public associated with improved nutritional properties, which led to increasing demand for organic vegetables.[15] However, there is a need for better scientific data to prove whether the hypotheses like "organic tomatoes contain more health-promoting compounds" or "some tomato cultivars are more suitable for cultivation in organic conditions than others" are true. Oliveira et al.[16] have found significantly higher content of vitamin C, soluble solids, and total phenolics in organically cultivated tomato fruits. At the same time, the authors also state that the dimensions of organic fruits were smaller. Rembialkowska[17] has shown in a review article that organic plant products contain more vitamin C, phenolic compounds, and minerals (Fe, Mg, P). Similar conclusions, pointed out by Hunter et al.,[18] showed higher contents of micronutrients in organic vegetables, cereals, and legumes. The higher contents of phenolic compounds in organic agricultural crops has also been confirmed by Brandt et al.,[19] Lima and Vianello,[20] and Lairon.[21] However, opposing views have been reported by Rosen[22] and Dangour et al.,[23] according to whom there is no difference in the chemical composition of organic and conventional food. Many factors may determine the level of secondary plant metabolites, polyphenols, and antioxidants in the plant food. Some factors depend on the cultivation conditions, plant genetics, agricultural practices, meteorological factors, soil fertility, pest-related factors, harvest time, and maturity of the crops.[24]

The aim of this study was to determine the differences in polyphenols contents, antioxidant capacities, and total phenolic contents in four tomato cultivars grown in organic and conventional conditions; to get more information about the polyphenolic composition and their antioxidant capacity in fruits of tomato cultivars bred in Estonia; and to evaluate the influence of cultivars, cultivation systems, and weather conditions in the growing years.

MATERIALS AND METHODS

Plant Material. The experiment was carried out in three consecutive years (2008−2010). Plants of four tomato cultivars were grown at the Jõgeva Plant Breeding Institute (58°44′N, 26°24′E), in two unheated plastic greenhouses, one for conventional and another for organic cultivation. Greenhouses with similar size and construction were located next to each other. Soil at the site was classified as a soddy−podzolic sandy loam. Every autumn soil was fertilized with cattle manure (60 t ha^{-1}) and enriched with peat (40 t ha^{-1}) incorporated into soil. For basic fertilization, the conventional experimental area was fertilized with a compound fertilizers including 90 kg ha^{-1} N, 60 kg ha^{-1} P, and 170 kg ha^{-1} K (plus other macro- and micronutrients).The seeds were sown in the heated greenhouse in March, transplanted twice, and planted in the middle of May in unheated greenhouses in double rows, six plants per plot, three replications per cultivar in different parts of greenhouses. Substrate for conventionally cultivated seedlings and transplants was a peat-based mixture fertilized with 2 kg m^{-3} PeatCare 11−25−24 (Kemira GrowHow) and 0.5 kg m^{-3} magnesium sulfate, mixed with dolomite lime (7 kg m^{-3}). Substrate for organically cultivated seedlings and transplants was peat mixed with dolomite lime (7 kg m^{-3}) and enriched with chicken manure pellets (1 L of pellets per 50 L of peat).

During the growing period, once or twice a week the plants were irrigated through tubes installed in the soil. The conventional experimental area was fertilized with 50 kg ha^{-1} N and 60 kg ha^{-1} K. The organic experimental area was fertilized with humic acids solution (fertilizer Humistar diluted by 1:50), resulting in a total supply of 0.6 kg ha^{-1} K, and with fermented nettle infusion 1:5 three times during the growing period. Tomatoes were grown without any pesticides in the organic and conventional area. Red-ripe tomato fruits were harvested in the beginning of September. Six fruits per replication of Maike, Malle F1, and Valve and 20 fruits of Gartenfreude were harvested. Fruits equal in size and ripeness were carefully selected to form the best representative samples for each cultivar.

Four tomato cultivars, Maike, Malle F1, Valve, and Gartenfreude, were selected for the tests. The first three cultivars have been bred in Estonia, at the Jõgeva Plant Breeding Institute (registered as new cultivars in 2003, 2004, 2003, respectively). In the previous years these cultivars have shown good results in yields and disease resistance. All the cultivars are early ripening type; the first fruits ripen within 105−115 days after germination, and the ripe fruits have red color. Maike is a determinate (with limited growth) cultivar with multibranched bunch and round, smooth fruits with average weight of 60−65 g. Malle F1 is an indeterminate (with unlimited growth) cultivar with uniform, medium-sized, slightly flattened fruits weighing about 80−90 g. Valve is a semideterminate cultivar with a single or multibranched bunch and with round or slightly elongated fruits weighing about 95 g. Gartenfreude is an indeterminate, cherry-type, high-yield cultivar with round-shaped fruits that are 2 cm in diameter and of an average weight of 15−20 g.

Weather Conditions in the Years 2008−2010. In the early summer of 2008 (May, June), the weather was warm, dry, and windy with very low relative air humidity. The end of June and all of July and August were rainy and cool. September was cloudy and the total sum of active air temperature (>10 °C) was 155 °C, which is 59 °C lower than the long period average (LPA, 80 years).

In 2009, the second half of May was cold and rainy, and low temperatures (even frosts) at night did not support plant growth. The first half of June was unusually warm (over 29 °C), but the second half was cold and very rainy (120−240% of normal). In the beginning of July, the temperature varied a lot, from 29 °C at daytime to frosts at night. August was cooler and rainier than usual; inversely, September was extremely warm with a total sum of active air temperature of 329 °C (LPA, 218 °C) with little rain.

May 2010 was extraordinarily warm, but temperatures in June were below the average level. Inversely, July and half of August were extremely warm. Weather favored the plant species that require a lot of heat. In the second half of August and in September, the temperatures dropped but still remained higher than average (the total sum of active air temperature was 241 °C, which was 23 °C more than the LPA).[25]

Sample Preparation and Extraction. Organically and conventionally grown tomato fruits, three samples of each cultivar, were taken to the laboratory and kept at room temperature overnight. The next day tomato fruits were washed, dried, sliced into segments, and divided into three groups: for hot air-drying at 45 °C in a ventilated drier Binder FED 53 (Binder GmbH, Tuttlingen, Germany), homogenization, and freeze-drying for previous and further experiments. In this study, the air-dried material was ground into fine powder using a Foss Knifetec 1095 (Foss Tecator, Höganäs, Sweden) laboratory mill, passed through a sieve, and additionally ground in a mortar. Samples were extracted without hydrolysis of glycosides. For extraction, 0.5 g of tomato powder was weighed and 5 mL of 80% (v/v) aqueous methanol (Romil Ltd., Cambridge, UK) was added. The samples were placed into a Biosan Multi RS 60 (BioSan, Riga, Latvia) rotator for 5 h and left at room temperature overnight. The next day the samples were centrifuged at 20 °C at 3220*g* for 10 min using an Eppendorf 5810 R (Eppendorf AG, Hamburg, Germany) centrifuge, and supernatant was poured into another tube. The samples were re-extracted with an additional 5 mL of 80% (v/v) aqueous methanol. After centrifugation, two supernatants were mixed and filtered through a 0.45 μm syringe filter, 20 μL of (0.8 mg mL^{-1}) daidzein methanol solution as internal standard was added, and samples were stored at −40 °C prior the chromatographic analysis.

Chromatographic Analysis. Single phenolic compounds were detected, identified, and quantified using tandem liquid chromatography with diode array detection−mass spectrometry (HPLC-DAD−ESI-MS/MS) in the negative ion mode at an Agilent 1100 Series (Agilent Technologies, Santa Cruz, CA) system, consisting of a binary pump, vacuum degasser, autosampler, thermostated column department, diode array detector, and ion trap analyzer with electrospray ionization (ESI). For the separation of compounds, a reversed-phase

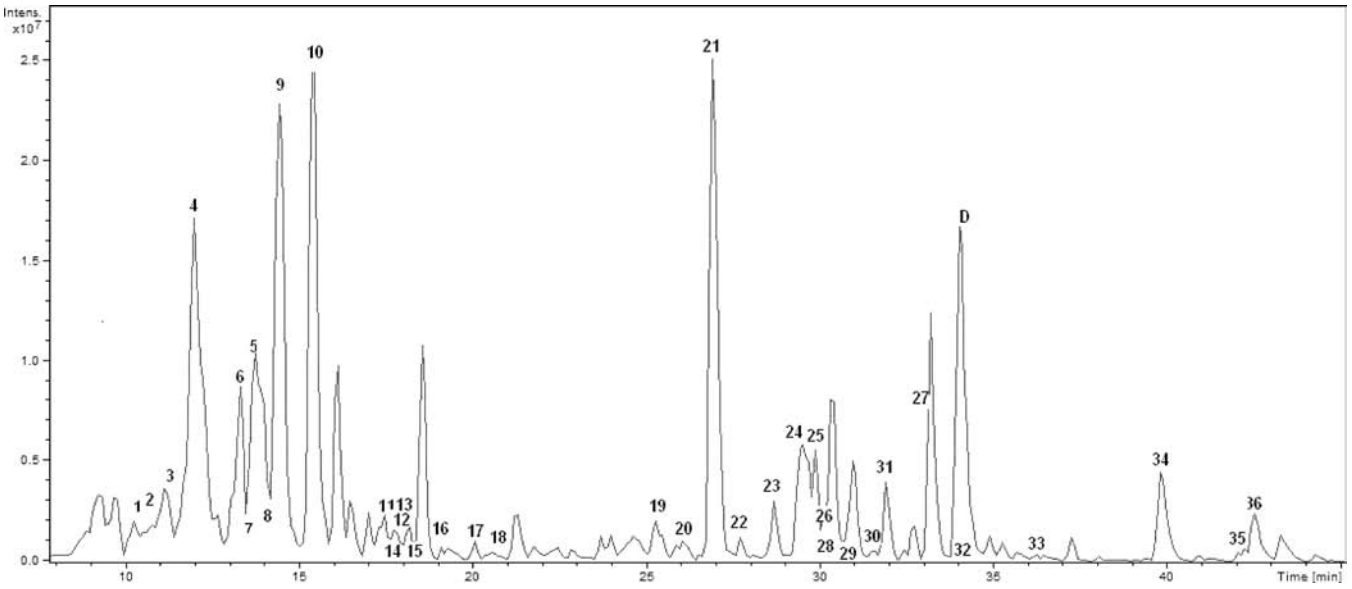

Figure 1. Phenolic compounds identified by HPLC−MS/MS in tomato fruit in negative ionization mode. MS-base peak chromatogram of the conventionally grown cultivar Gartenfreude (2010). Peak numbers designate identified compounds: **1**, **2**, **3**, **4**, and **5**, caffeic acid hexosides; **6**, homovanillic acid hexoside; **7**, caffeic acid; **8**, *p*-coumaroyl hexoside; **9**, chlorogenic (3-caffeoylquinic) acid; **10**, cryptochlorogenic (4-caffeoylquinic) acid; **11**, neochlorogenic (5-caffeoylquinic) acid; **12** and **13**, apigenin hexosides; **14**, *p*-coumaric acid; **15**, naringenin dihexoside; **16**, rutin hexoside; **17**, apigenin acetylhexoside; **18**, ferulic acid; **19**, eriodictyol hexoside; **20**, quercetin dihexoside; **21**, quercetin rutinoside (rutin); **22**, kaempferol rutinoside pentoside; **23**, phloretin dihexoside; **24**, naringenin glucoside; **25**, dicaffeoylquinic acid I; **26**, dicaffeoylquinic acid II; **27**, dicaffeoylquinic acid III; **28**, kaempferol rutinoside; **29**, naringin; **30**, caffeic acid derivative; **31**, dihydrocaffeic acid dihexoside; **32**, eriodictyol; **33**, quercetin; **34**, naringenin; **35** tricaffeoylquinic acid; **36**, naringenin chalcone; **D**, daidzein (internal standard).

(RP) Zorbax 300SB-C18 column (2.1 × 150 mm, 5 μm; Agilent Technologies) was used. The mobile phase gradient was formed of 0.1% formic acid (Fluka Chemie GmbH) (solvent A) and acetonitrile (Romil Ltd., Cambridge, UK) (solvent B), and stepwise gradient elution program was from 1% solvent B up to 28% in 1−45 min, in 45−55 min solvent B concentration was raised up to 95% and remained there for 5 min. Subsequently, the solvent B content was decreased to the initial conditions and for 13 min the column was re-equilibrated. The total run time was 73 min. The column flow was 0.3 mL min^{-1} and the thermostat was regulated at 35 °C. The injection volume of samples was 4 μL. The conditions of MS/MS detection were as follows: m/z interval, 50−1000 amu; target mass, 400 amu; number of fragmented ions, two; maximal collection time, 100 ms; compound stability, 100%; drying gas (N_2 from agenerator) speed, 10 L min^{-1}; gas temperature, 350 °C; gas pressure 30 psi; collision gas (He) pressure, 6×10^{-6} mbar. Data were collected and analyzed by an Agilent 2D ChemStation Software with a ChemStation Spectral SW module. Phenolic compounds were tentatively identified by their retention time, mass to charge ratio (m/z), UV spectra, and MS fragmentation spectra reported in the literature. Eight commercially available standards: caffeic acid, chlorogenic acid, *p*-coumaric acid, ferulic acid, rutin, naringin, quercetin, and naringenin (Sigma-Aldrich Chemie GmbH, Steinheim, Germany) were used to confirm the identification.

Determination of Total Phenolic Content. The content of total phenolics was determined spectrophotometrically with the Folin−Ciocalteau reagent (Sigma-Aldrich Chemie GmbH, Steinheim, Germany) according to the method described by Waterhouse.[26] The absorbance was measured at 765 nm using an AnalyticJena Specord 200 spectrophotometer (AnalyticJena AG). Gallic acid (Sigma-Aldrich Chemie GmbH, Steinheim, Germany) was used as the standard, and the results were expressed as gallic acid equivalent (GAE) milligrams per gram of dry matter.

Antioxidant Capacity Assay. The DPPH (2,2-diphenyl-1-picrylhydrazyl) free radical scavenging assay was performed according to the method described by Helmja et al.[27] and Lee et al.[28] with some modifications. The absorbance was measured at 515 nm using an AnalyticJena Specord 200 spectrophotometer (AnalyticJena AG). A solution of DPPH (Sigma-Aldrich Chemie GmbH, Steinheim, Germany) in methanol (23.7 mg L^{-1}) was freshly prepared, 100 μL of tested extracts was mixed with 3900 μL of DPPH solution, and the absorbance results were recorded immediately after mixing and after every 10 min during a 60 min period until a steady state of the reaction was registered. The reference cuvette (blank) contained 80% (v/v) aqueous methanol. The percentage inhibition was calculated by the formula:

$$\%\text{inhibition} = [(\text{Abs}_0 - \text{Abs}_{\text{sample,60min}})/\text{Abs}_0] \times 100$$

As a reference compound and a positive control, *tert*-butyl-1-hydroxytoluene (BHT, Sigma-Aldrich Chemie GmbH, Steinheim, Germany) was used. The results were expressed as millimole of BHT equivalents per gram of dry matter.

Statistical Analysis. Four tomato cultivars grown conventionally and organically were analyzed in triplicate. MS extracted ion chromatogram (EIC) peak areas were used in statistical analyses to compare the polyphenols contents of organically and conventionally cultivated tomato fruits. The principal component analysis was applied to find the common patterns in single phenolic compounds. Two- and three-way ANOVA was applied to test the statistical significance of cultivar, year, and cultivation method effect on single polyphenols, on the total content of polyphenols evaluated as a sum of contents of single polyphenols, and on the total phenolic content and antioxidant capacity. Pearson correlation analysis was used to estimate the relationships between single polyphenols, total phenolic content, and antioxidant capacity. All statistical analyses were conducted using R statistical software (version 2.14.1) and STATISTICA software (version 10.0). All image manipulations were done using R statistical software, open source Inkscape Vector Graphics Editor (version 0.48.3.1), and MS Excel 2010.

RESULTS AND DISCUSSION

Several previous studies have compared[29−32] qualitative characteristics in relation to different tomato cultivars and growing conditions. In our study, we focused on identified phenolic acids and flavonoids reported by Helmja et al.,[27] Moco

dx.doi.org/10.1021/jf500792k | J. Agric. Food Chem. 2014, 62, 5173−5180

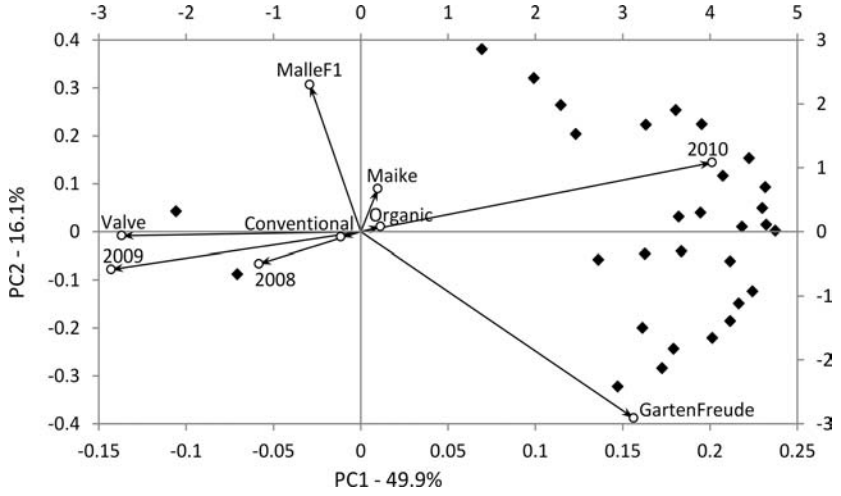

Figure 2. Principal component analysis (PCA) biplot expressing the relation of the first two principal components with polyphenols (black rhombus according to the primary axes) and average scores by cultivars, years, and cultivation methods (arrows according to the secondary axes).

et al.,[33] Martínez-Valverde et al.,[34] Gómez-Romero et al.,[3] and Slimestad and Verheul.[35] Differently, in sample preparation we did not use hydrolysis, and therefore, the main identified compounds are glycosylated. Six identified aglycons, which showed very low levels, were excluded from the statistical analysis.

Single Polyphenols. Kähkönen et al.[36] reported that synthesis of phenolic compounds in plants is greatly influenced by the internal factors like genetics, nutrients, and enzymes, as well as by the external factors like sunlight, temperature, and humidity. Since in our experiment the greenhouses were situated close to each other, the same degree of illumination, hours of daylight, temperature, and humidity for all plants could be expected.

When analyzing the chemical constitution of tomato fruits, particular attention was paid to polyphenols, which are naturally present in plants, fruits, berries, and vegetables. In tomatoes, polyphenols comprise basically phenolic acids and flavonoids, and 36 phenolic compounds (numbered peaks in Figure 1) were identified tentatively or by comparison with authentic standards. Unmarked peaks in Figure 1 may belong to other classes of compounds (e.g., amino acids, fatty acids) eluting at the same retention time as phenolic acids and flavonoids. Some compounds had several peaks or isomers that eluted at different retention times. Following the list of phenolic compounds described by Gómez-Romero et al.,[3] there were several compounds in our cultivars that we could not detect, or it was not possible to identify them by fragmentation because of their very low contents.

In our samples, phenylacetic acids were represented by homovanillic acid, and hydroxycinnamic acids that formed the main phenolic acids subgroup were represented by caffeic, chlorogenic, *p*-coumaric and caffeoylquinic acids and their derivatives. Mattila and Kumpulainen[37] reported that the most common hydroxycinnamic acid derivatives frequently occur in tomatoes as simple esters with quinic acid or glucose. Chlorogenic acids and related compounds are the main phenolic compounds besides flavonoids in tomatoes. Chlorogenic acids are good antioxidants, but they may be also responsible for a somewhat astringent taste of tomato fruits.[35]

Identified flavonoid glycosides belong to the subgroups of flavones (apigenin), flavonols (quercetin, kaempferol), flavanones (eriodictyol, naringenin), dihydrochalcones (phloretin), and chalcones (naringenin chalcone). Caffeic acid hexoside, chlorogenic acid, and quercetin rutinoside (rutin) were the main phenolic constituents in our tested tomato fruits.

Chalcones and dihydrochalcones are precursors in the flavonoids biosynthesis pathway and are widely investigated for their chemopreventive and antitumor activity,[38] but there is limited knowledge about their contents in tomatoes. In 2008, Slimestad et al.[39] described for the first time a compound representing dihydrochalcones in tomatoes, phloretin dihexoside, as dihydrochalconaringenin (phloretin) 3′,5′-di-C-*β*-glucopyranoside and confirmed the structure by NMR. A powerful antioxidant but unstable naringenin chalcone has been found in great amounts in fresh tomatoes,[39] but in our study we found quite low amounts of naringenin chalcone. Most probably, during sample drying at 50 °C and the extraction procedure this polyphenol was converted into other compounds.

Principal Component Analysis (PCA). The principal component analysis of the whole data set shows that the most common pattern in phenolic compounds reflects the differences between years (Figure 2). All detected compounds except apigenin hexosides (black rhombus on the left side of Figure 2) show the higher values for the year 2010 and lower values for 2008 and 2009. The second principal component mainly distinguishes the cultivars Malle F1 and Maike from Gartenfreude. The difference between cultivation methods is only fractional.

On the basis of the results, we need to bring out the fact that some phenolic compounds had higher concentrations only in one cultivar in all three years either in conventional or organic fruits, e.g., eriodictyol hexose in cultivar Maike organic fruits and in cultivar Valve conventional fruits. Obviously, these compounds were more influenced by cultivation mode than by weather conditions. In all three years, but only in one cultivar, Maike had four compounds with higher concentrations for the organic fruits and five compounds (out of 30) for conventionally grown fruits. Cultivar Malle F1 showed higher concentrations for 17 compounds in organic fruits and none of the compounds in the conventional fruits. Cultivar Gartenfreude had six compounds with higher concentrations in favor of the organic and four in the conventional cultivation method. Cultivar Valve had higher contents of two compounds in

dx.doi.org/10.1021/jf500792k | J. Agric. Food Chem. 2014, 62, 5173−5180

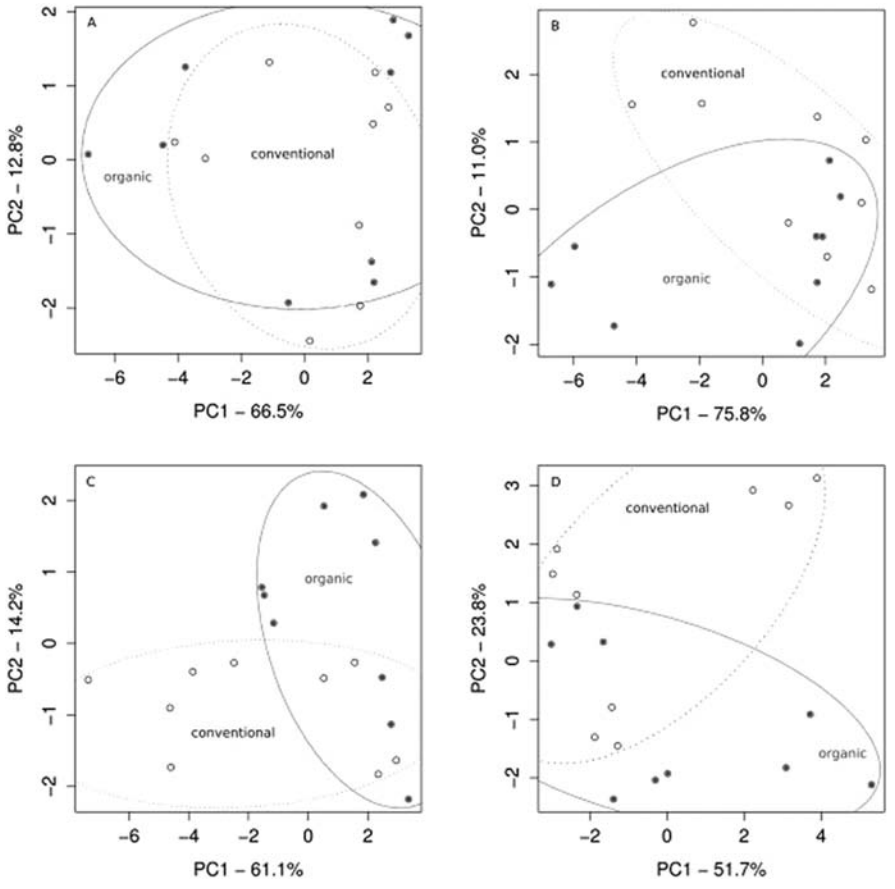

Figure 3. Biplots of principal component analysis (PCA) scores expressing the differentiation of polyphenols in organically and conventionally grown tomato cultivars: Maike (A), Malle F1 (B), Valve (C), and Gartenfreude (D).

organically grown fruits and eight compounds in conventionally grown fruits.

When the PCA was applied separately to all four studied tomato cultivars, these otherwise minor differences between cultivation methods could easily be observed (Figure 3). It is interesting to note that the effect of the cultivation method was cultivar dependent. When differences between the organic and conventionally grown Malle F1 were clearly distinguishable on the PCA biplot, the phenolic composition of cultivar Maike showed no difference.

Impact of Cultivars on the Content of Polyphenols. While using three-way ANOVA analysis we observed that the content of almost all polyphenols, except one isomer of apigenin hexoside and caffeic acid hexoside, was statistically significantly affected by cultivar ($P < 0.001$). Fruits of cultivar Gartenfreude had the highest contents of 19 compounds out of 30, while the fruits of cultivar Valve had the lowest contents of 18 compounds out of 30. The total content of polyphenols of cultivar Gartenfreude was the highest but had no statistically significant differences from Maike and Malle F1. Cultivar Valve differed from other cultivars Gartenfreude ($P < 0.001$), Maike ($P < 0.05$), and Malle F1 ($P < 0.05$), having the lowest total content of polyphenols. Martínez-Valverde et al.[34] also concluded that the concentration of various phenolic compounds as well as the antioxidant capacity was significantly influenced by the tomato cultivar.

In our study, all identified compounds were found in all tested cultivars in lower or higher amounts. It is essential to mention that in all three consecutive years and in both cultivation modes an extremely low amount of apigenin acetylhexoside was found in fruits of cultivars Gartenfreude and Valve ($P < 0.001$), compared with cultivars Maike and Malle F1. Also Gómez-Romero et al.[3] found that the presence of apigenin acetylhexoside was greatly cultivar-dependent.

Impact of the Growing Year on the Content of Polyphenols. While assessing the influence of the year we can report that the content of all polyphenols was affected by the year ($P < 0.001$). Hallmann[32] also pointed out that growing season has a large impact on the variability of content of phenolic compounds. As the weather conditions varied between the years greatly, it also impacted the content of polyphenols, and all three years were significantly different. The levels of detected compounds (except apigenin hexosides) as well as the total content of polyphenols in all cultivars were the highest in 2010 ($P < 0.001$) due to very good weather conditions in September and the lowest levels were in 2009 ($P < 0.001$), which can be explained by the cold and rainy weather during the harvesting period. Despite the fact that the growing period in 2008 was rainy and suitable for spreading gray mold, the percentage of damaged fruits in all cultivars was low. We suppose that the cultivars themselves had good resistance characteristics or the suitable concentration of phenolic compounds, with higher content in 2008 compared with year 2009.

Impact of Cultivation Method on the Content of Polyphenols. In the current study under these growing conditions the cultivation method had generally minor impact on the content of phenolic compounds (Figure 2). We found

dx.doi.org/10.1021/jf500792k | J. Agric. Food Chem. 2014, 62, 5173−5180

that some compounds had higher content in all cultivars only in one year. In 2008, the higher contents of naringenin chalcone ($P < 0.01$), naringenin glucoside ($P < 0.001$), phloretin dihexoside ($P < 0.05$), and neochlorogenic acid ($P < 0.05$) were found in all organic fruits and quercetin dihexoside ($P < 0.05$) in conventional fruits.

In 2010, the same findings were observed for caffeic acid derivative ($P < 0.05$), dihydrocaffeic acid dihexoside ($P < 0.01$), phloretin dihexoside ($P < 0.05$), apigenin acetylhexoside ($P < 0.01$), chlorogenic acid ($P < 0.05$), *p*-coumaroyl hexoside ($P < 0.05$), homovanillic acid hexoside ($P = 0.01$), caffeic acid hexoside I ($P < 0.05$). The exception is naringenin dihexoside, which was found in higher content in conventionally grown fruits ($P < 0.01$).

Considering the effects of cultivar and year with three-way ANOVA, we found that there still exist several compounds showing statistically significant differences between cultivation methods generally. We can highlight three compounds (with statistical significance $P < 0.001$), phloretin dihexoside, caffeic acid hexoside I, and apigenin acetylhexoside, whose contents were higher in the organic fruits irrespective of years and cultivars. The results are displayed as a volcano plot (Figure 4).

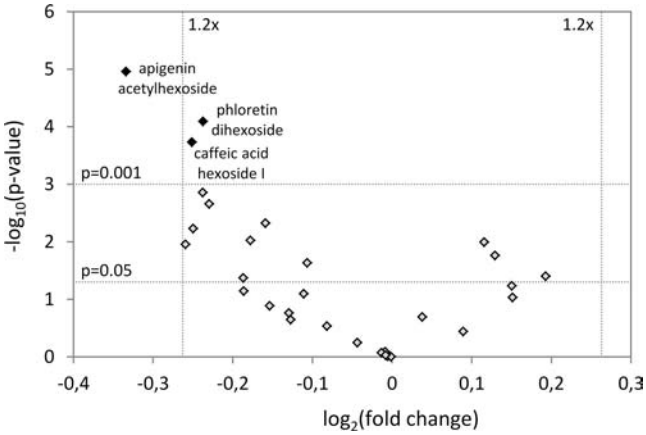

Figure 4. A volcano plot, where the *X*-axis represents the difference between organic and conventional cultivation methods and the *Y*-axis represents the statistical significance of the difference evaluated according to the three-way ANOVA considering effects of cultivar, year, and cultivation method. Every individual compound is displayed as a point. Negative values on the *X*-axis represent compounds that accumulate better under organic practices and vice versa. Statistically significantly ($P < 0.001$) different compounds are presented with names.

Comparing organic and conventional fruits of different cultivars grown in 2008−2010, organically cultivated cultivars Gartenfreude and Malle F1 had statistically significantly higher total contents of polyphenols than the organically cultivated cultivar Valve ($P < 0.01$, $P < 0.05$, respectively). Contrary, fruits of the cultivar Valve had the best results in the conventional growing system. This finding can be used in selection of tomato cultivars for cultivation systems.

Total Phenolics Content. Different methods can be used to determine the antioxidant capacity. In our study we used total phenolics assay by the Folin−Ciocalteu reagent and free radical scavenging method with DPPH. Both methods are the most frequently used techniques based on electron transfer from the antioxidant and color change of the oxidant in the reaction.[40]

The means and standard deviations of triple analysis are shown in Table 1. The total phenolic contents were the highest in conventional Gartenfreude in 2010 and the lowest in organic Maike in the same year, ranging from 5.70 to 8.54 mg GAE g^{-1} DW, respectively. Compared with others, cultivar Gartenfreude had higher content of total phenolics in all three years ($P < 0.001$). Comparing total phenolics contents in organic or conventional fruits of cultivars Maike, Gartenfreude, and Valve, there was no statistically significant difference in growing systems. Statistically higher total phenolics content was found only for cultivar Malle F1 in 2008 in conventional cultivation and in 2010 in the organic system ($P < 0.005$ and $P < 0.05$, respectively). According to the three-way ANOVA, the total phenolics contents were affected only by cultivar ($P < 0.001$).

Free Radical Scavenging Capacity. Antioxidant capacity results, presented in Table 1, show the highest DPPH radical scavenging capacity in three consecutive years ($P < 0.001$) in fruits of the cherry-type cultivar Gartenfreude. These results can be explained by the highest levels of several polyphenols and other compounds having high antioxidant capacity. None of the cultivars showed higher radical scavenging results either in organic or conventional system in all three years. Obviously, the antioxidant capacity of tomato extracts is not clearly influenced by cultivation mode, although the results were slightly in favor of the conventional cultivation. In the three year experiment, the free radical scavenging capacity depended first of all on cultivar ($P < 0.001$). The descending order of cultivars by the antioxidant capacity was again Gartenfreude, Malle F1, Maike, and Valve. Although in the organic fruits of cultivar Malle F1 17 polyphenols had higher contents in all three years, the radical scavenging tests did not confirm better results in favor of organic fruits of this cultivar. Polyphenols provide only part of the total antioxidant capacity and the remaining is the result of lycopene, vitamin C and other compounds.

Nevertheless, a strong positive correlation between total phenolics content and free radical scavenging capacity with $r = 0.80$ ($P < 0.001$) shows the leading role of polyphenols in the overall scavenging effect. The polyphenols having the strongest statistically significant ($P < 0.001$) positive correlation with free radical scavenging capacity of tomato samples were rutin hexoside ($r = 0.75$), dihydrocaffeic acid dihexoside ($r = 0.72$), eriodictyol hexoside ($r = 0.64$), homovanillic acid hexoside ($r = 0.61$), naringenin glucoside ($r = 0.59$), caffeic acid hexoside II ($r = 0.59$), phloretin dihexoside ($r = 0.53$), and dicaffeoylquinic acids ($r = 0.53$).

In summary, it was found that the growing year and cultivar had a major impact on the variations in the content of individual polyphenols, total phenolic contents, and free radical scavenging capacity of tomato fruits. The cultivation method, organic or conventional, affected some of the polyphenolic constituents of tomato fruits, but the direction of the effect was usually dependent on the cultivar. The contents of several polyphenols in single years were significantly influenced by the cultivation system. Especially three of them, apigenin acetylhexoside, phloretin dihexoside, and caffeic acid hexoside I, were positively influenced by the organic cultivation method in the fruits of all cultivars in all three years.

The results indicate that the cherry-type tomato Gartenfreude clearly differed from the other cultivars, having the highest free radical scavenging capacity, total phenolics, and several individual polyphenols contents. This phenomenon can be explained by smaller dimensions of the fruits of this cultivar

Table 1. Total Phenolics Content (mg GAE g^{-1} DW) and Antioxidant Capacity (mmol BHT equiv g^{-1} DW) of Four Tomato Cultivars Grown in Organic and Conventional Conditions in 2008−2010[a]

and accumulation of the polyphenols mainly in the peel. The cultivars Malle F1 and Gartenfreude showed higher overall polyphenols content when grown organically. These cultivars are evidently more reasonable for organic cultivation; cultivar Valve, on the contrary, is more appropriate for conventional cultivation, accumulating more phenolic compounds under these cultivation conditions. For the cultivar Maike, the weather conditions in growing years affected the chemical composition more than the cultivation method.

[a]R = A/G, Y = C/T; restriction sites incorporated into the primers are underlined.

Restriction endonucleases and DNA polymerase LA *Taq* were purchased from TaKaRa Corporation (Japan). DNA polymerase *Pfu* was obtained from Promega (Madison, WI). T4 DNA ligase was purchased from New England Biolabs (Ipswich, MA). *p*-Nitrophenol (*p*NP), *p*-nitrophenyl *β*-gluopyranoside (*p*NP-Glu), *p*-nitrophenyl *β*-galactopyranoside (*p*NP-Gal), *p*-nitrophenyl *β*-*N*-acetylglucosaminide (*p*NP-GlcNAc), and *p*-nitrophenyl *β*-*N*-acetylgalactosaminide (*p*NP-GalNAc) were obtained from Sigma Chemical Co. (St. Louis, MO). All other chemicals used in this study were of analytical grade unless otherwise stated.

Cloning of Full-Length cDNA of a GlcNAcase and Sequence Analysis. DNA manipulations were performed as described by Sambrook and Russell.[30] Genomic DNA was isolated from *R. miehei* CAU432 mycelia by the CTAB method.[31] Total RNA was isolated by use of the Trizol kit (Invitrogen, Carlsbad, CA), and mRNAs were purified by use of the Oligotex mRNA midi kit (Qiagen, Germany). For mycelia collection, *R. miehei* CAU432 was cultivated at 50 °C for 2 days in the medium containing (grams per liter) glucose 10, tryptone 10, yeast extract 10, $MgSO_4·7H_2O$ 0.3, $FeSO_4$ 0.3, and $CaCl_2$ 0.3, and then the fungal mycelia were collected by centrifugation (5000*g*, 10 min) and washed twice with sterilized water at 4 °C.

Genomic DNA of *R. miehei* CAU432 was used as template for subsequent polymerase chain reaction (PCR) amplification. To clone the GlcNAcase gene, degenerate primers NAGF and NAGR (Table 1) were designed on the basis of conserved amino acid sequences IAVDQENG and KHFPGHGDT derived from other known GH family 3 GlcNAcases' sequences by use of the CODEHOP algorithm.[32] PCR conditions were as follows: a hot start at 94 °C for 5 min; 20 cycles of 94 °C for 30 s, 65−45 °C for 30 s, and 72 °C for 1 min; followed by 20 cycles of 94 °C for 30 s, 55 °C for 30 s, and 72 °C for 1 min. Target amplifications were TA cloned into pMD18-T vector and sequenced.

On the basis of partial sequence information, the SMART RACE cDNA amplification kit (Clontech) was used to clone both 5′ and 3′ ends of the cDNA. For the 5′ RACE, the PCR was performed with primers NAG5′GSP and UPM, which was followed by a nested PCR using nested gene-specific primer NAG5′NGSP and NUP (Table 1). For the 3′ RACE, primers NAG3′GSP and UPM were used, followed by a nested PCR using the nested gene-specific primer NAG3′NGSP and NUP (Table 1). The PCR conditions for RACE were as follows: a hot start at 94 °C for 5 min; followed by 30 cycles of 30 s at 94 °C, 30 s at 60 °C, and 1 min at 72 °C; and finally 10 min at 72 °C. All products were purified, TA cloned, and sequenced. Compiled nucleotide sequences were subjected to BLAST analysis. The GlcNAcase (RmNag) cDNA sequence from *R. miehei* CAU432 was deposited in the GenBank nucleotide sequence database under accession number KC357713.

Nucleotide sequence and its deduced amino acid sequence were analyzed by use of DNAMAN 6.0 software (LynnonBiosoft). Protein sequence was analyzed by SignalP 4.0 server (http://www.cbs.dtu.dk/services/SignalP/) and Motif Scan (http://myhits.isb-sib.ch/cgi-bin/motif_scan). BLAST analysis was performed at NCBI server (http://blast.ncbi.nlm.nih.gov/Blast.cgi). Amino acid sequence alignment was performed by use of the ClustalW2.0 program (http://www.ebi.ac.uk/Tools/clustalw2/index.html).

Heterologous Expression of GlcNAcase Gene in *E. coli*. The amplified gene (*RmNag*) products were digested with *Bam*HI and *Not*I. The resulting fragments were cloned into *Bam*HI/*Not*I-digested pET28a(+) expression vector, and the recombinant plasmids were transformed into *E. coli* BL21(DE3) for protein expression. *E. coli* BL21(DE3) cells transformed with *RmNag* were inoculated into LB medium (containing 50 *μ*g/mL kanamycin) and cultured at 37 °C on a rotary shaker (200 rpm) until the optical density OD_{600} reached about 0.8−1.0. Then isopropyl *β*-D-thiogalactopyranoside (IPTG) was added to the culture to a final concentration of 1 mM, and the culture was continuously grown at 30 °C for 12 h.

Purification of Recombinant GlcNAcase. The cells were centrifuged, suspended in 50 mM phosphate buffer (pH 7.4), and disrupted by ultrasonication. Cell debris was removed by centrifugation at 10000*g* for 10 min. The supernatant was loaded onto a nickel−iminodiacetic acid (Ni-IDA) column (1× 5 cm) (GE Life Sciences) pre-equilibrated with 50 mM phosphate buffer (pH 7.4) containing 500 mM NaCl and 20 mM imidazole. The bonded proteins were then eluted by 50 mM phosphate buffer (pH 7.4) containing 500 mM NaCl and 50 mM imidazole, followed by 50 mM phosphate buffer (pH 7.4) containing 500 mM NaCl and 200 mM imidazole at a flow rate of 1 mL/min. The fractions were monitored by enzyme activity assay, and the purity of enzyme was checked by sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS−PAGE). The purified GlcNAcase (RmNag) was used for further studies.

Enzyme Assay and Protein Determination. GlcNAcase activity was determined spectrophotometrically with *p*NP-GlcNAc as the substrate. A 200 *μ*L assay mixture containing 50 *μ*L of enzyme solution, 100 *μ*L of *p*NP-GlcNAc (2 mM), and 50 *μ*L of 200 mM phosphate buffer (pH 6.5) was incubated at 50 °C for 10 min. The reaction was terminated by the addition of 200 *μ*L of 0.5 M NaOH solution, and then the amount of *p*NP released was determined by measuring the absorbance at 410 nm. One unit of enzyme activity was defined as the amount of enzyme required to liberate 1 *μ*mol of *p*NP/min under the assay conditions.

Protein concentration was determined by Lowry method[33] with bovine serum albumin (BSA) as the standard. Specific activity was expressed as units per milligram of protein.

SDS−PAGE and Molecular Mass Determination. SDS−PAGE was performed according to the method of Laemmli et al.[34] with 12.5% (w/v) separating gel and 4.5% stacking gel. Protein bands were visualized by Coomassie brilliant blue R-250 staining. The molecular mass of the GlcNAcase was calibrated by use of a low molecular weight calibration kit (TakaRa, Japan) containing phosphorylase *b* (97.0 kDa), bovine serum albumin (66.0 kDa), ovalbumin (45.0 kDa), carbonic anhydrase (30.0 kDa), trypsin inhibitor (20.1 kDa), and *α*-lactalbumin (14.4 kDa).

The native molecular mass of the purified RmNag was determined on a Superdex-300 (GE Life Science) gel-filtration column (1.0 × 40 cm). The purified enzyme was loaded onto the column and eluted with 20 mM phosphate buffer (pH 6.5) at a flow rate of 0.3 mL/min. The calibration standard proteins used were catalase (247.0 kDa), alcohol dehydrogenase (150.0 kDa), phosphorylase *b* (97.2 kDa), fetuin (from fetal calf serum, 68.0 kDa), and albumin (from chicken egg white, 45.0 kDa).

Effect of pH and Temperature on Activity and Stability of Purified GlcNAcase. The effect of pH on the enzyme activity was determined in different buffers (50 mM) within pH 4.5−10.5. The buffers used were citrate (pH 4.5−6.0), 2-(*N*-morpholino)-ethanesulfonic acid (MES) (pH 5.5−6.5), phosphate (pH 6.0−8.0),

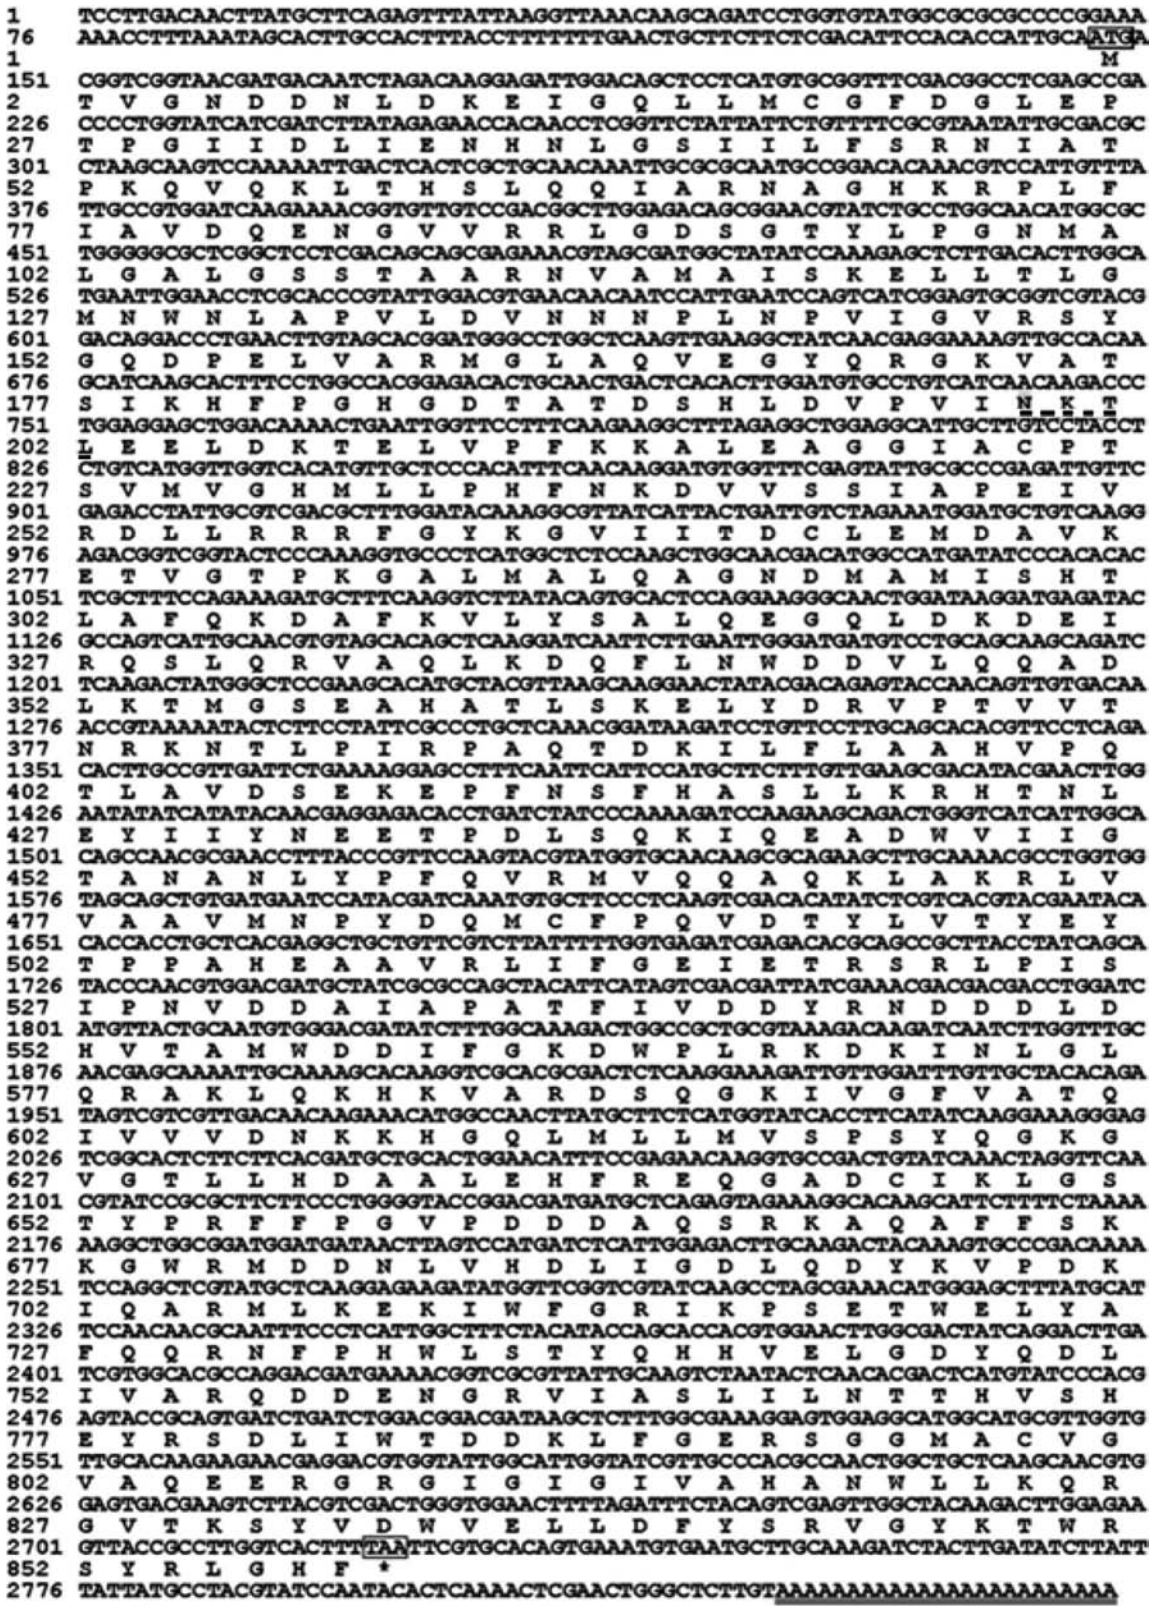

Figure 1. Nucleotide and deduced amino acid sequences of GlcNAcase (RmNag) from *R. miehei* containing the ORF and 5′ and 3′ flanking regions. The translational initiation codon ATG is boxed in frame. The termination codon, TAA, is boxed and marked by an asterisk (*). A poly(A+) tail is double-underlined. The N-linked glycosylation site is marked by a dotted line.

Tris-HCl (pH 7.5−9.0), and glycine−NaOH (8.5−10.5). For pH stability, the purified enzyme was incubated in different buffers mentioned above at 30 °C for 30 min, and the residual activities were measured at 50 °C in 50 mM phosphate buffer (pH 6.5).

The optimal temperature of RmNag was examined in the temperature range 25−65 °C in 50 mM phosphate buffers (pH 6.5). To determine the thermostability, the enzyme was incubated at different temperatures for 30 min, and the residual activities were measured at 50 °C in 50 mM phosphate

dx.doi.org/10.1021/jf500912b | J. Agric. Food Chem. 2014, 62, 5181−5190

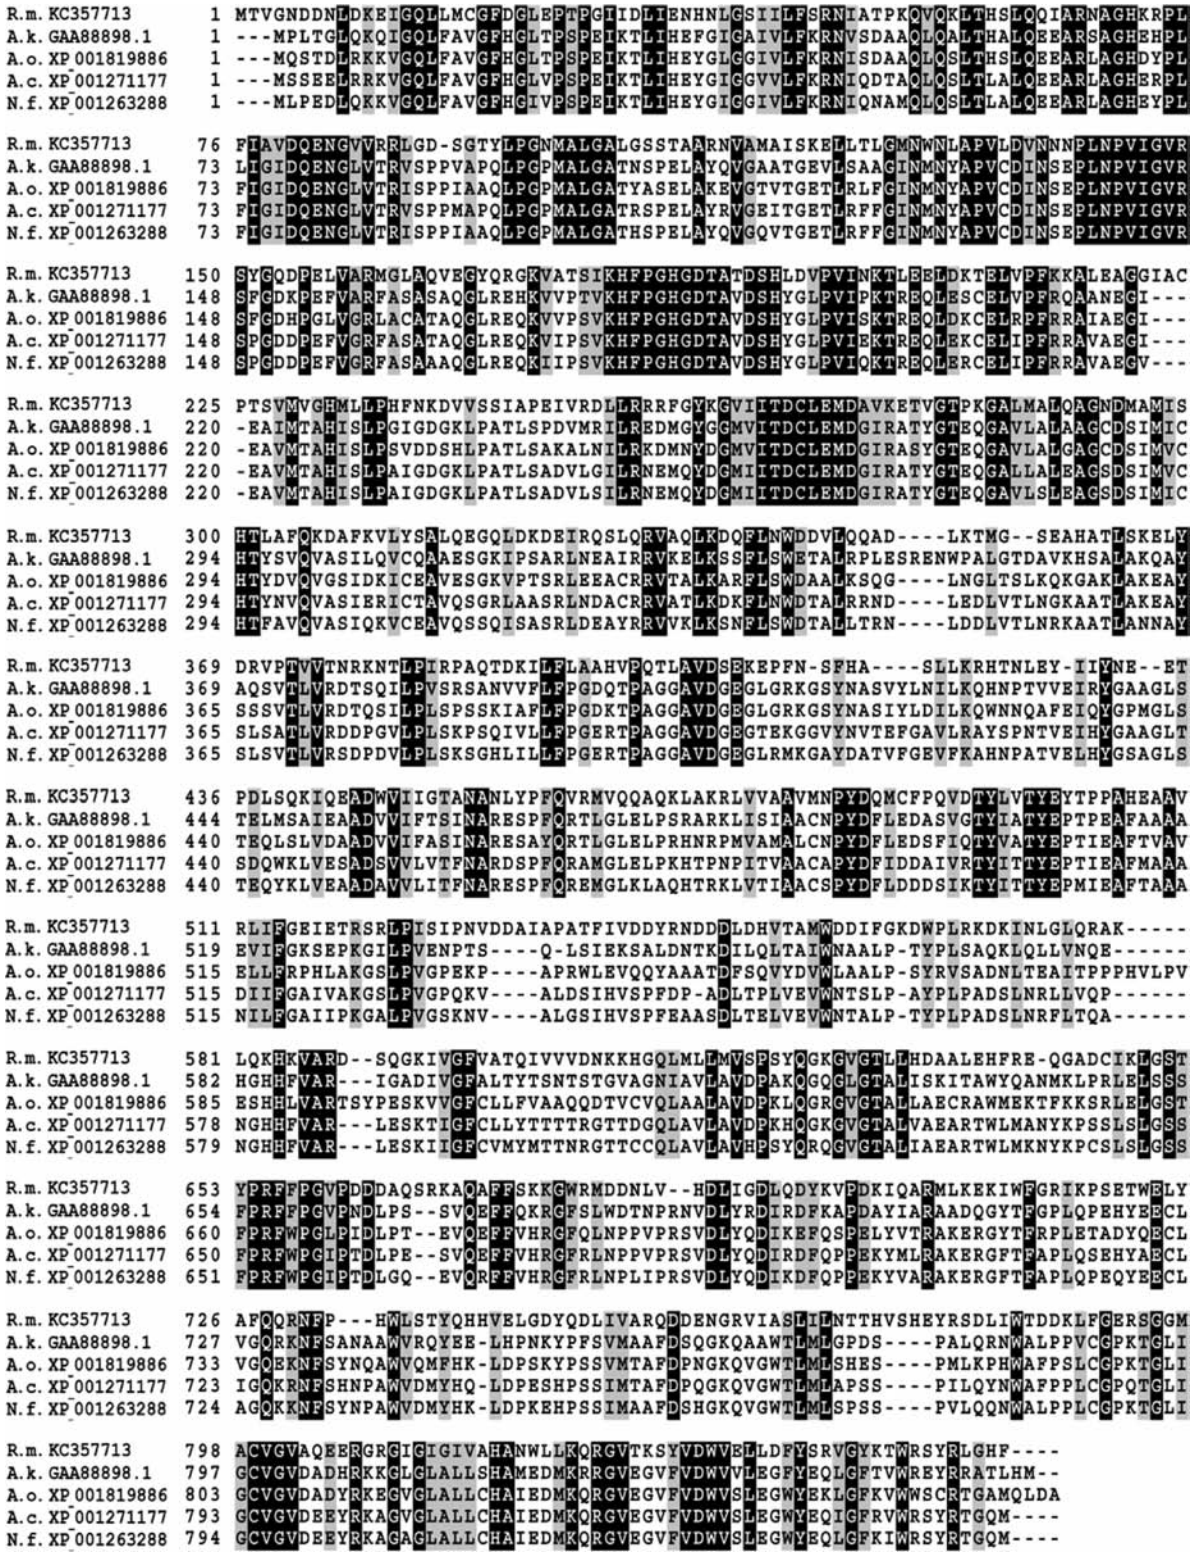

Figure 2. Multiple alignment of amino acid sequences for RmNag and other putative fungal GlcNAcases. Numbers on the left are the residue numbers of the first amino acid in each line. Abbreviations and accession numbers of those GlcNAcases are as follows: *Rhizomucor miehei* CAU432 (R.m. KC357713), *Rhizopus delemar* RA 99-880 (R.d. EIE86479), *Aspergillus kawachii* IFO 4308 (A.k. GAA88898.1), *Aspergillus oryzae* RIB40 (A.o. XP_001819886.2), *Aspergillus clavatus* NRRL 1 (A.c. XP_001271177.1), and *Neosartorya fischeri* NRRL 181 (N.f. XP_001263288.1). Identical residues are shaded in black and conserved residues are shaded in gray.

buffer (pH 6.5). For thermal denaturing half-lives of RmNag, the enzyme was incubated at different temperatures (40, 45, and 50 °C) for 4 h, and then the residual activities of the samples withdrawn at different time intervals were measured in 50 mM phosphate buffer (pH 6.5) at 50 °C.

The effect of metal ions and agents on GlcNAcase activity was determined by incubating the enzyme in 50 mM phosphate buffer (pH 6.5) with various metal ions and reagents (1 mM) at 30 °C for 30 min. The residual activities were then measured by standard enzyme assay.

Substrate Specificity and Kinetic Parameters. The substrate specificity of RmNag was determined by measuring the enzyme activity with various substrates including polysaccharides (1% w/v) such as chitin, chitosan, barley glucan, lichenin, laminarin, carboxymethylcellulose, birchwood xylan, and pullulan; *N*-acetyl chitooligosaccharides (1% w/v) with degrees of polymerization (DP) of 2−5; and *p*NP derivatives (1 mM) such as *p*NP-Gal, *p*NP-Glu, and *p*NP-GalNAG in 50 mM phosphate buffer (pH 6.5) at 50 °C for 10 min. The released reducing sugars from polysaccharides were determined by the dinitrosalicylic acid (DNS) method[35] with glucose as the standard. The released GlcNAc from *N*-acetyl chitooligosaccharides was estimated by HPLC on an Agilent series 1200 system (Agilent) equipped with a Cosmosil column. The oven temperature was set at 45 °C, and acetonitrile/water (3:1) solution was used as mobile phase (1 mL/min). The released *p*NP was measured at 410 nm. One unit of enzyme activity was defined as the amount of enzyme required to release 1 μmol of reducing sugar or GlcNAc or *p*NP per minute under the above conditions.

The kinetic parameters of RmNag toward *p*NP-GlcNAc were determined by measuring the enzyme activities with different substrate concentrations in 50 mM sodium phosphate buffer (pH 6.5). The constant kinetic parameters of K_m and V_{max} were calculated by use of GraFit software.

Hydrolytic Property of Purified GlcNAcase. Hydrolysis of *N*-acetyl chitooligosaccharides $(GlcNAc)_{2-5}$ by the purified RmNag was performed by incubating 1 mL of 1% (w/v) various substrates dissolved in 50 mM phosphate buffer (pH 6.5) with 2 units of purified enzyme at 30 °C for 4 h. Samples were withdrawn at different time intervals, terminated by boiling for 5 min, and then qualitatively analyzed by thin-layer chromatography (TLC). For TLC analysis, samples (2 μL) were applied to a Merck silica gel 60 plate with *n*-butyl alcohol/acetate/water (2:1:1 v/v/v) as developing solution. The plate was first sprayed with solution I [12.5% (w/v) KOH dissolved in ethanol and 1% (v/v) acetyl acetone dissolved in *n*-butyl alcohol at a ratio of 1:20 (v/v)] and dried, then sprayed with solution II [3.33% (w/v) dimethylaminobenzaldehyde dissolved in a solution of ethanol/HCl/1-butanol (6:6:1 v/v/v)]. The compounds separated on the TLC plate were visualized by heating at 130 °C for a few minutes.

Tolerance of Purified GlcNAcase to GlcNAc. The extent of GlcNAc inhibition on GlcNAcase activity was determined by incubation of 50 μL of enzyme solution, 100 μL of *p*NP-GlcNAc prepared in distilled water, 50 μL of 200 mM phosphate buffer (pH 6.5), and various amounts of GlcNAc with a final concentration of 1−20 mM at 50 °C for 10 min. Then the GlcNAcase activities were determined according to the standard enzyme assay. K_i was calculated by nonlinear regression fit of Michaelis−Menten with GraphPad Prism software.

RESULTS

Cloning of GlcNAcase Gene from *R. miehei*. A partial gene fragment was obtained by PCR with degenerate primers NAGF and NAGR (Table 1). Complete cDNA sequence of the GlcNAcase (designated as RmNag) was obtained by the rapid amplification of complementary DNA ends (RACE) method. The 2849-bp RmNag cDNA sequence contains an open reading frame (ORF) of 2577 bp encoding 858 amino acids, a 146-bp 5′ untranslated region (UTR), and a 126-bp 3′ UTR, and no intron was found in the coding region (Figure 1). The mature protein has a predicted molecular mass of 96.1 kDa and a theoretical p*I* of 6.73. No potential signal peptide was detected in the *N*-terminal region of the gene. One potential N-glycosylation site was identified in the amino acid sequence of the mature protein at residues 199−202. The RmNag cDNA sequence has been submitted to NCBI GenBank under accession number KC357713.

RmNag showed low similarities to those of putative GH family 3 GlcNAcases from fungi, such as *Aspergillus clavatus* NRRL 1 (37%, XP_001271177.1), *Neosartorya fischeri* NRRL 181 (37%, XP_001263288.1), *Aspergillus kawachii* IFO 4308 (36%, GAA88898.1) and *Aspergillus oryzae* RIB40 (35%, XP_001819886.2), and very low similarities to those of other known bacterial GlcNAcases. Multiple sequence alignment of RmNag with other GH family 3 GlcNAcases in the GenBank database is indicated in Figure 2. A typical amino acid sequence, KHFPGHGDTxxDSH, that is highly conserved among GH family 3 GlcNAcases[19] was found in RmNag.

Expression and Purification of Recombinant RmNag. The RmNag gene was successfully expressed in *E. coli* BL21 as a soluble intracellular enzyme. The recombinant RmNag was purified to apparent homogeneity by Ni-IDA chromatography with purification of 7.9-fold and recovery yield of 45.8% (Table 2).

Table 2. Purification Summary for Recombinant GlcNAcase (RmNag) from *R. miehei*

purification step	total activity[a] (units)	protein (mg)	specific activity (units/mg)	purification factor (*x*-fold)	recovery (%)
culture supernatant	278.6	103.2	2.7	1	100
Ni-IDA agarose	127.6	6.0	21.2	7.9	45.8

[a]Enzyme reactions were carried out at 50 °C in 50 mM phosphate buffer (pH 6.5) for 10 min.

The specific activity of the enzyme increased from 2.7 to 21.2 units/mg (Table 2). The molecular mass of the purified RmNag was determined to be 96 kDa on SDS−PAGE (Figure 3) while

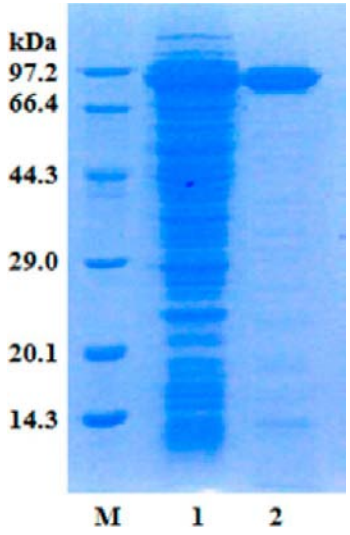

Figure 3. SDS−PAGE analysis of proteins during the purification process of recombinant GlcNAcase (RmNag) from *R. miehei*. Lane M, low molecular mass standard proteins; lane 1, crude enzyme; lane 2, after Ni-IDA column.

determined to be 200.8 kDa by Superdex-300 gel-filtration chromatography (data not shown), indicating that the enzyme was a homodimer.

Effect of pH and Temperature on Enzyme Activity and Stability of RmNag. The optimal pH of RmNag was found to be pH 6.5 in 50 mM phosphate buffer (Figure 4A). At pH 6.0−7.0, the enzyme showed relatively high activity, with more than 80% of the maximum activity retained, while a rapid decline was observed at pH below 5.5 or above 7.5 (Figure 4A). The enzyme was stable in the pH range 6.0−8.0, since more than 80% enzyme activity was remained after 30 min incubation in various buffers

dx.doi.org/10.1021/jf500912b | J. Agric. Food Chem. 2014, 62, 5181−5190

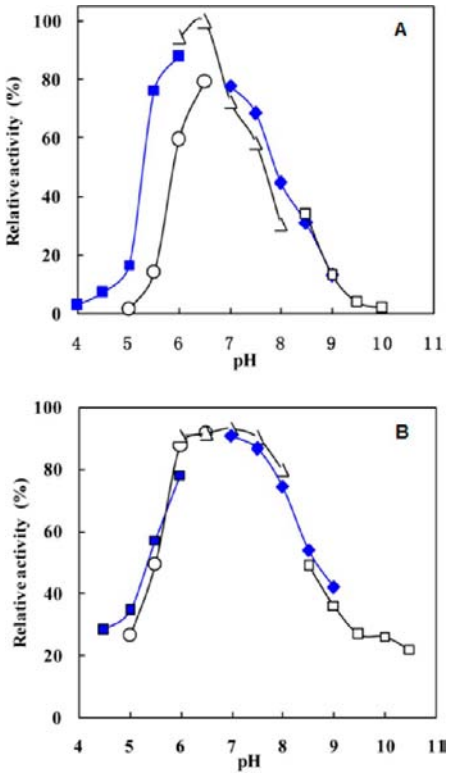

Figure 4. (A) Optimal pH and (B) pH stability of purified RmNag. The influence of pH on GlcNAcase activity was determined at 50 °C with 50 mM different buffers. Residual activities were measured after the enzyme was incubated at 30 °C for 30 min over various pH ranges. Buffers used: (■) citrate, (●) MES, (▲) phosphate, (◆) Tris-HCl, and (□) glycine−NaOH.

(Figure 4B). RmNag was most active at 50 °C and showed a relatively wide range of optimal temperature at 40−55 °C, having more than 80% of its maximum activity (Figure 5A). The enzyme was stable up to 45 °C, as more than 90% of its activity was retained (Figure 5B). The thermal denaturing half-lives of RmNag at 40, 45, and 50 °C were determined to be 1190, 494, and 42 min, respectively (Figure 5C). The enzyme activity was markedly inhibited by more than 30% in the presence of 1 mM Ag^{+}, Cu^{2+}, Zn^{2+}, Co^{2+}, Hg^{2+}, and SDS, while no obvious effect was observed for Ba^{2+}, K^{+}, Na^{+}, and some other metal ions (Table 3).

Substrate Specificity and Kinetic Parameters of Purified RmNag. The specificity of RmNag for various substrates is presented in Table 4. Among the tested chromogenic substrates, RmNag efficiently hydrolyzed only *p*NP-GlcNAc, with specific activity of 21.2 units/mg, and could hardly hydrolyze *p*NP-GalNAc (0.2 unit/mg). The enzyme showed no activity on the tested polysaccharides. Among the tested *N*-acetyl chitooligosaccharides, RmNag exhibited the highest activity toward $(GlcNAc)_3$, followed by $(GlcNAc)_2$, $(GlcNAc)_4$, and $(GlcNAc)_5$ (Table 4).

The Michaelis−Menten constant K_m and V_{max} values of RmNag toward *p*NP-GlcNAc were determined to be 0.13 mM and 49.3 μmol·min^{-1}·mg^{-1}, respectively.

Hydrolytic Properties of Purified RmNag on *N*-acetyl Chitooligosaccharides. The hydrolytic pattern of RmNag on *N*-acetyl chitooligosaccharides was analyzed by TLC (Figure 6). It can be seen that RmNag efficiently hydrolyzed all chitin oligomers tested (DP 2−5), yielding GlcNAc as the end product, and in the hydrolysis process, the enzyme cleaves one GlcNAc at a time until all the intermediates were converted to GlcNAc (Figure 6).

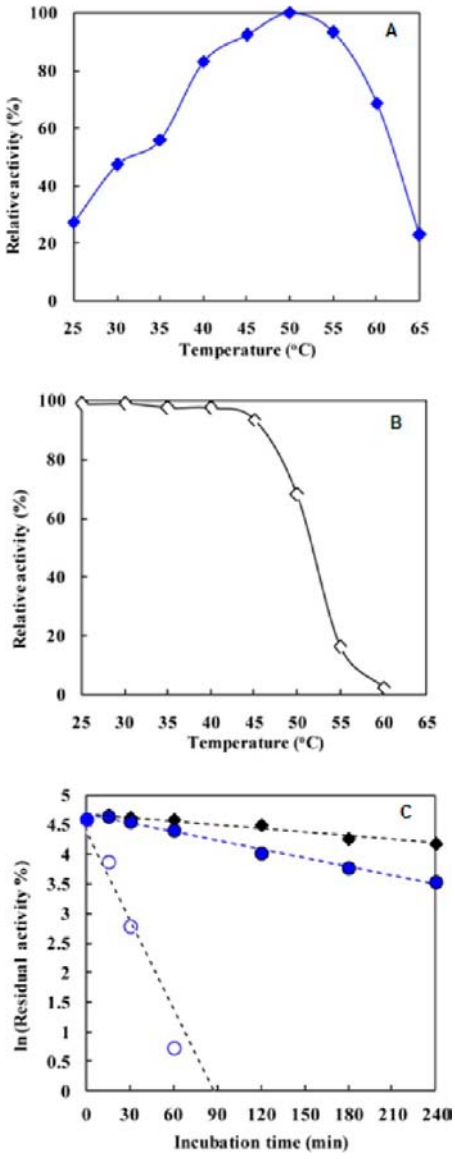

Figure 5. (A) Optimal temperature, (B) thermostability, and (C) thermal denaturing half-life of purified RmNag. The temperature profile was measured at different temperatures in 50 mM phosphate (pH 6.5). For determination of thermostability, residual activity of the treated enzyme was measured according to the standard assay after a 30 min preincubation at different temperatures. For thermal denaturing half-life, the enzyme was incubated at (◆) 40, (●) 45, and (○) 50 °C.

These results suggested that the enzyme was an exo-type enzyme acting on the nonreducing end of the substrate to release GlcNAc one by one.

Tolerance of RmNag to GlcNAc. The effect of various concentrations of GlcNAc on GlcNAcase activity was studied (data not shown). The enzyme activity of RmNag was inhibited by 49.9% in the presence of 9 mM GlcNAc. RmNag was competitively inhibited by GlcNAc with a K_i value of 9.68 mM.

DISCUSSION

GlcNAcases play important roles in chitin degradation, as well as in the cell wall recycling process of bacteria. To date, a number of GlcNAcases have been identified, gene cloned, and characterized from a wide variety of organisms, including bacteria, plants, insects, and animals.[4,9,11,15] Nevertheless, there is only scant information on GlcNAcases from fungi[15,24,25] and no report on

Table 3. Effect of Metal Ions and Reagents on Activity of RmNag

metal ion or reagent (1 mM)	specific activity[a] (units/mg)	relative activity (%)
control	21.1	100
Fe^{3+}	18.2	86.1
Cr^{2+}	13.5	63.8
Ag^{+}	0.2	0.8
Cu^{2+}	0.2	0.7
Ni^{2+}	13.8	65.2
Mg^{2+}	17.5	83.0
Sn^{2+}	12.0	56.7
Zn^{2+}	2.7	12.8
Mn^{2+}	20.7	98.2
Co^{2+}	4.8	22.5

EDTA	14.3	67.6
β-mercaptoethanol	18.5	87.5

[a]Activity was determined at 50 °C in 50 mM phosphate buffer (pH 6.5) for 10 min.

Table 4. Substrate Specificity of Purified RmNag

substrate	specific activity[a] (units/mg)	relative activity (%)
*p*NP-GlcNAc	21.2	100
*p*NP-GalNAc	0.2	0.7
$(GlcNAc)_2$	1.06[b]	5.0
$(GlcNAc)_3$	1.11	5.2
$(GlcNAc)_4$	0.88	4.1
$(GlcNAc)_5$	0.68	3.2

[a]Specific activities toward *N*-acetyl chitooligosaccharides were determined by measuring the released GlcNAc by HPLC. Reactions were performed in 50 mM phosphate buffer (pH 6.5) at 50 °C for 10 min. [b]Specific activity was divided by 2, as the hydrolysis of 1 mol of $(GlcNAc)_2$ can release 2 mol of GlcNAc.

fungal GlcNAcases belonging to GH family 3. Here, to the best of our knowledge, is the first report on a fungal GlcNAcase belonging to GH family 3.

GlcNAcases have been classified into three GH families, 3, 20, and 84, in the CAZy database on the basis of their amino acid sequence similarities.[26] GH families 3 and 84 GlcNAcases are mainly distributed in various bacteria and metazoan cells, respectively, while GH family 20 GlcNAcases are versatile enzymes mainly abundant in fungi and insects.[36] Analysis of the nucleotide sequence of *RmNag* indicated that the deduced amino acid sequence contained a typical motif, KHFPGHGDTxxDSH (KHFPGHGDTMVDSH) (Figure 1), which is highly conserved among GH family 3 GlcNAcases.[19] Besides, multiple amino acid sequence alignment revealed that RmNag showed the highest identity with a putative GH family 3 GlcNAcase from *A. clavatus* NRRL 1 (Figure 2). These results suggest that RmNag should be a novel member of GH family 3 GlcNAcases. Hence it may represent the first fungal GH family 3 GlcNAcase.

The molecular masses of most reported bacterial GH family 3 GlcNAcases are mainly distributed in the range 36–89 kDa,[11,18,20,23] while those of fungal GlcNAcases (GH family 20) are somewhat higher, mainly above 70 kDa, such as the enzymes from *Trichoderma harzianum* P1 (72 kDa),[17] *Lentinula edodes* (79 kDa),[4] *T. harzianum* (150 kDa)[16] and *P. oxalicum* (160 kDa).[24] The denatured molecular mass of RmNag in the present study was estimated to be 96.1 kDa on SDS–PAGE (Figure 3), while the native molecular mass was determined to be 200.8 kDa by gel filtration, indicating the enzyme is a homodimer. This is distinct from most known bacterial GH3 GlcNAcases but similar to the GlcNAcases from two fungi: *P. oxalicum*[24] and *T. harzianum*.[16]

RmNag was most active at pH 6.5 and was stable within pH 6.0–8.0 (Figure 4). The optimal pH is similar to that of most other reported GlcNAcases in the range 6.0–7.0.[9,13,15,23] RmNag was most active at 50 °C (Figure 5). The GH family 20 GlcNAcases from *C. paraputrificus*[12] and *L. edodes*[4] are also most active at 50 °C. However, the optimal temperature of RmNag is lower than that of the GH family 3 enzymes from thermophilic bacteria *S. thermoviolaceus* (60 °C)[5] and *T. maritima* (65–75 °C).[23] It is worth noting that RmNag exhibited a wide range of temperature optimum at 40–55 °C and was stable up to 45 °C, with a thermal denaturing half-life of 494 min (Figure 5).

Generally, GH family 3 GlcNAcases have broad substrate specificity, while GH family 20 GlcNAcases exhibit strict substrate specificity.[19,37] However, the differences of GlcNAcases from each other still exist, even within the same GH family.[13] RmNag showed the highest activity toward *p*NP-GlcNAc among the tested *p*NP drivatives and appeared to have the highest activity against $(GlcNAc)_3$ (the activities for $GlcNAc_2$ and $GlcNAc_3$ are almost the same) among tested *N*-acetyl chitooligosaccharides (Table 4). This property is similar to fungal GH family 20 GlcNAcases, which have the highest catalytic efficiency for $(GlcNAc)_2$ among natural substrates and do not hydrolyze or hardly hydrolyze long-chain chitomaterials,[4] but is different from most other reported bacterial GH family 3 GlcNAcases. For example, the specific activity of NagA, a GH family 3 GlcNAcase from *S. thermoviolaceus*, increased with the DP of the *N*-acetyl chitooligosaccharides substrates.[5] GlcNAcase from *S. thermophilum* showed much lower specific activity for *p*NP-GlcNAc than for *N*-acetyl chitooligosaccharides substrates (DP 2–5).[20] It appears that the GlcNAcases reported to date possess two major types of substrate specificity. The first type of enzymes prefers to hydrolyze *N*-acetyl chitobiose, while the other type of enzymes favors chitooligomers (DP 3–6) over *N*-acetyl chitobiose. However, GlcNAcases from both GH families 3 and 20 are randomly distributed in the two types from this classification aspect. GlcNAcases from *T. harzianum*,[16] *S. thermophilum*,[20] and *L. edodes*[4] belong to the first type, while GlcNAcases from *S. thermoviolaceus*[5] and *V. harveyi*[9] are classified into the second type. RmNag belongs to neither of the two types of GlcNAcase, but it is closer to the first type as it exhibited almost equal highest activities for $(GlcNAc)_3$ and $(GlcNAc)_2$ and low activities for $(GlcNAc)_4$ and $(GlcNAc)_5$ (Table 4). Many GlcNAcases are also called *N*-acetylhexosaminidases as they showed high activity toward *p*NP-GalNAc.[4,20,21,23] However, RmNag showed a trace amount of activity for *p*NP-GalNAc. The GlcNAcase from *S. thermoviolaceus* also showed no activity for *p*NP-GalNAc.[5] RmNag exhibited no activity toward chitin polymers, which is in accordance with most other reported GH family 3 GlcNAcases.[5,23] However, there are still a few GlcNAcases showing chitin-degrading ability in both GH families 3 and 20.[4,9,13] Thus, RmNag exhibited unique enzymatic properties with respect to all the reported GlcNAcases.

Degradation pattern of RmNag toward *N*-acetyl chitooligosaccharides was analyzed by TLC. RmNag hydrolyzed chitin oligomers (DP 2–5), yielding GlcNAc as the sole end product

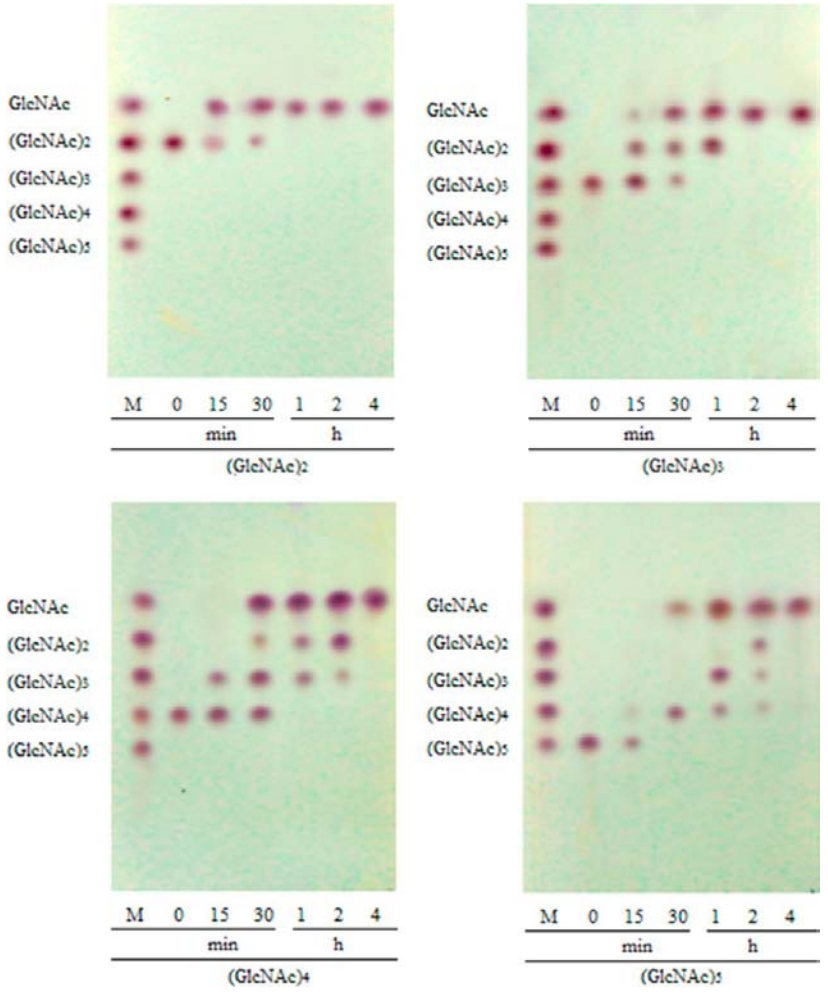

Figure 6. TLC analysis of hydrolytic products of *N*-acetyl chitooligosaccharides by purified RmNag. Reactions were performed in 50 mM phosphate buffer (pH 6.5) at 30 °C for various times.

(Figure 6). During the hydrolytic reaction, all substrates were hydrolyzed exolytically, that is, $(GlcNAc)_n$ ($n < 5$) was first converted to $(GlcNAc)_{n-1}$ and equivalent amount of GlcNAc, and then the intermediate product $(GlcNAc)_{n-1}$ was further converted to $GlcNAc_{n-2}$ and equivalent amount of GlcNAc, and the reaction continued until all the intermediate products were converted to the final end product GlcNAc (Figure 6). These results clearly indicated that RmNag released GlcNAc from the nonreducing end of the substrate and exhibited an exo-type cleavage mechanism. Similar results were also reported for the GlcNAcases from *A. hydrophila*,[21] *T. maritima*,[23] and *V. harveyi*,[9] which belong to GH families 20, 3, and 20, respectively.

High concentration of GlcNAc tolerance is an advantage for GlcNAcases in the complete enzymatic hydrolysis of chitin. However, most reported GlcNAcases are inhibited by their hydrolysis product (GlcNAc), with K_i values ranging from 0.2 to 2 mM.[12,18] The enzyme in the present study exhibited relatively high tolerance to GlcNAc, with a K_i value of 9.68 mM, which is much higher than that of the GlcNAcases from *V. furnissii* (K_i = 0.21 mM),[18] *A. oryzae* (K_i = 1.6 mM),[38] *T. harzianum* (K_i = 1.6 mM),[39] and *Spodoptera frugiperda* (K_i = 2.0 mM).[12] GlcNAcase from *Trichinella spiralis* was also GlcNAc-tolerant, with a K_i value of 15.75 mM, which represents the highest tolerance to GlcNAc.[40] The high GlcNAc tolerance is an attractive feature, which may enable the enzyme great potential in chitin conversion industry, especially for biofuel production.

In conclusion, this study reported the gene cloning, expression, and biochemical characterization of the first fungal GH family 3 GlcNAcase. The recombinant enzyme exhibited maximal activity at pH 6.5 and 50 °C. It hydrolyzed *N*-acetyl chitooligosaccharides to yield mainly GlcNAc as the only final product, and it exhibited relative high GlcNAc tolerance with a K_i value of 9.68 mM. These excellent properties may enable the enzyme to have great potential in industry.

using a commercial gas-fired roaster (IMSA, Lima, Peru). Batch size was 4.5 kg approximately Three roasting conditions were applied to obtain the corresponding degrees of roasted kernels: lightly roasted (75−81 °C × 9 min), medium roasted (83−86 °C × 10 min), and highly roasted (99−102 °C × 10 min). The light roasting conditions correspond to the minimum roasting level that eliminates the astringent flavor. Weight loss during roasting ranged from ∼5.5−6.6%. After roasting, the kernels were immediately cooled with the built-in fan of the roaster.

Oil Extraction, Clarification and High Temperature Storage. Oil extraction was achieved by pressing the kernels the following day after roasting. The unroasted and the three roasted samples were pressed with a laboratory Komet expeller (IBG Monforts GmbH, Monchengladbach, Germany). The press temperature of 100−110 °C was measured by inserting a thermocouple in the cake mass that emerged from the expeller. The extracted oil with fine suspended solids was immediately placed in amber glass bottles (0.5 L) and filled to the top to minimize headspace. The bottles were stored in the dark and under refrigeration (5 °C) until clarification by centrifugation. The nonclarified oil yield increased with roasting temperature with values of ∼42, 49, and 65% by weight for lightly, medium and highly roasted samples, respectively.

Oil samples were clarified by centrifuging at 29 000*g* for 15 min in a laboratory centrifuge Beckman Model J2−21 (Fullerton, CA, U.S.A.). The clarified samples were placed in amber glass bottles (120 mL) and flushed with nitrogen and stored in the dark under refrigeration at 5 °C until testing time.

For high temperature storage studies, oil samples (50g) were placed in 100 mL beakers (in triplicate) and stored in an oven at 60 °C in the dark for 30 days. Samples were analyzed for peroxide value, *p*-anisidine, tocopherols, and fatty acid profile at 0, 8, 18, and 30 days of accelerated storage while antioxidant capacity, by measuring total phenols and DPPH, were done on samples at days zero and 30. All analyses were performed in triplicate.

Peroxide Value and *p*-Anisidine Value. The peroxide value was determined using the AOCS Cd 8−53 official method.[9] This method determines all substances in the oil that oxidize potassium iodide (KI) under test conditions. The assumption is that these substances are peroxides or similar compounds that resulted from lipid oxidation. Results are expressed as peroxide milliequivalents/1000 g oil. The *p*-anisidine value was determined using the AOCS Cd 18−90 official method.[9] This method quantifies the amount of aldehydes (especially, 2-alkenals and 2,4-dienals) present in the oil through the reaction between aldehydes and *p*-anisidine in an acetic solution. Absorbance was measured at 350 nm with an 8452A photodiode array spectrophotometer (Hewlett-Packard, Palo Alto, CA).

Antioxidant Capacity. Two methods were used to measure antioxidant capacity: Total phenols and DPPH assay. Previously, phenolic extracts, to be used for both methods, were prepared from oil samples. Phenolic extracts were prepared according to a procedure by Ninfali and others[10] with some modifications: 0.5 g oil were diluted in 25 mL 80% methanol−water and vortexed for 1 min, then stirred using a gyratory shaker model G2 (New Brunswick Scientific Co., Inc., NJ) at 200 rpm × 1 h. The mixture was centrifuged (29 000*g* × 15 min) using a Beckman Model J2−21 centrifuge (Fullerton, CA, U.S.A.) and an 8 mL aliquot of supernatant was taken. The solvent of the supernatant was removed using a rotovapor and then a laboratory freeze-dryer FTS Systems Inc. (Stone Ridge, NY) for ∼8 h. The solid residue was redissolved in 500 μL methanol (900 μL for samples from intensely roasted seeds). These extracts were used for total phenols and DPPH analyses.

Total Phenols Using the Folin Assay. A procedure was used based on the method by Swain and Hillis.[11] Four milliliters of distilled water was added to a 250 μL aliquot of phenolic extract and mixed for 30 s in a vortex. Folin-Ciocalteu reagent (250 μL) was added and allowed to react for exactly 3 min. Then 500 μL 1N Na_2CO_3 solution was added, and the mixture was allowed to react in the dark for 2 h, after which absorbance was read at 725 nm in a spectrophotometer. Chlorogenic acid was used as standard and results were expressed as mg chlorogenic acid/g oil.

DPPH (2,2-Diphenyl-1-picrylhydrazyl) Assay. This analysis was based on the method used by Thaipong and others.[12] In this method, antioxidant activity was determined using DPPH as free radical. The procedure is as follows: A 150 μL aliquot of phenolic extract and 2.85 mL of DPPH solution were mixed. After a 24-h period of incubation in the dark, the absorbance was measured at 515 nm with a spectrophotometer. A blank was prepared using methanol instead of phenolic extract. A linear standard curve was built using trolox as the reference reactant in a range from 25 to 800 μM. Antioxidant capacity was expressed as μg trolox equivalents/g oil. A higher trolox equivalent is indicative of a greater antioxidant potential or reducing power.

Tocopherol Content. Sample preparation to be analyzed by chromatography was based on the method used by Rodas-Mendoza and others,[13] which is described briefly. A 0.5 g oil sample was diluted in 2 mL methanol and mixed for 1 min, afterward, 500 μL hexane was added and mixed in a vortex. The mixture was then centrifuged (2500*g* × 10 min) and a 1 mL aliquot of supernatant was removed and filtered with a PTFE filter (pore size 0.2 μm) before 20 μL volume injection into the HPLC. The samples were run using a Waters Millennium 3.2 software (Milford, MA, U.S.A.). The HPLC system was equipped with a binary pump system (Waters 515, Milford, MA, U.S.A.), an autoinjector (Waters 717 plus, Milford, MA, U.S.A.), a photodiode array (PDA) detector (Waters 996, Milford, MA, U.S.A.), and a column heater (SpectraPhysics SP8792, San Jose, CA, U.S.A.). The column used was a Tracer Spherisorb ODS2 C_{18}, 250 × 4.6 mm (i.d.), particle size 5 μm (Tracer Analitica, Barcelona, Spain) protected by a column guard of the same composition (Waters Corp., Milford MA, U.S.A.). Methanol was used as the mobile phase, and elution took place at a flow rate of 1 mL/min. The column temperature was kept at 50 °C. Detection was done at 295 nm. Chromatographic peaks were identified by comparing sample retention times with those of standards, and quantification was achieved by external standardization.

Fatty Acid Profile. Sample preparation for GC analysis was based on the method used by Misir and others.[14] This method consisted in the formation of methyl esters of fatty acids from the corresponding fatty acids. The procedure used is as follows: 0.15 g of oil was diluted in 3 mL of diethyl ether in a test tube to which 0.2 mL of 20% tetramethylammonium hydroxide was added. The mixture was stirred for 2 min and allowed for phase separation. One drop of thymol blue indicator was added, followed by dropwise addition of 0.5 N HCl methanol solution until the color changed from blue to yellow. Finally, 0.5 mL methanol was added to make the samples homogeneous.

The chromatographic method used was that described by Misir and others.[14] The fatty acid methyl esters were analyzed with a Varian CP 3800 gas chromatograph (Palo Alto CA, U.S.A.) equipped with a Varian CP 8200 automatic injector and a flame ionization detector (FID). A Varian FAME fused silica capillary column (100 m × 0.25 mm, i.d.) (Varian CP-Select). The oven temperature had the following program: 0−30 min at 185 °C and 30−45 min at 235 °C, with increments of 20 °C/min. The FID temperature was 270 °C. The flow rates of helium, air, and hydrogen were 1.6, 300, and 35 mL/min.

Statistics. Results are reported as mean values of three replicates and their corresponding confidence intervals at a 95% confidence level ($p < 0.05$).

RESULTS AND DISCUSSION

Roasting Process Effect on Sensorial Characteristics of Kernel and Oil. The varying degrees of roasting of Sacha-inchi seeds resulted in changes in seed color and kernel taste. The color changed from cream in unroasted kernels to light brown—similar to roasted peanuts—in lightly roasted Sacha-inchi kernels, to brown and dark brown, in medium and highly roasted kernels, respectively (Figure 1). The typical astringent taste of unroasted kernels disappeared with roasting; lightly roasted kernels had no astringent taste but rather a slightly sweet taste; medium roasted kernels had no sweet taste but rather a slightly burnt taste; highly roasted kernels had a bitter and burnt taste. The color of Sacha-inchi oil from lightly

roasted seeds did not differ visually from that of unroasted seeds. However, oil from medium and highly roasted seeds exhibited darker oils (Figure 2).

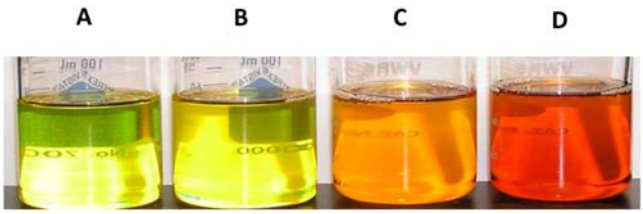

Figure 2. Visual appearance of Sacha-inchi oil samples at day 0 from unroasted (A), slightly roasted (B), medium-roasted (C), and highly roasted seeds (D).

Roasting Process Effect on Oil Oxidation, Composition and Antioxidant Activity. *Peroxide Value.* Oil peroxide value (PV) did not follow a distinct trend with seed roasting (Table 1). Oil from unroasted seeds gave a value of 0.57 mEq/kg oil. PV increased with light and medium roasting to 3.35 and 4.09, respectively; and then decreased with high roasting to 0.5 mEq/kg oil. As a comparison, flaxseed oil had a PV of 0.47. All these values are below the maximum acceptable PV value of 15 set by the Codex Alimentarius[15] for nonrefined oils.

According to the lipid oxidation theory, hydroperoxides begin to form at the initial stages of oxidation until reaching a maximum, and then decline at the latter stages of oxidation because of decomposition to secondary products (aldehydes, ketones, etc.). In light of the results obtained, one might be tempted to suggest that oils from lightly and medium roasted seeds are on the ascending hydroperoxide curve, and therefore, on the initial stages of oxidation; whereas, oils from highly roasted seeds are on the descending hydroperoxide curve, and therefore, on the latter stages of oxidation. However, an alternative explanation would be that roasting produced two opposing effects. On the one hand, it might have favored lipid oxidation, which is reflected in an increase in PV; but on the other hand, it could have favored production of phenolic compounds with potent free radical scavenging abilities, especially in highly roasted seeds (as will be explained later), which resulted in low PV in oils from highly roasted seeds.

These results differ from those of Yoshida,[4] who studied the effect of roasting seeds on sesame oil, where PV is reported to increase with roasting intensity, especially when roasting temperature surpasses 200 °C. Alternatively, Yoshida and Takagi[5] observed an increase in PV in roasted sesame seeds compared to unroasted seeds; however, no PV differences were detected between roasting temperatures in the range 160−220 °C. It is important to keep in mind that different roasting temperatures may have different oxidation and transformation processes reflected in peroxides and aldehydes with completely different behaviors, thus the need to elucidate the specific compounds formed.

p-Anisidine Value. Results for *p*-anisidine showed a well-defined trend in relation to roasting intensity (Table 1). The highest value corresponded to Sacha-inchi oil from the highly roasted seeds, 12.32, followed by medium roasted, slightly roasted, and unroasted seed oils, 9.40, 3.72, and 0.43, respectively, whereas the *p*-anisidine value obtained for flaxseed oil was zero. These results indicate that oil from seeds subjected to increased roasting show increasing amounts of secondary compounds of oxidation as a result of decomposition of hydroperoxides. This is in agreement with the results obtained on sesame seed oil by Yoshida[4] and by Yoshida and Takagi.[5]

In relation to the increased *p*-anisidine values and low PV observed before in highly roasted seed oil, we surmise that early in the roasting process, kinetics favors hydroperoxide scission into secondary oxidation products; whereas, in the latter part of the roasting process, kinetics favors the reaction of the antioxidant compounds generated with hydroperoxides.

Total Phenols. Oils from unroasted and lightly roasted seeds exhibited similar total phenol values, 2.32 and 2.55 mg chlorogenic acid/100g oil, respectively (Table 1). However, total phenol values increased with roasting intensity; thus, oils from lightly, medium, and highly roasted seeds had total phenol values of 2.55, 6.31, and 13.85 mg/100g oil (Table 1). These results could suggest that as roasting intensity increases, the formation of phenolic compounds, with stronger antioxidant capacities, is favored. Phenolic compounds have antioxidant properties, which can be increased by specific changes in the ring substitution groups.[16] An example of changes in phenols with roasting that lead to the formation of phenols with more potent reducing capacities is the conversion of sinapic acid into vinylsyringol (canolol) in rapeseed (canola).[7,8] Total phenol values can be correlated with oil color: the higher the phenol value, the darker the oil color (Figure 2).

DPPH Assay. Roasting increased the antioxidant capacity of Sacha-inchi oil as measured by DPPH. Roasting intensity increased DPPH values further. The values obtained were 18.2, 23.8, 47.6, and 95.0 μg TE/g oil for oils from unroasted, slightly, medium, and highly roasted seeds, respectively (Table 1). These results suggest that roasting of Sacha-inchi seeds increases the antioxidant capacity of the corresponding oils, with roasting intensity further increasing the antioxidant capacity. As mentioned in the previous section, this could be

[a]The ± values indicate the 95% confidence interval for the respective mean.

due to the formation of phenolic compounds with more potent antioxidant capacities. However, Maillard reaction products, which form during roasting of seeds, are also known to possess antioxidant capacities.[16] Furthermore, the formation of oxidative products with reducing power like aldehydes,[17] as reflected by the increase in *p*-anisidine in the present study could also have contributed partially to the observed increase in antioxidant capacity.

Tocopherol Content. Sacha-inchi oil, variety Pinto Recodo, showed a high tocopherol content, compared to flaxseed oil (Table 1). Only γ- and δ-tocopherols were detected in Sacha-inchi oil, 70.6 and 12.6 mg/100g oil, respectively. Oil from roasted seeds had a slightly lower γ-tocopherol content than oil from unroasted seeds; whereas, δ-tocopherols were unaffected by roasting. Oils from seeds roasted to different degrees had similar tocopherol contents (Table 1). These results indicate that only γ-tocopherols were slightly affected by roasting, however, no further decrease in content was detected by increasing roasting intensity.

Fatty Acid Profile. The fatty acid profile of Sacha-inchi is shown in Table 2 (day 0). The most abundant fatty acid corresponds to α-linolenic acid (18:3), 48.2%; followed by linoleic acid (18:2), 34.1%; oleic acid (18:1), 8.9%; palmitic acid (16:0), 4.7%; and stearic acid (18:0), 3.3%. These results confirm the high content of α-linolenic acid in Sacha-inchi oil reported previously by Hamaker and others.[2] However, the α-linolenic acid content of flaxseed oil obtained in our study is ~57.5% (Table 2, day 0).

It is worth noting the very low content of saturated fatty acids (8.0%) and the very high content of unsaturated fatty acids (91.2%) of Sacha-inchi oil. As a reference, flaxseed oil had 8.9% saturated and 89.9% unsaturated fatty acids. Roasting did not have any major effect on the fatty acid profile of Sacha-inchi oil, which is in agreement with previous results obtained for other oilseeds.[3−5]

High Temperature Storage and Roasting Intensity Effect on Oil Stability. *Peroxide Value.* The PV of all oil samples increased continuously during storage at 60 °C for 30 days (Figure 3). Sacha-inchi oils from roasted seeds had lower PV than that from unroasted seeds during storage, especially at the end of the storage period (30 days). Roasting intensity slowed down the PV rate of increase of oils during storage, although at the end of the storage period (30 days) the difference in PV between the oils from the lightly and the

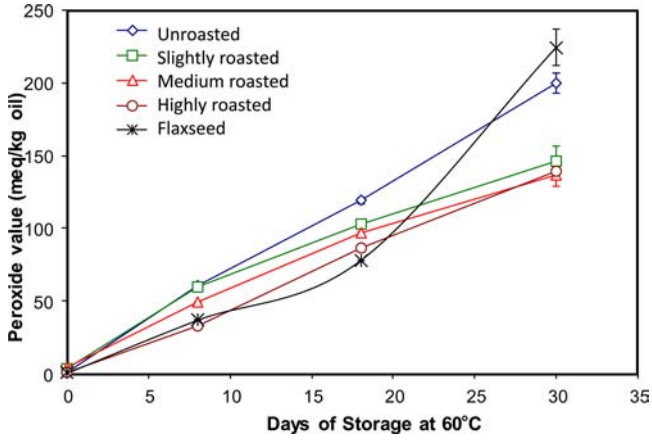

Figure 3. Peroxide values of Sacha-inchi oil unroasted and roasted samples during high-temperature storage at 60 °C for 30 days. Bars for each mean value indicate the 95% confidence interval.

dx.doi.org/10.1021/jf500936j | J. Agric. Food Chem. 2014, 62, 5191−5197

highly roasted seeds was not significant. The explanation for the lower peroxide content in Sacha-inchi oil from roasted seeds during storage, compared to that from unroasted seeds, seems to be due to the antioxidative protection of the phenolic compounds formed during roasting. Although residual lipoxygenase activity could have been a factor in the oxidation of oil from unroasted seeds, it is unlikely, because the temperature reached at the expeller for the unroasted seeds was around 110 °C. It has been previously shown that this temperature would be high enough to inactivate lipoxygenase.[18]

p-Anisidine Value. All Sacha-inchi oil samples showed an increase of *p*-anisidine values during high temperature storage (Figure 4). These values increased rapidly up to day 18, and

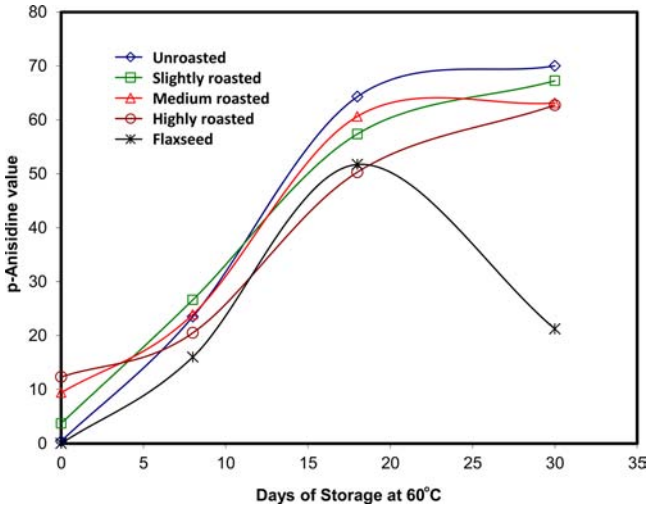

Figure 4. *p*-Anisidine values of Sacha-inchi oil unroasted and roasted samples during high-temperature storage at 60 °C for 30 days. Confidence intervals (95%) are so small that bars do not appear.

from there up to day 30, the increase in *p*-anisidine values slowed down. Prior to high-temperature storage, Sacha-inchi oil from unroasted seeds showed lower *p*-anisidine values than oil from roasted seeds. However, during and at the end of the storage period, the reverse is true, indicating that in oils from roasted seeds, *p*-anisidine values increase at a slower rate than in oil from unroasted seeds during storage (Figure 4).

The higher resistance to oxidation of oils from roasted seeds could be attributed to the formation of phenolic compounds with higher antioxidant activity, during the roasting process, possibly derived from precursor compounds with lower antioxidant activity, such as was observed in sesame and canola oil.[5−8] Maillard reaction products with antioxidant properties, generated during roasting, may also contribute to the higher stability of oil to oxidation.[16,19−21]

Total Phenols and DPPH Antioxidant Assays. Sacha-inchi oil samples from unroasted and lightly roasted seeds increased their antioxidant capacity—measured as total phenols and DPPH—during the high-temperature storage period. However, the antioxidant capacity decreased in oils from medium and highly roasted seeds, especially from the latter (Figures 5 and 6). We surmise that this increase in antioxidant activity in unroasted and lightly roasted oils during storage would be associated with the formation of oxidative products with reducing power as reported previously for aldehydes.[17] Alternatively, the decrease in antioxidant activity in medium and highly roasted oils could be due to reactions taking place

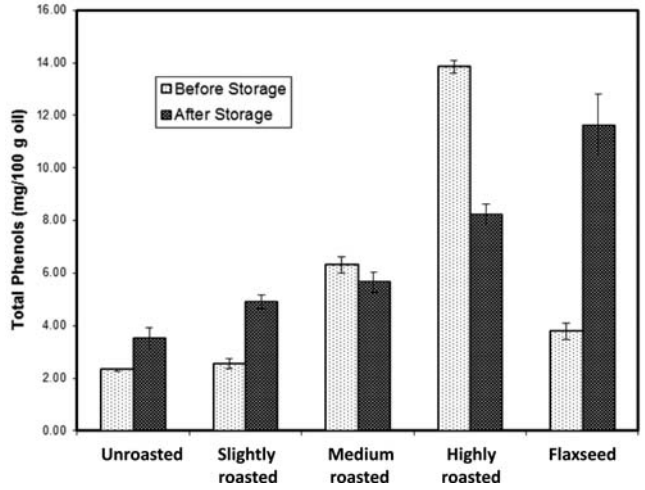

Figure 5. Total phenol values of Sacha-inchi oil unroasted and roasted samples during high-temperature storage at 60 °C for 30 days. Bars for each mean value indicate the 95% confidence interval.

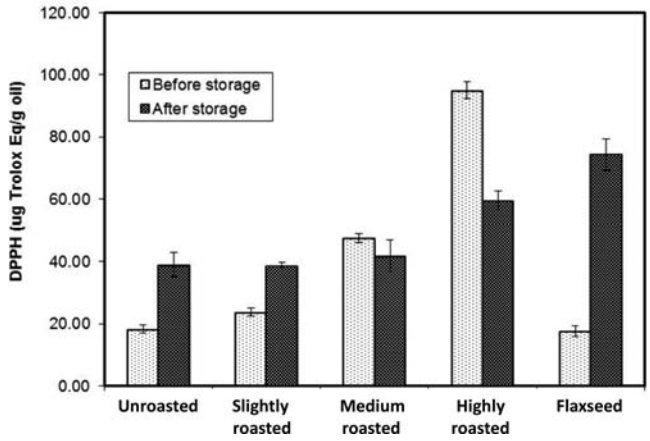

Figure 6. DPPH antioxidant activity of Sacha-inchi oil unroasted and roasted samples during high-temperature storage at 60 °C for 30 days. Bars for each mean value indicate the 95% confidence interval.

between phenols and hydroperoxides and possibly through partial regeneration reactions of oxidized tocopherols.[22] This is in agreement with the observation that roasting reduces the formation of hydroperoxides and the loss of tocopherols during storage (Figures 3, 7). It is worth noting that total phenols and DPPH exhibited the same trend in all samples.

Tocopherol Content. Tocopherol content (both γ- and δ-tocopherol) was notably reduced during storage at high temperatures in all oil samples (Figure 7). However, tocopherol degradation rate was slower in oils from roasted seeds compared to oil from unroasted seeds; moreover, tocopherol degradation rate was slower in oil samples from more intensely roasted Sacha-inchi seeds (Figure 7). This lower degradation rate of tocopherols in Sacha-inchi oil from roasted seeds seems to result from additional protection from oxidation due to roasting; specifically, higher antioxidant capacity stemming from the formation of compounds with higher antioxidant properties during roasting of seeds.

Fatty Acid Profile. Slight changes in the fatty acid profile of all Sacha-inchi oil samples were observed during the high-temperature storage period (30 days) (Table 2). There is a slight trend for the α-linolenic acid relative content to decrease,

dx.doi.org/10.1021/jf500936j | J. Agric. Food Chem. 2014, 62, 5191−5197

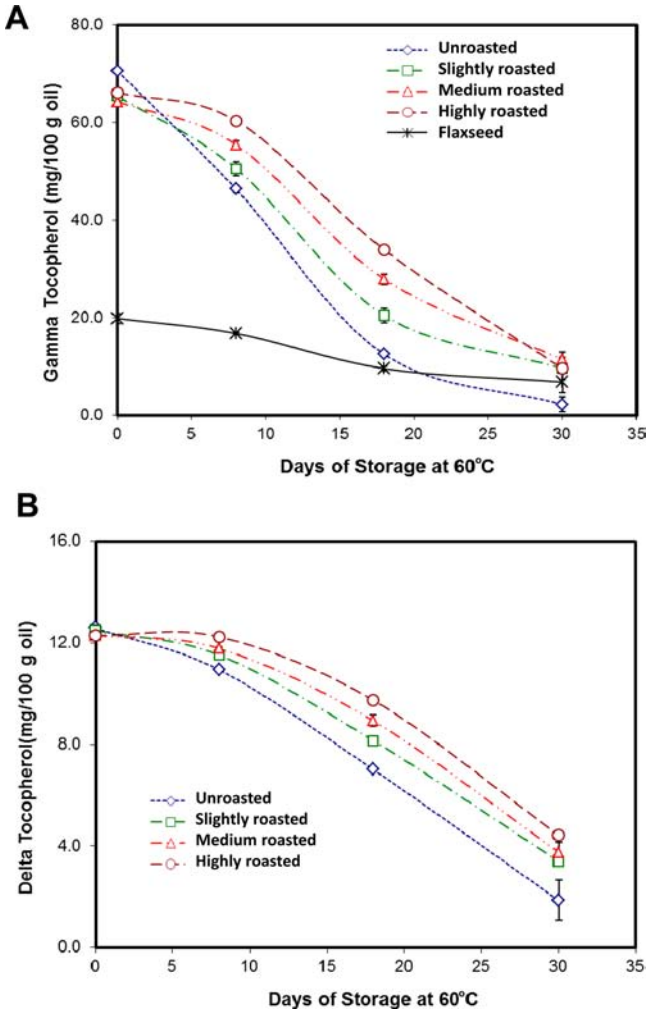

Figure 7. Tocopherol content of Sacha-inchi oil unroasted and roasted samples during high-temperature storage at 60 °C for 30 days. (A) γ-tocopherol and (B) δ-tocopherol. Bars for each mean value indicate the 95% confidence interval.

while the percentage of all other fatty acids (linoleic, oleic, palmitic, and stearic acids) showed a slight increasing trend. From these results, it can be inferred that the most unsaturated fatty acid, α-linolenic acid, was the fatty acid most susceptible to oxidation during high-temperature storage. This is in agreement with the fact that the higher the unsaturation of a fatty acid the more readily it is oxidized.[23]

In conclusion, the roasting process of Sacha-inchi seeds caused a slight increase of the oxidation indicators, such as the peroxide value and *p*-anisidine value of the oil; however, it also increased the antioxidant capacity of the oil as expressed by total phenols and DPPH, which seemed to provide some protection to the oil against oxidation during its storage at high temperatures. During storage stability studies, oils from roasted seeds exhibited lower oxidation and higher tocopherol content compared to oil from unroasted seeds. The intensity of roasting had an important effect in enhancing the protection against oxidation during storage. The fatty acid profile was not affected by roasting. In general, we have shown in this study that roasting favors the stability of Sacha-inchi oil and is recommended for extending its shelf life. Further studies are needed to elucidate the specific compounds formed due to oxidation as well as to characterize the formation of Maillard reaction products or new phenolic compounds formed during seed roasting that seem to favor the oil protection.

including borate precipitation and reconstitution of vegetable protein. CE−SDS with UV detection was used to detect soy protein in milk powder. The limit of detection (LOD) for soy was about 10% w/w, unless tetraborate precipitation is used, which can lower the LOD to 1% soy.[18]

MS and HPLC−MS have been successfully used to detect adulteration of food. Matrix-assisted laser desorption ionization-time-of-flight (MALDI-TOF) mass spectrometry detected adulteration of ewe's milk with 5% cow's milk.[19] MALDI-TOF detected adulteration of fresh cow's milk with powdered milk at the 1% level using a targeted, proteomics method.[20] Quadrupole-time-of-flight MS (Q-TOF-MS) coupled to HPLC was used to detect 5% soy and pea protein added to SMP in a nontargeted approach, but the method required a borate buffer enrichment step and specialized proprietary software for data analysis.[21,22] The MS-based methods are sensitive and accurate but require extensive sample pretreatment in the case of peptide marker methods, which require protein digestion and borate buffer enrichment.

Amino acid analysis with a standard amino acid analyzer has been used to detect adulteration of SMP by whey proteins.[23] An immunochemical sensor was developed to detect soy, pea, and soluble wheat proteins in milk powders added at 1−5% levels using affinity-purified monoclonal antibodies.[24]

Near-Infrared (NIR) spectroscopy combined with chemometric data analysis is a widely used technique for food authentication and has been applied to dairy products.[25,26] NIR is a simple and fast technique but requires extensive data processing with multivariate techniques to extract useful information from the broad and overlapped spectral features.

Ultrahigh-performance liquid chromatography with UV detection (UHPLC−UV) is a method that provides more discriminating features in the form of sharper, more resolved features (peaks) than NIR.[27] However, the variable axis of UHPLC−UV (retention time) is not as reproducible as NIR (wavelength) due to typical drift and changes in HPLC conditions over time. Software alignment of the UHPLC retention time axis could improve peak alignment and enable UHPLC−UV to be an effective fingerprinting tool for food adulteration detection.

In this study, our objective was to develop a simple, nontargeted UHPLC−UV method for detection of adulteration of SMP by foreign-protein-containing substances using a simple procedure aimed at minimizing sample preparation time. The simplicity of this procedure derives from the data analysis by comparing chromatographic profiles as fingerprints. The fingerprint approach considers the overall pattern of the chromatogram and eliminates the need for protein standards and calibration curves to quantify individual peaks.

MATERIALS AND METHODS

Reagents. Water, acetonitrile, methanol, and formic acid for UHPLC were Optima LCMS grade from Fisher Scientific, (Fairlawn, NJ). Trifluoroacetic acid (Fluka LCMS TFA), sodium citrate tribasic dihydrate, guanidine hydrochloride, and dithiothreitol were all greater than 98% purity from Sigma (St Louis, MO).

Samples. All samples of SMP and protein adulterants were obtained by USP, Rockville, MD, and provided to our laboratory. Medium-heat skim milk powder lot S-085 (32.44% protein) and lot S-094 (32.44% protein) were from sources in the United States. Skim milk powder lot S-095 (32.7% protein) was from a New Zealand source. Soy protein isolate (SPI) lot A-027 (86.95% protein) was from China. Pea protein isolate (PPI) lot A-011 (84% protein), brown rice protein concentrate (BRP) lot A-017 (90.1% protein), and lightly hydrolyzed wheat protein (HWPI) lot A-028 (82.7% protein) were from the United States.

Sample Preparation. Samples were prepared for UHPLC analysis following a procedure based on that of Bordin et al.[28] SMP aliquots of 50.0 ± 0.5 mg were weighed into a 15 mL polypropylene tube, and 10 mL of denaturing buffer (6 M guanidine HCl, 20 mM dithiothreitol, 5 mM trisodium citrate, pH 7) was added to samples. The tubes were immediately vortexed for approximately 30 s and shaken to disperse the SMP. The samples were shaken on a model 2010 Geno-Grinder (Spex Sample Prep, Metuchen, NJ) for 15 min at 1000 rpm. If necessary, the samples were sonicated at room temperature and shaken again on a Geno-grinder to ensure complete dissolution of the SMP. Aliquots of 0.5 mL from the 5 mg/mL samples were further diluted with 1.0 mL of denaturing buffer to produce samples with nominal SMP concentrations of 1.67 mg/mL in microcentrifuge tubes. The samples were vortexed and placed in a refrigerator at 4−8 °C for a minimum of 30 min. Samples were checked for precipitation and then centrifuged at 12 000 rpm for 10 min at 10 °C. Some samples (brown rice protein) required filtering with 0.2 μm polyvinylidene difluoride (PVDF) syringe tip filters. Approximately 1 mL of the samples was transferred to autosampler vials for UHPLC−UV analysis.

Stock solutions (5 mg/mL) of the potential adulterant proteins were prepared as described above for SMP. Volumes of the adulterant stock solution were added to the 5 mg/mL SMP stock to produce the desired level of adulterant in the SMP sample. The percent weight of adulteration is based on the actual weight of materials blended, not on the percentages of protein in SMP and the adulterant protein substances. For example, to make a 1% mixture of adulterated SMP, 100 μL of the adulterant 5 mg/mL stock solution was transferred into a 15 mL polypropylene tube containing 9900 μL of the 5 mg/mL SMP stock solution. The sample was shaken on a Geno-Grinder for 15 min at 1000 rpm. The adulterated SMP sample solution was then processed as described above by further dilution, refrigeration, centrifugation, and transfer to autosampler vial for UHPLC analysis. Five samples of SMP S-085 were prepared and injected multiple times, resulting in 18 chromatograms, and two samples of SMP S-094 and S-095 were prepared and injected twice, for a total of 26 authentic SMP chromatograms. Two preparations of each SPI-adulterated were made and injected four times resulting in eight replicate chromatograms of SPI-adulterated SMP. Single preparations of the PPI-, BRP-, and HWPI-adulterated SMP were made and injected two times, resulting in two replicate chromatograms for each protein adulterant material. The UHPLC sample analysis was initially conducted with authentic SMP S-085 and the adulterated samples of SMP S-085. In a second set of sample analysis, SMP S-085, S-094, and S-095 were chromatographed to provide a larger set of authentic SMP samples. Two samples of each SMP lot were prepared, and each was injected in duplicate to provide four replicate chromatograms. These two sets of samples are identified as sets 1 and 2.

UHPLC Instrumentation. An Acquity UHPLC system from Waters (Milford, MA) equipped with Acquity Sample Manager Module and with e-Lambda PDA wavelength range 190−800 nm with 1.5 μL titanium flow cell was used for UHPLC analysis. The column was a BEH C4 (150 × 2.1 mm, 1.7 um packing) and the guard column was a Vanguard (BEH C4) from Waters. The Acquity Sample Manager module was temperature-controlled, and the sample loop volume was 10 μL. The chromatographic data system was Masslynx from Waters.

RP-HPLC−UV Analysis. Mobile phase A was water + 0.1% TFA. Mobile phase B was acetonitrile + 0.1% TFA. The sample manager weak flush solvent was 10/90 acetonitrile/water, and the strong flush solvent methanol + 0.1% formic acid was used to flush the sample loop after injection. The sample compartment temperature was 10 °C, and the inject volume was 7.5 μL in partial loop needle overflow mode. The mobile phase gradient is shown in Table 1. Column temperature was maintained at 50 °C. The PDA collected 210−800 nm spectra at a sampling rate of 5 Hz, resolution of 1.2 nm, and filter time constant of 0.4 s. The 215 nm wavelength was used for data analysis. Sample sets typically consisted of 14−20 injections. The column was flushed with methanol followed by 70/30 acetonitrile/water (column storage

solvent) after each sample set. A few conditioning injections of dilution buffer and SMP samples were made prior to collection of chromatograms for inclusion into the sets for statistical analysis. These injections were made to ensure that retention times were stabilized.

Chromatographic data were collected 300 times a minute for 32 min (from 3 to 35 min) to provide a profile of 9600 points. The result was a final sample matrix that consisted of 82 samples (rows) by 9600 variables (chromatographic profile), including 26 nonadulterated samples and 56 adulterated samples. The chromatographic conditions were chosen after an initial method development period in which parameters such as solvent strength, gradient steepness, flow rate, and temperature were investigated. The conditions used for sample analysis provided a good compromise between resolution, sensitivity, and run time.

Data Formatting For Statistical Analysis. The 0−3 min retention window was excluded, since it gave a very large off-scale "solvent front" peak. Peak retention time (t_R) drift was compensated for by software alignment of chromatograms. Since pure protein standards were not employed in this work, alignment of the independent variable (time) axis is critical to ensure meaningful statistical comparisons and classification of samples as authentic or adulterated without peak integration. Then the raw chromatographic data (3−35 min window) from the data system was copied as a time−intensity list into ASCII format and pasted into a calculation spread sheet (Excel, Microsoft, Redmond WA). The chromatogram data table was imported into Pirouette (Infometrix, Bothell, WA), and the file was saved in a CDF format. The CDF chromatograms of authentic SMP and mixed SMP were aligned to a target SMP chromatogram using correlation-optimized warping (COW) (Lineup, Infometrix, Bothell, WA), and the correlation of the peak profiles was improved to greater than 0.9 in most cases using a warp factor of 10 and segment size of 30 or 60. The target is the standard to which all other sample chromatograms in the set are aligned. In this study a total of 82 chromatograms comprised the data set. The sampling rate of 5 Hz over the elution window of 3−35 min gave a data matrix with 9600 time point variables. The target for alignment was an authentic SMP sample with peaks in the approximate center of the observed range of drift. Aligned files were then copied and combined into a Pirouette table.

Statistical Analysis. *Point-by-Point Data Analysis.* A nontargeted "threshold" classification approach using classical statistics was developed and investigated for its capability to discriminate between nonadulterated SMPs and those adulterated with plant proteins. The threshold classification is based on a t test at each data point as described by Yuk et al.[29] Retention-time-aligned chromatographic files were transferred from Pirouette to Excel, and baseline normalization was performed in Excel to improve the reproducibility of SMP chromatographic fingerprints on the vertical axis (UV response). The baselines were normalized at T = 35 min, where no UV-absorbing analytes eluted at the end of the chromatographic profile. The mean UV intensity at T = 35 min of all chromatograms was subtracted from each data point to perform the normalization. The 99% confidence interval boundaries at each point in the chromatographic profile for nonadulterated SMP were generated by calculating the mean ± 3SD (standard deviations) for all nonadulterated sample chromatograms in the data set. The chromatographic profiles of each adulterated and nonadulterated sample were then compared point-by-point to the 99% confidence boundaries for nonadulterated SMP. The total number of chromatographic points falling outside the 99% confidence boundary was then calculated. A "threshold" was chosen for classification of profiles as nonadulterated or adulterated, corresponding to the total number of chromatographic points that fell outside the 99% confidence.

Chemometric Analysis. Data were analyzed using principal component analysis (PCA) and soft independent modeling of class analogy (SIMCA) using both Pirouette (Infometrix, Bothell, WA) and Solo (eigenvector Research, Inc., Wenatchee, WA). Pretreatment for both PCA and SIMCA consisted of normalization and mean-shifting of the chromatograms to align the data from separate experiments (see below).

Mean-Shifted Chromatograms. Draper et al.[30] have described "mean intensity shifting" as a preprocessing means of removing bias or drift between batches of data collected over long intervals. In this report, we used "mean-shifted chromatograms" to remove differences in the chromatographic profiles that occurred between experiments (see Table 2). For the first experiment, the mean chromatogram was based on only the 14 runs of the pure SMP (S085), and in the second experiment the mean chromatogram was based on the 12 runs of S085, S094, and S095. In each case, the chromatograms were normalized prior to mean shifting. Subtraction of the mean chromatograms from the pure samples provided residuals at each point that were randomly distributed around the means. Subtraction of the mean chromatogram from the adulterated SMP samples provided residuals that were not random but showed systematic deviations due to chemical differences.

S085	BRP	1.0	2	
S085	BRP	3.0	2	
S085	BRP	10.0	2	

PCA. Data matrices consisting of 82 samples by 9600 variables (full chromatograms) or smaller intervals (e.g., 82 samples by 5100−5500 variables, the optimum region determined by visual comparison of the nonadulterated SMP and SMP adulterated with 10% SPI) were submitted to PCA. Preprocessing of the data consisted of mean-shifting the chromatograms, applying mean scatter correction to vertically align the spectra, and normalizing the intensities of each sample (sum of squares of intensities = 1.0).

SIMCA. There are many options available for chemometric treatment of a large data set. In general, PCA is used as an exploratory method to visually look for patterns and SIMCA is a modeling method for classifying samples as authentic or nonauthentic (adulterated). This treatment was recently used to detect adulterated *Ginkgo biloba* supplements.[31] SIMCA was used to establish the confidence level for

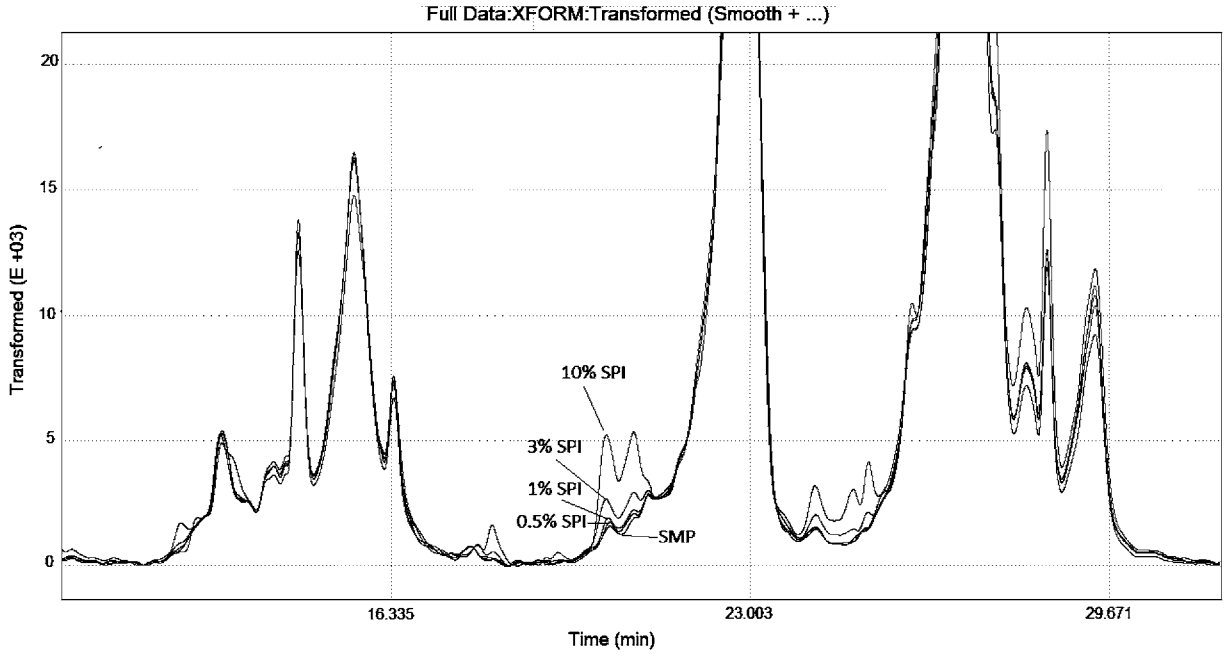

Figure 1. Chromatographic profiles (215 nm) of SMP and SMP mixed with 0.5, 1, 3, and 10% SPI.

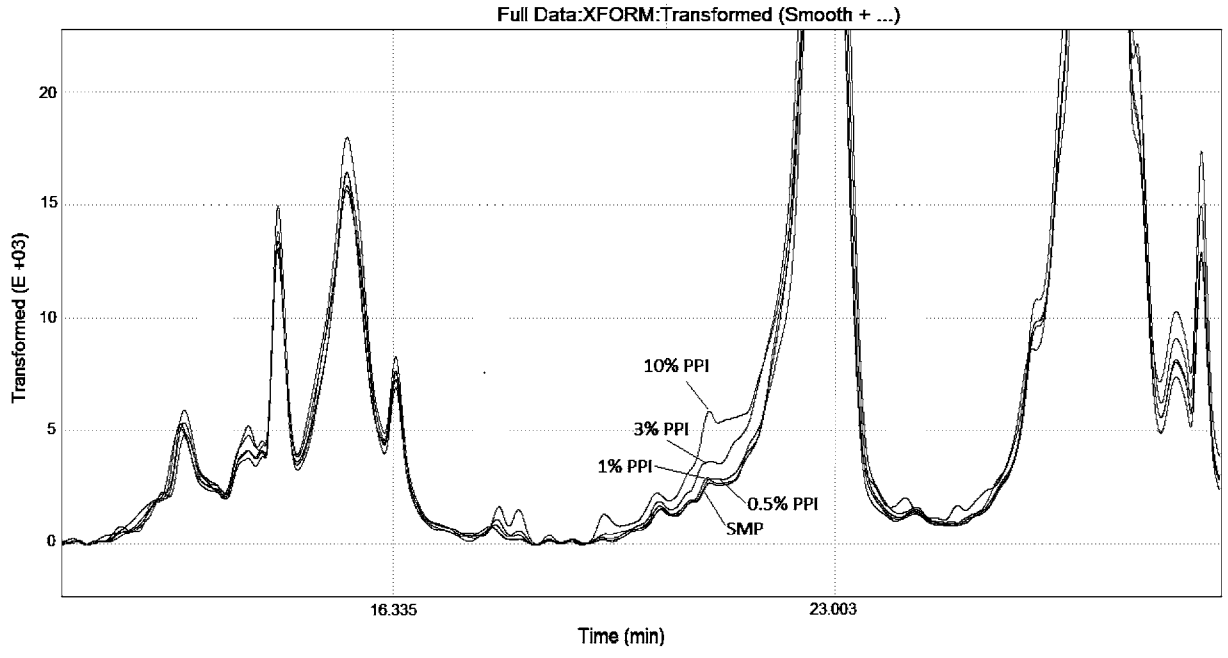

Figure 2. Chromatographic profiles (215 nm) of SMP and SMP mixed with 0.5, 1, 3, and 10% PPI.

detection of protein adulterants in SMP in this study. A single PCA model was constructed on the basis of the nonadulterated SMPs to establish the model boundaries. The Hotelling T^2 residual describes the sample variance accounted for by the model, and the Q residual describes the remaining variance, i.e., the variance not accounted for by the model. Consequently, the Q residual is a good indicator of adulteration if the sample lies outside the 95% confidence limit (or any other predetermined limit).[32]

RESULTS AND DISCUSSION

Chromatographic Profiles. Figure 1 shows overlaid chromatograms of an authentic SMP sample and SMP adulterated with SPI. At the 3% and 10% SPI levels, additional peaks are clearly visible in the SMP chromatographic profile at the 20 and 24 min marks. The visual difference is not as readily observable at the 1% and 0.5% SPI levels, and a statistical treatment of the chromatograms is needed to see if the lower levels of adulteration can be detected with confidence. Figure 2 shows overlaid chromatograms of an authentic SMP sample and SMP adulterated with PPI. The presence of additional peaks at the 21 min mark are visible for the 3 and 10% PPI-adulterated samples. Figure 3 shows overlaid chromatograms of an authentic SMP sample and SMP adulterated with BRP. The presence of additional peaks at the 31 min mark are visible at 3 and 10% adulteration level. At the 0.5% and 1.0% adulteration levels the presence of the additional peaks is hard to visualize and a statistical treatment is clearly necessary to identify SMP

contaminated with these proteins at levels below 3%. The HWPI-adulterated SMP samples produced chromatograms that were visibly identical to the pure SMP samples (data not shown). Chromatograms of the pure adulterant protein materials are shown in the Supporting Information (Figure S1).

Point-by-Point *t* Test Data Analysis. After vertical alignment, the 99% confidence interval boundaries were determined at each point in the chromatogram by calculating the mean ± 3SD for all 26 nonadulterated chromatograms in the data set. Figure 4 shows chromatograms of 10% w/w blends of each model adulterant overlaid on the 99% confidence

[a]Bold values indicate incorrect classification. [b]Threshold is number of data points exceeding the mean ± 3SD boundary. [c]NEG = nonadulterated, POS = adulterated.

interval (mean ± 3SD) boundaries for nonadulterated SMP (dotted lines). Figure 4 demonstrates that all tested adulterants at the 10% spike level, except hydrolyzed wheat protein, exhibit clear chromatographic features that fall outside the 99% confidence boundaries for nonadulterated SMP that should enable correct classification of these samples as adulterated.

