In summary, the carotenoids in the provitamin A biofortified maize showed virtually no degradation when the maize was cooked into *nshima* and porridge, for most of the maize genotypes. When the maize was cooked into *samp*, the degradation was more significant but still showed a wide range among genotypes from 50% to 100% retention. After an initial drop, the retention of provitamin A was maintained consistent throughout the six months of storage. Therefore, the 50% of provitamin A degradation assumed in the original calculation of the target levels for provitamin A for maize was somewhat accurate, concluding that the values for retention were satisfactory in ultimately providing adequate amounts of vitamin A through biofortification. In addition, we recognize the need for upstream research identifying genotypes with higher provitamin A retention during storage in order to achieve the maximum benefit of biofortified maize. Further research could also identify the mechanisms that make one genotype more resistant to provitamin A degradation than another. An effort to optimize postharvest storage methods is also recognized in order to minimize provitamin A degradation, particularly soon after harvest where the decay pattern for BCE is in excess of 40-50% in the first 15 days. More improvements and optimization of cooking methods could also increase retention of carotenoids in provitamin A biofortified maize for the benefit of populations who consume maize in the rural settings in Africa. Overall, these results are very encouraging for the biofortification program in Zambia.

(F) The differentiation rate of stage-III cells analyzed by the flow cytometer: (a) the unstained control group; (b–d) the percentage of stage-III nestin-positive neural rosettes from three independent samples. (G) The differentiation rate of stage-V cells analyzed by flow cytometer: (a) the unstained control group; (b–d) the percentage of stage-V TH-positive DAergic neurons from three independent samples.

model system due to their unlimited self-renewal and pluripotency.[9] Consequently, the primary objective of the present study was to establish an in vitro differentiation platform derived from hESCs to enhance the preclinical predictable values. To reach the goal, the utility of the established cell-based model was first verified, and we sought evidence that the final differentiated cells were functional midbrain DAergic (mDA) neurons with SN-A9 neuron phenotypes and special voltage-gated ion channel expression for dopamine release. Then, two neurogenic DR drugs (bromocriptine and 7-OH-DPAT) were used to illustrate that the cell model can be used as a platform for screening neurogenic compounds. Finally, since the neuroprotective effects of tea catechins[18] and ginsenosides[19] have been verified

using animal model, these two phytochemicals were also investigated using our in vitro model for their mDA differentiation-boosting abilities.

MATERIALS AND METHODS

Culturing Undifferentiated hESCs. The NIH-registered H9 (WA-09, karyotype XX) cell line was used in this study. The culture and maintenance of undifferentiated hESC cell line H9 (passage 40−55) were performed at the National Taiwan University (NTU) Stem Cell Core (NTU Center of Genomic Medicine, Taipei, Taiwan) according to National Stem Cell Bank (NSCB) protocols. Briefly, undifferentiated hESC cells were cultured on γ-irradiated mouse embryonic fibroblasts (MEFs) in 3.5 mm dishes containing 20% knockout serum replacer (KOSR; Invitrogen Life Technologies, Grand Island, NY, USA) medium. This medium consisted of Dulbecco's modified Eagle's medium/nutrient mixture F-12 (DMEM/F12; Invitrogen) supplemented with 1% nonessential amino acid (NEAA; Invitrogen), 0.1 mM 2-mercaptoethanol, 1 mM L-glutamine (Invitrogen), 4 ng/mL basic fibroblast growth factor (bFGF; BD Biosciences, Sparks, MD, USA), and 20% KOSR. Fresh medium was replaced every 2 d. For continual propagation of cells, hESC colonies were manually lifted, dissected into small clumps, and then replated on fresh γ-irradiated MEFs every 7 d. The propagation of undifferentiated hESC cells was regarded as the first stage of our differentiation process (as shown in Figure 1A).

Induction and Differentiation of mDA Neurons. The induction and differentiation of hESC cells followed the procedures reported by Iacovitti et al.[20] with modification; the complete procedure is presented in Figure 1A. First, hESC colonies were grown on a monolayer of γ-irradiated MEF feeder cells in 12-well plates with 20% KOSR medium until 80−90% confluence. To induce the differentiation, hESC colonies were dissected with a Laser Enabled Analysis and Processing (LEAP; Cyntellect, San Diego, CA, USA) workstation to obtain a uniform hESC colony size distribution with diameter ∼1 mm. After they were gently dissociated with 1 mg/mL type IV collagenase (Invitrogen; dissolved in DMEM/F12 medium) from feeder layers, hESC colony clumps were suspended on 10 cm bacterial-grade Petri dishes in 20% KOSR medium at 37 °C for 3 days to form embryoid bodies (EBs) in stage II. Medium was renewed on the second day of this stage. During stage III, EBs were then cultured on Matrigel (BD; diluted 1:2 in DMEM/F12 medium) coated 12-well plates in defined medium supplemented with 5 μg/mL fibronectin (Sigma-Aldrich Chemicals, St. Louis, MO, USA) and 200 ng/mL recombinant human noggin (BioVision Inc., Milpitas, CA, USA) at 37 °C for 4 d to induce formation of neural progenitor rosettes. The defined medium was composed of DMEM/F12, 100 U/mL penicillin/streptomycin, 1.5 mM L-glutamine, 6 mg/mL glucose, and 1% ITS premix (Invitrogen; containing human recombinant insulin, human

transferrin, and selenous acid, all at 5 μg/mL). Medium was also changed on the second day of stage III. Neural rosettes were further expanded in stage IV on Matrigel-coated plates containing defined medium with 20 ng/mL bFGF at 37 °C for 7 d. Medium was replaced every 2−3 d. For differentiation of dopaminergic neurons in stage V, expanded rosettes were gently lifted with 0.5 mg/mL dispase (dissolved in DMEM/F12 medium) and reseeded on Matrigel-coated 12-well plates in defined medium with 1 mM dibutyryl cyclic adenosine monophosphate (dbcAMP; Santa Cruz Biotechnology Inc., Santa Cruz, CA, USA) at 37 °C for 7 days.

Immunostaining of Cultured Cells. For immunostaining analysis, cells were cultured on Matrigel-coated glass coverslips in 12-well plates under the same culture conditions during stage III or V. After washing cells in phosphate buffered saline (PBS), they were fixed with 4% formaldehyde (in PBS) at room temperature for 20 min. Thereafter, they were washed twice with PBS containing 0.05% Tween 20, and the fixed cells were then permeabilized with 0.1% Triton X-100 (in PBS) at room temperature for 10 min, washed twice with 0.05% Tween 20 (in PBS), and blocked with blocking solution containing goat serum (GeneTex Inc., Irvine, CA, USA) at room temperature for 30 min to minimize the nonspecific binding. Subsequently, the samples were incubated at room temperature for 1 h with appropriate primary antibodies, including anti-nestin, 1:50 (#MAB353; EMD Millipore Corp., Billerica, MA, USA), anti-tyrosine hydroxylase (TH), 1:50 (#AB152 and #AB9702; Millipore), anti-β-III-tubulin, 1:50 (#04−1049; Millipore), and anti-dopamine transporter (DAT), 1:50 (#MAB369; Millopore). The cells were then incubated at room temperature for 1 h with appropriate 488- or 549-fluorescence-tagged secondary Dylight antibodies (Rockland Immunochemicals Inc., Gilbertsville, PA, USA) after being washed twice with 0.05% Tween 20 (in PBS). Finally, 0.4 ng/mL 4′,6-diamidino-2-phenylindole (DAPI) was added to the cells for nuclear staining. The immunostained cells were observed using a LEICA TCS SP5 II confocal microscope system (Leica Microsystems Inc., Buffalo Grove, IL, USA) with Leica Application Suite Advanced Fluorescence (LAS AF) software.

Reverse-Transcriptase PCR (Polymerase Chain Reaction) and Real-Time PCR. Total RNA was isolated from cells at various stages by using Rezol C&T reagent (Protech Technology, Taipei, Taiwan) according to the manufacturer's instructions, and cDNA was synthesized from 5 ng of total RNA in a 20 μL reaction using iScript cDNA Synthesis kit (Bio-Rad Laboratories, Inc., Hercules, CA, USA.). Reverse-transcriptase PCR was carried out using EconoTaq PLUS GREEN 2X Master Mix kit (Lucigen Corp., Middleton, WI, USA). Primers used in reverse-transcriptase PCR are shown (Table 1). Amplification conditions were as follows: denaturation at 94 °C for 20 s, annealing at 55 or 60 °C for 20 s, and extension at 72 °C for 7 min. The number of cycles varied from 30 to 45, and the length of the amplified products is shown (Table 1). Real-time PCR was performed using iQ SYBR Green Supermix (Bio-Rad) reagent kit and an Applied Biosystems StepOne real-time PCR system (Life Technologies Corp., Carlsbad, CA, USA). The thermal parameters were 95 °C for 2 min, followed by 45 cycles of 95 °C for 15 s and 60 °C for 1 min. The relative gene (mDA marker *TH* and *GIRK2*; neurotrophin *BDNF* and *NT-3/4*) quantities were obtained using the comparative Ct method after normalization to an internal control (*G3PDH*). Primers included the following: *TH* (5′-CGTGCTAAACCTGCTCTT-3′, 5′-CGTCTCAAACACCTTCACA-3′), *GIRK2* (5′-CTCAGTTATTCAGATTGACAAGGT-3′, 5′-GTACAACACATGCAGGTAAGT-3′), brain-derived neurotrophic factor (*BDNF*) (5′-GAGTATTACCTCCGCCATGC-3′, 5′-ATTCACGCTCTCCAGAGTCC-3′), neurotrophin-3 (*NT-3*) (5′-TGGCATCCAAGGTAACAACA-3′, 5′-CTCTGTTGTCGCAGCAGTTC-3′), *NT-4* (5′-AGCGAAACTGCACCAGCGAG-3′, 5′-CACCTTCCTCAGCGTTATCA-3′), and *G3PDH* (5′-GCTCAGACACCATGGGGAAGGT-3′, 5′-GTGGTGCAGGAGGCATTGCTGA-3′).

Flow Cytometry. Differentiation rates of stage-III and stage-V cells were determined using flow cytometry. Briefly, cells were centrifuged, resuspended in PBS, fixed with BD Cytofix Fixation Buffer (BD), and permeabilized with ice-cold BD Phosflow Perm Buffer III (BD) at room temperature for 20 min in the dark. Nestin expression in differentiated stage-III neural rosettes was labeled using a direct immunofluorescence method. Permeabilized stage-III cells were then rinsed and incubated with nestin phycoerythrin (PE)-conjugated antibody (#561230; BD) at room temperature for 30 min. Conversely, TH expression in differentiated stage-V cells was detected using an indirect method. Permeabilized stage-III cells were reacted with rabbit anti-TH polyclonal antibody (#GTX61717; GeneTex) at room temperature for 30 min. Thereafter, cells were washed and treated with fluorescein isothiocyanate (FITC)-conjugated goat anti-rabbit antibody (#GTX77059; GeneTex) at room temperature for 30 min in the dark. Finally, the fluorescence analysis of the labeled cells was performed using a Cytomics FC500 flow cytometer (Beckman-Coulter Inc., Brea, CA, USA). Approximately 10,000 events per sample were analyzed for $n = 3$ independent cultures. The percentages of nestin-PE and TH-FITC positive cells were respectively determined with CXP software version 2.2 (Beckman). The unstained stage-III and stage-V cells were taken as the control groups.

Ratiometric Calcium Ion Imaging. Stage-V cells grown on Matrigel-coated glass coverslips were treated with 1 μM acetoxymethyl-ester Fura-2 (fura-2 AM) (TefLabs, Austin, TX, USA) at 37 °C for 1 h in the dark. Fura-2 AM, as a fluorophore, rapidly binds to calcium ion (Ca^{2+}) and shifts its absorption spectrum to lower wavelengths upon binding, enabling determination of intracellular calcium concentrations. After washing three times with Hanks balanced salt solution (HBSS) buffer, the stage-V cells on coverslips were mounted on the imaging chamber. To perform real-time microscopic ratiometric fluorescence imaging, the light from a xenon lamp (Lambda DG-4; Sutter Instrument Co., Novato, CA, USA) was directed through narrowband fluorescence filters (Chroma Technology, Brattleboro, VT, USA) centered at 340 nm (for Ca^{2+}-bound fura-2; F_{340}) and 380 nm (for Ca^{2+}-unbound fura-2; F_{380}). The excitation light was then passed into an inverted Zeiss Axiovert 200 M microscope (Carl Zeiss Axiovert, Göttingen, Germany) with 20× objective lens (Carl Zeiss Axiovert). Subsequently, emitted light from the mounted stage-V cells with fura-2 fluorescence was passed through an appropriate dichroic filter and an emission filter centered at 510 nm. The resulting photomicrographic series were obtained with a cooled charge-couple device (CCD) camera (CoolsnapFx; Roper Scientific, Tucson, AZ, USA) every 300 ms as controlled by MetaFlour software (Molecular Devices, Downingtown, PA, USA), which was also used for postexperiment image and data analysis. The ratio was computed as $R = F_{340}/F_{380}$, and the change of ratio reflected the change in $[Ca^{2+}]_i$. To depolarize the stage-V cells for observing the transient Ca^{2+}, a high-potassium solution ([KCl] = 150 mM) was applied around the 35th second. The HBSS solution contained 138 mM NaCl, 5.6 mM glucose, 4 mM $NaHCO_3$, 0.3 mM Na_2HPO_4, 0.5 mM $MgCl_2$, 0.41 mM $MgSO_4$, 5.33 mM KCl, 1.26 mM $CaCl_2$, and 0.44 mM KH_2PO_4 (pH 7.3).

Dopamine Determination. Dopamine (DA) release was determined using reversed-phase HPLC. At the end of 21 d culture, stage V differentiated cells in 12-well plates were rinsed with Hanks balanced salt solution (HBSS) twice, and then incubated in 0.5 mL of HBSS or HBSS supplemented with 56 mM KCl solution for 15 min to induce depolarization. After that, the medium was collected and stabilized with 0.1 mM ethylenediaminetetraacetic acid (EDTA) for further analysis. DA contents were analyzed at 0.5 V by HPLC system coupled to an amperometric detector LC-4C (BASi, West Lafayette, IN, USA). Samples (20 μL) were injected by an autosampler (LaChrom Elite autosampler L-2200; Hitachi HTA, Inc., Schaumburg, IL, USA) into an Apollo C-18 reverse-phase column (5 μm; particle size, 250 × 4.6 mm; Alltech Associates, Inc., Deerfield, IL, USA). The mobile phase (per liter) consisted of 20.5 g of NaH_2PO_4, 185 mg of EDTA, 130 mg of 1-octanesulfonic sodium salt (SOS), 2 mM KCl, and 200 mL of methanol (pH 3.11, adjusted with H_3PO_4), and was pumped at a flow rate of 0.5 mL/min. DA levels were calculated by external DA standard curve.

Sample Treatment. Dopamine receptor (DR) agonist and antagonist drugs used in the present study included bromocriptine (Sigma), 7-hydroxy-2-(dipropylamino)tetralin (7-OH-DPAT; Sigma),

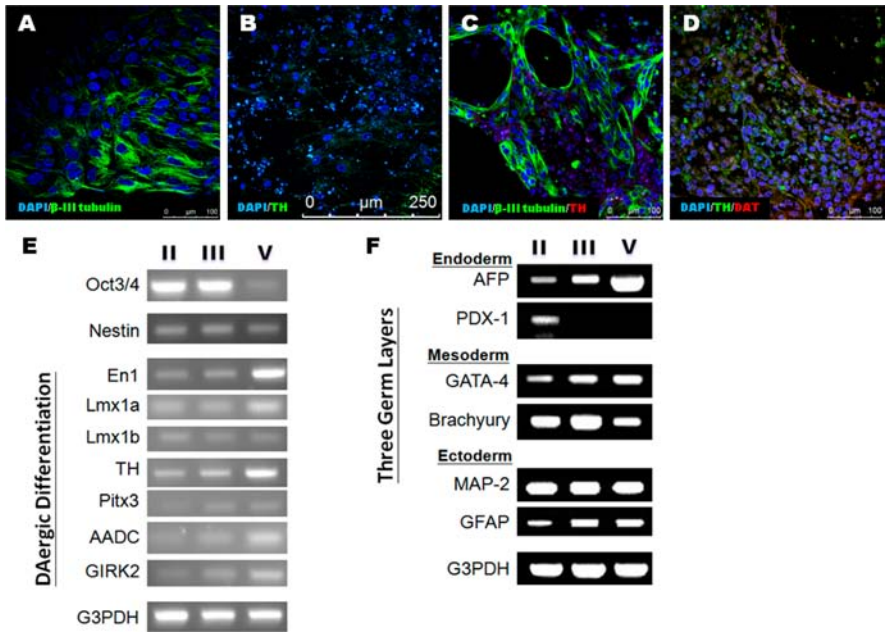

Figure 2. Characterization of differentiated hESCs. (A–D) Immunofluoroscence staining results of stage-V differentiated DAergic neurons. (A) β-III tubulin-positive neurons (green) and merge with DAPI nucleic acid staining (blue). Scale bar = 100 μm. (B) TH-positive neurons (green) and merge with DAPI nucleic acid staining (blue). Scale bar = 250 μm. (C, D) Double-label staining results for β-III tubulin (green) and TH (red) (C); TH (green) and DAT (red) (D) and all merged with DAPI nucleic staining (blue). Scale bar = 100 μm. (E, F) Gene expression profile during hESC differentiation. Semiquantitative reverse-transcriptase PCR analyses from stage-II embryoid bodies (EBs), stage-III neural progenitors (NPs), and stage-V DAergic neurons. (E) Markers specific to undifferentiated hESCs (Oct3/4), neural progenitors (nestin), and DAergic differentiation (En1, Lmx1a, Lmx1b, TH, Pitx3, AADC, and GIRK2). (F) Markers of other germ layers. Abbreviations: TH, tyrosine hydroxylase; DAT, dopamine transporter; AADC, aromatic L-amino acid decarboxylase; AFP, alpha-fetoprotein; PDX-1, pancreatic and duodenal homeobox gene 1; GATA-4, GATA-binding protein 4; MAP2, microtubule-associated protein 2; GFAP, glial fibrillary protein.

and sulpiride (Sigma), while the phytochemicals included epigallocatechin-3-gallate (EGCG; Sigma), epicatechin-3-gallate (ECG; Sigma), epicatechin (EC; Sigma), ginsenoside Rg1 (ChromaDex Inc., Santa Ana, CA, USA), ginsenoside Rg3 (ChromaDex), and ginsenoside Rb1 (ChromaDex). All samples were prepared in water as 1000 μM stock solutions and subsequently diluted to the appropriate concentrations. These prepared samples were added into the medium at the beginning of stage-V cultivation. After cultivation for 7 d, the cells were collected and analyzed for mRNA expression of TH and GIRK2 for evaluating the respective effects of these samples on differentiation of mDA neurons.

Statistical Analysis. Statistical significance was determined by one-way analysis of variance (ANOVA), and the comparisons between means were performed by Duncan's multiple range test. Differences were considered significant $p < 0.05$. All statistical analyses were performed with a SAS 9.2 software package (SAS Institute Inc., Cary, NC, USA).

RESULTS AND DISCUSSION

Differentiation of hESCs into mDA Neurons. To overcome the limitation of PD medicine, stimulation of endogenous DAergic neurogenesis in SN by exogenous factors seems to be a feasible approach.[21] The human-derived cells, especially human pluripotent stem (PS) cells such as embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs), provide an opportunity to create more relevant and accurate cellular models than the low-efficacy or propagation restrictions of traditional models, e.g., recombinant immortalized cells or primary cells. Thus, the main purpose of this study was to establish a reliable cellular model for screening potential neurogenic candidates. However, the pluripotent state, transcribed genes, differentiation abilities, epigenetic memories, and mutation loading of iPSCs have also been questioned as being distinctly different from native ESCs.[9] Therefore, we chose ESCs to develop the in vitro platform for screening mDA neurogenesis-boosting compounds with potential to relieve clinical signs of PD.

The mDA differentiation process is shown (Figure 1A). In stage I, hESC H9 cells were cultured on MEFs. The MEFs acted as feeder cells to support the hESC growth and maintained the hESC in an undifferentiated state. To initiate neural differentiation, propagated hESC colonies were then lifted by LEAP workstation to obtain uniform sized cell aggregates around 1 mm (Figure 1B–D). The cell aggregates were then allowed to grow in suspension using bacterial-grade dishes for 3 d to form EBs in stage II. General methods to induce ESC differentiation include feeder-dependent coculture of ESCs with stromal cells and spheroid-shaped EB formation from ESCs. Although the culture of hESC on feeder monolayers tends to simplify culture conditions and reduce steps, the 3-D EB aggregation technique is more capable to recapitulate the situation of early embryogenesis because hESCs will spontaneously differentiate into three-germ layer derivatives during EB formation.

For neural induction, cells were further seeded onto Matrigel-coated dishes with noggin and fibronectin (in stage III). Although type IV collagen-coated dishes have been used in our experience, it is difficult to make EBs attach on these dishes. Therefore, mouse sarcoma-secreted matrigel was used because it has a three-dimensional structure which could facilitate cell attachment, and it comprises extracellular matrix (ECM) components which promote cell growth. Noggin in the system has neural-inducing properties through inhibiting the bone morphogenic protein (BMP) signal.[22] Furthermore, fibronec-

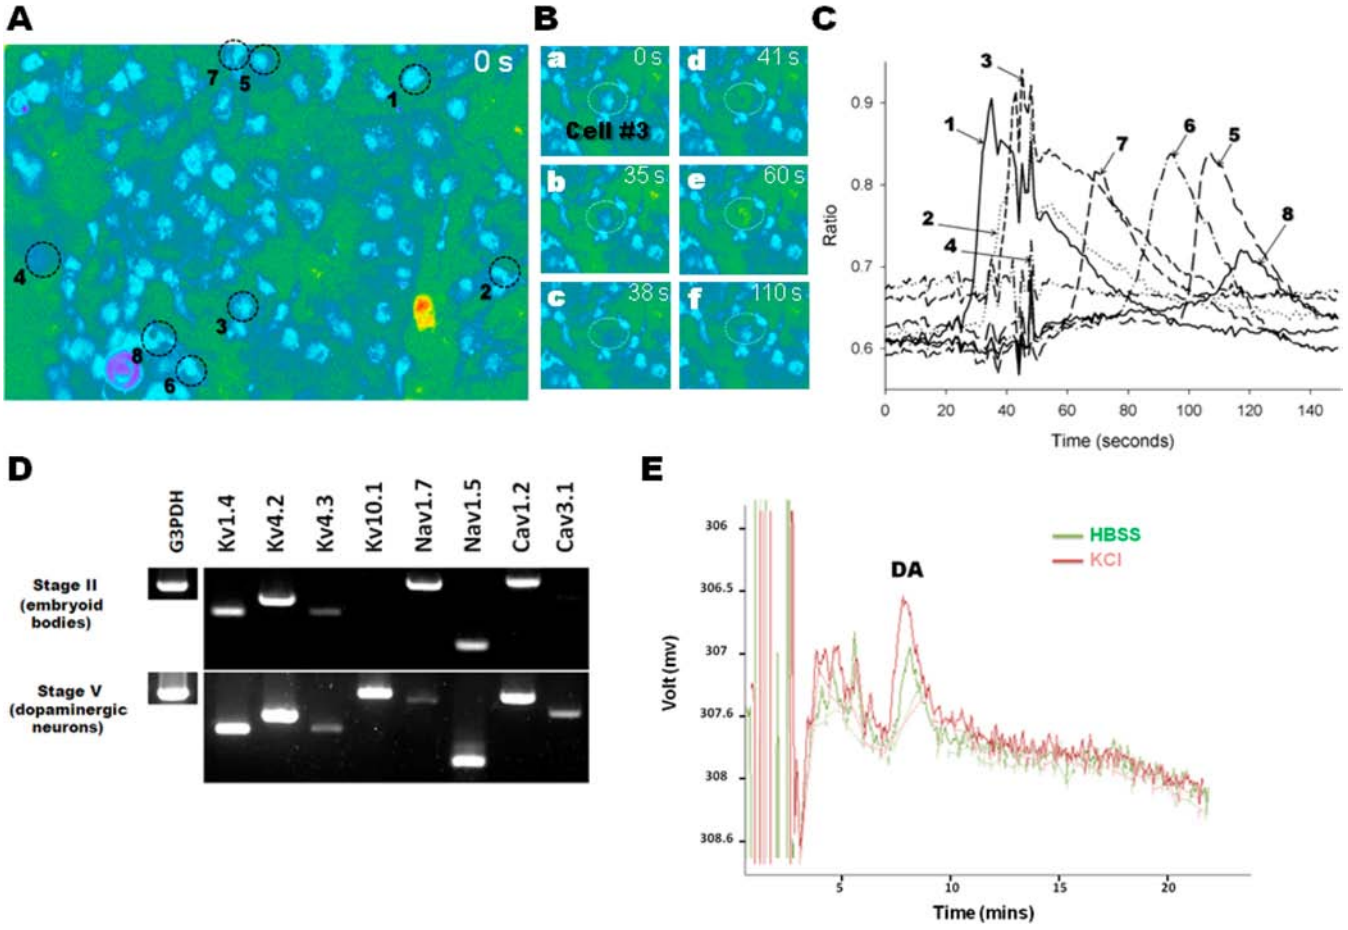

Figure 3. Ion channel related expression of stage-V differentiated DAergic neurons. (A) Image of selected stage-V cells before stimulation with high potassium solution ([KCl] = 150 mM). (B) Time-lapse images showing intracellular calcium ion transients induced by KCl solution in cell 3. (C) Calcium ion transients of all selected cells (cells 1 to 8) over 140 s. The transients are plotted in terms of the fura-2 fluorescence intensity ratio $R = F_{340}/F_{380}$. (D) Voltage-gated ion channel mRNA expression in stage-II EBs and stage-V differentiated DAergic neurons. tin, a kind of ECM, contributes to the enhancement of cell attachment, growth, and differentiation.[23] The differentiated neural progenitor rosettes with nestin-positive expression (Figure 1E) were formed after 4 d of culture, and the percentage of nestin-positive cells was 33.9−50.3%, suggesting the neural induction (Figure 1F). Then, the expansion of neural rosettes was achieved by culturing cells with bFGF for 7 d in stage IV, which relied on the mitogenic effects of bFGF.[24] To complete the final differentiation of mDA neurons after 7 d, the medium was replaced with defined medium (DM) containing dbcAMP. The DAergic proliferation and differentiation effects of dbcAMP are well-established.[25] As a rate-limiting enzyme during the synthesis of DA, TH is often used as a marker of DAergic neurons, but it should be noted that the TH staining could only verify the existence of catecholamine neurons here. As shown in Figure 1G, the percentage of TH-positive cells was 32.8−53.6%. Compared to previous reports, the predominant points of our protocol included a higher DAergic differentiation rate[26,27] and shorter differentiation periods.[26,28−30] Although higher differentiation rates have been claimed, those studies only counted colonies rather than single cells as used in our study.[20,31]

Characterization of hESC-Derived Cells. Since our differentiation process of hESC into mDA neuron tried to recapitulate the development of mDA neurons, specific transcriptional or nuclear factors would be expressed in distinct stages. Thus, after establishing in vitro mDA differentiation process, expression of DAergic neuronal markers including β-III-tubulin, TH, and DAT in stage-V cells were determined with an immunofluorescence assay. Differentiated DAergic neurons derived from hESCs indeed expressed β-III-tubulin (Figure 2A) and TH (Figure 2B). Results of double staining confirmed not only expression of β-III-tubulin and TH (Figure 2C) but also expression of DAT and TH (Figure 2D). In addition, during the process of differentiation of hESCs into mDA neurons, several other markers were detected by semiquantitative reverse-transcriptase PCR (RT-PCR) (Figure 2E). Oct-3/4 is an essential regulator for maintenance of self-renewal and pluripotency in undifferentiated stem cells,[27] and we found a significant decrease in Oct-3/4 (Figure 2E). Our results further indicated that the early mDA neuron marker En1 and Lmx1a expression kept increasing until the stage-V final differentiation, whereas neural progenitor marker nestin slightly diminished (Figure 2E). The A9 clusters of DAergic neurons in ventral midbrain (VM) ultimately give rise to the SNpc, resulting in a close association with PD. Consequently, GIRK2 was also adopted as a phenotypic marker in SN-A9 DAergic neurons because of its specific expression. Based on RT-PCR results in

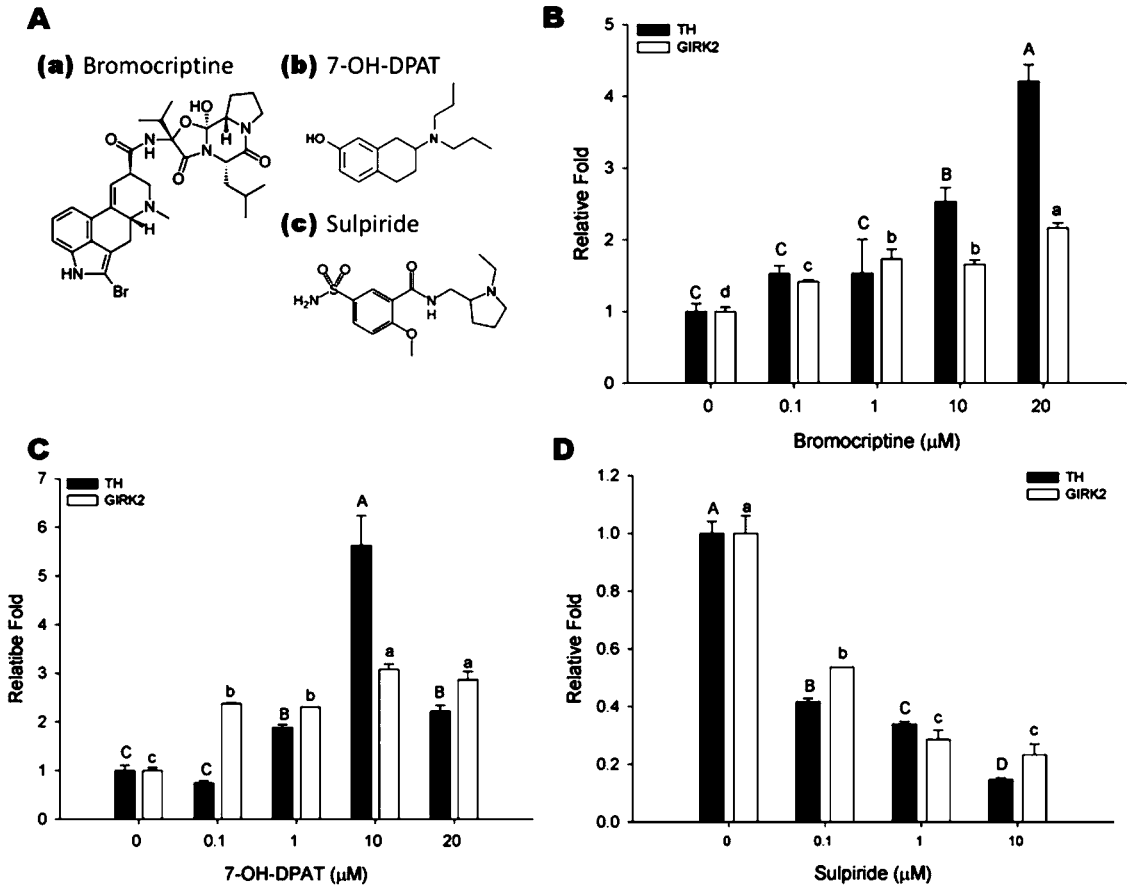

Figure 4. (A) Structure of dopamine receptor (DR) agonist, bromocriptine (a), 7-OH-DPAT (b), and DR antagonist, sulpiride (c). (B–D) TH and GIRK2 mRNA expression in stage-V cells incubated without/with bromocriptine (0.1, 1, 10, and 20 μM) (B); 7-OH-DPAT (0.1, 1, 10, and 20 μM) (C); or sulpiride (0.1, 1, and 10 μM) (D). Each value presents mean ± SD (n = 3). Means without a common uppercase letter A–C differed in TH expression ($p < 0.05$). Means without a common lowercase letter a–c differed in GIRK2 expression ($p < 0.05$).

the present study, enhancements in DA synthesis enzyme TH, AADC, and SN-A9 marker GIRK2 were clearly apparent in the differentiated stage-V cells with mild upregulation in mature mDA marker Pitx3 (Figure 2E). Other germ layer and astrocyte-related (glial fibrillary acidic protein; GFAP) markers were also examined. The PDX-1 (endoderm pancreatic marker) completely disappeared at stage III, whereas brachyury (mesoderm marker) gradually reduced during the course of differentiation (Figure 2F). The mRNA analyses of the three germ layers confirmed the heterogeneous cell populations of the differentiated stage-V cells.

Functional Analysis of hESC-Derived Dopaminergic Neurons. Rapid Ca^{2+} influx through voltage-dependent calcium channels (VDCC) upon membrane depolarization results in neurotransmitter release and other neuronal activities. To further clarify the functional differentiation of stage-V cells, Ca^{2+} dynamics of specific cells were investigated under depolarization induced with a high-potassium solution (cells 1 to 8; Figure 3A). A series of time-lapse images (Figure 3B) reflected transient Ca^{2+} concentrations within the specific cell (cell 3). Furthermore, the fura-2A emissions ratios of all selected cells (cells 1 to 8; Figure 3A) are shown (Figure 3C). It was noteworthy that cell 1 responded immediately after KCl stimulation, whereas other cells had delayed responses. In addition for real-time Ca^{2+} influx detection, the mRNA expression of various common neuronal voltage-gated ion channels including voltage-gated potassium (Kv), voltage-gated sodium (Nav), and voltage-gated calcium (Cav) channels was investigated in stage-II EBs and stage-V differentiated DAergic neurons (Figure 3D). The strong upregulated expression of most ion channels in stage-V cells was prominent, and strikingly, expression of Cav3.1 and Kv10.1 was only detected in stage-V cells (Figure 3D). The Cav3.1 channel has been demonstrated to cooperatively modulate motor function in essential tremor (ET),[32] whereas the Kv10.1 channel is able to maintain the electrophysiological activity of mDA neurons due to its colocalization with DAergic neurons and its reduction induced by a neurotoxin lesion.[33]

Besides, the ability of dopamine (DA) release of differentiated cells was examined by reverse-phase HPLC. Higher DA levels (red line: 7.28 ± 1.30 ng/mL, n = 3) were detected in KCl-evoked samples as compared with control samples (green line: 2.89 ± 0.34 ng/mL, n = 3) (Figure 3E). The combined characterization of differentiated cells following the protocol developed in this study strongly indicated the presence of functional mDA neurons after 21 d of culture.

Validation of the hESC-Derived Model by Dopamine Receptor Agonists and Antagonist. Involvement of DR agonists in adult neurogenesis has been proven in recent studies.[21] The D2L agonists, e.g., bromocriptine (Figure 4A-a) and 7-OH-DPAT (Figure 4A-b), significantly increased neurogenesis of SVZ precursors, whereas the D2L antagonist sulpiride (Figure 4A-c) inhibited the neurogenic effect of bromocriptine.[5] Moreover, 7-OH-DPAT infusion induced cell

Means without a common lowercase letter a–c differed in GIRK2 expression ($p < 0.05$).

proliferation in the striatum,[6] even in SN,[7] and 7-OH-DPAT also recovered locomotor functions of 6-hydroxydopamine (6-OHDA) PD rats.[8] These findings demonstrated that activation of D2/D3 receptors could stimulate SN neurogenesis. Therefore, the present study also investigated the effect of bromocriptine, 7-OH-DPAT, and sulpiride on the expression of SN-A9 markers (TH and GIRK2) to validate the established in vitro differentiated model. As predicted, the D2L agonist bromocriptine (0.1–20 μM) upregulated TH and GIRK2 expression in a concentration-dependent manner; their highest expression all appeared at 20 μM with a 4.5- and 2-fold increase ($p < 0.05$), respectively (Figure 4B). Furthermore, ≥0.1 μM bromocriptine in the culture medium of stage-V cells increased expression of GIRK2 ($p < 0.05$) (Figure 4B). However, bromocriptine concentrations ≥10 μM were required to enhance expression of TH as compared to the control ($p < 0.05$) (Figure 4B). In addition, GIRK2 expression was also significantly enhanced upon treatment with 0.1 μM 7-OH-DPAT (Figure 4C). Expression of TH dramatically increased due to 7-OH-DPAT treatment at doses of 1, 10, and 20 μM; the highest increase, approximately 6-fold, was also at the dose of 10 μM ($p < 0.05$; Figure 4C). Interestingly, 7-OH-DPAT activation reached its highest expression at a lower concentration (10 μM) than that in the bromocriptine-treated group (20 μM; Figures 4B and 4C). This result might be caused by the crucial role of D3 receptor in neurogenesis suggested by its long-term presence in the nervous system, and in contrast to bromocriptine, 7-OH-DPAT has a greater affinity for D3 receptors compared to D2 receptors.[34] Conversely, the D2L antagonist sulpiride (0.1–10 μM) decreased expression of TH and GIRK2 at all concentrations ($p < 0.05$) (Figure 4D). The highest reduction in TH expression was with 10 μM sulpiride (Figure 4D). These observations confirmed the neurogenic potentials of bromocriptine and 7-OH-DPAT in our model.

Screening of Phytochemicals with DAergic Differentiation-Boosting Potential by the Established Model. Although so far there is still no preclinical model able to recapitulate pathological features of PD, 6-hydroxydopamine (6-OHDA), 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), and rotenone are three commonly used neurotoxins to induce DAergic neurodegeneration in vitro and in vivo.[10] By using these neurotoxin-based models, tea cathechins and ginsenosides are identified as two natural anti-PD compounds. Individual polyphenolic catechins and crude tea extracts all have protective effects on 6-OHDA-treated PC12 cells[35]/SD rats[36] and MPTP-induced C57BL6 mice[37] by inhibition of ROS-nitrogen oxygen (NO) synthetic pathway. Blocking of MPP^+ uptake through dopamine transporter (DAT) is another identified function of green tea polyphenols.[38] Ginseng and ginsenosides can also prevent primary and PC12 cells from oxidative injury from glutamate[14] and rotenone.[12] Ginsenosides can recover the inhibition of neurite growth caused by MPP^+ damage in primary cell model[13] and decrease overload of iron in MPTP-induced C57BL6 mice.[16] Prevention of DAergic

neuron loss by ginseng and ginsenosides has been clarified in MPTP-parkinism C57BL6 mice[15] and 6-OHDA-treated Wistar rats.[17] Moreover, ginsenoside Rg1 has been found to induce glucocorticoid receptor (GR)-dependent neural differentiation in mouse ESC model,[19] while green tea activates neuronal survival and plasticity via enhancement of brain-derived neurotrophic factor (BDNF) and antiapoptotic B-cell lymphoma-2 (Bcl-2) levels in aged rats.[18]

Different from aforementioned studies, our model is for screening phytochemicals with mDA differentiation-boosting potential. As shown in Figure 5B, EGCG significantly enhanced the expression of TH and GIRK2 at dose ≥6.25 μM ($p < 0.05$), and the highest increases of TH and GIRK2 were 1.5- and 4-fold, respectively, which were both at the dose of 12.5 μM. In contrast, ECG had no effect on the enhancement of GIRK2 expression ($p > 0.05$), but it upregulated TH expression, and the highest (4-fold) upregulation occurred at the dose of 25 μM (Figure 5C). Although EC significantly increased both TH and GIRK2 expression as compared with the control group ($p < 0.05$), the levels of increases were rather low (Figure 5D). The mDA differentiation-boosting order of tea catechins might be correlated with their structure (Figure 5A). EGCG, with 3,4,5-trihydroxyl group at B ring as well as D ring galloyl moiety, was the most potent one among the tested tea catechins. The possible antioxidative neuroprotective mechanism contributed from different parts of EGCG structure has been proposed.[39]

Better than tea catechins, ginsenoside Rg1 and Rb1 dramatically induced the expression of A9-SN markers in differentiated stage-V cells, which was even higher than 14-fold (Figures 6B and 6D). However, the enhancement of TH and GIRK2 by Rg1 had a controversial trend. Increase of TH expression appeared at lower doses (3.125 and 6.25 μM), but GIRK2 expression was upregulated at higher doses (12.5 and 25 μM) (Figure 6B). Upon Rg3 treatment, the GIRK2 expression had no obvious enhancement, while the TH expression was significantly increased at all Rg3 concentrations ($p < 0.05$) (Figure 6C). The highest increase of TH expression was at 3.125 μM and gradually decreased when Rg3 concentration increased (Figure 6C). Among tested ginsenosides, Rb1 induced the highest increases of TH and GIRK2 expression at 6.25 μM (Figure 6D). Ginsenosides Rg1, Rg3, and Rb1 all contain a dammarane skeleton with various sugar moieties attached to the C-3 and C-20 positions (Figure 6A). The diversity of ginsenoside structure might contribute to the differences of mDA differentiation abilities. However, we found that Rb1 treatment increased several neurotrophin mRNA levels probably derived from surrounding supporting cells such as astrocytes. In fact, the cross-talk interaction of mDA neurons and astrocytes or microglia has been extensively discussed recently to explain the neural survival, growth, and differentiation.[40] Moreover, brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), and neurotrophin-4 (NT-

dx.doi.org/10.1021/jf501640a | J. Agric. Food Chem. 2014, 62, 6326–6336

4) secreted by astrocytes are crucial neurotrophins responsible for neuronal survival and differentiation.[41] As shown in Figure 7, the significant upregulation of BDNF and NT-3 consistently

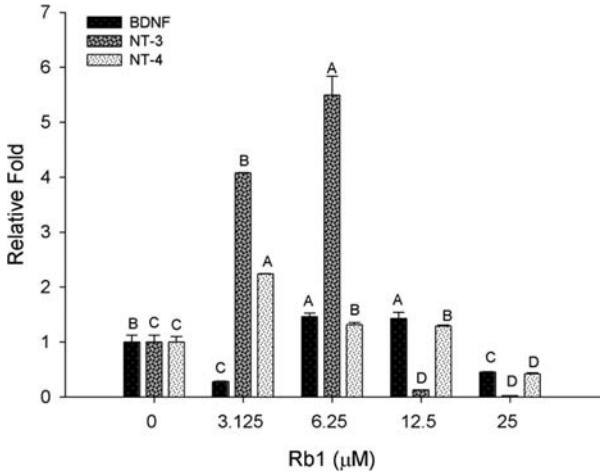

Figure 7. BDNF, NT-3, and NT-4 mRNA expression in stage-V cells incubated without/with Rb1 (3.125, 6.25, 12.5, and 25 μM). Means without a common uppercase letter A–C differed in BDNF, NT-3, or NT-4 expression ($p < 0.05$).

appeared at 6.25 μM ($p < 0.05$), and particularly, NT-3 had a 6-fold increase, thus neurotrophin might also play a vital role in mDA differentiation effects of Rb1.

Although the existence of neural stem cells (NSCs) in SN is debatable, or it is rarely proliferative in SN,[42] stimulation of NSCs resident in active SVZ and SGZ to migrate and differentiate into mDA neurons in SN by drugs or certain phytochemicals to compensate the loss of mDA neurons in damaged PD brains seems to be possible. In addition, induction of protective neurotrophin secretion by surrounding astrocytes or microglia by phytochemicals may be also possible. In this report, we described a five-stage mDA differentiation process that combined D2/D3 agonist bromocriptine, 7-OH-DPAT, and D2L blockade sulpiride respectively as positive and negative controls. Their working concentrations were 20 μM bromocriptine, 10 μM 7-OH-DPAT, and 10 μM sulpiride. The final differentiated cells were functional mDA neurons with SN-A9 neuron phenotypes and special voltage-gated ion channel expression including Cav3.1 and Kv10.1. DA release was also detected in response to K^+ depolarization. Compared to other differentiation protocols, our differentiation period (21 d) was much shorter, with an acceptable differentiation rate between 32.8 and 53.6%. These results manifested the predictive potential of our model for screening phytochemicals with mDA neurogenesis-boosting abilities. Using this model, we found that Rb1 is a very potent phytochemical for relieving PD, and it might induce mDA differentiation and upregulate the expression of BDNF and NT-3 from surrounding cells like astrocytes.

disease, antidementia, anti-inflammation, antitumor, antiaging, and free radical scavenging.[13,14] EGb761 has been one of the most commonly used herbal dietary remedies in many countries, including China, the United States, France, and Germany. In rats with osteoarthritis on the knee and LPS-treated chondrocytes, EGb761 was found to reduce the inflammatory effects by production of prostaglandin (PG)E2 and nitric oxide (NO), expression of cyclooxygenase (COX)-2 and inducible nitric oxide synthase (iNOS), and phosphorylation of NFκB.[15] In murine macrophages, *Ginkgo biloba* extract reduces LPS-induced production of NO and PGE2 through expression of iNOS and COX-2 via NFκB phosphorylation.[16] Previously, we have demonstrated that EGb761 attenuates LPS-induced ALI via inhibition of oxidative stress and the NFκB-dependent matrix metalloproteinase-9 pathway.[17] In the present study, we aimed to verify the protective mechanism of EGb761 via MAPK and Akt pathways on LPS-induced ALI in an in vivo animal model.

MATERIALS AND METHODS

Materials. EGb761 was obtained from the laboratory of Dr. Willmar Schwabe (Karlsruhe, Germany). Antibodies against p38 MAPK, ERK, JNK, Akt, IκB, phospho-Akt (Ser473), phospho-IκB (Ser32), phospho-ERK (Thr212/Tyr204), phospho-JNK (Thr183/Tyr185), COX-2, iNOS, and β-actin were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). The antibody against phospho-p38 MAPK (Thr180/Tyr182) was purchased from Cell Signaling Technology (Danvers, MA, USA). Secondary antibodies were obtained from Jackson Immuno Research Laboratories (Baltimore, MD, USA). NFκB p65 Transcription Factor Kit was obtained from Thermo Fisher Scientific (Waltham, MA, USA). Enzyme-linked immunosorbent assay (ELISA) kits were obtained from Cayman (Ann Arbor, MI, USA). LPS from *Escherichia coli* Serotype 0111:B4, dimethyl sulfoxide (DMSO), and other reagents, unless specifically stated elsewhere, were purchased from Sigma-Aldrich (St. Louis, MO, USA). The concluding volume of DMSO in the reaction mixture was <0.5%.

Animals. Adult male ICR mice weighing 25−30 g were purchased from BioLASCO Taiwan (Taipei, Taiwan). All mice were housed under standard laboratory conditions and fed a standard laboratory diet and water ad libitum. All mice were cared for following guidelines provided by the Institutional Animal Ethics Committee of Chung Shan Medical University.

Murine Model of LPS-Induced ALI. The ALI induced by LPS was performed as described in previous studies.[8,9] Sixty mice were randomly subdivided into six groups: a sham operation group and five treatment groups. The sham operation group received vehicle intraperitoneally (IP) for 30 min followed by intratracheal (IT) administration of 50 μL of saline, while the five treatment groups were pretreated with 0, 10, 100, and 1000 μg/kg of EGb761 or 1000 μg/kg of dexamethasone (DEX) IP for 30 min, respectively, before administration of 100 μg/50 μL of LPS IT. After 6 h, the mice were sacrificed, and samples were collected.

Bronchoalveolar Lavage Fluid (BALF) Collection. The collection of BALF was performed as previously described.[8,9] The airways and lungs were flushed with sterile saline three times through a tracheal cannula, installed up to a total volume of 1 mL. The pooled BALF was collected on ice and centrifuged at 700*g* for 10 min at 4 °C. The cell-free supernatant was subsequently stored at −20 °C for cytokine and chemokine concentration analysis, the sediment cells were stained with Giemsa stain solution, and the numbers of neutrophils were counted.

Blood Gas Analysis of Arterial Blood. After euthanasia, blood samples were collected from the abdominal aorta. Partial pressures of oxygen (PaO_2) and carbon dioxide ($PaCO_2$) and acidity (pH) in arterial blood were measured immediately by a blood gas analyzer (Radiometer ABL 700 blood gas analyzer, Copenhagen, Denmark).

Histopathological Studies of Lung Tissues. After midsternal thoracotomy, the lungs were removed rapidly, fixed in 4% isotonic paraformaldehyde, embedded in paraffin, sliced into 3 μm sections with a microtome, and stained with hematoxylin and eosin (H&E) for histopathological studies.

Wet to Dry Weight Ratio of Lung Tissues. The lungs were dissected immediately, and the wet weight was recorded. Then the tissues were baked in an incubator at 80 °C for 24 h to obtain the dry weight. The ratio of wet weight to dry weight was calculated to evaluate the extent of lung edema.

Measurement of Cytokines and Chemokines. Measurement of cytokines and chemokines, such as tumor necrosis factor (TNF)α, macrophage inflammatory protein (MIP)-2, and interleukin (IL)-6, in BALF was performed with commercially available ELISA assay kits. The quantification of cytokines and chemokines was performed according to the manufacturer's instructions.

Western Blot Analysis of Lung Tissue. As previously described, lungs were harvested, rinsed with saline, and frozen in liquid nitrogen immediately until homogenization.[17] Tissue extracts were homogenized in a tissue protein extraction solution (T-PER; Pierce, Rockford, IL, USA) containing 1% proteinase inhibitor cocktail and phosphatase inhibitor cocktail. Protein samples, 100 μg each, were separated by SDS-PAGE and electrophoretically transferred to polyvinylidene difluoride membranes. The membranes were blocked with phosphate-buffered saline (PBS) containing 0.1% Tween-20 (PBST) and 5% nonfat milk (w/v) for 1 h at room temperature. After they were washed with PBST, the membranes were probed with antibodies including iNOS, COX-2, β-actin, phosphory-IκB, and phosphorylated and nonphosphorylated forms of JNK, ERK, p38 MAPK, and Akt. The membranes were washed again with PBST, then a 1/10000 (v/v) dilution of horseradish peroxidase labeled IgG was added at room temperature for 1 h, and the blots were developed using ECL Western blotting reagents.

NFκB Activation. The preparation of nuclear extract from lung homogenates and measurement of NFκB activation in nuclear extract were performed with a nuclear extraction kit and NFκB p65 Transcription Factor Kit (both from NEPER Nuclear and Cytoplasmic Extraction Reagents, Thermo Science), respectively, according to the manufacturer's instructions.

Statistical Analysis. Statistical analyses were performed using ANOVA followed by the Bonferroni *t* test for multigroup comparisons; $p < 0.05$ was considered significant for all tests. Data are expressed as mean ± standard deviation (SD).

RESULTS

Effects of EGb761 on Arterial Blood Gas in LPS-Induced ALI. To study the effects of EGb761 on LPS-induced ALI, the mice were pretreated with EGb761 for 30 min before LPS administration. As shown in Figure 1, pH and PaO_2 were significantly decreased while $PaCO_2$ was significantly increased in the LPS-treated group. However, all these effects were attenuated by EGb761 in a dose-dependent manner; a significant inhibitory effect began at 100 μg/kg ($p < 0.05$).

Effects of EGb761 on Histopathological Changes in the Lung of LPS-Induced ALI. Severe lung damage, including diffuse hemorrhage, edema, thickening of the alveolar septum, formation of hyaline membranes, and infiltration of inflammatory cells into the lung parenchyma and alveolar spaces, occurred after LPS administration for 6 h (Figure 2B). In contrast, no pathohistological change was observed in the control group (Figure 2A). However, administration of EGb761 significantly attenuated these pathohistological changes in a concentration-dependent manner (Figure 2C−E).

Effects of EGb761 on LPS-Induced Neutrophils Infiltration and Lung Edema. Neutrophil infiltration was significantly increased in LPS-treated mice in comparison with the control group ($p < 0.05$). Pretreatment with EGb761 reduced LPS-induced neutrophil infiltration in a concentration-dependent manner starting at 10 μg/kg ($p < 0.05$, Figure 3A). Neutrophil infiltration results in increasing vascular permeability, which leads to edema formation in LPS-treated lung tissue. As shown in Figure 3B, lung edema was significantly increased in LPS-treated

Effects of EGb761 on LPS-induced neutrophil infiltration and lung edema: (A) neutrophil infiltration determined by leukocyte counts in BALF; (B) lung edema determined by quantifying the wet to dry weight ratio. Values are expressed as mean ± SD ($n = 4$ in each group). * represents a significant difference between the indicated and normal control group, and # represents a significant difference between the indicated and LPS groups, $p < 0.05$.

mice in comparison to the control group ($p < 0.05$). Pretreatment with EGb761 reduced LPS-induced lung edema in a concentration-dependent manner starting at 100 μg/kg ($p < 0.05$, Figure 3A).

Effects of EGb761 on LPS-Induced TNFα, IL-6, and MIP-2 Generation. TNFα, IL-6, and MIP-2 are important proinflammatory cytokines and chemokines participating in the recruitment of leukocytes into the lungs in LPS-induced ALI.[17−19] The effect of EGb761 on TNFα, IL-6, and MIP-2 generation in the BALF was analyzed by ELISA. The concentration of TNFα, IL-6, and MIP-2 increased significantly after the mice were treated with LPS for 6 h in comparison with the control group ($p < 0.05$). Pretreatment of EGb761 at 100 μg/kg

and up reduced the generation of TNFα, IL-6, and MIP-2 significantly in a concentration-dependent manner ($p < 0.05$, Figure 4).

Effects of EGb761 on LPS-Induced COX-2 and iNOS Expression. Expression of COX-2 and iNOS in lung tissue is a critical sign of LPS-induced ALI.[20,21] After LPS treatment, COX-2 and iNOS were dramatically expressed in lung tissues in comparison to the control group ($p < 0.05$). Pretreatment with EGb761 reduced LPS-induced COX-2 and iNOS expression in a concentration-dependent manner starting at 100 μg/kg ($p < 0.05$, Figure 5).

Effects of EGb761 on LPS-Induced NFκB Activation and IκB Phosphorylation. The activation of NFκB is critically required for the generation of proinflammatory cytokines and chemokines in LPS-induced ALI.[7] After LPS treatment, NFκB activation was significantly expressed in lung tissues in comparison with the control group ($p < 0.05$). Pretreatment with EGb761 reduced the expression of LPS-induced NFκB activation in a concentration-dependent manner starting at 100 μg/kg ($p < 0.05$, Figure 6A). Phosphorylation and degradation of IκB participate in NFκB activation.[7] After LPS treatment, phosphorylation of IκB was significantly expressed in lung tissues in comparison with the control group ($p < 0.05$). Pretreatment with EGb761 reduced LPS-induced phosphorylation of IκB in a concentration-dependent manner starting at 100 μg/kg ($p < 0.05$, Figure 6B).

Effects of EGb761 on LPS-Induced Phosphorylation of JNK, ERK, p38 MAPK, and Akt. JNK, ERK, p38 MAPK, and Akt have been demonstrated as the upstream factors in NFκB activation in LPS-induced ALI.[10−12,22] LPS stimulation significantly increased JNK, ERK, p38 MAPK, and Akt phosphorylation in comparison to the control group ($p < 0.05$). EGb761 suppressed LPS-induced phosphorylation of JNK and Akt pathways in a concentration-dependent manner starting at 100 μg/kg ($p < 0.05$, Figure 7A,D). However, significant inhibition on the phosphorylation of ERK and p38 MAPK by

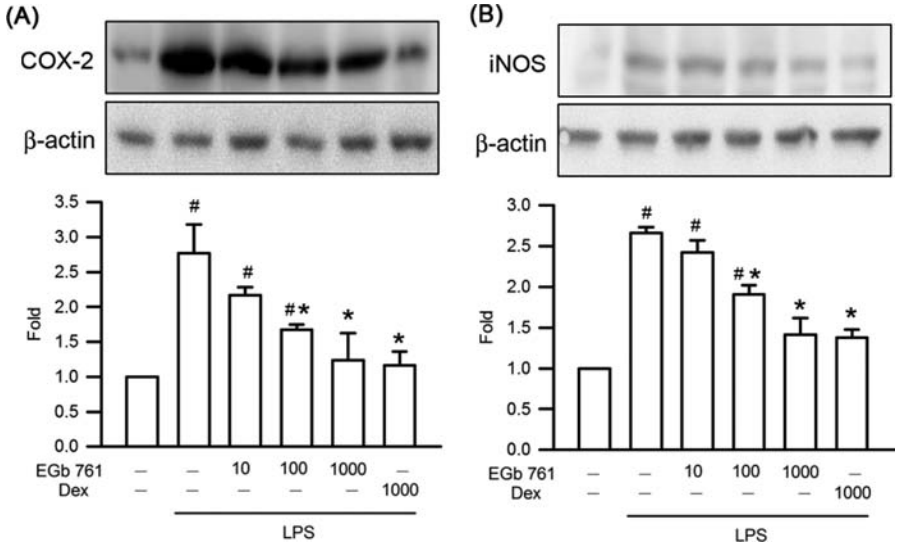

Figure 5. Effect of EGb761 on LPS-induced COX-2 and iNOS expression in lung. Lung tissues harvested from post-treated mice were analyzed by Western blotting. The fold of COX-2 (A) and iNOS (B) expressions between the treated and control groups was calculated. Values are expressed as mean ± SD ($n = 3-5$ in each group). * represents a significant difference between the indicated and normal control group, and # represents a significant difference between the indicated and LPS groups, $p < 0.05$.

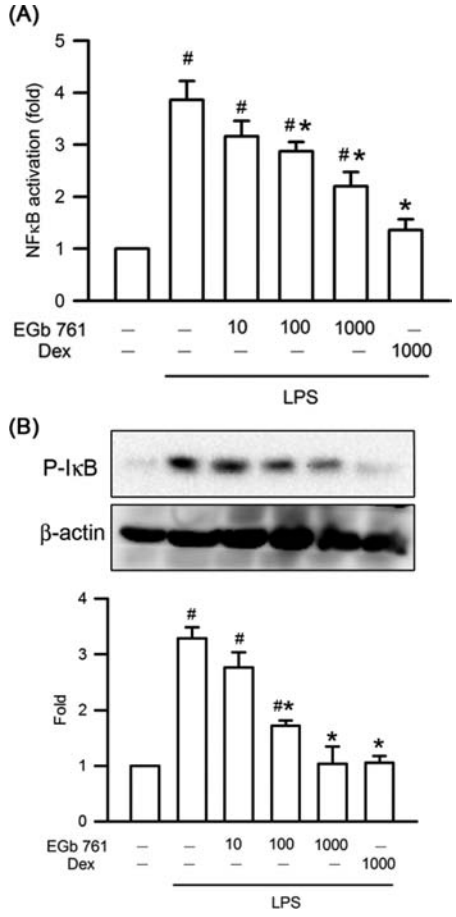

Figure 6. Effect of EGb761 on LPS-induced NFκB activation and IκB phosphorylation in lung. (A) Lungs were harvested from post-treated mice, and nuclear extracts from whole lung tissues were analyzed by p65 transcription factor assay to study the activation levels of NFκB. The fold of NFκB activation between the treatment and control groups was calculated. In addition, lung tissues harvested from post-treated mice were analyzed by Western blotting. (B) The fold of IκB phosphorylation between the treated and control groups was calculated. Values are expressed as mean ± SD (n = 3−5 in each group). * represents a significant difference between the indicated and normal control group, and # represents a significant difference between the indicated and LPS groups, $p < 0.05$.

EGb761 was not observed until the concentration was up to 1000 μg/kg ($p < 0.05$, Figure 7B,C).

DISCUSSION

In the present investigation, evidence had shown that pretreatment with EGb761 prevented the pathological changes occurring in response to the endotoxin, LPS, induced ALI in the murine model. EGb761 not only effectively prevented LPS-induced changes in blood gas parameters and lung histopathology, neutrophils infiltration, lung edema, and generation of proinflammatory cytokines and chemokines, such as TNFα, IL-6, and MIP-2, but also reduced the LPS-induced expression of COX-2 and iNOS, phosphorylation of p38 MAPK, ERK, JNK, Akt, and IκB, and activation of NFκB.

The progression of ALI is related to the systemic inflammatory responses due to direct or sequential injury, such as sepsis.[1] The major causal factor in the development of sepsis is mediated in part by endotoxin. LPS is one of the prototypical endotoxins and a component of the Gram-negative bacteria cell wall. The characteristics of ALI induced by LPS administered intratracheally in mice are the most similar in pathological features to those of human patients.[23] In the early stage, ALI is represented by the disruption of the alveolar−capillary barrier, which results in neutrophil infiltration and protein-rich fluid leakage into the alveolar space.[6] Typical pathophysiological appearances include gas exchange damage, dyspnea, hypoxemia, bilateral infiltrates on chest radiograph, and noncardiogenic pulmonary edema.[24] Pathohistological appearances contain the hyaline membrane formation, hemorrhage, alveolar septal thickening, and neutrophil infiltration.[25] In a previous study, we have demonstrated that EGb761 suppresses the LPS-induced ALI in mice via reduction of leukocyte infiltration and protein leakage.[17] With the present study, our investigation on the protective effect of EGB761 in LPS treated mice was extended further to the verification of its ability to improve the blood gas exchange. Moreover, we found that LPS-induced pathohistological changes were reduced by EGb761. These results indicated EGb761 was able to prevent and ameliorate the ALI induced by endotoxin.

Neutrophils are on the first line of innate immune defense against invading bacteria through the generation of proinflammatory mediators, such as superoxide anions and its related active metabolites, nitric oxide, and proteolytic enzymes. Excessive generation of proinflammatory mediators by activated neutrophils induces peripheral normal tissue injury.[26] In clinical trials, neutrophil infiltration is an important hallmark in the pathogenesis of ALI.[6] In animal studies, intratracheal administration of LPS induces activation or injury of alveolar macrophages and respiratory membrane which contained alveolar epithelial cells, capillary endothelial cells, and basement membrane. Generation of proinflammatory cytokines and chemokines from respiratory membrane results in neutrophil activation in peripheral tissue followed by transmigration into alveolar space due to broken respiratory membranes. Previous studies have demonstrated that LPS induces neutrophil infiltration in the mouse model.[8,17] At present, we also found neutrophil infiltration in LPS-treated mice. Ginkgolide B, a component of *Ginkgo biloba* extracts, significantly decreases neutrophil infiltration in ovalbumin-challenged mice.[27] Recently, we proposed that EGb761 significantly suppressed the number of infiltrating leukocytes in BALF caused by LPS.[17] In the present study, the data collected had further confirmed our earlier hypothesis that EGb761 significantly decreased neutrophil infiltration caused by LPS in BALF. These results strongly suggested that EGb761 was capable of improving LPS-induced ALI via reducing the neutrophil infiltration.

Activation of alveolar macrophages and respiratory membranes can be induced by LPS administration, which leads to the generation of proinflammatory cytokines and chemokines such as TNF-α, IL-6, and MIP-2.[17−19] However, TNF-α and IL-6 induce the expression of adhesion molecules on capillary endothelial cells. MIP-2, a homologue of human IL-8 in mice, is a potent chemokine for neutrophils.[19] Together, they induced the infiltration of peripheral neutrophils into the alveolar space.[17−19] *Ginkgo biloba* extracts are found to protect against mercury(II)-induced TNF-α in rat serum and LPS-induced TNF-α in RAW264.7 macrophages.[16,28] In rats with trinitrobenzenesulfonic acid induced colitis, *Ginkgo biloba* extract reduces the generation of TNF-α and IL-6 in colon tissues.[29] When LPS is administered intratracheally, EGb761 reduced the generation of TNF-α, IL-6, and MIP-2 in BALF. The parallel trends between cytokine and chemokine generation and neutrophil infiltration can both be inhibited by EGb761.

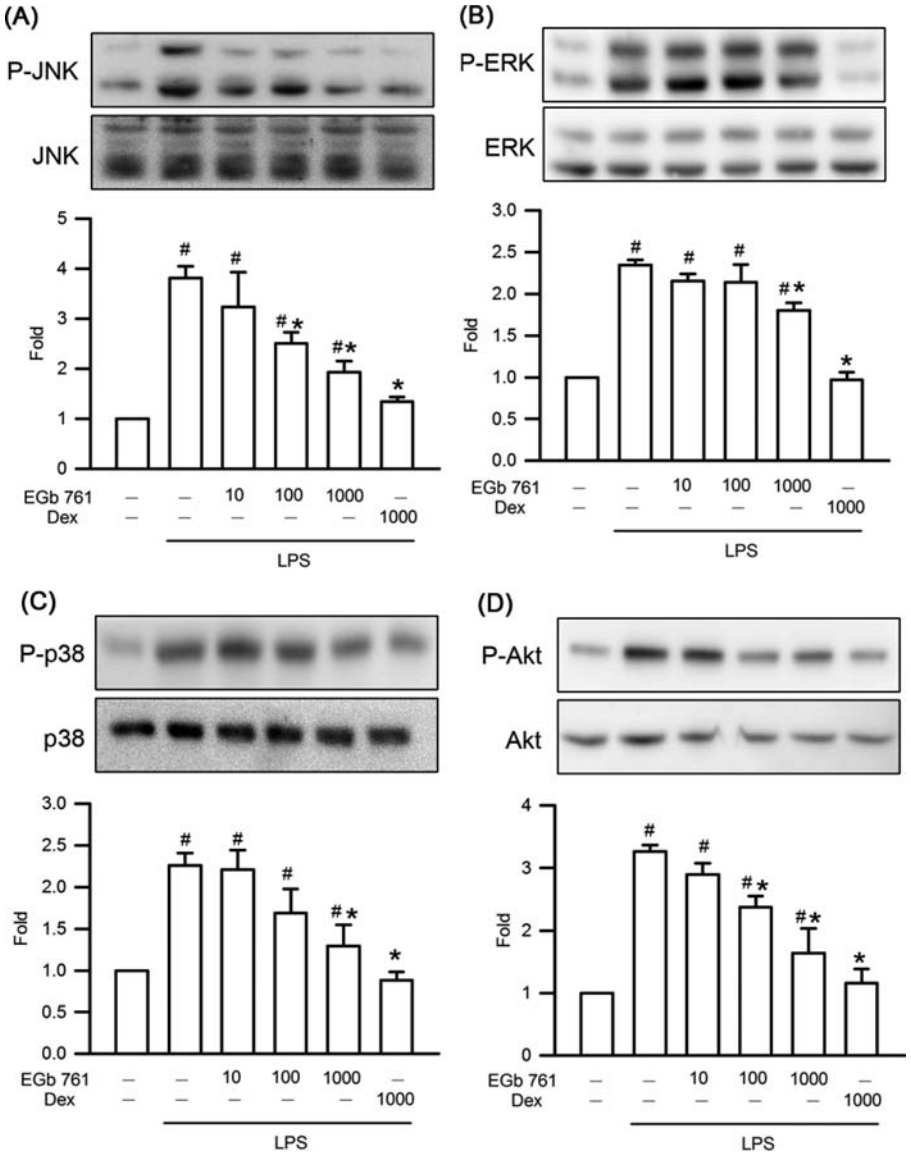

Figure 7. Effect of EGb761 on LPS-induced JNK, ERK, p38 MAPK, and Akt phosphorylation in lung. Lung tissues harvested from post-treated mice were analyzed by Western blotting. The fold of JNK (A), ERK (B), p38 MAPK (C), and Akt (D) phosphorylation between the treated and control groups was calculated. Values are expressed as mean ± SD (n = 3–5 in each group). * represents a significant difference between the indicated and normal control group, and # represents a significant difference between the indicated and LPS groups, $p < 0.05$.

Therefore, the reduction of neutrophil infiltration by EGb761 was partially due to its inhibitory effect on the production of proinflammatory cytokines and chemokines.

PGE2 and NO are involved in the lung tissue damage of LPS-induced ALI.[30,31] After LPS administration, PGE2 and NO are reflected in BALF.[9] In addition, TNF-α and IL-6 can amplify and accelerate the process of LPS-induced ALI by stimulating the expression of PGE2 and NO.[32,33] NO and PGE2 are produced by iNOS and COX-2. The inflammatory responses caused by LPS, production of PGE2 and NO, and protein expression of COX-2 and iNOS are reversed by EGb761 in human chondrocytes.[15] In RAW264.7 macrophages, *Ginkgo biloba* extract inhibits LPS-induced production of PGE2 and NO and protein and mRNA expression of COX-2 and iNOS.[16] On the basis of the present results, we conclude with fair certainty that EGb761 suppresses LPS-induced expression of iNOS and COX-2 in lung tissues.

NFκB, a transcription factor that is a key component of the inflammatory responses in ALI, is involved in the production of proinflammatory cytokines and chemokines, generation of PGE2 and NO, and expression of COX2 and iNOS.[34,35] In the inactive state, NFκB is bound to IκB, an inhibitor of NFκB, and remains in cytosol through masking nuclear localization signals of NFκB.[35] LPS, TNF-α, and IL-6 can trigger the activation of IκB kinase complex, which results in its phosphorylation, ubiquitination, and degradation. NFκB, which is liberated from phosphorylated IκB, translocates to the nucleus and activates transcription genes for proinflammatory mediators.[34] After LPS administration, *Ginkgo biloba* extract reduces NFκB activation and IκB degradation in RAW264.7 macrophages.[16] In a previous study, we demonstrated that pretreatment with EGb761 prevents NFκB phosphorylation and IκB degradation in LPS-induced ALI.[17] The present study further demonstrates that, while intratracheal administration of LPS results in phosphorylation of IκB and activation of NFκB in lung tissue, EGb761 reduces these phenomena significantly in a concentration-dependent manner. These results indicated that the generation of proinflammatory

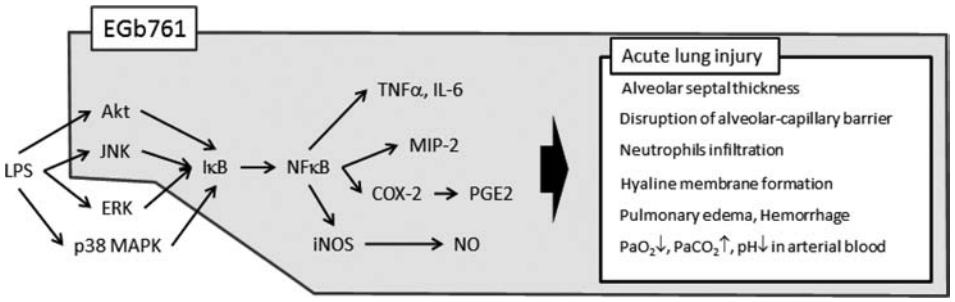

Figure 8. Schemes of the protective mechanism of EGb761 on LPS-induced ALI. The gray area indicates the molecules reduced by EGb761.

mediators reduced by EGb761 was due to inhibition of NFκB activation via IκB phosphorylation.

Akt and MAPK pathways participate in the activation of NFκB in LPS-induced ALI.[8−12] Akt is a downstream factor of phosphoinositol 3 kinase, involved in LPS-stimulated activation of alveolar macrophages, peripheral neutrophils, and the cells in the respiratory membrane in the lung.[36] The three different MAPKs p38 MAPK, ERK, and JNK also play a critical role in the inflammatory responses from innate immunity and respiratory membrane caused by LPS administration.[10−12] In RAW264.7 macrophages treated with LPS, EGb761 had no effect on the phosphorylation of JNK but inhibited the phosphorylation of p38 MAPK and ERK.[37] In mice with ovalbumin-induced asthma, ginkgolide B attenuates the phosphorylation of ERK but not p38 and JNK in lung.[27] When SH-SY5Y human neuroblastoma cells are cotreated with Aβ (1−42) and EGb761, the phosphorylation of ERK, JNK, and Akt is completely inhibited.[38] In our present study, Western blot assays showed that the phosphorylation of JNK and Akt inhibited by various concentrations of EGb761 was in direct correlation with the generation of inflammatory responses induced by LPS. However, inhibition of the marker on the phosphorylation of ERK and p38 required higher concentration of EGb761 than that of JNK and Akt. On the basis of these results, we suggested that phosphorylation of JNK and Akt reduced by EGb761 was a primary signal pathway in LPS-induced ALI.

As shown in Figure 8, we demonstrated that EGb761 significantly improved the histopathological changes and inflammatory responses, such as neutrophils infiltration, pulmonary edema, hyaline membrane formation, and arterial blood exchanges, in the mouse model of LPS-induced ALI. The molecular mechanisms involved in the protective effect of EGb761 were (1) decreased generation of proinflammatory cytokines and chemokines, such as TNF-α, IL-6, and MIP-2, (2) decreased expression of COX-2 and iNOS, (3) decreased IκB phosphorylation and NFκB activation, (4) downregulation of Akt and JNK phosphorylation as the primary pathway, and (5) downregulation of ERK and p38 MAPK phosphorylation as the secondary pathway. These results suggested the possibility of EGb761 as a preventive agent against ALI associated with infection caused by LPS via reversing the pathway of JNK- and Akt-dependent NFκB activation.

MATERIALS AND METHODS

General Experimental Procedures. Optical rotations were measured on a JASCO P-2200 polarimeter. NMR spectra were recorded on a Bruker AVANCE-500 instrument (^{1}H NMR, 500 MHz; ^{13}C NMR, 125 MHz) using TMS as an internal standard. High resolution electrospray ionization mass spectra (HRESIMS) were obtained on a Waters LCT Premier. CD spectra were run on a CD-J600 spectropolarimeter (JASCO). Column chromatography was performed with silica gel 60N (63-210 μm, Kanto Kagaku), Sephadex LH-20 (25−100 μm, GE Healthcare Bioscience), and MCI gel CHP20P (75−150 μm, Mitsubishi Chemical Corporation). HPLC was performed on a JASCO apparatus consisting of a PU-980 prep pump, UV-970 UV/VIS (at the wavelength of 280 nm), and Cosmosil 5C$_{18}$-AR-II (5 μm, φ20 × 250 mm^2, nacalai tesque), or Cosmosil π-NAP (5 μm, φ20 × 250 mm^2, nacalai tesque). TLC was conducted on precoated silica gel 60 F$_{254}$ (0.20 mm, Merck), and spots were detected by UV illumination and by spraying $FeCl_3$ reagent or cerium sulfate reagent followed by heating.

Plant Material. The stems and leaves of *Desmodium caudatum* (Thunb.) H. Ohashi were collected in Tokushima, Japan, in December 2011. The plant was identified by one of the authors (K.I.), and a voucher specimen (MSO08001) was deposited at the herbarium of Faculty of Pharmaceutical Sciences, The University of Tokushima.

Extraction and Isolation of Compounds. The stems (1.9 kg) of *D. caudatum* were extracted three times with MeOH (5 L × 3) at room temperature for 3 days. The MeOH extracts were concentrated in vacuo to give a residue (132 g), which was partitioned between EtOAc and H_2O. The EtOAc layer was concentrated to give a residue (15 g). The EtOAc-soluble fraction was dissolved in EtOH, loaded onto a Sephadex LH-20 column (4.2 × 27 cm^2), and eluted with EtOH (4L) to give eight fractions (frs.1−8). The spots of fraction 3 and 4 on the TLC plate (TLC solvent; $CHCl_3$/MeOH = 10:1) were yellow and orange, detected by UV illumination and by spraying with $FeCl_3$ reagent. Fraction 3 (1.3 g) was subjected to chromatography over MCI gel CHP20P (3.0 × 30 cm^2) [eluted with H_2O−MeOH gradient (1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 200 mL] to give 15 further fractions (frs. 3.1−3.15). Sephadex LH-20 chromatography (3.0 × 30 cm^2) [eluted with H_2O−MeOH gradient (4:1, 7:3, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] of fr. 3.6 (136.6 mg) gave **10** (13.9 mg) [R_f 0.35 ($CHCl_3$/MeOH =10:1)]. Fr. 3.8 was subjected to chromatography over Sephadex LH-20 (3.0 × 30 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] to give **2** (8.4 mg) [R_f 0.35 ($CHCl_3$/MeOH = 10:1)] and **5** (97.3 mg) [R_f 0.38 ($CHCl_3$/MeOH = 10:1)], together with 16 fractions (frs. 3.8.1−3.8.16). Fraction 3.8.9 (2.1 mg) was purified by HPLC on 5C$_{18}$-AR-II [MeOH−H_2O (7:3), flow rate 3.5 mL/min, UV at 280 nm, eluted at 70 min] to furnish **15** (1.0 mg) [R_f 0.18 ($CHCl_3$/MeOH = 10:1)]. Fr. 3.8.10 was separated by HPLC on 5C$_{18}$-AR-II [MeOH−H_2O (7:3), flow rate 3.5 mL/min, UV at 280 nm, eluted at 100 min] and then purified by HPLC on π-NAP [MeOH−H_2O (7:3), flow rate 3.5 mL/min, UV at 280 nm, eluted at 88 min] to give **13** (2.3 mg) [R_f 0.35 ($CHCl_3$/MeOH = 10:1)]. Fraction 3.9 (61.7 mg) was fractionated by Sephadex LH-20 (2.5 × 27 cm^2) [eluted with H_2O−MeOH gradient (3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] into 12 fractions (frs. 3.9.1−3.9.12). Fr. 3.9.7 (6.8 mg) was purified by HPLC on 5C$_{18}$-AR-II [MeOH−H_2O (1:1), flow rate 3.5 mL/min, UV at 280 nm, eluted at 78 min] to furnish **1** (3.2 mg) [R_f 0.38 ($CHCl_3$/MeOH = 10:1)]. Fr. 3.9.11 was separated by HPLC on 5C$_{18}$-AR-II [MeOH−H_2O (1:1), flow rate 3.5 mL/min, UV at 280 nm, eluted at 128 min] to give **6** (1.7 mg) [R_f 0.25 ($CHCl_3$/MeOH = 10:1)]. Fr. 3.10 was subjected to Sephadex LH-20 chromatography (3.0 × 30 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] to afford **8** (41.0 mg) [R_f 0.48 ($CHCl_3$/MeOH = 10:1)] and a fraction that was further purified by HPLC on 5C$_{18}$-AR-II [MeOH−H_2O (45:55), flow rate 3.5 mL/min, UV at 280 nm, eluted at 98 min] to give **19** (0.5 mg) [R_f 0.33 ($CHCl_3$/MeOH = 10:1)]. Fr. 3.11 (93.2 mg) was chromatographed over Sephadex LH-20 (3.0 × 30 cm^2) [eluted with H_2O−MeOH gradient (3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] to furnish **7** (2.2 mg) [R_f 0.45 ($CHCl_3$/MeOH = 10:1)] and a fraction that was further purified by HPLC on 5C$_{18}$-AR-II [MeOH−H_2O (45:55), flow rate 3.5 mL/min, UV at 280 nm, eluted at 122 min] to give **25** (0.7 mg) [R_f 0.35 ($CHCl_3$/MeOH = 10:1)]. Fr. 3.12 (45.4 mg) was subjected to chromatography over Sephadex LH-20 (2.5 × 27 cm^2) [eluted with H_2O−MeOH gradient (3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] and then purified by HPLC on 5C$_{18}$-AR-II [MeOH−H_2O (3:7), flow rate 3.0 mL/min, UV at 280 nm, eluted at 164 min] to yield **3** (0.7 mg) [R_f 0.28 ($CHCl_3$/MeOH = 10:1)]. Chromatography of Fr. 3.13 (187.3 mg) over Sephadex LH-20 (2.1 × 13 cm^2) [eluted with H_2O−MeOH gradient (1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] furnished **14** (83.8 mg) [R_f 0.40 ($CHCl_3$/MeOH = 10:1)] and a fraction that was further purified by HPLC on 5C$_{18}$-AR-II [MeOH−H_2O (3:7), flow rate 3.0 mL/min, UV at 280 nm, eluted at 84 min] giving **9** (0.4 mg) [R_f 0.48 ($CHCl_3$/MeOH = 10:1)]. Sephadex LH-20 chromatography (2.5 × 27 cm^2) [eluted with H_2O−MeOH gradient (1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] of fr. 3.14 (47.6 mg) gave **11** (14.0 mg) [R_f 0.55 ($CHCl_3$/MeOH = 10:1)] and **12** (4.3 mg) [R_f 0.60 ($CHCl_3$/MeOH = 10:1)]. Fraction 4 (781.2 mg) was applied to a MCI gel CHP20P column (3.0 × 24 cm^2) with a gradient of H_2O−MeOH (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1, each solvent volume 200 mL) to give 22 further fractions (frs. 4.1−4.22). Fr. 4.7 (123.7 mg) was chromatographed over Sephadex LH-20 (3.0 × 30 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] to afford **20** (3.5 mg) [R_f 0.58 ($CHCl_3$/MeOH/H_2O = 8:2:0.2)]. Sephadex LH-20 chromatography (2.1 × 15 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] of fr. 4.12 gave **23** (1.2 mg) [R_f 0.65 ($CHCl_3$/MeOH/H_2O = 8:2:0.2)]. Fr. 4.15 was subjected to Sephadex LH-20 chromatography (2.6 × 28 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] to furnish **21** (9.8 mg) [R_f 0.63 ($CHCl_3$/MeOH/H_2O = 8:2:0.2)], **22** (3.6 mg) [R_f 0.65 ($CHCl_3$/MeOH/H_2O = 8:2:0.2)], and 11 fractions (frs. 4.15.1−4.15.11). Fr. 4.15.9 (5.5 mg) was purified by HPLC on 5C$_{18}$-AR-II [MeOH−H_2O (3:2), flow rate 3.5 mL/min, UV at 280 nm, eluted at 51 min] to furnish **26** (0.9 mg) [R_f 0.71 ($CHCl_3$/MeOH/H_2O = 8:2:0.2)]. Sephadex LH-20 chromatography (2.6 × 26 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] of fr. 4.13 (26.0 mg) gave **4** (3.7 mg) [R_f 0.60 ($CHCl_3$/MeOH/H_2O = 8:2:0.2)].

The leaves (0.5 kg) of *D. caudatum* were extracted three times with MeOH (3 L × 3) at room temperature for 3 days. The MeOH extracts were concentrated in vacuo to give a residue (116 g), which was partitioned between EtOAc and H_2O. The EtOAc layer was concentrated to give a residue (25 g). The EtOAc-soluble fraction was dissolved in EtOH, loaded onto a Sephadex LH-20 column (6.0 × 20 cm^2), and eluted with EtOH (4 L) to give ten fractions (frs. 1−10). The spots of fraction 2 on the TLC plate (TLC solvent; $CHCl_3$/MeOH = 10:1) were yellow and orange, detected by UV illumination and by spraying with $FeCl_3$ reagent. Fraction 2 (1.7 g) was subjected to chromatography over MCI gel CHP20P (3.6 × 24 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 200 mL] to give 20 further fractions (frs. 2.1−2.20). Fr. 2.9 was subjected to chromatography over Sephadex LH-20 (2.6 × 27 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] to give **13** (1.6 mg) [R_f 0.65 ($CHCl_3$/MeOH/H_2O = 8:2:0.2)] and **5** (4.0 mg) [R_f 0.58 ($CHCl_3$/MeOH/H_2O = 8:2:0.2)]. Fr. 2.10 (69.1 mg) was rechromatographed over Sephadex LH-20 (2.0 × 16 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] to furnish **1** (6.0 mg) [R_f 0.59 ($CHCl_3$/MeOH/H_2O = 8:2:0.2)]. Sephadex LH-20 chromatography (2.6 × 27 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9, 0:1), each solvent volume 100 mL] of fr. 2.11 (78.9 mg) gave **8** (10.6 mg) [R_f 0.40 ($CHCl_3$/MeOH = 10:1)]. Fr. 2.12 (59.7 mg) was subjected to chromatography over Sephadex LH-20 (2.0 × 16 cm^2) [eluted with H_2O−MeOH gradient (7:3, 3:2, 1:1, 2:3, 3:7, 1:4, 1:9,

Compound **6**. Yellow amorphous powder; $[\alpha]^{20}_{D}$ +5.0 (c 0.20, MeOH). CD (MeOH; c 2.7 × 10^{-4} M; $\Delta\varepsilon$ λ_{max}): 326 (+1.76), 295 (−4.40), 247 (+1.92), 223 (+6.30), 210 (+2.55). HRESIMS: m/z 371.1136, $[M - H]^-$(calcd for $C_{20}H_{19}O_7$, 371.1131). ^{1}H NMR (acetone-d_6, 500 MHz): δ 7.08 (1H, d, J = 2.0 Hz, H-2′), 6.93 (1H, dd, J = 8.5, 2.0 Hz, H-6′), 6.86 (1H, d, J = 2.0 Hz, H-5′), 6.06 (1H, s, H-6), 5.16 (1H, t, J = 5.5 Hz, H-2″), 4.98 (1H, d, J = 11.5 Hz, H-2), 4.55 (1H, d, J = 11.5 Hz, H-3), 3.17 (2H, d, J = 5.5 Hz, H-1″), 1.59 (3H, s, H-4″), 1.56 (3H, s, H-5″).

Compound **15**. Yellow amorphous powder; $[\alpha]^{20}_{D}$ +34.9 (c 0.12, MeOH). HRESIMS: m/z 371.1113, $[M - H]^-$ (calcd for $C_{20}H_{19}O_7$ 371.1131). CD (MeOH; c 2.7 × 10^{-4} M; $\Delta\varepsilon$ λ_{max}): 317(+1.13), 295 (−1.78), 224 (+3.99). ^{1}H NMR (acetone-d_6) and ^{13}C NMR (acetone-d_6) spectroscopic data, see Table 2.

Compound **16**. Yellow amorphous powder; $[\alpha]^{20}_{D}$ −7.1 (c 0.11, MeOH). CD (MeOH; c 2.7 × 10^{-4} M; $\Delta\varepsilon$ λ_{max}): 325 (+0.27), 300 (−3.79), 286 (−2.53), 258(+1.93), 221(+2.96). HRESIMS: m/z 391.1117, $[M + Na]^+$ (calcd for $C_{21}H_{20}O_6Na$, 391.1158). ^{1}H NMR (acetone-d_6) and ^{13}C NMR (acetone-d_6) spectroscopic data, see Table 1.

Compound **17**. Yellow amorphous powder; $[\alpha]^{20}_{D}$ +3.9 (c 0.10, MeOH). CD (MeOH; c 2.6 × 10^{-4} M; $\Delta\varepsilon$ λ_{max}): 330 (+0.31), 293 (−0.94), 254 (+0.70). HRESIMS: m/z 407.1091, $[M + Na]^+$ (calcd for $C_{21}H_{20}O_7Na$ 407.1107). ^{1}H NMR (acetone-d_6) and ^{13}C NMR (acetone-d_6) spectroscopic data, see Table 2.

Compound **18**. Yellow granules, mp 132−138 °C; $[\alpha]^{20}_{D}$ −10.6 (c 0.54, MeOH). HRESIMS: m/z 391.1150, $[M + Na]^+$ (calcd for $C_{21}H_{20}O_6Na$ 391.1158). CD (MeOH; c 2.7 × 10^{-4} M; $\Delta\varepsilon$ λ_{max}): 320 (+2.33), 298 (−6.22), 248 (+5.50), 232 (+2.23). ^{1}H NMR (acetone-d_6) and ^{13}C NMR (acetone-d_6) spectroscopic data, see Table 1.

Biological Evaluation. *Test Microorganisms and Media.* Two osmophilic yeasts of *Z. rouxii* K122 and F51 were kindly provided from Tokushima Prefectural Industrial Technology Center, Tokushima, Japan. *Z. rouxii* K122, which has been industrially used for miso-making, was used as a typical non-film-forming strain and F51 as a film-forming strain. Both strains of *Z. rouxii* were cultured in slant agar media of Sabouraud dextrose agar (SDA; Difco) supplemented with 10% NaCl [NaCl 8.4 g] and a soy sauce [10 mL (salt conversion 1.6 g) per 100 mL SDA] and 50 μg/mL chloramphenicol at 25 °C for 2 weeks.

MIC Measurement. The MICs of Tween 80 and the isolated compounds (purity >95%) against the film-forming growth of *Z. rouxii* F51 were determined by the broth microdilution method in 96-well microtiter plates (Well Plate; Becton Dickinson Labware) using Sabouraud dextrose broth (SDB; Difco) supplemented with 10% NaCl [NaCl 8.4 g] and a soy sauce [10 mL (salt conversion 1.6 g) per 100 mL SDB]. The compounds were serially diluted with DMSO to prepare the solutions, which contained from 5000 to 4.8 μg/mL of the samples. Aliquots (5 μL) of the test compound solution were added to wells of the plate, which contained 50 μL of double-strength SDB and 35 μL of water. The 2-week cultures of the test strains were harvested and suspended into saline and finally adjusted to obtain the concentration of 10^6 CFU/mL. Aliquots (10 μL) of the suspensions were then added into wells of the plate. The plate was incubated at 25 °C for 2 weeks. Optical density (OD) at 540 nm was measured with a microplate reader (Sunrise; TECAN Group Ltd.) on the start day and after 2-week cultivation. The effects of compounds were evaluated by the difference of OD values on the start day and the 2-week cultivation. When the OD value was increased more than 0.1, compound was considered to have no inhibitory activity against the film-forming growth of *Z. rouxii* F51. Five microliters of DMSO did not inhibit the film-forming growth of *Z. rouxii* F51 at all. In contrast, the tested compounds, Tween 80, and DMSO have no effects on the growth of non-film-forming strain K122 on the same evaluation procedure as for *Z. rouxii* F51.

RESULTS AND DISCUSSION

Structure Elucidation and Identification. The stems of *D. caudatum* were extracted with MeOH at room temperature, and the MeOH extract was partitioned between EtOAc and H_2O. Repeated chromatography of the EtOAc-soluble fraction over Sephadex LH-20 and MCI gel CHP20P and purification by HPLC afforded four new flavonoids (**1**−**3**, **15**), together with 18 known flavonoids (**4** −**14**, **19**−**23**, **25**, **26**) (Figure 1).

The MeOH extract of leaves of *D. caudatum* was partitioned between EtOAc and H_2O. Repeated chromatography of the EtOAc-soluble fraction over Sephadex LH-20, MCI gel CHP20P, and SiO_2 and purification by HPLC afforded four new flavonoids (**1**, **16**−**18**), together with nine known compounds (**5**, **7**−**9**, **11**−**14**, **24**) (Figure 1). The known compounds were identified as 6-*C*-prenyl-5,7,2′,4′-tetrahydroxydihydroflavanonol (**4**),[2] 8-*C*-prenyl-5,7,2′,4′-tetrahydroxydihydroflavanonol (**5**),[2] 8-*C*-prenyldihydroisohamnetin (**7**),[8] 3-hydroxy-8-*C*-prenylnaringenin (**8**),[9] lespedezaflavanone C (**9**),[10] dihydrokaempferol (**10**),[11] 7,8-(2,2-dimethyl-2*H*-pyran)-5,2′-dihydroxy-4′-methoxyflavanonol (**11**),[2] glysapinol (**12**),[12] 8-*C*-prenyl-chromanochroman (**13**),[2] yukovanol (**14**),[13] lespecyrtin A1 (**19**),[14] garbanzol (**20**),[15] 6-*C*-prenyl-5,7,2′,4′-tetrahydroxydihydroflavonol (**21**),[3] kaempferol (**22**),[16] luteoline (**23**),[17] citrusinol (**24**),[18] leachianone G (**25**),[19] and apigenin (**26**)[20] by comparison of their physical and spectral data with those reported in the literature. The structure of compound **6** was assigned as 8-*C*-prenyldihydroquercetin by analysis of the spectral data. Since the spectroscopic data of this compound has not been reported previously, the data are shown in the experimental section. Compounds **6**, **9**, **12**, **19**, **20**, **22**, **23**, and **26** were isolated from *D. caudatum* for the first time.

The molecular formula of compound **1** was assigned as $C_{20}H_{18}O_7$ by HRESIMS (m/z 393.0950 $[M + Na]^+$). The ^{1}H and ^{13}C NMR spectra showed signals due to a 1,4-disubstituted benzene ring, a 1,2,3,4,5-pentasubstituted benzene ring, two oxygenated methines, a tertiary-methyl, an oxymethylene, a pair of *cis*-coupled olefinic doublets, and an oxygen-bearing quaternary sp^3 carbon (Table 1). These spectroscopic data were similar to those of the flavanonol derivatives with a 2,2-dimethyl-2*H*-pyran ring either at C-6,7 or C-7,8, except for the absence of the signal due to one of the tertiary methyl groups of a 2,2-dimethyl-2*H*-pyran moiety. The HMBC correlations of the tertiary methyl signal with the oxygen-bearing quaternary sp^3 carbon, one of the sp^2 methines (δ_C 124.6), and the oxymethylene suggested that one of methyl groups of 2,2-dimethyl-2*H*-pyran moiety was replaced by a hydroxymethyl group. This was further supported by the fact that acetylation of **1** with Ac_2O/pyridine yielded a tetraacetate of **1**. The positions of the 2-hydroxymethyl-2-methyl-2*H*-pyran ring were concluded to be at C-7 and C-8 from the HMBC correlations of H-1″ with C-7, C-8, and C-9 and of H-2″ with C-8. The 2,3-*trans* configuration was assigned from the coupling constant value of H-2/H-3 (11.5 Hz). In addition, the absolute configuration at

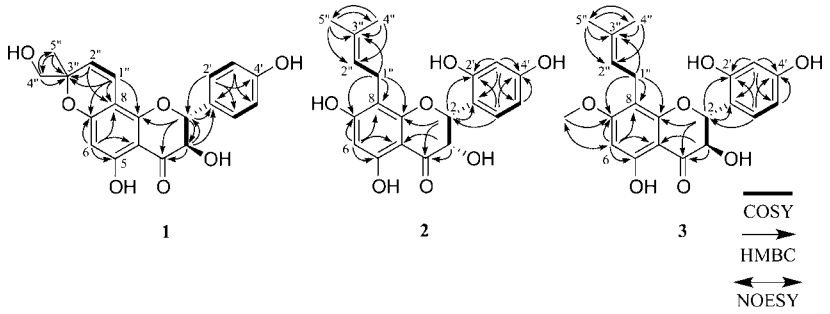

Figure 2. Selected COSY and HMBC correlations for compounds **1**, **2**, and **3**.

C-2 was assigned as 2*R* by the CD spectral analysis; the positive Cotton effect at 321 nm and the negative one at 295 nm were similar to those of the related compounds.[21−23] However, the configuration of C-3″ could not to be determined by spectral analyses. On the basis of this observation, the structure of **1** was established as shown (Figure 1).

Compound **2** gave a $[M + Na]^+$ ion peak at *m*/*z* 395.1107 in the HRESIMS, indicating the molecular formula of $C_{20}H_{20}O_7$. The ^1H NMR spectrum of **2** quite resembled those of 8-*C*-prenyl-(+)-dihydromorin (**5**), except for the signals due to H-2 and H-3 with small coupling constant values. The $^1H-^1H$ COSY and HMBC correlations shown in Figure 2 were in good agreement with the positions of the prenyl group at C-8 and the hydroxyl groups at C-5, C-2′, and C-4′. The 2,3-*cis* configuration was judged from the small coupling constant value of H-2/H-3 (2.0 Hz), and the absolute configuration at the C-2 was assigned as 2*R* by the CD spectral analysis, in which the positive Cotton effect at 340 nm and the negative one at 295 nm were similar to those of the related compounds.[21−23] On the basis of this observation, the structure of **2** was characterized as shown (Figure 1).

Compound **3** gave a quasi-molecular ion peak at *m*/*z* 409 $[M + Na]^+$ in the ESIMS, and its molecular formula was confirmed as $C_{21}H_{20}O_7$ by HRESIMS. The ^1H and ^{13}C NMR spectra of compound **3** were quite similar to those of **5** except for the observation of a methoxy signal [δ_H 3.90 (3H, s), δ_C 56.8]. Taking its molecular formula into account, compound **3** was considered to be a monomethyl ether of **5**. The location of the methoxy group in **3** was assigned to be at C-7 by the analysis of HMBC and NOESY spectra. The OMe resonance only showed a NOESY correlation with H-6. A planar structure for **3** was assigned by the $^1H-^1H$ COSY and HMBC analyses (Figure 2). The 2*R* configuration in **3** was assigned by the analysis of CD spectra, which showed similar Cotton effects to those found in **1**. From this examination, the structure of **3** was assigned as shown (Figure 1).

The molecular formula of compound **15** was assigned as $C_{20}H_{20}O_7$ by HRESIMS (*m*/*z* 371.1113 $[M - H]^-$). The ^1H and ^{13}C NMR spectra were correlated to those of **27** except for the absence of the *cis*-coupled olefinic signals, but instead signals due to two methylenes [δ_H 2.57, 1.61 (each 2H, t, *J* = 8.0 Hz), δ_C 18.2, 43.8] were observed. This spectral data, coupled with the molecular formula of **3**, implied the presence of a 2,2-dimethyl-dihydro-2*H*-pyran ring. The HMBC correlations of tertiary methyl signals with C-3″ and C-2″, H-2″ with C-8, and H-1″ with C-7, C-8, C-9, and C-3″ indicate that the 2,2-dimethyl-dihydro-2*H*-pyran ring was attached to C-7 and C-8 (Figure 3). The 2,3-*trans* configuration was assigned from the *J* value of H-2/H-3 (11.5 Hz), and the 2*R* configuration was elucidated by analysis of the CD spectrum.

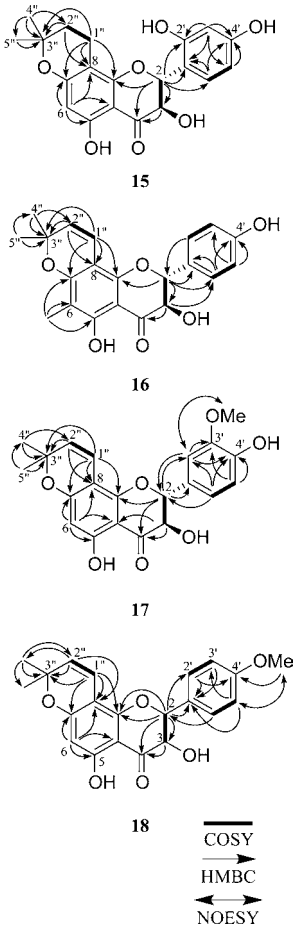

Figure 3. Selected COSY and HMBC correlations for compounds **15**−**18**.

Based on this examination, the structure of **15** was elucidated as shown (Figure 1).

The molecular formula of **16** was determined as $C_{21}H_{20}O_6$ by HRESIMS (*m*/*z* 391.1117 $[M + Na]^+$). The ^1H and ^{13}C NMR spectra were well correlated with those of **14**. However, an aromatic signal due to the A-ring of flavonoid was absent, but instead a *C*-methyl proton signal [δ_H 1.95 (3H, s), δ_C 7.2] was observed, suggesting compound **16** to be a *C*-methyl-flavanonol derivative with a 2,2-dimethyl-2*H*-pyran ring. The HMBC correlations of the H-1″ with C-7, C-8, and C-9 indicated that the 2,2-dimethyl-2*H*-pyran ring was attached to C-7 and C-8, while the location of the methyl group was concluded to be at C-6 from the HMBC correlations of the methyl signal with C-5, C-6, and C-7 (Figure 3). The *trans*-configuration of H-2 and H-3 was assigned from the *J*-value of H-2 and Hax-3 (11.5 Hz),

[a]The log *P* values were calculated using ACD software.

and the absolute configurations at the C-2 were determined to be *R* from the positive Cotton effect at 325 nm, and a negative one at 286 nm in the CD spectrum, being similar to those found in the related compound.[21−23] On the basis of this examination, the structure of **16** was characterized as shown in Figure 1.

The ^{1}H NMR spectra of compounds **17** and **18** were well correlated to each other except for the signals due to the B-ring moiety; compound **17** gave a ^{1}H NMR spectrum quite similar to that of **12**, but the signals arising from the B-ring moiety were slightly different, while that of **18** showed the presence of a 1,4-disubstituted B-ring moiety. This observation suggested that the position of the methoxy group in compound **17** is different from that in **12**. The oxygen functions at C-3′ and C-4′ were indicated by the HMBC correlations of H-2′ and H-6′ with C-2, while the methoxy group was assigned to be at C-3′ from the NOESY correlation of the OMe resonance with H-2′. In contrast, the ^{1}H NMR spectrum of **18** was similar to that of **17** except for the appearance of A_2B_2-type aromatic signals instead of signals due to a 1,3,4-trisubstituted benzene ring, suggesting that the oxygen function of the B-ring is present only at C-4′. This was consistent with the HRESIMS of **18**, which showed an $[M + Na]^+$ peak at *m*/*z* 391.1158, being 16 mass units less than that of **17**, and was further confirmed by the HMBC correlations of H-2′,6′ with C-2 and C-4′ (Figure 3). Besides, the position of the methoxy group was assigned to be at C-4′ based on the HMBC and NOESY correlations; the OMe resonance only showed a NOESY correlation with H-3′,5′ (Figure 3). The HMBC correlations shown in Figure 3 were in good agreement with the structures for **17** and **18**. From these examinations, the structures of **17** and **18** were characterized as shown in Figure 1.

Biological Evaluation. Seventeen flavonoids (**1**, **2**, **4**, **5**, **7**−**14**, **20**−**22**, **24**, **25**) obtained in this study, together with 11 flavonoids (**27**−**37**) previously isolated from the roots of this plant, were evaluated for their effect on the film-forming growth of a film-forming strain (F51) of *Z. rouxii*. The film-forming growth inhibitory activity of nine compounds (**3**, **6**, **15**−**19**, **23**, and **26**) could not be evaluated owing to the small amount of samples. Under the cultivation conditions in the present work, not only *Z. rouxii* K122 but also F51 grew well in the presence of the tested flavonoids. Therefore, the effect of these flavonoids on the characteristic film-forming property of *Z. rouxii* F51 was examined by the broth microdilution method in 96-well microtiter plates (Table 3).

Compound **11** demonstrated potent inhibitory activity against the film-forming growth of *Z. rouxii* F51 with an MIC value of 7.8 μg/mL. Compounds **5**, **12**, **14**, **28**, **32**, **33**, and **35** also showed moderate inhibitory activity with MIC values ranging from 15.6 to 31.3 μg/mL. Compounds **2**, **4**, **21**, **25**, **27**,

dx.doi.org/10.1021/jf5020439 | J. Agric. Food Chem. 2014, 62, 6345−6353

28, and **33** were weak inhibitors (MIC value of 62.5 μg/mL), while compounds **1**, **7**−**10**, **13**, **20**, **24**, **29**−**31**, **36**, and **37** did not show inhibition at 125 μg/mL. Regarding the active flavanonol derivatives, the compounds possessing a 2,2-dimethyl-2*H*-pyran group in the A-ring (**11**, **12**, **14**, **27**, and **28**) were more potent (MIC values ranging from 7.8 to 62.5 μg/mL) compared with those (MIC values ranging from 31.5 to 62.5 μg/mL) having a prenyl group (**2**, **4**, and **5**), suggesting that the 2,2-dimethyl-2*H*-pyran group in the A-ring may contribute more critically to the film-forming growth of a film-forming strain (F51) of *Z. rouxii*. Flavonols possessing a 2,2-dimethyl-2*H*-pyran group (MIC values ranging from 15.6 to 62.5 μg/mL) also tend to show more potent activity than those having a prenyl group, except for compound **24**. In contrast, flavones and flavanones were less active compared with flavanonols and flavonols. Therefore, the hydroxyl group at C-3 might be important for the activity, whereas a double bond at C-2−C-3 seems to be not essential, since flavanonols and flavonols showed similar activities. In addition, compounds having hydroxyl groups at C-2′ and C-4′ tend to show better activity. Overall, flavonoids possessing either a prenyl or a 2,2-dimethyl-2*H*-pyran group in the A-ring or oxygen functions at C-2′ and C-4′ in the B-ring or both, which were the typical structural features of the constituents in *D. caudatum*, showed inhibitory activity against film-forming growth of *Z. rouxii* F51.

Compounds that possess an amphiphilic character, like Tween, are considered to interact with membrane altering the properties of membranes of cells.[24] Since the cell surface of *Z. rouxii* F51 has higher hydrophobicity than non-film-forming strain K122, amphiphilies were also considered to decrease surface tension of culture solution resulting in inhibition of the film-forming growth.[7] However, the active flavonols with a 2,2-dimethyl-2*H*-pyran group had higher CLog *P* values than the less active ones. In contrast, a trend of relationship between inhibitory activity and CLog *P* values in the flavonols with a prenyl group was opposite. In the case of flavonol, flavanone, and flavone, the relationship between inhibitory activity and CLog *P* values was not found. Therefore, the inhibitory activity of flavonoids against the film-forming growth of *Z. rouxii* F51 could not be explained only by amphiphilic character. Since the ATPase activity of *Z. rouxii* F51 was more than twice the activity of *Z. rouxii* K122,[25] flavonoids might have effects on the ATPase activity of plasma membrane.

Considering the fact that 9 of 15 active compounds were isolated as new compounds from *D. caudatum*, they are characteristic compounds of this plant. Since the contents of compounds **11** and **14** are higher than the other flavonoids in roots, leaves, and stems, they especially play important roles for inhibiting the film-forming growth of *Z. rouxii* F51. In consideration of the biological activity coupled with yields of the compounds from leaves and stems, compounds **2**, **4**, **5**, **11**, and **14** were considered to be mainly involved in the application as well as the Japanese name of this plant. In addition, compounds **27** and **28**, which were isolated only from the roots of this plant, were found to have similar inhibitory activity against the film-forming growth of *Z. rouxii* F51.

Table 1. Effect of the Calcium Concentration and Source on the Gelation Characteristics and CaP Yield

CaP type	concn (g/100 g of pectin) abbrev	gelling behavior	CaP yield (mean ± SD) (%)
C-CaP	$CaCl_2$ 10	The mixture became viscous flowable and did not gel at all after 0.5 h of standing.	
	$CaCl_2$ 12	The mixture became viscous and initiated a certain gel formation after 0.5 h of standing	68.2 ± 1.61
	$CaCl_2$ 14	A gel formed immediately as $CaCl_2$ solution was added; however, it was not strong enough for a real gelation.	77.6 ± 1.14
	$CaCl_2$ 16	A compact gel was formed as $CaCl_2$ solution was added.	79.1 ± 1.53
	$CaCl_2$ 18	A compact gel was formed before all of the $CaCl_2$ solution was added.	
HO-CaP	$Ca(OH)_2$ 10.8	The mixture became viscous flowable with addition of $Ca(OH)_2$. Bits of broken gel could be found in the bottom of the solution.	
	$Ca(OH)_2$ 11.6	The mixture became viscous and initiated a certain gel formation.	52.8 ± 1.08
	$Ca(OH)_2$ 12.5	A gel formed when $Ca(OH)_2$ suspension was added.	81.6 ± 1.74
	$Ca(OH)_2$ 13.3	A compact gel was formed when $Ca(OH)_2$ suspension was added.	83.9 ± 0.29
	$Ca(OH)_2$ 14.1	A compact gel formed when $Ca(OH)_2$ suspension was added. Undissolved $Ca(OH)_2$ was observed in the gel.	

pectin (abbreviated as $CaCl_2$ 10, $CaCl_2$ 12, $CaCl_2$ 14, $CaCl_2$ 16, and $CaCl_2$ 18) and 10.8, 11.6, 12.5, 13.3, and 14.1 g of $Ca(OH)_2$/100 g of pectin [abbreviated as $Ca(OH)_2$ 10.8, $Ca(OH)_2$ 11.6, $Ca(OH)_2$ 12.5, $Ca(OH)_2$ 13.3, and $Ca(OH)_2$ 14.1]. A gel was formed after the mixture stood for 0.5 h. The end product (C-CaP or HO-CaP) was then separated through filtration, washed with deionized water, and lyophilized. The yield of CaP was calculated using the following equation:

$$X\ (\%) = \frac{m_{\mathrm{CaP}}}{m_{\mathrm{pectin}}} \times 100 \quad (1)$$

where X is the yield of CaP (%), m_{CaP} is the mass of CaP (g), and m_{pectin} is the mass of pectin (g).

Decalcification Process. To obtain the decalcified pectin (DC-pectin), C-CaP ($CaCl_2$ 14) and HO-CaP [$Ca(OH)_2$ 12.5] were suspended in a 60% acidified ethanol–water solution (the pH was adjusted to 0.5 with 37% HCl) in a ratio of 1:40 (w/v), and the resulting suspension was homogenized for 2 min. The suspension was filtered, washed with 95% ethanol, and then heated at 35 °C in an air-circulated oven for 4 h. To separate the soluble pectin and insoluble CaP, DC-pectin was again suspended in deionized water in a ratio of 1:100 (w/v) with stirring. Five replications were performed. The pectin recovery was calculated as

$$Y\ (\%) = \frac{m_{\text{DC-pectin}} - m_{\text{I-CaP}}}{m_{\text{DC-pectin}}} \times 100 \quad (2)$$

where Y refers to pectin recovery (%), $m_{\text{DC-pectin}}$ is the mass of DC-pectin (g), and $m_{\text{I-CaP}}$ is the mass of insoluble CaP (g).

FTIR. An FTIR analysis was carried out to investigate the CaP and DC-pectin functional groups. These functional groups included free carboxyl, an ionized carboxyl group, and a carbomethoxy group. Frequently, functional group changes will cause a measurable change in the infrared spectrum of the molecule. According to Table 1, CaP was generated only when the calcium concentration fell within the range of 12–16 g of $CaCl_2$/100 g of pectin or 11.6–13.3 g of $Ca(OH)_2$/100 g of pectin. Therefore, only the CaPs formed in the above concentration ranges were then used for FTIR analysis. Moreover, the DC-pectins prepared from C-CaP ($CaCl_2$ 14) and HO-CaP [$Ca(OH)_2$ 12.5] were also used for the FTIR analysis.

For the spectroscopic measurements, a 2% (w/w) sample was mixed with KBr before compression into a disk[20] and then ground into a fine powder using an agate mortar. Each disk was scanned at a resolution of 4 cm^{-1} over a spectral range of 400–4000 cm^{-1} using an Equinox 55 FTIR spectrometer (Bruker, Germany). FTIR spectral parameters, including band frequency and band area, were acquired by a software package (OMNIC FTIR software, version 6.0, Thermo Fisher Scientific, Madison WI). The data represent the mean of triplicate experiments.

Rheology. The rheological properties of the C-CaP gel ($CaCl_2$ 14) and HO-CaP gel [$Ca(OH)_2$ 12.5] were characterized using a Kinexus Pro rheometer (Malven, Worcestershire, U.K.) equipped with a parallel plate geometry (diameter 20 mm, gap size 0.5 mm, temperature 20 ± 0.1 °C). To assess the viscoelastic properties, a frequency sweep test was performed over a range of 0.01–10 Hz at a strain of 1%. A strain sweep test was carried out over a range of 0.1–100% at 1 Hz. The storage modulus (G') and loss modulus (G'') were measured as a function of the frequency and strain. Each experiment was conducted in three replicates.

SEM. To examine the internal microstructure of CaP, lyophilized CaP gels [$CaCl_2$ 14 or $Ca(OH)_2$ 12.5] were scanned with scanning electron microscopy (Philips XL-30 ESEM, Royal Philips, Holland). Before scanning, the lyophilized CaP gel sample was fixed on the conductive material of the copper vector and then sputter coated with gold–palladium under argon. The photographs were recorded using an accelerating voltage of 20 kV.[15,21]

XRD. The structure of the egg-box junction zone was investigated with a Bruker MSAL-XD2 Discovery X-ray diffractometer (Germany) equipped with a Cu Kα source and Ni filter. The X-ray diffractometer was operated under the following conditions: voltage 36 kV, current 20 mA, scanning regions of the diffraction angle 2θ = 10–30°, and scanning rate 0.05 deg (2θ) min^{-1}.[22] Standard sample holders were carefully filled with approximately 0.5 g of CaP powder [$CaCl_2$ 14 or $Ca(OH)_2$ 12.5]. The relative crystallinity was measured according to Nara and Komiya,[23] and the separation methods of the crystalline and amorphous portions are shown in Figure 1. The diffractogram was smoothed using the fit Gaussian method with Origin 7.0 (OriginLab Corp., Northampton MA). The relative crystallinity was calculated using the following formula:

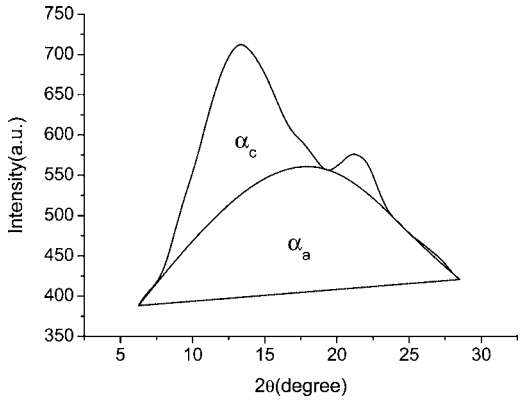

Figure 1. Calculation of the relative degree of crystallinity in the X-ray diffractogram. α_c (upper area) and α_a (lower area) indicate the crystalline and amorphous portions, respectively.

dx.doi.org/10.1021/jf5004545 | J. Agric. Food Chem. 2014, 62, 6354–6361

$$X_c = \frac{\alpha_c}{\alpha_a + \alpha_c} \quad (3)$$

where X_c is the crystallinity, α_a is the area of the amorphous region, and α_c is the area of the crystalline region.

RESULTS

Effect of the Calcium Concentration and Source on the CaP Yield. Table 1 provides a summary of the CaP gelling state and yield obtained under varied calcium concentrations and sources. A CaP gel formed when the calcium concentration was in the range of 12−16 g of $CaCl_2$/100 g of pectin or 11.6−13.3 g of $Ca(OH)_2$/100 g of pectin. The rate of CaP gel coagulation accelerated with increased calcium concentration, regardless of the calcium source. At 14 g of $CaCl_2$/100 g of pectin and 12.5 g of $Ca(OH)_2$/100 g of pectin, a better gelling quality and greater yield were achieved. In addition, at all concentrations investigated, the yield of CaP from $Ca(OH)_2$ was significantly higher than it was from $CaCl_2$.

As indicated from earlier studies, pectin can form a gel in the presence of calcium by the formation of the egg-box junction zones. Thus, the gel strength increases with increasing calcium concentration, since the number of junction zones formed is also increased.[3,24] If the calcium concentration were too low, the egg-box junctions would be insufficient to form the gel, but if the calcium concentration were too high, inferior gels would form due to instant gel formation in some areas, which would not only lower the CaP yield, but also negatively affect the gel structure. Therefore, the calcium concentration was a critical factor in the formation of the egg-box structure.

Calcium Binding Stability of CaP. The calcium binding stability of CaP was determined by the pectin recovery (eq 2). Higher pectin recovery indicates easier decalcification and less stability for CaP. During decalcification, H^+ in acidified alcohol can displace Ca^{2+} and thus convert CaP into pectin.[25] As shown in Table 2, the average pectin recovery from HO-CaP (90.9%) was significantly higher than that from C-CaP (72.6%). Thus, C-CaP exhibited a higher calcium binding stability due to difficult decalcification.

Table 2. Pectin Recovery from Calcium Pectinate during Decalcification

	pectin recovery (%)						
CaP type	1	2	3	4	5	mean (%)	SD
C-CaP	71.8	72.5	72.1	73.8	72.7	72.6	0.76
HO-CaP	90.5	89.8	91.7	92.4	90.1	90.9	1.11

Overall, HO-CaP exhibited a higher yield (Table 1) and weaker calcium binding affinity (Table 2) than did C-CaP. To explain these differences, the structural variability between HO-CaP and C-CaP was evaluated by using FTIR, rheology, SEM, and XRD.

FTIR Spectra of CaP. FTIR spectra of C-CaP ($CaCl_2$ 14) and HO-CaP [$Ca(OH)_2$ 12.5] are illustrated in Figure 2. The spectra are divided into two wavenumber areas: A (3500−1350 cm^{-1}) and B (<1350 cm^{-1}). The broad and intense band at 3450 cm^{-1} corresponds to the absorption due to stretching vibration of the O−H groups from carboxylic acid and polysaccharides,[26,27] while the band at a lower wavenumber of 2930 cm^{-1} corresponds to the infrared C−H stretching of the methyl group. The C═O stretching band of the carbomethoxy group at 1740 cm^{-1} was partially overlapped by the strong COO− band. Therefore, the change in the carbomethoxy group could be elucidated by analysis of the C═O and $-CH_3$ bands. Two strong absorptions at 1610 and 1420 cm^{-1} indicate antisymmetric and symmetric stretching vibrations of the ionized COO− in CaP.[28] Since both wavenumber areas could reflect the change of COO-Ca content simultaneously, the absorption at 1610 cm^{-1} was selected for subsequent analysis. Area B (Figure 2) is considered to be a fingerprint region which reflects the stretching vibration absorption of C−C, C−O−C, C−OH, and glycosidic bonds in pectin.[16] There are many absorption bands in this region; therefore, area B is not suitable for functional group analysis. In contrast, special interest is focused on area A, where two groups, carbomethoxy ($-CH_3$, 2930 cm^{-1}; C═O, 1740 cm^{-1}) and carboxylate (asymmetric stretching vibration at 1610 cm^{-1}), are observed.

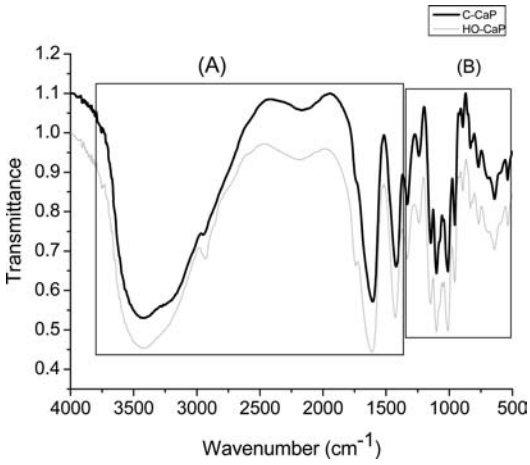

Figure 2. FTIR spectra of C-CaP and HO-CaP. Two areas, A (3500−1350 cm^{-1}) and B (<1350 cm^{-1}), are divided according to wavenumber.

The structural variation could be reflected by the wavenumber, peak area, and peak intensity of the functional groups, including $-CH_3$, C═O, and COO−. The spectral characteristics of three bands ($-CH_3$, C═O, COO−) in C-CaP and HO-CaP are summarized as a function of the calcium concentration and source (Figures 3−5, Table 3). There are two main aspects shown in the results.

1. The Wavenumber Values of the Functional Groups [$-CH_3$, C═O (Esterified), COO−] Changed with the Calcium Concentration and Source. The carbomethoxy group (C═O, $-CH_3$) wavenumber values for the two CaPs shifted significantly with increasing calcium concentration (Figure 4a,b). This shift may be due to the addition of calcium and a modification of the functional group environment.[29] The changes of carbomethoxy wavenumbers in HO-CaP ($\Delta\nu_{-CH_3}$ = 5; $\Delta\nu_{C=O}$ = 2) were less than those in C-CaP ($\Delta\nu_{-CH_3}$ = 15; $\Delta\nu_{C=O}$ = 8) (Table 3), which indicated that the effect of calcium on carbomethoxy from HO-CaP was weaker than it was on carbomethoxy from C-CaP.[16] The wavenumbers for COO− from the two CaPs (Figure 4c) were apparently decreased compared to that from pectin. This finding indicated that calcium binding with pectin could change the wavenumber for COO−.[29,30] From early studies, electrostatic interactions exist between Ca^{2+} and COO− in the egg-box model.[31,32] As an electron-withdrawing ion, calcium induces a charge deviation, which results in a change of the band vibration.[26] In addition,

dx.doi.org/10.1021/jf5004545 | J. Agric. Food Chem. 2014, 62, 6354−6361

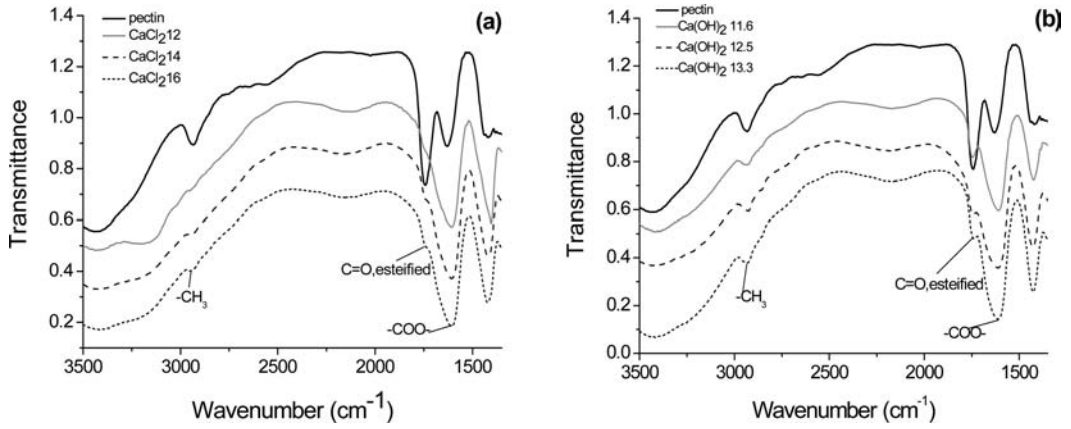

Figure 3. FTIR spectra for (a) C-CaP and (b) HO-CaP at different calcium concentrations.

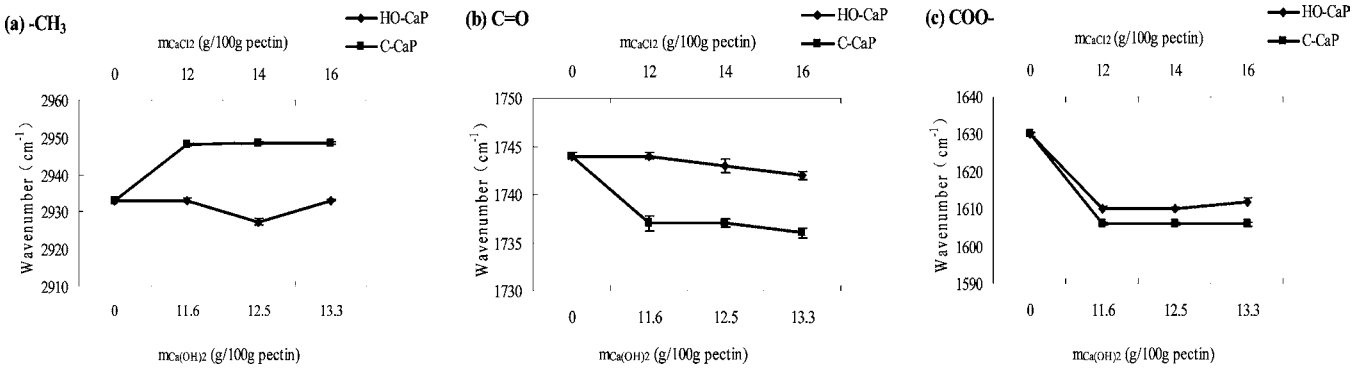

Figure 4. Calcium concentration dependence of the wavenumber values of (a) $-CH_3$, (b) C═O (esterified), and (c) COO− for C-CaP (■) and HO-CaP (◆).

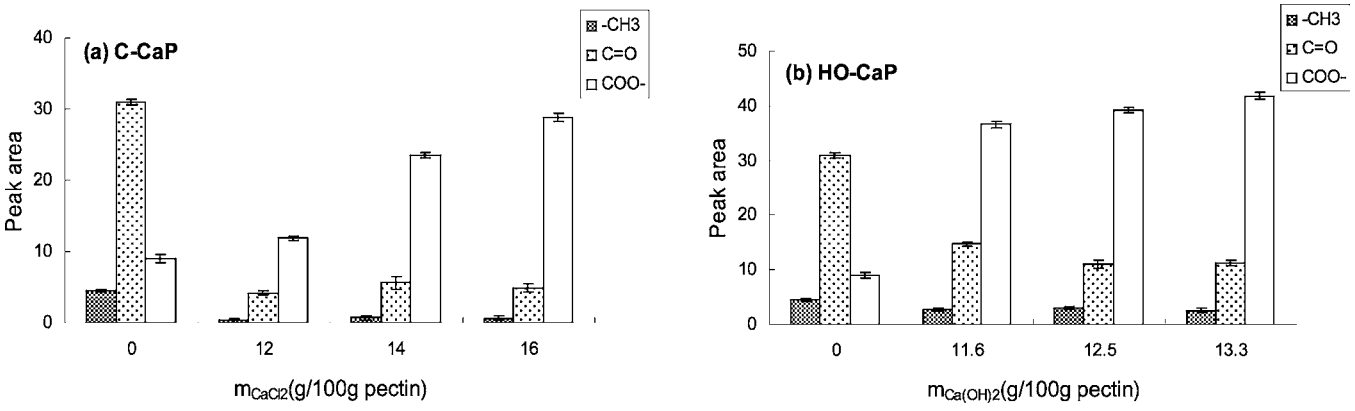

Figure 5. Calcium concentration dependence of the absorption area of the functional groups ($-CH_3$, C═O, COO−) for (a) C-CaP and (b) HO-CaP.

Table 3. Change of Wavenumber for Three Functional Groups in C-CaP and HO-CaP[a]

CaP type	$\Delta\nu_{-CH_3}$ (cm^{-1})	$\Delta\nu_{C=O}$ (cm^{-1})	$\Delta\nu_{COO-}$ (cm^{-1})
C-CaP	15	8	24
HO-CaP	5	2	20

[a] $\Delta\nu = |\nu_{max} - \nu_{min}|$.

$\Delta\nu_{COO-}$ from HO-CaP ($\Delta\nu_{COO-} = 20$) was smaller than it was from C-CaP ($\Delta\nu_{COO-} = 24$) (Table 3). This result indicates a weaker electrostatic interaction between Ca^{2+} and COO− in HO-CaP than in C-CaP. In summary, the changes in the wavenumber for the three functional groups indicate that the interaction between calcium and pectin is much stronger in C-CaP than it is in HO-CaP. This result is consistent with the decalcification result.

2. The Peak Areas of the Functional Groups [$-CH_3$, C═O (Esterified), COO-] Changed with the Calcium Concentration and Source. As shown in Figure 5, the COO− function quantity increased gradually with increasing calcium concentration. The COO− peak area is one index to reflect the yield of CaP. HO-CaP had a larger COO− quantity than C-CaP, which indicated a higher yield than that of C-CaP. This finding

dx.doi.org/10.1021/jf5004545 | J. Agric. Food Chem. 2014, 62, 6354−6361

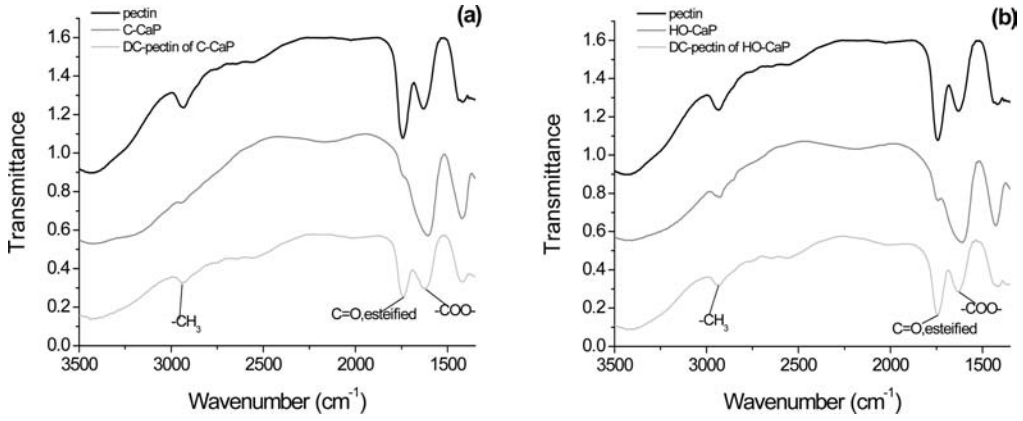

Figure 6. Effect of decalcification on the FTIR spectra of (a) C-CaP ($CaCl_2$ 14) and (b) HO-CaP [$Ca(OH)_2$ 12.5]. Pectin (black curve), CaP (gray curve), and DC-pectin (light gray curve) are measured.

is consistent with the result seen for the CaP yield, as evident in Table 1.

The carbomethoxy (C═O, $-CH_3$) quantities fell sharply after C-CaP formed (Figure 5a), whereas for HO-CaP, they did not have such an obvious change. To identify whether calcium binding caused this reduction, FTIR analysis of DC-pectin was further investigated. As shown in Figure 6, the absorptive intensity of carbomethoxy disappeared with the addition of Ca^{2+}; however, it reappeared after Ca^{2+} was removed by decalcification. Therefore, incorporation of Ca^{2+} into pectin resulted in the disappearance of the FTIR absorptive intensity for carbomethoxy.[16] Ravanat and Rinaudo[33] previously demonstrated that Ca^{2+} induces chain−chain associations to form stable egg-box junction zones. The ordering and arrangement of junction zones may be different under various gel conditions.[22] For C-CaP, the sharp decrease in carbomethoxy intensity might be because this functional group was embedded into the highly ordered or compact egg-box junction zones, and thus, its infrared absorption was masked. For HO-CaP, carbomethoxy was exposed and its infrared absorption was easier to detect because the egg-box junction zones became less well organized or were in a metastable form.

Rheological Properties of CaP. The rheological behaviors of C-CaP gel ($CaCl_2$ 14) and HO-CaP gel [$Ca(OH)_2$ 12.5] were evaluated. Figure 7 shows the frequency dependence of the storage modulus G' and loss modulus G'' for C-CaP and HO-CaP. C-CaP showed higher G' and G'' values than did HO-CaP, which means that C-CaP was more elastic and viscous. Moreover, the higher difference in magnitude between G' and G'' of C-CaP indicates that C-CaP has a stronger cross-linked network structure compared with HO-CaP.[34,35] The values of G' and G'' were also plotted as a function of strain in Figure 8. C-CaP had a greater range of elastic behavior than did HO-CaP. Both G' and G'' values tended to decrease beyond the crossover point, consistent with the large deformation. Therefore, the rheological properties were clearly different in the C-CaP and HO-CaP gels. The C-CaP gel showed a broader range of elastic behavior and needed a higher force to break down its structure, indicating a predominant cross-linking network and more stable junction zones.[17]

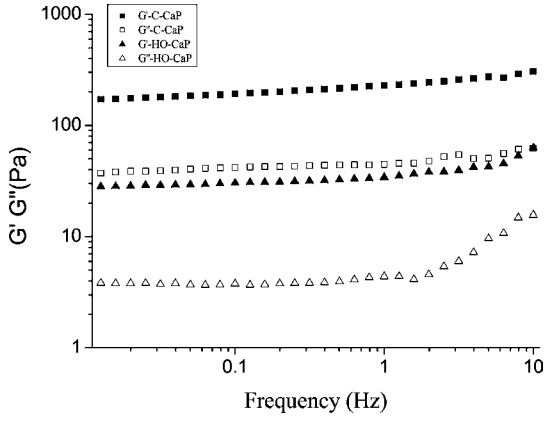

Figure 7. Frequency dependence of G' (filled symbols) and G'' (open symbols) measured at 1% strain for the C-CaP gel ($CaCl_2$ 14, squares) and HO-CaP gel [$Ca(OH)_2$ 12.5, triangles].

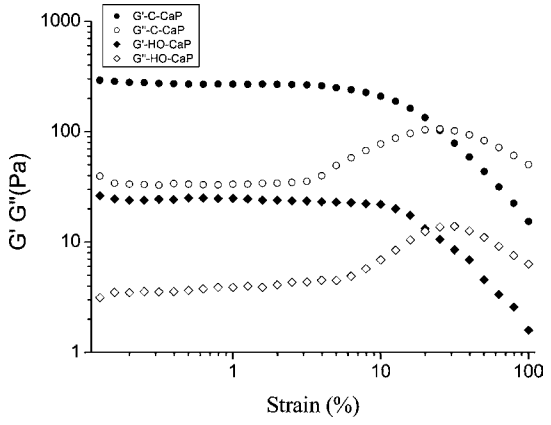

Figure 8. Strain dependence of G' (filled symbols) and G'' (open symbols) measured at 1 Hz for the C-CaP gel ($CaCl_2$ 14, circles) and HO-CaP gel [$Ca(OH)_2$ 12.5, tilted squares].

Morphology of CaP under SEM. The morphologies of C-CaP ($CaCl_2$ 14) and HO-CaP [$Ca(OH)_2$ 12.5] lyophilized gels were examined by SEM and showed some differences (Figure 9). Generally, two CaPs were made up by irregular membranes, but HO-CaP was more porous. For C-CaP, the membranes were relatively even and the surface was quite smooth (Figure 9a), which suggested a tight structure. On the contrary, for HO-CaP, the whole structure was loose and the membranes were rolled with more pores. The surface of HO-CaP was rough with

dx.doi.org/10.1021/jf5004545 | J. Agric. Food Chem. 2014, 62, 6354−6361

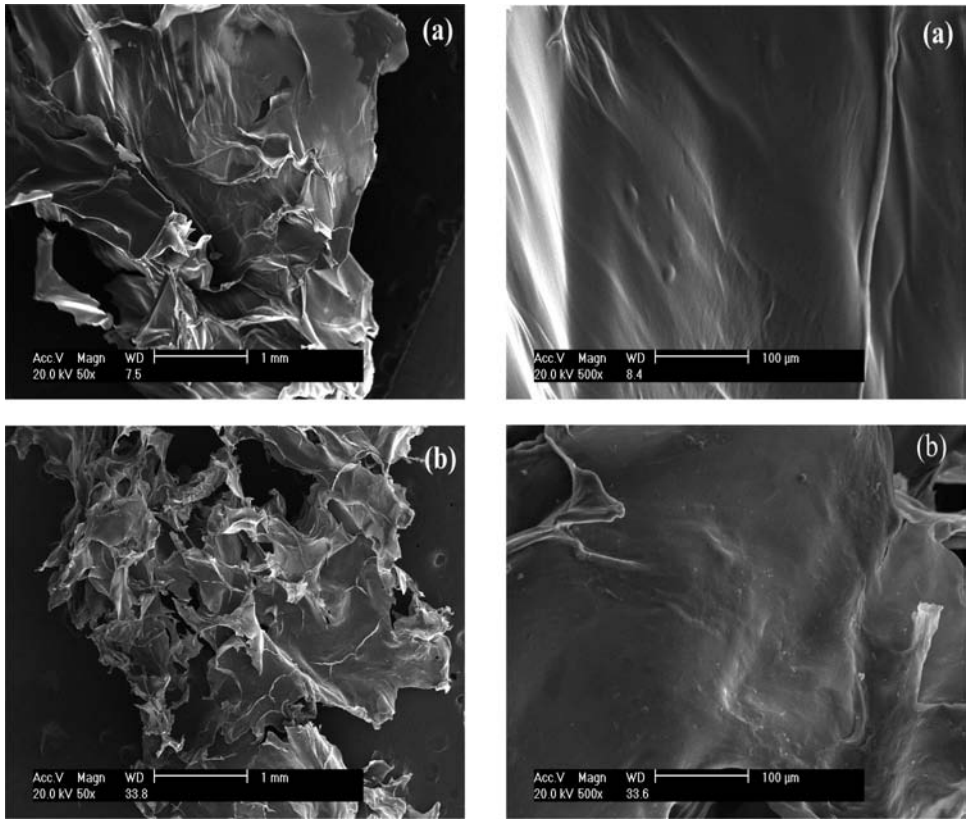

Figure 9. SEM photographs of lyophilized CaP gels for (a) C-CaP ($CaCl_2$ 14) and (b) HO-CaP [$Ca(OH)_2$ 12.5] at 50× (left) and 500× (right) magnification.

some particles, which were more likely undissolved $Ca(OH)_2$, scattered on it (Figure 9b).

Morphology is the macroreflection of molecular permutations in a material. Thus, it is inferred that the morphological differences between C-CaP and HO-CaP are ascribed to the different arrangements of the egg-box junction zones in CaP. When egg-box junction zones present an orderly and stable arrangement, CaP will show a smooth surface and form a gel too strong to break during lyopilization. Thus, it may be concluded that C-CaP maintains more orderly and stable junction zones than HO-CaP. This result is in agreement with decalcification, FTIR, and rheological analysis findings that the calcium binding of C-CaP is stronger than that of HO-CaP.

XRD Patterns of CaP. To determine whether the ordering of the egg-box junction zone had an effect on the functional groups and morphological structure, the structures of the junction zones were further investigated by X-ray diffraction. Figure 10 shows X-ray diffraction patterns of C-CaP ($CaCl_2$ 14) and HO-CaP [$Ca(OH)_2$ 12.5]. The XRD intensity curves of the egg-box junction zones of CaP exhibited patterns similar to those of calcium alginate which were reported by Li et al.[22] Because the junction zones are relatively regular, two main peaks appeared at ∼13° and ∼21.5° (2θ) and can be detected by XRD. Li et al. fitted the two peaks into the egg-box model.[22] According to eq 3, the crystallinities of the C-CaP and HO-CaP samples were 0.49 and 0.41, respectively. These results indicated that the arrangements of the junction zones in the two CaPs were different. Compared to HO-CaP, the egg-box junction zone in C-CaP was more regular and tighter. Therefore, the distinction of the junction zones could be responsible for the differences in the calcium binding stability,

FTIR spectra, rheological properties, and morphological structure.

DISCUSSION

The egg-box junction zone conformation of calcium alginate was used as a reference to identify the junction zone of CaP. In the present study, using the same XRD operating conditions as those of Li et al.,[22] we found that the diffraction peaks of CaP were identical with those of calcium alginate. Alginate is a polysaccharide consisting of 1,4-linked D-guluronate and L-mannuronate that can appear in homopolymeric blocks of each monomer.[36] The egg-box junction zone in calcium alginate is formed due to the binding of Ca^{2+} with poly(guluronic acid), while in CaP it is formed due to the binding of Ca^{2+} with

dx.doi.org/10.1021/jf5004545 | J. Agric. Food Chem. 2014, 62, 6354−6361

poly(galacturonic acid). Poly(guluronic acid) and poly-(galacturonic acid) are nearly mirror images in their structure (with the only exception being at C3)[37] and solid circular dichroism spectra. Furthermore, the same egg-box model was proposed for the junction zones of calcium alginate and CaP.[38,39] Therefore, the egg-box junction zone in CaP could be confirmed on the basis of the diffraction peaks.

In the current study, CaPs were prepared with high methoxyl pectin under alkaline conditions. C-CaP was formed when the pH value was 9.75. For HO-CaP, the pH value was stable at 9.77 after $Ca(OH)_2$ addition. Generally, under alkaline conditions, demethylation often occurs and a great number of egg-box junction zones may be formed, which could improve the crystallinity of CaP. Considering the gelling pH of CaP in the current study, demethylation and β-elimination may occur. However, on the basis of the previous report, less than 5% methyl ester had been saponified in 1/2 h at room temperature.[40] The initial reaction rate of β-elimination is very low at pH 9.5−10.[41] Thus, there was limited demethylation and β-elimination in the process of CaP formation.

The results from decalcification, FTIR, rheology, and SEM indicated that there were significant differences between C-CaP and HO-CaP in certain aspects of calcium binding stability, functional group, gel strength, and microstructure. These differences were mainly caused by the distinction of the egg-box junction zones. It was observed that the infrared absorption of the functional groups, gel strength, and microstructure were changed with the quantity of the junction zones. A higher crystallinity (XRD) indicated that C-CaP preserved a more organized structure than HO-CaP (Figure 10). The difference between the two CaP structures could be ascribed to the calcium sources used and the process of gel formation. When preparing C-CaP, the pH was adjusted before the addition of the calcium reagent. However, for HO-CaP, pH adjustment and addition of the calcium reagent were performed simultaneously. Thus, further investigations are needed to explain the kinetic and structural differences during gel formation.

Investigation of different properties of these two CaPs is valuable for their potential application in related areas. Currently, pectin is mostly extracted from citrus peel and apple pomace by the traditional ethanol method, which has a high energy and ethanol cost. With a loose structure, a high yield, and fast decalcification, HO-CaP is therefore suitable for pectin production. However, the pectin obtained by this method may preserve different properties compared with pectin obtained by the traditional method. Further investigation is therefore necessary to characterize the molecular weight, the DE, and the gelling behavior. In addition, considering HO-CaP has a weaker binding with calcium, it may be used as a calcium supplement with further study. Due to its compact structure and chemical stability, C-CaP is not easily degraded and is more suitable as a carrier of active ingredients or some oral drugs to provide protection or control release.[13,42] It also has been used as the outer membrane to maintain the moisture and increase the thermal stability of fried food.[11]

to ^{14}C-protein contamination.[20] Advances in high resolution nuclear magnetic resonance spectroscopy (NMR) and the development of methodologies to completely solubilize the entire plant cell wall[21] make it possible to observe structural transformations of lignocellulose components. For example, this approach has been previously employed to look for evidence of lignin decomposition by brown rot fungi[22] and in the structural characterization of thermochemically treated plant biomass.[23]

The objective of this study was to look for evidence of chemical changes in lignin during anaerobic decomposition of different woody plant materials under mesophilic and thermophilic conditions. To our knowledge, this is the first time that high resolution 2D NMR of completely dissolved cell walls has been used to look for evidence of chemical transformations during anaerobic decomposition of lignocellulosic materials in their native state (i.e., when the natural complex associations between cellulose, hemicelluloses, and lignin are retained).

MATERIALS AND METHODS

Experimental Design. Anaerobic decomposition experiments were conducted with lignocellulosic materials (HW, hardwood *Quercus rubra*; SW, softwood *Pinus taeda*; and ONP, old newsprint Washington Post) at mesophilic (37 °C) and thermophilic (55 °C) temperatures. ONP was selected to represent a pulp and paper product in which the lignin remains in the product. Copy paper was selected as a positive control because it contains primarily cellulose and very little lignin.

Each material was incubated under conditions optimal for anaerobic decomposition in 160 mL serum bottles containing an inoculum and biological growth medium. Decomposition was allowed to proceed until no significant methane production was measured so as to allow the bioavailable substrates to be consumed. In order of preference, lignin degradation will not proceed unless readily degradable substrates such as cellulose and hemicelluloses have been depleted. The incubation period for different materials ranged from 467 days to 585 days. At the completion of incubation, the solid residue was recovered by drying the entire contents of the bottle at 50 °C. The solid residue was subjected to the wet chemical and spectroscopic analyses described below.

Sample Collection and Preparation. Mature wood samples (oven-dried at 105 °C for 48 h and stored at room temperature) were obtained from the collection of Dr. Ilona Peszlen of the Department of Forest Biomaterials at NC State University. The copy paper used in the experiments is a commercially available white paper. The ONP was represented by the Washington Post and was collected in August 2011. Samples were dried at 50 °C, then ground to pass a 60-mesh screen (0.251 mm opening) in a Wiley mill, and then redried at 50 °C to constant weight. This temperature is well below the predicted glass transition temperature of lignin.[24] Samples were stored in Mason jars at room temperature until used.

Preparation of Anaerobically Decomposed Materials. The goal of the preparation of decomposed materials was to generate solids for subsequent analysis with negligible background lignin, cellulose, and hemicelluloses. Anaerobically decomposed materials were prepared following the biochemical methane potential (BMP) test with some modifications.[9] Test material weighing 2 g was incubated in a 160 mL serum bottle with 80 mL of reduced medium and 20 mL of inoculum according to Wang et al.[9] The bottle was capped with a butyl rubber stopper and then sealed with an aluminum crimp. The head space was flushed with a mixture of CO_2/N_2 (20:80, v/v). Flushing was done for about 10 min at a flow rate of at least 100 mL/min. This was sufficient to replace the headspace gases with CO_2/N_2 (20:80, v/v). The BMP inoculum described in Wang et al.[9] is rich in humic materials that could interfere with lignin analyses. Thus, it was necessary to prepare mesophilic and thermophilic inocula with negligible background lignin.

The mesophilic inoculum has been maintained on ground (<1 mm) residential MSW in our laboratory for over 15 years at 37 °C. The thermophilic inoculum was obtained from a thermophilic anaerobic sludge digester (Carrboro, NC) operated at 55 °C and was collected in March 2011. Serial transfer (1:1, v/v) of the inoculum was done every 2 weeks into a fresh mixture of reduced medium with copy paper as the growth substrate until no significant lignin was detected by CuO analysis, a process that required about 14 transfers over 7 months. The copy paper was initially tested for methane potential (~250 mL of CH_4/g) to ensure that the paper does not contain inhibitory substances. Copy paper used in the experiments contained less than 1% Klason lignin. The viability of the inoculum was monitored by measuring gas production.[9]

Analytical Methods. *CuO Digestion and HPLC Detection.* A sample containing 2−5 mg of C equivalent was placed in a 25 mL Teflon vial with 0.5 g of CuO powder, 0.1 g of $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$, and 5 mL of 2 M NaOH ($O_2$-free), sealed, and locked under a N_2 headspace in an anaerobic hood. Digestion was conducted in a furnace at 150 °C for 3 h. After digestion and cooling, the liquid portion of the digestate was separated by centrifugation and then acidified (pH ≤ 2). An aliquot of this solution was diluted as necessary to obtain a concentration within the calibration range (0.05−25 μM for each phenolic monomer) and was analyzed using a LC-20AT high performance liquid chromatograph (HPLC) equipped with a degasser (DGU-20A5) and a SPD 20A photodiode array detector (PDA) (Shimadzu, Canby, OR). Chromatographic analyses were conducted using a gradient program at 55 °C with a Kinetex 2.6u C18 100A column (Phenomenex, Torrance, CA) as described previously.[25,26]

Peak integration for each lignin phenol (LP) was done at its respective maximum wavelength using LC solutions software (Shimadzu, Canby, OR). The 11 LP liberated during CuO oxidation that were analyzed are as follows with the corresponding chemical structure number and are illustrated in Figure 1: [4-hydroxybenzaldehyde (**1**); 4-hydroxyacetophenone (**2**); 4-hydroxybenzoic acid (**3**); 4-hydroxy-3-methoxybenzaldehyde (vanillin, **4**); 4-hydroxy-3-methoxyacetophenone (acetovanillone, **5**); 4-hydroxy-3-methoxybenzoic acid (vanillic acid, **6**); 3,5-dimethoxy-4-hydroxybenzaldehyde (syringaldehyde, **7**); 3,5-dimethoxy-4-hydroxyacetophenone (acetosyringone, **8**); 3,5-dimethoxy-4-hydroxybenzoic acid (syringic acid, **9**); 4-hydroxycinnamic acid (*p*-coumaric acid, **10**); 4-hydroxy-3-methoxycinnamic acid (ferulic acid, **11**)]. All HPLC samples and standard solutions were filtered through 0.2 μm Millex Teflon filter (Millipore, Billerica, MA) prior to injection. Aqueous solutions were prepared using filtered (0.2 μm) and UV-treated deionized water. Standard LPs were purchased from Sigma-Aldrich (St. Louis, MO) at the highest purity available.

Cellulose, Hemicelluloses, Klason, and Acid-Soluble Lignin. A ~1 g sample was extracted with 140 mL of toluene/ethanol (2:1, v/v) and then dried. A known weight (~0.1−0.3 g) of ground sample was subjected to a two-stage acid hydrolysis.[27,28] Sugars (arabinose, galactose, glucose, mannose, and xylose) liberated from acid digestion were then analyzed by HPLC using an ICS 2500 pulsed electrochemical detector (Dionex, Sunnyvale, CA).[27,28] Anhydro correction was done to convert glucose to cellulose and the other sugars to hemicelluloses. Klason lignin was measured from the solids remaining after acid hydrolysis as the weight loss on ignition at 550 °C for 2 h. Acid-soluble lignin was determined from UV absorbance at 205 nm (extinction coefficient of 110) of the filtered (0.45 μm) acid hydrolysate from the second stage digestion.[19,29]

Total Organic Carbon (TOC). Total organic carbon (TOC) was measured with a PE 2400 CHN analyzer (PerkinElmer, Akron, OH). All samples were acid washed (1 M HCl) to eliminate inorganic carbon prior to analysis.[30]

Methoxyl Group Determination. The lignin methoxyl group content of the samples was determined by gas chromatography as developed previously with some modifications.[31] Briefly, a 10 mg sample was digested with 0.5 mL of 57% HI in a Tekmar 22 mL Teflon septum-sealed headspace vial (Teledyne, Thousand Oaks, CA) at 130 °C for 35 min. The digestate was allowed to cool to room

temperature and neutralized by addition of 0.5 mL of 6 M NaOH. The headspace was analyzed for methyl iodide using an 7890A GC (Agilent, Santa Clara, CA) equipped with a model 7000 headspace auto sampler (Teledyne, Thousand Oaks, CA), capillary column (30 m × 0.25 mm × 0.1 μm), and flame ionization detector (FID) at 250 °C. The carrier gas was 3.8 mL of He/min. Headspace gas concentration was determined from an external calibration curve constructed by the full evaporation technique, injecting 0.1 to 10 μL of pure methyl iodide as previously described.[31]

Cell Wall Dissolution. Complete dissolution of plant cell walls for subsequent high resolution solution state nuclear magnetic resonance (NMR) spectroscopy has been described.[21,32,33] A ground sample (<60 mesh) weighing 2 g was ball-milled in toluene using alumina fortified porcelain jars charged with zirconia grinding medium (6.4 × 6.4 mm) in a 0.4 L jar mill (Cole-Parmer, Vernon Hills, IL) rotating at 30 rpm under a N_2 headspace.[34,35] Optimal charging of 45−55% (v/v) was used as per the manufacturer's instructions. A ball-milling experiment showed that complete dissolution is possible after 14−28 days depending on the sample. Studies have shown that ball-milling results in only a minor increase in detectable cleaved lignin structures, and ball-milling in toluene is recommended as it serves to regulate temperature and acts as a radical scavenger.[34,35] After ball-milling, the sample suspended in toluene was centrifuged at 2850 rpm for 15 min. The toluene layer was aspirated and the remaining solvent was removed by evaporation at 50 °C under vacuum.

A ball-milled sample weighing 600 mg was dissolved in 10 mL of dimethyl sulfoxide (DMSO) and 5 mL of *N*-methylimidazole. A clear amber color solution was produced after stirring for at least 4 h. The solution was acetylated in situ by addition of 3 mL of acetic anhydride and stirred for 1.5 h, after which a dark brown solution was formed. The acetylated cell wall solution was precipitated in 2 L of deionized water, stirred overnight, recovered by vacuum filtration (0.2 μm nylon filter), washed with 250 mL of DI water, and then dried under vacuum (50 °C). The yield of acetylated cell wall was about 136% of the initial weight of material, which is typical for sample acetylation.[21] After drying, 90 mg of acetylated cell wall was dissolved in 0.75 mL of DMSO-d_6 (Cambridge Isotope Laboratories, Tewksbury, MA) and then transferred to a 5 mm NMR tube for analysis.

Nuclear Magnetic Resonance (NMR) Spectroscopy. One-bond $^{1}H-^{13}C$ heteronuclear single quantum coherence (HSQC) NMR spectra were obtained at the Bio-NMR facility of the Department of Molecular and Structural Biochemistry, NC State University, using an Avance III 700 MHz spectrometer (Bruker, The Woodlands, TX) equipped with QNP cryoprobe implementing the Bruker's hsqcetgpsisp2.2 pulse sequence program at 30 °C. HSQC is a 2D NMR

experiment which creates cross peaks that correlate the hydrogen in a molecule with its directly attached carbon.[36] The F_2 acquisition time for these NMR experiments were about 8 h with about 1 h for F_1 acquisition time. The DMSO-d_6 peak (δ_H/δ_C = 2.49 ppm/39.5 ppm) was used for internal calibration reference. Data processing and integration were done using Topspin 3.2. No attempts were made to conduct NMR experiments using nonacetylated samples. Acetylation of the whole cell wall does result in the loss of information on the natural acetates found on mannan and xylan.

NMR Quantitation. Peak assignment was performed using the lignin NMR database[37] and comparison with previously published lignin spectra for different lignin preparations.[33,38−41] Calculations to obtain absolute quantitation of different substructures were done as follows (eq 1) using the methoxyl group content obtained from wet chemical analyses as a reference.[22]

$$C_{\text{linkage}}\left[\frac{\text{mmol}}{\text{g of sample}}\right] = 2D_{\text{linkage}} \times \frac{C_{-\text{OCH}_3}\left[\frac{\text{mmol}}{\text{g of sample}}\right]}{2D_{-\text{OCH}_3}} \quad (1)$$

where C_{linkage} [mmol/(g of sample)] = concentration of a given linkage or substructure; $2D_{\text{linkage}}$ = HSQC volume integral of a given linkage or substructure; $C_{-\text{OCH}_3}$ [mmol/(g of sample)] = concentration of methoxyl group in the sample as determined by wet chemistry; $2D_{-\text{OCH}_3}$ = HSQC volume integral of the methoxyl group. Since the intensity of the HSQC regions are dependent on a coupling constant, comparisons of the different substructures were done on the basis of their Hα−Cα correlations having a similar chemical environment. The resinol volume was divided by 2 as two correlations are involved in each linkage unit. To quantitate the C_9 units of lignin, the volume integral for $H_{2/6}$−$C_{2/6}$ correlations of the HSQC spectra was used for *p*-hydroxyphenyl (H) and syringyl (S) units while H_2−C_2 was used for guaiacyl (G) units. The volume integral of H_2−C_2 correlation of G units was logically doubled because it involves a single correlation.[32] The different lignin substructures were normalized to C_9 units assuming a molecular weight of 220 mg/mmol and 198 mg/mmol for HW and SW, respectively. The molecular weight of ONP was assumed to be equal to that of SW.

RESULTS AND DISCUSSION

Carbon Loss. Variation in carbon loss from anaerobic decomposition of different lignocellulosic materials representative of MSW components was observed (Figure 2). The high carbon losses in the copy paper positive control demonstrate the viability and the suitability of the anaerobic inocula to anaerobically convert substrate to methane. While methane yields were not measured, the gas composition data over the entire incubation period showed that the gas produced was methane and carbon dioxide. The carbon losses observed in HW and ONP were comparable, while the lowest carbon loss was recorded in SW. The carbon losses presented in Figure 2 are higher than previously reported using laboratory-scale decomposition experiments.[42,43] The differences in carbon loss are perhaps a result of the smaller particle size and lower solids to liquid ratio in BMP tests conducted here relative to reactor studies designed to measure methane yields under simulated landfill conditions in which materials were shredded (3 × 4 cm) and had a higher solids to liquid ratio.

The inoculum used in this study was enriched on copy paper which does not contain significant amounts of lignin. This may have promoted changes in the relative abundance of different microbial communities in the culture. However, the carbon losses measured in this study for lignocellulosic substrates are comparable to values reported previously in tests with an inoculum enriched on MSW that would contain lignocellulosic

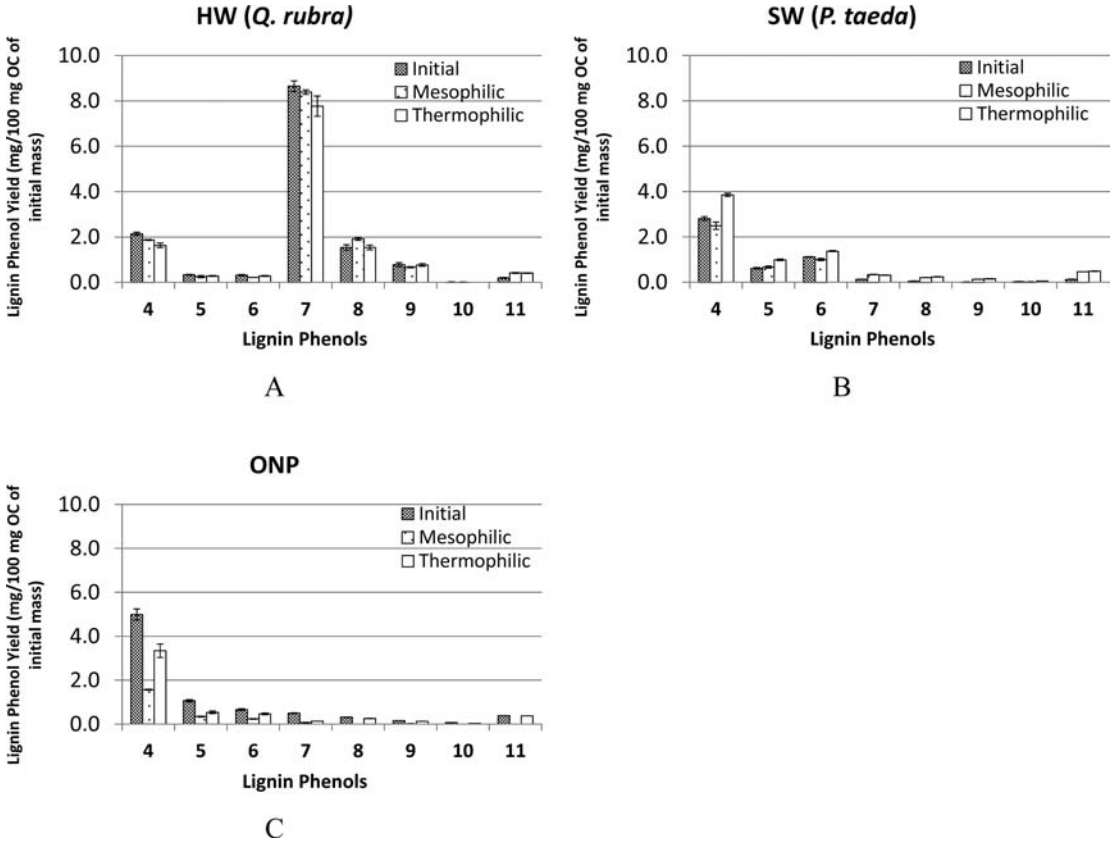

Figure 4. Changes in CuO lignin composition during anaerobic decomposition under mesophilic and thermophilic conditions normalized to the initial mass of the sample. Error bar represents ± sd (n = 3).

substrates.[9,42,43] Thus, the use of a lignin-free inoculum did not influence the extent of decomposition and the measured C conversions. This suggests that all of the readily degradable substrates have been depleted or that the accessibility to the readily degradable substrates is limited by the lignin in which the polysaccharides are encased, putting pressure on microorganisms to utilize more recalcitrant substrates such as lignin.

Structural Carbohydrates. The plant cell wall is composed of the structural carbohydrates cellulose and hemicelluloses, which account for the majority of its dry mass. Cellulose is a homopolymer of glucose linked together by β (1→4) glycosidic linkages. The linear structure of cellulose makes up its crystalline tertiary structure, which is the building block of cellulose microfibril. Hemicelluloses are heteropolymers of different sugar residues, the composition of which varies according to tissue type. Evidence has shown that hemicelluloses link cellulose microfibrils and lignin together, making up the cell wall lignocellulose composite.[44] The plant cell wall's rigidity and chemical reactivity is attributed to these intricate and complex associations between lignin and structural carbohydrates.

The changes in sugar residues after anaerobic decomposition of different lignocellulosic materials could provide insights on the reactivity and the preferential attack of anaerobic microorganisms to the different cell wall carbohydrates (Figure 3). For HW, the major sugar residues are glucose from cellulose and xylose from xylan, with xylan being a major component in angiosperms. About 12% and 36% of the initial glucose and about 36% and 30% of the initial xylose were lost after mesophilic and thermophilic anaerobic decomposition, respectively.

No significant change in sugars was observed in SW (Figure 3). This result is surprising because we observed relatively small but significant C losses in SW for both mesophilic and thermophilic decomposition (Figure 2). The result of the sugars analysis suggests that the methane and carbon dioxide mineralization in softwood did not come from cellulose and hemicelluloses.

In contrast, in ONP, a SW mechanical pulp based on CuO oxidation products (Figure 4), the glucose loss was 57% and 46%, while mannose loss was about 34% and 30% for mesophilic and thermophilic decomposition, respectively. Mannose sugar residue comes from glucomannan, which is a major component of SW hemicelluloses. The data suggests that the conversion of cell wall sugars is highly correlated to bioavailability rather than the differences in the reactivity of individual sugars.

While ONP was derived from SW pulp, its decomposition behavior is significantly different from the SW that was tested. Significant carbon loss from cellulose and hemicelluloses was recorded in ONP. This demonstrates the effect of mechanical pulping as well as the role of lignin on the accessibility/bioavailability of cellulose and hemicelluloses in SW. Mechanical pulping could involve mechanical, thermal, and some chemical processes, resulting in chemical modifications of lignin leading to disruption of the S2 layer and releasing the cellulose fiber. This process is different from Wiley milling used during sample preparation, which is a mechanical process of particle size reduction.

Lignin CuO Oxidation Products. The CuO oxidation products of initial and anaerobically decomposed samples are presented in Figure 4. For HW, the sum of 8 LP (Figure 1), Λ_8

[Λ_8 = LP **4** + LP **5** + LP **6** + LP **7** + LP **8** + LP **9** + LP **10** + LP **11**, mg/100 mg of organic carbon (OC)], after mesophilic and thermophilic decomposition is not significantly different when compared with the initial material (14.0 ± 0.6 mg/100 mg of OC). The Λ_8 is a measure of total releasable CuO lignin monomers normalized to OC and could indicate degradation/repolymerization of lignin during decomposition. The *p*-hydroxy phenols (LP **1**, **2**, and **3** in Figure 1) could have nonlignin sources such as amino acids tyrosine and phenylalanine and therefore were excluded from the sum of LP. Similarly, for HW, the acid (LP **6**) to aldehyde (LP **4**) ratios of vanillyl phenols $(Ad/Al)_V$ of the initial material (0.15) and after mesophilic (0.12) and thermophilic (0.17) decomposition are not significantly different ($p > 0.05$) from each other. The $(Ad/Al)_V$ is a measure of the extent of degradation of lignin. The result suggests that HW lignin was not significantly degraded after anaerobic decomposition.

For SW, the Λ_8 of mesophilic decomposed substrate (5.3 ± 0.3 mg/100 mg of OC) is not significantly different when compared with the initial material (4.9 ± 0.2 mg/100 mg of OC). The Λ_8 increase in thermophilic (7.5 ± 0.2 mg/100 mg of OC) is anomalous, and there is no indication that it is a result of decomposition as indicated by the constant $(Ad/Al)_V$ of 0.4 for SW initial material, after mesophilic and after thermophilic decomposition.

The CuO oxidation products of lignin can also be used as a biomarker to fingerprint the plant tissue source of lignin in an unknown sample.[45] The ratio of S (S = LP **7** + LP **8** + LP **9**) to vanillyl (V) (V = LP **4** + LP **5** + LP **6**) (S/V) has been used to discriminate between angiosperm (HW, leaves, and grasses) and gymnosperm (SW and needles) tissues while the ratio of cinnamyl (C) (C = LP **10** + LP **11**) to V phenols (C/V) has been used to discriminate between woody (HW and SW) and nonwoody (leaves, grasses, and needles) tissues.[45] The low C/V and low S/V ratios indicate that the source of lignin in ONP is softwood.

While the lignin CuO oxidation products of ONP are similar to those of SW, their decomposition behaviors are different. Significant loss of VAL phenols was recorded in ONP for both mesophilic and thermophilic decomposition. The $(Ad/Al)_V$ of fresh ONP (0.13) is not significantly different from those of materials decomposed under mesophilic (0.15) and thermophilic (0.14) conditions ($p > 0.05$). This indicates that the lignin polymer has not been significantly depolymerized during decomposition. The loss of VAL without a corresponding increase in $(Ad/Al)_V$ is an indication that no significant lignin cleavage occurred during anaerobic decomposition of ONP. This result suggests that reaction of VAL is limited to side chain oxidation without destruction of the aromatic structure.

Lignin Methoxyl Group. Losses in lignin methoxyl group were observed after anaerobic decomposition (Figure 5). The C_9 normalized methoxyl group contents of initial materials were 1.74, 1.00, and 0.54 mmol $-OCH_3$/mmol of C_9 unit for HW, SW, and ONP, respectively. As SW is dominated by G units, with minute amounts of S units,[44,46] it contains one methoxyl group per C_9 unit. Similarly, since HW is a combination of both S (that contains two methoxyl groups per C_9 unit) and G units, the methoxyl group content per C_9 unit is between one and two. The methoxyl group content of ONP confirms the SW character of this material having one methoxyl group per C_9 unit.

After anaerobic decomposition, the loss of methoxyl group was 23% and 13% for HW, and 35% and 20% for ONP, for mesophilic and thermophilic decomposition, respectively. The loss in the methoxyl group content of SW for both mesophilic and thermophilic decomposition was not statistically significant ($p > 0.05$). The loss of methoxyl group content in ONP is statistically similar between mesophilic and thermophilic conditions. In contrast, the methoxyl group loss in HW was significantly greater under mesophilic conditions ($p < 0.05$).

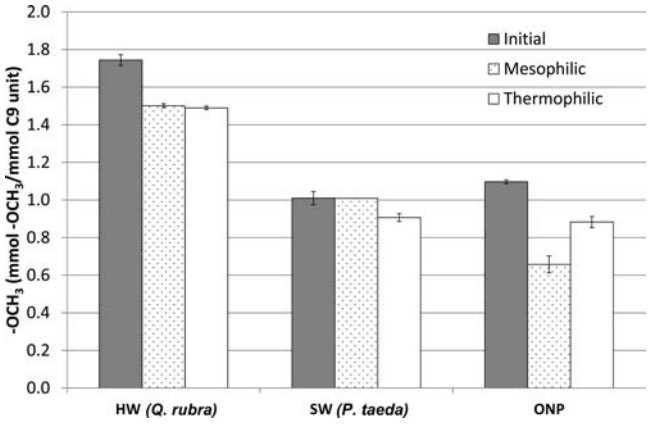

Figure 5. Changes in lignin methoxyl group composition during decomposition under mesophilic and thermophilic conditions normalized to the initial mass of the sample. Error bar represents ± sd ($n = 3$).

Evidence of the demethoxylation of lignin-derived molecules under anaerobic conditions has been reported previously where ^{14}C-labeled aromatic $-OCH_3$ was metabolized to CO_2 and acetates.[13] The results of this study support the notion that one of the first steps in the metabolism of aromatic molecules is the removal of aromatic substituents such as methoxyl groups,[14,15] which in turn can be metabolized by acetogens.[13] Perhaps because of the complexity of SW lignin polymer, these initial steps in SW lignin decomposition are more difficult compared to other lignocellulosic substrates.

Klason and Acid Soluble Lignin. The Klason and acid-soluble lignin (ASL) contents of initial and anaerobically decomposed samples are presented in Figure 6. While Klason lignin is operationally defined as the volatile fraction of the acid-insoluble material remaining after acid hydrolysis, it is widely used to measure the total lignin of a sample.[19,44]

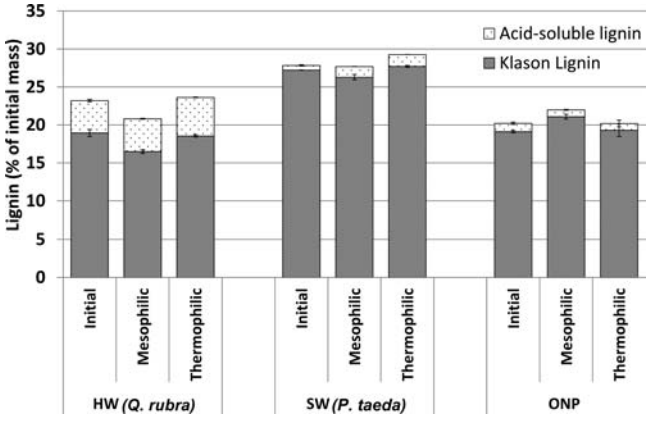

Figure 6. Changes in Klason and acid-soluble lignin composition during decomposition under mesophilic and thermophilic conditions normalized to the initial mass of the sample. Error bar represents ± sd ($n = 3$).

dx.doi.org/10.1021/jf501653h | J. Agric. Food Chem. 2014, 62, 6362−6374

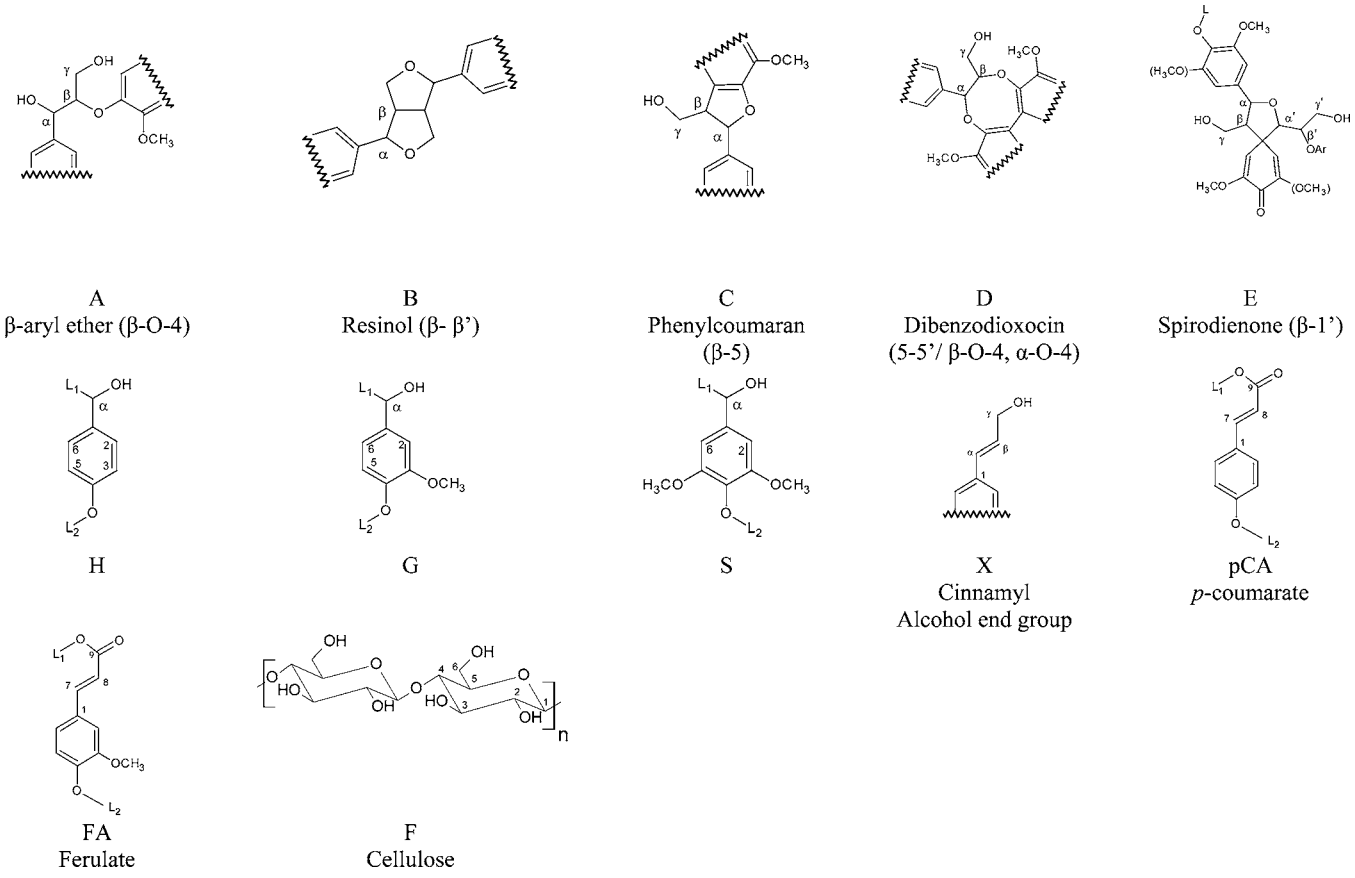

Figure 7. Linkages and substructures in lignin and lignocellulose. L, lignin polymer.

The loss of HW Klason lignin under mesophilic conditions (13%) was significant ($p < 0.05$) while no significant difference was observed under thermophilic conditions. In contrast, losses of HW ASL were significant only under thermophilic conditions. In some tissues such as in nonwoody angiosperms, the amount of ASL can be significant. Moreover, the amount of ASL could also be an indicator of the extent of decomposition as some lignin can be broken down to lower molecular weight fractions and then to soluble fractions rendering them more amenable to anaerobic decomposition. There was no significant change in either Klason lignin or ASL in ONP.

There were no significant losses in either Klason lignin or ASL for SW. As noted above, anaerobic decomposition of SW resulted in a small but significant carbon loss. It is interesting to note, however, that, based on chemical analyses, the carbon loss recorded in SW was not due to the cellulose, hemicelluloses, or lignin but from other components. To evaluate whether this observation is plausible, the amount of carbon that can be attributed to these major lignocellulosic components was estimated assuming empirical formulas for cellulose, hemicelluloses, and lignin as $(C_6H_{10}O_5)_n$, $(C_5H_8O_4)_n$, and $C_{(9)}H_{(7.92)}O_{(2.40)}(OCH_3)_{(0.92)}$, respectively. Based on the empirical formulas and their corresponding compositions, about 85% of the carbon in SW can be attributed to cellulose, hemicelluloses, and lignin. Thus, the uncharacterized cell components of SW (e.g., proteins, tannins, extractives, etc.), amounting to about 15% of the total carbon (estimated by difference), in theory could explain the observed carbon loss. This possibility is supported by the result of extractives in the softwood sample which was determined to be 17 ± 0.73% of the initial mass.

It is well-documented that SW lignin is dominated by G units. This lignin unit is more complex because of more branching as a result of the availability of the 5-position in lignin phenolic units to cross-link, making the SW lignin polymer more difficult to depolymerize.[19,44] Moreover, the complex structure of SW lignin hinders microbial enzyme access to structural carbohydrates, resulting in minor mineralization of cellulose, hemicelluloses, and lignin.

Lignin Substructures. Decomposition of lignocellulose components may not necessarily result in mass loss due to mineralization to CH_4 and CO_2. The ability of lignin to depolymerize and repolymerize makes the study of the transformation of lignin complicated.[47] In this section, evidence of lignin transformations was examined using HSQC NMR spectroscopy. The different lignin and carbohydrates substructures are illustrated in Figure 7. Figures 8 to 10 show the aliphatic and the aromatic regions of the HSQC spectra of different test materials. The spectra for initial and decomposed materials are quite similar, and the only difference was the intensities of different contours. As such, only the spectra of the initial material are presented. The difference between the initial and decomposed material is reflected in the volume integrations of different contours corresponding to different lignin substructures as summarized in Table 1. The HSQC spectra were color referenced for easy comparison.

Quantitative comparisons of the absolute amount of different substructures normalized to C_9 unit are presented in Table 1 for different materials (initial material, and after mesophilic and thermophilic decomposition). The relative abundance of different lignin substructures has been reported for different types of tissues. The majority of inter C_9 unit linkages in lignin

dx.doi.org/10.1021/jf501653h | J. Agric. Food Chem. 2014, 62, 6362−6374

are *β-O*-4, followed by significantly smaller and varying amounts of resinol, phenylcoumaran, spirodienone, and dibenzodioxocin structures (Figure 7). For example, in white birch (*Betula pendula* Roth) MWL, the relative abundance of lignin inter C_9 unit linkages is about 69% *β-O*-4, 17% resinol, 3% phenylcoumaran, and 4% spirodienone estimated from 2D HSQC spectra.[48]

The HSQC spectrum of the HW aliphatic region (Figure 8A) illustrates the well-resolved peak corresponding to the H*α*−C*α* (δ_H/δ_C = 5.91 ppm/74.3 ppm) correlation in the *β-O*-4 linkage with distinct separation between the *threo* and *erythro* diastereomers. Figure 8A also shows the intense methoxyl group peak (δ_H/δ_C = 3.60 ppm/55.3 ppm). Three of the major inter C_9 unit linkages in lignin were quantified as presented in

dx.doi.org/10.1021/jf501653h | J. Agric. Food Chem. 2014, 62, 6362−6374

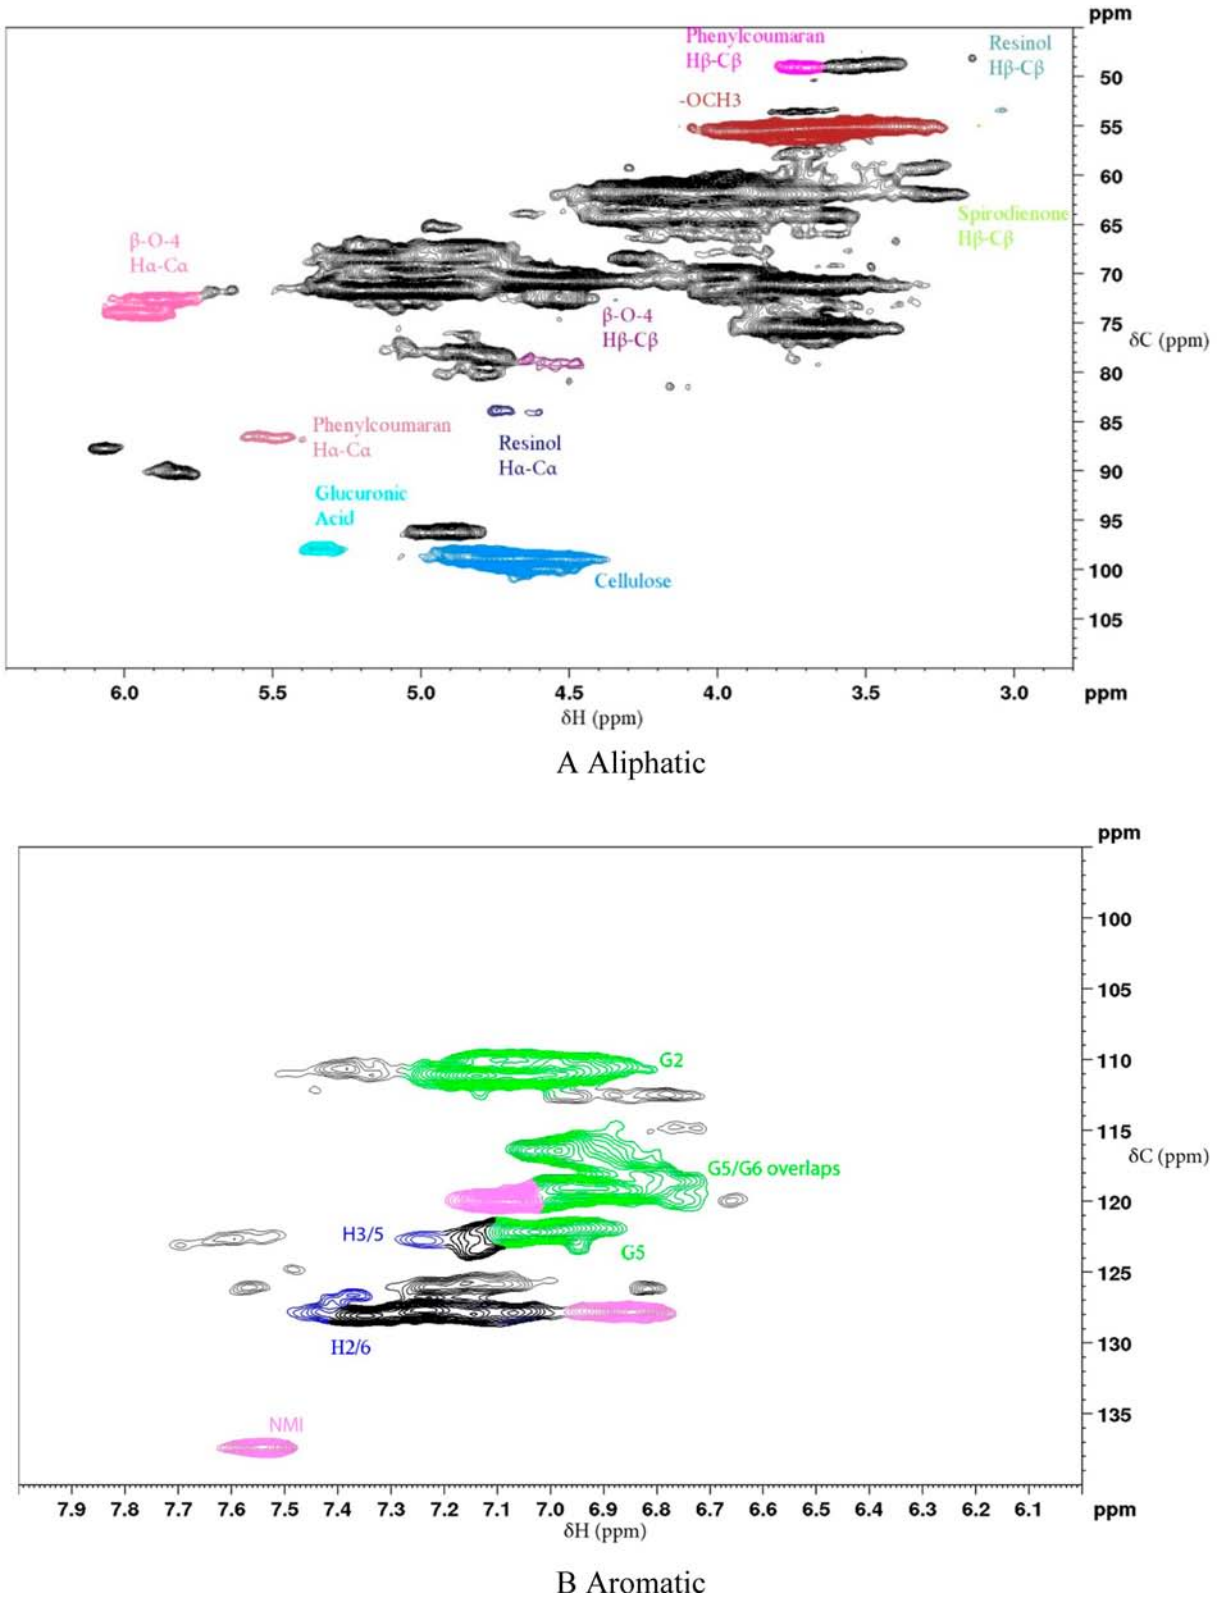

Figure 9. HSQC spectra of SW (*Pinus taeda*): (A) aliphatic region; (B) aromatic region.

Table 1. While other lignin substructures have been identified, their quantities were not calculated because the relative amounts are small and are subject to high uncertainty. In addition to lignin substructures, Figures 8−10 show the different structures found in cellulose and hemicelluloses. The black regions in the aliphatic regions of HSQC spectra are unidentified overlapping peaks primarily due to carbohydrates.

In the aromatic regions (Figure 8B), the intense $H_{2/6}$−$C_{2/6}$ (δ_H/δ_C = 6.65 ppm/102.7 ppm) contour region is due to S units, which are the major C_9 unit in angiosperms such as HW. In a majority of the HSQC spectra, *N*-methylimidazole

dx.doi.org/10.1021/jf501653h | *J. Agric. Food Chem.* 2014, 62, 6362−6374

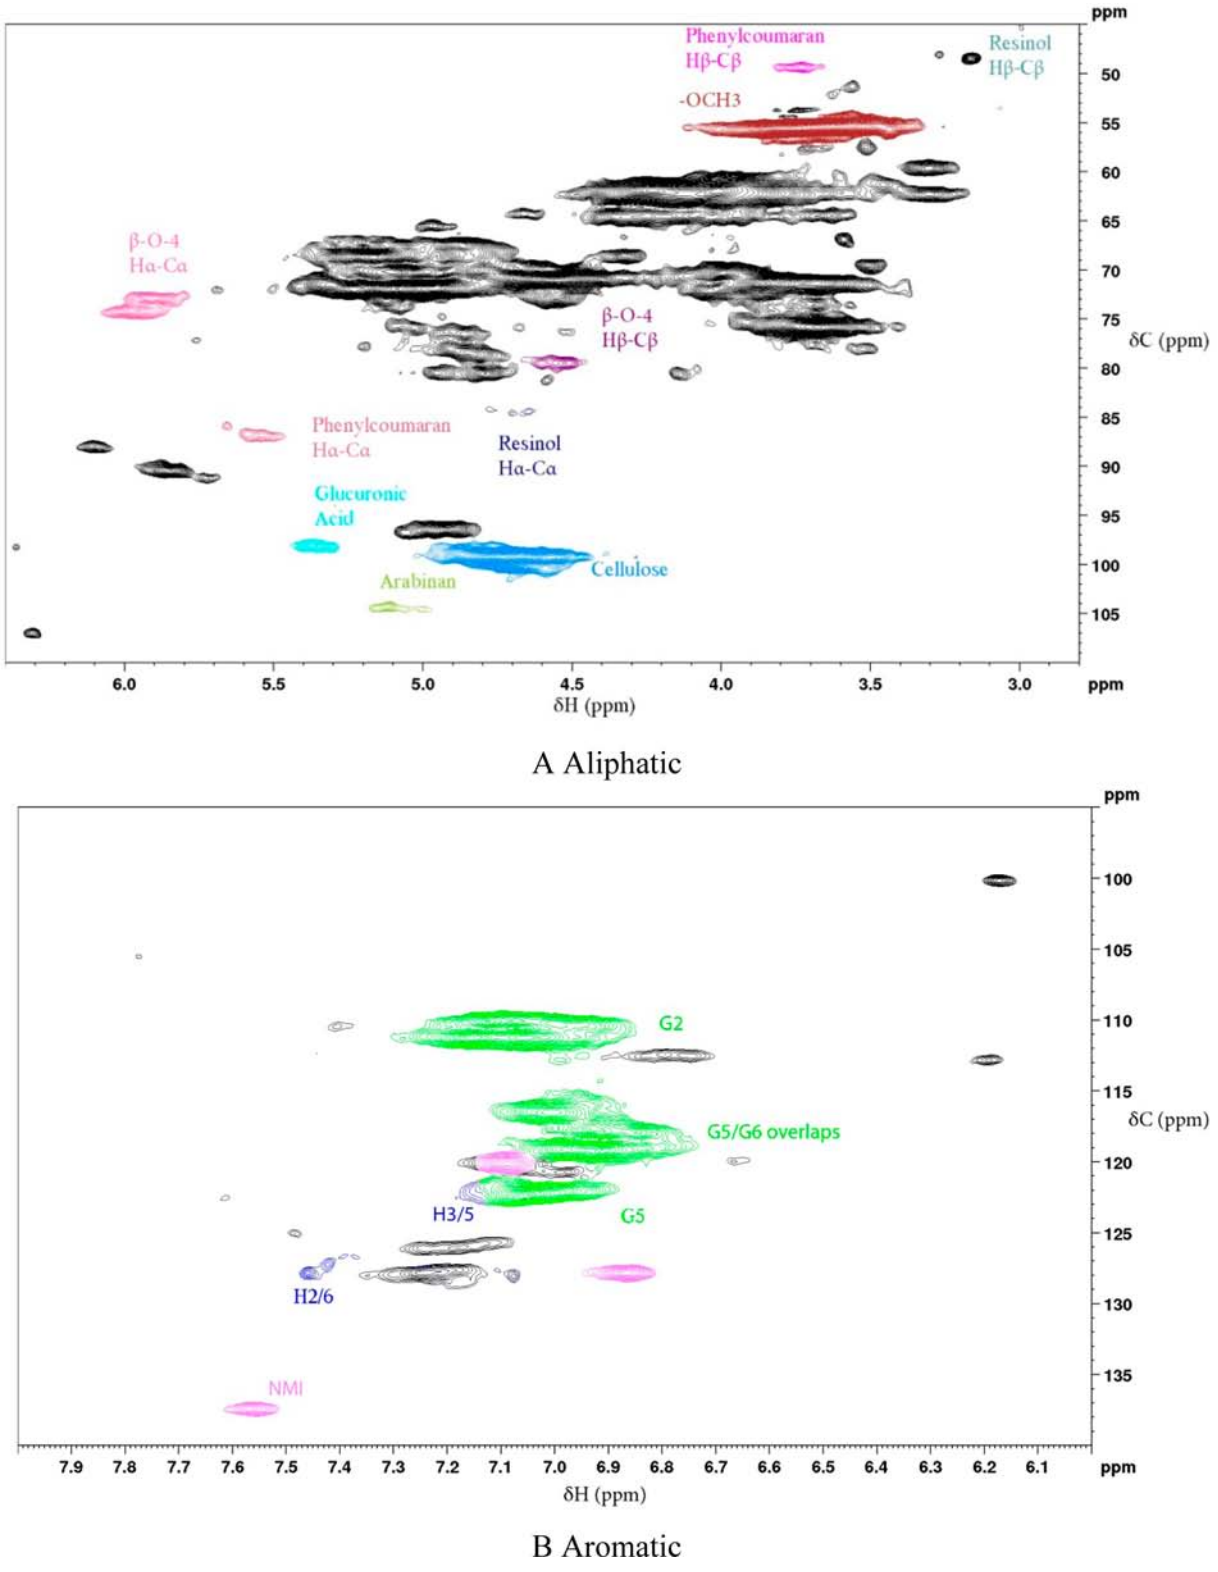

Figure 10. HSQC spectra of ONP: (A) aliphatic region; (B) aromatic region.

contamination due to incomplete washing was detected. This did not affect the NMR quantification as *N*-methylimidazole peaks did not overlap with regions that were used for quantification. The H_2-C_2 correlation in G units is also well-resolved in the HW aromatic region of the HSQC spectra. The low proportion of H is a characteristic of woody tissues.

As expected, the major lignin inter C_9 unit linkage is *β-O*-4. A slight reduction in the amount of this linkage in HW for mesophilic and thermophilic decomposition respectively was observed (Table 1). Anaerobic decomposition resulted in a decrease in the amount of *β-O*-4 linkage brought about by *α*-oxidation. For both mesophilic and thermophilic anaerobic

[a]I = initial material; M = mesophilic decomposition; T = thermophilic decomposition; ND = no data was acquired for SW degraded samples. [b]Determined by wet chemistry.

decomposition of HW, α-carbonyl ($S_{2/6}$ α-ketone) slightly increased (data not shown).

The NMR spectra of decomposed SW were not acquired because there is no evidence of lignin degradation observed using degradative methods as described previously. The spectrum of the initial material is presented here for completeness (Figure 9).

The aliphatic region of the ONP HSQC spectrum (Figure 10A) is quite similar to that of SW with the well-resolved H_2-C_2 correlation of the G aromatic peak (δ_H/δ_C = 7.01 ppm/110.8 ppm). The majority of the lignin inter C_9 unit linkages are *β-O*-4, which was observed to decrease for mesophilic and thermophilic decomposition (Table 1). Decrease in resinol and phenylcoumaran content was observed in mesophilic anaerobic decomposition of ONP.

In the aromatic region (Figure 10B), the absence of the $S_{2/6}$ peak confirms that the ONP sample was made from SW pulp. The low proportion of the H group is a characteristic of woody tissues as observed in HW and SW. It is interesting to note that, similar to HW, the amount of G decreased when compared with the initial material (Table 1).

The HSQC spectra showed only slight reductions in *β-O*-4 linkage, suggesting no significant lignin depolymerization for any substrate. The loss of H_2-C_2 of G units in HW and ONP is surprising as it is well-documented that the S units are more reactive than G units. This could be a subject of further research. Nonetheless, the Klason and acid soluble lignin data as well as CuO lignin data indicate no substantial depolymerization of lignin. It is possible that the loss of the G_2 region in HW and ONP is primarily a result of side chain reactions with no destruction of the aromatic structure. The study suggests that the presence of lignin in its natural form will result in carbon storage from plant biomass in a strictly anaerobic environment such as the deep layer of soil and marine sediments. In addition, the varying reactivity of different plant tissues has implications on the estimates of life cycle emissions of forest products where wood and similar tissues are treated as having the same decomposition rates under current greenhouse gas reporting protocols.[49]

[a]Reaction conditions: 4 mL of reaction mixture containing 0.4 mmol of soybean oil and 1.6 mmol of different alcohols, *n*-heptane used as the solvent, 50 °C, 150 rpm, 10% enzyme based on oil weight, a_w = 0.225. [b]pCPL-GX: partially purified lipase prepared from the crude *Carica papaya* latex bought from Guangxi province. [c]pCPL-GD: partially purified lipase prepared from the crude *Carica papaya* latex bought from Guangdong province. [d]"One" represents one step addition of alcohol at 0 h; "three" represents three step addition of alcohol at 0 h, 6 h, and 14 h, respectively.

the *Carica papaya* latex is needed. In other words, the insoluble substance is treated as a waste during papain purification. However, the CPL is attached to the insoluble substance. Recovering the waste insoluble substance can be used as a new product (CPL) and play a role in waste recycling. According to the preliminary estimate, the price of CPL is approximately about one-third that of crude *Candida rugosa* lipase and 1/30 that of Novozym 435.[12,13] In this work, this low cost CPL was investigated as a catalyst to catalyze the FABE production. The cost of enzymatic butyl-biodiesel production would be considerably reduced by using this low cost plant lipase.

MATERIALS AND METHODS

Materials. Crude *Carica papaya* latex was bought from Guangzhou Huaqi Biotech Co., Ltd. (Guangdong province, China) and Biology Institute, Guangxi Academy of Sciences (Guangxi province, China). *Pistacia chinensis* Bunge oil, *Jatropha curcas* L. oil, sunflower oil, corn oil, cottonseed oil, castor oil, olive oil, soybean oil, rapeseed oil, and peanut oil were all purchased locally. Standard alkyl esters of palmitic acid, stearic acid, oleic acid, linoleic acid, linolenic acid, erucic acid, ricinoleic acid, and heptadecanoic acid were bought from Sigma and were chromatographically pure. All other chemicals and reagents were obtained commercially and were of analytical grade. All the organic solvents were treated with 3 Å molecular sieves for several days before being used.

Preparation of Partially purified *Carica papaya* Lipase. The partially purified *Carica papaya* lipase was prepared according to the reported method with modification.[14] To 20 g of the crude *Carica papaya* latex was added 200 mL of deionized water at 4 °C with gentle stirring for 30 min. The resultant solution was centrifuged at 10000 rpm for 15 min, and the supernatant was discarded. This procedure was repeated three times. The remaining precipitate was then collected and fast frozen using liquid nitrogen and then lyophilized for 8 h. This preparation was used as partially purified *Carica papaya* lipase (pCPL) in this work. Notations pCPL-GX and pCPL-GD refer to pCPL prepared from the crude *Carica papaya* latex bought from Guangxi province and Guangdong province, respectively.

