated overnight at 4.0 °C using 1 volume of LiCl (2.5 M). After pellets were washed, RNA was suspended in water. Quality and quantity of extracted RNA were assessed using gel-electrophoresis and the NanoDrop, respectively. The extracted RNAs were purified using RNeasy MinElute Cleanup Kit (Qiagen, Valencia, CA) and subsequently subjected to DNase treatment (RNase-Free DNase Set; Qiagen, Valencia, CA).

The qPCR analyses were conducted using a LightCycler 480II from Roche Diagnostics Deutschland GmbH (Mannheim, Germany) and SensiMix kit from Bioline GmbH (Luckenwalde, Germany). Taqman RT-PCR reagents from Applied Biosystems (Foster City, CA) were used to synthesize cDNA (2 μg DNA-digested RNA from each sample using random hexamer primers). Sequences from the NCBI database and also from the available literature, in particular Zifkin et al.,[20] served to design the following gene-specific primers using Primer3 software: *VcCHS*-F, 5′-cttgactgaggaaatcttgaagg-3′; *VcCHS*-R, 5′-agcctctttgcc-caatttg-3′ (GenBank: JN654702.1); *VcF3′H*-F, 5′-cgagattcgatg-cgtttctgagtg-3′; *VcF3′H*-R, 5′-gatttcggtatcggtgagcttcc-3′; *VcDFR*-F, 5′-cactgagtttaaggggattcctaagg-3′; *VcDFR*-R, 5′-cccttctccctacaagtgtcaatgg-3′; *VcANS*-F, 5′-cttcatcctccacaacatggt-3′; *VcANS*-R, 5′-gctcttgta-cttcccattgctc-3′ (GenBank: JN654701.1); *VcGAPDH*-F, 5′-ggttatcaatgataggtttggca-3′; *VcGAPDH*-R, 5′-cagtccttgcttgatggacc-3′ (GenBank: AY123769.1). *VcGAPDH* served as a reference gene. For each treatment and sampling date, there were two biological replicates, each with three technical replicates. The quantification of the expression levels of the targeted genes were calculated relative to the transcript abundance of the reference gene employing relative quantification with efficiency correction.[21]

Statistical Analysis. The experimental design was completely randomized with a single factor, namely the storage conditions. The CoStat statistical package (CoHort Software, Monterey, CA) was used for the analysis of variance (ANOVA). Comparisons of means were conducted using Student−Newman−Keuls test at $P \leq 0.05$. Moreover, the standrad error (SE) values were calculated and included ($n = 3$ for all parameters, except gene expression analyses; for those analyses $n = 2$ (two biological replicates, each with three technical replicates).

Table 1. Influence of Controlled Atmosphere Storage Condition (kPa O_2 + kPa CO_2) on Fruit Firmness (g × mm^{-1}), Total Soluble Solids (TSS, °Brix), and Titratable Acidity (meq) of Blueberries (cv. Duke) after Harvest (HT) and after Four and Eight Weeks Storage at 1 °C[a]

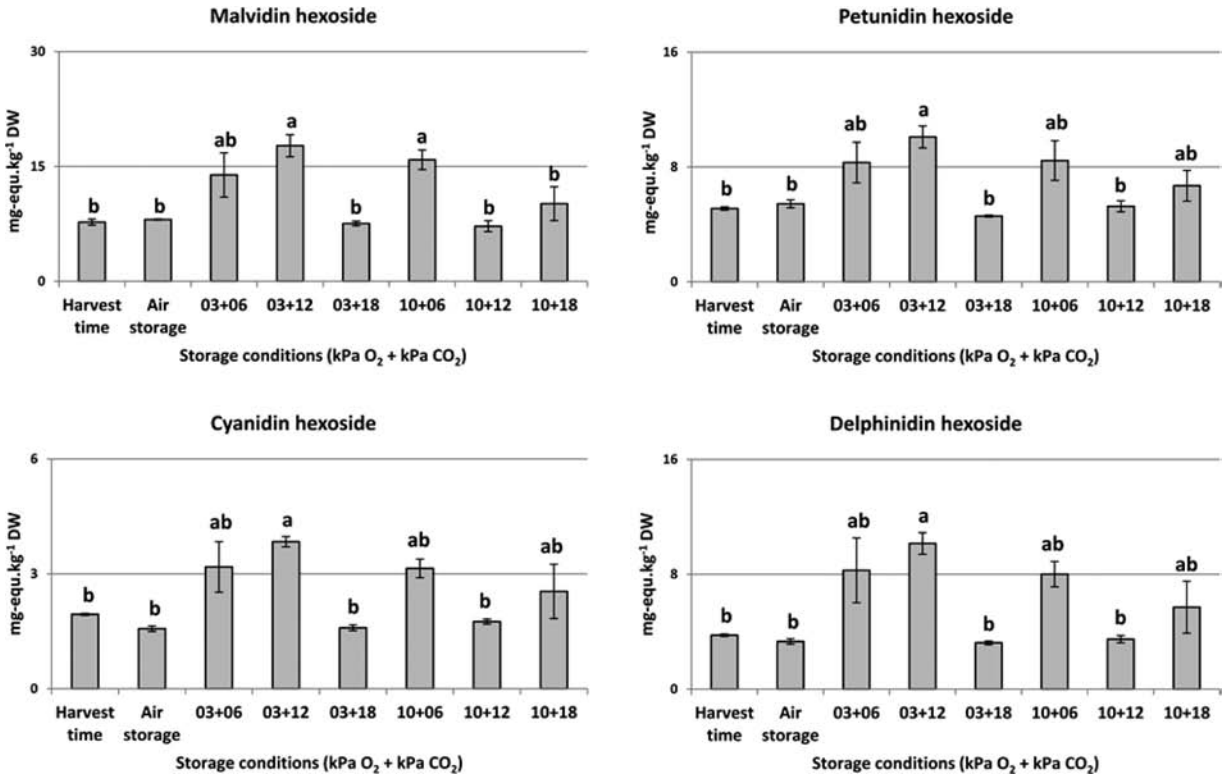

Figure 1. Influence of controlled atmosphere storage condition (kPa O_2 + kPa CO_2) on the relative content (mg-equ kg^{-1} DW) of malvidin hexoside, petunidin hexoside, cyanidin hexoside, and delphinidin hexoside of blueberries (cv. Duke) after 8 weeks storage at 1 °C. Mean separations were conducted using Student−Newman−Keuls test at $p \leq 0.05$ (n = 3). Values followed by the same letter do not differ significantly at $p \leq 0.05$. Error bars are SE values. Contents (Y-axis) are calculated relative to the internal standard (Biochanin A).

RESULTS

Quality Parameters. Storing blueberries for 8 weeks resulted in an accelerated softening of fruits that were stored under high CO_2 partial pressure (18 kPa) (Table 1), but with no significant differences between treatments in respect to total soluble solids contents. However, air-stored berries showed significant decrease in titratable acidity (TA) after 8 weeks of storage. Moreover, the sensory evaluation by the end of the storage trial revealed that berries stored under 3 + 6, 3 + 12, 10 + 6, and 10 + 12 (kPa O_2 + kPa CO_2) storage conditions tasted "good", whereas berries stored under 3 + 18 and 10 + 18 (kPa O_2 + kPa CO_2) had alcoholic off-flavor (data not shown).

Semiquantitative Changes in Polyphenols. The effects of various storage conditions on sets of polyphenols are shown in Figures 1−4. Figure 1 shows changes in the first group of polyphenols (hexosides of malvidin, petunidin, cyanidine, and delphinidin), and it is evident that the storage condition with very high CO_2 partial pressure (18 kPa) and low O_2 prevented the increase in the levels of these polyphenols. Moreover, it was found that blueberries had significantly lower levels of these polyphenols at harvest time as compared to berries that were stored at 3 kPa O_2 with 6 or 12 kPa CO_2. In addition, it is evident that the 3 kPa O_2 + 12 kPa CO_2 storage condition resulted in the highest levels for all compounds of the first group, whereas the levels of these compounds in air-stored

dx.doi.org/10.1021/jf5024774 | J. Agric. Food Chem. 2014, 62, 7460−7467

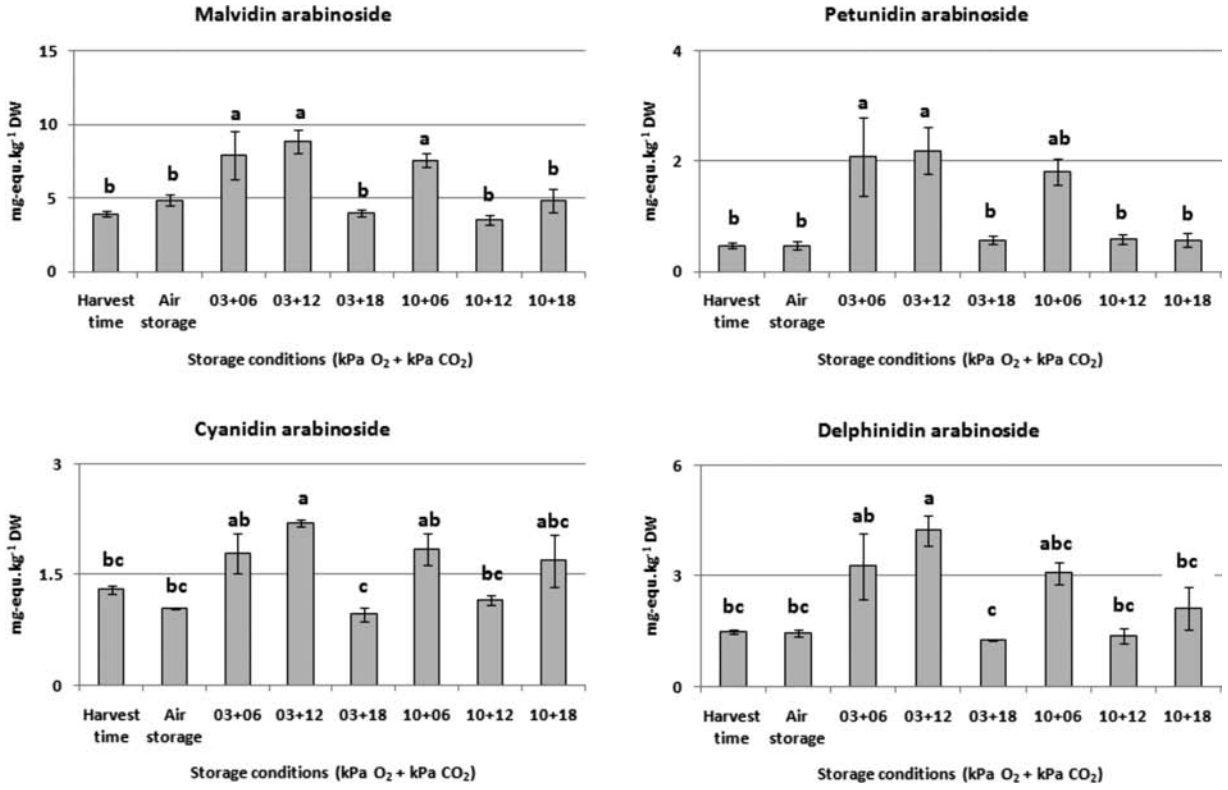

Figure 2. Influence of controlled atmosphere storage condition (kPa O_2 + kPa CO_2) on the content (mg-equ kg^{-1} DW) of malvidin arabinoside, petunidin arabinoside, cyanidin arabinoside, and delphinidin arabinoside of blueberries (cv. Duke) after 8 weeks storage at 1 °C. Mean separations were conducted using Student−Newman−Keuls test at $p \leq 0.05$ ($n = 3$). Values followed by the same letter do not differ significantly at $p \leq 0.05$. Error bars are SE values. Contents (*Y*-axis) are calculated relative to the internal standard (Biochanin A).

berries remained low with no significant differences with regard to harvest time.

The second group of polyphenols (arabinosides of malvidin, petunidin, cyanidine, and delphinidin; Figure 2) shows a similar trend to the first group, but with slight differences. Increasing O_2 partial pressure to 10 kPa led mostly to lower levels of the compounds. With this group of compounds, the influence of the highest CO_2 partial pressure (18 kPa) was more pronounced than with compounds of the first group.

The polyphenols of the third group (Figure 3) behaved differently. The highest CO_2 partial pressure (18 kPa) had less influence on their content. Moreover, it is clear that most storage conditions significantly induced, in comparison to harvest time, the biosynthesis of chlorogenic acid.

As for the compounds of the last group (Figure 4), two trends are clear: catechin (and also epicatechin; data not shown) levels were already high at harvest time, and declined steadily with all storage conditions, except under regular air-storage. The decrease was most noticeable under 3 kPa O_2 + 18 kPa CO_2. The second trend is for the unknown compounds (only unknown 1 is shown; Figure 4). It is clear that the highest partial pressure of CO_2 (18 kPa), irrespective of O_2 level, resulted in highly elevated levels of these compounds.

Expression of Polyphenol-Related Genes. Figure 5 depicts the expression levels of a few genes that encode enzymes involved in the biosynthesis of various polyphenols. The expression levels of chalcone synthase (*VcCHS*) and dihydroflavonol-4-reductase (*VcDFR*) were already high at harvest time, but declined significantly and drastically upon storage under very high CO_2 partial pressure levels. For both *VcCHS* and *VcDFR*, the decrease in the expression levels correlates well with the increasing partial pressure of CO_2, especially when combined with 3 kPa O_2. For both flavonoid 3′-hydroxylase (*VcF3′H*) and anthocyanidin synthase (*VcANS*) genes, berries at harvest time showed the highest expression levels, and differences between storage treatments are minimal with no clear trends between storage conditions.

DISCUSSION

A CO_2 enriched storage atmosphere is highly recommended to control decay in various fruits, including strawberry and blueberry.[17] Blanch et al.[22] attributed this antifungal efficacy of high CO_2 atmosphere to the induction of the biosynthesis of catechin, which is believed to reduce fungal decay. Despite this positive effect, our previous studies[23] showed that CO_2 partial pressure (above 12 kPa) led to an accelerated softening of fruits that renders them to be unmarketable. In the current study, several polyphenols (Figures 1 and 2) showed significant increases following storage under nonstressful CO_2 partial pressure (6−12 kPa), in particular when coupled with low O_2 partial pressure (3 kPa). Similar trends were reported by Kalt et al.,[24] who found that anthocyanins continued to be synthesized during storage. Schotsmans et al.[25] also found that blueberries showed the highest antioxidant activity after 6 days at 20 °C (shelf life), which indicates that the enzymatic machinery for flavonoids biosynthesis is still active during storage. Our results reveal also that medium to high (6 or 12 kPa) CO_2 partial pressure as well as low O_2 (3 kPa) partial pressure preserved the capacity of cells to synthesize flavonoids. This was clear with the major polyphenols, in particular malvidin hexoside, which is considered one of the major polyphenols in blueberry.[6] In contrast, Beaudry[26] set the lower O_2 limits for the storage of

blueberry (cvs 'Bluecrop' and 'Elliot') at 6, 7, and 11 kPa O_2 for the 5, 20, and 40 kPa CO_2 treatments, respectively. Taking into account that 'Duke' blueberries were used in our study, and that 3 kPa O_2 caused no negative effect, it is possible to predict that genotypes differ in their tolerance.

Referring to the above-mentioned impact of medium to high CO_2 partial pressure and low O_2 partial pressure on the biosynthesis of flavonoids, it is hard to elucidate the possible mechanism for such impact. Earlier studies showed that elevating CO_2 partial pressures in storage resulted usually in the prevention of significant increases in the levels of polyphenols. Since studies addressing blueberry, a nonclimacteric fruit, are rare, studies with other nonclimacteric fruits (e.g., strawberry and table grapes) will be used for further comparison and interpretation of the current results. With strawberry, it was found that air-storage, as well as storage under low CO_2 concentrations, resulted in higher levels of anthocyanin and intense red coloration compared to strawberries stored under elevated CO_2 concentrations.[14,15] In addition, it was reported that arils of pomegranates stored under 10 kPa CO_2 had lower anthocyanin concentration than air-stored fruit.[16] Moreover, various studies reported significant reductions in organic acids, mainly malic acid, upon storage at high CO_2 atmospheres.[14,27] Regarding anthocyanins, Holcroft and Kader[28] assumed that the slight changes in pH may affect the biosynthesis of anthocyanins. In this sense, it is worth

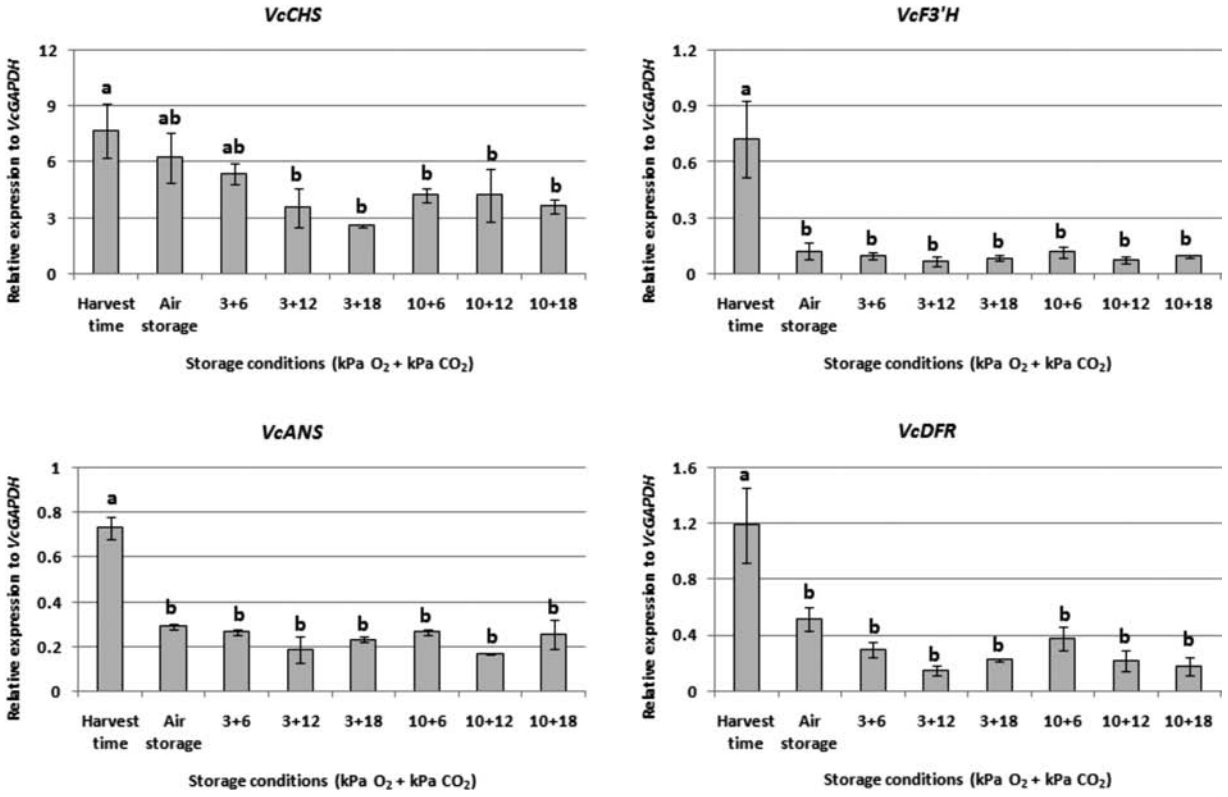

Figure 5. Influence of controlled atmosphere storage condition (kPa O_2 + kPa CO_2) on the expression levels of chalcone synthase (*VcCHS*), flavonoid 3′-hydroxylase (*VcF3′H*), anthocyanidin synthase (*VcANS*), and dihydroflavonol-4-reductase (*VcDFR*) of blueberries (cv. Duke) normalized to *VcGAPDH* (reference gene) after 8 weeks storage at 1 °C. Mean separations were conducted using Student−Newman−Keuls test at $p \leq 0.05$ ($n = 2$). Values followed by the same letter do not differ significantly at $p \leq 0.05$. Error bars are SE values.

mentioning that pH is an important factor in maintaining the stability of anthocyanins,[29] and lowering pH values improved the stability of strawberry color more than any other factor.[30] Concerning the slightly negative impact of 10 kPa O_2, compared to 3 kPa, it is most probable that the high O_2 partial pressure promoted the oxidation of polyphenols. Odriozola-Serrano et al.[31] reported that high O_2 concentrations around stored strawberries promoted greater losses of phenolic acids and vitamin C compared to low O_2 levels. Moreover, it was evident that oxygenation had a detrimental effect on bioactive phenolic compounds of red wine.[32]

In addition to the above-mentioned reductions in flavonoids under the highest CO_2 levels, changes in chlorogenic acid levels deserve special attention. This is due to the fact that chlorogenic acid is the main representative of the chlorogenic acid pathway and the major hydroxycinnamic acid in blueberries.[5,17] In the current study, high CO_2 coupled with either low or high O_2 levels had no negative impact on chlorogenic acid contents. In contrast, these conditions led to significant increases in chlorogenic levels during storage. Similar trends were also observed with loquat fruits, either during fruit ripening[33] or under CA-storage.[34] With pears, the chlorogenic acid content was the lowest by air-stored fruits, compared to fruits stored in CO_2 enriched environment.[35] In another study with 'Red d'Anjou' pear, 1-MCP treatment inhibited the transcription of key flavonoid biosynthetic genes with the concomitant decrease of chalcone synthase activity, which resulted in the diversion of the carbon flux from flavonoid pathway to chlorogenic acid pathway.[36]

Our results, as well as results from the above-mentioned studies, clearly indicate that the biosynthesis of chlorogenic acid through the chlorogenic acid pathway is independent from other polyphenols (Figures 1 and 2) that are synthesized by the flavonoid pathway. Accordingly, we hypothesize that high CO_2 may have negative impact on the expression of certain enzymes (e.g., chalcone synthase (*VcCHS*)) that are involved in flavonoid biosynthesis. In the current study, the expression level of *VcCHS* by freshly harvest blueberries is significantly higher than that for blueberries that were stored for 8 weeks under 18 kPa CO_2 condition (Figure 5); comparing storage treatments alone (without the harvest time) reveals that the expression level by air-stored blueberries is also significantly higher than those stored under 18 kPa CO_2 (data not shown). With grapes, a nonclimacteric fruit, storage under air at 0 °C increased phenylalanine ammonia-lyase, chalcone synthase and stilbene synthase mRNA levels in the skin, whereas the accumulation of these transcripts was lower in the skin of grapes that were stored for 3 days under high CO_2 level.[37] Taking into account that chalcone synthase is the first committed enzyme in flavonoid biosynthesis that catalyzes the formation of naringenin chalcone from 4-coumaroyl-CoA and malonyl-CoA to naringenin chalcone, its expression is crucial for the biosynthesis of a large set of polyphenols (e.g., malvidin hexoside). Although the start points for the control of anthocyanin differ between plant species,[38−40] we assume that the reduction in the expression of *VcCHS* is significant and may contribute highly to lower levels of polyphenols that are synthesized through the flavonoid pathway. In this respect, Gil et al.[15] reported that elevated CO_2 atmospheres led to bleaching of the strawberry internal flesh.

In conclusion, it is evident that storing 'Duke' blueberries under 18 kPa CO_2 significantly retarded, in comparison to

dx.doi.org/10.1021/jf5024774 | J. Agric. Food Chem. 2014, 62, 7460−7467

other conditions with lower CO_2 partial pressures, the biosynthesis and accumulation of polyphenols from the flavonoid pathway. Such an effect was not recorded on polyphenols from the chlorogenic pathway. Further investigations are planned to assess changes at metabolome and transcriptome levels to elucidate the causes of the rapid loss of polyphenols upon storage under high CO_2 partial pressure. In addition, the interaction between the low levels of polyphenols and the rapid softening of blueberries, which were stored under 18 kPa CO_2, deserves further investigations.

2. MATERIALS AND METHODS

2.1. Materials. *Plant Material.* The outer fresh leaves, a byproduct from the cauliflower harvest, were collected from a local farm in West-Flanders, Belgium, during the harvesting of cauliflowers from one field in July 2012. The leaves were kept frozen at −18 °C until further analysis.

Chemicals and Reagents. Folin-Ciocalteu reagent and sodium carbonate (Na_2CO_3) were purchased from VWR International (Leuven, Belgium), and gallic acid, hesperetin, and rutin were from Sigma-Aldrich (Bornem, Belgium). Viscozyme L and Rapidase vegetable juice were purchased from Novozyme (Bagsvaerd, Denmark) and DSM Food Specialties (Delft, The Netherlands), respectively.

Viscozyme L, produced by *Aspergillus aculeatus*, contains different polysaccharide-degrading enzymes, including beta-glucanase, cellulase, hemicellulase, and xylanase. The specific enzyme activity of Viscozyme L, as given by the supplier, is 120 Fungal Beta-Glucanase units (FBG)/mL, in which 1 FBG is the amount of enzyme required under standard conditions (30 °C, pH 5.0, and 30 min reaction time) to degrade barley α-glucan to reducing carbohydrates with a reducing power corresponding to 1 μmol glucose/min.

Rapidase vegetable juice is an enzyme mixture produced by both *Aspergillus niger* and *Trichoderma longibrachiatum*. As stated by the supplier, it contains pectinase and hemicellulase (optimal pH 4.0−5.0, optimal temperature 10−55 °C).

2.2. Experimental Procedure. *Enzyme-Assisted Pretreatment.* The frozen outer leaves of cauliflower were cut into pieces (2 × 5 cm), followed by 3 min mixing using a kitchen homogenizer. Enzymes were first dissolved in water taking into account the appropriate concentrations to obtain a correct E/S (cauliflower outer leaves) ratio. The cabbage mixture (60 g) then was placed in a 500 mL glass vial, and 90 mL of aqueous enzyme solution was added. In a first series of experiments, we searched for the optimal conditions for the two enzyme pretreatments. A first set of incubations was done at 40 °C, pH 4.0 with different enzyme concentrations (0−5% E/S ratio). In the second set with the optimal enzyme concentrations (E/S ratio of 0.2% for Viscozyme L and 0.5% for Rapidase), the incubation temperature varied from 30 to 50 °C, always at pH 4.0. In a last step, the optimal enzyme concentrations and optimal temperature (35 °C) were used, while the pH value varied from 3.0 to 6.0. All incubations were performed in a temperature-controlled water bath with agitation. Samples of the treated cabbage were taken at 0, 6, and 24 h for methanol extract, and a sample of the supernatans was taken at 24 h, representing the aqueous extract. All samples were stored at −18 °C for further analysis of total phenolic content. All incubations were done in triplicate.

Using the optimal conditions for both enzymes obtained in the first experiment, a second series of experiments was performed to investigate the enzymatic kinetics of the two enzymes. All of the experimental parameters were the same as in the first series of experiments, except that samples were taken at 2 h intervals during the first 12 h and then at 30 h. All incubations were done in triplicate. Samples were stored at −18 °C for analysis of total phenolic content, and to profile the individual phenolic compounds.

Extraction of Phenolic Compounds. Samples were divided into two parts. Supernatant from the liquid phase, after 24 h of incubation, was obtained by centrifugation (13 000*g*, 10 min, 4 °C) and filtered through filter paper (VWR, grade 413) (aqueous extract, AE). The solid samples at 0, 6, 12, and 24 h of incubation were extracted by the method according to Olsen et al.[23] In brief, 15 mL of methanol was added to 5 g of sample, and the suspension was homogenized at 9500 rpm using an ultraturrax for 40 s, followed by incubation in ice water for 15 min. Supernatant was collected after centrifugation (13 000*g*, 10 min, 4 °C). The pellet obtained was then re-extracted by the same procedure, using 10 mL of methanol/water (80/20; v/v). Both extracts were pooled and filtered through filter paper (VWR, grade 413) before adding methanol to a final volume of 25 mL (methanolic extract, ME).

2.3. Analytical Methods. *Determination of Total Phenolic Content.* Total phenolic content was determined according to Folin−Ciocalteu,[24] with slight modifications. In brief, 1.8 mL of deionized water was added to 0.2 mL of sample. After thorough mixing, Folin−Ciocalteu reagent (0.5 mL) was added, and the tube was shaken vigorously. After 6 min, 1.5 mL of sodium carbonate solution (20%) was added, followed by adding deionized water to a final volume of 5 mL and mixing well again. The solution was then allowed to stand in the dark for 2 h at ambient temperature, and the absorbance was read at 760 nm. Total phenolic content (TPC) was expressed as milligrams of gallic acid equiv per 100 g of dry weight (mg GAE/100 g DW) by using a standard curve of gallic acid in the range of 10−100 mg/L. The blank was prepared with 0.2 mL of methanol instead of sample solution.

Sample Purification Using SPE. In brief, 1 mL of sample was diluted in water (0.1% formic acid) up to 20 mL of total volume, followed by adding 100 μL of 100 μg/mL hesperetin as internal standard. The mixture was slowly loaded onto a solid-phase extraction (SPE) C18 column (50 mg, 4 mL; Davison Discover Science, Deerfield, IL), which was previously preconditioned with methanol (0.1% formic acid). The column then was washed with 5 mL of water (0.1% formic acid) prior to loading 3 mL of methanol (0.1% formic acid). The eluent obtained was evaporated under nitrogen flux. After drying, the residue of the sample was redissolved in 100 μL of methanol (0.1% formic acid) prior to adding 900 μL of water (0.1% formic acid). The sample obtained was kept at −18 °C until UPLC-DAD-HDMS-TOF-MS analysis.

Quantification and Identification of Phenolic Compounds by UPLC-DAD-HDMS-TOF-MS. UPLC-DAD analysis was performed on a bride ethylene hybrid (BEH) C18 column (150 × 2.1 mm, 1.7 μm particle size) by using an Ultimate U(H)PLC (Dionex, Breda, The Netherlands). The column and autosampler temperatures were kept at 40 and 4 °C, respectively. The mobile phase was formed by two solvents, solvent A (water containing 0.1% formic acid; v/v) and solvent B (methanol containing 0.1% formic acid; v/v). A stable flow rate of 250 μL/min was applied at 0 min, 90% A; followed by linear and isocratic gradient of eluting solvents as 0−6 min, 20% B linear; 6−12 min, 20% B isocratic; 12−13 min, 30% B linear; 13−23 min, 50% B linear, 23−30 min, 90% B linear; 30−35 min, 90% isocratic; 35−40 min, 10% B linear; and 40−45 min 10% B isocratic. Quantification was achieved by comparing the peak areas to a calibration curve made using rutin. Quantities of the compounds were expressed as rutin equivalents (RE).

Identification was achieved using an ACQUITY UPLC system (Waters, Milford, MA) coupled to a Synapt HDMS-TOF mass spectrometer (Micromass, Manchester, UK), equipped with an electrospray ionization source. The working conditions of MS analysis were: capillary voltage, 2 kV; sampling cone voltage, 40 V; extraction cone voltage, 4 V; source temperature 150 °C; desolvation temperature, 350 °C; cone gas flow rate, 50 L/h; desolvation gas flow rate, 550 L/h. Collision energies for the trap and transfer were set at 6 and 4 V for low energy, while a ramp of 15−45 V was applied for the high energy collision-induced dissociation. The instrument was operated in negative and positive continuum mode, and data were acquired using Waters MassLynx software. Detailed information on the MS analysis and peak identification is described by Gonzales et al.[25]

2.4. Statistical Analysis. The data are given as mean ± standard deviation (SD) for the optimization of the enzyme treatment and as mean with the standard error of mean (SEM) for the individual phenolic compounds. One-way and two-way ANOVA were used to determine significant differences between individual means using Tukey posthoc test for P values < 0.05. Principal component analysis (PCA) was applied to visualize differences in effects between treatments as well as incubation times based on the contents of individual phenolic compounds. The SPSS software v.22 (IBM, Chicago, IL) was used for all statistical analyses.

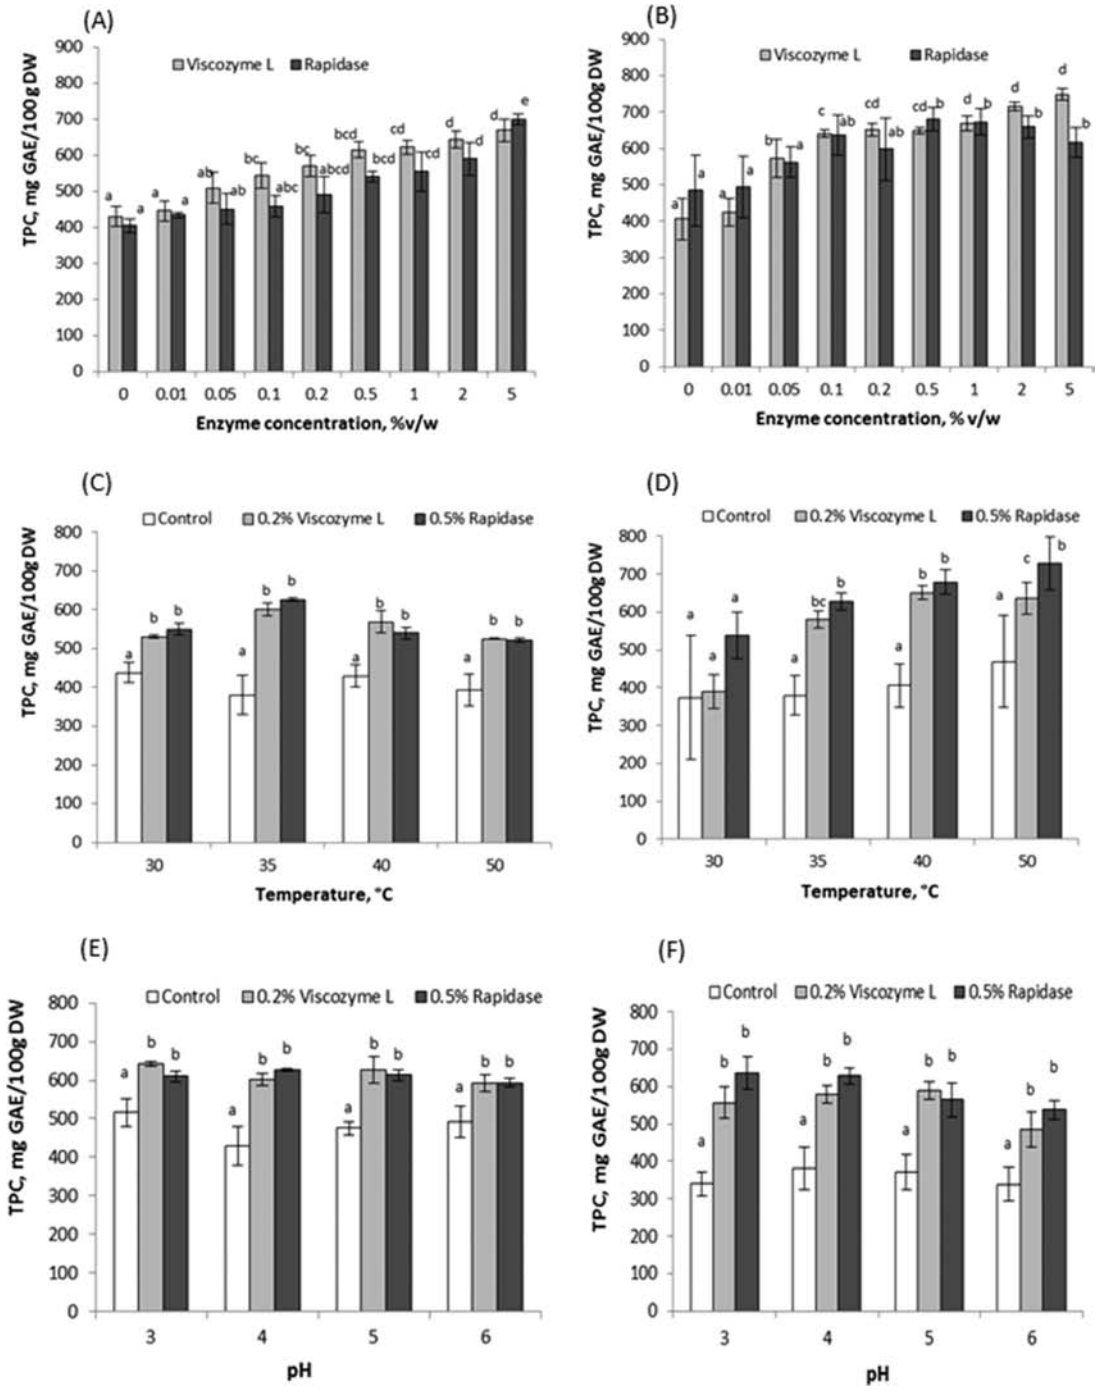

Figure 1. Effect of enzyme concentration (A,B), temperature (C,D), and pH (E,F) on the extraction of phenolic compounds from outer leaves of cauliflower after 24 h of incubation. (A,C,E) Total phenolic content in AE assisted by enzymes. (B,D,F) Total phenolic content in ME after enzymatic pretreatment. Different letters (a−e) indicate significant difference (P value < 0.05) within the same color column. The total phenolics of methanolic extract from cabbage solid residue at 0 h of incubation (control sample): 336 ± 30 mg GAE/100 g DW (n = 3).

3. RESULTS

3.1. Optimization of Enzyme-Assisted Extraction of Phenolic Compounds. Independent of the treatment (type of enzyme, concentration of enzyme, temperature, and pH), the TPC at 0 h of incubation in the ME was 336 ± 30 mg GAE/100 g DW. During 24 h of incubation, it was observed that enzyme dosages, temperature, and pH, as well as their two-way interaction term with time significantly affected the total phenolic release (P-value < 0.001), with an exception for Rapidase concentration × time.

Effect of Enzyme Concentration. The total phenolic contents of AE (Figure 1A) and of ME (Figure 1B) after 24 h enzyme-assisted extraction at 40 °C and pH 4.0 of the cauliflower outer leaves were measured in response to the different concentrations of enzymes (Viscozyme L and Rapidase) used. The level of phenolic compounds in both extracts was significantly increased after 24 h of incubation as compared to the control incubation, when 0.1% Viscozyme L and 0.5% Rapidase were added. Viscozyme L resulted in a higher concentration of phenolic compounds in AE, ranging

from 429 ± 28 mg GAE/100 g DW at 0% E/S (control) to 614 ± 23 mg GAE/100 g DW at 0.5% E/S, with no further significant increase in TPC at higher enzyme concentrations (Figure 1A). Similar results were found for the ME, whereby the TPC in ME significantly increased to 650 ± 18 mg GAE/100 g DW at 0.2% E/S, without further significant improvement between 0.2% and 5% E/S (Figure 1B). The Rapidase treatment with 0.5% E/S resulted in a greater release of phenolic compounds, mainly in the ME and to a lesser extent in the AE, as compared to the control sample (Figure 1A,B), whereas an increased Rapidase concentration from 0.5% to 5% did not enhance the TPC in AE and ME, except for AE from sample treated with 5% Rapidase (Figure 1B). On the basis of the results of the different enzyme concentrations, it was chosen to work further with 0.2% Viscozyme L and 0.5% Rapidase.

Temperature. The influence of incubation temperature on the extraction of phenolic compounds from cauliflower outer leaves using 0.2% Viscozyme L or 0.5% Rapidase at a pH of 4 is given in Figure 1C and D. The treatments with Viscozyme L and Rapidase resulted in a significant improvement of TPC at all temperature points examined, ranging from 30 to 50 °C, as compared to the control (no enzyme) incubation, except for ME at 30 °C, where no difference between enzymatic treatment and control sample was found (Figure 1D). Although a trend toward a higher release of phenolic compounds with higher temperatures was observed in the ME, this was not observed in AE. The TPC in ME was significantly higher at 35 °C than at 30 °C for Viscozyme L and Rapidase treatment, whereas no further increase in total phenolic release between 35 to 50 °C was observed for both ME and AE. Even the TPC at 50 °C was lower than that at 40 °C with Viscozyme L treatment. Therefore, 35 °C was chosen as the optimal incubation temperature for both enzymes.

Effect of pH. During enzymatic treatment, the pH values were varied from 3 to 6 to investigate its effect on extraction

yields of total phenolic compounds (Figure 1E and F). The results obtained showed that the TPC did not significantly change in response to the difference in pH values during extraction for both AE and ME, within one enzymatic treatment.

3.2. Identification and Quantification of Phenolic Compounds. Using the optimal conditions for the enzyme treatment, the individual phenolic compounds released from the cauliflower outer leaves were identified and quantified. The shift in the phenolic profile during time of incubation and type of enzyme was studied.

Kinetics of the Release of TPC at Optimal Conditions. Selecting the optimal conditions obtained for enzyme treatment (0.2% Viscozyme L or 0.5% Rapidase, temperature 35 °C, and pH 4), we evaluated the effects of incubation time on the phenolic extraction from outer leaves of cauliflower (Figure 2). The TPC in ME of the control incubation remained stable. A significant increase in the TPC in the ME after enzyme treatment was observed, with a more than 100% increase after 12 h of incubation for the enzyme-treated incubations as compared to the control ones. The TPC of ME increased as a function of incubation time. No difference in TPC in the ME extract was observed between the two enzyme treatments. After 12 h of incubation, the TPC in the ME remained constant, and this trend was observed for both enzymes. The enzymatic treatments also caused significant effects on released phenolic compounds in AE after 30 h of incubation, increasing to 581 ± 16 mg GAE/100 g DW (with Viscozyme L) and to 604 ± 9 mg GAE/100 g DW (with Rapidase) as compared to 457 ± 23 mg GAE/100 g DW for the control without enzyme treatment.

Identification and Quantification of Individual Compounds by UPLC-DAD-HDMS-TOF-MS. The phenolic com-

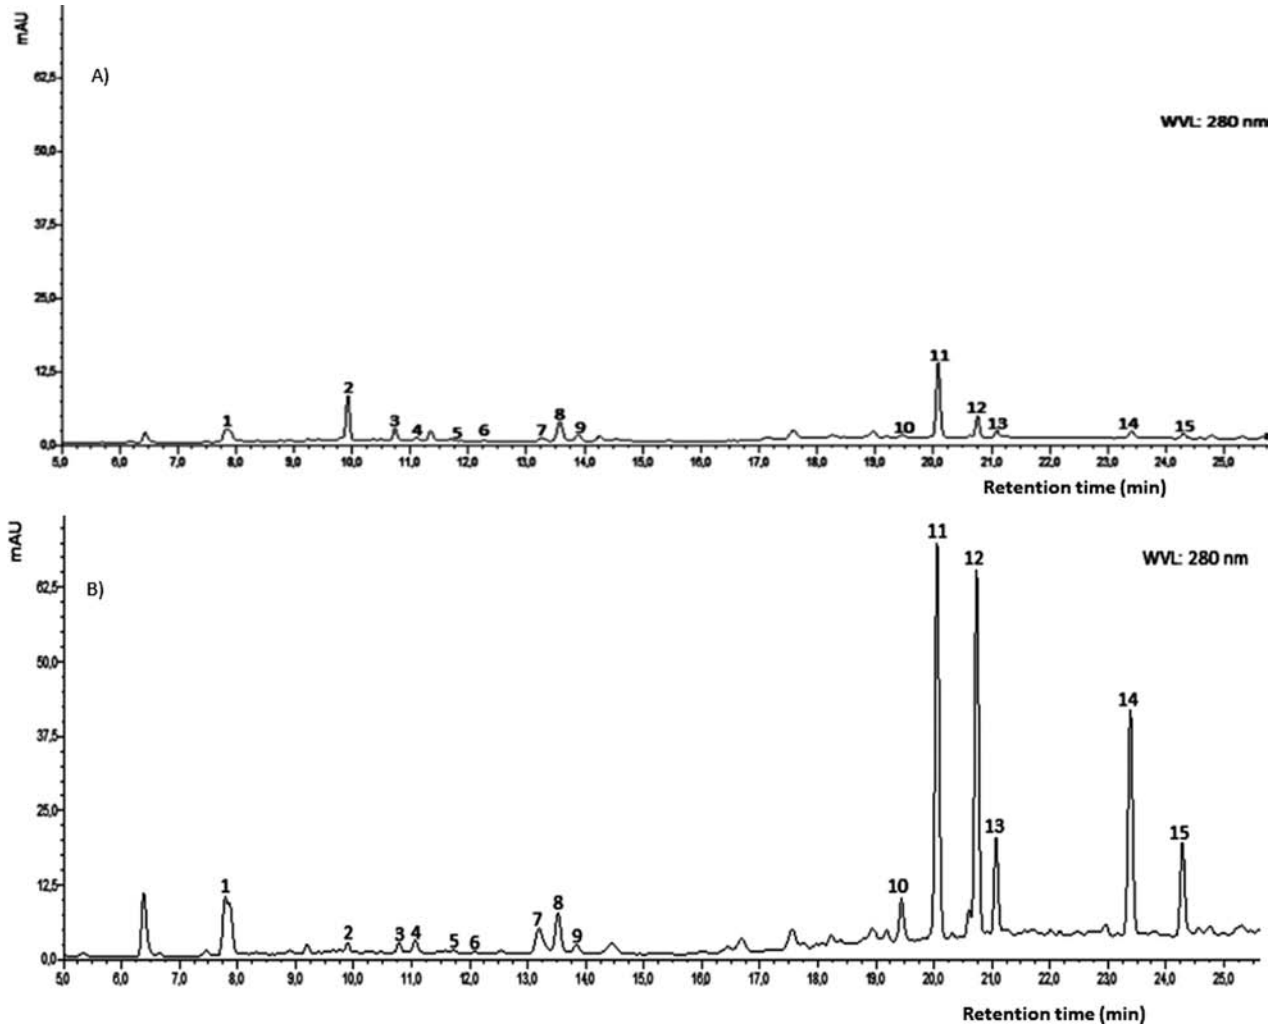

Figure 3. U(H)PLC profile of phenolic compounds from cauliflower byproduct extracts obtained by an incubation of 0 h (A) and 12 h (B) with Rapidase, recorded at 280 nm (see Table 1 for identification of peaks).

pounds in cauliflower outer leaves extracts were quantified by UPLC-DAD and identified by the UPLC-MS/MS method. As there was no interaction effect between treatment and time of incubation on the content of the individual phenolic compounds, results are presented for the main factors separately, that is, treatment and time of incubation in Tables 2 and 3, respectively.

As shown in Figure 3 and Table 1, 15 individual compounds were identified, of which three components in the extracts could not be identified by our protocol (unknown 1, 2, and 3). All individual phenolic compounds present in the extracts and identified by our analysis belonged to different derivatives of kaempferol. The results also indicated that the treatment with Rapidase did not enhance the amount of all identified compounds released as compared to the control with an exception for kaempferol-3-glucoside. In contrast, there was a clear increase in identified compounds by Viscozyme L treatment. The release of kaempferol-3-feruloyltriglucoside-7-glucoside (compound 8; 21.0 mg RE/100 g DW), kaempferol-3-feruloyldiglucoside (compound 12; 37.8 mg RE/100 g DW), and kaempferol-3-glucoside (compound 14; 58.4 mg RE/100 g DW) was sharply improved by Viscozyme L treatment, as compared to the control sample (9.0, 17.2, and 8.1 mg RE/100 g DW, respectively) (Table 1). As shown in Table 2, in general the release of the total phenolic compounds increased during time of incubation, although the increase was not significant. However, the amounts of individual components including kaempferol-3-feruloyldiglucoside (compound 12), kaempferol-3-coumaroyldiglucoside (compound 13), kaempferol-3-glucoside (compound 14), and kaempferol-*C*-feruloylglucoside/kaempferol-3-feruloylglucoside (compound 15) were significantly increased after 12 or 24 h of incubation in comparison with nontreatment samples (0 h).

The changes in profiles of phenolic compounds affected by different treatments were visualized by using PCA (Figure 4). The PC 1 (86.69%) described the distinct difference between the samples without adding enzymes (control-AE) and the samples treated by enzymes, which are mostly localized on the positive axis of PC1, except for control-ME. All of the phenolic components released were positively related to the Viscozyme L and Rapidase used. The PC2 (13.20%) can be expressed as a factor associated with the profile of individual compounds in ME, as compared to AE. The observation from the graph indicated that the high values of compounds 7, 8, 12, 13, 14, and 15 are associated with AE (cluster of Viscozyme-AE, Rapidase-AE), while the phenolic profile in ME exhibited higher content of compounds 2, 4, 5, 6, 9, and 11.

dx.doi.org/10.1021/jf502543c | *J. Agric. Food Chem.* 2014, 62, 7468−7476

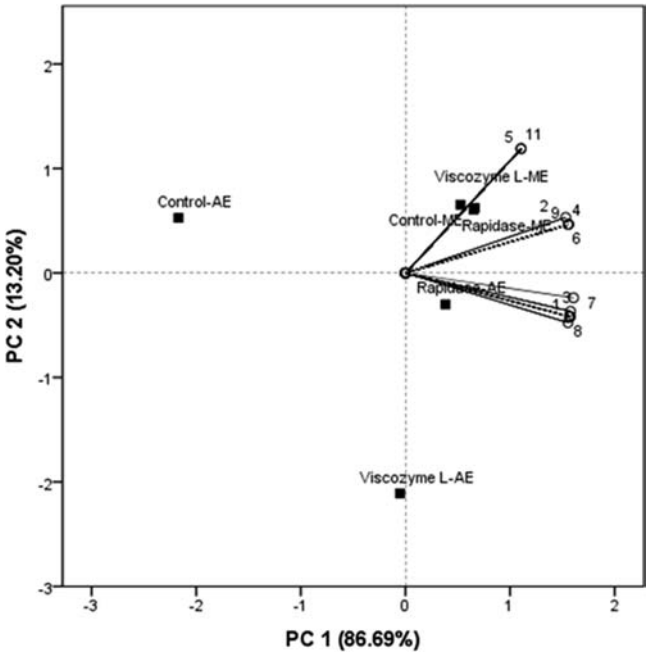

Figure 4. Principal component analysis of the individual phenolic compounds in AE and ME by different treatments (n = 3). The numbers in the PCA plot represent the different phenolic compounds as described in Table 1. Control-AE, aqueous extract obtained by an incubation of 30 h without enzyme; Viscozyme L-AE, aqueous extract obtained by an incubation of 30 h with Viscozyme L; Rapidase-AE, aqueous extract obtained by an incubation of 30 h with Rapidase; Control-ME, methanolic extract obtained by an incubation of 12 h without enzyme; Viscozyme L-ME, methanolic extract obtained by an incubation of 12 h with Viscozyme L; Rapidase-MA, methanolic extract obtained by an incubation of 12 h with Rapidase.

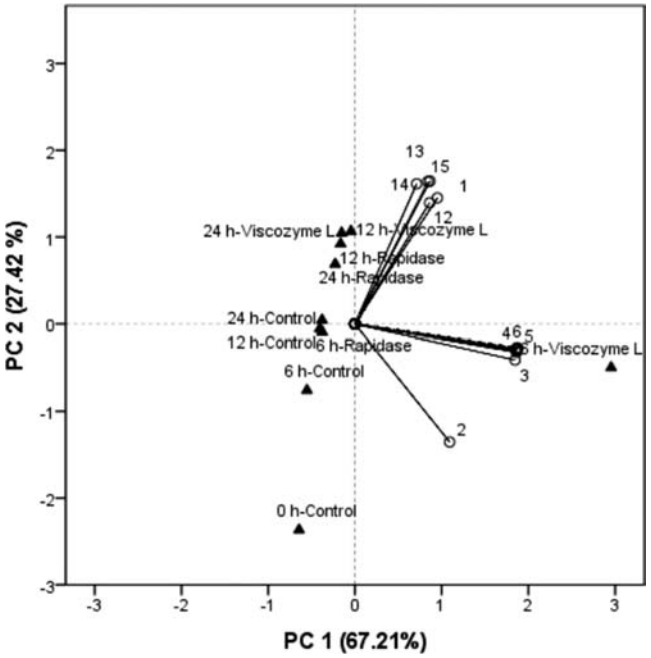

Figure 5. Principal component analysis of the individual phenolic compounds in ME from different time of treatments (n = 3). The numbers in the PCA plot represent the different phenolic compounds as described in Table 1. 0 h-Control, 6 h-Control, 12 h-Control, 24 h-Control represent methanolic extracts obtained by an incubation of 0, 6, 12, and 24 h without enzyme, respectively; 0 h-Viscozyme L, 6 h-Viscozyme L, 12 h-Viscozyme L, 24 h-Viscozyme L represent methanolic extracts obtained by an incubation of 0, 6, 12, and 24 h with Viscozyme L, respectively; 0 h-Rapidase, 6 h-Rapidase, 12 h-Rapidase, 24 h-Rapidase represent methanolic extracts obtained by an incubation of 0, 6, 12, and 24 h with Rapidase, respectively.

Figure 5 shows the effect of incubation time on the profile of phenolic release. Two PCs are responsible for 94.63% of the total variance of data. An incubation of 6 h with Viscozyme L was characterized for the high amount of compounds 2, 3, 4, 5, and 6, while the longer period of Viscozyme L and Rapidase treatments (12 h, 24 h) positively contributed to the high content of compounds 1, 12, 13, 14, and 15.

4. DISCUSSION

The enzyme-assisted extraction yield of phenolic compounds depends on multiple variables including type of enzyme and concentration, incubation temperature, pH, and incubation time. In this experiment, the optimization of Viscozyme L and Rapidase-assisted enzymatic pretreatment was studied on cauliflower outer leaves, with the focus on the identification of the released phenolic compounds. The significantly improved release of total phenolic compounds in both AE and ME for Viscozyme L (0.2%) and Rapidase (0.5%) treatment as compared to the control treatment clearly indicated that the hydrolysis of cell-wall components of cabbage improves the extraction yields of phenolic compounds. This observation could be explained by an increased degradation of the cell-wall structure as a result of the hydrolysis of cell-wall components, especially glycosidic bonds/linkages between phenolic compounds and cell-wall polysaccharides.[12,26] In addition, it is known that the permeability and porosity of plant cells increase by the breakdown of cell-wall polymers, improving the solubility of cell internal components, and in turn this results in an increase in concentration of phenolic compounds present in the extracts.[10,16] The treatments with higher enzyme doses did not increase the release of total phenolic compounds (p > 0.05), which could be due to competitive adsorption to the cell-wall polysaccharide when a higher enzyme concentration is applied. This leads to steric hindrance of binding positions of enzymes to the substrate, which negatively influences the breakdown of cell-wall components.[27,28] The lack of improvement at higher enzyme concentrations is in accordance with previous studies, for example, on black currant pomace,[27] or on unripened apples.[22]

The increased phenolic concentration in both AE and ME at all temperature incubations in comparison with the control sample demonstrates the importance of enzymatic catalysis to release phenolic compounds from cauliflower leaves. The significant enhancement of TPC in ME by treatments with 0.2% Viscozyme L and 0.5% Rapidase at higher temperature (35, 40, and 50 °C) could be caused by an increase of the hydrolysis activity and overall porosity of cell-wall structure, improving hydrolysis of the linkages between bound-phenolics and cell-wall compositions.[12,29] However, at 50 °C for Viscozyme L, there was a significant decrease in TPC in ME, as compared to 40 °C. This finding might be explained by a decreased activity of one of the enzymes in Viscozyme L, which is lower at 50 °C. Also, a possible loss of phenolic compounds has been observed due to thermal degradation,[26] which is mainly attributed to an increased oxidation.[30] This observation is consistent with results of Kapasakalidis et al.,[27] who reported a reduction of phenolic concentration by cellulase-assisted

dx.doi.org/10.1021/jf502543c | J. Agric. Food Chem. 2014, 62, 7468−7476

extraction at 50 °C as compared to 40 °C. As the different pH values tested did not affect the level of TPC in both AE and ME, it can be concluded that the commercial enzyme mixture has a broad pH activity range.