A threshold value was established for classification of samples as nonadulterated or adulterated. The threshold was the minimum number of data points in a chromatogram that had to exceed the 99% confidence limits before a sample was classified as adulterated. Table 3 shows the results for this approach based on entire chromatograms (3−35 min window) for 56 adulterant-spiked samples preprocessed using the same retention time and baseline alignment as used for the authentic SMP samples. Four different thresholds from 25 to 200 chromatographic points (0.26−2% of chromatographic points) were investigated. A sample was classified as adulterated if the number of points falling outside the 99% limit exceeded the threshold. Because the test is searching for adulterated samples, a positive result is defined as a sample that exceeds the threshold. In Table 3 there are two distinct trends: the number of "positive" results (samples identified as adulterated) increases as the threshold is decreased, and the number of positive results increases as the level of adulteration increases.

Table 3 makes it clear that the number of false positives (a nonadulterated sample is identified as adulterated, a type I error) and false negatives (an adulterated sample is identified as nonadulterated, a type II error) is dependent on the threshold. For example, if the threshold is 25, then 4 of the authentic SMP samples were identified as adulterated (false positives). With the same 25 point threshold, 6 of the SMP samples adulterated with 0.5% SPI were identified as nonadulterated (false negatives). The number of false positives decreases as the threshold increases and the number of false negatives decreases as the level of adulteration increases. It can be seen that each threshold represents a compromise, the number of false positives for the nonadulterated SMPs balanced against the number of false negatives for the adulterated SMPs

The "detection capability" value can be defined as an estimate of the lowest adulterant spike levels that could be classified as adulterated with 0% false positive classification rate (i.e., no adulterated samples were classified as nonadulterated) based on the data analyzed. There were no misclassifications (false positives) of authentic SMP at the 200 point threshold. Using this strict criteria, the detection capabilities were 3.0% for SPI, 10% for PPI, 10% for BRP, and greater than 10% for HWPI.

The better detection capabilities for PPI and SPI compared to BRP and HWPI can be explained on the basis of the respective fingerprint profiles of each adulterant. SPI and PPI both exhibited more chromatographic profile features compared to BRP and HWPI (Supporting Information). There was a very large peak observed in the void region of the chromatogram, approximately 1.0−2.5 min. This region was not evaluated for differences between chromatograms but would be expected to contain the nonretained species such as amino acids. Therefore, only the 3−35 min retention window was evaluated and processed for this statistical comparison.

Multivariate Data Analysis. Initially, PCA was applied to the full chromatograms (9600 data points) of the authentic samples and SPI adulterated samples from set 1. The PCA score plot showed poor discrimination between the authentic and adulterated samples (data not shown). Only the 10% SPI was clearly separated from the cluster of authentic samples. This observation was also supported by a SIMCA model (data not shown).

Visual examination of Figure 1 shows that there are two regions (20.0−21.3 and 28.0−29.5 min) where there are distinct differences between the SMP and SPI chromatographic profiles. PCA score plots of just the data from 20.0−21.3 min showed a clear separation of the 1%, 3%, and 10% adulterated samples from the authentic samples (Figure 5A). Supporting results were obtained with SIMCA (Figure 5B). All samples with 10% SPI fell above the 95% confidence limit and were judged to be adulterated. Seven of the eight samples with 1% SPI and six of the eight samples with 0.5% SPI were judged to be adulterated.

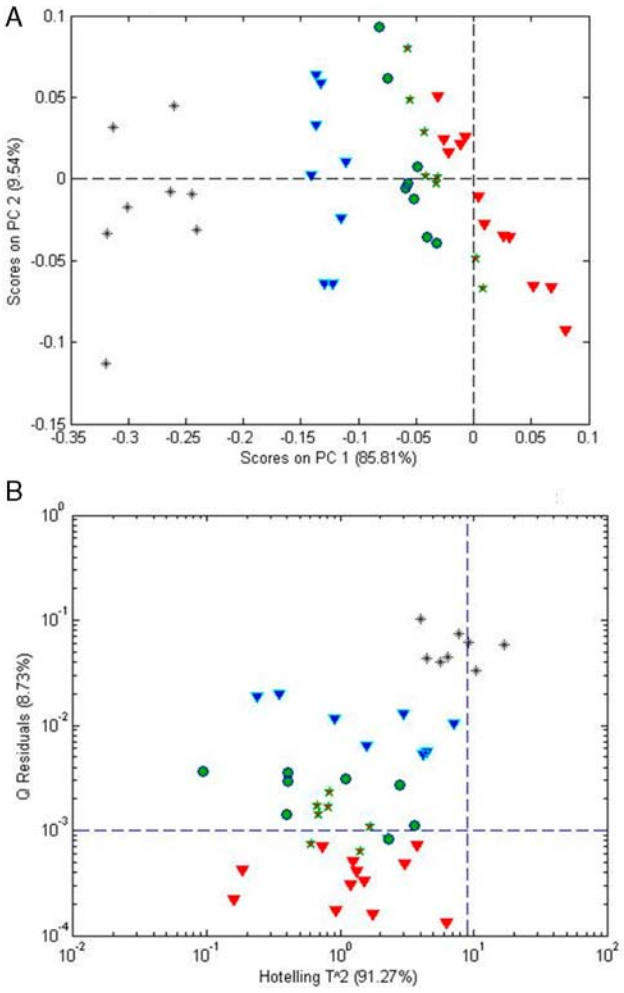

Figure 5. (A). PCA score plot of non-adulterated and SPI-adulterated SMP samples from Set 1: red triangles = SMP lot S085; green stars = 0.5% SPI; green circles = 1.0% SPI; blue triangles = 3.0% SPI; black asterisks = 10% SPI. (B) SIMCA plot of Q-Residuals versus samples for non-adulterated and SPI-adulterated SMP samples from Set 1: red triangles = SMP lot S085; green stars = 0.5% SPI; green circles = 1.0% SPI; blue triangles = 3.0% SPI; black asterisks = 10% SPI.

PCA of SMP samples adulterated with PPI produced results similar to those adulterated with SPI (data not shown). Poor discrimination was observed using the full chromatogram, but the same selected time interval (20.0−21.3 min; see Figure 2) produced improved separation. SIMCA identified 100% of the samples with 10% and 3% PPI as adulterated but was unable to detect adulteration at the 1% or 0.5% level. PCA of SMP samples adulterated with HWPI and BRP failed to reveal any adulteration using the full chromatogram or any selected time interval (data not shown). Additional lots of SMP were analyzed in a second analytical set, experiment 2, to provide a broader range of authentic SMP to model.

PCA of the combined data from sets 1 and 2 showed distinct differences between the authentic samples (Supporting Information, Figure S2). In fact, the authentic and adulterated (with SPI) samples from set 1 were more similar than the authentic samples from sets 1 and 2. This is particularly revealing since the authentic sample from set 1 (S085) was repeated in set 2. SIMCA based on the nonadulterated SMP from set 1 (S085) showed that the nonadulterated SMPs from set 2 (S085, S094, and S095) were well outside the 95% confidence limit (Supporting Information, Figure S3). These results were observed for both the full chromatogram and the 20.0−21.3 min range. It was apparent that there was a major shift in the chromatograms between the two experiments.

The disparity in the chromatograms was minimized by mean-shifting the data (see Materials and Methods). Briefly, the mean chromatogram for the nonadulterated SMPs of each experiment (sets 1 and 2) was subtracted from all the samples of that experiment. Thus, the basic chromatographic shape was removed from the data, leaving randomly distributed residuals for the nonadulterated SMPs. Only the systematic bias of the adulterated samples provided nonrandom residuals. After mean-shifting sets 1 and 2, the PCA scores of the authentic samples were well-aligned (Supporting Information, Figure S4), and SIMCA showed that both sets of authentic samples fell within the 95% confidence limit (Supporting Information, Figure S5).

Figure 6 shows PCA and SIMCA plots after all the authentic samples from both data sets have been combined into one model and labeled identically. The plot shows adulteration with SPI examined over the 20.0−21.3 min interval. Figure 6A clearly shows that there is no difference in the authentic SMPs from sets 1 and 2. All but the 0.5% SPI samples appear well-separated from the authentic SMPs. This is also shown in the Q residuals plot for SIMCA in Figure 6B. Six of the eight samples with 1% SPI and four of the eight samples with 0.5% SPI are judged to be adulterated.

For the combined data sets, SIMCA identified all of the samples with 10% and 3% PPI as adulterated using the chromatographic region between 20.0 and 21.3 min. One of the two samples with 1% PPI was judged adulterated and none of the 0.5% PPI samples were determined to be adulterated. None of the samples containing HWPI or BRP were judged to be adulterated, either examining the full chromatogram or an isolated region.

In general, the results obtained by multivariate analysis were very similar to those obtained using point-by-point analysis. This is expected since both methods examine deviations of the chromatographic signal with respect to the analytical variance. Multivariate analysis of the entire chromatogram is less sensitive to changes in chromatographic features than a point-by-point analysis, since the variance of the whole chromatogram, even for random noise, accumulates with the square root of the number of data points. Thus, the variance for the 9600 data points of the full chromatogram is roughly 100 times greater than seen using a point-by-point analysis. The point-by-point analysis can detect much smaller changes in the chromatogram but is also more subject to random variations. Consider that 1% of the data will fall above the 99% confidence limit. For 9600 points, that is 96 possible false positives. However, the data are not totally random, they are correlated with their near neighbors since the chromatographic peaks have a finite width. Possibly the best strategy is achieved by using point-by-point analysis to identify a selected region for application of multivariate analysis. This process of feature selection is warranted when an unknown test material can be compared to an authentic material.

Experimental Factors. The chromatographic data for the two experiments, which occurred 6 months apart, suggest that additional sample analysis will be required to verify the utility of UHPLC fingerprinting with chemometric data treatment. The change in protein peak retention times is relatively small over a given run of consecutive samples and time-axis shifts are easily

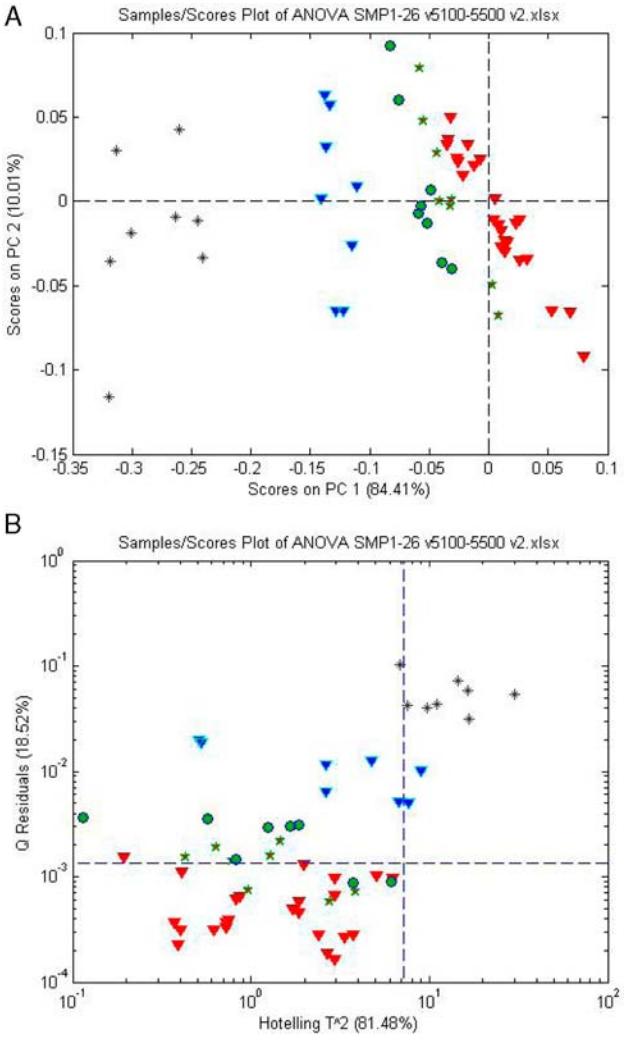

Figure 6. (A). PCA score plot of non-adulterated and SPI-adulterated SMP samples from Set 1 and 2 combined: red triangles = SMP lots S085, S094, and S095; green stars = 0.5% SPI; green circles = 1.0% SPI; blue triangles = 3.0% SPI; black asterisks = 10% SPI. (B) SIMCA plot of Q-Residuals versus samples for non-adulterated and SPI-adulterated SMP samples from Set 1 and 2 combined: red triangles = SMP lots S085, S094, and S095; green stars = 0.5% SPI; green circles = 1.0% SPI; blue triangles = 3.0% SPI; black asterisks = 10% SPI.

aligned by the COW software. Dealing with the peak intensity changes over time and between batches is more difficult. The variance in the SMP peak intensities is fairly high for the major peaks. Normalization of the chromatograms is likely to reduce or change adulterant peak height along with SMP peak height and lead to error in estimation of the adulterant peak intensity. Regions of the SMP chromatogram that show the least variance (show relatively flat baselines) should be selected for statistical analysis. This allows detection of prominent adulterant peaks that elute in selected retention windows for best probability.

Chromatograms of the SMP proteins were evaluated at 215 and 280 nm. The profiles appeared to have very similar signal-to-noise (S/N) ratios. The 215 nm wavelength produced higher absolute intensities for the protein peaks, so it was chosen as the wavelength for data processing. The S/N with UHPLC–UV systems is negatively impacted by TFA in the mobile phase. TFA is a known to induce baseline noise due to its strong absorbance at the low-UV wavelengths needed to detect proteins.[33]

In summary, the potential of single wavelength UHPLC to classify SMP as pure versus adulterated by foreign proteins is demonstrated. Feature-rich protein adulterants, such as SPI and PPI, present in SMP at approximately at or above 3% w/w produce observable additional peaks in the nominal SMP UHPLC profile. The UHPLC–UV fingerprinting technique shows the ability to differentiate SMP from SMP adulterated with SPI at 3% w/w from point-by-point *t* test comparison of chromatograms. With SIMCA analysis after mean-shifting the profiles it was possible to incorporate samples from different experiments and to differentiate all SPI-adulterated samples in the range from 1.0 to 10.0% at 95% confidence level. A larger sample set including SMP from more sources is needed to confirm and validate the procedure.

[a]The data of *n*-3 DPA, EPA, and DHA of all studied species[26] and the mean of MeHg concentration of majority studied species[27] could be obtained from Chinese published articles.

for regional specific assessment.[18] The concentrations of specific fatty acids and total mercury in some Chinese marine/freshwater fish were reported,[12,19] but there are clear location differences in MeHg concentrations and species differences in DHA concentrations in marine fish,[20] and there is little information on assessment of net neurodevelopmental effect via maternal marine fish consumption in China. In response to this public health concern, we calculated and integrated benefits of DHA and risks of MeHg caused by maternal consumption of some edible marine fish farmed or grown in Zhoushan, southeast China, to assess the net neurodevelopmental effect of these species according to the aforementioned FAO/WHO approach.

MATERIALS AND METHODS

Samples Collection and Preparation. Common edible marine fish were collected between September and October 2011 from Zhoushan archipelago, which is a major fish farming area in southeast China. A total of thirty-one species (6 samples/species, 1 individual fish/sample) were purchased from local piers or traditional markets. All fish samples were farmed or grew locally and were medium-sized (Table 1). Scientific names have been used to represent the species in this article.

Edible parts of samples were prepared by collectors. The processed filet of each sample was homogenized and expressed directly into a separate plastic container, and was frozen immediately at −20 °C for further analysis.

Sample Analysis. Total lipids were extracted from 2 g of thawed sample by 50 mL of chloroform−methanol (2:1, by volume[21]). The preparation of fatty acid methyl esters (FAME) was operated according to a method described previously.[22] FAME was analyzed by gas chromatography. Heneicosanoic acid was used as internal standard.

MeHg was extracted from 1 g of thawed sample, and the concentrations of MeHg were analyzed by a method published previously.[23]

Methodology of Assessment of Net Neurodevelopmental Effect. The benefit−risk assessment approach developed by FAO/WHO[18] was used. Equations for quantitative integration which focus on net IQ point gain are listed as follows, and the meanings of all parameters in eqs 1 and 2 are available in a published brochure:[18]

$$\text{IQ point loss} = [\text{MeHg}] \times 100(x/7) \div 60 \times 9.3 \times (-0.18 \text{ or } -0.7) \quad (1)$$

where −0.18 is the central estimate of IQ points gained per microgram per gram of hair mercury gained, and −0.7 is the upper-bound estimate of IQ points gained per microgram per gram of hair mercury gained.[18] In our study we choose −0.7 for the reason of more conservative assessment.

$$\text{IQ point gain} = [\text{EPA} + \text{DHA}] \times 100 \times 0.67 \times (x/7) \times 0.04 \quad (2)$$

The maximum IQ gain from maternal consumption of EPA plus DHA was estimated at 5.8 points, with no further benefits with increasing consumption thereafter.[18]

Combining eqs 1 and 2 then gives a relationship between net IQ point gain and specific species consumption due to MeHg and *n*-3 LCPUFA intake:

$$\text{net IQ point gain} = \{[\text{EPA} + \text{DHA}] \times 2.68 \div 7 - [\text{MeHg}] \times 1.55\}x \quad (3)$$

where [EPA + DHA] is the total concentration of EPA plus DHA in fish (mg/g); MeHg] is the concentration of methylmercury in fish (μg/g); and x is the number of maternal servings of fish per week (100 g/serving).

We estimated maternal intake of EPA plus DHA and MeHg from specific species consumption by two possible consumption patterns. According to "2002 China National Nutrition and Health Survey" (2002 CNNHS), the mean value of fish intake (including marine fish and freshwater fish) in China was 24.8 g/standard man-day (i.e., about 175 g/week of fish consumption), but coastal Chinese appear to have much higher consumption of aquatic foods, especially marine fish. According to data from "2007 Chinese Total Diet Study", people who live in Fujian province, which is a coastal province of southeast China, had the highest marine fish consumption among all studied provinces in China (64.47 g/day, i.e., about 450 g/week of marine fish consumption).[24] Therefore, 175 and 450 g/week of filet consumption were applied in equations, respectively, to represent the maternal common and extreme consumption scenarios of specific species.

The joint FAO/WHO expert committee on food additives (JECFA) has established a provisional tolerable weekly intake (PTWI) of 1.6 μg/kg bw for MeHg.[25] In our study, 60 kg was considered to be the body weight of a pregnant woman/mother,[18,25] in order to determine if the calculated results of maternal weekly MeHg intake exceeded the PTWI.

We used probabilistic computation to represent uncertainty of sample variations, if the calculated results of the FAO/WHO deterministic approach could not provide a clear dietary recommendation for some species. Monte Carlo simulation was applied in probabilistic computation for these species to generate probabilistic distribution for the net neurodevelopmental effect caused by quantified uncertainties.

There would be an optimal number of weekly servings (i.e., "optimal x") of specific species for neurodevelopment according to eq 3, because the maximum positive effect from intake of EPA plus DHA is definite (5.8 points[18]). The "optimal x" of specific species could be determined by the relationship between the value of "net IQ point gain" and x, on the premise that the "[EPA + DHA]" and "[MeHg]" were known in eq 3. If the value of "net IQ point gain" increases with the increment of x in eq 3, then the "optimal x" of the species would be the value of x, by which the calculated result of "IQ point gain" equals 5.8 points in eq 2; if the value of "net IQ point gain" decreases with the increment of x in eq 3, then the "optimal x" of the species would be zero, that is, no recommended consumption of the species.

Statistical Analysis. Data are expressed as mean and standard deviation. Pearson correlation analysis was used to assess relationships

between concentrations of total lipids and MeHg, and between concentrations of EPA plus DHA and MeHg. A value for $p < 0.05$ was considered to indicate statistical significance. All data analysis (including Monte Carlo simulation) was carried out by Statistical Analysis System 9.1 (SAS Institute Inc., Cary, NC, U.S.).

RESULTS

The concentrations of total lipids, main LCPUFAs (in the form of mean and standard deviation), and MeHg (in form of mean) of species could be obtained from Chinese published articles.[26,27] The standard deviation of MeHg of all species was never published before this article. The mean concentrations of EPA plus DHA (in the form of mg/100 g edible part) of all species ranged from 75.5 (*Scoliodon sorrakowah*) to 2458.2 (*Auxis thazard*); the mean concentrations of MeHg (in the form of μg/kg edible part) of all species ranged from 7.7 (*Mugil cephalus*) to 166.6 (*Scoliodon sorrakowah*). It is noteworthy that the concentrations of *n*-3 LCPUFAs of all species would increase by about 10% if *n*-3 LCPUFAs included *n*-3 docosapentaenoic acid (*n*-3 DPA) (Table 1).

Obviously, the largest exposure of MeHg in this study would be found in extreme scenario consumers when they consumed the species with the highest concentration of MeHg (*Scoliodon sorrakowah*). The intake amount of MeHg in this maternal group (1.68 μg/kg bw/week) was slightly higher than the PTWI, when mean plus 1.96 standard deviations was considered to be the extreme MeHg concentration of the species. The extreme consumption scenario of other species and the common consumption scenario of all species could not result in a weekly MeHg intake over 1.0 μg/kg bw.

Except for *Scoliodon sorrakowah*, both 175 and 450 g of other species weekly maternal consumption would result in a positive neurodevelopmental effect in terms of change of net IQ points (Table 2). *Scoliodon sorrakowah* would cause an unclear neurodevelopmental effect via both consumption scenarios: the calculated results of two samples belonging to this species showed negative net IQ point gain (−0.108 points and −0.076 points via common consumption scenario, −0.278 points and −0.195 points via extreme consumption scenario, respectively), and the net IQ point gain via both consumption scenarios of the other four samples belonging to this species were positive but the values were less than 0.5 points.

Both consumption scenarios of *Scoliodon sorrakowah* would result in a net beneficial neurodevelopmental effect according to probabilistic computation based on 10000 times simulated sampling (Table 3).

Table 3. Results of Probabilistic Computation for *Scoliodon sorrakowah*

scenario	sample size	times of simulated sampling	mean of net IQ point gain	lower 95% CI for mean	upper 95% CI for mean
common	6	10000	0.0545	0.0536	0.0554
extreme	6	10000	0.1401	0.1377	0.1425

Net IQ point gain decreases with the increment of weekly servings of the two aforementioned samples belonging to *Scoliodon sorrakowah*. Therefore, the optimal weekly consumption (or "the optimal *x*") of this species is zero for the reason of more conservative assessment. The optimal weekly consumption (g) of other species ranged from 63.0 (*Auxis thazard*) to 1580.7 (*Seriola quinqueradiata*). The maximum IQ point gain via other species optimal consumption ranged from 4.9 (*Raja porosa*) to 5.8 (*Coilia nasus*), and optimal weekly consumption of all species does not cause a PTWI-exceeded MeHg exposure (Table 4).

Table 4. Weekly Optimal Maternal Consumption (g) and the Maximum IQ Point Gain and MeHg Exposure (μg/kg bw/week) via Weekly Optimal Consumption of Specific Species

There was a positive relationship between concentrations of total lipids and specific *n*-3 LCPUFAs (*n*-3 DPA, EPA, and DHA),[26] but no relationship between concentrations of total lipids and MeHg ($r = 0.011$, $p = 0.880$). There was also a positive relationship between concentrations of EPA plus DHA and MeHg in the studied samples, though the relationship appeared to be moderate ($r = 0.200$, $p = 0.006$).

DISCUSSION

We have presented results on a benefit−risk assessment based on fish samples collected from a major fish farming area in southeast China, and found that there would be neurodevelopmental benefits when almost all species were consumed at either the common or extreme consumption scenario. As Zhoushan archipelago is a main fishing ground in China and it provides aquatic foods to the whole country, our results are likely applicable to a majority of the population in China.

IQ score was also applied as a common metric in other studies which focused on risk−benefit analysis on child neurodevelopment, but methodologies of quantitative integra-

tion of net IQ point change varied.[28−30] The physiologically based pharmacokinetic (PBPK) model and several epidemiological studies were applied by Zeilmaker et al. to estimate the relationship between maternal DHA/MeHg intake via specific species consumption and change of IQ score.[28] The results of their study indicated that the adverse effect of MeHg outweighed the beneficial effect of DHA in a majority of studied species (about 30 species), except a few oily fish species. Our results are more optimistic, partially because of the generally lower concentration of MeHg in species of our study (the ranges of MeHg concentration were 7.7−166.6 μg/kg in 31 species of our study and 0.011−0.829 mg/kg in 31 species of their study, respectively). Moreover, maternal fish consumption in that study was considered as 100 g/day, which is relatively higher than the actual intake amount in Chinese maternal population. Net IQ loss/gain calculated based on quality adjusted life year (QALY) required some basic information on the target population, for example, number of births to women in a specific age group,[29,30] which was difficult to obtain in some instances. "Visual response memory points" (VRM) was applied as a "tentative" common metric to assess in utero neurodevelopmental health end point by risk−benefit index (RBI) equation,[31] but the results of wild fish consumption in Alaska calculated by the VRM-RBI equation indicated that it is "difficult to craft consistent consumption advice" because net effects of consumption of many species varied significantly among regions or studies within the same region.[32] A minimum ratio of DHA intake to mercury exposure ("de minimus", 17 mg of DHA to 1 μg of MeHg) was calculated according to the women's minimum daily recommended intake of DHA (100 mg) and the reference dose for MeHg (RfD, 0.1 μg/kg bw/d, proposed by the US Environmental Protection Agency).[33] When the ratio of DHA to MeHg in one species was higher than "de minimus", a woman would meet the daily recommended intake for DHA while not exceeding the RfD for MeHg.[33] There was application of this ratio to "illustrate which species may be most beneficial for consumption".[20] The upper limit for MeHg intake proposed by US Environmental Protection Agency appeared to be more conservative than by JECFA: according to the PTWI for MeHg, "de minimus" would be about 7.3 mg of DHA to 1 μg of MeHg. In consideration of different characteristics of studies mentioned above, we considered that the FAO/WHO approach would be most suitable for our data. We did not find a report about net neurodevelopmental effect of Western Pacific species consumption assessed by the FAO/WHO deterministic approach before this study.

Consumption of fish at high trophic level would cause a significant negative neurodevelopmental effect, because of bioaccumulation of MeHg.[28] That is in accordance with our data: the species with the highest MeHg concentration in our study (*Scoliodon sorrakowah*) would be the top species in the local food pyramid. *Scoliodon sorrakowah* also has the lowest EPA plus DHA concentration in our studied species. All of these would be reason why consumption of this species would have the lowest net IQ point gain. Though the results of probabilistic computation for this species were positive, we still do not consider that its consumption scenarios deserve to be recommended. After all, there were samples of this species that showed negative results, while all samples of other species can provide a net beneficial outcome according to deterministic computation, which indicates that there would be more risk when a sample of *Scoliodon sorrakowah* was consumed; in other words, negative net IQ gain would be more likely to occur via both consumption scenarios of this species, at least compared with both consumption scenarios of other species. Moreover, the positive results of *Scoliodon sorrakowah* consumption scenarios obtained by probabilistic computation almost equal zero, which indicates that the net neurodevelopmental benefit of consumption scenarios of this species would be negligible.

Though the net IQ point gain via optimal weekly consumption is maximal according to the FAO/WHO deterministic approach, it appears that the application of common or extreme consumption scenario is more practical than of optimal weekly consumption, because filet consumption of the two scenarios is quantitative, which means that recommendation of common or extreme consumption scenario is more feasible than of optimal weekly consumption, in addition to *Scoliodon sorrakowah*.

In most instances, *n*-3 LCPUFAs refer to EPA and DHA, and according to FAO/WHO expert consultation, "EPA plus DHA data were used to represent LCn3PUFAs, because it was considered that the evidence in the literature was most robust for these specific fatty acids".[18] That means some other *n*-3 LCPUFAs and their beneficial effects would be omitted, for example, *n*-3 DPA, which would exert neuroprotective effects according to animal study and could be a precursor to synthesize DHA in vivo.[34] Our results showed that concentration of *n*-3 DPA provided about 10% of concentration of EPA plus DHA, which indicated that there would be underestimation about beneficial neurodevelopmental effect caused by both consumption scenarios when *n*-3 DPA in samples was ignored. However, the dose−response relationship between *n*-3 DPA and its biological effects would be uncertain, because "*n*-3 DPA has not been extensively studied".[34] Alpha linolenic acid (ALA) is the primary member of the *n*-3 PUFAs family, which is rich in some kinds of culinary oil such as rapeseed oil and soybean oil. ALA also could be a precursor to synthesize DHA in vivo.[35] Study about fish-eaters and non-fish-eaters (including meat-eaters, vegetarians, and vegans) showed that intake of *n*-3 LCPUFAs was much higher in fish-eaters but the differences of EPA and DHA concentrations in plasma of different dietary groups were "considerably smaller", because precursor−product ratio of ALA to *n*-3 LCPUFAs would be greater in non-fish-eaters.[36] Moreover, young women seem to be fairly efficient at converting ALA to DHA, compared with men.[37] The efficient conversion capability of young women would be an important physiological compensative mechanism for meeting the development of fetus and neonate during pregnancy and lactation. Indeed, the high consumption of ALA-rich culinary oil such as rapeseed oil or soybean-salad oil by pregnant women in some regions of China could be a reason why the DHA concentrations of colostrum in these regions with different aquatic food consumption are more similar than the aquatic food consumption difference would indicate they might be.[22] Consumption of culinary oil in the Chinese dietary pattern tends to be relatively high (data from 2002 CNNHS showed that a Chinese metropolitan consumed about 44 g of culinary oil per day), and ALA-rich vegetable oil seemed to be the main culinary oil in many regions of China according to 2002 CNNHS. Therefore, we consider that methodologies about assessment of neurodevelopment caused by maternal fish consumption would refer to the potential benefit of other *n*-3 LCPUFAs and the endogenous production of EPA and DHA to a greater extent, which would contribute to revise the

beneficial effects caused by marine fish derived EPA and DHA intake in assessment.

Our analysis about net neurodevelopmental effect could be part of risk−benefit assessment of fish consumption. Besides neurodevelopmental benefit, *n*-3 LCPUFAs were also known as a beneficial factor to the adult cardiovascular system[38] and immune system.[39] Moreover, fish contain other contaminants, such as dioxin-like compounds (DLCs), which would cause cancers[40] and diabetes[41] and also be neurotoxic.[42] The FAO/WHO expert consultation also proposed equations to assess net change of mortality caused by DLCs and *n*-3 LCPUFA intake via fish consumption.[18] A further risk−benefit assessment which refers to the net change of mortality would be considered if the DLC data of samples could be obtained.

Besides IQ point change, there are still some other end points which were applied to assess adverse neurodevelopmental effect caused by prenatal MeHg exposure in cohort studies from Faroe Islands[13,43] and Seychelles.[44−46] Findings showed that impacts of prenatal MeHg exposure on these end points varied, but there would be little information about the impact of *n*-3 LCPUFAs on them, and they are not regarded as common metrics by which risks and benefits could be compared at present. However, a sustained concern on these end points would be worth considering.

Even though the consumption amount of the general population was used to estimate the consumption amount of pregnant women/mothers, the error would not be significant as the majority of Chinese pregnant women/mothers usually share foods with their family members.[11,22] There would be a high concentration of *n*-3 LCPUFAs in some species of shellfish,[18] but the consumption mean of shellfish in the Chinese dietary pattern (4.8 g/standard man-day, according to 2002 CNNHS) would be negligible when compared with fish, though high consumption of shellfish was found in a few regions of China.[24] Therefore, shellfish samples were not considered in our study.

In summary, the current study indicates that there was no recommendation of maternal consumption scenarios of *Scoliodon sorrakowah*. Common and extreme maternal consumption scenarios of other studied species from Zhoushan would be beneficial to neurodevelopment, and both consumption scenarios of other species would deserve to be recommended according to calculated results of the FAO/WHO assessment approach. The MeHg exposure via optimal weekly consumption of all studied species would not exceed the PTWI. More factors would deserve to be considered in future analysis.

Paulo, Brazil). Poly(ethylene glycol) (PEG) was obtained from Isofar Ltd.a. (Duque de Caxias, Brazil). Difco Laboratories (Detroit, MI, USA) supplied bacteriological peptone.

Essential Oil Concentrations. The concentrations of clove bud and oregano essential oils to be incorporated into the antimicrobial films were determined by diffusion through solid medium in cavity-containing plates[29] against *Aspergillus niger* (ATCC 16404) and *Penicillium* sp. (ATCC 2147), common spoilage fungi in bakery products. Aliquots of 100 μL of fungal suspension ($(8.0 \pm 1.4) \times 10^5$ CFU mL^{-1}) were spread onto solidified PDA in 90 mm diameter Petri dishes. A 6 mm diameter cavity was made in the PDA with a sterilized borer at the midpoint of each dish. Cavities were filled with 50 μL of essential oil aqueous solutions at concentrations of 40, 20, 10, 5, 2.5, 1.25, and 0 (control) mg mL^{-1}. An aqueous stock solution comprising 4% (w/v) of clove bud or oregano essential oil, 1.6% (w/v) of Tween 80, and 0.2% (w/v) of PEG was 2 times serially diluted in sterilized distilled water to achieve the mentioned concentrations. Plates were sealed and incubated at 25 ± 2 °C for 5 days before inhibition haloes around cavities were measured to the nearest 0.01 mm with a digital caliper from Mitutoyo Manufacturing (Tokyo, Japan). Six plates were prepared for every essential oil concentration and fungus, three for each repetition.

Emulsification. Coarse oil-in-water emulsions were formed by mixing clove bud or oregano essential oil (at the concentration determined in the previous item), 3% (w/v) of Tween 80, and double-distilled water at 1000 rpm for 5 min. An ultrasonicator (model DES500) from Unique Group (Indaiatuba, Brazil) was used to prepare nanoemulsions by ultrasonicating the coarse emulsions at 20 kHz (frequency) and 400 W (nominal power input) for 10 min.

Droplet Size and Polydispersity Index (PdI). The mean droplet diameter and the PdI were determined through light scattering in a Nanophox from Sypatec GmbH (Clausthal-Zellerfels, Germany) after emulsion samples had been diluted in double-distilled water to $^1/_{10}$ of their initial concentration to avoid multiple scattering effect. Droplet size was indicated by the *Z*-average, which measures the scattering intensity-weighed mean diameter of the droplets present in an emulsion.

Film Casting. To emulsions were added 2% (w/v) of methylcellulose, as the polymeric matrix, and 0.2% (w/v) of PEG, as a plasticizer to improve film handling. The resulting film-forming solution was gently homogenized for 30 min at 6 rpm, rested for 2 h to eliminate air bubbles, cast onto glass plates, and allowed to dry at 25 ± 2 °C overnight. Control films were produced likewise except for the essential oil concentration, which was zero for comparison purposes. Table 1 shows the compositions of all film-forming solutions. For sliced bread shelf life evaluation, the films were cast directly onto the metalized layer of metalized polypropylene sheets, selected for their low gas transmission rates.[11]

Table 1. Compositions of Aqueous Film-Forming Solutions

NOF	2.0	0.2	4.0		3.0	ultrasound

[a]MC, methylcellulose. [b]PEG, poly(ethylene glycol). [c]OEO, oregano essential oil. [d]CBEO, clove bud essential oil.

Scanning Electron Microscopy (SEM). Films were characterized as to their morphologies through SEM images taken in a tabletop microscope (model TM3000) from Hitachi High Technologies America, Inc. (Schaumburg, IL, USA) operating with an accelerating voltage of 15 kV and at a magnification of 10000×.

Mechanical Properties. At least seven films from each treatment were shaped into 100 mm × 25 mm test strips according to ASTM D882-12. Their thicknesses were measured to the nearest 0.001 mm in five random positions with a digital micrometer from Mitutoyo Manufacturing (Tokyo, Japan). Films' tensile strength (TS), elastic modulus (EM), and elongation at break (EB) were determined in a universal testing machine (model 3367) from Instron Corp. (Canton, MA, USA), fitted with a 1 kN load cell and set to stretch the film strips from an initial gauge length of 50 mm at 50 mm min^{-1}. TS was calculated by dividing the highest load that a film strip withstood prior to breakage by its initial cross-sectional area. EM was given by the relationship between stress and strain at the initial slope of the chart. EB was calculated by dividing the deformation of a film strip right before breaking by its initial length and multiplying by 100 to be expressed as percentage.

Bread Storage. Preservative-free bread slices (18.98 ± 0.95 g) were bought at a local bakery in Viçosa, MG, Brazil. They were placed, two by two, inside methylcellulose film/metalized polypropylene bags, which were sealed and stored at 25 ± 2 °C in an effort to simulate usual commercialization conditions of bakery products. The storage system with two slices also aimed at reproducing the typical distribution of sandwiches due to convenience reasons. Preservative-free slices packaged alongside essential oil-free films were used as control (C−). Bread slices with an added commercial antifungal comprising sorbic acid, calcium propionate, ethanol, and grain alcohol were packed likewise, except for the absence of the inner layer (methylcellulose film) of the package system (C+). This antifungal mixture is used in the sliced bread sold at the bakery, and this evaluation allowed the comparison of the shelf life extension provided by the films developed here and by the commercially applied preservation method that advertises a shelf life of 7 days for this product. Table 2 summarizes the components of each storage set.

Table 2. Components Present (+) or Absent (−) in Each Sliced Bread Storage System

treatment	preservative	film	essential oil	emulsion
C−	−	CF	−	−
RC	−	RCF	clove bud	coarse
NC	−	NCF	clove bud	nano
RO	−	ROF	oregano	coarse
NO	−	NOF	oregano	nano
C+	+	−	−	−

Microbiological Evaluation. Counts of yeasts and molds, microorganisms that are known to spoil bakery products in a short period of time, were monitored after 0, 5, 10, and 15 days of storage. Bread slices (25 ± 0.2 g) were randomly and aseptically sampled, diluted in 225 mL of 0.1% (w/v) bacteriological peptone solutions, and homogenized for 2 min in a stomacher from ITR Ltd.a. (Esteio, Brazil). Serial 10-fold dilutions (10^{-1}–10^{-4}) were prepared and inoculated in Petrifilm plates from 3 M do Brasil Ltd.a. (Sumaré, Brazil), specific for counting yeasts and molds. The plates were incubated at 25 ± 2 °C for 5 days before counts of yeasts and molds were reported as colony-forming units per gram of sliced bread, in a logarithm scale (log CFU g^{-1}).

Statistical Analysis. All data were submitted to one-way analysis of variance (ANOVA) followed by Tukey's test at the 5% of probability level in statistical software (version 9.1) from SAS Institute Inc. (Cary, NC, USA).

RESULTS AND DISCUSSION

Essential Oil Concentrations. Table 3 shows the inhibition halo values of *Penicillium* sp. and *A. niger* for each essential oil concentration. No inhibition halo was recorded at concentrations lower than 20 mg mL^{-1}, regardless of the microorganisms and essential oil. The largest ($p < 0.05$) inhibition halo of *A. niger* and *Penicillium* sp. was provided by clove bud and oregano essential oils at 40 mg mL^{-1} (Table 3). Thus, 40 mg mL^{-1} was the concentration used for film

production. The antimicrobial activities of the essential oils from oregano and clove bud against several foodborne pathogenic and spoilage microorganisms, including fungi from *Aspergillus* and *Penicillium* genera, have been widely reported.[11,30−34]

Droplet Size and Polydispersity Index. The mean diameters and PdI values obtained for droplets of both clove bud and oregano essential oils in coarse emulsions and nanoemulsions are shown in Table 4. Coarse emulsions produced at low mixing speed had droplets with diameters of a couple of micrometers, which is in accordance with the values (1−20 μm) previously reported in the literature.[21] The formation of a coarse emulsion prior to a high-energy process improves both droplet size reduction and polydispersity of the resulting emulsion.[35]

Table 4. Droplet Diameters and Polydispersity Index (PdI) Values of Aqueous Coarse Emulsions and Nanoemulsions of Clove Bud and Oregano Essential Oils

essential oil	emulsion	droplet diameter[a] (nm)	PdI
clove bud	coarse	1999.03 ± 1856.82 a	0.863
	nano	250.43 ± 100.67 b	0.162
oregano	coarse	1313.38 ± 1302.41 a	0.983
	nano	180.59 ± 84.76 b	0.220

[a]Mean values ± standard deviations followed by different letters are significantly different ($p < 0.05$).

Coarse emulsion droplets were remarkably larger ($p < 0.05$) than those present in nanoemulsions (Table 4), regardless of the essential oil used. Droplet breakdown is a nonspontaneous process that requires enough energy input to enhance droplet interfacial area by overcoming its surface free energy,[21] and the low-speed process used for coarse emulsion preparation did not provide the required energy to reduce droplet size to the nanoscale. Ultrasonication, however, created thoroughly disruptive forces resulting from an intense acoustic field, leading to rapid formation and collapse of microbubbles at the droplet interface.[36] The collapse of microbubbles, known as cavitation, induced turbulence and shock waves that disrupted droplets to the nanoscale level.[35,37,38] The type of essential oil did not affect ($p > 0.05$) droplet size either in coarse emulsions or in nanoemulsions (Table 4).

Another remarkable difference between the coarse emulsions and nanoemulsions produced here was the PdI. Coarse emulsions had PdI values close to unity (Table 4), indicating a multimodal, wide droplet size distribution. Nanoemulsions, however, had a narrow size distribution as indicated by low PdI values. This difference is attributable to the increased energy input of ultrasonication when compared to the low-speed mixing used in coarse emulsification, given that droplets tend to assume an equilibrium diameter as the energy input increases, leading to a more uniform emulsion having reduced PdI values.[21,25]

Scanning Electron Microscopy. SEM images aimed at confirming that droplet aggregation and coalescence did not take place during film drying and that droplet diameters remained stable in the final films. Figure 1 shows typical SEM micrographs of the methylcellulose films. As expected, the essential oil-free film showed a homogeneous surface without any droplets (Figure 1A). Contrastingly, droplets are easily

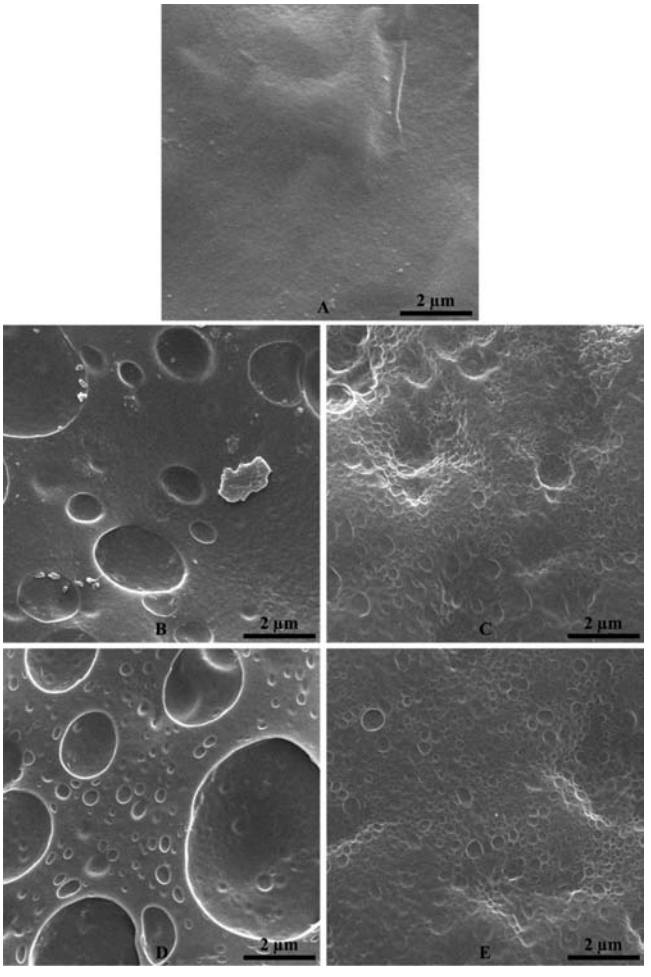

Figure 1. Typical SEM micrographs of methylcellulose films (A) with added clove bud or oregano coarse emulsions (B and D, respectively) or nanoemulsions (C and E, respectively).

Table 5. Mechanical Properties of Methylcellulose Films Incorporated or Not with Clove Bud or Oregano Essential Oil Coarse Emulsions or Nanoemulsions

essential oil	emulsion	TS[a] (MPa)	EM[a] (MPa)	EB[a] (%)
		5.40 ± 1.13 a	118.86 ± 24.53 a	20.46 ± 2.71 a
clove bud	coarse	6.07 ± 1.11 a	53.97 ± 8.71 b	40.29 ± 4.53 b
	nano	6.11 ± 1.26 a	56.79 ± 16.58 b	56.61 ± 5.59 c
oregano	coarse	8.05 ± 1.45 a	104.21 ± 4.15 a	34.08 ± 5.17 b
	nano	7.61 ± 1.32 a	72.94 ± 10.97 b	54.77 ± 1.66 c

[a]Mean values ± standard deviations followed by different letters within the same column are significantly different ($p < 0.05$).

observed in the emulsified films. Methylcellulose films with added coarse emulsions (Figure 1B,D) presented much larger droplets and a more heterogeneous size distribution profile than films with added nanoemulsions (Figure 1C,E), regardless of essential oil type. This validates the droplet diameter and PdI values obtained through light scattering (Table 4) and also indicates that the emulsion remained stable with regard to droplet diameter during film polymerization at the tested conditions.

Mechanical Properties. The mechanical attributes tensile strength (TS), elastic modulus (EM), and elongation at break (EB) of the films produced here are summarized in Table 5. The essential oils added to methylcellulose films had a plasticizing effect, as suggested by reduced ($p < 0.05$) EM and increased ($p < 0.05$) EB when compared to those of essential oil-free films. However, TS was not affected ($p > 0.05$) by the addition of essential oils. Similarly to our results, essential oils have been widely reported to weaken the intermolecular interactions between polymeric chains, resulting in less rigid and more extensible and flexible films.[19,39−44] The reduction in droplet size led to an even more remarkable plasticizing effect, because smaller droplets increased ($p < 0.05$) the EB and reduced ($p < 0.05$) the EM of the methylcellulose films. The addition of clove bud essential oil nanodroplets provided almost a 3-fold increase in EB and a 2-fold decrease in EM when compared to control films. Oregano essential oil showed a similar behavior.

Microbiological Evaluation. The counts of yeasts and molds throughout the storage of sliced bread are illustrated in Figure 2. At the very beginning of the storage period, the counts of yeasts and molds did not differ ($p > 0.05$) among the different treatments because no time was available for microbial development, even in C− in which neither synthetic preservatives nor antimicrobial films had been used. As expected, there was a trend of increasing counts of yeasts and molds during storage, regardless of treatment. Different storage conditions (Table 2), however, led to different survival patterns.

After 5 days, the counts in all treatments were not different ($p > 0.05$), except in slices packaged alongside clove bud nanoemulsion films (NC), which showed counts lower ($p < 0.05$) than the other treatments. The synthetic antifungal present in C+ worked just as well as the antimicrobial films until day 5, but the emulsified films were more efficient ($p < 0.05$) in lessening microbial growth at all further analysis times. At 10 days of storage, the essential oil-free treatments (C− and C+) allowed greater ($p < 0.05$) growth of yeasts and molds when compared to the treatments that included antimicrobial films. This suggests that neither the essential oil-free film (C−) nor the synthetic preservative (C+) was effective in preventing microbial development after 10 days of storage at 25 ± 2 °C,

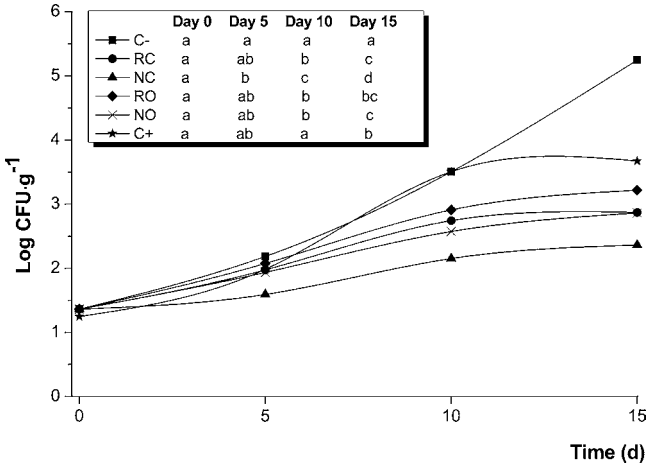

Figure 2. Counts of yeasts and molds in bread slices containing (C+) or not (C−) synthetic antifungal and packaged alongside methylcellulose films incorporated with clove bud and oregano essential oils coarse emulsions (RC and RO, respectively) or nanoemulsions (NC and NO, respectively), throughout 15 days of storage at 25 ± 2 °C. In the table, different letters within the same column indicate different means ($p < 0.05$).

conditions that simulate conventional commercialization practices of bakery products. At 15 days of storage, C− bread showed the greatest ($p < 0.05$) count of yeasts and molds, followed by C+ and then antimicrobial film-containing treatments. This corroborates the hypothesis that clove bud and oregano essential oils are effective in lessening microbial development in food matrices, even when compared to the commercial antimicrobial technique currently used (C+).

Overall, clove bud and oregano essential oils within the same droplet diameter range displayed similar ($p > 0.05$) antimicrobial activities against yeasts and molds, although clove bud nanodroplets were more effective ($p < 0.05$) than oregano nanodroplets at days 10 and 15. The antifungal activities of clove bud and oregano essential oils are related to their major phenolic constituents eugenol and carvacrol (Figure 3), respectively.[45] These phenols interact with and alter the

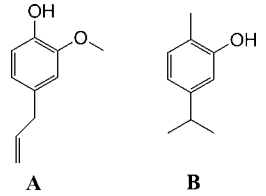

Figure 3. Chemical structures of eugenol (A) and carvacrol (B).

dx.doi.org/10.1021/jf501055f | J. Agric. Food Chem. 2014, 62, 5214−5219

permeability of cell membranes, leading to leakage of cell contents, which are essential to microorganism survival.[46] The similarity observed here is also attributable to the presence of hydroxyl groups (Figure 3) and delocalized electrons.[47,48] The delocalized electrons allow proton release from the hydroxyl groups in a way that the proton gradient through cell membrane is reduced. The reduced proton gradient, along with the resulting depletion of the ATP pool, kills microbial cells.[45]

Droplet size reduction from a few micrometers to a few hundreds of nanometers improved ($p < 0.05$) the antimicrobial properties of the clove bud essential oil-containing films (Figure 2). Although this difference was not significant ($p > 0.05$) for oregano essential oil, there is a clear trend of decreasing the counts of yeasts and molds by smaller droplets. This observation is attributable to the increased bioavailability of nonpolar bioactive compounds encapsulated in smaller droplets, which possess a higher surface-to-volume ratio and are able to more easily penetrate cell membranes.[22,26] This improvement in antimicrobial properties of nanoemulsified films provided by reduced droplet diameters had already been reported for cinnamaldehyde emulsions, but in laboratory medium.[25]

In summary, emulsion films were successfully produced with plant essential oils that displayed antimicrobial activity against spoilage fungi in bakery products. Ultrasonication was effective in reducing droplet diameter and in narrowing droplet size distribution. Both essential oils acted as plasticizers in methylcellulose films, as well as provided them with antimicrobial activity against yeasts and molds in sliced bread. Droplet size reduction was shown to increase both plasticizing and antimicrobial behaviors of essential oils. The antimicrobial films developed here improved sliced bread shelf life, even when compared to the commercial antifungal agent that is currently used in bakeries. The improvement of antimicrobial properties of an essential oil simply by reducing its droplet size has clear implications for food preservation, as lower preservative contents may be used to deliver the same antimicrobial efficiency if encapsulated in smaller particles. Future works are needed to validate the efficiency of the system proposed here in prolonging the shelf life of different food products and to study its impacts on product acceptance by consumers as well as to assess the feasibility of scaling up this system to a large-scale food production scenario.

demonstrate the development of an easy, effective, and sensitive MISPE protocol for OTA determination in wine matrices.

EXPERIMENTAL PROCEDURES

Materials. Ochratoxin A standard solution at a concentration of 10 μg/mL in acetonitrile (standard Oekanal) was supplied by Sigma (Milano, Italy) and was stored at −20 °C. The imprinted polymer was prepared by using as template a mimic of OTA, *N*-(4-chloro-1-hydroxy-2-naphthoylamido)-L-phenylalanine, **2** (Figure 1), according to the published literature.[23−25] Acetonitrile and methanol (HPLC gradient grade), ethanol (95% v/v), tetrahydrofuran, and acetone were supplied by VWR International (Milano, Italy).

Citric acid monohydrate, potassium chloride, sodium chloride, sodium hydrogen carbonate, tartaric acid, acetic acid, and poly-(ethylene glycol) 8000 were all of analytical grade and were supplied by Sigma.

A citrate−tartrate buffer (named "hydroalcoholic citrate−tartrate buffer") was prepared by mixing 30 mM citric acid, 0.5 mM tartaric acid, and 8 mM potassium chloride and titrating at pH 3.2 with 0.1 M NaOH. It was mixed with ethanol to obtain a final buffer composition containing 10% v/v of ethanol. It was used to simulate the wine matrix as previously described.[26] All of the buffered solutions were filtered after preparation on 0.22 μm nylon membrane from Alltech Italia (Milano, Italy) and preserved at 4 °C until use. The water for buffer preparation was deionized on mixed ion exchange columns, and it was ultrapurified in a Purelab Prima System from Elga (Marlow, UK) for HPLC eluents.

The real sample matrices were constituted by 18 red wines provided with Protected Designation of Origin label, from different Italian regions and produced in the years 2005−2012. Blank wine samples certified to be free from OTA contamination were kindly provided by Neotron SpA (Modena, Italy).

The commercial immunoaffinity columns were OchraTest from VICAM (Watertown, MA, USA). Solid phase extraction (SPE) was performed with a VacMaster-10 sample processing manifold, equipped with a vacuum control valve and PTFE cartridge adapters (VWR International).

HPLC Method. Reversed phase HPLC analysis was used for OTA determination after SPE in accordance with the literature.[11] A LaChrom Elite HPLC system composed of programmable binary pump L-2130, autosampler L-2200, UV detector L-2400, and fluorescence detector L-2480 and provided with EZChrom Elite software for instrumental programming, data acquisition, and data processing was from Merck-Hitachi (Milano, Italy).

The column used was a 250 mm × 4.6 mm i.d., 5 μm, Li-Chrospher 100 RP-18 (Merck, Milano, Italy). The mobile phase was composed of acetonitrile/water/acetic acid 40:59:1 v/v/v, and the elution was performed in isocratic conditions at a flow rate of 0.5 mL/min. The sample volume injected was 10 μL, and OTA was detected by setting the excitation wavelength at 333 nm and the emission wavelength at 460 nm. In these instrumental conditions OTA retention time is 20.3 ± 0.1 min.

Reference standard solutions of OTA at concentrations of 5, 3, 2, 1, 0.75, 0.5, 0.25, and 0.1 ng/mL were prepared both in the eluent solution for the external calibration method and in blank wine sample for the standard addition method and immediately analyzed three times consecutively, and peak areas were plotted against concentration. A calibration curve was drawn using a weighted linear regression (weight = 1/conc).

Optimization of MISPE Protocol. All of the SPE experiments were made in 3 mL polypropylene SPE cartridges, packed with 250 mg of OTA-imprinted imprinted polymer. All measurements were performed in triplicate so that the analyte recoveries were evaluated as the averages of the repeated measures to estimate the method repeatability. Different experiments of loading, washing, and elutions were performed to optimize the extraction procedure. Before each experiment, the stationary phase was conditioned with 5 volumes of hydroalcoholic citrate−tartrate buffer.

To measure the MISPE cartridge loading capacity, 1 mL of 250 ng/mL standard solution of OTA in hydroalcoholic citrate−tartrate buffer was loaded by applying the vacuum. The eluate was analyzed by HPLC. After the sample loading, the cartridge was washed with 5 mL of methanol/acetic acid 9:1 v/v to remove OTA.

To investigate the effect of different washing solutions on removal of the mycotoxin from the cartridge, 1 mL of OTA solution at the concentration of 25 ng/mL in hydroalcoholic citrate−tartrate buffer was loaded and a vacuum was applied to facilitate the passage of the sample through the cartridge bed. After sample loading, air was passed through the columns for 5 min. Then, the cartridges were sequentially washed with 1 mL of water containing increasing amounts of organic solvent (0, 10, 20, 30, 40, 50, 60, 70, 80, 90, and 100% v/v). The organic solvents investigated for elution were acetonitrile, methanol, tetrahydrofuran, and acetone. A final wash with 5 mL of methanol/acetic acid 9:1 v/v was performed to completely remove the mycotoxin from the stationary phase.

To investigate the effect of different elution conditions, 1 mL of OTA solution at the concentration of 25 ng/mL in hydroalcoholic citrate−tartrate buffer was loaded and the vacuum was applied. Thereafter, air was passed through the columns for 5 min and a washing step with 1 mL of deionized water was performed. The cartridge was then sequentially washed with 1 mL of acetonitrile containing increasing amounts of acetic acid (1, 2 and 5% v/v) by drying the stationary phase after each addition. The different aliquots were recovered and analyzed by HPLC to measure OTA concentration. A final washing step with 5 mL of methanol/acetic acid 9:1 v/v was performed to remove all compounds still bound.

MISPE of Real Samples. The MISPE protocol was evaluated on wine samples. The analytical performance of the MISPE extraction protocol was compared with those obtained with commercial immunoaffinity columns. All of the experiments were performed in triplicate as in the previous protocol optimization with OTA standards.

Preliminary wine treatment was performed in accordance with the literature.[11] Tannins were precipitated by diluting the red wine samples 1:2 v/v with a 1% v/v aqueous solution of PEG 8000, incubated at 4 °C overnight, centrifuged at 8000 rpm for 15 min, and filtered on 0.22 μm polypropylene membranes.

Extraction of OTA from wine samples was performed by loading 2 mL of pretreated wine sample on the cartridge and applying a vacuum. Afterward, the cartridge was washed with 1 mL of the following solutions: (1) water/acetone 4:1 v/v; (2) water/acetonitrile 4:1 v/v; (3) water/tetrahydrofuran 4:1 v/v. The OTA elution was then performed with 2 mL of acetonitrile/acetic acid 49:1 v/v, as optimized in the MISPE protocol with OTA standards. A final wash of the stationary phase was performed with 5 mL of methanol/acetic acid 9:1 v/v. To investigate the minimum volume capable of washing away the retained interferents when loading volumes >1 mL were applied, a set of additional experiments were performed by loading 10 mL of pretreated wine sample, and subsequent washing steps were performed by using increasing amounts of washing solution (2, 3, 4, and 5 mL).

Recovery of OTA from red wine samples was performed on 2 mL of pretreated wine samples spiked with 0.25, 0.5, 1, 2, and 5 ng/mL of OTA. Then, samples were extracted according to the optimized protocol above-described. The peak areas measured by the external calibration method allowed the determination of OTA recovery.

Preconcentration of OTA from red wine samples was performed on pretreated wine samples (2, 5, 10, and 20 mL) spiked with amounts of OTA to final mycotoxin concentrations of 2, 0.8, 0.4, and 0.2 ng/mL. In this way, an ochratoxin amount equal to 4 ng was added to each volume and loaded into the MISPE cartridge. The wine samples were then extracted and analyzed.

IAC Procedure. Pretreated wine samples (10 mL) were loaded on the IAC column and passed through it at a flow rate of about 1 drop/s without allowing the column to dry. The column was washed with 5 mL of a 2.5% m/v aqueous solution of sodium chloride, 0.5% m/v sodium hydrogen carbonate, pH 8.1, and then with 5 mL of water, allowing the column to dry by passing air through it. OTA elution was performed with 2 mL of methanol, and the eluate was evaporated under a gentle stream of dry nitrogen. OTA was redissolved in 0.25

mL of HPLC mobile phase, sonicated for 5 min, and immediately analyzed.

RESULTS AND DISCUSSION

The high selectivity toward OTA of a molecular imprinted polymer obtained by a thermal polymerization of methacrylic acid as functional monomer and ethylene glycol dimethacrylate as cross-linker in the presence of *N*-(4-chloro-1-hydroxy-2-naphthoylamido)-L-phenylalanine as mimic template has been previously described.[23−25] The present work starts from these results to develop a solid phase extraction procedure tailored for red wines as real matrices. To this purpose, we first investigated the behavior of the imprinted polymer in loading and recovery of the analyte and in removing the interfering substances. Once the optimal operating conditions were defined by using a standard solution of OTA, the experimental work concerned the refining of the extraction protocol on Italian red wines.

Development of MISPE Protocol. A MISPE protocol was developed by using OTA standard solutions diluted in a hydro-organic buffer containing ethanol, the so-called hydroalcoholic citrate−tartrate buffer, that has previously been shown to mimic real wine samples.[26]

The assessment of the loading capacity of the MISPE cartridge allowed us to define how much mycotoxin could be loaded on the stationary phase without a detectable amount of OTA in the flow-through. The loading of 250 ng of ochratoxin A, a very high amount compared to the maximum permitted level in wine samples, allowed us to verify that no target compound was unretained in the loading step.

The washing step removed interfering substances from the MISPE cartridge retaining at the same time the target analyte. Thus, these experiments aimed to evaluate the capability of water−organic solvent mixtures to keep loaded OTA bound to the MISPE cartridge. The considered organic solvents have different polarities, although they are all water-soluble, allowing their use in aqueous mixture at variable percentages. Figure 2 shows the different trends obtained with different water−organic solvent mixtures. All of the profiles show a maximum

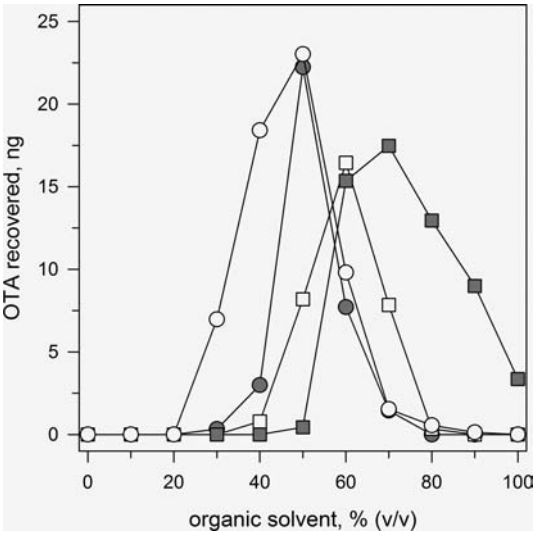

Figure 2. Recovery profiles of OTA in the cartridge washing step as a function of different water−organic solvent mixtures: acetonitrile (open circle); tetrahydrofuran (solid circle); acetone (open square); methanol (solid square).

OTA elution at a given solvent percentage that is related to the solvent elution strength following the order acetonitrile ∼ tetrahydrofuran > acetone > methanol. These results allowed us to make some preliminary considerations about the kind of organic solvent and its relative percentage useful for both washing and elution steps of OTA in the MISPE protocol. However, the final choice was dependent on the results obtained for real samples by considering that the properties of the organic solvent could also affect the selectivity of the extraction protocol.

The recovery of OTA was performed in experimental conditions minimizing the required volume, that is, the target analyte dilution. The organic solvents that more efficiently eluted the mycotoxin were acetonitrile and tetrahydrofuran, although the best choice for chromatographic analysis reasons was acetonitrile. As a consequence, this solvent was tested in elution experiments, also with the addition of variable amounts of acetic acid as hydrogen bond disruptor. Figure 3 summarizes

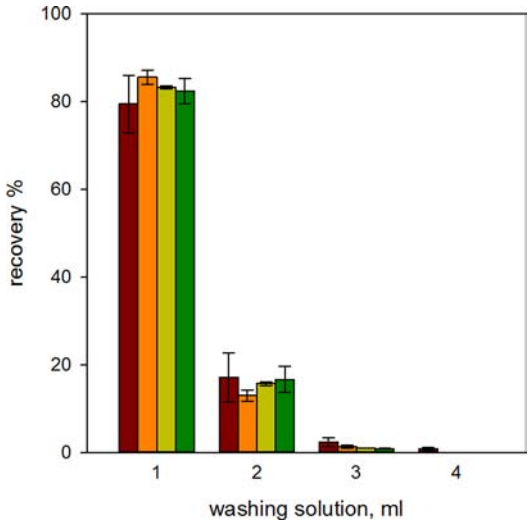

Figure 3. Recovery of eluted OTA by using acetonitrile with increasing percentages of acetic acid: acetonitrile (red bar); acetonitrile + 1% v/v acetic acid (orange bar); acetonitrile + 2% v/v acetic acid (pale green bar); acetonitrile + 5% v/v acetic acid (dark green bar).

the results obtained in terms of recovered percentages of OTA: the use of acetic acid allowed the quantitative recovery of OTA (>99%) in 2 mL. As a consequence, OTA elution was performed with 2 mL of acetonitrile/acetic acid 98:2 v/v.

Refining the MISPE Protocol on Real Wine Samples. The MISPE protocol developed in the previous section was then applied to different wine samples for a further improvement in the presence of real matrices. Therefore, after the preliminary wine treatment, the washing solution composition was refined, considering again several washing mixtures by using an OTA-negative certified wine sample.

The choice of the tested washing solutions was made on the basis of the experimental results reported in Figure 2, where acetonitrile and tetrahydrofuran seemed to be the strongest eluents, followed by acetone. Hydro-organic mixtures (water/solvent 80:20 v/v) were tested to refine the ability to wash away the interfering matrices from the MISPE cartridge while minimally affecting OTA retention. The comparison of chromatographic profiles obtained by the analysis of pretreated red wine samples, loaded and recovered from the MISPE cartridge by using three different washing solutions, showed

dx.doi.org/10.1021/jf5010995 | J. Agric. Food Chem. 2014, 62, 5220−5225

that the difference in the chromatograms mainly concerned the analytical signals in the first 5 min, far from the peak corresponding to OTA. Thus, a 2 mL washing solution made of water/acetonitrile 4:1 v/v was chosen as appropriate to remove matrix interferents.

The minimum volume capable of washing away the retained interferents even in the case of loading volumes >1 mL was further investigated. This step was useful to preconcentrate the target analyte. No significant differences were observed, confirming that all potentially interfering substances were easily removed from the MISPE cartridge even with large sample volumes. Thus, a minimum volume of 2 mL was then considered as the best choice.

Choice of HPLC Method Calibration. The complexity and the variety of the wine matrix pose a question about what kind of HPLC calibration is more suitable for OTA determination. In fact, if the matrix effect is completely eliminated by the optimized MISPE extraction, then it would be possible to use external calibrators, whereas if a matrix effect is present, the addition standard method should be preferred. However, it should be noted that this last approach is more cumbersome because it requires different calibrations for different matrices and so is less practicable.

To compare the two approaches, the analytical signals (i.e., peak areas) obtained from wine samples spiked with OTA in the concentration range of 0.25−5 ng/mL were used to set up a standard addition plot (LoD, 0.080 ng/mL; LoQ, 0.285 ng/mL) and read on the external calibration plot described under Optimization of MISPE Protocol (LoD, 0.075 ng/mL; LoQ, 0.225 ng/mL). In this way, added concentrations were plotted versus found concentrations. The goodness of fit (r^2_{adj} = 0.9857, SEE = 0.2167) highlights that the matrix effect is well compensated so that we chose the calibration plot based on the use of external standards for OTA determination in red wines combined with the optimized MISPE extraction above-described.

The recovery and preconcentration tests were performed on an OTA-certified negative red wine according to the optimized MISPE protocol. The experimental results show the overall good performance of the MISPE column. In the concentration range of 0.25−5 ng/mL of OTA, the recoveries lie between 92 and 110%, and a substantial independence of these values from loaded analyte concentration can be observed. When increasing volumes of wine (2−20 mL) containing a fixed amount of OTA are loaded, a satisfying target analyte recovery, between 88 and 102%, was obtained, allowing a 10-fold increase of the method sensitivity with respect to the initially optimized MISPE protocol. Hence, this condition leads to a preconcentration factor of 5 taking into account the initial untreated wine.

MISPE of Real Samples. Finally, to evaluate the effect of the matrix variability, the MISPE protocol was applied to 17 red wine samples of different types and from several regions of Italy. A HPLC chromatogram of a wine sample eluted by the MISPE cartridge is shown in Figure 4. The amounts of OTA found by MISPE-HPLC and determined on 20 mL of pretreated wine samples were compared with those obtained by the conventional IAC-HPLC procedure. The obtained results (Table 1) show a good agreement between the two extraction methods fit (r^2_{adj} = 0.9817, SEE = 0.0262) (Figure 5) without any bias effect due to different geographic origin of wines. Therefore, the MISPE procedure can be considered a reliable alternative to the conventional IAC protocol. Although the preconcentration factor is more reduced for MISPE with respect to IAC, the cleanup procedure is simple and capable of successfully eliminating most of the matrix effects. Moreover, the combination of the MISPE with the sensitive fluorescence detection allows OTA determination well below the legal limit of 2 ng/mL.

[a]Comparison between results by MISPE and by IAC. Each result was the average of three replicates.

In conclusion, we have developed a MISPE protocol for the extraction and preconcentration for HPLC analysis of OTA in red wine samples. The molecularly imprinted polymer, prepared through a mimic template approach, was used for the preparation of a MISPE stationary phase. The assessment of a SPE protocol indicates that a careful choice of both the washing and eluting conditions allows the optimization of a reliable MISPE extraction protocol, selective for the mycotoxin and capable of preconcentrating the analyte well below the

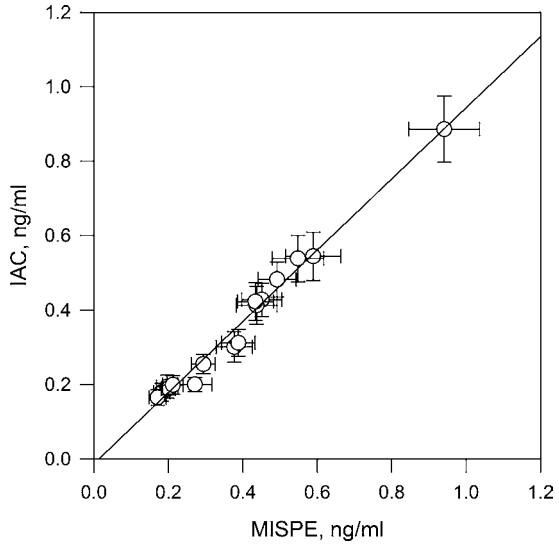

Figure 5. Comparison of OTA detemination in wine samples by IAC versus MISPE.

maximum permitted levels. Recoveries performed on different Italian red wine samples spiked with OTA showed good reproducibility and agreement with those obtained by the IAC method, demonstrating the potentiality of this procedure to substitute for the current IAC-HPLC protocol.

and quantities of mycotoxins and plant defense compounds in plant tissue (i.e., zealexins, fatty acid-derived oxylipins).

MATERIALS AND METHODS

Chemicals. Authentic standards for 3-hexen-1-ol, heptan-2-ol, 1-octen-3-ol, octan-3-one, and octan-3-ol were purchased from Sigma-Aldrich, Munich, Germany. β-Macrocarpene and β-bisabolene were produced using recombinant TPS6. The enzyme was heterologously expressed in *Escherichia coli*, purified, and incubated with the substrate farnesyl pyrophosphate. Enzyme products were collected from the headspace of the assay using SPME. Heterologous expression, enzyme assays, and product analysis were carried out as described earlier.[12] α-Selinene and β-selinene were identified using celery (*Apium graveolens*) seed oil (Carl Roth, Karlsruhe, Germany).[14]

Plant Material and Growth Conditions. Experiments were performed on two corn varieties, including the commercial hybrid variety Ronaldinio (obtained from KWS Saat AG, Einbeck, Germany) and the dwarf corn variety GaspeFlint landrace (originally collected in Quebec, Canada, provided by Prof. Dr. J. Schirawski, RWTH Aachen University, Germany).

Corn was grown under greenhouse conditions at 26 ± 5 °C with a 16 h photoperiod (6600 lx at ear height) and a relative humidity of 58%. Corn seeds were sown in a soil mix consisting of 30% sand (<2 mm particle size granularity) and 70% commercial plant substrate (Fruhstorfer Erde, Typ T25, HAWITA Group, Vechta, Germany). After 21 days of growth, the hybrid corn plants were separated, and single plants were transferred to plastic pots (18 × 18 × 25 cm). Dwarf corn seedlings were sown and raised in plastic pots (11 × 11 × 12 cm). Plants were irrigated with tap water as required. After 1 month of growth, plants were supplemented weekly with a macronutrient fertilizer (N:P:K = 15:10:15) dissolved in the irrigation water.

Fungal Strains. Hybrid corn ears were inoculated with two strains of *Fusarium graminearum* (FG1 and FG2), two strains of *Fusarium verticillioides* (FV1 and FV2), and one strain of *Fusarium subglutinans* (FSUB). FG1 is a nivalenol (NIV) chemotype strain, and FG2 is a deoxynivalenol (DON) chemotype strain. Infection of dwarf corn ears included one strain each for *F. graminearum* (FG1), *F. verticillioides* (FV1), and *Fusarium avenaceum* (FA). The sources of fungal material and abbreviations used in this study are described in the Supporting Information (Table S1). These strains/species of *Fusarium* were selected for their different abilities to infect corn and also because of their ability to produce different mycotoxins.

Fungal spores were produced under sterile conditions in liquid mung bean medium following a modified protocol.[15] Modifications included an additional initial cultivation step for 5 days at 28 °C to enhance final spore concentration. Final cultures were filtered through cotton wool and were centrifuged at 7000*g* for 5 min. The supernatant was discarded, and spores were suspended in glycerol (15% v/v, Carl Roth, Karlsruhe, Germany). Suspensions were mixed gently, and the spores were counted with a Thoma chamber (0.0025 mm^2). Spore suspensions were stored at −70 °C, and germination tests were regularly performed on potato dextrose agar (PDA, Carl Roth, Karlsruhe, Germany) to assess viability.

Inoculation of Corn Ears. Commercial corn ears of the hybrid variety were inoculated with fungal strains FG1, FG2, FV1, FV2, and FSUB. Ears of the dwarf corn variety were inoculated with FG1, FV1, and FA only. A summary of the treatments and parameters monitored for each treatment is provided in Table 1. The harvested spores were suspended in autoclaved tap water containing the detergent Tween 20 (0.14%, Applichem, Darmstadt, Germany), which prevented clumping. For inoculation of hybrid corn ears, the spore concentration was 10^6 mL^{-1} for *F. verticillioides* and *F. subglutinans* and 10^5 mL^{-1} for *F. graminearum* (the latter species is more aggressive than the other two species). Each hybrid corn ear was treated with 1.0 mL of inoculum, and control plants were treated with 1.0 mL of water containing 0.14% Tween 20. For inoculation of dwarf corn ears, the spore concentration was 10^5 mL^{-1} for *F. graminearum* and 2×10^5 mL^{-1} for *F. verticillioides* and *F. avenaceum*. Because the ears of dwarf corn are small, only 0.5 mL of inoculum was injected per ear, and control plants were treated with 0.5 mL of water containing 0.14% Tween 20. Hybrid and dwarf corn ears were inoculated by injecting the spore suspension into the silk channel at the main flowering stage (BBCH 65).[16,17]

Table 1. Overview of *Fusarium* Species and Strains Used To Inoculate Hybrid Corn and Dwarf Corn, Timing of Sample Collection, and Variables Measured[a]

		hybrid maize		dwarf maize
maize ears treated with	abbreviation for treatment	maize ears at milk ripeness (~24 dpi)	maize ears at 4, 8, 12, 16, 20, and 24 dpi	maize ears at milk ripeness (~14 dpi)
noninfected control	CONT	SPME, OLS, oxylipins; DS; DNA; mycotoxins		SPME, zealexins, GEA; DS; DNA
F. graminearum strain 1	FG1	SPME, OLS, oxylipins; DS; DNA; mycotoxins		SPME, zealexins, GEA; DS; DNA
F. graminearum strain 2	FG2	SPME, OLS, oxylipins; DS; DNA; mycotoxins	SPME; DS; DNA	
F. verticilloides strain 1	FV1	SPME, OLS, oxylipins; DS; DNA; mycotoxins	SPME; DS; DNA	SPME, zealexins, GEA; DS; DNA
F. verticilloides strain 2	FV2	SPME, OLS, oxylipins; DS; DNA; mycotoxins		
F. subglutinans	FSUB	SPME, OLS, oxylipins; DS; DNA; mycotoxins		
F. avenaceum	FA			SPME, zealexins, GEA; DS; DNA

[a]Volatiles were sampled by solid phase microextraction (SPME) and by open-loop stripping (OLS). For hybrid corn and SPME and OLS at 24 days postinoculation (dpi), n = 4 ears/treatment. For hybrid corn and SPME in the time series (4−24 dpi), n = 3. For dwarf corn at 14 dpi, n = 6. Nonvolatile defense compounds were quantified in hybrid corn (oxylipins, n = 4) and dwarf corn (zealexins n = 4−6) along with gene expression analysis of *tps6/11* (GEA, n = 4−6). Mycotoxins were quantitied in hybrid corn ears at 24 pdi (n = 4). Disease severity (DS) was evaluated visually on dehusked corn ears, and fungal biomass (as indicated by DNA) was quantitied by RT-PCR.

Collection of Plant Material for Chemical and Molecular Analysis. Hybrid corn and dwarf corn ears were harvested at the early milk ripeness maturity stage, BBCH 73,[17] which was 24 days postinoculation (dpi) for hybrid corn and 14 dpi for dwarf corn. Hybrid corn was also harvested at 4, 8, 12, 16, 20, and 24 dpi (Table 1). Corn ears were dehusked, and disease severity was visually estimated as the percentage of affected/infected surface (from 0 to 100%). Afterward, corn ears were cut longitudinally into halves. Immediately after harvest, corn ears were placed on ice and within 30 min frozen at −20 °C (samples for SPME, mycotoxin, oxylipin, and qPCR analysis) or shock frozen in liquid N_2 (samples for zealexin quantitation and gene expression analysis). Handling of the samples on ice or with liquid N_2 was performed to ensure that the profiles of secondary metabolites measured in this study were attributed to *Fusarium* infection and not to the damage of the ears induced by cutting. Additionally, to validate the results obtained by SPME on cut material, volatiles were also sampled from undamaged infected and uninfected corn ears on live plants (see Collection of Volatiles by Open-Loop Stripping).

dx.doi.org/10.1021/jf500560f | J. Agric. Food Chem. 2014, 62, 5226−5236

From the cut corn ears, a 2.0 g quantity of kernels from the tip of the first half was transferred to an SPME vial, which was sealed airtight and stored at −20 °C for subsequent volatile analysis. Kernels from the second half were used for further chemical and molecular analysis. Hybrid corn material from the second half was susequently freeze-dried and ground with a ball mill (Retsch, Haan, Germany). Subsamples of homogenized material were used for fungal biomass quantitation by quantitative real-time PCR and for the analysis of mycotoxins and oxylipins (Table 1). Dwarf corn material from the second half was homogenized in liquid nitrogen immediately after cutting and used for fungal biomass quantitation by quantitative real-time PCR, for gene expression analysis, and for the detection of zealexins (Table 1).

Collection of Volatiles by SPME. Samples (2.0 g of corn kernels) were enclosed in 20 mL SPME vials (VWR, Darmstadt, Germany) that had screw caps containing a silicone/polytetrafluoroethylene (PTFE) septum (1.3 mm, VWR). The samples were extracted by SPME using a polydimethylsiloxane divinylbenzene (PDMS-DVB) fiber (65 μm coating thickness, Supelco, purchased from Sigma-Aldrich, Taufkirchen, Germany). The SPME fiber was conditioned according to the manufacturer's instruction before extraction. Before extraction, the samples, which were initially frozen at −20 °C, were allowed to equilibrate to room temperature for 3 h and were then incubated at 40 °C for 25 min. Headspace SPME was then carried out for 10 min at 40 °C, resulting in equilibrium extraction. The fiber was immediately injected into the GC inlet (heated to 260 °C) for VOC desorption and chromatographic analysis. Blank runs using empty SPME vials were regularly performed to check for carry-over effects.

Collection of Volatiles by Open-Loop Stripping (OLS). Because SPME was used on frozen and cut corn kernels, OLS was used as another, independent volatile-sampling technique to validate the SPME results. Specifically this was done to ensure that the volatiles identified by SPME were not artifacts due to cutting or freezing the samples. In the OLS setup used here, volatiles were collected from live corn ears on intact plants. The maturity stage of the corn ears was the same as that of the ears subjected to SPME; that is, the ears were at the main flowering stage (BBCH 65[17]). Corn ears were enclosed in commercial, polyester cooking bags (50 cm adjusted length, Toppits, Minden, Germany), and air was circulated in the bags with a flow of 1.5 L min^{-1} to carry/strip the volatiles away using an N86KT.18 pull pump equipped with a PTFE-coated membrane (VWR). Incoming air was precleaned on steam-activated charcoal pellets (1 mm diameter, Sigma-Aldrich) to minimize background signal. Volatiles from corn ears were trapped in a glass cartridge containing a 1.5 mg activated charcoal filter (from D. Graenicher, Daumazan sur Arize, France), and extraction was performed for 24 h to exclude diurnal variations. The quantity of 1.5 mg of activated charcoal was sufficient to trap all volatiles emitted from corn ears within 24 h, and no trap saturation or volatile breakthrough was observed (this was validated by sampling the volatiles of a *Fusarium*-infected corn ear using three cartridges in a row). Blank runs were performed with empty bags to determine the background signal of the system. Pump, bags, volatile trap, and precleaning cartridge were all connected using silicon tubing.

After extraction of the volatiles, traps were rinsed with 100 μL of dichloromethane spiked with 8 μg mL^{-1} nonyl acetate (FCC grade, Sigma-Aldrich) as an internal standard. A 2 μL volume was used for volatile analysis by gas chromatography coupled to mass spectrometry (GC-MS). Because cartridges were used many times, they were cleaned/reconditionned between each run by rinsing them three times with dichloromethane and three times with *n*-pentane. Organic solvents were then removed by vacuum for 2 min. This reconditioning step was performed to make sure that no volatile contamination was carried over from one sampling to the next.

Gas Chromatography–Mass Spectrometry (GC-MS) Conditions for Volatile Profiling. An Agilent 6890 gas chromatograph that was coupled with an Agilent 5973 mass selective detector (Agilent, Waldbronn, Germany) and equipped with an autosampler for SPME vials (PAL Combi, CTC Analytics AG, Zwingen, Switzerland) was used to analyze the SPME samples and extracts of OLS. The GC was equipped with a capillary HP-5MS column (0.25 mm nominal diameter × 30 m length × 0.25 μm film thickness, Agilent). Conditions were as follows: inlet pressure, 48.5 kPa; helium flow, 19 mL min^{-1}; injector, 250 °C; transfer line, 260 °C; and electron energy, 70 eV. The GC was programmed as follows: 40 °C (2 min isothermic), increasing at 3.2 °C min^{-1} to 140 °C followed by 80 °C min^{-1} to 250 °C (3.38 min isothermic) and operated in splitless mode; carrier gas (helium), 1 mL min^{-1}. The scan range was between 40 and 450 atomic mass units.

Comparison of SPME and OLS Extraction Methods. Without proper calibration, SPME is considered at best semiquantitative. Furthermore, because SPME is a nonexhaustive extraction method, matrix effects cannot be ruled out. To estimate possible matrix effects, we compared results obtained with SPME (no standard) and OLS (internal standard) on the same samples. For this purpose, kernels of hybrid corn ears were collected at 24 dpi with FG1 and homogenized in a mortar. A 5 g quantity of the fresh material from the mortar was distributed to each of three replicates of SPME vials and glass Petri dishes. HS-SPME was conducted as described before in 20 mL SPME vials. For OLS, the glass Petri dishes containing the homogenized kernels were placed in polyester bags; volatiles were trapped by flushing the bags for 4 h and were collected as described before for live corn ears.

Mycotoxin Extraction and Analysis. For each sample of homogenized corn flour, a 500 mg quantity was transferred to a 15 mL centrifuge tube. The material in the tube was then mixed with 5 mL of extraction solvent (methanol/isopropanol/water/acetic acid, 79:5:15:1, v/v/v/v, Carl Roth), followed by an overnight extraction on a rotary shaker (170 rpm) and centrifugation at 7000*g* for 10 min. A 1.0 mL volume of the clear supernatant was evaporated to dryness under vacuum at 35 °C, redissolved in 500 μL of methanol/water (1:1, v/v), and defatted with cyclohexane. Mycotoxin content was determined by HPLC-MS/MS using the instrument, columns, and methods previously described for trichothecenes[18] and for zearalenone and fumonisins.[19,20]

Quantitation of Fungal DNA. DNA was extracted from 100 mg samples of corn ear material following a protocol described earlier.[21] DNA quality was checked by agarose electrophoresis. Standards were produced in noncontaminated corn matrix spiked with pure fungal DNA. DNA extraction from fungal mycelium was conducted as described in ref 21, but an additional phenol extraction step was included and DNA concentration was determined by densitometry. Real-time PCR with species-specific primers was used to determine fungal biomass in plant tissue according to protocols published for *F. graminearum*[21] and *F. verticillioides*.[22] *F. subglutinans* and *F. avenaceum* were quantified with the aid of species-specific primers described elsewhere[23,24] using a reaction mixture consisting of 16 mM $(NH_4)_2SO_4$, 67 mM Tris-HCl pH 9.0, 0.3 μM each primer, 0.1× SYBR Green I (Invitrogen, Karlsruhe, Germany), 1 u/50 μL BIOTaq DNA polymerase (Bioline, Lückenwalde, Germany), 0.1 mM dNTP, and $MgCl_2$ (3.5 mM for *F. subglutinans* and 2 mM for *F. avenaceum*). The following thermocycler program was used: initial denaturation for 2 min/94 °C followed by 34 cycles of 30 s/94 °C, 30 s/64 °C (*F. subglutinans*) or 25 s/62 °C (*F. avenaceum*) and 40 s/72 °C (*F. subglutinans*) or 30 s/72 °C (*F. avenaceum*). The final extension was carried out for 5 min at 72 °C.

Gene Expression Analysis of Terpene Synthase Genes *tps6/11*. Total RNA was extracted from 100 mg samples of fresh matter (ground with a mortar and pestle in liquid nitrogen) using the RNeasy Plant Mini Kit (Quiagen, Hilden, Germany). The quality and quantity of RNA were assessed by gel electrophoresis (1.2% (w/v) agarose gels).

DNase digestion was carried out, followed by the synthesis of cDNA using Super Script III polymerase (Invitrogen, Karlsruhe, Germany). Each volume was diluted 2:1 (v/v). Amplification of DNA was accomplished for each candidate primer pair using Phusion High-Fidelity DNA-Polymerase (Biozym, Hessisch Oldendorf, Germany). PCR products were purified with the QIAquick PCR Purification Kit (Quiagen). The DNA fragments were ligated in the pCRBlunt II-TOPO vector (Invitrogen) following the manufacturer's instructions. The vector was transformed in competent cells of *Escherichia coli*

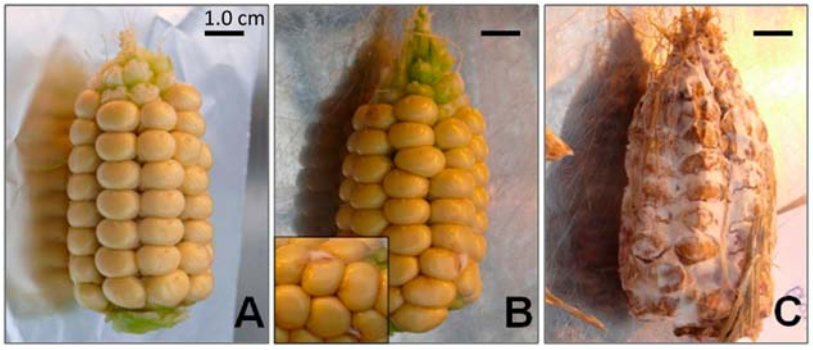

Figure 1. Photographs showing typical symptoms of *Fusarium* infection on corn ears. The representative dwarf corn ears were at the milk ripeness maturation stage and had been inoculated 14 days earlier with (A) water as a control treatment (no symptoms), (B) *F. verticillioides* (inset illustrates mycelium of *F. verticilllioides* on single kernels), and (C) *F. graminearum* (the whole ear is heavily colonized). Infection symptoms for hybrid corn ears were comparable.

(TOP10, Invitrogen). Colony PCR was carried out to identify successfully transformed colonies. Plasmid DNA was extracted from the *E. coli* cultures with the NucleoSpin Plasmid Kit (Macherey-Nagel, Dueren, Germany). Extracted plasmids were sequenced to confirm correct insert sequence. Quantitative real-time PCR was carried out for a housekeeping gene[25] (putative APT1a for adenine phosphoribosyltransferase 1; primer forward HG5:5′-AGGCGTTCCGTGACACCATC-3′, primer reverse HG6:5′-CTGGCAACTTCTTCGGCTTCC-3′) and candidate genes (*tps6/11*, QRT5:5′-TGGTAATTTGGACTTAGTTTCACG-3′; QRT6:5′-CACTGTCTCTCCATGAATCCTC-3′) using Brilliant III Ultra-Fast qPCR master mix (Stratagene, La Jolla, CA, USA). Because of the high sequence similarity, only one primer pair was used for the amplification of both *tps6* and *tps11*. Primer specificity was confirmed by agarose gel electrophoresis, melting curve analysis, standard curve analysis, and sequence verification of cloned PCR amplicons (see above). ROX was used as a reference dye. The following PCR conditions were applied for all reactions: initial incubation at 95 °C for 3 min followed by 40 cycles of amplification (95 °C for 20 s, 60 °C for 20 s). Plate reads were taken during the annealing and the extension step of each cycle. Data for the melting curves were recorded at the end of cycling from 55 to 95 °C.

All samples were run on the same PCR machine (MxPro-Mx3000P, Stratagene, Agilent Technologies, USA) in an optical 96-well plate. Five biological replicates were analyzed as triplicates in the qRT-PCR for each of the three treatments. Data for the relative quantity to calibrator average (dRn) were exported from the MXPro software.

Detection of Oxylipins and Zealexins. Aliquots of freeze-dried hybrid corn material, corresponding to 2 g of fresh weight, were extracted as described earlier.[26] Extraction was performed with the internal standard (6*Z*,9*Z*,11*E*,13*S*)-13-hydroxy-6,9,11-octadecatrienoic acid (13γ-HOT), and extracts were methylated with trimethylsilyldiazomethane (2 M in hexane, Sigma-Aldrich). Hydroxyl fatty acids were purified by reverse phase HPLC using an ET250/2 Nucleosil 120-5 C18 column (Macherey-Nagel) as described earlier.[26] The eluate fraction was collected between 8.0 and 13.5 min, evaporated to dryness, and redissolved in 2 μL of acetonitrile. After the addition of 2 μL of *N*,*O*-bis(trimethylsilyl)trifluoroacetamide (Sigma-Aldrich), analysis was carried out with the GC-MS system as described earlier for the volatile profiling. Standard curves were constructed by plotting ion intensities versus concentrations of known hydroxyl fatty acids. For determination of the recovery of the hydroxyl fatty acids, 13γ-HOT was used.

For zealexin analysis, a 100 mg quantity of fresh dwarf corn ear material was transferred to a 2 mL reaction tube. Samples were extracted without an internal standard, derivatized, and identified as described by others.[13,27] Samples (1 μL) were injected into an GC-MS system as described earlier for the volatile profiling. Conditions were as follows: inlet pressure, 52.5 kPa; helium flow, 11 mL min^{-1}; injector, 260 °C; transfer line, 260 °C; and electron energy, 70 eV. The GC was programmed as follows: 50 °C (1 min isothermic), increasing at 10.0 °C min^{-1} to 260 °C (15 min isothermic), and operated in split mode (split ratio of 7:1); carrier gas (helium), 1 mL min^{-1}. Tentative identification of zealaxins A1 and A3 was based on mass spectral data.[13]

Data Processing, Relative Quantitation of Volatiles, and Statistical Analysis. Chromatograms of OLS and SPME samples were integrated automatically using Agilent MSD ChemStation software (version D.01.02.16, June 15, 2004, Agilent). Integration parameters were set to initial area reject = 1, initial peak width = 0.02, shoulder detection = OFF, and initial threshold =14. Kovat's retention indices (KI) were calculated on the basis of a homologous series of *n*-alkanes.[28] Peaks in different samples corresponding to the same volatile were realigned manually using an RT shift of maximum ±0.1 min. This low RT shift was appropriate because of the good resolution of the chromatograms and the low temporal shift among peaks. Two separate data matrices, including aligned retention times and corresponding integrated peak areas for all samples, were constructed, one for the SPME/GC-MS data set and one for the OLS/GC-MS data set. Relative quantitation was performed to be able to compare the concentration of each volatile among samples as follows: peak areas of the SPME/GC-MS data were normalized to the total ion current (TIC), whereas OLS/GC-MS peak areas were normalized to the peak area of the internal standard. Background signals (empty vial/empty bag sample) were subtracted from the corresponding matrices. Because our aim was to identify volatiles for which occurrence/concentration was affected by fungal infection, relative quantitation was appropriate because it allows comparison of the concentration of specific volatiles among samples. No absolute quantitation of volatiles was performed.

A nonparametric Kruskal–Wallis test[29] was used to identify those volatiles for which concentrations significantly differed between control and individual *Fusarium* infection treatments. This was performed on the SPME-GC/MS data of hybrid corn at 24 dpi. The Kruskal–Wallis test is included in the package "pgirmess: data analysis in ecology" for R (version 2.14.2; this recent version is available at http://cran.r-project.org/web/packages/pgirmess/index.html). Volatiles that significantly differed between one or more infection treatments and the healthy controls were considered as infection markers.

Markers were identified by calculation of retention indices (KI), when possible by injection of authentic standards, and by comparison of their MS fragmentation patterns with those available in mass spectral libraries, including NIST 08 (National Institute of Standards and Technology, Gaithersburg, MD, USA), the Adams library,[30] and the Wiley Registry of Mass Spectral Data.[31] Appropriate parametric and nonparametric statistical tests were used for statistics. The exact statistical tests are described in the captions.

RESULTS AND DISCUSSION

Specific Volatiles Are Induced/Repressed in *Fusarium*-Infected Corn Ears. In a first experiment, SPME volatile

[a]Volatiles identified as markers of *Fusarium* infection in hybrid corn. Overview of volatile markers for Fusarium infection of hybrid corn ears at milk ripeness stage (24 dpi). Values are peak areas (± SE) normalized to TIC (% TIC). KI = calculated Kovats indices; Compounds were fully identified (**a**) based on the comparison of their MS fragmentation patterns to the NIST and Adams MS libraries, comparison of their KI to the values listed in literature, and comparison of their retention times to those of authentic standards. If no authenthic standards were available (**b**), compounds were *tentatively identified* based only on MS data and KI. Values in bold significantly differed from the control treatment (uninfected corn ears) ($p < 0.05$ according to the Kruskal-Wallis test.[29] + Indicates that infection marker occurrence was confirmed by open loop-stripping (OLS) using charcoal cartridges. [b]ID refers to the mode of identification. Volatiles a were identified on the basis of MS, KI, and authentic standards. Compounds b were tentatively identified on the basis of MS and KI only.

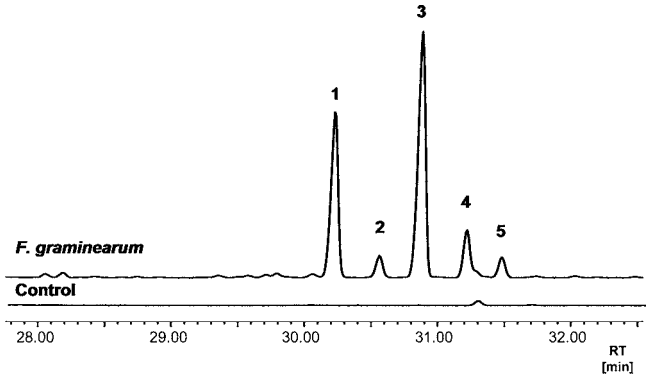

Figure 2. Major sesquiterpene volatiles induced in corn ears following fungal infection. Stacked chromatograms (TIC from SPME-GC/MS) of volatile profiles from ears inoculated with water (control) or *F. graminearum*. The profile for *F. graminearum*-infected ears illustrates the *de novo* synthesis of the defined and main VOC markers for infection: (1) *β*-selinene; (2) *α*-selinene; (3) *β*-macrocarpene; (4) *β*-bisabolene; (5) trichodiene (only in *F. graminearum* infection).

profiles of *Fusarium*-infected hybrid and dwarf corn ears were compared to the profiles of healthy hybrid and dwarf corn ears at the milk ripeness maturation stage. Under the experimental conditions of this study, milk ripeness was reached in hybrid corn at 24 dpi and in dwarf corn at 14 dpi. Photographs of uninfected and *Fusarium*-infected corn ears at the milk ripeness maturation stage are provided in Figure 1. Statistical analysis of the profiles revealed that the concentrations of 22 volatiles significantly differed between the infected and the uninfected ears. Infection markers included volatiles that were emitted at significantly higher or lower concentrations from infected than from healthy ears or that were detected only from infected ears. Nine infection markers were identified using authentic standards, MS fragmentation patterns, and Kovats retention indices, whereas 13 other markers were tentatively identified only on the basis of their MS fragmentation patterns and Kovats retention indices (Table 2). Infection markers comprised C_6–C_8 volatiles, including alcohols, a ketone, terpenoids, and unidentified volatiles (Table 2). The mass spectra of six unidentified markers were characterized as having

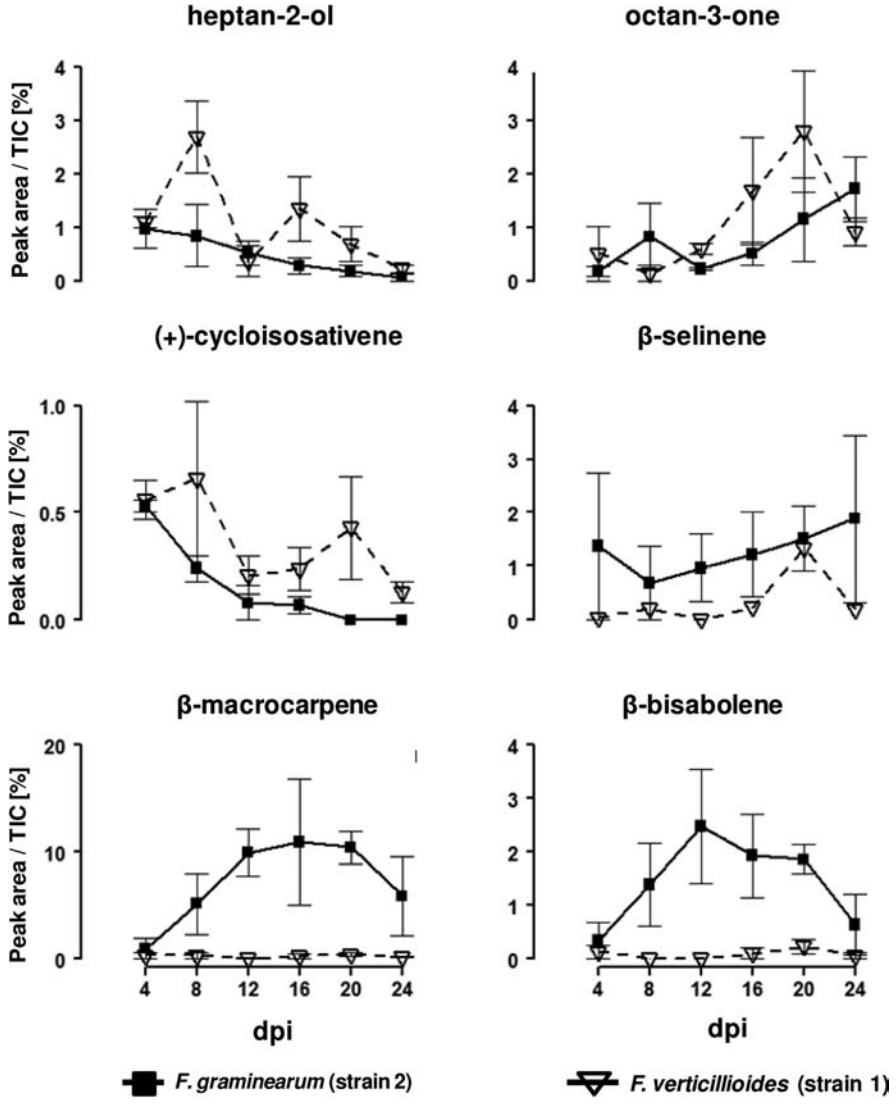

Figure 3. Emission of six selected volatile markers over time from *Fusarium*-infected hybrid corn. The abbreviation dpi refers to days postinoculation with *F. graminearum* (FG2) and *F. verticillioides* (FV1). Relative quantities of volatiles, as determined by SPME/GC-MS, are reported as mean peak areas (± standard error, n = 3) normalized by total ion chromatogram (TIC).

[a]Influence of inoculation with *Fusarium* strains on the formation of the mycotoxins deoxynivalenol (DON), zearalenone (ZEN), nivalenol (NIV), and fumonisins B1 and B2 (FB1, FB2) in hybrid corn ears at 24 dpi. [b]Concentration exeeds range of detection (trichothecenes, >50 mg kg^{-1}; fumonisins, >10 mg kg^{-1}).

a parent ion with *m/z* 204 and typical daughter ions having *m/z* values of 189 and 93 (Supporting Information Figure S1). On the basis of these properties, the six unidentified markers were tentatively assigned as sesquiterpenoids (SQTs).

Sesquiterpenoids represented the major class of infection markers, and five sesquiterpenes, including β-selinene, α-selinene, β-macrocarpene, β-bisabolene, and trichodiene, were dominant in the chromatograms (Figure 2). Trichodiene was emitted only by ears infected with FG1 and FG2, whereas β-selinene, α-selinene, β-macrocarpene, and β-bisabolene were emitted by ears infected with all *Fusarium* species/strains tested. Healthy hybrid corn ears released high levels of (+)-cycloisosativene and α-ylangene. These volatile sesquiterpenoids were absent or at low concentration in the headspace of *Fusarium*-infected samples. Most infection markers, including alcohols and major sesquiterpenoids that were detected from infected hybrid corn, were also detected from infected dwarf corn (not shown).

The majority of sesquiterpenoids identified in this study as infection markers have been previously described as herbivore-induced corn volatiles[32−34] and are consequently most likely derived from the plant. Nevertheless, *Fusarium* also has the ability to produce the sesquiterpenoid β-bisabolene,[35] and a mixed fungal and plant origin for the latter volatile cannot be ruled out. Interestingly, some of the major (defined as TIC normalized peak area in Table 2 >1.00%) volatile infection markers detected in *Fusarium*-infected corn ears (β-macrocarpene and β-bisabolene) appear to be minor or undetectable infection markers in corn leaves, stems, and roots,[11,36] where they might be fully transformed to nonvolatile zealexins involved in plant defense.[36] Other major infection markers included the sesquiterpenoids α- and β-selinene, which are known components of celery oil.[14] Both compounds have been reported to be involved in defense against pathogens and insects in plants other than corn[37,38] and might have a similar role in corn.

Infection Markers Are Detectable before Infection Symptoms Appear on Dehusked Corn. A second experiment was performed to investigate how quickly volatile infection markers were detectable after inoculation. This experiment was performed by sampling *F. graminearum* (strain FG2)- or *F. verticillioides* (strain FV1)-infected ears every 4 days, from 4 to 24 dpi. The earliest time point of 4 dpi was selected because at this time almost no infection symptoms are evident on ears that have not been dehusked. SPME/GC-MS analysis revealed that the majority of infection markers identified at 24 dpi (Table 2) were already detectable between 4 and 8 dpi (see Figure 3 for selected markers and the Supporting Information (Figure S2) for a heatmap of all markers). The induction of the major SQT markers β-macrocarpene and β-bisabolene was clearly the strongest with the most aggressive *Fusarium* species (*F. graminearum*, Figures 3 and 4A). Some volatiles, such as heptan-2-ol and (+)-cycloisosativene, decreased in concentration over time (i.e., after infection with *F. graminearum*), whereas others, such as octan-3-one, β-selinene, β-macrocarpene, and β-bisabolene, increased over time and reached a maximum at 16−24 dpi (Figure 3 and Supporting Information Figure S2).

Because most volatile markers were detectable at a very early stage of infection, they could be used for the early, nondestructive detection of fungal infection in the field (patent application, University of Goettingen, Germany, DE 101012204237.7). Sensitive portable devices such as ion mobility spectrometers (IMS) could be used for detection of infected ears in the field or during postharvest processes (i.e., storage, transport, or feed production). In the field, distinguishing healthy from infected corn plants might help guide decisions concerning the application of fungicides. In postharvest processes, infected corn ears might be separated from healthy ones and used for applications where mycotoxins are not a concern (i.e., for the production of biofuels).

Sesquiterpenoid Infection Markers Are Also Detectable from Corn Ears on Live Plants. SPME and OLS were used to capture the volatiles emitted by corn ears. SPME was performed on cut and frozen ears, whereas OLS was carried out

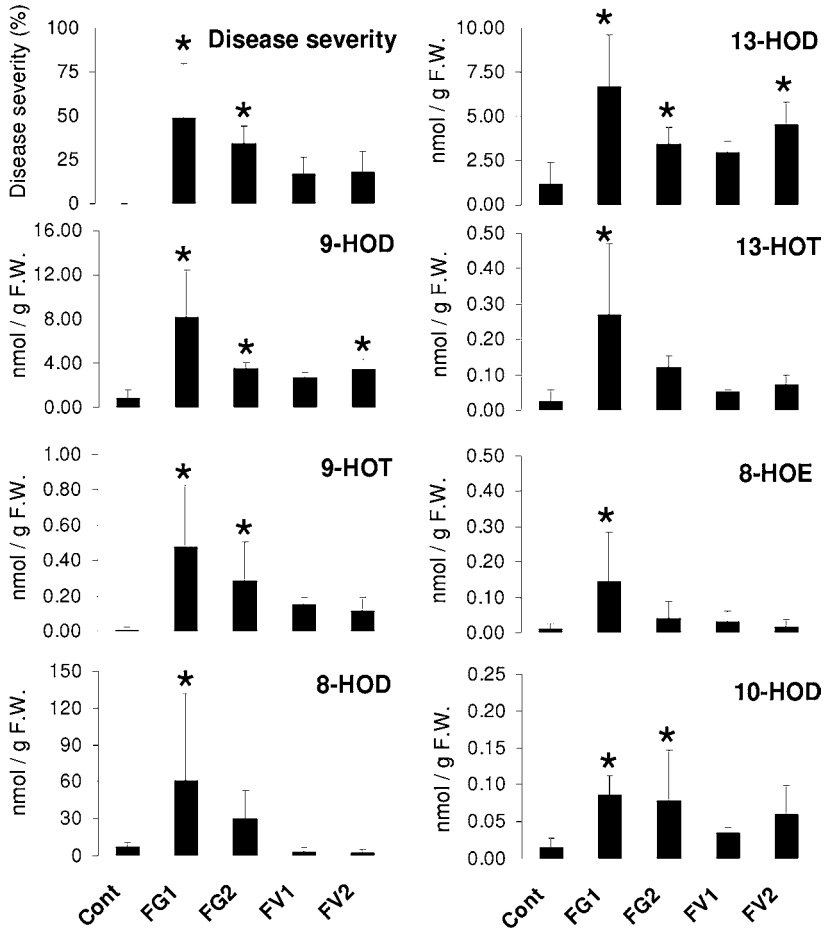

Figure 5. Disease severity and fatty acids in *Fusarium*-infected hybrid corn ears at 24 dpi. 13-HOD, (9*Z*,12*Z*)-8-hydroxy-9,12-octadecadienoic acid; 9-HOD, (10*E*,12*Z*)-9-hydroxy-10,12-octadecadienoic acid; 8-HOD, (9*Z*,12*Z*)-8-hydroxy-9,12-octadecadienoic acid; 13-HOT, (9*Z*,11*E*,15*Z*)-13-hydroxy-9,11,15-octadecatrienoic acid; 9-HOT, (10*E*,12*Z*,15*Z*)-9-hydroxy-10,12,15- octadecatrienoic acid; 8-HOE, (9*Z*)-8-hydroxy-9-octadecenoic acid; 10-HOD, (8*E*,12*Z*)-10-hydroxy-8,12-octadecadienoic acid. The asterisk indicates statistical differences from control treatment ($p < 0.05$, Dunnet test). See Figure 4 caption for explanation of strain abbreviations. F.W. = fresh weight.

on both cut and frozen ears as well as undamaged ears attached to live plants. One advantage of SPME compared to OLS is that SPME requires minimal sample preparation; quantitation, however, is more difficult with SPME than with OLS. SPME (no internal standard) and OLS (nonyl acetate as internal standard) were used here for relative quantitation of volatiles.

First both OLS and SPME techniques were compared on the same frozen material (equal aliquots *F. graminearum*-infected corn ears). Considering the major sesquiterpenoids identified in this study, the results obtained with SPME and OLS were highly correlated ($R^2 = 0.998$) (Supporting Information Figure S3). This indicates that even without the use of an internal standard, the SPME data generated here can be used for relative quantitation. OLS was further performed on live corn ears that were undamaged through cutting to ascertain that the markers identified by SPME were not an artifact due to cutting or freezing. SPME (frozen and cut ears) and OLS (live and undamaged ears) gave similar results for most but not all sesquiterpenoids, whereas C_6 and C_8 alcohols were identified only by SPME (Table 2 and Supporting Information Table S2). These differences might be explained by the fact that many short-chain alcohols are poorly retained on the activated carbon[39] in the OLS traps, whereas they are better retained on polymers such as the PDMS-DVB used here for SPME.[40] Another reason might be that the freezing and cutting of the SPME samples might have released enzymes/substrates that would not colocalize in live plants. Despite these differences, both methods confirmed that sesquiterpenoids were major markers of *Fusarium* infection of corn ears (Table 2).

Disease Severity Is Correlated with the Amount of Fungal DNA in Corn Ears. Disease severity, the percentage of the ears showing infection symptoms, was visually assessed for dehusked hybrid corn ears at the milk ripeness stage after inoculation with single *Fusarium* strains (Figure 4A). Strain FG1 was the most aggressive (>90% disease severity), FV2 and FSUB were the least aggressive (<25% disease severity), and FG2 and FV1 were intermediate (Figure 4A). Fungal biomass (as indicated by fungal DNA) (Figure 4B) was correlated with disease severity ($R^2 = 0.75$, $p = 0.026$). DNA quantity was much lower with FG2, FV2, and FSUB than with FG1 and was intermediate with FV1. Despite the low DNA level, FG2 induced average disease symptoms, confirming the high aggressiveness of *F. graminearum* compared to other *Fusarium* species. In a time series, corn ears were inoculated with either FV1 or FG2, and disease severity was assessed every 4 days, from 4 to 24 dpi. Disease severity for both *Fusarium* species averaged about 10% at 4 dpi and increased to 50 − 70% at 20 dpi (Supporting Information Figure S4).

Mycotoxins, Oxylipins, and Zealexins in *Fusarium*-Infected Corn Ears. An overview of mycotoxin concentrations

dx.doi.org/10.1021/jf500560f | J. Agric. Food Chem. 2014, 62, 5226−5236

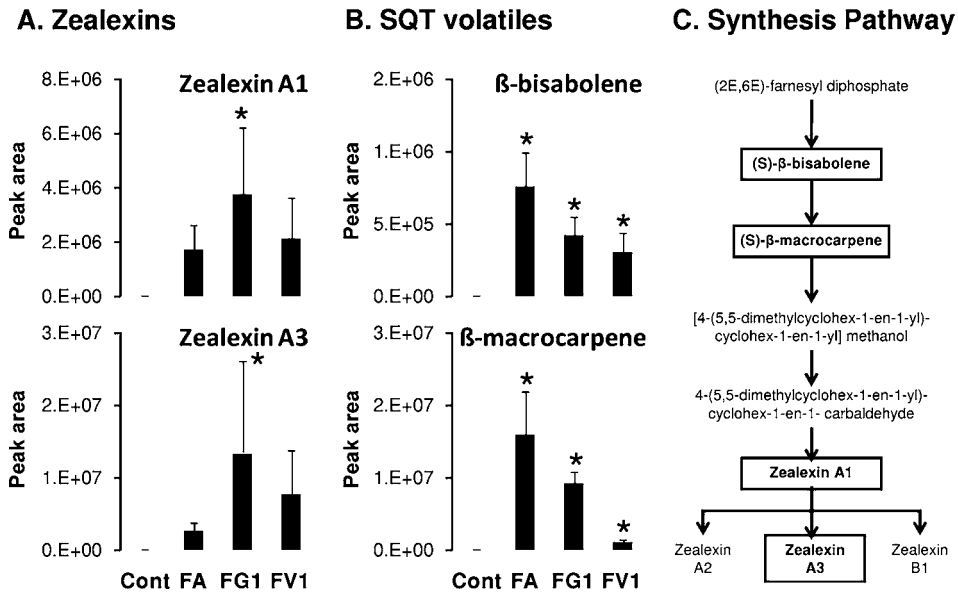

Figure 6. Zealexins and their volatile intermediates in *Fusarium*-infected dwarf corn ears at 14 dpi: (A) induction of zealexins A1 and A3 and (B) their volatile precursors (bisabolene and macrocarpene) after inoculation with water (Cont), strain FA of *F. avenaceum*, strain FG1 of *F. graminearum*, or strain FV1 of *F. verticillioides*. Values are mean peak area of TIC ± SE (n = 3 to 6). The asterisk indicates statistical differences from control treatment (p < 0.05, Mann–Whitney U test). (C) Zealexin biosynthetic pathway (modified from http://pmn.plantcyc.org/PLANT/NEW-IMAGE?type=PATHWAY&object=PWY-6888).

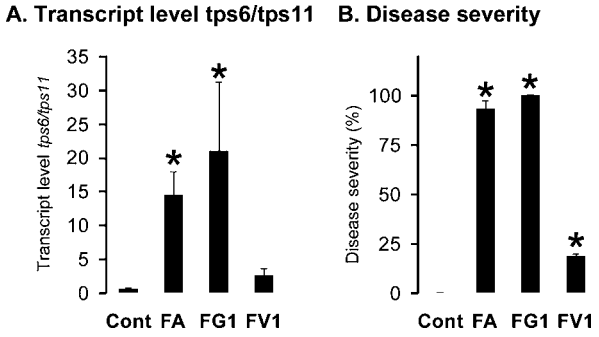

Figure 7. Gene expression and disease severity in dwarf maize ears at milk ripeness (14 dpi). Values are means ± SE for three to four replicate per treatment. The asterisk indicates difference from control treatment (p < 0.05, Mann–Whitney U test). Note that transcript levels of *tps6/tps11* were normalized to the expression level of a housekeeping gene, which was stable in Cont, FA, and FV1 but which was reduced in FG. This reduction might reflect either RNA degradation (i.e., due to fungal infection) or the fact that an important share of the total RNA in the FG samples was of fungal origin.

in hybrid corn ears at 24 dpi is provided in Table 3. FG1 produced NIV and FG2 produced DON at concentrations >50 mg kg^{-1}. Zearalenone (ZEN) was irregularly produced by *F. graminearum* strain 2 (FG2). Both *F. verticillioides* strains produced fumonisins B1 and B2, but FV1 produced much larger quantities of these mycotoxins than FV2 (Table 3).

In time series with FG2 and FV1, DON was detectable at 4 dpi, whereas fumonisin FB1 was detectable only at 16 dpi (Supporting Information Figure S5). The relationship between emission of volatile markers and mycotoxin concentration over time is also presented in the Supporting Information (Figure S5). The relative quantity of trichodiene, which is the volatile precursor of trichothecenes, showed roughly the same pattern as DON production until 20 dpi (the correlation $R^2_{4-20dpi}$ = 0.43). The correlation became nonsignificant at 24 dpi ($R^2_{4-24dpi}$ = 0.02). The emission of octan-3-one, a common fungal volatile, was most abundant in *F. verticillioides*-treated corn and showed a slight correlation with FB1 (R^2 = 0.25).

Oxidized fatty acids, so-called oxylipins, and zealexins were induced at different levels in infected corn ears depending on which *Fusarium* species was used as inoculum (Figure 5). In hybrid corn ears, oxidized fatty acids (8/9/10/13-hydroxy octadecadienoic acid (8/9/10/13-HOD) and 9/13-hydroxy octadecatrienoicacid (9/13-HOT)) as well as 8-hydroxy-(9Z)-octadecenoic acid (8-HOE) were all induced by the most aggressive *F. graminearum* strain (FG1), whereas only some of the oxylipins were induced by the other *Fusarium* species/strains. The number of oxylipins significantly induced upon infection was highly correlated with disease severity (R^2 = 0.78, p = 0.019, see also Figure 5).

The zealexin biosynthetic pathway was investigated in dwarf corn ears. Compounds tentatively identified as zealexins A1 and A3, which are nonvolatile sesquiterpenoids derived from β-bisabolene and β-macrocarpene, were induced in dwarf corn ears upon *Fusarium* infection. Their relative concentrations in corn ears infected with different *Fusarium* species are shown in Figure 6 along with the concentrations of their volatile precursors. Relative to their expression in uninfected corn ears, the terpene synthase genes *tps6* and *tps11* were up-regulated in the aggressive strain FA and FG1 (disease severity >90%), whereas a slight yet not significant increase was detected in FV (disease severity <20%) (Figure 7). In the case of FG1 (disease severity >90%), an up-regulation in *tps6/11* gene expression was also observed, but the expression of the housekeeping gene was reduced compared to uninfected plants. Possible explanations for this reduction are that RNA was degraded (i.e., due to fungal infection) or that a substantial proportion of the total RNA in the FG1 samples was of fungal origin. Both cases, however, should influence target genes and housekeeping genes at the same level. Overall, disease severity and expression levels of *tps6/tps11* were correlated (R^2 = 0.35, p = 0.006).

The up-regulation of zealexins A1 and A3 as well as of the terpene synthase genes *tps6/11* indicates that β-macrocarpene and β-bisabolene, known to be fully transformed into nonvolatile zealexins in corn leaves, stems, and roots,[12,36] are also partially transformed into zealexins in corn ears. However, the massive amounts of β-macrocarpene and β-bisabolene released by corn ears suggest that these volatiles might be further involved in direct plant defense or possibly in communication with neighboring plants (i.e., defense priming).[41]

Some of the fatty acid-derived volatiles (i.e., oxylipins[42]) identified in this study as infection marker volatiles are commonly produced by fungi and plants. Their source (fungal vs plant) can be determined by their different biosynthetic origins. Plants oxidize polyunsaturated fatty acids from membranes via the so-called lipoxygenase or oxylipin pathway, leading to the formation of green leaf volatiles such as 3-hexen-1-ol via 13-H(P)OT as an intermediate (13-H(P)OT is the hydroperoxyl derivative of 13-HOT) (Figure 5).[43] These green leaf volatiles (C_6 volatiles) play a role in priming neighboring corn plants against insect attack.[44] In addition, 13-H(P)OT may serve as a substrate for the formation of the phytohormone jasmonic acid, which is a master regulator of plant reaction against wounding and necrotrophic pathogens.[45] In contrast, fungi oxidize the same substrates by a different enzyme family called psi-factor producing oxygenases.[46] In fungi, 10-H(P)OD serves as the intermediate for the formation of C_8 volatiles. Moreover, 8- and 10-H(P)OD regulate sexual reproduction and mycotoxin formation in ascomycetes.[47,48] Indeed, the latter oxylipins were induced by *Fusarium* infection in the current study (Figure 5). Interestingly, the concept that oxylipins regulate mycotoxin formation is supported by the combined accumulation of the mycotoxin fumonisin B1 and octan-3-one.[49] Similarly, levels of thrichodiene, which is a known volatile precursor of thricothecenes in *F. graminearum*,[50] were correlated with DON concentrations (Supporting Information Figure S5), again indicating a fungal origin.

In summary, the volatile markers identified here might be used to discriminate healthy from *Fusarium*-infected corn ears. Unlike most existing techniques for detecting fungal infection in plants, volatile detection is nondestructive. If combined with the right technology, the markers identified in this study might be used for the management of corn fields and postharvest facilities.

Author Contributions

P.K. wrote the proposal and secured funding. E.-M.B., R.S., and P.K. drafted the manuscript with input from all other coauthors. E.-M.B. handled all fungal and plant material, preformed corn ear infections, and monitored disease severity. E.-M.B., with guidance from R.S., carried out volatiles sampling by SPME, by OLS-GC/MS, zealexins extraction and quantitation and data analysis. E.-M.B., with guidance from P.K., extracted DNA for fungal biomass quantitation by RT-PCR, RNA for gene expression analysis, and mycotoxins for quantitation by HPLC-MS. E.-M.B., S.I., and T.K. analyzed the gene expression of *tps6/11*. I.F. and C.H. quantitied oxylipins. E.-M.B. analyzed and processed all data. E.-M.B. and R.S. performed the statistics.

Funding

Funding for part of this research was provided by the German Federal Ministry of Education and Research (BMBF) within the framework of the project MykoSensExpert.

Notes

The authors declare the following competing financial interest(s): EMB, RS and PK have applied for a patent describing the use of the volatile markers discovered in this study for identifying fungal infection in maize (patent application, University of Goettingen, Germany, DE 101012204237.7). The other author(s) declare that they have no competing interests.

■ ACKNOWLEDGMENTS

Katharina Döll and Philip Kössler are gratefully acknowledged for running the mycotoxin analysis on the HPLC-MS. We are thankful to J. Schirawski (RWTH Aachen University, Germany) for providing the seeds of dwarf-corn, to A. Prodi (University of Bologna, Italy) for *Fusarium* strain FV2, and to T. Miedaner (University of Hohenheim, Germany) for *Fusarium* strain FG1.

focused on global gene expression profiling with Affymetrix GeneChip Yeast Genome 2.0 arrays. To be able to correlate PYR-triggered transcriptional responses with the yeast outcome at the phenotypic level, we first examined the fungicide concentration-dependent effects on the growth of a yeast population. Then, gene expression profiles representing the yeast global response to two exposure conditions eliciting sublethal effects of increasing magnitude from 20% to 50% inhibition of growth rate were examined. Molecular indicators of PYR toxicity were identified in the yeast, and insights into mechanisms involved in response to PYR inhibitory effects revealed from the microarray data are discussed in the context of their potential relevance for wine yeasts and other relevant eukaryotes, particularly when PYR is misused or applied under extreme agricultural practices.

MATERIALS AND METHODS

Yeast Strain, Culture Conditions, and Growth Experiments with Pyrimethanil (PYR). *Saccharomyces cerevisiae* strain BY4741 (Mat*a, his3Δ1, leu2Δ0, met15Δ0, ura3Δ0*) (Euroscarf collection) was batch-cultured at 30 °C with orbital agitation (250 rpm) in MMB basal medium (pH 6.5) that contained, per liter: 1.7 g of Yeast Nitrogen Base without amino acids or NH_4^+ (Difco Laboratories, Detroit, MI, US), 20 g of glucose, 2.65 g of $(NH_4)_2SO_4$ (both from Merck, Darmstadt, GE), 20 mg of histidine, 20 mg of methionine, 60 mg of leucine, 20 mg of uracil (all from Sigma, SP).[22] Pyrimethanil (Pestanal) was purchased from Sigma-Aldrich (Seelze, GE). Examination of its effects in the yeast growth curve was carried out as described elsewhere.[22] Briefly, standardized exponential yeast cultures grown in MMB medium, with optical density at 640 nm (OD_{640nm}) equal to 0.25 ± 0.05, were supplemented with adequate volumes of a stock solution of PYR (55000 mg/L, in dimethyl sulfoxide) to obtain fungicide concentrations up to 150 mg/L (slightly above the aqueous solubility limit of 121 mg/L, 20 °C). Final dimethyl sulfoxide in all cultures including control (CT) without added PYR was equal to 0.2% (v/v).[22] Cell suspensions were immediately incubated at 30 °C with orbital agitation (250 rpm), and yeast growth was monitored by measuring over-time culture OD_{640nm}. The culture specific growth rate and the percentage of inhibition of growth rate by PYR were estimated as described elsewhere.[22] At least three independent growth experiments were carried out for each test concentration.

Exposure Experiments and RNA Preparation. Exponential yeast cell suspensions in MMB medium (OD_{640nm} = 0.25 ± 0.05) were supplemented with 10, 20, or 110 mg/L of PYR, or nonsupplemented with the fungicide (CT cells), as described above (the latter three for DNA microarray analysis, and all four for qRT-PCR analysis). After a 2 h incubation period at 30 °C and 250 rpm, cells were harvested by centrifugation (10000 rpm, 5 min, 4 °C), immediately frozen in liquid nitrogen, and stored at −80 °C. Total RNA isolation (hot-phenol method) and further examination of RNA concentration, purity, and integrity were performed as described before.[22]

DNA Microarray Analysis. Independent biological triplicates for each exposure condition (indicated above) and CT cells were processed and analyzed. For each biological replicate, 100 ng of total RNA was processed for use on Affymetrix GeneChip Yeast Genome 2.0 Arrays (Santa Clara, CA, US), according to the manufacturer's GeneChip 3′ IVT Express kit user manual. Further details on RNA processing and on array hybridization, washes, and double-stain protocols (FS450_0003; GeneChip HWS kit, Affymetrix) performed on an Affymetrix GeneChip Fluidics Station 450 are described elsewhere.[22] Arrays were scanned on an Affymetrix GeneChip scanner 3000 7G. Analysis of the nine scanned arrays for quality control and Absent/Present calls using Affymetrix Expression Console software, and with DNA-Chip Analyzer (dChip 2010; Wong Lab, Stanford, CA, US), for normalization and gene expression calculations, were performed as described elsewhere.[22] Genes were considered as differentially expressed if the 90% lower confidence bound of the fold change (hereafter designated as lbFC) between the PYR treatments and the baseline (for CT cells) was above 1.2, with a median false discovery rate (FDR) <5%, as described before.[22] Microarray data are deposited in the Gene Expression Omnibus (GEO) repository under accession number GSE53126.

Interpretation of Gene Expression Profiles. Annotations for the 5716 *S. cerevisiae* transcripts represented on the DNA microarrays were obtained from Affymetrix.[25] Functional description of the genes is also available in *Saccharomyces* Genome Database (SGD)[26] and in MIPS Functional Catalogue Database (FunCatDB).[27] Functional clustering of the differentially expressed genes in the microarray data sets was performed using the hypergeometric-distribution-based FunSpec bioinformatics tool[28] and the hierarchically structured Functional Distribution of Gene Lists tool of the MIPS FunCatDB.[27] Similar results were obtained with both tools unless otherwise indicated. Enrichment of a functional category, compared with gene frequency in the entire yeast genome, was considered whenever the respective p value was <0.01. Search for proteins of diverse fungi and higher eukaryotes with potential sequence homology to yeast proteins encoded by genes differentially expressed in response to PYR was performed in the National Center for Biotechnology Information database using the BLASTP algorithm, as described elsewhere.[22]

Real-Time Quantitative Reverse Transcriptase PCR (qRT-PCR). To confirm microarray data and potential indicators of PYR toxicity in the yeast, modifications in the transcript levels of selected genes upon PYR exposure were assessed based on the two-step SYBRGreen I dye assay in a 7500 Real-Time PCR system (Applied Biosystems, Carlsbad, CA, US) as described elsewhere.[22] Briefly, specific primers for the selected genes were designed using Primer Express Software, and primer sequences are available in Table S1 in the Supporting Information. Independent biological triplicates for each PYR exposure condition and CT cells were processed and analyzed (indicated above). Treatment of total RNA samples with TURBO DNA-free Kit (Ambion, Life technologies Europe BV, Porto, P), spectrophotometric assessment of purity and quantity, and further processing of samples, including reverse transcription (using Applied Biosystem's TaqMan Reverse Transcription reagents kit), PCR steps (using Life Technologie's Power SYBRGreen PCR Master Mix), and control assays, were carried out as described elsewhere.[22] Relative quantification of fold changes (FC) in gene transcription was performed by the $\Delta\Delta C_T$ method according to the Applied Biosystems Expression Analysis Technical Manual instructions. *ACT1* mRNA level was used as internal control. Normalized FC values are relative to CT cells (set as 1). Data reported are average values of at least three gene expression determinations from the independent triplicates. Statistical analysis of FC values to identify differences in relation to CT and between exposure treatments was based on one-way analysis of variance (ANOVA), followed by the post hoc Tukey honest significant difference multiple comparison test for unequal sample size, using Statistica 7.0 software (StatSoft, Inc., Tulsa, OK, US).