Water Activity (a_w) Equilibration. In order to control the initial a_w of the CPL catalyzed reaction, the CPL, substrates and reaction solvents were separately adjusted to the desired a_w in sealed containers for at least 2 days, at 25 °C, with the vapor phase of saturated salt solutions of known a_w: KNO_3 (a_w 0.936), KCl (a_w 0.843), NaCl (a_w 0.753), $Mg(NO_3)_2$ (a_w 0.528), K_2CO_3 (a_w 0.432), $MgCl_2$ (a_w 0.328), CH_3COOK (a_w 0.225), LiCl (a_w 0.113), and 3 Å molecular sieves (a_w 0.02).

General Procedure for CPL Catalyzed Biodiesel Production in Batch Reactor. A certain molar ratio of vegetable oil and alcohol in an organic solvent (4 mL) was mixed with appropriate amount of pCPL in a 25 mL screw capped vial. The average molecular weight of different oil was calculated according to the formula M (g/mol) = 56.1 × 1000 × 3/(SV − AV), where SV is the saponification value (mg KOH/g oil) of the oil and AV is the acid value (mg KOH/g oil) of the oil. SV and AV can be obtained by the methods of Chinese National Standard GB5534-85 and GB/T5530-1998, respectively. The average molecular weight of different oil obtained in this method was used to calculate the molar ratio in each experiment. The alcohol may be added by a one-step method (at 0 h) or a three-step method (at 0 h, 6 h, and 14 h). The reactions were carried out at different temperatures and 150 rpm in a thermostated shaker. Aliquots (50 μL) of the reaction mixture were taken at intervals and centrifuged at 10000 rpm for 5 min. Samples (6 μL) were withdrawn and mixed with 7.5 μL of 20 mM heptadecanoic acid methyl ester (served as internal standard) and 136.5 μL of *n*-heptane, and were analyzed by gas chromatography.

Continuous Biodiesel Production in the CPL Packed-Bed Reactor. Figure S1 in the Supporting Information shows the schematic diagram of the packed-bed reactor (PBR) experimental apparatus. A column (1.5 cm × 25 cm) with a water jacket was packed with a mixture of pCPL-GD and glass beads (1:1.5, w/w) as the CPL packed-bed reactor. The upper and lower ends of the column were layered with glass wool. The substrate mixture was mixed by a stirrer in the substrate reservoir and preheated by a constant temperature bath. Then the substrate mixture was fed upward through the column by a peristaltic pump. The system temperature was maintained by a circulating water bath. The reaction progress was monitored by analyzing regular samples with gas chromatography.

Gas Chromatography. Samples prepared as described above were analyzed by injecting 1 μL of *n*-heptane solution and internal standard

into an Agilent 6890 gas chromatograph, equipped with a HP-5 capillary column (5% phenyl methyl siloxane capillary, 30.0 m × 320 μm × 0.25 μm nomimal). The column temperature was kept at 180 °C for 1 min, heated to 300 °C at 10 °C/min, and then maintained for 2 min. The temperatures of the injector and detector were set at 260 and 280 °C, respectively. All samples were measured in triplicate, with reproducibility always within 3%. The qualitative analysis of different fatty acid alkyl esters was based on the retention time of standard fatty acid alkyl ester on the GC. Because the standard fatty acid isobutyl ester, amyl ester, and isopentyl ester could not be obtained from commercial suppliers, some assumptions in qualitative analysis of these fatty acid alkyl esters were made based on the fatty acid composition of different oils and the retention time of different standard fatty acid methyl esters and/or fatty acid ethyl esters.

RESULTS AND DISCUSSION

Comparison of Different CPL Source and Alcohol Acyl Acceptor. *Carica papaya* is a soft-stemmed and unbranched tree able to grow up to 20 m in height. As a native to the Central America, the papaya tree has been successfully established in many ecological niches in tropical and subtropical climates. China is now one of the papaya distribution centers. Papaya mainly is distributed in the south provinces of China such as Guangdong, Guangxi, Hainan, Yunnan, Fujian, Sichuan, Guizhou, and Taiwan. The largest papaya output is produced in Guangdong and Guangxi. Therefore, the crude *Carica papaya* latex produced in Guangdong and Guangxi was chosen as the source of different CPL in this work. Gandhi et al.[15−17] and Caro et al.[18] reported that the crude papaya lipase showed strict selectivity toward the alcohol acyl acceptor in catalyzing esterification or transesterification reaction. In order to achieve the naturally immobilized CPL catalyzed alcoholysis of vegetable oil for biodiesel production, the selectivity of pCPL-GX and pCPL-GD toward different alcohol acyl acceptor was first investigated. The results are shown in Table 1. As for the primary alcohols, the conversion increased along with the increase of carbon chain length. This result was consistent with previous works.[15−18] When making comparison between primary alcohols and secondary alcohols, it could be found that using secondary alcohols except isopropanol as acyl acceptors resulted in conversions similar to those of primary alcohols. These results were not in accordance with the previous works, which reported that the conversions obtained by using secondary alcohols as acyl acceptors were lower than those obtained by using primary alcohols as acyl acceptors.[15−18] Comparison between one-step addition and three-step addition of alcohol acyl acceptor showed that the inhibition of methanol on CPL activity was the largest, followed by the ethanol. Step addition of methanol and ethanol to reduce their amount in the reaction system could decrease their inhibition on CPL activity. Alcohol acyl acceptor with a carbon chain length more than three would not impair the CPL activity because one-step and three-step addition of the alcohol gave almost the same conversions. As far as the CPL source is concerned, the pCPL-GD catalyzed alcoholysis gave rise to higher conversions than those of pCPL-GX catalyzed alcoholysis. The pCPL-GD was chosen for the following study. The *n*-butanol can be produced by fermentation, and its boiling point is moderate. In order to fulfill complete renewable biodiesel production, the *n*-butanol was chosen as the acyl acceptor in the following experiments.

Effect of Reaction Solvents. Lipases are diverse in their sensitivity to solvents with different polarity. Log *P* is an index of the polarity of the solvent and is generally used to correlate solvent polarity with enzyme activity and stability in non-aqueous media. According to log *P* trends, the less hydrophobic the organic solvent, the lower the activity of enzyme in the solvent.[19] Organic solvents with various log *P* values were taken as reaction solvents to investigate their effects on the CPL catalyzed butanolysis. The results are shown in Figure 1. In the presence of organic solvents having log *P* greater than 3, the conversions were all high. The highest conversion was attained in *n*-heptane solvent. Solvents with log *P* values below 3 were not suitable for CPL catalyzed butanolysis. The CPL catalyzed alcoholysis activities (conversions) were better correlated with the log *P* values of the reaction solvents. Only the acetonitrile was an exception. Similar activity correlation was also found in CPL catalyzed alcoholysis resolution of amino esters in our previous work.[20]

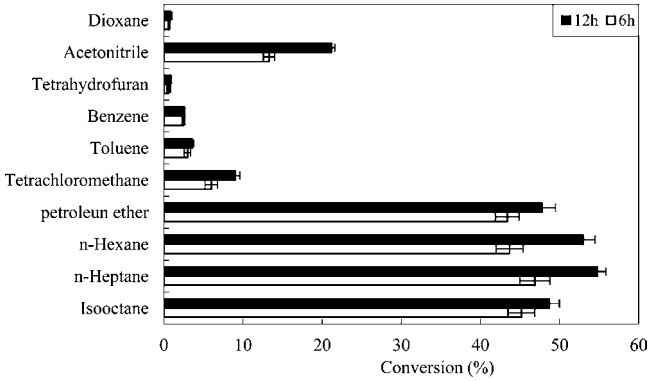

Figure 1. Effect of reaction solvents on the pCPL-GD-catalyzed alcoholysis of soybean oil with *n*-butanol. Reaction conditions: 50 °C, 150 rpm, *n*-butanol/soybean oil molar ratio of 4:1, 10% pCPL-GD based on oil weight, a_w = 0.225.

Effect of Substrate Molar Ratio. In Table 1, the conversions of CPL catalyzed alcoholysis reactions remained almost the same after 12 h. This showed that the reactions reached equilibrium at 12 h. In Figure 1, the conversions attained at 12 h were only a little higher than those attained at 6 h. This showed that the conversions increased slowly after 6 h. Caro et al. reported that the optimal alcohol/triacylglycerol molar ratio for crude papain lipase catalyzed interesterification was as high as 40:1.[18] Therefore, we hold that the conversions not increasing or increasing slowly along with the reaction time resulted from low molar ratio of alcohol/oil (4:1) used in our experiments. The molar ratio used was so low that the CPL catalyzed alcoholysis reaction reached equilibrium at lower substrate conversion. Various substrate molar ratios were performed to test their effects on the CPL catalyzed butanolysis reaction. As showed in Figure 2, the conversion increased along with the increase of alcohol/oil molar ratio until 12:1, attained the maximum at 12:1, and then decreased with the increase of alcohol/oil molar ratio. On one hand, the CPL catalyzed butanolysis reaction required excessive *n*-butanol to drive the reaction forward. Alcohol/oil molar ratio less than 12:1 could not satisfy this requirement, and thus led to low conversion. On the other hand, along with the increase of *n*-butanol addition the log P_{mix} of mixed solvent formed between *n*-heptane and *n*-butanol would decline gradually.[21] The low log P_{mix} of mixed solvent affected the CPL activity adversely (Figure 1), which could explain the reason that the conversion would decrease when alcohol/oil molar ratio was more than 12:1.

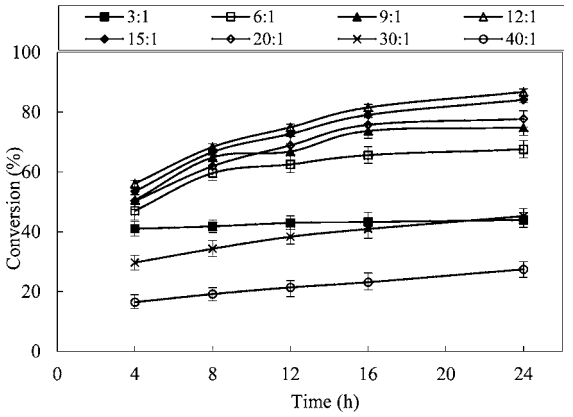

Figure 2. Effect of the alcohol/oil molar ratio on pCPL-GD-catalyzed alcoholysis of soybean oil with *n*-butanol. Reaction conditions: 50 °C, 150 rpm, 10% pCPL-GD based on oil weight, a_w = 0.225.

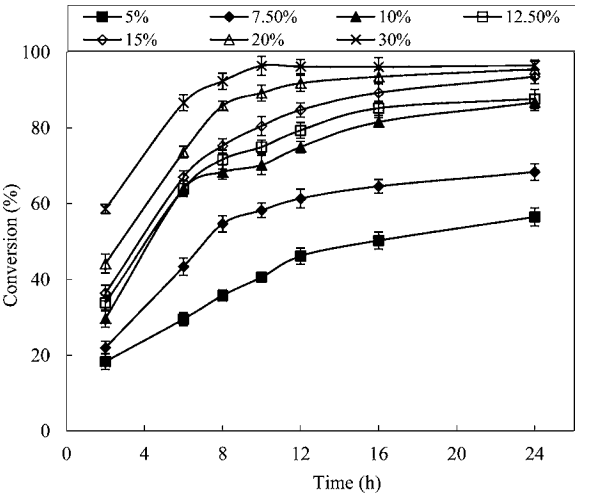

Figure 3. Effect of the pCPL-GD amount on the alcoholysis of soybean oil with *n*-butanol. Reaction conditions: 50 °C, 150 rpm, alcohol/oil molar ratio of 12:1, a_w = 0.225, reaction time 24 h.

In addition to being an important chemical raw material, *n*-butanol can also be used as solvent for the extraction of oilseeds, herbs, and spices. In this work, the optimal alcohol/oil molar ratio for CPL catalyzed butanolysis reaction was 12:1, at which the amount of *n*-butanol had exceeded that of oil. Therefore, the *n*-butanol was taken as both the reaction solvent and acyl acceptor for further investigation. As shown in Figure S2 in the Supporting Information, the CPL could catalyze the biodiesel production with *n*-butanol as the reaction solvent and acyl acceptor at the same time. However, the conversions attained were obviously lower than those obtained in the organic solvents at the same alcohol/oil molar ratio. The *n*-butanol is a medium polar solvent with a log *P* value of 0.8, which could impair the CPL activity to some degree just as in the discussion in Effect of Reaction Solvents.

Effect of CPL Amount. The previous work reported that the reaction rate of crude papain lipase catalyzed alcoholysis increased along with the increase of CPL addition amount until 15%.[17] Foglia and Villeneuve found that 15% of crude papain could lead to the best transesterification effect.[22] In this work, the CPL used was partially purified from the crude *Carica papaya* latex, and free from the water-soluble matter such as the proteases. Therefore, the effect of CPL amount was examined with amount ranging from 5% to 30% on the weight base of oil. The results are shown in Figure 3. There was a gradual increase in the conversion with the CPL amount increasing from 5% to 15%, and the conversion increased continuously with the lengthening of reaction time during 24 h. The conversion increased unobviously when the CPL amount was more than 15%. The alcoholysis reaction equilibrated at 12 h when 20% of CPL amount was used, and equilibrated at 10 h when 30% of CPL amount was used. In contrast, 15% was the optimal CPL addition amount. At first glance, the results obtained in this work were very inconsistent with the previous works.[18,22] In their works the optimal enzyme amount was 15% when the crude papain lipase was used. In this work the partially purified CPL was used, and thus the optimal enzyme amount should be much lower than 15%. Through analyzing their works in detail, it was found that the enzyme addition amount was calculated on the basis of all the substrates. However, the CPL addition amount was calculated only on the basis of oil not including the *n*-butanol in this work. According to the same addition amount of 15%, the enzyme amount used in their work was about 40 times higher than that used in this work. From Figure 3, it was also found that the conversion exceeded 80% at 24 h when more than 10% of CPL amount was used. The CPL shows sn-3 stereoselectivity in hydrolysis or interesterification of triacylglycerols.[8,11,18,22] In theory, the conversion should not surpass 67% in the CPL catalyzed alcoholysis reaction. However, more than 80% conversions were obtained in this work. Therefore, acyl transfer had been thought to occur during the CPL catalyzed alcoholysis.[23]

Effect of Temperature. Temperature has a clear impact on the catalytic activity of lipases. Some plant lipases derived from plant extracts can be catalytically active at temperatures above their physiological activity temperature.[24] Optimum temperature determined for various plant lipases used in biosynthesis generally ranges between 30 and 55 °C.[24] The effect of temperature on CPL catalyzed butanolysis reaction was investigated in the range from 45 to 70 °C. As showed in Figure 4, the CPL showed high catalytic activity between 50 and 60 °C with the 55 °C as the optimum temperature. This result was consistent with the previous works.[18,20] The optimum temperature range of CPL catalyzed biodiesel production is similar to that of commercial Novozym 435.[25]

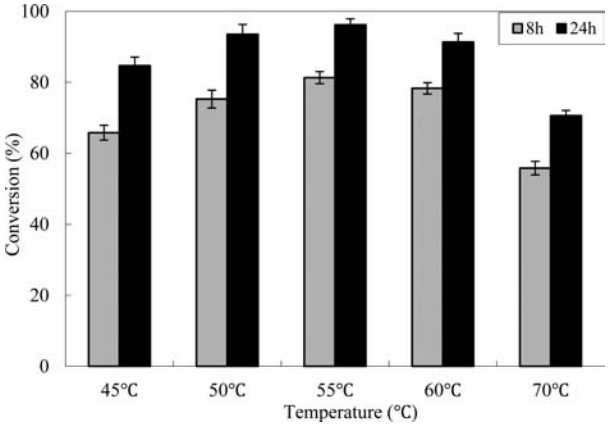

Figure 4. Effect of the temperature on the pCPL-GD-catalyzed alcoholysis of soybean oil with *n*-butanol. Reaction conditions: 150 rpm, alcohol/oil molar ratio of 12:1, 15% pCPL-GD based on oil weight, a_w = 0.225.

dx.doi.org/10.1021/jf501993v | J. Agric. Food Chem. 2014, 62, 6375−6381

Effect of Water Activity. The water thermodynamic activity (a_w) is conditioning the lipase spatial structure and thus its catalytic activity either toward synthesis or hydrolysis. For each lipase catalyzed synthesis reaction performed in nonaqueous system, an initial hydration level ruled by the initial a_w, for which the best synthesis performance is obtained, does exist.[4] The effect of a_w on the CPL catalyzed butanolysis reaction was investigated at various initial a_w (from 0.02 to 0.936). As shown in Figure 5, the conversion exhibited a bell

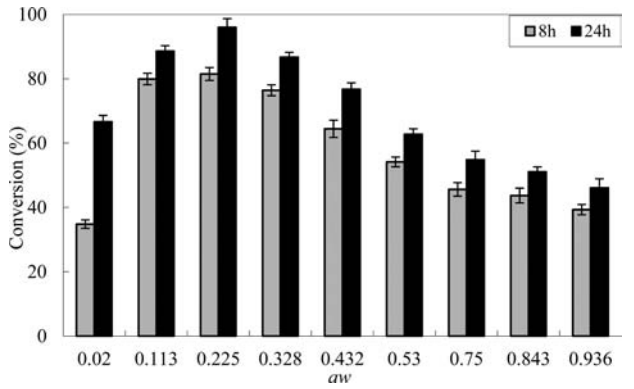

Figure 5. Effect of the water activity on the pCPL-GD-catalyzed alcoholysis of soybean oil with *n*-butanol. Reaction conditions: 55 °C, 150 rpm, alcohol/oil molar ratio of 12:1, 15% pCPL-GD based on oil weight.

shape, when the reaction conversion was plotted as a function of water activity. The CPL showed the maximum catalytic activity at 0.225 water activity, which generated a conversion of 96%. The conversion was about 2 times lower than the maximum at higher water activity of 0.936. These results suggested that water activity strongly influenced the hydration level of the CPL, which in turn affected the catalytic activity. At lower water activity the CPL showed lower catalytic activity due to the shortage of water to form enough oil−water interfaces. However, at higher water activity the CPL showed lower conversion, and this could be due to aggregation of enzyme or increased reverse hydrolysis reaction.

CPL Catalyzed Butanolysis of Other Vegetable Oils. In the above the soybean oil was taken as a model substrate to investigate the CPL catalyzed butanolysis for biodiesel production. Several key parameters had been optimized. In order to further investigate the capacity of CPL catalyzed biodiesel production, some other vegetable oils were chosen as the substrates. The result is shown in Figure 6. All the vegetable oils tested attained high conversion (about 90%), which showed that the CPL could catalyze the butanolysis of different oils, and could be used as a promising lipase for biodiesel production.

Continuous Biodiesel Production in the CPL Packed-Bed Reactor. The selection of a proper reactor type is critical to bioprocesses and plays a major role in large-scale production. The bioreactors widely used in today's bioindustry are mainly those developed in the past decades purely for chemical reactions. Among them, batch stirred tank reactor (BSTR) and packed-bed reactor (PBR) find the widest application. Batch reactor is often used in the laboratory for experiments of reaction kinetics, thermodynamics, and small scale production. It has the disadvantages of high labor costs per batch, the variability of products from batch to batch, and the difficulty of

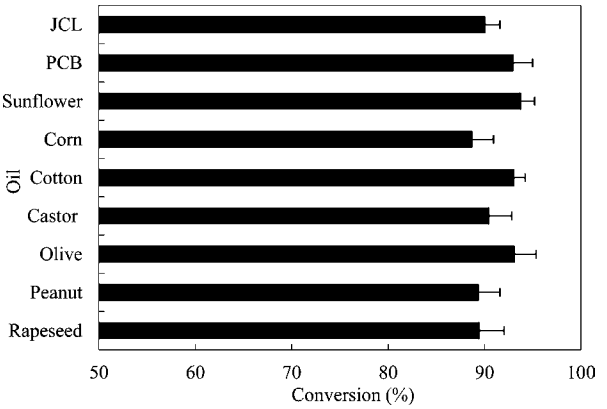

Figure 6. pCPL-GD-catalyzed alcoholysis of different oils with *n*-butanol. Reaction conditions: 55 °C, 150 rpm, alcohol/oil molar ratio of 12:1, 15% pCPL-GD based on oil weight, a_w = 0.225; JCL, *Jatropha curcas* L. seed oil; PCB, *Pistacia chinensis* Bunge seed oil.

large-scale production. Continuous PBR may be a way to solve the problems mentioned. The PBR can offer low cost, high efficiency, high stability of enzyme, automatic separation of product from enzyme, and ease of operation.[26] It may provide many opportunities for transferring the protocols of enzyme-catalyzed synthesis from the laboratory to an industrial scale. After systematic investigation of the CPL catalyzed butanolysis in the batch reactor, a CPL packed-bed reactor was further developed for the continuous biodiesel production.

Effect of Residence Time. The residence time of the reactants inside the reactor is one of the most important factors in the PBR, and it is defined as the average time that the reactants spend in a PBR. The effect of residence time on the CPL catalyzed butanolysis in PBR was investigated by varying the substrate feed flow rate. As shown in Figure S3 in the Supporting Information, the conversion increased fast with the decrease of flow rate because of the long residence time of substrates in the PBR. The conversion reached about 96% at the residence time of 40 min, and remained almost the same after 40 min. The residence time determined the contact time between the substrates (soybean oil and *n*-butanol) and the CPL. At the shorter residence time, the CPL did not have enough time to catalyze the alcoholysis of soybean oil with *n*-butanol, and thus generated lower conversion.

Long-Term Operation of PBR System. The long-term operational stability of the enzyme is an important characteristic of the PBR. For the CPL catalyzed butanolysis in the PBR, the long-term operational stability was examined under the operational parameters optimized at batch reactor. As shown in Figure 7, the operational stability of the PBR system was longer than 150 h, and the conversion was maintained almost the same during this continuous reaction time. When calculating on the basis of the optimal residence time of 40 min, 150 h was equivalent to 225 batches. The high operational stability of this CPL packed-bed reactor mainly resulted from the high stability of CPL. The cost of lipase necessary for the biodiesel production plays a decisive role in determining whether a process could possibly be considered by the industry. For a certain amount of lipase, the cost could be reduced by improving its operational stability. In this work, the CPL showed a very high operational stability in the PBR. Hence, the alcoholysis continuously catalyzed by CPL in the PBR has the potential for being applied in the large-scale production of biodiesel. Furthermore, the PBR system developed in this work

dx.doi.org/10.1021/jf501993v | J. Agric. Food Chem. 2014, 62, 6375−6381

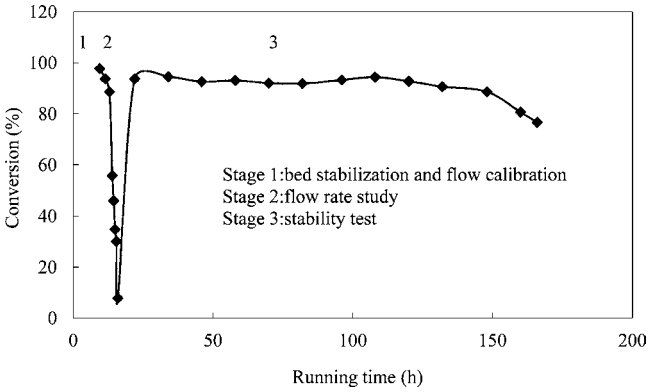

Figure 7. Operational stability of the pCPL-GD packed-bed reactor for continuous alcoholysis of soybean oil with *n*-butanol. Reaction conditions: 55 °C, alcohol/oil molar ratio of 12:1, residence time of 40 min, a_w = 0.225.

held another advantage, namely, the glycerol produced in the alcoholysis could dissolve in the *n*-butanol, and thus an auxiliary glycerol-separating system integrated with the PBR was not necessary.[27]

In conclusion, the alcohol acyl acceptor, reaction solvent, alcohol/oil molar ratio, enzyme amount, reaction temperature, and water activity all affected the CPL catalyzed alcoholysis process. Under the optimized conditions, the highest conversion of about 96% could be attained in 24 h. The CPL packed-bed reactor could stably operate for more than 150 h, which showed obvious potential for large-scale production. Therefore, the low cost naturally immobilized *Carica papaya* lipase was successfully used to catalyze butanolysis for butyl-biodiesel production in this work.

damage or injury because of insects or fungal infection. They were manually separated into pulp and pericarp. The latter was immediately washed and freeze-dried for 72 h, and then they were ground into fine powders. These fine powders were stored at −20 °C before analyses.

Extraction and Fractionation of PAs. Freeze-dried powders (10.0 g) were ultrasonically extracted with 7:3 (v/v) acetone/water solution containing 0.05% ascorbic acid (3 × 250 mL) at room temperature. Each extract was filtered and pooled, and the acetone was removed by evaporation under vacuum (40 °C). The remaining aqueous residue was subsequently extracted three times with petroleum ether (3 × 150 mL) and ethyl acetate (3 × 150 mL), yielding dried crude tannin extracts. The crude tannin fraction was chromatographed on a 50 × 1.5 cm i.d. Sephadex LH-20 column (Pharmacia Biotech, Uppsala, Sweden), the column was washed with 500 mL of methanol/water (50:50, v/v) to remove sugars, glycosides, and monomeric polyphenols and then eluted with methanol/H_2O (80:20, v/v), acetone/methanol/H_2O (40:40:20, v/v/v), and acetone/water (70:30, v/v) to obtain fraction A (FA), fraction B (FB), and fraction C (FC) (each 500 mL), respectively. Organic solvents were removed, and the remaining aqueous fractions were freeze-dried. Their yields were calculated and are listed in Table 1. Three fractions were freeze-dried after the organic solvents were eliminated and stored at −20 °C before analyses. The fractionation experiment was repeated three times. In addition, UV−vis spectra of three fractions showed a pronounced and symmetrical peak near 280 nm with no band broadening beyond 300 nm. This kind of spectrum is typical of the PAs.

MALDI-TOF MS Analysis. MALDI-TOF MS analysis was performed by using a Bruker Reflex III MALDI-TOF mass spectrometer (Bruker, Bremen, Germany). The parameters for positive mode spectra in the reflectron mode and linear mode were set according to our previous study.[15] Parameters for positive pattern spectra in the reflectron pattern were as follows: accelerating voltage, 20 kV; reflectron voltage, 23.0 kV; delayed extraction voltage, 16.32 kV; lens voltage, 9.45 kV. Parameters for positive pattern spectra in the linear pattern were as follows: accelerating voltage, 20.0 kV; delayed extraction voltage, 16.25 kV; lens voltage, 10.0 kV. Cs^+ was used as the cationization and 2,5-dihydroxybenzoic acid was selected as the matrix. Amberlite IRP-64 cation-exchange resins (Sigma-Aldrich, USA) were used to deionize the analyte and matrix solution. An aqueous solution of cesium chloride (1.5 μL, 1.52 mg/mL in aqueous) was added to the sample solution (1.5 μL, 10 mg/mL in 30% aqueous acetone) followed by the addition of an equal volume of 2,5-dihydroxybenzoic acid (10 mg/mL in aqueous). The mixture (1 μL) was spotted to a steel target and introduced into the mass spectrometer.

Thiolysis of Polymeric PAs for Reversed-phase HPLC-ESI-MS Analysis. A thiolysis method based on that described by Guyot et al.[16] was carried out with a minor modification. Degradation products of thiolysis were analyzed by reversed-phase HPLC-ESI-MS. PAs used for thiolysis were 5 mg/mL. The high-performance liquid chromatograph (HPLC) was performed on an Agilent 1200 system (USA). The thiolysis medium was further analyzed using LC-MS (QTRAP 3200, USA). Two solvents, 0.5% trifluoroacetic acid (A) and acetonitrile (B), were used. The linear gradient elution process was as follows: 0−45 min, 12−80% B; 45−50 min, 80−12% B. The column temperature was 25 °C, and the flow rate was 1 mL/min. The detection wavelength was set at 280 nm. Degradation products were identified on chromatograms according to their retention times and LC-MS. The calculation of the mean degree of polymerization (mDP) was based on the following equation:

$$\text{mDP} = (\text{total area of the extender units}) / (\text{total area of the terminal units}) + 1$$

Normal-Phase HPLC-ESI-MS Analysis. The HPLC equipment consisted of an Agilent 1200 liquid chromatograph system as described above. Concentration values of the solutions used for analysis were 5 mg/mL. The column temperature was 35 °C, and the injection volume was 20 μL. The mobile phase consisted of A, dichloromethane/methanol/water/acetic acid (41:7:1:1, v/v/v/v), and B, dichloromethane/methanol/water/acetic acid (5:43:1:1, v/v/v/v). The 60 min linear gradient was as follows: 0−13.5% B (0−20 min); 13.5−29.2% B (20−50 min); 29.2−100% B (50−55 min); 100% B (55−60 min).[17] Then the eluting stream (1 mL/min) was introduced into a QTRAP 3200 mass spectrometer. Peaks were identified on chromatograms according to their retention times and LC-MS.

Enzyme Assay. *Inhibitory Effects Assay.* Enzyme reaction was performed by using a 3 mL system established by our laboratory.[18] In brief, L-tyrosine was selected as substrate for the monophenolase reaction assay and 3,4-dihydroxyphenylalanine was selected as substrate for the diphenolase reaction assay. The reaction medium (3 mL) contained 12 mM L-tyrosine or 0.5 mM 3,4-dihydroxyphenylalanine in 50 mM sodium phosphate buffer (pH 6.8). The final concentrations of tyrosinase were 33.33 μg/mL for the monophenolase reaction and 6.67 μg/mL for the diphenolase reaction. Absorption was detected by using a Beckman UD-800 spectrophotometer (USA). The extent of inhibition by the addition of the sample was expressed as the percentage necessary for 50% inhibition (IC_{50}) for the enzyme activity assay. A lower value of IC_{50} indicates better anti-tyrosinase activity. Controls, without inhibitor but containing equal H_2O, were routinely carried out. All measurements were carried out at 30 °C.

Inhibitory Mechanism and Type Assay. An inhibitory mechanism assay was carried out by changing the enzyme concentration in the reaction medium. The plots of the remaining enzyme activity versus the concentrations of enzyme in the presence of inhibitors with diffierent concentrations gave a family of straight lines. If the inhibition is reversible, all straight lines intersect at the origin; when the inhibition is irreversible, these straight lines are parallel. An inhibition type assay was achieved by changing the substrate concentration in the reaction medium. The inhibition type was assayed by using a Lineweaver−Burk plot.

Fluorescence Emission Spectra of Mushroom Tyrosinase in Solutions with Different Concentration of PAs. The fluorescence assay was measured with a Varian Cary Eclipse fluorescence spectrophotometer. The reaction medium (3 mL) contained 600 μL of mushroom tyrosinase solution, 2.1 mL of 50 mM sodium phosphate buffer (pH 6.8), and 300 μL of sample solution with different concentrations. The experiment was performed with an excitation wavelength of 290 nm at a constant temperature of 25 °C.

Fluorescence Emission Spectra of L-Tyrosine or 3,4-Dihydroxyphenylalanine in Solutions with Different Concentrations of PAs. The fluorescence assay was carried out on a Varian Cary Eclipse fluorescence spectrophotometer. In brief, L-tyrosine (12 mM) or 3,4-dihydroxyphenylalanine (0.5 mM) solution (200 μL) was added into 50 mM sodium phosphate buffer (pH 6.8), and sample solution was then added at a constant temperature of 25 °C (the final

medium is 1 mL), preincubated for 30 s before fluorescence spectra measurements with an excitation wavelength of 290 nm.

DPPH Radical Scavenging Capacity. The DPPH method was achieved in compliance with the study of Brand-Williams et al.[19] with minor modification. Mainly, sample solution (0.1 mL) was mixed with 3 mL of DPPH solution (25 mg/L in methanol). Methanol (0.1 mL) and 3 mL of DPPH served as the control. After the mixture was shaken and kept at room temperature for 30 min, the absorbance at 517 nm was measured. The calculated equation for scavenging percentage of DPPH was

$$\text{DPPH \% inhibition} = [(A_1 - A_2)/A_1] \times 100$$

where A_1 = the absorbance of the control reaction and A_2 = the absorbance in the presence of the sample. The quality of the antioxidants about the PAs was determined by the IC_{50} values (the concentration that led to a 50% decrease in absorbance). A lower value of IC_{50} indicates better antioxidant activity. In addition, Trolox and ascorbic acid were selected as reference. All fractions were analyzed in three replicates.

ABTS Radical Scavenging Activity. ABTS assay was conducted in accordance with the procedure described by Re et al.[20] $ABTS^+$ was generated by reacting 7 mM ABTS and 2.45 mM potassium persulfate after incubation at room temperature in the dark for 16 h. The $ABTS^+$ solution was then diluted with 80% ethanol to an absorbance of 0.700 ± 0.050 at a wavelength of 734 nm. Tested sample solution (0.1 mL) was added to $ABTS^+$ solution (3.9 mL), and the mixture was mixed well. The absorbance of the reactive mixture was recorded at 734 nm on a Beckman UD-800 spectrophotometer after being kept at room temperature for 6 min. The results were expressed the same as for the DPPH assay described previously, with ABTS % inhibition and IC_{50} value.

Ferric Reducing Antioxidant Power (FRAP). The FRAP assay was performed according to the method of Benzie and Strain[21] with slight modification. Mainly, 3 mL of FRAP reagent (10 mM TPTZ, 20 mM ferric chloride, and 300 mM sodium acetate buffer were mixed at a ratio of 1:1:10) was mixed with test sample solution (0.1 mL) or methanol (blank). The absorbance of the reaction mixture at 593 nm was measured after incubation at room temperature for 10 min. The FRAP values, expressed in millimoles of ascorbic acid equivalents (AAE) per gram fraction, were derived from a standard curve. A higher absorbance corresponds to a higher ferric reducing power.

Statistical Analysis. All data were expressed as means ± standard deviation of three independent determinations. One-way analysis of variance was used, and the differences were considered to be significant at $P < 0.05$. All statistical analyses were performed with SPSS 13.0 for Windows.

RESULTS AND DISCUSSION

MALDI-TOF MS Analysis. Reflectron MALDI-TOF MS spectra (Figure 1) of three fractions were obtained when 2,5-dihydroxybenzoic acid was selected as the matrix and Cs^+ was used as the cationization. The results indicated that the studied polymeric mixture exhibited mass spectra with a dominating set of peaks with differences of 288 Da, corresponding to the mass difference of one (epi)catechin monomer unit. Other repeated patterns within each main set of peaks were the signals separated by the subset of masses 16 Da difference. These masses were produced by propelargonidin-type (which lack one hydroxyl group at the 3′-position of the B-ring compared to procyanidin-type flavan-3-ol units) and prodelphinidin-type flavan-3-ol units (which possess one hydroxyl group at the 5′-position of the B-ring compared to procyanidin-type flavan-3-ol units). It was further suggested that the PAs from fruit pericarps of kiwifruit contain prodelphinidin, procyanidin, and prodelphinidin when the absolute masses corresponding to each peak were obtained. Procyanidins were the dominating constituent of kiwifruit pericarp PAs. A series of peaks with additional 132

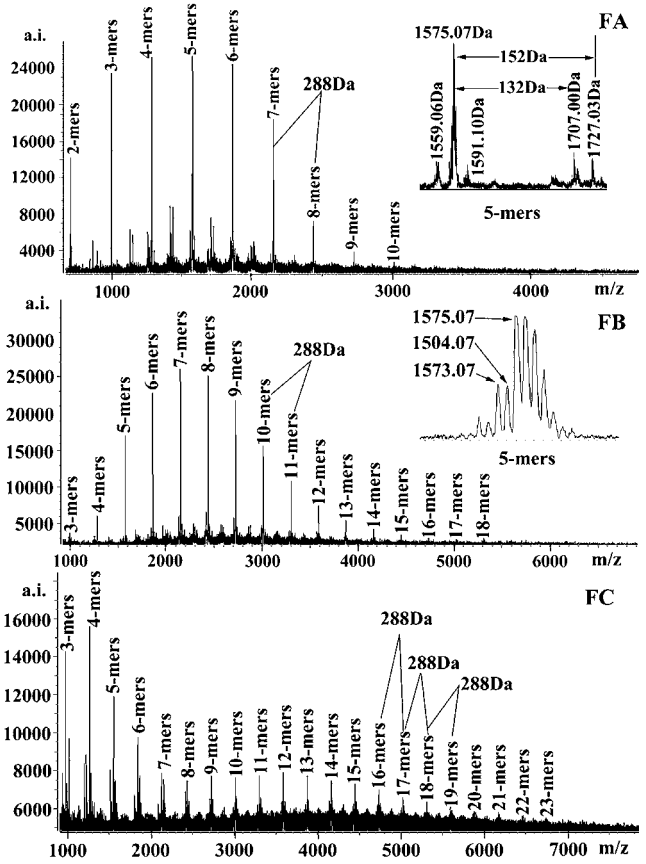

Figure 1. MALDI-TOF positive-ion (Cs^+) mode mass spectra of polymeric kiwifruit pericarp PAs in the reflectron mode.

Da (which are produced by synchronous attachment of two Cs^+ and the absence of a proton $[M + 2Cs^+ - H]^+$)[22] and 152 Da (corresponding to the addition of one galloyl group at the heterocyclic C-ring)[23] were also detected. Additionally, the A-type interflavan linkages with characteristic signals 2 Da smaller than the B-type linked PAs (due to the loss of two hydrogen atoms with the formation of the ether bond) were not detected in the mass spectra.

The distributions of polymerization degree and predominant polymers were clearly different among the three fractions, the DP varying from 2-mers to 10-mers, from 3-mers to 18-mers, and from 3-mers to 23-mers for FA, FB, and FC, respectively. MALDI-TOF mass spectra provided evidence that PAs from kiwifruit pericarp possessed structural heterogeneity and distinct DP distribution in each fraction. In this study, up to 23-mers were present in the spectra of FC, which might be attributed to the improvement of fractionation in the MALDI-TOF MS analysis as stated in a previous paper.[24] Therefore, fractionation of lower oligomers (FA) on the Sephadex LH-20 column would significantly enhance the sensitivity of the detection of larger polymers (FB) under MALDI-TOF MS analysis.

PA polymers extracted from kiwifruit pericarp were then characterized by MALDI-TOF MS in the positive-ion (Cs^+) linear mode (Figure 2). In the mass spectra, an equispaced series of signal groups corresponding to the polymeric distribution of the PAs was observed. The distance between each degree of polymerization was 288 Da. This agreed well with the results obtained from reflectron mode. PAs with DP up to 29-mers could be detected working in the linear mode.

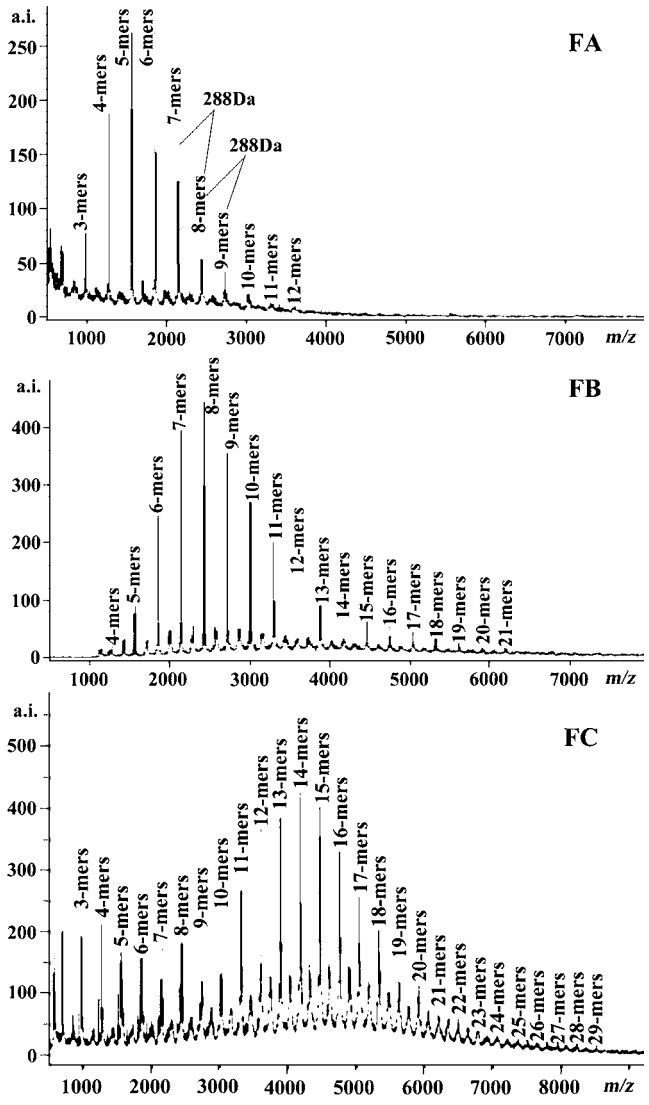

Figure 2. MALDI-TOF positive-ion (Cs^+) mode mass spectra of polymeric PAs extracted from kiwifruit pericarp in the linear mode.

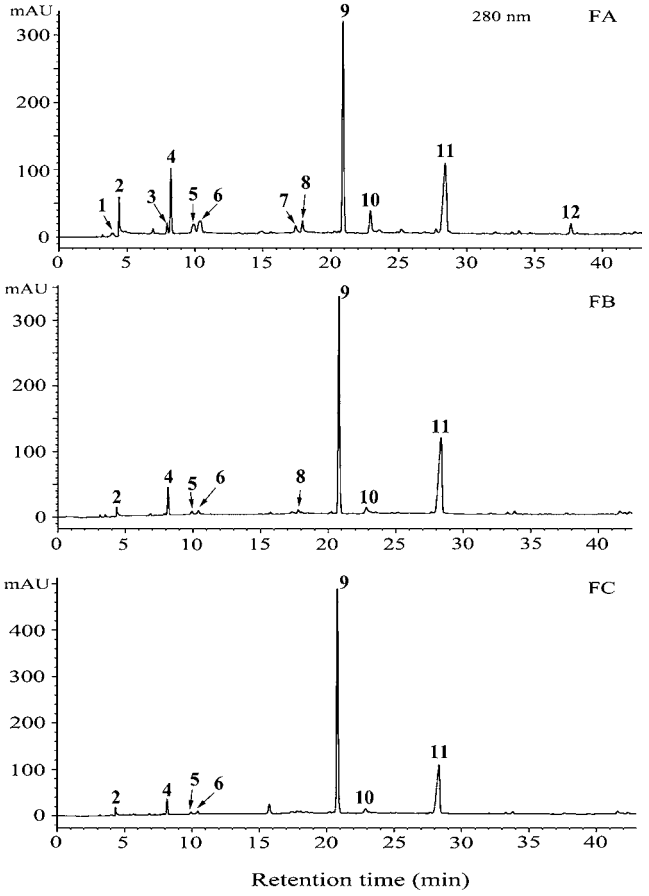

Figure 3. Reversed-phase HPLC chromatograms of polymeric PAs extracted from kiwifruit pericarp after thiolytic degradation. Peaks: 1, gallocatechin (305 Da, $[M - H]^-$); 2, catechin (289 Da, $[M - H]^-$); 3, epigallocatechin (305 Da, $[M - H]^-$); 4, epicatechin (289 Da, $[M - H]^-$); 5, catechin gallate (441 Da, $[M - H]^-$); 6, epicatechin gallate (441 Da, $[M - H]^-$); 7, gallocatechin benzylthioether (427 Da, $[M - H]^-$); 8, epigallocatechin benzylthioether (427 Da, $[M - H]^-$); 9, epicatechin benzylthioether (411 Da, $[M - H]^-$); 10, (epi)afzelechin benzylthioether (395 Da, $[M - H]^-$); 11, benzyl mercaptan.

Therefore, the linear mode provided better information about the DP distribution of the PAs present in the sample. However, high mass resolution power in the reflectron spectrum allowed the mass of the isotopic peaks to be distinguished with enough accuracy (Figure 1).

Reversed-Phase HPLC-ESI-MS Analysis followed Thiolysis Reaction. The chromatograms of thiolytic products of FA, FB, and FC are illustrated in Figure 3. The results showed that the terminal units contained catechin (peak 2), epicatechin (peak 4), gallocatechin (peak 1), epigallocatechin (peak 3), catechin gallate (peak 5), and epicatechin gallate (peak 6) for the FA. However, gallocatechin and epigallocatechin were not detected in FB and FC. The extension units of FA contained (epi)afzelechin (peak 10), epicatechin (peak 9), gallocatechin (peak 7), and epigallocatechin (peak 8), with the epicatechin dominating. However, gallocatechin benzylthioether and epigallocatechin benzylthioether were not found in FB and FC. A-type PAs could not be detected in the chromatogram. The profile after thiolysis demonstrated that PAs extracted from kiwifruit pericarp are B-type procyanidin (the most abundant type of PAs in plants), propelargonidin, and prodelphinidin. B-type procyanidin dominates. These results confirmed the findings obtained from MALDI-TOF MS analysis. In addition, the mDP for the polymers was estimated by thiolysis to be in a range from 4.3 ± 0.3 to 13.6 ± 0.7 (Table 1). The contents of terminal units decreased in the order FA > FB > FC (Table 1).

Normal-Phase HPLC-ESI-MS Analysis. The normal-phase HPLC profile of kiwifruit pericarp PAs is illustrated in Figure 4. The result indicated the presence of PAs with different degrees of polymerization. The good resolution between each oligomeric class suggested that the PAs are quite homogeneous, showing only minor differences in their constituent units and the linkages between them. HPLC performance implied the precise separation of PAs from monomers to 6-mers and the presence of isomers. However, the polymers could not be resolved by normal-phase HPLC. They showed a profile with a single broad peak at the end of the run with a retention time of approximately 55.7 min. No PAs with DP higher than 10-mers could be separated. Our results agreed well with the finding of Gu et al.[17] on the analysis of PAs from lowbush blueberry.

Inhibition Effect, Mechanism, and Type of Kiwifruit Pericarp PAs on the Monophenolase Activity and Diphenolase Activity of Mushroom Tyrosinase. The monophenolase and diphenolase activity may be both

dx.doi.org/10.1021/jf501009v | J. Agric. Food Chem. 2014, 62, 6382−6389

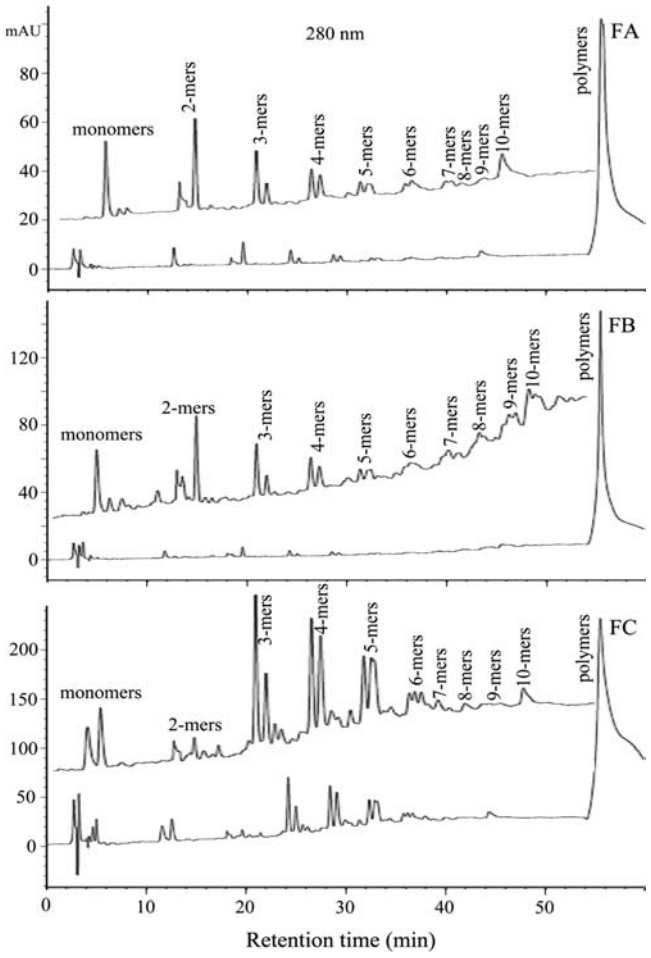

Figure 4. Normal-phase HPLC chromatograms of PAs from kiwifruit pericarp. The degree of polymerization of the peaks is labeled in expanded insets.

negatively affected by adding of kiwifruit pericarp PAs as shown in Table 2. The IC_{50} values for the monophenolase activity were estimated to be 180.2 ± 6.5, 80.1 ± 4.1, and 48.9 ± 4.6 μg/mL for FA, FB, and FC, respectively. As for diphenolase activity, the inhibitor concentrations leading to 50% (IC_{50}) enzyme activity decrease were estimated to be 390.2 ± 12.6, 192.6 ± 10.3, and 64.9 ± 3.2 μg/mL for FA, FB, and FC, respectively. In previous studies, the methanol extracts from sorghum distillery residue[25] and red koji extracts[26] (containing a high percentage of PAs) showed inhibitory effect with IC_{50} values of 580 and 5570 μg/mL on mushroom tyrosinase activity, respectively. Therefore, PAs from kiwifruit pericarp in this study were potent inhibitors on tyrosinase. In the present study, we further found that DP, that is, molecular weight, had an obvious effect on the inhibition of mushroom tyrosinase activity. The PAs with higher DP possessed a better inhibition on the activity of tyrosinase. This revealed the possible use of these compounds (especially FB and FC) as whitening agents, insect control agents, and food additives.

The inhibitory mechanism and type of the three fractions on the monophenolase and diphenolase enzyme reactions were then investigated. The results obtained from inhibitory mechanism analysis showed that the inhibition was reversible. It could be concluded that the presence of inhibitor did not bring down the amount of enzyme, but led to a decrease in activity of the enzyme for oxidation of L-tyrosine and 3,4-dihydroxyphenylalanine. This further indicated that DP had no effect on the inhibitory mechanism. Inhibition type analysis indicated that they were mixed-type inhibitors of the enzyme. The results revealed that these fractions combined with free enzymes as well as enzyme−substrate complexes. The results also displayed that the three fractions had the same type of inhibition on the enzyme.

Fluorescence Quenching Analysis. The fluorescence of tryptophan, which existed in tyrosinase molecules, has been frequently examined to obtain information about conformational changes.[27] The interaction of tyrosinase with PAs and its conformational alteration were evaluated by measuring the intrinsic fluorescence intensity of the protein in the presence or absence of PAs. The fluorescence emission spectra were collected from a range of 300−500 nm with the excitation wavelength set at 290 nm. The result showed that the addition of fractions caused a dramatic decrease in the fluorescence emission spectra. The fluorescence intensity decreased by 51.3, 80.0, and 85.6% (Figure 5A) for FA, FB, and FC, respectively, at 100 μg/mL. Undoubtedly, FC had better interaction with the tryptophan residue in the enzyme than did FA and FB. This indicated that PAs with high DP combined with the tryptophan residue more effectively. Therefore, these findings may be one reason for the strong inhibition of PAs on the tyrosinase. In addition, an obvious blue shift was also present in the spectra of FB and FC. These results indicated that PAs induced the change of enzyme conformation and also led to inactivation of the enzyme after binding to the enzyme molecule. Moreover, the interaction of PAs with the tryptophan of tyrosinase implied that the tyrosinase became disagglomerated and its structure got loosened. It was concluded that the tryptophan residue is one of the essential groups of the enzyme activity and it is situated on the surface of the enzyme and easily influenced by PAs. However, the results showed that PAs of FA did not affect the conformation of tyrosinase. Further study should be carried out to illustrate this. Tyrosinase possesses two copper ions in the active center, and they are of great importance for tyrosinase activity.[28] The inhibitory effects of PAs on the tyrosinase might be due to binding with copper ions (which is

Table 2. Effects of PA Fractions from Kiwifruit Pericarp on the Activity of Mushroom Tyrosinase for the Oxidation of L-Tyrosine and 3,4-Dihydroxyphenylalanine

	monophenolase			diphenolase		
sample	IC_{50}[a] (μg/mL)	inhibition	inhibition type	IC_{50}[a] (μg/mL)	inhibition	inhibition type
FA	180.2 ± 6.5c	reversible	mixed	390.2 ± 12.6c	reversible	mixed
FB	80.1 ± 4.1b	reversible	mixed	192.6 ± 10.3b	reversible	mixed
FC	48.9 ± 4.6a	reversible	mixed	64.9 ± 3.2a	reversible	mixed

[a]Values are expressed as the mean of triplicate determinations ± standard deviation. Different letters (a−c) in the same column show significant differences from each other at the $P < 0.05$ level.

dx.doi.org/10.1021/jf501009v | J. Agric. Food Chem. 2014, 62, 6382−6389

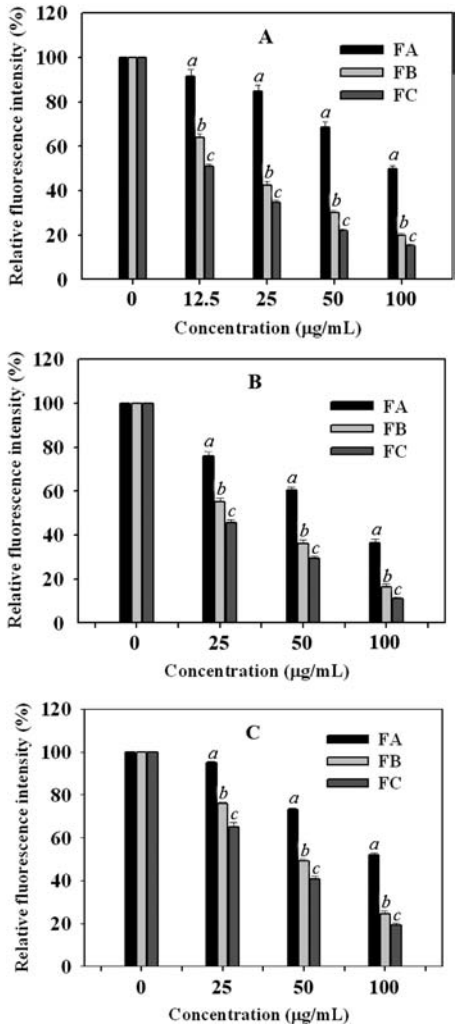

Figure 5. (A) Relative fluorescence intensity of tyrosinase in solution with different concentrations of PAs. The concentrations of PAs were 0, 12.5, 25, 50, and 100 μg/mL, respectively. (B) Relative fluorescence intensity of L-tyrosine in solution with different concentrations of PAs. The concentrations of PAs were 0, 25, 50, and 100 μg/mL. (C) Relative fluorescence intensity of 3,4-dihydroxyphenylalanine in solution with different concentrations of PAs. The concentrations of PAs were 0, 25, 50, and 100 μg/mL, respectively. The excitation wavelength for fluorescence analyses was set at 290 nm. Different letters (a–c) in the same column show significant differences from each other at the $P < 0.05$ level.

the metal at the center of the active site of tyrosinase) with their −OH group. Because the −OH group of PAs presents an anionic form at pH 6.8, they might interact electrostatically with copper ions in the mushroom tyrosinase. The copper-chelating properties of the PAs were thought to be another reason for their strong inhibitory activity on tyrosinase.[29]

Fluorescence Emission Spectra of L-Tyrosine or 3,4-Dihydroxyphenylalanine in Solutions with Different Concentrations of PAs. The interaction of three fractions with L-tyrosine, which was used as a substrate of monophenolase, was first investigated by the fluorescence quenching method. The fluorescence emission spectra were recorded in the range of 300–400 nm with excitation wavelength set at 290 nm. The results showed that fluorescence intensity decreased distinctly with the increase of PA concentration. The fluorescence intensity decreased by 63.7, 83.7, and 89.1% (Figure 5B) for FA, FB, and FC, respectively, at 100 μg/mL.

Then fluorescence emission spectra of 3,4-dihydroxyphenylalanine, which used as a substrate of diphenolase, were recorded in the presence of PAs with different concentrations. The excitation was the same as L-tyrosine assay. The results showed that fluorescence intensity decreased distinctly with the increase of PA concentration. The fluorescence intensity decreased by 47.9, 75.5, and 80.7% (Figure 5) for FA, FB, and FC, respectively, at 100 μg/mL.

These results provided the first evidence that PAs are the effective binding agent of L-tyrosine and 3,4-dihydroxyphenylalanine. Obviously, PAs could effectively stop the reaction of substrate and tyrosinase in this way. It could be another reason for the strong inhibition of PAs on the tyrosinase catalytic reaction. These findings were significant in both designing and screening of potent novel tyrosinase inhibitiors. The results also indicated that combining capacities with L-tyrosine and 3,4-dihydroxyphenylalanine decreased in the order FC > FB > FA. These were also proof that DP is an important factor for the inhibition of PAs on the enzyme.

Determination of Antioxidant Capacity. DPPH, ABTS, and FRAP assays were simultaneously used for measuring the antioxidant properties of three fractions to better reflect their potential protective effects. Table 3 shows the scavenging effect

Table 3. Antioxidant Activities of the PAs Fractionated from Kiwifruit Pericarp Using the DPPH Free Radical Scavenging Assay, the ABTS Free Radical Scavenging Assay, and the FRAP Assay

	antioxidant activity[a]		
sample	IC_{50}/DPPH (μg/mL)	IC_{50}/ABTS (μg/mL)	FRAP (mmol AAE/g)
FA	105.3 ± 1.8b	74.7 ± 2.5c	7.4 ± 0.2c
FB	67.7 ± 1.5a	60.1 ± 1.8b	9.5 ± 0.3a
FC	69.3 ± 0.9a	39.5 ± 1.2a	9.6 ± 0.9a
ascorbic acid	102.6 ± 3.9b	82.5 ± 0.6d	
Trolox	111.9 ± 2.9c	89.1 ± 2.7e	8.3 ± 0.4b

[a]Values are expressed as the mean of duplicate determinations ± standard deviation. Different letters (a–e) in the same column show significant differences from each other at the $P < 0.05$ level.

on the DPPH radical decreased in the order FC ≈ FB > FA ≈ ascorbic acid >Trolox. The order for the ABTS radical scavenging activity was FC > FB > FA > ascorbic acid > Trolox. The antioxidant activity of kiwifruit pericarp PAs was also measured by FRAP assay. The FRAP values for FA, FB, and FC were 7.4 ± 0.2, 9.6 ± 0.3, and 9.6 ± 0.9 mmol AAE/g (Table 3), respectively. At each concentration, FB and FC exhibited distinctly higher reducing power than that of Trolox. In addition, with increasing concentration of the compounds, the antioxidant activity of PAs was observably increased in a concentration-dependent pattern.

Yokozawa et al.[30] confirmed that an increase of galloyl groups, molecular weight (DP), and o-hydroxyl structure enhanced the scavenging activity of tannins. In this study, the results obtained from three antioxidant analyses revealed that PAs were potent antioxidants. This can be explained by the fact that PAs possessed abundant hydroxyl groups. FB and FC possessed obviously higher antioxidant properties than FA. The result revealed that DP was a key factor for the antioxidant capacity of PAs. Hagerman et al.[31] provided insights into the

mechanism of procyanidin as a potential antioxidant, which showed that high molecular weight and hydroxyl groups were important factors for free radical scavenging by tannins. Our results agreed well with Hagerman's findings. In conclusion, our results indicated for the first time that PAs from kiwifruit pericarp might be a good resource for further development as antioxidants. This indicated the possible use of these compounds (especially FB and FC) in medical, cosmetic, food, and agricultural industries.

Structure−Activity of PAs from Kiwifruit Pericarp. Fractions FA, FB, and FC, with distinguishing DP ranges, were selected for discussing the structure−activity relation of PAs. In previous studies, many researchers had focused on the relationship between DP and antioxidant activity. Ariga et al.[32] found that the ability to scavenge peroxyl radicals was proportional to DP after testing several oligomeric flavonoids. Zhou et al.[33] thought that 9−10 mDP PAs should be considered as a dividing point for predicting the structure−activity of mangosteen pericarp PAs. In the present study, the antioxidant activity of kiwifruit pericarp PAs increased from mDP = 4.3 (fraction F1) to 9.1 (fraction F2), but remained stable after that when using DPPH and FRAP assays. However, an increasing antioxidant activity of PAs was displayed following the increase of mDP when using the ABTS assay. Our results partly agreed with the findings of Zhou et al.[33] As for anti-tyrosinase activity, our results revealed that activities (the monophenolase activity and the diphenolase activity) increased following the increase of PAs mDP. However, Shoji et al.[34] fractionated the procyanidins according to the DP using normal-phase chromatography, and no correlation between the DP and tyrosinase inhibitory activity was observed. It was suggested that methods are used to separate PAs from other polyphenols and to fractionate them according to the DP important. In a word, appropriate fractionation might be a feasible way to screen better antioxidant and anti-tyrosinase agents.

In conclusion, the structures of proanthocyanidin fractions (FA, FB, and FC) from kiwifruit pericarp were successfully characterized and elucidated. They possessed structural heterogeneity in monomer units and polymer length. Furthermore, the PAs exhibited excellent efficiency in inhibiting the activities of the mushroom tyrosinase, including the monophenolase activity and the diphenolase activity. The anti-tyrosinase activity of kiwifruit PAs increased with mDP. PAs were found to be reversible and mixed-type inhibitors of the enzyme. Moreover, the inhibition was carried out mainly through the interaction of the hydroxyl groups of the condensed tannins with the active center of the enzyme and the substrate of the enzymatic reaction. Additionally, these proanthocyanidin fractions, especially FB and FC, could effectively scavenge DPPH, ABTS radical, and Fe^{3+}−TPTZ. The antioxidant activity of kiwifruit pericarp PAs increased from mDP = 4.3 (fraction F1) to 9.1 (fraction F2), but remained stable after that when using DPPH and FRAP assays. However, the antioxidant activity of these compounds increased with mDP when using the ABTS assay. The elucidation of the anti-tyrosinase mechanisms and antioxidant activity of the PAs is significant in both designing and screening of novel tyrosinase inhibitiors and potent antioxidant.

tion is available on the oxidation and physicochemical changes in frozen pork dumpling filler. In our previous study, the influence of the storage temperature and temperature oscillation on lipid and protein oxidation and flavor changes in frozen pork dumpling filler was evaluated.[18] The aim of the present study is to assess the influence of the fat content on the oxidation and physicochemical changes in pork dumpling filler at various frozen durations. In particular, protein thermal stability, dynamic rheological properties, and sensory attributes were investigated.

MATERIALS AND METHODS

Materials and Chemicals. Six Landrace × Large white × Duroc crossbred pigs (90−100 kg body weight, 6 months old) were harvested at a local processing plant. The animals were reared intensively and fed until they reached a commercial slaughter weight. Animals were humanely slaughtered in a commercial abattoir (Beidahuang Meat Corp., Harbin, Heilongjiang, China) following standard industry procedures. After evisceration, carcasses were split immediately and chilled at 4 °C. At 12 h after slaughter, 40 kg of pork neck and shoulder lean meat and 10 kg of backfat (thickness = 2−2.5 cm) were obtained. The samples were kept on ice and transported to the laboratory and used on the same day. Bovine serum albumin and 2,4-dinitrophenylhydrazine (DNPH) were purchased from Sigma Chemical Co. (St. Louis, MO, USA). All other chemicals were purchased from Wantai Biomedicals Inc. (Harbin, China) and were of at least analytical grade.

Sample Preparation. Three batches of dumplings were manufactured in a pilot plant (10−12 °C), and each batch was used as a replicate. Pork shoulder and neck meat were ground through a 4 mm plate and mixed with porcine back fat and ingredients according to the product formulations (Table 1). Four fat levels (0, 10, 20, and 30% w/w, i.e., back fat/lean ratios of 0:100, 10:90, 20:80, and 30:70) of dumpling filler were prepared. In the dumpling filler preparation, fresh pork trims and ingredients were mixed by blending for 5 min with a KitchenAid mixer (SYM-10, Guangzhou Shanyou Machinery Equipment Co., Ltd., Guangdong, China) at a speed of 160 rpm. Dumplings with 10 g of filling each were shaped by hand with wheat dough as the dumpling wrapper. Then they were frozen at −25 °C for at least 20 h to ensure the core temperature of dumplings was below −18 °C. The dumplings were placed in styrene foam trays, wrapped with an oxygen-permeable polyvinyl chloride film (8 μm thickness and 18500 $cm^3/m^2/24$ h/atm of oxygen permeability; Weiguang Plastic Co., Ltd., Jiangsu, China), and stored for 0, 30, 60, 90, and 180 days at −18 °C. To determine the cooking loss and breaking strength accurately, some of the raw dumpling filler (30 samples for each treatment and 40 g of raw filler for each sample) were directly stuffed into polyvinyl chloride (PVC) casing (20 mm of diameter) to obtain shape-consistent "casing dumpling" samples, and then they were stored at −18 °C. A strict sanitation procedure was followed to avoid microbial contamination by implementing sanitation standard operating procedures. All equipment and tools were cleaned and sanitized with hot water (>82 °C), and the personnel hand disinfection was in accordance with standard procedures. For each fat level, 230 dumplings were used. At 0 days, 50 dumplings (44 ordinary dumplings and 6 casing dumplings) from each fat level were used for analysis. Among them, 5 raw dumplings were peeled off for proximate composition, 19 raw dumplings were peeled off for physicochemical analysis, 6 casing dumplings were cooked and used for cooking loss and breaking strength, and 20 dumplings were cooked for a sensory panel evaluation. At 30, 60, 90, and 180 days, only 45 dumplings (39 ordinary dumplings and 6 casing dumplings) were used, because there was no need to analyze proximate composition at these storage times.

Table 1. Formulations (in Grams) for Dumpling Fillers with Different Levels of Fat

	fat level[a]			
ingredient	0%	10%	20%	30%
lean meat	1000	900	800	700
fat	0	100	200	300
soy oil	6	6	6	6
salt	30	30	30	30
soy sauce	40	40	40	40
water	100	100	100	100
fresh ginger	20	20	20	20
green onion	20	20	20	20
spices	8	8	8	8
total	1224	1224	1224	1224

[a]The fat level (%) means the percentage of fat added to the total meat amount.

Proximate Composition. The proximate composition was analyzed according to the method of Hou.[19] The moisture in the fillers was determined by drying the samples in a 105 °C oven to a constant weight. Crude lipid was extracted by petroleum ether in a Soxhlet apparatus for 2.5 h at 60 °C. Protein was measured by the Kjeldahl method (KDN-F, FOSS Corp., Slangerupgade, Hilleroed, Denmark), and a 6.25 nitrogen-to-protein conversion factor was used for the calculation. The ash content was measured as the residue after overnight heating of the samples in a 550 °C muffle furnace (SX2-25-10, Zhonghuan Experimental Stove Corp., Tianjin, China) for 5 h.

Preparation of Myofibrillar Protein (MP). MP was prepared from dumpling filler according to the procedure of Xia et al.[8] Thawed dumpling filler was homogenized by blending for 30 s in a Waring Blendor with 4 volumes (w/v) of an isolation buffer (0.1 M NaCl, 10 mM sodium phosphate, 1 mM EGTA, and 2 mM $MgCl_2$, pH 7.0). The filler homogenate was centrifuged at 2000*g* for 20 min, and the supernatant was discarded. The pellet was washed two more times with 4 volumes of the same isolation buffer using the same centrifugation and blending conditions as mentioned above. The myofibril suspension was filtered through four layers of cheesecloth to remove connective tissue, and its pH was adjusted to 6.0 with 0.1 M HCl prior to centrifugation. The MP was stored in a tightly capped bottle and utilized within 24 h. The protein concentration of the myofibril pellet was measured according to the biuret method. The MP solution was used for carbonyl content determination and dynamic rheological testing.

Thiobarbituric Acid-Reactive Substances (TBARS). TBARS were determined according to the method of Wang and Xiong.[20] The TBARS value, expressed as milligrams of malonaldehyde per kilogram of dumpling filler sample, was calculated using the equation

$$\text{TBARS [mg malondialdehyde (MDA)/kg meat]} = (A_{532}/W_s) \times 9.48$$

where A_{532} is the absorbance (532 nm) of the assay solution, W_s is the dumpling filler weight (g), and 9.48 is a constant derived from the dilution factor and the molar extinction coefficient (152,000 M^{-1} cm^{-1}) of the red thiobarbituric acid reaction product. The assay was carried out with three samples, and each sample was analyzed in triplicate.

Carbonyl Content Determination. The carbonyl groups were detected by reaction with DNPH to form protein hydrazones according to the method of Xia et al.[8] Absorbance was measured at 370 nm for the DNPH-treated sample against HCl control. The amount of carbonyl is expressed as nanomoles of DNPH fixed per milligram of protein using an absorption coefficient of 22000 M^{-1} cm^{-1} for protein hydrazones.

Differential Scanning Calorimetry (DSC). In dumpling filler, the pork was ground through a 4 mm plate, so it existed in the form of small muscle particles. The minced muscle particles were separated from dumpling filler and were used for DSC analyses for thermal denaturation on a PerkinElmer DSC system 6 device (PerkinElmer Co. Ltd., Waltham, MA, USA) according to the method of Srinivasan

dx.doi.org/10.1021/jf5008083 | J. Agric. Food Chem. 2014, 62, 6390−6399

Table 2. Proximate Analysis of Dumpling Fillers with Different Added Fat Levels (Mean Value ± SD)[a]

fat level[b] (%)	protein	lipid	moisture	ash
0	18.09 ± 0.13a	5.13 ± 0.84d	70.50 ± 0.57a	3.44 ± 0.01a
10	15.32 ± 0.11b	12.14 ± 2.52c	64.38 ± 0.43b	3.07 ± 0.20a
20	14.53 ± 0.01c	20.53 ± 3.05b	56.45 ± 1.97c	2.98 ± 0.14a
30	13.71 ± 0.01d	28.09 ± 2.52a	52.86 ± 2.88d	2.89 ± 0.22a

[a]Means (n = 3) in the same column with different letters differ significantly ($P < 0.05$). [b]The fat level (%) means the percentage of fat added to the total meat amount.

et al.[21] The muscle samples (15−18 mg) were weighed accurately into aluminum pans and hermetically sealed. An empty pan was used as reference. The instrument was calibrated for temperature and enthalpy using indium and naphthalene as standards. DSC scans were recorded from 30 to 100 °C at a constant rate of 10 °C/min. The transition temperature (T_{max}) was recorded, and the total transition enthalpy change (ΔH) associated with protein denaturation was calculated from the peak area using PerkinElmer software and expressed in joules per gram of sample material. All DSC scanning was performed in triplicate.

Dynamic Thermomechanical Analysis (DTMA). The DTMA of the prepared MP solution during thermal gelation was performed using a Bohlin Gemini2 rheometer (Malvern Corp., UK) as described by Xia et al.[9] The MP samples (40 mg/mL protein in 0.1 M NaCl) were loaded in the 1 mm gap between the two parallel plates (diameter of upper plate = 6 cm) by shearing the sample in an oscillatory mode at a fixed frequency of 1 Hz with a maximum strain of 0.02 and heated at a rate of 2 °C/min from 20 to 85 °C. Distilled water was filled to a groove fixed on the upper parallel plate, and then the samples were coated with a stainless cover to prevent drying. The dynamic rheological properties of myofibril samples were described in terms of the shear storage modulus (G', the elastic response of the gelling material), and tan δ values (the ratio of G''/G') ae presented to demonstrate the relative viscosity to elasticity, which was also continuously recorded during the rheological testing.

Cooking Loss Determination. The frozen casing dumplings were weighed (W_0) individually and then cooked directly in boiling water (100 °C) for exactly 10 min and chilled to equilibrate to room temperature (20 °C). Then, a needle was inserted into the casing of the casing dumpling; the juice in the wrapper was released, and then the filler was weighed again (W_1). The cooking loss (%) of the samples was calculated as follows:

$$\text{cooking loss (\%)} = \frac{W_0 - W_1}{W_0} \times 100\%$$

All measurements were made in six replicates, and the mean values from these replicates are reported. After cooking loss measurement, the fillers were subjected to breaking strength analysis.

Breaking Strength Determination. The breaking strength of the cooked fillers was measured by compression tests using a texture analyzer (Stable Micro System; TA: XT2i, UK) with a flat-surface cylindrical probe (P/50) 50 mm in diameter attached to a 25 kg load cell with a 60 mm/min crosshead speed of the probe. From each cooked filler, 25 × 20 mm (high × diameter) cores were compressed until the structure was disrupted. Both the break force (B) and distance (D) of the first break point were recorded automatically by the software, and the breaking strength was expressed as

$$\text{breaking strength (N/m)} = B/D$$

All measurements were made in six replicates, and the mean values from these replicates are reported.

Sensory Evaluation. The sensory qualities of the cooked dumplings were evaluated by eight persons (selected staff, faculty, and graduate students) who had prior experience with meat product evaluation. The panel was trained to identify the specific sensory traits of dumplings using 20 other cooked dumplings in preliminary sessions. A total of five panel sessions, corresponding to 0, 30, 60, 90, and 180 days of frozen storage, were conducted. At the beginning of every panel session, a "warm-up" sample (cooked dumplings) was assessed as a reminder of the score range for each sensory trait. During the sensory sessions, no visible signs of psychological or physical anomaly were observed in any of the panelists. The number of dumplings sampled from each treatment at each frozen storage time was 20, and the total number of samples per session was 80. The sensory evaluation room contained partitioned booths each illuminated with normal lights. The juiciness, texture, rancid odor, and overall acceptability were assessed. Each assessor was served two dumplings on hot plates from the same group immediately after cooking. The samples were assigned random numbers and given to the panelists randomly. The panelists scored the dumplings using a 10-point scale as follows: for texture, 1 = rough, 10 = smooth; for rancid odor, 1 = undetectable, 10 = sharply pungent smell; for juiciness, 1 = dry, 10 = juicy; and for overall acceptability, 1 = low and 10 = high. Between sample evaluations, the panelists were given water to rinse their mouths.

Statistical Analyses. The effects of fat addition levels (0, 10, 20, and 30%) and storage duration (0, 30, 60, 90, and 180 days) at −18 °C on the oxidation and physicochemical changes of frozen pork dumpling filler were evaluated. Three batches of dumplings were prepared, and all specific experiments were repeated at least three times to test the quality changes in the dumplings. Data were analyzed using the General Linear Model procedure of Statistix software 8.1 (Analytical Software, St. Paul, MN, USA). Analysis of variance (ANOVA) was conducted to determine the significance of the main effects. Significant differences ($P < 0.05$) between means were identified using Tukey's HSD test for multiple comparisons.

RESULTS AND DISCUSSION

Proximate Composition. Proximate analyses for raw dumpling fillers in four formulations are given in Table 2. There were significant differences in the percentages of moisture, protein, and lipid among different fat level groups. As the fat level increased from 0 to 30%, the lipid content increased from 5.13 to 28.09% ($P < 0.05$), and the percentages of protein and moisture decreased from 18.09 and 70.50% to from 13.71 and 52.86%, respectively ($P < 0.05$). The results are in agreement with those reported by Serdaroğlu and Değırmencioğlu,[22] who reported that the fat content of raw meatballs increased from 5.8 to 22.2%, whereas the moisture and protein percentages decreased from 67.8 and 19.8 to 58.1 and 16.2%, respectively. Guerra et al.[23] also found in goat mortadella that the protein and moisture levels decreased with increased fat percentages.

Lipid Oxidation. As shown in Figure 1a, the TBARS in the frozen dumpling filler steadily increased from 0.18, 0.30, 0.33, and 0.43 mg MDA/kg meat (0 days) to 1.60, 1.98, 2.41, and 3.29 mg/kg for 0, 10, 20, and 30% fat addition ($P < 0.05$), respectively, over 180 days of storage. TBARS production was significantly enhanced with increased fat levels, which indicated that high fat contents could significantly increase the formation of malonaldehyde or other secondary products. The influence of the frozen storage duration on TBARS was significantly higher than that of the fat levels ($P < 0.05$). The results of the present study were in good agreement with the results of Soyer

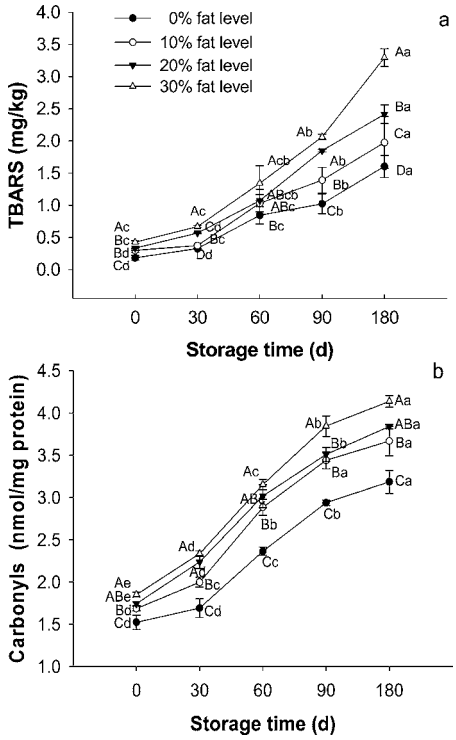

Figure 1. Influence of different fat levels on TBARS and carbonyl content in frozen dumpling fillers. The fat level (%) means the percentage of added fat to the total meat amount. Means (n = 3) for the same storage time with different upper case letters (A–D) differ significantly (P < 0.05); means for the same fat level with different lower case letters (a–e) differ significantly (P < 0.05).

et al.,[24] who suggested that the fat level increased the frozen storage effect on lipid oxidation.

Oxidation is a major cause of the reduction of the quality and acceptability of meats and meat products, leading to the development of rancidity, off-flavor compounds, polymerization, and other reactions resulting in the reduction of shelf life.[25] During frozen storage, lipids in the dumpling filler are oxidized, and unsaturated fatty acids form hydroperoxides that subsequently decompose to generate various secondary products, such as aldehydes, and other carbonyl compounds that cause rancidity flavors.[18] The dumpling filler in this experiment consisted mainly of comminuted pork meat and fat; the pro-oxidants in comminuted meat are released and diffused from various broken cellular organelles, and oxygen from the air also can be an accelerator of lipid oxidation processes by enabling oxygen to react with muscle components.[26,27] Lipid oxidation is commonly linked to the textural attribute of meat products, leading to increasing cooking loss and weakening springiness and cohesiveness of the gel matrix.[8] In our previous study, the free fatty acid (FFA) composition and FFA content in the dumpling filler were determined. The results showed that the total FFA concentration generally increased and the percentage of unsaturated fatty acids in total lipids decreased with increasing frozen storage time in the dumpling samples at −18 °C (P < 0.05).[18] The formation of FFAs is attributed to lipid oxidation and lipid hydrolysis occurring in the dumplings during frozen storage, and FFAs may also have interacted with other constituents during storage.

Protein Oxidation. An increase in the carbonyl contents during frozen storage for all products was observed (Figure 1b). Similar to the fat level and storage duration effect on lipid

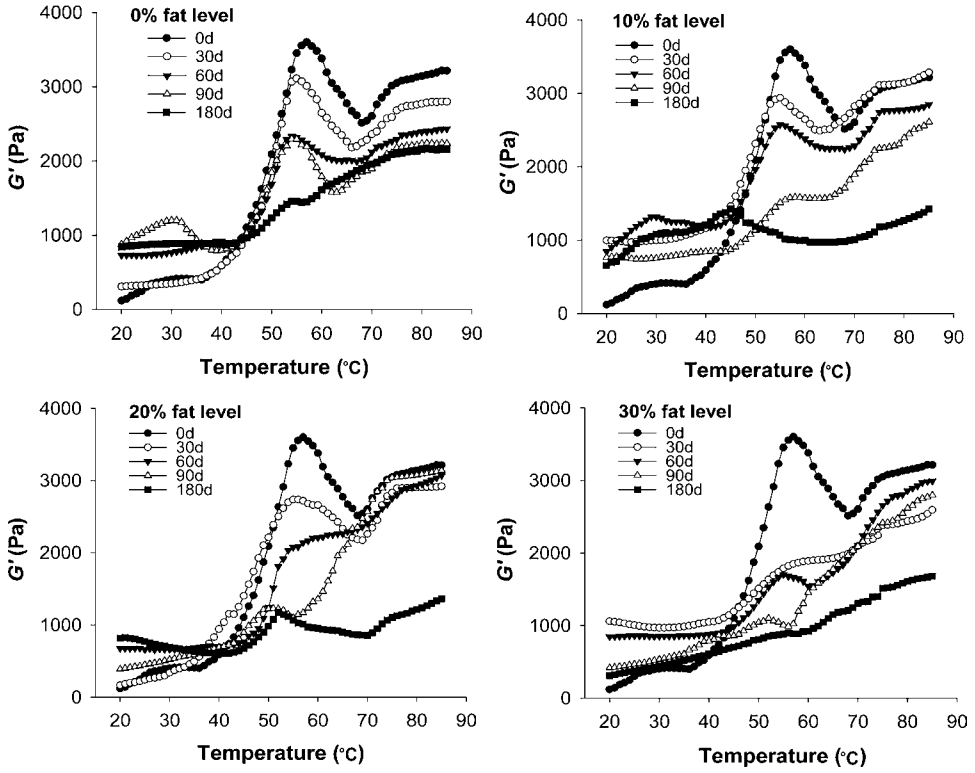

Figure 2. Influence of different fat levels on shear storage modulus (G') of porcine myofibrillar protein in frozen dumpling fillers. The fat level (%) means the percentage of fat added to the total meat amount. Each data point represents the mean from three replications (n = 3).

oxidation, protein oxidation progressed strikingly in four formulations (P < 0.05). At 0 days, the protein carbonyl contents were 1.52, 1.68, 1.74, and 1.85 nmol/mg protein and significantly increased to 3.18, 3.69, 3.84, and 4.14 nmol/mg protein for samples with 0, 10, 20, and 30% fat levels (P < 0.05), respectively, over 180 days of storage. The protein carbonyl contents in 10, 20, and 30% fat levels were all significantly higher than that in the 0% fat level, and carbonyl groups in the 30% fat level were significantly higher than that in 10% fat level (P < 0.05). There were no significant differences between 20 and 30% fat levels over the 180 days of storage except at 90 days. The results were in good agreement with Soyer et al.,[24] who reported significant increases of the total amount of protein carbonyls in chopped chicken meat after 6 months of frozen storage at −18 °C. The increase of protein carbonyls showed that muscle proteins in dumpling fillers were susceptible to oxidative reactions leading to carbonyl gain.

Many of the amino acid side-chain groups, such as those with NH_2 or NH−, are well-known to be sensitive to hydroxyl radical attack. These groups are easily converted to carbonyls when oxidized.[28] Protein carbonyls can also be produced by peptide bond cleavages. Additionally, exogenous carbonyls may be introduced into proteins by reaction with lysine residues.[29] Oxidation causes quality losses in frozen meat products characterized by discoloration, flavor deterioration, destruction of nutrients, and the possible formation of toxic compounds.[30] Formation of carbonyl compounds is one of the most marked changes occurring during the oxidation of proteins. In the present experiments, mincing and the low temperatures applied during storage could have disrupted the tissues, thereby promoting protein oxidation in the dumpling fillers. Muscle proteins are susceptible to oxidative reactions initiated by secondary products of lipid oxidation, such as malonaldehyde.[20,31] The aldehydes formed by lipid oxidation can react with the side-chain amino groups of proteins, such as lysine, in myofibrils to produce Schiff bases, which may cause deterioration in the flavor, texture, and overall quality of muscle foods.[24]

Changes in Protein Thermal Stability. DSC is a suitable method for studying the protein thermal stability during processing and storage. As shown in Table 3, transition temperatures in the muscle protein conformation were assayed to occur within different temperature ranges such as 56.2−58.5 °C for myosin, 63.1−67.4 °C for collagen and sarcoplasmic proteins, and 76.9−80.8 °C for actin, which were similar to the literature reports.[32] The temperature maxima for transitions (T_{max}) of lean meat from frozen dumpling fillers shifted to lower temperatures with increased frozen storage duration. The fat level nearly has no significant effect on transition temperatures except the $T_{max\text{-}1}$ in 20 and 30% fat levels were significantly higher than that in the 0% fat level (P < 0.05). The $T_{max\text{-}1}$, $T_{max\text{-}2}$, and $T_{max\text{-}3}$ of frozen dumplings (0 days) were 58.5, 67.4, and 80.8 °C, and they decreased to 57.5, 63.7, and 78.0 °C, respectively, for the 0% fat level group and to 56.2, 63.2, and 76.9 °C, respectively, for the 30% fat level group after 180 days. A remarkable decrease (P < 0.05) in T_{max} indicated that the thermal stability of the protein reduced, which was possibly because of the dissociation of subunits and protein denaturation.[33] The T_{max} of an endothermic peak designates the maximum transition temperature during the thermal denaturation of a protein. Thus, the smaller the T_{max}, the lower the thermal stability of the protein. Similarly, the total enthalpy (ΔH) of the protein denaturation was substantially reduced during storage. It decreased from 0.52 J/g (0 days) to 0.34 J/g for the 0% fat level group and to 0.19 J/g for the 30% fat level group (P < 0.05) after 180 days. The ΔH was significantly

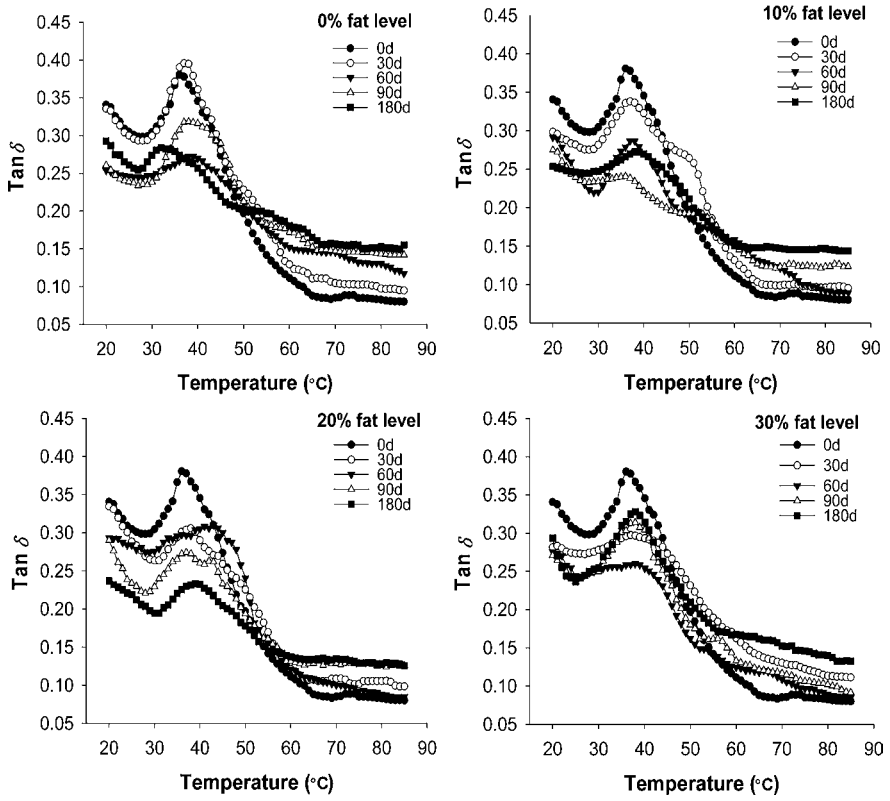

Figure 3. Influence of different fat levels on tangent δ of porcine myofibrillar protein in frozen dumpling fillers. The fat level (%) means the percentage of fat added to the total meat amount. Each data point represents the mean from three replications (n = 3).

decreased only in the products with 30% fat after 90 days of storage ($P < 0.05$). This suggests that protein destabilization in dumping fillers occurred more seriously for a long time of frozen storage, and the higher fat level (30%) further destabilized the proteins.

It is postulated that a possible cause of quality loss was a partial loss of the native structure of meat protein in the dumpling fillers during frozen storage. The reduced conformational stability of muscle protein would also affect negatively the physical attributes of cooked dumpling fillers, such as sensory texture and juiciness. The muscle in dumpling filler was in a minced state, and most likely the previous processing and some ingredients induced a greater alteration of protein structures. A decrease in the thermal stability of protein was also a presumable consequence of oxidative modifications to their primary structures, which were demonstrated by protein oxidation (Figure 1b). Moreover, it is also worth mentioning the possible contribution of some ingredients to the protein thermal stability because of the proportion of some ingredients present in the formulation, such as NaCl, for example. Salt plays an important role in decreasing the hydrogen bonds or augmenting protein aggregation and, consequently, the protein is expected to need lower denaturation energies.[34]

Changes in Dynamic Rheological Properties. The dynamic rheological properties monitored the transformation of a protein solution to a three-dimensional gel network. Curves of storage modulus (G') of MP extracted from dumpling fillers are depicted in Figure 2. For 0% fat level samples at 0 days, the G' started to increase from the beginning of heating to a maximum value (3602 Pa) when the temperature reached approximately 57 °C. From 57 to 68 °C, the G' dropped rapidly and then rose again until 85 °C. This observation was in agreement with other reported findings[35] and is typical of muscle protein rheological patterns and reflects the transitions of heavy meromyosin and light meromyosin. When the dumpling was stored for up to 30, 60, 90, and 180 days, the first peak G' values of the MP gel were decreased to 3109, 2331, 1825, and 1527 Pa, respectively, and the peak temperature was reduced by 2−4 °C. The G' for MP samples from the other three fat levels had a similar reducing trend, and the G' and peak temperature decreased more rapidly with increased fat levels. The transition temperatures of the subfragments of myosin suggested the stability of protein; thus, the decreases in transition temperatures indicated that the reduction in stability of MP was affected by oxidation or denaturation. The rheological changes were also illustrated by the temperature-dependent shifts in tan δ, which describes the relative distribution of "viscosity" compared with "elasticity" during the protein gel matrix formation. As shown in Figure3, the samples (0 days) produced a rheogram composed of a tan δ peak (0.38) at 37 °C followed by a sharp decline to the final heating temperature. The increase in tan δ at the initial heating stage resulted from the formation of a more viscous sol by myosin upon heating to >30 °C. The "viscous" feature of the gelling system outweighs the "elastic" component of the pregel; thus, there is an overall increase in tan δ. As the temperature was increased from 67 to 85 °C, the tan δ dropped steadily, and all gels showed a phase shift angle of <8°, which suggested that the conformation of the myosin molecule changed further and formed a firm, irreversible, and thermal gel. A similar rheological pattern of MP was obtained in the samples at each fat level stored for 30, 60, 90, and 180 days. With increased frozen storage time, the tan δ decreased at the initial heating stage (30−50 °C) and increased at the final heating

dx.doi.org/10.1021/jf5008083 | J. Agric. Food Chem. 2014, 62, 6390−6399

stage (>60 °C). The increase in tan δ at the final heating stage was referred to as "gel weakening", leading to a loose network gel formation.

A possible explanation for the deleterious effect of the high fat level on dynamic rheological properties of MP is that the high content of fat can cause more severe lipid oxidation (proven by TBARS, Figure 1), and the aldehydes formed by lipid oxidation can react with the amino groups of proteins, causing protein structural changes, protein denaturation, and a decrease in the protein stability, which essentially agreed with the DSC results (Table 3). The decrease in G' and increase in tan δ indicated a decrease in the gel-forming ability of MP, which is the most important functional property of comminuted meat products. As displayed in Figure 2, the viscoelasticity of MP decreased as frozen storage time was prolonged and fat level increased, which contributed to explaining the reduction in breaking strength and cooking loss as seen below (Figure 3).

Cooking Loss. Cooking loss of dumpling fillers was affected by the fat level ($P < 0.05$) (Figure 4a). In dumpling fillers of 0, 10, 20, and 30% fat levels, the cooking losses were 17.8, 19.4, 20.4, and 21.5% at 0 days and increased to 22.0, 23.1, 24.3, and 27.0%, respectively, after 180 days ($P < 0.05$). The cooking losses in all products increased during storage, but their increasing rate in each fat level during storage was similar. The fat content in dumpling filler was positively related to the total cooking losses, which was probably due to an insufficient amount of meat proteins to hold all of this added fat and water.

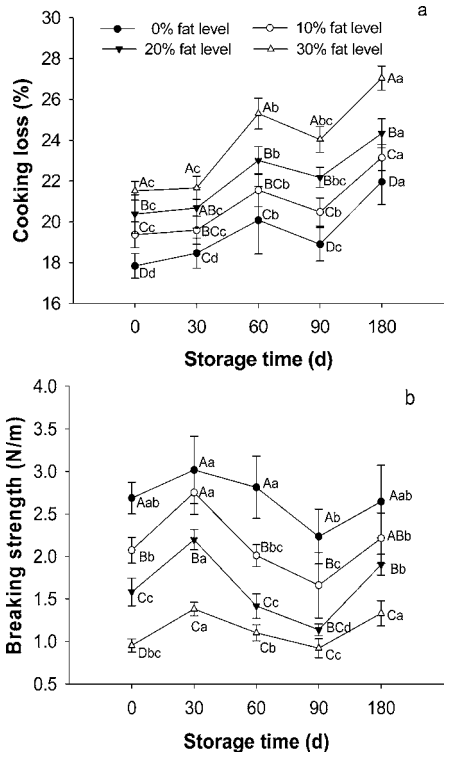

Figure 4. Influence of different fat levels on cooking loss and breaking strength of frozen dumpling fillers. Means ($n = 6$) for the same storage time with different upper case letters (A–D) differ significantly ($P < 0.05$); means for the same fat level with different lower case letters (a–d) differ significantly ($P < 0.05$).

Water loss affects meat and meat product appearance, texture, and sensory properties, and it is most relevant to water-binding capacity.[36] The cooking loss of muscle can lead to less acceptability because of the loss of some taste constituents, such as some nucleotides or amino acids. The liquid of cooking loss comes mainly from constitutive water and fat that melts during heating because of the effect of freezing and frozen storage on muscle structure; hence, its capacity to retain water could be attenuated with increased frozen storage time. The increased cooking loss of filler samples during frozen storage may also be construed as a result of increased protein oxidation as demonstrated above (Figure 1) and possibly the weakening of the myofibril lattices because of protein denaturation (Table 2 and Figure 2). Muscle proteins play a key role in the three-dimensional gel matrix development in meat products; the denatured and reduced protein decreased the gel-forming ability of fillers, so the poorly formed gel matrix possessed lower water- and lipid-holding capacities,[37] which resulted in an increase in loss of water as the frozen storage time increased. McCord et al.[38] suggested that the addition of the higher fat content apparently led to a weaker and more deformable gel structure and decreased the binding between meat particles. Additionally, increasing cooking losses were observed with increasing fat levels, which suggested that a larger fat to protein ratio would also generate a much less stable gel matrix with reduced binding properties and would most likely lead to a greater release of water and fat.[39]

Breaking Strength. The fat addition levels had a remarkable effect on the breaking strength of the dumpling fillers. The increase of fat level significantly lowered the breaking strength ($P < 0.05$) (Figure 4b). No change of breaking strength was observed during 180 days of storage in products except for the products with 20 and 30% fat, in which the breaking strength slightly increased after 180 days of storage. In dumpling fillers of the 0, 10, 20, and 30% fat levels, the breaking strengths were 2.69, 2.07, 1.58, and 0.95 N/m on 0 days and changed to 2.65, 2.21, 1.90, and 1.33 N/m, respectively, after 180 days. There was a significant increase ($P < 0.05$) at 30 days of storage in the breaking strength in all of the filler samples except that in 0% fat addition, and then they decreased until 90 days, which may be attributed to the modest protein oxidation of MP as proven by the carbonyl content measurement (Figure 1b). This observation was in agreement with the findings of Bess et al.,[40] who reported that the breaking strength of ground pork patties stored frozen for 6 weeks was higher than that of patties stored for 9 weeks. Liu et al.[41] confirmed that slow and mild-to-moderate oxidation could facilitate the formation of disulfide cross-links in myofibrils, resulting in the formation of a stronger gel. An increase of the damage to the three-dimensional network structure of the dumpling filler could result in a decrease in the breaking strength of the dumpling filler. The pronounced decrease in breaking strength might be related to the fact that cohesiveness tended to decrease as animal fat content increased in the meat treatments, as suggested by Youssef and Barbut.[42] An increase in the fat content and a decrease in the protein content will lower the ability to form a stronger and denser gel/emulsion matrix, which can affect the internal structure of the product, resulting in weakened binding properties. Furthermore, freezing and frozen storage can cause chemical and structural changes of muscle protein, which negatively affects the quality attributes of meat products, that is, texture, water- and fat-binding properties, sensory characteristics, and others.[43]

Sensory Evaluation. The sensory panel results on the dumpling fillers with different fat levels stored at −18 °C for

[a]Means (n = 8) in the same column with different letters differ significantly ($P < 0.05$). [b]Texture = 1 (rough) to 10 (smooth); rancidity = 1 (slight) to 10 (sharply pungent smell); juiciness = 1 (dry) to 10 (juicy); overall acceptability = 1 (low) to 10 (high). [c]The fat level (%) means the percentage of fat added to the total meat amount.

Table 5. Correlation Coefficients (r) between Oxidation and Physicochemical Properties of Dumpling Filler[a]

	cooking loss	breaking strength	$T_{max\text{-}1}$	ΔH	G'	tan δ
TBARS	0.83**	−0.16	−0.90**	−0.92**	−0.67*	0.81*
carbonyl content	0.75*	−0.13	−0.97**	−0.97**	−0.85**	0.88**

[a]**, correlations are significant ($P < 0.01$); *, correlations are significant ($P < 0.05$). $T_{max\text{-}1}$ represents the transition temperature of myosin. ΔH value represents the total enthalpy change for all transitions. G' and tan δ are the values at the end of thermal gelation at the highest temperature (Figures 2 and 3).

180 days are presented in Table 4. During frozen storage, the dumplings with a 30% fat level had significantly higher texture, juiciness, and overall acceptability scores ($P < 0.05$) and also had higher rancidity scores ($P < 0.05$) than those with a 0% fat level and lower fat level samples, indicating that the fat addition was able to improve the texture and juiciness. Independent of the fat level, all of the samples exhibited sensory quality deteriorations with extended frozen storage time. Juiciness is the amount of perceived juices in the meat during chewing or mastication; thus, it is one of the major meat attributes influencing eating quality.[44] From the results of the present study, the juiciness scores decreased with increased frozen storage time, which was consistent with the results of Huff-Lonergan et al.[45] The rancidity change was very significant in all samples ($P < 0.05$) and followed a tendency similar to that of the TBARS value (Figure 1a). As storage time increased, the rancid flavor of the dumpling filler with a 30% fat level developed to a higher extent, whereas the samples with a 0% fat level deteriorated more severely in texture and juiciness. Although rancidity scores of samples with a 30% fat level stored for 180 days developed to a higher level, they were still in the sensory acceptable range. The juiceless and waxy qualities of dumplings may have some relationship to protein denaturation and the increase in ice crystal size during frozen storage.

Relationship between Oxidative and Physicochemical Properties. The relationships between oxidation (TBARS and carbonyl content) and physicochemical properties (cooking loss, breaking strength, transition temperature $T_{max\text{-}1}$, enthalpy, G', and tan δ) of dumpling filler were determined through regression analyses (Table 5). Most of the oxidative and physicochemical indices were all significantly correlated ($P < 0.01$ or $P < 0.05$) except between oxidation indices (TBARS and carbonyl content) and breaking strength, indicating that the oxidative modifications of protein were ultimately responsible for the observed physicochemical property changes including cooking loss, protein thermal stability, and dynamic rheological properties. However, the breaking strength, an index expressing the degree of cohesiveness of the filler mixture, was not significantly affected by the oxidation ($P > 0.05$). In dumpling fillers, salt-soluble myofibrillar proteins exert a cohesive force to bind meat particles together and stabilize fat particles in the matrix,[46] and fat content significantly affects the binding properties as observed in Figure 4. Jost et al.[47] claimed that some large fat globules may disturb protein reticulation and were likely to be excluded from a protein gel

matrix, which may result in poor protein-binding properties. Therefore, fat levels may play vital roles in decreasing the breaking strength of dumpling fillers.

In conclusion, the results of this study demonstrated that the frozen dumplings stored at −18 °C underwent lipid and protein oxidation and exhibited deterioration in physicochemical and sensory properties. The fat level and frozen storage duration have strong effects on lipid and protein oxidation, protein thermal stability, gel-forming ability, cooking loss, breaking force, and sensory attributes. Lipid and protein oxidation was closely related to protein denaturation and gel-forming ability deterioration. The dumplings with a high fat level stored for long periods of time had significantly enhanced lipid and protein oxidation and cooking loss and lowered protein thermal stability, viscoelasticity, and breaking strength. The sensory qualities revealed that the dumplings with a high fat level had significantly higher texture, juiciness, and overall acceptability scores but also had higher rancidity scores. Therefore, considering the palatability brought about by fat, it is imperative to add proper fat into dumpling fillers. Additional experiments are needed to evaluate whether the addition of natural antioxidants to pork dumpling filler will help to keep its quality during frozen storage.

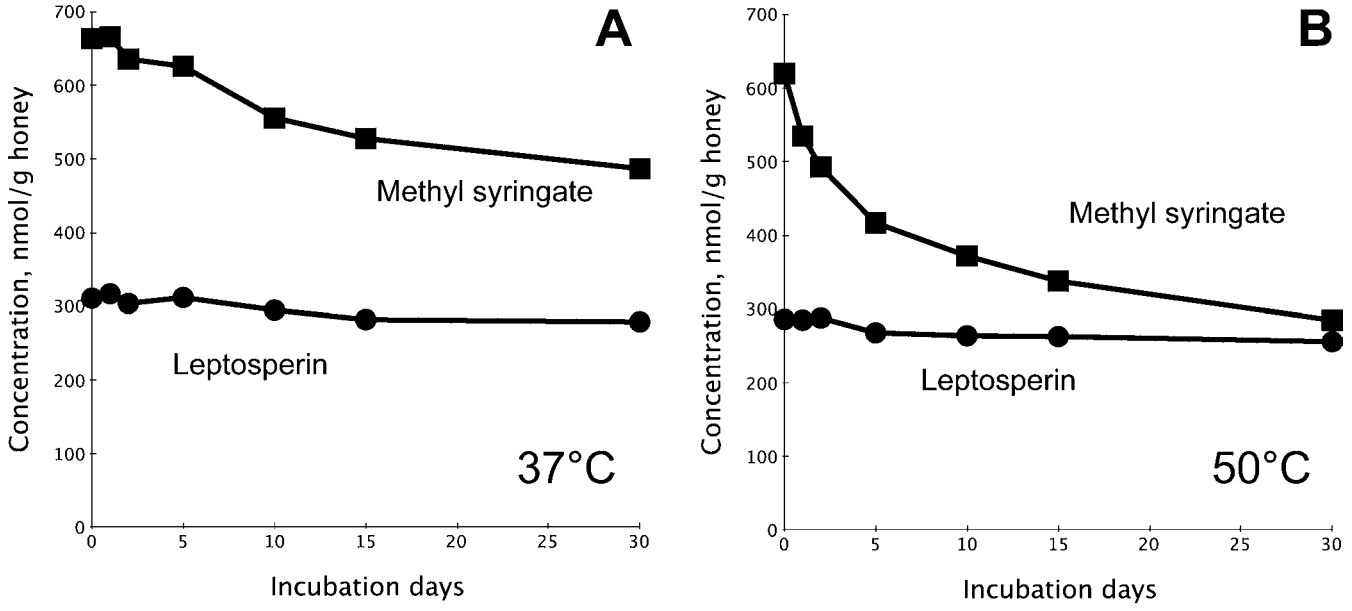

Figure 1. Time-dependent changes in the amounts of leptosperin or methyl syringate in manuka honey during incubation under warm conditions [37 °C (A) or 50 °C (B)].

mL of water, stirred at room temperature (r.t.) for 30 min, and filtered to remove impurities. The filtrate and 400 mL of (wet) Diaion Sepabeads HP20 resins (Mitsubishi Chemical Co., Tokyo, Japan), pretreated with methanol and then water, were mixed in a bottle and incubated with gentle shaking for 3 h at r.t. and subsequently filtered. HP20 resins were washed with water (500 mL) and 20% methanol (500 mL). Subsequently, the materials were eluted with methanol (2 L). Following the evaporation of methanol, materials were dissolved in 100 mL of water and transferred to a separating funnel. An equal volume of ethyl acetate was added, and the mixture washed three times. The water fraction was collected and concentrated. The concentrate was applied to an open column filled with HP20 resin and preequilibrated with water. The column was washed with 200 mL of water and 20% methanol, and elution performed with 50% methanol (500 mL). The eluate was fractionated, and absorbance at 262 nm was measured. The fractions containing leptosperin were pooled in a flask and evaporated. The concentrate was purified using reversed-phase HPLC with Develosil Combi-RP (20 × 100 mm, Nomura Chemical Co., Ltd., Aichi, Japan) containing 0.1% acetic acid/CH_3CN = 85/15 at a flow rate of 5 mL/min with monitoring at 262 nm. The peak was collected and repurified under the same conditions.

Honey and Related Samples. Twenty certified samples of manuka honey were obtained from the Unique Manuka Factor Honey Association. Information on NPA (phenol equivalent) and methylglyoxal contents of the 20 samples was provided by Hill Laboratories. Other kinds of honey and samples were obtained from retail stores between 2011 and 2014 in Japan, China, Brazil, and New Zealand. The samples were dissolved in water at a concentration of 0.1 g/mL and centrifuged. The supernatant was collected and directly used for HPLC or diluted 100-fold with water before application of liquid chromatography tandem mass spectrometry (LC/MS/MS), as described below. In addition, in the case of sample no. 26 (Table 2), the original honey solution (0.1 g/mL) was directly analyzed using LC/MS/MS. Samples of candy, cosmetics, or toothpaste were dissolved in 0.1% formic acid/CH_3CN (9/1) at a concentration of 0.1 g/mL. In some cases, in particular for candy, samples were crushed into small pieces and dissolved at 60 °C for 30 min. After centrifugation, the supernatant was collected and diluted 2−100 fold, which was estimated by preliminary analysis of each sample. Vodka was eightfold diluted with water and then used. Tea samples were extracted with 500 mL of boiled water for 5 min using two bags and directly used for mass analyses.

HPLC Measurement. The honey solution (0.1 g honey/mL) was analyzed using a HPLC-photodiode-array detector (PDA), as described previously,[9] with some modifications. In brief, a 5 μL sample was injected into the HPLC connected to a Develosil ODS-HG-5 column (4.6 × 150 mm, Nomura Chemical Co., Ltd.). The separation was performed with gradient elution using a two-solvent system (solvent A, 0.1% formic acid; solvent B, CH_3CN) at a flow rate of 0.8 mL/min with the following gradient program: 0 min (A90%), 10 min (A60%), 11 min (A90%), 25 min (A90%). Leptosperin and methyl syringate were quantified at 262 and 275 nm, respectively.

LC/MS/MS Measurement. Analyses were performed using the API3000 tandem mass spectrometer (AB Sciex Instruments, Foster City, CA) connected with a HPLC system using a Develosil ODS-HG-3 column (2 × 50 mm, Nomura Chemical Co., Ltd.). The flow rate was 0.2 mL/min, and 0.1% formic acid (A) and CH_3CN (B) were used as solvents. The time program was as follows: 0 min (A90%), 6 min (A60%), 6.4 min (A90%), 15 min (A90%). The leptosperin content in honeys and samples was measured using electrospray ionization (ESI) with multiple reaction monitoring (MRM) negative mode (ESI-MS/MS). Simultaneous measurement of leptosperin and methyl syringate was accomplished using atmospheric pressure chemical ionization (APCI) with MRM negative mode (APCI-MS/MS). For APCI-MS/MS, the duration time was divided into two periods (6 and 9 min) for effective ionization settings of the respective compounds. Prior to MS analyses, internal standards (100 nM PNPG and 250 nM TMBZ) were added to both samples and standard cocktails. The MRM transitions by collision-induced fragmentation were as follows: leptosperin, 581.0/323.2 (APCI), 581.0/210.9 (ESI); methyl syringate, 211.1/181.1; PNPG, 346.2/138.1; TMBZ, 211.1/152.1. In addition, $[M-HCOO^-]^-$ (581.10) was selected for Q1 transition of leptosperin (M.W. 536).

Marker Stability. Honey samples (raw) were directly aliquoted into screw-capped microtubes, which were sealed tightly and incubated at 37 or 50 °C. At various intervals, tubes were individually removed and stored at −80 °C until analysis. The samples were dissolved in water at a concentration of 0.1 g/mL, and the changes in the leptosperin and methyl syringate contents were analyzed using HPLC as described above.

Statistical Analysis. The relationship between the two markers was calculated using SPSS Statistics ver. 17.0 with Spearman's correlation.

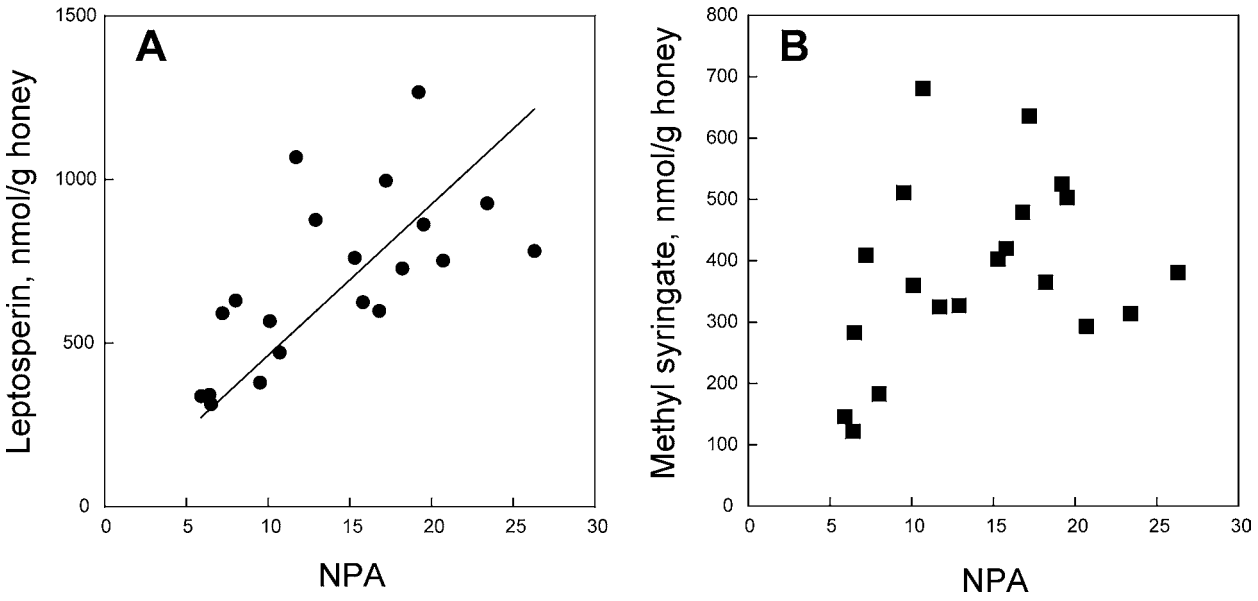

Figure 2. Correlation of the amount of leptosperin (A) or methyl syringate (B) with nonperoxide antibacterial activity (NPA). Methyl syringate and leptosperin contents were measured using HPLC.

RESULTS

Heat Stability of Leptosperin and Its Aglycone, Methyl Syringate. Stabilities of leptosperin and methyl syringate in manuka honey were examined. As shown in Figure 1, methyl syringate was significantly decreased with increasing incubation times. We observed a loss of approximately 30% of methyl syringate over a period of 30 days at 37 °C. At a higher temperature of 50 °C, approximately 50% of methyl syringate was lost over the 30 day period. In contrast, leptosperin was relatively stable at the same temperatures.

Correlation of Leptosperin and Methyl Syringate with Antibacterial Activity. Leptosperin and methyl syringate contents in 20 certified manuka honey samples were analyzed using HPLC. Leptosperin and methyl syringate amounts varied from 314 to 1268 and 122 to 681 μmol/g of honey, respectively (Table 1). NPA of honey samples were independently determined by an authentic organization, as described in Materials and Methods. NPA has a high correlation with leptosperin content (r = 0.732, p < 0.001) but not significant with that of methyl syringate (Figure 2A, B). Our results are similar to those reported in a previous study.[9]

Establishment of LC/MS/MS Analyses for Leptosperin and/or Methyl Syringate. Leptosperin can be measured using the negative mode of ESI with MRM using 581/211 or 581/323 transitions. MRM chromatograms of a standard and typical honey sample using ESI (MRM 581.10/210.9) are shown in Figure 3A. The limit of detection (LOD) for

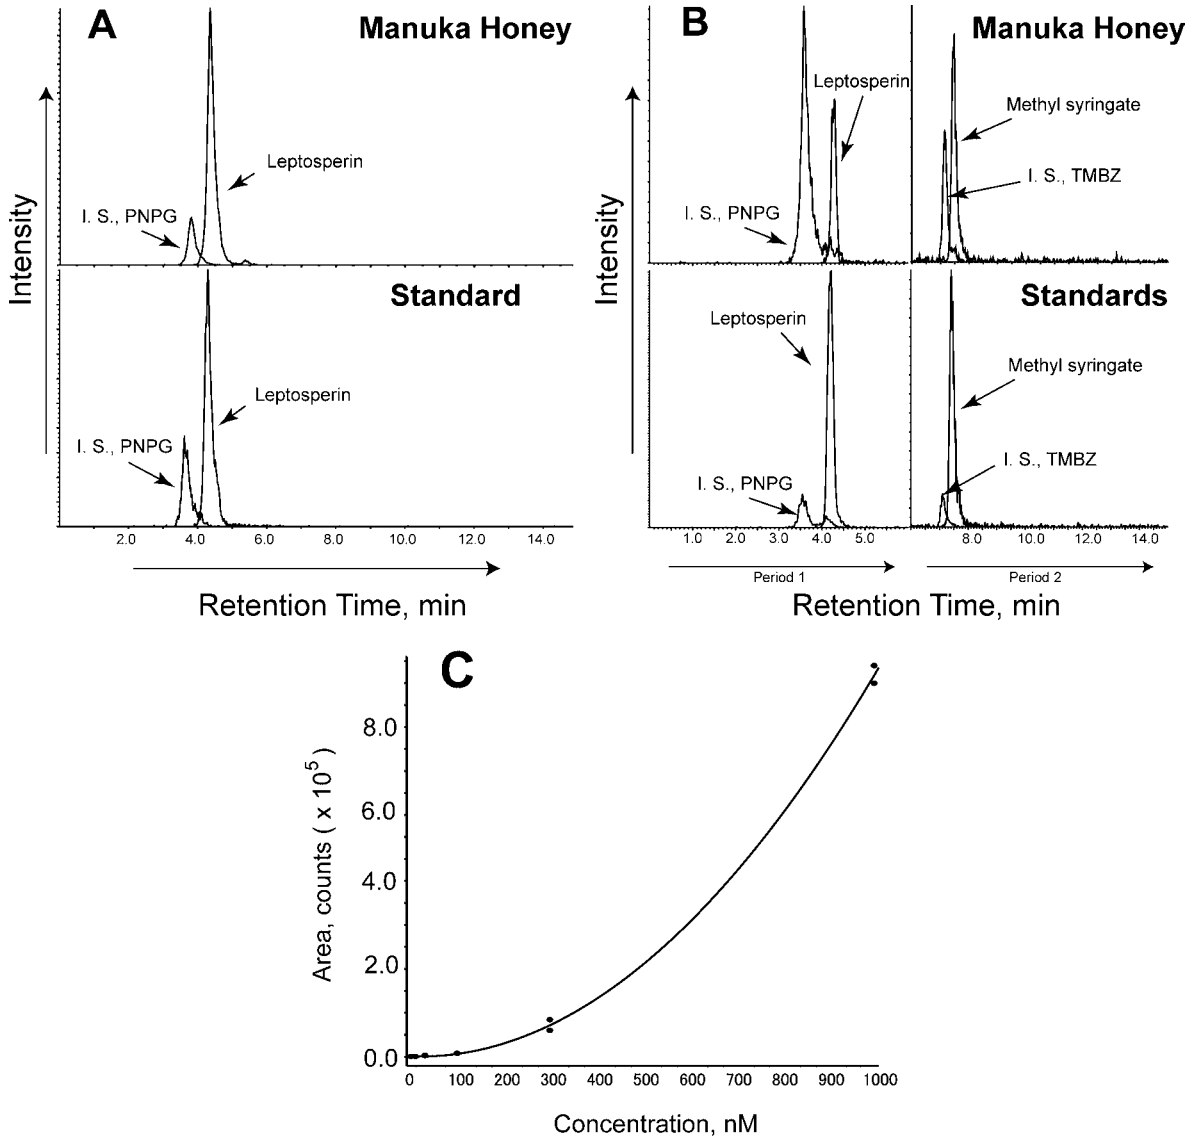

Figure 3. Electrospray ionization (ESI) with multiple reaction monitoring (MRM) negative mode (ESI-MS/MS) or atmospheric pressure chemical ionization (APCI) with MRM negative mode (APCI-MS/MS) analyses of standards and honey sample. (A) Chromatograms of ESI-MS/MS analysis of leptosperin with internal standard (I.S.), *p*-nitrophenyl-*β*-D-glucopyranoside (PNPG). Upper chart, manuka honey; lower chart, standard leptosperin. (B) Chromatograms of APCI-MS/MS analysis of leptosperin or methyl syringate with internal standards, PNPG or 3,4,5-trimethoxybenzoic acid (TMBZ). Upper chart, manuka honey; lower chart, standard of leptosperin and methyl syringate. (C) Quadratic standard curve of leptosperin using APCI-MS/MS.

leptosperin was 3 nM (1.5 fmol/injection), and the peak area linearly increased up to 2000 nM. PNPG was used as the internal standard for leptosperin measurement. However, methyl syringate was barely detected using ESI-MS/MS at a concentration lower than approximately 1 μM. Leptosperin contents in the 20 manuka samples were analyzed using ESI (Table 1). High linearity of leptosperin data was observed between HPLC and ESI-MS/MS (r = 0.947, p < 0.001). In addition, APCI-MS/MS negative mode was developed to analyze methyl syringate with leptosperin (Figure 3B). In this ionization mode, methyl syringate could be analyzed at concentrations of 10−1000 nM, but LOD of leptosperin (30 nM) was lower than that of ESI ionization (3 nM). TMBZ was selected as the internal standard for methyl syringate (Figure 3B). The standard curve of leptosperin was not linear and was then adapted using a quadratic curve fitting (Figure 3C). Leptosperin and methyl syringate contents in the 20 samples were also analyzed using APCI-MS/MS. Each correlation of leptosperin and methyl syringate between APCI-MSMS and HPLC was significantly high (r = 0.812 and 0.949, respectively). However, the amount of leptosperin detected with LC/MS/MS methods, in particular APCI-MS/MS, was lower than that observed with HPLC-PDA, indicating that the reliability of APCI-MS/MS for determining leptosperin content is relatively lower compared with that of the other two methods. Similar to the HPLC analyses, the correlation between leptosperin and NPA observed using both LC/MS/MS methods was significant. On the other hand, the methyl syringate content was not correlated with antibacterial activity.

Plausible Authentication of Manuka Honey by Measuring Leptosperin. We analyzed the leptosperin and methyl syringate contents in commercial manuka honey samples, along with some nonmanuka honey samples (Table 2). Manuka honey authenticated using UMF, MGO, or Active

contained high concentrations of leptosperin (664, 383, or 538 nmol leptosperin/g honey on average, respectively), whereas the leptosperin contents in noncertified manuka honey were lower (on average, 323 nmol leptosperin/g honey). However, some noncertified honey samples (no. 21 and 24) were also rich in leptosperin. As shown in Figure 4 and Table 2, one nonauthenticated manuka honey sample (no. 26) obtained at an online store by a Japanese agent contained only trace amounts of leptosperin (22 nmol/g of honey), which could be quantified using ESI-MS/MS without 100-fold dilution but not using HPLC (Figure 4, trace line B′). The leptosperin level was only 1.7%−2.5% compared with the relatively high content in manuka honey "O" (Table 1, ESI or HPLC). Manuka honey (no. 27), which had the same label as sample no. 26, except for the expiration date and was purchased at a retail store in New Zealand, contained 164 nmol leptosperin per g of honey [Figure 4, trace line B, and Table 2 (HPLC)]. The leptosperin content in no. 27 was calculated as 13% of the manuka honey "O" and 7.5 fold richer than that of no.26. Certified UMF15+ honey (no. 03, Table 2) showed strong signals derived from leptosperin and methyl syringate (Figure 4, trace line A).

Plausible Authentication of Manuka Honey Products by Measuring Leptosperin with Methyl Syringate. Manuka honey is added to commercial foods, cosmetics, and toothpaste for expected medicinal purposes, which may not be expressed on the label or attached brochure. We then investigated the detection of leptosperin using ESI-MS/MS and methyl syringate using APCI-MS/MS from some market products. As shown in Tables 3 and 4, leptosperin was detected in the examined samples, including manuka honey, but not in the toothpaste containing manuka honey. In addition, no leptosperin signals from nonmanuka candies were observed. The methyl syringate pattern was similar to that of leptosperin, although one nonmanuka candy contained trace amounts of methyl syringate. These results collectively validate the

application of leptosperin as a preferable chemical marker for manuka honey authentication.

DISCUSSION

Manuka honey is one of the most premium kinds of honey worldwide. On the basis of its unique antibacterial activity, the quality of manuka honey is certified and ranked for consumers using UMF, Active, or MGO. The honey is applied for medicinal purposes, such as treatment of wounded skin. Honey intake/treatment is also expected to promote health; therefore, not only manuka honey but also products containing manuka honey such as candies and cosmetics have been available in the market.

chamomile with lemon balm and manuka honey tea (U.K.)	240	9

Methylglyoxal is the key compound underlying the antibacterial activity of honey. Twenty certified honey samples displayed a high correlation between NPA and methylglyoxal contents (Table 1). Methylglyoxal is probably generated from the predicted precursor molecule, dihydroxyacetone, in the honey.[3] This is consistent with the finding that the UMF rating is enhanced by storage, which is known to the beekeeper/honey industry.[12] Moreover, because both methylglyoxal and dihydroxyacetone are available as reagents, artificial addition of these compounds into manuka or nonmanuka honey to increase antibacterial activity is possible. Supplementation with chemicals is often used for preparation of manuka honey mimics.[13,14] That is, it is possible to disguise other kinds of honey, including multifloral honeys, as manuka honey. The association of UMF is setting up traceability of UMF-certified manuka honey from the marketplace to ensure that the products are from the stated origin to protect the consumer from counterfeiting.

The main purpose of this study was to evaluate the application of leptosperin[9] as a potential chemical marker for authentication of manuka honey. Stability and reliability are important characteristics of an effective chemical marker. The leptosperin level remained constant during incubation at both 37 °C and higher temperatures of 50 °C (Figure 1A, B). This is probably because leptosperin has less reactive moieties than phenolics, such as methyl syringate, which has phenolic hydroxyl. Methylation of phenolic components in honey has been suggested.[12] As discussed above, the amount of the other major key component, methylglyoxal, is known to be nonconstant because methyglyoxal is generated from dihydroxyacetone and could be lost during further incubation/storage.[3] These findings suggest that either methylglyoxal or dihydroxyacetone is not suitable as chemical markers for manuka honey.

As shown in Figure 2A, B, NPA is highly correlated with leptosperin (r = 0.732, p < 0.001) but not with methyl syringate. Oelschlaegel et al. also reported that the leptosperin content in manuka honey has good correlation with that of methylglyoxal (r = 0.848, p = 0.000), which is a well-known strong germinant.[11] On the other hand, leptosperin only displays antibacterial activity at a high concentration range.[9] The underlying reason for the strong association of leptosperin content with antibacterial activity remains to be established.

A number of plausible chemical candidates have been identified for manuka honey authentication. A recent study showed that 2-formyl-5-(2-methoxyphenyl)pyrrole, a unique compound in manuka honey, is correlated with NPA (r^2 = 0.364).[15] Another study also reported that 2-methoxybenzoic acid in fresh honey (n = 10) is highly correlated with

dx.doi.org/10.1021/jf501475h | J. Agric. Food Chem. 2014, 62, 6400−6407

methylglyoxal (r^2 = 0.7968).[12] Fearney et al. identified a novel glycoside of TMBZ in honey, but its correlation with NPA (UMF) or methylglyoxal (MGO) is yet to be established.[16] In this study, we developed a plausible authentication method on the basis of leptosperin measurement, which is a specific compound of manuka honey.[9]

Apart from the reports on manuka honey, few studies focused on authentication of different kinds of honey. For example, over 100 chemicals in lavandin honey, a monofloral product of recent proliferation obtained from a hybrid of *Lavandula angustifolia* and *L. latifolia* species, were assessed as possible markers for authentication, with the aim of distinguishing it from the more common Lavender honey (*L. latifolia*).[16] Authentication of monofloral Yemeni Sidr honey using ultraviolet spectroscopy and chemometric analysis has also been proposed.[17]

As shown in Figure 4, one sample of manuka honey (no. 26) obtained from an online shop in Japan contained an extremely low level of leptosperin (22 nmol/g honey), which could be only analyzed using ESI-MS/MS. However, the honey sample (no. 27) with the same label, obtained from a retail store in New Zealand, displayed relatively low amount of leptosperin. We suspected that sample no. 26 was produced and sold improperly. In a masked study, five of six volunteers felt that the taste of "manuka honey" in no. 27 was more prominent compared with no. 26 (unpublished observation). In addition, UMF 15+ honey (no. 04), made by the same maker as no. 26 and no. 27 products, contained significant amounts of leptosperin and methyl syringate (Table 2). Therefore, the quantification of leptosperin with methyl syringate as a supplement may serve as an effective authenticator of manuka honey.

Few cosmetics or foods in the market indicate additional inclusions of manuka honey as a component. However, there is no simple way to chemically validate supplementation of honey by consumers and even producers at the present time. In our study, leptosperin (or methyl syringate) was detected in vodka, soap, or candy using mass spectrometry. Some of the samples contained trace amounts of leptosperin and methyl syringate, which could be detected using mass spectrometry.

Gaps in data were observed between HPLC and mass spectrometry analyses (Table 1), but mass spectrometry was suitable for detection of trace leptosperin and methyl syringate. In this study, we have also selected PNPG as the internal standard for leptosperin analyses using the MS/MS, but the PNPG is the substrate for β-glycosidase. Therefore, if active β-glycosidase is contaminated in the sample, it may interfere with the quantitation of leptosperin. On the other hand, TMBZ, the internal standard for quantitation of methyl syringate, is a possible component of manuka honey.[12] In the future, stable isotopic leptosperin and methyl syringate should be synthesized as the preferable internal standards.[18]

In summary, we investigated the possible application of leptosperin with methyl syringate for authentication of premium manuka honey using HPLC, ESI-MSMS, and APCI-MS/MS. The detection and quantitation of leptosperin with methyl syringate as an adjunct would be applicable for manuka honey authentication.

Porridge Preparation. Porridges were prepared according to the recipes in Table 1 in a stainless steel pot. For white rice porridge, 1 L of distilled water was boiled to 98 ± 2 °C in the pot, and then 75 g of white rice was dropped into the pot. For mixed grain porridge, 75 g of mixed grains was soaked in 500 mL of distilled water for 6 h first. Another 500 mL of distilled water was boiled to 98 ± 2 °C in the pot. After that, the mixed grains together with the water used for soaking were poured into the pot. For white rice porridge added with gum arabic, 10 g of gum arabic was dissolved in 1 L of distilled water in the pot first, then boiled to 98 ± 2 °C. After that, 75 g of white rice was dropped into the pot. For mixed grain porridge added with gum arabic, mixed grains were soaked in 500 mL of distilled water for 6 h first. Ten grams of gum arabic was dissolved in another 500 mL of distilled water in the pot, then boiled to 98 ± 2 °C. After that, the mixed grains together with the water used for soaking were poured into the pot. For all of the porridges, the pot was boiled with frequent stirring for 60 min after water boiling again to cause full gelatinization of starches. The cooked porridge was then transferred to a glass container and left to cool at room temperature.

Table 1. Preparations of Different Porridges

porridges	recipes
porridge 1[a]	white rice (75 g) boiled in 1 L of water
porridge 2	mixed grains (75 g) boiled in 1 L of water[b]
porridge 3	white rice (75 g) and gum arabic (10 g) boiled in 1 L of water
porridge 4	mixed grains (75 g) and gum arabic (10 g) boiled in 1 L of water

[a]Porridge 1, white rice porridge; porridge 2, mixed grain porridge; porridge 3, white rice porridge fortified with gum arabic; porridge 4, mixed grain porridge fortified with gum arabic. [b]Mixed grains: oat (15 g), buckwheat (15 g), brown rice (15 g), corn dregs (6 g), peanut (6 g), red bean (6 g), kidney bean (6 g), and coix seed (6 g).

Determination of Apparent Viscosity of Porridges. Apparent viscosity of each porridge was measured at 25 °C with a Brookfield DV-Ultra Programmable rheometer (Brookfield, Stoughton, MA), equipped with a CP52 spindle (spindle multiplier constant = 9.83, shear rate constant = 2).[19]

Simulated Gastric and Intestinal Digestion of Porridges in Vitro. *Digestion Media Used Throughout the Digestion Experiments.* All chemicals and enzymes were obtained from Sigma Chemical Co. (St. Louis, MO) and Amano Enzyme Inc. (Nagoya, Japan). The simulated gastric and intestinal fluids were prepared according to the protocol used by a model gastrointestinal system (TNO Intestinal Model 1, TIM1 from TNO Zeist, The Netherlands), which simulates the physiological conditions of the human stomach and small intestine.[20,21]

Gastric Medium Preparation. The gastric medium was prepared according to the method by Tedeschi et al. with some modifications.[22] The gastric electrolyte solution (GES) consisted of 3.1 g L^{-1} NaCl, 1.1 g L^{-1} KCl, 0.15 g L^{-1} $CaCl_2{\cdot}2H_2O$, and 0.6 g L^{-1} $NaHCO_3$. The final pH was adjusted to 3 by addition of HCl (0.1 N). Next, 37.5 mg of gastric lipase (Lipase DF Amano 15, Amano Enzyme Inc., Japan) and 35.4 mg of pepsin from porcine gastric mucosa (Sigma) were added to a solution of 150 g of GES and 1.5 mL of CH_3COONa (1 M, pH 5). The solution was gently mixed for 10 min on a magnetic stirrer at room temperature, and simultaneously the pH was adjusted to 3 by additions of HCl (0.1 N). The solution was stored on ice before use.

Small Intestinal Alkaline Medium. The small intestinal medium was prepared according to the method by Tedeschi et al.[22] The simulated small intestinal electrolyte solution (SIES) consisted of 5.4 g L^{-1} NaCl, 0.65 g L^{-1} KCl, and 0.33 g L^{-1} $CaCl_2{\cdot}2H_2O$. The pH was adjusted to 7 using NaOH (0.1 M). To simulate a duodenum residue solution, bile salt was added to a SIES containing the enzymes pancreatine and trypsin. A SIES with enzymes and bile salts was first prepared (SIENZY). The SIENZY solution contained 100 g of SIES, 100 g of pancreatin solution (7%, w/w, Sigma), 13 mg of trypsin (Sigma), and 200 g bile salt solution (4%, w/w). For the pancreatin solution, 14 g of pancreatin was dissolved in 200 g of water, and the solution was mixed for 10 min with a magnetic stirrer and centrifuged for 10 min at 2800*g*. The supernatant (100 g) was used for the preparation of the SIENZY solution. The dilution was performed using SIES as dilution medium, and the pH was adjusted to 7.5 by NaOH (0.1 M).

Simulated Digestion. Digestion studies were performed using an RC806 flow-through dissolution system (Tianfa Corp., Tianjing, China), equipped with a temperature circulator-controller, which allowed one to maintain the temperature at 37 °C throughout all of the experiments. Stirring paddles (Tianfa Corp., Tianjing, China), which were at the top of sample cells, were also equipped with a flow-through dissolution system for simulating the gastric peristalsis. In addition, several pumps (HL-2D, Qingpu Corp., Shanghai, China) were connected to the dissolution system to pump in the gastric and intestinal medium for digestion. Further, a pH meter (XB89-PH-2612, XG Corp., Beijing, China) was also connected to the dissolution system for controlling the pH in digestion system. The pH was monitored and continuously controlled by adding either water or 1 M HCl into the stomach, and either electrolytes or 1 M $NaHCO_3$ into the small intestine. Before each experiment, the system was washed with detergent and rinsed with water. For the gastric digestion tests of porridges, cells were loaded with 100 mL of porridge, and 150 mL of gastric medium was pumped through the cells at a constant flux of 0.4 mL min^{-1}. For the intestinal digestion of porridges, porridges that were predigested by gastric medium were placed inside another sample cells. Around 200 mL of small intestinal medium was pumped at a constant flux of 0.56 mL min^{-1}. For all of the experiments, a fraction collector (BSZ-100, Jingke Corp., Shanghai, China) was used to withdraw 3 mL samples at specified time intervals. The collected samples were used for the determination of glucose concentration and the calculation of glucose amount.

The gastric digestion of the porridges was followed for 6 h. Samples were analyzed before and after digestion. Glucose concentration was determined at 0, 0.5, 1, 2, 3, 4, 5, and 6 h according to the hexokinase method of Yokoyama et al.[2] Three independently replicated extractions were performed for each sample. The intestinal digestion of the porridge was also followed for 6 h. Samples were analyzed after digestion, and the glucose concentration was determined after 0.5, 1, 2, 3, 4, 5, and 6 h according to the hexokinase method.[2] Three independently replicated extractions were performed for each sample. The maximum producing velocity of glucose (V_{max1}) for porridges during intestinal digestion was calculated as follows. The experimental data were fitted with an equation of parabola:

$$Y = ax^2 + bx + c$$

where Y is the glucose concentration (mM); x is time (min); and a, b, and c are coefficients. The equation to calculate the producing rate (Y') at any time is $Y' = 2ax + b$. When x is close to 0, $Y' = V_{max1} = b$.

Determination of Glucose Diffusion. The residue digestion mixtures of porridges after digestion were used to determine diffusion of glucose according to the method by Ou et al. with some modifications.[23] Briefly, a total of 12 samples (3 replicates of 4 different porridges), 25 mL each, were dialyzed in dialysis bags with a molecular weight cutoff of 8000−14 000 against 200 mL of deionized water at 37 °C. The glucose concentration in 2.0 mL of the dialysate was determined after 10, 20, 30, 60, 90, 120, 150, 180, 240, 300, and 360 min (the results at 12 h proved 360 min was enough for equilibrium) according to the hexokinase method.[2]

The maximum diffusion velocity of glucose (V_{max2}) was calculated as follows. The experimental data were fitted with an equation of parabola:

$$Y = ax^2 + bx + c$$

where Y is the glucose diffusion concentration (mM); x is time (min); and a, b, and c are coefficients. The equation to calculate the diffusion

dx.doi.org/10.1021/jf501557b | J. Agric. Food Chem. 2014, 62, 6408−6416

rate (Y') at any time is $Y' = 2ax + b$. When x is close to 0, $Y' = V_{max2} = b$.

Animal Study. Male 6-week-old Kunming mice (20.0 ± 2.0 g) were individually housed in stainless steel cages in a room with controlled temperature (25.0 ± 0.5 °C), relative humidity (50 ± 5%), and 12 h/12 h light/dark cycle. All mice were fed with the same amount of basal diet, which was prepared according to the published formula,[24] and water was provided ad libitum. Food was stopped to the mice 12 h before the experiment. All mice were randomly divided into four groups: (1) porridge 1 group, mice were given oral administration of white rice porridge at 25 mL/kg body weight (solid content = 1.875 g solid/kg body weight); (2) porridge 2 group, mice were given mixed grain porridge at 25 mL/kg body weight (solid content = 1.875 g solid/kg body weight); (3) porridge 3 group, mice were given white rice porridge fortified with gum arabic at 25 mL/kg body weight (solid content = 2.125 g solid/kg body weight; gum arabic content = 0.25 g/kg body weight); (4) porridge 4 group, mice were given mixed grain porridge fortified with gum arabic at 25 mL/kg body weight (solid content = 2.125 g solid/kg body weight; gum arabic content = 0.25 g/kg body weight). Each group had 12 mice, and 6 mice were put in one cage. The blood glucose of each mouse was determined before oral administration (0 h) and also 0.5, 1, 2, and 3 h after being given oral administration of porridge. Blood glucose levels were obtained by using an Accu-Chek Performa blood glucose meter (Roche, Mannheim, Germany).

In Vitro Fermentation of Porridges. *Fecal Slurry Preparation.* The fresh fecal samples were collected from four healthy donors who never had large bowel disease before. The donors also had followed normal diets and had not been treated with antibiotics for at least 3 months. Collected fecal samples were mixed with an equal amount of feces from each donor. The mixed fecal samples were immediately stored in an anaerobic jar before use.[25]

Preculture. Mixed fecal samples (120 g) was precultured in 1 L of preculture medium (10 g of tryptone, 5 g of yeast, 10 g of NaCl, 5 g of glucose, and 6 g of maltose) anaerobically. After overnight growth, 120 mL of the preculture was filtered through sterile gauze sponges to remove large particles and stored in an anaerobic jar before use.[26]

Fermentation. The composition of 1 L growth medium was: 4.5 g of NaCl, 4.5 g of KCl, 1.5 g of $NaHCO_3$, 0.69 g of $MgSO_4 \cdot H_2O$, 0.8 g of L-cysteine $HCl \cdot H_2O$, 0.5 g of KH_2PO_4, 0.5 g of K_2HPO_4, 0.4 g of bile salt, 0.08 g of $CaCl_2$, 0.005 g of $FeSO_4 \cdot 7H_2O$, 1 mL of Tween 80, and 4 mL of resazurin solution (0.025%, w/v) as anaerobic indicator.[25] Growth medium was sterilized at 121 °C for 15 min before use and divided into sterile anaerobic vessels.

The porridge samples (after gastrointestinal digestion) were subjected to the in vitro fermentation with the precultured human fecal microbiota. The total volume of the fermentation slurry was 50 mL. For the tested samples, the final fermentation volume was 40% growth medium, 40% human fecal preculture, and the last 20% was porridge or distilled water (control). All samples and the fecal preculture were introduced in different anaerobic sealed tubes containing growth medium, under the condition of 10% H_2, 10% CO_2, and 80% N_2 in Forma Anaerobic System (Thermo Electron Corp., Marietta, OH).[27] Separated tubes were prepared for each replicate at each time point (0, 6, 12, and 24 h during fermentation). The anaerobic sealed tubes were then incubated at 37 °C for 24 h in a TC-2112B Thermostat shaker (160 rpm, Shanghai Nuoji Corp., Shanghai, China).

SCFA Measurement. The fermentation cultures were centrifuged at 4800*g* for 15 min. The supernatants were used for determination of SCFA. Chromatographic analysis was carried out using the Agilent 6890 N GC system according to our published method.[28] A GC column (HP-INNOWAX, 190901N-213, J & W Scientific, Agilent Technologies Inc., U.S.) of 30 m × 0.32 mm i.d. coated with 0.50 μm film thickness was used. Nitrogen was supplied as the carrier gas at a flow rate of 19.0 mL/min with a split ratio of 1:10. An initial column temperature was held at 100 °C for 0.5 min, then programmed at a rate of 4 °C/min to 180 °C. The temperature of the FID and injection port was 240 °C. The flow rates of hydrogen and air were 30 and 300 mL/min, respectively. The volume of injected standard SCFA and sample for GC analysis was 0.2 μL, and the running time for each analysis was 20.5 min. The independently replicated determinations were performed three times for each sample. Data handling was carried out with HP Chem Station Plus software (A.09.xx, Agilent).

Statistical Analysis. All of the experiments were done in triplicate. Statistical analysis was carried out using SPSS (version 16.0, Chicago, IL). The results were expressed as mean ± standard deviations and compared using the Tukey test at 5% confidence level.

RESULTS AND DISCUSSION

Apparent Viscosity of Porridges. There was some difference in the apparent viscosity among porridges (Table 2). The apparent viscosity level (shear rate = 30 or 50 s^{-1}) of white rice porridge was higher than that of mixed grain porridge. The difference in the apparent viscosity between white rice porridge and mixed grain porridge may be due to the difference of the materials in the porridges. This was consistent with previous result reported by Wood et al.[29] However, apparent viscosity of the two porridges was significantly increased after addition of gum arabic ($p < 0.05$). The apparent viscosity of white rice porridge was improved from 633 ± 3 to 720 ± 4 mPa s^{-1} at shear rate = 30 s^{-1} and increased from 342 ± 4 to 435 ± 2 mPa s^{-1} at shear rate = 50 s^{-1}. Meanwhile, the apparent viscosity of mixed grain porridge increased from 602 ± 2 to 683 ± 2 mPa s^{-1} at shear rate = 30 s^{-1} and increased from 303 ± 2 to 410 ± 3 mPa s^{-1} at shear rate = 50 s^{-1}. This may result from the addition of gum arabic to porridges. Viscous water-soluble dietary fibers could affect the apparent viscosity of solution.[30] A higher viscosity of solution could be provided by gum arabic.[31] In addition, gum arabic was reported to belong to the family of dietary fiber, and our results agreed well with those of other dietary fibers, which could improve the values of apparent viscosity.[30,32] The increase in the apparent viscosity may have an effect on the glucose production and diffusion, which affect the blood sugar response.[29]

Table 2. Apparent Viscosities of Different Porridges at Different Shear Rates (s^{-1})[a]

sample	apparent viscosity (mPa s^{-1})	
	30 s^{-1}	50 s^{-1}
porridge 1[b]	633 ± 3 a[c]	342 ± 4 a
porridge 2	602 ± 2 b	303 ± 2 b
porridge 3	720 ± 4 c	435 ± 2 c
porridge 4	683 ± 2 d	410 ± 3 d

[a]Data are presented as means ± standard deviations of triplicate measurements. [b]Porridge 1, white rice porridge; porridge 2, mixed grain porridge; porridge 3, white rice porridge fortified with gum arabic; porridge 4, mixed grain porridge fortified with gum arabic. [c]Mean values in the same column with different letters are significantly different (Tukey test, $p < 0.05$).

Glucose Production of Porridges during Gastric Digestion. As shown in Table 3, the total amount of glucose in white rice porridge was 40 mmol at the beginning and then increased to 460 mmol at 6 h. These amounts of the glucose may result from hydrolysis of the starch in the white rice porridge, which may be due to the acid environment of the gastric medium (pH = 3) because there was no enzyme in gastric medium that could hydrolyze the whole starch in white rice porridge to glucose. In addition, the glucose amount of white rice porridge fortified with gum arabic was significantly lower than that of the white rice porridge at the same time point throughout the whole gastric digestion ($p < 0.05$). This

[a]Data are presented as means ± standard deviations of triplicate measurements. [b]Porridge 1, white rice porridge; porridge 2, mixed grain porridge; porridge 3, white rice porridge fortified with gum arabic; porridge 4, mixed grain porridge fortified with gum arabic. [c]Mean values in the same column (from the same digestion) with different letters are significantly different (Tukey test, $p < 0.05$).

may be because the gum arabic coated on the surface of grains, which could affect the starch in the white rice porridge to get in touch with the gastric medium and delay the glucose production. Furuta et al. also found the coating of another dietary fiber, water-soluble soybean polysaccharides, on the surface of cooked rice grains.[33]

The glucose amount in mixed grain porridge at 0 h was only 5 mmol, and the amount increased to 160 mmol at 6 h (Table 3). The lower initial glucose amount of mixed grain porridge would be due to less rice in the formula. The increase of glucose amount would also result from weak hydrolysis of the carbohydrates in mixed grain porridge, which was due to the acid environment of the gastric medium (pH = 3). The glucose amount of mixed grain porridge fortified with gum arabic was significantly lower than those of mixed grain porridge at the same time points during gastric digestion ($p < 0.05$), and very little glucose was produced in mixed grain porridge fortified with gum arabic during gastric digestion (22−80 mmol). This may be also because the gum arabic could inhibit the carbohydrates in mixed grain porridge to get in touch with the gastric medium and thus reduce the glucose production.

Glucose Production of Porridges during Intestinal Digestion. The glucose amounts of porridges during intestinal digestion were also shown in Table 3. The glucose amount of white rice porridge was high (approximately 3.0 mol) in the initial time point (0.5 h), and the glucose amount differed significantly from 0.5 to 6 h. The glucose amount of white rice porridge increased along with the digestion time, with the maximum level of 22.6 mol at 6 h, for there was an enzyme, amylase, which could hydrolyze the starch in white rice to glucose. However, after addition of gum arabic, the level of glucose amount in the white rice porridge was significantly decreased at all time points ($p < 0.05$), with a maximum level of around 16.8 mol at 6 h. The maximum glucose producing velocity (V_{max1}) of white rice porridge fortified with gum arabic (0.2233 ± 0.0010 mM min^{-1}) was significantly lower than that of white rice porridge (0.2880 ± 0.0015 mM min^{-1}) (Table 4, $p < 0.05$).

As presented in Table 3, the glucose amount of mixed grain porridge was approximately 2.0 mol at the initial time point (0.5 h), and it differed significantly from 0.5 to 6 h. The glucose amount of mixed grain porridge increased along with the digestion time, with the maximum level of around 14.8 mol at 6 h. However, after addition of gum arabic, the level of glucose amount in the mixed grain porridge was significantly decreased

Table 4. Maximum Producing Velocity of Glucose (V_{max1}) and Maximum Diffusion Velocity of Glucose (V_{max2}) for Different Porridges[a]

	V_{max} (mM min^{-1})	
samples	V_{max1}	V_{max2}
porridge 1[b]	0.2880 ± 0.0015 a[c]	0.0348 ± 0.0007 a
porridge 2	0.1779 ± 0.0008 b	0.0250 ± 0.0010 b
porridge 3	0.2233 ± 0.0010 c	0.0297 ± 0.0005 c
porridge 4	0.1350 ± 0.0005 d	0.0196 ± 0.0008 d

[a]Data are presented as means ± standard deviations of triplicate measurements. [b]Porridge 1, white rice porridge; porridge 2, mixed grain porridge; porridge 3, white rice porridge fortified with gum arabic; porridge 4, mixed grain porridge fortified with gum arabic. [c]Mean values in the same column with different letters are significantly different (Tukey test, $p < 0.05$).

at all time points ($p < 0.05$), with a maximum level of around 11.7 mol at 6 h. The maximum glucose producing velocity (V_{max1}) of mixed grain porridge fortified with gum arabic (0.1350 ± 0.0005 mM min^{-1}) was significantly lower than that of mixed grain porridge (0.1779 ± 0.0008 mM min^{-1}) (Table 4, $p < 0.05$).

Annison and Topping reported that dietary fibers can be adsorbed to starch and thus decreased hydrolysis of starch by α-amylase in the intestinal digestion.[34] The activity of α-amylase was also influenced to some extent by the kind of dietary fiber. However, further studies are needed to investigate whether the gum arabic is a competent inhibitor of α-amylase or simply acts as a barrier between the enzyme and starch.[23]

Diffusion of the Glucose. Diffusion of glucose was different for different porridges (Table 5). Diffused glucose for white rice porridge was significantly higher than that for white rice porridge fortified with gum arabic at all of the time points ($p < 0.05$). The maximum diffusion velocity (V_{max2}) of white rice porridge fortified with gum arabic was (0.0297 ± 0.0005) mM min^{-1}, which was significantly lower than that of white rice porridge (0.0348 ± 0.0007 mM min^{-1}) (Table 4, $p < 0.05$). Diffused glucose for mixed grain porridge was also significantly higher than that for mixed grain porridge fortified with gum arabic at all of the time points (Table 5, $p < 0.05$). The maximum diffusion velocity (V_{max2}) of mixed grain porridge fortified with gum arabic was 0.0196 ± 0.0008 mM min^{-1} and was notably lower than that of mixed grain porridge (0.0250 ± 0.0010 mM min^{-1}) (Table 4, $p < 0.05$).

[a]Data are presented as means ± standard deviations of triplicate measurements. [b]Porridge 1, white rice porridge; porridge 2, mixed grain porridge; porridge 3, white rice porridge fortified with gum arabic; porridge 4, mixed grain porridge fortified with gum arabic. [c]Mean values in the same column with different letters are significantly different (Tukey test, $p < 0.05$).

The viscosity of porridge may influence the diffusion of glucose. For example, Wood et al. reported that the rates of glucose diffusion from the high viscous solution were considerably less than diffusion in low viscous solution.[29] Thus, the increase of the apparent viscosity of porridges due to addition of gum arabic (Table 2) may have some effects on the glucose diffusion. Water-soluble dietary fibers were also reported to have the effects of hampering the diffusion of glucose and postponing the absorption.[2] Thus, the addition of gum arabic in porridges may also have the ability of slowing the diffusion of glucose, which was similar to other dietary fibers, such as guar gum, xanthan gum, and oat gum.[23,29]

Mouse Blood Glucose Rise after Oral Administration of Porridges. As shown in Figure 1, the initial glucose level of all groups of mice was near 4.5 mmol/L. The blood glucose levels of all of the mice then increased from 0 to 0.5 h after oral administration of porridges and reached the maximum levels at 0.5 h. However, the blood glucose level of mice in white rice porridge fortified with gum arabic group (10.7 ± 0.4 mmol/L) was notably less than that in the white rice porridge group at 0.5 h (13.0 ± 0.8 mmol/L, $p < 0.05$). The blood glucose level of mice in mixed grain porridge fortified with gum arabic group (7.5 ± 0.3 mmol/L) was also obviously lower than that of the mixed grain porridge group at 0.5 h (9.9 ± 0.4 mmol/L, $p < 0.05$). The blood glucose levels of mice in these porridge groups decreased from 0.5 to 1 h, and porridges fortified with gum arabic group mice had significantly lower blood glucose level than that of the unfortified porridges group of mice at 1 h ($p < 0.05$). The blood glucose levels of these porridge groups returned to the normal level at 2 and 3 h, and there was no significant difference among them ($p > 0.05$).

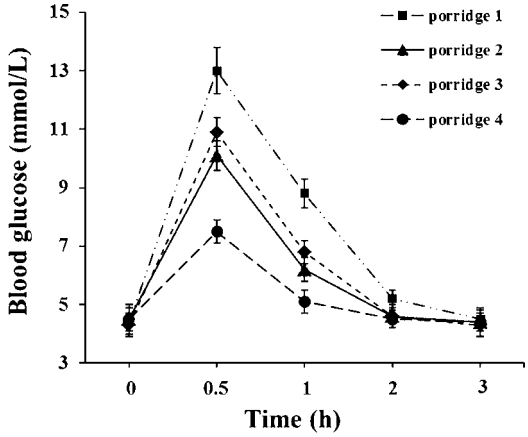

Figure 1. Changes of blood glucose level in mice orally given different porridges.

It can be recognized that the response of blood glucose rise after oral administration of porridges could be significantly lowered due to the addition of gum arabic ($p < 0.05$). This was consistent with our results for the glucose production (Table 3) and glucose diffusion (Table 5) in this study. It may be also because the gum arabic carried out some effects on the blood glucose rise after oral administration of the porridge. This was similar to the results reported by Schweizer et al.,[35] and they compared the serum glucose response of a study group with low dietary fiber intake and a group with high dietary fiber intake. They found that the glucose index of the former was 100% higher than that of the latter. Furthermore, dietary fibers

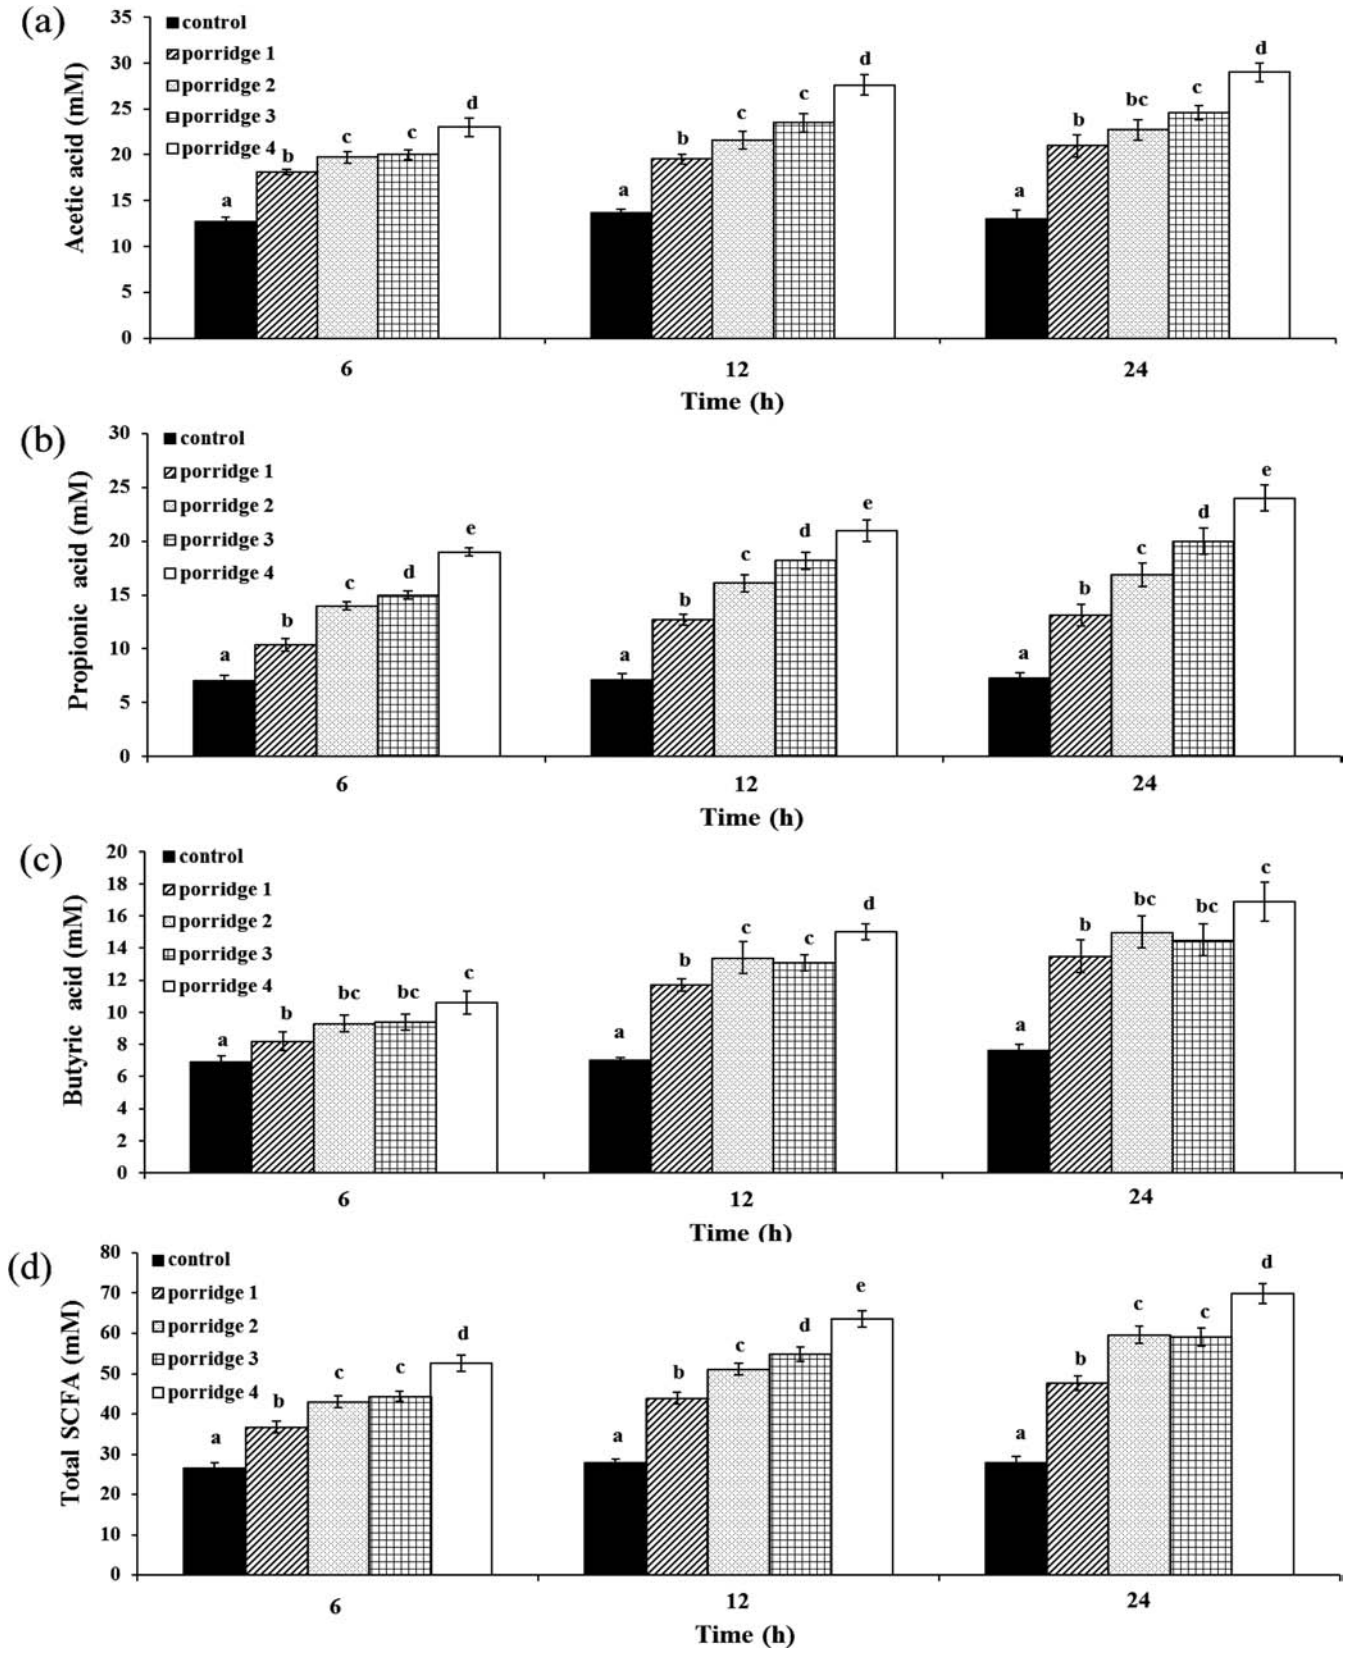

Figure 2. Changes in acetic acid (a), propionic acid (b), butyric acid (c), and total SCFA (d) concentrations after 6, 12, and 24 h of fermentation (37 °C, anaerobic) of different porridge samples (after gastrointestinal digestion) and the control (distilled water). Porridge 1, white rice porridge; porridge 2, mixed grain porridge; porridge 3, white rice porridge fortified with gum arabic; porridge 4, mixed grain porridge fortified with gum arabic. Data are expressed as means ± standard deviations. Values from the same time point differ significantly ($p < 0.05$) when not sharing a common letter. Values for the start of the fermentation experiment (time 0 h) are 9.5 ± 0.3, 4.1 ± 0.2, 3.7 ± 0.3, and 17.3 ± 1.0 mM for (a), (b), (c), and (d), respectively.

dx.doi.org/10.1021/jf501557b | J. Agric. Food Chem. 2014, 62, 6408−6416

have been reported to help lower the blood glucose rise and glycemic level in serum by increasing the function of the upper gastrointestinal tract as well as the plasma levels of the intestinotrophic factor,[36] lowering the insulin response,[37] and slowing glucose absorption through an effect on gastric emptying and/or entrapment of materials in the viscous digesta.[38]

Microbial SCFA Production of Porridge Fermentation. In this study, mixed fresh fecal samples from four donors were used to minimize the difference of the feces from different people.[25] In addition, according to the references, the intestinal anaerobic species, *Bacteroides*, *Eubacterium*, *Clostridium*, *Lactobacillus*, and *Bifidobacterium*, were found in high numbers and were considered to be the main anaerobic microbes in the stools of normal adults and children. These anaerobic species were also found as the main species in the precultured human fecal slurry that may degrade and ferment carbohydrates.[26,39] During the fermentation of porridges, acetic, propionic, and butyric acids were found as the dominant components in total SCFA (Figure 2). As shown in Figure 2a, acetic acid concentrations were strongly increased for all porridge samples upon incubation with human fecal microbiota, the increase being the strongest in the first 6 h of incubation. After 24 h, acetic acid concentrations of the porridge fermented cultures were always significantly higher than that at the time of 0 h (9.5 ± 0.3 mM). At all time points, fermentation of porridges fortified with gum arabic resulted in significantly ($p < 0.01$) higher concentrations of acetic acid than fermentation of the unfortified porridges. This may result from the addition of the gum arabic, which is a kind of soluble dietary fiber. It was reported that acetic acid is a SCFA that is produced as a result of colonic bacterial fermentation of dietary fiber, and acetic acid exerts beneficial effects on glucose homeostasis in diabetes.[40] Several reports have reported that increased acetic acid production in the bowel might, in part, account for the reduction of the postprandial glycemic response, which is one of the beneficial metabolic effects of dietary fiber. Acetic acid was also considered to be beneficial in enhancing glycogen repletion after fasting.[41]

It has been demonstrated that propionic acid could lower fatty acids content in liver and plasma, and improve tissue insulin sensitivity. Thus, increased production of propionic acid by the microbiota might be considered beneficial in the context of reducing postprandial glycemic response. The concentration of propionic acid was presented in Figure 2b, and it was increased for all porridges with incubation time. Values after 6, 12, and 24 h incubation differed significantly ($p < 0.05$) from that at the start (4.1 ± 0.2 mM), and the highest level (at 24 h) was 3.5−6.0 times higher than that at time 0 h. At all time points, fermentation of porridges fortified with gum arabic resulted in significantly ($p < 0.05$) higher concentrations of propionic acid than fermentation of the responding unfortified porridges. Research indicated that dietary fiber had a profound effect on general health, which included the increase of postmeal satiety and the decrease of body weight, fat mass, and the severity of diabetes.[41,42] These effects may be contributed via the fermentation of dietary fiber by the colonic microbiota and in turn the production of propionic acid production.[43,44] Good evidence exists that systemically relevant concentrations of propionic acid might exert a beneficial effect on insulin sensitivity, and thus propionic acid may well form the link for prebiotics supplementation and their beneficial effects on diabetes and related diseases.[5]

Butyric acid was also considered to have some beneficial effects on diabetes. In this study, butyric acid concentration differed significantly ($p < 0.05$) from that at the start of the experiment (3.7 ± 0.3 mM) for all porridges after 6 h incubation (Figure 2c). It continued to increase upon further incubation, and values after 12 and 24 h of incubation were 3−4 times and 4−5 times higher than that at time 0 h, respectively. Fermentation of porridges fortified with gum arabic resulted in significantly higher concentrations of butyric acid than fermentation of the responding unfortified porridges at the time point of 12 h ($p < 0.05$). This may be also due to the addition of the gum arabic to the porridges. As a product of the dietary fiber fermentation, the butyric acid was found to have some effects on preventing and treating diet-induced diabetes and insulin resistance in mouse models. The mechanism of the butyric acid action is related to the promotion of energy expenditure and induction of mitochondria function.[5]

In addition, concentrations of total SCFA at 6, 12, and 24 h during fermentation are presented in Figure 2d. The fermentation cultures for porridges fortified with gum arabic contained significantly higher concentrations of total SCFA than the responding unfortified porridges at all time points ($p < 0.05$).

There have been extensive studies on the health benefit of gum arabic on glucose level and SCFA production. Because of the physical properties of gum arabic, such as viscosity, it was found to be a good in vitro glucosidase inhibitor and have effects on the retardation and delay of carbohydrate and glucose absorption.[45−47] Gum arabic was also reported to reach the large intestine without digestion in the small intestine, and it can be mostly fermented by intestinal bacteria to SCFA, particularly propionic acid, in large intestine and feces.[46−48] Previous studies mainly focused on the gum arabic itself on glucose level and SCFA production. Limited information is available for the effects of gum arabic on glucose levels and microbial SCFA production in food models.

Therefore, our results showed in vitro and in vivo information about the effects of gum arabic on glucose levels and microbial SCFA productions in food model (white rice porridge model and mixed grain porridge model) for the first time. Apparent viscosity of the two porridges was significantly increased after addition of gum arabic, and the glucose productions of porridges were both notably lowered at the same time points during gastrointestinal digestion. Diffused glucose amount was also significantly decreased after gum arabic addition. Furthermore, blood glucose rise after oral administration of porridges fortified with gum arabic in mice was considerably lower than the responding unfortified porridges. Microbial short-chain fatty acid production of porridges during in vitro fermentation was also significantly increased after addition of gum arabic. Therefore, gum arabic may be a helpful ingredient, which could be added in porridges to have benefits for the reduction of postprandial glycemic response.

between the phenolic compounds present in the PGJ and milk proteins and its impact on the antioxidant activity of the yogurt.

MATERIALS AND METHODS

Materials and Chemicals. Commercial starter cultures of *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus* (Ezal MY900, Rhodia Food-Danisco A/S, Sassenage, France) were used at the concentrations recommended by the suppliers. For all the study, the same batch of skim milk powder was used (34% protein, 52% lactose, 1% fat, 6.8% ash, 5.2% moisture) (Central Lechera Asturiana, CAPSA, Granada-Siero, Spain).

2,2-Diphenyl-1-picrylhydrazyl (DPPH$^{\bullet}$), Folin−Ciocalteu reagent, gallic acid, iron(III) chloride, trichloroacetic acid (TCA), aluminum chloride, Trolox, and formic acid were from Sigma Chemical Company (Germany). Methanol of HPLC ultragradient grade, HCl, potassium chloride, sodium acetate, dibasic potassium phosphate, sodium nitrite (II), sodium hydroxide, sodium carbonate, and dibasic sodium phosphate were from Merck (Darmstadt, Germany). Potassium hexacyanoferrate was from Fluka BioChemika (Germany). Ellagic acid was from Tocris Bioscience (Ellisville, MO, USA), and pure punicalagins were from Chengdu Biopurity Phytochemicals Ltd. (Sischuan, China). Cyanidin-3,5-*O*-diglucoside and -glucoside, pelargonidin-3-*O*-glucoside, and delphinidin-3-*O*-glucoside, were from Extrasynthese (Genay, France). Acetonitrile for HPLC-DAD and LC/MS (Gradient grade) was from Merck (Darmstadt, Germany). LC grade water, prepared by using an HLP SMART 1000s system (Hydrolab, Gdańsk, Poland), was additionally filtered through a 0.22 μm membrane filter immediately before use.

Plant Material. Mature PG fruit cultivar "Mollar de Elche", with no visible external cuts or spoilage was purchased from a local market. The PG fruits were peeled manually, and the arils were introduced in a blender Ju2000 Vitae (Moulinex, Barcelona, Spain) to obtain PGJ. PGJ was filtered through cotton gauze to remove particles and was kept frozen until use.

Yogurt Manufacture. Set-type yogurt was produced following the manufacture method developed by Trigueros et al.[10] Briefly, skim milk powder (SMP) was reconstituted with deionized water at 15% w/v total solids to serve as control. SMP was reconstituted at 25% w/v total solids to be further completed with PGJ to have a final solid content of 15% w/v after pasteurization. PGJ, 15% reconstituted skim milk (RSM), and 25% RSM were separately pasteurized at 80 °C for 30 min. After cooling to 43 °C, PGJ was added to the RSM to a final concentration of 40% v/v. At this point, the starter culture was added and the inoculated mix was incubated at 43 °C for 4 h and then cooled and stored at 4 °C for 28 days.

Colorimetric Analysis. The CIE LAB color space of yogurts was studied, and the following color coordinates were determined: lightness (L^*), redness (a^*, ± red−green), and yellowness (b^*, ± yellow−blue). Color determinations were made at 12 ± 2 °C by means of a Minolta CM-2002 (Minolta Camera Co., Osaka, Japan) spectrophotometer, with a liquid accessory CR-A70 (Minolta Camera Co., Osaka, Japan), with illuminant D_{65} and an observer of 10°.

Preparation of the Free-Protein Phase (Permeate). To quantitatively estimate the interaction of phenolic compounds with proteins, a protein-free phase (permeate) was obtained with a laboratory scale ultrafiltration (UF) cartridge (Amicon Ultra-15; Merck Millipore Ltd., Ireland), with a nominal cutoff of 10000 Da and a nominal area of 7.6 cm^2 was used. To remove caseins, 30 g of yogurt were centrifuged at 7000 rpm for 30 min, at 4 °C. The supernatant was ultrafiltrated through the cartridge at 5500 rpm for 30 min, at 4 °C, and permeate was collected for further analysis.

Extraction of Phenolics from PJ and Yogurt Permeate. PGJ and permeates (10 mL) were extracted with 30 mL of acidified methanol (methanol containing 100 μL concd HCl) for 30 s at 12000 rpm (IKA T25 digital ULTRA-TURRAX, IKA Werke Staufen, Germany). Then, the mixtures were centrifuged at 5000 rpm for 10 min at 4 °C. Then 5 mL of the extract was separated for determining anthocyanin content. The remaining portions were evaporated to dryness using a rotary evaporator R-205 (Büchi, Flawil, Switzerland) under reduced pressure (<100 mbar) at 50 °C and used for determining total phenolics, total flavonoids, antioxidant activities, and HPLC analysis.

Extraction of Phenolics from PJ Yogurt. Yogurt samples (20 g) were mixed with 30 mL of acidified methanol. Then the mixture was left at 4 °C for overnight incubation. The mixture was filtered by using no. 1 Whatman filter paper, and residue was washed with acidified methanol until it became colorless.[14] Ten milliliters of the extract were separated for determining anthocyanin content. The remaining portions were concentrated as previously described and used for determining total phenolics, total flavonoids, antioxidant activities, and LC and HPLC analysis.

HPLC-DAD Analysis (Nonanthocyanin Phenolics). Phenolic compounds were analyzed by high performance liquid chromatography coupled with a diode array detector (HPLC-DAD) as previously described by Benavente-García et al.[15] Samples (20 μL) were injected into a Hewlett-Packard HPLC series 1200 instrument (Woldbronn, Germany) equipped with a C18 Teknokroma column (Mediterranean sea$_{18}$ 25 cm × 0.4 cm, Teknokroma, Barcelona, Spain) and detected by absorbance at 280 and 360 nm. UV spectra of individual peaks were recorded in the range of 200−600 nm. The separation columns were controlled thermostatically at 35 °C. Phenolic compounds were analyzed in standard and sample solutions using a gradient elution at 1 mL/min with the following gradient program (0−20 min 95−75% A, 20−40 min 75−50% A, 40−45 min 50−95% A) with 4.5% formic acid in water (v/v) as solvent A and 100% of acetonitrile as solvent B. Peaks were identified by comparing retention times and photodiode array spectra with analytical standards. The phenolic compounds were quantified by the absorbance of their corresponding peaks with calibration curves of standard compounds. For this purpose, stock solutions were diluted to concentrations of 10−160 mg/L (ellagic acid) and 25−800 mg/L (punicalagins isomers).

LC-PDA/MS Analysis (Anthocyanins). Identification of phenolic compounds was carried out using an ACQUITY Ultra Performance LC system (UPLC) with binary solvent manager and photo diode array (PDA) detector (Waters Corporation, Milford, MA, USA) and a Micromass Q-TOF Micro mass spectrometer (Waters, Manchester, UK) equipped with an electrospray ionization (ESI) source operating in negative and positive mode. Separations of individual phenolic compounds were carried out using a UPLC BEH C18 column (1.7 μm, 2.1 mm × 100 mm; Waters Corporation) at 30 °C. Samples (10 μL juice and 2 μL yogurt and permeate extracts) were injected and elution completed in 20 min with a sequence of linear gradients and isocratic flow rates of 0.45 mL/min. The mobile phase was composed of solvent A (4.5% formic acid in water, v/v) and solvent B (100% of acetonitrile). The program began with isocratic elution with 99% A (0−1 min), and then a linear gradient was used until 15 min, lowering A to 75%, and then 2.5 min for 0% of solvent A and 2.5 min, returned to the initial composition (99% A) and then held constant to re-equilibrate the column. Analysis was carried out using full-scan, data-dependent MS scanning from m/z 100 to 1500. The mass tolerance was 0.001 Da, and the resolution was 5000. Leucine enkephalin was used as the internal reference compound during ESI-MS accurate mass experiments and was permanently introduced via the LockSpray channel using a Hamilton pump. The lock mass correction was ±1000 for Mass Window. All TOF-MS chromatograms are displayed as base peak intensity (BPI) chromatograms and scaled to 12400 counts per second (cps) (= 100%). The effluent was led directly to an electrospray source with a source block temperature of 130 °C, desolvation temperature of 350 °C, capillary voltage of 2.5 kV, and cone voltage of 30 V. Nitrogen gas used as desolvation gas at a flow rate of 300 L/h.

The characterization of the single components was carried out via the retention time and the accurate molecular masses. Each compound was optimized to its estimated molecular mass in the negative and positive mode before and after fragmentation. The data obtained from LC/MS were subsequently entered into the MassLynx 4.0 ChromaLynx Application Manager software. On the basis of these data, the software is able to scan different samples for the characterized substances.

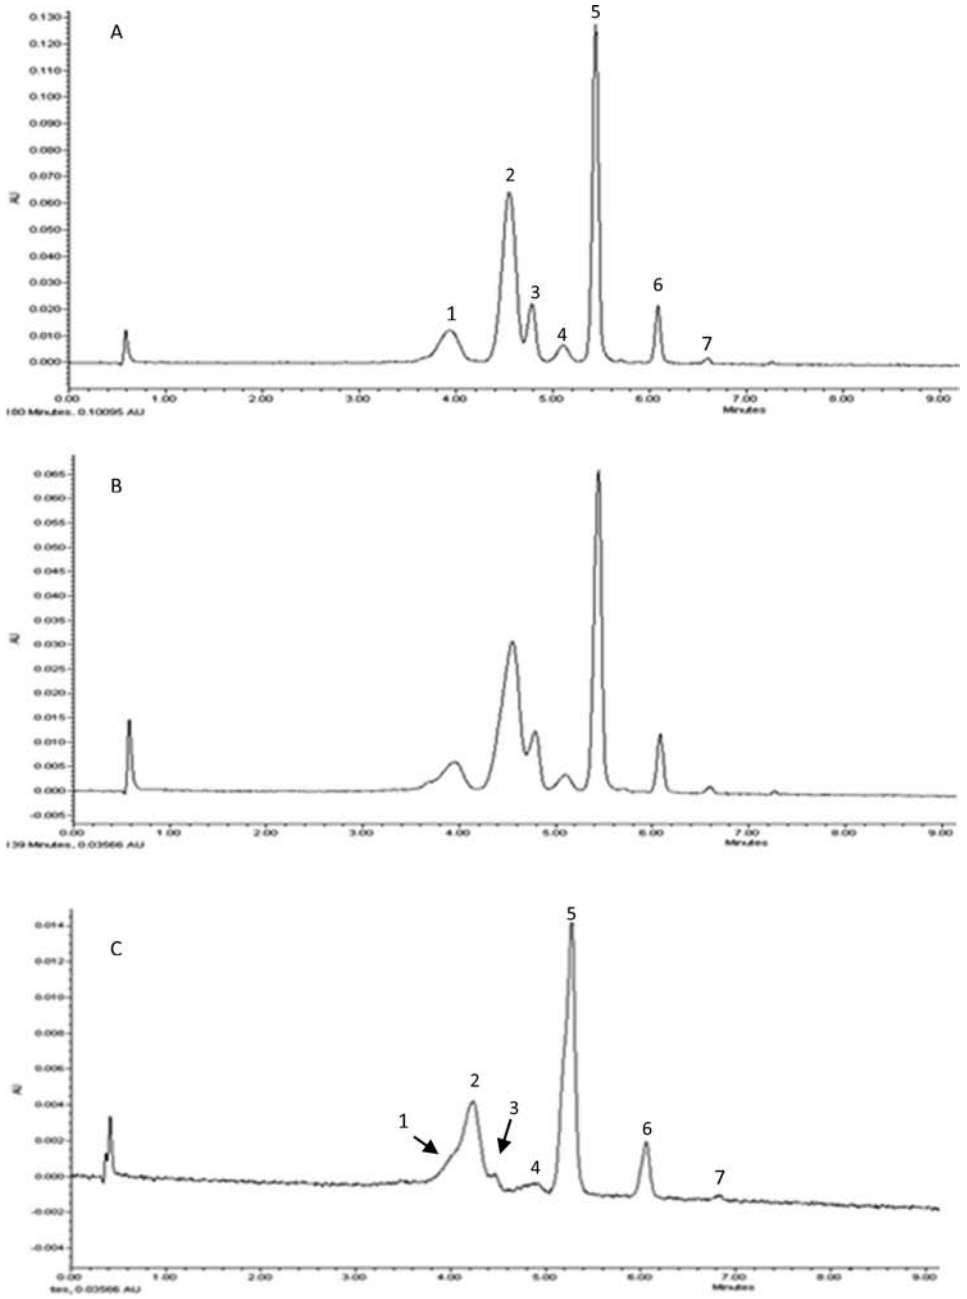

Figure 1. Chromatograms of anthocyanins in (A) pomegranate juice, (B) pomegranate juice yogurt, and (C) permeate from pomegranate yogurt at 520 nm.

For quantification of anthocyanin compounds spectra were measured over the range 200−600 nm in steps of 2 nm. The run was monitored at 520 nm. Calibration curves at concentration ranging from 0.05 to 5 mg/L ($r^2 \leq 0.9997$) were made from cyanidin-3,5-*O*-diglucoside and -glucoside, pelargonidin-3-*O*-glucoside, and delphinidin-3-*O*-glucoside. Delphinidin-3,5-*O*-diglucoside was expressed as delphinidin-3-*O*-glucoside, pelargonidin-3,5-*O*-diglucoside as pelargonidin-3-*O*-glucoside, and cyanidin-pentoside as cyanidin-3-*O*-glucoside. All determinations were done in triplicate. Results were expressed as milligrams per L.

Determination of Total Phenol Content, Total Flavonoid Content, and Total Anthocyanin Content by Colorimetric Methods. The total phenol content (TPC) in the yogurts, PGJ, and permeates was determined using the Folin−Ciocalteu's reagent.[16] Volumes of 0.3 mL of the methanolic extracts were introduced into test tubes followed by 2.5 mL of Folin−Ciocalteu's reagent (diluted 10 times with water) and 2 mL of sodium carbonate (7.5% w/v). The tubes were vortexed and incubated at 50 °C for 5 min. Absorption at 760 nm was measured with a HP 8451 spectrophotometer (Hewlet Packard, Cambridge, UK) and compared to a gallic acid calibration curve. The results were expressed as mg gallic acid equivalents (GAE)/g sample. Samples were analyzed in triplicate.

For total flavonoid content (TFC) the method based on Blasa et al.[17] with some modifications, was used. One milliliter of the methanolic extracts of yogurts, PGJ, and permeates was mixed with 0.3 mL of $NaNO_2$ (5%), and 0.3 mL of $AlCl_3$ (10%) were added after 5 min. Samples were mixed and after 6 min, were neutralized with 2 mL of NaOH solution (1 M). Absorbance was read at 510 nm, and the quantification was carried out using a calibration curve. Different concentrations of rutin (8.5−170 μg/mL) were used for calibration. The results were expressed in mg rutin equivalents (RE)/100 g of sample as mean of three replicates.

Total anthocyanin content (TAC) in the yogurts and PGJ were determined by the pH differential method described by Wrolstad[18]

dx.doi.org/10.1021/jf501503h | J. Agric. Food Chem. 2014, 62, 6417−6425

using a UV−vis HP 8451 spectrophotometer. Absorbance of the samples in 0.2 N potassium chloride buffer (pH 1.0) and 1 M sodium acetate buffer (pH 4.5) were measured at 520 and 700 nm. Anthocyanin content was determined using the equation: $A = (A_{\lambda 520} - A_{\lambda 700})_{\text{pH 1.0}} - (A_{\lambda 520} - A_{\lambda 700})_{\text{pH 4.5}}$ with a molar extinction coefficient of 29600. Results were expressed as mg of cyanindin-3-glucoside equivalent/L of sample as mean of three replicates.

Quantification of Antioxidant Activity by (i) DPPH• Radical Scavenging Method and (ii) Ferric Reducing Antioxidant Power Assay. Free radical scavenging activities of the PGJ, yogurts, and permeates were determined by DPPH• (2,2-diphenyl-1-picrylhydrazyl) assay with minor modifications as described by Brand-Williams et al.[19] A 0.1 mM solution of DPPH• in ethanol was prepared. A volume of 0.1 mL of various concentrations of the PGJ and yogurt methanolic extracts diluted in methanol was added to 2.9 mL of DPPH• solution. The mixtures were well shaken in a Vortex (2500 rpm) for 1 min and then placed in a dark room. The decrease in absorbance at 517 nm was determined with a HP 8451 spectrophotometer after 1 h for all samples. Methanol was used to zero the spectrophotometer. Absorbance of the radical without extract was used as control. The amount of sample necessary to decrease the absorbance of DPPH• by 50% (IC_{50}) was calculated graphically. The inhibition percentage of the DPPH• was calculated from the following equation: $\%I = [(A_C - A_S)/A_C] \times 100$, where I = DPPH• inhibition %, A_C = absorbance of control sample (t = 0 h) and , A_S = absorbance of a tested sample at the end of the reaction (t = 1 h).

The ferric reducing antioxidant power (FRAP) of PGJ, yogurts, and permeates was determined by using the potassium ferricyanide−ferric chloride method.[20] One mL of the PGJ, yogurt, and permeate methanolic extracts of four different concentrations (2.5, 5.0, 7.5, and 10.0 g/100 mL) was added to 2.5 mL of phosphate buffer (0.2 M, pH 6.6) and 2.5 mL of potassium ferricyanide (1%). The mixtures were incubated at 50 °C for 20 min, after which 2.5 mL of trichloroacetic acid (10%) was added. An aliquot of the mixture (2.5 mL) was taken and mixed with 2.5 mL of water and 0.5 mL of 0.1% $FeCl_3$. The absorbance at 700 nm was measured after allowing the solution to stand for 30 min. The FRAP of a sample is estimated in terms of Trolox equivalent antioxidant capacity (TEAC) in mmol Trolox/L. Each essay was carried out in triplicate.

Statistical Analysis. Statistical analysis and comparison among means were carried out using the statistical package SPSS 20.0 (IBM SPSS Statistics, Chicago, IL, USA). ANOVA test was used to evaluate factors: sample type (pomegranate yogurts and permeates) and storage time (days 1, 14, 28). Tukey's pair wise comparisons test was used for means comparison (95% confidence level). The whole experiment was independently run three times.

RESULTS AND DISCUSSION

Individual Phenolic Compounds Content from Pomegranate Juice, Yogurts, and Permeates. Pomegranate anthocyanins were characterized by comparison of their UV−vis spectra (λ_{max}), retention times (R_t), and mass spectra (MS) before and after fragmentation (MS/MS) with standards, if available, and published data. Figure 1 shows a typical UPLC chromatogram of pomegranate juice (A), pomegranate yogurt (B), and yogurt permeate (C) anthocyanins recorded at 520 nm. The retention times, UV−vis, and mass spectral characteristics as well as peak assignments for all compounds are specified in Table 1.

The anthocyanin profiles of the pomegranate juice (PGJ) and pomegranate yogurts (PGY) were similar; however, the amount of individual compounds differed. A total of seven anthocyanins were detected, three cyanidins and two delphinidins and two pelargonidins. Each of these anthocyanins were associated by monoglucoside or diglucoside. The anthocyanins revealed the typical mass spectrometric behavior in ESI(+) experiments, i.e., they showed M^+ ions in the MS experiments and the sequential loss of their saccharide moieties, releasing the aglycones in the MS/MS experiments (Table 1). These results agreed quite well with recently published data.[21,22] In accordance with our results, previous analysis of juices produced from arils alone[21,23,24] reported that anthocyanins were identified as the most abundant phenolic compounds; other phenolics including ellagic acid and punicalagins were also present.[24] Ellagic acid (EA) has exhibited both antioxidant[25] and anticarcinogenic[26] properties together that it combines with proteins to form insoluble sediments.[27] EA content was 21.17 mg/L in PGJ, 8.58 in PGY at first day and 11.75 mg/L in PGY at 28th day. Our findings for EA in PGJ were in the range detected by Mena et al.[28] (3.6−152.8 mg/L) and Gil et al.[23] (33.2 mg/L) and slightly higher than those reported by Qu et al.[24] (2.1−15.3 mg/L) in juices made solely from arils. Regarding punicalagins ($\alpha + \beta$) content in PGJ was 46.35 mg/L, 31.90 mg/L in PGY at first day, and 31.37 mg/L in PGY at 28th day of storage, being the content for all samples tested higher in the β anomer (data not shown), which is typical of noncommercial juices.[28] In this sense, our results are in accordance to those reported by Mena et al.[28] ($\alpha + \beta$, 2.0−44.1 mg/L) and higher than the amounts reported by Gil et al.[23] (22.8 mg/L) and Qu et al.[24] (4.1−22.8 mg/L). Many authors attribute the high antioxidant capacity of pomegranate juice to hydrolyzable tannins including punicalagins.[23,29] In permeates, EA remained stable, showing values of 9.95 mg/L at the first day of storage and 10.87 mg/L at the 28th day of the storage, meaning that EA did not bind to milk proteins. However, no punicalagin content was detected in yogurt permeates, indicating a high affinity to milk proteins. Hence, only EA remained in free form in yogurt. The increase of EA during 28th days of storage PGY and permeate is the result of the transformation of ellagitannins to ellagic acid. Ellagic acid is transformed by human gut bacteria to the dibenzopyranone type urolithins that are much better absorbed because of the higher lipophilicity of the resulting components compared to intact form of punicalagins and ellagitannins.[30]

Table 2 shows the content of anthocyanins previously identified in pomegranate juice, yogurts, and permeates. Anthocyanins have been associated with prevention of cardiovascular disease, obesity, and diabetes,[31] and they are phenolic compounds responsible for pomegranate juice color.

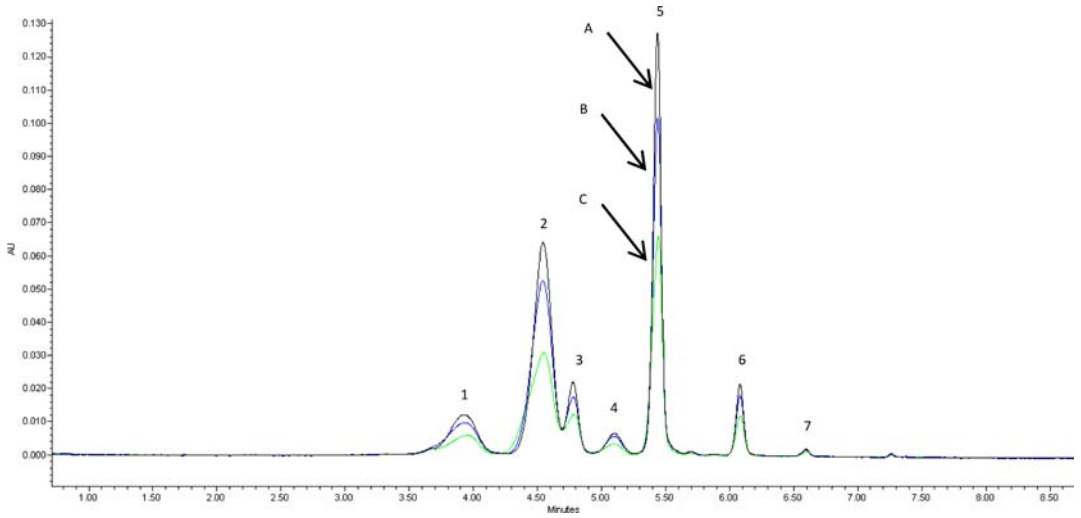

Figure 2. Chromatograms of anthocyanins in pomegranate yogurts after 1 (A), 14 (B), and 28 (C) days of cold storage.

In contrast to the other phenolic compounds identified, PGJ was extremely rich in anthocyanins (641.48 mg/L). Similar to our data, Fischer et al.[21] reported an anthocyanin content of 558 mg/L in a handmade juice from arils. Cyanidin-3-*O*-glucoside was the predominant anthocyanin in juice; that predominance is characteristic for "Mollar de Elche" varieties.[32,33] In yogurts, the relative quantitative distribution of the individual anthocyanins was slightly different from PGJ. In yogurt samples, the predominant anthocyanin was cyanidin-3,5-*O*-glucoside followed by cyanidin-3-*O*-glucoside at all days analyzed. In other PGJ fermentation processes, it has been studied for losses up to 61% in the anthocyanin content, mainly occurring during the initial fermentation. The structure influenced the stability in the way that monoglucosides were less stable than diglucosides.[32] In the present study, both cyanidin-3-*O*-glucoside and pelargonidin-3-*O*-glucoside were the most affected anthocyanins in the fermentation process whereas cyanidin-3,5-*O*-diglucoside was the most stable one. A similar trend has also been displayed in the pomegranate winemaking process described by Mena et al.[32] Additionally, the yogurt polymer network and gel matrix might have protected the polyphenols to some extent, through reducing the oxidation rates of these sensitive components.[34] During the storage period, significant losses in the individual anthocyanin content were observed especially at the end of the storage (Figure 2). Degradation of anthocyanins has been widely studied, and it is well-known that most anthocyanin follow a first-order reaction kinetics[35−37] and even bacterial culture could affect the anthocyanin content during storage probably associated with the production of antimicrobial compounds by the starter culture.[38] Results from permeates revealed that most of the anthocyanins remained bound to milk proteins; cyanidin-3,5-*O*-diglucoside, the main anthocyanin present in the yogurts, was not detected in the permeate, neither delphinidin-3-*O*-glucoside and cyanidin-pentoside did it. Delphinidin-3,5-*O*-diglucoside was found to be the most stable anthocyanin and showed the lowest interaction rate with milk proteins. The 84.73% of total anthocyanins remained bound to proteins at first day of storage and 90.06% after 28 days of cold storage. Indeed, retentates (proteic phase) had a more pronounced reddish color than their corresponding permeates. That could be explained due to the monoglucosides of flavonoids showing stronger binding affinities with milk proteins than their polyglucoside forms.[39] It has been demonstrated that antioxidant activity of polyphenols decreases as interactions of milk proteins−polyphenol complexes increase.[39] As far as we know, no previous studies have been conducted on the extent of interaction between individual anthocyanins and milk proteins, so results from this study would provide a first overview about the degree of anthocyanin−milk protein interaction, giving knowledge about which anthocyanins are available to exert the beneficial action. On the other hand, the interactions between other flavonoids such as tea catechins have widely studied[7,8,40] and moreover the effect of such interaction on antioxidant activity.[41] Arts et al.[41] found that the antioxidant activity of tea components was masked due to the

addition of proteins, i.e., assessing separately the antioxidant activity of flavonoid and protein yields higher values than the antioxidant activity of the mixture tea−milk. Additionally, they proved that masking not only depends on the type of protein but also on the type of flavonoid; proteins which contains more proline groups and flavonoids such as epigallocatechin gallate (EGCG) and epicatechin gallate in green tea and gallic acid in black tea are responsible for the masking. However, the protein−polyphenol interaction could be both reversible and irreversible depending on pH, temperature, and protein and flavonoid concentration.[42] Nevertheless, new findings have pointed out to a protective role of milk as a carrier of bioactive molecules such as flavonoids, arguing that binding of flavonoids such as EGCG to the casein micelles did not affect the bioefficacy of EGCG.[43]

Total Phenol Content, Total Flavonoid Content, and Total Anthocyanin Content. Figure 3 shows total phenol content (TPC), total flavonoid content (TFC), and total anthocyanin content (TAC) of pomegranate juice, pomegranate yogurts, pomegranate yogurt permeates, and control yogurts. As expected, among the assayed samples the higher phenolic content was observed in the PGJ (707.25 mg GAE/L). We found lower phenolic substances than did previous reports[10,28] for the same pomegranate cultivar group. Both aril composition and differing textural properties of fruit tissues may influence the transfer of phenolic compounds into the juices upon processing.[11] PGY contained 40% of juice and presented 241.44 mg GAE/L of total phenolic substances, which means 85.35% of the theoretically expected. On the first day of storage, the TPC in JY permeates was 111.92 mg GAE/L, which means that nearly 54% of the total phenolic substances remained in the proteic phase interacting with milk proteins. At the end of the storage period, this percentage decreased (40.50%), the TPC in PGY and yogurt permeates being 142.60 mg GAE/L and 111.92 mg GAE/L, respectively. PGY exhibited the most remarkable decrease (40.94%) in phenolic concentration ($p < 0.05$) during the storage period followed by yogurt permeates (24.19%), CY being the most stable (4.32%) sample. Other studies showed the same tendency in phenolic content reducing in enriched yogurts with phenolic compounds stored during 14 days[14] and 7 days.[44] The stability of pigments and phenolics in yogurts is affected by storage temperature, pH, phenolic content, fat,[38,44] and the type of bacterial culture used.[38] Taking into account the TFC in the juice (75.50 mg RE/100 g), that observed in JY was higher than expected (34.13 mg RE/100 g). Permeates retained the 65.78% and 90% of the flavonoids on the first day and 28th day, respectively. So we have estimated by colorimetric methods that flavonoids have less affinity to proteins than other phenolic compounds. Interestingly, although yogurt is not being considered as a significant source of phenolic compounds,[13] CY presented 39.08 mg GAE/L and 3.78 mg RE/100 g on the first day of storage for TPC and TFC. During the storage period, TFC decreased 39.93%, 17.82%, and 23.28% in PGY, yogurt permeates, and CY, respectively (Figure 3), although such decrease was only statistically significant for PGY. The phenolic and flavonoid contents can be used as important indicators of antioxidant capacity in the screening of natural sources of antioxidants.[45]

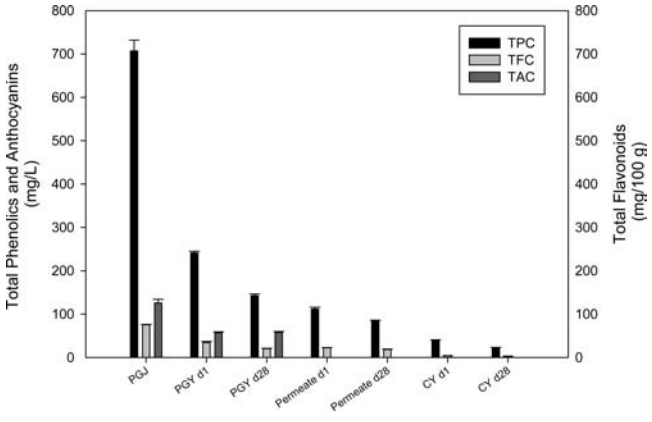

Figure 3. Total phenol content (TPC; mg GAE/L), total flavonoid content (TFC; mg RE/100 g), and total anthocyanin content (TAC; mg cyanidin-3-glucoside/L) of pomegranate juice and yogurts and permeates over 28 days of storage at 4 °C.