The kinetic study of phenolic release at optimal conditions (Figure 2) indicates that the TPC in ME greatly increased during the first 12 h of enzymatic treatment with the maximum level reached at 12 h of incubation. This finding can be attributed to the catalytic action of carbohydrate-cleaving enzymes[31] as a pretreatment process. It can also be concluded that an incubation of 12 h is sufficient for Viscozyme L and Rapidase to hydrolyze the substrate. The stable level of total phenolic content in ME between 12 and 30 h incubation can be attributed to deactivation, even inactivation, of cellulase, hemicellulase, and pectinase by bioactive inhibitors, such as phenolic compounds and lignin, released from the substrate.[32] Indeed, Berlin et al.[33] and Tejirian et al.[34] reported that phenolics, flavonoids, and polymeric lignin could strongly adsorb onto cellulase and pectinase, limiting the enzyme activity and/or precipitation of enzyme. Our results confirm the possibility of enzymes as an effective method to improve the yield of phenolic compounds released from waste material. However, it is also important to know if the enzyme treatment resulted in the release of specific phenolic compounds or in a change in their structure, as compared to the nonenzymatic treated outer leaves. As far as we know, the effect of enzymatic treatment on the release of individual phenolic compounds from vegetable waste material has not been reported before.

The LC−MS analysis revealed that the main components found in ME and AE from controls (no-enzyme treatment) were kaempferol glycosides. This indicates that most phenolic compounds, naturally produced by cauliflower plants, are present in conjugated form, as was also reported on cauliflower byproducts by Llorach et al.[35,36] and Gonzales et al.[37] Similar results were also observed after the enzymatic treatment with Viscozyme L and Rapidase, meaning that no aglycones were formed. This is probably due to the insufficiency or absence of β-glycosidase, which is known for its capacity of deglycosylation by hydrolyzing the β-1,4 glycosidic bonds in aryl and alkyl β-D-glucosides as well as glycosides containing disaccharides and oligosaccharides.[38,39] The presence of the β-glycosidase was not specified by the supplier for the enzyme mixtures used. Viscozyme L was more efficient in hydrolyzing the substrate to obtain higher amounts of kaempferol-3-feruloyldiglucoside (compound 12) and kaempferol-3-glucoside (compound 14). The large increase in kaempferol-3-feruloyldiglucoside (compound 12) can be the result of the deglycosylation of two glucose molecules from kaempferol-3-feruloyltriglucoside-7-glucoside (compound 8). The large increase of kaempferol-3-glucoside (compound 14) by both enzymatic treatments is probably the result of removing one glucose molecule from kaempferol-3-diglucoside (compound 11). These cleavages may be caused by the presence of cellobiase activity or other unknown enzymatic actions in the commercial enzymes Viscozyme L and Rapidase. However, a full characterization of these commercial enzyme mixtures and their activity is not available. This behavior has also been confirmed by the results on time of incubation in the profile of phenolic release. The longer the samples were treated, the lower was the concentration of compounds 2, 8, and the higher was the amount of compounds 11, 12, and 14. However, no difference in the individual components of AE was observed as a function of the treatment, although a substantial increase in TPC was measured by Folin−Ciocalteu assay for the enzymatic treatments as compared to the control. This apparent difference can be attributed to the reaction of Folin−Ciocalteau reagent with other interfering components such as protein, enzymes, sugars, as well as ascorbic acid present in AE.[24,27,40]

Although no phenolic aglycones were found in comparison with extract from native cauliflower byproduct, the study showed that the use of Viscozyme L or Rapidase enzyme mixture results in a higher yield of kaempferol-glucosides extracted from the cauliflower outer leaves. Further treatment with β-glycosidase, either with or without Viscozyme L or Rapidase, could result in the release of kaempferol as aglycone form, a flavonoid that is characterized by several bioactivities.[41,42]

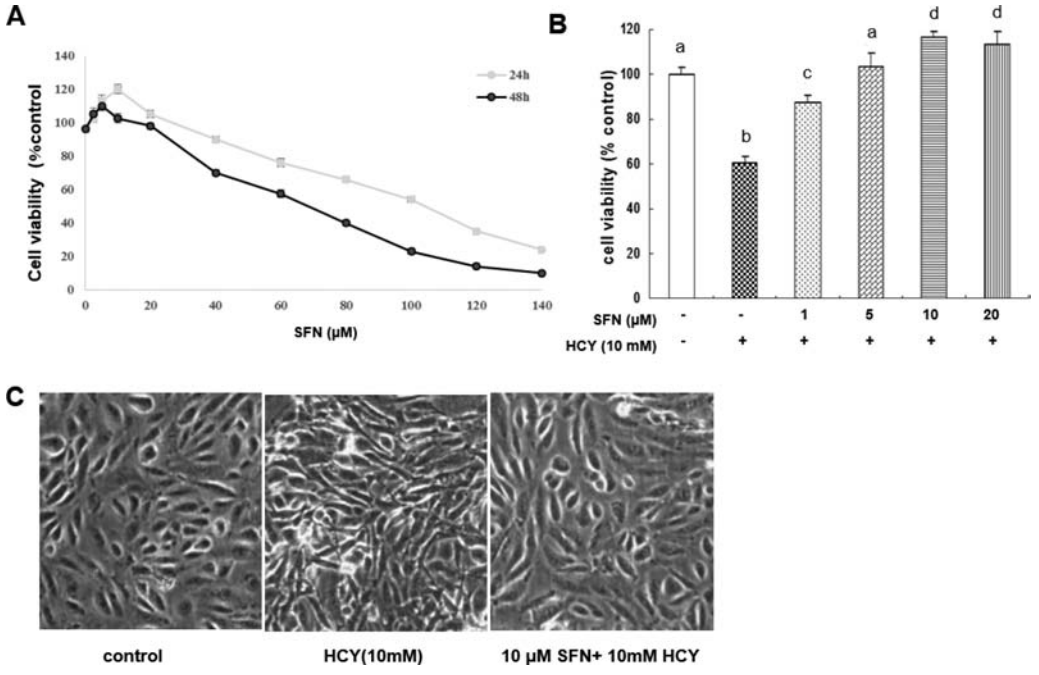

Figure 1. Dual-growth control and morphological improvement in HHL-5 cells by SFN. (A) Cells (10^4/well) were seeded in a 96-well plate and incubated with 1−140 μmol/L SFN for 24 and 48 h. (B) HHL-5 cells were preincubated with 1, 5, 10, and 20 μmol/L SFN for 24 h and then incubated with 10 mmol/L HCY for 24 h. The absorbance was measured by a microplate reader at 490 nm. Data are presented as the mean ± SD (n = 6). (C) Cells were grown in DMEM/F12 medium, 10 mmol/L HCY, or 10 μmol/L SFN plus 10 mmol/L HCY for 24 h. Cell morphological changes were observed under an inverted microscope (×100). Bars with no letters in common are significantly different ($p < 0.05$).

antioxidants and phase II enzymes.[18] Accordingly, impaired Nrf-2 signaling heightens ER stress response in the lungs of patients with chronic obstructive pulmonary disease.[19]

Given the potent antioxidant effects of SFN, it is of keen interest to determine whether SFN can protect against the HCY-induced injuries of which HCY is responsible for the mechanisms of numerous disorders. Our present results demonstrate that SFN improves both the ER swelling and reactive oxygen species (ROS) production by HCY. The underlining mechanism may be involved with enhancing phase II enzymes and reversing ER stress, all of which may be related to the activation of Nrf-2.

MATERIALS AND METHODS

Chemicals and Reagents. Sulforaphane (1-isothiocyanato-4-(methylsulfinyl) butane, SFN, purity ⩾98%) was purchased from LKT laboratories (St. Paul, MN), dissolved in dimethyl sulfoxide (DMSO) and stored as a stock solution of 100 mmol/L at −20 °C.[20] DL-homocysteine (purity ⩾ 95%), 2′,7′-dichlorofluorescin diacetate (H_2DCFDA), and 3-[4,5-dimethylthiazol-2-yl]-2, 5-diphenyl tetrazolium bromide (MTT) were obtained from Sigma (St. Louis, MO). Dulbecco's modified Eagle's medium−Ham's F-12 medium (DMEM-F12) and fetal bovine serum (FBS) were from Hyclone (Logan, UT). Antibodies against glucose-regulated protein-78 (GRP78), protein kinase RNA (PKR)-like ER kinase (PERK), phospho (p)-PERK, thioredoxin reductase-1 (TrxR-1), NAD(P)H:quinone oxidoreductase 1 (NQO1), Nrf-2, LaminB1, and β-actin were from Santa Cruz Biotechnology (Santa, CA). Other chemicals and solvents used were of the highest analytic grade. The nuclear extraction kit was purchased from Chemicon International (UK).

Cell Culture and Treatments. Immortalized human hepatocytes (defined as HHL-5) were kindly supplied by Professor Duncan McGeoch, Medical Research Council (MRC) Virology Unit, UK. Immortalized human hepatocytes HHL-5 were maintained in DMEM/F12 medium supplemented with 10% FBS, 2 mmol/L L-glutamine, 100 U/mL penicillin, and 100 μg/mL streptomycin in a humidified atmosphere of 5% CO_2 at 37 °C. SFN was dissolved in dimethyl sulfoxide (DMSO), with a final concentration in the medium was ⩽0.1% (v/v).[20]

DL-HCY was freshly prepared in serum-free medium and sterilized by 0.22 μm filtration. The range of DL-HCY concentrations was selected on the basis of other research[21] and our preliminary tests. HHL-5 cells were pretreated with 1−20 μmol/L SFN for 24 h (for dose course) or 20 μmol/L SFN for 6−48 h (for time course) followed by 10 mmol/L HCY for 6 h.

Cell Survival Assay. MTT assay was performed according to the manufacturer's protocol (Sigma) and our previous method.[22] Briefly, cells (1×10^4/well) were seeded in 96-well plates and grown to 80% confluence. Various concentrations of SFN or HCY were exposed to HHL-5 cells or vehicle for the desired time. Afterward, MTT (5 mg/mL in PBS) was added to each well and incubated at 37 °C for 4 h. Formazan crystals formed were dissolved by DMSO, and its optical density was measured with a microplate reader (Bio-Tek Instruments, Inc., USA) at 490 nm. Cell viability was calculated from the optical density readings, when vehicle-treated cells were taken as 100% viable. The experiment was repeated three times, and the IC_{50} value was calculated with the SPSS13.0 software.

Morphological Changes. HHL-5 cells were seeded in a 6-well plate and attached overnight. Then, the cells were grown in DMEM/F12 medium, 10 mmol/L HCY, or 10 μmol/L SFN with 10 mmol/L HCY for 24 h. Cell morphological changes were observed under an inverted microscope and photographed (Olympus Optical Co., Ltd., Japan).

Determination of ROS Generation. The membrane-permeable probe 2′,7′-dichlorofluorescin diacetate (H_2DCFDA) enters the cells and produces fluorescence after intracellular oxidation by ROS such as hydrogen peroxide (H_2O_2) and hydroxyl radical. Intracellular oxidant stress was monitored by changes in fluorescence intensity resulting from intracellular probe oxidation.[23] Following treatment, cells were incubated with 5 μmol/L DCFH-DA at 37 °C for 30 min in the dark and then rinsed with PBS three times. Intracellular ROS was imaged using an Olympus X70 fluorescence microscope with ultraviolet (UV)

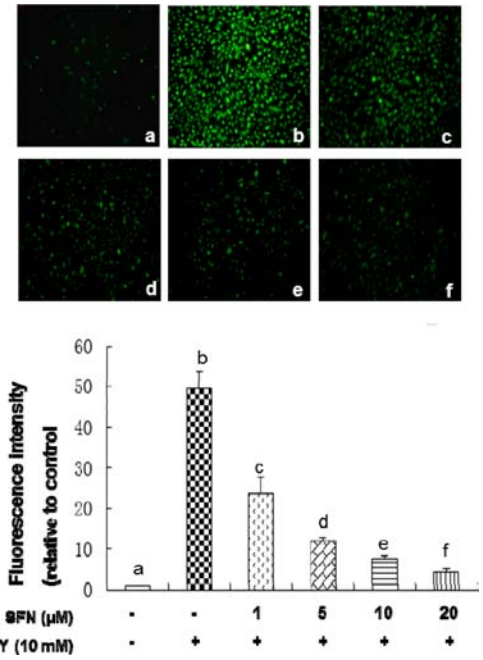

Figure 2. Protective effect of SFN on ROS production by HCY. HHL-5 cells were seeded in a 6-well plate and incubated with or without SFN (1−20 μmol/L) for 24 h, followed by exposure to 10 mmol/L HCY for 6 h. (Top) ROS fluorescence intensity was visualized using a confocal fluorescence microscope (×100). (a) Control; (b) HCY; (c) 1 μmol/L SFN + HCY; (d) 5 μmol/L SFN + HCY; (e) 10 μmol/L SFN + HCY; (f) 20 μmol/L SFN + HCY. (Bottom) The relative fluorescence densities of ROS were analyzed with image analysis software (ImageJ 1.45 s, USA) and standardized by the control. The data are representative of at least three independent experiments with a microscope (×100). Bars with no letters in common are significantly different ($p < 0.05$).

excitation at 300−500 nm. Fluorescence images were analyzed with image analysis software (ImageJ 1.45s, USA).[24]

Aminotransferases Activities Assays. Activities of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were measured in the culture medium.[25] Preincubated with various concentrations of SFN for 24 h or 20 μmol/L SFN for different times, the cells were then exposed to 10 mmol/L HCY for 6 h. After treatment, the supernatant medium was collected for ALT and AST activity measurement immediately using E-test kits (Biosino Biotechnology Company Ltd., via a Hitachi Automatic Analyzer (Hitachi, Inc., Japan)). All procedures were performed according to the manufacturer's instructions.

Determination of Malondialdehyde (MDA). Lipid peroxidation was determined by measuring the level of MDA.[26] The concentration of protein was determined by the method of Bradford. The MDA content in cell lysates was spectrophotometrically measured by using thiobarbituric acid-reacting substance (TBARS) production at 532 nm, according to the manufacturer's instruction from Jiancheng Bioengineering Institute (Nanjing, China). The results were expressed as nmol MDA produced per mg protein.

Transmission Electron Microscope Examination of ER. Transmission electron microscopy was performed on HHL-5 cells pretreated with 10 μmol/L SFN for 24 h and then replaced with 10 mmol/L HCY for 6 h. Transmission electron microscopy of cells was done as described previously.[27] Briefly, samples were fixed with 3% glutaraldehyde dissolved in 0.1 mol/L sodium cacodylate, postfixed in osmium tetroxide, dehydrated with graded acetone series, and finally embedded in Epon. Ultrathin sections were stained with uranyl acetate and lead citrate, examined in a JEM 1220 transmission electron microscope operated at 80 kV.

Preparation of Cell Lysates and Western Blotting. After various treatments, cells were washed twice with ice-cold PBS and subjected to whole cell lysis buffer [50 mmol/L Tris-HCl (pH 7.4), 150 mmol/L NaCl, 2 mmol/L EDTA, 10% glycerol, 1% Nonidet P-40 containing 0.1 mol/L PMSF, and 1× protease inhibitor cocktail (Sigma)] for 30 min on ice. After centrifugation at 16,000g for 10 min at 4 °C, the supernatants were collected for Western blot analysis. Equal amounts of protein (40−60 μg) were separated on 8% to 10% SDS−PAGE and transferred to polyvinylidene difluoride (PVDF) membranes (Millipore, Bedford, MA). The membrane was blocked with 5% nonfat milk for 30 min at room temperature and were then incubated at 4 °C overnight with the following primary antibodies: NQO1, TrxR-1, GRP78, PERK, P-PERK, Nrf-2, LaminB1, and β-actin. The membrane was then incubated with the secondary alkaline phosphatase-conjugated IgG and detected with Western Blue Stabilized Substrate for alkaline phosphatase (Promega). The relative densities of the individual bands were analyzed densitometrically using the ChemiImager 4000 instrument (Alpha Innotech, USA).

Nuclear Extraction. Nuclear protein extraction was regularly performed as previously described.[28] After SFN treatments, cells were harvested and washed with phosphate-buffered saline (PBS). Nuclear and cytoplasmic extractions were isolated using Chemicon Nuclear Extraction Kit. Then, each pellet was suspended in cell lysis buffer containing 1% Nonidet P-40, 50 mmol/L Tris (pH 7.4), 150 mM NaCl, 1 mmol/L PMSF, and 1× protease inhibitor cocktail, then incubated on ice for 30 min. Lysates were centrifuged at 10,000g for 10 min at 4 °C, and the supernatant was used for Western blot analysis.

Statistical Analysis. All results shown are representative of at least three independent experiments. Data are presented as the mean ± SD. Statistical analysis was performed by one-way ANOVA, followed by Dunnett's test and SNK test using the SPSS 13.0 software. Probability values of <0.05 were considered to be statistically significant.

RESULTS

Cell Proliferation and Morphology of HHL-5 Pretreated with SFN. Cells were treated with 1−140 μmol/L SFN in six replicate wells for 24 or 48 h. Dual regulation of cell growth by SFN was observed (Figure 1A). Lower doses of SFN ($\leqslant$20 μmol/L) promoted the proliferation of HHL-5 cells. At the dose of 10 μmol/L, for instance, cell viabilities were even achieved to 120 ± 2.3% (24 h) and 108 ± 2.6% (48 h). The IC_{50} values were 106.3 ± 2.6 μmol/L (24 h) and 60.9 ± 1.5 μmol/L (48 h). Therefore, the range of SFN concentrations (1−20 μmol/L) was selected for the following experiments.

To confirm whether SFN presents the protective effects on HHL-5 cells against HCY, the MTT assay and morphological examination were performed. As shown in Figure 1B, after challenging with 10 mmol/L HCY for 24 h, the cell viability significantly declined to 60.4 ± 3.1%. However, preincubation with SFN (1−20 μmol/L) for 24 h before HCY exposure cell viabilities were increased to 87.7 ± 2.9%, 103.7 ± 5.7%, 116.3 ± 2.8%, and 113.4 ± 5.5%. The statistical analysis showed that significant differences in any two groups among 1 μmol/L, 5 μmol/L, 10 μmol/L, and 20 μmol/L SFN except for the two groups between 10 μmol/L and 20 μmol/L SFN ($p < 0.05$).

Under light microscopy, cells in the control group appeared spindle-shaped (Figure 1C). When exposed to 10 mmol/L HCY for 24 h, a large number of cells displayed morphological changes such as shrinkage, rounding up, floating, or death. However, upon preincubation with 10 μmol/L SFN for 24 h the injured cells became narrower and had clear cell boundaries. Apparently, SFN enables the improvement of the morphological defect of HHL-5 cells injured by HCY.

Protective Effect of SFN on Oxidative Injury by HCY in HHL-5 Cells. Oxidative stress due to excessive production of

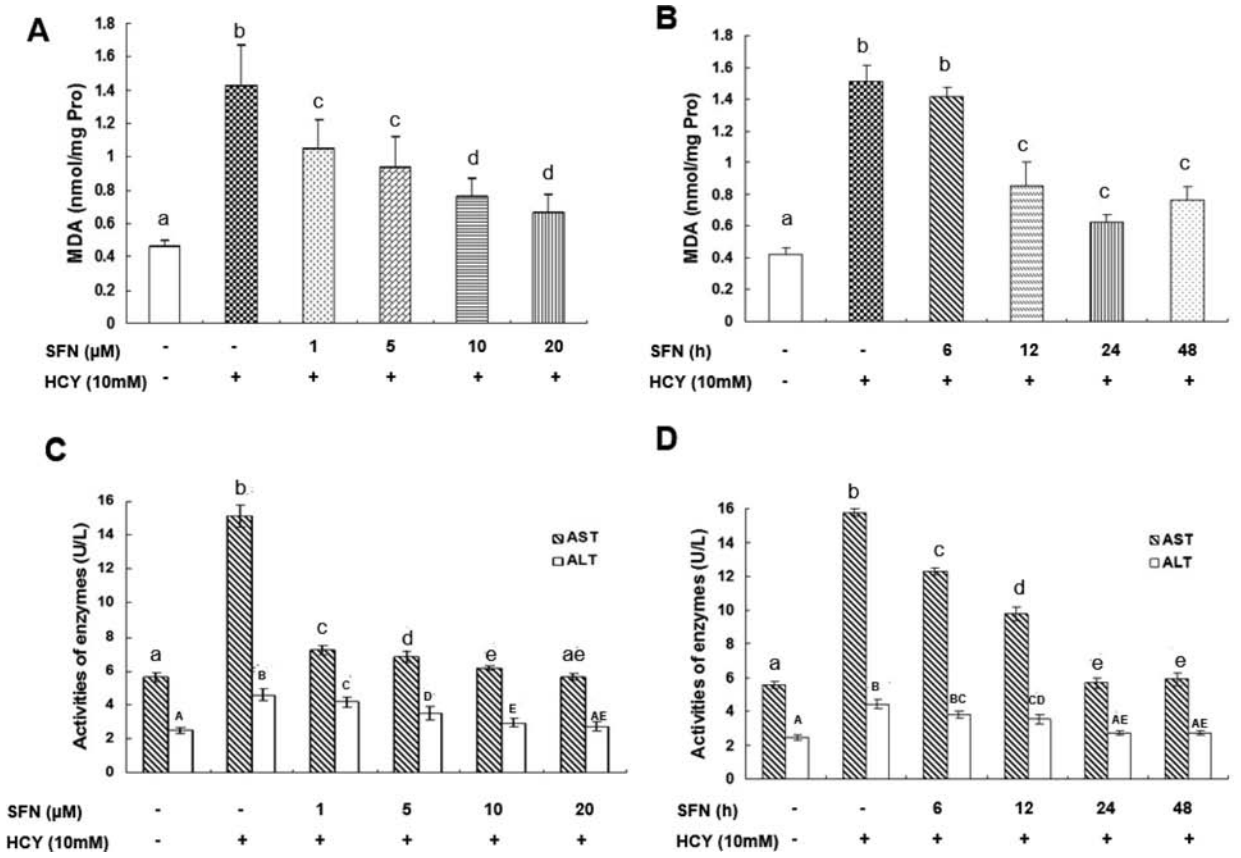

Figure 3. Protective effect of SFN on oxidative damage by HCY. Cells were pretreated with graded concentrations of SFN for 24 h (A and C) or 20 μmol/L SFN for 6−48 h (B and D), then exposed to 10 mmol/L HCY for 6 h. The supernatant was collected for quantifying the contents of MDA and activities of AST and ALT. All results represent the mean values ± SD from three independent experiments. Bars with no letters in common are significantly different ($p < 0.05$).

ROS has been suggested as one of the important mechanisms for HCY-induced injury.[29] After incubation with HCY (10 mmol/L) for 1 h, intracellular ROS was significantly enhanced (Figure 2b), whereas these fluorescent signals were rarely detected in nontreated cells (Figure 2a). Treatment of the cells with SFN (1−20 μmol/L) for 24 h prior to HCY exposure effectively nullified ROS accumulation (Figure 2c−f). Compared to the HCY group (Figure 2b), the lowest dose of SFN (1 mmol/L) significantly decreased the fluorescence intensity (Figure 2c and bottom panel), while higher SFN entirely abolished ROS generation (Figure 2d−f and bottom panel). Statistical analysis showed the significant differences in any two groups among 1 μmol/L SFN, 5 μmol/L SFN, 10 μmol/L SFN, 20 μmol/L SFN, and HCY group ($p < 0.05$). These results indicated that SFN could antagonize HCY-induced oxidative stress.

MDA, an indicator of lipid peroxidation, was drastically elevated after 6 h of incubation with HCY (10 mmol/L) by more than 3-fold as compared with the control, which indicated that the cells had suffered severe oxidative stress conditions (Figure 3A−B). The results in Figure 3A showed that preincubation with 1−20 μmol/L SFN decreased the enhanced levels of MDA by 45−75% significantly ($p < 0.05$). Similarly, the increased levels of MDA by HCY were reduced significantly by 43−65% after pretreatment with 20 μmol/L SFN by 6−48 h (Figure 3B, $p < 0.05$). To confirm the hepato-protective effects of SFN on HHL-5 cells against HCY, the enzymatic activities of ALT and AST in the medium were tested. Compared to the control group, HCY increased the AST and ALT activities by 3-fold and 2-fold, respectively (Figure 3C and D). The lowest dose of SFN (1 μmol/L) significantly inhibited the enhanced AST activity by HCY by 1.7-fold. The activity of ALT was noticeably decreased by 5−20 μmol/L SFN (Figure 3C). After pretreatment with 20 μmol/L SFN for 6−48 h, the increased activities of AST and ALT were decreased to 37%−77% and 62%−86%, respectively (Figure 3D, $p < 0.05$).

Phase II Enzymes Were Involved in the Protection of SFN against HCY Injury. After treatment with 10 mmol/L HCY for 6 h, both NQO1 and TrxR-1 were decreased almost to half of the control (Figure 4). SFN ameliorated the decreasing expression of TrxR-1 and NQO1 in a dose- and time-course. Compared to the HCY group, preincubation with 1−20 μmol/L SFN increased the levels of TrxR-1 by 1.68- to 4.31-fold (Figure 4A, $p < 0.05$) and of NQO1 by 1.5-fold to 2.9-fold (Figure 4B, $p < 0.05$). TrxR-1 showed a time-dependent manner until 48 h, whereas NQO1 reached a plateau at 24 h. Preincubation with 20 μmol/L SFN for 6−48 h increased the levels of TrxR-1 by 2.7-fold to 5-fold (Figure 4C, compare with HCY, $p < 0.05$) and increased the levels of NQO1 by 2.7-fold to 3-fold (Figure 4D, compare with HCY, $p < 0.05$).

SFN Minimizes the Injuries of the ER and Abrogates the Aberrant Expression of GRP78 and PERK Protein by HCY. According to the results in Figure 5, HCY (10 mmol/L) treatment severely damaged the structure of ER with visible swelling; conversely, pretreatment with SFN significantly improved ER dilation. To obtain further evidence for ER

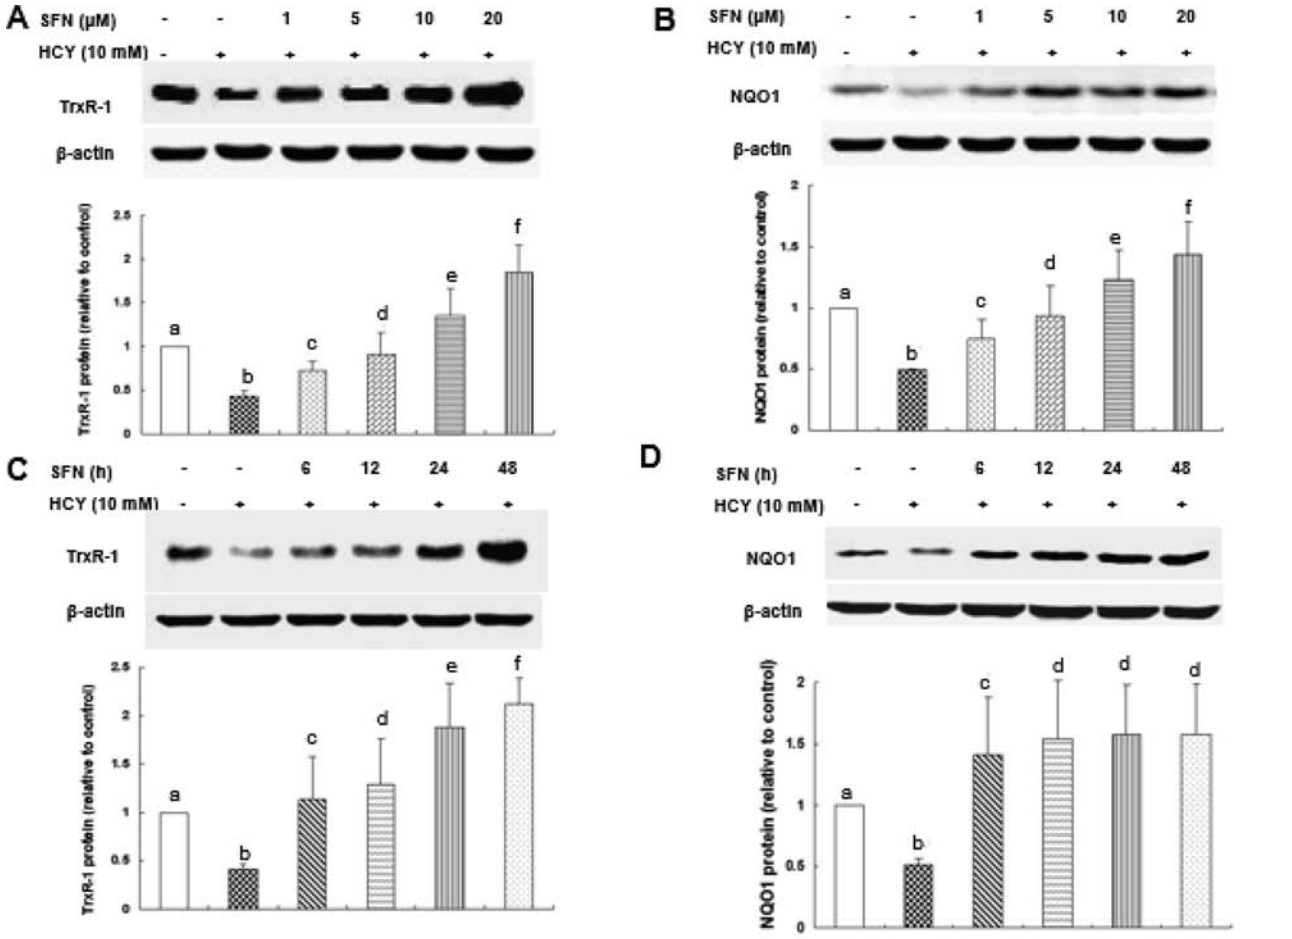

Figure 4. SFN enhanced the expressions of TrxR-1 and NQO1 weakened by HCY. Cells were pretreated with 1−20 μmol/L SFN for 24 h (A and B) or treated with 20 μM SFN for the indicated times (C and D), then followed with 10 mmol/L HCY for 6 h. Cytosolic protein was isolated and subjected to Western blot analysis. The relative densities of the target proteins were scanned with a ChemiImager 4000 digital system (Alpha Innotech Corporation, USA) and standardized by the control (β-actin). The data are representative of at least three independent experiments. Bars with no letters in common are significantly different ($p < 0.05$).

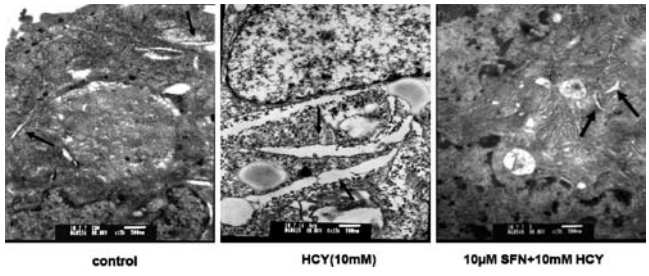

Figure 5. SFN improved ER dilation caused by HCY in HHL-5 cells. Cells were pretreated without or with 10 μmol/L SFN for 24 h then eventually with 10 mmol/L HCY for 6 h. After a series of washing, dehydration, and staining, cells were visualized for the structure of the ER with electron microscopy. Arrows refer to the individual ER in the cells. The data are representative of at least three independent experiments.

stress, we investigated the expressions of ER stress specific proteins. GRP78, an ER molecular chaperone serving as a central regulator of ER stress, was up-regulated by 10 mmol/L HCY with 2.5-fold of the control. SFN abrogated GRP78 up-regulation caused by HCY (Figure 6A and C). PERK, an ER resident sensor associating with GRP78 in the absence of ER stress, was investigated. PERK phosphorylation was strongly increased by HCY with 6.5-fold of the control, while it was strikingly abolished by preincubation with SFN (Figure 6B and D). Compared with the HCY group, preincubation with 1−20 μmol/L SFN for 24 h decreased the levels of GRP78 by 38% to 69% (Figure 6A, $p < 0.05$) and of p-PERK by 30% to 47% (Figure 6B, $p < 0.05$). Similarly, preincubation with 20 μmol/L SFN for 6−48 h decreased the levels of GRP78 by 45% to 73% (Figure 6C, $p < 0.05$) and of p-PERK by 30% to 70% (Figure 6D, $p < 0.05$).

Effect of SFN on Nrf-2 Translocation to the Nucleus. Nrf-2 regulates many of the antioxidant and phase II detoxifying enzymes, including TrxR-1 and NQO1.[30,31] The nuclear protein was extracted to test the translocation of Nrf-2 into the nucleus, and LaminB1 was chosen as the internal control instead of β-actin.[32,33] As shown in Figure 7, the expression of p-Nrf-2 was decreased to nearly 85% after treatment with HCY (Figure7A and B). Pretreatment with SFN abolished the inhibition of p-Nrf-2 by HCY, and phosphorylation of Nrf-2 (p-Nrf-2) in the nucleus was no longer decreased by HCY but increased by 3−4-fold after preincubation with SFN (Figure 7A and B).

DISCUSSION

The present findings show that SFN presents its protective effects on hepatic injury caused by HCY in immortalized

dx.doi.org/10.1021/jf501944u | J. Agric. Food Chem. 2014, 62, 7477−7485

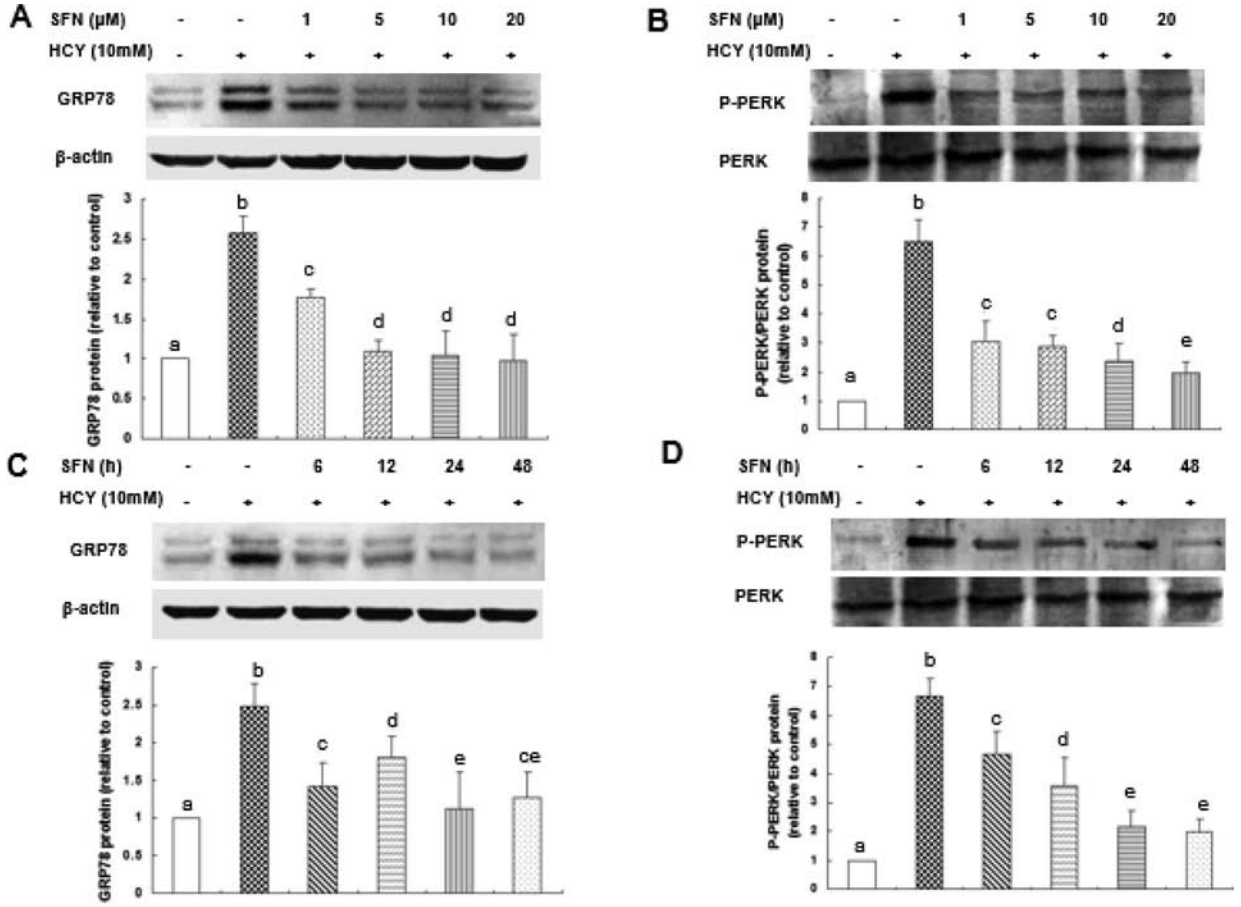

Figure 6. SFN inhibited the expression of GRP78 and phosphorylation of PERK induced by HCY in HHL-5 cells. Cells were preincubated with 1, 5, 10, and 20 μmol/L SFN for 24 h (A and B) or 20 μmol/L SFN for 6, 12, 24, and 48 h (C and D), then treated with 10 mmol/L HCY for 6 h. Protein was isolated and subjected to Western blot analysis. The relative densities of the target proteins were scanned with a ChemiImager 4000 digital system and standardized by a control. Data were from three independent experiments. Bars with no letters in common are significantly different ($p < 0.05$).

human hepatocyte line HHL-5 through inducing antioxidant enzymes and reducing ER stress. Furthermore, the results suggest that Nrf-2 activation might be a key factor in attenuating oxidative damage caused by HCY. On the basis of these findings, our results have strongly implied the potential roles of SFN in the prevention of HHCY-related disorders.

It is well established that Nrf-2 protects against oxidative stress-mediated damage to cells through activating the basic zipper (bZIP) transcription factor and binding to ARE-dependent gene expression.[34,35] Nrf-2 activator attenuated the histological injury induced by α-naphthylisothiocynate (ANIT) in mice.[36] Chemicals and drugs have been shown to reduce oxidative stress through activating the Nrf-2 regulatory pathway, which indicates a hepatoprotective role of Nrf-2 activation against various liver diseases.[37,38] Our previous research also demonstrated that SFN exhibited its potential in the prevention of human bladder cancer by targeting Nrf-2 activation.[39]

ER stress plays a pathogenic role in a variety of diseases, including Alzheimer's, Parkinson's diseases, cancer, cardiac and cerebral ischemia/reperfusion injury, diabetes, and atherosclerosis.[36,37,40,41] Chemicals that function through the ER stress pathways have been proved to be effective, building enthusiasm for the therapeutic potentials of ER stress response augmentation. For instance, *trans*-4,5-dihydroxy-1,2-dithiane (DTTox) stimulated an increase in GRP78 expression and protected the proximal tubular epithelium against a nephrotoxic chemical.[42]

To date, few studies have implicated the underlining relationship between Nrf-2 and ER stress regulation. Unfolded protein response (UPR), a well-conserved intracellular signaling invoked by ER stress, modulates the oxidative stress-inducible Nrf-2 pathway or the hypoxia-inducible factor (HIF) pathway to enhance the expression of the target genes, which support cell survival. Importantly, the accumulation of intracellular ROS caused by ER stress is attenuated by the double-stranded RNA-activated PERK pathway of UPR, which simultaneously activates oxidative stress-inducible transcription factor Nrf-2 and maintains redox homeostasis, thereby ensuring cell survival.[43] In the present findings, the expression of p-Nrf-2 was decreased to 85% by HCY treatment compared with that of the control group ($p = 0.052$). These results showed that, to some extent, HCY attenuated the phosphorylation of Nrf2, although no significant difference was observed. As far as we know, a few of the mechanisms were involved in HCY-stressed cells. Apart from oxidative injury, the inflammatory signal also takes the predominant role.[44] Moreover, NF-κB has been reported to be an important target of HCY.[45,46] Our previous studies have confirmed that NF-κB is a targeting transcription factor controlled by SFN.[28] Therefore, we postulate that Nrf-2 plays a part in the effect. During the early phase of ER stress,

dx.doi.org/10.1021/jf501944u | J. Agric. Food Chem. 2014, 62, 7477−7485

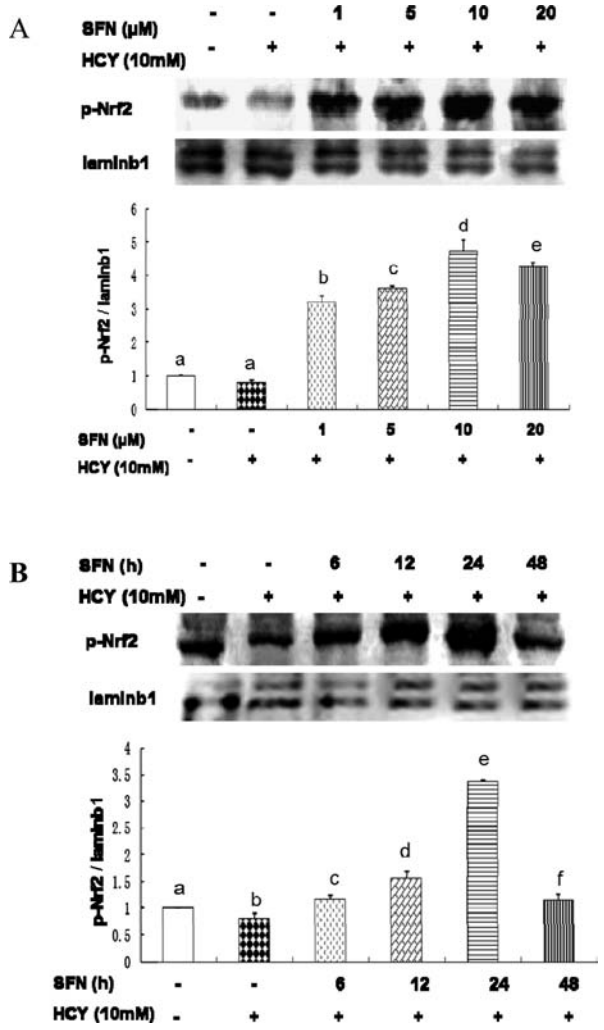

Figure 7. SFN activated Nrf-2 translocation into the nucleus. Cells were preincubated with 1, 5, 10, and 20 μM SFN for 24 h (A) or 20 μM SFN for 6, 12, 24, and 48 h (B), then treated with 10 mM HCY for 6 h. Protein was isolated and subjected to Western blot analysis. The relative densities of the target proteins were scanned with a ChemiImager 4000 digital system and standardized by a control. Data were from three independent experiments. Bars with no letters in common are significantly different ($p < 0.05$).

PERK activation may be beneficial for the cell's self-defenses.[47,48] However, continuous activation of PERK was phosphorylated by the initiation of apoptosis signaling and/or abnormal redox state and will lead to the cell injury and even death.[49−51] As shown in the present findings, the translocation of Nrf-2 was activated by SFN (Figure 7), accompanied by the lower phosphorylates of PERK (Figure 6), which suggested the potential regulation of PERK phosphorylation through Nrf-2 signaling. It should be noted that Nrf-2 activation plays a vital role in UPR activation and functions like an effector of PERK cell survival signaling during the process of ER stress.[43] Therefore, more studies should be done to expose their relationships. Taken together, SFN prevents oxidative injury induced by HCY through attenuating ER stress and initiating Nrf-2 translocation and subsequently enhancing the expressions of TrxR-1 and NQO1 in the immortalized human hepatocyte line HHL-5 (Figure 8). These findings suggest that SFN may be a powerful agent for relieving liver injury caused by HCY.

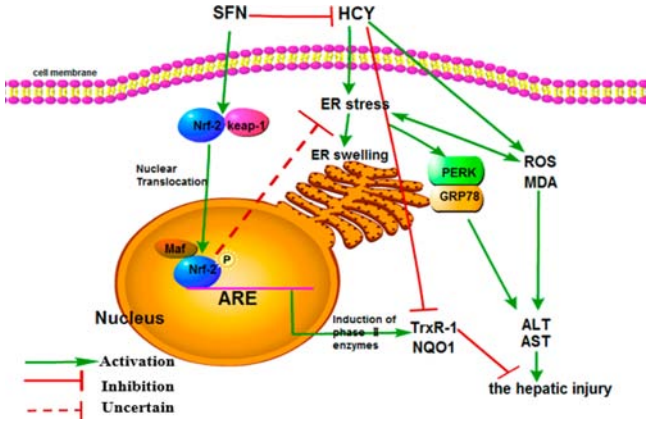

Figure 8. A proposed mechanism of SFN protect the oxidative injury-induced by HCY in immortalized human hepatocyte line HHL-5. SFN improved the oxidative injuries that were caused by HCY in immortalized human hepatocyte line HHL-5, such as ER swelling, excessive ROS generation, increased MDA levels, and increased activities of ALT and AST. The hepatoprotective effect of SFN was through attenuating the ER stress and inducing Nrf-2/phase II enzymes in immortalized human hepatocyte line HHL-5.

strain culture; yeast encapsulation requires special technology that can be difficult to use; and the flocculation yeast must be recycled, resulting in high power consumption and a complex process. *A. nidulans* does not have the ability to convert xylose into ethanol, and its ethanol productivity is lower than that of *S. cerevisiae* with regard to glucose utilization.[19] Hence, microbial and in situ detoxification technology should be further investigated as an inexpensive and convenient alternative.

A modified method is proposed in this study. Rice straw was first pretreated by SE or BSE, and then the exploded rice straw was immediately fermented without the separate detoxification procedure. The proposed technology includes detoxification, saccharification, and fermentation as a single step, and the exploded material is gradually added into the fermented mash to overcome the inhibitors, which has not been previously performed. After optimizing the simultaneous saccharification and cofermentation (SSCF) of detoxified material, the SSCF of non-detoxified material was investigated to determine the possibility of omitting the advance detoxification and strain pre-adaptation steps. A 10 L fermenter was employed because of its larger scale, better accuracy, and practical application.

MATERIALS AND METHODS

Materials. Dried rice straw was obtained from a rural area (Meisan, Sichuan, China). The dried rice straw was sheared into 2 mm long straw pieces that were stored at room temperature and used as feedstock for the explosions. The compositions of the rice straw, the SE rice straw, and the BSE rice straw are listed in Table 1.

Table 1. Compositions of the Different Rice Straws (%, w/w)[a]

component	rice straw	SE[b] rice straw	BSE[c] rice straw
crude protein	4.7 ± 0.3	1.8 ± 0.2	3.2 ± 0.3
crude fat	1.4 ± 0.3	0.8 ± 0.4	1.1 ± 0.3
ash	18.1 ± 0.5	19.3 ± 0.5	18.8 ± 0.6
moisture content (% total)	9.8 ± 0.4	21.3 ± 0.6	47.8 ± 1.4
lignin	19.3 ± 0.5	17.2 ± 0.3	18.5 ± 0.5
starch	4.9 ± 0.4	0.6 ± 0.3	1.9 ± 0.3
hemicellulose	21.9 ± 0.5	14.8 ± 0.6	17.7 ± 0.6
cellulose	33.6 ± 0.8	34.7 ± 0.9	36.2 ± 0.7
glucose[d]	36.6 ± 0.6	31.4 ± 0.5	34.6 ± 0.8
xylose[d]	24.1 ± 0.4	18.7 ± 0.3	21.3 ± 0.4
total sugar[d]	67.3 ± 1.1	55.1 ± 1.2	61.8 ± 1.0

[a]All values are reported as a % dry basis except when otherwise noted. [b]SE, steam explosion. [c]BSE, butanone solution explosion. [d]The glucose, xylose, and total sugar contents were determined from the material hydrolysate, which was prepared using concentrated acid hydrolysis, as recommended by the National Renewable Energy Laboratory of Biomass Analysis Technology (NREL BAT).

The enzyme activities per milligram of protein of cellulase, xylanase, and β-glucosidase, purchased from commercial corporations (Sigma products agented by Gensheng Biology Technology Co. Ltd., Shang Hai, China), were 2.76 filter paper activity units (FPU), 45 units units of xylanase activity, and 0.55 cellobiose units (CBU), respectively. The filter paper activity and β-glucosidase activity were determined according to standard International Union of Pure and Applied Chemistry (IUPAC) procedures.[20] One FPU is defined as the amount of enzyme able to release 1 μmol of glucose equivalents from Whatman no. 1 filter paper per minute. One CBU in international units (IU) is defined as the amount of enzyme that converts 1 μmol of cellobiose to 2 μmol of glucose per minute. Xylanase activity was assayed by using Chinese standard GB/T23874-2009. One unit (1 U) of xylanase activity is defined as the enzymatic loading that releases 1 μmol of reducing sugar from a 5 mg/mL xylan solution per minute at 37 °C and pH 5.5. The total protein was measured using a Bio-Rad Protein Assay, and bovine serum albumin was used as the standard.

Butanone, $(NH_4)_2SO_4$, and H_2SO_4 were analytically pure.

Explosion and Detoxification. The conditions of the BSE were as follows:[4] butanone concentration, 0.9 mol/L; explosive pressure, 3.1 MPa (170 °C); residence time, 7 min; and rice straw dry matter-to-water ratio, 1:3 (w/w). Following the explosion, the feedstock was stored in the explosion machine for 2 h, using the residual heat to evaporate the butanone. The conditions for the SE were as follows: pressure, 3.7 MPa (245 °C); residence time, 3 min; and water content of the rice straw, 5.5% (w/w, as will be used throughout this paper). The exploded rice straws were stored and used as feedstocks for in situ detoxification and SSCF.

To produce the detoxified feedstocks for SSCF comparison, the SE rice straw was detoxified by washing until the 65 °C deionized water was colorless,[5] and the BSE rice straw was detoxified by drying at 90 °C for 8 h.[4] The water contents of the detoxified feedstocks were 73.4 ± 2.4% after washing and 18.6 ± 0.6% after drying.

Optimized SSCF Technology of Detoxified Feedstocks. On the basis of a previous study,[21] we set up an optimized SSCF technology for the detoxified feedstocks using the following procedures. The detoxified BSE rice straw (860 g) or 2500 g of detoxified SE rice straw was mixed with a 0.05 mol/L citrate buffer solution, and the resulting dry matter content was adjusted to 10% in a 10 L ventilated fermenter (model SFY-C-10L, Zhengjiang Jianggong Bioengineering Equipment Co., Ltd., China). After the pH of the mixture was adjusted to 5.0 with 0.1 mol/L H_2SO_4 followed by sterilization at 100 °C for 35 min, the slurry was cooled to 50 °C, and the mixed enzymes were added, using cellulase of 12 FPU/g dry matter, β-glucosidase of 5 IU/g dry matter, and xylanase of 10 U/g dry matter. The mixture was maintained at 50 °C and 180 rpm for 25 h (BSE rice straw) or 27 h (SE rice straw), and then the first *S. cerevisiae* fermentation of the SSCF was initiated at 37 °C by transferring 8% inoculum into the culture. The fermentation was performed at 37 °C for 34 h. The temperature of the fermented mash was subsequently adjusted to 35 °C,[22] and the *C. shehatae* starter was then inoculated into the fermented mash at an inoculum concentration of 8%. The second or mixed fermentation was performed at 35 °C and 0.3 L/(min·L) of air volume for 144 h (BSE rice straw) or for 147 h (SE rice straw).

Studying the SSCF Technology of the Non-detoxified Feedstocks. The SSCF of the non-detoxified feedstocks was designed and investigated according to the amounts of materials used in the previously optimized SSCF. The water contents differed between the non-detoxified materials (Table 1) and the detoxified materials. Therefore, to maintain the same level of total dry matter as in the fermentation of the detoxified feedstocks, 1341 g of non-detoxified BSE rice straw or 845 g of non-detoxified SE rice straw was used as the total amount. Part of the exploded rice straw, $(NH_4)_2SO_4$, and citrate buffer solution (containing all of the water and part of the citrate from the 0.05 mol/L citrate buffer solution used in the optimized SSCF of the detoxified feedstocks) were blended into the 10 L ventilated fermenter. The pH of the mixed slurry was adjusted to 5.0 by adding 0.1 mol/L H_2SO_4. After the mixed slurries were sterilized at 100 °C for 35 min and then cooled to 35 °C, all three enzymes and all of the *S. cerevisiae* and *C. shehatae* starters were added to the slurries (the amounts were the same as those used in the detoxified feedstock fermentation). The mixed fermentation was performed at 35 °C and 0.3 L/(min·L) of air volume, as in the optimized SSCF of detoxified feedstocks. An added feedstock was then gradually introduced into the mash. Here, the rest of the non-detoxified and exploded rice straw, 0.1 mol/L H_2SO_4, citrate (based on the optimized SSCF technology), and $(NH_4)_2SO_4$ were blended and used as the added feedstocks, which was sterilized at 100 °C for 35 min. After the feedstock increase was complete, the fermentation time was determined as the point at which the ethanol concentration ceased to increase, as measured at 4 h intervals.

A solid material feeder constructed by our laboratory was used to add the feedstocks from 0 to 200 mg/min, on the basis of the amount

of exploded rice straw. The amounts of citrate and 0.1 mol/L H_2SO_4 were divided into two parts with an initial dosage and an added dosage in the same proportion to the dry matter amount of exploded rice straw as in the optimized SSCF of the detoxified materials. Therefore, after the addition of feedstock was finished, the dry matter content of the exploded rice straws, the citrate concentration, the enzyme loadings, and the H_2SO_4 concentration were purposefully maintained at the same level as the optimized SSCF of detoxified materials, except that $(NH_4)_2SO_4$ was added in the proportion to the dry matter amount of exploded rice straw, too.

This in situ detoxification and SSCF were divided into three stages, including the adaptation time from inoculation to the beginning of feedstock addition, the addition time of feedstocks from beginning to end, and the secondary fermentation time from the end of the feedstock addition to the end of the fermentation. On the basis of the SSCF parameters of the detoxified material, an additional five factors must still be explored, including the initial dry matter content, the yeast adaptation time, the required amount of additional $(NH_4)_2SO_4$, the addition time (or addition rate), and the secondary fermentation time.

Starter Preparation. *C. shehatae* (No. 1967) from the China Center of Industrial Culture Collection (CICC) was prepared in four stages. The activation medium was composed of 3 g/L yeast extract, 3 g/L malt extract, 5 g/L peptone, and 15 g/L xylose, and deionized water was added to reach a final volume of 1000 mL. After the activation medium had been sterilized at 125 °C for 25 min, ethanol was added at 15 g/L, and the medium was then inoculated with *C. shehatae*. The activation culture was incubated in a 250 mL shake flask at 25 °C and 160 rpm for 48 h. This procedure was repeated four times, and the temperature of the subsequent stages was raised by 2 °C at each stage. An inoculum concentration of 10% (w/w) was used, and the incubations were set at 160 rpm for 96 h at each stage. The culture from the fourth stage was reserved as the starter for xylose fermentations.

S. cerevisiae was obtained from Sichuan Swellfun Co., Ltd. (Chendu, Sichuan, China). Liquid potato medium was prepared for the yeast as follows. Peeled and crushed potatoes (200 g) were added to 1000 mL of tap water. After boiling for 30 min, the mixture was filtered, and tap water was added to the filtrate to a final volume of 1000 mL. After sterilization of the activation medium at 125 °C for 25 min, it was inoculated with the yeast at a concentration of 10%. The activated culture was subsequently prepared using the four-stage method outlined above. In accordance with the four-stage process, the first-stage culture temperature was 26 °C, and the temperature was raised by 2 °C at each subsequent stage. The inoculum concentration and culture time for each stage were 8% and 72 h, respectively. The culture from the fourth stage was reserved as the starter for the glucose fermentations.