RESULTS AND DISCUSSION

Effect of PYR on Yeast Growth. Exposure of a yeast growing population to PYR concentrations equal or higher than 5 mg/L (up to 150 mg/L) affected its growth curve. For each fungicide concentration the yeast population continued exponential growth without a significant lag-phase lengthening, but the specific growth rate was reduced in a concentration-dependent manner (Figure 1, and data not shown). Based on these data, the PYR concentrations leading to 10%, 20%, and 50% inhibition of *S. cerevisiae* BY4741 growth rate (hereafter designated as IC10, IC20, and IC50, respectively) under the experimental conditions used were estimated approximately equal to 10, 20, and 110 mg/L, respectively (Figure 1).

Concentrations close to the lowest values herein found toxic for the yeast (e.g., between 5 and 10 mg/L) have been detected in must from grapes treated with PYR under extreme agricultural practices,[1,4,5] and were associated with alterations on the course and final outcome (e.g., aromatic composition,

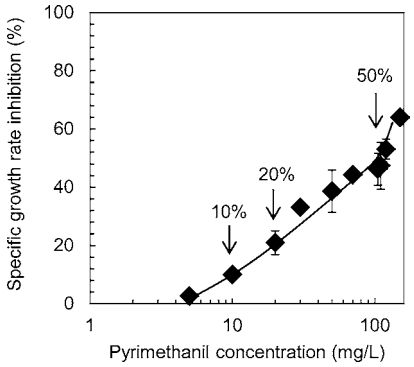

Figure 1. Effect of exposure of an exponentially growing population of *S. cerevisiae* BY4741 to increasing concentrations of pyrimethanil supplemented to the growth medium. The results, expressed as the percentage of inhibition of the yeast specific growth rate compared with control growth in fungicide absence, are means ± SD.

volatile acidity) of spontaneous and inoculated wine fermentations.[6,7] On the other hand, for example, the PYR IC20 value estimated is of an order of magnitude similar to that of the concentrations reported as cytotoxic toward the yeast antiandrogen test system (EC20 ~ 33 mg/L)[8] or inhibiting ATP production in human neuronal and glial cell lines (IC50 ~ 9 mg/L).[9] In the environmental context also, they are relatively close to or moderately higher than levels of concern reported for nontarget freshwater primary producers (e.g., chronic EC50 ~ 23.1 mg/L for *Scenedesmus acutus*, or chronic EC50 ~ 46.1 mg/L for *Lemna minor*)[15,16] or organisms in higher trophic levels (e.g., chronic EC50 = 1.18 mg/L or acute LC50 = 2.9 mg/L for *Daphnia magna*, and acute LC50 = 10.6 mg/L for fish).[16]

Since we intended to get relevant information on modifications that PYR might trigger on yeast transcriptome and that could be associated with its effects at a higher level of biological organization (e.g., growth inhibition), we chose 20 and 110 mg/L as test concentrations for the assessment of the global gene expression changes in the yeast in response to PYR challenge. The IC20 exposure condition would allow transcriptional insights associated with moderate phenotypic effects to be obtained without a substantial deterioration on cellular function, thus representing presumably a transient cellular response.[22,24] On the other hand, the IC50 was chosen to represent a higher challenge, thus eliciting a stronger and more informative transcriptional response in the yeast cells.[24]

Outline of PYR Transcriptional Response. Overall, a total of 1677 genes (about 28% of the yeast genome) showed significant changes in expression levels (777 upregulated; 900 downregulated) following yeast exposure to both PYR concentrations considered altogether, compared with CT cells not challenged with the fungicide (Figure 2A). The genes found differentially expressed in the IC50-stressed cells (~72% of the total) were considerably more in number (3.3-fold) than those in the IC20-exposed cells (Figure 2A, and Table S2 in the Supporting Information), and this increment was slightly above the one in growth inhibition (2.5-fold). Most of the IC20-responsive genes (88% or 63% of up- or downregulated, respectively) were also present in the data set of genes differentially expressed by the IC50 of PYR (Figure 2A, Table S2 in the Supporting Information). In general, for the majority of these genes with expression modified in both exposure conditions, the lower-bound of fold change values (relative to CT cells) were lower in the IC20-challenged cells compared to the IC50 ones (Table 1, Tables S3 and S4 in the Supporting Information). This is consistent with the different stress intensity sensed by the yeast cells.[22,24] In all data sets, about 80% of the differentially expressed genes have known or inferred biological functions, the rest being uncharacterized open reading frames.

To interpret biological relevance of gene expression profiles in the PYR-stressed cells, functional clustering of the induced or repressed genes in the microarray data sets (complete lists in Tables S2, S3 and S4 of the Supporting Information) was analyzed for significance compared to the entire yeast genome. The main functional categories significantly enriched ($p < 0.01$) with genes differentially expressed by both the IC20 and the IC50 of PYR (186 upregulated; 167 downregulated) (Figure 2A) were in general coincident with those found when the complete IC20 data set was analyzed, and they are summarized in Figure 2B. Significantly, besides these over-represented functional categories common to the IC20 and IC50 exposures (Figure 2B), a number of additional ones were involved in the response to the IC50 only (Figure 2C, Table S5 in the Supporting Information), and this difference was far more notable for the data sets of repressed genes (Table S5 in the Supporting Information). Overall, results thus suggest that there were clearly higher numbers and diversity of over-represented functional categories in the yeast in response to the IC50 compared to the IC20, which may be associated with the stronger deleterious effect of the fungicide at the phenotypic level.

Effects of PYR on Metabolism Related Genes. From functional clustering analysis of microarray data sets, it became evident that a core transcriptional response elicited by both concentrations of PYR involved upregulation of genes related to amino acid metabolism, mostly focused on biosynthesis of arginine (~5.6% or 1.4% of the IC20 or IC50 complete data sets, respectively) and metabolism of the sulfur amino acids methionine, cysteine, and the nonprotein one homocysteine (overall, ~3.8 or 1.8%, respectively) (Figure 2 and Table S5A in the Supporting Information). A particularly relevant finding seems the increased expression of the whole set of genes assigned to biosynthesis of arginine (from *ARG1* to *ARG11*, and *CPA1/CPA2*) in the microarray data (Table 1). Significantly, the modifications in transcription of these genes were confirmed by qRT-PCR measurements in cells subjected to increasing growth-inhibitory concentrations of PYR in independent exposure experiments (Figure 3A). Concretely, this set of PYR-responsive genes comprised the four involved in the biosynthesis of ornithine (a precursor of arginine biosynthesis) from glutamate in the mitochondrion, *ARG11* (also named *ORT1*) encoding the mitochondrial inner membrane that exports ornithine into the cytosol, the three genes involved in the interconversion of ornithine, citrulline and arginine in the cytosol (known as urea cycle), and *CPA1* and *CPA2* that encode the two subunits of the cytosolic carbamoyl-phosphate synthase catalyzing formation of carbamoyl-phosphate (precursor of citrulline) from glutamine[29] (Figure 4). These data suggest that the fungicide may somehow affect arginine and ornithine metabolism and/or their cellular compartmentation[29] in the yeast. It seems less likely that the reported increases in transcription of *ARG* and *CPA* genes might be associated with a situation of amino acid limitation or imbalance[30] due to lowering in metabolism rate in the PYR-stressed cells; indeed, microarray data did not support such an all-inclusive transcriptional modification in any other of the amino acid metabolism categories also enriched with PYR-induced genes

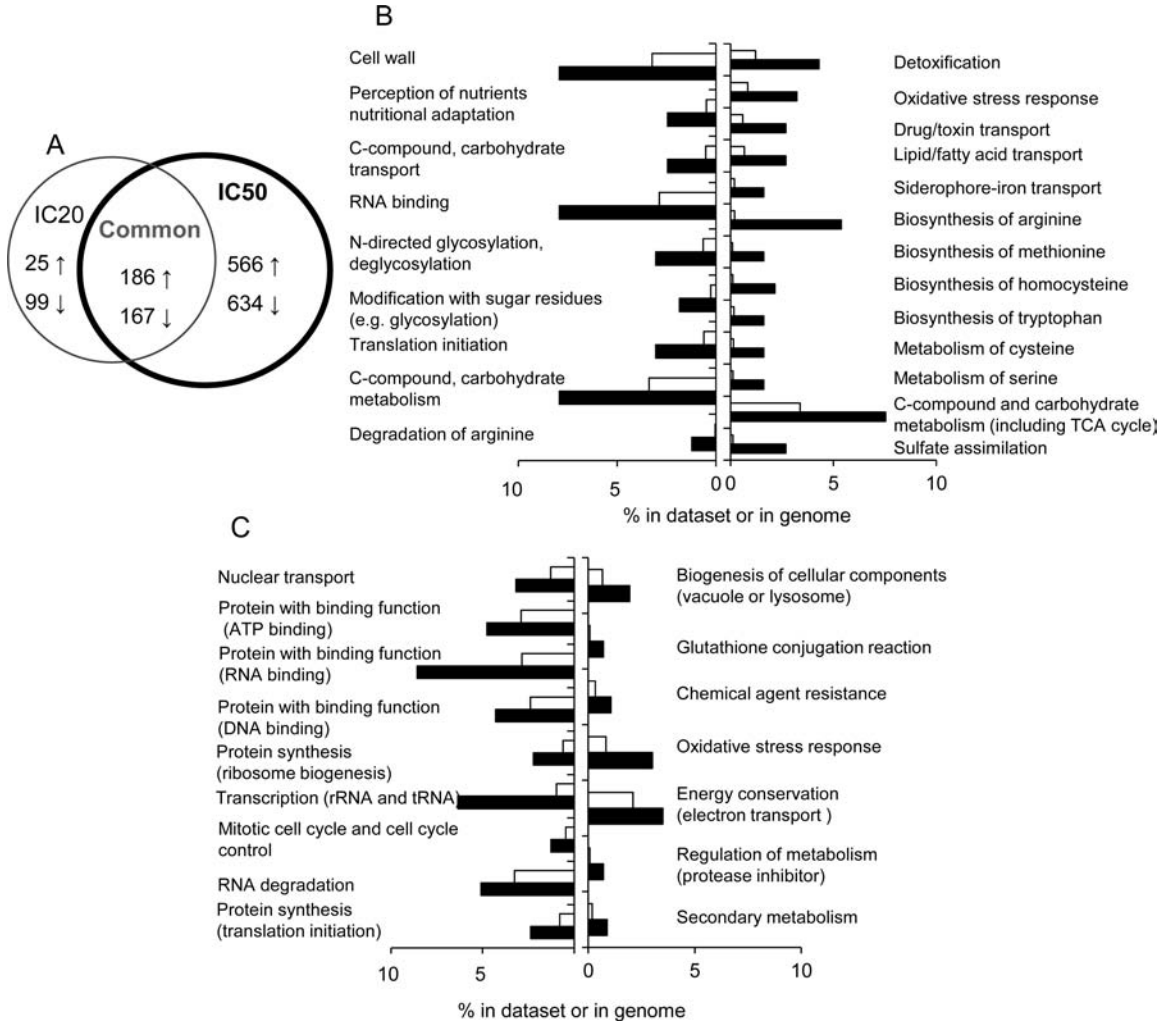

Figure 2. Categorization of gene expression profiles in *S. cerevisiae* BY4741 cells upon 2 h exposure to the 20%-inhibitory (IC20; 20 mg/L) and/or the 50%-inhibitory concentrations (IC50; 110 mg/L) of pyrimethanil. (A) Venn diagrams illustrate the distribution and overlap of the data sets of genes differentially expressed (↑ = induced; ↓ = repressed) on exposure to the IC20 or the IC50 of pyrimethanil compared with its absence. (B, C) Functional clustering of the genes with expression increased (right panel) or decreased (left panel) (B) by both PYR concentrations (IC20 and IC50 common), or (C) uniquely by the IC50. Only the classes found to be statistically over-represented in each data set (black) compared with the frequency in the yeast genome (white) ($p < 0.01$) are represented.

(namely, biosynthesis of sulfur amino acids, of serine, or of tryptophan), but on the contrary only a few genes of these pathways were in general affected (Table 1, and Table S5 in the Supporting Information). Besides, none of the genes encoding regulators (e.g., *GCN* or *GCD*) of the general amino acid control system[30] were found induced in the microarray data sets (Tables S3 and S4 in the Supporting Information); this system coregulates yeast transcription of arginine's and at least 11 other amino acid biosynthesis pathways in response to amino acid limitation.[30] Additionally, the fact that transcription of *CAR1* (encodes arginase; Figure 4) was not significantly modified, as confirmed by qRT-PCR (Figure 3A), and *CAR2* (mediates further ornithine catabolism; Figure 4) was repressed (Table 1 and Figure 3A) suggests that PYR-stressed cells may have sufficient levels of nitrogen source available for their physiological needs.[29,30] Based in the herein reported transcriptional evidence, we propose that this response may reflect a novel aspect of PYR mode of action in the yeast. To the best of our knowledge, the mode of action of PYR was not assigned before to arginine or ornithine metabolism either in yeast or in target phytopathogenic fungi.[10,12] But, in a transcriptional profile analysis upon exposure to the closely related structural analogue cyprodinil, *S. cerevisiae*'s *ARG1*, *ARG3*, *ARG5,6*, and *ARG8* were also reported to be upregulated.[23]

Most of the proteins encoded by these arginine metabolism genes were found to share significant amino acid sequence homology and conserved function with proteins of *B. cinerea*[10] and *Penicillium digitatum*,[12] and (except for Arg7p, Arg2p, and Arg5,6p) of species representative of nontarget higher eukaryotes that might be exposed to PYR residues via contaminated foodstuffs[4,9] or in the environment[8,14−16] (Figure 5, and data not shown). Arginine and its associated metabolites (e.g., citrulline and ornithine) are known to have important biological roles, as precursors of proteins, polyamines, and nitric oxide, in fungi,[31,32] plants,[33] mammals,[34] and fish,[35] and have been associated with freeze tolerance in the yeast[36] and oxidative stress response in diverse eukaryotes.[31,33,34] Imbalance in arginine metabolism and/or availability can have repercussions on dysfunction/disease states and affect early stages of development in mammals[34] or fish.[35] Yeast's *CAR2*, *ARG1*, *ARG3*, and *ORT1* are also homologues of human disease-related genes.[19,37] Further studies are thus required to clarify the mechanisms underlying PYR interference with yeast arginine gene transcription and to

Table 1. Selected Differentially Expressed Genes and Over-Represented Functional Categories on *S. cerevisiae* Transcriptome upon Cells' Exposure to the IC20 or the IC50 of Pyrimethanil

gene name[a]	function	lbFC[b] IC20	lbFC[b] IC50
	Biosynthesis of Arginine[c]		
ARG2	first step in biosynthesis of arginine precursor L-ornithine (mitochondrial)	1.3	1.4
ARG5,6	second and third steps in L-ornithine biosynthesis (mitochondrial)	2.8	3.3

ARG7	fifth step of arginine precursor L-ornithine biosynthesis (mitochondrial)	1.5	1.7
ARG11	ornithine transporter in the inner mitochondrial membrane	1.8	1.9
ARG3	ornithine carbamoyltransferase; sixth step in arginine biosynthesis	2.4	2.5
CPA1	small subunit of carbamoyl phosphate synthetase	1.6	1.8
CPA2	large subunit of carbamoyl phosphate synthetase	1.5	1.6
ARG1	argininosuccinate synthetase	1.4	1.4
ARG4	argininosuccinate lyase; final step in the arginine biosynthesis pathway	1.6	2.1
	Degradation of Arginine		
CAR1	arginase; first step of arginine degradation	−1.2	−1.9
CAR2	L-ornithine transaminase; second step of arginine degradation	−2.2	−2.2
	Metabolism of Sulfur Amino Acids (Methionine, Cysteine, Homocysteine)		
MET28	transcriptional activator in the regulation of sulfur metabolism	2.7	9.9
MET32	transcriptional regulation of the methionine biosynthetic genes	1.3	2.0
STR2	cystathionine gamma-synthase, converts cysteine into cystathionine	1.3	2.2
STR3	cystathionine beta-lyase, converts cystathionine into homocysteine	4.1	12.7
SAM4	*S*-adenosylmethionine-homocysteine methyltransferase	1.3	1.4
MHT1	*S*-methylmethionine-homocysteine methyltransferase	ne[d]	1.5
MET2	L-homoserine-*O*-acetyltransferase (methionine biosynthetic pathway)	1.5	2.6
ADI1	acireductone dioxygenease (methionine salvage pathway)	1.6	1.8
	Sulfate Assimilation		
MET16[e]	3′-phosphoadenylsulfate reductase (reduced thioredoxin as cosubstrate)	1.7	2.4
MET5[e]	sulfite reductase beta subunit	1.8	2.3
MET10[e]	assimilatory sulfite reductase alpha subunit	2.2	3.3
MET3	ATP sulfurylase (first step of intracellular sulfate activation)	ne	1.6
MET14	adenylylsulfate kinase	1.4	2.2
MET22	dephosphorylates intermediates of the sulfate assimilation pathway	1.3	1.6
	Energy Metabolism (Electron Transport; TCA Cycle; Fatty Acid β-Oxidation)		
CYB2	cytochrome b2 (L-lactate cytochrome-*c* oxidoreductase)	1.3	2.5
CIT2	citrate synthase (condensation of acetyl coenzyme A and oxaloacetate)	1.4	1.5
CIT3	dual specificity mitochondrial citrate and methylcitrate synthase	1.3	1.5
COX5B	subunit Vb of cytochrome *c* oxidase	1.2	1.5
COX12	subunit VIb of cytochrome *c* oxidase	ne	1.3
CRC1	mitochondrial inner membrane carnitine transporter	1.8	2.5
RSB1	putative integral membrane transporter or flippase of sphingoid LCB	7.2	46.2
RTA1	integral membrane protein (fungal lipid-translocation exporter family)	2.6	19.3
PDR16	phosphatidylinositol transfer protein controlled by the regulator Pdr1p	1.6	4.3
ICT1	lysophosphatidic acid acyltransferase	1.4	5.3
	Cell Rescue and Defense/Detoxification/Related to Pleiotropic Drug Resistance (PDR)		
SNQ2[f]	plasma membrane ATP-binding cassette (ABC) transporter	1.8	4.3
PDR5[f]	plasma membrane ABC transporter; regulated by Pdr1p and Pdr3p	1.5	2.4
PDR10[f]	plasma membrane ABC transporter; regulated by Pdr1p and Pdr3p	ne	2.9
PDR15[f]	plasma membrane ABC transporter; regulated by Pdr1p, Pdr3p, Pdr8p	ne	9.6
YLR346c	regulation by transcription factors involved in PDR	2.2	34.6
PDR1	zinc cluster protein regulator of the PDR network	ne	1.3
PDR3	transcriptional activator of the PDR network	ne	4.8
YOR1[f]	plasma membrane ABC transporter	1.2	4.3
AZR1	plasma membrane transporter of the major facilitator superfamily	1.2	6.1
	Cell Rescue and Defense/Oxidative Stress Response		
GRE2	NADPH-dependent methylglyoxal reductase; general stress response	1.5	8.2
POS5	mitochondrial NADH kinase	1.4	1.9
MXR1	methionine-*S*-sulfoxide reductase; protects iron−sulfur clusters	1.7	2.1
MXR2	methionine-*R*-sulfoxide reductase; protects iron−sulfur clusters	ne	1.4
HMX1	heme-binding peroxidase, endoplasmic reticulum localized	ne	1.8
GPX2	membrane-located phospholipid hydroperoxide glutathione peroxidase	ne	1.7
TSA2	stress inducible cytoplasmic thioredoxin-dependent peroxidase	ne	2.2
PRX1	mitochondrial peroxiredoxin with thioredoxin peroxidase activity	ne	1.7
DOT5	nuclear thiol peroxidase	ne	1.3
TRX2	cytoplasmic thioredoxin isoenzyme; part of thioredoxin system	ne	1.4
TRX3	mitochondrial thioredoxin	ne	1.6
	Detoxification by Modification/Glutathione Conjugation Reaction		
GTO2[g]	omega class glutathione transferase	ne	2.3
GTT1[g]	endoplasmic reticulum associated glutathione *S*-transferase	ne	1.9
GTT2[g]	glutathione *S*-transferase	ne	1.3
GRX1[g]	glutathione-dependent disulfide oxidoreductase	ne	1.6
GRX2[g]	glutaredoxin; involved in maintaining redox state of target proteins	ne	1.5
	Cell Rescue and Defense/Others		
HSP12	plasma membrane localized 12 kDa heat shock protein	1.5	10.6
HSP26	small heat shock protein with chaperone activity	1.6	6.1
HSP31	possible chaperone and cysteine protease	1.6	2.5
HSP32	possible chaperone and cysteine protease	1.4	2.6
YGP1	cell wall-related secretory glycoprotein; induced by nutrient deprivation	1.9	3.8

Table 1. continued

gene name[a]	function	lbFC[b] IC20	lbFC[b] IC50
	Miscellaneous/Related to Volatile Acid Production		
AAD10	aryl-alcohol dehydrogenase (degradation of aromatic compounds)	1.8	1.7
PLB2	lysophospholipase B involved in phospholipid metabolism	−1.2	−1.5
EEB1	acyl-coenzymeA:ethanol *O*-acyltransferase	−1.7	−2.0
ATF2	alcohol acetyltransferase; forms volatile esters during fermentation	−1.8	−1.8
ALD4	mitochondrial aldehyde dehydrogenase	−1.5	−1.3
ALD6	cytosolic aldehyde dehydrogenase	−1.4	−1.2
ADH5	alcohol dehydrogenase isoenzyme V	1.3	1.6
PHD1	transcriptional activator (metabolic regulation; pseudohyphal growth)	−1.4	−1.4
SOK2	nuclear protein (negatively regulates pseudohyphal differentiation)	ne	1.3
STE12	transcription factor (mitogen-activated protein kinase signaling cascade)	−1.3	−1.7

[a]Genes belong to the indicated functional categories statistically over-represented ($p < 0.01$), unless they are included in the miscellaneous group. Genes underlined were selected for further examination of transcriptional changes by qRT-PCR. [b]Lower bound of fold change (lbFC) of transcript levels of the selected genes in microarray data sets following exposure to pyrimethanil IC20 or IC50 compared to CT cells not exposed to the fungicide. [c]Subheadings in the table represent categories. [d]Not significantly differentially expressed in microarray experiments. [e]Also in categories methionine and homocysteine metabolism. [f]Also in category drug/toxin transport. [g]Also in category oxidative stress response.

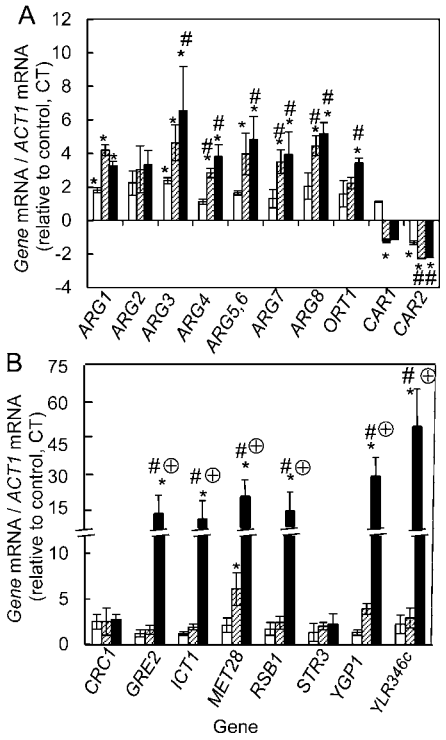

Figure 3. Normalized gene expression modification profiles obtained by qRT-PCR for the indicated genes selected as PYR-responsive from microarray data sets. Relative values of gene mRNA/*ACT1* mRNA were determined for (A) the genes involved in arginine metabolism and (B) genes involved in other functions, in *S. cerevisiae* BY4741 cells exposed during 2 h to pyrimethanil concentrations that exerted 10% (white), 20% (hashmarks), or 50% (black) growth inhibition, compared to control (CT) cells incubated in fungicide absence. Results are expressed as means ± SD; *, #, and ⊕ indicate mean statistically different ($p < 0.05$) from CT cells and from the ones exposed to the 10%- and the 20%-inhibitory concentrations, respectively.

elucidate the actual role of arginine pathway and metabolites in the ambit of PYR mode of action in yeast, mycelial fungi, and other relevant eukaryotes.

After PYR exposure, the genes encoding Str2p and Str3p (cystathionine γ-synthase and cystathionine β-lyase, respectively) (Figure 4) were also upregulated (Table 1, Figure 3B); they catalyze conversion of cysteine into homocysteine via the trans-sulfuration pathway.[38] Homocysteine is an essential intermediate in the biosynthesis of methionine and *S*-adenosyl methionine (AdoMet), the end-product of the sulfur amino acid biosynthesis pathway in diverse organisms.[38,39] A related gene also significantly upregulated in the microarray data and confirmed by qRT-PCR was *MET28* (Table 1, Figure 3B); it encodes a positive regulator of *MET* genes when endogenous AdoMet is low.[38] In addition, genes encoding Sam4p and Mht1p (reported to play major roles in AdoMet recycling and maintenance of equilibrium between its levels and methionine),[39] Met32p (regulator of sulfur amino acid metabolism in combination with Met28p),[38] Met2p (catalyzes the first step of methionine biosynthetic pathway),[38] and several genes of the sulfur assimilation pathway[38] were induced by PYR (Table 1, Figure 4). Proteins were found in phytopathogenic fungi that share homology with yeast Str2p, Str3p, and Sam4p, but not with Met28p (Figure 5, and data not shown). The increased expression of *STR2*, *STR3*, *SAM4*, *MET28*, and *MET32* is consistent with the idea that PYR may affect homocysteine and methionine metabolism in the yeast cells. This insight seems particularly interesting in the context of PYR mode of action because it is still not clear whether methionine metabolism and cystathionine β-lyase or cystathionine γ-synthase are anilinopyrimidine primary targets in *B. cinerea* and other phytopathogenic fungi.[10,12]

In the yeast and other eukaryotes, major consumption of AdoMet is as a methyl donor in the synthesis of major macromolecules and of essential metabolites such as polyamines.[32,34,38] A link appears to exist also between arginine metabolism and polyamine biosynthesis via the common intermediate metabolite ornithine[32,34] (Figure 4). However, we detected no induction of the genes involved in the polyamine biosynthesis pathway (e.g., from *SPE1* to *SPE4*)[32] (Figure 4), and the ones encoding the Spe1p regulators *OAZ1* and *MEU1*[32] were differentially expressed in opposite directions in the PYR-challenged cells (Tables S3 and S4, in the Supporting Information). Nevertheless, we speculate that the transcriptional alterations triggered by PYR in the genes of arginine, methionine, and homocysteine pathways (Figure 4) would allow intracellular arginine, ornithine, and/or AdoMet to be kept at appropriate levels for their essential cellular roles in the stressed cells, including for instance formation of polyamines and macromolecule turnover.[31−34,38,39] For example, spermine is a precursor of coenzyme-A via β-alanine and pantothenate (Figure 4), and three genes (*FMS1*, *CAB1*, and *CAB2*) encoding enzymes of this pathway were also induced by PYR (Tables S3 and S4, in the Supporting Information). It is worth noting that polyamines have been proposed as biomarkers of insecticide effects related to embryonic malformation in tadpoles and frogs.[40] A protective role of AdoMet against acid stress in the yeast was also reported.[41]

dx.doi.org/10.1021/jf5007775 | J. Agric. Food Chem. 2014, 62, 5237−5247

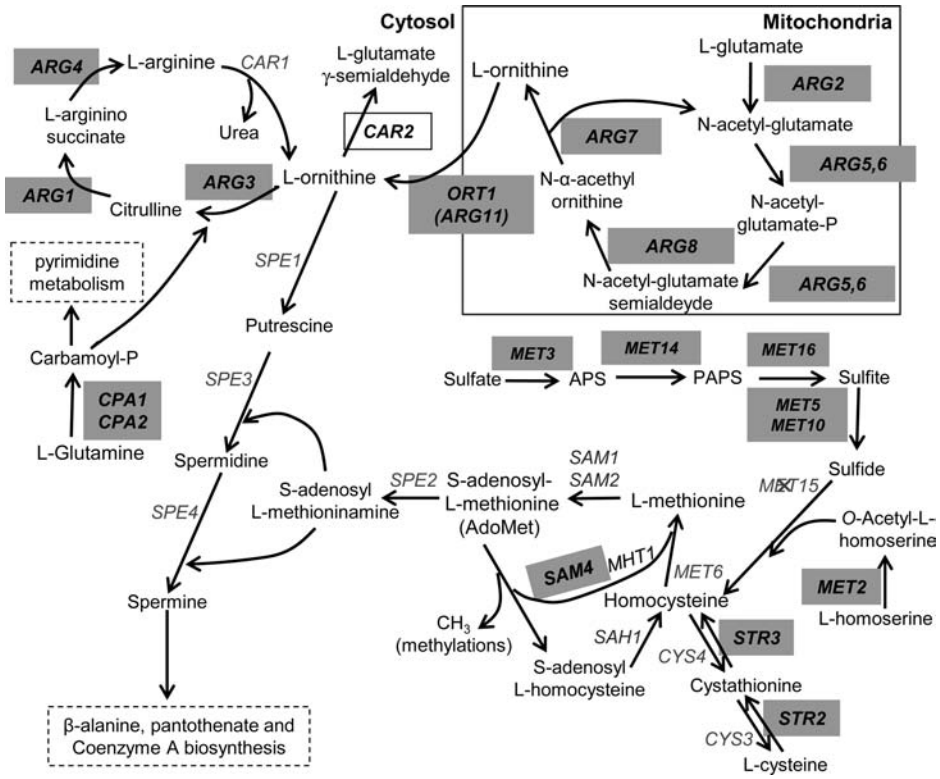

Figure 4. Biochemical steps and corresponding genes involved in the pathways of L-arginine/L-ornithine biosynthesis, sulfur amino acid metabolism, and polyamine biosynthesis in *S. cerevisiae* (adapted from published literature[29,32,38,39] and from the "arginine biosynthesis pathway", the "methionine salvage pathway", and the "polyamine pathway" in SGD[26]). The genes induced (gray box) or repressed (white box) as a result of cells' exposure to the IC20 and the IC50 of pyrimethanil are indicated. APS = 5′-adenylylsulfate; PAPS = 3′-phospho-5′-adenylylsulfate; × means gene eliminated in the auxotrophic strain BY4741.

Effects on Genes Related to Volatile Acid Production. A number of yeast genes that are relevant in the context of production of volatile aroma impact compounds during alcoholic fermentation[42−44] were also transcriptionally modified by PYR. They were, concretely, *AAD10* (overexpression in wine *S. cerevisiae* strains influence levels of propionic, valeric, hexanoic, and decanoic acids, ethyl caprylate, isobutanol, and 2-phenyl ethanol, in the end of fermentation);[42] *PLB2* (a determinant of octanoic and decanoic acid and ethyl ester production);[44] *EEB1* (key gene in synthesis of medium-chain fatty acid ethyl esters and respective acids);[42,44] *ATF2*, *ALD4*, and *ALD6* (expression levels influence formation of diverse volatile aroma impact products);[42] and *STE12*, *PHD1*, *YAP6*, and *SOK2* (encode transcriptional factors that showed variable expression patterns in different industrial wine yeast strains that produce diverse aroma profiles)[43] (more detail in Table 1). The whole picture of the specific roles of these yeast genes is not fully characterized, and it is well-known that laboratory and industrial yeast strains are highly diverse in this respect.[42−44] However, these results point to potential interference of PYR in the network of pathways that influence the patterns of volatile aroma compounds during alcoholic fermentation (e.g., fatty acid and amino acid metabolism, lipid and sterol biosynthesis) in the yeast,[42−44] thus possibly imparting variable organoleptic properties and influencing the quality of the final wine, at least in worst-case situations associated with fungicide misuse.[4,6,7]

Alterations on Genes Related to Stress Response. As expectable for transcriptional responses initiated in response to growing chemical challenges in the yeast,[18,22,24] a significant number of gene expression alterations related to cell rescue, defense, and detoxification increased considerably in cells exposed to the IC50 of PYR compared with the IC20s (Table 1, and Table S5 in the Supporting Information). It may correspond to enhanced requirements for reprogramming gene expression in order to maintain cellular homeostasis under sublethal PYR stress before more detrimental effects and cell deterioration may be activated.[22,24] Among them, a number of genes within the over-represented categories RNA degradation, transcription, ribosome biogenesis, translation initiation, protein synthesis, and mitotic cell cycle control were repressed (Figure 2C, and Table S5 in the Supporting Information). This type of transcriptional response is considered to help the cell to safeguard energy while adapting to the new challenging conditions.[24] Consistently, the number of upregulated genes in over-represented categories related to TCA cycle and membrane-associated electron transport/energy conservation increased from the IC20 to the IC50 PYR-stressed cells (Figure 2, Table 1, and Table S5 in the Supporting Information). They may contribute to provide energy for the function of ATP-depleting processes presumably involved in cells' protection against stress (e.g., drug transport, iron homeostasis/siderophore-iron transport, detoxification).[22,24] In the context of potential energy expenses in the PYR-stressed cells, it seems relevant that activity of the "ornithine carbamoyltransferase-carbamoyl phosphate synthetase couple"[29] encoded by the upregulated *ARG3*, *CPA1*, and *CPA2* genes (Figure 4) is an important ATP consumer in eukaryotic cells,[29] as are the presumably PYR-affected AdoMet synthesis and sulfate assimilation pathways (Figure 4) in the yeast.[38,39] Other major consumers of cellular energy include putative multidrug/pleiotropic active transmembrane transporters[45,46] encoded by

dx.doi.org/10.1021/jf5007775 | J. Agric. Food Chem. 2014, 62, 5237−5247

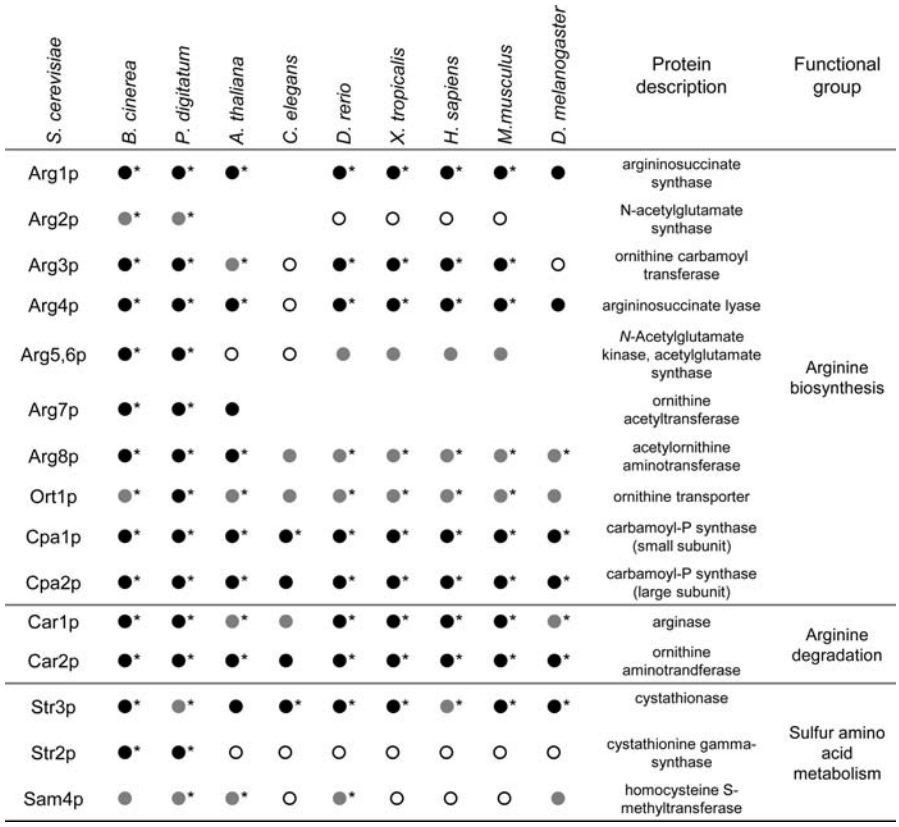

Figure 5. Homology between yeast proteins encoded by selected pyrimethanil-responsive genes and proteins from the phytopathogenic fungi *Botrytis cynerea* and *Penicillium digitatum* and from higher eukaryotes that are representative of ecologically relevant organisms (namely, *Arabidopsis thaliana*, *Caenorhabditis elegans*, *Danio rerio*, *Drosophila melanogaster*, *Homo sapiens*, *Mus musculus*, and *Xenopus tropicalis*). Symbols provide information on the best similarity hit of each query protein, as follows: (black) score ≥ 200 bits and identity ≥ 40%; (gray) 90 ≤ score < 200 bits and 22% ≤ identity < 40%; (white) 35 ≤ score < 90 bits and/or 20% ≤ identity < 22%; (empty space) homologue absent. On the right side, the description of the conserved gene product indicated with an * is shown, as well as the respective functional group.

genes also induced due to PYR stress and enriched in the over-represented functional category "detoxification" (detailed in Table 1). In addition, *RSB1* and the closely related *RTA1*[47] were also strongly induced because of PYR exposure (Table 1, Figure 3B). Their encoded transmembrane proteins may play roles in hampering accumulation of aberrant metabolites and presumably also of xenobiotics in the cytoplasm.[47] These gene expression modifications suggest a possible contribution of export of the intact and/or the biotransformed fungicide molecule from the cytosol among the PYR detoxification processes, as proposed for other xenobiotics.[20,45,46] It is worth noting that five genes encoding enzymes that can act as glutathione-*S*-transferases in the yeast (e.g., *GTT1*, *GTT2*, *GTO2*, *GRX1*, *GRX2*),[48] with presumable roles in xenobiotic detoxification,[18,20,48] were also among the PYR-responsive genes (Table 1). As far as we are aware, there is no report of conjugation reactions of PYR in the yeast. In rats, evidence of biotransformation of the structurally analogue cyprodinil that culminated in formation and excretion of sulfate-conjugated metabolites, were reported.[49] A high level of functional conservation exist within multidrug resistance mechanisms among eukaryotes.[21,45,46] The actual role of multidrug resistance in response of field strains of phytopathogenic fungi to PYR and other fungicides is of utmost importance.[10−12]

Also significantly over-represented in the transcriptome of PYR stressed cells were several upregulated genes that encode cytosolic and/or mitochondrial glutathione (GSH)-dependent glutaredoxins and thioredoxins, thioredoxin-dependent methionine-*S*-sulfoxide reductases, thioredoxin- or GSH-dependent peroxidases, in different locations, and a number of glutathione-*S*-transferases with dual roles (Figure 2; more detail in Table 1). They are known to have critical roles in defense against oxidative stress and regulation of the redox state of protein sulfydryl groups that is essential for many cell functions.[48] It is worth noting that genes encoding enzymes more typically specialized in reactive oxygen species (ROS) detoxification, like superoxide dismutases, catalases, or other peroxidases,[18,24,48] were apparently not induced following PYR exposure (Tables S3 and S4 in the Supporting Information). However, possible increases by PYR of ROS flux cannot be ruled out, associated for instance with electron flow disruption, as proposed with respect to PYR detrimental effects on ATP yield in neuronal cell lines (presumably linked with neurotoxicity)[9] or on chlorophyll production and photosynthesis in the aquatic primary producer *Lemna minor*.[15] Given the type of antioxidant response genes herein detected (Table 1), which encode enzymes where GSH is the major redox donor,[48] we hypothesize PYR-stressed cells possibly experiencing enhanced endogenous GSH depletion. It might for instance be due to modulation of the redox state of protein sulfur amino acids, because methionine and cysteine are major targets for protein oxidation,[48] and/or with GSH-dependent conjugation reactions of PYR molecule mediated by glutathione-*S*-transferases (Table 1) in xenobiotic detoxification.[48] Other genes that may be relevant in the context of cell response and adaptation to PYR stress were strongly induced, like those encoding the cytosolic Gre2p (Table 1, Figure 3B) and the heat-shock

proteins with chaperone activity (*HSP26*, *HSP31*) or involved in maintenance of membrane organization under stress conditions (*HSP12*) (Table 1). These genes, but not *HSP31*, were also induced in *S. cerevisiae* on exposure to the anilinopyrimidine cyprodinil,[23] and are typically associated with general stress response in the yeast.[24]

This analysis of potential effects of PYR in the yeast is restricted to transcriptional response, and further information on post-transcriptional and translational control of the gene products and on physiological performance is necessary to gain a complete picture. Nevertheless, the transcriptional modifications discussed above allowed novel questions to be raised over PYR mode of action, for instance whether the arginine pathway may be a specific target, whether PYR may act as pro-oxidant, whether interplay may exist between arginine, polyamines, methionine, and AdoMet metabolism and antioxidant defense[31−34,38] and PYR may interfere on it, or what yeast processes influencing volatile aroma product formation during wine fermentations may be impacted by PYR residues. These insights deserve further in-depth studies in relevant wine yeast strains and phytopathogenic fungi to gain better understanding of PYR action, with possible repercussions on control of fungicide resistance in target fungi[10−12] and in enology.[4,6,42−44] In this respect, it is noteworthy that, besides PYR,[4,6,7] other new fungicides that may be used alone or together with anilinopyrimidine fungicides to treat vineyards, and whose residues can persist in grapes, have been reported to alter wine yeast biosynthesis of volatile products that contribute to the wines' sensorial properties.[50,51] In the (eco)toxicological context, we are aware that there are differences in xenobiotic susceptibility across species and a discrepancy exists between the fungicide concentrations herein used and those usually found in aquatic compartments under regulatory agricultural practices (e.g., <22−90 μg/L in vineyards).[14−16] Despite that, we propose that the transcriptional insights gained in this work may contribute to assist planning of toxicological studies in nontarget and experimentally less accessible eukaryotes, to predict potential adverse side effects of bioavailable PYR, particularly with respect to irregular scenarios of fungicide misuse in agricultural fields[1,4−6] or accidental spills. For example, possible exposure of useful microbiota and/or higher eukaryotes from ecosystems to fungicide residues in contaminated soil, water, and sediments[14−16] in agricultural or adjacent regions, and/or of humans due to consumption of fruit, vegetable, and wine products[1,4,5,8,9] or occupational activities,[52] may be of toxicological concern.

Molecular Indicators of Toxicity. Several experimental advantages that contribute to lower costs and time in chemical toxicity testing have been attributed to yeast-based assays.[18,21,22] However, assays relying solely on phenotypic end points[21] often lack sensitivity and provide no mechanistic information. Therefore, we also examined the possible suitability of several PYR-responsive genes as indicators of toxicity in the yeast. Of the 20 genes selected for confirmation of transcription modification by PYR using qRT-PCR (Table S1 in the Supporting Information), five involved in the main affected metabolic pathways (e.g., *ARG3*, *ARG4*, *ARG5,6*, *ARG8*, and *MET28*) displayed consistent transcription variation profiles that correlated well with the concentration-dependent inhibition of yeast growth by the fungicide (Figure 3A,B). Moreover, for example, modifications in their expression between 4.0- and 6.1-fold (depending on the gene) compared with CT cells were detected in cells exposed to a PYR concentration that inhibited growth by only 20% (Figure 3). This suggests that measuring transcriptional changes of these genes is more sensitive than the phenotypic end point based on effects in yeast growth. Therefore, they could be interesting for instance to incorporate in yeast-based cellular reporters or biosensors for purposes of biomonitoring or preliminary screening of fungicide toxicity, in line with the 3Rs attempt to "reduce, refine, and replace" animal models in toxicity testing.[17,21]

Plant Material. Soybeans seeds (*Glycine max* (L.) Merr.) were supplied from the Botanical Garden in Lublin. The plants were germinated from seeds on wet filter paper in a thermostat-controlled chamber. After 7 days, the seedlings were transferred into Hoagland's nutrient solution for 3 days, and then the growth medium was removed. The composition of Hoagland's solution was modified by addition of Sr^{2+} ions to obtain appropriate concentrations (0.5, 1.0, 1.5, 2.0, 2.5, and 3.0 mM). Additionally, iron citrate was removed and $Mg(NO_3)_2{\cdot}6H_2O$ instead of $MgSO_4{\cdot}7H_2O$ was used in order to avoid precipitation of insoluble strontium salt.

Twenty plants for each concentration of Sr were grown in modified Hoagland's medium for another 14 days at a day/night cycle of 16/8 h and 24/17 °C, respectively, relative humidity 60−70%, and photosynthetic photon flux density of 150 μmol/m^2 s. The nutrient solution with Sr^{2+} ions was changed every 3 days. After harvest, the plants were separated into roots and shoots and accurately weighed. Some material was frozen in liquid nitrogen and stored at −80 °C prior to analysis of the content of chlorophylls and carotenoids.

Atomic Absorption Spectrometry (AAS) Procedure. Fresh roots were washed with deionized water three times to remove Sr^{2+}adsorbed on the surface. Five roots and two shoots were taken per replication. The plant material was dried at 80 °C to constant weight and pulverized. The shoots and roots were accurately weighed (0.5 and 0.3 g respectively) and mineralized in a microwave-assisted high-pressure digestion closed system (UniClever BM-1, 350 W, Plazmotronika, Poznań, Poland) with the use of a mixture containing 4 mL of 65% nitric acid and 10 mL of deionized water. The mineralization parameters were as follows: the power of the microwave generator at 60%, 80%, and 100% during 10, 15, and 20 min, respectively. The mineralizates were weighed. Sr^{2+} contents were determined by flame atomic absorption spectrometry (High-Resolution Continuum Source atomic absorption spectrometer ContrAA 700, Analytik Jena AG, Germany). A xenon lamp working in an optimized Hot-Spot-Mode and a CCD array detector (185−900 nm) with high quantum efficiency and increased UV-sensitivity were employed. The measurements were performed at λ = 460.733 nm, and the concentration range of strontium for the calibration curve was from 0 to 20 mg/L (n = 5). The validation parameters obtained were as follows: correlation coefficient R = 0.9999, the value of characteristic concentration for 1% of absorbance was 0.04513 mg/L, calibration equation $y = (-0.0001968 + 0.0580274)/(1 + 0.0201765x)$, and precision expressed as relative standard deviation (% RSD) 0.7−2.9%.

Chlorophyll and Carotenoid Analysis. Chlorophyll *a* (Chl*a*), chlorophyll *b* (Chl*b*), and carotenoids (Car) were extracted with 80% acetone, and their contents were spectrophotometrically determined (Shimadzu UV 160A) at λ = 663, λ = 646, and λ = 470 nm, respectively. The concentrations (mg/g) were calculated according to Wellburn.[25]

Statistical Analysis. Statistical analysis was conducted using the STATISTICA ver.10 (StatSoft, Inc., USA) program. Data was analyzed by ANOVA, and the significances of differences were examined using Fisher's LSD test. The statistical confidence was set at p = 0.05.

RESULTS AND DISCUSSION

Phytoextraction of metals is a common effect which may be used for phytoremediation of soil contaminated by toxic elements or radionuclides[26] or for biofortification with microelements, for instance essential for plant physiology.[27] Here we present the results of the influence of strontium fertilization on accumulation of the metal in *Glycine max*. Our research may be useful to obtain phytoestrogen-containing vegetable products or herbal formulations enriched with strontium to alleviate the risk of osteoporosis effects for postmenopausal women.

In our investigations, hydroponic cultivation was employed to ensure controlled conditions of the plant culture; otherwise, such components of soil as other ions could influence the uptake of strontium.

Table 1. Content of Strontium in Different Parts of *Glycine max* Treated with Various Sr Concentrations (±SD)[a]

	content of Sr (mg/kg) DW	
concn of Sr in medium (mM)	shoot (n = 10)	root (n = 4)
0.5	175.06 ± 10.21	18.40 ± 1.97
1	351.06 ± 17.12	37.39 ± 2.61
1.5	673.85 ± 31.19	85.20 ± 4.20
2	885.80 ± 40.05	111.26 ± 5.11
2.5	1014.85 ± 50.43	147.20 ± 7.07
3	1246.13 ± 65.63	180.22 ± 9.94

[a]The concentration of Sr in control was below the limit of detection.

Accumulation and Translocation of Strontium in soy. The accumulation of strontium in plants strongly depends on its concentration in the growth medium and the type of biota. Its content may vary from a few to even more than 2000 ppm.[23] Moreover, differences in the amount of strontium between above-ground and under-ground plant parts have been observed,[28−30] with higher concentrations generally present in shoot.[23,31] As our experiments showed, soy has a pronounced tendency toward accumulation of Sr^{2+} in shoots. Its content ranged from 87.4% to 90.4% of the total amount of the ions in the plants (Table 1). A positive linear correlation (R^2 > 0.98) between the amount of strontium in the growth medium and its content in the plant was also observed (Figure 1).

[a]The values followed by the same letters were not significantly different (p < 0.05).

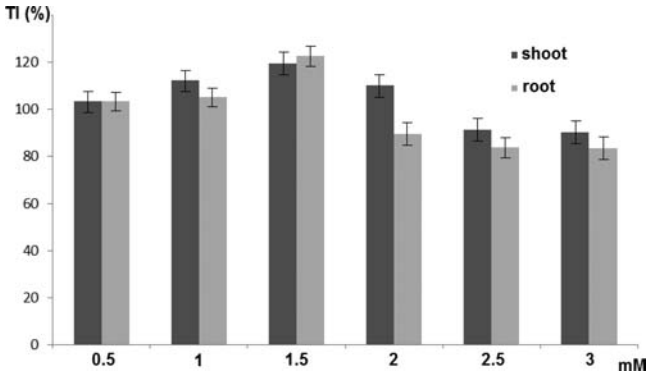

Figure 2. Tolerance index for the shoots and roots of *Glycine max* to different concentrations of strontium.

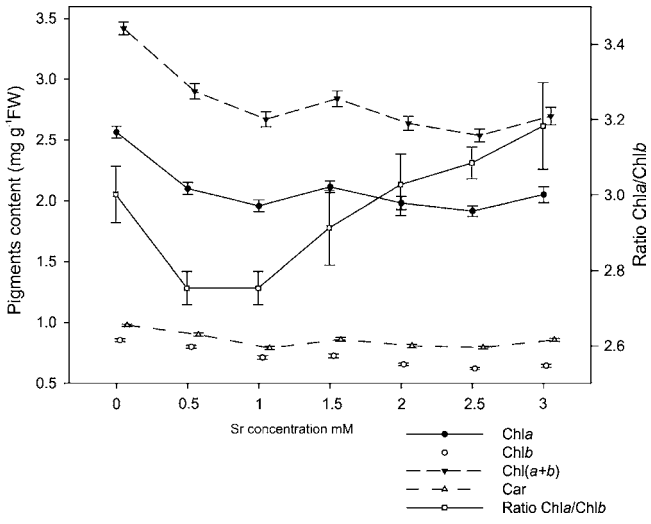

Figure 3. Effect of different strontium concentrations on the content of chlorophyll *a* (Chl*a*), chlorophyll *b* (Chl*b*), and carotenoids (Car) and on the chlorophyll *a*/*b* ratio in *Glycine max*.

The ability to accumulate a metal from the medium can be estimated by the bioconcentration factor (BCF), expressed as the ratio of the ion content in plant (*S*, shoot, or *R*, root) to its concentration in the environment (*M*, medium). The tendency toward translocation of a metal in the plant can be described by the transfer factor (TF), which is defined as the ratio of the ion content in shoots to roots.[32] The calculated BCF and TF values are presented in Table 2.

The TF for strontium content in the shoots was 6.89−9.39 times higher than in the roots, which proves that Sr^{2+} are effectively transferred to the above parts of the plants and accumulated therein. The active transport from the roots to shoots decreased at higher concentrations and resulted in lower values of TF.

As it can be seen in Table 2, the BCF depends on the content of the metal in the medium. The BCF for the roots was increased for all the investigated concentrations of strontium; however, it reached the highest value at 1.5−2 mM of Sr^{2+} for the shoots (BCF = 5.13−5.06). A value of the BCF higher than 1 indicates that soy has a strong capacity to absorb strontium.[29]

Effect of Strontium on Soy Growth. The average fresh (FW) and dry (DW) weight of biomass, of both the root and the shoot, obtained after 24 days of cultivation (including 14 days of treatment with various concentrations of strontium) and the weight of the control cultivated without strontium addition are shown in Table 3.

At concentrations up to 1.5 mM, strontium stimulated plant growth by approximately 19.42% FW (14.70% DW) and 22.62% FW (22.66% DW) for the shoots and roots, respectively (Table 3). However, toxic effects occurred at concentrations higher than 2 mM. The total amount of fresh and dry weight at concentration 3 mM was lower by approximately 12.84−14.37%, in comparison to the control.

A similar tendency was observed by Moyen and Roblin[29] for hydroponic cultivation of maize. This study on maize showed that the moisture content remained at a constant level; the FW/water ratio was from 1.13 to 1.14.

Table 4. Coefficient of Correlation between the Indexes of *Glycine max* and the Strontium Treatment (n = 10)

correlation coeff	Sr content in plant	FW	DW	chlorophyll content	chlorophyll *a*/*b* ratio	carotene content
			Concentration Range 0−1.5 mM			
Sr content in medium	0.969	0.867	0.801	−0.544	−0.124	−0.382
Sr content in plant		0.961	0.918	−0.558	−0.133	−0.395
			Concentration Range 1.5−3.0 mM			
Sr content in medium	0.9930	−0.861	−0.840	−0.294	0.986	−0.010
Sr content in plant		−0.834	−0.822	−0.255	0.994	−0.004

dx.doi.org/10.1021/jf501257r | J. Agric. Food Chem. 2014, 62, 5248−5252

The tolerance index (TI) is commonly used to quantify tolerance of plant organs to metals. It is calculated from the formula: TI = ($FW_{S\ or\ R}/FW_{control}$) 100%. As can be seen in Figure 2, the concentration of strontium in the range 0.5−1.5 mM turned out to be nontoxic.

This finding may be explained by the physical and chemical similarity of strontium to calcium, which is an essential component for plant growth and can be partially replaced by Sr^{2+}.[33] The TI for the roots was significantly lower than that for the shoots at the higher concentration of strontium. Inhibition of root growth is one of the fastest physiological reactions to stress.[34,35]

Effect of Strontium on the Content of Plant Pigments. It has been reported that strontium significantly affected the content of plant pigments depending on its amount and time of exposure.[29,33] Figure 3 shows changes in the chlorophyll *a*, *b*, and carotene content after 24 days of cultivation (including 14 days of treatment with the increasing concentrations of strontium).

The total amount of plant pigments decreased at the 0.5 mM concentration of strontium, in comparison to plants without Sr. However, the changes in the plant pigments were not correlated with the metal concentration. The differences were not significant ($p > 0.05$). In comparison to the control, a decrease in the chlorophyll *a*/*b* ratio was observed. This finding may be explained by greater sensitivity of Chl*a* than Chl*b* to strontium.

The present data showed a positive correlation between the Sr concentration in the media and Sr content in plants. Sr concentrations up to 1.5 mM stimulated plant growth; however, at a higher concentration, a negative correlation between concentration and fresh and dry weight was observed (Table 4).

Soy has a relatively high ability (BCF >1) to accumulate strontium, which may be useful to obtain phytoestrogen-containing vegetable products or herbal formulations for prevention postmenopausal osteoporosis. In vivo and in vitro studies showed high efficiency of strontium salts in osteoporosis therapy and lack of their toxicity in animals and human.[36] Our further investigations will focus on examining the activity and toxicity of extracts from soy enriched with strontium.

Herein, we reported the first fluorometric assay for NO_2 absorbance capacity (abbreviated as NO_2 AC) of antioxidants by taking advantage of the novel NO_2-selective probe reported by our group previously, using diethylamine NONOate (DEANO) as the NO_2 source.[17] The chemical mechanisms behind NO_2 scavenging by phenolic compounds were deduced from the reaction products formed as revealed by liquid chromatography−mass spectrometry (LC−MS) and secondary mass, using epicatechin (EC) and gallic acid as examples. Through measuring the antioxidant capacity of flavanols and related polyphenolic compounds as well as characterization of the reaction products, the structure−activity relationship was established, which provides a rational explanation on the good correlation of peroxyl radical scavenging activity and NO_2 scavenging activity.

EXPERIMENTAL SECTION

Materials and Instruments. All experiments were performed with reagents of analytical grade or high-performance liquid chromatography (HPLC) grade. Chemicals were purchased from Sigma-Aldrich Chemical Co. (Singapore) and used without further purification. A NO_2-selective fluorescent probe, a sulforhodamine-B-containing nickel(II) dithiocarbamate complex, was prepared according to our previous reported method.[17] Fluorescence measurements were gathered using a Synergy HT microplate fluorescence reader from Bio-Tek Instruments, Inc. (Winooski, VT), installed with KC4 software. The fluorescence spectrum was obtained on a PerkinElmer LS55 fluorometer with a slit width at 10 nm for both excitation and emission. Ultraviolet−visible (UV−vis) spectroscopic studies were obtained on a Shimadzu UV-1601 UV−vis spectrophotometer accompanied by a quartz cell and installed with UVProbe software. HPLC analysis was performed on a Waters 2695 HPLC system equipped with an Alliance 2659 separation module and a Waters 2996 photodiode array (PDA) detector (Milford, MA) and installed with an Empower program. A C18 reverse-phase column (Waters Atlantis T3, 6 μm, 4.6 × 150 mm) was used throughout this study. The photodiode array (PDA) acquisition wavelength range was set at 210−700 nm. LC−MS spectra were acquired using a Bruker Amazon ion trap mass spectrometer (Billerica, MA) equipped with an electrospray ionization (ESI) source and a Dionex ultimate 3000RS HPLC system (Bannockburn, IL), installed with Chameleon, Hystar, and Trapcontrol software. The heated capillary and spray voltage were maintained at 200 °C and 4.5 kV, respectively. Nitrogen was operated at 80 psi for sheath gas flow rate and 20 psi for auxiliary gas flow rate. The full-scan mass spectra from m/z 70 to 1000 were obtained in negative-ion mode with a scan speed of 1 scan per second.

Construction of the Dose Response Curve for DEANO. NO_2 probe stock solution was diluted in methanol to a final concentration of 3 μM. A series of concentrations of DEANO (0, 200, 400, 500, 600, 700, 800, 900, and 1000 μM) was obtained by dilution with sodium hydroxide solution and mixed with phosphate buffer and probe solutions in a ratio of 1:1:8 to a final volume of 3.0 mL. The fluorescence intensities were measured 5 min after the addition of DEANO stock solutions on the fluorescent spectrometer (see Figure S2A of the Supporting Information). The data in Figure S2B of the Supporting Information was obtained using the microplate reader. Preparations of reagents followed the above procedure but were mixed to a final volume of 200 μL in each well of the 96-well microplate. Fluorescence intensities were monitored over a period of 10 min.

Experimental Procedure for Nitrogen Dioxide Radical Absorbance Capacity Assay (NO_2 AC). NO_2 probe solution (4.3 μM) was prepared in methanol, and DEANO (8.0 mM) was completely dissolved in sodium hydroxide solution (10 mM, pH 12) and kept in an ice bath. Stock solutions of phenolic compounds were diluted with methanol to 10, 20, 30, and 40 μM working solutions. Fluorescent probe (140 μL), sample (20 μL in methanol), phosphate buffer (10 mM, 20 μL), and DEANO solution (20 μL) were pipetted and mixed in individual wells of a 96-well flat-bottom microplate. In the resulting reaction solution, the fluorescent probe concentration is 3.0 μM, the DEANO concentration is 0.80 mM, the phosphate buffer concentration is 1.0 mM, and the methanol concentration is 80%. Fluorescence intensity of each well was immediately monitored upon addition of DEANO solution every minute for 15 min with excitation wavelength of 540 nm and emission wavelength of 590 nm at 37 °C. Before each reading, the microplate was shaken for 4 s at low intensity to ensure sample homogeneity. Methanol control (20 μL) was conducted in parallel for each of the samples on the same microplate as a blank.

Data Processing (NO_2 AC Value). With a half life of 2 min, DEANO decomposes to give NO when dissolved in psychological pH medium at 37 °C.[18] Under aerobic ambient conditions, NO undergoes autoxidation, generating NO_2.[9,19,20]

$$2\,{}^{\bullet}NO + O_2 \rightarrow 2\,{}^{\bullet}NO_2 \tag{1}$$

NO_2 produced will either react with the fluorescent probe (P) or be scavenged by an antioxidant (AH). There exists competition between them for the constant flux of NO_2 (R_i).[21]

$$P + {}^{\bullet}NO_2 \xrightarrow{k_p} \text{fluorescent products} \tag{2}$$

$$AH + {}^{\bullet}NO_2 \xrightarrow{k_{AH}} A^{\bullet} + NO_2^{-} + H^{+} \tag{3}$$

The radical $A^{\bullet}$ can further react with NO_2 to form an adduct, as we have shown in the mechanistic study (*vide infra*). The radical coupling reaction is not likely to be a rate-limiting step. For the initial reaction, reaction 3 is dominant because the antioxidant concentration is at its highest. Therefore, the rate of probe oxidation can be expressed by the following equation:

$$V = -\frac{d[P]}{dt} = \frac{k_p[P]R_i}{k_p[P] + k_{AH}[AH]} \tag{4}$$

In the absence of antioxidant ([AH] = 0), the uninhibited reaction rate is

$$V_0 = R_i \tag{5}$$

From eqs 4 and 5, the following relation between the fluorescence increase rates in the absence (V_0) and presence (V) of an antioxidant can be drawn

$$\frac{V_0}{V} = 1 + \frac{k_{AH}[AH]}{k_p[P]} \tag{6}$$

The plot of V_0/V against [AH] will yield a linear function with an intercept at (0, 1) and a slope of $k_{AH}/k_p[P]$. With reference to Figure 1A, a tangent at the second minute was plotted on each kinetic curve to obtain the initial fluorescence increase rates for each concentration. The V_0/V values are plotted against their corresponding [AH], as expressed in Figure 1B. Under the experimental conditions, the probe concentration [P] is constant at the initial reaction stage; thus, $k_p[P]$ is a constant. Therefore, the k_{AH} value can be obtained from the slope and is the NO_2 AC value as

$$k_{AH} = S_{AH}k_p[P] \tag{7}$$

where S_{AH} is the slope for the antioxidant (AH). However, to obtain the absolute values for k_{AH}, k_p needs to be determined. If a reference standard can be used, there is no need to obtain the absolute k_{AH} values for comparison of relative NO_2 scavenging activity. We selected one of the most common flavanols, EC, as a reference standard to compare to samples. Therefore

$$S_{EC} = k_{EC}/(k_p[P]) \tag{8}$$

$$\therefore k_{EC} = S_{EC}k_p[P] \tag{9}$$

Normalizing k_{AH} with k_{EC}, we have

dx.doi.org/10.1021/jf5001925 | J. Agric. Food Chem. 2014, 62, 5253−5258

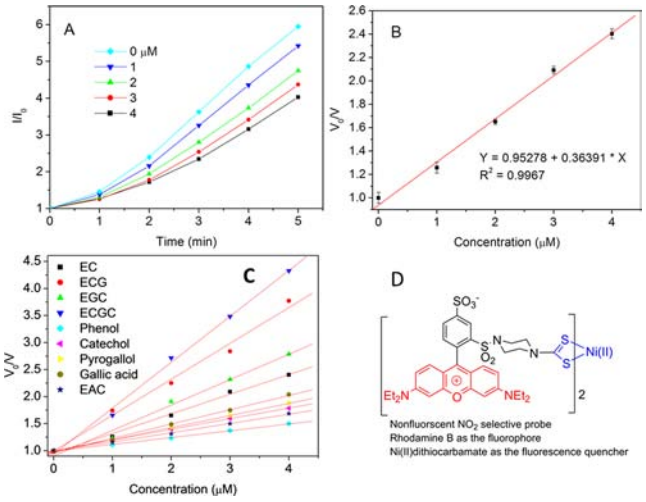

Figure 1. (A) Increments of fluorescence intensity of the probe (3 μM) against time after the addition of DEANO (800 μM) and EC at different concentrations. (B) V_0/V as a function of the concentration of EC. (C) Dose responses of V_0/V versus different concentrations of selected antioxidants. (D) Molecular structure of the fluorescent probe that is selective to NO_2 detection.

$$\text{NO}_2\text{ AC value of AH} = \frac{k_{\text{AH}}}{k_{\text{EC}}} = \frac{S_{\text{AH}}k_{\text{p}}[\text{P}]}{S_{\text{EC}}k_{\text{p}}[\text{P}]} = \frac{S_{\text{AH}}}{S_{\text{EC}}} \quad (10)$$

On the basis of eq 10, k_{AH} can be obtained because k_{EC} was measured recently as 1.0×10^8 M^{-1} s^{-1} by a pulse radiolysis study.[21,22] For convenience sake, epicatechin equivalency (ECE) is used to express the NO_2 AC. For single compounds, the concentrations used were the same, and the NO_2 AC values for polyphenolic compounds are dimensionless. The NO_2 AC value for EC is defined as 1 because it is the reference. For samples that are composed of mixtures of antioxidants, the unit of NO_2 AC will be micromoles of ECE per gram (for solid) or micromoles of EC equivalents per liter for liquid samples, such as fruit juices.

Preparation of NO_2 Gas. NO_2 gas was prepared by adding concentrated nitric acid dropwise to copper wire and collected in a dry round-bottom flask with phosphorus pentoxide inside. The flask was sealed and kept in a dark and cool place. NO_2 gas at certain concentrations was prepared by diluting pure NO_2 with argon. Caution: The highly toxic NO_2 gas should be used with extreme caution and handled only in relative small quantities in a well-ventilated fume hood.

Preparation of NO Gas and Its Reaction with EC. Reaction of sodium nitrite and ascorbic acid was reported to give NO gas.[23] Sodium nitrite (2.87 g) was dissolved in deionized water, and ascorbic acid (3.67 g) were accurately weighed. EC (3 mg/mL) was prepared by dissolution in methanol. All reagents were placed in the airtight setup, and then the system was flushed with argon gas for 30 min to ensure an inert environment, so that there would be absence of NO autoxidation. Aqueous $NaNO_2$ solution in the buret was then released in a dropwise manner to react with ascorbic acid placed in the round-bottom flask for generation of NO gas. Approximately 1 L of NO gas was generated and passed through concentrated NaOH (4 M) first to remove acidic gas before NO is bubbled to EC solution. There was no visible color change for the EC solution after 6 min. The resulting EC solution was flushed with argon for 0.5 h to remove any NO in the solution and analyzed by HPLC.

HPLC and LC–MS Studies of the Reaction Product. The reaction products between NO_2 and EC (2.0 mg/mL) in methanol were analyzed by HPLC with a detection wavelength from 210 to 700 nm. The mobile phases were water (solvent A) and methanol (solvent B). The sample (10 μL) was injected into the HPLC system with the column equilibrated with 60% solvent A. Gradient elution was used and programmed to obtain a linear increase in the solvent A ratio from 60 to 0% in 60 min at a flow rate of 0.2 mL/min. The column was equilibrated to 60% A in 10 min prior to the next run. The above was also performed for the analysis of the reaction product from EC and NO. The LC conditions for LC–MS analysis were similar to those mentioned above, except with 5 μL of sample injected and detection wavelengths at 280 and 350 nm. The same procedure was used for analysis of product between gallic acid and NO_2.

RESULTS AND DISCUSSION

Fluorescent Approach for Quantification of NO_2 Scavenging Activity. Here, we present an accurate and highly efficient assay to assess antioxidant capacity against NO_2, monitoring competitive reaction kinetics between an introduced antioxidant and probe. In this assay, we applied our newly developed, NO_2-selective "turn on" fluorescent probe containing $(\text{dithiocarbamato})_2\text{Ni}^{\text{II}}$ as a fluorescence quencher and NO_2 reaction center.[17] The fluorescence of the rhodamine fluorophore was quenched by $(\text{dithiocarbamato})_2\text{Ni}^{\text{II}}$ via photo-induced electron transfer. The fluorescence "turn on" is caused by oxidation of the complex by NO_2 that triggered release of oxidized ligands.[17] This probe demonstrated good selectivity because NO_2 is the only radical that can turn on the fluorescence, while other common ROS, such as ClO^-, H_2O_2, $ONOO^-$, O_2^-, NO, $HO^\bullet$, and $ROO^\bullet$, could not.[17] Furthermore, it is evident that this probe is photostable and the antioxidants examined will not influence the fluorescence (see Figure S1 of the Supporting Information); therefore, this probe was suitably used for monitoring the NO_2 scavenging activity of antioxidants. DEANO was proven to be a good NO_2 source in oxygenated solution to establish the dose–response curve for the NO_2 fluorescent probe, yielding the identical products as NO_2 gas after reacting with the probe.[17] There exists a good linear relationship between the fluorescence intensity ratio and the concentration of DEANO (see Figure S2B of the Supporting Information), and 800 μM was selected for use in the assay. It should be pointed out that DEANO or other similar NO donors have been applied in the investigation of NO scavenging activity of polyphenolic compounds. However, we found that NO does not react with EC under air-free conditions. It is likely that the reaction is due to other RNS with polyphenolic compounds. Characterization of the reaction products showed that NO_2 is the species responsible for the reaction. Our results highlighted the importance of eliminating oxygen when one intended to measure NO scavenging activity.

We took advantage of the sensitive NO_2 fluorescent probe as a reporting reaction in a competitive reaction system, where generated NO_2 reacts with probe and antioxidants, which protect the probe from being oxidized, as shown by a reduced rate fluorescence intensity change (Figure 1A). The initial fluorescence increase rates in the presence of different amounts of antioxidants were determined from the plot. V_0/V versus the antioxidant concentrations yield excellent linear curves (panels B and C of Figure 1). The slopes of the curves for different antioxidants were normalized with that of EC and shown in Table 1. The rate constants of the compounds with NO_2 can be readily obtained by multiplying the NO_2 AC values with k_{EC}, which is quantified as 1×10^8 M^{-1} s^{-1}.[22] Therefore, our assay provides a rapid and sensitive method to quantify NO_2 scavenging activity. Our results are in good agreement with the rate constants of epigallocatechin gallate (EGCG) and gallic acids measured using pulse radiolysis methods, which shown

dx.doi.org/10.1021/jf5001925 | J. Agric. Food Chem. 2014, 62, 5253–5258

Table 1. NO_2 AC Values (EC Equivalents) of Phenolic Compounds

phenolic compounds	slope ($k_{AH}/k_p[P]$)	NO_2 AC value (S_{AH}/S_{EC})
EC (standard)	0.36	1.00 ± 0.08
ECG	0.67	1.83 ± 0.10
EGC	0.47	1.29 ± 0.04
EGCG	0.85	2.33 ± 0.03
phenol	0.13	0.35 ± 0.03
catechol	0.20	0.54 ± 0.02
pyrogallol	0.22	0.62 ± 0.01
gallic acid	0.26	0.73 ± 0.02
EAC	0.17	0.47 ± 0.05

that EGCG has a rate constant of 2.3 times larger than that of EC and the rate constant for gallic acid is half that of EC.[22,22]

Structure and Activity Relationship of NO_2 Scavenging Activity of Flavanols. We have quantified the NO_2 scavenging activity of five common flavanols, including epiafzelechin (EAC), EC, epigallocatechin (EGC), epicatechin gallate (ECG), and EGCG (Figure 2), and four compounds of

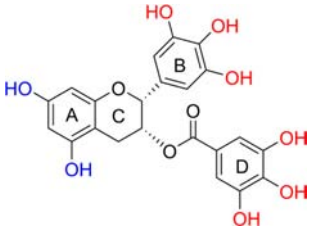

Figure 2. Structure of EGCG, indicating four ring numbers. The OH groups in red are responsible for its NO_2 scavenging activity, while those in blue contribute little.

structural relevance to flavanols. They are phenol, catechol, pyrogallol, and gallic acid. From the data, a few observations are remarkable: (1) The scavenging potential of these nine compounds against the NO_2 radical are in the order of phenol < EAC < catechol < pyrogallol < gallic acid < EC < EGC < ECG < EGCG. (2) For the flavanols, the one with the most phenolic hydroxyl groups exhibits the greatest scavenging activity. A similar trend is observed for phenol, catechol, and pyrogallol. (3) The flavanols are seen to exert a greater antioxidant effect than their model phenolic compounds, such as catechol and phenol.

From these observations, we can conclude that the *ortho*-dihydroxyl groups are an important structural feature for high NO_2 scavenging activity, while the *meta*-OH units in the A ring of the flavanols have little contribution in NO_2 scavenging activity. The galloyl ester unit in EGC and EGCG further enhance the NO_2 scavenging activity in comparison to EC and EGC, yet the addition of one more *ortho*-OH group in the B ring of flavanol has much less effect on NO_2 scavenging activity (by comparing EC to EGC).

Reaction Products and Mechanisms of Catechin/Gallic Acid with NO_2. It is commonly known that the B and D rings (galloyl) of the flavanols are responsible for their radical scavenging activity (Figure 2).[22,24,25] To shed some light on the NO_2 scavenging activity, we characterized the reaction products of NO_2 with EC by HPLC and LC–MS/MS. The HPLC chromatograms of the reaction products are shown in Figure 3B. EC (R_t = 18.4 min) reacted with NO_2 generated three isomeric products with a retention time at 29.8, 31.8, and

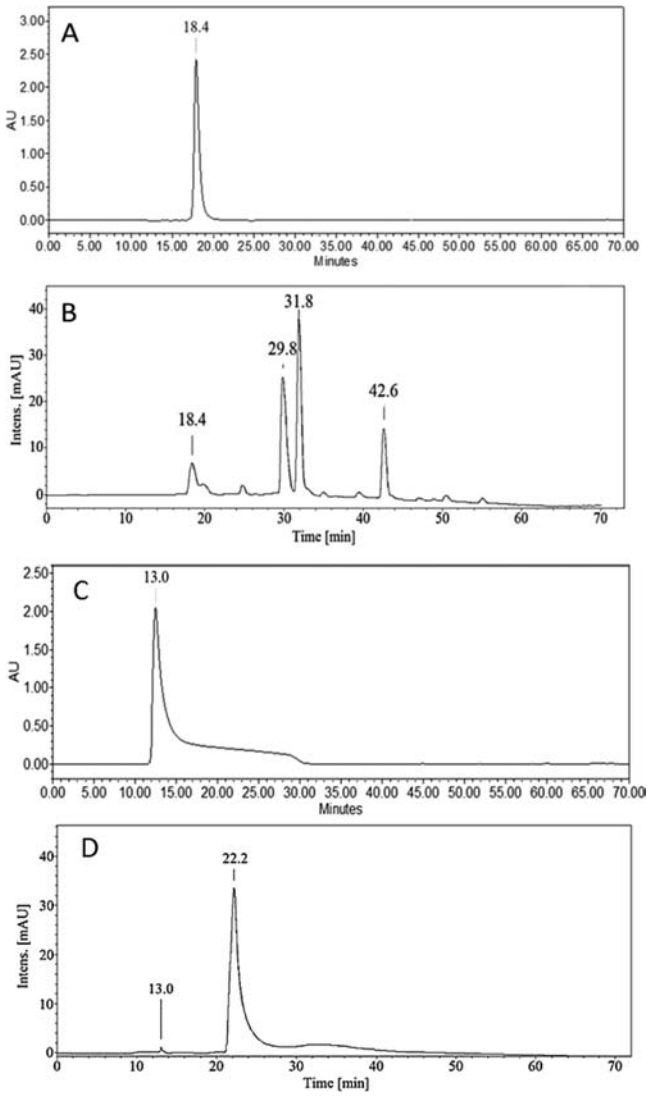

Figure 3. (A) HPLC profile of pure EC, recorded at 280 nm. (B) LC–MS LC profile of EC and its oxidized product with NO_2, recorded at 350 nm. The ESI (anionic mode)–MS of the three products has m/z of 334, and they give the same MS^2 pattern with major peaks at m/z of 124.8, 164.7, and 287.8. (C) HPLC profile of pure gallic acid, recorded at 280 nm. (D) LC–MS LC profile of gallic acid and its oxidized product with NO_2, recorded at 350 nm. The ESI (anionic mode)–MS of the product has m/z of 169.7, and it gives the MS^2 pattern with a peak at m/z of 124.2.

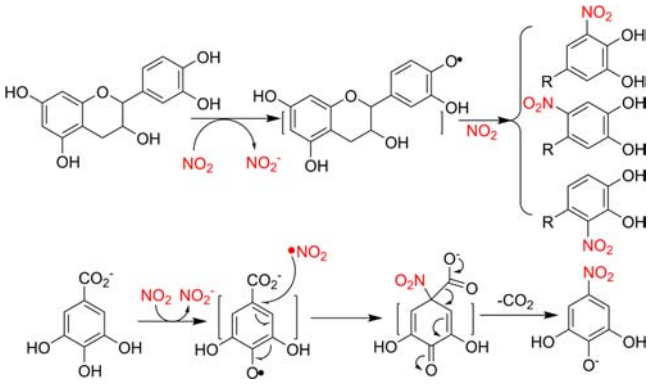
42.6 min, respectively, with m/z 334.0 ($[M - H]^-$) and m/z 669.0 ($[2M - H]^-$). Fragmentation of MS^2 for m/z 334.0 gave rise to peaks with m/z of 287.8, 124.8, and 164.7. The m/z 287.8 peak corresponds to the loss of NO_2 (molecular weight of 46) from the molecular ion, while the m/z 124.8 and m/z 164.7 ions were formed from the characteristic heterocyclic ring fragmentation (see Figure S3 of the Supporting Information).[26,27] This fragmentation pattern indicates that NO_2 is not attached in the A ring. The phenoxyl radical derived by hydrogen atom abstraction from the B-ring OH groups of EC is delocalized among three resonance structures.[28] The combination of the radical with NO_2 will lead to three isomers observed by LC–MS (Scheme 2). The nitrated B ring absorbs light at a longer wavelength at the visible light range as the solution color turned from colorless to light yellow, and the UV–vis spectra of the products gave rise to multiple bands centered at 350 nm

Scheme 2. Proposed Mechanism for NO_2 Radical Scavenging by EC and Gallic Acid[a]



[a]R = moiety of A and C rings of EC.

and stretched to 400 nm (see Figure S4A of the Supporting Information).

The reaction between gallic acid and NO_2 gave rise to an unusual product with an UV−vis absorption maximum at 350 nm, indicating a NO_2 adduct with phenyl (Figure 3D). The mass spectrum shows peaks at m/z 170 and 341, which fit that of nitrogallol (molecular weight of 171) and its dimer (molecular weight of 342). We proposed that the reaction happens via two steps (Scheme 2): first, hydrogen atom abstraction (or electron transfer followed by the loss of a proton) by NO_2 resulted in a phenolic radical, and second, NO_2 would attack carbon at the *para* position of the phenol radical to give a ketone intermediate. Subsequent decarboxylation resulted in the observed product, 4-nitrogallol. The molecular weight of the product is only 1 unit more than that of gallic acid and can be deceptive to assign its structure at the first sight. MS^2 of gallic acid and that of nitrogallol give rise to the same fragment gallol anion at m/z 125. The structure of nitrogallol requires further confirmation by preparative-scale synthesis, infared spectroscopy, and X-ray crystallographic data. Overall, the mechanistic study using EC and gallic acid validate the conclusion made by several other researchers that the radical scavenging by catechin will produce a phenoxyl radical localized on the B or D ring (represented by gallic acid, a common moiety for the D ring).[20,23,24]

UV−vis spectroscopic analyses on the products between EC and NO_2 and those of EC and DEANO under normal aerobic conditions produced the same spectra (see Figure S4A of the Supporting Information), showing product absorbance peaks from 300 to 400 nm. However, as a NO donor, DEANO does not release NO_2 directly but releases NO, which is also a radical species. To figure out whether phenolic compounds scavenge NO_2 directly or scavenge NO to prevent NO_2 generation, UV−vis spectroscopic analyses for the reaction between EC and NO gas and that of EC with DEANO (under deaerated conditions) were performed. As demonstrated in Figure S4B of the Supporting Information, no change was found, in comparison to the EC spectra. This observation is reaffirmed by HPLC analysis (see Figure S5 of the Supporting Information), which exhibited only a single absorption peak for EC (R_t = 18 min), suggesting that there was no reaction between EC and NO.

ECG and EGCG contain an additional gallate moiety (D ring) compared to EC and EGC, respectively. The gallate group enhanced the NO_2 scavenging activity of ECG (NO_2 AC value of 1.83 ± 0.10) and EGCG (NO_2 AC value of 2.33 ± 0.03) by about twice that of EC (1.00 ± 0.08) and EGC (1.29 ± 0.04), respectively. This correlates well with ECG and EGCG having twice the number of catechol/pyrogallol moieties compared to EC and EGC, respectively. These results are in agreement with the notion that the NO_2 scavenging effect is attributed to the *ortho* OH groups in the B and D rings.[24] The bimolecular rate constants of NO_2 and EC, EGCG, and gallic acid were quantified by a pulse radiolysis method to be 1.0×10^8, 2.3×10^8, and 5.3×10^7 M^{-1} s^{-1}, respectively.[22,21] The NO_2 scavenging activity measured using our method is in good agreement with these values. Using reaction rate constants to determine NO_2 AC values is accurate but technically complicated. It should be pointed out that the linearity range is not very large between the concentration of antioxidants and the rate changes. This may limit its application to food sample measurements when, particularly, their antioxidant activity is unknown. For application of this method to a large amount of samples, end point readings would be more convenient in providing IC_{50} for comparison of the NO_2 scavenging activity of different samples.

Under air-saturated conditions, NO is reported to react with oxygen as the dominant pathway to give NO_2. The kinetic analysis of the NO oxidation reaction in the presence of thiols and amine was identical to that obtained for the autoxidation of NO.[29] Nitrosylation of thiols only occurs under oxygenated conditions. Therefore, NO_2 is responsible for the reaction. In agreement with this pioneering work, we have demonstrated that NO failed to react with EC even with 30 min at room temperature with a large excess of NO. In the presence of oxygen, EC is nitrosylated by NO_2. Because of the strong oxidative power of NO_2 and its relevancy of NO_2 formation as a result of endogenously formed NO, the scavenging activity of NO_2 (and not NO) is an important but neglected aspect of antioxidants.

Our assay overcomes the technical hurdle to quantify the NO_2 scavenging capacity of dietary antioxidants, including flavanols. Given the fact that there are a wide range of ROS/RNS that are important to biological systems, different antioxidant capacity assays are needed to comprehensively evaluate antioxidant activity. These reactive oxygen species and their related scavenging capacity assays include peroxyl radicals ($ROO^•$) in the $ORAC_{FL}$ assay,[30] hydroxyl radical (M^{II}/H_2O_2) averting capacity assay,[31] superoxide anion absorbance capacity assay (SORAC assay),[32] NO_2 AC, peroxynitrite ($ONOO^-$) absorbance capacity assay, hypochlorous acid absorbance capacity assay, and singlet oxygen absorbance capacity assay. Because these ROS/RNS species have different reactivity patterns, it is essential to use different methods to quantify their scavenging activity. This is only possible with validated and convenient assays in place.

perfluoroalkyl chains) has not always been achieved. For difficult separations unusual stationary phases or mobile phase components have been used and in many cases successfully. Using fluorinated stationary phases[21−23] or methylpiperidine as eluent modifier,[24] separation of PFNA and PFOS has been achieved successfully. In addition, a number of publications show the separation of PFNA and PFOS with C_{18} stationary phases from different manufacturers; however, variations in eluent compositions and stationary phases make it difficult to systematically analyze the retention mechanisms of those compounds on the basis of literature data.[25,26]

From a mass spectrometric point of view PFOS displays some other inconvenient aspects when compared with perfluorinated carboxylic acids of similar chain length. In the MS/MS regime it has a relatively low fragmentation yield and, as a consequence, a low S/N ratio. In the case of PFOS an MRM "transition" 499 → 499 (i.e., monitoring the non-fragmented parent) has been proposed.[27] However, the problem of accuracy remains, because in this case it has also been shown that certain steroidic bile acids present in fish samples have the same nominal m/z ratio of 499 with a similar fragmentation pattern and a retention time close to that of the PFOS and therefore may strongly affect the peak area of PFOS.[22,27]

The selection of eluent additives in LC-MS is limited by the volatility requirement. Fluorinated alcohols are volatile compounds of weak to medium acidity and are neutral in protonated form. These properties make them a potentially promising class of compounds to be used as weak acids for preparing buffers of pH value above 7 for use in LC-MS.

1,1,1,3,3,3-Hexafluoro-2-propanol (HFIP, pK_a = 9.3)[24] has been used as an additive to the LC mobile phase in several studies.[28−35] The suitability of fluoroalcohols, HFIP and 1,1,1,3,3,3-hexafluoro-2-methyl-2-propanol (HFTB, pK_a = 9.6)[36], as buffer additives at concentration levels from 1 to 10 mM has been studied, and application for separation of antibiotics−fluoroquinolones and sulfonamides is demonstrated.[37,38] It turned out that mobile phases with perfluorinated alcohols provide retention mechanisms that differ from the ones traditionally observed with regular eluent modifiers for C_{18} stationary phases.[38]

Alternatively, a promising group of stationary phases that have been successfully applied in pharmaceutical and drug analysis are fluorinated (pentafluorophenyl and pentafluorophenylpropyl) stationary phases.[39−41] Fluorinated stationary phases are associated with various interaction mechanisms improving retention and chromatographic resolution. Most similar to common stationary phases are perfluorinated alkyl chains, for example, C_8F_{17}, used for their alternative retention in several applications for separating polar molecules,[42,43] especially halogenated analytes,[44−47] but also for aromatic polycyclic hydrocarbons due to the interactions between π-electrons of analytes and C−F dipole of the stationary phase.[46,48] The performance of fluorinated columns has improved in recent years with respect to their pH stability and column lifetime. Additionally, stationary phase bleeding is reduced, allowing the use of these stationary phases also in MS applications. The retention of all analytes has been reported to be overall lower on the fluorinated stationary phase than on C_{18}.[47] Therefore, the retention of PFCs using a fluorinated stationary phase and fluoroalcohols with a regular C_{18} stationary phase is of interest.

The focus of this work is the LC-ESI-MS analysis of PFOA, PFNA, and PFOS in raw fish samples using a different approach for chromatographic separation and signal improvement: replacement of common eluent buffers (ammonium acetate) with a polyfluorinated alcohol−ammonia buffer.[34,36]

MATERIALS AND METHODS

Instrumentation for Sample Preparation and Analysis. For primary sample homogenization a Retsch Grindomix GM 200 homogenizer was used. A Heidolph 900 DIAX homogenizer was used during the PFC extraction step, and a centrifuge Eppendorf 5430R was used during sample preparation. Chromatographic separation of the analytes was carried out on a Waters 2695 series chromatograph (Waters, Milford, MA, USA) equipped with a binary pump, degasser, autosampler, and column thermostat. Detection and quantification of analytes was carried out with a QuattroMicro triple-quadrupole mass spectrometer (Micromass, Manchester, UK). Tested analytical columns were Epic FO LB (150 mm × 3.0 mm, 3 μm) and YMC Triart C18 columns (150 mm × 3 mm, 3 μm). Preliminary tests for chromatographic separation were performed with an Agilent 1290 series UHPLC (Agilent) and a J-320 mass spectrometer (Varian).

Chemicals. PFOA, PFNA, potassium perfluorooctanesulfonate standards, HFIP, HFTB, and anhydrous $MgSO_4$ were purchased from Sigma (St. Louis, MO, USA). Acetonitrile and methanol were obtained from J. T. Baker (Deventer, The Netherlands), formic acid and ammonium hydroxide were from Riedel-de-Haën, and ammonium acetate was from Fluka (Buchs, Germany). All solvents were of reagent grade or higher quality. Water was purified in-house using a Milli-Q Advantage A10 system from Millipore (Bedford, MA, USA).

Standard and Buffer Solutions. Calibration solutions were prepared in methanol so that the concentrations were in the range of 0.5−500 ng/mL. Spiking solutions were prepared in acetonitrile at concentrations of 7.5, 75, and 750 ng/mL; in that case the analyte concentrations in samples were 1.0, 10, and 100 μg/kg, respectively. Solvent A (see below) was prepared by dissolving 0.965 g of HFTB in 1 L of Milli-Q water, and the pH was adjusted to 10.0 by adding a concentrated solution of ammonium hydroxide.

Sample Preparation. The fish samples were purchased from local markets and delivered to the laboratory on the same day for homogenization. Samples included the most common fish species available on the Estonian market (Table 1). The initial amount of sample was typically >1 kg. Upon arrival, the fish samples were cleaned of skin, intestines, and bones. Edible parts of fish (muscle and fat tissue) were homogenized with a Retsch Grindomix GM 200 at 2000 rpm for 4 min. Homogeneous samples were stored in a freezer at −20 °C until analysis. Further sample preparation was carried out using a modified "Quick, Easy, Cheap, Effective, Rugged, and Safe" protocol (QuEChERS), essentially as described in ref 49. As a modification, the cleanup step with dispersive SPE was omitted, because there was no need for it due to the already low matrix effects. In addition, the use of HFTB/HFIP increased analyte signal intensity and reduced matrix effects.

Homogenized fish tissue was weighed (7.5 g) into a 50 mL polypropylene (PP) tube, and 10 mL of water was added. The sample was then additionally homogenized during 1 min with a Heidolph Diax 900 homogenizer at 18000 rpm. Fifteen milliliters of acetonitrile was added to the tubes, and the tubes were shaken by hand for 10 s. A preweighed mixture of salts (6 g of anhydrous $MgSO_4$ and 1.5 g of NaCl) was then added to the samples, and the tubes were shaken vigorously by hand for 1 min and for 1 min on a vortex-mixer. Samples were then centrifuged at 7000 rpm for 15 min. Twelve milliliters of clear supernatant was transferred into a 15 mL PP tube containing 1.8 g of anhydrous $MgSO_4$. Tubes were shaken once more for 1 min by hand and on a vortex mixer and then centrifuged at 7000 rpm for 15 min. Eight milliliters of supernatant was transferred into a 15 mL glass vial and evaporated to dryness under a stream of nitrogen at 40 °C. The dry residue was dissolved in 1 mL of methanol. The final extract was filtered through a 0.45 μm regenerated cellulose syringe filter into a chromatographic vial.

Chromatographic and Mass Spectrometric Conditions. Analytes were separated on a YMC Triart C_{18} column (150 mm × 3 mm, 3 μm). This stationary phase was used because of its good retention properties and excellent stability toward pH in the range from 1 to 12.[50] The mobile phase was composed of 5 mM HFTB (pH adjusted to 10 with saturated aqueous ammonia) (solvent A) and methanol (solvent B). Gradient elution at a flow rate 0.3 mL/min started at 20% methanol for 1 min and was raised to 50% within 4 min, then the methanol concentration was slowly raised to 65% by the 18th minute, and after that the methanol concentration was raised to 100% within 0.3 min. Methanol concentration was kept at 100% for 5 min, lowered to 10% in 1 min, and equilibrated at 20% for 5 min. The column temperature was set to 40 °C, and the injection volume was 10 μL. ESI-MS/MS measurements were performed in negative MRM detection mode. The first quadrupole was set to the m/z of the deprotonated $[M - H]^-$ ions of the analytes: m/z 413 (PFOA), 463 (PFNA), 499 (PFOS). Mass spectrometer parameters for ESI-MS/MS were as follows: desolvation gas (N_2) flow rate, 300 L/h, and temperature, 350 °C; source temperature, 135 °C; cone gas flow rate, 50 L/h; capillary voltage, −3 kV; cone voltage, 10 V. Fragmentation of deprotonated analyte molecules was performed with argon gas. Detected fragment ions and fragmentation parameters were as follows: PFOA, m/z 369, 169 (E_{coll} 10 and 15 eV); PFNA, m/z 419 and 219 (E_{coll} 10 and 15 eV); PFOS, m/z 99, 80 (E_{coll} 45 eV). LC and MS instruments were controlled by MassLynx 4.1 software (Waters). Data analysis was carried out using QuanLynx 2 software (Waters).

Validation of the Method. Validation of the method was performed according to the FDA Guidance for Industry Bioanalytical Method Validation.[51] Partial validation was performed, and estimation of process efficiency, matrix effects, sample preparation recovery, limit of detection (LOD), limit of quantification (LOQ), accuracy, precision, and measurement uncertainty were carried out.

RESULTS AND DISCUSSION

Retention Mechanism and MS Signal Improvement. Separations of structurally similar perfluorinated compounds on C_{18} stationary phases have been problematic in several previous studies.[10,17−20]

In this study the retentions of the analytes on the C_{18} stationary phase were similar using 0.1% formic acid (pH 2.6) and MeCN in eluent, and separation between the three analytes was not achieved. Asymmetrical and wide peaks eluted with 82% of MeCN.

However, the previous studies indicate separation of PFOA, PFNA, and PFOS using perfluorinated stationary phase,[21] and retention of fluorinated compounds is enhanced on fluorous stationary phases.[47] The separation of PFOA, PFNA, and PFOS was studied using an alkyl perfluorinated stationary phase. Fluorinated analytes' retention on the fluorinated stationary phase is mainly influenced by the amount on fluorine atoms in the analyte molecule.[47] The number of fluorine atoms in PFOA molecule is 15; on the other hand, PFNA and PFOS have equally similar 17 fluorine atoms in the molecule.

To achieve advanced separation for analytes, a fluorinated stationary phase was tested in this work. An Epic FO LB (150 mm × 3.0 mm, 3 μm) column meant for separating fluorinated compounds demonstrated significant column bleed and contaminated the source very quickly. In addition, separation of PFNA and PFOS was not observed (Figure 1). Because the Epic FO LB column showed inadequate separation of compounds and significant source contamination was observed, and in addition the column maximum pH range was 8, further attempts were made with a C_{18} stationary phase using 5 mM ammonium acetate at higher pH values (pH 9 and 10) as a component of eluent.

Therefore, the change in eluent pH was made and 5 mM ammonium acetate (pH 10) was used for elution. Increased eluent pH with the C_{18} column (YMC Triart C18) led to better peak shape on the chromatogram, but the analysis of PFNA and PFOS was still problematic due to the low S/N ratio (Figure 2).

To enhance separation of analytes on the C_{18} stationary phase, alternative eluent components were used: 5 mM HFIP and 5 mM HFTB at the same pH as ammonium acetate (pH 10).

The resolution, assessed as the R_s values, of the analyzed compounds using 5 mM HFTB was slightly better at pH 10 (Figure 3) compared to ammonium acetate and HFIP buffer. However, the used MeOH content at the retention time of the

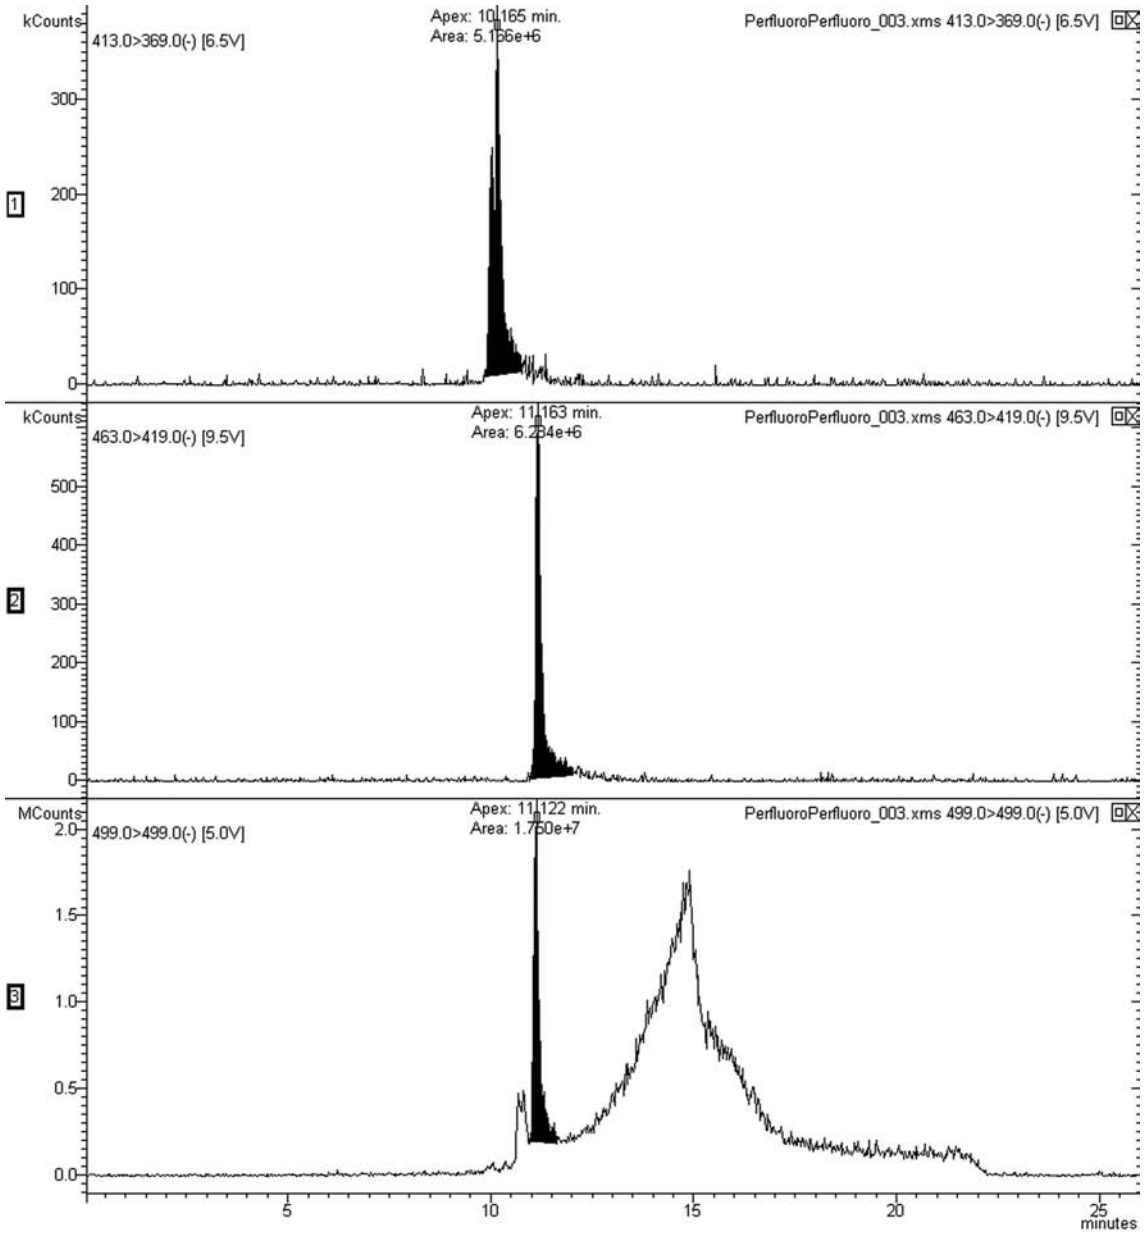

Figure 1. Separation of PFOA, PFNA, and PFOS achieved with fluorinated stationary phase using an Agilent 1290 UHPLC with a J-320 mass spectrometer.

analyte was different; with HFTB the MeOH content was in the range of 62−63%, and with ammonium acetate the content was in the range of 83−84%.

Thus, the use of polyfluorinated alcohols can enhance the separation of fluorinated compounds, leading to alternative selectivity due to the fluoroalcohol competition over the C_{18} stationary phase surface. Fluoroalcohols tend to "stick" on the C_{18} surface, covering the surface with a fluorous layer and shifting the stationary phase properties nearer to a fluorinated stationary phase. This enhances the separation of PFAAs. On the other hand, the stationary phase has a negative charge on its surface due to the negatively charged HFTB molecules at pH 10. PFOS and PFNA are deprotonated at pH 10, and the two anions are rather similar by their size and charge distribution. As a difference, however, the negative charge on the PFOS anion is more efficiently delocalized over the larger SO_3^- moiety than is possible in the PFNA anion's smaller CO_2^- moiety. This leads to more efficient solvation of the carboxylate center by water molecules than of the sulfonate center.[52,53] The negative charge localization in the PFNA anion leads to two consequences: (1) it is better solvated by the polar mobile phase and is thus less forced out of the mobile phase and (2) possibly the repulsion between the partially negatively charged stationary phase surface and the PFNA anion is stronger than the repulsion between the stationary phase and the PFOS anion, leading to decreased retention of the PFNA anion on the stationary phase, compared to the PFOS anion. This difference between the anions of PFNA and PFOS is small, however, and therefore their retention times are still very similar. In addition, their retention can be decreased due to the competition of buffer additive and analytes for the stationary phase surface.

Even though the MeOH content of eluent was lower at the analyte's retention time using 5 mM HFTB as additive, significant signal improvement (by 2−8 times in peak area) was

dx.doi.org/10.1021/jf5007243 | J. Agric. Food Chem. 2014, 62, 5259−5268

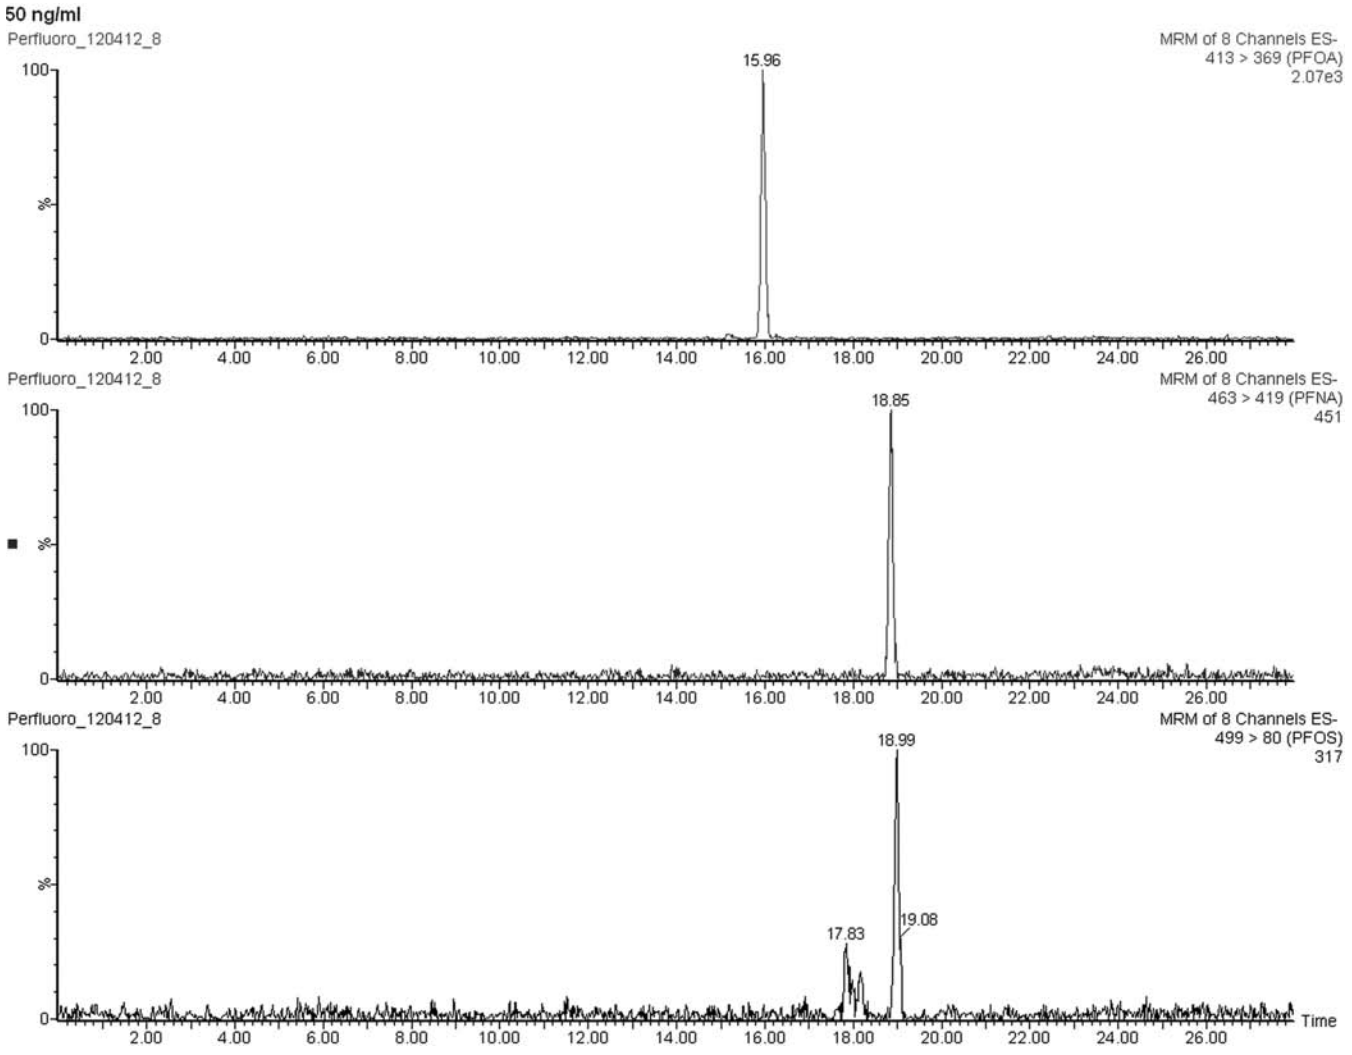

Figure 2. Chromatographic separation of PFOA, PFNA, and PFOS using 5 mM ammonium acetate at pH 10. The R_s between PFNA and PFOS is 0.7.

observed when using HFTB as eluent component when compared to the ammonium acetate at low analyte concentrations (10 ng/mL) (Figure 4).

Method Validation. For the calibration graph solutions, appropriate dilutions from working standard in the concentration range of 1−600 ng/mL (n = 14) for PFOA, PFNA, and PFOS were made in MeOH. The overall range was divided into three independent narrower calibration ranges: 1−15 ng/mL (n = 5), 15−110 ng/mL (n = 6), and 110−600 ng/mL (n = 5). The calibration graphs showed adequate linearity in the narrower concentration ranges ($r^2 \geq 0.9902$). An unweighted linear regression analysis of representative calibration curves resulted in slopes of 17.3 (PFOA), 18.2 (PFNA), and 4.0 (PFOS) in the lower concentration region and of 13.5 (PFOA), 14.3 (PFNA), and 2.5 (PFOS) in the higher concentration region. The intercepts of the calibration curves were taken into account for PFOA (50.6), PFNA (5.9), and PFOS (1.1) in the lower concentration range and for PFOA (499.6), PFNA (600.6), and for PFOS (186) in the higher concentration range.

Spiking experiments for method validation were performed so that concentrations in samples corresponded to 1, 10, and 100 μg/kg. Samples were spiked before the second homogenization step with 1 mL of spiking solutions with different concentrations (7.5, 75, and 750 ng/mL) and mixed thoroughly. After homogenization, 14 mL of acetonitrile was added and the procedure was continued as described above.

The average process efficiency (including sample preparation recovery and matrix effect) for the studied compounds was in the range of 99−116% and exceptionally 115−143% for PFOS in the low concentration range. The matrix effects were evaluated using post extraction spiking (salmon extract) and a signal-enhancing effect was determined: up to 120−141% for PFOA, 136−178% for PFNA, and 132−189% for PFOS. The recovery rates were estimated over the calibration range and were in the ranges of 88−133% for PFOA, 85−108% for PFNA, and 70−98% for PFOS.

The LOQ and LOD were estimated (as 10 and 3.3 times the standard deviation, respectively) from six replicate analyses of unspiked and pre-extraction spiked salmon samples (Figure 5).

Method accuracy and precision were estimated from the spiked salmon samples at the three concentrations of 1, 10, and 100 μg/kg. Accuracy was estimated as the closeness of mean test results obtained by the method to the true concentration value of the analyte and ranged from 2 to 9% for all analytes at high, medium, and low concentrations.

Precision was estimated as coefficient of variation (CV) at three concentration levels and is presented in Table 2.

dx.doi.org/10.1021/jf5007243 | J. Agric. Food Chem. 2014, 62, 5259−5268

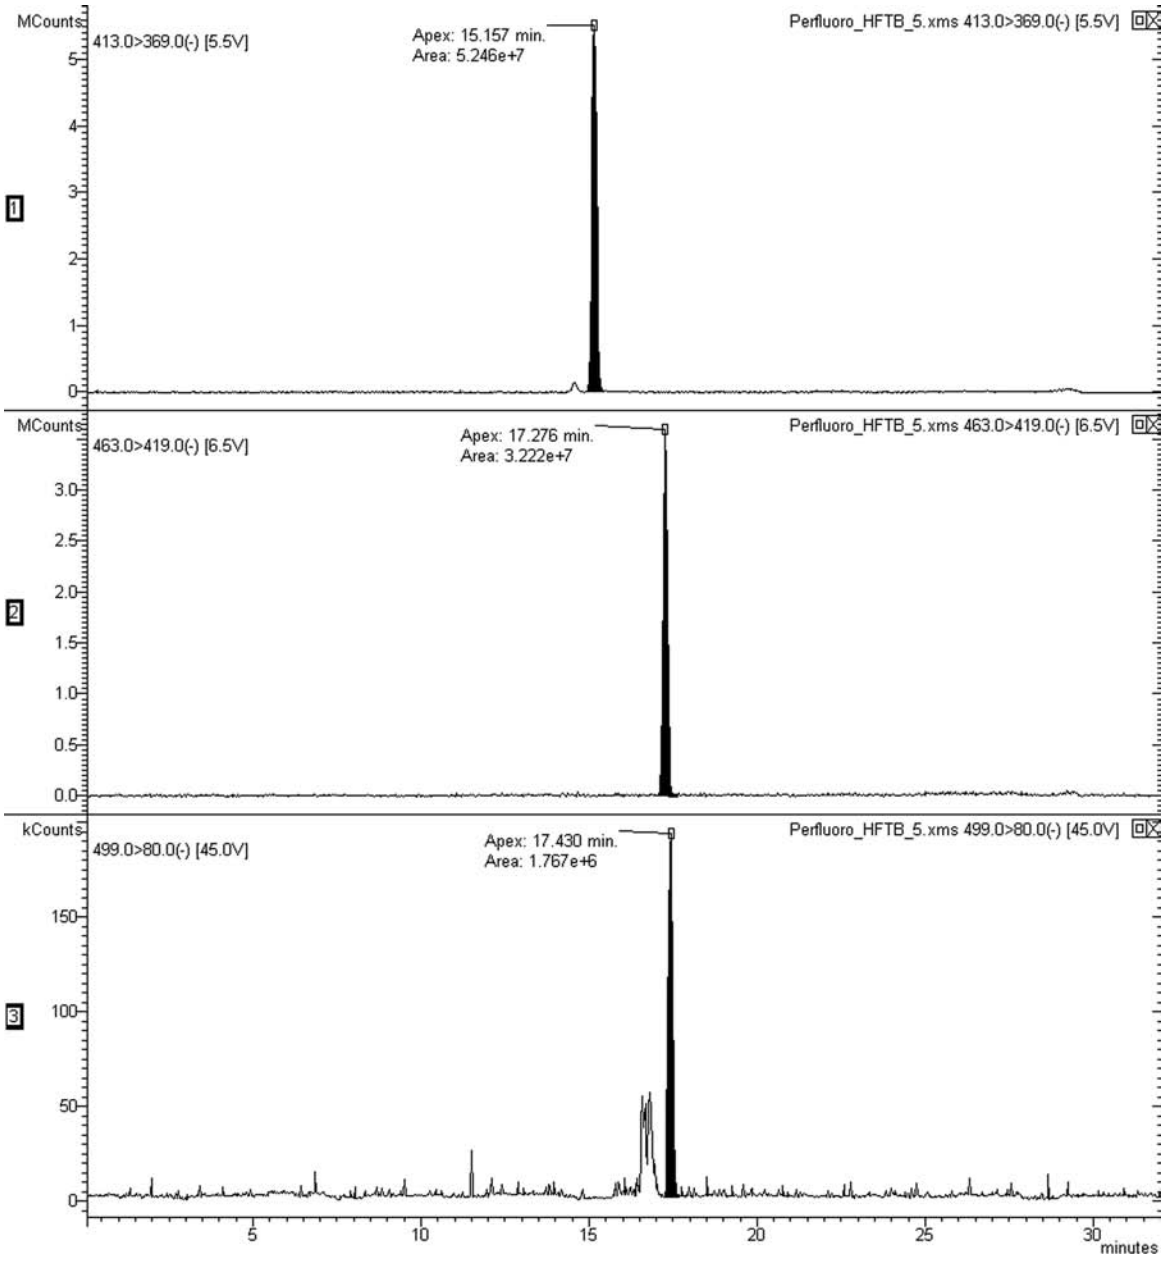

Figure 3. Standard solution analyzed using an Agilent 1290 UHPLC with a J-320 MS and 5 mM HFTB as eluent component. The R_s between PFNA and PFOS is 1.1.

It has been stressed that due to the Teflon tubing of chromatographic systems a significant contamination of PFAAs might occur and therefore a trapping column has been used, which catches PFAAs originating from tubing.[49] In this work a trapping column was not used and blank injections were monitored constantly to determine the extent of contamination, and the average area of blank injection peaks within sequences was subtracted from standard and sample chromatograms.

Method Application to Fish Samples. For practical application this method was transferred to a different LC-MS system, validated for the Estonian Health Board Tartu laboratory, and tested on number of samples available in Estonia.

Of the 20 analyzed samples, 7 originated from the Baltic sea, 3 from Norway, 4 from fresh water fish farms, and 6 from fresh waters of Estonia. All of the samples were analyzed twice on two separate days. The content of PFOA remained below the LOD in all samples. PFNA was found to be present at low concentrations in seven samples, and in two cases the content exceeded the LOQ. PFOS was found to be present in six samples, and the concentration exceeded the LOQ in three samples (see Table 1).

Due to the low salinity of the Baltic Sea many species that usually live in fresh water can also be found in marine water. The obtained results for the fish samples from the Baltic Sea are comparable with previous studies.[54] PFC bioaccumulation in organisms has increased significantly, and the research conducted in the Baltic Sea area has focused on analyzing fish, predatory mammals, and birds. The concentrations of PFAAs is significantly higher in mammals and birds.[55,56]

PFOS is one of the core indicators for the Baltic Marine Environment Protetction Commission (HELCOM), and its levels in fish livers and muscle have been analyzed overa long

dx.doi.org/10.1021/jf5007243 | J. Agric. Food Chem. 2014, 62, 5259−5268

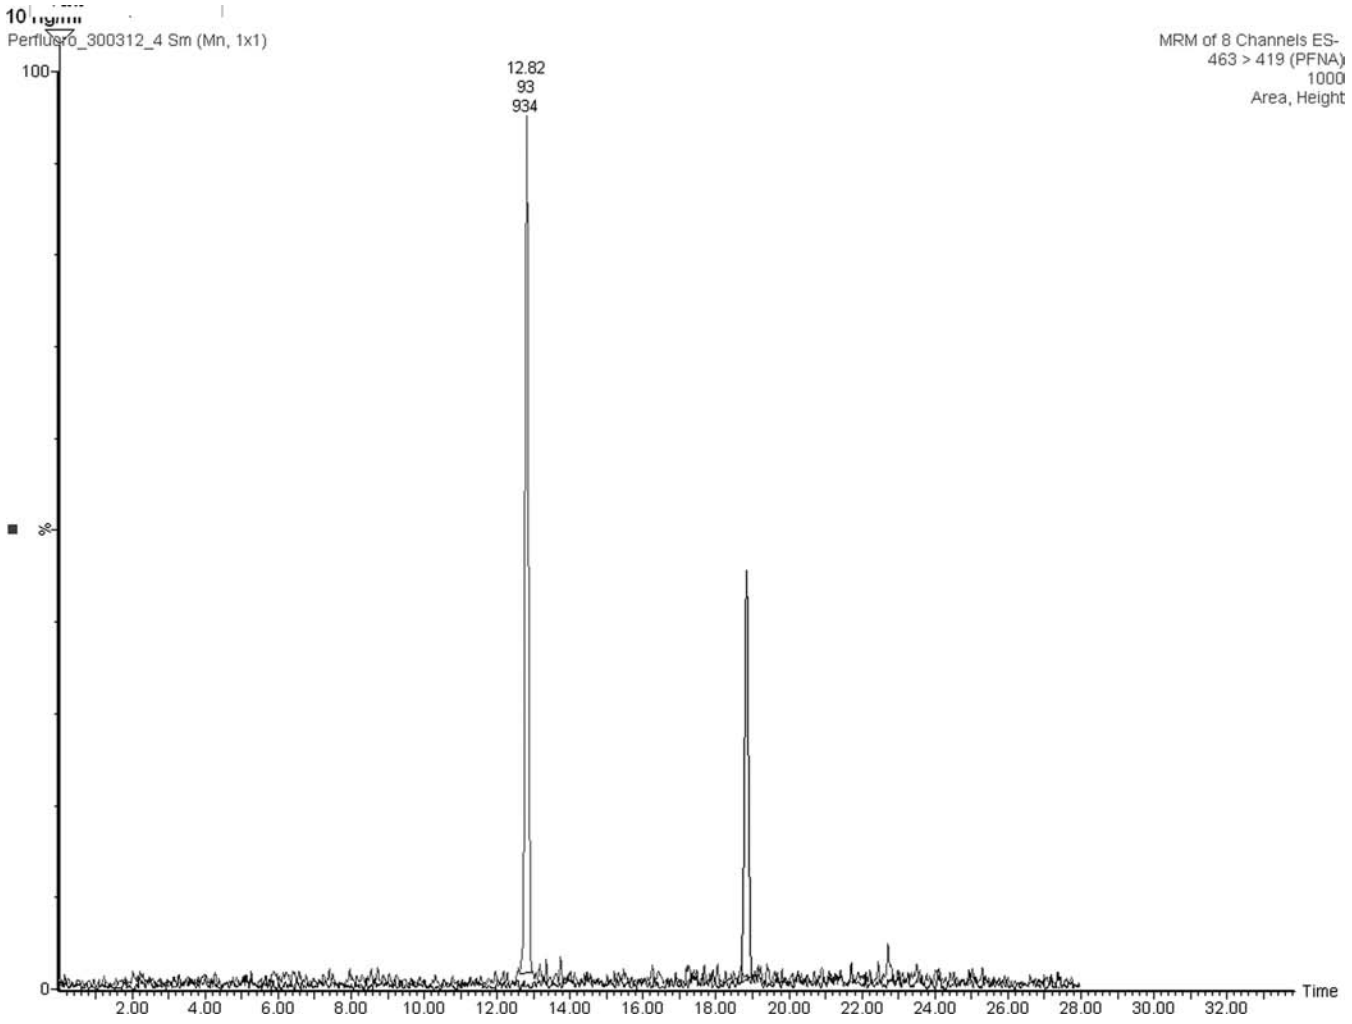

Figure 4. Overlaid PFNA signals obtained by injecting a 10 ng/mL solution under the same chromatographic gradient and mass spectrometric conditions as in the cases of HFTB (t_r = 12.82 min) and ammonium acetate (t_r = 18.85 min) buffer additive.

period of time. Concentrations of PFOS have been dependent on the species of fish and catching area, showing elevated levels of PFOS from parts of the Baltic Sea where industrial activity is more intense.[56]

In 2010 Hradkova et al. analyzed the contents of PFOA, PFOS, and perfluorooctane sulfonamide in canned fish products available in Czech Republic and found that most contaminated samples originated from the Baltic Sea.[58] Their study showed also that concentrations of PFOS and PFOA vary to a great extent despite the similarities between samples; one particular type of sample originating from the same country (sardines in oil) contained PFOS from below the LOQ (0.3 μg/kg) to 12.8 μg/kg and PFOA from below the LOQ (0.2 μg/kg) to 5.1 μg/kg of PFOA, which is supposedly related to the catch site.[57] Similar variations of PFOS and PFOA contents were also shown by Lacina et al. in the case of canned cod liver originating from the Baltic Sea.[49]

In the current work, similarly to previous studies, PFOS was found to be in higher content than other PFAAs. However, the content of PFOS was higher in fish samples originating from the Baltic Sea than compared with fresh water. Obtained results are diverse compared with previous studies.[54,59] This can be explained by a lower population density and the lack of intense industrial activity in Estonia compared with Germany and Sweden.

QuEChERS-type sample preparation with cleanup has proven to be a reliable method on many occasions when different types of contaminants such as pesticides, acrylamide, and mycotoxins have been analyzed in food samples.[60−62] Sample preparation is fast and simple and removes unwanted sample components such as fats, proteins, and starch from the extract.

Conclusions. This work describes an alternative method for LC-MS/MS analysis of perfluorinated compounds in fish using a novel eluent additive. The method uses simplified sample treatment but still provides sufficient LC selectivity and enhanced signal intensities for analytes. An important factor for achieving this is applying polyfluorinated alcohol (HFTB) in the chromatographic separation. Brief monitoring of Estonian fresh and marine water fish was carried out, and the content of PFAAs was low.

MATERIALS AND METHODS

Reagents, Materials, and Apparatus. HA, HIS, tyramine (TYR), phenylethylamine (PEA), 3-mercaptopropyltriethoxysilane (MPTES), and tetraethoxysilane (TEOS) were supplied by Sigma-Aldrich (St. Louis, MO, USA). Polyvinyl chloride (PVC, M_w = 8000) and dichloromethane (DCM) were obtained from Alfa Aesar (Tianjin, China). Methanol, acetonitrile, NaH_2PO_4, Na_2HPO_4, and other reagents were purchased from Tianjin No. 1 Chemical Reagent Factory (Tianjin, China). All chemicals were analytical reagent grade. Cans of sardines, mackerel, saury, tuna, salmon, and Spanish mackerel for sample analysis were purchased from a local market.

Phosphate-buffered saline (PBS; pH 7.6) was prepared by mixing 0.2 M NaH_2PO_4 with 0.2 M Na_2HPO_4 (1:4 v/v).

Frequency change (Δf, Hz) was recorded using a QCM (QCM-922, Princeton Applied Research, Princeton, NJ, USA) equipped with a quartz crystal resonator (AT-cut, 9 MHz, platinum electrode (0.196 cm^2, 100 Å), Princeton Applied Research) and Teflon holder (Princeton Applied Research). The quartz crystal was positioned in the Teflon holder to ensure that only one side of the Pt electrode was in contact with the solution. The holder was placed vertically in a static detection cell to minimize any gravity-induced precipitation on the crystal surface. A magnetic stirrer (HJ-6A, Jin Tan Sheng Lan Instrument Co., Jiang Su, China) was used throughout the experiments to ensure homogeneous and complete interaction between agents. UV spectrophotometer (Cary 50-Bio, Varian, Palo Alto, CA, USA) was used to evaluate the ability of the MIP to adsorb the analyte. The morphology of the modified quartz crystals was investigated by scanning electron microscopy (SEM, SU1510, Hitachi, Tokyo, Japan). An HPLC analyzer (LC-10ATVP, Shimadzu, Kyoto, Japan) was used to validate the results obtained for real samples using the HA-MIP QCM sensor.

Sol–Gel Synthesis of HA-MIP. A novel HA-imprinted polymer was synthesized through hydrolytic cross-linking of silanol groups using a sol–gel process as follows: HA (0.10 g) was dissolved in methanol (5.0 mL) and mixed with MPTES (0.5 mL) in a 25 mL round-bottomed flask. After 30 min, TEOS (1.09 mL) and 0.1 M $NH_3{\cdot}H_2O$ (0.5 mL) were added and the mixture was incubated at 55 °C in a water bath for 12 h. The product was filtered and then aged in a vacuum oven at 60 °C for 10 h. After protonation in a mixture of CH_3OH and 1.0 M HCl (4:1 v/v, 100 mL) for 4 h, the solid product was collected by vacuum filtration and rinsed with deionized distilled water until the eluent reached neutral pH. Then, the product was dried in a vacuum oven at 60 °C until constant weight was obtained. The original template was removed by Soxhlet extraction in a mixture of methanol and acetic acid (9:1 v/v, 300 mL) until no HA was detected by UV absorbance measurement at 210 nm. The obtained polymer was dried in a vacuum oven at 60 °C and stored hermetically until further use. All solutions were mixed by gentle magnetic stirring to ensure homogeneous distribution and complete interaction between agents. Nonimprinted polymer (NIP) was also prepared in a manner identical to that used to synthesize MIP, except that the template was omitted.

Adsorption of HA-MIP. HA-MIP (20.0 mg) was mixed with PBS (5.0 mL, pH = 7.6) containing different concentrations of HA (10, 20, 30, 40, 60, 80, 100, and 120 mg L^{-1}) in polypropylene centrifuge tubes. After vigorous shaking at 150 rpm for 2 h and centrifugation at 4500*g* for 10 min, the amount of unbound HA in each supernatant was determined by UV absorbance measurement at 210 nm. The adsorption capacity (Q, mg·g^{-1}) of HA-MIP was calculated as follows:

$$Q = (C_i - C_f) \times V/W \quad (1)$$

where C_i and C_f are the initial and final concentration of analyte in solution, respectively (mg L^{-1}), V is the volume of solution (L), and W is the mass of polymer (g).

Scatchard analysis of binding isotherms was used to evaluate the binding capacity of HA-MIP for the template. The relevant equation is

$$Q/C = (-Q + Q_{max})/K_d \quad (2)$$

where C is the initial concentration of analyte in solution (mg L^{-1}), Q is the adsorption capacity at adsorption equilibrium (mg·g^{-1}), K_d is the equilibrium disassociation constant at the binding site (mg L^{-1}), and Q_{max} is the saturated adsorption capacity (mg·g^{-1}).[25−27]

The NIP was also tested using the above procedure. Mean adsorption values obtained from triplicate measurements of MIP and NIP were determined and compared.

Modification of a Quartz Crystal Surface with HA-MIP. Before modification, the quartz crystal electrode surface was cleaned in piranha solution (30% H_2O_2:98% H_2SO_4; 1:3 v/v) for 2 min to remove possible residual chemicals, and thoroughly rinsed with deionized water. HA-MIP or NIP (48.50 mg) was suspended in PVC-DCM (0.7 wt % solution). After ultrasonication to obtain a homogeneous solution, 5.0 μL of the mixture was carefully dispensed onto the immobilized quartz crystal surface. The modified quartz crystal was dried (30 min, 25 °C) and stored at room temperature in a vacuum chamber before use. Figure 1 outlines the processes of HA-MIP sensor construction and adsorption.

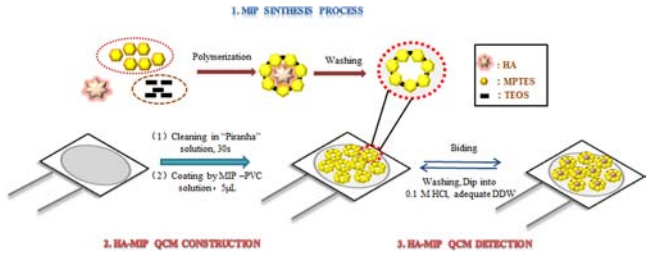

Figure 1. HA-MIP sensor construction and adsorption.

QCM Sensor Detection. After anchoring of the prepared quartz crystal into the Teflon holder, the assembled HA-MIP QCM sensor was immersed in PBS (20.0 mL) at room temperature. A steady resonant frequency (f_0, Δf < 1.0 Hz) was obtained after equilibration for 5 min. A small aliquot of analyte solution was injected into the solution. After equilibration for 5 min, a stable frequency change caused by analyte binding was obtained and recorded. After each test, the MIP-modified quartz crystal was washed with 0.1 M HCl and deionized water until the frequency recovered to f_0 and the crystal could be reused. Throughout the entire testing process, the solution was stirred at 240 rpm to accelerate the transmission of analyte. Analyses were performed in triplicate, and the average value of the obtained frequency shift (Δf, Hz) was used to calculate the mass of HA adsorbed onto the crystal surface according to the Sauerbrey equation:[28]

$$\Delta f = -2.26 \times 10^{-6} \Delta m f_0^{\,2}/A \quad (3)$$

where f_0 is the original frequency of the quartz crystal (Hz), Δm is the mass change (g), and A is the surface area of the electrode (cm^2).

For comparison, the NIP-modified QCM sensor was also tested using the same procedure.

Sample Preparation for HA-MIP QCM Sensor Analysis. Sample slurry (1.0 g) was mixed with $HClO_4$ (10.0 mL, 0.4 M) to induce protein precipitation. After homogenization for 15 min, the mixture was centrifuged. The collected supernatant was extracted with *n*-hexane (2:1 v/v) for further fat separation; the *n*-hexane supernatant was discarded. The defatting procedure was repeated twice, and then the product was dried using a rotary evaporator at 45 °C. The residue was redissolved in PBS (20.0 mL, pH = 7.6) and analyzed using the HA-MIP QCM sensor.