PGJ presented a total anthocyanin content of 126.04 mg of cyanidin-3-glucoside equivalents/L. Quantitatively, our results are higher than those reported by Elfalleh et al.[46] (39.19 mg CGE/L) and Ozgen et al.[47] (60.0 mg CGE/L) as analyzed by the same method, but lower than our own LC-MS results an those of by Gil et al.[23] (306.0 mg/L) as assessed by chromatographic method. Chromatographic methods and results are considered more accurate than colorimetric methods given their limitations and expression under an individual representative compound. However, colorimetric methods may be still of interest where more sophisticated chromatographic methods are not available.

Because naturally neither milk nor control yogurts provide anthocyanins, we found that such content was relatively high in PGY during the storage period (56.91 and 57.60 mg of cyanidin-3-glucoside equivalents/L at first and 28th day, respectively). Anthocyanin concentrations of PGY as assessed by colorimetric methods were not affected ($p > 0.05$) by storage time, which is not correlated with the previous HPLC results. But these results were in accordance with those obtained from color determinations in yogurt (Table 3).

Table 3. Color Characteristics of Yogurts during 28 Days of Cold Storage[a]

type of yogurt	L^*	a^*	b^*
control	84.61 ± 1.16^{b}	-2.73 ± 0.06^{a}	5.27 ± 0.17^{c}
PGY d1	66.65 ± 0.41^{a}	5.61 ± 0.10^{b}	4.93 ± 0.11^{b}
PGY d14	65.95 ± 0.05^{a}	5.78 ± 0.02^{b}	$4.83 \pm 0.05^{a,b}$
PGY d28	65.24 ± 0.52^{a}	6.26 ± 0.04^{c}	4.56 ± 0.04^{a}

[a]Values expressed as means of triplicate ± standard error. Significant differences between values in the same column are indicated by different small letters ($p < 0.05$) according to Tukey's multiple range test.

During the storage period, the recorded a^* and b^* values showed significant variations: redness (a^*) increased and yellowness (b^*) decreased, meaning that the reddish color was reinforced. Although not statistically, lightness (L^*) decrease during storage was also a clear sign of pigment stabilization. This stabilization could be due to intermolecular/intramolecular, copigmentation, and self-association reactions.[42] Furthermore, Jing and Giusti[48] found that anthocyanins were more stable in milk matrices than in a phosphate buffer solution used as control. In the study carried out by Srivastava et al.,[49] a relatively superior content of malvidin glucosides was observed

Table 4. Antioxidant Activity of Pomegranate Juice and Yogurts and Protein-Free Permeates during Storage at 4 °C Measured by the DPPH• Assay and the FRAP Method at Different Concentrations (A = 2.5 g/100 mL, B = 5 g/100 mL, C = 7.5 g/100 mL, D = 10 g/100 mL)[e]

in a stored blueberry extract. In yogurt permeates, non-anthocyanin content was detected by colorimetric quantitative methods.

Antioxidant Activity in Pomegranate Juice, Yogurts, and Permeates. In this study, the in vitro antioxidant activity (AA) of pomegranate juice and yogurts and permeates during 28 days of storage was measured by two different analytical methods: DPPH• and FRAP (results shown in Table 4). The free radical scavenging activity of the samples were reported as the amount of the juice, yogurt, or permeate (g/100 mL) required to scavenge 50% of DPPH• (IC_{50}), and the lower the IC_{50} values the higher the antioxidant power. PGY displayed the highest AA in comparison to the other samples. PGJ showed a poor free radical scavenging activity by DPPH• method, similar to the reported in a previous own study, 7.47.[10] Considering the results obtained for CY, it is possible that a synergistic action is taking place when the pomegranate yogurt is produced. Indeed, we analyzed the unfermented mix of milk and PGJ (data not presented), resulting in a IC_{50} value of 4.72. During the storage time, enriched yogurts slightly increased the radical scavenging activity, and the same pattern was found in the study carried out by Jiménez et al.[50] Nonetheless, at the end of the storage, TPC and TFC decreased significantly (Figure 3), anthocyanins (TAC) being the phenolic compound which remained stable. Hence, is it possible that the radical scavenging activity of the PGY could be done by the anthocyanins. Oppositely, studies carried out in yogurts fortified in phenolic extracts showed a tendency in decreasing the AA during the storage period.[14]

According to the FRAP values, a concentration-dependent ferric reducing capacity was found for all the samples analyzed. PGJ showed by far the highest ($p < 0.05$) ferric reducing capacity in terms of Trolox concentrations. In juice, FRAP was strongly correlated with TPC and TAC (Table 6). In PGY at day 1 of storage, results from FRAP assay corresponded to nearly 40% of those of PGJ, so due to the low AA of CY detected by this method, the AA of PGY was done by PGJ. In Table 5, we could easily intuit how the same potentially antioxidant sample behaves differently in the face of different antioxidant methods. Only the ferric reducing capacity was affected ($p < 0.05$) by the storage time in PGY. At the end of the storage, no difference were found between PGY and permeates. Furthermore, the AA in CY was correlated with TPC (Table 6).

Table 5. Relative Antioxidant Activity of Pomegranate Juice and Yogurts and Protein-Free Permeates[a]

sample	DPPH•	FRAP
juice	++	++++
PGY	++++	++
PGY permeate	−	++
CY	+++	+

Table 6. Correlation Matrix between Antioxidant Capacity Methods and Total Phenol Content (TPC), Total Flavonoid Content (TFC), and Total Anthocyanin Content (TAC) in Pomegranate Juice, Pomegranate Yogurts, Protein-Free Permeates, and in Control Yogurts[d]

		TPC	TFC	TAC
PGJ[a]	DPPH•	0.98	0.10	1
	FRAP	0.99	0.45	0.92
PGY[b]	DPPH•	0.64	0.88	0.24
	FRAP	0.89	0.77	0.72
PGY permeates	DPPH•	0.90	0.99	
	FRAP	0.99	0.98	
CY[c]	DPPH•	0.57	0.01	
	FRAP	0.84	0.42	

[a]PGJ, pomegranate juice. [b]PGY, pomegranate yogurt. [c]CY, control yogurt. [d]The r value of the correlation is given. All correlations were significant at $p < 0.05$.

A point worth mentioning is the poor correlation between phenolic compounds and antioxidant activity in PGY in comparison to juice and permeates (Table 6). Permeates and juices are free of proteins, so phenolics are mainly in free form. However, yogurt is a complex matrix where several interactions could occur, so it is not clear whether the antioxidant capacity of the PGY is given by phenolics alone or by a multifactorial cause. This fact may mean that other components naturally present in PGJ, such as ascorbic acid or vitamin E, need to be investigated for their contribution to the AA.[12]

In conclusion, yogurts enriched in pomegrante juice are especially rich in anthocyanins, and also other phenolic compounds such ellagic acid and punicalagins are present at significant levels. Fermentation process affects the anthocyanin profile; the content in cyanidin-3-*O*-glucoside, the main anthocyanin present in the juice, is significantly reduced

dx.doi.org/10.1021/jf501503h | J. Agric. Food Chem. 2014, 62, 6417−6425

whereas cyanidin-3,5-*O*-diglucoside remains much more stable, pointing out that structure (mono or diglucoside form) affects the anthocyanin stability. During the storage period, the individual anthocyanin content is diminished, which is not detected in color measurements of yogurt. Results from permeates reveal that the interaction of phenolic compounds with milk proteins occurs at different levels depending on the type of phenolic; ellagic acid and delphinidin-3,5-*O*-diglucoside show the lowest affinity to bind proteins.

Considerable variation in antioxidant activity is observed depending on the antioxidant assay. Pomegranate juice shows the strongest ferric reducing capacity, whereas pomegranate yogurts display the highest radical scavenging activity. The presence of PGJ in yogurt enhanced radical scavenging performance, whereas all the observed ferric reducing power ability of PGY was strictly due to the PGJ present. Pomegranate yogurt can be considered a good antioxidant dairy product and also during the storage period in terms of scavenging activity. Permeates in general had a poor antioxidant activity. The interaction of PG phenolics with milk proteins does not affect the antioxidant activity of yogurts.

The influence of different processing methods on preservation of bioactive compounds in strawberry has been studied,[21,22] and color stability of fruits has been reported.[23] However, sensory evaluation of strawberry juice based on processing methods is seldom mentioned. The simultaneous utilization of E-nose and E-tongue will make it possible to clearly show and assess how processing methods influence a juice's sensory and quality indirectly.

Conventional heat treatments ensure safety and extend the shelf life of the juices but can lead to undesirable changes both in sensorial and in nutritional properties. This study applied processing approaches (i.e., microwave pasteurization, steam blanching, HTST, and frozen−thawed) as alternative preservations and focused on exploring the influences of processing approaches on strawberry juice quality changes. An E-nose and an E-tongue were utilized as a new detection system to discriminate juice types and to predict quality parameters. The main objectives of this study is (1) to characterize five types of strawberry juices based on different processing approaches (i.e., microwave pasteurization, steam blanching, frozen−thawed, HTST, and freshly squeezed) by E-nose and E-tongue and to measure juice quality parameters (vitamin C, pH, TSS, TA, and sugar/acid ratio) by traditional measuring methods; (2) to solve classification and regression problems based on Random Forest (RF) and Support Vector Machine (SVM), including searching the best parameters for RF and SVM, and contrasting two networks according to cross-validation performance; (3) to explore if the simultaneous utilization of the two instruments will increase the extent of information or, on the contrary, will they lead to data redundancy.

MATERIALS AND METHODS

Experimental Conditions. Strawberries (*Fragaria* × *ananassa* Duch.) were picked at a strawberry garden in southeast Hangzhou city of China, and the picking time was in the morning on 13 May 2011. Strawberries were selected for this experiment based on uniform size, weight, and color. After being cleaned, the strawberry fruits were divided into five groups randomly. Five different kinds of processing approaches were chosen: microwave pasteurization, steam blanching, HTST, frozen−thawed, and freshly squeezed. The details of the five approaches were as follows:

1. Microwave Pasteurization. Microwaves have the ability to destroy the microbes or enzymes at sublethal temperatures according to following theories: selective heating, electroporation, and cell membrane.[24] Samples in beakers were put into the microwave oven (G80F23N1P-M8, Guangdong Galanz Group Co., Ltd.) under the power of 240 W for 1 min.

2. Steam Blanching. Steam blanching is an excellent tool for inactivating enzymes as well as to prevent microorganism growth without considering the reduction of sensory and nutrient quality in foods.[25] Samples were put in the steamer above boiling water and steamed for 3 min.

3. High Temperature Short Time Pasteurization. HTST, which is commonly used for heat treatment in the juice industry, is quite efficient in preventing microbial spoilage of juice.[26] Samples were put into the hot water directly at 90 °C for 2 min.

4. Frozen−Thawed. Freezing is used to maintain product quality over long storage and results in a slower rate of most deteriorative reactions such as senescence, enzymatic decay, chemical decay, and microbial growth.[27] Samples were packed in plastic bags, frozen at −23 °C (BD(C)-238N, Qindao AUCMA Co., Ltd., China) for 1 day to have sufficient time to be frozen, and then thawed at room temperature next day.

5. Freshly Squeezed. Fresh strawberry samples were squeezed directly without any process, and this group was regarded as a reference for the quality assessment.

After being processed, all the strawberry fruits were squeezed into juice by the juicer (JYL-C051, Joyoung Co., Ltd., China), and then the juice was filtered through four and eight layers of 120 mesh cotton respectively in order to remove the solid particles. Four groups (microwave pasteurization, steam blanching, HTST, and freshly squeezed) were measured by the E-nose and E-tongue immediately to minimize the quality losses, except the group of frozen−thawed, which needed 1 day to be completely frozen. Twenty replicates were prepared in each group both for E-nose and E-tongue detection. The environment temperature during samples preparation was at 20 °C ± 3 °C. The samples were juiced by a juicer without any heating or refrigerating apparatus.

The Instrument Systems and Sampling Procedure. *Electronic Nose System and Sampling Procedure.* The headspace analysis was performed with the E-nose (PEN2, Airsense Analytics, Germany). The PEN2 system consists of a sampling apparatus, a detector unit containing the array of sensors and pattern-recognition software for data recording and elaboration. The sensor array system was composed of 10 metal oxide semiconductors (MOS) of different chemical compositions and thicknesses to provide selectivity toward volatile compound. The details of sensor array have already been introduced in previous work of Hong.[20]

A 10 mL of sample juice was taken into a 500 mL beaker, and the beaker was sealed by plastic wrap for a headspace generation time of 30 min to ensure that the headspace volatiles could be enough for detection. According to previous work,[20] employing hydrous sodium carbonate as desiccant to remove the moisture in the headspace does not improve the performance in the qualitative and quantitative analysis. Samples (20 samples × 5 groups) were detected by E-nose immediately. The measurement phase lasted for 80 s, which was long enough for the sensors to reach stable signal values. After each experiment, cleaning gas (nitrogen) was pumped into the sample gas path for 60 s, which was long enough to normalize sensor signals. During the sampling process, the sample gas was transferred into the sensor chamber at a flow rate of 200 mL min^{-1} and per second a signal was collected. All the samples were detected at 20 °C ± 3 °C.

Electronic Tongue System and Sampling Procedure. An E-tongue (α-Astree, Alpha MOS Company, France) was employed to classify and characterize the strawberry juices. This instrument mainly consists of seven potentiometer chemical sensors (ZZ, BA, BB, CA, GA, HA, and JB), a reference electrode of Ag/AgCl, data acquisition system, and basic data analysis software. The sensitivity of the seven chemical sensors is different from that of the five tastes (sourness, saltiness, sweetness, bitterness, and savory). The details of sensor array have already been introduced in the previous work of Tian.[28]

Experiment was carried out with filtrated strawberry juice to avoid the influence caused by solid particles. The amount of strawberry sample was 80 mL to ensure that the sensors could be fully immersed in the liquid. The measurement time was set to 120 s for each sample, which was long enough for the sensors to reach stable signal values, and the sensors were rinsed for 10 s using deionized water to minimize and correct the drift of sensors. All the samples were detected at 20 ± 3 °C, and the number of samples was the same as in the E-nose experiment.

Determination of Quality Parameters. Fruit juice quality parameters were determined according to the methods proposed by Chinese national standardd. Vitamin C was estimated by titration with a colored oxidation/reduction indicator, 2,6-dichloroindophenol.[29] The value of pH was measured by a titrimeter (Ti-Touch-916, Metrohm, Switzerland). Total soluble solid (TSS), expressed as °Brix, was determined by using a temperature compensating refractometer (digital refractometer 2WA-J 0−32% Shanghai, China). Total acid (TA), expressed as percentage of citric acid, was determined by titration to pH 8.2 ± 0.1 with 0.1 M NaOH.[30]

In fruit juice quality properties analysis, three replicates were carried out for each group, and the mean values of vitamin C, pH, TSS, and TA were expressed as the original values, respectively.

Data Processing. *Linear Discriminant Analysis.* Linear discriminant analysis (LDA) was used as a supervised learning technique to extract features which preserve class separability. LDA explicitly

Table 1. Average Values and Standard Deviation for Strawberry Juice Quality Parameters in Different Pretreatments

pretreatment method	vitamin C (g kg^{-1})	pH	TSS (°Brix)	TA (%)	TSS/TA ratio
microwave pasteurization	0.581 (± 0.025)	3.86 (± 0.40)	8.4 (± 0.5)	0.68 (± 0.03)	12.35 (± 1.34)
steam blanching	0.406 (± 0.025)	3.76 (± 0.40)	8.4 (± 0.5)	0.64 (± 0.03)	13.12 (± 1.47)
HTST	0.483 (± 0.035)	3.80 (± 0.35)	7.9 (± 0.5)	0.67 (± 0.04)	11.79 (± 1.54)
frozen−thawed	0.360 (± 0.025)	3.84 (± 0.35)	7.8 (± 0.5)	0.69 (± 0.03)	11.3 (± 1.27)
freshly squeezed	0.400 (± 0.035)	3.74 (± 0.42)	8.0 (± 0.5)	0.70 (± 0.03)	11.42 (± 1.27)

models the difference between the classes of data, and tries to maximize the variance between categories and minimize the variance within categories.[31] The LDA is a robust statistical technique that can be applied even when small violations of the above-mentioned requirements are observed.[32] It provides a classification model, characterized by a linear dependence of the classification scores with respect to the descriptors.

Partial Least Squares Regression. Partial least squares regression (PLSR) technique is based on multiple linear regression (MLR), which is suitable for large problems where the amount of computation with standard methods of matrix inversion or diagonalization becomes prohibitive.[33] PLSR produces a technique that is able to accept collinear data and separate out the sample noise in order to make linear combinations in the dependent concentration matrix.[34]

Random Forest. RFs are a nonparametric and nonlinear classification and regression algorithm first proposed by Ho[35] and further developed by Breiman.[36] RF is a method based on a kind of learning strategy, "ensemble learning", with generating many classifiers and aggregating their results. According to its algorithm, RF does not need any data preprocessing which is one of its main advantages. This approach materialized the "bootstrap strategies" put forward by L. Breiman[37] combining "random subspace" method proposed by Ho[38] successfully. RF runs very fast, and that is a very important factor in the field of online and in situ measurements especially in the field of E-nose and E-tongue detections.

The RF ensemble grows multiple unpruned trees (*mtree*) on bootstrap samples of the original data.[31] Each tree is grown on a bootstrap sample ($^2/_3$ of the original data known as "in-bag" data for training, and $^1/_3$ of the original data known as "out of bag" data for testing) taken with replacement from the original data. Trees are split to many nodes using random subsets of variables (*mtry*); the default *mtry* value is the square root of the total number of variables.[39] A single tree in RF is a weak classifier because a random subset sample is used to train a tree, while the aggregation from all trees is considered as a strong classifier. The measure of classification accuracy is based on an internal estimate known as "out of bag" data (OOB) error, which is calculated from the prediction of the data that is not used for growing the classification trees.[31]

Support Vector Machine. SVM is the hot issue accompanying artificial neural network in machine learning which involves any practical problems such as classification and regression estimation. Originally as an effective classification method, SVM has been proposed on the basis of statistical learning theory (SLT) by Cortes and Vapnik.[40] SVM is a linear machine working in the high dimensional feature space formed by the nonlinear mapping of the n-dimensional input vector x into a K-dimensional feature space ($K > n$) through the use of a function. SVM neural network applies one hidden layer of nonlinear neurons, one-output linear neuron, and a specialized learning procedure leading to the global minimum of the error function and excellent generalization ability of the trained network.[41]

Distribution of Data Sets and Cross-Validation. Before data treatment, the E-nose and E-tongue signal values were normalized by setting the mean value at the origin of each variable and then dividing them by their standard deviation in order to eliminate the effect of index dimension from this two detection system except for RF models. In this paper, data treatments included two parts: qualitative classification and quantitative regression.

For qualitative classification, a stepwise LDA was applied for visual classification. Leave-one-out (LOO) cross-validation was used to verify stepwise LDA classification model. For neural networks (RF and Lib-SVM), data sets (E-nose system, E-tongue system, and the fusion of E-nose and E-tongue system) were divided into two subsets (15 samples of each pretreatment were randomly selected as the training set, and 5 samples of each pretreatment were considered as the testing set). Generally, the larger accuracy rates both in the training set and testing set are, the better classification model is.

For quantitative regression, PLSR, Lib-SVM, and RF were utilized. Data set was designed into two subsets (15 samples of each group were randomly selected as the training set, and the remaining 5 samples as the testing set). Prediction performance of PLSR, Lib-SVM, and RF were estimated using the parameters obtained from the fitted equation: correlation coefficient (R^2) and root-mean-square error (RMSE) between predicted and experimental values. The larger R^2 and the lower RMSE are, the better the prediction model is.

The data processing method LDA was performed by Statistical Product and Service Solutions v16.0 (International Business Machines Corporation, USA). PLSR was analyzed by Minitab 15 software (Minitab Inc. USA). RF and Lib-SVM[42] were performed by MATLAB 2012a software (MathWorks, USA).

RESULTS AND DISCUSSION

Quality Parameters of Strawberry Juices. The average values of the quality parameters of strawberry juice were represented in Table 1. The group processed by freshly squeezed was taken as a reference. The proportion of vitamin C was raised dramatically when processed by microwave pasteurization due to microwave technology is an appropriate means of achieving the required level of enzyme inactivation to prevent food deterioration. In frozen−thawed, vitamin C was much lower than the reference. Accordingly, freezing results in cell decompartmentalization which allows reactions between genuine enzyme activities and their corresponding substrates. Therefore, ascorbic acid may already be degraded during thawing due to their interaction with oxidative enzyme activities such as polyphenoloxidases (PPO) and ascorbic acid oxidases (AAO).[43] The TSS content of those five types strawberry juices varied from 8.4 to 7.8 °Brix. The amounts of TSS obtained from microwave pasteurization group and steam blanching group were the highest.

Organic, nonvolatile acids are the second most important component of strawberry flavor, after soluble sugars. The main compound accounting for TA is citric acid, which is predominant in strawberry. Those acids regulate the value of pH and may influence the nutrition stability. The values of TA declined no matter what kind of processing approach was (range from 0.64% to 0.7%). So, the quality parameter of pH raised no matter what kind of processing approach was, but the changes of TA and pH were not significant.

The ratio of TSS/TA was chosen as another criterion because this ratio is generally considered to reflect flavor quality and may be more important for quality and perceived sweetness by a sensory panel than soluble solids alone.[44] As shown in Table 1, the highest TSS/TA ratio was detected in the steam blanching group (13.12), whereas the lowest was in frozen−thawed group (11.3), but the difference between frozen−

[a]Twenty samples of each group were tested, and the RSD of sensor values demonstrated high stability of the test. Significant ($P < 0.001$) obtained from one-way ANOVA of sensors values measured in 100 samples in total. S1−S10 sensors belong to E-nose, and sensors (ZZ, BA, BB, CA, GA, HA, and JB) belong to E-tongue.

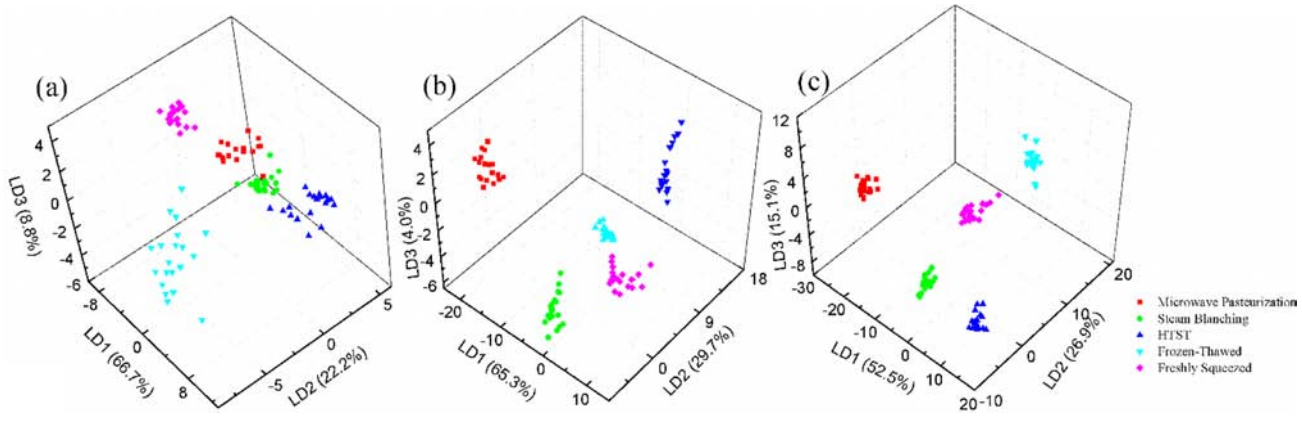

Figure 2. LDA discrimination of five strawberry juices with pretreatment: (a) is obtained by E-nose measurement, (b) is obtained by E-tongue measurement, and (c) is obtained by the fusion of E-nose data and E-tongue data.

thawed group (11.3) and freshly squeezed (11.43) was not obvious.

ANOVA Results. Parts a and b of Figure 1 are typical responses of E-nose and E-tongue during the measurement of a strawberry juice sample. Figure 1a shows that the responses of E-nose sensors reached dynamic balance after 30 s. The responses at the 60th second were selected as an original data. In Figure 1b, significant changes took place in 0−10 s and then

dx.doi.org/10.1021/jf501468b | J. Agric. Food Chem. 2014, 62, 6426−6434

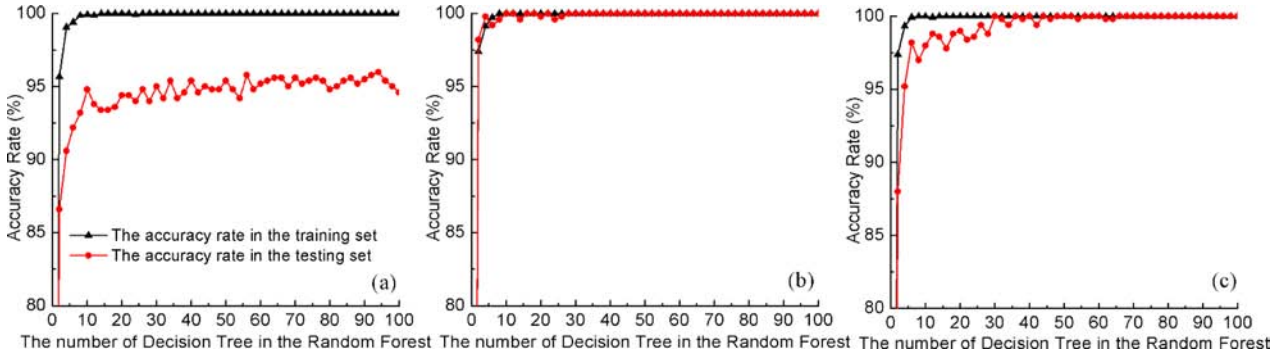

Figure 3. Performance of RF network according to the number of Decision Tree: (a) based on E-nose data set, (b) based on E-tongue data set, (c) based on the fusion of E-nose data set and E-tongue.

achieved dynamic balance except for sensor BA, whose signals had showed a slight increase during the subsequent period. The signal values of E-tongue sensors at 120th second were chosen as the original data. The stability of sensors' responses (E-nose at 60th second and E-tongue at 120th second) was analyzed by calculating the relative standard deviation (RSD). Only those sensors that exhibit good stability (small RSD) in the target matrix were included in the sensor array used for evaluation employing that matrix.[45] The result indicates a high stability of each sensor in Table 2. The result of one-way ANOVA for 17 sensors is presented in Table 2, and the values mean that significant difference was found ($p < 0.001$) between different strawberry juice samples.

The Classification Result Based on Linear Discriminant Analysis. A stepwise LDA procedure with leave-one-out cross-validation was carried out to visualize distribution of strawberry juice samples. The stepwise technique, using the Wilks' lambda method with the usual probabilities of F (0.05) for a variable to be included and F (0.10) to be removed from the model, was applied for variable selection. To verify which canonical discriminant functions were significant, the Wilks' Lambda test was applied. A leaving-one-out cross-validation procedure was carried out to avoid overoptimistic data modulation.

In the E-nose data treatment, the use of the stepwise LDA resulted in a discriminant model with four discriminant functions, and those four discriminant functions were significant according to Wilks' Lambda test ($P < 0.001$); 99% of samples were correctly classified for the original groups, and 98% for the cross-validation procedure. Figure 2a shows the effect of the first three discriminant functions in the classification of the strawberry juices. These three functions explained 97.7% of the total variance of the E-nose data (the first explaining 66.7%, the second 20.6%, and the third 8.8%).

In the E-tongue LDA analysis, all variables were selected into the model by the stepwise procedure. Four discriminant functions ($P < 0.001$ for the Wilks' Lambda test) were found in the discriminant model. The model showed a very satisfactory classification performance, allowing correct classification of 100% of samples for the original groups, and 98% for the cross-validation procedure. These three functions explained 99.0% of the total variance of the E-nose data (the first explaining 65.3%, the second 29.7%, and the third 4.0%) as shown in Figure 2b.

E-nose data and E-tongue data were combined directly after the data were preprocessed, so 17 variables were included (10 variables from E-nose and 7 variables from E-tongue). Finally, 15 variables were selected into the coalescent model by the stepwise procedure, thus sensor S4 and S6 from E-nose were excluded. Four discriminant functions ($P < 0.001$ for the Wilks' Lambda test) were found in the discriminant model. The model showed an excellent classification performance with 100% accuracy both for the original groups and the cross-validation procedure. Figure 2c shows the distribution of samples according to the first three discriminant functions. These three functions explained 94.5% of the total variance of the E-nose data (the first explaining 52.5%, the second 26.9%, and the third 15.1%).

In summary, the results show that the simultaneous utilization of both the instruments from perceptual knowledge could be a better performance than individual utilization of E-nose or E-tongue in the stepwise LDA procedure.

The Classification Results Based on Random Forest. *Model Design and Parameter Optimization for Random Forest.* In this section, a base scenario is presented to analyze the model design and parameter according to its behavior and performance. RF is an ensemble of unpruned classification and regression tree (CART) and adds an additional layer of randomness to Bagging (i.e., first drawing a bootstrap sample through Bagging method and then selecting the best split among a randomly chosen subset of *mtry* rather than all descriptor variables at each node). So the main parameters for RF network design are the value of *mtry* and the number of decision trees. The default *mtry* value is the square root of the total number of variables, so the values of *mtry* for three analysis systems (E-nose, E-tongue, and the simultaneous utilization) were 3, 3, and 4, respectively. Experiment was carried out according to the number of decision trees from 0 to 100 at 2 trees intervals, and the training accuracy rate and testing accuracy rate were considered as evaluation criteria. In Figure 3a, the testing accuracy rate of RF network based on E-nose data set could not reach to 100% no matter how large of the number of decision trees was. Parts b and c of Figure 3 show that when the number of decision trees was large enough, the training accuracy rate and testing accuracy rate could both reach to 100%. Comparing Figure 3b with Figure 3c, RF network based on E-tongue data set could achieve better results with less decision tree, which might mean that the fusion of E-nose data set and E-tongue data set lead to information redundancy.

The Classification Results of E-Nose, E-Tongue, and the Fusion of E-Nose and E-Tongue. According to the preparative work, the RF network design is that the number of decision tree was 100 and the values of *mtry* for three analysis systems (E-nose, E-tongue, and the simultaneous utilization) were 3, 3, and

4 respectively. Results of this analysis are shown in Table 3 including training accuracy rate, OOB error rate, and testing rate. OOB error is calculated from the prediction of the data that are not used for growing the classification trees. For E-nose date treatment, classification results based on RF was not perfect (100% accuracy rate for training set, 96% accuracy rate for testing set, and 4% error rate for OOB). Both the E-tongue system and the simultaneous system classified the strawberry juice samples based on different pretreatments successfully (100% accuracy rate both for training testing sets, 0% error rate for OOB).

Table 3. Comparative Classification Results of RF Network

data set	training rate (%)	OOB error (%)	testing rate (%)
E-nose	100	4	96
E-tongue	100	0	100
fusion of E-nose and E-tongue	100	0	100

The Classification Results Based on Support Vector Machines. In the approach of Lib-SVM, 5-fold cross-validation was applied to get the best performance of classification, and radial basis function (RBF) was chosen as the core function. The first step is to optimize penalty parameter C and kernel parameter gamma (γ) in Lib-SVM model for obtaining the optimal Lib-SVM models. Best combination of C and γ is often selected by a grid search method with exponentially growing sequences of C and γ. Here, log 2C and log 2 (γ) range from $[-10, 10]$ at an interval of 1. Each combination of parameter choices (C, γ) is checked using cross-validation, and the parameters with best cross-validation accuracy are picked. Results of this analysis are shown in Table 4. In the E-nose data treatment, the classification results based on Lib-SVM were not perfect (98.67% accuracy rate in 5-fold cross-validation, and 84% accuracy rate in the testing set) with best parameter choices (1, 0.125). The E-tongue system classified the strawberry juice samples successfully both in the training set and testing set (100% accuracy rate) with best parameter choices (0.00097656, 0.25). After searching the best parameter choices (0.00097656, 0.0039), the simultaneous system of E-nose and E-tongue classified the strawberry juice samples successfully in the training set (100% accuracy rate). However, the testing set were only correct about 88%, thus might combined pattern caused data redundancy.

Table 4. Using of Lib-SVM for the Classification of Strawberry Juices Based on Different Data Sets

	parameter			
data set	best C	best γ	5-fold cross-validation rate (%)	testing rate (%)
E-nose	1	0.125	98.67	84
E-tongue	9.7656×10^{-4}	0.2500	100	100
fusion of E-nose and E-tongue	9.7656×10^{-4}	0.0039	100	88

Quantitative Regression of Quality Indices Based on E-Nose, E-Tongue, and the Fusion of E-Nose and E-Tongue, Respectively. *Quantitative Regression of Quality Parameters Based on Partial Least Squares Regression.* PLSR was used to establish a correlation between sensor signals and the strawberry juice quality parameters (vitamin C, pH, TSS, TA, and TSS/TA ratio), which were obtained by conventional analytical methods.

Fifteen sets of independent regression models were performed. The first five sets of models correlated the results of the E-nose with five quality parameters, and the second five sets of models correlated the results of the E-tongue with parameters. The last five sets of models merge the information obtained from both the E-nose and E-tongue with quality parameters. Table 5 summarizes the statistical parameters for the PLSR regression models and shows the value of RMSE and R^2 at calibration and testing sets. The relations found between the E-nose output and the values of five juice quality parameters were not good, which might mean that E-nose can provide global information on the composition of the headspace, however, fail to be related to the chemical composition of liquid phase based on PLSR. The regression models based on E-tongue signals had good performance ($R^2 >$ 0.95 in calibration sets, except for TA) but were not good in the validation sets ($R^2 < 0.87$). Furthermore, performances based on fusion were much better than based on sole usage of E-nose or E-tongue ($R^2 > 0.97$ in calibration sets, $R^2 > 0.85$ in calibration sets). Figure 4 visualizes the distributions between predicted and experimental values. As shown in Figure 4a1, Figure 4a2, Figure 4a3, Figure 4a4, and Figure 4a5, the unorganized data points might mean that E-nose sensors can not build good correlation with specific substances which are dissolving in the solutions not as gas in the headspace. As it is

shown in Figure 4c1, Figure 4c2, Figure 4c3, Figure 4c4, and Figure 4c5, there are close relationship between quality parameters from conventional analytical methods and those estimated by the PLSR models based on the fusion. In this way, a good prediction of these variables could be performed from the fusion of E-nose and E-tongue.

Quantitative Regression of Quality Parameters Based on Support Vector Machines. For Lib-SVM regression models, the E-nose data set, and E-tongue data set, the fusion and the quality parameters were processed same as Lib-SVM classification did. Then 5-fold cross-validation was applied to get the best performance of classification, and radial basis function (RBF) was chosen as the core function. Parameter C

dx.doi.org/10.1021/jf501468b | J. Agric. Food Chem. 2014, 62, 6426−6434

and kernel parameter gamma (γ) in SVM model were also optimized in the Lib-SVM regression models. Results of this analysis are shown in Table 6. On the whole, regression models based on Lib-SVM were not good as regression models based on PLSR were according to R^2 in this strawberry juice case. Better predictions of these variables were performed from the fusion of E-nose and E-tongue, compared to an individual apparatus utilization.

Quantitative Regression of Quality Parameters Based on Random Forest. The regression results based on RF are summarized in Table 7. The overall level of regression based on RF is higher than models established by PLSR and Lib-SVM. The predictive models, built on the responses of the E-nose, have higher value of R^2 in the calibration and in the validation sets than models by Lib-SVM did. In this section, the result of the fusion data is slightly higher than models built by E-tongue data. The RF algorithm may be able to extract useful information more effectively than Lib-SVM and PLSR do in the field of E-nose and E-tongue data processing.

Table 7. Comparison of Three Predictive Models Built on the Responses of the E-Nose Data Set, E-Tongue Data Set, and the Fusion of E-Nose and E-Tongue by RF

This work presented a comprehensive and systematic experimental analysis of the performance of E-nose and E-tongue to discriminate processed strawberry juices and to predict juice quanlity changes. Conclusions were reached here: (1) E-tongue system reached higher accuracy rate compared to E-nose system both in the classification and regression, and the combination did have a slight advantage in the LDA classification and PLSR regression. (2) The network design and parameter optimization adjusted RF and SVM to perfection for classification and regression, and RF has shown outstanding and indisputable performances in the qualitative and quantitative analysis when compared with Lib-SVM in this experiment. To our knowledge, there has been no previous study to RF analysis in the E-nose or E-tongue data processing for regression, and future work may consider the utilization of data sampling with respect to the RF learner. This work indicates that the simultaneous utilization of E-nose and E-tongue with appropriate algorithm can discriminate between processed fruit juices and predict quality changes successfully for the beverage industry in replacement of existing detection systems.

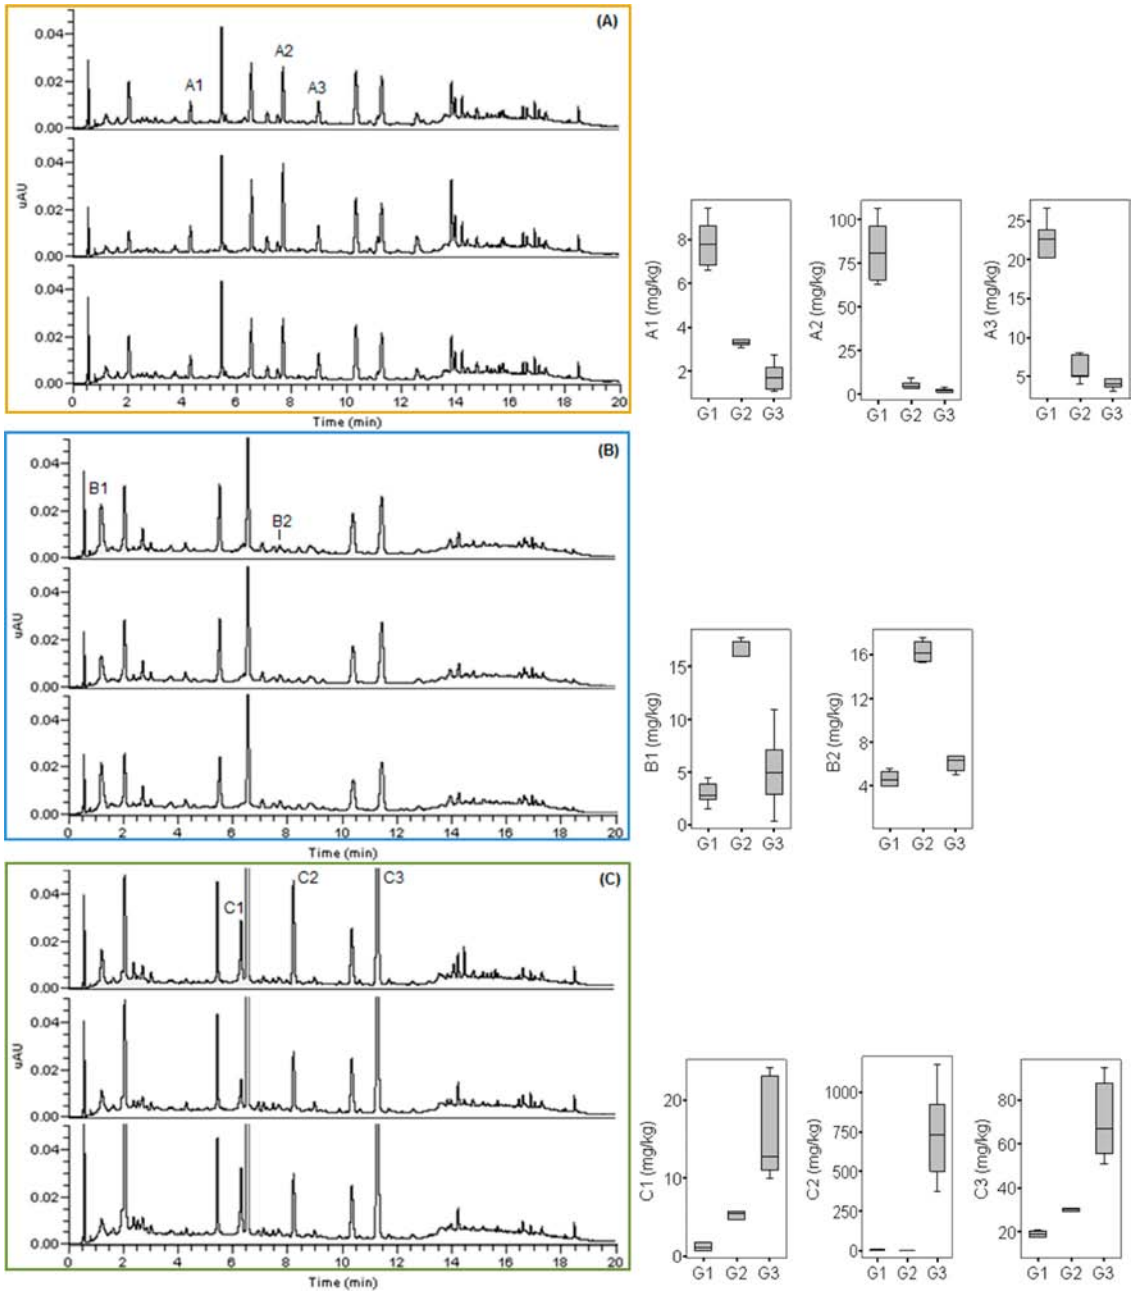

Figure 1. UHPLC-PDA-MS/MS example profiles, λ = 272 nm: group classification extracted from the publication by Oelschlaegel et al.[11] of commercially available manuka honeys; numbered peaks are characteristic compounds of each group. (A) group 1 (25%), (B) group 2 (25%), (C) group 3 (50%); (A1) 4-hydroxybenzoic acid, (A2) dehydrovomifoliol, (A3) benzoic acid; (B1) kojic acid, (B2) 2-methoxybenzoic acid; (C1) syringic acid, (C2) 4-methoxyphenyllactic acid, (C3) methyl syringate.

isophorone, 3,4,5-trimethylphenol, benzoic acid, and phenylacetic acid were specific for group 1 (Figure 2). The honeys of group 2 contained the highest intensities of 2-methylbenzofuran, 2′-hydroxyacetophenone, and 2′-methoxyacetophenone, and group 3 honeys contained a high intensity of *cis*-linalool oxide. Because of the high MGO content determined for group 2, which strongly differed from the two other groups, Oelschlaegel et al.[11] assumed that group 2 represents pure manuka honeys. For kanuka honey, 4-methoxyphenyllactic acid is said to be characteristic according to Stephens et al.[14]

The Australian native jelly bush (*Leptospermum polygalifolium* Salisb.) honey or berringa honey whose nectar plant is classified to the same genus as the manuka shrub needs to be considered as well. Its nonperoxide antibacterial activity caused by approximately the same quantities of MGO has already been noted as a New Zealand equivalent.[15,16] The fact of the same botanical classification but a different geographical origin constitutes a very important distinction. In the literature, only Yao et al.[17] investigated the two different manuka species concerning flavonoids and phenolic acids. They described myricetin, luteolin, and tricetin as main flavonoids for jelly bush honey and quercetin, isorhamnetin, luteolin, and an unknown flavanon for manuka honey. In regard to the phenolic acids, gallic acid was measured to be dominant in manuka honey, jelly bush honey should additionally contain coumaric acid.

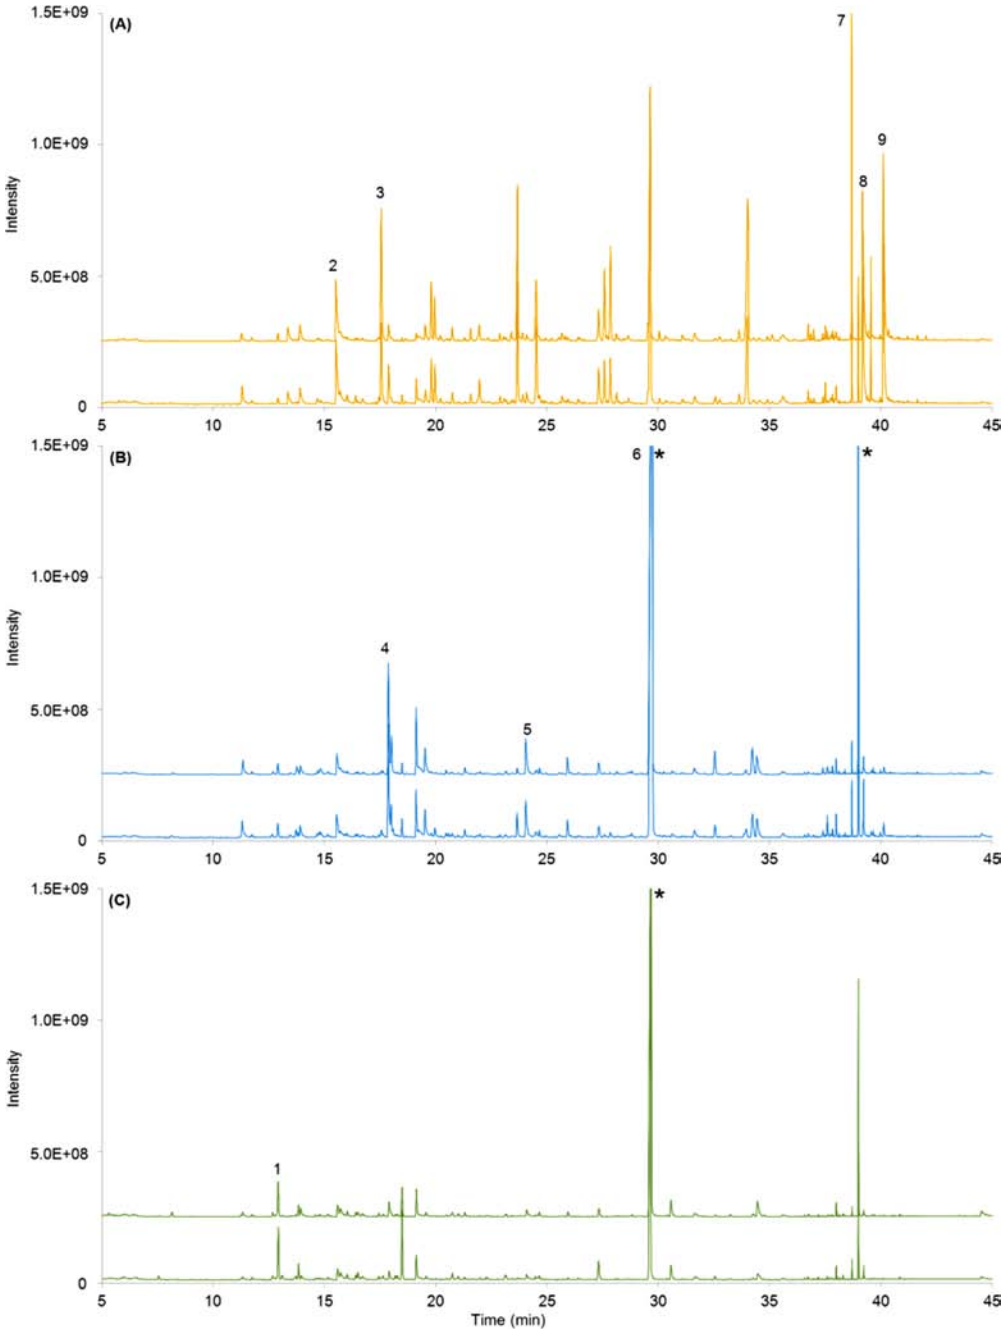

Figure 2. HS-SPME-GC/MS example profiles: group classification of commercially available manuka honeys according to Oelschlaegel et al.[13] (A) group 1 (25%), (B) group 2 (50%), (C) group 3 (25%); (1) *cis*-linalool oxide, (2) benzaldehyde, (3) α-isophorone, (4) 2-methylbenzofuran, (5) 2′-hydroxyacetophenone, (6) 2′-methoxyacetophenone, (7) 3,4,5-trimethylphenol, (8) benzoic acid, (9) phenylacetic acid; * peak cut.

The aim of this study was to establish chemical marker compounds for the three different monofloral honeys in order to differentiate between them. This was achieved by analyzing both the nonvolatile compounds such as phenolic substances or norisoprenoides obtained by UHPLC-PDA-MS/MS and the volatile compounds by HS-SPME-GC/MS. By a subsequent comparison of the resulting PDA- and GC-MS-profiles, marker compounds could be worked out for the first time allowing for a clear differentiation of the three honeys derived from monocultures among themselves on the basis of chemometrics.

MATERIAL AND METHODS

Honey Samples. Eight monofloral manuka honeys (New Zealand), seven monofloral kanuka honeys (New Zealand), and one jelly bush honey (Australia) were received from UMFHA, which also performed pollen-analytical studies. According to the information obtained from UMFHA, the monofloral honeys were harvested in regions with only one of the three honey cultivars in 2012. All the samples were stored in a refrigerator at 6 °C.

Chemicals. Methanol (HPLC grade and LC-MS grade) and acetonitrile (HPLC grade) were purchased from Fisher Scientific (Schwerte, Germany). Daidzein standard, 2′-hydroxyacetophenone, 2′-methoxyacetophenone, and 2,6,6-trimethyl-2-cyclohexene-1,4-dione were acquired from Alfa Aesar (Karlsruhe, Germany). The 4-methoxy-^{13}C, d_3-benzoic-2,3,5,6-d_4 acid as internal standard for LC-

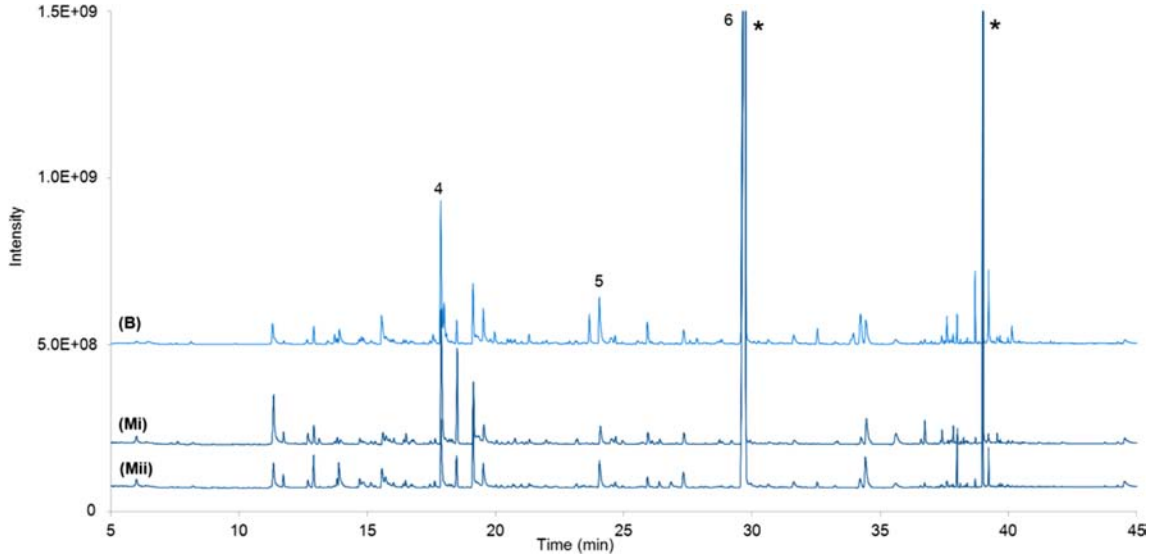

Figure 3. HS-SPME-GC/MS profiles: comparison of Oelschlaegel's group 2[13] (B) with pure manuka honeys (Mi), (Mii); (4) 2-methylbenzofuran, (5) 2′-hydroxyacetophenone, (6) 2′-methoxyacetophenone; * peak cut.

MS/MS was supplied by Isotec via Sigma-Aldrich (Steinheim, Germany). Acetic acid 100% glacial was from Fluka via Sigma-Aldrich (Steinheim, Germany). Sodium chloride was purchased from VWR International (Darmstadt, Germany) and benzaldehyde-d_6, phenethyl alcohol, *cis*-linalool oxide, *p*-anisaldehyde, and 2-methyl-6-propyl phenol from Sigma-Aldrich (Steinheim, Germany). 3,4,5-Trimethylphenol and 2-methylbenzofuran were purchased from Dr. Ehrenstorfer GmbH via VWR International (Darmstadt, Germany). All the chemicals used in this study were of analytical grade. Bidistilled water was generated by the Bi-Distilling Apparatures Bi 18E QSC GmbH (Maintal, Germany).

Head Space Solid Phase Microextraction (HS-SPME). The HS-SPME-GC/MS was carried out as described by Oelschlaegel et al.[12] Briefly, honey was homogenized with sodium chloride and water in a SPME vial. Deuterated benzaldehyde was used as internal standard. Before measuring, the DVB/CAR/PDMS fiber which is described as the most suitable fiber for honey volatiles was conditioned.[18] Subsequently, the analytes were desorbed in the PTV injector. The HS-SPME holder was part of a Combi PAL (CTC Analytics, Zwingen, Swiss).

GC/MS Detection. A Thermo Scientific Trace GC Ultra interfaced with a Thermo Scientific DSQ II (Thermo Fisher, Dreieich, Germany) was used. The MS was operated in the positive EI mode at 70 eV, and the mass range was m/z 50−600. EI source temperature was set at 200 °C. Spectral data recording started only after 4 min due to the huge solvent peak. Identification of the compounds based on a comparison of the MS spectra with those of the NIST-08-mass spectral library, with linear retention indices (LRI) and with reference substances (retention time, MS spectrum).

UHPLC-PDA-MS/MS Detection. Prior to the UHPLC analyses, a solid phase extraction was carried out and has already been described.[11] Briefly, 2 g of honey were dissolved in 2% sodium chloride (pH 2−3) with subsequent SPE cleanup using Chromabond cartridges. Chromatographic analyses were performed with an Acquity Ultra Performance UPLC-PDA system (Waters, Eschborn, Germany) on a Nucleodur C18 column with a water/methanol/formic acid gradient within 20 min. Mass spectrometric investigations were carried out using a coupled TSQ Quantum Access MAX (Thermo Fisher, Dreieich, Germany). The identification of the compounds was realized via retention time, UV maxima, and also timed SRM (single reaction monitoring).

Statistical Analyses. The data matrix consists of rows representing the different honeys (objects) and columns, which includes SPE-UHPLC-PDA-MS/MS data of the substances (variables) previously described as characteristic. For PCA and k-means, the matrix covered 16 objects × 13 variables. For this, SPSS 22.0 was used. All data were standardized (z-values) before chemometrics.

RESULTS AND DISCUSSION

Comparison of the HS-SPME-GC/MS Profiles. The volatiles were examined in seven manuka, two kanuka, and one jelly bush honey using the HS-SPME-GC/MS method by Oelschlaegel et al.[12] Because of the rather small sample size, this investigation comprised less honeys than those analyzed by

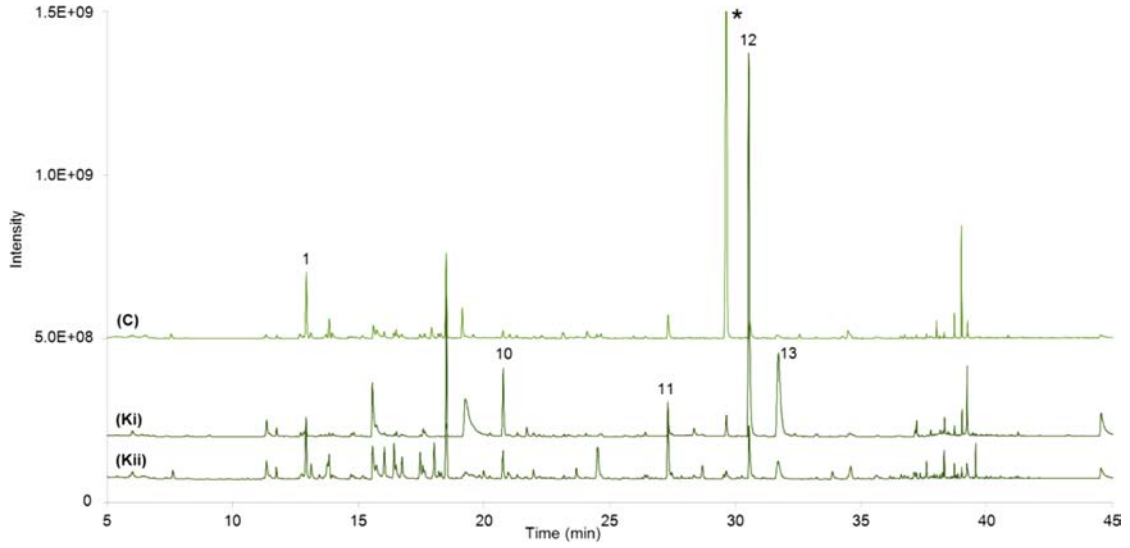

Figure 4. HS-SPME-GC/MS profiles: comparison of Oelschlaegel's group 3[13] (C) with pure kanuka honeys (Ki), (Kii); (1) *cis*-linalool oxide, (10) 2,6,6-trimethyl-2-cyclohexene-1,4-dione, (11) phenethyl alcohol, (12) *p*-anisaldehyde, (13) unknown; * peak cut.

Figure 5. the UHPLC-PDA-MS/MS method. The chromatographic profiles of the three honey sorts were compared; the resulting characteristic compounds are listed in Table 1.

In the samples of the monofloral manuka honey, mostly the compounds of Oelschlaegel's group 2 were detected as well (Figure 3).[13] The following volatile substances could be confirmed as characteristic for manuka honey: 2-methylbenzofuran, 2′-hydroxyacetophenone, and 2′-methoxyacetophenone. In contrast, for kanuka honey, subsequent compounds proved to be prominent: 2,6,6-trimethyl-2-cyclohexene-1,4-dione, phenethyl alcohol, *p*-anisaldehyde, and an unknown compound, which refers to a similarity to Oelschlaegel's group 3 (Figure 4).[13] 2,6,6-Trimethyl-2-cyclohexene-1,4-dione and phenethyl alcohol, although already known in honey in general, were now described for kanuka honey for the first time.

2′-Methoxyacetophenone as characteristic for manuka honey has already been reported by Daher et al.,[19] whereas Tan et al.[20] described this compound for manuka/kanuka honeys without differentiation. In one Portuguese multifloral honey, 2′-methoxyacetophenone was analyzed with an equivalent high peak intensity as well, however, this honey showed a completely different MS-profile.[21] Because of our findings that this compound could only be detected in negligible intensities for kanuka honey under the chosen conditions, 2′-methoxyacetophenone can be used as a criterion distinguishing manuka honey from kanuka honey. Nevertheless, 2-methylbenzofuran and 2′-hydroxyacetophenone are present exclusively in manuka honey in reference to the three monofloral honeys. For kanuka honeys, there are two characteristic peaks which are present in other honeys, especially in European ones, in definitely small quantities: one has been identified as anisaldehyde, the second is unknown.[22−29] The latter was first assumed to be *p*-propyl anisole, which was proposed by Visser et al.[29] and later by Daher et al.[19] as a marker for manuka honey. However, both groups of authors identified this component solely via the NIST

in manuka nor in kanuka honey. Subsequent studies with a further suggested compound by the NIST database, with 2-methyl-6-propyl phenol as a reference substance, also failed, although the MS spectrum was the same. The investigations concerning the identification are still ongoing.

An Australian jelly bush honey also provided by UMFHA was analyzed to do a profile matchup with manuka honey as well (Table 1). Because of the notably lower intensities of 2′-methoxyacetophenone and higher concentrations of *cis*-linalool oxide and 3,4,5-trimethylphenol in the jelly bush honey profile, a differentiation toward manuka honey was possible (Figure 5). However, a confirmation of the distinctive features would require further analyses of more jelly bush honeys.

Comparison of the UHPLC-PDA Profiles. In all, eight manuka, seven kanuka, and one jelly bush honey were investigated according to the UHPLC-PDA-MS/MS method described by Oelschlaegel et al.[11] (Table 2). Comparing the PDA profiles (λ = 254 nm), an unambiguous distinction among the pure manuka and pure kanuka honeys can immediately be recognized. Additionally, all the investigated samples of manuka, kanuka, and jelly bush honey were analyzed by UHPLC-HRMS and evaluated by Braggins et al. (Analytica Laboratories Ltd., Waikato, New Zealand).[30] Results are noted in Table 2.

Leptosin was detected as the principal analyte of manuka honey (Figure 6). In contrast, kanuka honey profiles were dominated by 4-methoxyphenyllactic acid and also by methyl syringate (Figure 7). Leptosin, a glycoside of methyl syringate, was already described exclusively for the *Leptospermum* species by Kato and cowriters[31] and, therefore, could be confirmed as a marker for manuka honey. 4-Methoxyphenyllactic acid was found in manuka/kanuka honeys by Tan et al.[20] and in one of six commercial manuka honeys analyzed by Le Gresley et al.[32] According to Stephens et al.,[14] the substance is uniquely characteristic for kanuka honey which, in turn, corresponds to our results. A large number of other characteristic substances in the profiles of pure monofloral honeys were worked out as follows: acetyl-2-hydroxy-4-(2-methoxyphenyl)-4-oxobutanate, 3-hydroxy-1-(2-methoxyphenyl)-penta-1,4-dione, and still unknown compounds M4 and M7 for manuka honey and, for kanuka honey, *p*-anisic acid and lumichrome (Figure 8). Kojic acid and 5-methyl-3-furancarboxylic acid which are well-marked for manuka may be a further distinction criteria. Acetyl-2-hydroxy-4-(2-methoxyphenyl)-4-oxobutanate and 3-hydroxy-1-(2-methoxyphenyl)-penta-1,4-dione were proved exclusively for manuka honey and had been isolated and subsequently identified via NMR-spectroscopy by Oelschlaegel et al.[11] Although lumichrome is currently discussed controversially as a marker substance, both for the country-specific Italian thistle honey (*Galactites tomentosa* Moench) and for the cornflower honey (*Centaurea cynaus L.*) (recent studies reported 2−3-fold higher contents in cornflower honey), the compound constitutes an important distinguishing criterion in the manuka/kanuka comparison due to its uniqueness to kanuka honey.[33−36] With a retention time similar to lumichrome, the unknown peak M7 existing in manuka honey with UV maxima at λ = 245 and 306 nm compared to lumichrome (λ = 259, 349 nm) has a markedly deviating UV spectrum and, after its identification, could serve as a further marker substance for manuka honey.

p-Anisic acid as well as methyl syringate could be used as differentiation criteria in the profile matchup for kanuka honey versus manuka honey due to the uniqueness or to the tendentially higher peak intensities. Their comparatively low occurrence in honeys from Europe and other honey from New Zealand can be neglected.[14,26,37−41] Senanayake[42] divided his manuka honeys into active and inactive samples on the basis of their UMF contents. The inactive samples contained higher 4-methoxyphenyllactic acid and methyl syringate than the active samples. On the basis of our results, kanuka honey, which verifiably does not have any nonperoxide antibacterial activity, might be contained in these honeys in larger quantities. In accordance with Oelschlaegel et al.,[11] group 2 represents the true manuka honeys (Figure 6). In contrast, group 3 includes honeys with a higher proportion of kanuka honey, and honeys of group 1 very probably contain only low proportions of both manuka honey and kanuka honey (Figure 7).

Distinguishing the so-called Australian manuka honey (jelly bush honey) from the New Zealand manuka honey is also of interest. Although both honey sorts show a giant leptosin peak, the PDA profiles are characterized by distinct differences (Figure 8). Whereas acetyl-2-hydroxy-4-(2-methoxyphenyl)-4-oxobutanate, 3-hydroxy-1-(2-methoxyphenyl)-penta-1,4-dione, and two unknown peas M4 and M7 are present in New

Zealand manuka honey, the Australian manuka honey is characterized by 2-methoxybenzoic acid and an unknown substance J2 (Figure 8). On the basis of these substances, it is possible to achieve a differentiation of these two kinds of honey, however, the prominent compounds of jelly bush honey would have to be ascertained by additional samples. The results reported by Yao et al.[17] who had analyzed honeys of both kinds of manuka honey could not be confirmed as already demonstrated by Oelschlaegel et al.[11] Neither could any high contents of abscisic acid nor gallic acid, which was declared as prominent for manuka honey, nor any different flavonoids be detected.

Final Assessment of Honey Characterization by Chemometrics. A PCA was calculated with the results of UHPLC-PDA-MS/MS. So, the marker potential of the above-mentioned characteristic substances for each of the three honeys was investigated. About 82% of the variation could be explained by the first two principal components (PC). Thereby, the first PC in negative is loading with lumichrome, 4-methoxyphenyllactic acid, and *p*-anisic acid, in positive through kojic acid, acetyl-2-hydroxy-4-(2-methoxyphenyl)-4-oxobutanate, 3-hydroxy-1-(2-methoxyphenyl)-penta-1,4-dione, unknown M4, and unknown M7 (Figure 9). If moving to the higher values of PC 2, 2-methoxybenzoic acid and unknown J2 are located. Looking at the scatter plot, the individual honeys are separated from each other. Negative values of PC 1 present the characteristic substances of kanuka honey, while positive values mark the typical manuka honey compounds. The analytes which are explained by PC 2 are referring to jelly bush honey (Figure 10). A few substances, which are listed below, do not permit a clear allocation: methyl syringate, leptosin, and 5-methyl-3-furancarboxylic acid. This is caused by the fact that the compounds are not clearly assigned only to one honey and, therefore, this kind of behavior in the loading plot was to be expected (Figure 9). Nonetheless, due to their huge peak height and individuality, a further consideration is indispensable in profile matchup. These results confirm that potential marker suitability is assured.

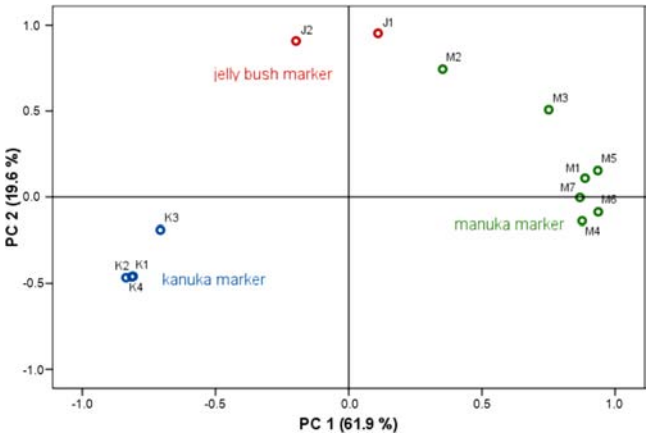

Figure 9. Loading plot (varimax rotation) for the first two principal components (PC1 with 61.9% of the total variance and PC2 19.6% of the total variance) of the determined UHPLC-PDA-MS/MS data; (K1) 4-methoxyphenyllactic acid, (K2) *p*-anisic acid, (K3) methyl syringate, (K4) lumichrome; (M1) kojic acid, (M2) 5-methyl-3-furancarboxylic acid, (M3) leptosin, (M4) unknown 1, (M5) acetyl-2-hydroxy-4-(2-methoxyphenyl)-4-oxobutanate, (M6) 3-hydroxy-1-(2-methoxyphenyl)-penta-1,4-dione, (M7) unknown 3; (J1) 2-methoxybenzoic acid, (J2) unknown 2.

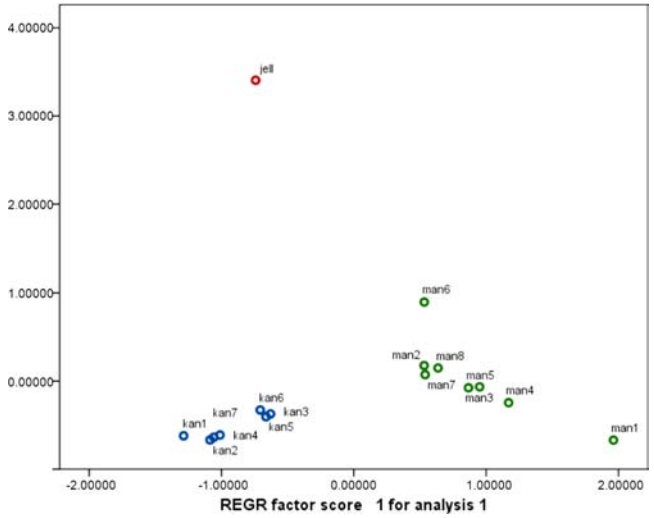

Figure 10. PCA score plot of manuka honeys (man), kanuka honeys (kan), and the jelly bush honey (jell) of the determined UHPLC-PDA-MS/MS data; number = sample number.

By means of the 13 declared substances, a cluster analysis was carried out to cluster the investigated honeys on the basis of their measured data. For this, a *k*-means with the requirement of 3 clusters was used. Before clustering, a successful test of dissimilarity was carried out. On the basis of Euclidean distance and subsequent iteration, a corresponding classification after cluster membership was generated. The aim to classify similar honeys in one cluster was achieved. Therefore, all manuka honeys were assigned to cluster 1, all kanuka honeys were assigned to cluster 2, and the last one, cluster 3, contains only the jelly bush honey. Chemometrics confirmed the characteristic substances for each honey that had already been worked out by profile matchup, allowing for a classification in three clusters to which only one kind of honey was assigned. A definite classification of the kind of honey requires numerous further investigations with a larger number of samples as well as with samples from different years and the various areas of New Zealand.

This is now a first approach to differentiating the manuka honeys from New Zealand and Australia as well as distinguishing the kanuka honeys among themselves by UHPLC-PDA-MS/MS and HS-SPME-GC/MS profile matchup.

100 g pin mixer (National Manufacturing, Lincoln, NE, USA) with 57.0 mL of deionized water (mixograph-derived water absorption), 6.0 g of sucrose, 5.3 g of compressed yeast (Bruggeman, Ghent, Belgium), and 1.5 g of salt. The mixed dough was transferred to a lightly greased bowl and put in a fermentation cabinet (National Manufacturing) at 90% relative humidity and 30 °C. Fermentation took 90 min, with intermediate punching after 52 and 77 min using a dough sheeter (National Manufacturing). After 90 min, dough was punched a last time and molded. It was then either placed in a lightly greased metal baking pan for conventional baking or put in a plexiglass ERO baking chamber. In both cases, dough was then transferred to the fermentation cabinet for a final proof stage of 36 min.

Conventional Baking. Proofed dough was baked at 215 °C for 24 min in a National Manufacturing rotary oven. After baking, depanning, and 120 min of cooling to room temperature, breads were weighed, packed in a hermetically sealed plastic bag to prevent moisture loss, and stored at room temperature until further analysis.

Baking in an Electrical Resistance Oven. Heating of dough by an ERO is based on the principle of Joule's first and Ohm's laws. Joule's first law expresses the relationship between the heat (Q) generated by the current (I) flowing through a resistance (R) for a time (t): $Q = I^2 \times R \times t$. Joule heating, also known as ohmic or resistive heating, is the process by which the passage of an electric current through a resistance releases heat. According to Ohm's law, the applied voltage (V) equals the current (I) × the resistance (R). In line with the above, at a given dough resistance, the intensity of the current rises and, as a result, the temperature in dough increases at a higher rate when the applied voltage is increased. Evidently, the heating rate also depends on dough/bread resistance. The ERO was based on a model described by Hoseney[1] with slight modifications (baking chamber made of plexiglass plates of 10 mm thickness with internal dimensions of 12.5 × 10.0 × 22.0 cm). Figure 1 shows the system, with indications of the positions of the thermocouples (see below). Dough was placed between two stainless steel plates (distance between the plates = 6.5 cm, plate thickness = 1.5 mm), which were coupled to a variable transformer (Hossoni, Hongbao, China; 0−250 V). A perforated (126 holes, each with a diameter of 1.5 mm) plexiglass plate (12.4 × 6.4 cm, plate thickness 10 mm), which could easily slide upward when the dough/bread expanded, was placed on top of the dough during proofing and baking to keep the surface of the bread flat. This ensured good contact of the baking dough/bread with the electrode plates and reproducible baking.

ERO baking was programmed to simulate the temperature profile of the center of dough/bread during conventional baking. The heating rate, and thus also dough temperature, was controlled by adjusting the applied voltage by a variable transformer. Temperature was monitored by thermocouples (see below) inserted into dough through a hole in the baking chamber 4.0 cm above the bottom of the oven or through holes in the perforated plate. The voltage−time profile applied during baking was chosen to simulate the temperature profile in the center of conventionally baked dough/bread and was as follows: 50 V (0−1 min), 100 V (1−8 min), 120 V (8−14 min). After baking, bread was removed from the oven and allowed to cool for 120 min. Afterward, it was weighed and packed individually in a hermetically sealed plastic bag to prevent moisture loss. It was then stored at room temperature for 7 days. Analyses at day 0 were those on breads cooled to room temperature and stored for 2 h.

Temperature Measurements during Baking. Temperature measurements were performed using a Datapaq (Cambridge, UK) temperature data logger (MultiPaq 21) with type T thermocouples. In conventional baking, a stainless steel thermal barrier (Datapaq) protected the MultiPaq temperature data logger. Temperature measurements were performed in triplicate.

Determination of Moisture Contents. Moisture contents were measured for samples withdrawn at eight different places (indicated in Figure 5) in fresh and aged bread according to AACC International method 44-15A.[11]

Differential Scanning Calorimetry (DSC). DSC was carried out with a Q1000 differential scanning calorimeter (TA Instruments, New Castle, DE, USA). Bread crumb samples were freeze-dried, ground,

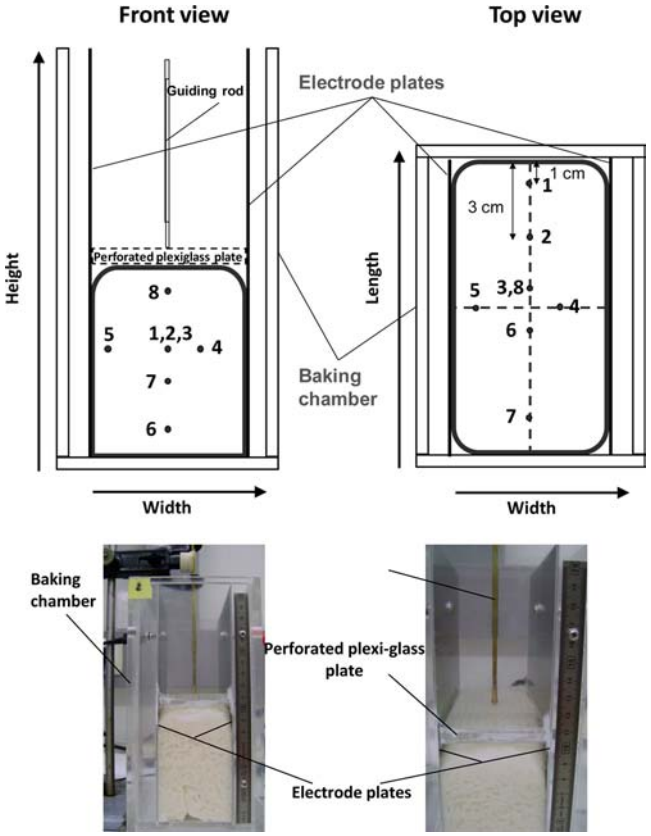

Figure 1. Schematic representation of baking chamber of the electrical resistance oven (ERO). The baking chamber is made from plexiglass. The voltage is applied by a variable transformer over the two electrode plates. A perforated plexiglass plate is used to keep the surface of the bread flat during final proof and oven rise. The produced gases can escape from the system through the pores. The numbers indicate the places where the thermocouples are placed.

and accurately (2.5−4.0 mg) weighed in three separate aluminum pans (PerkinElmer, Waltham, MA, USA). An excess of deionized water was added [1:3 w/w sample dry matter (dm)/water]. The pans were hermetically sealed. After equilibration at room temperature for at least 20 min, the pans were heated from 0 to 120 °C at 4 °C/min. An empty pan was used as reference. Calibration was with indium. TA Universal Analysis software was used to determine the onset (T_o), peak (T_p), and conclusion (T_c) temperatures and melting enthalpy (ΔH) of retrograded amylopectin.

Polarized Light Microscopy. The gelatinization process during baking using both conventional and ERO technologies was visualized using polarized light microscopy. For these analyses, samples obtained from dough before baking and from fully baked bread were prepared by putting a small piece of dough/crumb collected from the center of the dough/bread on a carrier glass. After the addition of a drop of deionized water, a cover glass was placed on it, and the samples were examined with an Olympus BH2 microscope (Olympus, Tokyo, Japan) in the polarization mode.

Proton Nuclear Magnetic Resonance Measurements. Measurements of proton distribution in fresh and stored bread crumbs were performed with a low-resolution proton nuclear magnetic resonance (^{1}H NMR) spectrometer (Minispec mq 20, Bruker BioSpin, Ettlingen, Germany) at an operating resonance frequency of 20 MHz for ^{1}H (magnetic field strength of 0.47 T) according to the method of Bosmans et al.[12] This technique detects differences in mobility of protons that are in different environments.[13−16] During measurements, the probe head was kept at 25 °C using an external water bath. Samples (approximately 0.3 g) were accurately weighed in a Bruker NMR tube (10 mm external diameter) and sealed to prevent moisture

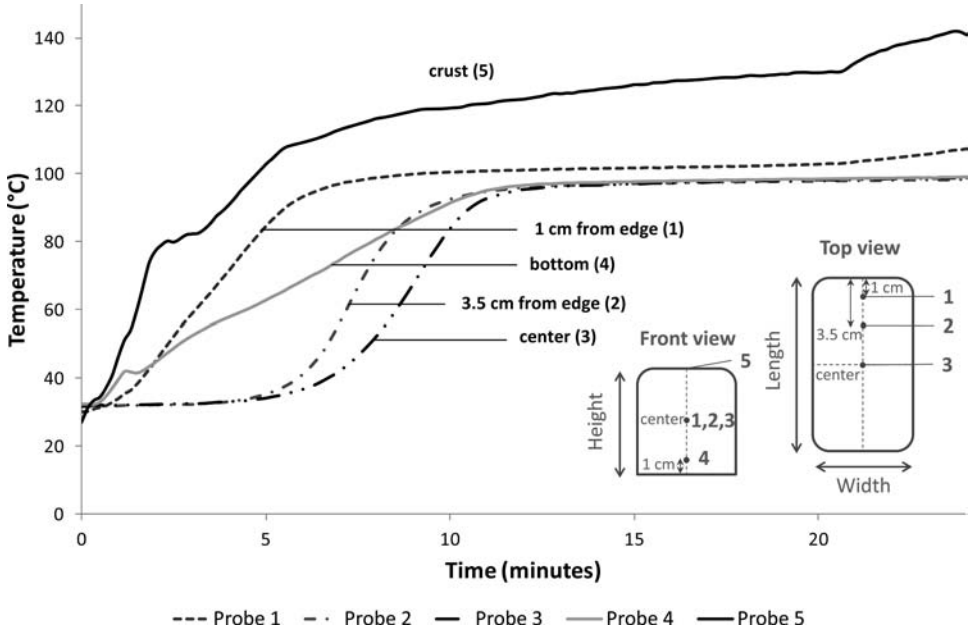

Figure 2. Temperature evolution of dough/bread during baking in a conventional rotary oven, measured at five different places.

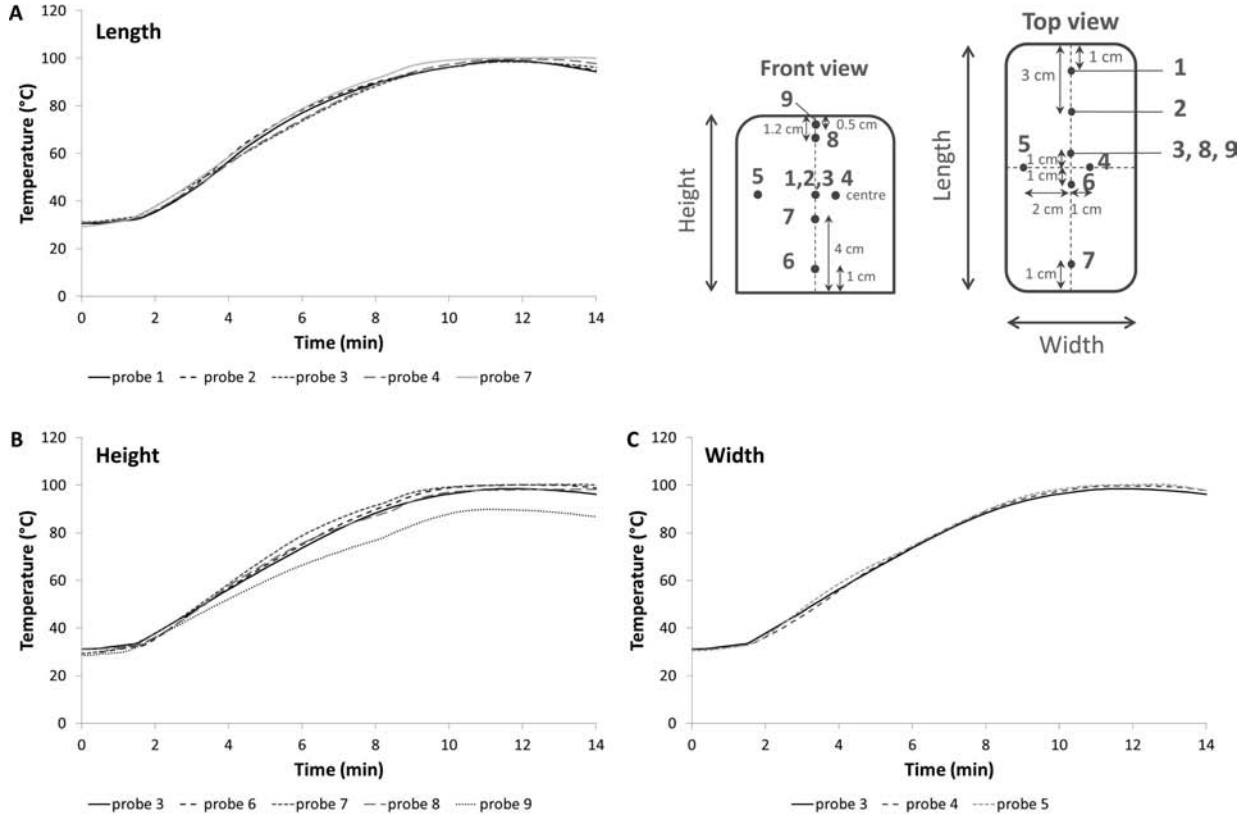

Figure 3. Temperature evolution in dough/bread during baking in an ERO, measured at nine different places in dough/bread, differing in length (A), height (B), and width (C).

loss. Three NMR tubes were filled to about 8 mm height with tightly compressed bread crumb (extracted from the loaf center) to avoid large air holes. Triplicate measurements were performed on each NMR tube. Transverse relaxation times (T_2) were measured. The transverse relaxation curves were developed using a single 90° pulse [free induction decay (FID)] and the Carr−Purcell−Meiboom−Gill (CPMG) pulse sequence. The pulse lengths were 2.86 and 5.42 μs, respectively. An acquisition period of 0.5 ms was used for FID measurements, and 500 data points were collected. The inhomogeneity of the static magnetic field affected the output for the most mobile FID population (around 0.5 ms). Therefore, this fraction was excluded from the analyses. The CPMG sequence had an interpulse spacing of 0.1 ms, and 2500 data points were acquired during the measurements. To increase the signal-to-noise ratio, 32 scans were performed with a recycle delay of 3.0 s for both measurements. The transverse relaxation curves were transformed with an inverse Laplace

dx.doi.org/10.1021/jf501856s | J. Agric. Food Chem. 2014, 62, 6445−6453

transformation to continuous distributions of T_2's using the Contin algorithm of Provencher (Bruker software).[17] Fast-relaxing protons, for example, protons of solids or protons strongly associated with solids, have a short transverse relaxation time. These can be observed in FID measurements. CPMG measurements are used to study protons with higher transverse relaxation times, such as water protons and solid protons in strong interaction with water.[14,16,18] The areas under the curves of the different proton populations are proportional to the quantity of protons in these populations for both FID and CPMG measurements. The areas were calculated by taking into account the exact weight of the bread crumb samples. Measurements were performed in triplicate to confirm the reproducibility.

RESULTS AND DISCUSSION

Breadmaking: From Dough to Fresh Bread. *Temperature Changes during Baking.* Monitoring the temperature at different places in dough/bread during conventional baking revealed that there were large gradients from the outside to the center of the dough (Figure 2). The closer to the dough center, the longer is the lag phase and the longer the temperature rise is postponed. In crumb, a maximum temperature of about 100 °C is reached. In contrast, the temperature increases to above 100 °C at the surface, when water vaporization has finished.

For ERO baking, He and Hoseney[8] observed that the resistance of dough changes during the baking process. At about 65 °C, the resistance of yeasted dough increases gradually. This is caused by starch gelatinization, which makes less free water available to the ionic solution to conduct the electric current.[7,8] In the present case, the total baking time (14 min) was shorter than in conventional baking (24 min) by omitting the isothermal phase around 30 °C (0−5 min) in the center of the bread crumb, which exists during conventional baking, and by shortening the final isothermal phase. The latter was done to avoid shrinking of the breads in the ERO and thereby losing contact with the electrode plates. Nevertheless, the baking process was considered to be complete because the bread crumb structure was set and no crumb collapse ("key-holing") was observed.

The temperature gradients during conventional baking are much larger than those during ERO baking. They were measured in the length, width, and height, as shown in Figure 3. Nearly no temperature gradients at points differing in height (measuring points 3, 6, and 7; Figure 3B) were noted. The differences in temperature between these measuring points were limited to maximally 2.3 °C. However, temperature gradients ran up to 13.1 °C near the surface (measuring point 9, Figure 3B). The differences were much lower (3.0 ± 0.7 °C) when the temperature was measured approximately 12 mm under the surface (measuring point 8, Figure 3B). In the length axis of the bread (measuring points 1−4 and 7, Figure 3A) and across the width (measuring points 3−5, Figure 3C), temperature gradients were limited to maximum differences of 2.8 and 2.5 °C, respectively. These small differences showed that ERO baking is almost gradient-free. At the end of baking (e.g., probes 1, 2, and 9, Figure 3), the temperature decreased when shrinking occurred and caused the bread to lose contact with the electrode plates at some places.

Starch Gelatinization during Baking As Visualized by Polarized Light Microscopy. Starch granules in dough are present as native semicrystalline granules with a typical Maltese cross when viewed under polarized light.[19] During the initial stages of both conventional and ERO baking, starch granules are still present as native granules (Figure 4A,B). Irrespective of the heating mode, at some point during baking, starch granules lost their Maltese crosses (Figure 4C,D) and thus were gelatinized.

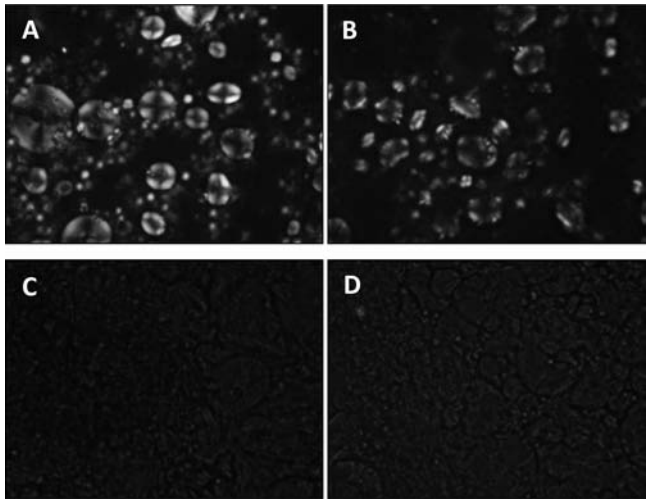

Figure 4. Polarized light microscope images of conventional (A, C) and ERO dough/bread (B, D) before baking (A, B) and after finishing the baking process (C, D).

Bread Moisture Content after Baking. During conventional baking, water evaporation occurs at the surface. Water vapor is lost through the crust into the surrounding hot air while another part of the water moves toward the cooler regions inside the crumb and condenses there.[20,21] In general, conventional bread had a lower weight than ERO bread, that is, 135.7 (±0.6) and 149.8 (±0.9) g, respectively. In conventional bread, the moisture content in the different parts of the crumb was relatively constant (approximately 43%). Possibly, moisture had redistributed during cooling. The moisture content in the crust of conventional bread was much lower, that is, approximately 12.9% (Figure 5). During ERO baking, water vapor condenses on the relatively cold surface of the bread and the plexiglass plates in contact with the ERO bread, whereas the air in a conventional oven is warmer and water vapor stays in the gas phase during the entire baking process. As a result, a small, relatively wet, and leathery layer was formed on top of ERO bread rather than a dry and crisp crust, as observed in conventional baking. Furthermore, the baking time of ERO bread is slightly shorter than that in conventional baking, which shortened the time span over which water could evaporate. Although the total amount of water was higher in ERO breads, the moisture contents in the different parts of the bread crumb were generally lower for ERO bread than for conventional bread. In addition the water was unequally distributed (Figure 5). The moisture content ranged from 33.0% (long side, bottom) to 41.0% (center, top). Overall, the center of ERO bread had a slightly higher moisture content than its outer parts. However, moisture content was higher in the "crust" of ERO breads, as described earlier by Martin et al.,[9] who reported that the exterior 5−10 mm of ERO bread contains approximately 47% moisture.[9] These observations can be explained by differences in water transport during ERO and conventional baking due to the differences in temperature gradient. In ERO bread, temperature gradients are small and the outer parts of the bread are in contact with relatively cooler surfaces (plexiglass and metal electrode plates). Water evaporation and subsequent condensation occur on the colder

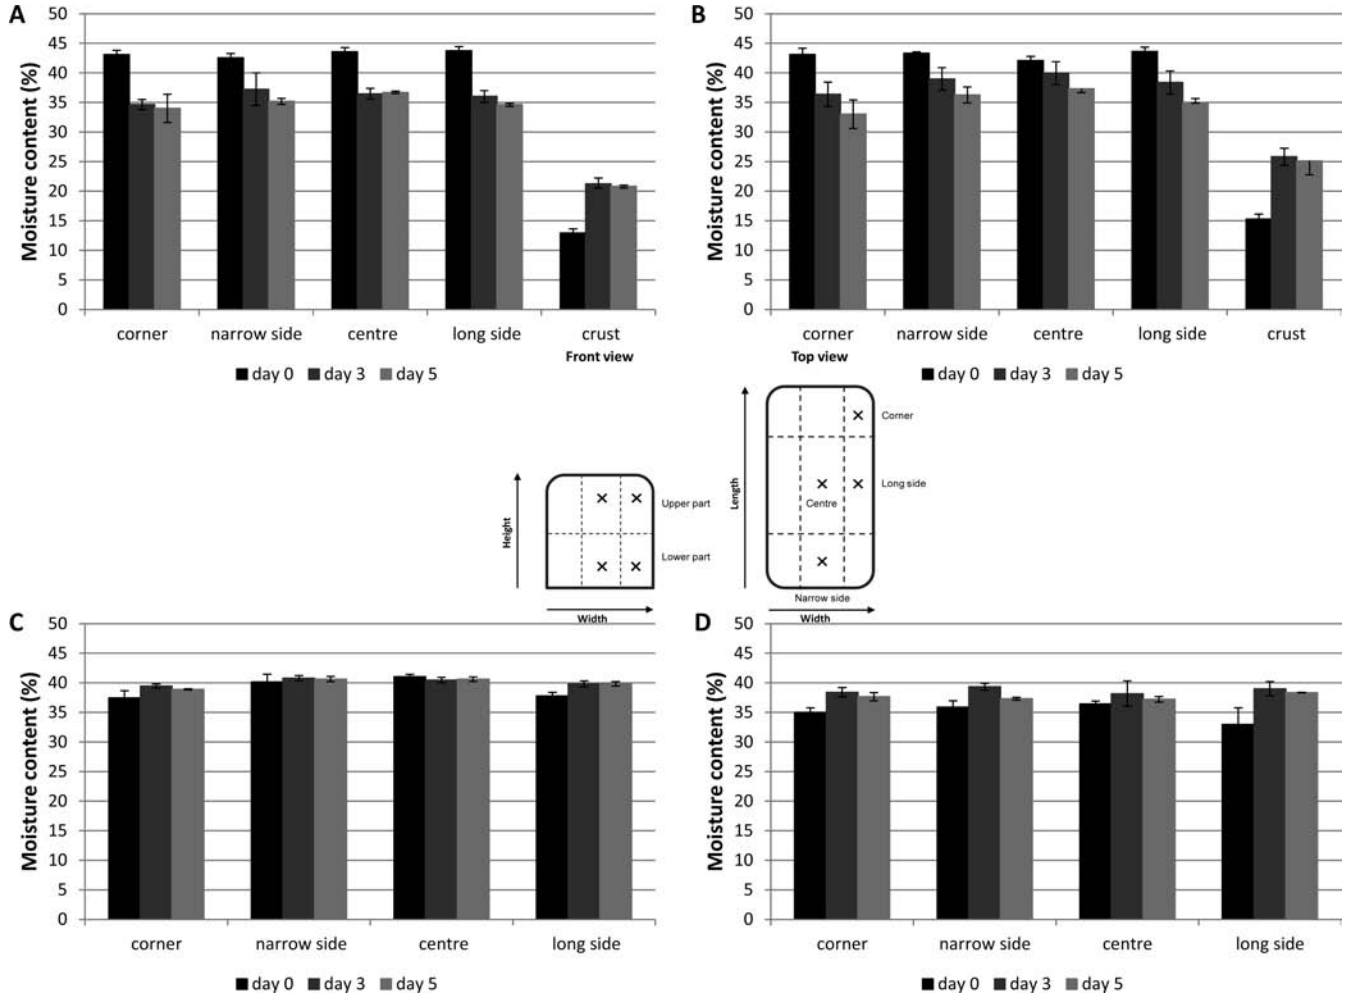

Figure 5. Moisture content during storage (days 0, 3, and 5) of conventional (A, B) and ERO (C, D) baked breads measured at four different places in the upper (A, C) and lower parts (B, D) of the breads.

plexiglass plates of the baking chamber or water evaporates and escapes to the surrounding air. In this way, a water distribution opposite that in a conventional bread (i.e., high moisture content on top of the ERO bread) was reached, similar to what has been observed earlier.[8,9] As a result, the moisture content of the upper part of ERO bread was higher than that of the lower parts.

Changes during Storage of Breads. *Macroscopic Changes in Moisture Gradient during Storage of Breads.* During storage of conventional bread, water migrates from the crumb to the crust. Figure 5 shows the evolution of the moisture content in different parts of the bread during storage. Moisture content decreased in every part of the crumb, whereas that of the crust increased. The largest shifts occurred during the first days of storage. After 5 days of storage, the moisture content of the crust seemed to have stabilized. In contrast to what one might expect on the basis of these data, only a slight weight loss occurred, that is, approximately 1.7 g on a total of 136 g. In contrast to conventional bread, freshly baked ERO bread does not have a dry and crisp crust. Previous studies showed the exterior layer (5−10 mm) of ERO bread to have a moisture content of approximately 47%,[9] whereas the moisture content of the crust in a conventional bread is <15% (Figure 5). As a result, water redistribution in ERO breads was less pronounced, as shown in Figure 5.

Amylopectin Retrogradation during Storage of Bread. Retrogradation of amylopectin was monitored by DSC analysis of crumb samples. Recrystallized amylopectin melted between 40 and 65 °C (peak temperatures around 50 °C). Figure 6 shows the increase in enthalpy of recrystallized amylopectin melting in crumb during storage of conventional and ERO baked breads. For both samples, very low enthalpy values were

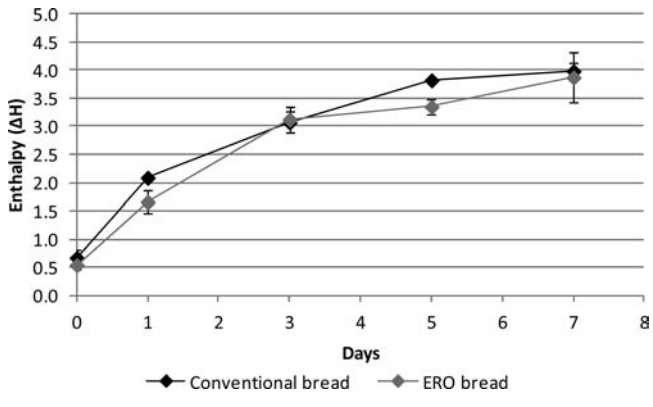

Figure 6. Melting enthalpy of retrograded amylopectin of crumb of conventional and ERO breads, measured by differential scanning calorimetry (DSC) and plotted as a function of bread storage time.

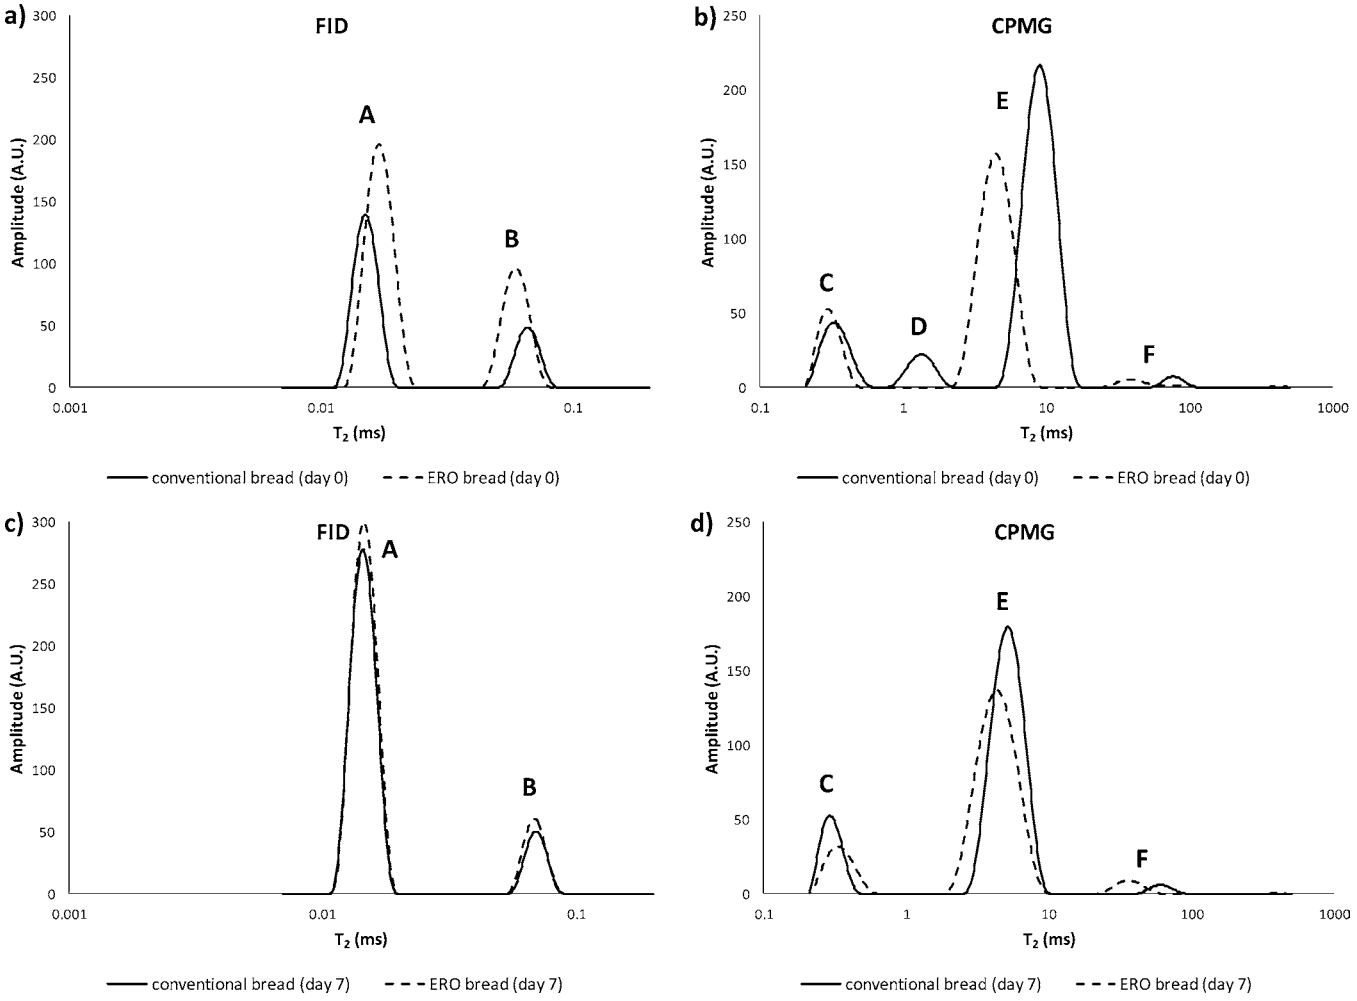

Figure 7. Distribution of transverse relaxation times of protons in the crumbs of ERO and conventionally baked bread on days 0 (a, b) and 7 (c, d), obtained by the inverse Laplace transformation of the free induction decay (FID) (a, c) and Carr−Purcell−Meiboom−Gill (CPMG) pulse sequence (b, d). Amplitudes are given in arbitrary units (A.U.).

obtained on day 0. This observation is in line with previous studies showing a very small endotherm corresponding to melting of retrograded amylopectin a few hours after baking.[22−24] During further bread storage, no significant changes were observed between melting enthalpies for ERO and conventional breads. The levels of recrystallized amylopectin increased in a very similar way in both the conventional and ERO breads (Figure 6).

Changes in Molecular Water Mobility of Bread during Storage. Water migration in conventional and ERO bread was studied using low-resolution ^{1}H NMR spectrometry. Conventionally and ERO baked breads were stored during 7 days in hermetically sealed plastic bags at room temperature. ^{1}H NMR measurements on bread crumb were carried out at different points in time. The large differences in moisture content of conventional bread crumb and crust cause water to migrate from the crumb to the crust. Next to crumb-to-crust water migration, redistribution of water also occurs in bread crumb. This may include incorporation of water in starch crystals.[12]

(a) ^{1}H NMR Analysis of Fresh ERO and Conventional Bread Crumb. Figure 7 compares the distribution of the transverse relaxation time curves of the crumb of ERO and conventional bread. In fresh conventional bread crumb, two FID proton populations (A and B) could be distinguished. Protons in FID population A were assigned to rigid nonexchanging CH protons of starch, that is, those of amylopectin crystals and densely packed amorphous starch not in contact with water, and rigid protons of gluten.[16] The protons in population B have been suggested to correspond to protons of a more mobile amorphous starch fraction in interaction with water.[16] Much as for conventional breads, two FID proton populations could be differentiated for ERO breads. However, the areas of proton populations A and B of ERO bread crumb were initially higher than those of the conventionally baked breads, suggesting lower proton mobility. The moisture content of ERO bread crumb was generally lower than that of crumb from conventional bread. This presumably explains the increase in FID proton populations A and B and hence the lower mobility of the protons in the ERO bread crumb at day 0. This higher initial area could not have resulted from amylopectin retrogradation because on day 0 hardly any amylopectin retrogradation had occurred and the levels of retrograded amylopectin were similar in both conventional and ERO bread crumb (Figure 6). Also, the observed higher initial value of FID population A in the crumb from ERO bread could not be ascribed to incomplete starch gelatinization because its starch had been completely gelatinized.

dx.doi.org/10.1021/jf501856s | J. Agric. Food Chem. 2014, 62, 6445−6453

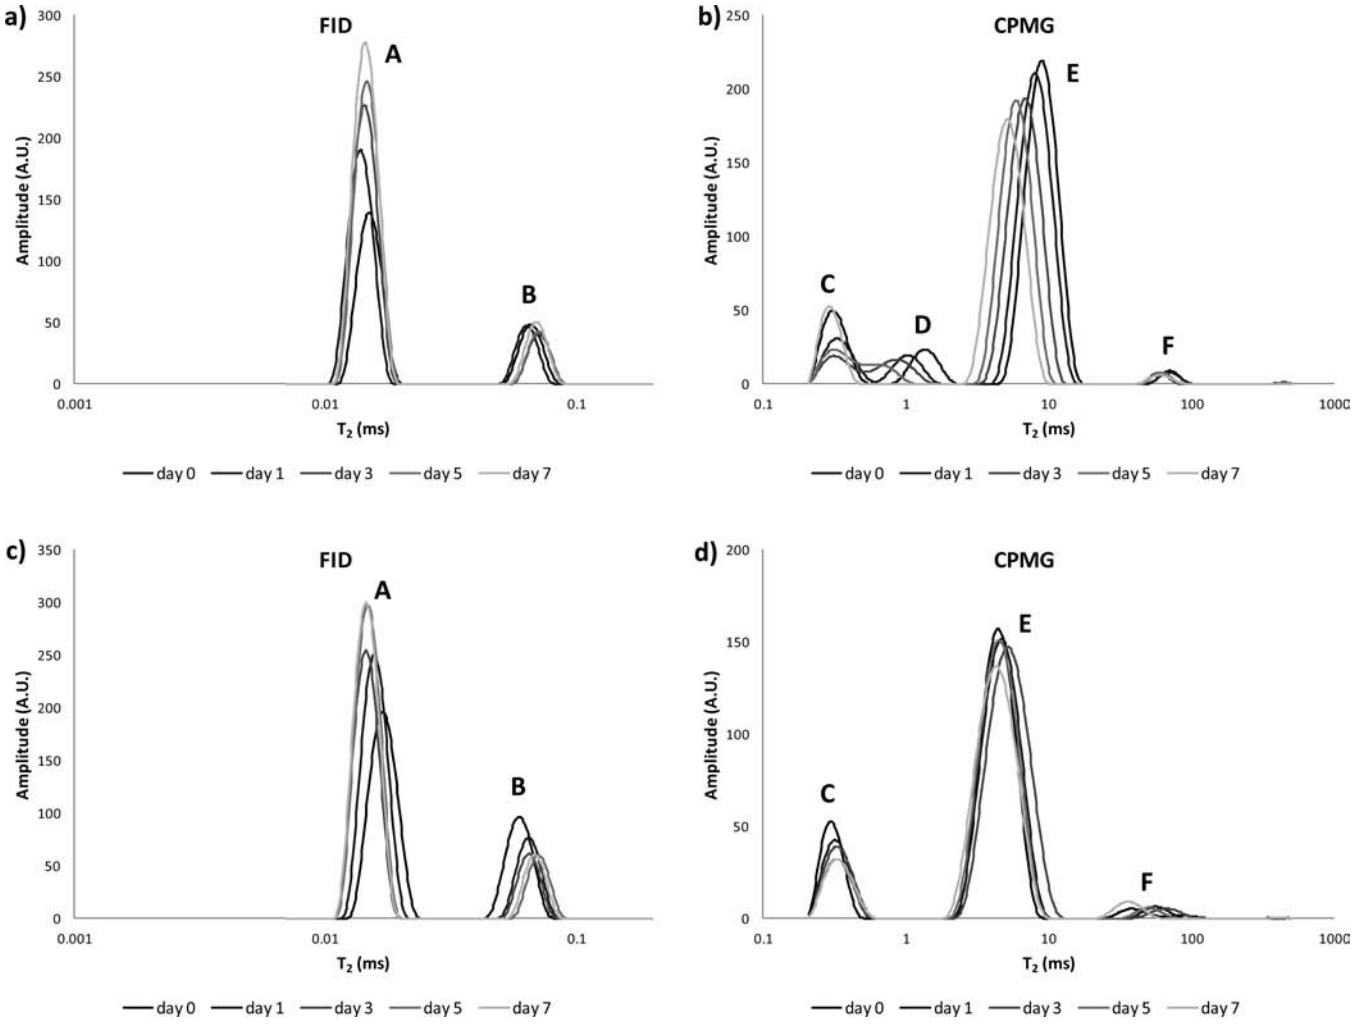

Figure 8. Distribution of transverse relaxation times of crumb from conventionally (a, b) and ERO baked bread (c, d) during storage for 7 days, obtained by the inverse Laplace transformation of the free induction decay (FID) and Carr−Purcell−Meiboom−Gill (CPMG) pulse sequence. Amplitudes are given in arbitrary units (A.U.).

The CPMG measurements of crumb from conventionally baked fresh bread showed four different proton populations (C, D, E, and F). Bosmans et al.[16] suggested that the protons in CPMG population C correspond to those in FID proton population B, because this population is affected in a similar way by heat treatment. Proton population D has been suggested to contain protons such as those of confined water exchanging with starch hydroxyl protons in the intragranular space.[16] Besides proton populations C and D, a very large CPMG proton population E was observed. Its protons are presumably mobile water protons in exchange with starch hydroxyl protons in the extragranular space.[16] In contrast to what was observed in CPMG measurements of conventional bread, in the crumb of ERO breads only three (instead of four) distinct proton populations (C, E, and F) were distinguished. Possibly, protons from proton population D shifted to proton population C or had merged with protons of population E. Furthermore, the proton populations (E in particular) of ERO bread crumb appeared at lower T_2 values than those of crumb from conventional bread. The lower mobility of this proton fraction is probably due to lower moisture content. In general, the observed differences between ERO and conventional bread crumb were presumably mainly due to the lower moisture content of the crumb of ERO breads on day 0 and, associated with this, an overall decrease in proton mobility.

(b) Changes in Water Mobility of Bread Crumb during Storage of Conventional Breads. Figure 8 (a, b) shows the distributions of the transverse relaxation times of protons of crumb from conventional bread during storage for 7 days. These were obtained by inverse Laplace transformation of the FID and CPMG pulse sequences. During storage of conventional bread, the area of FID proton population A increased due to both amylopectin crystallization and loss of water from crumb to crust. Additional experiments in which moisture migration from crumb to crust was prevented by storage of crumb rather than bread itself showed that this increase occurred to a lesser extent in the former case (results not shown). These observations suggest that both amylopectin crystallization and loss of water from crumb to crust reduce mobility in the bread matrix, as suggested earlier by Curti et al.[15] The area of FID population B did not change during storage of bread (thus allowing moisture migration from crumb to crust) (Figure 8a), whereas it decreased during storage of bread crumb as such (results not shown). Possibly, when both amylopectin retrogradation and moisture migration from crumb to crust occur, the decrease in the area of FID proton population B is compensated by an increase due to decreased

dx.doi.org/10.1021/jf501856s | J. Agric. Food Chem. 2014, 62, 6445−6453

proton mobility as bread crumb loses moisture. The decrease in area of FID proton population B is partly caused by amylopectin retrogradation. It seems likely that the amorphous amylopectin CH protons of population B become incorporated into crystal structures and lose mobility, and consequently part of this population appears in proton population A. This has also been observed by Bosmans et al.[12]

As a result of storage of bread, the areas of both CPMG proton populations C and D decreased. After 3 days of storage of conventional bread, its proton populations C and D had merged (Figure 8b). This was also noted after 5 days when crumb rather than bread had been stored (results not shown). Thus, both moisture migration from crumb to crust and other changes in the crumb (including starch retrogradation) contribute to the decrease in proton mobility.

Probably, the decrease in crumb moisture content also contributes to these changes in proton mobility. The simultaneous decrease in the areas of both FID proton population B and CPMG proton population C as a result of bread storage is in line with earlier suggestions that FID proton population B and CPMG proton population C correspond to the same proton population.[16] Besides proton populations C and D, also a large CPMG proton population E was observed. These protons are suggested to correspond to mobile water protons in exchange with starch hydroxyl protons in the extragranular space.[16] When moisture migration from crumb to crust was allowed to occur, the area of proton population E gradually decreased and shifted to lower T_2 values during further storage. The area of proton population E hardly changed during storage of bread crumb from which the crust had been detached (results not shown). Only a small decrease in T_2 was noted in samples stored for 5 and 7 days. The migration of water molecules from crumb to crust over time explained the decrease in the area of proton population E such as observed in Figure 8b. Also, proton population E shifted to lower T_2 values, indicating reduced mobility. Lastly, a small proton population (F) was observed at high T_2. This population presumably corresponded to protons of shortening used to grease mixing bowls, sheeter, and baking pans during breadmaking, as lipid protons usually appear at higher T_2 values.[16,25]

(c) Changes in Water Mobility of Bread Crumb during Storage of ERO Breads. Figure 8 (c, d) shows the distribution of the transverse relaxation times of ERO baked breads stored during 7 days. These were obtained by inverse Laplace transformation of FID and CPMG pulse sequences. The relative intensities of FID proton populations A and B increased and decreased, respectively, during storage for 7 days. Protons in FID population A were assigned to rigid CH protons of starch and gluten, whereas those in population B have been suggested to correspond to protons of a more mobile amorphous starch fraction in interaction with water.[16] The area of FID proton population A increased by almost 60% during storage of ERO breads. This increase is associated with amylopectin retrogradation.[16] As noted above, amylopectin retrograded to similar extents in both ERO and conventional breads during storage (Figure 6). Figure 7 (c, d) compares the transverse relaxation curves of ERO and conventional breads on day 7. The FID profiles of ERO or conventional bread that had been stored for 7 days were very similar. This may well be due to the comparable moisture contents of ERO and conventional breads on day 7 (Figure 5).

With CPMG measurements, three different proton populations (C, E, and F) were observed in ERO bread. As a result of storage, similar to what was observed for FID proton population B, the area of proton population C decreased. The area of proton population E was hardly affected by storage. In general, the CPMG profiles of ERO and conventional bread were more comparable on day 7 than on day 0 (Figure 7). These observations emphasize again the importance of bread moisture content and moisture migration.

In conclusion, this study compared the starch populations and moisture contents of bread baked in a conventional oven with those of bread baked in an ERO. ERO allows imposing specific temperature/time profiles during baking as well as only small temperature gradients in the different parts of the dough/bread during baking and produces crustless bread. ERO breads generally had a lower moisture content than conventional breads (39 vs 43%). The upper parts of ERO breads had a higher moisture content than the lower parts, whereas, in conventional bread, the moisture content increases from crust to crumb.

Over time, the moisture contents in the different parts of bread change more in conventional than in ERO breads. That of conventional bread decreases throughout the crumb and, concomitantly, the crust moisture content rapidly increases. Due to the absence of crust in ERO bread, the moisture content did not significantly decrease throughout the crumb. Large differences in moisture migration during storage of ERO and conventional breads were not reflected in differences in the retrogradation of amylopectin.

Finally, the use of proton NMR measurements to compare the water mobility in both conventional and ERO bread revealed a lower proton mobility in ERO than in conventional bread.

In conclusion, ERO baking technology allows the study of temperature-dependent transitions during baking. It is also a powerful tool to straightforwardly change the heating rate of dough/bread in a controlled way and to interrupt the baking process at specific and uniform temperatures.

However, whether H_2 plays a specific role in the modulation of UV-A-induced anthocyanin accumulation is largely unknown, and the molecular mechanisms underlying interactions between UV and H_2 signaling remain to be elucidated in anthocyanin regulation. In this paper, we report that hydrogen-rich water (HRW) reestablishes reactive oxygen species homeostasis but exerts differential effects on anthocyanin synthesis in two contrasting varieties of radish sprouts under UV-A irradiation.

MATERIALS AND METHODS

Plant Materials and Growth Conditions. Seeds of two contrasting radish (*Raphanus sativus* L.), i.e., cv. Qingtou (low level of anthocyanin, LA) and cv. Yanghua (high level of anthocyanin, HA), were soaked in either distilled water or hydrogen-rich water (HRW) for 12 h and then germinated for 1 d at 25 °C in darkness. Uniform gemmiparous seeds were then chosen and transferred to plastic chambers and cultured in nutrient medium (quarter-strength Hoagland's solution) prepared with HRW or distilled water. Four treatments with 3 replicates each were established, i.e., white light (W + Con), white light plus HRW (W + HRW), UV-A (UVA + Con), and UV-A plus HRW (UVA + HRW), respectively. The nutrient medium was replaced every 12 h. Radish sprouts were grown in the incubator at 25 °C in the dark for 2 d, and then transferred to a white or UV-A illuminating incubator (Ningbo Haishu Safe Instrument Experimental Factory, Zhejiang, China) at 25 °C for 24 h. The light intensity of white light was set at 50 ± 5 $\mu mol \cdot m^{-2} \cdot s^{-1}$, while the UV-A dose was set at 5.5 $W \cdot m^{-2}$ measured with a pocket UV light meter (UV-340A, Lutron, Taiwan).

Preparation of HRW. Purified hydrogen gas (99.99%, v/v) generated from a hydrogen gas generator (SHC-300; Saikesaisi Hydrogen Energy Co., Ltd., Shandong, China) was bubbled into 4000 mL of distilled water (pH 5.87, 25 °C) at a rate of 150 $mL \cdot min^{-1}$ for 1 h, a sufficient duration to saturate the solution with H_2 (about 0.22 mM).[28,30] Then, the corresponding HRW (pH 6.32, 25 °C) was immediately diluted to the required concentrations [1, 10, and 100% concentration (v/v)]. In our experimental conditions, the H_2 concentration in freshly prepared HRW analyzed by gas chromatography (GC) was 0.22 mM, which was defined as 100% HRW. The H_2 concentrations were about 22 μM in 10% HRW, 2.2 μM in 1% HRW, and maintained at a relatively constant level in 25 °C for at least 12 h.

Observation of the Hypocotyl Cross Section. The hypocotyls of radish sprouts were transected with a blade, then observed under a light microscope (model Stemi 2000-C; Carl Zeiss, Germany), and photographed on color film (Powershot A620, Canon Photo Film, Japan).

Determination of Thiobarbituric Acid Reactive Substances (TBARS). Lipid peroxidation was estimated by measuring the amount of TBARS as previously described.[31] About 500 mg of fresh tissues was ground in 0.25% 2-thiobarbituric acid (TBA) in 10% trichloroacetic acid (TCA) using a mortar and pestle. After heating at 95 °C for 30 min, the mixture was quickly cooled in an ice bath and centrifuged at 10000*g* for 10 min. The absorbance of the supernatant was read at 532 nm and corrected for unspecific turbidity by subtracting the absorbance at 600 nm. The blank was 0.25% TBA in 10% TCA. The concentration of lipid peroxides, together with oxidatively modified proteins of plants, was thus quantified in terms of TBARS amount using an extinction coefficient of 155 mM^{-1} $cm^{-1}$and expressed as nmol g^{-1} fresh weight (FW).

Antioxidant Enzyme Assays. The activity of antioxidant enzymes was determined as described by Jin et al. (2013).[28] Frozen radish plants (approximately 200 mg) were homogenized in 5 mL of 50 mM potassium phosphate buffer (pH 7.0) containing 1% polyvinylpyrrolidone for superoxide dismutase (SOD), peroxidase (APX), and catalase (CAT) assay. The homogenate was centrifuged at 12000*g* for 20 min at 4 °C, and the supernatant was used as the crude enzyme extract. Total SOD activity was measured on the basis of its ability to reduce nitroblue tetrazolium (NBT) by superoxide anion generated by the riboflavin system under illumination. One unit of SOD was defined as the amount of crude enzyme extract required to inhibit the reduction rate of NBT by 50%. APX activity was measured by monitoring the decrease in absorbance at 290 nm as ascorbic acid (AsA) was oxidized for at least 1 min in 3 mL of reaction mixture. CAT activity was spectrophotometrically measured by monitoring the consumption of hydrogen peroxide (H_2O_2) at 240 nm for at least 3 min.

Real-Time RT-PCR Analysis. Total RNA was isolated from 100 mg (fresh weight) of excised radish hypocotyls by grinding with mortar and pestle in liquid nitrogen until a fine powder appeared and using TRIzol reagent (Invitrogen, Gaithersburg, MD) according to the manufacturer's instructions. DNA-free total RNA (5 μg) from different treatments was used for first-strand cDNA synthesis in a 20 μL reaction volume containing 1 μL of RevertAid M-MuLV reverse transcriptase (Thermo Fisher Scientific Inc., USA) and 1 μL of oligo $(dT)_{18}$ primer. Real-time quantification RT-PCR reactions were performed using a Mastercycler ep *realplex* real-time PCR system (Eppendorf, Hamburg, Germany) with Bestar SybrGreen qPCR Mastermix (DBI, Bioscience Inc., Germany) according to the manufacturer's instructions. The cDNA was amplified using the primers as described as Table S1 in the Supporting Information.

Histochemical Staining. Stress-induced generation of O_2^- in situ was detected by nitroblue tetrazolium (NBT) staining.[32] Seedling leaves were stained with 0.1% solution of NBT in K-phosphate buffer (pH 6.4), containing 10 mM sodium azide (NaN_3) until a purple-blue color became visible, and the chlorophyll of the treated leaves was removed with 95% ethanol. Hydrogen peroxide (H_2O_2) production was detected by 3,3′-diaminobenzidine (DAB) staining.[27] Leaves were stained with 0.1% DAB solution for 6 h, and then chlorophyll was removed with 95% ethanol. After washing extensively, all the decolorized leaves were observed under a light microscope (model Stemi 2000-C; Carl Zeiss, Jena, Germany) and photographed on a color film (Powershot A620; Canon Photo Film, Tokyo, Japan).

Extraction and Assay of Anthocyanins, Total Phenolic, and DPPH Radical Scavenging Activity Assay. Anthocyanin measurement was performed according to the method reported by Zhou et al. (2013)[33] with some modifications. Briefly, 0.5 g samples were cut up and incubated in 10 mL of 1% HCl in methanol at room temperature in the dark for 24 h. Tubes were shaken with a vortex mixer every 6 h. The anthocyanins in the aqueous phase were then quantified by spectrophotometry ($A_{530}-A_{600}$) (UV-5200 spectrophotometer, Shanghai Metash Instruments Co., Ltd., Shanghai, China), and one unit (U) of anthocyanin was defined as the amount of 0.01 difference value. In the end, the quantity was normalized to the total fresh mass of tissue used for each sample.

Determination of total phenols was performed according to the method reported by George et al. (2005)[34] with some modifications. Samples (~0.5 g) were homogenized in 50% (w/v) acetone and shaken in ultrasonic wave cleaner for 30 min, and then centrifuged at 4000*g* for 20 min at 4 °C. One milliliter of extract was added to 2 mL of Folin−Ciocalteu reagent. The mixture was incubated for 2 min at room temperature, and 10 mL of 10% sodium carbonate was added. The mixture was incubated for 1 h at 50 °C and finally cooled in a water−ice bath. The specific absorbance at 765 nm was immediately measured.

The DPPH radical scavenging activity assay was performed according to the method reported by Chen et al. (2013).[35] Briefly, standard solutions or DMSO (control) was prepared and added to a 70 μmol/L DPPH methanolic solution; the mixtures were shaken vigorously and left to stand in the dark for 30 min at room temperature, and then absorbance was read at 517 nm. Radical scavenging capacity was expressed as percentage effect (%) and calculated using the following equation:

$$\text{percentage effect (\%)} = \left(\frac{\text{Abs}_{\text{control}} - \text{Abs}_{\text{sample}}}{\text{Abs}_{\text{control}}}\right) \times 100$$

Identification and Quantification of Anthocyanidins. *Sample Preparation.* Fresh samples (1.0 g) were homogenized in 3 mL of 70% (w/v) ethanol containing 1% methanoic acid. The mixtures were

dx.doi.org/10.1021/jf5019593 | J. Agric. Food Chem. 2014, 62, 6454−6462

shaken in ultrasonic wave cleaner for 10 min and then centrifuged at 6000*g* for 20 min, and finally 2 mL of supernate was taken out. The residue was combined with 1 mL of 70% ethanol and then shaken and centrifuged as done above. Another 2 mL of supernate was taken out and merged with the supernate above. Daidzein standard samples (20 μL, 25 μM) were added into the extract and used as internal standard. After mixture and centrifugation, 5 μL was taken out for injection. The relative abundance of anthocyanidins was estimated as the ratios of peak areas of samples to peak areas of Daidzein standard samples.

LC-MS/MS Analysis. The anthocyanidins were detected by a UHPLC system (Dionex, Thermo, USA) connected to a LTQ-Orbitrap XLhybrid mass spectrometer (Thermo Fisher Scientific). The instrument was controlled through Tune 2.6.0 and Chromeleon programs. The UHPLC column was Hypersil GOLD C18 (100 mm × 2.10 mm, 3 μm particle size, Thermo Fisher Scientific). Solvent A was 0.1% formic acid in water, B was 0.1% formic acid in acetonitrile, and separation was carried out in 30 min at a flow rate of 0.2 mL/min under the following conditions: 0−4 min, 5% B; 4−21 min, 5−95% B; 21−25 min, 95% B; 25.2−30 min, 5% B. Column oven temperature was set at 35 °C, and autosampler temperature was set at 10 °C. The capillary temperature was 300 °C, and the source voltage was set at 4 kV. Accurate mass spectra were recorded from 150 to 1200 m/z. The external mass calibration of the Orbitrap was performed once a week to ensure a working mass accuracy <5 ppm. Data dependent scan mode was applied for MS/MS fragmentation. Ion source was equipped with a heated electrospray ionization (HESI) source. The product ions were generated by the LTQ ion trap at normalized collision energy of 35%, q-activation of 0.25 using an isolation width of 2 Da. Data was processed using the Xcalibur software.

Statistical Analyses. Values presented are means ± standard deviation (SD) of three replicates. Data were subjected to analysis of variance (ANOVA), and mean values were compared by Duncan's multiple range test ($p < 0.05$). All the statistical analysis was performed using SPSS 19.0 for Windows.

RESULTS

UV-A Induced Inhibition of Hypocotyl Elongation and Increase of Anthocyanin Accumulation. The inhibition of hypocotyl elongation and accumulation of anthocyanin are two widely characterized phenotypic parameters in UV photomorphogenic responses of seedlings.[36] To assess the stress caused by exposure to UV-A, the hypocotyl elongation and anthocyanin content of radish sprouts at 0, 3, 6, 12, and 24 h were determined after exposure to UV-A (Figure 1). As shown in Figure 1B, the hypocotyl elongation of LA sprouts was generally longer than that of HA sprouts. In addition, compared with that under white light, the inhibition of hypocotyl elongation by exposure to UV-A for 3, 6, 12, and 24 h was in a time course dependent manner in the two radish varieties tested, exhibiting a 30% inhibition at 24 h. As expected, the anthocyanin content in the hypocotyls of HA was very high, about 40−60 U·g^{-1} FW, compared to 2 U·g^{-1} FW in LA. Higher anthocyanin accumulation in hypocotyls was observed under UV-A compared with white light in the two varieties at 24 h (Figure 1A,C). Above all, we performed the following experiments by exposing sprouts to white light or UV-A for 24 h.

HRW Alleviated UV-A-Induced Oxidative Damage and Increased Antioxidant Enzyme Activity. To investigate whether UV-A-mediated phenotypic parameters are influenced by HRW, HA sprouts were grown in the presence of various concentrations of HRW (1, 10, 50, and 100%). The results showed that treatments with different concentrations of HRW (10, 50, and 100%) increased anthocyanin contents, especially 100% of HRW (by 25%). However, the hypocotyl elongation was not dose-dependently influenced by HRW (see Figure S1 in the Supporting Information). Based on these, we chose 100% HRW as the following experimental concentration.

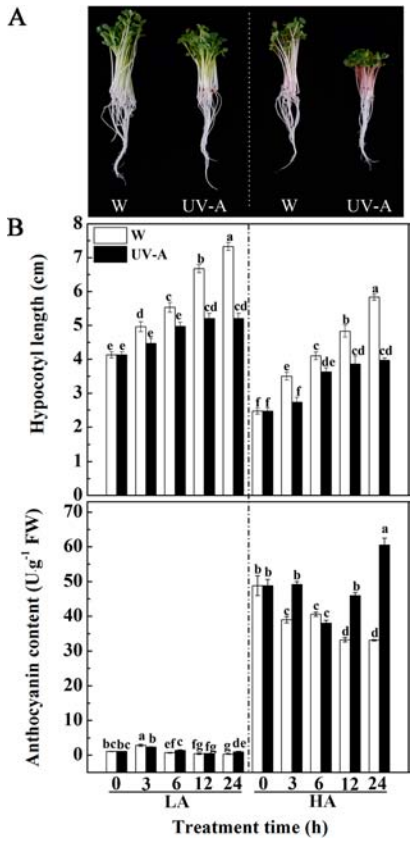

Figure 1. Effects of 24 h UV-A treatment on the morphology of radish sprouts (A), bar = 2 cm. Changes in hypocotyls elongation (B) and anthocyanin content (C) in the hypocotyls of two radish (*Raphanus sativus* L.) varieties' (LA and HA) sprouts upon UV-A stress. Seedlings were incubated under UV-A, and hypocotyl elongation and anthocyanin content were measured after 0 h, 3 h, 6 h, 12 h, and 24 h incubation. Values are the means ± standard error of three independent experiments with at least three replicates for each. Measurements in the same column followed by different letters are significantly different at the $P < 0.05$ level.

Abiotic stress-induced ROS has been demonstrated to cause oxidative damage to plants, and O_2^- and H_2O_2 are believed to be the most important components.[37] Figure 2 showed that leaves of radish sprouts under white light produced low production of O_2^- (NBT staining) and H_2O_2 (DAB staining), while those under UV-A were stained extensively. Compared to UV-A, fewer stains were observed in the leaves under UV-A + HRW treatment. To confirm the cytoprotective role of HRW in UV-A-induced oxidative stress in radish sprouts, we measured the content of TBARS, which was used as an indicator for lipid peroxidation in vitro. Interestingly, exposure to UV-A for 24 h failed to increase the TBARS content in the hypocotyls of LA sprouts; HRW had no effect either. But in HA sprouts, exposure to UV-A for 24 h caused an increase in levels of TBARS, while HRW significantly blocked this increase (Figure 3A).

To further assess whether there is a close link between oxidative stress and HRW-induced alleviation of UV-A stress, changes in several antioxidant enzyme activities in the hypocotyls in radish sprouts were compared. The activities of SOD and APX were increased under UV-A, especially APX

dx.doi.org/10.1021/jf5019593 | J. Agric. Food Chem. 2014, 62, 6454−6462

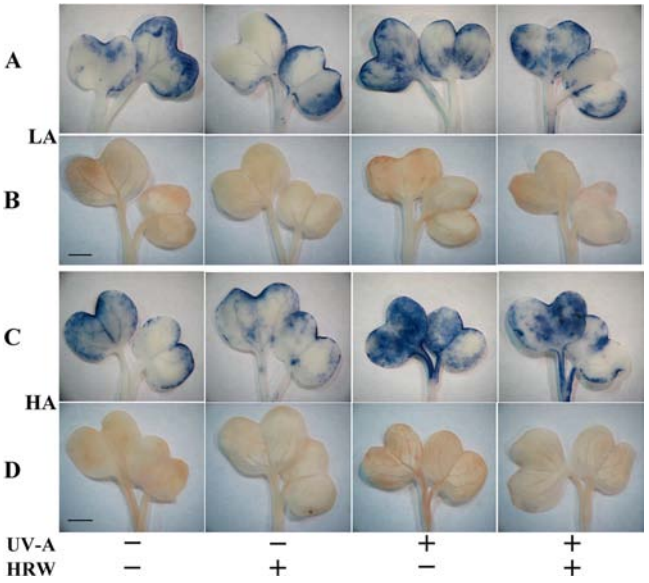

Figure 2. Effects of HRW on the ROS homeostasis in the leaves of radish sprouts. To detect O_2^- and H_2O_2, leaves of LA sprouts were stained with NBT (A) and DAB (B); leaves of HA sprouts were also stained with NBT (C) and DAB (D), respectively. Sprouts cultivated in distilled water (H_2O) or 100% HRW were exposed to white light or UV-A for 24 h. Bar = 1 cm.

(nearly 3-fold higher than that under white light). With the exception of APX in HA, this UV-A-induced increase was apparently enhanced by HRW (Figure 3B,D). However, no consistent changes in the activity of POD were observed (Figure 3C).

HRW Enhanced the UV-A-Induced Total Phenols and Anthocyanin Accumulation in HA. Besides the antioxidant enzymes, nonenzymic components are also involved in antioxidant responses. To investigate whether HRW influences the phenolic biosynthesis, the phenols content and DPPH scavenging effect were determined. As shown in Figure 4,

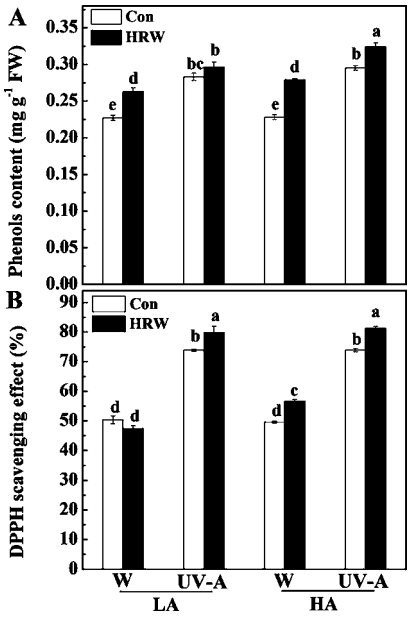

Figure 4. Total phenols content (A) and DPPH scavenging effect (%) (B) in the hypocotyls of radish sprouts. Sprouts cultivated in distilled water (H_2O) or 100% HRW were exposed to white light or UV-A for 24 h. Error bars represent SD with three repeats performed. For each repeat, more than 30 sprouts were analyzed. Measurements in the same column followed by different letters are significantly different at the $P < 0.05$ level.

exposure to UV-A for 24 h significantly increased the phenolics content and DPPH scavenging effect in both varieties tested. HRW treatment further enhanced them, though no significant difference was observed in LA sprouts (Figure 4A). Consistent

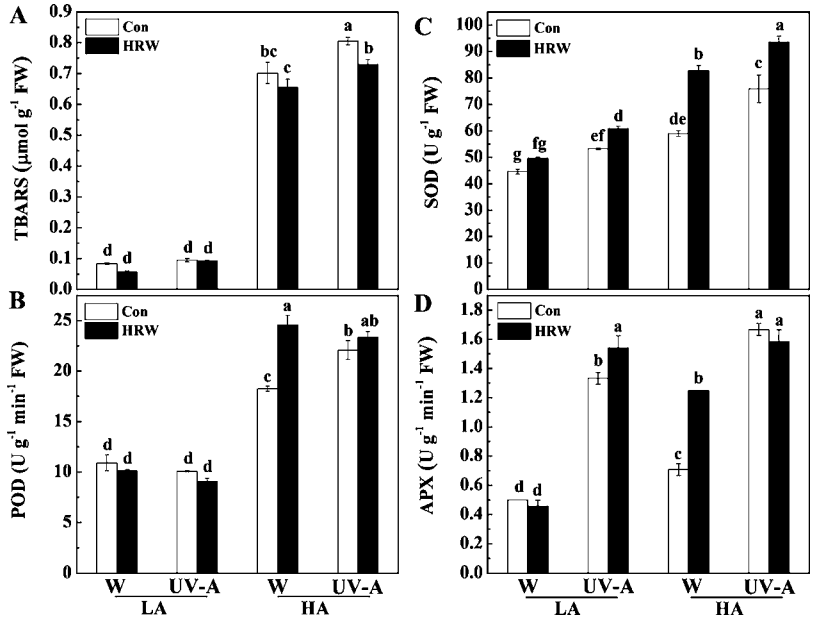

Figure 3. Lipid peroxidation, measured as TBARS content (A), SOD (B), POD (C), and APX (D) activities in the hypocotyls of LA and HA sprouts. Sprouts cultivated in distilled water (H_2O) or 100% HRW were exposed to white light or UV-A for 24 h. Error bars represent SD with three repeats performed. For each repeat, more than 30 sprouts were analyzed. Measurements in the same column followed by different letters are significantly different at the $P < 0.05$ level.

dx.doi.org/10.1021/jf5019593 | J. Agric. Food Chem. 2014, 62, 6454−6462

with this finding, HRW also significantly enhanced UV-A-induced increase of DPPH scavenging effect (Figure 4B).

Results of Figure 5 showed that the anthocyanin content in the hypocotyls of HA sprouts treated with HRW was increased

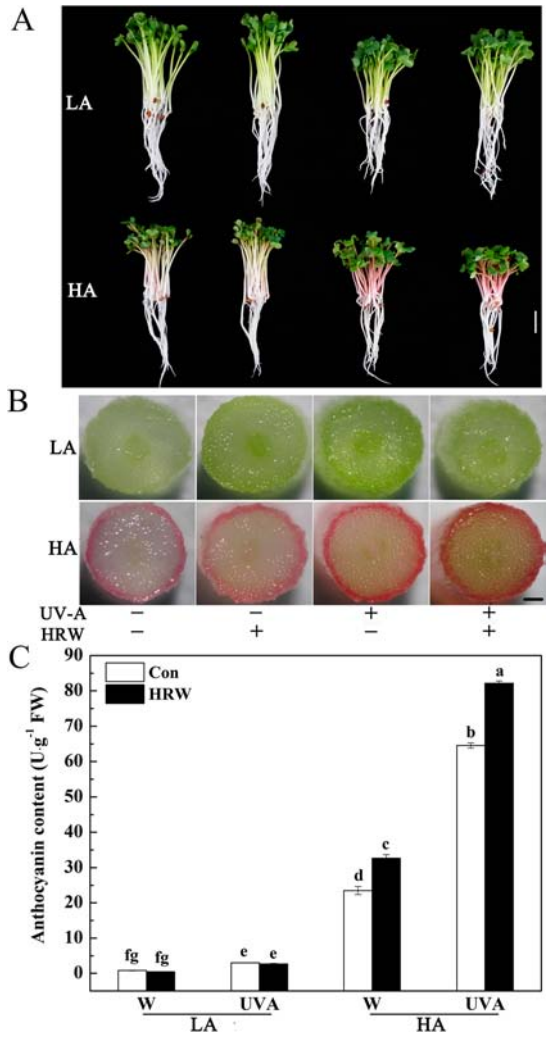

Figure 5. Phenotypes (A) and the transection (B) and anthocyanin accumulation (C) of the hypocotyls of two radish sprouts. Sprouts cultivated in distilled water (H_2O) or 100% HRW were exposed to white light or UV-A for 24 h. Error bars represent SD with three repeats performed. For each repeat, more than 30 sprouts were analyzed. Bar in A was 2 cm, in B was 0.3 mm. Measurements in the same column followed by different letters are significantly different at the $P < 0.05$ level.

significantly (by about 25%) compared with the control, but no changes of anthocyanin accumulation existed in LA sprouts (Figure 5C). These results were in accordance with the observation of the transection of the radish hypocotyls (Figure 5B). In addition, anthocyanin accumulation was observed mainly in the epidermis of hypocotyls of HA sprouts (Figure 5B).

HRW Increased the Main Anthocyanidin (Cyanidin) Content in HA. There are mainly six anthocyanidins, namely, cyanidin (Cy), delphinidin (Dp), pelargonidin (Pg), peonidin (Pn), petunidin (Pt), and malvidin (Mv) in plants.[5] To understand which anthocyanidin was predominant in radish sprouts and if this anthocyanidin was influenced by HRW, we detected the anthocyanidins in LA and HA sprouts using LC-MS. Five kinds of anthocyanidins were identified in HA sprouts, while only two were detected in LA sprouts with cyanidin (Cy) being the main anthocyanin monomer in radish sprouts. As expected, the Cy content in HA sprouts was above 10-fold higher than that in LA sprouts. Additionally, HRW treatment had neither effect on Cy content in the hypocotyls of LA sprouts exposed to both white light and UV-A, nor in HA sprouts exposed to white light, but significantly enhanced the Cy accumulation in the hypocotyls of HA sprouts exposed to UV-A for 24 h (Table 1).

HRW Upregulated the Expression Levels of Anthocyanin Biosynthesis-Related Genes. The findings obtained prompted further investigation into the mechanism of the increase of anthocyanin induced by HRW. To examine whether anthocyanin biosynthesis-related genes were influenced by H_2, quantitative real-time PCR analyses were performed on the hypocotyls of radish sprouts (Figures 6 and 7). As shown in Figures 6 and 7, the transcript levels of *PAL*, *CHS*, *CHI*, *F3H*, *DFR*, and *ANS* were all in a time-dependent manner. In LA sprouts, exposure to UV-A for 12, 24, or 36 h all significantly increased the transcriptions of *PAL*, *CHS*, *CHI*, *F3H*, *DFR*, and *ANS* compared to those under white light. With the exception of *CHI*, a combination of UV-A + HRW upregulated intensely the transcript levels of *PAL* at 24 h, *CHS* at 12 h, *F3H* at 24 and 36 h, *DFR* at 24 h, and *ANS* at 12, 24, and 36 h, respectively (Figure 6).

Similarly, UV-A significantly increased the transcriptions of these six genes in HA sprouts, but to a larger extent. Despite its different effect on LA sprouts, UV-A + HRW upregulated the transcript levels of *PAL*, *CHS*, *CHI*, *F3H*, *DFR*, and *ANS* at almost all time points and more intensely in HA. We also noticed that the responses of related genes to HRW appeared at different treatment times. The expressions of *PAL*, *CHS*, and *F3H* were upregulated by more than 1.5- to 2-fold under the combination of UV-A + HRW than under UV-A alone at 12 h after treatment. The transcript level of *CHI*, *DFR*, and *ANS* was higher under the combination of UVA + HRW than that under UV-A alone at 36 h, especially *DFR*, which was 5-fold higher (Figure 7). These results indicated that there was a time sequence in the response of different genes to HRW.

Though the expression of genes under UVA + HRW was all much higher than that under UVA + Con in the two varieties of radish sprouts tested, the expression level was 5- to 10-fold higher in HA sprouts than in LA sprouts (Figure S2 in the Supporting Information).

DISCUSSION

In recent years, the roles of H_2 in plant physiology, especially in abiotic stress, immediately drew widespread attention. Xu et al. (2013)[38] and Xie et al. (2012)[29] discovered that hydrogen-rich water could alleviate salt stress in rice and *Arabidopsis*. Jin et al. (2013)[28] reported that HRW was able to enhance plant tolerance to paraquat-induced oxidative stress. Furthermore, Zeng et al. (2013)[39] reported that hydrogen is involved in phytohormone signaling and stress responses in mung bean and rice. In the present study, we observed that hydrogen-rich water (HRW) enhanced radish sprout tolerance to UV-A, but the two radish varieties exhibited different sensitivities to HRW.

In higher plants, it is well-known that UV damage is mediated by oxidative stress and that UV not only inhibits hypocotyl elongation and seedling growth but also affects redox homeostasis.[40] Consequently, we investigated the effects of HRW on lipid peroxidation, the activity of some representative

enzymes, and the ROS content in radish sprouts. Low level of TBARS content detected in the hypocotyls of LA sprouts (nearly 6-fold lower than that in HA sprouts) (Figure 3A) confirmed that LA sprouts might be more tolerant to UV-A radiation. In HA sprouts, we noticed that UV-A treatment resulted in a significant increase in the level of TBARS content,

dx.doi.org/10.1021/jf5019593 | J. Agric. Food Chem. 2014, 62, 6454−6462

however, HRW significantly blocked this increase (Figure 3A). These results were supported by upactivation of SOD and APX (Figure 3B,D). In agreement with these, we also observed that UV-A radiation for 24 h resulted in a distinct increase in the level of O_2^- and H_2O_2 in the leaves of both LA and HA sprouts, while HRW treatment blocked this increase partly (Figure 2). All of this information suggests that HRW protected radish sprouts from UV-A by reestablishing reactive oxygen species homeostasis.

Radish sprouts have been recognized as richer sources of healthy phytochemicals than radishes. Red radishes contain anthocyanins which are very effective antioxidants, and are the most characteristic bioactive nutrients in berries and other "red−purple healthy food".[41] To better understand the relationship between anthocyanin biosynthesis and HRW, we chose two contrasting varieties of radish sprouts, LA sprouts (white hypocotyls, low level anthocyanin content, about 1 U g^{1-}) and HA sprouts (red hypocotyls, high level anthocyanin content, about 30 U g^{1-}), to study anthocyanin accumulation influenced by HRW. We found that HRW only increased anthocyanin accumulation in the hypocotyls of HA sprouts, but not in LA sprouts (Figure 5C). However, the anthocyanin biosynthesis-related structural genes were all upregulated in both LA and HA sprouts treated with UV-A + HRW compared to the UV-A treatment, although the gene expression level of LA was much lower than that of HA (Figures 6 and 7 and Figure S2 in the Supporting Information). This apparent paradox may be explained if the anthocyanidins produced in LA sprouts were used immediately (through coupled or channeled reactions) for the production of flavonoid compounds using endogenous modification and polymerization enzymes in vivo.

Among the six anthocyanidins in plants, we observed that Cy was the main anthocyanidin in radish sprouts and it was strongly enhanced when treated with UV-A + HRW (Table 1). These results indicated that HRW mainly enhanced the Cy accumulation in the hypocotyls of radish sprouts to increase the anthocyanin content.

Anthocyanin accumulation in the hypocotyls promotes the photoprotection to allow seedling survival during early development,[42] and to protect the plant's DNA from damage by ultraviolet (UV) light.[43] So, the anthocyanin content in the hypocotyls of HA sprouts under UV-A was increased significantly compared with that under W (about 2-fold) (Figure 5). However, the anthocyanin accumulation under HRW + UV-A was more than that under UV-A. This prompted us to hypothesize that HRW enhanced the tolerance of HA sprouts to UV-A. To confirm this hypothesis, the total phenols content and the DPPH scavenging effect of the total content in the hypocotyls of radish sprouts were first measured. As expected, HRW increased the total phenols content and the DPPH scavenging effect in radish sprouts under the combination of UV-A + HRW, though no significant difference was noted between the total phenols content in the hypocotyls of LA sprouts (Figure 4). All these results indicate that HRW has different effects on anthocyanin biosynthesis in LA and HA sprouts, though it has consistent impacts on antioxidant response.

In conclusion, we first reported that, in the present study, HRW alleviated UV-A induced oxidant damage via increasing the activity of SOD and APX, and reducing the ROS and TBARS content of radish sprouts (Figures 2 and 3). More importantly, we presented experimental evidence showing that HRW enhanced UV-A-induced anthocyanin accumulation in the hypocotyls of HA sprouts, while no effect was noted in LA sprouts, by upregulating the anthocyanin biosynthesis-related genes in HA sprouts (Figures 5−7). Anthocyanins belong to a diverse group of ubiquitous secondary metabolites known as flavonoids,[44] which are involved in protection against UV-light and pathogens. Cryptochromes perceive UV-A[45] and interact with COP1 to prevent the MYB from being ubiquitinated and degraded, so that MYB directly binds to the promoters of anthocyanin biosynthetic genes and activates their expression, finally increasing the anthocyanin accumulation.[46] In this paper, we observed that HRW enhanced the UV-A-induced anthocyanin increase. Carvalho et al. (2010)[42] reported that hormones modulated photomorphogenesis-controlled anthocyanin accumulation in tomato hypocotyls, and later, Zeng et al. (2013)[39] discovered that hydrogen was involved in phytohormone signaling. These prompted us to hypothesize that the HRW-induced increase of anthocyanin accumulation in the hypocotyls of radish sprouts in the present study may be mediated by phytohormone. On the other hand, as HRW significantly upregulated the expression of anthocyanin biosynthesis-related genes, HRW may influence MYB or COP1 transcriptional factors to enhance the anthocyanin accumulation. All these hypotheses need further complementary genetic approaches to support. A model summarizing these points is presented in Figure 8.

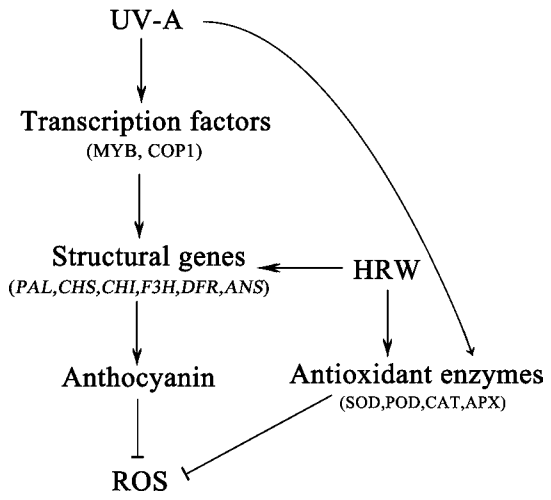

Figure 8. Model of HRW regulation of UV-A-induced increase of anthocyanin accumulation in the hypocotyls of radish sprouts. As a stress environment, UV-A incurs generation of active oxygen species (ROS), which eventually results in lipid peroxidation, leading to high concentration of thiobarbituric acid reactive substances (TBARS). On the other hand, when the photoreceptors of UV-A were activated, they acted to suppress COP1 and activated MYB upregulating the anthocyanin biosynthesis-related structural genes (*PAL*, *CHS*, *CHI*, *F3H*, *DFR*, and *ANS*) to enhance the anthocyanin accumulation, while hydrogen-rich water (HRW) act on the structural genes or antioxidant enzymes to participate in the UV-A-regulated anthocyanin metabolic pathway.

Recent studies revealed that hydrogen may serve as a modulator of signal transduction in the human body[47] and has a huge potential as a safe and potent therapeutic medical gas, as well as several potential advantages over current pharmacological therapies.[26] In addition, the safety of hydrogen for humans had been demonstrated by its application in driving.[48] In this study, we observed that exogenous hydrogen donor

(HRW) could enhance UV-A-induced anthocyanin accumulation in HA sprouts, suggesting that HRW will provide practical applications for enhancing the nutritional quality of radish sprouts in the sprout industry or commercially after further research on food quality and safety assessments.

kernels.[6,8,9] Insect-injured, infected kernels are often highly contaminated with fumonisins or other mycotoxins. Kernel-feeding insects are most effectively controlled through the use of transgenic maize hybrids expressing insecticidal proteins (*Bt* maize)[7] which have been shown to have reduced fumonisin levels.[10]

Bt maize has been grown in the United States since 1996, and, as of 2013, 76% of all maize planted in the U.S. expressed some form of *Bt*-derived insect protection.[11] *Bt* maize hybrids produce insecticidal proteins derived from the soil bacterium *Bacillus thuringiensis* which confer resistance to select lepidopteran insects, but are nontoxic to humans and other nontarget species. *Bt* maize plants have an important advantage over foliar insecticides in that they produce insecticidal proteins for targeted insect control in desired plant tissues during the entire growing season. Management with foliar insecticides is costly, often requiring multiple applications that must be timed around larval hatching. Insects in the class Lepidoptera are common targets of the insecticidal proteins produced by *Bt* maize as these insects are some of the most significant pests of maize worldwide. Commercial maize hybrids that express either Cry1Ab or Cry1F proteins target European corn borer (*Ostrinia nubilalis* (Hübner)) (ECB), the most notable lepidopteran pest in maize, and are available in the U.S. and other countries.

Prior to the cultivation of *Bt* maize, annual yield losses attributable to ECB alone have been estimated near US$ 1 billion.[12] In addition to ECB control, the Cry1F protein also is effective against Western bean cutworm (*Striacosta albicosta* (Smith)) (WBC), southwestern corn borer (*Diatraea grandiosella* Dyar), fall armyworm (*Spodoptera frugiperda* (J.E. Smith)), and black cutworm (*Agrotis ipsilon* (Hufnagel)), and mildly effective against corn earworm (*Helicoverpa zea* (Boddie)) (CEW). *Bt* maize has shown high efficacy against ECB feeding, reducing overall ECB populations in areas of high *Bt* adoption.[13] This is a significant benefit to maize growers in the U.S., however, maize pests which had previously been considered secondary to ECB are now competing for this viable food source. The arrival of WBC in the Midwest U.S. in the early 1990s has posed a new threat in this maize-intensive region. Catangui and Berg[14] observed that naturally infested fields of Cry1Ab maize experienced higher WBC infestation than ECB. In a laboratory setting, WBC has displayed increased survival on Cry1Ab maize in comparison with its two primary competitors for this food source, ECB and CEW.[15] Intraguild competition for this food source is currently changing hands with WBC as a potential candidate, but minimal study has been conducted on the influence of WBC on fumonisins in various *Bt* hybrids, especially in the field. The contribution of *Bt* maize to reducing insect injury is paramount to management of *Fusarium* infection and fumonisin contamination of grain. There is a considerable lack of data with regard to impacts of WBC infestation on both *Fusarium* infection of maize and fumonisin contamination as well as the ability of various *Bt* proteins to control this species and mitigate these issues.

MATERIALS AND METHODS

Safety. Fumonisin B_1, **1**, is a group 2B carcinogen, and sodium cyanide is highly toxic. Both should be handled with appropriate caution and personal protective equipment.

Field Trials. Field experiments were conducted in Story County, IA, in 2007 (preliminary), 2008, 2009, and 2010 to assess the effects of *Bt* transformation of maize hybrids on fumonisin contamination of grain manually infested with ECB and WBC. Six commercial maize hybrids were grown; four hybrids expressed *Bt* genes which produced insecticidal proteins. Two hybrids, with maturities of 109 and 113 d, were genetically engineered to produce Cry1F insecticidal proteins (Pioneer brand hybrids 33D14 and 34A20, DuPont Pioneer, Des Moines, IA); two, with maturities of 107 and 111 d, produced Cry1Ab insecticidal proteins (DEKALB hybrids DKC57-79 and DKC61-69, Monsanto Co., St. Louis, MO); and two, with maturities of 108 and 111 d, were near-isogenic, non-*Bt* hybrids not engineered to produce any insecticidal proteins (Pioneer 34A14 and DEKALB DKC61-72). In all experiments, plots were approximately 3 m by 6.1 m and contained 4 rows. Only the middle two rows of the plot were used for insect infestation treatment and grain harvest. Plots were arranged in a randomized complete block design, and the experiment included 5 replications of each combination of maize hybrid and insect infestation treatment.

ECB infestation was performed using a volumetric dispenser to apply neonatal larvae (reared in-house) mixed with maize cob grits (Table 1).[16] All plants in the middle two rows of the assigned plots were infested. In 2007, approximately 50 neonates were applied at the base of the primary ear, near the collar, and 50 on the silks of the primary ear. In 2008, plants were infested with approximately 50 neonatal larvae on two consecutive days, the first day on the silks of the primary ear and the second day on the silks of the second-highest ear on the plant. If there was only one ear on the plant, it was infested again. In 2009 and 2010, approximately 100 neonatal larvae were applied on the primary ear, 50 at the base (near the collar) and 50 on the silks.

Table 1. Summary of 2007−2010 Field Trials

insect infestation treatments[a]	planting date	ECB infest	WBC infest	harvest date
		2007		
ECB natural WBC	May 14	July 19	July 18, 23	Oct 19
		2008		
ECB natural	May 14	July 30, 31	n/a	Oct 28
		2009		
ECB natural WBC	May 8	July 30, 31, Aug 6	July 28	Oct 30
		2010		
ECB natural WBC	April 21	July 14, 16	July 20	Oct 5

[a]Insect infestation treatment abbreviations are as follows: ECB, European corn borer (*Ostrinia nubilalis*); WBC, Western bean cutworm (*Striacosta albicosta*); natural, no insects applied.

WBC infestation methods differed by year. In 2008, three second- or third-instar larvae (hatched out of egg masses collected from naturally infested fields) were applied to the silks of each primary ear on ten ears per plot with a small painter's brush. In 2009 and 2010, egg masses on maize leaf tissue, which were collected from naturally infested fields, were attached at the base of the primary ear of 20 plants per plot, on 10 consecutive ears in each of the treatment rows. In 2009 the maize leaves were first fixed to a section of plastic screen and then attached at the base of the ear, but in 2010 the screen was not used.

Sampling. In all experiments, harvest entailed collecting ten ears per plot by hand from infested plants or, in the case of naturally infested plots, the ears were taken from the middle two rows of the plot. Ears were stored in a cold room (~4 °C) until drying to inhibit fungal metabolism and further fumonisin production. Postharvest, ears were visually assessed for insect injury and *Fusarium* ear rot severity and then dried at approximately 38 °C to below 15% moisture. In

dx.doi.org/10.1021/jf5011897 | J. Agric. Food Chem. 2014, 62, 6463−6472

2008 the maize was shelled prior to drying on Nov 18. In 2009 and 2010, maize was dried on-the-cob on Nov 10 and Oct 14, respectively, followed by shelling. Shelled kernels from the ten harvested ears per plot were combined and ground using a Romer Laboratories mill (Romer Laboratories, Inc., Union, MO).

Mycotoxin Analyses. *Enzyme-Linked Immunosorbent Assay (ELISA).* In 2007, fumonisin analysis was conducted by the Pioneer Hi-Bred Grain Analysis Laboratory (DuPont Pioneer, Johnston, IA) using a quantitative, competitive enzyme-linked immunosorbent assay (ELISA) with proprietary antibodies for the detection of FB_1, **1**. Samples were finely ground, and a 3 g subsample was extracted for analysis. Precoated, stabilized plates were prepared by Beacon Analytical Systems, Inc. (Saco, ME). Maize extract samples and horseradish peroxidase conjugated fumonisin B_1 were coincubated at 20−25 °C for 60−62 min with shaking in the dark. Substrate was added following washing of the plates. The substrate reaction was allowed to proceed for 30−32 min at 20−25 °C with shaking in the dark. The reaction was stopped, and the resulting color intensity of the wells was read at 450 nm. The measuring range of the fumonisin ELISA was 0.8 mg/kg to 2000 mg/kg. This method has been validated in comparison to HPLC[17] using AOAC-approved methods.[18]

In 2008 and 2009, total fumonisin concentration (FB_1 + FB_2 + FB_3), **1**−**3**, in a 10 g subsample of ground maize was determined for each plot using AgraQuant Total Fumonisin Assay 0.25/5.0 (Romer Laboratories Inc., Union, MO), a direct-competitive ELISA capable of measuring fumonisins in solution at concentrations between 0.25 and 5 mg/kg. Samples exceeding 5 mg/kg were subject to additional extract dilution to bring it within range of the ELISA test. At the time of analysis, this method was among the USDA-GIPSA performance-verified rapid test kits for the determination of total fumonisins in ground maize.

HPLC. In the preliminary experiment (2007), only the ELISA method was used. HPLC was used in 2008, 2009, and 2010.

Reagents. Fumonisin standards in 50:50 acetonitrile:water were obtained from BioPure (Tulln, Austria) and stored at 4 °C. Naphthalene 2,3-dicarboxaldehyde (NDA) was purchased from Sigma-Aldrich (Buchs, Switzerland). All other chemicals were purchased from Fisher Scientific (Fair Lawn, NJ). Unless otherwise noted, 0.2 μm filtered Barnstead Nanopure deionized water (Thermo Fisher Scientific, Waltham, MA) was used in solution and sample preparation. Reagents were prepared monthly according to Bennett and Richard[19] with the modification of pH adjustment of 0.05 M phosphate buffer to 7.4 with phosphoric acid.

Sample Preparation. Sample extraction was adapted from European Standard EN 14352,[20] with modification. Briefly, 10 g of ground sample was extracted with 25 mL of methanol/acetonitrile/distilled water (25:25:50, v/v/v) by shaking on an orbital shaker for 20 min and then centrifuged at 2500*g* for 10 min. The supernatant was filtered through Fisherbrand G6 glass fiber filter paper (Thermo Fisher Scientific, Waltham, MA) and the supernatant collected in a 50 mL conical centrifuge tube. The solids were extracted in the same manner with a second 25 mL volume of extraction solution, and the collected filtrates were combined. Filtrates were stored at −23 °C prior to cleanup and analysis. Fumonisins were purified from sample extracts using Fumonistar immunoaffinity columns (Romer Laboratories, Inc., Union, MO, USA) and evaporated to dryness with a Visiprep SPE vacuum manifold (Supelco, Sigma-Aldrich, St. Louis, MO) according to package instructions.

Derivatization. Samples were derivatized with NDA reagent according Bennett and Richard[19] with some modification. Sample residues were reconstituted with 0.5 mL of methanol, followed by the sequential addition of 0.5 mL of 0.05 M sodium borate buffer, 0.25 mL of sodium cyanide reagent, and 0.25 mL of NDA reagent. Samples were heated in a 60 °C water bath for 20 min and then transferred to 4 °C for 4 min. Samples were diluted with 3.5 mL of 0.05 M phosphate buffer (pH 7.4)/acetonitrile (40:60, v/v) and transferred to 1 mL amber autosampler vials. Postderivatization, samples were stored at −23 °C for up to 24 h until transfer to the autosampler for injection, and sample analysis was completed within 2 h of this transfer.[21]

HPLC Instrumentation and Parameters. The LC system consisted of a Varian ProStar 210 pump, 410 AutoSampler (run with tray cooling at 4 °C and column oven 30 °C), and 363 fluorescence detector. The LC column was a Zorbax Eclipse Plus-C18, 3.5 μm (4.6 × 100 mm), and was preceded by a Zorbax Eclipse Plus-C18, 5 μm (4.6 × 12.5 mm), guard column (Agilent Technologies, Santa Clara, CA). Fumonisins were eluted isocratically in a mobile phase consisting of filtered deionized water/acetonitrile/glacial acetic acid (52:47:1, v/v/v) at a flow rate of 2.0 mL/min. Fumonisin−NDA derivatives were detected using 420 nm excitation and 500 nm emission wavelengths.

Method Quality Control. Limits of detection (LOD) were determined by dividing the standard deviation of the calibration curve residuals by the slope of the calibration curve at levels approaching the LOD and multiplying the result by 3.3. Limits of quantitation were calculated by multiplying 3 times the calculated LOD.[22] Method accuracy was tested by artificially contaminating duplicate ground maize samples with known amounts of fumonisin at 2 levels of contamination and testing the recoveries. Low level artificial contamination in ground maize was equivalent to 4.1, 1.2, and 0.51 μg/g FB_1, FB_2, and FB_3, respectively, and high level artificial contamination was equivalent to 6.8, 2.0, and 0.82 μg/g for FB_1, FB_2, and FB_3, respectively (Table 2). Method precision was measured by analyzing extracts of the same maize sample performed 4 times over a period of 2 weeks.

Table 2. Percent Recoveries by HPLC of FB_1, 1; FB_2, 2; and FB_3, 3; and Total Fumonisins for Low and High Spike Levels[a]

	FB_1 (%)	FB_2 (%)	FB_3 (%)	total FB recovery (%)
low spike	92.8, 104.8	81.0, 89.5	99.7, 117.6	90.9, 102.7
high spike	76.5, 85.5	71.6, 76.5	82.6, 92.2	76.0, 84.2

[a]Results are listed as repetition 1, repetition 2.

Statistical Analysis. Analysis of variance (ANOVA) was performed on log-transformed data using the PROC GLIMMIX procedure in SAS Version 9.3 software (SAS Institute Inc., Cary, NC) fitting the data to a gamma distribution. Insect feeding injury, severity of *Fusarium* ear rot symptoms, and total fumonisin concentration (FB_1 + FB_2 + FB_3) in grain were evaluated. Factorial analysis was used to determine simple effects of maize event, insect infestation treatment, and their interaction. Where interactions were present, multiple comparison analysis was performed using a Tukey−Kramer adjustment. ANOVA analysis revealed significant treatment differences among years of the study with regard to insect injury and *Fusarium* ear rot. As a result, data for these dependent effects were analyzed separately by year. Treatment effects among years of the study did not differ significantly for grain fumonisin contamination as measured by both ELISA and HPLC. The independent variable "hybrid" used for analysis combines results from each pair of hybrids used in the study which produced the same *Bt* insecticidal protein, either Cry1F, Cry1Ab, or none.

RESULTS AND DISCUSSION

Influences of Hybrid and Insect Infestation on Kernel Injury. In the 2007 preliminary study, hybrid and insect infestation significantly affected insect injury ($F_{2,77}$ = 5.93, P = 0.0040, and $F_{2,77}$ = 4.41, P = 0.0154, respectively). In 2008 and 2009, hybrid, insect treatment, and their interaction were significant factors (P < 0.0001 to P = 0.0169). In 2010, hybrid had a significant effect on insect injury ($F_{2,77}$ = 11.22, P < 0.0001). In 2007, WBC-infested plots suffered more kernel injury than either ECB (P = 0.0122) or naturally infested plots (P = 0.0123). In 2008, WBC were not available for infestations, and ECB-infested, non-*Bt* plots suffered more kernel injury (mean 6.5%) than any other hybrid/insect combination (P <

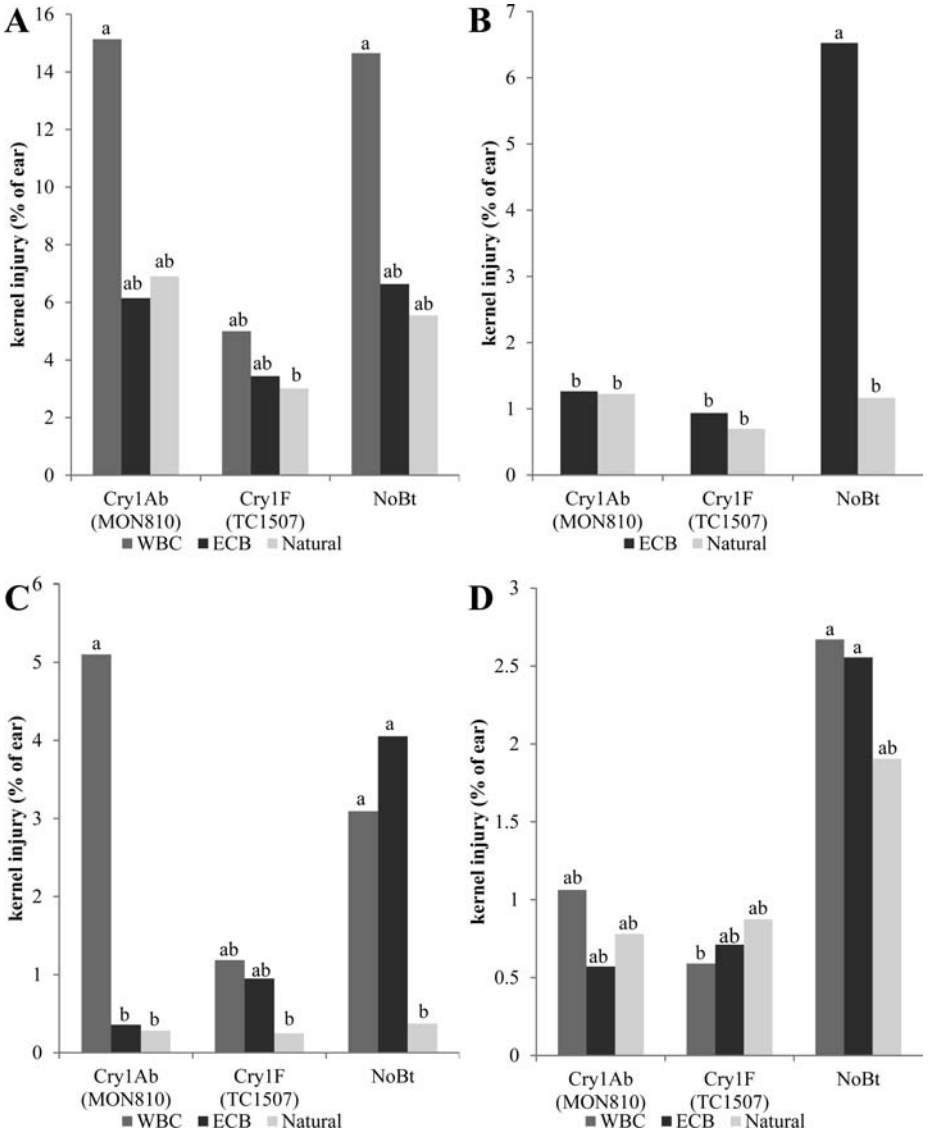

Figure 2. Insect injury (average percentage of kernels per ear) by *Bt* event for (A) 2007; (B) 2008; (C) 2009; and (D) 2010. Data are means of five replications each of two hybrids. Letters denote significant differences ($P < 0.05$) between hybrid/insect infestations within years.

0.0001 to $P = 0.0023$) (Figure 2B). In 2009, non-*Bt* hybrids infested with WBC and ECB exceeded naturally infested non-*Bt* plots ($P = 0.0035$ and $P = 0.0003$) in injury, and WBC infested Cry1Ab hybrids exceeded ECB or naturally infested Cry1Ab hybrids ($P < 0.0001$) (Figure 2C).

The susceptibility of Cry1Ab hybrids to WBC was marked in 2007 and 2009. In these years, WBC-infested Cry1Ab hybrids suffered the most kernel injury (mean 15.1% and 5.1%, respectively) (Figures 2A and 2C). Cry1F maize hybrids (*Bt* event TC1507), protected against both ECB and WBC, had very little kernel injury. In 2007, Cry1Ab hybrids and non-*Bt* hybrids experienced similar levels of kernel injury, but Cry1F hybrids suffered less injury than either Cry1Ab ($P = 0.0077$) or non-*Bt* hybrids ($P = 0.0142$). In both 2008 and 2009, non-Bt hybrids suffered more kernel injury than either Cry1Ab ($P = 0.0143$ and $P = 0.0179$) or Cry1F ($P = 0.0001$ and $P = 0.0053$) hybrids. In 2010, there were higher levels of injury in non-*Bt* as compared with either Cry1Ab ($P = 0.0005$) or Cry1F hybrids ($P = 0.0002$), and WBC incited more injury in non-*Bt* as compared to Cry1F plots (Figure 2D).

Manual insect infestations were used in this study to ensure that populations were present in the field with relatively uniform distribution. Their presence increases the likelihood of fungal infection in maize tissues affected by feeding injury and fungal spore dispersal by active larvae.[6,8] In 2007, 2008, and 2009, manual infestation significantly increased levels of kernel damage, indicating survival of manually infested insects. Insect infestations were chosen based on their traditional (ECB) and recent (WBC) significance in the growing area as well as the spectra of control provided by the *Bt* hybrids used in the study. Feeding patterns differ between ECB and WBC; WBC feeding is typically isolated at the tip of the ear and results in complete kernel destruction. ECB feeding is generally more widespread throughout the ear; the larvae leave partially intact kernels in their path as they migrate through the ear. "Railroading" is also common in ECB-infested maize, as small larvae move along a silk channel causing small amounts of injury to many kernels.[23]

Research has revealed a decline in natural ECB populations in several Midwest states as a result of the high adoption of *Bt* maize.[13] Historically, ECB has been the predominant lepidopteran pest of Midwest maize. In the years of this

dx.doi.org/10.1021/jf5011897 | J. Agric. Food Chem. 2014, 62, 6463−6472

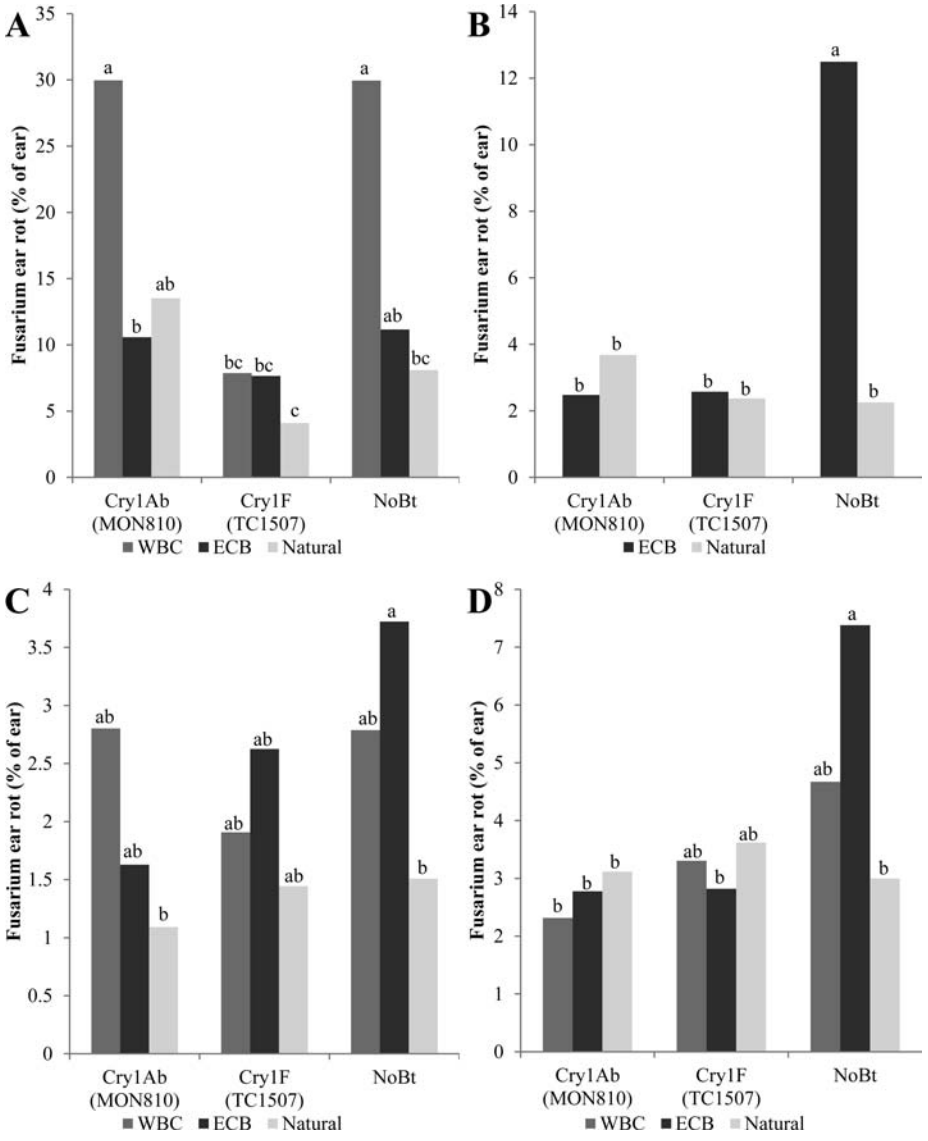

Figure 3. *Fusarium* ear rot (shown as average percent of kernels displaying visible symptoms of *Fusarium* infection per ear) by *Bt* event for (A) 2007; (B) 2008; (C) 2009; and (D) 2010. Data are means of five replications each of two hybrids. Letters denote significant differences ($P < 0.05$) between hybrid/insect infestations within years.

study, naturally infested plots did not differ in injury between susceptible and *Bt*-protected hybrids, indicating that natural ECB populations were low and injury was due to other endemic insects such as CEW. In maize-intensive regions of the U.S., regional suppression of ECB may result in predominance of pests that have historically been considered secondary to the ECB. WCB is a candidate, whose range has recently expanded from its recorded origin, Arizona,[24] all the way to Michigan, Ohio, and Pennsylvania in the U.S. as well as into Quebec.[25−27] WBC has also displayed a competitive advantage over another potential pest, CEW, when fed a diet of Cry1Ab (MON810) maize.[15] Reduced competition from ECB for maize in the Midwest will increase the need for WBC population monitoring for effective pest management, and hybrid selection will become even more important. The use of "stacked" Bt genes with different spectra of control and different modes of action may be necessary. In Puerto Rico, planting of Cry1F hybrids has been halted due to *Spodoptera frugiperda* (Lepidoptera: Noctuidae) resistance development.[28] A number of unique factors may have contributed to resistance development: little insect species migration into or off of the island; year-round maize cultivation; poor compliance with insect resistance management (IRM) requirements; and concurrent use of *Bt*-derived foliar insecticides; but this highlights the need for population monitoring and proactive resistance prevention and management in all regions where *Bt* maize is grown. Resistance has not spread to the mainland U.S.[29] and has not been noted in other lepidopteran species. In the U.S., the IRM strategy was developed to prevent resistance and, employed along with planting of *Bt* hybrids that produce different or multiple stacked *Bt* genes, can help reduce resistance development to any single gene on its own. IRM compliance is likely to improve significantly with the widespread commercialization of hybrid mixtures that include transgenic and non-transgenic (refuge) seeds in the same bag.

Influences of Hybrid and Insect Infestation on *Fusarium* Ear Rot. Hybrid and insect infestation effects on *Fusarium* ear rot were similar to those for kernel injury. Completely destroyed kernels were considered in the insect injury scores but were not physically present to contribute to

Fusarium ear rot scores or fumonisin contamination; nevertheless, a strong correlation was evident between insect injury and *Fusarium* ear rot (R = 0.74, P < 0.0001). In 2007, hybrid and insect infestation treatment were both significant factors influencing *Fusarium* ear rot severity ($F_{2,77}$ = 16.46 and $F_{2,77}$ = 15.26, respectively, P < 0.0001 for both). Hybrid, insect infestation treatment, and their interaction were all significant factors in 2008 ($F_{2,50}$ = 5.48 and P = 0.0071, $F_{1,50}$ = 7.64 and P = 0.0080, $F_{2,50}$ = 7.96 and P = 0.0010, respectively). In 2009, *Fusarium* ear rot severity was influenced by insect infestation treatment ($F_{2,77}$ = 5.18, P = 0.0077), and, in 2010, it was significantly influenced by hybrid ($F_{2,77}$ = 6.43, P = 0.0026) and the interaction of hybrid and insect infestation treatment ($F_{4,77}$ = 3.69, P = 0.0084). In 2007−2009, manual insect infestations resulted in higher levels of ear rot as compared with natural (P < 0.0001 to P = 0.0213), with the exception of 2007 ECB infestation. Cry1F hybrids suffered less ear rot than Cry1Ab and non-*Bt* maize hybrids (P < 0.0001 for both) in 2007 or non-*Bt* hybrids in 2008 (P = 0.0060). Non-*Bt* hybrids subject to ECB infestation in 2008 experienced higher levels of ear rot (mean 12.5%) than any other hybrid/insect combination (P < 0.0001 to P = 0.0106) (Figure 3B). Mean ear rot levels were low among all hybrids in 2009 (2.7%, 1.8%, and 2.0% for non-*Bt*, Cry1Ab, and Cry1F hybrids, respectively) and did not differ significantly (Figure 3C). The highest level was found in ECB infested, non-*Bt* plots at 3.7%. In 2010, Cry1Ab hybrids experienced the lowest level of ear rot (mean 2.7%), which was less than that of non-*Bt* hybrids (mean 5.0%, P = 0.0019). In 2010, ECB infested non-*Bt* hybrids experienced more ear rot (mean 7.4%) than naturally infested non-*Bt* hybrids (mean 3.0%, P = 0.0072), ECB infested Cry1F hybrids (mean 2.8%, P = 0.0078), or Cry1Ab hybrids under any insect infestation treatment (P = 0.0008 to P = 0.0059) (Figure 3D).

Fumonisin Contamination. *HPLC and ELISA Method Performance.* Accurate and repeatable determination of maize fumonisin content is a crucial step in commodity management. ELISA kits are used in grain-handling industries because of their ease-of-use, rapid results, minimal sample preparation, and affordability. In this industry, overestimation of mycotoxin contamination can result in false rejections, unnecessary limitations on grain usage, and subsequent economic loss. It also restricts marketability and impacts profitability, possibly affecting maize prices and available supplies. The AgraQuant Total Fumonisin ELISA used in years 2008 and 2009 of this study has limits of detection quantitation of 0.20 mg/kg and 0.25 mg/kg, respectively. This is less sensitive than results from the HPLC method used, for which the performance characteristics follow. HPLC calibration curves for FB_1, FB_2, and FB_3 had linear regression coefficients (R) of 0.999, 0.996, and 0.998. The limits of detection for FB_1, FB_2, and FB_3 were 0.11 ng, 0.18 ng, and 0.18 ng injected, respectively, which correspond to 40 μg/kg, 65 μg/kg, and 67 μg/kg in the maize sample (at 15% grain moisture). The limits of quantitation for FB_1, FB_2, and FB_3 were 0.33 ng, 0.54 ng, and 0.54 ng, respectively, which correspond to 120 μg/kg, 195 μg/kg, 200 μg/kg in maize (at 15% grain moisture).

Recoveries for FB_1 and FB_2 were within the acceptable range established by the European Commission, but ranges for FB_3 were not established in the EC directive.[30] The mean and standard deviations for FB_1, FB_2, and FB_3 in recovery samples were 1575 ± 121, 388 ± 27, and 70 ± 1.3 ng/g, respectively. The coefficients of variation for FB_1, FB_2, and FB_3, which are representative of precision and were obtained from independent extracts of the same maize sample, were 7.7%, 7.0%, and 1.9%, respectively. For fumonisin levels determined by HPLC and samples with FB_1, FB_2, and FB_3 levels all within their respective ranges of quantitation, FB_1 constituted 69.3 ± 4.7% of the total fumonisin contamination in the grain samples (N = 24).

Occurrence of Fumonisins and Range of Concentrations in Maize Samples. ELISA determinations of fumonisin B_1, **1**, in grain from 2007 indicated a range of FB_1 sample contamination from LOD to 80.62 mg/kg with a mean of 9.98 mg/kg. Fumonisin levels were below 2 mg/kg in 19 samples, 20 samples were between 2 and 4 mg/kg, and 51 samples exceeded 4 mg/kg. Hybrid and insect infestation treatment were significant influences on FB_1 concentrations in maize ($F_{2,77}$ = 4.76, P = 0.0112, and $F_{2,77}$ = 15.70, P < 0.0001). Non-*Bt*, Cry1Ab, and Cry1F hybrids averaged 13.14 mg/kg, 11.96 mg/kg, and 4.84 mg/kg FB_1, respectively. ELISA determi-

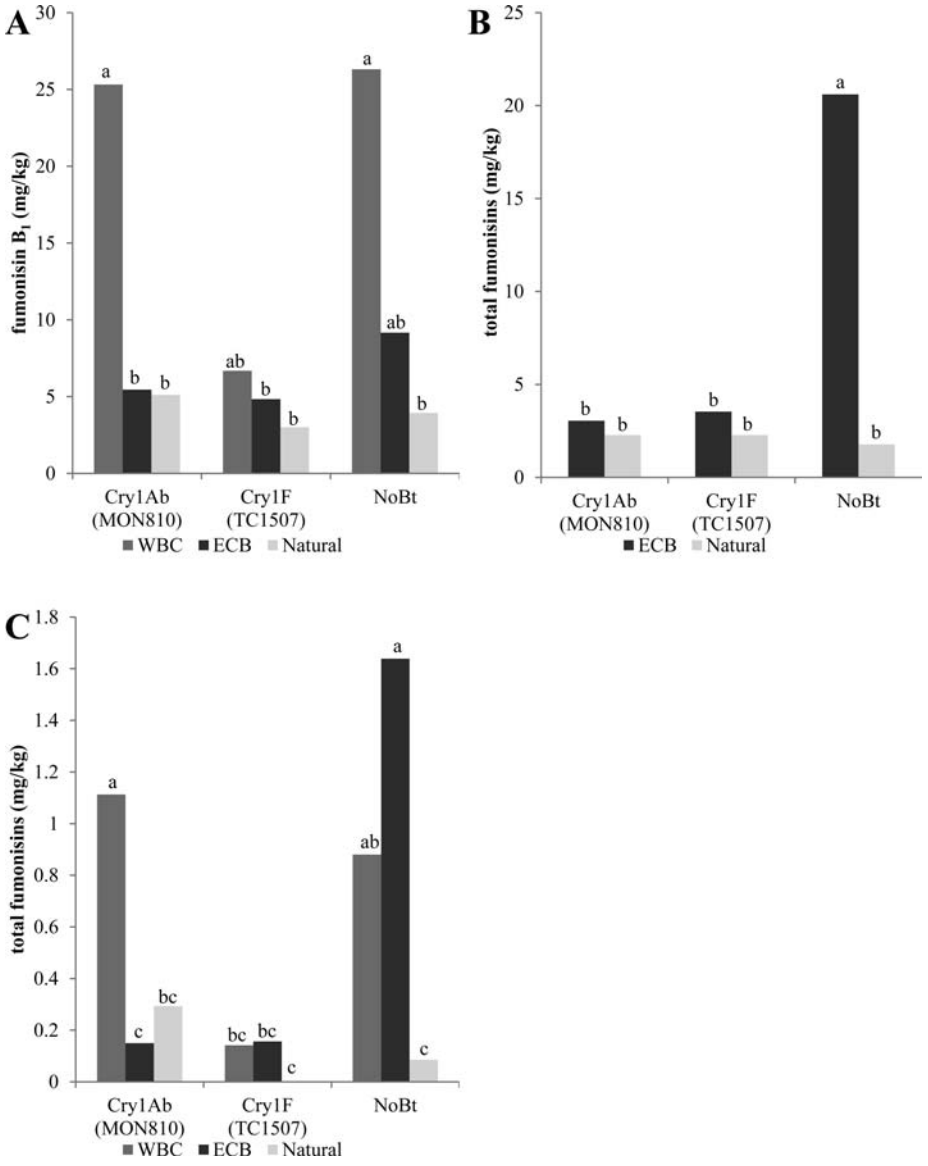

Figure 4. Fumonisin contamination in maize (mg/kg) as determined by ELISA. FB_1 contamination, **1**, is depicted for (A) 2007; total fumonisin contamination (FB_1 + FB_2 + FB_3), **1**−**3**, is depicted for (B) 2008 and (C) 2009. Data are means of five replications each of two hybrids. Letters denote significant differences ($P < 0.05$) between hybrid/insect infestations within years.

nations of total fumonisin levels (FB_1 + FB_2 + FB_3), **1**−**3**, in 2008−2009 ranged in samples from 0 to 48 mg/kg with a mean of 2.55 mg/kg. 109 samples had total fumonisin levels below 2 mg/kg, 20 samples were between 2 and 4 mg/kg, and 21 samples exceeded 4 mg/kg. ANOVA analysis revealed significant differences between years of the study ($F_{1,132}$ = 51.43 and $P < 0.0001$) with mean fumonisin levels higher in 2008 (5.59 mg/kg) than 2009 (0.50 mg/kg). In 2008, hybrid, insect infestation treatment, and their interaction were all significant factors contributing to the severity of total fumonisin contamination as determined by ELISA ($F_{2,50}$ = 4.31 and P = 0.0187, $F_{1,50}$ = 17.47 and $P = 0.0001$, $F_{2,50}$ = 5.15 and P = 0.0092, respectively) and likewise, in 2009 ($F_{2,77}$ = 15.55 and $P < 0.0001$, $F_{2,77}$ = 14.24 and $P < 0.0001$, $F_{4,77}$ = 8.11 and $P <$ 0.0001, respectively).

Total fumonisin levels as determined by HPLC ranged in individual samples from LOD to 34.87 mg/kg with a mean and standard deviation of 1.28 ± 3.19 mg/kg. A total of 197 samples had total fumonisin levels below 2 mg/kg, 17 samples were between 2 and 4 mg/kg, and 13 samples exceeded 4 mg/kg. Fumonisin contamination in maize grain (as determined by HPLC) was highest in 2008 (3.22 mg/kg), followed by 2010 (0.57 mg/kg), and lowest in 2009 (0.40 mg/kg) (Table 3).

Hybrids susceptible to WBC, namely, Cry1Ab and non-*Bt* hybrids, were significantly more contaminated with FB_1 than Cry1F hybrids which expressed insecticidal proteins against this insect. In 2007, ELISA results showed that Cry1F hybrids had less FB_1 contamination than Cry1Ab (P = 0.0423) or non-*Bt* hybrids (P = 0.0154). WBC infested plots had the highest mean FB_1 content in 2007 (19.44 mg/kg), greater than either ECB (6.48 mg/kg, P = 0.0019) or naturally infested plots (4.01 mg/kg, $P < 0.0001$) (Figure 4A). ECB infestation exacerbated total fumonisin contamination in comparison to naturally infested plots in 2008 ($P = 0.0001$ and $P = 0.0005$ for ELISA and HPLC, respectively). In 2008, non-*Bt* hybrids had higher levels of contamination than Cry1Ab hybrids or Cry1F hybrids. Among all hybrid/insect combinations in 2008, ECB infested non-*Bt* hybrids suffered this highest level of fumonisin

dx.doi.org/10.1021/jf5011897 | J. Agric. Food Chem. 2014, 62, 6463−6472

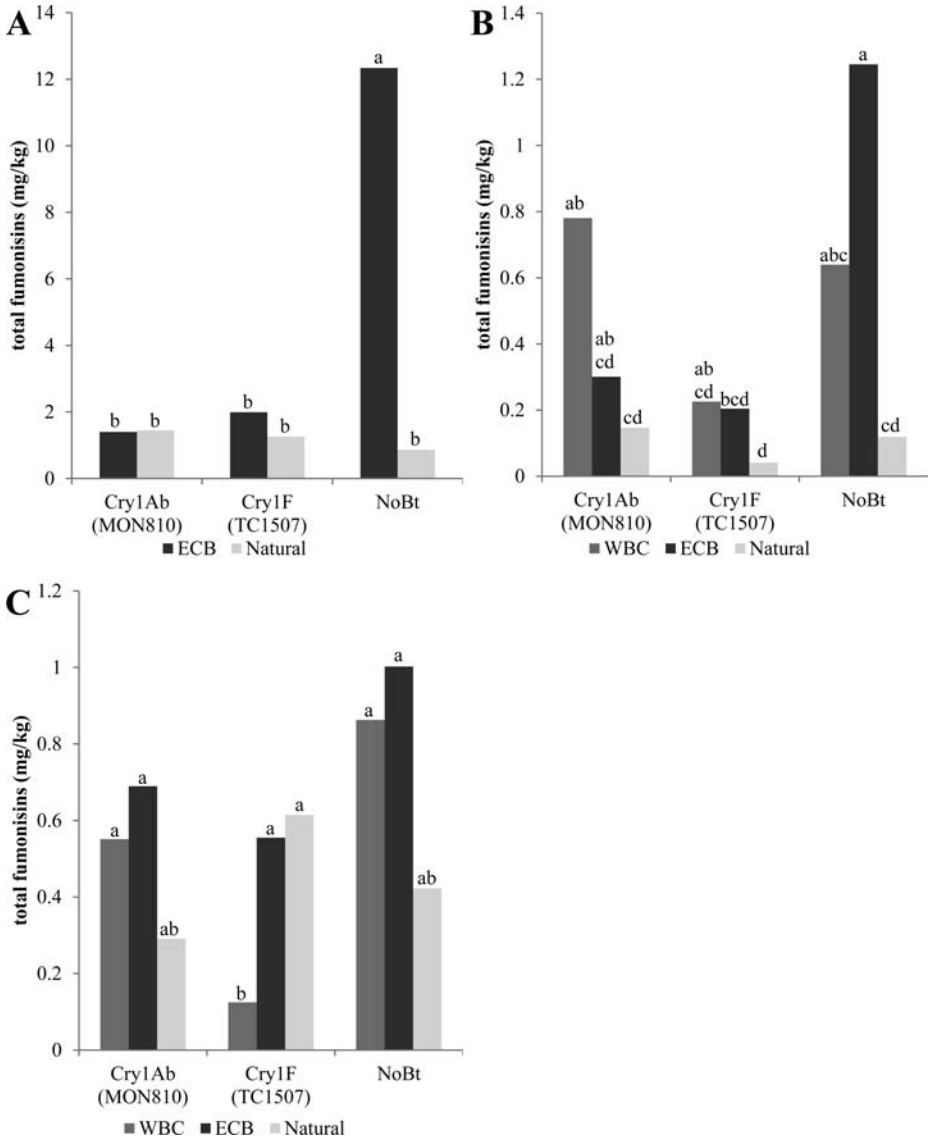

Figure 5. Fumonisin contamination, **1**−**3**, in maize (mg/kg) as determined by HPLC for (A) 2008, (B) 2009, and (C) 2010. Data are means of five replications each of two hybrids. Letters denote significant differences ($P < 0.05$) between hybrid/insect infestations within years.

contamination ($P < 0.0001$ to $P = 0.0062$) (Figure 4B and Figure 5A). In 2009, plots infested with WBC or ECB suffered higher levels of fumonisin contamination than naturally infested plots ($P < 0.0001$ and $P = 0.0012$, respectively (ELISA); $P < 0.0001$ and $P = 0.0002$, respectively (HPLC)). Cry1F hybrids in 2009 had less fumonisin contamination than Cry1Ab ($P = 0.0003$ by ELISA, $P = 0.0064$ by HPLC) or non-*Bt* hybrids ($P < 0.0001$ by ELISA, $P = 0.0005$ by HPLC) (Figure 4C and Figure 5B).