Analysis Methods. The starch, crude protein, crude fat, crude ash, and moisture contents were determined according to Chinese standards GB/T 20194-2006, GB/T 6432-1994, GB/T 6433-2006, GB/T 6438-2007, and GB/T 6435-2006, respectively. The glucose, xylose, and total sugar contents were determined from material hydrolysates. To hydrolyze the cellulose, the hydrolysate was prepared by concentrated acid hydrolysis at room temperature followed by dilute acid hydrolysis at 121 °C, as recommended by the National Renewable Energy Laboratory Biomass Analysis Technology (NREL BAT).[23] The glucose, xylose, and total sugar contents of the hydrolysate were determined using a Glucose Assay Kit II (Biovision), a D-Xylose Assay Kit (Megazyme), and a 3,5-dinitrosalicylic acid (DNS) method,[20] respectively. The cellulose, hemicellulose, and lignin contents were determined using the NREL method.[23] The lignin contained acid-soluble and acid-insoluble lignin and lignin ash.

Fermented mash (20 mL) was centrifuged at 5000 rpm for 10 min, and the supernatant was used to determine the sugar contents as described above.

The ethanol and butanone concentrations were determined by gas chromatography (GC) analysis. Fermented mash (1.5 mL) was centrifuged at 13000 rpm for 10 min, and the supernatant was analyzed using a GC model GC7890 equipped with an AE. An SE-54 column (15 m × 0.25 m × 0.33 μm, Lanzhou Atech Technologies Co., Ltd., Lanzhou, China) was used. The analysis conditions were as follows: column temperature, 145 °C; detector temperature, 260 °C; sample injection temperature, 240 °C; measuring range, 10; attenuation, 0; and sample volume, 1 μL.

The furfural, 5-HMF, and acetic acid contents were determined by high-performance liquid chromatography (HPLC). The exploded slurries (1 mL) were centrifuged at 13000 rpm for 10 min; the residual solid matter was washed with deionized water at 65 °C until the wash water was colorless; and then the wash water and the supernatant were mixed for HPLC analysis. The fermented mash (15 mL) was filtered prior to HPLC analysis. A model LC-10AT HPLC equipped with an SPD-$10A_{vp}$ visible−ultraviolet detector, a Synergi Hydro RP column (4 μm, 4.6 × 250 mm, FLM Inc., Guangzhou, China), and an SCL-$10A_{vp}$ analysis system was used. The analysis conditions were as follows: reactor temperature, 50 °C; column temperature, 60 °C; detected wavelength, 250 nm; mobile phase, 0.005 M H_2SO_4; velocity, 1.2 mL/min; and sample volume, 10 μL.

Data Processing. The ethanol yield was based on the rice straw dry matter, as calculated using the following equation.

$$\text{ethanol yield (g/100 g rice straw dry matter)} = [(\text{ethanol (g) produced from SSCF})/\text{rice straw dry matter (g)}] \times 100$$

Triplicate samples were used for all analytical determinations, and the data were presented as the means of the three replicates. Differences between the samples and orthogonal tests were statistically analyzed by SPSS software (version 19). Design expert software (version 8.0.5.0) was used for the central composite design (CCD) and response surface methodology (RSM) experiments.

RESULTS

SSCF of Detoxified and Exploded Rice Straw. The BSE rice straw was dried for detoxification and then used for SSCF. The SSCF parameters were optimized using the Plackett−Burman (PB) method, the steepest ascent method, CCD, and RSM. Some of the changes introduced over the course of fermentation are shown in Figure 1. The whole SSCF was divided into three stages as follows: enzymatic hydrolysis (EH),

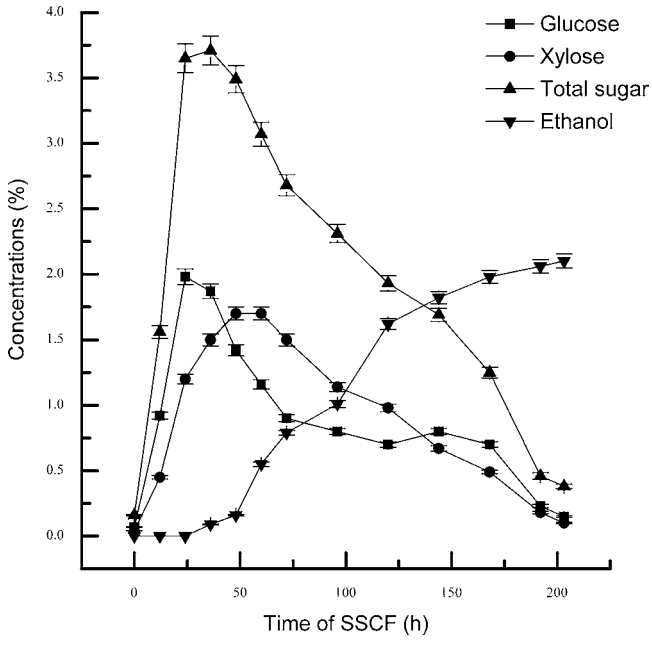

Figure 1. Substance changes over the course of SSCF for the detoxified rice straw exploded by 0.9 mol/L butanone solution.

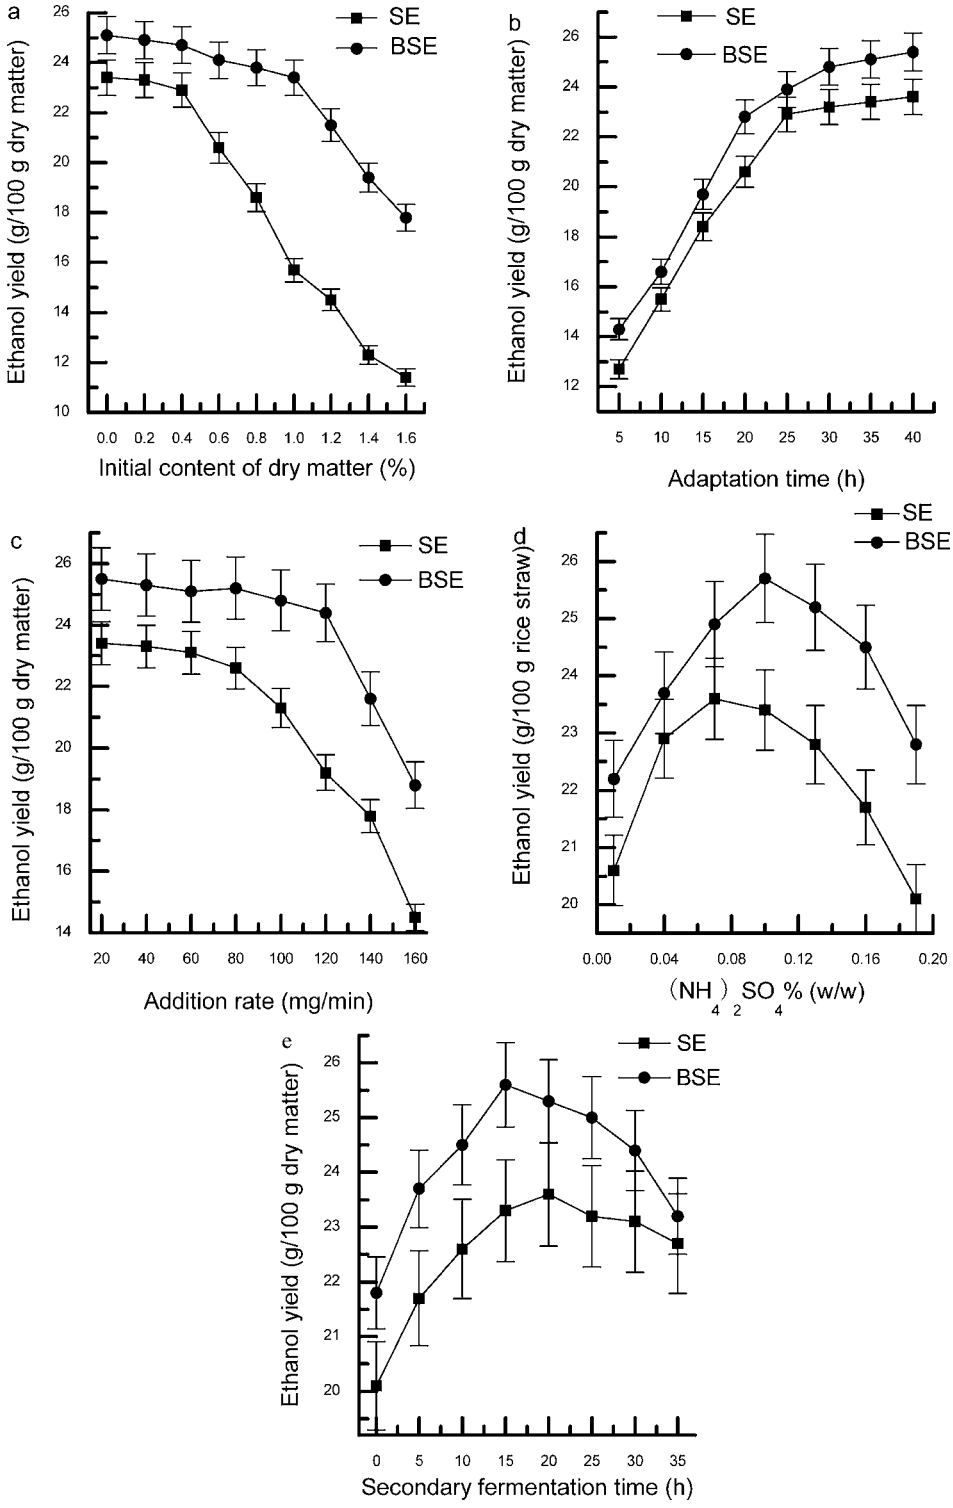

Figure 2. Key factor effects on the ethanol yield of in situ detoxification and SSCF. The two lines in panel a were drawn using the following conditions: adaptation time, 25 h; addition rate, 80 mg/min for SE rice straw and 100 mg/min for BSE rice straw; $(NH_4)_2SO_4$%, 0.1%; and secondary fermentation time, 20 h. The lines in panel b were drawn using the following conditions: initial content, 0.4% for SE rice straw and 0.8% for BSE rice straw; addition rate, 80 mg/min for SE rice straw and 100 mg/min for BSE rice straw; $(NH_4)_2SO_4$%, 0.1%; and secondary fermentation time, 20 h. In panel c, the addition rate was expressed using the amount of exploded rice straw. The lines in panel c were drawn using the following conditions: initial content, 0.4% for SE rice straw and 0.8% for BSE rice straw; adaptation time, 25 h; $(NH_4)_2SO_4$%, 0.1%; and secondary fermentation time, 20 h. In panel d, the $(NH_4)_2SO_4$ dose was expressed as $(NH_4)_2SO_4$% (w/w) = [(total amount of $(NH_4)_2SO_4$) (g)]/[(total amount of fermented mash) (g)] × 100%. Here, the total amount of fermented mash was referred to as the total of all matter introduced into the fermentation. The lines in panel d were drawn using the following conditions: initial content, 0.4% for SE rice straw and 0.8% for BSE rice straw; adaptation time, 25 h; addition rate, 80 mg/min for SE rice straw and 100 mg/min for BSE rice straw; and secondary fermentation time, 20 h. The lines in panel e were drawn using the following conditions: initial content, 0.4% for SE rice straw and 0.8% for BSE rice straw; adaptation time, 25 h; addition rate, 80 mg/min for SE rice straw and 100 mg/min for BSE rice straw; and $(NH_4)_2SO_4$%, 0.1%.

dx.doi.org/10.1021/jf501703j | J. Agric. Food Chem. 2014, 62, 7486−7495

first fermentation (*S. cerevisiae* fermentation), and second fermentation (mixed yeast fermentation). According to the optimized result (Figure 1), the total SSCF time was 203 h. The sugars and ethanol were estimated at 12 h intervals during the initial 72 h and at 24 h intervals after 72 h.

The glucose and total sugar concentrations increased with time from 0 to 36 h and then decreased after 36 h ($P < 0.05$). The xylose concentration simultaneously increased with time from 0 to 60 h and then decreased after 60 h ($P < 0.05$). After the *C. shehatae* was inoculated into the fermented mash at 59 h, the xylose concentration decreased. The ethanol concentration increased from 0 to 2.63% with increasing time ($P < 0.05$). The solid residue of the fermented mash was analyzed to determine the glucose, xylose, and total sugar contents using the rice straw analysis method. The results showed that after the SSCF, the glucose, xylose, and total sugar in the rice straw could be used at 91.4 ± 2.3, 84.7 ± 1.9, and 87.3 ± 2.5%, respectively, and the ethanol yield was 26.2 ± 0.8 g/100 g rice straw dry matter.

The SSCF course of the detoxified SE rice straw was similar to the course shown in Figure 1, but the sugar and ethanol yields were lower than the yields of the BSE ($P < 0.05$). Because the SE condition was harsher than the BSE condition, the sugar loss was greater with SE, as shown in Table 1. When SE rice straw was used as feedstock, the glucose, xylose, and total sugar in the rice straw dry matter could be used at 83.0 ± 2.1, 73.4 ± 1.3, and 79.1 ± 2.7%, respectively, and the ethanol yield was 23.7 ± 0.6 g/100 g rice straw dry matter after a total fermentation time of 208 h.

Factor Effects on in Situ Detoxification and SSCF. The impacts of five factors on ethanol yield for the non-detoxified materials are shown in Figure 2.

The ethanol yields decreased with increasing initial dry matter contents (Figure 2a). The dry matter content increased from 0 to 1.6%, whereas the ethanol yield of the SE rice straw significantly decreased from 23.4 to 11.4 g/100 g dry matter ($P < 0.05$) and the ethanol yield of the BSE rice straw significantly decreased from 25.1 to 17.8 g/100 g dry matter ($P < 0.05$). According to the analysis of variance, 0.4 and 1.0% of the dry matter contents were inflection points for SE rice straw and BSE rice straw ($P < 0.05$), respectively. The various inhibitor amounts continued to increase with increasing dry matter contents. However, the yeasts exhibited some ability to resist the inhibitors only if the inhibitor concentration was less than a specific value, as confirmed by the existence of the inflection points. There were different inflection points between SE rice straw and BSE rice straw, which could be explained by the fact that the amounts of inhibitors were different in the two types of exploded rice straw. A lower dry matter content might provide a high ethanol yield, but the lower the dry matter content, the longer the fermentation time. Therefore, 0.4 and 1.0% dry matter contents were selected as the center levels for the next orthogonal tests.

In Figure 2b, the ethanol yield increased from 12.7 to 23.6 g/100 g dry matter with an increase in the adaptation time from 5 to 40 h for SE feedstock ($P < 0.05$), and the ethanol yield increased from 14.3 to 25.4 g/100 g dry matter with an increased adaptation time from 5 to 40 h for BSE feedstock ($P < 0.05$). At an adaptation time of 25 h, the ethanol yields were 22.8 and 23.9 g/100 g dry matter for SE rice straw and BSE rice straw, respectively. The 25 h of adaptation time might have served as the inflection points for the two types of exploded rice straws. Although the initial dry matter content was lower than in the traditional method, the yeasts still needed time to adapt to the environment. An adaptation time of >25 h might be beneficial for the ethanol yield at the cost of delaying the total fermentation time, but the increased ethanol yield was insignificant ($P > 0.05$). However, the inflection points exhibited no great difference between the two types of exploded rice straw, which demonstrated the stability of the yeasts with respect to the different explosion pretreatments. If the adaptation time was not sufficient, the additional feedstock could seriously damage the yeasts and reduce the ethanol yield.

The ethanol yields of the two exploded rice straws decreased with increasing addition rate (Figure 2c) ($P < 0.05$). At addition rates of 80 and 120 g/min, the ethanol yields were 22.6 and 24.4 g/100 g dry matter for SE rice straw and for BSE rice straw, respectively, and the two points could be used as inflection points in the analysis. The ethanol yields of the two feedstocks could be maintained at a high level until the addition rate was increased to a specific level, which illustrated that an excessively fast addition rate resulted in yeast inhibition. The gradual feedstock increase differs from traditional fed-batch technology because the traditional method generally employed an added substrate and the feedstock content of the substrate was not greatly different from that of fermented mash. However, because of the technical feature of the added feedstock, this in situ and SSCF technology may be suitable for an exploded material and not for an acid-pretreated material. As shown in Figure 2c, a lower addition rate might lead to a high-level ethanol yield, but the total fermentation time could be greatly delayed. Therefore, 80 and 120 g/min addition times were selected as the center levels for the orthogonal tests.

An additional N source was not necessary in the SSCF of the detoxified and exploded rice straws because the added $(NH_4)_2SO_4$ did not greatly increase the ethanol yield in a previous study ($P > 0.05$). An excessive N source could result in cell growth with the consumption of fermentable sugars. However, as shown in Figure 2d, the ethanol yields peaked only when $(NH_4)_2SO_4$ was added to the fermented mash at a specific concentration ($P < 0.05$). At $(NH_4)_2SO_4$ addition values of 0.07 and 0.1%, the ethanol yield peaks were 23.4 and 25.7 g/100 g dry matter for SE rice straw and BSE rice straw, respectively. Using the same type of exploded rice straw as feedstock, the ethanol yield peaks obtained from SSCF exhibited no significant difference between the detoxified feedstock and non-detoxified feedstock ($P > 0.05$). It can be concluded that the additional N source can be used to grow the cells without exhausting the fermentable sugars. Too little N may weaken the yeasts' ability to digest the inhibitors, and too much N may cause more sugars to be consumed during cell growth. Therefore, the 0.07 and 0.1% $(NH_4)_2SO_4$ doses were selected as the center levels for the next orthogonal tests.

As shown in Figure 2e, the yeasts needed a period of time after the feedstock addition to ferment before the ethanol yield began decreasing (BSE rice straw) ($P < 0.05$) or was maintained at a higher level without an obvious decrease (SE rice straw) ($P < 0.05$). Therefore, fermentable sugars could still be released from the feedstocks, and the saccharification process was not finished, although the feedstock addition procedure was finished. The 15−20 h of secondary fermentation time was acceptable and suitable for the two types of feedstocks ($P < 0.05$).

Optimized Technology of in Situ Detoxification and SSCF. The five factors, with three levels for each factor, and the results of the orthogonal tests are listed in Table 2.

[a]SE, steam explosion; BSE, butanone solution explosion. [b]Values in parentheses are the values for butanone solution-exploded rice straw, and values outside parentheses are the values for steam-exploded rice straw. [c]k_1, k_2, and k_3 are the mean levels for the factors.

By employing SE rice straw as feedstock, the optimum result was $A_2B_3C_2D_2E_2$ according to the mean levels of k_1, k_2, and k_3; that is, the highest ethanol yield could be obtained when the SSCF conditions were set at an initial dry matter content of 0.4%, an adaptation time of 30 h, an addition rate of 80 mg/min, an $(NH_4)_2SO_4$ addition amount of 0.07%, and a secondary fermentation time of 18 h. From a variance analysis of the orthogonal test, the marked order of the factors was *D* (addition amount of $(NH_4)_2SO_4$, %) > *E* (secondary fermentation time, h) > *B* (adaptation time, h) > *C* (addition rate, mg/min) > *A* (initial dry matter content, %). Among these factors, *B*, *D*, and *E* were significant ($P < 0.05$), whereas *C* and *A* were not significant ($P > 0.05$).

Using BSE rice straw as feedstock, the optimum result was also $A_2B_3C_2D_2E_2$; that is, the highest ethanol level was obtained when the SSCF conditions were set at an initial dry matter content of 1.0%, an adaptation time of 30 h, an addition rate of 120 mg/min, an $(NH_4)_2SO_4$ addition amount of 0.1%, and a secondary fermentation time of 18 h. However, the marked order of the factors was *D* (addition amount of $(NH_4)_2SO_4$, %) > *E* (secondary fermentation time, h) > *B* (adaptation time, h) > *A* (initial dry matter content, %) > *C* (addition rate, mg/min), which had a slight difference in the placement of *A* and *C* when compared with the order for SE rice straw. Furthermore, *D* was the only significant factor ($P < 0.05$), and the others were not significant ($P > 0.05$). Hence, these differences indicated that the SSCF of the SE rice straw was more easily influenced by changes in parameters than that of the BSE rice straw.

These optimized parameters were used for confirmation, and the resulting ethanol yields were 23.3 ± 0.7 and 25.8 ± 0.6 g/100 g dry matter for SE rice straw and BSE rice straw, respectively. In comparison with the SSCF of the detoxified feedstocks, the ethanol yields were not significantly different from the feedstocks that were exploded by the same method ($P > 0.05$). Therefore, in situ detoxification and SSCF are effective.

According to the in situ detoxification and SSCF experiment, the total fermentation time was 224 h for SE rice straw and 234 h for BSE rice straw. In comparison with the SSCF of detoxified feedstocks, the fermentation time was delayed by approximately 31 h for BSE rice straw and by 16 h for SE straw. $(NH_4)_2SO_4$ was used at 0.10% for BSE rice straw and at 0.07% for SE rice straw, and a fermentation temperature of 35 °C and an air volume of 0.3 L/(min·L) were maintained from start to finish. The other loadings, including the feedstock, enzymes, H_2SO_4, and citrate, were used at the same levels as the SSCF of detoxified feedstocks.

Substance Changes during the Course of the in Situ Detoxification and SSCF. The changes in several inhibitors in the fermented mash are shown in Figure 3. The concentrations of furfural, 5-HMF, and acetic acid significantly increased as fermentation time increased ($P < 0.05$) regardless of whether the feedstock was SE rice straw or BSE rice straw, except during the initial 30 h and the secondary fermentation time ($P > 0.05$). After fermentation, the furfural, 5-HMF, and acetic acid concentrations were 197, 136, and 330 ppm (w/w in all cases) for SE rice straw, respectively. However, if all of the non-detoxified feedstocks were immediately introduced for fermentation, the initial inhibitor concentrations would be 1615 ppm of furfural, 803 ppm of 5-HMF, and 2651 ppm of acetic acid. Therefore, most of the inhibitors were removed by the fermented mash through the gradual increase in feedstock.

For the BSE rice straw, the furfural, 5-HMF, and acetic acid concentrations were 204, 152, and 312 ppm, respectively, after the completion of the fermentation. If all of the non-detoxified feedstock was immediately introduced, the initial inhibitor concentrations would be 503 ppm of furfural, 378 ppm of 5-HMF, and 1122 ppm of acetic acid, respectively. Decreases also occurred. The BSE rice straw contained more butanone than the SE rice straw because of the additional butanone in the explosion. Although the butanone content was reduced by drying with the residual heat of explosion, the content still

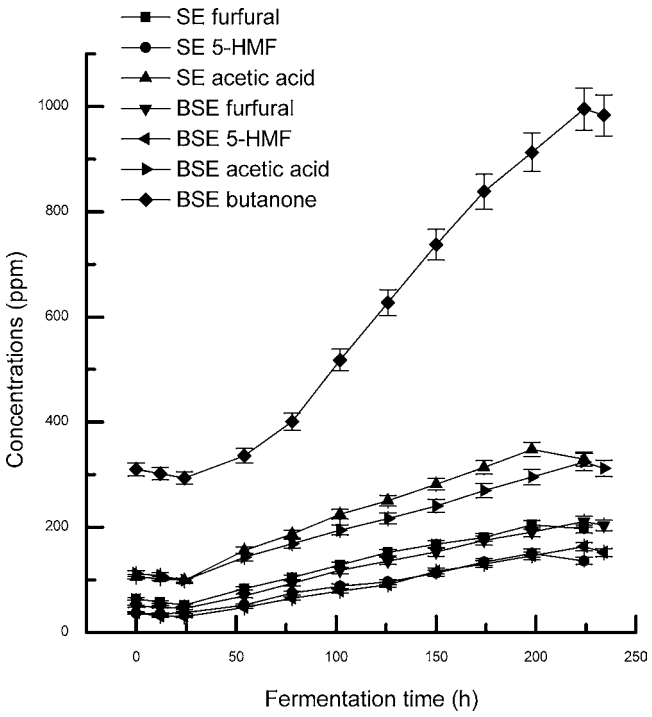

Figure 3. Concentration changes of certain inhibitors during in situ detoxification and SSCF. The parts per million of the vertical axis units is expressed as the mass ratio.

reached 3.1 ± 0.1% in the exploded rice straw. Approximately two-thirds of the butanone was removed during the in situ detoxification and SSCF.

Over the course of the fermentation, three types of sugar and ethanol concentration changes occurred, as shown in Figure 4. The ethanol concentrations significantly increased with increasing fermentation time ($P < 0.05$), and the maximum concentration was obtained at 2.55 ± 0.06%. This maximum ethanol concentration was slightly lower than in the detoxified feedstock SSCF, but the difference was not statistically significant ($P > 0.05$). Sugar changes were different between Figures 1 and 4. First, the highest sugar concentrations were significantly lower in Figure 4 ($P < 0.05$). The enzyme loadings were high enough that the feedstock could be quickly degraded into sugars, and then the sugars could be immediately used by the yeasts without great accumulation. Second, the highest sugar concentrations appeared during late fermentation (Figure 4) rather than during early fermentation (Figure 1). These differences can be attributed to the technical features of the gradual increase in feedstock. However, one of the same points regarding the sugars between Figures 1 and 4 was the change in the increasing trend and then the decline ($P < 0.05$). In addition, the three types of sugar and ethanol concentration changes for SE rice straw were similar to the ones in Figure 4 and are not shown.

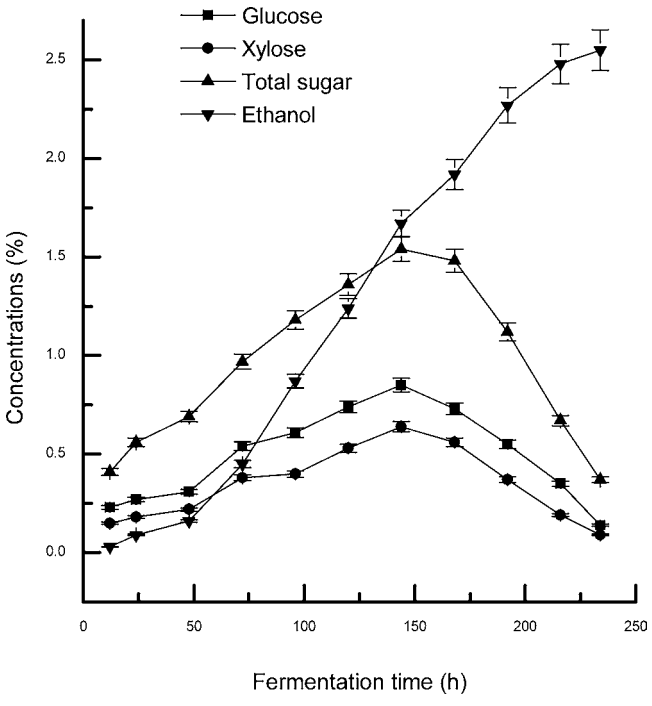

Figure 4. Substance changes during the in situ detoxification and SSCF for BSE rice straw.

DISCUSSION

The Current State of the SSCF for Bioethanol Production. Because *S. cerevisiae* normally lacks the ability to produce ethanol by fermenting the xylose obtained from hemicellulose,[24,25] there are extensive studies underway to develop yeasts that can produce high bioethanol yields from xylose. To this end, genetic improvement strategies have been based on the metabolism of wild yeasts, such as *S. cerevisiae*[26] or *C. shehatae*,[27] and a coculture process, such as a coculture of *Zymomonas mobilis* and *P. stipitis*[28] or of *S. cerevisiae* and *P. stipitis*,[29] has also been reported as an effective way to ferment both glucose and xylose. However, the recombinant yeasts are still far from industrial use because of the defective stability of the strains and because the coculture methods always exclude saccharification and detoxification; thus, saccharification and detoxification must be performed before fermentation. To overcome the mutual inhibition between strains in mixed fermentation, some co-immobilized fermentation methods were examined with *S. cerevisiae* and *C. shehatae*.[30,31] However, the methods did not obviously improve xylose utilization and were difficult to apply.

In addition, previous studies of certain single factors, such as temperature control,[32] dissolved oxygen,[33] feedstock concentration,[34] and the mixed enzymes system,[35] have provided a basis for this study, although the reported technologies are completely different from the in situ detoxification and SSCF technology. The literature[3,4] has recently reported a SSCF technology. However, its details were unclear, and the parameters were not optimized. More importantly, the reported SSCF was not an in situ detoxification technology because it required a pre-detoxification procedure and strain pre-adaptation for subsequent fermentation, resulting in higher cost and more complex procedures. Therefore, the combination of biodetoxification and SSCF is rarely observed and must be further explored.

Technical Characterisations of the SSCF for Detoxified and Non-detoxified Feedstocks. As shown in Figure 1, the highest concentrations of glucose and ethanol were below 1.98 and 2.63%, respectively, which should not inhibit *C. shehatae* from converting xylose into ethanol.[33,36] In addition, although an aerobic fermentation condition was beneficial for *C. shehatae*,[33] *S. cerevisiae* could still compete with *C. shehatae* to obtain glucose for producing ethanol under a micro-oxygenated

condition.[37,38] Therefore, this condition should support a higher ethanol yield. Glucose and xylose could be simultaneously fermented by *C. shehatae*[39] if the glucose and ethanol concentrations of the fermented mash were limited to below a specific level.[40,41] However, the theoretical ethanol productivity of *C. shehatae* is lower than the theoretical productivity of *S. cerevisiae*[42] if an equal number of glucose molecules were consumed by each strain. Therefore, the SSCF of detoxified feedstock could be completed as follows. *S. cerevisiae* was first inoculated into the hydrolysate to ferment glucose into ethanol, and most of the glucose was used by *S. cerevisiae*. However, with the accumulation of xylose released from the feedstocks, *C. shehatae* was required because of xylose's inhibition of enzymes.[43,44] Afterward, cofermentation was conducted through the competition of *S. cerevisiae* and *C. shehatae*. Because of the low glucose concentration, the glucose could not inhibit *C. shehatae* from converting xylose into ethanol and *S. cerevisiae* could ferment glucose into ethanol. Hence, some key points of the detoxified feedstock SSCF are as follows: limitations in dissolved oxygen and the N source, lower concentrations of glucose and xylose, and separate glucose and xylose fermentation for different strains as much as possible.

The SSCF of non-detoxified materials have some of the same features as the detoxified feedstocks of SSCF, for example, dissolved oxygen limitations under a micro-oxygenated condition, low glucose and xylose concentrations, and separate glucose and xylose fermentation for different strains as much as possible. However, the technology has certain intrinsic features attributable to the added detoxification within the process.

The decreases in these inhibitors (Figure 3) may be primarily attributed to the role of the micro-organisms. For example, furfural and 5-HMF were consumed by *S. cerevisiae*,[10] and this yeast was able to use phenolic and furan compounds.[45] When the acetic acid concentration was below a limited level, *S. cerevisiae* could remove the acetic acid through metabolic consequences.[46] A higher butanone concentration may result in *S. cerevisiae* aneuploidy[47,48] and may confer quantitative proteome changes and phenotypic variation.[49] Therefore, these changes may reduce the butanone concentration during the fermentation process. However, because the inhibitors were controlled at a very slow addition rate, abnormal changes may not occur in all cells, and the yeasts may have time to adapt to the environment, resulting in normal cells that can employ fermentable sugars to produce ethanol. In addition, although there are few reports about how *C. shehatae* responds to the inhibitors, it could be concluded that the micro-organism can also attempt to negate the harmful effects of the environment. This finding would be confirmed by the pre-adaptation of the micro-organisms.[50,51]

Therefore, in situ detoxification and SSCF technology have the following intrinsic features. Sufficient proportions of enzymes and yeasts were employed to gradually overcome the inhibition and to maintain their advantage without overdosing or multiple additions, in contrast to traditional fermentation methods. Very low sugar concentrations and the addition of a nitrogen source impelled some of the cells to seek other carbon sources and resulted in metabolic change, but the extended fermentation time kept most cells normal by virtue of yeast self-adaptation.

Potential Applications of the in Situ Detoxification and SSCF. The ethanol yields displayed no significant difference between the detoxified materials and non-detoxified materials, indicating that the in situ detoxification and SSCF were effective in terms of the fermentation time cost and the N source but eliminated the need for a separate detoxification procedure and the pre-adaptation of strains. If all of the glucose and xylose contained in the rice straw were calculated, 86.7% of the theoretical ethanol yield for BSE rice straw could be obtained. Few studies can be compared for ethanol yields because of their different analyses, and ,thus, the calculation and methods criteria in various literature regarding acid-pretreated material greatly differ for exploded materials. This study supplies a reference for the further study of in situ detoxification and SSCF technology for converting lignocellulosic material into ethanol in scale applications. Furthermore, given an increased scale, the addition procedure will become simpler, as in the 10 L example.

Those cells anchoring mini-scaffoldins were optimized to produce approximately 1138 mg/L ethanol from microcrystalline cellulose within 4 days. However, it should be noted that the ethanol titer and cellulose consumption were lower than those obtained when using a yeast self-assembled mini-cellulosome.[13] Attending to the length of scaffoldin II, Fan and colleagues[12,13] reported a higher display level on yeasts with smaller scaffoldin II (lower amount of cohesin II), as well as a maximum ethanol production when the mini-cellulosome had only two cohesins II. Considering the number of cohesin I domains, Jaeho et al.[14] obtained a little difference in the effects on cellulosic and hemicellulosic substrates produced by three different *C. cellulovorans* recombinant mini-cellulosomes containing either endoglucanase EngB or endoxylanase XynA bound to mini-CbpA with one (mini-CbpA1), two (mini-CbpA12), or four (mini-CbpA1234) cohesin domains when the cellulosomal enzyme concentration was held constant, regardless of the copy number of cohesins in the cellulosome. However, a synergistic effect was observed when the enzyme concentration was increased to be proportional to the number of cohesins in the mini-cellulosome. Comparing mini-cellulosome with free cellulosomal enzymes, Murashima et al.[15] reported an enhanced activity toward crystalline cellulose when using mini-cellulosomes.

Cereal-based diets may contain high levels of soluble nonstarch polysaccharides (NSPs) that significantly affect the digestive process, impairing animal performance. It is now well-known that barley incorporation in poultry diets is limited by its high content in soluble β-1,3−1,4-glucans that upon solubilization lead to an increase in digesta viscosity, reducing digesta passage rate and affecting the interaction of the endogenous digestive enzymes with their target substrates.[16−18] In addition, higher viscosities also lead to prolonged digesta passage rates, promoting modifications in gut physiology such as the enlargement of gastrointestinal organs, which are detrimental to the final carcass yields.[16] High digesta viscosity also favors the proliferation of anaerobic microbes in the upper parts of the gastrointestinal (GI) tract, thus affecting the animal's health.[18] To reduce the negative effects associated with the presence of barley β-glucans, commercial enzyme mixtures expressing high levels of β-glucanase activity are currently added to broiler diets.[19] Exogenous enzymes added to poultry diets reduce the degree of polymerization of soluble glucans, leading to a reduction in digesta viscosity and improvements of diet digestibility and feed intake, thus contributing to improved animal performance.[19] However, little is known about the mechanisms affecting the efficiency of exogenous enzymes used to improve the nutritive value of cereal-based diets in vivo.

Here we aim to produce mini-cellulosomes expressing β-1,3−1,4-glucanase activity and use the engineered nanomachines to improve the nutritive value of barley-based diets for broilers. These mini-cellulosomes are based on *C. thermocellum* CipA scaffoldin and incorporate one or three *Ct*Glc16A enzymes in a single nanomachine.

MATERIALS AND METHODS

Bacterial Strains and Plasmid. Genomic DNA of *C. thermocellum* ATCC 27405 was purchased from DSMZ (Braunschweig, Germany). *E. coli* DH5α cells were used for cloning, and *E. coli* BL21 (DE3) was used as the expression host. The plasmids used for cloning and expression were pET-21a (+) derivatives. All of the above-mentioned items were procured from Novagen (Madison, WI, USA).

Gene Isolation and Cloning. The thermostable β-1,3−1,4-glucanase of *C. thermocellum*, termed *Ct*Glc16A,[20] is a modular enzyme containing an N-terminal glycoside hydrolase family 16 catalytic domain followed by a C-terminal type I dockerin. The gene encoding mature *Ct*Glc16A (residues 30−334) was amplified from *C. thermocellum* genomic DNA through PCR using the NZYProof DNA polymerase (NZYTech Ltd., Lisboa, Portugal) and the following primers: 5′-CACACACA**GCTAGC**ACTGTGGTAAATACGCC-3′ and 5′-CACACACA**GGATCC**TCAAAGTGACGGAATTG-3′ (NZYTech Ltd.). Primers included engineered *Nhe*I and *Bam*HI restriction sites (in bold) that allowed the subsequent cloning of the resulting nucleic acid into similarly restricted pET21a, generating the plasmid pGH16-Doc21a. pGH16-Doc21a encodes the bimodular *Ct*Glc16A, containing aN N-terminal GH16 β-1,3−1,4-glucanase catalytic domain and a C-terminal type I dockerin. Previously we observed that dockerins are highly unstable when expressed in *E. coli* cells. However, cellulosomal enzymes are stabilized once dockerins bind their cohesin counterpart.[21] Thus, cohesin−dockerin complexes are usually assembled in vivo in cells coexpressing the genes encoding the dockerin- and cohesin-containing proteins. Previously we produced a *C. thermocellum* mini-cellulosome containing three CtCel8A cellulases bound to a mini-scaffoldin comprising cohesin modules 3, 4, and 5 of CipA (residues 562−1030).[21] The mini-cellulosome was produced in *E. coli* cells transformed with a pET21a derivative containing the genes encoding the cellulase and the tricohesin mini-scaffoldin organized in tandem and under the control of separate T7 promoters (the plasmid was termed pG8D3C21a;[21] for details). Here we used pG8D3C21a construct and replaced the gene encoding CtCel8A by *Ct*Glc16A gene through restriction digestion. Thus, pGH16-Doc21a was digested with *Sph*I and *Bam*HI, and the DNA fragment containing the β-glucanase gene and the 5′-region of pET21a was cloned into a truncated version of pG8D3C21a from which the CtCel8A gene was excised after a *Sph*I−*Bgl*II digestion, generating pG16D3C21a. pG16D3C21a contains the genes encoding the *Ct*Glc16A glucanase and the three-cohesin mini-scaffoldin organized in tandem. to prepare a protein−protein complex resulting from the binding of a single-cohesin domain protein to *Ct*Glc16A, to use as a control in the biochemical experiments described below, the same approach was employed to produce plasmid pGH16Doc-1Coh21a by replacing CtCel8A with *Ct*Glc16A in plasmid pG8D1C21a, which contains the gene encoding CtCel8A followed by the gene encoding a single cohesin, cohesin 3, of CipA scaffoldin. The two resulting plasmids used in this study, pGH16Doc-3Coh21a (GH16-3C) and pGH16Doc-1Coh21a (GH16-1C), were subsequently sequenced to confirm that no mutations were accumulated during gene amplification and the resulting subcloning steps. The engineered cohesin-containing proteins (3Coh and 1Coh) contain a C-terminal His tag, allowing the direct purification of the assembled complex and unbound scaffoldins by immobilized metal affinity chromatography (IMAC). Because cohesin-containing proteins are usually expressed at low levels in *E. coli*, it is expected that in both cases the majority of the proteins recovered by affinity chromatography will constitute the protein complexes.

Expression and Purification of *Ct*Glc16A Mini-cellulosomes. *E. coli* BL-21(DE3) cells were transformed with pGH16Doc-3Coh21a and pGH16Doc-1Coh21a as described elsewhere.[22] Recombinant cells were grown in Luria−Bertani medium supplemented with ampicillin (100 μg mL^{-1}) at 37 °C, 200 rpm, until midexponential phase ($A_{600\ nm} \approx 0.4$). Recombinant gene expression was induced by adding 1.0 mM isopropyl-1-thio-β-D-galactopyranoside (NZYTech), and cells were further incubated at 19 °C for 16 h. The cells were harvested at 5000*g*, and the resulting pellet was resuspended in 10 mM imidazole buffer (10 mM imidazole, 50 mM NaHepes, 1 M NaCl, 5 mM $CaCl_2$, at pH 7.5), submitted to ultrasonication, and centrifuged at 4 °C and 17000*g* during 30 min; finally, the obtained His_6-tagged recombinant protein extracts were purified by IMAC using 5 mL HiTrap chelating columns (GE Healthcare, Piscataway, NJ, USA) as described by Fontes et al.[23] The purity of the protein complexes was analyzed by SDS-PAGE.[24]

Analytical Procedures. Unless otherwise stated, enzyme assays were determined following the method described by Fontes et al.[25] by measuring the release of reducing sugars resulting from carbohydrate

hydrolysis in phosphate citrate (PC) buffer (64 mM K_2HPO_4 and 12 mM citric acid; pH 6.5) at 40 °C. The substrates used in this study were barley β-glucan, hydroxyethylcellulose, carboxymethylcellulose, arabinoxylan, xyloglucan, galactomannan, and glucomannan (Megazyme, Wicklow, Ireland) at a 0.3% (w/v) final concentration. Reactions were stopped by adding a DNSA-based solution (1% DNSA, 1% NaOH, and 0.2% phenol) following the method described by Miller.[26] To explore the pH profiles of pGH16Doc-3Coh21a and pGH16Doc-1Coh21a plasmids and compare them with *Ct*Glc16A, 50 mM 2-*N*-morpholinoethanesulfonic acid (MES) (pH 4.5−7), 50 mM Tris-HCl (pH 7−9.5), and 50 mM $NaHCO_3$ (pH 9.5−11) buffers were used in enzyme assays employing 0.25% barley β-glucan as the substrate. For thermostability experiments, the three proteins were incubated at temperatures ranging from 60 to 90 °C. After 20 min at the required temperature, samples were withdrawn and residual activity was determined at 50 °C by measuring the amount of reducing sugar released from barley β-glucan as described above. Determination of the temperature of maximal enzyme activity was performed by incubating the enzyme at temperatures ranging from 50 to 90 °C and measuring reducing sugar release as previously described. One unit of catalytic activity is defined as the amount of enzyme required to release 1 μmol of product per minute.

In a previous study it was shown that levels of endogenous β-glucanase activity affect the efficacy of exogenous enzymes used to improve the nutritive value of barley-based diets for poultry.[27] To select barley batches expressing lower levels of endogenous β-glucanases, five different barley lots available commercially were selected. The barley lots were milled at 0.5 mm, and enzyme extraction was performed by adding 1 mL of PC buffer into 0.75 g of barley. The supernatant was recovered and used to quantify the β-glucanase activity using a β-glucanase commercial assay kit (Megazyme), following the manufacturer's protocol. The incubation period was extended to 3 h. The barley lot expressing the lowest endo-β-glucanase activity was used as the main component of the basal diet described below.

To standardize the number of enzyme units used to supplement the animal diets, the catalytic activity of the recombinant enzymes, including the commercial enzyme mixture (Rovabio Excel AP), was determined in parallel at 40 °C by measuring the release of reducing sugars.[25] The extract containing the commercial enzyme was prepared by ressuspending 250 mg of the enzyme in 10 mL of PC buffer, followed by an overnight incubation at room temperature with gentle agitation and centrifugation at 16000*g* for 10 min.

To evaluate the levels of β-glucanase activity present in the four animal diets and in digesta samples collected in different parts of the broilers' GI tract, samples were initially centrifuged at 16000*g* for 5 min, and the supernatants were recovered for analysis. The barley and feed samples (0.75 g) were previously mixed in 1 mL of PC buffer. The mixed samples were subjected to vigorous stirring during 30 min and centrifuged, and the supernatant was analyzed. Qualitative analysis of β-glucanase activity was assessed in agar plates, using barley β-glucan at 0.1% (w/v) mixed with agar at 2% (w/v) final concentration, in 10 mM Tris-HCl (pH 8.0). Catalytic activity was detected on the basis of the method described by Ponte and colleagues[28] with some modifications. Briefly, a Pasteur pipet was used to create wells in the agar plates, which were filled with 20 μL of enzyme extract from digesta samples. Subsequently, the plates were incubated for 16 h at 37 °C and dyed with 1% Congo Red (E. Merck, Darmstadt, Germany) in10 mM Tris-HCl (pH 8) for 30 min. To observe regions where the polysaccharides were degraded, the plates were subjected to three 15 min washes with 1 M NaCl in 10 mM Tris-HCl (pH 8). For measuring the viscosity of small intestine contents, samples collected from the duodenum plus jejunum and from the ileum were centrifuged for 10 min at 10867*g*, and the viscosity of sample supernatant was measured at 6 rpm using a viscometer (model LVDVCP-II, Brookfield Engineering Laboratories, Middleboro, MA, USA) with a cup maintained at 24 °C.

Incorporating Mini-cellulosomes in Poultry Diets. Bird experiment was conducted in accordance with the Ethics Committee of CIISA, Faculdade de Medicina Veterinária, and approved by the Animal Care Committee of the National Veterinary Authority (Direcção Geral de Veterinária, Lisboa, Portugal), following the appropriate European Union guidelines (Council Directive 86/609/EEC). One hundred and sixty 1-day-old Ross 308 male broiler birds were assigned to 40 pens of 4 birds each. Chicks were wing-banded for individual identification. The 40 pens were randomly assigned to four treatments consisting of four different diets provided to the animals. A barley-based diet was not supplemented (treatment NC) or supplemented with the commercial enzyme Rovabio Excel AP (Adisseo, Antony, France; treatment Rov), supplemented with pGH16Doc-1Coh21a (treatment 1C), or supplemented with pGH16Doc-3Coh21a (treatment 3C). The commercial enzyme manufacturers guarantee activity of endo-1,4-β-xylanase and endo-1,3(4)-β-glucanase. All three enzymes were incorporated at a calculated dose of 1500 U/kg feed. The calculated 1500 U/kg feed of the commercial enzyme corresponded to the manufacturer's recommended dose of 50 g of enzyme per ton of feed. The duration of the trial was 28 days. The basal diet (Table 2) contained 618 g/kg of barley and was formulated to ensure a nutrient availability as defined by the NRC.[29] Throughout the experiment, chicks were given free access to water and feed, which were provided with drinking nipples and hanging feeders, respectively. Broilers were raised in wired floor pens that were located in an environmentally controlled room adjusted daily to the recommended temperatures, according to standard brooding practices.[30] Feed consumption and body weight (BW) were determined weekly throughout the experiment, and mortality was recorded daily. At 28 days of age, one bird per pen was slaughtered by cervical dislocation. The weight of the crop, gizzard, and liver, and the length of the duodenum, jejunum, ileum, and cecum were determined. Digesta samples were collected at duodenum and jejunum and ileum compartments to determine contents viscosity as described above.

Zymogram Analysis and Resistance of Mini-cellulosomes to Proteinase Attack. Zymogram analysis was performed as described by Fontes et al.[23] and Ribeiro et al.[31] In brief, digesta proteins were separated through SDS-PAGE in 14% acrylamide gels containing 0.1% of barley β-glucan (Megazyme), according to the method of Laemmli.[24] After electrophoresis, polypeptides were renatured by subjecting the gel to five 30 min washes in 100 mM sodium succinate, pH 6.3, 10 mM $CaCl_2$, and 1 mM DTT. The gels were incubated for 16 h at 37 °C in the same buffer, and proteins were stained in a solution comprising 40% (v/v) methanol, 10% (v/v) glacial acetic acid, and 0.4% (w/v) Coomassie Brilliant Blue R. After destaining, gels were washed in 0.1 M Tris-HCl (pH 8) for 20 min. β-Glucanase activity was detected using a 0.1% (w/v) Congo Red solution for 15 min and washing with 1 M NaCl in 10 mM Tris-HCl (pH 8) until excess dye was removed. After Congo Red staining, the gels were counterstained with 1 N HCl as described elsewhere.[32] Areas of catalytic activity appeared as colorless zones in a gray background.

The ability of mini-cellulosomes to resist protease degradation was evaluated by incubating the two protein complexes (approximately 30 μg) with50 μg of pancreatin from porcine pancreas (Sigma, P-1500) in buffer A (50 mM Hepes, 50 mM NaCl, 5 mM $CaCl_2$, pH 7.5) at 37 °C during 30 min. Negative controls consisting of the reaction without pancreatin were prepared, as well as a reaction only with pancreatin in buffer A. Mini-cellulosome integrity was evaluated by SDS-PAGE, as described above.

Statistical Analyses. Data related to bird performance from each experiment were subjected to ANOVA according to the general linear models procedure of SAS.[33] The least-squared means procedure was used to detect significant differences between treatment groups. The experimental unit was the cage of fpur animals (n = 10). Differences were considered significant when $p < 0.05$.

RESULTS AND DISCUSSION

Construction of Mini-cellulosomes Expressing β-1,3−1,4-Glucanase Activity. The open reading frame of *Ct*Glc16A, amplified by polymerase chain reaction, was used to replace the gene encoding CtCel8A in plasmids previously prepared to produce a mini-cellulosome containing CtCel8A

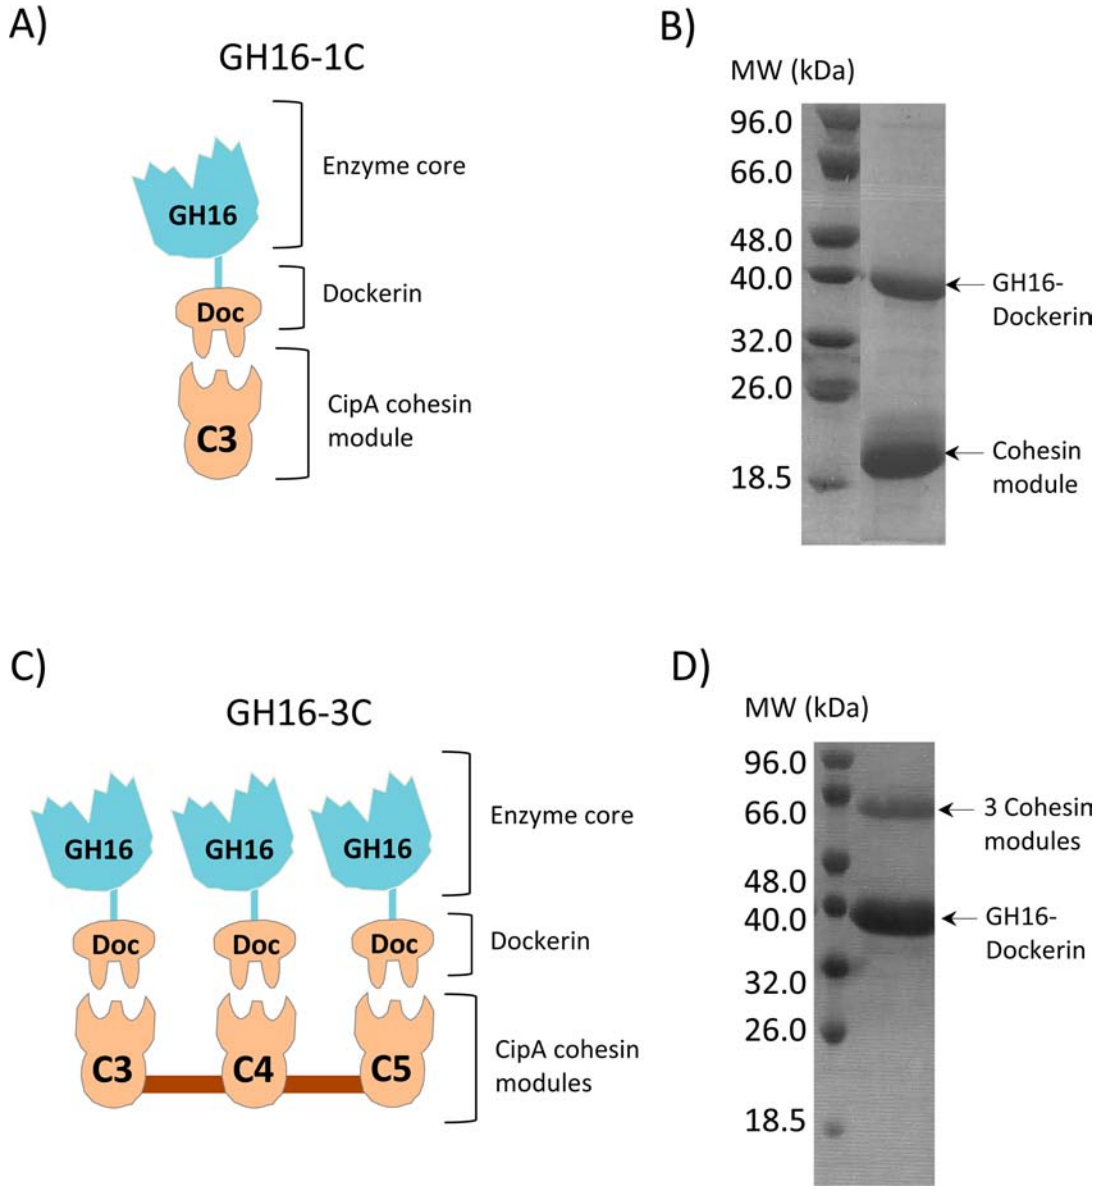

Figure 1. Molecular architecture of mini-cellulosomes (A, C) and protein purification (B, D). The molecular architectures of mini-cellulosomes containing one cohesin fused to one *Ct*Glc16A enzyme or three cohesin domains fused to three *Ct*Glc16A enzymes are displayed in panels A and C, respectively. The two complexes were expressed and assembled in vivo in *E. coli* and purified through IMAC using a polyhistidine tag located at the C-terminus of the mini-scaffoldins as the affinity tag. SDS-PAGE was used to confirm complex homogeneity as observed in panels B (GH16-1C) and D (GH16-3C), respectively.

bound to mini-scaffoldins containing either one or three cohesin domains.[21] Two *C. thermocellum* mini-cellulosome protein complexes (Figure 1a) of roughly 52 and 156 kDa, respectively, were produced. The complexes comprising one (C3; 16.5 kDa) or three cohesin modules (C3−C4−C5; 51.2 kDa) derived from CipA bound to one or three cellulosomal *Ct*Glc16A glucanases (34.9 kDa), respectively, were purified from *E. coli* via nickel affinity chromatography (Figure 1b). The genes encoding the truncated versions of CipA (C3 or C3−C4−C5) and *Ct*Glc16A were coexpressed in the bacterium under the control of separate T7 promoters (see Materials and Methods). The recombinant CipA derivatives, C3 and C3−C4−C5, were engineered to contain a C-terminal His6-tag. The levels of expression of *Ct*Glc16A were estimated to be at least 5 times higher than the levels of expression of C3 or C3−C4−C5 mini-scaffoldins (not shown). Thus, during expression, the mini-scaffolds became saturated with the cellulosomal glucanase, allowing the purification of homogeneous complexes through affinity chromatography that targeted the C-terminal His6-tag of C3 or C3−C4−C5, respectively.