For the recovery test, slurries of sardine, mackerel, or saury were spiked with HA at 25, 100, and 400 μg kg^{-1}; the procedure used to extract HA was the same as that described above.

Sample Pretreatment for HPLC Analysis. HPLC was used to confirm the accuracy of the developed sensor. The procedure up until rotary evaporation was the same as described above; the residue was then reconstituted with $HClO_4$ (4.0 mL, 0.4 M) and derivatized as described in previous literature[29] with slight modification. The

dx.doi.org/10.1021/jf501092u | J. Agric. Food Chem. 2014, 62, 5269−5274

redissolved solution (1.0 mL) was placed in a 5 mL brown volumetric flask. NaOH (200 μL, 2.0 M), saturated $NaHCO_3$ (300 μL), and dansyl chloride (4.0 mL, 0.02 M) were added in succession. After incubation at 60 °C for 30 min, $NH_3{\cdot}H_2O$ solution (100.0 μL, 25 wt %) was added to remove excess dansyl chloride. Each solution was adjusted to 5.0 mL with acetonitrile and filtered through a 0.22 μm filter before HPLC analysis.

HPLC Analysis. In HPLC analysis, an analytical octadecylsilyl-3 column (4.6 × 250 mm, 5 μm particle size, Shimadzu) was used with acetonitrile:water (65:35 v/v) as the mobile phase at a flow rate of 1.0 mL min^{-1}. The injection volume and detection wavelength were 20 μL and 254 nm, respectively. All spectral and chromatographic data were obtained and processed using Class-VP software.

RESULTS AND DISCUSSION

Adsorption of HA-MIP. The abilities of the prepared MIP and reference NIP to adsorb HA were evaluated in PBS (pH = 7.6) containing different concentrations of HA. The adsorption isotherms of the polymers were obtained and assessed by Scatchard analysis (Figure 2). As shown in Figure 2A, with

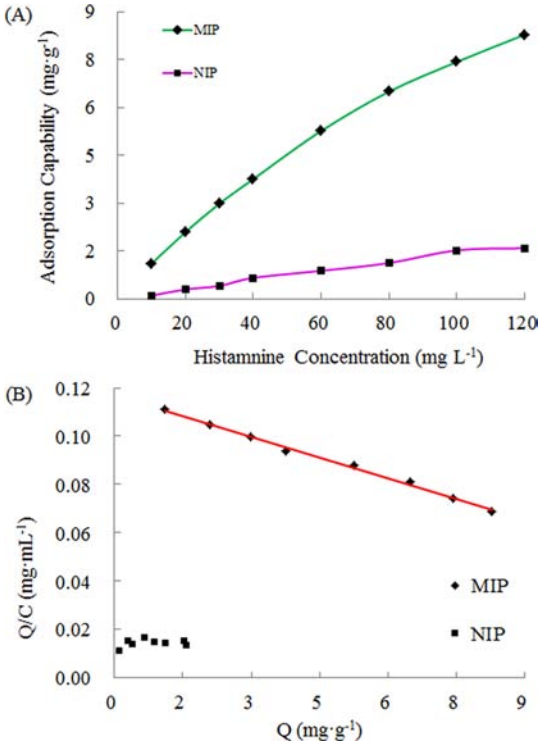

Figure 2. (A) Binding isotherms and (B) Scatchard plots of MIP and NIP for HA.

increasing HA concentration, the adsorption capacities (Q, mg·g^{-1}) of both the MIP and NIP increased. At an HA concentration of 120 mg L^{-1}, Q of MIP (8.28 mg·g^{-1}) was 5.2 times that of NIP (1.60 mg·g^{-1}), indicating that MIP has a markedly greater ability than NIP to adsorb HA. The Scatchard plot in Figure 2B reveals that a good linear relationship between Q/C and Q (mg·g^{-1}) was obtained of $Q/C = -0.0057Q + 0.1169$, with a correlation coefficient of 0.9964. K_d and Q_{max} calculated using this model were 175.44 mg L^{-1} and 20.51 mg·g^{-1}, respectively, suggesting that the MIP has a high affinity for HA. These results also demonstrate that recognition sites or cavities (presumably based on the acid−base pair resulting from the reaction between $-NH_2$ of HA and −SH of MPTES) form in the MIP; these would play an important role in the selective recognition of HA by the MIP. The nonlinearity of the Scatchard model plot for the NIP (Figure 2B) was caused by the disordered arrangement of recognition sites in the NIP system resulting from the lack of template during the polymerization process. The lower adsorption of HA by the NIP compared with that by the MIP could be attributed to the lack of specific binding sites within the polymer matrix.

Optimization of the PVC:HA-MIP Ratio. In this experiment, PVC was chosen as the matrix material to immobilize the prepared HA-MIP particles on the quartz crystal, because the recognition sites of a MIP encapsulated in PVC are easily accessible to the template[30] and the solubility of PVC in DCM could enhance the processability of the insoluble MIP.[31] The PVC:HA-MIP ratio used to modify the quartz crystal surface affected the capability of the prepared HA-MIP QCM sensor. Although more PVC could enhance the attachment of MIP particles, the amount of MIP immobilized on the surface of the quartz crystal was decreased, reducing the sensitivity and specificity of the modified sensor. Therefore, to ensure maximum and steady adsorption of HA on the quartz crystal surface, the amount of MIP used should be as large as possible while still effective adhering to the crystal. In this work, frequency changes (Δf) of HA-MIP QCM sensors prepared using PVC-DCM solutions (0.7 wt %) containing various ratios of PVC to MIP (PVC:MIP = 1:1, 1:2, 1:3, 1:4, 1:5, and 1:6 m/m) were compared at the same HA concentration (4.45×10^{-2} mg L^{-1}). Δf increased with the ratio of PVC to MIP until it reached 1:5. Adding further MIP (1:6) caused Δf to decrease sharply. Based on these results, a ratio of PVC to MIP of 1:5 was chosen for modification of the QCM sensor.

Morphological Characterization. SEM was used to evaluate the morphology of the HA-MIP-modified quartz crystal surface (Figure 3). Figure 3A shows that the layer containing MIP was completely adhered to the transducer surface, with a relatively uniform dispersion of polymer particles. Compared with the bare electrode (Figure 3B), the modified one possessed a much rougher surface, which provided a larger surface area for the specific adsorption of the target molecule.

Influence of Test Solution pH on QCM Detection. In the process of HA recognition, the HA-MIP QCM sensor selectively recognizes HA through the acid−base interaction between the immobilized −SH groups of the sensor and $-NH_2$ group of HA; the latter is affected by the adsorption microenvironment, particularly pH. Therefore, it is necessary to optimize the pH of the test solution so that the analyte readily adsorbs onto the prepared sensor. HA solutions (4.45×10^{-2} mg L^{-1}) with different pH ranging from 6.0 to 8.8 were prepared in PBS for frequency analysis. Δf increased slowly for pH 6.0−6.8, before reaching a peak at pH 7.6; it then decreased continuously as the solution pH value increased beyond 7.6. This phenomenon might be attributed to the competition between the abundant H^+ and −SH to react with $-NH_2$ of HA under acidic conditions. The interaction between HA and MPTES would be decreased by the abundance of OH^- groups when the pH exceeded 7.6. Therefore, the optimum pH of the test solution was 7.6, which was used in further tests to guarantee excellent recognition ability of the developed QCM sensor.

Evaluation of Binding Performance. The frequency responses of the MIP and NIP QCM sensors for HA were compared in solutions with HA concentrations ranging from 0.11×10^{-2} to 6.67×10^{-2} mg L^{-1} to evaluate their specific

dx.doi.org/10.1021/jf501092u | J. Agric. Food Chem. 2014, 62, 5269−5274

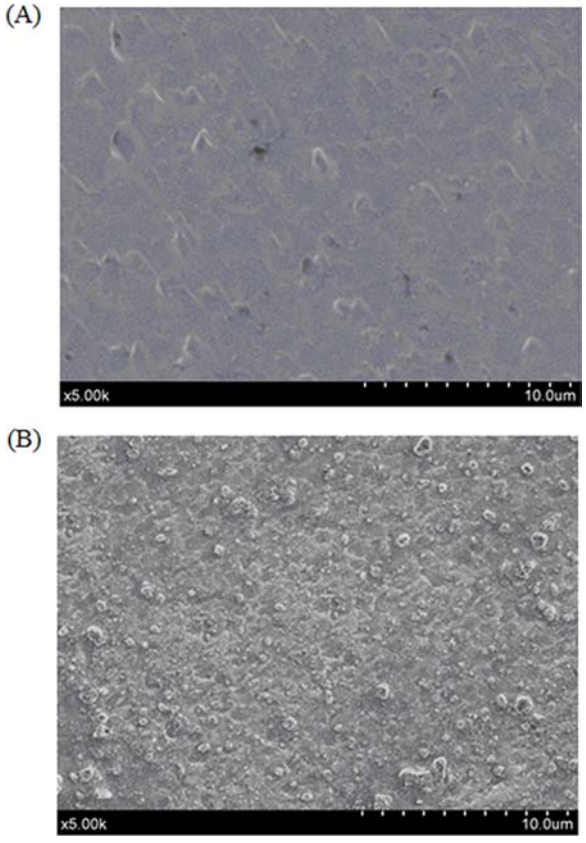

Figure 3. SEM images of the surface of a quartz crystal (A) before and (B) after HA-MIP modification.

adsorptive capability; the results are presented in Figure 4. Δf increased with HA concentration for both modified sensors. At

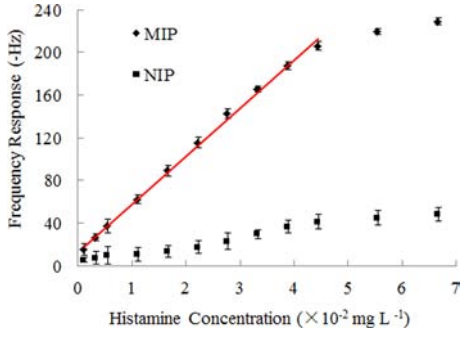

Figure 4. Frequency responses of MIP and NIP QCM sensors in solutions containing different concentrations of HA.

any particular concentration, the HA-MIP QCM sensor showed a larger frequency response than the NIP one, demonstrating the differential binding capability of the MIP sensor for HA. At an HA concentration of 6.67×10^{-2} mg L^{-1}, the frequency change for the MIP sensor was −229.0 Hz, about 5 times that of the NIP one (−45.0 Hz). This might be caused by imprinting the MIP with HA, which caused cavities that specifically fit HA in terms of spatial structure and functional groups to form during polymerization. The frequency response tended to equilibrate at HA concentrations above 6.67×10^{-2} mg L^{-1}, because the MIP became saturated with adsorbed HA. The small response of the NIP-modified QCM sensor is attributed to nonspecific adsorption of HA.

Good linearity of the relationship of frequency change with concentration was obtained for HA concentrations from 0.11×10^{-2} to 4.45×10^{-2} mg L^{-1} (correlation coefficient = 0.9978). The calculated detection limit (S/N = 3) of the MIP QCM sensor for HA was 7.49×10^{-4} mg kg^{-1}, which is lower than that for HA by HPLC (0.054 mg kg^{-1}).[6]

A PVC-modified QCM sensor did not show any detectable frequency response to HA at selected concentrations, indicating that PVC used to immobilize the MIP on the electrode surface did not affect the specific recognition of HA by the proposed sensor.

Kinetic and Selectivity Experiments. The adsorption kinetics of the developed sensor were tested in PBS containing HA (4.45×10^{-2} mg L^{-1}, pH = 7.6) under continuous stirring. A steady frequency response (−206.1 Hz) was obtained within 10 min, indicating that the HA-MIP QCM sensor could achieve adsorption equilibrium in a short period, which would be helpful for rapid detection of HA.

The selectivity (or specificity) of the prepared QCM sensor is another important parameter to evaluate. For this purpose, different concentrations (0.11×10^{-2} to 4.45×10^{-2} mg L^{-1}) of TYR, HIS, and PEA (Figure 5A), which are structurally

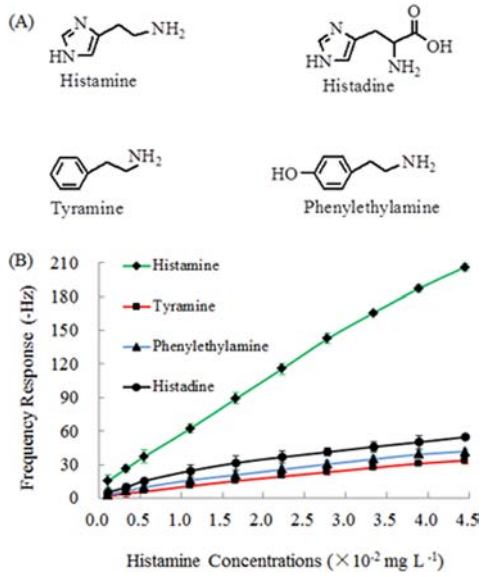

Figure 5. (A) Chemical structures of HA, HIS, TYR, and PEA. (B) Selectivity of the HA-MIP QCM sensor for different analytes.

similar to HA, in PBS (pH = 7.6) were tested with the HA-MIP QCM sensor. The selectivity coefficient (SC), defined as $\alpha_{HA}/\alpha_{analyte}$, where α is the slope of the analyte calibration curve, was used to assess the selectivity of the HA-MIP QCM sensor for HA. The detection results illustrated in Figure 5B reveal much weaker frequency responses for HIS, TYR, and PEA than for HA with SC of 4.18, 6.43, and 5.17, respectively, indicating that the developed sensor has excellent selectivity and specificity for HA. This selectivity results from the tuned cavities of the HA-MIP that are complementary to HA in size, shape, and functional groups.

Reproducibility and Stability. The reproducibility and stability of the developed QCM are important for successful HA detection. Therefore, the same HA-MIP QCM sensor was used to evaluate the frequency change in PBS containing HA (4.45×10^{-2} mg L^{-1}, pH = 7.6) 7 times continuously. After each test, the imprinted sensor was washed with 0.1 M HCl and

dx.doi.org/10.1021/jf501092u | J. Agric. Food Chem. 2014, 62, 5269−5274

deionized water sequentially until the resonance frequency reached its original value. The frequency change during repeated testing decreased slightly from 206.1 to 196.3 Hz; this loss of just 4.8% confirmed the good recyclability and stability of the MIP QCM sensor for HA detection. The stability of the HA-MIP QCM sensor over a long period of time was also demonstrated. After hermetic storage at room temperature for 6 months, the average frequency shift of the quartz crystal was 195.0 Hz, which is only 5.4% less than the initial frequency shift of 206.1 Hz. This result further confirms the excellent stability of the developed QCM sensor, which suggests that the MIP is also highly stable.

Recovery Test. Samples of canned sardines, saury, and mackerel were spiked with HA at three levels (25, 100, and 400 $\mu g\ kg^{-1}$). The HA concentration of each sample was detected 3 times under the same conditions. The relative standard deviation (RSD, %) of the repeated measurements was calculated to determine the precision of the method; the results are listed in Table 1. The overall precision ranged from 0.3 to 4.4%, and the recovery values were also good, ranging from 93.2 to 100.4%, suggesting that results obtained using the HA-MIP QCM sensor were both accurate and reproducible.

Table 1. Recoveries of HA from Spiked Food Samples Determined by the HA-MIP QCM Sensor (n = 3)

sample	orig concn ($\mu g\ kg^{-1}$), mean ± SD	spiked concn ($\mu g\ kg^{-1}$)	detected concn ($\mu g\ kg^{-1}$), mean ± SD	RSD (%)	recovery (%)
canned sardines	67.7 ± 0.1	25	92.8 ± 1.9	2.0	100.4
		100	167.1 ± 2.5	1.5	99.4
		400	446.8 ± 2.6	0.6	94.8
canned saury	55.2 ± 0.5	25	79.8 ± 3.5	4.4	98.4
		100	148.4 ± 2.1	1.4	93.2
		400	429.3 ± 1.1	0.3	93.5
canned mackerel	102.7 ± 0.3	25	127.9 ± 1.1	0.9	100.2
		100	200.8 ± 1.4	0.7	99.1
		400	494.6 ± 3.5	0.7	98.4

Actual Sample Analysis. Using the established sample pretreatment method, the concentration of HA in six different samples (canned sardines, mackerel, saury, tuna, salmon, and Spanish mackerel) was measured by the HA-MIP QCM sensor. The results of these measurements are shown in Table 2.

HPLC Validation. Traditional HPLC was used to validate the results obtained using the HA-MIP QCM sensor. The concentration of HA in six different samples (canned sardines, mackerel, saury, tuna, salmon, and Spanish mackerel) was determined by HPLC. The results of both methods were recorded, and the regression equation was calculated to be $y = 1.0086x - 0.0214$ with a correlation coefficient of 0.9965, signifying the accuracy of the HA-MIP QCM sensor.

Table 2. Content of HA in Samples Detected by the HA-MIP QCM Sensor and HPLC (n = 3)

	HA-MIP QCM sensor		HPLC	
sample	detected concn ($\mu g\ kg^{-1}$), mean ± SD	RSD (%)	detected concn ($\mu g\ kg^{-1}$), mean ± SD	RSD (%)
canned sardines	76.7 ± 1.5	2.0	67.7 ± 0.1	0.1
canned tuna	299.0 ± 1.6	0.5	278.4 ± 0.5	0.2
canned salmon	669.4 ± 3.9	0.6	666.3 ± 1.2	0.2
canned mackerel	111.5 ± 1.7	1.5	102.7 ± 0.3	0.3
canned Spanish mackerel	463.8 ± 2.5	0.5	427.6 ± 0.7	0.2
canned saury	91.4 ± 2.6	2.8	55.2 ± 0.5	0.9

Compared with HPLC, the developed QCM sensor enhanced HA detection efficiency greatly because it is sensitive, easy to operate, stable for more than 6 months, and portable for field analysis, and it does not require pre- or postcolumn derivation. The results show that the MIP-based QCM sensor can be used for accurate HA detection in food samples.

1-butyl-3-methylimidazolium tetrafluoroborate		BF_4^-

solvent extraction is common, popular, and yet with unavoidable disadvantages, for example, contamination to the environment and human health. Until now, IL-based one-step micellar extraction has not been applied for the analysis of multiclass compounds in sample preparation, and no work has been reported on the use of IL-micelles for the extraction of hydrophobic and hydrophilic components from food samples.

Hawthorn is well-known as both a fruit and food supplement in Europe and China. Recent studies have demonstrated that hawthorn fruits were mainly used in the treatment of indigestion, hyperlipidemia, hypertension, abdominal pain, and amenorrhea for many years.[20] Several analytical methods including high-performance liquid chromatography (HPLC),[21] capillary electrophoresis (CE),[22] and liquid chromatography–mass spectrometry (LC-MS)[23] have been reported to analyze the bioactive constituents, especially phenolic compounds, of this fruit. However, to date, there are no studies related to the utilization of a sub 2 μm particle size column-based LC system for the separation of hawthorn samples, especially coupled with Q-TOF/MS.

In the current study, an IL-based one-step micellar extraction followed by UHPLC-Q-TOF/MS was established and further applied for the determination of multiclass phenolic compounds (protocatechuic acid, chlorogenic acid, epicatechin, hyperoside, isoquercitrin, quercetin) in hawthorn fruits. The effects of various experimental parameters, such as selection of ILs and surfactant concentration, as well as extraction time, were investigated systematically. The proposed method is environmentally friendly with good repeatability and is expected to have wider utilization instead of organic solvents in the future.

MATERIALS AND METHODS

Reagents and Samples. The ionic liquids tested in the present study, including 1-ethyl-3-methylimidazolium bromide ([emin]Br), 1-hexyl-3-methylimidazolium bromide ([hmin]Br), 1-butyl-3-methylimidazolium methanesulfonate ([bmim]SO_3), 1-butyl-3-methylimidazolium tetrafluoroborate ([bmin]BF_4), 1-dodecyl-3-methylimidazolium chloride ([C_{12}mim]Cl), 1-dodecyl-3-methylimidazolium bromide ([C_{12}mim]Br), 1-dodecyl-3-methylimidazolium trifluoromethanesulfonate ([C_{12}mim]CF_3SO_3), 1 -dodecyl-3-methylimidazolium nitrate ([C_{12}mim]NO_3), and 1-dodecyl-3-methylimidazolium hydrogen sulfate ([C_{12}mim]HSO_3), were purchased from Chengjie Chemical Co. Ltd. (Shanghai, China) and used without further purification (Table 1). HPLC grade methanol and acetonitrile were obtained from Sigma-Aldrich, Inc. (St. Louis, MO, USA). All other chemicals were of

dx.doi.org/10.1021/jf501171w | J. Agric. Food Chem. 2014, 62, 5275−5280

analytical grade (Aladdin Reagent Inc., Shanghai, China), and ultrapure water (Milli-Q system) was used throughout.

Analytical standards of protocatechuic acid (1), chlorogenic acid (2), epicatechin (3), hyperoside (4), isoquercitrin (5), and quercetin (6) were provided by Shanghai Winherb Medical Technology Co., Ltd. (Shanghai, China). The hawthorn fruits were obtained from a local drugstore in Hangzhou, China.

Preparation of Sample Solution. One gram of accurately weighed hawthorn fruit was extracted with 20 mL of various solvents (ionic liquids, water, or methanol) by ultrasonication for 40 min. The suspension was then filtered through a 0.2 μm disposable membrane filter and stored at room temperature before injection.

Instrumental Conditions. Chromatographic analysis was performed on a modular Agilent UHPLC system (Agilent 1290 Infinity LC, Agilent Technologies, Santa Clara, CA, USA) equipped with a vacuum degasser, a binary solvent delivery system, a thermostated autosampler, and a thermostabilized compartment. An Agilent Zorbax Extend-C_{18} column (2.1 mm × 50 mm, 1.8 μm) was used for separation at a room temperature of 35 °C. The mobile phase was a mixture of acetonitrile (A) and water with 0.1% formic acid (B) using a gradient elution of 10−15% A at 0−2.5 min, 15−15% A at 2.5−3.0 min, 15−40% A at 3.0−6.0 min, and 40−100% A at 6.0−7.0 min, with an equilibrium time of 5 min. The injection volume was 1 μL, and the flow rate was set at 0.4 mL/min.

This UHPLC system was connected to a 6530 Q-TOF/MS (Agilent Technologies) equipped with a dual ESI source, operating in the negative ion mode, using the following operation conditions: nebulizer pressure, 45 psig; drying gas, 12 L/min; gas temperature, 350 °C; capillary voltage, 3500 V; fragmentor voltage, 175 V; skimmer voltage, 65 V; octopole RF, 750 V. The data recorded were controlled by MassHunter software (version B 05.00 Qualitative Analysis), and the mass range was recorded in the range m/z 100−2000.

RESULTS AND DISCUSSION

Optimization of IL-Based Micellar Extraction. To obtain the highest extraction ratios for the investigated analytes, some parameters of micellar extraction such as type of IL, concentration of IL, and extraction time were explored systematically.

Selection of ILs. The structures of ILs have great impacts on their physical and chemical properties, such as density, viscosity, and solubility, which might greatly affect the micellar extraction yield of target compounds.[24] To find the optimal IL and evaluate its performance in the micellar extraction of six analytes of hawthorn fruit, 1-dodecyl-3-methylimidazolium type ILs with different anions were tested using protocatechuic acid, chlorogenic acid, epicatechin, hyperoside, isoquercitrin, and quercetin as model compounds. In this study, five long-chain ILs including $[C_{12}mim]Cl$, $[C_{12}mim]Br$, $[C_{12}mim]CF_3SO_3$, $[C_{12}mim]NO_3$, and $[C_{12}mim]HSO_3$ were compared as extraction solvents. These ILs have the same hydrocarbon chain length but different hydrophilic groups, presenting varied properties by different amphiphilic molecular structure. All five IL surfactants were found to be water-soluble and could enhance water miscibility of solutes. Actually, compared with traditional cationic surfactants, the investigated ILs with long chains were demonstrated to have significantly lower CMC values, which means these ILs more easily formed ionic surfactants. Figure 1 indicates that when the other conditions were constant, the anions of ILs strongly affected the extraction yield of the compounds of interest. Moreover, it shows that the extraction yields of hydrophobic and hydrophilic compounds were largely anion-dependent, which was consistent with a previous paper.[25] As shown in Figure 1E, $[C_{12}mim]Cl$ exhibited the highest extraction yields for all investigated analytes, especially for analytes 1 and 2 compared with other ILs. It was

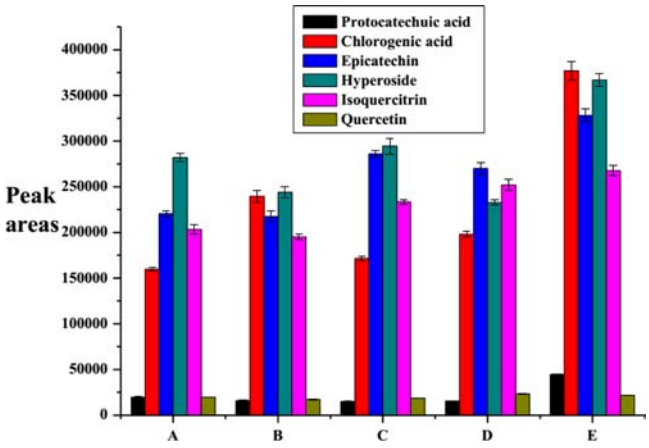

Figure 1. Impact of type of IL on extraction efficiency: (A) $[C_{12}mim]Br$; (B) $[C_{12}mim]CF_3SO_3$; (C) $[C_{12}mim]NO_3$; (D) $[C_{12}mim]HSO_3$; (E) $[C_{12}mim]Cl$. Extraction conditions: 1.0 g of dried hawthorn samples was mixed with 20 mL of different ionic liquids and then extracted for 40 min at 100 W ultrasonic power. Analytes: protocatechuic acid, chlorogenic acid, epicatechin, hyperoside, isoquercitrin, quercetin.

supposed that the two analytes had stronger interactions with the tested IL, giving rise to higher dissolubility in plant cells. With regard to analyte 6, however, these five ILs had no significant effect on the extraction yield with an extraction time of 40 min. These results suggested that the micellar extraction was a complex result of distinct multiple interactions including the viscosity of sample solution and solvent, solubilities of analytes in ILs, the diffusion coefficient, partition coefficient of the solutes, etc. Thus, $[C_{12}mim]Cl$ was selected as extraction solvent in the subsequent experiments.

Optimization of Surfactant Concentration and Extraction Time. In previous studies, it was shown that the surfactant concentration was an essential factor which could influence the extraction efficiency of target analytes.[25] In this study, the effect of $[C_{12}mim]Cl$ concentration on the extraction of multiclass polar compounds from hawthorn fruit was examined in the range of 50−250 mM, and the results are exhibited in Figure 2. The extraction yields of six analytes were found to increase with the rising surfactant concentration until 150 mM as the maximum and then decrease when the surfactant concentration went higher. The first part of the positive correlation phenomenon was attributed to the higher

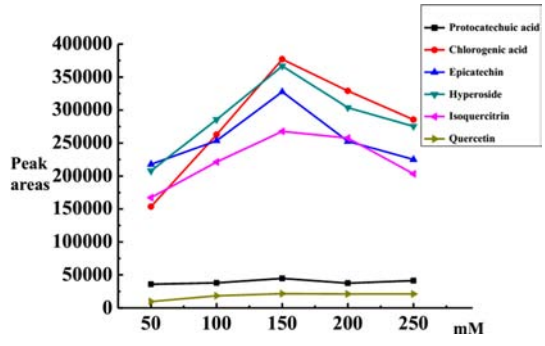

Figure 2. Effect of $[C_{12}mim]Cl$ concentrations on the extraction yields of target ingredients. One gram of dried samples was mixed with 50−250 mM $[C_{12}mim]Cl$ and then extracted for 40 min at 100 W ultrasonic power. Other conditions were as in Figure 1.

dx.doi.org/10.1021/jf501171w | J. Agric. Food Chem. 2014, 62, 5275−5280

$[C_{12}mim]Cl$ concentration exhibiting greater solvency, resulting in higher rates of analytes transferring to the extraction solvent. After a certain concentration, more $[C_{12}mim]Cl$ would be dissolved into the sample solution, which possibly reduced the molecular interaction of solvent and compounds, giving rising to a decreased solubility of investigated analytes. Thus, the negative correlation phenomenon was observed for analytes 2, 3, 4, and 5 when extracted by higher concentrations of ILs after 150 mM. On the other hand, the extraction efficiency for analytes 1 and 6 rarely changed when the hawthorn sample was extracted. This was probably due to the chemical structures of the two compounds, which made their distribution between the micellar phase and the aqueous phase insensitive to the IL concentration. Considering the extraction efficiency, the optimized concentration of 150 mM $[C_{12}mim]Cl$ was adopted in the following experiments.

Generally, extraction time was an important factor usually studied in the conventional extraction process, which could affect the effectiveness of extraction of analytes. In micelle-assisted extraction, the effects of extraction time were evaluated in the range of 20−80 min employing 150 mM $[C_{12}mim]Cl$. Results showed the chromatographic peak areas increased almost linearly when the extraction time went up from 20 to 40 min for all analytes. With longer extraction times, the extraction efficiency decreased on the contrary (data not shown). Therefore, the extraction time was set to 40 min in the following study.

Comparison of Different Extraction Methods. To compare the efficiencies of micellar-based and conventional solvent extractions, water, several ILs with the short alkyl chains, and methanol were used to extract six analytes from hawthorn fruit in the present study. It can be observed from Figure 3F that water exhibited much higher extraction yields for

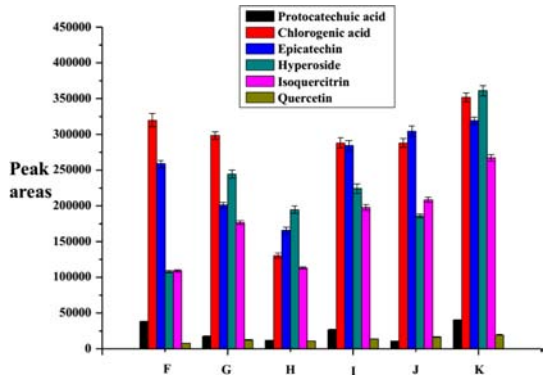

Figure 3. Comparison of different extraction methods: (F) water; (G) [emin]Br; (H) [hmin]Br; (I) $[bmim]SO_3$; (J) $[bmin]BF_4$; (K) methanol. Other conditions were as in Figure 1.

the hydrophilic components than the hydrophobic ones, indicating itself to be an unsuitable extraction solvent for multiclass polar compounds. When the short-chain ILs (Figure 3G−J) were used as extraction solvents, the yields of hydrophobic compounds were distinctly higher than that of water solvent, and yet lower than that of micellar-based or methanol extraction. In the case of hydrophilic analytes, the change of peak areas resulted from the dissolving of the IL drop in sample solutions. As seen in Figure 3, the analytes extracted by methanol presented much higher yields than those by water and short-chain ILs. In addition, the results shown in Figures 1 and 3 indicated that, as extraction solvents, the micellar solution and methanol had no significant difference in the extraction of target analytes from hawthorn fruit. In other words, the long-chain ILs could be an alternative solvent to replace toxic organic solvents. Moreover, IL micelle was a rapid and effective means for simultaneous extraction of hydrophilic and hydrophobic compounds from foods.

Performance of UHPLC-Q-TOF/MS. Electrospray ionization (ESI) is a soft ionization technique used widely for the analysis of various analytes ranging from small organic molecules to biomolecules of hundreds of kilodaltons.[26] Generally, the sensitivity is often low in the positive or negative ion mode when the analyte of interest is prepared along with the matrix in involatile salts. In this study, it was fortunate to find that the IL matrix provided similar signal intensities compared to commonly used methanol solvent. The results indicated that no significant signal suppression occurred for the six tested analytes and, thus, matrix effect could be neglected in the experiment.

To achieve a good separation for multiple ingredient determination, several mobile phase systems including methanol−water, methanol−0.1% formic acid, acetonitrile−water, and acetonitrile−0.1% formic acid were investigated. The result demonstrated that the optimal MS separation of six compounds detected in negative ion mode was achieved by using a gradient elution with 0.1% formic acid−water and acetonitrile at 0.4 mL/min in 6 min (Figure 4). Different columns including an Agilent Zorbax Extend-C_{18} column (2.1 mm × 50 mm, 1.8 μm), a Zorbax Eclipse XDB-C_{18} column (2.1

quercetin	5.380	302.0350	20	229.0457	151.0038	107.0144	0.0186

mm × 50 mm, 1.8 μm), and a Zorbax StableBond-C_{18} column (2.1 mm × 50 mm, 1.8 μm) were also investigated. It was found that the Zorbax Extend-C_{18} column at a temperature of 40 °C was suitable to separate the constituents present in hawthorn fruit. ESI parameters also played major effects in the signal response and peak shape measured for $[M - H]^-$ ions of analytes. As a result, higher signal intensity was observed in negative mode at the following conditions: capillary voltage, 3500 V; nebulization gas flow rate, 12 L/min at a temperature of 350 °C; nebulizer, 45 psig; and fragmentor, 175 V.

Method Evaluation. To evaluate the proposed micellar extraction method for simultaneous determination of multiclass polar compounds in hawthorn fruits, linearity, precision, limits of detection (LODs), repeatability, and recovery were determined under the optimized conditions. Linearity was investigated at seven different concentration levels ranging from 0.1 to 40 μg/mL for the six analytes. Results shown in Table 2 indicate that good linearity of all target compounds was obtained with correlation coefficients (r^2) ranging from 0.9934 to 0.9999. The intraday precision was examined by analyzing six determinations within 1 day, and interday precision was determined within consecutive 3 days among a middle concentration of linear range. As shown in Table 2, the intra- and interday variations regarding peak areas and retention time were less than 3.3% (n = 6) and 5.3% (n = 3) for all analytes, respectively, which indicated that the developed method had good precision. The sensitivity of the proposed method was evaluated by determining the LODs at low concentration levels giving a signal-to-noise ratio of 3. The LODs ranged from 0.0030 to 0.0054 μg/mL for all analytes (Table 2). Accredited repeatability was achieved by relative standard deviations (RSDs, n = 5) between 2.1 and 4.3% for the determination of five repeated extractions of hawthorn fruit samples. Recoveries were studied by standard addition method for the accuracy evaluation of the proposed method. Each target compound was added at concentrations ca. 0.5, 1, and 1.5 times the observed concentration in hawthorn fruit samples and then determined by UHPLC-Q-TOF/MS. Results manifested that the recovery values were from 89.3 to 106% for the six analytes with RSDs lower than 5.5%. Considering all validation results, the newly developed method was accurate and reliable for detecting analytes in hawthorn fruit samples.

Analysis of Real Samples. The proposed method was applied to the analysis of target compounds in hawthorn samples collected from the local drugstore in China. All analytes 1−6 produced abundant $[M - H]^-$ ions as the base peaks in negative ESI-MS spectra because $[M - H]^-$ provided better sensitivity compared with the other protonation states. The $[M - H]^-$ ions were selected as the precursor ions to produce MS/MS spectra at optimal collision energies (Table 3). In the current research, all of the compounds could be easily identified by their retention time, characteristic accurate masses (error < 5 ppm), and fragment ions (Table 3). Typical LC-MS chromatograms demonstrating the separation of six analytes are shown in Figure 4. The contents of the targeted compounds were found to be different in hawthorn fruit sample (Table 3). The analytical results manifested that the micellar extraction was a precise and reliable method, which could be substituted for the conventional methanol extraction to detect multiclass polar compounds in the complex samples.

In conclusion, a new method of IL-based micellar extraction coupled with UHPLC-Q-TOF/MS has been developed for the determination of multiclass polar compounds in hawthorn fruit samples. The optimum micellar extraction conditions were 150 mM $[C_{12}mim]Cl$, a solid−liquid ratio of 1:20 (g/mL), and an ultrasonication time of 40 min under ultrasonic power of 100 W. Compared to conventional extraction techniques, the developed method provided higher extraction yields and reduced the consumption of volatile organic solvent. More important, the IL-based extraction technique was not only reliable by its good repeatability and precision but also environmentally friendly. This green sample preparation approach is bound to have much wider applications in dealing with food samples.

and seed of different tomato cultivars from Sinaloa, Mexico, to take advantage of these byproducts to enrich animal or human food and have ecological and economic benefits, reducing tomato agricultural and industrial wastes.

MATERIALS AND METHODS

Chemicals and Reagents. HPLC grade acetonitrile and methanol were purchased from Karal (Leon, Gto., Mexico). Minimal glucose agar and Oxoid nutrient broth were bought from Oxoid Microbiology Products (Thermo Fisher Scientific, New York, NY, USA). Solvents and other reagents, including the phenolic standards (gallic acid, caffeic acid, ferulic acid, *p*-coumaric acid, *o*-coumaric acid, (+)-catechin hydrate, quercetin anhydrous, rutin hydrate, kaempferol, isorhamnetin, and myricetin) were ACS grade solvents or reactives and pure grade standards (Sigma Chemical Co., St. Louis MO, USA).

Biological Material. Organically grown tomatoes, cultivated in Sinaloa (a state in northwestern Mexico) during the autumn/winter 2010−2011 season, of four varieties (saladette, bola, grape, and cherry) were collected (20 kg/cultivar) in the breaker stage (USDA, 1991) during the morning and within the period from December 17, 2010, to January 23, 2011. Collected tomato materials were transported to the laboratory and stored at 20 °C until they reached the red stage (last stage in the color scale). Commercial saladette tomatoes (20 kg) were bought in a local market to get simulated industrial byproducts; saladette tomatoes are the main material used for the regional tomato-processing industry to produce tomato paste.

Color Analysis. The color of ripe tomatoes was measured with a chroma meter CR-400 (Konica Minolta Sensing, Inc., Japan); 10 whole fruits of each type were evaluated in five points, three equidistant equatorial points and two axial. Chroma and a^*/b^* data were calculated from L^*, a^*, and b^* CIELab parameters, using a white standard CR-A43.

Sample Processing. For the chemical analysis, the peel and seeds of all tomato types were manually separated from the pulp, frozen (−20 °C)m and freeze-dried (Labconco Co., Kansas City, MO, US). The simulated commercial tomato byproducts were prepared as suggested by an engineer from a local processor in the tomato industry (personal communication); ripe saladette tomato (20 kg) was cut into cubes of 2 cm^3, ground in a conventional blender until juice appearance, and heated at 80 °C during 1 h in an aluminum pot with constant stirring to get the higher yield of juice. The mixture was filtered with a gauze swab, juice was discarded, and the remnants of peel and seeds were manually separated, frozen at −20 °C, and freeze-dried. Dried byproducts were ground in a laboratory mill (Thomas Wiley, Thomas Scientific, Swedesboro, NJ, USA) until we had a fine flour (80 mesh size) and stored (4 °C/protected from light) until analyses. Three biological replicates of each variety of tomato were processed.

Proximal Composition Analysis. Proximal composition was determined by the following methods described in the AOAC (2005) standard methodologies:[18] 930.15 for humidity; weight difference method 942.05 for ashes; 976.05 for total nitrogen; 976.05 for total lipids; and 978.10 for total crude fiber. All quantifications were conducted in triplicate.

Preparation of the Methanolic Extract. Peel and seed flour were extracted as described by Ferreres et al.[10] with some modifications. Samples (0.5 g) were suspended in 5 mL of methanol in 15 mL plastic tubes, sonicated during 1 h (mixed with a vortex every 10 min), transferred into 125 mL Erlenmeyer flasks, and made up to 20 mL with methanol. Then, samples were incubated for 22 h (25 °C/darkness/220 rpm) and centrifuged at 1409*g*/3 min in a rotor J600R2004 (Solbat S.A. de C.V., Puebla de Zaragoza, Mexico), the supernatant was decanted and stored at −20 °C, and the pellet was re-extracted by adding 20 mL of methanol and following the previously described steps. After re-extraction, both supernatants were combined and concentrated to dryness at 37 °C in a rotary evaporator (Yamato, Santa Clara, CA, USA). The extract were reconstituted with 3 mL of methanol, filtered through 0.22 μm Durapore syringe filters (Millipore, Carrigtwohill, Co. Cork, Ireland), and kept stored at −20 °C until use (this was called the methanolic crude extract). Each tomato sample was made in triplicate.

Total Polyphenol Content. The total polyphenol content of crude methanolic extract was quantified using the Folin−Ciocalteu spectrophotometric method, according to Nurmi et al.,[19] with modifications made by Ramírez-Mares et al.[20] Briefly, methanolic crude extract was dissolved in methanol (1:30 p/v), and 100 μL of the solution was mixed with 1 mL of 0.5 N Folin−Ciocalteu's phenol reagent and 2 mL of a 20% (w/v) Na_2CO_3 solution; the mixture was allowed to stand for 15 min at darkness, and the absorbance was measured at 734 nm. Gallic acid (GA) and (+)-catechin hydrate (CAT) were used to prepare calibration curves, and results were reported as milligrams of gallic acid equivalents per gram of flour (mg GAE/g) or catechin equivalents (mg CE/g). Groups of phenolic compounds were quantitated by spectrophotometry[21] at 320 nm for tartaric esters of phenolic acids and at 404 nm for flavonoids in a Thermo Spectronic Genesys 2 spectrophotometer (Thermo Fisher Scientific). Results of groups of phenolic compounds were expressed as caffeic acid or quercetin equivalents per gram of peel or seed flour, for phenolic tartaric esters or flavonoids, respectively.

Antioxidant Activity. The antioxidant activity of crude methanolic extracts was measured by the DPPH,[22] ABTS,[23] and ORAC[24] methods. DPPH and ABTS are free stable oxidative radicals, and we measured spectrophotometrically their decrease in absorbance (as the effect of the phenolic compounds presents in the samples). In the ABTS method, the $ABTS^{\bullet+}$ radical was chemically prepared (7 mM in methanol); the ABTS reagent was mixed with potassium persulfate (2.45 mM), incubated during 16 h at room temperature, and diluted with methanol to get an absorbance value of 0.70 ± 0.02 at 734 nm. To measure the antioxidant activity, 10 μL of the concentrated methanol crude extract (controls or standard) was mixed with 1000 μL of $ABTS^{\bullet+}$ and vortexed gently during 20 s, and the absorbance at 734 nm was registered.

For the DPPH assay, the radical (125 μM in methanol) was daily prepared and kept at 4 °C/darkness. Assay was done in a 96-well microplate; 20 μL of the concentrated methanol crude extract (controls or standard) was mixed with 200 μL of DPPH solution, and absorbance (515 nm) was read at 0, 10, 20, 30, 40, 50, 60, 70, 80, and 90 min with a DTX 880 multimode detector (Beckman Coulter, Brea, CA, USA). Trolox standard curve was constructed at 30 min.

For the Oxygen radical absorbance capacity (ORAC) (performed fluorometrically) assay,[24] analysis was done at 37 °C in pH 7.4, 75 mM phosphate buffer, peroxyl radical was generated using AAPH (70 mM), and fluorescein (87 μM) was the substrate. Twenty-five microliters of diluted (1:100) sample (control or standard) was mixed with 200 μL of fluorescein and 50 μL of AAPH, and the decrease of fluorescence was calculated in a DTX 880 multimode detector, using the following conditions: excitation wavelength of 485 nm and emission wavelength of 530 nm; 76 cycles were read, every 2 min. In all cases we report antioxidant activity as Trolox equivalents, a standard curve was prepared with a correlation coefficient up to R = 0.99, and the equivalents were calculated as micromole equivalents of Trolox per 100 g of flour. Three independent experiments were conducted in each assay.

Profile of Phenolics by HPLC-DAD. The HPLC profile of phenolics in the methanolic crude extract was established with a Dionex UltiMate 3000 liquid chromatograph, equipped with a titanium quaternary pump (LPG-3400AB), an autosampler (WPS-3000TBPL), a column oven, and a photodiode array detector DAD-3000(RS) (scan range 190−800 nm and scan speed 2 nm/s) from Thermo Scientific. Separation was carried out using an analytical column Acclaim 120 A (C18, 5 μm, 120 Å, 4.6 × 250 mm), from Dionex (Thermo Fisher Scientific), at ambient temperature. Elution was done with a gradient of two solvents: water acidified with acetic acid (pH 2.8) (A) and acetonitrile (B). The gradient for phenolic acids[25] was 100% phase A, 6% phase B, from 0 to 8 min; from 6 to 12% B from 8 to 14 min; from 12 to 20% B from 14 to 18 min; from 20 to 35% B from 18 to 24 min, from 35 to 95% B from 24 to 27 min; from 95 to 100% B from 27 to 30 min; and from 100% B to 100% A in 10 min. The fixed wavelengths were 260, 270, 275, 280, 285, 290, 295, and 300 nm.

Table 1. Parameters of Color of Whole Tomato Fruits from Several Varieties Cultivated in Northwestern Mexico ($X \pm$ SD, $n = 10$)[a]

tomato type	L^*	a^*	b^*	chroma	a^*/b^*
cherry	31.4 ± 1.45 b	13.8 ± 1.64 ab	11.2 ± 1.29 b	17.5 ± 3.72 a	1.24 ± 0.17 a
grape	34.2 ± 1.58 a	17.2 ± 1.50 a	13.0 ± 0.96 ab	21.6 ± 1.36 a	1.32 ± 0.15 a
bola	36.7 ± 1.30 a	15.9 ± 1.74 a	15.1 ± 0.96 a	20.1 ± 3.14 a	1.05 ± 0.13 ab
saladette	35.6 ± 1.36 a	15.9 ± 1.35 a	15.0 ± 0.92 a	19.4 ± 4.03 a	1.06 ± 0.09 ab
byproducts	34.8 ± 1.80 a	17.5 ± 2.60 a	12.9 ± 2.10 ab	18.2 ± 4.40 a	1.37 ± 0.11 a

[a]Values marked by the same letter within the same column are not statistically significantly different (multiple-range test; Tukey, $p \leq 0.05$).

The gradient for the elution of flavonoids was 100% A, 10% B, from 0 to 2.5 min, from 10 to 12% B from 2.5 to 6 min; from 12 to 23% B from 6 to 18 min; from 23 to 35% B from 18 to 24 min; from 35 to 95% B from 24 to 27 min; from 95 to 100% B from 27 to 30 min; and from 100% B to 100% A in 10 min; 260 and 342 nm were the fixed wavelengths for flavonoids. The flow rate was 0.5 mL/min. The injection volume was 10 μL. Chromatographic peaks were identified by comparing the retention times and UV−visible absorption of pure standards (i.e., gallic, caffeic, ferulic, *p*-coumaric, and *o*-coumaric acids; and flavonoids (+)-catechin hydrate, quercetin, rutin hydrate, kaempferol, isorhamnetin, and myricetin). A standard curve was constructed with the mix of all phenolic acids and another with the mix of all flavonoids. Each sample was injected three times. The data were processed using Chromeleon 7.0 software (Dionex, Thermo Fisher Scientific).

Antimutagenic Activity Test. The antimutagenicity of the methanolic crude extracts was determined, the extracts were concentrated to dryness under a nitrogen flow, and the solid extract was resuspended in sterilized DMSO. The antimutagenic activity was done by the microsuspension assay using YG1024 *Salmonella typhimurium* as tester strain and 1-nitropyrene as mutagen, according to the method of Santos-Cervantes et al.[26] A dose−response curve of mutagen and different sample concentrations was constructed. An aliquot (10 μL) of resuspended extract was homogenized with the components of the incubation mix, including 1-nitropyrene. A mix of bacteria plus mutagen was used as a positive control of mutation reversion. The capacity of tomato seed or peel extracts to prevent the action of 1-nitropyrene against the cells was measured with the follow equation:

$$\%\ \text{antimutagenic activity} = [(\text{His}^+\ \text{revertants of positive control plate} - \text{His}^+\ \text{revertants of sample test plate}) / \text{His}^+\ \text{revertants of positive control plate}] \times 100$$

Statistical Analysis. A totally random experimental design was used to evaluate the color parameters and a factorial design 5 × 2 for the chemical and antimutagenic analysis; the first factor was tomato type, and the second one was the anatomic part of the tomato fruit. ANOVA analysis and a multiple-ranges test (Tukey, $p \leq 0.05$) were done with the SAS 7.0 statistic program (SAS Institute Inc., Cary, NC, USA). A correlation test between total phenolics/individual phenolic content and antioxidant or antimutagenic activity was done through SAS 7.0 using the Pearson's correlation coefficient option. Three biological replicates and at least two independent experiments were performed.

RESULTS AND DISCUSSION

Color and Proximal Composition. Maturity stage was not significantly different among tomato varieties considered in this study. Tomato color was uniform inter- and intratomato varieties, as indicated by the low variability of the color parameters (L^*, a^*, b^*, chroma, and a^*/b^* values) and their statistical similarity (Table 1). The ripeness stage for these tomatoes corresponded with that accepted for marketing.[27]

The proximal composition of peel and seed of all tomato types can be observed in Figure 1. All measured parameters

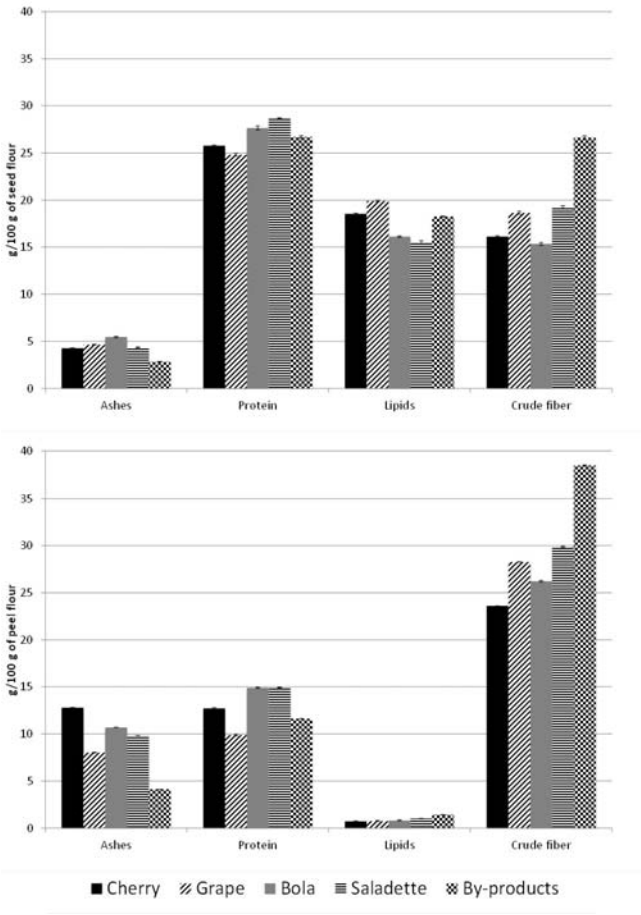

Figure 1. Proximal composition of flour from peel (A) and seeds (B) of different tomato types and tomato byproducts. Data are the average of three replicates ± standard deviation. Statistical analysis of proximal composition is not shown in this figure, but significant differences between treatments were observed.

were higher than the average values previously reported for whole tomato fruit,[28] except total lipids in peel,[6] and were closer than those reported for seed and peel from tomato pomace.[11,29] Notable protein content was found in all seed samples, >24 g/100 g, closer than that reported by Fuentes et al. for tomato seed from pomace.[29] saladette type had the highest protein percentage (28.7 g/100 g of flour), and a high ash content was quantified in the majority of tomato types (6.7 g/100 g of flour, on average); the mentioned parameter was superior to that reported by different authors in flour of

dx.doi.org/10.1021/jf5012374 | J. Agric. Food Chem. 2014, 62, 5281−5289

tomato byproducts (5 g/100 g of flour).[5,6,29] Crude fiber of seed plus peel of each tomato type was superior that previously reported for tomato pomace.[28] The byproducts contained the highest fiber content (38.5 g/100 g of flour) ($p \leq 0.05$). This effect could be the result of the heat process, as it has been previously reported in other vegetables that insoluble dietary fiber increased as a result of a cooking process.[30] Total lipids in peel correspond to 3% of the proximal composition and are represented by waxes, mainly.[15] In seeds, total lipids represented up to 15 g/100 g of flour, and in the case of grape tomato seeds, these compounds reached 20 g/100 g of flour; it could be important to analyze the fatty acid profile and other hydrophobic compounds as phytosterols to determine a potential commercial use. Analysis of variance (ANOVA) showed that all proximal composition parameters were affected by tomato type, the part of the fruit analyzed (peel or seed), and the interaction of both factors.

High protein and total fiber contents found in our samples suggest that the peel or seed of tomato dry flour can be used as a source of those substances to enrich animal or human food.

Total Phenolic Content, Groups of Phenolic Compounds, and Antioxidant Capacity. Crude methanolic extracts showed levels of phenolic content (Table 2) comparable with those of other fruits recognized for their phenolic content, such as kiwi and grapes.[31] The ranges were from 71.6 to 351.6 mg equiv gallic acid (GA)/100 g peel flour samples (208.2 mg equiv GA/100 g flour, on average) and from 67.3 to 121.8 mg equiv GA/100 g seed flour (95.2 mg equiv GA/100 g flour, on average); these values were superior to those reported for peel and seed from several tomato varieties and tomato byproducts.[17,28] In the case of the total phenolic content expressed as milligram equivalents of (+) catechin (CAT), data ranged between 464.3 and 1824.1 mg equiv oCAT/100 g peel flour samples (1136.8 mg equiv CAT/100 g flour, on average) and between 438.3 and 682.8 mg equiv CAT/100 g seed flour (569.4 mg equiv CAT/100 g, on average) in seed samples and were superior to thosee previously reported by George et al. in tomato peel.[32] There were found statistically significant differences ($p \leq 0.05$) due to the interaction of tomato type and part of the fruit and the notable presence of a higher amount of phenolic compounds in peel flour than in seed flour, as has been reported by Chandra et al.[17] Grape peel flour was the material with the best total phenolic content in both ways of expressing phenolic concentration (351.6 mg equiv GA/100 g flour and 1824.1 mg equiv CAT/100 g flour), whereas byproduct seed flour showed the lowest phenolic content (67.3 mg equiv GA/100 g flour and 464.3 mg equiv CAT/100 g flour) than saladette (byproducts were produced from a saladette tomato type); perhaps this decrease in phenolic content could be due to the heat processing.[33] In addition, phenolics oxidation could have occurred during homogenization of the fresh fruit due to polyphenol oxidase,[33] but the total phenolic concentration in byproducts remains attractive for their use as a source of phenolic compounds. Sagdic et al.[34] in 2011 reported the content of total phenolic compounds in byproducts from grape fruit; our data obtained in cherry and grape tomato peel flours were comparable to those reported by these authors. Differences in the phenolic content for effect of tomato genotype have been reported;[17,32] the highest amount of phenolic compounds found in cherry and grape tomato types could be due to these genotypes being less genetically manipulated than saladette and bola, and it is known that

[e]mg equivalents of (+) catechin (CAT) per 100 g of sample. [f]mg equivalents of caffeic acid (CA) per 100 g of sample. [g]mg equivalents of quercetin (QUER) per 100 g of sample. [h]μmol equivalents of Trolox per 100 g of sample.

dx.doi.org/10.1021/jf5012374 | J. Agric. Food Chem. 2014, 62, 5281–5289

crops that have been largely genetically improved show reduced concentration of some metabolites, even phenolic compounds.[35] The amount of the different phenolic groups can be observed in Table 1. The major group was flavonoids, ranging from 83.7 mg/100 g flour in byproducts to 572.2 mg/100 g of grape tomato peel flour; in the case of seed samples, flavonoids were quantified from 50.0 to 69.2 mg/100 g in byproducts and grape tomato flour, respectively. On the other hand, phenolic tartaric esters ranged from 3.1 to 16.9 mg/100 g for byproducts and cherry tomato peel flours, respectively; meanwhile in seeds a decrease in content until 2.6 times ranged from 3.2 to 6.3 mg/100 g for byproducts and grape tomato seed, respectively. In the same way as happened with total phenolic content, flavonoid and ester phenolics concentrations were higher in the peel flour than in seed flour, in most of cases. Statistically significant differences ($p \leq 0.05$) were observed between treatments. We observed that approximately 60% of total phenolic content corresponded to flavonoids and 30% to phenolic acids, in the same way that has been found in several samples.[36] Oomah et al.[21] reported levels of flavonols similar to those that we found in tomato peel in hull fractions and residues from red and green lentils, but this previous study was done with acetone and hot water extracts, and the proportion of phenolic compounds extracted varies widely according to the extraction solvent, so our results and those reported previously are not completely comparable.

Antioxidant activity was determined with three methodologies, ABTS, DPPH, and ORAC, and results were expressed as micromole equivalents of Trolox per 100 g of flour (peel or seed) in all cases. Peel samples showed the best results in all cases. ABTS and DPPH methodologies have a similar chemical makeup, but the data obtained with these two methods were different between the same samples. ABTS measured a more major antioxidant activity than DPPH in the peel samples of all evaluated genotypes except in byproducts, in which case there was no significant difference ($p \leq 0.05$) in the antioxidant activity due to the radical used (ABTS or DPPH). In contrast, in seed samples, the DPPH methodology showed the best results in all genotypes. Due to the previously described behavior, it can be inferred that the qualities of the extracted compounds are different between peel and seed samples because both extracts reacted differently on the same free radical, as observed before.[37] The best results were obtained in grape tomato genotype, again. This sample showed 405.7 μmol equiv Trolox/100 g flour by ABTS and 181.4 μmol equiv Trolox/100 g flour by DPPH in peel and 139.6 μmol equiv Trolox/100 g flour by ABTS and 156.2 μmol equiv Trolox/100 g flour with DPPH methodology in seed sample. Antioxidant activity determined by ABTS was superior to that previously reported in aqueous extracts from tomato plants and yellow cherry whole tomato fruits.[2,32]

Antioxidant capacity calculated with ORAC methodology was significantly higher than those quantified with ABTS and DPPH methodologies ($p \leq 0.05$); values were in the range between 705.3 and 4131.7 μmol equiv Trolox/100 g of flour in peel samples and from 1028.3 to 1825.0 μmol equiv Trolox/100 g flour in the case of seed samples. In both cases the lowest activity corresponded to byproducts. The highest activity was measured in grape tomato type ($p \leq 0.05$). Despite this, the antioxidant activity of the byproducts remained at high levels.[21,37] Several studies have shown that ORAC methodology is more adequate to quantify antioxidant activity, due to its resemblance to a biological process in vivo, regarding the peroxyl free radicals. It is, however, desirable that our results were validated through an in vivo antioxidant activity methodology, reducing confounding factors that affect the action of phenolic compounds over free radicals. The ORAC methodology does not take into account those factors; thus, further studies are required.[38] There was observed an influence of the tomato type, as has been reported before by Chandra et al.,[17] the part of the fruit analyzed, and the interaction of these two factors on the antioxidant activity measured by the three methodologies used.

Correlations analysis (Pearson, SAS 7.0) between total phenolic and antioxidant activity and between groups of phenolic compounds and antioxidant activity were done (data not shown). We calculated R values >0.8 in all cases except when we correlated flavonoids with antioxidant activity determined by the DPPH method. R values >0.8 are considered higher. It has been reported that not all extractable compounds that can be measured as total phenols or belonging to a phenolic group may have the capacity to act against a free radical used in a particular methodology to determine antioxidant activity (scavenging activity, mainly); this may be due to structural aspects or steric impediments of the different compounds that are present in the extract.[34,39]

Phenolic Compounds Profile by HPLC-DAD. Results of phenolic compounds profile by HPLC-DAD of each tomato sample (peel and seed flour) are summarized in Table 3, and Figure 2 shows the chromatograms obtained in the peel of grape tomato type. We have identified and quantified 16 compounds in total, 8 phenolic acids and 8 flavonoids. It is interesting that byproducts did not always present the lowest concentration of individual phenolic compounds, but the trend was to diminish the content of the evaluated compounds in byproducts, perhaps by the heat-processing effect,[29] as has been mentioned above. Flavonoids were found in higher concentration than phenolic acids in all tomato types (as happened in phenolic groups evaluation). The most abundant phenolic acids were caffeic acid, in concordance with that reported before in whole red tomato fruit,[40] followed by vanillic, ferulic, sinapic, and chlorogenic acids; in the case of flavonoids, the most concentrated were quercetin-3-β-O-glycoside, rutin, isorhamnetin, and kaempferol. Rutin (and its diverse chemical drivatives) is localized in the last steps of the phenolic biosynthesis route and is related to a commercially mature stage of fruits.[41] The content of all phenolic acids and flavonoids determined by HPLC-DAD, in our samples, was 3−5 times greater than that evaluated with the total phenolic methodology (Folin−Ciocalteu). There are diverse reports about the individual content of phenolic compounds in tomato fruits and seeds generated as byproduct, including an effort to characterize tomato metabolome, from a mix of 96 cultivars from the Iberian peninsula; these works were done by HPLC and HPLC coupled to mass spectrometry.[2,11,12,29,42] The main phenolic compounds found in tomato in previous studies (caffeic, ferulic, p-coumaric, and sinapic acids, rutin, quercetin, and kaempferol) are almost the same as those found in our work and were present in comparable levels to those reported by other authors. There have been reported attractive phenolic compounds such as caffeic, ferulic, and chlorogenic acids and rutin in tomato industrialized products (tomato juices and ketchup) in important levels, and we observed the presence of these phenolics in our byproduct samples. Therefore, we can mention that these compounds remain after a heat or cooking process.[11]

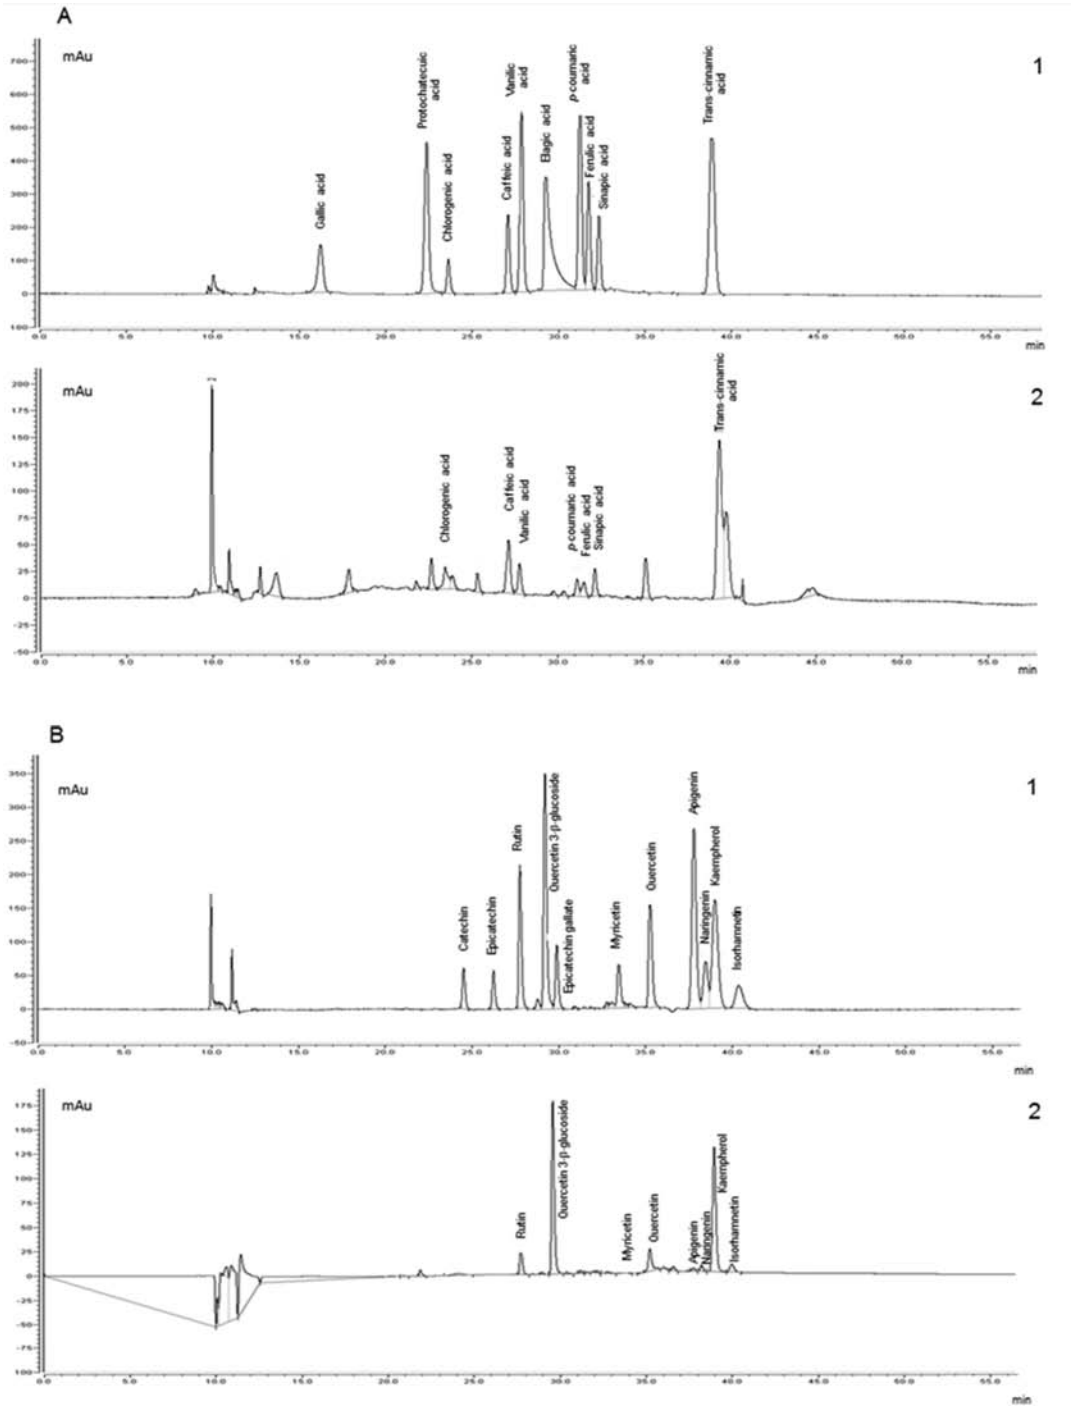

Figure 2. HPLC-DAD chromatograms of phenolic compound standards and phenolics and flavonoids determined in a methanolic extract from the peel of grape tomato. (A1) Phenolic acids standard mix, absorbance at 260 nm, labeled peaks in order from left to right are gallic, protocatechuic, chlorogenic, caffeic, vanillic, ellagic, *p*-coumaric, ferulic, sinapic, and *trans*-cinnamic. (A2) Phenolic acids detected in grape tomato peel methanolic extract at 260 nm (retention times): 23.7 min = chlorogenic acid, 27.1 min = caffeic acid, 27.9 min = vanillic acid, 31.3 min = *p*-coumaric acid, 31.8 min = ferulic acid, 32.3 min = sinapic acid, and 38.9 min = *trans*-cinnamic acid; other signals unknown. (B1) Flavonoids standard mix, absorbance at 360 nm, labeled peaks from left to right are catechin, epicatechin, rutin, quercetin 3-β-glucoside, epicatechin gallate, myricetin, quercetin, apigenin, naringenin, kaempferol, and isorhamnetin. (B2) Flavonoids found in grape tomato peel methanolic extract, main signals detected at 360 nm, retention times of the identified compounds are 27.7 min = rutin, 29.1 min = quercetin 3-β-glucoside, 33.3 min = myricetin, 35.1 min = quercetin, 37.9 min = apigenin, 38.4 min = naringenin, 39.0 min = kaempferol, and 40.1 min = isorhamnetin; other signals unknown.

Attractive biological activities have been reported in the phenolic compounds found in the higher concentrations in this work; that is, ferulic and sinapic acids have been correlated with antioxidant and anti-inflammatory activities and act as chemoprotector agents, if they are frequently consumed in the diet;[43] rutin and quercetin are able to suppress mutagenesis and have antitumoral capacity.[43]

Mathematical correlation analysis (data not shown) revealed that the compounds that showed the highest level of correlations (R = 0.8) with antioxidant activity were those that were detected

dx.doi.org/10.1021/jf5012374 | J. Agric. Food Chem. 2014, 62, 5281−5289

in high levels, but only quercetin-3-β-*O*-glycoside, quercetin, and naringenin showed correlation with antioxidant activity evaluated with at least two methodologies. The high correlations found between individual phenolic concentrations and antioxidant activity, in many cases, suggest that the antioxidant activity determined in this work could be given by the action of the quantified phenolic compounds or by the interaction between the different compounds present in the extract, although further studies are necessary to prove this.

Antimutagenic Activity Test. Antimutagenic activity, expressed as percentage of mutagenic inhibition, as a response to methanolic tomato peel and seed extracts was determined (Figure 3). A dose−response curve using 0.0, 5.0, 10.0, 20.0, 30.0, and 40.0 mg/mL of solid extract (using seed saladette tomato type extract) was constructed; no differences in the percentage of mutagenic inhibition were obtained at concentrations ≥20 mg/mL; for that reason, the following experiments were done at 20 mg/mL extract concentration. There were no statistically significant differences ($p \leq 0.05$) between peel and seed flours, except for byproduct flours, where peel samples had a higher antimutagenic activity than seed samples. Percentages of mutagenic inhibition were between 40 and 60%; peel extracts from byproducts showed an antimutagenic activity greater than those of bola and saladette tomato types and very similar to the activities determined in cherry and grape tomato genotypes. We suggested that the heat process did not affect compounds, which conferred the antimutagenic activity. Bunkova et al.[44] reported in antimutagenic studies made with green tea (using TA98 *S. typhimurium* strain) that the percentage of mutagenic inhibition between 40 and 60% represents an antimutagenic activity from moderate to strong.

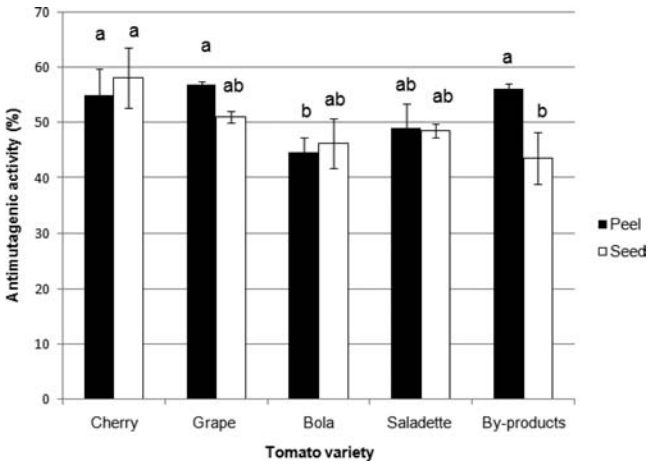

Figure 3. Antimutagenic activity of methanolic extracts (20 mg solid extract/mL) from peel and seed flour from different tomato types. Values are the mean of three replicates of two independent experiments. Different letters indicate statistically significant difference between treatments (multiple-range test; Tukey, $p \leq 0.05$).

Correlation analyses between total phenolic content and antimutagenic activity and between groups of phenolic compounds and antioxidant activity and also profile of individual phenolic compounds (by HPLC-DAD) and antimutagenicity were done. We were not able to obtain a strong linear, second- or third-grade correlation between all evaluated parameters and the percentage of antimutagenicity. In relation to this negative correlation, it could be that the antimutagenic activity observed results from the action of several compounds (or their interactions), some of them not identified with the used methodology. More work is needed to determine which compounds impart the antimutagenic activity observed in our extracts and their mechanisms of action.

Finally, we can affirm that methanolic extracts from peel and seed of several tomato types cultivated in northwestern Mexico, including industrial byproducts, can be a potential source of compounds with attractive antioxidant and antimutagenic activities. These extracts could be utilized as nutraceutical ingredients in animal or human food or as nutritional supplements. For this reason, further studies are needed to complete the metabolite characterization of these materials and to realize in vivo assays.

investigated the intestinal cell permeability of hydroxycinnamic acids in a Caco-2 cell transport model.

MATERIALS AND METHODS

Samples and Chemicals. α-Amylase, pepsin, pancreatin, pancreatic lipase, and bile extract were purchased from Sigma-Aldrich for simulated digestion. All cell culture reagents, including Dulbecco's modified Eagle's medium (DMEM), fetal bovine serum, 1 M 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES), phosphate-buffereds saline (PBS), 100× penicillin and streptomysin, and trypsin/EDTA, were obtained from Gibco (Carlsbad, CA). Hank's balanced salt solution (HBSS) and 100× nonessential amino acids were purchased from Sigma-Aldrich. Transwell permeable polycarbonate inserts (0.4 μm) and 12-well cell culture plates were obtained from Corning Inc. Solvents used for HPLC were purchased from Fisher Scientific (Springfield, NJ). Unless indicated, all other chemicals were supplied by Sigma-Aldrich. The standard for quantitative analysis, chlorogenic acid, was purchased from Aldrich Chemical Co. (St. Louis, MO). Caftaric acid, chicoric acid, luteolin-7-*O*-glucuronide, and 3,5-DCQA were purified from *C. denticulatum* by open column chromatography and semipreparative HPLC. Chemical structures were confirmed by ^{1}H and ^{13}C nuclear magnetic resonance data by comparison with the references.[16,20,21]

Sample Preparation. The whole plants of *C. denticulatum* were collected at the Wild Vegetable Experiment Station, Pyeongchang, Korea, in June 2012. For simulated digestion, the whole plants of *C. denticulatum* were dried at room temperature and ground to a powder before being used. All extracts were filtered (0.45 μm, 13 mm, syringe filter GHP, Smartpor) and analyzed in the HPLC system. All experiments were conducted in triplicate.

***In Vitro* Simulated Digestion.** Simulated digestion was performed according to the method described by Garrett et al.[22] with minor modifications. To simulate *in vitro* digestion, digestive steps were conducted sequentially. Briefly, *C. denticulatum* powder (1 g) was homogenized in 10 mL of saline solution containing 120 mM NaCl, 5 mM KCl, and 6 mM $CaCl_2$ (pH 5.5). Then, 1000 units of α-amylase was added, and the pH was adjusted to 6.5. After the saline solution had been added to a volume of 12.5 mL, the samples were incubated at 37 °C for 5 min in a shaking water bath (Lab companion, Jeio Tech, Korea) at 95 rpm for the simulated oral phase of digestion. To mimic the gastric phase of human digestion, the pH of the sample was acidified to 2.2 with HCl and 0.5 mL of a porcine pepsin solution (0.075 g/mL in 0.1 N HCl) was added. The samples were suspended in a saline solution to a volume of 15 mL and incubated at 37 °C for 2 h in a shaking water bath at 95 rpm. To simulate the intestinal phase more accurately and specifically, that phase was separated into three intestinal parts (duodenum, jejunum, and ileum) and simulated sequentially. In the duodenum part, 250 mg of bile extract, 0.5 mL of pancreatic lipase (0.01 g/mL of 0.1 M sodium bicarbonate), and 0.5 mL of pancreatin (0.08 g/mL saline) were added and the pH was increased to 4.0 by adding 1 M sodium bicarbonate. Samples were incubated for 30 min at 37 °C (final volume of 20 mL). In the jejunum part, the pH was adjusted to 5.5 and the sample incubated for 90 min at 37 °C (final volume of 22.5 mL). Finally, the pH was adjusted to 7.0 and the sample incubated for 300 min at 37 °C (final volume of 25 mL) to mimic the ileum part. At the end of each digestion, digestates (100 μL) were collected and added to aqueous ethanol [1:1 (v/v)] to determine the bioaccessibility of hydroxycinnamic acids. To measure the digestive stability of hydroxycinnamic acids, digestates of each intestinal phase were added to ethanol (25 mL) and extracted by sonication for 1 h. After the mixtures had been centrifuged at 12300*g* for 10 min, their supernatants were collected and filtered through a 0.45 μm GHP filter prior to HPLC analysis.

Transport of Hydroxycinnamic Acids via a Caco-2 Cell Monolayer. Caco-2 cells (HTB-37, American Type Culture Collection, Rockville, MD) were maintained for cellular transport experiments, according to the method of Hubatsch et al.[23] For the experiments, cells were seeded at a density of 3×10^5 cells/cm^2 on the tissue culture-treated polycarbonate filter in 12-transwell plates. The cultures were grown for 21−29 days to obtain a differentiated intestinal cell monolayer. Transepithelial electrical resistance (TEER) measurements were taken twice weekly using a Millipore Millicell-ERS system (Millipore Corp., Bedford, MA) to ensure the monolayer was intact. Once the TEER values reached 600−800 Ω/cm^2, the monolayer was used for transport study.

To initiate the transport experiments, the culture media in the donor and receiving compartments were carefully aspirated, and the cells were rinsed with prewarmed transport medium [HBSS supplemented with 25 mM HEPES (pH 7.4)]. Following a 30 min equilibration with the transport medium at 37 °C, the cells were incubated with each hydroxycinnamic acid for 2 h for transport studies. The transport studies were performed in both directions as follows. For apical-to-basolateral (a-to-b) transport, 1.2 mL of transport medium was added in the basolateral part, 0.45 mL of each hydroxycinnamic acid (2 mM) dissolved in the transport medium was added in the apical part, and 0.05 mL of the sample (C_0) was immediately withdrawn into a collection tube. After 2 h, 0.6 mL of basolateral transport medium was withdrawn for the analysis and replenished with an equal volume of fresh transport medium. For basolateral-to-apical (b-to-a) transport, 1.25 mL of each hydroxycinnamic acid dissolved in the transport solution was added in the basolateral part and a 0.05 mL sample was immediately withdrawn, followed by 0.4 mL of transport medium being added in the apical part; 0.2 mL of apical transport medium was withdrawn after 2 h and replenished with the same volume of fresh transport medium. The TEER values were measured after the experiment to confirm the cell integrity status. All of the collected samples were added to the same volume of 0.6% formic acid in acetonitrile to increase the stability of hydroxycinnamic acids prior to liquid chromatography−MS analysis. The apparent permeability coefficient (P_{app}) was calculated as

$$P_{app} = \frac{\partial Q}{AC_0\,\partial t}$$

where $\partial Q/\partial t$ is the permeability rate, A is the surface area of the membrane filter, and C_0 is the initial concentration in the donor compartment (the apical compartment in the a-to-b transport study and the basolateral compartment in the b-to-a transport study).

HPLC Analysis. HPLC was used for the quantitative analysis of hydroxycinnamic acids in *C. denticulatum* during simulated digestion. The HPLC system consisted of an Agilent Series 1200 liquid chromatography system with a G1379B vacuum degasser, a G1312A binary pump, a G1329A autosampler, a G1316A column oven, a G1315B diode array detector (DAD), and ChemStation (version B.02.01, Agilent, Waldbronn, Germany). The separation was undertaken with a Shiseido Capcell pak MG II C18 column (4.6 mm × 250 mm, 5 μm). The mobile phase consisted of 0.3% formic acid in water (solvent A) and 0.3% formic acid in acetonitrile (solvent B) with the following conditions: 82:18 [A:B (v/v)] isocratic mode for 30 min. The flow rate was 1.0 mL/min, and the oven temperature was set at 35 °C. Detection was conducted at 330 nm, and the injection volume of the standards and extracts was 10 μL.

HPLC−PDA−MS Analysis. HPLC−PDA−MS analysis was used for the identification of major compounds in *C. denticulatum* and the quantitative analysis of hydroxycinnamic acids during the intestinal Caco-2 cell permeability test. All analyses were performed using a Thermo HPLC−PDA−MS system (Thermo Fisher Scientific Inc., San Jose, CA) equipped with an ACCELA photodiode array detector, an autosampler, a quarternary pump, and an LCQ FLEET ion trap mass spectrometer with an electrospray ionization source. Thermo Xcalibur (version 2.1) was used for data acquisition and processing. The mobile phase was the same as that previously described in the HPLC analysis section. A Waters Acquity BEH C18 column (3.0 mm × 100 mm, 1.7 μm) was used. The gradient mode was as follows: from 0 to 10 min, initial mobile phase solvent A/B [90:10 (v/v)]; from 10 to 45 min, 70:30 linear gradient and reconditioning steps to initial condition for 15 min. The flow rate was 150 μL/min, and detection was conducted at 330 nm. The injection volume of samples was 10 μL. The mass spectrometer conditions were as follows: negative ion mode; mass

range, m/z 100−1000; capillary voltage, −7.0 V; tube lens, −45 V; sheath gas flow rate (N_2), 50 arbitrary units; auxiliary gas flow rate (N_2), 12 arbitrary units; capillary temperature, 350 °C.

Data Analysis. A minimum of three independent observations were made in each experiment. All data are expressed as means ± the standard error of the mean (SEM). Statistical comparisons between the experimental groups and the control group were performed using the Student's t test. The Student−Newman−Keuls test was performed to separate the means of experimental groups when significant differences ($P < 0.05$) occurred. Statistical analyses were performed using GraphPad Prism version 5.

RESULTS AND DISCUSSION

Identification and Quantitative Analysis of Hydroxycinnamic Acids in *C. denticulatum*. The aqueous ethanol extracts of *C. denticulatum* were injected into the HPLC system. Following separation, five major compounds were detected in their HPLC profiles with a DAD chromatogram (Figure 1A). HPLC−ESI-MS was used to identify the four hydroxycinnamic acids and one flavonoid, and the mass spectra of the five compounds are shown in Figure 1B. Peak 1 showed $[M - H]^-$ ions at m/z 311, and fragmentation in the MS experiment produced a caffeic acid (m/z 179) as a prominent fragment. Peak 1 appeared to be caftaric acid. Peak 2 was identified as chlorogenic acid by mass spectra. Fragmentation of the $[M - H]^-$ ion at m/z 353 was characterized by the loss of a caffeic acid moiety, resulting in a product ion at m/z 191. Peak 3 showed $[M - H]^-$ ions at m/z 473. The fragmentation of peak 3 produced a product ion at m/z 311 (loss of a caffeoyl moiety) and m/z 293 (loss of the caffeic acid and an additional loss of water). Peak 3 was assigned to chicoric acid. Peak 4 showed $[M - H]^-$ ions at m/z 461 and another characteristic fragment at m/z 285 of the aglycone, corresponding to the loss of a glucuronide moiety. Therefore, peak 4 was assigned to luteolin-7-*O*-glucuronide following a comparison against the reference compound. Peak 5 showed $[M - H]^-$ ions at m/z 515 and a product ion at m/z 353 after the loss of one caffeic acid. This fragment is typical of dicaffeoylquinic acid. Peak 5 was identified as 3,5-DCQA through comparison with an authentic compound. Five compounds were identified as caftaric acid, chlorogenic acid, chicoric acid, luteolin-7-*O*-glucuronide, and 3,5-DCQA by comparing their MS data with references[24,25] and

co-injections of authentic standards. Five concentrations of each standard compound were injected in triplicate to establish the calibration curves. As shown in Table 1, the limits of detection (LOD) and quantification (LOQ) for each standard were determined at the standard deviation (SD) of the response and the slope with values of ∼3.3 and ∼10, respectively. Intra- and interday variability was determined three times each day and on three separate days. Variations are indicated by the relative standard deviations (RSDs).

Digestive Stability and Bioaccessibility of Hydroxycinnamic Acids in *C. denticulatum* during Simulated Digestion. The contents of hydroxycinnamic acids in *C. denticulatum* were measured by HPLC to evaluate the digestive stability and bioaccessibility of the major compounds (Figure 2). The stability of each compound was checked by measuring the amount of compound remaining after each digestion step. Values for chlorogenic acid, chicoric acid, and 3,5-DCQA remained at 66.6, 65.1, and 57.0%, respectively, during the initial digestion phase from food to the mouth, while the value for caftaric acid decreased only slightly throughout the digestion phase from the mouth to the jejunum, indicating that caftaric acid was stable under general digestive conditions compared with chlorogenic acid, chicoric acid, and 3,5-DCQA. Values for caftaric acid, chlorogenic acid, and chicoric acid remained at 38.2, 20.4, and 23.1%, respectively, after harsh digestion in the ileum at pH 7.0 for 5 h. The value for 3,5-DCQA was also markedly degraded after simulated digestion and remained at only 5.1% in the soluble fraction of the ileum phase. Unlike the four hydroxycinnamic acids, luteolin-7-*O*-glucuronide was stable and was preserved after total simulated digestion (residual percentage, 65.3%). The degradation of caftaric acid, chlorogenic acid, chicoric acid, and 3,5-DCQA might be dependent on the pH, and the stability of these compounds tends to be decreased under higher-pH conditions (pH >6.0).[26]

Bioaccessibility is defined as the relative amount of phytochemicals "released" from a complex food matrix during digestion, which could potentially also be available for absorption.[27] Five compounds were released from their food matrices during simulated digestion, and the digestates of the

[a]$P_{app\ A\ to\ B}$, transport of the compounds from the apical to basolateral compartment. [b]$P_{app\ B\ to\ A}$, transport from the basolateral to apical compartment. [c]The $P_{app\ A\ to\ B}/P_{app\ B\ to\ A}$ ratio is the ratio of $P_{app\ A\ to\ B}$ to $P_{app\ B\ to\ A}$. Data are means ± SEM (n = 3−6). [d]No detection.

soluble fraction were available for uptake by absorptive epithelial cells.[28] Because of their hydrophilic properties, 1.12, 0.28, and 2.52 mg of caftaric acid, chlorogenic acid, and chicoric acid, respectively, were released from the food matrix. A significant increase appeared in the bioaccessibility of caftaric acid (87.8%) and chlorogenic acid (61.3%) during simulated digestion (Figure 2A,B). More than 60% of caftaric and chlorogenic acid was released in the stomach and duodenum phase. However, the bioaccessibility of chicoric acid was very low through the mouth and stomach step, which suddenly underwent a change in pH from 6.5 to 2.2 (Figure 2C). Because of the pH change, chicoric acid (stomach phase, 1.36 mg) was aggregated during digestion and was insoluble in the digestate. The solubility of chicoric acid was shown at various pH values in the absence of gastric enzymes (Figure 3A) and was low at pH 2 and 3 compared to that at pH 4 and 5. This result may explain why the result in Figure 2C was obtained. The additional experiment was conducted using the solvent partition of chicoric acid from the digestate to evaluate the insoluble chicoric acid at various pH values (Figure 3B). The lower phase (aqueous fraction) and upper phase (ethyl acetate fraction) were analyzed by HPLC to evaluate the chicoric acid content. Chicoric acid, which was insoluble at pH <3, was more soluble when the pH increased. The bioaccessibility of chicoric acid recovered to 2.66 and 3.56 mg during the intestinal digestion phase. In the case of 3,5-DCQA, it was markedly degraded during simulated digestion, and only 8% of 3,5-DCQA remained in the digestate. Caftaric acid, chlorogenic acid, chicoric acid, and 3,5-DCQA were degraded during ileum intestinal digestion. The stability of these compounds may be affected by the pH and digestion time during the ileum phase. These results highlight how four hydroxycinnamic acids were bioaccessible during the simulated stomach and upper parts of intestinal digestion and were available for absorption in the duodenum and jejunum phase. Our results are similar to those of Lafay et al.,[19] showing that the absorption percentage of chlorogenic acid in the small intestine was only 8% using the *in situ* perfusion model. The release of luteolin-7-*O*-glucuronide after simulated digestion is shown in Figure 2D. The luteolin-7-*O*-glucuronide was released slightly during small intestinal digestion, and the bioaccessibility of luteolin-7-*O*-glucuronide was stable with pH conditions and solubility.

Permeability of Hydroxycinnamic Acids in Intestinal Cells. A cell permeability study for the four hydroxycinnamic acids and one flavonoid was performed using a Caco-2 cell monolayer. Both a-to-b and b-to-a directional transport were evaluated, as shown in Table 2. Transport of the hydroxycinnamic acids from a to b ranged from 0.025×10^{-6} to 0.119×10^{-6} cm/s, indicating the extremely low cell permeability of hydroxycinnamic acids. However, the P_{app} for b-to-a flux of hydroxycinnamic acids was $>10^{-6}$ cm/s, except for that of chlorogenic acid (0.839×10^{-6} cm/s). In particular, there were significant differences between the $P_{app\ B\ to\ A}$ of each hydroxycinnamic acid, and the ratio of $P_{app\ A\ to\ B}$ to $P_{app\ B\ to\ A}$ was approximately 5−9 times higher in chlorogenic acid and caftaric acid than in chicoric acid and 3,5-DCQA. According to previous sudies,[29,30] chlorogenic acid was not well absorbed in the Caco-2 cell transport model, rat chronic absorption study, or human clinical study. The ratio of $P_{app\ A\ to\ B}$ to $P_{app\ B\ to\ A}$ of caftaric acid, chicoric acid, and 3,5-DCQA was even lower than that of chlorogenic acid. This result indicates that some efflux mechanisms may exist with hydroxycinnamic acids in their transport across the Caco-2 cell monolayer. Luteolin-7-*O*-glucuronide, which was the most stable compound among the five main components from *C. denticulatum* during simulated digestion, has a $P_{app\ B\ to\ A}$ far higher than those of four hydroxycinnamic acids. This agreed well with other studies that demonstrated that flavonoid glycosides such as luteolin-7-*O*-glucuronide were poorly absorbed in Caco-2 cells because of the active extrusion of P-glycoprotein.[31−33] Interestingly, chicoric acid is most abundant in *C. denticulatum*, followed by caftaric acid, 3,5-DCQA, and chlorogenic acid. However, caftaric acid and chlorogenic acid might be more important hydroxycinnamic acids in humans when considering their entire bioavailability such as their digestive stability, their efficiency of release from the food matrix, and their intestinal absorption. Further research using *in vivo* rat models and clinical studies will be required to clarify the bioavailability of these hydroxycinnamic acids.

In conclusion, this study shows that hydroxycinnamic acids from *C. denticulatum* were rapidly accessible in the stomach and duodenum phase, maximizing the possibility of absorption in intestinal Caco-2 cells. However, the intestinal cell permeability of hydroxycinnamic acids indicated that some efflux mechanisms might exist with hydroxycinnamic acids in their transport across the Caco-2 cell monolayer. The digestive stabilities of hydroxycinnamic acids from *C. denticulatum* were markedly low after simulated digestion and remained minimal in the soluble fraction of the ileum phase. Further, *in vivo* rat models and human clinical studies are needed to clarify the bioavailability of hydroxycinnamic acids.

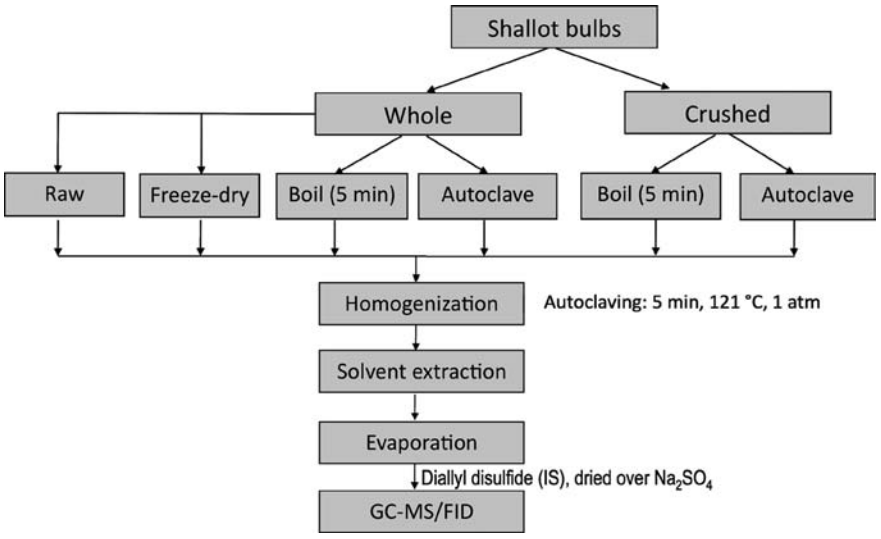

Figure 1. Overview of the processing treatments evaluated in the present study.

Enterprise (Singapore) while citric acid was from Avantor Performance Materials (USA).

Processing of Shallot before Extraction. Shallots from Vietnam were purchased from a local fruit and vegetable wholesale center in Singapore in July 2013. Shallot bulbs were immediately frozen (−20 °C) until further processing. Shallots were sorted out according to their physical qualities (e.g., size), and the first thin layer of the skin was peeled off using a knife. The peeled shallots were then washed with deionized water and wiped dried with sanitary paper towels. To evaluate the effect of the processing conditions on the enzyme-mediated production of organosulfides, 5 kg of shallot bulbs were divided into 3 portions and processed by different methods. The bulbs of portion 1 were crushed and homogenized using a Philips HR2001 food processor, and incubated at room temperature for 30 min in a shaker. Portion 2 was directly subjected to the processing treatments as described below. Portion 3 was freeze-dried. Triplicate samples coming from portions 1 and 2 were boiled for 5 min. The homogenates/bulbs and the heating medium (water) were collected and subjected to solvent extraction as described below. The remaining samples from portions 1 and 2 were subjected to autoclaving (1 atm, 121 °C, 5 min) using a Hiclave HV-50 autoclave (Hirayama Manufacturing Corp., Japan). Portion 3 samples were either freeze-dried using an Advantage Plus ES-53 VirTis freeze-dryer for 72 h (−50 °C, under a vacuum of 180 mTorr) or ground immediately without any pretreatment. After each treatment, homogenates or the whole bulbs were further crushed and homogenized followed by solvent extraction, as described in the following section. Tested samples were assigned as whole-boiled (WB), whole-autoclaved (WA), crushed-boiled (CB), crushed-autoclaved (CA), and freeze-dried (FD). The entire experiment was carried out in triplicate. Figure 1 gives an overview of the processing conditions tested.

Effect of pH Adjustment. A 3 kg portion of bulb samples from the same batch was allotted for the pH adjustment experiment. Freshly peeled shallot bulbs (200 g) were crushed and homogenized with an equal amount of deionized water for 1 min in a commercial blender. The homogenate was then placed on a shaker at room temperature for 30 min to allow the alliinase-mediated polysulfide formation to take place, after which the pH was immediately adjusted to 3.0, 7.0, and 9.0 using food grade citric acid (3.0 M) or sodium carbonate (2.0 M) solutions. A pH 5.0 experiment was not performed because the pH of homogenized shallot was about 5.35. The resulting pH-adjusted homogenates were incubated at room temperature (22 ± 2 °C) for 90 min in a shaker followed by solvent extraction. Three solvent extractions for each pH level, including control (pH not adjusted) were carried out to give three replicates.

Solvent Extracted Shallot Oil. Shallot bulbs (200 g) were crushed and homogenized with an equal amount of deionized water and incubated with shaking at room temperature. After 30 min of incubation, shallot homogenates were quantitatively transferred into a 1-L flask and extracted (at room temperature with shaking) with diethyl ether (200 mL) spiked with 0.1 mL of 10,000 ppm of diallyl disulfide in dichloromethane as internal standard. Extraction was repeated two more times. The combined ether extracts were concentrated using a rotary evaporator at 30 °C under vacuum. The pungent oil recovered was dried over anhydrous Na_2SO_4 and stored at (−20 °C) until further analysis.

Hydrodistillation of Shallot Oil. A portion of the shallots coming from the same batch was subjected to hydrodistillation. Preparation of the homogenate was carried out as described above. After standing for 30 min, the homogenate was placed in a 500 mL round-bottom flask and charged to a distillation apparatus and immediately subjected to hydrodistillation for 3 h. The milky distillate was extracted 3 times with diethyl ether spiked with the same amount of internal standard in dichloromethane. Diethyl ether extracts were then concentrated using a rotary evaporator and dried over anhydrous Na_2SO_4. The shallot oil obtained was kept at −20 °C until further analysis.

GC and GC-MS/FID Analyses. A portion (100 μL) of the oil recovered was diluted with dichloromethane to 1.0 mL and filtered through a Sartorius Minisart polytetrafluoroethylene (PTFE) membrane (0.45 μm) into a GC-vial. The gas chromatographic analyses were performed with an Agilent 7890A gas chromatography system equipped with a fused silica DB-5MS (30 m × 0.25 mm i.d., 0.25 μm film thickness) column. Injector and transfer line temperatures were 250 and 270 °C, respectively. The initial temperature was 50 °C (3 min), raised to 150 °C (3 min) at the rate of 3 °C/min and further ramped to 250 °C (5 min) at 25 °C/min. Helium (99.999%) was the carrier gas with a flow rate of 1 mL/min. Samples of 1.0 μL were injected using an autosampler (Agilent 7683B) at a 1:5 split ratio. For GC-MS detection, the GC system was interfaced with an Agilent 5975C MS unit operated under the EI mode (70 eV) with an ion source temperature of 200 °C at a mass range of 40.0−500.0. Carrier gas was helium (99.99%) at a flow rate of 1 mL/min.

GC-FID analysis of the hydrodistilled oil and lipophilic extracts was performed using a Varian CP 3800 GC system equipped with a SUPELCO fused silica capillary column (30 m × 0.25 mm I.D., film thickness = 0.25 μm). Carrier gas was helium (99.99%) at a flow rate of 1 mL/min and an injector temperature of 250 °C. The GC conditions were similar as described above. Diluted samples of 1.0 μL were injected manually. The components were identified by matching their retention times with those of the compounds identified by GC-MS.

Identification and Quantification of Organosulfides. Identification of compounds was based on comparison of their mass spectra with those of the National Institute of Standards and Technology

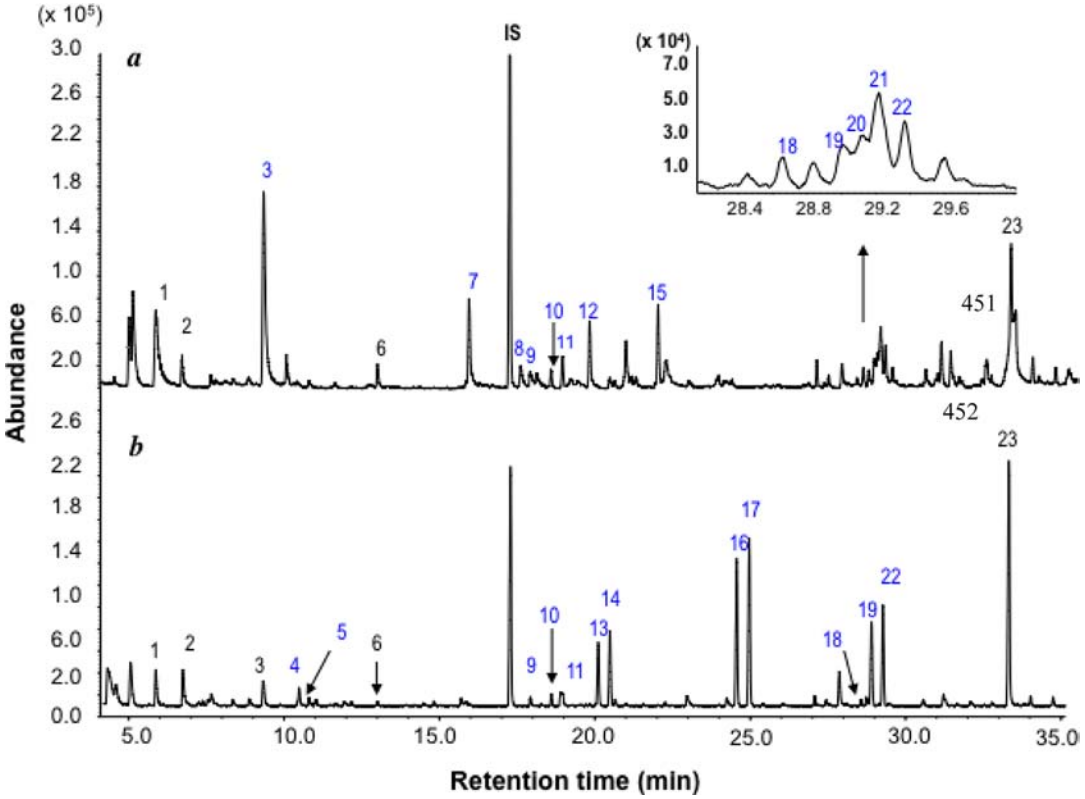

Figure 2. Typical GC chromatograms of organosulfides in (a) solvent extracted and (b) hydrodistilled shallot oil. Peak numbers correspond to the peaks listed in the first column of Table 1. The analytical conditions are described in the text. Peak numbers in blue indicate organosulfides.

(NIST 0.5a) database library of the GC/MS system and by comparing mass spectra with either those of available authentic compounds or published data.11[11,17] When neither a good library match nor published information was available, the identification was established by interpreting the fragmentation pattern of mass spectra. The relative GC peak area of each ion spectrum was calculated against the internal standard and was used to obtain the concentration of each compound expressed in ppm. The relative response factors (RRFs) were measured under the same conditions using the available standard compounds and were calculated as RRF = $(C_{compound}A_{IS})/(C_{IS}A_{compound})$, where $C_{compound}$ and $A_{compound}$ were the concentration and corresponding GC peak area of the compound, C_{IS} and A_{IS} were the concentration and GC peak area of the internal standard.[18] The RRFs of the commercially unavailable compounds were assumed to be 1.0.

Statistical Analysis. Results were expressed as means ± standard deviations (SD) of three separate experiments. Differences between the concentration of organosulfides in solvent extracted and hydrodistilled shallot oil were analyzed by Student's t test ($p < 0.05$). The effect of pH and processing conditions on the yield of organosulfides was analyzed by ANOVA ($p < 0.05$) using OriginPro 8 (OriginLab, USA). Posthoc analysis using Tukey's test was carried out to determine significant differences among the means ($p < 0.05$).

RESULTS AND DISCUSSION

Organosulfide Profiles of Solvent Extracted vs Hydrodistilled Shallot Oil. Shallot oil was obtained by hydrodistillation and extraction using anhydrous diethyl ether. Yellowish oil with pungent odor was obtained at a yield of 0.3−0.5%. The typical GC profile of the oil constituents identified in the solvent extracts and hydrodistilled oil is shown in Figure 2. The solvent extracted samples have more peaks in comparison with hydrodistilled oils. Among them, 14 peaks were identified as sulfur-containing compounds, accounting for 76.47% of the total number of volatile components. Table 1 lists the identified compounds along with their mass spectral characteristics, chemical structures, and GC retention times.

For the solvent extracted oil (Figure 2a), peaks 9 and 11 were acyclic organosulfides identified as trans or cis isomers of propyl-1-propenyl disulfide based on the similarity of their mass fragmentations to those reported in the literature.[19] The other disulfide identified was dipropyl disulfide (peak 10). Three trisulfides were detected as dipropyl trisulfide (peak 18) and cis/trans propyl-1-propenyl trisulfide (peak 20 and 21) based on the comparison of their mass spectra with the mass spectral data of Wu et al.[11] and Sinha et al.[17d] Cyclic organosulfides identified include 3,4-dimethylthiophene (peak 3), cis/trans 2-ethyl-3-methylthiophane (peak 7 and 8), 3-ethyl-1,2-dithi-5-ene (peak 12), and 3-ethyl-1,2-dithi-4-ene (peak 15). A number of nonsulfur flavor compounds were also identified as 2-methyl-2-pentenal (peak 1), *n*-hexanal (peak 2), 2-pentylfuran (peak 6), and 2-hexyl-5-methyl-3(2H)-furanone (peak 23). They are decomposition products fatty acids except 2-methyl-2-pentenal, which was previously reported in solvent extracts of Welsh onions and scallions[17c] and suggested to be the decomposition product of the onion lachrymatory factor (LF).[20] 2-Hexyl-5-methyl-3(2H)-furanone has previously been detected in shallot.[11]

The hydrodistilled oil (Figure 2b) contains two acyclic disulfides, methyl propyl disulfide and methyl 1-propenyl disulfide (peaks 4 and 5, respectively), which are not found in solvent extracted oil. On the other hand, cis and trans propyl-1-propenyl trisulfide (peaks 20 and 21) were not detected in hydrodistilled oil but were present in the solvent extracted oil. Four additional peaks not present in solvent extracted oil were identified as cis/trans 3,5-dimethyl-1,2,4-trithiolane (peaks 13

Table 1. Identity and Mass Spectral Data of Sulfur-Containing and Other Volatile Compounds in Shallot Oil

No[a]	Retention time (min)	Compound	Chemical structures	*m/z* (%)[b]	Identification[c]

and 14) and cis/trans ethyl 1-propenyl trisulfide (peaks 16 and 17), respectively. Formation of the isomers of 3,5-dimethyl-1,2,4-trithiolane may be due to thermal decomposition of cysteine,[21] while peaks 16 and 17 (m/z = 166) were assigned as isomeric forms of ethyl 1-propenyl trisulfide.[22] Peaks 19 and 22, identified as cis/trans 3,5-diethyl-1,2,4-trithiolane, showed notably larger peak areas and good peak separation in hydrodistilled oil.[21] 3,5-Dimethyl-1,2,4-trithiolane has previously been identified in diethyl ether and ethyl acetate extracts of garlic.[23] The relative abundance of sulfur-containing compounds from *Alliums* may vary according to the method of isolation. Kuo and Ho[19] found that methylene chloride extracts of Welsh onions and scallions contained 30 volatile components, including 7 sulfur-containing compounds that were not found in the hydrodistilled oils of the same plants.[24]

A comparison of the organosulfide concentrations (Table 2) in solvent extracted and hydrodistilled oil showed that the solvent extracted one had significantly higher total organosulfides content (266.82 ppm) as compared to hydrodistilled oil (97.81 ppm). In solvent extracted oil, the major cyclic organosulfides were 3,4-dimethylthiophene (58.39 ppm), cis/trans 2-ethyl-3-methylthiophane (68.88 ppm), 3-ethyl-1,2-dithi-4-ene (23.66 ppm), and 3-ethyl-1,2-dithi-5-ene (20.54 ppm). The major linear organosulfides were cis/trans propyl 1-propenyl disulfide (37.75 ppm), cis/trans propyl 1-propenyl trisulfide (27.19 ppm), and dipropyl trisulfide (22.95 ppm). In the hydrodistilled oil, the predominant organosulfides include cis/trans ethyl 1-propenyl trisulfide (41.17 ppm), cis/trans 3,5-diethyl-1,2,4-trithiolane (23.06 ppm), and cis/trans 3,5-dimethyl-1,2,4-trithiolane (19.71 ppm). In terms of the cyclic organosulfide components, trans 2-ethyl-3-methylthiophane, 3-ethyl-1,2-dithi-4-ene, and 3-ethyl-1,2-dithi-5-ene, which were major organosulfides in solvent extracts, were not detected in hydrodistilled oils. Similarly, a significantly ($p < 0.05$) lower amount of 3,4-dimethylthiophene was observed in hydrodistilled oil (3.67 ppm) as compared to those of the solvent extracts. It is remarkable that four isomeric cyclic polysulfides (cis/trans 3,5-dimethyl-1,2,4-trithiolane and cis/trans 3,5-diethyl-1,2,4-trithiolane) predominated in the hydrodistilled oils.

Hydrodistilled oil had significantly lower ($p < 0.05$) concentrations of acyclic polysulfides (95 ppm) as compared to the solvent extracted counterpart (51 ppm). Notable changes in the acyclic polysulfides include reduced amounts of cis/trans propyl 1-propenyl disulfide (1.88 ppm) and dipropyl disulfide (1.15 ppm) in hydrodistilled oil from 37.75 and 22.95 ppm, respectively, in solvent extracted oil. This is in agreement with the literature report that alkyl-1-propenyl disulfides may decompose into saturated disulfides upon heating.[1]

Effect of pH on the Organosulfide Profiles of Shallot Oil. Media acidity is an important factor in transformation of organosulfides in *Alliums* because thiols (RSH) and sulfenic acid (RS(O)H) are weak acids. Therefore, we examined the effect of pH on organsulfide profiles and the results are shown in Figure 3. It is clear that the total acyclic disulfides were favored at basic conditions (pH 9.0, 87.99 ppm). Dipropyl disulfide increased 2-fold at pH 9.0 compared to that in control. Methyl propyl disulfide and cis/trans methyl 1-propenyl disulfide were detected only at pH 9.0 (Table 3). On the other hand, total acyclic trisulfides have the highest concentration at pH 3.0 (83.01 ppm) as compared to control (50.14 ppm), pH 7.0 (20.67 ppm), and pH 9.0 (41.37 ppm). Significantly reduced concentrations of individual trisulfides were also observed (Table 3) upon increase of pH values. In terms of total cyclic organosulfides, the highest concentration was observed at pH 3.0 (299.68 ppm), much higher than the sample treated at pH 9.0 (80 ppm). In particular, the concentration of 3,4-dimethylthiophene was 8 times higher (193 ppm) at pH 3.0 compared to that at pH 9.0 (23.35 ppm). Similarly, 3-ethyl-1,2-dithi-4-ene and 3-ethyl-1,2-dithi-5-ene showed significantly higher ($p < 0.05$) concentrations at pH

[a]Data are expressed as means ± SD, and the difference among treatments was analyzed by Tukey's test at a level of significance $p < 0.05$. Values across rows without a common letter differ significantly. n.d.: not detected.

3.0 as compared to control and pH 9.0 and 7.0. Finally, cis- and trans-2-ethyl-3-methylthiophane were significantly higher at pH 3.0 (42.95 ppm) compared to pH 7.0 (17.72 ppm) and pH 9.0 (15.85 ppm) but showed the highest concentration at pH 5.3 (68.88 ppm).

In general, acyclic disulfides were favored at basic pH (9.0) whereas acyclic trisulfide formation is favored at weakly acidic pH (5.3) and pH 3.0. On the other hand, cyclic sulfides were highest at pH 3.0. The trends we observed were consistent with a literature report on garlic oil.[25] Our results were also in agreement with a literature report that formation of methyl allyl disulfide and methyl propyl disulfide was favored at pH 9.0 while that of diallyl trisulfide and methyl allyl trisulfide was favored in the neutral or weak acidic pH range.[26] Optimal formations of trisulfides at pH 5.0 or neutral pH could be due to their stability in this pH range rather than at other pH values.[27] The unstable intermediates that are formed after alliinase catalyzed conversion of ACSO may decompose easier into disulfides at pH 9.0, explaining the notable increases of these compounds at this pH.[24]

Effect of Processing Methods on Organosulfides. We further examined different ways of processing, nonthermal and thermal methods, and evaluated their effects on the organosulfide profiles of shallot. Freeze-drying is a nonthermal method for food preservation and is recognized for retaining the quality and health-promoting attributes of onions.[28] We freeze-dried some shallots and extracted the organosulfides using solvent extraction and analyzed the organosulfide profile. Our results show that the ratio of acyclic to cyclic organosulfides in raw (35.7:64.3) remained essentially the same as that of freeze-dried samples (34.7:63.3), although changes in the concentrations of some of the individual polysulfides were observed (Table 4). In freeze-dried shallots, cis/trans propyl 1-propenyl disulfide (23.84 ppm) and dipropyl trisulfide (14.97 ppm) decreased significantly ($p < 0.05$) as compared to raw extracts (37.75 and 22.95 ppm, respectively). Moreover, the total cyclic organosulfides of the freeze-dried sample (138.11 ppm) significantly decreased as compared to the raw one (171.48 ppm), but this reduction was mainly due to the loss of 3-ethyl-1,2-dithi-5-ene. Only slight differences were observed in the levels of cis/trans 2-ethyl-3-methylthiophane, 3-ethyl-1,2-dithi-4-ene, and 3,4-dimethylthiophene between raw and freeze-dried samples. In general, although the total organosulfide content of freeze-dried samples (211.57 ppm) decreased significantly ($p < 0.05$) as compared to those of raw shallots (266.82 ppm), most of the organosulfides remained essentially the same except a few acyclic and cyclic polysulfides, which may have evaporated out during the freeze-drying process. Colina-Coca et al.[27] found that freeze-drying retained ACSO in diced onions. Their result may indicate that the organosulfides of onions can be maintained after the freeze-drying process. In another study, Colina-Coca et al.[28] found that dipropyl disulfide and dipropyl trisulfide significantly ($p < 0.05$) decreased in freeze-dried onions (*Allium cepa* L. var. cepa, "Recas") as compared to diced onions. Our results are in agreement with this except for dipropyl disulfide.

dx.doi.org/10.1021/jf500739n | J. Agric. Food Chem. 2014, 62, 5296−5304

The typical GC chromatograms of shallot oils treated by thermal and freeze-dried processing methods are shown in Figure 4. GC-FID quantification revealed significant changes (p < 0.05) in the concentrations of the individual organosulfide as a result of the different processing methods evaluated. It is apparent that thermal treatments significantly (p < 0.05) reduced the contents of total organosulfides (Figure 5). Boiling (100 °C) and autoclaving (121 °C) temperatures will inactivate the thermal-labile alliinase (80% inactivation at 50 °C for 10 min).[29] Consequently, individual polysulfides dramatically decreased or were completely lost after the heat treatment. In the case of crushed and boiled shallots and crushed and autoclaved samples, the homogenates were allowed to stand for 30 min after crushing before heat treatment was applied. Thus, alliinase shall have sufficient time to react with ACSOs. This treatment is responsible for significantly higher (p < 0.05) organosulfides of crush-boiled and crushed-autoclaved samples as compared to the whole shallots treated in the same manner. Notably lower organosulfide contents of crushed boiled and autoclaved samples suggested that the thiosulfinates or polysulfides in shallot are thermally degraded to nonvolatile compounds. Thiosulfinates showed sensitivity to heat in a time- and intensity-dependent manner.[12] It was suggested that a short heat treatment (boiling for 6 min) did not reduce the *in vitro* antiplatelet activity (IVAA) of onion extract; however, increasing the temperature and heating time resulted in complete loss of activity.

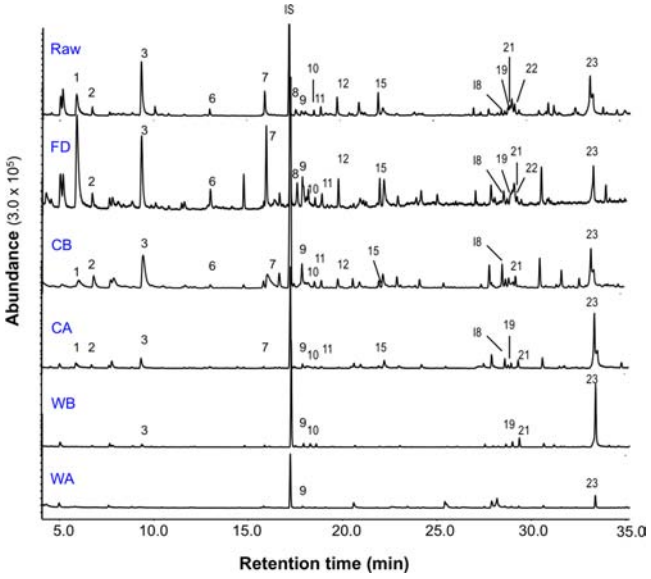

Figure 4. GC chromatograms of organosulfides in (a) raw, (b) freeze-dried (FD), (c) crushed-boiled (CB), (d) crushed-autoclaved (CA), (e) whole-boiled (WB), and (f) whole-autoclaved (WA) shallot. The analytical conditions are described in the text.

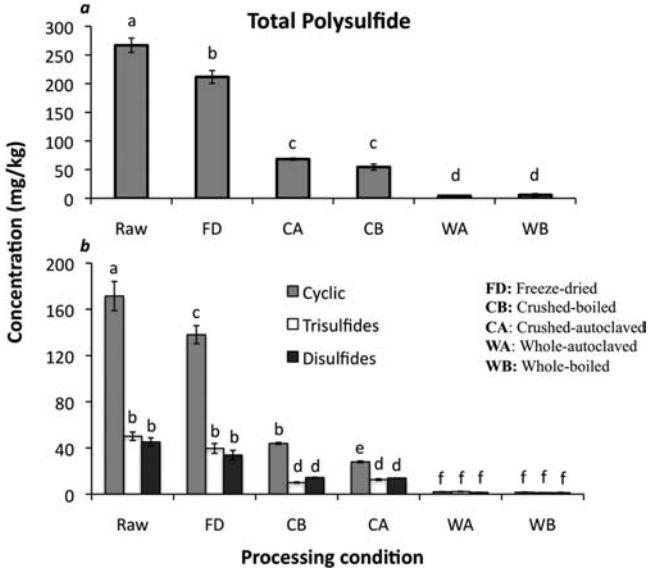

Figure 5. Effect of processing on the (a) total polysulfide content and (b) polysulfide distribution profile of shallot. Data are expressed as means ± SD, and the difference among treatments was analyzed by Tukey's test at a level of significance p < 0.05. Bar graphs without a common letter differ significantly.

Another study demonstrated that although in general degradation of thiosulfinates in onions (*Allium cepa* L.) was affected by heating, the extent to which these antiplatelet agents are destroyed varied depending upon the method (whole, quarters, crushed) of sample preparation.[13] Moreover, the effect of domestic cooking on allicin and pyruvate levels as estimators of the IVAA of cooked garlic extracts was investigated.[16] Oven-heating (200 °C) and boiling for 3 min or less resulted in similar antiplatelet activity as that of the raw extracts; however, crushed garlic subjected to 6 min of boiling or oven heating retained some antiplatelet activity as compared to the uncrushed samples, which completely lost their IVAA. The allicin and pyruvate contents of crushed and uncrushed garlic showed similar trends in IVAA in both cooking methods, suggesting that the thiosulfinates in garlic (mainly allicin) are responsible for the antiaggregatory response.[16] Concordant with the findings of these studies, our results suggest that, in order to allow formation of organosulfides and their retention after processing, shallot should be crushed prior to cooking under mild heat. Intense heating may not only result in the degradation of thiosulfinates. Significant reduction in the polysulfide contents of shallots as an effect of thermal treatment has also been reported.[11]

GC-MS is suggested by Block et al. to be an analytical tool of choice for analysis of volatile organosulfides.[15] In our study, we obtained distilled and diethyl ether extracts after allowing sufficient reaction time to ensure formation of polysulfides. The weakly polar solvents (e.g., diethyl ether and hexane) used favor extraction of polysulfides. In addition, the oil distillate obtained shall not contain thiosulfinates, as these compounds decompose readily to polysulfides during the distillation step.

Block et al. analyzed *Allium* homogenate extracts for their thiosulfinates content. They suggested that there is a serious problem in artifact formation when using GC-based analysis of *Allium* flavorants due to the sensitivity of thiosulfinates to the high temperature conditions during GC analysis.[15] The focus of their study was on the detection of thiosulfinates from *Allium* homogenates while the present study deals with the polysulfides that are present after isolating the lipophilic extracts and distilled oils in shallots that were subjected to different processing conditions and oil isolation methods.

In summary, we have demonstrated that thermal processing by boiling and autoclaving results in significant loss in the cyclic and acyclic organosulfides of shallot while freeze-drying retains the majority of organosulfides. Although freeze-drying resulted

in a significant decrease in the total polysulfide content, this reduction was only attributed to a few organosulfides while the majority of the organosulfides remained the same. In light of the goal of isolating optimal amounts of organic polysulfides with potential H_2S-releasing activity, direct extraction is the preferred method and freeze-drying is a good alternative. Adjusting pH prior to solvent extraction alters the amounts of organosulfides in shallot, with trisulfides showing the highest concentrations at weakly acidic (pH 5.0) to acidic pH (3.0) while disulfides were highest at pH 9.0. It should be pointed out that organic polysulfides that are present only in hydrodistilled oil may be of interest as potential H_2S donors and that the H_2S donating activity of the different oils obtained demands further evaluation using biological models such as cell-line and experimental animal.

*(8R,8′R)-4′-Fluoro-4-methoxy-3-lignanol (**59**).* Colorless oil; $[\alpha]_D^{25}$ −26 (c 0.6, $CHCl_3$); ^{1}H NMR (400 MHz, $CDCl_3$) δ 0.80 (3H, d, J = 6.7 Hz), 0.81 (3H, d, J = 6.5 Hz), 1.70−1.78 (2H, m), 2.33 (1H, dd, J = 13.5, 8.3 Hz), 2.38 (1H, dd, J = 13.5, 8.4 Hz), 2.54 (1H, dd, J = 13.5, 6.1 Hz), 2.60 (1H, dd, J = 13.5, 6.1 Hz), 3.86 (3H, s), 5.54 (1H, s), 6.55 (1H, dd, J = 8.2, 2.0 Hz), 6.68 (1H, d, J = 2.0 Hz), 6.73 (1H, d, J = 8.2 Hz), 6.93 (2H, m), 7.03 (2H, m); ^{13}C NMR (100 MHz, $CDCl_3$) δ 13.8, 13.9, 38.1, 38.2, 40.6, 40.7, 56.0, 110.4, 114.8 (d, J = 21.1 Hz), 115.1, 120.3, 130.2 (d, J = 7.8 Hz), 134.9, 137.2 (d, J = 3.0 Hz), 144.6, 145.2, 161.1 (d, J = 242.6); ^{19}F NMR (376 MHz, $CDCl_3$) δ −119.1; MS (EI) m/z 302 (M^+, 92), 137 (100); HRMS (EI) m/z calcd for $C_{19}H_{23}FO_2$ 302.1682, found 302.1679.

Cytotoxic Assay. Human cervical carcinoma cell line HeLa cells and human promyelocytic leukemia cell line HL-60 cells were obtained from American Type Culture Collection (Manassas, VA). Colon 26 colon adenocarcinoma cells derived from BALB/c mouse were kindly provided by the Institute of Development, Aging and Cancer, Tohoku University (Sendai, Japan). Vero cells (JCRB0111) were purchased from JCRB Cell Banks. These cells were cultured in the DMEM medium (Sigma, St. Louis, MO) supplemented with 10% fetal bovine serum (FBS) at 37 °C in a humidified atmosphere of 5% CO_2. HeLa, Colon 26, and Vero cells were inoculated in 96-well culture plates at 2.0 × 10^4 cells/well suspended in the DMEM medium, and HL-60 cells were inoculated in 96-well culture plates at 1.0 × 10^4 cells/well suspended in RPMI1640 with FBS and various concentrations of different compounds. After cultivation for 48 h, the cell viability was assessed by a WST-8 reduction assay (Dojin Laboratories, Japan). The WST-8 reduction activity of the cells is presented as the ratio of cell activity. Briefly, a WST-8 solution was added to the culture medium at 10% concentration and incubated for 1 h at 37 °C prior to colorimetry at 450 nm. The single cytotoxic assay was performed in triplicate.

RESULTS AND DISCUSSION

Syntheses of Derivatives. As shown in Scheme 1, 9- and 9′-derivatives of (8*R*,8′*R*)-DGA **6**−**15** were synthesized from dibenzyloxymatairesinol **61**. The aromatic derivatives **16**−**59** were synthesized by the previously described method[15] with modification.

Cytotoxic Activities of 9- and 9′-Derivatives against HL-60 and HeLa Cells. Table 1 shows the cytotoxic activity of dietary (8*R*,8′*R*)-secoisolariciresinol (SECO) (**1**) and its 9 and 9′-derivatives against HL-60 and HeLa cells. (8*R*,8′*R*)-SECO (**1**) and (8*R*,8′*R*)-9,9′-anhydrosecoisolariciresinol (**2**), which is a metabolite from (−)-(8*R*,8′*R*)-SECO, did not show the remarkable activity at 100 μM, suggesting that the oxidations at

59	4′-F	5.8 ± 0.7	9.9 ± 0.3

9- and 9′-positions on the butane chain are disadvantageous for the activity. This fact was ascertained by the examination using dihydroguaiaretic acids (DGA) **3**−**5**, whose 9- and 9′-positions were reduced. All stereoisomers of dihydroguaiaretic acids exhibited the almost same level of activities (IC_{50} = 22−41 μM). The stereochemistry of 8 and 8′-positions did not affect the activity. The activity of 9, 9′-acetoxy derivative **6** was 2−3-fold less potent than DGA stereoisomers, and the activity of 9, 9′-nitrile derivative **8** was very weak (IC_{50} > 100 μM); however, a similar level of activity to DGA stereoisomers was observed in 9, 9′-methoxy derivative **7**. Compared with inactive tetrahydrofuran structure **2**, the disadvantage of the ring structure was suggested. Even if the oxygen atoms are present at 9- and 9′-positions, the methoxy derivative kept the activity. For further research on the 9-position, the activities of 9-derivatives of (8*R*,8′*R*)-DGA **9**−**15** were tested. Compared with inactive (−)-(8*R*,8′*R*)- SECO (**1**), 9′-dehydroxy SECO **9** showed the weak activity (IC_{50} = 79−98 μM). The activities of 9-acetoxy and 9-methoxy DGA derivative **10** and **11** were the same level as those of all stereoisomers of DGA **3**−**5**, 9,9′-acetoxy **6**, and 9,9′-methoxy **7** derivative. On the other hand, 9-alkyl DGA derivative **13** and **14** displayed 3−4-fold higher activity than that of (8*R*,8′*R*)-DGA (**3**). The activity level of 9-butyl DGA **13** and 9-isopropyl DGA **14** was similar, indicating the importance of higher hydrophobic structure for the higher activity. Because 9-fluoro derivative **12** showed comparable activity to that of (8*R*,8′*R*)-DGA (**3**), the activity would not be affected by an electron-withdrawing atom. The activity of basic derivative, 9-dimethylamino DGA derivative **15**, was very low. The relationship between cytotoxic activity and 9-, 9′-structure of butane-type lignan containing dietary secoisolariciresinol became clear. The higher hydrophobic compounds exhibited higher activity.

Cytotoxic Activities of 7-Aryl Derivatives against HL-60 and HeLa Cells. As a next step, the effect of the substituent

Table 4. Cytotoxic Activities of 3, 38, and 47 against Colon 26 and Vero Cells (IC_{50}± SD, n = 3)

Compounds	Colon 26 IC_{50} (μM) ± SD	Vero IC_{50} (μM) ± SD	HL-60 IC_{50} (μM) ± SD	HeLa IC_{50} (μM) ± SD
 (8*R*,8′*R*)-DGA (**3**)	32.3 ± 4.4	35.7 ± 1.8	25.7 ± 0.9 (Table 1)	21.7 ± 4.1 (Table 1)
 **38**	17.4 ± 0.8	28.7 ± 4.0	8.7 ± 1.2 (Table 2)	7.5 ± 0.5 (Table 2)
 **47**	6.9 ± 1.4	10.2 ± 2.2	0.8 ± 0.4 (Table 3)	1.7 ± 0.6 (Table 3)

dx.doi.org/10.1021/jf5010572 | J. Agric. Food Chem. 2014, 62, 5305−5315

of the aromatic ring on the activity was examined. Table 2 shows the activities of 7-derivatives of (8*R*,8′*R*)-DGA. Without a substituent on the 7-aromatic ring, derivative **16** showed 2.6-fold higher activity than (8*R*,8′*R*)-DGA (**3**) against HL-60 cells and similar activity to **3** against HeLa cells. It could be assumed that the 3-methoxy group and 4-hydroxy group of **3** do not play an important role to keep 10−30 μM of IC_{50} values. As for 2-substituted derivatives **17**−**22**, all derivatives showed 2−4-fold higher activity than that of (8*R*,8′*R*)-DGA (**3**) against HL-60 cells. The activities of 2-methoxy derivative **18**, 2-butoxy derivative **19**, and 2-methyl derivative **20** bearing an electron donor group were about 2-fold higher than those of hydrophilic 2-hydroxy derivative **17** and 2-halo derivative **21** and **22** bearing an electron-withdrawing group, suggesting that the hydrophobic and electron donor substituents on the 2-position are favorable for higher activity against HL-60 cells. Because the activity of 2-butoxy derivative **19** was similar to that of 2-methoxy derivative **18** against HL-60 cells, the length of alkoxy group would not affect the activity. Against HeLa cells, hydrophilic 2-hydroxy derivative **17** and 2-butoxy derivative **19** bearing a longer alkoxy group exhibited 2-fold higher activity than that of (8*R*,8′*R*)-DGA (**3**). On the other hand, the same level of activities as that of (8*R*,8′*R*)-DGA (**3**) were observed in 2-methoxy derivative **18**, 2-methyl derivative **20**, and 2-halo derivative **21** and **22**. The 2-hydroxy derivative **17** and 2-butoxy derivative **19** showed higher activity than (8*R*,8′*R*)-DGA (**3**) against both cells. The effect of 3-substituent was also examined. It was shown that the activities of 3-hydroxy derivative **23** and 3-methoxy derivative **24** were similar to that of (8*R*,8′*R*)-DGA (**3**) against both HL-60 and HeLa cells. The more hydrophobic derivatives, 3-butoxy derivative **25**, 3-methyl derivative **26**, 3-fluoro derivative **27**, and 3-chloro derivative **28** were 2−3-fold more effective than (8*R*,8′*R*)-DGA (**3**) against HL-60 cells. Against HeLa cells, the activity level of 3-methyl derivative **26**, 3-fluoro derivative **27**, and 3-chloro derivative **28** was almost the same as that of (8*R*,8′*R*)-DGA (**3**); however, 3-butoxy derivative **25** exhibited 2-fold more potent activity than (8*R*,8′*R*)-DGA (**3**). The 3-butoxy derivative **25** bearing a longer and hydrophobic group displayed the highest activity among the 3-substituted derivatives against both cells. In the case of the 4-position, 4-hydroxy derivative **29** and 4-butoxy derivative **31** were 4-fold more potent and 4-methoxy derivative **30** and 4-halide derivative **33** and **34** were 2-fold more potent than that of (8*R*,8′*R*)-DGA (**3**) against HL-60 cells. Against HeLa cells, 2-fold higher activities than that of (8*R*,8′*R*)-DGA (**3**) were observed in 4-hydroxy derivative **29** and 4-butoxy derivative **31**. The activities of 4-methyl derivative **32** against HL-60 and HeLa cells and 4-methoxy derivative **30** and 4-halide derivative **33** and **34** against HeLa cells were similar to that of (8*R*,8′*R*)-DGA (**3**). The phenolic derivative and longer alkoxy derivative were more effective at the 4-position as well as the 2-position against both cells. The activities of all monosubstituted derivatives are not less potent than that of (8*R*,8′*R*)-DGA (**3**). Especially, the IC_{50} values of 2-hydroxy derivative **17** and 2-butoxy derivative **19** were less than 10 μM against both HL-60 and HeLa cells. The activities of disubstituted compounds **35**−**40** were also compared. The 3,4-dihydroxy derivative **35** was 5-fold more potent against HL-60 cells and 2-fold more potent against HeLa cells than 3,4-dimethoxy derivative **37** and 3,4-methylenedioxy derivative **40**, whose activities were similar to that of (8*R*,8′*R*)-DGA (**3**). The 3,5-dihydroxy derivative **36** showed 3-fold and 4-fold higher activity against HL-60 cells and HeLa cells, respectively, than 3,4-dimethoxy derivative **37**. These facts mean that the hydrophilic disubstituted compound is advantageous for higher activity. The longer-chain derivative, 3-ethoxy-4-hydroxy derivative **39** enhanced the activity, showing 4-fold higher activity than (8*R*,8′*R*)-DGA (**3**) against HL-60 cells; however, similar activity to (8*R*,8′*R*)-DGA (**3**) was observed against HeLa cells. It is noteworthy that 3-hydroxy-4-methoxy derivative **38**, in which the positions of substituents are exchanged from that of natural DGA, showed 3-fold more potent activity than (8*R*,8′*R*)-DGA (**3**) against both cells. The positions of the hydrophobic and hydrophilic group affected the activity. The addition of a methoxy group to the 5-position of (8*R*,8′*R*)-DGA (**3**) enhanced the activity. The activity of 3,5-methoxy-4-hydroxy derivative **41** was 3-fold more potent than (8*R*,8′*R*)-DGA (**3**) against both cells. Compared with HeLa cells, HL-60 cells were more sensitive to more hydrophilic DGA derivatives. The activity of 3,4,5-hydroxy derivative **42** and pentahydroxy derivative **43** was 2-fold higher and comparable to (8*R*,8′*R*)-DGA (**3**), respectively. On the other hand, against HeLa cells, the activities of 3,4,5-hydroxy derivative **42** and pentahydroxy derivative **43** were similar to and much lower than (8*R*,8′*R*)-DGA (**3**), respectively. The position and the number of hydrophobic and hydrophilic groups affected the activity. The 7-(3-hydroxy-4-methoxy)-7′-(3-methoxy-4- hydroxy) derivative **38** showed less than 9 μM IC_{50} value against both cells.