ELISA was not performed in 2010; HPLC results show that Cry1F hybrids were less contaminated than non-*Bt* hybrids ($P = 0.0101$) while Cry1Ab hybrids suffered an intermediate level of contamination relative to these, which did not differ from Cry1F or non-*Bt* hybrids. Averaged over all hybrids 2010, fumonisin contamination was the most severe in ECB infested plots, least in naturally infested plots ($P = 0.0146$), and WBC did not differ from either of these treatments. Cry1F plots infested with WBC in 2010 suffered the lowest levels of fumonisin contamination, less than either non-*Bt* or Cry1Ab plots infested with WBC ($P = 0.0002$ and $P = 0.0065$, respectively), or Cry1F plots subject to ECB or natural insect infestation treatment ($P = 0.0224$ and $P = 0.0277$, respectively) (Figure 5C). Overall, hybrids with *Bt* genes yielded grain with less kernel injury, *Fusarium* ear rot, and fumonisins compared to non-*Bt*, near-isogenic hybrids. Expression of *Bt* genes *cry1F* and *cry1Ab* in maize hybrids prevented insect feeding, thereby reducing the capability of toxigenic fungi to colonize the ear and produce mycotoxins. As a result, they experienced reduced contamination with fumonisins, compared to non-*Bt* hybrids, when grown under conditions of insect infestation. Total fumonisin contamination in maize obtained from *Bt* hybrids measured in 2008−2010 was consistently below FDA guidance levels.[31] In 2008, non-*Bt* grain would have suffered market limitations as a result of its fumonisin contamination, which exceeded 6 mg/kg as determined by HPLC and 11 mg/kg by ELISA.

In addition to the prevention of insect feeding by *Bt* maize that can result in reduced fumonisins, recent evidence also points to direct effects of *Bt* gene expression on fumonisin-producing *Fusarium* species. Rocha et al.[32] and Reis et al.[33] found that expression of genes in the fumonisin biosynthesis pathways was reduced when *F. verticillioides* fungus was grown

dx.doi.org/10.1021/jf5011897 | J. Agric. Food Chem. 2014, 62, 6463−6472

on maize kernels which express either Cry1Ab[32] or Cry1F[33] as compared with near-isogenic controls. In the current study, hybrids expressing Cry1Ab and Cry1F had reduced fumonisin contamination when exposed to pest pressures for which they expressed insecticidal proteins. Cry1F hybrids had the lowest fumonisin levels in 2007, 2009, and 2010, the three years in which WBC insect infestation was used. In all years of the study, Cry1F and Cry1Ab performed similarly under ECB infestation. Under nontarget pest pressures, *Bt* hybrids did not display a significant advantage over non-*Bt* hybrids. The rise of pests vying for maize as a secure food source will increase the need for planting hybrids which target a broader spectrum of pests. This will aid in reducing kernel injury and subsequently reducing toxigenic fungi colonization and mycotoxin accumulation in maize hybrids.

HPLC versus ELISA Results. There was a strong correlation ($r = 0.95$, $P < 0.0001$, $N = 138$) between total fumonisin results of HPLC and ELISA methods obtained for 2008−2009, the two years of the study for which both methods were used (Figure 6). ELISA results were, on average, higher than HPLC

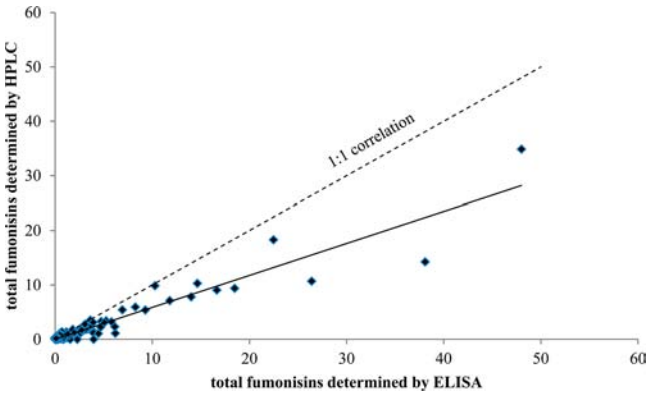

Figure 6. Correlation between total fumonisin concentration (FB_1 + FB_2 + FB_3) (mg/kg), **1**−**3**, determined by HPLC and ELISA (n = 138). Data are from 2008 and 2009.

results for the same sample, but the difference was not constant. Fumonisin contamination as determined by ELISA was correlated with insect injury ($R = 0.52$, $P < 0.0001$) and *Fusarium* ear rot ($R = 0.70$, $P < 0.0001$). These correlations were weaker when HPLC results were used to determine correlations with both insect injury ($R = 0.47$, $P < 0.0001$) and *Fusarium* ear rot ($R = 0.52$, $P < 0.0001$). Statistical significance of hybrid and insect infestation effects were generally the same for both HPLC and ELISA methods except for one case, a significant interaction effect in the 2009 ELISA data which was not significant for the HPLC data (Figures 4B and 5A, and Figures 4C and 5B). In this particular year, however, means calculated by hybrid-insect treatment combinations did not exceed 2 mg/kg for either method; it is, therefore, unlikely that market implications would have arisen from this discrepancy. Ghali et al.[34] also reported fumonisin contamination in maize by both HPLC and direct-competitive ELISA. In all commodities tested, ELISA gave more fumonisin-positive samples than HPLC. For samples detected as positive by both methods they found a significant coefficient of determination, $r^2 = 0.978$ ($N = 25$). Adoption and use of rapid test kits like ELISA in commercial settings is valuable to ensure that the mycotoxin contamination does not exceed market needs imposed by end-users. It may be appropriate to apply a correction factor to results obtained by rapid test kits, if their results differ from a validated analytical technique by a predictable factor. It is crucial, however, to use these techniques in the appropriate manner, ideally with regular check samples performed with validated analytical techniques.

fluorescence spontaneously when exposed to an allergen antigen. CD63 glycoprotein can be easily found on basophilic granular membranes in many cells, such as basophils, mast cells, and platelets.[22,23] The integration of cytoplasmic granules with the plasma membrane occurs when the basophils or mast cells are activated along with the successive release of inflammatory mediators, such as histamine,[24,25] although CD63 antigen expression on mast cell surfaces has always been detected by flow cytometric analysis.[26] However, the real-time expression of CD63 in individual cells cannot be observed.[27] Therefore, this study employed confocal fluorescence microscopy to examine CD63 surface expression on RBL mast cells stimulated with antigen, resulting in a rapid quantification method for fish PVs.

This study developed a novel, mast-cell-based, fluorescent sensor to quantify fish PV and evaluate IgE-mediated hypersensitivity. We contructed and transfected CD63−EGFP plasmid into RBL cells, to obtain stable genetically fluorescent cell lines. We also explored the use of the real-time surface expression of CD63−EGFP in anti-2,4-dinitrophenyl (DNP) IgE pre-sensitized RBL-2H3 cells exposed to DNP−bovine serum albumin (BSA) as a model for fluorescence detection by confocal laser scanning microscopy (CLSM). We measured changes in fluorescence intensity induced by the fish PV on mast cells and analyzed the relationship between different allergen concentrations and impedance signals. These RBL cell sensors successfully detected and identified target allergens within minutes, and the allergic reaction process was monitored in real time by CLSM.

EXPERIMENTAL PROCEDURES

Reagents and Chemicals. Mouse monoclonal anti-DNP IgE antibody, DNP−BSA, sulforhodamine B (SRB), bromochloroindolyl phosphate, nitro blue tetrazolium, and trichloroacetic acid were obtained from Sigma-Aldrich, Inc. (St. Louis, MO). Purified fish PV and mouse monoclonal anti-fish PV IgE antibody were purchased from Novus Biologicals (Littleton, CO). RBL cells were obtained from the Cell Bank of Chinese Academy of Sciences (Shanghai, China). RPMI 1640 medium and fetal bovine serum (FBS) was obtained from Gibco Laboratories (Gaithersburg, MD). Glass-bottomed dishes (35 mm) were purchased from Shengyou Biotechnology Co., Inc. (Hangzhou, China). Other conventional reagents were purchased from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). All solutions were prepared with deionized water, and all reagents were of analytical grade.

Instrumentation. Fluorescence signals were recorded by CLSM (LSM 710, Carl Zeiss Microscopy GmbH, Göttingen, Germany). A FACS Calibur flow cytometer (BD Biosciences, San Jose, CA) was used to evaluate cell apoptosis. RBL cells were incubated in a CO_2 incubator (Thermo Scientific Forma Series II Water Jacket, Thermo Fisher Scientific, Inc., Waltham, MA).

Construction of a CD63−EGFP Prokaryotic Expression System. The complete coding sequence of mouse CD63 (NM_001042580) was retrieved from the National Center for Biotechnology Information (NCBI) GenBank database and amplified from mouse liver cDNA. The primers employed were mCD63, 5′-cgc gtc gac atg gcg gtg gaa gga g-3′ (forward) and 5′-gcg gga tcc cat tac ttc ata gcc ac-3′ (reverse). The mCD63 PCR products and apEGFP-N1 vector were digested with *Bam*HI and *Sal*I, and the resulting fragments were purified and ligated with T4 DNA ligase. The ligated product was transformed into DH5a competent cells and an isolated positive clone named pEGFP-N1-mCD63.

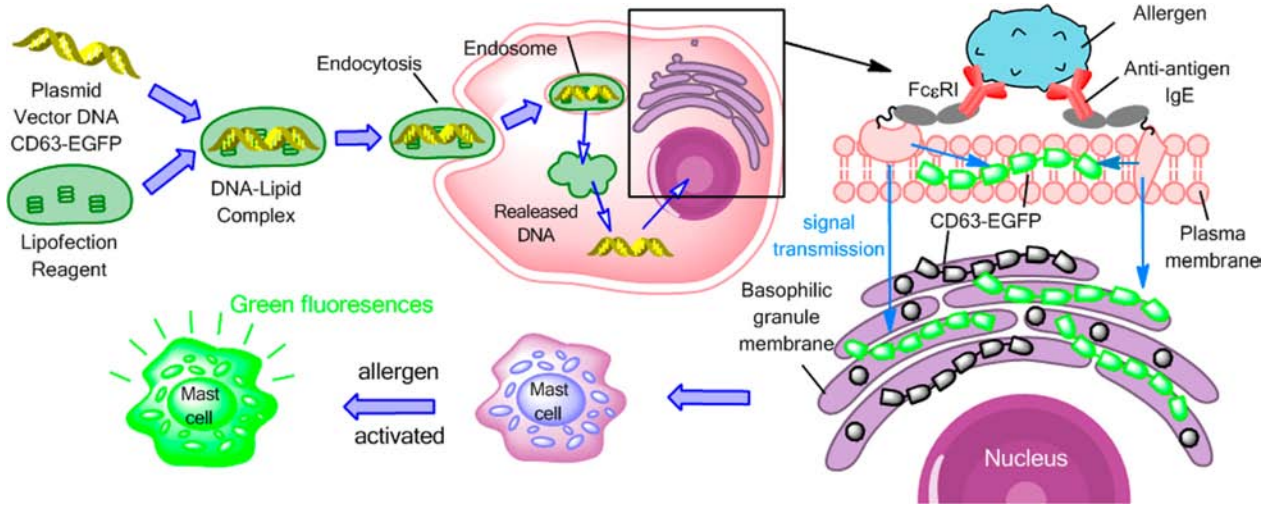
Transfection of Plasmid DNAs. At 1 day before transfection, plates were prepared containing 2×10^5 RBL mast cells in 500 μL of growth medium without antibiotics, such that the cells were 90−95% confluent at the time of transfection. The ratio of cationic carrier/DNA was optimized on the basis of the instructions of the manufacturer. Briefly, 4 μg of DNA were diluted in 50 μL of Opti-MEM I reduced serum medium without serum (Gibco Invitrogen, Life Technologies) and mixed gently. A total of 10 μL of Lipofectamine2000 (Invitrogen, Life Technologies, Grand Island, NY) was mixed gently before use and added to 50 μL of Opti-MEM I medium. After a 5 min incubation at room temperature, diluted DNA was combined with the diluted Lipofectamine 2000 (total volume of 100 μL) and incubated for 20 min at room temperature. Then, the mixture was added to RBL cell plates. After 4 h for DNA transfection, the transfection medium was replaced with fresh culture medium and these cells with CD63−GFP plasmid DNA were cultured in 35 mm dishes for a few days. Then, stable transfectants were obtained by selection with the antibiotic G418 (Gibco Invitrogen) and a stable transfectant RBL cell line with EGFP selected.

Western Blot Analysis for CD63−EGFP Expression. To each tube of harvested cells (in 20 μL), 180 μL of radio-immunoprecipitation assay (RIPA) lysis buffer containing phenylmethylsulfonyl fluoride (PMSF) was added and incubated for 10 min at room temperature (RT). Equal amounts of proteins were separated using 10% sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE) after boiling for 5 min in 4× loading buffer and transferred onto Immobilon-P membranes (Millipore Corp., Billerica, MA). The membranes were then incubated with anti-EGFP antibody and a second antibody immunoglobulin G (IgG horseradish peroxidase (HRP) (Santa Cruz Biotechnology, Santa Cruz, CA). Immunoreactivity was detected using the enhanced chemiluminescence (ECL) detection system (GE Healthcare Bio-Sciences Corp., Piscataway, NJ). The target protein bands were quantified by scanning densitometry using ImageJ processing software and normalized to the signal intensity of GAPDH.

***In Vitro* Cell Proliferation and Apoptosis Assay.** RBL cells seeded on a 96-well plate at 2×10^5 cells/well were infected with CD63−EGFP using the procedures described above or received only changes with fresh media, as controls. At 1, 2, or 3 days post-infection, SRB assays were performed as described by Cung at al.[28] In brief, cells were fixed at 4 °C and in 3.3% (w/v) trichloroacetic acid for 1 h without removing the culture media. After removal of the fixation solution by tapping until the plates were completely dry, each well of cells was incubated with 100 μL of 0.057% (w/v) SRB at RT for 30 min. The wells were then rinsed 4 times with 1% (v/v) aqueous acetic acid and dried, and the stained cells were dissolved in 200 μL of 10 mM Tris base (pH 10.5) with shaking for 5 min. Finally, the 510 nm absorbance was measured on a microplate reader (BioTek Instruments, Inc., Winooski, VT). The influence of EGFP gene transfer on cell survival was examined by evaluating apoptosis via fluorescence-activated cell-sorting analysis, including an annexin-V−EGFP apoptosis detection kit (Nanjing KeyGen Biotech Co., Ltd., Shanghai, China). Briefly, RBL cells on 12-well plates were harvested by trypsinization at 3 day after infection with CD63−EGFP plasmid. After neutralization by washing with culture media containing FBS and phosphate-buffered saline, the cells were resuspended in 100 μL of annexin-V binding buffer and stained in the dark with 4 μL of annexin-V−EGFP (an apoptosis marker) and 4 μL of propidium iodide (PI, a necrosis marker) for 15 min at room temperature as a control. After 400 μL of annexin-V binding buffer was added, 10 000 cells per sample were analyzed by flow cytometry and CellQuest software. Fluorescent signals from EGFP and PI were distinguished by three color detectors.

PV Purification. The PV from crucian carp, bream, and silver carp was extracted as described previously.[29] Briefly, 2 g of white muscle of each sample was extracted with 10 mL of 20 mM Tris−HCl (pH 7.5), using a homogenizer (NS1001 L2K, Niro Soavi, Italy). Supernatants were obtained as PV crude extracts after centrifugation at 8000*g* for 30 min. To achieve a clear solution for test, crude extracts were purified by taking advantage of their thermostability, heating at 70 °C for 5 min, and then immediately cooled in ice water, followed by centrifugation at 40000*g* for 30 min. Supernatants composed mainly of PV were analyzed by SDS−PAGE. Then, the extract solutions were subjected to anti-PV antibody pre-sensitized RBL cells, which were monitored by a confocal laser scanning (CLS) microscope for fluorescence analysis.

Scheme 1. Schematic Illustration of the Working Principle of a RBL Cell Sensor[a]



[a]Fusion plasmid CD63−EGFP was introduced into RBL cells to obtained stable transfectant fluorescent RBL cells. When allergen antigen bound to the antibody pre-sensitized mast cells, cytoplasmic granules would be fused with the plasma membrane and trigger the expression of CD63 and fluorescent protein on the cell surface. Therefore, allergen antigen would be detected by the elevation of intracellular fluorescence emitted by EGFP expression in RBL cells.

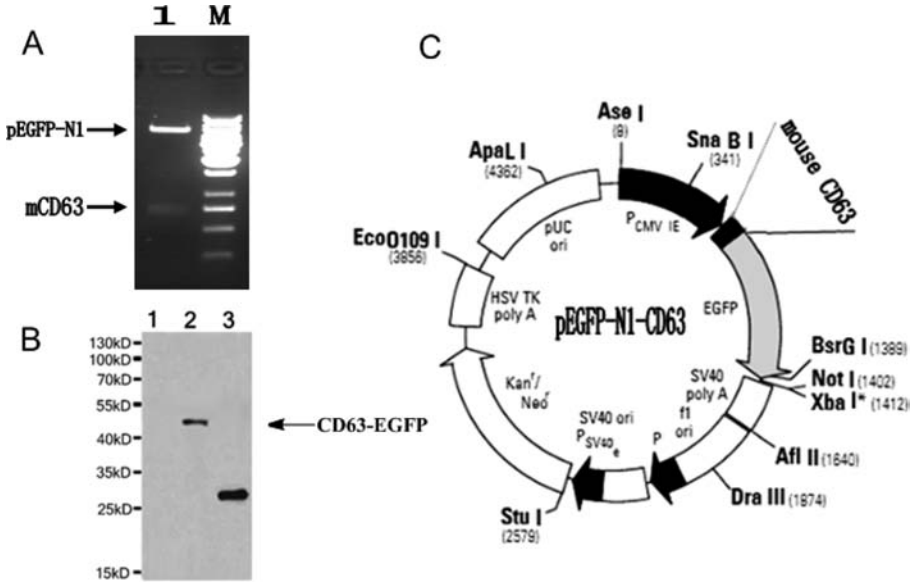


Figure 1. Construction of the pEGFP-N1-mCD63 vector and expression of the CD63−EGFP protein. (A) pEGFP-N1-mCD63 plasmid double-digested results, where M represents DNA markers (250, 500, 750, 1000, 1500, 2000, 2500, 3000, 3500, 4000, 45000, 5000, 6000, and 7000 bp) and 1 represents the pEGFP-N1-mCD63 plasmid double digested with *Bam*HI and *Sal*I. (B) Western blotting of lysates prepared from RBL cells at 24 and 48 h after transfection with the pEGFP-N1-mCD63 vector with anti-EGFP antibodies: 1, negative control (non-transfection cell); 2, CD63−EGFP fusion protein; 3, positive control (cell transfected with pEGFP-N1). (C) Map of the pEGFP-N1-CD63 plasmid. Mouse CD63 gene (not including the stop codon) was introduced at the *Sal*I and *Bam*HI restriction sites of the multiple cloning site (MCS) region of the pEGFP-N1 (Clontech, PT3027-5) vector.

RBL Cell Sensor Assay. RBL-2H3 cells were cultured in a flask in RPMI 1640 medium supplemented with 10% fetal calf serum, penicillin (100 μg mL^{-1}), and streptomycin (100 μg mL^{-1}) at 37 °C in a humidified atmosphere containing 5% CO_2. At the growth retardation stage after 3 days, cells reached the logarithmic growth phase, after which they were plated onto 35 mm glass-bottomed dishes (2×10^5 cells/dish) to form a monolayer overnight. Cells were then washed with Tyrode's buffer (Maishi BioTech, Suzhou, China) and pre-sensitized by incubation with Tyrode's buffer containing 10 mg/mL antibodies and 2.5 mM probenecid at 37 °C for 30 min. The resulting cells were then washed and maintained in Tyrode's buffer. A volume of 50 μL of serially diluted samples containing DNP−BSA or fish PV antigen was prepared in Tyrode's buffer and subjected to the prepared RBL sensor cells. The cell responses were monitored using a LSM 710 CLS microscope (Carl Zeiss Microscopy GmbH). Time-lapse sequences of RBL cells, recorded every 30 s, were collected, and the total fluorescence intensity for each image was calculated using Scion Image software (Scion Corp., Frederick MD). Cells not exposed to DNP−BSA (or fish PV antigen) served as controls.

β-Hexosaminidase Assay for Measurements of Cell Degranulation. A β-hexosaminidase assay was performed to validate the result of fluorescence analysis by IgE-mediated allergic response.[30] Cells growing in 96-well plates were washed, incubated in Tyrode's buffer, and stimulated with medium containing different allergen

dx.doi.org/10.1021/jf501382t | J. Agric. Food Chem. 2014, 62, 6473−6480

concentrations. After 1 h, the supernatant was removed and the cell monolayer was lysed in Tyrode's buffer containing 0.5% TX-100 to obtain the total cellular β-hexosaminidase activity. This activity was measured in both supernatant and lysates by adding 50 μL of substrate *p*-nitrophenyl-*N*-acetyl-β-glucopyranoside (1 mg/mL) to each well. After incubation at 37 °C for 1 h, the reaction was quenched by the addition of 150 μL of 0.4 M glycine at pH 10.7 and the 405 nm absorbance was read in an ELISA reader (BioTek Instruments, Inc.). The ratio of β-hexosaminidase release was calculated using the following formula: β-hexosaminidase release (%) = 100 × [(supernatant/blank supernatant)/(supernatant/blank supernatant) + (total cell lysate/blank total cell lysate)]. Cells incubated in medium without allergen served as blanks.

RESULTS AND DISCUSSION

Working Principles of RBL Cell Sensors. Scheme 1 illustrates the working principle by which a RBL cell sensor recognizes and quantifies a target antigen. In this study, we fused EGFP to mouse CD63, in which the C terminus of CD63 was conjugated with EGFP. Then, we introduced the fusion plasmid CD63−EGFP into RBL cells through a highly efficient, lipid-mediated, DNA-transfection procedure. DNA−lipid complexes were fused with the membrane by endocytosis, and the fluorescent protein gene was diffused throughout the intracellular membranes, thus entering the nucleus. Next, RBL cells were selected with the antibiotic G418 to obtained stable transfectant cells. Results show that CD63 expression on cell surfaces increased, along with the successive expression of fluorescent protein upon antibody activation in RBL mast cells pre-sensitized with allergen antigen (see the enlarged drawing on the right of Scheme 1). In this way, we monitored cell responses and quantified the allergen antigen through intracellular fluorescence changes observed under a CLS microscope.

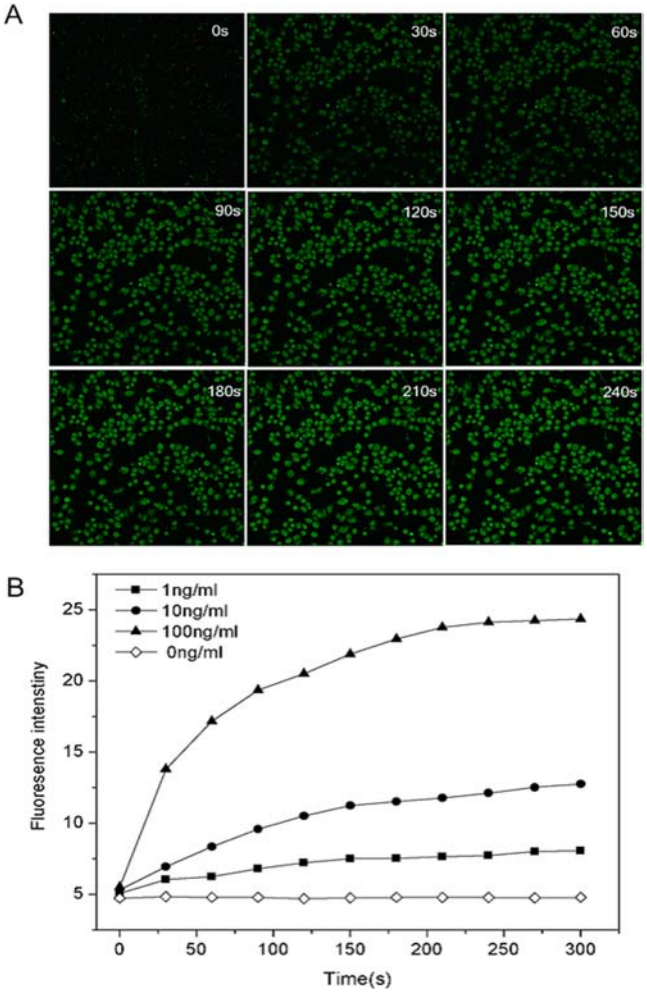

Figure 2. Fluorescence intensity changes of mast cells exposed to various concentrations of DNP−BSA. (A) Time-dependent images of cell fluorescence intensity responses. DNP−BSA (100 ng/mL) was employed to stimulate anti-DNP IgE pre-sensitized RBL cells. The images were recorded every 5 s and displayed every 30 s. (B) Quantification of fluorescence intensity in RBL cells after sensitization with 10-fold serial dilutions of DNP−BSA.

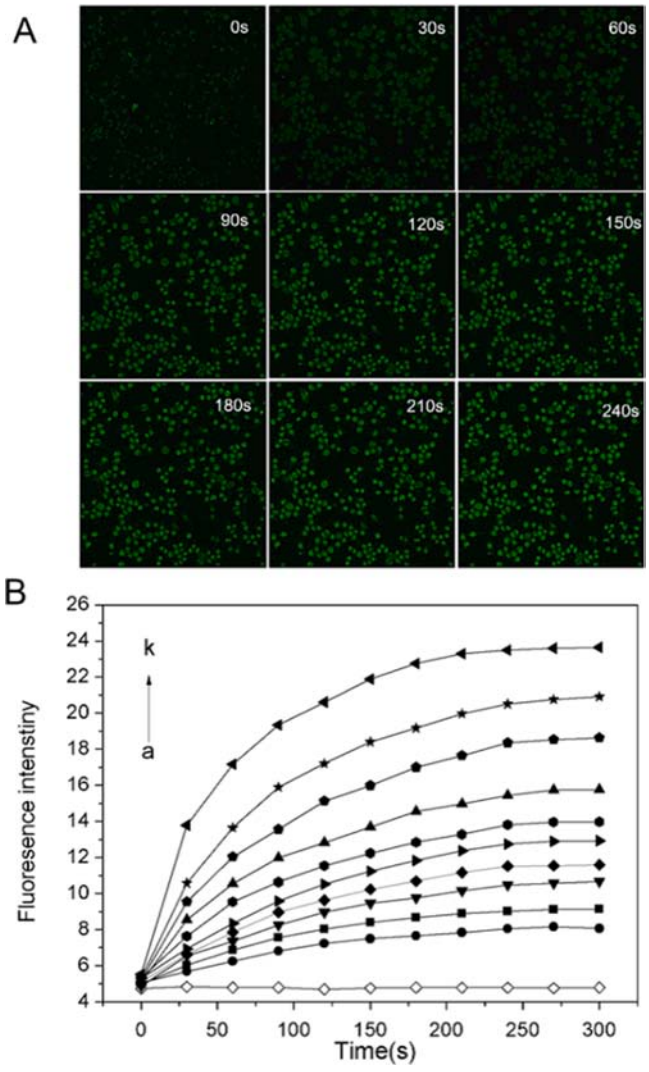

Figure 3. Fluorescence intensity changes of RBL cells with different concentrations of fish PV. (A) Time-dependent images of cell fluorescence intensity variation. PV (100 ng/mL) was used to stimulate RBL cells that pre-sensitized with anti-PV antibodies. The images were recorded at an interval of 5 s and exhibited every 30 s. (B) Quantification of fluorescence intensity in RBL cells exposed to 10 different concentrations of PV (from a to k: 0, 1, 2.5, 5, l0, 20, 40, 60, 80, and 100 ng/mL).

Successful Construction and Expression of CD63−EGFP Chimera Proteins. We amplified the CD63 gene from cDNA of mouse liver tissue with oligonucleotides, so that *Sal*I and *Bam*HI restriction sites were introduced at the 5′ and 3′

ends, respectively. The PCR products and pEGFP-N1 plasmids were also double-digested with *Bam*HI and *Sal*I, ligated with T4 DNA ligase, and transfected into DH5a competent cells (Figure 1A). The recombinant plasmids were double-digested with *Bam*HI and *Sal*I, and the positive clone was named pEGFP-N1-mCD63 (Figure 1C). The anti-EGFP antibody was used to detect CD63−EGFP fusion protein expression. One major band, ~46 kDa (the CD63 and EGFP fusion protein), was observed (Figure 1B), which was in good agreement with the sum of the molecular sizes of CD63 and EGFP. The RBL cells infected with CD63−EGFP showed strong fluorescence signals from EGFP expression at day 3 after antigen stimulation, indicating a high transfection efficiency of about 83.27 ± 1.45% through fluorescent observation and flow analysis (see Figure S1A of the Supporting Information).

SRB-based proliferation assays were performed to investigate potential adverse effects during the transfection process. Results show no difference in RBL cell numbers at 1, 2, and 3 days between the CD63−EGFP-infected and control groups (see Figure S1B of the Supporting Information). Flow cytometric analyses were conducted at day 3 for the CD63−EGFP-infected and control groups, using annexin V−EGFP and PI as markers for apoptosis and necrosis, respectively. Results show similar low rates of early apoptosis (0.86 ± 0.21 versus 0.72 ± 0.18%, respectively) and necrosis (0.17 ± 0.13 versus 0.23 ± 0.15%, respectively; see Figure S1C of the Supporting Information).

Quantification of Fish Allergen PV by RBL Cell Sensors. Naive RBL cells cannot recognize any antigens. They can only recognize antigens when anti-antigen IgE antibodies bind tightly to the high-affinity receptors (FcεRI) on their cell surfaces. This binding allows them to be stimulated by cross-linking with protein allergens to initiate a sequence of biochemical events, including cellular degranulation and release of inflammatory molecules.[31] We verified the use of cell sensors to recognize allergen antigen recognition with DNP−BSA, a multivalent model antigen, to stimulate RBL cells pre-sensitized with anti-DNP IgE.

We also used time-lapse imaging of cell responses after stimulation with DNP−BSA (100 ng/mL) and measured fluorescence intensity changes over time to determine the amplitude and speed of cell responses. Results show that both declined with a decreased DNP−BSA concentration (panels A

dx.doi.org/10.1021/jf501382t | J. Agric. Food Chem. 2014, 62, 6473−6480

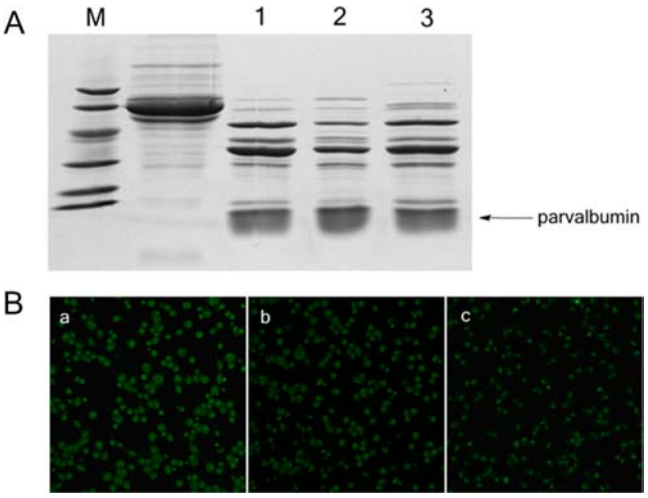

Figure 5. (A) SDS–PAGE analysis for PV from three kinds of different fish purifications: M, protein marker (97, 66, 44, 29, 20, and 14 kDa); 1, crucian carp; 2, silver carp; and 3, bream. (B) Quantification of three kinds of fish PV by a RBL-2H3-cell-based sensor: (a) crucian carp, (b) silver carp, and (c) bream.

Table 1. Concentration and Content of PV in Three Kinds of Fish[a]

sample	crucian carp	silver carp	bream
fluorescence intensity (mean ± SD)	18.84 ± 0.08	14.88 ± 0.14	13.68 ± 0.16
PV concentration (ng/mL ± SD)	64.08 ± 0.22	31.08 ± 0.35	21.08 ± 0.33
PV content (mg/g ± SD)	1.92 ± 0.23	0.93 ± 0.28	0.63 ± 0.26

[a]SD = standard deviation (n = 5).

and B of Figure 2, respectively). These results are in accordance with previous reports. They indicate the presence of target antigens and demonstrate that RBL cell sensor responses can be monitored in real time with CLSM.[19]

Next, fish PV standards were applied to evaluate the feasibility of RBL cell sensors. We prepared cell sensors using pre-sensitized RBL cells with anti-fish PV antibodies. We monitored the resulting cell fluorescence changes with CLSM in real time. Time-lapse images of RBL cell sensors responding to fish PV (100 ng/mL) reveal that activating mast cells with antigens led to a rapid and robust increase in cell fluorescence intensity (Figure 3A). We also measured the response of sensors to different PV concentrations in terms of the fluorescence intensity versus time (Figure 3B). PV samples were added after a stable fluorescence signal was obtained. At low PV concentrations (1–100 ng/mL), from the time of addition (at 0 s), RBL cells showed a slow increase in fluorescence intensity. This indicates the initiation of CD63–EGFP chimera protein expression on cytoplasmic granular and plasma membranes. This, in turn, created a non-uniform distribution of fluorescence on the cell surface and in the cytoplasm, leading to a lower fluorescence intensity.

At high PV concentrations, cell fluorescence intensity rose rapidly, reaching a plateau of sustained saturation within 60 s after stimulation. Further investigation of the allergic responses of these cells reveals that high activation of mast cells induced fusion of cytoplasmic granular membranes with plasma membranes. This resulted in the degranulation of secretory vesicles and release of inflammatory molecules, such as histamine and β-hexosaminidase.[32] We also examined fluorescence changes on the surface of single cells, and the result is in accordance with previous results (see Figure S2 of the Supporting Information).

A histogram of the linear relationship between the fish PV concentrations and fluorescence intensity clearly shows that fluorescence signals follow the same trend as that of DNP–BSA-activated cells (Figure 4A). Fluorescence intensity was proportional to PV, ranging from 1 to 100 ng/mL. A β-hexosaminidase assay was performed to confirm the fluorescence analysis results (inset of Figure 4A). This indicates that the β-hexosaminidase release rate increased gradually at low PV concentrations, while it grew rapidly at high concentrations. These data agreed well with the dose–response curve obtained from fluorescence measurements.

At both low and high PV concentrations, fluorescence intensities exhibited good linear relationships with fish PV concentrations, with correlation coefficients of 0.992 and 0.991 (low and high PV concentrations in panels B and C of Figure 4, respectively). The limit of detection (LOD) calculated from Figure 4B was 0. 35 ng/mL, according to the formula: LOD = $3s/m$, where s represents the blank sample standard deviation (n = 3) and m represents the slope of the related PV calibration curve. These measurements were performed in triplicate to assess the reproducibility and precision of freshly fabricated cell sensors. The relative standard deviation (RSD) of the detection results were all <5%, showing acceptable performance.

Real Sample Measurements. To assess the utility of these sensors for rapidly recognizing target allergens from the complex food matrix, we used crucian carp, bream, and silver carp extra to test the performance of this sensor. As shown in Figure 5A, purified PV was applied to the gel and SDS–PAGE was performed. There was a major protein band at 12 kDa, which was identified by Coomassie Brilliant Blue staining (arrow in Figure 5A). This indicated substantial purification on PV. Then, the activation of cell sensors with three kinds of fish extracts also led to a rapid and robust increase in cell fluorescence intensity (Figure 5B). The concentrations and contents of PV in three fish samples calculated from the standard curve of the fluorescence intensity versus PV standards in Figure 4B are shown in Table 1. The results obtained using the RBL sensors were similar to those reported methods, which confirms that this biosensor can be applied effectively for the detection and prediction in real allergen samples.

Investigation of RBL Cell Sensor Specificity and Reproducibility. We also assessed the effectiveness of this new sensor for recognition of fish PV by challenging RBL sensor cells that were pre-sensitized with anti-fish PV antibodies, fish PV, shrimp allergen Pen a 1, and peanut allergen Ara h 1 (prepared in-house). Non-specific interactions between cells and antigens were excluded by challenging naive, unsensitized RBL sensor cells in parallel with pre-sensitized cells. Shrimp allergen Pen a 1 or peanut allergen Ara h 1 produced few observable responses (see Figure S3 of the Supporting Information). Therefore, it can be assumed that contamination with shrimp and peanut allergens would not influence sensor recognition of fish PV in heterogeneous mixed-food samples containing various allergens.

To demonstrate the reproducibility of this cell-based sensor, measurements were performed in triplicate with the same prepared RBL cells to assess reproducibility and precision (SD = 0.446 ± 0.04). Moreover, RBL cells were repeatedly activated

by anti-PV IgE and PV antigens within a 24 h interval. Results of fluorescence analysis show that reactivated RBL cells in response to PV levels retained 80% of the original value (as seen in Figure S6 of the Supporting Information), which well illustrates the reproducible characteristics of the sensor.

compound, the Maillard reaction leads to brown color melanoidins and flavor compounds including pyrazines, pyrroles, furans, oxazoles, and so on.[16,17] There have been many research studies into the Maillard reaction's products in terms of color and flavor.

Various analytical methods to determine the presence of 4-MI have been developed, based on gas chromatography−mass spectrometry (GC−MS), high-performance liquid chromatography (HPLC), and liquid chromatography−tandem mass spectrometry (LC−MS/MS).[17−19] These methods require expensive equipment and specialized technical skills. Therefore, development of an index such as color parameters or volatile compounds would be useful for determining the presence of 4-MI.

The specific aim of this study was to examine the effect of food additives in the formation of 4-MI and determine the correlation among color parameters, pyrazines as dominant flavor compounds, and 4-MI. A caramel model system was chosen that consisted of glucose and ammonium hydroxide (as class III) with food additives such as metal ions (Fe^{2+}, Ca^{2+}, Zn^{2+}, Mg^{2+}) and amino acids (cysteine, tryptophan), each at different levels.

MATERIALS AND METHODS

Reagents. 4-Methylimidazole (4-MI, purity ≥98%), 2-ethylimidazole (2-EI, purity ≥98%), D-glucose (purity ≥99.5%), sodium sulfite (purity ≥98%), ammonium hydroxide solution (purity ≥29%), acetic acid (purity ≥99.7%), bis-2-ethylhexylphosphate (BEHPA, purity ≥97%), and isobutyl chloroformate (IBCF, purity ≥98%) were purchased from Sigma-Aldrich Chemical Co. (St. Louis, MO). Isooctane, acetonitrile (MeCN), pyridine, and isobutyl alcohol (purity ≥99%) were Lichrosolv quality and purchased from Merck (Darmstadt, Germany). Magnesium sulfate ($MgSO_4{\cdot}7H_2O$) and zinc sulfate ($ZnSO_4{\cdot}7H_2O$) were purchased from Junsei Chemical Co. (Tokyo, Japan), and iron sulfate ($FeSO_4$) was purchased from Kanto Chemical Co. (Tokyo, Japan). Calcium sulfate ($CaSO_4{\cdot}0.5H_2O$) was purchased from Yukari Pure Chemical Co. (Osaka, Japan), and tryptophan (purity ≥99%) and cysteine (purity ≥99.5%) were purchased from Junsei and Fluka (Neu-Ulm, Germany), respectively. All reagents were analytical grade.

Standard stock solutions of 4-MI and 2-EI used as an internal standard (IS) were prepared in 0.1 M HCl at a concentration of 20 and 1 mg/kg, respectively. All the solutions were kept at 4 °C until used.

Sample Preparations of the Caramel Model Systems. Glucose and ammonium hydroxide both were dissolved in 30 mL of HPLC-grade water in a swing top bottle, each at a concentration of 1 M. To compare the influences of food additives on the formation of 4-MI, all additives were added to glucose/ammonium solution individually at three distinct concentrations: 0.1, 0.05, and 0.01 M. The food additives were Fe^{2+} (as $FeSO_4$), Ca^{2+} (as $CaSO_4$), Zn^{2+} (as $ZnSO_4{\cdot}7H_2O$), Mg^{2+} (as $MgSO_4{\cdot}7H_2O$), cysteine, sodium sulfite, and tryptophan. The caramel model system solutions were heated at 100 °C for 2 h in an oven to instigate the Maillard reaction and cooled under running cold water to room temperature immediately in order to stop the reaction progress. All samples were stored at 4 °C, until they were analyzed.

Analysis of 4(5)-Methylimidazole. The procedure to extract 4-MI from a sample was carried out in the manner specified in a previous study.[17] Each sample (100 μL) was added to 4 mL of phosphate buffer that was extracted from 8 mL of 0.1 M BEHPA in chloroform by mixing for 1 min and centrifugation at 3500 rpm for 10 min. A 7.5 mL portion of the chloroform phase was transferred to a second vial containing 4 mL of 0.1 M HCl and mixed again by vortexing for 1 min. After centrifugation at 3500 rpm for 5 min, a 1 mL aliquot of the aqueous phase was added with 100 μL of 2-EI used as IS, which was placed into a vial and mixed with 1 mL of MeCN−isobutyl alcohol−pyridine (50:30:20, v/v) and 120 μL of IBCF for derivatization by hand for 30 s. Subsequently, 500 μL of a 1.0 M sodium bicarbonate solution and 500 μL of isooctane were added, and the mixture was mixed for 4−5 s. Then, 2 μL of the upper layer was injected into the GC−MS system.

The determination of 4-MI was conducted using an Agilent gas chromatograph interfaced to an inert 5975 mass selective detector (Palo Alto, CA) with an electron impact (EI) ionization chamber and equipped with a 7683B Series injector/autosampler. A DB-5 ms column (30 m × 0.25 mm i.d. × 0.25 μm film thickness; J&W Scientific, Folsom, CA) was used. The injection was carried out in splitless mode at 270 °C. Helium was applied as a carrier gas with a constant flow of 1.3 mL/min. The oven temperature was programmed as follows: An initial temperature of 80 °C was maintained for 1 min and then elevated to 280 °C at 30 °C/min and then held for 1.83 min. The temperature of the MS transfer line was 280 °C. The mass spectrometer was operated by electron impact at 70 eV, in selective ion monitoring (SIM) mode. Ions at m/z 68, 82, 109, and 182 were used for 4-MI and those at 95, 109, and 196 for 2-EI with a dwell time of 100 ms each. The temperatures of the ion source and quadrupole were 230 and 150 °C, respectively. Agilent Chemstation was used to control the GC−MS system.

Color Measurement from the Caramel Model System. Color parameters of the prepared solutions from various caramel model systems were monitored by a Nippon Denshoku NE 4000 colorimeter, using the 1976 CIELAB system. The sample solution (200 μL) was diluted with 10 mL of distilled water, and the colors were measured in transmittance mode. The parameters were L^* (brightness; $L^* = 0$ for black, and $L^* = 100$ for white), a^* (red-green component; $-a^*$ = greenness and $+a^*$ = redness) and b^* (yellow−blue component; $-b^*$ = blueness and $+b^*$ = yellowness). The color differences were calculated by the expression: $\Delta E = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$.[20] To evaluate color changes, ΔE was calculated with L^*, a^*, and b^* values of the caramel model systems with different food additives added, with respect to those in glucose/ammonium hydroxide 1 M model system.

Analysis of Pyrazines in the Caramel Model System. Each sample (3 g) was weighed into a 20 mL headspace vial and sealed with an unlined crimp cap containing polytetrafluoroethylene (PTFE)/silicone septa (Agilent). The assayed SPME device was divinylbenzene/carboxen/polydimethylsiloxane (DVB/CAR/PDMS, 50/30 μm thickness) fiber (Supelco, Bellefonte, PA). After the samples were equilibrated for 5 min at 50 °C, the SPME fiber was inserted to extract chemicals for 30 min at 50 °C under magnetic stirring.

Analyses were performed using a GC−MS system equipped with a DB-Wax column (60 m × 0.25 mm i.d. × 0.25 μm film thickness; J&W Scientific, Folsom, CA). The SPME fiber was inserted into the injection port of the GC, which was in splitless mode, and maintained at 260 °C for 5 min. The oven temperature program started at 50 °C, increased by 3 °C/min to 220 °C, and stayed at 220 °C for 10 min. The temperature of the transfer line was 280 °C, and the mass spectrometer was operated by electron impact at 70 eV. Quantification was performed by a GC that was equipped with a flame ionization detector under the same conditions that were described for the GC−MS system. The quantitation of identified pyrazines was carried out with undecane as the internal standard.

Pyrazines were identified through comparison with the Kovats gas chromatographic retention index I, by comparing the mass spectra with their authentic compound and through Wiley 275 libraries.

Statistical Analysis. All experiments were performed in triplicate. The data were analyzed using one-way ANOVA tests, and Duncan's new multiple range test was used for comparison of significant differences ($p < 0.05$) between the replicates ($n = 3$).

RESULTS AND DISCUSSION

Measurement of 4-MI in Caramel Model System Solution. As mentioned earlier, 4-MI was not detected in caramel colors I or II but was identified in both colors III and IV. Thus, glucose and ammonium hydroxide, which create

[a]Values followed by the same letter in a given column are not significantly different at $p < 0.05$. [b]Glucose/ammonium hydroxide model system was used as a control group for calculation of color differences.

colors III through heating, were used as a control group of the caramel model system in the present study. In a previous study, the Maillard reaction was investigated by using a model system that consisted of a sugar and an amine compound, and 4-MI was found in the glucose/ammonium hydroxide model system at a level that ranged from 490 to 710 μg/mL.[21]

An absolute calibration curve was obtained (y = 0.7958x + 2.6264, R^2 = 0.9937) using 4-MI standard solutions with various concentrations (1, 5, 10, 20, 50, and 100 μg/mL). The recovery and precision of the caramel model system solution of glucose/ammonium hydroxide (1 M) with added sodium sulfite (0.1 M) were determined, and each test was replicated five times. The recoveries that were measured for samples spiked with 4-MI at two concentration levels (20 and 100 μg/mL) ranged from 84 to 111%. The precision of the interday and intraday analysis, expressed as the relative standard deviation (RSD), were 0.9% and 4.9−6.5%, respectively.

Table 1 shows the amount of 4-MI formed in the caramel model system solutions that include each food additive at a level of 0.1, 0.05, and 0.01 M. A glucose and ammonium hydroxide (1 M) model system was used as a control. As each group was compared to the glucose/ammonium hydroxide model system, a reduction of 4-MI was observed in most caramel model systems with the 0.1 M food additives. In

dx.doi.org/10.1021/jf502008q | J. Agric. Food Chem. 2014, 62, 6481−6486

particular, there was a significant reduction of 4-MI formation in the caramel model system with 0.1 M Fe^{2+}, but the amount of 4-MI increased in the caramel model system with the addition of 0.1 M Ca^{2+}.

When the D-glucose and ammonium hydroxide were heated, the amount of 4-MI formed was 556 ± 1.3 μg/mL. The addition of 0.1 M sodium sulfite increased the 4-MI formation by up to 583 ± 2.6 μg/mL (5%), whereas the formation level and reduction rate of 4-MI through the addition of food additives were 110 ± 0.7 (80%) in 0.1 M Fe^{2+}, 483 ± 2.0 (13%) in 0.1 M Mg^{2+}, 460 ± 2.0 (17%) in 0.1 M Zn^{2+}, 409 ± 4.4 (26%) in 0.1 M tryptophan, and 397 ± 1.7 μg/mL (29%) in 0.1 M cysteine. The degree of contribution to the reduction of 4-MI from food additives had the following order: Fe^{2+} > cysteine > tryptophan > Zn^{2+} > Mg^{2+}. The formation levels of 4-MI ranged from 110 ± 0.7 (0.1 M Fe^{2+}) to 452 ± 2.9 (0.01 M Fe^{2+}), from 483 ± 2.0 (0.1 M Mg^{2+}) to 576 ± 1.3 (0.01 M Mg^{2+}), from 656 ± 3.4 (0.1 M Ca^{2+}) to 652 ± 2.6 (0.01 M Ca^{2+}), from 460 ± 2.0 (0.1 M Zn^{2+}) to 581 ± 5.7 (0.01 M Zn^{2+}), from 409 ± 4.4 (0.1 M tryptophan) to 556 ± 1.8 (0.01 M tryptophan), and from 397 ± 1.7 (0.1 M cysteine) to 444 ± 0.8 μg/mL (0.01 M cysteine). As a higher concentration of food additive was added, apart from the case of Ca^{2+}, the amount of 4-MI created by the Maillard reaction solution decreased, while an especially low concentration of food additive was not sufficient to reduce the formation of 4-MI. Furthermore, the addition of 0.01 M of Ca^{2+}, Mg^{2+}, Zn^{2+}, cysteine, and tryptophan led to a higher level of 4-MI than the control caramel model system, which was the Maillard reaction solution of 1 M glucose and 1 M ammonium hydroxide without additives. These results clearly suggest that some food additives at an appropriate concentration have a positive effect on the reduction of 4-MI in the Maillard reaction. This effect of the food additives on the formation of 4-MI in the Maillard reaction system was not previously reported. As food additives could be used in the manufacturing of foods, adding these food additives may be useful for reducing the formation of 4-MI during the Maillard reaction process.

Color Differences in the Caramel Model System Solutions. Since the Maillard reaction induces a brown color with formation of melanoidins, color is one of the important factors when considering how much 4-MI is formed during the Maillard reaction. Table 2 shows the results obtained for three series of color differences: L^*, a^*, and b^*. Significant differences according to the Duncan post hoc test are indicated by superscript letters. The L^* values of the caramel model systems with added 0.1 M food additives including 0.1 M sodium sulfite decreased compared to glucose/ammonium hydroxide (1 M) model system, except for Mg^{2+} and cysteine. Contrarily, values of a^* increased in the same caramel model systems, denoting the rise of redness characteristics when adding food additives. The b^* values did not show a significant change for any caramel model system. Although the measurement of color from the Maillard reaction model systems has not been reported, the decrease of L^* and the increase of a^* were observed in the foods due to the brown pigment formation that was induced by the Maillard reaction.[22,23] In the studies of Wang et al. and Ramonaitytė et al., the absorbance of the Maillard reaction model system showed increases at 420 and 450 nm, respectively, with addition of metal ions as a result of the Maillard reaction, indicating that the addition of metal ions accelerated the formation of the final browning compounds.[24,25]

In order to determine the correlation between the 4-MI concentration and color, a linear regression analysis was performed on each L^*, a^*, b^*, and ΔE. The total color difference, expressed as ΔE, showed a lack of negative correlation with the 4-MI concentration ($r = -0.4826$). On the other hand, L^*, a^*, and b^* values had no significant correlation with 4-MI ($p < 0.05$).

Pyrazines Formed in Caramel Model System Solutions. Table 3 lists the 12 kinds of pyrazine detected in the study of the caramel model system solutions. The majority of the pyrazines detected were 2-methylpyrazine, with a peak area ratio (PAR) ranging from 2.27 to 6.29, followed by 2,6-dimethylpyrazine ranging from 0.84 to 2.56 and 2,3-dimethylpyrazine ranging from 0.10 to 0.33. It is generally known that pyrazines are among the typical products of the Maillard reaction between amino compounds and carbonyl compounds.[26] All of the 12 pyrazine compounds confirmed in the present study were consistent with the previous literature that had investigated the pyrazines that could be derived from the Maillard reaction.[26−29]

It was difficult to find a relatively substantial relationship between 4-MI and the pyrazines formed in the greatest amounts, whereas 2-ethyl-6-methylpyrazine was among the 12 kinds of pyrazine compounds that showed a correlation with the concentration of 4-MI. Figure 1 showed a negative correlation ($r = -0.8239$) between 4-MI and 2-ethyl-6-methylpyrazine, indicating that 2-ethyl-6-methylpyrazine is formed in inverse proportion to the 4-MI concentration ($p < 0.05$). When the 4-MI declined by 80% with the addition of Fe^{2+} into the glucose/ammonium hydroxide 1 M solution, the content of 2-ethyl-6-methylpyrazine increased from 0.03 to 0.21 PAR.

Figure 2 shows the proposed formation pathway of 4-MI and 2-ethyl-6-methylpyrazine from methylglyoxal on the basis of the previous studies.[13,21,26,30,31] Methylglyoxal, as the sugar-derived reactive intermediate during the Maillard reaction, reacts with ammonia. Interestingly, the nitrogen-containing reactive intermediates formed from methylglyoxal with ammonia can produce either 4-MI by interacting with formaldehyde or 2-ethyl-6-methylpyrazine by reacting with ethylglyoxal. Therefore, if the nitrogen-containing reactive intermediates generated 4-MI with formaldehyde, the formation of 2-ethyl-6-methylpyrazine might be reduced. Further study that elucidates a more accurate correlation between 4-MI and 2-ethyl-6-methylpyrazine will be needed.

4-MI investigated in the present study has received much attention from regulatory agencies as a possible carcinogenic compound. Therefore, it is important to find a way to reduce the 4-MI produced by the Maillard reaction. The results of the present study demonstrate that the addition of food additives such as metal ions and amino acids at an appropriate level could reduce the formation of 4-MI. With current results various food products such as a bakery product could be applied to reduce the amount of 4-MI. However, more detail application study would be carried out in the future. In addition, a correlation between 2-ethyl-6-methylpyrazine and the 4-MI concentration was determined. Since the analysis of 4-MI requires expensive technology and specialized knowledge, the correlation between color, pyrazine levels, and 4-MI levels could be useful for the evaluation of the 4-MI formed during the Maillard reaction.

compounds and as the chelating agent of alkoxides. As a bioactive compound, it shows great potential in microbiology, botany, and pest control as well.[5]

Because acetoin has broad usages, it is valuable to study its production. Although there is industrial natural acetoin available from several small fermentation plants, current commercial acetoin is mainly produced by chemical synthesis from fossil-based raw materials and then added into our foods as a flavor enhancer.[5] There are currently three main routes that can be used for the synthesis of acetoin: route A, exploiting the transformation processes from structural analogues such as diacetyl and 2,3-butanediol; route B, utilizing the hydrolysis processes from halogenated butanone; and route C, seeking a direct synthesis from aldehyde.

Route A. The main disadvantage of using diacetyl as the raw material for the production of acetoin is the high cost as diacetyl or related compounds are fine chemical products. There are also additional issues associated with high equipment requirements and more stringent reaction conditions and controls. If over-reduced, acetoin can be further converted to 2,3-butanediol, decreasing the reaction yield. Similar issues would occur if 2,3-butanediol is used as the raw material. For these reasons there has been no report of industrial uptake of this route.[6]

Route B. In this route butanone is usually used as the starting material, involving the first step of halogenation to make 3-halogenated butanone and the second step of hydrolysis to make acetoin (Figure 1, top). Methyl ethyl ketone is a commonly used raw material. Route B thus has much reduced raw material cost. In addition, it has milder reaction conditions, lower equipment specifications, and no special catalysts required either. It is thus not surprising to see its extensive uses in industry. However, the hydrogens on the α-position of butanone tend to have greater reactivity. Apart from the target halogen-substituted ketone, other reactions also occur to produce 1-substituted butanone, 3,3-dihalobutanone, and other derivatives, causing the yield reduction of the 3-halogenated product. Furthermore, under the alkali hydrolysis in step 2, byproducts such as 1-hydroxy-2-butanone make separation and purification more difficult.[7]

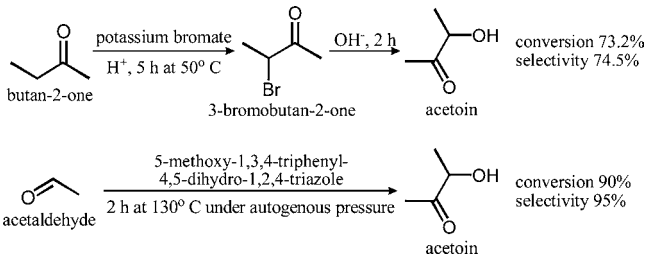

Figure 1. Industrial chemical synthesis routes of acetoin.

Route C. Acetaldehyde is used as the starting material, and the product is produced from condensation reaction under the catalysis of triazolium ylide or thiazolium ylide (Figure 1, bottom). This method also benefits from the lower cost of the starting material, less demanding equipment, fewer byproducts, higher yield, and simpler separation and purification, thereby enjoying more widespread industrial applications than route B. The main disadvantage lies in the complicated process of the catalyst preparation. Furthermore, acetaldehyde has a low boiling point. It is volatile and flammable and is difficult to transport and store. It can become easily lost during handling, resulting in environmental pollution and compromising safety. Most of these issues can be resolved by using paraldehyde but require the extra step of paraldehyde depolymerization, increasing the complexity and decreasing the yield.[8]

NATURAL ORIGINS OF ACETOIN

In contrast to the organic chemistry routes, however, acetoin can be generated by various natural or "green" routes. Generally speaking, natural acetoin has three origins, microorganisms, plants, and animals, and exists widely in some fermented products, fruits, crops, insects, mammals, and so on. Table 2 gives some examples of the natural origins of acetoin.

Table 2. Some Natural Origins of Acetoin

material	origin of acetoin

PHYSIOLOGICAL ROLES

Acetoin biogenesis has different physiological roles in different biological species. Current knowledge on the physiological functions of acetoin biogenesis can be summarized into three categories: biological functions in microorganisms, semiochemical functions in higher plants and insects, and biological functions in higher animals.

dx.doi.org/10.1021/jf5013902 | J. Agric. Food Chem. 2014, 62, 6487−6497

The biogenesis of acetoin in bacteria and yeasts has been well investigated partly because acetoin is tightly related to many traditional fermentative dietary products. Furthermore, just like acetic acid, ethanol, and lactic acid, acetoin/2,3-butanediol is another popular primary metabolite in bacteria. The ability to secrete acetoin is a routine classification marker (i.e., the Voges−Proskauer test) used in bacterial identification. In a sugar-rich culture medium, the fast assimilation of carbon source and accumulation of 2,3-butanediol other than organic acids can avoid cellular acidification. When the fermentable sugars are depleted, 2,3-butanediol is transformed back to acetoin, regenerating the reducing force (NADH or NADPH).[40] Acetoin is further reutilized as an alternative carbon and energy source.[41] In addition, acetoin biosynthesis is closely related to the branched-chain amino acid pathway and the regulation of cell life in certain bacteria.[4]

In higher organisms, the secretion ability of acetoin/2,3-butanediol is substantially weakened or completely abolished. However, due to its moderate volatile ability, characteristic odor, and chemical structure, acetoin has great potential as a semiochemical, especially in some insects (Table 3), flowers, and fruits (Table 2). Acetoin and some other characteristic fermentative products such as acetic acid and isovaleric acid convey a selective message of fermentation and sugar-rich substrates,[48] which is highly attractive to ants, bugs, beetles, flies, wasps, honeybees, and moths. Acetoin synthesis in plant cells was confirmed,[49] and together with other odorous compositions, acetoin gives these plants rich fragrances, attracting insects and higher animals to help their pollination, breeding, and propagation. However, on the opposite side, pests are attracted. Mass-trapping techniques have been developed using acetoin as an active component of artificial lures against the corresponding pests (as some references in Table 3).

Table 3. Acetoin as a Semiochemical in Insects

species	function

fly[46]	attractant
nymphalid butterflies *Kaniska canace* and *Vanessa indica*[47]	attractant
African fruit chafer *Pachnoda marginata*[48]	attractant

In the model organism fruit fly *Drosophila melanogaster*, acetoin has been recognized as a natural ligand for an olfactory sensory neuron[50] and the strongest known stimulus for the glomerulus VA2, which is associated with the close-range attraction of this fly to vinegar.[51] As a male pheromone, acetoin has been well studied in cockroaches. *Nauphoeta cinerea*, *Leucophaea maderae*, and *Henschoutedenia flexivitta* all belong to Oxyhaloinae and have the same mating behavior pattern. However, acetoin is the only compound common to the pheromone blends of the three species.[36] Acetoin is attractive to female *L. maderae* at low dosages (0.1−5 ng).[43] In *N. cinerea*, males must have the ability to secrete acetoin; otherwise, physiologically defective individuals without this ability will not be successful in female mate choice.[52] In male−male interactions, the secretion of acetoin plays an important role as well. Microgram levels of acetoin are released by aggressive cockroaches at high rates in strong attacks.[53] The dominant males release acetoin strategically to flaunt their dominance.[42] Therefore, acetoin is multifunctional in the world of cockroaches.

Acetoin is a well-known fermentative product, but it is perhaps less well-known to be the third most abundant volatile compound in fresh human sweat (ethanol, 15.1%; acetic acid, 10.9%; acetoin, 9.5%).[39] Acetoin was also detected in blood and urinary samples from normal male students after ethanol ingestion.[38] A pathway with acetoin as a key metabolite was proposed to explain the detoxication mechanism of acetaldehyde in mammals.[37,38] Under pathological conditions, acetoin has a role in regulating intermediate metabolism in mammalian systems.[54] However, the underlying mechanisms of acetoin biogenesis in higher organisms are largely unknown.

■ ACETOIN BIOSYNTHESIS

As shown in Table 2, acetoin biosynthesis widely exists in various food materials. In contrast, bacteria have very efficient acetoin biosynthesis systems.[5] Although the production of acetoin by eukaryotic cells is relatively less efficient, it is important due to its relationships with our foods. Acetoin biogenesis and dissimilation were seldom reported in archaea. Thus, the following discussion will focus on acetoin biosynthesis in eukaryotic systems with emphasis on enzymatic aspects by comparative study.

Currently, acetoin's precursor 2-acetolactate can be synthesized by five enzymes: α-acetolactate synthase (ALS, EC 2.2.1.6), acetohydroxy acid synthase (AHAS, EC 2.2.1.6), pyruvate oxidase (POX, EC 1.2.3.3), pyruvate decarboxylase (PDC, EC 4.1.1.1), and pyruvate dehydrogenase (PDH, EC 1.2.4.1). These enzymes share substantial similarities not only in amino acid sequences (Figure 2) but also in protein structures and catalytic mechanisms. All five enzymes are thiamin pyrophosphate (TPP)-dependent, and they all need a divalent metal ion such as Mg^{2+} to work properly. Furthermore, all five enzymes except ALS contain flavin adenine dinucleotide (FAD) in their structures. However, ALS replaced the position of FAD with reorientated amino acid side chains, and the overall structure of ALS remained unchanged.[55] Another good example of structural and functional similarity among the enzymes is that the D28A and D28N variants of yeast PDC resemble ALSs, which synthesize 2-acetolactate as a major product.[56]

All five enzymes follow a common mechanism of 2-acetolactate synthesis. Presumably, a pyruvate and an enzyme form an initial intermediate, an enzyme-bound lactyl-TPP (lactyl-TPP-E). Then the initial intermediate decarboxylates to form hydroxyethyl-TPP-E ("active acetaldehyde"). The active acetaldehyde reacts with another pyruvate to form 2-acetolactate (the so-called carboligase reaction).[49] POX, PDC, and PDH can also perform the carboligation of hydroxyethyl-TPP-E with an acetaldehyde moiety to direct yield acetoin.

However, although these five enzymes retain much commonality, evolution has taken place to fit differentiation and refinement functions. ALS exists only in some bacteria. The five genera in the ALS clade in Figure 1 are representatives of the most efficient acetoin producers.[5] ALS serves as the first key enzyme of the acetoin/2,3-butanediol biosynthesis pathway in these bacteria. Its sole duty is the condensation of pyruvate to

dx.doi.org/10.1021/jf5013902 | J. Agric. Food Chem. 2014, 62, 6487−6497

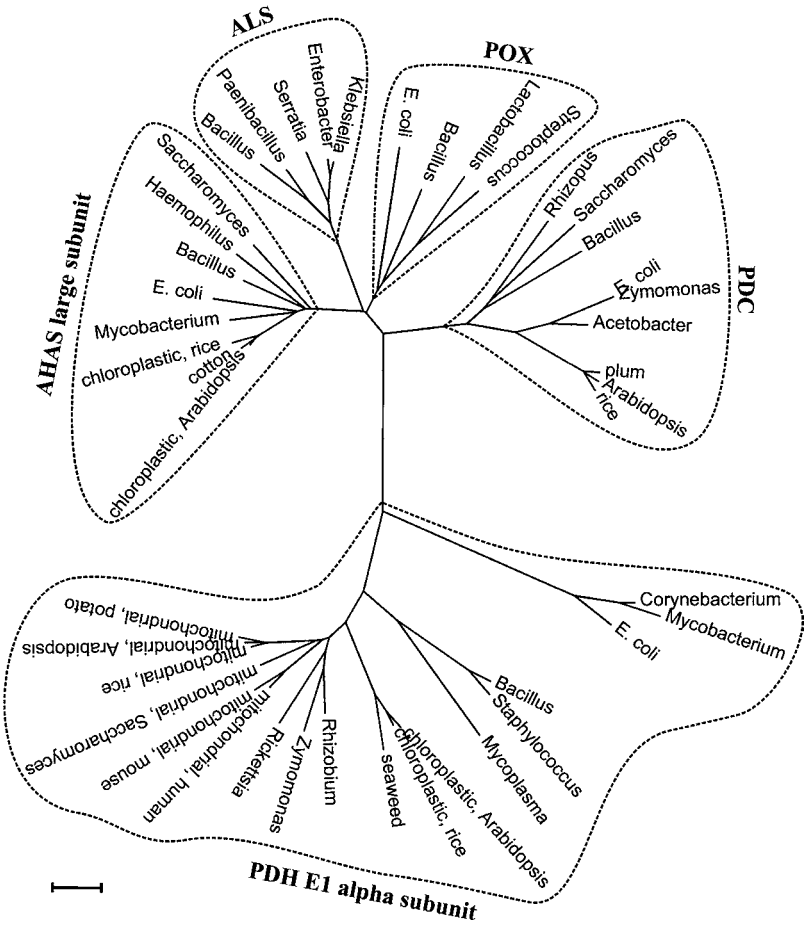

Figure 2. Simplified phylogenetic tree based on typical amino acid sequences of putative acetoin and/or 2-acetolactate biosynthesis enzymes. Representative sequences from typical species were extracted from the UniProt database. yield 2-acetolactate with highest biological efficiency. Another major enzymatic reason for efficient acetoin biosynthesis in these bacteria is that they apply a specific enzyme, 2-acetolactate decarboxylase (ALDC, EC 4.1.1.5), to catalyze the yield of acetoin from 2-acetolactate. Similarly, ALDC has not been found in eukaryotes or archaea. To avoid 2-acetolactate accumulation during beer brewing, ALDC genes were often integrated into the chromosomes of brewer's yeasts.

AHASs were mainly found in bacteria, fungi, and plants. It has vital roles in the branched-chain amino acids (BCAAs) biosynthetic pathway. Each AHAS has a larger subunit and a smaller subunit, which perform catalysis and regulation functions, respectively. AHAS catalyzes the same reaction as ALS does but with comparatively much lower efficiency. The product 2-acetolactate is then channelled into the synthesis pathway of leucine and valine. AHAS also turns pyruvate and 2-oxobutyrate into 2-aceto-2-hydroxybutyrate, which is an intermediate of the isoleucine biosynthesis pathway.

Although AHAS evolved from an FAD-dependent POX-like ancestor,[57] FAD works purely for structural integrity in AHAS. The ALS sequences form a close cluster, and they belong to a larger group that includes AHAS and POX in the phylogenetic tree (Figure 1), indicating that ALS came from the same POX-like ancestor as AHAS did.[55] However, mutations occurred in ALS; that is, amino acid substitutions took place and ALS became dispensed with the requirement for FAD, after separation from the AHAS evolutionary lineage. By structural evolution, ALS achieved great activity enhancement. For example, the turnover number of the ALS from *Klebsiella pneumoniae* is 533 s^{-1}. This speed is about 10-fold faster than that of any other AHAS.[58]

POX, PDC, and PDH have their own main functions in different organisms. Acetoin and 2-acetolactate are only the byproducts of the three enzymes under certain circumstances. This side reaction has been well studied, for example, POX from *Escherichia coli* and *Pediococcus pseudomonas*;[59] PDC from *Zymomonas mobilis*,[60] yeast,[56] mammalian liver,[61] and very likely plant cells;[49] PDH from *Streptococcus mutans*,[62] animal tissues,[63] and mammalian tumor mitochondria.[64] Therefore, it is the general consensus from these studies that probably most,

dx.doi.org/10.1021/jf5013902 | J. Agric. Food Chem. 2014, 62, 6487−6497

if not all, TPP-dependent enzymes have the ability to form acetoin by condensing the hydroxyethyl group of the active acetaldehyde intermediate with an acetaldehyde acceptor molecule to give acetoin.[59]

The rate of acetoin formation by POX of *E. coli* is much slower than the oxidative reaction (approximately $^{1}/_{10}$ of the oxidative rate).[59] In yeast, the formation of acetoin and 2-acetolactate was estimated to be about 1% of the total reaction catalyzed by PDC.[56] Even though this kind of side reaction takes place at very low levels, the apparent widespread presence may account for important roles as discussed under Physiological Roles.

INTERCONVERSIONS AND DERIVATIVES

As discussed above, acetoin can be generated from 2-acetolactate by ALDC or the direct carboligation of pyruvate and acetaldehyde by POX, PDC, or PDH. 2-Acetolactate is not a stable molecule, and it can decarboxylate spontaneously to yield acetoin at acid pH or high temperature. Acetoin can also be generated from diacetyl by reductase. The formation of diacetyl in vivo is generally accepted to be the nonenzymatic oxidative decarboxylation result of 2-acetolactate.[4] As a central intermediate, acetoin plays important roles in the production of various types of derivatives: diols, esters, glycosides, heterocyclic compounds, etc. (Figure 3). Most of the derivatives are of importance in foods due to their rich odors and potential dietotherapy functions.

Diols, Esters, Glycosides, and Other Possible Enzymatic Derivatives. 2,3-Butanediol, the reduced form of acetion, is another regular product of the acetoin pathway in bacteria.[5] The reversible transformation of acetoin and 2,3-butanediol is catalyzed by acetoin reductase (2,3-butanediol dehydrogenase) in vivo. Acetoin's precursor, 2-acetolactate, can be spontaneously decarboxylated to diacetyl. Even though this spontaneous decarboxylation remains in very low levels in different cultures, diacetyl can be easily detected, for example, by scent or odor due to its very low perceptible threshold (0.001 ppm in Emmentaler cheese).[9] Therefore, it is not surprising that acetoin, 2,3-butanediol, and diacetyl often occur simultaneously in fermented foods, for example, in cheese[9] and wine.[17]

In acetoin-degrading bacteria, diacetyl could have another choice of transformation other than the production of acetoin by reductase. In this case diacetyl is catalyzed by the acetoin dehydrogenase enzyme system (AoDH ES) to yield 3-hydroxy-3-methyl-2,4-pentanedione (common name, acetylacetoin), which could be further reduced to a diol product, 3,4-dihydroxy-3-methylpentan-2-one (common name, acetylbutanediol).[4] Xiao et al. proposed a new biosynthetic method of acetylbutanediol from acetoin using *Bacillus pumilus*, a safe industrial species.[65] Thereafter, a novel diol, butyrylbutanediol (2,3-dihydroxy-3-methylheptan-4-one), was discovered during a thermophilic fermentation study of acetoin and 2,3-butanediol.[66] Butyrylbutanediol was postulated to be the synthetic product of acetoin and butyryl-CoA, following a similar synthetic mechanism as acetylbutanediol. However, the biosynthesis mechanisms of these diols largely remained unclear. These small molecular diols may have multiple usages in chemical synthesis, foods, and cosmetics due to their reactive hydroxyl groups, high water solubility, and hygroscopic properties.[65]

Dietary fruits usually have pleasant odors, and volatile esters account for a large portion of the aroma compounds. Alcohol

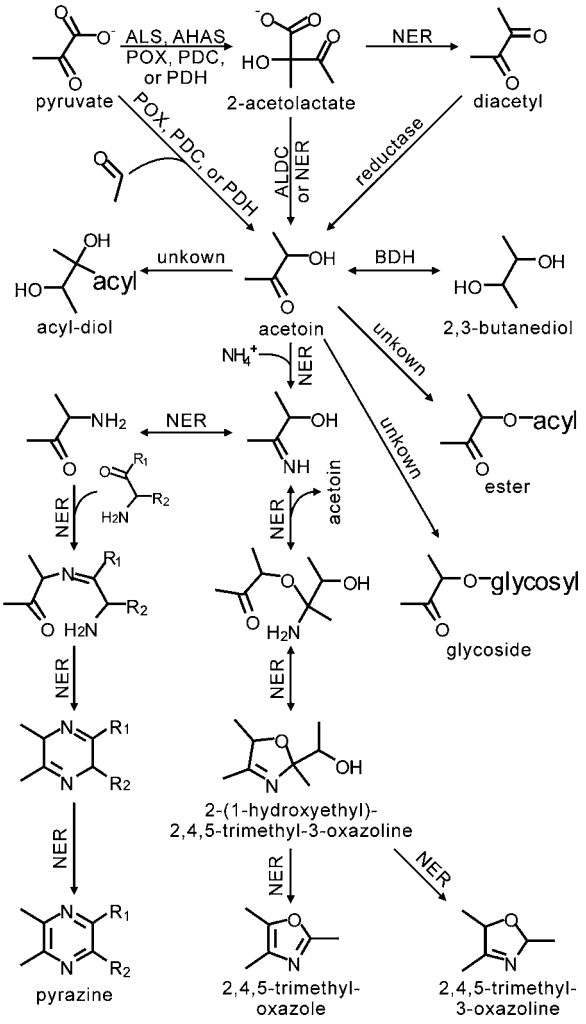

Figure 3. Generation pathways of acetoin and its derivatives. ALS, α-acetolactate synthase, which catalyzes the conversion of pyruvate to 2-acetolactate, was found only in bacteria. AHAS, acetohydroxy acid synthase, which catalyzes the synthesis of 2-acetolactate and 2-aceto-2-hydroxybutyrate, was mainly found in bacteria, fungi, and plants. POX, pyruvate oxidase, which converts pyruvate to acetate and carbon dioxide as its main catalytic function, was reported only in bacteria. PDC, pyruvate decarboxylase, which converts pyruvate to acetaldehyde as its main catalytic function, was found from microorganisms to higher plants. PDH, pyruvate dehydrogenase complex, which catalyzes the decarboxylation of pyruvate to acetyl-CoA as its main catalytic function, exists from lower prokaryotes to higher organisms including human beings. POX, PDC, and PDH can transfer pyruvate to 2-acetolactate and/or acetoin as a side reaction. NER, nonenzymatic reaction.

acyltransferases usually link alcohols to acyl moieties in the last step of ester biosynthesis. The hydroxyl groups of acetoin and 2,3-butanediol are also ready for the esterification reaction in some fruits. For example, plentiful acetoin esters and 2,3-butanediol esters were detected in pawpaw fruit,[18] and 2,3-butanediol acetates were also detected in banana extracts.[21] The odors and tastes of acetoin and 2,3-butanediol esters[18] support the popular characteristics of these fruits. Acetoin acetate and 2,3-butanediol acetate are sometimes present in some particular flowers, vinegars, and wines as well.[33]

Acetoin was found to be capable of acting as an aglycone and exist in glycosidically bound form in some vegetables and fruits. These glycosides are nonvolatile but may contribute to the

dx.doi.org/10.1021/jf5013902 | J. Agric. Food Chem. 2014, 62, 6487−6497

tastes. For example, acetoin was revealed as the major and key odor active aroma constituent (7.6 μg/kg) of ash gourd. Acetoin was also found to be the major constituent (24.00 mg/kg) existing as glycosidic conjugate in ash gourd.[25] In guar beans, the proportion of acetoin in free aroma constituents is even up to 95%, and acetoin is also the major component among the glycosidically bound aglycones in both guar beans (50%) and French beans (54%).[24] In lychee fruit acetoin was postulated to be a major characteristic aroma compound, but only a trace amount of glycosidically bound acetoin was detected.[22] Even until now, the formation mechanisms of these glycosides remain unknown. However, 2,3-butanediol-glucuronide was postulated to be the conjugation result of 2,3-butanediol and uridine diphosphate glucuronide by glucuronyltransferase in rats[37] and humans.[38] Therefore, the glycosidic bound reaction of acetion might be an enzymatic process in plant cells.

Acetoin could be precursors of other biological products. Speranza et al. postulated that the 2-butanol existing in distillates and wines most likely originated from 2,3-butanediol by the action of lactobacilli.[67] Yokota and Sasajima studied the enzymatic transformation of acetoin and D-ribose 5-phosphate to a monosaccharide, 1-deoxy-D-*altro*-heptulose 7-phosphate, by a transketolase mutant of *Bacillus pumilus*.[68] However, these two examples have no further or closely relevant reports.

Heterocyclic Compounds. Acetoin-derived heterocyclic derivatives include alkylpyrazines, oxazolines, oxazoles, and their homologues. Pyrazines are extensively used in food, agriculture, and medicine. Their occurrence is nearly ubiquitous in nature, and the alkylated ones are the most abundant among pyrazines.[69] According to the nature of the alkyl substituents, alkylpyrazines possess different flavors, but these flavors can be generally described as nutty, roasty, and toasty aroma.[70] Oxazolines and oxazoles are responsible for green, sweet, and nutty aromas and have strong sensory quality even at low concentrations. They have wide occurrence in processed foods such as coffee, soy sauce, wheat, and cooked beef.[71]

2,3,5,6-Tetramethylpyrazine (TTMP) is one of the main pyrazines found in Chinese vinegars,[73] tortillas,[26] rice cakes,[27] cocoa bean- or soybean-based fermented foods,[72] etc. In these foods, acetoin, sometimes with 2,3-butanediol and diacetyl, will always appear accompanied by the emergence of TTMP. TTMP is also a GRAS substance with FEMA No. 3237. Furthermore, TTMP is a biologically active ingredient in the medicinal plant *Ligusticum wallichii*. In addition to the flavoring contribution to foods, TTMP has potential dietotherapy functions. For example, TTMP is held to be good for cardiovascular and cerebrovascular health[74] and has a possible cognitive enhancement effect.[75] Therefore, research on TTMP has attracted widespread interests.

The formation mechanism of alkylpyrazines in vivo has two main controversial viewpoints:

(I) The enzymatic condensation biogenic pathway. This viewpoint is supported by only a few authors.[69] However, the enzymes or genes responsible for the condensation reaction have never been reported.

(II) The "Biochem-Chem" route. The precursors of alkyl pyrazines are prepared by biosynthesis pathways in vivo, but the subsequent condensation is a nonenzymic process. This route has gained convincing experimental support and obtained wider approval.

As early as 1988, Rizzi reviewed the possible formation mechanisms of food-related pyrazines and expressed his preference for the second mechanism.[76] In the same period, he observed the spontaneous formation of TTMP from acetoin and ammonium salts in water solution under mild conditions.[77] If other kinds of acyloins were supplied, other kinds of alkylpyrazines would be produced. During further studies on the reactions between acetoin and ammonia precursors under mild conditions, another major product, 2-(1-hydroxyethyl)-2,4,5-trimethyl-3-oxazoline (HE-TM-oxazoline), was identified.[78] The dynamic processes of TTMP and HE-TM-oxazoline were recorded in a 3 week storage study, and the mechanisms were postulated (Figure 3). Mechanistic studies of Fu and Ho supported these postulates, and another two heterocyclic derivatives, 2,4,5-trimethyl-3-oxazoline and 2,4,5-trimethyloxazole, were identified from an acetoin/ammonium acetate aqueous system.[79] Le Quéré et al. also hypothesized a chemical synthesis route of 2-alkyl-2,4,5-trimethyl-2,5-dihydrooxazole homologues in cheese from the precursors including acetoin, ammonia, and methyl ketones, which are abundant in cheeses.[10] If sulfide is present in acetoin/ammonium reaction systems, similar sulfur-containing heterocyclic compounds will be produced.[80]

HE-TM-oxazoline was manifested to be relatively unstable, and TTMP would be the main product either under an elevated reaction temperature[79] or in a prolonged storage time.[78] The dynamics of TTMP and its precursors during the industrial production process of a Chinese vinegar were investigated using GC-MS.[73] The results indicated that the main precursor of TTMP, that is, acetoin, was accumulated in the fermentation process, and then it condensed to TTMP during the subsequent storage period. The phenomenon is consistent with the "Biochem-Chem" route and the previous result of the 3 week storage dynamic study by Shu and Lawrence.[78]

Other kinds of alkylpyrazines and pentaheterocyclic compounds were often detected in acetoin-containing fermentation systems. For example, 2,3-dimethylpyrazine was found in tortillas[26] and rice cakes,[27] and 2,3,5-trimethylpyrazine was found in rice cakes[27] and Chinese vinegars.[11] During TTMP formation in a *Bacillus* fermentation process using glucose as the carbon source (actually the "Biochem-Chem" process), 2,3,5-trimethylpyrazine, 2-ethyl-3,5,6-trimethylpyrazine,[72] and a homologous product of 2,4,5-trimethyloxazole, 2,4,5-trimethylimidazole, were detected.[81] An extreme example is that a dozen kinds of alkylpyrazines, along with a very complex mixture of other volatile compounds, were also detected in a *Bacillus subtilis* fermentation process when cooked, roasted soybean cotyledons were applied as the substrate.[82] These diverse products might be closely related to the selection and pretreatment of raw materials for fermentation. Soybean cotyledons are rich in complex compounds, and the cooking and roasting processes will increase the complexity significantly. Shu used acetoin to react with amino acids at 250 °C and showed that all reactions between acetoin and α-amino acids generate TTMP and the corresponding Strecker aldehydes, indicating that alkylpyrazines could also be generated during food processing.[83]

Then, acetoin, sometimes with diacetyl, could be responsible for the generation of many kinds of heterocyclic derivatives, but these derivatives should share a common characteristic: each molecule has at least two adjacent methyl groups, a clear hallmark from the molecular structure of acetoin. Other kinds of alkyl heterocyclic compounds could be the derivatives of

[a]Acetoin's alkylpyrazine derivatives are not included here. [b]Data from the National Institute of Standards and Technology (http://webbook.nist.gov/chemistry/).

amino ketones, acyloins (hydroxyketones) other than acetoin, or diketones other than diacetyl. Amino ketones could be generated from cellular processes, for example, the metabolism of threonine.[70] Less common hydroxyketones and diketones could be produced by certain organisms.

ANALYSIS OF ACETOIN AND ITS DERIVATIVES IN FOOD MATERIALS

As discussed above, acetoin has various types of derivatives, but, generally speaking, these derivatives are not very difficult to identify and quantify because most of them are volatiles and can be determined using GC-MS techniques. Those nonvolatile derivatives, mainly glycosides per current knowledge, can also be determined by GC-MS after enzymatic[22] or acidic[25] hydrolysis of the glycosidic bonds. The identification of acetoin's alkylpyrazine derivatives, such as TTMP, is straightforward because the corresponding pure chemical standards are easily available and they have reference mass spectra in GC-MS workstations. However, the other derivatives are more complicated for confirmation, but representative ones have been synthesized or extracted from complex samples. Here, we show some of their MS data in Table 4.

The mass spectra of acetion, 2,3-butanediol, and diacetyl are also presented in Table 4 to provide comparison of the complex derivatives with these basic structures. Most of the molecules, except for the heterocyclic compounds, contain high abundance m/z 43 and/or 45. They are the characteristic fragments of acetoin, that is, $[CH_3CO]^+$ and $[CH_3CHOH]^+$, respectively. The diols and esters share another molecular fragmentation characteristic pattern in common; that is, these molecules are rather fragile in EI MS even when the ionization voltage is set at 20 eV.[18] To get the corresponding molecular ion peak and meanwhile rich fragments, CI MS has been proved to be useful from the results shown in Table 4. Of particular note is that some intermediates and products are very active due to the hydroxyl and/or carbonyl group(s). The components of the samples containing acetoin may change during storage.[78]

The analysis methods and quantitative results of acetoin and its derivatives in typical food materials are presented in Table 5. The overall feature is that no reliable clues can be drawn about the amount of acetoin or its derivatives in various foods. Even in the same food category, the differences are large. This mainly arises from uncertainties in the sources of raw materials and differences in processing methods, stages, etc.

In summary, great advances have been achieved in acetoin research, especially in microorganisms, during the past decades.[4,5] Current knowledge of acetoin and its derivatives in higher organisms is very limited and is mainly confined to the analysis of products using relatively simple methods, for example, GC-MS. However, due to the limitation of the gas chromatographic method, nonvolatile derivatives may have been overlooked. Still, the existing diverse results have led us into many unknown fields. The range of possible physiological roles and dietary functions of acetoin and its derivatives should not be underestimated. New experimental work should

Table 5. continued

food material	sample preparation and analysis methods	compound	concentration (ppm)
tortilla flour from USA[26]	high-flow dynamic headspace trapping, GC, GC-MS	acetoin	0.04
		diacetyl	0.06
corn tortilla from USA[26]	high-flow dynamic headspace trapping, GC, GC-MS	acetoin	0.31
		diacetyl	0.006
taco shell from USA[26]	high-flow dynamic headspace trapping, GC, GC-MS	acetoin	0.08
		diacetyl	nd
2 rice cakes from USA[27]	high-flow dynamic headspace trapping, GC, GC-MS	acetoin	av 0.675
		2,3-butanediol	av 0.050
		2,3-dimethylpyrazine	av 0.130
		trimethylpyrazine	av 0.245
Eucalyptus honey from Spain[28]	steam distillation, simultaneous distillation extraction, GC, GC-MS	acetoin	av 1.34, min 0.43, max 2.4
5 other monofloral honeys from Spain[28]			nd

[a]To be precise, diacetyl is not one of the derivatives, but one of the precursors of acetoin (Figure 3). However, because diacetyl belongs to the acetoin reaction system and has flavor importance, it is included in this table. [b]av, average. [c]min, minimum. [d]max, maximum. [e]nd, not detected.

investigate the acetoin series products in more categories of higher organisms using more kinds of analytical techniques, but, importantly, more attention should be paid to enzymes, genes, synthesis mechanisms, and the possible biological roles of these acetoin derivatives to achieve the goal of better control and use.

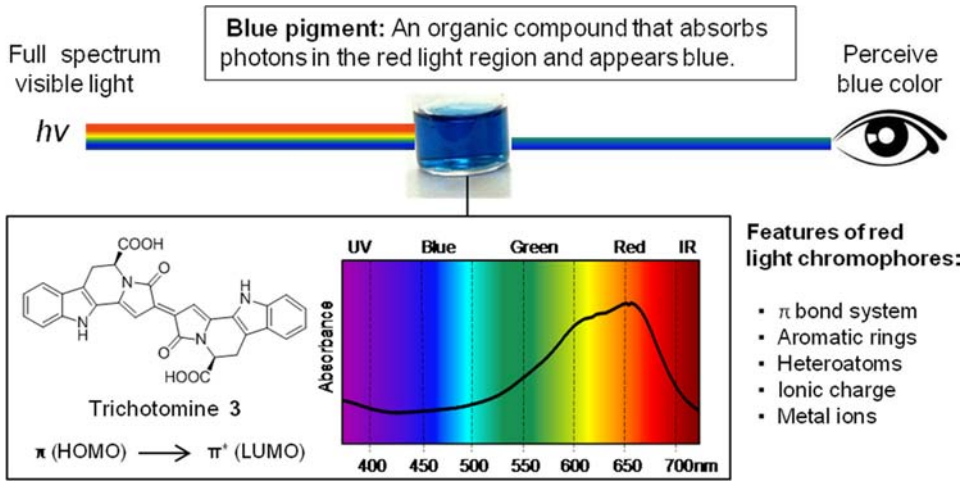

Figure 2. Color perception for a blue pigment using the visible absorbance spectrum of trichotomine (**3**) (λ_{max}, methanol, 660 nm) as an example. The typical properties of red light absorbing molecules are listed.

not absorbed, photons. Color can also result from diffraction or scattering of light. Only pigmentation by the absorptive processes of organic molecules is within the scope of this review. A *blue pigment* is defined as an organic molecule that absorbs red light (600 nm region) and appears blue by ordinary color perception (Figure 2). The origin of color in molecules, electron spectroscopic theory, and the processes of color perception are well-known.[10−12]

Why are blue pigments (red light absorbing molecules) relatively uncommon in nature? The answer lies in electronic absorption theory. When the energy of an incident photon matches an energy gap ($\Delta E = h\nu$) between molecular orbitals (σ, n, or π), the photon is absorbed by an electron that is promoted to the next higher energy orbital. Most molecules absorb ultraviolet photons by $\sigma \rightarrow \sigma^*$ and $\sigma \rightarrow \pi^*$ transitions. Far fewer molecules exhibit the lower energy $\pi \rightarrow \pi^*$ and n $\rightarrow \pi^*$ transitions that are required to absorb visible light, and these molecules appear to have color. Conjugation of π-bond systems can lower the HOMO → LUMO energy gap for $\pi \rightarrow \pi^*$ transitions to occur into the blue light region (400−500 nm, ΔE = 3.1−2.5 eV) and this produces red, orange, and yellow colors as in carotenoids.

Linear π-bond conjugation alone does not lead to absorption in the red light range (600−700 nm, ΔE = 2.1−1.8 eV). Blue pigments (red light absorbers) typically possess π-bond conjugation, aromatic ring systems, heteroatoms, and ionic charges. Also, organometallic and transition metal complexes are often brightly colored because their *d*-orbitals afford many lower energy electronic transitions. Heteroatom groups (−NH_2, −OH, =O, −Cl, etc.), sometimes called auxochromic groups, can further reduce the transition energies to produce the required bathrochromic shift. For example, red carotenoids can appear blue when complexed with iodine or converted to cations or through interactions with amino acid side chains such as those in blue carotenoproteins.[13] All of the blue pigments reviewed here contain two or more of these features. Compared with other pigments, natural blue pigments are uncommon because a more complex combination of molecular features is required to absorb red light.

IDEAL COLORANT PROPERTIES

Whether from natural or synthetic sources, all new color additives must meet stringent requirements before use. Gaining regulatory approval is the most critical step. The U.S. Code of Federal Regulations[14] provides details of the petitioning process. In addition, new colorants must meet targets for hue, stability, suitability for the target application, and cost. Natural colorants rarely match the intensity of FD&C dyes. Most natural and synthetic color additives have ε_{max} values on the order of 10^5 or 10^6.[7] Colorants with lower ε_{max} values must be used at higher levels to achieve the desired appearance, thereby increasing costs and the risk of off-flavors. Colorants must also be stable enough to avoid significant degradation throughout distribution and sales of both the ingredient and the food or beverage, which might include storage from days to years at refrigerated or ambient conditions. Common causes of instability include heat, light, oxygen, acid, and exposure to oxidants such as ascorbic acid and trace metals. Product developers might have additional requirements such as water- or oil-soluble formulations for specific applications. Insoluble forms may be necessary to prevent colorant migration. Finally, new natural colorants must be sourced from raw materials with a commercial supply and at levels that make extraction economically feasible.

NATURAL BLUE PIGMENTS

Blue colors are not uncommon in nature. Although brilliant blue shades can be seen in flowers, berries, bird feathers, and mushrooms, these colors derive from very different sources. Blue color in animals is typically caused by reflection of blue light from nanoscale structures (schemochromes). Examples include blue bird feathers (*Sialia* sp.) and iridescent butterfly wings (*Morpho* sp.). This effect is not limited to the animal kingdom. Quandong fruits (*Santalum acuminatum*) appear bright blue but contain no blue pigments.[15] Anthocyanins are the sources of most blue, red, and purple colors in plant leaves, berries, and roots. Plants may also contain blue copper metalloproteins for redox functions. Cyanobacteria often contain blue light harvesting proteins for photosynthesis such as phycocyanin. Some fungi and microorganisms produce a wide variety of blue secondary metabolites, which are often made in response to environmental stress or predators. Blue chromophores from underexplored sources such as marine microorganisms have been reviewed previously.[16]

Searching natural products databases for blue pigments is not straightforward, because they are organized by attributes such as molecular weight and composition instead of color. Publications often neglect to report the absorbance spectra or colors of newly identified natural products. In addition, the color of a given

dx.doi.org/10.1021/jf501419q | J. Agric. Food Chem. 2014, 62, 6498−6511

compound may vary with conditions such as pH, solvent, and the presence of trace metals or other compounds. Given these challenges, no review can be comprehensive. This review organizes organic blue chromophores by structural class. Inorganic blue compounds, such as copper salts, are not included.

Flavanoids. Anthocyanidins (Figure 3) and their glycosides, anthocyanins, are ubiquitous in the plant world and are

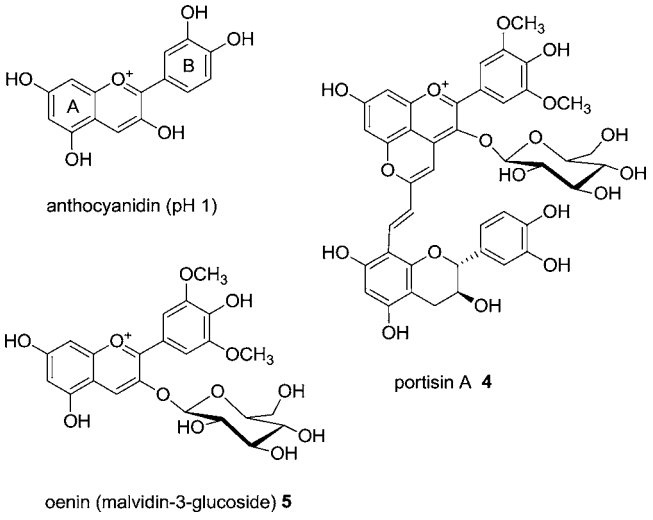

Figure 3. Chemical structures of blue flavanoid-derived natural products.

responsible for many of the colors of flowers and fruits.[15,17,18] Anthocyanins from fruits and vegetables are commonly used as food colorants, but their color is highly pH dependent. The blue quinoidal form predominates under neutral or alkaline conditions, whereas the red flavylium cation forms under acidic conditions (Figure 3). At least six pH-dependent structural forms are known.[1,19−21] Stability is a function of both structure and complex interactions such as acylation and copigmentation.[21]

Research into the biosynthesis and modification of anthocyanins is extensive and has been driven by the desire for blue cultivars of flowers such as roses and carnations. A recent review summarizes these complex pathways.[22] Anthocyanin color is influenced by its structure, intra- and intermolecular interactions, and pH. Increasing hydroxylation of the B-ring shifts anthocyanins to bluer shades, as seen with delphinidin, the pigment responsible for the blue color of delphiniums.[21,23] The formation of complexes with copigments such as flavones and with metal cations can also shift the hue.[21] A familiar example is the use of aluminum compounds to shift the color of hydrangea blossoms from pink to blue.

After synthesis, anthocyanins are transported to vacuoles for storage. The color of anthocyanins within the vacuole is a function of the anthocyanin type, its structural form when complexed with other components, and the vacuolar pH. These vacuoles have been suggested as food colorants.[23] The internal pH of the vacuole is higher than that of typical foods, so the anthocyanins will appear blue. It is not clear if anthocyanin vacuolar inclusions can survive the rigors of food processing and storage or if they can be produced efficiently on a commercial scale.

Complex blue anthocyanin-derived compounds such as portisin A (**4**) have been isolated from aged red wine.[24−26] At low pH, the portisins show a bathochromically shifted absorption maximum (portisin A (**4**), λ_{max} pH 1, 587 nm) relative to common anthocyanins such as oenin (malvidin-3-glucoside) (**5**) (λ_{max} pH 1, 538 nm). Portisins are purple rather than pink at low pH values.[24,26] These compounds face the same challenges as other new food colorants. Additional studies will be required to determine solubility and stability. These compounds are present at such low levels that isolation from wine is not feasible; new processes for commercial production will be required.

A thorough discussion of the structural variety and stability of anthocyanins is beyond the scope of this review. The chemistry, structural diversity, biosynthesis, distribution, safety, and stability of these compounds have been reviewed extensively.[1,27−29] The structures of some of these anthocyanin pigments are shown in Figure 3.

Quinones and Quinoids. The inclusion of carbonyl groups within an aromatic ring system can lead to the absorption of the lower energy visible spectrum photons required to produce absorption in the visible spectrum. Dyes based upon the 9,10-anthraquinone skeleton (Figure 4) were first isolated and synthesized for commercial use in the 19th century.[30,31] Varying substitutions on this skeleton for specific auxochromic effects have resulted in dyes of every color. Not all quinoid dyes are suitable for food use due to biological activity, and few are blue under acidic conditions.

Many natural blue anthraquinone or quinoid dyes are blue at alkaline pH but red or orange at neutral or acidic pH. One example is the chemotherapeutic anthraquinone drug daunorubicin (**6**). Isolated in 1964 from *Streptomyces peucetius*,[32] daunorubicin was among the first chemotherapeutic compounds derived from soil microbes. Daunorubicin interchelates between DNA strands and is prescribed for acute myeloid and lymphocytic leukemia.[33]

Streptomyces coelicolor excretes the benzoisochromaquinone actinorhodin (**7**) and its analogues at yields of up to 3 g L^{-1} of fermentation medium.[34−36] The actinorhodins have been proposed as food colorants, but as with most anthraquinones, they are blue only under alkaline conditions, limiting their use in foods and beverages. The actinorhodins show weak antibiotic activity but are not cytotoxic. For example, the MIC of actinorhodin against *Staphylococcus aureus* is 30 μg mL^{-1},[36] whereas its LD_{50} in mice is >15 g kg^{-1}.[34] Other blue benzoisochromaquinone-like antibiotics include granaticin B (**8**) and related analogues isolated from various *Streptomyces* species.[37−39] The granaticins are cytotoxic and not blue at low pH. Diosindigo A (**9**) is a blue bis(quinone) that has been isolated from the heartwood of at least seven *Diospyros* botanical species, but little additional information such as stability is available.[40,41]

Natural anthraquinoid compounds are rarely blue under acidic conditions, but there are a few exceptions for those with an extended aromatic ring system. These include the dark blue microbial metabolites anthracyclinone-blue B (**10**) from a *Streptomyces galilaeus* mutant[42] and kyanomycin (λ_{max} methanol, 600 nm, ε = 11480), from *Nonomuria* sp. NN22303.[43] Another blue compound with an extended quinone structure, ventilein A (**11**) (λ_{max} methanol, 645 nm), was isolated as a minor constituent from *Ventilago calyculata* root bark[44] and from *Ventilago goughii*.[45] Blepharismin and stentorin are red photosensory pigments from the protists *Blepharisma japonicum*[46] and *Stentor coeruleus*[47] with a fused eight-ring conjugated quinone system identical to hypericin (bright red). Photoreaction products of the blepharismins, such as oxyblepharismin A (**12**) and analogues, are blue.

Quinoid pigments are responsible for the blue colors of many fungi such as Basidiomycetes.[48] The bluing reactions of several mushroom species are due to the oxidation of conjugated

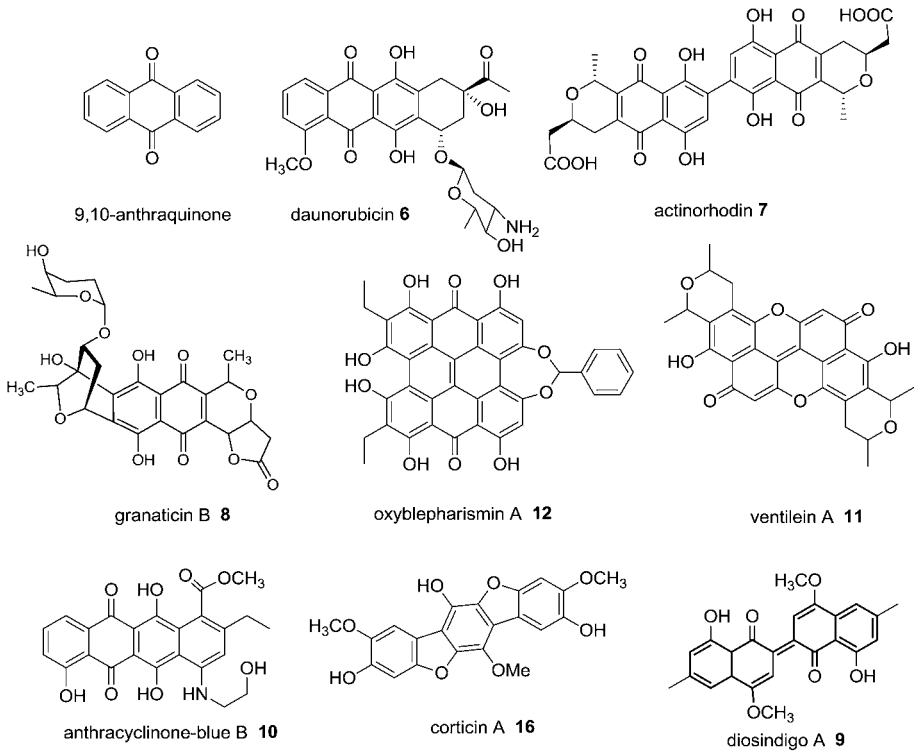

Figure 4. Chemical structures of some blue-colored natural quinoids and quinones.

furanoquinones to blue anionic compounds such as gyrocyanin,[49] variegatic acid (**13**),[50] xerocomic acid,[51] and chamonixin.[52] Although relatively little research has been reported on these furanoquinone oxidation products, anecdotal evidence of subsequent fading of blue-bruising fungi suggests that these oxidation products are unstable. The variegatic acid anion (**14**) fades to brown in <60 min.[50] The meroterpenoid quinone albatrellin (**15**) was identified as the source of blue color in the skin of *Alabtrellus flettii* (Basidiomycete) fruiting bodies.[53] The pigment is blue in chloroform or dichloromethane, but violet in methanol (λ_{max} methanol, 535 nm, ε = 3200). Corticin A (**16**), a derivative of the benzofuranoquinone fungal pigment thelephoric acid, was determined to be the blue pigment of the fungus *Corticium caeruleum*.[54] A bis(quinoid) fungal metabolite containing an imine linkage, scleroderris blue (**17**), was isolated from the canker fungus *Gremmeniella abietina*[55,56] and later from *Penicillium herquei* as a zinc complex.[57] The compound is intensely blue colored (λ_{max} CH_2Cl_2, 612 nm; ε = 50000) but relatively unstable; scleroderris blue can be converted to scleroderris green with a weak reducing agent.[56] Popolohuanone B (**18**), a pigment containing an aminoquinone chromophore, was isolated from a blue-purple *Dysidea* sp. sponge.[58] Structures of blue pigments of the quinoid or quinone class are shown in Figures 4 and 5.

Linear Tetrapyrrole Alkaloids. Tetrapyrroles cover every color of the visible spectrum. Blue tetrapyrroles are responsible for the blue coloration of bruises.[59] Biliverdins, heme degradation products found in bile, are among the few natural blue compounds in the animal kingdom. The bile pigment biliverdin-IX_a (oocyan) (**20**) is responsible for the pigmentation of bird egg shells.[60,61] The light harvesting protein phycocyanin in *Cyanobacteria* contains a bound linear tetrapyrrole phycocyanobilin (**19**) as the blue chromophore.[62,63] The difference between the intense blue phycocyanobilin and the heme byproduct urochrome, the source of yellow color in urine, is extended conjugation across four pyrrole rings via one additional unsaturation. Phycocyanin is commercially extracted from the alga *Spirulina platensis* and is used as a colorant in confections. However, phycocyanin is not stable enough for most food and beverage applications.

Bactobilin (**21**),[64,65] isolated from *Clostridium tetanomorphum* and *Propionibacterium shermanii* (used in Swiss cheese production), is one of the few known bacterial bile pigments.[66] Bactobilin shares the same blue chromophore as phycocyanobilin but has eight methyl ester side chains. The stability of bactobilin has not been reported, but because alkylation or acylation enhances the stability of chromophores such as anthocyanins, bactobilin should be more stable than phycocyanobilin.

A blue prodigiosin tetrapyrrole (**22**) analogue of the cytotoxic microbial red pigment prodigiosin has been isolated from a variety of sources including a mutant *Serratia marcescens* strain,[67] the marine bacterium *Hahella chejuensis* KCTC 2396,[68] some blue marine ascidians,[69,70] a blue bryozoan,[71] and the nudibranch *Nembrotha kubaryana*.[72] *N. kubaryana* might derive its color from feeding on blue ascidians and bryozoans. The prodigiosin tetrapyrrole is distinguished from bile pigments by having directly coupled pyrrole rings rather than methine spacers. Unlike the bile tetrapyrroles, prodigiosin and its analogues usually exhibit cytotoxic and antimicrobial activities.[73] Structures of these blue tetrapyrrole pigments are shown in Figure 6.

Phenazine Alkaloids. Hundreds of natural phenazine molecules have been isolated and characterized, primarily from *Pseudomonas* and *Streptomyces* species.[74,75] The colors of these compounds span the entire visible spectrum. One of the first identified and best known phenazines is the blue compound pyocyanin (**23**), the highly cytotoxic cystic fibrosis virulence factor from *Pseudomonas aeruginosa*.[76,77] Other blue phenazines include the *N*-terpenoid-substituted metabolites phenazinomycin (**24**) isolated from *Streptomyces* sp. WK-2057 mycelia[78,79]

dx.doi.org/10.1021/jf501419q | J. Agric. Food Chem. 2014, 62, 6498−6511

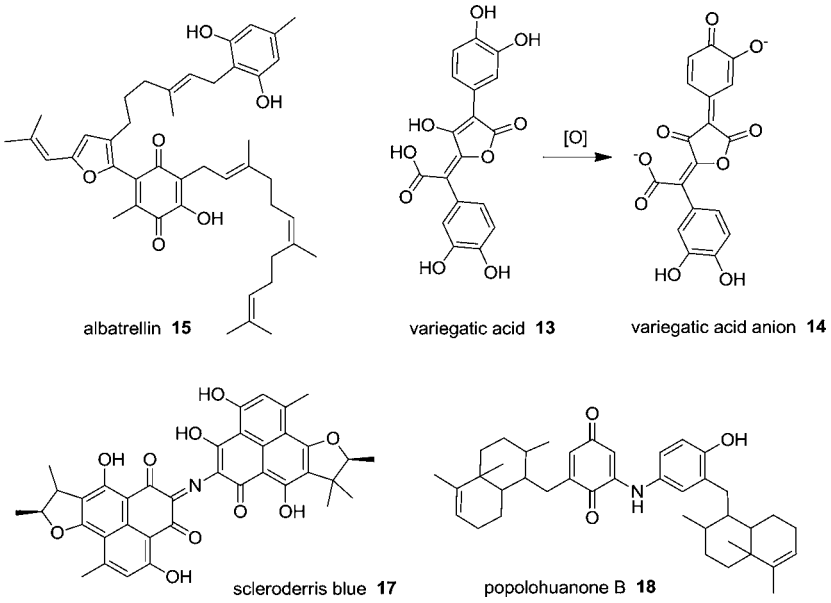

Figure 5. Chemical structures of some additional blue natural quinoids and quinones.

and lavanducyanin (**25**) from *Streptomyces aeriouvifer*.[80,81] The absorption maxima and molar absorptivities of phenazinomycin (λ_{max} methanol, 745 nm, ε = 6600) and lavanducyanin (λ_{max} methanol, 705 nm, ε = 1700) are similar to those of pyocyanin (λ_{max} methanol, 746 nm, ε = 5800). Both show broad visible absorbance in the far-red light region with relatively low molar absorptivity. Benthocyanin A (**26**) from *Streptomyces pruni-color*[82,83] contains an additional lactone ring and has a higher molar absorptivity in the red light region presumably due to the larger chromophore surface area (λ_{max} methanol + HCl, 638 nm, ε = 16200; λ_{max} methanol + NaOH, 616 nm, ε = 18400). Although many blue pigments of the phenazine class are blue under acidic conditions, they are usually cytotoxic or otherwise biologically active,[75,79,81] thereby excluding them from consideration as food colorants. Structures of these blue phenazines are shown in Figure 7.

Indole Alkaloids. A small fraction of the thousands of known indole alkaloids are blue. Indigo dyes from the tropical plants woad (*Isatis tinctoria*) and true indigo (*Indigofera tinctoria*) have a long history of use in textiles.[30,84] The bis(indole) indigotin (**27**) is responsible for the blue color of indigo-based dyes[85] and today is produced synthetically. Its disulfonate sodium salt, FD&C blue no. 2, is produced for the food and cosmetic industries.[7] Indigotin and its derivatives lack the pH and light stability often required for food and beverage products. Blue 5,5′-dichlorinated analogues of indigotin, akashins A (**28**), B, and C, were recently isolated from the marine *Streptomyces* sp. GW48/1497.[86,87] Whereas indigotin is not cytotoxic, the akashins showed activity against cancer cell lines with IC_{50} values near 3 μg mL^{-1}.[87] Candidine (**29**), a blue alkaloid originally isolated from *Candida lipolytica*,[88,89] is a constituent of the traditional Chinese medicinal herb qing-dai (*Indigo naturalis*).[90] Its bis(indole) chromophore is similar to indigotin.

Kusagi berries from the Asian shrub *Clerodendron trichotomum* have a bright blue skin.[91] Extracts of these berries have been used to dye textiles.[92,93] The berry skin contains the blue bis(indole) alkaloid trichotomine (**3**) and its glycosides,[94−96] which are structurally more complex and intensely colored than indigotin (Figure 8). The larger absorptive surface area of the compound imparts a blue color with a molar absorptivity similar to that of

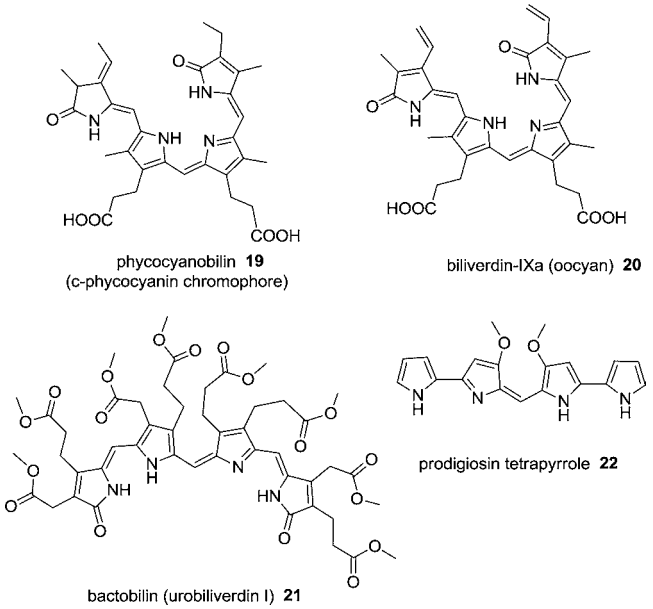

Figure 6. Chemical structures of some blue-pigmented linear tetrapyrroles.

FD&C blue no. 1 (**1**). Trichotomine and its derivatives are among the very few compounds that produce the same shade of blue as FD&C blue no. 1.

Violacein, a deep violet indole alkaloid first reported 1888, was isolated from *Chromobacterium violaceum*, a species native to the Amazon River.[97] It has been studied extensively for its biological activities[98] and as a textile dye.[99] Prodeoxyviolacein (**30**), a biosynthetic precursor of violacein, is blue in acid and red under neutral or alkaline conditions.[100,101] Deep red or violet microbial and sponge pyrroloquinoline metabolites containing the indole moiety have been reported.[102] Ammosamide A (**31**), isolated from the marine *Streptomyces* CNR-698, is similar in structure but contains an unusual thio-γ-lactam group contributing to its deep blue color.[103] The thionyl group ammosamide A slowly oxidizes in air to form a carbonyl group and the red compound ammosamide B. Both compounds are active against a variety of

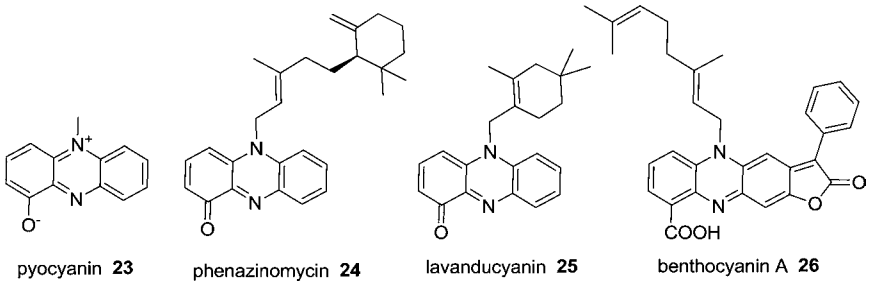

Figure 7. Chemical structures of natural blue phenazine molecules.

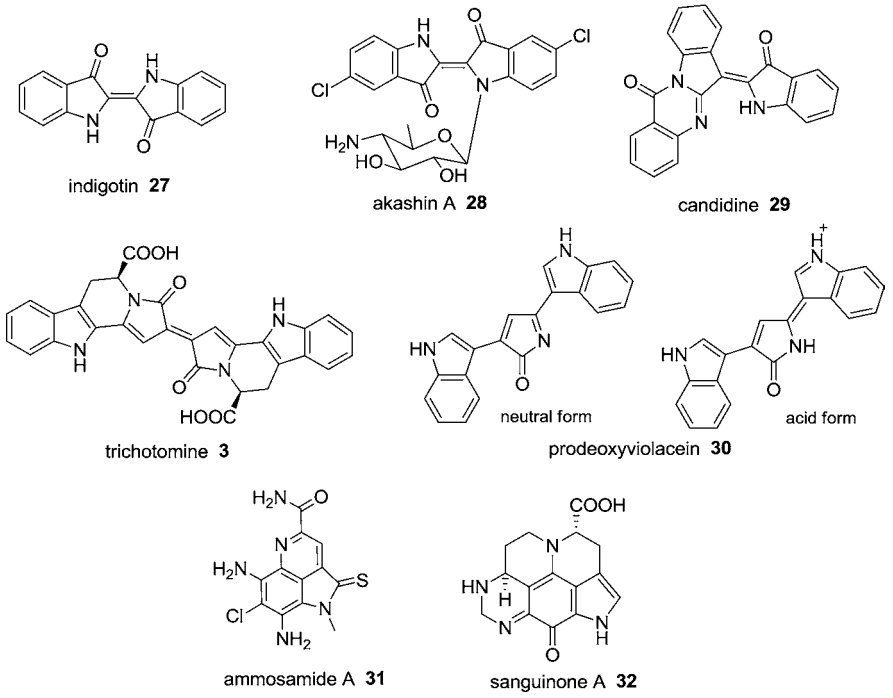

Figure 8. Chemical structures of indole-derived blue natural products.

cancer cell lines with IC_{50} values from 1 μM to 20 nM. The structurally related blue alkaloid sanguinone A (**32**) has been isolated and characterized from the mushroom *Mycena sanguinolenta*.[104] Data on its biological activity and stability have not been reported. See Figure 8 for the chemical structures of these indole-derived blue pigments.

Pyridine Alkaloids. Blue pigments containing 3,3′-bipyridyl chromophores (Figure 9) have been isolated from a variety of microbial sources. Indigoidine (**33**) and indochrome A (**34**) (also known as amylocyanin) were isolated in the 1960s as part of studies on the structurally related blue pigments of *Arthrobacter* sp., *Erwinia* sp., and *Corynebacterium* sp.[105−107] An unnamed blue pigment (**36**), a 3,3′-bipyridyl uncatalyzed oxidation product of 2,3,6-trihydroxypyridine, was identified as a side product of 2-hydroxypyridine metabolism in *Nocardia* sp.[108,109] Compound **36** was shown to be identical to the acidic hydrolysis product of indigoidine (**33**).[110] Similar but unidentified blue pigment byproducts such as "nicotine blue"[111] have been observed during the metabolism of various pyridine compounds by *Arthrobacter* sp.,[110−112] *Pseudomonas* sp.,[107] *Corynebacterium* sp.,[113] and *Bacillus* sp.[114] More recently, an *N*,*N*-dialkylated indigoidine analogue (**35**) was isolated and characterized from the deep sea marine microorganism *Shewanella violacea* DSS12.[115] Lemonnierin (**37**), a blue metabolite produced by *Pseudomonas lemonnieri*, contains a similar 3,3′-bipyridal blue chromophore.[116,117] Glaukothalin (**38**), isolated from the marine microorganism *Rheinheimera* sp. HP1,[118,119] contains a rare bis(oxazepinone) chromophore reminiscent of the 3,3′-bipyridyl chromophores. Glaukothalin has a LD_{100} of 0.1 mg mL^{-1} against brine shrimp. Little information is available concerning the stabilities and biological activities of most of the 3,3′-bipyridyl pigments.

Gardenia blue and huito juice are iridoid-derived mixtures with limited approval as food colorants. Colorless iridoids from *Genipa americana* and *Gardenia jasminoides* extracts can be converted to blue colorants by reacting the aglycones with a primary amine in the presence of oxygen.[1,120−122] The resulting mixture of polymeric pigments is not well-defined, but characterizations of some brown-red intermediates[123,124] and of a blue dimer product genipocyanin G_1 (**39**)[125] have been reported. The reaction converts the iridoid scaffold (**40**) into an aromatic 2-pyridine [5 + 6] scaffold (**41**) that has visible absorbance properties distinct from the indole ring.[126] Structures of these pyridine-derived compounds are shown in Figure 9.

Azulenes. The azulene (**42**) [5 + 7] ring system (Figure 10) is the only reported blue organic chromophore found in nature that does not contain heteroatoms. Guaiazulene (**43**) and related blue sesquiterpenes such as lactarazulene (**44**) and

dx.doi.org/10.1021/jf501419q | J. Agric. Food Chem. 2014, 62, 6498−6511

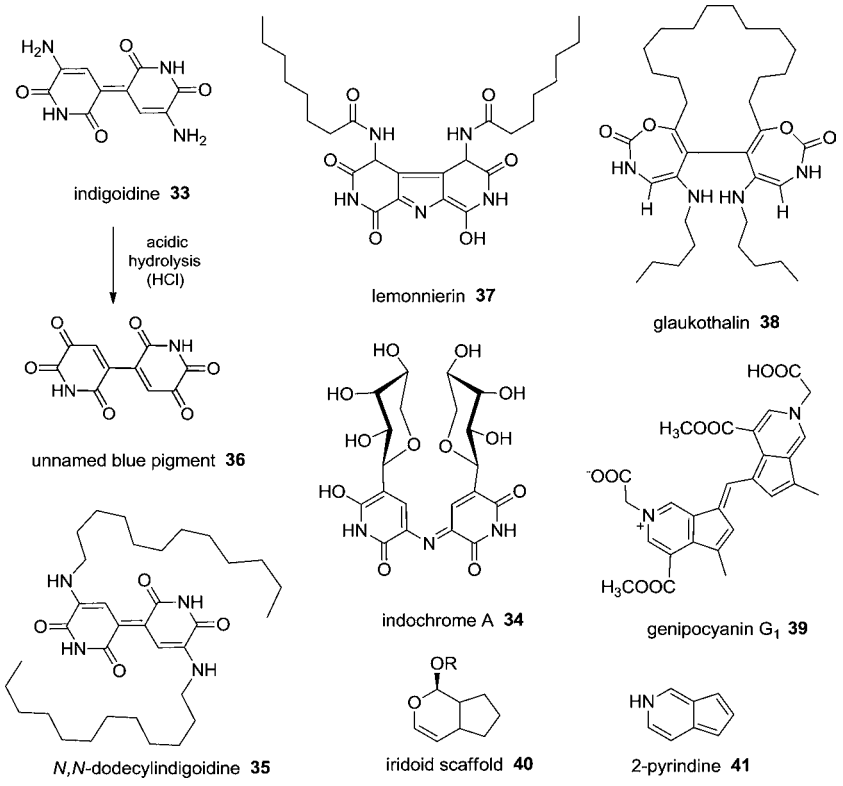

Figure 9. Chemical structures of blue pyridine-derived natural products.

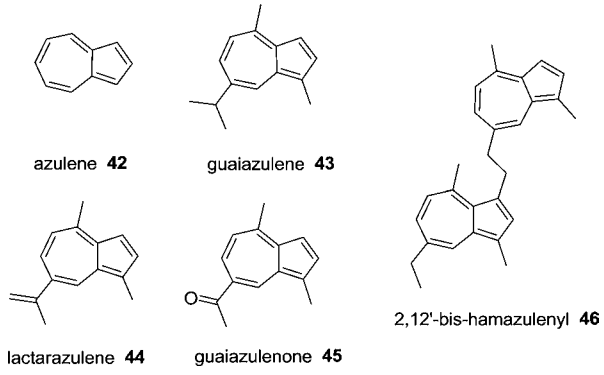

Figure 10. Chemical structures of some natural blue azulenes.

guaiazuleneone (**45**) have been isolated from various fungi (*Lactarius* sp.) and plant essential oils (*Matricaria* sp., *Artemisia* sp.).[127−129] Blue chlorinated and brominated analogues of guaiazulene and dimeric guaiazulene derivatives (anthogorgienes A−O) have been isolated from marine Gorgonian species.[130,131] Most dimeric azulene derivatives are not blue but purple or green. The 2,12′-bis(hamazulenyl) (**46**) dimer isolated from *Ajania fruticulosa*[132] is blue because the saturated ethyl linkage does not significantly alter the azulene chromophore. Azulene and its derivatives tend to be lipophilic, have low molar absorptivities, and poor stabilities.[127,131,134,135] Guaiazulene is approved for use in cosmetics by the U.S. FDA.[136] Structures of some blue azulene natural products are shown in Figure 10.

Organometallics and Metalloproteins. Blue metalloproteins and organometallic complexes have been identified in natural sources. A ferric ceratenolone complex (**47**) is thought to be responsible for the blue color of the pine rot fungus *Ceratocystis minor*[137] and a pale blue colored vanadium V^{4+} complex, amavadin (**48**) (Figure 11), has been isolated from

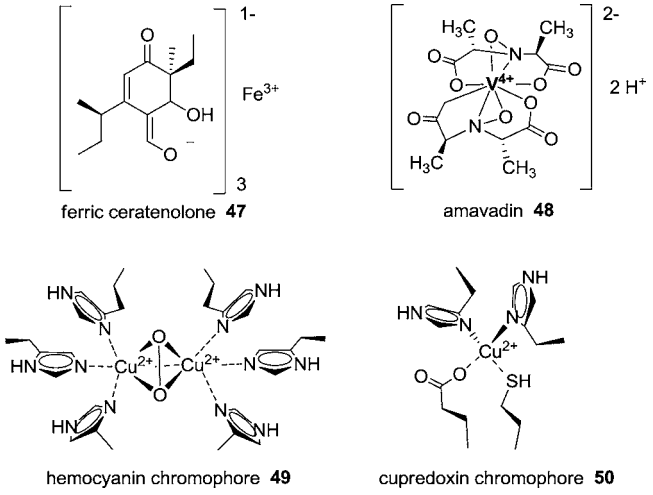

Figure 11. Chemical structures of some natural blue organometallic complexes.

Amanita muscaria, which is known to accumulate vanadium.[48,138] Crustaceans and arthropods have blue blood due to the respiratory protein hemocyanin instead of the iron-based hemoglobin.[139] The hemocyanin chromophore (**49**) contains a binuclear copper active site that reversibly binds O_2 molecules (Figure 11). Each copper is coordinated by three histidyl residues. Other blue copper proteins occur in some plants and bacteria, where they usually serve biosynthetic functions involving electron transfer.[140] Stellacyanin[141] and plastocyanin[142,143] are type I copper binding proteins (cupredoxins) common to vascular plants. The blue cupredoxin chromophore (**50**) found in stellacyanin contains a cupric ion coordinated by one cysteine and two histidines (Figure 11).[141] Other type I copper binding proteins include cuscacyanin and phytocyaninin

from cucumber,[144,145] umecyanin from horseradish root,[146] and allergen Ra3 from ragweed.[147]

Bacterial type I copper-binding proteins include amicyanin from *Thiobacillus versutus*[148] and *Paracoccus denitrificans*[149] as well as halocyanin from the halophilic archaea *Natronomonas pharaonis*.[150] Halocyanin is one of the few pigmented compounds known from the Archaea. The blue arsenate reductase enzyme azurin (14 kDa) found in some *Pseudomonas* sp. and *Alcaligenes* sp. also contains the blue cupredoxin chromophore (Figure 11).[151,152] Auracyanin (12.8 kDa) from

Table 2. Natural Blue Compounds According to Biological Source

compound name (no.)	compound class	biological sources
	Synthetic	
FD&C blue no. 1 (**1**)	triphenylaryl	none
FD&C blue no. 2 (**2**)	bis(indole)	derivative of natural indigo dye
	Animal	
biliverdin-IX$_a$ (**20**)	linear tetrapyrrole	*Aves* (egg shell); mammal bile pigment
oxyblepharismin A (**12**)	naphthodianthrone	*Blepharisma japonicum* (protist)
popolohuanone B (**18**)	diterpene azaquinone	*Dysidea* sp. (marine sponge)
	Plant	
oenin (**5**)	anthocyanin	*Vitis vinifera* skin, aged wine
portisin A (**4**)	pyranoanthocyanin	*Vitis vinifera*; aged wine
diosindigo A (**9**)	benzoisochromaquinone	*Diospyros sp.* (tree; heartwood)
ventilein A (**11**)	naphthodianthrone	*Ventilago goughii* (root bark)
indigotin (**27**)	bis(indole)	*Indigofera tinctoria* (Indigo plant)
trichotomine (**3**)	bis(indoloid)	*Clerodendron trichotomum* (fruit callus)
genipocyanin G$_1$ (**39**)	2-pyrindine	*Gardenia jasminoides, Genipa americana*
azulene (**42**)	azulene	*Artemisia* sp. (oil), *Lactarius* sp. (fungi)
guaiazulene (**43**)	sesquiterpene	*Matricaria chamomilla* (oil), various fungi
lactarazulene (**44**)	sesquiterpene	*Artemisia* sp. (oil), *Lactarius* sp. (fungi)
2,12′-bis(hamazulenyl) (**46**)	bis(azulene)	*Ajania fruticulosa* (essential oil)
	Fungal	
variegatic acid anion (**14**)	benzofuranoquinone	Basidiomycete fungi
albatrellin (**15**)	meroterpenoid quinone	*Alabtrellus flettii* (Basidiomycete)
corticin A (**16**)	bis(benzofuranone)	*Corticium caeruleum* (fungus)
candidine (**29**)	bis(indoloid)	*Candida lipolytica* (yeast)
	Fungal	
sanguinone A (**32**)	indoloquinone	*Mycena sanguinolenta* (fungus)
scleroderris blue (**17**)	azobisquinone	*Gremmeniella abietina* (fungus)
	Microbial	
daunorubicin (**6**)	anthraquinone	*Streptomyces peucetius*
actinorhodin (**7**)	benzoisochromaquinone	*Streptomyces coelicolor*
granaticin B (**8**)	benzoisochromaquinone	*Streptomyces violaceoruber*
anthracyclinone-blue B (**10**)	tetracyclic quinone	*Streptomyces galilaeus* mutant
phycocyanobilin (**19**)	linear tetrapyrrole	*Spirulina* sp., common among cyanobacteria
bactobilin (**21**)	linear tetrapyrrole	*Clostridium tetanomorphum*
prodigiosin tetrapyrrole (**22**)	linear tetrapyrrole	*Serratia marcescens, Hahella* sp. (marine)
pyocyanin (**23**)	phenazine	*Pseudomonas aeruginosa*
phenazinomycin (**24**)	phenazine	*Streptomyces* sp. WK-2057 mycelia
lavanducyanin (**25**)	phenazine	*Streptomyces aeriouvifer*
benthocyanin A (**26**)	phenazine	*Streptomyces prunicolor*
akashin A (**28**)	bis(indole)	*Streptomyces* sp. GW 48/1497 (marine)
prodeoxyviolacein (**30**)	bis(indoloid)	*Chromobacterium violaceum*
ammosamide A (**31**)	thiopyrroloquinoline	*Streptomyces* CNR-698 (marine)
indigoidine (**33**)	3,3′-bipyridoid	*Corynebacterium insidiosum*
indochrome A (**34**)	3,3′-bipyridoid	*Arthrobacter polychromogenes*
N,N-dodecylindigoidine (**35**)	3,3′-bipyridoid	*Shewanella violacea* DSS12 (marine)
blue pigment (unnamed) (**36**)	3,3′-bipyridoid	*Arthrobacter* sp., *Nocardia* sp.
lemonnierin (**37**)	3,3′-bipyridoid	*Pseudomonas lemonnieri*
glaukothalin (**38**)	bis(oxazepinone)	*Rheinheimera* sp. HP1 (marine)

Chloroflexus aurantiacus is similar in structure to azurin but serves a role in photosynthesis.[153] Rusticyanin (16.5 kDa) from *Thiobacillus ferrooxidans* has the highest redox potential and best acid stability among the cupredoxin proteins.[154,155] Nevertheless, rusticyanin showed a color loss of 50% after 2 weeks at pH 2.0 and 4 °C.[154] Consequently, none of these copper proteins has sufficient stability for use as a food colorant.

Unidentified Blue Pigments. The source of blue coloration of many marine animals remains underexplored. A novel class of blue chromoprotein was recently isolated from the barrel jellyfish *Rhizostoma pulmo*, but the structure of the chromophore has not been determined.[156] Studies of the blue pigmentation of *Pollicopora* sp. and *Acropora* sp. corals led to the isolation of still unidentified chromoproteins.[157] An investigation of abalone shells in Japan has resulted in the partial characterization of a novel blue compound (electrospray MS m/z 581.8, $[M - H]^-$), but the structure remains unknown.[158] Investigations of the consumer preferred greening of cultured oyster[159] led to the isolation and partial characterization of a blue polyphenolic substance, marennine (λ_{max} water pH 8, 672 nm, $\varepsilon = 7200$) from an associated marine diatom, *Haslea ostrearia*.[160,161] Although its structure has not yet been determined, marennine (~10 kDa) is not composed of peptide, flavanoid, anthocyanin, or hydrolyzable tannin units and is not a metal complex.

Blue pigments observed in some fungi such as *Penicillin* sp. and *Hypocrea* sp. have been investigated but remain unidentified[162,163] due to challenges in isolating sufficient material for analysis. Some *Psilocybe* sp. fungi bruise blue when the tissue is broken and exposed to air, and the pigment structure is unknown but thought to be a psilocybin-related or indole oxidation product.[164] An unidentified water-soluble and unstable pigment reported from a soil strain of *Pantoea agglomerans* remains uncharacterized.[165] *Bacillus subtilis* var. *aterrimus* ATCC 6461 excretes an unidentified blue-black substance that is believed to be melanin related.[166] Our attempted characterization found the pigment too unstable for isolation. Future work to isolate and characterize blue compounds from natural sources will certainly continue to reveal novel blue chromophores.

Potential New Colorant Additives. The challenges of developing a new blue colorant cannot be overstated. The colorant must meet targets for hue, color intensity, and solubility. Ideally, it should be stable to heat, acid, light, and oxygen. The pigment should not contribute flavor or interact with other ingredients. Raw materials and processes must be in place for commercial production. Even if all of these criteria are met, the new colorant must be safe and go through the petitioning process for new color additives to get regulatory approval for use. This may require extensive safety and toxicity testing. Petitioning

Table 3. Summary of Leading Blue Colorants and Natural Colorant Candidates

compound name	compound class	λ_{max} (nm)	ε (M^{-1} cm^{-1})	acid color	commercial colorant applications
		Synthetic			
FD&C blue no. 1 (**1**)	triphenylaryl	629 (w)[a]	134000	blue	widespread commercial use in beverages and food
FD&C blue no. 2 (**2**)	bis(indole)	607 (w)	7920	blue	commercial textile dye; limited food applications
		Natural			
trichotomine (**3**)	bis(indoloid)	658[b] (chl)[a]	70000	blue	textile dye and natural ink (Japan)
guaiazulene (**43**)	azulene	648 (acn)[a]	407	blue	cosmetics
phycocyanobilin (**19**)	tetrapyrrole	604 (m)[a]	17100	blue	solid packaged food formulations
gardenia blue (**39**)	2-pyrindine	595[c] (w)	43700	blue	used in food (Asia); skin and hair dye (South America)
portisin A (**4**)	pyranoanthocyanin	587 (m) (A)	82900	purple	none
actinorhodin (**7**)	benzoisochromaquinone	640 (w) (B)	25300	red	none

[a](A), acidic conditions; (B), alkaline conditions; (w), water; (m), methanol; (chl), chloroform; (acn), acetonitrile. [b]For trichotomine dimethyl ester. [c]For the genipocyanin G_1 dimer.

must be repeated in every region with a separate regulatory process.

Table 1 summarizes the published information on the blue pigments covered in this review. Table 2 provides additional information on the sources of these natural blue pigments. As previously discussed, these compounds must meet stringent criteria before being considered for use in foods. Ideally, the natural blue pigment should have a shade and brilliance similar to those of FD&C blue no. 1. Visible λ_{max} and ε_{max} data are provided in Table 1 for comparison. New color additives must be safe, stable, and effective in the target application. Commercial production requires an abundant supply of the raw material and high pigment concentrations for economical extraction. Most of the reviewed pigments have not been investigated as potential colorants, and so specific data on human safety, application stability, and commercial production are not available. Nonetheless, it is apparent from published data that none of the blue pigments cited in this review are likely to meet all of these criteria.

Table 3 lists the most promising candidates in the opinion of the authors. Very few of the compounds listed in Table 1 have extinction coefficients approaching that of FD&C blue no. 1, so higher concentrations would be required to achieve the same appearance in food applications. In general terms for the structure classes, the phenazines are toxic, the azulenes and tetrapyrroles lack robust stability, and many of the quinoids and flavanoids are not blue in acid. The indole alkaloids are blue in acidic conditions but tend to have bioactivity or toxicity. Scarce data exist for the bipyridal pigments. Fungal and microbial secondary metabolites show great structural diversity and are good candidates for production on an industrial scale.[167,168] Unfortunately, compounds from these sources are often produced as part of a defense mechanism and have biological activities that render them unsuitable for food use.

The portisins come close to providing the desired color, but additional information about their stabilities and solubilities is required. Furthermore, portisins are found at only very low levels in wine, so an alternate pathway for commercial production will be required. Trichotomine is among the few pigments considered a good match for FD&C blue no. 1 in terms of shade and intensity in acidic solutions. Trichotomine has limited water solubility and stability, but its glycosylated derivatives are far more soluble and may be more stable. Research is currently limited by the limited supply of kusagi berries and the low concentration of pigment in these berries. It will be challenging to develop an alternate method of production because the biosynthetic pathway has not been identified. Anthocyanin and trichotomine derivatives are among the best candidates for new blue colorants.

Food and beverage producers continue to look for a naturally derived alternative to FD&C blue no. 1. The previous sections reviewed known naturally derived organic blue compounds. These compounds fall into seven structural classes and are derived from a broad range of sources. Blue colors in nature often arise from optical effects of reflected light rather than from blue pigment molecules. Anthocyanins are the primary source of blue in fruits, vegetables, and flowers, but as their color is pH dependent, they appear pink in most foods and beverages. Fungi and microorganisms produce a diverse array of blue compounds, often in response to environmental stress or predators. The associated biological activities of these compounds so far have rendered them unsuitable for food use. The best candidates for new blue color additives, anthocyanin and trichotomine derivatives, will require significant investment for development and regulatory approval.

Table 2. Characteristics of Grape-Derived Odorants Important to Chardonnay Wine Typicity[a]

name and structure	aroma descriptor(s)	threshold (μg/L)	reported content in Chardonnay (μg/L)
linalool 	fruit, citrus[28,29]	25[30b]	2.0 – 142[31,32]
α-terpineol 	floral, musty, orange[33]	250[30b]	0.3 – 181[31,34]
1,1,6-trimethyl-1,2-dihydronaphthalene (TDN) 	kerosene, petrol[35]	2[36c]	1 – 30[37]
β-damascenone 	stewed fruit, apple, peach[28,33]	0.05[38d]	66 –170[39]
3-oxo-α-ionol 	spicy[40]	N.A.[e]	19 – 2674[32,40]
3-sulfanylhexan-1-ol 	passionfruit, grapefruit[41]	0.06[41f]	0.010 – 0.148[42]
3-sulfanylhexyl acetate 	box tree, passion fruit[43]	0.004[43f]	0.006 – 0.100[42]
4-methyl-4-sulfanyl-pentan-2-one	box tree[41]	0.0008[41f]	0.0007 – 0.023[42]
4-ethylguaiacol 	spice, phenolic[44]	33[30b]	0.2 – 50[40,45]
4-ethylphenol 	horse stable, medicinal, leather, phenolic[46,47]	440[48g]	<1 – 1194[49,50]
4-vinylphenol 	spicy, pharmaceutical[29]	180[51g]	44 – 638[29]
4-vinylguaiacol 	smoke, phenolic[52]	40[38d]	2.9 – 410.6[34,53]
methyl vanillate 	vanillin[46]	3,000[54f]	N.A.[e]

[a]Compounds are included in this table on the basis that they are present in grape berries or, more often, have precursors which are present in berries that are modified during fermentation or aging; that is, they are not produced de novo by winemaking microorganisms. Nonetheless, they may also be associated with other aspects of wine production, for example, storage in oak barrels. [b]11% aqueous ethanol solution containing 7 g/L glycerol and 5 g/L tartaric acid; pH adjusted to 3.4. [c]Calculated in a Chardonnay wine. [d]10% aqueous ethanol solution. [e]N.A., data not available. [f]10% aqueous ethanol solution; pH adjusted to 3.5. [g]Model aqueous alcohol solution.

means that the pathway for water to move back from the berry to the vine closes as cell vitality decreases, effectively stopping water backflow and late-ripening weight loss (shriveling).[16] Due to its anisohydric character, Chardonnay possesses a higher hydraulic conductance, which enables it to recover more rapidly from water stress after irrigation. Under water stress conditions, the decrease in stomatal conductance that Chardonnay undergoes is lower when compared to that of isohydric varieties, which in turn enables this variety to sustain a higher photosynthetic level and capacity.[18]

Chardonnay is undoubtedly a commercially important variety for the world's wine-producing nations, and its popularity among consumers is driven by the underlying chemical composition of the wines. In particular, aromas and flavors, resulting from volatile compounds derived from grapes, fermentation, and aging, are important to the quality of Chardonnay wines and, therefore, contribute to consumer liking.[19−22] The reported impacts of different viticultural and production practices that influence the aroma and flavor profiles and perceived quality of Chardonnay wines are summarized in this review. Future directions for research into factors that contribute to the differences in Chardonnay aroma composition are also outlined.

WINE AROMA AS AN INDICATOR OF QUALITY

Quality is a very subjective notion that, among other factors, drives the price a bottle of wine might fetch in the market. Wine quality depends not only on the physicochemical composition of the wine but also on what the consumer expects from it. Expectation will vary depending on the type of wine and from which standpoint quality is viewed from: young wine versus aged wine; producer versus consumer; low involvement versus high involvement level consumer.[23] Individual consumers will define this concept differently depending on their expectations and needs.[24] Various authors describe wine quality in terms of its fitness for purpose and the absence of faults,[19,23,25−27] but these terms are more related to production and establish only a very basic level of quality.

Consumers also rate quality according to how much pleasure it affords them[23] (which is too subjective to use as a parameter for production), ongoing trends, and wine flavor in particular.[23]

The flavor or "style" of a wine depends on its chemical composition; this relates to perceptions of astringency, bitterness, and acidity, among others, due to nonvolatile components, but relies particularly on the type and concentration of volatile molecules contributing to wine aroma. For Chardonnay wines, the most relevant aroma compounds are listed in Tables 2–4. A recent, but somewhat limited, study by Saliba et al.[21] of 21 commercial Australian Chardonnay wines identified at least five distinct styles (A–E), which are outlined in Figure 1. The presence of particular odorants such as diacetyl, thiols, and esters above their aroma thresholds allows the perception of attributes such as "butter", "tropical fruit", and "citrus" (Tables 2–4). These attributes in turn characterize the different styles described by Saliba et al.[21] and consequently have a major impact on Chardonnay quality and acceptance by consumers. However, the identification of strong links between Chardonnay grape and wine composition remains a holy grail. If wine producers are to fully exploit the capability of producing wines of a targeted style and quality for a specific market segment, a detailed understanding of Chardonnay impact odorants and the contribution of grape precursors and winemaking inputs is paramount in helping to address this need.

The advancement in extraction and analytical techniques has allowed scientists to delve further into the precursors and volatile molecules that contribute to the aroma of most wine varieties. However, given the wide array of existing styles and production techniques available to winemakers, the makeup of Chardonnay wine aroma and its relationship to quality have yet to be completely comprehended. Nonetheless, despite all of the possible combinations of enological techniques, studies by authors such as Jaffre et al.[55] and Ballester et al.[56] have demonstrated that a common olfactory representation (or prototype, as Ballester et al.[56] described it), independent of vintage and origin, does exist for Chardonnay wines among industry experts. It should be remembered, however, that it is the opinions and perceptions of consumers that matter in the marketplace, and these are underpinned by their notions of quality.

Ongoing research appears to be delving deeper into the understanding of Chardonnay wine quality and the different factors that affect it. The literature covers an array of fields, from studies on how quality is perceived by consumers[55,57,58] to the effect of winemaking techniques to incorporate more flavor, character, and uniqueness, such as the use of new yeast strains and sequential inoculation and thermotreatment of grapes, among others.[59−63] Particular interest exists among researchers in understanding "minerality", which is an essential (although somewhat poorly characterized) attribute of some of the most famous Chardonnay wines in the world such as those from Chablis and Burgundy.[64] Given the changes in global climate, studies are also required into the adaptation of viticultural practices and clone selection to continue producing high-quality wines, particularly as related to a drive to reduce alcohol levels. Even though anecdotal knowledge exists among producers as to the quality and style of fruit that can be obtained from each different Chardonnay clone available, there is a lack of scientific information as to the characteristics of these clones, and studies are needed on how they adapt to different terroirs and rootstocks.

Table 4. Odorants Derived from Oak Contact or Formed during Aging That Are Important to the Typicity of Chardonnay Wines

name and structure	aroma descriptor(s)	threshold (μg/L)	reported content in Chardonnay (μg/L)
vanillin 	vanilla[33]	200[38a]	3.9 – 1223[40,53]
acetovanillone 	floral, clove, vanilla[46]	1000[54b]	N.A.[c]
ethyl cinnamate 	cinnamon, sweet, floral, strawberry, plum[28,44,99]	1.1[30d]	1 – 33[40]
furfural 	almond[48]	14100[46d]	1 – 21190[40,45]
5-methyl-furfural 	warm, spicy[100]	20000[101]	trace – 37.5[45]
guaiacol 	phenolic, chemical, spice[28,33,44]	9.5[30d]	1.6 – 284[40,45]
tyrosol 	N.A.	N.A.[c]	600 – 17040[59,70]
cis-oak lactone 	coconut[77]	24[102e]	33 – 382[40]
trans-oak lactone 	coconut, oak[103]	172[102e]	10.2 – 1355[40,45]
eugenol 	clove[48]	6[30d]	10 – 362[40,49]
2-methyltetrahydro-thiophen-3-one	metallic, natural gas[104]	0.09[105a]	18000[106g]
2-furan-methanethiol 	roasted coffee[107]	0.0004[107f]	0.014[108]
benzene-methanethiol 	smoky, gunflint[109]	0.0003[109f]	0.03 – 0.04[109]
sotolon 	burnt, curry[28,33]	5[38a]	1.1 – 4.7[110]

CHARDONNAY AROMA PROFILES

The headspace of Chardonnay wines has been tentatively determined to contain 243 volatiles detected through GC×GC-time-of-flight-mass spectrometry (TOF-MS),[65] which belong to a complex mixture of diverse chemical families including, but not restricted to, C_{13}-norisoprenoids, esters, alcohols, polyfunctional thiols, lactones, monoterpenoids, phenols, and acids.[39] Of these, the compounds derived from the grapes, winemaking, and aging listed in Tables 2–4 have been reported as having a positive relationship to the typicity of Chardonnay wines (i.e., the extent to which a wine is typical of the variety and is a good example of the Chardonnay wine concept), and some can be considered as character-relevant compounds for this variety.[29,55,56,66,67]

Not all of the compounds present in Tables 2–4 have an odor activity value (OAV) >1, which is normally taken as the value required for a compound to be a likely contributor to characteristic aroma. Their apparent importance to typical Chardonnay wine aroma highlights the fact that OAVs based on threshold values in a specific matrix (e.g., neutral white wine or 10% v/v aqueous ethanol) act merely as a guide when determining the importance of a compound to wine aroma, due to a significant effect of the matrix.[90–92]

When dealing with the typicity of a wine, with Sauvignon blanc being a good example, rather than search for impact compounds alone, researchers are also looking for those odorants that are essential for the wine to fit within a perceptual concept for that variety.[93] Similarly to quality, defining typicity requires a sensory analysis of samples; a number of sensory techniques are available for this purpose such as requiring the panelists to rate how well a wine belongs to a certain category and descriptive analysis or sorting of the samples, culminating with pairing and discrimination of the results based on the volatile composition of good and bad samples.[55,56,93] Other strategies to target relevant compounds include reconstitution analysis, which reveals the importance of certain volatiles to the overall aroma of the wine in question.[40] Consideration also needs to be given to the interactions among odorants, where differing concentrations of compounds in a mixture may have

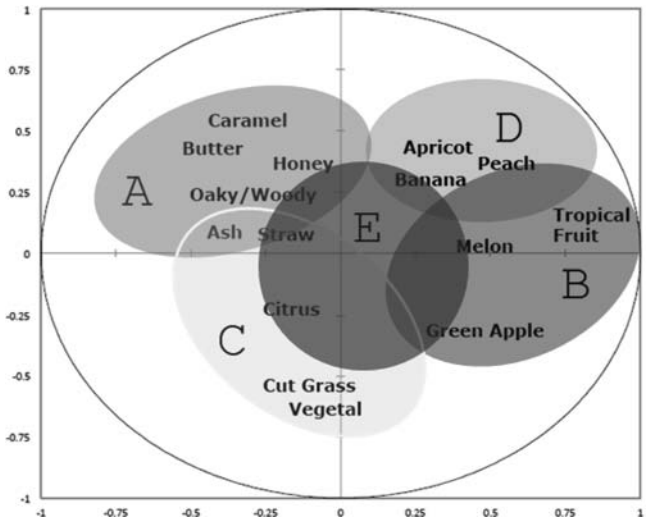

Figure 1. Representation of Chardonnay flavor profiles. A–E denote different commercial wine styles (based on data from Saliba et al.[21]).

synergistic or antagonistic effects and aromas may be enhanced or suppressed or odor quality altered as a result.[94−98]

Along the lines of seeking a perceptual concept for varietals, Louw et al.[67] analyzed 125 young unoaked Chardonnay wines, among other monovarietals from South Africa, using liquid−liquid extraction (LLE) and GC-flame ionization detection (FID), together with multivariate analysis and a "most used subset" of compounds to determine characteristic molecules that could be used to discriminate among cultivars. They showed that Chardonnay wines can be discriminated (with 74% correctly classified) by using the following eight volatile compounds: 2-phenylethanol, decanoic acid, diethyl succinate, ethyl hexanoate, ethyl decanoate, ethyl octanoate, hexyl acetate, and 1-propanol (Table 3). This prediction model, however, remains to be used to classify other sets of Chardonnay wines, particularly more developed ones, and the links between grape and wine composition for these eight specific compounds need clarification. They also observed that unlike most yeast-derived compounds (i.e., alcohols, acids, and esters such as those in Table 3), 2-phenylethanol, acetic acid, ethyl hexanoate, hexanoic acid, isoamyl alcohol, and 1-propanol were not affected by vintage, which could signify that their concentrations are characteristic of the Chardonnay cultivar. More work has to be done to confirm this, however.

Chardonnay juice does not possess any distinct aroma; however, certain precursors can be found in the must as well as the following volatile hydrolysis products: C_{13}-norisoprenoids, benzene derivatives, monoterpenoids, and aliphatic compounds as isolated by Sefton et al.[111] by reverse-phase chromatography followed by LLE and GC-MS. Although monoterpenoids (such as linalool and α-terpineol, Table 2) characterize the aroma of grape varieties such as Gewürztraminer and Muscats, Chardonnay is mostly deficient in these compounds, instead being dominated by C_{13}-norisoprenoids.[111] Studies by Lee and Noble,[40] Sefton et al.,[111] and Simpson et al.[39] suggest that the most relevant C_{13}-norisoprenoids to this variety's overall aroma are β-damascenone, 3-oxo-α-ionol, 1,1,6-trimethyl-1,2-dihydronaphthalene (TDN), and vitispirane.

C_{13}-Norisoprenoids such as β-damascenone and TDN are formed downstream from the oxidative cleavage of carotenoids (particularly lutein and β-carotene, with minor amounts of violaxanthin, neoxanthin, and several others), which occurs during grape berry ripening (e.g., Figure 2).[112−114] Although C_{13}-norisoprenoids can be found in their free form in the juice, they are usually present as glycoconjugates and easily degraded under acidic conditions.[115] β-Damascenone is a powerful odorant (odor threshold in model wine of 50 ng/L, Table 2) and aroma enhancer that, depending on concentration, can exhibit different odor qualities. At perithreshold concentrations, β-damascenone exhibits a "lemon balm" aroma, whereas at a concentration some 2 orders of magnitude higher it can be characterized as having "apple", "rose", and "honey" nuances.[116] Although β-damascenone is a ubiquitous wine component,[117] TDN, which possesses a "kerosene" aroma (Table 2), is typically associated with aged Riesling wines.[118] As determined by Lee and Noble[40] using GC−olfactometry (GC-O), 3-oxo-α-ionol possesses "spicy" notes at the concentrations found in Chardonnay wines (Table 2).

Polyfunctional thiols such as 3-sulfanylhexan-1-ol (3-SH), 3-sulfanylhexyl acetate (3-SHA), and 4-methyl-4-sulfanylpropan-2-one (4-MSP) are extremely potent odorants with very low aroma thresholds (60, 4.2, and 0.8 ng/L, respectively; Table 2) and aromas reminiscent of "box-tree", "grapefruit", and "passion fruit".[119,120] Both 3-SH and 4-MSP occur naturally in grapes as odorless glutathione and cysteine conjugates, which are released by yeast during alcoholic fermentation; 3-SHA is formed during alcoholic fermentation by esterification of 3-SH by alcohol acetyltransferase (AAT).[43,121,122] Although of particular significance to the typicity of Sauvignon blanc wines, these compounds are not as abundant in Chardonnay, yet still appear to be important.[42,119,123,124] The presence of other thiols such as benzenemethanethiol (BM) and 2-furanmethanethiol (FFT) at concentrations above their perception thresholds (0.3 ng/L[109] and 0.4 ng/L,[107] respectively) must also be noted (Table 4). BM has been described as having "flinty" and "smoky" (i.e., empyreumatic) notes, which may be related to Chardonnay wines' "mineral" character[64] and has an inconclusive formation

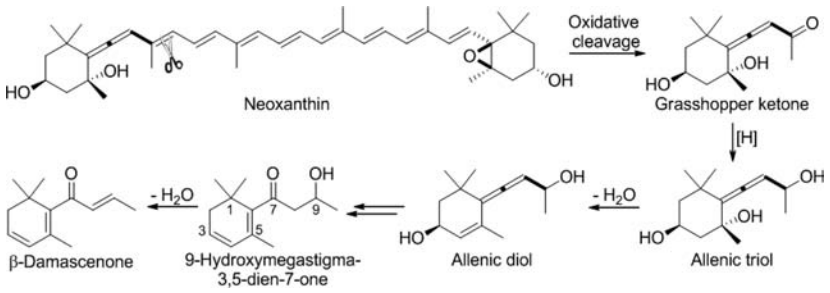

Figure 2. Formation of C_{13}-norisoprenoid β-damascenone from the carotenoid neoxanthin via oxidative cleavage, carbonyl reduction [H], and acid-catalyzed reactions. Although not depicted, glycosylated intermediates are also featured in this pathway.

pathway. On the other hand, FFT, with its strong "roast coffee" aroma, is formed from the furfural released by oak barrels and hydrogen sulfide formed during alcoholic fermentation.[125] Using a specific thiol extraction method (*p*-hydroxymercuribenzoate) together with GC-MS analysis, Tominaga et al.[109] determined that among wines from several appellation regions in France, Chardonnay possessed the highest concentrations of BM (30−32 ng/L), at 100 times above its detection threshold and 2−3 times more than all other assayed varieties. Mateo-Vivaracho et al.[42] have also confirmed the presence of suprathreshold concentrations of BM in Chardonnay (0.6−1.4 ng/L) through solid-phase extraction (SPE) and GC-MS analysis with negative chemical ionization (NCI). The different methodologies as well as the different origins of the wines employed by both research groups may account for the differences in quantities of BM found and in the hierarchy between Sauvignon blanc and Chardonnay in terms of these compounds. Comparison of Sauvignon blanc wines from different origins by Mateo-Vivaracho et al.[42] emphasized the importance that origin has on the content of all polyfunctional thiols (3-SH, 3-SHA, 4-MSP, BM, and FFT); BM concentration was highest in New Zealand wines, and FFT contents were found to be highest in French wines and lowest in those from Chile. However, these differences may be also due to viticultural and enological practices in each region. These two compounds have also been found at concentrations well above their perception thresholds in aged French Champagnes and have been shown to increase during aging.[126] Unfortunately, as with other polyfunctional thiols, analysis of BM and FFT is not a trivial undertaking (e.g., low abundance and reactive), and this may account for the fact that they have not been reported as characteristic of certain Chardonnay styles as yet.

Other important compounds are the esters (Table 3), which constitute the second most significant chemical group in the volatile fraction of Chardonnay wines. The esters are formed in excess during alcoholic fermentation by yeast metabolism and are responsible for "fruity" and "floral" aromas.[127,128] Wines contain two main types of odor-active esters: acetates of higher alcohols (formed by yeast AAT enzymes Atf1p and Atf2p, via condensation of their corresponding higher alcohols and acetyl CoA[129−131]) and ethyl esters of fatty acids (thought to be formed by esterification of the activated fatty acids (acyl CoA) during lipid biosynthesis mediated by acyl CoA:ethanol *O*-acyltransferase (EAT) enzymes Eeb1 and Eht1 together with other as yet unidentified enzymes[132]). Acetates are synthesized at higher concentrations than ethyl esters, and the ratio between both, as well as the concentration at which acetates are produced, is affected particularly by fermentation temperature, must nutrient content, and yeast strain rather than grape variety. Although both acetates and ethyl esters are liposoluble, excretion of ethyl esters through the yeast cell membrane becomes more difficult as chain length increases (only 8−17% of all ethyl decanoate produced by yeast is excreted into wine during alcoholic fermentation),[133] whereas 100% of all acetates produced are released.

The production of esters is modulated by the presence of cosubstrates and the activity of related synthesis and hydrolysis enzymes (esterases).[134] Formation of acetates depends on the concentration of unsaturated fatty acids (which inhibit AAT activity) available in the medium and carbon-to-nitrogen ratio.[134] A dynamic equilibrium exists between acetates and their corresponding acids and alcohols, which depends on the conditions of the medium.[135] Ethyl esters respond to the modification of most winemaking parameters in a similar way as acetates (albeit increases in nitrogen content or fermentation temperature have more pronounced effects on acetate formation). Higher concentrations of unsaturated fatty acids decreased ethyl ester production; however, inclusion of an additional carbon source to the medium increased only acetate production. Unlike acetates, synthesis of ethyl esters depends more on the availability of substrate (medium-chain fatty acids) rather than on enzyme expression level;[134] in turn, the amount and type of fatty acids available[136] depend on agricultural conditions and grape variety, making ethyl ester profiles more variety-dependent than that of acetates (except for hexyl acetate).[137] According to Smyth,[66] the most relevant esters for unwooded Chardonnay aroma appear to be ethyl hexanoate, ethyl octanoate, ethyl decanoate, ethyl 2-methylpropanoate, ethyl 2-methylbutanoate, ethyl 3-methylbutanoate, hexyl acetate, 2-methylbutyl acetate, and 3-methylbutyl acetate.

Moio,[138] Lorrain,[29] and Lee and Noble[40] all agree on the importance of volatile compounds such as guaiacol, *cis*- and *trans*-oak lactones, 4-ethylphenol, 4-ethylguaiacol, 4-vinylphenol, vanillin, methyl vanillate, and 5-methylfurfural (Tables 2 and 4) to the typicity of Chardonnay wines. These compounds derive mainly from aging in oak barrels, and some of them are even considered to be off-odors if they are present at concentrations above their perception threshold, as they are commonly associated with the metabolism of *Brettanomyces/Dekkera*.[47] However, some of these compounds, such as 4-vinylguaiacol, can also be found in wines that have had no contact with oak. 4-Vinylguaiacol is responsible for "smoke" and "phenolic" notes,[79] and although usually associated with aging in barrels, higher concentrations of this compound have been detected in some Chardonnay wines aged in stainless steel.[40] Spillman et al.[49] refer to 4-vinylguaiacol, 4-ethylguaiacol, 4-ethylphenol, and 4-vinylphenol as fermentation products rather than as compounds derived from oak contact. They are formed through decarboxylation of natural grape components ferulic and *p*-coumaric acids by *Saccharomyces cerevisiae* enzymatic activity[139] (hence their inclusion in Table 2). The concentration of these compounds appears to depend more on factors such as higher fermentation temperature and contact with lees than on the influence of oak wood.[140]

In their assessment of Australian Chardonnay wines, Saliba et al.[21] observed that five distinct styles resulted from the sensory analysis (Figure 1); among these, style A (a more "traditional/oaky" Chardonnay style, marked by "caramel", "butter", "honey", and "oak" attributes) and style B (a "crisp/fruity" style, with "tropical fruit", "melon", and "green apple" notes) seem to dominate the current market. From a volatile compound perspective, style A wines were marked by "woody", "smoky", "vanilla", "spicy", and "clove" odors, which are attributed to the presence of vanillin, guaiacol, 4-vinylguaiacol, furfural, and *cis*- and *trans*-oak lactones (Tables 2 and 4).[40,87] From the correlation matrix by Spillman et al.,[49] it can be inferred that the "smoky" notes present in Chardonnay wines aged in oak barriques are caused by the combined presence of guaiacol, 4-methylguaiacol, furfural, 5-methylfurfural, and, to a lesser extent, 4-ethylguaiacol and vanillin. Other oak-related aromas such as "cinnamon" and "coconut" were positively correlated to vanillin and *cis*-oak lactone (followed by guaiacol), respectively.

Unlike what might have been expected, the difference in resulting overall aroma between such A and B styles is not necessarily due to a different composition of characteristic

Table 5. Concentration (Micrograms per Liter) and Comparison of Volatile Compounds in Two Styles of Chardonnay Wines ("Fruity" and "Oaky") As Determined in Separate Studies

	Buettner et al.[87]			Lee and Noble[40]

volatile molecules. A study by Buettner[87] of the potent odorants identified in two Chardonnay wines representative of a "traditional/oaky" and a "crisp/fruity" style (i.e., styles A and B according to Saliba et al.[21] in Figure 1) showed that they were both composed of the same volatiles, but each contained different amounts, leading to different time persistence levels for each attribute. Retronasal sensory assessment of both samples showed that the notes related to "oak" in style A were more persistent when judged by time−dilution analysis than the "fruity" ones in style B. Table 5 shows some of the results of this study, revealing that the concentration of *cis*-oak-lactone ("coconut" notes, Table 4) as measured by high-resolution (HR) GC-MS using stable isotope dilution analysis (SIDA) was almost 13 times higher in the A style wine than in the B style wine, and 3-methylbutyl acetate ("banana" notes, Table 3) was 6 times more abundant in the B style wine.

Lee and Noble[40] studied an array of California Chardonnay wines, two of which were characterized as belonging to the "crisp/fruity" and "traditional/oaky" styles (Figure 3). A comparison of their results to those obtained by Buettner[87] demonstrates similarities for certain compounds (Table 5). Both studies found concentrations of *cis*-oak lactone in the A styles that were approximately 13 times higher than in style B, as well as twice the concentration of ethyl cinnamate in the woodier styles than in the fruitier ones. The differences observed in the content of compounds related to fruity attributes were not as high as expected, and in some cases the difference found between both styles was not significant (i.e., ethyl hexanoate and ethyl butanoate). The use of aroma models and similarity tests by Lee and Noble[31] showed that even when trying to replicate wines with a high intensity of "fruity" aroma attributes, it was also necessary to incorporate "oak/spicy" volatiles (e.g., vanillin, furfural, 2-acetylfuran, *cis*- and *trans*-oak lactone, eugenol). The wines to which only "fruity" related aroma molecules (ethyl butanoate, 3-methylbutyl acetate, linalool, α-terpineol, and 2-phenylethyl acetate) were added were less representative and closer in profile to the base wine rather than the original "crisp/fruity" wine sample.

This highlights the potential importance of "oak" and "spicy" attributes to Chardonnay aroma even for "crisp/fruity" styles and explains the predominance of "woody" and "spicy" notes in

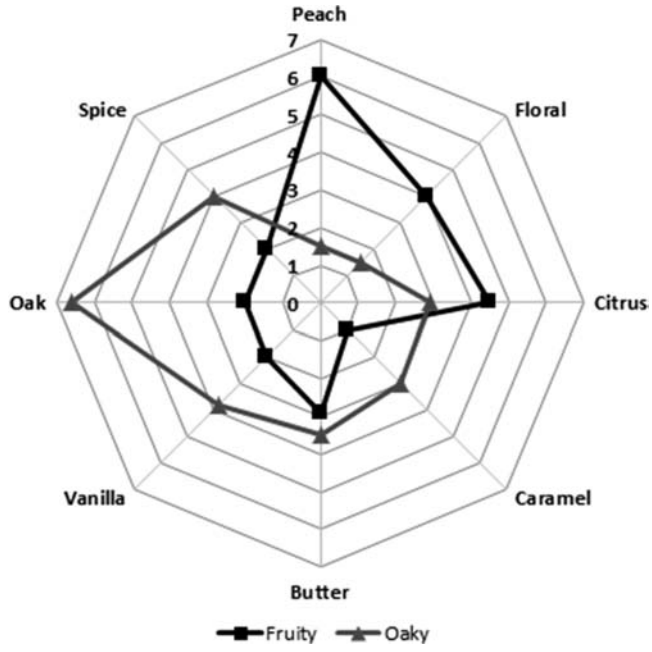

Figure 3. Aroma profiles of "fruity" and "oaky" Chardonnay wines (data from Lee and Noble[40]).

the "oaky" wine and lack thereof in the "fruity" style in the study by Buettner et al.[87] The only compounds not detected by tasters in the "fruity" sample were *cis*- and *trans*-oak lactone and eugenol; likewise, 3-methybutyl acetate was not detected by the tasters in the "oaky" wine and was, in fact, less abundant in the "oaky" style by a factor of 5.[87] The "fruity" style was also characterized by a higher detection frequency of linalool and α-terpineol,[40] which have been described as having "citrus" and "floral" notes.[40,79] Wines described as being "oaky" are seldom described as "fruity", and the work of Arrhenius et al.[37] showed a very significant negative correlation existed between the attributes "citrus" and "caramel/pumpkin" (this term is positively correlated to the presence of TDN). On the other hand, esters, which contribute "fruity" aromas, are often present in Chardonnay wines at concentrations well above their

dx.doi.org/10.1021/jf501945s | J. Agric. Food Chem. 2014, 62, 6512−6534

detection thresholds; therefore, no significant differences have been observed in the detection frequency of most of these compounds between both wine styles.[40]

FACTORS AFFECTING AROMA DEVELOPMENT

A range of factors determine the aroma composition of a wine, including but not limited to grape maturity, vine nutrition, harvest method, alcoholic and malolactic fermentation, and aging. Among these, grape maturity and alcoholic fermentation are considered the most critical stages.[26] Compounds related to grape variety and typicity, such as monoterpenoids, C_{13}-norisoprenoids, pyrazines, and polyfunctional thiols, which derive from the berry itself, can vary in concentration and can be found either in free form or bound as glycosides or amino acid conjugates, depending on the grape variety.[141−143] During fermentation, *S. cerevisiae* metabolism produces many of the olfactory compounds identified as being important to wine, such as esters and fusel alcohols, from the nutrients, elements, and different compounds present in the juice or must.[141,144,145]

Juice Composition and Nutrient Content. A balanced content of nutrients in the juice (nitrogen, amino acids, lipids, vitamins, and metal cations), as well as optimum oxygen and pH levels before the start of fermentation,[62] are determinant of yeast biomass formation, yeast metabolism, and alcoholic fermentation rate. Chardonnay appears to be the variety with the most reported cases of difficult fermentations in Australia as per Schmidt et al.,[146] most probably due to low pH and, in some cases, low potassium (K) concentration. The pH of juice appears to affect yeast performance in one of three ways; either the strain is unaffected, or its performance is affected (negatively) but can be corrected by adding K to the medium, or it is affected and K cannot correct the problem. A low pH combined with a low K concentration alters the redox potential of the medium, which is then corrected by an excess production of acetic acid, which is itself inhibitory for yeast metabolism and thereby further compromises the progression of fermentation.[146]

Nutrient deficiencies increase the risk of incomplete fermentations, leading to the appearance of off-odors (e.g., H_2S and other sulfur compounds) and unstable wines prone to bacterial spoilage. By supplementing a juice deficient in yeast assimilable nitrogen (YAN), usually in the form of diammonium phosphate (DAP) as an ammonium source, lower amounts of higher alcohols (for example, those in Table 3) and branched-chained acids (isoacids) are produced, and a higher concentration of esters is synthesized, improving overall sensory quality.[75] However, an excessive addition of DAP will tend to produce wines with an undesirable "solvent" character and higher ethyl acetate and acetic acid contents.[82,147]

In terms of the type of nitrogen supplement used, Torrea et al.[82] demonstrated that the addition of inorganic ammonium nitrogen (as NH_4Cl) to Chardonnay juices resulted in an increased concentration of acetic acid in the corresponding wines, but lower quantities of higher alcohols than with other forms of nitrogen (i.e., amino acids and ammonium). When the amount of ammonium supplementation was increased, the final wine had low fruit-related aromas and high "acetic" and "nail polish remover" notes, due to acetic acid and ethyl acetate, respectively; of 16 aroma descriptors evaluated, 14 changed significantly when different types and quantities of nitrogen were supplied.[82] These results can be explained on the basis of yeast metabolism, in which amino acids may play a role in certain metabolic pathways or may act as precursors to esters.[148]

If nitrogen is supplied in the form of amino acids, greater amounts of esters will be produced and higher alcohol concentrations will decrease.[75,82] In general, higher amino acid content improves the capacity of yeast to adapt to and/or work under anaerobic conditions, activating the synthesis of fatty acids and increasing the amount of ethyl esters produced.[75] However, there appears to be no correlation between higher alcohol acetates and amino acid levels; the extent of utilization of a particular amino acid by yeast will depend on the nature of the amino acid. As an example, greater amounts of leucine (a precursor to 3-methyl-1-butanol) were utilized in fermentations in which it was supplemented, but the final concentration of 3-methylbutyl acetate was similar to that of control fermentations.[149]

It should be mentioned that not all yeasts are equally sensitive to every nitrogen source. Certain strains were revealed to be insensitive to specific sources, whereas strain 254D, which is a moderate ester producer, was very responsive to changes in nitrogen source. For example, the content of ethyl and 3-methylbutyl acetates produced by 254D was significantly higher when using DAP than when nitrogen was incorporated as amino acids. Furthermore, use of amino acids when working with 254D yielded the lowest maximum and final concentrations of acetate esters and fatty acid ethyl esters determined in the study when compared to DAP-supplemented and control fermentations.[149]

Nutrients other than nitrogen are important to fermentation performance and metabolite profile. Varela et al.[62] demonstrated that aroma composition can be affected through lipid and oxygen supplementation, thereby influencing ester and higher alcohol production in Chardonnay wines while limiting production of fatty acids, especially of acetic acid, as well as lowering acetaldehyde concentrations.[62] Furthermore, supplementation of musts with these nutrients not only stimulated yeast growth and metabolism but improved fermentation rates significantly and diminished the amount of residual sugar in the final product. Addition of either oxygen or lipids changed the proportions of acetate to ethyl esters and of branched-chain to medium-chain fatty acids while, unfortunately, also increasing, by approximately 2-fold, the amount of higher alcohols to levels oscillating between 320 and 400 mg/L. This means higher alcohols were above the value indicated by Rapp and Mandery[68] as contributing positively to wine complexity (300 mg/L). These authors also suggested that concentrations of higher alcohols in excess of 400 mg/L no longer contribute positively to the overall aroma of a wine but rather detract from it. Addition of lipids (as unsaturated fatty acids) and sterol yielded Chardonnay wines with more esters overall, whereas incorporation of oxygen (with and without addition of lipids) increased acetate esters but strongly diminished the total content of ethyl esters. In either case there was a reduction in hexanoic acid but an increase in 3-methylpropanoic acid and variable effects on the other volatile acids (excluding acetic acid, which was reduced as mentioned above). Addition of lipids can also improve the fermentation progress of overly clarified juices and avoid stuck fermentations and high acetic acid concentrations.[62,146,150]

Use of Enzymatic Preparations. Endogenous grape glycosidases have a low enzymatic activity at the pH and/or sugar content of most grape juices and are therefore capable of only a limited level of aroma release through glycoside

cleavage.[151,152] In addition, different enzymes are required to release bound volatiles such as monoterpenoids and C_{13}-norisoprenoids from their different glycosidic forms (i.e., β-D-glucosides and disaccharides).[153,154] Winemaking yeasts possess glycosidase activity[155] as highlighted by Chassagne et al.,[152] who revealed differences in the extent of glycoside hydrolysis during fermentation of a Chardonnay must. Model fermentations containing a Chardonnay glycosidic extract also showed that yeast glycosidases exhibited different extents of hydrolysis depending on the type of sugar involved (mostly glucose, arabinose, and rhamnose); by the end of fermentation 47% of glucose contained within the glycoside pool had been hydrolyzed, whereas glycosides containing rhamnose and arabinose had been almost completely metabolized.[61]

The use of enzymatic preparations with glycosidase activity has been demonstrated to increase the content of total monoterpenoids and C_{13}-norisoprenoids,[153,154] and enological preparations (of fungal origin) are available for use in winemaking to help improve aroma profiles.[155,156] Enzymes are typically added prior to fermentation during commercial winemaking (i.e., preparations used for juice extraction and clarification containing glycosidase side activities), but in a study of Chardonnay wines, glycosidases were added postfermentation, leading to increases of around 50% or more in total monoterpenoids and C_{13}-norisoprenoids.[32] Unlike grape glycosides, fungal glycosides are not inhibited under normal wine conditions[151] and have even been shown to enhance aroma characteristics when applied to dealcoholized wine containing grape aroma precursors.[157]

Winemaking Techniques. In response to current market trends and the popularity of certain wines, two marked tendencies exist now for Chardonnay aroma profiles: fruity and light styles are opposed by more flavored and complex (and possibly more evolved) styles. These disparate styles are targeted through choices made during winemaking, which have a strong influence on the overall aromas of Chardonnay wine, perhaps more so than any other white wine variety. Yeast produces esters during alcoholic fermentation, and given that they constitute one of the main groups of sensorially important compounds in Chardonnay, the choice of fermentation conditions and yeast strain will play a major role in overall wine aroma.[145] This explains why some non-Chardonnay wines, produced in the same style as a Chardonnay, have been confused by experts as belonging to the latter category during tasting.[55] In particular, Chardonnay aroma is marked by the presence of the ethyl esters of fatty acids (i.e., butanoate, hexanoate, octanoate, and decanoate) along with hexyl acetate (Table 3); the "fruity" nuances derived from variation in the concentrations of these compounds will be dependent on yeast strain, providing uniqueness to wine aroma.[158]

Chardonnay is one of the few white varieties that can endure a prolonged maceration.[159] This is fortuitous, because as shown with various grape varieties, a number of aroma compounds and precursors are located preferentially in grape skins; among them are monoterpenoids and their glycosides and precursors to β-damascenone and polyfunctional thiols.[53,160−163] Extended skin contact increases the total aroma content both in terms of concentrations of volatile molecules and as evaluated by sensory analysis.[34,164,165] Increased concentrations of linoleic and linolenic acids (precursors to C_6 compounds such as hexenals and, ultimately, 1-hexanol) have also been revealed through extended skin contact of Chardonnay musts,[166] and maceration with skins produced wines that were described as being more intense and "fruitier".[34,164] Macerated wines were also shown to be richer in C_6 compounds, particularly 1-hexanol.[34] According to Colagrande et al.,[167] the effect of C_6 alcohols and aldehydes depends on their concentration; when at low concentrations (<0.5 mg/L) their contribution is actually positive, adding to the typical aroma of Chardonnay wines, but they are also responsible for herbaceous flavors when their content is higher. The production of fruitier wines can be partly explained by the results of Dennis et al.,[137] which confirmed the role of certain C_6 compounds (1-hexanol, hexanal, (*E*)-2-hexenal, (*E*)-2-hexen-1-ol, and (*Z*)-3-hexen-1-ol) as precursors to hexyl acetate after the respective reduction and/or acetylation. Hexyl acetate, with its pleasant "apple" aroma (Table 3), is typical of unwooded Chardonnay wines.[66]

It is worth noting that skin maceration will necessarily increase the extraction of grape phenolic compounds (i.e., nonvolatiles associated with taste, mouthfeel, and color (browning of white wine)), potentially having an adverse effect on white wine sensory properties. However, despite total phenolics being increased linearly with maceration time, no significant differences in bitterness or astringency of Chardonnay wines were found in studies employing different times for maceration treatments. After 16 or 24 h of maceration, the sensory effect of an increased level of phenolics was no different from the wines that did not undergo skin contact.[164,165] Temperature plays an important role, however, such that cooler temperatures minimize the extraction of phenols without overly affecting the extraction of aroma components.[168] Furthermore, maceration affected the pH, titrable acidity, total nitrogen and amino acid contents, and potassium, calcium, and magnesium levels.[164,165] Some of these parameters will influence fermentation performance and contribute to differences in aroma profiles.

Thermotreatment of grapes is usually reserved for red wines, where higher polyphenol and anthocyanin contents are sought for their effects on color and mouthfeel. Chardonnay juices or wines may also benefit from thermotreatments to improve the extraction of determinate compounds from grapes and accelerate the level of hydrolysis of glycosylated aroma precursors. A study by Francis et al.[61] showed that heat treatments of Chardonnay wines at around 45 °C for several weeks resulted in wines with sensory properties similar to those of wines that had been bottle-aged for several years. Thermal treatment reduced "floral", "pineapple", and "grassy" characters of the resulting wines and intensified their "oak", "honey", and "smoky" characteristics. On the contrary, heating of juices or wines for a short time (i.e., around 2−12 min) at 90 °C on a pilot scale (250 L) was shown not to produce any discernible sensory differences when compared to the unheated control wine. In either case, there were no oxidized, cooked, or maderized aromas. Thermal treatment of Chardonnay juice or wine using mild temperatures could be envisaged as a more rapid and economical alternative to ordinary aging of wines to obtain a more "evolved" profile.

A choice of fermentation vessels is available to winemakers when producing Chardonnay wines. Tanks constructed of steel, cement, or plastic as well as oak barrels and vats may be used, depending on the desired style, available infrastructure, and budget. Unlike stainless steel, barrels are not inert and interact with the juice during fermentation, resulting in higher concentrations of certain volatile compounds. According to González-Marco et al.[70] the total concentration of about 186 mg/L for higher alcohols in wines produced in new French oak

barrels was 42% greater than for stainless steel, but below the 400 mg/L total suggested as detrimental to wine aroma.[68] Ethyl acetate formed in oak barrels was approximately 32% higher, whereas other esters totaled almost 18 mg/L and were up to 4 times higher, particularly those of short- and medium-chain fatty acids, 3-methylbutyl acetate, and diethyl and monoethyl succinate, compared to stainless steel tanks. Hexanoic, octanoic, and decanoic acids were up to 6 times higher in oak barrel fermentations as well.

These outcomes can be rationalized by considering compositional differences between the fermentations in each type of vessel. Wood contains even-numbered saturated fatty acids (C2:0−C26:0), among a range of other volatile and nonvolatile compounds, which are extracted during fermentation, thus increasing the amount of esters and acids in the wine. The improved production of higher alcohols seemed to relate to a reduced consumption of amino acids in barrel-fermented wines, with the biggest differences being observed for 2-phenylethanol, benzyl alcohol, 1-hexanol, 1-propanol, 3-(methylthio)-1-propanol, methanol, tyrosol, and tryptophol.[70] Fermentation of wines in oak barrels also favors the extraction of typical oak-related volatiles such as oak lactones and furfurals, which undergo reduction to the corresponding furan alcohols because of a prolonged contact with lees.[140]

Yeast Influences. Yeasts affect the aroma composition and therefore quality of a wine in a number of ways. They synthesize odorant molecules de novo, such as esters and higher alcohols, release odorless precursors, and alter wine perception and flavor through the production of ethanol and the release of yeast constituents such as mannoproteins.[169] As well, the level of stress a yeast strain may tolerate will influence the amount of sulfur-containing malodorous compounds that will be formed in low-nitrogen situations. As outlined earlier, esters formed during fermentation comprise an important class of "fruity" aroma compounds in Chardonnay wine. Genetic variation between wine yeast strains and must composition leads to differences in expression of genes related to ester synthesis and hydrolysis.[149,169] Yeasts are also responsible for the cleavage of cysteinyl and glutathionyl conjugates and release of the corresponding polyfunctional thiols 3-SH, 3-SHA, and 4-MSP (see Table 2).[169] Typically, winemakers inoculate with selected strains of *Saccharomyces cerevisiae*, but a large diversity of yeast genera which can affect ester production exist as indigenous microflora.[170] A quick analysis of Australia's and America's major fine Chardonnay producers (based on wines with scores above 92 points as defined by James Halliday[171] and *Wine Spectator*) shows that many winemakers are choosing "natural" (i.e., wild or spontaneous) fermentations with indigenous yeasts (dominated initially by non-*Saccharomyces* yeast)[172] as a vehicle to incorporate more complexity and uniqueness into their wines. Wines from "natural" fermentations are not always scored better than inoculated wines, despite often possessing a higher aromatic intensity. This is because the use of non-*Saccharomyces* yeasts produces higher intensities of both positive and negative aromas, so scoring of the wine will depend on the balance between these compounds and the preference of the wine judge or consumer.[173]

Medina et al.[59] found that the use of commercial yeasts together with highly standardized procedures results in wines with uniform characteristics. Richter et al.[158] studied and characterized the metabolic footprint of 69 commercial yeast strains in Chardonnay wines. Despite the large number of strains studied, only four clusters, and therefore four wine aroma profiles, were identified through hierarchical clustering of their metabolites. Each cluster was identified by its particular ratio of acetate to ethyl esters, primarily due to a fluctuation in acetates. Each type of ester arises from discrete sets of precursors and enzymes, highlighting phenotypic differences among the clusters as a result of potential genetic variations. The final concentrations of esters in the wine depend on the maximum level attained during alcoholic fermentation, and the rate of formation, volatilization, and hydrolysis thereafter.[149] Esters are formed at different rates during fermentation, in particular, hexyl acetate and ethyl hexanoate, which derive from the modification of C_6 compounds by yeast. The earlier onset of production of these esters was suggested to depend on yeast cell growth, which relates to both the yeast strain and the medium conditions;[174] concentrations of hexyl acetate and ethyl hexanoate dropped significantly as fermentation progressed and ester degradation or volatilization overcame formation.[149]

New yeasts are still being selected and/or developed to provide winemakers with greater options to introduce complexity and increase diversity in aroma profiles. Strategies for the development of new strains include hybridization, mutagenesis, directed evolution, and genetic modification techniques such as the overexpression and introgression of genes related to the formation of specific aroma molecules or specific metabolic pathways.[169,175] Although genetically modified organisms are not currently permitted for use in the majority of wine-producing countries, and are anyhow met with high reticence by the public, they do constitute a very useful research tool. Gene deletions allow for metabolic pathways involved in the formation of key metabolites to be identified and comprehended, as has been the case in the elucidation of the mechanisms leading to the formation of polyfunctional thiols.[176] Even under the most favorable conditions (optimum fermentation temperature, extended skin maceration[177,178]), commercial yeast strains are able to release only 10% of all polyfunctional thiol precursors available. In response to this limitation, both Swiegers et al.[179] and Holt et al.[180] have developed yeast strains capable of releasing higher amounts of polyfunctional thiols due to enhanced carbon−sulfur (CS) lyase activity, through the insertion of the *Escherichia coli tna*A gene and by overexpressing the yeast gene *STR3*, respectively, in the commercial yeast VIN13 (considered to impart a high yield of thiols). Swiegers et al.[179] achieved a strain capable of releasing up to 25 times more 4-MSP and 3-SH than the original VIN13 strain, and Holt et al.[180] were able to confirm the CS β-lyase role of *STR3* gene product as well as design a yeast strain capable of releasing close to 10 times as much 3-SH as the original strain. Unfortunately, neither of these strains can be commercially applied.

Saberi et al.[63] isolated and studied two unique Burgundian strains individually and in cofermentations using Chardonnay juice, showing they were similar to each other and generally produced intermediate levels of higher alcohols, and ethyl and acetate esters, compared to the six commercial strains, which were more disparate to one another. The sensory profiles of the wines were estimated from descriptors and OAVs, showing the Burgundian strains produced higher alcohols (in particular, 1-butanol, 1-hexanol, and isobutanol) with OAVs of much less than 1 (minimizing fusel characters) and ethyl esters, responsible for pleasant "fruity" aromas, above their perception threshold (OAV > 1). Fermentations with mixed Burgundian strains tended to produce greater diversity in their profile of

volatile compounds, indicating some form of metabolic interaction.

Likewise, Orlic et al.[60] isolated seven indigenous strains of *Saccharomyces paradoxus* from the Zagreb region in Croatia. These strains have the capacity to produce higher levels of glycerol than *S. cerevisiae* and lower total amounts of higher alcohols. When used to ferment Chardonnay juice, *S. paradoxus* produced wines of similar or better organoleptic quality than those in which *S. cerevisiae* was used, with higher concentrations of 1-propanol and 1-hexanol and lower concentrations of isobutanol, capric acid, and ethyl acetate. However, they also produced lower amounts of 3-methylbutyl acetate and total volatile esters. Cell−cell communication and modification of gene expression through quorum sensing have been raised previously and may explain this phenomenon.[172] The results of Miller et al.[149] showed that no one yeast strain possesses a higher rate of accumulation for all of the desirable esters, so a choice has to be made according to the compounds that are to be maximized. Fermentations with mixed yeast populations therefore provide a potential means to better achieve the desired aroma outcome.

Unlike inoculated fermentations in which a single *S. cerevisiae* strain dominates throughout the whole process, spontaneous fermentations resemble more a relay course where different species and strains of yeast succeed one another as alcohol content increases and nutrients become scarcer. Sequential inoculations with chosen strains seek to imitate this progression while affording the winemaker more control over the process than in spontaneous fermentations; however, these schemes rarely incorporate more than two different yeasts. Medina et al.[59] used the apiculate yeast *Hanseniaspora vineae* (as a starter culture) together with *S. cerevisiae* to barrel ferment Chardonnay; this approach produced wines with more intense "fruity" characters and flavors than the wines fermented with only *S. cerevisiae*. Similarly, Soden et al.[181] produced Chardonnay wines with more intense desirable attributes such as "floral", "honey", and "apricot" when including *Candida stellata*. However, in both cases the concentration of ethyl acetate in the wine resulting from the sequential inoculation was almost double that of the control fermented with only *S. cerevisiae*, at levels above the perception threshold of this compound. When above its perception threshold, ethyl acetate possess a "solvent"/"varnish" aroma that is considered a fault and decreases wine quality. Contreras et al.[182] proved that sequential inoculation of Chardonnay musts with *Metschnikowia pulcherrima* and *S. cerevisiae* produced wines with lower ethanol contents as well as higher contents of esters (particularly the "pear" and "banana" smelling 2- and 3-methylbutyl acetate; see Table 3). Sequential inoculation with *M. pulcherrima* increased the concentration of higher alcohols, however, although these remained below their perception threshold, and augmented ethyl acetate 6.5-fold to a level above its perception threshold, at which it is negative to overall wine quality. As observed above, sequential inoculations can be used for a number of purposes, be it to incorporate more aroma complexity into the wine or to produce a wine with a certain desired characteristic, such as reduced ethanol content.

Unlike *S. cerevisiae*, where strains have been isolated, selected, and industrialized to minimize the production of off-odors and negative secondary products such as higher alcohols, acetic acid, and ethyl acetate, while ensuring the consumption of all fermentable sugars, similar work is still being undertaken for alternative yeasts. When using yeasts other than *S. cerevisiae*, a compromise is usually made by the winemaker in favor of the desired characteristic (e.g., trade-off with suboptimal fermentation performance). Parameters such as the optimum ratio between yeast strains and the ideal moment of inoculation with *S. cerevisiae*, depending on the desired style, have yet to be determined, and any possible synergistic effects among the different yeast species requires study. Ciani et al.[183] stated that using more than one yeast species may have unpredictable results, such as unexpected compounds or anomalous levels of components that can alter the final aroma of the wine; all of which must be tested before they can be commonly applied industrially.

White wine fermentations are typically conducted at cool temperatures (i.e., 10−18 °C), and bisulfite is a common winemaking additive used to eliminate indigenous yeasts on grapes prior to inoculation with *S. cerevisiae*. Fermentation temperature and sulfite addition are crucial when indigenous yeasts are used, however, as they are more sensitive to higher temperatures and the presence of sulfite than *S. cerevisiae*. At 21 °C, *S. cerevisiae* is 10 times more viable than any indigenous yeast, whereas an addition of 50 mg SO_2/L (as bisulfite) reduces any non-*Saccharomyces* population by a factor of 10.[173] Furthermore, for inoculated fermentations, ester formation will be affected by the level of inoculum and the sugar content (total soluble solids, TSS) of the must. When lower TSS are present, yeast should be inoculated at a higher level to maximize the ester formation potential. Due to a higher cell count and maximum percentage of viable cells, a high level of inoculation doubles the amount of esters produced in a low TSS situation compared to a low level of inoculation; however, this means that no differences can be detected from a per cell point of view. When TSS is higher and carbon energy sources sufficient, higher inoculation levels do not produce any significant effects on ester production.[127]

Despite the interesting aroma characteristics that may be obtained from using autochthonous yeasts, widespread preference for commercial options can be easily explained by the certainty they give the winemaker for the strain being inoculated and the favorable characteristics they will impart to the wine. Indigenous microflora can include a number of yeasts that produce undesired characteristics (i.e., elevated quantities of acetic acid and ethyl acetate, haziness, off-odors, etc.), that can induce wine spoilage such as *Kloeckera apiculata*, *Metschnikowia pulcherrima*, and *Brettanomyces* spp. For example, *Zygosaccharomyces bailli* produces elevated quantities of acetoin and *Saccharomyces prostoserdovii*, *Saccharomyces bayanus*, and *Zygosaccharomyces fermentati* generate flor-like films under aerobic conditions.[184]

Good hygiene and sound enological practices together with inoculation with selected commercial yeasts have basically eradicated problems with any of the aforementioned yeasts. However, given their resistance to high alcohol and SO_2 levels and low sugar content, *Brettanomyces* spp. pervade all winemaking regions. Contamination with *Brettanomyces* spp. results in higher concentrations of volatile phenols and isobutyric, isovaleric, and 2-methylbutyric acids (sweaty and cheesy aromas). Volatile phenols possess "smoky", "barnyard", "horse sweat", and "spicy" odors and arise from the decarboxylation of hydroxycinnamic acids into vinylphenols, which are then reduced into their corresponding ethylphenols.[47,184] Some strains such as *Brettanomyces intermedius* and *Brettanomyces lambicus* also have the ability to produce "mousy"-smelling 2-acetyltetrahydropyridine/pyrroline from

amino acid precursors;[185] others may produce high amounts of octanoic and decanoic acids (also known as "toxic fatty acids") that inhibit *S. cerevisiae* metabolism when present at the start of alcoholic fermentation.[184]

Bacterial Influences. Malolactic fermentation (MLF) of Chardonnay wines is a common practice in regions such as Burgundy and contributes the typical "buttery", "hazelnut", and "fresh bread" notes (and diminishes the intensity of "fresh" varietal odors such as "apple" and "grapefruit−orange")[186] associated with this variety from lactic acid bacteria (LAB) metabolites, particularly diacetyl and acetoin (Table 3). The contributions from MLF can differ due to grape variety[186] and, to some extent, the relative amounts of diacetyl and acetoin also relate to variety (thus, wine composition), with work by Flamini et al.[187] showing Chardonnay had a higher acetoin/diacetyl ratio than Cabernet Sauvignon. The desirability of this process depends on the style of wine being produced; winemakers have the choice of completely suppressing MLF, allowing it to occur only partially or on a portion of the wine, letting it take place naturally or encouraging it by adding LAB in the form of strains of *Oenococcus oeni*. In addition to deacidifying and helping stabilize wine by transforming malic acid into lactic acid, LAB also possess enzymatic activity, which further modifies wine aroma during MLF.[188] Grimaldi et al.,[189] D'Incecco et al.,[190] and Hernandez-Orte et al.[191] have confirmed the existence of glycosidase activity in *O. oeni* and its ability to release terpenes, C_{13}-norisoprenoids, and other glycoconjugates in model wine, even when MLF does not take place. This means that LAB not only contribute to the aroma of a wine through the production of diacetyl and acetoin but can also increase the amount of desirable compounds that are related to its typicity.[189]

As with yeast, development of indigenous bacteria can also have detrimental effects on the quality of the wine if production is not properly monitored and hygiene is not strictly observed. Several factors contribute to the spoilage of wines by bacteria such as high wine pH, elevated storage temperatures, insufficient SO_2, duration of MLF, strain of LAB present, and presence of residual sugar or O_2 during storage and aging.[184,192] Certain LAB, in particular *Pediococci* and *O. oeni*, possess enzymes that can decarboxylate amino acids into biogenic amines in wines with a high pH; these enzymes remain active even after the bacteria die.[193,194] These two strains are also responsible for the occurrence of "ropiness", in which high amounts of mucilaginous exopolysaccharides such as β-1,3-glucans are produced, conferring to the wine an oily appearance and a viscous texture, albeit no anomalous tastes or smells.[184,192] *Lactobacillus brevis* and *O. oeni* can cause what is known as "Tourne" disorder by fermenting tartaric acid into oxaloacetic acid, and subsequently succinic acid, or acetic acid and CO_2, causing a rise in pH, off-odors ("sauerkraut" and "mousy"), and a flat taste.[184] "Mousy" odors can also appear when 2-acetyltetrahydropyridine, 2-acetyl-1-pyrroline, and 2-ethyltetrahydropyridine are metabolized from ornithine and lysine.[195,196]

Of the eight known acetic acid bacteria (AAB) species, only *Acetobacter* sp. and *Gluconobacter* sp. are commonly found in grapes and wines.[184] These bacteria oxidize glucose and ethanol into acetic acid, acetaldehyde, and ethyl acetate.[192] Spoilage of musts occurs during pressing, when grapes are moldy and exhibit high levels of AAB.[184] Wines exposed to oxygen during aging (under *ullage* or with insufficient SO_2) are also susceptible to the development of AAB.

Contributions from Oak, Aging, and Lees. Chardonnay allows winemakers more stylistic choices than any other white wine variety; depending on the desired style, wines can be aged in oak and stored after bottling for long periods of time. Storage encompasses a number of variables (temperature, time, storage vessel, exposure to light, and closure) of which time and temperature are the most important ones,[74] because these promote and accelerate determinate chemical reactions among the different volatile and nonvolatile molecules in the wine. Unlike most other white wine varieties that are not aged, Chardonnay wines commonly spend a period of time, which may vary between several weeks and a year, in oak barrels. During barrel aging, furfural, 5-methylfurfural, furfuryl alcohol, guaiacol, 4-methylguaiacol, 4-propylguaiacol, eugenol, syringol, and oak lactone (both isomers) are extracted into wine from barrels (Table 4); the contents of 2-phenylethanol, 4-vinylguaiacol, and diethyl succinate also increase.[197]

Freshly cut oak does not contain the compounds that are desired in barrels and has too high a percentage of water; therefore, it must be seasoned and toasted before it can come into contact with wine.[198] Seasoning allows the wood to dry and prevents any shrinkage once the barrel has been formed. Compounds such as oak lactone and eugenol are formed during seasoning, and their concentration will depend on the wood's origin and where and for how long the wood is dried.[199,200] Furan aldehydes (furfural, 5-methylfurfural), vanillin, guaiacol, eugenol, and 4-methylguaiacol are degradation products formed by heat during wood cooperage from cellulose, hemicellulose, and lignin.[199] All of these oak compounds are responsible for the "smoky" and "spicy" aromas associated with barrel-aged Chardonnay wines.[140] Moio et al.[138] determined that guaiacol, derived from contact with oak, is one of Chardonnay's main impact odorants, denoting the relevance if this treatment for the typicity of certain styles of wine for this grape variety.

The amount of volatiles extracted from oak will vary according to the pH and ethanol content of the wine, as well as the barrel lot, its origin, and the number of years in use.[140] Although new French oak possesses on average 2−4 times more total volatile phenols than American oak, these compounds are formed during toasting and will depend on the degree of toasting rather than the origin of the wood. Certain compounds such as syringol, eugenol, and 4-methylguaiacol can decrease drastically between new and 2-year-old barrels to the point where no eugenol or 4-methylguaiacol may be found in wines aged in second-use barrels. Oak lactones are mainly formed from (3*S*,4*S*)-3-methyl-4-*O*-(6′-*O*-galloyl)-β-D-glucopyranosyloctanoic acid (galloylglucoside) and (3*S*,4*S*)-*cis*- and (3*S*,4*R*)-*trans*-3-methyl-4-*O*-β-D-glucopyranosyloctanoic acid during toasting and wine aging.[201] Oak lactones seem to be the exception to the general trend observed for most oak-derived compounds in wines, as the concentration of both isomers increased after 1 year of barrel use, with a more pronounced augmentation of the *cis*- rather than the *trans*-isomer. The ratio at which the *cis*- and *trans*-isomers are present will primarily depend on the origin of the wood, although seasoning can also play a role.[199] Among the oak lactones, the *cis*-isomer is more relevant to wine aroma and represents 57−90% of all oak lactones present,[202] and as highlighted by Maga,[203] only one enantiomer of each isomer can be found naturally in oak, that is, (4*S*,5*S*)-*cis*- and (4*S*,5*R*)-*trans*-oak lactones. *cis*-Oak lactone has been correlated with the intensity of "coconut" aroma in Chardonnay wine;[204] it is usually extracted at concentrations above its perception

Table 6. Concentration (Micrograms per Liter) and Standard Deviation (in Parentheses) of Odorants Relevant to Chardonnay Wine Typicity (Young, Bottle-Stored, and under Accelerated Aging Conditions)[a]

compound	young wine			stored wine (1 year; 18 °C)			accelerated aging

[a]Data from Cejudo-Bastante et al.[74] Where present, different letters across a row indicate significant differences ($p < 0.05$).

threshold (24 μg/L in white wine[102]) and at a low concentration is responsible for the "oaky" and "vanilla" aromas and of "coconut" notes when its concentration increases. The *trans*-isomer possesses a higher detection threshold of 172 μg/L (in white wine) and even when present at high levels does not seem to have an important influence on the overall aroma of the wine.[102,140,205]

As can be observed in Figure 1, Chardonnay wines can either have "smoky", "caramel", and "butter" attributes characteristic of a wine aged in oak or a more "fruity/crisp" character, dominated by "green apple" and "tropical fruit" notes. The Spearman rank-order correlation matrix by Spillman et al.[49] appears to support this claim. From the ranking of attributes the "green apple" attribute appears as very negatively correlated to guaiacol, 4-ethylguaiacol, furfural + furfuryl alcohol, and maltol and less significantly negatively correlated to 4-methylguaiacol, 5-methylfurfural, and furfuryl alcohol. "Green apple" was found to be highest in the control wine that had no contact with oak and exhibited a particularly significant negative correlation to "smoky"; the degree to which the "green apple" attribute was suppressed depended directly on the level of toasting of the barrel.