Assembly of *Ct*Glc16A in Mini-cellulosomes Does Not Affect pH and Temperature Stability of the Enzyme. *Ct*Glc16A is a typical β-glucanase as it does not exhibit any activity against soluble cellulosic substrates and hemicelluloses but displays specificity for β-1,3−1,4-glucans, such as lichenan and barley β-glucan.[20] The enzyme displays a broad pH optimum (pH 6−9), with maximal activity at pH 8.0, and is thermostable at temperatures of ~70 °C. In addition, *Ct*Glc16A was found to be completely resistant to proteolytic inactivation.[20] Thus, *Ct*Glc16A biochemical properties suggest that the enzyme is particularly suited to resist the harsh conditions observed during feed processing and poultry

Organization of cellulases and hemicellulases in mini-cellulosomes is supposed to confer additional stability to the enzyme complex and improve activity on the hydrolysis of recalcitrant substrates.[1] Here we investigate the biochemical properties of *Ct*Glc16A when organized in mini-cellulosomes containing one (GH16-1C) or three cohesin (GH16-1C) mini-cellulosomes. The data, presented in Figure 2, reveal that mini-cellulosomes GH16-1C and GH16-3C displayed optimum temperature and pH similar to those expressed by uncomplexed *Ct*Glc16A. The mini-cellulosomes expressed a broad pH optimum (6−9) and displayed unaltered optimum temperatures and thermostability when compared with *Ct*Glc16A. The substrate specificities of GH16-1C and GH16-3C were also probed against a range of natural substrates at optimized pH and temperatures. The data, presented in Table 1, reveal that the two mini-cellulosomes retained a strict specificity for β-1,3−1,4-glucans. Thus, reflecting the specificity displayed by *Ct*Glc16A, the mini-cellulosomes were unable to degrade cellulosic substrates and a range of the most frequent hemicelluloses. In addition, the capacity of the enzyme to degrade β-glucans is not affected by the binding to the mini-scaffoldins, although a slight reduction of the activity of GH16-3C during the hydrolysis of barley β-glucan is observed. This might reflect a restriction of *Ct*Glc16A flexibility upon its organization in mini-cellulosomes. This flexibility is of primary importance in the hydrolysis of soluble substrates. In contrast, organization of mini-cellulosomes is of primary importance to improve the catalytic efficiency of hydrolysis of recalcitrant substrates such as cellulose.

Using Mini-cellulosomes To Improve the Nutritive Value of Barley-Based Diets for Poultry. The effect of assembling *Ct*Glc16A in mini-cellulosomes organized by scaffoldins containing one (GH16-1C) or three (GH16-3C) cohesins, respectively, in improving the nutritive value of barley-based diets for poultry was analyzed in an animal trial using 160 broiler chicks. Mini-cellulosome GH16-1C was used as a control mini-cellulosome as it contains exclusively one enzyme per protein complex and should thus behave as a typical single enzyme. Basal diet (Table 2) containing a major proportion of barley (>60%) was formulated to provide nutrients to requirements as defined by the NRC.[29] Barley contains a significant proportion of β-glucans, which, due to its intrinsic viscosity, displays considerable antinutritive properties for monogastric animals, in particular for poultry. Thus, the basal diet was fed without the addition of exogenous enzymes (negative control group, NC) or with the addition of one of three different β-glucanase preparations, the mini-cellulosome GH16-1C (GH16-1C), the mini-cellulosome GH16-3C (GH16-3C), and a commercial enzyme (Rov). The four diets were fed to broiler chicks during a 28 day trial. Animal performance data, presented in Table 3, revealed that as early as day 7 and during the entire trial animals from the NC group had lower ($p < 0.05$) body weight than animals fed diets supplemented with the exogenous enzyme preparations. At days 7 and 14, animals from the Rov group presented the highest body weights, which were similar to the animals from the GH16-1C treatment ($p > 0.05$). In addition, although GH16-3C animals had body weights similar to those of animals from the GH16-1C group ($p > 0.05$), they presented lower weights ($P < 0.05$) than animals supplemented with the commercial enzyme. These data suggest that in the initial period of the broiler growing cycle assembling *Ct*Glc16A in a three cohesin mini-cellulosome might restrict the efficacy of the exogenous β-glucanase. Weekly weight gains were only significantly different until day 14 (Table 3). During the first week of the trial, animals from the NC group displayed the lowest weight gains, whereas broiler chicks of the Rov and GH16-1C groups displayed the best performances. In addition, during this initial trial period GH16-3C broilers presented an intermediate weight gain, suggesting a lower efficacy resulting from enzyme assembly. Overall, the data suggest that exogenous enzymes act predominantly during the initial period of the broilers' growth (before day 14). This has previously been observed in other studies using barley-based diets for poultry,[18] suggesting that as birds age the capacity of the endogenous enzymatic repertoire is improved and can face the inherent increase in digesta viscosity resulting from the presence of high levels of β-glucans (see below). Data presented in Table 3 also reveal that supplemented animals presented higher feed intakes ($p < 0.05$) when compared with nonsupplemented animals, and this difference predominates at the initial periods of the trial. In addition, the feed conversion ratio (FCR) was lower for animals of the supplemented groups during the first 2 weeks of the experiment. Thus, the better performance revealed by animals supplemented with microbial β-glucanases results not only from a higher feed intake but also from an improved efficacy of nutrient digestibility as reflected by the improved FCR revealed by animals receiving exogenous enzymes. The mortality rate of the experiment was 1.25% and was not related to treatments. Taken together, the data suggest that exogenous enzymes improve the nutritive value of barley-based diets for broilers. This effect operates during the first 2 weeks of broiler growth. In addition, assembling of β-glucanases in mini-cellulosomes seems to restrict their initial efficacy as a

result of a lower enzyme flexibility imposed by cellulosome assembly upon the hydrolysis of a predominantly soluble substrate.

The relative weight and length of the bird's GI compartments, as well as digesta viscosity, are presented in Table 4. The relative weight of the bird's GI compartments was affected by treatment for the ileum ($p < 0.05$) and jejunum ($p < 0.1$). Ileum and jejunum from supplemented animals were lighter than those from animals not subjected to feed supplementation. In addition, the relative length of a bird's duodenum and jejunum was affected by enzyme supplementation. Animals from supplemented groups had shorter duodenum and jejunum when compared with the nonsupplemented animals. Several studies have reported a lower overall size of the GI tract in birds subjected to supplementation with exogenous plant cell wall degrading enzymes.[34,35] Exogenous enzymes contribute to decrease digesta viscosity, which is the main factor contributing to the enlargement of the birds' GI tract. Hence, data presented in Table 4 reveal that digesta viscosity in the duodenum + jejunum and ileum was different among birds fed the different diets. Digesta viscosity in the duodenum + jejunum and in the ileum was lowest ($p < 0.05$) for animals of the GH16-1C and GH16-3C groups. However, duodenum + jejunum and ileum viscosity was also significantly lower in the animals from the

dx.doi.org/10.1021/jf502157y | J. Agric. Food Chem. 2014, 62, 7496–7506

Rov group in comparison with the nonsupplemented animals, for which the viscosity reached the highest values.

Molecular Integrity of Minicellulosomes upon Passage through the GI Tract. Data concerning the qualitative detection of β-glucanase activity in digesta samples collected in various GI compartments are presented in Table 5, and the qualitative β-glucanase activity present in the feed is presented in Figure 3. The results revealed that β-glucanase activity could be detected in the crop and also in the cecum of animals in all treatments. However, only supplemented animals, in particular those of the GH16-1C and GH16-3C treatments, presented significant levels of β-glucanase activity in the gizzard, duodenum, jejunum, and ileum. This observation suggests an improved stability of *Ct*Glc16A when compared with the commercial enzymes upon passage through the GI tract. It is intriguing that β-glucanase activity was detected in digesta samples collected in the crop of the nonsupplemented animals. However, the intensity of the halos corresponding to β-glucanase crop activity of nonsupplemented animals was considerably weaker when compared with the supplemented groups. Although a barley lot expressing lower levels of endogenous β-glucanase activity was selected for this study, the sensitivity of the plate assay implemented to screen for exogenous enzymes was sufficient to detect it.

Table 5. Number of Birds, of 10 Animals Analyzed, Fed a Barley-Based Diet Not Supplemented (NC) or Supplemented with a Commercial β-Glucanase (Rov), the GH16-1C Construct, or the GH16-3C Construct, Presenting β-Glucanase Activity in Digesta Samples Collected from Various Gastrointestinal Compartments

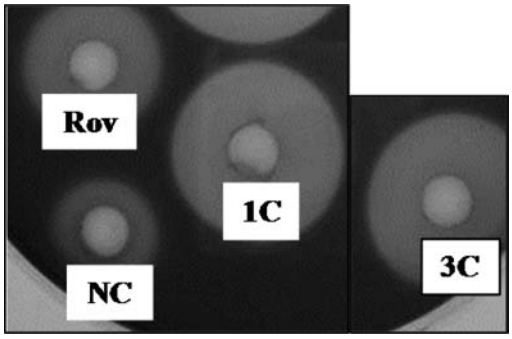

Figure 3. Qualitative plate assay for detection of β-glucanase activity in the barley-based diet not supplemented (NC) or supplemented with a commercial β-glucanase (Rov) or with mini-cellulosome GH16-1C (1C) or GH16-3C (3C).

The integrity of exogenous enzymes during passage through the GI tract was verified through zymogram analysis. The data, presented in Figure 4, reveal that the cecum of all animals is populated with a large range of β-glucanases presenting molecular masses ranging from 20 to 100 kDa. In contrast, a limited number of polypeptides expressing β-glucanase activity are present in other portions of the GI tract. In particular, a prominent 96 kDa protein is present in the majority of the digesta samples collected in both supplemented and nonsupplemented animals, and this might constitute an endogenous enzyme expressed in barley seeds. In addition, a second potentially endogenous but nonetheless less prominent polypeptide is identified in samples of the majority of the animals and presents approximately 34 kDa (Figure 4A). Digesta samples collected in the gizzard, duodenum, jejunum, and ileum of supplemented animals display the presence of highly active polypeptides. The majority of the β-glucanase activity expressed by birds supplemented with the commercial enzyme mixture seems to be represented by two polypeptides of 32 and 36 kDa, respectively (Figure 4B). These proteins are clearly visible in the small intestine of supplemented animals, although in some GI fractions they seem to be absent. This may result from a partial inactivation of the polypeptides due to pH denaturation or proteolysis.

With the exception of the gizzard, zymogram analysis of digesta samples of animals supplemented with mini-cellulosome preparations revealed the presence of β-glucanase activity. Zymogram analysis is preceded by SDS-PAGE. During SDS-PAGE protein denaturation will lead to the disassembling of mini-cellulosomes. Thus, zymogram analysis of mini-cellulosomes should reveal exclusively the polypeptide bands corresponding to the cellulosomal catalytic units. The data, presented in Figure 4, panels C (GH16-1C) and D (GH16-3C), suggest that in the crop of animals receiving the GH16-1C and GH16-3C mini-cellulosomes, *Ct*Glc16A is present in two forms, with molecular masses of 28 and 35 kDa, respectively. These two bands in the crop are present approximately in similar proportions. In contrast, when duodenum, jejunum, and ileum digesta fractions are analyzed (Figure 4C,D), *Ct*Glc16A is observed exclusively in the 28 kDa form. *Ct*Glc16A used in this study is a bimodular enzyme containing an N-terminal GH16 β-glucanase catalytic domain and a C-terminal dockerin module, which is responsible for anchoring the enzyme into the cellulosome. The two modules are separated by a proline-rich linker region. Data presented in Figure 4C,D suggest that the linker sequence separating the two *Ct*Glc16A modules is prone to proteolysis in the avian GI tract, and the 28 kDa band corresponds in size to a *Ct*Glc16A truncated derivative lacking the C-terminal dockerin. Proteolytic cleavage of the bimodular exogenous β-glucanase starts in the crop, where only 50% of the enzyme was present in the intact form. Taken together, the data presented here suggest that proteolysis affects the integrity of mini-cellulosomes used to supplement barley-based diets for poultry by removing the dockerin sequence of *Ct*Glc16A, most probably through cleavage of the linker region separating the two sequences.

To confirm that endogenous proteases are contributing to unbound *Ct*Glc16A from mini-cellulosomes through the removal of the enzyme C-terminal dockerin, the two protein complexes were incubated in vitro with a pancreatic mixture of proteases (see Materials and Methods for details). After 30 min of incubation at 37 °C, the proteins were separated through SDS-PAGE to evaluate mini-cellulosome integrity. The data, presented in Figure 5, confirm that *Ct*Glc16A is indeed susceptible to proteolysis and that proteases cleave the full-length enzyme to generate a truncated version of the recombinant β-glucanase consisting exclusively of the enzyme's

catalytic domain (28 kDa). Linker regions play an important function in the efficacy of CAZYmes and cellulosomes by contributing to the flexibility of the modular enzymes and the quaternary structure of protein complexes.[36] Glycosylation of protein linker regions is known to protect them from proteolytic cleavage.[37] *Ct*Glc16A was recombinantly produced in *E. coli* that is unable to glycosylate proteins.[38,39] It is presently unknown if *C. thermocellum* cellulosomal enzymes are glycosylated at their linkers. However, this study clearly indicates that protection of linker regions of cellulosomal enzymes from proteolytic cleavage is fundamental to maintain cellulosome integrity. Finally, cohesin domains seem to resist the protease attack, although mini-scaffoldin C3−C4−C5 was susceptible to proteolysis at its linkers (Figure 5, lane 4).

In conclusion, this study reports the in vivo construction of two mini-cellulosomes based on scafoldins with one or three CipA-derived cohesin domains. The protein complexes were purified, and protein stability studies revealed that *Ct*Glc16A

biochemical properties are not significantly affected by protein complexation. However, the catalytic efficacy of GH16-3C mini-cellulosomes seems to be slightly reduced. This may represent a decrease in enzyme flexibility resulting from the assembling in a multiprotein complex. Protein flexibility is highly important for the hydrolysis of soluble carbohydrates. The two mini-cellulosomes are shown to be very effective in improving the nutritive value of barley-based diets for poultry. However, the efficacy of the recombinant nanomachines is not improved when compared with that of commercially available enzyme mixtures. Whether this represents a comparable efficacy of the three enzyme systems under analysis (commercial unbound enzymes, GH16-1C, and GH16-3C) or a saturation of the animal feed with exogenous enzymes remains to be established. In addition, endogenous proteases were shown to affect the integrity of the recombinant mini-cellulosomes by cleaving the linker region that separates *Ct*Glc16A catalytic and dockerin domains. Thus, in future studies protection of linker regions needs to be improved as the molecular integrity of mini-cellulosomes is critical to potentiate its use in a variety of biotechnological applications.

[a]Values in this row indicate the concentrations of the free radical-generating system. [b]Values in this row followed by different letters are significantly different ($P < 0.05$).

μm mesh), and collagen was eliminated by filtration on the sifter. The filtrate was centrifuged at 2000g for 15 min at 4 °C. The pellet was washed twice with 100 mL of a 50 mM KCl solution at pH 6.4 and once with 100 mL of 20 mM phosphate buffer at pH 6.0. Myofibrils were adjusted to a certain concentration (12 mg/mL) for use.

The protein contents of myofibrils were 88 ± 2% (dry basis). The water contents of myofibrils were 4.1 ± 0.6% (after freeze-drying).

Lipid Extraction and Analysis of the Fatty Acid Composition by Gas Chromatography and Mass Spectrometry (GC−MS). Lipids were extracted from myofibrils with a chloroform/methanol mixture [2:1 (v/v)] according to the method described by Qiu et al.[19] The extracts were dried under vacuum on a rotary evaporator and finished with a nitrogen flow.

The fatty acid composition of lipids from myofibrils was determined by gas liquid chromatography of methyl esters prepared using the method described by Qiu et al.[19] The GC−MS system consisted of a Trace Ultra gas chromatograph (ThermoFinnigan, San Jose, CA), a Trisplus automated sampler, and a quadropole DSQ II mass spectrometer. GC was performed on a TR-5MS capillary column [30 m × 0.2 mm, 0.25 μm (Thermo)]. Chromatograms and mass spectra were evaluated using Xcalibur software bundle version 2.0 (ThermoFinnigan). The relative percentages of fatty acids were determined by the peak areas.

Chemical Induction of Myofibril Oxidation. Chemical oxidation was conducted according to the method described by Morzel et al.[17] Myofibrils (final concentration of 10 mg/mL) were incubated for 3 h at 37 °C in 20 mM phosphate buffer at pH 6.0 with an $FeSO_4$/diethylenetriaminepentaacetic acid (DETAPAC)/H_2O_2 (Fenton's reagent) mixture at various concentrations (from 0 to 10 mM). The H_2O_2 concentration was adjusted by the absorbance at 240 nm. Phosphate was used in this study because, as opposed to other buffers commonly used for protein studies, it has no marked effects on protein oxidation.[20] After 3 h, no residual H_2O_2 could be detected by absorbance at 240 nm ($\varepsilon = 43.6\ M^{-1}\ cm^{-1}$), but to prevent subsequent oxidation, butylated hydroxyl toluene (BHT, at a final concentration of 1 mM) was added to the incubation medium. Samples were centrifuged at 4000g for 10 min, and the pellets were washed extensively with corresponding buffers. The pellet was washed twice with 100 mL of distilled water. The washed myofibril pellet was freeze-dried for XPS (which can investigate the surface chemical composition of biological powders obtained by freeze-drying). The protein oxidation level was evaluated by the carbonyl content and free thiol group content. Results (not shown) were similar to those of previous studies[16,17] and indicated that protein oxidation did occur.

Particle Size Distributions. Particle size distributions of myofibrils were measured by an integrated-laser light scattering instrument (Mastersizer 2000, Malvern Instruments Co. Ltd., Worcestershire, U.K.). The relative refractive index and absorption were set as 1.414 and 0.001, respectively. $D_{4,3}$ is the mean diameter in volume, whereas $D_{3,2}$ is the mean diameter in surface called the "Sauter diameter". The specific surface area (square meters per gram) was also recorded. $D_{v,0.5}$ is the size for which 50% of the sample particles have a lower size and 50% have an upper size. These indexes of protein were analyzed using Malvern Mastersizer software (version 5.12c, Malvern Instruments Co. Ltd.).

Sodium Dodecyl Sulfate−Polyacrylamide Gel Electrophoresis (SDS−PAGE). SDS−PAGE was performed on myofibrils according to the method described by Flores et al.[21] Briefly, 2 mg lyophilized samples were dissolved in 500 μL of sample buffer with and without 5% β-mercaptoethanol (β-ME), and the samples with β-ME were boiled for 3 min before centrifugation (10000g for 10 min). Then, 9 μL samples were loaded onto the polyacrylamide gel made of a 13.5% running gel and a 5% stacking gel and subjected to electrophoresis at a constant current of 25 mA per gel using a Mini-PROTEAN 3 Cell apparatus (Bio-Rad Laboratories, Hercules, CA).

Salt Solubility. The concentration of KCl in the myofibril stock suspension was increased to 0.6 M by adding 2.0 M KCl containing 20 mM sodium phosphate buffer (pH 6.5), and the solution (1 mg/mL) was kept at 0 °C for 2 h and centrifuged at 5000g and 4 °C for 30 min to separate salt-soluble fractions (supernatants) from the insolubles. Protein contents were determined by the Biuret method using bovine serum albumin as a standard. Salt solubility was expressed as the percentage of total protein.

X-ray Photoelectron Spectroscopy (XPS). X-ray photoelectron spectroscopy data were collected with an AXis Ultra DLD spectrometer (Kratos Analytical) using Al Kα monochromic X-ray radiation ($h\upsilon$ = 1486.6 eV, 150 W). The X-ray source was run at 15.0 kV and 10 mA. Samples were placed in a vacuum chamber (5.0×10^{-10} Torr). The takeoff angle of the photoelectrons was perpendicular to the sample. Elemental compositions were determined from spectra acquired at a pass energy of 160 eV. High-resolution spectra were recorded using an analyzer pass energy of 40 eV. The binding energy was set by fixing the C−(C,H) component of the C 1s peak at 284.8 eV. Data analysis was performed using PeakFit version 4.12 (SPSS Inc., Chicago, IL). Atomic concentrations were calculated from photoelectron peak areas. The areas of the bands were calculated by integration of the corresponding fitted band with a Gaussian−Lorentzian fitting procedure and after subtraction of a linear baseline (full width at half-maximum of 1.4 eV and a maximal resolution factor).

Microstructure. The microstructure of the myofibril sample was observed with a scanning electron microscope (S-3700N, Hitachi Co., Tokyo, Japan) at an operating voltage of 10 kV. The samples were deposited on silicon wafers and coated with a conductive material (gold) to ensure sufficient electron refraction. They were then mounted on an aluminum stub with epoxy and coated with a gold platinum alloy in a sputter-coating device.

Statistical Analysis. Statistical calculation was investigated using SPSS version 11.5 (SPSS Inc.) for one-way analysis of variance. The least-squares difference was used for comparison of mean values among treatments and to identify significant differences ($P < 0.05$) among treatments.

RESULTS AND DISCUSSION

Lipid Analysis. During the isolation of myofibrils, proteins are co-extracted with a certain amount of lipid. As shown in Table 1, lipid contents in dry myofibrils were between 3.38 ± 0.70 and 4.16 ± 0.92%. Oleic acid (C18:1) was the most abundant fatty acid followed by palmitic acid (C16:0). With the addition of an increasing amount of oxidizing agent, the proportions of linoleic acids (C18:2) and arachidonic acid (C20:4) decreased, but the proportions of oleic acid increased except at 10.0 mM. The decrease in the contents of these fatty acids (polyunsaturated fatty acids) might be due to the occurrence of oxidation. This result was in agreement with the report of Qiu et al.,[19] showing that the polyunsaturated fatty acids are more oxidized than the monounsaturated fatty acids.

Particle Size Distributions. The particle size distributions of myofibrils as a function of free radical-generating system concentration are shown in Figure 1. Compared with that of the control, the volume of large particles (100−1000 μm) of myofibrils treated with 37 °C decreased slightly. Promeyrat et al.[22] have found that cooking can produce a decrease in the volume of large particles of myofibrils. Addition of an oxidizing agent between 0.2 and 1.0 mM also led to a decrease in the volume of large particles in a concentration-dependent manner. However, at 3.0 mM oxidizing agent, the particle size distribution showed a relatively obvious double peak, indicating that the distributions of large particles and small particles increased simultaneously. At 5.0 and 10.0 mM oxidizing agent, the particle size range between 10 and 100 μm increased remarkably, while the particle size range between 100 and 1000 μm decreased correspondingly.

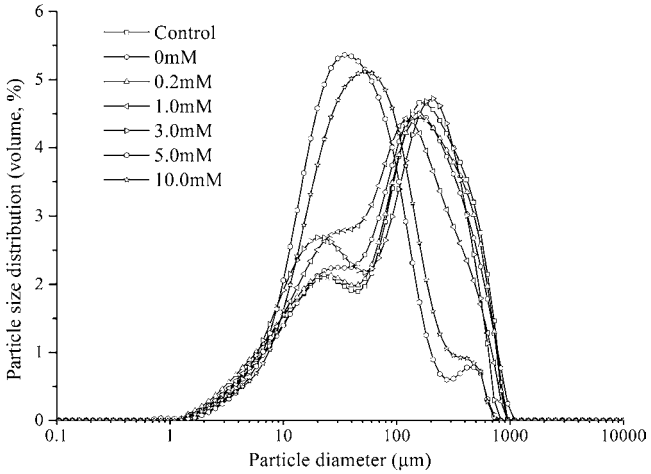

Figure 1. Effect of different concentrations of the free radical-generating system on particle size distributions of myofibrils.

As shown in Table 2, the $D_{3,2}$ value of myofibrils treated with 37 °C showed no significant difference ($P > 0.05$) compared to that of the control, while the value of $D_{4,3}$ decreased significantly ($P < 0.05$). Because large droplets or droplet aggregates have weights in the calculation of $D_{4,3}$ higher than that in the calculation of $D_{3,2}$, samples with similar $D_{3,2}$ values but different $D_{4,3}$ values would differ mainly in the amount of large droplets or droplet aggregates. Addition of an oxidizing agent could produce a decrease in $D_{3,2}$ and $D_{4,3}$, but not in a concentration-dependent manner. Under poorly oxidative conditions (0.2 and 0.5 mM), $D_{3,2}$ and $D_{4,3}$ decreased significantly ($P < 0.05$). Between 1.0 and 3.0 mM oxidizing agent, $D_{3,2}$ increased significantly ($P < 0.05$), whereas the value of $D_{4,3}$ further decreased at 1.0 mM. The lowest values of $D_{3,2}$ and $D_{4,3}$ (21.33 and 63.93 μm, respectively) were observed at 5.0 mM oxidizing agent. At 10.0 mM oxidizing agent, $D_{3,2}$ and $D_{4,3}$ increased slightly compared to the values at 5.0 mM. Changes in $D_{v,0.5}$ were similar to changes in $D_{4,3}$. For a specific surface area, a reciprocal change compared to $D_{3,2}$ was also found during the oxidative process. Span is the width of the distribution regardless of the median size, indicating the uniformity of the measured system.[23] Compared to that of the control, a significant increase in span (from 3.57 to 3.81) was observed after incubation for 3 h at 37 °C without an oxidizing agent. Span increased to a maximum at 1.0 mM and thereafter decreased continuously during the later stage.

Protein oxidation can lead to changes in the physical properties of the proteins, including cleavage of peptide bonds (fragmentation), modification of amino acid side chains, and formation of intra- and intermolecular cross-links.[12,13] The hydrophobic surfaces frequently act as the interfaces between the interacting molecules. Protein oxidation can enhance protein surface hydrophobicity by exposing hydrophobic amino acids, which are buried inside in native status.[16] The heat treatment also can induce partial unfolding of the proteins, thereby exposing certain sites that are normally hidden within proteins.[24] A decrease in the particle size due to heat treatment and oxidation could be explained by the formation of intermolecular cross-links and protein aggregates, and these aggregates look like a disorganized stack of fibers with no preferential orientation.[22] Bityrosine and Schiff base formation between protein molecules can also lead to polymerization and aggregation.[16,20] An increase in span after incubation for 3 h at 37 °C without an oxidizing agent or under poorly oxidative conditions confirmed this cross-link process.

Table 2. Effects of Different Concentrations of the Free Radical-Generating System on Average Particle Size, Specific Surface Area, and Span of Myofibrils[a]

	$D_{3,2}$ (μm)	$D_{4,3}$ (μm)	$D_{v,0.5}$ (μm)	specific surface area (m^2/g)	span

[a]Values in the same column followed by different letters are significantly different ($P < 0.05$). [b]Values in this column are the concentrations of the free radical-generating system.

SDS−PAGE and Salt Solubility Analysis. As shown in Figure 2, in the absence of β-ME, myosin heavy chain (MHC)

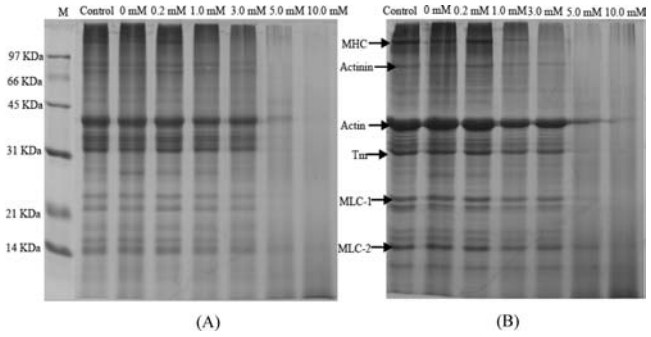

Figure 2. Effect of different concentrations of the free radical-generating system on the SDS−PAGE pattern of myofibrils in the absence (A) and presence (B) of 5% β-mercaptoethanol.

gradually showed a decreased band intensity and even vanished after the addition of an oxidizing agent. All bands were lost upon addition of excess oxidizing agent (>5.0 mM), indicating over-cross-linking of myofibrillar proteins. MHC under highly oxidative conditions could not be recovered in the presence of β-ME. This indicated that most cross-linking that originated from myosin was not only through disulfide bonds. The actin band was relatively more stable, and their band intensity exhibited a progressive decrease at higher oxidant concentrations. These results were in accordance with a previous work.[17] Under highly oxidative conditions, the band appeared to be much more diffused, indicating the degradation or fragmentation of myofibrils. As shown in Figure 3, salt solubility

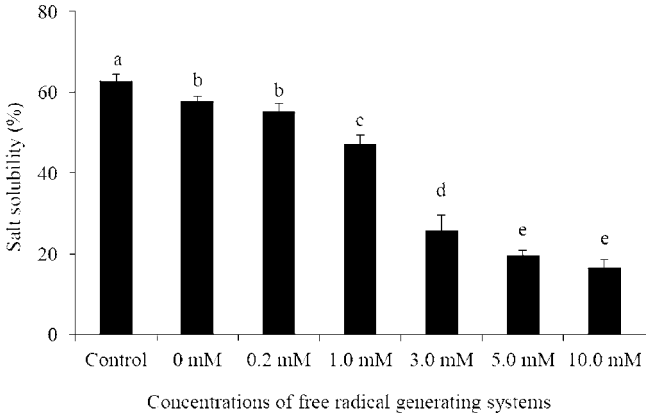

Figure 3. Effect of different concentrations of the free radical-generating system on the salt solubility of myofibrils.

decreased with an oxidizing agent ($P < 0.05$). Salt solubility can reflect the extent of myofibril aggregation after oxidation.[25] Protein aggregates induced by hydroxyl radicals can be formed mainly via bityrosine formation and carbonyl formation.[17] Aggregation due to disulfide cross-linkages is also involved. Fragmentation of the protein is a consequence of the direct attack by hydroxyl radicals on the polypeptide backbone or on the side chains of glutamyl or prolyl residues.[26]

XPS Analysis. XPS analysis was used to identify the chemical functions and the components located at the surface of myofibrils and to try to quantify the surface concentrations of components.

Surface Composition. As expected, XPS survey scans obtained from myofibrils give major signals corresponding to C, O, N, and P (Table 3). It was notable that the detection of S 2p elements was possible due to the very good detectivity of the XPS equipment, but this element was neglected because of its very low content and high noise level. The relative atomic concentrations of carbon, nitrogen, oxygen, and phosphorus measured for myofibrils are listed in Table 3. The relative atomic concentrations of carbon showed no significant difference after heat treatment and oxidation. The relative atomic concentrations of nitrogen and oxygen changed significantly ($P < 0.05$). These results indicate that the surface properties of myofibrils have changed after oxidation. Zhao et al.[27] showed the correlation was found between the elemental composition and particle size of ginger powder. Differences in particle size distributions could lead to slight differences in elemental composition.[27] However, in this work, no statistically significant correlation was found between the elemental composition and particle size of myofibrils. This discrepancy might be attributed to not only changes in particle sizes but also oxidation and structural changes that involved changes in elemental composition during the oxidative process. Myofibril aggregation induced by oxidation, heat treatment, and freeze-drying could also contribute to this phenomenon. The P 2p element was detected in this work, which confirmed the presence of phospholipids at the myofibril surface. However, no statistically significant correlation was found between the P 2p element atomic concentration at the surface and the lipid content of myofibrils. In addition, N2/P was changed during the oxidative processing. These results indicated that only a portion of the phospholipids are located at the surface layers of myofibrils, and the phospholipid distribution was altered during the oxidative processing.

Because of the presence of the lipid within the surface layers of myofibrils and different amino acids that are prone to being located in the surface layers of myofibrils, the decreased N/C atom ratios and O/C ratios (0.111 and 0.222, respectively) were compared to the theroitcial chemical composition of $C_1H_{1.88}O_{0.45}N_{0.27}S_{0.005}$ [according to amino acid analysis (data not shown)]. The changes in N/C atom ratios might be caused by protein structural changes, oxidation, and phospholipid distribution. Protein oxidation can result in conformational changes in the myofibrillar protein.[12,28] Under highly oxidative conditions, protein fragmentation led to more amino groups exposed, resulting in increases in N/C ratios. Oxidation of the myofibril surface[29] and a change in the interaction between myofibrils yield increases in lipid-induced O/C ratios. Decreases in O/C ratios might be due to protein fragmentation.

C 1s Spectra. The XPS survey scans for myofibrils were analyzed to assign the C 1s peaks to chemical functions. As shown in Figure 4, four main protein functional groups for the C 1s peak were identified. The major component at 284.8 eV (C1) was due to C making a single bond with C or H (C−C or C−H, respectively) and indicated the presence of aliphatic lateral chains of amino acids and lipid in the myofibrils.[7,30,31] The peak (C2) at 286.1−286.2 eV was attributed to C making a single bond with O or N (C−O or C−N, respectively) in amide functions in proteins.[7,30] The peak (C3) at 287.5−287.7 eV was identified as C making two single bonds or one double bond with O (O−C−O, O=C−N, or O=C) in ester and amide functions in proteins.[30,32] Lastly, the carboxyl group was found at 288.7−288.9 eV (C4), which was C making one double or single bond with O (O=C−OH or O=C−OR).[7,32]

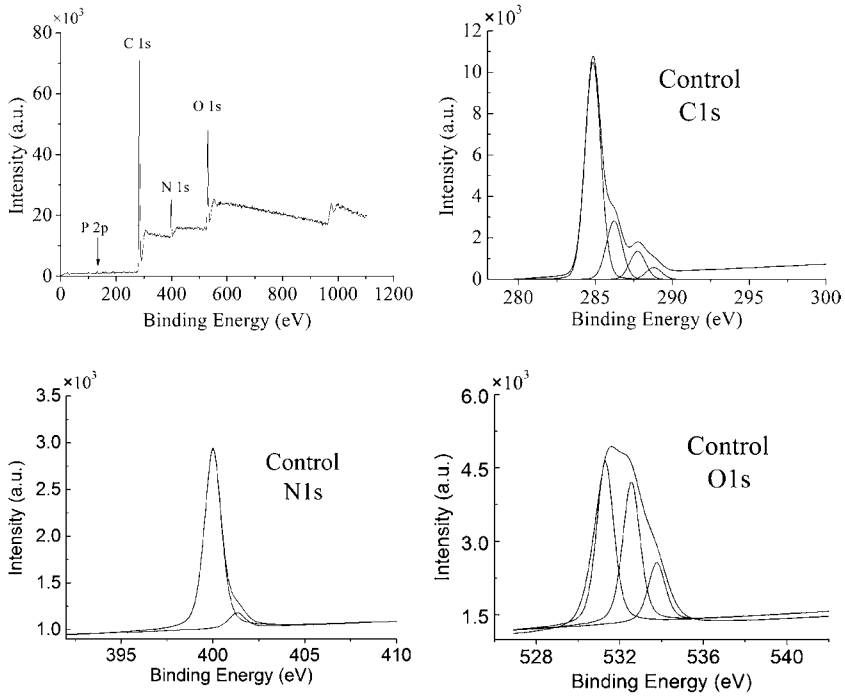

Figure 4. XPS survey spectra and typical deconvoluted C 1s, N 1s, and O 1s high-resolution XPS spectra of myofibrils.

The corresponding results of the curve fitting analysis are listed in Table 3. The binding area of C1 showed no significant difference ($P > 0.05$) under oxidative conditions from 0 and 1.0 mM. At 3.0 mM oxidizing agent, it decreased significantly ($P < 0.05$) and increased to the former value at 5.0 and 10.0 mM oxidizing agent. The key points for the change in the binding area of C2 and C3 were also observed at 3.0 mM oxidizing agent ($P < 0.05$). Reciprocal changes in the binding area of C4 were found during oxidative processing.

Amino acids with the NH or NH_2 moiety on their side chains can react with free oxygenated radicals (such as $OH^{\bullet}$ generated by Fenton reaction) that involves the formation of carbonyl moieties.[33] Protein carbonyl derivatives can be generated through oxidative cleavage of proteins by either the α-amidation pathway or oxidation of glutamyl side chains, leading to the formation of a peptide in which the N-terminal amino acid is blocked by an α-ketoacyl derivative.[12,13] The changes in C 1s binding area, especially for C3 and C4 during oxidative processing, could be due to the formation of carbonyl groups. Protein fragmentation might result in the C3 and C4 binding area decreasing during the last oxidative processing. In addition, myofibril particle size variations due to aggregation could also contribute to changes in C 1s spectra.[7] Myofibril aggregation might alter their surface properties by exposure of different amino acid residues.

N 1s Spectra. Figure 4 shows the peak decomposition for the N 1s peak, decomposed into two peaks. The peak (N1) at 399.7−399.9 eV was attributed to uncharged nitrogen, typical of amine (C−NH2)[7] or amide (O═C−NH2 and O═C−NH−C) in proteins.[7,30] The peak (N2) at 401.1−401.3 eV was attributed to positively charged N ($C-\underline{N}H_3^+$) in protonated amine or quaternary ammonium functions in proteins.[32]

As shown in Table 3, upon addition of an increasing amount of oxidizing agent, the binding area of N1 decreased slightly to the minimum of 89.10% ($P > 0.05$) at 10.0 mM oxidizing agent. Reciprocal changes in the binding area of N2 were found during oxidative processing. An increase for positively charged N ($C-\underline{N}H_3^+$) of N2 indicated that amino acid residues in proteins were attacked by $OH^{\bullet}$. Protonated nitrogen was formatted during protein carbonylation.[12,13,34] Phospholipids are also attributed to protonated amine. Alteration of the phospholipid distribution could partially explain changes in N2.

O 1s Spectra. The O 1s peak is decomposed into three peaks. The peak (O1) at 531.2−531.4 eV is attributed to O doubly bound to C (O═C−O, O═C−N, or O═C−OH), due to amide, ester, and carboxyl in proteins.[7,31] Two oxygen atoms bound to phosphorus (P═O and $P-O^-$) in phospholipids also contribute below 532 eV.[8] The peak (O2) at 532.3−532.5 eV is attributed to O making single bonds with C (C−OH, C−O, or C−O−C) in amino acid side chains of proteins.[7,30] The peak (O3) at 533.6−533.8 eV is attributed to O singly bound to C (O═C−O−R) in ester and carboxyl functions in proteins.[7] However, O2 may be due to the overlapping of carboxyl groups,[30] peptide groups,[30] or C−O groups,[32] and O1 may be due to similar functional groups.[31]

As shown in Table 3, the binding area of O1 decreased first and then increased during the later stage. Reciprocal changes in the binding area of O2 and O3 were found during the oxidative processing. Some researchers suggested that the O 1s spectra did not provide useful chemical-state information because so many O-containing species were present, which could not be resolved by XPS because of their closely spaced binding energies,[5,35] but using these values, the results in this study suggested that O-containing functional groups of the myofibril surface changed significantly after oxidation. In addition, a significant correlation between the binding area of O1 and N2/C was observed. However, no significant correlations between N2/C and C3 and P were found. These results might imply that protein carbonylation and phospholipid alteration are involved in changes in O 1s spectra.

Microstructure. To understand the effect of oxidation on the surface characterization of myofibrils, the microstructure

dx.doi.org/10.1021/jf501272p | J. Agric. Food Chem. 2014, 62, 7507−7514

was observed by scanning electron microscopy (SEM) at a magnification factor of 300-fold. Figure 5 shows a set of SEM images of myofibrils. Myofibrils (control) showed a complex heterogeneous structure consisting of clumps with different sizes and shapes. Incubation for 3 h at 37 °C without an oxidizing agent led to a slight increase in clump size. This observation was consistent with particle size analysis. Addition of 0.2−1.0 mM oxidizing agent could induce the appearance of the filaceous curliness structure. In particular, fibrous curliness was observed at 0.2 mM oxidizing agent. Formation of the structures described above on the surface of oxidized myofibrils had been attributed to modification of amino acid side chains that rendered protein intra- and intermolecular cross-links and aggregates. Some relative homogeneous flake or clumps structures were exhibited in the samples of 3.0, 5.0, and 10.0 mM oxidizing agent. These structural features suggested protein fragmentation due to cleavage of peptide bonds. These results of the microstructure analysis were in agreement with span (Table 2).

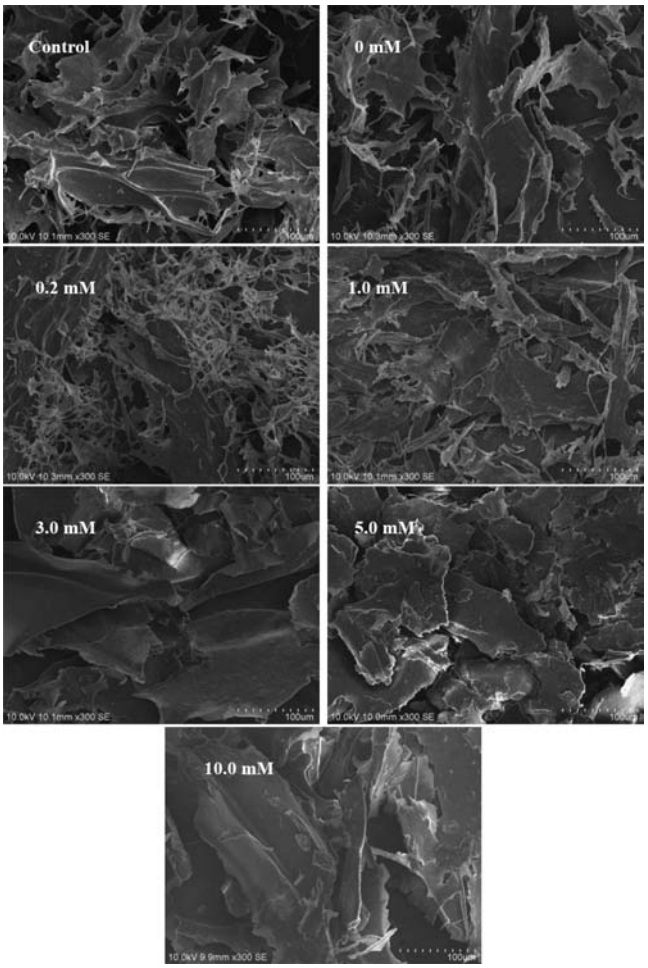

Figure 5. Scanning electron micrographs of control myofibrils and oxidized myofibrils.

In this investigation, particle size, XPS, and SEM analysis yielded complementary and essential information for the evaluation of myofibril surface changes during oxidative processing. Results presented as XPS data, including the C 1s, N 1s, and O 1s spectra, led to the conclusion that surface compositions were modified during oxidative processing, which correlate with cleavage of peptide bonds, modification of amino acid side chains, formation of intra- and intermolecular cross-links, and phospholipid alteration. The results of SEM analysis further confirmed it. This study would be helpful for understanding the relationship between surface characterization and functional properties of myofibrils after oxidation.

wines produced from the hybrid grapes Corot noir and Marechal Foch, as compared to an average of 500 mg/L in *vinifera* wines.[18−20] Furthermore, vinification techniques aimed at increasing hybrid wine condensed tannin, including extended maceration, pectinase enzyme addition, and exogenous tannin addition, were shown to be ineffective.[8] However, concentrations of tannin in the skin and seeds of the hybrid grapes were comparable to literature reports of tannin in red *vinifera* grapes.[18,19] Although interpretation of these results is complicated by the fact that the studies were performed in different regions and with different winemaking protocols, they suggest that variation in wine tannin may result from differences in grape tannin extractability rather than grape tannin concentration. The impact of tannin extractability on final wine tannin concentrations has been recognized in studies on *vinifera*. In contrast to anthocyanin pigments, tannins in grapes are reported to be uncorrelated with tannins in finished wines, even under identical winemaking conditions.[21] Multiple authors have reported that a significant portion of grape tannin remains bound to insoluble cell wall materials after fermentation and that the ability of both berry skin and flesh cell walls to bind tannin could account for the incomplete extraction of tannin into wine.[21,22] Potentially, greater tannin−cell wall interactions and thus poorer tannin extractability could also explain low tannin concentrations in red hybrid wines.

In this work, we first confirmed that tannin concentrations were significantly lower in wines produced from hybrid grapes in comparison to *vinifera*, as had been observed in limited previous studies. We then evaluated two separate hypotheses to explain these differences, either that the grape species differed in tannin concentration or that they differed in tannin extractability. The latter was investigated by quantifying tannin binding by grape cell wall material and appeared to be the more important explanation. Finally, we hypothesized that differences in tannin binding among cell wall fractions could be related to differences in the major tannin-binding macromolecular classes, protein and pectin.

MATERIALS AND METHODS

Chemical Reagents. Ethanol (reagent grade), (+)-catechin hydrate, albumin from bovine serum, iron(III) chloride, triethanolamine (TEA), sodium dodecyl sulfate (SDS), Viscozyme L, sodium tetraborate, 3-phenylphenol, sulfamic acid, and D-(+)-galacturonic acid monohydrate were obtained from Sigma-Aldrich (St. Louis, MO, USA). Acetic acid, sodium hydroxide, hydrochloric acid, potassium metabisulfite, acetone, L-(+)-tartaric acid, Clinitest tablets (Bayer, Pittsburgh, PA, USA), sodium acetate anhydrous, and sulfuric acid were sourced from Fisher Scientific (Waltham, MA, USA). A grape tannin extract, BioTan, was provided by Laffort (Petaluma, CA, USA). Diammonium hydrogen phosphate (DAP) was purchased from Presque Isle Wine Cellars (North East, PA, USA). GoFerm Protect, Fermaid K, and Lalvin ICV-GRE yeast were obtained from Lallemand (Santa Rosa, CA, USA).

Survey of Tannins in *V. vinifera* versus Hybrid (*Vitis* spp.) Wines. Ten commercial *vinifera* varietal wines and 10 interspecific hybrid wines from the Finger Lakes (NY) American Viticultural Area (AVA) were purchased from a local store (Geneva, NY, USA). Wines covered the vintages 2010−2012. Additionally, two *V. vinifera* varietals and two interspecific hybrid wines from these vintages were provided by the Cornell Vinification and Brewing facility (Geneva, NY, USA). Protein-precipitable tannin was measured using the Adams−Harbertson assay, as described elsewhere.[23]

Grape Sample Collection. Six *vinifera* cultivars (Pinot noir, Merlot, Lemberger, Sangiovese, Cabernet Sauvignon, and Cabernet franc) and six *Vitis* spp. hybrids (French−American hybrids Baco noir, Leon Millot, Maréchal Foch, and DeChaunac; neo-American hybrids Corot noir and Noiret) were hand harvested across two vineyard locations within the Finger Lakes AVA in New York state at commercial harvest time points in 2012. Three kilograms of each cultivar was collected, from which 50 berries were randomly selected and pressed for juice analysis. Titratable acidity was measured using a Titrino Plus 848 doser and 869 autosampler (Metrohm USA, Riverview, FL, USA), soluble solids were determined with an Atago digital pocket refractometer (Japan), and pH was analyzed using an Accumet Excel XL25 pH meter (Thermo Fisher Scientific, Waltham, MA, USA). Harvested fruit not used for winemaking was kept frozen at −20 °C for further analyses.

Winemaking. From each harvested sample, fresh berries were manually destemmed, and 750 g was crushed into 1 L fermenters in duplicate. Musts were treated with 100 mg/L sulfur dioxide, added as potassium metabisulfite, before inoculation with yeast (0.2 g/L, rehydrated with GoFerm according to the manufacturer's instructions). Fermaid K and DAP were added at rates of 0.25 and at 0.3 g/kg, respectively, after 48 h. All samples were fermented at 18 °C on the skins with daily punch downs. After 7 days, residual sugar was determined to be below 0.5 g/L in all fermentations by Clinitest, and wines were pressed manually using cheesecloth. Wines were supplemented with 60 mg/L sulfur dioxide, bottled in 187 mL glass bottles under nitrogen, and crown capped (Waterloo Container, Waterloo, NY, USA). Bottled wine was stored in the dark at 2 °C until analyzed.

Condensed Tannin Measurements in Experimental Wine and Grape Samples. Condensed tannin in wine was measured by the Adams−Harbertson protein precipitation assay as described elsewhere.[23] Samples that fell below the limit of quantification (100 mg/L, or an absorbance change of <0.3 AU[24]) were concentrated in an Eppendorf vacufuge (Hamburg, Germany) until the volume was reduced by half, and the protein precipitation assay was rerun. To determine condensed tannin in fruit, a frozen 50 berry subsample (in duplicate) was dissected on ice into skin, flesh, and seed fractions using forceps and a scalpel. Freshly dissected sample weights of each tissue were recorded. An extract was prepared from the skins by agitation in 100 mL of 70% acetone overnight, and solids were separated by vacuum filtration and saved for cell wall material preparation. Acetone was removed from 1 mL of extract under reduced pressure at 30 °C, and volumes were adjusted to 1 mL with filtered water (Millipore Corp., Billerica, MA, USA) before measurement of protein-precipitable tannin. Seeds were extracted with 25 mL of 70% acetone overnight with agitation. Solids were filtered as for skins, acetone was removed from a 1 mL aliqout and the final volumes were adjusted to 1 mL with Milli-Q filtered water before measurement of protein-precipitable tannin. Tannin extractability was calculated as the ratio of protein-precipitable tannin quantities (mg) in a volume of wine (L) to protein-precipitable tannin quantities in a corresponding weight of berries (mg/g, skin plus seed):

$$\text{tannin extractability} = \left[\frac{\text{wine tannin } \frac{\text{mg}}{\text{L}}\ \text{CE} \times \text{wine yield (L)}}{\left(\text{seed} + \text{skin tannin } \frac{\text{mg}}{\text{g}}\ \text{CE}\right) \times \text{initial must wt (g)}}\right] \times 100\% \quad (1)$$

Preparation of Alcohol-Insoluble Cell Wall Material. Cell wall material was prepared as alcohol-insoluble solids in a manner similar to that of de Vries and co-workers.[25] For each 50 berry subsample replicate, acetone-extracted skins (from above) were extracted in 200 mL of hot 95% ethanol for 10 min and vacuum filtered. The procedure was repeated twice for each replicate. The alcohol-insoluble cell wall material was then rinsed with acetone and allowed to dry overnight in a 40 °C oven, weighed, ground to a fine powder using a Genogrinder 2000 (Spex SamplePrep, Metuchen, NJ, USA), and stored at −20 °C until use. This procedure was repeated for the grape flesh fractions, isolated as described in the previous section.

Evaluation of Tannin Binding by Cell Wall Material. Tannin binding experiments were performed in model wine, consisting of 1500 mg/L BioTan, 12% (v/v) ethanol, 5 g/L tartaric acid, and Milli-Q filtered water with the pH adjusted to 3.3 using NaOH. Ten milligrams of each skin or flesh cell wall fraction was weighed into a 1.5 mL microcentrifuge tube in duplicate. To each tube was added 1 mL of the BioTan model wine solution. Controls containing only the BioTan model wine and no cell wall material were prepared in triplicate. Microcentrifuge tubes were sealed with Parafilm and incubated overnight at room temperature (23 °C) on a shaker in the dark to allow for tannin−cell wall binding, after which insoluble material was pelleted by centrifugation at 10000*g* for 5 min. The protein-precipitable tannin was then measured for the supernatant from each tube. For each tube, the amount of condensed tannin bound to cell wall material was calculated as the difference between the protein-precipitable tannins measured in the controls and the tube's supernatant. For this paper, a distribution coefficient, *K*, was used to quantify the degree of tannin binding, where a lower *K* value indicates stronger binding. *K* was calculated by dividing the concentration of tannin remaining in the model wine solution after incubation with cell wall materials by the apparent concentration of tannin bound to cell wall material:

$$K = \frac{[\text{tannin in supernatant}]}{[\text{tannin in control} - \text{tannin in supernatant}]} \quad (2)$$

Protein and Pectin in Cell Wall Materials. Percent nitrogen was determined for all cell wall samples using a Thermo Delta V isotope ratio mass spectrometer interfaced to an NC2500 element analyzer at the Cornell Isotope Laboratory (Ithaca, NY, USA). Crude protein was calculated as milligrams per gram nitrogen × 5.27.[26] Pectin was measured as the uronic acid content following enzymatic digestion. Enzymatic digestion was selected because it yields superior galacturonic acid recovery with less degradation in comparison to traditional hot acid hydrolysis.[27] Briefly, 5 mg of cell wall material was incubated in 950 μL of 25 mM acetate buffer, pH 4.8, in a screw-capped 1.5 mL microcentrifuge tube. Ten microliters of Viscozyme was added to each tube. Samples were mixed by vortexing and incubated at 30 °C for 18 h on a shaker. After incubation, samples were centrifuged at 13000 rpm for 5 min, and supernatant containing uronic acids was collected for analysis. Uronic acids were quantified using a spectrophotometric method with D-galacturonic acid as standard, as previously described.[28]

Statistical Analysis. For the Finger Lakes wine survey, samples that fell below the limit of quantification (100 mg/L CE, or an absorbance change <0.3 AU[24]) were assigned a value of half the quantification limit (50 mg/L CE) for statistical testing.[29,30] A similar approach was taken for experimental wines with unquantifiable tannin, except that the quantification limit was 50 mg/L CE because of the concentration step, and a value of 25 mg/L CE was assigned to these wines for statistical purposes.[29,30] JMP Pro 10 (by SAS, Cary, NC, USA) was used to perform all statistical testing and modeling for this study, with a type 1 error rate set to 0.05. Student's *t* test was performed to compare *vinifera* and hybrid wine tannin in the commercial wine survey. One-way ANOVA was performed on grape tissue weights, cell wall yields, skin tannin, seed tannin, total tannin, tannin extractability, and tannin binding cell wall experiments and for measurements of protein and pectin. When significant differences were observed following ANOVA, Tukey's range test was performed to determine if differences existed between individual groups. To investigate the effects of cultivar, harvest location, and grape classification on wine tannin, a multivariate fixed-effects modeling approach was used to identify significant variables. Graphics were generated using GraphPad Prism version 5.0c (GraphPad Software, San Diego, CA, USA).

RESULTS AND DISCUSSION

Recent papers have indicated that hybrid-based wines have low tannin concentrations as compared to literature papers for *vinifera* varietal wines, but these studies have been limited in scope.[8,18,19] We performed a survey consisting of hybrid- and *vinifera*-based wines, mostly commercial, using the Adams−Harbertson protein precipitation assay[31] to quantify condensed tannins (Supporting Information Figure S1). One challenge to using the Adams−Harbertson assay is its relatively high limit of quantification (LOQ), and several wines had nonquantifiable tannin even after preconcentration. The average protein-precipitable tannin was significantly higher in *vinifera*- than hybrid-based wines (255 vs 61 mg/L CE, $p < 0.05$). Furthermore, 10 of 12 of these wines fell below the LOQ (100 mg/L CE[24]), and only one hybrid-based wine contained >200 mg/L CE tannin. By comparison, only 3 of 12 *vinifera*-based wines in our survey had <200 mg/L CE of tannin, and a larger survey of red *vinifera*-based wines observed only about 8% had <200 mg/L CE of tannin.[20]

The tannin concentrations of *vinifera* wines in our commercial wine survey were approximately 50% of that measured by the same assay in red wines from California, Washington, Oregon, and Australia, 544 mg/L CE.[20] Although the distribution of varietal wines included in the two surveys was different, lower concentrations were typically observed for the same varietal wine. For example, the average protein-precipitable tannin in Cabernet Sauvignon wines from Washington State averaged 660 mg/L CE, whereas the Cabernet Sauvignon wines included for this survey from the Finger Lakes averaged 266 mg/L CE. The Finger Lakes region of New York is a cool-climate region having fewer growing degree-days, heat summation, and sunlight and more precipitation than many of the aforementioned warmer regions.[32] Several of these factors are reported to decrease grape or wine tannin concentrations. For example, increases in heat summation between fruit set and veraison have been associated with increased tannin in Pinot noir berries and their respective wines,[11] and greater water availability has been linked to decreases in flavonoid biosynthesis.[33]

Tannin in Experimental Wines Produced from Different Cultivars. Because winemaking protocols can have a profound effect on wine tannins, an alternative explanation for observed differences in tannins between *vinifera*- and hybrid-based wines could be that commercial wineries utilize different practices for these grapes. Additionally, U.S. labeling laws allow the addition of 25% of varieties other than those listed on the label. To control these variables, we collected fruit from 12 cultivars (4 French−American hybrids, 2 neo-American hybrids, and 6 *vinifera* cultivars), with each cultivar collected from two different sites for a total of 24 grape lots. Basic fruit chemistry is shown in Supporting Information Table S2. Fruit was then vinified using a standardized small-scale winemaking protocol and tannin quantified in the finished wines using the Adams−Harbertson assay (Figure 1A).