Cytotoxic Activities of 7′-Aryl Derivatives against HL-60 and HeLa Cells. With the results of the cytotoxic experiment on 7-aryl derivatives, we selected 3-hydroxy-4-methoxyphenyl group as an aryl group for 7-position to detect the effect of the 7′-aryl group on the activity. The cytotoxic activities of 7-(3-hydroxy-4-methoxyphenyl)-7′-aryl derivatives **44**−**59** were evaluated. The activity of 7′-phenyl derivative **44** was comparable to that of 7′-(3-methoxy-4-hydroxyphenyl) derivative **38**. The presence of substituent on 7′-aryl group is not necessary to exhibit the activity level of **38**. Introduction of the substituent to the 2′-position of **44** enhanced the activity against both cells. The 2′-hydroxy derivative **45** and 2′-F derivative **51** showed 2-fold higher activity, and 2′-methoxy derivative **46** and 2′-methyl derivative **50** were 5-fold and 3-fold more potent, respectively, than **38** against HL-60 cells. These facts mean that the electron donor substituent is more effective than the hydrophilic and electron-withdrawing substituent on the 2′-position. The activity of 2′-ethoxy derivative **47** was 2-fold potent than 2′-methoxy derivative, showing the highest activity among 2′-derivatives; however, the longer and bulky substituent at the 2′-position decreased activity. The butoxy **48** and isopropoxy **49** derivative exhibited 2−4-fold less potent activity than that of the 2′-methoxy derivative. Against HeLa cells, 2′-ethoxy derivative **47** was also most effective among the 2′-derivatives, showing 4-fold higher activity than **38**. The shorter alkoxy derivative **46** and longer and bulker alkoxy derivative **48** and **49** showed weaker activity than that of 2′-ethoxy derivative **47** against HeLa cells as well as against HL-60 cells. The activities of 2′-methyl derivative **50**, 2′-fluoro derivative **51**, and 2′-hydroxy derivative **45** were 1.6−2-fold higher than that of **38** against HeLa cells. The 3′- and 4′-derivatives **52**−**59** showed comparable activity to **38** against both cells except for 4′-hydroxy derivative **56** and 4′-methoxy derivative **57**, which were 1.6-fold more potent than **38** against HL-60 cells. The presence of substituent on 2′-position of 7-(3-hydroxy-4-methoxyphenyl)-7′-aryl derivatives was important for the higher activity. 7-(3-Hydroxy-4-methoxyphenyl)-7′-(2′-

dx.doi.org/10.1021/jf5010572 | J. Agric. Food Chem. 2014, 62, 5305−5315

ethoxyphenyl) derivative **47** showed the most potent activity against both cells in this research. The shorter and longer alkoxy group at the 2′-position decreased activity (Table 3).

Cytotoxic Activity against Colon 26 and Vero Cells. Finally, the natural (8*R*,8′*R*)-DGA (**3**) and the higher active derivatives **38** and **47** against HL-60 and HeLa cells were applied to cytotoxic assay against colon 26 as colorectal cancer cells and Vero cells as normal cells (Table 4). Although the activities against colon 26 cells were weaker than against HL-60 and HeLa cells, these derivatives were also effective. Especially, the IC_{50} value of compounds **47** against colon 26 was less than 10 μM. Theses derivatives were also effective against Vero cells; however, their activities were weaker than against HL-60 and HeLa cells. The activity of derivative **38** was 3-fold less active, and derivative **47** showed 4−8.5-fold less activity against Vero cells than against HL-60 and HeLa cells, respectively. The most specific activity against cancer cells was observed in derivative **47**.

In conclusion, we clarified the structure-cytotoxic activity relationship of butane-type lignan containing dietary lignan, secoisolariciresinol, for the first time. The hydroxy groups on 9- and 9′-positions of secoisolariciresinol are disadvantageous for the activity. This fact was confirmed by the appearance of activity of 9- and 9′-reductive type lignan, dihydroguaiaretic acid (DGA), whose all stereoisomers showed same level of activities. In the course of the evaluation of activities of the derivatives, 9-butyl (8*R*,8′*R*)-DGA derivative **13**, 7-(2-hydroxyphenyl) (8*R*,8′*R*)-DGA derivative **17**, 7-(2-butoxyphenyl) (8*R*,8′*R*)- DGA derivative **19**, 7-(3,5-dimethoxy-4-hydroxy (8*R*,8′*R*)-DGA derivative **41**, and 7-(3-hydroxy-4-methoxyphenyl) (8*R*,8′*R*)-DGA derivative **38** showed 2−4-fold higher activity than (8*R*,8′*R*)-DGA (**3**). Finally, 7-(3-hydroxy-4-methoxyphenyl)-7′-(2′-ethoxyphenyl) DGA derivative **47** showed highest cytotoxic activity in this research, showing 32-fold and 13-fold higher activity against HL-60 cells (IC_{50} = 0.8 μM) and HeLa cells (IC_{50} = 1.7 μM), respectively, than (8*R*,8′*R*)-DGA (**3**). This derivative **47** was also effective against colon 26 cells. Although (8*R*,8′*R*)-9,9′-anhydrosecoisolariciresinol (**2**), which is a candidate for metabolite of dietary secoisolariciresinol, did not show the cytotoxic activity in this research, the higher cytotoxic active dihydroguaiaretic acid (DGA) derivative was prepared as a new lead compound, whose main chemical structure is same as that of dietary secoisolariciresinol. Since there is a possibility that dietary lignan derivatives will be detected as a metabolite, the study on structure−activity relationship of lignan should be promoted to examine the effect of dietary lignan on health and safety. This result would contribute to development of newer lead compounds of medicine based on natural dietary compounds.

concentrations of $LFP_{91\text{-}3}A2$ for 24 h. The cell pellets were washed with PBS after centrifugation and having supernatant removed, and they were stained with annexin V-FITC and PI in binding buffer according to the manufacturer's protocol. Cells were incubated at room temperature for 15 min in the dark, and flow cytometry was conducted using emission filters of 525 and 575 nm within 10 min, respectively.

Transmission Electron Microscope. For conventional transmission electron microscopy, the sample was postfixed with 1% buffered osmium at 4 °C for 2 h, dehydrated by an ethanol series and embedded in EPON 812. The semithin sections were stained by 1% Toluidine blue dye (TB) .

Statistical Analysis. All data are expressed as mean ± SD. Statistical analysis was evaluated by one-way analysis of variance (Anova), and calculations were done by the SPSS/Win 13.0 software. $P < 0.05$ was considered as the statistically significant difference.

RESULTS

Purification of $LFP_{91\text{-}3}A2$. The *Lentinula edodes* $C_{91\text{-}3}$ mycelium fermentative liquid extract from $(NH_4)_2SO_4$ precipitation (95% saturation) was applied on the DEAE−cellulose column. Four peaks (A, B, C and D) were eluted (Figure 1), and peak A ($LFP_{91\text{-}3}A2$) showed distinctive biological activity and then was subjected to a Sephacryl S-200 HR column in the next step; two peaks were obtained from the Sephacryl S-200 HR column, and the biological activity was largely confined to the fraction peak A2 ($LPF_{91\text{-}3}A2$) (Figure 1). The homogeneity of purified $LFP_{91\text{-}3}A2$ checked by SDS−PAGES appeared as a single band with a molecular mass of 26 kDa (Figure 1). At the same time, a single peak with the same molecular mass was obtained upon rechromatography on Superdex 75. The protein gel did not stain with the periodic acid-Schiff (PAS) reagent after being subjected to glycoprotein staining.

Polysaccharides isolated from mushrooms are best known for their antitumor macromolecules both *in vitro* and *in vivo*; some are already used in clinical cancer treatment.[7,8] Recently, various protein compounds, such as polysaccharide−peptides and polysaccharide−protein complexes, have been proven to possess effective antitumor activities;[9] however, only a few reports about proteins from mushroom have been identified and even fewer characterized, although mushrooms are an abounding source of diverse proteins. SDS-PAGE results and PAS negatively demonstrated that the $LPF_{91\text{-}3}A2$ is a pure protein without any polysaccharide conjugates.

Mushrooms contain a large number of biologically active proteins and peptides. The general protocol for isolating and purifying the target bioactive protein in a pure form consists of several steps.[10,11] In our study, two-step serial gel chromatography and ion exchange chromatography to isolate and purify protein $LPF_{91\text{-}3}A2$ proved to be simpler and more rapid than the frequently used protocol for separating protein from mushroom.

Assay of Antiproliferative Activity of $LPF_{91\text{-}3}A2$ on Tumor Cell Lines in Vitro. The cytotoxicity of $LFP_{91\text{-}3}A2$ on tumor cells and normal cells was examined in vitro by using the MTT microculture assay. H22, S180, A549 and the chick embryo fibroblasts growth proliferation were investigated after different incubation periods with different concentrations of $LPF_{91\text{-}3}A2$ (Figure 2). H22 and A549 cell growth were pressed in a dose-dependent manner which responded to increasing concentrations of $LPF_{91\text{-}3}A2$ (5−15 μg/mL). S180 growth also proliferated by $LFP_{91\text{-}3}A2$; although it had low significance in contrast to the other tumor cell lines, the difference was

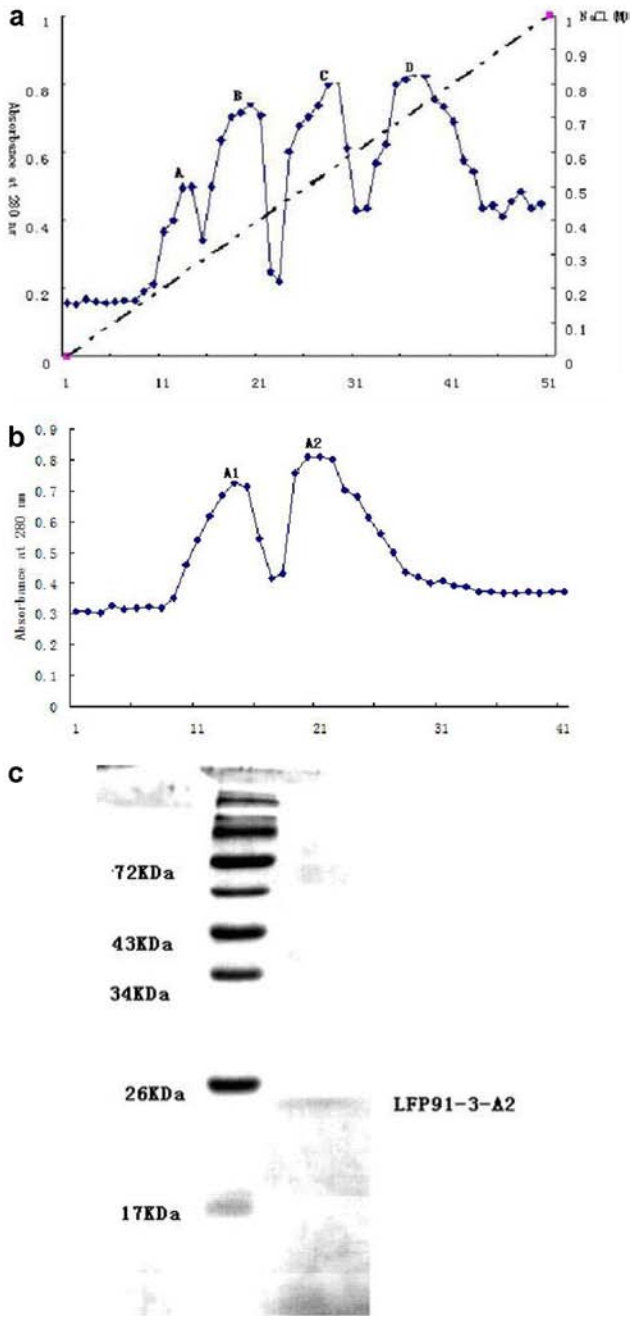

Figure 1. (a) Ion exchange chromatography on DEAE-cellulose of the mycelium fermentative liquid extract of *Lentinula edodes* C91-3. Adsorbed fraction A showed prominent biological activity. (b) Gel filtration on a Sephacryl S-200 HR column of peak A. Two peaks were obtained, and biological activity was largely confined to fraction peak A2. (c) SDS-PAGE of LFP91-3A2. significant compared with the negative control groups ($p < 0.05$). H22 cells had a more insignificant inhibition rate after being treated with $LPF_{91\text{-}3}A2$, so this lineage was used to test exact the proliferation mechanism further. The growth of the chick embryo fibroblasts was not suppressed at given concentrations of $LFP_{91\text{-}3}A2$, and the difference was not significant compared with the negative control groups. The tumor cells were also inhibited by 5 μg/mL of DDP but with no more pronounced effects compared with the groups treated

dx.doi.org/10.1021/jf500316f | J. Agric. Food Chem. 2014, 62, 5316−5320

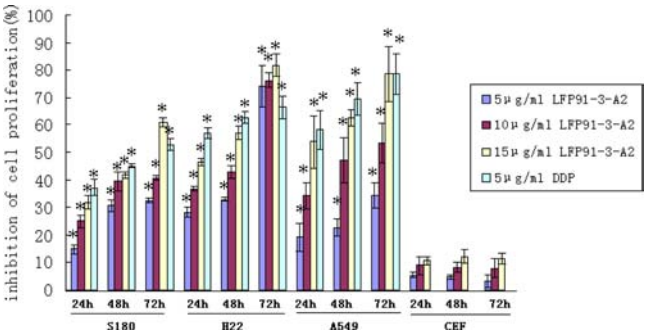

Figure 2. Effect of $LFP_{91\text{-}3}A2$ on viability of cell lines S180, H22, A549 and the normal chick embryo fibroblasts (CEF). The cytotoxicity of $LFP_{91\text{-}3}A2$ on the tumor lines S180, H22, A549 and against the normal chick embryo fibroblasts was performed by MTT reduction assay. The test cells were treated with different concentrations of $LFP_{91\text{-}3}A2$ (5−15 μg/mL) for 24, 48, and 72 h of culture in microplates. 5 μg/mL of DDP was used as positive control. Results represent the mean ± SD (standard deviation) of three experiments run in three replicates. *p < 0.001 compared to control.

with different concentrations of $LPF_{91\text{-}3}A2$ under the same conditions. Our findings revealed that $LFP_{91\text{-}3}A2$ suppressed tumor cells remarkably without side effects on the normal cells. This is particularly important, since many traditional chemotherapeutic agents and ratios exhibit severe toxicity against the normal cells, causing undesirable side effects and thus limiting their application in the clinical field.[10,12]

For further characterization, $LPF_{91\text{-}3}A2$ induced tumor cell death was analyzed by flow cytomery after staining H22 cells with annexin V-FITC/PI. As shown in Figure 3, the early and late apoptosis rates of the cells which were incubated for 24 h were significantly higher compared with those of the control group at 5, 10 and 15 μg/mL of $LPF_{91\text{-}3}A2$, and it induced H22 cell apoptosis in a dose-dependent manner. All the experiments were repeated three times and obtained similar results.

Although the MTT and the flow cytometry assay results present strong evidence that $LFP_{91\text{-}3}A2$ could activate the apoptotic pathway in tumor cells, the morphological characteristics in apoptosis need to be observed by transmission electron microscopy to consolidate the results of cytotoxicity tests. Morphological changes of the H22 cells were observed after treatment by 5 μg/mL of $LFP_{91\text{-}3}A2$ in 24 h. Transmission electron microscopy observation showed that H22 cells had the early changes of apoptosis, such as cell shrinkage, floating of the cell bodies and microvilli disappearance, nuclear chromatin condensation and formation of a crescent clump, which are the typical morphological appearance of apoptosis (Figure 4a). After treatment with 15 μg/mL of $LFP_{91\text{-}3}A2$, chromatin was condensed strongly, forming a high-density area, and the apoptotic body was observed in the H22 cell (Figure 4b). The morphological changes in $LFP_{91\text{-}3}A2$ treated tumor cells observed by transmission electron microscopy gave further evidence of the antitumor activity.

The antitumor activities of polysaccharides and polysaccharide−protein complexes from *Lentinula edodes* are considered dependent on activation of the host immune system rather than direct cytotoxic effects on the cancer cells.[13−15] Recently, a few studies demonstrated that polysaccharide from *Lentinula edodes* inhibited tumor cell proliferation not only by enhancing the host immunity but also by directly inducing tumor cell apoptosis.[11,16,17] $LPF_{91\text{-}3}A2$ showed direct cytotoxic and cell growth inhibitory effects without being accompanied by

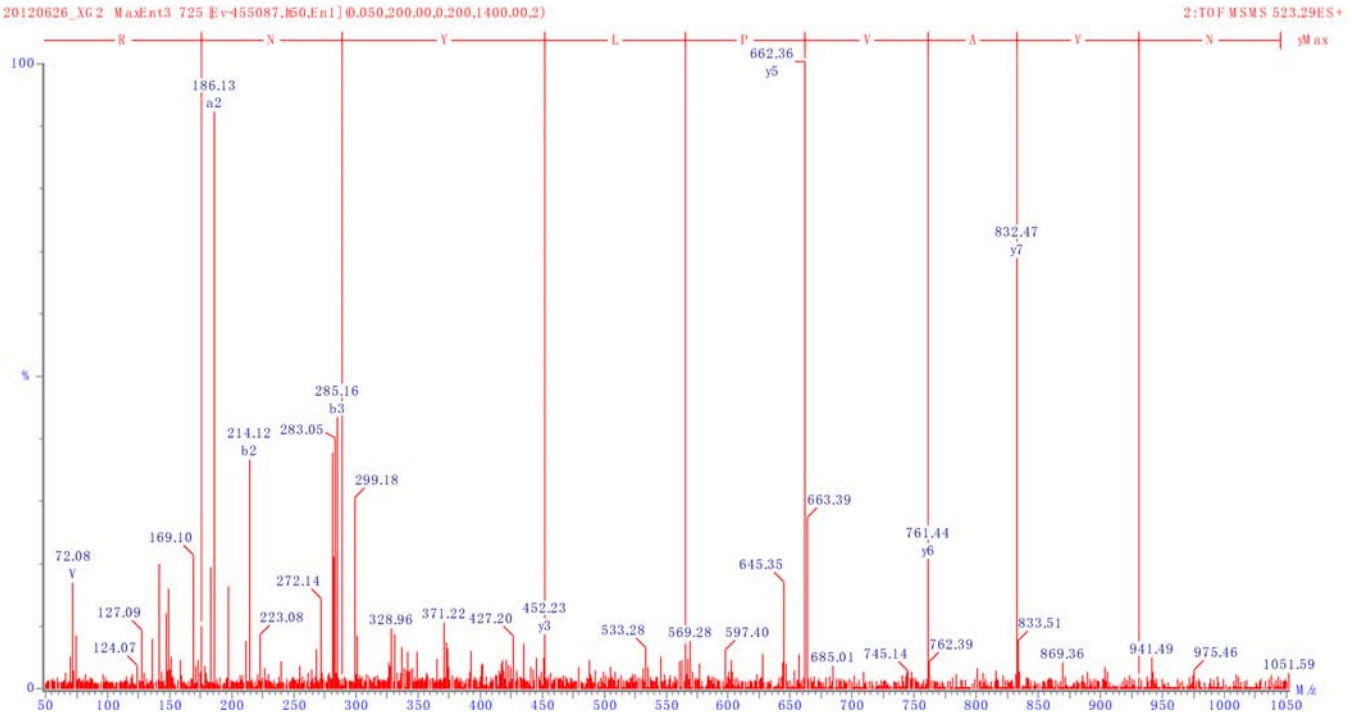

Figure 5. Peptide fragments of $LFP_{91\text{-}3}A2$ generated by trypsin cleavage analysis by MS/MS.

stimulating the immune system, which is distinct from extracts previously mentioned.

Mass Spectrometric Identification of Novel Proteins. The purified sample of $LPF_{91\text{-}3}A2$ was excised, digested by trypure in-gel and characterized by matrix assisted laser desorption/ionization/time of flight (MALDI-TOF) MS. Using the Mascot search engine (http://www.matrixscience.com), the MALDI-TOF data obtained from $LPF_{91\text{-}3}A2$ was matched significantly with adenylate kinase isoenzyme2 mitochondrial [*Harpengnathos saltalor*](gil307198091). The score of mascot search matching was 85, and sequence coverage was 27%. Adenylate kinase isoenzyme2 is localized in the space of mitochondrial intermembrane and plays a role in mediating a novel intrinsic apoptotic pathway that may be involved in tumorigenesis processes. Adenylate kinase isoenzyme2 is released from mitochondria during the early phase of the apoptotic process.[18,19] The antitumor activity of $LFP_{91\text{-}3}A2$ was supposed to be related to the similar molecular structure with adenylate kinase isoenzyme2. Three peptide fragments generated from $LFP_{91\text{-}3}A2$ by trypsin cleavage were subjected to MS/MS analysis for sequencing (Figure 5). The amino acid sequences were (a) NVAVPLYNR, (b) SDGANGLLTK and (c) NKYEDELNKR. However, the BLAST searches in several databases of de novo amino acid sequences derived from analysis of the 26 kDa band failed to identify any homologous proteins.[20] The paucity of related fungi protein amino acid sequences in accessible databases may be the reason why we found no homologous proteins from mushroom. In order to well know the properties of $LPF_{91\text{-}3}A2$, we leveraged Solexa sequencing technology in de novo assembly of *Lentinula edodes* $C_{91\text{-}3}$ transcriptome and obtained 28,923 unigene sequences including 18,120 unigenes with a coding sequence.[6] Based on this gene information, we can obtain deep insight into the medical function, especially antitumor activity at the protein level in *Lentinula edodes*.

The present study was carried out to purify and characterize active antitumor protein $LPF_{91\text{-}3}A2$ from the mycelium fermentative liquid extract of *Lentinula edodes* $C_{91\text{-}3}$. $LPF_{91\text{-}3}A2$ was isolated and purified to homogeneity after $(NH_4)_2SO_4$ precipitation and two steps of chromatography analysis. SDS-PAGE results are in accordance with MALDI/MS analysis, which show an approximate molecular weight of 26 kDa. The role of protein molecules from natural resources in drug and toxin-induced apoptosis is not clearly defined. In fact, very little

dx.doi.org/10.1021/jf500316f | J. Agric. Food Chem. 2014, 62, 5316−5320

information is available in the literature about this regard. A few articles, published recently, revealed that some protein molecules from various plant sources possess activities like those of our protein, although these reports do not describe any mechanism of protective action or structural features of the active principles.[21−23] In this study, we isolated and partially characterized antitumor protein $LFP_{91\text{-}3}A2$ from *Lentinula edodes* $C_{91\text{-}3}$ However, the identities and detailed characteristic properties of $LFP_{91\text{-}3}A2$ remain unknown up to now. Further studies are needed such as molecular properties, gene clone, expression and characterization of $LFP_{91\text{-}3}A2$. All these experiments are now under investigation in our laboratory based on the transcriptome sequence.[24] These antitumor studies would be helpful for its potential medical application in the future.

AC were found, including polysaccharide, maleic/succinic acid derivatives, triterpenoids, benzenoids, and benzoquinone derivatives.[7,8] Recent studies have various biological activities of AC, including antioxidant, anti-inflammation, liver fibrosis, antimetastasis, vasorelaxation, immunomodulation, and anticancer activities.[9−11] In addition, different fermentation processes have been conducted in either liquid or solid states of *A. camphorata* mycelium. Ergostatrien-3β-ol (EK100), a triterpenoid isolated from the liquid fermentation of *A. camphorata* mycelia, was demonstrated to exhibit significant anti-inflammatory and hepatoprotective bioactivity in vitro.[9,12] However, this study investigated whether oral treatment of MAC could attenuate ALI induced by LPS in vivo and explored the molecular mechanism of this regulatory pathway. The results demonstrated that MAC may protect against LPS-induced lung injury in mice and possibly exert its activity through the regulation of antioxidant enzyme activity, NF-κB, and MAPKs signaling pathways.

MATERIALS AND METHODS

Chemicals. LPS (*Escherichia coli* 055:B5) and dexamethasone (Dex) were obtained from Sigma (St. Louis, MO, USA). TNF-α, IL-1β, and IL-6 were obtained from Biosource International Inc. (Camarillo, CA, USA). The polyclonal antibodies against iNOS, COX-2, NF-κB, IκB-α, ERK, JNK, p38, p-ERK, p-JNK, p-p38, and β-actin were purchased from Abcam (Cambridge, UK). Polyvinylidene fluoride transfer membranes (Immobilon P) were from Millipore Corp. (Bedford, MA, USA).

Plant Material. The powder of AC of the submerged whole broth (batch MZ-247) was obtained from Biotechnology Center of Grape King Inc. (Chung-Li City, Taiwan). The preparative processes were all of commercial security.

Fingerprint Chromatogram of MAC Extracts by HPLC. The chromatographic system consisted of a quaternary gradient pump (SFD 2100), a C-18 column (4.6 i.d. × 250 mm; TSK gel column, ODS-80TM; 5 μm particles, Merck), and an S-3210 photodiode array detector (PDA) (Schambeck SFD GmbH, Bad Honnef, Germany). The samples were detected with H_2O (solvent A) and 100% methanol (solvent B) at 280 nm. The solvent gradient started with solvent A (10%) for 0 min and then linearly increased to solvent B (100%) for another 120 min. This linear gradient was followed by a solvent B elution until 180 min. The flow rate was 0.6 mL/min, and the injection volumes of standards and samples were 10 μL. Identification of EK100 was based on retention time and UV spectra by comparison with standards.

Animals. All animal procedures adhered to the NIH *Guide to the Care and Use of Laboratory Animals*. All tests were conducted under the guidelines of the International Association for the Study of Pain (IASP). Male imprinting control region (ICR) mice (6 weeks old) were obtained from the BioLASCO Taiwan Co., Ltd. The animals were kept in isolation for at least 1 week before the experiment with the temperature maintained within 22−23 °C. Mice were given ad libitum access to food and water.

LPS-Induced Acute Lung Injury in Mice. ALI was induced by intratracheal administration of LPS as previously described.[13] Fifty-four mice were randomly divided into six groups, the control group and five treatment groups. Normal mice were given 50 μL of normal saline without LPS. LPS (1.0 g/kg; 50 μL/per mouse) was administered intravenously to induce lung injury. MAC [25, 50, and 100 mg/kg; distilled water dissolved with 0.5% carboxymethyl cellulose (CMC)], dexamethasone (DEX; 10 mg/kg), or vehicle (PBS) was administered orally 1 h before 50 μL of LPS intratracheal (I.T.) instillation.

Lung tissue samples were collected for Western blot assay, MPO assays, and antioxidant enzyme (SOD) activity assays. In these studies, bronchoalveolar lavage fluid (BALF) was collected for protein concentration assay (Bio-Rad, Hercules, CA, USA) and leukocyte infiltration assessment. The BALF samples were centrifuged (700*g* for 10 min at 4 °C) and their supernatants were frozen at −80 °C for protein and cytokine ELISA. The cell pellets were resuspended in PBS (1 mL) and the total cell counts were determined using a hemocytometer in the BALF. Lung tissues from mice were collected but not subjected to BALF collection and then stored at −80 °C for further experiments.

Histopathological Analysis. At 6 h after treatment with LPS, mice were euthanized and lung tissues were harvested and fixed in 4% paraformaldehyde. For light microscopic examination, the lung tissue was dehydrated, then paraffin embedded, and sliced. After hematoxylin and eosin (H&E) staining of lung tissue slices, pathological changes were observed.

Measurement of Myeloperoxidase (MPO) Activity. The MPO activity was determined to assess neutrophil accumulation, and it was measured as described previously.[14] The lung tissues were homogenized in 80 mM phosphate buffer, pH 5.4, and then homogenate was centrifuged (12000*g* for 15 min, at 4 °C). Ten microliters of sample was added to 290 μL of 50 mM potassium phosphate buffer (pH 6.0) containing 0.167 mg/mL *o*-dianisidine chloride and 0.0005% H_2O_2 as a substrate. Oxidized *o*-dianisidine was determined by spectrophotometry ($OD_{460\ nm}$) (Molecular Devices, Sunnyvale, CA, USA). MPO content was expressed as relative MPO activity ($OD_{460\ nm}$/mg protein of lung tissue).

Lung Wet-to-Dry Weight (W/D) Ratio. The lung tissues were excised, immediately weighed, and then placed in an oven at 80 °C for 48 h to obtain the "dry" weight. The W/D ratio was then calculated.

Measurement of BALF TNF-α, IL-1β, and IL-6 by an Enzyme-Linked Immunosorbent Assay (ELISA). The concentrations of cytokine levels of TNF-α, IL-1β, and IL-6 in the BALF were measured by ELISA using commercially available reagents according to the manufacturer's instruction (Biosource International Inc.). TNF-α, IL-1β, and IL-6 were determined from a standard curve.

Measurement of Nitric Oxide/Nitrite. Nitrite and nitrate could have a role by producing NO. The nitrite level was determined by the Griess reagent in BALF.[15] One hundred microliters was applied to 96-well plates, followed by 100 μL of Griess reagent. The Griess reagent was prepared by mixing equal amounts of 0.1% *N*-1-naphthylethylenediamine dihydrochloride and 1% sulfanilamide. Absorbance at 540 nm was measured after 10 min of incubation at room temperature using a microplate reader (Molecular Devices). A standard curve was plotted with the concentration of sodium nitrite.

Total SOD activity Measurements. Total SOD activity was determined by an indirect method involving the reduction of cytochrome *c*.[16] For the cytochrome *c* reaction, the SOD mediated inhibition of ferricytochrome *c* reduction in the presence of a superoxide anion generating system (xanthine/xanthine oxidase) was determined by monitoring the change in absorbance at 550 nm. One SOD enzyme unit was defined as the amount of enzyme that causes a 50% inhibition.

Western Blot Analysis. Lung tissues were homogenized in the protein extract solution and protease inhibitors and centrifuged at 12000*g* for 20 min. The supernatants were frozen at −20 °C until use. The amount of protein (50 μg) from the supernatant was resolved on 10% SDS-PAGE and transferred onto nitrocellulose membranes. The membrane was incubated with an appropriate dilution of specific primary antibodies (anti-iNOS, anti-COX-2, anti-COX-2, anti-IκBα, and anti-NF-κB) followed by appropriate horseradish peroxidase-conjugated (Sigma), goat anti-mouse, or anti-rabbit IgG. The bands were detected by enhanced chemiluminescence (ECL) by using hyperfilm and ECL reagent (Thermo). Band intensity on scanned films was quantified using Kodak Molecular Imaging software (version 4.0.5, Eastman Kodak Co., Rochester, NY, USA) and expressed as relative intensity compared with the control group.

Statistical Analysis. Data are expressed as the mean ± standard error of the mean (SEM). Statistical analyses were performed by one-way analysis of variance (ANOVA followed by Scheffe's multiple-range tests). The levels of statistical significance are expressed as (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$.

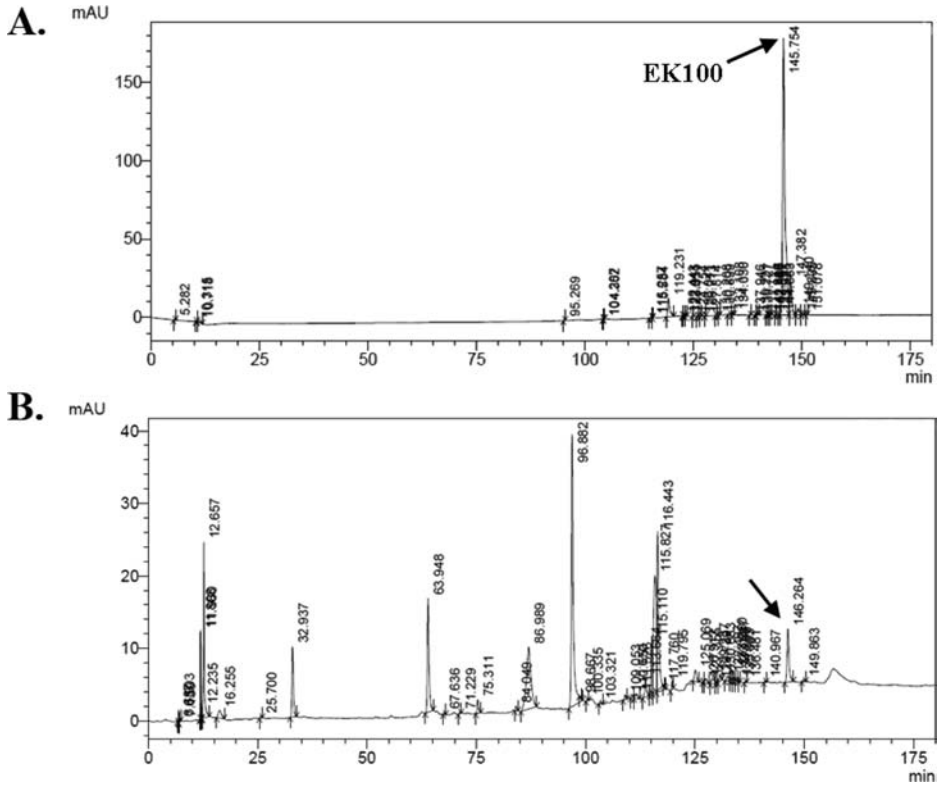

Figure 1. HPLC analysis of the compound identification of EK100 (retention time = 145.75 min) (A) and MAC (methanol extract of *Antrodia camphorata*) (B). Total volume of 20 μL was loaded into the HPLC column to measure the relative content of ST1 in MAC extract according to the concentration of standard compounds.

RESULTS

Fingerprint Chromatogram of MAC by HPLC. The fingerprint chromatogram of MAC was established for the quality control of the liquid fermentation of *A. camphorata* mycelia. The structure of ergostatrien-3β-ol (EK100) was elucidated by its retention time, UV absorbance of purified standards, and comparison with the literature.[17] Figure 1 shows the predominant constituents identified as EK100.

MAC Reduces LPS-Induced Lung Injury in Vivo. To evaluate the LPS-induced lung injury after MAC treatment, we observed the histological changes of lungs in the different groups. In the control group, no obvious histological alteration was found in lung tissues (Figure 2). In the LPS-induced lung injury group H&E staining evidenced a large number of infiltrations of inflammatory cells, lung tissue damage, and marked alveolar wall edema. These pathological changes were improved by treatment with MAC (25, 50, and 100 mg/kg) and DEX (10 mg/kg), suggesting that MAC could protect against histological changes in the LPS-induced ALI model.

Effects of MAC on Inflammatory Cell Count and MPO Activity on LPS-Induced ALI in Mice. Six hours after LPS-induced ALI, the total cell numbers in the BALF increased compared with the control group, significantly ($p < 0.001$). MAC (100 mg/kg) and DEX (10 mg/kg) significantly also decreased the number of total cells ($p < 0.001$) compared to LPS-induced ALI mice (Figure 3A).

Polymorphonuclear leukocyte (PMN) infiltration plays a central role in inflammation, and it is also a major cause of tissue damage. MPO activity can be considered a good indicator of lipid peroxidation in lung tissues. As Figure 3B shows, the intratracheal instillation of LPS increased MPO activities (0.41 ± 0.04 OD $_{460\ nm}$/mg protein) in mouse lung tissues, significantly ($p < 0.001$). Pretreatment with MAC (25, 50, 100 mg/kg) decreased MPO activity to 0.23 ± 0.03, 0.27 ± 0.04, and 0.32 ± 0.02 OD $_{460\ nm}$/mg protein, respectively, and DEX decreased it to 0.26 ± 0.02 OD$_{460\ nm}$/mg protein. These data indicated that MAC prevented excessive infiltration of neutrophils into the lung tissues in LPS-induced ALI mice.

MAC Attenuates the Lung Wet-to-Dry Ratio and Protein Concentration Induced in LPS-Induced ALI Mice. To assess lung edema, we determined the lung water content in ALI mice 6 h after LPS treatment. LPS challenge increased the lung vascular permeability, as shown by the lung W/D ratio as compared to the control group, significantly. Therefore, we further investigated the W/D ratios and protein concentrations of different groups, and as shown in Figure 4, the W/D ratio and protein concentration expanded in the LPS group compared with the control group and the pretreatment with MAC (100 mg/kg) and DEX ameliorated the W/D ratio and protein concentration compared with the LPS group. These results indicated that MAC could suppress lung edema in LPS-induced ALI mice.

Effect of MAC on Anti-inflammatory Cytokines in Lung Tissues of LPS-Induced ALI mice. LPS-induced ALI is related to the various pro-inflammatory cytokines. In this study, the levels of pro-inflammatory cytokines (NO, TNF-α, IL-1β, and IL-6) in BALF were measured 6 h after LPS instillation. As shown in Figure 5, the pro-inflammatory cytokine NO, TNF-α, IL-1β, and IL-6 levels of LPS-induced ALI mice in the BALF were improved compared to those in the control group, significantly ($p < 0.001$). MAC (100 mg/kg) and DEX significantly reduced NO, TNF-α, IL-1β, and IL-6 production compared to the LPS-induced ALI group.

dx.doi.org/10.1021/jf405113g | J. Agric. Food Chem. 2014, 62, 5321−5329

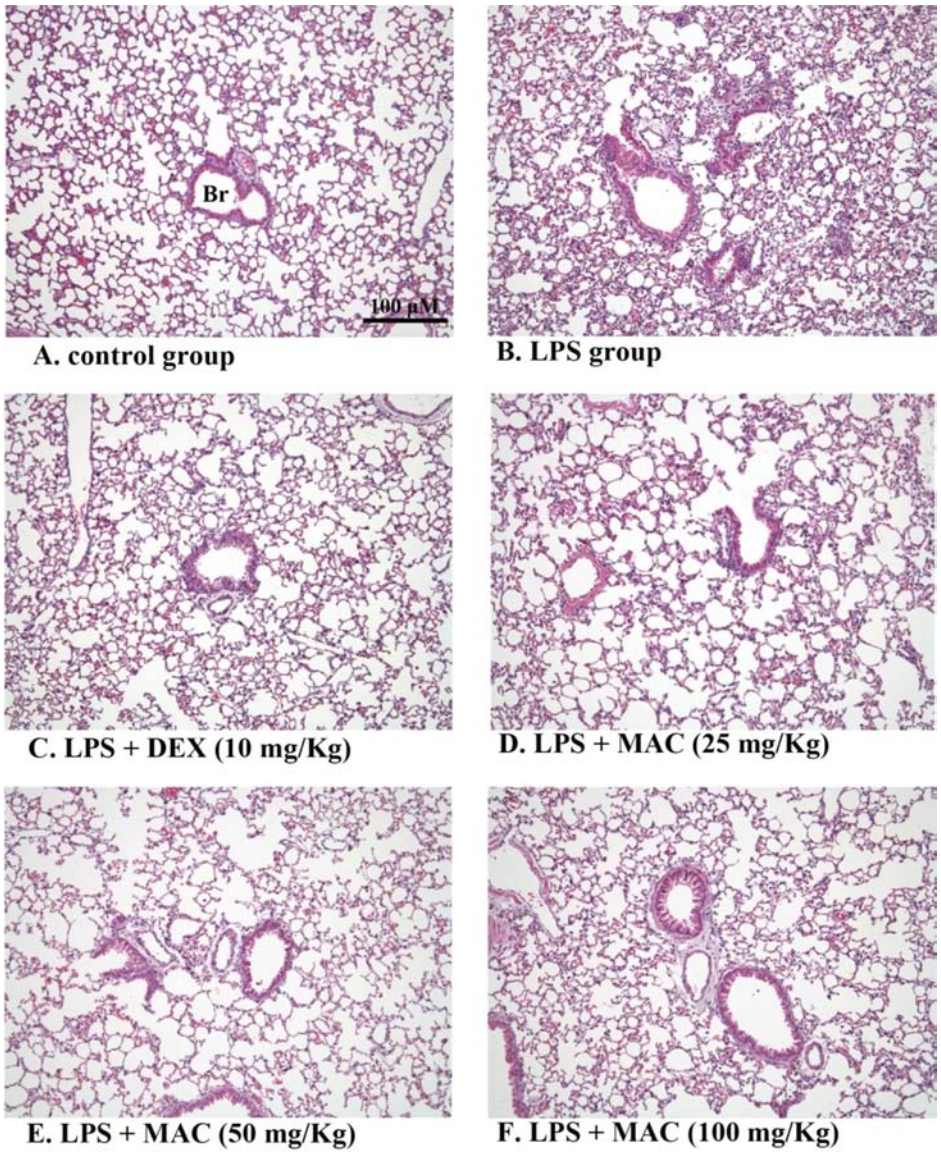

Figure 2. Effects of MAC on lung histopathological changes in LPS-induced ALI mice. Mice were killed at 6 h after LPS stimulation. The left lungs were excised and embedded in 10% formalin and sectioned, followed by H&E staining; magnification ×100. Images are representative of three experiments. Br, bronchi; DEX, dexamethasone.

Effects of MAC Protect against Oxidative Stress in LPS-Induced ALI Mice. Oxidative stress may lead to apoptosis and lung injury. SODs are a class of enzymes that can acting as the chief ROS scavenging enzyme, and the activity of SODs has decreased in some reports of LPS-induced ALI mice. The data presented demonstrated that the pretreatment with MAC (100 mg/kg) and DEX increased SOD activity in mice as compared to the LPS-induced ALI group (Figure 6). Therefore, in this study, we demonstrated that MAC might be attributed to its antioxidant enzyme activities in the inflammatory response og LPS-induced ALI mice.

Effects of MAC on iNOS and COX-2 Protein Expressions in LPS-Induced ALI Mice. To investigate possible mechanisms of whether the level of NO was due to regulated iNOS and COX-2 protein expressions, the effects were studied by Western blot in the LPS-induced ALI. The results showed that the pretreatment with MAC (100 mg/kg) for 6 h inhibited iNOS and COX-2 protein expression in lung tissues of LPS-induced ALI mice (Figure 7A).

Effect of MAC on NF-κB and IκBα Inactivation in LPS-Induced ALI Mice. NF-κB is activated by a variety of stimuli including LPS, TNFα, and IL-1β. The effect of MAC on NF-κB expression in lung tissue of LPS-induced ALI mice was assessed by Western blot. In this study, Figure 7B shows that LPS-induced IκBα and NF-κB degradation was inhibited by pretreatment with MAC in LPS-induced ALI mice. The signal of NF-κB inhibition is regulated by interaction with inhibitory IκBα proteins. Overall, our findings provide support that the NF-κB inhibitor IκBα contains a functional nuclear export signal.

Effect of MAC on MAPK Signaling Pathway in LPS-Induced ALI Mice. To examine the mechanisms of the LPS-induced ALI mice, we investigated the effect of MAC on the MAPKs signal pathway. As shown in Figure 8, MAPKs were activated in LPS-induced ALI. Furthermore, MAC (100 mg/kg) and DEX dramatically inhibited the phosphorylation of ERK, JNK, and p38 protein expressions. These results

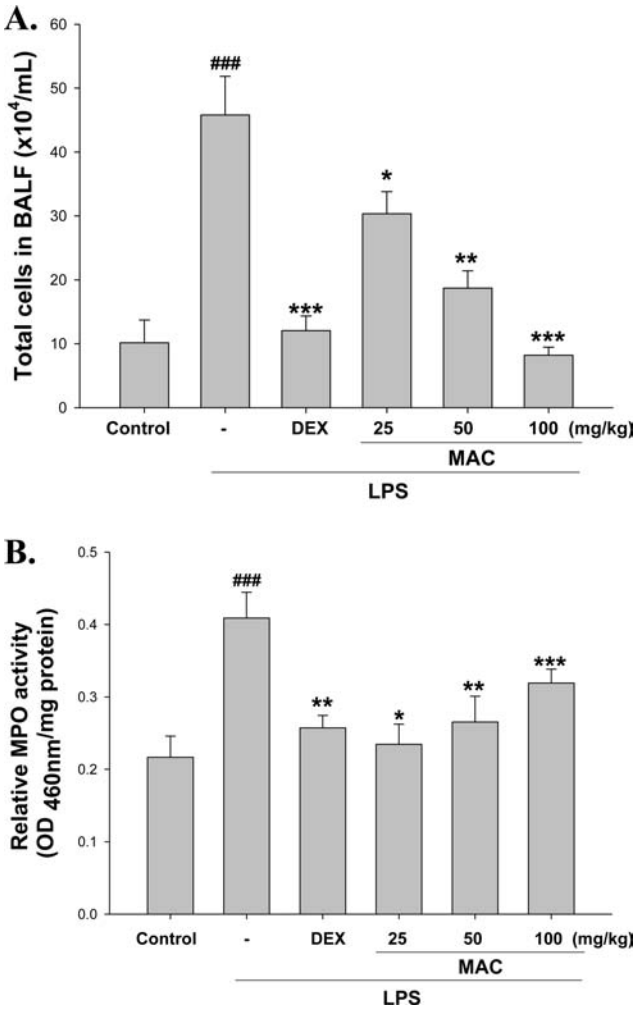

Figure 3. Effects of MAC on the number of total cells in the BALF of LPS-induced ALI mice: (A) number of total cells; (B) myeloperoxidase activity (MPO) performed at 6 h after LPS challenge. Its activity reflects the neutrophil infiltration in the lungs. Cell counts were performed with a hemocytometer. Each value represents the mean ± SEM. (###) $p < 0.001$ as compared with the control group; (*) $p < 0.05$, (**) $p < 0.01$, and (***) $p < 0.001$ as compared with the LPS group (one-way ANOVA followed by Scheffe's multiple-range test).

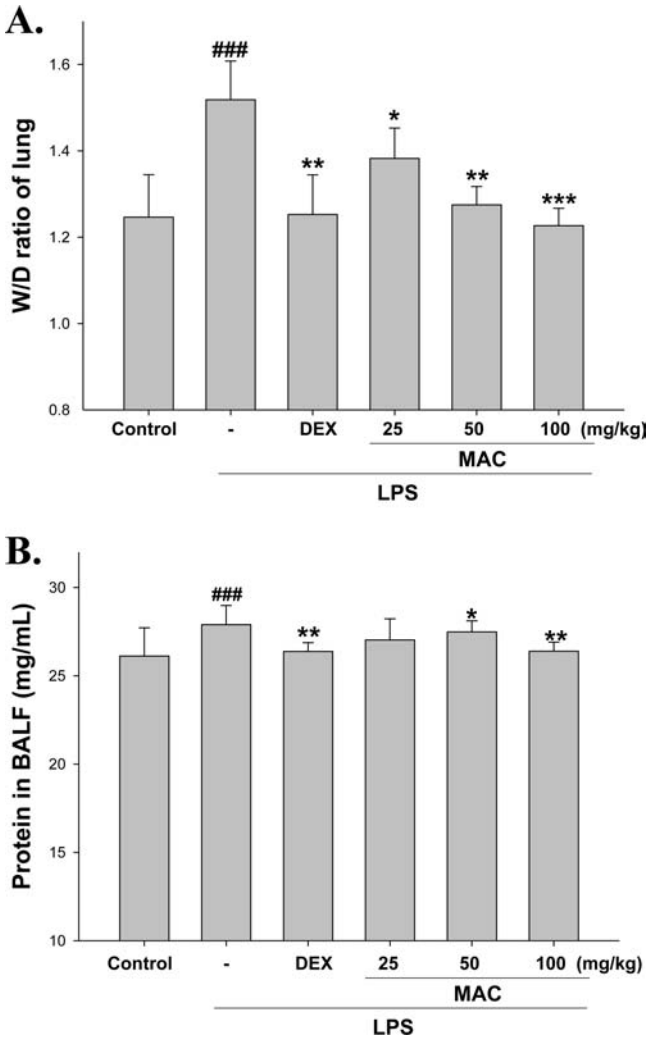

Figure 4. Effects of MAC on the lung W/D ratio and total protein level in the BALF of LPS-induced ALI mice. Mice were given MAC (25, 50, or 100 mg/kg) 1 h prior to an intratracheal (I.T.) instillation administration of LPS. The lung W/D ratio (A) and total protein concentration in the BALF (B) were determined 6 h after the LPS challenge. Each value represents the mean ± SEM. (###) $p < 0.001$ as compared with the control group; (**) $p < 0.01$ and (***) $p < 0.001$ as compared with the LPS group (one-way ANOVA followed by Scheffe's multiple-range test).

demonstrated that MAC inhibited the activity of MAPK pathways in LPS-induced ALI.

DISCUSSION

In this study, these data are the first to demonstrate the anti-inflammatory activity of MAC in LPS-induced mice ALI. In our experiment, we used this model to determine whether MAC could prevent ALI induced by LPS intranasal instillation. The MAC has been reported to exhibit anti-inflammatory properties in vitro and in vivo.[18] Thus, this study is the first to investigate the effects of MAC inhibition on NF-κB and MAPK activation occurring together with IκBα degradation in a mouse model of LPS-induced ALI.

ALI/ARDS are diseases of multifactorial etiology by acute respiratory failure that cause acute lung tissue edema, lung injury, and inflammatory responses. Multiple clinical studies have reported the development of ALI associated with sepsis, pulmonary injury from pneumonia and aspiration, aspiration of gastric contents, and pulmonary injury from trauma.[19] ALI has added to the understanding of the epidemiology and pathogenesis, but the reason for the morbidity and mortality in critically ill patients is unclear.[20] Administration of LPS-induced ALI in mice has been used to study the pathophysiological and biological pathways.[21] Intratracheal or intranasal bacterial products such as LPS administration trigger the optimal ALI, which is characterized by increased capillary permeability, hemorrhage, intra-alveolar and interstitial edema, and an influx of inflammatory cells into the lung. Currently, DEX, a strong synthetic glucocorticoid, is the most used anti-inflammatory and antioxidative drug in the clinical treatment of ALI because it regulates an efficient decrease of inflammation.[22] Therefore, in this study, the anti-inflammatory effect of DEX was a positive control in LPS-induced mice ALI.

Lung edema is one of the important features of ALI.[23] Furthermore, we investigated the lung W/D ratio and protein concentration in the BALF to quantify the magnitude of lung edema. Here, we found that MAC decreased the lung W/D

dx.doi.org/10.1021/jf405113g | J. Agric. Food Chem. 2014, 62, 5321−5329

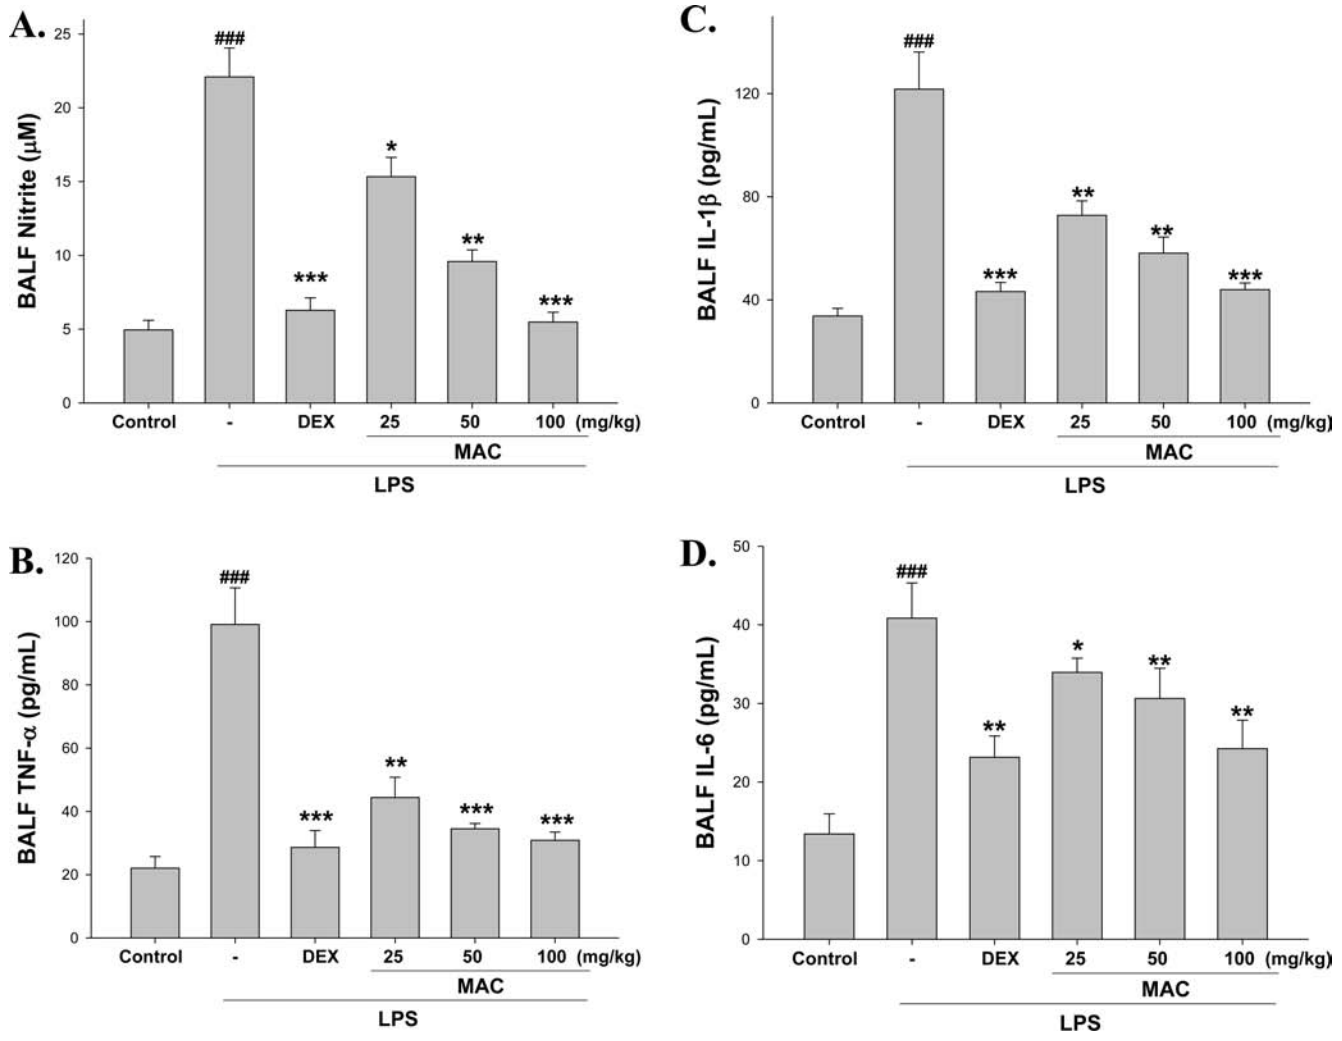

Figure 5. Effect of MAC on NO, TNF-α, IL-1β, and IL-6 expression from mice with ALI. Mice were given MAC (25, 50, or 100 mg/kg) by intraperitoneal injection 1 h before challenge with LPS. BALF was collected at 6 h following LPS challenge to analyze the inflammatory cytokines NO (A), TNF-α (B), IL-1β (C), and IL-6 (D). Each value represents the mean ± SEM. (###) $p < 0.001$ as compared with the control group; (**) $p < 0.01$ and (***) $p < 0.001$ as compared with the LPS group (one-way ANOVA followed by Scheffe's multiple-range test).

ratio after pretreatment 1 h before mice were subjected to LPS-induced ALI. In addition, we also evaluated that lung sections were stained by H&E staining and analyzed by light microscopy after pretreatment with MAC in LPS-induced mice. This result identified the inhibition of MAC or DEX in LPS-induced pulmonary edema and inflammation by lung morphological examination.

In vivo the I.T. administration of LPS is a well-known model for the induction of lung inflammation.[23] Leukocytes move within 1 h to the lung tissue and are replaced by monocytes and macrophages cells and influence the level of inflammatory reaction.

Neutrophil infiltration associated with a LPS-induced inflammatory reaction and the free radical productions from neutrophils have potent antimicrobial activity in acute infections consisting of oxidants, proteinases, and cationic peptides that lead to lung injury.[24] In this study, we found that total numbers of cells and the expressed of MPO activity in neutrophils were decreased after pretreatment with MAC in LPS-induced mice and were relative to the oxidative stress, and free radicals may intensify inflammatory reaction.[25] In this regard, it has been proposed that oxidative stress may be related with corticosteroid resistance and increased the severe inflammatory response, including ALI/ARDS. LPS-induced mouse ALI is characterized by neutrophil infiltration in lung tissues that reduced SOD activity and increased MPO activity.[26] It was supposed that LPS-induced mouse ALI stimulates the neutrophil to migrate into the BALF, and LPS induced pro-inflammatory mediator expressions.[4] This paper suggests that MAC potently inhibited the neutrophil infiltration, MPO activity, and edema formation and increased the SOD activity. LPS-induced mouse ALI displays some characteristics such as neutrophil accumulation, pro-inflammatory cytokine production, and lung injury. The levels of pro-inflammatory cytokines such as TNF-α, IL-1β, and IL-6 can be used to evaluate lung injury and inflammatory level.[27] Our previous studies also have reported that MAC can decrease iNOS and COX-2 protein expression in vitro and in vivo.[18] In this experiment, we found that pretreatment with MAC reduced the TNF-α, IL-1β, and IL-6 expressions in BALF. These results indicate that MAC could effectively improve the LPS-induced ALI in mice.

NO acts as a second messenger with multiple functions, including neural activity, blood flow, and pain modulation.[28] Excessive levels of NO produced from iNOS lead to a reaction

dx.doi.org/10.1021/jf405113g | J. Agric. Food Chem. 2014, 62, 5321−5329

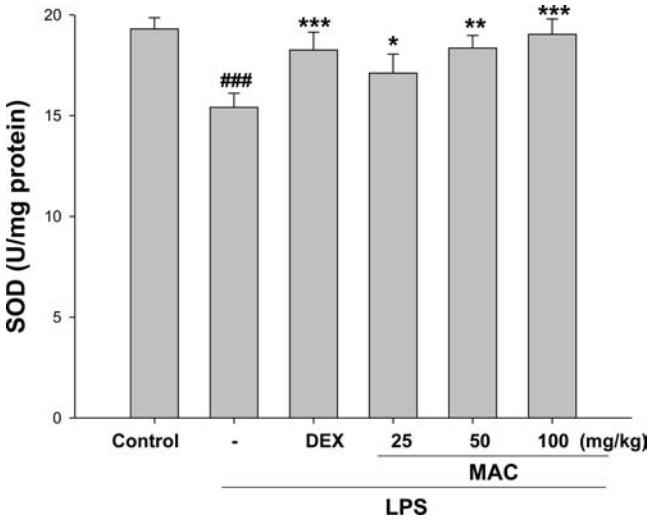

Figure 6. Effects of MAC on SOD activity in lungs from mice with ALI. Lung homogenates were prepared for measuring SOD activity. Each value represents the mean ± SEM. (###) $p < 0.001$ as compared with the control group; (**) $p < 0.01$ and (***) $p < 0.001$ as compared with the LPS group (one-way ANOVA followed by Scheffe's multiple-range test).

of NO with superoxide to create $ONOO^-$. $ONOO^-$ formation represents one of the major mechanisms of acute lung injury, including substantial oxidative/nitrative stress, destruction of cellular constituents, and induction of cell apoptosis and necrosis.[29]

Transcription factor NF-κB plays a critical role that controls multiple key cellular processes. Members of the NF-κB family include p50 and p65 heterodimers. The translocation of NF-κB p65 is related to cancer, inflammation, and acute immune response.[26] Inhibition of the NF-κB pathway has been shown to recover septic dysfunction and inhibit the expression of pro-inflammatory cytokines, including TNF-α, IL-1β, and IL-6.[30] The results from the present study show that pretreatment with MAC inhibits the degradation of IκBα and NF-κB in the LPS-induced mouse ALI.

MAPK families (ERK, JNK, and p38) play an important role in regulating cytokine release and signal transduction pathways. JNK and p38 MAP kinase have been reported to identify regulatory pro-inflammatory cytokines (such as IL-1 and TNF-α).[29] MAPK pathways (ERK, p38, and JNK) have been demonstrated as participating in LPS-induced mouse ALI.[31] In addition, p38 regulated the LPS-induced NF-κB activation by blocking neutrophil infiltration into the lung in LPS-induced mouse ALI.[2] In this study, pretreatment of MAC inhibited LPS-induced phosphorylation of MAPKs (ERK, JNK, and p38). Thus, it is possible that the inhibition of pro-inflammatory (TNF-α, IL-1β, and IL-6) expressions by pretreatment with MAC occurs through pathways that inhibit the phosphorylation of MAPKs and IκB activation in LPS-induced acute lung injury.

The fruiting body and mycelium of AC are well-known as a traditional medicine for many diseases. The anti-inflammatory

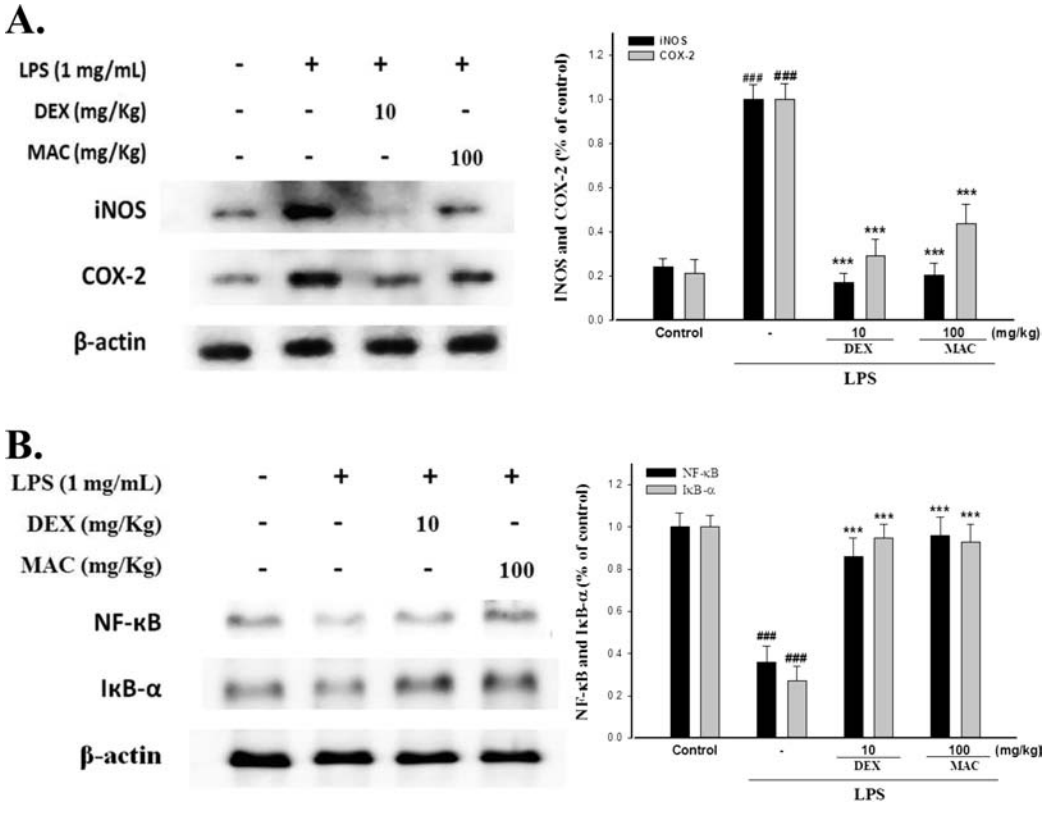

Figure 7. Inhibition of iNOS, COX-2 (A), IκBα, and NF-κB (B) protein expression by MAC in LPS-induced ALI mice. Tissues suspended were then prepared and subjected to Western blotting by using an antibody specific for iNOS, COX-2, IκBα, and NF-κB. β-Actin was used as an internal control. A representative Western blot from two separate experiments is shown. (###) Compared with sample of control group. Data represent the mean ± SD for the three different experiments performed in triplicate. (***) $p < 0.001$ compared with the LPS-alone group (one-way ANOVA followed by Scheffe's multiple-range test).

dx.doi.org/10.1021/jf405113g | J. Agric. Food Chem. 2014, 62, 5321−5329

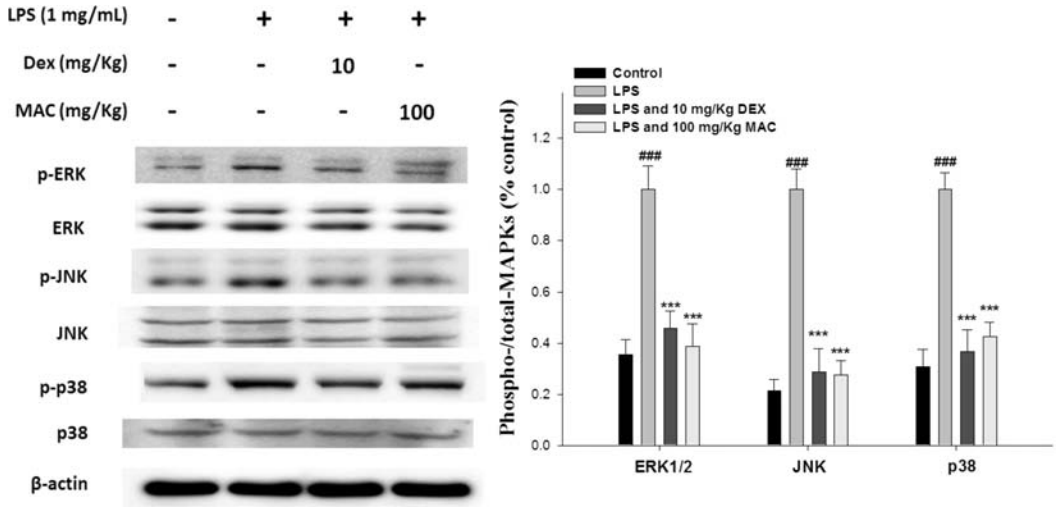

Figure 8. Effects of MAC on LPS-induced phosphorylation of MAPK in LPS-induced ALI mice. Mice were pretreated with different concentrations of MAC for 1 h and stimulated with LPS. Cellular proteins from the lungs were used for the detection of phosphorylated or total forms of three MAPK molecules, ERK, p38, and JNK. A representative Western blot from two separate experiments is shown. (###) Compared with sample of control group. Data represent the mean ± SD for the three different experiments performed in triplicate. (***) $p < 0.001$ compared with the LPS-alone group (one-way ANOVA followed by Scheffe's multiple-range test).

activity of *A. camphorata* mycelium contributed to prevent inflammatory disease through repression of iNOS and COX-2 protein expression.[18,28] Eburicoic acid and dehydroeburicoic acid, an active ingredient from solid-state culture of AC, were evaluated for anti-inflammatory and hepatoprotective effects.[10,11] In our previous paper, we showed that ergostatrien-3β-ol (EK100) had analgesic, anti-inflammatory,[9] and hepatoprotective[12] activities. Thus, we used EK100 to evaluate the quality of *A. camphorata* mycelium using high-performance liquid chromatography in this study. Antrocamphin A, antcin A, antcin B, and eburicol from AC have anti-inflammatory activity by inhibition of *N*-formylmethionylleucylphenylalanine (fMLP)-induced superoxide anion generation.[32]

In summary, our study shows protective effects of MAC on LPS-induced mouse ALI. MAC pretreatment reduced lung histological changes, lung edema, and leukocyte infiltration in lungs, changed the wet/dry ratio in the lung tissue, and inhibited the release of inflammatory mediators in the BALF. These data suggested that MAC was proposed as a novel therapeutic strategy for inflammatory diseases through inhibition of the NF-κB pathway by directly blocking phosphorylation and degradation of inhibitory IκBα via inhibition of MAPK-responsive signaling pathways. Thus, MAC exerts an anti-inflammatory effect in rodents, and more research needs to be done before a clinical trial of this drug can be realized.

beginning of the study. During the interview, each subject was asked, item-by-item, whether they usually ate each food and, if so, how much they usually ate. For this purpose, three different serving sizes of each cooked food were presented in pictures to the participants so that they could choose from up to seven serving sizes (from "less than the small one" to "more than the large one"). For some of the foods consumed, amounts were recorded in household units, by volume, or by measuring with a ruler. Information was also collected about the cooking practices, number and amount of ingredients used in each recipe (e.g., type of oil used, type of milk), and other relevant information for the study, such as the consumption of skin in fruit. Furthermore, variability in the consumption of some foods, especially fruits and vegetables, according to the season was taken into account. Methodological issues concerning dietary assessment have been detailed elsewhere.[19] The consumption of foods was converted into energy intake using the nutrient Food Composition Tables developed by the Centro de Enseñanza Superior de Nutrición Humana y Dietética.[20] The intake of nonstarch dietary fiber, soluble (pectin and hemicellulose) and insoluble types (pectin, hemicellulose, Klason lignin, and cellulose), in the sample was determined using the Marlett et al. food composition tables.[21] These authors used the enzymatic–chemical method developed by Theander et al.,[22] by which pectin content is determined using a colorimetric assay, cellulose and hemicellulose are determined by high-performance liquid chromatography (HPLC), and Klason lignin is estimated as the insoluble material after a Saeman acid hydrolysis.[23] Resistant starch intake was calculated using the tables published by Roberts et al., which collect information from eight scientific publications,[24] and the consumption of polyphenols in the sample was obtained using the Phenol-Explorer Database, which contains information mainly determined by HPLC, gas chromatography (GC), and capillary electrophoresis (CE) from more than 1300 publications.[25]

Microbiological Analyses. Each volunteer was asked to provide a single fecal sample immediately after the interview for nutrition assessment. Fecal samples were immediately frozen at −80 °C and stored until further analyses. One gram of fecal sample was employed for DNA extraction by using the QIAamp DNA stool mini kit (Qiagen, Hilden, Germany) as previously described.[26] Quantification of different bacterial populations (*Akkermansia*, *Bacteroides*, *Bifidobacterium*, *Blautia coccoides* group, *Clostridium leptum* group, and *Lactobacillus* group) in feces was performed with a 7500 Fast Real Time PCR System (Applied Biosystems, Foster City, CA, USA) using SYBR Green PCR Master Mix (Applied Biosystems) as previously described.[27]

Statistical Analysis. Statistical analysis was performed using SPSS version 19.0 (SPSS Inc., Chicago, IL, USA). Goodness of fit to normal distribution was analyzed with the Kolmogorov–Smirnov test. For descriptive purposes, mean values were presented on untransformed variables. Multiple linear regression analysis was used to investigate the correlations between the intake of fibers and polyphenols and fecal levels of the studied microorganisms. We also introduced age and energy intake as covariates in the models. Because the fibers and polyphenols significantly related to microbiota are usually present in the same foods, multiple stepwise regression models were carried out to explore whether their association with microbial groups remained with independence of covariates and other related variables included in the model. The statistical parameters employed were β (standardized regression coefficient) and R^2 (coefficient of multiple determinations). The conventional probability value (0.05) for significance was used in the interpretation of results. Considering the standard deviation of the microbial levels and the standard deviation of the regression errors, we could reject the null hypothesis with an estimated probability around 0.97 and a type I error probability of 0.05 for all models in which the slope of the line is above 0.3 [calculated using the software PS: Power and Sample Size Calculation version 3.0.43 (Vanderlbilt University, Nashville, TN, USA)].

RESULTS

General characteristics of the studied human sample are described in Table 1. Results showed that in the diet of the participants the consumption of dairy products, fruits and vegetables, and cereals prevailed, with a moderate intake of meat, fish, and seafood. Tables 2 and 3 present the mean intakes of nonstarch and resistant starch dietary fibers (types and subtypes) and polyphenols (classes and subclasses), respectively, together with their respective association with intestinal microbial groups. With regard to the fibers, soluble pectin was negatively associated with *B. coccoides* and *C. leptum*. This latter microbial group, which includes important intestinal microorganisms such as *Faecalibacterium prausnitzii* and several *Ruminococcus* species, was also inversely associated with insoluble pectin. On the contrary, a positive association was found between *Akkermansia* and *B. coccoides* levels and resistant starch. *Lactobacillus* was also positively associated with soluble fiber, hemicellulose (soluble and insoluble), cellulose, and resistant starch. From all of the evaluated polyphenols, only flavanone intake was found to be negatively associated with both *B. coccoides* and *C. leptum* groups.

To explore these associations, the main food sources of the fibers and polyphenols significantly associated with microbiota were calculated (Figure 1). Orange consumption was found as the top contributor to insoluble hemicellulose, pectin (soluble and insoluble), cellulose, and flavanone intake, whereas white

Table 4. Combined Effect of Fibers, Polyphenols, and Their Food Sources on Fecal Levels of Microbial Groups (Log No. Cells per Gram Feces) (n = 38)[a]

	B. coccoides[b]			*C. leptum*[b]			*Lactobacillus*[b]		
model	variable	R^2	β	variable	R^2	β	variable	R^2	β
1[c]	–[1]			flavanone	0.121	−0.348*	hemicellulose I		0.819**
	resistant starch[2]	0.134	0.366*				resistant starch		0.316*
							energy	0.520	−0.389*
2[d]	orange[1]		−0.532*	orange	0.131	−0.362*	white bread	0.266	0.515**
	energy	0.244	0.389*						
	pasta[2]	0.110	0.331*						

[a]No results are presented for *Akkermansia* because neither resistant starch nor any of its food sources persisted in the models. [b]Based on multiple stepwise regression analysis adjusted by age and energy intake. Hemicellulose I, insoluble hemicellulose; β, standardized regression coefficient; R^2, coefficient of multiple determinations. *, $p \leq 0.05$; **, $p \leq 0.001$. [c]Model 1 (fibers and polyphenols): *C. coccoides* [1](age; energy; soluble and insoluble pectin and flavanone intakes) and [2](age; energy; and resistant starch intake), *C. leptum* (age; energy; soluble pectin and flavanone intakes), *Lactobacillus* (age; energy; soluble fiber, soluble and insoluble hemicellulose, cellulose, and resistant starch intakes). [d]Model 2 (food sources): *B. coccoides* [1](age; energy; orange, orange juice, lentils, apple, lettuce, green bean, kiwi, and banana intakes) and [2](age; energy; banana, lentil, white bread, potato, breakfast cereal, biscuit, muffin, and pasta intakes), *C. leptum* (age; energy; orange, orange juice, kiwi, green bean, apple, and banana intakes), *Lactobacillus* (age; energy; orange, white bread and whole bread, lentil, lettuce, green bean, apple, potato, spinach, pasta, banana, muffin, breakfast cereal, rice, and biscuit intakes).

bread was the main food source of soluble hemicellulose and banana was the main supplier of resistant starch.

Multiple stepwise linear regression analyses were carried out to explore the association between the fibers, polyphenols, or any of their food sources and the microbiota (Table 4). These dietary components and foodstuffs are highly correlated. Therefore, to avoid findings that can be explained by any other highly correlated variable, fibers and polyphenols which appeared in our study as significantly associated with microbiota were placed in a model at the same time. The same approach was used to explore

the association between food sources and microbial groups. *B. coccoides* levels were negatively associated with orange intake and positively with resistant starch from pasta; *C. leptum* variation was explained, in part, by the intake of flavanones from oranges, whereas *Lactobacillus* was associated with insoluble hemicellulose and resistant starch from white bread.

DISCUSSION

Most research about diet and intestinal microbiota has been traditionally focused on the effect of single food components (usually soluble fibers) acting as prebiotics to promote the growth of some beneficial bacterial groups, such as *Lactobacillus* or *Bifidobacterium*. To the best of our knowledge, this is the first attempt to analyze the impact of the consumption of different types of fibers, together with polyphenols and their dietary sources, on the fecal microbiota, within the context of a regular diet in healthy adults.

The detection of a direct association between dietary fibers provided by white bread and the levels of *Lactobacillus*, as well as the identification of an inverse association between flavanones and pectins from orange and *B. coccoides* and *C. leptum*, confirms the complexity of the diet−microbiota interrelationship.

Previous studies indicated that pectin evades digestion by human digestive enzymes and reaches the colon, where it is metabolized by several microbial groups, then favoring their growth.[28] However, in the present study we have found an inverse association between pectin intake and fecal levels of *B. coccoides* and *C. leptum*, which include important groups such as *Lachnospira*, *Ruminococcus*, or *Faecalibacterium*. Because this result was unexpected, we checked the possibility that part of this effect of pectin may be due to its interaction with other components present in the same foods,[18] as is the case of flavanones. It has been recently suggested that the absorption of flavanones takes place in both the small and large bowels, being compounds with a reduced bioavailability.[29] Also, processing of flavanone-rich foods, such as citrus fruits, can lead to the precipitation of these flavonoids by combination with pectins or other macromolecules,[30] resulting in compounds with less bioavailability than the original ones.[31] Therefore, given that an appreciable amount of polyphenols passes the small intestine in tandem with dietary fiber[32,33] and the high grade of correlation between their intake, some authors have suggested that both compounds should be approached together.[34] In accordance with this, pectin and flavanone intake in our sample were highly correlated ($r = 0.734$; data not shown); oranges were identified as the main contributor to the intake of both dietary compounds, accounting for aproximately 45 and 69% of pectin and flavanone intake, respectively. The inclusion of both pectins and flavanones, together, in a linear regression model revealed that only flavanone intake persists as a predictor of *C. leptum* levels. Therefore, it seems plausible that the inverse association previously reported for pectins may be actually due to their interaction with flavanones. Although no information is currently available on the effect of flavanones on *Clostridium*, in vitro experiments conducted by other authors have demonstrated the antimicrobial activity of some flavanones and their metabolites.[35,36] This antimicrobial activity may be involved in the inverse association with the levels of *B. coccoides* and *C. leptum* groups observed in the present study.

In terms of food consumption, probably the most novel finding of our study was the positive association between the intake of white bread and *Lactobacillus* levels. This genus has been traditionally considered, together with *Bifidobacteria*, as the target of prebiotic action.[37−39] To date, the prebiotic effect of cereals has been traditionally attributed to whole-grain foods[40,41] because of their high fiber content. However, our results reveal that the consumption of refined grains, often undervalued in this regard, could beneficially modulate intestinal microbiota. These data are of great interest because refined foods are the cereals more consumed in Western societies (white bread consumption in our sample was 105.68 ± 117.06 g/day). Consistent with this, some authors have also found, in human intervention studies, higher levels of *Lactobacillus* in control subjects that had eaten white bread,[42] thus supporting our results. The hemicellulose content in white bread, which represents about 25.8% of total hemicellulose intake in the sample, could be the basis of the prebiotic effect observed in our study, being consistent with the direct association found between this type of fiber and *Lactobacillus*. In this sense, previous results have demonstrated the ability of arabinoxylans, one of the main cereal hemicelluloses, to positively modulate some beneficial intestinal bacterial groups.[43,44] Moreover, other components present in white bread could underlie this association, as is the case of resistant starch, directly associated with *Lactobacillus* levels. However, it is important to consider that determining the amount of this compound originating from foods is difficult, because it depends on several factors that are not well standardized in nutritional studies, such as food structure and processing, as well as consumer-related factors, such as mastication.[24] Also, it might be possible that the association between white bread and *Lactobacillus* could be mediated by other foods usually consumed with bread, although we have not found such an association between any of these foodstuffs and *Lactobacillus* in our study (data not shown). The association found between the intake of pasta and *B. coccoides* levels is noteworthy, because the amount of this foodstuff in the diet of the participants is low (9.62 ± 7.92 g/day) and provides only 2% of total resistant starch intake. Nevertheless, our results could be due to the high content of resistant starch in pasta, being one of its main sources in countries where this food is more frequently consumed.[45]

Finally, the lack of effect of polyphenol and fiber intake on the fecal levels of other microorganisms, such as *Bacteroides* group, including *Prevotella* or *Bifidobacterium*, evidenced in our work, does not support the associations previously reported in intervention studies.[46,47] At this point, it should be considered that the intake of polyphenols in our sample could be insufficient to influence certain members of the intestinal microbiota and that the mean fiber intake of this study is below the recommended value of 16−24 g/day for nonstarch polysaccharides,[48] 47.4% of the sample being under the acceptable intake of fiber. Some factors related to the content of fibers and polyphenols in foods (plant variety, degree of maturity, or cooking, storage, and processing practices) are not considered in food composition tables and, consequently, are not taken into account in nutritional studies. Also, polyphenols are compounds showing a high variability in their bioavailability, strongly influenced by factors such as food matrix, food processing, and microbial metabolism. In addition, although the limited sample size and high interindividual variability do not allow firm conclusions to be established, our study highlights the complex diet−microbiota interactions and the importance of considering the diet as a whole, rather than isolated components, on such interactions.

In conclusion, our results provide further evidence regarding the relationship between components of a regular diet and fecal

microbiota in healthy adults. The identification of an association between the intake of regular foods, such as oranges or white bread, and certain microbial groups emphasizes the requirement of future research focused on diet rather than on isolated compounds.

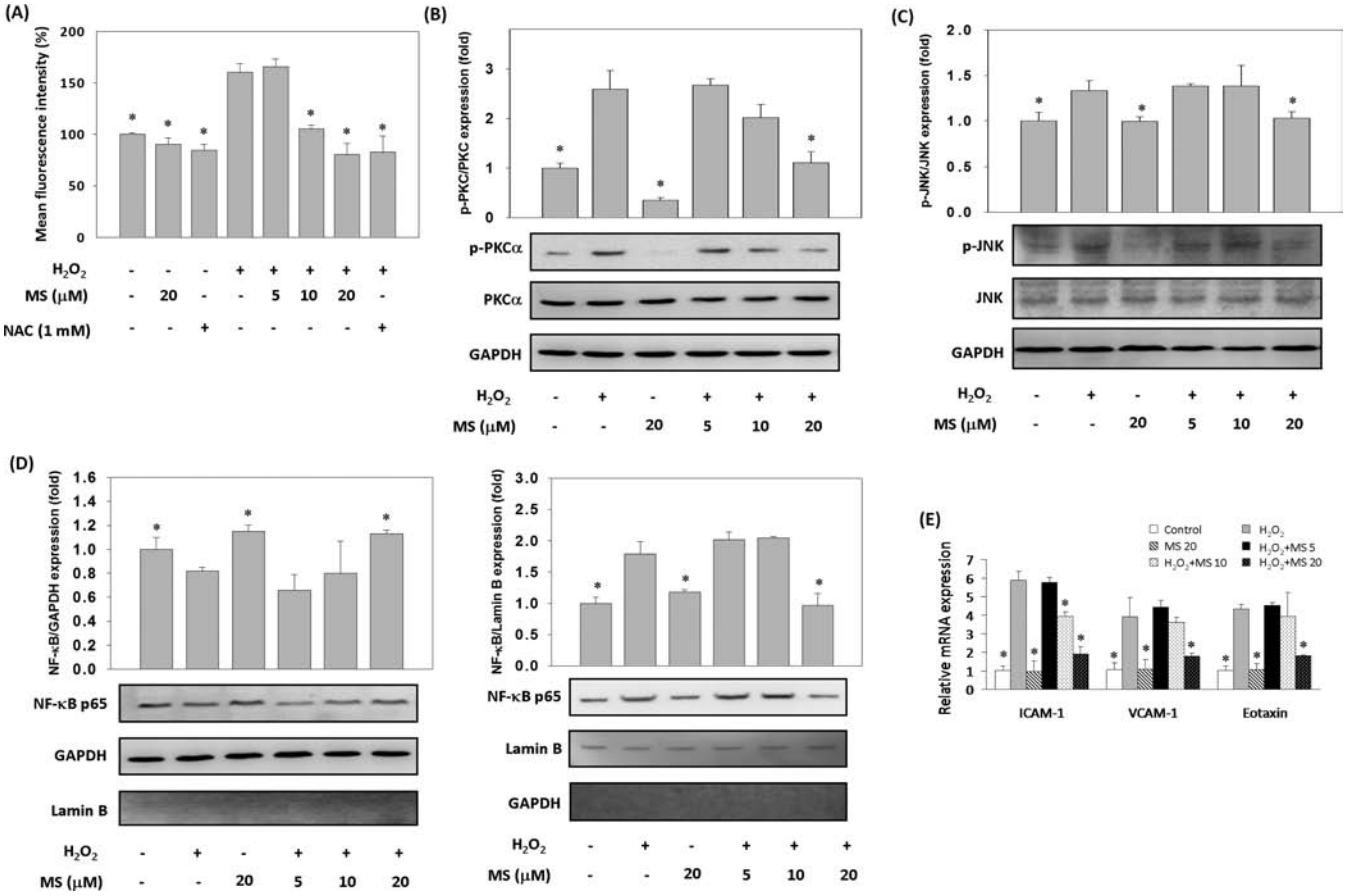

Figure 1. MS attenuated H_2O_2-induced lung oxidative damage in airway epithelial cells. A549 cells were treated with H_2O_2 and different concentrations of MS for 12 h. (A) Effect of H_2O_2 and/or MS on intracellular ROS levels in A549 cells. MS significantly attenuated H_2O_2-mediated ROS generation. (B–D) Western blot analysis of protein extracts obtained from A549 cells. Cells were lysed and immunoblotted with antibodies against (B) phosphorylated-PKC, (C) phosphorylated-JNK, (D) cytosol NF-κB, and nuclear NF-κB. Each protein was normalized with total (B) PKC, (C) JNK, (D) GAPDH, and Lamin B. MS reduced PKC and JNK phosphorylation as well as NF-κB translocation caused by H_2O_2. (E) Real-time PCR analysis of adhesion molecules expression in cells. GAPDH was used as a control. MS decreased ICAM-1, VCAM-1, and eotaxin mRNA expression induced by H_2O_2. Results are expressed as the mean ± SD ($n = 3$). (∗) Significantly different from the H_2O_2 treatment alone group at $p < 0.05$. H_2O_2, hydrogen peroxide (400 μM); MS, monascin; NAC, *N*-acetylcysteine (1 mM); ROS, reactive oxygen species; PKC, protein kinase C; JNK, c-Jun NH_2-terminal kinase; NF-κB, nuclear factor-κB; ICAM-1, intercellular adhesion molecule-1; VCAM-1, vascular cell adhesion molecule-1.

ties, MS may have potential to improve lung inflammation by regulating the oxidative stress pathway.

MATERIALS AND METHODS

Chemicals and Reagents. 2,7-Dichlorodihydrofluorescein diacetate (DCFH-DA), D-glucose, hydrogen peroxide (H_2O_2), *N*-acetylcysteine (NAC), *tert*-butylhydroquinone (tBHQ), and trypsin were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Fetal bovine serum (FBS) was purchased from Life Technologies (Carlsbad, CA, USA). Dimethyl sulfoxide (DMSO) was purchased from Wako Pure Chemical Industries (Saitama, Japan). Ham's F-12K medium was purchased from HyClone Laboratories (Logan, UT, USA). Sodium dodecyl sulfate (SDS) was purchased from Merck (Darmstadt, Germany). The Bio-Rad protein assay dye was from Bio-Rad Laboratories (Hercules, CA, USA). PPAR-γ antagonist GW9662 was purchased from Cayman Chemical Co. (Ann Arbor, MI, USA).

Monascin Purification. MS (Supporting Information Supplemental Figure 1) was obtained as previously described,[14] which was identified by nuclear magnetic resonance (NMR, Varian Gemini, 200 MHz, FT-NMR, Varian Inc., Palo Alto, CA, USA) and electrospray ionization-mass spectrometry (ESI-MS, FinniganMAT LCQ, Thermo Electron Co., Waltham, MA, USA) analysis.

Cell Culture. Human lung adenocarcinoma epithelial cell line A549 was obtained from the Bioresource Collection and Research Center (BCRC 60430; Food Industry Research and Development Institute, Hsinchu, Taiwan). Cells were maintained in Ham's F-12K medium supplemented with 10% FBS, streptomycin (100 mg/mL), and penicillin (100 U/mL) in a 5% CO_2 incubator at 37 °C. All experiments were performed when cells were 80–90% confluent.

Determination of ROS Level. The assay for oxidative stress was monitored by the measurement of ROS.[10] A549 cells were collected and stained with 10 μM DCFH-DA prior to incubation for 30 min at 37 °C. ROS level was analyzed by FACS (Becton-Dickinson Lmmunocytometery Systems, San Jose, CA, USA).

Immunoblot Analysis. A549 cells were lysed, and the cell lysates were centrifuged (10000*g* for 10 min) to recover the supernatant. The supernatant was taken as the cell extract. The protein concentration in the cell extract was 50 μg and was determined using a Bio-Rad protein assay kit. The samples were subjected to 10% SDS–polyacrylamide gel electrophoresis (PAGE). The protein spots were electrotransferred to a polyvinyldiene difluoride (PVDF) membrane. The membrane was incubated with block buffer and then probed with primary antibody overnight at 4 °C. The membrane was washed and shaken in a solution of HRP-linked anti-rabbit IgG secondary antibody. The expressions of proteins were detected by enhanced chemiluminescent (ECL) reagent (Millipore, Billerica, MA, USA).

Nuclear and Cytosol Protein Extraction. Cells were collected for nuclear protein extraction according to the fractionation kit protocol supplied from BioVision (Mountain View, CA, USA). Briefly,

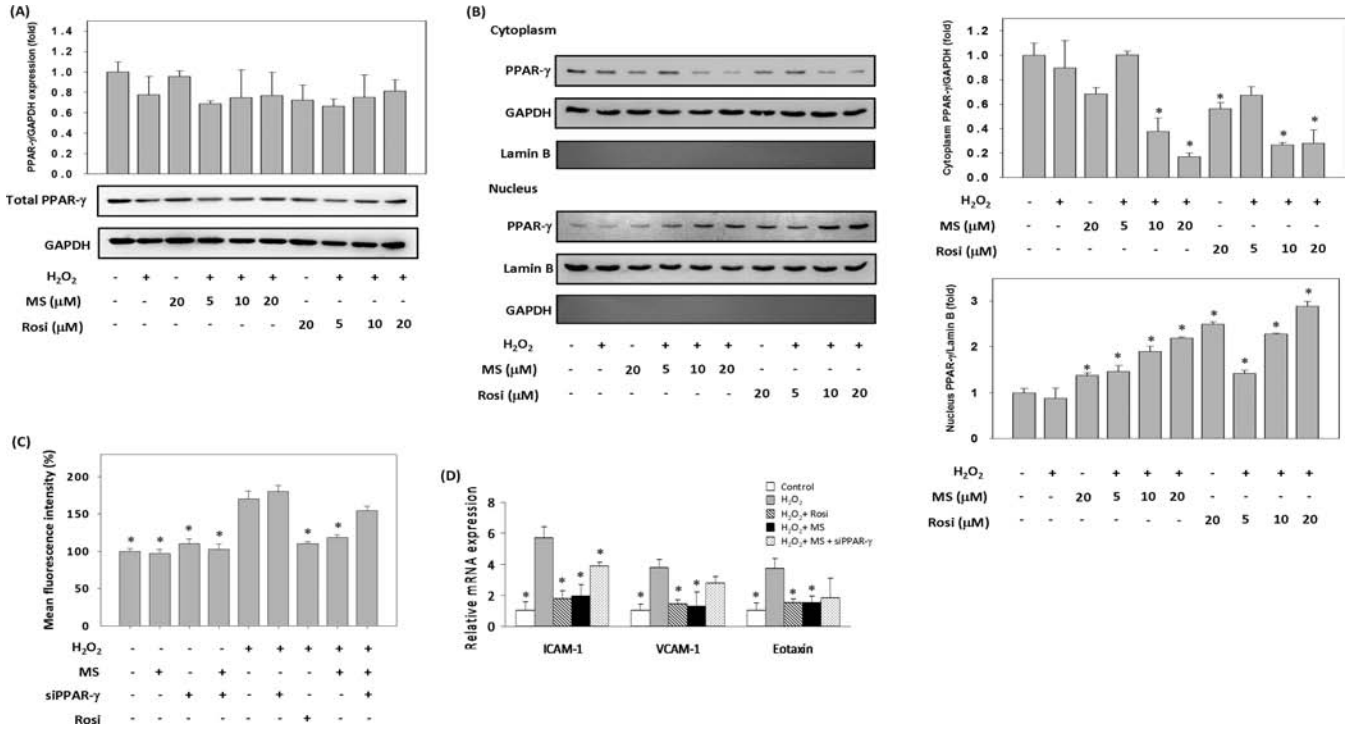

Figure 2. MS ameliorated lung oxidative and inflammatory injury through PPAR-γ regulation in airway epithelial cells. A549 cells were treated with H_2O_2 and different concentrations of MS for 12 h. (A, B) Western blot analysis of protein extracts obtained from A549 cells. Each protein was normalized with GAPDH or Lamin B. MS elevated PPAR-γ expression and promoted PPAR-γ translocation from cytoplasm to the nucleus. (C) Intracellular ROS levels in A549 cells. MS and Rosi significantly reduced H_2O_2-mediated ROS generation, whereas ROS level was restored by siPPAR-γ. (D) Real-time PCR analysis of adhesion molecules expression in cells. GAPDH was used as a control. The inhibitory effect of MS on adhesion molecules expression was abolished by siPPAR-γ. Results are expressed as the mean ± SD (n = 3). (∗) Significantly different from the H_2O_2 treatment alone group at $p < 0.05$. H_2O_2, hydrogen peroxide (400 μM); MS, monascin (20 μM); Rosi, rosiglitazone (20 μM); siPPAR-γ, siRNA against PPAR-γ (50 nM); ICAM-1, intercellular adhesion molecule-1; VCAM-1, vascular cell adhesion molecule-1.

cells were harvested and added to 200 μL of cytosol extraction buffer containing dithiothreitol (DTT) and protease inhibitors. After vortexing and 10 min of incubation on ice, the extracts were centrifuged at 16000g for 5 min at 4 °C, and the supernatant was removed to separate the cytoplasmic fraction from nuclei. The nuclei pellets were then further added to 100 μL of nuclei extraction buffer, vortexed, and set on ice every 10 min for 40 min. After centrifuging, the supernatant nuclear extracts were stored at −80 °C for future use. The protein concentration of the cell extract was determined using a Bio-Rad protein assay kit.

RNA Preparation and Real-Time PCR. Total RNA was isolated using Trizol (Life Technologies) according to the manufacturer's instructions. cDNA from 3 μg of RNA was generated using a SuperScript III First-Strand Synthesis System for RT-PCR (Life Technologies) according to the manufacturer's instructions. The reverse transcription product was diluted in water, and a volume corresponding to 30 ng of original RNA was used for real-time PCR. Real-time PCR amplification and detection were performed using the SYBR Green qPCR SuperMix-UDG with ROX (Life Technologies) in a fluorescence thermal cycler (StepOne Real-Time PCR System, Life Technologies) according to the manufacturer's protocol. All amplifications were conducted within the linear range of the assay, normalized to respective GAPDH levels using SPSS version 17.0 (SPSS Institute, Inc., Chicago, IL, USA).

Transfection of Cells with Small Interfering RNA (siRNA). PPAR-γ and Nrf-2 siRNA were purchased from Santa Cruz Biotechnology Inc. (Burlingame, CA, USA), and specific siRNA was transfected into A549 cells by lipofectamine RNAiMAX reagent (Invitrogen, Carlsbad, CA, USA).

PPAR-γ and Nrf-2 Luciferase Assay. The specific PPAR-γ reporter assay was carried out in A549 cells according to the previous study.[19] The plasmid was designed by Blossom Biotechnologies Inc. (Taipei, Taiwan). In addition, we used a DNA fragment containing three copies of the ARE4 elements from the GCL gene (5′-CCC GTG ACT CAG CGC TCC GTG ACT CAG CGC TCC GTG ACT CAG CGC T-3′), which was subcloned into a pGL3-promoter vector to construct pGL3-ARE4-Luc. A549 cells were transiently transfected with a DNA mixture containing 2 μg of pGL3-ARE4-Luc and 0.5 μg of control plasmid pRL-TK (Promega, Madison, WI, USA) using the lipofectamine-2000 transfection reagent in serum-free medium (Invitrogen). After treatment with samples for various times, luciferase activity was conducted utilizing the Dual-Luciferase Reporter Assay System (Promega). Luciferase activity of pRL-TK was used to normalize the transfection efficiency.

PPAR-γ DNA Binding Assay. Nuclear extracts were prepared from A549 cells by means of a commercially available kit and performed according to the instructions of the manufacturer. The binding activities of the PPAR-γ were measured by using specific transcription factor assay kits (Panomics, Redwood City, CA, USA). Oligonucleotides encoding for the human PPAR-γ consensus binding site were bound to microtiter plates. The binding of activated PPAR-γ-heterodimers, in the prepared nuclear extracts, to the immobilized DNA was revealed by incubation with PPAR-γ specific antibody using ELISA technology. Optical density was determined at 450 nm.

Statistical Analysis. The statistical significance was determined by one-way analysis of variance (ANOVA) using the general linear model procedure of SPSS software (SPSS Institute, Inc.), followed by ANOVA with Duncan's test. The results were considered to be statistically significant if the p value was <0.05. Data are presented as the mean ± SD or SEM.

RESULTS

MS Attenuates Oxidative Stress-Induced Lung Inflammation in A549 Cells. The endogenous levels of ROS in

dx.doi.org/10.1021/jf501373a | J. Agric. Food Chem. 2014, 62, 5337−5344

A549 cells were quantified. We found clear induction of ROS production for 160.2% in the group treated with 400 μM hydrogen peroxide (H_2O_2) compared to the control group, as expected (Figure 1A). MS decreased the ROS level in H_2O_2-induced cells in a dose-dependent manner ($p < 0.05$), whereas MS treatment alone did not influence ROS production. Antioxidant *N*-acetylcysteine (NAC) (1 mM) was used as a positive control group, which reduced the production of ROS to a level similar to that of the control and MS-treated group (Figure 1A).

ROS stimulates phosphorylation of protein kinase C (p-PKC), leading to the activation of NF-κB.[20] ROS and other oxidative stress factors also promote phosphorylation of c-Jun NH_2-terminal kinase (JNK), a member of the mitogen-activated protein kinase (MAPK) family that activates transcription factors such as NF-κB and activator protein (AP)-1.[21] As shown in Figure 1, 400 μM H_2O_2 induced phosphorylation of PKCα (Figure 1B) and JNK (Figure 1C), but this was blocked by treatment with 20 μM MS. Likewise, H_2O_2 activated NF-κB translocation from the cytoplasm to the nucleus; however, treatment with MS prevented the NF-κB translocation (Figure 1D).

Leukocytes are recruited into tissues by adhesion molecules and chemokines. Adhesion molecule expression is induced in the endothelium or epithelium by several mediators, including cytokines or ROS, in a variety of chronic inflammatory conditions.[22] Figure 1E shows that whereas H_2O_2 increased mRNA expression of various adhesion molecules, treatment with 20 μM MS attenuated this effect ($p < 0.05$).

MS Ameliorates Lung Oxidative Inflammation through PPAR-γ Regulation. The mechanism underlying the antioxidative and anti-inflammatory effects of PPAR-γ in multiple tissues has been under investigation. It has been shown that PPAR-γ antagonizes signal transducing kinases and transcriptional regulators such as AP-1, nuclear factor of activated T cell, and NF-κB.[23] PPAR-γ also represses inflammatory mediators such as cytokines, chemokine receptors, and adhesion molecules.[24,25] A known PPAR-γ agonist, rosiglitazone (Rosi), was used as a positive control group. Our results indicate that there was no significant difference for the total PPAR-γ protein level in each group (Figure 2A). After treatment with H_2O_2 and MS/Rosi for 12 h, the translocation of PPAR-γ from the cytoplasm to the nucleus was increased (Figure 2B). Notably, 20 μM MS or Rosi treatment alone also promoted PPAR-γ translocation.

We next determined if there was a relationship between the MS-induced inhibition of ROS generation and adhesion molecule expression and its effect on the expression of PPAR-γ. The PPAR-γ antagonist GW9662 (10 μM) was added to A549 cells treated with H_2O_2 (400 μM) and/or MS/Rosi (20 μM). As previously observed in Figure 1, the H_2O_2-induced ROS generation, JNK and PKCα activation, and increase in adhesion molecule expression were inhibited by MS treatment. However, the inhibitory effect of MS on oxidative damage was abated by addition of the PPAR-γ antagonist (Supporting Information Supplemental Figure 2).

Next, we used siRNA against PPAR-γ (siPPAR-γ) to verify that the regulation of MS during lung oxidative injury was mediated by PPAR-γ. Specific siRNA for PPAR-γ was transfected into A549 cells, and PPAR-γ protein levels were decreased after treatment with siRNA for 48 and 72 h (Supporting Information Supplemental Figure 3). Hence, 48 h was chosen for the further experiments. Our results show that although MS or siPPAR-γ treatment alone did not change the ROS level, both Rosi and MS (20 μM) decreased ROS generation compared to the H_2O_2-induced group, but the ROS level was restored when cells were treated with both MS and siPPAR-γ (Figure 2C). Moreover, the inhibitory effect of MS on adhesion molecule expression was clearly abolished by siPPAR-γ in both mRNA and protein levels (Figure 2D and Supporting Information Supplemental Figure 4). These results provide further evidence indicating that the effect of MS on oxidative damage in epithelial cells was partly mediated by PPAR-γ.

To further elucidate that MS may act as PPAR-γ activator, we first wonder whether MS promotes PPAR-γ activity. The specificity of MS for the PPAR response element (PPRE) sequences was then determined by transfecting A549 cells with the luciferase reporter construct harboring this element. At 24 h following transfection, MS was applied, and enhanced luciferase activity was observed and analyzed. The data presented in Figure 3A clearly indicate that 20 μM MS enhanced luciferase activity at 2.38-fold compared with the control group for 12 h, whereas 20 μM pioglitazone (Pio) and Rosi enhanced the activity at 1.69- and 2.95-fold, respectively ($p < 0.05$).

A DNA binding assay was performed to confirm that MS has the ability to bind to PPAR-γ. We first investigated PPAR-γ expression after MS treatment for 2, 4, 8, and 12 h. After treatment with 20 μM MS for 4 h, the translocation of PPAR-γ from the cytoplasm to the nucleus was increased, with the most prominent translocation at 8 and 12 h of treatment (Supporting Information Supplemental Figure 5). We next examined the effect of MS on the DNA binding activity of PPAR-γ. As shown in panels B and C of Figure 3, treatment with 20 μM MS significantly elevated PPAR-γ binding to DNA at 8 and 12 h after treatment, and 20 μM Rosi clearly elevated PPAR-γ binding to DNA at 4, 8, and 12 h after treatment, whereas 400 μM H_2O_2 decreased the binding activity after 24 h of treatment when compared with the control group. Moreover, MS and Rosi still significantly increased PPAR-γ binding activity in H_2O_2-treated cells at 8 and 12 h.

MS Elevates Nrf-2 Translocation in A549 Cells. The transcription factor Nrf-2 is involved in lung defense against oxidative injury.[12] Nrf-2 plays a critical part in basal activity and coordinated induction of genes encoding heme oxygenase-1 (HO-1).[26] We found that MS accelerated the translocation of Nrf-2 from the cytoplasm to the nucleus in a dose-dependent manner in H_2O_2-induced cells. Moreover, translocation of Nrf-2 to the nucleus was markedly increased in the MS treatment alone group ($p < 0.05$). However, Rosi did not have the ability to promote Nrf-2 translocation. Furthermore, the expression of HO-1, a downstream molecule of Nrf-2, also increased following either MS treatment alone or MS treatment combined with H_2O_2 (Figure 4A,B).

We then investigated Nrf-2 expression after MS treatment for 2, 4, 8, and 12 h. After treatment with 20 μM MS for 4 h, the translocation of Nrf-2 from the cytoplasm to the nucleus was increased, with the most prominent translocation at 8 and 12 h of treatment (Supporting Information Supplemental Figure 6). Figure 4C reveals that 20 μM MS significantly promoted luciferase activity at 1.70-fold compared with the control group at 12 h ($p < 0.05$). However, treatment with Rosi did not enhance luciferase activity compared with the control group. tBHQ was used as a positive control group, which enhanced luciferase activity at 2.11-fold.

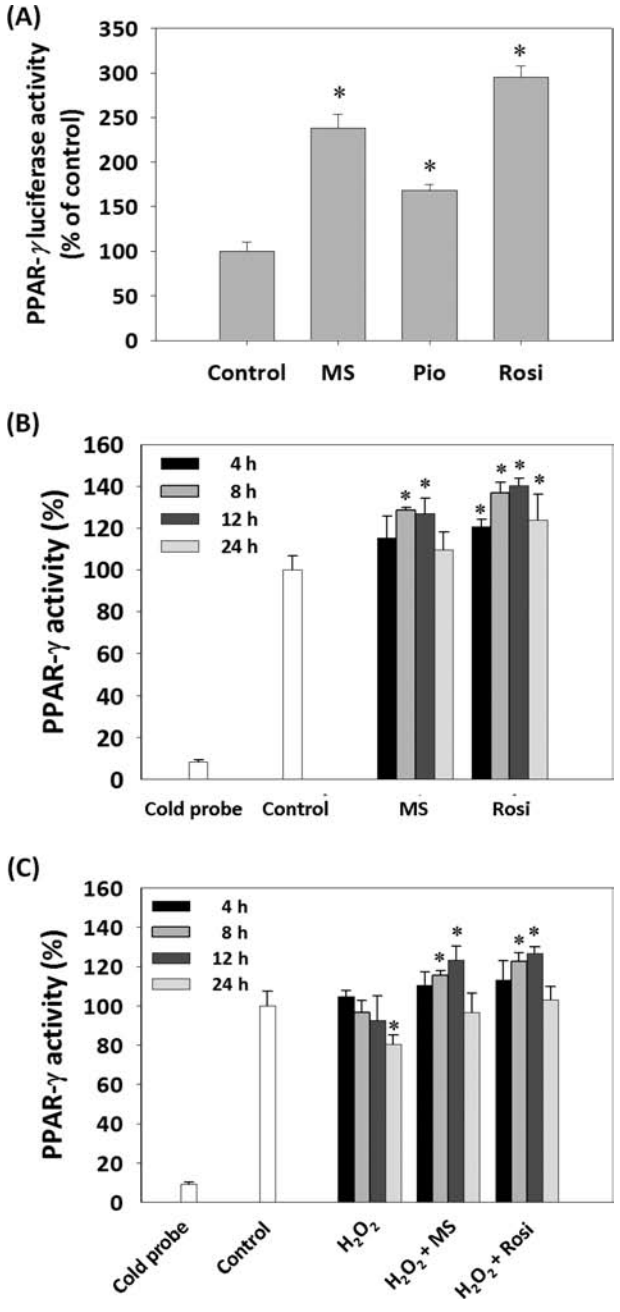

Figure 3. MS promoted PPAR-γ activity in A549 cells. (A) Luciferase assay. The specificity of MS for the PPAR-γ sequences was determined by transfecting A549 cells with the luciferase reporter construct harboring this element. At 24 h following transfection, MS was applied and enhanced luciferase activity was observed and analyzed. MS enhanced luciferase activity at 2.38-fold compared with the control group for 12 h, whereas Pio and Rosi were 1.69- and 2.95-fold, respectively. Pio and Rosi were used as positive control groups. (*) Significantly different from the H_2O_2 treatment alone group at $p < 0.05$. (B, C) DNA binding acitivity. A549 cells were treated with 20 μM of MS alone or combined with H_2O_2 for 4, 8, 12, and 24 h: (B) MS significantly elevated PPAR-γ binding to DNA for 8 and 12 h treatment; (C) H_2O_2 attenuated this binding activity compared to the control group after 24 h of treatment. MS significantly recovered the alleviation of PPAR-γ binding activity caused by H_2O_2 treatment at 8 and 12 h. Results are expressed as the mean ± SEM (n = 3). (*) Significantly different from the control group at $p < 0.05$. MS, monascin (20 μM); Pio, pioglitazone (20 μM); Rosi, rosiglitazone (20 μM); H_2O_2, hydrogen peroxide (400 μM).

DISCUSSION

Lung inflammation is central to the pathogenesis of airway disorders, and oxidative stress has been shown to be related to the pathogenesis of inflammatory lung diseases.[2,3] Oxidative stress is caused by a large variety of free oxygen radicals, including superoxide anion, hydroxyl radicals, and oxygen derivatives such as hydrogen peroxide, hypochlorous acid, peroxynitrite, and ozone; collectively, these are referred to as ROS.[2] ROS are important in the pathogenesis of various lung disorders, such as asthma, chronic obstructive pulmonary disease, and acute lung injury. ROS can beget endothelial barrier dysfunction, with subsequent increased permeability to inflammatory cells.[2,4] Using A549 human lung epithelial cells, we have identified several protein targets involved in modulating the expression of adhesion molecules that are affected by both H_2O_2-induced oxidative stress and MS treatment.

H_2O_2 is one of the most abundant ROS in aerobic biological systems and has been widely used to induce oxidative stress in cellular systems in vitro. H_2O_2 was chosen to induce injury because airway disorder is associated with chronic oxidative stress. In addition, patients with asthma demonstrate increased production of ROS, including H_2O_2, which is released in relatively large amounts by activated leucocytes during the process of lung inflammation in asthma.[27] ROS cause oxidative stress and activate p-PKC, which is a kinase that stimulates the inflammatory cascade, as well as transcription factors such as NF-κB.[20] NF-κB controls many adhesion molecules and cytokines in the epithelium and is an important signaling module for the synthesis of mediators such as cytokines and adhesion molecules in the processes of chronic airways diseases. The expression of these molecules will further amplify inflammation by recruiting monocytes and facilitating their binding to and migration through the endothelium.

In addition to NF-κB activation, JNK is also activated by environmental insults, such as ROS and inflammatory stimuli.[28] JNK regulates the transcription of inflammatory genes, leading to the activation or coactivation of redox-sensitive transcription factors such as NF-κB and AP-1. Activation of JNK is implicated in the synthesis of pro-inflammatory cytokines and plays a role in cellular responses in the pulmonary epithelium. In this study, we found that MS attenuated oxidative stress-induced ROS generation, and we considered that this may be mediated by PKCα and JNK inactivation and reduced the translocation of NF-κB from the cytoplasm to the nucleus (Figure 1), indicating that MS has the potential to protect airway epithelial cells against oxidative injury.

PPARs inhibit the phosphorylation of JNK by interacting with the JNK-responsive region of c-Jun and other transcriptional coactivators such as p65 and cAMP-responsive element-binding protein-binding protein (CBP). Activation of PPARs represses both c-Jun- and p65-induced transcription of the human IL-6 promoter and further suppresses the inflammatory gene response.[29] In the present study, we demonstrated that MS decreased the abundance of adhesion molecules by elevating the expression of PPAR-γ, and this was confirmed using a PPAR-γ antagonist and siRNA against PPAR-γ. Furthermore, luciferase assay and DNA binding activity were used to affirm that the protective effect of MS on epithelial cells may be due to its ability to promote PPAR-γ binding to DNA, thereby enhancing the transcription of anti-inflammatory and antioxidant genes, and inhibition of NF-κB translocation by MS

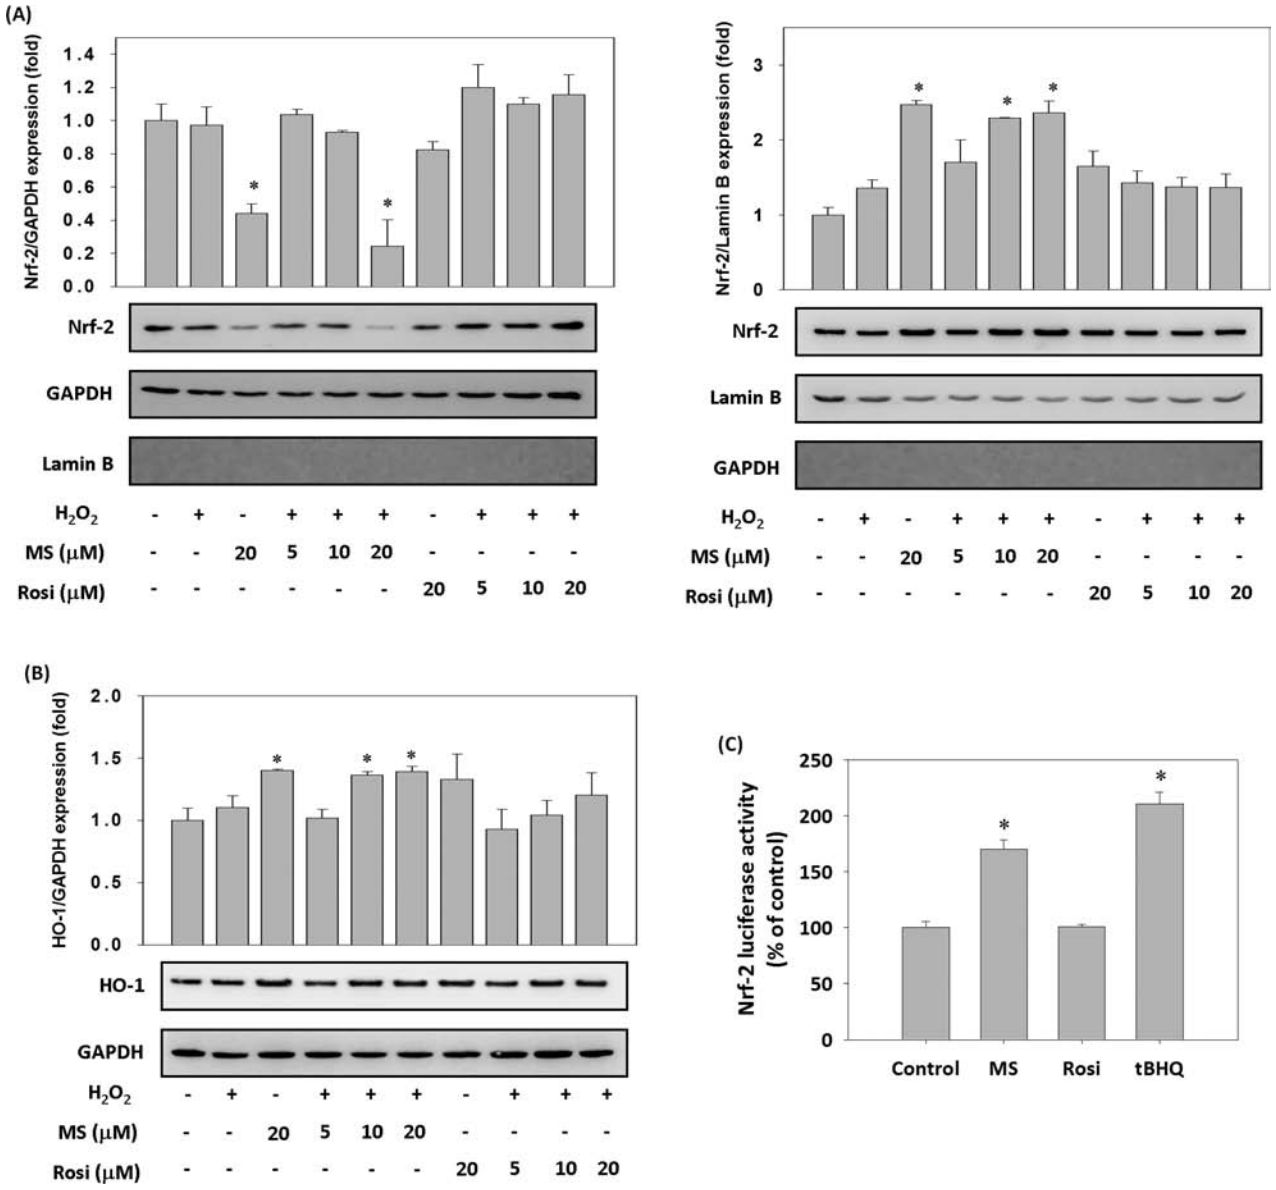

Figure 4. MS activated Nrf-2 in A549 cells. Western blot analysis of Nrf-2 and HO-1 in A549 cells. (A) MS up-regulated Nrf-2 translocation and (B) HO-1 expression. A549 cells were treated with H_2O_2 and different concentrations of MS for 12 h. (∗) Significantly different from the H_2O_2 treatment alone group at $p < 0.05$. (C) Luciferase assay. The specificity of MS for the ARE sequences was determined by transfecting A549 cells with the luciferase reporter construct harboring this element. At 24 h following transfection, MS was applied and enhanced luciferase activity was observed and analyzed. MS enhanced luciferase activity at 1.70-fold compared with the control group for 12 h, whereas Rosi and tBHQ were 1.00- and 2.11-fold, respectively. Results are expressed as the mean ± SEM ($n = 3$). (∗) Significantly different from the control group at $p < 0.05$. H_2O_2, hydrogen peroxide (400 μM); MS, monascin (20 μM); Rosi, rosiglitazone (20 μM); tBHQ, *tert*-butylhydroquinone (50 μM).

may also be involved. Consequently, MS treatment was sufficient to ameliorate the increase in adhesion molecule expression induced by H_2O_2.

PPAR-γ enhances the transcription of anti-inflammatory and antioxidant genes, including Nrf-2. The Nrf-2-mediated cellular antioxidant and anti-inflammatory effects play a crucial role in the defense against oxidative stress. The activation of Nrf-2 and up-regulation of the downstream enzymes provides vascular protection during oxidative stress and inhibits inflammatory responses via suppression of the NF-κB pathway and expression of adhesion molecules such as ICAM-1 and VCAM-1.[30] Our results suggest that MS promoted the translocation of Nrf-2 and increased Nrf-2 activity, thereby elevating the level of the antioxidant HO-1.

Pharmacological agents that enhance lung antioxidant levels have been extensively investigated in airway disease. Some compounds such as phenols, flavonoids, isothiocyanates, diterpenes, and sulforaphane have phenolic hydroxyl groups and have been used to mediate antioxidative gene expression through the ARE either via the disruption of Nrf-2-keap1 complexes or via the activation of the transcriptional complex of Nrf-2.[31] Growing evidence suggests that the activation of Nrf-2 signaling contributes to the health benefits of natural compounds including curcumin, resveratrol, epicatechin, glucoraphanin, and isothiocyanate that have been reported in the treatment of lung,[32] neurological,[33] and cardiovascular diseases.[34] PPAR-γ is also a novel target for chronic inflammatory lung diseases due to its anti-inflammatory

dx.doi.org/10.1021/jf501373a | J. Agric. Food Chem. 2014, 62, 5337−5344

capacity. The above compounds such as resveratrol and curcumin have been demonstrated to prevent lung diseases, obesity, or other metabolic diseases via PPAR-γ activation.[35−39] Our group previously demonstrated that pigment MS derived from *Monascus* increases PPAR-γ mRNA expression and prevents PPAR-γ phosphorylation, thereby increasing the uptake of the deoxyglucose analogue 2-NBDG to exhibit antidiabetic activity in C2C12 myotubes.[40] The primary aim of the current study was to evaluate the therapeutic potential of MS against lung epithelial cell oxidative damage. Our results reveal that MS prevented oxidative stress-induced adhesion molecule expression in epithelial cells through PPAR-γ translocation and inhibited NF-κB translocation, leading to a decrease in the expression of inflammatory mediators. However, this regulatory ability was abolished by PPAR-γ antagonist GW9662 and siRNA against PPAR-γ, implying that MS has the potential to modulate PPAR-γ activity. Our results also indicate that MS elevated antioxidant enzyme expression via Nrf-2 activation. We further demonstrated this hypothesis by using luciferase and a DNA binding assay, which suggest that MS may be a novel PPAR-γ agonist and Nrf-2 activator.

Our research group has previously found that MS could act as a PPAR-γ activator to attenuate carboxymethyllysine-induced fibrosis in hepatic stellate cells[41] and inflammation in monocytes[42] and inhibit Th2 cytokine production in T cells.[43] Moreover, we have shown that MS prevented type 2 diabetes in methylglyoxal-treated Wistar rats via PPAR-γ and Nrf-2 activation.[44] In our data, similarly, MS activated PPAR-γ and Nrf-2 in the lung cells, which means that MS has the ability to improve inflammation- and oxidative stress-associated diseases through PPAR-γ- and/or Nrf-2-dependent pathways. It is worth noting that this is the first study to point out that MS has the ability to bind to PPAR-γ using a DNA binding activity assay.

Our findings hypothesize that MS may act as a novel PPAR-γ agonist to inhibit NF-κB translocation and further avoid adhesion molecules expression, which accelerated immune cells infiltration (Figure 5). MS also activated Nrf-2 and downstream antioxidant enzymes to attenuate lung oxidative inflammation. MS can regulate PPAR-γ and Nrf-2, and therefore MS has a stronger ability in lung protection than rosiglitazone, which is a known synthetic PPAR-γ ligand. Taken together, MS could regulate PPAR-γ and Nrf-2 activities, and both of these two transcription factors are involved in protecting the lung during airway disease. Hence, MS may regulate the oxidative stress pathway to improve lung inflammation.

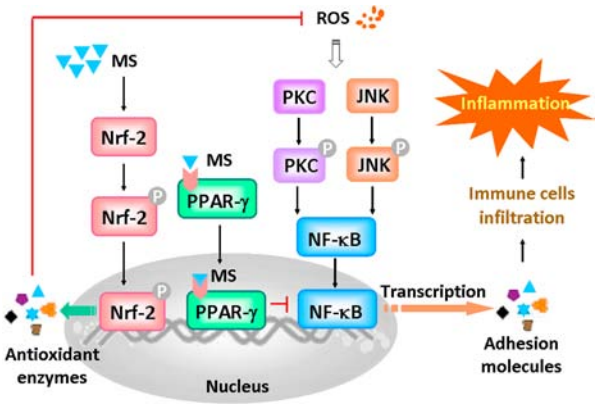

Figure 5. Proposed mechanism of MS-mediated amelioration of oxidative stress-induced lung inflammation. MS prevented oxidative stress-induced lung inflammation in epithelial cells through PPAR-γ translocation, which further inhibited NF-κB translocation and avoided adhesion molecule expression that accelerates immune cell infiltration. MS also activated Nrf-2 via phosphorylation and downstream antioxidant enzymes to attenuate lung oxidative injury.

Preparation conditions: HTC at 393−513 K for 10 h, followed by sulfonation at 363 K for 10 h. (b) Effect of the carbonization time on esterification activity of the corncob-derived solid acid. Preparation conditions: HTC at 453 K for 1−15 h, followed by sulfonation at 363 K for 10 h. (c) Effect of the sulfonation temperature on esterification activity of the corncob-derived solid acid. Preparation conditions: HTC at 453 K for 10 h, followed by sulfonation at 333−423 K for 10 h. (d) Effect of the sulfonation time on esterification activity of the corncob-derived solid acid. Preparation conditions: HTC at 453 K for 10 h, followed by sulfonation at 363 K for 1−15 h. Esterification reaction conditions: ratio of methanol/oleic acid of 10 (for a typical experiment, 10 g of oleic acid and 11.34 g of methanol were added), 10% catalyst (on the basis of the mass of oleic acid), 353 K, 300 rpm, and 2 h.

its structure−function relationship was investigated with scanning electron microscopy (SEM), Fourier transform infrared spectroscopy (FTIR), X-ray diffraction (XRD), elemental analysis (EA), and ^{13}C solid-state nuclear magnetic resonance (NMR).

MATERIALS AND METHODS

Material. Corncob was provided by the maize base of Anhui Agricultural University, Hefei, China, milled into powder, and dried at 378 K for 24 h. All of the reagents and chemicals were purchased from Sinopharm Chemical Reagent Co., and the acid value of oleic acid used in the esterification was 196 mg of KOH/g.

Preparation of the Novel Carbon-Based Solid Acid. The catalysts were prepared by a low-temperature hydrothermal method under a range of conditions. In a typical preparation, the corncob powder was pretreated at first by ultrasonic wave and dilute alkali and then 5 g of corncob powder and 40 mL of water were maintained in a sealed, Teflon-lined autoclave at a specific temperature (393−513 K) for 1−15 h. After cooling to room temperature, the resulting material was washed with pure water several times and oven-dried at 378 K for 10 h. Then, 5 g of the above dried powder was heated in 25 mL of concentrated H_2SO_4 to introduce SO_3H groups under hydrothermal conditions. After sulfonation of the mixture for 1−15 h at a specific temperature (333−423 K), the mixture was cooled to room temperature and the black precipitate was filtered and washed repeatedly with hot distilled water (>353 K) until the washing liquid was neutral. Finally, the black solid was oven-dried at 378 K for 24 h.

Catalytic Activity of the Catalysts. The esterification reaction system contained 10 g of oleic acid and 11.34 g of methanol, with the ratio of methanol/oleic acid of 10 and 10 wt % catalyst loading based on the mass of oleic acid. The reaction system was conducted at 353 K and 300 rpm for 2 h. The yield of the esterification was determined according to the changes of the acid value in the oil phase and calculated as follows:

$$\text{ester yield}\ (\%) = (AV_0 - AV_1/AV_0) \times 100\% \quad (1)$$

where AV_0 and AV_1 are the acid values of the oleic acid and products, respectively.

Analysis Methods. The morphology of the solid acid was analyzed using SEM (Sirion 200, FEI Electron Optics Company, Hillsboro, OR) coupled with energy-dispersive X-ray (EDX, INCA Energy, U.K.). FTIR spectra were recorded on a Bruker Vector 33 FTIR spectrometer in the range of 4000−500 cm^{-1} with a resolution of 4 cm^{-1}. The XRD was performed using a Rigaku D/MAX β power X-ray diffractometer using Cu Kα radiation (λ = 0.184 15 nm) at 30 kV and 30 mA in the scanning angle of 3−60° at a scanning speed of 10°/min. EA was performed on an Elementar Vario Micro Cube. ^{13}C cross-polarization/total sideband suppression (CP/TOSS) NMR spectra were measured at room temperature using a Bruker Avance III 400

dx.doi.org/10.1021/jf500490m | J. Agric. Food Chem. 2014, 62, 5345−5353

spectrometer at a ^{13}C Larmor frequency of 100 MHz. A Bruker magic angle spinning (MAS) probe head was used with a 4 mm zirconia rotor. The spinning rate of the sample was 5 kHz. Sub-spectra for non-protonated and mobile carbon groups were obtained by combining the ^{13}C CP/TOSS sequence with a 40 μs dipolar dephasing.