It is worth mentioning that oak barrel alternatives[45,206−208] (i.e., powders, chips, staves, plastic tanks lined with new or reclaimed oak staves) and different woods[209,210] (e.g., chestnut, beech, pine, cherry) have received attention from researchers. Although not specific to Chardonnay alone, as a whole, the use of oak barrel alternatives in particular offers an economical means of incorporating some of the desirable aroma compounds from oak without the time or expense associated with storing wine in oak barrels. The main factors to be considered when employing oak alternatives are the amount and surface area (shape and size) of the materials used. Chip-treated and barrel-aged wines differ in their contents of a range of volatiles, including vanillin, guaiacol, and furfural,[211] which translates accordingly into different aromas and flavors such as more pronounced "coconut" and "vanilla" together with more bitterness and astringency in white wines treated with chips.[45,212] Use of chips may also decrease the amount of perceived "fresh" and "unripe fruit" aromas and increase the

overall concentration of esters and wood-related compounds as well as the intensity of "oak" aromas in the treated wine.[213] In general, relative to unoaked wines, the use of oak chips improved the liking of wines by the assessors in a number of studies,[45,211,213] which makes it a useful and cost-effective technique for incorporation of oak into certain Chardonnay wines.

Unlike oak, glass is inert, and once a wine is bottled, it is deemed ready to be consumed. Nonetheless, bottle-aging encompasses a different set of changes from those taking place when wine is stored in barrels. For instance, from studies performed on Champagne wines, it is known that the concentration of FFT increases proportionally to the time spent in the bottle, whereas BM reaches a peak at 13−15 years, after which its concentration falls.[126] With regard to other aging phenomena, esters are particularly affected due to their acid−ester equilibria;[214,215] for a wine that had spent 1 year stored in a bottle at 18 °C, Cejudo-Bastante et al.[74] found a significant decrease in the concentration of acetates and certain short-chain fatty acid ethyl esters (C_8−C_{12}) responsible for "fruity" aromas of Chardonnay wines. As evidenced by those results (Table 6), time (storage period) and temperature (accelerated aging) introduced several of these changes in the aromatic profile of Chardonnay wines. Modifications included a decrease in acetates and short-chain fatty acid ethyl esters of octanoic, decanoic, and dodecanoic acid, and the disappearance of 3-methyl-3-buten-1-ol, citronellol, geranic acid, (*Z*)-2-hexen-1-ol, 3-hydroxy-*β*-damascenone, and 3-oxo-*α*-ionol (for the latter three the disappearance was true only in the case of storage time), thereby changing the aromatic profile of the wine. Storage time and accelerated aging induced the appearance of benzofuran, ethyl 4-oxopentanoate, 4-hydroxyhexanoic acid lactone (i.e., *γ*-caprolactone), 5-methyl-2-furancarboxaldehyde (i.e., 5-methylfurfural), and TDN. These compounds are responsible for some of the tertiary aromas of wine, and therefore wines containing high quantities of these volatiles are referred to as more "evolved".

Aging can take place in the presence or absence of yeast lees (autolyzed yeast cells). Aging on lees (often in barrel, but also in tank or bottle as is the case for Champagne) improves the organoleptic score of wines (including overall quality, persistence, color, and taste, as well as aroma) and attenuates the impact of wood on the wine's aroma.[106] During yeast autolysis, polysaccharides (mainly mannoproteins), amino acids, assimilable nitrogen, and other cell contents are released into the wine.[216,217] The presence of lees contributes to the formation of "floral" and "fruity" scented ketones and lactones and to an increase in monoterpenoid concentrations due to the release of *β*-glucosidase enzymes acting on precursors.[106] However, this technique also results in wines with a lower global ester content as yeast autolysis releases esterases, which hydrolyze some of the esters present, into the medium.

During aging, lees both adsorb positive compounds such as esters and glycosylated compounds and strip the wine of off-odors such as volatile phenols and malodorous sulfur compounds (e.g., methanethiol and ethanethiol; however, hydrogen sulfide, dimethyl sulfide, and thiophene were not absorbed).[218,219] In general, aging on lees creates a highly reductive environment that both protects the wine from oxidation and increases the possibility that these negative sulfur volatiles will be formed. This latter effect can be countered by frequent stirring to resuspend lees and create a limited oxidation, as well as by performing an early racking of the gross lees before any reduction odors appear. With time, lees do lose their ability to generate foul-smelling sulfur volatiles as sulfitoreductase activity progressively subsides.[220] Furthermore, both adsorption and hydrolysis reactions are enhanced when lees are stirred.[152,217] When volatile compounds are present at low concentrations, mannoproteins have been observed to enhance the perceived intensity of a number of aroma attributes in Chardonnay wines.[216] However, this effect on overall aroma and individual aroma attributes is not discernible when volatile compound concentrations are high.[106]

The presence of lees also affects the absorption of wood volatiles. Towey and Waterhouse[197] showed that during the last 60 days of a 150 day aging trial, the adsorption on lees of oak volatiles exceeded that of extraction by the wine. This implies that aging on lees decreased the overall oak volatile content in wine, which can be either positive or negative depending on the style of wine sought, the degree of toasting, and the age of the barrel.

Terroir: Regional and Environmental Effects. Terroir has been proven to be an important element in wine aroma profiles. Enological variables aside, each wine-producing region will impart certain aromatic characteristics to the wines produced through the unique combination of weather, soil composition, latitude, longitude, altitude, and viticulture practices.

Fruit set, ripening, and the accumulation and concentration of aroma precursors and free compounds in the berry are affected by environmental and agronomic practices such as canopy management, fertilization, and yield.[26,221−224] Berry development is very susceptible to changes in solar radiation, temperature, rainfall, irrigation, soil composition, and altitude.[225] In particular, sunlight seems to have the most impact on monoterpenoid and C_{13}-norisoprenoid concentrations among all cited parameters; an increase in sun exposure increases the amount of glycosidic aroma precursors present.[116,226] As mentioned previously, C_{13}-norisoprenoids arise from the enzymatic breakdown of carotenoids; if the berry receives a higher amount of sun exposure before veraison, the concentration of carotenoids will increase. If exposure to sunlight is higher after veraison, it will generally accelerate carotenoid breakdown and induce an increase in the amount of glycosylated C_{13}-norisoprenoids present.[227,228] Likewise, higher sunlight exposure increases monoterpenoid concentrations, with this effect being more pronounced in cooler years.[229] It must be noted, however, that the opposite seems to be true for the ubiquitous C_{13}-norisoprenoid *β*-damascenone, at least in the case of Cabernet Sauvignon. As Lee et al.[228] observed, concentrations of *β*-damascenone were highest and those of TDN, lowest, at lower sunlight exposure and temperature.

Arrhenius et al.[37] showed that within wines of a higher quality, sensory attributes were significantly correlated to the wine's origin. In turn, they found that aroma attributes were correlated only to secondary volatiles, such as 3-methylbutyl acetate with the term "green-apples/pears", TDN with "honey", and ethyl 2-hydroxypropanoate with "buttery". In fact, high-quality Chardonnay wines from the Carneros and Napa regions in California could be discriminated from other California wines on the basis of the concentration of 3-methylbutyl acetate, the level of which is unique to each of these regions. Environmental factors could be responsible for differentiating the regions; for example, the Carneros region has a different photoperiod from the Central Coast of California that may affect the rate of formation and accumulation of certain

compounds. This region could further be differentiated from the rest because of higher linalool content.[37] Williams et al.[230] and Marais et al.[231] observed that certain degradation products of carotenoids can be used as geographic markers for Chardonnay wines, because their concentrations vary depending on the temperature of the region; this is likely to be true of Australian Chardonnays, which seem to possess a distinct concentration of C_{13}-norisoprenoids that yield characteristic sensory attributes.[111,230]

Changes in environmental conditions between different vintages also affect the volatile composition of wines from a single vineyard (i.e., vintage effect). Louw et al.[67] showed that, with the exception of 2-phenylethanol, acetic acid, ethyl hexanoate, hexanoic acid, 3-methyl-1-butanol, and propanol, the level of 20 of 26 volatiles varied significantly during three consecutive South African vintages. That is, changes to fatty acids and their ethyl esters, along with higher alcohols and their acetates, were deemed to be caused by vintage effects. These compounds are associated with the volatiles derived from fermentation, implying an underlying change in grape composition (e.g., differences in amino acids and other nutrients) that was materialized upon fermentation.

Depending on intensity and timing, water deficit induces a reduction in Chardonnay wine quality, generating wines with high pH and low acidity and prone to atypical aging (i.e., wines with a lower intensity of varietal aromas and evident faults reminiscent of "acacia blossom", "furniture polish", "medicinal", and "naphthalene").[232,233] Atypical aging can be caused by suprathreshold levels of 2-aminocetophenone and other compounds such as sotolon that remain to be conclusively identified.[233−235] Research conducted by Reynolds et al.[236] showed that Chardonnay wines made from vines irrigated for different lengths of the season possessed higher intensities of "apple" and "citrus" compared to the nonirrigated controls and lower "earthy" aromas in three of four cases; however, consistent with the controls, wines showed greater atypical aging potential when the vines were subjected to irrigation up until lag phase or veraison. From their results, water stress could have interfered with the ability of grape berries to synthesize and accumulate monoterpenoids and ester precursors and may have promoted accumulation of compounds responsible for the atypical age character depending on the timing of water stress.

The characteristics of the soil where vines are planted is another environmental variable to consider when effects on wine composition are evaluated.[237] Soil properties can influence the depth that roots can penetrate, the availability of micronutrients, the retention of water, and therefore the level of hydric stress the plant is subjected to. All of these variables can affect the overall aroma of the subsequent wines. As Reynolds et al.[238] demonstrated, vineyards with high clay textures tended to yield Chardonnay wines with "vegetal", "earthy", and "citrus" characteristics, whereas wines made from grapes grown in sandy soils had "floral" and "melon" aromas. Although this study provides some guidance, at times there was a relationship between vine size and soil texture, and it was possible that vines in high-clay zones experienced some level of water stress. However, the results highlight the need to consider the impacts of the multiple facets of terroir on wine quality.

Weather can be partly countered through different agricultural techniques such as leaf removal and crop thinning. Leaf removal is particularly recommended in cold and cool climates to decrease the presence of "green" and "unripe" sensory attributes in the wine.[239] Under these conditions, leaf removal has been shown to increase the positive "floral" and "fruity" attributes. The effect of this treatment depends on when in the berry development cycle it is practiced; when applied during fruit set and veraison, the results are similar.[239] In areas with a high luminosity and potential for sunburn, a shaded bunch zone is preferable because a combination of high light intensity and temperature of the berry surface between 40 and 43 °C for only 5 min is enough to cause sunburn of mature Chardonnay berries. Sunburn damages the skin of the berry, decreasing quality and increasing concentrations of total phenolics, hydroxycinnamates, flavonoids, and tannins,[240−242] whereas under high light intensity and temperature conditions, shading can lead to crisper and more elegant wines that have more "citrus", "apple", and "quince" aromas.[16,224]

FUTURE DIRECTIONS

Given the popularity of Chardonnay wines and the global economic relevance of this variety, producers are always striving to produce better wines that cater to the current market trends. Understandably then, much work has been done to comprehend the volatile compounds present and the impact of each production step on the final aroma of Chardonnay wines. Over the years, quality has improved such that, for consumers, finding a good-quality wine is now extremely easy, but at the same time a certain homogeneity of flavor has appeared in the market, with two dominant styles arguably being responsible for most Chardonnays available in the market. In an industry where brand recognition goes only so far, uniqueness of the product is necessary. Determining whether this uniqueness is achieved at the vineyard level or via increased extraction of grape aroma compounds or through the use of different winemaking techniques requires more emphasis and understanding of the terroir dimension as well as a search for originality through the use of different yeast strains while preserving the typicity of Chardonnay.

Despite the definite existence of a typicity concept for Chardonnay, this has only started to be comprehended and requires deeper studies as this is a variety that can express itself in a multitude of profiles; Chardonnay is not as straightforward as other varieties (i.e., Sauvignon blanc or Muscats), which are dominated by distinct varietal compounds. Tackling its typicity requires multidisciplinary studies that analyze a number of variables responsible for the final product, rather than a one-directional focus.

Excellent advances in compositional knowledge have been detailed above, yet studies need to be carried out to confirm whether vintage-related changes between fatty acids and higher alcohols and their corresponding esters also occur in Chardonnay produced in different parts of the world and whether a trend can be determined. A better comprehension of the fate of aroma compound precursors extracted from the grapes is still required, as is the combined effect of the many components of terroir and how the most important ones are best manipulated and controlled. More work is therefore needed to correlate viticulture management with aroma/sensory profiles of the wines. In addition, very little is known of the potential of currently available Chardonnay clones, their interrelation with rootstocks, and any new clones that might be in development as related to other parameters such as yield, salt and drought tolerance, and vigor. Climate change will demand transformation and adaptation to new weather conditions with new choices that preserve the current quality standards.

Due to health concerns and taxation implications, as well as in response to the augmentation of alcoholic strength due to global warming and opting for riper fruit, low-alcohol wines and dealcoholization techniques have become a prime concern for the industry. Viable and cost-effective techniques that yield palatable and high-quality wines need to be formulated and tested on Chardonnay to determine the best alternative for producers. In a similar way, higher rates of individuals being susceptible to SO_2 and other industry additives, as well as dietary restrictions, pose new challenges for the wine industry, which will require the help of researchers to be solved.

■ NOTE ADDED AFTER ASAP PUBLICATION

This article published July 7, 2014 with errors in Tables 2, 3, and 4. The correct version published July 8, 2014.

Declaration and approved by the Ethics Committee from CSIC (Madrid, Spain) (Table 1). All volunteers gave their written informed consent prior to participation, and they had not taken antibiotics during 4 weeks before the trials. In the three intervention trials, volunteers consumed their usual diet but avoided ellagitannin-containing food products during the study and 1 week before starting.

In the first intervention study, healthy volunteers (n = 20, 11 men and 9 women) aged between 21 and 55 years consumed 30 g of walnuts (edible part)/day for 3 days. Walnuts were purchased in a local supermarket. After the last intake, 24 h urine samples were collected. Urinary volume was measured, and the samples were immediately stored at −20 °C.

In the second intervention study, healthy volunteers (n = 20, 10 men and 10 women) aged between 18 and 23 years ingested four capsules of pomegranate extract in a single intake (total dose = 1.8 g of extract). Urine samples were also collected for 24 h after the intake and were immediately stored at −20 °C.

In the third trial, overweight healthy subjects (n = 49, 32 men, 17 women; body mass index (BMI) > 27 kg/m^2) aged between 40 and 65 years ingested two daily capsules of pomegranate extract (0.9 g/day) for 3 days. Urine samples were collected for 24 h after the last intake, and the urine was stored at −20 °C until further analysis. In both interventions 2 and 3 capsules containing pomegranate extract were kindly supplied by Laboratorios Admira S.L. (Alcantarilla, Murcia, Spain).

Extraction Protocol of Urolithin Metabolites. Urine and feces samples were processed as previously reported.[4,5]

LC-MS Analysis. Samples were analyzed by HPLC-DAD-ESI-MS/MS or UPLC-ESI-QTOF-MS as previously reported.[4]

RESULTS AND DISCUSSION

We report here that human subjects can be consistently clustered within three phenotypes, that is, "phenotype A", "phenotype B", or "phenotype 0" according to their different capacities for excreting urolithins, independent of their demographic characteristics, health status, or ellagitannin-containing food product (Table 1). This has been observed in three dietary interventions in healthy volunteers (present study) as well as after re-examining available data for urinary profiles from previous studies.

Urolithins are mainly detected either as aglycones in feces or as phase II metabolites in systemic organs or biological fluids (glucuronide or sulfate derivatives). Overall, urolithin A (**1**) is the main metabolite produced in humans and previously identified as a urinary biomarker after consumption of ellagitannins/ellagic acid from different food products.[6] In the present study (Table 1), interventions 1−3 with healthy volunteers, some volunteers excreted only urolithin A metabolites (phenotype A), whereas other subjects, in addition to urolithin A (**1**), also excreted urolithin B (**3**) and isourolithin A (**2**) showing a more complex urinary metabolite profile (phenotype B) (Figure 2). Furthermore, a third group that did not excrete urolithins in urine was also identified (phenotype 0). The same three phenotypes were observed after intake of walnuts (intervention 1) or pomegranate extracts (interventions 2 and 3).

This observation prompted us to re-examine the excretion profiles observed in previous studies that we had previously completed in our laboratory or in collaboration with other research groups, as well as data available from other published studies. These three phenotypes were also found in intervention studies either with healthy volunteers or with those volunteers having some disease situations, confirming that these three phenotypes are quite robust and consistent (Table 1). In accordance with the three interventions described here, the three phenotypes were also observed no matter the

Table 1. Urolithin Urinary Phenotype Distribution in Different Human Trials

trial	food (quantity ingested, total ellagic acid content after hydrolysis/day)	analytical technique	N	age	BMI (kg/m^2)	health status	phenotype		
							A	B	0
intervention 1 (this study)	walnuts (30 g/day, 162.8 mg of total ellagic acid)	HPLC-DAD-ESI-IT-MS/MS	20 (10 men, 10 women)	21−55	23.8 ± 2.3	healthy	13 (65%)	4 (20%)	3 (15%)
intervention 2 (this study)	pomegranate extract (1.8 g, 220 mg of total ellagic acid)	UPLC-ESI-QTOF-MS	20 (10 men, 10 women)	18−23	20.5 ± 2.1	healthy	16 (80%)	2 (10%)	2 (10%)
intervention 3 (this study)	pomegranate extract (0.9 g/day, 110 mg of total ellagic acid)	UPLC-ESI-QTOF-MS	49 (32 men, 17 women)	40−65	30.4 ± 3.4	healthy-overweight	30 (60%)	15 (30%)	4 (10%)
González-Sarrías et al.[7]	walnuts (35 g/day, 190 mg of total EA), pomegranate juice (200 mL/day, 165.7 mg of total ellagic acid)	HPLC-DAD-ESI-IT-MS/MS	28 (men)	56−90	27.7 ± 3.6	prostate cancer or benign prostate hyperplasia	17 (60%)	4 (15%)	7 (25%)
Truchado et al.[8]	strawberry (200 g of fresh strawberries or the equivalent in puree, 150 mg of total ellagic acid)	HPLC-DAD-ESI-IT-MS/MS	20 (8 men, 12 women)	25−30	not available	healthy	16 (80%)	3 (15%)	1 (5%)
Puuponen-Pimia et al.[9]	strawberry (100 g/day, 75 mg total EA) + raspberry (100 g/day, 147 mg of total ellagic acid) + cloudberry (100 g/day)	HPLC-DAD-ESI-IT-MS/MS	20 (10 men, 10 women)	50−65	31.8 ± 4.4	metabolic syndrome	5 (25%)	10 (50%)	5 (25%)
Tulipani et al.[11]	nuts (unpeeled), (30 g/day, 81.4 mg of total ellagic acid) (15 g of walnuts + 7.5 g of almonds + 7.5 g of hazelnuts)	HPLC-DAD/ESI-QqQ-MS/MS and HPLC-ESI-IT-MS	22 (13 men, 9 women)	31−63	31.0 ± 2.9	metabolic syndrome	11 (50%)	9 (41%)	2 (9%)
Núñez-Sánchez et al.[4]	pomegranate extract (0.9 g/day, 110 mg of total ellagic acid)	UPLC-ESI-QTOF-MS	26 (14 men, 12 women)	52−89	28.9 ± 3.9	colorectal cancer	11 (42.3%)	11 (42.3%)	4 (15.4%)

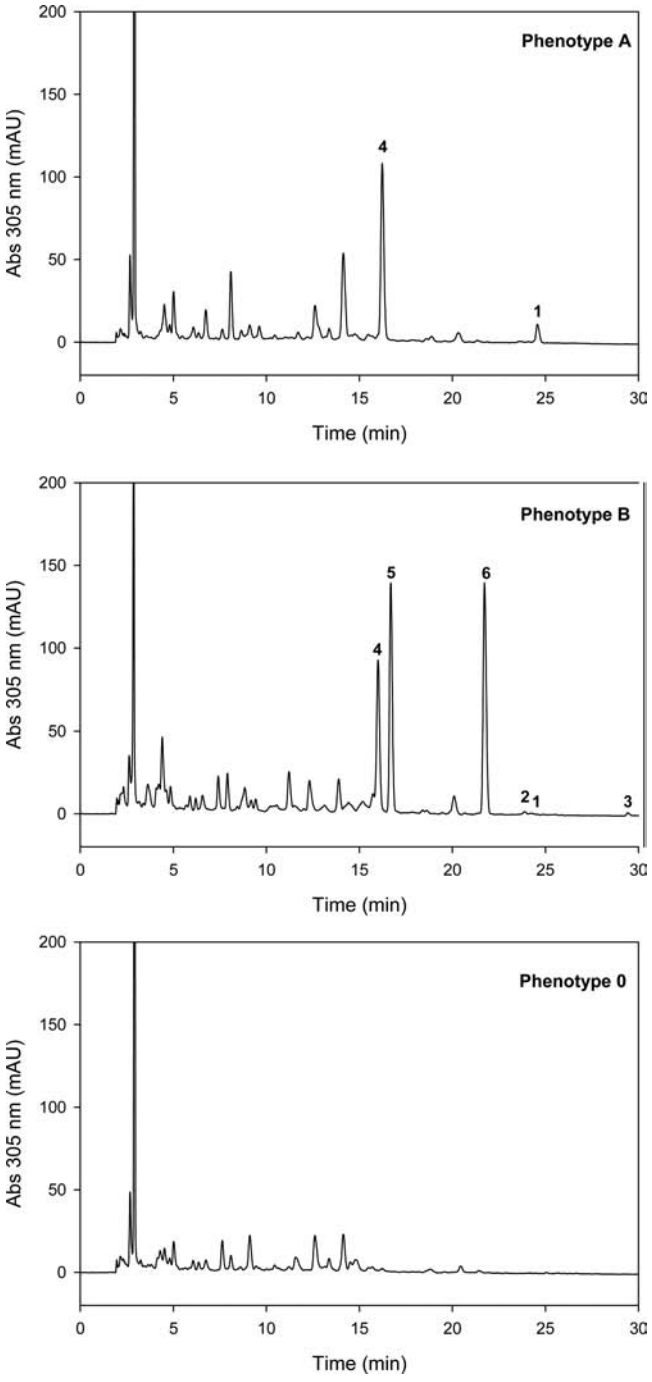

Figure 2. Characteristic HPLC-UV chromatograms showing the urolithin metabolite profiles corresponding to the three urinary phenotypes observed after the intake of walnuts.

source of ellagitannins and the amount of ellagic acid ingested. They were identified after the intake of walnuts, pomegranate juice,[7] pomegranate extracts,[4] strawberries,[8,9] raspberries,[9,10] cloudberries,[9] and unpeeled nuts.[11]

In healthy volunteers as well as in those patients with illnesses that are not characterized by gut dysbiosis (prostate cancer or benign hyperplasia), phenotype A was the main urinary profile (Table 1; Figure 3). In this regard, phenotype A was also the most abundant profile in patients with chronic obstructive pulmonary disease (age 60 ± 11 years) that consumed pomegranate juice for 5 weeks,[12] although data were not available for quantitative re-examination of the urinary

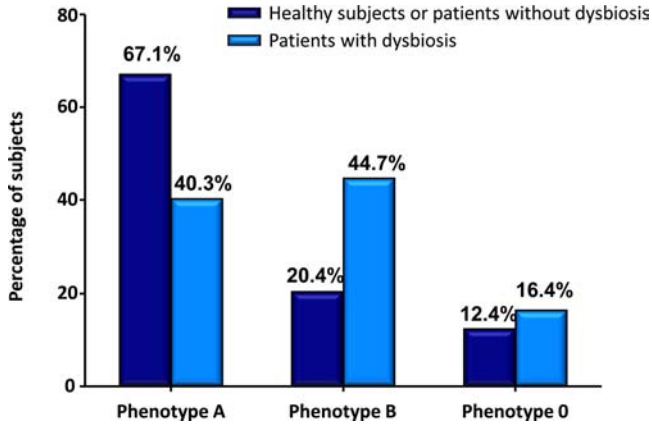

Figure 3. Mean distribution of the three phenotypes present in healthy subjects and patients without dysbiosis (n = 137) as well as in those patients with illnesses associated with gut dysbiosis (metabolic syndrome, n = 42; and colorectal cancer, n = 26).

profiles (results not shown). In contrast, the ratio between phenotypes A and B changed in patients with illness associated with gut dysbiosis such as metabolic syndrome or colorectal cancer, where phenotype B gained increasing relevance (Table 1; Figure 3). Age, gender, BMI, and geographical location did not affect urolithin urinary profiles (Table 1). We hypothesize that gut dysbiosis is the cause of the increase in the abundance of isourolithin A and urolithin B (phenotype B) in the patients with colon cancer and metabolic syndrome (Table 1). Therefore, a urolithin production test could be a useful biomarker to monitor certain gut microbial imbalances or to assess treatment efficacy.

Previous studies from other groups also showed the presence of these three phenotypes, which were within the ranges shown here. For example, a previous study of the urinary urolithins produced after the intake of raspberries by healthy volunteers (n= 10) showed that 70% were only urolithin A excreters (phenotype A), 20% excreted in addition isourolithin A and urolithin B (phenotype B), and 10% were nonexcreters (phenotype 0).[10] Interestingly, despite the relatively low number of volunteers, the distribution of the three phenotypes was similar to that observed in the three trials with healthy subjects shown here. A recent study[13] has reported the presence of three urinary urolithin excretion patterns after the intake of tropical highland blackberry juice by healthy volunteers that is also consistent with our results. However, demographic characteristics (age, gender, BMI) of volunteers were not described, and the ratio between phenotypes A and B was closer to that found in patients with gut dysbiosis than that observed in healthy subjects. In addition, in this previous study, the correlation of the production of urolithin B with that of isourolithin A was not described, as isourolithin A was not analyzed.

Our results show that stratification of subjects according to their urolithin phenotype should be considered in ellagitannin and ellagic acid intervention trials. Three consistent enterotypes, with different gut microbiota communities, have been described in humans.[14] In line with the trend highlighted by a previous study,[15] the challenge now is to investigate the correlation between these enterotypes, the three urolithin phenotypes, and the possible impact on human health.

Urolithins seem to be responsible for some health effects after ellagitannin intake;[2] therefore, volunteers in phenotype 0

dx.doi.org/10.1021/jf5024615 | J. Agric. Food Chem. 2014, 62, 6535−6538

will probably not benefit from them, and this should be demonstrated in further studies. Ellagic acid either remains unmetabolized in these volunteers or could be metabolized in a different way, leading to compounds different from urolithins that need to be further investigated.

climate site compared with a subcontinental climate location (i.e., a location where autumn-sown crops undergo severe low-temperature stress during winter).[19] A second study, including some varieties and one ecotype grown in two climatically contrasting Italian sites, revealed large genotypic variation for various seed quality traits, along with large genotype × environment interaction variation for grain yield.[7] Subcontinental climate conditions determined higher QA content than Mediterranean conditions, leading various low-alkaloid varieties to exceed the limit of 200 mg/kg.[20]

The objective of this study is providing a thorough assessment of the relative contribution of genotypic, environmental, and genotype × environment interaction effects to variation in key production and quality traits of white lupin seeds. Our study included eight elite, phenotypically contrasting genotypes, which were grown in two climatically contrasting Italian locations for two cropping years, and we assessed grain yield, seed weight, and the content of oil, TOC, and QA.

MATERIALS AND METHODS

Chemicals. Hexane, dichloromethane, and 2-propanol were purchased from Baker (Deventer, The Netherlands); 36% hydrochloric acid was from Merck (Darmstadt, Germany); 25% NH_4OH was from Carlo Erba (Rodano, Italy); and standards of tocopherols were from Calbiochem (EMD Biosciences, Merck, Darmstadt, Germany).

Plant Material and Growing Environments. The test white lupin genotypes were (i) Multitalia, which is the only commercial variety of white lupin registered in Italy; (ii) seven advanced breeding lines produced by a joint selection program of CRA and Jouffray-Drillaud, coded hereafter as P2, P3, 4-3, 7-44, 7-7, 8-28, and 8-483. These lines were selected from a large number of breeding lines on the ground of wide or specific adaptation to subcontinental and Mediterranean climate locations of Italy, with the further objective of ensuring the presence of large morphophysiological variation within the set of tested material.[21] Modern white lupin varieties can be classified according to their phenological characteristics as spring (S) or autumn (A) types (which recall their suitability for spring or autumn sowing in cool temperate regions such as France); as tall (t), semidwarf (sd), or dwarf (d) types, according to genes affecting internode length and plant stature; and as indeterminate (I) or

dx.doi.org/10.1021/jf405615k | J. Agric. Food Chem. 2014, 62, 6539−6545

determinate (D) types, depending on the presence or absence of genetically determined ability to flower on secondary and higher-order branches.[22,23] The breeding lines exhibited the following combinations of traits: (i) lines P2 and P3, S/t/I; (ii) lines 4-3 and 7-44, A/sd/I; (iii) line 7-7, A/t/I; (iv) lines 8-28 and 8-483, A/d/D. Multitalia is t/I/ phenologically intermediate between S and A.

The eight genotypes were grown in Lodi (Lombardy, Italy, 45° 19′ N, 9° 03′ E) and Sanluri (Sardinia, Italy, 39° 30′ N, 8° 50′ E) in rain-fed autumn-sown field experiments, which were repeated in the seasons 2006−2007 and 2007−2008. Lodi has a subcontinental climate with cold winters and more favorable rainfall pattern than Sanluri, which has a Mediterranean climate (Table 1). The soils of both locations, featuring pH < 7.5 and active lime below 0.4%, were favorable for lupin cropping. Each experiment was designed as a randomized complete block with three replications. Each plot included 54 sown seeds arranged on three rows. Before sowing, the seeds were treated with Germipro UFB (BASF Agro, Ecully, France; 350 g/L iprodione + 177 g/L carbendazim) at the rate of 2.6 mL/kg, to limit possible damage by anthracnose (*Colletotrichum gloeosporioides*). They were inoculated with NPPL HiStick (Becker Underwood, Toulouse, France), to ensure proper nodulation and N fixation by *Bradyrhizobium* strains. The experiment in Lodi was fertilized with 40 kg/ha N and 120 kg/ha P_2O_5 and K_2O, whereas soil analyses suggested no fertilization requirement for Sanluri. Chemical weed control was performed in both sites by applying 4 L/ha Stomp 330 (BASF Agro; pendimentalin 32%). Individual plots were harvested individually when they reached crop maturity, which occurred in the first two weeks of July in Lodi and the second and third week of June in Sanluri. Grain yield was expressed at 13% seed moisture, after moisture determination on a random sample of 200 seeds per field replicate. These seed samples were also used for assessing the individual seed weight, expressed on a dry matter basis. Another random sample of 20 g of seed/replicate was used for assessing oil, TOC, and QA contents.

Extraction of Oil. Impurities were removed from the seeds, and the cleaned seeds were hand-dehulled, ground in a household mill (Braun, Germany), and sieved through a 60-mesh sieve. The oil was extracted with hexane for 6 h with a Soxhlet apparatus using cellulose extraction thimbles (123 mm × 43 mm i.d.; Whatman International, Brentford, U.K.); its content was gravimetrically determined and expressed as milligrams per gram of flour.[7,19] Each sample was independently extracted three times.

Extraction and Determination of Tocopherols. Tocopherols (TOC) were determined as previously reported.[6] Briefly, the oil was diluted in hexane, filtered through a 0.45 μm filter (Grace, Milan, Italy), and analyzed by a 1100 series HPLC (Agilent Technologies, Santa Clara, CA) equipped with an autosampler and a fluorometric detector (λ_{assn} = 295 nm, λ_{exc} = 290 nm, λ_{em} = 330 nm, frequency 55 Hz, gain 10). The analyses were performed on a Lichrosorb Si60 column with *n*-hexane/2-propanol (99:1 v/v) as mobile phase; the injection volume was 10 μL and the flow rate was 1 mL/min. The relative amounts of TOC were calculated by comparing their peak areas with standard curves, as previously reported.[6] The total TOC content was calculated by summing up the values of each detected isomer. TOC concentration was expressed as milligrams per gram of flour. Each sample was independently analyzed three times.

Extraction and Determination of Quinolizidine Alkaloids. Quinolizidine alkaloid (QA) extraction was performed as previously reported.[20,24] Briefly, 1 g of defatted flour was suspended in 8 mL of 0.1 N HCl and stirred at room temperature for 17 h; the mixture was centrifuged at 6000*g* for 50 min at 4 °C, the supernatant was collected, and the solid was washed twice with 5 mL of 0.1 N HCl. The gathered extracts were alkalinized with 5% NH_4OH to pH 10−11 and then applied onto an Extrelut NT 20 column (Merck, Darmstadt, Germany). The alkaloids were eluted with CH_2Cl_2 (4 × 20 mL), and the solvent was evaporated to dryness under vacuum. The residue was diluted in dichloromethane and analyzed by gas chromatography−mass spectrometry (GC-MS). Each sample was independently extracted at least three times. The GC-MS analyses were performed on a Shimadzu QP-5000 GC-MS instrument equipped with an AOC20i autosampler (Shimadzu) using an AT-1 ms capillary column 30 m × 0.25 mm i.d., 0.25 μm (Supelco, Milan, Italy). The temperature program was as follows: 150 °C for 5 min, from 150 to 300 °C at 5 °C/min, and then 300 °C for 15 min. Analyses were performed in split mode (split ratio 1:25), the injection volume was 1 μL, the injection temperature was 250 °C, the interface temperature was 300 °C, and the acquisition was in the range 50−450 *m*/*z*. The source operated in electron ionization (EI) mode. Each analysis was repeated three times. The identification and quantification of QA was performed as previously reported.[20,24] The total content, expressed as milligrams per gram of flour, is the sum of nine alkaloids (reported here in elution order): albine, angustifoline, α-isolupanine, lupanine, 11,12-seco-12,13-didehydromultiflorine (formerly *N*-methylalbine), multiflorine, 13α-hydroxylupanine, 13α-angeloyloxylupanine, and 13α-tigloyloxylupanine. Figure 1 reports a typical GC-MS chromatogram and chemical structures of QA. Each sample was independently analyzed three times. In Supporting Information, the main analytical features of the detected QA (Table S1) and composition of single QA (Table S2) are available.

Statistical Analysis. Chemical analysis replications belonging to same field plot were averaged prior to statistical analyses, which were performed on the three field plot replications available for each genotype−environment combination (considered more representative of treatment variation due to environmental effects than chemical replications). An analysis of variance (ANOVA) including the fixed factors genotype, location and year and the random factor experiment block was performed on plot values of grain yield, individual seed weight, oil content, TOC content, and QA content, to assess the significance of all genotypic, environmental, and GE interaction sources of variation. A second ANOVA including the fixed factors genotype and cropping environment (as defined from the four location−year combinations) and the random factor block aimed to compare mean values of genotypes and environments using Duncan's multiple range test at $p < 0.05$. The size of genotypic, environmental, and GE interaction effects was assessed by estimating the respective ANOVA components of variance through a restricted maximum likelihood method, assuming in this case that genotypes and environments were a random sample of the genetic and environmental variation relevant to a breeding program. ANOVAs were also carried out for each trait in each experiment, reporting least significance difference (LSD) values for genotype mean comparison at $p < 0.05$. All analyses were performed with Statistical Analysis System (SAS) software (1999).

RESULTS

Climatic information for test years and the long term at the test locations, particularly that with a bearing on the extent of winter cold stress and terminal drought stress, is given in Table 1. As expected, the subcontinental climate site (Lodi) was characterized by colder winters (in terms of number of frost days and absolute minimum temperature) and more rainy springs than the Mediterranean climate site (Sanluri). However,

[a]Environments were formed by the combination of one subcontinental (Lodi) or Mediterranean (Sanluri) climate location by each of two cropping years (2006−2007 and 2007−2008). Least significant difference (LSD) at $p < 0.05$ for genotype mean comparison within and across environments is also shown. [b]Environment row means, or genotype column means across environments, that are followed by different letters differ at $p < 0.05$ according to Duncan's test.

dx.doi.org/10.1021/jf405615k | J. Agric. Food Chem. 2014, 62, 6539−6545

milder winters and higher mean temperatures than the long term in Lodi (particularly in the first year), and wetter springs (particularly in the first year) and lower winter and mean temperatures (in the second year) than the long term in Sanluri, made the two locations less climatically contrasting over the test years than in the long term (Table 1).

Mean values of grain yield and seed quality traits for the eight lupin genotypes grown in the four environments formed by the combination of two climatically contrasting sites (Lodi or Sanluri) and two cropping years (2006−2007 and 2007−2008) are reported in Table 2, whereas ANOVA results for genotype, location and year factors and their interactions are given in Table 3. Significant variation among genotypes was detected

both across and within environments for all traits. Genotype responses, however, interacted significantly with location and year in all cases (Table 3).

Averaged across genotypes, the lupin crop in the subcontinental climate site exhibited, in comparison with the Mediterranean location, almost 3-fold higher grain yield, larger seed (actually only in the first year), about 8% lower oil content, and definitely higher QA content (Table 2). The grain yield advantage of the former site over the latter was about 2-fold when the genotypes capable of maximizing the crop yield in each location are considered, that is, 7-44 in Lodi (site mean yield 7.27 t/ha), and P3 in Sanluri (site mean yield 3.46 t/ha) (Table 2). The mean crop response across environments tended to be more consistent and predictable for oil content (location factor was significant at $p < 0.05$; year, and location × year interaction were not significant) than for the other variables (Table 3). In contrast, site variation for TOC was inconsistent across years due to large location × year interaction (Table 3), since the Mediterranean location exhibited both the highest (first year) and the lowest (second year) environment mean value for this variable (Table 2).

The relative size of genotypic, environmental and GE interaction components of variance differed depending on the trait (Table 4). Grain yield variation was outstandingly affected by the cropping environment on the basis of the much greater size of the environmental component of variance relative to the genotypic and GE interaction variance components. Genotype yield responses were more affected by GE interaction than by purely genetic effects (as indicated by the almost 4-fold greater size of GE interaction variance relative to genotypic variance). Seed weight was affected by the environment and, to a lesser extent, by the genotype, in a fairly consistent manner (as indicated by the relatively smaller size of the GE interaction

Table 4. Estimates of Genotypic and Environmental Components of Variance for Grain Yield and Grain Quality Traits of Eight *Lupinus albus* Genotypes[a]

[a]Environments are combinations of two climatically contrasting locations by two cropping years. All variance components different from zero at $p < 0.01$.

variance component relative to the genotypic and environmental components of variance). Oil content variation was mainly affected by genotypic differences, which were partly inconsistent across environments (as indicated by comparable genotype and GE interaction variance). Purely genetic variation for TOC content had negligible size (although being statistically significant in Table 3) when compared with the outstanding variance of cropping environment and GE interaction (Table 4). Finally, QA content variation in this data set was largely affected by the genotype (Table 4), as further discussed later on.

Grain yield responses of the cultivars were heavily influenced by their phenological characteristics, as highlighted in greater detail in an analysis of adaptation that is reported elsewhere.[21] Spring types (lines P2 and P3) were top-yielding in the Mediterranean site, performed fairly well in the mild winter year of the subcontinental climate site, and yielded very poorly in the cold winter year of the same site (Table 2) because of severe winter mortality. Autumn types, including the remaining breeding lines, displayed the opposite adaptation pattern, whereas Multitalia (phenologically intermediate) was moderately adapted to any test environment (Table 2). Multitalia also featured larger seed than any breeding line (Table 2).

The genetic variation for mean value of oil content was sizable (range of genotype means across environments 9.2−11%), whereas that for TOC was modest (range of genotype means across environments: 0.121−0.133 mg/g) (Table 2). In both cases, they were unrelated to phenological types (Table 2). In absolute terms, the highest recorded values for these quality traits were 12.3% for oil content (line 7-44 in the first cropping year at Lodi) and 0.153 mg/g for TOC content (line 8-483 in the first year at Sanluri) (Table 2).

Multitalia exhibited extremely high QA content, exceeding by at least 12-fold the limit of 200 mg/kg even in the most suitable environment for producing low-QA lupins (Table 2). All breeding lines except for line P3 exceeded the 200 mg/kg limit in at least one test environment (Table 2).

DISCUSSION

Our results can contribute to choices and strategies of product supply for seed lupin processing industries, as well as to variety selection strategies, for production areas of southern Europe. This region includes Mediterranean climate areas (represented here by Sanluri) that are widespread in central and southern Italy and in coastal areas of the Iberian and Balkan peninsulas and southern France, as well as subcontinental climate areas (represented by Lodi) placed in northern Italy and in inland areas of the Iberian and Balkan peninsulas and southwestern France. However, conclusive indications for these climatic

regions, especially for areas outside Italy, would require verification from experiments in a larger sample of test environments.

Assessing also site crop production, as in the current study, has great practical importance for the seed market, particularly with respect to plant material with locally highest yielding ability and in case a trade-off existed between grain yield and quality. The Mediterranean climate growing site offered two seed quality advantages, namely, consistently higher oil content and much lower risk of exceeding the safety QA level of 200 mg/kg, compared with the subcontinental climate site. These results confirm earlier findings relative to other white lupin cultivars.[7,19,20] These advantages may justify the attribution of somewhat higher market price to seeds produced in Mediterranean environments, which could partly counterbalance the much lower grain yield of these environments relative to subcontinental climate ones.

Besides its use as a traditional or functional food, white lupin could be used as a dual-purpose crop for oil extraction and for use of the residual from extraction as a high-protein feed (as ordinarily done for soybean). This option would be reinforced by the excellent food quality of its oil.[6,7] This study confirmed that Mediterranean environments are more suitable than subcontinental climate ones to produce oil-rich seeds. However, the oil content of locally adapted material (lines P3 and P2 and Multitalia) never exceeded 12% (Table 2). Although their oil contents were higher than those reported for other white lupin material in the United States (highest value 8.2%)[25,26] and Turkey (highest value 10.7%),[27,28] they might be too low to justify the oil extraction. Higher oil content (up to 13.6%) was previously observed in another Mediterranean climate Italian site, which featured, however, extremely low grain yield.[19] On the whole, these results emphasize the potential interest of screening large germplasm collections with the aim to identify material with outstanding oil content. The selection from such material of improved varieties is encouraged by the current finding that about half the genetic variation for oil content is not subject to GE interaction and can, therefore, be expressed consistently across cropping environments. This finding agrees with previous results for different cultivars of white lupin,[7] as well as with results for narrow-leafed lupin (*L. angustifolius*) in Australia.[29]

This study confirms the large GE interaction for grain yield across south-European environments that had already emerged for other sweet-seeded cultivars[30] and for a world collection of ecotypes of white lupin.[31] This GE interaction depends to a large extent on the site-specific importance of flowering time, as early material is more susceptible to winter frost but more tolerant to terminal drought than late material, and vice versa.[31] More generally, white lupin breeding for European regions needs to cope with particularly large specific-adaptation effects.[32]

The amount of QA in white lupin cultivars is genetically controlled by one major recessive gene and various minor genes.[22] The current content of QA referred to the sum of albine, angustifoline, multiflorine, 11,12-seco-12,13-didehydro-multiflorine, lupanine, α-isolupanine, 13α-hydroxylupanine, 13α-angeloyloxylupanine, and 13α-tigloyloxylupanine. The lower QA content exhibited by seed produced in the Mediterranean environments agrees with the finding by Christiansen et al.[33] that terminal drought stress tends to decrease the white lupin seed content of QA. Large environmental effects that were substantially unrelated to rainfall were reported for narrow-leafed lupin in Australia.[29] The outstanding QA seed content of Multitalia is probably due to extensive contamination, which may have arisen at first from pollen of neighboring bitter-seed plants and then built up in the cultivar stock across the many cycles of multiplication of this 25-year old cultivar. The average QA value of Multitalia in Lodi (5.6 mg/g) may imply over 30% bitter seeds, considering that the most bitter-seed Italian ecotypes displayed around 15 mg/g QA in the same location.[20] A contamination of 3% bitter seeds may lead to 25% bitter seeds after eight generations of seed multiplication, owing to the advantage of high QA plants under natural selection.[22] Although much lower, the QA content of most current breeding lines occasionally exceeded the limit of 200 mg/kg, probably because of slight contamination that arose at some stage of the selection process.

Tocopherols exist in four different congeners (vitamers) called α, β, γ, and δ. The most abundant are α, which is the main contributor to vitamin E activity, and γ, which shows the highest antioxidant activity in foods.[10] White lupin seeds contains α-, γ-, and δ-TOC (unlike narrow-leafed lupin, which lacks the third one).[6] The occurrence of fairly wide variation for TOC values had already been reported.[34,35] While confirming that (absolute range 0.107−0.153 mg/g; Table 2), our study also shows that this variation is substantially unpredictable and not exploitable, being largely inconsistent both across locations in different years and across genotypes in different environments.

Large seed is important essentially for direct lupin utilization as a traditional food. No tested material featured seed large enough for that use. Our results suggest, however, that genetically based differences for seed weight are largely repeatable across environments and, hence, selectable through breeding. The environmental effect is larger than the genetic one but is partly predictable, as somewhat larger seed can be obtained from more favorable growing environments.

In conclusion, the different white lupin traits object of our study offer different challenges and opportunities for breeders and crop production stakeholders. Some traits, such as oil content, alkaloid content, and to a lesser extent seed size, are affected by the agroclimatic area in a fairly consistent manner across cropping years and could be selected for on the basis of the relative size of purely genetic effects. The reverse is true for the total content of TOC, despite its fairly wide range of variation across genotypes and cropping environments. Grain yield is largely affected by the cropping site, and it would require the selection of different cultivars for climatically contrasting regions.

Fourier transform/infrared-attenuated total reflectance (FT/IR-ATR) molecular spectroscopy can be used as a rapid, direct, nondestructive bioanalytical technique to detect heat-induced changes in protein molecular structures.[7,15] The objectives of the present study were to reveal MIR induced changes in protein molecular structures of hulless and hulled barley and to correlate these structural changes to changes in (1) chemical profile, (2) CP subfraction composition, and (3) in situ rumen CP degradation and intestinal digestibility of RUP. We hypothesized that MIR for different durations (3 or 5 min) will alter protein molecular structures to different extents in hulled and hulless barley, which will correspond to different levels of alteration in protein nutritive value and digestibility.

MATERIALS AND METHODS

Samples Preparation and Treatment. Grains from two newly developed hulless cultivars (CDC Fibar and HB08302) with altered starch composition (amylose/amylopectin ratio) and a normal hulled cultivar (Copeland) of barley were evaluated in the present study. The samples were provided by Dr. Aaron D. Beattie (Crop Development Center, University of Saskatchewan, Saskatoon, Canada). The CDC Fibar is a zero-amylose (0% amylose and 100% amylopectin) waxy cultivar, and HB08302 is a high-amylose (40% amylose and 60% amylopectin) cultivar. Copeland is a normal two-row malting barley cultivar. Grains were sampled (~2 kg) from four replicate plots of each cultivar grown at the Kernen Crop Research Fields (52°9′ N and 106°32′ W) of the Crop Development Center (CDC; University of Saskatchewan, Saskatoon, SK, Canada) during two consecutive years (2009 and 2010). For each cultivar, eight samples were used for heat processing. A subsample (~500 g) of each sample was heated in a microwave oven (DMW904W, Findlay, OH, US), operated at a power of 900 W (1.33 W/g) and an irradiation frequency of 2450 MHz for 3 min (MIR3) or 5 min (MIR5) in two replicate runs. Raw grains (MIR0) were used as control.

The control and heat-treated samples were ground (Retsch ZM-1, Brinkmann Instruments Ltd., Mississauga, ON, Canada) through a 0.25 mm screen for molecular spectral analysis; through a 2 mm screen for in situ rumen incubation studies, and through a 1 mm screen for all other wet chemical analysis.

Chemical Analysis. The ground (1 mm) samples of barley were analyzed for the contents of DM (method 930.15), ash (method 942.05), CP (method 984.13; using a Kjeltec 2400 autoanalyzer; Foss Analytical A/S, Hillerød, Denmark), and ether extract (EE; method 920.39) according to the standard procedures of the AOAC.[16] The contents of neutral detergent insoluble CP (NDICP) and acid detergent insoluble CP (ADICP) were analyzed according to the method of Licitra et al.[17] The content of SCP was analyzed according to the method of Roe et al.[18] with slight modification as described by Peng et al.[7] The non-protein nitrogen (NPN) content was analyzed according to the method of Licitra et al.[17] The true protein in feeds was precipitated with tungstic acid, and the NPN content was calculated as the difference between total CP content and CP content of the residues after filtration.

Fractionation of Crude Protein. The CP content of the feeds was fractionated into immediately solubilized protein (PA), potentially degradable true protein (PB), and unavailable true protein (PC) according to the Cornell Net Carbohydrate Protein System (CNCPS).[19] The subfraction PB was further fractionated into three subfractions that are believed to have different rates of ruminal degradation. PB1 is the rapidly degradable subfraction with a degradation rate of 120−400%/h, PB2 is the intermediately degradable subfraction with a degradation rate of 3−16%/h, and PB3 is the slowly degradable subfraction with a degradation rate of 0.06−0.55%/h.[21] PA is calculated as NPN × 6.25; subfraction PB1 is the buffer-soluble protein and calculated as SCP − PA; subfraction PB2 is calculated as CP − (PA + PB1 + PB3 + PC); subfraction PB3 is calculated as NDICP − ACDIP; and subfraction PC is the ADICP.

In Situ Rumen Incubation. Three lactating Holstein dairy cows, each fitted with flexible rumen cannula with an internal diameter of 10 cm (Bar Diamond Inc., Parma, ID, USA), were used for the in situ rumen incubation studies. The fistulated cows were handled according to the guidelines of the Canadian Council on Animal Care.[20] The cows were individually fed a balanced TMR (15 kg/head/day on DM basis), containing 510 g of barley silage, 150 g of chopped alfalfa hay, and 340 g of concentrate per kg DM. The concentrate contained 560 g of barley, 50 g of wheat, 50 g of oats, 330 g of dairy supplement pellets, and 10 g of molasses per kg DM, whereas the pellet dairy mixture contained 316 g of soybean meal, 270 g of canola meal, 100 g of peas, 85 g of premix (University of Saskatchewan), 55 g of corn gluten meal, 55 g of corn grain, 47 g of sodium bicarbonate, 30 g of ground barley, 20 g of canola oil, 16 g of salt, and 7 g of Dynamate (K and Mg sulfate, University of Saskatchewan) per kg DM. The TMR was formulated according to NRC requirements for dairy cows[21] and fed twice daily (8:00 a.m. and 4:00 p.m.) in equal portions. All cows had 24 h/day access to fresh drinking water.

The in situ nylon bag technique as described by Peng et al.[7] was used to determine the rumen degradation kinetics of the feeds. Briefly, 7 g of the coarsely ground (2 mm) sample of each treatment of each barley cultivar was weighed into preweighed and coded nylon bags (10 × 20 cm) with a pore size of 41 μm (Nitex 03-41/31 monofilament open mesh fabric, Screentech Corp., Mississauga, ON, Canada). The ratio of sample size to bag surface area was 19 mg/cm^2. The gradual addition, all-out method was used. The bags were randomly incubated for 48, 24, 12, 8, 4, 2, and 0 h in rumen of the three fistulated cows in two replicate runs. To get enough residues for chemical analysis, multiple bags were used. The multiple bags for 48, 24, 12, 8, 4, 2, and 0 h incubation periods were 5, 4, 4, 2, 2, 2, and 2, respectively. A large polyester mesh bag (45 × 45 cm, fixed to rumen cannula with a 90 cm long rope) was used to hold the bags in rumen. To hold the bags in bottom liquid phase of the rumen, a 250 mL plastic bottle filled with gravel was placed in the polyester mesh bag. The bags were removed from the rumen at the end of incubation period and immediately gently rinsed (six times) in a bucket with cold tap water to remove adhering ruminal contents and stop microbial/enzymatic degradation. The 0 h samples were washed under similar conditions without rumen incubation. The bags were subsequently dried at 55 °C for 48 h, cooled, and reweighed. Residues were pooled together per incubation time for each run. The dried residues were ground and stored at 4 °C for chemical analysis.

Rumen Degradation Kinetics. The rumen degradation characteristics of DM and CP were computed according to the first-order kinetics equation of Ørskov and McDonald[22] with slight modifications as proposed by Tamminga et al.[23]

$$Y(t) = U + (100 - S - U) \times e^{-kd(t-T_0)}$$

where $Y(t)$ is the DM/CP (%) present in the residues at t hours of incubation; S is the soluble subfraction (%); U is the rumen undegradable subfraction (%); K_d is the degradation rate of potentially degradable subfraction (%/ h); and T_0 is lag time (h). The in situ parameters were analyzed using the nonlinear (PROC NLIN) procedure with iterative least-squares regression (Gauss−Newton method) of the Statictical Analysis System (SAS).[24] The effective degradability of DM (EDDM) and CP (EDCP) was computed according to the NRC-2001 dairy model[21] as

$$\text{ED (DM/CP)} = S + D \times \left[\frac{K_d}{(K_d + K_p)}\right]$$

where D is the potentially degradable subfraction (%) and estimated as $D = 100 - S - U$ and K_p is the estimated outflow rate of digesta from rumen, which was assumed to be 6%/h.[23] The rumen undegraded DM and CP was calculated as follows:

$$\text{RU (DM/CP)} = U + D \times \left[\frac{K_p}{(K_d + K_p)}\right]$$

[a]Means within a row with different lower case (a–c) or capital (A–C) letters differ at $P < 0.05$. [b]For each treatment (MIR0, MIR3, and MIR5) each sample was run two times. [c]Heated treated by microwave irradiation for 0 (MIR0), 3 (MIR03) or 5 (MIR05) min. [d]For each barley cultivar eight replicate samples were analyzed. [e]ns, not significant; †, $P < 0.1$; *, $P < 0.05$; **, $P < 0.001$; ***, $P < 0.001$. [f]SEM, standard error of the mean. [g]DM, dry matter; EE, ether extract. [h]CP, crude protein; NDICP, neutral detergent-insoluble protein; ADICP, acid detergent-insoluble protein; SCP, soluble CP; NPN, non-protein nitrogen. [i]The interactions of irradiation time and barley cultivar were significant ($P < 0.05$); therefore, no letter is given for the treatment means.

Intestinal Digestibility of Rumen Undegraded Protein. The three-step in vitro procedure as described by Calsamiglia and Stern[25] was used to determine the intestinal digestibility of RUP. Briefly, a calculated amount of dried ground residues of 16 h rumen incubation, containing approximately 15 mg of N, was transferred to 15 mL centrifuge tubes. Subsequently, 10 mL of 0.1 N HCl solution containing 1 g/L pepsin was added to the residues. The mixtures were then vortexed and incubated in a shaking water bath at 38 °C for 1 h. After incubation, 0.5 mL of 1 N NaOH was added to the mixture to neutralize the pH. Subsequently, 13.5 mL of phosphate buffer (pH 7.8) containing 37.5 mg of pancreatin was added to the mixture, vortexed, and further incubated at 38 °C for 24 h. After incubation, 3 mL of 100% (w/v) TCA solution was immediately added to precipitate the undigested protein and stop enzymatic reactions. The mixtures were vortexed and then centrifuged at 10000*g* for 15 min at a room temperature (20–22 °C). The supernatant was collected and analyzed for (soluble/digested) N content. Duplicate blank (without sample) tubes were run to correct for background effect of the solutions and enzyme mixtures used during the analysis. The intestinal digestibility of RUP was computed by dividing the content of TCA-soluble N by total N in the residue sample.

Molecular Spectroscopy. The protein molecular spectral analyses were carried out at the molecular spectroscopy laboratory of the Department of Animal and Poultry Science, University of Saskatchewan (Saskatoon, Canada). The molecular spectral profiles were generated using a JASCO FT/IR-ATR-4200 (Jasco Inc., Easton, MD, USA), equipped with a deuterated L-alanine doped triglycine sulfate detector and a ceramic IR light source and fitted with a MIRacle ATR accessory module with a ZnSe crystal and pressure clamp (Pike Technologies, Madison, WI, USA). The spectra were generated in a transmission mode in the mid-IR (ca. 4000–800 cm^{-1}) and amide fingerprint (ca. 1732–1483 cm^{-1}) regions, with 128 co-added scans and a spectral resolution of 4 cm^{-1}. Each sample was run five times. The spectra were collected and corrected for background and CO_2 noise using Jasco Spectra Manager II software. The protein primary and secondary structure related molecular spectral features from the FT/IR spectra were quantified using Ominic 7.3 software (Spectra-Tech Inc., Madison, WI, USA). The spectral bands of the protein functional groups (C═O, C—N, and N—H), representing the primary molecular structures, were identified and assigned using published information.[7,26] Briefly, amide I (~80% C═O and ~10% C—N stretching vibration and 10% N—H bending vibration; centered at a wavelength of ca. 1655 cm^{-1}) and amide II (~60% N—H bending vibration, ~40% C—N stretching vibration; centered at ca. 1565 cm^{-1}) were quantified for the characterization of protein primary structures. For characterization of protein secondary structures, the FSD spectrum was generated using Fourier self-deconvolution (FSD) or the secondary derivative functions in the OMNIC software. The FSD spectrum was further resolved into several multicomponent peaks in the protein amide I region, where α- helices (centered at ca. 1653 cm^{-1}) and β-sheets (centered at ca. 1630 cm^{-1}) were identified. Peak area, height of the spectral intensities of amide I and amide II, and α-helix and β-sheet were measured and ratios were calculated.

Statistical Analysis. Data on chemical profiles, CP subfractions, digestible nutrients, energy values of FT/IR spectra, in situ rumen degradation characteristics, and intestinal digestibility of RUP were analyzed according to the PROC MIXED procedure of the Statistical Analysis System (SAS).[24] The model used for analysis was

$$Y_{ijk} = \mu + \mathrm{MIR}_i + \mathrm{BC}_j + e_{ijk}$$

where Y_{ijkl} is an observation on the dependent variable *ijkl*; μ is the overall population mean; MIR_i is the fixed effect of MIR (control and 3 and 5 min of irradiation); BC_j is the fixed effect of the barley cultivars (CDC Fibar, HB08302, and Copeland); and e_{ijk} is random error associated with the observation *ijk*. Except for a few parameters, the interactions of MIR and barley variety were nonsignificant and hence removed from the final model. Significant ($P < 0.05$) interactions are reported in the footnotes of the tables. Post hoc analyses were carried out using the Tukey–Kramer test to compute pairwise differences in the means. Means with different letters were obtained with "pdmix 800 SAS macro".[27] The PROC CCORR of SAS[24] was used to determine the strength of relationship between protein molecular structural characteristics and chemical profiles, CP subfractions, in situ rumen degradation characteristics, and intestinal digestibility of RUP.

The agglomerative hierarchical cluster analysis (CLA) and principal component analysis (PCA) were performed on the spectral data at the fingerprint region og ca. 1732–1483 cm^{-1} (representing amide I and II bands) to visualize and classify the difference in intrinsic protein molecular structures of the feeds using Statistica software (version 8, StatSoft Inc., Tulsa, OK, USA). The detailed concepts and procedure of using CLA and PCA for FTIR/ATR spectral analysis were described earlier.[13]

RESULTS AND DISCUSSION

Microwave Irradiation Induced Changes in Chemical Profile. Results of the MIR induced changes in the mean chemical profile of different cultivars of barley are shown in Table 1. Compared with the raw grains, MIR increased ($P <$

0.001) the content of DM, indicating that MIR decreased the moisture-holding capacity of barley grains. Previous studies have shown a decrease in DM content with dry heating of Camelina[7] and moist heating of flaxseed.[14] Compared with the raw grains, the contents of NDICP and ADICP increased with increasing duration of the MIR. Samadi and Yu[15] and Penge et al.[7] also observed an increase in cell wall bound CP with moist heating (60 min at 120 °C) of soybean and camelina seeds, respectively. The increase in fiber-bound CP could be related to the heat-induced cross-linkages between amino acids and reducing sugars such as during Maillard reactions.[7] The MIR markedly decrease (from 50.84 to 17.56% CP) the SCP content of barley. This is in agreement with previous findings of a marked decrease in the SCP subfractions of camelina seeds (from 52.73 to 20.41% CP),[7] soybeans (from 43.38 to 11.35% CP),[15] and flaxseeds (from 51.88 to 8.82% CP)[14] with moist heating (at 120 °C for 60 min). In contrast, the NPN content increased ($P < 0.001$) with MIR. The present result is supported by the findings of Doiron et al.[14] and Peng et al.[7] However, Mustafa et al.[28] and Samadi and Yu[15] observed a decrease in NPN content during heat processing. This discrepancy may be related to the differences in heating methods (MIR vs dry toasting, moist heating) or to the inherent differences in seed types (cereal grains vs oilseeds) and NPN methodologies (tungstic acid vs TCA, differences in filter papers pore size, etc.). Overall, our present findings suggest that a short-term (5 min) MIR induces more or less similar changes in the CP profiles of feed as have been reported for other feeds after 60 min of dry/moist heating at 120 °C. Except SCP for which the interaction was significant (results not shown), the MIR induced changes in chemical profile were independent of barley type. As discussed in detail earlier,[5] the hulless barley cultivars had higher ($P < 0.001$) contents of CP and EE than the hulled barley.

Microwave Irradiation Induced Changes in Crude Protein Subfractions. Results on the MIR-induced changes in CP subfractions are presented in Table 2. The contents of all CP subfractions in barley grains altered ($P < 0.05$) with MIR, and PB1 was the only subfraction that decreased ($P < 0.05$) in concentration. The MIR for 3 min increased ($P < 0.05$) the PA (soluble) subfraction, whereas further irradiation for 5 min had no significant effect on PA subfraction. The major changes in CP subfractions, however, occurred in the contents of PB1 and PB2. The PB1 (rapidly degradable) subfraction markedly decreased from 45.22 to 6.36% (% CP), whereas the PB2 (intermediately degradable) subfraction markedly increased from 35.84 to 59.43% (% CP). The increase (from 5.62 to 11.19% of CP) in the PA (NPN × 6.25) subfraction with MIR was quantitatively small. Therefore, the shift from the ruminally degradable PB1 subfraction to a partially ruminally degradable PB2 subfraction demonstrates an overall decrease in ruminal CP degradation rate in the irradiated barley grains. The changes in CP subfractions with MIR have not been evaluated previously. The changes in PB1 and PB2 subfractions after MIR (for 5 min) were comparable with the changes produced by moist heating at 120 °C for 60 min.[7,14] The moist heating decreased the PB1 subfraction of flaxseed from 45.9 to 10.5% CP with a concomitant increase in the PB2 subfraction from 43.0 to 73.3% CP.[14] Similarly the moist heating of camelina seeds decreased the PB1 subfraction from 45.06 to 16.69% CP and increased the PB2 subfraction from 45.28 to 70.58% CP.[29] Compared to raw grains, MIR for 3 min did not change the PB3 and PC subfractions. However, MIR for 5 min significantly increased ($P < 0.05$) the PB3 and PC subfractions. PB3 is believed to be more slowly degraded in the rumen, and a large portion of this subfraction escapes ruminal degradation and is digested in the small intestine. Therefore, the increase in the PB3 subfraction will contribute to the digestible RUP supply to the small intestine. Subfraction PC is considered nondegradable in the rumen, and CP in this subfraction is heat damaged or bound to other compounds such as lignin, tannins, and Maillard reaction products.[19] MIR for 3 min decreased ($P < 0.05$) the PB1 subfraction and increased ($P < 0.05$) the PB2 subfraction but did not alter the PC subfraction (Table 2). These results suggest that MIR for 3 min decreased CP degradability in the rumen but did not overprotect the CP from digestion in the small intestine. However, MIR for 5 min significantly increased (from 0.97 to 5.32% CP) the PC subfraction, suggesting an overheating and protection of protein from intestinal digestion. These results show that MIR can decrease the ruminal degradation of feed CP in a

relatively shorter time with much less energy inputs compared to conventional heating systems.

The MIR induced changes in CP subfractions were independent of barley type. Except PB1, which was lower ($P < 0.001$) in hulless barley, the mean contents of all other CP subfractions did not significantly differ due to barley type (hulless vs hulled). Across the barley varieties, CDC Fibar had a higher ($P < 0.05$) PB2 subfraction and a lower ($P < 0.05$) PC subfraction. These findings are in general agreement with Yang et al.,[5] who observed no significant differences in the S and D subfractions of hulless and hulled barley, whereas the degradation rate was higher for the hulled (Copeland) cultivar.

Microwave Irradiation Induced Changes in Rumen Degradation and Intestinal Digestibility. Results of MIR induced changes in ruminal DM and CP degradation kinetics and intestinal digestibility of CP are presented in Table 3. MIR5 decreased ($P < 0.05$) the EDDM and increased ($P < 0.05$) rumen undegraded DM. The S subfraction of DM did not significantly change, and the D subfraction increased ($P < 0.01$) with MIR5. Therefore, the decrease in EDDM of the irradiated barely could mainly be related to the marked decrease (from 13.08 to 7.37%/h) in the K_d of the D subfraction. In agreement with our findings, a 6 min MIR markedly decreased the K_d of canola seeds (from 10.2 to 5.5%/h),[10] cottonseed meal (from 7.6 to 4.7%/h),[11] corn grain (from 5.1 to 4.3%/h),[12] and canola meal (from 7.0 to 4.9%/h).[9] MIR3 did not significantly alter any of the DM and CP degradation parameters. In contrast, there was a significant shift from PB1 to PB2 the CP subfraction after MIR3. This discrepancy may be, partly, explained by the higher K_d of barley grain in the rumen. Although the S subfraction of DM did not change with MIR5, the S subfraction of CP consistently decreased (from 6.45 to 0.00%; $P < 0.05$) with MIR. This means that the S subfraction of nutrients other than CP increased with MIR. Starch represents the bulk of non-CP DM of barley grains, and previous studies have shown that MIR for 5 min increased the S subfraction of starch in cereal grains,[12,30] partly due to gelatinization of starch with heating.[6] Decreases in the S subfraction of CP with 6 min MIR of corn grains,[12] canola seeds,[10] and cottonseed meal[11] have been reported. MIR5 decreased ($P < 0.001$) the EDCP with a concomitant increase ($P < 0.001$) in the supply of RUP to the postruminal tract (Table 3). The lower ruminal EDCP of the irradiated barley could be related to both lower S subfraction and lower K_d of D subfraction. Moreover, changes in CP subfractions such as the decrease in the rapidly degradable (PB1) subfraction and the increase in the intermediately degradable (PB2) and slowly degradable (PB3) subfractions could explain the lower ruminal EDCP.[7,15] These results demonstrate that a short-term (5 min) MIR induced a major shift in the site of CP digestion from the rumen to the postruminal tract. Digestion of feed protein in the small intestine results in lower losses of protein and essential amino acids. Moreover, the gradual degradation of the D subfraction in the irradiated barley can optimize the efficiency of rumen microbial protein synthesis with a consequent decrease in NH_3-N losses to the environment. However, overheating can reduce protein digestion in the postruminal tract.[15] In the present study, MIR for 5 min significantly

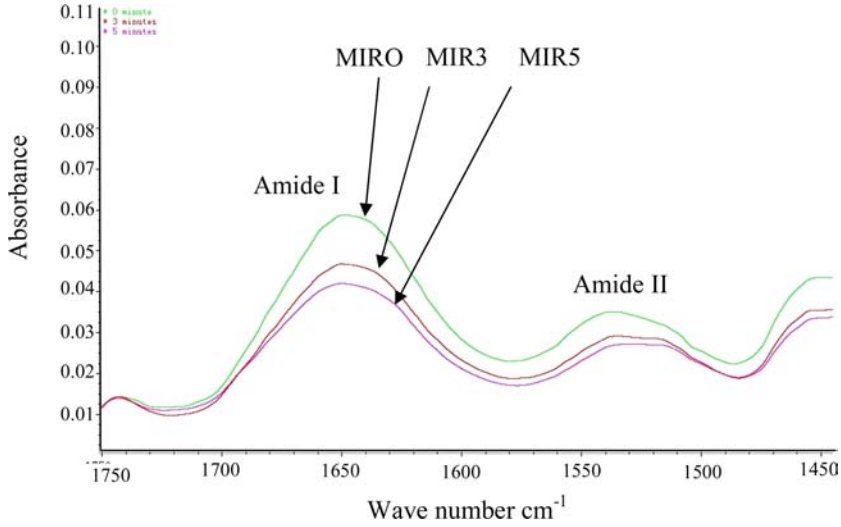

Figure 1. Biomolecular spectral parameters of protein (baseline region, ca. 1732–1483 cm^{-1}) of barley grains heat treated by microwave irradiation for 0 (MIR0), 3 (MIR03), or 5 (MIR05) min.

decreased (from 79.35 to 67.86%; $P < 0.05$) the intestinal digestibility of RUP. The lower intestinal digestibility of RUP is supported by the significant increase in the PC subfraction (Table 3), which is considered as nondigestible in the whole digestive tract. The lower intestinal digestibility offset some of the positive effects of MIR5 on the ruminal degradation characteristics of barley. However, the overall supply of digestible RUP as a percentage of feed CP increased to the small intestine. These results demonstrate that it is important to quantify the intestinal digestibility of RUP when heat-induced changes in the ruminal degradation of feed CP are evaluated to more accurately establish optimal heating regimens.

Microwave Irradiation Induced Changes in Protein Molecular Structure. Any temperature change in the environment of the protein that can modify the noncovalent interactions in protein molecules can lead to an alteration of the protein internal structures.[13] Heat processing of plant-derived protein feeds decreases ruminal CP degradation by altering the protein molecular structures such as by the uncoiling of the pleated structures or by denaturing the whole protein molecule.[7,13] The subsequent liberation of hydrophobic amino acids, racemization, and establishment of cross-linkages among the uncoiled peptides and between amino acids and reducing sugars can all reduce CP solubility.[29−32] Heating at a higher temperature or for a longer duration can denature the whole protein molecule, leading to more complex cross-linkages and advanced Maillard products. Thus, the protein molecules become more resistant to rumen microbial degradation and enzymatic hydrolysis.[13,31] Recent investigations have shown that FTIR molecular spectroscopy can be used to quantitatively evaluate the heat-induced changes in protein primary and secondary molecular structures.[7,15,26] The amide I and amide II spectral intensities in terms of peak area and height can be used to reveal changes in the primary structures of protein.[33,34] In this study, MIR for 3 and 5 min consistently decreased ($P < 0.05$) the amide I and amide II heights and areas. Our results are consistent with the findings of

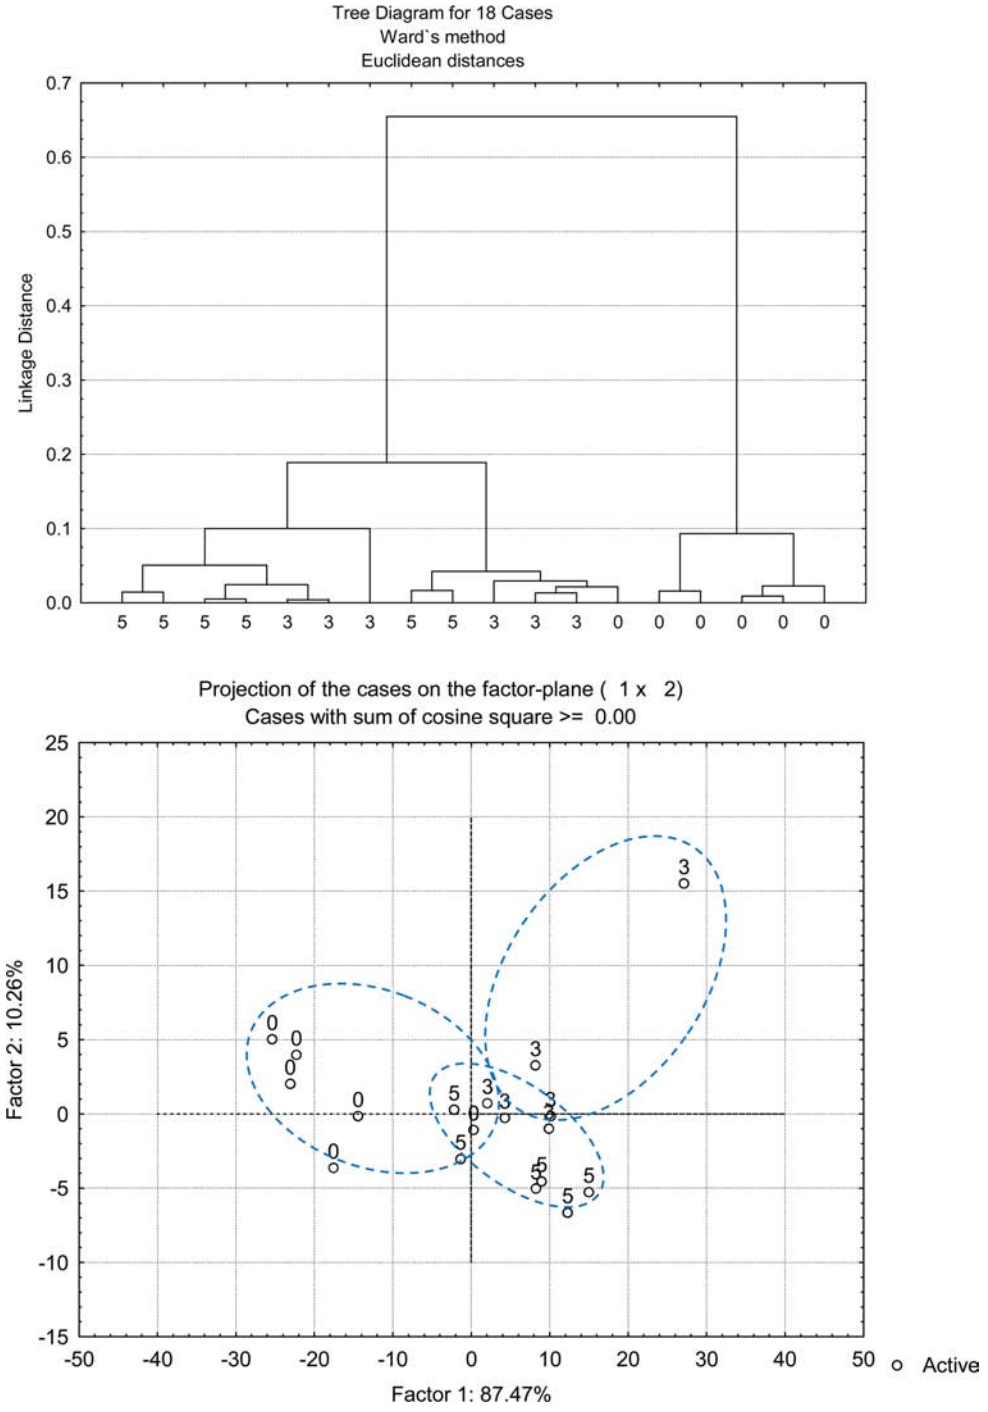

Figure 2. Agglomerative hierarchical cluster analysis (CLA) dendograms (top) and PCA scatter plot (bottom) visualizing the overall spectral differences in the protein primary structures in the amide regions (ca. 1732−1483 cm^{-1}) of untreated and heat-treated barley grains (untreated = 0; heat treated by microwave irradiation for 3 min = 3; or heat treated by microwave irradiation for 5 min = 5).

Samadi and Yu.[15] The decreases in amide peak bands were associated with a decrease in CP solubility and ruminal degradation. The protein secondary structures affect access to gastrointestinal digestive enzymes,[13,33] and heat-induced changes in protein secondary structures can alter protein digestibility in the rumen and intestine of dairy cattle.[7,33] The α-helix and β-sheet heights consistently decreased ($P < 0.05$) with increasing duration of MIR, whereas the ratio of α-helix to β-sheet increased with MIR. The changes in α-helix:β-sheet ratios show changes in structural makeup of the whole protein molecules and strongly reflect the difference in digestibility and utilization of protein molecules.[13,33] Although no study could be found on the molecular structures of the hulled barley cultivars (Copeland), the pattern of differences in molecular structural parameters of the hulless barely cultivars (CDC Fibar vs HB08302; Table 4) are consistent with the findings of Dariman and Yu.[33] The varietal differences in barley protein molecular structures in relation to ruminal CP degradation have been discussed in detail earlier.[13,33]

Multivariate Analysis. CLA and PCA were performed on the overall spectral data from the fingerprint region (ca. 1732−1483 cm^{-1}; Figure 1) to classify and visualize the MIR induced

changes in protein molecular structural characteristics. The CLA dendrograms (Figure 2, top) showed that protein molecular spectral data of irradiated barley grains could be separated from raw grains at a linkage distance of <0.7, demonstrating structural differences between the raw and irradiated grains. Only one spectrum of raw grains and irradiated grains was similar. The mixed dendograms show that the molecular spectral data of 3 and 5 min irradiated barley grains could not be distinguished from each other. Results of the PCA are visualized in a scatter plot between the first two principal components (Figure 2, bottom). The first and second principal components explained 97.73% of the total variation in protein molecular structures of the raw and irradiated barley grains. The PCA results show that the protein molecular spectra of raw grains could be almost completely distinguished from the irradiated (3 and 5 min) barley. Like CLA dendograms, only on spectrum was common between the raw and irradiated feeds, indicating some similarity in protein intrinsic molecular structures. The results of the present study showed that CLA and PCA analyses were able to classify differences in protein structural−chemical makeup.

Correlations between Protein Molecular Structural Characteristics and Crude Protein Availability and Utilization. Table 5 shows the coefficients of correlation (Pearson) and their significance levels between protein molecular spectral band characteristics and CP chemical profiles, CP subfraction, and CP digestion in the rumen and intestine of dairy cows. The MIR induced changes in all measured structural bands intensities (area and height) of protein primary and secondary structures had significant ($P < 0.05$) negative correlations with ADICP ($r \geq -0.66$) and significant positive correlations with SCP ($r \geq 0.58$). This means that protein denaturation during heating decreased the SCP and increased the nondegradable protein (ADICP). Our results are consistent with the findings of Dorion et al.[14] Moreover, the measured structural band intensities had significant ($P < 0.05$) positive correlations ($r \geq 0.57$) with the PB1 subfraction and strong negative correlations with PA ($r \geq -0.63$), PB2 ($r \geq -0.43$), and PC ($r \geq -0.66$) subfractions (Table 5). With the in situ parameter, changes in protein primary and secondary structural band intensities during MIR were positively correlated to the S subfraction ($r \geq 0.77$) and EDCP ($r \geq 0.52$) and negatively correlated to the D subfraction and the RUP contents. Except for amide II peak height, all other primary and secondary spectral bands showed a significant ($P < 0.05$) positive correlation with K_d. These

dx.doi.org/10.1021/jf501024j | J. Agric. Food Chem. 2014, 62, 6546−6555

results demonstrate that there is a close relationship between MIR-induced changes in inherent protein molecular structures and changes in CP chemical profile, CP subfractions, and ruminal degradation kinetics. There was, however, no correlation between the spectral band intensity and intestinal digestibility of RUP (Table 5). Yu and Nuez-Ortín[35] suggested that the spectral band intensities can be used as indicators for the changes in nutritive value of protein during heat processing, which is supported by the findings of the present study. However, it needs to be mentioned here that only limited numbers of samples and irradiation durations (3 or 5 min) were evaluated in this study, and further studies will be required to establish this relationship and develop regression equations.

In summary, MIR of barley grains for 5 min significantly changed CP chemical profiles, CP subfractions, rumen degradability, intestinal digestibility, and protein molecular structures compared to raw grains. MIR for 5 min significantly decreased SCP and K_d of the D subfraction, causing a marked decrease in CP degradation in the rumen. As a consequence, the total supply of digestible RUP to the postruminal tract increased. These changes in CP chemical profile and digestion were strongly associated with the alteration in protein intrinsic molecular structures. In contrast, MIR for 3 min did not alter protein molecular structures and did not induce significant changes in rumen CP degradation, RUP content, and intestinal digestibility compared with raw grains. These results showed that MIR for a short period and lower energy input can improve the nutritive value and utilization of CP in barely grains.

Present Address

⊥(N.A.K.) Department of Animal Nutrition, University of Agriculture Peshawar, Pakistan.

Funding

Research projects of the chair group (P.Y.) have been supported by grants from the Ministry of Agriculture Strategic Research Chair Program, Natural Sciences and Engineering Research Council of Canada (NSERC), SaskCanola, and Saskatchewan Agricultural Development Fund (ADF). X.Y.'s postdoctoral fellowship was financially supported by the China Scholarship Council (CSC) for research work in P.Y's laboratory at the University of Saskatchewan, Canada.

Notes

The authors declare no competing financial interest.

ACKNOWLEDGMENTS

We thank Dr. Aaron D. Beattie (Crop Development Center, University of Saskatchewan, Saskatoon, Canada) for providing hulless and hulled barley samples and Zhiyuan Niu (research assistant in the Department of Animal and Poultry Science, University of Saskatchewan) for providing assistance and arranging samples.

the (1) chemical profile; (2) CP subfractions according to Cornell Net Carbohydrate and Protein System (CNCPS); (3) ruminal CP degradation characteristics and intestinal digestibility of rumen nondegraded protein (RUP); and (4) the protein's molecular structural features using Fourier transform/infrared-attenuated total reflectance (FT/IR-ATR) molecular spectroscopy of newly developed CDC yellow flaxseed in comparison with that of brown flaxseed. The fifth objective was to quantify the relationship between the protein's molecular structural features and their chemical profiles and digestive behavior in the rumen and intestine of dairy cattle.

MATERIALS AND METHODS

Flaxseeds, Samples Collection, and Heat Processing. Four varieties of flaxseed (*Linum usitatissimum* L.), including two brown oilseed flax varieties (CDC Bethune and CDC Sorrel) and two newly developed yellow oilseed flax breeding lines (coded as FY11140 and F08×425) were selected for this study. Seeds (∼2 kg) from each genotype were sampled from two replicate plots at two different locations, namely, from the crop grown on a clay-loam soil at Kernen Crop Research Farm (52°9′ N and 106°32′ W; University of Saskatchewan, Saskatoon, SK, Canada) and from the crop gown on a silty-clay soil at Melfort Research Station (52°8′ N and 104°59′ W; Melfort, SK, Canada) of Agriculture and Agri-Food Canada. The samples of each genotype were pooled by location and mixed, and subsamples of ∼1 kg were collected and stored at −20 °C for laboratory analysis. Subsequently, the seeds were ground through a 2 mm screen for in situ studies and through a 1 mm screen for wet chemical analysis using a laboratory mill (Retsch ZM-1, Brinkmann Instruments Ltd., Mississauga, ON, Canada). The seeds were ground through a 0.25 mm screen for molecular spectral analyses. Because of high oil content of the seeds, the samples were kept cool and gradually fed to the grinder to avoid sticking and clumping and to make sure that the seeds were cracked and not extruded.

Molecular Spectroscopy. The samples were analyzed for the protein's molecular spectral profiles using a JASCO FT/IR-ATR-4200 (Jasco Inc., Easton, MD) at the molecular spectroscopy laboratory of the Department of Animal and Poultry Science, University of Saskatchewan (Saskatoon, SK, Canada). The spectrometer was outfitted with a ceramic IR light source, a deuterated L-alanine doped triglycine sulfate detector, and a MIRacle ATR (Pike Technologies, Madison, WI, USA) sampling accessory equipped with a pressure clamp and ZnSe crystal plates. The molecular spectrum was generated in the mid-IR region (ca. 4,000−800 cm^{-1}) at a spectral resolution of 4 cm^{-1}. For each sample, five spectra were obtained, and each spectrum was generated with 128 co-added scans. Jasco Spectra Manager II software (Jasco Inc., Easton, MD) was used to collect, correct (against background and CO_2 noise), and process the molecular spectral data. Ominic 7.3 software (Spectra-Tech Inc., Madison, WI, USA) was used to identify and quantify the absorbance bands associated with the protein's primary and secondary structures. The protein's primary structural characteristics were quantified from two bands at the amide I (1712−1580 cm^{-1}; Figure 1) and amide II (1,580−1482 cm^{-1}; Figure 1) regions using literature information as reported earlier.[14] The protein's secondary structural characteristics were quantified from the absorption peak height of the α-helix (centered at ca. 1,653 cm^{-1}) and β-sheet (centered at ca. 1,630 cm^{-1}) in the amide I region. The α-helix and β-sheet peaks were indentified using Fourier self-deconvolution spectra, obtained with the second-derivative function of OMNIC 7.2 as described by Yu.[13]

In Situ Rumen Incubation. Four rumen fistulated (10 cm internal diameter; Bar Diamond Inc., Parma, ID, USA) lactating Holstein dairy cows (body weight, 680 ± 10 kg) were used for in situ incubation. The cows were handled and cared for according to the recommendations of CCAC.[17] A balanced TMR was individually fed to the dairy cows twice daily (8:00 and 16:00 h) in equal portions. The TMR contained 53% dairy concentrate, 31% barley silage, and 16% chopped alfalfa hay. Detailed information on the ingredients and chemical composition of the concentrates, barley silage, and alfalfa hay has been reported earlier.[18] All cows had 24 h/d access to fresh drinking water.

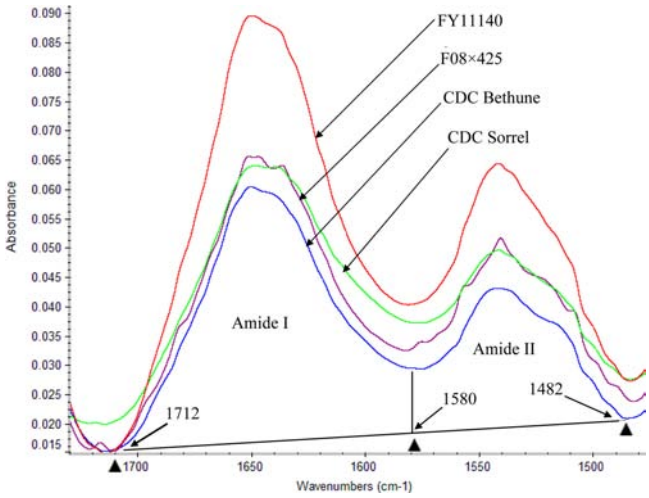

Figure 1. Protein molecular spectra of raw brown flaxseed varieties (CDC Bethune and CDC Sorrel) and newly developed yellow flaxseed breeding lines (FY11140 and FO8×425) in the amide I and amide II regions (1712−1482 cm^{-1}).

The standard in situ nylon bag protocol described by Peng et al.[14] was used to determine the rumen degradation kinetics of DM and CP. Briefly, 7 g of ground (2 mm) sample of each feed was randomly incubated for 48, 24, 12, 8, 4, 2, and 0 h in rumen of the four cows, using preweighed and coded nylon bags (10 × 20 cm) with a pore size of 41 μm (Nitex 03-41/31 monofilament open mesh fabric, Screentec Corp., Mississauga, ON, Canada). All samples were incubated in two replicated runs, and multiple bags were used for each incubation time to obtain more representative data and enough residues for chemical analysis. For 48, 24, 12, 8, 4, 2, and 0 h incubation periods, the replicate bags were 4, 4, 4, 2, 2, 2, and 2, respectively. The gradual addition, all out method was used. A maximum of 20 bags were incubated in the rumen at any given time. All bags were removed from the rumen at the end of 48 h of incubation and immediately washed (6 times) in a bucket with cold tap water to remove adhering ruminal contents and stop enzymatic and microbial degradation. The bags were subsequently dried (55 °C for 48 h), cooled to room temperature (20−22 °C), and reweighed. Residues were pooled together as per incubation time and run, ground to 1 mm particle size, and stored at 4 °C for chemical analysis.

Rumen Degradation Kinetics. Rumen degradation kinetics of DM and CP was computed according to the first-order kinetics equation of Ørskov and McDonald[19] with a slight modification on lag time.[20,21]

$$Y(t) = U + (100 - S - U) \times e^{-kd(t-T_0)}$$

where $Y(t)$ was the residues at t h of incubation; S was the soluble fraction; U was the rumen nondegradable fraction; kd was the ruminal degradation rate (%/h) of the potentially degradable fraction, and T_0 was the lag time (h). The kd, U fraction, and T_0 were estimated from the in situ data using the nonlinear (PROC NLIN) procedure of SAS[22] with iterative least-squares regression (Gauss−Newton method). The rumen nondegraded DM (RUDM) and RUP were computed according to the NRC-2001[23] as follows:

$$\text{RUDM/RUP} = U + D \times \left[\frac{K_p}{(K_d + K_p)}\right]$$

where D is the potentially rumen degradable fraction and calculated as D = 100 − S − U, and K_p is the passage rate of digesta from the rumen, which was supposed to be 0.06/h.[21] The rumen degradable DM (RDDM) and CP (RDP) were calculated as

dx.doi.org/10.1021/jf501284a | J. Agric. Food Chem. 2014, 62, 6556−6564

$$\text{RDDM/RDP} = \text{S} + \text{D} \times \left[\frac{K_\text{d}}{(K_\text{d} + K_\text{p})}\right]$$

Chemical Analysis. The standard methods of the AOAC[24] were used to analyze the contents of DM (method 930.15), CP (method 984.13; adopted for Kjeltec 2400 autoanalyzer; Foss Analytical A/S, Hillerød, Denmark), ash (method 942.05), and ether extract (EE, method 920.39). The content of SP was analyzed according to the method of Roe et al.[25] with slight modifications as described by Peng et al.[14] The contents of acid detergent-insoluble protein (ADIP), neutral detergent-insoluble protein (NDIP), and nonprotein N (NPN) were analyzed according to the methods described by Licitra et al.[26] The 3-step in vitro method of Calsamiglia and Stern[27] was adopted to analyze the digestibility of RUP in air-dried rumen residues of 16 h rumen incubation as described by Peng et al.[18]

Fractionation of Crude Protein. The CP subfractions were computed according to the Cornell Net Carbohydrate and Protein System (CNCPS).[28,29] The CP was partitioned into NPN (PA), true protein (PB), and ADIP (PC). The PA fraction contains peptides, free amino acids, ammonia, amides, amines, ureides, nucleotides, and nitrates, and is considered to degrade in the rumen at the rate of 200%/h.[30] The PB fraction was further fractionated into a rapidly (10 to 40%/h) degradable fraction (PB1); a moderately (3 to 20%/h) degradable fraction (PB2); and slowly (0.06 to 0.55%/h) degradable fraction (PB3).[30] PB1 was computed as SP − PA; PB2 as CP − (PA + PB1 + PB3 + PC); and PB3 as NDIP − ADIP. These CP fractions were computed from the data obtained with wet-chemical analysis using the following approach, the trichloroacetic acid precipitated CP = PB1 + PB2 + PB3 + PC; borate-phosphate buffer insoluble CP = PB2 + PB3 + PC; NDIP = PB3 + PC; and ADIP = PC.[26]

Statistical Analysis. The data on chemical composition, CP subfractions, and the protein's molecular spectral characteristics were analyzed using the PROC MIXED procedure of SAS.[22] The model used for analysis was

$$Y_{ijk} = \mu + V_i + L_j + e_{ijk}$$

where Y_{ijk} is an observation on the dependent variable *ijk*; μ is the population mean; V_i was the fixed effect of flaxseed variety (CDC Bethune, CDC Sorrel, FY11140 and F08×425), L_j is the random effect of crop location (Kernen and Melfort) and e_{ijk} is the random error associated with the observation *ijk*.

The data on in situ rumen degradation parameters and intestinal digestibility were analyzed with the following model:

$$Y_{ijk} = \mu + V_i + R_k + e_{ijk}$$

where Y_{ijk} is an observation on the dependent variable *ijk*; μ is the population mean; V_i is the fixed effect of flaxseed variety, R_k is the random effect of in situ experimental run, and e_{ijk} is the random error associated with the observation *ijk*. When significant ($P < 0.05$) effects were observed, posthoc analyses were conducted on the least-squares means to compute pairwise differences among the means, using the Tukey-Kramer test adjusted for multiple comparisons.

The PROC CORR procedure of SAS[22] was used to compute the strength of relationships between the protein's molecular structural characteristics and CP chemical profile, subfractions, in situ degradation parameters, and intestinal digestibility of RUP. The PROC REG procedure of SAS[22] with stepwise selection at $P < 0.05$ was used to obtain multiple regression equations for the prediction of the chemical profile, CP subfractions, in situ degradation parameters, and intestinal digestibility of RUP. The independent variables tested in the model were amide I area, amide II area, and their ratio; amide I height, amide II height, and their ratios; and α-helix and β-sheet height and their ratios. Only equations contributing significantly ($P < 0{\cdot}05$) to the estimation of dependent variables are reported.

Multivariate analysis, the agglomerative hierarchical cluster analysis (CLA), and principal component analysis (PCA) were performed on the entire spectral data (n = 249 spectral bands), obtained from the amide fingerprint region (ca. 1732−1483 cm^{-1}), to classify and visualize varietal differences in intrinsic protein molecular structures. The concepts and procedure of using CLA and PCA for FT/IR-ATR spectral data are described earlier.[31]

RESULTS AND DISCUSSION

Chemical Profiles. The results of chemical profiles of the brown flaxseed varieties and yellow flaxseed breeding lines are shown in Table 1. Except for ash, the contents of all nutrients varied ($P < 0.05$) among the four genotypes. On average, the yellow-seeded lines had higher ($P < 0.001$) contents of EE (44.54 vs 41.42% DM) and CP (24.94 vs 20.91% DM) compared to those of the brown-seeded varieties. The higher contents of CP and EE in the yellow-seeded lines could be related to their larger seed size[32] and thinner and translucent seed coat[32,33] that results in a relatively greater proportion of oil and protein containing mass (cotyledons and endosperm) and smaller proportion of fiber containing mass (seed coat) compared to those of the brown seeded varieties.[11] In agreement with our findings, higher contents of CP and EE have been reported for yellow-seeded canola meal compared to that of its brown-seeded counterpart.[11,34] Within the yellow-seeded lines, FO8×425 had a higher ($P < 0.05$) content of EE; and within the brown-seeded varieties, CDC Bethune had a higher ($P < 0.05$) content of EE and CP. The latter findings suggest some genotype differences in the chemical profiles of flaxseed within the yellow and brown seed types.

The CP chemical profile revealed that on average the CP in yellow flaxseed lines had a higher ($P < 0.01$) content of ADIP (7.80 vs 3.38% CP). The ADIP is believed to be nondegradable in rumen and nondigestible in the postruminal tract. In contrast to our findings, previous studies have reported lower contents of ADIP in yellow-seeded carinata strains and canola meal compared to their brown-seeded counterparts.[11,12] This discrepancy may be related to the inherent genetic variation

in these seeds. Compared to brown-seeded varieties, the content of NDIP was lower ($P < 0.01$; 16.45 vs 11.44% CP) in the yellow-seeded lines, which is in line with literature findings.[11,12] Among the yellow-seeded lines, the content of ADIP was higher ($P < 0.05$) in F08×425, whereas no significant differences were observed in the CP chemical profile among the brown-seeded varieties. Overall, the results of chemical profiles showed that the yellow-seeded lines had higher contents of EE and CP; however, the CP in the yellow-seeded lines may not be optimally utilized by dairy cows due to the relatively high proportion of rapidly degradable SP (data not shown) and nondigestible ADIP fractions.

Crude Protein Subfractions. Results of the CNCPS CP subfractions of the brown-seeded and yellow-seeded flax are presented in Table 2. The contents of all CP subfractions varied ($P < 0.05$) among the four genotypes. The yellow-seeded lines had significantly ($P < 0.01$) higher contents of the nonprotein fractions, namely, the instantaneously solublilized (PA) fraction (10.88 vs 3.91% CP). In contrast, Theodoridou and Yu,[11] found lower content of the PA fraction (0.24 vs 3.1%) in yellow-seeded canola meal compared to that in brown-seeded canola meal. Whereas, Xin et al.[12] found no differences in the PA content of yellow- and brown-seeded carinata strains. Moreover, the yellow-seeded lines contained a high content of nonavailable (PC) fraction (7.80 vs 3.38% CP) compared to

The α-helix and β-sheet were centered at 1,653 and 1,630 cm^{-1}, respectively.

that in brown-seeded varieties. As a consequence of high PA and PC fractions, the true protein fraction of the yellow-seeded lines was markedly lower ($P < 0.01$; 81.31 vs 92.71% CP) than that in the brown-seeded varieties. The PA fraction very rapidly (200%/h)[31] degrades to NH_3-N in the rumen and often contributes to NH_3-N losses in the environment. Whereas, the PC fraction neither degrades in the rumen nor is digested in the postruminal tract and excreted in feces to the environment.[28] These results suggest that CP in the yellow flaxseed genotypes is not optimally digested and utilized in the gastrointestinal tract of dairy cows compared brown flaxseed varieties. However, the brown flaxseed varieties had a markedly higher (13.13 vs 3.65% CP) PB3 subfraction. The PB3 slowly (0.06 to 0.55%/h)[29,31] degrades in the rumen, and a large fraction of PB3 bypasses the rumen and is digested in the small intestine. Indeed, the in situ results showed higher RUP (35.1 vs 29.2% CP) contents for the brown-seeded varieties. Among the brown-seeded varieties, CDC Sorrel had lower ($P < 0.05$) PB1 and higher ($P < 0.05$) PB2 and PB3 fractions (Table 2), suggesting that CP in CDC Sorrel will be more gradually broken down to NH_3-N in the rumen and that a higher fraction of CP will bypass the rumen. This was confirmed by the in situ results, which showed high RUP values for CDC Sorrel (Table 3).

Rumen Degradation and Intestinal Digestibility. Results on the ruminal DM and CP degradation kinetics and intestinal digestibility of RUP in the yellow-seeded lines and brown-seeded varieties are shown in Table 3. The yellow-seeded lines had lower ($P < 0.001$) content of RUDM compared to that of the brown-seeded varieties. The D fraction of DM did not significantly change among the two seed coat types. Therefore, the lower content of RUDM of the yellow-seeded lines could be related to its higher ($P < 0.05$) S fraction and *kd* of the D fraction. The lower proportion of fiber (hull), higher proportion of CP and EE,[11,32] and higher *kd* of CP (Table 3) can all contribute to the lower RUDM of the yellow seed coat genotypes. Within the yellow seed coat genotypes, FY11140 had higher ($P < 0.05$) S fraction and lower ($P < 0.05$) D fraction; however, no significant differences were observed in the RUDM among the two yellow-seeded lines. In the brown flaxseed varieties, CDC Sorrel had higher ($P < 0.05$) RUDM. As the *kd* was not significantly different among the two brown-seeded varieties, the higher RUDM of CDC Sorrel was mainly caused by its markedly lower S-fraction (7.56 vs 20.72% CP) compared to that of CDC Bethune.

Except for lag time, all ruminal CP degradation parameters varied ($P < 0.05$) between the brown-seeded and yellow-seeded genotypes. The brown-seeded varieties had a higher ($P < 0.001$) content of RUP compared to that of the yellow-seeded genotypes. The higher RUP content of brown-seeded varieties could be related to their lower S fraction and lower *kd* of the D fraction compared to those of the yellow-seeded genotypes. However, there were significant differences in the in situ CP degradation parameters within the yellow- and brown-seeded genotypes. Among the brown-seeded flax, CDC Sorrel had a higher ($P < 0.05$) content of RUP. The higher RUP content of CDC Sorrel could be related to its markedly lower S fraction and lower *kd* of the D fraction compared to those of CDC Bethune (Table 3). In the yellow-seeded lines, FY08×425 had a significantly higher content of RUP. As the *kd* was not different between the two genotypes, the higher RUP content of FY08×425 was mainly caused by its markedly lower S fraction and higher lag time. The RUP in the yellow flaxseed lines were more ($P < 0.001$) digestible in the small intestine compared to that in the brown flaxseed varieties.

These results are consistent with earlier findings.[11] The high intestinal digestibility of RUP in yellow-seeded genotypes was, however, not supported by its significantly higher content of PC subfraction. Previous studies have shown a strong negative correlation ($r = -0.81$) between the PC (ADIP) subfraction and the total tract digestibility of CP,[35] and a strong positive correlation ($r = 0.84$) between the content of PC and the content of N excreted in the feces.[36] Nevertheless, the (in vitro)-intestinal digestibility of RUP in the brown flaxseed varieties was close to the reported values of intestinal digestibility for the brown flaxseed measured with the mobile nylon bag technique.[7] The lower digestibility of RUP in the brown flaxseed could be partly explained by the presence of condensed tannins in the brown seed coat.[11,37,38] Condensed tannins can make bonds with protein as well as with digestive enzymes and can decrease protein digestibility.[39,40] Overall, these results suggest that the CP in yellow-seeded lines was more extensively degraded in the rumen causing a lower supply of RUP to the small intestine compared to that in brown-

seeded varieties. However, the RUP in the former seeds were more digestible in the small intestine. These findings also demonstrate that it is important to determine the intestinal digestibility of RUP in order to more accurately estimate the metabolizable protein supply to dairy cattle.

Protein's Molecular Structures. Recently, advance molecular spectroscopy methods have been developed to quantitatively evaluate the primary and secondary molecular makeups of feed protein.[31,41] In general, the amide I and amide II spectral intensities in terms of peak area and height reveal information about the concentration of protein in feed.[18,42] Table 4 shows that the yellow seed coat FY11140 line had greater ($P < 0.05$) amide I and II height and amide I and II peak area among the four genotypes, which correspond to the higher concentration of CP in this variety. In agreement with our findings, Dariman and Yu[42] found that greater amide I and II height and area in zero-amylose waxy cultivar of barley were associated with a higher content of CP compared to those of waxy, high amylose and normal cultivars. However, the ratios of amide I/II and α-helix/β-sheet reveal information about the protein's molecular makeup.[42,43] The molecular makeup of feed protein strongly influences CP degradation in the rumen and the digestibility of RUP by affecting their solubility and access to microbes and proteolytic enzymes.[16,31] Among the four genotypes, CDC Sorrel had the highest amide I/II area ratio and lowest α-helix/β-sheet ratio, which were associated with the lowest contents of PA and PB1, and the highest content of RUP. Our results are consistent with the findings of Samadi and Yu[15] and Peng et al.[18] The correlation analysis (Table 5) showed that the amide I/II area ratio had a significant ($P < 0.05$) negative correlation to SP ($r = -0.77$) and the in situ S fraction ($r = -0.94$) and significant positive correlations to the D fraction ($r = 0.88$), RUP ($r = 0.96$), and intestinal digestibility of RUP ($r = 0.63$). The α-helix/β-sheet ratio had significant ($P < 0.05$) positive correlation to the content of SP ($r = 0.85$), kd ($r = -0.82$), S fraction ($r = 0.91$), and RDP ($r = -0.92$), and had significant negative correlations to the D fraction ($r = -0.88$), RUP ($r = -0.92$), and intestinal digestibility of RUP (-0.71). These results demonstrate that there is a strong relationship between the protein's molecular structures and CP chemical profiles, ruminal degradation characteristics, and intestinal digestibility of RUP.

Multivariate Analysis. Figure 2 shows the results of multivariate CLA and PCA analyses that classify and visualize the overall differences in the protein's inherent molecular makeup of brown-seeded and yellow-seeded genotypes. The CLA dendrograms (Figure 2a) show that the protein's molecular spectral data of CDC Sorrel can be distinguished from the other genotypes at a linkage distance of <0.18. CDC Bethune could also be distinguished from CDC Sorrel and FY11140 at a linkage distance of 0.02. The mixed dendograms of the two yellow-seeded lines (FY11140 and F08×425) demonstrate similarity in the structural makeup of their protein. Results of the PCA are visualized in a scatter plot between the first two principal factors (Figure 2, panel b). The scatter plot explained 90.14% of the total variation in the protein's molecular structures of the brown and yellow flaxseed. The protein's molecular spectra of CDC Bethune, CDC Sorrel, and FY11140 were clustered together into separate groups, demonstrating similarities within their molecular makeup. At the same time, these groupings show that CDC Bethune, Sorrel, and FY11140 could be completely distinguished from each other as demonstrated by CLA dendograms. These results confirm genotype differences in the protein's molecular makeup.

Table 5. Coefficient of Correlation (Pearson)[a] and Its Level of Significance between Protein Molecular Structural Characteristics and Nutrients Profile, Crude Protein Subfraction Profile, in Situ Degradation Kinetics, and Intestinal Availability in Yellow- and Brown-Seeded Flaxseed

Multiple Regression Equations. Table 6 shows the multiple regression equations, based on the protein's spectral parameters, and their predictive power for the estimation of the contents of chemical components, CP subfractions, in situ CP degradation parameters, and intestinal digestibility. The results showed that the contents of CP ($R^2 = 0.87$) and SP ($R^2 = 0.92$) can be predicted from the amide I/II height and area ratios and α-helix height. Similarly, the protein spectral parameters could be used to estimate the in situ CP degradation parameters such as kd ($R^2 = 0.62$), S fraction ($R^2 = 0.88$), D fraction ($R^2 = 0.85$), RUP ($R^2 = 0.97$), and intestinal digestibility of RUP ($R^2 = 0.71$). The relatively good predictive powers of the regression equations, based on the protein's spectral parameters, for the estimation of total CP, SP, and RUP could have important practical implications in feed evaluation. FT/IR-ATR molecular spectroscopy is a fully established, noninvasive, and non-destructive analytical technique that can analyze the molecular structures of the proteins of a large number of feed samples in a relatively short time. Yu and Nuez-Ortín[16] and Becker and Yu[44] suggested that the ratios of amide I/II and α-helix/β-sheet can be used as an indicator for the changes in CP nutritive value during heat-related processing or among different feed types,

dx.doi.org/10.1021/jf501284a | J. Agric. Food Chem. 2014, 62, 6556−6564

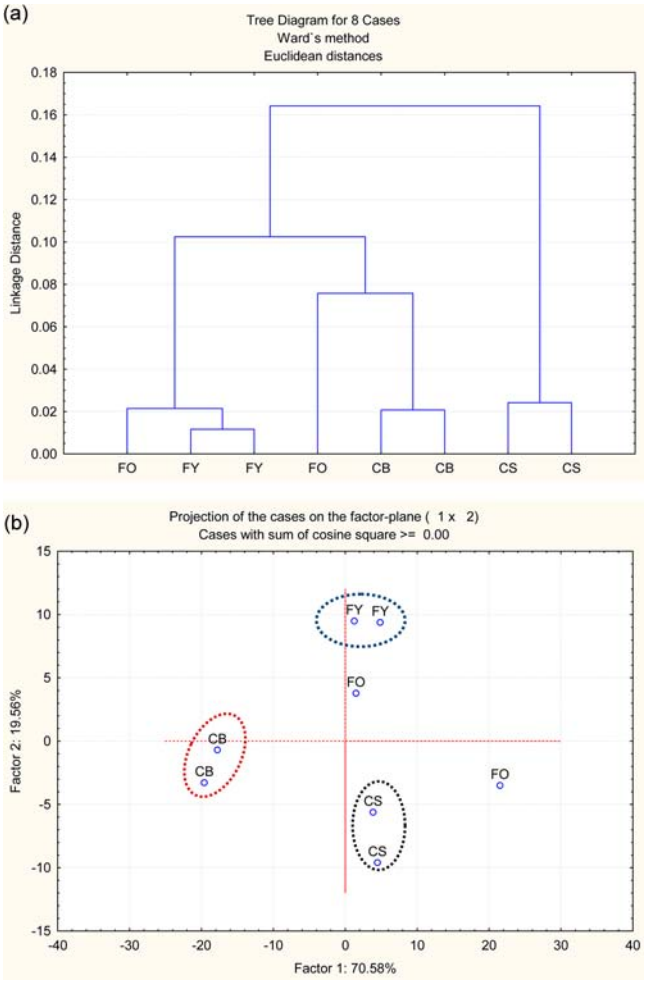

Figure 2. Agglomerative hierarchical cluster analysis (CLA) dendograms (a) and principal component analysis (PCA) scatter plot (b) visualizing the overall spectral (n = 249 spectral bands; collected at ca. 1712−1482 cm^{-1}) differences in the protein molecular makeup of brown seeded (CB = CDC Bethune; CS = CDC Sorrel) and newly developed yellow seeded (FY = FY11140; FO = FO8×425) flaxseed genotypes. (a) Agglomerative hierarchical cluster analysis (CLA) dendograms. (b) PCA scatter plot of the 1st principal factor versus 2nd principal factor.

which is supported by the findings of the present study. However, it is pertinent to mention here that these prediction equations were derived from limited samples based on one type of oilseed. Prediction equations based on a large number of samples with diverse sources will be required to illustrate the actual relationship between spectral parameters of protein and CP subfraction composition and digestive behavior.

In conclusion, the newly developed yellow flaxseed breeding lines had significantly higher contents of oil and CP compared to those of the brown flaxseed varieties. However, the CP in yellow-seeded lines had higher contents of PA and PC subfractions. As a consequence, the true protein subfraction was significantly lower in yellow-seeded lines. Moreover, the CP in the yellow-seeded lines was more extensively degraded in rumen resulting in the lower content of RUP than that in the brown-seeded varieties. However, the RUP in yellow-seeded lines was more digestible in the small intestine than that in the brown-seeded varieties tested; as a result, the total supply of digestible RUP was not different between the two seed color types. The molecular spectroscopy study revealed significant differences in the inherent molecular structures of protein, and these structural differences were strongly correlated to the CP chemical profile, ruminal degradation kinetics, and intestinal digestibility. The multiple regression equations showed that the protein's molecular spectral features can be used to estimate the contents of total CP, SP, RUP, and intestinal digestibility of RUP with relatively good predictive power. FT/IR-ATR spectroscopy can characterize feed molecular structures within cellular dimension, and the spectral parameters can be used as predictors for the estimation of CP subfractions, rumen degradation, and intestinal digestibility.

show three-dimensional variability with highly complex relationships between bioavailability and biodegradation in both subsoil and topsoil.[12] Understanding the extent of this three-dimensional variation and its controlling factors is essential in the risk assessment of environmental exposure. Additionally, pesticide quantitative-diversely distributes at different parts of plants (cuticle and internal parts or above-ground and underground parts, etc.), which results in differences in human intake risk. It is necessary to discuss the distribution of pesticides in the different parts of the plant. Wang et al. reported that the plasma of tomato initially accumulated the highest pesticide concentration, and the concentrations of chlorothalonil and chlorpyrifos in tomato followed the order cuticle > plasma > pulp.[13] However, few studies thoroughly focused on the distribution of pesticides in soils and plants. Another purpose of this work is to determine the time-dependent dynamic distribution of CHP in different parts of bamboo area (bamboo shoots and soil) and the influencing factors. This study would help to provide basic information for developing regulations to safeguard the use of CHP in bamboo shoot cultivation and to prevent health problems in consumers. This may further lead to the development of optimized pesticide removal procedures.

MATERIALS AND METHODS

Reagents and Solutions. Pesticide analytical standards were purchased from National Information Center for Certified Reference Materials (Beijing, China), certified quality. Individual pesticide stock solutions (100 mg/L) were prepared in methanol or acetonitrile and stored at −20 °C. Then, a series of dilutions containing the mixture of standards were prepared (10 mg/L) in methanol. HPLC-grade acetonitrile and methanol were obtained from Merck (Darmstadt, Germany). A Milli-Q-Plus ultrapure water system from Millipore (Milford, MA, USA) was used throughout the study to obtain the HPLC-grade water used during the analyses. Other solvents were from Shanghai Sanying Chemical Reagents (Shanghai, China), pesticide residue analysis quality.

HPLC-MS/MS. The LC system consists of a high-performance liquid chromatograph (Waters, Milford, MA, USA) with an HSS T3 column (5 μm, 100 mm × 2.1 mm, i.d., Waters). A mobile phase consisting of solvent A (0.1% formic acid, in water) and solvent B (methanol) was used with the following gradient program: 80:20 A:B (initial), 10−90% A with 90−10% B (0−5 min), 10:90 A:B (5−10 min), 10−80% A with 90−20% B (10−14 min), 80:20 A:B (14−15 min). A subsequent requilibration time (3 min) was performed after each injection. The flow rate was 0.3 mL/min, and the injection volume was 10 μL. The column and sample temperatures were maintained at 35 °C.

MS/MS was performed on a Waters Quattro Premier triple-quadruple mass spectrometer equipped with an ESI source (Waters, Milford, MA, USA). MS/MS detection was performed in positive ion mode for CHP and in negative mode for TCP separately. The monitoring conditions were optimized for target compounds. Acquisition parameters were as follows: capillary voltage 3.5 kV, cone voltage 45 V, source block temperature 80 °C, cone gas 50 L/h, desolvation temperature 450 °C, desolvation gas (nitrogen gas) 550 L/h, respectively. As the precursor ion for CHP, 352 (m/z) was selected, and its quantitative and qualitative product ions were 97 (m/z) and 198 (m/z), respectively, when the collision energies were both 30 V. As for TCP, 196/35 was selected as the quantification ion transition, and 198/37 were selected as the confirmatory ion transition with all the collision energies at 15 V. Multireaction monitoring mode was selected as the scan mode. Under the described conditions, the retention times of CHP and TCP were approximately 9.92 and 7.88 min, respectively.

Pesticide Analysis. A portion (20.0 g) of prehomogenized sample (bamboo shoot) was weighed in a 250 mL glass breaker. The sample was extracted with 50 mL of acetonitrile by homogenization with a high-speed blender (Ultra-Turrax T18, IKA, Germany) for 2 min. After the addition of 6 g of $MgSO_4$ and 4 g of NaCl, each mixture was shaken intensively for 1 min and centrifuged for 5 min at 8000 rpm. An aliquot of the organic phase (25.0 mL) was transferred and concentrated by a rotatory evaporator at 40 °C to near dryness, then dissolved in 1.0 mL of methanol. Prior to analysis, the methanolic analyte was filtered through a 0.22 μm PTFE filter (Milford, MA, USA).

A 2.0 g sample of soil (sieved through a 2 mm mesh) was mixed with 1 mL of distilled water for 5 min. Then methanol (5 mL) was added and vortexed for 2 min, and the sample was centrifuged for 5 min (4000 rpm). A 2.0 mL portion of the superstratum was transferred and filtered through a 0.22 μm PTFE filter.

Chemical and Biological Analyses of Soils. Soil characteristics were examined including moisture content, pH, and organic carbon. Moisture content was measured according to Bending et al.[12] Soil pH was measured in water with a soil to water ratio of 1:5 (w/v). Organic carbon was determined by dichromate oxidation and titrated with ferrous ammonium sulfate, followed by converting to soil organic matter content using the Van Bemmelen factor 1.724.[14]

Field Experiments and Sampling Procedure. The trial field (red soil) was located in Fuyang, Zhejiang Province, China. The recommended dosage is 120 kg/ha for 3% chlorpyrifos granules (Tianyi Agriculture Chemistry Company, Zhejiang, China). The field experiment was started on Nov 6, 2012. After the pesticide application, the surface soil was turned to mix uniformly. On the next day, compound fertilizer was applied by hand (1000 kg/ha), and the soil surface was covered by straw (20 cm in thickness). Representative soil samples were collected by random sampling, and CHP and its metabolic residues were measured using the method described above. The soil (0−20 cm) was divided into three layers (0−5, 5−10, and 10−20 cm) and collected (1 kg). Samples were collected randomly from each plot at 0, 6, 13, 21, 29, 38, 62, 83, 111, 140, 170, 201, 250, and 300 day intervals after pesticide application. The bamboo shoot samples were collected randomly from each plot at 83, 111, 115, 119, 125, 129, 132 day intervals after pesticide application. Each sample (1 kg) was chopped and divided into two samples.

Data Analysis. To determine the kinetics of the degradation, plots of concentration against time were made, and an exponential regression analysis (first-order rate equation) was then performed on each data set.

$$c = c_0 e^{-kt}$$

where c represents the concentration of pesticide at time t, c_0 represents the initial concentration, and k is the rate constant.

RESULTS AND DISCUSSION

Efficiency of Analysis Method. The accuracy and precision of the method were obtained with recovery studies by spiking tested compound-free soil and bamboo shoots at three levels (Table 1). The control samples from untreated plots and reagent blanks were also processed in the same way so as to find out the interferences, if any, due to the substrate and reagents, respectively. The peaks of CHP and its metabolic TCP were free from interfering peaks of soil and bamboo shoots. For the blank sample substrate, there was no peak detectable in the range of runtime. The recovery of CHP and TCP from soil and bamboo shoots ranged from 70.5% to 108.2% with RSD (relative standard deviation) ranging from 3.4% to 10.5%. The lowest spiked concentration of the analyte, which could be determined with acceptable precision and accuracy, was considered as the limit of detection (LOD) of the method. From the validation data presented in Table 1, it can be observed that the LODs were 0.10 mg/kg (soil) and 0.01 mg/kg (bamboo shoot), respectively.

Table 1. Recoveries and RSD of Fortified Soil and Bamboo Shoot Samples

matrix	compound	fortified level (mg/kg)	recoveries (%)			RSD (%)
soil	CHP	0.1	85.2	89.6	80.3	5.5
		0.25	93.2	95.7	105.6	6.7
		0.5	93.2	98.7	106.7	6.8
bamboo shoot	CHP	0.01	100.2	95.7	93.4	3.6
		0.05	91.3	86.7	92.5	3.4
		0.1	108.2	100.7	99.3	4.7
soil	TCP	0.1	93.6	82.3	85.1	6.8
		0.25	73.2	86.7	89.6	10.5
		0.5	89.4	96.3	87.2	5.2
bamboo shoot	TCP	0.01	79.3	70.5	85.4	9.6
		0.05	88.2	76.8	85.1	7.1
		0.1	92.4	88.6	83.7	4.9

Dynamics of CHP in Soil. The subsoil represents a very different physical, chemical, and biological environment from the topsoil. Previous studies showed that pesticide degradation rates declined with soil depth.[15] In this study, the soil layer (0−20 cm, the cultivation soil layer for bamboo root growing) was divided into three parts: top layer (Tl, 0−5 cm), middle layer (Ml, 5−10 cm), and bottom layer (Bl, 10−20 cm). The dynamic curves of CHP in the covered (CP) and noncovered cultivation (NCP) are shown in Figure 1. The original deposits

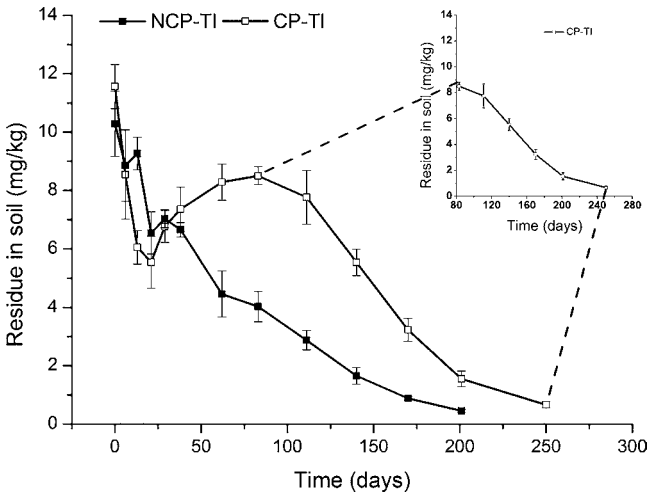

Figure 1. Dissipation curves of CHP residues (mg/kg), fitted to the first-order kinetics model, in the top layer of soil (0−5 cm). Data are means ± SD (n = 3).

in the soils in two cultivation patterns were 11.57 mg/kg (CP) and 10.29 mg/kg (NCP), respectively. The degradation dynamic in NCP-Tl could be fitted to a first-order exponential decay model.[16] The equation was $C_t = 10.84e^{-0.0144t}$ (R^2 = 0.96), and the half-life was 48.1 days. However, the degradation dynamics in CP-Tl could not be fitted to any decay model. CHP degraded rapidly in Tl by more than 52% in 21 days. Then the dissipation curve pattern in Tl showed a fluctuant ascent until 83 days and a subsequent descent. This performance was due to the character of granule formulation of CHP, which was slowly released during the experiment, and then the quantity of CHP residue in the soil increased. After 83 days, the slow-release effect weakened or disappeared. From 83 to 250 days, the degradation equation in Tl was $C_t = 11.52e^{-0.0164t}$ (R^2 = 0.87), with a half-life 42.3 days. From 29 to 140 days, the CHP residue could be detected in Ml (Table 2), with the concentrations ranging from 1.25 to 0.15 mg/kg.

Table 2. Distribution of CHP in the Middle Layer (Ml) and Bottom Layer (Bl) of CP Soil

time (day)	Ml (±SD, mg/kg)	Bl (±SD, mg/kg)
0−21	<LOD	<LOD
29	1.25 ± 0.12	<LOD
38	0.79 ± 0.07	0.54 ± 0.07
62	1.03 ± 0.08	0.78 ± 0.08
83	0.56 ± 0.06	0.31 ± 0.03
111	0.34 ± 0.04	0.11 ± 0.02
140	0.15 ± 0.02	<LOD
170−250	<LOD	<LOD

Between day 38 and 111, the CHP residues in Bl ranged from 0.78 to 0.11 mg/kg. The appearance of CHP residue in Ml and Bl demonstrated that CHP could gradually migrate from the top layer of soil to the bottom, which is likely to result in some risk for underground water or other species in the subsoil. However, in the NCP soil, the CHP residue could be detected only in Tl, which meant that CHP was fixed in the topsoil with reduced risk. In addition, there was almost no slow-release effect in NCP, and CHP degraded rapidly. Obviously, the soil surface mulching cultivation could lead to the slow release and migration of CHP. The previous studies have suggested the half-life of CHP (emulsifiable concentrate) in soil was 36.5 days.[17] In other studies where CHP was applied directly to bare tropical field soils (23−25 °C), shorter half-lives in the range 0.6−5.4 days were found,[18] and the residue of CHP in the soil could range up to 120 days,[16] even one year, depending on soil type, insecticide dose, climate, and other environmental factors.[19,20] The slower CHP (granule formulation) degradation under bamboo shoot soil may also be attributed to shading of the soil, resulting in less photodegradation and volatilization.

CHP Residue in Bamboo Shoots. The bamboo shoot samples (edible part, with average length 15−20 cm) were divided into two parts: an upper part (10−15 cm length) and a bottom part (5 cm). For CP bamboo shoots, the residues at harvest time were found mainly in the bottom part: the residues at harvest time were 38.3 μg/kg (83 d), 20.5 μg/kg (111 d), and 10.9 μg/kg (115 d), respectively (Table 3). The concentration in the upper part was only detected at 83 and 111 days, with 24.2 and 12.8 μg/kg, respectively. The maximum residue limits (MRLs) of CHP and TCP in bamboo shoot have not established in China. However, China established 50 μg/kg as the MRL for asparagus. The EU and USA set 50 μg/kg as the MRL for CHP in bamboo shoots, and the MRL for bamboo shoots in Japan (Positive List System) is 500 μg/kg. All the quantities for CHP detected in this work were below the MRLs mentioned above. It is worth noting that the total quantity of residue in 83 days was 62.5 μg/kg, which was above the MRLs (except for Japan). However, bamboo shoots could be found only sporadically before 111 days and could not be put on the market. So there is no risk for consumers. Obviously, the concentration in the bamboo shoot was higher for CP compared with NCP. The CHP residues in NCP bamboo shoots were below the LOD of the method (10 μg/kg). This result might be due to the immobility of CHP in the topsoil;

dx.doi.org/10.1021/jf501540e | J. Agric. Food Chem. 2014, 62, 6565−6570

Table 3. Distribution of CHP in Bamboo Shoots

time after pesticide application (d)	residues in bamboo shoot of CP (±SD, μg/kg) upper	bottom	time after pesticide application (d)	residues in bamboo shoot of NCP (±SD, μg/kg) upper	bottom
83	24.2 ± 3.32	38.3 ± 5.47	132	<LOD	<LOD
111	12.8 ± 1.88	20.5 ± 2.10	136	<LOD	<LOD
115	<LOD	10.9 ± 1.39	139	<LOD	<LOD
119	<LOD	<LOD	145	<LOD	<LOD
125	<LOD	<LOD	148	<LOD	<LOD
129	<LOD	<LOD	153	<LOD	<LOD
132	<LOD	<LOD	160	<LOD	<LOD

the CHP could not reach the root of the bamboo and adsorb into the bamboo shoot. In addition, the harvest time for NCP is behind the CP by almost 30 days, and the total quantity of CHP residue in the soil is relatively less in that period.

Metabolism of CHP in Soil and Bamboo Shoots. When a pesticide is applied, it enters a hostile environment and is subjected to a wide range of biological (enzymes), chemical (hydrolysis), and physical (photolysis) reactions, which may change its chemical nature.[21] The degradation products (metabolites) have different inherent properties from their parent pesticides, and the effects of these changes need to be assessed in terms of both environmental and human safety. Metabolism studies are conducted to provide a detailed understanding of the fate and behavior of the pesticide in the environment.[22,23] Liang et al. found TCP was most likely to leach through paddy soil into groundwater.[24] In this work, the results showed that CHP could be degraded into TCP in bamboo shoot soil (Figure 2). The rainfall had a notable effect

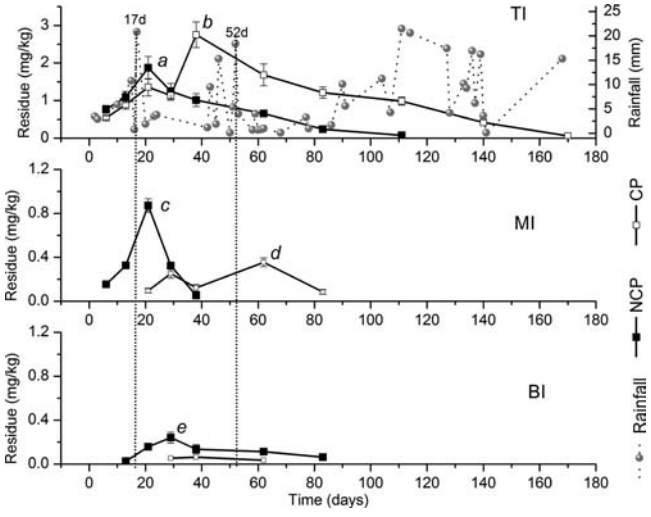

Figure 2. Distribution of TCP in different layers of soil.

on the leaching of TCP in the soil. After a rainfall, TCP in Tl could leach into Ml, and even Bl. This was especially obvious when a large-scale rainfall occurred. In NCP soil, the CHP degraded rapidly between day 17 and 21 (rainfall capacity was 20.7 mm on day 17); residue peaks of TCP in Tl (point *a*) and Ml (point *c*) were reached on day 21. The rainfall accelerated the degradation of CHP; on the other hand, a strong leaching effect occurred. However, in CP soil, the residue peaks occurred relatively late. TCP residues in Tl and Ml were 2.75 mg/kg on day 38 (point *b*) and 0.35 mg/kg on day 62 (point *d*), respectively. The leaching delay resulted from the adsorption of rain from the covering materials, which led to the slow leaching effect for TCP. In CP soil, the leaching of TCP was a gradual process. In addition, most of TCP residues gathered and degraded in Tl before the migration process occurred. Although the TCP residue levels in the topsoil (Tl) were higher in CP than that in NCP, the latter had higher residue values in the subsoil (Ml and Bl). The concentration of the degradation product TCP did not exceed 3 mg/kg during the 180-day experimental period. For bamboo shoots, there were no TCP residues detected. The high hydrophilicity of TCP made it diffcult to penetrate the hydrophobic shell of bamboo shoots. In addition, the nonresidue detected in bamboo shoots was also closely related to the minor residue of TCP in the root layer (Bl).

pH Change of Soil and Its Effect on Pesticide Behaviors. Soil pH is known to play a key role in controlling the structure of soil microbial communities, which could influence pesticide metabolism indirectly. In addition, the soil pH could influence pesticide hydrolysis directly. The degradation rate of several pesticides has been found to be related to pH.[25] In a study of Canadian and French soils, the soils with a pH over 6.5 typically showed growth-linked metabolism of atrazine, and those with a pH lower than 6.5 showed slower co-metabolic degradation.[12] Additionally, pH is known to affect the extent to which some pesticides adsorb to soil organic matter and, therefore, determine the bioavailability of such pesticides to the degradative community. From Figure 3, in 0−5 cm surface soil, the pH in the CP treatment increased

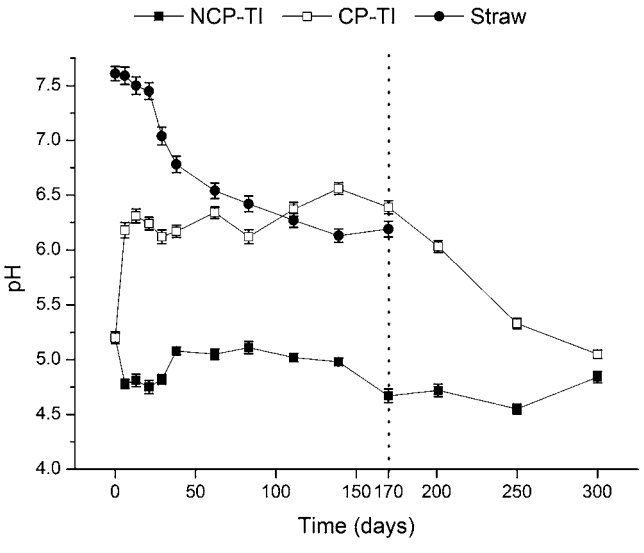

Figure 3. pH changes of the topsoil in different treatments.

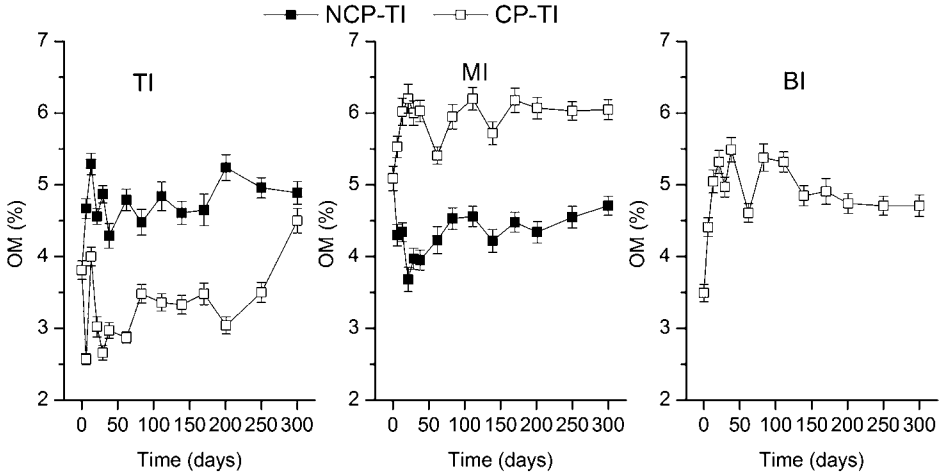

Figure 4. OM changes of soils in different treatments.

from 5.2 to 6.18 after the experiment was carried out for 6 days, while the NCP treatment reduced the pH from 5.2 to 4.78. The reduction of pH from NCP surface soil might be induced by acid rain. There was a small amount of precipitation on days 2 and 3 after the experiment's beginning. The pH of the rain ranged from 4.7 to 5.2. In the CP treatment, the rain washed the straw, and then the leachate (pH above 6.0) of the straw leached into the soil surface, leading to a higher pH value. During the experiment period, 0−170 days, the pH of the CP treatment of the topsoil was significantly higher than that of the NCP treatment; after 170 days, the pH difference between the two treatments was significantly smaller with the cover material removed, which indicated that the alkalinity or acidity of covering material itself could affect the pH value of the topsoil. In the subsoil, there were little differences in pH between the CP and NCP treatments (not exceeding 0.3 unit of pH), which illustrated that the leachate of the covering material was mainly in the 0−5 cm of surface soil, and the leachate containing some substance capable of changing the soil pH did not readily leach into the soil below 5 cm. The pH value of the surface soil in the CP treatment was higher than that in the NCP treatment, and the pH of the 0−5 cm surface layer was higher than that of the 5−10 and 10−20 cm soil layers. The higher pH can directly accelerate the degradation of pesticides, which explained the fast degradation of CHP from day 0 to 21 in the CP treatment.

OM Change of Soil and Its Effect on Pesticide Behaviors. Pesticide adsorption can also show significant spatial variability at both the catchment and field level. Several authors have shown that adsorption of pesticides decreases with soil depth, with the pattern governed by soil organic matter (OM) content.[12,26] Since adsorption can be an indicator of bioavailability, a change in the amount or variability of adsorption with depth could affect patterns of biodegradation, even though the significance of any changes would be expected to depend on the strength of adsorption of individual compounds. One of the factors for the high persistence of fipronil in soil was the high organic carbon level and low pH.[22] CHP was strongly adsorbed to soil particles, which may retard its degradation.[27] The results from NCP obtained in the present investigation seem to be in agreement with the above studies. In the three stratified soil types of the NCP treatment, soil OM content significantly decreased with depth, ranging between 2.24% and 5.89% in topsoil and from 0.78% to 2.80% at 5−20 cm depth (Figure 4). However, in the three stratified soil types of the CP treatment, the OM of the subsoil layer (5−20 cm) was obviously higher. Compared with the NCP treatment, OM decreased in topsoil and increased in subsoil from the CP treatment, which may be due to the insulation of the covering material (the OM of straw was 36.1%) or the leachate from the straw into the subsoil.

Usually, there is a negative correlation between OM and pH.[14] In this work, the topsoil performed in agreement with the principle. The OM of topsoil in the CP treatment was lower than that in the NCP treatment, and the former had a higher pH over the latter. The topsoil with a low pH and high OM could absorb more CHP in the NCP treatment, which explained why CHP was fixed in the 0−5 cm soil layer. Correspondingly, the topsoil with lower OM in the CP treatment had less adsorption capacity for CHP than that in the NCP treatment, so CHP in CP treatment will produce significant leaching effects. However, TCP did not show a significant positive correlation with OM values. The high hydrosolublity of TCP led to its notable leaching effect in the NCP treatment.

Effect of Soil Surface Mulching on Pesticide Behaviors. Due to the slow-release effect from the granule formulation of CHP, its degradation process could result in a degradation rate of CHP that is slower than the other formulations with a non-slow-release effect. This difference is particularly evident in the soil surface mulching cultivation and may cause persistence of pesticides and long-term environmental risks. In the soil surface mulching cultivation, the straw used as the mulched material, with higher OM and pH, had some regulatory role in changing the pH and OM characteristics of the soil. Thus, the straw could indirectly affect the adsorption and degradation behavior of CHP and TCP in soil. CHP was more easily fixed in the 0−5 cm soil layer of the NCP treatment; thus it was difficult to produce a leaching effect and cause further effects. The rain leaching delay performance from the mulched materials led to the slow-leaching effect for TCP. TCP could generate an obvious leaching capacity to enter into the subsoil. In contrast, CHP was easy to leach in the CP treatment, and the leaching capacity of TCP in the CP treatment was not more obvious than that in the NCP treatment. Although the CHP and TCP residues in the harvested bamboo shoot samples from mulched ground did not basically exceed the MRLs, a sample close to the MRL value still existed. This deserved our attention regarding food safety

dx.doi.org/10.1021/jf501540e | J. Agric. Food Chem. 2014, 62, 6565−6570

issues. In general, although CHP granule formulation leads to high efficiency for insect control under soil surface mulching, additional risks for consumers, agriculture workers, and the environment should be taken into account due to prolonged persistence and leaching of high residue levels in the soil.

antibacterial,[14] and antifungal[15] properties and so on. The compound can be used to treat several ailments.[16]

Another natural product, stelladerol (Figure 2), is a strong inhibitor of cyclooxygenase enzyme and phospholipid oxidation.[17] The compound 2-hydroxynaphthalene-1-carbaldehyde itself is known to possess moderate antibacterial property.[18] Naphthol is a precursor for a variety of insecticides and is a well-known component with contact insecticidal properties.[19]

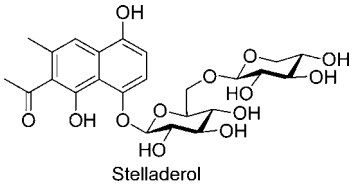

Figure 2. Structure of naphthalene glycoside, stelladerol, which has potential biological activities.

As our group is involved in the synthesis of β-naphthol-based synthetics,[20] we designed and synthesized a series of naphthalene-based hybrid molecules using a novel green protocol to screen them for their dual inhibitory activity as angiotensin converting enzyme inhibitors and calcium channel blockers in treating resistant hypertension. In a recent study Venugopala et al. reported that these compounds show good antimosquito properties.[21] The existing literature and recent studies drove us to screen our compounds for their antifeedant and toxic properties against major agricultural pests. In the present paper we describe the synthesis of 2-aminobenzothiazolomethylnaphthol derivatives using a green protocol and their influence on the feeding behavior and toxicity effects against a major polyphagous pest, *Spodoptera litura*, and a monophagous pest, *Achaea janata* (L).

MATERIALS AND METHODS

Instruments. Commercially available reagent grade chemicals and solvents were used in all reactions and purification processes. All of the reactions were monitored by TLC on E. Merck Kieselgel 60 F_{254}, with detection by UV light, charring with PMA charring solution, or exposure to I_2 vapors. The ^{1}H (300 MHz) and ^{13}C NMR (75 MHz) were recorded on Avance-300 in DMSO-d_6. The spectra were acquired with sufficiently long relaxation delay to ensure quaternary carbon relaxation. Also, more scans were used to obtain reasonable sensitivity of the ^{13}C NMR spectra. Multiplicities arising from ^{13}C−^{19}F couplings were low in intensity and present over a large area, so they were counted independently. Chemical shift values are reported in parts per million relative to DMSO as internal reference. Coupling constant value J is measured in hertz. s (singlet), d (doublet), t (triplet), brs (broad singlet), dd (double doublet), m (multiplet). Mass spectra were recorded on an Agilent LC/MSD trap SL 1100 series spectrometer with a 70 eV ESI probe, and high-resolution mass spectra were obtained by using ESI-QTOF mass spectrometry. Infrared spectra were recorded on a Thermo Nicolet Nexus 670 FT-IR spectrometer.

General Synthesis. To a 10 mL RB flask were added aldehyde (1.0 mmol), 2-aminobenzothiazole (1.0 mmol), and β-naphthol (1.0 mmol); these were mixed thoroughly and heated in preheated oil bath at 110−120 °C for an appropriate time (Table 1). After completion of reaction as indicated by TLC, the reaction mixture was allowed to cool. The so-formed solid was powdered, washed with methanol (8 mL × 3 times for compounds except fluoro and methoxy derivatives, 4 mL × 3 times in the case of fluoro and methoxy derivatives), and dried under vacuum to obtain the corresponding pure 2-aminobenzothiazolomethylnaphthol derivative. However, in the case of fluoro- and methoxy-substituted derivatives, care must be taken during washing or unreacted material present in the reaction mixture may dissolve in methanol and help methanol to dissolve the product, resulting in a decrease in the overall yield. Moreover, the solubility of fluoro and methoxy derivatives is better in methanol when compared to other derivatives. A schematic representation of the reaction is given in Scheme 1.

Test Insects. *S. litura* and *A. janata* larvae used in this study were obtained from a laboratory colony maintained in the Biology and Biotechnology Division, IICT, Hyderabad, India. The culture has been continuously maintained on castor leaves (*Ricinus communis*) at room temperature (26 ± 2 °C), 65 ± 5% relative humidity, and 16:8 L:D photoperiod in the laboratory.

Antifeedant Bioassay. The antifeedant activity of the compounds was tested against tobacco caterpillar, *S. litura* (F.), and castor semilooper, *A. janata* (L.). The experiments were conducted according to the classical no-choice leaf disk method described earlier by Akhtar et al.[22] To study the antifeedant activity of the test compounds, a small circular disk of 4 cm diameter was cut from fresh castor leaves. The leaf disks were treated on their upper surface with individual concentrations of the test compounds; after that, the leaf disks were air-dried at room temperature, and each leaf disk was transferred to a separate Petri plate of 15 cm diameter containing wet filter paper. Control leaf disks were treated with the same volume of the DMSO only. The third-instar larvae of *S. litura* and *A. janata* (starved for 4−5 h prior to the experiment) were allowed to feed to assess antifeedant activity. Progress of the consumption of the leaf area was measured at 6, 12, and 24 h period intervals in both treated and control leaf disks. Areas of control and treated leaf disks consumed were measured after 24 h using a leaf area meter (AM-300, ADC Bioscientific Limited, Hoddesdon, UK). The antifeedant index was then calculated as $(C - T)/(C + T) \times 100$, where C is the consumption of control leaf disks and T is consumption of treated leaf disks.[23] For each concentration, 10 experimental sets were assayed. All tests were replicated three times. The mean of the 30 sets was taken for each compound. Means were subjected to probit analysis.[24]

Topical Bioassay. Toxicity of the test compounds was determined by topical application to the third instar larvae of test insects.[25] Two micrograms of compounds was applied directly to the dorsum of the larva in a 1 μL drop of DMSO using a micro applicator. Insects treated with solvent alone were considered as controls. The treated and control larvae were treated on fresh castor leaves. Mortality was measured daily until 2 days after treatment. Larvae that lost elasticity and heavy water loss from their body and showed no responses when their tails were pinched with forceps were regarded as dead. On the basis of three independent trials, each experiment was conducted in five replicates, leading to 15 replicates with each concentration of compounds. The mean of 15 replicates was taken for each compound, and the percentage of mortality with standard deviation was calculated.

Data Analysis. Antifeedant index was calculated using five different concentrations of each test compound, and data were subjected to probit analysis[24] to determine the ED_{50} value representing the concentrations that caused 50% feeding deterrence along with the 95% fiducial limits. The data were analyzed by completely randomized, one-way analysis of variance (ANOVA), and the means were separated using the Tukey HSD test (Biostat 2008).

RESULTS AND DISCUSSION

Scheme 1 illustrates the general procedure for the synthesis of 2-aminobenzothiazolomethylnaphthol derivatives. The synthesis procedure is completely green, economic, and high-yielding. A total of 17 derivatives were synthesized and screened for their antifeedant effect (Table 2) and toxicity (Table 3) against *S. litura* and *A. janata*.

[a]Fiducial limits.

The antifeedant activity of the 2-aminobenzothiazolomethylnaphthol derivatives was studied using the no-choice leaf disk method. The results are summarized in Table 2. It is interesting to note that most of the derivatives synthesized have good antifeedancy against *S. litura* and *A. janata*. A few of them, **4d**, **4f**, **4i**, and **4j**, show a high level of antifeedancy even at lower concentrations (5−100 μg/cm^2) against both insects. Derivatives **4d**, **4f**, **4i**, and **4j** showed significant antifeedant activity (ED_{50}) at lower doses of 16.4, 19.3, 7.0, and 5.2 μg/cm^2 against *S. litura* and lower doses of 13.9, 17.2, 10.2, and 7.7 μg/cm^2 against *A. janata*, respectively.

Compounds **4a−q** were primarily screened for their toxicity using topical bioassay method at a dosage of 0.5 μg/insect (Table 3). Compounds **4d**, **4f**, **4i**, and **4j** showed 100% mortality against both species. Interestingly, two compounds, **4l** and **4m**, showed 100% mortality against *A. janata* but were least toxic to *S. litura*. To estimate the mortality rate at a lower dose, we again screened the compounds at a dosage of 0.2 μg/insect (Table 3). Derivative **4j** produced high mortality >95% against the larvae of both *S. litura* and *A. janata*, whereas derivative **4i** showed high mortality, that is, >95%, against *S. litura* but only moderate mortality, that is, >85% and <95% against *A. janata*. On the contrary, derivatives **4d** and **4m** showed moderate mortality against *A. janata*, leaving them least toxic to *S. litura*. Larval death took place soon after exposure to the treatment. Derivatives **4i** and **4j** are very potent in penetrating the larval body through cuticle and cause lethal effects because in these

[a]Mortality at a dosage of 0.5 μg/insect. [b]Mortality at a dosage of 0.2 μg/insect.

treatments the feeding was absolutely prevented. It appears, from the results, that derivative **4j** is a strong feeding deterrent and strongly toxic, where as **4i** is a strong feeding deterrent but strongly toxic against *S. litura* and moderately toxic against *A. janata*. On the other hand, compound **4f** is a strong feeding deterrent but least toxic against both *S. litura* and *A. janata*. The treatments could cause desirable impact on larval feeding and survival and could totally achieve the management of these two major crop pests under laboratory conditions. Therefore, these compounds can be used as both antifeedants and pesticides.

It is clear from their structures that the compounds were differently substituted on the phenyl ring, leaving naphthyl and benzothiazole rings unsubstituted. Even though it may not be appropriate to draw a precise structure−activity relationship with the present data, we can observe from the results that the 4-bromophenyl (**4e**) and 4-phenoxyphenyl (**4g**) derivatives are completely nontoxic at a dosage of 0.2 μg/insect, whereas the 3,4,5-trimethoxyphenyl (**4j**) derivative is strongly toxic, leaving the others in between. Fused and bulky substituted phenyl derivatives **4b**, **4e**, **4g**, **4h**, **4k**, and **4q** are inactive or least active along with unsubstituted phenyl derivative **4a**, whereas 3,4,5-trimethoxy-substituted (**4j**) phenyl has strong antifeedancy and toxicity. However, in the case of the 4-methoxy (**4i**) phenyl derivative toxicity increases for *S. litura* and decreases for *A. janata*. The derivatives substituted with chloro, cyano, dimethylamino, dichloro, and fluoro substituents have comparatively low antifeedancy and are least toxic. From the above results we may conclude that the 3,4,5-trimethoxy derivative is strongly antifeedant and toxic, but 4-methoxy derivatives are strong antifeedants with selective toxicity against *S. litura*.

Overall, we identified a novel class of synthetic molecules that do not belong to organochlorides, organophosphates, carbamates, neonicotinoids, and anthranilamides as potent antifeedants and insecticides. These results may enlighten a way to search for natural product inspired synthetic antifeedants and insecticides. Compounds **4i** and **4j** may be useful in protecting crops from the above insects. Derivatives **4d** and **4m** are worth considering as feeding deterrents along with moderate insecticidal properties, and derivative **4f** can be considered as a strong feeding deterrent with least toxicity. Their potential field applicability is yet to be explored.

sulfate (4.9 mg/L), total chloride (6.3 mg/L), total magnesium (2.7 mg/L), total calcium (25 mg/L), and total sodium (4.4 mg/L). Natural water was also filtered through a 0.2 μm filter for sterilization.

For each aqueous photolysis experiment, 20 or more incubation vessels were prepared for irradiation and an equal number were prepared for use as nonirradiated (dark) controls. Individual test systems were composed of either pH 4 buffer or natural water spiked with (CN−^{14}C)-CNAP or (PC−^{14}C)-CNAP in separate incubation vessels. Likewise, the BC- and PC-labeled materials were used for CLAP degradations. The two sites of radiolabel served as replicates for both test compounds. Reactions were conducted at 1 and 0.6 ppm concentrations for CNAP and CLAP, respectively, with a maximum 1% acetonitrile as cosolvent. Samples were collected at various time intervals and analyzed by HPLC for determination of component amounts.

Test vessels for soil photolysis consisted of glass cuvettes (dimensions $L-W-D$ = 52 mm−31 mm−60 mm) with quartz lids, which were connected to a series of three traps; a safety trap, an ethanediol trap for collection of ^{14}C-organic volatiles, and a NaOH trap for collection of $^{14}CO_2$. The test soil (Nambsheim Clay Loam) originated from a field site in Nambsheim, France. Soil was characterized as sand (21%), silt (47.8%), clay (31.2%), pH in 0.01 M $CaCl_2$ (7.5), organic matter (3.5%), total nitrogen (1796 mg/kg). The soil was stored at ca. 20 °C until air dried and passed through a 2 mm sieve after which it was stored at ambient temperature. Aliquots of soil (ca. 5 g oven dry equivalents) were weighed into borosilicate glass incubation vessels, and sufficient Milli-Q water (3 mL) was added to produce water−soil slurry. The entire slurry was poured into a glass cuvette to prepare one of many samples generated in a similar manner. Each sample was then air dried at ambient temperature. Moisture content was adjusted to a soil moisture of 50% field capacity (75% of 1/3 bar, moisture content 20.03%) with a soil depth of ca. 2 mm. Once each sample was at the target moisture level the total weight was recorded and this weight used as the target for all subsequent moisture adjustments. The test substance was applied dropwise as a 100 μL aliquot of a solution containing 50 μg/mL of the test substance (for CNAP). Soil photolysis experiments were conducted in alternating light and dark cycles, with 12 h of irradiation followed by 12 h of dark over each 1 day period.

Agilent 1100 series HPLC System (Agilent Technologies, Palo Alto, CA) equipped with a photodiode array detector and a radiochemical detector attached in tandem. Column: Luna C18, 250 mm × 4.6 mm; 5 μm particle size (Phenomenex). Guard column: Securiguard C18, 3.0 × 4.0 mm (Phenomenex). Column temperature: 40 °C. Injection volume: 20 μL to 1.0 mL. Autosampler temperature: 10 °C. Flow rate: 1.0 mL/min. UV detection wavelength: 210 and 254 nm. For HPLC gradient program: solvent A 0.1% formic acid in water; solvent B 0.1% formic acid in acetonitrile. Gradient started at 38% B, increasing to 51% over 10 min, and then to 100% over 20 min. Separation of the observed degradates is illustrated by sample chromatograms for CLAP in Figure 2. Similar separation was observed for CNAP degradates, although retention times were different as expected.

LC/MS System: Micromass (Waters) LCT Mass Spectrometer equipped with MassLynx version 3.5 software controller (Micromass, Manchester, UK). Ionization method: electrospray positive (ESI±). Cone voltage: 30 V. Capillary voltage: 3 kV. Source temperature: 125 °C. Desolvation temperature: 300 °C. NMR (^{1}H NMR) data was collected using a Bruker BioSpin Avance 600 MHz Digital NMR Spectrometer.

Product Identification. Prior to the start of photolysis work for CLAP, three degradates observed in preliminary experiments had been isolated in larger quantities and their structures elucidated. Samples of all three CLAP photoproducts were available for identification by cochromatography. Preparation and structure identification of all three degradates for CLAP have been independently verified[6] and therefore not repeated here. For identification of CNAP degradate structures, larger amounts needed for structure elucidation were prepared as described below. Synthetic standards of CNAP_M1−M6 and CLAP_M1−M5 were also generated by unambiguous synthetic routes, and they were used to confirm the degradate identities via cochromatography experiments. Identification of degradate CNAP_M1 has been published previously in our work.[11]

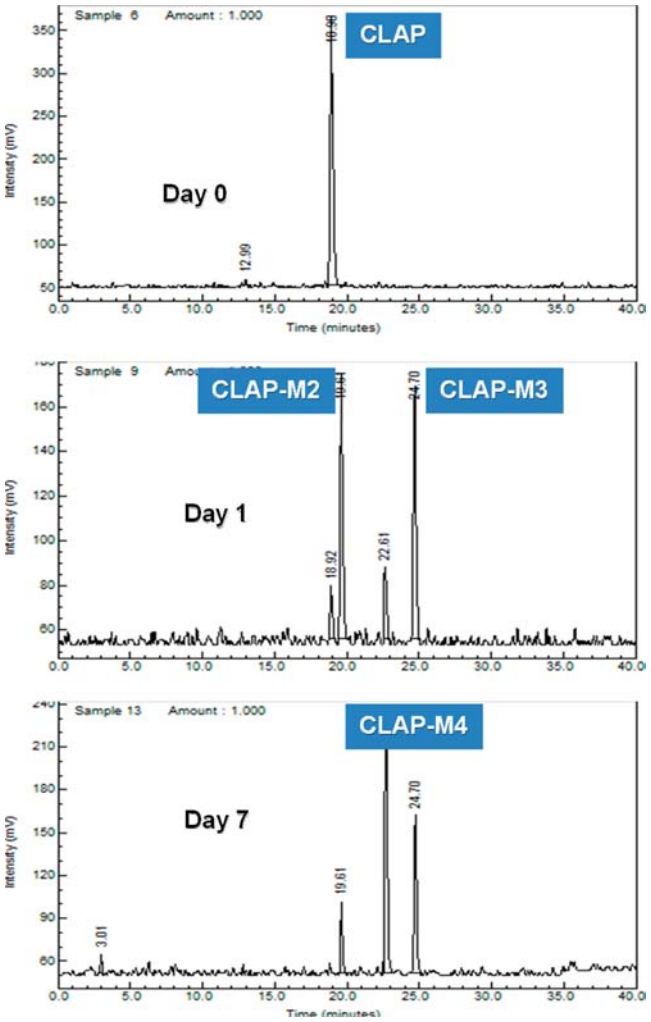

Figure 2. Chromatograms for chlorantraniliprole photolysis in natural water.

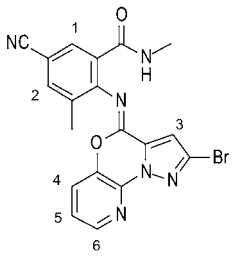
Identification of CNAP_M2. A 300 mL amount of sterilized 0.01 M pH 5 acetate buffers was added to a water-jacketed beaker, and the solution was treated with 2.25 mL of the 2000 ppm stock solution of CNAP. The beaker was covered with a quartz lid and placed in a Heraeus Suntest unit, and the beaker was connected to a water bath set at 20 °C. The sample was irradiated for 5 days until there was approximately >85% conversion to CNAP_M2 as measured by HPLC-UV. The solution containing CNAP_M2 was acidified to pH 3 with acetic acid to prevent its degradation. The acidified solution was applied to a 2 g, 12 cc C18 Mega Bond Elut SPE cartridge (Varian Inc., Lake Forest, CA) and washed with 2 mL of 0.1% formic acid. The column was flushed dry with hexane and vacuum dried. The product was eluted with 10 mL of ethyl acetate with 0.1% formic acid.

LC/MS analysis of the sample, in ESI positive mode, gave a molecular weight of 437 and molecular formula $C_{19}H_{13}BrN_6O_2$, and the isotope cluster was consistent with a molecule containing one bromine. LC-IR analysis of the sample showed absorption bands for CN at 2228, benzamide C═O at 1695, and C═N at 1651 cm^{-1}, which were characteristic of functional groups in the structure. Additional heterocycle and benzene double bonds were also present at 1591, 1518, and 1453 and C−O at 1195 cm^{-1}. A portion of the sample was loaded on to SPE cartridge, and the degradate was recovered in acetonitrile-d_3 to acquire ^{1}H NMR data.

Identification of CNAP_M3. A 300 mL aliquot of the solution containing CNAP_M2 was transferred to a 1 L Erlenmeyer flask, an

dx.doi.org/10.1021/jf5017175 | J. Agric. Food Chem. 2014, 62, 6577−6584

CNAP_M2

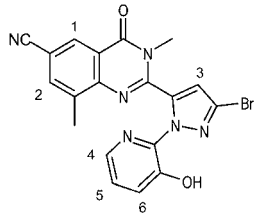


Phenyl-CH_3 observed at δ 2.20 s, NH-CH_3 at 2.70 d, Pyridine H6 at 7.39 dd and H5 at 8.33 dd, H4 at 7.49 as broad s; Phenyl-H1 at 7.73 and H2 at 7.90; broad s for NH at 7.13, H3 as s at 7.38. These assignments were confirmed with a COrrelation SpectroscopY (COSY) experiment, at 2°C.

equal volume of 0.01 M pH 9 borate buffer was added, and the mixture was stored under ambient conditions of temperature and light for 2 days, until there was approximately 89% conversion to CNAP_M3 as measured by HPLC-UV analysis. The solution containing M3 was concentrated using a 2 g, 12 cc C18 Mega Bond Elut SPE cartridge using pH 5 acetate buffer for preconditioning instead of 0.01% formic acid. The photoproduct was eluted with acetonitrile and reduced to dryness by nitrogen evaporation. The dry solid containing 87% M3 was analyzed by LC-MS/MS, LC-IR, and LC/^{1}H NMR-MS. The solid was dissolved in deuterated acetonitrile prior to LC/^{1}H NMR analysis.

LC/MS analysis of the sample in ESI positive mode gave a molecular weight consistent with structure of M3 (molecular weight 437) and isotope cluster pattern consistent with a molecule containing one bromine. The IR spectrum showed a cyano stretch at 2229 cm^{-1}, cyclic amide C═O at 1683, C−O stretch at 1250, and ring double bonds at 1461, 1592, and 1528 cm^{-1}. ^{1}H NMR further verified the assigned structure.

CNAP_M3

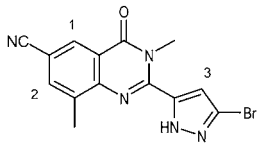


Phenyl-CH_3 observed at δ 2.33 s, N-CH_3 at 3.36 s, Pyridine H6 at 7.43 d and H5 at 7.19 dd, H4 at 7.63 as d; Phenyl-H1 at 7.87 and H2 at 8.47; broad s for OH at 9.64, H3 as s at 6.96. These assignments were confirmed with a COrrelation SpectroscopY (COSY) experiment, at 2°C, of the aromatic region.

Identification of CNAP_M4. The 600 mL solution containing CNAP_M3 was transferred to a water-jacketed beaker covered with a quartz lid and placed in a Heraeus Suntest unit in a water bath set at 20 °C. The sample was irradiated for 2 days until there was approximately 88% conversion to M4 as measured by HPLC-UV. The solution containing CNAP_M4 was concentrated using a 2 g, 12 cc C18 Mega Bond Elut SPE cartridge. The cartridge was preconditioned with one column volume of acetonitrile followed by one column volume of 1:1 pH 5 acetate buffer/pH 9 borate buffers. The solution was applied to the column and washed with 5 mL of H_2O. The column was then flushed dry using house vacuum. The photoproduct was eluted with acetonitrile. The eluate was reduced to dryness by nitrogen evaporation. The dry solid was analyzed by LC-MS/MS, LC-IR, and LC/^{1}H NMR-MS. The sample generated contained approximately 93% of M4 by HPLC analysis.

LC/MS analysis of the sample, in ESI positive mode, gave a molecular weight consistent with that of CNAP_M4 (molecular weight 344, with acetate adduct at mass 387). The isotope cluster pattern is consistent with a molecule containing one bromine atom. LC-IR of the sample gave an IR spectrum which showed cyano functionality at 2227 cm^{-1}, cyclic amide C═O at 1678, and ring double bonds at 1581, 1471, and 1476 cm^{-1}.

CNAP_M4

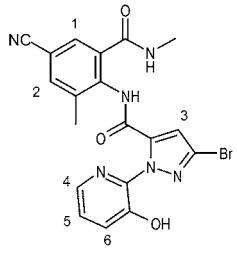


Phenyl-CH_3 observed at δ 2.66 s, N-CH_3 at 3.73 s, Phenyl-H1 at 7.91 and H2 at 8.42; H3 as s at 7.02. NH was not observed possibly due to rapid tautomeric shift. Spectrum of the aromatic region is illustrated below

Identification of CNAP_M5. The solution containing CNAP_M2 was acidified to a pH of approximately 2−3 with formic acid and the container placed in a water bath at 70 °C for 2 days. The container was then stored under ambient conditions of temperature and light for 5 days, until there was approximately 30% conversion to M5 as measured by HPLC-UV analysis. The solution containing M5 was concentrated using a 2 g, 12 cc C18 Mega Bond Elut SPE cartridge preconditioned with one column volume of methanol followed by one column volume of water containing 0.1% formic acid. The solution was applied to the column and washed with 15−20 mL of 0.1% formic acid. The photoproduct was eluted with a 40/60 acetonitrile/water−0.1% formic acid. The eluate was reduced to a small volume by nitrogen evaporation and quick frozen using the shelling technique in a dry ice−acetone bath. Remaining solvents were removed on a lyophilizer overnight. The lyophilized sample was stored in a freezer. Final purification was conducted by HPLC prior to recording the spectra. An aliquot of the sample was analyzed by LC-MS/MS, LC-IR, and LC/^{1}H NMR.

LC/MS analysis of the sample, in ESI positive mode, gave a molecular ion at 455/457 (1:1) consistent with the structure of M5. Prominent fragments at 424/426 and 266/268 (both showing peak cluster ratios of 1:1 indicative of Br atom in structure) resulted from acylium ion formed from loss of CH_3NH and the pyrazole acylium ion moiety after cleavage of the benzamide side. The IR spectrum showed CN at 2232, two amide C═O peaks at 1670 and 1639 cm^{-1}, and C−O stretch at 1266 cm^{-1}.

CNAP_M5

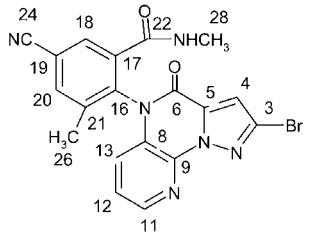


Phenyl-CH_3 observed at δ 2.21 s, NH-CH_3 at 2.73 s, Pyridine H4 at 7.94 dd and H5 at 7.41 dd, H6 at 7.36 as dd; Ph-H1 at 7.75 and H2 at 7.66; pyrazole H3 as s at 7.02, signals for OH and NH protons were not detected due to deuterium exchange. These assignments were confirmed with a COSY experiment, at 2°C.

dx.doi.org/10.1021/jf5017175 | J. Agric. Food Chem. 2014, 62, 6577−6584

Identification of CNAP_M6. LC/MS analysis of the sample, in ESI positive mode, gave a molecular weight consistent with that of CNAP_M6 (molecular weight 436). The exact mass suggested a molecular formula of $C_{19}H_{13}BrN_6O_2$, and the isotope cluster pattern was consistent with a molecule containing one bromine atom. The molecule was clearly an isomer of CNAP_M2 and M3 but quite different in HPLC retention time, and it was stable to base. Stability to base ruled out the possibility of *E*/*Z* isomers of M2. Structure assignment was based on the MS fragmentation; NMR of an isolated sample was obtained by aqueous photolysis of CNAP_M1 (ca. 20% yield). NMR spectra for this sample verified the structure.

CNAP_M6



^{1}H-NMR in CD_3CN: Phenyl-CH_3 observed at δ 2.16 s, NH-CH_3 at 2.58 s, Pyrazole H4 at 7.33 s, Pyridine H11 at 8.43 d, H12 at 7.38 dd, H13 at 7.03 d; Ph-H18 at 7.95 d, and H20 at 8.02; signals for NH proton at 6.83 br. These assignments were confirmed with COSY experiments.

Determination of Rate Constants. Optimization of kinetics and rate constant calculations was conducted by building a first-order kinetics model in ModelMaker (software purchased from apbenson.com). The models represented by the sequence of transformations are discussed in the Results and Discussion section. In each case alternative models with a different order of transformations, which appeared to be logical based on chemistry, were also tested. The models presented gave the best optimization fit for the observed data. The rate constants generated for optimized kinetics of all experiments are summarized in Table 1, and the data fit is illustrated in various figures.

RESULTS AND DISCUSSION

CLAP and CNAP have a water solubility of 1.2 and 14.6 μg/mL, respectively. It has been shown in our previous work[11] that both compounds are vulnerable to hydrolytic degradation at alkaline pH, therefore, photodegradations were conducted in buffers of either pH 4 (CNAP) or 7 (CLAP) because the contribution from hydrolysis reactions was expected to be minimal and photodegradation reactions were anticipated to dominate. A generalized photodegradation pathway applicable to both compounds is displayed in Figure 3. All products displayed in the figure were not necessarily observed for both compounds under various conditions, and the degradations observed were consistent with those reported earlier.[4,6] The similarities and differences between the experiments for both test compounds are discussed.

Photodegradation of Chlorantraniliprole. Photolysis of CLAP in pH 7 buffer generated three products which appeared to have been formed sequentially. Degradation initially led to formation of M2, which reached a peak quickly by day 1. As M2 declined, the concentration of M3 increased, which also started to decline during the study period, leading to progressively

higher amounts of M4 (Figure 4). A similar incubation in the absence of light showed no degradation of CLAP.

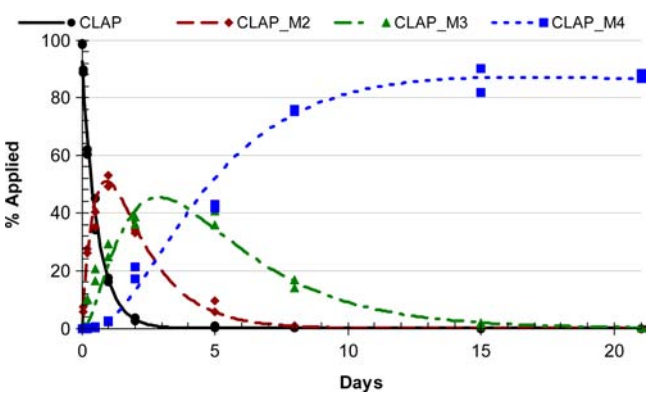

Figure 4. Chlorantraniliprole photolysis, pH 7 buffer.

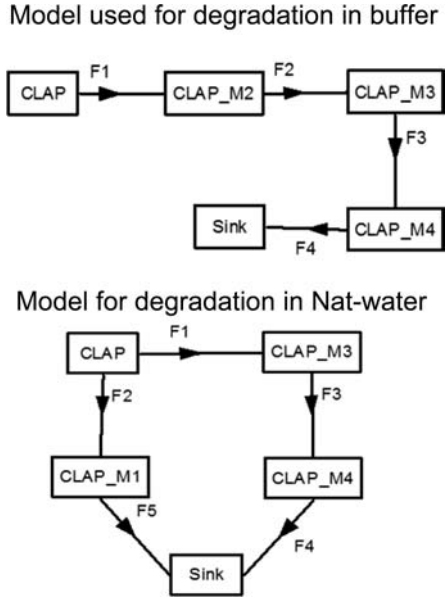
The observed data for degradation in buffer were fitted to a kinetics model, illustrated below, in which each successive transformation product is generated as a result of first-order reaction from the preceding component and the last degradate leading to minor unknown products. Optimized kinetics parameters resulting from such a degradation scheme showed a good fit for all significant components (Figure 4), which verified that the products were indeed generated in succession. Even though degradates M2 and M3 had identical molecular weights and mechanistically it was possible to rationalize transformations leading to formation of both compounds directly from the parent, kinetics modeling verified that these two products were indeed formed in succession. Lack of stability of M2 and its hydrolytic transformation to M3 further supported the sequential transformations. Optimized rate constants for each step are listed in Table 1.

Photolysis of CLAP in natural water (pH 7.4) also produced the same degradates as the buffer, except degradate M2, which



was not observed. Instead, degradation proceeded directly to M3, which again declined rapidly, leading to increasing amounts of M4. There was a gradual decline in the amount of M4 as the photolysis period progressed. A parallel incubation in the absence of light showed slow degradation of CLAP and formation of a small amount of M1. However, conversion of CLAP to M1 was too slow to make a meaningful contribution to the degradation observed in the presence of light. Therefore, inclusion of degradation to M1 in natural water as a parallel hydrolytic degradation did not alter the kinetics optimization of the photodegradation process. For model optimization in natural water, degradate M2 was ignored, since it was not observed. Instead, direct transformation of CLAP to M3 followed by M4 was optimized to derive the rate constants. The optimized model provided a good fit for the observed data. Figure 5 illustrates the result of inclusion of a simultaneous

dx.doi.org/10.1021/jf5017175 | J. Agric. Food Chem. 2014, 62, 6577−6584

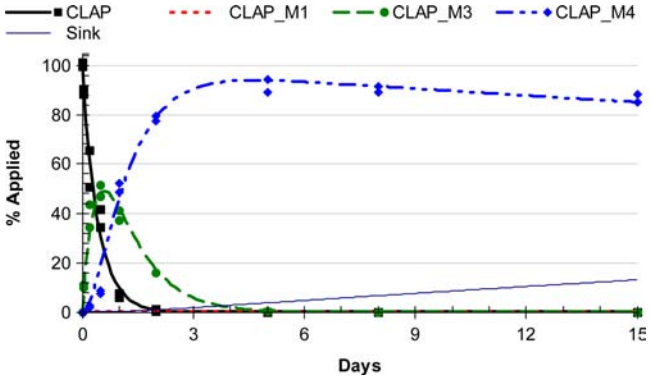


Figure 5. Chlorantraniliprole photolysis, nat-water.

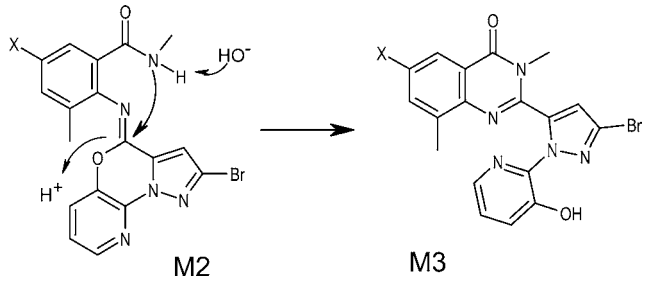
degradation to M1 using a CLAP to M1 rate constant of 0.0032 day^{-1} (calculated from dark control experiment). A good data fitting (Figure 5) verified that partial hydrolysis due to increased pH played no significant role in the photodegradation of CLAP. Nevertheless, constituents of natural water did alter the overall photodegradation in two ways. First, the degradation rate increased, and second, a key degradate M2 was no longer detected.

Even though M2 was not observed in natural water photodegradation, it was presumed that M2 was a transient intermediate. Apparently, M2 underwent hydrolytic degradation in natural water too rapidly (possibly due to higher pH) to have been detected. Degradation of M2 to M3 under alkaline conditions was noted while attempting to isolate samples of M2, and indeed, it showed rapid conversion to M3 under slightly alkaline conditions. Some hydrolytic conversion of M2 to M3 even in pH 7 buffer cannot be ruled out, since stable isolation of M2 required acidic pH of 5 or less. However, the increase in photolysis rate in natural water probably was not merely due to the higher pH of natural water, because all subsequent transformations were also expedited. The transient behavior of M2 became even more obvious when the analogous product CNAP was investigated, as discussed later. It appeared more likely that faster photochemical reactions were due to dissolved ions and/or organic matter, a phenomenon noted by others as well.[7,8] Conversion of parent compound (P) to M3, which was controlled by P to M2 rate constant in buffer, increased by a factor of about 1.5 in natural water (2.3 vs 1.7 day^{-1}, data in Table 1). A faster degradation rate of CLAP was observed in natural water not only for the parent compound but each subsequent transformation M3 to M4 as well as M4 to unknown products. The presence of carbonate, nitrates, sulfates, and dissolved organic carbon has been reported to enhance generation of OH radicals or hydroperoxide radicals.[9] Other investigators have also reported quenching of radicals by the same species;[10] therefore, it cannot be stated with certainty as to which constituents of natural water facilitated the phototransformation rates. While the transformation mechanism for M2 to M3 (displayed in figure below) is believed to occur with OH anion (pH effect), the same reaction could just as well be triggered by OH radical (photodegradation). In reality, both mechanisms may have been operative to expedite this transformation so much that its degradation in natural water was faster than its formation; hence, M2 was not observed.

A comparison of the rate constants for transformation of M3 to M4 (data in Table 1) shows that this reaction was nearly 4-



fold faster in natural water as compared to buffer. Even degradation of M4 to minor unknown products (sink) was faster by a factor of 2.5, indicating that degradation of CLAP as well as all photodegradates accelerated in natural water. If pH alone was the primary factor, enhanced degradation of M3 and M4 would not be expected.

Degradation of CLAP in soil was not significant over the 30 day duration of the experiment.

Photodegradation of Cyantraniliprole. Degradation of CNAP showed many similarities with CLAP photodegradations, but there were substantial differences. A lower pH buffer was chosen for CNAP degradation because only at pH 4 was photodegradation with the least contribution from hydrolytic degradations. Control solutions of CNAP in pH 4 buffer kept in the dark showed minimal conversion to M1. However, unlike CLAP, substantial degradation to cyclodehydration product, CNAP_M1, was noted in natural water dark control (Figure 6).

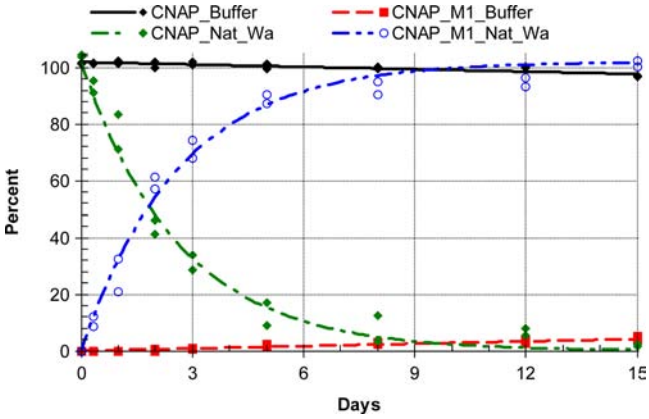


Figure 6. Cyantraniliprole, dark controls.

This clearly was due to the higher pH (7.4) of natural water. A faster hydrolytic degradation of CNAP in alkaline water, especially when compared with CLAP, has been discussed in detail previously;[11] therefore, hydrolytic degradation was anticipated to compete with photodegradation for CNAP in alkaline natural water.

Since cyantraniliprole is hydrolytically stable in pH 4 buffer, photodegradation was expected to occur with little contribution from hydrolytic reactions. As noted in Figure 7, degradation was faster than degradation of CLAP, resulting in formation of one main product M2. This product M2 degraded slowly, but it did degrade to three other products. Two of these, M3 and M4, were analogous to those found in CLAP degradation, while M5 was new to CNAP photolysis. Optimization of data using kinetics modeling suggested that M5 was derived from M2 and not from CNAP. It was surprising that CNAP_M2 was slower to degrade photochemically, as compared to CLAP_M2. In part, slower degradation of M2 may have been due to lower pH

dx.doi.org/10.1021/jf5017175 | J. Agric. Food Chem. 2014, 62, 6577−6584

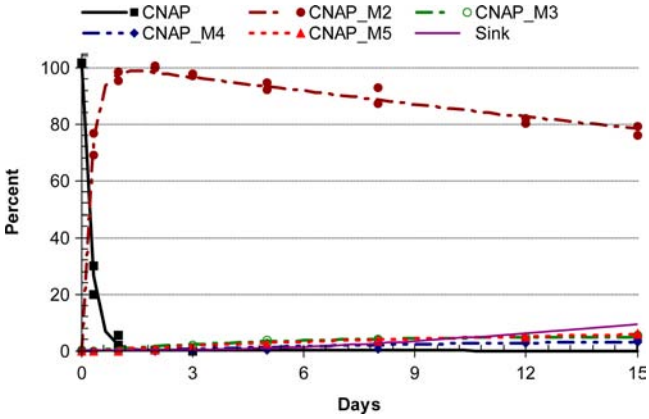

Figure 7. Cyantraniliprole photolysis in pH 4 buffer.

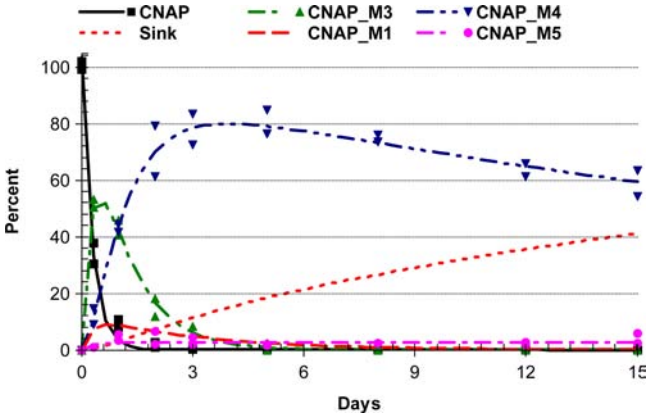

Figure 8. Cyantraniliprole photolysis, nat-water.

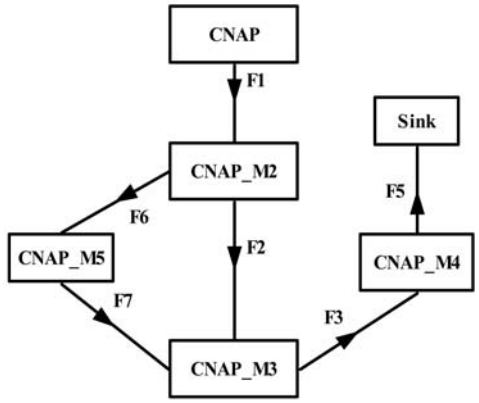
of the buffer used, which provided stability toward hydrolytic degradation of M2 to M3. Additional stability toward photodegradation of M2 may also have been caused by the "CN" group due to the extended conjugation of the phenyl and pyrazole rings. Such stabilization possibly made CNAP_M2 somewhat reluctant toward further degradation at pH 4 and allowed it the opportunity to generate an additional degradate M5 in small amounts.

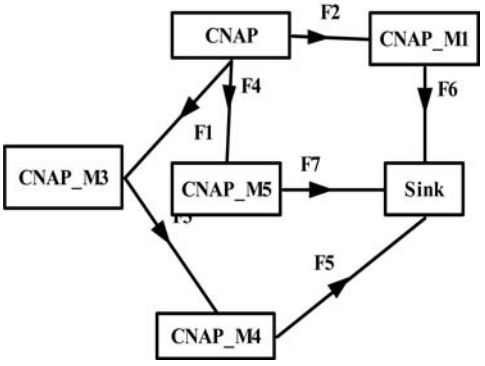
Conversion of CNAP_M2 to M3 and M5 is probably due to hydrolytic reactions, even though a photolytic reaction mechanism due to OH radicals can be envisioned equally well. During degradate purification work it was noted that both M2 and M5 were easily converted to M3 in the presence of base or even at pH 7. Therefore, it was not surprising that photodegradation in natural water showed no CNAP_M2 and only a small amount, seldom exceeding 3−4%, for CNAP_M5. Initial formation of M2 undoubtedly did occur in natural water, but its further degradation to M3 was too rapid to allow detection of M2, just as it was noted for CLAP. A small portion did, however, manage to transform to M5 even in natural water. Similar to CLAP, further degradations, such as M3 to M4 and M4 to other unknown products, were observed in buffer as well as natural water, except that these transformations were again accelerated in natural water even for CNAP.

In the case of CNAP it was anticipated that formation of M1 via hydrolysis should compete with photolysis in natural water. Since CNAP_M1 was not actually observed during photolysis, we decided to explore this issue via kinetic modeling. While all observed degradates in natural water were optimized for their formation/degradation rates, the rate constant for hydrolysis in natural water was added to the kinetic model (figure below) using a rate constant computed from the dark control experiment. Such modeling for CNAP suggested that nearly 5−10% of total residue should have been observed as M1 in early stages of the study (Figure 8). After all, the presence of light would not be expected to shut down the hydrolytic degradation. Given that this hydrolytic pathway to CNAP_M1 occurs without light, not finding it means that M1 must be photodegrading just as it is formed via hydrolysis. This indeed was found to be the case when a new photodegradate CNAP_M6 was detected and identified. M6 was only observed at a few sampling intervals and accounted for ∼3−4% of the total mixture. Formation of M6 from M1 was verified by direct photolysis of CNAP_M1 in a separate experiment, albeit yielding a maximum of ∼20% only. The small amount of M6 being observed was attributed to its instability under photodegradation conditions. Due to the small amount observed, optimization of its formation rates via modeling was not feasible. Hence, it was not included in kinetics and treated as part of a "sink", a normal practice in kinetics modeling to deal with all minor and unknown products.

CNAP Degradation Model in Buffer



CNAP Degradation Model in Natural Water



Degradation of cyantraniliprole in air-dried soil was slow, and the degradation rates in the presence as well as in the absence of light showed no meaningful differences. However, its degradation in moist soil, which was maintained at approximately 50% of maximum water-holding capacity, did display significant degradation. CNAP degradation in soil kept in the dark led primarily to formation of CNAP_M1 (Figure 9) along with numerous minor products. Photolysis in moist soil

dx.doi.org/10.1021/jf5017175 | J. Agric. Food Chem. 2014, 62, 6577−6584

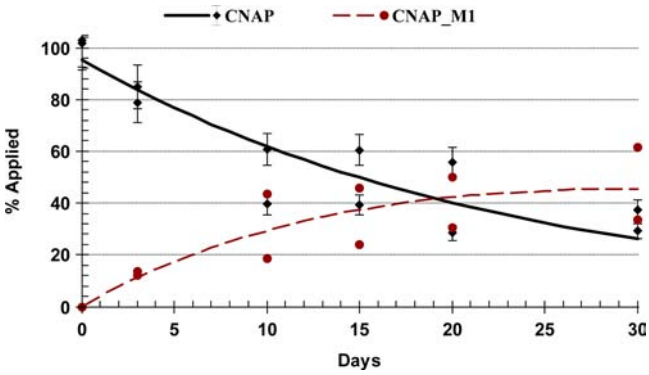


Figure 9. Cyantraniliprole soil photolysis, dark control.

enhanced the overall degradation rate of CNAP, and formation of most aqueous photolysis products was noted. Degradation occurred via two distinct pathways. One pathway proceeded via initial formation of CNAP_M1, the hydrolysis product, and its subsequent degradation to M6, while the other followed the natural water photolysis sequence. A kinetics assessment using a model similar to that employed for natural water degradation showed a good fit for all observed components, and the kinetics fits are displayed in Figure 10. Photodegradation in a moist soil

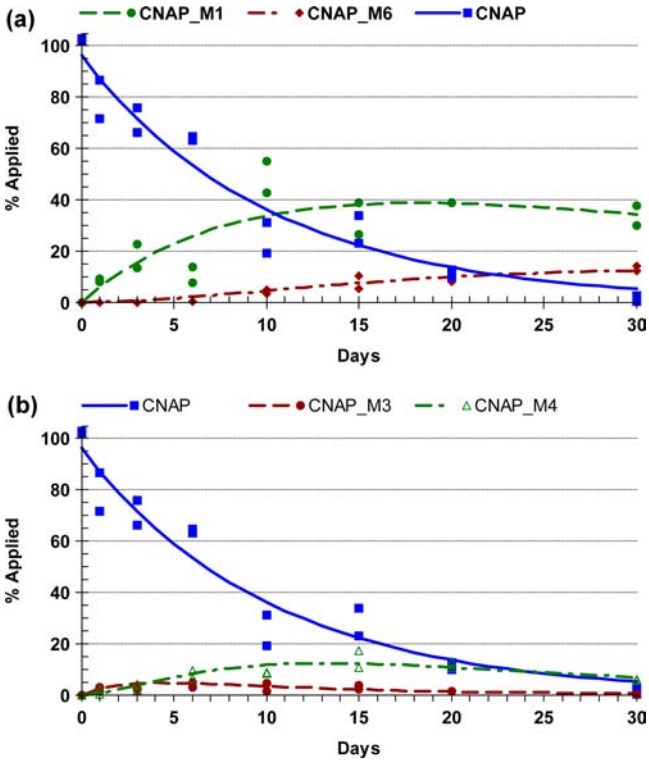

Figure 10. (a) Cyantraniliprole soil photolysis. (b) Cyantraniliprole soil photolysis.

surface was clearly faster than degradation in moist soil maintained in the dark due to participation of photolysis reactions. However, the rate of photodegradation even in moist soil was much slower than photodegradation in water itself. This experiment implies that photodegradation of CNAP on the soil surface may not be a significant degradation pathway in the environment because moist soils tend to dry out quickly in sunlight.

One can conclude from this investigation that both CLAP and CNAP are degraded by light essentially along the same pathway in water, leading primarily to formation of degradates M3 and M4. M2 may be encountered in water under acidic pH, but it is unlikely to be observed in significant quantity in natural water or soil. The degradation reactions observed were consistent with those reported previously, except for minor additional products observed for CNAP. Kinetics modeling of the data not only served to compute the degradation rates but also undoubtedly helped clarify the degradation pathway as well.

of immature fruit.[24] Juice from asymptomatic and symptomatic fruit has also been shown to contain more bitter compounds, but in concentrations lower than taste threshold values.[14,24]

The value of Florida's sweet orange crop for 2011−2012 alone is reported to be $1.2 billion. Hamlin and Valencia varieties make up 42.6% and 55%, respectively, of this value.[25] In our previous study, we evaluated the juices prepared from Valencia oranges of varying stages of CLas infection and harvested from a single location.[21] Additionally, we have examined the impact of environmental differences such as variations in elevation and soil depth on the metabolome of Mandarin oranges.[26] Recognizing that the state of HLB infection, as well as varietal and regional differences, could influence the metabolome of citrus juices, this study was undertaken to investigate the metabolite differences between healthy and infected fruit of two different citrus varieties grown in different regions. It is important to understand the impact of regional and varietal variation on the juice metabolome during infection, as this may provide insight into differences in response to infection depending on location or cultivar, and therefore help determine if these variables may confound the ability to detect disease using this method.

MATERIALS AND METHODS

Plant Materials. *Citrus sinensis* cultivars Valencia and Hamlin fruit samples were used in this study. The presence of CLas bacteria in symptomatic and asymptomatic trees, and its absence in control trees, was confirmed by polymerase chain reaction (PCR) using standard methods as described.[27] Control Hamlin fruit samples were collected from CLas$^-$ (PCR negative), and asymptomatic and symptomatic Hamlin fruit were collected from different CLas$^+$ (PCR positive) trees. Asymptomatic fruit were visually indistinguishable from control (CLas$^-$) fruit. A total of 54 Hamlin samples were collected: 18 control, 18 asymptomatic, and 18 symptomatic. Control Valencia fruit samples were collected from CLas$^-$ (PCR negative) trees; symptomatic Valencia fruit were collected from CLas$^+$ (PCR positive) trees and showed visual symptoms of HLB. A total of 36 Valencia samples were collected: 18 control and 18 symptomatic.

All samples were collected from mature trees approximately 20 years old. In each region, fruit were gathered from up to three different blocks, and in each block, samples were taken from three different trees. The per-tree sample size consisted of 15−20 fruits that were juiced, aliquoted, and stored at −20 °C until used for analysis. Sampling of Valencia fruits was conducted from May 2009 to June 2009 and Hamlin fruits from December 2009 to January 2010. For each cultivar, trees were from commercial orchards in south and east Florida. For the Hamlin oranges, 36 samples came from east Florida (12 samples from each infection stage), and 18 came from south Florida (6 samples from each infection stage). For the Valencia oranges, 18 samples came from east Florida, and 18 came from south Florida (9 samples from each infection stage for both locations).

°Brix and Limonin Measurements and NMR Data Collection. °Brix, limonin measurements, and NMR data collection were performed as previously described by Slisz et al.[21] Briefly, °Brix was determined by measuring total soluble solids with a Rudolph Research model J257 automatic refractometer (Hackettstown, NJ). Limonin was measured by high-performance liquid chromatography (HPLC) and represents limonin concentration after a 48 h thaw at 4 °C to allow conversion of limoninoate A-ring lactone into limonin. A 50 × 2.0 mm Phenomenex Phenosphere-Next-4 μm phenyl column with a guard column of the same material was used with solvent flow rate at 1.0 mL/min comprised of 70% 10 mM formic acid and 30% ACN.

For NMR analysis, juice samples were thawed, centrifuged, and then filtered (Nanosep Omega-3 3000 molecular weight cutoff (Pall Life Sciences, Ann Arbor, MI)). Internal standard containing 5 mM 3-(trimethylsilyl)-1-propanesulfonic acid-d_6 (DSS-d_6) in >98% D_2O and 0.2% NaN_3 (for a final DSS-d_6 concentration of 0.5 mM, 0.02% NaN_3, and approximately 10% D_2O in each sample) was added to a mixture of 400 μL of juice filtrate and 185 μL of ultrapure H_2O to ensure a sample volume of 600 μL required for NMR analysis. Sample pH was adjusted to 6.8 ± 0.1 using NaOH, and then 600 μL of sample was transferred to 5 mm NMR tubes. NMR spectra were acquired at 298 K using the Bruker "noesypr1d" experiment on a Bruker Advance 600 MHz NMR spectrometer equipped with a SampleJet with the following acquisition parameters: 12 ppm sweep width, 2.5 s acquisition time with 2.5 s relaxation delay, and 100 ms mixing time. Water saturation was applied during the relaxation delay and mixing time. The resulting spectra were zero-filled to 128 000 data points, and an exponential apodization function corresponding to a line-broadening of 0.5 Hz was applied. Spectra were processed in Chenomx NMRSuite Processor v7.6.

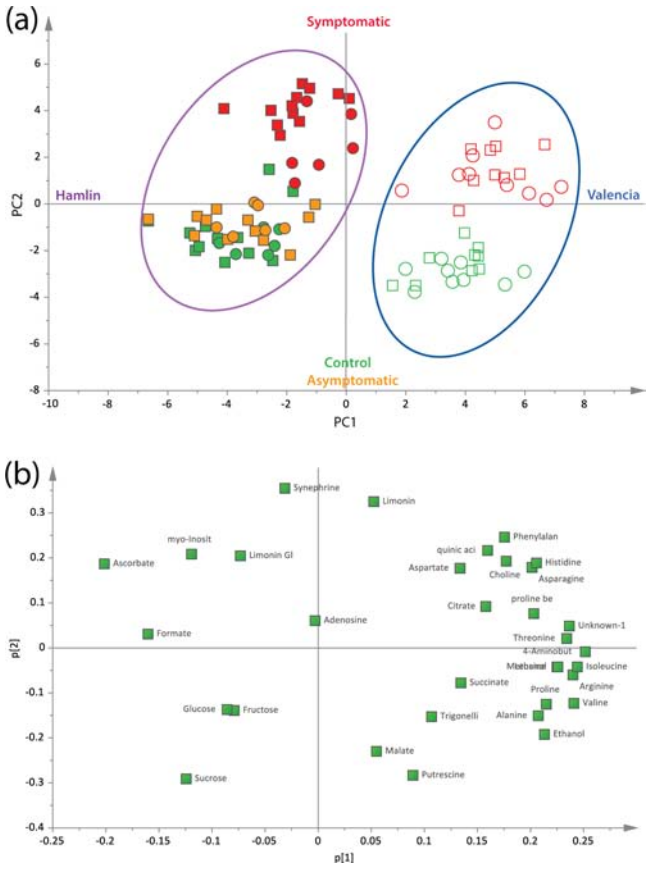

Figure 1. Comparison of composition of both Hamlin (filled) and Valencia (open) orange juice samples. (a) PCA scores plot comparing control (green), asymptomatic (orange), and symptomatic (red) samples. Circle and square markers indicate south or east Florida origin, respectively. Principal component 1 (PC1) explains 45.1% of the variation, and PC2 explains 17.9% of the variation. R^2X = 0.787; Q^2 = 0.658. (b) Loadings plot corresponding to panel a.