A multivariable fixed-effects model fitting wine tannin with variables "classification" (French−American hybrid, neo-American hybrid, or *vinifera*), "cultivar" nested within classification, and "location" revealed that location did not have a significant influence on wine tannin ($p = 0.51$). Cultivar was a significant factor ($p < 0.05$) in the model, similar to other findings.[34] Additionally, belonging to a classification group of "French−American hybrid", "neo-American hybrid", or "*vinifera*" was a significant determinant of wine tannin ($p < 0.05$). Wines produced from classic French−American hybrid grapes had significantly lower tannin concentrations than *vinifera*-based wines based on mean values, 45 versus 248 mg/L CE, respectively (5.5-fold lower, $p < 0.05$). Even though wine-

(B) Protein-precipitable tannin per gram of berries by cultivar. (C) Tannin extractability by variety.

making practices were kept constant, the range in wine tannin from these two classes reached a maximum variation of >17.4-fold. Notably, tannins in both *vinifera*- and hybrid-based wines were comparable to data for commercial wines in Supplementary Figure 1, indicating that our experimental wines were comparable to commercial wines.

The neo-American hybrids had higher tannin concentrations than the classic French–American hybrids. Noiret had the highest amount of tannin of all hybrid-based wines, averaging 354 mg/L CE. The other neo-American hybrid in this study, Corot noir, was variable, with Corot noir wine produced from fruit from one site having 203 mg/L CE wine tannin, whereas Corot noir from the second site had tannin below the LOQ for the protein precipitation assay.

Although the neo-American hybrids investigated have a percentage of *vinifera* in their background similar to that in the French–American hybrids (~50%), the pedigrees of most neo-American hybrids involve several backcrosses, including Corot noir, Noiret, and Vincent (wine 22 from Figure 1).[3] In contrast, many classic French–American hybrids result from a direct cross (F1) of *vinifera* with a wild *Vitis* species (or crosses of wild *Vitis*). A potential explanation for low wine tannin in the classic French–American grapes is that traits that lead to higher wine tannin are derived from *vinifera* and recessive and that backcrossing is necessary for hybrid grapes to yield high wine tannin.

Relationship of Grape Tannin and Tannin Extractability to Wine Tannin in Experimental Wines. To evaluate if differences in wine tannin concentrations arose from differences in grape tannin, the tannin in skins or seeds was quantified. These data are reported on a per berry weight basis in Figure 1B. Skin and seed tannin among grape classes were evaluated by a one-way ANOVA and were significantly different ($p < 0.05$). Total tannin (skin + seed) concentrations were significantly higher in *vinifera* grapes (mean = 1.27 mg CE/g berry) as compared to French–American hybrid grapes (0.71 mg CE/g berry). Tannin concentrations in *vinifera* grapes were similar to previous reports using the same protein precipitation method. Harbertson and colleagues reported values from Cabernet Sauvignon, Pinot noir, and Syrah ranging from 0.99 to 1.44 mg CE/g berry.[23] Although the 1.8-fold higher total tannin concentrations in *vinifera* grapes may serve as a partial explanation for differences in wine tannin, it cannot fully account for the 5.5-fold higher tannin concentrations (and 17-fold maximum difference in wine tannin vs 6.1-fold maximum difference in berry tannin) between *vinifera*- and French–American hybrid-based wines. This indicates that the cultivar classifications must also vary in tannin extractability.

Tannin extractability was calculated as described in eq 1, and data are shown in Figure 1C. Extractability from French–American hybrids was lower than that of the other two classes (one-way ANOVA, $p < 0.05$) and ranged from 2.2 to 5.7% in French–American hybrids, from 6.6 to 26.1% in neo-American hybrids, and from 8 to 22% in *vinifera*. The low tannin extractability observed from French–American hybrids is comparable to previous reports from our group,[18,19] and the extractability observed for *vinifera* is on the lower end reported by others (4.9–61%).[23]

We observed that skin tannin was better correlated with final wine tannin across cultivars ($r^2 = 0.73$, $p < 0.05$), as compared to total tannin ($r^2 = 0.44$, $p < 0.05$) and seed tannin (ns) (Table 1). Thus, differences in grape skin tannin may partially explain

Table 1

	wine tannin			tannin extractability		
predictor	p value	r^2	RMSE	p value	r^2	RMSE
total tannin	0.0179	0.44	99.7	0.21	0.15	7.08
skin tannin	0.0004	0.73	69.1	0.0001	0.79	3.52
seed tannin	0.75	0.01	133	0.51	0.04	7.52

both differences in wine tannin and apparent tannin extractability during fermentation. The median concentration of skin tannin in *vinifera* is 2.7-fold higher than in French–American hybrids (0.54 vs 0.20 mg CE/g berry). Skin tannin is extracted more quickly than seed tannin, with one paper stating that skin tannin extraction reaches a maximum after 5 days, whereas seed tannin extraction occurs more slowly and does not reach equilibrium by the time the fermentation is at dryness.[11] Assuming 29% skin tannin and 6% seed tannin extraction during maceration (excluding any other calculated binding effects) as previously reported by Kennedy,[35] the

[a]Significant differences ($p < 0.05$) by Tukey–Kramer HSD among cultivars are denoted by not sharing lower case letters for skin tissue (a, b, c, d) or flesh tissues (w, x, y, z). Significant differences among classes (French–American, neo-American, *V. vinifera*) are indicated by capital letters for skin tissue (A, B, C) or flesh tissue (X, Y, Z).

predicted average French–American hybrid wine would be 126 mg/L CE, whereas the average *vinifera* wine would be 261 mg/L CE, a 2.1-fold difference. However, *vinifera*-based wines averaged 5.5-fold higher tannin concentrations than French–American hybrids (Figure 1A), indicating that other factors beyond skin tannin likely contribute to differences in tannin extractability.

Tannin Binding by Cell Wall Material. Factors that contribute to variation in tannin extraction among grape sources under consistent winemaking conditions are not fully understood, but binding of tannins by cell wall material has been proposed.[22] We observed 17% more skin tissue by weight for *vinifera* versus French–American hybrids, whereas cell wall yields from skins by fresh weight were not significantly different (Table 2). A small, but significant, increase in flesh cell wall material yield was observed for French–American hybrids relative to *vinifera* (12.3 vs 10.2 mg/g fresh weight, Table 2). The neo-American hybrid grapes had significantly more skin cell wall material, but not flesh cell wall material, than both *vinifera* and French–American hybrid fruit by fresh tissue weight (56.0 vs 46.7 and 44.9 mg/g, respectively; Table 2). Because differences in cell wall material quantity were small, they were thought unlikely to affect extractability.

To investigate if tannin binding affinity rather than cell wall material concentration could contribute to differences in wine tannin among the classes, alcohol-insoluble residues were prepared from skins and flesh from each grape source. The protocol selected was previously employed for preparing cell wall material samples from *vinifera* grapes and results in isolation of carbohydrates, proteins, phenolic compounds, and cell wall microstructure with lower cost and preparation time per sample than comparable methods.[36]

Equal masses (10 mg) of cell wall material were incubated with a commercial tannin product (BioTan) in a winelike medium to evaluate tannin binding of each fraction. BioTan was selected for this study on the basis of previous work that showed it had the highest concentration of iron-reactive protein-precipitable tannin (48%) for commercial grape-derived products.[37] In close agreement with Harbertson and co-workers, we calculated the iron-reactive protein-precipitable tannin to be 47% by weight.[37] Phloroglucinolysis analysis by other authors indicates that BioTan is more similar to seed tannin than skin in size (mDP = 6.93[38]).

dx.doi.org/10.1021/jf5023274 | J. Agric. Food Chem. 2014, 62, 7515–7523

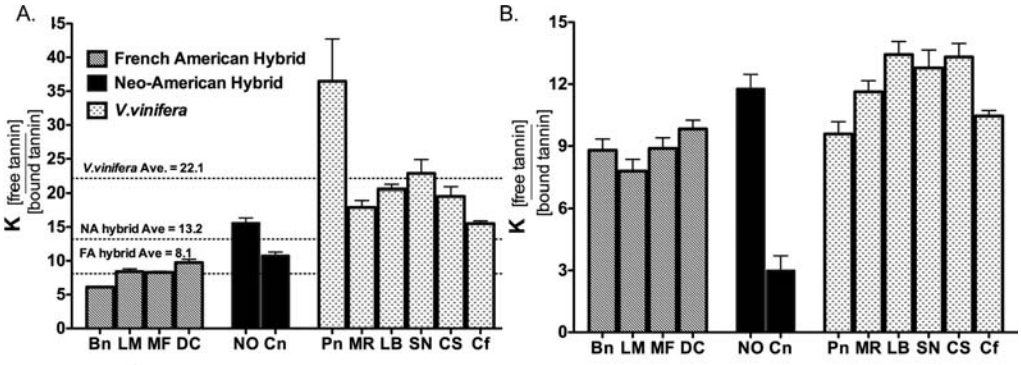

Figure 2. Distribution coefficients, calculated as ratio of free to bound tannin, after an 18 h incubation of tannin with skin cell wall (A) and flesh cell wall (B) materials from different cultivars (n = 8, bars indicate standard error of the mean).

Skin cell wall materials from French–American hybrid grapes were able to bind significantly more tannin on a by weight basis than *vinifera* ($p < 0.05$, Figure 2A). For this paper, we define the binding affinity of skin cell wall material as a distribution coefficient (K), calculated as the ratio of tannin in model wine versus the skin cell wall material during incubation experiments. K was 2.7-fold greater in *vinifera* than in French–American hybrids. The ability of neo-American hybrid skin materials to bind tannins was not significantly different from that of *vinifera* or the French–American hybrids, and the average distribution coefficient fell between the other two groups. Flesh cell wall materials from all three classes were not significantly different in their binding ability (Figure 2B, $p > 0.05$). Although tannin binding by cell wall material from neo-American grapes did not differ significantly from that of French–American or *vinifera* grapes, Noiret flesh demonstrated significantly less binding than both Corot noir and the French–American hybrids (Figure 2). We also observed that the Corot noir flesh cell wall sample with the highest binding affinity corresponded to the Corot noir wine with undetectable tannin. Whereas cell wall binding could potentially explain the greater tannin extractability observed in Noiret as compared to Corot noir (Figure 1C), Noiret also had significantly greater skin tannin (Figure 1B), and it is not currently possible to decouple which of these effects is more important.

As a caveat, these distribution coefficients are specific for the test conditions employed. Tannin–cell wall interactions do not follow simple Langmuir or Freundlich binding patterns and may involve cooperative binding.[39] Using a different tannin preparation (e.g., a skin-derived tannin fraction) would be expected to lead to different absolute K values and may reveal additional differences in the tannin binding behavior between cell wall fractions.[40] Given that skin tannin was found to be a significant factor in determining final wine tannin, further characterizing the interaction of cell wall material with skin tannin would benefit our current understanding of tannin extractability. Additionally, we used cell wall materials from grapes, which may not account for cell wall changes that occur during fermentation. However, our work does appear comparable to that of Bindon and colleagues, who recently reported on tannin binding by Shiraz cell wall material.[41] In agreement with their work, *vinifera* flesh cell wall materials in our study bound significantly more tannin than skin cell wall material. Although this previous work expressed binding in different units than in our current study, it was possible to determine distribution coefficients from the data presented.[41] We calculate that the Shiraz-derived cell wall material incubated with seed tannins had K values of 17 (flesh) and 30 (skin), comparable to the values reported here for *vinifera*.

Characterization of Cell Wall Material: Protein and Pectin Content. Because the reasons for differences in tannin binding among classes or cultivars could arise from differences in grape composition and/or structure, we quantified the two major classes of tannin-binding macromolecules, pectin and protein.[40,42,43] Pectin was quantified as uronic acids (in galacturonic acid equivalents) presuming galacturonic acid is the main constituent of grape pectin and glucuronic acid is a minor constituent of grape cell walls.[44,45] Results are reported in Table 2. The gravimetric recovery of cell wall materials reported here is within the range of values previously reported.[26] Pectin and crude protein quantities in both skin and flesh cell wall materials are also within the range of other studies using similar methods of quantification.[26] We observed that French–American hybrid grape skin cell walls had significantly more pectin (as uronic acids). Pectin has been shown to bind tannin more efficiently than other less flexible carbohydrates,[26,46,47] and pectin differences may contribute to observed differences in extraction from French–American hybrids. We also observed that pectin content was weakly correlated with K distribution coefficients ($p < 0.05$, $r^2 = 0.255$). As a caveat, the pectin molecular weight and degree of substitution were not analyzed in this study and may account for additional small differences in tannin binding affinity.

An even stronger correlation was observed between K values and flesh protein ($p < 0.05$, $r^2 = 0.597$, Figure 3). As a specific example, Corot noir flesh contained the highest amount of protein by weight and the lowest K values (strongest binding). This is in agreement with Bindon et al., who observed that

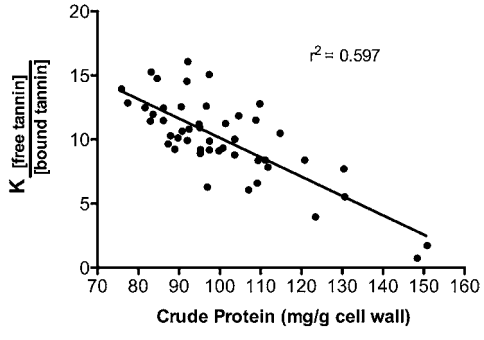

Figure 3. Flesh cell wall distribution coefficients (K) versus corresponding cell wall crude protein content.

dx.doi.org/10.1021/jf5023274 | J. Agric. Food Chem. 2014, 62, 7515–7523

crude protein was higher in Cabernet Sauvignon cell wall fractions possessing greater tannin affinity.[26] French−American hybrid skin cell walls also had higher crude protein than *vinifera*, although differences were small and the correlation of *K* and skin protein was worse ($p < 0.05$, $r^2 = 0.19$). Protein concentrations in our study ranged from 8 to 14%, although these values may be higher due to precipitation of cytoplasmic proteins with the ethanol precipitation method of cell wall preparation.[22,48] Interactions between structural cell wall proteins, such as the hydroxyproline-rich extensin, and tannin have been recently discussed, but their impact on wine tannin has not been thoroughly investigated.[22] Because of the nature of this study, it is not possible to determine if flesh protein content is a direct cause of low tannin extractability or merely correlated.

In agreement with previous studies using *vinifera* cultivars, flesh cell walls bound more tannin than skin cell walls in this classification, but had less pectin and protein by weight in comparison in this study.[40] This could be due to the presumably more flexible nature of flesh cell wall material facilitating stronger tannin interactions, but additional information is needed to address this. Bindon and colleagues reported that cell wall flexibility was an important aspect for tannin adsorption, and increased adsorption with decreasing acid-insoluble fiber and insoluble bound tannin was reported for Cabernet Sauvignon,[26] but these two parameters were not quantified in this study. An increase in cell wall porosity and surface area has also been reported to increase tannin binding.[49,50] Thus, although pectin and protein contents may contribute to tannin extraction differences among cultivars, more detailed compositional analysis may be necessary to understand differences in tannin binding between tissues.

This publication did not evaluate all possible factors that could affect tannin extractability. For example, the French−American hybrids are reported to have high anthocyanin concentrations as compared to *vinifera*.[51,52] Although anthocyanins can bind cell walls,[53] a competitive binding effect seems unlikely because low anthocyanin concentrations are reported to decrease tannin extraction.[54,55] Differences in tannin composition, particularly tannin size (mDP) and, to a lesser extent, degree of galloylation, could also decrease extraction by increasing binding efficiency to cell wall material.[41] Differences in tannin composition between hybrids and *vinifera* were not investigated in this work, but may be of interest to future studies.

Potential Consequences to Winemaking with Hybrid Grapes. Our data indicate that lower tannin concentrations (5.5-fold, up to a maximum of 17.4-fold) are present in hybrid-based wines as compared to *vinifera*-based wines both in commercial wines and in wines produced under standardized winemaking conditions. Although these differences can be partially explained by differences in berry tannin (particularly skin tannin), differences in tannin binding by cell wall material appear to explain an equal or greater amount of the variation. The demonstrated importance of skin tannin to final wine tannin in this study, in conjunction with the timing of skin tannin extraction during winemaking reported elsewhere, emphasizes the critical impacts of cell wall interactions on final wine tannin. The high tannin binding of hybrid grapes may explain the lack of success observed with winemaking approaches designed to increase wine tannin, especially in the early stages of winemaking. For example, recent work on hybrid grapes observed that prefermentation tannin additions to must resulted in a less than expected increase in wine tannin.[8] Additionally, the mDP of hybrid wine condensed tannin in this previous work was low as compared to *vinifera*-based wines (mDP < 4) and decreased throughout the course of fermentation. These low molecular weight tannins are anticipated to contribute more bitterness than astringency. Other work on *vinifera* has demonstrated selective removal of high mDP tannins by cell wall materials, resulting in lower mDP for tannins remaining in solution.[41] Because skin tannin both has higher mDP and is extracted more rapidly than seed tannin during fermentation, there will be a preferential loss of skin tannin due to cell wall binding.[40] Thus, the higher binding affinity of hybrid grape cell wall material may account not only for low tannin but also for a reduction in mDP. Furthermore, removing or degrading the tannin-binding compounds may prove more effective for increasing the final tannin concentrations in these wines (hybrid or *vinifera*) than commercial tannin addition. As our data indicate that the protein content of grape flesh is correlated with tannin binding, one strategy for increasing tannin extractability may be to use proteases during maceration. Pectin content was also correlated with tannin binding, although previous work has shown that pectinase enzyme additions are ineffective at increasing tannin concentrations in wines produced from by hybrid grapes.[8]

Finally, identification of grape components that limit tannin extractability may make for an interesting target to facilitate breeding of high-quality winegrapes. Interspecific hybrids are of interest to the grape and wine industries due to their better economic and environmental sustainability. Modern genetic tools, such as marker-assisted selection, have been used to facilitate grape breeding, especially for viticulturally important traits such as disease resistance. Whereas a few genetic markers for wine quality related attributes have been identified, such as for herbaceous-smelling methoxypyrazines,[56] wine tannin concentrations pose a particular challenge because they are poorly correlated with grape concentrations and thus are not currently well suited for high-throughput phenotyping in grape-mapping populations. Future work to identify compounds that limit tannin extraction from grapes could facilitate these studies.

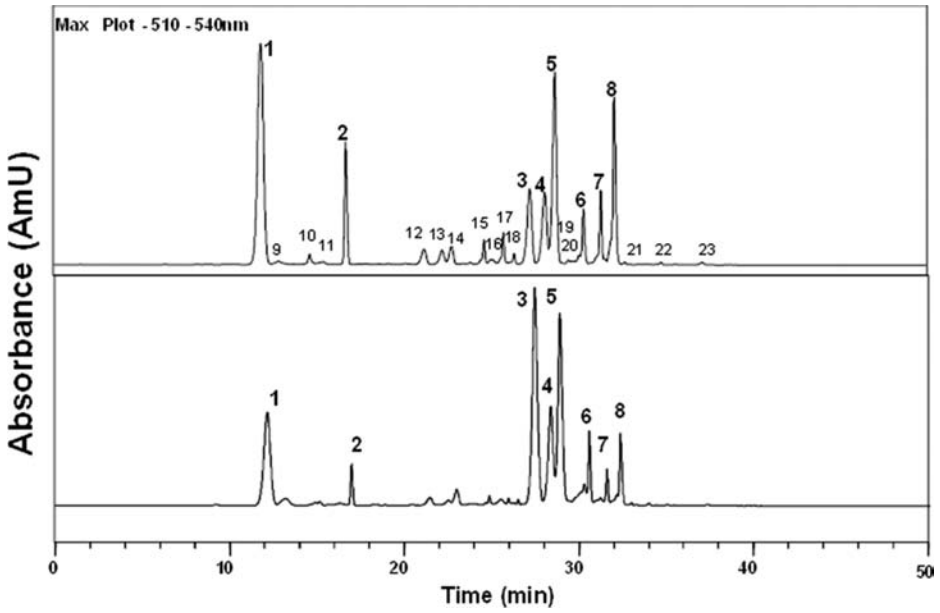

Figure 1. HPLC chromatograms of two representative red cabbage anthocyanin extracts: second-harvested Cairo (top) and first-harvested Integro (bottom) red cabbage at 510−540 nm. Refer to Table 1 for major peak identifications. HPLC conditions: solvent A, 4.5% formic acid in LC-MS grade water; solvent B, LC-MS acetonitrile; gradient, 0−50 min, 0−30% B. The major peaks (1−8) were found in all other red cabbage samples.

and the anthocyanins were recovered with acidified methanol (0.1% formic acid). The methanol was removed using the rotavapor, and the volume was taken to 25 mL with acidified water (0.1% formic acid).

Anthocyanins Content. The total monomeric anthocyanin was determined by using the pH differential method according to Giusti and Wrolstad.[29] The extract was diluted using pH 1 (0.025 M potassium chloride) and pH 4.5 (0.4 M sodium acetated) buffers with a dilution factor of 100. The solutions were allowed to equilibrate for 15 min in the dark. Absorbance was read on 1 cm path length cuvettes at 520 and 700 nm using a Shimadzu UV−visible spectrophotometer (Shimadzu, Columbia, MD, USA). The total monomeric anthocyanin was calculated on the basis of the dry matter (DM) and fresh matter (FM) and reported as milligrams of cyanidin-3-glucoside (Cy3G) per 100 g of sample using the equation

$$\text{total monomeric anthocyanin (mg/L)} = [((A_{520} - A_{700})_{\text{pH1}} - (A_{520} - A_{700})_{\text{pH4.5}}) \times \text{DF} \times 1000 \times \text{MW}]/(\varepsilon \times P)$$

where DF is the dilution factor, MW is the molecular weight (449.2 for Cy3G), ε is the molar absorptivity coefficient (26900 cm^{-1} mg^{-1} for Cy3G), and P is the cuvette path length.

Alkaline Hydrolysis of Anthocyanins. Alkaline hydrolysis (saponification) was adopted from the method of Giusti and Wrolstad.[28] Purified red cabbage anthocyanin extract (10 mL) was mixed with 10 mL of 10% KOH in a capped test tube and set aside for 15 min at room temperature in the dark. The solution was neutralized using 2 N HCl until the color turned pink. The neutralized sample was then purified using a Sep-Pak C18 cartridge (Waters Corp., Milford, MA, USA) and prepared for HPLC analysis.

Chromatographic Analysis. A Shimadzu Prominence reverse phase high-pressure LC-MS was coupled to an SPD-M20-A photodiode array and a single-quadrupole electrospray ionization (ESI) mass spectrophotometer (Shimadzu Scientific, Inc.). For data analysis, LC-MS Solution software was used (Shimadzu Scientific, Inc.). The column was a 100 × 4.5 mm Kinetex PFP 2.6 μm (Phenomenex Inc., Torrance, CA, USA). The solvents were phase A, 4.5% formic acid in LC-MS grade water, and phase B, LC-MS acetonitrile (Fisher Scientific Inc., Fair Lawn, NJ, USA), and the gradient was 0−50 min, 0−30% B. Injection volume was 20 μL. Spectral data were obtained from 250 to 700 nm, and elution of anthocyanins was monitored at 510−540 nm. Peak areas at this region were then integrated and normalized. The proportion of the total peak area of each individual anthocyanin was calculated and reported as percentage of total peak area at 510−540 nm.

For MS analyses, a 0.2 mL/min volume was diverted into the MS and ionized under positive ion condition using an electrospray probe. Data were monitored using total ion scan (SCAN) (m/z 200−1200) and selected ion monitoring at m/z 271 (pelargonidin), m/z 287 (cyanidin), m/z 301 (peonidin), m/z 303 (delphinidin), m/z 317 (petunidin), and m/z 331 (malvidin).

Color and Spectrophotometric Analyses. A ColorQuest XE colorimeter (HunterLab, Hunter Associates Laboratories Inc., Reston, VA, USA) was used to measure the color characteristics (Hunter CIE LCh) of the samples. The equipment was set for transmittance with specular included, and D65/10° was used for the measurements. Samples were placed in a 1 cm path length plastic cuvette and CIE L^*, a^*, b^*, chroma (c^*), and hue angle ($h°$) were measured.

To measure the color in acidic condition, the extract was mixed (in triplicate) with distilled (DI) water (1:20 v/v). The pH of the solutions were measured after 30 min of equilibration and was 3.5. To measure the color in neutral conditions, the extract was diluted with water (1:2 v/v, in triplicate). The diluted solutions were then mixed with 0.1 M potassium phosphate buffer (pH 7) with a dilution factor (DF) of 20. The maximum absorbances (λ_{max}) in the visible range of the neutral solutions were recorded using a Shimadzu UV−visible spectrophotometer 2450.

FD&C Red No. 3, FD&C No. 40, and FD&C Blue No. 2 (Noveon Hilton Davis, Inc., Cincinnati, OH, USA) were also dissolved in DI water to concentrations that most closely matched the lightness (L^*) and chroma (c^*) of the samples.

Statistical Analysis. Seven different cultivars at two maturity stages (three heads each) for a total of 42 samples were analyzed using principal component analysis (PCA). PCAs for total monomeric anthocyanin, nonacylated, monoacylated, and diacylated pigments (based on the proportional peak areas shown in Table 2) were performed. Autoscaling was used to normalize each variable before the analysis.

To compare the anthocyanin contents and profile, normality of the variables were first checked using the Kolmogorov−Smirnov test (α = 0.05). Analysis of variance (ANOVA) was then used to analyze the total monomeric anthocyanin and the proportion of each group of pigments separately using the following model: $Y_{ijk} = \mu + v_i + t_j + vt_{ij} +$

$\alpha_k + \varepsilon_{ijk}$, where Y is the individual variable, μ is the grand mean, v_i is the cultivar effect, t_j is the harvesting time effect, vt_{ij} is the interaction between the main factors, α_k is the heads effect defined as random factor, and ε_{ijk} is the random error of the model. When a significant difference was obtained (P value < 0.05), the Tukey means-comparison test was used to compare each pair of means.

All statistical analyses were done on the basis of at least three independent replicate samples from each individual head. Results were analyzed by using Minitab 16 statistical software (Minitab Inc.).

RESULTS AND DISCUSSION

HPLC-PDA-MS and Identification of Major Pigments. According to the HPLC-PDA data obtained at 510−540 nm, up to 23 peaks were observed. In previous studies, up to 36 different anthocyanins have been detected in red cabbage.[29−31] Figure 1 shows examples of anthocyanin profiles (Cairo and Integro extracts) obtained by HPLC-PDA. The eight major peaks, representing ≃90% of the total anthocyanins and common to all seven cultivars at both maturity stages, were selected for further identification and analyses. The λ_{max} at the UV and vis ranges, molecular ions, and fragments along with tentative identification of each peak are presented in Table 1. The pigments were identified using HPLC-PDA and HPLC-MS and compared with data reported in the literature.[11,12]

Table 1. PDA Absorbance and MS Data for Red Cabbage Anthocyanins[a]

peak	RT[b] (min)	λ_{vis}[c] (nm)	λ_{acyl}[d] (nm)	M^{+}[e]	identification
1	12.13	513		773 (287)	Cy-3diG-5G

3	27.41	523	313	919 (287)	Cy-3diG-5G + *p*-coumaric
4	28.33	523	326	949 (287)	Cy-3diG-5G + ferulic
5	28.85	524	329	979 (287)	Cy-3diG-5G + sinapic
6	30.53	536	319	1125 (287)	Cy-3diG-5G + ferulic and ferulic
7	31.55	536	330	1155 (287)	Cy-3diG-5G + sinapic and ferulic
8	32.31	536	331	1185 (287)	Cy-3diG-5G + sinapic and sinapic

[a] m/z 287 was the major fragment in all eight peaks. Cy-3diG-5G, cyanidin-3-diglucoside-5-glucoside. [b] Retention time. [c] λ vis−max. [d] λ of acylation. [e] Mass ion. [f] Tentative identification.

As shown in Table 1, m/z 287 was the fragment in all eight anthocyanins indicating that cyanidin derivatives were the major aglycon as reported in previous studies.[12,30,32−34] All of the pigments were nonacylated, monoacylated, and diacylated derivatives of cyanidin-3-diglucoside-5-glucoside (Cy-3diG-5G), which was also confirmed by saponification (results are not shown). The acylating groups were aromatic acids: sinapic, ferulic, and *p*-coumaric acids (Table 1).

Anthocyanin Content and Proportion of the Pigments. *Principal Component Analysis of Red Cabbage Anthocyanin Extracts.* The analysis of the objects (i.e., red cabbage cultivars at two maturity stages) is performed visually using the scores plot (Figure 2), where the objects are represented as a function of the principal components (PCs). As shown in Figure 2, PC1 correlated positively with monoacylated pigments as opposed to the diacylated pigments. PC2, on the other hand, was more affected by the nonacylated pigments and the total monomeric anthocyanin. PC1 and PC2 extracted 83.7 and 12.8% of the total variances, respectively.

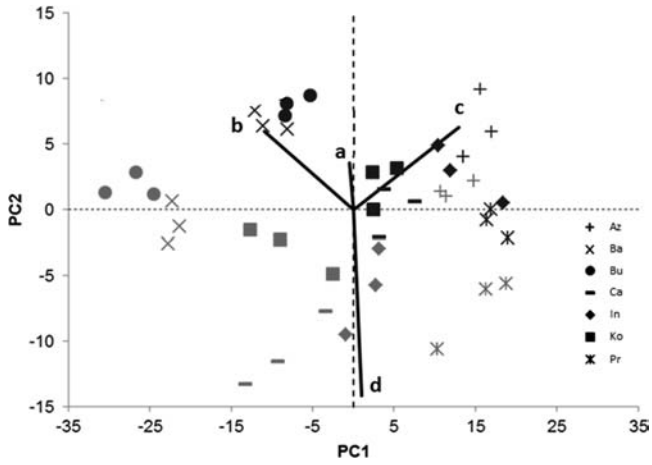

Figure 2. Correlation between the first two principal components and the variables as well as score plot with respect to cultivars and harvesting time for seven different red cabbage cultivars: a, total monomeric anthocyanin; b, diacylated pigments; c, monoacylated pigments; d, nonacylated pigments. AZ, Azurro; Ba, Bandolero; Bu, Buscaro; Ca, Cairo; In, Integro; Ko, Kosaro; Pr, Primero. Symbols in black and gray represent harvest times after 13 or 21 weeks, respectively.

According to this analysis, the samples were clearly separated diagonally on the basis of their maturation time. With maturation the percentage of diacylation increased for most samples, so for most of the second-harvested samples PC1 is negative. Also, because the early mature samples (week 13) had slightly higher amounts of total monomeric anthocyanin, PC2 tend to be more positive (Figure 2).

PCA is a proper way to obtain relevant information from the original variables into fewer new latent variables (PCs). According to our results, this analysis was helpful in classification of the samples at two maturity stages. Most samples with different maturity times were separated on the basis of the first two principal components. Azurro and Primero cultivars, however, were exceptions because their pigment profiles were not significantly changed with maturation.

Anthocyanin Content. The average anthocyanin contents for the 13- and 21-week-harvested plants were ≃1442 and 1269 mg Cy3G/100 g DM respectively, and these values for the fresh matter were ≃150 and 145 mg Cy3G/100 g FM, respectively. Piccaglia et al. also reported the anthocyanin content of three red cabbage cultivars in Italy to be >1000 mg/100 g DM.[10] The anthocyanin content for the fresh weight red cabbage reported by Oregon State University database and Wu et al. were, however, 25 and 322 ± 40.8 mg/100 g FW, respectively.[35,36] According to our findings, cultivar made a difference in anthocyanin contents at both maturity stages.

As shown in Table 2, Buscaro and Integro harvested after 13 weeks had the highest anthocyanin contents. Anthocyanin contents, however, did not change significantly from the first to the second harvest except for the Buscaro (DM) cultivar, which showed a lower anthocyanin content when plants were left longer on the ground (Table 2). Accumulation of anthocyanins can be explained by developmental factors, which could be different in different varieties.[23]

Proportion of Major Pigments. Although red cabbage is known to have more than 20 different anthocyanins, relative proportions of 8 of them (Figure 1 and Table 1) represented ≃90% of the total anthocyanins and were measured and

compared among cultivars and maturation stages as they are more likely to affect the color and stability of the extract. The pigments were also grouped into nonacylated, monoacylated, and diacylated.

According to our results, nonacylated pigments represented an average of ≃19.6% (±4.5) of the major pigments (Table 2). Charron et al. also found the percentage of nonacylated pigment in red cabbage to be 21.3%.[31] Among the major pigments identified, the amounts of mono- and diacylated

dx.doi.org/10.1021/jf501991q | J. Agric. Food Chem. 2014, 62, 7524−7531

anthocyanins were on average 54.4 (±12.6) and 15.8% (±8.7), respectively (Table 2). Red cabbage has been identified as a highly acylated anthocyanin source according to previous research.[30,31]

Before the percentages of each group of pigments were compared using ANOVA, the normality test was done to verify the validity of the test, and none of the variables had a p value smaller than 0.05.

Cultivar had a significant (p value < 0.05) impact on pigment profile. The proportions of monoacylated and diacylated pigments were the major differences found among the cultivars. Primero and Azurro had the highest proportions of monoacylated pigments and the lowest proportions of diacylated pigments, whereas Buscaro and Bandolero varieties had the lowest proportions of monoacyltaed pigments and the highest proportion of diacylated pigments. The effect of maturity on pigment profile was largely dependent on the cultivar for monoacylated and diacylated pigments (p value < 0.05); this interaction was not observed for the nonacylated pigments.

As shown in Table 2, the proportion of nonacylated pigments increased significantly in the 21-week-mature plants except for Azurro and Buscaro cultivars, which did not show a significant increase. More mature Primero, Cairo, and Integro had highest amounts of nonacylated pigments.

The proportions of monoacylated anthocyanins were, however, decreased with longer maturation time, except for Primero and Azurro cultivars, which did not show a significant decrease on monoacylated pigments. The proportion of monoacylated pigments was highest (≃67%) for cultivar Primero, Integro, and Azurro first harvests as compared to the other cultivars (≃54%) harvested at the same time (Table 2).

The proportion of diacylated pigments varied remarkably among cultivars. They increased significantly in Kosaro and Buscaro due to maturation. Buscaro and Bandolero, harvested after 21 weeks, had the highest (≃30%) proportion of diacylated pigments, whereas Primero (≃4%) had the lowest at both maturity stages (Table 2).

Because the plants were grown side by side, the main reason for the profile differences could arise from intrinsic factors such as plant genetics and enzymes and their activities throughout the maturation, which influence the anthocyanin synthesis within the plant. Variation in anthocyanin structures can be correlated with alteration of single genes, which influence the enzymatic step of anthocyanin synthesis pathways.[37] The reason for accumulation of certain anthocyanins in certain cultivars could be due to the difference in the activities of different genes. Also, during the maturation, the activity of the genes controlling the synthesis of monoacylated pigments could have slowed, whereas those responsible for the synthesis of nonacylated anthocyanins or for the addition of a second acyl group may have remained active.

Color Characteristics and Stability. *Color in Acidic pH.* Table 3 shows the color characteristics of solutions colored with red cabbage anthocyanin extracts from the different cultivars at pH 3.5 and their color comparisons to synthetic colorants FD&C Red No. 3 and No. 40. The lightness of the samples was approximately between 60 and 77 (Table 3). The synthetic colorant solutions were also adjusted to have a similar lightness. Extracts from all seven cultivars produced a deep pink color at pH 3.5 with a hue angle close to 350°. Chroma values of the samples were higher for solutions prepared with Bandolero and Buscaro extracts as opposed to Primero. The wavelengths of maximum absorbances (λ_{max}) of the samples were similar to that of Red No. 3 (≃520 nm) except for late-harvested Bandolero and Buscaro cultivars ($\lambda_{max} \simeq 530$ nm). Generally, samples showed more similar color characteristics to FD&C Red No. 3 than to FD&C Red No. 40 synthetic dyes ($\Delta E_1 < \Delta E_2$). Under acidic pH, maturation of the plants did not seem to significantly affect the color of the solutions. Early-harvested Azurro, Kosaro, Cairo, and Integro at the tested concentrations were the samples that produced colors most similar to FD&C Red No. 3 with similar λ_{max} and ΔE between 6.1 and 8.8 (Table 3).

Stability in Neutral pH. The spectral characteristics of the samples at pH 7 were monitored over 72 h of refrigerated storage. Figure 3 shows the changes in λ_{max} for three

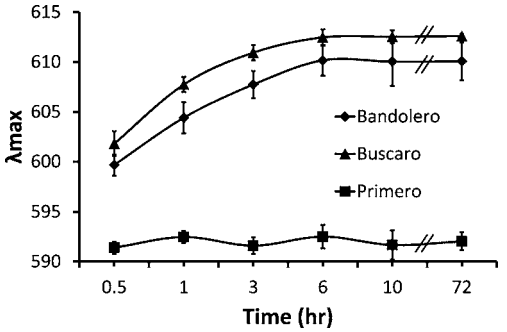

Figure 3. Change in λ_{max} for the second-harvested Buscaro, Bandolero, and Primero at pH 7 over 72 h of refrigeration. Most color changes happened during the first 6 h of storage.

representative samples. Solutions colored with Buscaro and Bandolero red cabbage extracts showed the highest variations in the λ_{max}, whereas solutions colored with Primero extract showed the least changes over the 72 h. Most of the changes observed happened during the first 5−6 h (Figure 3). Table 4 shows the λ_{max} of all seven varieties 30 min after the extracts were mixed with buffer pH 7 and 6 h afterward (refrigerated storage). The λ_{max} for samples containing significantly higher amounts of diacylated anthocyanins (Buscaro and Bandolero) at this pH seemed to be the highest (≃600 nm) compared to the other samples. Torskangerpoll and Andersen also investigated the absorbance and color change in cyanidin 3-(2″-(2‴-sinapoylglucosyl)-6″-sinapoylglucoside)-5-glucoside (a diacylated pigment isolated from red cabbage) at different pH values. They also found out that at pH 7.2 the pigment had λ_{max} of ≃605 nm.[38] A bathochromic effect of up to 7 nm was observed for most samples after 6 h of refrigerated storage. More mature Buscaro and Bandolero varieties produced a λ_{max} (≃610 nm) similar to that of FD&C Blue No. 2. For other samples such as Primero and Integro, however, minute bathochromic effects were observed (Table 4).

Anthocyanins tend to have lower stabilities at neutral to alkaline pH values.[14,39] After mixing with buffer pH 7 followed by 6 h of refrigeration, the color degradation was highest (≃53%) and lowest (≃19%) for the second-harvested Primero and Buscaro, respectively (Table 4). Higher stabilities of the Buscaro and Bandolero cultivars at the tested pH values could be explained by the larger number of diacylated anthocyanins, which have higher stabilities due to the pigments intramolecular and/or intermolecular copigmentation and self-association reactions.[15] Torskangerpoll and Andersen also demonstrated

Table 4. Maximum Absorbance (λ_{max}) of Red Cabbage Extracts at Two Different Harvesting Times Measured after 30 min and 6 h of Refrigeration Storage in Buffer pH 7 Compared to FD&C Synthetic Blue No. 2 and Stabilities (Percent Degradation) during This Time[a]

[a]Percent degradation was calculated by dividing the absorbance at λ_{max} after 6 h by the absorbance at λ_{max} after 30 min in buffer pH 7 × 100. [b]Harvesting time.

that diacylation of anthocyainins increases their color stabilities.[38]

The color characteristics of pH 7 buffer solutions colored with the different red cabbage extracts after 6 h of refrigeration compared to FD&C Blue No. 2 are shown in Table 5. The lightness of the samples ranged between ≃60 and 85. Chroma values were higher for Bandolero and Buscaro cultivars at the tested pH value (Table 5). The synthetic FD&C Blue No. 2 was diluted until the lightness was similar to that of the evaluated samples. ΔE values of the samples when compared to this synthetic dye were between 17.6 and 26.4 (Table 5). The color difference with FD&C Blue No. 2 at the tested concentration for the late-harvested Kosaro sample was the smallest; however, the λ_{max} values for the second-harvested Buscaro and Bandolero cultivars were closer to this value for FD&C Blue No. 2 (Tables 4 and 5). Acylation of anthocyanins with aromatic acids (e.g., cinnamic acid) has proven to increase the λ_{max} and shift the hue angle to purple color under acidic conditions.[16,17] As shown in Table 1, late-harvested Buscaro and Bandolero cultivars, with the highest percentages of diacylated pigments, also exhibited the highest λ_{max} under neutral conditions.

In conclusion, anthocyanin content varied among red cabbage cultivars, and leaving the cabbages in the ground for additional time did not increase the pigment content. The pigment profiles changed among the cultivars and maturation stages. For most cultivars, the amount of nonacylated and diacylated pigments increased as opposed to the monoacylated pigments. Cultivars with lower proportions of diacylated pigments better reproduced the color of FD&C Red No. 3 under acidic conditions, whereas cultivars with higher proportions of diacylated pigments better matched the colors of FD&C Blue No. 2 at neutral pH. Pigment profile also affected the color stability at neutral pH. For future studies,

stirrer input power (IP) on the loading of curcumin in OSG micelles using response surface methodology (RSM). Moreover, the curcumin-loaded OSG was characterized by using dynamic light scattering (DLS), transmission electron microscopy (TEM), atomic force microscopy (AFM), Fourier transform infrared (FT-IR) spectroscopy, differential scanning calorimetry (DSC), and X-ray diffraction (XRD).

MATERIALS AND METHODS

Materials. Commercial soluble β-glucan (80 wt% β-glucan content) extracted from oats was purchased from Zhangjiakou Yikang Biological Technology Co., Ltd. (China). 2-Octen-1-ylsuccinic anhydride (product no. 416487) was purchased from Sigma Chemical Co. (USA). Curcumin (bis(4-hydroxy-3-methoxyphenyl)-1,6-heptadiene-3,5-dione, 98% purity) was supplied by Adamas Reagent Co., Ltd. (China). IR spectroscopy grade KBr was purchased from Guangfu Reagent Chemical Co., Ltd. (China). Chromatographic grade acetonitrile and formic acid were also used. All chemicals were used in this study without further purification.

Oat β-Glucan Solution Preparation and Hydrolysis. Oat β-glucan (2.500 g) was dispersed in 1 L of distilled water and heated at 80 °C with magnetic stirring for 2 h. The resultant dispersion was cooled to room temperature with tap water. An oat β-glucan solution (1.953 ± 0.075 g/L) was obtained as the supernatant by centrifuging the dispersion at 3000g for 10 min. Oat β-glucan was hydrolyzed according to a previously described method.[29] Two hydrolysates of oat β-glucan (OG1 and OG2) were prepared in the present study. In detail, 100 μL (OG1) and 200 μL (OG2) of hydrochloric acid (6 M) were mixed with 100 mL of the above-prepared oat β-glucan solution (0.195 g oat β-glucan), respectively. Then, the mixtures were inoculated at 50 °C for 10 min to allow the intended hydrolysis. After hydrolysis was completed, hydrolysates were rapidly cooled to room temperature and neutralized (pH 6~7) with 2 M NaOH. The hydrolysates were successively dialyzed against tap water and distilled water for 24 h in a dialysis bag (MD44-14, Union Carbide Co., Seadrift, TX, USA) with a size exclusion of 14 000 g/mol for globular molecules. Then, they were subjected to lyophilization to obtain OG1 (0.192 ± 0.007 g) and OG2 (0.188 ± 0.004 g). The M_w values of oat β-glucan, OG1, and OG2 were determined as 16.8×10^4, 11.9×10^4, and 7.3×10^4 g/mol, respectively, on a high-performance size-exclusion chromatography (HPSEC) system.[30] Different M_w values (4×10^4, 7×10^4, 10×10^4, and 200×10^4 g/mol) of standard dextrans (Pharmacia Fine Chemicals, Uppsala, Sweden) were used as M_w standard reference.

Synthesis of Octenylsuccinate of Oat β-Glucan and Its Hydrolysates. Oat glucan, OG1, and OG2 were octenylsuccinated according to our previously proposed method, and the DS of each was determined by elemental analysis using an Elementar CHNS analyzer (Vario EL III, Elementar Analysensysteme, Germany).[28,31] Detailed information on reaction conditions and DS of the resultant products was shown in Table 1.

Loading Curcumin into OSG Micelles. Freeze-dried OSG powder (40 mg) was dissolved in 20 mL of distilled water by heating at 100 °C for 2 min continuous stirring. After complete cooling at room temperature, the volume of the resultant solution was complemented to 20 mL by adding distilled water. Curcumin powder (10 mg) was introduced into the solution, and the suspension was homogenized at 12 000 rpm for 1 min in a homogenizer (IKA T18 basic, IKA-Werke GmbH & Co., Staufen, Germany). Then, the resultant homogenate was continuously stirred under different input power of the stirrer (IP) (Table 2) at 25 °C for 24 h to complete the transfer of curcumin into OSG micelles. Finally, the suspension was centrifuged at 5600g for 10 min to recover the supernatant for determining the CLC of OSG micelles. The CLC values of OSG micelles were determined as described previously and calculated by using the following equation:[28]

Table 1. Degree of Substitution (DS) and Reaction Condition for Preparing Octenylsuccinate Oat β-Glucan (OSG)[a]

no.	oat β-glucan[b]	OSA[c] (mL)	time (h)	DS	M_w[d] (g/mol)
1	OG	0.3	2	0.0076 ± 0.0010	17.0×10^4
2	OG	0.6	2	0.0169 ± 0.0038	17.1×10^4
3	OG	0.6	3	0.0266 ± 0.0022	17.3×10^4
4	OG1	0.3	2	0.0085 ± 0.0007	12.0×10^4
5	OG1	0.6	2	0.0175 ± 0.0032	12.2×10^4
6	OG1	0.6	3	0.0281 ± 0.0021	12.3×10^4
7	OG2	0.3	2	0.0080 ± 0.0005	7.4×10^4
8	OG2	0.6	2	0.0172 ± 0.0025	7.5×10^4
9	OG2	0.6	3	0.0273 ± 0.0015	7.5×10^4

[a]All reactions were carried out at 45 °C. [b]The molecular weights of oat β-glucan (OG), OG1, and OG2 were 16.8, 11.9 and 7.3×10^4 g/mol. The molecular weights of OG, OG1, and OG2 were determined before derivatization with OSA. [c]OSA, 2-octen-1-ylsuccinic anhydride. [d]The molecular weight of octenylsuccinate oat β-glucan was calculated according to the DS and molecular weight of oat β-glucan.

Table 2. Level of Various Independent Variables at Coded Values of Response Surface Methodology Experimental Design

		coded values		
independent variable	symbol	−1	0	1
degree of substitution	X_1	0.0080	0.0172	0.0273
molecular weight (10^4 g/mol)	X_2	7.3	11.9	16.8
stirrer input power (W)	X_3	3.3	3.8	4.4

$$\text{curcumin loading capacity (μg/mg)} = \frac{\text{mass of loaded curcumin in 1 mL of OSG solution (μg)}}{\text{mass of used OSG in 1 mL of OSG solution (mg)}} \quad (1)$$

Experimental Design. RSM based on the Box−Behnken design was adopted to observe the effects of DS and M_w of OSG as well as IP of operation on CLC of OSG micelles. A three-level, three-variable design was used in the present study. The three independent variables are DS (X_1), M_w (X_2), and IP (X_3), and CLC was used as the dependent variable response. The factorial design consisted of 12 factorial points and 5 central points. The coded and uncoded independent variables used in the RSM design are listed in Table 3. To fulfill this experiment, totally, nine OSG should be synthesized. Theoretically, as the requirement of the experiment design, nine OSG could be evenly divided into three groups, and the OSGs in the same group own the identical DS but the differentiated M_w. Actually, it is an impossible task to obtain an identical DS for oat β-glucans with different M_w. Therefore, three OSG with different M_w and non-significantly differentiated DS were grouped in the present study (Table 3). All trials were performed in triplicate. A Design-Expert software version 7.0 (STAT-EASE Inc., Minneapolis, MN, USA) was used to generate the experimental designs, statistical analysis, and regression model. A second-order polynomial equation was used to express the predicted responses (CLC) as functions of the independent variables, as shown in the following equation:

$$Y_i = a_0 + a_1X_1 + a_2X_2 + a_3X_3 + a_{12}X_1X_2 + a_{13}X_1X_3 + a_{23}X_2X_3 + a_{11}X_1^2 + a_{22}X_2^2 + a_{33}X_3^2$$

where X_i represents the independent variables, a_0 is a constant, and a_i, a_{ii}, and a_{ij} are the linear, quadratic, and interactive coefficients, respectively.

Characterization of OSG Micelles. OSG micelles (2 mg/mL OSG) and curcumin-loaded OSG (2 mg/mL OSG) were prepared

[a]Values bearing different on-line lowercase letters in the same column are significantly different ($p < 0.05$) by Tukey's HSD test. [b]Experiments were conducted in a random order. [c]X_1 = degree of substitution, X_2 = weight-average molecular weight (10^4 g/mol), X_3 = stirrer input power (W).

under above obtained optimal conditions (DS = 0.0199, M_w =16.8 × 10^4 g/mol, and IP = 4.4 W) and subjected to DLS, TEM, and AFM analyses. Moreover, the lyophilized micelles were analyzed by FT-IR spectroscopy, DSC, and XRD.

DLS. The size and ζ potential of OSG micelles in aqueous solution were determined based on DLS and laser doppler electrophoresis by using a Zetasizer Nano ZS90 (Malvern Instruments Ltd., UK) equipped with a He–Ne laser (633 nm) and 90° collecting optics. The results of size and ζ potential were expressed as nanometers and millivolts, respectively. The particle size distribution is reported as a polydispersity index (PDI). The temperature was maintained at 25 °C during the measurement. These measurements were performed in triplicate.

TEM. The appearance of the samples was determined by TEM measurements. A drop of the curcumin-loaded OSG solution was placed in a carbon-coated copper TEM grid, negatively stained with 1% uranyl acetate (w/v) for 10 min, and air-dried. Imaging was performed at 200 kV using a JEOL JEM-2100 instrument (JEOL, Japan) equipped with a Gatan 94 Ultrascan 1k charge-coupled device camera.[32]

AFM. The shape of curcumin-loaded OSG micelles (COMs) were further characterized by AFM (Dimension Icon, Bruker, Germany).[33] A drop of the curcumin-loaded OSG solution (2 mg/mL) was placed on freshly cleaved mica. After 5 min of incubation at room temperature, the surface of the mica was gently rinsed with 5 mL of deionized water and blown with dry nitrogen. The sample was air-dried at room temperature and mounted on the microscope scanner. The shape was observed and imaged in a noncontact mode.

FT-IR Spectroscopy. FT-IR spectra of native curcumin, OSG, their physical mixture (OSG/curcumin =100:1), and curcumin-loaded OSG were obtained using an FT-IR spectrophotometer (Spectrum 100, Perkin–Elmer, Akron, OH, USA) in the range 500–4000 cm^{-1} through the KBr method.

DSC. DSC measurements were carried out with a thermal analyzer (DSC 4000, Perkin–Elmer). Up to 5 mg of native curcumin, OSG, their physical mixture (OSG/curcumin = 100:1), and curcumin-loaded OSG were placed in an aluminum sample pan, which were hermetically sealed, and were quickly transferred to the sample holder of the instrument. Then, the pans were heated from 30 to 200 °C with a heating rate of 10 °C min^{-1} in a nitrogen atmosphere. The recorded DSC curve of a sealed empty pan was used as reference.

XRD. The patterns of native curcumin, OSG, their physical mixture (OSG/curcumin = 100:1), and curcumin-loaded OSG were obtained using an X-ray diffractometer (D8 Advance, Bruker, Germany). The measurements were performed with 40 kV and 25 mA. The scanned angle (2θ) was set from 5° to 40°, and the scan rate was 2° min^{-1}.

UV Stability Study. To verify the effective loading of curcumin by OSG micelles, a methanol–water (5:95, v/v) solution of curcumin and curcumin-loaded OSG micelles were subjected to UV light (253 nm) using a superclean bench (SW-CJ-1F, China). Sampling was carried out at various time points (10, 20, 30, 40, 50, and 60 min), and the amount of curcumin in the samples was determined by high-performance liquid chromatography.[28] The percent of curcumin refers to the ratio of the content of curcumin retained in the sample after UV irradiation to the original one in the sample.

Statistical Analysis. Results were expressed as the mean with standard deviation of at least three measurements. SPSS 19.0 was used to analyze the data. Analysis of variance (ANOVA) was utilized to determine the least significance at $p < 0.05$ by Tukey's HSD test.

RESULTS AND DISCUSSION

Results of RSM. The data of 17 experiments represented in Table 1 relating the CLC value of OSG micelles were fitted to multiple regressions. A second-order polynomial function was built to describe the effects of independent factors, namely, DS (X_1), M_w (X_2), and IP (X_3), on the dependent variable *CLC* (Y), which was given as follows:

$$Y = 1.914 - 0.0113X_1 - 0.4595X_1^2 + 0.4288X_2 - 0.1545X_2^2 + 1.5X_3 + 0.243X_3^2 + 0.23X_1X_2 - 0.0125X_1X_3 + 0.2475X_2X_3$$

The coefficients of the response surface model as described above were evaluated. The ANOVA was shown in Table 4. In

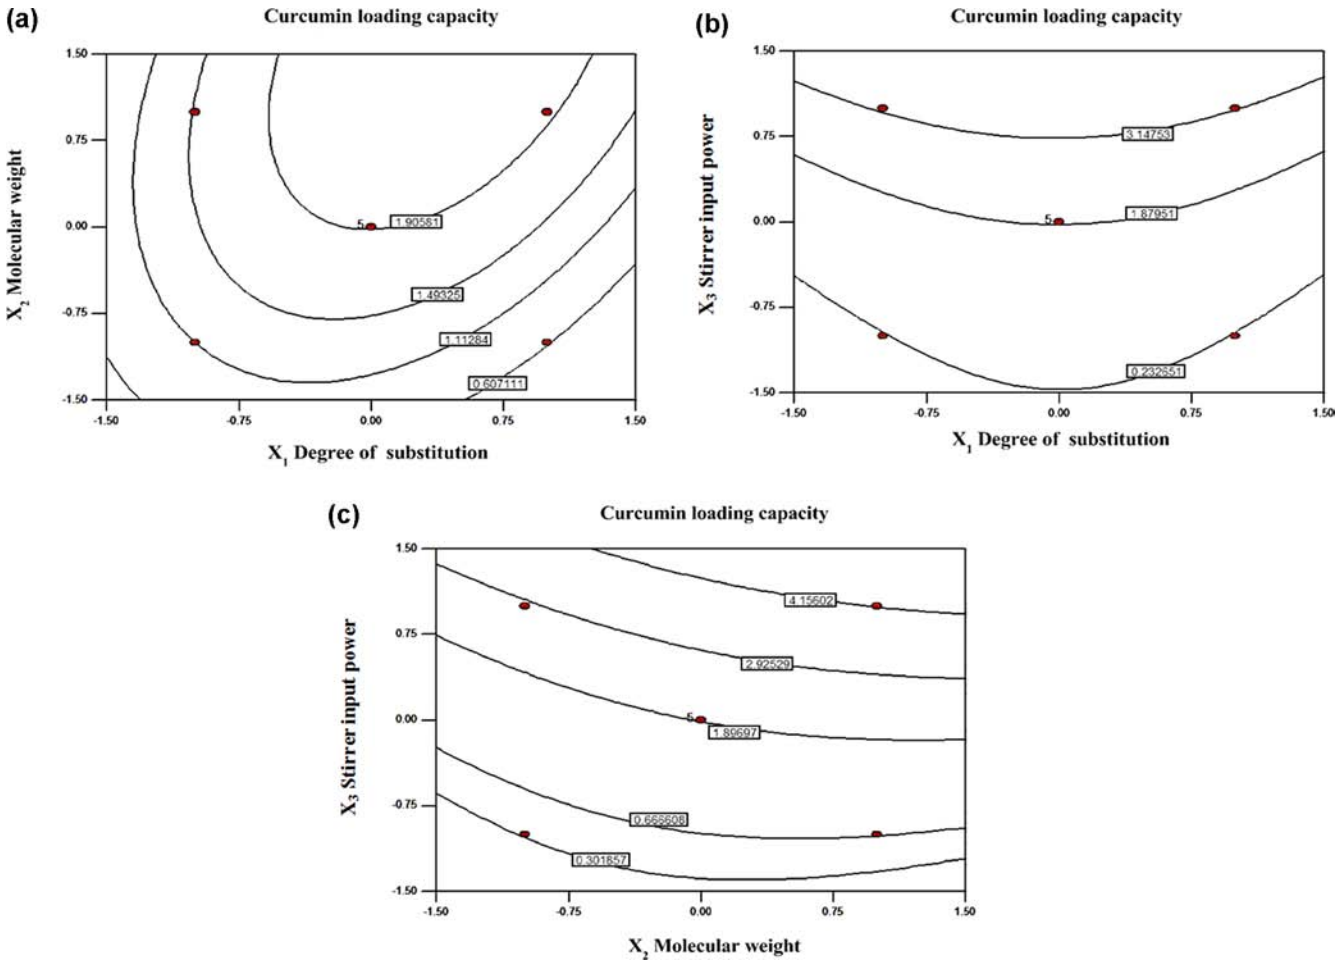

Figure 1. Response surface plots showing the interactive effects of degree of substitution (X_1), molecular weight (X_2), and stirrer input power (X_3) on the curcumin loading capacity (a–c) of octenylsuccinate oat β-glucan (OSG) micelles.

the present study, a preliminary screening experiment was first fulfilled in order to rank the significance of three key parameters on the resultant CLC of OSG micelles. The total of three parameters consisted of two structural and one process related factors: DS and M_w of OSG and IP of process, respectively. The p values are used as an indicator to judge the significance of each of the coefficients, which in turn, are necessary to reveal the pattern of mutual interactions between the test variables. The smaller the magnitude of the p value, the more significant is the corresponding coefficient. The coefficient with a p value less than 0.05 was significant. The coefficient estimates and the corresponding linear p values implied that M_w and IP were significant variables and the variable of DS (p = 0.8883) was insignificant in the present study. In addition, IP (p < 0.0001) posed a higher effect on CLC than M_w (p = 0.0009).