Reusability of the Corncob-Derived Solid Acid Catalyst. To assess the catalytic stability of the corncob-derived solid acid, the reusability of the catalyst was investigated for the esterification of oleic acid and methanol. The reaction was conducted under the same conditions mentioned above for 8 cycles (2 h of reaction time per cycle). After each reaction cycle, the catalyst was recovered by filtration and washed with methanol or *n*-hexane until no methyl oleate was detected in the washing. The catalyst was then dried for the removal of the organic solvent and water under vacuum at 378 K for 2 h before reuse.

RESULTS AND DISCUSSION

The catalytic activities of the resulting corncob-derived solid acids were investigated by the esterification of oleic acid with methanol. Different preparation variables have different influences on the esterification activity of the synthesized catalysts (Figure 1). Within the tested range of 393−513 K, the HTC temperature greatly influenced the activity of the catalysts (Figure 1a). In comparison to the samples carbonized below 453 K, the resulting solid acids prepared at higher temperatures (453−513 K) were more active, with greater methyl oleate yields of nearly 90%. Similarly, increasing the carbonization time to 10 h resulted in an obvious increase in the catalytic activity of corncob-derived catalysts (Figure 1b). This may be attributed to the higher OH density in the samples carbonized at lower temperatures or in shorter times; these conditions allow for more water from esterification to be absorbed on the surface of the resulting catalyst, which can poison the acid sides and hinder the relatively hydrophobic reactants from accessing the catalyst.[23,24] In addition, samples carbonized at lower temperatures or in shorter times are less rigid; their aromatic and SO_3H groups will be leached out at high reaction temperatures or when higher fatty acids are used as reactants, resulting in a rapid deactivation of the catalyst. Therefore, taking both energy efficiency and time into consideration, 453 K and 10 h were selected as the suitable carbonization conditions for subsequent experiments.

Panels c and d of Figure 1 show the influences of the sulfonation temperature and time on the performance of the catalyst, respectively. After carbonization at 453 K for 10 h, the catalytic activity of the solid acid is largely dependent upon the sulfonation temperature. The catalyst sulfonated at 363 K displayed the highest esterification activity; the catalytic activity then dropped markedly with increasing temperature from 363 to 423 K (Figure 1c). This may be because the further carbonization by H_2SO_4 during sulfonation at higher temperatures generated a more rigid catalyst with a lower SO_3H density, which was confirmed in the structural characterization and elemental analysis. As shown in Figure 1d, 10 h was determined to be the optimal sulfonation time for the prepared catalyst. At this sulfonation time, the density of SO_3H groups at the suitable sulfonation temperature of 363 K reached a plateau, which is consistent with previous reports.[25]

Within the tested range, the optimal preparation conditions for the most effective catalyst are found to be HTC at 453 K for 10 h, followed by hydrothermal sulfonation at 363 K for 10 h. Under these conditions, a relatively high yield of methyl oleate (nearly 90%) was reached by catalysis with the corncob-derived solid acid after only 2 h of esterification. The structural differences in the catalysts prepared under different conditions will be discussed.

Figure 2 illustrates the morphologies of the corncob powders, the pretreated corncob, and the hydrothermal carbon

Figure 2. (F and G) Corresponding EDS spectra of the hydrothermal carbon material before and after sulfonation.

samples before and after sulfonation. In comparison to the raw material (Figure 2A), the pretreated corncob had a relatively rough surface and a distinctly looser structure with more pores, attributed to the swelling effect of the alkaline solution. A remarkable morphological transformation of corncob can be observed in panels C and D of Figure 2. When hydrothermally treated at 453 K, the fibrous corncob network was disrupted and carbon spheres with an average diameter of 400 nm started forming, indicating that the carbonization of corncob indeed occurred in the hydrothermal process. After sulfonation, the solid acid derived from corncob showed a completely different morphology (Figure 2E). By the further oxidation effect of H_2SO_4 and the intercalation of SO_3H groups, the spherical particles disappeared and aggregated to form irregular particles with highly granular surfaces. The S of the SO_3H groups can be observed in the EDX spectra after sulfonation (panels F and G of Figure 2).

Figure 3 shows the FTIR spectra of the carbon precursors derived from corncob and the catalysts prepared under different conditions. According to the spectra shown in Figure 3a, the carbonized samples produced at 393−513 K (Figure 3a) contained both aromatic and aliphatic hydrocarbons, as indicated by the peaks at approximately 2899 cm^{-1} (aliphatic C−H stretching) and 894 cm^{-1} (aromatic C−H bending).[18,19] The peaks assigned to OH and C−O near 3314 and 1037

dx.doi.org/10.1021/jf500490m | J. Agric. Food Chem. 2014, 62, 5345−5353

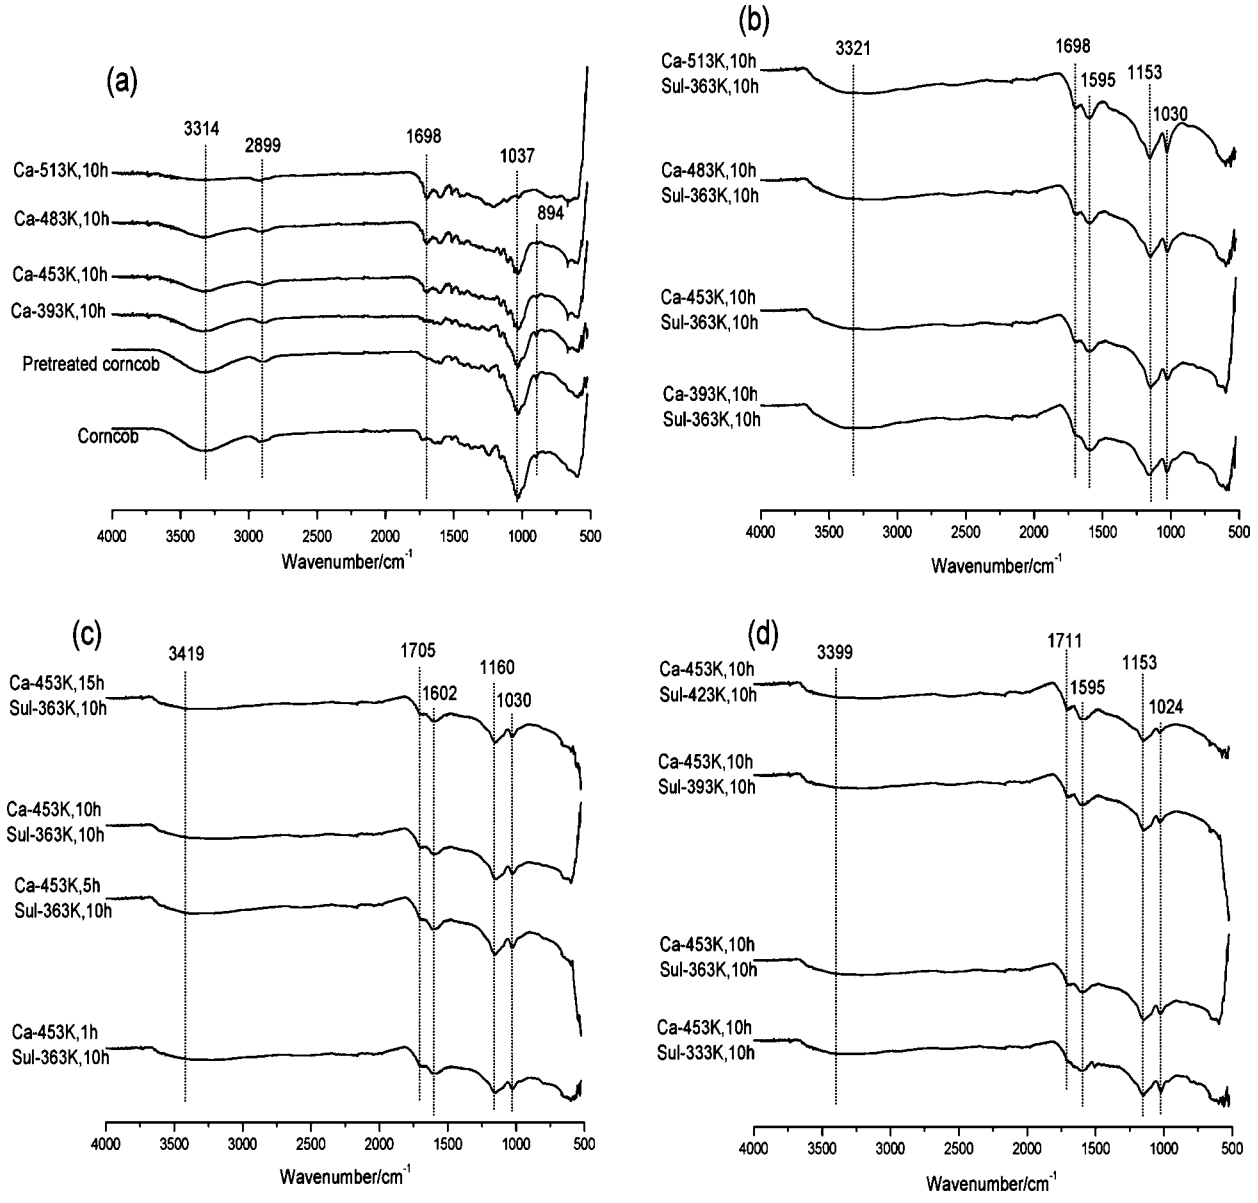

Figure 3. FTIR spectra of the carbon precursors and the catalysts prepared under various conditions. (a) Spectra of the carbon precursors hydrothermally carbonized at different temperatures (393−513 K) for 10 h (corncob and pretreated corncob are also shown as controls). (b) Spectra of the catalysts prepared at different carbonization temperatures (393−513 K) for 10 h, followed by sulfonation at 363 K for 10 h. (c) Spectra of the catalysts prepared under carbonization at 453 K for 1−15 h, followed by sulfonation at 363 K for 10 h. (d) Spectra of the catalysts prepared under carbonization at 453 K for 10 h, followed by sulfonation at different temperatures (333−423 K) for 10 h.

cm^{-1},[26] respectively, became weaker as the carbonization temperature increased, while the C═O peak at approximately 1698 cm^{-1} was enhanced. This suggests that incomplete carbonization reactions occurred at hydrothermal conditions, resulting in structural changes in the carbon precursors. The structural changes could also be clearly observed in the SEM images (panels c and d of Figure 3). This result is consistent with previous studies of the HTC of cellulose and waste biomass.[21] In comparison to the carbonized samples, the most obvious changes after sulfonation were the appearance of peaks at approximately 1030 and 1153 cm^{-1}, which are identified as the O═S═O symmetric stretching and SO_3 stretching modes in SO_3H, respectively (panels b−d of Figure 3). This can be further confirmed by EA, detailed below. In addition, the C═C peak intensity at approximately 1595 cm^{-1} was significantly enhanced, and the aliphatic C−H peak (2899 cm^{-1}) diminished after sulfonation. All of these observations indicate that the sulfonation process not only introduced SO_3H groups into the solid acid but also led to the further carbonization of the carbon precursors, which was also demonstrated by the color change of the samples from brown to black after sulfonation.

The peak intensities because of C═O and SO_3H were enhanced, while that for the OH group was significantly decreased, when the hydrothermal temperature was above 393 K (Figure 3b). Similarly, catalysts prepared at lower carbonization times (below 10 h) contained more OH groups (Figure 3c). This could partially explain why the catalysts carbonized at 393 K or in shorter times (below 10 h) had much lower catalytic activities, because greater water absorption by the OH groups during esterification can easily poison the acid sides of the catalysts and reduce the catalyst activity.[23,27] The C═O and SO_3H peak intensities were strongly dependent upon the

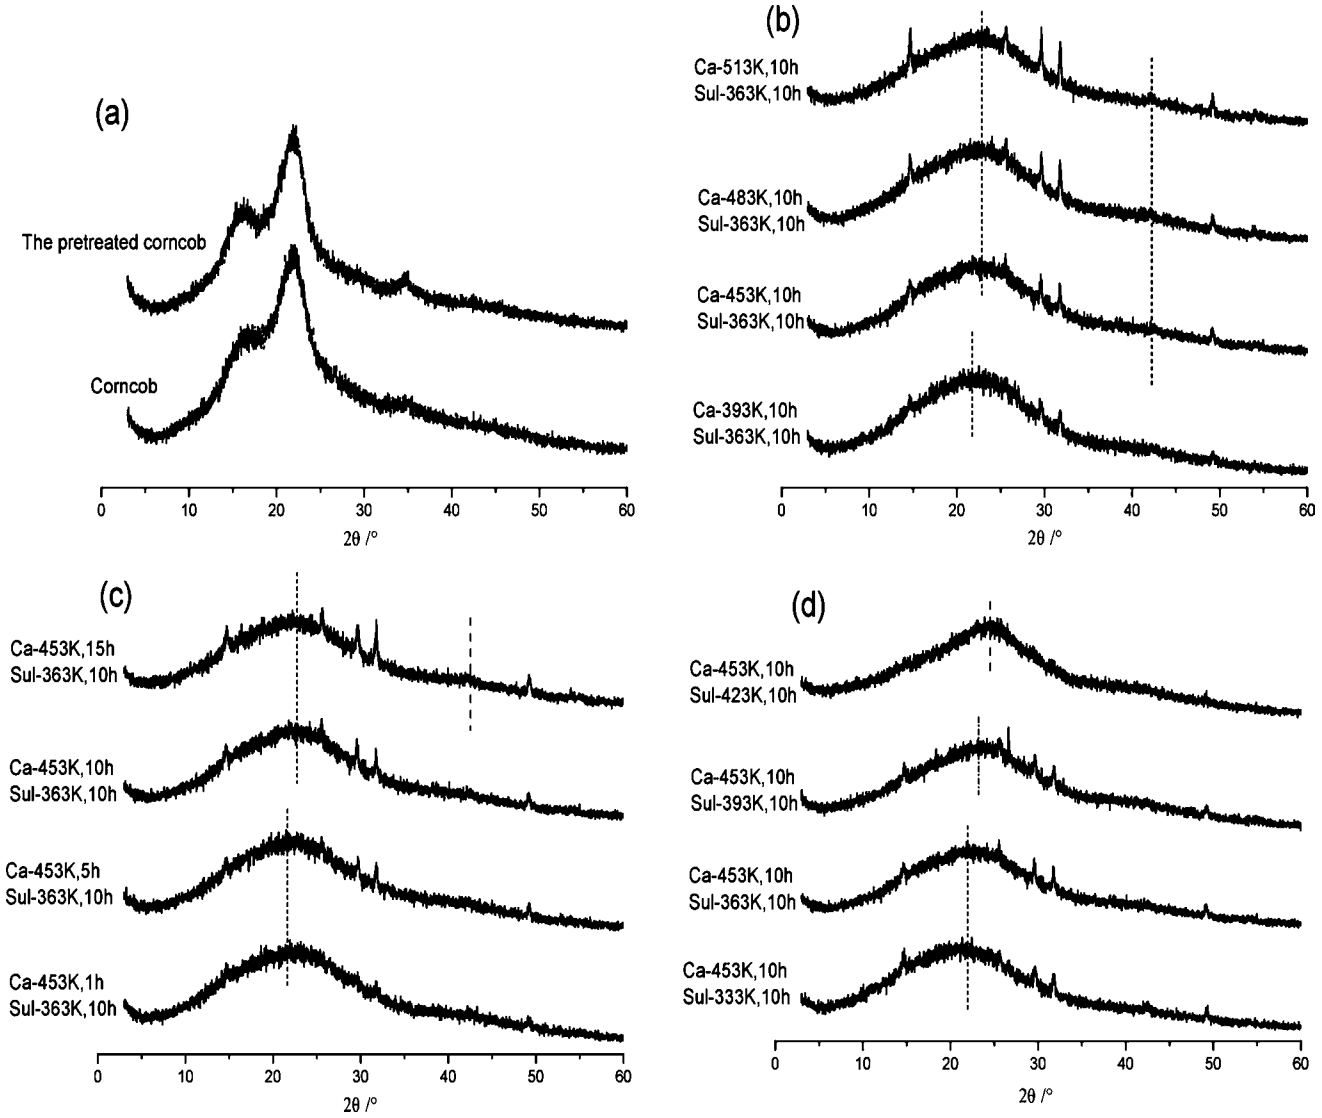

Figure 4. XRD patterns of the catalysts prepared under various conditions. (a) Catalysts prepared with carbonization at different temperatures (393−513 K) for 10 h, followed by sulfonation at 363 K for 10 h (corncob and pretreated corncob are also shown). (b) Catalysts prepared with carbonization at 453 K for different times (1−15 h), followed by sulfonation at 363 K for 10 h. (c) Catalysts prepared with carbonization at 453 K for 10 h, followed by sulfonation at different temperatures (333−423 K) for 10 h.

sulfonation temperature (Figure 3d). The FTIR spectra of catalysts sulfonated for different times showed only slight differences (data not shown), indicating that the sulfonation time was less important in determining catalytic activity than the other variables. This result is in agreement with the esterification results (Figure 1d).

Figure 4 illustrates the XRD patterns of the raw material, pretreated corncob, and catalysts prepared under different conditions. In comparison to the raw material, the characteristic peaks of pretreated corncob became more obvious, indicating that pretreatment removed impurities without destroying the "core" structure of corncob (Figure 4a). All of the XRD patterns of the corncob-derived catalysts exhibited a broad diffraction peak (2θ = 15−30°) attributable to amorphous carbon composed of polycyclic aromatic carbon sheets oriented in a considerably random fashion.[8,28] With an increasing carbonization temperature, time, and sulfonation temperature, the amorphous carbon diffraction peak became more obvious and shifted to higher angles (panels b−d of Figure 4), indicating the production of a more carbonized structure composed of large carbon sheets. Simultaneously, the weak diffraction peak (2θ = 40−45°) became more visible as well. This suggests that further carbonization during sulfonation yields a graphite-like carbon structure in the catalysts. Noticeably, when the carbonized sample was sulfonated at 423 K, the broad diffraction peak at 2θ = −30° became sharp and moved to a higher angle because of the formation of a more carbonized and rigid structure, which would prevent large molecular reactants from coming into contact with the SO_3H groups.[28] This also contributed to a lower SO_3H content in the catalyst, which is consistent with the result of EA and the limited esterification activity of the catalyst.

EA was employed to estimate the S content of the catalysts prepared under different conditions. The SO_3H density was calculated from the S content because all S atoms were present as SO_3H groups. The S contents in the raw material and pretreated corncob are not shown in Table 1 because both of them contained little S, as illustrated by EDX (Figure 2). As seen in Table 1, the density of SO_3H contained in various

dx.doi.org/10.1021/jf500490m | J. Agric. Food Chem. 2014, 62, 5345−5353

Table 1. S Content and SO_3H Density of Catalysts Prepared under Various Conditions

sample[a]	S content[b] (wt %)	SO_3H density[c] (mmol/g)
Ca-393 K, 10 h−Sul-363 K, 10 h	2.26	0.70
Ca-423 K, 10 h−Sul-363 K, 10 h	3.81	1.19
Ca-453 K, 10 h−Sul-363 K, 10 h	4.93	1.54
Ca-483 K, 10 h−Sul-363 K, 10 h	4.63	1.45
Ca-513 K, 10 h−Sul-363 K, 10 h	4.67	1.46
Ca-453 K, 1 h−Sul-363 K, 10 h	3.56	1.11
Ca-453 K, 5 h−Sul-363 K, 10 h	3.99	1.25
Ca-453 K, 15 h−Sul-363 K, 10 h	4.33	1.35
Ca-453 K, 10 h−Sul-333 K, 10 h	3.96	1.24
Ca-453 K, 10 h−Sul-393 K, 10 h	3.56	1.11
Ca-453 K, 10 h−Sul-423 K, 10 h	2.21	0.69
Ca-453 K, 10 h−Sul-363 K, 1 h	4.35	1.36
Ca-453 K, 10 h−Sul-363 K, 5 h	4.45	1.39
Ca-453 K, 10 h−Sul-363 K, 15 h	4.83	1.51

[a]The solid acid samples prepared at various conditions are denoted with different abbreviations. For example, Ca-393 K,10 h−Sul-363 K,10 h indicates that the catalyst was prepared by carbonization at 393 K for 10 h, followed by sulfonation at 363 K for 10 h. [b]The S content was estimated by EA. [c]The density of SO_3H groups was calculated from the S content.

catalysts ranged from 0.69 to 1.54 mmol/g and largely depended upon the preparation conditions.

The SO_3H density was dramatically enhanced (from 0.7 to 1.54 mmol/g) as the HTC temperature increased from 393 to 453 K, whereas it showed a slight decline (from 1.54 to 1.46 mmol/g) when the temperature exceeded 453 K. This may be because the sulfonation of the sample carbonized at 453 K resulted in amorphous carbon composed of small aromatic carbon sheets, to which the SO_3H group can be easily bonded. In contrast, the carbon precursors carbonized at low temperatures (below 453 K) had higher densities of aliphatic C−H and lower densities of cyclic aromatic hydrocarbons, which would be oxidized by the consumption of H_2SO_4 in the sulfonation process and, thus, reduce the SO_3H density in the catalyst. On the other hand, the sulfonation of the samples carbonized at high temperatures (above 453 K) resulted in increased sp^2-hybridized cross-linking among the carbon sheets, which can be shown by the decreasing amounts of phenolic OH and COOH groups in NMR spectra (Figure 5a).[25,29,30] As a result, this would prevent the intercalation of SO_3H groups into the carbon sheets and limit reactant access to SO_3H groups. Similar effects on SO_3H density were observed for carbonization time and sulfonation temperature. Although they had the same SO_3H density of 1.11 mmol/g, the catalyst Ca-453 K, 10 h-Sul-393 K, 10 h exhibited a much higher esterification activity than Ca-453 K, 1 h-Sul-363 K, 10 h (panels b and c of Figure 1). This could be explained by the distinct difference in the OH density of these two catalysts, which can be observed in the NMR spectra (panels b and c of Figure 5), because a higher water absorption by the OH group in the esterification reaction can easily poison the acid sides of the catalysts and, thus, reduce the catalyst activity.

Figure 5 displays the spectra of ^{13}C CP/TOSS and ^{13}C CP/TOSS with dipolar dephasing (DD) of the raw corncob, with its carbon precursors (Figure 5a) and the catalysts (panels b−d of Figure 5) prepared under different conditions. ^{13}C CP/TOSS spectra provided semi-quantitative structural information for all carbon sites, and DD spectra selected the signals of non-protonated carbons and carbons of mobile groups, such as CCH_3 groups. In Figure 5a, the spectrum of raw corncob was shown as a reference to evaluate the structural changes of the carbon precursor carbonized at different hydrothermal temperatures (393−513 K). The ^{13}C CP/TOSS spectrum of raw corncob is dominated by cellulose signals from 60 to 110 ppm. Signals in much lower abundances are seen for lignin (110−160 ppm) and hemicellulose [$-OC(=O)-CH_3$ at approximately 20 ppm and approximately 175 ppm]. Most of these carbon signals arose from protonated carbons and were selectively dephased in the DD spectrum (Figure 5a). The carbon precursor obtained at 393 K had a spectrum similar to that of raw corncob, indicating that nearly no structural changes occurred at the low temperature. Note that the signals associated with hemicellulose were less visible. Major spectral changes occurred as the hydrothermal temperature increased from 453 to 513 K. The signals for aliphatic groups (0−60 ppm) and aromatic groups (110−180 ppm) were enhanced in ^{13}C CP/TOSS spectra. At 513 K, the signals associated with cellulose disappeared; the spectrum was composed of the signals from mostly non-protonated polycyclic aromatic carbons (130 ppm), phenolic OH/aromatic C−O−C (153 ppm), and nonpolar alkyl carbons (0−60 ppm). Carbons of mobile groups, such as CCH_3 (22 ppm) and OCH_3 (57 ppm), also became more abundant. This indicates the initial formation of aromatic carbon sheets and other altered lignin residues at 453 K, as observed with FTIR and SEM.

Panels b−d of Figure 5 show the spectra of the solid acid catalysts prepared by the hydrothermal sulfonation of carbon precursors under different conditions: carbonization temperature from 393 to 513 K (Figure 5b), carbonization time from 1 to 15 h (Figure 5c), and sulfonation temperature from 333 to 423 K (Figure 5d). In comparison to the spectra of carbon precursors before sulfonation (Figure 5a), those of solid acids produced by hydrothermal sulfonation lost cellulose signals and were composed primarily of signals from mostly non-protonated aromatic carbons (130 ppm), phenolic OH/aromatic C−O−C (153 ppm), and nonpolar alkyl carbons (0−60 ppm). Signals from COOR carbons (178 ppm) and ketone carbons (approximately 200 ppm) were also present.[25,28,31] The aromatic C−O signals became gradually less abundant in the solid acids prepared from higher temperature carbon precursors. Furthermore, the aliphatic carbon peaks of the solid acid (0−60 ppm) were markedly reduced in intensity compared to those of the carbon precursor carbonized at 513 K (Figure 5a). All of these results revealed that the structure of the carbon precursor was further modified by H_2SO_4 during sulfonation, possibly leading to the development of polycyclic aromatic sheets in the solid acid.[8,25,29,30] According to panels b−d of Figure 5, the strong suppression of the aliphatic C signals after DD indicated that most of the sp^3-hybridized carbons were protonated, except of mobile carbons of CCH_3 and OCH_3. In addition, the peak because of aromatic carbon-bearing SO_3H groups could not be distinguished in the spectra of the sulfonated samples because the broad aromatic carbon (130 ppm) and aromatic C−O (150 ppm) peaks obscure the $Ar-SO_3H$ (140 ppm) peak.[25,29,30]

A remarkable reduction in the aromatic C−O peak intensity and an enhancement of the aromatic carbon peak with an increasing carbonization temperature from 393 to 513 K were observed in the CP/TOSS and DD spectra of the solid acids (Figure 5b). This might result from enhanced cross-linking between the carbon sheets at high temperatures, which would

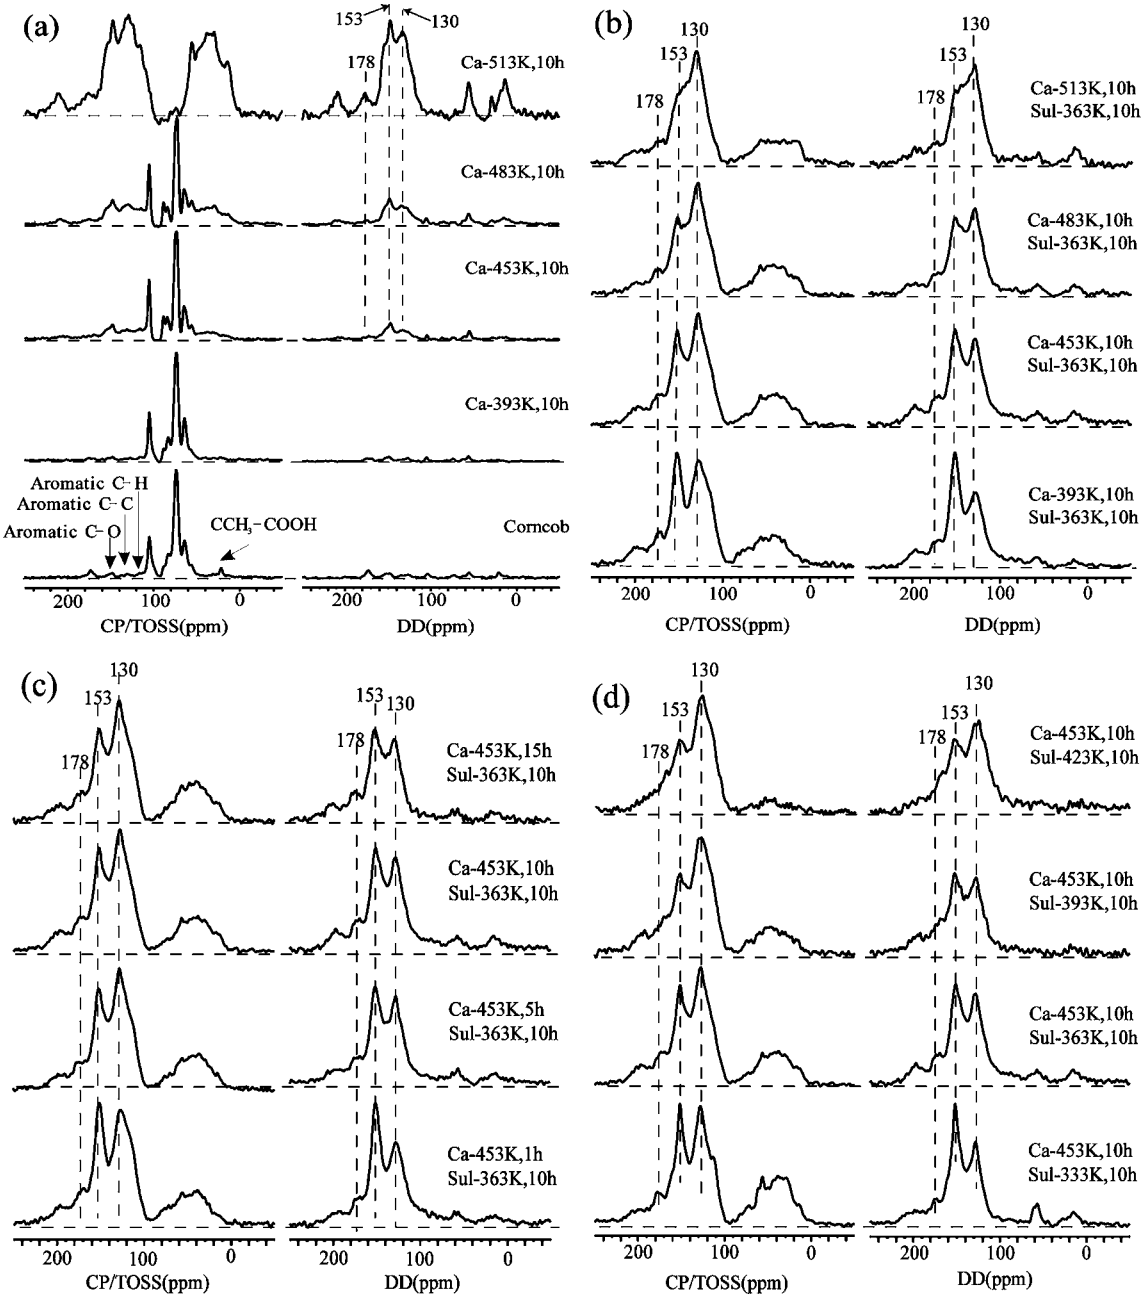

Figure 5. Spectra of ^{13}C CP/TOSS and corresponding ^{13}C CP/TOSS with DD. (a) Spectra of raw corncob and carbon precursors hydrothermally carbonized at different temperatures (393−513 K). (b) Spectra of corncob-derived solid acids prepared at different carbonization temperatures (393−513 K). (c) Spectra of corncob-derived solid acids prepared with different carbonization times (1−15 h). (d) Spectra of corncob-derived solid acids prepared at different sulfonation temperatures (333−423 K).

prevent the incorporation of reactants in the carbon bulk and hinder reactant access to SO_3H groups.[5,25] As a result, the aggregation of small carbon sheets with high cross-linking would decrease the reactivity of SO_3H groups, partially explaining the relatively low esterification activity of solid acids carbonized above 453 K. Figure 5b also shows that the catalyst prepared at 393 K had the highest content of aromatic C−O, such as phenolic OH groups, which caused its inefficiency in the esterification reaction, as mentioned before. Therefore, the sample carbonized at 453 K had the highest catalytic activity. As expected, the changes in peaks corresponding to the aromatic C−O groups and aromatic carbons in panels c and d of Figure 5 were similar to those seen in Figure 5b, as a result of the varying carbonization time from 1 to 15 h and the sulfonation temperature from 333 to 423 K, respectively. When the sulfonation temperature was above 363 K, however, the resonances of aliphatic carbon and COO groups significantly decreased (Figure 5d). At the same time, the COO peak shifted to 170 ppm because of the reduction in aliphatic carbon intensity. This result reveals that the concentrated H_2SO_4 acted as not only a sulfonating reagent but also a strong oxidant during sulfonation at high temperatures (above 363 K). This probably generated a prominent reduction in catalytic activity by contributing to a rigid catalyst structure with fewer SO_3H groups. In addition, it should be noted that the catalytic activity of the solid acids may

dx.doi.org/10.1021/jf500490m | J. Agric. Food Chem. 2014, 62, 5345−5353

not simply depend upon the synergetic combination of their structure and their functional groups, as suggested by previous studies.[1,31] The catalytic activity also depends upon the functional groups (such as SO_3H, COOH, and phenolic OH) being bonded to the carbon sheet in adequate amounts and, more importantly, in proper proportions.

To evaluate the catalytic performance of the new catalyst, a comparative study was performed using different catalysts for the esterification of oleic acid with methanol at 353 K to form methyl oleate. The same amount of catalyst was used in all cases. The catalysts tested were concentrated H_2SO_4, Amberlyst-15, niobic acid, and corncob-derived solid acid. As shown in Table 2, no methyl oleate was detected when the reaction was conducted for 24 h in the absence of catalysts, implying the critical role of the catalyst in this esterification reaction. The corncob-based solid acid possessed a high catalytic activity, with an 89.2% esterification yield after only 2 h. The yields of Amberlyst-15 and niobic acid after 2 h were 68.8 and 29.6%, respectively. The synergetic effect of three different functional groups (SO_3H, COOH, and phenolic OH groups) in the corncob-derived solid acid may be the main reason for its high catalytic activity compared to the conventional catalysts (niobic acid and Amberlyst-15), which contain only one functional group.[28,31] Although its catalytic activity was a little lower than that of concentrated H_2SO_4 (95.4% for 2 h), the corncob-derived solid acid can be easily recovered and reused at the end of each step. Additionally, the corncob-derived solid acid can prevent corrosion, which normally occurs in the presence of H_2SO_4, and can be successfully prepared from biomass by hydrothermal methods, providing a holistic and green approach to biomass conversion. In this regard, the corncob-derived solid acid prepared by the hydrothermal method is more promising and competitive.

Table 2. Comparison of the Esterification Yield of Oleic Acid with Methanol Catalyzed by Various Catalysts[a]

catalyst	reaction time (h)	yield of methyl oleate (%)
control (no catalyst)	24	
corncob-based solid acid	2	89.2
Amberlyst-15	2	68.8
niobic acid	2	29.6
concentrated H_2SO_4	2	95.4

[a]Reaction conditions: ratio of methanol/oleic acid of 10 (for a typical experiment, 10 g of oleic acid and 11.34 g of methanol were added), 353 K, 2 h, 300 rpm, and 10 wt % catalyst loading based on the mass of oleic acid.

The recycling performance of the corncob-derived solid acid catalyst was also investigated using the esterification reaction of oleic acid with methanol. Between each cycle of the reaction, methanol and *n*-hexane were employed as washing solvents to recovery the catalyst. As shown in Figure 6, the catalytic activity of the corncob-derived solid acid was maintained with a 66% conversion for methanol washing and a 75% conversion with *n*-hexane washing after 8 cycles of reuse. As reported by Mo et al.,[32] sulfonated catalysts were deactivated during the washing procedure mainly because of the leaching of polycyclic aromatic hydrocarbons containing $-SO_3H$ groups because these hydrocarbons are not completely insoluble in common solvents. Therefore, the different recycling performances of the corncob-derived solid acids in methanol and *n*-hexane might result from the varying solubilities of the polycyclic aromatic hydrocarbons in the different washing solvents. Although the deactivation of the catalytic activity was noticed in the case of carbon-based solid acid,[33−35] the corncob-derived catalyst prepared in this work still gave a satisfactory yield of methyl oleate after 8 cycles, indicating the high stability of the catalyst.

To the best of our knowledge, this is the first report of the synthesis of carbon-based solid acids from lignocellulosic biomass employing a hydrothermal method. The high catalytic activity of the corn-derived catalyst obtained under optimal hydrothermal conditions (453 K carbonization for 10 h and 363 K sulfonation for 10 h) can be attributed to the synergetic combination of the specific structure (polycyclic aromatic carbon sheets) and three functional groups (SO_3H, COOH, and phenolic OH groups) in adequate amounts. This work

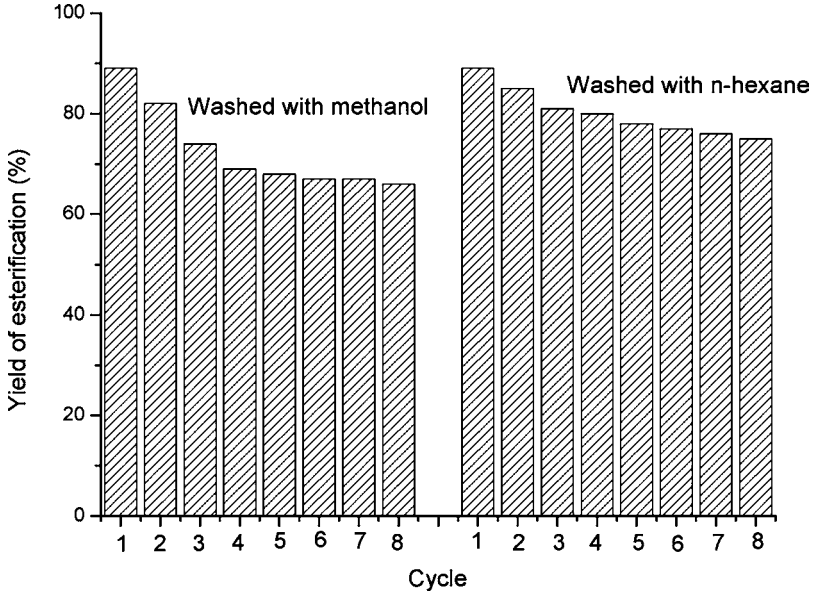

Figure 6. Reusability of the novel corncob-derived solid acid (prepared under the optimized conditions). Reaction conditions for each cycle: molar ratio of methanol/oleic acid of 10 (10 g of oleic acid and 11.34 g of methanol), 353 K, 300 rpm, and 2 h of reaction time per cycle.

dx.doi.org/10.1021/jf500490m | J. Agric. Food Chem. 2014, 62, 5345−5353

provides a simple and energy-efficient method to synthesize carbon-based catalysts from lignocellulosic biomass and develops a holistic and green approach to biomass conversion and environmental protection.

purification.[18−21] Recently, several enzymes, such as *Yarrowia lipolytica* lipases, *Candida antarctica* lipase B, and *Enterobacter* sp. FMB-1 sucrose isomerase, have been successfully immobilized onto the yeast cell surface, and their potential as biocatalysts for industrial applications has been investigated.[17,21,22]

In the present study, the phospholipase D gene (*pld*) cloned from *Streptomyces chromofuscus* was efficiently expressed on the cell surface of *P. pastoris* GS115 with FS as anchor protein. The enzymatic properties of the displayed PLD (dPLD) were systematically investigated. Importantly, the dPLD was successfully applied in the PS production so as to assess its potential in industrial applications.

MATERIALS AND METHODS

Chemicals and Enzymes. Choline oxidase (EC 1.1.3.17 from *Alcaligenes* sp.), peroxidase (EC 1.11.1.7 from horseradish), PC, PS, and PA were purchased from Sigma-Aldrich Co. (St. Louis, MO, USA). DNA modifying enzymes, such as restriction endonucleases, T4 DNA ligase, and La Tap DNA polymerase were purchased from Takara Co. (Dalian, China).

Strains, Media, and Vectors. *S. chromofuscus* AS 4.331 used for amplifying the PLD gene was purchased from China General Microbiological Culture Collection Center and was used to amplify the PLD gene. *E. coli* DH5α [F$^-$ φ80*lac*ZΔM15 Δ(*lac*ZYA-*arg*F) U169 *rec*A1 *end*A1 *hsd*R17 (r_k-, m_k+) *pho*A *sup*E44 λ^- *thi*-1 *gyr*A96 *rel*A1] was purchased from Takara Biotechnology Co. Ltd. and used as a host for general gene manipulation. *P. pastoris* GS115 [*his*4] and the pKFS vector were kind gifts from Professor Ying Lin (South China University of Technology). *P. pastoris* GS115 was employed as a host for the expression of the yeast cell display vector. Yeast extract−peptone−dextrose (YPD), buffered glycerol complex (BMGY), and buffered minimal methanol (BMMY) media were prepared according to the instructions of the Original *Pichia* Expression Kit (Invitrogen, USA).

The FS anchor sequence was amplified and inserted into the vector pPIC9K without signal peptide, resulting in recombinant plasmid designated pKFS. The pKFS vector was employed as the yeast cell surface display vector. Heterologous PLD was displayed on the *P. pastoris* cell surface by fusion with FS via the N-terminal anchor system, which adhered to the cell surface via noncovalent interactions with the mannan chain of the cell wall.[22]

Construction of the PLD Expression Plasmid. The PLD gene was amplified from genomic DNA of *S. chromofuscus* using the following primers: P1 5′-ccg<u>acgcgt</u>*tacccatacgacgtcccagactacgct*gccgaccaggcgcccgccttcct-3′ and P2 5′-ccg<u>gaattc</u>cctacacggggtcgtaggtgcgc-3′. (Recognition sites of *Mlu*I and *Eco*RI are underlined, and the HA tag sequence is shown in italics.) The amplified fragment was digested with *Mlu*I and *Eco*RI and subsequently cloned into the pKFS vector to generate the plasmid pKFS-*pld*. To construct the codon-optimized PLD gene (*pldh*), the rare codon used in the PLD sequence was replaced according to the preferred codon usage of *P. pastoris*. The synthesized *pldh* (Sangon Co., Ltd., Shanghai, China) was cloned into the pKFS vector to generate the plasmid pKFS-*pldh*. All plasmids were confirmed by sequencing.

Yeast Transformation of pKFS-*pld* and pKFS-*pldh*. Recombinant plasmids (pKFS-*pld* and pKFS-*pldh*) were transformed into *P. pastoris* GS115 cells using electroporation according to the instructions provided with the Original Pichia Expression Kit. The pKFS vector without the PLD gene insertion was transformed into *P. pastoris* GS115 (GS115/pKFS) as control. Transformation was performed according to the manufacturer's instructions. Ten micrograms of plasmid DNA linearized by *Sal*I was mixed with 80 μL of electrocompetent cells and subjected to electroporation at 1500 V (25 μF, 5 ms, BTX ECM399). Next, 1 mL of 1 M ice-cold sorbitol was added to the cuvette immediately after pulse discharge. Subsequently, 200 μL aliquots were plated in MD medium containing 13.4 g/L yeast nitrogen base (YNB) without amino acids, 20 g/L glucose, 4×10^{-4} g/L biotin, and 15 g/L agar. The *P. pastoris* transformants harboring pKFS-*pld* (GS115/pKFS-*pld*) and pKFS-*pldh* (GS115/pKFS-*pldh*) were selected by incubation at 30 °C for 48 h on MD plates.

Immunofluorescence Assay and Enzyme Assay. The transformants were precultured in YPD medium at 30 °C for 12 h and used to inoculate 50 mL of BMGY medium (13.4 g/L YNB, 10 g/L yeast extract, 20 g/L peptone, 20 g/L glycerol, and 4×10^{-4} g/L biotin) in a 250 mL shake flask at an initial OD_{600} value of 0.2. After incubation for 24 h, the cells were harvested by centrifugation at 4500 rpm for 10 min and resuspended in BMMY medium (13.4 g/L YNB, 10 g/L yeast extract, 20 g/L peptone, and 4×10^{-4} g/L biotin) containing 5 g/L methanol. To maintain the induction of the fusion protein, methanol was added to the culture every 24 h to a final concentration of 5 g/L, and the cells were incubated for 8 days at 30 °C with agitation (250 rpm).

An immunofluorescence assay was performed using a mouse monoclonal antihemagglutinin (HA) tag and a fluorescein isothiocyante (FITC)-conjugated goat anti-mouse IgG. Yeast cells were harvested and washed with phosphate-buffered saline (PBS, 10 mM, pH 7.4) containing 1 mg/mL bovine serum albumin (BSA), and then the cells were incubated with the mouse monoclonal antihemagglutinin (HA) tag in a dilution of 1:100 in PBS for 30 min on ice, washed twice with PBS containing 1 mg/mL BSA, and mixed with FITC-conjugated goat anti-mouse IgG diluted 1:200 on ice for 30 min. After a washing with PBS, the cells were observed with a fluorescence microscope.

The induced cells were harvested by centrifugation and washed twice with deionized water and lyophilized for activity assays.[22] The PLD activity in this study, represented as the hydrolytic activity due to its convenience of determination, was determined according to the method of Uhm et al. with minor modifications.[23] The PLD hydrolytic activity was determined by measuring the amount of choline released from the substrate PC. The cells were resuspended in 10 mM Tris-HCl (pH 8.0) at a concentration of 100 mg dry cells/mL. The reaction was initiated by adding 100 μL of cell solution to 10 mM Tris-HCl (pH 8.0) containing 10 mM $CaCl_2$, 20 mM TX-100, and 10 mM PC in a final volume of 1.5 mL at 37 °C for 10 min and was terminated by adding 0.5 mL of a solution containing 1 M Tris-HCl (pH 8.0) and 0.5 M ethylenediaminetetraacetic acid (EDTA). The reaction mixture was boiled for 5 min to completely arrest the reaction and then subsequently centrifuged at 6000 rpm for 5 min and mixed with 2 mL of 10 mM Tris-HCl (pH 8.0) containing 1 unit of choline oxidase, 1 unit of peroxidase, 0.4 mg of 4-aminoantipyrine, and 0.2 mg of phenol. The solution was then incubated for 20 min at 37 °C. The absorbance of the resulting mixture was measured spectrophotometrically at 500 nm.

One unit (U) of hydrolysis activity of PLD was defined as the amount of enzyme that produced 1 μmol of choline per minute under these assay conditions.

Enzyme Characterization. The optimal temperatures of the dPLD and secreted PLD (sPLD) were assayed by incubating the reaction mixture at various temperatures ranging from 30 to 65 °C in 50 mM sodium acetate buffer (pH 8.0). The thermostability of the enzyme was determined by incubating the enzyme at various temperatures ranging from 20 to 65 °C at pH 8.0 for 1 h. The remaining activity was then measured under standard conditions.

Optimum pH values for the two forms of PLD were determined by measuring the hydrolytic activity with 1 mM PC as the substrate in the pH range of 4.0−6.0 using 50 mM sodium acetate buffer, in the pH range of 7.0−8.0 using 50 mM potassium phosphate buffer, and in the pH range of 9.0−11.0 using 50 mM Tris-HCl buffer at 37 °C. The stability of PLD at various pH values was determined by preincubating the PLD in solutions at various pH values, ranging from 4.0 to 11.0, at 25 °C for 1 h. The residual activity was then quantified under standard assay conditions.

Organic Solvent Stability of the Enzyme. In this study, the conversion of PC to PS was performed in biphasic systems consisting of water-insoluble organic solvent. Diethyl ether was used as the organic solvent for the production of PS by dPLD as our previous studies demonstrated its suitability for sPLD-mediated reactions (data

dx.doi.org/10.1021/jf405836x | J. Agric. Food Chem. 2014, 62, 5354−5360

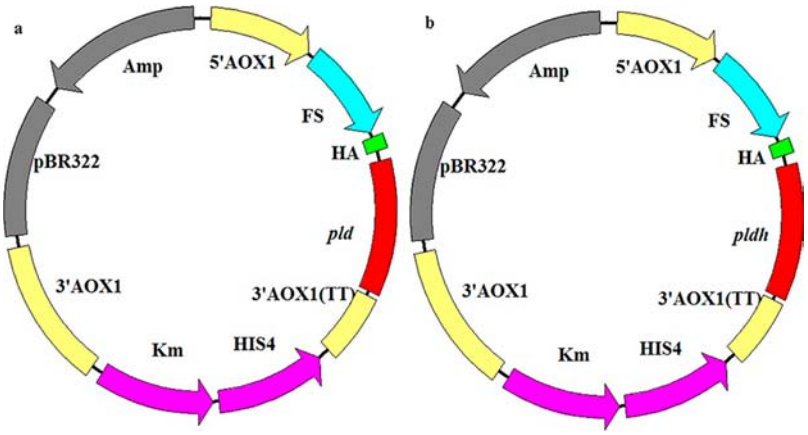

Figure 1. Schematic diagram of (a) plasmid pKFS-*pld* and (b) plasmid pKFS-*pldh* encoding the PLD protein.

not shown). To determine the effect of diethyl ether on the activity of dPLD, 5 mL of the enzyme preparation (containing 40 U of dPLD) was added to 5 mL of diethyl ether in a final concentration of 50% and incubated at 37 °C for specific times at a rotor speed of 200 rpm. The residual enzymatic activity of dPLD was then determined under standard assay conditions.

Conversion of PC to PS. To obtain the optimum dPLD-catalyzed transphosphatidylation conditions, the reaction was carried out in biphasic systems with various volume ratios between buffer and organic solvent (2.0:1.0, 1.5:1.0, 1.0:1.0, 1.0:1.5, 1.0:2.0), in which PC (0.05, 0.1, 0.15, 0.2, 0.25, 0.3 M) was dissolved in the organic solvent phase (diethyl ether), whereas dPLD (1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0 U/mL) and serine (0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5 M) were dissolved in 0.2 M sodium acetate buffer phase (containing 0.1 M $CaCl_2$). The mixture was stirred vigorously at different reaction temperatures (20, 30, 40, 50, 60, 70 °C) and pH values (3.5, 4.0, 4.5, 5.0, 5.5, 6.0) for 6, 8, 10, 12, 14, or 16 h with different rotor speeds (200, 300, 400, 500, 600, 700 rpm) to obtain a homogeneous emulsion. The optimum sPLD (from *S. chromofuscus*)-catalyzed transphosphatidylation conditions was obtained as control. The amount of biotransformation reaction products was determined using HPLC. The transphosphatidylation conversion rate (%) of PC to PS was defined as the percentage of PS obtained compared with the initial PC.

Recycling of the dPLD. The repeated use of dPLD was investigated on the basis of the optimal reaction conditions. After one cycle of reaction finished, The yeast cells were harvested, washed with 0.2 M sodium acetate buffer (pH 4.5), and used for the next batch under the same conditions. Recyclability of dPLD was evaluated by the conversion rate (%) of PS in each batch.

High-Performance Liquid Chromatography (HPLC) Analysis. The phospholipids PC, PS, and PA in the reaction mixture were analyzed via high-pressure liquid chromatography using an Agilent 1200 Infinity HPLC (Palo Alto, CA, USA) equipped with an Agilent 1260 Infinity diode array detector (wavelength = 205 nm). The column (purchased from Waters, Milford, MA, USA) was a μPorasil 10 μm 125 Å (3.9 × 300 mm), which was maintained at 25 °C. The eluting solvent was acetonitrile/methanol/85% phosphoric acid (100:8:0.8, v/v) with the flow rate of 1.0 mL/min. Prior to sampling, the agitation was stopped, and the reaction mixture was left undisturbed until the two phases were completely separated. After solvent evaporation, the fraction residue was redissolved in normal hexane/isopropanol (70:30, v/v), and 10 μL of a solution containing phospholipids was directly injected into the HPLC column. The relative concentrations of phospholipids were estimated from the peak area of the integrator. Each phospholipid peak was determined via the elution retention time using a standard phospholipid solution.

RESULTS AND DISCUSSION

Comparison of Wild-Type *pld* and *pldh*. The *S. chromofuscus* PLD possesses unusual codons compared with condon usage of *P. pastoris*. It has been shown that a correlation existed between the codon bias of a gene and its expression levels in a given organism. Codon optimization has been shown to be effective for maximizing the production of heterologous proteins in yeast.[24,25] Thus, consistent with the codon usage frequency of *P. pastoris* using the statistical method, the *pld* codons were optimized. The synthesized 1533 bp *pldh* showed 74% homology with the wild-type *pld*. Compared with the *pld*, the synthesized *pldh* contains 404 nucleotide variations, involving 396 of 511 codons. Meanwhile, the overall GC content of the synthesized *pldh* was reduced to 49.38 from 72.02%.

Construction of Yeast Strains for the Cell Surface Display of PLD. Yeast surface display is a powerful technique that is used to engineer proteins with enhanced affinity, specificity, stability, and catalytic activity. Several studies have successfully employed engineered yeast cells to display lipases on their surfaces as biocatalysts such as *C. antarctica* lipase B, *Rhizopus oryzae* lipase, and *Rhizomucor miehei* lipase.[22,26,27]

In this study, the yeast surface display system of *P. pastoris* was employed to immobilize PLD. The *pld* and *pldh* were ligated into the expression vector pKFS of *P. pastoris* to generate the plasmids pKFS-*pld* and pKFS-*pldh* (Figure 1). The recombinant plasmids were then linearized by *Sal*I and electroporated into *P. pastoris* GS115 to obtain the pKFS-*pld*/GS115 and pKFS-*pldh*/GS115, in which the recombinant PLD was displayed on the yeast cell surface by FS and its secretion signal peptide.

Localization of dPLD in *P. pastoris* and dPLD Activity Assay. To examine whether the dPLD was indeed displayed on the surface of *P. pastoris*, the cells that displayed PLD on GS115/pKFS-*pld* and GS115/pKFS-*pldh* were examined by immunofluorescence microscopy. As shown in Figure 2, the cells containing the recombinant vectors pKFS-*pld* and pKFS-*pldh* were labeled with green fluorescence on the surface, whereas the control cells containing pKFS were not fluorescent. This observation confirmed that dPLD was successfully displayed on the cell surface of the yeast.

Following induction, the activity of the *P. pastoris* cells that displayed PLD on GS115/pKFS-*pld* and GS115/pKFS-*pldh* and the culture supernatant were examined. As shown in Figure 3, the activity of PLD displayed on GS115/pKFS-*pldh* was higher compared to the PLD displayed on GS115/pKFS-*pld* after induction, whereas the activity of the culture supernatant was negligible. Meanwhile, the activity of PLD displayed on

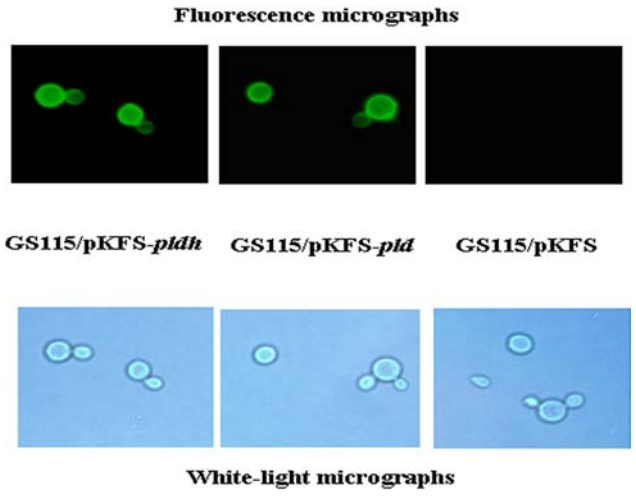

Figure 2. Immunofluorescent labeling of PLD on the cell surface of *Pichia pastoris* cells harboring the plasmids pKFS-*pld* and pKFS-*pldh*. The cells were immunologically labeled with the anti-HA antibody as the first antibody and FITC-conjugated anti-IgG as the second antibody. Control cells (GS115/pKFS) showed no fluorescence.

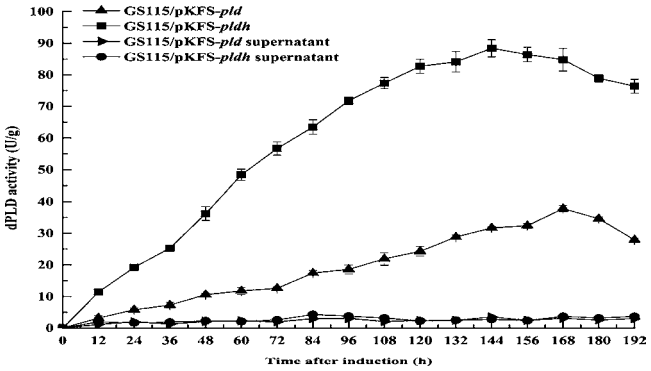

Figure 3. Activity of dPLD expressed on the surface of recombinant *Pichia pastoris* harboring pKFS-*pld* and supernatant at different induction times. Activity of dPLD expressed on the surface of recombinant *Pichia pastoris* harboring pKFS-*pldh* and supernatant at different induction times. The activity of dPLD on the surface of *P. pastoris* and supernatant was determined by sampling 10 mL of the fermentation broth and assaying the activity of cells and supernatant. The data points represent the mean ± SD (error bars) of three independent experiments.

GS115/pKFS-*pldh* reached a maximum of 88.4 U/g after 144 h of culture, which was 2.8 times that of PLD displayed on GS115/pKFS-*pld*. These results demonstrated that the PLD was all firmly immobilized on the yeast cell surface and the production of PLD was improved by codon optimization of *pld*.

Characterization of the dPLD. The enzymatic characteristics of dPLD were determined and compared with those of sPLD from *S. chromofuscus*. The optimum temperature for activity was increased after the enzyme was displayed on the yeast surface. The sPLD showed the highest activity at 50 °C, whereas the dPLD showed a maximum activity at 55 °C. At a temperature of 65 °C, the sPLD was nearly inactive, whereas the dPLD maintained >90% of its optimal activity (Figure 4a). The stability of the enzyme was determined by incubating the enzyme at various temperatures, ranging from 20 to 65 °C, for 1 h. As shown in Figure 4b, the residual enzyme activity of the dPLD was 72.3% after incubation at 60 °C for 1 h, whereas the sPLD lost >80% of its initial activity. Moreover, after 1 h of

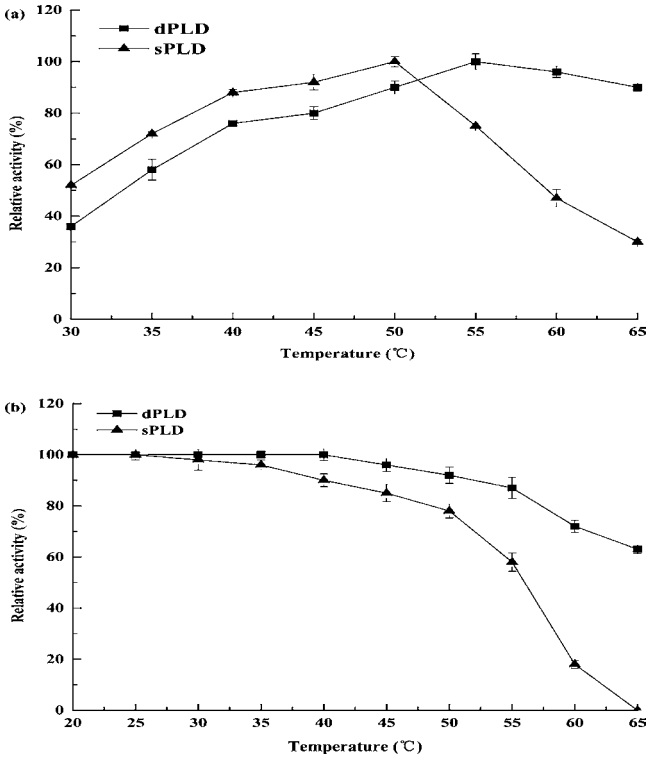

Figure 4. (a) Effects of temperature on PLD. Influence of temperature on dPLD and sPLD activity was investigated by assaying the activity from 30 to 65 °C in 50 mM sodium acetate buffer (pH 8.0). (b) Effects of temperature on PLD stability. Thermostability of the dPLD and sPLD was studied by incubation at various temperatures ranging from 20 to 65 °C at pH 8.0 for 1 h. The residual activity was then measured under standard conditions. The data points represent the mean ± SD of three replicates.

incubation at 65 °C, the sPLD had no detectable activity, whereas the remaining dPLD activity was 63.0%. On the basis of these results, dPLD was active over a broader temperature ranges and had a higher thermostability than sPLD, which is beneficial to industrial applications.

The activity of dPLD and sPLD at different pH values is shown in Figure 5a. The sPLD exhibited an optimal pH value at pH 7.0, whereas the dPLD had a maximum activity at pH 6.0. Interestingly, the dPLD maintained high activity at all pH ranges studied, whereas the sPLD showed dramatically decreased activity by moving 1 pH unit away from the optimal pH value. This might be related to the higher stability of the dPLD. Importantly, the yeast surface display also greatly enhanced the stability of the enzyme at the highest pH (11.0) and lowest pH (4.0) values studied (Figure 5b). Although the sPLD could not withstand incubation at pH 4.0 for 1 h, the dPLD retained >70% activity. These results suggested that the pH stability of the dPLD was significantly improved by immobilization on the yeast cell surface. Thus, dPLD showed the property of acid stability, which might serve as a basis for further application in industry.

Tolerance of PLD Activity to Organic Solvents. The synthesis of PS by PLD is usually performed in biphasic systems consisting of water-insoluble diethyl ether. The tolerance of PLD to diethyl ether was investigated by determining the stability of the enzyme in diethyl ether at 37 °C for 60 h. The activity of sPLD showed a rapid decline, whereas that of dPLD was maintained. Compared with the

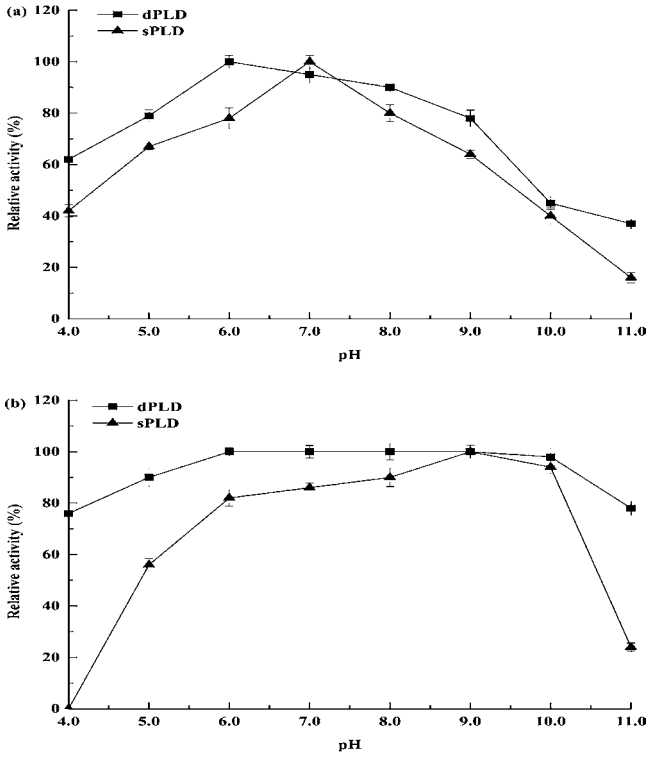

Figure 5. (a) Effects of pH on PLD. Optimal pH was determined by assaying the dPLD and sPLD at various pH values (pH 4.0−6.0, 50 mM sodium acetate buffer; pH 7.0−8.0, 50 mM potassium phosphate buffer; pH 9.0−11.0, 50 mM Tris-HCl buffer), at a temperature of 37 °C. (b) Effects of pH on PLD stability. Influence of pH on stability of dPLD and sPLD was determined by preincubating the PLD in solutions at various pH values, ranging from 4.0 to 11.0, at 25 °C for 1 h. The residual activity was then measured under standard conditions. The data points represent the mean ± SD of three replicates.

sPLD, which retained only 12.4% of its initial activity after incubation for 30 h, dPLD could maintain 63.1% residual activity (Figure 6). After 40 h of incubation, the sPLD showed no detectable activity, whereas the remnant dPLD activity was 53.8%.

When PLD was displayed on the cell surface of *P. pastoris*, the stability of dPLD in organic solvents was significantly enhanced, which was beneficial to the application of PLD in the synthesis of PS.

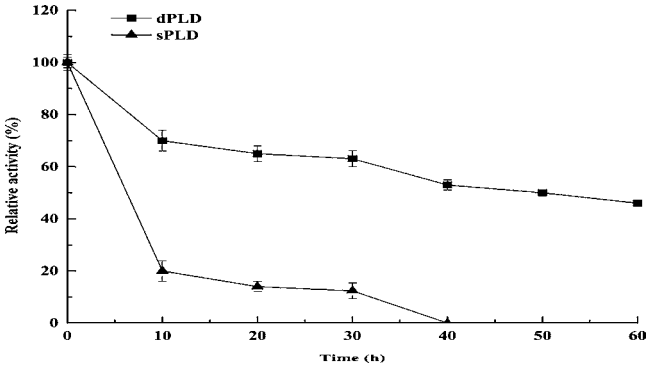

Figure 6. Effect of diethyl ether at a concentration of 50% (v/v) (5 mL of diethyl ether/5 mL of enzyme liquid) on dPLD and sPLD activities. The time course of the remaining PLD activity was assayed under previously described standard conditions. The data points represent the mean ± SD of three replicates.

Conversion of PC to PS. In this enzymatic reaction, several factors, including the volume ratios between buffer and organic solvent, PC concentrations, dPLD concentrations, serine concentrations, pH value, reaction temperature, reaction time, and rotor speed, can affect PS yield. In view of this, the effects of these parameters on the reaction were assayed to maximize PS yield.

The conversion rate of PC catalyzed by dPLD was compared with those of sPLD. Under optimum conditions (buffer/diethyl ether ratio 1.0:1.0, 0.1 M PC, 3.0 U/mL dPLD, 2.0 M serine, pH 4.5, 40 °C, rotor speed 600 rpm), 67.5% of PC in the reaction system could be converted by dPLD within 10 h, whereas the sPLD could convert 86.7% of PC in its optimum reaction conditions (data not shown). These results indicated that the dPLD on the surface of *P. pastoris* had the correct spatial configuration and could convert PC to PS with high efficiency. The dPLD had several advantages through display PLD on the yeast cell surface. By standard fermentation, dPLD could be readily produced as a yeast whole cell biocatalyst; thus, no further work was required to either purify or immobilize the enzymes. Furthermore, when compared with sPLD, dPLD exhibited favorable thermostability, acid stability, and organic solvent tolerance.

Operational Stability of dPLD. In industrial applications, recycling of PLD is required to reduce the production costs. Thus, the operational stability of dPLD was examined. The dPLD whole cells were recovered by centrifugation after each batch reaction, followed by washing with 0.2 M sodium acetate buffer (pH 4.5), and then added to fresh reactants. The result showed that the conversion rate of PS was >50% after seven batches (Figure 7), indicating that the dPLD whole cell biocatalyst exhibits a relatively good operational stability and that it is particularly suitable for conversion of PC to PS.

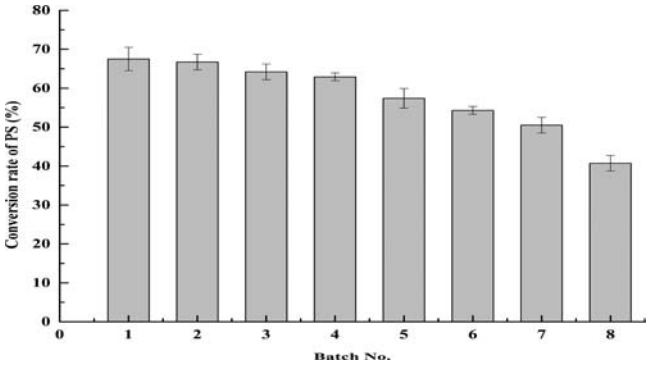

Figure 7. Investigation of repeated use of dPLD. After one cycle of reaction finished, the yeast cells were harvested, washed with 0.2 M sodium acetate buffer (pH 4.5), and used for the next batch under the same conditions. The conversion rate of PS in each detected batch (from the first to the eighth batch) was calculated. The data points represent the mean ± SD of three replicates.

The yeast cell surface display is a convenient method for preparing soluble, correctly folded recombinant proteins with native activity. Recently, several studies have successfully used yeast cells displaying recombinant proteins on their surfaces as whole cell biocatalysts, such as lipase from the fungus *Geotrichum* sp. for enriching eicosapentaenoic acid and docosahexaenoic acid in fish oil[28] and linoleic acid isomerase

from *Propionibacterium acnes* for bioconversion of linoleic acid to conjugated linoleic acids.[29] Here we report successful PLD display on the cell surface of *P. pastoris*. Previous studies on the enzymatic synthesis of PS involved the use of sPLD. For instance, sPLD from *Actinomadura* sp. was used for PS synthesis using a bile salt mixed micelle system, achieving a transphosphatidylation conversion rate of 57% after 24 h.[30] PS synthesis with the conversion rate up to 88% was also documented using the sPLD from *Streptomyces racemochromogenes*.[31] However, PLD-associated costs are still a major limiting factor for a sPLD-based process for efficient commercial PS production. In this study, we have demonstrated that the dPLD on the surface of *P. pastoris* converted 67.5% of PC to PS within 10 h. Although the PS yield was relatively lower compared with some of the sPLD-based process, the conversion rate of PS remained >50% after seven batches. Moreover, the thermostability, acid stability, and organic solvent tolerance of the dPLD were significantly enhanced compared with the sPLD. Considering the relatively high cost of sPLD, PLD-displaying whole cell biocatalysts might be particularly suitable for cost-effective PS production.

and genotype. However, reports on the genetic analysis of the genotype by environment interaction effects for the polyphenol content and antioxidant capacity in whole grain rice have been rare.

Twenty rice accessions including cultivars, germplasm lines, and landraces were introduced from the OryzaSNP project[20] and used in this study. These rice materials have been well sequenced and have been used in the genetic diversity analyses for root growth and drought avoidance responses,[20−22] water uptake,[23] biomass traits,[24] and nutritional components of cooked rice.[25] This panel has also been used to identify genes and genetic pathways that are critical to biomass traits[24] and nutritional components in cooked rice.[25] While in this study, the set was planted in the winter season of year 2011 and 2012 in Hainan province (South China), and the objectives were to investigate the genotype, environment, and genotype × environment effects for the polyphenol and antioxidant capacity traits. In addition, we identified single nucleotide polymorphism (SNP) loci that were strongly associated with these traits using the association mapping approach.

MATERIAL AND METHODS

Rice Materials. Twenty rice accessions (*Oryza sativa* L.) including cultivars, germplasm lines, and landraces were introduced from the OryzaSNP project (http://www.oryzasnp.org/),[20] and these included 5 genotypes with red pericarp and 15 with white. All the accessions were planted in 2 years in Lingshui, Hainan province, China. Ten rows with six plants per row were planted for each accession in the field with two replications per year. The seeds were sowed in early December of 2010 and 2011, managed using nutrient and pest control procedures to ensure the production in this area, and harvested in April of 2011 and 2012, respectively. Hereafter, 2 years (environments) are denoted 2011 and 2012 for when the grain was harvested.

The grains were air-dried to a moisture content of about 12%, stored at room temperature for 2 months and then at 4 °C in the dark, until all the grain materials were obtained. The samples were dehulled on a Satake Rice Machine (Satake Co., Tokyo, Japan) and milled to pass through a 100 mesh sieve on a Cyclone sample mill (UDY Corporation, Fort Collins, CO, U.S.A.).

Chemicals. Analytical grade methanol, hexane, and sulfuric acid were purchased from Sinopharm (Sinopharm Chemistry Reagent Co., Ltd., Shanghai, China). Sodium carbonate, aluminum chloride, sodium nitrite, potassium peroxydisulfate, sodium hydroxide, and vanillin were purchased from BBI (Toronto, ON, Canada). Folin−Ciocalteu reagent, gallic acid, catechin, DPPH (1,1- diphenyl-2-picrylhydrazyl radical, Trolox (6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid), and ABTS (2,2-azino-bis-(3-ethylbenzothiazoline-6-sulfonic acid) diammonium salt) were purchased from Sigma (St. Louis, MO, U.S.A.).

Extraction. Before extraction, 0.5 g of whole grain flour was defatted twice with 10 mL of hexane, and the mixture was shaken on an oscillator at 250 rpm (HZ-9210K Desktop frozen oscillator, Jiangsu, China) for 30 min at room temperature. After centrifuging at 10 000*g* (Sorvall ST16R, Thermo Scientific, Osterode, Germany) for 10 min, the residue was dried at room temperature in a fume hood and then extracted with 10 mL of 80% methanol twice. After shaking at 250 rpm for 45 min per extraction, the mixture was centrifuged at 10 000*g* for 15 min. The supernatants of each duplicate extraction were collected and combined together, and they were stored at −20 °C for further analysis. Duplicate extractions were carried out for each sample.

Determination of Total Phenolic Content (TPC). TPC was determined using the method of Folin−Ciocalteu assay[26] modified by Shen et al.[8] Appropriately diluted sample extracts or standard solutions (200 μL) were mixed thoroughly with 1.5 mL of 10-fold-diluted Folin−Ciocalteu reagent. After incubating for about 5 min, 1.5 mL of saturated sodium carbonate (75 g/L) was subsequently added to the mixture. After reacting for 2 h at room temperature in dark, the absorbance of the resulting blue color was measured by a spectrophotometer (UNICAM UV300, Thermo scientific, England, Britain) at 725 nm. TPC was expressed as milligrams of gallic acid equivalent per 100 g of rice flour (mg GAE/100 g). Duplicate determinations were conducted for each extract.

Determination of Total Flavonoid Content (TFC). TFC was assayed using a colorimetric method with minor modifications.[8,27] In short, 150 μL of 5% $NaNO_2$ was mixed with 500 μL of the appropriately sample diluted extracts or standard solutions in 15 mL polypropylene tubes and then incubated for 5 min. After adding 150 μL of 10% $AlCl_3{\cdot}6H_2O$ and allowing 5 min of reaction time, 1 mL NaOH (1 M) and then 3 mL ddH_2O were added. Before measuring the absorbance at 510 nm, the contents were thoroughly mixed and reacted for about 10 min. TFC was expressed as milligrams of catechin equivalent per 100 g of rice flour (mg CAE/100 g). Duplicate determinations were conducted for each extract.

Determination of Total Proanthocyanidin Content (TPAC). TPAC was measured by the method of vanillin assay with slight modifications.[28] Two solutions were prepared before measurement: (A) 1% vanillin solution in methanol; (B) sulfuric acid/methanol solution (1:4, V/V). Appropriately diluted sample extracts or standard solutions (0.6 mL) were added to 1.5 mL of solution A and mixed thoroughly. They were then allowed to react with 1.5 mL of solution B for 20 min in a 30 °C water bath. The absorbance was measured at 500 nm. In order to eliminate interferences (e.g., anthocyanins, which are present mainly in black rice), samples treated with 100% methanol instead of solution A were used as blank. TPAC was expressed as mg catechin equivalent per 100 g sample (mg CAE/100 g). Duplicate determinations were conducted for each extract.

Determination of DPPH Radical Scavenging Activity. The DPPH assay was conducted as described before.[29] The DPPH working solution (100 μmol/L) was prepared by using methanol. Appropriately diluted extracts or standards (200 μL) were mixed with 3 mL of DPPH solution. The absorbance was measured at 517 nm after incubating for 45 min in the dark. The DPPH scavenging activity (%) of both samples and standard (Trolox) was calculated as follows:

$$\text{DPPH\%} = (1 - A_{\text{sample}}/A_{\text{control}})\,100\%$$

The results were expressed as Trolox equivalent DPPH radical scavenging activity per 100 g of sample (μmol TE/100 g). Duplicate determinations were conducted for each extract.

Determination of $ABTS^{\bullet+}$ Radical Scavenging Activity. Total antioxidant capacity was carried out using a spectrophotometer by the improved $ABTS^{\bullet+}$ radical cation method, as described previously.[8,30] The aqueous $ABTS^{\bullet+}$ stock solution was prepared using 7 mM ABTS and 2.45 mM potassium peroxydisulfate (V/V = 2:1) and agitated overnight. The $ABTS^{\bullet+}$ working solution was diluted by methanol to adjust the

[a]LSD: least significant difference ($P < 0.05$). [b]The results are presented as mg of gallic acid equivalent/100 g of rice. [c]The results are presented as mg of catechin equivalent/100 g of rice. [d]The results are presented as μmol of Trolox equivalent/100 g of rice.

absorbance to 0.700 ± 0.020 at 734 nm. Appropriately diluted extracts or standard solution (0.1 mL) were mixed with $ABTS^{\bullet+}$ working solution (3.9 mL) and reacted for about 6 min before measuring the absorbance at 734 nm. Results were expressed as μmol of Trolox equivalent antioxidant capacity per 100 g of rice flour (μmol TEAC/100 g). Duplicate determinations were conducted for each extract.

Statistical Analysis. All the chemical parameters were measured at least in duplicate. Data analyses were performed with the SAS program version 8 (SAS Institute Inc., Cary, NC, U.S.A.). Analysis of variance (ANOVA) was carried out to determine genotypic and environmental variation among the parameters using the general linear model procedure (Proc glm). Means of different genotypes and environments were determined using Proc means, followed by Tukey multiple comparison tests at $P < 0.05$. Correlation analysis among the parameters in (or between) the two environments were conducted by Proc corr procedure.

Genotype Data and Association Mapping. The publically available genotype data were downloaded from the Gramene Web site (http://www.gramene.org/) on March 10, 2013. During downloading, we first removed the reference genome data, and we then filtered sites with the following parameters: minimum count was 16 out of 20 sequences, and minimum frequency was set at 0.25. Finally, a total of 32 655 SNPs distributed in 12 chromosomes were downloaded.[31]

The population structure (Q) among the 20 rice accessions was performed using the software package STRUCTURE version 2.2.[32] The optimum number of populations was three.[31] Principle component analysis (PCA) was calculated and input into association mapping, which was performed with GAPIT.[33] To avoid the probability of spurious association between markers and traits, six models (i.e., ANOVA, K (Kinship), P (PCA), Q (structure), P + K, Q + K) were compared with GAPIT,[33] and the best model for each trait was chosen according to the Bayesian information criterion (BIC) value. The results with the best model were presented at the significance level of $P < 0.005$.

RESULTS

Analysis of Variations for Nutritional Parameters. ANOVA indicated that TPC, TFC, TPAC, ACA, and ACD differed dramatically among 20 genotypes. The genotypic variance accounted for 94.56%, 97.78%, 97.24%, 94.58%, and 95.95% of the total variation, respectively (Table 1). Effects of year were significant, with all traits slightly higher in 2012 than in 2011 harvested seed (Table 1; Table 2). In addition, G ×

[a]*** indicate significance at 0.001 levels; below diagonal: 2011; above diagonal: 2012; in diagonal: 2011 and 2012.

year were also significant ($P < 0.001$), although in total they explained less than 5% of the total variance (Table 1).

The selected rice materials had different phytochemicals and antioxidant activities (Table 2). The average TPAC, TPC, TFC, and ACD levels were similar in the 2 years. However, ACA differed significantly ($P < 0.05$) between the 2 years with the average values of 1266.7 in 2011 and 1439.8 in 2012 (Table 2). TPAC was only detected in red rice, so it was not surprising that red rice had higher TPC, TFC, ACA, and ACD than white rice. Among the red rice, Rayada was significantly high for TPAC, TPC, TFC, ACA, and ACD. Conversely, Aswina was consistently low, and LTH, Pokkali, and FRI3A were almost the same. Among the white rice, the TPC, TFC, ACA, and ACD ranged from 39.8 to 63.7 mg GAE/100 g, from 18.6 to 26.6 mg CAE/100 g, from 225.8 to 409.7 μmol TE/100 g, and from 117.5 to 236.6 μmol TE/100 g, respectively, in 2011, and ranged from 40.6 to 66.3 mg GAE/100 g, from 20.3 to 31.8 mg CAE/100 g, from 267.8 to 490.7 μmol TE/100 g, and from 139.0 to 272.6 μmol TE/100 g, respectively, in 2012. The ranges of ACA and ACD between 2 years were different in white and red rice. For ACA and ACD of white rice, there were about 1 and 0.5 μm TEAC/g differences across 2 years, whereas for that of red rice, there were 20 and 10 μm TEAC/g differences due to environmental effects.

Correlation Analysis. The correlation coefficients among TPAC, TPC, TFC, ACA, and ACD of 20 genotypes in 2 years are listed in Table 3. The correlations among TPAC, TPC, TFC, ACA, and ACD were at the significant level of 0.001. The correlation coefficients between 2 years were more than 0.96 ($P < 0.001$), also suggesting that these traits were quite stable across different planting years.

Association Mapping. Given the distinct population structure among three subspecies (*indica*, *japonica*, and *aus*) of the 20 rice accessions,[20] the optimal model was first chosen according to BIC values using GAPIT.[33] Six models (i.e., ANOVA, K (kinship), P (PCA with the principal components ranging from 1 to 3), Q (structure), P + K, and Q + K) were compared (Supplementary Table 1). For TPC, the Q model was the best for the 2011 data, and ANOVA was the best for the 2012 data. For the traits of TFC, TPAC, and ACA, the P2 was the best model for the 2011 data, and ANOVA was the best for the 2012 data. For ACD, the K model was the best one in both years' data (Supplementary Table 1). Then, the strong association signals were identified with the best model at $P < 0.005$, discarding all but the most significant signals for each parameter if there was an excess of strong associations (Table 4). Manhattan plots of association mapping results are shown in Figure 1. In the year of 2011, there were more peaks for the TFC, TPAC, ACA, and ACD than those in 2012.

In total, we identified 23 unique loci for TPC, TFC, TPAC, ACA, and ACD in the 2 years, and they were mainly located on chromosomes 1, 4, 6, and 12 (Figure 2). The locus at 34 679 495 bp on chromosome 1 and the locus at 27 875 425bp on chromosome 4 were associated with TPC, TFC, ACA, and ACD in the 2 years. The locus at 11 522 358 bp on chromosome 1, the locus at 5 416 397 bp on chromosome 2, the locus at 1 585 914 bp on chromosome 3, and the locus at 27 240 579 bp on chromosome 6 were associated with TFC, TPAC, ACA, and ACD in the year of 2011, but no such associations were found in 2012. On the contrary, the locus at 25 206 526 bp on chromosome 12 was significantly associated with TFC, TPAC, ACA, and ACD in the year of 2012, but it was not detected in 2011.

TPC was mainly affected by genotype, and the same significant association signals on chromosome 1, 4, and 12 were identified in 2 years. The minor allele frequencies of qPC1, qPC12, and qPC4 were 0.20, 0.25, and 0.20, respectively, with the former two having negative effects and the latter one having positive effects in both years.

The QTLs of qFC1-2 and qFC4 on chromosome 1 and 4, respectively, were significantly associated with TFC in both years. Both alleles had the same minor allele frequencies of 0.20. When the major allele (T) of qFC1-2 was replaced by the minor allele (C), TFC decreased by 129.30 mg CAE/100 g in 2011 and decreased by 116.90 mg CAE/100 g in 2012. However, the change from major allele (C) to minor allele (T) of qFC4 caused the increase of the TFC in the 2 years. The QTLs of qFC1-1, qFC2, qFC3, and qFC6 located on chromosome 1, 2, 3, and 6, respectively, were only detected in 2011, whereas the QTLs of qFC5 and qFC12 were only detected in 2012.

The QTLs for TPAC were mainly located on chromosome 1, 4, 6, and 7 with more QTLs detected in 2011 than detected in 2012. The QTLs of qPAC4/qPAC4-3 and qPAC12-2 were almost at the same position as qPC4/qFC4 and qPC12/qFC12, respectively. qPAC1-1, qPAC2-2, qPAC3, and qPAC6-2 were allelic to qFC1-1, qFC2, qFC3, qFC6 for TFC. Two groups of QTLs had the same minor allele frequency and P value in 2011: (1) qPAC2-1, qPAC7-1, qPAC7-2, qPAC7-3, qPAC8, and qPAC11; (2) qPAC1-2, qPAC1-3, qPAC4-1, qPAC4-2, qPAC4-3, qPAC6-3, and qPAC6-4. These loci were clearly derived from the linkage disequilibrium in the same chromosome (i.e., chromosome 4 and 7) or from different chromosomes. In 2012, there were only three significant signals associated with TPAC (qPAC1, qPAC4, qPAC12-2).

The antioxidant capacity was measured with two methods: $ABTS^{\bullet+}$ and DPPH radical scavenging capacities. The significant association signals with the two methods were almost the same except that the qACA5 was detected only in 2012 for the ABTS. qACA3/qACD3 had the highest signals in Manhattan plots in 2011 by ABTS and DPPH (Figure 1). The QTLs of qACA1-2/qACD1-2 and qACA4/qACD4 on chromosome 1 and 4, respectively, were detected in 2 years. The QTLs of qACA1-1/qACD1-1, qACA2/qACD2, and qACA6/qACD6 were detected only in 2011, whereas qACA12/qACD12 was detected only in 2012.

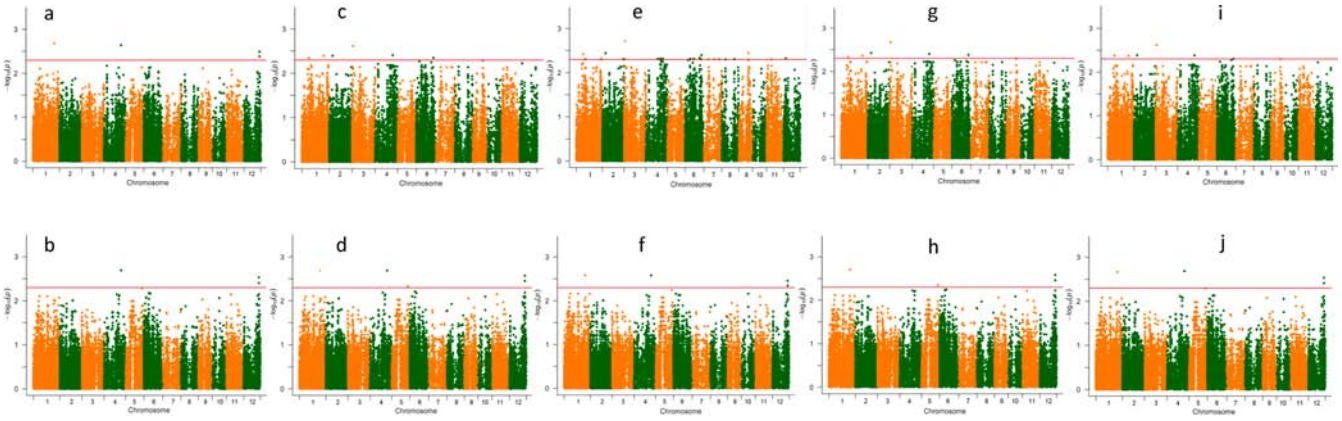

Figure 1. Manhattan plots of the association mapping of polyphenol and antioxidant capacity traits in 2 years. TPC (a, 2011; b, 2012), TFC (c, 2011; d, 2012), TPAC (e, 2011; f, 2012), ACA (g, 2011; h, 2012), and ACD (i, 2011; j, 2012).

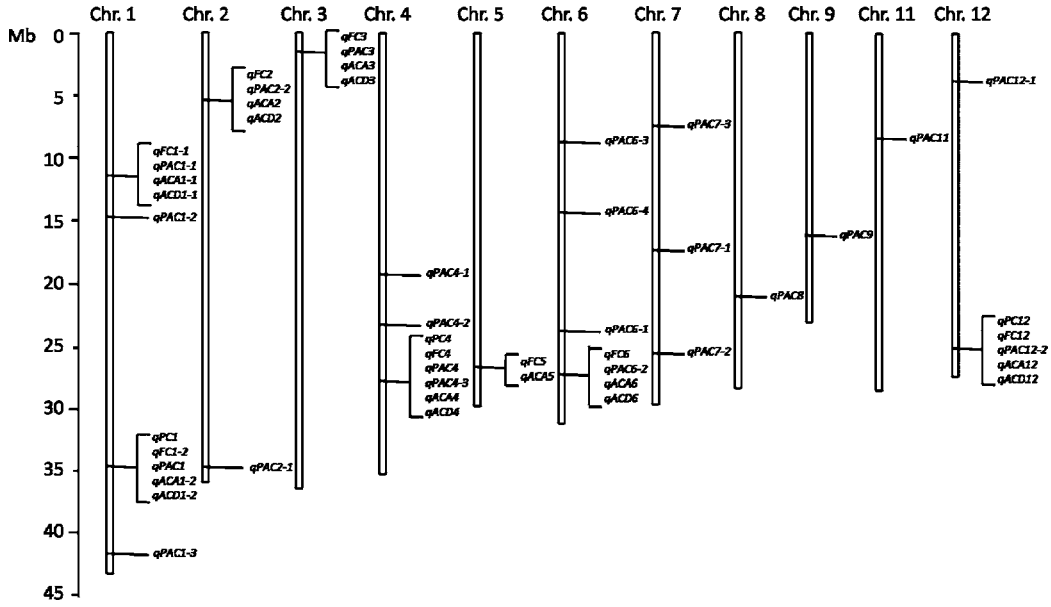

Figure 2. Positions of QTLs in rice chromosomes detected by association study.

DISCUSSION

The 20 rices in this study have been widely used in genetic diversity and genetic mapping studies.[21−25] Genomic regions and SNPs have been identified for biomass traits[24] and nutritional components in cooked rice.[25] In this study, the 20 rices have been used to study the genetic diversity in the polyphenols and antioxidant capacity traits of whole grain rice (Table 2). Total phenolic, flavonoid, proanthocyanidin contents, and total antioxidant capacity of rice grain are affected by heredity as well as environment (Table 1). An ANOVA showed that TPC, TFC, TPAC, ACA, and ACD are mainly affected by genotype, which indicated that the content of polyphenols and the antioxidant capacity of rice grain were controlled by certain genes (Table 1). The high correlation between 2 years also suggested that these traits are quite stable across different years and genotypes (Table 3). The high correlations found among these five traits may be due to pleiotropy or genetic linkage. Plant breeders could either improve correlated traits simultaneously or reduce undesirable side effects when improving only one of the correlated traits.[34]

Red-pericarp grain accumulates proanthocyanidin,[5] which had significantly higher TPC, TFC, and antioxidant capacity than white rice (Table 2). The color of red rice is controlled by two loci, brown pericarp and seed coat (*Rc*) and red pericarp and seed coat (*Rd*), which are located on chromosome 7 and 1, respectively.[9] *Rc* encodes a transacting regulatory factor with a bHLH motif, and *Rd* encodes a DFR protein which is a key enzyme in the biosynthesis of proanthocyanidin.[9,10] These two loci present together will produce red seed color, whereas the absence of *Rc* or *Rd* will produce no phenotype or brown seed color.[9] Association mapping with 416 rice accessions including red rice and black rice showed that *Rc* and *Ra* were the main effect loci associated with TPC, TFC, and antioxidant capacity.[14] Genetic analysis with a double haploid population derived from a cross between *japonica* and weedy rice showed that pericarp color was associated with the major genes of *Rc* and *Rd*.[13] One QTL identified in this study, qPAC7-3 (7 473 184 bp) was significantly associated with TPAC, which is near to *Rc* (6 061 890−6 068 318 bp). The signal was only detected in 2011 but not in 2012, indicating that environment affected TPAC. Three QTLs on the chromosome 1 were associated with TPAC, but none of them were near to the *DFR* locus at the 25 382 714 bp position. *Rd*, as a structural gene, should express in red-pericarp rice. No detectable QTL signal for

dx.doi.org/10.1021/jf500951e | J. Agric. Food Chem. 2014, 62, 5361−5368

TPAC at the *DFR* locus might be due to the small population and few red rice involved. It also might be due to other QTLs flanking this locus but showing an opposite effect.

One locus at the position of 27 875 425 bp on chromosome 4 was significant for all five traits. It is very close to the *Ra* gene (27 764 248−27 770 504 bp). Previous study also identified the *Ra* locus for these traits by association mapping with 416 rice accessions including red rice and black rice.[14] The color of black rice is controlled by two loci, *Pb* (*Prp-b*) and *Pp* (*Prp-a*), located on chromosome 4 and 1, respectively.[12] Wang and Shu suggested that the *Ra* gene may be the *Pb* gene and that the purple pericarp characteristic of rice is caused by two bases deletion (GT) within exon 7 of the *Ra*.[35] However, there is no black rice in this study. It is plausible that other genes or regulatory factors nearby may affect polyphenol biosynthesis, such as *Plw-OsB1* and *Plw-OsB2*.[36]

In addition to the loci which colocate at the major genes, we also identified other QTLs that associated with rice polyphenol and antioxidant capacity traits. The QTL cluster on chromosome 1, qFC1-1/qPAC1-1/qACA1-1/qACD1-1, was around the QTL detected for antioxidant capacity by linkage mapping in a double haploid population.[15] qPC1/qFC1-2/qACA1-2/qACD1-2 could be detected in the 2 years, so it might be a new important locus affecting the nutritional quality of the whole grain. Similarly, qPC12/qFC12/qPAC12-2/qACA12/qACD12 and qPAC2-1 were nearby the QTLs detected for TPC and TFC by linkage mapping.[15]

In conclusion, we conducted an association study for polyphenol contents and antioxidant capacity traits among 20 rice accessions. With 32 655 SNPs, a total of 23 unique loci have been identified using the best model selected from ANOVA, K, P, Q, P + K, and Q + K models. The peak signals at five loci (qPAC7-3, qPC4, qPC12, qFC1-1, and qPAC2-1) were very close to previously identified genes or QTLs. Among these five loci, qPAC7-3 was near to *Rc*, and qPC4 was near to *Ra*. The qPC1/qFC1-2/qACA1-1/qACD1-1 cluster could be detected in the two environments. However, the loci of qFC1-1/qPAC1-1/qACA1-1/qACD1-1, qFC2/qPAC2-2/qACA2/qACD2, qFC3/qPAC3/qACA3/qACD3, qFC6/qPAC6-2/qACA6/qACD6, and qFC12/qPAC12-2/qACA12/qACD12 were easily affected by environment, and were only detected in one year. Results of the present study demonstrated that association mapping in rice is an effective method to find more potential loci for polyphenol and antioxidant capacity traits. The loci could be further finely tagged with candidate genes and applied in maker-assisted selection to improve the polyphenol and antioxidant capacity traits in whole grain rice. Functional studies of the candidate genes are also needed to reveal their connections to the known phenotypes (i.e., polyphenol content and antioxidant activities) at the molecular biological levels.

amylases.[5,16,17] This could mean that the required diastatic power for sufficient starch degradation in rice malt could be lower than in barley malt. One of these amylolytic enzymes is limit dextrinase, a debranching enzyme which catalyzes the hydrolysis of the α-1,6-glucosidic linkages in starch and related oligosaccharides and exhibits activity levels in rice several-fold higher than in barley malt.[6,13] Another enzyme, α-glucosidase, shows high activity in rice malt and an optimum temperature of 55 °C, while in barley malt its activity is low and the optimum temperature is 35−40 °C. Above 50 °C in barley malt the enzyme is inactivated very rapidly.[18] Evidently the same enzyme can have different features in different cereals. But the suitability of rice malt for brewing depends not only on its enzymatic activity but also on an adequate gelatinization of the starch in a temperature range where the amylolytic enzymes are still active; otherwise the amylolytic enzymes cannot degrade the starch to fermentable sugars and dextrins. This gelatinization temperature is quite high for unmalted cereals, in the case of barley 70−80 °C, but it can be lowered, according to Narziß and Back,[4] up to 20 °C in the presence of enzymes. It depends on the malting conditions. So the high gelatinization temperature of rice (65−85 °C) should also be lowered after maltation. But there is no knowledge about the real optimal temperature range of the amylolytic enzymes of rice malt, which can differ from that of barley malt. Moreover Keßler[18] notes that the starch granules are already attacked by enzymes during germination, and therefore the starch can be also hydrolyzed below the gelatinization temperature. Therefore, the main objective was to verify the complete saccharification of the rice malt starch during mashing with the iodine test, because in this case gelatinization occurred and enough endogenous malt enzymes were present. And, given that the overall enzymatic activity of the rice malt depends on the malting conditions,[3,9,12] a key aspect of the study was to find the optimal malting parameters.

2. EXPERIMENTAL SECTION

2.1. Rice Samples. Ten paddy-rice varieties of *O. sativa* L. cultivated in Italy were examined. Eight belong to the subspecies japonica, Centauro, Creso, Selenio, Karnak, Arborio, Vialone Nano, Crono, and Balilla (respective amylose contents by percent: 16.3, 18.0, 18.1, 20.9, 17.3, 22.8, 16.4, 18.5),[19] and two to the subspecies indica, Sirio and Libero (respective amylose contents: 26.5 and 23.0).[19] Furthermore, three different samples of the Centauro variety were studied that differed in harvest year and origin.

2.2. Rice Analysis. The following quality attributes of the paddy-rice grains were determined in duplicate using the Analytica-EBC methods:[20] grain moisture (%), EBC method 3.2; thousand kernel weight (TKW, g), EBC method 3.4; total protein content (% dry matter (DM)), EBC method 3.3.1 (total $N \times 5.95$); the germinative energy and water sensitivity, modified EBC method 3.6.2 (germination temperature, 28 °C).

2.3. Micromalting. An automatic micromalting system from Custom Laboratory Products (Keith, Scotland), containing a steep and germination unit separate from the kilning unit, was used as previously described.[21]

2.4. Malting Procedure. *2.4.1. Steeping and Germination.* Three malting trials were performed. The first trial was performed by steeping the rice samples continuously in water at 28 °C for 47 h (steeping/germination A); the second, at 22 °C for 73 h (steeping/germination B). The third trial (steeping/germination C) was done under improved conditions (Figure 1). The total steeping and germination time for all trials was 8 days.

2.4.2. Kilning. Two kilning programs were tested with the green malt produced in trial steeping/germination B, one for 21 h at 50 °C (kilning program 1) and the other for 21 h at 50 °C, then 3 h at 72 °C, and finally 3 h at 82 °C (kilning program 2).

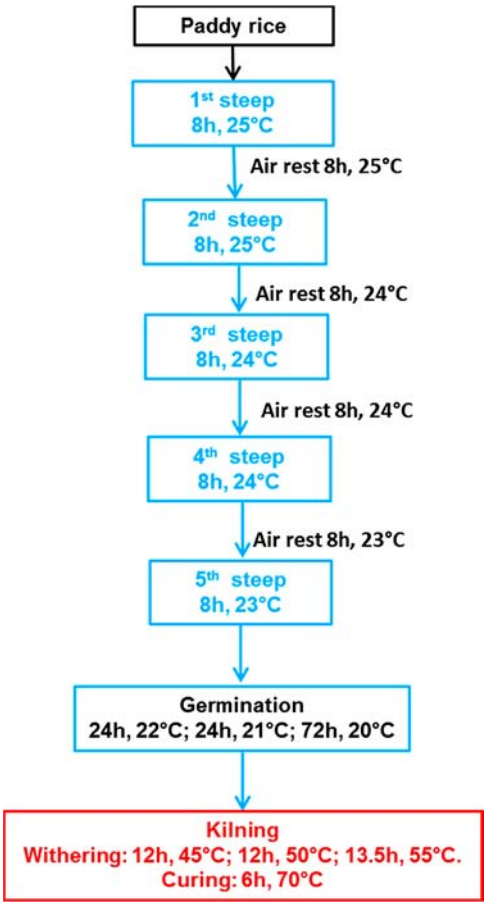

Figure 1. Improved malting conditions (steeping/germination C).

An improved kilning program was tested with the green malt produced in trial steeping/germination C (kilning program 3) (Figure 1).

2.5. Malt Quality. *2.5.1. Rice Malt Analysis.* Rice malt quality was assessed in duplicate using the following Analytica-EBC methods:[20] moisture content (%), EBC method 4.2; extract yield (% DM), iodine test/saccharification rate time (min), and filtration rate, EBC method 4.5.1, modified EBC method 4.5.1 (changing the temperature rests to 30 min at 45 °C, 30 min at 64 °C, and 30 min at 74 °C); colored malt extract, EBC method 5.5; total nitrogen content (% DM), EBC method 4.3.1; soluble nitrogen content (mg/L), soluble nitrogen content (% DM) as a portion of total nitrogen content (% DM), and Kolbach index, EBC method 4.9.1; free amino nitrogen content (FAN; mg/L), EBC method 4.10; viscosity (mPa s at 20 °C and 8.6 °P (from the Plato scale)), EBC method 4.8; apparent final attenuation (%), EBC method 4.11.1; diastatic power (Windisch−Kolbach units (WK)), EBC method 4.12; pH, EBC method 8.17; malt color, EBC method 4.7.1.

The activity of α-amylase, β-amylase, and limit dextrinase of malted rice was determined using the Megazyme Assay Kits.

The dimethyl sulfide (DMS) concentration was determined in the static headspace using a gas chromatograph equipped with a mass spectrometer coupled with an autosampler after sample preparation. DMS precursors were calculated as the difference between total and free DMS.[22]

Aspartic acid, glutamic acid, serine, threonine, arginine, histamine, methionine, valine, leucine, isoleucine, lysine, glycine, alanine, tyrosine, and phenylalanine were determined in rice malt worts by high-performance liquid chromatography (HPLC) quantifying the fluorescence of the orthophtaldialdehyde (OPA)/mercaptoethanol derivatives.[23,24]

[d]Steeping/germination C and kilning 3: see Figure 1.

The carbohydrate concentration in rice malt worts was determined by HPLC coupled with evaporative light scattering detector (ELSD) as reported by Floridi et al.[25]

2.5.2. Mashing Tests To Improve Saccharification and FAN Content. The following mashing tests were utilized: 1, EBC method 4.5.1; 2, EBC method 4.5.1 with the addition of 10 mL of an aqueous solution of $CaCl_2 \cdot 2H_2O$ at a concentration of 22 g/L; 3, rice malt with acrospires and rootlets applying the EBC method 4.5.1 with the addition of 10 mL of an aqueous solution of $CaCl_2 \cdot 2H_2O$ at a concentration of 22 g/L; 4, EBC method 4.5.1 with modified temperature rests (30 min at 45 °C, 30 min at 64 °C, and 30 min at 74 °C); 5, EBC method 4.5.1 with modified temperature rests and the addition of 10 mL of an aqueous solution of $CaCl_2 \cdot 2H_2O$ at a concentration of 22 g/L; 6, EBC method 4.5.1 with modified temperature rests and the addition of 0.144 mL of lactic acid at a concentration of 80% (v/v).

2.6. Statistical Analysis. Statistical analysis was performed using SigmaPlot Software (version 11.0; Systat Software, Inc., San Jose, CA, USA). Comparisons of the different matrices were made by one-way repeated measures analysis of variance, and the results were further analyzed using the Holm-Sidak test and the Tukey test.

3. RESULTS AND DISCUSSION

The rice grain quality attributes of the different samples are reported in Table 1. The moisture content of the rice samples (11.0−14.1%) permitted their storage at low temperatures without pretreatment. The total protein content was in a range of 7.3−9.6% (w/w) and were higher in comparison to the values found in the literature for rice (5.8−7.7% (w/w));[26] however they were still low compared to brewing barley (10.5−11.5% (w/w)).[27] The protein content in brewing is very important for foam stability, taste, and yeast nutrition during fermentation, so the Selenio sample was excluded from malting because of its very low protein content of 6.3%. Of all rice varieties, Karnak, Arborio, and Vialone Nano showed higher TKW values, but they were lower than typical TKW values of barley (38−40 g).[28] The germinative energy gives information about the proportion of grains that will germinate under the conditions of a specified test,[29] and the corresponding EBC method (method 3.6.2) requires a germination temperature of 20 °C. In this study the germination temperature was set at 28 °C which is more appropriate for rice. The resulting values for the rice varieties Crono, Creso, Selenio, Centauro 1, Sirio, Libero, Centauro 2, Centauro 3, and Balilla were below 96%, which is a minimum for commercial brewing malt, but enough to try a pilot malting. They showed no water sensitivity. All of the samples with a good high germinative energy germinated on the third day. This indicates that kernel processing should be homogeneous during malting.[28] On the other hand, the varieties Karnak, Arborio and Vialone Nano have an inadequate germinative energy (77, 87, and 63%, respectively) and were water sensitive (67, 69, and 54%, respectively). Because these last values were likely due to the presence of mold, these samples were excluded from malting.

Three steeping/germination trials were done. Steeping/germination A and steeping/germination B were characterized by long and unusual steeping times, in order to favor the water uptake and solubilize any inhibitors for germination, the hull features of rice and barley being different. The steeping/germination A was performed with the varieties Creso, Centauro 1, and Sirio by steeping the rice continuously in water at 28 °C for 47 h to achieve 42−44% water uptake after

fermentability (%)	n.t.	73.2a	71.2b

[a]n = 2 repetitions; DM = dry matter; n.t. = not tested. Values in the same row followed by a different letter are statistically different ($p \leq 0.05$). [b]Mashing test 1: A-EBC method 4.5.1. [c]Mashing test 2: A-EBC method 4.5.1 with the addition of $CaCl_2$ aqueous solution. [d]Mashing test 3: A-EBC method 4.5.1 with the addition of $CaCl_2$ aqueous solution, acrospires and rootlets.

steeping, which is necessary for good rice endosperm modification.[6] The resulting water uptake was 39, 40, and 38% for Creso, Centauro 1, and Sirio, respectively. After 8 days of steeping/germination there was clearly the odor of a mold infestation. To avoid a microbiological hazard, another trial (steeping/germination B) with a lower germination temperature of 22 °C was conducted with continuous steeping for 73 h. The longer steeping time was used to compensate for the lower water temperature. According to Kunze,[27] the warmer the steeping water the faster the water is taken up, and vice versa. In this case, the water uptake was 40, 39, and 38% for Creso, Centauro 1, and Sirio respectively and there was no evident mold formation. The green malts of steeping/germination B were kilned at 50 °C for 21 h (kilning program 1), and the diastatic power was analyzed. As expected, the diastatic power values were not very high: 78, 42, and 118 WK respectively for Creso, Centauro 1, and Sirio (Table 2). This is in strong contrast with pale barley malt, which normally contains 240−260 WK.[27] The moisture content was 6.7, 6.1, and 6.7% respectively for Creso, Centauro 1, and Sirio. These relative high moisture contents do not guarantee a stable final malt, so the malting was repeated using kilning program 2 with higher temperatures (21 h, 50 °C; 3 h, 72 °C; and 3 h, 82 °C) to achieve less than 5% moisture, an increased aroma, and less undesirable flavors. With this approach a lower moisture content was achieved, but the diastatic power was decreased to 56, 34, and 86 WK for Creso, Centauro 1, and Sirio. The same conditions (steeping/germination B and kilning program 2) were also tested on Libero and Crono, where Crono showed no diastatic power and Libero was in the same range of the other tested rices.

It was also important to explore if rice malt starch underwent an adequate gelatinization. For this purpose the Analytica EBC method 5.5 was applied. In this method, the Congress mash is made with 25 g of rice malt and 25 g of standard malt, and the amylases of the added standard malt compensate for the poor enzyme content of the rice malts. Consequently complete saccharification depends only on the complete gelatinization, and it was possible to eliminate the rice malt varieties which did not gelatinize under the conditions of the Congress wort. Then we could improve the mashing conditions ($CaCl_2$, lactic acid) for the enzymes, being sure that at least gelatinization occurred. Only the variety Centauro 1 had saccharified after 15 min. The other varieties showed a dark blue color still after 60 min by the iodine test. Therefore, only the rice malt Centauro 1 was used for the subsequent tests.

To increase the water absorption, another steeping and germination trial (steeping/germination C) was performed only with Centauro 1 by alternating steeping and drying periods every 8 h at 25 °C, and then decreasing the germination temperature to 20 °C (Figure 1). The water uptake of Centauro 1 was 42%. After 8 days of steeping and germination the malt did not show any evidence of mold and had a good smell and appearance.

The kilning program was improved to better protect the enzymes of the green malt during kilning (kilning program 3). Rice's hull is likely why paddy-rice absorbs water slowly and it dries also slowly for this reason; therefore the withering time was extended to 37.5 h to bring the water content to 10−12% before a higher temperature is used, because the enzymes tolerate dry heat better than wet heat.[27] The first drying step at 45 °C was introduced in order to extend the time for cytolysis.[29] Lastly a moderate final temperature of 70 °C for 6 h was selected. The diastatic power of the resulting Centauro 1 malt was 42 WK, which was equal to the value obtained with the kilning program 1, and also a moisture content of <5% was achieved (Table 2).

Thus, the optimized malting program was established: germination C and kilning program 3. The malt from Centauro 1 was analyzed with mashing test 1, mashing test 2, and mashing test 3 for the saccharification rate, speed of filtration, pH, color, viscosity, soluble nitrogen content, and free amino nitrogen content of the laboratory wort. These are all quality attributes used for evaluating the potential of a brewing malt. Table 3 shows the results. Mashing test 1 did not yield a positive saccharification. The reason seemed the low enzyme content; therefore a $CaCl_2$ solution was added to protect the few enzymes present in the malt (mashing test 2).[30] After 50 min the saccharification was completed. Another benefit was the soluble nitrogen content of mashing test 2 (482 mg/L). It was slightly higher compared to mashing test 1 (450 mg/L); however compared to barley malt both values were still low.[27]To improve the soluble nitrogen content, mashing test 3 was performed on a sample of rice malt without removing the acrospires and rootlets after kilning. During germination acrospires and rootlets grow out of the rice's hull, unlike in barley where only the rootlets grow outside. That means for rice that the acrospires will be eliminated after malting together with the rootlets during processing and the rice malt, which is already poor in protein, will lose additional protein.[24] As Table 3 shows, the soluble nitrogen content in mashing test 3 was increased.

All FAN values were surprisingly high compared to barley malt wort in relation to the soluble nitrogen content. Normally in a good brewing malt the FAN content is around 22% of the soluble nitrogen.[4] In this case it was 32, 31, and 33% respectively for mashing tests 1, 2, and 3. This could be an overstimation that depends on the method for FAN determination, which is a color reaction with ninhydrin. The test is a cumulative method for the estimation of amino acids, ammonia, and the terminal α-amino groups of the peptides and proteins,[24] where the individual amino acids give different color intensities,[31] and for this the comparison between barley malt and rice malt could be less significant. There was no difference in the FAN values of mashing test 1 and mashing test 2, but in mashing test 3 the FAN value was increased.

The fine extracts were nearly the same for the three trials and showed very good results considering the fact that the hull accounts for up to 20% of the kernel's mass and contributes less to the extract.[1]

The optimized malting program was repeated with Centauro 2 and Centauro 3, but surprisingly, the results of mashing test 2 and Analytica EBC method 5.5 revealed an incomplete saccharification (data not shown). The color of the iodine test remained light blue instead of yellow. The reason for that could be a slightly higher gelatinization temperature of Centauro 2 and Centauro 3, because the values of the diastatic power of all three rice malts were nearly the same: 42, 44, and 31 WK respectively for Centauro 1, Centauro 2, and Centauro 3. According to Narziß and Back,[6] the gelatinization temperature depends on the variety and cultivation area and particularly on the climate during the crop year. Therefore, the final congress temperature of 70 °C did not permit a complete gelatinization, and a new mashing program tailored specifically for rice malt was developed. The conditions of this new standardized mashing program correspond to the typical EBC Congress Mash but with different temperature rests (Figure 2): 30 min at 45 °C, 30 min at 64 °C and 30 min at 74 °C (mashing test 4). In mashing test 5 this test was performed with the aqueous solution of $CaCl_2$ while in mashing test 6 the $CaCl_2$ was replaced with lactic acid to lower the pH of the mash and to determine if the improved saccharification was due to a lower pH or the presence of calcium or chloride ions. The results are shown in Table 4. Centauro 2 and Centauro 3 saccharified completely without the use of exogenous enzymes in 20 min after reaching 74 °C with the addition of an aqueous solution of $CaCl_2$ as well as with the addition of lactic acid. Therefore, the improved saccharification in tests 5 and 6 was probably due to the lower pH value. The very low value of the diastatic power could not be decisive for assessing good saccharification, but there should be other important amylolytic enzymes in rice malt such as limit dextrinase,[14] pullulanase,[17]

and α-glucosidase[18] that significantly contribute to the degradation of the rice malt starch. The filtration time of the laboratory worts last more than an hour despite rice wort's low viscosity. The cause may be the cooling of the wort after the laboratory mashing process to 20 °C where the pectin begins to form a gel, and this could hinder the filtration; however this should not be a problem in beer production where the filtration is carried out at 78 °C.

Soluble protein increased in both samples from mashing test 4 to mashing test 5 to mashing test 6. There was also a positive correlation with the FAN values. Compared to Centauro 3, Centauro 2 displayed higher rice malt quality values probably due to its higher total protein content in the crude rice (Tables 1and 5) that could provide more soluble nitrogen and FAN but could also imply a greater protein enzyme endowment. For every sample the fine extract of mashing tests 4, 5, and 6 was nearly the same; meanwhile the viscosity decreased with the addition of $CaCl_2$ and lactic acid, but for all tests it was in an acceptable range.

Table 5. Starch Degrading Enzymes in Rice Malt as Mean and Standard Deviation[a]

	Centauro 2	Balilla
limit dextrinase (U/(malt kg))	6940 ± 21	6129 ± 25
α-amylase (Ceralpha (U/g))	47.4 ± 1.1	48.3 ± 0.1
β-amylase (Betamyl-3 (U/g))	3.8 ± 0.3	8.4 ± 0.2

[a] n = 2 repetitions.

The optimized malting and mashing trials were repeated again using the variety Balilla which has similar characteristics (subspecies *japonica*, 16−18% amylose content) as Centauro. This variety gave even better results than Centauro (Table 4) in spite of the low diastatic power of 34 WK. The saccharification occurred also without the addition of $CaCl_2$ or lactic acid after 30 min. The fermentability, extract content, FAN, soluble nitrogen, and Kolbach Index were all higher than those of Centauro 2 and 3.

The α- and β-amylases as well as limit-dextrinase content of the rice malts Centauro 2 and Balilla were analyzed (Table 5). The α- and β-amylase values are very low and correspond to the very low diastatic power; meanwhile the results of the limit-dextrinase activity was 6940 and 6129 U/(malt kg) for Centauro 3 and Balilla, respectively, which is much higher than in barley malt (200−400 U/(malt kg));[5] so limit dextrinase is certainly one of the supplemental enzymes that contribute to the degradation of the rice malt starch in conjunction with α- and β-amylases. Table 6 shows the sugar profiles of the laboratory rice malt worts. All of the rice malt worts from the different mashing programs produced a wide range of sugar spectra which are characterized by the greater amount of glucose than maltose highlighting the different trend with respect to barley malt wort and could be due to the presence of different enzymes. The data also differed from the results obtained by Agu et al. in 2012[8] perhaps of a different malting and mashing process. Table 7 reports the amino acid profile of the rice malt worts. Histidine and arginine are the amino acids present in major amount. The amino acid profile of the samples did not change a lot between the different mashing programs and varieties. The total amino acid concentration of the rice malt worts is in the range of a barley malt Congress wort[28] even if the total nitrogen content is lower than a barley malt wort. This confirmed the high FAN values. The DMS

values (free, total, and precursor) for Centauro 2 and Balilla were determined (Table 8). They were higher than the accepted values for a commercial barley malt (5−6 mg/kg) and could be due to the high germination temperatures and the relatively low curing temperature.[32]

Table 8. Dimethyl Sulfide (Total, Free, and Precursor) Of Rice Malts (mg/kg)[a]

rice malt	total DMS	free DMS	DMS-P
Centauro 2	17.15 ± 0.74	3.66 ± 0.01	13.50 ± 0.74
Balilla	12.70 ± 0.69	2.52 ± 0.07	10.18 ± 0.70

[a] $n = 2$ repetitions.

In conclusion, a malting program to produce rice malt for brewing was developed and 10 rice varieties were screened. Probably due to the resistant hull of paddy-rice, five steeping steps were necessary to achieve at least 42% of steeping-out moisture, and a long-time kilning program was developed with a particular drying step at 45 °C for 12 h to impair the degradation of the cell walls. Another 12 h at 50 °C and 13.5 h at 55 °C dried the malt enough to protect the enzymes from the following heat (6 h at 70 °C). But this curing temperature and time were not enough to eliminate the high DMS values found in the rice malt. It was shown that the amount of the endogenous rice malt enzymes is high enough to saccharify the rice malt starch and that their optimal temperature and pH conditions are different from those of barley malt. So the conventional Congress mash (mashing test 1) was slightly changed. With different temperature rests and the addition of $CaCl_2$ and lactic acid a complete saccharification of the rice malt starch was achieved. Balilla and Centauro of the subspecies *japonica* are the most suitable varieties for the production of an all-rice malt beer. The addition of lactic acid also yielded higher soluble nitrogen and FAN contents and enhanced fermentability. In the case of the Balilla rice malt, the saccharification occurred also without the addition of $CaCl_2$ and lactic acid. The soluble nitrogen and FAN values of rice malt wort can be increased by incorporating the acrospires and rootlets during mashing. Work is in progress for brewing an all-rice beer with the malt obtained from this study.

consensus has been established regarding the impact of MLF or bacteria strains on the intensity of the fruity aroma. The lack of fundamental data on aromatic markers of red wine fruity notes and the dearth of concomitant biochemical, chemical, and sensory studies are probably two of the reasons why the impact of yeast and bacteria strains on fruity flavor in Bordeaux red wines has remained elusive.

This study aims at evaluating the formation and evolution of yeast- and LAB-derived volatile compounds during wine aging. In particular, we assessed the influence of three active dry *Saccharomyces cerevisiae* yeast strains and two commercial *Oenococcus oeni* strains on ester levels and organoleptic characteristics from the end of AF until 12 months of aging. Ester levels were quantified using a HS-SPME-GC/MS method developed by Antalick et al.[15] in our laboratory. Sensory analyses were also carried out to highlight the influence of the interaction of these microorganisms on the aroma profile of wines produced in conditions of "macro-vinification" and in industrial-scale winemaking conditions. To our knowledge, this is the first report evaluating the effect of both yeast and LAB strains on ester levels as assessed by sensory analysis in aged Bordeaux red wines.

MATERIALS AND METHODS

Yeast and Bacteria Strains and Nutrient Composition. The yeasts strains *Saccharomyces cerevisiae,* Actiflore cerevisiae (522D), Zymaflore FX10 (Laffort Oenologie, Floirac, France) and Excellence XR (Lamothe-Abiet, Canéjan, France) and the bacterial strains *Oenococcus oeni*, Lactoenos 450 PreAc, and Lactoenos B28 PreAc (Laffort Oenologie, Floirac, France) used were commercially dried preparations. Controls of the implantation of yeast commercial starter cultures were performed by PCR at the SARCO laboratory (Laffort Oenologie, Floirac, France) (data not shown). Controls of the implantation of bacterial commercial starter cultures were performed by the Microflora laboratory (Univ. Bordeaux, France) based on a method developed by Claisse and Lonvaud−Funel[29] (data not shown).

Yeast nutrient Superstart/Dynastart (Laffort Oenologie, Floirac, France) is approximately composed of 45% proteins, 35% carbohydrates, 7% total nitrogen, and 6% minerals. Energizer bacterial nutrient (Laffort Oenologie, Floirac, France) contains approximately 55% proteins, 20% carbohydrates, 9% total nitrogen, and 7% lipids.

Winemaking. Complete experimentation on the 2011 Bordeaux appellation vintage was performed in the Laffort Wine Experimental Center (WEC) located in the "Graves de Vayres" area. Cabernet Sauvignon grapes were harvested by hand, destemmed, crushed, and homogeneously distributed into nine 2 hL stainless steel tanks (150 kg of grapes in each). A sample of each batch was analyzed before AF for sugar and nitrogen content, total acidity, and pH (Table 1). Grape must was treated by addition of Lafase Fruit enzyme (Laffort Oenologie, Floirac, 3 g/100 kg) containing pectinase (6700 PGNU/g). Yeast assimilable nitrogen in musts was corrected to around 210 mg N/L. AF was conducted at 19−22 °C and initiated by inoculation with rehydrated dry yeast. The yeast nutrient Superstart/Dynastart was added during rehydration of active dried yeast, according to the manufacturer's recommendations. AF was performed using three different yeast strains in triplicate. Implantation controls were performed for each tank at the middle of AF (density close to 1.040). At completion of AF (<0.2 g/L glucose/fructose), wine composition was analyzed (sugar and malic acid content, total acidity, total SO_2 content, pH, and alcohol content) (Table 1). Samples were collected for volatile compound analysis in a 0.75 L glass bottle and stored at 10 °C for 1 week after addition of 5 g/hL SO_2. Wines were then decanted and frozen at −18 °C before being analyzed.

Each 2 hL tank was divided into two stainless steel barrels of 30 L for MLF. Bacterial cells were rehydrated with Energizer bacterial nutrient according to the manufacturer's instructions and inoculated into wines at the recommended rate. For the entire duration of MLF, the malic acid concentration was measured once a week to monitor the bacterial metabolism. At the end of MLF (<0.1 g/L malic acid), 50 g/hL of SO_2 were added. Samples were collected like those after AF to assess chemical composition (Table 1) and volatile compounds. Wines were drained into 20 L stainless steel barrels for 3 months of aging. After 3 months, they were sampled in a 0.75 L glass bottle for chemical and volatile analysis, and were decanted and frozen like those after AF and MLF. Sub-batches (3 × 20 L) of each wine were racked and mixed to ensure homogeneity. Wines were bottled in two 0.75 L glass bottles for sensory analysis and then evaluated. The rest of the wine was stored in a 30 L stainless steel barrel for 3 more months of aging. SO_2 content was measured and adjusted if necessary. After the sixth month of aging, the wines were bottled and frozen for those destined for analysis or analyzed immediately for the purpose of sensory analysis. Some of the wines were also bottled in 1.5 L glass bottles and stored at 10 °C for one year of aging. These wines were then analyzed like the others with chemical and sensory analysis.

The same experimentation was also performed during the 2012 vintage. Cabernet Sauvignon grapes harvested for the WEC 2012 experimentation were thermovinified, (i.e., heated at 70 °C for 6 h). The complete experimental design is shown Figure 1.

Two other experimentations were also performed in 2012 on two other Bordeaux region sites, Vineyard A (V-A) with Cabernet Sauvignon grapes and Vineyard B (V-B) with Merlot grapes in order to observe yeast/LAB interactions at industrial-scale winemaking during 2012. AF in Vineyard A was performed in one 65 hL stainless steel tank with 522D or FX10 strains and was performed in one 120 hL stainless steel tank with 522D or XR strains in Vineyard B (Table 2). For both experimentations, MLF and storage were achieved in plastic food barrels of 30 and 20 L, respectively. Only MLF and the first 3 months of aging were performed in triplicate. These experimentations were stopped after six months of aging.

Chemicals. Deuterated compounds ethyl butyrate-4,4,4-d_3 (>99%), ethyl hexanoate-d_{11} (>98%), ethyl octanoate-d_{15} (>98%), and ethyl *trans*-cinnamate-d_5 (phenyl-d_5) (>99%) were obtained from Cluzeau (Sainte Foy la Grande, France). Ethanol (≥99.9%) was obtained from Merck (Damstadt, Germany) and sodium chloride (norma pure) from VWR (Fontenay-sous-Bois, France).

Standard Chemical Analysis. The standard chemical parameters of wines (as total acidity, sugar, malic acid, yeast assimilable nitrogen, SO_2 contents, pH, and alcohol) were analyzed by SARCO laboratory (Laffort Oenologie, Floirac, France) which has been accredited by COFRAC since 1995 (NF EN ISO 17025, accreditation no. 1-0588). Analyses were carried out using the official methods or those recommended by the International Organization of Viticulture and Wine.

Sensory Analysis. Sensory analyses were performed as described by Martin and de Revel.[30] Samples (about 50 mL) were poured into clear INAO wine glasses (NF V09-110, 1971), labeled with random three-digit codes and covered with half of a plastic Petri dish. Evaluations were performed in a dedicated room (ISO 8589:2007) equipped with individual booths to prevent communication between assessors, under normal daylight, and at room temperature (around 20 °C). All the 20 panelists were from research laboratory staff at ISVV, Bordeaux University, or from the Laffort Company and had previous experience with the sensory evaluation of wines. Analyses were carried out by orthonasal and gustative evaluations.

Napping positioning and ultraflash profiling[31] were used to evaluate WEC wines for the 2011 vintage after 3, 6 and 12 months of aging. The six wines were simultaneously presented to each judge in random order. They had to position the six glasses on a sheet of paper (40 × 60 cm) in such a way that two wines were very near if they were globally perceived similar and that two wines were distant from one another if they seemed different, on the basis of their own criteria. After Napping, judges were asked to enrich their tablecloth by adding a few terms to describe the wines or groups of wine. They were encouraged to choose specific descriptors of each wine or groups of wine they had previously separated.

Table 1. Main Technological Parameters of the Different Musts and Wines after Alcoholic and Malolactic Fermentations

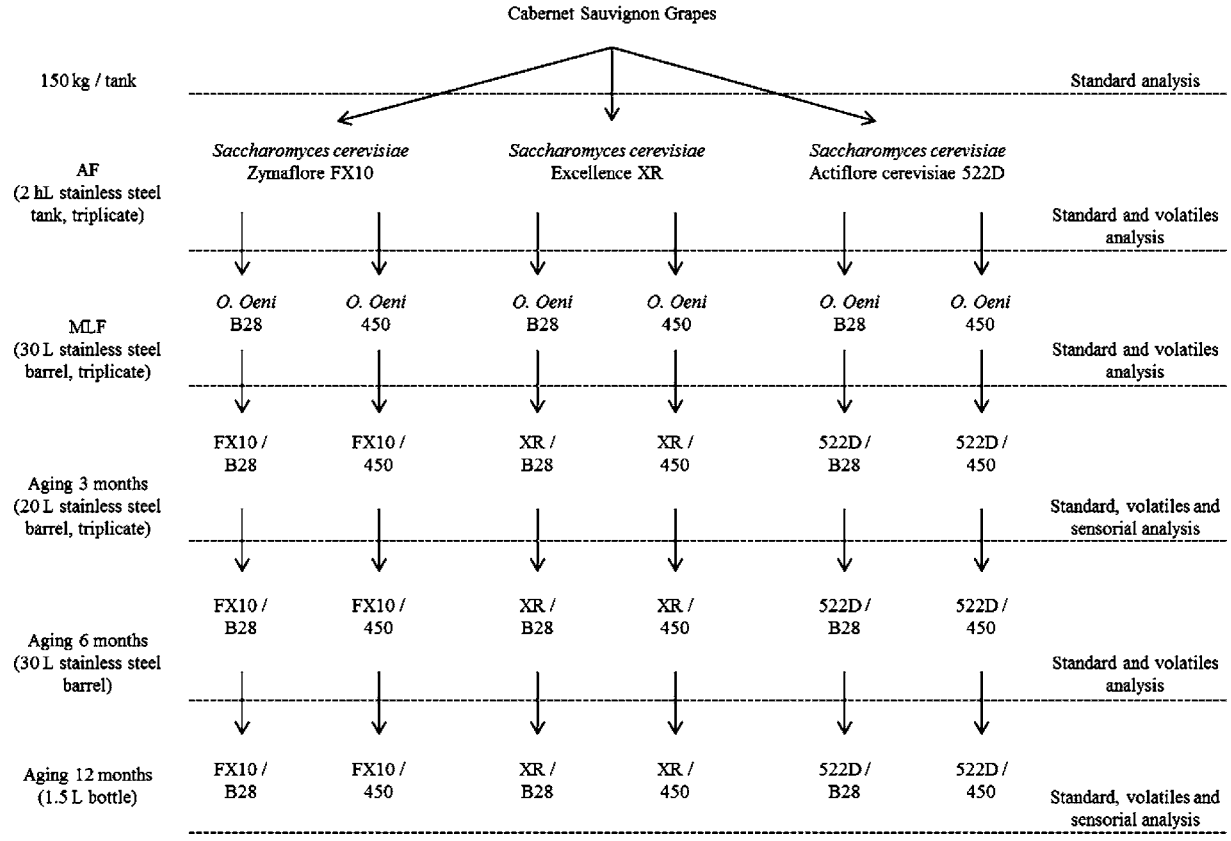

Figure 1. Experimental design in wine experimental center (WEC) for vintages 2011 and 2012.

Ranking tests (ISO 8587:2006) were used for 2012 vintage wines. To evaluate the influence of an experimental factor on the perceived fruitiness in wine, the samples were presented simultaneously to the panel. The members were asked to order each of the 4 (V-A or V-B wines) or 6 samples (WEC wines) according to its fruitiness, from the least to the most. Equal ranking was not allowed.

Finally, comparison profiles (ISO 13299:2003) were used on both 2011 and 2012 vintages, to compare the aroma profiles of wines of the same age (3, 6 and 12 months of aging). A list of five odorant descriptive terms was previously proposed. The odorant terms chosen were based on the fruity aroma ("fermentation aroma", "fresh fruit", and "cooked fruit") and overall aroma potentially having a masking impact on the fruity aroma ("vegetal" and "smoked/toasted"). The panelists evaluated the intensity of the five attributes on a discontinuous scale from 0 to 7.