Data Analysis. Metabolites in orange juice samples were identified and quantified using targeted profiling[28] with Chenomx NMR suite v7.6 (Chenomx Inc., Edmonton, Alberta, Canada). In total, 32 metabolites were assigned and quantified as previously described[21] and included sugars (fructose, glucose, sucrose, and myo-inositol), amino acids (alanine, arginine, asparagine, aspartate, histidine, isoleucine, leucine, phenylalanine, proline, threonine, and valine), organic acids (citrate, succinate, malate, formate, ascorbate, and γ-aminobutyric acid (GABA), and others (adenosine, choline, ethanol, limonin glucoside, methanol, proline betaine, putrescine, quinic acid, trigonelline, synephrine, and an unknown metabolite with peaks at 0.8, 1.1, and 1.4 ppm). The concentration of limonin was determined using HPLC and was included in statistical analysis. For NMR measured metabolites, the profiled concentrations were corrected for dilution by multiplying the measured concentration by the final volume (650 μL)

dx.doi.org/10.1021/jf5017434 | J. Agric. Food Chem. 2014, 62, 6585−6591

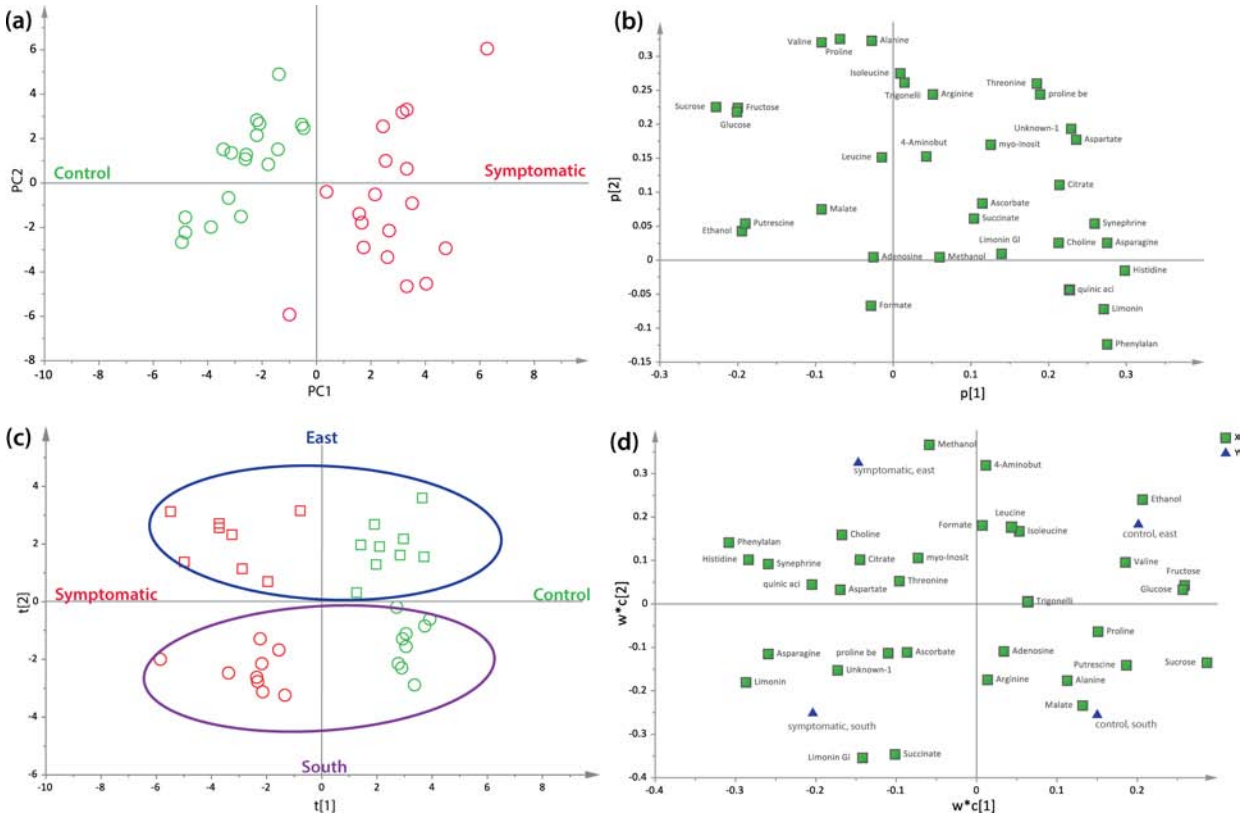

Figure 2. Comparison of composition of Valencia oranges. (a) PCA scores plot of control (green) and symptomatic (red) Valencia orange juice samples. PC1 explains 29% of the variation and PC2 23.3%. $R^2X = 0.812$; $Q^2 = 0.496$. (b) Loadings plot corresponding to panel a. (c) PLS-DA scores plot of Valencia samples classified by both region and infection status. Square and circle markers represent fruit from east and south Florida, respectively. R^2 and Q^2 were 0.587 and 0.532, respectively, and validation by random permutation (100 permutations) had y-intercepts for R^2 and Q^2 of 0.111 and −0.238, respectively, and both had positive slopes. (d) Loadings plot corresponding to panel c.

and dividing by the volume of juice used (400 μL). Final metabolite concentrations were subjected to $\log_{10}$ transformation to ensure normal distribution as described by Zhang et al.[26] Multivariate statistical data analyses, including principal component analysis (PCA) and partial least-squares-discriminant analysis (PLS-DA), were performed using SIMCA-P with mean centering and unit variance scaling. The quality of the models was judged by the goodness-of-fit parameter (R^2X or R^2Y) and predictive ability parameter (Q^2), as well as permutation testing (for the PLS-DA models), where each data point was randomly assigned a class 100 times, and the corresponding R^2Y and Q^2 calculated and compared to the original model. From the PLS-DA models, variable influence in projection (VIP), which is a weighted sum of squares of the PLS loading weights that takes into account the amount of explained Y-variation in each dimension, was used to assess those variables of significance for further scrutiny. Metabolites with a VIP value greater than 1 were selected for further discussion.[29] Significance testing, using Mann−Whitney test for Valencia samples, and Kruskal−Wallis test and Dunn's multiple comparison test for Hamlin samples, was performed on raw untransformed data using GraphPad Prism with significance set at $\alpha = 0.05$. Kruskal−Wallis test and Dunn's multiple comparison test were selected for the Hamlin samples due to unbalanced numbers in the selected sample groups.

RESULTS

We previously published on the metabolite composition of control and asymptomatic Valencia fruit.[21] However, that study only examined one variety of fruit from one location in Florida. Here, we analyzed the composition of two citrus varieties from different growing regions in the context of infection by CLas (control (PCR CLas$^-$), asymptomatic (PCR CLas$^+$), and symptomatic (PCR CLas$^+$) Hamlin fruit, as well as control (PCR CLas$^-$) and symptomatic (PCR CLas$^+$) Valencia fruit). The contributions of variety and growing region (south or east Florida) were assessed to evaluate the impact of these variables on tree metabolic response to infection by CLas.

All Orange Samples. Multivariate analysis of all of the Hamlin and Valencia samples (Figure 1) showed clear separation by principal components analysis (PCA) (R^2X = 0.787 ; Q^2 = 0.658) based on their cultivar and infection status (healthy, HLB-asymptomatic or HLB-symptomatic). Samples were discriminated by cultivar along principal component 1 (PC1), and were separated by infection status along principal component 2 (PC2). These data show that orange cultivar represents the major difference in the fruit metabolome, followed by infection status. Many metabolites were higher in the Valencia juice samples including GABA, isoleucine, arginine, valine, and threonine. Ascorbate and formate were higher in the Hamlin juice samples (Figure 1b). To understand and compare the impact of CLas infection on each cultivar, statistical analyses were conducted independently on each variety and are shown below.

Valencia Samples. Figure 2a shows a PCA for Valencia fruit samples (R^2X = 0.812; Q^2 = 0.496). Sucrose, glucose, fructose, proline, ethanol, and putrescine were higher in concentration in control fruit as compared to symptomatic fruit (Figure 2b). Sucrose concentration was over 2-fold higher in control. Phenylalanine, histidine, limonin, synephrine, quinic acid, and asparagine were higher in symptomatic fruit (Figure 4 and Supporting Information Figure S1). The symptomatic fruit had over 2-fold higher phenylalanine and asparagine, and 2.6-fold higher limonin concentration. °Brix content was significantly

Table 1. °Brix for Hamlin and Valencia Juice Samples, Grouped by Infection Status[a]

Hamlin				Valencia	
group 1	group 2	group 3	symptomatic	control	symptomatic
10.66 ab	12.05 a	12.90 a	8.73 b	12.18	8.79[b]

[a]Comparisons are within each cultivar. For Hamlin, values with different letters are significant at $p < 0.05$. [b]For Valencia, denotes significance at $p < 0.0001$.

lower in symptomatic Valencia oranges as compared to control oranges (Table 1).

To determine the impact of the growing region on metabolite composition, fruit classified by both their region and their infection status were compared using PLS-DA. Figure 2c shows the scores plot, and Figure 2d shows the loadings plot. Interestingly, although regional differences could be observed, the ability to differentiate fruit on the basis of infection status was clearly evident, as metabolites responsible for regional variation differed from those responsible for variation due to infection (Figure 2d).

Hamlin Samples. To investigate the influence of infection and growing region on metabolite composition of Hamlin orange samples, PLS-DA was employed (Figure 3a). A similar trend was observed for Hamlin oranges as was observed for Valencia oranges. The control and CLas$^+$ symptomatic samples separated along component 1. The control and CLas$^+$ asymptomatic samples clustered together on component 1, but some differentiation could be observed along component 2. The low Q^2 value (0.436), which represents the predictive ability of the model, reflects the overlap between the control and asymptomatic samples; however, permutation testing revealed a valid model. Although separation was not complete, a pattern emerged that appeared as mainly control fruit in the lower right-hand quadrant that transitioned to mostly CLas$^+$ asymptomatic fruit in the upper right-hand quadrant. Proposed groupings based on this clustering are circled and labeled as groups 1−3 in Figure 3a. Distinctions in metabolite composition included higher ethanol and malate in group 1 (mostly control), and higher fructose, glucose, proline, and sucrose in group 3 (mostly asymptomatic) fruit (Figure 4). Malate and ethanol exhibited a stepwise decrease in concentration from group 1 to group 3 fruit (Supporting Information Figure S2). Fructose, glucose, sucrose, °Brix, and proline initially increased from group 2 (mixture of control and asymptomatic) to group 3 (mostly asymptomatic) fruit, and then decreased in symptomatic fruit. Sucrose was approximately 2-fold higher in group 3 fruit as compared to symptomatic fruit. Phenylalanine, histidine, synephrine, asparagine, GABA, choline, limonin, and quinic acid were higher in symptomatic fruit as compared to control and group 3 fruit (Supporting Information Figure S2). Phenylalanine was approximately 3.8-fold higher, histidine 3-fold higher, and asparagine 2-fold higher in symptomatic fruit as compared to group 3 fruit. °Brix was significantly lower in symptomatic fruit as compared to fruit classified as groups 2 and 3 (Table 1).

To understand how different growing regions contribute to Hamlin fruit metabolite composition during infection, the fruit were classified based on the combination of infection status and growing region (Figure 3b). As with the Valencia juice samples, juice samples from Hamlin oranges discriminated by infection status along component 1, and by region along component 2, and metabolites that characterized growing regions differed from those that characterized infection stage (Figure 3c).

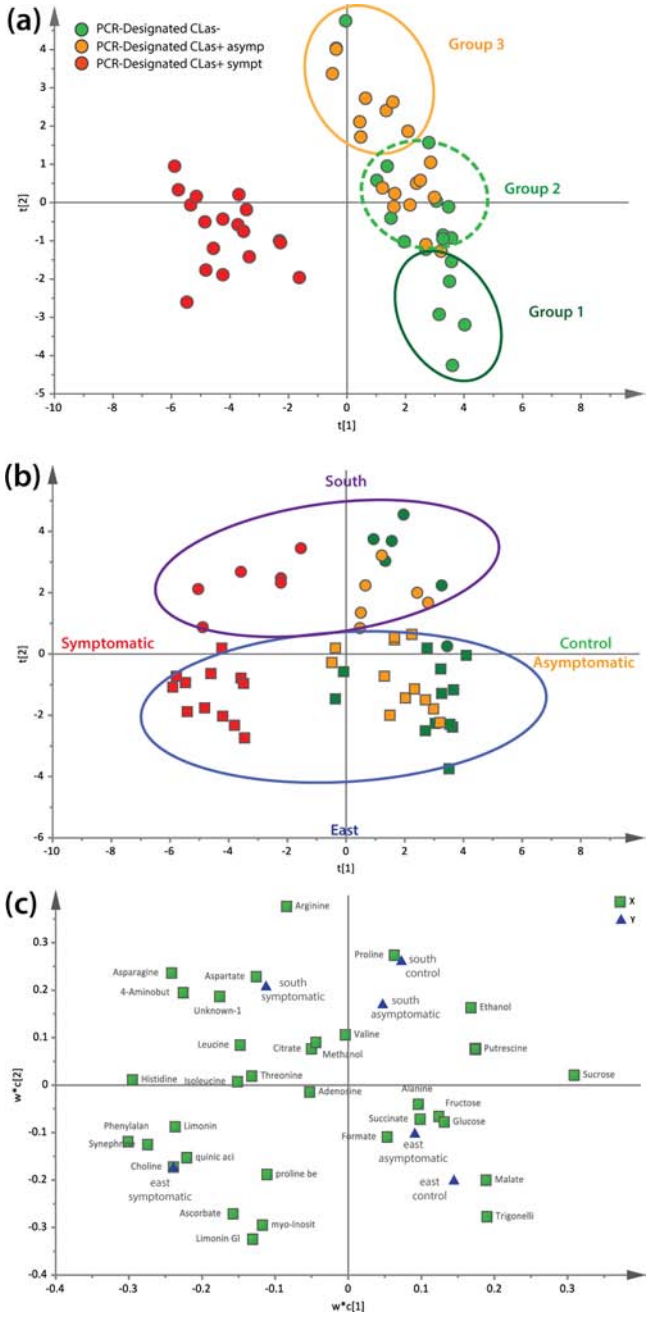

Figure 3. Comparison of composition of Hamlin orange juice samples. (a) PLS-DA scores plot of control (green), asymptomatic (orange), and symptomatic (red) Hamlin samples. $R^2 = 0.537$ and $Q^2 = 0.436$; validation by random permutation (100 permutations) showed positive slopes for R^2 and Q^2, and intercepts of 0.118 and −0.187, respectively. (b) PLS-DA scores plot of Hamlin samples based on infection status (control (green), asymptomatic (orange), and symptomatic (red)) and the sample's growing region (south (circle) and east (square) Florida). R^2 and Q^2 are 0.33 and 0.292, respectively, and random permutation (100 permutations) revealed positive slopes with R^2 and Q^2 intercepts of 0.054 and −0.147, respectively. (c) Loadings plot corresponding to panel b.

DISCUSSION

Analysis of Hamlin and Valencia oranges revealed that the two varieties are distinguishable from one another on the basis of their metabolite composition. Although the samples originated from varying locations and were from two cultivars, the ability

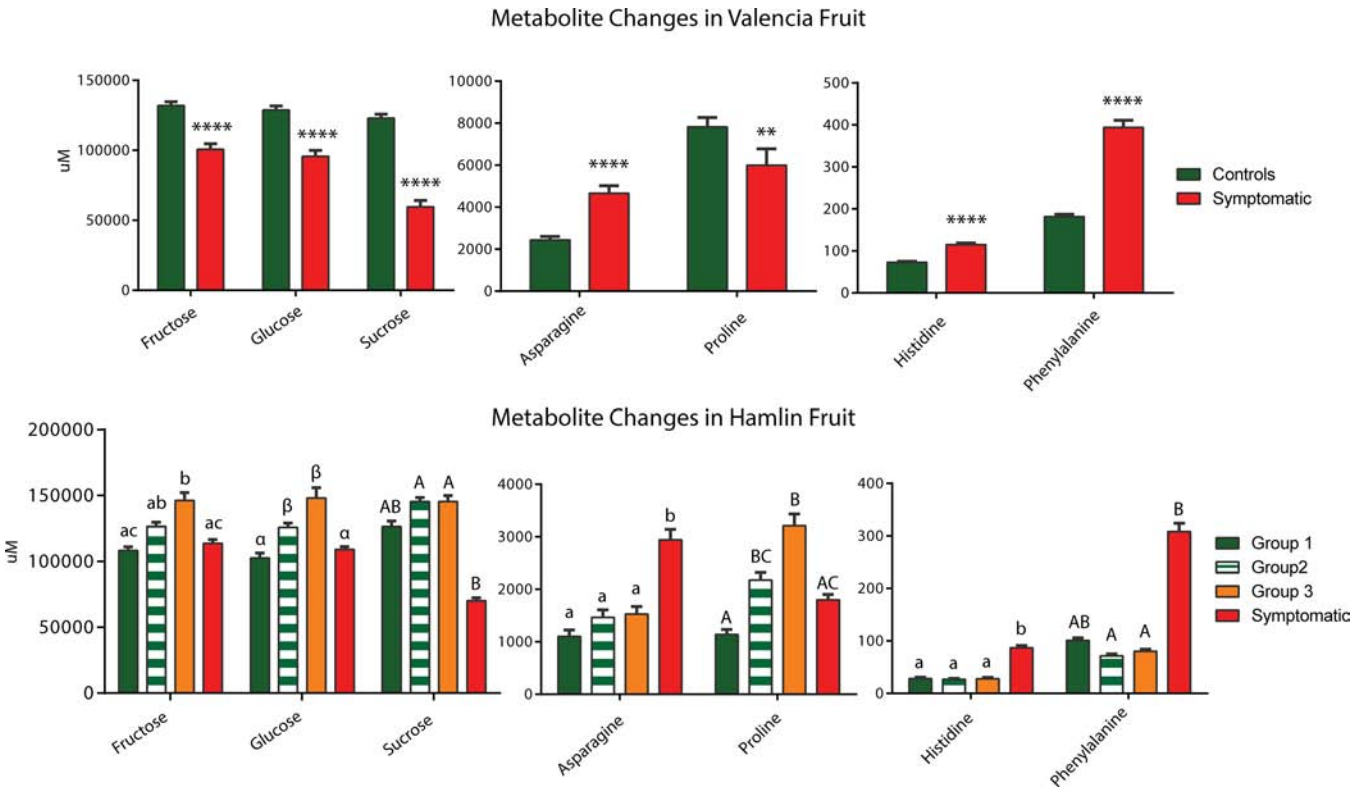

Figure 4. Metabolite concentration (average ± SEM) at varying states of CLas infection in Hamlin and Valencia orange juice samples. Valencia samples are grouped according to whether they are control or symptomatic ($CLas^-$ or $CLas^+$ via PCR, respectively). $^{**}p < 0.01$ and $^{****}p < 0.0001$. Hamlin samples are classified as group 1, group 2, group 3, and symptomatic. Samples with shared letters/symbols indicate no significant difference between those samples at $p < 0.05$.

to discriminate samples on the basis of infection status was not impaired. The concentrations of phenylalanine, histidine, asparagine, and limonin were lower in the control and asymptomatic Valencia or Hamlin fruit as compared to symptomatic fruit in both varieties (Figure 4). This is in agreement with another study on juice,[14] as well as our previous study in which we reported increases in amino acids such as asparagine, histidine, and phenylalanine in symptomatic Valencia oranges as compared to healthy and asymptomatic Valencia oranges.[21]

Examination of the PLS-DA (Figure 3a) of Hamlin fruit revealed a cluster of samples delineated as control fruit (PCR $CLas^-$) in the lower right quadrant, and a cluster of mostly asymptomatic fruit (PCR $CLas^+$) in the upper right quadrant. A mixture of control and asymptomatic samples was between the two. Similarity in metabolite composition among samples in groups 2 and 3 suggests that some of the controls were possible false negatives by PCR. PCR is a nucleic acid-based method that can be used to determine the presence or absence of a bacterium by testing for the presence of its genetic material. Indeed, PCR is prone to false negatives, as it requires a minimum bacterial titer for detection, and bacteria are not evenly distributed throughout the tree.[30,31] Since detection of HLB in Florida in 2005, the entire state is now under quarantine for HLB and ACP.[15] It is unknown how many truly $CLas^-$ trees remain in Florida. These results suggest a potential role for metabolomics to detect infection earlier than PCR. Detecting infection early and understanding the tree response to infection is important for developing treatment plans. These results will need to be further investigated with a broader range of citrus varieties to establish global metabolite biomarkers of CLas infection.

Fructose, glucose, sucrose, and proline concentrations were significantly lower in symptomatic fruit as compared to control Valencia. However, differences in these metabolite concentrations between group 1 (primarily control fruit) and symptomatic Hamlin failed to reach significance. There may be different reasons for this discrepancy. First, there is a difference in sample size, with fewer samples in group 1 as compared to symptomatic fruit. Second, not all Valencia control samples may be truly control, and some could come from trees not yet testing positive for CLas. While Hamlin fruit are harvested from October to January, Valencia fruit are late season fruit and harvested from March to June. Indeed, lower amplification of CLas during the spring months has been reported,[32] and thus the difference in harvest time may contribute to the presence of false negatives by PCR. However, because there are no asymptomatic Valencia samples in this study, we cannot attempt to tease out possible PCR false-negatives based on similarities in metabolite composition as we have done with the Hamlin samples, and it is unknown if the Valencia control samples may contain samples that are analogous to Hamlin groups 2 and 3.

Comparison of fructose, glucose, sucrose, and proline concentrations between group 3 and symptomatic Hamlin and control and symptomatic Valencia revealed similar trends (Figure 4). In the asymptomatic Hamlin samples (groups 2 and 3), these metabolites increase. Symptoms of HLB include starch accumulation in the leaves and phloem impairment.[20,33,34] The decrease in sugars during symptomatic infection could reflect altered carbohydrate transport. Fructose and glucose have been shown to increase in tomatoes subjected to water and nematode stress,[35] and sucrose, fructose, and glucose accumulated in strawberries infected

dx.doi.org/10.1021/jf5017434 | J. Agric. Food Chem. 2014, 62, 6585−6591

with *Colletotrichum nymphaeae*.[36] Defensive mechanisms are costly,[37] and the influx of sugars during asymptomatic infection could indicate mobilization of plant defenses prior to symptom development. Thus, these metabolite concentrations measured in Hamlin group 1 could reflect true control concentrations, and those measured in groups 2 and 3 reflect changes in plant metabolism with early infection. Because there are no asymptomatic Valencia samples, however, it is unknown if a similar pattern can be observed during early infection in Valencia oranges.

Although we previously reported decreases in the concentrations of fructose, glucose, sucrose, and proline when comparing healthy and asymptomatic Valencia fruit,[21] it is important to note that there were differences in the appearance of the asymptomatic fruit as compared to this study. This may explain why the results presented here for asymptomatic Hamlin fruit differ from those of asymptomatic Valencia fruit in the Slisz et al. paper.[21] Indeed, the fruit in that article showed minor signs of HLB such as a slight reduction in average size and small amounts of greening. Here, the asymptomatic Hamlin fruit were visually indistinguishable from control fruit, although they were $CLas^+$ by PCR. Unfortunately, no asymptomatic Valencia fruit were available for this study, and thus a difference between cultivars in how asymptomatic fruit differ in terms of metabolite content cannot be ruled out. Nonetheless, this brings to light a need for standardization of the term "asymptomatic" because it currently relies on subjective interpretation of visual symptoms. A chemical profile that classifies the fruit may be desirable to promote sampling uniformity and to reduce possible misunderstandings.

Although Hamlin and Valencia oranges are two distinct orange varieties harvested during different parts of the year, the presence of CLas has a substantial effect on the metabolite composition of the fruit. The overall pattern for change in many metabolites remained consistent in both Hamlin and Valencia cultivars. Asymptomatic Hamlin oranges revealed more details about nuances in metabolite changes during early infection. Although differences due to the tree location can be detected, this does not impair our ability to discriminate the fruit on the basis of their infection status.

In summary, the present data suggest that metabolomics may be useful to detect trees in the early stage of infection (asymptomatic), and differentiate from those in later stages (symptomatic).

chemiluminescence,[28,29] and electrochemical methods.[30,31] However, most of them have some limitations such as poor selectivity, insufficient sensitivity, and time-consuming procedure, which limit their applications to real sample analysis. Especially, although fluorescence analysis can provide high sensitivity and good selectivity, those developed fluorescent measurements based on oxidation-enhanced fluorescence,[23,24] lanthanide-sensitized fluorescence,[25,26] and quantum dots,[27] remained poorly sensitive for FA. Consequently, further research is needed to develop a highly sensitive fluorescence sensor for folic acid.

Metal nanoclusters, especially Au and Ag nanoclusters, have received much attention during the past decades due to their ultrasmall size, nontoxicity, biocompatibility, and high fluorescence properties, and various fluorescence sensors using metal nanoclusters have been developed.[32−45] However, until now, fluorescence sensors for detecting FA on the basis of metal nanoclusters have not been reported. Herein, polyethylenimine-capped silver nanoclusters (PEI-AgNCs) were introduced as a new fluorescent platform for sensing FA. The interactions between PEI and FA bring FA and AgNCs into close proximity, and a two-step electron transfer from FA to AgNCs through PEI results in the decrease in fluorescence (Scheme 1). A two-step electron-transfer quenching mechanism was proposed and discussed. As expected, this sensing system has been applied successfully to the detection of FA in real samples. Those substances coexisting with FA could not lead to any significant fluorescence decrease of AgNCs. Consequently, our research would be a promising candidate for practical application.

MATERIALS AND METHODS

Chemicals. Silver nitrate ($AgNO_3$), hyperbranched polyethylenimine (PEI, Mw = 10000, 99%), formaldehyde (35 wt %), 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), and folic acid as well as all amino acids were purchased from Aladdin Reagent Co., Ltd., Shanghai, China. Saccharides, vitamins, creatine, creatinine, uric acid, and urea were obtained from Shanghai Sangon Biotechnology Co., Ltd., Shanghai, China. Other reagents were of analytical reagent grade, and all chemicals were used as received without further purification. The PEI-AgNCs stock solution was synthesized according to the previous paper from our group.[42] This stock solution was diluted 10-fold with ultrapure water (18.2 MΩ cm), and the diluted AgNCs was used as the probe to measure the concentration of FA in this assay. The FA stock solution was prepared daily by adding 0.10 M NaOH solution to an opaque system containing FA and ultrapure water until clear. Then, the clear FA solution was serially diluted to required concentrations with ultrapure water. The stock Britton−Robinson (BR) buffer solutions were prepared with 0.20 M NaOH solution and the mixed acid solution containing 0.04 M phosphate solution, 0.04 M boric acid solution, and 0.04 M acetate solution. All solutions were freshly prepared before use, and ultrapure water was used throughout the experiments.

Detection of Folic Acid. In the quenching studies, 900 μL of ultrapure water, 50 μL of BR buffer solution (pH 11.0), 10 μL of diluted AgNCs, and 40 μL of FA solution at different concentrations were vortex mixed for 1 min. After 20 min of incubation at room temperature, the fluorescence emission spectra of PEI-AgNCs were recorded on a Hitachi F-4500 fluorescence spectrophotometer (Tokyo, Japan) at an excitation wavelength of 375 nm, and the fluorescence intensity at an emission wavelength of 452 nm was monitored. Three trials for each sample were performed, and the results represent the average of measurements. In addition, 10 μL of diluted AgNCs and 6 μM FA were used in the optimization of the sensing system.

Sample Preparation. One tablet of folic acid was fully dissolved in 5 mL of 0.10 M NaOH solution,[46] and the resulting mixture was centrifuged for 10 min at 12000 rpm. The supernatant was used as sample solution.

Wheat flour was obtained from a local market. The sample preparation was done as described by Xiao,[47] with a slight modification. First, wheat flour (0.5 g) or wet fermented dough (1.0 g) was dispersed in 5.0 mL of 0.1 M NaOH solution. Then, 10 min of centrifugation was performed at 12000 rpm. Finally, the supernatant was filtered using a 0.22 μm micropore filter membrane, and the filtrate was collected and used as the sample solution.

A urine sample was stored in a refrigerator immediately after collection.[48] After 10 min of centrifugation at 12000 rpm at 10 °C, an appropriate volume of 0.1 M $AgNO_3$ solution was added to the supernatant and the mixture was shaken well. Another centrifugation later, the pH value of the supernatant was adjusted to 12 with NaOH solution. The pH-adjusted system was further centrifuged, and the supernatant was filtered using a 0.22 μm micropore filter membrane.

Liquid milk and milk powder were first deproteinized according to the literature.[49] Milk powder (0.5 g) or liquid milk (1.0 g) was uniformly dispersed in 0.05 M HAc solution, and the mixture was centrifuged for 20 min at 12000 rpm at 10 °C. The supernatant was collected, in which appropriate amounts of 0.1 M $BaCl_2$ and $AgNO_3$ solutions were added in turn. After thorough shaking, the following treatments, including centrifuging, pH-adjusting, centrifuging, and filtering, were the same as those for the urine sample.

RESULTS AND DISCUSSION

Establishment of the Fluorescence Sensing System for Folic Acid. The fact that the fluorescence of PEI-AgNCs is quenched by FA was observed in an exploratory experiment. To achieve the best sensing performance, several conditions such as pH, buffer system, concentration of buffer solution, and reaction time were optimized, respectively. The effect of the pH value on the sensing system was investigated first because the fluorescence quenching efficiency ($1 - F/F_0$) of PEI-AgNCs is pH-dependent (Supporting Information Figure S1). F_0 and F denote the fluorescence intensity of PEI-AgNCs in the absence and presence of FA, respectively. To cover a wide pH range, BR buffer solutions were used as the medium for optimizing the pH value. Figure S1 in the Supporting Information shows that, in the presence of FA, high-efficiency fluorescence quenching was observed at pH >7.0, and the highest quenching efficiency was obtained at pH 11.0. Therefore, a basic medium at pH 11.0 would ensure the sensitive detection of FA.

The influence of different buffer systems on FA analysis was studied as the result of the influence of the ionic species on the stability of PEI-AgNCs.[42] Apart from BR buffer solution (50 μL mL^{-1}: 1 mL of solution contains 50 μL of stock BR buffer solution), another four buffer solutions, including $Na_2B_4O_7$−NaOH (10 mM), $Na_2B_4O_7$−Na_2CO_3 (10 mM), Na_2HPO_4−NaOH (10 mM), and NH_2CH_2COOH−NaOH (20 mM), were employed to test the quenching of the PEI-AgNCs fluorescence by FA. In consideration of the better stability of the diluted PEI-AgNCs and almost zero ionic strength of ultrapure water as well as the low ionic strength of sodium hydroxide solution at pH 11.0, ultrapure water and sodium hydroxide solution at pH 11.0 were also used as the medium for investigating the changes in fluorescence intensity of PEI-AgNCs (Supporting Information Figure S2). The quenching efficiencies of PEI-AgNCs are higher, and only a little difference was observed for ultrapure water, sodium hydroxide solution, and BR buffer. Therefore, the other four buffers were excluded at first. Meanwhile, the BR buffer can give a greater ability to resist interference than ultrapure water and the pure acid or

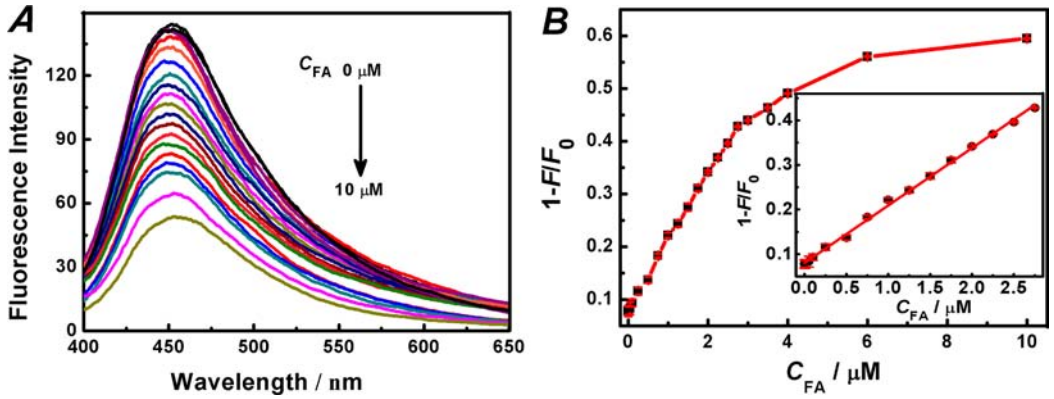

Figure 1. Fluorescence emission spectra (A) and fluorescence quenching efficiencies (B) of PEI-AgNCs upon addition of different concentrations of FA: 0, 0.1, 1.0, 10 nM; 0.1, 0.25, 0.5, 0.75, 1.0, 1.25, 1.5, 1.75, 2.0, 2.25, 2.5, 2.75, 3.0, 3.5, 4.0, 6.0, 10.0 μM. The inset in panel B displays the linear relationship between the fluorescence quenching efficiency $(1 - F/F_0)$ and the concentration of FA from 0.1 nM to 2.75 μM. F_0 and F denote the fluorescence intensity of PEI-AgNCs in the absence and presence of FA, respectively.

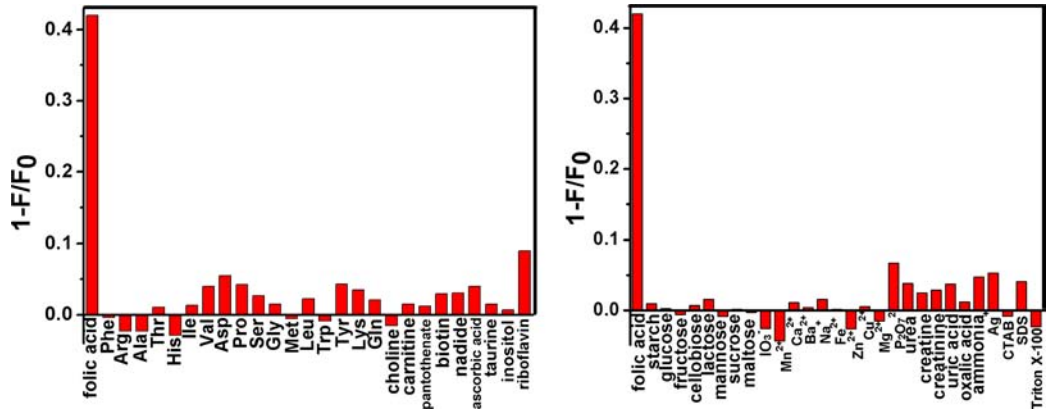

Figure 2. Selectivity of PEI-AgNCs for the detection of FA over other potential coexisting constituents. The concentration of FA is 2.75 μM; the concentration of saccharides is 5 mM; the concentrations of amino acids, carnitine, pantothenate, biotin, taurine, inositol, urea, creatine, creatinine, uric acid, oxalic acid, Ba^{2+}, Ca^{2+}, Na^+, NO_3^-, CH_3COO^-, $P_2O_7^{2-}$, IO_3^-, and $NH_3{\cdot}H_2O$ are 1 mM; the concentrations of choline, nadide, and ascorbic acid are 100 μM; the concentrations of riboflavin, Cu^{2+}, Mg^{2+}, Zn^{2+}, Ag^+, and Fe^{2+} are 1 μM, respectively; the concentrations of CTAB, SDS, and Triton X-100 are 0.2, 0.2, and 1 mM, respectively. F_0 and F represent the fluorescence intensity of PEI-AgNCs in the absence and presence of FA (or other species), respectively; $(1 - F/F_0)$ is the fluorescence quenching efficiency of PEI-AgNCs by FA or other species.

basic solution. Therefore, to gain more outstanding sensing performance, BR buffer is the only medium that can be adopted in this work.

According to the literature,[42] not only do the ionic species have different influences on the stability of PEI-AgNCs, but also the ionic strength has a nonnegligible effect. The ionic strength is tied to the concentration of ions, so the effect of the concentration of BR buffer on sensing performance was also investigated. Figure S3 in the Supporting Information indicates that the fluorescence quenching efficiencies of PEI-AgNCs in the presence of FA were decreased by increasing the concentration of BR buffer solution (pH 11.0). To gain the most satisfactory results, 50 μL mL^{-1} BR buffer solution was used for sensing FA.

Finally, under the optimum conditions mentioned above, the effect of reaction time on the fluorescence intensity of the system was investigated. The fluorescence intensity of PEI-AgNCs in the presence of FA was monitored for 60 min. The maximum quenching and stable fluorescence intensity was observed after 20 min of interaction (Supporting Information Figure S4), indicating that the interaction between FA and PEI-AgNCs was complete within 20 min and the fluorescence of PEI-AgNCs/FA was stable for at least 40 min. Consequently, all measurements were carried out after the FA solution or real sample solution was incubated with PEI-AgNCs in the BR buffer (pH 11.0) for 20 min.

Sensitivity of the Sensing System. The linearity and detection limit of this measurement were evaluated by varying the concentration of FA under optimum conditions discussed above. The fluorescence of PEI-AgNCs was quenched proportionately over the FA concentration range of 0.1 nM–2.75 μM (Figure 1). A good linear correlation (R^2 = 0.9981) was found, and a detection limit of 0.032 nM (3σ/slope) was obtained. Compared to other FA sensors reported in recent years (Supporting Information Table S1), our method provides a better linear range and a lower detection limit.

Selectivity of the Sensing System. To investigate whether this sensing system is specific for FA, the fluorescence response of PEI-AgNCs to other potential coexistent substances was studied under optimum conditions. Figure 2 shows that 5 mM saccharides, 1 mM amino acids, carnitine, pantothenate, biotin, taurine, inositol, urea, creatine, creatinine, uric acid, oxalic acid, Ba^{2+}, Ca^{2+}, Na^+, NO_3^-, CH_3COO^-, $P_2O_7^{2-}$, IO_3^-, and $NH_3{\cdot}H_2O$, 100 μM choline, nadide, and ascorbic acid, 1 μM riboflavin, and 1 μM Cu^{2+}, Mg^{2+}, Zn^{2+}, and Fe^{2+} (according to the solubility product constants (K_{sp}^{θ}) of the

corresponding hydroxides, the concentrations of these metal ions are not higher than 1 μM in this testing system) could not lead to any significant fluorescence decrease of PEI-AgNCs. The surfactants, including 0.2 mM hexadecyltrimethylammonium bromide (CTAB, cationic), 0.2 mM sodium dodecyl sulfonate (SDS, anionic), and 1 mM Triton X-100 (nonionic), also show only little effect on the determination of FA. These results indicate that the proposed assay has a good selectivity for FA.

Analytical Applications in Real Sample. To assess the applicability of the sensing system, the proposed method was used for the analysis of FA in tablet, human urine, wheat flour, wet fermented dough, liquid milk, and milk powder samples. The results are listed in Table 1. The recovery from 96.0 to 105.0% and the relative standard deviation (RSD) smaller than 5% were satisfactory. Furthermore, the measured result of 205 μg FA 100 g^{-1} milk powder is in good agreement with the testing value of 183 μg 100 g^{-1} by official method[50] in the Comprehensive Test Center of China Academy of Inspection and Quarantine. The found values of 0.407 mg tablet^{-1} and 1.68 μg mL^{-1} human urine according to the ref 25 also show a good correspondence with the values found by the proposed method (0.401 mg tablet^{-1} and 1.55 μg mL^{-1} human urine, respectively). Therefore, the proposed design is feasible for FA detection in practical applications.

Mechanism for the Recognition of Folic Acid. To understand the mechanism of the fluorescence quenching of PEI-AgNCs by FA, the absorption and the fluorescence spectra of PEI-AgNCs, FA, and PEI-AgNCs/FA were studied. Figure 3A shows three similar fluorescence excitation wavelengths and three similar fluorescence emission wavelengths, suggesting that fluorescence resonance energy transfer as a possible mechanism for AgNCs fluorescence quenching is ruled out. Moreover, the absorption spectrum of PEI-AgNCs/FA exhibits no new peak (Figure 3B) compared to those of both AgNCs and FA, which implies that the decrease in fluorescence intensity was not induced by the change in the excitation wavelength or the aggregation of AgNCs, thereby excluding possible mechanisms including static quenching upon formation of the ground-state complex and AgNCs aggregation-induced self-quenching.[44,52] In addition, evidence from the IR spectral data and the high-resolution transmission electron microscopy (HRTEM) image also support the above inference, because IR spectra of PEI-AgNCs/FA were almost a simple superposition of those of both PEI-AgNCs and FA (Figure 3C) and AgNCs remained dispersed upon addition of FA, which were similar to the original PEI-AgNCs (Figure 3D).

As for the quenching mechanism, theoretically, fluorescence quenching in this system could occur by the nonfluorescent ground-state complex, aggregation of AgNCs, energy transfer,

[a] a_i represents the amplitudes of components i at t = 0; τ_i is the decay time of component i; $\bar{\tau}$ is the average fluorescence lifetime.

dx.doi.org/10.1021/jf4054534 | J. Agric. Food Chem. 2014, 62, 6592−6599

or electron transfer. As discussed above, only the electron transfer is expected in the quenching process. The proposed electron-transfer quenching mechanism was further examined using fluorescence decay kinetics. The fluorescence decay profiles of PEI-AgNCs in the absence and presence of FA together with FA in the absence and presence of PEI-AgNCs are shown in Figure 4A, respectively. The fluorescence decay of all samples could be fitted using a three-exponential function, and the fitted results are given in Table 2. The average fluorescence lifetime ($\bar{\tau}$) was estimated using the equation[51]

$$\bar{\tau} = \frac{\sum a_i \tau_i^2}{\sum a_i \tau_i} \quad (1)$$

where a_i represents the amplitude of the component i at $t = 0$ and τ_i is the decay time of the component i. As shown in Table 2, the average fluorescence lifetime estimated for FA was approximately 7.22 ns. In the presence of PEI-AgNCs, the average lifetime for FA decreased to 2.78 ns. On the basis of the literature,[52] we can deduce that the decrease in lifetime is due to the efficient electron transfer from FA to PEI-AgNCs, wherein FA acts as an electron donor. In addition, before and after the addition of FA, the lifetime of PEI-AgNCs increased from 798 ps to 2.54 ns. This opposite change provided evidence for electron-transfer sequence from FA to PEI-AgNCs.

Interestingly, the fluorescence of FA could also be quenched by PEI. The fluorescence quenching mechanism based on electron transfer is speculated because we did not observe any absorption band in the absorption spectrum of PEI, and the absorption spectrum of FA did not vary after PEI was added (Supporting Information Figure S5). The feasibility of the electron-transfer quenching was examined by further measuring the fluorescence decay dynamics of FA solution in the presence of PEI (plot e in Figure 4A). An average lifetime of 3.94 ns was obtained, and considering the average lifetime of 7.22 ns for FA, we conclude that the excited electrons of FA can be transferred to PEI. Meanwhile, the oxidation potential of both PEI and FA was further adopted to confirm the direction of electron transfer. The oxidation potential of PEI was measured to be +0.68 V versus Ag/AgCl (saturated KCl) [0.90 V vs normal hydrogen electrode (NHE)], and FA exhibited a more positive oxidation potential of +0.83 V versus Ag/AgCl (1.05 V vs NHE), as shown in Figure 4B. According to the test results, the electron transfer from FA to PEI can also be concluded.

On the basis of the conclusions of the foregoing discussion and the sequence of 7.22 ns (the average lifetime of FA) > 3.94 ns (the average lifetime of FA with addition of PEI) > 2.54 ns (the average lifetime of FA in the presence of PEI-AgNCs), we put forward a two-step electron-transfer process in the system comprising FA and PEI-AgNCs, in which an electron is transferred from FA to AgNCs through the PEI molecule. Moreover, we note that a similar energy transfer mechanism has been proposed for ethidium bromide in the complex comprising a cationic conjugated polymer, a fluorescein molecule linked to one terminus of the DNA, and ethidium bromide.[53] FA is brought into close proximity to the template molecule PEI for AgNCs through the electrostatic interactions between FA and PEI, and electron transfer from FA to PEI changes the electronic properties of PEI. As metal nanoclusters are both excellent electron donors and acceptors, the fluorescence of the nanoclusters can be quenched by electron acceptors or donors.[54] Therefore, electron transfer from PEI to AgNCs quenched the fluorescence of AgNCs. Although interactions between FA and PEI shortened the distance between FA and AgNCs, the distance was still longer than that between PEI and AgNCs. To our knowledge, electron transfer is distance-dependent,[55] so electrons are more easily transferred from PEI to AgNCs. Consequently, the two-step electron-transfer process was reasonably proposed, in which FA served as an electron donor, AgNCs as an electron acceptor, and PEI as an electron-transfer bridge.

In conclusion, a highly sensitive method for the detection of FA based on the fluorescence quenching of PEI-AgNCs was developed in this study, and the mechanism of fluorescence quenching through a two-step electron-transfer process was proposed. We believe that the research is of importance in the development of metal nanoclusters and FA detection in real samples.

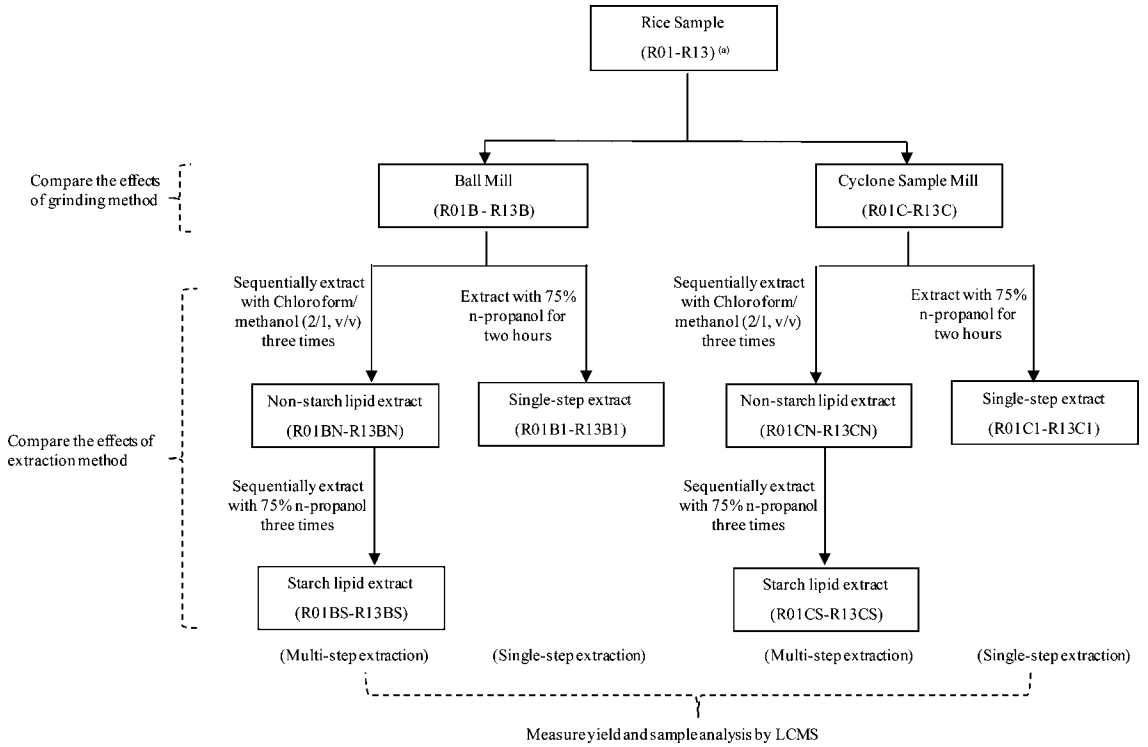

Figure 1. Rice samples and their grinding, extraction, and LC-MS analysis of rice lipids. [a]Rice sample numbers are the same as in Table 1.

mass detector (LC-MS) has become significantly cheaper and more accessible to many researchers. We have accumulated considerable experience in successfully analyzing metabolites in cereal grains using this approach.[15,16] The aim of this research was to develop a fast, reliable, and low-cost LC-MS method to analyze starch LPLs in rice grain. Because starch LPLs form inclusion complexes with amylose and require a different procedure for extraction,[6] we also investigated the effects of different grinding and extraction methods on total rice starch LPL content. This extraction and analytical strategy is most likely suitable for analyzing starch LPLs in cereals other than rice.

MATERIALS AND METHODS

Plant Materials, Reagents, and Standards. Rice accessions (Table 1) were obtained from the Key Laboratory of Zhejiang Province and Chinese Ministry of Agriculture for Nuclear-Agricultural Sciences, Zhejiang University, China. The rice grains were harvested in October 2012. The rice grains were air-dried, stored at room temperature for 2 months until the physiochemical properties of the rice grain stablized,[17,18] and then stored at 4 °C until analyzed in March 2013.

All organic solvents used were of HPLC or LC-MS grade. The LPL standards, 1-oleoyl-2-hydroxy-*sn*-glycero-3-phosphoethanolamine (LPE 18:1), 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphoethanolamine (LPE 16:0), 1-oleoyl-2-hydroxy-*sn*-glycero-3-phosphocholine (LPC 18:1), and 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphocholine (LPC 16:0), were purchased from Avanti Polar Lipids Inc. (Alabaster, AL, USA).

Sample Grinding and Amylose Content Determination. Rice samples were milled to white rice using a Satake rice machine (Satake Corp., Japan). A laboratory ball mill (Mixer Mill MM301, Retsch) and a cyclone sample mill (UDY Corp., Fort Collins, CO, USA) were used separately to produce rice flour samples (Figure 1). For the cyclone grinding, the milled rice was ground into flour and passed through a 0.5 mm mesh sieve. For the ball mill, the grinding jar was filled with about 8 g of white rice each time and shaken at 30 r/s for 15 s to produce the rice flour samples. The moisture content of the flour was measured by loss on drying; the flour samples were dried under vacuum (6 kPa) and at 60 °C overnight until constant weight.

dx.doi.org/10.1021/jf500585j | J. Agric. Food Chem. 2014, 62, 6600−6607

Apparent amylose content was determined using the iodine staining method.[19] The absorbance of the solution was measured at 620 nm against the blank solution using a spectrophotometer. The apparent amylose content was determined in duplicate for each sample.

Multistep Extractions. The multistep extraction was carried out in triplicate for each sample. In the first step of extraction, rice flour (0.5 g) from each sample was weighed accurately and placed in a 16 × 125 mm, Pyrex culture tube. Chloroform/methanol (2:1, v/v; 8 mL) was added to each tube, and the tubes were capped with rubber liners and placed on ice; the supernatant was removed after 15 min[20] (Figure 1). This extraction was repeated two times for each sample (a total of three extractions). The supernatants from each of the three sequential extractions were combined and dried under N_2. This concentrated extract (R01BN−R13BN and R01CN−R13CN, Figure 1) was dissolved in isopropanol/acetonitrile (50:50, v/v) for LC-MS analysis. The chloroform/methanol extracted rice flour was carefully dried under N_2 in the culture tube before the next extraction step.

In the second step of extraction, the chloroform/methanol extracted rice flour above was extracted with 75% *n*-propanol (*n*-propanol/water, 75:25, v/v; 8 mL) for 2 h under nitrogen at 100 °C in the same culture tube following the method of Morrison and Coventry[21] (Figure 1). The supernatant was removed and the extraction repeated, once for 2 h and once for 1 h. The supernatants from each sequential extractions were combined in a 25 mL volumetric flask, and a 1 mL aliquot was transferred to a vial for LC-MS analysis. The remaining 24 mL of extract (Figure 1; R01BS−R13BS and R01CS−R13CS) was dried using a rotational vacuum concentrator (CHRiST, Osterode am Harz, Germany) and redissolved in 1 mL of 75% *n*-propanol for LC-MS analysis.

Single-Step Extraction. Rice flour (~0.15 g) from each sample was weighed accurately, placed in a culture tube and extracted for 2 h under nitrogen at 100 °C with 75% *n*-propanol (8 mL). The culture tubes were weighed before and after heat extraction to ensure there was no loss of solvent, which would have affected the solvent/sample ratio (w/w). A 1 mL aliquot of the extract (Figure 1; R01B1−R13B1 and R01C1−R13C1) was transferred to a vial for the LC-MS analyses. Triplicate extractions of each sample were undertaken.

LC-MS Analysis. The analysis of extracts was undertaken using an Agilent HPLC (series 1290) equipped with a vacuum degasser, binary pump, autoinjector, and diode array detector (DAD, 1260), coupled to an Agilent quadrupole mass detector (MSD, 6120). A Phenomenex Luna C18 column (5 μm; 150 × 4.6 mm internal diameter) was used for analysis of rice grain lipids. Column temperature was set at 40 °C. Absorbance was monitored between 190 and 600 nm. The injection volume was set at 5 μL per injection. The LC-MS system was controlled using ChemStation software.

Two linear gradient elution programs based on our previous research of the lipophilic components in wheat grain[15,16,22] were used for the qualitative analysis of concentrated rice lipid extracts (Figure 1; R01BN−R13BN, R01CN−R13CN, R01BS−R13BS, and R01CS−R13CS). The first linear gradient contained methanol with 0.005% trifluoroacetic acid (TFA) and 2-propanol with 0.005% TFA. The solvent gradient was programmed from 10 to 95% 2-propanol with 0.005% TFA in 15 min with a flow rate of 1.0 mL/min. The second linear gradient contained acetonitrile with 0.005% TFA and water with 0.005% TFA. The solvent gradient was programmed from 10 to 99% acetonitrile in 30 min with a flow rate of 1.0 mL/min and held at 99% acetonitrile for 5 min.

The MSD was carried out in two ionization modes: atmospheric pressure chemical ionization (APCI) and electrospray ionization (ESI). The APCI mode used the following parameters: scan mass range, 100−1200; fragmentor, 150; capillary voltage, 3000 V (positive); corona current, 4.0 μA; drying gas flow, 5.0 L/min; drying gas temperature, 350 °C; vaporizer temperature, 350 °C; nebulizer pressure, 35 psig. The ESI mode used the following parameters: scan mass range, 100−1200; fragmentor, 150; capillary voltage, 3000 V (positive); drying gas flow, 12.0 L/min; drying gas temperature, 350 °C; vaporizer temperature, 350 °C; nebulizer pressure, 35 psig. All LC-MS settings and parameters above were optimized on the basis of the manufacturer's recommendations and a number of flow injection experiments.

Quantification of Starch LPLs. The same Agilent LC-MS equipment above was used to quantify LPLs. A much shorter and lower volume Agilent Eclipse Plus C18 RRHD column (1.8 μm; 50 × 2.1 mm internal diameter) was used for the quantitative analysis of rice starch LPLs. A shorter linear gradient elution program was used for the quantitative analysis, with a mobile phase containing water and 0.005% TFA and acetonitrile with 0.005% TFA programmed from 10 to 99% acetonitrile in 10 min with a flow rate of 0.3 mL/min and held at 99% acetonitrile for 1.5 min. For this quantitative analysis, the injection volume was set at 3 μL per injection.

The rice starch LPLs were quantified using an external standard method. The MSD was operated using the same parameters as for the ESI method above except that single ion monitoring (SIM) mode was used rather than scan mode. Four available MSD signal channels were employed to detect 10 ions simultaneously as shown in Table 2.

Table 2. LC-MS Single Ion Monitoring (SIM) Mode Setting for Quantification of Starch Lysophospholipids in Rice

[a]LPC 18:3 for 1-linolenoyl-2-hydroxy-*sn*-glycero-3-phosphocholine. [b]LPC 18:2 for 1-linoleoyl-2-hydroxy-*sn*-glycero-3-phosphocholine. [c]LPC 18:1 for 1-oleoyl-2-hydroxy-*sn*-glycero-3-phosphocholine. [d]LPC 14:0 for 1-myristoyl-2-hydroxy-*sn*-glycero-3-phosphocholine. [e]LPC 16:0 for 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphocholine. [f]LPE 18:3 for 1-linolenoyl −2-hydroxy-*sn*-glycero-3-phosphoethanolamine. [g]LPE 18:2 for 1-linoleoyl −2-hydroxy-*sn*-glycero-3-phosphoethanolamine. [h]LPE 18:1 for 1-oleoyl-2-hydroxy-*sn*-glycero-3-phosphoethanolamine. [i]LPE 14:0 for 1-myristoyl-2-hydroxy-*sn*-glycero-3-phosphoethanolamine. [j]LPE 16:0 for 1-palmitoyl-2-hydroxy-*sn*-glycero-3-phosphoethanolamine.

Standards were prepared at concentrations of 32, 160, 800, 4000, 20,000, 100,000, and 200,000 pM. LPLs eluted at similar retention times were allocated to different signal channels (Table 2). The LPLs without commercially available standards were quantified using LPLs of similar structure (Table 2). The method was validated for linearity, precision, limit of detection, limit of quantification, and working concentration range prior to quantification.

Statistical Analysis. All of the LPLs data were measured at least in triplicate. Data analyses were performed with the SAS program version 9.1 (SAS Institute Inc., Cary, NC, USA). The analysis of variance (ANOVA) was performed to determine the effects of grinding methods and extraction methods on the starch lipids and nonstarch lipids with the general linear model procedure (Proc GLM). The multiple comparisons of different mean values for test of significance were determined with Proc means. The correlation coefficients between the parameters were conducted with Proc corr.

RESULTS AND DISCUSSION

Sample Grinding and Multistep Extraction. Ball and cyclone sample mills were chosen for this experiment as they are

the two most commonly used sample grinding methods for plant material prior to solvent extraction and instrumental analysis. Ball mills are widely available in most analytical laboratories, where they are used for general purpose plant sample preparation, whereas cyclone sample mills are often used for grain quality assessment, such as Rapid Visco-Analyzer (RVA) test of pasting viscosity. In this experiment, we used a very gentle ball mill method (30 r/s for 15 s) as severe ball-milling may destroy starch granule structure and affect quantitative extraction of lipids.[21] The rice flour produced by this gentle ball mill method has visibly larger particle size than flour generated by the cyclone sample mill. The moisture content of the flour was between 10.39 and 11.47% (Table 1).

The multistep extraction conditions were chosen carefully on the basis of our previous review.[6] The first step of the multistep extraction with chloroform/methanol was designed to extract nonstarch lipids, and it is a classic method for lipid extraction. The second step of the multistep extraction with *n*-propanol aqueous solution was designed to extract starch lipids. As rice starch lipids (including the LPLs) are protected by the impermeable starch granules and form inclusion complexes with amylose, they are not readily extracted by organic solvent at room temperature. Efficient extraction of internal starch LPLs requires both water and heat to swell or gelatinize the native starch granule to permit the alcohol to penetrate and extract the lipids.[21] The starch lipids were initially suspected to be an artifact formed during starch isolation. Later, ^{13}C cross-polarization/magic angle spinning nuclear magnetic resonance (^{13}C CP/MAS NMR) analysis confirmed that the LPLs exist in vivo in native rice starch granules.[23]

The multistep extraction procedure included three repeated extractions for each step to exhaustively extract and separate nonstarch and starch lipids in rice endosperm. The extraction of nonstarch lipid was carried out at low temperature (0 °C) as a precautionary measure to slow enzymatic reactions during extraction and to reduce the coextraction of nonlipid components.[6] These preventative measures were proven to be effective to reduce the action of lipase and phosphatase as no degradation products (such as phosphatidic acids) were found by subsequent LC-MS analysis. Through the multistep extraction, <1% of starch LPLs was found in the nonstarch lipid fraction by subsequent LC-MS analysis, suggesting the multistep sequential extraction of rice flour was capable of separating the nonstarch lipids from starch lipids.

The yields (%) of nonstarch lipids extracted by chloroform/methanol (2:1, v/v) varied from 0.10% (R04CN) to 1.34% (R02CN) (Table 1; Figures 1 and 2). For some samples such as R02, R03, R07, R08, and R09, the yields (%) of nonstarch lipid extracts of cyclone-milled samples were significantly higher than those of ball-milled samples ($P < 0.001$), which may be due to the effects of different grinding methods. The yields (%) of starch lipids extracted by 75% *n*-propanol were higher than the nonstarch lipids extracted by chloroform/methanol ($P < 0.05$) and varied from 0.70% (R01BS) to 2.24% (R12CS) (Figure 2). In general, the yields of extracted lipids are higher from the cyclone-milled flour than from the ball-milled flour, which may be attributed to the finer flour generated by the cyclone mill, which has higher contact surface with the extraction solutions. However, the two grinding methods were shown to have no significant effects on the quantification of total LPLs by subsequent LC-MS analysis ($P = 0.363$). As yield (%) calculations were based on extraction from a very small quantity of rice flour (0.5 g for each extraction), these results should be considered only as a preliminary indication of the relative nonstarch lipid and starch lipid content in rice grain. Although different rice samples were used, the yields obtained are higher than those reported by Juliano[24] for nonstarch lipid (0.41−0.81%) and starch lipid (0.12−0.57%) ($P < 0.05$), suggesting a possible coextraction of nonlipid components in our experiment.

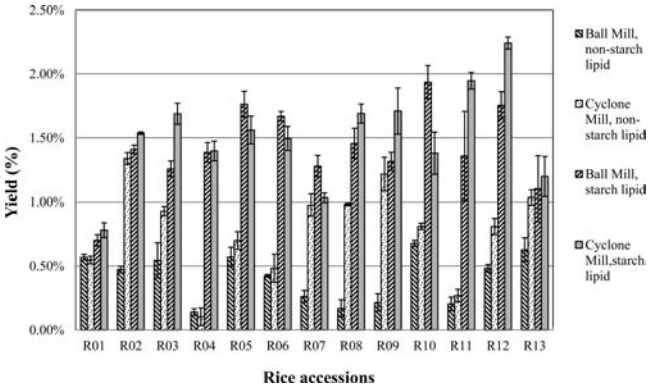

Figure 2. Extraction yields (%) of nonstarch and starch lipids of rice by multistep extraction.

LC-MS Analysis of Lipids Extracted from Multistep Extraction. The concentrated extracts from multistep extraction (Figure 1; R01BN−R13BN, R01CN−R13CN, R01BS−R13BS, and R01CS−R13CS) were analyzed using the 2-propanol/methanol LC-MS method. The total ion chromatograph (TIC) clearly indicated that the major components in the first-step extract of multistep extraction (nonstarch lipids) were the relatively nonpolar triglycerides (eluted at 8−11 min) as discussed in our previous papers (Figure 3a; TIC of R10BN was used as an example).[15,16] The extract (starch lipids) from the second step of the multistep extraction contained relatively more polar lipids (Figure 3a; TIC of R10BS was used as an example), which are further investigated using the acetonitrile/water gradient (Figure 3b).

The extracts (starch lipids) from the second step of the multistep extraction were better separated in the acetonitrile/water gradient than in the 2-propanol/methanol gradient (Figure 3b; TIC of R10BS was used as an example). There was little response observed for the starch lipid samples with the mass detector (MSD) working in the atmospheric pressure chemical ionization (APCI) mode (Figure 3b), with only two LPEs (LPE 18:2, m/z 478 [M + H$^+$] and LPE 16:0, m/z 454 [M + H$^+$]) identified in the TIC of starch lipids (Figure 3b). We explored many parameters in the APCI mode but were unable to detect any LPC. A method using electrospray ionization (ESI) mode was developed and optimized, on the basis of the method of Xia and Jemal.[25] It is apparent that LPLs, including LPEs and LPCs, have a much stronger response in the ESI mode than in the APCI mode (Figure 3b). Seven peaks including both LPCs and LPEs were identified between 19 and 26 min in the ESI mode (Figure 3b), and so this was used for all subsequent experiments (see Supporting Information for the mass spectra).

The LPL composition of rice grains was analyzed on the basis of the starch LPLs reported by Maningat and Juliano[7] using an extract ion method in the TIC of starch lipids (Figure 3c). Ten major LPLs, including five LPCs and five LPEs, were clearly identified, and coelution of some LPLs was observed (Figure 3c). Different mobile phases and columns were used in an attempt to separate the coeluted components. However, we were unable to

obtain an improved separation, indicating that SIM may be the only option to quantify this class of LPLs.

Interestingly, Figure 3c shows two peaks for each of the LPCs or LPEs, whereas to date there has been no mention of this phenomenon in the literature on the quantification of LPLs using LC-MS. The standards purchased from Avanti also displayed two peaks for the same compounds, suggesting the two peaks for one compound could result from the amphoteric or zwitterionic nature of the LPLs, containing both $-O-P(O_2^-)-O-$ (anionic phosphate) and $-N^+(CH_3)_3$ (cationic quaternary ammonium

(c) Correlation between total LPLs and apparent amylose contents.

Figure 4. Quantification of total LPLs using different grinding and extracting methods.

for LPC) or $-NH_3^+$ (ammonium ion for LPE). On the basis of the study by Xia and Jemal,[25] we attempted to run the samples and standards at different pH values (2.7, 3.2, 4.4 and 9.3) and at different column temperatures (30, 40, 50, and 60 °C), but the two peaks for each LPL remained in all conditions. Subsequent ^{1}H NMR analysis (see the Supporting Information) demonstrated that the two peaks were actually positional isomers of 1-acyl-2-hydroxy and 2-acyl-1-hydroxy LPLs, which were formed via acyl migration.[26] We tried to isolate pure 1-acyl-2-hydroxy LPC/LPE, the thermodynamically favored isomer,[26] using preparative HPLC. However, it underwent migration during separation attempts, forming a mixture of 1-acyl-2-hydroxy and 2-acyl-1-hydroxy isomers and so we were unable to obtain pure 1-acyl-2-hydroxy or 2-acyl-1-hydroxy LPC/LPE within the scope of this study. The ^{1}H NMR analysis indicated that the isomer mixtures generally contained up to 10% 2-acyl-1-hydroxy isomer.

LC-MS Quantification of LPLs. The LC-MS method used for the qualitative analysis could also be used to quantify LPLs with modification of mass detection from scan mode to SIM mode. However, this method was not suited for testing a large number of samples as it took 45 min and consumed approximately 25 mL of acetonitrile and 540 L of high-purity N_2 for each analysis. Therefore, an ultraperformance liquid chromatography (UPLC) approach was introduced, with the optimized method involving about 30% of the time (a decrease from 45 to 15 min) and 10% of the cost (e.g., a decrease from 25 to 2.5 mL of acetonitrile) for each analysis. In this UPLC method, the effect of column length reduction (from 150 to 50 mm) on chromatography resolution was compensated by the finer column packing particles (a decrease from 5 to 1.8 μm).

As some LPL standards are not commercially available and every LPL standard has two positional isomers, quantification has to be based on the assumption that LPLs with similar

dx.doi.org/10.1021/jf500585j | J. Agric. Food Chem. 2014, 62, 6600−6607

structures have similar response factors (area/concentration) in our LC-MS analysis. The area under each peak was integrated by the ChemStation software, and the areas of two positional isomers were summed and considered as one LPL. Plots of the LPL concentrations and the areas were used to obtain second-order polynomial regression equations (Figure 4a). The response factors of LPCs are larger than LPEs. Compared to the LPE, the two LPCs have very similar response factors (Figure 4a).

In this study, the limit of detection (LOD) was defined as the concentration of LPL that was required to produce a signal >3 times the standard deviation of the noise level (S/N > 3). The limit of quantification (LOQ) was defined as the concentration of LPL that was required to produce a signal >10 times the standard deviation of the noise level (S/N > 10). The signal-to-noise ratio (S/N) was calculated using Agilent Chemstation software (rev. B04.03). Under the LC-MS conditions used in this study, the LOD was about 6 pM (about 3 pg/mL) and the LOQ was about 30 pM (about 15 pg/mL). On the basis of the current extraction and sample preparation methods, we can detect and quantify each LPL when its concentration in the rice grain is >0.75 ng/g (about 1 ppb).

The R^2 values of the LPL standard curves were all >0.9996 over the working concentration range (between 32 and 200,000 pM). The precision of the instrument was determined by injecting a standard mix solution six times (n = 6). The average of the relative standard deviation (RSD) values for each LPL was about 1% of the six repeated analyses.

Total Starch LPLs by Multistep Extraction. The 10 major starch LPLs extracted by the second-step extraction of the multistep extraction were quantified using the LC-MS method above and added together as the total starch LPLs. The total starch LPLs (from R01CS−R02CS and R01BS−R02BS, Figure 1) varied between 516 and 675 μg/g for the waxy rice (or glutinous rice, amylose content <2%) and 5733−8139 μg/g for the nonwaxy rice (R03CS−R12BS) (Figure 4b). Our starch LPL results were greater (P < 0.05) than those (~3 mg/g for nonwaxy rice) reported by Choudhury and Juliano[27] but similar to those (4070−8110 μg/g for nonwaxy rice) reported by Morrison et al.[9] Our method could quantify low levels of starch LPLs in waxy rice with <2% amylose content, which is more sensitive than the TLC-GC method used by Morrison et al.[9] The lower starch LPL values for the nonwaxy rice reported by Choudhury and Juliano[27] may be due to the limitation of column chromatography (CC) and gravimetric method used at that time. However, the difference may be also due to the nature of the samples themselves, as different rice samples have been used in this study.

Total starch LPLs were well correlated with apparent amylose content (P < 0.001) when waxy and nonwaxy rice samples were considered together (Figure 4c), similar to the finding reported by Morrison et al.[9] However, this correlation did not exist when the nonwaxy rice was considered alone. The correlation between total LPLs and amylose content has been found in other waxy and nonwaxy cereal grains, such as barley.[28] This correlation is possibly affected by both varietal and environmental factors in rice.[9] Therefore, such a correlation, if it exists, can be revealed only by investigating a sufficient number of rice samples grown in controlled environments.

Individual Starch LPLs by Multistep Extraction. We found that LPL16:0 is the single most abundant (45.4−63.2%) starch LPL in both waxy and nonwaxy rices, followed by LPC 18:2 (10.5−23.4%) (Table 3), in agreement with Maniñgat and Juliano.[7] Palmitic acid (16:0) (up to ~76%) and linoleic acid (18:2) (up to ~29%) are the two major fatty acids within both starch LPC and LPE. The fatty acids of LPLs in waxy rice were more saturated than those found in nonwaxy rice. Although the minor LPLs in waxy rice, such as LPC 18:3 and LPE 18:1, are below the limit of quantification, their presence can still be clearly identified in the chromatogram.

Table 3. Individual Starch LPL/Total Starch LPLs in Waxy and Nonwaxy Rice[a]

individual LPL[b]	% of total LPLs in waxy rice	% of total LPLs in nonwaxy rice
LPC 18:3	n/a[c]	0.2−0.7
LPC 18:2	10.5−15.0	14.7−23.4
LPC 18:1	5.9−7.1	4.9−12.7
LPC 14:0	5.6−11.6	3.1−7.6
LPC 16:0	56.5−63.2	45.4−53.4
LPE 18:3	n/a	0−0.1
LPE 18:2	0.6−0.9	3.6−5.9
LPE 18:1	0−0.3	0.7−1.9
LPE 14:0	0.1−0.6	0.4−1.0
LPE 16:0	9.1−12.3	8.8−13.3

[a]The data are obtained from ball-milled samples with multistep extraction for the starch LPLs. [b]LPL codes are the same as in Table 2. [c]Lower than quantification limit.

The percentage of individual LPLs can sometimes vary by almost 4-fold between different rice genotypes. For example, LPC 14:0 varied from 3.1 to 11.6% among the rice accessions analyzed (Table 3). As reported by Chang et al.,[14] the individual LPL differences observed in this study may be caused by the combination of varietal and environmental effects. To unravel how environmental variation contributes to the rice starch LPLs, growing environments should be studied at different stages of rice development.

Increased Sample Throughput with the Single-Step Extraction Method. The 10 major starch LPLs extracted by the single-step extraction were quantified using the LC-MS method above and added together as the total LPLs in rice. ANOVA analysis indicated that extraction methods had a significant effect on total LPLs (P < 0.001). In most cases, total LPLs were slightly higher in the single-step extraction than total starch LPLs in the multistep extraction (Figure 4b). This difference is possibly due to the minimal amount of nonstarch LPLs in rice,[10] which represented only <1% of starch LPLs in our study and were included in the total LPLs by the single-step extraction but not included for the total starch LPLs by the multistep extraction. However, the difference may be also due to loss through the extended multistep extraction.

To analyze a large number of samples for genetic and metabolomics studies, reducing the time for a single sample preparation is paramount. The multistep extraction method (6 samples in triplicate for 2 days) takes about 6−8 times longer compared to the single-step extraction (24 samples in triplicate for 1 day) for each sample prepared. The simplification from multistep to single-step extraction can significantly reduce the sample preparation time as well as the risk of human error in removing and combining supernatants. As the total LPLs are almost the same as total starch LPLs, we recommend the single-step extraction method for screening large numbers of samples followed by a multistep extraction of samples of particular interest identified by the initial screening.

This is the first report of the determination of starch LPLs in rice using LC-MS. Compared to previous TLC-GC methods, the

LC-MS method developed here is more efficient and sensitive and can simultaneously quantify individual LPLs. The comparison of grinding methods indicates that ball or cyclone mills are equally effective for determination of total starch LPLs. The rapid single-step extraction method significantly simplifies sample preparation, improves consistency, and increases throughput for lower cost. The combination of efficient extraction and LC-MS method for the first time provides an opportunity to analyze starch LPLs within extensive collections of rice grain samples and should contribute to unravelling genetic and environmental contributions to variation in starch LPLs and may also help to improve the understanding of the effects of starch LPLs on rice grain quality. Starch LPLs in other cereal grains may be also determined using this strategy, and this should be further explored for grain research and development.

studies focused primarily on the changes in fatty acid composition, but rarely report complete fatty acid composition of TAG and phospholipid (PL) species.[19] Composition of TAG and PL species in conjunction with fatty acid composition of CLA-rich egg yolks would provide a more complete description of the deposition and the nutritional significance of CLA-rich soy oil in poultry diets.

Rapid matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF-MS) characterization methods have been used to qualitatively determine fatty acid composition of specific lipids, such as TAG and PL, in crude samples. Yolk lipids have a combination of TAG and PL, but direct MALDI-TOF-MS biased the detection of PL species over TAG.[22] Decreased TAG detection is a result of suppression by phosphatidylcholine (PC).[20−22] Fuchs et al.[23] reported an alternative method that couples thin-layer chromatography (TLC) with MALDI-TOF-MS to avoid suppression of other lipid classes by PC. However, this method only described the egg yolk PL and disregarded the detection of the more abundant TAG. Emerson et al.[24] addressed suppression by applying solid-phase extraction (SPE) to separate TAG and PL species from beef and yolk lipid samples that could be then be analyzed by direct MALDI-TOF-MS analysis. However, analytical replications using this approach were found to be extremely difficult due to inherent heterogeneity in matrix crystallization in the MALDI MS preparation.

Direct flow infusion electrospray ionization MS (DFI ESI-MS) is an alternative method that has been used for PL and TAG lipid identification and characterization. However, only free fatty acids and small PL molecules are analyzed, while major TAG species remain undetected.[25] Also, lipids that have different molecular elemental compositions may actually yield ions with the same ionic elemental compositions, depending on the ionic adduct that is formed upon ESI-MS. To solve this problem, Fhaner et al.[25] dissolved a lipid extract mixture of various PLs and TAGs in a Folch solvent system modified with 20 mM ammonium formate to enable ESI-MS identification and quantification of each PL and TAG species. This technique decreased molecular species containing sodium ions in the crude lipid extract and lessened the possibility of isobaric mass overlap. Combining lipid profiling analysis using direct flow infusion ESI/MALDI MS along with fatty acid methyl esters (FAMEs) will provide a thorough description of the effect of CLA-rich soy oil on the lipid composition in egg yolks.

Eggs enriched with 140 mg of CLA per egg were produced at The University of Arkansas Poultry Farm using CLA-rich soy oil in a standard commercial hen diet and subsequently used in the following study. The goal of this study was to quantify differences in the fatty acid and lipid composition in CLA-rich eggs relative to control eggs. Fatty acid compositions were determined using FAMEs by gas chromatography with flame ionization detection (GC-FID). FAME studies by GC-FID were carried out directly from total lipid extracts and also from individual classes of lipids separated by TLC to estimate fatty acid composition differences. Lipid extracts were analyzed by direct MALDI-TOF-MS, DFI ESI-MS, and TLC-UV-MALDI-MS to obtain fatty acid composition using the intact lipid form.

In summary the objectives of the investigation were to (1) determine the fatty acid composition of total lipids in CLA-rich egg yolks relative to control eggs; (2) quantify the CLA content in TAG and PL fractions of CLA-rich egg yolks; and (3) compare TAG and PL species in CLA-rich egg yolks and control yolks.

MATERIALS AND METHODS

Materials. Control eggs were produced by adding 10% (wt) refined, bleached, deodorized (RBD) soy oil to a standard commercial diet for six commercial white leghorn hens, 25 weeks old. (Riceland Foods, Stuttgart, AR). CLA-rich eggs were produced by adding 10% (wt) CLA-rich soy oil to a standard commercial feed for six additional commercial leghorns. The CLA oil contained 15% CLA. Diets were prepared by combining oil and feed in a Hobart stand mixer and mixing at speed level 2 for 5 min (Hobart Legacy HL-200). CLA-rich eggs were collected after 12 days of treatment administration. CLA feeding was approved by the University's Institutional Animal Care and Use Committee.

All solvents used for sample preparation were analytical grade, and solvents used for TLC-UV-MALDI-MS, direct MALDI-MS, and DFI ESI-MS were HPLC grade. The PL standards, including PC, phophatidyl ethanolamine (PE), lyso-phosphatidyl choline (LPC), and sphingomyelin (SM), were purchased from Cayman Chemical Co (Ann Arbor, MI). The FAME standards used were purchased from Supelco (Bellefonte, PA). Primuline dye was purchased from Sigma−Aldrich (cat. no. 206865-1G, St. Louis, MO).

Methods. *Fatty Acid Composition of Total Lipids. Yolk Lipid Extractions.* Nine eggs were randomly collected from each of the CLA-rich eggs and control eggs. Three eggs from each egg type were pooled. This was performed three times to produce triplicate pooled samples. Eggs were carefully broken, and a stainless steel yolk separator was used to separate the egg yolks for each replicate. Yolks were combined in 50 mL plastic centrifuge tubes and vortexed for 3 min to homogenize the pooled samples.

Lipids were extracted using a rapid hexane/isopropanol (IPA) solvent extraction protocol.[26] Duplicate 5 g samples from each yolk replicate were dissolved in 10 times hexane/IPA (1:1, v/v), vortexed for 5 min, and filtered using Whatman #4 filter paper; the solvent was evaporated using a rotoevaporator (Buchi Rotavapor R-210). The extract was weighed, and the yield was recorded. These extracts were used to determine the yolk total fatty acid composition, the fatty acid composition of individual lipid classes, and the lipid composition.

Fatty Acid Analysis from Total Lipids by GC-FID. FAMEs were prepared from all yolk extractions using a rapid, micro FAMEs preparation method.[27] Samples of 0.1 g were weighed (Mettler Toledo Classic AB204-S) in 50 mL centrifuge tubes. A 1% heptadecanoic acid methyl ester (HME, C17:0; Sigma−Aldrich) solution in hexane was prepared. HME equivalent to 5% of the extract weight was added to each centrifuge tube as an internal standard. A 1 mL amount of toluene and 4 mL of 0.5 M sodium methoxide in methanol were added to each tube. The tubes were heated to 50 °C in a water bath for 10 min and then cooled at ambient temperature for 5 min. To inhibit sodium hydroxide formation, 0.2 mL of glacial acetic acid was added to each centrifuge tube. FAMEs were efficiently extracted in to hexane by a solvent-extraction procedure. The tubes were vortexed for 2 min and then placed on the benchtop for phase separation. The upper hexane layer was pipetted out and dried over anhydrous sodium sulfate for 15−20 s. Fatty acid profiles were obtained by measuring FAMEs in duplicate by GC using an SP 2560 fused silica capillary column (100 m × 0.25 mm i.d. × 0.2 μm film thickness; Supelco Inc., Bellefonte, PA) with FID (model 3800, Varian, Walnut Creek, CA). Samples of 2.0 μL were injected by an auto sampler (Varian). The GC-FID settings were as follows: oven temperature, 250 °C; sensitivity, 12; He gas, 30 mL/min; H_2, 31 mL/min; air, 296 mL/min; and oven program time, 111 min. Fatty acid concentrations were calculated by the following equation:

$$[\%\text{fatty acid}] = ([\text{HME}] \times \text{sample peak area} \times \text{relative response factor})/\text{HME peak area}$$

dx.doi.org/10.1021/jf501100y | J. Agric. Food Chem. 2014, 62, 6608−6615

Statistical analysis was performed using JMP 10.1 software. Relative percentages of fatty acids were analyzed using a studentized t test (α level = 0.05).

Fatty Acid Composition of TAG and PL Fractions. TLC-FAMEs-GC-FID. Lipids were fractionated from yolk extraction samples using 20 cm × 20 cm TLC silica plates (T_{254}, Merck, Darmstadt, Germany). Samples of 0.3 g (±0.005) were dissolved in 100 μL and applied to a TLC plate as 20 μL aliquots, carefully to prevent smearing. Four TLC plates were placed into a closed chamber with chloroform, ethanol, water, and triethylamine (5:5:1:5) for approximately 2 h to perform chromatographic separation of all lipid classes. After separation, the TLC plates were allowed to dry under the hood. Then, one of the TLC plates was sprayed with 0.05% Primuline dye to visualize individual classes using Gel Logic GL2200 (Carestream Health, Inc., Rochester, NY).[28] Once the locations of the TAG and PL on the TLC were determined, on the basis of the Primuline spray, TAG and PL fractions were scraped into separate 50 mL disposable centrifuge tubes, and the lipid extracts were converted to FAMEs using the method described above.[26] Autosampler injection volume was increased to 8.0 μL to account for the lower sample concentration. Statistical analysis was performed using JMP 10.1 software. Relative percentages of fatty acids among egg yolk types were analyzed using a studentized t test (α level = 0.05).

Intact Lipid Composition. TLC-UV-MALDI-MS Analysis Determination of TAG and PL Species. Triplicate pooled samples from all three egg types plus a standard TAG and PL solution with a concentration of 50 mg/mL in $CHCl_3$ were applied to a TLC plate (TLC Silica Gel 60 5 cm × 7.5 cm, T_{254}, Merck, Darmstadt, Germany) as 1 μL droplets to avoid smearing during the TLC loading. The mass of the dried sample loaded onto a TLC plate did not exceed 80 μg. TLC plates were developed using chloroform, ethanol, water, and triethylamine (5:5:1:5) for 45 min. After the separation was completed, the TLC plate was allowed to dry under the hood. An airbrush sprayer attached to a high-purity nitrogen tank was used to homogeneously coat the entire TLC plate with a 0.05% Primuline dye solution.[28] The dye allowed visualization and quantification of lipid classes on the TLC plate using UV excitation followed by monitoring 535 nm emission using Gel Logic GL2200.

A separate TLC plate developed simultaneously with plates for UV analysis, as described above, was used for direct TLC-MALDI-MS analysis. An airbrush sprayer attached to a nitrogen tank was used to homogeneously coat the entire TLC plate with a MALDI-MS matrix aerosol (10 mL of 100 mg/mL DHB in acetonitrile/water, 4:1 v/v). After complete drying, the plate was fitted to a 5 × 7.5 MALDI TLC plate holder. The TLC plate was imaged by an Ultraflex II MALDI-TOF/TOF with a 200 Hz smart beam laser in the reflector mode. The extraction voltage was set to 25 kV, and matrix suppression was set to m/z < 200. Data were acquired using FlexControl (FC 3.0) and FlexImaging 2.0 software under Compass 1.2 settings. A pixel raster of 600 μm × 600 μm spots was set during the imaging run on the entire TLC lane area. For each pixel, 200 laser shots were accumulated. Certain colors were assigned based on the m/z to each lipid, and the spatial distribution of lipids across the TLC plate was extracted from the MALDI-MS total ion count and displayed as a heat map. The data were processed using Bruker FlexImaging 2.0, Flex Analysis 2.4/3.0, and ClinProTools 2.2 software. Lipid species were identified by submitting both low- and high-resolution monoisotopic m/z peaks, and the fatty acid composition information, was obtained from FAMEs analysis to the www.lipidmaps.org database.

Direct Infusion ESI-MS and Direct MALDI-MS Quantification of Major TAG and PL Species. A Bruker Esquire 2000 (Billerica, MA) LC ion trap mass spectrometer (Bruker, Daltonics Corp., Germany) was used to acquire all the mass spectra in this study. Triplicate pooled lipid extracts from each egg type were dissolved in chloroform to reach a final concentration of 50 mg/mL. A 5 μL amount of lipid extract was mixed with 200 μL of IPA/MeOH/$CHCl_3$ (4:2:1, v/v/v) containing 20 mM ammonium formate.[26] A 5 μL sample was directly infused into the ESI source for MS analysis using a syringe. The mass spectrometer was scanned from 400 to 1500 Da at a spectral averaging rate of 10 s^{-1} with low skimmer voltage optimized for ions at m/z 800. The mass spectrometer was operated in both positive and negative ion modes with a nebulizing gas pressure (N_2) of 12 psi and a drying gas flow of 7 mL/min maintained at 150 °C. The spectra data were analyzed by Bruker Daltonics Data Analysis 3.0 software (Bruker Daltonik GmbH, Germany). Statistical analysis was performed using JMP 10.1 software. Relative percentages of lipid species among egg types were compared using a studentized t test (α level = 0.05).

RESULTS AND DISCUSSION

Fatty Acid Composition of Total Lipids. *Fatty Acid Analysis from Total Lipids by GC-FID.* Extractions resulted in a total lipid content of 34.7 ± 0.05% per volume of yolk with no significant difference in egg type. Table 1 shows the fatty acid composition of the control and CLA-rich egg yolk lipid extracts. Administration of the CLA-rich diet resulted in 2.02 ± 0.08% CLA of total fatty acids, equating to 120 mg of CLA in the egg yolk. Myristic, palmitic, and stearic acid concentrations, all saturated fatty acids (SFAs), were significantly higher in CLA-rich eggs, relative to the control eggs (p < 0.001). Palmitoleic and oleic acid concentrations were significantly lowered in CLA-rich eggs. These changes in SFA and monounsaturated fatty acid (MUFA) concentrations in response to dietary CLA have been reported multiple times.[12−17] Linoleic and linolenic acid, both 18 carbon polyunsaturated fatty acids (PUFAs), were significantly higher in CLA-rich eggs. This increase corresponds to the increased linoleic and linolenic acid amounts in the CLA-rich diet. Eicosenoic acid concentration was significantly higher in control yolks (p < 0.001).

Table 1. Fatty Acid Composition of Yolk Lipids from Control and CLA-Rich Eggs[a]

fatty acid	control yolk fatty acid (% FA)	CLA-rich yolk fatty acid (% FA)
myristic acid (C14:0)	0.33 ± 0.00b	0.39 ± 0.03a
palmitic acid (C16:0)	24.46 ± 0.09b	26.21 ± 1.17a
palmitoleic acid (C16:1)	1.33 ± 0.05a	0.84 ± 0.09b
stearic acid (C18:0)	10.36 ± 0.05b	14.50 ± 1.16a
oleic acid (C18:1)	32.49 ± 0.49b	27.32 ± 1.22b
linoleic acid (C18:2)	24.27 ± 0.61b	26.24 ± 0.90a
linolenic acid (C18:3)	0.72 ± 0.03b	0.93 ± 0.09a
CLA (C18:2 *c*-9,*t*-11)	0.00	0.13 ± 0.01a
CLA (C18:2 *t*-9,*c*-11 and *c*-10,*t*-12)	0.00	0.34 ± 0.01a
CLA (C18:2 *t*-10,*c*-12)	0.00	0.31 ± 0.02a
CLA (C18:3 other isomer)	0.00	0.08 ± 0.00a
CLA (C18:2 *t*,*t*)	0.00	1.17 ± 0.02a
total CLA	0.00	2.02 ± 0.02a
eicosenoic acid (C20:1)	1.69 ± 0.05a	1.57 ± 0.08b
eicosatrienoic acid (C20:3)	0.18 ± 0.00a	0.17 ± 0.00a
arachidonic acid (C20:4)	1.27 ± 0.05a	1.01 ± 0.03b
docosahexaenoic acid (C22:6)	0.72 ± 0.01a	0.53 ± 0.10b

[a]Values are expressed as % of total fatty acids in crude lipid extracts. Values in the same row with the same letter are not significantly different (α level = 0.05).

Figure 1 shows the fatty acid type composition for each treatment yolk. CLA-rich eggs contain 43.1% SFA, which is significantly higher than control eggs at 36.0% SFA (p < 0.001). The PUFA concentrations in CLA-rich yolk was also significantly lower in comparison to both commercial egg types (p < 0.001). The CLA-rich yolk MUFA concentration was 31.5%, which was significantly lower than both commercial egg types (p < 0.001). The PUFA concentration was highest in

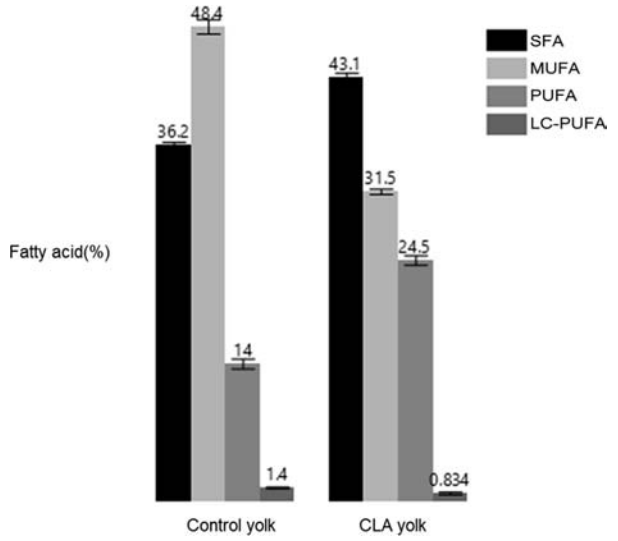

Figure 1. Total fatty acid composition of yolk lipids from control eggs and CLA-rich eggs. Fatty acids are grouped by degree of unsaturation: saturated fatty acid (SFA), monounsaturated fatty acid (MUFA), polyunsaturated fatty acids (PUFA), long-chain polyunsaturated fatty acid (LC-PUFA). Error bars are one standard error from the mean.

CLA-rich yolks at 24.5%, while control eggs contained 14.0%. Long-chain PUFA (LC-PUFA) concentrations were highest in control yolks at 1.4% while CLA-rich yolks contained only 0.8%.

Fatty Acid Composition of TAG and PL Fractions. *TLC-FAMEs-GC-FID.* Table 2 shows the fatty acid composition of the TAG fraction of the control and CLA-rich yolks. Yolk lipids are generally composed of 62% TAG, 33% PL, and 5% cholesterol.[29] The TAG fraction CLA content was 0.9% of the total fatty acids. The relative proportions of CLA isomers in TAG reflected total lipid CLA isomers. CLA TAG had significantly more myristic, palmitic, and stearic acid, relative to control TAG fractions ($p < 0.001$). Control yolk TAG had the highest concentration of C24:0 at 3%, which was significantly higher than CLA-rich yolk TAG.

Table 2. TAG Fatty Acid Composition of Control and CLA-Rich Yolks[a]

fatty acid	control yolk TAG fatty acid (%)	CLA-rich yolk TAG fatty acid (%)
myristic acid (C14:0)	0.21 ± 0.01b	0.49 ± 0.07a
palmitic acid (C16:0)	23.15 ± 1.62b	32.07 ± 1.22a
palmitoleic acid (C16:1)	1.61 ± 0.08b	1.1 ± 0.08c
stearic acid (C18:0)	11.09 ± 1.04b	14.3 ± 0.49a
oleic acid (C18:1)	43.23 ± 1.02a	34.2 ± 0.96b
linoleic acid (C18:2)	13.42 ± 2.12b	16.06 ± 0.04b
linolenic acid (C18:3)	0.33 ± 0.06b	0.46 ± 0.01b
CLA (C18:2 *c*-9,*t*-11)	0	0.18 ± 0.01a
CLA (C18:2 *t*-9,*c*-11 and *c*-10,*t*-12)	0	0.12 ± 0.02a
CLA (C18:2 *t*-10,*c*-12)	0	0.14 ± 0.02a
CLA (C18:2 *t*,*t*)	0	0.41 ± 0.07a
total CLA	0	0.86 ± 0.11a
eicosenoic acid (C20:1)	0.10 ± 0.04a	0.15 ± 0.01a
eicosatrienoic acid (C20:3)	0.1 ± 0.03a	0.06 ± 0.01a
arachidonic acid (C20:4)	0.42 ± 0.04a	0.16 ± 0.01b
tetracosanoic acid (C24:0)	3.23 ± 0.18a	0.08 ± 0.004b
docosahexaenoic acid (C22:6)	3.1 ± 0.79a	0.02 ± 0.002b

[a]Values are expressed as % of total fatty acids. Values in the same row with the same letter are not significantly different (α level = 0.05).

Figure 2 presents TAG fatty acid concentration for control and CLA-rich yolks, grouped by degree of unsaturation. The relative proportions of fatty acid groups closely resemble what was seen in the total lipid fatty acid composition. SFA concentration in CLA-rich yolk TAG was 46.9%, which was significantly higher than the control commercial yolk at 37.7%. CLA-rich yolk TAG had a significantly lower MUFA concentration at 35.4%, while control yolk TAG had 45%. Regular eggs yolks contained the highest levels of LC-PUFA in TAG at 3.6%, relative to CLA-rich yolk at 0.2%.

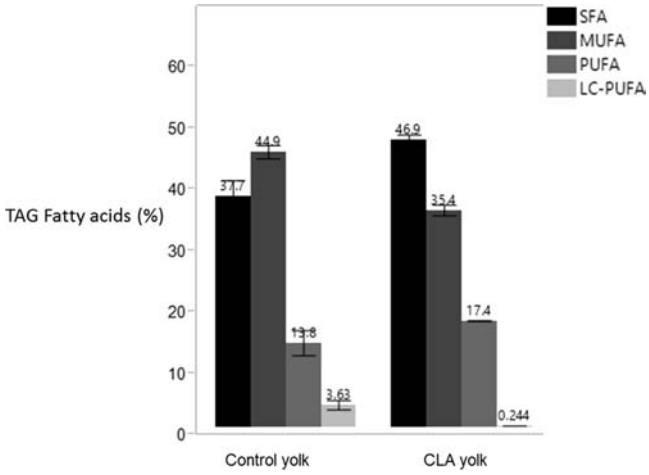

Figure 2. Triacylglycerol (TAG) fatty acid composition of yolk lipids from control and CLA-rich yolks. Fatty acids are grouped by degree of unsaturation: saturated fatty acid (SFA), monounsaturated fatty acids (MUFA), polyunsaturated fatty acids (PUFA), and long-chain polyunsaturated fatty acids (LC-PUFA). Error bars are one standard error from the mean.

Table 3 shows the fatty acid composition of the PL fraction of control and CLA-rich yolks. Yolk lipids contained approximately 33% PL.[29] The CLA contained in the PL fraction was 1.7% of the total fatty acids. CLA-rich yolk PL contained 20% stearic acid, which is significantly higher than control yolk PL at 16%. However, CLA-rich and control PL had no other significant differences in individual fatty acid concentrations.

Figure 3 depicts the PL fatty acid concentration for control and CLA-rich yolks, grouped by degree of unsaturation. CLA-rich yolk PL total SFA concentration was 45.8%, significantly higher than control yolk PL at 42.6%. Control yolk PL had significantly less SFA. The amount of MUFA in control regular yolk PL is surprisingly higher in control eggs at 59%.

Intact Lipid Composition. *TLC-UV-MALDI MS Analysis Determination of TAG and PL Species.* Figure 4 depicts the separation and visualization of lipid classes by TLC-UV, including LPC, SM, PC, PI, PE and total TAG, which were validated by TLC-MALDI imaging mass spectrometry (image not shown), identifying 2 LPC species, 1 SM species, 17 PC species, 19 TAG species, and 9 PE species (Table 4) based on observed m/z values. PI species had relatively low ion intensities in positive ion mode as expected due to its ability to easily form a negative ion rather than a positive ion under the MALDI positive reflector mode analysis and could not be

eicosatrienoic acid (C20:3)	0.13 ± 0.01b	0.54 ± 0.13a
arachidonic acid (C20:4)	0.9 ± 0.04b	4.94 ± 1.58a
tetracosanoic acid (C24:0)	0.31 ± 0.02b	1.61 ± 0.52a
docosahexaenoic acid (C22:6)	0.21 ± 0.01c	1.73 ± 0.59b

[a]Values are expressed as % of total fatty acids. Values in the same row with the same letter are not significantly different (α level = 0.05).

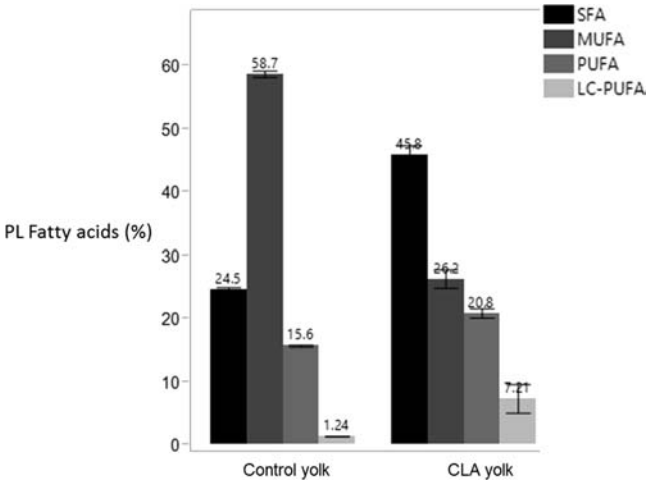

Figure 3. Phospholipid (PL) fatty acid composition of control commercial egg yolk, CLA-rich yolk, and omega-3 commercial yolk. Fatty acids are grouped by degree of unsaturation: saturated fatty acid (SFA), monounsaturated fatty acids (MUFA), polyunsaturated fatty acids (PUFA), and long-chain polyunsaturated fatty acids (LC-PUFA). Error bars are one standard error from the mean.

identified. We did not see overall changes in lipids in CLA-rich egg yolk compared to both commercial eggs.

Direct Infusion ESI-MS and Direct MALDI MS Quantification of Major TAG and PL Species. Both direct infusion ESI-MS and direct MALDI MS results lead to similar conclusions. Figure 5 shows representative average spectra for yolk lipid extracts. In the direct MALDI-TOF-MS spectra, TAG were not detected due to PC suppression.[22] When the lipid samples were fractionated by SPE before MALDI MS analysis, PL species intensities were much greater than TAG, although TAG are the more abundant in egg yolk lipids. ESI-MS resulted in a spectra of both TAG and PL species with an intensity ratio that was representative of the TAG and PL abundances. Direct flow Infusion ESI-MS in general had less peak intensity variation

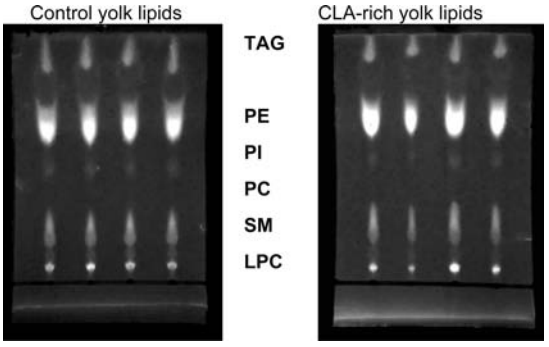

Figure 4. Lipid species separations from three yolk types: control regular commercial yolk, CLA-rich yolk, and omega-3 commercial yolk. These images were developed from the primuline sprayed TLCs as described in the Methods section.

leading to lower standard deviation in estimating relative composition. Therefore, we used only the DFI ESI-MS data to calculate yolk lipid relative composition, shown in Table 4.

Lysophosphatidylcholine and Sphingomyelin. LPC 16:0 and LPC 18:0 were significantly higher in CLA-rich yolks, relative to both controls ($p < 0.001$). Higher C16:0 and C18:0 levels were observed in CLA-rich yolk PL fractions, reported in Table 3. SM intensities were highest in control egg yolks ($p < 0.001$).

Phosphatidylcholine Species. ESI-MS relatively quantified 13 PC species in the positive ion mode and 4 additional species in the negative ion mode. CLA-rich yolks had significantly higher PC C34:2, which contains linoleic and palmitic fatty acid chains. Palmitic and linoleic acid concentrations were higher in the CLA PL fraction, which explains this higher intensity. The PC C34:1 levels were not significantly different among CLA-rich and control yolks. This is despite the fact that oleic acid concentrations were significantly lower in CLA yolks. The PC C34:0 was highest in control yolk. This species was expected to be at higher concentrations in CLA due to the elevated SFA levels seen in the PL fatty acid profiles (Figure 3), but this was not the case. PC C36:4 contains two linoleic acid chains, and PC C36:3 and C36:2 both contain one. It was not surprising that these three species were at highest concentration in CLA-rich yolks, in response to the elevated total linoleic acid levels in the CLA-rich soy oil. The C36:2 concentration was even more elevated in CLA-rich yolks due to increased stearic, linoleic, and possibly CLA concentrations observed in the PL fraction. PC C36:1 had two possible species identifications, one containing C16:0 and C20:1 chains and the other containing C18:0 and C18:1. By using the FAMEs profiles for the PL fractions, it seems that the control yolk C36:1 contains only C18:0 and C18:1, while CLA-rich yolks have elevated C16:0 and C20:1 levels and could contain a mixture of both species. There were no significant differences between PC C38:6 and C38:5 among yolk types ($p = 0.3$). There were two PC species containing one docosahexaenoic acid chain. PC38:6 was identified in both positive and negative ion modes.

Triacylglycerols. CLA-rich yolk contained elevated levels of all TAG species containing only SFA (C48:0, C50:0, C52:0, and C54:0). This again coincides with the elevated saturated fat concentrations observed in CLA-rich yolks. A substantial amount of variation was found between species with 52 carbon chains. C52:5 and C52:4 were elevated in CLA-rich yolks. By using FAMEs data with the www.lipidmaps.org mass spectra analysis tool, C52:5 and C52:4 were identified differently for

Table 4. Lipid Species Identified by TLC-MALDI MS and Intensities Quantified by ESI-MS, Including LPC, SM, PC, TAGs, and PE[a]

[a]Values in the same row with the same letter are not significantly different ($P = 0.05$). Lipid species with m/z (−) indicates species was detected in negative ion mode. Values in the same row with the same letter are not significantly different (α level = 0.05).

control eggs than for CLA eggs. CLA yolks contain a C52:5 TAG species that has a linoleic, linolenic, and palmitic acid chains, while control yolks have a species that has myristic, oleic, and arachidonic acid chains. It is likely that all three yolks have both isobaric mass species, and the database indicated the most probable species based on the FAMEs for each yolk type. The three fatty acids identified in C52:5 were all present at elevated levels in CLA yolks. The same rationale holds for the difference in C52:4 identifications for the three egg types. The C52:4 species contains two linoleic acid chains coupled with a palmitic chain. CLA-rich yolks contained the highest amount of this particular species, and it is a likely candidate for CLA incorporation. This species was also significantly higher in CLA-rich yolks, but this species more likely contains two linoleic acid chains and one oleic chain. The increased prevalence of this species in CLA-rich yolks also indicates a potential candidate for CLA incorporation. Other TAG species containing one, two, or three oleic chains were significantly lower in CLA-rich yolk lipids (C54:4, C54:3, C54:2, C54:1) compared to control yolks.

Phosphatidylethanolamine Species. All PE species were detected in the negative ion mode ESI-MS. CLA-rich yolks had significantly lower C36:1, C38:6, C38:5, and C38:4 compared to control commercial yolk PE. There were no significant difference in any of the PE species abundances between both commercial egg types.

In summary, the CLA rich eggs with 120 mg of CLA had significantly more SFAs and less MUFAs than did the control eggs. Comparable findings have been previously reported,[12−18] but this study provided a comprehensive overview of intact lipid species and determined differences among CLA and commercially available eggs. The separated TAG fatty acid compositions of all three yolk types were similar to their respective total fatty acid composition. In CLA-rich yolks, 50% of the CLA was in the TAG and located predominately in species C52:5 and C52:4. Other TAG species containing linoleic acid were not at elevated levels. The PL fatty acid composition was not significantly different among egg types. All PC species containing one or two linoleic acid chains were most abundant in CLA-rich yolks. CLA-rich yolks contained more LPC than did the controls. Although CLA and control yolks did not show differences in total PE, CLA did lower the amount of certain PE species relative to the control eggs.

The TAG and total PL fractions contain similar amounts of CLA. A previous study using a commercially available CLA source reported preferential CLA incorporation in the TAG

dx.doi.org/10.1021/jf501100y | J. Agric. Food Chem. 2014, 62, 6608−6615

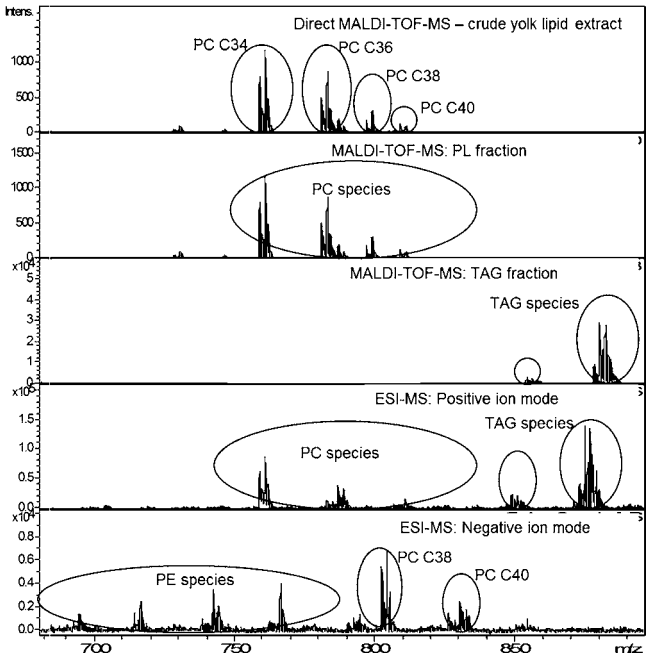

Figure 5. CLA-rich egg yolk lipid extract spectra resulting from different MS analysis. In direct MALDI-TOF-MS, the presence of PC suppressed TAG peaks. Fractionating the PL and TAG eliminated suppression. ESI-MS in positive ion mode allowed quantification of TAG and PC species, while negative ion mode allowed quantification of PE.

fraction versus PC and PE CLA content.[19] Their method of lipid species fractionation did not enable them to ensure complete separation without possible contamination. TLC allowed complete separation and collection of species without any overlap. TAG fractions contained more SFAs and less PUFAs than did the control egg yolks. CLA incorporation showed increased LPC concentration and modified the total PL composition. Although the yolk fatty acid composition is substantially different as a result of CLA incorporation, the relative composition of the lipid classes are maintained. Describing egg yolk lipids by both fatty acid analysis and molecular species analysis may help characterize the functional properties of different lipid species in egg nutrition studies.

Interest in egg yolk PC production for pharmaceutical applications has increased due to their high levels at 33% of total yolk lipids. This study illustrated that CLA-enriched PLs and TAGs are produced through feed modification and may be isolated for further nutraceutical uses. This extensive yolk lipid profiling described how CLA incorporation affected other lipid species in the yolk. Providing the most comprehensive egg lipid profile to date may offer insight in further physiological and nutritional studies on CLA-rich and other designer eggs.

of winter wheat grain due to an enriched atmospheric CO_2 concentration.

Therefore, the aim of the present study was to get more detailed information on the structural composition of the protein fractions prolamin and glutelin of winter wheat, winter barley and maize grains cultivated using the FACE technique. Osborne fractionation was performed to isolate the single protein fractions followed by proving the purity by SDS-PAGE. To characterize prolamins and glutelins in detail a size exclusion high performance liquid chromatography (SE-HPLC) method was developed. In addition, kernels were observed by scanning electron microscopy (SEM) to study differences in protein-starch bodies. These investigations should also explain the observed variations in digestibility of crude protein. The study intended to assess the potential impact of a future atmospheric CO_2 concentration expected by 2050 on the protein composition and quality of these important animal feedstuffs.

MATERIAL AND METHODS

Materials. The experiment with winter wheat and barley was conducted on a 22 ha experimental field site and the investigation on maize was performed on a 10 ha field site located at the experimental station of the Friedrich Loeffler Institute (FLI), Federal Research Institute for Animal Health, Braunschweig, Germany. A FACE system engineered by Brookhaven National Laboratory and previously described by Weigel and Manderscheid[7] with experimental rings of 20 m in diameter was used to study CO_2 enrichment effects on maize cv. Romario (silage maize), winter wheat cv. Batis (one of most frequently cultivated bread wheat varieties in Germany) and barley cv. Theresa (one of most frequently cultivated barley varieties in Germany) as well as the influence of N fertilization of winter wheat and barley. Therefore, two (barley and wheat) or three (maize) of the FACE rings were treated with blowers with air of ambient CO_2 concentration (AMBI, 380 ppm atmospheric CO_2) and the other two (barley and wheat) or three (maize) with blowers with CO_2 enriched air (FACE, 550 ppm atmospheric CO_2). The FACE rings were placed exactly at the same position in each growing season.

For winter wheat and barley, two different N fertilization levels were applied in each half of the rings to study interactions between CO_2 enrichment and N supply. One was an adequate N fertilization (N100) for each crop species and one was a reduced fertilization with 50% (N50) of the adequate N treatment as it was described by Weigel and Manderscheid.[22] For both crops the space between the two fertilization levels was set to approximately 1 m.

Varieties of all three cereals were chosen because of their general reliable yield forecasts. For analytical use, kernels of winter wheat and winter barley of the two cultivation seasons and kernels of maize cultivar were predried, milled at 1 mm and stored at −20 °C.

Protein Extraction. A modified Osborne fractionation according to Wieser et al.[23] was performed to separate the protein fractions of all three cultivars. 0.5 g milled (1 mm) flour was extracted two times with 0.5 mol L^{-1} sodium chloride (NaCl, ≥ 99%, Ph.Eur., USP, Carl Roth GmbH Co., Karlsruhe, Germany) for 10 min at room temperature (RT ∼ 23 °C).

Supernatant (albumins/globulins) was dialyzed (ZelluTrans, regenerated Cellulose Tubular Membrane, 6000−8000 Da, 1.67 mL/cm, Carl Roth GmbH Co., Karlsruhe, Germany) against water to separate both protein fractions in water - soluble albumins and water insoluble globulins.

Precipitate (prolamins/glutelins) was extracted twice with 70% ethanol (EtOH, Rotipuran, ≥ 99.8%, p.a., Carl Roth GmbH Co., Karlsruhe, Germany) for 30 min at RT. The supernatant consisted of EtOH-soluble prolamins. Precipitate was extracted twice with a solvent of 50% 1-propanol containing 1% dithiothreitol (DTT), 0.05 M tris-HCl, and 2 M urea (all chemicals at least ≥99%, p.a. quality, Carl Roth GmbH Co., Karlsruhe, Germany) for 20 min at 60 °C.

Each extraction step was initiated by vortexing until complete mixing and continued by vortexing at 600 rpm (MS1 minishaker, JKA Works Ic., Wilmington, NC, U.S.A.). All separations of supernatants and precipitates were performed by centrifugation for 10 min at 3000 rpm (Varifuge 3.OR, Heraus Sepatech, Osterode, Germany). All supernatants were dried to constant mass at 60 °C by centrifugal evaporator (Christ RVC 2-18HCL, Osterode, Germany).

SDS-PAGE. Isolated protein fractions were treated with 7 mM SDS (>99%, Carl Roth GmbH Co., Karlsruhe, Germany) and 200 mM DTT prior to separation in 4−20% Mini-PROTEAN TGX gels (Bio−Rad, Hercules, CA, U.S.A.) using a modified method of Laemmli.[24] Proteins were completely dissociated by boiling the samples at 95 °C for 5 min. Electrophoresis was carried out at 50 V for 30 min followed by 200 V for 1 h until the tracking dye, bromophenol blue (ACS, Carl Roth GmbH Co., Karlsruhe, Germany), had reached the bottom of the gel. Molecular weight markers were Roti-Mark 10−150 and Roti-Mark PRESTAINED (Carl Roth GmbH Co., Karlsruhe, Germany) to identify the individual protein groups on the gel. After electrophoresis, gels were stained in a Coomassie brilliant blue G-250 (Carl Roth GmbH Co., Karlsruhe, Germany) solution overnight and destained in water−methanol−pure acetic acid (40/10/50, v/v/v).

SE-HPLC. SE-HPLC was performed by using a Shimadzu instrument (liquid chromatograph, LC-20AT; autosampler, SIL-20AC; column oven, CTO-10ASvp; diode array detector, SPD-M20A) and a Yarra 3 μ SEC-2000 column (300 × 7.8 mm, Phenomenex; Torrance, CA) with guard cartridges (Phenomenex; Torrance, CA). Data was collected and analyzed using the CLASS-VP-6.14 SP2A software (Shimadzu). Mobile phases (50 mM phosphate buffer containing 0.1% SDS) were prepared by mixing a 50 mM disodium hydrogen phosphate dihydrate solution and a 50 mM sodium dihydrogen phosphate monohydrate solution according to Henderson−Hasselbalch equation for required pH values of 6.60 (A) and 6.94 (B).

Gliadin (from wheat, Sigma, Steinheim, Germany) and glutenin standards (Osborne fractionation of gluten, from wheat, Sigma, Steinheim, Germany) as well as grain protein samples (concentration: 2−35 mg mL^{-1}) were weighed and dissolved in mobile phase B by using an ultrasonic bath (FB15051, Fischer Scientific, Singen, Germany). Standards and samples were filtered (syringe filters, 0.45 μm, PVDF, anchor GmbH) before injection (50 μL). The measurements were performed at 25 °C with a flow rate of 0.7 mL/min and a gradient of mobile phase (0 min 100% B, 16 min 0% B, 22 min 100% B for re-equilibration). The monitoring wavelength was 214 nm with a run time of 30 min. Calibration and evaluation of logarithm scale with the standard proteins bovine serum albumin, ovalbumin, myoglobin, and cytochrome c were carried out to determine the sizes of the single protein subfractions.

SEM. For scanning electron micrographs of milled kernels of all three cultivars, an environmental SEM (EVO LS25, Carl Zeiss SMT GmbH, Oberkochen, Germany) was used. The voltage of the electron beam was 8.0 kV and a secondary electron detector was used. In preparation, kernels were fractured at ambient temperature at 1 mm.

Statistics. Data were evaluated by analysis of variance (ANOVA) after testing for normal distribution and variance homogeneity using the Kolmogorov−Smirnov test and the Bartlett-χ-square test, respectively. A complete 3-factorial design of ANOVA was used to evaluate the results for wheat and barley with the cultivation year (2000 and 2003), the CO_2 level (AMBI and FACE), the N-fertilization level (50 and 100% of adequate N-supply) and the corresponding interactions being the fixed factors. For evaluating the maize results the CO_2 level was the only fixed factor. Significance was assumed at $p < 0.05$ and STATISTICA for Windows Operating System (Version 10.0., StatSoft, Inc., 2011) was used for statistical evaluations.[25]

RESULTS

Protein Extraction and SDS-PAGE. The relative amounts of the single protein fractions were obtained by gravimetric analysis after Osborne fractionation. Tables 1−3 summarizes the effect of different N fertilization, CO_2 treatment and crop growing year on the percentages of the four fractions of winter barley, wheat, and maize.

Albumins, total glutelins and hordeins, the prolamin fraction of winter barley (Table 1) did not show any variations in contrast to globulins which increased significantly from about 19 to 24% in 2000 and from about 12 to 20% in 2003 under elevated CO_2. Additionally, the crop growing conditions of the different years also led to varied globulin contents.

Significant influences of the crop growing year for all four fractions of winter wheat could be demonstrated (Table 2). The relative amount of albumins and globulins increased significantly from approximately 12−30% and 10−14% in 2002 to about 38−42% and 38−44% in 2005, whereas the percentages of gliadins, the prolamin fraction of wheat, and glutenins, wheat glutelin fraction, decreased strongly by 5−10% within these years. Moreover, globulins were significantly reduced by about 2 or 3% at a higher N supply.

Table 3 and Figure 1 summarize the effects of an atmospheric CO_2 enrichment on maize. All fractions, except albumins showed significant changes. The content of globulins decreased significantly from 12 to 5% under elevated atmospheric CO_2 concentration. Zein, the prolamin fraction of maize, and glutelins were strongly increased due to a higher CO_2 supply. Both fractions rose by 14 and 18%, respectively.

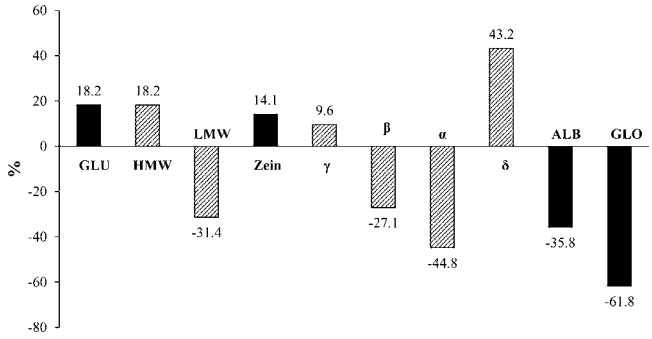

Figure 1. Relative percentage changes of the amounts of protein fractions and subfractions of maize grains by elevated CO_2 (FACE) compared with ambient CO_2 (AMBI), abbreviations see Table 3.

After Osborne fractionation, SDS-PAGE was done to prove the purity of the isolated protein fractions. All four fractions showed their typical lanes in the gel. For example, wheat grain prolamins were recognized at a molecular weight of 27 000−35 000 (α-, β-, and γ-gliadins) and at 37 000−52 000 (ω1,2- and ω5-gliadins). Glutelin subfractions were analyzed at a molecular weight of 32000−35000 (LMW subunits), at 60000−88000 (x-type HMW subunits) and at 96 000 to 120 000 (y-type HMW subunits).

SE-HPLC. Validation of the developed SE-HPLC method resulted in a relative standard deviation (RSD) of not more than 4.1% for repeatability and 13.9% for day-to-day precision of standard glutenin. The limit of quantitation (LOQ) with a signal-to-noise ratio (S/N) of 10 amounted to 308 μg/mL. Standard gliadin showed a RSD of maximum 6.4% for repeatability and 14.8% for day-to-day precision. LOQ was 164 μg/mL.

Prolamin and glutelin fractions of all three analyzed cultivars could be separated with the same developed method. Chromatograms of winter wheat gliadin and glutenin are shown exemplary in Figure 2 and 3. The main subfractions could be clearly separated. The relative amounts and the statistical results of these subfractions are also summarized in Tables 1−3 for the respective cultivar.

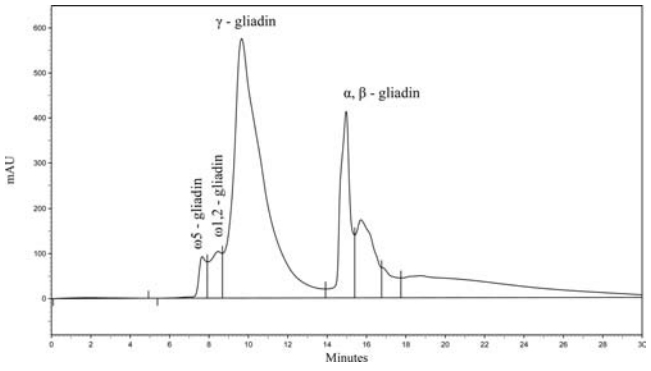

Figure 2. SE-HPLC chromatogram of the prolamin fraction of winter wheat.

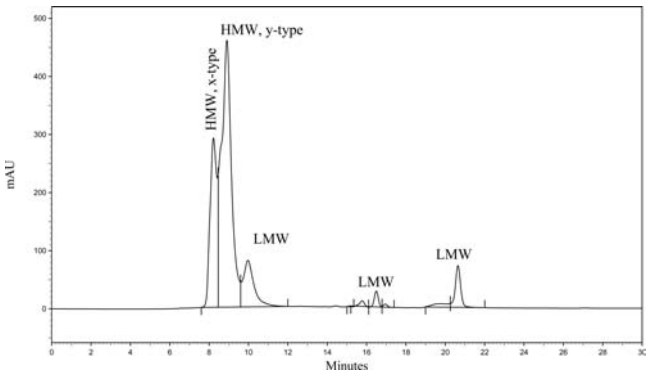

Figure 3. SE-HPLC chromatogram of the glutelin fraction of winter wheat.

Different crop growing years had a strong influence on the content of all winter barley hordein and glutelin polymers, except for γ-hordein (Table 1). A significant decrease of D- and C-hordein and LMW polymer as well as a strong increase of B-hordein and HMW polymer from 2000 to 2003 is stated. An enriched atmospheric CO_2 concentration induced a considerable increase of B-hordein in a range from 1 to 11%. Comparing the different N fertilization levels, the relative amounts of D-hordein, γ-hordein, and HMW polymers rose strongly and B-hordein and LMW polymers declined significantly from N50 to N100.

Table 2 summarizes the relative amounts of gliadin and glutenin subfractions of winter wheat. Comparing the growing years 2002 and 2005, the content of ω1,2- and α/β-gliadins increased by about 3 and 10%. In contrast, the relative amount of γ-gliadin decreased strongly by approximately 8% from 2002 to 2005. A higher N fertilization indicated a significant decline of ω5-gliadin and LMW subunits and a significant increase of y-HMW subunits. Depending on the growing year, N supply and CO_2 treatment, the content of y-HMW subunits rose from AMBI to FACE by about 2% at N100 in 2002 and by 6% in 2005. Furthermore, an increase from FACE to AMBI by 3% at N50 in 2002 and by 2 in 2005 was observed. A comparable effect of year, N supply and CO_2 interaction was observed in x-HMW subunits. For example, their amount was increased by 30% from FACE, N100 to FACE, N50 in 2002.

The percentages and the changes of zein and glutelin subfractions of maize are given in Table 3 and Figure 1. Both, HMW and LMW polymers as well as α- and δ-zeins were strongly affected by atmospheric CO_2 concentration. The contents of HMW polymers and δ-zein were significantly enhanced from 64 to 76% and from 19 to 27% under elevated CO_2 supply. In contrast, LMW polymers and α-zein were considerably reduced by more than 30%.

Protein−Starch Bodies Observed by SEM. Scanning electron micrographs of barley, wheat, and maize grown under different CO_2 treatments showed some marked differences. Barley grown under AMBI conditions (Figure 4a) showed some small agglomerates of proteins at starch granules. Starch granules of barley treated with elevated CO_2 were more intensively covered with this protein matrix (Figure 4b, note smaller scale compared to part a). In Figure 5, the starch bodies of winter wheat kernels of both CO_2 treatments are adjacent to densely packed protein bodies and no obvious differences between both treatments could be observed. The most pronounced differences were found for maize. Starch granules of AMBI maize kernels were relatively free of adherent protein material and only some granules were tightly covered with this (described by arrows in the figure), whereas protein bodies of FACE maize grains were densely wrapped with starch (Figure 6).

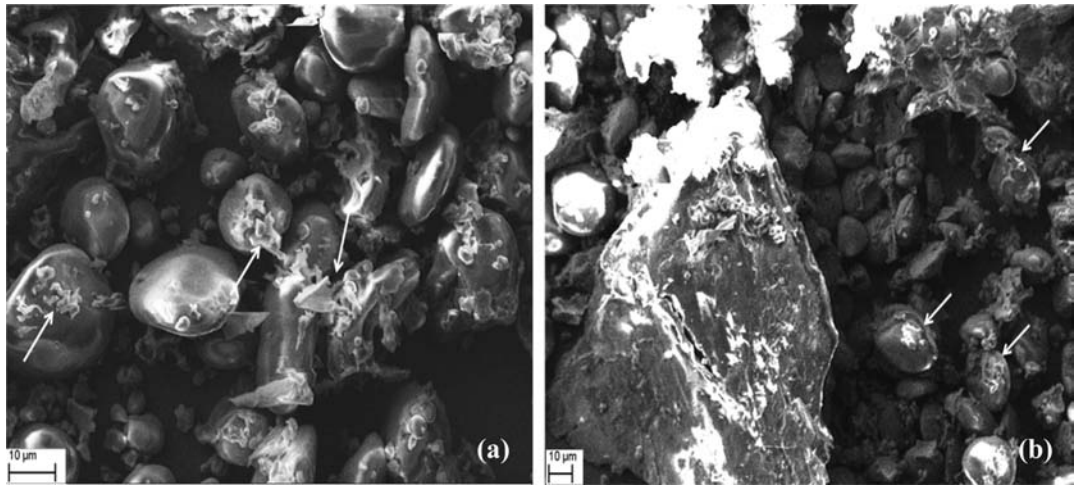

Figure 4. Scanning electron micrographs of winter barley grain cultivated under ambient (a) and elevated (b) atmospheric CO_2 concentration, some typical protein bodies are arrowed.

DISCUSSION

The present study investigated the effects of different CO_2 and N treatment on the content and composition of proteins in winter wheat and barley of two different crop growing years. Furthermore, influences of elevated CO_2 concentration were studied on maize proteins.

The effect of N fertilization on wheat crude protein and albumin content is in agreement with previous studies,[15,21,26,27] showing an increase of crude protein due to a higher N supply and a small influence on albumins. Investigations of Wieser and Seilmeier[28] and Wieser et al.[21] on the relative amounts of all wheat gluten subfractions indicated an increase at a higher N supply. Furthermore, Shewry et al.[17] found that the protein composition in barley grains was influenced by the N level in soil. A higher N fertilization increased the total gluten protein content in barley grains. The present results partly support these observations. The subfractions of wheat glutenin were significantly influenced, except for x-HMW glutenin subunits. The LMW glutenin subunits showed a significant decrease, and y-HMW glutenin subunits are strongly increased under a higher N fertilization level (Table 2). In general, LMW glutenin subunits within the total glutenin fraction are low and the proportion of HMW subunits is high. Total glutenin consists predominately of LMW glutenin subunits and HMW glutenin subunits belong to the minor components of the gluten proteins.[19] Wieser[15] found in his studies approximately twice as many LMW subunits as HMW subunits. In contrast, a contrary result of both subfractions was described in the present study. Possibly, there was not a clear separation of HMW and LMW glutenin subunits in the SE-HPLC analysis or some high molecular weight gliadins could be as a residue in glutenin Osborne fraction. The gliadin subfractions were not significantly affected by a higher N supply, only ω5-gliadin decreased (Table 2). The total gluten content in barley was not affected by N fertilization in the present study, but most of its subfractions were influenced significantly (Table 1). In contrast to the already mentioned literature, Wang et al.[29] described only small differences in the content of all protein main fractions, which is in agreement with the results of this study. Consequently, differences in percentage composition of the protein fractions seem to depend on the cultivar itself and on the N supply level.[30,31] Moreover, it is stated that the response of single protein fractions to agronomic factors such as sowing date and application time varied with the type of protein fraction and with genotype.[29] The quality of grains is often affected by the crop growing year and the cultivars itself, where the growing season significantly influences wet gluten content and rheological properties and different cultivars

dx.doi.org/10.1021/jf501958a | J. Agric. Food Chem. 2014, 62, 6616−6625

showed variations in quality parameters. These differences were based on genetic specificity according to expression of quality characteristics and cultivar reaction to environmental factors. Especially the quality parameters and environmental factors have impacts on prolamins and glutelins from ripening to maturity.[31] Therefore, methods for mass spectrometry and 2-D electrophoreses were developed to identify the gluten proteins in detail and to construct databases including cultivar specific gluten protein sequences. On this basis, several authors[32−34] documented changes of individual proteins of different cultivars by proteome maps resulting from applications of mineral nutrients or/and different air temperatures. Hurkman et al.[32] described an alteration of individual gliadin and glutenin accumulation profiles of wheat cv. Butte 86 during grain development due to higher temperature and a variation in the fertilizer regime. They found that both high temperature and fertilizer will increase the proportions of most HMW subunits and ω-gliadins and some of the α-gliadins while the proportions of LMW subunits and few γ-gliadins will decrease. In addition, Altenbach et al.[33] analyzed an increase in the ratio of HMW to LMW subunits and of gliadins to glutenins in experiments with a postanthesis fertilizer in wheat cv. Butte 86. According to the results of the present study, the ratio of gliadins/glutenins of winter wheat did not show any significant influences of N fertilization level, CO_2 enrichment, or environment. All ratios were in the same range whereas the ratio of HMW/LMW subunits significantly rose with an increased N supply in the present study. Additionally, an environmental effect was observed in winter barley, where the HMW/LMW polymer ratio differed significantly due to the crop growing year and different N fertilizer level. Both zein to glutelin and HMW to LMW polymer ratios were strongly affected by the different atmospheric CO_2 concentrations of maize. The zein/glutelin ratio decreased from 1.83 to 0.60 and the HMW/LMW polymer ratio increased from 1.77 to 3.05 in the present study.

Environmental conditions, such as precipitation or global radiation can also influence the proportion and amount of proteins in the developing kernel. The decrease in crude protein, albumins, globulins, and glutelins and the increase of prolamins in winter wheat and barley within the two growing years may be related to a diversity in climate conditions, for example higher precipitation in 2002 or a stronger global radiation in 2005.[22] Dupont et al.[34] also described the influence of variations in air temperature on the protein composition of wheat cv. Butte 86. The study was done under controlled environments, a moderate regime (24 °C at day/17 °C at night) and a high temperature regime (37 °C at day/28 °C at night) in combination with postanthesis mineral supply. They analyzed increased protein content under moderate temperatures with mineral supply. Increases in the content of ω-gliadins and HMW glutenin subunits and a decrease in LMW glutenin subunits were analyzed. In contrast, the high temperature regime had only little effects on the protein composition due to mineral supply. Several other authors[27,35,36] stated that kernel growth is directly influenced by soil N and air temperature. Therefore, it can be summed up that N supply could directly increase grain protein content especially monomeric gliadins, but this effect may differ between cultivars. Moreover, heat or drought could increase the protein content in combination with a reducing yield because of their effects on starch production.[34] As there are no relevant changes of the grain weight of wheat[37] (e.g., in 2002: AMBI/N100, 40.6 mg; AMBI/N50, 40.7 mg; FACE/N100, 42.7 mg; FACE/N50, 42.4 mg) and barley[38] (e.g., in 2000: AMBI/N100, 44.4 mg; AMBI/N50, 42.3 mg; FACE/N100, 45.8 mg; FACE/N50, 43.2 mg) no dilution effects caused by an enhanced starch production are expected. However, the grain weight of maize was significantly increased from 255 mg to 273 mg due to an elevated atmospheric CO_2 concentration.[35] Therefore, differences between zein and α-zein were not significantly influenced with increased CO_2. However, all other protein fractions and subfractions showed strong variations. A dilution caused by increased starch content could be denied.

The elevated atmospheric CO_2 concentration resulted in a decrease of crude protein content of barley (Table 1) and wheat grain (Table 2), but in a constant concentration in maize grain (Table 3), which correlates with several previous studies.[26,39−41] Moreover, the results of the present study revealed changes in the proportion of the different protein fractions and subfractions of barley and maize grain caused by CO_2 enrichment. Prolamins of barley are rich in proline and glutamine.[18] Wroblewitz et al.[40] showed a decrease of the relative amounts of proline and glutamine of barley which could explain the reduced C-hordein fraction, which consists of approximately 40% glutamine.[42] Hence, a direct correlation between the CO_2 effect on specific protein fractions and their glutamine content might be deduced.

Assessing the observed effects, an impact on the nutritional value may be possible. Akin et al.[43] investigated effects of an elevated atmospheric CO_2 concentration on the digestibility of nutrients. They found that the in vitro digestibility of young leaf blades of wheat grown under elevated CO_2 concentration tended to be higher than of plants cultivated under ambient CO_2. This was accompanied by a loss of crude protein and an increase of fiber fractions under elevated CO_2. An influence on the digestibility and degradability of maize grain, cultivated at different atmospheric CO_2 concentrations was also studied by Wroblewitz et al.[20] They observed an increased crude protein digestibility in broiler chicken trails and a lowered degradability of FACE maize grain proteins in in sacco studies. The decreased degradability could be caused by differences in the protein fractions albumin, globulin, zein, glutelin, and their subfractions. Also, differences in the stage of maturity could affect the structure and consequently the degradability of proteins.[44] During maturation the percentage of zein rose from about 5 to 35% and the distribution of albumin and globulin changed.[45] Therefore, analyses regarding the composition and amounts of globulins, albumins, zein, and glutelin could help to interpret variations in protein digestibility and ruminal degradability.

In addition, a change in amino acid composition of winter wheat and barley as described by Wroblewitz et al.[40] could also hint at a shift in the protein fractions and subfractions, as suggested by the present results, with consequences for digestibility and degradability. For evaluating the nutritional value, a look on the limiting amino acids lysine, methionine, threonine and tryptophan is necessary. A decrease of them could result in malnutrition of monogastric livestock when not counterbalanced.[10] The sulfur-containing amino acids such as methionine and other essential amino acids, especially lysine, are mostly represented in the metabolic proteins, albumins, and globulins. Storage proteins (prolamins and glutelins), which are primarily responsible for many aspects of grain quality[46] are rich in glutamine and proline. Hence, a higher digestibility and better nutritional value could be expected with enhanced globulin content as it was found in the present study for barley.

Moreover, structural differences of protein-starch bodies could affect the digestibility and degradability of cereal grain due to physicochemical constellations hampering the accessibility of digestive enzymes. McAllister et al.[47] described a

relationship between kernel hardness and affinity between starch and protein. Increased kernel hardness was correlated with a higher degree of association between both components.[48] In addition, a high correlation of protein-starch bodies and digestive properties in the rumen was stated. By increasing hardness the concentrations of zein increase and glutelin decrease. Zein limits the accessibility of the starch granules to ruminal microbes.[44] The structure of the protein-starch body seems to be responsible for differences in ruminal degradability of maize grains.[47] The present study could show differences in the starch−protein structure of barely and maize, which could be caused by the variation of protein fractions and subfractions. Hence, an impact on digestibility and degradability parameters is possible. As it is shown in the study of Wroblewitz et al.,[20] the crude protein degradability of FACE maize grain is significantly reduced. This could be affected by an increased kernel hardness and consequently by a shift in zein and glutelin fractions which was confirmed by the present SE-HPLC analysis. However, the changes in the starch−protein structure and, as a result, in kernel hardness were not distinct enough to influence starch degradability.

The reported changes in protein composition and quality of cereal grains under elevated CO_2 concentration could result in a necessity of dietary counterbalancing with other protein compounds and/or pure amino acids to meet the required nutrients for an adequate human and animal nutrition.

Beside influences on digestibility and degradability, differences in the protein composition could also affect bread making quality and malt quality. The rheological behavior of dough depends on the amounts and proportions of gluten protein fractions and subfractions, which are responsible for crumb structure and bread volume.[21] One of the most important characteristics for baking quality is the bread volume, which has been shown to be strongly correlated with crude protein content, total gluten proteins and glutenin macropolymers.[11] Numerous studies have shown that differences in amounts and proportions of gluten protein fractions and subfractions have significant effects on dough properties.[21,49] All of these parameters were significantly reduced by CO_2 enrichment in the present investigation. The present study also examined variations in the proportion of gliadins and glutenin subfractions due to crop growing year, N supply and significantly reduced crude protein content. Thus, a decrease in bread volume and a negative effect on wheat grain quality could be expected. However, only a single wheat cultivar was examined in one site. To get a more knowledge of expected reductions in relevant grain proteins, it is necessary to perform studies at diverse sites and with more cultivars.

Barley is used for malting and subsequently for the production of beer. According to Wang et al.[29] the protein concentration in barley grains is negatively correlated with malt extract and viscosity and malt quality is influenced by different N applications. Several authors[29,50,51] described a great effect of N fertilization level on the protein content and the protein fractions. Howard et al.[50] compared the hordein composition and the malt quality of three barley cultivars grown at five N regimes in each of two years. They determined a great variation in grain protein contents, malt extract values and in the proportions of the B-, C- and D-hordeins, whereas D-hordein partly varied over a 10-fold range. Moreover, they stated that the total protein displayed a strong, negative correlation with malt extract. D-hordein showed the most negative correlation with malt extract, which was independent of cultivar. Therefore, they declared that the measurement of D-hordein offers an option for the prediction of malting quality over a wide range of environmental conditions and cultivars. Molina-Cano et al.[51] showed that regional trends affect the negative correlation between malt extract yield and barley protein content from different varieties. In general, a trend decreasing malt extract yield with rising protein content was observed. In the present study, a wide variation of the hordein subfractions, especially D-hordein, and crude protein content due to environmental differences, such as the N supply, was observed. These results indicate the importance of adopting suitable N supply regimes that are specific for individual malting barley varieties to improve resulting malt quality. Furthermore, these observations could also indicate an influence of CO_2 supply on malt quality.

The current investigation demonstrated clearly that an elevated atmospheric CO_2 concentration and reduced N supply will alter the protein composition and hence the grain quality and nutritional value of wheat, barley, and maize. The protein fractions globulins and B-hordeins of barley were significantly enhanced due to an elevated atmospheric CO_2 concentration. Under same CO_2 enrichment, the protein fractions zein, δ-zein, maize glutenin, and its HMW polymers were also significantly increased, whereas globulins, α-zein, and maize LMW polymers were extensively decreased. A reduced N fertilization level affected mostly the prolamin subfractions of winter barley and wheat. D- and γ-hordein of barley significantly declined and B-hordein increased at a reduced N fertilizer level. In wheat, ω5-gliadin was significantly enhanced at reduced N supply. An influence of other crop growing conditions could be proved by analyzing barley and wheat grains of two different growing years. The present study shows that the developed SE-HPLC method is a quite rapid and cheap tool to characterize proteins and changes in protein composition. It could help to draw conclusions on variations in the composition of amino acids, on the protein quality and consequently on the nutritional value. Supplementations of proteins or amino acids on feedstuff would need a respective adjustment in the future. The present study only investigated one cultivar of each cereal. To get more information on the reaction of different cultivars on the factors such as crop growing year, N fertilization, and atmospheric CO_2 concentration, additional investigations would be interesting. This method builds a basis for further studies to explain whether other genotypes as well as high quality grain will react in the same way. Whether additional N supply to the soil may compensate the CO_2 effects and reshift the equilibrium of C- and N-providing resources remains open and is critical for economic as well as ecological reasons.

Instrumentation. An Agilent 1260 HPLC (Santa Clara, CA) was used for all chromatographic analyses. The HPLC system consisted of a model G1311B pump and degasser, G1329B autosampler, G1315C DAD/UV−vis detector, G1316A column heater, and a system controller. Data were processed using ChemStation for LC 3D systems, version B.04.03.

Samples and Sample Preparation. Tannins from grape (pre-veraison Cabernet Sauvignon berry skin tissue) as well as wine (2010 and 2012 Cabernet Sauvignon) were used for standard additions and thermodynamic standards. Extraction, purification, and separation into different molecular mass fractions were accomplished using a previously described procedure.[26] The resultant tannin fractions used in the current study have been previously characterized.[9] Whenever powdered tannin standards were dissolved in solution, solutions were subsequently allowed to equilibrate for at least 24 h before use. This allowed for stable thermodynamic measurements to be obtained.

Wines used for analysis were sourced from either various wineries within California or a wine merchant in the case of the Bordeaux. Wines were sterile-filtered with 13 mm, 0.45 μm polytetrafluoroethylene (PTFE) filters (Grace Davison Discovery Sciences, Waukegan, IL) before injection. For 2012 and 2013 wines, analyses took place approximately 4 months after pressing. For all other wines, only vintage information was available.

Phloroglucinolysis for the Mean Degree of Polymerization (mDP) Determination. Phloroglucinolysis, according to the method by Kennedy and Jones,[27] using a modified HPLC method,[26] was used to determine mDP of isolated tannins.

Serial Dilutions. To determine the impact of tannin concentration on tannin stickiness, high and low average molecular mass wine tannin fractions (mDP of 15.4 and 2.9, respectively), previously shown to vary in their retention thermodynamics (ΔH = −12 088 and −2328 J/mol, respectively[9]), were dissolved (10 g/L) in an aqueous buffer solution (pH 4.6) containing methanol (15%, v/v), 40 mM sodium acetate, and 20 mM HCl and were serially diluted with this buffer, to 0.31 g/L. Solutions were analyzed using the optimized HPLC method. In addition to serially diluted tannin samples, a wine (2012 California north coast Cabernet Sauvignon press wine) was serially diluted 5 times with the same aqueous buffer solution prior to analysis (experiment conducted 10 months after pressing).

Standard Additions. Purified wine tannin fractions varying in enthalpy of interaction were added to a 2012 California north coast Petit Verdot wine to examine their impact on wine stickiness. Low-molecular-weight (mDP = 2.9) and high-molecular-weight (mDP = 22.7) tannins were added in half, equivalent, and double the experimentally measured tannin concentration of the wine.

Gelatin Fining. Fining experiments were carried out using Inocolle Extra N1 gelatin (15 000 MM, Scott Laboratories, Petaluma, CA). Gelatin (20 mg) was rehydrated in water (500 mg/L) according to manufacturer guidelines. A total of 2 mg of wine tannin (mDP = 15.4) was rehydrated in an aqueous solution (pH 4.6, 2395 mg/L) containing methanol (15%, v/v), 40 mM sodium acetate, and 20 mM HCl and allowed to equilibrate for 48 h before analysis. After 48 h, the gelatin solution was serially diluted with water from its initial concentration to a minimum concentration of 7.8 mg/L. Gelatin-containing solutions were then mixed with the tannin solution in a 1:1 ratio in microcentrifuge tubes. After mixing, samples were centrifuged at 735*g* for 2 min in an Eppendorf 5415 C centrifuge (Hamburg, Germany) and the supernatant was then analyzed.

Optimized HPLC Method. The optimized HPLC method for measuring tannin stickiness used a polystyrene divinylbenzene reversed-phase column (PLRP-S, 2.1 × 50 mm, 100 Å, 3 μm, Agilent Technologies, Santa Clara, CA) protected with a guard column (PRP-1, 3 × 8 mm, Hamilton Company, Reno, NV).

The mobile phases consisted of 1.5% (w/w) 85% H_3PO_4 in water (153 mM, mobile phase A) and 20% (v/v) mobile phase A in acetonitrile (B) with a flow rate of 0.30 mL/min. The linear gradient was as follows: time in min (% B), 0 (14%), 10.0 (34%), 10.0−13.5 (34%), 15.3 (70%), 15.3−17.0 (70%), and 17.0−20.0 (14%). This method was modified from previously published methods,[9,28] with modifications designed to reduce run time.

To determine tannin stickiness, samples were run at four column temperatures (25−40 °C, in 5 °C increments). A blank sample (water) was run at all temperatures and was subtracted from sample signals to eliminate background absorbance. All temperatures were converted into kelvin to calculate thermodynamic parameters in SI units. Tannin elution was monitored at 280 nm.

Calculations. Chromatograms were integrated as described previously, with minor modifications.[9] Briefly and following baseline subtraction of a water blank, a baseline at 0 mAU across the sample peak area was performed. Following this, the resulting peak area was split at 16.8 min, corresponding to the elution of tannin_P. The tannin eluting prior to 16.8 min was separated from overlapping resolved material by tangent skimming.

From integration results, the alternative retention factor was calculated as follows:

$$k_{alt} = \frac{\text{tannin}_T}{\text{tannin}_T - \text{tannin}_P} \quad (1)$$

where, as previously described,[9] tannin_T is the total tannin peak area and tannin_P is the partial tannin peak area.

The alternative retention factor is related to thermodynamics of interaction according to the following equation:

$$\ln k_{alt} = -\frac{\Delta H^\circ}{RT} + \frac{\Delta S^\circ}{R} + \ln \text{Ø} \quad (2)$$

where ΔH° and ΔS° are the specific enthalpy and entropy of interaction, respectively, R is the gas constant, T is temperature, and Ø is the mobile phase ratio. The specific enthalpy was calculated by plotting the natural logarithm (ln) of k_{alt} versus the reciprocal of the column temperature in kelvin at each of the four temperatures (i.e., van't Hoff plot in Figure 1). The specific enthalpy of interaction (tannin stickiness) was calculated from the slope of the best fit line (slope equivalent to $-\Delta H^\circ/R$).

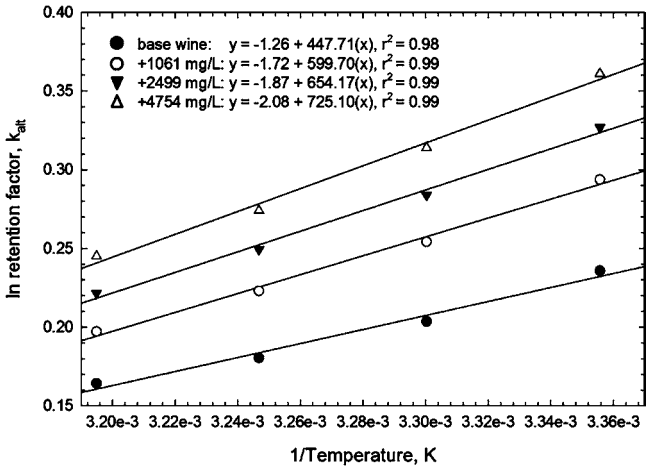

Figure 1. van't Hoff plot of the alternative retention factor (k_{alt}) versus the reciprocal temperature (in K) for the retention of red wine tannins on polystyrene divinylbenzene, following the standard addition of a tannins (mDP = 15.4), with best fit equations shown.

The concentration of tannin (on the basis of tannin_T) was reported in (−)-epicatechin equivalents using an (−)-epicatechin standard and was determined at 303 K (30 °C). In addition to (−)-epicatechin, a grape skin or wine tannin standard (mDP = 39.0 and 15.4, respectively) served as a stickiness standard. Stickiness standards were prepared by dissolving grape skin or wine tannins in an aqueous solution containing methanol (15%, v/v), 40 mM sodium acetate, and 20 mM HCl. Stickiness standards did not vary by more than 10% across all experiments. Given that the variation in experimental results

dx.doi.org/10.1021/jf501666z | J. Agric. Food Chem. 2014, 62, 6626−6631

was less than 5% suggests that the stickiness standards changed over time.

RESULTS AND DISCUSSION

The mouthfeel quality of red wine is an important management consideration, and tannins, which contribute astringency, are central to it. In addition to tannin, the matrix of red wine (e.g., ethanol, residual sugar, and polysaccharides) is known to have an impact on astringency perception. With regard to tannins and in addition to concentration, its composition (e.g., subunit composition, size distribution, pigment incorporation, and oxidation) is considered to affect tannin activity or its stickiness. Stickiness is defined as the observed variation in the enthalpy of interaction between tannin and a hydrophobic surface. In this case, the hydrophobic surface is polystyrene divinylbenzene, and previous studies have found that stickiness variation with the tannin structure is similar to variations observed when using ITC to monitor the tannin interaction with poly-L-proline.[8,9] In contrast to analytical methodology available for measuring the tannin concentration, methodology for the measurement of stickiness is lacking. Stickiness measurements based on the thermodynamics of the tannin interaction with a hydrophobic surface suggest that this analytical approach has utility. The current study was initiated to develop a method for measuring tannin stickiness in red wine by reversed-phase HPLC following direct injection.

250.0	286	23.9	1997	16.7

[a]The initial concentration was adjusted 50% to adjust for 1:1 dilution.

The analytical method that forms the basis of this method has been described previously.[9] In that study, a modified analytical method was used to measure the stickiness of various grape and wine tannins. In the present study, alterations to the HPLC method were made to increase throughput and remove potential baseline interference. To increase throughput, the flow rate was increased to 0.3 mL/min and the number of temperatures monitored was reduced to four. The binary mobile phase gradient remained identical to the previous method but with alterations made to compensate for the increased flow rate. With regard to a reduction in the number of temperature points, the elimination of higher temperatures resulted in a linear van't Hoff plot. Following baseline subtraction, integration, and k_{alt} determination, van't Hoff plots from data collected at 298−313 K had good correlation (Figure 1; r^2 = 0.99). The slope of the line from this relation was used to determine the enthalpy of interaction as described previously.[29] The enthalpy of interaction is referred to as tannin stickiness.

Tannin Stickiness Is an Intensive Property. Unlike the tannin concentration and wine matrix components that change with dilution, compositional variation should not be affected by dilution. Therefore, tannin stickiness, if related to composition/conformation, should be an intensive thermodynamic property. To explore this, solutions of tannin (in wine and wine-like systems) were serially diluted. In addition, a wine was subjected to a standard addition of tannins with varying degrees of stickiness.

With regard to serial dilutions, the stickiness of serially diluted solutions containing high-molecular-weight (mDP = 15.4) and low-molecular-weight (mDP = 2.9) wine tannin fractions was determined. Tannin concentrations in the six serially diluted solutions varied from 10 to 0.31 g/L. The stickiness for the high-molecular-weight samples was −11 928 ± 257 J/mol (±standard deviation, 2.16% error). Similarly, the stickiness for low-molecular-weight tannin solutions was −2261 ± 93 J/mol (±standard deviation, 4.11% error). A 2012 Cabernet Sauvignon press wine, which was serially diluted 5 times, had a stickiness value of −4905 ± 152 J/mol (±standard deviation, 3.10% error).

To provide additional evidence that the value for stickiness was a feature of tannin contained in the sample and not related to the concentration, a 2012 Petit Verdot wine was subjected to the standard addition of two wine tannins varying in stickiness (Figure 2). To the base wine (stickiness = −3894 J/mol) was added two tannins (either −2038 or −7283 J/mol). As expected from the results obtained from serially diluted systems, the experimental results were consistent with calculated results and were a function of the fractional contribution of the base wine tannin and the added tannin. In so far as tannin stickiness is sensorially relevant to wine, these results suggest that the addition of exogenous tannins will modify tannin perception beyond concentration alone. Furthermore, the results from standard addition and serial dilution collectively indicate that the analytical method provided good reproducibility and confirmed that stickiness is an intensive property.

Effect of Wine Production Practice: The Case of Gelatin Fining. The results above indicate that stickiness is a property of tannin and is concentration-independent, and thus, stickiness can be distinguished from the concentration. This

[a]Tannin concentration and stickiness, with stickiness equivalent to the negative enthalpy of interaction. [b]Ranking of the tannin concentration and stickiness, with lower numbers ranked higher in concentration and stickiness. [c]Percent of the highest tannin concentration and stickiness. [d]Region where fruit was produced (CA = California).

method can therefore be used to explore the role of grape and wine production practices on stickiness. Previous studies indicate that tannin size, plant tissue origin (seed versus skin), and wine age will affect stickiness.[8,9] The effects of a myriad of additional factors on stickiness are intriguing candidates for study (e.g., fruit maturity, vine water status, wine microoxygenation, and pigment incorporation). To provide an example of utility, the effect of gelatin fining on the wine tannin concentration and stickiness was explored.

The protein interaction with tannin is considered the basis of astringency and is used for the removal of excess tannin in wine. From previous studies on the interaction of tannins with macromolecules,[30−34] it would be expected that gelatin should preferentially remove larger molecular mass tannins and with potential effects on composition. It would be predicted therefore that as the concentration of tannin declined with gelatin addition, so too would tannin stickiness. To explore this, solutions of serially diluted gelatin were combined with a prepared wine tannin solution (initial stickiness of −11 927 J/

dx.doi.org/10.1021/jf501666z | J. Agric. Food Chem. 2014, 62, 6626−6631

mol). As expected, the results indicated that, as the concentration of tannin declined, so too did its stickiness (Table 1). Previous research has shown that gelatin additions to wines decrease the tannin concentration,[32] but the current result suggests that the strength of the hydrophobic tannin−protein interaction plays an important role in perceived astringency in gelatin-fined wines as well.

Analysis of Wines. To provide some insight into stickiness variation, a set of commercial wines was analyzed. The wines presented in Table 2 were Bordeaux varietals and were sourced from commercial vineyards or a wine shop. Wines varied in age and region. The concentration of tannin and stickiness for the wines varied considerably. A linear regression across the set of wines analyzed yielded a line with a positive slope (e.g., an observed increase in stickiness with the concentration) although with a low correlation (r^2 = 0.24). It is particularly interesting to note that a range of stickiness values is possible at any given tannin concentration. A ranking of wines in order of increasing concentration and stickiness confirmed that varied concentration−stickiness relationships existed. There was a greater variation in the tannin concentration in this set of wines, where the lowest concentration observed was at 26% of the maximum. This is in contrast to the least sticky wine being 44% of the maximum stickiness. It is evident that a much larger data set needs to be gathered, with associated sensory analysis, to understand the extent to which stickiness varies and is relevant to wine production, management, and appreciation.

Implications. Historically, tannin structure−activity relationships in red wine have been limited by our understanding of the tannin structure. Considerable effort has been invested into red wine tannin structure elucidation,[35−37] yet paradoxically, our knowledge as a proportion of material presence remains limited. Added to this, understanding the role that various grape and wine production practices have on sensory properties is often thought to be limited by our understanding of how process affects structure. Finally, understanding activity of tannins has been dependent upon sensory studies. In addition to the complexity of using humans as analytical instruments, wine matrix and tannin concentration often confound sensory evaluation.[38,39] The development of an objective method for measuring tannin activity provides a new avenue for exploring the effect of various processes on activity without first understanding structure and, therefore, has increased our ability to explore process−activity relationships. In addition, this method provides researchers with a method for measuring the effect of known structure variation on activity without the use of human subjects.

To fully understand the new information provided by this analytical method, the relationship between tannin stickiness and sensory perception needs to be investigated. Although data to date are consistent with tannin stickiness being related to anecdotal differences in astringency quality between grape and wine tannins, direct relationships between stickiness and perception need to be explored.

ingredients obtained from natural sources, which can often fully replace potentially dangerous synthetic additives.

MATERIALS AND METHODS

Chemicals. The constituents of plant EOs studied included eugenol (Eug; 4-allyl-2-methoxyphenol), carvacrol (Ca; 5-isopropyl-2-methylphenol), thymol (T; 2-isopropyl-5-methylphenol), borneol (B; endo-(1*S*)-1,7,7-trimethylbicyclo[2.2.1]heptan-2-ol), and eucalyptol (Euc; 1,8-cineole; 1,3,3-trimethyl-2-oxabicyclo[2.2.2]octane). The DNA-damaging agent used was hydrogen peroxide (H_2O_2). Positive controls included gallic acid (GA), ascorbic acid (AA), butylated hydroxytoluene (BHT), quercetin, and ethylenediaminetetraacetic acid disodium salt dihydrate ($Na_2EDTA{\cdot}2H_2O$), and reagents 1,1-diphenyl-2-picrylhydrazyl radical (DPPH), dimethyl sulfoxide (DMSO), cremophor EL, ethidium bromide (EtBr) were obtained from Fluka or Sigma, Sigma-Aldrich Co. (Steinheim, Germany, or St. Louis, MO, USA). *R. officinalis* essential oil (Ph. Eur. 4) was purchased from Calendula Inc., Nova Lubovna, Slovakia (lot 5-014-009-12-06, containing approximately 25% 1,8-cineole, 19% α-pinene, 19% camphor, 17% *p*-cymene, 9% camphene, 5% β-pinene, 2% borneol, and 4% unidentified compounds as specified by the manufacturer). All plant volatiles were kept at room temperature and diluted in appropriate reaction mixtures just before the experiments. William's medium was purchased from PAN-Biotech GmbH (Aidenbach, Germany), fetal bovine serum (FBS) and antibiotics were purchased from GIBCO BRL (Paisley, UK), and phosphate-buffered saline (PBS; Ca^{2+}- and Mg^{2+}-free) was purchased from Oxoid Limited (Basingstoke, UK). All other reagents and chemicals used were of analytical grade.

Reducing Power Assay. The reducing capacities of the plant volatiles were determined according to the method of Zhao et al.[6] In this assay, the yellow color of the test solution is changed to various shades of green and blue, depending on the reducing power of each compound. The presence of reducing agents (i.e., antioxidants) induces the conversion of the Fe^{3+}/ferricyanide complex into the ferrous forms. In brief, different concentrations of selected essential oil components, intact RO, and GA, used as a positive control, were mixed in 1 mL of methanol with 2.5 mL of phosphate buffer (0.2 M, pH 6.6) and 2.5 mL of potassium ferricyanide $[K_3Fe(CN)_6]$ (1%). The mixtures were incubated at 50 °C for 20 min. Trichloroacetic acid (2.5 mL, 10%) was added to each mixture and centrifuged at 3000 rpm for 10 min. Finally, the upper layer of supernatants (2.5 mL) was mixed with 2.5 mL of distilled water and 0.5 mL of $FeCl_3$ (0.1%), and the absorbances were recorded at 700 nm (GENESYS 10 Bio, Spectronic). The higher absorbance of the reaction mixture indicates the higher reducing power.

1,1-Diphenyl-2-picrylhydrazyl Radical Scavenging Activity. Selected plant volatiles were investigated for their radical scavenging activity using a modified DPPH assay.[7] DPPH is a stable free radical. The methanolic solution of this compound is dark purple (absorbs light at a wavelength of 517 nm) at the radical state. When DPPH reacts with an antioxidant, by providing hydrogen atoms or by electron donation, it is reduced to the molecular form, which is yellow. In brief, methanol (100 μL) solution of DPPH radical at the concentration of 0.05 mg/mL was added to 50 μL of various concentrations of plant volatiles or AA, used as a positive control. The experiments were carried out at room temperature. The decrease in absorbance at 500 nm was measured at 0, 15, 30, and 60 min using a spectrophotometer (Multiscanreader RC, Labsystems, Vantaa, Finland), and the DPPH$^{\bullet}$ scavenging activities of plant volatiles were then expressed as percentage of DPPH$^{\bullet}$ scavenging activity using the formula

$$\text{scavenging of DPPH radicals (\%)} = [(A_{\text{control}} - A_{\text{sample}})/A_{\text{control}}] \times 100$$

where A_{control} is the absorbance of the control reaction, containing all reagents except the tested compounds, and A_{sample} is the absorbance of tested compounds. Methanol was used as a blank.

Hydroxyl Radical ($^{\bullet}$OH) Scavenging Activity. For the determination of $^{\bullet}$OH scavenging activity, hydroxyl radicals ($^{\bullet}$OH) were generated in an L-ascorbic acid/$CuSO_4$ system. The assay is based on quantification of cytochrome *c* oxidation.[8] In this experiment, OH radicals were generated in 1 mL of 0.15 mM sodium phosphate buffer (pH 7.4) containing 100 μM L-ascorbic acid, 100 μM $CuSO_4$, 12 μM cytochrome *c*, and the samples of plant volatiles to be tested at different concentrations. The mixture was incubated at 25 °C for 90 min. The change in transmittance caused by the color change of cytochrome *c* was measured at 550 nm using a spectrophotometer (GENESYS 10 Bio, Spectronic). The inhibition of $^{\bullet}$OH generation by 500 μg/mL thiourea was taken as 100%. BHT was used as a positive control. The inhibition ratio was calculated using the formula

$$\text{scavenging of OH radicals (\%)} = [(T - T_2)/(T - T_1)] \times 100$$

where T is the transmittance of the $^{\bullet}$OH generation system and T_1 and T_2 are the transmittances of the control (no $^{\bullet}$OH generation) and test systems, respectively.

DNA Topology Assay. The method of electrophoretically monitored DNA-damaging activity and DNA protectivity was described in detail by Cipak et al.[9] In brief, the reaction mixture (final volume of 10 mL) contained 200 ng of plasmid DNA in buffer and either Fe^{2+} alone, tested compounds alone, or combinations of tested compounds with Fe^{2+}. Specific details of agent concentrations are given in the caption of Figure 6. Single- (ss) and double-strand (ds) DNA breaks were assayed by measuring the conversion of supercoiled DNA, form I, to relaxed forms (II + III, Figure 1).

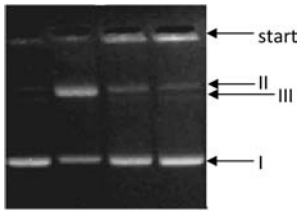

Figure 1. Electrophoretic changes induced in the plasmid DNA by the influence of Fe^{2+} (form I = supercoiled DNA, form II = ssDNA breaks, form III = dsDNA breaks).

Topological changes of DNA molecules correspond with the electrophoretical mobility of DNA topoisomers. Analysis of DNA modifications was made by agarose gel electrophoresis (1.5% agarose, 60 min, 60 V). The DNA was visualized by staining with EtBr (1 mg/mL) and UV illumination (UV Transilluminator MiniBISPro, DNR Bio Imaging Systems Ltd.).

Fe^{2+}-Chelating Activity Assay. Some results obtained by the above-mentioned techniques were verified by Fe^{2+}-chelating activity assay, as one of the mechanisms of antioxidant action is a chelation of transition metals, which prevents decomposition of hydroperoxide and Fenton-type reactions. Fe^{2+}-chelating assay uses an iron reagent, ferrozine, which forms complexes with Fe^{2+}. In the presence of chelating agents, the complex formation is disrupted with the result of color reduction. The chelating activity of borneol and two positive controls (quercetin and $Na_2EDTA{\cdot}2H_2O$) toward ferrous ions was studied by using the method described by Rajic et al.[10]

HepG2 Cell Line and Treatment of Cells. Malignant human hepatoma HepG2 cell line was obtained from Prof. A. R. Collins (University of Oslo, Norway) and cultured in William's medium, supplemented with 10% FBS and antibiotics (penicillin, 200 U/mL; streptomycin and kanamycin, 100 μg/mL). Cells were cultured on plastic Petri dishes at 37 °C in a humidified atmosphere of 5% CO_2.

Eugenol, carvacrol, and eucalyptol were dissolved immediately before use in complete culture medium to final concentrations of 0.05−0.6 (Eug), 0.025−0.2 (Ca), and 0.5−5 (Euc) mM, respectively. Thymol (T) was disolved in DMSO and diluted to final concentrations of 0.1−0.5 mM in complete culture medium. RO was dissolved in cremophor EL and 70 °C William's medium to 1.25%

stock solution and further diluted to final concentrations of 0.00625−0.0625‰ in complete culture medium. Borneol (B) was disolved in ethyl alcohol (500 mM) and diluted to final concentrations of 0.5−3 mM in complete culture medium. Appropriate control cells were kept in complete William's medium with or without the addition of solvents. HepG2 cells were treated for 24 h.

Single-Cell Gel Electrophoresis (SCGE; Comet Assay). Assessment of DNA damage in HepG2 cells was performed by the use of the SCGE (comet assay), which represents a sensitive method for measuring DNA damage at the level of single cells. The method of SCGE according to Singh et al.[11] was followed with minor modifications made by Gabelova et al.[12] In brief, appropriate controls and HepG2 cells preincubated with volatiles for 24 h were trypsinized, centrifuged, and resuspended in 0.75% low melting point agarose in PBS. A volume of 85 μL of the cell suspension (approximately (2−2.5) $\times$ 10^4 cells) was spread on a base layer (100 μL of 1% normal melting point agarose in PBS) on a microscopic slide. When the agarose had solidified, half of the samples (slides) was submerged for 5 min in 250

dx.doi.org/10.1021/jf501006y | J. Agric. Food Chem. 2014, 62, 6632−6639

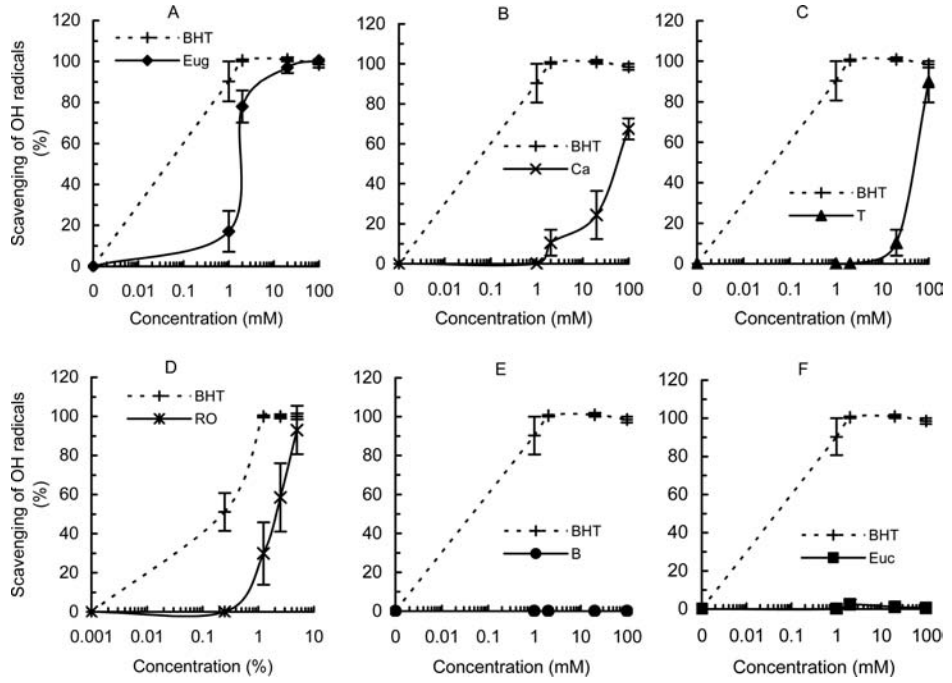

Figure 4. Hydroxyl radicals scavenging activity of eugenol (A), carvacrol (B), thymol (C), *Rosmarinus officinalis* oil (D), borneol (E), and eucalyptol (F). Butylated hydroxytoluene (BHT) is shown as a positive control.

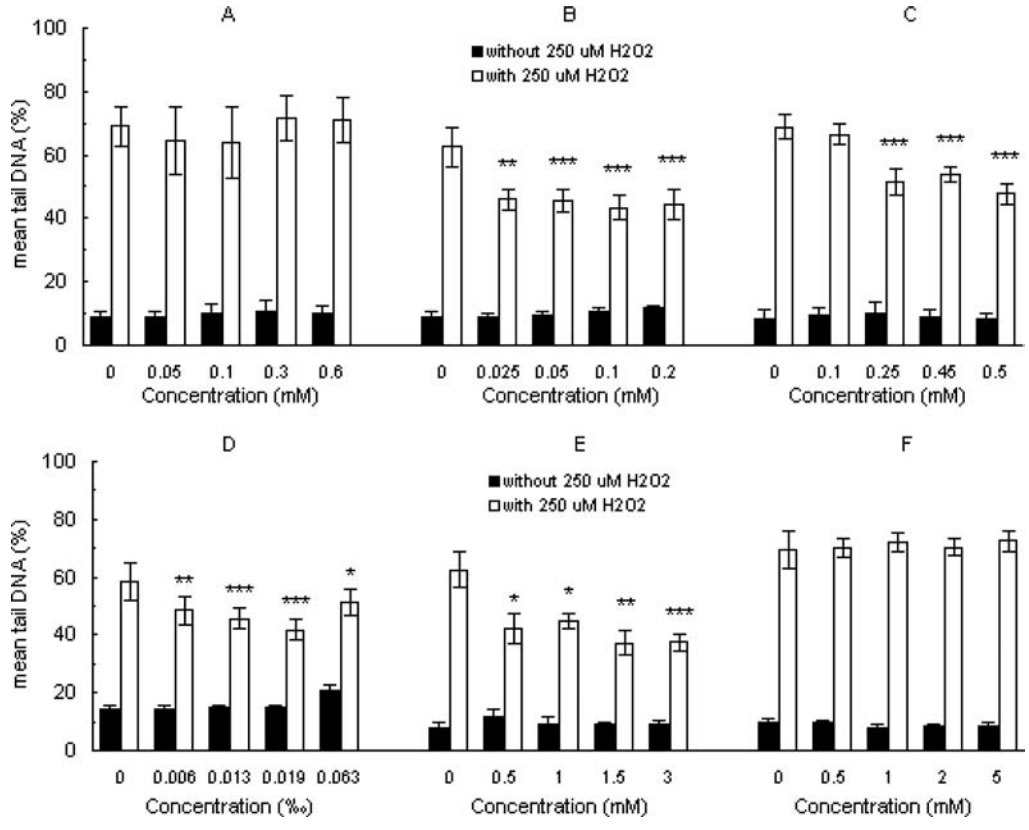

Figure 5. Effects of 24 h of pretreatment of HepG2 cells with eugenol (A), carvacrol (B), thymol (C), *Rosmarinus officinalis* oil (D), borneol (E), and eucalyptol (F) on DNA damage induced by 250 μM H_2O_2. Black columns represent the level of DNA strand breaks induced by 24 h of treatment with EOs or RO; white columns represent the level of DNA strand breaks induced by H_2O_2 alone (0) or after pretreatment with different concentrations of the EOs or RO studied and then with H_2O_2. (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ indicate significant differences between HepG2 cell cultures treated with H_2O_2 alone and cultures pretreated with volatiles and then exposed to H_2O_2.

μM H_2O_2 in PBS on ice for induction of DNA damage and then placed in a lysis mixture (2.5 M NaCl, 0.1 M Na_2EDTA, 10 mM Tris-HCl, pH 10.0, 1% Triton X-100) for 1 h at 4 °C to remove cellular proteins. The second part of the samples was placed in a lysis mixture

dx.doi.org/10.1021/jf501006y | J. Agric. Food Chem. 2014, 62, 6632−6639

immediately after 5 min in cold PBS. After lysis, the slides were transferred to an electrophoresis buffer (0.3 M NaOH, 1 mM Na_2EDTA, pH >13.0) for unwinding (40 min at 4 °C). A current of 25 V (0.3 A) was then applied for 30 min. The slides were neutralized with 0.4 M Tris-HCl (pH 7.5) and stained with EtBr (5 μg/mL). For each sample, 100 EtBr-stained nucleoids were evaluated and scored with an Olympus fluorescent microscope and computerized image analysis (Komet 5.5, Kinetic Imaging, Liverpool, UK) for determination of the percentage of DNA in the tail.

Statistical Analysis. The results are expressed as means ± standard deviations (SD) from at least three independent experiments carried out in triplicates. Student's *t* test was performed to determine the significance of differences between HepG2 cell cultures treated with H_2O_2 and cultures pretreated with volatiles and then exposed to H_2O_2 in the comet assay. Differences with p values <0.05 were considered to be statistically significant.

RESULTS AND DISCUSSION

Although reactive oxygen species (ROS) are unavoidable byproducts of cellular oxygen metabolism,[13] damage to cellular macromolecules such as lipids, proteins, and DNA may occur if production of ROS overcomes the antioxidant capacity of cells. It is thought that such a state of "oxidative stress" contributes to the pathogenesis of a number of human diseases.[13,14] Reducing power assays can show that the tested compounds are electron donors. They can reduce the oxidized intermediates of lipid peroxidation.[15] The synthetic nitrogen-centered DPPH radical and also the •OH radical are often used in testing of scavenging activity (antioxidant capacity) of compounds. •OH radical is one of the extremely potent ROS in biological systems. It can rapidly react with and degrade susceptible biologically relevant substrates.[16] In the DPPH assay the polar phase of radical scavenging is measured; at scavenging of •OH radicals the oxidation of cytochrome *c* is assayed.[8,15]

Antioxidant Effects of Eug, Ca, T, RO, B, and Euc. With the help of the reducing power assay we measured antioxidative activities (the presence of reducers) in the substances tested (Figure 2). Reducing power capacity was compared with that of GA, which is known to be a strong reducing agent. Eugenol was the most active among the samples, followed by carvacrol and thymol. RO, borneol, and eucalyptol did not manifest any reducing power in comparison to the positive control used.

Figures 3 and 4 show that the volatiles tested are capable of different degrees of DPPH and OH radical scavenging. In the DPPH assay the highest activity was shown by eugenol. Lower activities were observed for carvacrol, thymol, and *R. officinalis* oil. These four volatiles were also able to scavenge •OH radicals at a significant level. Borneol and eucalyptol were not active in any of these tests. The results obtained suggest that some of EO components tested could prevent reactive radical species from reaching biomolecules such as lipoproteins, polyunsaturated fatty acids, DNA, amino acids, proteins, and sugars.

DNA-Protective Effects of Eug, Ca, T, RO, B, and Euc. For the evaluation of EOs from the point of view of DNA damage or DNA protection, we used the single-cell gel electrophoresis assay (comet assay). At the given concentration ranges (IC ≤ 50) EO components and intact RO did not induce DNA damage in HepG2 cells. H_2O_2, a strong oxidant, induces in HepG2 cells a significant increase of DNA damage. This compound represents a useful oxidant not only for investigating the mechanism of oxidative cell injury but also for the study of protective effects of different natural compounds.

Figure 5 represents the percentage of DNA strand breaks induced in human hepatoma HepG2 cells after 24 h of treatment with different concentrations of the compounds tested, as well as the DNA-protective effect of 24 h of preincubation of HepG2 cells in the presence of the above-mentioned compounds.

As shown in Figure 5A, preincubation of HepG2 cells in the presence of a strong antioxidative compound (eugenol) did not reduce DNA lesions induced by H_2O_2. Similar results were obtained in mammalian cells of different origin (HepG2, Caco-2, and VH10 cells) in our previous study.[17] Thompson et al.[18] described hepatotoxicity of eugenol manifested by different phenomena: suppression of gap junction-mediated intercellular communication, depletion of glutathione, membrane depolarization of mitochondria, rise of intracellular Ca^{2+}, and depolarization of plasma membrane as well as acidification of cytoplasm. On the other hand, various authors discovered numerous useful effects of eugenol. This compound manifests DNA-protective and anti-inflammatory properties against liver injury in rats influenced by thioacemide,[19] protects murine peritoneal macrophages in vitro against toxicity of nicotine,[20] reduces chemically induced skin cancer in mice,[21] protects rat kidney against nephrotoxicity induced by gentamicine,[22] protects rats against acute cardiotoxicity induced by doxorubicin,[23] reduces gastric damage in vivo,[24] attenuates pulmonary damage induced by exhaust particles,[25] etc.

Panels B and C of Figure 5 show statistically significant DNA-protective effects of antioxidants carvacrol and thymol. Ozkan and Erdogan[26] proved that carvacrol and thymol were able to protect human lung H1299 cells against H_2O_2-induced cytotoxicity as well as against membrane and DNA damage. It was also found that carvacrol protects primary rat hepatocytes against exogenous oxidative DNA damage induced by H_2O_2.[27] Beneficial effects of carvacrol and thymol were investigated many times also in tests on experimental mice and rats. Carvacrol and thymol improved H_2O_2-induced injury on isolated rat pancreas cells,[28] suppressed inflammatory marker gene D-galactosamine expression in rats,[29] and ameliorated hepatotoxicity induced by thioacemide in the liver of Wistar rats.[30] Carvacrol also protects rat livers against defects caused by ischemia and reperfusion.[31] Lower, nontoxic concentrations of carvacrol and thymol significantly reduced 2-amino-3-methylimidazo[4,5-*f*]-quinoline (IQ)- and mitomycin C (MMC)-induced DNA damage.[32] Thymol moreover protects Chinese hamster lung fibroblasts[33,34] as well as Swiss albino mice and Sprague–Dawley rats[35] against oxidative stress induced by radiation or aflatoxin.

Figure 5D shows that although the antioxidative effect of RO is not unambiguous (panel D in Figures 2–4), this compound manifests a significant DNA-protective effect against H_2O_2-induced DNA lesions in HepG2 cells. Zegura et al.[36] proved that extract of rosemary reduces mutations in *Salmonella typhimurium* TA98 and provides DNA protection against oxidative agents in HepG2 cells. In our previous study we found that the administration of RO to rats efficiently and significantly decreased the level of DNA damage in primary hepatocytes, which were influenced by H_2O_2 and other oxidative agents.[37] The protective effects of RO toward the status of antioxidant enzymes in older rats proved the findings of Posadas et al.,[38] Ngo et al.[39] highlighted the importance of RO in cancer prevention.

As previously mentioned, borneol and eucalyptol did not manifest any antioxidant activity (panels E and F in Figures 2–4). These results correspond with observations of Sokmen et al.,[40] who did not determine any antioxidant activity of borneol

and eucalyptol in DPPH assay, on thin layer chromatography (TLC), at inhibition of superoxide radicals, in TBARS assay, and at inhibition of lipid peroxide formation. It is therefore interesting that pre-H_2O_2-treatment of HepG2 cells in the presence of borneol, a compound that has no antioxidant activity, significantly reduced the level of H_2O_2-induced DNA lesions and manifested a significant protective effect (Figure 5E). Borneol is also active ex vivo because if it was added to the drinking water of male Sprague–Dawley rats, the level of oxidant-induced DNA lesions in isolated hepatocytes was reduced.[41] Eucalyptol, the last tested compound, shows neither antioxidative nor DNA-protective effects. It is noteworthy that eucalyptol, which represents one of the main components of rosemary oil, has a much lower antioxidant activity than rosemary oil alone.[42] Although unable to protect DNA of HepG2 cells against H_2O_2, eucalyptol was able to protect DNA of HepG2 and B lymphoid NC-NC cells against *tert*-butyl hydroperoxide.[43]

Chelation Ability of Eug, Ca, T, RO, B, and Euc. It is known that the main cause of flavonoid-mediated DNA protection against effects of H_2O_2 represents chelation of iron ions.[44] We therefore tried to ascertain the chelation ability of the substances tested. DNA topology assay, which responds sensitively to the occurrence of metals and generation of free radicals in a reaction medium, was used with this aim. The assay is based on electrophoretic detection of topological changes induced in plasmid DNA.[45] As in DNA topology assay, both chelating and antioxidative activities can be detected. We used the Fe^{2+}-chelating activity assay for estimation of chelation activity of borneol. The method is based on the measurement of ferrozine complexes with Fe^{2+}. In the presence of chelating agents the complex formation is disrupted and can be detected spectrophotometrically.[15]

Figure 6 shows the electrophoretic monitoring of changes induced in the structure of plasmid DNA by the influence of Fe^{2+} and changes of DNA topology after application of EOs or RO. These changes could indicate a creation of DNA lesions or DNA repair. Whereas Fe^{2+} treatment of plasmid generated ssDNA breaks (Figure 6, lanes 2), treatment with EOs and RO did not induce any ssDNA breaks (Figure 6, lanes 3–6). DNA-protective effect was assessed by measuring the degree of protection against Fe^{2+}-induced DNA breaks (Figure 6, lanes 7–10). As is evident from Figure 6, carvacrol (Figure 6B, lanes 7–10), RO (Figure 6D, lanes 7–10), and eucalyptol (Figure 6F, lanes 7–10) showed no protective effect in DNA topology assay. Eugenol and thymol were able to preserve plasmid DNA only at the higher concentrations (Figure 6A,C, lanes 7 and 8). The most effective DNA-protective capacity was manifested by borneol; it preserved plasmid DNA against Fe^{2+}-induced damage at all concentrations tested (Figure 6E, lanes 7–10).

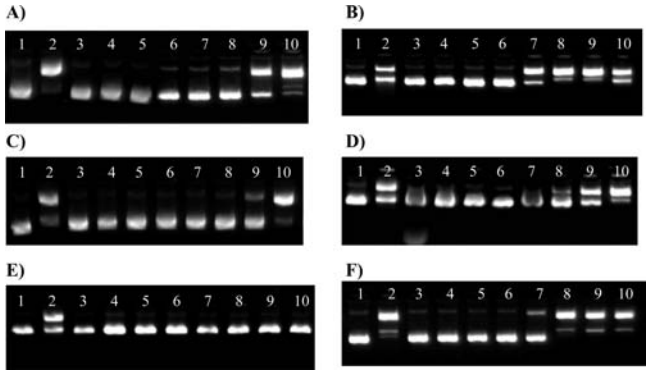

Figure 6. Electrophoretic monitoring of changes induced in the structure of plasmid DNA by the influence of Fe^{2+} and changes of DNA topology after application of EOs or RO (eugenol (A), carvacrol (B), thymol (C), *Rosmarinus officinalis* oil (D), borneol (E), eucalyptol (F)). Lanes (A–F): 1, pBR; 2, pBR + Fe^{2+}; 3, pBR + 10 mM EOs; 4, pBR + 1 mM EOs; 5, pBR + 0.1 mM EOs; 6, pBR + 0.01 mM EOs; 7, pBR + 10 mM EOs + Fe^{2+}; 8, pBR + 1 mM EOs + Fe^{2+}; 9, pBR + 0.1 mM EOs + Fe^{2+}; 10, pBR + 0.01 mM EOs + Fe^{2+}.

Antioxidative and Chelation Effects of Natural Compounds. Different authors had interest in this topic. Ogata et al.[46] proved that eugenol and dieugenol have different mechanisms of antioxidant effect. It was also found that eugenol suppresses the creation of the superoxide anion in the system xanthine–xanthine oxidase and prevents the oxidation of Fe^{2+} in Fenton reaction, which generates $^{\bullet}OH$.[47] Investigation of the structure–activity relationship in isoeugenol and eugenol showed that the lipid peroxidation and autoxidation of Fe^{2+} ions were inhibited by the influence of isoeugenol and less effectively by eugenol. These observations suggest that side-chain structure in addition to the phenolic ring had an important role in the antioxidant function of eugenol.[48] Carvacrol and thymol decreased peroxidation of phospholipid liposomes in the presence of Fe^{3+} and ascorbate. They are good scavengers of peroxyl radicals,[49] and their antioxidant effects are manifested in β-carotene bleaching (BCB) test and in DPPH and TBARS assays.[50] Bounatirou et al.[51] found that carvacrol, a monohydroxylated compound, was not able to form the complex with Fe^{2+}. The findings of these authors correspond with results of DNA topology assay. We assume that observed differences between activity of carvacrol (Figure 6B) and its isomer thymol (Figure 6C) correlate with a better stabilization of radicals in the chemical structure of thymol.

R. officinalis oil shows certain $DPPH^{\bullet}$ and $^{\bullet}OH$ scavenging activities (Figures 3D and 4D), but it has no reducing power and is not able to protect plasmid DNA against Fe^{2+}-induced damage. The antioxidative activity of RO confirmed the results of Viuda-Martos et al.,[52] which were obtained using various techniques. Similar to eucalyptol, borneol showed no reducing power or radical-scavenging activity. It is therefore very interesting that in the DNA topology assay borneol manifested a strong protective effect against DNA damage caused by Fe^{2+} ions (Figure 6E, lanes 7–10). It is not inconceivable that borneol protects plasmid DNA by a mechanism independent of its antioxidant properties, which are very weak or nonexistent (as was proved in reducing power and $DPPH^{\bullet}$ and $^{\bullet}OH$ radical scavenging assays). The DNA-protective mechanism of borneol can be explained only partially by its Fe^{2+}-chelating ability, which was relatively weak (10%, $ChEC_{50}$ = 48.73 mM) compared to, for example, $Na_2EDTA{\cdot}2H_2O$ (97%, $ChEC_{50}$ = 0.515 mM) and quercetin (85%, $ChEC_{50}$ = 2.92 mM) used as positive controls. Borneol, a secondary alcohol, possesses high lipophilic properties resulting from its large bicyclic terpenoid skeleton besides some hydrophilic properties based on its relatively small alcoholic functional group. We proposed that in the DNA topology assay borneol molecules can protect DNA by hydrogen bond interactions with DNA. This reaction could proceed on the polar phosphates in the DNA backbone via van der Waals interactions between neighboring big borneol hydrocarbon skeletons, forming a protective lipophilic shield around plasmid DNA. To support this explanation of borneol protective properties, other experiments with basic lipophilic

dx.doi.org/10.1021/jf501006y | J. Agric. Food Chem. 2014, 62, 6632–6639

semibulky *tert*-butyl and isobutyl alcohols were set up. The results corresponded to those obtained for borneol; for example, plasmid DNA was protected against the damaging effect of Fe^{2+} (data not shown).

On the basis of six independent techniques used in this paper we can conclude that the components of EOs (Eug, Ca, T, B, Euc) and intact RO showed various degrees of reducing power, radical scavenging, chelating, and DNA-protective capacity. It is remarkable that a high antioxidative activity of eugenol had no DNA-protective effect toward H_2O_2. On the other hand, borneol, which lacks antioxidant activity, was able to protect DNA of HepG2 cells against H_2O_2 as well as plasmid DNA against Fe^{2+}-induced damage. We expect that the protective effect of borneol against the DNA-damaging effects of H_2O_2 and Fe^{2+} ions may be evoked mainly by its lipophilic chemical character. The comparison of the antioxidative activities of the studied phytochemicals with their DNA-protective effects did not confirm direct relationships between observed characteristics. Different causes of protective effects of natural compounds have been considered and discussed by various scientists (in addition to antioxidative activity and metal chelation ability, also induction of antioxidative enzymes, modulation of gene expression, and interactions with signal transduction pathways). We think that the DNA-protective effects of various natural compounds represent an extensive complex of known and hitherto unknown molecular mechanisms and need further detailed investigations.

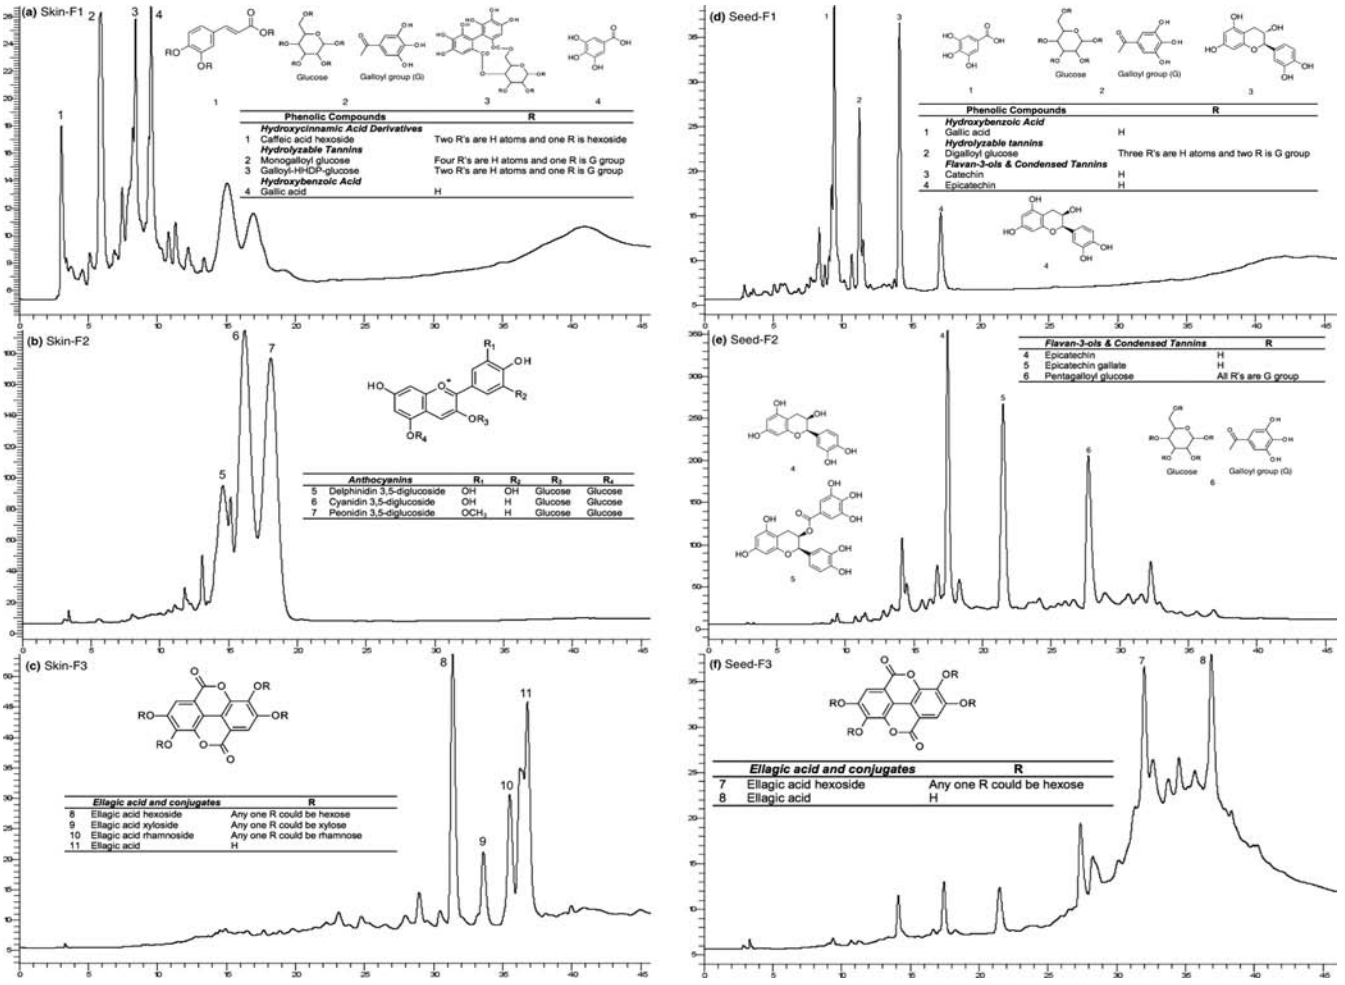

Figure 1. Phenolic compounds and their structures found in muscadine grape skin and seeds: (a, b, and c) Noble skin fractions 1, 2, and 3, respectively; (d, e, and f) Noble seed fractions 1, 2, and 3, respectively.

O157:H7 (204P) strains were obtained from Dr. Tung-shi Huang's laboratory at Auburn University, Auburn, AL, USA.

Antibiotics and Chemicals. Ampicillin and streptomycin were purchased from Fisher Scientific (Fair Lawn, NJ, USA). Nalidixic acid was purchased from Sigma-Aldrich (St. Louis, MO, USA). Plant-derived phenolic standards, including gallic acid, caffeic acid, catechin, ellagic acid, and quercetin, were purchased from Sigma-Aldrich. All of the above commercially purchased chemicals were dissolved in sterile distilled water to a concentration of 5000 mg/L. Folin and Ciocalteu's phenol reagent (2 N), 2,2-diphenyl-1-picrylhydrazyl (DPPH), and 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox) were purchased from Sigma-Aldrich. Sodium carbonate and HPLC grade organic solvents were purchased from Fisher Scientific Co. (Pittsburgh, PA, USA).

Grape Materials and Extraction, Separation, and Identification of Grape Phenolic Compounds. Fully ripened muscadine grape (*Vitis rotundifolia* Michx.) cv. Noble (red) and cv. Carlos (bronze) were harvested from the Center for Viticulture and Small Fruit Research (latitude 30.65 N, longitude 84.60 W) at Florida A&M University on August 24, 2012. Harvested samples were shipped to the University of Florida on the same day and stored under refrigeration (4 °C). Grape skin and seeds were separated manually from berries and freeze-dried in a freeze-dryer (Advantage, The Virtis Co., Gardiner, NY, USA) within the following 3 days. The freeze-dried samples were stored in vacuum-packaged polyethylene pouches at −20 °C until analyzed.

Plant-extracted phenolic compounds (Figure 1) were prepared in-house at the Food and Environmental Toxicology Laboratory from muscadine grape skin and seeds. Phenolic compounds from grape were extracted and isolated according to a method adapted from a previous study.[16] Freeze-dried grape skin and seeds (defatted) were ground sufficiently with a stainless steel grinder (Omni-Mixer 17105, OCI Instruments, Waterbury, CT, USA) to a fine powder (≤0.25 mm). Powder (5 g) from each sample was extracted with 30 mL of 70% methanol. The extraction flasks were vortexed for 30 s, sonicated for 10 min, kept at room temperature (22 °C) for 60 min, and sonicated for an additional 5 min. The extracts were transferred to tubes and centrifuged at 2820*g* and 0 °C for 10 min (J-LITEJLA-16.250, Beckman Coulter Inc., Brea, CA, USA), and the supernatant was collected in separate glass tubes. Residue was re-extracted with the same procedure. The collected supernatant (60 mL) was evaporated in a rotary evaporator (Büchi, Labortechnik AG, Flawil, Switzerland) under reduced pressure at 40 °C to remove solvent. The concentrates obtained after evaporation were redissolved in 5 mL of distilled water and sonicated for 5 min.

A solid-phase extraction technique adapted from a previous study[17] was used to separate fractions of phenolic compounds. Briefly, two C18 Sep-Pak cartridges (Whatman Chromatography, ODS-5) were connected and preconditioned by sequentially passing 12 mL of ethyl acetate, 12 mL of absolute methanol, and 12 mL of 0.01 N aqueous hydrogen chloride (HCl) through the cartridges. The prepared redissolved extract (0.5 mL) was loaded onto cartridges. Each cartridge was rinsed separately with 12 mL of 0.01 N aqueous HCl (fraction 1, F1), 12 mL of 10% methanol (F2), and 12 mL of 30% methanol (F3) for Carlos skin extract; for Noble skin extract, the cartridges were rinsed with 4 mL of 0.01 N aqueous HCl (F1), 15 mL of 10% methanol (with 0.1% HCl) (F2), and 12 mL of methanol (with 0.1% HCl) (F3); and finally for Carlos and Noble seed extracts, the

dx.doi.org/10.1021/jf501073q | J. Agric. Food Chem. 2014, 62, 6640−6649

cartridges were rinsed with 12 mL of 0.01 N aqueous HCl (F1), 12 mL of 30% methanol (F2), and 12 mL of 50% methanol (F3). To obtain a sufficient volume for subsequent study, four individual separations of each extract were performed and then combined. The collected fractions were evaporated in a rotary evaporator under reduced pressure at 40 °C to remove the solvent. The concentrates obtained after evaporation were dissolved in distilled water and stored at 4 °C until analyzed.

The above-described extracts and their fractions were subjected to chromatographic analyses by HPLC (Hitachi, L-7000 series, Japan) with an analytical SB-C18 column (Zorbax Stablebond, 4.6 mm × 250 mm, 5 μm, Agilent Technologies). Mobile phase was 0.5% formic acid in water (solvent A) and 0.5% formic acid in 60% methanol (solvent B) under the following gradient: 0−3 min, 5% B; 3−8 min, 30% B; 8−25 min, 50% B; 25−30 min, 70% B; 30−35 min, 80% B; 35−47 min, 100% B; 47−51 min, 5% B. The flow rate was 0.9 mL/min. Injection volume was 20 μL. Detection was accomplished with a UV detector (Hitachi, L-7400, Japan) set at an absorbance wavelength of 280 nm. The retention times for each eluted component in the analyzed samples were compared to those of the following standards: gallic acid, caffeic acid, catechin, epicatechin, epicatechin gallate, *trans*-resveratrol, ellagic acid, quercetin, and cyanidin-3,5-diglucoside.

Standards for caffeic acid hexoside, mono-, di-, and pentagalloyl glucose, ellagic acid hexoside, xyloside, rhamnoside, delphinidin-3,5-diglucoside, and peonidin-3,5-diglucoside were not available. Thus, a second HPLC system was employed to confirm their identification by ESI-MS detection in the selective reaction monitoring (SRM) mode. The LC-MS analyses were performed on a Thermo-Finnigan Surveyor HPLC system (Thermo-Finnigan, San Jose, CA, USA) equipped with a TSQuantum controlled by XCalibur data analysis software (version 1.3, Thermo-Finnigan). The column and mobile phase used were the same as described above for the HPLC analysis. The MS acquisition was with ESI interface in negative ionization mode at the following conditions: sheath gas (N_2) pressure, 42 arb; auxiliary gas (N_2) pressure, 20 arb; spray voltage 3.96 kV; capillary temperature, 414 °C; collision gas pressure, 1.5 mTorr; collision energy, 22 V. These compounds were identified on the basis of their mass fragmentation data compared with and identical to those reported by the literature.[18]

Phenolic Content and Antioxidant Activity Assay. Total phenolic content of each extract or fraction was determined by the Folin−Ciocalteu colorimetric method[19] with an ultraviolet−visible Beckman Coulter DU-640 spectrophotometer (Beckman Instruments, Fullerton, CA, USA) and expressed as milligrams of gallic acid equivalents per gram of dry matter. The unitary antioxidant activity of each extract or fraction was evaluated using the DPPH radical scavenging capacity assay[20] and expressed as moles of Trolox equivalents per gram of polyphenols.