Effects of DS on CLC. Concerning DS, it presented extremely significant quadratic effects (DS^2) on the CLC value of OSG micelles (p < 0.01). However, its linear effect (DS) and interactive effects with M_w (DS × M_w) and IP (DS × IP) were insignificant (p > 0.05) (Table 4). The contour plots of DS versus M_w and DS versus IP revealed (Figure 1a, b) that CLC maximized at medium DS (0.0172) and decreased as DS increased or lowered. This could be explained by the effects of DS on the hydrophobic nature of OSG molecules and the particle size of OSG micelles. The higher the DS, the more the physically entrapped curcumin in the micelles, which mainly resulted from hydrophobic interactions through interaction between the aromatic groups of curcumin and octenyl succinate groups of OSG. Thus, hydrophobic interaction was the driving force for the OSG micelle to encapsulate curcumin. Besides the hydrophobic interactions, hydrogen bonding and π–π stacking interactions were also observed in the physical entrapment of curcumin.[32,34−39] However, the lower CLC was observed as the DS of OSG increased from 0.0172 to 0.0273. This result can be attributed to two related factors. First, the less accommodation of curcumin could be caused by the smaller micelle cavity. Our previous study revealed that increase in DS could cause a significant decrease in the OSG micelle size (476 to 267 nm, DS from 0.0172 to 0.0387).[28] Second, highly substituted OSG with amounts of octenyl succinate groups presenting in the core of micelles may further hinder the loading of curcumin. The complexation of sulfoalkyl ether β-cyclodextrins with steroids also showed the same observation.[40]

Effects of M_w on CLC. As revealed by the ANOVA (Table 4), the linear term of M_w had a significant (p < 0.01) effect on the CLC of OSG micelles. However, its quadratic effect and interactive effects with IP (M_w × IP) were insignificant (p > 0.05). The contour plots of M_w versus DS and M_w versus IP (Figure 1a, c) revealed that CLC increased with the increase of M_w. Compared with molecular chains of OSG with higher M_w, the chains of OSG with lower M_w are relatively short, and possibly make the physical entrapment of curcumin difficult.[41] The encapsulation of curcumin in the pluronic block copolymer

Table 5. Size, ζ Potential, and Polydispersity Index (PDI) of β-Glucan and Octenylsuccinate Oat β-Glucan (OSG) before and after Curcumin Loading.

sample	DS	size (nm)	ζ potential (mV)	PDI
β-glucan[a]	–	691.0 ± 10.5a	−8.7 ± 0.2c	0.459 ± 0.020a
OSG	0.0199	404.2 ± 3.5b	−12.4 ± 0.5b	0.356 ± 0.012b
curcumin-loaded OSG	0.0199	308.0 ± 10.2c	−10.8 ± 0.2a	0.233 ± 0.014c

[a]Size, ζ potential, and PDI of β-glucan was reported by Liu et al.[28]

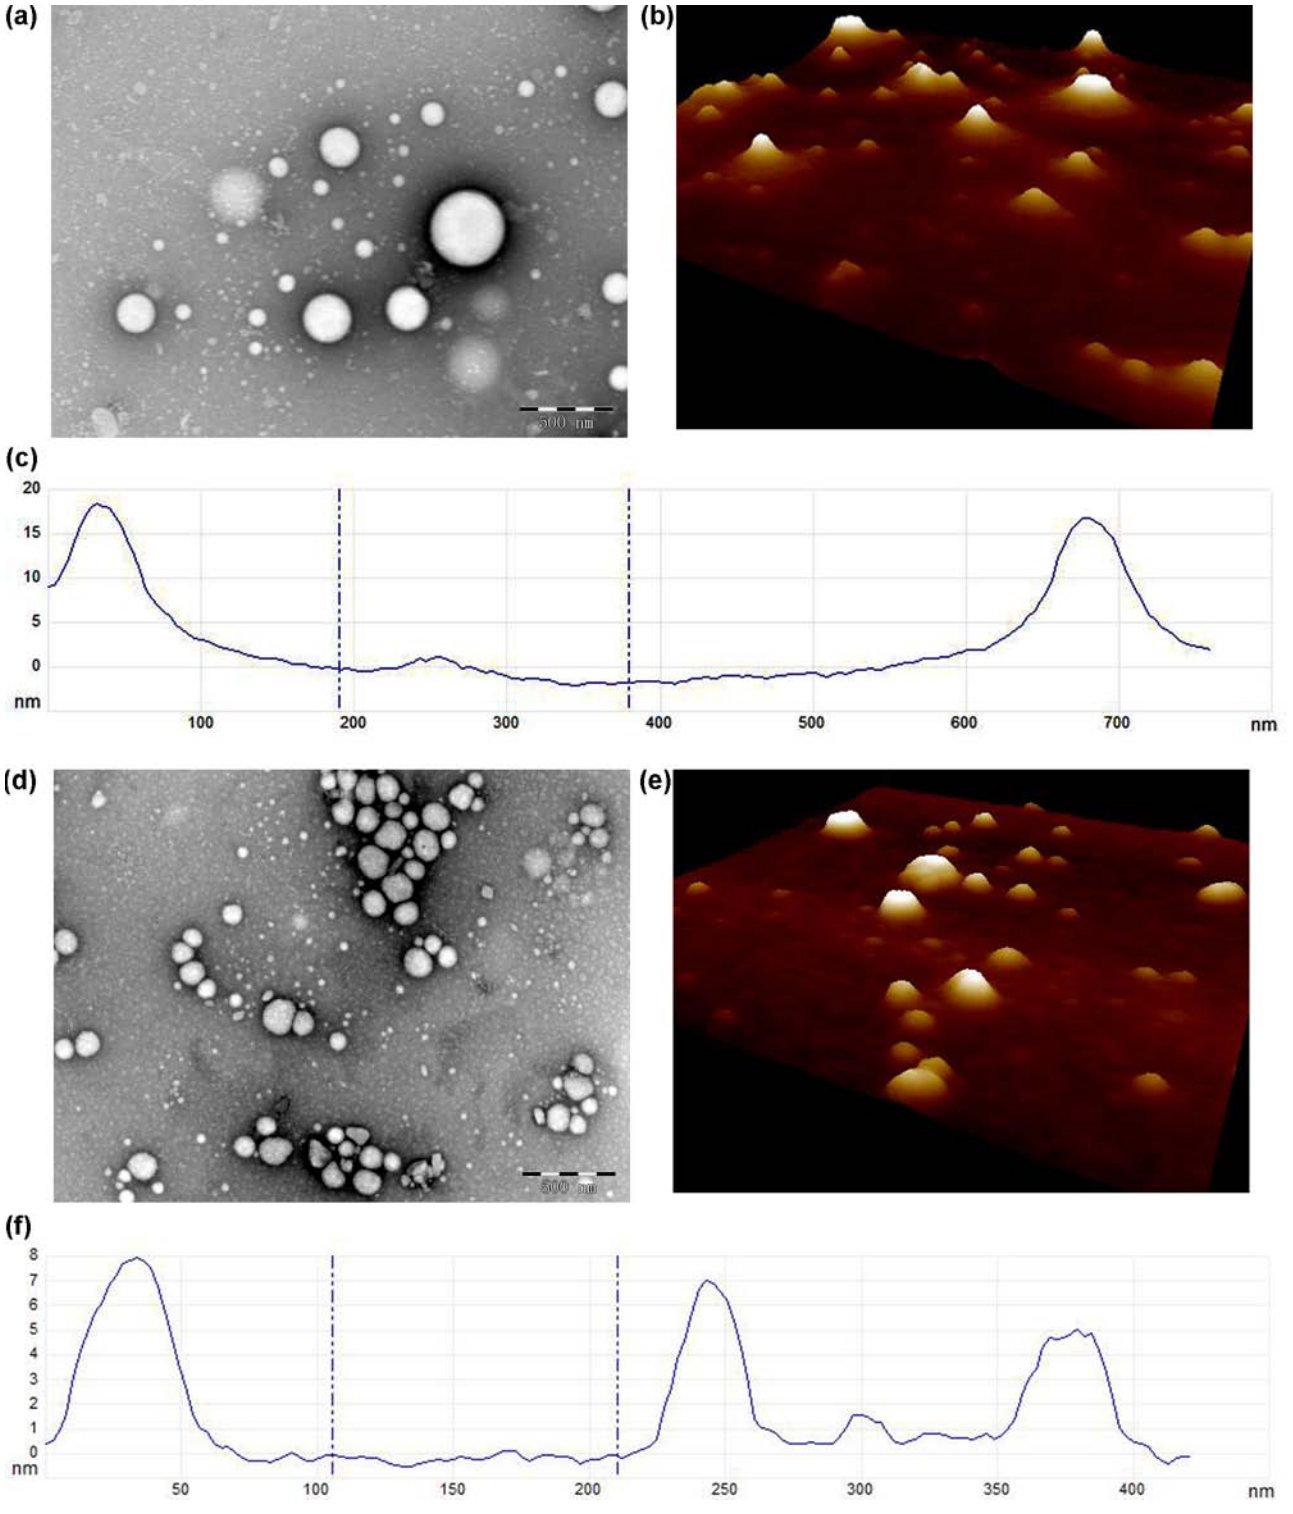

Figure 2. Transmission electron micrograph, three-dimensional view, and size distribution of octenylsuccinate oat β-glucan (OSG) micelles before (a–c) and after (d–f) curcumin loading.

dx.doi.org/10.1021/jf5014692 | J. Agric. Food Chem. 2014, 62, 7532–7540

and PEO-PCL micelles also showed that polymers with higher molecular weights had a better CLC.[42,43]

Effects of IP on CLC. As revealed by the ANOVA (Table 4), the linear term of IP had a significant effect ($p < 0.01$) on the CLC of OSG micelles. However, its quadratic effect was insignificant ($p > 0.05$). CLC of OSG micelles increased as IP increased from low input power levels to high input power levels (Figure 1b, c). The OSG micelles underwent a process of disassembly and reassembly during the agitation, which allowed the loading of curcumin into the OSG micelle core. Thus, increasing IP can increase the contact opportunity of curcumin and OSG micelles. More importantly, an increase of IP can promote the diffusion of the hydrophobic compounds toward the dispersed phase.[44]

Predicted Model and ANOVA. ANOVA results in Table 4 indicated that the regression model was adequate for the prediction. The coefficient of determination R^2 was found to be 0.9844, indicating that 98.44% of the variability in the response could be explained by the obtained model. The value of R^2 was always in the range 0∼1.0, and the closer the R^2 was to 1.0, the stronger the model and the better it predicted the response. The adjusted R^2 (0.9644) is in good agreement with the coefficient of determination R^2 (0.9844), suggesting an excellent correlation between the predicted values and the experimental results. The model showed that the p value for CLC (0.3091) was higher than 0.05, which implied that the lack-of-fit was not significant relative to the pure error. Verification of the model equation was conducted using the selected optimal conditions. Under optimal conditions (DS = 0.0199, $M_w = 16.8 \times 10^4$ g/mol, and IP = 4.4 W), the maximum CLC of OSG micelle was 4.21 ± 0.16 μg/mg, which agreed with the predicted value of 4.20 μg/mg. No significant difference ($p > 0.05$) was observed between the experimental and predicted values. Therefore, the results indicated the suitability of the model employed and the success of RSM in the optimization of CLC.

Characterization of Curcumin-Loaded OSG. *Particle Size, ζ Potential, and Morphology.* Particle characteristics of β-glucan and OSG before and after curcumin loading were shown in Table 5. After derivatization (OSG), the size, PDI, and ζ potential of micelles decreased due to the strong intra- and intermolecular hydrophobic interactions among octenylsuccinic groups, causing the hydrophobic substituent groups to self-assemble and form a uniform distribution of size.[28] DLS results (Table 5) revealed that the mean diameter and PDI of the OSG micelles were decreased from 404.2 to 308 nm and 0.356 to 0.234 after curcumin loading. The size and PDI of micelles formed by monomethoxyl poly(ethylene glycol)-poly(1,3-bis(*p*-carboxy-phenoxy)propane) also showed a significant decrease after curcumin incorporation.[45] Hong et al. ascribed the decreased size of micelles to the stronger hydrophobic interaction between curcumin and polymers.[45] After loading of curcumin into OSG micelles, ζ potential values of COMs were increased from −12.4 to −10.8 mV. Furthermore, TEM showed that smooth spherical and irregular-shaped particles were observed for the OSG micelles before and after curcumin loading. AFM results confirmed that both OSG micelles and COMs were elliptical in shape with a horizontal size of 20−200 nm and a vertical size of 5−18 nm (Figure 2 b, c and e, f). The mean diameter of COMs determined by DLS was slightly larger than the size observed by TEM and AFM. The difference of reported diameter between DLS and TEM was probably due to the process of the sample preparation. DLS determined the size in the hydrated state of the sample, whereas TEM and AFM observed the size in the dried state of the sample.

FT-IR Spectra. The FT-IR spectra of curcumin, OSG, their physical mixture, and curcumin-loaded OSG were shown in Figure 3. The characteristic peaks at 1727 and 1574 cm^{-1} in

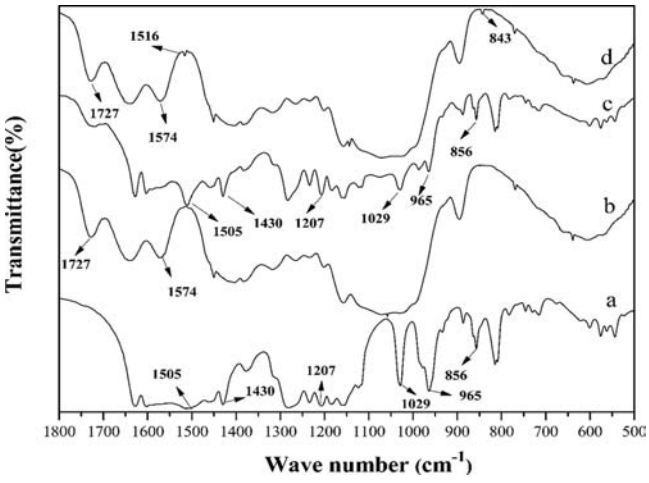

Figure 3. FT-IR spectra of curcumin (a), octenylsuccinate oat β-glucan (b), their physical mixture (c), and curcumin-loaded octenylsuccinate oat β-glucan (OSG) (d).

OSG and curcumin-loaded OSG are attributed to the OSG carbonyl group (−CO−) and the asymmetric stretch of vibration of the carboxylate group ($RCOO^-$). Several absorbance peaks are observed in the spectra of curcumin. Six of them are also observed in the physical mixture (curcumin and OSG). These peaks at 1505, 1430, 1207, 1029, 965, and 856 cm^{-1} are assigned to the vibration of C═O stretching, C—C stretching, (trans) olefinic C—H bending stretching, and asymmetric C—O—C stretching. The spectra of curcumin-loaded OSG nearly overlapped with that of OSG. This observation indicates that the curcumin is loaded into the micelle and no free curcumin is observed.[46,47] Nevertheless, the peaks at 1505 and 856 cm^{-1} shifted toward 1516 and 843 cm^{-1} in the spectra of curcumin-loaded OSG. The peaks at 1430, 1206, 1029, and 965 cm^{-1} disappeared in the spectra of curcumin-loaded OSG. These shifted and disappeared vibrations in the spectra of curcumin-loaded OSG compared with curcumin and the mixture are an evidence for the successful loading of curcumin into OSG micelles.

DSC. DSC studies were employed to investigate the crystal transformation of the curcumin-loaded OSG (Figure 4). The results showed that the endothermic peak of native curcumin was found at approximately at 182 °C. OSG showed a broad endothermic peak at around 75 °C. However, a weak endothermic peak at 182 °C indicates that the crystalline structure of curcumin is still present in the physical mixture of OSG and curcumin. More interestingly, the characteristic peak was not observed in the lyophilized powder of curcumin-loaded OSG. This observation indicates that curcumin is dispersed by loading into OSG micelles forming an amorphous state.[48]

XRD. To study the interactions between curcumin and OSG polymer, XRD was used. The characteristic peaks at a diffraction angle of 2θ (8.89°, 14.48°, 17.22°, 18.18°, 23.3°, 24.60°, and 25.52°) suggested the high crystalline structure of curcumin (Figure 5a). A weak peak at 8.89° and 17.22°

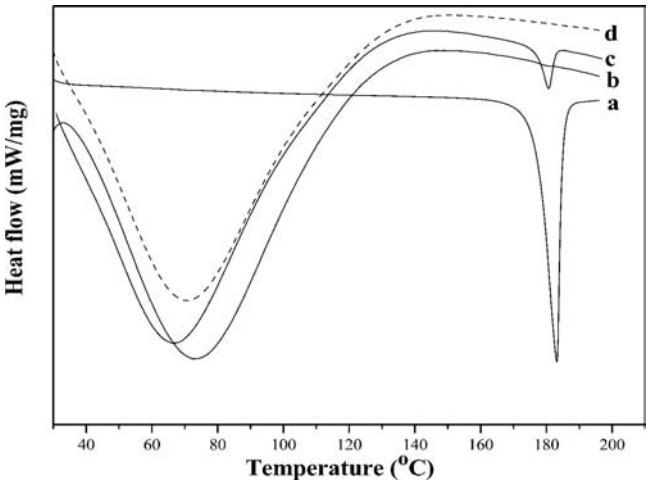

Figure 4. DSC curves of curcumin (a), octenylsuccinate oat β-glucan (b), their physical mixture (c), and curcumin-loaded octenylsuccinate oat β-glucan (OSG) (d).

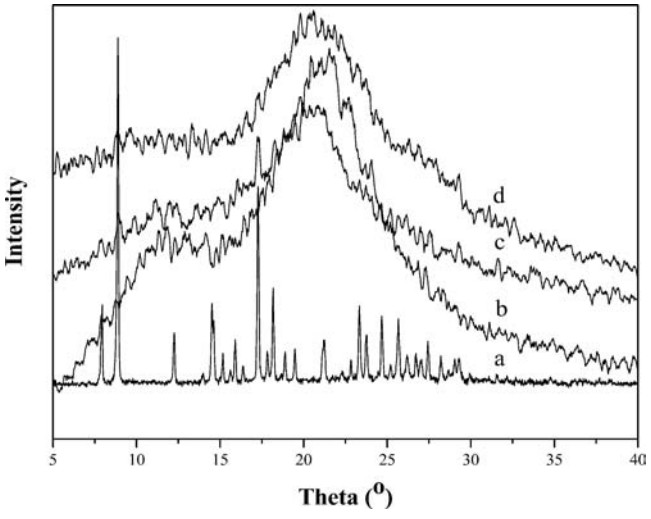

Figure 5. XRD patterns of curcumin (a), octenylsuccinate oat β-glucan (b), their physical mixture (c), and curcumin-loaded octenylsuccinate oat β-glucan (OSG) (d).

indicated that the crystalline structure of curcumin was still present in the physical mixture of the OSG micelles. However, no characteristic curcumin peaks were observed in the spectrum of curcumin-loaded OSG (Figure 5d). The absence of the crystalline order of curcumin in the curcumin-loaded OSG indicated that the formation of an amorphous complex through the intermolecular interactions between curcumin and OSG.[49]

UV Stability Study. The data from the UV stability study were summarized in Figure 6. More than 90% of curcumin was unchanged in OSG micelles as compared to less than 20% for curcumin in methanol−water (5:95, v/v) solution at the end of 6 h. Obviously, the curcumin loaded in OSG micelles showed a better stability under UV irradiation than in methanol−water (5:95, v/v) solution. This is due to the OSG cavity originates a sort of "shield" effect of the curcumin against the UV irradiation. This phenomenon strongly supports the successful loading of curcumin into OSG micelles.

In summary, the dependence of CLC of OSG micelles on the structural parameters of OSG and the characterization of

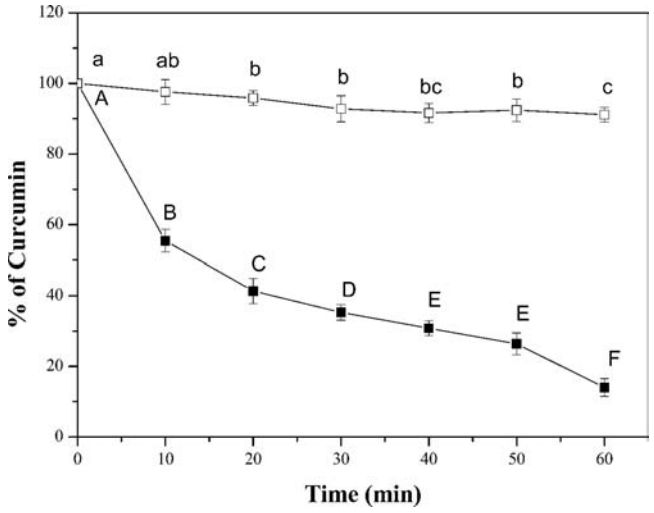

Figure 6. UV stability study of curcumin (■) and curcumin-loaded octenylsuccinate oat β-glucan (OSG) micelles (□). Values are given as the mean of three independent experiments, and error bars represent the SD. Different lower case letters indicate a significant difference ($p < 0.05$).

curcumin-loaded OSG were first investigated in this work. CLC highly depended on the structural characteristics of OSG. The CLC increased with an increase in the DS of OSG from 0.0080 to 0.0172, indicating that the hydrophobic interaction was the driving force for the increased dispersibility of curcumin. However, a decrease in the CLC was observed as further increase in the DS, due to the smaller micelle cavity of OSG micelles and the hindrance of curcumin loading into the micelle by amounts of octenyl succinate groups on the highly substituted OSG. OSG with higher M_w, offering a longer chain to encapsulate curcumin, also resulted in a higher CLC. The FT-IR, DSC, and XRD analyses confirmed that curcumin was loaded in OSG micelles to form an amorphous complex through the intermolecular interactions. Besides, the UV stability study supported the successful loading of curcumin into OSG micelles. This study suggested that OSG could be used as a nanovehicle for the loading of hydrophobic bioactive compounds.

Acetonitrile and methanol (HPLC gradient grade) were purchased from VWR (Darmstadt, Germany). Silica gel for column chromatography (0.06−0.2 mm) was obtained from Roth (Karlsruhe, Germany). Diethylenetriaminepentaacetic acid (DTPA) was obtained from Merck (Darmstadt, Germany). Methanol-d_4 (CD_3OD) and trichloromethane-d ($CDCl_3$) were purchased from Armar Chemicals (Döttingen, Switzerland). 4-Methyl-2-pentenoic acid and isovaleryl chloride were obtained from Alfa Aesar (Karlsruhe, Germany). The hop extract was kindly provided by the Hasseröder brewery (Wernigerode, Germany).

4-Methyl-3-pentenoic Acid. 4-Methyl-3-pentenoic acid was prepared according to the literature with some modifications.[20] One milliliter of 4-methyl-2-pentenoic acid (8.4 mmol) was dissolved in 20 mL of 6 M potassium hydroxide solution and heated to 105 °C for 48 h. After cooling to room temperature, the reaction mixture was acidified to pH 1 with 2 M hydrochloric acid and extracted three times with dichloromethane (30 mL). The combined organic layers were dried with sodium sulfate, and the solvent was removed under reduced pressure to afford a mixture of the target compound and the educt as a colorless liquid (90% 4-methyl-3-pentenoic acid, determined by gas chromatography as its trimethylsilyl derivative and NMR). ^{1}H NMR (400 MHz, $CDCl_3$), δ 1.65 (s, 3H), 1.79 (d, 3H, ^4J = 0.9 Hz), 3.08 (d, 2H, ^3J = 7.2 Hz), 5.30 (m, 1H); ^{13}C NMR (400 MHz, $CDCl_3$), δ 18.1, 25.8, 33.6, 115.2, 136.5, 178.3.

General Method for the Preparation of *N*-Acyl-L-proline Derivatives. The preparation was based on a method described in the literature with some modifications.[21] One equivalent of L-proline was suspended with 1.1 equiv of triethylamine in 10 mL of dry dichloromethane. The mixture was flushed with argon and cooled to 0 °C. Then 1 equiv of carboxylic acid chloride dissolved in 5 mL of dry dichloromethane was added dropwise. The reaction mixture was then stirred at room temperature for 15 h. After completion, the reaction mixture was washed two times with 15 mL of 1 M hydrochloric acid. The aqueous phase was re-extracted with 25 mL of dichloromethane. The combined organic layers were dried with sodium sulfate, and the solvent was removed under reduced pressure. The crude product was purified using flash chromatography (silica gel 60, *n*-hexane/acetone/trifluoroacetic acid 66:33:1). Fractions containing the desired product (TLC (silica gel 60, *n*-hexane/acetone/trifluoroacetic acid 66:33:1); detection, mixture of ninhydrine and *p*-toluenesulfonic acid (1%, 3%) in isopropanol) were collected and concentrated in vacuo.

***N*-Isovaleryl-L-proline (3-Methylbutyric Acid Proline Amide).** Six hundred and thirty-three milligrams of L-proline (5.5 mmol), 837 μL of triethylamine (6 mmol), and 671 μL of isobutyryl chloride (5.5 mmol) were used according to the general procedure. The product (TLC, R_f 0.31) was yielded as a yellowish oil (98%) from which the *trans* derivative was precipitated as colorless crystals at room temperature. ^{1}H NMR (500 MHz, $CDCl_3$, *trans* derivative), δ 0.97−0.99 (2d, 6H, ^3J = 6.4 Hz), 1.85−2.35 (m, 7H), 3.45−3.68 (m, 2H), 4.54−4.59 (m, 1H), 11.00 (s br, 1H); ^{13}C NMR (125 MHz, $CDCl_3$, *trans* derivative), δ 22.6. 22.7, 24.8, 25.7, 43.2, 48.0, 59.6, 173.9, 174.4; HR-MS, m/z 198.1135 (found), m/z 198.1135 (calcd for $C_{10}H_{17}NO_3$ $[M - H]^-$).

***N*-4-Methyl-3-pentenoyl-L-proline (4-Methyl-3-pentenoic Acid Proline Amide).** One milliliter of 4-methyl-3-pentenoic acid (7.6 mmol) was dissolved in 1 mL of thionyl chloride (13.8 mmol) and refluxed for 2 h. Excess thionyl chloride was removed under reduced pressure. The product, 967 mg of L-proline (8.4 mmol), and 1.25 mL of triethylamine (9 mmol) were used according to the general procedure. The product (TLC, R_f 0.31) was yielded as a brown oil (74%). ^{1}H NMR (500 MHz, $CDCl_3$, *trans* derivative), δ 1.63 (s, 3H), 1.73 (s, 3H), 1.88−2.17 (m, 2H), 2.18−2.35 (m, 2H), 3.10 (d, 2H, ^3J = 6.5 Hz), 3.38−3.68 (m, 2H), 4.48−4.57 (m, 1H), 5.23 (t, 1H, ^3J = 6.3 Hz), 10.30 (s br, 1H); ^{13}C NMR (125 MHz, $CDCl_3$, *trans* derivative), δ 18.2, 24.8, 25.7, 28.4, 34.5, 47.8, 59.7, 115.2, 136.3, 173.7, 174.2; HR-MS, m/z 210.1135 (found), m/z 210.1136 (calcd for $C_{11}H_{17}NO_3$ $[M - H]^-$).

Preparation of *n*-Humulone and *trans*-Isohumulone. A mixture of α-acids was obtained by multilayer coil countercurrent chromatography (MLCCC) using *n*-hexane, methanol, and water as tertiary system (10:8.2, v/v/v). The crude MLCCC product was further purified by preparative HPLC as described below (water/methanol (25:75, v/v)) to give pure humulone. To obtain *trans*-isohumulone, humulone was isomerized by using a modified literature protocol.[22] One gram of pure humulone was dissolved in 250 mL of methanol and flushed with argon before the isomerization was begun. The solution was radiated with a mercury-vapor lamp until the educt was completely vanished (monitored by HPLC). After removal of the solvent under reduced pressure, the crude product was purified by preparative HPLC as described below (water/methanol (50:50, v/v)) to yield *trans*-isohumulone with a purity of 98% (HPLC-DAD). Structure was confirmed by NMR experiments (^{1}H, ^{13}C; CD_3OD) in accordance with literature data.[23]

Preparation of *trans*-Humulinic Acid. Pure humulone was converted into *trans*- and *cis*-humulinic acid by using a modified literature protocol.[24] Humulone was stirred in 2 M aqueous sodium hydroxide at 95 °C for 2 h to give a mixture of *trans*- and *cis*-humulinic acid (89:11). After acidification with hydrochloric acid, the solution was extracted with diethyl ether and concentrated under reduced pressure. The individual isomers were isolated by preparative HPLC as described below (water/methanol (65:35, v/v)) to yield pure *trans*-humulinic acid. NMR spectra (^{1}H, ^{13}C; CD_3OD) were in line with the literature.[24,25]

Preparation of Hydroxy-*trans*-alloisohumulone. Pure *trans*-isohumulone was incubated in 0.1 M phosphate buffer at pH 7 after the addition of 10% vol ethanol for 1 week at 50 °C. After acidification with hydrochloric acid, the incubation was extracted with ethyl acetate, dried over sodium sulfate, and concentrated in vacuo. The crude extract was further processed by preparative HPLC (water/methanol (80:20, v/v)) to give hydroxy-*trans*-alloisohumulone with a purity of 95% (HPLC-DAD). NMR spectra (^{1}H, ^{13}C; CD_3OD) were in line with the literature.[6]

MLCCC. The MLCCC system (Ito, multilayer separator-extractor model, P. C. Inc., Potomac, MD, USA) was equipped with a constant-flow pump (Waters 510, Waters Corp., Milford, MA, USA) and a Jasco UV-2075 detector (Jasco, Gross-Umstadt, Germany) operating at 250 nm. Eluted liquids were collected in fractions of 16 mL with a fraction collector (LKB Ultrorac 7000). Chromatograms were recorded on a plotter (Servogor 200). The multilayer coil was prepared from a 1.6 mm inner diameter polytetrafluoroethylene (PTFE) tubing. The total capacity was 270 mL. The MLCCC was run at a revolution speed of 790 rpm and a flow rate of the mobile phase of 2 mL/min in head-to-tail modus. Separation was performed by using binary solvent systems (upper phase as stationary phase and lower phase as mobile phase). The sample was dissolved in a 1:1 mixture of upper and lower phase (10 mL) and injected into the system. The collected fractions were dried for further processing.

Preparative HPLC-UV. A Besta HD 2-200 pump (Wilhelmsfeld, Germany) was used at a flow rate of 20 mL/min. Elution of material was monitored by a UV detector (Jasco UV-2075). Detection wavelength for α-acids, iso-α-acids, and *trans*-humulinic acid was set at 270 and 250 nm for hydroxy-*trans*-alloisohumulone. Chromatographic separations were performed on a stainless steel column (KNAUER, Berlin, Germany; Eurospher-100-10 C18, 250 × 20 mm, 10 μm). All target substances were separated isocratically with mixtures of water and methanol containing 0.2% formic acid. The fractions containing target material were combined and dried under reduced pressure.

***trans*-Isohumulone Incubation Setup.** Individual iso-α-acids were incubated in 0.1 M ethanolic phosphate buffer (10% vol. ethanol) at two different pH values (5 and 7) with 25 mM L-proline for up to 21 days at 50 °C. The final iso-α-acids concentration was 5 mM. The incubations were performed under aerated and deaerated conditions. Deaerated conditions were achieved by adding diethylenetriaminepentaacetic acid (1 mM), degassing the buffer with helium, and flushing the residual headspace with argon. All samples were prepared in triplicate.

Incubation of *trans*-Isohumulone with $H_2{}^{18}O$. The buffer (300 μL) described above (aerated, pH 7) was lyophilized and redissolved with 270 μL of $H_2{}^{18}O$ (97 atom % ^{18}O). Thirty microliters of an ethanolic *trans*-isohumulone solution (50 mM) was added to meet the

conditions described above. Samples were incubated for 21 days at 50 °C.

Analytical HPLC-UV for Determination of Residual Iso-α-acid Levels. Analyses were performed on a Jasco HPLC system (PU-2089plus, AS-2055plus, UV-2075plus; Gross-Umstadt, Germany). Chromatographic separations were performed on a stainless steel column (KNAUER; Eurospher 100-5 C18, 250 × 4.0 mm, 5 μm) using a flow rate of 1 mL/min at 20 °C. The mobile phase used consisted of eluent A (water, 20 mg/L DTPA, 0.2% formic acid) and eluent B (acetonitrile/water (90:10, v/v), 0.2% formic acid). The incubation solutions were diluted with methanol and injected at 50% B. After 20 min, B was raised to 100% within 5 min (held for 5 min) and returned to starting conditions within 2 min (held for 8 min). The detection wavelength was set at 270 nm.

Extraction and Derivatization of Carboxylic Acids from Iso-α-acid Incubations. First, all of the samples (200 μL) were spiked with 100 μL of aqueous butyric acid solution (0.1 mM) as internal standard. After acidification with concentrated hydrochloric acid (25 μL), the precipitate was removed by centrifugation. An aliquot of the supernatant (200 μL) was saturated with sodium chloride and extracted with 300 μL of toluene. Two hundred microliters of the organic layer was dried with sodium sulfate. An aliquot was then derivatized with an equal volume of hexamethyldisilazane at 50 °C for 3 h prior to GC-MS analysis. External calibration samples were prepared in the same manner.

GC-LCI-MS Determination of Carboxylic Acid Trimethylsilyl Derivatives. One microliter of the samples described above was injected to a Thermo Finnigan Trace GC Ultra coupled to a Thermo Trace DSQ (Thermo Fisher Scientific, Bremen, Germany). Separation was carried out on a DB-5MS GC column (30 m × 0.25 mm × 0.25 μm; Agilent Technologies, Palo Alto, CA, USA). Helium 5.0 was used as carrier gas in constant flow mode (linear velocity = 28 cm/s, flow = 1 mL/min). The split flow was set at 20 mL/min. Injector and transfer lines were heated to 220 and 250 °C, respectively. The oven program was as follows: 40 °C (1 min), 4 °C/min to 100 °C (0 min), 20 °C/min to 270 °C (10 min). LCI mass spectra were obtained at 70 eV (source, 190 °C; emission current, 50 μA) in SIM mode using methanol as reagent gas. The retention times and SIM parameters for the silylated acid derivatives were as follows: butyric acid at 7.7 min (m/z 161), isovaleric acid at 9.2 min (m/z 175), and 4-methyl-3-pentenoic acid at 14.3 min (m/z 187).

LC-MS/MS Analyses of Humulinic Acid and Hydroxy-*trans*-alloisohumulone. Analyses were performed on a Jasco HPLC system (AS2057plus and PU-2080plus). Chromatographic separations were performed on a stainless steel column (KNAUER; Eurospher 100-5 C18, 250 × 4.6 mm) using a flow rate of 1 mL/min at 25 °C. The mobile phase used consisted of eluent A (30 mM ammonium formate buffer, pH 5.5) and eluent B (methanol). For analyses of incubations, samples were diluted with methanol (1:1). The respective samples (20 μL) were injected to the LC system at 25% B. After 10 min, B was raised to 30% within 12 min and then to 70% within 3 min (held for 5 min) and returned to starting conditions within 1 min (held 5 min). The LC system was connected to the probe of the mass spectrometer. The mass analyses were performed using an Applied Biosystems API 4000 quadrupole instrument (Applied Biosystems, Foster City, CA, USA) equipped with an API source using an electrospray ionization (ESI) interface. Nitrogen was used as sheath and auxiliary gas. For electrospray ionization in negative mode the following specifications were used: sprayer capillary voltage, −4.5 kV; nebulizing gas flow, 50 mL/min; heating gas, 60 mL/min at 500 °C; and curtain gas, 40 mL/min. For multiple reaction monitoring (MRM), declustering potential (DP), collision energy (CE), and cell exit potential (CXP) were optimized by syringe injection of reference compounds. Quantitation was based on matrix-assisted calibration. The LC-MS/MS parameters are given in Table 1A.

LC-MS/MS Analyses of Amides. Analyses were performed on a Jasco HPLC system (AS2057plus and PU-2080plus). Chromatographic separations were performed on a stainless steel column (Vydac 218TP54, RP18, 5 μm 250 × 4.6 mm; Hesperia, CA, USA) using a flow rate of 1 mL/min at 25 °C. The mobile phase used consisted of eluent A (water, 1.2 mL/L heptafluorobutyric acid) and eluent B (methanol/water (70:30, v/v), 1.2 mL/L heptafluorobutyric acid). For analyses the samples were diluted with methanol (1:1) and injected to the LC system at 20% B. After 10 min, B was raised to 70% within 20 min and then to 100% within 2 min (held for 13 min) and returned to starting conditions within 5 min for equilibration (10 min). The LC system was connected to the probe of the mass spectrometer. The mass analyses were performed using an Applied Biosystems API 4000 quadrupole instrument equipped with an API source using an electrospray ionization (ESI) interface. Nitrogen was used as sheath and auxiliary gas. For electrospray ionization in positive mode the following specifications were used: sprayer capillary voltage, 4 kV; nebulizing gas flow, 70 mL/min; heating gas, 70 mL/min at 500 °C; and curtain gas, 50 mL/min. For MRM, declustering potential (DP), collision energy (CE), and cell exit potential (CXP) were optimized by syringe injection of reference compounds. Quantitation was based on matrix-assisted calibration. The LC-MS/MS parameters are given in Table 1B. Proline amides were extracted from Pilsener type beer after acidification to pH 2 with hydrochloric acid by means of solid phase extraction (Bakerbond C_{18} Polar Plus; Avantor, Deventer, The Netherlands). After elution with methanol, the extract was concentrated and redissolved in methanol/water (7:3, v/v). The crude extract was filtered and fractionated by analytical HPLC runs with the setup described above to isolate 3-methylbutyric acid proline amide. Fractions were collected by an automated fraction collector (1 min/fraction; CHF122SB, Advantec, Japan). Fractions containing the desired amide were dried and redissolved in a mixture of methanol and water (1:1) for LC-MS analysis. MS^2 spectra were generated by using the parameters described above (collision energy = 19 eV). The same experiment was performed with the authentic reference compound.

Table 1. Mass Spectrometer Parameters for Quantitation (MRM Mode)

	t_R (min)	mass (amu) Q1	mass (amu) Q3	DP (V)	CE (eV)	CXP (V)
		A				
trans-humulinic acid	21.2	265.1	154.9	−75	−30	−24
hydroxy-*trans*-alloisohumulone	23.5	377.1	195.2	−90	−41	−16
		B				
3-methylbutyric acid proline amide	22.0	200.2	116.1	50	20	6
4-methyl-3-pentenoic acid proline amide	24.7	212.1	116.2	56	25	10

Nuclear Magnetic Resonance Spectroscopy (NMR). NMR spectra were recorded on a Varian VXR 400 spectrometer operating at 400 MHz for ^1H and 100 MHz for ^{13}C or on a Varian Unity Inova 500 instrument operating at 500 MHz for ^1H and 125 MHz for ^{13}C, respectively. Chemical shifts are given relative to external $SiMe_4$.

Accurate Mass Determination (HR-MS). The high-resolution positive ion ESI mass spectra (HR-MS) were obtained from a Bruker Apex III Fourier transform ion cyclotron resonance (FT-ICR) mass spectrometer (Bruker Daltonics, Billerica, MA, USA) equipped with an Infinity cell, a 7.0 T superconducting magnet (Bruker, Karlsruhe, Germany), a radio frequency (RF)-only hexapole ion guide, and an external electrospray ion source (Apollo; Agilent, off-axis spray). Nitrogen was used as drying gas at 150 °C. The samples were dissolved in methanol, and the solutions were introduced continuously via a syringe pump at a flow rate of 120 μL/h. The data were acquired with 256K data points and zero filled to 1024K by averaging 32 scans.

RESULTS

Preparation of *N*-Acyl-L-proline Derivatives. For the analyses of the amino acid amides authentic reference material was necessary. In the case of proline the synthesis led to *cis*- and *trans*-configured amides due to the partial double character of

dx.doi.org/10.1021/jf501826h | J. Agric. Food Chem. 2014, 62, 7541−7549

the amide moiety. In this context the *trans* isomer is considered to be the thermodynamically more stable species, which was confirmed by the performed syntheses.[26,27] The proline-originated α-methine proton was used as a probe for the *cis*/*trans* ratio (1:5.7−6.5, Figure 1). The crystals precipitated from

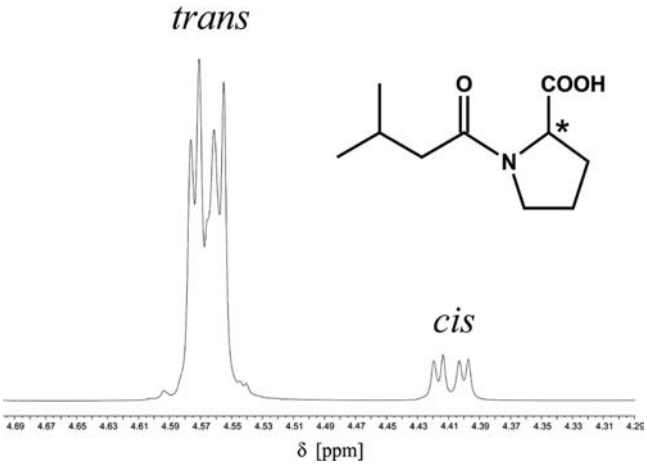

Figure 1. 3-Methylbutyric acid proline amide ^{1}H NMR spectra (excerpt) showing the α-methine proton of the *trans* (4.57 ppm) and *cis* (4.41 ppm) isomer.

3-methylbutyric acid proline amide were identified as the *trans* derivative by crystal structure analysis (data not shown). Interestingly, redissolution of *trans* crystals in deuterated chloroform, followed by NMR analysis, resulted in the reconstitution of the isomeric ratio stated above. Furthermore, the isomers could not be distinguished by LC-MS analyses.

Determination of Carboxylic Acids in Incubations. For quantitation the carboxylic acids had to be separated from the matrix. Residual *trans*-isohumulone led to artifacts during derivatization with hexamethyldisilazane and thus had to be removed by precipitation through acidification with hydrochloric acid. The carboxylic acids were extracted from the isohumulone-free supernatant (verified by HPLC-UV) with toluene. Butyric acid was used as internal standard because it cannot be formed from *trans*-isohumulone. The optimized workup provided a minimization of matrix effects and led to reproducible results.

Formation of *trans*-Isohumulone Degradation Products. *trans*-Isohumulone was incubated from 3 to 21 days at two different pH values under aerated and deaerated conditions. An overview of the substances analyzed in incubations is given in Figure 2.

Figure 3 (**1**) shows the degradation of *trans*-isohumulone. At acidic pH values it was almost completely vanished after 3 weeks (up to 97% degradation), although slightly more slowly at deaerated conditions (95%). On the contrary, relatively high amounts of unaltered *trans*-isohumulone were remained at pH 7, at which 72% was degraded in deaerated samples and 85% under oxidative conditions.

Along with the degradation of *trans*-isohumulone, the levels of 3-methylbutyric acid (MBA) increased over the incubation time in all incubation setups, preferably at neutral and aerated conditions with concentrations up to 86 mmol/mol *trans*-isohumulone (Figure 3, **2a**). The concentrations found in deaerated samples (35 mmol/mol) were approximately 3 times lower. At pH 5 the highest concentrations were also observed under oxidative conditions (34 mmol/mol), that is, about one-

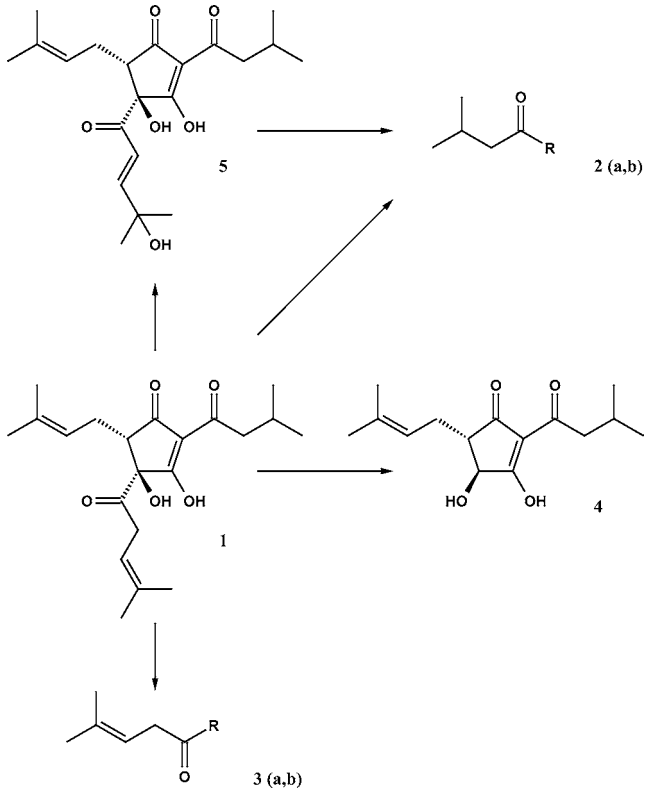

Figure 2. Overview of the structures analyzed in *trans*-isohumulone (**1**) incubations: 3-methylbutyric acid (**2a**, R = OH), 3-methylbutyric acid proline amide (**2b**, R = L-proline), 4-methyl-3-pentenoic acid (**3a**, R = OH), 4-methyl-3-pentenoic acid proline amide (**3b**, R = L-proline), *trans*-humulinic acid (**4**), hydroxy-*trans*-alloisohumulone (**5**).

third of the level determined at pH 7. A pH of 5 and deaeration led to concentrations of 24 mmol/mol after 3 weeks. The results for the formation of 4-methyl-3-pentenoic acid (MPA) (Figure 3, **3a**) revealed an almost identical pattern as seen for MBA. However, MPA levels were about 4−6 times lower compared to MBA concentrations. Again, the maximum was found at pH 7 and oxidative conditions (20 mmol/mol), whereas under deaeration half as much MPA was formed (10 mmol/mol). At pH 5 the levels were about 3 times lower after 3 weeks (4.1 mmol/mol for deaerated vs 6.6 mmol/mol for aerated samples). The carboxylic acids in the stable isotope experiment with $H_2{}^{18}O$ were analyzed analogously to the regular incubations. The incorporation of ^{18}O was monitored by analyzing additionally the [M + 2] molecular ion. For pH 7 and oxidative conditions about 90% of both carboxylic acids incorporated ^{18}O. As an example, the SIM chromatograms for the unlabeled (m/z 175) and labeled (m/z 177) MBA are given in Figure 4. Additional incubations were also performed without proline. However, there were no significant differences in the levels of carboxylic acids (data not shown).

On the basis of isolated authentic reference compounds, *trans*-humulinic acid and hydroxy-*trans*-alloisohumulone were also quantitated in the incubations. *trans*-Humulinic acid was preferentially formed at a pH of 7 under deaerated conditions (Figure 3, **4**; 11.6 mmol/mol after 3 weeks). Oxidative conditions led to levels up to 9.4 mmol/mol at the same pH. In contrast, in acidic incubations *trans*-humulinic levels were significantly higher at oxidative conditions (4.9 vs 3.0 mmol/mol in deaerated incubations). Hydroxy-*trans*-alloisohumulone had its maximum for pH 5 and oxidative conditions after 3 days

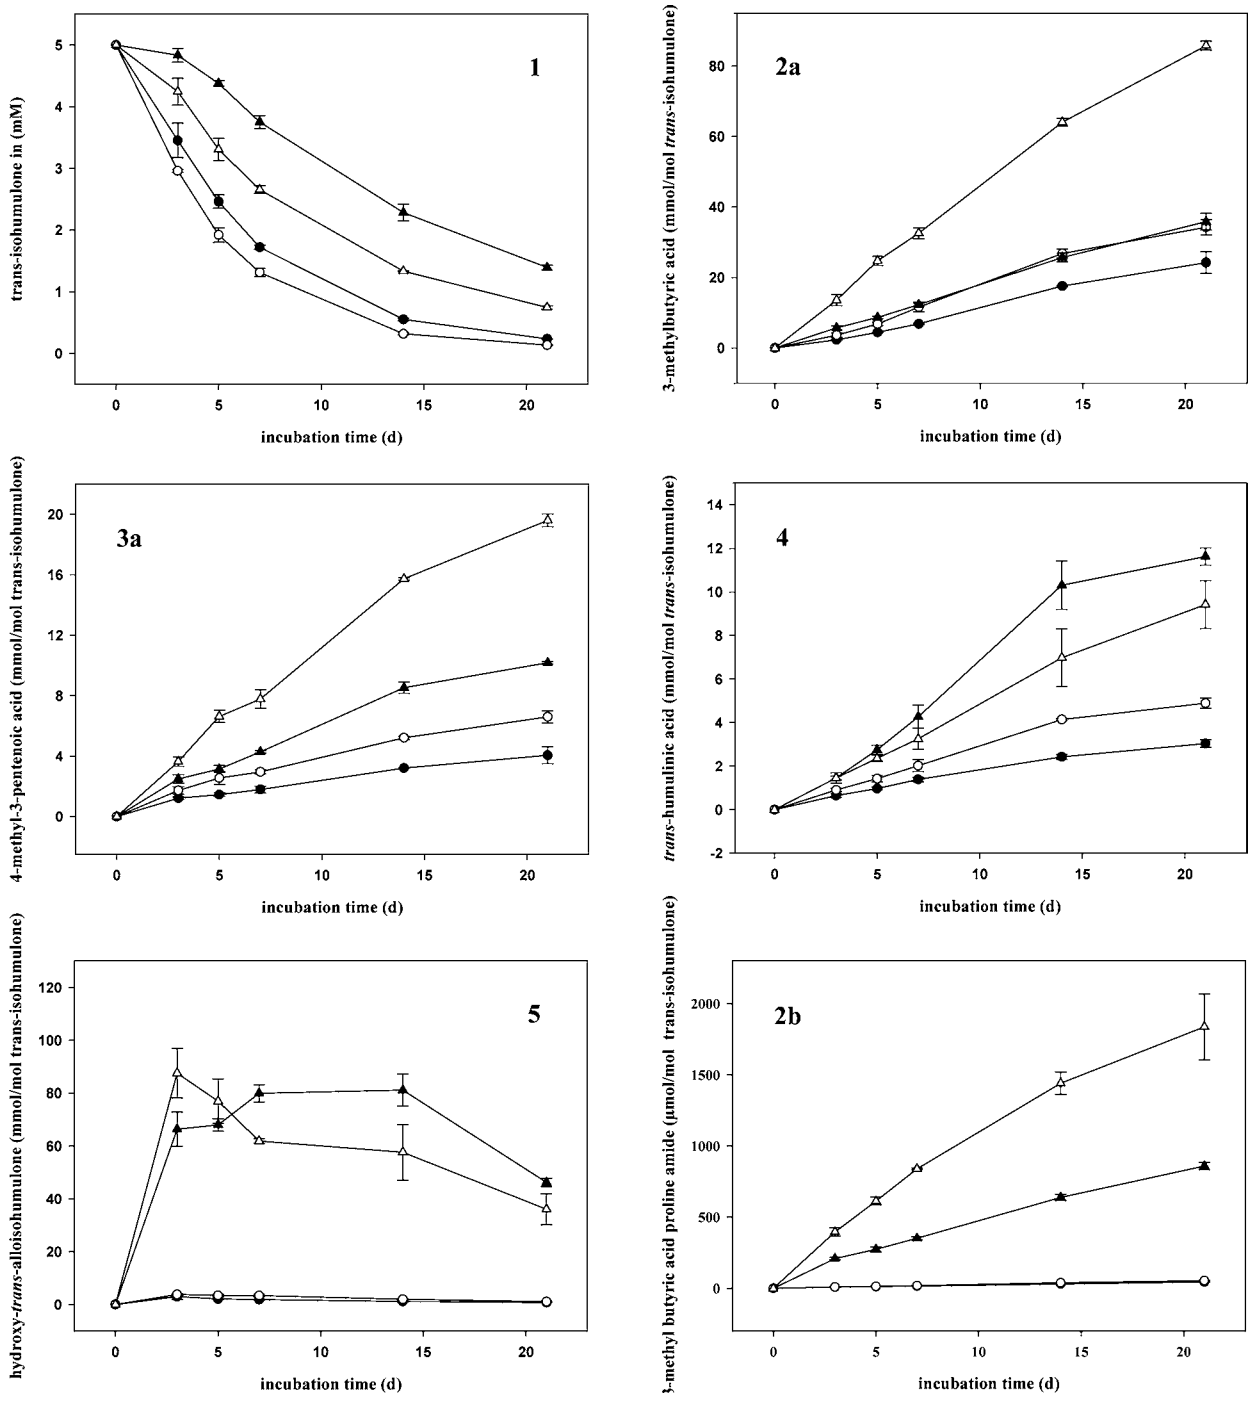

Figure 3. Degradation of *trans*-isohumulone (**1**) and formation of 3-methylbutyric acid (**2a**), 4-methyl-3-pentenoic acid (**3a**), *trans*-humulinic acid (**4**), hydroxy-*trans*-alloisohumulone (**5**), and 3-methylbutyric acid proline amide (**2b**) at pH 7 (aerated, △; deaerated, ▲) and pH 5 (aerated, ○; deaerated, ●).