Statistical Analyses Applied to Sensory Analysis. Results obtained from comparison profiles and ranking tests were statistically interpreted according to the norms published by the international organization for standardization (ISO).

Results from Napping were processed by Multiple Factor Analysis (MFA) as by Pagès.[31] Vocabulary generated with ultraflash profiling was treated as described by Perrin et al.[32]

The second test implemented here consisted in a ranking test with no preordained order, so the Friedman test was applied. For each assessor, a value between 1 and 4 was attributed to each sample, depending on the response of the assessor (1 for samples designated as the least intense, 4 for the most intense). The sums of the ranks were obtained for each sample, then parameter F was calculated using Friedman test specifications and compared with a χ^2 value in order to determine whether the result of the test was significant ($F \geq \chi^2$) or not ($F < \chi^2$).

Statistical significance of data from the comparison profile was evaluated with a three-way analysis of variance (yeast, bacteria, and yeast/bacteria interaction). To compensate for idiosyncratic scale usage, attribute ratings were normalized to obtain equal means and standard deviations for each subject. ANOVA was analyzed by a Duncan *post hoc* test to confirm differences between groups.

Statistical analyses (ANOVA and Duncan's *post hoc* tests) were performed using XL-STAT (Addinsoft, Paris, France), whereas graphical representations of MFA were performed using R v2.15.0 (R Development Core Team 2009, Vienna, Austria, R Foundation for Statistical Computing).

Esters Quantification by HS-SPME-GC/MS Analyses. Each wine sample from the same winemaking step was analyzed at the same time after defrosting. Analyses were performed in triplicate.

The method developed and validated by Antalick et al.[15] was used to quantify 32 esters: ethyl fatty acid esters, acetates of higher alcohol, ethyl branched acid esters, isoamyl esters, methyl esters, ethyl

cinnamates, and some other esters (Table 3). A mixture of ethyl butyrate-4,4,4-d_3, ethyl hexanoate-d_{11}, ethyl octanoate-d_{15}, and ethyl *trans*-cinnamate-d_5 (phenyl-d_5) at about 200 mg/L in ethanol was used as internal standard. In accordance with this method, 20 μL of internal standard solution was added to 25 mL of wine. An aliquot of 10 mL of this wine was introduced into a 20 mL standard headspace vial filled with 3.5 g of sodium chloride. The samples were extracted by HS-SPME and analyzed by GC/MS. The fiber used was polydimethylsiloxane 100 μm (PDMS-100) (Supelco, Bellefonte, PA, U.S.A.). They were conditioned before use, as recommended by the manufacturer. Quantification was performed with calibration curves built in red wines.

Statistical Analysis for Esters Quantifications. Volatile compound concentrations (micrograms per liter) were expressed as mean ± standard deviation. The effects of yeast and LAB strains on each variable were tested by two-way analysis of variance (yeast strain, LAB strain and yeast*LAB strain interactions). ANOVA was followed by a Duncan *post hoc* test to identify differences between groups using a 95% confidence interval.

To obtain a general overview of the data, a PCA was performed from ester concentrations (32 esters). We sought whether the different factors (sampling time, vintage, yeast/LAB couples) allowed clear clustering of the data. Since the matrix effect was considerable, the data were standardized independently, i.e., the data were mean-centered and scaled for each vintage in order to reveal the impact of the other factors. PCA was run using the ade4, car, and plotrix packages from the R program.

Statistical analyses (ANOVA and Duncan's *post hoc* tests) and graphical representations were performed using R v2.15.0 (R Development Core Team 2009, Vienna, Austria, R Foundation for Statistical Computing).

RESULTS AND DISCUSSION

First Approach for Characterizing the Impact of Yeast/Bacteria Couples on Red Wine Aromatic Profiles. Napping is one of the best sensory tests to evaluate global aroma and taste.[32] It permits the global characterization of wines and allows each judge to build his/her representation based on sensory dimensions he/she considers important. Representations of attributes and wines from the 2011 vintage after 3 and 12 months of aging are presented in Figure 2. The most frequently used descriptors to define the aroma of these wines belonged to the lexical field of fruit (fruity, fresh fruits, cooked fruits, red fruits, black fruits, fermentation aroma), as expected for young Bordeaux red wines. Other descriptors used to qualify these wines were "smoked", "toasted", and "vegetal".

Figure 2b for 3 months aged wines and Figure 2d for 12 months aged wines show the projection of the sensory variables on the plane formed by Principal Components 1 and 2 (58% of the total variance) and by PC 2 and 3 (45% of the total variance), respectively. For wines after 3 months of aging, the first component (36%) is defined by the smoked/toasted descriptor, whereas the second component (22%) is mainly characterized by fruity descriptors (fruity, red fruits, fermentation aroma, cooked fruits). The second component (24%) of Figure 2d (wines aged 12 months) highlights the contrast between the fresh fruits on one side and the smoked and toasted descriptor on the other, positioning the latter aromas as a potential mask of fruity aroma. The third axis (21%) opposes "fruity" (red and cooked fruits, fermentation aroma, fruity) and "pleasant mouthfeel" terms to the vegetal attribute.

Projections of wines after 3 and 12 months of aging in the bidimensional plot are presented in Figure 2a,c. As shown, samples were scattered over the map, principally according to the "fruity" vector: in both cases, the trained panel perceived FX10s and XRs wines as being fruitier than 522D fermented wines. Moreover, wines were also separated according to the bacteria strain: samples fermented with the 450 *O. oeni* strain appeared more smoked and toasted in wines after 3 months of aging than the wines where the B28 strain performed MLF. After 12 months of aging, a separation of wines regarding to the bacteria strain were also observed (axis 1, 24.5%, data not shown), but no correlation with none descriptors could be established to confirm 3 months aging results.

According to these initial results obtained with wines at two different steps of aging, the differences observed between wines seemed to be correlated with yeast strain. Most descriptors used for discriminating wines refer to fruity notes. This suggests that yeast strains could be the predominant factor involved in the modulation of fruity aroma, which is not surprising in young wines (after 3 and 12 months of aging). Nevertheless, a bacterial strain effect was also observed, to a lesser extent, and seemed to be linked to smoked/toasted descriptors. The development of these notes during MLF has already been observed by Antalick et al.[19] and could play a role in the masking of the perception of fruity aroma. They also hypothesized that interactions between yeast and LAB could play a key role in the modification of aroma in wine during MLF, but at this point, the hypothesis of an effect of the yeast/LAB association on the fruity aroma of red wines seemed less probable.

Impact of Yeast and Bacterial Strain on Fruity Aroma Perception. Descriptors associated with fruity notes were proposed by each judge during the Napping tests to characterize a wine or group of wines. Thus, a ranking test and comparison profile were performed with wines from the 2012 vintage to investigate the impact of the choice of yeast and LAB strains on fruity aroma perception.

Table 2. Experimentations Implemented[a]

sites	vintage	volume* (hL)	grape cultivars	yeast	bacteria
WEC	2011	2	Cabernet Sauvignon	522D, FX10, XR	450, B28
WEC	2012	2	Cabernet Sauvignon**	522D, FX10, XR	450, B28
vineyard A (V-A)	2012	65	Cabernet Sauvignon	522D, FX10	450, B28
vineyard B (V-B)	2012	120	Merlot	522D, XR	450, B28

[a]Volume* correspond to the volume of stainless steel tank used for AF; ** thermovinification.

First, each taster had to assign 1 point to the least fruity wine and 4 (V-A, V-B) or 6 points (WEC) to the fruitiest one. The sum of the ranks was calculated for each modality from each experiment. Statistical analysis was significant at 1% (Table 4) with wines in the WEC experiment, which means that the tasters were able to distinguish different strains according to their fruity perception. Moreover, the highest sum of ranks was observed for the associations FX10/B28 and FX10/450, followed by 522D/B28 and 522D/450, and XR/B28 and XR/450. Results were in agreement with those of the Napping tests. Furthermore, they were similar to those obtained in Vineyard A and in Vineyard B in the Bordeaux region with two different grape cultivars in real conditions of winemaking. The Friedman test was significant at 0.1% with wines from the V-A

essay and significant at 5% with V-B wines (Table 4). The highest sum of ranks for V-A wines was observed with the associations FX10/B28 and FX10/450, followed by 522D/450, and finally 522D/B28. Results with wines from V-B confirmed that wines inoculated with the 522D yeast strain appeared less fruity, since the highest sum of ranks was observed for XR/B28, XR/450, 522D/B28 ,and then 522D/450. These results observed in 3 different wines, made in "macro-vinification" or in real winemaking conditions confirmed the impact of the yeast strain on fruity aroma in Bordeaux red wines, despite a potential matrix effect (different region, grape cultivars or winemaking process).

Next, each judge had to attribute a score for each modality from 0 to 7 for 5 descriptors potentially involved in the modulation of fruity aroma (Figure 3). Statistical analyses confirmed that the judges differentiated wines inoculated with yeast strain FX10 from the others. Indeed, for WEC wines (Figure 3a), the FX10/450 association appeared significantly different from the others with "fermentation aroma" notes ($P < 0.01$). Wines fermented with yeast strain FX10 also seemed to be different from the other wines and were described as having more "fresh fruit" notes (yeast effect: $P < 0.01$). Alternatively, wines inoculated with yeasts XR or 522D were described as less fruity and more vegetal (yeast effect: $P < 0.05$) than FX10 wines. A bacterial strain effect was also observed for "fresh fruit" notes, indicating that wines fermented with B28 LAB seemed more fruity than those with the 450 strain (LAB effect: $P < 0.01$). Similar results were observed in wineries, especially in Vineyard A (Figure 3b), where both FX10/450 and FX10/B28 wines were described as fruitier than 522D/450 and 522D/B28 wines, thereby confirming the results from the ranking test. In contrast, the two latter wines appeared more smoked and toasted than the others (yeast effect: $P < 0.01$). Finally, results obtained with Vineyard B wines (Figure 3c) were less clear, perhaps indicating a less significant difference between yeasts XR and 522D. This is consistent with observations made with wines from WEC, where differences were perceived only between FX10 and XR wines and FX10 and 522D wines, but where no significant difference was observed between wines inoculated with XR or 522D.

In this study, the yeast strain appears to be a dominant factor involved in the modulation of fruity notes in Bordeaux red wines. Wines inoculated with FX10 were perceived as fruitier, regardless of the vintage or grape cultivar, after 3 and 12 months of aging. These findings highlight the persistence of a yeast strain effect on fruity aroma over time. The impact of bacterial strains is not as clear.

There is known to be a decrease in fruity notes further to an intensification of the lactic aroma after MLF,[33] mainly due to the increase in diacetyl levels. However, no reference was made to lactic or buttery notes during the Napping test to characterize the differences between wines. It seems unlikely that diacetyl is responsible for the modulation of fruity aroma. Recent studies highlight the difficulty to perceive lactic notes in very young wines,[19,22] probably because of interactions between diacetyl and sulfur dioxide.[33] The olfactory mask of smoked notes over the fruity aroma described by Antalick et al.[19] could also explain differences observed between wines. The bacterial effect observed mostly with the Napping test could be due to sulfur compounds such as hydrogen sulfide or dimethyl sulfide synthesized by certain LAB strains with toasted notes.[34,35] However, the link between bacterial strain and these notes is not clear, and other compounds with reduction notes might be involved. Finally, the question is which aromatic compounds could be responsible for the differences observed. Esters are considered to be the primary source of fruity aroma.[36] They are mainly synthesized by yeast during alcoholic fermentation but LAB can modulate their concentration during MLF close to their perception threshold. These variations could explain the differences observed during sensory tests.

Overview of Changes in Ester Composition Due to Yeast/Bacteria Associations over Time. The PCA scores plot and corresponding loadings plot in Figure 4 provide an overview of ester profiles associated with the metabolic activity of the six associations from the end of AF to 12 months of aging in WEC 2011 and 2012 wines.

Separation along the first axis (48.3% of the total variance) was due to an effect of sampling time. Samples taken at the same time (AF11 and AF12, MLF1 and MLF12, and so on) overlapped and were situated toward the first axis in chronological order, with clear separations between AF, MLF samples, and those collected during wine aging. Indeed, samples after AF for both vintages are positioned to the left of the scores plot and are strongly correlated with esters with long carbon chains such as ethyl decanoate, ethyl octanoate, ethyl hexanoate, octyl acetate, hexyl acetate, and methyl decanoate. This indicates that samples after AF have high levels of these esters. MLF11 and MLF12 samples are positioned toward the left of the scores plot and associated with a lesser extent with long carbon chain esters, indicating lower concentrations in post MFL wines than in post AF wines. Samples after 3, 6, and 12 months of aging are positioned toward the right of the scores plot. Separation between the three aging times is less prominent but the chronology still seems to be respected. They are inversely correlated to long carbon chain esters, indicating lower concentrations than post MLF and post AF wines. This is in accordance with other studies that highlighting the decrease in EFAE and AHA concentrations during wine aging.[37,38] Wine aging samples (12m12, 6m12, 3m12, and to a lesser extent 6m11 and 3m11) are correlated with ethyl branched acid esters (C2iC4, C2–

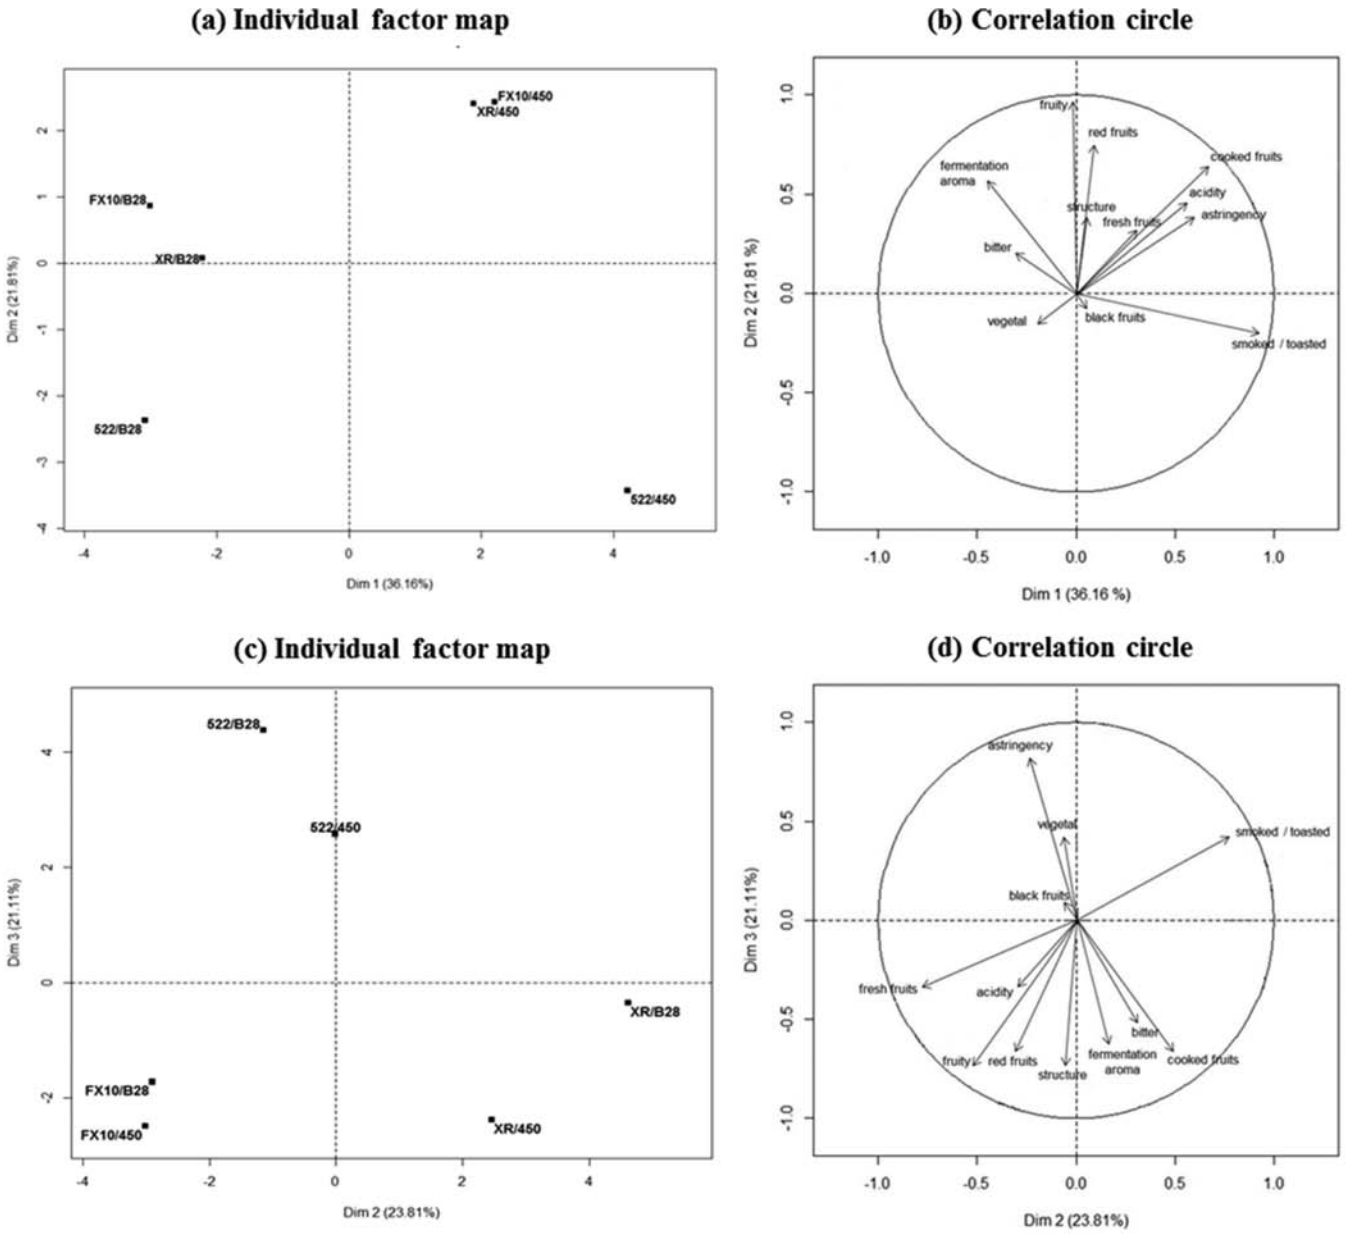

Figure 2. Wines representation (a, c) and characterization (b, d) emerging from Napping combined with Ultra-Flash Profiling (MFA, plane 1−2 and 2−3), realized with wines after 3 months (a, b) and 12 months (c, d) of aging, 2011 vintage.

Table 4. Ranking of Perceived Fruitiness in Wines after 3 Months of Aging in Vintage 2012

		strains and sums of ranks							
wine	no.	XR/B28	XR/450	FX10/B28	FX10/450	522D/B28	522D/450	F[a]	results[b]
WEC	22	72	53	95	94	76	72	16.10	significant at 1%
vineyard A	24			75	72	39	54	21.15	significant at 0.1%
vineyard B	18	59	44			42	35	10.2	significant at 5%

[a] F was calculated as described in ISO 8587:2006 for Friedman test. $F = (12 \times \sum_p^{i=1} R_i^2)/(n \times p \times (p+1)) - 3 \times n \times (p+1)$ with n represents the number of tasters, p represents the number of modalities and R_i represents the sum of the ranks for the modality i. [b] With six modalities (WEC), the test was significant at 5% when $F > 11.07$, at 1% when $F > 15.09$ and at 0.1% when $F > 20.52$. With four modalities (V-A, V-B), the test was significant at 5% when $F > 7.81$, at 1% when $F > 11.34$ and at 0.1% when $F > 16.27$.

2mC4, and C2iC5), indicating higher levels in these samples than in MLF11, MLF12, AF11, and AF12, and therefore an increase in the concentration of EBAE during wine aging.[39,40]

The second axis (11.6% of the total variance) seems to separate samples with regard to the yeast strain. Samples inoculated with strain 522D (represented with circles in Figure 4) are positioned toward the bottom of the scores plot and are associated with propyl acetate, 2-phenylethyl acetate, ethyl propanoate, ethyl phenylacetate, and methyl butanoate. Wines fermented with strain FX10 (represented by squares) tend to

dx.doi.org/10.1021/jf500707e | J. Agric. Food Chem. 2014, 62, 5378−5389

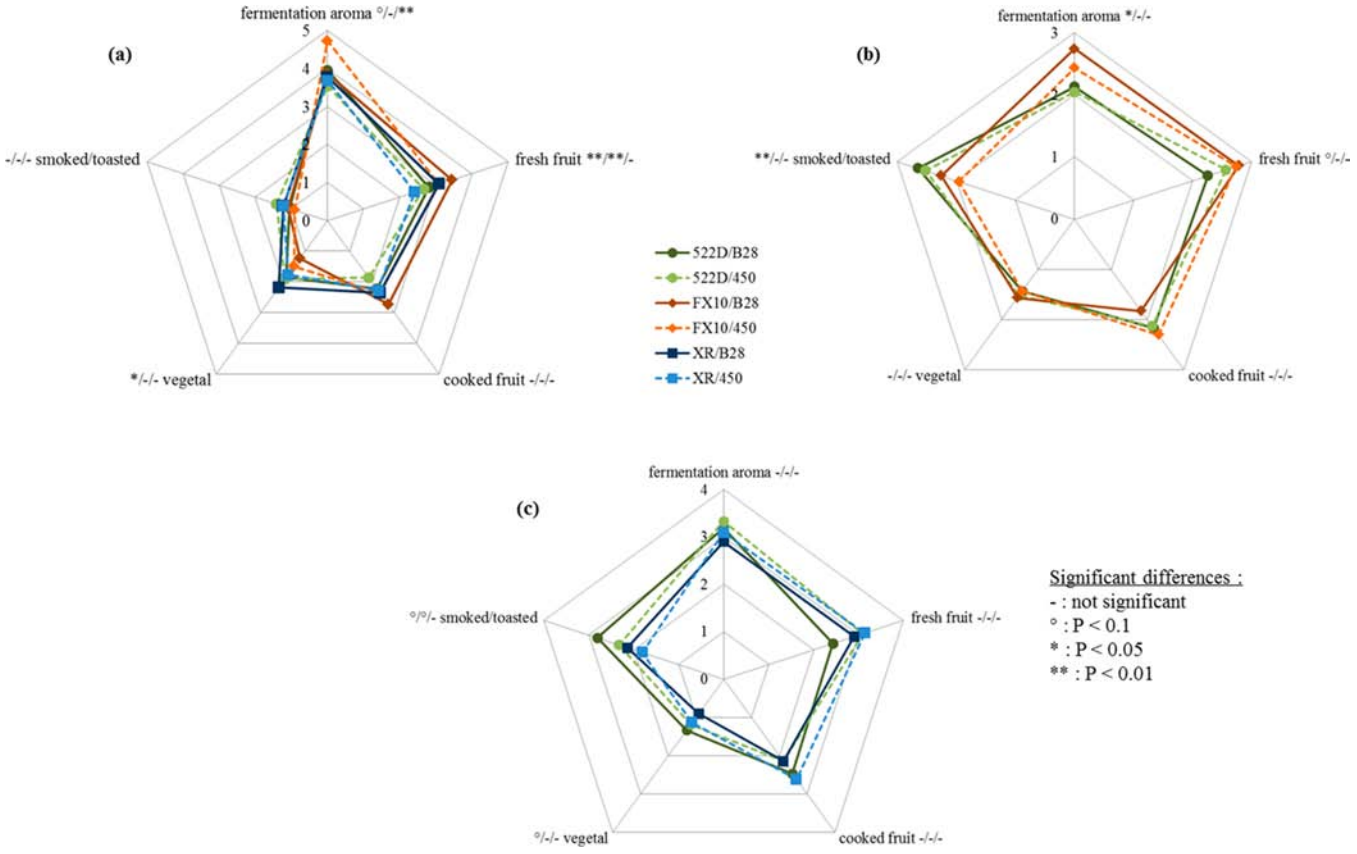

Figure 3. Mean sensory descriptor values for WEC (a), Vineyard A (b), and Vineyard B (c) red wines after 3 months of aging made in 2012 vintage with six yeast/bacteria couples. Significant differences are indicated with asterisks (yeast strain effect/LAB strain effect/yeast × LAB interaction effect).

cluster in the middle of the scores plot, whereas XR samples (denoted with diamonds) are positioned toward the top of the scores plot and are inversely correlated to almost all esters, indicating that the levels of esters in these samples are lower than in FX10 and 522D samples. Interestingly, samples inoculated with the same yeast overlap in the scores plot regardless of bacteria strain. The synthesis of esters by yeast has been known for decades, whereas the impact of bacteria is still controversial. Evidence exists of esterase activity in *O. oeni*[41,42] and several reports have shown changes in ester concentrations in wines after MLF with *O. oeni*. However, no consensus has been established, since these variations differ between studies.[19,43,44] In the present study, the impact of bacterial metabolism on ester concentrations seems very limited compared to that of yeast, which seems to be the predominant factor.

Ester Profiles and Link with Sensory Analysis. Significance levels of a yeast effect calculated with the Analyses of Variance on the different wines are presented Table 5. Significant effect of yeast strain was observed for all esters in all wines at almost each step of winemaking. Quantitative data of the 32 esters analyzed in the experimental wines are summarized in Figure 5, while the entire data collected are available in the Supporting Information (SI, Tables S1−S4). In terms of valuable contribution to the fruity aroma of red wines, three subfamilies of esters can be highlighted: ethyl fatty acid esters (EFAE), acetates of higher alcohols (AHA), and ethyl branched acid esters (EBAE).[3,19] All esters from the same family generally presented the same pattern, so we assumed that total concentration in esters in each family would be a good representation.

Changes in ethyl fatty acid esters depended on both matrix and yeast strain. FX10 yeast strain tended to produce significantly higher EFAE concentrations in WEC 2012 and Vineyard A wines, in accordance with the sensory results. However, Napping tests in the WEC on 2011 wines clearly differentiated 522D wines from FX10 and XR wines, which were described as fruitier, whereas chemical analysis demonstrated higher EFAE levels in 522D wines after 3 and 12 months. Similar results were observed with Vineyard B wines, fermented with Merlot grapes, which were described as fruitier when inoculated with XR than with 522D, even though the latter synthesized more EFAE. A recent study suggested that precursor availability rather than the expression level of genes responsible of ethyl ester synthesis is the limiting factor in esters production.[45] In other words, matrix effect could be the predominant factor responsible for the modulation of ethyl ester levels, and it appears that EFAE might not explain yeast differences observed during sensory analyses. Similar observations were made with acetates of higher alcohols, which were found in comparable concentrations in wines inoculated with 522D and FX10 as in wines from WEC 2011, WEC 2012, and V-A, while their aromatic profiles were significantly different. Finally, 522D also significantly synthesized more ethyl branched acid esters than XR and FX10 in all wines analyzed in this study. Overall, wines fermented with yeast strains FX10 and 522D had roughly the same profile in terms of ester levels, but 522D wines appeared less fruity. These observations are not

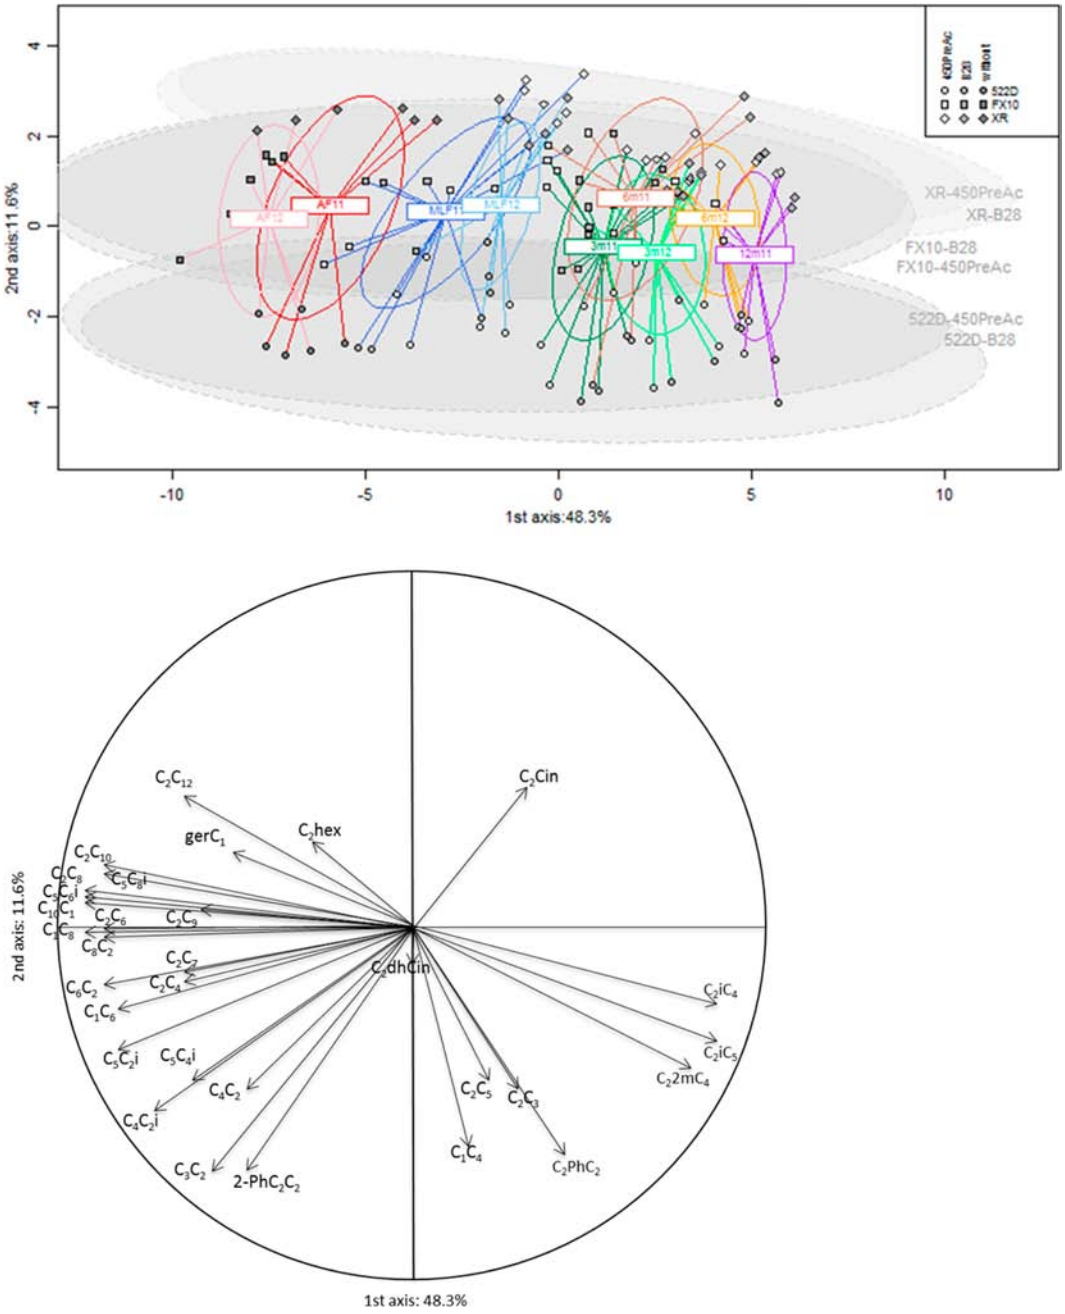

Figure 4. Principal Component Analysis (PCA) providing a visual overview of changes in the esters composition over the time in WEC wines from 2011 (AF11 to 12m11) and 2012 (AF12 to 6m12) vintages: after Alcoholic Fermentation (AF), Malolactic Fermentation (MLF), 3, 6, and 12 months of aging (3m, 6m, 12m). The data were mean-centered and scaled for each vintage in order to decrease the matrix impact and to reveal the impact of the other factors. Yeasts strains are represented by circle (522D), square (FX10), and diamond (XR); empty geometric shapes represent 450 LAB strain and full ones are for B28 LAB strain. Abbreviations of esters in the correlation circle are listed in Table 3.

as surprising and confirm results from other studies investigating fruity aroma in red wine over the past decade. In fact, wine consists of a highly complex mixture of volatiles, but only a few of these compounds are known to contribute directly to wine aroma.[46,47] However, the perception of flavors is not the result of a single dominant compound, but rather stems from the result of interactions between a multitude of volatiles.[48] Thus, no key aromatic compounds responsible for fruity aroma in Bordeaux red wines have yet been identified, although several studies highlight the indirect potential role of a certain number of compounds. Moreover, Ferreira et al.[49] suggested that the concentrations of compounds from the same chemical family had a cumulative effect, resulting in a perception of their overall fruity character. Pineau et al.[3] highlighted the importance of esters and acetates in the red- and blackberry aroma, which was confirmed subsequently.[4,14] They also demonstrated in dearomatized wines that very small variations in ester levels can be perceived by a panelist, even at concentrations far below their olfactory threshold, and that this can affect the perception of fruity aroma. Ester profiles of 522D and FX10 strains may look quite similar, but small variations in the concentration of only a few esters could cause a flavor profile to be perceived completely differently. However, the study of minor esters as isoamyl esters, methyl esters, or ethyl

cinnamates also failed to establish a link with fruity aroma perception (available in SI Table S5).

Other interactions involving volatile compounds from other families could also be responsible for the modulation of fruity aroma. Empirical observations have shown that the addition of copper sulfate in Cabernet Sauvignon or Merlot wines leads to a significant decrease in the perception of fruity flavor. This suggests the contribution of sulfur-derivative compounds and especially odorous thiols in the development of the aromatic complexity of red wines. Varietal compounds revealed by yeast during AF such as mercaptans present in Cabernet Sauvignon and Merlot wines may participate in the toasted and blackcurrant nuances of these wine aromas.[50,51] Small variations in the release of these powerful odoriferous volatile compounds due to yeast strain during AF may be sufficient to modulate the aromatic expression of wines.

In summary, sensory analyses of wines from different Bordeaux appellations at different fermentation and aging times allowed the impact of both yeast and bacteria strain on fruity aroma to be investigated. The perception of fruity notes in Bordeaux red wines was particularly impacted by the yeast strain, while bacterial strain had little impact on the modulation of fruity aroma. Ester profiles alone cannot account for the differences in the perception of fruity notes, despite their important role. Yeast strains also had a large impact on ester composition in wines, to such an extent that significant differences detectable at the end of alcoholic fermentation were unaffected by MLF and aging. The impact of these micro-

dx.doi.org/10.1021/jf500707e | J. Agric. Food Chem. 2014, 62, 5378−5389

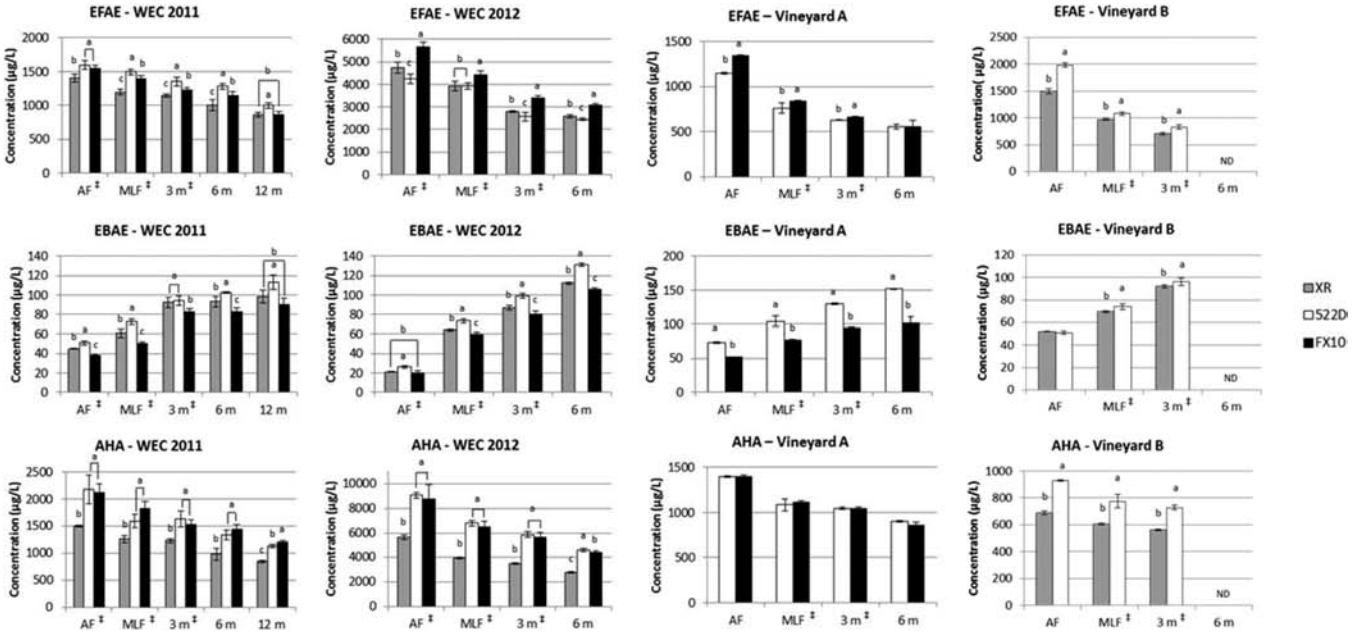

Figure 5. Sum of mean concentrations with standard deviations (micrograms per liter) of esters after alcoholic fermentation (AF), malolactic fermentation (MLF), 3, 6, and 12 months of aging (3m, 6m, 12m) in wines from WEC 2011, WEC 2012, Vineyard A (V-A) and Vineyard B (V-B). Esters were grouped in families described in Table 3 regarding yeast strains. Samples with biological triplicates were injected twice each. For samples which were not triplicated, three injections were carried out. Different alphabetical letters indicate significant differences. EFAE: Ethyl Fatty Acid Esters; EBAE: Ethyl Branched Acid Esters; AHA: Acetates of Higher Alcohols; ND: No Data; the ‡ indicates biological triplicates.

organisms on the concentration of other compounds involved in the modulation of fruity notes should lead to better correlation between sensory and chemical analyses. Henceforth, winemakers have a sensory parameter choosing industrial yeast strains and no longer need to rely only on kinetic and technical specifications.

Supporting Information

Mean concentrations with standard deviations (micrograms per liter) after AF, MLF, 3, 6, and 12 months of aging in WEC 2011, WEC 2012, Vineyard A, and Vineyard B wines for each yeast strain are presented in Tables S1, S2, S3, and S4 respectively. Results of Duncan *post hoc* tests for yeast effect on the different esters quantified are presented in Table S5. Indicated groups represent yeasts which had synthesized the most esters after AF, 3 months, and 12 months (only for WEC 2011 wines) of aging. Figure 1. ISO induces apoptosis in HepG2 cells. (A) Chemical structure of ISO. (B) HepG2 cells were treated with ISO at the indicated concentrations for 24 h. The levels of TNF-α in the supernatant was measured using an ELISA assay kit, the results are shown as the mean ± standard deviation (SD) of nine separate experiments. Representative immunoblots for (C) Fas, FasL, caspase-8, and Bid and (D) p53, IκB, p-IκB, and NF-κB are shown. α-Tubulin and lamin B were used as internal controls.

In the present study, we investigated the mechanisms by which ISO affects autophagy in HepG2 cells and demonstrated the interplays between apoptosis and autophagy induced by ISO in HepG2 cells.

MATERIALS AND METHODS

Reagents and Antibodies. ISO (purity of ≥98%) was purchased from Forever Biotechnology, Ltd. (Shanghai, China). RPMI-1640 cell cultures, fetal bovine serum (FBS), and the BCA protein kit were purchased from Thermo Fisher (Shanghai, China). 3-(4,5-Dimethylthiazol-2-yl)-2,5-diphenyltetrazoliunbromide (MTT) (purity of ≥93%) was obtained from Wolsen Biotechnology, Ltd. (Xian, China). *N*-Acetyl-L-cysteine (NAC) (purity of ≥99%), pyrrolidinedithiocarbamic acid (purity of ≥99%), 3-methyladenine, rapamycin (purity of ≥95%), and pifithrin-α (purity of ≥95%) were purchased from Sigma. Acridine orange (AO), LY294002 (purity of ≥98%), and ZVAD-fmk were provided by Beyotime Institute of Biotechnology (Jiangsu, China).

Antibodies against Bcl-2 (SC-492), Bax (SC-493), cytochrome *c* (SC-7159), caspase-8 (SC-56070), FasL (SC-6237), α-tubulin (SC-5286), lamin B (SC-6216), and horseradish-peroxidase-conjugated secondary antibodies were purchased from Santa Cruz Biotechnology (Santa Cruz, CA). Beclin-1 (1353R) and cleaved caspase-3 (p17) (BS7004) were obtained from Abcam (Hong Kong) and Bioworld Technology, Inc. (Louis Park, MN). Nuclear factor (NF)-κB p65 (8242), IκB (9242), p-IκB (Ser32/36) (9246), poly(ADP-ribose) polymerase (PARP) (9542), LC3A/B (4108), p53 (9282), Fas (8023), p-Akt (Ser473) (9271), and Akt (9272) polyclonal antibodies were purchased from Cell Signaling Technology Company (Shanghai, China). An enzyme-linked immunosorbent assay (ELISA) kit for TNF-α was obtained from the Xinle Biology Technology (Shanghai, China). All other chemicals made in China were of analytical grade.

Cell Culture and Treatment. Human hepatoblastoma HepG2 cells were obtained from the Fourth Military Medical University (Xian, China) and cultured in RPMI-1640 medium with 10% FBS and 1% penicillin/streptomycin at 37 °C in a humidified incubator (5% CO_2 and 95% air). For the ISO treatment, ISO was dissolved in dimethyl sulfoxide (DMSO) and further diluted to final concentrations with serum-free culture medium.

Measurement of Cell Viability. Cell viability was determined using the MTT assay. Cells were seeded at a density of 1×10^6 cells/mL in 96-well polystyrene culture plates at 37 °C with 5% (v/v) CO_2 for 1 day. After 24 h of incubation, 100 μL of medium was removed from each well and 100 μL aliquots of different concentrations of ISO were added to the cells and incubated for 24 h. Subsequently, 100 μL of 0.5% (w/v) MTT dissolved in phosphate-buffered saline was added to each well and incubated for 4 h. The formazan crystals formed by live cells were solubilized with 100 μL of DMSO, and absorbance at 490 nm was measured with a microplate reader (Bio-Rad Laboratories, Ltd., China). Cell viability was expressed as a percentage of the control (untreated cells).

Measurement of TNF-α. Cells were treated with ISO for 24 h. The levels of TNF-α in the culture medium were measured using an ELISA kit according to the instructions of the manufacturer.

Detection of Autophagic Vacuoles by AO. Autophagy is the process of sequestering cytoplasmic proteins into the lytic component and is characterized by the formation and promotion of acidic vesicular organelles, as described previously. AO was always used to detect the acidic cellular compartment, which emits bright red fluorescence in acidic autophagic vacuole vesicles, but green fluoresces in the cytoplasm and nucleus. After treatment, cells were incubated with 1 μg/mL AO for 15 min. Then, the AO was removed and observed using a fluorescence microscopy (Olympus Optical Co., Ltd., Tokyo, Japan).

Observation and Quantification of Monodansylcadaverine (MDC) Staining. MDC staining was introduced to analyze autophagy induction in cells. After treatment, cells were rinsed with phosphate-buffered saline (PBS) and stained with 50 m/L MDC at 37 °C for 1 h. Finally, cells were washed with PBS, and the cellular fluorescence changes were observed using fluorescence microscopy (Olympus Optical Co., Ltd., Tokyo, Japan), and the MDC fluorescent intensity changes were determined by the microplate reader with excitation light at 488 nm and emission light at 530 and 650 nm (Molecular Devices Co., Sunnyvale, CA).

Transmission Electron Microscopy (TEM). HepG2 cells were treated with ISO, and then the cell pellets were fixed with a 0.1 M PBS solution containing 2.5% glutaraldehyde for 12 h. They were then washed with 0.1 M PBS, embedded in 2% agarose gel, and postfixed in 4% osmium tetroxide solution for 1 h. Next, the examples were

dx.doi.org/10.1021/jf500903g | J. Agric. Food Chem. 2014, 62, 5390−5400

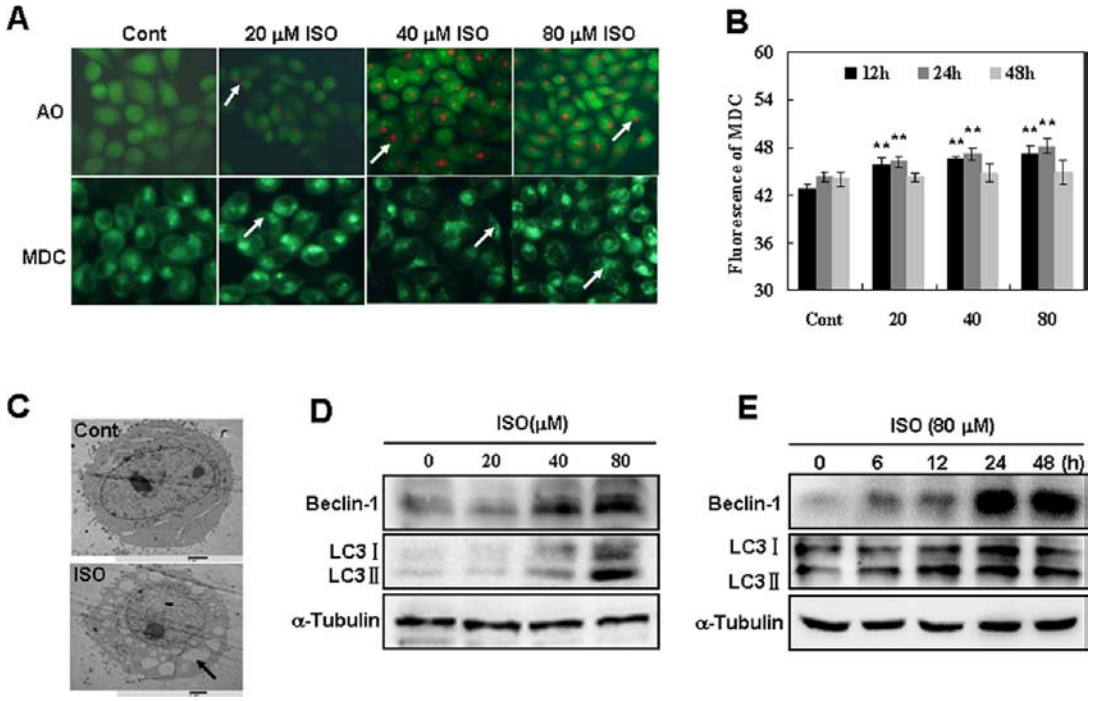

Figure 2. ISO induces autophagy in HepG2 cells. (A) Cells were seeded at a density of 1×10^5 cells/mL in 96-well polystyrene culture plates at 37 °C with 5% (v/v) CO_2 for 1 day. Then, cells were incubated with variable concentrations of ISO for 24 h, then exposed to AO and MDC, and observed by fluorescent microscopy. Arrows indicated the cells containing autophagic vacuoles. (B) Cells were incubated with variable concentrations of ISO for 12, 24, and 48 h, respectively, and were determined by the microplate reader of MDC staining at the emission wavelength of 525 nm. The results are shown as the mean ± SD of nine separate experiments. (**) $p < 0.01$ versus the corresponding control. (C) TEM shows the ultrastructure of cells treated with 80 μM ISO for 24 h. Arrows indicate autophagosomes, including residual digested material and empty vacuoles. (D) Cells were incubated with variable concentrations of ISO for 24 h, and (E) cells were treated with ISO at 80 μM for 0, 6, 12, 24, and 48 h before collection and lysis, respectively. Beclin-1 and LC3 were assessed by western blot analysis, and α-tubulin was used as an internal control.

desiccated with a range of ethanol concentrations and embedded in epoxy resin. The resin was polymerized at 30 °C for 24 h and 60 °C for 48 h, respectively. Ultrathin sections obtained with an ultramicrotome were stained with uranyl acetate and lead citrate and examined under TEM (HT7700, Hitachi, Japan).

Measurement of Mitochondrial Membrane Potential (MMP) by JC-1. The MMP was measured using the mitochondria-specific lipophilic cationic fluorescence dye JC-1. As a monomer, JC-1 is capable of selectively entering the mitochondria. Under normal conditions, JC-1 aggregates within the mitochondria and emits red fluorescence, but when the MMP collapses during apoptosis, JC-1 emits green fluorescence. The ratio of red/green JC-1 fluorescence reflects the change in MMP. Cells were seeded into 96-well polystyrene culture plates. After treatment, medium was removed from each well and 100 μL of 5 μg/mL JC-1 was added to the cells for 1 h. Finally, cells were washed twice with PBS and then quantitatively analyzed by a microplate reader (Molecular Devices Co., Sunnyvale, CA).

Detection of Intracellular Reactive Oxygen Species (ROS) Production. Cellular ROS was measured with 2′,7′-dichlorodihydrofluorescein diacetate (H_2DCFDA, Sigma). This dye is a stable nonpolar compound that diffuses readily into cells and yields DCFH. Intracellular ROS in the presence of peroxidase changes DCFH to the highly fluorescent compound DCF. Thus, the fluorescent intensity is proportional to the amount of ROS produced by the cells. After treatment, 10 μM H_2DCFDA was added to the wells for 30 min at 37 °C. Then, cells were washed twice with PBS, lysed in cell lysates, and centrifuged at 15000*g* for 10 min at 4 °C. The DCF fluorescence intensity of the supernatant was measured via a fluorescence microplate reader at 485 nm excitation and 535 nm emission. Cellular ROS levels were expressed as relative DCF fluorescence per microgram of protein.[20]

AO–Ethidium Bromide (EB) and Hoechst 33258 Staining Assay. Cells were seeded into 35 mm polystyrene culture dishes at a seeding density of 1×10^4 cells/mL and cultured with 2 mL of cell culture medium overnight. After treatment, cells were washed with PBS twice, and then cells were incubated with 5 μL of 100 μg/mL AO–EB at room temperature in the dark, followed by observation under a fluorescence microscope. Cells were stained with 1 mg/mL Hoechst 33258 for 30 min at 37 °C and observed using a fluorescence microscope (Olympus Optical Co., Ltd., Tokyo, Japan).

Sodium Dodecyl Sulfate (SDS)–Polyacrylamide Gel Electrophoresis (PAGE) and Western Blot Analysis. After the cells were subjected to the indicated treatments, they were harvested and lysed with cell lysis buffer (Beyotime Institute of Biotechnology, Jiangsu, China) and nuclear extraction reagent (Xianfeng Biotechnology, Xian, China) as cytosolic extract (cytosol) and nuclear extract (nucleus), respectively. The total protein concentration was determined using the BCA protein kit (Thermo Fisher, Shanghai, China). The homogenates were treated with SDS sample buffer and then immediately heated at 95 °C for 10 min. The proteins were separated by SDS–PAGE and electrotransferred onto a polyvinylidene fluoride (PVDF) membrane (0.45 μm, Millipore) using a semi-dry transfer apparatus (Bio-Rad, Shanghai, China). Blocking was carried out for 2 h in 5% nonfat dry milk in TBST (20 mM Tris, 166 mM NaCl, and 0.05% Tween 20 at pH 7.5). Then, the membrane was washed with TBST for 15 min. The primary antibodies were added at the manufacturer-recommended dilutions in TBST buffer overnight at 4 °C. Secondary antibodies were added and incubated at 25 °C for 2 h. The blots were subjected to another three washes with TBST, developed with a chemiluminescent substrate (Thermo Fisher, China), and exposed using a Molecular Imager ChemiDoc XRS system (Bio-Rad, Shanghai, China).

Statistical Analysis. All experiments were performed 3 times, and the data are presented as the mean ± standard error (SE). Significant differences between measurements for the control and treated samples were analyzed using one-way factorial analysis of variance (ANOVA), followed by Duncan's post-hoc test (SPSS 16.0).

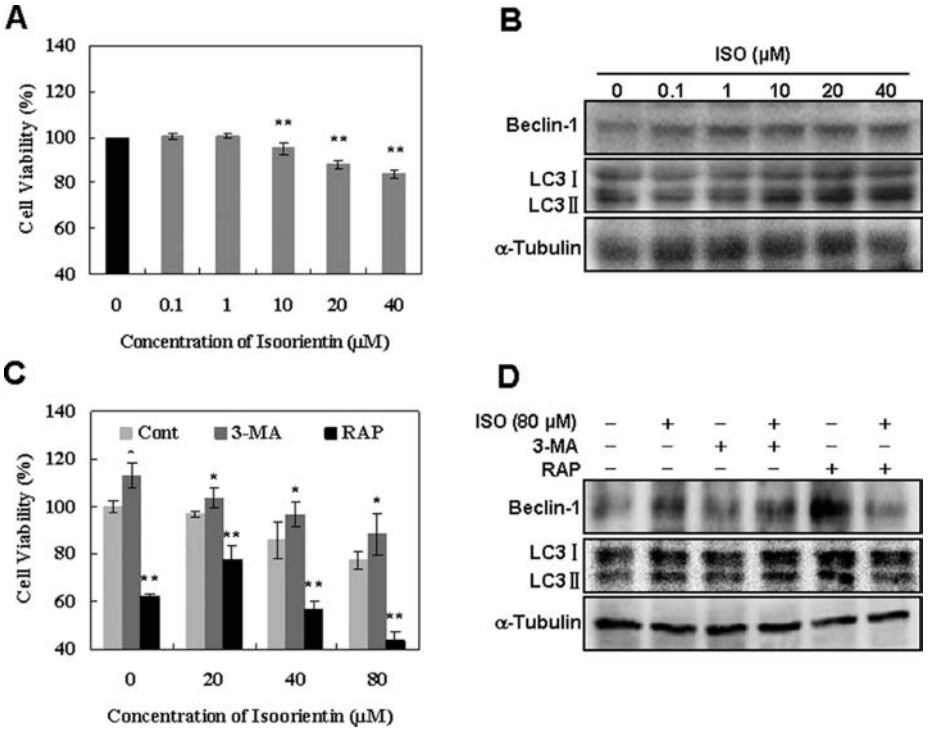

Figure 3. ISO induces autophagic cell death in HepG2 cells. (A) Cells were incubated with ISO at the indicated concentrations for 24 h and then processed for MTT assay. (B) Representative immunoblots for Beclin-1 and LC3 are shown. (C) Cells were incubated with variable concentrations of ISO for 24 h in the presence of 3-MA or RAP, respectively, and then processed for the MTT assay. The results are shown as the mean ± SD of nine separate experiments. (**) $p < 0.01$ and (*) $p < 0.05$ versus the corresponding control. (D) Cells were pretreated with 3-MA or RAP prior to exposure to ISO, respectively. Beclin-1 and LC3 were assessed by western blot analysis. α-Tubulin was used as an internal control.

RESULTS

Effect of ISO on Apoptosis in HepG2 Cells. Apoptosis includes two major pathways: the cell-death-receptor-mediated (extrinsic) apoptotic pathway and the mitochondrial-mediated (intrinsic) apoptotic pathway. We found that ISO induces apoptosis in HepG2 cells through the mitochondrial-mediated (intrinsic) apoptotic pathway. In the present study, we examined the effect of ISO on the cell-death-receptor-mediated (extrinsic) apoptotic pathway. As shown in Figure 1B, ISO increased the levels of TNF-α in HepG2 cells in a dose-dependent manner, but there was no significant difference in the TNF-α levels between the ISO-treated group and control group. ISO also notably increased the protein expression of Fas and FasL, decreased caspase-8 levels, and eventually caused the cleavage of Bid, increasing the protein levels of t-Bid (Figure 1C). In addition, we also found that ISO markedly increased p53 levels and the protein expression of NF-κB in the cytosol and decreased the phosphorylation of IκB and the level of NF-κB in the nucleus (Figure 1D). These results indicated that ISO induced apoptosis in HepG2 cells by activating the Fas receptor-mediated apoptotic pathway, increasing p53 levels and blocking the nuclear translocation of NF-κB.

Effect of ISO on Autophagy in HepG2 Cells. To investigate whether ISO induces autophagy in HepG2 cells, we examined the formation of autophagic vacuoles using the specific fluorescent dyes AO and MDC. Figure 2A shows predominantly green fluorescence in the control cells and considerable red fluorescence in a dose-dependent manner in the cells treated with ISO. ISO treatment also resulted in an increase in the accumulation of MDC, indicating an increased formation of the MDC-labeled vacuoles compared to the untreated cells. Furthermore, the fluorescence intensity of MDC was significantly ($p < 0.01$) enhanced by ISO in a dose- and time-dependent manner and reached its maximum intensity at an ISO dose of 80 μM for 24 h (Figure 2B). A TEM assay confirmed that numerous autophagic vacuoles and empty vacuoles were present in the HepG2 cells treated with 80 μM ISO (Figure 2C). Additionally, the expression level of Beclin-1 and the conversion of LC3-I to LC3-II, both of which indicate autophagy, were increased after ISO treatment in a dose- and time-dependent manner and reached their maximum levels at an ISO dose of 80 μM for 24 h (panels C and D of Figure 2). Taken together, the results suggest that ISO induces autophagy in HepG2 cells.

Effect of Autophagy on ISO-Induced Cell Death in HepG2 Cells. A significant inhibition in cell viability was observed in the ISO high-concentration groups (10, 20, and 40 μM), while no significant effects were observed in the lower concentration groups (0.1 and 1 μM) (Figure 3A), and the IC_{50} of ISO was 71.77 μM. There were also no significant changes in the protein expression of Beclin-1 and LC3-II in cells treated with ISO at 0.1 and 1 μM (Figure 3B). More importantly, the effects of the autophagy inhibitor 3-methyladenine (3-MA) and the autophagy activator rapamycin (RAP) on cell viability were also examined (Figure 3C); the results showed that 3-MA significantly ($p < 0.05$) increased cell viability and weakened the inhibitory effect of ISO on cell viability. However, RAP notably ($p < 0.01$) decreased cell viability and strengthened the inhibitory effect of ISO on cell viability. Additionally, 3-MA diminished the expression levels of Beclin-1 and LC3-II, and RAP increased their expression in HepG2 cells (Figure 3D). These results indicated that ISO induced autophagic cell death to decrease cell viability of HepG2 cells.

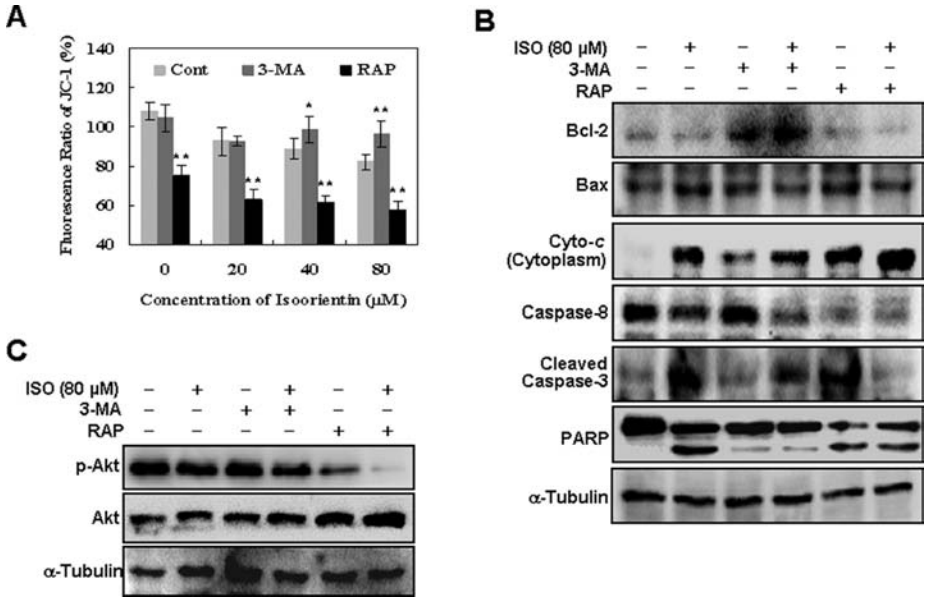

Figure 4. Effect of autophagy inhibitor and activator on ISO-induced apoptosis. (A) Cells were incubated with variable concentrations of ISO for 24 h in the presence of 3-MA or RAP, respectively. Then, cells were stained with JC-1 at 37 °C for 1 h. The fluorescence intensity of JC-1 was detected by a multifunctional microplate reader. The results are expressed as the mean ± SD of nine separate experiments. (**) $p < 0.01$ and (*) $p < 0.05$ versus the corresponding control. Representative image of immunoblots for (B) autophagic marker proteins and (C) Akt and p-Akt. α-Tubulin was used as an internal control.

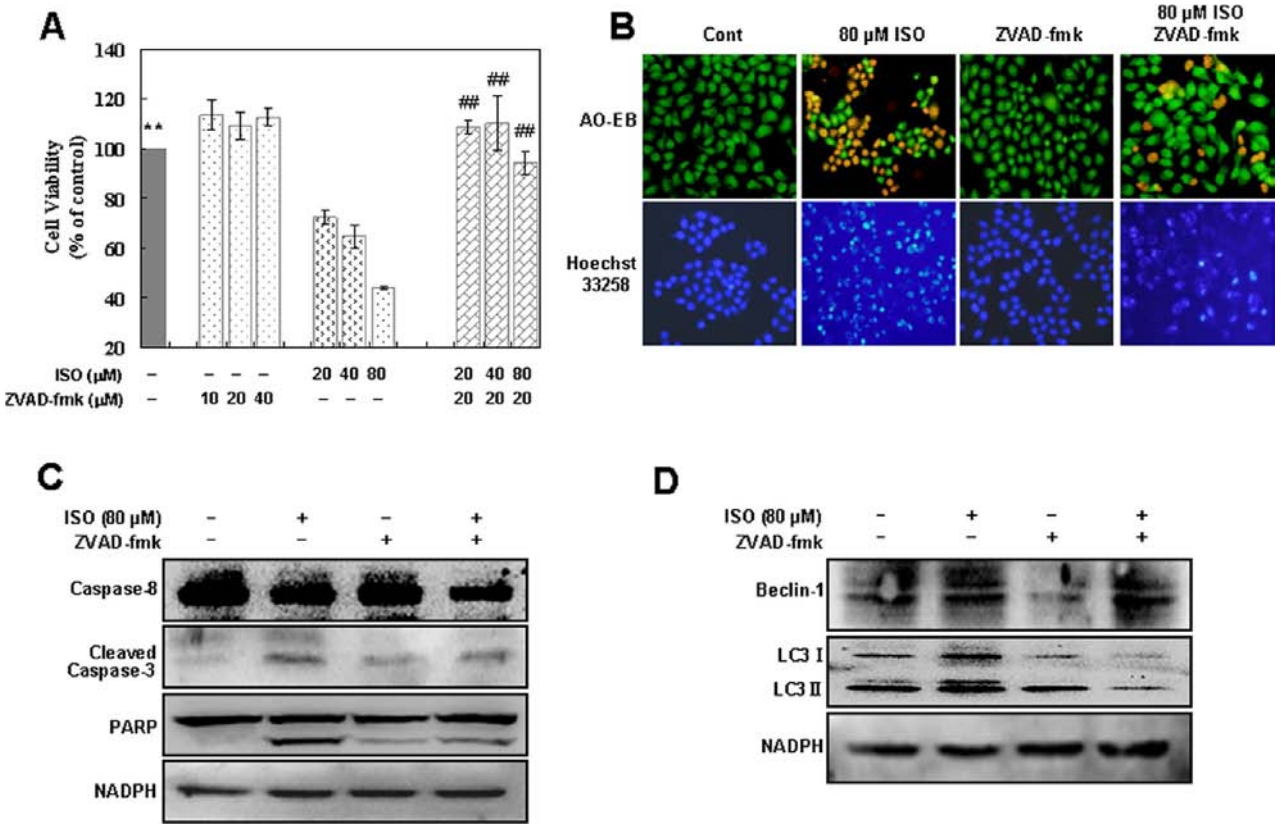

Figure 5. Effect of the apoptosis inhibitor on ISO-induced autophagy in HepG2 cells. (A) Cells were incubated with ISO for 48 h in the presence of ZVAD-fmk and then processed for the MTT assay. The results are shown as the mean ± SD of nine separate experiments. (**) $p < 0.01$ versus other treatments and (##) $p < 0.01$ versus the ISO treatment group. (B) Cells were incubated with ISO for 24 h in the presence of ZVAD-fmk, and then cells were exposed to AO−EB or Hoechst 33258. Green cells were counted as live cells; yellow cells were counted as early apoptotic cells; and orange cells were counted as late apoptotic cells. Chromatin condensation and nuclear fragmentation were considered to indicate apoptotic cells. Scale bar = 50 μm. (C) Caspase-8, cleaved caspase-3, and PARP and (D) Beclin-1 and LC3 were assessed by western blot analysis. NADPH was used as an internal control.

dx.doi.org/10.1021/jf500903g | J. Agric. Food Chem. 2014, 62, 5390−5400

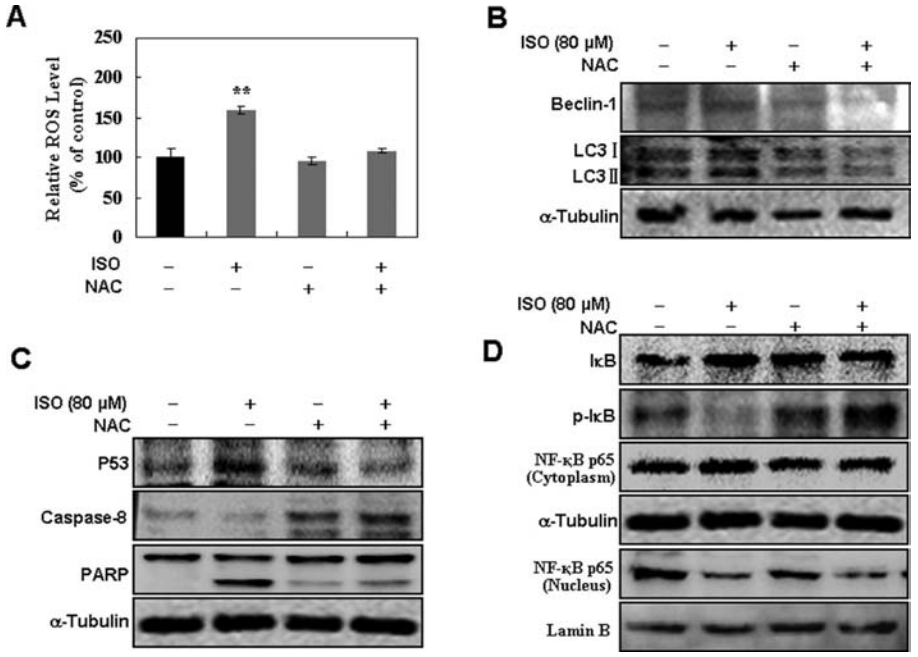

Figure 6. Effect of ROS on ISO-induced autophagy and NF-κB signaling pathway. (A) After treatment, cells were stained with H_2DCFDA for 30 min prior to detection using a fluorescence microplate reader. The results are expressed as the mean ± SD of nine separate experiments. (**) $p < 0.01$ versus the control group. (B) Beclin-1 and LC3 were assessed by western blot analysis. (C) Protein expressions of p53, caspase-8, and PARP were analyzed by western blotting. (D) Protein expressions of the NF-κB signaling pathway were analyzed by western blotting. α-Tubulin and lamin B were used as an internal control.

A complicated interplay exists between autophagy and apoptosis. To demonstrate whether ISO-triggered autophagy promotes or inhibits apoptosis, we examined apoptotic markers after treatment with the autophagy inhibitor 3-MA and the autophagy activator RAP. As shown in Figure 4A, 3-MA significantly ($p < 0.01$) attenuated the MMP collapse induced by ISO, while RAP increased MMP levels. In addition, in comparison to ISO alone, 3-MA markedly inhibited the expression of Bax, cytochrome *c* (in the cytoplasm), cleaved caspase-3, and PARP and increased the levels of Bcl-2 and caspase-8 in the presence of ISO (Figure 4B). In contrast, RAP notably enhanced the effects of ISO on the expression of these proteins. Furthermore, 3-MA significantly increased the phosphorylation of Akt. RAP strongly suppressed the phosphorylation of Akt, not only by itself but also in the presence of ISO (Figure 4C). These results suggest that the suppression of autophagy diminished the ISO-induced apoptosis in HepG2 cells.

To confirm these results, we further investigated the effect of the apoptosis inhibitor ZVAD-fmk on HepG2 cells. As shown in Figure 5A, the cell viability inhibition caused by ISO was strongly ($p < 0.01$) decreased in the presence of ZVAD-fmk and ZVAD-fmk alone did not have any cytotoxic effects. The fluorescence microscopy showed that the typical characteristics of apoptosis, such as cell shrinkage, chromatin condensation, and EB signals, were obviously attenuated in the cells treated with ZVAD-fmk and that ZVAD-fmk strongly reversed the apoptosis-inducing effect of ISO (Figure 5B). Other apoptotic hallmarks, including caspase-8, cleaved caspase-3, and PARP cleavage, were also suppressed by ZVAD-fmk in ISO-treated cells (Figure 5C). Additionally, ZVAD-fmk markedly decreased Beclin-1 and LC3-II levels, which had been increased by ISO, indicating that the inhibition of apoptosis blocks autophagy (Figure 5D). Taken together, these results suggest that ISO decreased cell viability simultaneously by inducing apoptosis and autophagy in HepG2 cells.

Effect of ISO-Stimulated ROS on Apoptosis and Autophagy. The molecular crosstalk between apoptosis and autophagy processes is complex, and they both may be triggered by common upstream signals; therefore, we next determined which interactions are demonstrated in the apoptosis and autophagy in HepG2 cells. Accumulating evidence indicates that intracellular ROS can trigger apoptosis and autophagy. We examined whether ROS stimulated by ISO induced apoptosis and autophagy in HepG2 cells. The ROS inhibitor NAC markedly ($p < 0.01$) decreased ROS generation, not only by itself but also in the presence of ISO (Figure 6A). NAC also significantly suppressed the protein expression of Beclin-1 and LC3-II and strongly reduced the effects of ISO on the expression of those proteins (Figure 6B). This suggests that a higher level of ROS may directly initiate autophagy. Similarly, a significant decrease in p53 and PARP cleavage and a increase in caspase-8, p-IκB, and NF-κB p65 (in the nucleus) were observed in NAC-treated cells (panels C and D of Figure 6). Taken together, these results showed that ROS is involved in the p53 signaling pathway, the phosphorylation of IκB, and the nuclear translocation of NF-κB as an upstream signal and that intracellular ROS controls apoptosis and autophagy induced by ISO.

Effect of the PI3K/Akt Signaling Pathway on Apoptosis and Autophagy. The PI3K/Akt signaling pathway is involved in the regulation of the cell cycle, growth, survival, metabolism, and tumorigenesis. In a previous study, we found that ISO induced apoptosis by inhibiting the PI3K/Akt pathway in HepG2 cells. To investigate the effect of the PI3K/Akt pathway on the crosstalk between the processes of apoptosis and autophagy, cells were pretreated with the PI3K/Akt inhibitor LY294002 prior to being exposed to ISO.

dx.doi.org/10.1021/jf500903g | J. Agric. Food Chem. 2014, 62, 5390−5400

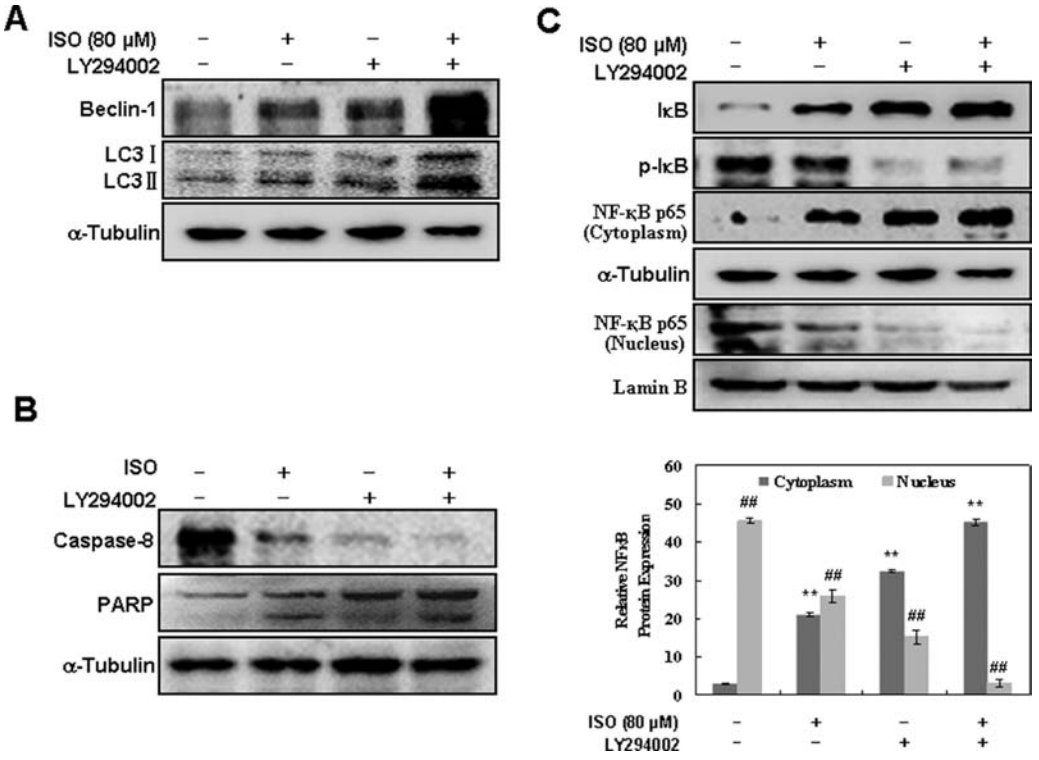

Figure 7. Effect of PI3K/Akt on ISO-induced autophagy and NF-κB. (A) Cells were incubated with 20 μM PI3K/Akt inhibitor LY294002 in the presence or absence of ISO. Beclin-1 and LC3 were assessed by western blot analysis. (B) Representative image of immunoblots for caspase-8 and PARP. (C) Protein expressions of NF-κB signaling pathway were analyzed by western blotting. α-Tubulin and lamin B were used as an internal control. The graph shows the levels of NF-κB in cytoplasm and nucleus. The densitometric analysis shows the mean ± SD of four independent experiments. (**) $p < 0.05$ and (##) $p < 0.05$ versus the control of cytoplasm and nucleus, repectively.

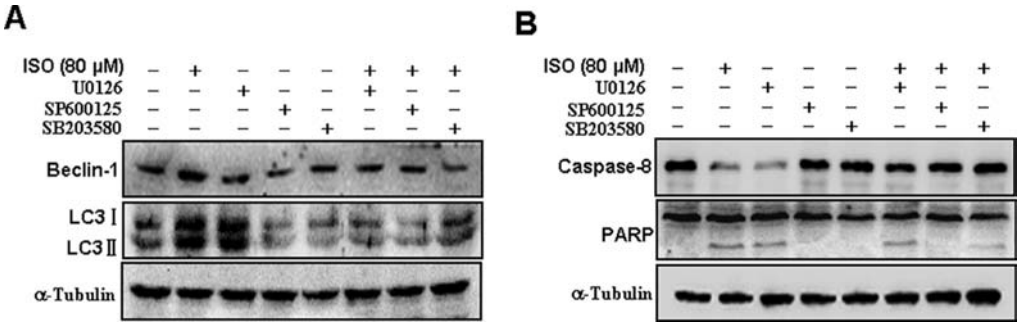

Figure 8. Effect of the MAPK signaling pathway on ISO-induced autophagy and apoptosis. Cells were treated with 5 μM U0126 (an ERK1/2 inhibitor), 10 μM SP600125 (a JNK inhibitor), or 10 μM SB203580 (a p38 inhibitor) for 30 min prior to exposure to ISO (80 μM) for 24 h. Representative images of immunoblots for (A) Beclin-1 and LC3 and (B) caspase-8 and PARP. α-Tubulin was used as an internal control.

In comparison to the control group, LY294004 markedly increased the protein expression of Beclin-1 and LC3-II, not only by itself but also in the presence of ISO (Figure 7A). Additionally, LY294004 significantly decreased caspase-8 levels and increased PARP cleavage levels in both the presence and absence of ISO (Figure 7B). Also, LY294004 obviously inhibited the phosphorylation of IκB and the nuclear translocation of NF-κB (Figure 7C). These data indicate that ISO induced apoptosis and autophagy simultaneously by inhibiting the PI3K/Akt signaling pathway.

Effect of the MAPK Signaling Pathway on ISO-Induced Apoptosis and Autophagy. To investigate the effect of the MAPK pathway on apoptosis and autophagy, cells were pretreated with U0126 (an ERK1/2 inhibitor), SP600125 (a JNK inhibitor), and SB203580 (a p38 inhibitor) prior to being exposed to ISO. As shown in Figure 8A, both SP600125 and SB203580 decreased the levels of Beclin-1 and LC3-II individually and in the presence of ISO and weakened the induced effect of ISO on the protein expression of Beclin-1 and LC3-II. It was interesting that the significant increase in Beclin-1 and LC3-II levels was observed in cells that were treated with U0126 alone, while U0126 inhibited the effect of ISO on Beclin-1 and LC3-II levels. In addition, U0126 markedly increased cleaved caspase-8 levels and PARP cleavage in the absence of ISO but did not change the activation effects of ISO on those protein levels. In contrast, SP600125 and SB203580 notably inhibited the levels of PARP cleavage, increased the protein expression of caspase-8, and reversed the activation effects of ISO on those protein levels (Figure 8B). Taken together, these results indicate that ISO induced apoptosis and autophagy by activating JNK and p38.

(A) Protein expressions of NF-κB signaling pathway were analyzed by Western blotting. (B) Representative images of immunoblots for Beclin-1 and LC3 and (C) apoptotic marker proteins. α-Tubulin was used as an internal control. The graph shows the relative expression of cleaved caspase-3. The densitometric analysis shows the mean ± SD of four independent experiments. (**) $p < 0.05$ versus the control.

dx.doi.org/10.1021/jf500903g | J. Agric. Food Chem. 2014, 62, 5390−5400

Effect of p53 on ISO-Induced Apoptosis and Autophagy. The effect of p53 on autophagy depends upon the cellular context. To determine the effects of p53 on autophagy and apoptosis, cells were exposed to the p53 inhibitor pifithrin-α prior to treatment with ISO. As shown in Figure 9A, pifithrin-α significantly inhibited the protein expression of p53, Beclin-1, and LC3-II and reversed the effects of ISO on p53, Beclin-1, and LC3-II (Figure 9A). This suggests that p53 promotes ISO-induced autophagy in HepG2 cells. In contrast, pifithrin-α upregulated the phosphorylation of IκB and the protein expression of NF-κB in the nuclear fraction of the cells (Figure 9B), indicating that p53 is involved in the activation of NF-κB as an upstream signaling molecule. Additionally, the upregulation of the Bax/Bcl-2 ratio, the release of cytochrome *c* into the cytosol, and an increase in the levels of cleaved caspase-3 and PARP cleavage were observed in pifithrin-α-treated cells in both the absence and presence of ISO (Figure 9C). Taken together, these data indicated that the activation of p53 induced apoptosis and autophagy in HepG2 cells.

Effect of NF-κB Activation on ISO-Induced Apoptosis and Autophagy. Accumulating evidence indicates that the activation of NF-κB inhibits apoptosis, activates autophagy, and regulates cell survival pathways. To confirm this evidence, cells were treated with the NF-κB inhibitor pyrrolidinedithiocarbamic acid (PDTC) prior to being exposed to ISO. PDTC notably decreased the phosphorylation of IκB and the protein levels of NF-κB in the nuclear fraction of the cells (Figure 10A). A significant decrease in the expression of Beclin-1 and LC3-II was also observed in cells treated with PDTC alone and in cells treated with PDTC and ISO (Figure 10B). In contrast, PDTC alone and with ISO caused a strong upregulation of cytochrome *c* (in the cytosolic fraction), cleaved caspase-3, and PARP cleavage levels, and PDTC enhanced the effects of ISO on these protein levels (Figure 10C). These results suggest that the inhibition of NF-κB suppresses autophagy and promotes apoptosis.

DISCUSSION

ISO is a naturally occurring *C*-glycosyl flavone and has been reported to reduce the proliferation of HepG2 cells, with no significant cytotoxicity on human liver cells (HL-7702) and buffalo rat liver cells (BRL-3A).[18] The present study showed that ISO induced cell death by activating both apoptosis and autophagy, which coexist and promote each other in HepG2 cells. ISO was able to induce apoptosis by activating the Fas receptor-mediated apoptotic pathway and suppressing the p53 and PI3K/Akt-dependent NF-κB signaling pathway. Also, we found that ROS-mediated p53, PI3K/Akt, JNK, and p38 were the common upstream signals that simultaneously triggered apoptosis and autophagy.

Apoptosis is a programmed cell death process, and a multitude of studies have suggested that the activation of apoptosis in tumor cells is an effective form of chemotherapy designed to hinder the development and progression of cancer.[3] Autophagy is another programmed cell death process, and it can have two effects on tumors. First, by removing damaged organelles, regenerating metabolic precursors, and reducing chromosomal instability, it aids the survival of cancer cells in a low-nutrient environment and increases the resistance of cancer cells to anticancer treatments preventing tumor suppression.[21] On the other hand, autophagy prevents tumor transformation and facilitates senescence, necrosis, and inflammation, processes that are induced by oncogenes; thus, autophagy eventually limits tumor growth.[22] A low level of constitutive autophagy has an important housekeeping role in cellular metabolism and is crucial for maintaining healthy cells. However, excessive autophagy or the activation of autophagy in a specific context has been implicated in autophagic cell death and may be harmful.[23] Numerous studies have revealed that autophagy is linked to cell death under certain circumstances. For example, the upregulation of autophagy contributes to the progress of cadmium-induced nephrotoxicity.[24] Also, our results showed that ISO decreased cell viability by inducing autophagic cell death in HepG2 cells (Figure 3).

Both apoptosis and autophagy are essential cellular degradation pathways that are often induced by similar stimuli and regulated by similar pathways. However, the relationship between apoptosis and autophagy is multifaceted, complex, and controversial. In some cellular settings, autophagy is necessary for apoptosis to occur. In other cellular settings, autophagy suppresses or delays apoptosis as a stress adaptation, and in some cell systems, the two processes occur independently.[8,25,26] In summary, autophagy and apoptosis can cooperate, antagonize, or assist each other to differentially influence the fate of the cell. It has been repotred that vitamin K2 induces autophagy and apoptosis simultaneously in leukemia cell,[4] and the survivin suppressant YM155 inhibits growth in both PC3 and LNCaP prostate cancer cells by inducing the autophagy-dependent apoptosis.[27] In the present study, the autophagy inhibitor 3-MA markedly inhibited ISO-induced apoptosis, and the apoptosis inhibitor ZVAD-fmk significantly decreased ISO-induced autophagy (Figures 4 and 5), suggesting that apoptosis and autophagy could exist simultaneously and work cooperatively in ISO-treated HepG2 cells.

ROS regulates a number of cellular pathways and, thus, plays critical roles in determining the fate of cells.[28] Accumulating evidence has revealed that autophagy can be stimulated in response to ROS injury in cancer cells, and ROS may have synergetic effects in apoptosis and autophagy.[29] Consistent with previous studies, we also found that both the autophagic markers (Beclin-1 and LC3-II) and apoptotic markers (caspase-8 and PARP) were suppressed by the ROS inhibitor NAC in ISO-treated cells (panels B and C of Figure 6). Our previous research showed that ROS is an upstream signal involved in the effects of ISO on the PI3K/Akt and MAPK signaling pathways, which impact apoptosis.[18,19] Numerous studies have demonstrated that autophagic cell death is triggered by the MAPK and PI3K/Akt pathways.[30−32] We further investigated the roles of the PI3K/Akt and MAPK pathways on the interactions of the apoptosis and autophagy processes. The results showed that the PI3K/Akt inhibitor LY294004 markedly increased autophagy; similarly, LY294004 notably promoted ISO-induced apoptosis (Figure 7), indicating that ISO simultaneously induced apoptosis and autophagy by inhibiting the PI3K/Akt signaling pathway. The mechanism behind this is the inhibition of the phosphorylation of mTOR by LY294002, resulting in the phosphorylation of autophagy protein-13 and the suppression of autophagy.[1] LY294002 also inhibits the phosphorylation of pro-apoptotic proteins, such as Bad, Bax, and caspase-9.[33,34] In addition, SP600125 (a JNK inhibitor) and SB203580 (a p38 inhibitor) obviously decreased autophagy that was induced by ISO (Figure 8A), and both SP600125 and SB203580 significantly inhibited ISO-induced apoptosis (Figure 8B). The effects of JNK and p38 on apoptosis and autophagy were consistent, because JNK and p38 kinases modulate the

expression and translocation of Bcl-2 and Bax in apoptotic cells.[35,36] JNK is able to trigger autophagy by targeting Bcl2/BclXL proteins and abrogating their binding to Beclin-1,[37] and p38 catalyzes the phosphorylation of mTOR.[38]

Furthermore, we found that the ROS inhibitor NAC also reversed the inhibitory effect of ISO on the protein expression of p53 and the nuclear translocation of NF-κB (panels C and D of Figure 6). The tumor suppressor p53 plays a major role in cell cycle arrest and/or apoptosis during the response of mammalian cells to stress, and p53 mutations and functional inactivation are linked to the pathology of more than half of all cancers.[39,40] Furthermore, p53 can both promote and inhibit autophagy, depending upon the cellular conditions.[8] In the current study, a p53 inhibitor promoted the induction of apoptosis by ISO and NF-κB nuclear translocation and inhibited autophagy (Figure 9). The transcription factor NF-κB is involved in the regulation of survival, death, differentiation, and migration.[41] The present study has shown that the NF-κB inhibitor PDTC efficiently suppressed ISO-induced autophagy and enhanced ISO-induced apoptosis (Figure 10). The results from several other studies also indicated that p53 and NF-κB promote apoptosis over autophagy.[42,43]

In summary, this study demonstrated that ISO simultaneously induced apoptosis and autophagy by inhibiting the ROS-related PI3K/Akt signaling pathway and activating the ROS-related JNK and p38 pathways. Moreover, ISO induced apoptosis by activating the Fas receptor-mediated apoptotic pathway and suppressing the p53 and PI3K/Akt-dependent NF-κB signaling pathway, with the subsequent increase in the release of cytochrome *c*, caspase-3 activation, and PARP cleavage. A schematic diagram of these observed effects of ISO is shown in Figure 11. These findings indicate that ISO inhibited cell viability by both apoptosis and autophagy and that autophagy induction by ISO may be a novel therapeutic method for the treatment of cancer.

Detection of Melamine in Foods Using Terahertz Time-Domain Spectroscopy

ABSTRACT: The aim of this study was to investigate the feasibility of detecting melamine in foodstuffs using terahertz imaging. The terahertz (THz) spectra and images of melamine mixtures were obtained in the frequency range of 0.1−3 THz at room temperature using THz time-domain spectroscopy. Characteristic absorption peaks of melamine were found at 2, 2.26, and 2.6 THz, and these peaks showed the same frequencies in the different food matrices. At 2 THz, the THz images of melamine were dose-dependently distinguishable from those of food components with or without the packaging materials used. The calibration curve of melamine showed a regression coefficient (R^2) of >0.913 and a detection limit of <13%. These results suggest that terahertz imaging has the potential to be used for the qualitative detection of melamine in food as a nondestructive analytical tool.

KEYWORDS: *melamine, terahertz time-domain spectroscopy, terahertz imaging, food matrices*

INTRODUCTION

Melamine (1,3,5-triazine-2,4,6-triamine) is a nitrogen-rich molecule ($C_3H_6N_6$), with 40% nitrogen by number of atoms. Because of its high nitrogen content, this chemical has been illegally added to foods such as milk powder to increase the total nitrogen concentration, which is used as an indicator to estimate the protein content. Ingestion of melamine by pets, cattle, and infants is known to lead to serious health problems related to the reproductive system and kidneys, and it can cause death in some cases.[1] Currently, regulatory limits of 0.5−2.5 mg/kg in general food and feed and a tolerable daily intake of 0.2 mg/kg body weight/day for melamine are set by several countries and organizations.[1] Therefore, because it is of great concern for food safety, a rapid and accurate measurement method to detect this contaminant in foods is required, particularly for packaged foods.

Terahertz time-domain spectroscopy (THz-TDS) can be used as a detection method with the advantages of fast analysis and simplicity. The absorption features in the THz region are dominated by intermolecular vibrations corresponding to motion associated with coherent, delocalized movements of large numbers of atoms and molecules.[2,3] Because these properties are unique to a particular molecule, it is possible to obtain a "THz absorption peak", enabling the identification of a compound.[3,4] It was reported that THz-TDS was used for the identification of chemicals using the transmission method coupled with the standard pellet technique.[4,5] Although this method has the advantage in qualitative and quantitative analysis of a homogeneous sample, it has a limitation in heterogeneous materials such food. When the spectrum of a sample comprising a heterogeneous mixture is obtained, the differences between components cannot be distinguished clearly because the peaks appear as a sum of each component. To overcome this disadvantage, image mapping of THz spectroscopic data can be used.

The wavelength (100 μm−1 mm) of the THz region can be resolved spatially, which is sufficient for imaging applications; that is, specific absorption peaks can be used for both identification and mapping of chemicals with the spatial distribution of individual chemical components in a heterogeneous mixture. Moreover, the THz wave can determine the differences in density and dielectric constant. This is because the THz wave can penetrate a wide range of dielectric materials, such as clothing, paper, cardboard, wood, plastic, and ceramics.[6] These advantages can be successfully applied to the nondestructive inspection of chemicals.[7]

With this background, we explored the detection of melamine in three food matrices and examined the effect of packaging materials on the nondestructive detection of melamine.

MATERIALS AND METHODS

Sample Preparation. Melamine (Daejung Chemicals & Metals Co., Ltd., Siheung, Korea), HDPE (TeraView Ltd., Cambridge, UK; particle size < 10 μm), and food matrices (flour, milk powder, and chocolate powder) pellets were prepared in different concentrations of

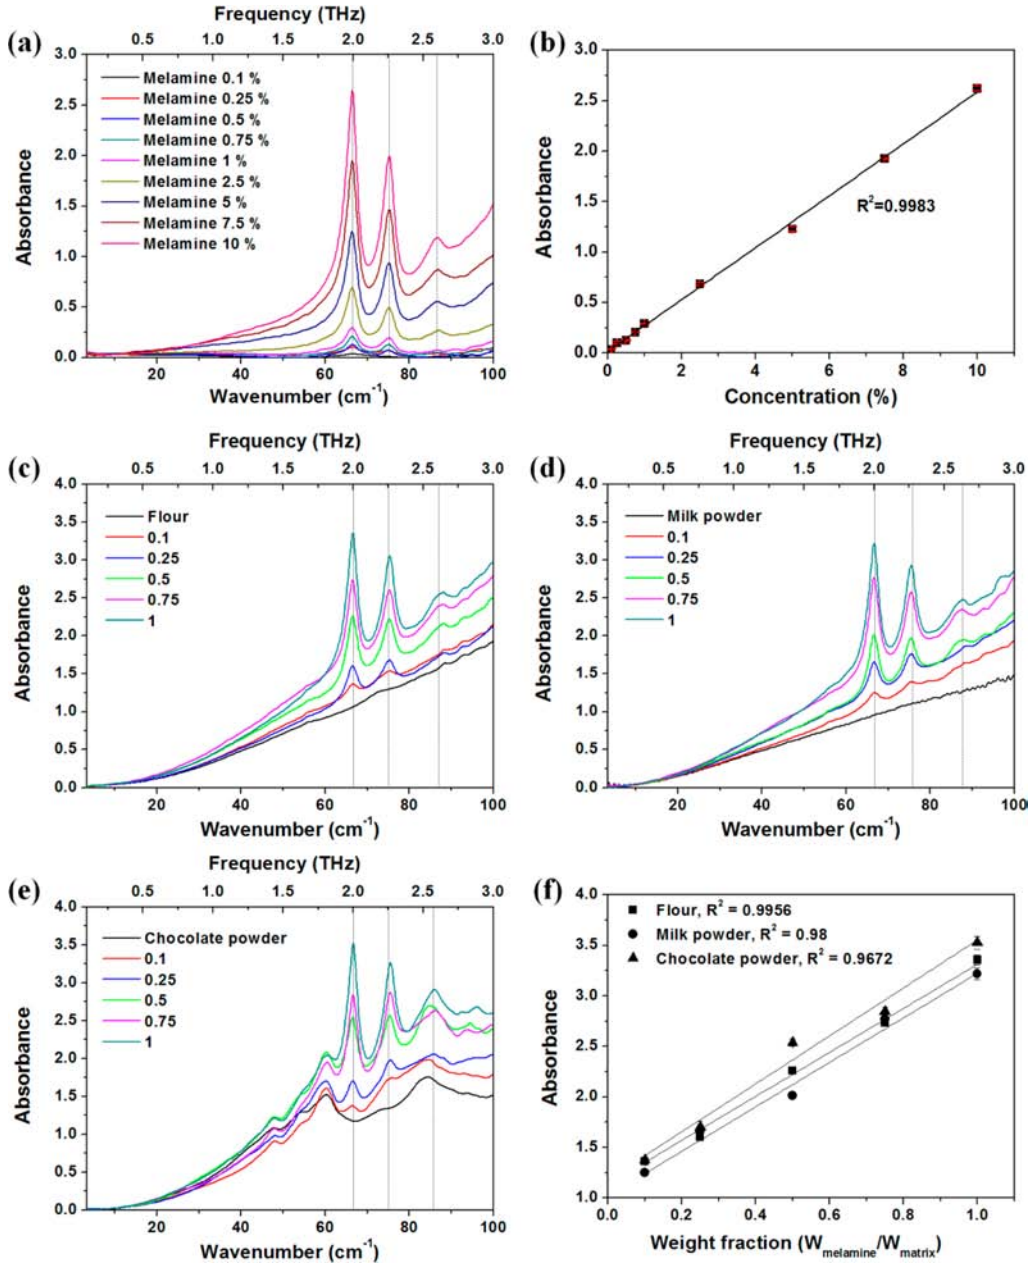

Figure 2. Absorption spectra of melamine mixtures in HDPE (a), flour (b), milk powder (c), and chocolate powder (d) and the calibration curve in HDPE (e) and the fitted curve in food matrices (f). Absorbance was measured using different ratios of melamine to matrices. The calibration curve and fitted curve were for absorbance at each ratio at 2 THz.

melamine, ranging from 0 to 10 wt %. Average particle sizes for flour, milk power, and chocolate powder were 50, 160, and 255 μm, respectively, and the water contents of three food matrices were <14%. The pellets were made of 360 mg of powder, using a hydraulic press (Specac Ltd., Orpington, UK; 13 mm diameter). To examine the effect of the packaging materials, oriented polypropylene/polyethylene (OPP/PE) film (vinyl film, thickness = 40 μm) and roll paper/polyethylene (roll paper/PE) film (paper film, thickness = 80 μm), which are widely used as food packaging materials, were selected. They were fixed at the top and bottom of the sample holder when the THz image was measured (Figure 1).

THz-TDS Spectra. The THz images and spectra of melamine mixtures were measured using a TPS spectra 3000 spectrometer (TeraView Ltd.).[8] This system acquired time-domain data using the time delay between the pulse generation and detection. The samples were measured in a stable and fast scan mode that allows 30 measurements in 1 s. Over a period of 1 min, 1800 scans were taken for each spectrum, and a Blackman−Harris three-term apodization was applied to the Fourier transformation. The signals that were transmitted by the pure HDPE pellets were used as the reference signal, and the signals that were transmitted by the center of the melamine mixture pellets were used as the sample signals.

Image Acquisition. THz spectral images were obtained by raster-scanning the reflected THz beam on the sample (Figure 1). For the analysis of melamine, a THz image was obtained at 2 THz. This was one of the frequencies for the absorption of melamine with a strong and clear peak. THz images were relatively expressed using false color for the THz signal amplitudes. The images indicate the highest THz signal in red and the lowest THz signal in blue.

Data Acquisition. The experiments and analyses were carried out at least in triplicate. Data were expressed as the mean ± standard deviation (n = 10). The calculation and statistical methods utilized were Excel and Origin 8.0 (Origin Lab, Northampton, MA, USA).

The fitted calibration curve of THz signals was extracted at 0% sample signal at 2 THz. The images indicate the highest THz signal in red and the lowest THz signal in blue.

RESULTS AND DISCUSSION

THz Spectra of Melamine in HDPE. The absorption spectra measured with different concentrations of melamine are shown in Figure 2a. The absorption peaks of melamine appeared at 2, 2.26, and 2.6 THz, which correspond to 66.6, 75.3, and 86.6 cm^{-1}, respectively. Harsha et al.[5] reported that melamine had specific absorbance peaks in the region of 0−3 THz. In their study, melamine exhibited absorption peaks at 2.01 and 2.26 THz, which correspond to 67 and 75.3 cm^{-1}, respectively.[5] On the basis of that study and our results, absorption peaks were identified at 2 and 2.26 THz. Because terahertz radiation is sensitive to the vibrational states of the entire molecule, these absorbance peaks were thought to correspond to the vibrational states of melamine.[4] However, further investigation in conjunction with solid-state theory is necessary to establish a relationship between the significant peaks and the molecular structure.[9] Figure 2b shows the calibration curves of absorbance at 2 THz. The calibration curve had a linear regression coefficient of >0.998 and a LOD of <0.2%. Because a linear relationship between the absorbance and the weight ratio was established, the qualitative and/or quantitative detection of melamine using our THz system can be feasible.

THz Spectra of Melamine in Food Matrices. The main absorption feature of melamine was identifiable when melamine was mixed with the three food matrices: flour, milk powder, and chocolate powder. Panels c−e of Figure 2 show the spectra of the melamine and food matrix mixtures measured at five different concentrations. Melamine absorption peaks were clearly identified in all of the measurements. The curves fitted by the absorbance of each pellet are shown in Figure 2f. The curves showed a linear relationship between the absorbance and the weight ratio with a linear regression coefficient (R^2) of >0.967. When the HDPE mixture was compared with the food matrices, a lower sensitivity was observed, possibly caused by scattering.[10]

THz Image of Melamine in HDPE. Figure 3 shows the THz image and THz signals of melamine in HDPE with different weight ratios (0, 1, 2.5, 5, 7.5, and 10%). The THz image and THz signal histogram obtained without wrapping materials are shown in Figure 3a. In the THz images, the false color of the pellets was changed from yellow to red as the concentration of melamine was increased from 0 to 10%. There was a clear contrast of absorption between melamine and the matrix; the false color of the 10% pellet was deep red, but the false color of the 0% pellet was light yellow. The THz images of the samples covered with the two wrapping materials (OPP/PE and roll paper/PE) are shown in Figure 3b,c. From Figure 3a−c we found that the wrapping materials had little effect on the THz image, suggesting that the wrapping materials have high transmittance in the THz region.[6] In Figure 3, the histogram shows the THz signals of each pellet, which increased as the concentration of melamine increased. The calibration curve obtained after the subtraction of 0% sample signal as a reference showed a linear regression coefficient (R^2) of >0.913. Thus, a linear relationship between the weight ratio of melamine and the amplitude of the THz signals is displayed. The LOD of melamine in HDPE was <2.45%, which suggested that the terahertz imaging method can be used to detect melamine in packaged foods.

THz Image of Melamine in Food Matrices. Figure 4 shows the THz images and histograms of melamine and mixtures of food matrices obtained from the amplitude of the THz signal. Those images and histograms were obtained from the samples containing the wrapping materials of OPP/PE wrapping material and roll paper/PE or not. As shown from all of the images, the false color of the pellets changed from yellow to red as the

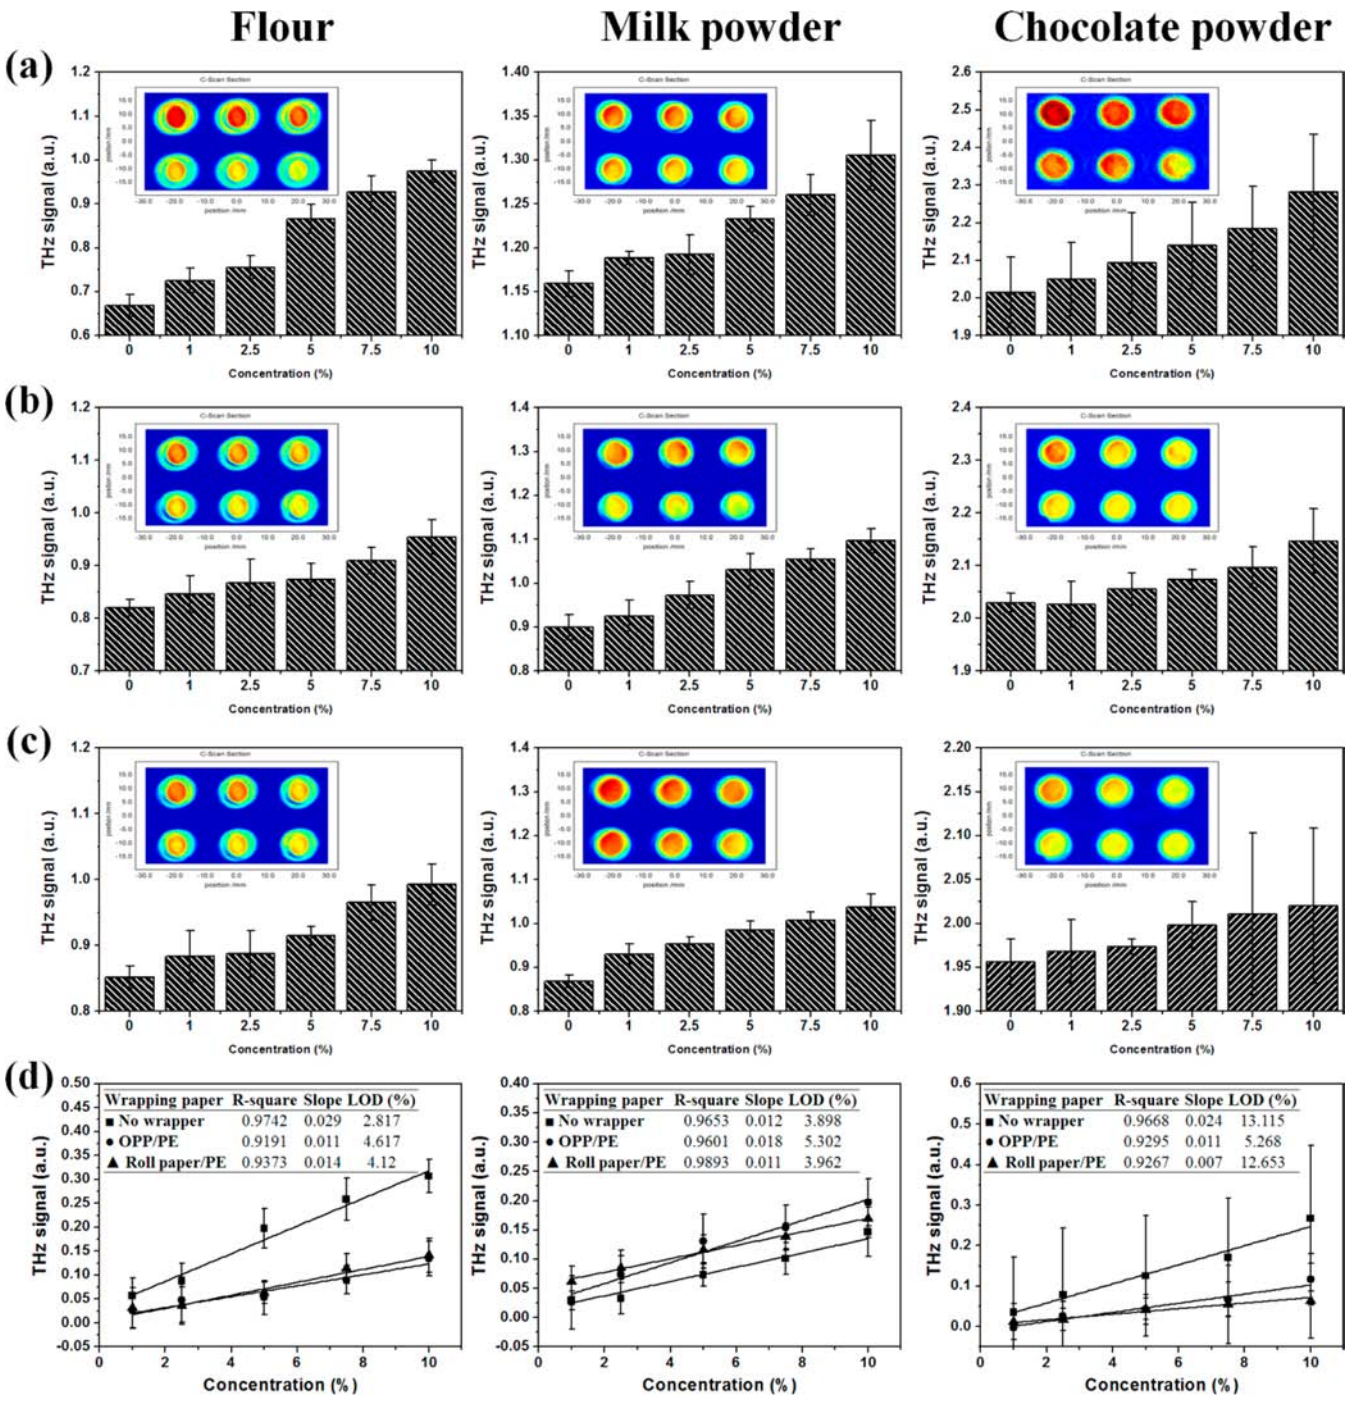

Figure 4. THz images and histograms of melamine in flour, milk powder, and chocolate powder without wrapping materials (a), covered with OPP/PE (b), and covered with roll paper/PE (c) and their fitted calibration curves (d). The fitted calibration curve of THz signals was extracted at 0% sample signal at 2 THz. The images indicate the highest THz signal fin red and the lowest THz signal in blue.

concentration of melamine increased from 0 to 10%. The images of the samples covered with wrapping materials showed a clear contrast of absorption between melamine and the matrix, like the images above. The histograms of the THz signals of each pellet are also shown in Figure 4. Similar to the images, the THz signals increased as the concentration of melamine increased. The calibration curves of THz signals are shown in panel d of Figure 4, for which the THz signal of a 0% sample was subtracted as a blank. The curve showed a linear regression coefficient (R^2) of >0.919, which indicated a good linear relationship between the weight ratio of melamine and the amplitude of the THz signals. The LOD of melamine in food was <13.12%. However, differences in the sensitivity among sample matrices with and without wrapping materials were found; the sensitivity was decreased in flour and chocolate powder covered with two wrapping materials. This decrease was assumed to be due to the combined effects of particle size and chemical composition of sample and wrapping material, and this assumption should be further investigated.

It was reported that terahertz imaging could be used not only for the identification of chemicals but also for the qualitative detection in a heterogeneous mixture.[8] Although the THz

dx.doi.org/10.1021/jf501170z | J. Agric. Food Chem. 2014, 62, 5403−5407

transmission method has a little higher sensitivity and lower LOD than the terahertz imaging method in this study, a terahertz imaging system can be a better choice for certain applications. For example, transmission spectral measurements require sample homogeneity, but the terahertz imaging system does not, because the terahertz imaging system scans the entire sample area, unlike the transmission method in which the THz ray is transmitted through the center of the sample. However, the terahertz imaging system had lower sensitivity and higher LOD than the other analytical methods. Considering that foods and agricultural products may contain contaminants in trace amounts, further research is required to improve the sensitivity and resolution.[11−13]

Overall, our results show the potential of THz-TDS for the qualitative analysis of melamine and for an identification and quantification technique in the food industry. Although THz-TDS cannot reach regulatory limits due to its low sensitivity, the ability of THz waves to pass through a wide variety of packaging materials can be used to characterize the molecular signature of many substances, which makes the terahertz imaging method attractive as a detection tool for enhanced food monitoring. For the routine application of THz spectroscopy, however, further research is required, including the development of a cost-effective THz spectrometer with high sensitivity and spectral databases for a wide variety of food chemicals.

Characteristics of an Organic Solvent-Tolerant β-Fructofuranosidase from *Arthrobacter arilaitensis* NJEM01 and Efficient Synthesis of Prebiotic Kestose

ABSTRACT: An organic solvent-tolerant β-fructofuranosidase (β-FFase) from *Arthrobacter arilaitensis* NJEM01 was purified, characterized, cloned, and overexpressed in *Escherichia coli*. The mature β-FFase contained 495 amino acid residues with an estimated molecular mass of 55 kDa. The purified β-FFase from strain NJEM01 was very stable in the buffer systems (pH 5.0−9.5) and showed high stability below 45 °C. Furthermore, the enzyme exhibited relatively high solvent stability in various aqueous organic mixtures and retained nearly 100% of its initial activity after incubation for 10 days in 20% (v/v) DMSO. In addition, the β-FFase exhibited high transfructosylation activity, synthesized prebiotic products of mainly 6-kestose (up to 476 g/L), and showed fructosyl receptor specificity to *C*-glucosyl flavone. A relatively high yield of FOS was achieved by the β-FFase from bacterium with a high concentration of sucrose. It made the β-FFase an exploitable biocatalyst for the production of glycosides of natural products and prebiotic kestose.

KEYWORDS: *β-fructofuranosidase, Arthrobacter arilaitensis NJEM01, high stability, overexpression, 6-kestose*

INTRODUCTION

Fructofuranosidases are powerful tools in industrial biotechnology, which catalyze the reactions of hydrolysis of sucrose and transfructosylation of fructose residue to suitable acceptors. The reaction is attractive owing to the feasibility and regio- and stereo-specificities controlling the synthesis of fructosyl-containing oligosaccharides and glycosides of aglycones.[1] Fructo-oligosaccharides (FOS) exhibit prebiotic properties, are a source of dietary fiber in food preparations, and exert a beneficial effect on human health because they are selectively fermented by colonic flora.[2,3]

We previously reported the glycosylation of puerarin/mangiferin to fructosyl puerarin/mangiferin derivatives with high concentration of substrate by the β-fructofuranosidase (β-FFase) from *Arthrobacter arilaitensis* NJEM01.[4,5] The greatesst advantage was that because of the highly efficient synthesis of fructosyl aglycones by the β-FFase in nonaqueous media using sucrose as donor, the β-FFase almost did not hydrolyze the newly formed glycoside products.[4,5] Thus, the great interest is the characteristics of the β-FFase to fully understand the enzyme's biological function.

In this paper, an organic solvent-tolerant β-FFase was purified, cloned, and heterologously expressed in *Escherichia coli*, and its biochemical properties were also investigated. In addition, the β-FFase was also applied to the efficient production of fructo-oligosaccharide, which suggested its potential use for prebiotic fructo-oligosaccharides.

MATERIALS AND METHODS

Strain and Culture Conditions for Producing β-FFase. The β-FFase producer, *A. arilaitensis* NJEM01 (deposited in China Center for Type Culture (CCTCC M2012155)),[5] culture media, and conditions were the same as in a previous study.[5] The β-FFase activity was analyzed by using 20% (w/v) sucrose as substrate (pH 6.5, 50 °C, for 15 min). One unit (U) of β-FFase activity was equivalent to 1.0 μmol of glucose liberated by the amount of the enzyme per minute.[6]

Purification and Biochemical Properties of Purified β-FFase. The purified β-FFase was obtained by employing $(NH_4)_2SO_4$ fractionation (50−90% saturation) and DEAE Sepharose FF chromatography. The purified β-FFase band on the SDS-PAGE gel was electrophoretically transferred to an Immobilon-PVDF membrane (Millipore, Bedford, MA, USA) and was used for N-terminal amino acid sequence analysis. The effects of pH on the activity and pH stability (40 °C, 2 h) of purified β-FFase were determined in various buffer systems (pH 3.0−11.0). The effects of temperature on the activity and thermostability (pH 6.5, 2 h) of purified β-FFase were determined at different temperatures (from 20 to 80 °C). The effects of metal ions (5 and 10 mM) on the activity of the β-FFase were investigated. For the analysis of organic solvent stability of the β-FFase, various solvents (DMF, methanol, ethanol, and DMSO (20%, v/v)) were added to the enzyme solution, respectively.

Cloning of β-FFase *aff* Gene and Expression of β-FFase in *Escherichia coli*. As the N-terminal sequence (containing 10 amino acid residues) of the β-FFase from strain NJEM01 showed 70% identity to the β-FFase from *Arthrobacter globiformis* IFO 3062,[6] the highly conserved region of the *aff* gene was amplified by using two primers (5′-GCTAGCGAACTCCCAAAACGT-3′ and 5′-GCTACTGCTTTGCCATTCTTCA-3′), designed on the basis of the nucleotide sequence alignment of the β-FFase from strain IFO 3062.[6] To determine the sequences upstream and downstream of the conserved region, an efficient PCR strategy called thermal asymmetric interlaced (TAIL) PCR was used. The basic procedure and thermal cycling conditions were described by Nakayama.[7] Each set of the nested specific primers was designed to accurately match a region of known sequence, and arbitrary degenerate primers were the same as Mishra described.[8]

The *aff* gene was amplified from the genomic DNA of strain NJEM01 by using the following primers: forward, 5′-GTTCATATG-GCCACCGAACCAGTGCCTG-3′ with an *Nco*I site (underlined), and reverse, 5′-CCCAAGCTTTTACTTTGCTACTGCTTTGC-3′) with a *Hin*d III site (underlined). The *Nco*I−*Hin*dIII-digested PCR-amplified fragment was cloned into the corresponding sites of pET-22b to produce recombinant plasmid pET-*aff*, which was then transformed into *E. coli* BL21 (DE3), and the expression of β-FFase was performed as described by Isono et al.[6] Then the cell-free supernatant after fermentation of the recombinant was used for enzyme activity assay and verified by SDS-PAGE.

Transfructosylation for FOS Production, Analysis, and Identification of the Product. After preliminary optimization, the fructo-oligosaccharide was synthesized (pH 7.5, 40 °C) in a reaction mixture containing 3.0 M sucrose and β-FFase (9.7 U/mL). The transfructosylation product was analyzed by HPLC and purified according to the method described by Mabel et al.[9] The purified product was further analyzed by MS (Voyager-DE MALDI-TOF MS, USA) and NMR spectrum (Bruker AV-500 spectrometer, Switzerland). All NMR spectra were obtained in D_2O using tetramethylsilane (TMS) as the internal standard.

RESULTS AND DISCUSSION

Purification and Characteristics of β-FFase from Strain NJEM01. The extracellular β-FFase was purified (Table S1). About 47.4% of total activity was covered with 22.8-fold purification to a specific activity of 348.43 U/mg protein. The purified β-FFase was homogeneous with an apparent molecular mass of 55 kDa by SDS-PAGE (Figure 1A). This molecular mass was similar to that of the β-FFase from strain IFO 3062 (54 kDa)[6] and from *Arthrobacter* sp. K-1 (60 kDa).[10]

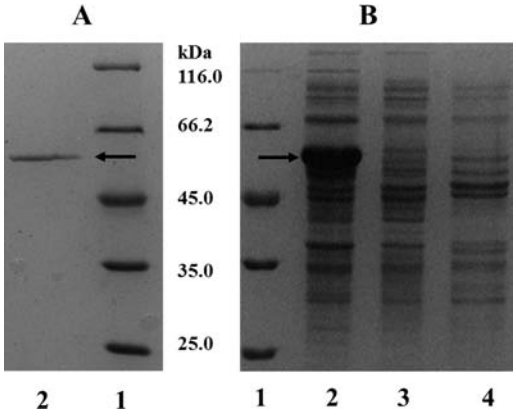

Figure 1. SDS-PAGE analysis of β-FFase purified from *A. arilaitensis* NJEM 01 (A) and β-FFase expressed in *E. coli* BL21 (DE3) (B). Lanes: 1 (A, B), marker; 2 (A), purified β-FFase; 2 (B), cell-free supernatant expressed in *E. coli*/pET-*aff* with IPTG; 3 (B), cell-free supernatant *E. coli*/ pET-*aff* without IPTG; 4 (B), cell-free supernatant *E. coli*/pET-22b with IPTG.

The purified β-FFase from strain NJEM01 showed a maximum activity at pH 6.5, and the enzyme was most active with broad range of pH from 5.0 to 7.0. Furthermore, the enzyme was very stable over the pH range of 5.0−9.5 for 2 h and retained >94% of its initial activity (Figure 2A). It has been reported that the action of hydrolysis and transfructosylation reactions of glycosidase preferentially occur at acidic and alkaline pH.[11] In addition, the hydrolyzing of product could be controlled by the alkaline pH.[11] Thus, the stability of β-FFase over the pH range of 5.0−9.5 would be beneficial for the regulation of transfructosylation.

The optimum temperature for the purified β-FFase was about 50 °C. The enzyme showed high stability below 45 °C (Figure 2B), which indicated its relatively good thermostability and was beneficial for the transfructosylation of functional and nutritional fructose-containing compounds.

There were no significant effects on the purified β-FFase activity with the supplementation of most of the metal ions and EDTA (Table S2). This finding was quite different from those reported enzymes from *Streptococcus salivarius* ATCC25975, *A. oxidans* J17-21, and *A. ureafacines* K2032,[12−14] which showed strong inhibition by several metal ions (Ni^{2+}, Mn^{2+}, Fe^{2+}, and Zn^{2+}). Interestingly, addition of 5 mM Fe^{3+} exhibited different effects on the hydrolysis and transfructosylation activities of the enzyme, whereas addition of Co^{2+} and EDTA could partially improve the transfructosylation activity of the purified β-FFase.

The purified β-FFase from strain NJEM01 exhibited relatively high stability in various hydrophilic solvent systems with concentration of 20% (v/v) (Figure 2C). It was noteworthy that activation of the β-FFase was obtained after 2 h of incubation in a medium containing 20% (v/v) DMSO. The β-FFase was very stable in the aqueous media with DMSO, retaining nearly 100% of its initial activity even after 10 days of incubation (data not shown). Enzymatic glycosylation in hydrophilic solvents could provide numerous industrially attractive advantages, such as reversal of the thermodynamic equilibrium of hydrolysis reactions and elimination of microbial contamination. In fact, in our previous studies, the β-FFase was successfully used in efficient and regioselective enzymatic fructosylation of puerarin[4] and mangiferin[5] in aqueous hydrophilic solvent system. Exceptionally high concentrations and high yields of mangiferin and puerarin fructosides were achieved by the solvent-stable β-FFase; the addition of hydrophilic solvents not only significantly promoted the solubility of flavone substrates (puerarin and mangiferin) but also produced a regulatory effect on the formation of the transfructosylation products,[5] the main products containing 111.3 g/L monofructosyl puerarin and 35.6 g/L difructosyl puerarin, with the total yield reaching 90%; 52.8 g/L

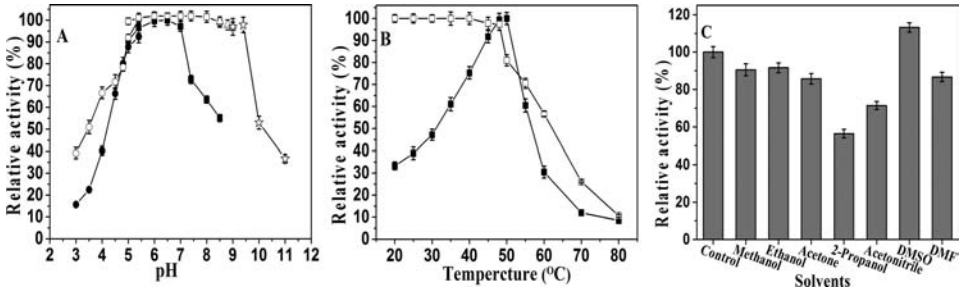

Figure 2. Characteristics of purified β-FFase: (A) effects of pH on the activity (solid symbols) of purified β-FFase and its pH stability for 2 h (hollow symbols); (B) effects of temperature on the activity (solid symbols) of purified fructofuranosidase and its thermostability for 2 h (hollow symbols); (C) solvent stability of purified β-FFase (the purified β-FFase was incubated in various solvent (20%, (v/v)) systems, at 40 °C for 2 h (under constant shaking at 200 rpm)). The β-FFase activities were measured in a buffer system (pH 6.5) at different temperatures and pH 3.0−5.4 (● and ○, citric acid buffer, 0.1 M), pH 5.0−8.6 (■ and □, KH_2PO_4−Na_2HPO_4, 0.05 M), pH 8.4−9.0 (△, Tris-HCl, 0.05 M), and pH 9.0−11.0 (☆, glycine−NaOH, 0.05 M).

dx.doi.org/10.1021/jf5020523 | J. Agric. Food Chem. 2014, 62, 5408−5411

monofructosyl mangiferin and 9.3 g/L difructosyl mangiferin were obtained, with the total yield reaching 91%.

Cloning and Expression of β-FFase. The N-terminal 10 amino acid residues of the purified β-FFase from strain NJEM01 were ATEPVPGFPQ and showed only 70% identity with the β-FFase from strain IFO 3062[6] and low similarity with the β-FFase from *Arthrobacter* sp. K-1[10] and strain K2032.[12] This suggested the differences of β-FFase from different strains.

The sequence of the *aff* gene had been elucidated in a patent.[15] The *aff* gene of the β-FFase from strain NJEM01 was cloned using degenerate PCR and TAIL PCR. The ORF of the *aff* gene (1647 bp) corresponded to the 548 residues (containing 53 residues of signal peptides) of the mature β-FFase of 495 residues. The amino acid sequence of the mature β-FFase from strain NJEM01 showed 91% identity with the β-FFase from strain IFO3062[6] and showed 80% identity to that from strain K-1.[10] This indicated the diversity of β-FFases from the *Arthrobacter* genus.

The recombinant plasmid pET-*aff* was constructed and the β-FFase was overexpressed in *E. coli* BL21 (DE3). The SDS-PAGE (Figure 1B) analysis indicated a thick band corresponding to a molecular mass of 55 kDa, which was the same as the purified native β-FFase. Furthermore, the recombinant β-FFase exhibited almost the same characteristics (data not shown) as the purified native β-FFase.

Efficient Production of FOS by the β-FFase. After preliminary optimization, the efficient transfructosylation was achieved in a reaction system (pH 7.5) containing a high concentration of the substrate (Figure 3). About 476 g/L 6-kestose was obtained from 3.0 M initial sucrose concentration, which corresponded to 45.7% (w/w) of the total carbohydrates in the reaction mixture. HPLC, MS, and NMR analyses suggested that the β-FFase from strain NJEM01 selectively synthesized almost only one kind of fructo-oligosaccharide. The amount of kestose obtained in the present work is much higher than that catalyzed by the β-FFase from *Schwanniomyces occidentalis* (including 4.2% (w/w) 1-kestose and 12.7% (w/w) 6-kestose).[16] The efficient production of FOS, including 1-kestose (234 g/L) and nystose (142 g/L), had also been produced by the β-fructofuranosidase from *Aspergillus* sp. 27H.[17] Moreover, the β-FFase from strain NJEM01 showed highly efficient transfructosylation of *C*-glucosyl flavone substrates, such as puerarin and mangiferin,[4,5] and also efficient transfructosylation for prebiotic fructo-oligosaccharide. A relatively high yield of prebiotic FOS was achieved by the β-FFase from bacterium NJEM01 with a high concentration of sucrose. All of these characteristics made it an exploitable biocatalyst for glycosides of natural products and prebiotic kestose.

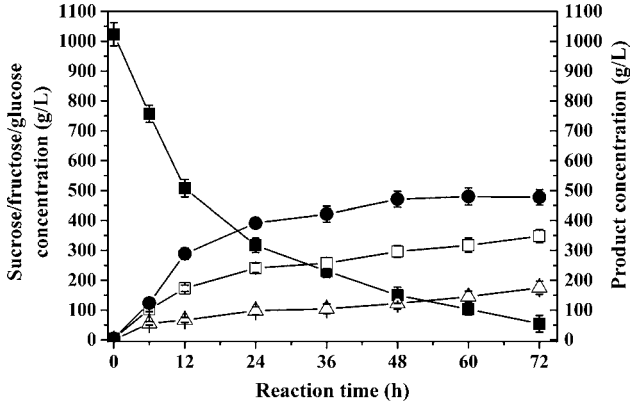

Figure 3. Time course of the transfructosylation for the production of microbial FOS by β-FFase from *A. arilaitensis* NJEM01: (■) sucrose; (●) FOS; (□) glucose; (△) fructose.

The fructo-oligosaccharide produced by the β-FFase was identified by combination of MS and NMR spectrum analyses. The purified product gave a main ion peak at m/z 527.16 $[M + Na]^+$ in a positive TOF-MS-ES spectrum. The NMR spectroscopic characterization (combination of HMBC, COSY, NOESY, and HSQC) revealed that the second fructose residue is β-(2 → 6)-linked to the fructose attached to the sucrose moiety. Thus, the fructo-oligosaccharide product was identical to that of an authentic 6-kestose.[9,16] The levan-type FOS (6-kestose, neokestose, and neonystose) exhibited increased prebiotic activity when compared to the usual inulin-type FOS (1-kestose, nystose, and ^{1}F-fructofuranosyl nystose).[18] The levan-type FOS could be selectively used by the beneficial intestinal bacteria, such as *Bifidobacterium adolescentis* and *B. longum*.[18]

The β-FFase could efficiently catalyze transfructosylation for the products of microbial FOS, with almost only one kind of kestose. In addition, exceptionally high concentrations and high yields of *C*-glucosyl flavone fructosides were also achieved.[4,5] Thus, this enzyme constitutes a profitable alternative for use in large-scale industrial prebiotic production while satisfying the growing needs of the population for healthy foods with bioactive compounds. Because of the important implications of the results obtained in the present work, further studies are currently underway to improve FOS production.

Effect of Seed Roasting on Canolol, Tocopherol, and Phospholipid Contents, Maillard Type Reactions, and Oxidative Stability of Mustard and Rapeseed Oils

Kshitij Shrestha and Bruno De Meulenaer*

NutriFOODchem Unit, Department of Food Safety and Food Quality (Partner in Food2Know), Faculty of Bioscience Engineering, Ghent University, Coupure Links 653, B-9000 Ghent, Belgium

ABSTRACT: This work was carried out to study the effect of roasting on different compositional parameters and oil oxidative stability of three *Brassica* species (*Brassica juncea* (BJ), *B. juncea* var. *oriental* (BJO), and *Brassica napus* (rapeseed, RS)). After 10 min of roasting at 165 °C, canolol contents of BJ, BJO, and RS oil reached 297.8, 171.6, and 808.5 μg/g, and the phospholipid phosphorus contents reached 453.6, 342.6, and 224.2 μg/g oil, respectively. The BJ and BJO seeds showed more prominent browning reactions than RS, due to the presence of higher amounts of reducing sugars, lysine, arginine and the occurrence of Maillard type browning reactions of phospholipids. The UV−visible spectra, fluorescence, and pyrrole content showed the presence of browning reaction products in the roasted seed oils. Roasting increased the oxidative stability of all varieties. Canolol formation could only partially explain such observations. Other roasting effects such as phospholipid extraction and Maillard type browning reaction products were also responsible for the increased stability.

KEYWORDS: *2,6-dimethoxy-4-vinylphenol (canolol), mustard, rapeseed, lipid oxidation, seed roasting, phospholipid browning, Maillard type reactions*

INTRODUCTION

Seed roasting has been known to increase the oil oxidative stability of different seeds, such as mustard,[1] sesame,[2] *Pistacia terebinthus*,[3] pine nut,[4] cashew,[5] perilla,[6] apricot,[7] pumpkin,[8,9] walnut,[10] and rapeseed (RS).[11] However, there are considerable differences in the manner by which roasting improves the oil oxidative stability of these seeds. For instance, production of different radical scavengers, such as sesamol in sesame seed[2] and canolol in RS,[11−14] during seed roasting are considered to play an important role in the such phenomenon. In some cases, increased phospholipid extraction after seed roasting has also been suggested.[6,9] In most cases, Maillard browning reactions between amino acids and reducing sugars have been proposed as an important contributing factor for such observation.[1,3−5,8,10,11] These results suggest that roasting can have different effects in different types of seeds. Hence, it is important to understand the roasting effects and the manner by which it improves the oil oxidative stability of each type of seed, separately.