Antibacterial Activity Assay. Antibacterial activities of the phenolics (experimental compounds) were determined by agar disc diffusion method,[21] and pathogenic bacteria for the test were listed above. Isolated colonies of test bacterial strains grown overnight on tryptic soy agar plates (TSA; Difco, Becton Dickson, Sparks, MD, USA) were cultured in Mueller−Hinton broth (MHB; Difco, Becton Dickinson) at 37 °C for 18 h. The turbidity of bacterial suspensions was adjusted to approximately 2.0 × 10^8 CFU/mL (optical density at 600 nm = 0.2). Bacterial suspensions were evenly swab-inoculated on surfaces of Mueller−Hinton agar (MHA; Difco, Becton Dickinson). Then each sterile blank disc (6 mm in diameter, Difco, Becton Dickinson) was placed on the surface of the test MHA plates, impregnated with 20 μL of experimental compounds (Table 2, in triplicate per compound), and incubated at 37 °C for 24 h. Commercial antibiotics (ampicillin, nalidixic acid, and streptomycin at 10 μg/disc) and distilled water prepared in the same manner as the experimental compounds were used as positive and negative controls, respectively. The size of the zone of inhibition was measured, and the antibacterial activity was expressed in terms of the average diameter of the zone of inhibition in millimeters. The absence of a zone of inhibition (≤6 mm) was interpreted as the absence of antibacterial activity.

The MIC was determined using an Alamar blue assay adapted from a previous study.[21] Briefly, serial dilutions of experimental compounds in MHB (100 μL) with test bacteria at a density of 5 × 10^6 CFU/mL were incubated in flat-bottom, polystyrene, non-tissue-culture-treated 96-well microtiter plates at 37 °C without shaking for 20 h. After 20 h, 10 μL of Alamar blue (AB; Invitrogen, Life Technologies, Carlsbad, CA, USA) was added to the wells and the plates were shaken gently and incubated for 1 h at 37 °C. Plates were gently shaken again, and absorbances at 570 and 600 nm were obtained in a microplate reader (ELX808 Universal, Bio-Tek Instruments, Winooski, VT, USA). Controls included medium alone (blank), diluted medium plus experimental compounds plus AB (negative), and medium plus cells plus AB (positive). Percent reduction of AB was calculated using the manufacturer's formula (absorbance difference between 570 and 600 nm for each experimental well divided by the difference in positive control). Assays were performed in triplicate, and the average percent reduction was used to determine MIC. The AB MIC was defined as the lowest concentration of the experimental compound resulting in ≤50% reduction of AB and a purplish well 60 min after the addition of AB.[22]

To investigate the correlation of Alamar blue reduction to colony-forming units per milliliter (CFU/mL), CFU/mL was obtained from the same wells used to obtain AB absorbances. Before AB was added to all treated wells, 10 μL of the well culture was removed and serially diluted (10-fold) in 0.1% peptone water followed by plating (20 μL of the dilution) on TSA. Colonies were counted after incubation at 37 °C for 24 h and recorded as CFU/mL. Pearson's two-tailed correlations were calculated between Alamar blue reduction and CFU/mL.

Time−Kill and Synergy Assay. Time−kill assays were performed using a method adapted from a previous study.[23] Briefly, bacteria were cultured to exponential phase (1.0 × 10^8 CFU/mL, OD_{600} = 0.15) in MHB and challenged with antibiotics or experimental compounds at 4 × MIC or 500 mg/L. Synergy between antibiotics and phenolic compounds was tested at 0.9 × MIC. Bacterial viability was monitored every hour (0−6 h) by plating cultures onto TSA and counting colonies after incubation at 37 °C for 24 h as described previously. To detect bacterial lysis following the challenge with antibacterial agents, the culture turbidity of early exponential phase cultures was monitored every hour (0−6 h) and finally at 24 h by absorbance measurements at 600 nm at 37 °C. Synergy between antibiotics and phenolic compounds was defined as follows, using $\log_{10}$ CFU/mL at 24 h: synergy was >2 $\log_{10}$ kill, additivity was >1−2 $\log_{10}$ kill, indifference was 1 $\log_{10}$ kill to 2 $\log_{10}$ growth, and antagonism was >2 $\log_{10}$ growth compared to the most active drug alone. Bactericidal activity was defined as a ≥3 $\log_{10}$ CFU/mL kill at 24 h from baseline.[24]

Antibiofilm Activity Assay. The planktonic cell susceptibility to polyphenols and polyphenols inhibiting biofilm formation were determined using the Alamar blue assay adapted from a previous study.[21] Briefly, serial dilutions of experimental compounds in MHB (100 μL, with diluted 2500 to 5 mg/L) with bacteria at a density of 5 × 10^6 CFU/mL were incubated in round-bottom, polystyrene, non-tissue-culture-treated 96-well microtiter plates at 37 °C without shaking for 20 h. After 20 h, visual MICs were identified by the dot at the bottom of the well (the well before dots appear is defined as the MIC point); then, the content of each well was aspirated and transferred to a new flat-bottom plate; 10 μL of Alamar blue was subsequently added to the new plate wells and analyzed as the previous procedure to determine the MICs of planktonic cells. After this, the original round-bottom plate wells (after transferring) were gently washed twice with 250 μL sterile physiological saline to remove nonadherent bacteria; 100 μL of sterile distilled water was added to these wells followed by 10 μL of Alamar blue and analyzed as the previous procedure to determine the minimum biofilm inhibitory concentration (MBIC).

To determine the reduction capability of polyphenols on preformed biofilm, assays were performed in flat-bottom plates with bacteria incubated at a density of 5 × 10^6 CFU/mL in 100 μL of MHB. First, plates were incubated at 37 °C without shaking for 24 h to allow biofilm formation. Then, 2-fold dilutions (diluted 2500 to 5 mg/L) of experimental compounds in MHB were prepared external to the

plates. After 24 h of incubation, well contents were aspirated from all experimental and control wells, wells were gently washed twice with 250 μL of sterile physiological saline, and 100 μL of the appropriate diluted compounds was added. Preformed biofilms were exposed to compounds for 20 h at 37 °C without shaking. After 20 h, 10 μL of Alamar blue was added to the wells and analyzed as previously described.

Statistical Analysis. Experimental results were expressed as means ± standard error (SE) of three independent replicates. Data were subjected to ANOVA, and significant differences were tested by post hoc comparison test (Student−Newman−Keuls) at $P < 0.05$. Microsoft Excel 2008 and SPSS 20.0 for Windows were used for this analysis and for calculating Pearson's correlation coefficients.

RESULTS

Muscadine Grape Phenolic Compounds and Antioxidant Activity. Phenolic compounds from muscadine grape (Noble and Carlos) skins and seeds were separated into three fractions, respectively, and chromatograms of identified phenolics from Noble skin and seed fractions are presented in Figure 1. Caffeic acid hexoside, hydrolyzable tannins, and gallic acid were the major phenolics in fraction 1 of Noble skin polyphenols (Figure 1a). Anthocyanins were the major phenolics in the corresponding fraction 2 (Figure 1b), and ellagic acid and its conjugates were in fraction 3 (Figure 1c). Polyphenol fractions from Carlos skin were different from those from Noble skin, with richer ellagic acid and conjugates in fraction 3, but almost no anthocyanins in fraction 2 (data not shown). However, polyphenol fractions from Noble and Carlos seeds showed similar profiles, with hydroxybenzoic acid, hydrolyzable tannins, and little flavan-3-ols distributed in fraction 1 (Figure 1d), major flavan-3-ols and condensed tannins distributed in fraction 2 (Figure 1e), and ellagic acid and its conjugates distributed in fraction 3 (Figure 1f). Overall, anthocyanins (fraction 2, 22.6 mg/g) were the major phenolics for Noble skin, whereas it was ellagic acid and its conjugates (fraction 3, 20.5 mg/g) for Carlos skin; flavan-3-ols and condensed tannins (fraction 2, 38.8, and 40.8 mg/g, respectively) were the major phenolics for Noble and Carlos seeds (Table 1).

Antioxidant activity of phenolic compounds varied greatly among tested samples (Table 1). For the polyphenol standards, gallic acid showed the strongest antioxidant activity per unit and ranked in order as gallic acid > ellagic acid > quercetin > catechin > caffeic acid. For the polyphenol extracts, fraction 3 showed the strongest antioxidant activity per unit and ranked in order as fraction 3 (ellagic acid and conjugates) > fraction 1 (hydroxybenzoic acid and hydrolyzable tannins) > fraction 2 (anthocyanins or flavan-3-ols and condensed tannins). As expected, antioxidant activity for the nonseparated grape skin or seed extracts varied among their corresponding activities of the fractions.

Antibacterial Activity of Phenolic Compounds. Antibacterial activity of phenolic compounds was initially screened by the standard agar disc diffusion method and then subjected to the MIC test. Table 2 showed that the inhibition of bacterial growth was quite drug and species dependent. Muscadine grape skin and seed polyphenol extracts exhibited a broad spectrum of antibacterial activity against Gram-positive bacteria (*S. aureus*), but exhibited little to no antibacterial efficacy against Gram-negative bacteria (*Salmonella enterica* ser. Typhimurium, *S. sonnei* ATCC 25931, and *E. coli* O157:H7 204P). Inhibition by seed polyphenols (Carlos seed vs Noble seed) against *S. aureus* was positively dependent on concentration, whereas skin polyphenols (Carlos skin vs Noble skin) were negatively dependent. Although Carlos skin was used at higher polyphenol concentration than Carlos seed, its inhibition was significantly weaker than that of the later. These findings indicated that the antibacterial activity of muscadine grape phenolic compounds was not only concentration dependent but also phenolic specific dependent. Gallic acid exhibited good antibacterial activity on tested *S. aureus* strains, whereas ellagic acid showed slightly less inhibition at 100 μg/disc. Caffeic acid, catechin, and quercetin exhibited little to no antibacterial efficacy against *S. aureus* at this concentration. None of these polyphenol standards was found to show inhibition on Gram-negative bacteria in this study. The susceptibility of all tested bacteria to the three antibiotics (positive control, 10 μg/disc) varied significantly with zones of inhibition ranging from 0 to 43.8 mm. In general, ampicillin and streptomycin showed stronger inhibition than nalidixic acid in this study.

Muscadine grape polyphenols were further demonstrated to have good antibacterial activity against Gram-positive bacteria (*S. aureus*) as shown by an MIC of 74−367 mg/L for skin polyphenols and 67−173 mg/L for seed polyphenols (Table 3). Inhibition for different phenolic fractions was significantly

[a]Results are expressed as means of triplicate determinations ± SE; results with different lower case letters in columns and different upper case letters in rows are significantly different ($P < 0.05$); results >6 mm were considered effective against bacteria, ≤6 mm were considered noneffective and recorded as 0. [b]Partial inhibition within a zone and not included in the statistical analysis.

different. In general, the nonseparated skin and seed polyphenols exhibited comparable or even better inhibition than some of their corresponding fractions. This indicated there might be a synergistic effect between different phenolics in inhibiting bacteria growth. Muscadine grape polyphenols also showed good antibacterial activity against Gram-negative bacteria (*S. sonnei* ATCC 25931) with an MIC of 112−735 mg/L while exhibiting fair antibacterial efficacy against *S. enterica* ser. Typhimurium and *E. coli* O157:H7 204P with MICs of 224−1976 and 304−1540 mg/L, respectively. The phenolic concentration required to inhibit Gram-negative bacteria ranged from 1 to 16 times higher than that required for Gram-positive bacteria. Unexpectedly, almost no inhibition (≥2500 mg/L) was found for the commercial polyphenol standards on all tested bacterial strains. The inhibition of antibiotic controls on all study strains, even though within the same species, varied greatly and were either very strong (≤20 mg/L) or almost none (≥1250 mg/L). By contrast, muscadine grape polyphenols displayed consistent antibacterial activity within one species, such as *S. aureus* (Table 3) and *Salmonella enterica* ser. Typhimurium (data not completely shown). This indicated that muscadine grape polyphenols had a broad spectrum of antibacterial activity and possibly could be used to treat these antibiotic-resistant strains.

Evaluation of Bacterial Killing and Synergistic Effect by Phenolic Compounds. To further evaluate the bactericidal activity of phenolic compounds, the killing kinetics of these compounds were assessed against *S. aureus* ATCC 35548 alongside established antibiotics. At 4 × MIC, Noble skin and seed polyphenols caused reductions in cell viability of 4.7 and 4.9 $\log_{10}$ CFU/mL after 6 h in MHB, respectively, whereas streptomycin caused a reduction of 6.1 $\log_{10}$ CFU/mL (Figure 2a). Gallic acid and ellagic acid caused only a slight bacteriostatic effect at 500 mg/L. Significant synergism between antibiotics and polyphenols at sub-MIC were observed. Ampicillin (150 mg/L), with a high MIC of 2500 mg/L, when added with gallic acid (500 mg/L), ellagic acid (500 mg/L), Noble skin (0.9 × MIC), and Noble seed (0.9 × MIC) caused reductions in cell viability of 0.5, 3.9, 5.1, and 4.8 $\log_{10}$ CFU/mL, respectively (Figure 2b), whereas the addition of streptomycin with gallic acid, ellagic acid, Noble skin, and Noble seed caused reductions in cell viability of 1.6, 4.0, 5.0, and 6.2 $\log_{10}$ CFU/mL, respectively (Figure 2c). Although both gallic acid and ellagic acid had little effect on bacterial viability individually, when combined with antibiotics, ellagic acid showed considerably stronger bactericidal activity than gallic acid, especially after 2 h. Synergy of streptomycin and Noble seed (at 0.9 × MIC) was better than streptomycin or Noble seed (at 4 × MIC) alone and was the strongest bactericidal activity among all of the treatments. These indicated that combining grape polyphenols with antibiotics could maximize the bactericidal activity while reducing the usage of antibiotics.

Bacterial lysis showed that, at 4 × MIC, Noble skin and seed polyphenols caused a reduction in culture turbidity over a 6 h period, whereas streptomycin exhibited an increase (Figure 2d). This indicated Noble skin and seed polyphenols were bactericidal and killed bacteria with concomitant cell lysis, whereas streptomycin was nonlytic but bactericidal. Antibiotics combined with Noble seed polyphenols exhibited stronger bacterial lysis ability than skin polyphenols (Figure 2e,f). Overall, there was a positive correlation ($r = 0.84$) between bacterial number ($\log_{10}$ CFU/mL) and culture turbidity (OD_{600}) at 6 h. After 24 h, as the turbidity of the control continued to increase, all treatments except gallic acid caused a reduction in culture turbidity. This suggests that with plenty of time, phenolic compounds promoted a loss of culture turbidity as well as a loss of bacterial viability.

Antibiofilm Activity of Phenolic Compounds. To investigate the resistance of biofilm versus planktonic-grown strains, Alamar blue MICs of nalidixic acid against a variety of

[a]MICs were determined by the Alamar blue assay. MIC is defined as the lowest experimental compound concentration resulting in ≤50% reduction of AB (average of three experiments) and a purplish well 60 min after addition of AB. Results with different lower case letters in columns and different upper case letters in rows are significantly different ($P < 0.05$). MIC values >2500 mg/L were not included in the statistical analysis. Test strains were inoculated at 5×10^6 CFU/mL in each well. [b]Fractions 1−3 for Carlos and Noble skins and seeds were eluted from tandem C18 Sep-Pak cartridges with different solvents: skins, F1, 0.01 N HCl; F2, 10% MeOH; F3, 30% MeOH; and seeds, F1, 0.01 N HCl; F2, 30% MeOH; F3, 50% MeOH.

pathogenic bacteria and MBICs against their preformed biofilm were studied (Table 4). Alamar blue MBICs increased at least 4-fold relative to planktonic MICs. These data are consistent with previous reports of many-fold increases in drug resistance of biofilm versus planktonic-grown strains.[22,25]

A variety of antibiotics and phenolic compounds with different mechanisms were further studied on planktonically grown *S. aureus* susceptibility, inhibition of biofilm formation, and resistance of preformed biofilm (Table 5). Visual and Alamar blue MICs for planktonically grown strains were identical, with ellagic acid as an exception. Thus, MICs can be generally determined visually or spectrophotometrically. MBICs for inhibiting biofilm formation were within 2-fold dilutions lower than MICs, whereas MBICs of preformed biofilm were at least 16-fold higher than MICs. For example, the MIC of Carlos seed polyphenols against planktonic-grown *S. aureus* ATCC 35548 was 40 mg/L, that against biofilm formation was 20 mg/L, and that against preformed biofilm was as high as 641 mg/L. These findings indicated that grape polyphenols were able to inhibit bacteria biofilm formation at a sub-MIC concentration without killing the bacteria; however, to eradicate the preformed biofilm, a high concentration of phenolic compounds is needed.

DISCUSSION

This study demonstrated that muscadine grape skin and seed polyphenols had potent bactericidal activity against planktonic cells and biofilm formation of Gram-positive bacteria *S. aureus*. The fact that polyphenols acted to cause cell lysis and therefore compromise the integrity of the bacterial membrane may explain why these compounds have the ability to eradicate *S. aureus* biofilms; potent antibiofilm activity is a property that is often associated with membrane-perturbing agents.[26] The limited activity of grape polyphenols against Gram-negative bacteria was probably because of the limited ingress across the outer membrane.[27] However, another intrinsic mechanism that has been insufficiently studied is efflux, and multidrug efflux pumps have been shown to be associated with the insusceptibility of *E. coli* to various biocidal agents.[28]

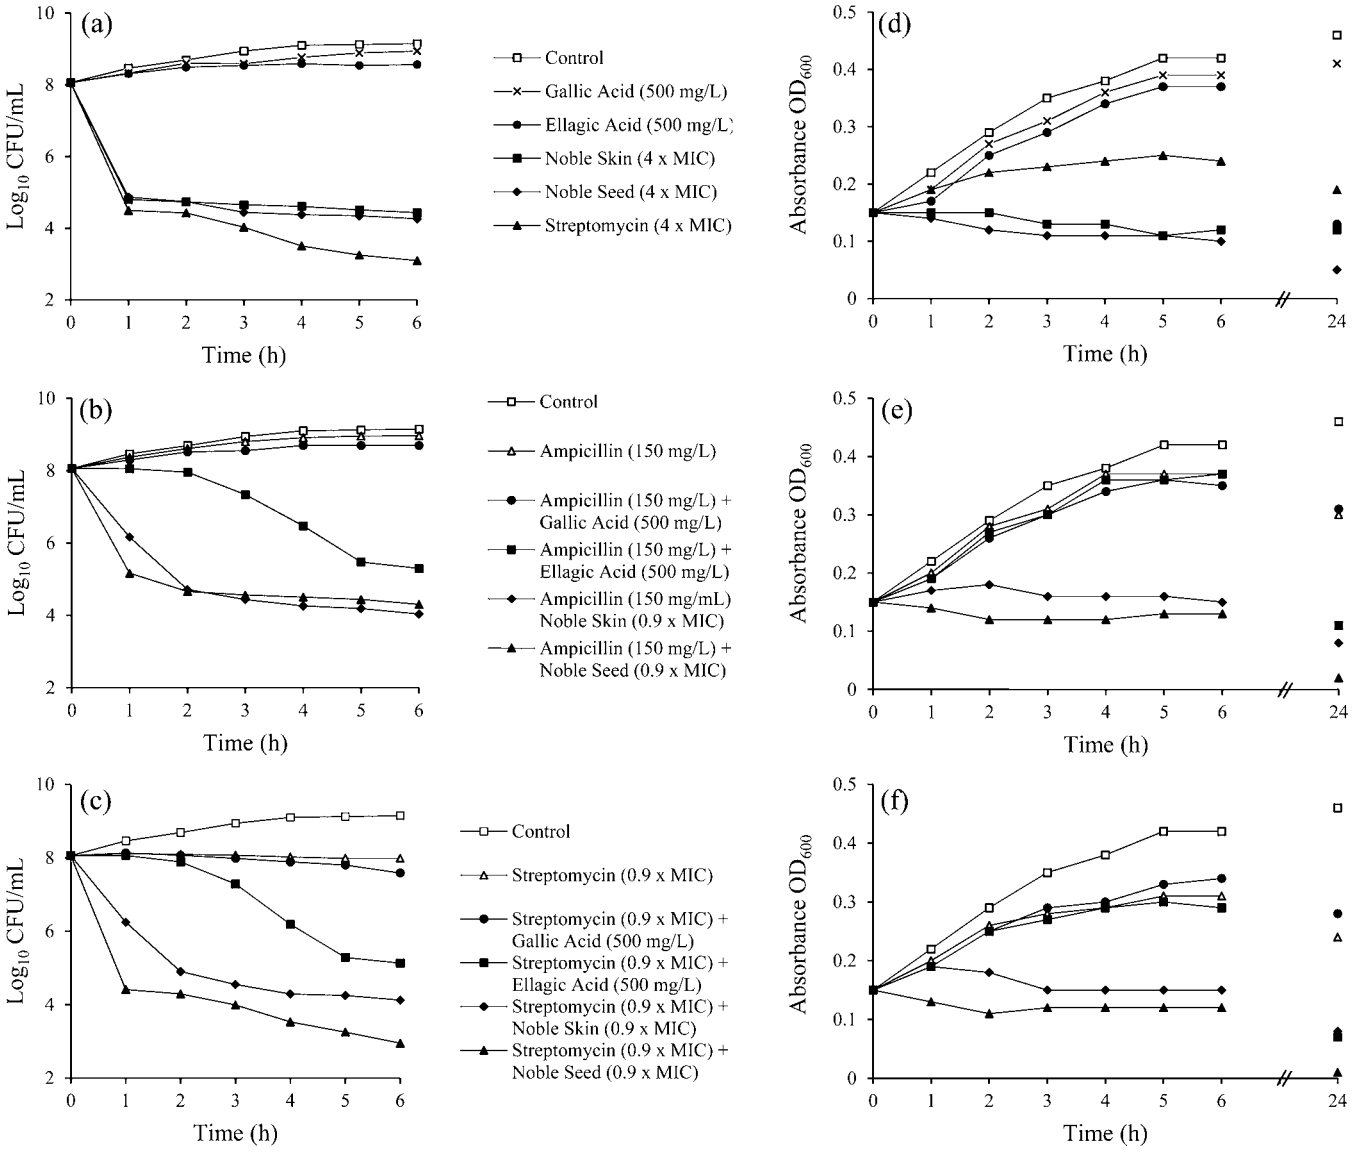

Figure 2. Evaluation of killing (a–c) and lytic (d–f) action of experimental compounds and their synergism with antibiotics against *S. aureus* ATCC 35548 in MHB (means of three independent replicates). MICs of Noble skin, Noble seeds, and streptomycin were 113, 88, and 20 mg/L, respectively.

A positive correlation (r = 0.72) between antioxidant (Table 1) and antibacterial (Table 2) activities of polyphenol standards against *S. aureus* on agar medium was found. Also, a weak positive correlation (r = 0.53) between antioxidant (Table 1) and antibacterial (Table 3) activities of muscadine polyphenols against *S. aureus* was observed. These findings suggested that the stronger the antioxidant activity per unit polyphenols, the better the antibacterial activity against *S. aureus*. However, strong antibacterial activity against *S. aureus* does not necessarily mean strong antioxidant activity because no antioxidant activity was demonstrated for antibiotics (ampicillin, nalidix acid, and streptomycin) (data not shown). Similar to a previous finding,[29] there was a positive correlation (r = 0.77) between total polyphenol content and total antioxidant activity for these grape extracts and fractions. Nonetheless, higher phenolic levels do not necessarily correlate with increased inhibition against *S. aureus* but rather the type and concentration of compounds present in these extracts.

Interestingly, compared to grape phenolic extracts, commercial phenolic standards gallic acid and ellagic acid exhibited stronger antioxidant activity per unit, 11.1 and 9.8 mmol/g, respectively (Table 1), and also showed good antibacterial activity on tested *S. aureus* strains using the disc diffusion method (Table 2). However, further Alamar blue MIC tests (Table 3) and time-killing study (Figure 2) suggested that gallic acid and ellagic acid possess negligible antibacterial efficacy against *S. aureus*. This contradictory finding indicated the very different antibacterial mechanism of gallic acid and ellagic acid on a solid surface versus in a liquid. Other phenolic standards, caffeic acid, catechin, and quercetin, exhibited little to no inhibition on the tested strains in all assays. Therefore, it seems that antibacterial activities of commercial phenolic standards were weaker compared to the muscadine grape phenolic extracts. One possible reason was that the antibacterial activities of these phenolics were lost during their processing or these phenolics existed as ineffective isomer forms. Another possible reason was that synergism between multiple phenolics

[c]*, significant differences between MICs (visual and planktonic cell) of experimental compounds versus MBICs (biofilm formation and reduction) ($P < 0.05$); #, significant differences between MBICs of experimental compounds against biofilm formation versus preformed biofilm reduction ($P < 0.05$).

increased their antibacterial activities. These findings can be further supported by other authors' reports that pure catechin and epicatechin possess negligible antibacterial activity against Gram-positive and Gram-negative bacteria,[30] whereas plant-extracted whole polyphenols exhibited good antibacterial activity against several foodborne pathogenic bacteria.[31] For instance, the mean MICs against *S. aureus* ranged from 98 to 389 mg/L and those against *E. coli* ranged from 450 to 1519 mg/L. Also, in this study, whole extracted skin and seed polyphenols exhibited comparable or even better inhibition than their corresponding fractions. Therefore, whole extracted polyphenols were used in the following studies.

This study also investigated the correlation between Alamar blue (AB) percent reduction by bacteria metabolic activity,[22] and the existing bacteria number per well on Carlos seed polyphenols and ellagic acid at various concentrations. Results showed that percent reduction of AB had a significant correlation (r = 0.94 and 0.92, respectively) with existing bacteria number (Figure 3). Carlos seed polyphenols at 40 mg/L inhibited the bacteria number at the initial level (6 $\log_{10}$ CFU/mL) with a 24.9% reduction of AB after 20 h of incubation, whereas at 160 mg/L (4 × MIC) bacteria were killed with no reduction of AB. Ellagic acid at 2500 mg/L reduced bacteria number by 1.4 $\log_{10}$ CFU/mL with a 39.2% reduction of AB after 20 h of incubation. These confirmed that the colorimetric AB assay is a reliable, reproducible means of determining bacteria antibiotic susceptibility. A previous study also showed that the AB assay was a good means of determining biofilm antibiotic susceptibility and had good to

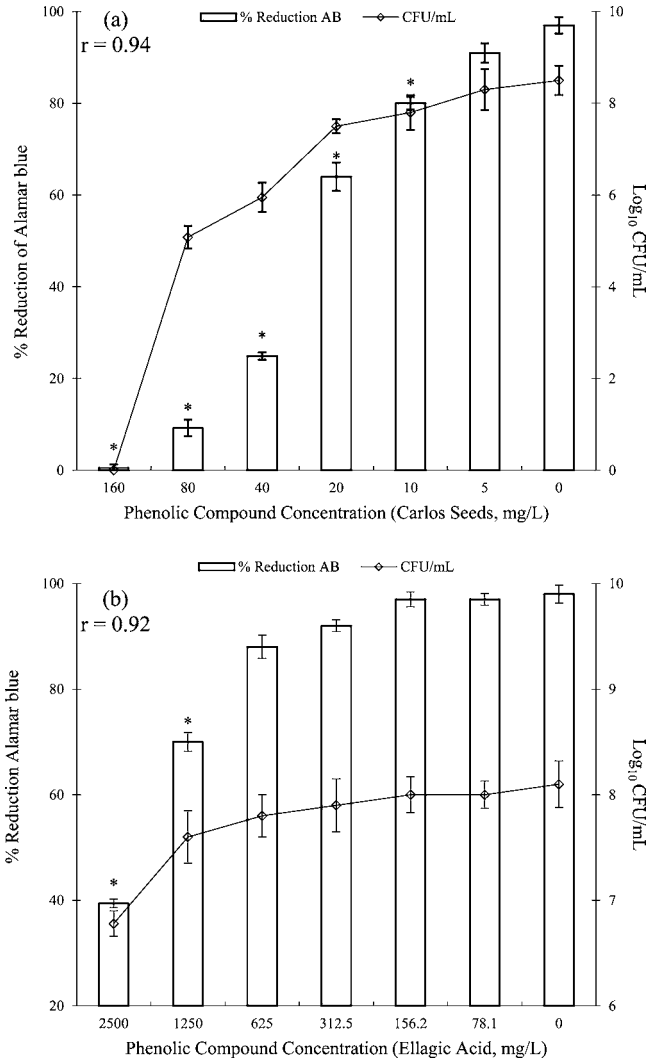

Figure 3. Percent reduction of Alamar blue (bars) and $\log_{10}$ CFU/mL (◇—◇) for phenolic compounds on *S. aureus* ATCC 35548: means of three independent replicates. Test strains were inoculated at 5×10^6 CFU/mL in each well. (*) Values differ significantly ($P < 0.05$) from values without phenolic compounds.

excellent correlation with two other biofilm susceptibility methods, XTT reduction and viable counts.[22]

The antibacterial mechanisms of phenolics are attracting more and more research in recent years. The membrane interaction of phenolics is a prevailing theory.[30] Phenolics are partially hydrophobic; this character may allow them to interact with the lipid bilayer of bacterial cytoplasmic membrane and lipopolysaccharide interfaces more effectively by decreasing membrane stability.[32] For example, epicatechin gallate could rapidly enter the cytoplasmic membrane, causing an immediate reduction in bilayer fluidity.[33] The cytoplasmic membrane constitutes the selective barrier controlling cellular ingress and egress of materials and houses many of the enzymes involved in bioenergetic functions, cell wall synthesis, and macromolecule secretion. Penetration of phenolics into this phospholipid bilayer will have a profound outcome on a wide range of essential cell functions. Intercalation of these chemical structures could induce membrane disruption that permits solute equilibration across the bilayer, resulting in cell death, but more subtle interactions at subinhibitory concentrations induce reorganization of membrane architecture with implications for the capacity of the target bacteria to cause disease in the susceptible host.[32] Phenolics also were found to prevent the formation of biofilms in this study (Table 5) as well as others' report.[34,35] This may further support the membrane-interactive mechanism because potent antibiofilm activity is a property that is often associated with membrane-perturbing agents.[26] Thus, phenolics exhibit at least two biological activities: inhibition of bacterial growth at high concentrations and/or induction of bacteria membrane disruption and prevention of biofilm formation at lower concentrations. In view of these activities, phenolics may be useful in a synergistic approach with conventional antibiotics against antibiotic-resistant forms of pathogens (e.g., multidrug-resistant clinical isolates, MRSA) in clinical medicine. Our time−killing study (Figure 2) indicated that muscadine Noble seed phenolics combined with ampicillin or streptomycin at subinhibitory concentrations greatly reduced *S. aureus* ATCC 35548 (MRSA) cell viability by 4.8 or 6.2 $\log_{10}$ CFU/mL, respectively.

Naturally occurring molecules, predominantly secondary metabolites, are the source of the majority of drugs in clinical use today, and they continue to be an important basis of new therapeutics for bacterial infectious diseases.[36] Phenolics are secondary metabolites in muscadine grapes and play important roles in the strong resistant character of this species to pests and diseases, including Pierce's disease.[37] Evidence is emerging that phenolics may be useful in the control of common oral infections, such as dental caries and periodontal disease.[38,39] In this case, phenolics can be incorporated into rinse and toothpaste formulations. Muscadine phenolics also have been proven to possess strong anticancer activities, such as inhibiting proliferation of colon[8] and prostate[9] cancer cells by inducing apoptosis. Importantly, phenolics are widely distributed in edible grapes,[40] and they have minimal toxicity.[41] Therefore, even though outstanding bactericidal properties cannot be achieved because of a relatively high concentration required in this study and the partial metabolism of these by intestinal bacteria,[42] phenolic agents still have promise as supplements for nutraceutical value and conventional antibacterial chemotherapies by inhibiting the growth of foodborne pathogens in the body. The broad ability of muscadine phenolics to have strong antibacterial activity, to inhibit biofilm formation, and to synergistically work with antibiotics may stimulate a muscadine byproduct market as natural food preservatives, potential antibiotic replacements, and/or natural sanitizers for processing equipment where foodborne pathogens reside.

tannins in chlorophyllous tissues of several tracheophyta species was investigated,[11] showing that tannins are polymerized in a new chloroplast-derived organelle, named the tannosome. More specifically concerning date tissues, ultrathin sections of frozen pericarp were observed by transmission electron microscopy by Shomer et al. (1998).[12] These authors suggested that tannins were specifically located in the cells of the epicarp. However, only TEM observation cannot clearly make the difference between tannins and other polyphenolic classes such as flavonols which are also present in date epidermis tissues.[1] Indeed, both flavonols and tannins are molecules containing C═C conjugated double-bond systems. Therefore, after the treatment of tissues with osmium tetroxide, both flavonols and tannins containing zones would appear as highly electron-dense on the TEM pictures.

Thus, the localization of tannins in dates tissues is still badly known with accuracy. By coupling light microscopy after specific staining and TEM, the purpose of this study is to give more accurate evidence of condensed tannin localization in edible tissues of dates. Their localization in the stones is also considered because these compounds were recently characterized and quantified in this part of the fruits.

MATERIALS AND METHODS

Solvents, Reagents, and Phenolic Standards. Ethanol and hydrochloric acid were from Merck (Allemagne). 4-Dimethylamino cinnamaldehyde (DMACA) and uranyl acetate were purchased from Sigma-Aldrich (France), and glutaraldehyde and LRwhite resin were purchased from Agar Scientific (UK). Water was purified using a Milli-Q system from Millipore (France).

Plant Materials. Ripe Deglet Nour dates (*Phoenix dactylifera* L.) were harvested during the 2009 season in the region of Kebili, Tunisia.

Microscopy. *Sample Preparation.* For light and electron microscopy observations, the fruit was thawed out and blocks of tissue (1 mm^3) were cut from the pericarp (including the epicarp and

dx.doi.org/10.1021/jf5013715 | J. Agric. Food Chem. 2014, 62, 6650−6654

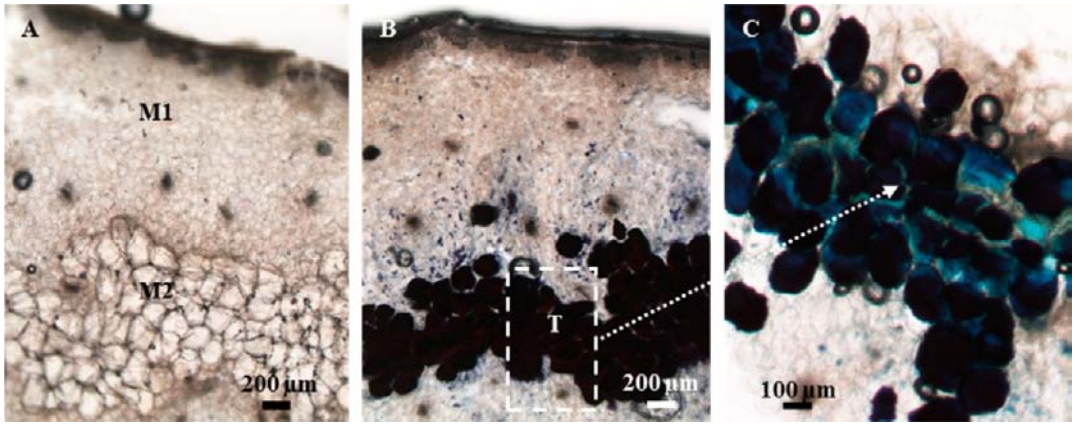

Figure 3. Tannins localization with DMACA staining. Light micrographs of Deglet Nour dates pericarp cross sections M1 + M2 (thick sections): (A) witness pericarp, (B) pericarp stained with DMACA, and (C) pericarp stained with DMACA at higher magnification. T, tannins; M1, external zone of the pericarp; M2, mesocarp zone.

mesocarp) and the stone were fixed with 3% glutaraldehyde in a 0.1 M phosphate buffer at pH 7.4 for 24 h at 4 °C, rinsed several times with 0.1 M phosphate buffer at pH 7.4, and then postfixed with 1% osmium tetroxide (OsO_4) in deionized water.

After being postfixed, tissues were rinsed 5 times with deionized water, followed by dehydration through a graded aqueous ethanol series (30, 50, 70, 85, 95, and 100%). The samples were then progressively infiltrated with London Resin White acrylic (LRW) according to the following schedule: 20, 40, 60, and 80% LRW/ethanol and overnight in pure LRW. The infiltrated samples were finally embedded by LRW resin and polymerized for 48 h at 55 °C.

For light microscopy, semithin sections (1 μm) were obtained using an ultramicrotome (UC7, Leica), mounted on glass slides, and stained with a solution of toluidine blue 1% in Na_2CO_3 2.5% for histology. The observation was carried out using an inverted epifluorescence microscope (Axiovert 135M, Carl Zeiss). The images are taken with the objectives ×10 and ×40. The software acquisition used is "Archimed". Observations were taken using a color camera (Retiga 2000R, Microvision).

For transmission electron microscopy, ultrathin sections (80 nm) contrasted with uranyl acetate 2% in aqueous solution were examined with a JEM-1230 (Jeol) with an accelerating voltage of 80 kV. The images were obtained with a camera (ES500W, Gatan) associated with software acquisition "Digital Micrograph."

Tannins Localization by Light Microscopy in Combination with DMACA Staining. Thick sections of the pericarp (150 μm) were obtained with a vibratome (HM 650 V, Microm). The operation consists of placing a drop of reagent DMACA (0.3% w/v) in a mixture of DMACA methanol/6 N HCl (1/1: v/v) on sections and has been incubated for 20 min at 4 °C. Rinsing is carried out several times in deionized water. The observation was made directly by light microscopy in bright field.[5]

RESULTS AND DISCUSSION

Cellular Organization of the Date Tissues. On the basis of images obtained with a binocular stereo zoom microscope and light microscope, Figure 2 describes the morphology of the soft tissues corresponding to the pericarp (edible part of the fruit) (Figure 2A,B) and the hard tissues corresponding to the stone (Figure 2C,D), respectively. Soft tissues were divided into four zones. Regarding the edible tissues, the most external zone (M1) included the epidermis (epicarp) and some subepidermal layers. The second zone (M2) corresponded to mesocarp tissues containing some large cells as observed on the lower part of Figure 2B. The M3 zone including the main part of the mesocarp and the most inner part of the soft tissues (F) revealed a fibrous zone corresponding to unstructured cells which encompasses the stone.

Obviously, the cellular architecture of the stone is very different from that of the pericarp. Two main different tissue zones are clearly observable: the testa, corresponding to the peripheral zone, is approximately 100 μm thickness which surrounds the endosperm that corresponds to the inner part (Figure 2D).

The testa shows several well-defined layers of cells. The most external is composed of small cells showing rectangular form and whose cell wall is very thick and sclerotized as can be deduced from the intense coloration by toluidine blue (Figure 2D). Then the most inner part of the testa is composed of two internal and parallel layers of well-organized cells situated approximately at 80 μm from the surface of the stone (Figure 2D). The most external layer appears more deeply stained by toluidine blue than the most internal one, suggesting that these two types of cells do not have the same composition. It is interesting to see that the testa shows this very particular tissue organization showing cells with different cell wall thickness, sizes, and orientations. This may confer to the testa very specific physical properties acting as a protective barrier. Below this external layer, an unstructured and inhomogeneous zone of around 50 μm thickness containing large free cells with very variable forms is observable (Figure 2D). Concerning the endosperm zone (Figure 2D) which corresponds to storage tissues, it is composed of large-sized cells only weakly colored by toluidine blue and orientated perpendicularly to the cells of the testa. This tissue likely contains proteins and oils the latter taking the form of globules of darker color clearly visible in the cells (Figure 2D).

Localization of Tannins in the Pericarp. *Tannins Localization by Light Microscopy in Combination with DMACA Staining.* In our recent study, condensed tannins were characterized in date tissues by phloroglucinolysis associated with HPLC-UV and mass spectrometry.[1]

We showed that these compounds were oligomers and polymers of (−)-epicatechin highly concentrated both in the edible parts and the stones.

The DMACA staining of condensed tannins allowed us to localize these compounds in the edible tissues of the date (Figure 3). Interestingly, the staining was not distributed in the whole tissues but was very specifically located in the external part of the mesocarp approximately at 1500 μm inside the

pericarp and with a thickness close to 1000 μm (Figure 3B). Higher magnification (Figure 3C) revealed that the tannins are located in 3−5 layers of very large spherical cells reaching 200 μm diameter and having thin cell walls. The intense blue coloration seems to fill almost completely the intracellular area suggesting the massive presence of these flavanols in the vacuoles. Although DMACA staining does not permit to distinguish between flavanol monomers (i.e., catechins) and condensed tannins (i.e., proanthocyanidins), it is likely that those flavanols mainly correspond to highly polymerized procyanidins as it was shown in our previous study.[1]

Localization of Tannins by Transmission Electron Microscopy (TEM). Polyphenols and particularly those containing *o*-diphenol groups in their structure are highly osmiophilic agents.[13] Therefore, when they are present in the tissues, condensed tannins are responsible for high electron density creating contrasted zones in TEM images.

In a previously published work conducted on dates using TEM observation, Shomer et al. (1998)[12] proposed that tannins were probably located in the subepidermal zone (M1) of the epicarp on the basis of high density areas of this tissue zone. This hypothesis was invalidated by our observations in light microscopy after specific staining of flavanols structures with DMACA. Tannins are specifically located in the mesocarp (M2) in large-sized cells situated at 1500 μm from the epicarp cells.

Electron-dense precipitates are visible in the vacuoles of the mesocarp cells after the treatment of samples by osmium tetroxide (Figure 4A). These precipitates are in the form of granules of different sizes. The size of the granules is up to 0.2

dx.doi.org/10.1021/jf5013715 | J. Agric. Food Chem. 2014, 62, 6650−6654

μm in diameter (Figure 4B). The precipitates sometimes form clusters fused to tonoplast.

Tannins Localization in the Dates Stone. *Tannins Localization by Light Microscopy.* The DMACA staining of cross sections of the stone allowed us to observe the organization of tannins (Figure 5B,C). Tannins are specifically located in a single cell layer situated approximately at 50 μm from the surface of the testa (Figure 5B). In addition, close to this layer, some very large cells containing tannins are observed in the unstructured zone of the testa. Interestingly, knowing that tannins are antimicrobial and antifungal agents,[14] this organization makes us think that they are located in a specific cell layer, forming a defensive barrier that likely protects the stone against pathogen attacks.

The flavonoid accumulation pattern was examined in young seedlings and mature tissues of wild-type *Arabidopsis*. Flavonoid accumulation in mature plants was localized in cauline leaves, pollen, stigmata, floral primordia and in the stems of young actively growing inflorescences.[15]

Tannins Localization by TEM. The tannins of these cells are characterized by a continuous deposit extremely dense to the electrons. It consists of similar elements and expressing the same characters. This layer is formed by rectangular cells stacked to one another. The observations by transmission electron microscopy allow us to have some information on the dimensions of the cells tannins whose sizes range from 20 to 40 μm (Figure 6A). One also notices that these cells are characterized by the plasmic membranes surrounded by a thick rigid cell wall.

These tannins are present in cells of different forms. They mainly occur in the form of a continuous deposit extremely dense to the electrons (Figure 6A) and sometimes in the form of granular units (Figure 6B). Generally speaking, we did not detect the tannins localized in the cell wall as in the case of the grape proved by Amrani Joutei et al. (1994).[9]

To conclude, the observation of pericarp tissues by light and transmission electron microscopy revealed that tannins are located in the vacuoles of very large mesocarp cells. These cells are in turn located at 1500 μm from the surface. The microscopic approach has allowed us, for the first time, to locate the tannins in the stone. Those tannins are located in a specific cell layer located at 50 μm from the surface.

From this work, we can conclude on the high specificity of tannins organization in the pericarp and the stone of the date. This very specific organization may be related to the physiological role of tannins as active components able to protect the fruit and the seed against pathogen attacks. Interestingly, tannins in the stones may be also involved in the germination mechanisms.[16] As perspectives to this work, we would like to observe different stages of ripening fruits in order to have a better understanding of the building of the tannin pool in the fruit (i.e., structure and location) during growing and maturation.

been shown to be a major contributor for vasodialatory mechanism,[27] and actives modulating NO production in endothelial cells have been classically used to screen molecules for vascular health benefits.[28] Additionally, there are also reports of some of the small molecular weight polyphenols being bioavailable[29] without any biotransformation.

A global database on the polyphenol levels of various black tea has been published.[21] The data suggest that there is a huge variation in polyphenol levels among the black teas grown across the globe.[21] There has been no attempt made to date to understand how these variations in the levels and composition of flavonoids correlate with their bioefficacy for vascular function. Also, it is not clear if bioefficacy of tea polyphenols is linked to their amount in general, or whether it is driven by specific composition of polyphenol in tea.[30]

In the present study, we investigated representative teas from select geographies for their influence on in vitro markers of endothelial function. Tea infusions were quantified for their polyphenolic content, and their biological functions were evaluated as free radical scavenging, intracellular antioxidant property, and NO production in endothelial cells. Further, the composition of all of these tea infusions were analyzed and correlated with investigated biological markers using the Pearson correlation. This study provides knowledge on the variability in polyphenolic content of WoBTs and their correlation to biological functions such as antioxidant property and NO enhancement properties implicated in endothelial function in vitro and therefore eventually might influence the in vivo cardiovascular benefits of tea.

MATERIALS AND METHODS

Materials. 4-Amino-5-methylamino-2′,7′-difluororescein diacetate (DAF FM-DA) and 5-(and -6)-chloromethyl-2′,7′-dichloro-dihydro-fluorescein diacetate acetyl ester (CM-H2DCFDA) were purchased from Invitrogen (OR). DMEM, 2,2-diphenyl-1-picrylhydrazyl free radical (DPPH), α-tocopherol, *N*-acetyl-L-cysteine (NAC) hydrogen peroxide (H_2O_2), Folin−Ciocalteu's phenol (FC) reagent, and water (HPLC grade) were purchased from Sigma Chemical Co. (MO). Unless specified, all other reagents were procured from Sigma Chemical Co. (MO). Black tea samples were procured from Unilever R&D, Colworth.

Preparation of Black Tea Infusion. Tea infusions were prepared as mentioned elsewhere.[21] Briefly, black tea was finely ground with mortar and pestle and passed through 0.5 mm sieve to remove tea fibers. 100 mL of boiling water (HPLC grade) was poured unto 2 g of ground powder and stirred. The content was allowed to stand for 2 min, followed by a stir. The content was filtered through 0.4 μm Whattman filter placed under vacuum. The infusion was immediately frozen in liquid nitrogen to prevent further oxidation or degradation. This process was employed to reduce variability during the extraction process as factors like particle size, fibers, and temperature play a very crucial role in the extraction process. The extraction process was standardized to maximize the yield of flavonoids and its batch to batch reproducibility.

Quantification of Polyphenol in the Infusion Using the Folin−Ciocalteu (FC) Method. The total polyphenol content of the infusion was determined colorimetrically using Folin−Ciocalteu (FC) phenol reagent[21] as per ISO 14502-1. Briefly, 20 μL of 1:20 diluted tea infusion was mixed with 40 μL of Na_2CO_3 in a 96-well microtiter plate. 50 μL of FC reagent was added after 5 min and incubated in the dark for 1 h. Reaction product was measured at 765 nm using TECAN-2000. Different concentrations of gallic acid were used as standard, and polyphenols were quantified as gallic acid equivalents.

Quantification of Catechin, Theobromine, and Gallic Acid by HPLC. Catechins, caffeine, theobromine (TB), and gallic acid (GA) were analyzed by ISO 14502-2:2005(E) method.[31] For HPLC analysis, a Phenomenx phenyl-hexyl, 5 μm, 4.6 × 250 mm HPLC column was used. The mobile phase A was 9% (volume fraction) acetonitrile, 2% (volume fraction) acetic acid with 20 μg/mL EDTA, and mobile phase B was 80% (volume fraction) acetonitrile, 2% (volume fraction) acetic acid with 20 μg/mL EDTA. Separation was carried out at 1 mL/min flow rate at 35 °C and detection at 278 nm using Agilent HPLC (1100 Series). HPLC analysis was carried out using a gradient elution. Binary gradient conditions: 0% mobile phase B for 10 min, then over 15 min, a linear gradient to 32% mobile phase B, and hold at this composition for 10 min; then reset to 0% mobile phase B to equilibrate for 10 min before next injection. Standard compounds were used to generate calibration curves.

Quantification of Theaflavins (TFs) by HPLC. Theaflavins were analyzed by using the HPLC method.[32] Nova-Pak C-18, 60A, 4 μm, 3.9 × 150 mm HPLC column was used. Mobile phase A was 2% (volume fraction) acetic acid, and mobile phase B was acetonitrile. Separation was carried out at 1 mL/min flow rate at 40 °C and detection at 380 nm using Shimadzu LC-10A HPLC. Standard theaflavins were used to generate calibration curves.

UPLC Fingerprinting of Thearubigins. The UPLC analysis of tea infusions was done using the method developed in house. For UPLC analysis, a Phenomenex Kinetex C18, 100 × 2.1 mm, 1.7u, 100A column was used. Mobile phase A was 0.5% (volume fraction) acetic acid in water, and mobile phase B was 100% acetonitrile. Separation was carried out at 0.2 mL/min flow rate at 35 °C and detection at 350 nm using the Agilent 1290 series system. UPLC analysis was carried out using a gradient elution. Binary gradient conditions: 0% mobile phase B for 5 min, then over 50 min, a linear gradient to 25% mobile phase B, 30% mobile phase B until 55 min and coming back to 0% mobile phase B at 56 min and then to equilibrate for 4 min before next injection. The known compounds like catechins, theaflavins, chlorogenic acid, caffeine, theogalline, gallic acid, theobromine, and flavonol glycosides were identified by injecting their standards, and all of the remaining peaks that were not identified were considered as thearubigin peaks. Because thearubigins are complex compounds and their standards are not commercially available, the method was validated for repeatability of retention time (RT) and recovery of known compounds by UPLC.

Determination of Free Radical Scavenging Property Using DPPH Assay. The radical scavenging capacities of black tea infusions were determined using the DPPH radical method.[22] Briefly, 1 mL of 1:20 diluted infusion was added to 1 mL of 2 mM ethanolic DPPH solution in a cuvette. The mixture was shaken vigorously, and the absorbance was measured at 517 nm at 0 and 30 min. α-Tocopherol (200 μM) served as a positive control. All of the tests were performed in triplicate, and the inhibition rate was calculated according to the formula of Yen and Duh.[33]

Cell Culture. The human endothelial cell line (EA.hy926) was procured from American Type Culture Collection (ATCC; VA). Cells were cultured in DMEM (Sigma) supplemented with 2 mM L-glutamine, 100 U/mL penicillin, 100 μg/mL streptomycin, and 10% vol/vol FBS (Gibco, Invitrogen). Human umbilical vein endothelial cells (HUVECs) were purchased from Lonza. HUVECs were cultured in M199 supplemented with endothelial growth factor, 0.001% heparin sulfate, 10% fetal bovine serum (FBS) (v/v), 1% penicillin (w/v), and streptomycin (w/v). Cells were incubated at 37 °C in 95% humidified air and 5% CO_2. After 70−80% confluence was attained, the cells were subcultured by trypsinization.

Determination of Antioxidant Property of Black Tea Infusion. Tea infusion-induced antioxidant property was determined as described previously.[34] Briefly, EA.hy926 (2.5×10^4) cells were seeded onto 96-well flat bottom tissue culture plates for 6 h. After adherence, cells were treated with black tea infusion for 24 h, followed by wash to remove adhered polyphenols. The cells were then loaded with DCF-DA (1 μM) for 30 min followed by a wash with serum free medium. Subsequently, cells were treated with 100 μM H_2O_2 for 5 min. The antioxidant capacity of cell is determined by its ability to quench H_2O_2 entering inside the cellular compartment. The free intracellular H_2O_2 was determined by its reaction with DCF dye. The fluorescence intensity was measured at excitation/emission maxima of

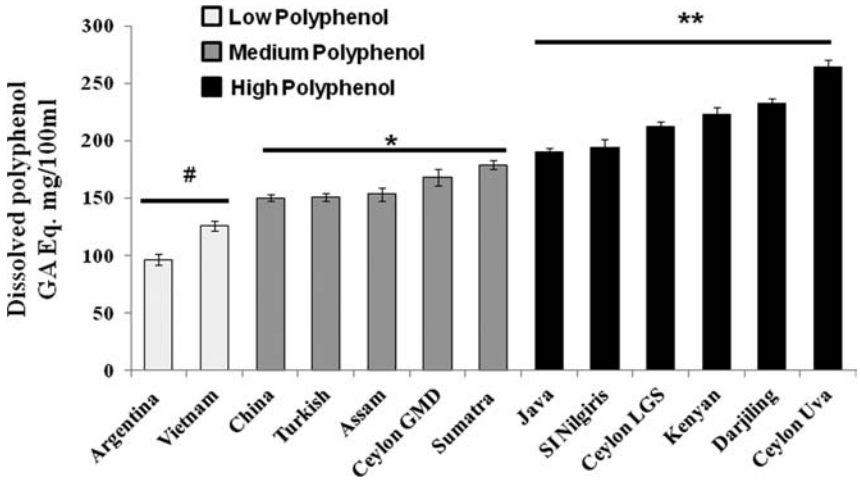

Figure 1. Dissolved polyphenol levels in the prepared tea infusion for the global black teas (WoTs). The samples were prepared and the polyphenol were quantified by Folin−Ciocalteu (FC) phenol method using gallic acid as standard. Data are presented as mean ± SD. Statistical comparisons were made using Student *t* test. "*" and "**" values were statistically significant (*$p < 0.05$; **$p < 0.01$) with respect to teas with low polyphenols (#).

495/515 nm, respectively, using TECAN 2000. Cells treated with the infusion but without H_2O_2 served as normalization control. NAC (25 μg/mL) was used as positive control.

Measurement of Intracellular Nitric Oxide (NO) in Endothelial Cells Using Flow Cytometry. Intracellular NO production was measured using flow cytometry.[35] EA.hy926 (1×10^5) cells were seeded in 24-well tissue culture plates. Cells were starved for 12−14 h after adherence to reduce basal NO levels. Cells were loaded with DAF FM-DA (1 μM) for 30 min and washed twice. Subsequently, cells were stimulated with black tea infusion for 30 min, in the presence or absence of L-NAME (10 mM; 30 min preincubation). The stimulated cells were trypsinized and fixed with 2% PFA for 15 min. A population of 10 000 cells were gated and segregated on the basis of their relative fluorescence intensities using FACS Calibur (Becton Dickenson; San Diego, CA). The mean fluorescence yield was measured and compared to the respective population in untreated cells.

Statistical Analyses. Data are presented as mean ± SD of at least three independent experiments ($n = 3$) in triplicate. Variances of mean values were statistically analyzed by the Student's *t* test. $p \leq 0.01$ was considered significant. Pearson correlation was carried out using Sigma stat software to observe the correlation between NO production and antioxidant property versus various ingredients in tea infusion.

RESULTS AND DISCUSSION

On the basis of the extent of fermentation, tea is classified into three major types: black (maximum oxidized), green (minimum oxidized), and oolong (partially oxidized) tea. The compositional profile of flavonoids also varies with the extent of oxidation reactions;[25] however, the amounts of total polyphenols in tea remain comparable, if made from the same leaf source.[34] Because the water extractability of flavonoid species differs, infusions of these teas also vary in terms of their end-cup composition.[34] Also, composition of flavonoids differs, based on the process of tea making (orthodox (rolling tea leaves) or CTC (cut, tear, curl)),[36] nature of tea variety,[34] and region in which it is grown.[21] This intrinsic variation of flavonoids within teas can affect both end-cup delivery of flavonoids and their composition. Considering flavonoids are the main efficacious species in tea, such variations are likely to cause differences in the extent of benefits delivered by various teas. In this Article, we investigated the polyphenol extractability of various black teas and evaluated their antioxidant property and NO enhancement ability in endothelial cells.

Polyphenol Content in Black Tea Across Geographies. Black teas originating from various geographies (Supporting Information Figure 1) were used in the study, and the tea infusions were prepared (as mentioned in M&M) and analyzed for their total polyphenol levels using Folin−Ciocalteu reagent[21] and expressed as gallic acid equivalents. The data are represented in Figure 1. There was a significant variation in the extractability of polyphenols under normally used conditions for brewing tea (data not shown). These findings are similar to those reported previously.[37,38] Variability of polyphenols in end cup may be the result of the inherent variation in polyphenol levels present in the tea leaves or due to their extractability.[38] The major reason for variation in extractability in turn arises due to the difference in the particle size and the nature of infusion protocol. We ensured minimum variability in extraction by standardizing the protocol for infusion preparation by maintaining uniformity in granule size (0.2−0.4 mm), infusion time (3 min), cycles of stirring (8 cycles), and filtration time (1 min), so as to get reproducible polyphenol extraction.

When analyzed for polyphenols levels in various tea infusions (Figure 1), Ceylon Uva (name associated with Uva province), Darjeeling, Kenya, Ceylon LGS (Ceylon, low grown semi-shaded), SI (South Indian) Nilgiries and Java teas contained high polyphenol levels (above 200 mg equiv GA/100 mL), while teas from Vietnam and Argentina contained the least amounts (∼100 mg equiv GA/100 mL). Chinese, Turkish, Assam, Ceylon GMD (Ceylon, good medium dust), and Sumatra teas contained intermediate polyphenols levels (125−175 mg equiv GA/100 mL). Our data suggest that the variation in the levels of polyphenol exists in black teas (ranging from ∼100−250 mg equiv GA/100 mL/2g black tea) across geographies (WoBTs). Such variations in polyphenol levels in teas from various geographies have previously been reported.[21] The difference in the polyphenol levels has been shown to be associated with the altitude in which these teas have been grown.[39,40] In these studies, they demonstrated that amounts of all of the catechins increased significantly with increasing altitude. Although higher levels of polyphenols would exhibit

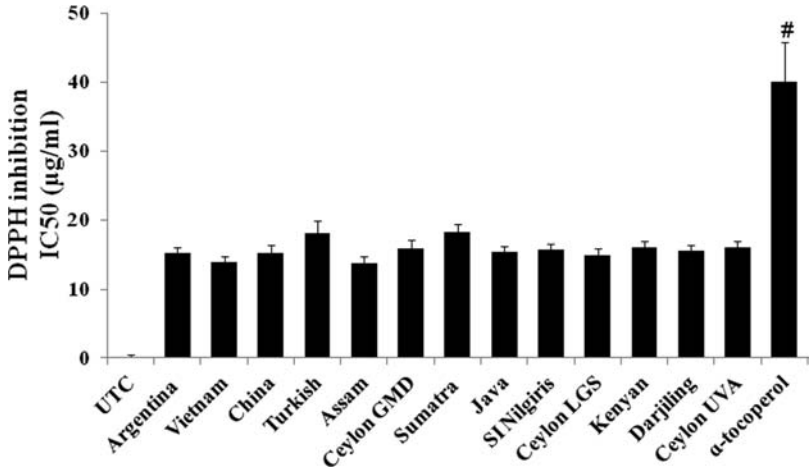

Figure 2. DPPH (1,1-diphenyl-2-picrylhydrazyl) free radical scavenging property of different black tea infusions normalized to polyphenol levels. The tea infusions were normalized to 25 μg/mL gallic acid equivalents. DPPH free radical scavenging property was determined as mentioned in M&M. Data represented as IC50 ± SD (μg/mL). α-tocopherol (200 μM) was used as positive control. Statistical comparisons were made using Student t test. The "#" values were statistically significant ($p < 0.01$) with respect to untreated control (UTC) and various tea samples. Free radical scavenging properties amongst WoT samples were not significantly different.

higher biological activities, to understand the influence of composition of polyphenol on biological activity, we equalized the polyphenol levels of different teas (WoBTs) and evaluated their biological functions.

Free Radical Scavenging Property of Different Black Teas. Oxidation of lipids and protein has been implicated in various diseases etiologies,[41] especially in vascular pathophysiology.[42,43] Mechanistically, increase in the levels of reactive species in the plasma leads to generation of oxidized lipid and proteins, which are electrophilic in nature.[44] These reactive molecules (reactive lipid/protein species) interact with cellular nucleophiles such as the amino acids cysteine, lysine, and histidine, which are components of cell surface receptors. Binding of electrophilic molecules changes the conformation or activation status of receptor, resulting in altered signaling pathways[44] or generation of intracellular ROS species. Also, increased levels of superoxides and peroxides react with NO produced in endothelial cells, resulting in reduced bioavailability of NO[12,13,45] for its function.

Consumption of phyto-chemicals rich in flavonoids is reported to increase oxygen radical absorbance capacity (ORAC), Trolox equivalent antioxidant capacity (TEAC), and total radical trapping parameter (TRAP) levels in plasma, which are physiological measures of free radical scavenging property in vivo.[46] On the basis of this hypothesis, we used the 1,1-diphenyl-2-picrylhydrazyl radical (DPPH)-based in vitro scavenging assay to test the ability of components to act as free radical scavengers or hydrogen donors and to evaluate the free radical scavenging property of tea phyto-chemicals.

The free radical scavenging properties of different teas were evaluated. The IC_{50} is represented in Figure 2. All of the tested tea infusions showed good DPPH scavenging property (Supporting Information Figure 2), but at equivalent polyphenol concentrations, their efficacies were not significantly different from each other (Figure 2). Similar correlation was deduced by Anesini et al.,[47] for Argentinean commercial teas. In general, the radical-scavenging property of flavonoids depends on the molecular structure and the substitution pattern of hydroxyl groups, that is, on the availability of phenolic hydrogen and on the possibility of stabilization of the resulting phenoxyl radicals via hydrogen bonding or by expanded electron delocalization.[48] However, in addition to free radical scavenging property, the intracellular antioxidant elements such as GSH and free radical reducing enzymes (SOD, catalase and peroxidase) play a crucial role in determining redox properties of cells. Such intracellular antioxidant systems prevent the uncontrolled generation of free radicals and activated oxygen species, or inhibit their reactions with biological materials, thereby preventing protein malfunction. eNOS uncoupling is one of such pathophysiological alterations observed in endothelial dysfunction.[9,49]

Ideally, vasodilatation measured as flow-mediated dilation (FMD) with tea intervention should be the basis of evaluation of VF in humans,[6] but such measurements are resource intensive and practically not viable for investigating multiple samples.[50] Therefore, physiologically relevant biomarkers such as antioxidant activity (AOX) and eNOS activity measured as increases in NO levels were chosen as representative surrogate in vitro measures of vascular function.[9,49]

Alteration in the in Vitro Redox Property by Various Black Teas. Cardiovascular risk factors such as hypertension, hypercholesterolemia, diabetes mellitus, or chronic smoking stimulate the generation of reactive oxygen species in the endothelium.[9] This increase in intracellular ROS species plays an important role in vascular damage and progression of various vascular diseases, including atherosclerosis, ischemic heart disease, hypertension, and congestive heart failure.[2,9,28] Cellular mechanisms of ROS production involve sources such as the mitochondrial respiratory chain family of NADPH oxidases, xanthine oxido-reductase, or uncoupled nitric oxide synthase. All of these enzyme levels are found to be up-regulated and activated in animal models of hypertension, diabetes, and in patients with sedentary lifestyle and cardiovascular risk.[9,51] On the other hand, an accelerated degradation of NO (by its reaction with $O_2^{\cdot-}$) is likely to occur in vascular disease, which in turn leads to eNOS uncoupling and enzyme dysfunction.[52] Generation of ROS is counteracted by its destruction through antioxidant systems like super oxide dismutase, catalase, glutathione redox cycle, and ROS scavengers.[12]

The antioxidant benefit of tea is largely due to its ability to increase antioxidant enzymes[2,3] and enhance intracellular ROS

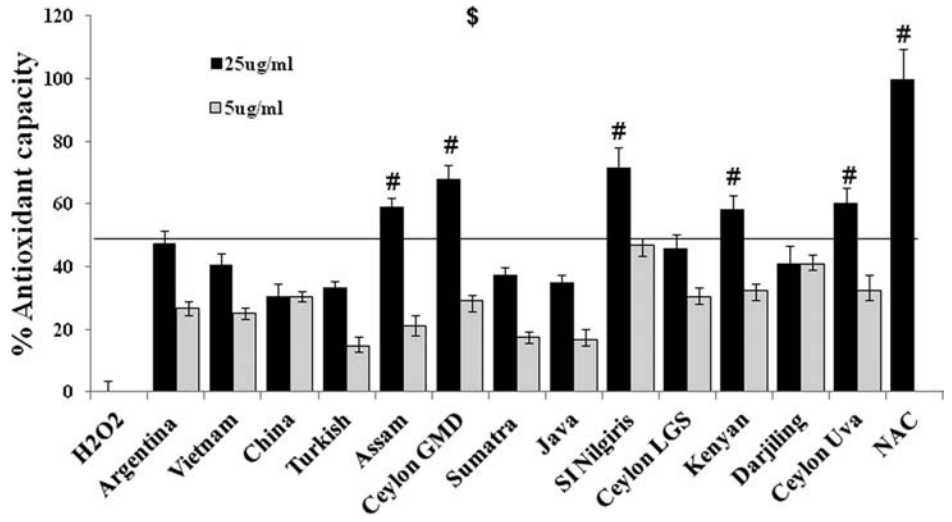

Figure 3. Antioxidant property of different black tea infusions at equivalent polyphenol levels in endothelial cells. EA.Hy926 cells were treated with different concentrations of tea infusions (5−25 μg/mL) for 24 h. *N*-Acetyl cystiene (NAC) was used as positive control (100% H_2O_2 scavenging). Cells treated with H_2O_2 served as negative control (0% H_2O_2 scavenging). Data represented for 25 μg/mL (■) and 5 μg/mL (□) with mean ± SD (n = 3). Statistical comparisons were made using the Student t test. Values were considered statistically significant ($^{\#}p < 0.01$) if % antioxidant capacity is above 50%. The antioxidant capacity of all WoTs was statistically significant ($^{\$}p$) to negative control ($H_2O_2$).

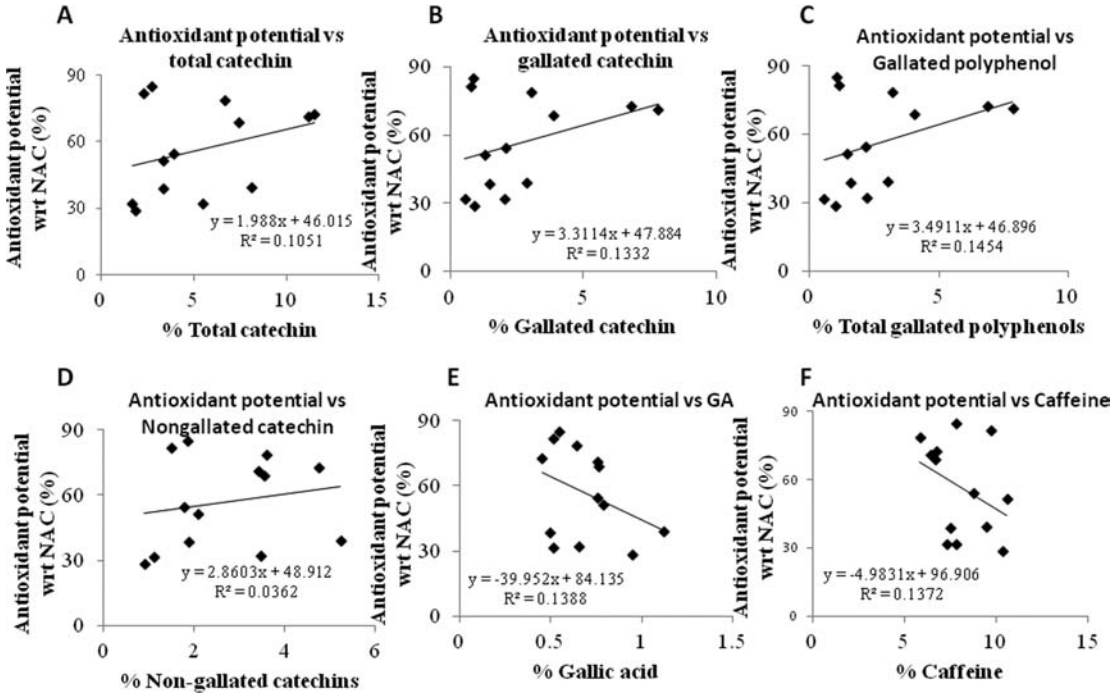

Figure 4. Pearson-correlation analysis between antioxidant property (AOX) and various components in tea infusion. (A) AOX versus total catechins; (B) AOX versus gallated catechin (EGCG+ECG+CG); (C) AOX versus total gallated polyphenols (EGCG+ECG+CG+TF4); (D) AOX versus nongallated catechins (EC+EGC+GC); (E) AOX versus gallic acid; and (F) AOX versus caffeine. The correlation graph was derived with 25 μg/mL PP of tea infusion.

scavengers such as GSH,[2,9] which prevents deleterious effects of intracellular ROS. Thus, this mechanism presumes to play a major role in mediating the cardio-protective effect of tea.[2,3,9,28] To evaluate the antioxidant property of these teas under cellular conditions, cells were pretreated with tea, followed by oxidant trigger, H_2O_2. *N*-Acetyl-L-cysteine (NAC) was used as positive control. The data are represented in Figure 3. The assays were performed at equated polyphenol levels to capture any effects due to compositional variations of tea infusions.

Among the tested black teas, infusions from Ceylon GMD, Nilgiries, Kenya, Assam, and Ceylon Uva showed higher antioxidant property (>50% H_2O_2 scavenging) (Figure 3) as compared to other teas. Because teas were tested at equated polyphenol levels, the data indicate that the chemical composition of tea infusion rather than polyphenol amount contributes to the observed antioxidant (AOX) benefit. Although we did not analyze the type of cellular antioxidant components like GSH, SOD, catalase, and other free radical scavenging enzymes, the results represent the total intracellular

dx.doi.org/10.1021/jf501611w | J. Agric. Food Chem. 2014, 62, 6655−6668

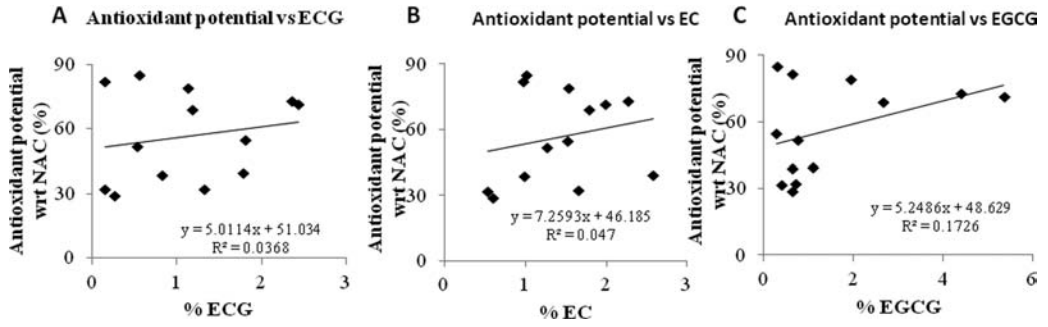

Figure 5. Pearson-correlation analysis between antioxidant property and specific catechins in tea infusion. (A) AOX versus ECG; (B) AOX versus EC; (C) AOX versus EGCG. The correlation graph was derived with 25 μg/mL PP of tea infusion.

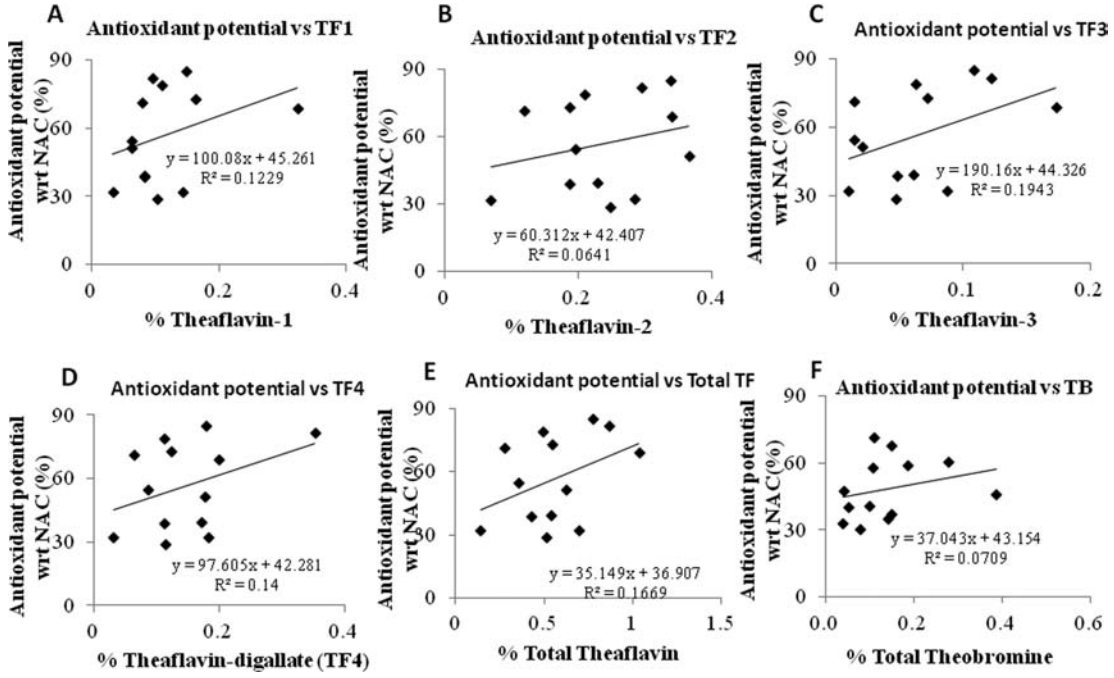

Figure 6. Pearson-correlation analysis between antioxidant property and specific theaflavins (TFs) and phenoli acids in tea infusion. (A) AOX versus TF1; (B) AOX versus TF2; (C) AOX versus TF3; (D) AOX versus TF4; (E) AOX versus total TFs; and (F) AOX versus theobromine (TB). The correlation graph was derived with 25 μg/mL PP of tea infusion.

scavenging capacity generated after pretreatment with tea infusion, which does represent the net effect of all of these protective enzymes.

There was no significant correlation between AOX property and various tea actives (Figures 4–7). However, there was nonsignificant positive association with total catechins, gallated catechins, and gallated polyphenols, while nongallated catechins showed neutral effect (Figure 4A–D). Specifically, epicatechin-gallate (ECG) and epicatechin (EC) showed neutral correlation, while epigallocatechin-gallate (EGCG) showed nonsignificant positive correlation (Figure 5A–C). Among theaflavins (Figure 6A–E), TF1 (r^2 = 0.12), TF3 (r^2 = 0.19), and TF4 (r^2 = 0.14) showed nonsignificant positive correlation, while TF3 showed neutral effect (r^2 = 0.06). However, nonflavonoid polyphenol was also evaluated for their function. Gallic acid (r^2 = 0.13) and caffeine (r^2 = 0.13) showed nonsignificant negative correlation (Figure 4E,F), while theobromine (r^2 = 0.07) showed neutral effect (Figure 6F).

A large proportion of polyphenols in black tea exists as oligomeric species termed as thearubigins (TRs); however, the complete chemical characterization of these TRs is still under investigation. Nicholai and others have reported extensive studies on SII TRs.[53−55] By employing advanced analytical techniques such as electronspin transform ion cyclotron resonance mass spectroscopy (ESI-FTICR), they[53] showed that TRs are comprised of several thousands of compounds, with a molecular weight ranging between 1 and 1.5KDa.[18,55] They also observed a typical Gaussian hump in caffeine precipitated SII TRs,[18] containing majorly trimers and tetramers of flavan-3-ols.[18] Spectroscopic studies showed that TRs have basic catechin structure with benzotropolone and *ortho*-quinone moieties.[53] The group has also investigated the possible mechanism on how these molecules are formed using MALDI-TOF studies of SII TRs. They suggest the formation of polyhydroxylated species, which are formed via oxidation and nuclieophilic addition of water and hydrogen peroxide to catechin dimer and oligomers. All of these extensive reports provide information that thearubigins have flavonoid backbone structure.[53,55]

Among flavonoids, flavan-3-ols (catechins) have absorption maxima at 278 nm, flavonols and chlorogenic acids at 350 nm, and oligomeric flavonoids (theaflavins) at 380 and 460 nm.[56]

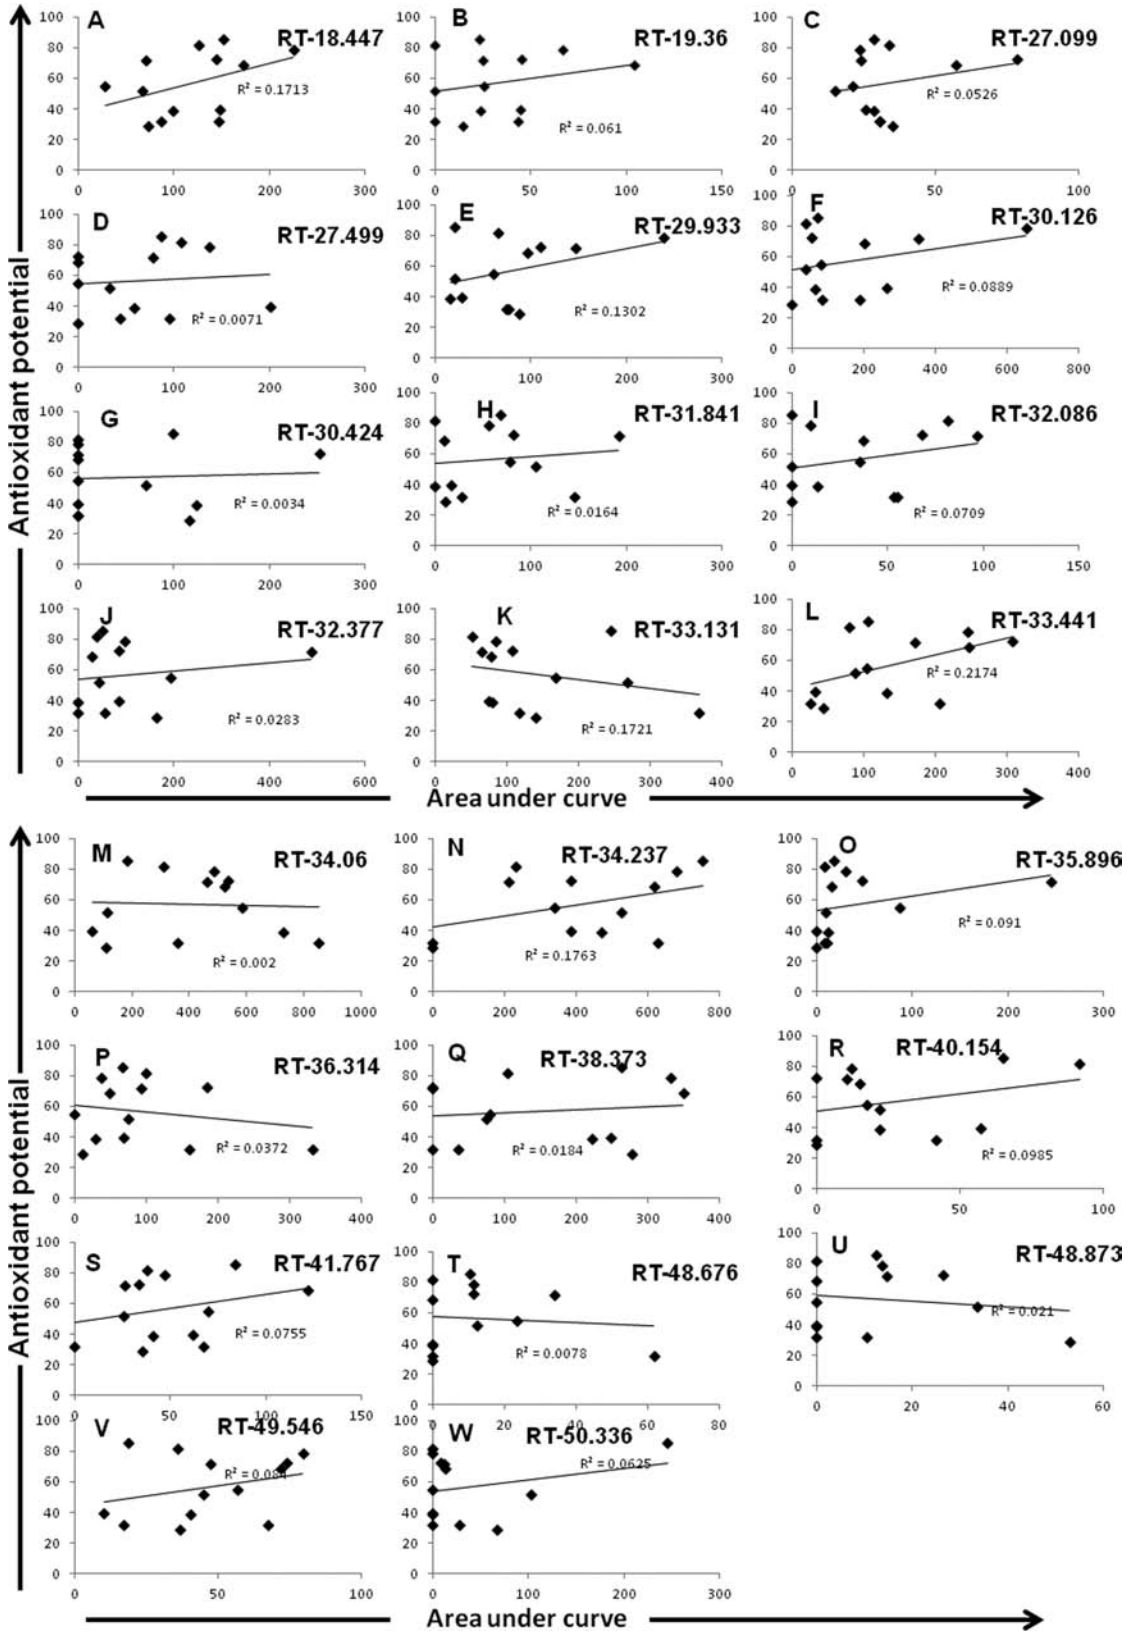

Figure 7. Pearson-correlation analysis between antioxidant property and various TRs (A–W) with specified retention time (RT) in tea infusion. The correlation graph was derived with 25 μg/mL PP of tea infusion.

During fermentation of tea, oxidation of monomeric flavonoids leads to formation of TRs. Such transformation involves oxidation followed by coupling and ring condensation reaction. These reactions would result in products with increased conjugation and absorption at longer wavelengths. Hence, oxidized catechins or TRs should have absorption maxima also at ~380 nm, which has been used to relatively quantify their amounts.[56] The known phenolic acids, flavonol glycosides, and

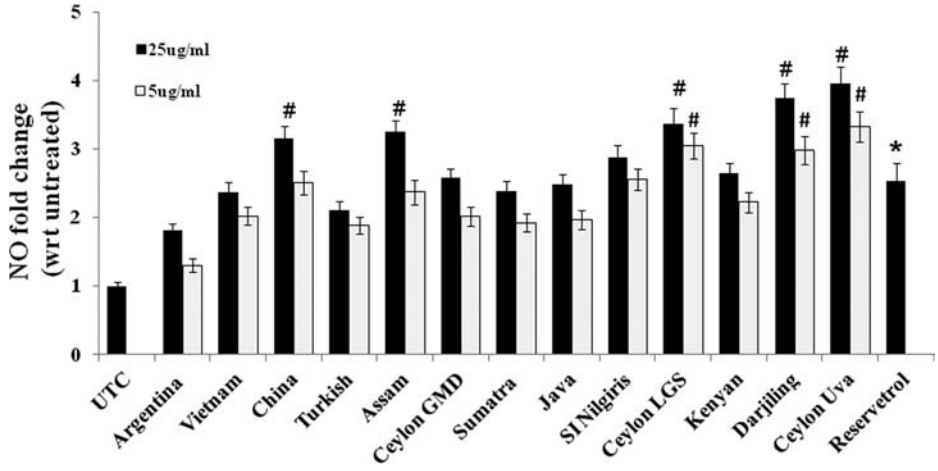

Figure 8. Nitric oxide stimulating potential of different black tea infusions at equivalent polyphenol levels in endothelial cells. The infusions were evaluated for NO enhancement in EAHy926 cells. The cells were treated with different concentrations of tea infusions (25 μg/mL (■) and 5 μg/mL (□)) for 30 min. Data are presented as mean ± SD (n = 5). Reservetrol (10 μM) was used as positive control. Statistical comparisons were made using Student t test. "#" and "*" values were statistically significant ($p < 0.01$) with respect to untreated control (UTC) and Argentinean tea sample (lowest in NO enhancement).

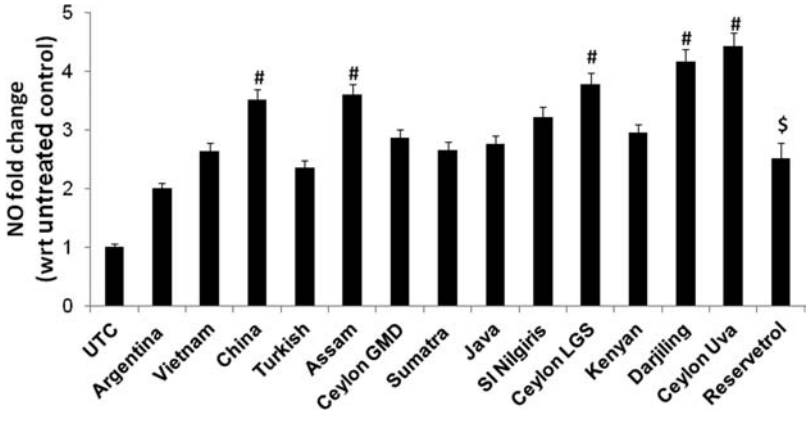

Figure 9. Nitric oxide stimulating potential of different black tea infusions at equivalent polyphenol levels in HUVEC. The data represent NO levels in primary HUVEC at 25 μg/mL concentration of tea infusion for 30 min. The "#" values were statistically significant ($p < 0.01$) with respect to reservetrol ($).

TFs that absorb at this wavelength were not considered for TR analysis.

We observed several peaks in the UPLC chromatogram (Supporting Information Figure 3A−C) after elimination of known components of black tea such as catechins, TFs, phenolic acids, and flavonol glycosides. The peaks that showed absorption at 380 nm and had retention time above 18 min were considered as thearubigin (TR) peaks. For correlation purpose, we only considered 29 major peaks that were consistently present in majority of the tea (Figure 7). The TR peaks having retention time of 18.447, 29.933, 33.441, and 34.237 (Figure 7A, E, L, and N) showed nonsignificant positive correlation with antioxidant potential, while TR peaks having retention time of 33.131 showed nonsignificant negative correlation (Figure 7K).

Among the tested black teas, infusions from Ceylon GMD, Nilgiries, Kenya, Assam, and Ceylon Uva showed higher antioxidant property. This may be due to the presence of a higher amount of theobromine and gallated catechins, which are previously reported to increase expression of antioxidant enzymes.[57,58] Our data suggest that none of the other actives analyzed showed significant correlation with antioxidant property of tea. However, these actives in tea showed nonsignificant positive correlation, indicating that positive species such as catechins, TFs, and some TRs might cumulatively be responsible for the observed AOX benefit of black tea. Further work is required to evaluate the mechanisms involved in the induction of cellular antioxidant property by specific flavonoids/phenolic acids.

In Vitro Efficacy of Teas To Promote Endothelial NO Production. Endothelial dysfunction (ED) significantly contributes to pathogenesis and clinical manifestation of CVD.[6,9] ED is characterized by decreased endothelial NO production in endothelial cell.[6,27] Black tea is reported to activate eNOS and thus enhance NO production in endothelial cells.[9,28] We analyzed 13 black teas, with distinct polyphenol amounts and composition, for their NO potentiating effect after normalizing for their polyphenol concentration. The results are represented in Figure 8. Variable response to agonist stimulation has been reported in different endothelial cell-types.[59] We evaluated NO production in response to various tea infusions (25 μg/mL) in primary HUVEC (Figure 9). The stimulatory response for the tested tea infusion behaved in a similar manner in both EA.hy926 (Figure 8) and HUVEC

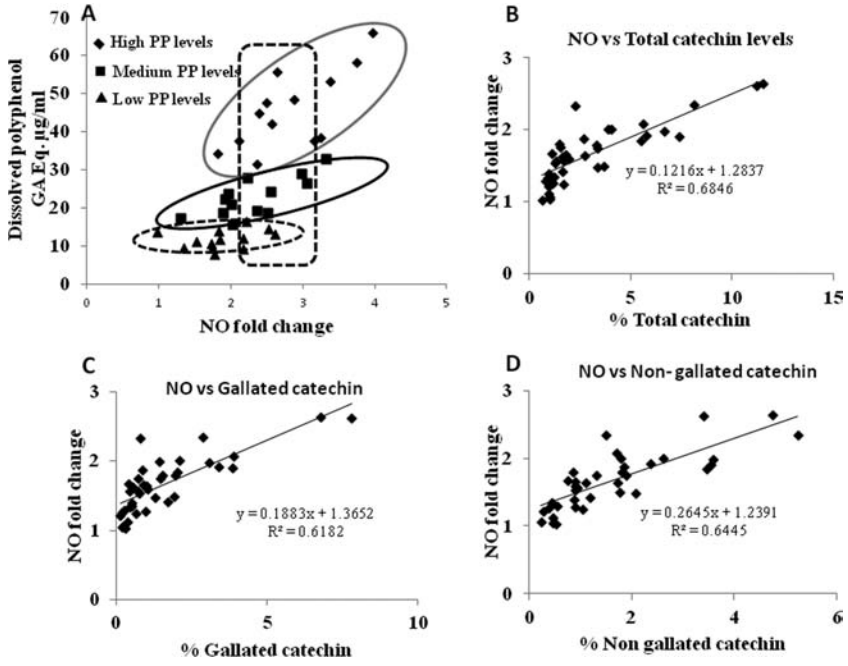

Figure 10. Pearson-correlation analysis between nitric oxide (NO) levels and various components in tea infusion. (A) NO versus total polyphenols (PP); the circled clusters indicate quantitative correlations of PP (gray circles (rhomboid) indicate PP range from 30 to 65 μg/mL GA equiv; black circles (square) indicate PP range from 15 to 30 μg/mL GA equiv, and black dotted circles (triangle) indicate PP range from 5 to 15 μg/mL GA equiv) with NO levels. The data indicate that NO potentiating effect increases with increasing concentration of PP. The dotted box represents qualitative correlation of PP with NO level. The data indicate that some teas are efficient enough to produce NO levels (2−3-fold) at very low PP concentration. (B) NO versus total catechins. (C) NO versus gallated catechin (EGCG+ECG+CG). (D) NO versus nongallated catechin (EC+EGC +GC). The correlation graph was derived with 25 μg/mL PP of tea infusion.

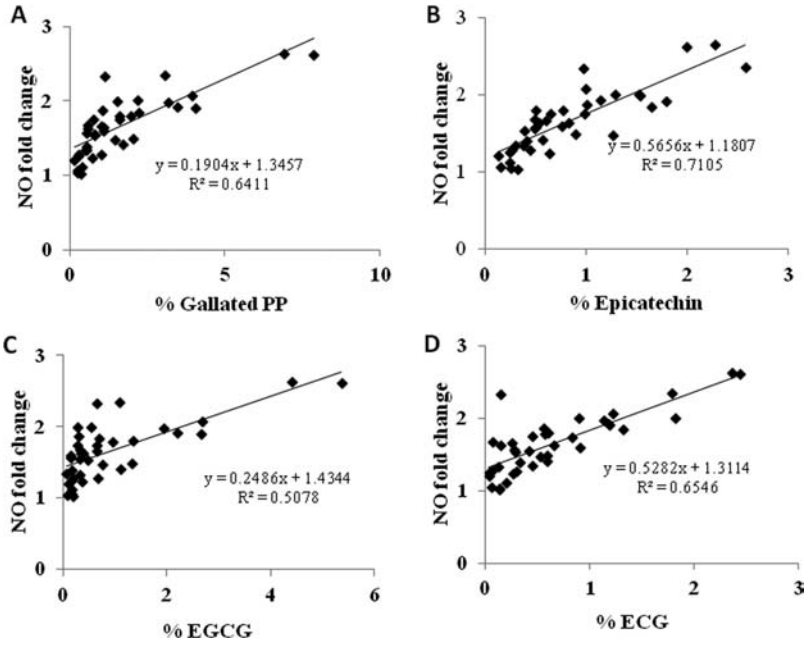

Figure 11. Pearson-correlation analysis between nitric oxide levels and specific flavonoids in tea infusion. (A) NO versus gallated PP (EGCG+ECG +CG+TF4); (B) NO versus EC; (C) NO versus EGCG; (D) NO versus ECG. The correlation graph was derived with 25 μg/mL PP of tea infusion.

(Figure 9). Although, in general, higher polyphenol levels resulted in higher NO levels (Figure 10A), the NO potentiating effect of WoBTs did not always correlate with the polyphenol levels (Figure 10A). Tea infusions from Assam, Darjeeling, and Ceylon (UVA), which had higher polyphenols as compared to other teas, showed higher NO enhancement as compared to other teas. Darjeeling teas, while being comparable in polyphenol levels to Kenyan teas, showed the highest NO enhancement (Figure 9).

The data suggest the possibility that composition of polyphenols, besides quantity, plays a significant role in eNOS activation by various geographical teas. Several functional species in tea are reported to stimulate eNOS enzyme and enhance NO production in endothelial cells. These include

dx.doi.org/10.1021/jf501611w | J. Agric. Food Chem. 2014, 62, 6655−6668

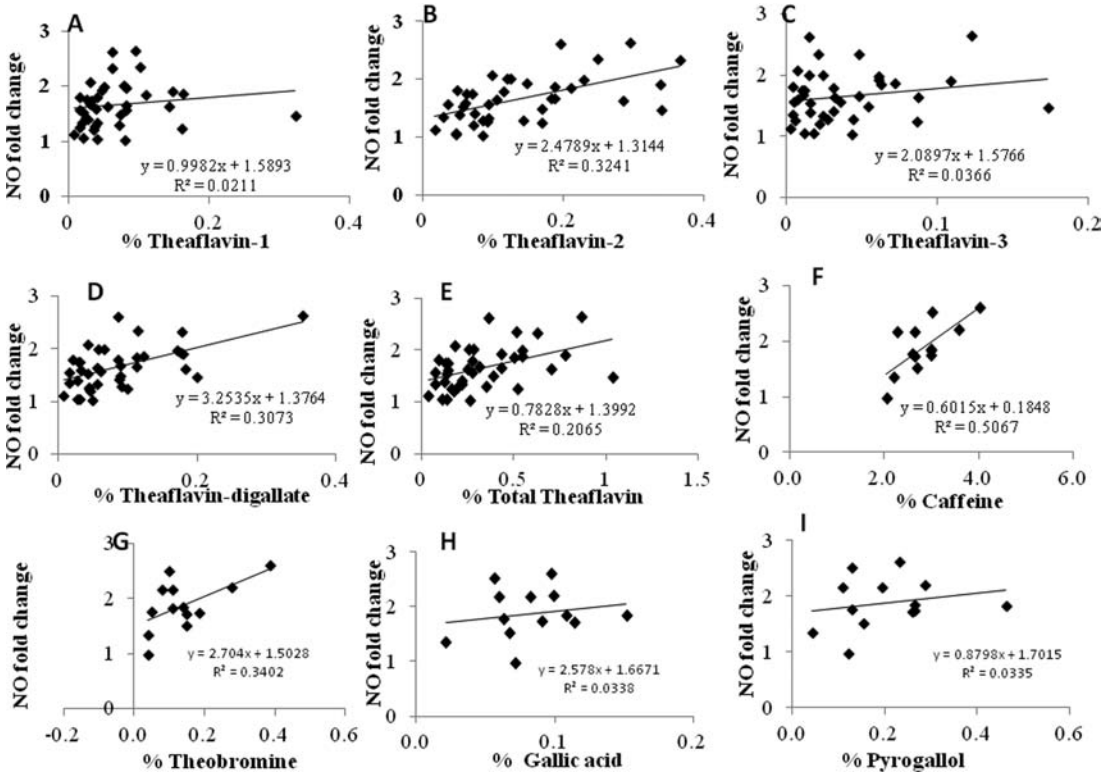

Figure 12. Pearson-correlation analysis between nitric oxide levels and specific theaflavins (TFs) and phenolic acids in tea infusion. (A) NO versus TF1; (B) NO versus TF2; (C) NO versus TF3; (D) NO versus TF4; (E) NO versus total TFs; (F) NO versus caffeine; (G) NO versus theobromine; (H) NO versus gallic acid; (I) NO versus pyrogallol. The correlation graph was derived with 25 μg/mL PP of tea infusion.

catechins,[5] theaflavins,[5,9,25] and flavones like quercetin, kaempferol, and rutin[3,24,26] and thearubigins.[5] Nonflavonoid components in tea like L-theanine,[60] theobromine,[61,62] and caffeine[63] are also reported to contribute to this function.

When analyzed for the correlation between NO production and different flavonoid components, total catechin showed significant correlation (Figure 10B; r^2 = 0.68). In general, the levels of catechins in black tea varied from 0.9% to 11.5%. There was a good correlation with gallated catechins (Figure 10C; r^2 = 0.61), nongallated catechins (Figure 10D; r^2 = 0.64), and gallated polyphenols (Figure 11A; r^2 = 0.64). This indicates that, in addition to gallated catechin, gallated polyphenols, which include gallated TFs and gallated TRs, would contribute to improve NO enhancement. There was no significant difference, however, between gallated and nongallated catechins (Figure 10C and D). Among the catechins, EC (Figure 11B; r^2 = 0.71), EGCG (Figure 11C; r^2 = 0.50), and ECG (Figure 11D; r^2 = 0.0.65) showed significant positive correlation.

We also analyzed the correlation for various TF species (Figure 12A–E). Total TFs showed mild positive correlation (r^2 = 0.20), although strong positive correlation was observed for gallated TFs like TF2 (r^2 = 0.32) and TF4 (TF4, r^2 = 0.30), while nongallated TFs like TF1 (r^2 = 0.02) and TF3 (r^2 = 0.03) showed neutral effects. The amounts of such TF species are very low; hence, their contribution toward NO stimulatory effect might be negligible. We also analyzed for some of the major phenolic acids in black tea such as caffeine, theobromine, gallic acid, and pyrogallol. Caffeine (r^2 = 0.50) and theobromine (r^2 = 0.34) (Figure 12F,G) showed significant positive correlation, while other phenolic acids failed to show any correlation (Figure 12H,I).

A large proportion (70%) of flavonoids in the black tea are present as TRs.[17] The TRs fractions are reported to show NO enhancement in endothelial cells and dilation of mesenteric arteries.[5] We evaluated the correlation between NO production and different TR peaks obtained by UPLC chromatogram. We could not find any significant positive correlation with the majority of the TR peaks (Figure 13). However, TR peak having retention time of 32.37 and 35.89 (Figure 13J and O) showed positive correlation with NO enhancement, while TR peak corresponding to retention time of 33.13 showed negative correlation (Figure 13K). From our data, it is evident that, among polyphenol, catechins (EC, EGCG, and ECG) are maximally active, while contribution by theaflavins remains miniscule. However, two of the investigated UPLC-based TR peaks showed positive correlation, while one TR peak showed negative correlation. This suggests that black tea has diverse pharmacological species, which strongly influence the NO potentiating effect in endothelial cells. Moreover, isolation, characterization, and screening of TRs would be an open area of investigation.

Among the tested tea infusion, Ceylon Uva, Darjeeling, Ceylon LGS, Assam, and China tea showed significant NO potentiating effect. We observed a higher amount of gallated catechin, TFs (TF2 and TF4), and some of the positive TR species to be present in these teas, which may alone or in combination explain enhanced NO production by these teas.

We also tried to understand the correlation between tea/tea ingredient-mediated increase in NO enhancement and antioxidant capacity of the cell. We observed no correlation between NO production in endothelial cell with enhanced intracellular free radical scavenging property (Figure 14; r^2 = 0.01). It is reported that increased levels of ROS would

dx.doi.org/10.1021/jf501611w | J. Agric. Food Chem. 2014, 62, 6655–6668

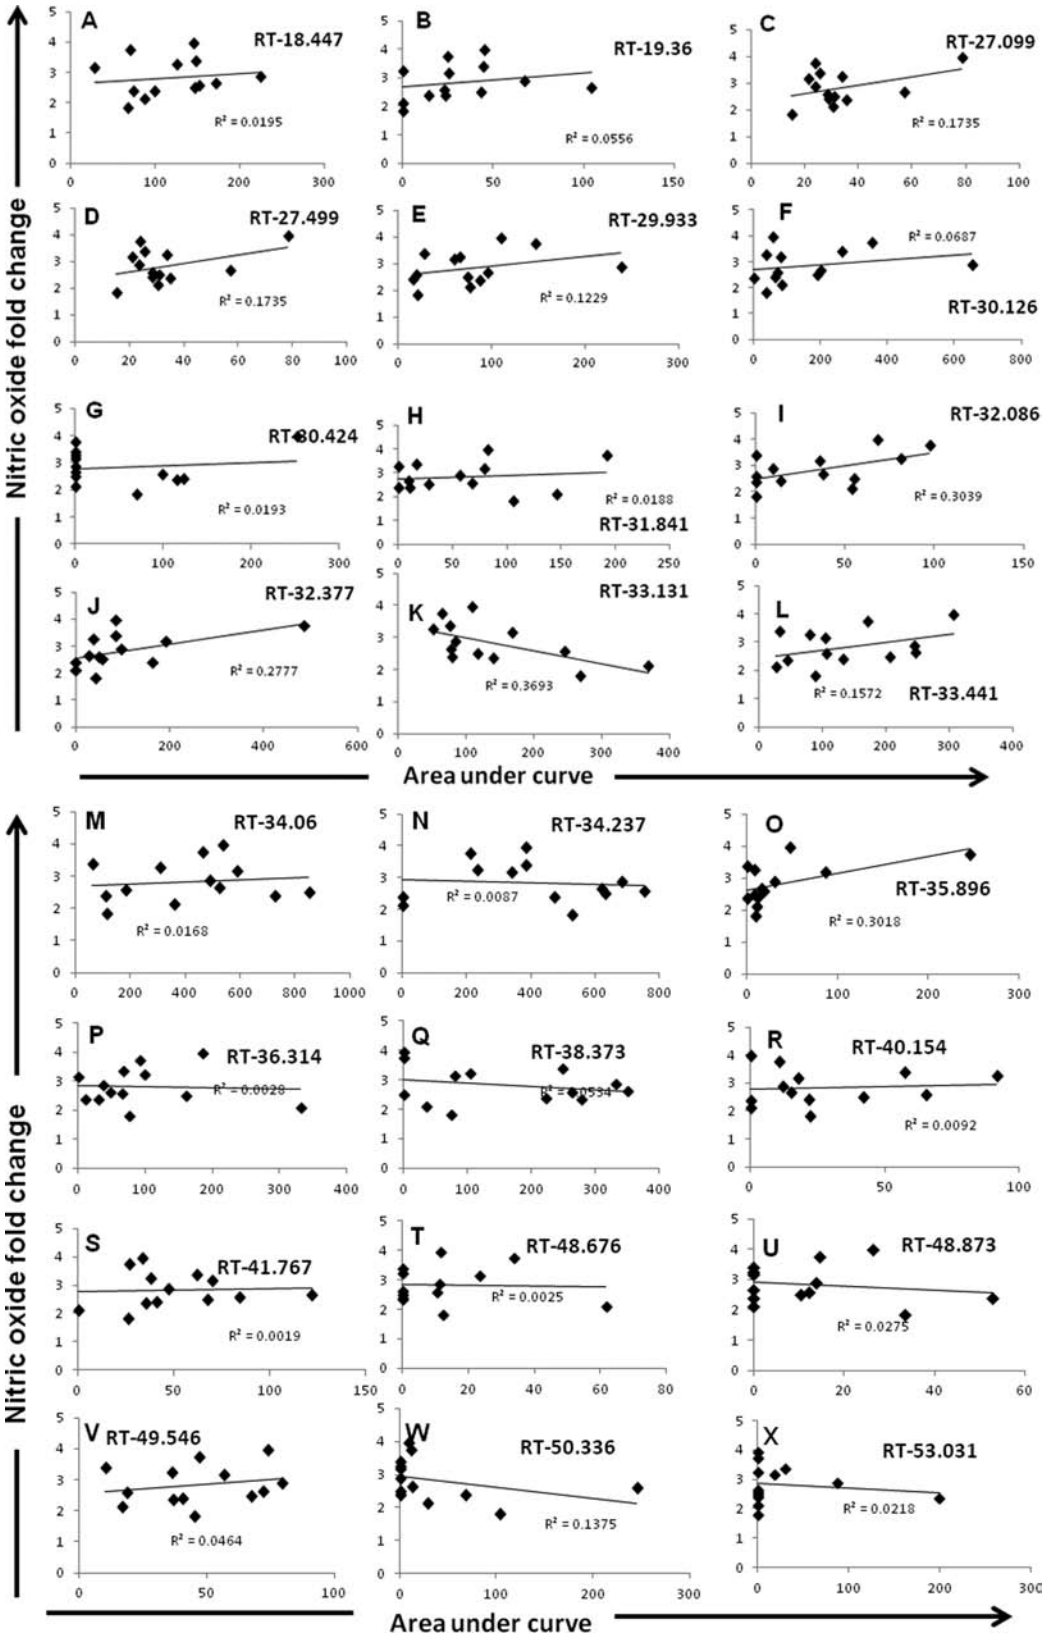

Figure 13. Pearson-correlation analysis between NO levels and various TRs (A–X) with specified retention time (RT) in tea infusion. The correlation graph was derived with 25 μg/mL PP of tea infusion.

dissipate NO levels and contribute toward ED. However, it needs to be further evaluated how the antioxidant activity of tea could potentiate NO bioavailability under stress conditions that would normally prevail in the in vivo situation, and both the antioxidant and the eNOS activity of tea synergistically could contribute to the vascular benefit efficacy of specific teas.

Further, spatial distribution of NO and ROS can also be crucial in NO dissipation under physiological stress. Under

dx.doi.org/10.1021/jf501611w | J. Agric. Food Chem. 2014, 62, 6655–6668

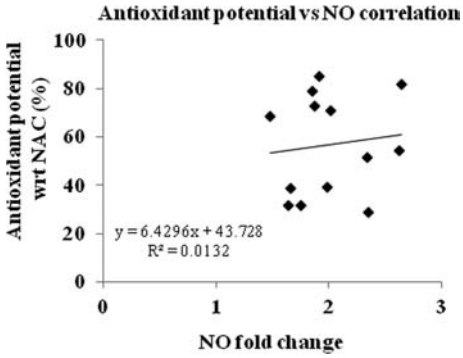

Figure 14. Pearson-correlation analysis between nitric oxide levels and antioxidant property of various tea infusions. The correlation graph was derived with 25 μg/mL PP of tea infusion.

condition of stress, ROS is generated from the mitochondria and has been shown to play a major role in NO dissipation.[9,49] In our experiments, we used H_2O_2 as the source of ROS (external species), which could be different from the ROS generated under physiological condition. Further experimentation would be needed to dissect their specific effects.

In summary, we used 13 black teas (WoBTs) representative of varied geographies, to address the contribution of quantity and composition of tea flavonoids on antioxidant and NO enhancement properties. Even though the endothelial cells were treated with tea infusions containing equated amounts of polyphenols, they induced different levels of cellular antioxidant activity and NO levels, suggesting that the composition of polyphenols in tea infusions determines the response. Statistical analysis using Pearson correlation indicated that the majority of ingredients in black tea such as catechins, TFs, TRs, and phenolic acids moderately influence antioxidant potential in endothelial cells, while its NO potentiating effect is mainly regulated by catechins in tea. Our data also suggest that the net effect of black tea on VF benefit may be due to a multitude of ingredients, majorly influencing NO enhancement, while also mildly contributed by its antioxidant benefit. Most interestingly, we also found that gallic acid and caffeine negatively affect antioxidant property, while caffeine and theobromine positively affect NO levels in endothelial cell.

One of the limitations in our study was the absence of characterization of specific TRs and evaluation of their efficacy on biological function. The study was also limited to in vitro investigation using cell free and cellular systems, as these systems do not adequately address issues of bioavailability and metabolic transformation. These would be the areas in which further investigations need to be undertaken.

[a]Assignments were performed by one-dimensional (1D) and two-dimensional (2D) [correlation spectroscopy (COSY), heteronuclear single-quantum coherence (HSQC), and heteronuclear multiple-bond correlation (HMBC)] NMR experiments.

temperature (each for 12 h). The extracts were combined and evaporated in vacuum. The resulting crude extract (9.52 g) was sequentially dispersed in water and extracted by petroleum ether (PE), EtOAc, and *n*-BuOH. The EtOAc extract (9.5 g) was dissolved in MeOH/tetrahydrofuran (THF) (50:50) and subjected to preparative HPLC on a column (50 × 250 mm, 10 μm) of 10 μm Agela Vennsil XBP C_{18}, at a flow rate of 100 mL/min and detection wavelength of 214/254 nm, using a CH_3CN−10 mM NH_4HCO_3 gradient as the eluant (0−15 min, 45−85% CH_3CN; 15−20 min, 95% CH_3CN; 20−24 min, 45% CH_3CN) to give six fractions (fractions 1−6). Fraction 4 eluting at 12.0−15.0 min was collected and further separated by Gilson-281 preparative HPLC on a Shimadzu C_{18} (21.2 × 250 mm, 15 μm) column, at a flow rate of 30 mL/min and detection wavelength of 214/254 nm, using a CH_3CN−0.1% HCO_2H−H_2O gradient as the eluant (0−20 min, 54−64% CH_3CN; 20−25 min, 95% CH_3CN) to afford six subfractions. Each subfraction was further purified repeatedly on a Gilson-215 preparative HPLC on an Agela Durashell C_{18} (21.2 × 50 mm, 5 μm) column, at a flow rate of 20 mL/min and detection wavelength of 214/254 nm, using a CH_3CN−10 mM NH_4HCO_3−H_2O gradient as the eluant (0−8 min, 65% CH_3CN; 8−11 min, 95% CH_3CN) to yield pure compounds **6** (3.8 mg), **3** (3.7 mg), **4** (110 mg), and **2** (10 mg). The PE extract (36.4 g) was chromatographed on Gilson-281 preparative HPLC on a Shimadzu C_{18} column (21.2 × 250 mm, 15 μm), eluting with a mixture of CH_3CN−0.1% FA−water gradient (0−16 min, 45−75% CH_3CN; 16−21 min, 95% CH_3CN; 21−25 min, 45% CH_3CN) to afford four fractions (CP-1−CP-4). CP-2 and CP-3 were further purified by the same chromatographic conditions to yield compounds **1** (29.6 mg), **5** (1.5 mg), and **7** (1.5 mg).

[a]Assignments were made by a combination of 1D and 2D (COSY, HSQC, and HMBC) NMR experiments.

Monte Carlo algorithm implemented in Spartan'10 using MMFF. All structures thus obtained were optimized with the DFT method using B3LYP functional and 6-31G(d) basis set.[10] The most stable B3LYP/6-31G(d) structures within 2 kcal/mol were re-optimized using B3LYP functional and 6-311+G(d,p) basis set.[10]

Preliminary TDDFT calculations were run using B3LYP and CAM-B3LYP functionals and Ahlrichs' SVP and TZVP basis sets.[11] The B3LYP/SVP combination was then employed for the final calculations, including 60 excited states (roots). CD spectra were generated using SpecDis[12] by applying a Gaussian band shape with 0.3 eV exponential half-width, from dipole-length rotational strengths. The difference with dipole velocity values was checked to be minimal for all relevant transitions.

Antifungal Bioassay. The test phytopathogenic fungi used in this study were *Fusarium solani*, *Fusarium oxysporum* f. sp. *vasinfectum*, *Cytospora* sp., and *Fusarium graminearum*. All of the fungi were isolated from infected plant organs at the Northwest A&F University.

Antifungal activity was examined by the microbroth dilution method in 96-well culture plates using a potato dextrose (PD) medium.[13,14] The test compounds was made up to 2 mg/mL in dimethyl sulfoxide (DMSO). Two commercial fungicides, carbendazim and hymexazol (Aladdin Chemistry Co., Ltd.), were used as a positive control, and the solution of equal concentration of DMSO was used as a negative control. The tested fungi were incubated in the PD medium for 18 h at 28 ± 0.5 °C at 150 rpm, and the spores of different microorganism concentrations were diluted to approximately 1×10^6 colony forming units (CFU)/mL with PD medium. Test compounds (10 μL) were added to 96-well microplates, and 90 μL of PD medium was added. Serial dilutions were made in the 96-well round-bottom sterile plates in triplicate in 50 μL of PD medium, and then 50 μL of the fungal suspension was added. After incubation for 48 h at 28 ± 0.5 °C, minimum inhibitory concentration (MIC) was taken as the lowest concentration of the test compounds in the wells of the 96-well plate, in which no microbial growth could be observed.

Insecticidal Assay. An insecticidal assay was performed by the method previously reported,[15] in which *Mythimna separata* was used as the test target. All samples for the insecticidal test were dissolved in acetone.

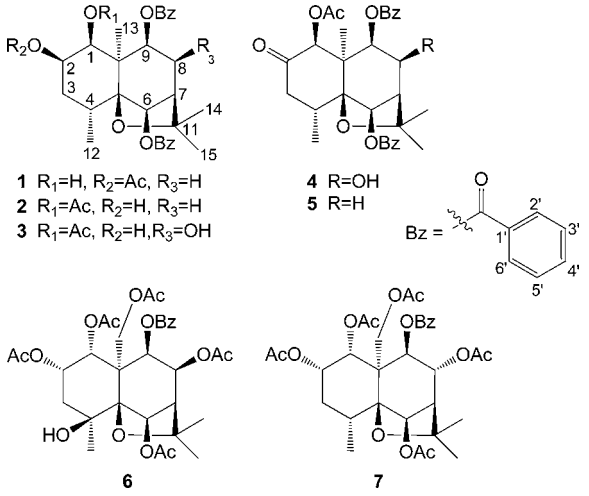
RESULTS AND DISCUSSION

Structural Elucidation. A 95% ethanolic extract of the dried whole plant of *P. wightiana* was successively partitioned between PE, EtOAc, *n*-BuOH, and water. The PE- and EtOAc-soluble extracts were separated and purified repeatedly by preparative reversed-phase HPLC to afford five new sesquiterpene compounds, wightianines A−E (**1**−**5**), along with two known compounds (**6** and **7**) (Scheme 1). Structural elucidation of the compounds was achieved by spectroscopic analysis and comparison to closely related compounds.

Compound **1** was obtained as an amorphous white powder with the molecular formula $C_{31}H_{36}O_8$, which was deduced from the HR-ESI−MS molecular ion at m/z 559.2321 ($[M + Na]^+$, calcd 559.2302). The IR spectrum shows the presence of hydroxyl (3506 cm^{-1}) and carbonyl (1718 cm^{-1}) groups, and the UV spectrum reveals the presence of an aromatic moiety (234 and 263 nm). The ^1H and ^{13}C NMR spectroscopic data of compound **1** (Tables 1 and 2) suggest that it belongs to a class

dx.doi.org/10.1021/jf501767s | J. Agric. Food Chem. 2014, 62, 6669−6676

Scheme 1. Structures of Compounds 1−7



of sesquiterpene polyol esters with a dihydro-β-agarofuran skeleton found in the Celastraceae plants.[16,17] The ^{1}H NMR spectrum (Table 1) shows the presence of one acetyl group (δ_H 2.05), two benzoate groups between δ_H 7.47 and 8.09, four methyl groups, including three tertiary methyl groups (δ_H 1.49, 1.53, and 1.42) and a secondary methyl group [δ_H 1.21 (d, J = 7.6 Hz)], two sets of methylene protons [δ_H 2.39 (1H, m), 1.87 (1H, dd, J = 15.1 and 1.4 Hz); 2.61 (1H, ddd, J = 16.1, 7.0, and 3.3 Hz), 2.28 (1H, dd, J = 16.4 and 3.1 Hz)], and six methine protons (δ_H 5.66, 4.61, 5.08, 5.34, 2.61, and 2.39), including one bearing an acetoxy group at δ_H 5.34 (m, H-2). The ^{13}C NMR and distortionless enhancement by polarization transfer (DEPT) spectra (Table 2) in combination with HSQC data indicate that compound **1** has an agarofuran skeleton[16] with 15 carbons, including four methyl carbons at δ_C 18.8 ppm (C-12), 19.2 (C-13), 26.1 (C-14), and 30.9 (C-15), two methylene carbons at δ 31.2 (C-3) and 31.6 (C-8), six methine carbons at δ_C 68.9 (C-1), 73.8 (C-2), 34.1 (C-4), 80.2 (C-6), 49.1 (C-7), and 73.3 (C-9), and three quaternary carbons at δ_C 90.0 (C-5), 51.5 (C-10), and 82.8 (C-11). The ^{13}C NMR quaternary signals at δ 90.0 (C-5) and 82.8 (C-11) are characteristic of dihydro-β-agarofuran.[8] All of these data indicate that compound **1** is a polyester sesquiterpene with a 1,2,6,9-tetrasubstituted dihydro-β-agarofuran skeleton.

The substitution pattern of compound **1** was established by a HMBC experiment (Figure 1). Correlations were found of H-1 (δ_H 4.61) with C-2, C-10, and C-13, H-2 (δ_H 5.34) with the carbonyl signal (δ_C 171.5) of the acetate group, and H-6 (δ_H 5.66) and H-9 (δ_H 5.08) with the carbonyls (δ_C 165.6 and 165.7) of the two benzoate moieties, respectively. The relative stereochemistry was established on the basis of the coupling constants and confirmed by a nuclear Overhauser effect spectrometry (NOESY) experiment. In this class of dihydro-β-agarofuran sesquiterpenes, the stereochemistry of the ring junctions is generally *trans* and H-6 is axial,[18−20] which is corroborated by the NOESY cross-peaks observed between H-1 (δ_H 4.61) and H-13 (δ_H 1.42) and between H-13 and H-9 (Figure 2). Furthermore, in the COSY experiment, the vicinal coupling constant of H-1/H-2 ($J_{1,2}$ = 3.6 Hz) indicates a *cis* relationship between H-1 and H-2. This evidence proves that the relative configuration of the substituents is 1β, 2β, 6β, and 9β.

Because compounds **1**−**5** contain two benzoate moieties each, their absolute configuration could be in principle assigned

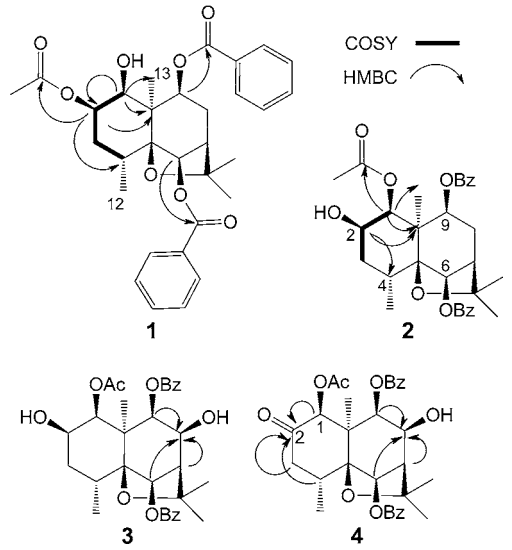


Figure 1. Key COSY and HMBC correlations of compounds **1**−**4**.

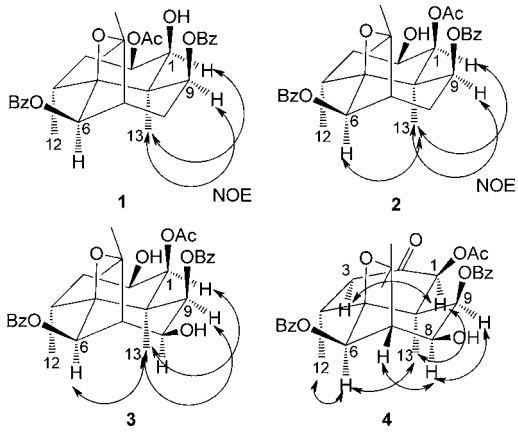

Figure 2. Key nuclear Overhauser effects (NOEs) of compounds **1**−**4**.

using the dibenzoate chirality method, the most common extension of the electronic CD exciton chirality protocol.[21] The exciton-coupled CD (ECCD) protocol is based on the sign of the bisignate CD bands (exciton couplet) observed in the major absorption region of the benzoates (π−π^* ^1L_a transition around 235 nm). The sign of the couplet is generally related to the absolute sense of twist between the electric transition dipole moments, which are oriented respectively along the long axes of the benzoate chromophores (C-1′/C-4′ direction). In compounds **1**−**5**, however, the dibenzoate 1,4-arrangement makes their π−π^* transition dipoles oriented almost parallel to each other. For exactly parallel arrangement, the predicted exciton coupling is zero. For slight deviations from the parallel, ECCD couplets are usually weak and difficult to predict.[21,22] Therefore, to assign the absolute configuration of compounds **1** and **4**, we preferred to apply quantum mechanic full CD calculations. This treatment, described in the next section, allowed us to establish compound **1** as (1*S*,2*R*,4*R*,5*S*,6*R*,7*R*,9*S*,10*S*)-2β-acetoxy-6β,9β-dibenzoyloxy-1β-hydroxydihydro-β-agarofuran and named wightianine A.

Compound **2** was also obtained as an amorphous white powder with the same molecular formula $C_{31}H_{36}O_8$ as compound **1**. The HR-ESI−MS molecular ion is at m/z 559.2305 [M + Na]$^+$ (calcd for $C_{31}H_{36}NaO_8$, 559.2302). Its IR

dx.doi.org/10.1021/jf501767s | J. Agric. Food Chem. 2014, 62, 6669−6676

spectrum shows absorption bands for hydroxyl (3448 cm^{-1}) and ester carbonyl (1718 cm^{-1}) groups, and the UV spectrum reveals the presence of an aromatic moiety (232 and 275 nm).

The ^1H NMR spectrum (Table 1) shows the presence of one acetyl group (δ_H 1.73), two benzoate groups between δ_H 7.45 and 8.09, four methyl groups, including three tertiary methyl groups (δ_H 1.44, 1.45, and 1.60) and a secondary methyl group [δ_H 1.31 (d, J = 7.6 Hz)], two sets of methylene protons [δ_H 2.40−2.44 (1H, m), 1.90 (1H, m); 2.49−2.60 (1H, m), 2.23 (1H, dd, J = 16.4 and 2.9 Hz)], and six methine protons (δ_H 5.67, 5.57, 5.04, 4.47, 2.49−2.60, and 2.40−2.44), including one bearing an acetoxy group at δ_H 4.47 (m, H-2). The ^1H and ^{13}C NMR spectra of compound **2** (Tables 1 and 2) closely resemble those of compound **1**, suggesting that compound **2** should be an isomer of compound **1**. A comparison of the similar ^1H and ^{13}C NMR spectra of compounds **1** and **2** reveals the presence of an acetyl group at C-1 (δ_C 74.1) in compound **2** because of the shifts of the signals of the H-1 proton from δ_H 4.61 in compound **1** to δ_H 5.57 in compound **2**. Thus, it is concluded that compound **2** was a 1-acetyl-2-deacetyl derivative of compound **1**. This is further confirmed by the HMBC correlations of H-1 (δ_H 5.57) with C-10 (δ_C 50.1), C-13 (δ_C 21.4), and the carbonyl signal (δ_C 169.8) of the acetate group (Figure 1). Unambigous assignments of the ^1H and ^{13}C NMR data and the relative configuration are deduced from the COSY, HMBC, and NOESY experiments (Figures 1 and 2). Its absolute configuration can be assigned from the biosynthetic point of view. Therefore, compound **2** is identified as (1*S*,2*R*,4*R*,5*S*,6*R*,7*R*,9*S*,10*R*)-1*β*-acetoxy-6*β*,9*β*-dibenzoyloxy-2*β*-hydroxydihydro-*β*-agarofuran and named wightianine B.

Compound **3** was isolated as an amorphous white powder with the molecular formula $C_{31}H_{36}O_9$, as evidenced by the HR-ESI−MS molecular ion at m/z 575.2242 ($[M + Na]^+$, calcd 575.2252). The molecular formula indicates that compound **3** contains one more oxygen atom than compound **2**. The IR spectrum shows the presence of hydroxyl (3438 cm^{-1}) and carbonyl (1725 cm^{-1}) groups, while the NMR spectra show one acetyl group (δ_H 2.06, s; δ_C 171.5, s, and 21.5, q) and two benzoyl groups (δ_H 7.49−8.08; δ_C 165.7, s, and 128.7−133.3). Further comparison of the ^1H and ^{13}C NMR spectroscopic data of compound **3** (Tables 1 and 2) to those of compound **2** reveals that compound **3** contains one less methylene group and one more methine bearing a hydroxyl group. The position of the hydroxyl group was determined to be at C-8 (δ_C 74.8) by the evidence of downfield shifts of the carbon signals from δ_C 49.0 (C-7) and δ_C 73.5 (C-9) in compound **2** to δ_C 55.7 (C-7) and δ_C 80.4 (C-9) in compound **3**, respectively. This conclusion is further supported by the HMBC correlations of H-6, H-7, and H-9 with C-8 (Figure 1). Analysis of the coupling constants for H-1/H-2 ($J_{1/2}$ = 3.5 Hz) and H-7/H-8 ($J_{7/8}$ = 3.4 Hz) reveals their *cis* configuration. Therefore, the hydroxyl and ester groups are located on the β face, as confirmed by the NOESY correlations shown in Figure 2. The locations and relative configurations of the esters and hydroxyl groups in compound **3** were deduced from analysis of its COSY, HMBC, and NOESY spectra (Figures 1 and 2). Similarly, its absolute configuration was assigned from the biosynthetic point of view. Thus, compound **3** is identified as (1*S*,2*R*,4*R*,5*S*,6*R*,7*R*,8*S*,9*R*,10*S*)-2*β*-acetoxy-6*β*,9*β*-dibenzoyloxy-1*β*,8*β*-dihydroxydihydro-*β*-agarofuran and named wightianine C.

Compound **4** gives the molecular formula $C_{31}H_{34}O_9$ based on the HR-ESI−MS molecular ion at m/z 573.2115 $[M + Na]^+$ (calcd for $C_{31}H_{34}NaO_9$, 573.2095), indicating that compound **4** contains two less hydrogens than compound **3**. The IR spectrum shows the presence of hydroxyl (3471 cm^{-1}) and carbonyl (1753 and 1725 cm^{-1}) groups. The NMR spectra prove the presence of one acetyl group (δ_H 1.72, s; δ_C 169.4, s, and 20.0, q) and two benzoyl groups (δ_H 7.42−8.06; δ_C 165.4 and 128.6−133.8). Further comparison of the NMR data of compound **4** (Tables 1 and 2) to those of compound **3** reveals that they are very similar, except for the presence of one ketonic carbonyl at δ_C 204.5 (s, C-2) in compound **4**, instead of one hydroxyl methine [δ_C 73.8 (d, C-2); δ_H 4.57 (m)] in compound **3**. The position of the ketone group was determined to be at C-2, as evidenced by the downfield shifts of the carbon signals from δ_C 68.8 (C-1), 31.3 (C-3), and 33.9 (C-4) in compound **3** to δ_C 77.6 (C-1), 44.0 (C-3), and 38.8 (C-4) in compound **4**, respectively. This is further supported by the HMBC correlations of H-1, H-3, and H-4 with C-2 (δ_C 204.5) (Figure 1). The coupling constant ($J_{7,8}$ = 3.2 Hz) for H-7 and H-8 indicates their *cis* relationship. This suggests that the hydroxyl group at C-8 is β-orientated. The locations and relative configurations of the ester groups in compound **4** were further assigned from its COSY, HMBC, and NOESY spectra (Figures 1 and 2). In addition, the absolute configuration of compound **4** was determined by quantum mechanic CD calculations (see the next section). Therefore, compound **4** is identified as (1*S*,4*R*,5*S*,6*R*,7*R*,8*S*,9*R*,10*S*)-1*β*-acetoxy-6*β*,9*β*-dibenzoyloxy- 8*β*-hydroxy-2-oxo-dihydro-*β*-agarofuran and named wightianine D.

Compound **5** gives the molecular formula $C_{31}H_{34}O_8$, as evidenced by the HR-ESI−MS molecular ion at m/z 557.2154 ($[M + Na]^+$, calcd 557.2146). The molecular formula indicates that compound **5** contains one less oxygen than compound **4**. Further comparison of the NMR data of compound **5** (Tables 1 and 2) to those of compound **4** reveals that they are very similar, except for the presence of a methylene [δ_C 32.5 (t, C-8); δ_H 2.57 (ddd, J = 16.3, 7.3, and 3.4 Hz, H-8*α*), 2.35 (dd, J = 16.3 and 2.9 Hz, H-8*β*)] in compound **5**, instead of one hydroxyl methine [δ_C 74.7 (d, C-8); δ_H 4.45 (t, J = 3.2 Hz)] in compound **4**. The locations and relative configurations of the esters in compound **5** were assigned on the basis of its HMBC and NOESY spectra (Figures 1 and 2). From the prospective of biosynthesis, its absolute configuration can be proposed. Thus, the structure of compound **5** is elucidated as (1*S*,4*R*,5*S*,6*R*,7*R*,9*S*,10*R*)-1*β*-acetoxy-6*β*,9*β*-dibenzoyloxy-2-oxo-dihydro-*β*-agarofuran and named wightianine E.

When their physical and spectral data were compared to those reported in the literature, two known dihydro-*β*-agarofurans **6** and **7** were identified as 1*α*,2*α*,6*β*,8*β*,13-pentaacetoxy-9*β*-benzoyloxy-4*β*-hydroxy-*β*-dihydroagarofuran,[8] isolated from *Celastrus angulatus* and Ejap-4 from *Euonymus japonicus*,[9] respectively.

To date, 462 dihydro-*β*-agarofuran sesquiterpenes have been reported from the Celastraceae plants.[23] These metabolites have usually been described as the primary characteristic constituents of the family. Interestingly, 2-oxo-dihydro-*β*-agarofuran-type sesquiterpenes are very rare natural products, as examplied by triptogelin A-4, which had been described previously in *Tripterygium wilfordii* var. Regelii.[24] To our knowledge, the present study is the second report of the sesquiterpenoids of this class from the alternative family Saxifragaceae. Importantly, the sesquiterpenes with a dihydro-*β*-agarofuran scaffold as "privileged structures" have attracted considerable attention from synthetic chemists and pharmacol-

ogists because of their complex structures and biological activities, such as immunosuppressive,[25,26] cytotoxic,[17,18] anti-HIV,[25,27] antiherpetic,[28] reversing multi-drug-resistance (MDR) phenotype,[29,30] antitumor,[31,32] and insecticidal[8] activities.

Conformational Analysis and Absolute Configuration Assignment. Compounds **1** and **4** were selected as representatives of the two classes of wightianines (with 2-hydroxy/2-acetoxy and 2-oxo substituents, respectively) to assign their absolute configuration by quantum mechanic CD calculations.[33] First, the conformation of compounds **1** and **4** was studied by means of a well-established protocol based on a preliminary conformational analysis based on molecular mechanics, followed by geometry optimizations with DFT.[22] Starting from a structure of compounds **1** and **4** with arbitrary (1*S*,2*R*,4*R*,5*S*,6*R*,7*R*,9*S*,10*S*)-**1** and (1*S*,4*R*,5*S*,6*R*,7*R*,8*S*,9*R*,10*S*)-**4** configurations, respectively, the conformational analysis was run using a Monte Carlo algorithm and the MMFF. All MMFF minima within 10 kcal/mol were optimized with DFT at the B3LYP/6-31G(d) level. Finally, the relevant DFT minima (within 2 kcal/mol) were re-optimized at the B3LYP/6-311G+(d,p) level. For compound **1**, four low-energy conformers were obtained with relative internal energies within 2 kcal/mol; they differed in the conformation of 9-benzoate and 2-acetate groups (Figure 3). For compound **4**, only two low-energy

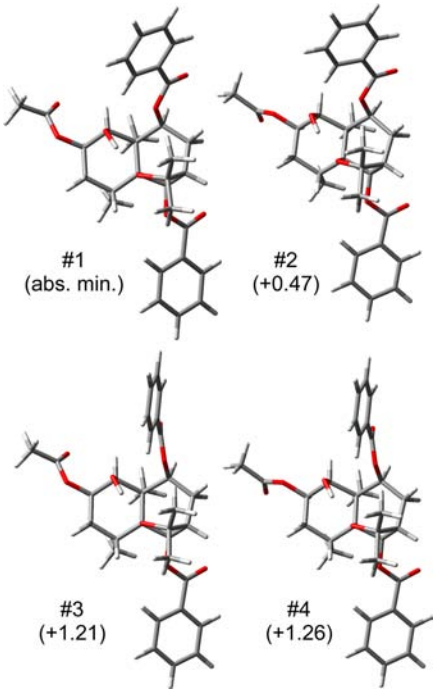

Figure 3. DFT-optimized [B3LYP/6-31G(d) level] low-energy structures for (+)-(1*S*,2*R*,4*R*,5*S*,6*R*,7*R*,9*S*,10*S*)-**1** and relative internal energies.

conformations were obtained, differing in the conformation of the 6-benzoate group (Figure 4). Both of them have the cyclohexanone ring in a twist conformation, probably to relieve the steric hindrance between 1β-acetate and 9β-benzoate groups, with the latter hydrogen-bonding to 8-OH. This conformation is confirmed by the strong NOE between H-1α and H-3α (see Figure 2).

The CD spectra of compounds (+)-**1** and (+)-**4** were recorded in methanol (Figures 5 and 6). They show several

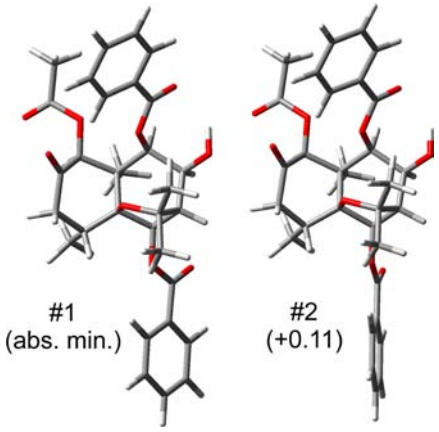

Figure 4. DFT-optimized [B3LYP/6-31G(d) level] low-energy structures for (+)-(1*S*,4*R*,5*S*,6*R*,7*R*,8*S*,9*R*,10*S*)-**4** and relative internal energies.

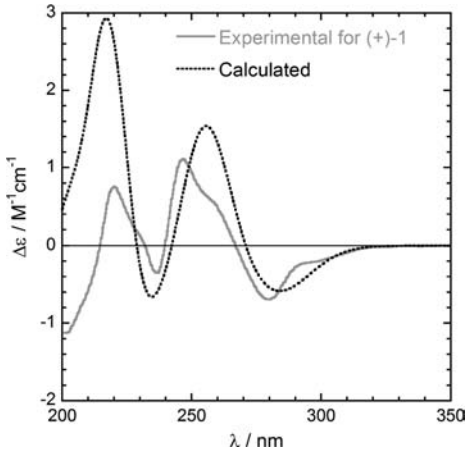

Figure 5. CD spectra of (+)-(1*S*,2*R*,4*R*,5*S*,6*R*,7*R*,9*S*,10*S*)-**1** recorded in methanol (1.9 mM, 0.1 cm cell, solid line) and calculated with TDDFT (B3LYP/SVP level, dotted line) as the Boltzmann average at 300 K for the four structures shown in Figure 3. The calculated spectrum was obtained as the sum of Gaussians with 0.3 eV bandwidth, and it is scaled and red-shifted by 30 nm for comparison.

bands between 200 and 350 nm, because of the benzoate and (for compound **4**) carbonyl chromophore. In both cases, the spectra are quite weak and there is no clear-cut exciton couplet with crossover (zero value) around 235 nm, where the benzoate $\pi-\pi^*$ ^1L_a transition occurs. This demonstrates that the ECCD protocol (see the previous section) cannot be applied directly.[21,22] Rather, we calculated the CD spectra of compounds **1** and **4** with TDDFT[33] using DFT-optimizing structures as input geometries and averaging the calculated spectra for the various low-energy conformations with the respective Boltzmann factors at 300 K (using internal energies). The calculated averages with B3LYP/SVP, shown in Figures 5 and 6, reproduce well the experimental CD profiles. Therefore, the absolute configurations of compounds **1** and **4** are established as (+)-(1*S*,2*R*,4*R*,5*S*,6*R*,7*R*,9*S*,10*S*)-**1** and (+)-(1*S*,4*R*,5*S*,6*R*,7*R*,8*S*,9*R*,10*S*)-**4**.

Biological Activity. Five compounds selected (because of a limited quantity of samples) were examined for their antifungal activity toward phytopathogenic fungi (*F. solani*, *F. oxysporum* f. sp. *vasinfectum*, *Cytospora* sp., and *F. graminearum*) *in vitro* using a mycelial growth inhibitory rate method.[13,14] As shown in

dx.doi.org/10.1021/jf501767s | J. Agric. Food Chem. 2014, 62, 6669−6676

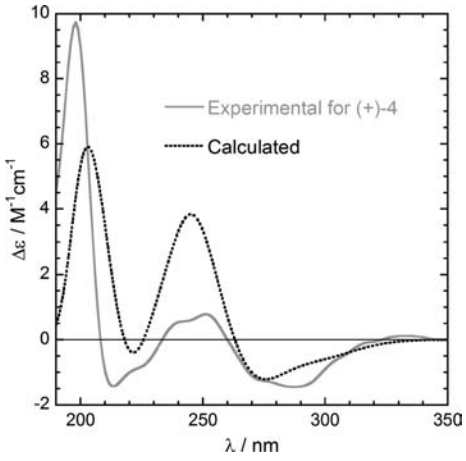

Figure 6. CD spectra of (+)-(1*S*,4*R*,5*S*,6*R*,7*R*,8*S*,9*R*,10*S*)-**4** recorded in methanol (1.5 mM, 0.02 cm cell, solid line) and calculated with TDDFT (B3LYP/SVP level, dotted line) as the Boltzmann average at 300 K for the two structures shown in Figure 4. The calculated spectrum was obtained as the sum of Gaussians with 0.3 eV bandwidth, and it is scaled and red-shifted by 20 nm for comparison.

Table 3, of these isolated compounds tested, only compounds **2** and **7** both inhibited mycelial growth of *Cytospora* sp. with minimum inhibitory concentration (MIC) values of 0.78 μg/mL, which are the same as the two positive controls hymexazol and carbendazim, demonstrating that these compounds were good fungicides. Additionally, compound **2** also showed marked antifungal effects on *F. graminearum* and *F. oxysporum* with their respective MIC data of 12.5 and 50 μg/mL. In contrast, the other compounds were almost inactive at 100 μg/mL of MIC data. A preliminary structure−antifungal activity relationship of these test compounds is given as follows. When a hydroxyl group attached to C-2 instead of an acetoxy group at C-2 of compound **1**, as seen in compound **2**, the antifungal activity against *F. graminearum* and *Cytospora* sp. was largely increased, as compared to that of compound **1**. However, conversion of OH at C-2 to a ketone group can lead to a loss of activity (compound **1** versus compound **4**). When theree is one H at C-4 instead of a tertiary OH at C-4 of compound **6**, as seen in compound **7**, the activity against *Cytospora* sp. was highly increased, as compared to that of compound **6**. From this evidence (Table 3), it can be concluded that the presence of the number, nature, and position of substituent groups of these test compounds could influence antifungal activity to the phytopathogens tested in this study.

Insecticidal activity of compounds **1**−**7** was tested against the fourth instar larvae of *M. separata*. However, in the present study, none of these tested compounds was found to display insecticidal activity to *M. separata*.

In conclusion, seven sesquiterpene esters (**1**−**7**) were isolated from the whole plant of *P. wightiana*, and their structures were elucidated by spectroscopic analyses and electronic CD studies. Compounds **2** and **7** were both found to display high antifungal property against the plant pathogen *Cytospora* sp.

Maranhao, and Minas Gerais have demonstrated both acceptable yields and consumer acceptance of the biofortified varieties.[17−19] These preliminary results have provided the impetus to continue breeding for further enrichment of βC content in cassava. Comparative studies on the impact of genotype and traditional style of cooking on retention of the provitamin A carotenoid and its bioaccessibility are needed.

Brazilians include cassava in many different food recipes. Boiled and fried cassava, as well as cassava flour, are the most common sources of this staple food. Previous studies have shown the preparation of cassava flour can markedly decrease the content of βC.[20] Research regarding the bioaccessibility of βC from different varieties of biofortified cassava grown in Brazil has been limited. Insights regarding the interactions among carotenoid content, home cooking styles, and the bioaccessibility of βC are needed to help direct the efforts of breeders, food scientists, and nutrition educators to strategically develop and implement programs aimed at increasing the vitamin A status of populations at risk of suboptimal vitamin A nutrition.

The primary objective of the present study was to investigate the effects of genotype and styles of traditional Brazilian preparation on the content, retention, and bioaccessibility of provitamin A in biofortified cassava developed and grown in Brazil.

MATERIALS AND METHODS

Reagents. Chromatographic grade solvents, fetal bovine serum (FBS), fungizone, penicillin−streptomycin, L-glutamine, and nonessential amino acids were purchased from Life Technologies Corp. (Grand Island, NY, USA). Dulbecco's modified minimum essential medium (DMEM) with 25 mmol/L glucose, Hepes buffer, bile extract, and bile extract and digestive enzymes were purchased from Sigma-Aldrich (St. Louis, MO, USA). All other reagents and supplies were purchased from ThermoFisher Scientific (Pittsburgh, PA, USA) unless otherwise indicated.

Varieties of Cassava. Cassava roots from two lineages were provided by the Biofortication program of the Brazilian Research Agriculture Corporation (Embrapa) and by the Nutritional Breeding program from the Agronomic Institute of Campinas (IAC) (Table 1). All varieties are considered "sweet" cassava because they have low cyanide content (<100 ppm) and are advantageous for small-scale production and domestic consumption. The six varieties provided by Embrapa were grown in the northeastern (NE) region at Cruz das Almas, Bahia, Brazil, and the roots were harvested at 14 months, that is, prior to senescence. One variety of white cassava was included as a control as it is commonly grown in NE Brazil. Three varieties from IAC were grown in the southeastern (SE) region at Santa Maria da Serra, São Paulo, Brazil, and harvested at 9 months, which is optimal for these lineages. Cassava roots were harvested in March 2013. Three separate plants from each of the nine varieties were randomly harvested. Roots were cleaned and immediately waxed for transport to Piracicaba, São Paulo, Brazil.

Table 1. Varieties of Cassava Investigated

variety	type	source
lineage 1[a]		
Saracura	control (Con)	Embrapa
Dourada	parental (PA)	Embrapa
Gema de Ovo	parental (PA)	Embrapa
Jari	progeny (PR)	Embrapa
clone 14-11	progeny (PR)	Embrapa
clone 03-15	progeny (PR)	Embrapa
lineage 2[b]		
576-70	parental (PA)	IAC
265-97	progeny (PR)	IAC
06-01	progeny (PR)	IAC

[a]Lineage 1. Saracura is a white cassava normally grown in NE Brazil. Dourada and Gema de Ovo were selected from a germplasm bank in 2001. Progeny were bred for high βC content and yield in 2003. [b]Lineage 2. Variety 576-70 was bred for acceptable agronomic and organoleptic characteristics in 1970. Varieties 265-97 and 06-01 were bred for high yield and increased βC content in 1997 and 2001, respectively.

Cooking of Cassava. Waxed roots were processed 24−48 h after harvest. Roots were washed, peeled, and cut in a room that excluded direct artificial or natural light to limit degradation of carotenoids. Initially, small cubes (3 cm^3) were used to determine average boiling times (see below). Afterward, roots from each plant were cut longitudinally into 10 cm fourths. Fourths from each root were either boiled or boiled and fried as described below. Raw and cooked cassava were stored at −80 °C in vacuum-sealed bags. Small cubes (3 cm^3) initially were used to determine average boiling times due to differences in moisture content and food matrix (see below). Three replicate samples of each were processed independently as follows.

Boiled Cassava. Twelve cubes (3 cm^3) of each variety were immersed in 7 L of distilled water and boiled at 100 °C. A stainless steel Mattson apparatus with 12 pins calibrated with 90 g weight was used according to the method of Oliveira et al.[21] to determine appropriate boiling time for each variety to standardize tenderness as generally done when cassava is cooked at home. Mean boiling time was defined as that required for penetration of 7 of the 12 pins into the cubes. Determined boiling times for each variety are listed in Table 2. Root fourths of 10 cm lengths from each genotype were then boiled in 7 L of water to determine carotenoid retention and for simulated digestion.

Fried Cassava. Two boiled fourths of 10 cm length from opposite sides of the root were randomly selected and placed in a stainless steel basket. The basket was immersed in soybean oil at 180 °C for 5 min in an electric deep fryer (Tedesco, FE-101). Samples remained suspended in the basket at room temperature until excess oil was drained.

Raw, boiled, and fried cassava were wrapped in aluminum foil to avoid exposure to light and packed under vacuum using nylon−polyethylene bags with low permeability to oxygen. Packages were frozen at −80 °C and shipped to The Ohio State University in Styrofoam containers with gelled ice. Samples arrived frozen and were immediately placed in a −80 °C freezer. Samples were stored frozen for a maximum of 4 months and thawed in a cold room overnight without light before homogenization in a food processor (Cuisinart Smart Stick Hand Blender) for analysis and further testing.

Moisture and Fat Contents. Moisture was determined according to an AOAC method.[22] Samples of each variety were weighed and maintained overnight at 65 °C with circulating air to constant weight. Lipids from raw and boiled cassava were first extracted into petroleum ether from three varieties. Results were similar to previous literature, that is, ≤0.3%.[23] Consequently, lipids were extracted only from fried samples for all varieties according to the method of Folch et al.[24] Samples of fried cassava (1.5 g) were homogenized with 3 mL of phosphate buffer saline (PBS) using a Polytron homogenizer, mixed with 4 mL of methanol, and vortexed for 2 min. After the addition of chloroform (8 mL), the mixture was vortexed for 2 min, centrifuged at 1000*g* for 15 min at 4 °C, and left overnight in a dark cold room. The lower phase was collected in weighed glass tubes, solvent was evaporated, and the difference in weight of the tube before use and after evaporation of solvent represented lipid content.

In Vitro Digestion. Oral, gastric, and small intestinal phases of simulated digestion were performed as described by Thakkar et al.[25] with slight modification. The quantity of fried cassava digested was 0.3−1.5 g, so that there was <0.075 g of adsorbed oil per reaction to ensure complete digestion of triglyceride. Because the bioaccessibility of hydrocarbon carotenoids requires the presence of lipid digestion products as well as bile salts,[26] soybean oil (2.5 wt %/wt) was added to boiled cassava (2.0−2.5 g per reaction) before digestion. As the concentration of βC in soybean oil was 1.1 μg/mL, it contributed

[a]Data for moisture and lipids are means ± SD, $n = 3$. Different lower case letters within columns for moisture, lipids, and total βC indicate that means for varieties differ significantly ($p < 0.05$). Different upper case letters within rows for moisture and total βC indicate that means for raw, boiled, and fried samples differ significantly ($p < 0.05$). [b]From Table 1: Con, control variety; PA, parental variety; PR, progeny (biofortified) variety. [c]Average boiling time was determined as time until 7 of 12 pins (90 g each) penetrated root sections.

55 ng of the carotenoid per digestion of boiled cassava. Assuming the concentration of βC in oil used for frying was similar, the amount of βC in adsorbed oil ranged from 2.0 to 13.7% of the wet weight (see Table 2) and was not accounted for in the presented results. Briefly, each cooked sample was digested in triplicate, and digestions were repeated at least once for a total of $n \geq 6$. Samples were homogenized with basal salts solution (120 mol/L NaCl, 6 mmol/L $CaCl_2$, and 5 mmol/L KCl) using a Polytron homogenizer. The same basal salts solution was used to properly adjust the volumes in each step. Synthetic saliva (6 mL) containing 106.6 units/mL α-amylase was added to cassava samples to initiate oral digestion in a shaking (85 rpm) water bath at 37 °C for 10 min. Samples were subsequently subjected to simulated gastric and small intestinal digestion with shaking (85 rpm) at 37 °C using the enzyme activities and bile extract content previously used in our laboratory for the coupled in vitro digestion/Caco-2 cell model.[27] These are (final concentrations) 1.7 units porcine pepsin/mL, 0.4 mg/mL porcine pancreatin, 8.3 units porcine pancreatic lipase/mL, and 2.4 mg bile extract/mL. After conclusion of the small intestinal phase of digestion, chyme was centrifuged at 5000*g* for 45 min at 4 °C to separate the aqueous fraction and nondigested materials. A portion of the aqueous fraction was collected and filtered (0.22 μm pores) to prepare the micelle fraction. Aliquots of chyme and micelle fraction were stored under nitrogen gas at −80 °C for a maximum of 1 week before extraction and analysis. Carotene contents of digested cassava (i.e., chyme) and the filtered aqueous fraction (i.e., mixed micelle fraction) are indicative of the stability of carotenoids in cooked cassava during digestion and the efficiency of micellarization (EM) during the small intestinal phase of digestion, respectively. Standard procedures were taken to minimize exposure to light and air during each stage of digestion.

Uptake of *all-trans*-βC by Caco-2 Cells. Human intestinal colonic carcinoma Caco-2 cells were purchased from American Type Culture Collection (ATCCHTB37). Details for the maintenance of the cultures have been described previously.[27] Briefly, T75 flasks were seeded with (0.4−0.6) × 10^6 cells and maintained in high-glucose DMEM supplemented with 4 mmol/L L-glutamine, 1% nonessential amino acids, 15 mmol/L HEPES buffer, antibiotics, and 15% (v/v) heat-inactivated FBS, pH 7.4, until the monolayer was confluent. FBS content of medium was reduced to 7.5% for postconfluent cultures, and fresh medium was added every 2 days. Cultures were incubated in a humidified atmosphere of 95% air/5% CO_2 at 37 °C. Monolayers from passages 22−31 were used for experiments when cultures were 10−14 days postconfluent, that is, once well differentiated. Cellular uptake of βC in micelles generated during digestion of boiled and fried cassava was performed for four varieties containing the highest concentrations of βC. Analysis was limited to *all-trans*-βC because accurate quantification of the relatively low amounts of *cis* isomers of βC in the cells was not possible. To initiate experiments, monolayers were washed once with basal DMEM before addition of 12.5 mL of DMEM (pH 6.5) containing 25% (v/v) mixed micelle fraction generated during the simulated digestion. The integrity of the monolayer was assessed by phase contrast microscopy after 0, 1, 2, and 4 h. No changes in gross morphology of the monolayer or cells were noted for any treatment. Test medium was removed after 4 h, and monolayers were washed once with ice-cold PBS containing 2 g/L bovine serum albumin and twice with ice-cold PBS to remove extracellular carotenoids. Ice-cold PBS (6 mL) was added to flasks, and cells were collected using a plastic scraper. The cell suspension was centrifuged at 400*g* for 5 min at 4 °C. Supernatant was discarded, and cell pellets were stored under nitrogen gas at −20 °C for a maximum of 1 week before extraction and analysis of carotenoids. Protein content per flask was determined by bicinchoninic acid assay (BCA) analyses with bovine serum albumin as standard. Average protein content per flask was 12.1 ± 0.8 mg/T75 flask.

Carotenoid Extraction and Analysis. Carotenoids were extracted according to the method of Kimura et al.[28] with slight modifications. Homogenized samples (3 g) of raw, boiled, and fried cassava were extracted to determine the profile and quantity of carotenoids. Samples were ground with cold acetone (50 mL) and Celite (~3 g) using a mortar and pestle. Extraction was repeated until the residue

dx.doi.org/10.1021/jf5018302 | J. Agric. Food Chem. 2014, 62, 6677−6686

was colorless. Combined extracts were mixed with petroleum ether in a separatory funnel, and the petroleum ether fraction was collected and filtered with aliquots transferred to vials for evaporation of the solvent. Thawed cell pellets were suspended in 5 mL of PBS and sonicated (5 s with tube in ice bath) to determine cell accumulation of carotenoids. Carotenoids in chyme and micelle fraction (aliquots of 5−7 mL) and cell pellets suspended in 5 mL of PBS were extracted into 10 mL of tetrahydrofuran/methanol (1:1, v/v) before the addition of 10 mL of hexane and mixing. Tubes were centrifuged at 3000*g* for 10 min at 4 °C. The upper layer was collected, and solvent was evaporated under a stream of nitrogen gas at 30−35 °C. Dried extracts were solubilized in appropriate volumes of methanol and MTBE (1:1, v/v), filtered (0.22 μm pores; Millipore), and analyzed. β-Apo-8′-carotenal (10 μg/mL in methanol) was used as internal standard to estimate the efficiency of recovery of carotenoids during extraction. Recoveries of β-apo-8′-carotenal when added to homogenates containing raw, boiled, and fried cassava were 97.5 ± 7, 96.9 ± 9, and 94.5 ± 10%, respectively. Recoveries of internal standard from chyme and aqueous fractions after digestions were 99.7 ± 3 and 95.7 ± 3%, respectively, for boiled cassava and 97.8 ± 4 and 90.9 ± 12%, respectively, for samples from fried cassava. β-Apo-8′-carotenal recoveries from sonicated samples of Caco-2 cells were 93.4 ± 6 and 91.9 ± 7% for experiments initiated with boiled cassava and fried cassava, respectively.

The HPLC system consisted of a Waters 2695 separation system with a 2996 photodiode array detector. An analytical polymeric YMC C_{30} column (4.6 mm × 150 mm, 5 μm; Waters, Milford, MA, USA) was protected by a C_{18} guard (4.6 mm × 50 mm) column containing the same material.[27] *all-trans* and *cis* isomers of βC were identified by comparison of retention times and spectra with pure standard for the former (>98% purity) and characteristics from the literature for the latter. βC was monitored at 450 nm. The area under the curve for *all-trans*-βC was compared to that for a six-point standard curve generated with pure βC and the concentration calculated using the absorption coefficient ($A^{1\%,\ 1cm}$) of 2592 for *all-trans*-βC.[29] *Cis* isomers of βC were identified by their UV−vis spectrum[29] and retention times as reported in the literature. The amounts of *cis* isomers of βC were estimated using area under the curve against the standard curve and absorption coefficient of *all-trans*-βC.

Data Analysis. Data were analyzed for significant differences using ANOVA for effects of genotype, cooking style, and interactions between genotype and cooking styles. The interactions analysis had a factorial model of 9 varieties × 3 cooking styles and were considered significant at 1% ($p < 0.01$). Means were compared using the Tukey test and significant at 5% ($p < 0.05$). Pearson's test of correlation was used and significant differences defined at 1% ($p < 0.01$). Software used for the ANOVA and Tukey tests was the Statistical Analysis System (SAS Inc., Cary, NC, USA), and correlation tests were performed using Statistical Assistance software Assistant 7.7 beta (UFCG, Campo Grande, PB, Brazil).

RESULTS

Effects of Variety and Style of Cooking on the βC Content in Cassava. Moisture content of raw cassava root for varieties in lineage 1 ranged from 60 to 83% and was greater than those in lineage 2 (Table 2; $p < 0.05$). The differences in moisture contents of these two lineages are likely due to differences in climate, cultivation conditions, and perhaps age at harvest in the two geographic locations. Cassava roots received from IAC were grown in southeastern Brazil for 9 months in a tropical climate, whereas roots received from Embrapa were grown in northeastern Brazil for 14 months in a semiarid climate. Moisture was minimally altered for seven of the nine varieties after boiling. There was approximately a 10% increase in moisture content of varieties 576-70 and 06-01 ($p < 0.05$) after boiling. Frying the boiled cassava resulted in significantly decreased moisture content of root flesh in all nine varieties, although the extent of loss differed across varieties. During frying, roots from lineage 2 varieties lost significantly more water than those from lineage 1. Accordingly, there was a significant interaction between variety and cooking styles as factors for moisture content ($p < 0.01$). Lipid content of the six fried varieties of cassava from lineage 1 ranged from 2.0 to 4.8% FW, whereas lipid content of the three fried varieties from lineage 2 was significantly greater (6.7−13.7% FW). The greater amounts of dry matter in cassava roots from lineage 2 than in roots from lineage 1 was positively correlated with increased capacity to adsorb oil during frying ($p < 0.001$, $r = 0.7546$).

βC was the only carotenoid detected in all tested genotypes of cassava, although its content varied markedly across the varieties (Figure 1). Roots from Saracura and clone 03-15

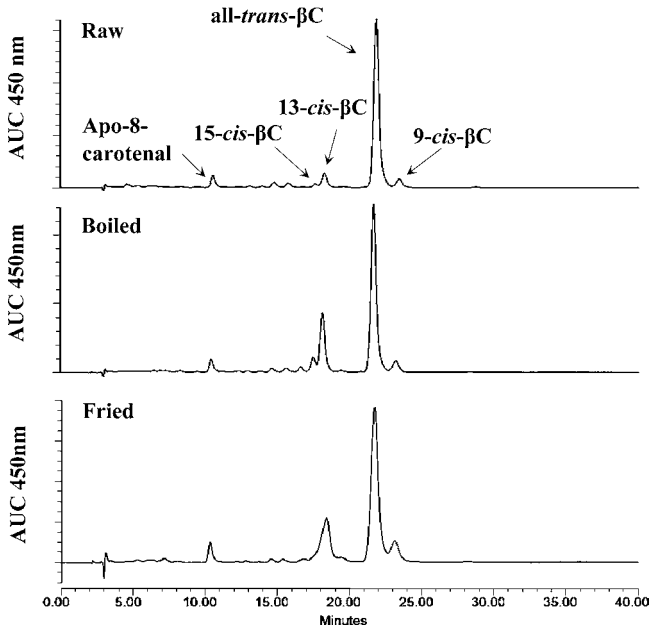

Figure 1. Representative chromatograms of raw, boiled, and fried cassava (Jari variety).

varieties had the lowest and highest concentrations of βC, respectively (Table 2). Varieties generated for the purpose of increasing provitamin A content contained at least 10−22-fold more βC per gram FW than the Saracura variety that is commonly grown and consumed in northeastern Brazil. With the exception of clone 14-11, the four other crossed varieties had significantly higher total βC per gram FW than the parental varieties. There was a significant interaction between variety and cooking styles for total βC per gram FW ($p < 0.01$). Boiling was associated with a decline in total βC content per gram FW for six of the nine varieties of cassava. With the exception of variety 06-01, total βC concentration was not further decreased ($p > 0.05$) when boiled cassava was briefly fried. Fried Jari contained the highest amounts of total βC among the ready-to-eat cassavas.

The quantities of *all-trans*- and *cis*-isomers of βC in raw and cooked varieties were determined (Table 3), because *all-trans*-βC has greater vitamin A equivalence than *cis* isomers.[3] Varieties with greater concentrations of total βC (Table 2) also contained higher amounts of *all-trans*-βC (Table 3). The four varieties with the highest total βC content had the greatest percentages of *all-trans*-βC (83−87%), whereas the four genotypes with lowest estimated amounts of total βC content contained 50−70% *all-trans*-βC (Table 3). These data indicate that breeding

[a]Data are means ± SD, $n = 6$. Different lower case letters within columns indicate that means of varieties differ significantly ($p < 0.05$). Different upper case letters within rows indicate that means of raw, boiled and fried samples differ significantly ($p < 0.05$). [b]From Table 1: Con, control variety; PA, parental variety; PR, progeny (biofortified variety). [c]RE, retinol equivalents. Calculated according to FAO[33] assuming approximately 33% of *βC* is available for absorption and conversion to vitamin A is 50% for *all-trans-βC* and 25% for *cis-βC*.[33] [d]Calculated as percent of Recommended Nutrient Intake (RNI) of 450 μg/day RE for children 4–6 years of age provided by consuming 100 g of cooked cassava.

for high *β*C was associated with selective enrichment of *all-trans-β*C. *all-trans-β*C content in cooked cassava was lower than in raw cassava, although the decrease was significant ($p < 0.05$) for only five of the nine varieties (i.e., clone 14-11, Jari, clone 03-15, 265-97, and 06-01). Both boiling and frying increased total *cis-β*C in varieties containing high amounts of total *β*C, suggesting at least partial isomerization of *all-trans-β*C. Several processes can affect the quantity and isomeric profile of carotenoids in cassava root during cooking. These include heat-induced oxidation, degradation, and isomerization, as well as mass interchanges with boiling water or heated oil.[30,31] The latter can mask the effects of carotenoid degradation and lead to errors in calculating retention.[31] Therefore, the retention of *all-trans-β*C (Figure 2) also was calculated on the basis of dry weight (DW). The general impact of cooking on the concentration of *all-trans-β*C per gram DW was similar to that when expressed on the basis of fresh weight. That is, boiling decreased the amount of *all-trans-β*C per gram DW to a greater extent in varieties containing relatively high concentrations of the carotenoid (Figure 2a), and frying significantly decreased the amounts of total *β*C (data not shown) and *all-trans-β*C per gram DW (Figure 2b) while increasing total *cis-β*C content per gram DW (data not shown) for all varieties. There was no significant correlation between retention of *all-trans-β*C and either boiling time or moisture content of raw cassava. 9-*cis*- and 13-*cis-β*C, along with lesser amounts of 15-*cis-β*C, were detected in all varieties of raw and cooked cassava. As expected with increasing temperature,[31] the 13-*cis* isomer of *β*C was preferentially increased during cooking (data not shown). For example, the estimated mean concentrations of 13-*cis-β*C were 3.1 and 9.4 μg/g DW in raw and fried cassava, respectively.

Potential retinol equivalents (RE) considers the amounts of *all-trans-β*C and *cis-β*C in ready-to-eat cassava.[33,34] Except for control and parental lines, the concentration of *all-trans-β*C in all progeny varieties significantly decreased as a result of cooking raw cassava. Nevertheless, the biofortified varieties of cooked cassava contained significantly more RE than their respective parental varieties (Table 3). *all-trans-β*C content per gram FW was not significantly different in boiled and fried cassava, except for the Jari and 06-01 varieties, for which the fried cassava had significantly higher and lower concentrations of the isomer, respectively. A 100 g portion of fried Jari cassava contained 28% of recommended nutrient intake (RNI) for 4–6-year-old children, which is 28 times greater than that provided by an equivalent consumption of the Saracura variety of fried white cassava.

Effects of Variety and Style of Cooking on the Bioaccessibility of *β*C in Cassava. As previously reported for cooked cassava,[25,32] recovery of *β*C in chyme following completion of the small intestinal phase of digestion exceeded 70% for boiled and fried Saracura and Jari varieties from lineage 1 and the three varieties in lineage 2 (data not shown). However, recoveries of *β*C in chyme for boiled and fried clones 14-11 and 03-15 and for boiled Dourada and Gema de Ovo varieties were only 40–60%. The losses were primarily associated with greater losses of *cis-β*C as recovery of *all-trans-β*C generally exceeded 80% (Figure 3a). *β*C released from the food matrix must be incorporated into mixed micelles during the small intestinal phase of digestion to be accessible for uptake by absorptive epithelial cells in the gut, possible cleavage to retinoids, and absorption of the carotenoid and its metabolites for delivery to peripheral tissues. The percentage of the carotenoid in the predigested sample that partitions in mixed

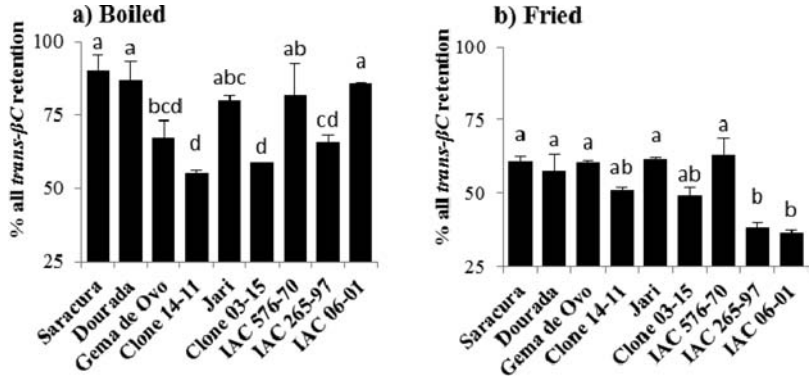

Figure 2. Relative retention of *all-trans-βC* per gram dry weight after boiling (a) and frying (b) cassava root. Data are the mean ± SD, $n = 6$. Different letters within each panel indicate means are significantly different ($p < 0.05$).

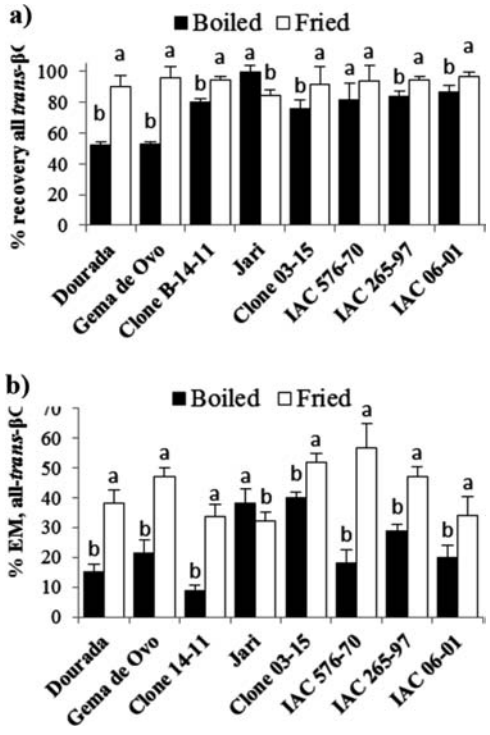

Figure 3. Recovery of *all-trans-βC* after simulated digestion of cooked cassava (a) and efficiency of micellarization (EM) of the carotenoid isomer (b). Recovery indicates the percentage of *all-trans-βC* in the cooked root that was detected in chyme at the end of the small intestinal phase of digestion. EM is the percentage of *all-trans-βC* in the cooked digestion before simulated digestion that partitioned in the filtered aqueous, that is, mixed micelle fraction of chyme. Data are the mean ± SD, $n = 6$. Different letters above error bars for each variety within a panel indicate that means for boiled and fried cassava of the variety differ significantly ($p < 0.05$).

micelles during the small intestinal phase of digestion is referred to as the efficiency of micellarization. The efficiency of micellarization of *all-trans-βC* in digested boiled cassava ranged from 9 to 40% (Figure 3b). There was a significant interaction ($p < 0.01$) between variety and cooking style. Frying cassava increased the efficiency of micellarization of *all-trans-βC* for seven of eight varieties. The efficiency of micellarization of *cis-βC* during digestion of varieties of boiled and fried cassava ranged from 8 to 25% and from 19 to 40%, respectively, and was significantly less than that of *all-trans-βC* for each respective variety cooked in the same manner (data not shown).

With the exception of clone 14-11, the estimated amount of bioaccessible, that is, micellarized, provitamin A after digestion of ready-to-eat biofortified varieties exceeded that of their respective parental varieties ($p < 0.05$, Table 4). The quantities of both *all-trans-βC* and *cis-βC* in mixed micelles after simulated digestion of fried cassava were significantly greater than that in micelles after digestion of boiled cassava. There was a robust correlation ($p < 0.01$) between the amounts of total *βC* and *all-trans-βC* in cassava root and the quantity incorporated into mixed micelles during simulated digestion (Figure 4). The trend for fried cassava exceeded that for boiled cassava because frying enhanced the efficiency of micellarization ($p < 0.05$).

Monolayers of differentiated Caco-2 cells were used to verify that *all-trans-βC* in the mixed micelles generated during digestion of cooked cassava for the four varieties with the highest concentrations was available for uptake across the brush border membrane. The quantity of *all-trans-βC* accumulated by Caco-2 cells was greater when monolayers were exposed to micelles generated during digestion of fried compared to boiled cassava (Table 5). Also, cellular accumulation of *all-trans-βC* from apical medium during exposure to the micelle fraction generated during digestion of fried variety 265-97 exceeded that in cells incubated with the micelle fractions after digestion of fried cassava for the other three varieties. The amount of *all-trans-βC* in the micelle fraction of fried and digested variety 265-97 was less than that in the micelle fractions for digested and fried Jari and clone 03-15 (Table 4). This suggests that other components in the micelle fraction may have influenced the transfer of *βC* from micelles across the apical membrane of the Caco-2 cells.

DISCUSSION

Biofortification represents a sustainable approach to reduce micronutrient and protein deficiencies in rural areas of developing countries.[35,36] It is important to ensure that biofortified staple food crops contain adequate concentrations of micronutrients to improve the nutritional status of populations at risk. To do so requires information about the impact of postharvest processing and styles of cooking on the amounts of nutrients of interest delivered to the plate, their bioacessibility, and consumer acceptance of the new varieties. We examined the influences of variety and two common domestic styles of cooking on the retention and bioaccessibility of *βC* in biofortified cassava. We chose to include white cassava (low *βC* content) in addition to several varieties from two parental lineages and their progeny containing elevated amounts of *βC* in the investigation

[a]Data are means ± SD, $n = 6$. Different lower case letters within columns indicate that the estimated amount of bioaccessible βC is significantly affected by style of cooking ($p < 0.05$). Different upper case letters within a row indicate that style of cooking significantly influences the amount of bioaccessible isomers of βC ($p < 0.05$).

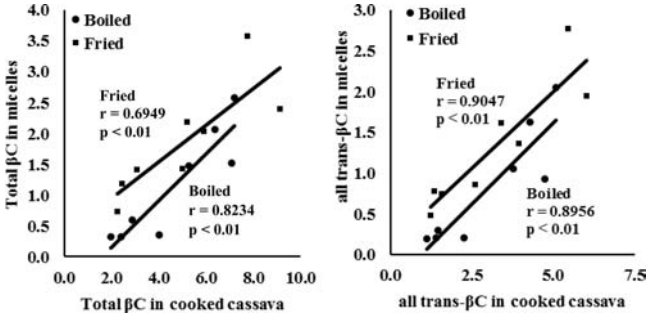

Figure 4. Total βC (a) and *all-trans*-βC (b) content in mixed micelles of digested boiled and fried cassava are highly correlated with βC content of cooked cassava. Data were analyzed by Pearson's correlation test for eight varieties of cassava that were either boiled or fried after boiling.

[a]Differentiated cultures of Caco-2 cells were incubated with mixed micelles generated during digestion of indicated varieties of cooked cassava for 4 h. Data are means ± SD, $n = 7$. Different lower case letters within columns indicate that means of varieties differ significantly ($p < 0.05$). Different upper case letters within rows indicate that means for cooking style differ significantly ($p < 0.05$). [b]Results were standardized per 1 g of fresh weight cassava.

because white cassava is widely consumed in NE Brazil. The basic differences in these two lineages of cassava were genotypic inheritance and geographical location of production (Table 1). Boiling cassava to acceptable texture and frying the boiled cassava in soybean oil were selected as common household styles of preparing cassava for investigation. Established methods were used to simulate the digestion of the cooked roots.[25,37,38] The predictive reliability of in vitro digestion of foods rich in carotenoids was reported by Reboul and colleagues,[37] who found that the percentage of carotenoids in foods recovered in micelles during in vitro digestion and in vivo during digestion by healthy humans were highly correlated ($r = 0.90$), as was the relative extent of micellarization during simulated digestion and relative bioavailability from meals with the same vegetables in human studies ($r = 0.98$). Among the key outcomes of the study are the following. Conventional breeding methods in Brazil produced progeny containing as high as 22-fold more βC on fresh weight basis than commonly consumed white cassava (Table 2) and the majority of the additional amount of the carotenoid was the *all-trans* isomer (Table 3). Cassava roots from lineage 2 grown in a tropical region had lower moisture content and greater capacity to adsorb oil during frying (Table 2). Also, frying boiled cassava generally did not induce additional significant reductions in cassava root compared to only boiling (Table 2). The amount of bioaccessible βC after simulated digestion of fried cassava exceeded that in boiled cassava due to increased efficiency of partitioning of the carotenoid in the former from the matrix to mixed micelles (Table 4; Figure 3b).

New varieties of cassava containing higher concentrations of βC have been generated by taking advantage of the biodiversity of cassava in Brazil. The Jari, 265-97, 06-01, and clone 03-15 varieties containing 7−10 μg/g FW of total βC are currently among the highest reported concentrations of total βC in biofortified cassava. Concentrations of total βC as high as 7 μg/g FW in cultivars of cassava in the Harvest Plus program of Nigeria were previously used to investigate the effects of genotype and cooking styles on the bioaccessibility of the provitamin.[25,38] Genetically modified cassava with roots containing as much as 6 μg βC/g FW[32] were similarly investigated. Ceballos et al.[39] reported that the use of a rapid cycling recurrent selection model for cross-breeding cassava in Colombia increased βC content in progenies to 10 μg/g FW. It is important to note that βC concentration is not the sole characteristic for selecting potential varieties for widespread planting as agronomic traits and economic viability also are important factors. Early efforts in Brazil produced the 576-70 variety of cassava that is characterized by its high yield, resistance to disease, increased content of βC, and favorable organoleptic properties.[40,41] This variety subsequently was crossed with SRT-797

dx.doi.org/10.1021/jf5018302 | J. Agric. Food Chem. 2014, 62, 6677−6686

Ouro do Vale variety to produce the 265-97and 06-01 varieties. Investments from Harvest Plus beginning in 2004 intensified breeding efforts with cassava that have generated new varieties including Jari and clones 03-15 and 14-11. Despite success with the biofortification of cassava with βC using conventional breeding,[25,39−43] further advances are needed to generate varieties with acceptable agroeconomic and organoleptic properties that will deliver adequate βC to the plate to meet up to 50% of the daily requirements for vitamin A.

The present study adds to recent reports that conventional breeding is useful for generating varieties of cassava that contain relatively high amounts of βC and possess other desirable agroeconomic characteristics.[14,39,43] There is a diverse germplasm from the Amazon region containing as high as 25 μg βC/g fresh weight in roots that can be used for crossing with varieties possessing other favorable characteristics.[43,44] To reduce VAD, both a relatively high content of βC and an abundance of *all-trans*-βC isomer are important because the *all-trans* isomer is cleaved into two molecules of retinal, whereas *cis* isomers produce only a single molecule of retinal when cleaved.[45] Retention of *all-trans*-βC in fried cassava (36−63%) was less than that after boiling, and there was preferential partial isomerization of *all-trans*-βC to 13-*cis*-βC as reported by others for fried yellow-fleshed cassava.[25,32,38,42,46,47] It is well established that heat induces isomerization of carotenoids prior to degradation and preferentially isomerizes *all-trans*-βC to 13-*cis*-βC because the activation energy for isomerization about the central double bound is lower than that for the other double bonds in the carotenoid.[30,31,48] Our findings suggest that a 100 g portion of ready-to-eat biofortified cooked cassava can provide as much as 28% of the recommended nutrient intake for 4−6-year-old children[33] depending on the variety, the content of βC in the root, and the style of cooking (Table 3). Similar results were obtained when we used the dietary reference intake values established by the Institute of Medicine as a reference.[49] As much as 55 μg/day of vitamin A expressed as retinol activity equivalent (RAE) is provided by 100 g of ready-to-eat biofortified cooked cassava for an additional 20% of the estimated average requirement (EAR) for children 4−6 years old (Supporting Information Table 1).

The bioacessibility of βC refers to the amount that is released from the food matrix and solubilized in mixed micelles for delivery to absorptive epithelial cells.[50] The three-phase (oral, gastric and intestinal) in vitro digestion method has been used to investigate the digestive stability and micellarization of provitamin A carotenoids from several high-starch foods including cassava, sweet potato, and grains.[25,32,51,52] Recovery of total βC after in vitro digestion of the majority of the biofortified varieties of cassava in the present study generally exceeded 70%, and simulated digestion of the cassava minimally affected the relative amounts of *all-trans*- and *cis*-isomers of the carotenoid as previously reported for other conventionally bred and transgenic biofortified varieties of cassava.[25,32,38] We noted a greater range in the efficiency of micellarization of βC during digestion of the different varieties of boiled cassava in this study, that is, 9−40%, than in boiled roots from conventionally bred cassava (25−30%) grown in Nigeria[38] and in transgenic cassava grown in Puerto Rico (30−45%).[31] With the exception of the cooked Jari variety, micellarization of βC during simulated digestion of fried cassava exceeded that for boiled roots. The greater adsorption of oil to fried cassava roots from lineage 2 than for fried roots from lineage 1 was associated with more efficient micellarization of βC during digestion. This observation is not surprising as dietary fat facilitates the solubilization and micellarization of carotenoids.[26,53] In contrast to our observation with the Jari variety, Gomes et al.[42] reported that micellarization of βC during digestion of fried Jari cassava was twice as great as that following digestion of boiled cassava. This difference may have been due to the greater fat content of the fried Jari root in the former study (11%/g FW) after boiling under pressure for 30 min before frying for 8 min as opposed to only 2% fat/g FW in our study in which cassava was boiled for 33 min at 1 atm and fried for 5 min. This suggests that the specific conditions of the boiling process and the moisture content of the root can affect the adsorption of oil during frying.

In agreement with our previous study with biofortified varieties developed in Nigeria,[25] the quantity of βC micellarized during simulated digestion of cooked cassava varieties was directly proportional to βC in the ready-to-eat cassava (Figure 4). Uptake of *all-trans*-βC by Caco-2 cells confirmed that micellarized βC was available to the enterocyte-like cells (Table 5). Together, these results suggest that breeders should continue to select for higher βC concentrations and palatability in high-yield varieties of cassava. Among the varieties investigated in the present study, fried biofortified cassavas from lineage 2 appear to be most beneficial from a nutritional perspective because of their relatively short boiling time, greater capacity to adsorb oil during the frying process, and relatively efficiency of micellarization of βC during digestion. The results from the present study further support the hypothesis that biofortification of cassava root with βC is a useful strategy for reducing VAD in vulnerable populations without requiring major changes in local and ethnic styles of home cooking.

32	2-[4-[2,3-dihydro-3-(hydroxymethyl)-5-(3-hydroxypropyl)-7-methoxy-2-benzofuranyl]-2,6-dimethoxyphenoxy]-1-(4-hydroxy-3-methoxyphenyl)-1,3-propanediol	211, 232(s),[a] 281
33	(*E*)-3,3′-dimethoxy-4,4′-dihydroxystilbene	222, 331

[a] "s" indicates a shoulder peak.

(arginine, threonine, proline, etc.), vitamins (riboflavin, niacin, thiamine, etc.), and organic acids (fumaric acid, malic acid, etc.) in maple materials.[7] Therefore, given our ongoing research interest in maple products, the primary objective of this project was to investigate the nutraceutical potential of a novel maple syrup derived extract (named MSX) produced under food-grade conditions starting from declassified maple syrup generated by the industry. Here we report (1) chemical compositional (quantification of sugars, minerals, amino acids, organic acids, vitamins, fiber, and ash), (2) phytochemical identification (by HPLC-DAD methods as well as by isolation and subsequent structure elucidation by NMR), (3) in vitro biological (antioxidant, anti-inflammatory, and glucose consumption bioassays), and (4) in vivo safety (acute animal toxicity) studies on MSX. This is the first chemical and biological study of a food-grade extract derived from maple syrup.

2. MATERIALS AND METHODS

2.1. General Experimental Procedures. All 1D nuclear magnetic resonance (^{1}H and ^{13}C NMR) and 2D NMR [^{1}H−^{1}H correlation

spectroscopy (COSY), heteronuclear single-quantum coherence (HSQC), heteronuclear multiple-bond coherence (HMBC)] experiments were acquired either on a Bruker 300 MHz or a Varian 500 MHz instrument. Unless otherwise stated, deuterated methanol (CD_3OD) was used as the solvent for all of the NMR experiments. HR-ESIMS data were acquired using a Waters SYNAPT G2-S QTOFMS system. High-performance liquid chromatography (HPLC) was performed on a Hitachi Elite LaChrom system (Pleasanton, CA) consisting of an L-2130 pump, L-2200 autosampler with L-2455 diode array detector (DAD), and L-2490 refractive index (RI) and L-2485 fluorescence (FL) detectors, all operated by EZChrom Elite software. Medium-pressure liquid chromatography (MPLC) was carried out on prepacked C18 columns. Optical rotation was performed on an AutoPol III automatic polarimeter (Rudolph Research, Flanders, NJ) with samples dissolved in methanol at room temperature. CD spectra were recorded on a JASCO J-810 spectropolarimeter.

2.2. Chemicals and Reagents. All solvents were either ACS or HPLC grade and were obtained from Pharmco-AAPER through Wilkem Scientific (Pawcatuck, RI). Sephadex LH-20, XAD-16 Amberlite resin, 2,2-diphenyl-1-picrylhydrazyl (DPPH), the Folin–Ciocalteau reagent, and all of the cell culture supplies were purchased from Sigma-Aldrich (St. Louis, MO). Standards of compounds used to aid in the phytochemical characterization of MSX were previously isolated and identified (by NMR) from maple syrup and maple sap by our laboratory.[4−7]

2.3. Production of MSX. In collaboration with the Federation of Maple Syrup Producers of Quebec (FPAQ), our laboratory has previously investigated the chemical constituents present in maple sap and syrup[4−7] and maple plant parts,[15−18] which has resulted in the isolation and identification (by NMR) of more than 100 compounds. Maple syrup is classified into different grades (light to dark) on the basis of light transmission. Notably, maple syrup with light transmission of <26.9% is classified as no. 3 dark (Canadian classification), and these products are not used for normal table consumption but rather as commercial ingredients. For the current project, we used two "declassified" grades of maple syrup samples named T_{15} and T_{21} (provided by FPAQ; T_{15} and T_{21} represent the degree of light transmission) which are also not suitable for normal table maple syrup consumption. With the ultimate goal of developing a food-grade maple syrup extract that would be suitable for human consumption, we initially developed laboratory-scale methods using an FDA food-grade approved resin, Amberlite XAD-16, and food-grade solvents (water and denatured ethanol) according to previously published methods.[19] Briefly, each of the maple syrup (T_{15} and T_{21}) starting materials were separately adsorbed onto the XAD-16 resin column and eluted with copious amounts of water to predominantly remove sugars. The adsorbed extract was subsequently eluted from the resin with denatured ethanol to yield MSX-1 (from T_{15}) and MSX-2 (from T_{21}) as dark brown free-flowing powders after solvent removal in vacuo. This small-scale laboratory method was then scaled-up to the pilot level (by SiliCycle Inc., Quebec City, Canada) using a glass column (height 6 feet, diameter 6 in.) filled with XAD-16 resin (ca. 6.7 kg of dry mass). The resin column was prewashed with deionized water (2 × 10 L) and then loaded with a 5 L portion of the declassified maple syrup sample diluted with 2.1 L of deionized water. Once the mixture was adsorbed, a second 5 L portion of the maple syrup sample (in 2.1 L of deionized water) was adsorbed onto the resin column, and sugars were eluted from the column with six consecutive 15 L portions of deionized water. Afterward, the adsorbed extract was eluted with three consecutive 15 L portions of denatured ethanol. The combined ethanol fractions were dried in vacuo on a rotary evaporator (temperature of the water bath <40 °C) to afford dark brown free-flowing solids of the MSX samples with yields of ca. 1.53−1.55 g/kg of the respective starting maple syrup sample. The XAD-16 resin column was then reconditioned with two 10 L portions of deionized water, and the process was repeated with fresh declassified maple syrup samples to yield additional samples of MSX-1 and MSX-2, ca. 300 g each. A portion of each of the MSX-1 and MSX-2 samples (ca. 100 g each) was shipped frozen to our laboratory and immediately stored at −20 °C on receipt.

2.4. Identification of Compounds 1−33 (by HPLC-DAD) in MSX. We have established HPLC-DAD methods to identify compounds (on the basis of comparison of retention times and UV spectra) in a variety of maple-derived materials using authentic standards previously isolated from maple sap and maple syrup by our group.[4−7] Therefore, on the basis of comparison of the HPLC-DAD profiles to that of pure maple syrup (chromatogram shown in Figure 2A), we were able to identify 33 compounds (**1−33**; compound identities shown in Table 1 and chemical structures shown in Figure 1) in phenolic-enriched extracts of each of the MSX samples (see Figure 2B,C). To accomplish this, phenolic-enriched extracts of the MSX samples (1.5 g each) were prepared as previously reported for pure maple syrup by liquid−liquid partitioning with ethyl acetate (40 mL × 3).[5,7] The combined ethyl acetate extracts were dried under reduced pressure in vacuo (water bath kept at 40 °C), and accurate masses were obtained as follows: 282 mg (for MSX-1) and 310 mg (for MSX-2). All samples were dissolved in dimethyl sulfoxide (DMSO), standardized to solid content (50 mg/mL), and then subjected to HPLC-DAD analyses using an Alltima C18 column (250 × 4.6 mm i.d., 5 μM; Alltech) with a flow rate of 0.75 mL/min and an injection volume of 20 μL. A linear gradient solvent system consisting of solvent A (0.1% aqueous trifluoroacetic acid) and solvent B (methanol) at room temperature was used as follows: 0−30 min, from 5% to 33.4% B; 30−80 min, from 33.4% to 71% B; 80−85 min, from 71% to 100% B; 85−86 min, from 100% to 5% B; 86−94 min, 5% B.

2.5. Isolation and Identification (by NMR) of Compounds S1−S9 from MSX. We pursued the isolation and structure elucidation (by NMR) of nine compounds (**S1−S9**; see Table 2) from the MSX samples which, despite their presence in pure maple syrup as evident from the HPLC-DAD profile (see Figure 2), were not obtained from our previous isolation studies.[4−6] Given the similarities in the HPLC-DAD profiles of the MSX-1 and MSX-2 samples (see parts B and C, respectively, of Figure 2), we sought to increase the quantity of initial starting material for our planned isolation studies by combining the MSX samples (1:1, w/w; total of 140.0 g). The combined MSX sample was subjected to liquid−liquid partitioning with ethyl acetate (700 mL × 3) to yield a dried MSX ethyl acetate extract (MSX−EtOAc; 29.0 g) after solvent removal in vacuo. The MSX−EtOAc (29.0 g) extract was subjected to C18 MPLC eluting with a gradient system of MeOH/H_2O (5:95 to 100:0, v/v) to afford eight major fractions (A1−A8). Fraction A1 (1.2 g) was chromatographed over a Sephadex LH-20 column (4 × 65 cm) with MeOH/H_2O (1:1, v/v) and was further purified by reversed-phase semipreparative HPLC with MeOH/0.1% TFA in water (0.8:99.2, v/v) to afford compound **S1** (9.2 mg, t_R = 19.5 min). Fraction A2 (1.5 g) was chromatographed over a Sephadex LH-20 column (4 × 65 cm) with MeOH/H_2O (1:1, v/v) and was further purified by reversed-phase semipreparative HPLC with MeOH/0.1% TFA in water (4:96, v/v) to afford compounds **S2** (2 mg, t_R = 29.8 min) and **S5** (10.1 mg, t_R = 19.4 min) and then with MeOH/0.1% TFA in water (2.6:97.4, v/v) to afford compound **S7** (9.8 mg, t_R = 37.1 min). Fraction A3 (0.5 g) was chromatographed over a Sephadex LH-20 column (4 × 65 cm) with MeOH/H_2O (1:1, v/v) and was then further purified by reversed-phase semipreparative HPLC with MeOH/0.1% TFA in water (10:90, v/v) to afford compounds **S6** (4 mg, t_R = 43.0 min) and **S8** (3.8 mg, t_R = 26.8 min) and with MeOH/0.1% TFA in water (5:95, v/v) to afford compound **S9** (5.1 mg, t_R = 34.7 min). Similarly, fraction A7 (0.9 g) was chromatographed over a Sephadex LH-20 column (4 × 65 cm) with MeOH/H_2O (1:1, v/v) and was then further purified by reversed-phase semipreparative HPLC with MeOH/0.1% TFA in water (41:59, v/v) to afford compounds **S3** (3 mg, t_R = 75.3 min) and **S4** (12.6 mg, t_R = 80.2 min).

*2.5.1. Data for (6R)-6-hydroxy-3-(hydroxymethyl)-2-cyclohexenone (**S1**):* yellow oil; $[\alpha]_D^{20}$ +27.8 (*c* 0.9, MeOH); CD (MeOH) 232 (Δε −4.62), 247 (Δε −10.49), 323 (Δε −0.39) nm; HR-ESIMS *m*/*z* 141.0557 $[M - H]^-$ (calcd for $C_7H_9O_3$, 141.0552); ^1H and ^{13}C NMR data shown in Table 3.

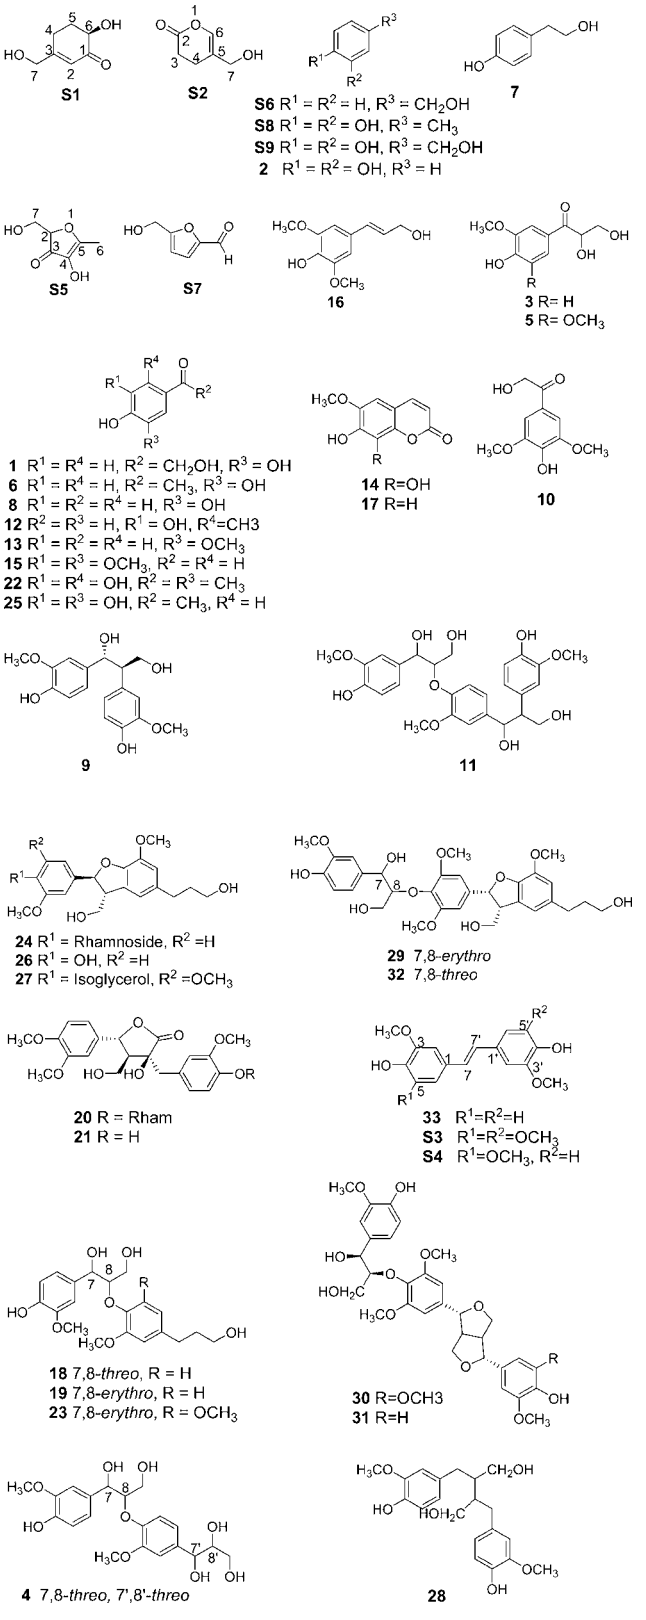

Figure 1. Chemical structures of compounds identified in MSX samples.