(3.9 mmol/mol) and then started slowly to decrease to a final level of 1.1 mmol/mol (Figure 3, **5**). The curve for deaerated incubation was similar, although concentrations were slightly lower (maximum, 3.0 mmol/mol; 0.7 mmol/mol after 3 weeks). At pH 7 levels of hydroxy-*trans*-alloisohumulone were considerably higher. The maximum at aerated conditions was reached after 3 days at 87 mmol/mol. Thereafter, the level decreased to 36 mmol/mol within 3 weeks. At nonoxidative conditions the maximum was reached after 2 weeks at 80 mmol/mol and decreased to 46 mmol/mol afterward.

In parallel to the carboxylic acids, the analogous L-proline amides were found in the incubations. The results for 3-methylbutyric acid amide (MBA amide) are given in Figure 3 (**2b**). Whereas for pH 7 relatively high concentrations of MBA amide were found (up to 1800 µmol/mol), about 50 times lower compared to MBA itself, only minor amounts (up to 54 µmol/mol) were found at pH 5. The ratio of the MBA amide levels between aeration and deaeration at pH 7 were almost identical to the ratio found for the analogous acid (2.4 to 2.1). In contrast, 4-methyl-3-pentenoic acid proline amide (MPA amide) reached a plateau after 3 days regardless of the presence

dx.doi.org/10.1021/jf501826h | J. Agric. Food Chem. 2014, 62, 7541−7549

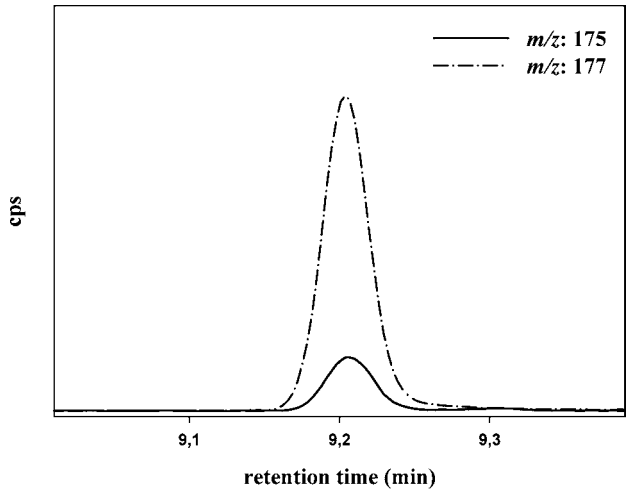

Figure 4. GC-LCI-MS chromatogram (SIM) of unlabeled (m/z 175; $[M + H]^+$) and labeled (m/z 177; $[M + H]^+$) 3-methylbutyric acid from *trans*-isohumulone incubation with $H_2{}^{18}O$. The ratio of 1:9 (unlabeled vs labeled) was calculated on the basis of the peak areas.

of oxygen and remained constant at levels around 170 μmol/mol at pH 7. An additional experiment showed that MPA amide was stable at these conditions. Analogous to MBA amide, MPA amide levels at pH 5 were extremely low (1.8 μmol/mol). MBA amide was also verified in beer by LC-MS/MS experiments (Figure 5). Although the spectrum of the isolate

(A) was much less intense, the fragmentation pattern was virtually identical to that of the authentic standard (B). For MPA amide, only traces were found in beer.

DISCUSSION

For the first time the degradation of *trans*-isohumulone in the presence of L-proline was thoroughly investigated in a model experiment. The clear impact of pH and oxidative conditions on the formation of carboxylic acids provided insights into the molecular mechanisms. In general, oxidative and hydrolytic reactions increased with higher pH. The question was whether the formation of carboxylic acids is based on hydrolytic or oxidative mechanisms or even a combination of both. Strong evidence for a hydrolytic cleavage was the formation of carboxylic acid amides. The nucleophilic L-proline nitrogen can react analogously to water or hydroxide, respectively. Obviously because of its weaker nucleophilicity compared to water, the amounts of the amides remain low. However, from a mechanistic point of view their formation is very important. As MBA amide was preferentially formed at oxidative conditions and the ratio between aerated and deaerated conditions was almost equal to that of the free acids, an identical mechanism must be assumed. To strengthen the postulated hydrolytic mechanism a stable isotope experiment with $H_2{}^{18}O$ was performed, revealing the incorporation of approximately 90% ^{18}O into the carboxylic acids, which supported the proposed hydrolytic cleavage. Incorporation of ^{18}O into free carboxylic acids was excluded by incubation of MBA and MPA with $H_2{}^{18}O$, resulting in no enrichment of the heavy isotope into the acids at these conditions. The remaining 10% must be explained by incorporation of molecular oxygen by yet unknown pathways, presumably including reactive oxygen species as intermediates. Thus, the difference in the formation of MBA under aeration versus deaeration is mainly not caused by the incorporation of molecular oxygen to the acid. Obviously there is an upstream oxidation step promoting the hydrolytic cleavage of *trans*-isohumulone.

trans-Isohumulone is a β-dicarbonyl structure and also a carboxylic acid with a pK_a of 3.23 and is almost completely deprotonated at pH 5 and entirely at pH 7.[28] Because of the β,β′-tricarbonyl system a negative charge after deprotonation is distributed over seven atoms. Thus, the anticipated carbonyl activity at the alkanoic side chain is limited in deprotonated isohumulones and does not support the preferred generation of carboxylic acid by hydrolytic β-dicarbonyl cleavage at neutral pH. Considering the given hydrolytic cleavage at oxidative conditions, we therefore postulate the mechanism shown in Figure 6.

After deprotonation, the isohumulate ion is oxidized via a one-electron oxidation, according to Huavere et al., giving a carbon-centered *trans*-isohumulone radical.[29] Reaction with molecular oxygen leads to the formation of the corresponding hydroperoxy radical. After abstraction of hydrogen, the hydroperoxide undergoes a Fenton-like redox reaction to form the alkoxy radical and subsequently the alcohol after a second abstraction of hydrogen. The now oxidized isohumulone has lost its ability to enolize, which comes along with a significantly increased carbonyl activity. Nucleophilic attack of water or L-proline at the carbonyl function at the alkanoic or alkenoic side chain then gives the free carboxylic acid or the carboxylic acid amide based on β-dicarbonyl cleavage, respectively. The difference between the concentrations of MBA and MPA is likely caused by lower reactivity of the alkenoic side chain compared to the β,β′-tricarbonyl system, a potential steric hindrance due to the prenyl side chain at the C5 of the isohumulone and the coinciding oxidation to hydroxy-*trans*-alloisohumulone. Hydrolytic cleavage of the latter would give 4-hydroxy-4-methyl-2-pentenoic acid.

The identification of the remaining cleavage products with intact ring structure would have been unambiguous proof for the present mechanism. Unfortunately, it was not possible to isolate these compounds. In contrast to the carboxylic acids and their amides, which represent stable reaction endproducts, the remaining isohumulone structures must be evaluated as highly reactive and thus can be further degraded. For instance, the cleavage of MBA gives a reductone structure, which is highly

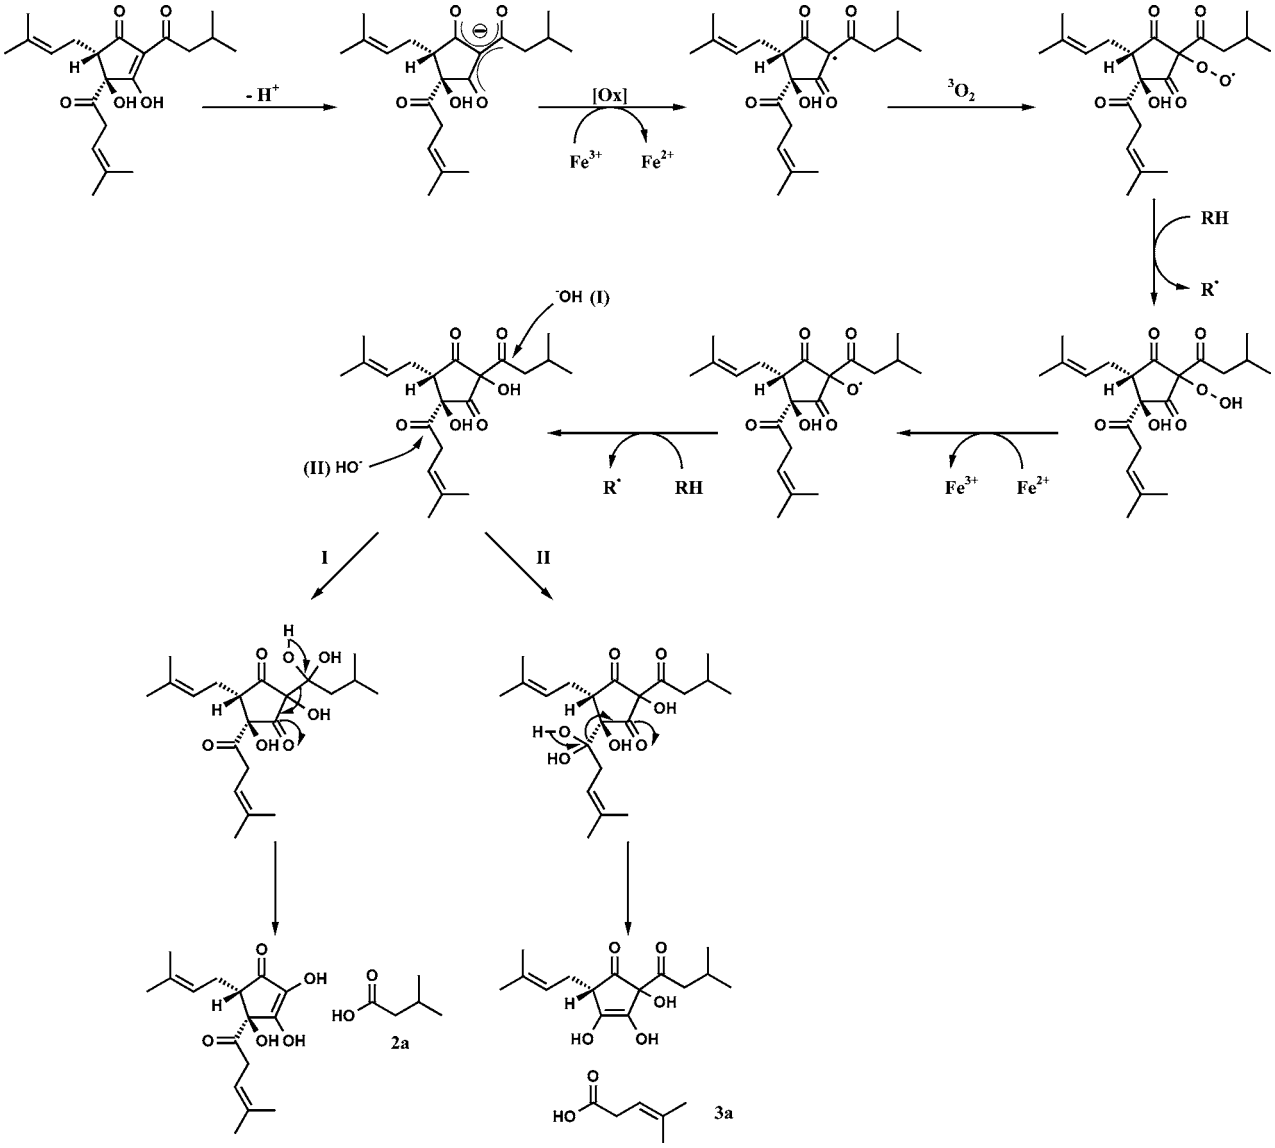

Figure 6. Proposed mechanism leading to the formation of 3-methylbutyric acid (**2a**) and 4-methyl-3-pentenoic acid (**3a**) from *trans*-isohumulone (**1**) by hydrolytic β-dicarbonyl cleavage after oxidation of the isohumulone ring structure.

susceptible to oxidation. This would also entail a loss or change of chromophoric properties to withdraw the products from the given detection systems. Therefore, in the present work, only *trans*-humulinic acid and hydroxy-*trans*-alloisohumulone were monitored as degradation products of *trans*-isohumulone.

Humulinic acids are known to form under harsh alkaline treatment. Here, we were able to detect *trans*-humulinic acid under mild conditions, preferably at pH 7. This per se nonoxidized structure must be formed by direct hydrolysis of the alkenoic side chain, which is not part of the tricarbonyl system and maintains its carbonyl activity. *trans*-Humulinic acid appeared to be stable under oxidative conditions and was not degraded significantly in an independent incubation (data not shown). Interestingly, higher amounts of *trans*-humulinic acid were generated at pH 7 under deaeration than in aerated incubations. This is reasonable considering the oxidation of *trans*-isohumulone according to above proposed mechanism leading to MBA and MPA. However, at pH 5 the picture is reversed and may be the result of a suppression of the initial oxidative step. Nevertheless, from our experiments the hydrolytic cleavage is evident at least for the alkenoic chain without previous oxidation. This is further supported by the fact that the levels of *trans*-humulinic acid and MPA were almost equal at pH 5, whereas MPA levels were significantly higher than *trans*-humulinic concentrations at pH 7 on the contrary. Obviously the oxidation of *trans*-isohumulone decreases the yield of *trans*-humulinic acid.

As a major degradation product under oxidative conditions at pH 7, 4-hydroxy-*trans*-alloisohumulone was isolated and analyzed in incubations. Together with its precursor, 4-hydroperoxy-*trans*-alloisohumulone, it has already been described by Intelmann et al.[6] The structure was relatively unstable and degraded after reaching a maximum more quickly under aerated conditions. In support, independent incubations of hydroxy-*trans*-alloisohumulone indeed revealed the formation of significant amounts of MBA, most likely according to our proposed mechanism (data not shown). We therefore must assume that MBA is not generated by only one precursor structure. As an alternative mechanism for the degradation of

dx.doi.org/10.1021/jf501826h | J. Agric. Food Chem. 2014, 62, 7541−7549

hydroxy-*trans*-alloisohumulone, Intelmann et al. assumed the formation of polycyclic compounds.[4]

In conclusion, we present a novel degradation mechanism that comprehensively explains the so far unknown formation of carboxylic acids from isohumulones. Stable isotope experiments with $H_2{}^{18}O$ as well as the generation of carboxylic acid amides unambiguously revealed a dominant hydrolytic mechanism. We showed that this reaction is relevant to brewing by the verification of MBA amide in beer. The lacking fragmentation counterparts and other reactive intermediates are subjects of current research. The actual influence of carboxylic acids derived from hops on the staling flavor of beer still has to be clarified. Nevertheless, our results are in good agreement with Williams and Wagner, who found increased levels of fatty acids during beer aging caused by the addition of hops.[14] Alternatively, MBA can also be formed by Strecker degradation of leucine, and molecular mechanisms may not be distinguishable in the aging of beer. It is very likely that the hydrolytic cleavage of isohumulones is also occurring during wort boiling after the addition of hops. High temperatures and exposure to oxygen would support the hydrolytic cleavage of isohumulones based on the proposed mechanism. Consequently, the formation of carboxylic acids from isohumulones at this stage would also promote the so-called staling esters during fermentation or beer storage. As we proved for L-proline, other nucleophiles besides water are able to react with isohumulones. Thus, also sulfur-containing substances may lead to potent odor-active compounds, such as *S*-methylthioisovalerate.[30]

where $C_{\text{molecular binding}}$ refers to the retained water that is molecularly bound to the globular protein (0.06−0.07 g of water/g of protein, where typically already 0.04 g of water is required to hydrate peptide bonds) and is, in this research, assumed to be constant. $C_{\text{submicron structure}}$ includes water held by building blocks dictated by protein−protein and protein−water interactions. $C_{\text{microstructure}}$ refers to porosity, connectivity, and deformability of the spatial gel microstructure and covers micrometer length scales. $C_{\text{disruption}}$ is determined by gel−water surface boundaries creating the rupture events, which could be on sub(micron) or supra(micron) length scales.

The aim of this paper is to show which length scales are most contributing to WH of soy protein-based gels when centrifugal compression is applied. In the presence of divalent salts and by varying their concentration during the gelation process, a variety of different gel structures can be obtained, of which the morphology was analyzed by confocal scanning laser microscopy (CSLM) and large deformation rheological responses were determined in relation to the WH for different centrifugal forces.

MATERIALS AND METHODS

Materials. Defatted soy flour was provided by Cargill BV (Amsterdam, The Netherlands). Anhydrous magnesium sulfate ($MgSO_4$) and magnesium chloride ($MgSO_4$) were obtained from Sigma−Aldrich (Steinheim, Germany). Reagents were of analytical grade and used without further purification.

Preparation of Enriched Soy Protein Solution. Defatted soy flour was suspended in reverse osmosis (RO) water at a ratio 1:10 (w/w) at 45 °C and stirred for 30 min. Then, the pH was adjusted to 8.0 with 5 M NaOH and stirred for an additional 30 min. The supernatant was collected by centrifugation (30 min, 6000*g*, 13 °C). Isolation of the globulins (glycinin and *β*-conglycinin) was achieved by isoelectric precipitation (pH 4.5, 6 M HCl). After mild stirring of precipitate overnight at 4 °C, the suspension was centrifuged (30 min, 6000*g*, 7 °C). The pellet was resuspended three times at pH 4.5 in RO water at a ratio 1:3 (w/w) to remove impurities followed by centrifugation (30 min, 6000*g*) and was finally suspended in RO water at ratio 1:4 (w/w) at pH 7.0 using 5 M NaOH. This material was denoted as enriched soy protein solution (SP). Protein content of SP was determined by Kjeldahl (calculated using N × 6.25) and was between 11% and 12% (w/w). The ratio of glycinin/*β*-conglycinin was estimated to be 50:50 by gel electrophoresis and reversed-phase high-performance liquid chromatography (results are not shown). SP was stored at 4 °C in solution in the presence of 0.02% sodium azide and used within a month after preparation. The enthalpy change, indicative for the protein nativity, was 15.2 J/g of protein measured by differential scanning calorimetry (DSC) (Q1000, TA Instruments, New Castle, DE, USA).

Preparation of Soy Protein Aggregates. Soy protein aggregates were prepared in 20 mM MOPS buffer pH 7.0 by mixing 0.1% (v/v) SP with 0.1−1.5 mM $MgSO_4$ or $MgCl_2$ salt at (i) 25 °C for 15 min, (ii) 25, 50, and 70 °C for 25 min, or (iii) 95 °C for 30 min and cooled to 25 °C. Prior to the experiments, all solutions were filtered with disposable syringe filters before mixing (Machery−Nagel Chromafil RC-20/25, pore size 0.2 *μ*m).

Turbidity. Turbidity was measured with a Hewlett−Packard 8435 diode array spectrophotometer (HP, Waldbronn, Germany) with integrated heating element and magnetic stirrer at 600 nm. Cuvettes with a light path of 10 mm were used. Samples were stirred at 200 rpm during measurements. Two different measurements were performed: (1) change in turbidity as a function of increased salt concentration after 15 min mixing protein with salt, and (2) 25 min measurements at fixed protein and salt concentrations, immediately after the addition of salt. Samples were measured at least in duplicate.

Aggregate Size. The size of protein aggregates was determined using a Zetasizer Nano ZS (Malvern Instruments, Worcestershire, UK) by 173° angle backward scattering. Measurements were performed at 25 °C and repeated 10 times per sample; data were analyzed using the general purpose model.

Preparation of Gels. SP was diluted to 10% (w/w) protein at pH 7.0 using Tris buffer to a final Tris concentration of 20 mM. The protein solution was mixed with different concentrations of $MgSO_4$ or $MgCl_2$. Gelation was performed in 20 mL syringes (20 mm in diameter), lubricated with paraffin oil, closed airtight to reduce air bubble formation during heating at 95 °C for 30 min in the water bath, and subsequently, cooled overnight at room temperature. Every sample was prepared in triplicate.

Water Holding Measurements. The centrifugation procedure was adapted from Kocher and Foegeding.[11] A microcentrifuge filtration unit was composed of an inner spin tube and a 2 mL Eppendof tube (Axygen Biosciences, Inc., Union City, CA, USA). Gels were cut in 10 mm height and 4.8 mm diameter cylinders using a cork borer and carefully placed on the bottom of the spin tube. The bottom of the spin tube was covered with a 5.5 mm diameter filter paper to reduce grid size. Centrifugation was performed at different maximal *g*-force ranging from 20 to 1000*g* for 10 min at 20 °C. No changes in WH were seen above 1000*g*. Exuded serum from the gel was collected at the bottom of the Eppendorf tube. Some samples exposed to high *g*-forces fractured in a number of pieces of which part co-eluted in the exuded serum. In that case, a strip of filter paper was used to carefully remove serum from the bottom of Eppendorf tube to eliminate the contribution of gel residue, and the removed weight was determined. The WH was calculated as the remaining water (%) in the gel after centrifugation (eq 1), where W_T is the total amount of water in the sample (g) and W_g is removed water from the sample at a given centrifugal force (*g*). Measurements were performed in duplicate.

$$\text{WH} = \frac{W_T - W_g}{W_T} \cdot 100 \quad [\%] \tag{1}$$

Obtained WH (%) at various centrifugal forces were fitted using an exponential decay (eq 2) analogous to the exponential decay as a function of time at constant force as reported by Kocher and Foegeding.[11] *A* represents the maximum amount of water that can leave the system between applied 0 and 1000*g* force, *B* (equals 100 − *A*) refers to the amount of water remaining in the gel, and *k* represents the coefficient reflecting how easy water leaves the system under applied force (in units of the gravitational acceleration, *g*):

$$\text{WH} = A \cdot e^{-kg} + B \tag{2}$$

Parameters *A* and *k* were obtained by least-squares minimization fitting of the experimented data on WH as a function of applied *g* force with Excel optimization tool Solver. Fitting the curves using two exponential decay did not give an improvement.

Confocal Laser Scanning Microscopy. Samples for microstructural analysis were stained with 0.1% fluorescent dye Rhodamine B to visualize proteins. Imaging of the samples was performed using a Leica TCS-SP5 confocal laser scanning microscope (Leica Microsystems (CMS) GmbH., Mannheim, Germany). Leica objective lenses HC PL APO 20×/0.70 IMM/CORR CS and HCX PL APO 63×/1.20 W CORR CS were used. The excitation wavelength and emission spectral regime of Rhodamine B was 561 nm and 570−725 nm, respectively.

Large Deformation Rheology. Gels were sliced with a gel slicer into cylinders of 20 mm in height and 20 mm in diameter. Fracture stress and fracture strain were measured by uniaxial compression with an AP-501 rheometer (Anton Paar, Graz, Austria) mounted with the 5 kg load cell. Paraffin oil was applied on top and bottom of the gel to prevent friction during compression. Gel samples were compressed to 90% of their initial height between two parallel plates at a constant deformation rate of 1 mm/s. Measurements were performed at 20 °C in triplicate, and mean values of fracture stress and strain were calculated. The compressive stress and strain was recalculated to true Hencky's stress and strain. True Hencky's strain ε_h is defined as

$$\varepsilon_h = \ln \frac{h(t)}{h_0} \quad [-] \tag{3}$$

where h_0 is the initial height of the gel sample and $h(t)$ is the height after certain deformation time t. The true strain is negative for compression but is expressed as an absolute value. It was assumed that the volume of gel samples did not change during deformation and that the cylindrical shape was retained. Therefore, the contact surface area A of the gel sample at compression time t can be defined as

$$A(t) = \frac{h_0}{h(t)} \cdot A_0 \quad [m^2] \tag{4}$$

where A_0 is the initial contact surface area of the gel sample. The true stress σ in the gel sample at time t is defined as

$$\sigma(t) = \frac{F(t)}{A(t)} \quad [Pa] \tag{5}$$

in which $F(t)$ is the force per unit of area $A(t)$. Fracture of the gel is described as a peak or discontinuity of the stress over strain curve. Young's modulus E_u was calculated from the linear part of the stress over strain curve within the region 0.05−0.15 of the fracture strain and is defined as

$$E_u = \left(\frac{d\sigma}{d\varepsilon_h}\right) \quad [Pa] \tag{6}$$

Recoverable energy was measured by compressing each gel to 50% of its fracture strain with a deformation speed of 1 mm/s. The measure that was used for the recoverable elastic energy (RE) was defined as the ratio of the released energy during decompression over the applied energy during compression. The areas below the stress over time curve (before and after the transition point between compression and decompression) were used to calculate the recoverable energy:

$$RE = \frac{\int_{t_{end}}^{t_{trans}} \sigma \, dt}{\int_{0}^{t_{trans}} \sigma \, dt} \times 100 \quad [\%] \tag{7}$$

We note that the measure we have defined for recoverable energy is a ratio and does not have a unit. We nonetheless refer to it as recoverable energy.

Fracture Events (Centrifugation). Over a range of centrifugal forces used (10−1000g), the gel either fractures on microscopic and/or macroscopic scales, depending on gel morphology and centrifugal speed used. To estimate which centrifugal force, F, leads to macrofracture of a gel, applied centrifugal acceleration (RFC) were transformed to uniaxial compression pressure (Pa) as follows:

$$F = m \cdot RCF \cdot 9.807 \tag{8}$$

where m is the effective mass of protein network (kg) (eq 9)

$$m = \Delta\rho \cdot V \tag{9}$$

with $\Delta\rho$ = 350 kg/m^3,[15] and V is the volume of the cylinder shaped gel (m^3). The calculated force (N) was converted to pascal (force/area) using the following definition:

$$P = F/A \tag{10}$$

where A is the area of the cylinder top surface (m^2).

Obtained values were plotted on a true strain over true stress curve to estimate in which region (linear, nonlinear, fracture, or above fracture) recalculated centrifugal force appears on the fracture curve. To make it more explicit, 200g used in centrifugation would be similar to 7 kPa in TA for compression of a 10% (w/w) soy protein gel. Compression speed in both the texture analyzer and the centrifuge tube were comparable, but time under compression differed.

RESULTS

The ability of a protein gel to retain or hold water has often been correlated to rheological properties, such as gel strength, and is suggested to be related to gel morphology. However, a concise study where it is attempted to link the macroscopic ability to retain water to properties at different length scales has not been reported. In this study, the aim was to create a variety of soy protein gels, based on either different microstructural building blocks or different gel morphologies. These gels were then subjected to WH measurements, microscopic imaging, and rheological characterization.

Variation in Aggregate Size. To investigate the contribution to WH of a gel determined by the aggregate level $C_{submicron\ structure}$, we studied the effect of $MgSO_4$ or $MgCl_2$ salts on soy protein aggregation. By varying salt concentrations, different types of aggregates can be created, as measured by turbidity. Results of 0.1% SP (v/v) mixed with 0.1−1.5 mM $MgSO_4$ or $MgCl_2$ salts at ambient temperature are shown in Figure 1. At a concentration higher than about 0.1 mM, a proportional dependence of turbidity with increasing salt addition was observed, suggesting larger or higher number of aggregates. Both salts showed the same salt concentration−turbidity dependence; however, $MgCl_2$ showed slightly higher turbidity above 0.7 mM concentration compared to $MgSO_4$.

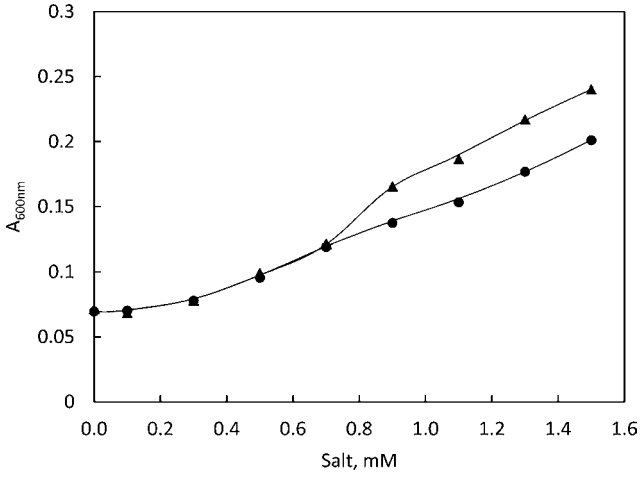

Figure 1. Turbidity measurement of 0.1% (v/v) SP mixed with 0.1−1.5 mM $MgSO_4$ or $MgCl_2$ (25 °C, reaction time 15 min): (●) $MgSO_4$; (▲) $MgCl_2$. The solid lines are fits to guide the eye.

Heat-induced soy protein aggregation kinetics in the presence of magnesium salts was monitored by changes in turbidity over time: first, to investigate the effect of anions (SO_4^{2-} or Cl^-) on aggregate formation, and second, to mimic the initial aggregation during heating and the gel formation. The protein to salt ratio was kept the same in both aggregation and gelation experiments. Results of 0.1% SP (v/v) mixed with 1.0 mM $MgSO_4$ or $MgCl_2$ at 25, 50, and 70 °C in time are shown in Figure 2. The major change in turbidity was completed within the first 5 min. At 50 and 70 °C, higher turbidity was measured indicating the formation of aggregates either larger or higher in number. Samples containing $MgCl_2$ salt showed a significant turbidity increase compared to those containing $MgSO_4$. With increasing temperatures, the impact on turbidity of chloride over sulfate became more pronounced.

The above-described effect of different salts on aggregate size was confirmed by Zetasizer measurements (Figure 3). In Figure 3a, protein aggregate sizes in 0.1% SP (v/v) mixed with or without 0.5 mM $MgSO_4$ or $MgCl_2$ at 25 °C (no heating) are shown. The addition of $MgSO_4$ increased the aggregate size

dx.doi.org/10.1021/jf501728t | J. Agric. Food Chem. 2014, 62, 7550−7558

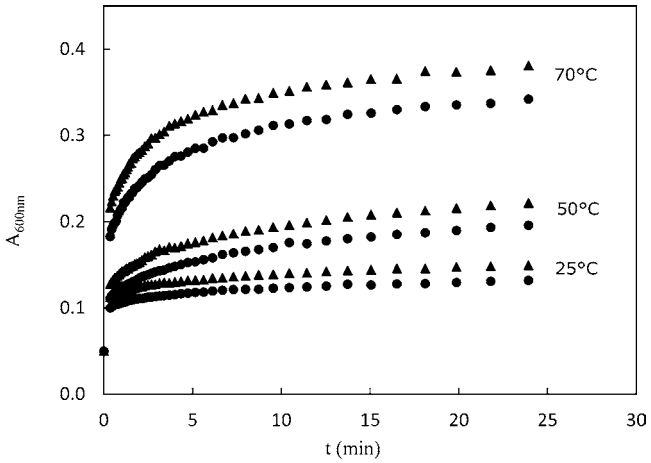

Figure 2. Turbidity measurements of 0.1% (v/v) SP with 1.0 mM salt in time at 25, 50, and 70 °C: (●) $MgSO_4$; (▲) $MgCl_2$.

from approximately 14 to 22 nm, while $MgCl_2$ resulted in a mixture of 20−65 nm aggregates. Effect of heating on soy protein aggregate size is shown in Figure 3b. Heating of 0.1% SP (v/v) in the absence of salt increased aggregate size from approximately 14 to 50 nm, while the addition of 0.5 mM $MgCl_2$ salt resulted in aggregate size of approximately 110 nm. From these results, it can be concluded that heating of SP in the presence of $MgSO_4$ and $MgCl_2$ results in typical different aggregates that will serve (at higher concentrations) as building blocks for network formation.

Soy Protein Gels: Variation in Morphology. To study the effect of the $C_{microstructure}$ contribution to WH of 10% (w/w) SP gels, we aimed to create a range of different morphologies of self-supporting gels without observable syneresis. As discussed above, by varying the type of salt ($MgCl_2$ and $MgSO_4$), different building blocks were created, and by varying the salt concentration (5−100 mM), different gel morphologies were obtained. With increasing salt concentration, the visual appearance of these gels changed. These varied from being translucent to white. Typically, $MgSO_4$ gels appeared smoother and more homogeneous compared to chloride gels. The 40−60 mM $MgCl_2$ gels showed syneresis, and therefore, these gels were discarded in this study.

Gel morphology was visualized with confocal laser scanning microscopy (CLSM) and imaged at 250 and 25 μm length scales (Figure 4a, b) (scale bars are indicated in the top left parts only). Heating in the presence of salts resulted in mixed

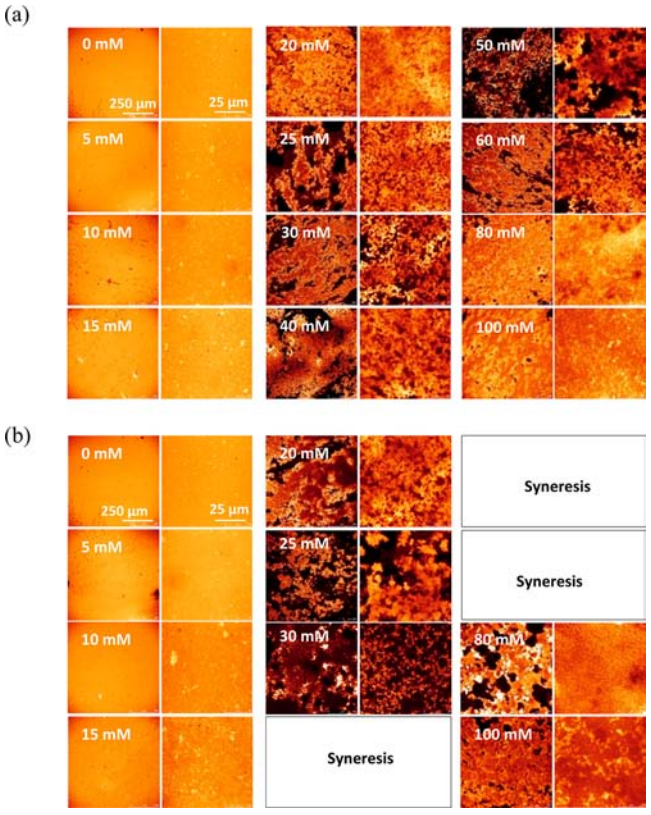

Figure 4. CLSM images of 10% (w/w) SP gels in the presence of 0−100 mM (a) $MgSO_4$ and (b) $MgCl_2$. Left image side stands for 250 μm scale, right side for 25 μm.

or particulate soy protein networks with different microstructures in terms of pore size, strand thickness, and homogeneity. As intended, a wide range of microstructures varying from fine to very coarse were obtained by using either $MgSO_4$ or $MgCl_2$ salts.

Rheological Gel Characteristics. Large deformation rheology measurements were performed to obtain mechanical characteristics of the formed gels. Young's modulus, which reflects the stiffness of the material, was determined from the

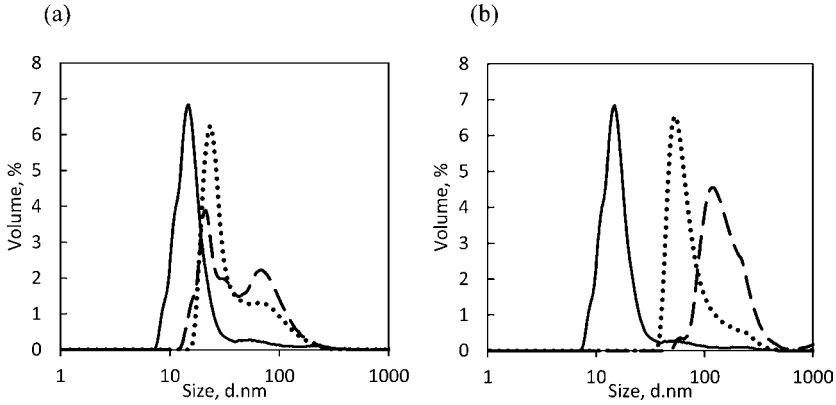

Figure 3. (a) Aggregate size of 0.1% (v/v) SP (solid line), 0.1% (v/v) SP with 0.5 mM $MgSO_4$ (dotted line), and 0.1% (v/v) SP with 0.5 mM $MgCl_2$ mixed for 30 min at 25 °C (dashed line). (b) Aggregate size of 0.1% (v/v) SP (solid line), 0.1% (v/v) SP heated at 95 °C for 30 min (dotted line), and 0.1% (v/v) SP with 0.5 mM $MgCl_2$ heated at 95 °C for 30 min (dashed line). All measurements were performed at 25 °C.

dx.doi.org/10.1021/jf501728t | J. Agric. Food Chem. 2014, 62, 7550−7558

initial slope of the resulting stress by applying a strain deformation. Figure 5a shows that both $MgSO_4$ and $MgCl_2$ SP gels increased in Young's moduli with increasing salt concentration indicating the formation of firmer structures, reaching a maximum around 30−40 mM salt and decreased again with further salt increment. The fracture stress (Figure 5b) followed the same pattern as the Young's moduli indicating harder structures formed with increasing salt concentration, and upon further increase softer structure were formed. All gels were comparable in fracture strain with the exception of 40−50 mM $MgSO_4$ gels with the higher fracture strain and 30 and 80 mM $MgCl_2$ SP gels with the lower fracture strain (Figure 5c). Typically, SP gels in the presence of $MgCl_2$ had lower fracture stress and strain compared to those with a similar concentration $MgSO_4$.

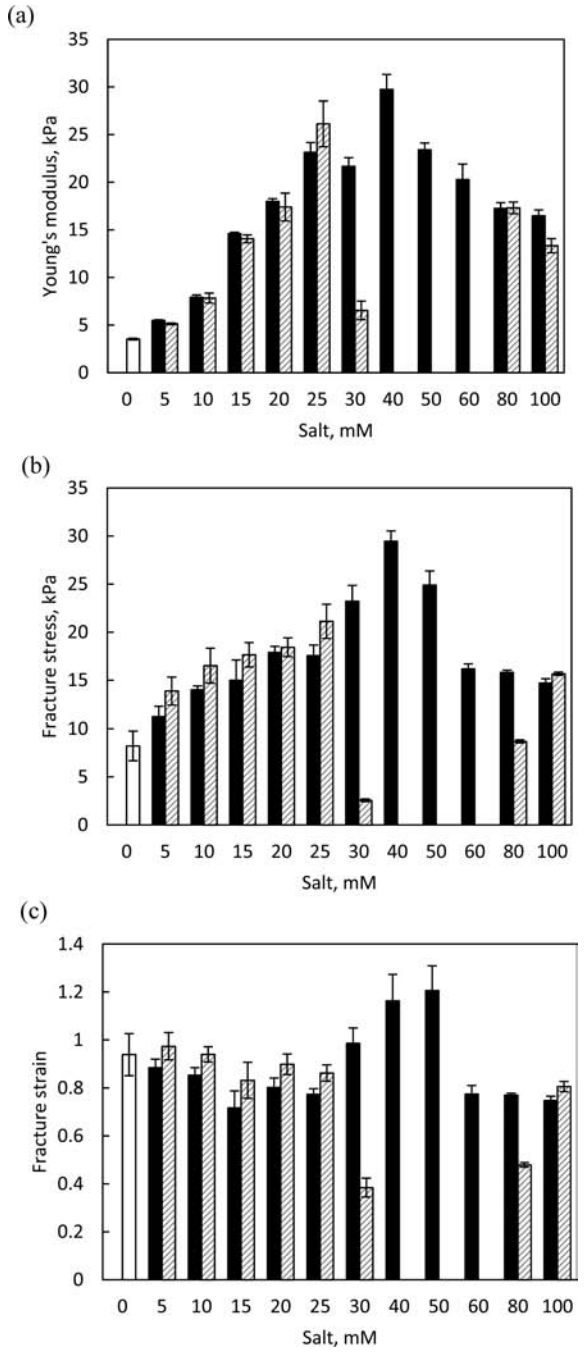

Figure 5. Large deformation rheology measurements of 10% (w/w) SP gels without salt (open bars) and mixed with 5−100 mM $MgSO_4$ (filled bars) or with 5−100 mM $MgCl_2$ (striped bars).

Recoverable Energy. Recoverable energy represents the energy that is elastically stored during deformation. Recoverable energy was measured by compressing a gel to half of its fracture strain followed by decompression. Recoverable energy results of $MgSO_4$ and $MgCl_2$ SP gels are shown in Figure 6.

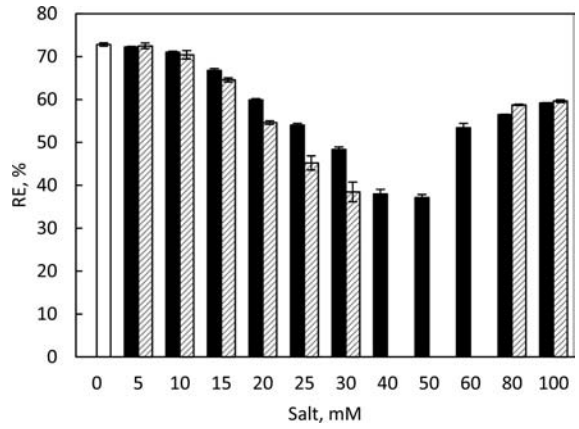

Figure 6. Recoverable energy 10% (w/w) SP gels measured at half of fracture strain: without salt (open bar) and mixed with 5−100 mM $MgSO_4$ (filled bars) or with 5−100 mM $MgCl_2$ (striped bars).

Recoverable energy decreased from approximately 70% to 40% with increasing salt concentration and increased with higher salt concentration (80−100 mM) up to 60%. Between 15 and 60 mM $MgSO_4$ gels gave significantly higher RE compared to $MgCl_2$ gels.

Water Holding Measurements. To measure WH, SP gels were centrifuged from 20 to 1000*g* for fixed time (10 min). The WH results of 10% (w/w) SP gels with 0−100 mM $MgSO_4$ and $MgCl_2$ salts are shown in Figure 7. Large differences in WH were observed by varying type of salt and its concentration. These data were further analyzed using eq 2 (dashed lines, Figure 7). The results of the obtained fitting parameters A and k are plotted in Figure 8. Up to 30 mM salt concentration, both k and A increased, indicating easier water removal (k) from the gel under applied force, as well as increased amount or removable water (A) from the gel. The 30−60 mM $MgSO_4$ gels were comparable in values of k and A. At higher salt concentrations, k slightly decreased as well as the amount of removable water (A).

DISCUSSION

In this work, the aim was to show which length scales are most contributing to WH of soy protein-based gels when centrifugal compression is applied. More specifically, it was attempted to differentiate between the contributions of submicron (aggregate level) and supramicron length scales (morphology) to WH by varying salt concentration and by employing the salt specificity ($MgSO_4$ and $MgCl_2$) on protein aggregation. Moreover, by applying different *g*-forces, the influence of macroscopic gel disruption on WH could be assessed.

Gel Microstructure and Water Holding. CSLM and scanning electron microscopy (SEM) imaging has been used to visualize gel microstructure on a (sub)micron scale, and observed differences in coarseness have been linked to WH

dx.doi.org/10.1021/jf501728t | J. Agric. Food Chem. 2014, 62, 7550−7558

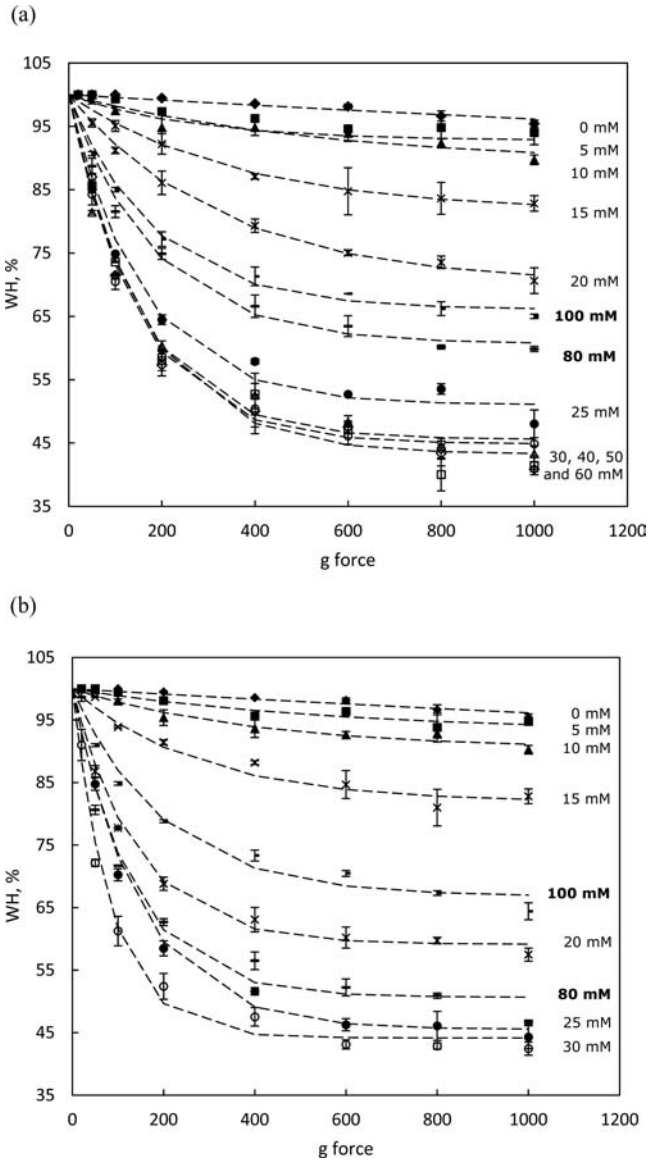

Figure 7. WH of 10% (w/w) SP gels with 0−100 mM (a) $MgSO_4$ gels and (b) $MgCl_2$ gels. The dashed lines represent the fits following the analysis as described in the text.

results[4,16−18] or used to estimated capillary pressure.[12,14] Fine stranded gels are homogeneous through different length scales, whereas coarse gels can be homogeneous on a (sub)micron scale but may be heterogeneous on submillimeter level. It was shown that addition up to 15 mM magnesium salt yielded gels with comparable microstructures on submicron to submillimeter length scales (Figure 4) but displayed different WH properties (Figure 7). Alternatively, for example, 30−60 mM $MgSO_4$ gels were different in microstructure but had a comparable WH. This illustrates that WH cannot be simply explained by a single length scale evaluation of gel microstructure. To ensure that the differences in coarseness provide a differentiation in porosity and pore dimensions, leading to differences in capillary pressures especially when salts are present as well, a more detailed study on WH was performed using capillary suction measurements. This has been reported in the Supporting Information. The outcome of that study is that capillary pressures in the different gels do not relate to the observed water holding capacities described for the various SP gels under the type of centrifugal deformation we applied.

Gel Stiffness or Fracture Properties and Water Holding. A correlation plot of WH (Figure 7) against the Young's moduli (Figure 5a) of the various SP gels is shown in Figure 9. A clear negative relation can be observed. The stiffer the gel, the more energy is needed to deform the network for a given deformation. The correlation shown in Figure 9 illustrate that such higher stiffness coincides with the inability of a gel network to hold water well. Correlation plots between WH and the fracture stress (Figure 5b) or fracture strain (Figure 5c) did not show any correlation (not shown), illustrating that the ability of a protein network to retain water in its structure under applied force does not show a relation to the inability of the network to withstand stress build-up leading to fracture events. Also Hermansson and Lucisano suggested that WH and rheological properties of blood plasma gels are not related.[10] Yet, few other studies on blood plasma gels indicated that stronger gels can lose more water than weaker ones,[10,19] in contrast to another study by Hu et al. on SP gels.[20] Alternatively, Pares et al. reported on gels with different strengths but comparable in WH.[17] Yang et al. found a positive correlation of G' and WH of SP emulsion filled gels.[21]

Recoverable Elastic Energy and Water Holding. Once energy is applied to the system, the energy can be stored in the system or dissipated by fracture, friction, or serum flow. RE can be regarded as the difference between applied and dissipated

dx.doi.org/10.1021/jf501728t | J. Agric. Food Chem. 2014, 62, 7550−7558

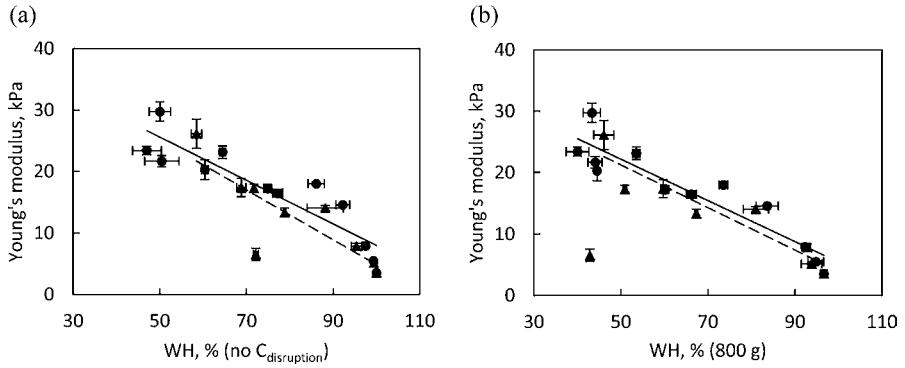

Figure 9. Correlation plots of WH as a function of Young's moduli, where (●) $MgSO_4$ and (▲) $MgCl_2$. (a) WH results when $C_{disruption}$ is eliminated; (b) WH results when fracture events are present. Horizontal error bars stand for WH, vertical for Young's moduli. Linear fitting was done as a guide to guide the eye, where solid line stands for $MgSO_4$ and dashed line for $MgCl_2$.

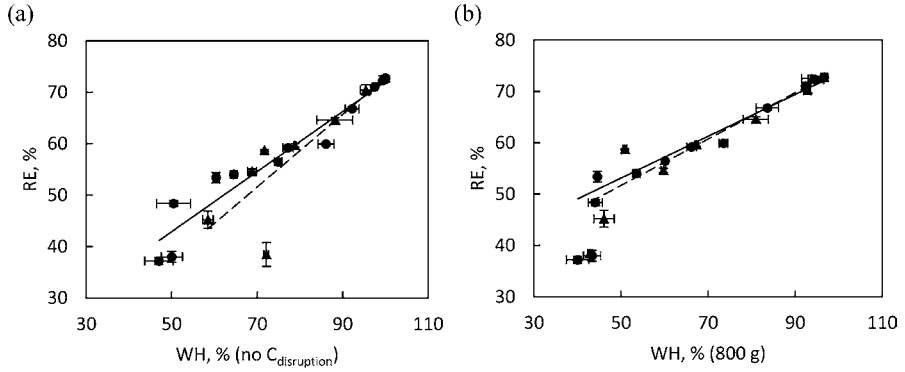

Figure 10. Correlation plots of WH as a function of RE, where (●) $MgSO_4$ and (▲) $MgCl_2$. (a) WH results when $C_{disruption}$ is eliminated; (b) WH results when fracture events are present. Horizontal error bars stand for WH, vertical for RE. Linear fitting was done as a guide to guide the eye, where solid line stands for $MgSO_4$ and dashed line for $MgCl_2$.

energy. When limited deformation is applied while determining the RE, macroscopic fracture events can be neglected, and a loss of RE might reflect predominantly the energy required to displace serum within the gel. Figure 10 shows RE (Figure 6) as a function of the WH (Figure 7) for the various SP gels. A clear positive correlation can be observed, showing an extrapolated intercept close to zero. This latter would imply that, when a protein gel would not be able to retain any water during mechanical deformation, it would also not be capable to store energy in the gel that can be regained after decompression. A comparable finding was obtained by Chantrapornchai and McClements for WPI gels.[12] The slope of the correlation shown in Figure 10 could be a measure for the efficiency by which a deformed protein network transduces its energy to viscous flow of the serum phase and thereby dissipates the applied energy.

Influence of Gel Disruption on Water Holding. A positive correlation of fracture strain to WH was reported in gellan gels,[22,23] but thus far, no information is available of fracture properties in relation to WH for protein-based gels. As already stipulated above, no correlations were found between gel fracture stress or fracture strain and WH for these gels (results are not shown). Comparing the correlation plots shown in Figures 9 and 10 at relatively low applied *g*-force (panel a) where the exerted stress in the systems is much lower than the recorded fracture stress (see the Materials and Methods section for the pressure-to-stress conversion) with those at high *g*-force (panel b) may provide insight in the contribution of gel disruption on the WH of these gels. When looking at the RE, the correlation with WH at higher applied *g*-force (Figure 10b) illustrates a general shift to lower WH and an offset in RE at zero WH. It can thus be suggested that the generation of microcracks introduces a small reduction in WH of a few percentage. Rupture of the protein network has thus a limited effect on WH, and the fragmented pieces (either at macro- of microlength scale) of the network still behave predominantly as an ensemble of intact smaller gel pieces.

Alternatively, when the stiffness of the gel under non-rupturing conditions is correlated to WH as determined at high *g*-force (Figure 9b), a similar dependence is found as compared to low applied *g*-force (Figure 9a). This supports the idea that, upon rupturing of the gel, the individual fragmented pieces behave as smaller intact gel pieces where the stiffness sets the WH ability of the gel pieces.

Discrimination of Sub- and Supramicron Contributions to Water Holding. In this work, the aim was to show which length scale was most important for WH of SP gels under compression as defined WH consisted of four different contributions covering from molecular to macro length scales. To this end, different gel morphologies (supramicron) were created based on different protein aggregates (submicron). The correlation graphs shown in Figures 9 and 10 show the data sets of both $MgSO_4$ (dashed lines) and $MgCl_2$ (solid lines) containing gels, where the first ones were based on smaller aggregates (Figures 1−3). It can be concluded that, when considering the Young's modulus (Figure 9), the aggregate level has no significant impact. But, also for the RE (Figure 10),

dx.doi.org/10.1021/jf501728t | J. Agric. Food Chem. 2014, 62, 7550−7558

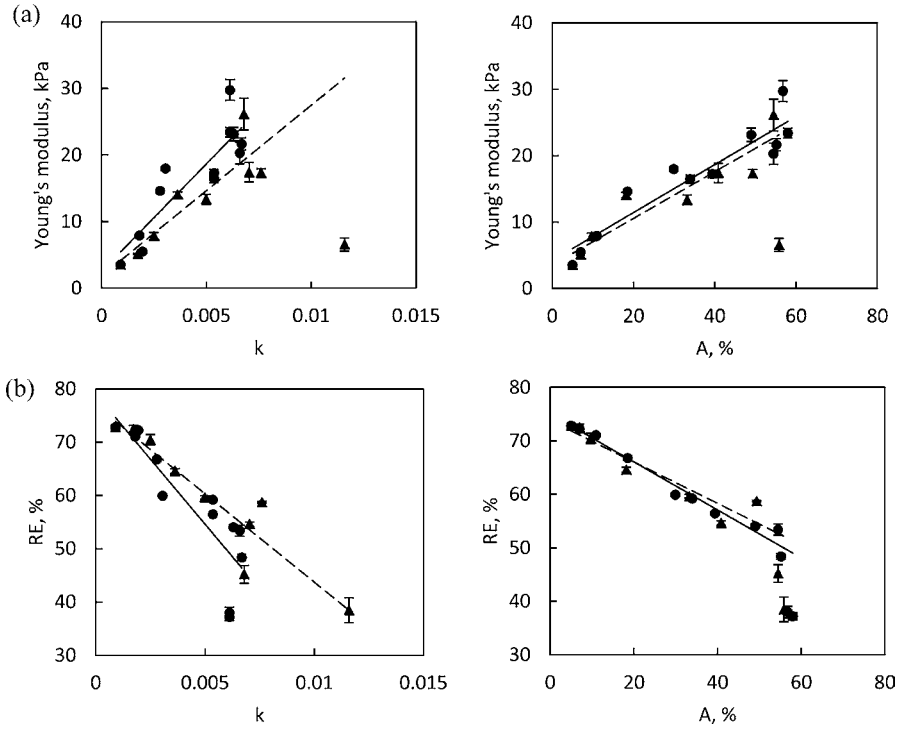

Figure 11. Correlation plots of fitting parameters k and A against (a) Young's moduli and (b) RE, where (●) $MgSO_4$ and (▲) $MgCl_2$. Vertical error bars stand for moduli and RE. Linear fitting was done as a guide to guide the eye, where solid line stands for $MgSO_4$ and dashed line for $MgCl_2$.

it cannot be concluded that there is an obvious effect when the outlier around a WH of around 72% for $MgCl_2$ is discarded.

It is then interesting to evaluate whether there might be a submicron differentiation when the kinetics is considered, as described in Figure 8 from fitting of the *g*-force curves. This is shown in Figure 11 for both the Young's modulus (panel a) and the RE (panel b) as a function of the k and A factors. It can be observed that the $MgCl_2$ gels show less steep dependence compared to the $MgSO_4$ gels when the ease by which water is removed from the gel (k) is considered. The physical implication of this finding is still unclear. On the other hand, the maximum quantity of water that can be removed (A) does not show a clear discrimination between the two different types of aggregates.

In summary, this work shows that straightforward microstructural analysis (CSLM or SEM) does not predict the WH of SP gels. The stiffness of the gels does show a negative correlation with WH, which in turn might set the propensity of the gel to reversibly store energy in the system during mechanical deformation. Fracturing characteristics, such as fracture stress and strain, have no correlation with the ability of the gel to hold water, while the occurrence of rupture events, either as micro- or macroscopic cracks, has only a limited impact on WH, as the WH of the gel fragments is still dominated by the inherent stiffness of these pieces. Comparison of gels derived from differently sized soy protein aggregates did not provide an indication that length scales at the submicron level are a determinant factor for WH of soy protein gels and that this latter property is predominantly set by larger length scales. The ease by which water may be removed from the gel (not the total amount) seems to be related to the initial building block size, which could be speculated to be related to the fine-structure of the microstructure elements that set up the network. Different aggregate characteristics might of course directly influence the gel morphology (coarseness) that can be derived and thereby set the WH capacity of the gels.

light has rarely been specified. Most precisely, "exposure to sunlight" was applied, although these experimental conditions might not reflect retail or consumer handling. In retail stores and households, cold fluorescent lights are most abundant, whereas exposure to sunlight might be more prevalent in developing countries where the oil is scooped into polyethylene terephthalate (PET) bottles from large open containers stored outside. Sunlight-exposed storage of RP-fortified soybean oil in closed PET bottles for 4 weeks at room temperature has been demonstrated to reduce the initial vitamin A concentration by 27.1 ± 12.1%, whereas additional oxygen exposure, induced by intermittent opening of the PET bottles, augmented the vitamin A loss to 88.6 ± 1.97%.[10] When the same oil samples were stored at room temperature in opened PET bottles in the dark, the mean retention of vitamin A was 97.4 ± 1.28%, clearly demonstrating that, at room temperature, protection from sunlight is more critical for preserving the vitamin A stability in edible oils than exclusion of oxygen. Whether the impact of cold fluorescent light, commonly installed in retail stores and households, is comparable to that of sunlight has not yet been studied.

Besides the need to study the vitamin A stability, the stability of vitamin E (total tocopherols) in soybean oil stored under household conditions needs also to be investigated as tocopherols were shown to affect the stability of vitamin A.[11] The presence of α-tocopherol, at a concentration of 156 μM, led to retention of 91 ± 4% of RP after air oxidation of the ethanolic RP solution for 4 h, compared to only 69 ± 4% retention of RP in the absence of α-tocopherol. However, the literature studying the stability of vitamins E and A in vegetable oils stored under domestic handling is scarce.

Thus, the current study investigated, for the first time, the stability of RP and vitamin E in vitamin A fortified soybean oil stored under household conditions in the presence of cold fluorescent light at 22 and 32 °C. Soybean oil was filled in transparent PET bottles, which were reopened periodically for sampling to mimic consumer handling. Mildly and highly oxidized soybean oil was used for fortification with RP to elucidate the effect of oxidative oil quality on RP stability.

MATERIALS AND METHODS

Chemicals. Transparent PET bottles (0.5 L; 19.4 ± 0.05 g) and corresponding screw caps were kindly provided by Rauch Fruchtsäfte GmbH, Rankweil, Austria. Refined soybean oil was purchased from Henry Lamotte Oils GmbH, Bremen, Germany. For illumination of the oil with visible daylight, a cold cathode fluorescent lamp (Philips Tornado 1450 lm, 103 W) was obtained from Philips, Eindhoven, The Netherlands. d_{12}-Hexanal was ordered from C/D/N Isotopes, Quebec, Canada. The internal standard *all-rac*-tocol was obtained from Matreya, Pleasant Gap, PA, USA. RP, which was stabilized with tocopherols, was kindly provided by DSM Nutritional Products, Kaiseraugst, Switzerland. All other chemicals were ordered from Sigma-Aldrich, Vienna, Austria, and Carl Roth, Karlsruhe, Germany.

Study Design. Soybean oil was homogenized and partly fortified with 31.6 IU/g (17.4 mg/kg) RP. To ensure a homogeneous distribution of RP in the oil, RP was premixed in 50 g of oil before it was slowly added under agitation to 20 kg of soybean oil. A total of 460 ± 1 g fortified soybean oil was filled in each of the 0.5 L transparent PET bottles, which were closed with a screw cap afterward. The soybean oil was stored at 22 ± 1 or 32 ± 1 °C following a 12 h dark/light cycle in the presence of cold fluorescent light for 56 days (Figure 1). To expose soybean oil to visible light, a 103 W (1450 lm) lamp was installed 34 cm above the bottles. A distance of 15 cm was kept between the bottles to ensure access to illumination. To investigate the influence of the oxidative status of soybean oil at the time of fortification on the stability of RP, a nonfortified soybean oil, which was exposed to cold fluorescent light at 22 ± 1 or 32 ± 1 °C, was stored until a POV of >10 mequiv O_2/kg was reached on day 28. Then, this oil was fortified with 31.6 IU/g RP and stored until the end of the study (day 56). To mimic consumer handling, the bottles were reopened on days 1, 7, 14, 21, 28, and 56, and sample volumes of 51.4 mL, 42.4 mL, 42.4 mL, 37.0 mL, 42.4 mL, and 51.4 mL, respectively, were withdrawn. On day 56, a headspace volume of 334 mL was determined. On days 1, 7, 14, 28, and 56, samples were withdrawn for analyses after gently agitating the bottles. Thus, the samples, which were withdrawn on day 21 to mimic consumer handling, were not subjected to further analyses.

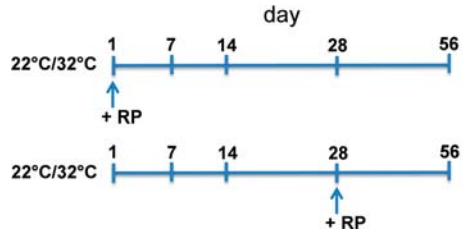

Figure 1. Study design. Fortified soybean oil was stored under different household conditions at 22 and 32 °C. Samples were withdrawn on the indicated days.

Quantification of Copper in Soybean Oil. Copper concentrations in oil samples were determined by means of atomic absorption spectrometry using a PinAAcle 900Z graphite furnace atomic absorption spectrometer (PerkinElmer, Vienna, Austria) as described previously.[12] A volume of 8 mL of 34% HNO_3 (TraceSELECT Fluka) was added to 0.2 g of oil sample and heated to 180 °C in a microwave MARS XPRESS system (CEM Corp., Kamp-Lintfort, Germany). After treatment in the microwave oven, double-distilled water was added, leading to a final volume of 20 mL, which was passed through a 0.2 μm PTFE filter prior to measurement. The limit of detection for copper was determined to be 0.02 μg/g.

Quantification of Retinol in Soybean Oil. Retinyl palmitate was analyzed as retinol after saponification. The quantification of retinol in soybean oil was performed according to the method of Bognar.[13] Sample preparation was conducted under nitrogen atmosphere in the dark. For saponification, 1 g of oil sample was mixed with 30 mL of double-distilled water, 20 mL of KOH (10.7 M), 100 mL of ethanol, 1 g of sodium ascorbate, and 2 mL of sodium sulfide (0.51 M) and heated to 80 °C under reflux for 30 min. Afterward, the reflux apparatus was rinsed with 20 mL of water. The mixture was cooled to 15 °C before 28 mL of cold, double-distilled water and 100 mL of *n*-hexane were added. The extraction was repeated twice with 100 mL of *n*-hexane and twice with 50 mL of *n*-hexane. The pooled hexane extracts were washed four times with 100 mL of cold, double-distilled water and dried with sodium sulfate. The solvent was removed from the dried extract under nitrogen by means of a rotating evaporator. The residue was dissolved in 5 mL of methanol before HPLC analysis. HPLC analysis was carried out on a Dionex Ultimate 3000 LC system (Thermo Fisher Scientific, Vienna, Austria), coupled to a diode array detector set to 325 nm. A volume of 20 μL of the samples was separated on a C18 column (Luna, 250 × 3.00 mm, 5 μm, Phenomenex, Aschaffenburg, Germany) with a flow rate of 0.5 mL/min at 25 °C. A mixture of methanol and double-distilled water (98:2, v/v) was used to elute retinol after 5.05 min. Quantification of retinol was performed by applying external calibration. Calibration curves for retinol ($y = 4.64x + 0.06$) were prepared in the beginning, middle, and end of the study. To determine the limit of detection the signal-to-noise method was applied by measuring the peak height of the analyte and the noise in proximity of the analyte. A signal-to-noise ratio of 3 was considered as the lowest amount for detection. The limit of detection for retinol was 3.27 ± 0.25 ng/mL. The corresponding limit of quantification for retinol was calculated to be 10.9 ± 0.84 ng/mL, corresponding to a signal-to-noise ratio of 10. The recovery of retinol was determined by spiking oil samples with 30.5 μM retinyl palmitate

followed by sample preparation as described above. The loss of vitamin A was evaluated by comparing the retinol content after sample preparation with 30.5 μM retinol standard. The recovery was determined to be 75.5 ± 7.78%.

Iodometric Quantification of the Peroxide Value. To quantify the peroxidic oxygen in the oil samples, the POV was determined according to AOCS official method Cd 8-53.[14] Briefly, a total of 5 g of oil sample was mixed with 18 mL of glacial acetic acid and 12 mL of chloroform. A volume of 0.5 mL of saturated solution of potassium iodide was added to the solution. After mixing for 1 min, 30 mL of double-distilled water and 2 drops of a saturated starch solution were added. The iodine was reduced with 0.1 N sodium thiosulfate until discoloration of the solution was obtained. The difference between the volumes of sodium thiosulfate needed to reduce the iodine in the oil samples and the control without the oil was multiplied by the concentration of the sodium thiosulfate and related to the amount of oil sample in kilograms. The unit of the POV corresponds to milliequivalents of O_2 per kilogram of oil.

Quantification of Hexanal in Soybean Oil. Analysis of hexanal in soybean oil was performed by applying static headspace GC-MS. Samples were prepared with slight modifications according to the method of Giuffrida et al.[15] A total of 2.5 g of oil sample was mixed with 2.72 mL of methanol/double-distilled water (1:1, v/v) filled in 20 mL glas vials sealed with gastight screw caps before 4 μg/mL of the internal standard, d_{12}-hexanal, was added. The mixture was incubated at 70 °C and agitated at 750 rpm on a CTC Combi Pal (CTC Analytics AG, Zwingen, Switzerland) for 15 min. A headspace volume of 1000 μL was injected with a syringe preheated at 90 °C using a split ratio of 1:5 into a Shimadzu GCMS-QP 2010 Ultra (Shimadzu, Vienna, Austria) at 250 °C. The samples were separated on a capillary column (ZB-WAX Zebron (PEG), 30 m × 0.25 mm × 0.25 μm, Phenomenex), at a column flow rate of 1.31 mL/min with an initial temperature of 35 °C held for 2 min. A temperature increase to 65 °C at 15 °C/min was followed by an increase to 80 °C at 2 °C/min. The final temperature of 230 °C, which was held for 5 min, was reached at 30 °C/min. Quantification of hexanal was performed by stable isotope dilution analysis using d_{12}-hexanal as internal standard. Mixtures of known amounts of hexanal and d_{12}-hexanal with different mass ratios (1:10−35:1) were analyzed to calculate the response factor. A response factor of 1.09 ± 0.08 was obtained. The concentration of hexanal was quantified using the linear equation $y = 1.07x + 0.12$, which was calculated by analyzing the mixtures of labeled and unlabeled hexanal. Hexanal and d_{12}-hexanal eluted after 5.21 and 5.12 min, respectively. Hexanal was identified with the corresponding standard and the NIST11 database for MS spectra by comparing the retention time and the fragmentation pattern with the reference spectrum. For quantification in the SIM mode, m/z of 72 and 80 were selected for hexanal and d_{12}-hexanal.[16] The limits of detection and quantification were 0.03 ± 0.02 and 0.10 ± 0.01 μg/mL, respectively.

Quantification of Total Tocopherols in Soybean Oil. Total tocopherols were analyzed according to the procedure of Gliszczynska-Swiglo and Sikorska.[17] Briefly, 0.05 g of oil sample was dissolved in 995 μL of 2-propanol and mixed with 5 μL of tocol (1 mg/mL). Prior to UHPLC analysis on a Dionex Ultimate 3000 LC system (Thermo Fisher Scientific, Vienna, Austria), samples were passed through a 0.22 μm nylon filter. Separation of the tocopherols was carried out on a C18 column (PFP Kinetex, 100 × 2.10 mm, 1.7 μm, Phenomenex) with a flow rate of 0.5 mL/min at 25 °C. After injection of 5 μL of sample, the tocopherol isomers and the internal standard were eluted at 5.59 min (δ), 6.10 min (β), 6.24 min (γ), 6.71 min (α), and 4.92 min (tocol), respectively. A methanol gradient, starting from 75% and finishing at 100% within 10 min, was used for proper separation. Pure methanol was held for 3 min before starting conditions with 75% methanol and 25% double-distilled water were reached again. Total tocopherols were detected at 295 nm and quantified using tocopherol standards for external calibration, with corresponding calibration curves for α- ($y = 0.05x - 0.08$), β- ($y = 0.04x + 0.01$), γ- ($y = 0.06x + 0.41$), and δ- ($y = 0.06x + 0.19$) tocopherols. The sum of the individual tocopherol isomers calculated corresponds to total tocopherols. The recovery of total tocopherols was analyzed by adding 0.5 μg/mL tocol as internal standard to the samples. By comparing the area under the curve of tocol in 2-propanol with the area under the curve of tocol in the samples, a recovery of 94.4 ± 12.1% could be determined. The limits of detection for α-, β-, γ-, and δ-tocopherols were calculated to be 0.24 ± 0.02, 0.20 ± 0.02, 0.04 ± 0.01, and 0.02 ± 0.01 μg/mL, respectively, according to the signal-to-noise method described above. The corresponding limits of quantification for α-, β-, γ-, and δ-tocopherols were calculated to be 0.80 ± 0.07, 0.67 ± 0.07, 0.13 ± 0.03, and 0.07 ± 0.03 μg/mL, corresponding to a signal-to-noise ratio of 10.

Statistical Analysis. All experiments were performed in quadruplets with two technical replicates. The results are shown as the mean value ± standard deviation after exclusion of outliers by applying the Nalimov outlier test. To analyze time effects and differences between storage conditions, one-way ANOVA followed by the Holm−Sidak post hoc test was applied using SigmaPlot 11 (Systat Software Inc., Chicago, IL, USA). To study the relationship between retinol or tocopherols and hexanal or POV, the Pearson product-moment correlation coefficient was calculated. Differences were considered statistically significant when the p value was <0.05.

RESULTS

Stability of Retinyl Palmitate in Soybean Oil. The impact of cold fluorescent light and ambient temperatures of 22 and 32 °C on RP stability was studied in fortified soybean oil filled in closed transparent bottles, which were reopened once a week within the first month of storage. The stability of RP in soybean oil was determined after saponification of RP as unesterified retinol. Figure 2 shows a significant decrease of

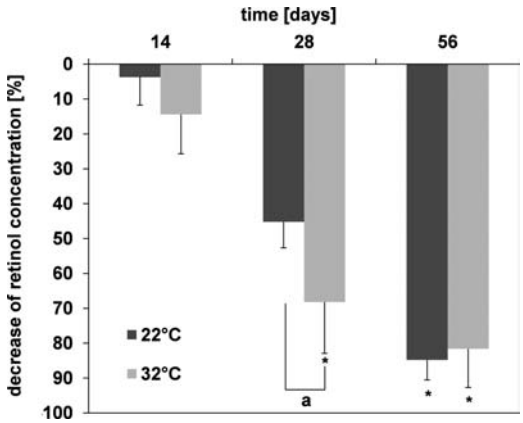

Figure 2. Percent decrease of retinol concentration in soybean oil after storage at 22 and 32 °C in the presence of cold fluorescent light for up to 56 days. Data are expressed as the mean ± SD ($n = 4$). Small letter (a) indicates statistically significant difference between storage temperatures ($p < 0.05$). Asterisks indicate statistically significant difference versus day 1 ($p < 0.05$).

retinol concentration by a maximum of 84.8 ± 5.76% after 56 days of storage under household-representative handling conditions. A significant decline of retinol concentration by 68.2 ± 14.7% was already obtained after 28 days for soybean oil exposed to cold fluorescent light at 32 °C. Thus, an accelerated degradation of RP was observed during storage of soybean oil under household conditions and handling, which was affected by an elevated ambient temperature of 32 °C on day 28.

Stability of Vitamin E in Soybean Oil. The decrease of vitamin A stability in fortified soybean oil stored under domestic conditions might also be associated with the degradation of vitamin E. With an initial concentration of 465 ± 5.25 μg/mL on day 1, total tocopherols decreased to

dx.doi.org/10.1021/jf502109j | J. Agric. Food Chem. 2014, 62, 7559−7566

46.7 ± 0.87 and 47.7 ± 1.46% of the initial content after storage at 22 and 32 °C, respectively, for 56 days (Figure 3A). After 28 days of storage, already a decrease of total tocopherols to about 86% of their initial content on day 1 was determined.

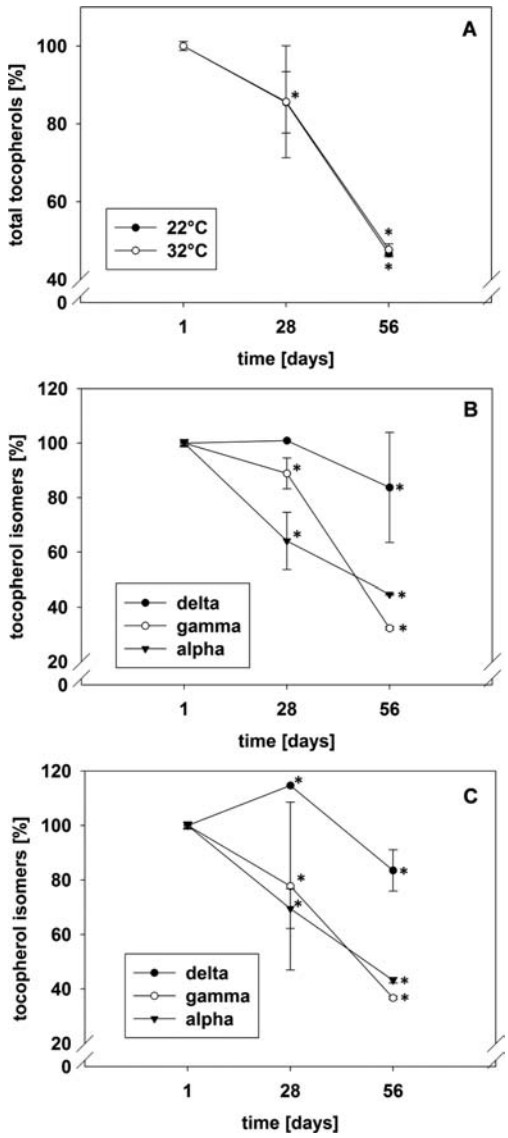

Figure 3. Decrease of total tocopherols (A) in soybean oil exposed to cold fluorescent light in the presence of RP at 22 or 32 °C for 56 days; decrease of tocopherol isomers in soybean oil exposed to cold fluorescent light in the presence of RP at 22 (B) or 32 °C (C) for 56 days. Data are expressed as the mean ± SD (n = 4). Asterisks indicate statistically significant differences versus the concentration of tocopherols on day 1 ($p < 0.05$).

Panels B and C of Figure 3 show the contribution of the individual tocopherol isomers to the loss of the total tocopherols during storage of soybean oil under consumer-representative handling at 22 and 32 °C, respectively. α- and γ-tocopherols exhibited the most pronounced decrease of tocopherol isomers. With initial values of 128 ± 1.31 and 227 ± 3.07 μg/mL, mean losses of 55.3 ± 0.29 and 67.7 ± 0.59% for α- and γ-tocopherol, respectively, were detected after storage of soybean oil at 22 °C for 56 days. Similar losses of 56.8 ± 1.01 and 63.2 ± 0.57% for α- and γ-tocopherols were obtained when the oil was stored at 32 °C. The decomposition of tocopherols differed between the tocopherol isomers during storage days 28−56 compared to the first 28 days. Whereas α-tocopherol decreased rapidly during the first 28 days of storage, the decomposition of γ-tocopherol was accelerated during the last 4 weeks of the study period. Compared to α- and γ-tocopherols, only moderate changes of the initial concentration of 103 ± 1.35 μg/mL of δ-tocopherol were observed throughout the study. β-tocopherol could be detected only on day 1 (0.67 ± 0.04 mg/100 g), whereas on the other sampling days β-tocopherol was below the limit of detection (0.20 ± 0.02 μg/mL).

Lipid Oxidation in Soybean Oil Stored under Domestic Conditions Correlates with Vitamin A and E Stability. To elucidate whether the low stability of vitamins A and E is associated with an increased oxidative deterioration of the study oil, lipid oxidation products were monitored. The formation of lipid oxidation products might be favored by the presence of transition metals, such as iron or copper. According to the analysis certificate of the manufacturer, the content of transition metals is <0.001%. However, even traces of metals might initiate lipid oxidation. Thus, soybean oil was characterized by its content of copper. Atomic absorption spectroscopic analyses revealed that the copper content was below the limit of detection of 0.02 μg/g, thereby limiting copper-induced autoxidation processes. The impact of traces of other metals, such as iron, on lipid oxidation cannot be excluded. Domestic storage of soybean oil for 56 days fortified with RP affected not only the stability of RP and vitamin E but also its susceptibility to lipid oxidation. Lipid oxidation was monitored by determining early and late oxidation markers. For analysis of early events in lipid oxidation, the POV was analyzed. An increase of the POV from 1.20 ± 0.004 to 24.3 ± 0.02 and 27.9 ± 0.33 mequiv O_2/kg was determined in soybean oil exposed to cold fluorescent light at 22 and 32 °C, respectively, after 56 days of storage (Figure 4).

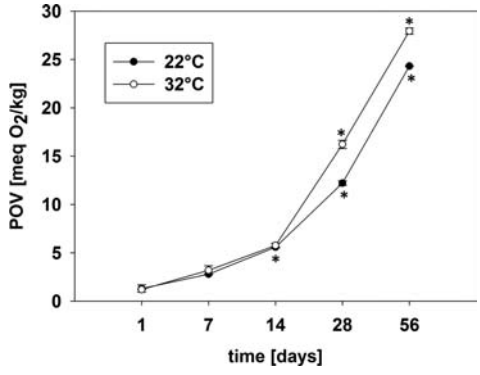

Figure 4. Increase of the POV (mequiv O_2/kg) in soybean oil exposed to cold fluorescent light in the presence of RP at 22 or 32 °C for 56 days. Data are expressed as the mean ± SD (n = 4). Asterisks indicate statistically significant differences versus the POV on day 1 ($p < 0.05$).

For analysis of the effects of soybean oil storage on late events in lipid oxidation, hexanal was chosen as a marker. Peak concentrations of hexanal of 2.13 ± 0.21 and 3.35 ± 0.69 μg/mL were reached after 28 days of storage at 22 and 32 °C, respectively, which differed significantly from the initial hexanal concentration of 0.91 ± 0.29 μg/mL on day 1 (Figure 5). Hexanal can be formed via degradation of hydroperoxides in linoleic acid-rich oils. However, an increased hexanal concentration does not necessarily lead to an decreased

dx.doi.org/10.1021/jf502109j | J. Agric. Food Chem. 2014, 62, 7559−7566

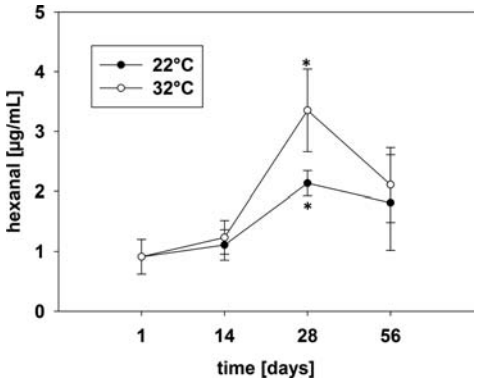

Figure 5. Alterations of the formation of hexanal (μg/mL) in soybean oil exposed to cold fluorescent light in the presence of RP at 22 or 32 °C for 56 days. Data are expressed as the mean ± SD (n = 4). Asterisks indicate statistically significant differences versus the hexanal concentration on day 1 (p < 0.05).

peroxide value, because the rate of peroxide formation might not be equal to the rate of peroxide decomposition. In the present study, the rate of peroxide formation might be higher than the rate of peroxide degradation, explaining the simultaneous increase in the peroxide value and the hexanal concentration.

To reveal any association between the RP stability and the progress of lipid oxidation, correlation analyses were performed. The relationship between RP stability and the lipid oxidation in soybean oil stored under domestic conditions was demonstrated by the negative correlation between lipid oxidation markers and retinol concentration (Figure 6). A significant correlation with a correlation coefficient of r = −0.930 (p < 0.001) and r = −0.725 (p < 0.01) was obtained between retinol concentration and the POV (Figure 6A) and the hexanal concentration (Figure 6B), respectively.

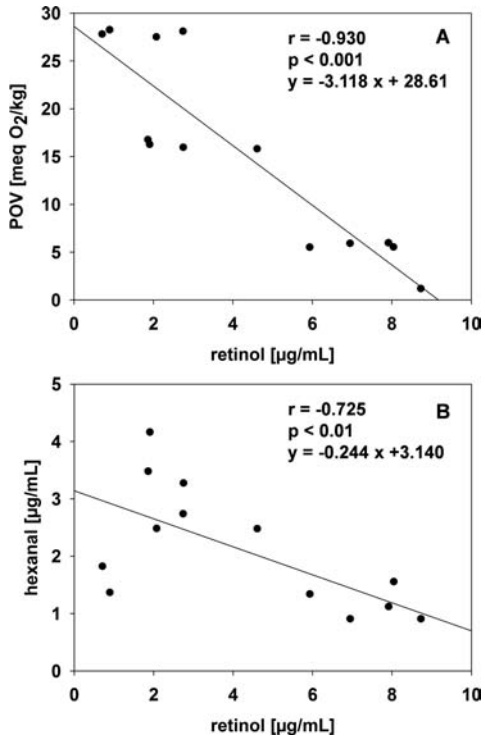

Figure 6. Correlation analyses between retinol and lipid oxidation markers, such as POV (A) and hexanal (B), as detected in soybean oil exposed to cold fluorescent light in the presence of RP at 32 °C for 56 days.

Besides the association between vitamin A stability and lipid oxidation, the stability of vitamin E was shown to depend on the oxidative status of the soybean oil (Figure 7). The storage-induced increase of the POV in mildly oxidized oil from 1.30 ± 0.38 to 24.3 ± 0.02 mequiv O_2/kg at 22 °C was associated with a decrease in total tocopherols from 465 ± 5.25 to 398 ± 6.21 μg/mL. In highly oxidized oil, characterized by a POV of 12.2 ± 0.23 mequiv O_2/kg and a tocopherol content of 398 ± 6.21 μg/mL, the 28 day storage period resulted in a tocopherol degradation to 177 ± 26.8 μg/mL.

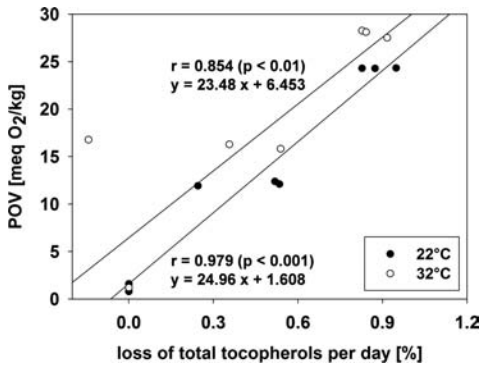

Figure 7. Loss of total tocopherols per day (%) in soybean oil with specific POV (mequiv O_2/kg). Data are expressed as the mean ± SD (n = 3).

Preoxidized Oil Lowered the Stability of RP. To confirm the correlation between RP stability and the progress of lipid oxidation, the impact of highly oxidized soybean oil, characterized by a POV of >10 mequiv O_2/kg, on the stability of RP was investigated. Besides the inverse association of RP and tocopherol concentration with lipid oxidation markers, RP stability was shown to depend on the oxidative oil quality at the time of RP fortification (Table 1). Domestic storage and handling of mildly oxidized soybean oil, which was fortified with RP at a POV of 1.43 ± 0.24 mequiv O_2/kg at day 1, led to average daily decreases of retinol concentration of 1.52 ± 0.10 and 1.46 ± 0.19% at 22 and 32 °C, respectively (p > 0.05). When highly oxidized soybean oil samples with POVs of 12.1 ±

Table 1. Percent Decrease of Retinol Concentration in Mildly and Highly Oxidized Soybean Oil, Which Was Fortified with RP on Days 1 and 28, Respectively, after Storage under Light Exposure at 22 and 32°C for 56 Days[a]

	POV at RP fortification (mequiv O_2/kg)	total decrease of retinol concentration at day 56 (%)	average decrease of retinol concentration per day (%)
mildly oxidized oil fortified with RP at day 1 (POV < 2 mequiv O_2/kg)			
22 °C	1.43 ± 0.24	84.8 ± 5.76*a	1.52 ± 0.10a
32 °C	1.43 ± 0.24	81.6 ± 11.1*a	1.46 ± 0.19a
highly oxidized oil fortified with RP at day 28 (POV > 10 mequiv O_2/kg)			
22 °C	12.1 ± 0.23	72.0 ± 1.72*a	2.57 ± 0.06b
32 °C	17.3 ± 0.18	80.3 ± 13.6*a	2.87 ± 0.49b

[a]Data are expressed as the mean ± SD (n = 4). Distinct letters within a column indicate statistically significant difference (p < 0.05). Asterisks indicate statistically significant difference with regard to the day of fortification with RP (p < 0.05).

dx.doi.org/10.1021/jf502109j | J. Agric. Food Chem. 2014, 62, 7559−7566

0.23 mequiv O_2/kg (stored at 22 °C) and 17.3 ± 0.18 mequiv O_2/kg (stored at 32 °C) were fortified with RP on day 28 and stored for another 28 days, average decreases of retinol concentration of 2.57 ± 0.06 and 2.87 ± 0.49% per day were determined. Thus, the daily decrease of retinol concentration was accelerated when highly oxidized soybean oil with a POV of >10 mequiv O_2/kg was used for fortification with RP, compared to mildly oxidized soybean oil with a POV of 1.43 ± 0.24 mequiv O_2/kg ($p < 0.05$). No statistically significant difference was reached with regard to the overall decrease of retinol concentration on day 56 between the highly oxidized oil fortified with RP on day 28 of the study compared to the mildly oxidized oil, which was fortified already on day 1 of the study ($p > 0.05$). However, the rate of RP degradation was approximately 2-fold higher ($p < 0.05$) in the highly oxidized oil compared to the mildly oxidized oil.

DISCUSSION

Consumption of vegetable oils fortified with RP is considered to prevent and combat vitamin A deficiency in populations at risk. Soybean oil is one of the most abundant vegetable oils used in vitamin A fortification programs. Storage conditions of edible oils affect not only the oxidative deterioration of the oil but also the stability of vitamin A. However, the effect of the oxidative status of soybean oil used for fortification with RP and the effect of domestic handling and storage conditions of the oil on the stability of RP are not yet clear. Besides the stability of vitamin A, other vitamins such as vitamin E might be affected by the oxidative status of the oil.

The current study demonstrated a remarkable loss of RP during storage under household-simulated conditions, yielding a maximal decrease of retinol concentration in soybean oil after 56 days of storage at 22 and 32 °C and a daily 12 h exposure to cold fluorescent light of 84.8 ± 5.76 and 81.6 ± 11.1%, respectively. After 28 days of storage, the decrease of retinol concentration was significantly enhanced from 45.2 ± 7.44% at a storage temperature of 22 °C to 68.2 ± 14.7% when the oil was stored at 32 °C. An even higher loss of vitamin A was obtained by Puysuwan et al.,[10] who detected a vitamin A loss of 88.61 ± 1.97% in fortified soybean oil that was stored with intermittent openings for sampling in closed PET bottles at room temperature in Thailand in the presence of sunlight on a kitchen shelf for 4 weeks. Comparable results were also obtained by Viana et al.,[18] showing high degradation of vitamin A to 21 and 9% of initial values in soybean oil stored at 25 and 40 °C, respectively, and exposed to light (2400 lm/m^2) for 4 weeks. Although the experimental conditions were quite similar to our approach, Puysuwan et al.[10] did not investigate the vitamin A decrease in fortified soybean oil under controlled light exposure. In the current study, the low stability of vitamin A in soybean oil exposed to light at room temperature might also be associated with a low content of antioxidant vitamins, such as tocopherols. The concentration of tocopherols in vegetable oils depends on the processing steps applied.[19] It could be shown that refined soybean oil contained 1438 μg/mL tocopherols, corresponding to a loss of 7.43% of tocopherols compared to the crude soybean oil.[19] The refined soybean oil in the current study contained only 50.7 mg/100 g (465 ± 5.25 μg/mL) tocopherols, consisting of 14.0 ± 0.14 mg/100 g α-tocopherol, 0.67 ± 0.04 mg/100 g β-tocopherol, 24.8 ± 0.33 mg/100 g γ-tocopherol, and 11.2 ± 0.15 mg/100 g δ-tocopherol. The comparatively low total tocopherol concentration might be one reason for the instability of RP in soybean oil stored for 56 days in this study. The reference values reported by the European Food Safety Agency (EFSA) are 7.5, 1.5, 79.7, and 26.6 mg/100 g for α-, β-, γ-, and δ-tocopherol, respectively.[20] Another reason for the instability of vitamin A might be the exposure of the oil to cold fluorescent light and/or the storage-induced progress of lipid oxidation. Photooxidative deterioration of vegetable oils was demonstrated to be induced by natural pigments in vegetable oils.[21] In the current study, storage of the oil, which was exposed to cold fluorescent light, for 14 days did not change the RP concentration independent of the conditions applied, likely due to sufficient availability of not yet degraded tocopherols or the less pronounced progress of lipid oxidation at the beginning of the study. The content of total tocopherols significantly decreased to almost 50% of its initial value after storage of the soybean oil for 56 days. These results are in agreements with findings reported by Player et al.,[22] demonstrating a remarkable loss of individual tocopherols when the soybean oil was stored in a forced-air oven at 50 °C for 24 days: whereas α-tocopherol was completely degraded after 16 days of storage in the oven, γ- and δ-tocopherols decreased by 28 and 17% after 24 days of storage at 50 °C. In the current study, α-tocopherol was rapidly degraded to 64.1 ± 10.5% of its initial value in soybean oil after the first 28 days of storage under domestic conditions at 22 °C, whereas γ-tocopherol was degraded to 88.9 ± 5.65% of its initial concentration ($p < 0.05$). The slight increase of δ-tocopherol in soybean oil after 28 days of storage might indicate antioxidant activity of δ-tocopherol on day 1 because its original concentration might be regenerated between days 1 and 28. δ-Tocopherol might be regenerated by phytosterols in soybean oil, such as brassicasterin. The certificate of analysis of the study oil confirmed the presence of brassicasterins (<0.3%) in the soybean oil. Kadoma et al.[23] also concluded that regeneration by flavonoids of δ-tocopherol was favored over other tocopherol isomers due to the lower steric effect of δ-tocopherol. Because it was reported that the stability of tocopherols is associated with its hydrogen-donating ability,[24] we hypothesize that the different decrease of tocopherol isomers during the storage days 28−56 and the first 28 days and the difference of the decrease between the isomers in the current study might be explained by the varying hydrogen-donating ability throughout the storage of soybean oil for 56 days.

Besides the low initial content of vitamin E and its low stability, which was shown to be associated with an increasing POV in soybean oil, the oxidative deterioration of the oil during storage might have contributed to the low stability of vitamin A as well. The current study demonstrated a progressive increase of lipid oxidation markers in soybean oil stored under household conditions applied. The POV increased from 1.20 ± 0.004 to 24.3 ± 0.02 mequiv O_2/kg, corresponding to a mean 20-fold increase, in RP-fortified soybean oil stored at 22 °C for 56 days. Recently, it was reported that household storage of non-RP-fortified soybean oil led to a comparable mean 15% rise of the POV.[25]

In the current study, hexanal, which represents a marker for late-stage lipid oxidation in linoleic acid-rich oils, was significantly enhanced from 0.91 ± 0.29 μg/mL on day 1 to 2.13 ± 0.21 and 3.35 ± 0.69 μg/mL in soybean oil after storage for 28 days at 22 and 32 °C, respectively. Despite the low RP stability in fortified soybean oil in the current study, RP could be shown to ameliorate the oxidative status of fortified soybean oil as evidenced by the hexanal formation, which is

approximately 16% lower in fortified soybean oil. Others proved that the beneficial effect of retinol on the oxidative status of vegetable oils is a result of the chain-breaking effect of retinol by forming carbon-centered radical adducts or by inducing one-electron reduction of peroxyl radicals.[26,27] Although the POV is regarded as a sensitive marker for assessing lipid oxidation, no lipid oxidation lowering effect of RP was detected by monitoring the POV in fortified soybean oil. RP might have a higher scavenging activity for radicals derived from decomposition of lipid hydroperoxides compared to lipid radicals formed during initiation of lipid oxidation. By scavenging the alkoxy radical derived from the decomposition of linoleic acid hydroperoxide, the formation of hexanal might be reduced by RP. Alkoxy radicals have been suggested to be 4 orders of magnitude more reactive toward lipids than peroxyl radicals, which might also be valid for the reaction between RP and alkoxy radicals.[27]

Due to the potential radical scavenging effect of RP, the remarkable loss of vitamin A is likely to be associated with the progress of lipid oxidation. The current study revealed a significant correlation between retinol stability and lipid oxidation markers. Laillou et al.[7] also identified a negative association between vitamin A concentration and the POV, as evidenced by a slope of −1.23 ($p < 0.001$). Ahmed et al.[28] showed a comparable relationship between carotenoids and POV in 100 mL soybean oil exposed to fluorescent light for 5 weeks. The POV in soybean oil increased from 3.89 to 20.8 mequiv O_2/kg, while the content of carotenoids decreased from approximately 19 to 5 μg/g, after 5 weeks of storage in the presence of fluorescent light. The present study confirmed the negative correlation between retinol concentration and the POV in soybean oil, as indicated by the correlation coefficient of $r = -0.930$ ($p < 0.001$). Thus, the vitamin A loss in soybean oil during household storage and consumer handling depends on the progress of lipid oxidation. To further prove this hypothesis for the vitamin A loss in soybean oil during storage conditions applied, the average daily decrease of retinol concentration was calculated for soybean oil with a low (POV < 2 mequiv O_2/kg) and a high (POV > 10 mequiv O_2/kg) oxidative status at RP fortification. It could be demonstrated that the RP concentration in soybean oil depends not only on the storage duration under domestic conditions and handling but also on the oxidative quality of the oil at the time of fortification with RP. Whereas fortification of the mildly oxidized soybean oil, characterized by a POV of 1.43 ± 0.24 mequiv O_2/kg at day 1, led to average decreases of retinol concentration of 1.52 ± 0.10 and 1.46 ± 0.19% per day at 22 and 32 °C, respectively, fortification of oxidized oil, characterized by a POV of 12.1 ± 0.23 or 17.3 ± 0.18 mequiv O_2/kg, induced more pronounced decreases of retinol concentrations of 2.57 ± 0.06 and 2.87 ± 0.49% per day at 22 and 32 °C, respectively. Thus, the decay of RP was approximately twice as high when oxidized soybean oil was used for fortification. Comparable results were obtained by Laillou et al.,[7] who demonstrated a higher loss of vitamin A of 23.1% in an oxidized (POV = 5.8 mequiv O_2/kg) oil mixture of soybean oil and sunflower oil (1:1), which was exposed to uncontrolled light during domestic storing on a shelf at 30 ± 5 °C for 4 weeks compared to a mildly oxidized oil mixture (POV = 0.4 mequiv O_2/kg) with a loss of vitamin A of only 7.3%. There, the degradation of vitamin A was about 3 times higher in the highly oxidized than in the mildly oxidized oil mixture. The relative loss of vitamin A in highly oxidized compared to mildly oxidized oil was slightly higher than in the present study, which might be attributed to different tocopherol concentrations. Laillou et al.[7] showed a 3 times higher loss of vitamin A, whereas in the present study, the loss of vitamin A was only twice as high in highly oxidized oil compared to mildly oxidized oil. The more pronounced loss of vitamin A in highly oxidized oil might also be due to different sample volumes withdrawn throughout storage compared to the current study. Whereas Laillou et al.[7] withdrew a total volume of 900 mL of oil from 1 L PET bottles, only 334 mL of oil was withdrawn from 0.5 L PET bottles in this study, the latter leading to a less pronounced increase of the headspace in the current study.

In conclusion, household-representative storage and handling of soybean oil fortified with RP at 22 or 32 °C in the presence of cold fluorescence light led to a pronounced decrease of RP. The remarkable loss of RP in fortified soybean oil was accompanied by a significant loss of vitamin E and an enhanced oxidative deterioration of the oil. It could be shown that the RP stability was influenced not only by storage duration but also by the oxidative status of soybean oil at the time of RP fortification. Fortifying highly oxidized soybean oil with RP enhanced RP loss by almost doubling the average decrease of retinol concentrations per day compared to fortified mildly oxidized soybean oil. Fortification programs should carefully consider the oxidative quality of the edible oil to be fortified and the use of a light-protecting container to ensure maximum stability and delivery of vitamins A and E throughout the intervention.

incompatible for strong electrostatic interaction. In this work, we attempt to investigate and understand in detail the structural changes and thermal stability of β-LG as a result of interacting with SBP using circular dichroism (CD), Fourier transform infrared (FTIR), and steady-state and time-resolved fluorescence spectroscopic techniques.

2. MATERIALS AND METHODS

2.1. Materials. Purified β-lactoglobulin (β-LG) powder (Lot no. JE001-0-415) was kindly donated by Davisco Foods International (Le Sueur, MN, USA). The reported composition (expressed as dry weight percent unless otherwise indicated) of the powder was as follows: >95% protein (of which 90% was β-lactoglobulin); <3.5% ash; <1.0% fat; < 1.0% lactose; <6.5% moisture (wet weight). HPLC analysis using previously published methods[29] revealed that the sample contains a total of 93.1% β-LG, distributed nearly evenly between genetic variants A and B, 51.2% and 48.8%, respectively.

Sugar beet pectin (Lot no. 30091) was donated by CP Kelco (San Diego, CA, USA). The composition of the pectin was supplied as the following: galacturonic acid (GalA), 58.5 ± 5.4%; degree of methyl esterification (DME), 57.4 ± 1.0%; degree of acetyl esterification (DAE), 21.7 ± 0.1%; neutral sugar, 37.3 ± 1.1% using previously published methods.[30,31] Ferulic acid (*trans*-4-hydroxy-3-meth- oxy-cinnamic acid) content in the pectin was determined to be 4.3 ppm by measuring the UV absorbance (Varian spectrophotometer Bio100 UV−visible, Agilent, Santa Clara, CA, USA). A molar extinction coefficient of 18.6 $mM^{-1}\cdot cm^{-1}$ at 322 nm (in ethanol) was used for ferulic acid (Sigma-Aldrich, St. Louis, MO, USA) to obtain the estimation.

Diluted hydrochloric acid solutions were prepared from a 12.1 N hydrochloric acid solution (Fisher Scientific, Fairlawn, NJ, USA). All other chemicals including ferulic acid (trans isomer), sodium hydroxide (NaOH), and sodium phosphate (monobasic and dibasic) were purchased from Sigma-Aldrich, reagent grade and used directly. All solutions were made with Millipore water (double-distilled/deionized) and filtered with a 0.45 μm syringe filter (Millex-HV, PVDF, Millipore Corp., Billerica, MA, USA).

2.2. Amino Acid and Protein Composition Analysis of SBP. SBP used in this work was subjected to amino acid composition analysis. Powdered sample (∼100 mg) was hydrolyzed in 6 N HCl containing a small amount of phenol. The hydrolysis flasks were extensively purged of oxygen using a PicoTag workstation (Waters Corp., Milford, MA, USA) and then incubated at 110 °C for 20 h. Hydrolyzed samples were filtered, dried under vacuum, and derivatized with AccQFluor reagent (Waters) following the manufacturer's directions. Chromatography was performed using procedures described as "system 1" in Cohen and De Antonis,[32] with α-aminobutyric acid as an internal standard. Separation was achieved using an AccQTag C18 reverse-phase column (Waters), and a fluorescence detector was used with 250 nm as the excitation and 395 nm as the emission wavelengths. Hydrolysis, derivitization, and analysis of each sample were performed in triplicate. The total protein content of the SBP was determined to be 4.78 ± 0.08%.

2.3. Preparation of Stock Solution. Dried β-LG and SBP samples were dissolved at 10.0 and 4.0 mg/mL respectively, in a 33 mM sodium phosphate buffer, pH 6.75. β-LG was easily soluble at the specified concentration. Dissolving SBP, on the other hand, required an overnight stirring followed by centrifugation at 27000*g* and 20 °C in a Sorval RC-5B centrifuge (DuPont Co., Wilmington, DE, USA) for 20 min. Only the SBP supernatant was removed and used in subsequent experiments. All β-LG and SBP solutions were filtered through a 0.45 μm syringe-driven filter (Millex HV, PVDF, Millipore). Appropriate dilution using the same phosphate buffered saline (PBS) buffer was made to obtain either individual β-LG or SBP or the mixture at specified concentrations as described in subsequent text.

Preheating treatment involved holding each solution of β-LG and SBP at the concentrations of 10.0 and 4.0 mg/mL respectively, at 80 °C for 10 min in a water bath. Heated solution was then allowed to cool to room temperature prior to subsequent analysis or mixing. The mixture of β-LG and SBP was prepared by either mixing the two untreated or preheated solutions, denoted as β-LG-h and SBP-h respectively, to obtain the final mixture containing 0.3 mg/mL of β-LG and 0.1 mg/mL of SBP for the CD and fluorescence experiments unless otherwise noted. All solutions were made fresh prior to each use.

2.4. Circular Dichroism Spectroscopy. CD spectroscopy was performed at 20 °C with an Aviv Model 420 CD spectrometer (Aviv Biomedical, Inc., Lakewood, NJ, USA). Spectra in the far-UV region (190−260 nm) were measured at the concentration of 0.3 mg/mL for β-LG and/or 0.1 mg/mL for SBP in a 0.05 cm path length quartz cell. The CD spectra in the near-UV region (250−320 nm) were acquired using β-LG concentration at 1.0 mg/mL and/or SBP at 0.33 mg/mL in a path length of 1 cm rectangular cuvette. All spectra were recorded with 0.5 nm step and 5 s average time. Spectra were corrected for buffer (33 mM sodium phosphate, pH 6.75) contribution and for SBP signal when present. The mean residue ellipticity, $[\theta]$ (degree cm^2 $dmol^{-1}$), was calculated from the formula $[\theta] = (M_w\theta)/(10Cln)$, where θ is the measured ellipticity (millidegrees), M_w is the molecular weight (M_w = 18320 Da, an average for a mixture of β-LG A and B variants), l is the path length of the cuvette (cm), C is the protein concentration (mg/mL), and n is the number of amino acid residues in β-LG (n = 162).

Analysis of the secondary structure of β-LG (untreated and heated) in the presence and absence of SBP (untreated and heated) in phosphate buffer (33 mM, pH 6.75) from the far-UV CD spectra was carried out using the software CDNN (v.2.1, Applied Photophysics, Ltd., Leatherhead, United Kingdom) developed by Dr. Gerald Böhm.[33] A database consisting of 33 reference proteins was used in the deconvolution analysis. The standard deviation (SD) was ±0.4% based on a set of triplicate CD experiments and followed by CDNN analysis.

Temperature dependence of far-UV CD (190−260 nm) spectra was carried out on solutions containing 0.3 mg/mL β-LG or/and 0.1 mg/mL SBP in the buffer containing 33 mM PBS (pH 6.75) in a 0.05 cm path length quartz cell. Temperature was adjusted using a solid-state Pelletier element, and a minimum of 30 min equilibration time was used between each temperature point. Each spectrum at each temperature was corrected for buffer and SBP (when present) contributions before being subjected to deconvolution using CDNN program.

2.5. FTIR Spectroscopic Measurements and Analysis. Infrared spectra were collected with a FTIR spectrometer (Nexus 670, Thermo Electron, Madison, WI, USA) equipped with a DTGS KBr detector and a KBr beam splitter. PBS buffer at reduced concentration, 20 mM, was used due to its IR contribution at the higher concentration (33 mM) used in all other experiments. β-LG and SBP samples were dissolved at 15 and 5 mg/mL respectively, and followed by subsequent mixing or/and preheating and then mixing. Aliquots of 200 μL each of the solutions investigated in this work were placed on a CaF_2 plate, allowed to air-dry overnight, and then vacuum-dried for 30 min prior to measurement. The thin film was scanned from 4000 to 1000 cm^{-1} at 20 °C with a nominal resolution of 2 cm^{-1} and 128 accumulative scans.

Analysis of the secondary structure of β-LG (untreated and heated) in the presence and absence of SBP (untreated and heated) from the FTIR spectra was carried out as previously reported.[34] The baselines were corrected automatically using the built-in software of the spectrophotometer (OMNIC v.7.3). By means of the second derivative in the amide I region, 1600−1700 cm^{-1}, eight and nine major peaks for β-LG in the absence and presence of SBP and β-LG-h in the absence and presence of SBP-h were resolved, respectively, and fitted using Peak Resolve (OMNIC v.7.3). A Gaussian function was used during the fitting routine for all peaks corresponding to α-helix (∼1660 cm^{-1}), unordered (∼1550 cm^{-1}), β-sheet (1610−1620 cm^{-1}), β-turn (1670−1690 cm^{-1}), and β-antiparallel sheet (∼1690 and 1630−1640 cm^{-1}) according to the assignments by Barth,[35] Dong et al.,[36] and Hasni et al.[37] A separate Fourier self-deconvolution procedure (OMNIC v.7.3)[38] was also used to independently confirm the positions of overlapping peaks (±2 cm^{-1}). The areas of all of the

component bands assigned to a given secondary structural element were then summed and divided by the total integrated area to yield the percentage of the element. The standard deviation of this analysis procedure was ±2%.

2.6. Fluorescence Spectroscopy. Fluorometric experiments were carried out on a FluoroLog-3 spectrometer (Horiba Scientific, Edison, NJ, USA) capable of both steady-state and time-correlated single-photon counting (TCSPC) lifetime measurements. Solutions containing either β-LG (0.3 mg/mL) or SBP (0.1 mg/mL), or a mixture, were prepared in 33 mM sodium phosphate buffer, pH 6.75, as described in section 2.3. The fluorescence spectra of β-LG in the absence and presence of SBP were recorded at 20 °C using λ_{ex} = 282 and 295 nm, and λ_{em} scanned from 320 to 450 nm. The fluorescence emission spectra (λ_{em}) of all solutions containing SBP were also recorded from 380 to 600 nm using excitation λ_{ex}= 330 nm. The bandwidths used for the excitation and the emission were 5 nm. The quartz cuvettes had 1 cm optical path lengths.

Temperature dependence analysis of Trp intrinsic and feruloyl fluorescence was carried out on solutions containing 0.3 mg/mL β-LG and 0.1 mg/mL SBP in the same buffer containing 33 mM PBS, pH 6.75, using λ_{ex} = 295 nm, λ_{em} = 330 and λ_{ex} = 330 nm, λ_{em} = 440 nm for the β-LG and SBP solutions, respectively. Ferulic acid solution (at 0.002 mg/mL) in the same buffer was also recorded as a comparison. Temperature was adjusted using a solid-state Pelletier element, and a minimum of 20 min equilibration time was used between each temperature point.

For the fluorescence lifetime measurements, the concentration of β-LG and SBP was adjusted to 3.0 and 1.0 mg/mL respectively, in 33 mM sodium phosphate buffer (I = 50 mM), pH 6.75. The excitation was performed using 296 nm or/and 331 nm NanoLEDs, and the corresponding emission was set at 340 and 440 nm, respectively. A Ludox solution was used as a scatter. Each fluorescence lifetime decay was analyzed with one, two, three, and four lifetime components, and then values of χ^2 were compared in order to determine the best fit using the software FluorEssence (v.2.5.2, Horiba Scientific). A minimal value of χ^2 indicates the best fit. A χ^2 value that approaches 1 indicates a good fit.

3. RESULTS AND DISCUSSION

3.1. Composition of the Sugar Beet Pectin. Figure 1 shows the UV−vis absorption spectrum of SBP in a 33 mM PBS buffer, pH 6.75, in comparison with that of ferulic acid (FA). It has a broad absorption band with a maximum at ∼325 nm and a shoulder of less intensity at ∼290 nm, which is consistent with the spectrum previously reported for other beet pectin.[39] In comparison, pure FA exhibited two distinctive sharp peaks at 312 and 287 nm with nearly equal intensity (see Figure 1). This difference in the overall absorption behavior of ferulic acid between its free form and its existence in SBP along with the obvious red shift, from 312 to 325 nm, of the main absorption peak provided further evidence for its covalent bonding nature with SBP, as demonstrated previously by other methods such as mass spectrometry.[40] In addition, we recently reported[28] the coexistence of a small amount of noncovalently bound ferulic acid in SBP, which clearly contributes to its absorbance behavior.

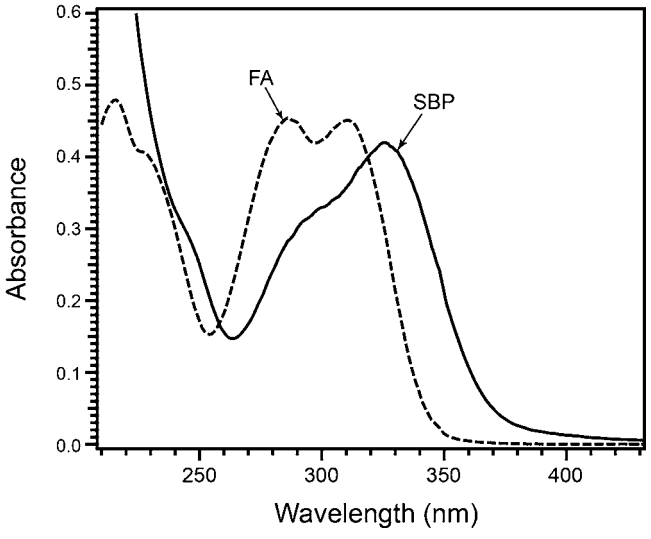

Figure 1. UV−vis absorption spectra of SBP and ferulic acid (FA) in 33 mM phosphate buffer at pH 6.75 and 20 °C. The concentration was 0.5 mg/mL for SBP and 0.005 mg/mL for FA.