*2.5.3. Data for 4,4′-dihydroxy-3,3′,5,5′-tetramethoxystilbene (**S3**):* purple amorphous powder; (+)ESIMS m/z 355.1076 $[M + Na]^+$, calcd for molecular formula $C_{18}H_{20}O_6$; ^{1}H NMR (300 MHz, CD_3OD) δ 3.83 (12H, s, 3,3′,5,5′-OCH_3), 6.76 (4H, s, H-2,2′,4,4′), 6.88 (2H, s, H-7,7′). The NMR data are consistent with those in the previous literature report.[20]

*2.5.4. Data for 4,4′-dihydroxy-3,3′,5-trimethoxystilbene (**S4**):* yellow amorphous powder; (+)ESIMS m/z 325.0977 $[M + Na]^+$, calcd for molecular formula $C_{17}H_{18}O_5$; ^{1}H NMR (300 MHz, CD_3OD) δ 3.81 (6H, s, 3,5-OCH_3), 3.83 (3H, s, 3′-OCH_3), 6.71 (1H, d, J = 8.0 Hz, H-5′), 6.74 (2H, s, H-2,6), 6.86 (2H, s, H-7,7′), 6.91 (1H, d, J = 8.0 Hz, H-6′), 7.05 (1H, s, H-2′). The NMR data are consistent with those in the previous literature report.[20]

*2.5.5. Data for 4-hydroxy-2-(hydroxymethyl)-5-methyl-3(2H)-furanone (**S5**):* yellow oil; (+)ESIMS m/z 167.0240 $[M + Na]^+$, calcd for molecular formula $C_6H_8O_4$; ^{1}H NMR (300 MHz, CD_3OD) δ 3.97 (1H, dd, J = 10.5 Hz, H-2), 4.03 (1H, dd, J = 10.5 Hz, J = 4.3 Hz, $-CH_2$), 4.18 (1H, dd, J = 10.5 Hz, J = 4.3 Hz, $-CH_2$), 1.89 (3H, s, $-CH_3$); ^{13}C NMR (300 MHz, CD_3OD) δ 15.5 (C-6), 68.9 (C-7), 72.5 (C-2), 132.6 (C-5), 161.1 (C-4), 189.1 (C-3). The NMR data are consistent with those in the previous literature report.[21]

*2.5.6. Data for benzenemethanol (**S6**):* colorless oil; (+)ESIMS m/z 131.0392 $[M + Na]^+$, calcd for molecular formula C_7H_8O; ^{1}H NMR (300 MHz, $CDCl_3$) δ 7.36 (2H, d, J = 7.5 Hz, H-2,6), 7.31 (3H, m, H-3,4,5), 4.67 (2H, s, H-7). The NMR data are consistent with those in the previous literature report.[22]

*2.5.7. Data for 5-(hydroxymethyl)-2-furaldehyde, also known as 5-(hydroxymethyl)furfural (HMF; **S7**):* yellow oil; (+)ESIMS m/z 149.0132 $[M + Na]^+$, calcd for molecular formula $C_6H_6O_3$; ^{1}H NMR (300 MHz, CD_3OD) δ 9.48 (1H, s, −CHO), 7.33 (1H, d, J = 3.5 Hz, H-3), 6.53 (1H, d, J = 3.5 Hz, H-4), 4.56 (2H, s, $-CH_2$). The NMR data are consistent with those in the previous literature report.[23]

*2.5.8. Data for 4-methyl-1,2-benzenediol (**S8**):* colorless amorphous powder; (+)ESIMS m/z 147.0342 $[M + Na]^+$, calcd for molecular formula $C_7H_8O_2$; ^{1}H NMR (300 MHz, CD_3OD) δ 6.52 (1H, d, J = 8.4 Hz, H-5), 6.47 (1H, s, H-3), 6.39 (1H, d, J = 8.4 Hz, H-6), 2.06 (3H, s, $-CH_3$). The NMR data are consistent with those in the previous literature report.[24]

*2.5.9. Data for 4-(hydroxymethyl)-1,2-benzenediol (**S9**):* colorless amorphous powder; (+)ESIMS m/z 163.0290 $[M + Na]^+$, calcd for molecular formula $C_7H_8O_3$; ^{1}H NMR (300 MHz, CD_3OD) δ 7.33 (1H, s, H-3), 7.33 (1H, d, J = 8.1 Hz, H-6), 6.79 (1H, d, J = 8.1 Hz, H-5), 4.73 (2H, s, $-CH_2$). The NMR data are consistent with those of the previous literature report.[25]

2.6. Quantification of Compounds S5 and S7 in MSX Samples. Because compounds **S5** and **S7** appeared as major compounds in the MSX-2 sample (HPLC-DAD chromatogram shown in Figure 2C), the levels of these compounds were quantified in both MSX samples. HPLC-DAD analyses were conducted using an Alltima C18 column (250 × 4.6 mm i.d., 5 μM; Alltech) with a flow rate of 0.75 mL/min and an injection volume of 20 μL. A linear gradient solvent system consisting of solvent A (0.1% TFA in water) and solvent B (methanol) at room temperature was used as follows: 0−19 min, from 5% to 23% B; 20−21 min, from 23% to 100% B; 22−23 min, from 100% to 5% B; 23−41 min, 5% B. For quantification purposes, calibration curves were constructed for each of the pure compounds, **S5** and **S7**, as follows: **S5** [$y = (4 \times 10^8)x + 102305$ with $r^2 = 1$]; **S7** [$y = (4 \times 10^8)x + 3 \times 10^6$ with $r^2 = 0.9974$].

2.7. Quantification of the Total Phenolic Content of MSX Samples. The MSX samples were quantified for total phenolic content using the Folin−Ciocalteau method on the basis of gallic acid equivalents (GAEs) as previously reported.[26] Briefly, each MSX sample (3.1 mg) was dissolved in 10 mL of methanol/H_2O (1:1, v/v), and 200 μL of each sample was incubated with 3 mL of methanol/H_2O (1:1, v/v) and 200 μL of Folin−Ciocalteau reagent for 10 min at 25 °C. After this, 600 μL of a 20% sodium carbonate (Na_2CO_3) solution was added to each tube and the resulting solution vortexed. The tubes were then further incubated for an additional 20 min at 40 °C and then immediately cooled in an ice bath to room temperature. The samples and standard (gallic acid) were processed identically. The absorbance was determined at 755 nm, and the final results were calculated from the standard curve obtained from a Spectramax plate reader (Molecular Devices, Sunnyvale, CA).

2.8. Antioxidant Activity of MSX Samples. The antioxidant potentials of the MSX samples were determined by the DPPH free radical scavenging assay as previously reported.[27] The assay was conducted in a 96-well format using serial dilutions of 100 μL aliquots of

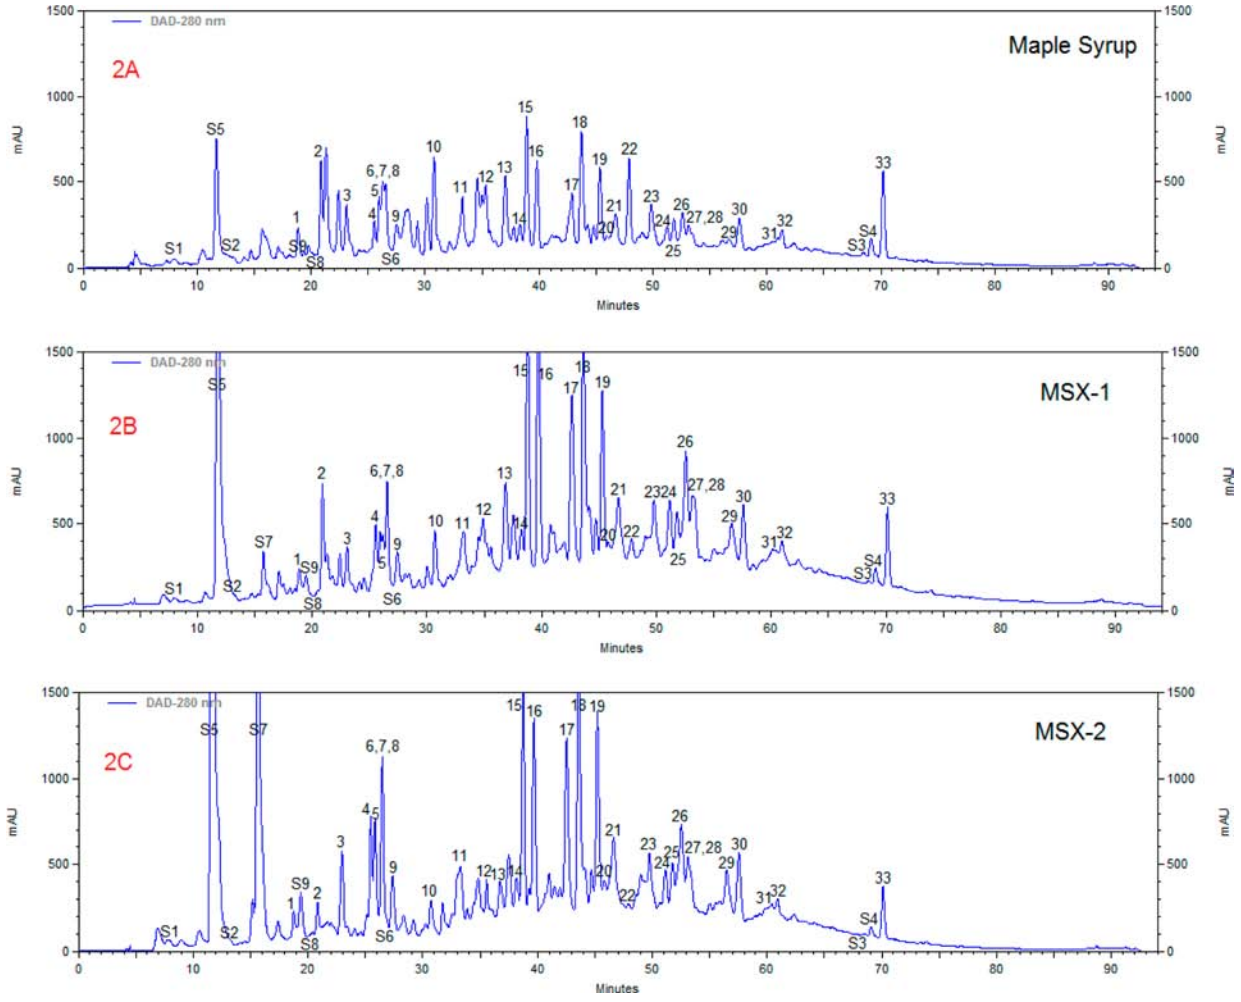

Figure 2. HPLC-DAD chromatograms of maple syrup (A), MSX-1 (B), and MSX-2 (C) at a detection wavelength of 280 nm. Peaks labeled **1**−**9** and **11**−**33** were identified by comparison to phenolic standards previously isolated from maple syrup.[4−6] Peak **10** was identified by comparison to phenolic standard previously isolated from maple sap.[7] Peaks S1−S9 were isolated and identified (by NMR) from MSX for the first time. The names of the compounds are listed in Table 1, and their chemical structures are shown in Figure 1

Table 2. Compounds S1−S9 Isolated from MSX and Identified by NMR

compd	identity	ref for NMR data
S1	(6*R*)-6-hydroxy-3-(hydroxymethyl)-2-cyclohexenone	
S2	3,4-dihydro-5-(hydroxymethyl)pyran-2-one	
S3	4,4′-dihydroxy-3,3′,5,5′-tetramethoxystilbene	20
S4	4,4′-dihydroxy-3,3′,5′-trimethoxystilbene	20
S5	4-hydroxy-2-(hydroxymethyl)-5-methyl-3(2*H*)-furanone	21
S6	benzenemethanol	22
S7	5-(hydroxymethyl)furfural	23
S8	4-methyl-1,2-benzenediol	24
S9	4-(hydroxymethyl)-1,2-benzenediol	25

test samples (ranging from 26 to 2500 μg/mL), and then DPPH (150 μL) was added to each well to yield a final DPPH concentration of 137 μM. The absorbance was determined after 30 min at 515 nm, and the scavenging capacity (SC) was calculated as SC (%) = $[(A_0 - A_1/A_0)] \times 100$, where A_0 is the absorbance of the reagent blank and A_1 is the absorbance of the test samples. The control contained all reagents except the compounds, and all tests were performed in triplicate. IC_{50} values denote the concentration (μg/mL) of sample required to scavenge 50% of the DPPH free radicals (Table 4).

Table 4. Total Phenolic Contents of MSX Samples and Their DPPH Free Radical Scavenging Activities

sample	total phenolic content of MSX[a] (mg/100 g of gallic acid equivalents)	total phenolic content of MSX−EtOAc (mg/100 g of gallic acid equivalents)	DPPH free radical scavenging activity of MSX[a,b] (IC_{50}, μg/mL)
MSX-1	16648.15	26278.28	97.6 ± 4.73
MSX-2	16337.83	27441.33	102.4 ± 7.25

[a]Assay conducted with neat samples of original MSX samples. [b]Positive controls, ascorbic acid and BHT, have IC_{50} values of 40 and 3000 μM, respectively.[5]

supplemented with 10% FBS, 100 units/mL penicillin, and 100 μg/mL streptomycin. Cells were incubated in a humidified atmosphere of 5% CO_2 at 37 °C.

2.10. Assay for Nitrite Concentration. The nitrite concentration assay was conducted according to methods previously described by our group for an ethyl acetate extract of pure maple syrup (MS−EtOAc).[14] Briefly, RAW 264.7 macrophages were seeded (1×10^5 cells/100 μL) in 96-well plates. After 24 h of incubation, the RAW 264.7 cells were stimulated with 100 ng/mL LPS followed by treatment with ethyl acetate extracts of the MSX samples (50 and 100 μg/mL solubilized in DMSO) for 24 h. The final DMSO concentration in the cell culture medium was <0.1%. After 24 h of incubation, cell culture supernatants were collected for nitrite (NO) and prostaglandin E2 (PGE_2) measurements (further described below). Cell culture supernatants were incubated with an equal volume of modified Griess reagent (Sigma-Aldrich) for 20 min at room temperature. The optical densities were measured at 540 nm, and the nitrite levels were determined by comparison to a standard curve. The assay was performed using three individual wells for each sample.

2.11. Assay for PGE_2 Release. PGE_2 was determined using the above cell supernatants as previously described.[14] Briefly, PGE_2 levels were measured using an enzyme immunosorbent (EIA) kit (Cayman Chemical, Ann Arbor, MI) according to the manufacturer's protocol. The experiment was performed with three individual samples per treatment.

2.12. Glucose Assay. The glucose assay was performed as described previously[28] with some modifications. Briefly, HepG2 cells were cultured in complete medium with 10% FBS to ∼80% cell confluence in 96-well plates and subjected to the assays. After the cells were confluent, the medium was replaced with medium containing 1% FBS and low glucose (1 mmol/L). After overnight incubation, the cells were treated with the MSX samples dissolved in DMSO (each at 50 and 100 μg/mL concentrations) for 7 h. The cell supernatants were assayed for glucose concentration using a glucose assay kit (Eton Bioscience Inc., Charlestown, MA). The absorbance was measured at 490 nm. The experiment was performed in triplicate.

2.13. Amino Acid Contents of MSX Samples by HPLC-FL. The amino acid contents of the MSX samples were determined by using the AccQ Tag amino acid analysis assay from Waters Corp. (Milford, MA) as previously reported.[7] Briefly, this assay uses the Waters AccQ Fluor reagent to derivatize amino acids which are subsequently separated by reverse-phase HPLC and quantitated by fluorescence detection (FL) using a Waters AccQ Tag column. Peaks were identified by comparison of their retention times to amino acid reference standards.

2.14. Organic Acid Contents of MSX Samples by HPLC-DAD. The organic acid contents of the MSX samples were determined by HPLC-DAD analyses using an Allure organic acid column (150 × 4.6 mm) purchased from Restek Corp. (Bellefonte, PA) as reported.[7] Peaks were identified on the basis of comparison of their retention times to those of organic acid standards. Each sample was injected in triplicate.

2.15. Vitamin Contents of MSX Samples by HPLC-DAD. The vitamin contents of the MSX samples were determined by HPLC-DAD analyses using a Luna 5 μm C18 column (250 × 4.6 mm) purchased from Phenomenex (Torrance, CA) with a flow rate of 1.0 mL/min and column temperature of 25 °C. A linear gradient solvent system consisting of solvent A (0.1% TFA in water) and solvent B (acetonitrile) was used as follows: 0−5 min, 0% B; 5−11 min, from 0% to 25% B; 11−17 min, from 25% to 40% B; 17−18 min, from 40% to 60% B; 18−20 min, from 60% to 0% B; 20−28 min, 0% B. For quantification purposes, calibration curves were constructed for each vitamin standard as follows: riboflavin (B2) [$y = 143176x + 8066.6$ with $r^2 = 0.9981$]; niacin (B3) [$y = 56212x - 813.11$ with $r^2 = 0.9975$]. Aliquots of each MSX sample (a 10-fold dilution of a stock solution of 100 mg/mL) were centrifuged at 10 000 rpm for 5 min, and then the supernatant (30 μL aliquots) was injected directly for HPLC-DAD analyses. Peaks were identified on the basis of comparison of their retention times to those of vitamin standards. Each sample was injected in triplicate.

2.16. Sugar Contents of MSX Samples by HPLC-RI. The sugar contents of the MSX samples were determined by HPLC-RI analyses using a Waters Sugar-Pak I column (300 × 6.5 mm, 10 μm) purchased from Waters Corp. according to methods previously reported.[7] The isocratic solvent system consisted of ethylenediaminetetraacetic acid calcium disodium salt (EDTA; 50 mg/L) over 15 min. The standard for the complex sugars (6.0 mg) eluted before sucrose and was isolated as a single peak after repeated injections of pure maple syrup using the same HPLC conditions as previously reported[7] except that pure deionized (DI) water was substituted for EDTA. For quantification purposes, calibration curves were constructed for each sugar standard (dissolved in DI water) as follows: sucrose [$y = 527830x + 312928$ with $r^2 = 0.9999$]; glucose [$y = 572734x + 1703$ with $r^2 = 1$]; fructose [$y = 545540x + 5351.5$ with $r^2 = 1$]; complex sugars [$y = 511030x + 93196$ with $r^2 = 1$]. Peaks were identified on the basis of comparison of their retention times to that of each of the standards. Each sample was injected in triplicate.

2.17. Mineral Contents of MSX Samples by Inductively Coupled Plasma Mass Spectrometry (ICP-MS). The analyses of the mineral contents of the MSX samples were conducted by using ICP-MS on a Thermo Scientific iCAP Qa instrument coupled to an ASX-510 HS high-speed autosampler (Thermo Scientific, West Palm Beach, FL) as previously reported.[7] Calibration standards of the minerals Na, Mg, Al, K, Ca, Fe, Mn, Cu, Zn, As, Se, Mo, and Cd and the internal standard, Y, were purchased from Ultra Scientific (North Kingstown, RI). A MARS5Microwave digestion system and reaction vessels for digestion of MSX samples were purchased from CEM Corp. (Matthews, NC). Each MSX sample (10 mg) was combined with nitric acid (1 mL; ICP-MS grade) and digested in reaction vessels in the microwave. The digested solutions were transferred to 1.5 mL centrifuge tubes and centrifuged for 10 min at 10 000 rpm at 4 °C. An aliquot of each digested solution (200 μL) was further diluted to 10 mL with DI water and then submitted for ICP-MS analysis. Standard curves for each of the minerals were obtained on the day of the analysis, and the internal standard, Y, was added to every sample to ensure the accuracy of the method.

2.18. Animal Toxicity Studies on MSX Samples. The animal toxicity studies were conducted by ITR Laboratories Canada Inc. (Quebec City, Canada) under a contract with FPAQ. The study followed a well-established protocol of a 7 day oral toxicity study in Sprague−Dawley rats ($n = 10$ consisting of 5 males and 5 females per treatment group) to determine the toxicity of the MSX samples. The test samples and control/vehicle treatments were administered once daily by oral gavage (using a gavage needle attached to a syringe) for 7 consecutive days at doses of 100, 300, and 1000 mg/kg/day for each MSX sample. Therefore, animals of group 1 were administered the vehicle item (0.5% carboxymethyl cellulose) alone, animals of groups 2, 3, and 4 were administered MSX-1 (at doses of 100, 300, and 1000 mg/kg/day, respectively), and animals of groups 5, 6, and 7 were administered MSX-2 (at doses of 100, 300, and 1000 mg/kg/day, respectively). The dose volume was 10 mL/kg for all animals, and the actual volume administered to each rat was calculated and adjusted on the basis of the body mass of each animal. All animals were euthanized upon completion of the treatment period (day 8), and following an overnight period without food, the animals were anesthetized with

isoflurane to allow collection of blood samples for clinical pathology evaluation, followed by exsanguination. To avoid autolytic changes, the necropsy examination of the carcass was conducted as soon as possible on all animals. Gross pathology consisted of an external examination, including identification of all clinically recorded lesions, as well as a detailed internal examination. A staff pathologist was available for consultation during all necropsies. For animals euthanized at termination, organs identified in the tissue preservation section were dissected, trimmed free of fat, and weighed, and the body mass to relative organ masses were calculated. The study plan was reviewed and assessed by the Animal Care Committee (ACC) of ITR, and the ACC acceptance of the study plan was maintained on file at ITR. All animals used in the study were cared for in accordance with the principles outlined in the current *Guide to the Care and Use of Experimental Animals* as published by the Canadian Council on Animal Care and the *Guide for the Care and Use of Laboratory Animals*, an NIH publication.

2.19. Ash and Fiber Contents of MSX samples. The ash and fiber contents of the MSX samples were carried out by Covance Laboratories (Madison, WI) using approved standard operating procedures (SOPs) that followed the Official Methods of Analysis of AOAC International (for ash and fiber contents).

3. RESULTS AND DISCUSSION

3.1. Preparation of MSX. Maple syrup is a popular and widely consumed natural sweetener, but to date, there are no reported studies of any food-grade extracts derived from this sweetener. Many plant food industries have expanded and diversified their product portfolios with commercial botanical extracts, e.g., grape seed and cranberry extracts (derived from the squeezed fruit pulp and seeds after juicing), which are widely used as functional food and nutraceutical ingredients. Notably, many of these generally regarded as safe (GRAS) extracts have grown in consumer acceptance and are being increasingly studied in both academic and industrial research laboratories for their chemical compositional and biological effects. Therefore, all of the aforementioned factors, in addition to our group's ongoing interest in maple products, prompted the initiation of this project, which sought to develop a proprietary maple syrup extract (named MSX). For this project, two declassified maple syrup samples (see the Materials and Methods for details) were used to generate the MSX samples, named MSX-1 and MSX-2. The MSX samples were produced in a pilot-scale facility using adsorption chromatography with an FDA food-grade approved resin (Amberlite XAD-16) and food-grade solvents (water and denatured ethanol). MSX appears as a dark brown free-flowing dried powder after solvent removal.

3.2. Chemical Composition of MSX. *3.2.1. Phytochemicals.* A total of 42 phytochemicals (the compound structures are shown in Figure 1, and the identities are listed in Table 1) were identified in MSX using a combination of (1) HPLC-DAD methods (by comparison to chemical standards previously isolated by our laboratory from maple sap and syrup)[4−7] and (2) isolation (by various chromatographic methods) and structure elucidation (by NMR) of those compounds for which chemical standards were lacking. Therefore, among the 42 compounds, 33 (**1**−**33**) compounds were identified by HPLC-DAD and 9 (**S1**−**S9**) compounds were isolated and identified by NMR. Notably, among the nine isolates, two compounds (**S1** and **S2**) are new compounds, and a detailed description of their structure elucidation is being reported here for the first time. Details of the phytochemical characterization of MSX are provided below.

*3.2.1.1. Identification of Compounds **1**−**33** in MSX by HPLC-DAD.* Figure 2A shows the HPLC-DAD chromatogram of an ethyl acetate extract of pure maple syrup from which compounds **1**−**33** were identified on the basis of comparison of their HPLC-DAD retention times and UV spectra (see Table 1) to those of authentic standards previously isolated from maple sap and syrup by our laboratory.[4−7] The HPLC profiles of the MSX-1 and MSX-2 samples (see parts B and C, respectively, of Figure 2) showed close similarities to the HPLC profile of pure maple syrup (Figure 2A), allowing for the identification of compounds **1**−**33** therein. The striking similarities of the HPLC profile of the pure maple syrup sample to the HPLC profiles of the MSX samples suggest that phytochemicals present in pure maple syrup persist in these declassified maple syrup samples. While it was not possible to determine the levels of all of the individual phytochemicals present in the MSX sample given the complex overlapping peaks in the HPLC-DAD profiles, we conducted quantitative studies based on two major compounds, namely, **S5** and **S7** (further described below; see Table 5) present therein. In addition, we quantified the MSX samples to total polyphenol contents (further described below).

Table 5. Levels (%) of Compounds S5 and S7 in the MSX Samples

sample	compd **S5**	compd **S7**
MSX-1	0.095	0.004
MSX-2	0.132	0.049

*3.2.1.2. Identification of Compounds **S1**−**S9** in MSX Samples by Isolation and Structure Elucidation (by NMR).* In the current study, apart from the identification of compounds **1**−**33** (by HPLC-DAD methods), an additional nine compounds (compounds **S1**−**S9**; Table 2) were isolated and identified (using mass spectral and NMR data and by comparison to literature data when available). Notably, all of these nine compounds were originally present in pure maple syrup (peaks are apparent in the HPLC chromatogram shown in Figure 2A), but these compounds were not isolated in our previous phytochemical studies.[4−7] Among the nine isolates, two are new compounds, (6*R*)-6-hydroxy-3-(hydroxymethyl)-2-cyclohexenone (**S1**) and 3,4-dihydro-5-(hydroxymethyl)pyran-2-one (**S2**), two are stilbene derivatives, 4,4′-dihydroxy-3,3′,5,5′-tetramethoxystilbene (**S3**) and 4,4′-dihydroxy-3,3′,5′-trimethoxystilbene (**S4**), two are furan derivatives, 4-hydroxy-2-(hydroxymethyl)-5-methyl-3(2*H*)-furanone (**S5**) and 5-(hydroxymethyl)furfural (**S7**), and three are Ar−C1 derivatives (**S6**, **S8**, and **S9**). Among these nine isolates, only **S7**, a known product of the Maillard reaction, has previously been reported from maple syrup,[29] and thus, all of the other eight isolates are being reported from maple syrup herein for the first time. Also, the isolation and structure elucidation of two additional stilbenoids (compounds **S3** and **S4**) supports our previous report of the occurrence of the stilbene phenolic subclass in maple syrup [where (*E*)-3,3′-dimethoxy-4,4′-dihydroxystilbene was previously reported[4]]. The NMR data for all nine isolates (**S1**−**S9**) are provided herein (see the Materials and Methods), but only the detailed structure elucidation of the two new compounds (**S1** and **S2**) is discussed below.

*3.2.1.2.1. Elucidation of Compound **S1**.* Compound **S1** was obtained as a yellow oil with a molecular formula of $C_7H_{10}O_3$ as determined by the HR-ESIMS m/z 141.0557 $[M - H]^-$ (calcd for $C_7H_9O_3$, 141.0552) data with 3 degrees of unsaturation. The ^1H and ^{13}C NMR data (Table 3) of compound **S1** revealed the presence of an α,β-unsaturated ketone moiety [δ_C 120.0, 167.0 and 200.3; δ_H 6.00 (1H, s)], one oxygenated methine group [δ_C 72.3; δ_H 4.05 (1H, m)], and three methylene groups (δ_C 25.1,

dx.doi.org/10.1021/jf501924y | J. Agric. Food Chem. 2014, 62, 6687−6698

31.0, and 63.3). The aforementioned NMR data and the HMBC correlations (see Figure 3) from H-2 (δ_H 6.00) to C-6, C-7, and

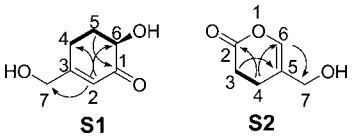

Figure 3. Key ^{1}H−^{1}H COSY (−) and HMBC (H → C) correlations of compounds **S1** and **S2**.

C-4, along with the C-4−C-5−C-6 spin system (from the ^{1}H−^{1}H COSY data) implied that the planar structure of compound **S1** was 6-hydroxy-3-(hydroxymethyl)-2-cyclohexenone. The only chiral center (C-6) in the structure of compound **S1** was assigned an *R* configuration on the basis of a negative Cotton effect at 323 nm ($\Delta\varepsilon$ −0.39, n → π^* transition of the α,β-unsaturated ketone) in the CD spectrum.[30] Notably, while this is the first reported occurrence of compound **S1**, its methoxylated derivative, 6-hydroxy-3-(methoxymethyl)-2-cyclohexenone, has been previously reported, but the latter compound was obtained by synthesis and not as an isolated natural product.[31]

*3.2.1.2.2. Elucidation of Compound **S2**.* Compound **S2** was isolated as an amorphous powder with a molecular formula of $C_6H_8O_3$ as established by the HR-ESIMS *m/z* 127.0396 [M − H]$^-$ (calcd for $C_6H_7O_3$, 127.0395) data with 3 degrees of unsaturation. The ^{13}C NMR data of compound **S2** showed resonance signals typical of an ester carbonyl group at δ_C 176.5, a single C−C double bond (δ_C 148.3 and 133.1), and three methylene groups (δ_C 21.7, 21.7 and 72.1). The linkage from C-2 to C-4 was determined by the ^{1}H−^{1}H COSY correlation of H-3/H-4 and the HMBC correlations (see Figure 3) from H-4 and H-3 to C-2. The HMBC correlation between H-4 and C-6 and between H-3 and C-5 and the carbon resonance signal of C-2 (δ_C 176.5) revealed the connection between C-2 and C-6 was via an oxygen. The HMBC correlations from H_2-7 (δ_H 4.76) to C-5 and C-6 indicated that an oxygenated methylene (CH_2-7) was attached to C-5. Therefore, the structure of **S2** was elucidated as that of the new compound 3,4-dihydro-5-(hydroxymethyl)-pyran-2-one.

3.2.1.3. Quantification Studies of MSX Based on Total Polyphenol Content. Given that maple syrup is known to contain phenolics,[4] the MSX-1 and MSX-2 samples were evaluated for total polyphenol content (see Table 4). As expected, because these are extracts, the polyphenol contents of the MSX samples were far greater than that of the original pure maple syrup (ca. 16% vs 0.04% GAEs). However, the polyphenol levels of MSX−EtOAc extracts (ca. 27% GAEs) were in a range similar to that of MS−EtOAc (ca. 30% GAEs) which we have recently reported shows anti-inflammatory effects in an LPS-stimulated RAW264.7 macrophage model[14] (further discussed below). However, the aforementioned MS−EtOAc extract was not produced under food-grade conditions, unlike the MSX samples which are being investigated in the current study for human consumption (i.e., for nutraceutical applications).

*3.2.1.4. Quantification Studies of MSX Based on the Levels of Compounds **S5** and **S7**.* Several furan derivatives, in particular, 5-(hydroxymethyl)furfural (HMF; compound S7), are well-known Maillard products formed during heat-processing of sugary foods, including the natural sweeteners honey and maple syrup.[28,32] Interestingly, HMF has been a subject of debate due to reports of its potential toxicity, although this is still a controversial issue as this compound has been shown to exert antioxidant, antitumor, and anti-inflammatory effects.[33,34] Thus, since the two furan derivatives isolated in this study, namely, compounds **S5** and **S7**, appeared as major peaks in the HPLC-DAD chromatogram of the MSX-2 sample (see Figure 2C), we sought to determine their levels in both of the MSX samples (see Table 5). Of the two MSX samples, MSX-2 contained higher levels of both compounds **S5** and **S7** (0.132% and 0.049%, respectively), and among the two compounds, **S5** was present in higher levels than **S7** in both of the MSX samples. We did not attempt to correlate the levels of any individual constituents present in the MSX samples to their overall biological activities (further discussed in section 3.4). However, given the occurrence of the furan derivatives therein, and the aforementioned controversial reports of the potential toxicity of HMF,[33,34] we also evaluated the MSX samples for toxicity using an animal model (further discussed in section 3.3). Moreover, animal toxicity studies are especially relevant if the MSX samples are to be utilized for future nutraceutical applications.

3.2.2. Sugars. The sugar contents (sucrose, glucose, fructose, and complex sugars) of the MSX samples were quantitated in this study (see Table 6). The MSX samples contained similar levels of total sugars (ca. 50%), and similar to pure maple syrup, sucrose was the most abundant sugar. Apart from sucrose, the MSX samples also contained complex sugars, glucose, and fructose. The detection of complex sugars in the MSX samples is not surprising considering that the presence of these constituents has been previously reported in pure maple syrup.[2] Complex polysaccharides are being increasingly used as functional food ingredients and have interesting biological effects,[35,36] and thus, their presence in MSX, beyond sucrose alone, is interesting from a human health perspective.

3.2.3. Amino Acids. The levels of amino acids, namely, arginine, threonine, proline, and histidine, in the MSX samples are shown in Table 7. Among these amino acids, proline was the most abundant, reaching levels of ca. 19 mg/100 g of the MSX samples.

3.2.4. Organic Acids. The levels of the organic acids, malic acid and fumaric acid in the MSX samples are shown in Table 7. Among the two organic acids, malic acid was the most abundant, reaching levels of ca. 781 and 341 mg/100 g in the MSX-1 and MSX-2 samples, respectively.

3.2.5. Minerals. The mineral contents of the MSX samples are shown in Table 8, and among the two samples, MSX-1 had greater mineral levels compared to the MSX-2 sample, which is in

Table 6. Average Sugar and Vitamin Contents of MSX Samples

	sugar content[a] (mg/100 g)				vitamin content[a] (mg/100 g)	
sample	sucrose	glucose	fructose	complex sugar	B2	B3
MSX-1	38635.18 ± 63.04	63.76 ± 9.25	6.99 ± 0.82	16231.72 ± 20.68	410.26 ± 0.43	7.13 ± 0.01
MSX-2	41136.41 ± 67.21	284.10 ± 11.16	233.65 ± 19.01	8927.52 ± 9.12	290.45 ± 0.06	9.83 ± 0.03

[a]Assay conducted with neat samples of original MSX samples.

Table 7. Average Amino Acid and Organic Acid Contents of MSX Samples

	amino acid content[a] (mg/100 g)			organic acid content[a] (mg/100 g)	
sample	arginine + threonine	proline	histidine	malic acid	fumaric acid
MSX-1	10.06 ± 0.18	19.13 ± 0.32	2.52 ± 0.05	780.99 ± 0.39	15.92 ± 0.02
MSX-2	9.93 ± 0.09	19.29 ± 0.28	0.80 ± 0.05	341.85 ± 0.17	7.51 ± 0.02

[a]Assay conducted with neat samples of original MSX samples.

Table 8. Average Mineral Contents of MSX Samples

	mineral content[a] (mg/100 g)							
sample	K	Ca	Mg	Na	Mn	Al	Zn	Fe
MSX-1	128.35 ± 6.66	380.48 ± 33.10	124.51 ± 9.54	4.86 ± 1.23	58.45 ± 4.06	0.32 ± 0.04	90.98 ± 8.08	0.70 ± 0.07
MSX-2	70.50 ± 7.68	212.78 ± 17.41	48.79 ± 3.94	3.52 ± 1.52	53.19 ± 4.43	0.46 ± 0.11	23.81 ± 2.59	0.44 ± 0.08

[a]Assay conducted with neat samples of original MSX samples.

agreement with the ash data for the two MSX samples (see Table 9, further described below). Among the minerals that were quantitated, magnesium, potassium, calcium, and zinc were the most abundant, reaching levels of ca. 124, 128, 380, and 90 mg/100 g in the MSX-1 sample.

3.2.6. Vitamins. Similar to pure maple syrup,[1] the MSX samples contained two major vitamins, namely, riboflavin (B2) and niacin (B3), and their levels are shown in Table 6. Among the two vitamins, riboflavin was the most abundant, reaching levels of 410 and 290 mg/100 g in the MSX-1 and MSX-2 samples, respectively.

3.2.7. Ash and Fiber. The ash and fiber contents of the MSX samples (assays conducted by Covance) are shown in Tables 9 and 10, respectively. The ash content of the MSX-1 sample was greater than that of the MSX-2 sample (ca. 2.2% vs 1.1%), which correlated with the higher mineral content of the MSX-1 sample compared to the MSX-2 sample (Table 8, discussed above). Interestingly, both of the MSX samples contained ca. 11% total dietary fiber, which was present primarily as soluble fiber (Table 10).

Table 9. Ash Contents of MSX Samples

sample	ash content[a] (%)
MSX-1	2.21
MSX-2	1.10

[a]Assay conducted with neat samples of original MSX samples.

Table 10. Fiber Contents of MSX Samples

	total dietary fiber content[a] (%)			
sample	insoluble dietary fiber	sum of measured fibers	high molecular weight soluble dietary fiber	low molecular weight soluble dietary fiber
MSX-1	<0.75	10.9	5.59	5.31
MSX-2	<0.75	10.9	5.59	5.31

[a]Assay conducted with neat samples of original MSX samples.

3.3. Animal Toxicity Studies in Sprague–Dawley Rat. Animal safety studies were conducted to determine the toxicity of the MSX-1 and MSX-2 samples following once daily oral gavage administration for 7 consecutive days to Sprague–Dawley rat. Parameters monitored during the study included mortality, clinical observations, body masses, and food consumption. In addition, hematology, coagulation, clinical chemistry, and urinalysis parameters were evaluated on day 8. At termination (day 8), all animals were euthanized and subjected to a gross necropsy examination and organ mass measurements. Subsequently, a complete list of tissues were retained and examined microscopically. There were no deaths, no clinical signs, and no changes in body masses, food consumption hematology, coagulation, clinical chemistry, urinalysis, or organ masses that could be attributed to the administration of either the MSX-1 or MSX-2 sample at doses of up to 1000 mg/kg/day. Similarly, there were no microscopic or macroscopic findings which could be attributed to the test samples. Thus, the daily oral administration of the MSX samples for 7 consecutive days to the Sprague–Dawley rat was well tolerated and did not result in any signs of overt toxicity.

3.4. In Vitro Biological Studies of MSX Samples. *3.4.1. MSX Samples Show DPPH Free Radical Scavenging Activity.* In the nutraceutical and functional food industry, many extracts which contain phenolic compounds are well-known to exhibit antioxidant activities. Moreover, published studies have shown that phenolic-enriched extracts of maple sap and maple syrup, as well as their purified phenolic constituents, show antioxidant effects.[4,5,13] Therefore, the MSX-1 and MSX-2 samples were evaluated for their antioxidant effects in the DDPH free radical scavenging assay, and they showed IC_{50} values of ca. 97 and 102 μg/mL, respectively (see Table 4), which were comparable to that of a phenolic-enriched ethyl acetate extract of pure maple syrup (further discussed below; IC_{50} = 75.5 μg/mL).[5] While these samples are all extracts and cannot be compared, on the basis of molar equivalents, to well-known antioxidants commonly used as positive controls, such as ascorbic acid (vitamin C) and butylated hydroxytoluene (BHT; a commercial synthetic antioxidant), we did evaluate the latter compounds in the DPPH assay, and they showed IC_{50} values of ca. 40 and 3000 μM, respectively.[5]

3.4.2. MSX Samples Lowered Nitrite and PGE_2 Concentrations in RAW 246.7 Cell Culture Media. Phenolic-enriched extracts of maple sap and maple syrup, derived by partitioning with ethyl acetate (EtOAc), have been reported to lower nitrite levels [measured as nitric oxide (NO) levels] in cell culture media in LPS-stimulated RAW 264.7 macrophages,[13] a bioassay which is widely used to evaluate the anti-inflammatory effects of natural products. Using the same RAW 264.7 macrophage model, our group has recently investigated the anti-inflammatory effects of an EtOAc extract of pure maple syrup (MS–EtOAc) which showed inhibition of both NO and PGE_2.[14] In that study, we also evaluated the anti-inflammatory effects of several

individual phenolic constituents present in the MS−EtOAc, and among these pure compounds, a stilbenoid, namely, 3,3′-dimethoxy-4,4′-dihydroxystilbene (compound **33**),[4] was the most active compound in the anti-inflammatory assay. However, overall, we observed that the anti-inflammatory effect of the total extract was greater than any of its single purified constituent alone. Notably, the MS−EtOAc extract that we studied in that previous project[14] is not suitable for human consumption (i.e., was not produced under food-grade conditions), unlike the MSX samples which are being studied here. Therefore, in the current study we additionally sought to evaluate the anti-inflammatory effects of phenolic-enriched MSX−EtOAc extracts (see Figure 4). As previously discussed, since we had found that a stilbene

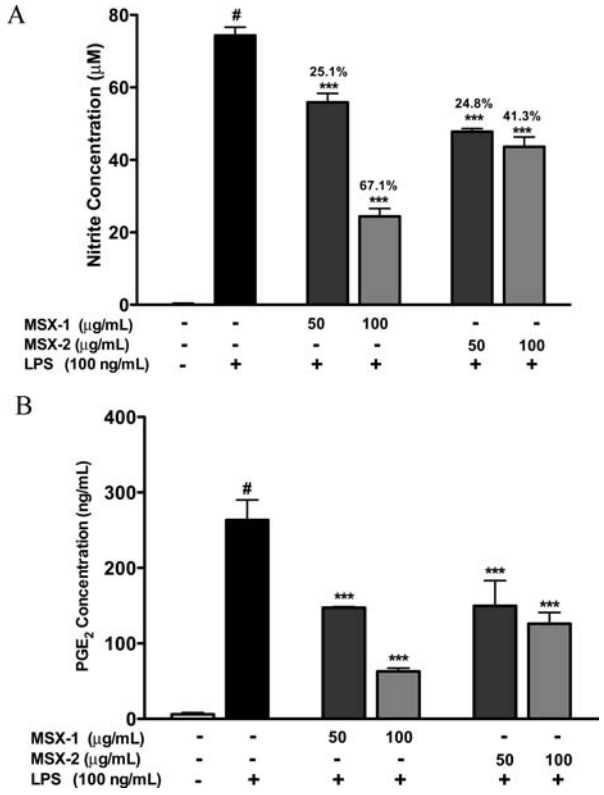

Figure 4. Effects of MSX ethyl acetate extracts on (A) nitrite and (B) PGE_2 production in LPS-stimulated RAW 264.7 cells. Cells were cotreated with LPS (100 ng/mL) and samples (50 and 100 μg/mL) for 24 h. MSX extracts inhibited NO and PGE_2 levels in LPS-stimulated macrophages in a concentration-dependent manner. The values are expressed as the means ± SD of three individual samples. Three asterisks indicate $P < 0.001$ as compared with the LPS-treated macrophages; significant differences between groups were determined using a one-way ANOVA test followed by Dunnett's multiple comparison test. A pound sign indicates $P < 0.001$ for the solvent control compared with the LPS-treated cells; the significant difference was determined using unpaired Student's t test.

(compound **33**) was the most active among the various subclasses of phenolic compounds in the anti-inflammatory assay,[14] and since we isolated two additional stilbene derivatives from the MSX samples reported herein, namely, 4,4′-dihydroxy-3,3′,5,5′-tetramethoxystilbene (**S3**) and 4,4′-dihydroxy-3,3′,5′-trimethoxystilbene (**S4**), we evaluated the two latter compounds for their ability to inhibit the NO level in the RAW 264.7 macrophages. Interestingly, while compound **S3** (at 25 and 50 μM concentrations) did not show any significant decrease in NO levels in the LPS-stimulated macrophages (approximately 2% inhibition), compound **S4** (at 25 and 50 μM concentrations) inhibited the NO levels by 38.8% ± 2.5% and 78.3% ± 2.8%, respectively. Similar to our previous report,[14] we confirmed that compound **33** significantly reduced the NO concentration in the LPS-treated macrophage media by almost 100% ± 1.3%. While it is difficult to make conclusive structure−activity-related (SAR) observations on the basis of data accumulated from only these three stilbenoids, it would appear that substitution of a methoxyl (OCH_3) group at position 5′ (i.e., the R^2 position as in compound **S3**) leads to a significant reduction in bioactivity in this assay.

Similar to our recent published data with MS−EtOAc, both of the MSX−EtOAc extracts significantly inhibited nitrite levels in cell media (Figure 4A). The MSX-1 ethyl acetate extract significantly reduced nitrite production by 25.1% (at 50 μg/mL) and 67.1% (at 100 μg/mL). Also, treatment with 50 and 100 μg/mL concentations of the MSX-2 ethyl acetate extract inhibited nitrite levels by 24.8% and 41.3%, respectively. Thus, the current results show that the MSX−EtOAc extracts lowered nitrite production in a concentration-dependent manner in LPS-stimulated RAW 264.7 cells similar to our previous report for MS−EtOAc.[14]

As a follow-up to the nitrite assay, we also evaluated the levels of PGE2 in cell media. As shown in Figure 4B, PGE_2 levels were elevated following LPS treatment (263.3 ± 26.5 ng/mL), whereas in the absence of LPS, the PGE_2 levels were close to baseline. The levels of PGE_2 were markedly reduced to 147.4 and 62.9 ng/mL by 50 and 100 μg/mL MSX-1 ethyl acetate extract treatment, respectively. Similarly, treatment with 50 and 100 μg/mL MSX-2 ethyl acetate extract lowered PGE_2 levels in LPS-stimulated macrophages to 149.7 and 126.1 ng/mL, respectively. Therefore, taken together, these results suggest that the MSX−EtOAc extracts were capable of reducing NO and PGE_2 in LPS-induced macrophages.

3.4.3. MSX Samples Decreased Glucose Levels in HepG2 Cell Media. Recent published data in a diabetic animal model have shown that pure maple syrup has the ability to reduce plasma glucose levels compared to sucrose solution alone.[11] It has been reported that plant extracts, such as rosemary extract, can regulate glucose and lipid metabolism in HepG2 liver hepatocytes.[27] Therefore, using this cell-culture model, we examined the potential of the MSX samples to regulate glucose consumption, along with the clinical drug metformin, a well-known AMP-dependent protein kinase (AMPK) activator. As shown in Figure 5, the MSX-1 and MSX-2 samples significantly

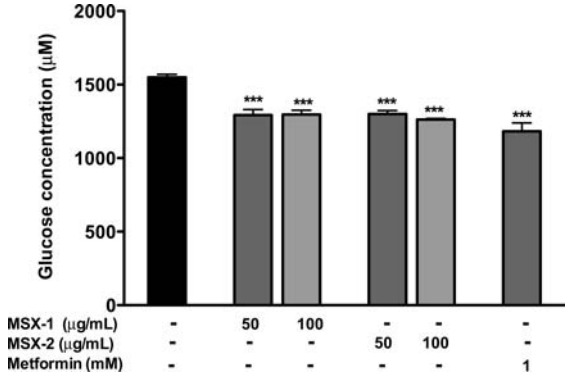

Figure 5. Effects of MSX samples on glucose consumption by HepG2 cells.

decreased glucose levels in the cell supernatants. The glucose levels in the media with 50 and 100 μg/mL MSX-1 treatment were lowered by almost 16% compared to that of the control group. Similarly, the MSX-2 treatment, at 50 and 100 μg/mL concentrations, reduced media glucose levels by about 16% and 18% respectively. Metformin, at 1 mM concentration, also dramatically decreased glucose levels by 23% as compared to that of the control in the HepG2 cell culture media. Therefore, our preliminary in vitro studies reported here lend support to the recent published in vivo study with maple syrup.[11]

In summary, in this project we have conducted chemical compositional, in vitro biological, and in vivo animal safety studies of a novel maple syrup derived extract for potential functional food and nutraceutical applications. To the best of our knowledge, this is the first reported study of a food-grade maple syrup extract.

Funding

This project was supported by Agriculture and Agri-Food Canada (AAFC) through the AgriInnovation program under the Growing Forward policy framework. The animal toxicity study was conducted by ITR Canada and was funded by the Federation of Maple Syrup Producers of Quebec (FPAQ) and AAFC. The large-scale production of the MSX samples was conducted by Silicycle Inc. and was funded by FPAQ. The NMR data were acquired at a research facility at the University of Rhode Island supported in part by National Science Foundation EPSCoR Cooperative Agreement No. EPS-1004057. The ICP mass spectral data were acquired on an instrument located at the University of Rhode Island in the RI-INBRE core facility obtained with Grant No. P20RR016457 from the National Center for Research Resources (NCRR), a component of the National Institutes of Health (NIH).

Barnyardgrass has also developed resistance to conventional synthetic herbicides.[22]

Brachiaria is also especially invasive in South America.[25] It is native to Africa, where it occurs in the savannas and is important in the diet of large herbivores from that continent. These plants were introduced to Brazil to serve as pasture but they have spread throughout the country.[26] They are very competitive to native plants, more tolerant to fire and they can markedly modify the environment in which they dominate.[27]

Our hypothesis is that allelochemicals from cardoon have phytotoxic potential and could inhibit the development of other invasive weeds such as barnyardgrass and brachiaria. The aim of the study described here was to bioprospect cardoon leaf extracts through the isolation and purification of secondary metabolites with phytotoxic activity. It was envisaged that the results could explain the invasive behavior and the compounds identified could be used as natural herbicide models in the future. As part of this study, we selected the most phytotoxic extract from the leaves of cardoon, as identified by etiolated wheat coleoptile and phytotoxicity bioassays. A bioassay-guided fractionation of this extract was carried out in order to isolate and identify the chemical constituents. Their bioactivity profiles were assayed on the standard target species lettuce, watercress, tomato, and onion, as well as the weeds barnyardgrass and brachiaria.

MATERIALS AND METHODS

General Experimental Procedures. Infrared (IR) spectra (KBr) were recorded on a Fourier transform infrared (FT-IR) Spectrum 1000 spectrometer (PerkinElmer, Waltham, MA, U.S.A.). Nuclear magnetic resonance (NMR) spectra were run on 500 and 400 MHz spectrometers (Agilent, Palo Alto, CA, U.S.A.). Chemical shifts are given in ppm with respect to residual ^{1}H signals of $CHCl_3$-d_1 (δ 7.25), and ^{13}C signals are referenced to the solvent signal (δ 77.00). Optical rotations were determined at room temperature on a polarimeter model 241 (PerkinElmer, Waltham, MA, U.S.A.) (on the sodium D line). HRMS were obtained on a Synapt G2 UPLC-QTOF ESI mass spectrometer (Waters, Milford, MA, U.S.A.). HPLC was carried out on a HPLC cromatographer (Merck-Hitachi, Tokio, Japan), with RI detection. Silica gel 0.060−0.200, 60A from Acros Organics (Geel, Belgium) and Lichroprep RP 18 (40−63 μm) from Merck (Darmstadt, Germany) were used for column chromatography. Thin layer chromatography were run on TLC Silica gel 60 F_{254} aluminum sheet and TLC Silica gel 60 RP-18 F_{254S} aluminum sheet from Merck (Darmstadt, Germany). HPLC columns used were a semipreparative column 250 mm × 10 mm i.d., 10 μm Lichrospher 100 RP-18 (Merck, Darmstadt, Germany) with a guard column LiChrospher RP-18 (Merck, Darmstadt, Germany) and an analytical column 250 mm × 4.5 mm i.d., 5 μm Gemini 110A RP-18 (Phenomenex, Torrance, CA, U.S.A.) with a guard column SecurityGuard Cartridges Gemini RP-18 (Phenomenex, Torrance, CA, U.S.A.).

Ultrasound extractions were performed in an ultrasonic bath (360 W, J.P. Selecta, Barcelona, Spain) in two series of 15 min.

Chemicals. Chloroform, *n*-hexane, methanol, dichloromethane, ethyl acetate. and acetone Hipersolv Chromanorm for HPLC were obtained from VWR Internacional (Radnor, PA, U.S.A.). MagniSolv Chloroform-D1 deuteration degree min. 99.8% for NMR spectroscopy from Merck (Darmstadt, Germany).

Isolation of Compounds. Aerial plant material was collected in Jerez de la Frontera (Cadiz, Spain) in the fifth growth stage (ripe fruits).[28] Leaves were dried in an oven for 72 h at 40 °C and powdered in an industrial mill. Dried material (472 g) with 4 L of *n*-hexane at room temperature (in portions of about 120 g of plant, 2 × 500 mL) using an ultrasonic bath in order to defat the material. The plant residue was re-extracted in two different steps.

In step one, dichloromethane, ethyl acetate, acetone, methanol, and water were used to extract defatted material (5 g each, 2 × 50 mL of solvent) using an ultrasonic bath and these extractions yielded, after removal of the solvent, 180 mg (dichloromethane), 305 mg (ethyl acetate), 449 mg (acetone), 490 mg (methanol), and 1643 mg (water). These extracts were bioassayed with etiolated wheat coleoptiles. The ethyl acetate extract was the most active.

In step two, the rest of the defatted material (418 g) was extracted with 6 L of ethyl acetate in portions of 70 g of plant with 2 × 500 mL each using an ultrasonic bath to yield 12.19 g of material. This extract was chromatographed in a column (250 mm × 60 mm i.d., 300 g of silica gel 60A) using hexane/acetone mixtures of increasing polarity from 0 to 100% in acetone increasing 10% each time and finishing with 100% methanol (500 mL of each polarity) to afford 11 fractions: A−L. These fractions were bioassayed with etiolated wheat coleoptiles and the most bioactive fractions were assayed for phytotoxicity on standard target species.

Fractions D, E, F, and G showed bioactivity in the wheat coleoptile bioassay and these were rechromatographed. Fraction D (hexane/acetone, 70:30 v/v, 512 mg) was subjected to chromatographic column (250 mm × 40 mm i.d., 175 gr of silica gel 60A) using hexane/acetone mixtures of increasing polarity from 20 to 100% in acetone, increasing 10% each time and finishing with 100% methanol (250 mL of each polarity) to afford 8 fractions (D1−D8). Fraction D4 (144 mg, 5 mg/injection) was purified by HPLC (RP-18 semipreparative column) using water/acetone (40:60 v/v, flow 3 mL/min) to yield **1** (23 mg, retention time 11 min). Fraction D5 (155 mg) was subjected to chromatographic column (200 mm × 30 mm i.d., 60 gr of silica gel 60A) using dichloromethane/acetone mixtures of increasing polarity from 30 to 100% in acetone increasing 10% each time and finishing with 100% methanol (150 mL of each polarity) to afford 4 fractions (D5.1−D5.4). Fraction D5.1 (55 mg, 5 mg/injection) was purified by HPLC (RP-18 semipreparative column) using water/acetone (45:55 v/v, flow 3 mL/min) to yield **2** (7.1 mg, retention time 6 min) and a second peak (retention time 7 min). This peak was further purified by HPLC using water/acetone (70:30 v/v, flow 1 mL/min, 0.5 mg/injection, RP-18 analytical column) to yield **3** (0.7 mg, retention time 19 min).Fraction E (hexane/acetone, 50:50 v/v, 301 mg) was subjected to chromatographic column (200 mm × 40 mm i.d., 140 g silica gel 60A) using dichloromethane/acetone mixtures of increasing polarity from 20 to 100% in acetone increasing 10% each time and finishing with 100% methanol (200 mL of each polarity) to afford 3 fractions (E1, E2, and E3). Fraction E1+E2 (146 mg) was subjected to a chromatographic column (60 × 95 mm i.d., 200 g of silica gel RP-18) using water/methanol mixtures from 10 to 100% in methanol increasing 10% each time (150 mL of each polarity) to afford four fractions (E1.1−E1.4). Fraction E1.1 (84 mg, 5 mg/injection) was purified by HPLC (RP-18 semipreparative column) using water/acetone (45:55 v/v, flow 3 mL/min) to yield **2** (10 mg, retention time 6 min) and a second peak (retention time 7.9 min). This peak was further purified by HPLC using water/acetone (75:25 v/v, flow 1 mL/min, 0,5 mg/injection, RP-18 analytical column) to yield **4** (1.5 mg, retention time 18.7 min). Fraction F was mainly composed of **5** (241 mg). Fraction G (hexane/acetone, 40:60 v/v, 352 mg) was subjected to chromatographic column (200 × 40 i.d., 140 g silica gel 60A) using dichloromethane/acetone mixtures of increasing polarity from 40 to 100% in acetone increasing 10% and finishing with 100% methanol (200 mL of each polarity) to afford 3 fractions (G1−G3). Fraction G2 (145 mg, 5 mg/injection) was purified by HPLC (RP-18 semi-preparative column) using water/acetone (40:60 v/v, flow 3 mL/min) to yield **6** (36 mg, retention time 9 min).

Coleoptile Bioassay. Wheat seeds (*Triticum aestivum* L. cv. Duro) were sown in 15 cm diameter Petri dishes moistened with water and grown in the dark at 25 ± 1 °C for 4 days.[29] The roots and caryopses were removed from the shoots. The latter were placed in a Van der Weij guillotine and the apical 2 mm were cut off and discarded. The next 4 mm of the coleoptiles were removed and used for bioassays. All manipulations were performed under a green safelight.[30] Crude extracts, fractions or pure compounds were predissolved in dimethyl sulfoxide (0.1%) and diluted in phosphate-citrate buffer containing 2% sucrose[30] at pH 5.6 to the final bioassay concentrations (0.8, 0.4, and

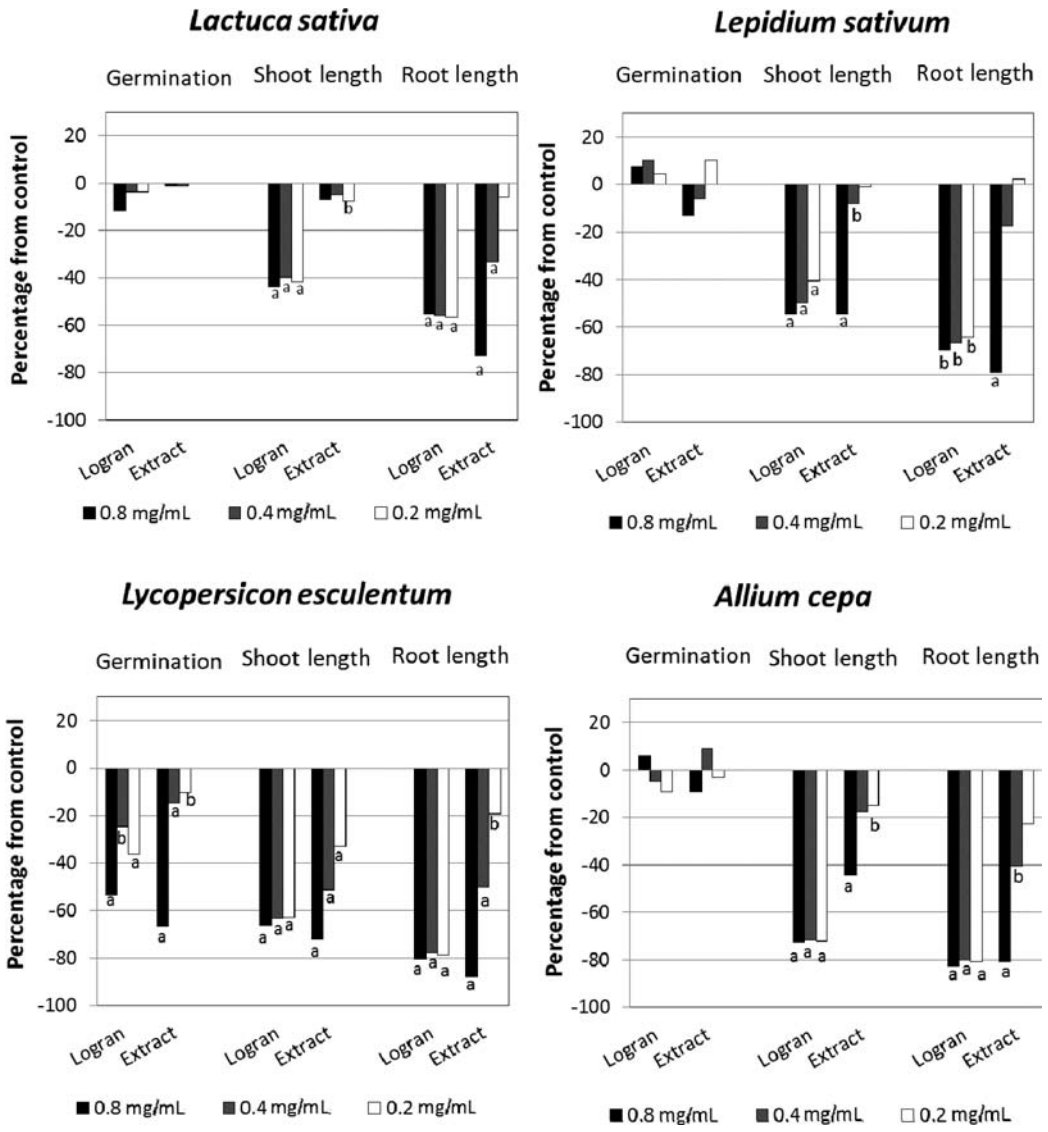

Figure 1. Effects of the herbicide Logran and ethyl acetate (EtOAc) leaf extract of cardoon (*Cynara cardunculus*) on standard target species growth. Values are expressed as percentage difference from control.

0.2 mg/mL for extracts and fractions, and 10^{-3}, 3×10^{-4}, 10^{-4}, 3×10^{-5}, and 10^{-5} M for compounds).

Parallel controls were also run. The commercial herbicide Logran, whose original formulation is a combination of N^2-*tert*-butyl-N^4-ethyl-6-(methylsulfanyl)-1,3,5-triazine-2,4-diamine (terbutryn, 59.4%) and 2-(2-chloroethoxy)-*N*-[(4-methoxy-6-methyl-1,3,5-triazin-2-yl)-carbamoyl]benzene-1-sulfonamide (triasulfuron, 0.6%), was used as positive control according to a comparison study reported previously.[31] This reference was used at the same concentrations and under the same conditions as reported previously. Control samples (buffered aqueous solutions with dimethyl sulfoxide and without any test compound) were used for all of the plant species assayed.

Each assay was carried out in duplicate. Five coleoptiles and 2 mL of solution were placed in each test tube (three tubes per dilution) and the tubes were rotated at 0.25 rpm in a roller tube apparatus for 24 h at 25 °C in the dark. The coleoptiles were measured by digitalization of their images. Data were statistically analyzed using Welch's test.[32] Data are presented as percentage differences from control. Thus, zero represents the control, positive values represent stimulation of the studied parameter, and negative values represent inhibition.

Phytotoxicity Bioassays. The selection of target plants was based on an optimization process carried out in our search for a standard phytotoxicity bioassay.[31] Several Standard Target Species were proposed, including the monocotyledon onion (*Allium cepa* L.) and the dicotyledons tomato (*Lycopersicon esculentum* Will.), cress (*Lepidium sativum* L.), and lettuce (*Lactuca sativa* L.), which were assayed for this study. In addition, two weed species were added as target plants in this bioassay: the monocotyledon barnyardgrass (*E. crus-galli* L.) and the dicotyledon brachiaria (*Urochloa decumbens* (Stapf) R.D. Webster).

Bioassays were conducted using Petri dishes (50 mm diameter) with one sheet of Whatman No. 1 filter paper as a support. Germination and growth were conducted in aqueous solutions at controlled pH by using 10^{-2} M 2-[*N*-morpholino]ethanesulfonic acid (MES) and 1 M NaOH (pH 6.0). The extracts, fractions or compounds to be assayed were dissolved in dimethyl sulfoxide and these solutions were diluted with buffer (5 μL dimethyl sulfoxide solution/mL buffer) so that test concentrations for each extract or fraction (0.8, 0.4, and 0.2 mg/mL) and compound (10^{-3}, 3×10^{-4}, 10^{-4}, 3×10^{-5}, and 10^{-5} M) were achieved. Parallel controls were also run as described before for coleoptile bioassays.

Four replicates were used for tomato, cress, onion, and lettuce, each containing 20 seeds. Treatment, control or internal reference solution (1 mL) was added to each Petri dish. After adding the seeds and aqueous solutions, Petri dishes were sealed with Parafilm to ensure

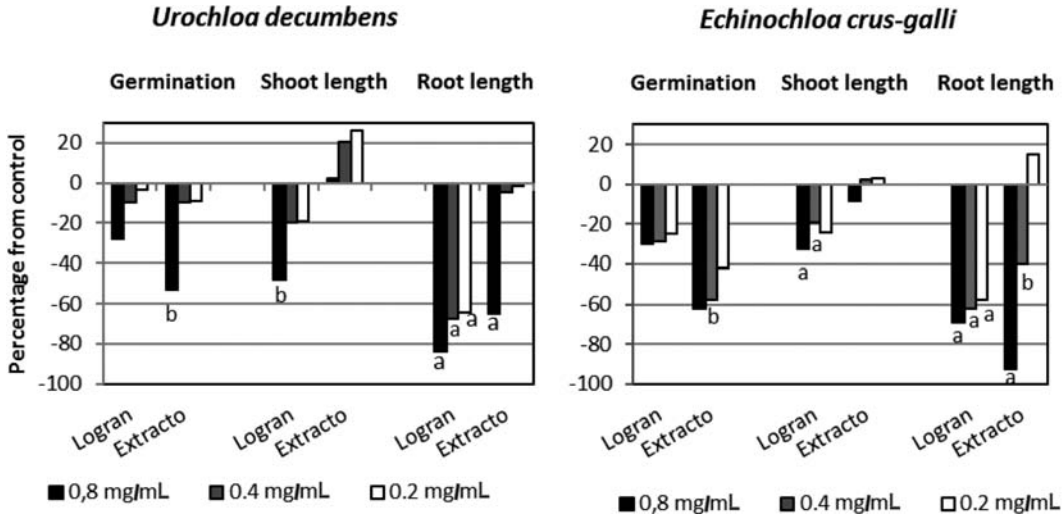

Figure 2. Effects of the herbicide Logran and ethyl acetate (EtOAc) leaf extract of cardoon (*Cynara cardunculus*) on weed growth. Values are expressed as percentage difference from control.

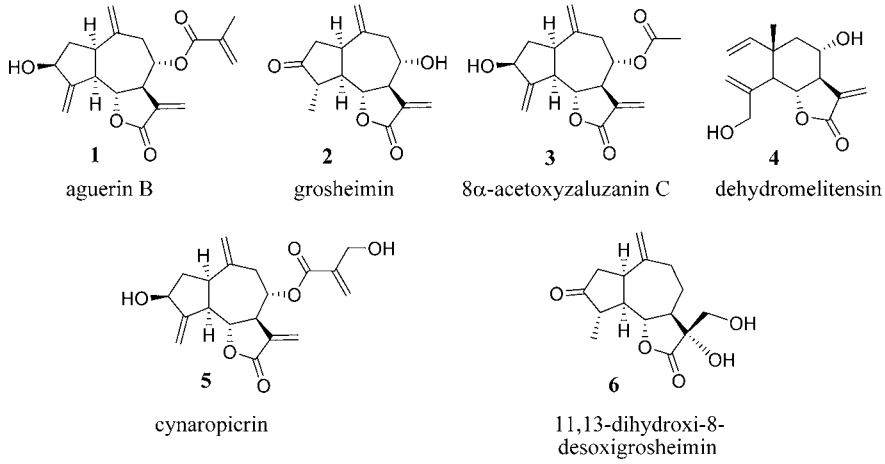

Figure 3. Compounds isolated from cardoon (*Cynara cardunculus*). Aguerin B, **1**, grosheimin, **2**, 8α-acetoxyzaluzanin C, **3**, and dehydromelitensin, **4**, cynaropicrin, **5**, and 11,13-dihydroxy-8-desoxygrosheimin, **6**.

closed-system models. Seeds were further incubated at 25 °C in a Memmert ICE 700 controlled environment growth chamber. The photoperiod was 24 h of dark for onion, tomato, cress, and lettuce, and 16/8 h light/dark for barnyardgrass and brachiaria. Bioassays took 4 days for cress, 5 days for tomato, 6 days for lettuce, 7 days for onion, and 8 days for barnyardgrass and brachiaria. After growth, plants were frozen at −10 °C for 24 h to avoid subsequent growth during the measurement process.

Evaluated parameters (germination rate, root length, and shoot length) were recorded using a Fitomed system,[33] which allowed automatic data acquisition and statistical analysis using its associated software. Data were analyzed statistically using Welch's test, with significance fixed at 0.01 and 0.05. Results are presented as percentage differences from the control. Zero represents control, positive values represent stimulation, and negative values represent inhibition.

RESULTS AND DISCUSSION

Dried leaves of cardoon (55 g) defatted with hexane were extracted with dichloromethane (dichloromethane, 0.33% yield), ethyl acetate (ethyl acetate, 0.55% yield), acetone (acetone, 0.82% yield), and methanol (methanol, 0.89% yield), and then with distilled water (water, 2.98% yield). The extracts were tested in the etiolated wheat coleoptile bioassay.[31] This is a rapid test that is sensitive to a wide range of bioactive substances[34] including plant growth regulators, herbicides, antimicrobials, mycotoxins, and assorted pharmaceuticals.

The extracts that showed the highest inhibition levels in the coleoptile bioassay were those extracted with dichloromethane, ethyl acetate, and acetone, which showed the highest inhibition values (around 90%) at 0.8 mg/mL. The methanol and water extracts showed lower inhibitory activity (77% and 58% at 0.8 mg/mL, respectively). The dichloromethane and ethyl acetate extracts retained high activity levels at lower concentrations. Thus, the inhibition of these extracts at 0.4 and 0.2 mg/mL were dichloromethane 90 and 75%, respectively, and ethyl acetate 87 and 69%, respectively.

Although dichloromethane and ethyl acetate extracts showed almost the same activity values, the ethyl acetate extract was selected for further study because the yield was higher. As a result, the ethyl acetate extract was evaluated in the phytotoxicity assay (Figures 1 and 2). The concentrations tested in this bioassay were identical to those described previously. The standard target species were lettuce, tomato, cress, and onion[31] (Figure 1) and the weed species were barnyardgrass and brachiaria (Figure 2).

The parameter that was most markedly affected by the extract was root length (Figures 1 and 2). The inhibition shown

by the extract was higher than or equal to that of Logran at 0.8 mg/mL on both standard target species and weeds roots, with values close to 80% inhibition in most species. The extract was also active on the germination of tomato, brachiaria, and barnyardgrass, and on the shoot length of cress, tomato, onion, and barnyardgrass.

These results clearly show that the extract obtained from cardoon has phytotoxic activity not only on standard target species plants but also on important weed species. Therefore, it was decided to isolate and identify the constituent compounds and study their bioactivity in an effort to understand the invasive behavior of the plant and to discover new tools for weed control.

The ethyl acetate extract was chromatographed on silica gel using hexane/acetone mixtures of increasing polarity to afford fractions A to L. These fractions were used in etiolated wheat coleoptile bioassays to biodirect the purification of the allelochemicals. The most active fractions were those with intermediate polarities, that is, fractions D, E, F, and G. In particular, fractions D, F and G presented inhibition values close to 100% at 0.8 mg/mL.

The chromatographic separation of fractions D, E, F, and G allowed us to isolate six sesquiterpene lactones. The isolated compounds were identified by their spectroscopic data (^{1}H NMR, ^{13}C NMR, HMQC, COSY, HMBC, IR, and MS) in comparison to those reported in the literature for aguerin B,[35] **1**, grosheimin,[36] **2**, 8α-acetoxyzaluzanin C,[35] **3** dehydromelitensin,[37] **4**, cynaropicrin,[35] **5** and 11,13-dihydroxy-8-deoxygrosheimin,[38] **6**. (Figure 3). Sesquiterpenic lactones are characteristic of Asteraceae.[39] Metabolites **2** and **5** have been reported recently from cardoon extracts[40] whereas compounds **1**, **3**, **4** and **6** are reported for the first time from this species.

The bioactivities of compounds **1**, **2**, **5**, and **6** were assessed in a wheat coleoptile bioassay from 10^{-3} M to 10^{-5} M. Compounds **3** and **4** were not tested because insufficient sample was available (less than 1 mg). Compounds **1**, **2**, and **5** showed high inhibitory activity on the coleoptile elongation, with almost 90% activity at 10^{-3} M (Figure 4). Compounds **1**, **2**, and **5** were also active at the second concentration (3.10^{-4} M) (70, 75 and 55% inhibition, respectively) and their activity decreased from a concentration of 10^{-4} M and below.

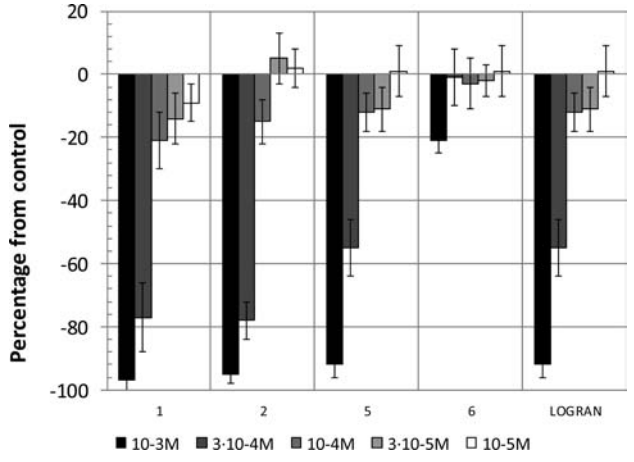

Figure 4. Effects of compounds aguerin B, **1**, grosheimin, **2**, cynaropicrin, **5**, and 11,13-dihydroxy-8-desoxygrosheimin, **6**, from cardoon (*Cynara cardunculus*) on the elongation of etiolated wheat coleoptiles.

Since compounds **1**, **2**, and **5** were very active in the coleoptile bioassay, their phytotoxicity was also tested on standard target species (Figure 5) development. Germination was the least affected parameter, although the compounds were much more active at 10^{-3} M on cress and tomato than the reference herbicide. Indeed, inhibition reached levels of almost 90% on tomato germination.

Shoot length was only affected by compounds at the highest concentration and, in most cases, the inhibition levels were higher than those of the reference herbicide, with values close to 70% in the cases of **5** on lettuce and **1** and **5** on cress and tomato (Figure 5).

Root length was the variable that was most affected by the allelochemicals, mainly at the first concentration (10^{-3} M) but also at the second one (3.10^{-4} M). As for other parameters, the compounds were more phytotoxic than the reference herbicide in most cases. Compounds **1**, **2**, and **5** were very active (from 70 to 90% inhibition) on root length of cress and tomato. Compounds **2** and **5** also showed activity on onion root length.

In view of the results described above, compounds **1**, **2**, and **5** were also tested on the weeds barnyardgrass and brachiaria with a photoperiod of 16/8 h light/dark (Figure 6). Germination was once again the parameter that was least affected and the compounds were more active at 10^{-3} M on brachiaria than the reference herbicide, with inhibition of 90% on brachiaria. Shoot length was not affected by any of the compounds with the exception of **2** on brachiaria at the highest concentration, which gave a value close to 80% inhibition.

As for the standard target species species, root length was the parameter that was most markedly affected by the allelochemicals, mainly at the first concentration (10^{-3} M). All compounds were more active than the reference herbicide (from 70 to 90%) on the root length of the two weeds barnyardgrass and brachiaria.

The extracts, fractions and compounds showed similar activity profiles in the wheat coleoptile and seedling bioassays (Figure 1, 2, 4, 5, and 6) and this indicates that the bioactivity of the extracts and fractions can be explained by the presence of the compounds identified.

The analysis of compounds **1**, **2**, **5**, and **6** enabled some observations to be made concerning the relationship between their structure and activity, considering the structures of the molecules and the differences between them. The absence of activity in **6** could be explained by the absence of an α-methylene group, which is present in the other compounds. Changes in the lateral chain or oxidation pattern at C-3 in **1**, **2**, and **5** seems to have little influence on the activity.

As observed in the phytotoxicity bioassay on the extracts (Figures 1 and 2), compounds **1**, **2**, and **5** were active not only on standard target species but also on the very important weeds (Figures 5 and 6). Other guaianolide sesquiterpene lactones have been reported to be cytotoxic,[41] fungicidal,[42] antiviral, and antimicrobial.[43] Allelopathic activity has also been described.[44−46] The amounts in which these compounds are biosynthesized and their wide spectrum of biological activity, including phytotoxicity, suggest that they may be involved in the defense mechanism of this species. This variety of biological activities supports the "economy of resources" principle, which states that a defense metabolite is cheaper in terms of resource investment if it can serve more than one purpose. Allelopathy, a general defense mechanism present in plants, can involve these metabolites.[47]

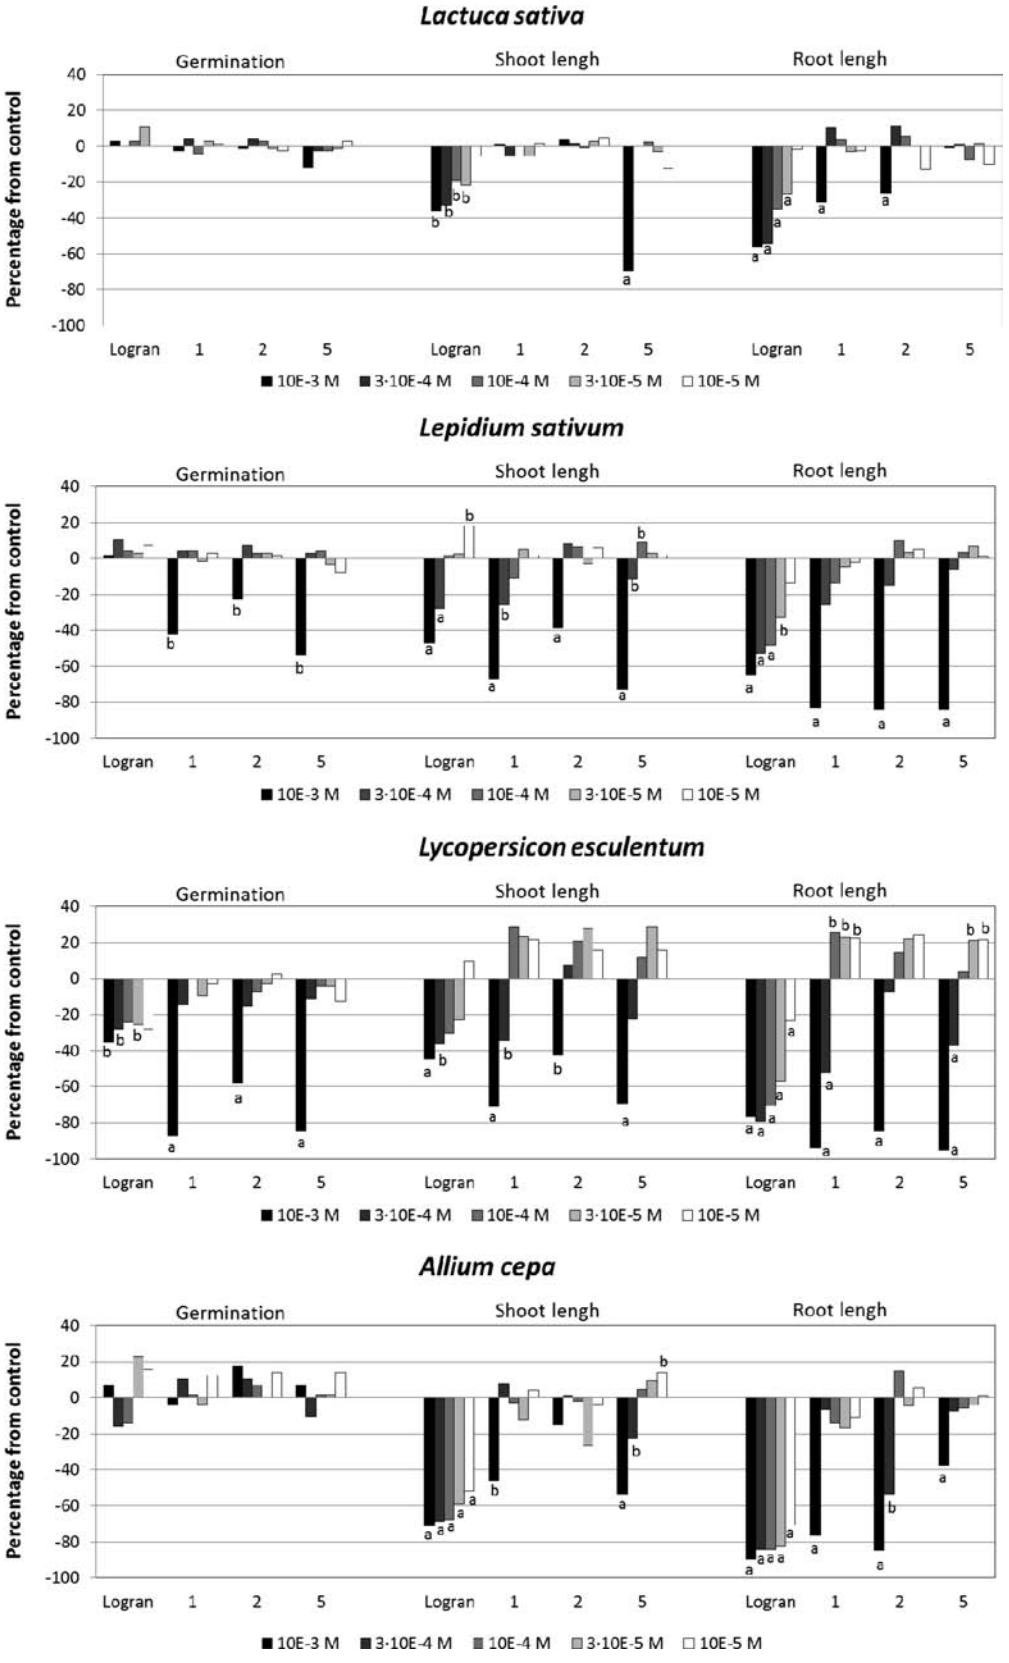

Figure 5. Effects of compounds aguerin B, **1**, grosheimin, **2**, and cynaropicrin, **5**, from cardoon (*Cynara cardunculus*) on standard target species growth. Values are expressed as percentage difference from control.

The strong phytotoxicity shown by the extracts and the pure major compounds aguerin B, **1**, grosheimin, **2**, and cynaropicrin, **5**, on the important weeds brachiaria and barnyardgrass demonstrates the strong potential of *C. cardunculus* for use in the biological control of weeds. This species could be used as a plant applied as a cover crop, as

reductant	sodium bisulfite	SB	allow protein rearrangement	38, 39

MATERIALS AND METHODS

Materials. Oilseed meals of crambe (11.1 ± 0.02% db water) and carinata (10.1 ± 0.06% db water) were produced by the petroleum distillate method of Appelqvist[31] performed at room temperature to avoid protein thermal denaturation. Carinata seeds were graciously provided by Agriculture Canada (Saskatoon, Canada) and crambe seeds (with pod) supplied by the Plant Research Institute (Wageningen, The Netherlands). Monosodium phosphate (NaH_2PO_4), as monohydrate, was provided by Baker (Deventer, The Netherlands), and glycerol (99.5%) was graciously supplied by Karlshamns Tefac AB (Karlshamn, Sweden). Trifluoroacetic acid (TFA) and acetonitrile (ACN) (Merck) were of spectroscopy grade and isocratic chromatography grade, respectively. All water was purified on a Milli-Q system (Millipore Corp., Bedford, MA, USA).

Additives Used. Ten different chemical additives across five different types were selected on the basis of previous literature. The selected chemical additives, the reason for their selection, and reference(s) related to their previous use in protein based plastics are summarized in Table 1. Addition levels were selected from the references.

Methods. *Protein Content.* Nitrogen content of the deoiled meal was performed in duplicate with the Dumas method (Flash 2000 NC Analyzer, Thermo Scientific, USA), nitrogen to protein conversion factor N × 6.25, and protein content together with an example of other constituents are given in Table 2.

Table 2. Selected Industrial Oil Meal Components (Percent, Dry Basis)

component	carinata	crambe
protein[a]	43.7 ± 1.9	20.5 ± 1.2
ash	5.7[47]	7.4[62]
glucosinolates	5.6[47]	4.5−7[62]
phytic acid	3.4[47]	NR[b]
fiber	34.9[47]	22.1[62]
soluble sugars	6.2[47]	8.3[48]
polyphenols	0.3[47]	NR

[a]Current study. [b]NR, not reported.

Mixing Procedure. All samples contained the same amount of water, 5.25 parts per 70 parts oilseed meal, to match the water contained in the highest level of ammonium hydroxide (25% solution). Where the additive was hydrated, this was accounted for in the water addition. Additives, water (if necessary), and glycerol (30 parts per 70 parts oilseed meal by weight) were premixed before addition to the oilseed meals. In cases when the additives were not soluble under these conditions (NaOH 4.5 parts, SDS 4.5 parts, SA, BP), they were added as a dry powder to the meal before mixing. All additive doses are listed as parts additive per hundred parts combined oilseed meal and glycerol (70 parts and 30 parts, respectively).

Hot Compression Molding. The oilseed meal was mixed with the additive/glycerol/water blend by hand using a mortar and pestle until evenly mixed (3−5 min). The mixture was then formed in a heated hydraulic press (Polystat 400s, Servitech, Germany) between aluminum plates with polyethylene terephthalate release film using a 0.5 mm thick aluminum frame with a 100 mm × 100 mm central opening to control the size and thickness of the film. A molding temperature of 130 °C, a pressure of 10 MPa on the sample area, and a pressing time of 10 min were used on all samples on the basis of previous work.[6] After removal from the press, the sheets were cooled in the frame between room temperature aluminum sheets. The cooled oilseed meal sheets were removed from the frame using a scalpel.

This process produced a wide range of macroscopic morphologies, from well-formed free-standing films to sticky incoherent films that were impossible to remove from the release films whole. All samples were processed via HPLC and water immersion; only well-formed films proceeded to tensile testing.

SE-HPLC. The amount and size distribution of soluble protein in the films were determined by a three-step extraction procedure.[40] Samples of each film were hand cut to a maximum particle size of approximately 0.2 mm, and triplicate samples of 16.5 (±0.05) mg each were weighed into 1.5 mL centrifuge tubes. Protein extractions were carried out in 1.4 mL of extraction buffer, 0.5% (w/v) SDS, 0.05 M NaH_2PO_4, pH 6.9. Three extractions were carried out serially on each sample. The extractions were as follows; extraction 1, vortexing for 10 s followed by shaking 5 min at 2000 rpm; extraction 2, 30 s of ultrasonication at an amplitude of 5 μm (Sanyo Soniprep, Tamro, Sweden); extraction 3, 30 + 60 s of ultrasonication at 5 μm. After each extraction, the supernatant was recovered for further analysis, and the residuals were resuspended in extraction buffer for the next extraction.

Analysis was performed with a Waters 2690 separations module and a Waters 996 photodiode array detector at a flow of 0.2 mL/min (50% ACN, 0.1% TFA; 50% H_2O, 0.1% TFA). A 20 μL sample of supernatant was injected onto a column, Phenomenex Biosep-SEC-S 4000 (300 mm × 4.5 mm, Torrance, CA, USA) with a prefilter (Phenomenex SecurityGuard GFC 4000). Absorption spectra were collected in 3D for 30 min and analyzed with Empower Pro software (Waters, Empower 2). Chromatograms were extracted at 210 nm and integrated into two arbitrary fractions: high molecular weights (HMw) from 8 to 18.3 min and low molecular weights (LMw) from 18.3 to 30 min. The solubility is defined as the area of the elution intervals normalized to the total protein extracted from the raw oilseed meals and corrected for individual sample meal content (eq 1). Error bars reported in HPLC data indicate one standard deviation. Interference due to the absorption of salicylic acid at 210 nm was removed from the data by manual peak selection.

$$\%\ \text{solubility} = \frac{\text{integrated fraction area}}{\text{total integrated raw meal area}} \times \frac{\text{total sample mass}}{\text{sample meal mass}} \times 100 \quad (1)$$

Tensile Testing. Tensile specimens were cut with an ISO 37, type 3, sample cutter (Elastocon AB, Sweden) and conditioned for a

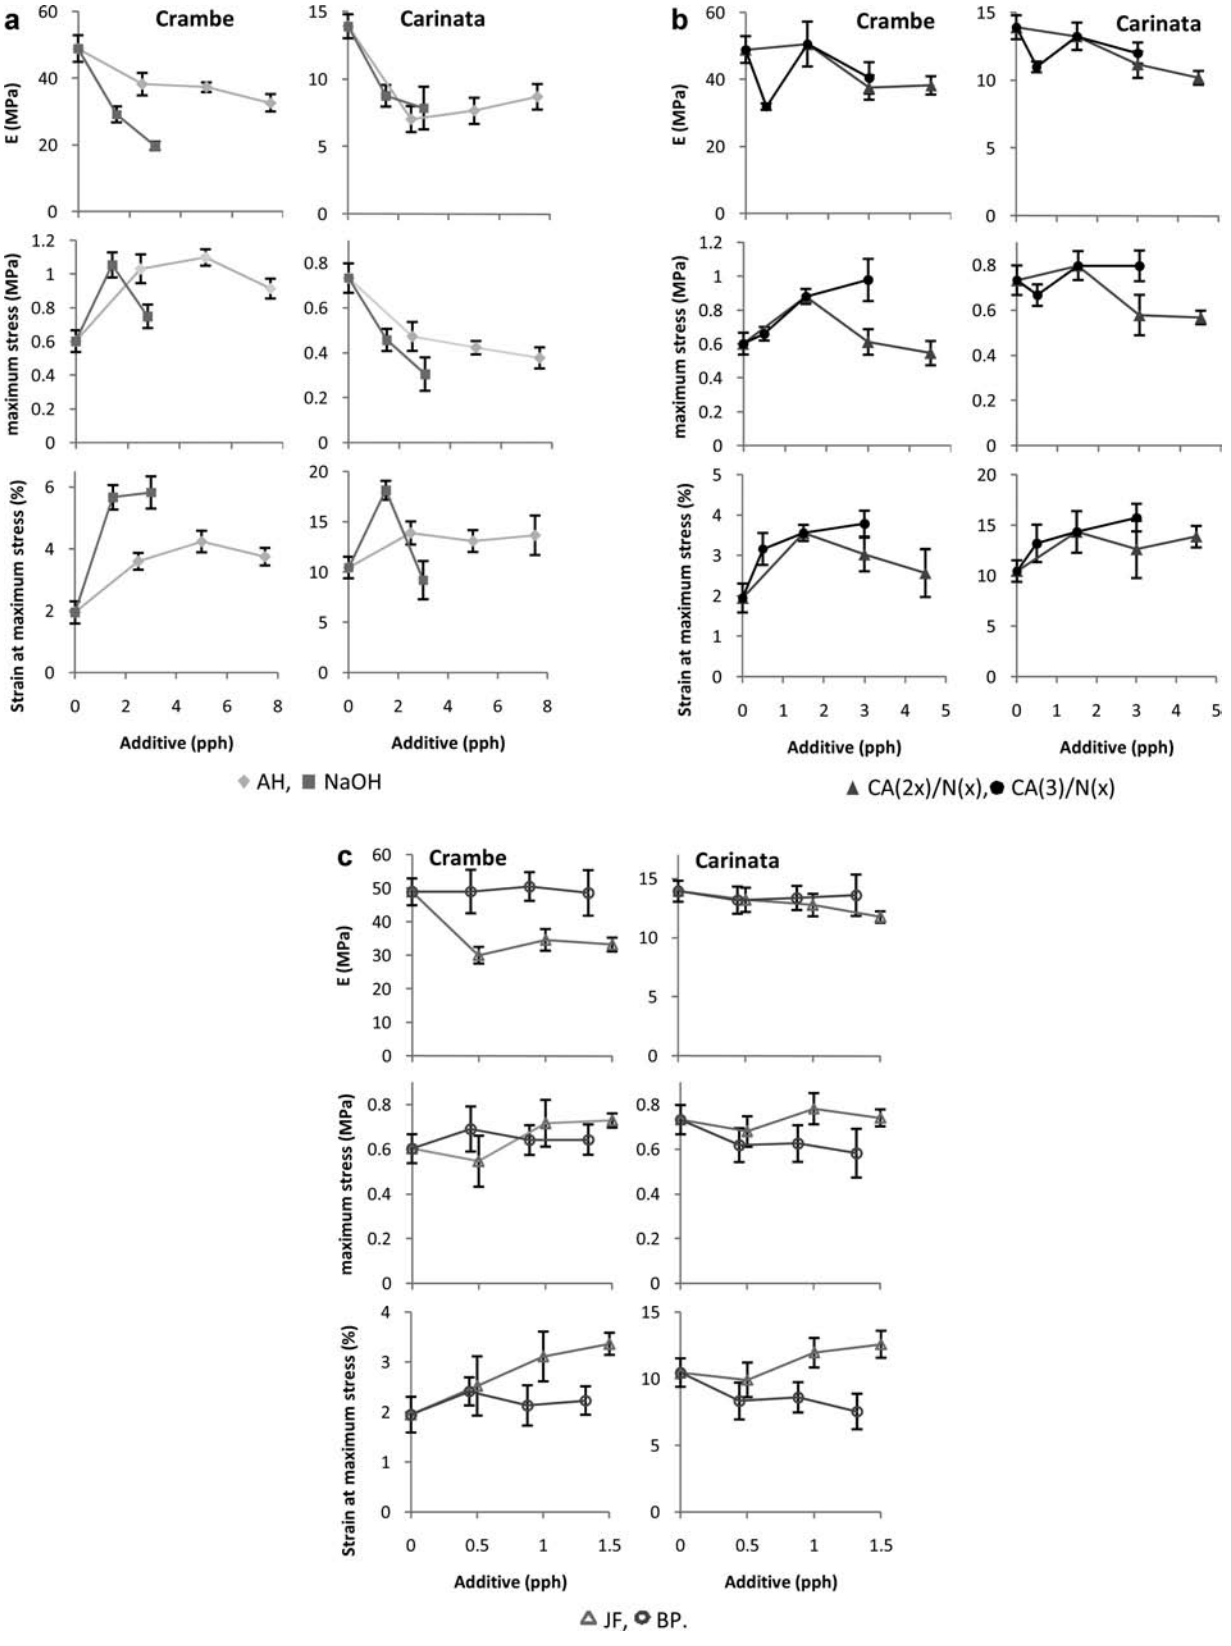

Figure 1. Tensile properties of compression-molded crambe and carinata oilseed meals. Error bars represent one standard deviation.

minimum of 48 h at 23 °C and 50% relative humidity prior to testing. The thickness was calculated as an average of five measurements, and the specimens were tested at 23 °C and 50% relative humidity using a crosshead speed of 10 mm/min and a 30 mm clamp separation (Instron 5566, Instron AB, Sweden).

The stress was calculated from the force divided by the cross-section area and the strain using the length of the reduced width section.[41] Strain at maximum stress was considered as the measurement for ductility as the failure mode was not consistent with slow tearing, making the determination of the strain at break inconsistent. Young's

dx.doi.org/10.1021/jf5015928 | J. Agric. Food Chem. 2014, 62, 6707−6715

modulus (E modulus) was calculated from the maximum slope after the initial toe correction.[41] A minimum of nine replicates were used; error bars in reported data indicate one standard deviation. Films excluded from tensile testing due to poor quality on pressing are listed as n/a in the Supporting Information.

Immersion Testing. Five replicate samples were removed from the oilseed meal films with a 5 mm diameter punch and weighed. Samples were lyophilized (Modulo, Edwards, UK) for a minimum of 48 h, weighed, and immersed in water for 24 h at 4 °C to prevent microbial growth. Following immersion, disks were removed from the water and held vertically for 10 s; the pendant drop was removed on fresh filter paper, and the disk was blotted between two dry pieces of filter paper (Munktell 1701, Falun, Sweden) under a 25 g weight, resulting in a pressure of 64.5 Pa for 10 s, then weighed. The disks were again lyophilized for a minimum of 48 h and weighed. The water absorption and mass loss during immersion were calculated on a dry basis. Error bars in reported data indicate one standard deviation. Films that lost coherence during immersion are listed as n/a in the Supporting Information.

RESULTS AND DISCUSSION

The present study on the effect of various additive types on tensile properties, protein solubility, protein molecular weight (Mw) distribution, and water uptake upon immersion produced a wide range of positive and negative results compared to a control with no additives. Here we have selected to present the results of those films with additives that contributed to interesting tensile properties. Those films with additives either having little effect or showing a negative

influence on properties are treated to only a limited extent, although all results are included in the Supporting Information.

Effect of Additives with a Basic pH. Addition of NaOH (1.5) and AH (2.5) resulted in increased strain at maximum stress for both crambe and carinata (Figure 1a) as well as increased maximum stress in crambe (Figure 1a). Protein solubility decreased with additions of NaOH (1.5) and AH (all levels) (Figure 2). In particular, the extractability of the HMw fraction decreased compared to controls at the NaOH doses that resulted in increased tensile properties (Figure 3). Previous work on protein-based plastic materials has shown increased strength and decreased protein solubility, especially of HMw proteins, when AH was used as an additive. The increased strength and decreased protein solubility at increased pH have been attributed to reorganization and polymerization of the proteins.[42−44]

Thermal processing of proteins under basic conditions has been found to favor the formation of residue−residue reactions such as lanthionine and isopeptide cross-links[43,45,46] and, as sugars are present in both meals,[47,48] Maillard type cross-links.[49] Thus, building on previous results of increased protein polymerization by creating a basic environment in protein systems, in this study we propose that increases in protein aggregation have occurred in the present oil crop residue based plastics in a similar way, despite the low protein content.

Increasing the NaOH dose above 1.5 resulted in decreased mechanical properties (Figure 1a), whereas at these doses solubility increased markedly (Figure 2). Increased levels of AH did not induce further strength increases in crambe (Figure 1a), nor did the solubility decrease for either meal (Figure 2). These tensile-solubility relationships at higher levels of NaOH and AH may be the result of exhaustion of the available mechanisms for solubility reduction already occurring at the lowest additive level. A pH environment far from the isoelectric point is known to improve the properties of protein-based films.[19] Although the isoelectric points for the individual proteins in our meals are not specifically known, combined carinata proteins demonstrated solubility minima at pH 3.5 and 5,[47] whereas the minimum for crambe is approximately 5.5,[50] both from aqueous alkaline extracted seed meal. The most common storage proteins in brassica, cruciferin and napin, have isoelectric points of approximately 7.2 and ≤10, respectively, as measured in rapeseed.[51] An alternative explanation of the effect of NaOH and AH is that the properties vary related to the distance from the isoelectric points of the proteins.

The pH is also known to affect the interaction between proteins and other constituents of brassica oilseed meals. Although the bulk of the evidence in this area is from aqueous solutions, increased pH enhances many processes including interactions between proteins and phenolic compounds,[52] Maillard reactions with sugars,[53] and phytic acid as a protein complexing agent that depends on pH.[51] Indeed, phenolic acids have been added to purified plant proteins as cross-linking agents.[54]

E modulus was not positively affected by NaOH and AH in any case examined, despite changes in protein solubility. *E* modulus is a composite property resulting from deforming of all components, whereas maximum stress and strain at maximum stress are local phenomena. If the protein fraction is considered under the polymer entropic elasticity theory,[55] secondary structure such as α-helix and β-sheet have been shown to have an effect on the response of protein materials that is not accounted for in their increased molecular weight due to aggregation. In our case the proteins exhibit increased aggregation, but do not contribute to an increased *E* modulus. The analysis of VanKleef[55] suggests that changes in secondary structure, which do not contribute to the SE-HPLC response, may be responsible for a lowered stiffness of the protein fraction despite increased aggregation.

Water uptake varied greatly between NaOH and AH, with NaOH showing markedly higher water uptake (Figure 4). It has been shown that in protein-based materials made with AH there is no residual pH effect as the free ammonia evaporates.[16] For NaOH it is expected that there will be a residual pH effect that can continue to modify the protein environment during the water uptake test, possibly allowing more complete protein unfolding in water. Lower protein aggregation at higher NaOH levels coupled with the residual pH effect could result in a very loose and easily expanded protein network, allowing high water uptake levels.

Citric Acid−NaOH Blends. Addition of CA(3)/N(x) blends resulted in increased strain at maximum stress for both crambe and carinata while also increasing the maximum stress in crambe in a dose-dependent manner (Figure 1b). Protein solubility showed a slight decrease with increased NaOH, although the lowest NaOH level (3/0.5) in crambe demonstrated a pronounced increase in solubility due to the high acidity (Figure 2). This indicates low protein polymerization, similar to additions of CA alone (Supporting Information). CA is known to suppress lysinoalanine cross-linking in food protein systems,[45] one possible mechanism for the increased solubility in this case.

Solution pH is also known to be a determining factor in the interaction of secondary plant metabolites in oilseed meal with proteins. For example, maximum precipitation of phytates occurs at low pH values for both napin and cruciferin in rapeseed,[56] whereas phenolic compounds (sinapic acid) have been found to bind tightly to canola cruciferin at pH 4 and adversely affect heat-set gels. It should be noted that the cited works on phenolic and phytate interaction with brassica proteins are in solution or gels at <100 °C, where the lack of water and high temperatures in our case could result in quite different effects.

Maximum stress results for crambe and carinata and strain at maximum stress for crambe indicate a behavior of increased tensile properties due to increased protein polymerization with a decreasing ratio of CA to NaOH. Thus, the changes in behavior are most likely a result of pH changes, which may also be the background factor in property changes from additions of NaOH and AH. The molecular weight distribution (Figure 3) indicates similar behavior as in the addition of bases without CA, with no indication of carboxylic acid cross-linking.

For CA($2x$)/N(x) the acid/base ratio was held constant as the total dose was increased. When this additive blend was applied, the maximum stress and strain at maximum stress peaked at the lowest dose and decreased thereafter, with a more pronounced behavior in crambe than in carinata (Figure 1b). Total solubility changed only slightly until the highest dose (9/4.5), at which crambe solubility decreased (Figure 2). The balanced addition of CA and NaOH resulted in only small changes in the Mw profile with dose until the highest dose (9/4.5), at which a marked decrease was seen in HMw solubility for crambe (Figure 3). If carboxylic acid cross-linking was occurring in the CA($2x$)/N(x) case, a dose-dependent decrease in solubility would be expected as more citric acid is available. The changes seen in behavior with dose could be due to interference by carboxylic acid groups with amino groups[57] or hydroxyl groups,[22] reducing protein−protein interactions without forming cross-links, as the behavior could not be explained by a pH shift because the ratio of CA to NaOH is constant. Neither CA/N treatment showed an appreciable effect on water gain, suggesting that the treatments have little consequence for the protein network (Figure 4).

Reactive Additives. The addition of JF resulted in an increase in strain at maximum stress for both crambe and carinata with little change in maximum stress (Figure 1c). Protein solubility in crambe was unaffected by JF additions, whereas carinata solubility decreased with dose of JF (Figure 2), with the decreases coming from the HMw part of the protein Mw distribution (Figure 3). Thus, the behavior of the JF films does not clearly indicate significant protein interactions. The increase in strain at maximum stress is possibly due to a small plasticizer effect by the JF terminal amino groups interrupting protein−protein interactions. The decrease in E modulus of crambe may also be due to a plasticizing effect, which is made more pronounced by the low protein content compared to carinata, resulting in higher plasticizer level per unit of protein. Water uptake changed little in crambe with JF addition, whereas in carinata there was an increase with dose (Figure 4), reflecting the slight changes seen in the carinata network through HMw protein polymerization (Figure 3). Although JF contains two reactive amino groups, there seems to be little interaction with the proteins at the conditions of hot pressing in this study. Shifting the system to a higher pH may promote reactions with amino acids as seen between amino group containing residues.[45]

In contrast to the previously discussed additives, benzoyl peroxide caused changes in protein Mw distribution with an increase in soluble LMw proteins with dose (Figure 3). Total protein solubility in crambe showed a steady increase, whereas carinata demonstrated an initial decrease followed by a rise in solubility with BP addition (Figure 2). These subtle Mw and solubility changes did not have appreciable effects on tensile properties (Figure 1c). The active peroxides produced by decomposing BP are known to cause protein aggregation or fragmentation depending on the details of the situation.[58] In the present films, peroxide behavior is further complicated by the presence of antioxidant plant phenolics,[59] which can neutralize reactive species. The change in carinata solubility (Figure 2) and water uptake (Figure 4) after the first dose (0.44) may indicate that at the lowest dose the peroxides have a site to act upon, reducing solubility, whereas above that dose there is an excess of reactive species resulting in protein fragmentation. In crambe it is possible that this threshold is passed below the lowest dose studied. In other protein systems, peroxides have been shown to need catalysts or enzymes to produce effective cross-linking,[30,35] and these have not been added. In our system there seems to be little overall peroxide effect.

Denaturing and Reducing Agents. In previous work denaturing agents such as SDS[26,27] and U[24,28,29] and the reducing agent SB[38,39] have been shown to have positive effects on protein-based materials. In our case these additives have a universally detrimental effect (Supporting Information). SDS addition is expected to result in a disruption of weak protein−protein interactions, allowing protein rearrangement; in our case it would seem that the disruption resulted in a plasticizing effect, but no advantageous protein−protein interactions resulted, perhaps due to the interference of phenolics or phytates. At our pressing temperatures U is likely to partially degrade into cyanate and ammonium,[60] resulting in protein carbamylation and loss of reactive lysine residues, preventing reactions such as lysinoalanine cross-linking. In solution U has been shown to result in the dissociation of rapeseed cruciferin at high concentrations such as 4 M.[56]

In addition to its use as an additive to improve protein-based plastics and adhesives[38,39] SB has been used to avoid phenol oxidation and polyphenol attachment in brassica protein extraction and purification,[61] and the prevention of these activities may adversely affect protein aggregation in our case. The presence of SB can also result in disulfide bond reduction reducing aggregation. It is this activity that is suggested as allowing protein unfolding and reorganization, but in our case it appears that during hot pressing the conditions do not allow the formation of aggregated forms after reorganization.

Protein Solubility and Tensile Property Relationships. SE-HPLC data (Figures 2 and 3) indicate that changes in solubility occur primarily in the HMw fraction of the proteins with additive type, with the exception of NaOH, which showed changes in both Mw categories. Total solubility of proteins in extraction buffer correlated to changes in maximum stress and strain at maximum stress for crambe (R^2 0.62 and 0.53, respectively), whereas for carinata only a weak relationship was found in strain at maximum stress (R^2 0.40; Figure 5). This reduction in total solubility is due to the proteins reaching a high degree of aggregation under the process conditions, indicating protein−protein interactions that result in improved properties. These relationships included all tensile data, including those cases where the performance was degraded compared to the control. Thus, a general increase in protein aggregation resulting in increased tensile properties could be noted. Despite the low protein content in the present oilseed residual plastic films, protein aggregation seems to be key, as has been reported in previous works on crop-based plastics, although many are at higher protein contents.[14,19,21,42]

Of the additives tested, NaOH had the greatest positive effect on tensile properties, with increases of 105% in maximum stress and 200% in strain at maximum stress for crambe and a 70% increase in strain at maximum stress for carinata (Figure 1a). These changes were reflected in protein solubility and Mw distribution changes (Figures 2 and 3), with the best performance occurring at the lowest NaOH concentration. As the properties generally decrease with increases in NaOH above the lowest dose, it is possible that the optimum NaOH level is lower than the lowest level investigated herein for both meals. The fact that AH had positive effects on the mechanical properties in a similar manner to NaOH (Figure 1a) suggests that an increased pH has a generally beneficial effect up to the pH at which protein fragmentation occurs (Figure 3).

The high content of other constituents in the oilseed meals,[47,48,62] for example, sugars, phenolics, and fiber, undoubtedly plays a role by interacting with both proteins and additives. Despite this fact, substantial increases in mechanical properties were accomplished where additives contributed to protein aggregation, and elevated pH will be a key parameter in future work to improve protein polymerization and thereby the properties of seed residual based materials.

[a]According to CRIBI Grape Genome (http://genomes.cribi.unipd.it/grape/).

anthocyanins,[22] Francisco et al.[23] recently reported that an ATP binding cassette protein (ABCC1) transports anthocyanidin 3-*O*-glucosides, with a preferential transport for malvidin 3-*O*-glucoside.

In this work we demonstrated the existence of significant variation for the anthocyanin profiles among clones from the same cultivar and also identified the variation in the amount of a particular anthocyanin as the main distinguishing factor within those profiles, where genetic variation and differential gene expression of particular genes seem to be important factors to determine the clonal difference in anthocyanin profile.

MATERIALS AND METHODS

Berry Sampling. The assays were performed during the vintages 2010 and 2012, at the Bodegas Esmeralda (BESA) clone collection localized at La Pirámide vineyard (Catena Zapata Winery, Agrelo, Mendoza; 34°55′21″ S, 69°7′4″ E). The collection included 131 clones (116 from BESA, 12 from FCA-UNCuyo, and 3 from INTA). Clones were sorted in 34 rows with four clones per row with a plantation density of 4000 plants per hectare (1.25 m × 2.00 m). The vineyard was a homogeneous field without slope, and all of the plants were under artificial irrigation. Each experimental unit (clone) was represented by approximately 45 plants. Ripening state of the samples was determined on the basis of berry density as an indicator of accumulated sugar levels. Density was estimated by berry flotation in a range of NaCl solutions, each having a decrease in salinity of 20 g NaCl L^{-1} (from 160 to 80 g NaCl L^{-1}).[24]

Varietal Identity Testing of the Clones through Microsatellite Analysis. Young leaves were sampled from every clone and kept frozen at −80 °C. DNA was extracted using a DNeasyTM Plant Mini Kit (Qiagen, Valencia, CA, USA) according to the manufacturer's protocol. Nine nuclear microsatellite markers were studied (VVS2, VVMD5, VVMD27, VVMD28, ssrVrZAG29, ssrVrZAG62, ssrVrZAG67, ssrVrZAG83, and ssrVrZAG112), using a multiplex PCR, according to the method of Ibáñez et al.[25]

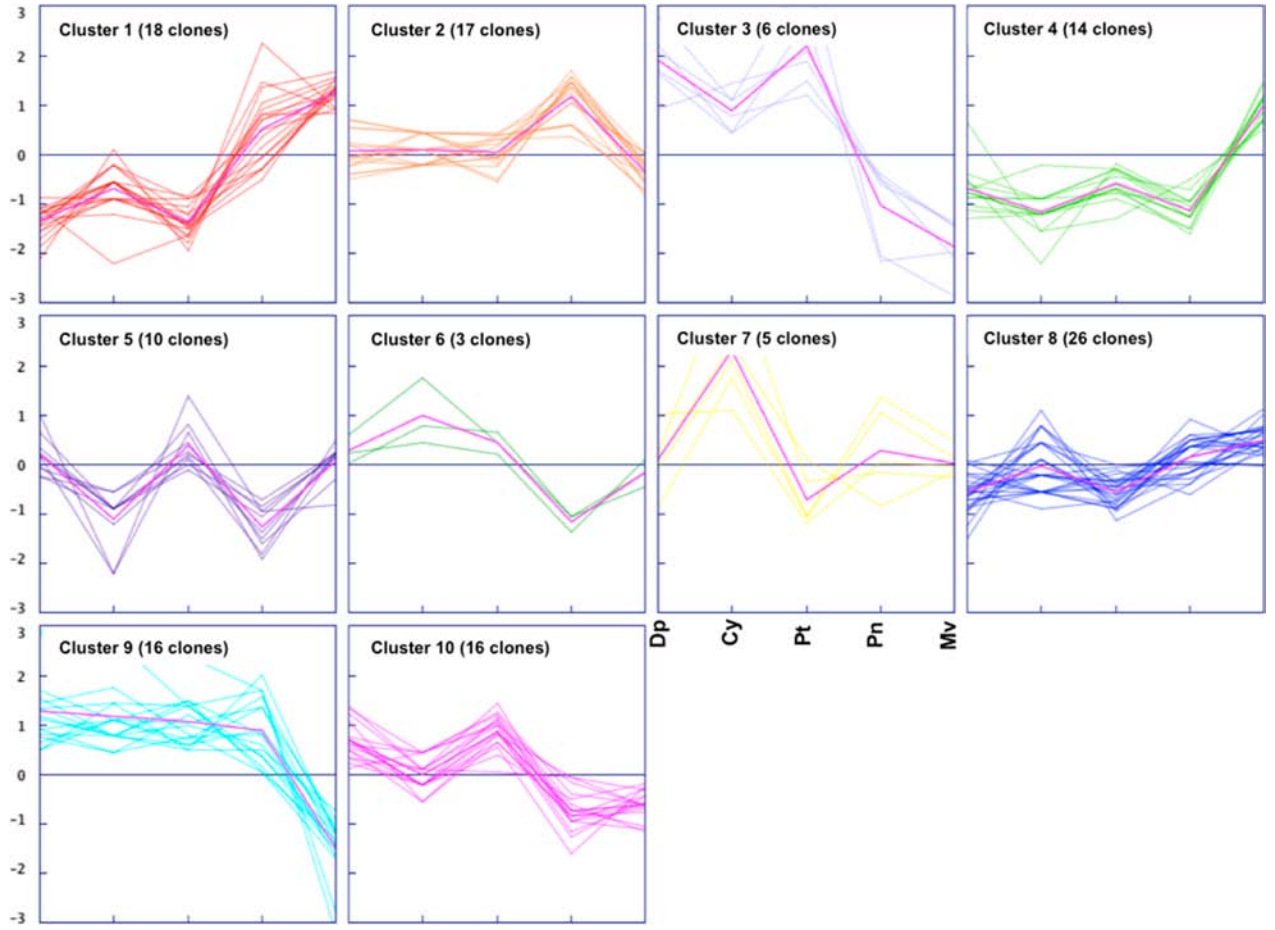

Figure 1. Clustering analysis of 131 Malbec clones according to their anthocyanin profiles using the *k*-means method. A five-point profile of each clone was obtained after adding up the glycosylated, acetylated, and coumaroylated forms for each anthocyanin: delphinidin (Dp), cyanidin (Cy), petunidin (Pt), peonidin (Pn), and malvidin (Mv). The number of clones per cluster is indicated in parentheses.

Extract Preparation from Skins. Three hundred berries per clone were randomly collected at a density of 140−160 g L^{-1} of NaCl (approximately 24 °Brix) in nylon bags from different positions within clusters from every plant. The samples were kept in ice to prevent dehydration and transported to the laboratory, where they were weighed, frozen, and conserved at −80 °C. Berry anthocyanins were extracted as previously described[3,26,27] with minor modifications. Briefly, skins and seeds were separated by hand from 50 berries, weighed, and ground with 30 mL of ultrapure water. Forty milliliters of hydroalcoholic solution (ethanol/water, 12:88, v/v) containing 5 g/L of tartaric acid was added to the ground material. The final weight of the suspension was adjusted to 100 g with ultrapure water. The pH of extracts was adjusted to 3.6 with NaOH or HCl. Extracts were macerated for 2 h at 25 °C using an orbital shaker at 200 rpm and then centrifuged for 15 min at 4000 rpm.

HPLC-DAD Analysis of Anthocyanins. Two milliliters of skin extracts per experimental unit were filtered through a 0.45 μm pore size nylon membrane, and then 100 μL was injected in the high-performance liquid chromatograph coupled to diode array detector (HPLC-DAD) system (PerkinElmer, Shelton, CT, USA). Separation was performed at 25 °C using a Chromolith Performance C18 column (100 mm × 4.6 mm i.d., 2 μm; Merck, Darmstadt, Germany) with a Chromolith guard cartridge (10 mm × 4.6 mm). A gradient consisting of solvent A (water/formic acid, 90:10, v/v) and solvent B (acetonitrile) was applied at a flow rate of 1.1 mL/min from 0 to 22 min and at flow rate of 1.5 mL/min from 22 to 35 min as follows: 96−85% A and 4−15% B from 0 to 12 min, 85−85% A and 15−15% B from 12 to 22 min, 85−70% A and 15−30% B from 22 to 35 min. This was followed by a final wash with 100% methanol and re-equilibration of the column. Photodiode array detection was performed from 210 to 600 nm, and the quantification was carried out by peak area measurements at 520 nm, according to the method of Fanzone et al.[28] Anthocyanin amount was expressed by using malvidin-3-glucoside chloride as standard (Extrasynthese, Lyon, France) for a calibration curve (R^2 = 0.98). Identification and confirmation of anthocyanic pigments were performed by HPLC-DAD/ESI-MS as described by Monagas et al.[29]

RNA Isolation, cDNA Synthesis, and Real-Time Quantitative PCR (qRT-PCR) Expression Analysis. For gene expression studies, post-véraison berries were harvested at a density of 100−120 g L^{-1} of NaCl, frozen, and conserved at −80 °C. Total RNA was extracted from berry skins according to the procedures described by Reid et al.[30] Final RNA purification and DNase digestion of contaminating DNA in the RNA samples were performed using the SV Total RNA Isolation System (Promega) following standard protocols. Reactions for cDNA synthesis and qRT-PCR were performed according to Lijavetzky et al.[31] using a StepOne Real-Time PCR System (Applied Biosystems, Life Technologies). Nontemplate controls were included for each primer pair, and each qRT-PCR reaction was completed in quadruplicate. Expression data were normalized against the grapevine *ACT1* gene (*VIT_04s0044g00580*). A normalization gene was chosen after the comparison of *ACT1*, *EFa1* (*VIT_06s0004g03220*) and *UBI* (*VIT_16s0098g01190*) genes using NormFinder software.[32] All three genes were previously tested for grapevine gene expression analysis.[30] Relative quantification was performed by means of the ΔΔCt method using StepOne software v2.2.2 (Applied Biosystems, Life Technologies). Gene-specific primers were designed using the QuantPrime web tool,[33] and the sequences are described in Table 1.

Statistical Methods. Clustering analysis of HPLC-DAD data was performed using the *k*-means method[34] implemented in Genesis

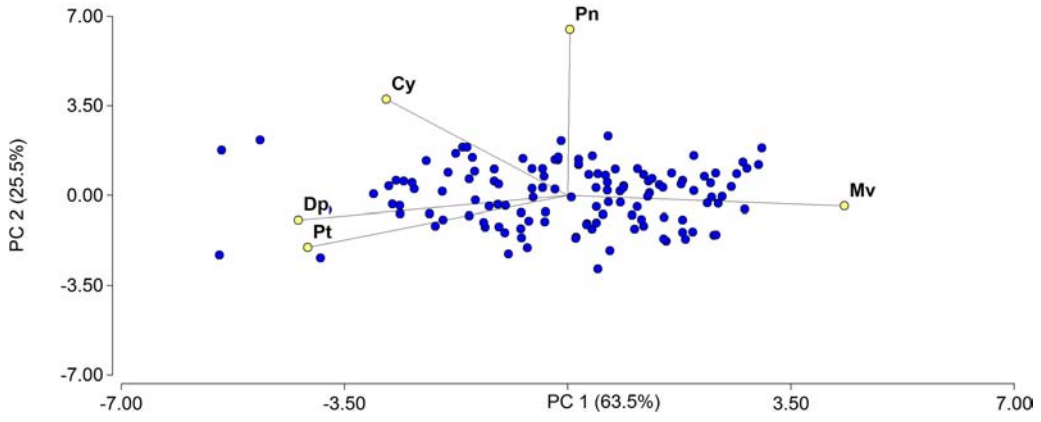

Figure 2. Principal component analysis (PCA) of the anthocyanin profile data of the 131 studied samples. The first (PC1) and second (PC2) principal components are represented. Each of the five points determining the profiles described in Figure 1 was treated as a variable (Dp, Cy, Pt, Pn, and Mv).

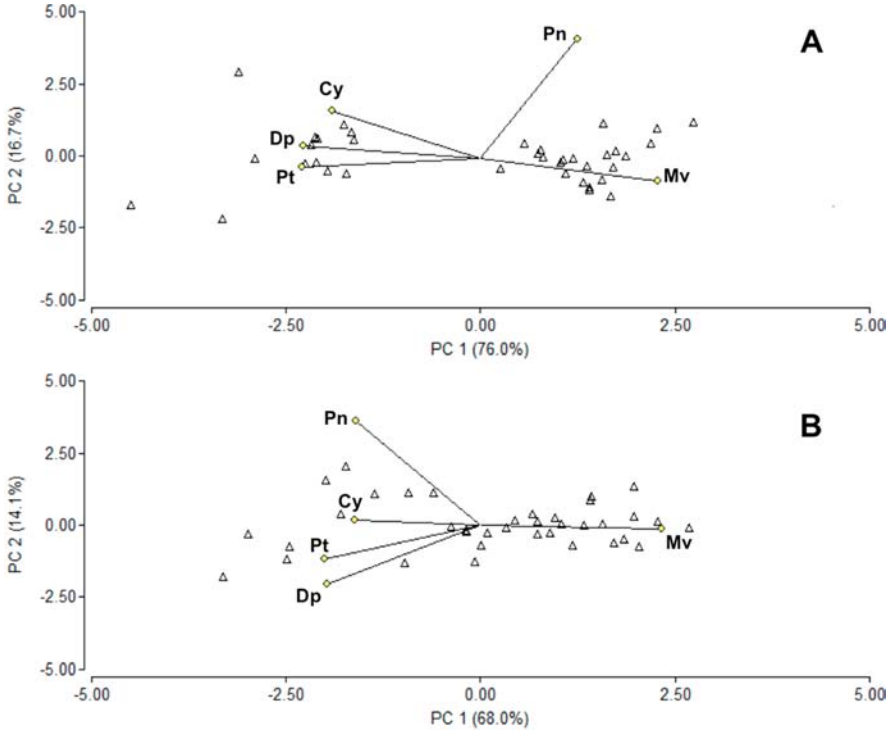

Figure 3. Principal component analysis (PCA) of the anthocyanin profile data of selected clones representing both extremes of the Mv content distribution described in Table S3 in the Supporting Information. Plots correspond to the data collected in 2010 (A) and 2012 (B). The first (PC1) and second (PC2) principal components are represented.

software v.1.7.6.[35] Principal component analysis[36] and linear regression analysis were carried out by means of InfoStat software.[37] Additional statistical calculations for the qRT-PCR analysis (group analysis: adjusted *p* values using Benjamini−Hochberg) were carried out with the help of DataAssist software v.3.01 (Applied Biosystems, Life Technologies).

RESULTS

All of the Clones Studied Belong to the Cultivar Malbec. Before performing any biochemical analysis, we first verified the cultivar identity of the 131 sampled clones by analyzing nine microsatellite markers. As shown in Table S1 in the Supporting Information, all of the samples presented the same genotype for the nine analyzed microsatellite markers. This genotype was compared with the ICVV database (www.icvv.es) and the European *Vitis* database (www.eu-vitis.de) and matched with Cot (prime name for Malbec at the *Vitis* International Variety Catalogue-VIVC, www.vivc.de). The total probability of identity found for this set of nine microsatellite markers was very low (6.93×10^{-12}),[25] and allows concluding that all of the studied samples belong to the cultivar Malbec.

Malbec Clones Can Be Discriminated by Their Anthocyanin Profiles. To evaluate the phenotypic variation for the anthocyanin profile of the 131 Malbec accessions of the studied collection, we performed a HPLC-DAD analysis.[3,26−28] For each Malbec clone 15 anthocyanins were considered: delphinidin (Dp), cyanidin (Cy), petunidin (Pt), peonidin (Pn), and malvidin (Mv) in their glycosylated, acetylated, and coumaroylated derivative forms (i.e., Dp3Gl, Cy3Gl, Pt3Gl, Pn3Gl, Mv3Gl, Dp3acGl, Cy3acGl, Pt3acGl, Pn3acGl,

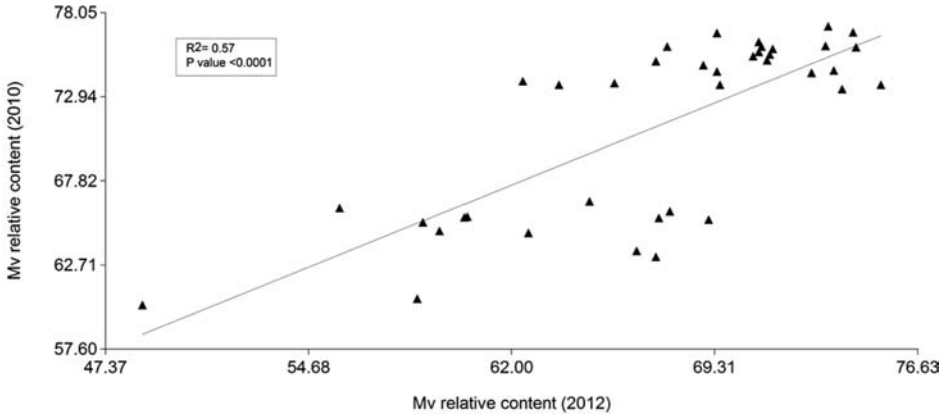

Figure 4. Correlation between malvidin (Mv) relative content of selected extreme clones during two different seasons (2010 and 2012).

Mv3acGl, Dp3cumGl, Cy3cumGl, Pt3cumGl, Pn3cumGl, and Mv3cumGl; Supporting Information Figure S1). The absolute and relative contents of those anthocyanins in samples of the clone collection are shown in Table S2 in the Supporting Information. Surprisingly, we obtained a broad spectrum of anthocyanin profiles among the clones. To have a comprehensive outlook of those different profiles, clones were grouped on the basis of their anthocyanin profiles using a *k*-means clustering analysis.[34] A five-point profile of each sample was obtained after adding the glycosylated, acetylated, and coumaroylated derivatives for each anthocyanin. As observed in Figure 1, the clones presenting similar profiles were clustered in 10 different profile groups. As expected, the larger cluster (cluster 8) included clones showing little variation with respect to the median profile. However, another five clusters grouped clones displaying high or low proportion of particular anthocyanins (clusters 1, 3, 4, 7, and 9).

Malbec Clones Are Mainly Separated by Variation in Mv Content. To further evaluate the variation observed within the Malbec clone collection, a principal component analysis (PCA) over the anthocyanin profile data of the 131 studied samples was performed (Figure 2). For this analysis each of the five points determining the profiles described in Figure 1 was treated as a variable (Dp, Cy, Pt, Pn, and Mv). First and second principal components (PC1 and PC2) explained together almost 90% of the variability for the anthocyanin profile (63.5 and 25.5%, respectively). PC1 pointed out the role of Mv content variation as the main discriminating factor within the clones. Dp and Pt contents were found negatively correlated with Mv, in agreement with both Dp and Pt being Mv precursors.[38] On the other hand, Pn content seems to be independent with respect to Mv, whereas Cy, a precursor of Pn, displayed an intermediate behavior (Figure 2).

Putative Genetic Effects on Mv Content and Anthocyanin Profiles Variation. After verifying the existence of different anthocyanin profiles within the clone collection and identifying the Mv content as the main variation source, we proceeded to evaluate the extent of conservation of the observed anthocyanin profiles in different years as an indication of the existence of an underlying genetic effect. For this purpose, we selected about 30% of clones representing both extremes of the Mv content distribution (Supporting Information Table S3). Data from the selected clones displayed similar PCA results as the complete collection, with an obvious increase of the PC1 (led by Mv) and a consequent decrease in the PC2 (Figure 3A). The same selected clones were further analyzed by HPLC-DAD in a second-year replication. The PCA performed on the selected clones during 2012 (Figure 3B) displayed again a large effect of Mv content on the evaluated phenotypic variation, as reflected in the PC1 value (68%). Besides the PCA results, this putative genetic effect could also be observed in Figure 4, where the linear regression analysis between the Mv content of the selected clones (2010 vs 2012) displayed highly statistically significant results with an $R^2 = 0.57$ (p value < 0.0001). Additionally, Dp and Pt presented also a highly significant correlation; Cy was just slightly correlated, whereas Pn showed no correlation (Table 2).

Table 2. Linear Regression Analysis between Individual Anthocyanin Contents Measured in 2010 and 2012

variable[a]	n	r^2	r^2 adj	p value
Mv	38	0.57	0.56	<0.0001
Dp	38	0.47	0.45	<0.0001
Pt	38	0.41	0.39	<0.0001
Cy	38	0.15	0.13	0.0168
Pn	38	0.04	0.01	0.2369

[a]Delphinidin (Dp), cyanidin (Cy), petunidin (Pt), peonidin (Pn), and malvidin (Mv) as the sum of their corresponding glycosylated, acetylated, and coumaroylated derivatives.

Variation in Mv Content Is Associated with Distinct Patterns of Gene Expression during Biosynthesis and Transport of Anthocyanins. We evaluated the putative influence of different genes related to biosynthesis and transport of anthocyanins on the variation in Mv contents (and the anthocyanin profiles) within the Malbec clone collection. To perform such analysis we designed qRT-PCR specific primers for 13 grapevine genes comprising 6 structural genes [(i) flavonoid 3′-hydroxylase (*F3′H*); (ii) flavonoid 3′,5′-hydroxylase (*F3′5′H*); (iii) UDP-glucose:flavonoid-3-*O*-glucosyltransferase (*UFGT*); (iv) *O*-methyltransferase 1 (*OMT1*); (v) *OMT2*; and (vi) *OMT3*],[17−19,39] 5 anthocyanin transporters [(i) glutathione-*S*-transferase (*GST*); (ii) ATP binding cassette C1 (*ABCC1*); (iii) anthoMATE1 (*AM1*); (iv) *AM2*; and (v) *AM3*;[18,22,23]], and 2 *MYB* transcription factors [(i) *MYBA1* and (ii) *MYB5b*].[14−16,18,40] Sequences for the forward and reverse primers as well as the PCR expected fragment size are detailed in Table 1. We measured the transcript accumulation of each gene in two groups of four clones corresponding to both Mv content extremes in the clone collection (Supporting Information Table S4). Clones selected

for each of the groups belong to (i) contrasting *k*-means clusters (Figure 1), (ii) opposite extremes at all PCAs (Figures 2 and 3), and (iii) opposite extremes of Mv content (Figure 5; Table S3 in the Supporting Information). Interestingly, although the anthocyanin profiles of both groups are clearly different (Figure 5b; Supporting Information Table S4), the total amount of anthocyanins is almost the same (Figure 5a). Consequently, with significant difference in Mv, the proportions of trisubstituted/disubstituted anthocyanins and methylated/unmethylated anthocyanins were higher in the high Mv content group (Supporting Information Table S4).

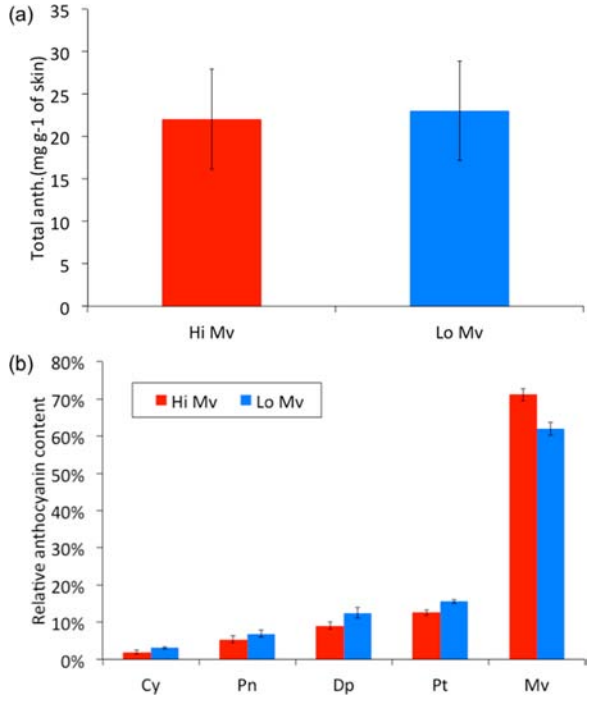

Figure 5. Anthocyanin content and metabolite profiles in berry skin of two groups of four Malbec clones corresponding to both Mv content extremes in the clone collection: (a) total anthocyanins expressed as mg g^{-1} of skin of malvidin equivalents; (b) anthocyanin profiles expressed as the relative concentration of cyanidin (Cy), peonidin (Pn), delphinidin (Dp), petunidin (Pt), and malvidin (Mv). High Mv content clones: MB25, FM5, FM4, and MB5. Low Mv content clones: MB81, MB30, MB77, and MB113.

As previously reported by Fournier-Level et al.[19] for other colored cultivars, no expression of *OMT3* was detected in grape skins of Malbec (data not shown). Unsurprisingly, most genes displayed slight difference between the two compared groups (Figure 6). Two of the structural genes showed significant variations, one related to anthocyanin hydroxylation (*F3′5′H*) and other involved in anthocyanin methoxylation (*OMT1*). The gene showing the more extreme differences was a putative anthocyanin transporter (*AM2*) with a fold change close to 2.9× and a *p* value of 0.0088. Finally, neither of the two *MYB* transcription factors analyzed (*MYBA1* and *MYB5b*) showed gene expression differences between the high and low Mv content groups (Figure 6).

DISCUSSION

Anthocyanin profiles, in combination with different statistical methods, have been efficiently employed as biochemical markers to discriminate grapevine varieties, hybrids, and wild accessions.[6,11,41,42] However, information about the use of those tools to depict intracultivar variation is very limited.[10] We tested the usefulness of anthocyanin profiles to identify variation among Malbec grapevine clones by analyzing a large collection comprising 131 accessions grown in the same vineyard. The amount of variation observed in the studied collection largely exceeded our expectations considering the close genetic relationship between the clones (Supporting Information Table S1). Accordingly, 10 different clone clusters were discriminated by means of *k*-means analysis. Even though this study shows a high proportion of clones with median-like profiles (Figure 1), about 41% of the clones are grouped in four clusters characterized by the predominance of high or low Mv relative contents (clusters 1, 3, 4, and 9). Moreover, the additional evaluation of the HPLC-DAD data by means of PCA (Figure 2) clearly indicates the key role of the Mv relative content variation for shaping the phenotypic distribution of the clones of the collection. As the value of PC1 indicates, Mv content explained 63.5% of the phenotypic variation for the anthocyanin profiles. The analysis of the anthocyanin profiles of six different Tempranillo clones was previously reported by Revilla et al.[10] The authors concluded that the analyzed clones were affected mostly by weather conditions despite slight differences in the profile of a particular clone. Conversely, the size of our collection and probably the diversity in the origin of the Malbec clones allowed in our case the detection of a broad variation spectrum (Supporting Information Table S2; Figure 1). These findings encouraged us to more deeply analyze the origins of the differences between the anthocyanin profiles among the Malbec clones.

The assessment of the genetic variation among clones of the same grapevine cultivar has been performed by means of different molecular marker techniques.[43−49] The aim of these works is looking for intravarietal variation at the DNA level of the studied cultivars. Some of the reports also describe the correlation between molecular markers and the geographical origin of the clones or with particular phenotypic traits.[43,47,49] Even though these reports clearly show the existence of intravarietal genetic variability at the DNA level, no information regarding the intravarietal analysis of genetic variation for particular quality traits has been presented so far. To contribute some information on this subject, we analyzed a large set of Malbec clones in two different seasons for their anthocyanin profiles. We particularly focused on the Mv relative content, the main source of phenotypic variation for that trait in our study (Figure 2). We selected two groups of clones from both extremes of phenotypic distribution after the 2010 experiment, and we tested them again during a subsequent season. Results from 2012 were similar to those of 2010, as observed in both the PCA and correlation analysis (Figures 3 and 4). These findings suggest a putative genetic effect on the regulation of the Mv content, because clones presenting low or high Mv content during 2010 performed correspondingly during 2012 season. Additionally, as a support of the conservation of the anthocyanin profiles, the two other trisubstituted anthocyanins (Dp and Pt) presented also a highly significant correlation. However, among the disubstituted anthocyanins, Cy was just slightly correlated, whereas Pn showed no correlation (Table 2). As expected, we also detected important environmental variation, which was presumably responsible for the more average-like behavior of some of the selected clones, that is, less extreme in 2012 than in 2010 (Figure 3). These results suggested that environmental effects seem to affect differentially

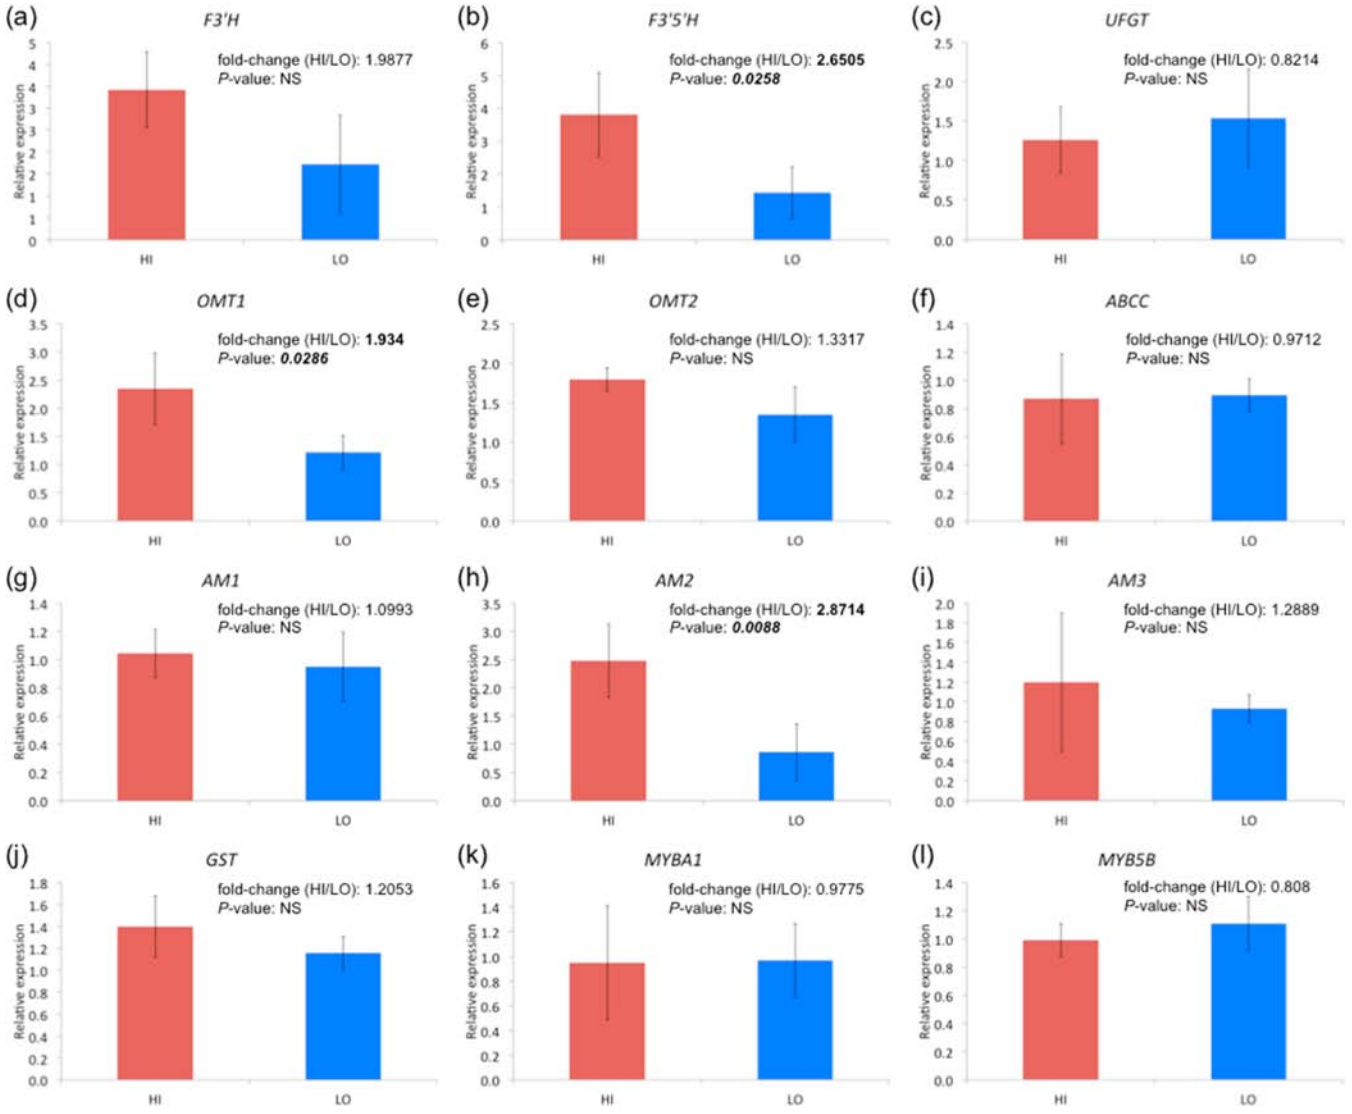

Figure 6. qRT-PCR amplification of 12 grapevine genes in berry skins of two groups of four Malbec clones corresponding to both Mv content extremes in the clone collection; comparison of the average relative expression (fold change) of high Mv content clones versus low Mv content clones: (a) F3′H; (b) F3′5′H; (c) UFGT; (d) OMT1; (e) OMT2; (f) ABCC; (g) AM1; (h) AM2; (i) AM3; (j) GST; (k) MYBA1; (l) MYB5b. NS indicates not significant Benjamini–Hochberg false discovery rate test.

the di- and trisubstituted anthocyanins, because Cy and Pn presented a higher environmental dependence than Dp, Pt, and Mv (Figure 4 and Table 2). We found little information on the analysis of genetic variation affecting anthocyanin profiles of clones of the same cultivar. In the paper on the Tempranillo cultivar mentioned above,[10] the authors concluded that the variation in the analyzed anthocyanin fingerprint depends mainly on agroclimatic factors and not on genetic differences among clones. Interestingly, the presented results showed that the only Tempranillo clone showing consistent differences was characterized by variations on the relative proportion of Mv during three different seasons. Despite the described variation indicating that the Tempranillo clones were affected mostly by weather conditions, genotypic effects seemed also to be present in that experiment.[10]

The huge natural variation for grape berry color is under the control of several genes and transcription factors that act at different points of the anthocyanin biosynthetic pathway.[50,51] Besides the master role of *UFGT* (and their main regulators, *MYBA1* and *MYBA2*) in determining the presence of anthocyanins in colored grapes,[13−16] the cultivar-specific function of other genes along the pathway is accepted to be involved in the regulation of the quantitative nature of grape skin color variation as well as of their different hues.[18,50] Whereas anthocyanin hydroxylases[18,39,52,53] participate in the modulation of anthocyanin composition upstream of *UFGT*, *O*-methyltransferases (*OMTs*)[19−21] and anthocyanin transporters[22,23] also play important roles downstream of *UFGT*. It is important to note that the molecular and biochemical studies mentioned above are mainly based on functional analyses of these significant genes by using different colored cultivars and usually by comparing white genotypes versus colored genotypes. In the present work we report for the first time the expression analysis of several of the genes involved in anthocyanin profile variation at an intravarietal level by evaluating a Malbec clone collection. We analyzed the expression of each gene in two groups of four clones corresponding to the extremes of the Mv content distribution (Supporting Information Table S4). Therefore, it is expected that differences in gene expression between the two groups

should be related to differences in the concentration of anthocyanins.

Several studies showed the correlation between the expression of *UFGT* and *GST* as well as those of the transcription factors *MYBA1* and *MYB5B* with the accumulation of total anthocyanins.[18,40,50,54] The expression of *UFGT*, *GST*, *MYBA1*, and *MYB5B* in our experiment showed no significant differences between the groups of high and low Mv (Figure 6c,j,k,l), in agreement with the total anthocyanin results displayed in Figure 5a, where both groups of clones presented similar mean values. We can infer from these results that profile differences between the groups of high and low Mv content are not due to variation in total amount of anthocyanins. As seen in Figure 5b and in Table S4 in the Supporting Information, the extreme value of Mv in the high Mv content group is compensated by a decrease in the other four anthocyanins.

Analysis of the transcriptional control of anthocyanin biosynthetic genes in different cultivars bearing extreme phenotypes for berry pigmentation showed that the predominance of trisubstituted anthocyanins (Dp, Pt, and Mv) was associated with higher ratios of *F3′5′H*/*F3′H* gene transcription.[18] Although our work was performed with clones of the same colored cultivar, we also observed a predominance of trisubstituted anthocyanins in the high Mv content group (Supporting Information Table S4; Figure 5b). Consistent with this result, the expression of *F3′5′H* showed a significant fold change (>2.65×; p value = 0.0258) between the contrasting Mv content groups (Figure 6b), whereas *F3′H* presented a lower and not significant fold change (Figure 6a). Accordingly, as mentioned above, in the comparison of 2010 and 2012 HPLC data, trisubstituted anthocyanins showed a putative higher genetic effect (Figure 4 and Table 2).

The positive correlation between the expression of different anthocyanin *OMTs* and the anthocyanin methylation level at ripening has been thoroughly studied.[18,19,51,55] Particularly, Fournier-Level et al.[19] showed that *OMT1* seems to be the fundamental gene for anthocyanin methylation, whereas *OMT2* may be responsible for fine and specific differences in the level of methylated anthocyanins. Additionally, the analysis of an OMT from Cabernet Sauvignon[20] showed that the highest specific activity of the enzyme was found for Dp, which is converted by this enzyme in two steps to Mv, the most abundant anthocyanin in most red grapes.[56] In agreement with these previous studies, we found a significant differential gene expression for *OMT1* (but not for *OMT2*) when comparing the high and low Mv content groups (Figure 6d,e). It is worth mentioning that the higher ratio of methylated/unmethylated anthocyanins reported for the high Mv content group in Table S4 in the Supporting Information is solely due to Mv, because the other methylated anthocyanins (Pn and Pt) presented lower percentages. We can infer that similarly to the observation reported by Lücker for Cabernet Sauvignon,[20] in the studied collection of Malbec clones, *OMT1* is involved in the conversion of Dp and Pt, which leads to the high contents of Mv of the extreme clones (Figures 2 and 3; Supporting Information Table S4).

Despite the increasingly deep understanding of anthocyanin biosynthesis and regulation, little is known about the molecular aspects of their transport.[22,23] In grapevine, different anthocyanin transporters have been characterized. Conn et al.[57] reported the involvement of *GST* in vacuolar accumulation of anthocyanins by exporting them to the tonoplast membrane. Two MATEs (*AM1* and *AM3*) have been described to specifically transport acylated anthocyanins, but not glucosylated ones.[22] More recently, a tonoplast-localized ABCC-type protein (ABCC1) was characterized with a preferential malvidin 3-*O*-glucoside transporter function.[23] As we mentioned above, *GST* showed no expression differences between the high and low Mv content groups (Figure 6j). Additionally, neither *AM1* and *AM3* nor *ABCC1* appeared to be involved in the variations in the profiles of Malbec clones in the collection (Figure 6f,g,i). Interestingly, the gene showing the highest expression differences between the extreme Mv content groups is a still uncharacterized anthoMATE (*AM2*).[22] As seen in Figure 6h, *AM2* presented a fold- change of 2.9× with a p value < 0.01, suggesting the putative involvement of this gene in the anthocyanin profile variation within the Malbec clones. As proposed by Gomez et al.,[22] the existence of other transport mechanisms has to be elucidated and characterized to have more evidence about a hypothetical relationship between the transport mechanisms and the final anthocyanin composition.

This work reveals the existence of variation for the anthocyanin profiles among clones from grapevine cultivar Malbec by using an appropriate sample size as well as suitable analytical and statistical tools. We also identified the variation in Mv derivative content as the main discriminating factor within the anthocyanin profiles, with a putative genetic variation involvement. We finally show that the increase in Mv content of the extreme clones is associated with a higher expression of different genes at distinct points of the anthocyanin biosynthesis pathway. Clones displaying relatively higher Mv content also presented elevated gene expression for anthocyanin hydroxylase (*F3′5′H*), an anthocyanin *O*-methyltransferase (*OMT1*), and a putative anthocyanin transporter (*AM2*). These results suggest focusing our attention on the gene expression variation at different steps of the anthocyanin biosynthesis pathway because modulation of the final anthocyanin profile seems to be fine-tuned by multiple genes performing different functions on the pathway.

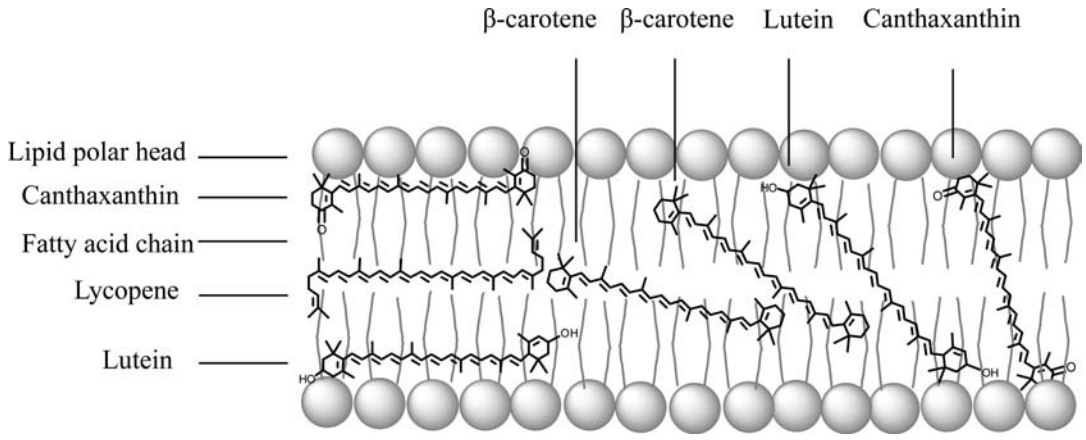

Figure 1. Schematic representation of the probable patterns of localization and orientation of carotenoid pigments in the egg yolk phosphatidylcholine (EYPC) membrane. The following carotenoids were used as examples: lycopene, β-carotene, lutein, and canthaxanthin.

biocompatible, biodegradable, and nontoxic. To our knowledge, there is a little consideration regarding the antioxidant activity of carotenoids in liposomes composed of mixed lipids including EYPC and nonionic surfactant Tween 80.

Moreover, it is noted that when liposome is utilized as a delivery system in nutraceuticals and functional food, one has to consider, primarily, the stability of liposomes during processing and storage. Therefore, encapsulated carotenoids should not only be able to exert antioxidant effects, but also maintain the physicochemical stability of the liposomes. However, carotenoids have contrasting effects on the membrane properties, owing to their various chemical structures. For instance, polar carotenoid incorporation can rigidify the lipid membranes and increase their stability, whereas the effects of apolar carotenoids are negligible or opposite.[18] Alternatively, the encapsulated concentration of carotenoids into liposomes may be much greater than that normally found in a natural membrane, since high loading contents are preferred for food applications. When exceeding a certain concentration, carotenoids probably display pro-oxidation properties. In turn, the liposomal membrane damaged by the lipid peroxidation would not effectively protect encapsulated carotenoids. Our recent study has also demonstrated the concentration-dependent capacity of lutein to adjust the penetration of oxygen into lipid bilayer and consequently, the liposomes stability.[19] Taking these factors into consideration, a compromise of carotenoids encapsulated concentration should be found in the design of carotenoid-loaded liposomal systems.

Further understanding of the influence of liposome encapsulation on the antioxidant activity of carotenoid will be crucial for the health benefits of encapsulated carotenoid. Herein, carotenes (lycopene and β-carotene) and xanthophylls (lutein and canthaxanthin) were studied that are known antioxidants commonly found in the human diet (Figure 1). The in vitro assays, including 2,2-diphenyl-1-picrylhydrazyl (DPPH) scavenging ability and ferric reducing antioxidant power (FRAP), were carried out to investigate the antioxidant activities of carotenoids; either after they were mixed with liposomes or after they were incorporated into liposomes. The lipid peroxidation inhibition capacity (LPIC) of these carotenoids during preparation, auto-oxidation, or induced by ferric iron/ascorbate was also evaluated by determining the lipids oxidation product, the thiobarbituric acid-reactive substance (TBARS). Meanwhile, the depletion of carotenoid after oxidation was determined. On the basis of the experimental data, the probable mechanism of LPIC as well as the self-protection of carotenoids were correlated to the effects of carotenoids on membrane properties (dynamic and structure).

MATERIALS AND METHODS

Materials. Egg yolk phosphatidylcholine (EYPC) was purchased from Chemical Reagent Plant of East China Normal University (Shanghai, China). Carotenoids, including lycopene, β-carotene, lutein, and canthaxanthin (all 98% purity), were a gift from Zhejiang Medicine Co., Ltd. (Zhejiang, China). Petroleum ether (30−60 °C) and polyoxyethylene sorbitan monooleate (Tween 80) were purchased from China Medicine (Group) Shanghai Chemical Reagent Co. (Shanghai, China). 2,2-Diphenyl-1-picrylhydrazyl (DPPH) was purchased from Sigma Chemical Co. (St. Louis, MO, U.S.A.). All other chemicals used were of analytical grade.

Preparation of Carotenoid-Loaded Liposomes. Liposomes loading carotenoids were prepared by the thin-film evaporation method according to our recent report.[20] Carotenoid was dissolved in 2 mL chloroform together with the lipids composed of EYPC and Tween 80 at the fixed mass ratio of 1:0.72. After dissolution, the liposomal system brought to dryness by the use of a rotary evaporator at 55 °C (organic solvent removal). The sample was further vacuum-dried in an oven (at 50 °C) to ensure complete removal of the solvent, followed by hydration with 40 mL of 0.01 M phosphate buffer solution, 150 mM NaCl, PBS, pH 7.4, under vortexing for 60 min at 55 °C. The liposomal suspension was then subjected to a probing sonication process in an ice bath for 10 min at 240 W with a sequence of 5 s of sonication and 5 s of rest using a sonicator (Sonics & Materials, Inc., 20 kHz). The final sample preparations were transferred in vials under nitrogen bed and stored in the refrigerator (at 4 °C in dark) until use.

Encapsulation Efficiency and Loading Content. The determination of encapsulation efficiency (EE) was performed by extraction according to our earlier method with a slight modification.[21] Briefly, aliquots of 0.5 mL carotenoid-loaded liposomes and 3 mL petroleum ether were mixed by being vortexed vigorously for 3 min at an ambient temperature. The mixed sample was centrifuged at 2000 r/min for 5 min, and the supernatant was collected. The above operation was repeated twice, and the collected supernatant was combined together in a tube, followed by dilution to 10 mL with petroleum ether. The free amount of carotenoids were quantified spectrophotometrically (UV-1600 spectrophotometer; Mapada Instruments Co., Ltd., China) at 470, 455, 440, and 460 nm for lycopene, β-carotene, lutein, and canthaxanthin, respectively, with petroleum ether as a blank. Each experiment was carried out in triplicate.

The total amount of carotenoid was expressed relative to the mass of lipids through the initial carotenoid concentration (IC = $m_{\text{carotenoid}}$/

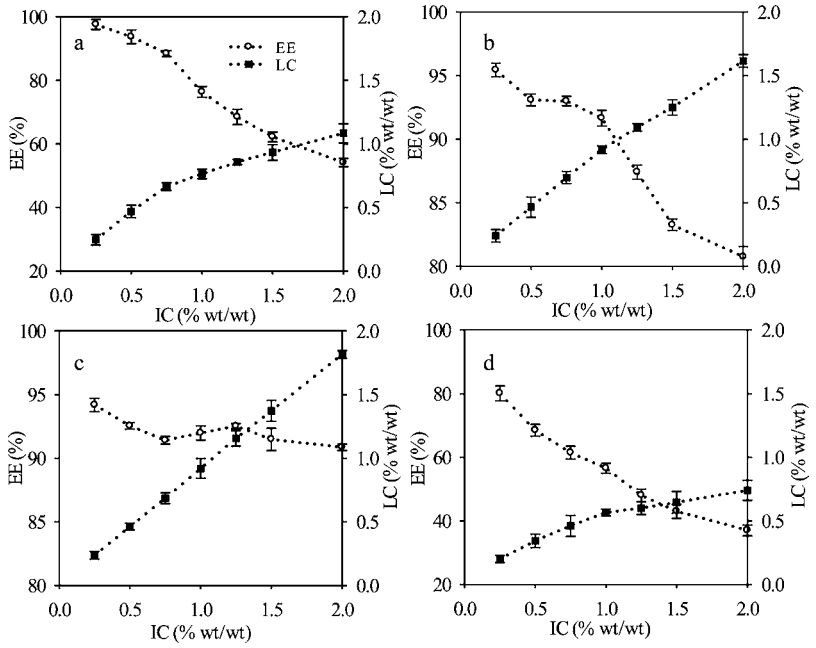

Figure 2. Encapsulation efficiency (EE) and loading content (LC) as a function of IC: lycopene (a); β-carotene (b); lutein (c); and canthaxanthin (d). Data were expressed as the mean value ± standard deviation (n = 3).

m_{lipids}, % wt/wt). The amount of carotenoid loaded into the liposomes was calculated as the difference between the total amount used to prepare loading liposomes and that recovered by extraction. The carotenoid encapsulation efficiency (EE, %) and loading content (LC, % wt/wt) was respectively calculated using the following equations:

$$\mathrm{EE} = \frac{\text{incorp. carotenoids}}{\text{total carotenoid}} \times 100$$

$$\mathrm{LC} = \frac{\text{incorp. carotenoids}}{\text{amount of lipid}} \times 100$$

where "incorp. carotenoids" is the incorporated amount of carotenoids and "total carotenoid" is the total amount of carotenoid.

DPPH Radical-Scavenging Activity. DPPH radical-scavenging activity of samples was measured according to the work published by our research group with a slight modification.[22] In the assay, 0.7 mL of carotenoid-loaded liposomes (or the direct mixture of carotenoid-DMSO solution and pure liposomes) was mixed with 0.2 mL of DPPH solution (0.4 mM in ethanol). The carotenoid in DMSO solution was adjusted to the same concentration as the carotenoid-loaded liposomes. Then, the solution was incubated at 37 °C in the dark for 40 min. Distilled water mixing with DPPH solution instead of the sample mixing served as a control. A sample blank was prepared by replacing the DPPH with ethanol. The absorbance of the sample after incubation was measured at 525 nm using a UV-1600 spectrophotometer (Meipuda Co., Shanghai, China). A low absorbance of the reaction mixture indicates a high free radical scavenging activity. The percentage of DPPH-scavenging ($\mathrm{DPPH_{scav}}$) activity was calculated as follows:

$$\mathrm{DPPH_{scav}}(\%) = \left(1 - \frac{A_{\text{sample}} - A_{\text{sample control}}}{A_{\text{blank}}}\right) \times 100$$

Ferric Reducing Antioxidant Power (FRAP) Assay. Either the carotenoid-loaded liposomes or mixture between carotenoid-DMSO solution and pure liposomes (1 mL) was mixed with 1 mL of potassium ferricyanide (2.5%, w/v) followed by incubation at 50 °C for 20 min. After incubation, 5 mL of trichloroacetic acid (10%, w/v) was added to the mixture, which was centrifuged at 5000 r/min for 2 min. The obtained supernatant (1 mL) was treated with 2 mL of distilled water and 0.5 mL of $FeCl_3$ (0.1%, w/v), followed by incubation for 10 min. The absorbance of the reaction mixture was measured at 700 nm with a UV-1600 spectrophotometer (Meipuda Co., Shanghai, China). The blank was the sample using water instead of potassium ferricyanide. The larger the absorbance, the higher the reducing power becomes.[7]

Lipid Peroxidation Analysis. The lipid peroxidation inhibition capacity (LPIC) was determined by thiobarbituric acid reactive substance (TBARS). The measurements were based on our recent study:[23] a solution containing thiobarbituric acid (15%, w/v) (TBA), trichloroacetic acid (0.37%, w/v) (TCA), and hydrochloric acid (1.8%, v/v) (HCl) was added to 1 mL of liposomal sample and mixed, followed by heating at 100 °C water bath for 30 min to promote the formation of a pink pigment resulting from the reaction with malondyaldehyde [$(MDA)_2$-TBA]. Afterward, the mixture was cooled rapidly with an ice bath, centrifuged for 5 min at 2000 r/min, and filtrated. The absorbance of the filtrate was measured by spectrophotometer at 535 nm (A_{535nm}). A_c and A_s were the absorbance at 535 nm of carotenoid-free liposomes and carotenoid-loaded liposomes, respectively. The inhibition activity of TBARS ($\mathrm{TBARS_{inhib}}$) during initial sample preparation procedure was calculated by following equation:

$$\mathrm{TBARS_{inhib}}(\%) = \frac{A_c - A_S}{A_c} \times 100$$

When evaluating the LPIC of carotenoid induced by Fe^{3+}/ascorbate, the liposomal samples were first mixed with $FeCl_3$ (1 mL, 400 μmol/L) and ascorbic acid (1 mL, 400 μmol/L). After incubation at 37 °C for 60 min, the TBA-TCA-HCl solution was added. When evaluating the auto-oxidation of liposomal membrane, all samples were incubated at 37 °C in an uncovered, shaking water bath. At proper time intervals, an aliquot (1 mL) of each sample was removed and combined with 5 mL TBA-TCA-HCl solution. The determination procedure of TBARS was the same as described above. The amount of retained carotenoid during oxidation treatment was measured by determining the total and free amount of carotenoid in the same way as the determination of EE as described above. The change in TBARS induced by Fe^{3+}/ascorbate or during auto-oxidation and retention rate (RR, %) were calculated, respectively, as follows:

$$\text{change in TBARS}(\%) = \frac{\text{TBARS ox} - \text{TBARS initial}}{\text{TBARS initial}} \times 100$$

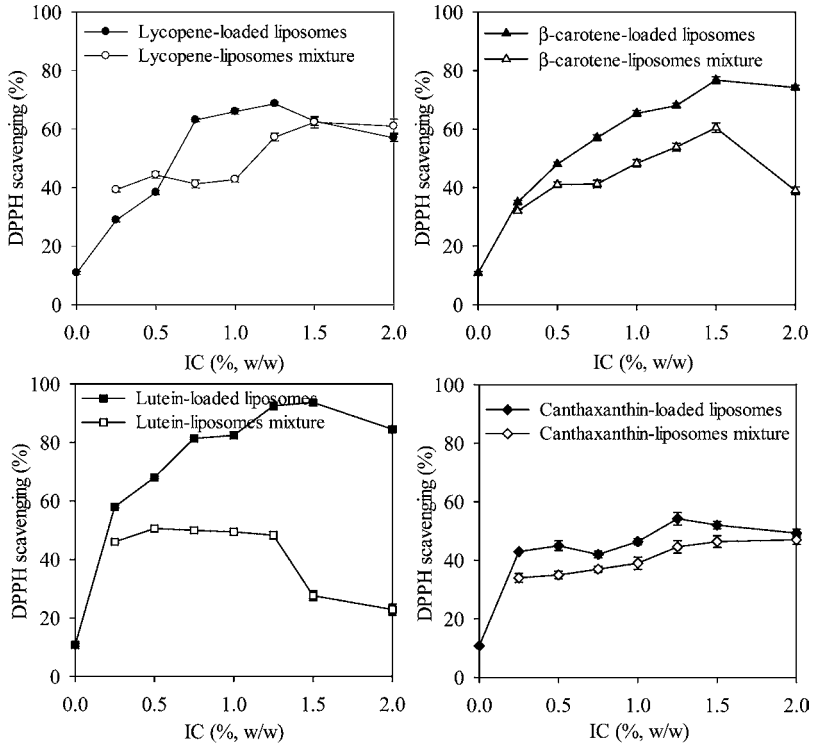

Figure 3. DPPH radical-scavenging activity of carotenoids when incorporated into liposomes or directly mixed with liposomes. Each point represents the mean value ± standard deviation (n = 3).

$$RR_{incorp.} = \frac{\text{incorp. carotenoids in liposomes after ox}}{\text{incorp. carotenoids initial}} \times 100$$

$$RR_{mixed} = \frac{\text{total carotenoid mixed susp ox}}{\text{total carotenoid initial}} \times 100$$

where "TBARS ox" is TBARS after predetermined oxidation time; "TBARS initial" is TBARS initially prepared; "incorp. carotenoids in liposomes after ox" is the inorporated amount of carotenoids in liposomes after oxidation treatment; "incorp. carotenoids initial" is the incorporated amount of carotenoid initially prepared; "total carotenoid mixed susp. after ox" is the total amount of carotenoid in mixed suspension after oxidation treatment; and "total carotenoid initial" is the total amount of carotenoid initially prepared.

Statistical Analysis. Data were presented as a mean value with its standard deviation indicated (mean ± SD). The experiments were done in triplicate. Statistical significance (P < 0.05) was determined using one-way analysis of variance (ANOVA) with SPSS 19.0 FOR Windows (SPSS Inc., Chicago, IL, U.S.A.).

RESULTS AND DISCUSSION

Carotenoids Loading. The carotenoid EE and LC in liposomal systems were analyzed separately by extraction and centrifugation. As shown in Figure 2a, the EE of lycopene exceeded 80% in the range of 0.25%−0.75%, whereas beyond this range the values greatly decreased. LC data also revealed that lycopene was incorporated only up to a very low concentration and membrane nearly reached saturation at 1.50%, corresponding to an LC value of around 0.95%. The poor incorporating ability can be explained by the strong lipophilicity of lycopene molecules, leading them positioned deeply in bilayer hydrophobic core.[24] EE of lutein and β-carotene were found at a high level; the values exceeded 90% and 80% respectively even though the concentration was increased to 2.00% (Figure 2b,c). Their LC values that were found to be very close to the initial concentration (IC), further indicated that the added carotenoids can be effectively incorporated into liposomal membranes within the studied concentration. β-carotene has been shown to have flexible location and orientation in liposomal membrane, owing to the presence of two-β ionone rings.[24] Lutein can orientate vertically to the membrane plane through hydrogen bonding between their polar end groups and membrane's polar region (as depicted in Figure 1). The vertical fashion contributed to the strong inserting ability because more molecules were able to be inserted across the bilayer besides their presence in the hydrophobic core. A similar conclusion has also been reported by an earlier study,[25] that liposomes containing lutein had the largest diameter compared with β-cryptoxanthin and zeaxanthin liposome. However, a great concentration-dependent decrease of EE was observed for canthaxanthin, where the value decreased to around 35% at the 2.00% concentration (Figure 2d). Lipid membrane nearly reached saturation by 1.00% canthaxanthin with the LC values of around 0.65%. Although polar canthaxanthin adopted similar orientation to lutein due to the presence of keto groups, its incorporating ability into liposomal membrane was very weak compared with other carotenoids. One probable explanation was that canthaxanthin molecules did not fit into the membrane architectures as well as did lutein, and they are not as lipid soluble as β-carotene and lycopene.[26]

DPPH Assay. The DPPH method, which is based on the reduction of DPPH· in alcoholic solution in the presence of a hydrogen-donating antioxidant, is the most frequently used one for in vitro antioxidant activity.[27] The DPPH scavenging activity of four kinds of carotenoids, either incorporated into liposomes or directly mixed with liposomes, is presented in Figure 3. In the mixture of carotenoids solution and liposomes, the addition of carotenoid increased the DPPH scavenging activity to some extent. When the concentration was <1.0%,

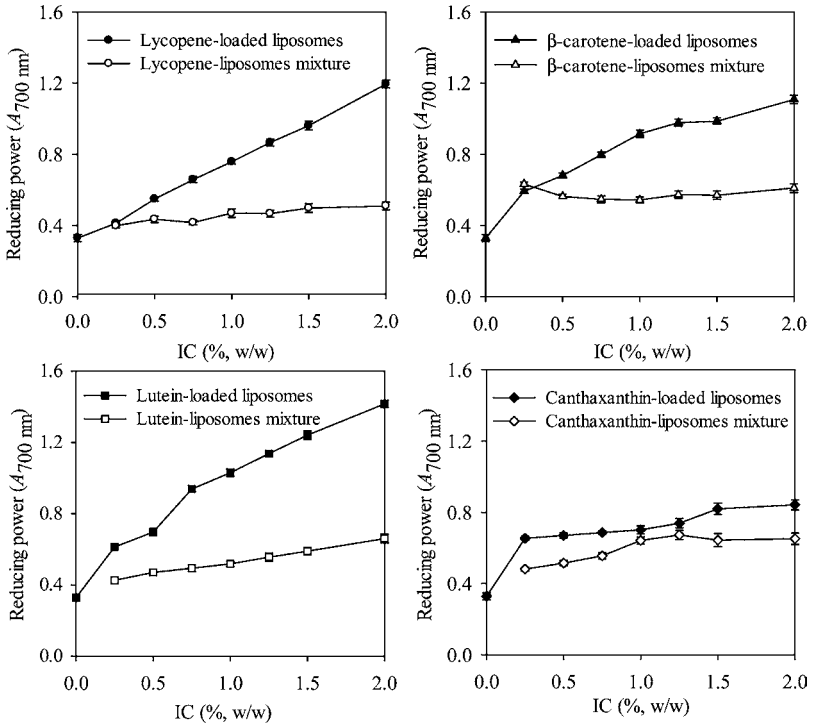

Figure 4. Reducing power of carotenoids when incorporated into liposomes or directly mixed with liposomes. Each point represents the mean value ± standard deviation (n = 3).

carotenoids displayed similar scavenging ability to each other and also showed concentration-dependency. Beyond 1.0%, lycopene displayed the highest DPPH scavenging activity, followed by β-carotene, canthaxanthin, and lutein. The scavenging ability to DPPH was mainly affected by the structural features in carotenoids, that is, the length of conjugated double bonds (CDB) and participation of chemical groups on the β-ionone ring. Owing to the fact that the orbital overlap in the chromophor is enough to form a stable carotenoid radical, acyclic carotenoid lycopene with 11 CDB has strong DPPH scavenging ability. Although β-carotene has 11 CDB, two double bonds in the cyclohexene rings are not planar with the rest of the molecular backbone.[28] For lutein and canthaxanthin, besides the low number of CDB (both 10), the presence of hydroxyl and keto functional groups on the terminal rings, respectively, considerably decreased their antioxidant efficiency for DPPH.[29]

When incorporated into liposomes, all carotenoids exhibited an increase in DPPH scavenging activity as compared to those directly mixed with liposomes. One probable reason was the enhanced water solubility and dispersion of carotenoids by liposome encapsulation. In the concentration range of 0.25%−1.25%, each carotenoid displayed a concentration-dependent increase of DPPH scavenging. Besides, the trend of antioxidant activity was modified, ranging from the strongest to the weakest: lutein > β-carotene > lycopene > canthaxanthin. Due to the vertical orientation in the opposite polar membrane zones, lutein and β-carotene are accessible to react with DPPH at the membrane surface. However, it is difficult for lycopene to trap DPPH because of its deep location in the bilayer hydrophobic core, far from the membrane surface (Figure 1). The poor scavenging ability of canthaxanthin was mainly due to the very low degrees of its incorporation into the lipid bilayer. It was interesting to find that the DPPH scavenging of each carotenoid decreased slightly when the concentration was >1.25%. It may be the consequence of the extent of carotenoid aggregation, causing the decrease of antioxidant efficiency.[4]

FRAP Assay. Some reducing substances in the sample could provide electrons to reduce Fe^{3+} to Fe^{2+}. The Fe^{2+} can be monitored by measuring the formation of Perl's Prussian blue at 700 nm. Figure 4 shows that when mixed with liposomes, lutein seemed to display relatively stronger FRAP activity than other carotenoids. FRAP activity was not only affected by the CDB number, but also by the steric hindrance between carotenoids and ferric *di*-TPTZ complex. Despite having 10 CDBs, the presence of hydroxyl functions in the 3(3,)-position at the ring system can reduce the steric hindrance, and consequently improve the FRAP activity of lutein.[29] However, the differences of FRAP activity between other carotenoids was not apparent and also no concentration-dependence was detected. This observation was a little different from the conclusion of a previous observation.[29] The contradiction might be due to the reaction conditions, such as reaction time, solvents, concentration, and wavelength used.[29,30] Another probable explanation was the inhomogeneous dispersion of carotenoids in their direct mixture with liposomes.

When incorporated into the lipid bilayer, the FRAP activity of each carotenoid was enhanced. It was probably due to the reduced steric hindrance of molecules after they were encapsulated. The highest FRAP activity was observed with lutein, followed by β-carotene, lycopene, and canthaxanthin. This trend was well in agreement with their activities to scavenge DPPH. However, ferricyanide is also an oxidizing agent impermeable through lipid bilayers and membrane, and therefore extensively used to assess the exposition of redox groups to the aqueous medium.[7] The vertical fashion made lutein and β-carotene favorable to react with ferric *di* -TPTZ complex at the membrane surface. Unexpectedly, although lycopene is located in the bilayer core, its FRAP activity showed highly concentration-dependent increase. It has been demon-

strated that the parallel fashion of lycopene could decrease the penetration barrier for small molecules to the liposomal membrane.[31] Thus, we speculated that the loosened membrane structure created more opportunities for lycopene to react with ferricyanide. For canthaxanthin, undoubtedly, the slight increase of FRAP activities and lower DPPH scavenging ability was the consequence of their poor incorporation ability.

Lipid Peroxidation Assay. Another mechanism of the antioxidant defense system is the lipid peroxidation inhibition capacity (LPIC). EYPC may undergo peroxidation due to the presence of polyunsaturated acyl chains in lipid molecules, leading to high membrane permeability.[32] Thus, the protection from lipid peroxidation owing to the carotenoids antioxidation may in turn retain the incorporated carotenoids more effectively. The product of peroxidation can be determined spectrophotometrically by the thiobarbituric acid reactive substances (TBARS), and the inhibition rate of TBARS after initial preparation of liposomes is shown in Figure 5. Within a certain concentration range, the lipid peroxidation during liposome preparation was inhibited by lycopene (0.25%−0.75%), β-carotene (0.25%−1.25%), lutein (0.25%−1.50%), and canthaxanthin (0.25%). In particular, the more lutein molecules incorporated (0.25% to 1.25%), the more significant the increase of TBARS inhibition rate became ($P < 0.05$). Beyond the above corresponding concentration ranges, the four kinds of carotenoids would display significant pro-oxidant properties in a concentration-dependent manner ($P < 0.05$). Meanwhile, it was noteworthy that the carotenoids having strong TBARS inhibition activity also had a high EE, but their EE decreased with the appearance of pro-oxidation phenomena. A previous study had revealed that there was a possibility of carotenoid oxidative degradation during the experimental procedures.[33] However, it was also indicated that there was a relationship between lipid peroxidation and carotenoid depletion, as discussed below.

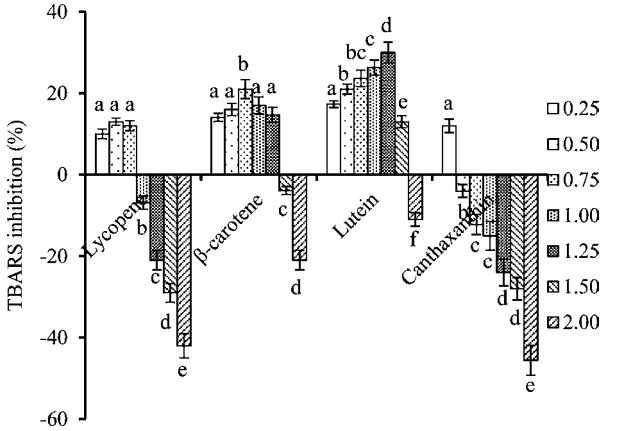

Figure 5. Effect of carotenoid incorporated in liposomes on the inhibition of thiobarbituric acid reactive substance (TBARS) formation in liposome system during preparation. Each point represents the mean value ± standard deviation ($n = 3$). Different letters represents a significant difference ($P < 0.05$).

Iron was used as an oxidizing agent on the consideration that it is present in human body and is involved in oxidative processes. Thus, it is necessary to investigate the lipid peroxidation inhibition capacity (LPIC) induced by Fe^{3+}/ascorbate mixture either after carotenoids were mixed with liposomes ($LPIC_{mixed}$) or after carotenoids were incorporated into liposomes ($LPIC_{inco}$). Without addition of carotenoids, serious lipid peroxidation was induced by iron, and the formation of TBARS was increased by around 120% (Figure 6). In the presence of carotenoids, the TBARS production was significantly reduced ($P < 0.05$) in both mixed and loaded liposomes, except for the liposomes loading canthaxanthin from 1.00% to 1.50%. Note that although lycopene (<1.00%) and canthaxanthin (0.25%) displayed significantly stronger $LPIC_{inco}$ than $LPIC_{mixed}$ ($P < 0.05$), at higher concentration, the effect was opposite. β-Carotene and lutein possessed stronger $LPIC_{inco}$, regardless of the concentration. At 1.25%, both β-carotene and lutein had the strongest $LPIC_{inco}$, with around 46% and 10% TBARS increase respectively, compared with $LPIC_{mixed}$ at around 80% and 75% in their direct mixture.

Table 1 shows that in the carotenoid−liposome mixture, the depletion of carotenoids did not show obvious concentration dependency. With the exception of lycopene at 2.00%, the retention rates of carotenoids in mixture (RR_{mixed}) were less than those in the liposomes (RR_{inco}). It was understandable because in mixed liposomal suspension, most of the carotenoids covered upon the membrane surface and directly reacted with pro-compounds. When incorporated into liposomes, the retaining ability of the lipid bilayer was highly affected by the type and concentration of the incorporated carotenoid. No significant differences in RR_{inco} for lycopene were found in the range of 0.25%−0.75% ($P > 0.05$), and the values were above 75%. Beyond this range, RR_{inco} decreased significantly ($P < 0.05$) which were even closer to RR_{mixed}. By contrast, liposomes strongly retained β-carotene and lutein in the wide concentration range of 0.25%−1.25% with RR_{inco} values above 70% and 80%, respectively. Note that the change tendency of RR_{inco} was consistent with $LPIC_{inco}$. Interestingly, the RR values of canthaxanthin still exceeded 70%, even though its $LPIC_{inco}$ was not pronounced.

The outcomes of the peroxidation assays are affected by the type and amount of initiator used in the system. The current study further employed the method which occurs under normal atmospheric oxygen conditions without addition of exogenous initiators, making the present model study more valid physiologically.[34] In addition, the method by monitoring the auto-oxidation of liposomes allowed us to observe the effects of carotenoids on the progress of peroxidation over a longer period of time compared with the conventional methods where membranes are exposed to higher concentration of free radicals over a shorter time period. Figures 7 and 8 show the change of TBARS in the carotenoid−liposome mixture and carotenoid-loaded liposomes during the auto-oxidation process, as well as the retention rate of the carotenoids. It was found that in the direct mixture, the addition of β-carotene, lutein, or canthaxanthin (especially at high concentrations) can retard and reduce the generation of TBARS, even though this $LPIC_{mixed}$ was not very pronounced (Figure 7). Meanwhile, the carotenoids were gradually depleted with prolonging the incubation time (Figure 8). Lycopene presented relatively effective $LPIC_{mixed}$ only at high concentration ranging from 1.00 to 2.00%. At lower concentrations, not only does the generated amount of TBARS product greatly increase, but also its RR_{mixed} decreases rapidly and greatly compared with the other carotenoids. Oxidation models initiated by peroxyl radicals also demonstrated that lycopene was destroyed most rapidly but was least effective as an antioxidant.[16] It was noted that both $LPIC_{mixed}$ and RR_{mixed} did not show obvious concen-

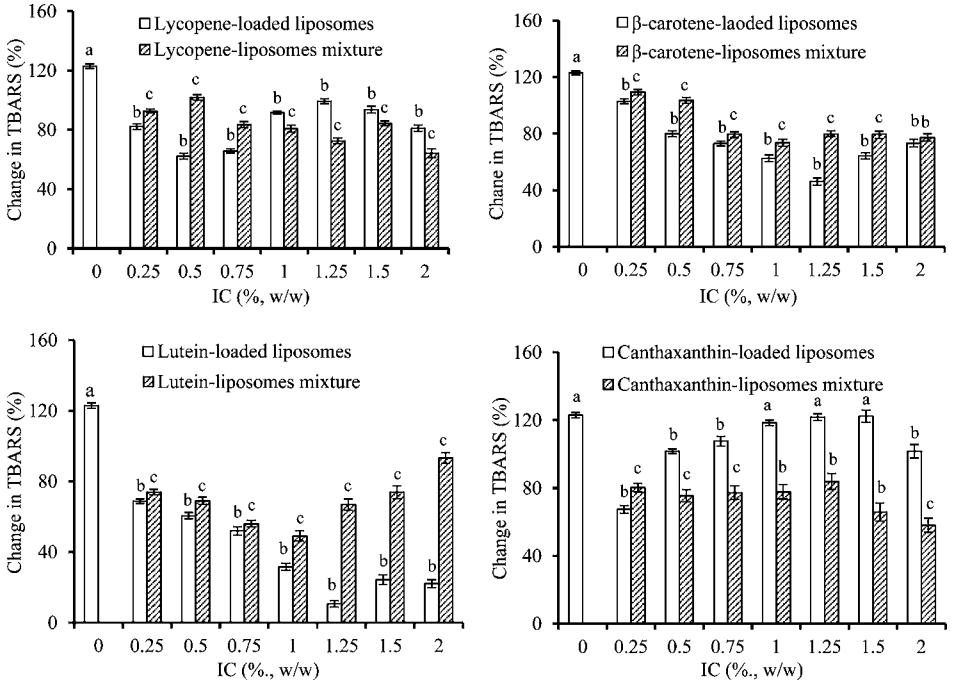

Figure 6. Effect of carotenoids either incorporated in liposomes or directly mixed with pure liposomes on the inhibition of thiobarbituric acid reactive substance (TBARS) formation in liposome system induced by Fe^{3+}/ascorbate. Each point represents the mean value ± standard deviation (n = 3). In each concentration, the increase of thiobarbituric acid reactive substance (TBARS) in pure liposomes, liposome-carotenoid direct mixture, and carotenoid-loaded liposome was compared with each other. Different letters represent a significant difference ($P < 0.05$).

Table 1. Retention Rates of Carotenoids in Liposomes (RR_{Inco}, %) and in Mixture (RR_{mixed}, %) as a Function of IC (%) after Lipid Peroxidation Induced by Fe^{3+}/Ascorbate Mixture[a]

	lycopene		β-carotene		lutein		canthaxanthin

[a]Results are expressed as mean value ± standard deviation (n = 3). Different letters represent a significant difference ($P < 0.05$).

tration-dependency, which may be due to the inhomogeneous dispersion of the system.

Lycopene (from 0.25 to 1.00%), when incorporated into liposomes, exhibited stronger $LPIC_{inco}$ than $LPIC_{mixed}$. The lipid peroxidation was retarded until 1 h, followed by a slight oxidation. Over a whole incubation period, the increase percentage of TBARS was kept below 30% (Figure 7). Furthermore, although their RR_{inco} gradually decreased, the values were maintained above 75% (Figure 8). At higher loading concentrations (>1.00%), however, liposomes began to be oxidized during the initial 0.5 h, even displaying a high degree of oxidation than pure liposomes. Additionally, the RR_{inco} of lycopene dramatically decreased, and after 2 h, the values were around 69% (1.25%), 65% (1.50%), and 62% (2.00%), respectively. By contrast, β-carotene and lutein exerted sustained and effective $LPIC_{inco}$ over the whole incubation period. In particular, in the range of 0.75%−1.25%, the generated TBARS amount as well as the depletion of carotenoids was almost leveled off after 1 h. β-Carotene and lutein displayed the strongest $LPIC_{inco}$ at 1.00% and 1.25%, respectively. The TBARS increase percentage was only 19% (β-carotene) and 13% (lutein), corresponding with the RR_{inco} values of around 85% and 90%, respectively. In the case of canthaxanthin, it seemed that its $LPIC_{inco}$ was strong only when incorporated at 0.25% and 0.50%. When the concentration increased further, the $LPIC_{inco}$ became less apparent, together with the appearance of a rapid oxidation process within 1 h. Besides, a highly concentration-dependent increase of depletion was observed. For liposomes with 2% canthaxanthin loading, their TBARS amount was increased by 44% at 2 h with around 30% depletion of incorporated canthaxanthin.

In addition to the direct reaction with pro-oxidant elements instead of lipids, the modulating effect of carotenoids on the physicochemical property of membrane could strongly control the $LPIC_{inco}$ of carotenoids. The effect of apolar carotenoid lycopene at low concentration, which guarantee a monomeric state of the pigment in the hydrophobic membrane core, may be negligible in the fluid state of the lipid phase.[35] Thus, the integrity of liposomal membrane was probably preserved, even though lycopene was incorporated into it. This conclusion can

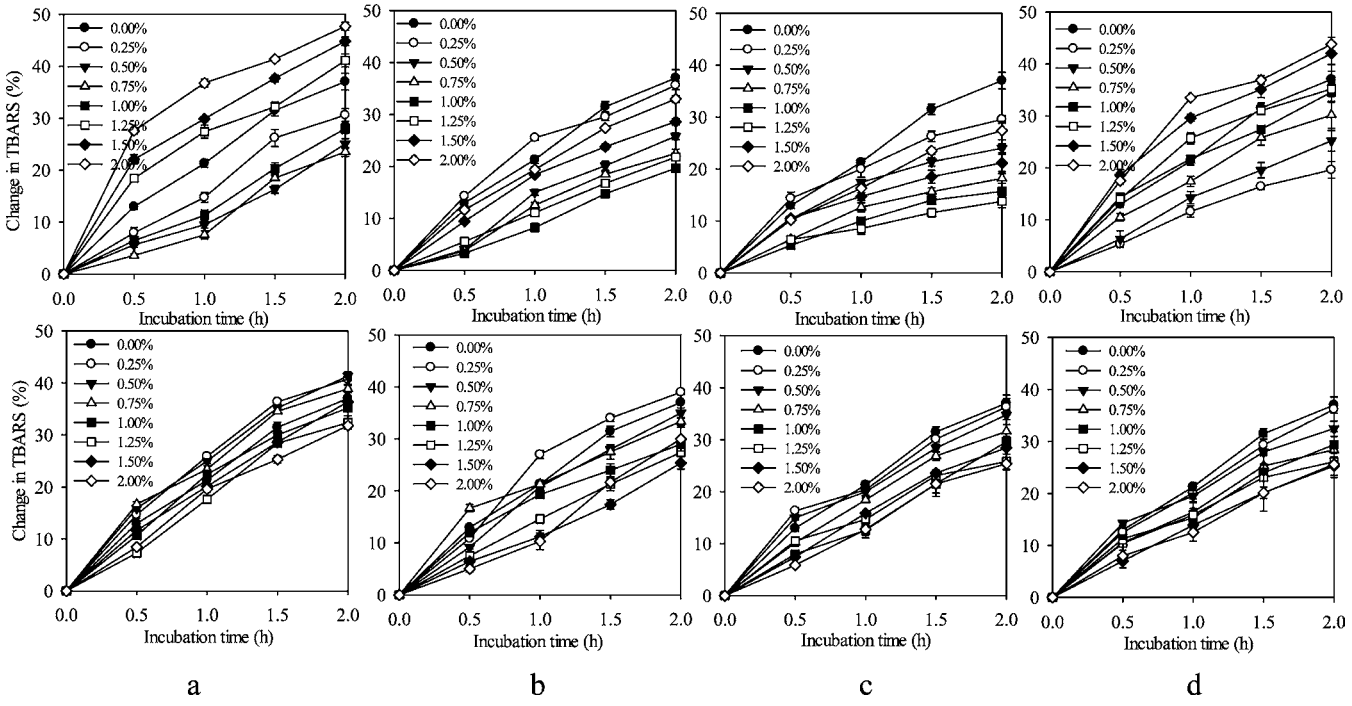

Figure 7. Effect of carotenoids either incorporated in liposomes (top image) or directly mixed with pure liposomes (bottom image) on the inhibition of thiobarbituric acid reactive substance (TBARS) formation in liposome system during 2 h incubation at 37 °C in an uncovered, shaking water bath. Lycopene (a), β-carotene (b), lutein (c), and canthaxanthin (d). Each point represents the mean value ± standard deviation (n = 3).

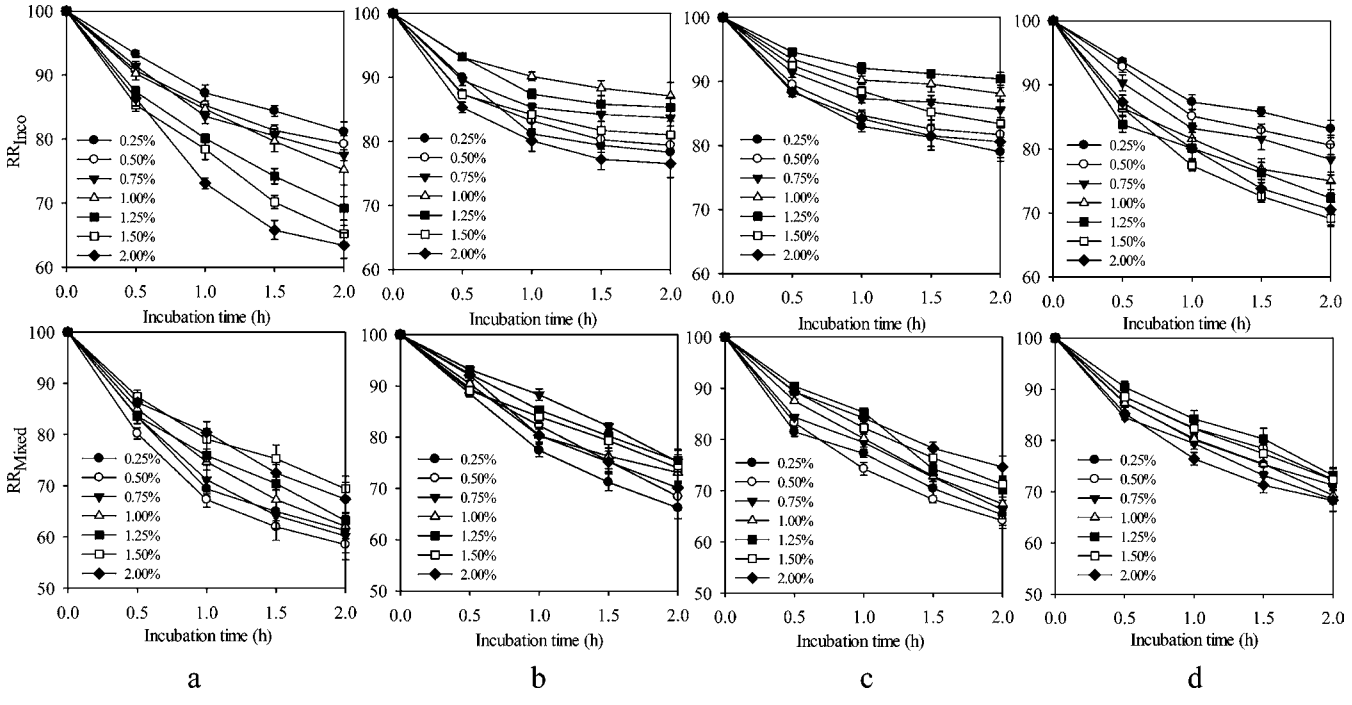

Figure 8. Retention rates of carotenoids in liposomes (RR_{inco}, %) and in mixture (RR_{mixed}, %) as a function of IC (%) during auto-oxidation of liposomes at 37 °C in an uncovered, shaking water bath. Lycopene (a), β-carotene (b), lutein (c), and canthaxanthin (d). Each point represents the mean value ± standard deviation (n = 3).

explain why lycopene (<1.00%) was not only effectively retained in hydrophobic core, but also displayed a certain antioxidation in each lipid peroxidation assay. However, with further increase in the concentration, lycopene probably disturbed the order of the lipid acyl chains and increased the motional freedom of lipids in the headgroup region, although the apolar carotenoid remained in the hydrophobic core, as supported by X-ray diffraction[34] and nuclear magnetic resonance.[31] Such a disturbing effect could decrease the penetration barrier for molecular oxygen and other small molecules to the liposomal membrane. As a consequence, lycopene was rapidly degraded by iron or oxygen, and the lipid was not effectively protected from peroxidation. Even lycopene displayed a pro-oxidation property during liposome preparation

dx.doi.org/10.1021/jf405622f | J. Agric. Food Chem. 2014, 62, 6726−6735

and autoperoxidation process. Our findings were consistent with those of Woodall et al.[16] that, in EYPC liposomes, the lycopene showed a high rate of destruction but poor protection against lipid peroxidation.

Owing to the vertical orientation, lutein can exert a rigidifying effect on the fluidity and order of the polar lipid heads and hydrophobic core.[36] Consequently, the liposomal membrane was less susceptible to the inversion of small molecules because lutein restricts not only the membrane permeation of polar molecules,[37] but also the depth of ion penetration into the bilayer.[38] This effect was also possible for β-carotene, in case it adopted a flexible orientation (Figure 1). In turn, the resultant compact membrane reduced the change of the direct reaction of carotenoids with an external pro-compound. Taking these points into consideration, it is understandable that the incorporation of lutein and β-carotene effectively inhibited the lipid peroxidation induced either by ferric iron or oxygen, while their own depletion was small. Furthermore, the $LPIC_{inco}$ of lutein was positively correlated with its incorporated concentration in the range of 0.25%−1.25%, as the more lutein incorporated, the more pronounced the rigidifying effect became. Nevertheless, it should be pointed out that at 1.50% and 2.00%, both lutein and β-carotene exhibited a decrease of antioxidant capacity to some extent. It was very likely due to the variation of location and orientation. In particular, in the case of lutein, parts of the molecules were probably horizontally oriented to the membrane plane owing to the terminal hydroxyl-containing ring having relative rotational freedom in structure (Figure 1).[39] As a result of this structural feature, lutein could produce a disturbing effect on the membrane structure and display similar antioxidation as apolar carotenoids do.[34]

Canthaxanthin tended to adopt vertical fashion as lutein did, concomitantly, exerting the rigidifying effects.[40] However, in each lipid peroxidation model, $LPIC_{inco}$ was pronounced only at 0.25%. Obviously, the incorporation tendency into the lipid bilayer limited its antioxidant efficiency. From 0.50%, canthaxanthin exerted very weak antioxidation or even pro-oxidation. There is a possibility that (in the case of lutein) a certain fraction of canthaxanthin adopts an horizontal orientation with respect to the plane of the lipid bilayer and links different polar lipid heads via hydrogen bonding.[40] The population of the horizontal fraction increases with the increase in the concentration of the pigment in the lipid phase. The resultant disturbing effect may explain, in part, the appearance of pro-oxidation. It was interesting to find that although canthaxanthin led to destabilization of liposomes, the depletion of its own was not considerable compared with lycopene. The proposed fact was that the electron withdrawing effect of the C═O groups in canthaxanthin resulted in low reactivity of the β-ring, which would be the first part encountered by aqueous radicals.[16]

CONCLUSIONS

This study investigated the influence of liposome encapsulation on the antioxidant activity of four kinds of dietary carotenoids. Through the antioxidant models, including DPPH, FRAP, and lipid peroxidation inhibition capacity, it has been demonstrated that carotenoid encapsulation in liposomes enhanced their antioxidant activity. Additionally, carotenoids exhibited various antioxidant activities in liposomes, ranging from the strongest to the weakest: lutein > β-carotene > lycopene > canthaxanthin. Furthermore, it was revealed that lutein and β-carotene incorporation not only inhibited the lipid peroxidation, but also protected them against pro-oxidation elements. By contrast, lycopene and canthaxanthin showed a high rate of destruction, but poor protection against lipid peroxidation. Conclusively, these findings were strongly correlated with the incorporation efficiencies of the aforementioned carotenoids into liposomal membrane and their modulating effects on the membrane dynamics and structural properties.