Mustard seeds are generally roasted before oil extraction, and the crude oil, extracted using a screw expeller, is consumed without refining in different south Asian countries such as India and Nepal.[1,15] The traditional mustard and RS varieties contain high amounts of erucic acid, whereas various low-erucic RS varieties have also been developed by breeding practices.[14] Although a number of seed roasting experiments have been reported for RS[11,12] and mustard varieties,[1,11] a clear insight to and an in-depth understanding of how roasting improves oxidative stability of these varieties are still lacking. For instance, all of these studies consider Maillard reactions to be partially responsible for increasing the oxidative stability of roasted seed oil; however, none of them clearly demonstrates the occurrence of such reactions by evaluating the loss of reducing sugars and amino acids and by analyzing the browning reaction markers in the roasted seed oil. Moreover, the formation of canolol and its contribution to the oxidative stability have been completely ignored in roasting experiments carried out on high-erucic mustard seed oil.[1] Recently, however, canolol formation during roasting has also been confirmed in those varieties.[14] Furthermore, most of the previous studies have ignored the possibility of Maillard type browning reactions involving the amino group containing phospholipid (e.g., phosphatidylethanolamine (PE)). Such browning reaction products have been demonstrated to be more lipophilic compared to Maillard reaction products between amino acids and reducing sugars.[16] Hence, they are more likely to be extracted with oil and can contribute to its antioxidative activity.[17,18] A correlation study considering the effect of all these different factors on the oxidative stability of roasted mustard seed oil has been published recently.[18] It has provided the novel insight that the presence of radical scavengers (such as canolol and tocopherol) could not solely explain the very high oxidative stability of roasted mustard seed oil. Such observation has been shown to be primarily linked with phospholipid content and the presence of lipophilic Maillard type browning reaction products, in addition to canolol that is formed during roasting.[18] However, that study was carried out on roasted mustard seed oils collected from the market and, hence, it does not clearly demonstrate how such antioxidative compounds are generated during seed roasting and if there exist

differences in the roasting effect among different mustard and RS varieties.

Therefore, the current study has been carried out to evaluate the seed roasting effect on different compositional parameters and oil oxidative stabilities of different *Brassica* species. The three species selected for the study were *Brassica juncea* (Indian mustard), *Brassica juncea* var. *oriental* (oriental mustard), and *Brassica napus* (European rapeseed).

MATERIALS AND METHODS

Materials and Reagents. The seeds of two high erucic acid mustard varieties (*B. juncea* (BJ) and *B. juncea* var. *oriental* (BJO)) and a low erucic acid rapeseed (RS) variety (*B. napus*) were collected from the local market of Ghent, Belgium. Tocopherol standard was obtained from DSM (New Jersey, USA). Syringaldehyde and 1,2-dioleoyl-*sn*-glycero-3-phosphoethanolamine were purchased from Sigma-Aldrich (Steinheim, Germany). Nonadecanoic acid was purchased from Fluka (Buchs, Switzerland). The HPLC grade hexane was bought from VWR International (Leuven, Belgium). Other reagents and solvents were of analytical grade and obtained from reliable commercial sources.

Synthesis of Canolol. Canolol was synthesized from syringaldehyde by condensation with malonic acid and then double decarboxylation under microwave condition as described previously.[14] Ultraviolet, fluorescence, liquid chromatography–mass spectrometry, and nuclear magnetic resonance spectra were used to confirm the identity and purity of the synthesized compound.[14] The synthesized canolol was used as a standard for quantification.

Analytical Methods. Fatty acid methyl esters were prepared using the boron trifluoride method (American Oil Chemists Society, 1990) and were analyzed on a gas chromatograph using the method described previously.[18] Nonadecanoic acid was used as an internal standard for the quantification.

Analysis of the total amino acid profile of seed sample was carried out using the previously described procedure[19] and included a full hydrolysis of the sample in acidic conditions and a liquid chromatographic analysis using fluorescence detection after derivatization. Thus, tryptophan and cysteine were lost and glutamine and asparagine were converted to glutamic and aspartic acid, respectively. Tryptophan was separately analyzed after basic hydrolysis followed by similar chromatographic conditions. Analysis of the free amino acids content was carried out after their extraction from the ground seeds with 15% trichloroacetic acid followed by similar chromatographic analysis, without acid hydrolysis. Sarcosine was used as an internal standard to quantify proline. Norvaline was used as an internal standard to quantify other amino acids.

Analysis of the sugar content in the seed sample was carried out gas chromatographically after aqueous extraction of the sugar and derivatization via oximation and silylation using the previously described procedure.[20] Phenyl-β-D-glucopyranoside was used as an internal standard for the quantification.

Tocopherol and canolol contents of the oils were analyzed in a high-pressure liquid chromatograph using a fluorescence detector, after separation in a silica column as described previously.[14]

The peroxide value (PV) of the oil was determined by using an iron-based spectrophotometric method.[21] A calibration curve was constructed using a standard iron(III) chloride solution as described in the same method. Calibration was done using six concentrations in duplicate in the range from 5 to 30 μg of iron(III). The multiple *R*-squared value was >0.99 for the calibration. Such a calibration curve was constructed just before the measurement of the peroxide value of the samples.

The phospholipid phosphorus content of the oil was analyzed spectrophotometrically after the formation of a phospholipid phosphorus–molybdate complex as described before.[18]

The pyrrolyzed phospholipid content of the oil samples was analyzed using a previously described procedure.[22] The absorbance of the Ehrlich adducts was measured at 512 nm, and the blank absorbance without Ehrlich reagent was subtracted during calculation. The reported value of the extinction coefficient of Ehrilich adducts (153000 M^{-1} cm^{-1}) with 1-[1-(2-hydroxyethyl)-1*H*-pyrrol-2-yl]-propan-1-ol was used in the calculation.[22]

UV–visible absorbance spectra of the oil solution in iso-octane (25 mg/mL) were measured using a Cary 50 UV–vis spectrophotometer (Varian) in a quartz cuvette. Fluorescence (excitation at 350 nm and emission at 440 nm) of the same oil solution was additionally measured using a Spectramax Gemini XS fluorescence spectrophotometer as described previously.[18] Fluorescence is expressed as the percentage fluorescence of 1 μM quinine sulfate solution in 0.1 M H_2SO_4.

Experimental Setup. Mustard seed and rapeseed were roasted in a beaker, which was dipped inside an oil bath maintained at 180 °C as reported earlier.[14] Briefly, 80 g of seed sample was added to a heated beaker placed in the oil bath (180 °C). The seed sample and heating oil were continuously agitated with two electric mechanical stirrers. The temperature of the seed sample and heating oil was continuously monitored using Testo thermostat probes. The oil temperature was maintained constant at 180 °C, and seed roasting was carried out for 10, 20, 30, 45, 60, and 90 min. The seed temperature profile with time followed the equation $T = 32.796 \ln(t) + 89.422$ ($R^2 = 0.99$) for the first 10 min of roasting, where T is the seed temperature (°C) and t is the roasting time (min). Afterward, seed temperature remained constant at 165 ± 3 °C.

The roasted and unroasted seeds were ground. The total amino acid profile was analyzed on unroasted seed powder. The reducing sugar content and free amino acid profile were analyzed on both unroasted and 10 min roasted seed powders.

The oil was extracted from unroasted and roasted seeds using petroleum ether.[14] Tocopherol, canolol, phospholipid, and browning reaction markers (absorbance, fluorescence, and pyrrolyzed phospholipid content) were analyzed on unroasted and roasted seed oils. The extracted oil (750 μL) was kept in a 1.5 mL loosely capped HPLC glass vial and stored at 104 °C to accelerate the oxidation process. Oil oxidation was monitored by analyzing PV at different time intervals. Both roasting and oxidation studies were carried out in independent triplicate experiments.

Statistical Analysis. All data are presented as mean values ± 95% confidence interval of the mean based on three independent experiments, unless otherwise stated. The logarithmic transformations of the different data were done, whenever necessary, to have homoscedasticity before the statistical analysis was carried out. ANOVA and post hoc Tukey test were performed using TIBCO Spotfire S+ 8.1 software. The significance level is $p < 0.05$, unless otherwise indicated.

RESULTS AND DISCUSSION

Effect of Roasting on Different Compositional Parameters. Mustard seed and rapeseed roasting is known to form canolol by decarboxylation of sinapic acid.[11,12,14,23,24] Roasting of seed before oil extraction increased the canolol content of oil in all varieties (Table 1). The maximum canolol content of oil was reached during 10−20 min of seed roasting. Oil from 20 min roasted RS contained the highest amount of canolol, which was 2.8 times higher compared to BJ seed oil and 4.9 times higher compared to BJO seed oil, roasted for the same time. Higher canolol formation in roasted RS compared to different mustard seed varieties was also reported previously.[14] Roasting for more than 20 min gradually reduced the canolol content in all varieties. The decrease in the canolol content during longer roasting time was also reported previously.[24] The canolol content of the roasted rapeseed oil was reported in a similar range previously.[23,24]

The tocopherol contents of the unroasted and roasted seed oils of different varieties are given in Table 1. The α-tocopherol content in the unroasted RS oil was more than double the amount present in both unroasted mustard seed oils. It remained stable during RS roasting, whereas a significant gradual degradation was observed for both BJ and BJO mustard varieties. The γ-tocopherol contents in all three varieties were quite comparable. Its degradation was observed in all varieties during 10 min of roasting. Afterward, it remained constant in RS, whereas a slight degradation was observed during BJO roasting. The BJ seed oil showed a gradual and the largest degradation in γ-tocopherol during longer roasting. The plastochromanol-8 content remained relatively stable in the BJ seed oil during roasting. On the other hand, a significant increment was observed in the BJO and RS oils during the first 10 min of roasting. The disruption of matrix during roasting could be responsible for the increased extractability. A longer roasting time had little effect on all varieties studied.

The phospholipid phosphorus content of the unroasted seed oils, extracted using petroleum ether, was in the range of 8−30 μg/g oil (Table 1). On the other hand, when the same unroasted seed powder was extracted with a chloroform/methanol solvent mixture (2:1, v/v), the phospholipid phosphorus content was 500−600 μg/g oil. Therefore, the lower phospholipid content of unroasted seed oil was due to the poor extractability with petroleum ether from the unroasted seed matrix. Roasting for 10 min significantly increased the oil phospholipid content for all varieties. This observation was similar to the increased extractability of plastochromanol-8 after seed roasting. The increased phospholipid content of the oil after seed roasting was also reported previously.[9] Roasting for more than 10 min showed a gradual decrease in the phospholipid phosphorus content in the oil of all varieties. The decrease in extractability could indicate its chemical modification; for instance, it could be covalently bound to matrix compounds.

The Maillard reaction is one of the most well-known nonenzymatic browning reactions in heat-treated food products. The possibility for such reactions during seed roasting was studied by evaluating the changes in the amino acid and reducing sugar contents. Among the free amino acids, RS contained a significantly higher quantity of glutamate, histidine, alanine, valine, isoleucine, and lysine compared to both BJ and BJO mustard varieties (Table 2). On the other hand, both BJ and BJO mustard varieties contained significantly higher quantities of free arginine compared to RS. After 10 min of roasting, >85% of free amino acids were lost, indicating the occurrence of Maillard reaction in all varieties. The losses of individual amino acids were quite comparable in all varieties. Therefore, the formation of low molecular weight antioxidative compounds from such reactions could also be comparable

[a]Values with different letters in thre same column are significantly different ($p < 0.05$).

Figure 1. Mustard (BJ and BJO) and rapeseed meals before and after 20 min of roasting.

among those varieties. On the other hand, the total amino acids content (on a fat-free dry matter (FFDM) basis) was higher in mustard varieties compared to that in RS (Table 3). Particularly notable was the presence of 30−40% higher arginine and 14−16% higher lysine in mustard varieties compared to that in RS. Because of the presence of a free amino group, these amino acids are particularly responsible for the Maillard reactions involving proteins. The formation of high molecular weight hydrophilic antioxidative compounds from such reactions could be much more pronounced in mustard varieties compared to that in RS.

The effect of seed roasting on the sugar content was additionally evaluated in all varieties (Table 4). Both mustard varieties contained significantly higher quantities of glucose and lower quantities of sucrose compared to RS before roasting. The fructose content of BJ mustard seed was also higher compared to both BJO seed and RS. After 10 min of roasting, the glucose content decreased significantly in all varieties compared to the amount present in the unroasted seed. The loss of glucose was around 4 times higher in both mustard varieties compared to that in rapeseed. Moreover, the sucrose content of both mustard varieties also decreased significantly, likely due to its hydrolysis into glucose and fructose. The increase in sucrose content in rapeseed after seed roasting could possibly due to its formation via the hydrolysis of stachyose and raffinose present in the matrix.[25]

The ground seed meals of different varieties before and after 20 min of roasting are shown in Figure 1. This picture illustrates that browning reactions during roasting were more pronounced in mustard varieties compared to RS. This could be linked with the presence of higher quantities of both reducing sugars and reactive amino acids (e.g., lysine, arginine) in mustard varieties compared to those in RS.

In addition to amino acids, the amino group containing phospholipid (e.g., PE) is also known to take part in the Maillard type browning reactions with reducing sugars.[17] Both types of browning reactions could be expected to happen simultaneously in the seed; however, their extraction in the oil could be affected by their polarity differences. In a previous study, it was shown that the amino group of PE was even more reactive with ribose than with lysine.[16] These authors reported that, when the aqueous reaction mixture of PE, ribose, and lysine was extracted with chloroform/methanol (2:1, v/v) to have phase separation, the brown compounds due to PE/ribose and lysine/ribose got separated into the organic and aqueous phases, respectively.[16] These observations showed that the

lysine/ribose Maillard reaction products are more hydrophilic, whereas the PE/ribose reaction system could produce lipophilic Maillard type reaction products. The same extraction method was used to characterize the brown compounds in the roasted seed oil. It was observed that the major brown compounds of oil remained in the organic phase, indicating that these brown compounds could be mainly due to phospholipid browning compared to the reducing sugar amino acid Maillard reactions. The possibility of such phospholipid browning reaction products was also reported previously on the basis of the high correlation observed between the phospholipid content, absorbance, fluorescence, and pyrrolyzed phospholipid content in roasted mustard seed oil.[18]

Changes in the browning reaction markers in the oil after seed roasting of different varieties were further evaluated (Table 1). The absorbance of oil at 350 nm gradually increased during roasting in all varieties. The choice of this marker is based on the recent report that the oxidative stability of the roasted mustard seed oil is highly correlated at this wavelength.[18] The BJ seed oil showed the highest increment in the absorbance and reached a maximum after 20 min of roasting, which was >3 times compared to that of RS oil and >2 times compared to BJO seed oil roasted for the same time. After 45 min of roasting, the absorbance values of all varieties remained almost constant. The absorbance values after 45 min were comparable between BJ and BJO seed oil and were around double the amount compared to RS oil. To illustrate that more clearly, the changes in the UV−visible absorbance spectra of oil after roasting for 10 and 90 min for all varieties are shown in Figure 2. This figure shows that the increase in the UV−visible absorbance due to browning reactions within the 10 min of roasting was highest in BJ followed by BJO and rapeseed oil. After 90 min of roasting, BJ and BJO seed oil showed similar UV−visible absorbance spectra. On the other hand, the UV−visible absorbance spectrum of roasted rapeseed oil (even after 90 min of roasting) was lower than that of 10 min roasted BJ oil. This showed that browning reactions were more prominent in BJ and BJO mustard varieties compared to that in rapeseed variety. In addition, roasting increased the oil fluorescence (excitation 350 nm and emission 440 nm) in all varieties (Table 1). However, fluorescence development was comparable in all varieties and could not differentiate the extent of browning observed with the absorbance at 350 nm. Furthermore, the presence of the Maillard type browning reaction products in the roasted seed oil was supported by the increment in the pyrrolyzed phospholipid content after seed roasting in all varieties (Table 1).

Oxidative Stability of Roasted Seed Oil of Different Varieties. The fatty acid compositions of all the oils are given in Table 5. Both mustard varieties were rich in erucic acid, whereas RS was rich in oleic acid. However, total saturated,

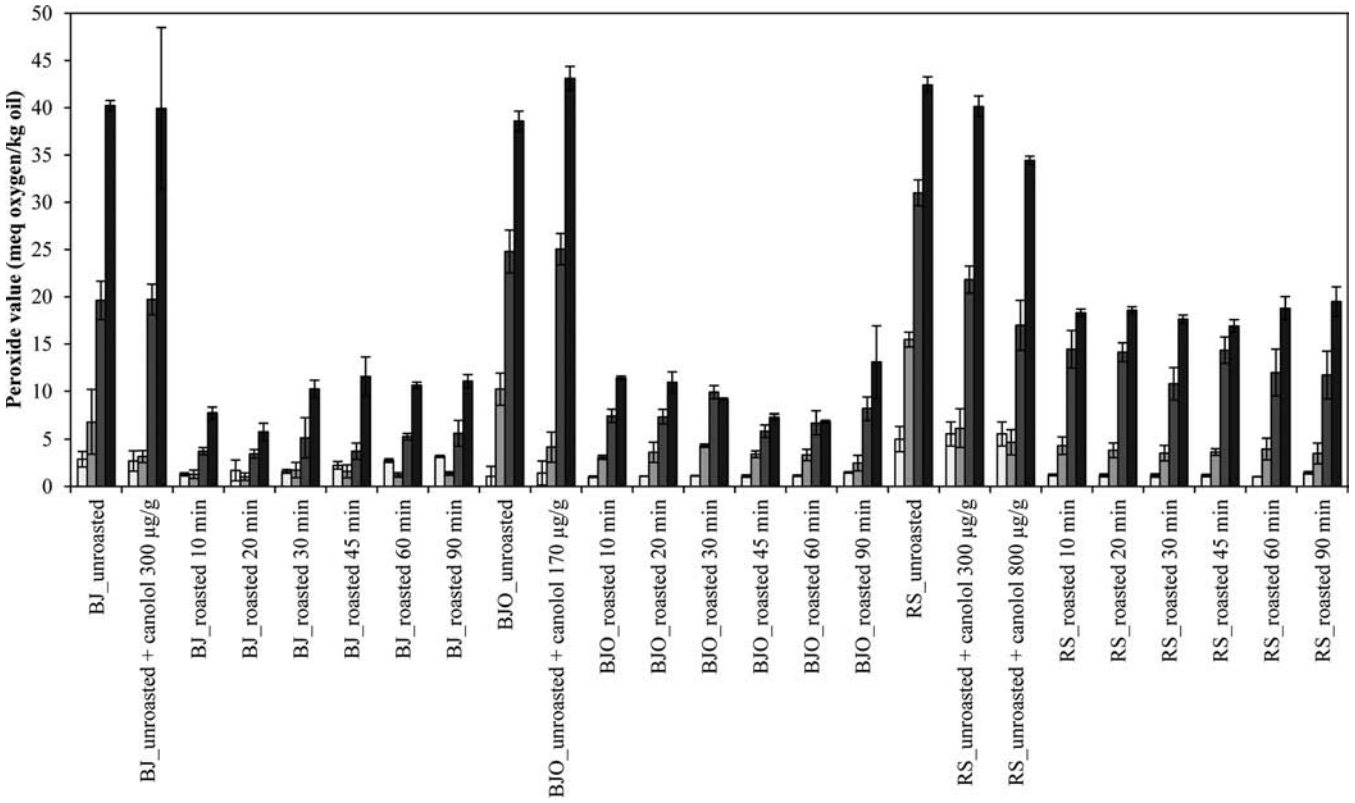

Figure 3. Changes in the PV of unroasted seed oil, roasted seed oil, and canolol added unroasted seed oil of different varieties stored at 104 °C (white bars, 0 h; light gray bars, 9 h; dark gray bars, 32 h; and black bars, 98 h).

monounsaturated, and polyunsaturated fatty acid contents were comparable in all varieties.

The oxidative stabilities of unroasted seed oil and roasted seed oil were evaluated by monitoring the changes in the PV during accelerated oxidation at 104 °C (Figure 3). A previous study showed that roasted mustard seed oil could have a very high oxidative stability with an induction period >60 days during storage at 50 °C.[18] Therefore, higher storage temperature (104 °C) was chosen to accelerate the oxidation. The vials were loosely capped so as to maintain a constant atmospheric oxygen concentration in the headspace. The experiment is similar to the active oxygen method used for the evaluation of oxidative stability of oil at 100 °C by saturating the oil with oxygen and monitoring the PV during storage. It is known that peroxides could degrade at this temperature and the oil oxidation could be different from the autoxidation; however, such effects could be similar in the oil samples with similar fatty acid compositions. Therefore, the results from this experiment should be taken as the relative oxidative stability among the samples with similar fatty acid compositions during accelerated oxidation.

Roasting for 10 min significantly improved the oxidative stability of all varieties compared to their respective unroasted seed oil (Figure 3). Such an increment in the oxidative stability due to roasting was more prominent in BJ and BJO varieties compared to the RS variety. Roasting for longer time had a smaller additional effect.

Canolol is a potent antioxidant and is known to play an important role in the oxidative stability of roasted rapeseed oil.[11,12] However, other factors in addition to canolol could also be responsible for the increased oxidative stability. To evaluate the role of canolol alone, oxidative stability was evaluated after the addition of canolol to the unroasted seed oil equivalent to the amounts formed after 10 min of roasting (Figure 2). In addition, the oxidative stability of unroasted rapeseed oil containing canolol equivalent to the amount in 10 min roasted BJ seed oil was also evaluated. Canolol addition to the unroasted mustard seed (BJ and BJO) could not increase their oxidative stability, whereas it showed a significant protective role in the rapeseed oil. In all varieties, 10 min roasted seed oil was more stable compared to the respective unroasted seed oil with an equivalent quantity of canolol added. These observations showed that canolol could play a significant role in increasing the oxidative stability of roasted RS oil; however, its formation alone could not be responsible for the increased oxidative stability after seed roasting. Furthermore, even though BJ and BJO varieties showed smaller increments in canolol during roasting compared to that in RS, the increment in oxidative stability after roasting was more prominent in BJ and BJO varieties compared to that in RS. This could be linked with other multiple effects of seed roasting such as increased extraction of phospholipid and formation of antioxidants via Maillard type reactions. Such roasting effects depend on the chemical composition of the seeds, which could be different in the different varieties. In the current example, BJ and BJO mustard seeds showed stronger Maillard type browning reactions compared to the RS variety. Maillard type browning reaction products are known to have strong antioxidative activity.[17,26] Such browning reaction products could be responsible for the increased oxidative stability of roasted mustard (BJ and BJO) seed oil in addition to the canolol formed during roasting. Further studies are required to isolate and identify the antioxidative compounds formed during such

reactions that can be used as a natural antioxidants in different food products.

ABSTRACT: The chemical structure of lignin from grape stalks, an abundant waste of winemaking, has been studied. The dioxane lignin was isolated from extractive- and protein-free grape stalks (*Vitis vinifera* L.) by modified acidolytic procedure and submitted to a structural analysis by wet chemistry (nitrobenzene and permanganate oxidation (PO)) and spectroscopic techniques. The results obtained suggest that grape stalk lignin is an HGS type with molar proportions of *p*-hydroxyphenyl (H), guaiacyl (G) and syringyl (S) units of 3:71:26. Structural analysis by ^{1}H and ^{13}C NMR spectroscopy and PO indicates the predominance of *β*-*O*-4′ structures (39% mol) in grape stalk lignin together with moderate amounts of *β*-5′, *β*-*β*, *β*-1′, 5-5′, and 4-*O*-5′ structures. NMR studies also revealed that grape lignin should be structurally associated with tannins. The condensation degree of grape stalks lignin is higher than that of conventional wood lignins and lignins from other agricultural residues.

KEYWORDS: *grape stalks, dioxane lignin, nitrobenzene oxidation, permanganate oxidation, ^{1}H NMR, ^{13}C NMR, HSQC, FTIR, UV−vis*

INTRODUCTION

Winemaking is an important agricultural sector contributing substantially to national economies around the world. Total worldwide wine production is around 262 millions hL, 60% of which is produced by European Union countries.[1] The main wastes generated in the winemaking process (grape pomaces) are skins, pulp, stalks, and seeds, which account for 25−35 kg/hL of produced wine.[2] Grape stalks are one of the major byproducts of the wine industry. On average, 1 hL of wine generates up to 4 kg of grape stalks.[2] The utilization of wine byproducts is gaining increasing attention due to the environmental concerns and potential profitable applications.[3,4] Besides current uses of grape stalks as fertilizers,[5,6] the possibilities of using such materials for the production of biosorbents,[7] dietary fibers,[8] antioxidant supplements,[9] activated carbon,[10] and cellulosic pulp[11] have been demonstrated.

Grape stalks are a lignocellulosic fiber material composed essentially by cellulose, hemicelluloses, lignin, and tannins.[3,4] Similarly to jute, cotton stalks, dhaincha,[12] kenaf (*Hibiscus cannabinus*),[13] and reed (*Arundo donax*),[14] grape stalks may be considered an alternative to wood sources of fibers for papermaking and biocomposites.[4,15] Carbohydrates contribute to >50% of grape stalks,[4,16] the most abundant being cellulose (ca. 30−35%) and *O*-acetyl-4-*O*-methylglucurono-*β*-D-xylan (ca. 10−15%). One specific feature of grape stalks is the high content of tannins, their amount being comparable to the lignin content.[4] Grape stalks contain several classes of polyphenolic compounds, such as phenolic acids, flavonols, and flavanonols. The major part of tannins consist of polymeric proanthocyanidins composed of (−)-epicatechin units together with smaller amounts of (+)-catechin, (−)-epicatechin gallate, and (−)-epigallocatechin.[17] Among other polyphenolic compounds, quercetin 3-glucuronide, catechin, caffeoyltartaric acid, and dihydroquercetin 3-rhamnoside (astilbin) have been detected.[17]

Often, condensed tannins are determined together with lignin in the acid-insoluble residue called Klason lignin, thus overestimating its content by almost twice.[4] The accurate determination of Klason lignin is possible only after the preliminary removal of extractives, proteins, and condensed tannins from grape stalks. The Klason lignin content in grape stalks corrected for extractives, proteins, and tannins is around 17%.[4] Despite increased research activity on the chemical processing of grape stalks, practically no reliable information on the chemical structure of lignin is available. However, the undefined structure of lignin and/or its possible association with tannins was suggested to be a reason for the extremely difficult delignification of grape stalks by oxygen-alkali and organosolv,[11] soda,[18] and kraft[4] pulping.

The main goal of this work was the structural evaluation of lignin isolated from grape stalks by a soft acidolytic technique (dioxane lignin). Lignin was characterized by wet chemistry (nitrobenzene and permanganate oxidation) and spectroscopic techniques (1D and 2D NMR, FTIR, and UV spectroscopy). The molecular weight was assessed by size exclusion chromatography (SEC).

MATERIALS AND METHODS

Preparation of Plant Material. Grape stalks from red grape pomace (*Vitis vinifera*) were collected after destemming at the Quinta do Serrado in Penalva do Castelo, Region of Dão (Portugal). The material was dried at room temperature, milled on a cross-beater mill SKI (Retsch, Haan, Germany), and sieved to 0.5−1.0 mm sawdust. The grape stalks were submitted to Soxhlet extraction with acetone (6 h) to remove extractives, according to Tappi standard T 204 om-88. Proteins were removed by the treatment of the extractives-free grape

stalks, with a 1% pepsin solution in 0.1 M HCl at 40 °C overnight, followed by hot water washing until neutral reaction of filtrate.[19] The tannins content was assessed in extractives- and proteins-free grape stalks by reflux with 0.3% NaOH solution (liquid-to-solid ratio of 100:1) under nitrogen atmosphere for 1 h. The lignin content was determined by the Klason method according to Tappi standard T 222 om-88, using grape stalks free of extractives, proteins, and tannins. The Klason lignin content in the grape stalks was 17.4%.

Isolation of Lignin. The lignin was isolated by acidolytic procedure from grape stalks free of extractives and proteins (DL_T) and from grape stalks free of extractives, proteins, and tannins (DL), according to the previously described method.[20] Typically, 10 g of dry extractives- and proteins-free grape stalks sawdust (0.5−1.0 mm) was submitted to three sequential extractions (each 60 min) with 500 mL of a dioxane/water solution (9:1, v/v) containing 0.1 M HCl, under a nitrogen atmosphere. The resulting extracts were further concentrated separately to a volume of ca. 150 mL. Finally, lignin was precipitated in distilled cold water (1.5 L), centrifuged, and washed with distilled cold water until filtrates were of neutral pH and vacuum-dried at room temperature (ca. 20 °C). Alternatively, another sample of dioxane lignin (DL) was isolated from extractives- and proteins-free grape stalks after additional treatment with 0.3% NaOH solution under nitrogen atmosphere, aiming to eliminate the concomitant condensed tannins.[4] The yields of DL_T and DL were about 70−75% of total lignin content in grape stalks (Klason lignin = 17.4%).

Chemical Analyses. The lignin in grape stalks sawdust and isolated dioxane lignins were characterized by oxidation with nitrobenzene under alkaline conditions, according to the previously described procedure.[21] The oxidation products were dissolved in 200 μL of pyridine and analyzed by GC-MS on a Trace Gas Chromatograph 2000 equipped with a Thermo Scientific DSQII mass spectrometer (Thermo Fisher Scientific, Austin, TX, USA). The conditions of GC analysis were as follows: column capillary, 30 m × 0.32 mm i.d. 0.25 μm, DB-1 (Agilent J&W, Santa Clara, CA, USA); initial temperature of the column, 100 °C; gradient of temperature, 4 °C/min; final temperature of the column, 270 °C; temperature of the injector, 240 °C; and temperature of the detector, 250 °C.

The permanganate oxidation of isolated lignin with tannins (DL_T) was performed as described previously.[22] The ethylated oxidation products were identified by GC-MS using the equipment as indicated above. The chromatographic conditions were as follows: initial temperature of the column, 180 °C; gradient of temperature, 4 °C/min; final temperature of the column, 290 °C; injector temperature, 250 °C.

Methoxy groups in lignins were analyzed according to the Zeisel−Vieböck−Schwappach method.[23]

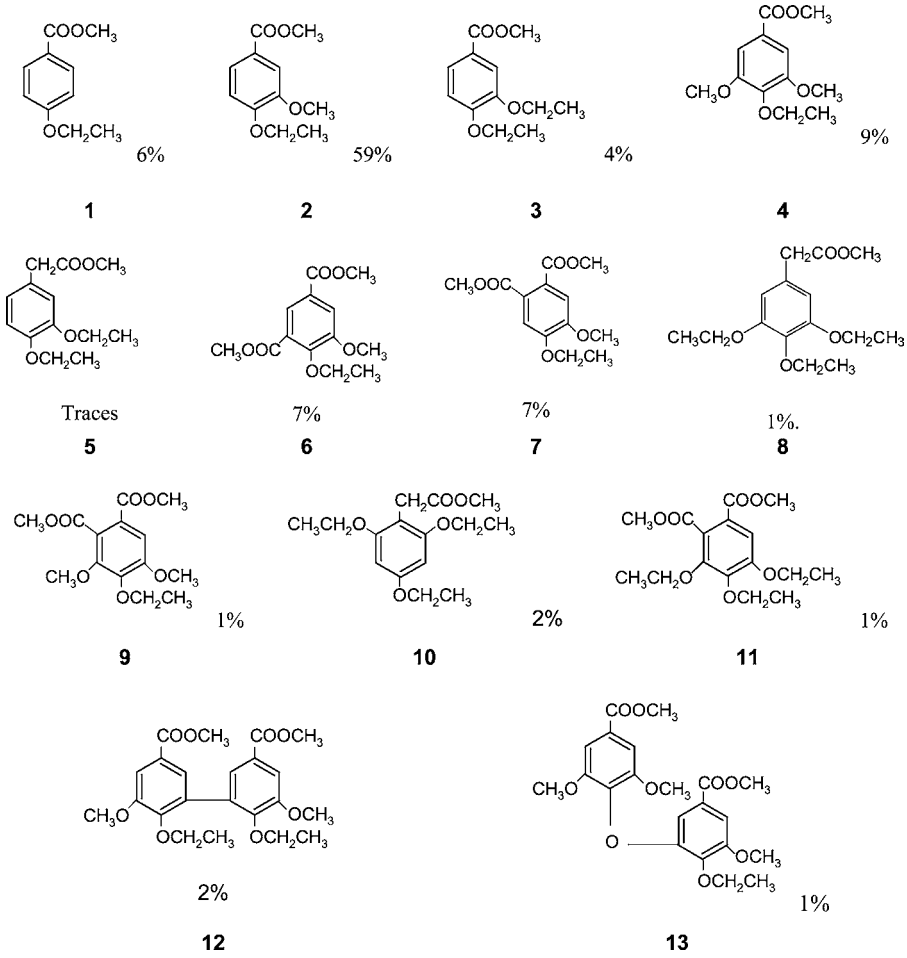

Figure 2. Frequency of occurrence (% mol) of carboxylic acid methyl esters obtained from oxidation of dioxane lignin (DL_T) with potassium permanganate.

Analysis by UV and FTIR Spectroscopy. Ultraviolet (UV) spectra of dioxane-lignin were recorded in 2-methoxyethanol on a JASCO V-560 UV−vis spectrophotometer (Jasco International, Tokyo, Japan), using 1 cm thick quartz cells. The FTIR spectrum of the dioxane-lignins was obtained on a Mattson 7000 spectrometer (Mattson Instruments, Madison, WI, USA), with a resolution of 4.0 cm^{-1} and 132 scans recorded in the medium-infrared area, which extends from 4000 to 400 cm^{-1}.

NMR Analyses. All NMR spectra were registered on an AVANCE 300 spectrometer (Bruker, Wissembourg, France). The ^1H NMR spectra of acetylated dioxane lignins dissolved in chloroform-d_1 (concentration ca. 3%), placed in a 5 mm diameter tube, have been carried out by operating at 300.1 MHz (298 K). The acquisition parameters were as follows: 12.2 μs pulse width (90°), 3 s relaxation delay, and 300 scans.

The quantitative ^{13}C NMR spectrum of dioxane lignin (DL) was recorded by operating at 75.47 MHz (318 K) with TMS as internal reference. DL was dissolved in DMSO-d_6 (ca. 25% concentration) and placed into 10 mm diameter tubes. The acquisition parameters were as follows: 4.1 ms pulse width (90° pulse angle), 12 s relaxation delay, 16K data points, and 20000 scans. The same lignin sample in DMSO-d_6 was placed into a 5 mm diameter tube, and 2D NMR spectra were recorded. The phase sensitive ^1H-detected heteronuclear single-quantum coherence (HSQC) spectrum was acquired over an F1 spectral weight of 12000 Hz and an F2 width of 2000 Hz with a 2048 × 1024 matrix and 128 transients per increment. The delay between scans was 2 s and the delay for polarization transfer was optimized for $^1J_{C-H}$ = 148 Hz. The heteronuclear multiple-bond correlation (HMBC) spectrum was recorded using a coupling evolution time of 110 ms ($^3J_{C-H}$ = 4.5 Hz).

Analysis by Size Exclusion Chromatography (SEC). Two dioxane lignins were analyzed by SEC using a PL-GPC 110 apparatus (Polymer Laboratories, Shropshire, UK), equipped with a precolumn, 10 μm, Plgel, and two 300 mm × 7.5 mm columns, 10 μm, Plgel MIXED D (Polymer Laboratories) and a refraction index detector. Columns and the injection system were maintained at a temperature of 70 °C. The eluent flow (0.1 M LiCl in DMF) was 0.9 mL/min. The lignin solutions (ca. 1%) were prepared just before the analysis by dissolution in eluent solution (0.1 M LiCl in DMF). The column calibration was carried out using lignin model compounds (monomers, dimers, and tetramers) and selected lignin samples (Mp = 950−3200 Da) previously characterized by ESI-MS.[24]

RESULTS AND DISCUSSION

Molecular Weight and Purity of Isolated of Dioxane Lignins. The molecular weights (M_w) of dioxane lignins free of extractives and proteins (DL_T) and free of extractives, proteins, and tannins (DL) were very close to each other (ca. 2600 Da). As could be expected, the removal of condensed tannins from grape stalks before the isolation of dioxane lignin led to much less contaminated lignin sample (DL). This fact was confirmed by FTIR spectroscopy and by analysis of methoxyl group content. Thus, the FTIR spectrum of DL_T showed typical strong signals for tannins and tannic acids at 2920/2860 cm^{-1} (sym/antisym C−H stretching in CH_2), 1718 cm^{-1} (C═O stretching in ketones), and 1610−1600 cm^{-1} (bending vibrations of aromatic ring),[25,26] which were drastically diminished in the spectrum of DL (Figure 1). The methoxyl

dx.doi.org/10.1021/jf502267s | J. Agric. Food Chem. 2014, 62, 5420−5428

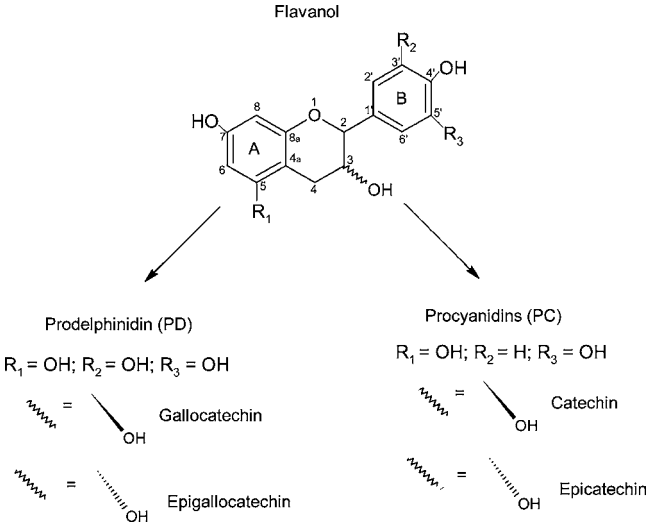

Figure 3. Monomeric units of representative flavanols constituting condensed tannins.

group content was 15.6% for DL_T and 17.3% for DL, which is consistent with the conclusion on the stronger contamination of the former with tannins. Because DL is purer than DL_T, the former is preferable for the qualitative and quantitative characterization by spectroscopic techniques. At the same time, the fact of preliminary alkaline extraction of grape stalks to remove tannins may cause the removal of the alkali-soluble lignin fraction. Hence, DL_T may provide some additional structural information when analyzed by degradation techniques.

FTIR and UV Spectroscopy. DL had FTIR spectrum patterns (Figure 1) typical for lignins constituted by guaiacyl (G) and syringyl (S) units.[27] Thus, besides characteristic aromatic ring bands at 1595, 1510, and 1425 cm^{-1} (aromatic skeletal vibrations in G and S rings), the bands at 1328 and 1266 cm^{-1} were detected and assigned to syringyl and guaiacyl rings breathing with Ar−OCH_3 stretching, respectively.[28] The shoulder at ca. 1636 cm^{-1} in the FTIR spectrum indicated the presence of lignin structures with C═C bonds in the propane chain conjugated to an aromatic ring.[29]

The UV spectrum of DL revealed the bands typically observed for dioxane lignins constituted by *p*-hydroxyphenyl (H), syringyl (S) and guaiacyl (G) units (HGS lignins) from kenaf[13] and banana plant.[30] The extinction coefficients (ε) at 212, 240, 284, and 320 nm were 54.8, 19.1, 9,8 and 5.7 L/g/cm, respectively. Attention is drawn to the bathochromic shifted band at 284 nm of relatively low intensity (ε = 9.7 L/g/cm) corresponding to the $\pi \rightarrow \pi^*$ electron transition in the aromatic ring, which usually appears in lignins at ca. 280 nm. Similar features were previously observed in dioxane lignin of kenaf bark contaminated by condensed tannins.[13] The relatively strong absorption at 320 nm could be assigned to the $n \rightarrow \pi^*$ transition in C═O groups conjugated to aromatic moieties and to $\pi \rightarrow \pi^*$ electronic transition in the aromatic ring conjugated with C═C moieties.[13,29]

Nitrobenzene Oxidation. Analysis of nitrobenzene oxidation (NO) products from DL, DL_T, and grape stalks was carried out to assess the molar ratio of structural units in lignin. It was evident that the grape stalk lignin is of HGS type with a relatively high proportion of G units and a small amount of H units (Table 1). H:G:S ratios were slightly different in terms of H unit abundance when NO was carried out on DL/DL_T or directly using grape stalk material (Table 1). This is especially notable for DL, which revealed a low content of H units. This can be tentatively explained by substantial alkaline hydrolysis of *p*-coumaric acid type structures during removal of condensed tannins prior to isolation of DL. The H:G:S ratio obtained by nitrobenzene oxidation of grape stalks was 3:71:26 and may be considered as the most credible because it was assessed on in situ lignin without modification during the isolation procedure.

By comparisin of the H:G:S ratios found in DL and DL_T, it may be proposed that during alkali pre-extraction of grape stalks, before the isolation of dioxane lignin, a small fraction of lignin rich in H and G structural units was removed from the starting material.

Permanganate Oxidation. The information about different "condensed" and "noncondensed" structures was assessed by analysis of products arising from permanganate oxidation (PO) of dioxane lignin isolated from extractives- and proteins-free grape stalks without preliminary alkaline extraction to remove condensed tannins (DL_T sample). DL_T was ethylated prior to oxidation, which allowed protection of the phenolic units against aromatic ring degradation and, at the same time, to distinguish PO products from lignin and structurally associated tannins, thus elucidating their eventual origin.

Detected and identified PO products and their frequencies of occurrence are summarized in Figure 2. Nearly 95% of PO products were identified, most of them belonging to lignin. Thus, products **1**, **2**, and **4** were assigned to noncondensed lignin structures derived from the *p*-hydroxyphenyl (**1**), guaiacyl (**2**), and syringyl (**4**) structural units, respectively. The isohemipinic acid methyl ester (**6**) originated from degraded phenylcoumaran (β-5′) structures, and the products **7** and **9** can be assigned to guaiacyl and syringyl units, respectively, linked by β-6′ and γ-*O*-α bonds (phenylisochroman type structures) or to some other type of still unknown condensed structures. The oxidation products **12** and **13** are derived from biphenyl-type structures (5-5′) and diaryl ether type (4-*O*-5′) structures, respectively. Attention is drawn to the high content of condensed guaiacyl units (products **6** and **7**), which are much more abundant than in lignins of such agricultural stuffs as kenaf,[13] reed, and [14] banana plant[30] or in hardwoods.[20,31] When the H:G:S ratio in DL_T (2:73:25) and the fact that only phenolic units are accessible for the PO analysis are taken into account, the relatively low abundance of syringyc acid methyl ester (**4**) among PO products (Figure 2) indicates that the lignin molecules constituted by syringic units should be much less ramified that those constituted of guaiacyl units. The ratio of uncondensed structural units (products **1**, **2**, and **4**) and the condensed units (products **6**, **7**, **9**, **12**, and **13**) was 64:21 (Figure 2), indicating a relatively higher degree of lignin condensation in grape stalks.

Rather abundant PO products **3**, **5**, **8**, and **10** belong to condensed tannins that are present in grape stalks. The same products were found previously in PO analysis of condensed tannins extracted from pine bark.[32] Thus, products **3** and **5** are derived from the B-ring of procyanidins and proanthocyanidins (Figure 3), which are the main types of condensed tannins in grape stalks.[4,11,17] The PO product **8** is derived from the B-ring of prodelphinidins and indicates the presence of this type of flavonoid in grape stalks. Accordingly, product **10** (Figure 2) is derived from the A-ring of the corresponding flavonoid units

resonance of methoxy groups at 3.6−4.0 ppm as an internal standard and integrating the proton intensities in the corresponding functionalities.[20] The average number of methoxy groups per PPU was calculated on the basis of the H:G:S ratio determined by NO in grape stalks and dioxane lignins (Table 1).

As was already highlighted by FTIR spectroscopy (Figure 1), the elimination of tannins from grape stalks by alkaline extraction before the lignin isolation by acidolytic technique allows much more pure lignin sample. This proposition was additionally confirmed by ^1H NMR showing the decrease of resonances at 0.7−1.8 ppm assigned to aliphatic moieties in extractives and the decrease of phenolic groups (OH_{ph}) in DL after tannin removal by alkaline extraction before the lignin isolation (Table 2). However, the amount of phenolic groups (OH_{ph}) in DL was still high (47/100 PPU) when compared to the amount of OH_{ph} usually reported in dioxane lignins (20−30/100 PPU).[20,31,33] This fact indicates that tannins still occur in this sample, which correlates with conclusions drawn by analysis of the UV−vis spectrum of DL suggesting the contamination of isolated lignin with condensed tannins.

The relatively low amount of *β-O-4′* structures detected in DL and DL_T (0.34−0.38/PPU), based on the H_α resonance in the corresponding structures at 5.8−6.3 ppm, may be explained by the significantly higher proportion of condensed structures (Table 3). The last proposition correlates with discussed data on PO analysis (Figure 2) and the relatively low content of aromatic protons per PPU detected in proton spectra of dioxane lignins (Table 3).

The amount of benzaldehyde- and cinnamaldehyde-type structures, calculated on the basis of the integral of formyl proton signals in the corresponding structures (Figure 4), was rather insignificant and similar in both studied lignins. Some lower amount of benzaldehyde type structures in DL than in DL_T may be explained by their partial removal during the alkaline extraction of grape stalks before lignin isolation.

^{13}C NMR Spectroscopy. The quantification of the main structures in grape stalk lignin was carried out by quantitative ^{13}C NMR spectroscopy of DL (Figure 5). The resonance assignments were done on the basis of the $^1H-^{13}C$ correlation

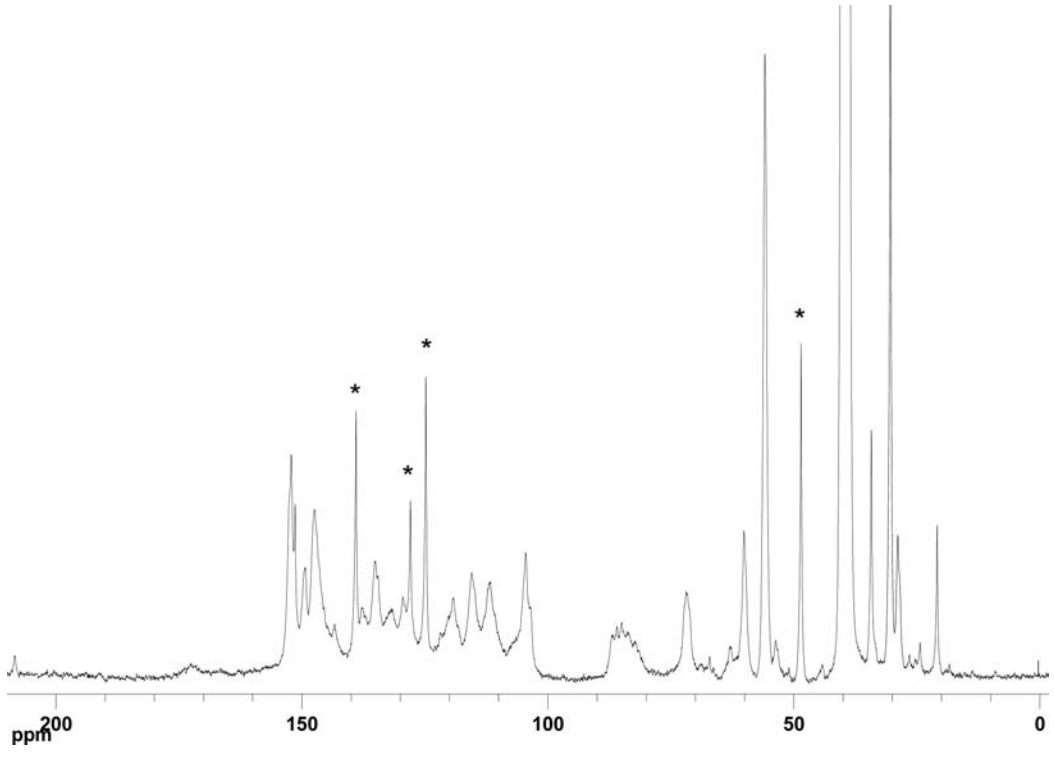

Figure 5. Quantitative ^{13}C NMR spectrum of dioxane lignin (DL) from grape stalks (DMSO-d_6). Solvent contaminants are marked by asterisks.

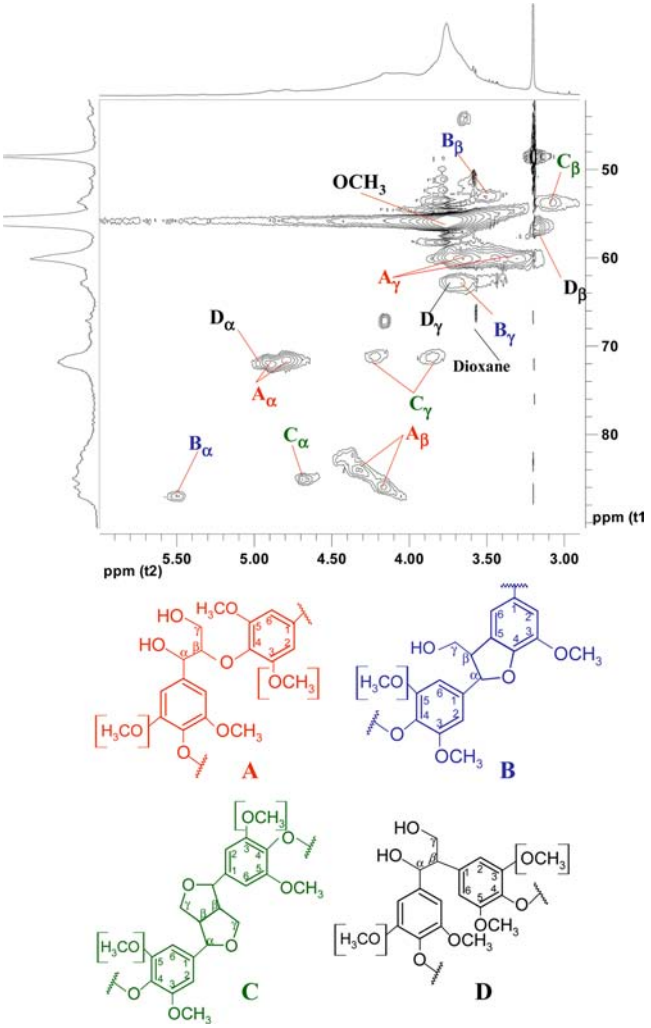

Figure 6. Oxygenated aliphatic region of HSCQ spectrum of DL from grape stalks. Major identified lignin structures, for which assignments are depicted in the spectrum, are presented below.

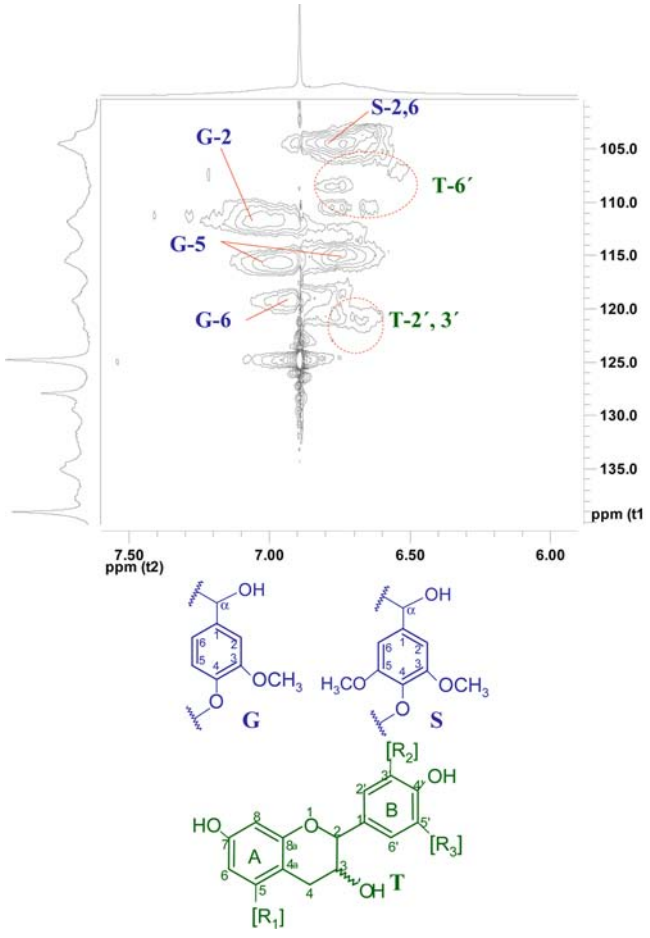

Figure 7. Aromatic region of HSCQ spectrum of DL from grape stalks. Identified guaiacyl (G), syringyl (S), and tannin (T) structures are depicted below.

(HSQC) spectra (Figures 6 and 7) using the well-known databases on lignin[34−36] and lignin model compounds.[37,38]

The primary analysis of the quantitative ^{13}C NMR spectrum of DL revealed unusual resonances for lignins in the range of 20−35 ppm assigned to aliphatic carbons (CH_3, CH_2, and CH) in extractives that were not eliminated during exhaustive extraction of grape stalks with acetone. The presence of condensed tannins was suspected on the basis of the unusually strong resonances for lignin at ca. 146 ppm (Figure 5) assigned to aromatic carbons in free phenolic moieties of proanthocyanidins.[39−41] In addition, the HSQC spectrum of DL (Figure 7) revealed $^{1}H-^{13}C$ correlation cross-peaks typical for the B-ring of procyanidins.[39−41] The cross-peaks typical for the A-ring of procyanidins were of a very low intensity, probably due to their lability under alkaline conditions[25,32,42] and the formation of a series of new structures difficult to assign. Due to the alkaline extraction of grape stalks at 100 °C before the isolation of DL, at least part of the procyanidins associated with DL might be in the form of catechinic acid arising as a result of intramolecular rearrangement reactions under alkaline conditions.[25,42] The notable resonance at ca. 208 ppm, assigned to ketone moieties in catechinic acid,[42] supports this proposition.

The fact of structural association of lignin with condensed tannins in grape stalk lignin supports earlier proposed chemical bonding between them.[4,11] The incorporation of tannins in a lignin network has been proposed in wood[43,44] and recently suggested in coconut coir[45] and in wheat straw[46] lignins. Hence, the formation of a lignin−tannin network could be realized also in the case of grape stalks. Besides this "natural" association, the new bonds could be formed between lignin and tannins during alkali pre-extraction of grape stalks and during acidolytic isolation of DL as depicted in Figure 8. The condensation of lignin with flavanols may explain the unusually high amounts of condensed structures detected in lignin by PO analysis (Figure 2). The cross peak at 44.3/3.62 ppm in the HSQC spectrum of DL (Figure 6) is very close to the corresponding carbon/proton chemical shifts reported for the C-2/H-2 condensed structures resulting from the reaction of procyanidins with phloroglucinol.[25] Unfortunately, the reliable identification of these lignin−tannin condensed structures using HMBC spectra was impossible due to their relatively low abundance in grape stalk lignin.

The quantification of major lignin structure has been done per aromatic ring (C_6) according to a previously described methodology.[20,30] The basic calculations involved are presented in Table 3, where the integral intensities of solvent contaminants were subtracted from intensities of carbons in the aromatic region at 102−156 ppm. Thus, the abundance of lignin structures linked by *β-O-4′* bonds was calculated on the

dx.doi.org/10.1021/jf502267s | J. Agric. Food Chem. 2014, 62, 5420−5428

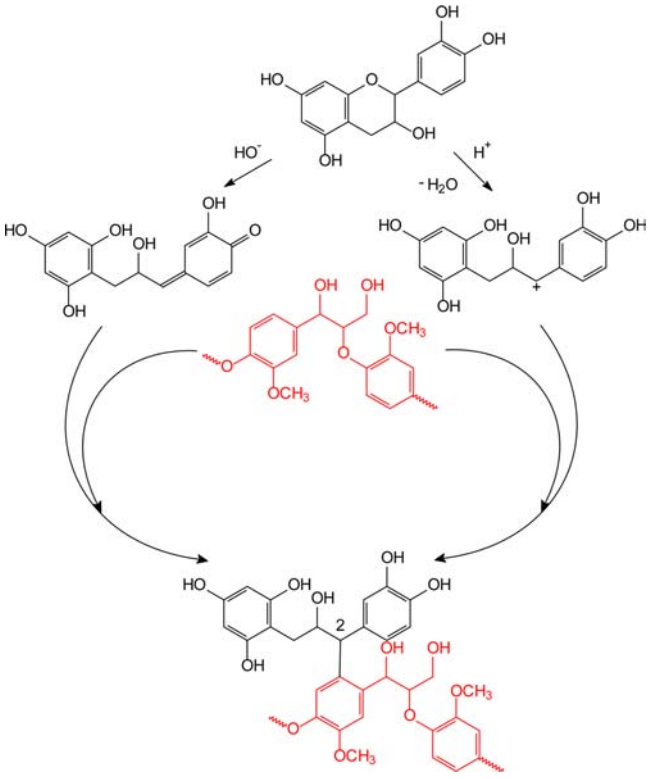

Figure 8. Schematic representation of lignin reaction with procyanidins under acidic and alkaline conditions.

basis of integral of signals at 59.0−61.0 ppm (C_γ resonance in *β*-*O*-4′ structures). The amounts of *β*-5′and *β*-*β*′ structures were assessed on the basis of C_β resonances in corresponding structures at 52.5−53.3 and 53.3−54.0 ppm, respectively, and the amount of *β*-1′ and *β*-5′ structures was calculated on the basis of the C_γ resonances in the spectrum region at 62.0−64.0 ppm (Table 3).

The data on abundance of *β*-*O*-4′ structures (Table 3) obtained by analysis of the ^{13}C NMR (0.39/C_6) in grape stalk dioxane lignin were consistent with those obtained by the ^{1}H NMR spectrum (0.38/C_9) (Table 3). A very similar abundance of *β*-*O*-4′ structures was reported previously for reed[14] and kenaf[13] dioxane lignins isolated from internode morphologic regions. ^{13}C NMR spectroscopy analysis (Table 3) also confirms a relatively high degree (Ar-C index of 1.50) of lignin condensation in grape stalks, which is comparable only to lignins isolated from nodes of reed.[14] According to the results of the PO analysis, most of the condensed lignin structures (ca. 17% mol) belongs to guaiacyl units substituted at C-5 and C-6 of the aromatic ring by aliphatic moieties (Figure 2). Meanwhile, the contribution of *β*-5′ structures (ca. 3% mol) (Table 3) to the total amounts of such condensed structures is not major. It may be proposed that a significant contribution to lignin condensation is due to its structural association with tannins. The condensation of tannins and lignin via ionic (e.g., quinone methide) mechanisms could occur under neutral/weakly acidic conditions due to tannin migration by diffusion from disintegrated cells to lignified cell tissues. Cell integrity may be violated both by natural reasons (e.g., down-regulated vacuole disrupts in parenchyma cells containing tannins) or by external factors during winemaking (e.g., during harvesting and destemming). In the last case the tannins from crushed grapes should also be taken into consideration. In addition, the contribution of the condensation reaction of lignin with tannins occurring under both alkaline (pre-extraction of grape stalks) and acidic (acidolysis) conditions during lignin isolation procedure cannot be excluded as well.

In conclusion, the results of the present study show that grape stalk lignin is of HGS type with a strong predominance of G units and a moderate amount of *β*-aryl ether structures, highly condensed, and, probably, structurally associated with tannins. This must be one of the reasons for difficult delignification of grape stalks by conventional pulping methods.

Unlike other lignins rich in G units, which possess a high abundance of biphenyl (5-5′), diaryl ether (4-*O*-5′), and *β*-5′structures, the high condensation degree of grape stalk lignin is due to unknown condensed structures of alkyl-aryl type. These structures, at least partially, must belong to lignin−tannin condensed structures. Among tannins involved in structural association with lignin, flavonols of gallocatechin and catechin types and ellagitannins were elucidated. The reasons for this lignin−tannin structural association are a challenge for future research.

Supporting Information

ABSTRACT: Three novel series of N_3-substituted imidacloprid derivatives were designed and synthesized, and their structures were identified on the basis of satisfactory analytical and spectral (^{1}H NMR, ^{13}C NMR, MS, elemental analysis, and X-ray) data. Preliminary bioassays indicated that all of the derivatives exhibited significant insecticidal activities against *Aphis craccivora*, with LC_{50} values ranging from 0.00895 to 0.49947 mmol/L, and the insecticidal activities of some of them were comparable to those of the control imidacloprid. Some key structural features related to their insecticidal activities were identified, and the binding modes between target compounds and nAChR model were also further explored by molecular docking. By comparing the interaction features of imidacloprid and compound **26** with highest insecticidal activity, the origin of the high insecticidal activity of compound **26** was identified. On the basis of the conformations generated by molecular docking, a satisfactory 2D-QSAR model with six selected descriptors was built using genetic algorithm−multiple linear regression (GA-MLR) method. The analysis of the built model showed the molecular size, shape, and the ability to form hydrogen bond were important for insecticidal potency. The information obtained in the study will be very helpful for the design of new derivatives with high insecticidal activities.

KEYWORDS: *synthesis, insecticidal activity, X-ray diffraction, molecular docking, QSAR*

INTRODUCTION

Neonicotinoid insecticides (NNs), acting selectively on the insect nicotinic acetylcholine receptors (nAChRs), have attracted the widespread interest of scientists continuously due to their broad spectrum of biological activities and high selectivity for crop protection and public health.[1−3] Since imidacloprid (**1**) was introduced in the 1980s as an insecticide for crop protection, NNs have gained dramatic developments and many new generation NNs, such as thiacloprid (**2**), acetamiprid (**3**), nitenpyram (**4**), thiamethoxam (**5**), clothianidin (**6**), and dinotefuran (**7**), were commercialized successively with their own prominence (Figure 1) and they account for at least 26% of the global insecticide market.[4−8]

Despite the tremendous amount of effort invested in the development of neonicotinoids, it remains essential to continually explore novel neonicotinoid candidates because significant increases in resistance and cross-resistance have been observed in various insect species after frequent field applications.[9−13] Modification of the structures of existing neonicotinoids can be an effective tactic to combat resistance. Accordingly, strategies for designing and synthesizing neonicotinoids remain an ongoing, attractive research area. These modification strategies includes replacement of the pyridine ring with a thiazole or other bioisosteric heterocyclic rings, substitution of the nitroimino group with other electron-withdrawing groups, and transformation of the imidazolidine moiety to novel heterocyclic equivalents.[3,8,14−21] Through various modifications, some analogues were found to exhibit either enhanced or comparable activity to **1**. Intriguingly, an acyclic neonicotinoid, sulfoxaflor (**8**), emerged as an alternative to overcome the drawbacks of **1** and has widely been commercialized for agricultural use now.[22] Also, divalent neonicotinoids,[23] proinsecticides of imidacloprid,[24] nenicotinoids with extended *N*-substituted-imine,[25] bis-neonicotinoid,[26] and crown-capped imidacloprid[27] have appeared consecutively in the literature in recent years. Overall, the excellent activity profiles of some derivatives, including improved potency, broad insecticidal spectra, low mammalian toxicity, and good systemic properties, suggested this compound class could be optimized through rational structural modification.

Although many research papers that discussed the structure optimization of neonicotinoid insecticides (NNs) are based on cyclic NNs, such as imidacloprid, few studies have focused on the structural modification of NNs at 3-position.[28] As is well-known, bioactive functional fragments or skeletons play a crucial role in biologically active chemicals, and modifications in the functional groups could improve or change the biological activity of parent compounds.[29−32] Furthermore, amidines[33,34] and triazoles[35,36] are identified as important pharmacophores and are widely used in pesticide and drug molecular design; also, the introduction of a sulfonyl group into a wide range of

heterocyclic compounds results in significant changes in the bioactivity of the compounds,[37,38] thus it was indicated that sulfonylamidines and sulfonyltriazoles may be useful structural motifs for optimization in the scaffold of bioactive molecules. Given these considerations, we developed an idea that substitution of the hydrogen on the nitrogen atom of imidacloprid with sulfonylamidino or sulfonyltriazolo substituents could optimize physicochemical properties and improve the biological activity of imidacloprid. To verify our speculation, in the present study, we incorporated the functional fragment sulfonylamidino or sulfonyltriazolo into imidacloprid at the *N*-3 position and synthesized three novel series of imidacloprid derivatives according to Schemes 1-3. As compared to conventional synthetic methods, our studies noted that the one-pot synthesis of a *N*-sulfonylamidino group using Cu-catalyzed three component coupling of sulfonyl (or phosphoryl) azide, alkyne, and amine could be an efficient and convenient method to combine several active moieties into one molecule, and it could be convenient to implement structural modification via alternation of diverse starting materials. To further study the role of the sulfonyltriazolo substituents played in the biological activities, another series of sulfonyltriazole-derived imidacloprid analogues were also synthesized using modified click chemistry. The insecticidal activities of the target compounds were evaluated against *Aphis craccivora*, and the median lethal concentrations (LC_{50}) were calculated accordingly. Additionally, to identify some key structural features responsible for their potency, the quantitative structure−activity relationship model was developed. Furthermore, the binding modes between target compounds and nAChR model were also explored by molecular docking, which generated useful information for future design of new neonicotinoid pesticides.

MATERIALS AND METHODS

General. Reagents were purchased from commercial sources and were used as received. All reagents and solvents were of reagent grade or purified according to standard methods before use. Analytical thin-layer chromatography (TLC) and preparative thin-layer chromatography (PTLC) were performed with silica gel plates using silica gel 60 GF254 (Qingdao Haiyang Chemical Co., Ltd.). Melting points were determined in Kofler apparatus and were uncorrected. Mass spectra were recorded on a Bruker Daltonics APEXII49e spectrometer (Bruker Company, USA) with ESI source as ionization. NMR spectra were recorded on a Bruker AM-400 spectrometer (Bruker Company, USA) at 400 and 100 MHz using TMS as the reference. Elemental analyses were determined on a Vario El GmbH elemental analyzer.

Synthesis of Key Intermediate ***9.*** Sodium hydride (60% oil dispersion, 80 mg, 2 mmol) was added portionwise to a stirred solution of **1** (514 mg, 2 mmol) in dimethylformamide (DMF) (30 mL) with ice cooling. After the addition, the stirring was continued for a further 30 min at room temperature. The reaction mixture was cooled again with an ice bath and treated with propargyl bromide (297.5 mg, 2.5 mmol). The mixture was stirred overnight at room temperature and then 9 h at 50 °C. After quenching the reaction with a drop of acetic

acid, the DMF was distilled off. The remaining solid was subjected to column chromatography on silica gel with ethyl acetate until no further **I** was detected in the fractions, then the elution was continued by replacing the eluting medium with ethyl acetate/methanol 5:1. The separated product was recrystallized from ethanol. Yield: 82%.

*General Synthetic Procedure for Target Compounds **10−54**.* Intermediate **9** (0.5 mmol) was added in CH_2Cl_2 (15 mL), and this mixture was stirred for 5 min when a clear solution was obtained. Under an N_2 atmosphere, sulfonyl azide (0.6 mmol), amines (0.5 mmol), and CuI (0.05 mmol) was added into this reaction mixture at room temperature. Triethylamine (0.6 mmol) was added. After the reaction was completed, as monitored by TLC, the reaction mixture was diluted by adding CH_2Cl_2 (4 mL) and aqueous NH_4Cl solution (6 mL). The mixture was stirred for an additional 30 min, and two layers were separated. The aqueous layer was extracted with CH_2Cl_2 (3 mL × 3). The combined organic layers were dried over $MgSO_4$, filtered, and concentrated in vacuo. The crude residue was purified by flash column chromatograph with an appropriate eluting solvent system.

*Data for Compound **10**.* Yield 52%; white solid; mp 120−123 °C. ^{1}H NMR (DMSO-d_6, 400 MHz) δ: 8.80 (s, 1H, NH), 8.37 (s, 1H, C5-H), 7.80 (d, 1H, J = 8.0 Hz, C3-H), 7.69 (d, 2H, J = 8.0 Hz, Ts-H), 7.52 (d, 1H, J = 8.4 Hz, C2-H), 7.33(d, 2H, J = 8.0 Hz, Ts-H), 4.42 (s, 2H, C6-H), 3.78 (t, 2H, J = 8.8 Hz, C7-H), 3.6 4(t, 2H, J = 9.6 Hz, C8-H), 3.58 (t, 2H, J = 6.8 Hz, C9-H), 3.07 (q, 2H, J = 6.4 Hz, $-\underline{CH_2}CH_2CH_3$), 2.91 (t, 2H, J = 6.8 Hz, C10-H), 2.50 (s, 3H, Ts-$\underline{CH_3}$), 1.45 (q, 2H, J = 7.6 Hz, $-CH_2\underline{CH_2}CH_3$), 0.82 (t, 3H, J = 7.6 Hz, $-CH_2CH_2\underline{CH_3}$). ^{13}C NMR (DMSO-$d_6$, 100 MHz) δ: 165.0, 160.5, 149.6, 149.5, 141.5, 141.4, 139.4, 130.3, 129.2, 125.6, 124.2, 46.6, 45.8, 45.2, 44.0, 43.1, 31.2, 20.9, 11.4. *General Synthetic Procedure for Target Compounds **55−57**.* Amine nucleophile (0.75 mmol, 1.5 equiv) was added to the mixture of phosphoryl azide (0.5 mmol, 1.0 equiv), **9** (1 mmol, 2.0 equiv), and CuI (0.05 mmol, 10 mol %) in CH_2Cl_2 (1 mL) at room temperature under N_2 atmosphere. Triethylamine (0.75 mmol) was added after the addition of the amine if necessary. After the reaction was completed, the same procedure was followed as for N_3-sulfonyl amidines **10−54**.

*Data for Compound **55**.* Yield 56%; white solid; mp 80−82 °C. ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 8.28 (s, 1H, C5-H), 7.65 (d, 1H, J = 6.4 Hz, C3-H), 7.22−7.64 (m, 9H, C2-H, $-(O\underline{Ph})_2$-H), 7.12 (t, 2H, J = 7.6 Hz, $-(O\underline{Ph})_2$-H), 4.45 (s, 2H, C6-H), 4.21 (m, 1H, $-N(\underline{CH}(CH_3)_2)_2$), 3.88 (t, 2H, J = 9.2 Hz, C7-H), 3.48 (m, 5H, C8-H, C9-H, $-N(\underline{CH}(CH_3)_2)_2$), 3.19 (t, 2H, J = 8.8 Hz, C10-H), 1.24 (d, 6H, J = 6.4 Hz, $-N(CH(\underline{CH_3})_2)_2$), 1.14 (d, 6H, J = 6.4 Hz, $-N(CH(\underline{CH_3})_2)_2$). ^{13}C NMR ($CDCl_3$, 100 MHz) δ: 163.9, 160.6, 151.6, 151.5, 149.2, 138.8, 129.3, 128.9, 124.7, 124.2, 120.4, 50.8, 47.9, 46.9, 46.3, 44.9, 44.8, 31.9, 20.7, 19.4. MS-ESI m/z: 749.3 $[M + H]^+$. Anal. Calcd For $C_{30}H_{37}ClN_7O_5P$: C, 56.12; H, 5.81; N, 15.27. Found: C, 56.03; H, 5.93; N, 15.34.

*General Synthetic Procedure for Target Compounds **58−64**.* Copper(I) thiophene-2-carboxylate (CuTC) (13.0 mg, 0.068 mmol) was added in 20 mL of $CHCl_3$. Then a solution of **9** (200 mg, 0.68 mmol) in 20 mL of $CHCl_3$ and a solution of sulfonyl azide

dx.doi.org/10.1021/jf501108j | J. Agric. Food Chem. 2014, 62, 5429−5442

(0.75 mmol) in 5 mL of $CHCl_3$ were added, and the reaction mixture was stirred for 6 h at room temperature. The resulting mixture was diluted with saturated NH_4Cl aq (50 mL) and extracted with $CHCl_3$ (3 × 50 mL). The combined organics were washed with brine, dried over $MgSO_4$, and concentrated under reduced pressure. The residue was purified by flash column chromatograph with an appropriate eluting solvent system.

Data for Compound ***58***. Yield 55%; white solid; mp 68−69 °C. ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 8.28 (s, 2H, C5-H, triazole-H), 8.01 (d, 2H, J = 8.0 Hz, Ts-H), 7.66 (d, 1H, J = 8.0 Hz, C3-H), 7.42 (d, 1H, J = 8.0 Hz, C2-H), 7.35 (d, 2H, J = 8.0 Hz, Ts-H), 4.56 (s, 3H, C6-H), 4.47 (s, 3H, C9-H), 3.83 (t, 2H, J = 8.8 Hz, C7-H), 3.54 (t, 2H, J = 10.4 Hz, C8-H), 2.47 (s, 3H, Ts-$\underline{CH_3}$). ^{13}C NMR (DMSO-d_6, 100 MHz) δ: 160.5, 149.7, 149.5, 145.0, 140.3, 139.5, 138.1, 130.5, 128.3, 125.5, 124.3, 46.5, 45.7, 45.5, 41.0, 20.8. MS-ESI m/z: 513.1 [M + Na]$^+$. Anal. Calcd For $C_{19}H_{19}ClN_8O_4S$: C, 46.48; H, 3.90; N, 22.83. Found: C, 46.59; H, 4.06; N, 22.98.

X-ray Crystallography. X-ray quality crystal of **11** was obtained from a solution of acetone/methanol after 7 d. The crystal structure of compound **11** was determined, and X-ray intensity data were recorded on a Bruker APEX II diffractometer using graphite monochromated Mo Kα radiation (λ = 1.54180 Å). A total of 13962 reflections were measured, of which 4913 were unique (R_{int} = 0.1631) in the range of 3.802 < θ < 70.070° (h, −22 to 23; k, −17 to 18; l, −7 to 11), and 2576 observed reflections with $I > 2\sigma(I)$ were used in the refinement on F^2. The structure was solved by direct method with the SHELXTL-97 program. All of the non-H atoms were refined anisotropically by full-matrix least-squares to give the final R = 0.1319 and WR = 0.3098. All hydrogen atoms were computed and refined using a riding model. The atomic coordinates for **11** have been deposited at the Cambridge Crystallographic Data Centre. CCDC-970304 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via CCDC CIF Depository Request Form for data published from 1994.

Insecticidal Assay. All compounds were dissolved in acetone and diluted with water containing Triton X-100 (0.1 mg/L) to obtain series concentrations of 500, 250, 100, 50, and 10 mg L^{-1} and others for bioassays. For comparative purposes, imidacloprid was tested under the same conditions. Each concentration was tested three times in parallel. The insecticidal activities of title compounds against *Aphis craccivora* were tested by leaf-dip method according to a previously reported procedure.[23] Horsebean plant leaves with 30 apterous adults were dipped in diluted solutions of the chemicals containing Triton X-100 (0.1 mg L^{-1}) for 5 s, and the excess dilution was sucked out with filter paper; the burgeons were placed in the conditioned room (25 ± 1 °C, 50% relative humidity (RH)). Water containing Triton X-100 (0.1 mg L^{-1}) was used as control. Assessments were made after 24 h by the number of killed and size of live insects relative to that in the negative control, and evaluations were based on a percentage scale of 0−100, in which 0 = no activity and 100 = total kill. The deviation of values was ±5%. The mortality rates were subjected to probit analysis, and the median lethal concentrations (LC_{50}) were calculated accordingly. All bioassay results are summarized in Tables 1−4.

Molecular Docking Study. All molecular structures were sketched in SYBYL6.9[39] software package. Energy minimizations were performed using the Tripos force field with a distance dependent dielectric function and Powell method with a convergence criterion of 0.05 kcal/mol. Partial atomic charges were calculated using Geisteiger−Huckel method. The local minimum energy conformations of these minimized compounds were generated using the multisearch method. Schrödinger's LigPrep program[40] was used to process the generated conformations. The crystal structure of the acetylcholine binding protein (AChBP) from *Lymnaea stagnalis* (Ls-AChBP) in complex with imidacloprid (IMI) (PDB: 2ZJU) was used for the molecular docking studies because there is still no crystal structure of nAChR of insect *Aphis craccivora* and Ls-AChBP has high homology to the extracellular domain of nAChR. Actually, Ls-AChBP has been used to study the interaction between compounds with nAChR.[41−43] Chain A, chain B, and crystal waters were selected and prepared for subsequent grid generation using the Protein Preparation Wizard in the Schrodinger Suite. The structure was further treated by adding hydrogen atoms, assigning protonation states. Grids were then generated based on the ligand in the crystal structure using the Receptor Grid Generation module in Glide.[44] Lastly, the docking was performed using Glide.

Quantitative Structure−Activity Relationships Analysis. The docked conformations of these derivatives were imported into Dragon software[45] and molecular descriptors calculated. These descriptors are respectively 0D molecular descriptors (constitutional descriptors), 1D molecular descriptors (functional groups counts, atom-centered fragments), 2D molecular descriptors (topological descriptors, walk and path counts, connectivity indices, information indices, 2D auto-correlations, edge adjacency indices, Burden eigenvalues, topological charge index, eigenvalue-based index), 3D molecular descriptors (Randic molecular profiles, geometrical descriptors, RDF descriptors, 3D-MoRSE descriptors, WHIM descriptors, GETAWAY descriptors), and other molecular descriptors (charge descriptors and molecular properties). To reduce the nonuseful and redundant information, constant variables, near-constant variables, and one of any two descriptors with a correlation coefficient of 0.98 or higher were excluded, and thus 694 descriptors were used in next step.

To build and validate the QSAR model, 55 compounds were used as training set and test set, respectively. The insecticidal activities of these compounds against *A. craccivora* expressed as pLC_{50} values were defined as dependent variable for the following analysis.

To search the feature space and select descriptors related with the insecticidal activities, a combination of genetic algorithm and multiple linear regression (GA-MLR)[46] was used. GA-MLR method has been applied in many studies.[47,48] MobyDigs software[49] was used to build QSAR model of these derivatives. The leave-one-out (LOO) cross validation correlation coefficient (Q^2_{loo}) was used as the fitness function. The population size was set to 100, and maximum allowed variables in a model was 6. Other corresponding parameters were set as default.

To validate the built model, several statistic terms including correlation coefficient (R^2), leave-one-out (LOO) cross-validated correlation coefficient (Q^2_{loo}), and root-mean-square error (RMSE) were used. Moreover, the external validation correlation coefficient (Q^2_{ext}) of these compounds from the test set was used to evaluate the predictive ability of the QSAR model.

The hat value was used to evaluate the applicability domain (AD) of the model, defined as follows:

$$h_i = x_i(X^TX)^{-1}x_i^T \quad (i = 1, ..., m)$$

where x_i, m, and X are respectively row vector of the descriptors of the query compound i, the number of query compounds, and the $n \times k$ matrix of the descriptors of the training set (n and k are the number of descriptors of training set and the model, respectively). The plot of hat values and cross-validated standardized errors (the Williams plot) visually display the application domain of the built model. The horizontal and vertical dashed lines display the limits of normal values in the plot. For example, if the hat value of one compound id greater than h^*, this compound is considered as an X outlier. The cross-validated standardized error of a compound is more than 3.0 standard deviation units, and thus the compound is a Y outlier in a model. The warning hat (h^*) is defined by $3k'/n$. Here, n and k are the number of compounds in training set and the number of descriptors plus 1, respectively.

RESULTS AND DISCUSSION

Synthesis. The synthetic routes to target compounds are outlined in Schemes 1−3. As outlined in Schemes 1−2, briefly, starting from imidacloprid **1**, a propargyl group was first introduced in the N_3-position of **1** upon reaction with propargyl bromide in the presence of sodium hydride to give key precursor **9** in 82% yield. Subsequently, key precursor **9** was successfully employed as an efficient reacting partner in the Cu-catalyzed three-component reaction with sulfonyl azides and amines to produce the corresponding N_3-imidacloprid sulfonyl amidines **10**−**54** in moderate yields. Under the optimized

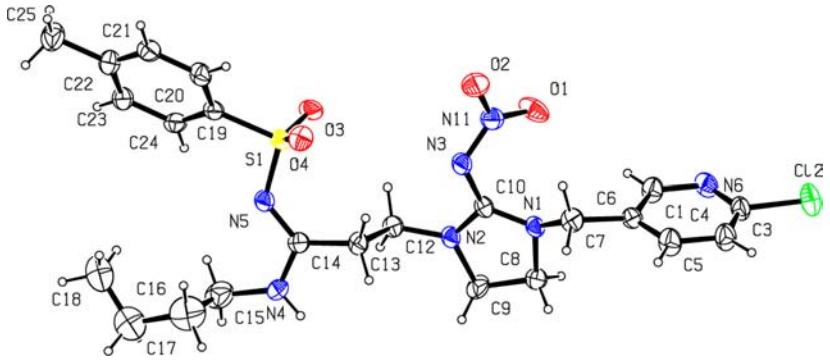

Figure 2. X -ray crystal structure of compound **11**.

conditions, a wide range of amines including primary, secondary, aliphatic, aryl, acyclic, and/or cyclic types were all efficiently coupled to furnish the corresponding amidines. Amino esters were likewise incorporated with almost the same efficiency. Moreover, the scope of the azide counterpart also turned out to be broad, and various types of such as sulfonyl azides and phosphoryl azides (**55**−**57**) were readily employed with high efficiency. The coupling reaction has a wide substrate scope, a high tolerance to various functional groups, and very mild reaction conditions. The reaction proceeds through a ketenimine intermediate, which is generated in situ from the triazole cycloadduct upon release of N_2 gas.[50]

As shown in Scheme 3, it has been reported that the introduction of a sulfonyl group into a wide range of heterocyclic compounds resulted in significant changes in the bioactivity of the compounds. Next, we initiate a new search for bioactive sulfonyl triazole molecules for structural modification using similar click chemistry. Interestingly, *N*-sulfonyl-1,2,3-triazoles **58**−**64** were expectedly obtained from **9** and sulfonyl azides in the absence of amines in good yields by the action of copper catalysts. In contrast to the traditional click methodology, the traditional click reaction using the $CuSO_4$/sodium ascorbate system resulted in both poorer conversions and selectivity. Addition of *tert*-butyl sulfide to the $CuSO_4$/sodium ascorbate system resulted in an improved ratio and maintained high conversion. During our attempts to achieve high conversion and selectivity by screening different copper(I) catalysts, copper(I) thiophene-2-carboxylate (CuTC) (Liebeskind's reagent) was found to be a convenient, effective catalyst for the synthesis of *N*-sulfonyl-1,2,3-triazoles at ambient temperature under anhydrous conditions. Furthermore, dichloromethane and chloroform were identified as optimal solvents for the CuTC-catalyzed 1-sulfonyl triazole synthesis, with both leading to complete reactions after 2−5 h.

All newly synthesized compounds were purified by column chromatography, and their structures were confirmed by ^{1}H NMR, ^{13}C NMR, ESI-MS, and elemental analysis. To obtain precise three-dimensional structural information and absolute configurations for **10**−**54**, compound **11** was recrystallized by slow evaporation from a solution of acetone/methanol and its single crystal structure was determined by X-ray crystallography as illustrated in Figure 2.

Insecticidal Activity against Aphis craccivora. On the basis of the methodology in Schemes 1−3, with 55 derivatives **10**−**64** in hand, we next examined their insecticidal activity against *Aphis craccivora*, imidacloprid was tested under the same conditions as a comparison compound. The results were summarized in Tables 1−4.

As shown in Tables1−4, all of the derivatives exhibited moderate to potent insecticidal activities against *Aphis craccivora*, with LC_{50} values ranging from 0.00895 to 0.49947 mmol/L. Among them, some of compounds were found to be equally potent or superior insecticidal activities to imidacloprid. For example, when *Aphis craccivora* were fed with the diet containing 500 mg L^{-1}, the corrected mortality rates of most of compounds had 100% inhibitory effect after 1 day. At reduced dosages, most of the target compounds still remaining had excellent inhibitory activity and had >80% mortality at 250 mg L^{-1}. Even at a 50 mg L^{-1} diet, compounds **18**, **26**, **41**, **47**, **48**, **49**, **62**, and **64** exhibited good insecticidal activity against *Aphis craccivora* and had >60% mortality. The LC_{50} values of those compounds were 0.05948, 0.00895, 0.07745, 0.07550, 0.06222, 0.07286, 0.06196, and 0.04470 mmol L^{-1}, respectively, whereas that of imidacloprid was 0.03602 mmol L^{-1}. Intriguingly, the insecticidal activity of compound **26** (LC_{50}: 0.00895 mmol L^{-1}) showed approximately 4-fold higher activities than that of imidacloprid based on the value of LC_{50}, which implied further possibilities for lead compound development.

As for the sulfonylamidine series **10**−**54**, the effects of different substituent groups in the sulfonylamidine side chains were investigated. As shown in Table 1, when the R_1 group was fixed as methylphenyl (**10**−**31**), changing the NR_2R_3 on in the sulfonylamidine side chains could lead to a remarkable change in activity. For example, linear alkyl groups, like *n*-propyl in **10**, lead to a much better efficacy than branched alkyl groups, like isopropyl in **14**. Substitution of the NR_2R_3 group with cycloalkyl (**15**), heterocycloalkyl (**16**−**19**), and amino esters (**52**−**54**) did not display a significant improvement in insecticidal activity as compared to **10**. Moreover, the potency of compounds with the aromatic or heterocycle rings (**20**−**31**) depended significantly upon the nature of the substitutes and their position at the aromatic ring, and compound **26** (*p*-Cl-C_6H_5) gave the best result compared with other synthetic derivatives. Interestingly, when the R_1 group was changed from methylphenyl to other substitutions (pyridinyl, dimethylamino, methyl, *p*-fluorophenyl, 2-naphthyl, etc.), the order of potency was somehow changed, and the substituents R_1 present in the functional group N═SO_2R_1 were also a crucial factor that governed activity. For example, the introduction of a pyridinyl group (**35**, 0.08106) into N═SO_2R_1 increased the insecticidal activities of the compounds (e.g., compounds **32**−**34**). While for compounds **37**−**39**, compound **39** bearing a fluorophenyl R_1 group displayed more potent activity than **38** with a pyridinyl R_1 group. Overall, considering the discussion above, these findings suggested that their insecticidal potency was dual-controlled by both the R_1 and NR_2R_3 groups in the sulfonylamidine side chain.

In addition to sulfonyl amidines, another two series of phosphoryl amidine derivatives (**55**−**57**) and sulfonyltriazolo-substituted 1-derivatives (**58**−**64**) were investigated as well. As indicated in Tables 3 and 4, all of the title compounds showed moderate to good insecticidal activities against *A. craccivora*, and some of them were either similar or better than that of imidacloprid. Significantly, compound **57** displayed the most potent activity among the tested compounds against *A. craccivora* and better than the positive control imidacloprid. In contrast, the activity of compounds with sulfonylamidino groups were predominantly higher than those of phosphoryl amidine or sulfonyltriazolo-substituted **1** derivatives, indicating that the electron distribution and substituents on N_3-position of **1** play an important role in the derivatives' activity. Taken together, these observations further underlined the insecticidal differences could be ascribed to a combination of factors, like the nature of the substituents (which may depend on the size of substituents, electronic characteristics of substituents, or other factors) or a different interaction at the site.

Meanwhile, it has been widely known that the physical properties of an insecticidal compound may be manipulated to obtain products with other selected types of activity by proper

selection of the derivative moiety. Encouraged by these investigations, some N_3-substituted imidacloprid derivatives, such as bis-imidacloprid,[26] crown-capped imidacloprid,[27] N_3-oxalyl imidacloprid derivatives,[51] have been prepared by different groups in recent years. It should be noted that these reported N_3-substituted compounds may act as pro-drug by hydrolyzing to IMI. Further biological data supported this conclusion that these N_3-substituted compounds as proinsecticides would likely be in vivo activated to release of the parent imidacloprid and such an assumption was supported by Kagabu et al.'s reported experimental method.[24] In the present study, the insecticidal effects of these derivatives may be similar to those seen in Kagabu's study. Therefore, one possibility is that these derivatives may be metabolized in vivo to regenerate imidacloprid, exerting insecticidal effects, although the exact mode is unknown.

Molecular Docking Analysis. It is noteworthy that the initially observed effects of these derivatives on *A. craccivora* were excitatory symptoms, such as tremors, followed by paralysis and mortality (personal observations). It could be postulated that the insecticidal activity of these synthetic derivatives could be due to potential effects on the insect nervous system, similar to the neuroactive imidacloprid.[52] To prove this hypothesis, imidacloprid and these derivatives were docked into the active site of AChBP. The most likely binding conformations were selected based on the score and the binding mode. In this way, the most possible conformations for all compounds were obtained. Imidacloprid was redocked to validate the docking reliability. The binding mode of redocked and co-crystallized imidacloprid is almost same in the active site of AChBP (Figures 3 and 4). For example, the nitrogen atom of the pyridine ring interacts with the carbonyl group of Leu102 and the amide group of Met114 by water-mediated hydrogen bonds. These H-bond interactions play important roles in the interaction of imidacloprid with the residues in the active site of AChBP.[41] The guanidine moiety of imidacloprid forms $\pi-\pi$ stacking interactions with the aromatic ring of Tyr185. The methylene (CH_2-CH_2) bridge of imidacloprid and Trp143 form $CH-\pi$ contacts.

After validating the docking reliability, all these derivatives were docked into the active site of AChBP. The 55 compounds show similar binding modes. To more clearly identify the origins of the high insecticidal activity of the compound **26**, the detailed interactions of compounds **26** and **11** with AChBP are shown in Figure 5. In the docked complex of compound **26** and AChBP, the imidacloprid skeleton of compound **26** is buried deep in the binding site and mainly interacts with loop D (Phe52-Trp58), loop B (Gly141-His145), and loop C (Tyr185-Glu193). Some studies have shown that these loops are essential to the high neonicotinoid sensitivity of insect nAChRs.[41] The nitro and sulfonyl group of compound **26** form hydrogen bonds with the side chain atoms of Tyr192 and Gln73, respectively. The pyridine ring forms $\pi-\pi$ stacking interactions with conserved Tyr185, which are crucial to the binding of imidacloprid derivatives with AChBP. The pyridine ring also contacts with the aromatic ring of Trp143 and side chain of Met114. The chlorine atom on the pyridine ring contacts the hydroxyl group of conserved Tyr185. The guanidine moiety of imidacloprid contacts the side chain of Tyr192. Arg104 and the nitro group have electrostatic interactions. The methylene (CH_2-CH_2) bridge of imidacloprid contacts the side chains of Cys187 and Cys188. The methylbenzene group of compound **26** has van der Waals

dx.doi.org/10.1021/jf501108j | J. Agric. Food Chem. 2014, 62, 5429−5442

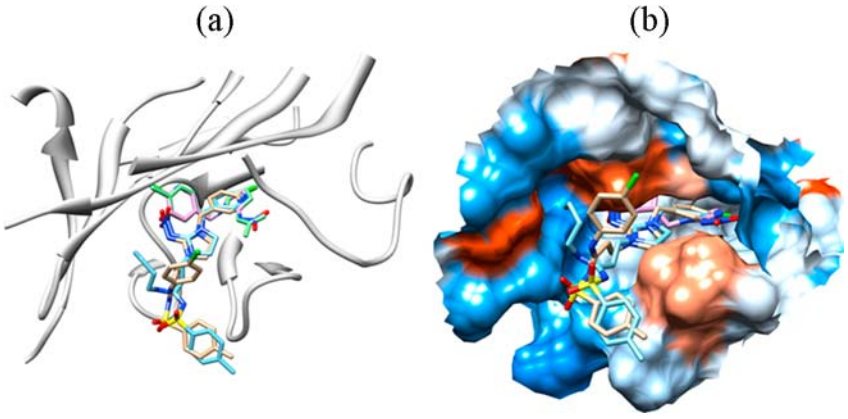

Figure 3. (a) The comparison of imidacloprid in the crystal structure and imidacloprid, compounds **26** and **11** in the docked complex by superimposing the coordinates of protein together. (b) A molecular surface of the active site of Ls-AChBP color-coded by amino acid hydrophobicity. The surface ranges from dodger blue for the most polar residues to orange−red for the most hydrophobic, with white in between. Imidacloprid in the crystal structure and imidacloprid, compounds **26** and **11** in the docked complex are shown in green, hot pink, orange, and cyan, respectively.

interactions with Cys188 and Pro189 of loop C. The main chain and side chain atoms of Arg104 form hydrogen bonds with main chain atom of Leu112 and side chain atom of Gln73, respectively (these H-bond interactions are not given in Figure 5). Under the influence of these hydrogen bonds, the side chain atoms of Leu112 contact with the aromatic ring of chloro-phenyl group.

The detailed interactions of compound **11** and residues of the active site of AChBP are shown in Figure 5b. The nitrogen atom (N4) of compound **11** and the side chain atom of Gln73 form one hydrogen bond. Like in compound **26**, the butyl group of compound **11** also contacts the side chain atoms of Leu112. The other interactions of compound **11** with AChBP are similar to the ones of compound **26**.

By comparing the binding mode and docking score of newly synthesized compounds and imidacloprid (shown in Figure 3.), the origin of the high insecticidal activity of the compound **26** can be identified. The docking scores of compound **26**, imidacloprid, and compound **11** are −7.078, −6.991, and −6.461, which are consistent with the insecticidal activity of these compounds. From the binding mode, in common, imidacloprid and the imidacloprid skeleton of compounds **26** and **11** are buried in the binding site and mainly interact with loop D (Phe52-Trp58), loop B (Gly141-His145), and loop C (Tyr185-Glu193). Several residues including Trp53, Met114, Trp143, Tyr185, and Tyr192 in the binding pocket form favorable hydrophobic and van der Waals interactions with imidacloprid and imidacloprid moieties of compound **26** and **11**. Differently, the methylbenzene groups of compound **26** and **11** form the additional van der Waals interactions with Cys188 and Pro189 compared with imidacloprid. The aromatic ring of chloro-phenyl group of compound **26** and the butyl group of compound **11** have favorable hydrophobic interactions with the side chain atoms of Leu112. Moreover, the hydrophobic contributions of aromatic ring of chloro-phenyl group of compound **26** are more favorable than ones of the butyl group of compound **11**. The nitrogen atom of the pyridine ring of imidacloprid forms hydrogen bonds with the carbonyl group of Leu102 and the amide group of Met114 by water. However, for compound **26**, there are two hydrogen bonds formed between the nitro group and the side chain atoms of Tyr192 and between the sulfonyl group and the side chain atoms of Gln73. For compound **11**, the nitrogen atom (N4) and the side chain atom of Gln73 form one hydrogen bond. Thus, the more favorable hydrophobic and van der Waals interactions and stronger hydrogen bonding interactions of compound **26** with the binding pocket contribute to its higher insecticidal activity.

QSAR Analysis. On the basis of the reasonable docked conformations, the following QSAR analysis was performed. GA method was used to select the most relevant descriptors to the insecticidal activities of these derivatives based on the training samples. The population size for the evolution was set to 100. Other parameters were set to the default value. The optimum number of variables (V_n) was selected when adding new descriptors did not improve the performance of the model significantly. Compared with the four-parameter model and five-parameter model, the six-parameter model with both higher internal and external predictive ability was adopted here.

The four-parameter and five-parameter models and corresponding statistical parameters were given as below:

$$\begin{aligned} pLC_{50} &= 0.01035T(O..Cl) - 0.66704EEig08d \\ &\quad + 0.04511RDF140u + 0.4984Mor12m \\ &\quad + 4.62595 \end{aligned}$$

$$N_{tr} = 46,\ N_{tst} = 10$$

$$R^2_{tr} = 0.7878,\ RMSE_{tr} = 0.1397$$

$$Q^2_{loo} = 0.7370,\ RMSE_{loo} = 0.1555$$

$$Q^2_{ext} = 0.7306,\ RMSE_{ext} = 0.1574$$

$$\begin{aligned} pLC_{50} &= 0.0097T(O..Cl) - 0.52152EEig08x \\ &\quad + 0.04153RDF140u + 0.56465Mor12m \\ &\quad + 0.40228Mor16m + 4.55723 \end{aligned}$$

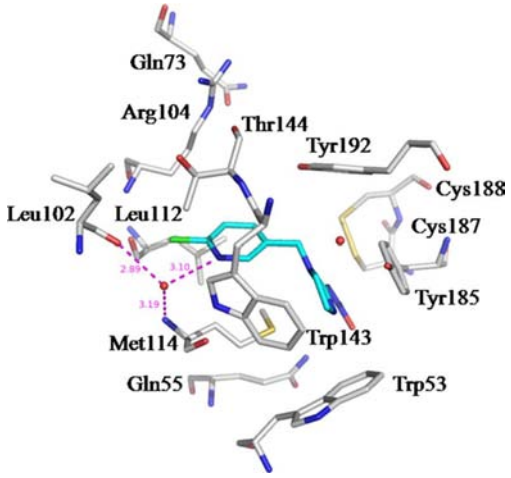

Figure 4. Interactions between imidacloprid and Ls-AChBP.

Compared with four-parameter model, the introduction of descriptor Mor16m into five-parameter model significantly improves the internal and external predictive abilities. The five-parameter model is statistically good with correlation coefficient R^2_{tr} of 0.9283, cross-validated correlation coefficient Q^2_{loo} of 0.9103, and the external validation coefficient Q^2_{ext} of 0.8780.

The best six-parameter model and corresponding statistical parameters were given as below:

$$\begin{aligned} pLC_{50} &= 0.00948T(O..Cl) - 0.65887EEig08x \\ &\quad + 0.52682BELm7 + 0.03658RDF140u \\ &\quad + 0.62012Mor12m + 0.40791Mor16m \\ &\quad + 4.31497 \end{aligned}$$

$$N_{tr} = 46,\ N_{tst} = 10$$

$$R^2_{tr} = 0.9479,\ RMSE_{tr} = 0.0692$$

$$Q^2_{loo} = 0.9287,\ RMSE_{loo} = 0.0810$$

$$Q^2_{ext} = 0.9270,\ RMSE_{ext} = 0.0819$$

Compared with five-parameter model, the external predictive ability of six-parameter model with Q^2_{ext} of 0.9270 was improved obviously by introducing the descriptor BELm7 (the lowest eigenvalue *n*, 7 of Burden matrix weighted by atomic masses).

The above results indicate that the built six-parameter model is stable, robust and predictive. The model exhibits a good external predictive ability with Q^2_{ext} of 0.9270 and $RMSE_{ext}$ of 0.0819. The experimental and predicted pLC_{50} are given in Table 5. The correlation plot of predicted and experimental values is shown in Figure 6. Figure 7 showed the Williams plot of the built model.

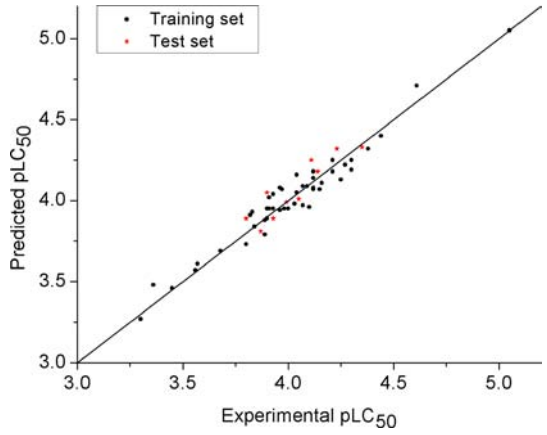

Figure 6. Experimental and predicted activities of target compounds in the training and test sets.

From Figure 7, it can be seen that the hat value (0.683) of imidacloprid is larger than the warning value (h^* = 0.457), and thus imidacloprid is considered as an *X* outlier. The molecular structure of imidacloprid differs greatly from other compounds. Moreover, the molecule docking also indicated the binding modes of this compound and other compounds with AChBP are different.

According to the regression model, the standardized regression coefficients (Std.Reg.Coeff) of the selected descriptors are 0.48696 (T(O..Cl)), −0.8566 (EEig08x), 0.25435 (BELm7), 0.47561 (RDF140u), 0.78685 (Mor12m), and 0.38254 (Mor16m),

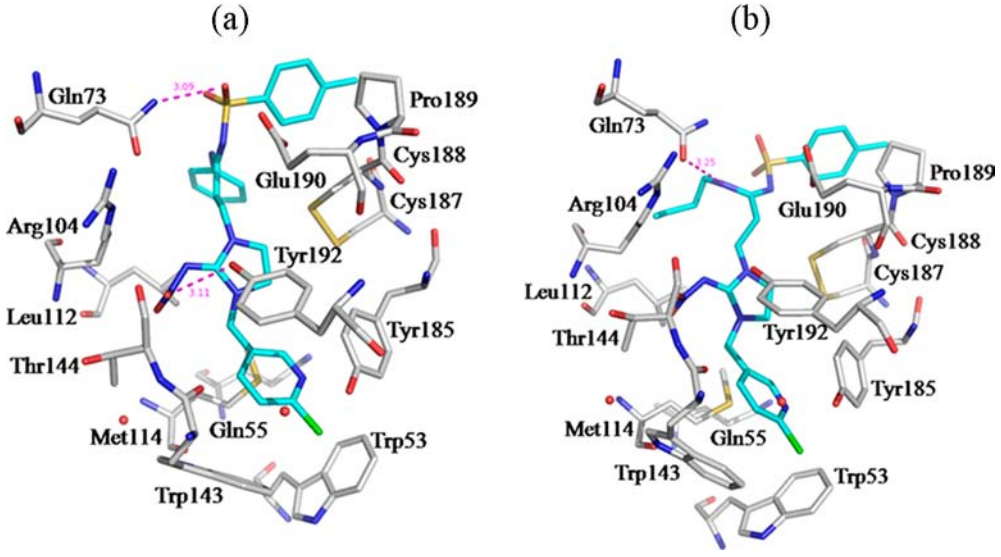

Figure 5. Binding mode of compounds **26** and **11** with Ls-AChBP. (a) Detailed interactions of compound **26** with the active site of Ls-AChBP. (b) Detailed interactions of compound **11** with the active site of Ls-AChBP.

[a]Compounds in test set.

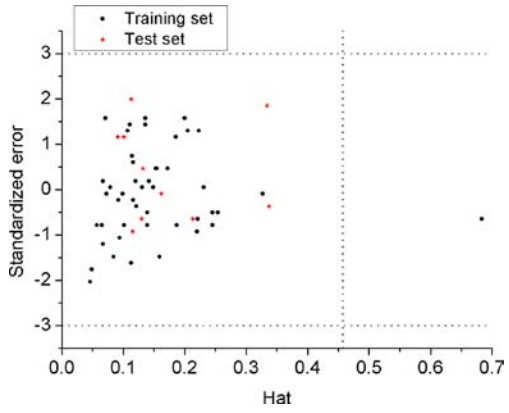

Figure 7. Williams plot of the training and test sets. The dashed lines are the warning value of hat (h^* = 0.457) and the 3σ limit, respectively.

respectively. The Std.Reg.Coeff determined the relative importance of these descriptors. The most important descriptor is an edge adjacency index EEig08x (eigenvalue 8 from edge adjacency matrix weighted by edge degrees).[53] This descriptor can reflect the molecular complexity and branching. The negative correlation coefficient of this descriptor indicates the larger the value of this descritpor is, the lower the biological activity of the compound is. The second important descriptor Mor12m is a 3D-molecule representation of structures based on electron diffraction (3D-MoRSE) descriptor. Mor12m is weighted by atomic masses.[54] It suggested that the molecular size has a close correlation with the activities of the studied compounds. The third important descriptor is T(O..Cl) descriptor (topological descriptors) representing the sum of topological distances between O and Cl.[55] From the above molecular docking analysis, the O and Cl atoms are involved in the formation of hydrogen bond between these derivatives and AChBP. The selection of the descriptor T(O..Cl) indicates the ability to form hydrogen bond of compounds has a high correlation with their activities. RDF140u (radial distribution function at 14.0 Å/unweighted) belongs to RDF descriptors which can be interpreted as the probability distribution of finding an atom in a spherical volume of radius R.[56] The RDF descriptors can provide information such as interatomic distances in the entire molecule, bond distances, ring types, planar, and nonplanar systems and atom types. Mor16m descriptor is another 3D-MoRSE descriptor. BELm7 is the lowest eigenvalue n 7 of Burden matrix weighted by atomic masses.[57] The Burden descriptors can reflect relevant aspects of molecular structure and are therefore useful for similarity searching. Except EEig08x, all other five descriptors have a positive correlation with the insecticidal activities of the studied compounds, indicating that the increase of the value of the descriptor will improve the biological activity of the compound in the application domain of the built model.

In summary, three novel series of N_3-substituted imidacloprid derivatives were designed and synthesized, and their structures were characterized by NMR spectroscopy, mass spectrometry, elemental analysis, and single-crystal X-ray diffraction analysis. The insecticidal activities against *Aphis craccivora* were evaluated. Preliminary bioassays indicated that some title compounds exhibited excellent insecticidal activities against *Aphis craccivora*, and their insecticidal activities against *Aphis craccivora* were comparable to those of the control imidacloprid. SAR analysis indicated that the size, electron density, and distribution of the substituents at the N_3 position are critical to the derivatives' activity. Furthermore, the

dx.doi.org/10.1021/jf501108j | J. Agric. Food Chem. 2014, 62, 5429−5442

molecular docking analysis indicated that imidacloprid and compounds **26** and **11** form the similar hydrophobic and van der Waals interactions with Trp53, Met114, Trp143, Tyr185, and Tyr192 in the binding pocket. Compared with imidacloprid, the more favorable van der Waals and hydrophobic interactions from the methylbenzene group and the aromatic ring of chloro-phenyl group of compound **26**, and stronger hydrogen bonding interactions from the nitro and sulfonyl group with the binding pocket contribute to higher insecticidal activity. From the QSAR analysis, the molecular size, shape, and the ability to form hydrogen bond are important for insecticidal potency. From the built QSAR model, the decrease of the value of selected descriptor EEig08x and the increase of the value of other descriptors will be favorable to improve the insecticidal activity of compound. These results can promote the understanding the interaction mechanism of these derivatives and nAChR and provide the useful information for further structural modification. Further structural optimization and mode of action studies are currently underway in our laboratories

ABSTRACT: A simple method has been described for simultaneous determination of phenolic acid, flavonoid, and other phenol contents in various natural honey samples collected from various regions of Yemen. Multi-walled carbon nanotubes were used as a solid-phase adsorbent for extraction of the polyphenols from honey samples. The total contents of phenolic acids, flavonoids, and phenolic components of the 12 different samples were found in the range of 363−2658, 261−1646, and 224−1355 μg/100 g of honey samples, respectively. The major phenolic acid, flavonoid, and phenolic compound in these samples were found to be 4-hydroxybenzoic acid (1410 μg/100 g), chrysin (850 μg/100 g), and cinnamic acid (1336 μg/100 g), respectively. A total of 25 compounds (10 phenolic acids, 9 flavonoids, and 6 phenols) were analyzed, and a total of 24 were detected, while only 23 compounds were determined quantitatively in the honey samples. The developed method showed potential usefulness for the analysis of honey and was used for the determination of polyphenols in honey extracts.

KEYWORDS: *liquid chromatography, honey, phenolic acids, flavonoids, phenols*

INTRODUCTION

Honey is a delicious viscous sweetener, which is made naturally by bees.[1] During the feast on flower, the bees collect the flower nectar and mix it with saliva inside their mouth to produce honey; they deposit it into the cells of the walls of the hive.[2] The honey can be made from a variety of different flowers, while its flavor and texture vary with the type of flower nectar from which it was collected.[2] Honey is a pure product and does not allow for the addition of any other substance.[3,4]

From the ancient times, honey has been used as both a confectionary food and a medicine. Many authors have reported that honey is a rich source of flavonoids and phenolic acids, which are mainly responsible for its significant antioxidant capacity.[5−9] It was reported that these phenolic constituents and flavonoids in honey could also be responsible for many pharmacologic effects, including wound healing,[10] contributing to the protection of cultured skin cells and tissues from oxidative damage,[11] and food preservation.[12,13] In addition, the quality of honey and its price is mainly evaluated on the basis of its floral origin and chemical composition.[14] Therefore, it is important to analyze honey and find out which flavonoids and phenolic compounds are present and in what amount.

Yemeni honey is a type of honey reputed for its flavor and medicinal qualities. It is a type of monofloral honey that has a characteristic taste because of the fact that the bees that produce it generally only gather nectar from one type of flower, the flowers of the "Sidr" tree (*Ziziphus spina-christi* L.). Numerous analytical methods have been reported in the literature for the analysis of honey contents and to make a correlation with floral source.[15−20] Many authors have reported the liquid chromatographic techniques for the analysis of organic acids in honey; these methods have proven to be very useful in determining the authenticity of the sample from the floral and geographical origin of honey.[15,18,21−23]

The aim of the present study was the separation and simultaneous quantitation of total phenolic acids, flavonoids, and phenols of various natural Yemeni honey using high-performance liquid chromatography (HPLC) and ultraviolet (UV) absorbance detection. Multi-walled carbon nanotubes (MWCNTs) were used as a solid-phase adsorbent for extraction of the polyphenols from honey samples, which show excellent recovery and regeneration properties. The developed HPLC−UV method was simple, sensitive, and easy to apply for routine analysis, and it would be a potential step forward in the analysis of various honey samples.

MATERIALS AND METHODS

Chemicals and Reagents. All solvents used were of HPLC grade. 4-Hydroxybenzoic acid, carvacrol, clorogenic acid, maleic acid, naringenin, and sinapic acid were purchased from Aldrich Chemicals Co. (Milwaukee, WI). Apigenin, caffeic acid, galangin, gallic acid, kaempferol, luteolin, *p*-coumaric acid, and quercetin were purchased from Sigma Chemicals Co. (St. Louis, MO). Acetic acid, acetonitrile, diethyl ether, ethanol, formic acid, hydrochloric acid, methanol, and

anhydrous sodium carbonate were purchased from BDH Chemicals Co. (U.K.). 4-Hydroxyphenyl acetic acid, chrysin, myricetin, naringin, syringic acid, thymol, and vanillic acid were purchased from Acros Organics (Morris Plains, NJ). Potassium acetate was purchased from Riedel de Haen Co. (Seelze, Germany). Benzoic acid was from Winlab. Cinnamic acid was from SAFC. Ferulic acid was from Fluka (St. Louis, MO). Phenol was from Merck (White House Station, NJ). Sodium sulfate was from Koch-Light Lab., Ltd. (Haverhill, Suffolk, U.K.). MWCNTs were from Timesnano (Chengdu Organic Chemicals Co., Ltd., China). Ultrapure water used for HPLC mobile phase and sample preparation was obtained using a Milli-Q water purification instrument from Millipore (Bedford, MA).

Sample Collection. All of the analyzed honey samples were collected from beehives fed with jujube flowers. Jujube (*Z. spina-christi* L.) is an evergreen tree native to southern and western Asia. It grows up to an elevation of 500 m. Mainly, 12 kinds of jujube honey from various Yemeni regions were collected in different harvesting seasons, to investigate the effect of geographical origin on the profile of polyphenols in honey composition. The samples were named as 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, and 12. All of these samples were preserved at a temperature below 0 °C. The production year and region of collection of these aforementioned honey samples are listed in Table 1.

Extraction Procedure. In the present study, MWCNTs were used as a solid-phase adsorbent for extraction of the polyphenols from honey samples. The unique chemical, physical, mechanical, and thermal properties of MWCNTs provide exceptionally better sorption capacity and high stability to the extraction procedure.[24−26] Additionally, their unique properties in combination with their cave structure and ability to form a wide range of interactions with foreign molecules make their application highly useful for achieving efficient extraction methodologies.[27,28] The characteristics of the used MWCNTs in the extraction procedure are as follows: length, ∼30 μm; outer diameter, <8 nm; purity, >95 wt %; ash, <1.5 wt %; and specific surface area, >500 m^2/g. First, a 200 g sample of each honey was dissolved thoroughly in three parts of distilled water (200 mL each), and the solution was acidified with HCl at pH 2.0. To perform the solid-phase extraction of the phenolic compounds, 1 g of MWCNTs was added to this acidified aqueous solution of honey. The prepared mixture solution was then magnetically stirred for 20−30 min; the extreme large surface area and the unique tubular structure of MWCNTs[29,30] allow for the adsorption of honey phenolics onto that.[31] The MWCNTs were then being separated by vacuum filtration on a cellulose nitrate membrane filter (47 mm diameter and 0.45 μm porosity). After that, the separated MWCNTs were washed first with 100 mL of acidified water (at pH 2.0) and then with 300 mL of ultrapure water to remove sugars and other polar constituents.[32] Therefore, the phenolic compounds retained on the surface of MWCNTs were eluted with methanol (300 mL). This elute was then concentrated under reduced pressure in a rotary evaporator (Buchi, model V-850, Switzerland) at around 40 °C. The residue substance was then mixed with distilled water (6 mL), extracted with diethyl ether (5 mL × 3), and then reconcentrated by removing diethyl ether with nitrogen flushing. Finally, this concentrated residue was dissolved in 2 mL of methanol, filtered through a 0.45 μm membrane filter, and injected into the HPLC system. The washed MWCNTs can further be solvent-cleaned and then used for extraction of polyphenols from another honey sample.

Instrumentation. The HPLC analyses of phenolic acid, flavonoid, and phenol contents were performed using a Finnigan Surveyor Plus system from Thermo Scientific (Waltham, MA), equipped with a quaternary LC Pump Plus, a photodiode array (PDA) detector (PDA Plus), and an Autosampler Plus. The chromatographic separation of honey samples was performed using a reversed-phase column Betasil C_{18} column (Thermo Scientific, Waltham, MA), 150 mm length and 4.6 mm inner diameter, packed with a particle having a size of 3 μm. Several mobile phases of various compositions of water, acetonitrile, methanol, and mixtures of 1% formic acid aqueous solution with methanol or acetonitrile were tested at different flow rates (in the range of 0.2−1 mL/min) in both isocratic and gradient elution modes to achieve the best separations of the samples. The PDA detection wavelengths were investigated in the range between 200 and 600 nm.[28] The effect of the column oven temperature was also checked from 30 to 60 °C. The standards and honey extracts were injected to the system with an auto-injector, and the total flavonoids and phenolic compounds were detected using a PDA detector. A Welch Duo-Seal vacuum pump (model 1400, Niles, IL) was used for sample filtration. A shaker (Janke and Kunkel IKA Labortechnik Ks501D) was used for mixing the solutions, and a pH meter (Metrohm 6.0228.000) was used for mixing and pH measurements of the samples.

RESULTS AND DISCUSSION

Optimization of Chromatographic Conditions. The preliminary studies were carried out on a standard solution including 25 flavonoids and phenolic compounds. The optimization of chromatographic conditions was performed to obtain the best separation and a good peak resolution and to avoid peak tailing of the target compounds. To find the optimum HPLC conditions for all of these 25 compounds, the different chromatographic parameters, such as mobile-phase composition, flow rate, and detection wavelength, have been investigated. We have carried out several experiments using the mobile-phase flow rate between 0.1 and 0.5 mL/min and used different solvents (water, acetonitrile, and methanol) as the binary mixture with various compositions, in either isocratic or gradient elution mode. In gradient elution, different solvent programs were tested for each mixture.

The best separation in the shortest time was achieved using a linear gradient elution mode with a binary mobile phase mixture of aqueous 1% formic acid (A) and methanol (B) at a constant flow rate of 0.2 mL/min. The initial composition was 85% A, was decreased linearly to 20% in 70 min, and then remains constant up to the total run time of the system of 90 min. The temperature of the column oven was set at 40 °C. The samples were injected with an autosampler, and the constituents were detected using a PDA detector to obtain the UV spectrum of each of the various phenolic acids, flavonoids, and phenols. The chromatograms of all standard samples were monitored in the range of 200−600 nm, but 270 nm was chosen as the optimum, because the majority of the honey flavonoids and phenolic acids show their UV absorption maxima around this wavelength (Figure 1), which is in good agreement with the reported results obtained by Martos et al.[33] The injection volume was 10 μL for all samples. For convenience, the UV wavelength corresponding to the absorbance maximum of each individual component with its retention time is tabulated in Table 2. The table also lists the abbreviation of each analyte.

Performance of the Proposed Method. Calibration standards at 0.05, 0.1, 0.5, 1, 5, 10, 50, and 200 μg/mL were prepared in methanol for each polyphenol. Under the optimal experimental conditions, a linear relationship of the suggested chromatographic quantitation method was established by investigating the detection signal as a function of the analyte concentration, with the aid of a linear regression equation by the method of least-squares. The calibration curve was plotted for each standard of phenolic acids, flavonoids, and phenols; it was linear over the range of 0.05−200 μg/mL. The correlation coefficient (r^2) obtained was >0.997 for each regression equation. The limit of detection (LOD) (corresponding to a signal-to-noise ratio of 3:1) and limit of quantification (LOQ) (signal-to-noise ratio of 10:1) values of the proposed method were calculated by analyzing three replicates of a blank sample (Milli-Q water) spiked with each standard at low concentration levels.[34] The LOD values were found between 0.015 and 0.041 μg/mL, while the LOQ values were between 0.051 and 1.35 μg/mL for each standard compound. The intra- and interday precisions of the proposed HPLC−PDA method were established by injecting five replicates of the standard mixture (100 μg/mL) on the same day and 15 replicates over 3 consecutive days (five replicates each day), respectively.[35] High intra- and interday precisions were achieved with relative standard deviation (RSD) values lower than 2.5% for all analyzed compounds. All obtained values of quality parameters are listed in Table 3. The low values of precision (<2.5% RSD) confirm that the proposed analytical method can be successfully used in the routine analysis of phenolic acids, flavonoids, and other phenols present in various natural samples, such as honey.

Real Sample Analysis. The recovery assay was performed to assess the applicability of the proposed extraction method for determination of phenolic acids, flavonoids, and phenol compounds. A total of 12 honey samples were analyzed in triplicate using the standard addition quantification method of two non-spiked and four spiked samples at different concentration levels (50, 100, 200, and 400%). The developed extraction

and HPLC−PDA method was applied for the simultaneous determination of all analyzed (total 25) phenolic acids, flavonoids, and phenol compounds in various natural honey samples. All of these target compounds were identified and quantitated with reference to their standard compounds mainly on the basis of the retention time and UV spectra.[18,23,33] The UV spectral data obtained by the developed HPLC−PDA method for the honey samples and their corresponding retention times were used as library data for the comparison and for identification for the phenolic acids, flavonoids, and phenol compounds. Figure 2 shows, as an example, the HPLC−PDA chromatogram and absorption spectra of all of the analyzed phenolic acids, flavonoids, and phenol compounds in sample 8. The chromatogram shows a good resolution, and no interferences from any other components were observed because no detectable matrix peaks were eluted in the retention time of the target compounds.[36]

The absorption spectra of the corresponding analyte were similar and found at the same wavelength as those obtained from analysis of the standard mixture solution (Figure 1). The compounds were quantitated by their absorbance in the HPLC chromatograms against the standards at their corresponding wavelength provided in Table 2. The percent recovery values were found between 89 and 96% depending upon the types of honey samples.

Phenolic Acids in Monofloral Jujube Yemeni Honeys. In the analyzed samples of Yemeni jujube (*Z. spina-christi* L.) honey, the total phenolic acid content was averaged to 1.921 mg/100 g of honey, while 4-hydroxybenzoic acid (54.59%) was the main component (0.766 mg/100 g of honey) (Table 4). On the other hand, syringic acid (12.37%) was the secondary compound (0.318 mg/100 g of honey) in all of the analyzed honey samples. The other phenolic acids present in the honey samples are relatively lower in proportion and were ranging from 1.84% (4-hydroxyphenyl acetic acid) to 9.49% (vanillic acid) of total phenolic acids (Table 4). However, the obtained results for all of the phenolic acids were different in each analyzed honey sample, and among them, sample 2 contains a much higher concentration of 4-hydroxybenzoic acid than other honey samples, while only in three samples, chlorogenic acid (1.03%) and 4-hydroxyphenyl acetic acid (1.84%) were found (Table 4).

Flavonoids in Monofloral Jujube Yemeni Honeys. The HPLC−PDA analysis of flavonoid compounds in Yemeni jujube honeys showed that chrysin was the main flavonoid present in most of the samples analyzed (Table 4). The experimental data show that, among the nine investigated flavonoids, eight were found in this type of honey and most of them occurred in small amounts, except chrysin. The total flavonoid content was found to be 8.989 mg/100 g of honey, with chrysin being 5.984 mg/100 g of honey (66.5%) (Table 4). In addition, quercetin (1.506 mg/100 g of honey) was found as the secondary main constituent representing 16.8% of the total flavonoids. The other flavonoids present in analyzed honey are in a lower proportion, ranging from 1.42 to 6.85% of the total flavonoids, while luteolin was not found in any honey sample. However, most of the analyzed honey samples showed a common flavonoid profile, comprising chrysin, quercetin, kaempferol, apigenin, and naringenin, suggesting that they could be used as characteristic floral markers for Yemeni jujube honeys.[32]

Other Phenols in Monofloral Jujube Yemeni Honeys. In the analyzed samples of Yemeni jujube honeys, the total other phenolic compounds were found to be 6.4460 mg/100 g

of honey, where the cinnamic acid (96.49%) was the main component (6.220 mg/100 g of honey) (Table 4). On the other hand, the other phenolic constituents present in the honey samples were relatively lower in proportion and were ranging from 0.0279% (phenol) to 3.001% (thymol) of total phenols.

However, the obtained results for all of the phenolic components were different in each analyzed honey sample, while sample 2 contains the highest concentration of cinnamic acid compared to other honey samples. In only four samples, carvacrol (0.0372%), benzoic acid (0.3754%), and phenol (0.0279%) were found in very low amounts, while maleic acid could not be detected in any honey sample (Table 4). According to the quantitative results showed in Table 4, there is no clear correlation between the geographical origin of the honey and its chemical composition because the concentration of each polyphenol varies in a wide range for samples collected from the same region.

In summary, a simple method has been described for the analysis of phenolic acid, flavonoid, and phenol contents in natural honey samples of Yemen. A total of 12 jujube honey samples were analyzed, and the total contents of phenolic acids, flavonoids, and phenolic components were found in the range of 363−2658, 261−1646, and 224−1355 μg/100 g (Table 4) of honey samples, respectively. Among phenolic acids, 4-hydroxybenzoic acid (1.41 mg/100 g) was found in a major quantity in all analyzed honeys, while chrysin (850 μg/100 g) was the main detected flavonoid and cinnamic acid was the main phenolic compound (1336 μg/100 g). Among the 25 investigated compounds, maleic acid and luteolin were not detected, while a common flavonoid profile corresponding to chrysin, quercetin, kaempferol, apigenin, and naringenin was established in all honey samples. In addition, the values of the quality parameters achieved with this proposed analysis method as well as the results obtained in the analysis of honey samples confirmed that they are sufficient to propose the extraction technique using MWCNTs coupled with HPLC−PDA as a new methodology for inexpensive and reliable analysis of polyphenols in natural honeys.

ABSTRACT: Corn steep liquor (CSL) is a liquid byproduct generated by the corn wet-milling industry. This agroindustrial residue is obtained when corn is digested with warm water and SO_2 in the presence of different spontaneously growing microorganisms. The microbial population of CSL includes lactic acid bacteria, which are widely known to produce biosurfactants. However, there is no information available about the possible existence of surface-active compounds in CSL. In this work the surface tension activity of CSL was evaluated and the biosurfactant contained in this residue was extracted with different organic solvents and characterized. The biosurfactant obtained from CSL was analyzed by Fourier transform infrared spectroscopy, and the composition in fatty acid was analyzed by gas chromatography−mass spectrometry. The hydrophobic chain of the biosurfactant contained in CSL comprised 50−55.2% linolelaidic acid, 15.7−22.2% oleic and/or elaidic acid, 5.9−14.6% stearic acid, and 14.9−19.6% palmitic acid.

KEYWORDS: *agroindustrial stream, corn steep liquor, biosurfactant, lipopeptide*

1. INTRODUCTION

Conventional corn wet-milling is designed to recover and purify starch and several other products, including germ, gluten, and steep liquor.[1] The process includes grain cleaning; steeping; germ, fiber, and gluten separation and recovery; and starch separation.[1] Corn steep liquor (CSL) is obtained when warm water is used to soften and swell the corn grain and the soluble material in the grain passes into the water. The corn is usually held in a series of silos through which the steep water passes.[2] The steeping process is carried out at approximately pH 4 and at 45−52 °C in the presence of SO_2 and active lactic acid fermentation. CSL contains soluble material collected at other stages of the milling or separation processes; as the processing water may be retained in the plant for approximately 2 weeks, additional fermentation often occurs at many times during the process.[3]

On the basis of the high nutritional content of CSL, various authors have proposed the use of this waste product as a nutrient supplement for microorganisms in diverse industrial fermentation processes.[4,5] Thus, CSL has been proposed as a nutritional supplement for producing transglutaminase,[6] lactic acid and biosurfactants,[7,8] succinic acid,[9] or ethanol.[10,11]

The annual global production of surfactants is about 13 million metric tons,[12,13] with approximately $23.9 billion of sales,[14] However, most of the surfactants produced worldwide are chemically synthesized using nonrenewable raw materials.

Several authors have recently proposed the use of biotechnological processes to produce microbial detergents, known as biosurfactants, as less toxic and more effective alternatives to chemical surfactants.[15] However, the major obstacle to the large scale industrial application of biosurfactants is the higher production cost and lower production rate in comparison with commercially available synthetic surfactants. Thus, in recent years several studies have focused on reducing the cost of producing biosurfactants by improving the yield and the use of either cost-free or low-cost feedstock or agricultural byproducts as carbon sources.[16]

Lactic acid bacteria (LAB) ferment water-soluble carbohydrates during the fermentation of many substrates. When LAB ferment food material, such as corn, they produce lactic acid, which inhibits microbiological growth by lowering the pH of the medium.[17] However, LAB produce many other substances in addition to lactic acid: bacteriocins, acetic acid, propionic acid, phenyl lactic acid, biosurfactants, and bioemulsifiers. However, the potential of CSL as a biosurfactant source has not yet been explored.

The aim of the present research was to explore the possible use of CSL as a source of biosurfactant and its stability. Biosurfactant from CSL was extracted using different organic solvents (chloroform, ethyl acetate, methyl *tert*-butyl ether, trichloroethylene, hexane, heptane, and dichloromethane) and characterized by Fourier transform infrared spectroscopy and gas chromatography−mass spectrometry.

2. MATERIAL AND METHODS

2.1. Chemicals. Chloroform stabilized with 50 ppm amylene (99.8%), ethyl acetate (99.5%), and methyl *tert*-butyl ether (99.8%) were purchased from Panreac (Barcelona, Spain). Trichloroethylene (≥99%) was supplied by Fluka Chemie AG (Buchs, Switzerland). Hexane (98%) and heptane (99%) were purchased from Analar Normapur (Fontenay-sois-Bois, France). Dichloromethane (99%) was supplied by Merk (Darmstadt, Germany).

Supelco37 Component FAME Mix: 10 mg mL^{-1} FAME reference standard mix in methylene chloride was purchased from Sigma-Aldrich (Steinheim, Germany).

Table 1. Description of the Corn Steep Liquors Used in This Study: Registry Number (CAS), Distributor, and Composition

product	CAS/lot	distributor	composition	observations
CSL-1	66071-94-1/MKBB5569	Sigma-Aldrich	concentrate of corn solubles, 50% solubles, pH = 4.2	store at room temp
CSL-2	66071-94-1/MKBH1451V	Sigma-Aldrich	concentrate of corn solubles, 45% solubles, pH = 4.5	store at 2−8 °C
CSL-3	66071-94-1/B1412	ChemCruz, Santa Cruz Biotechnology, Inc.	approx 50% solids (corn solubles, vitamins, amino acids, minerals, and other growth stimulants), glucose monohydrate, phytin, sulfur dioxide, water (>40%), pH = 4.5	store at 4 °C

2.2. Corn Steep Liquor. Three different batches of CSL were tested in this study: CSL-1 and CSL-2 were supplied by Sigma-Aldrich (St. Louis, MO, USA), and CSL-3 was provided by Santa Cruz Biotechnology (USA). Table 1 shows the properties of the three different CSLs as reported by the companies from which each batch was obtained. All are viscous concentrates of corn soluble substances such as vitamins, amino acids, minerals, and other growth stimulants.

2.3. Surface Activity Determination. Surface activity was evaluated using a KRUSS K6 tensiometer equipped with a 1.9 cm Du Noüy platinum ring, at room temperature. All the determinations were carried out in triplicate.

2.4. Determination of Critical Micelle Concentration of CSL. The critical micelle concentration (CMC) of CSL was determined from the intersection of the tangent to the curve at the inflection point with the horizontal tangent through the points at low concentration. The calibration curve was prepared using solutions containing different concentrations of CSL of known surface tension. When the concentration of CSL is lower than the CMC, the surface tension of water in the presence of CSL is linearly related to the concentration of surfactant, and thus it is possible to establish a relationship between the CSL concentration and the surface tension.[18] The CMC of CSL was expressed as g L^{-1}.

2.5. Study of the CSL Surfactant Stability. Three different batches of CSL at the CMC (CSL-1, CSL-2, and CSL-3) were exposed to different temperatures (4 °C, 25 °C, and 65 °C) and pH (4, 5, and 8). Experiments were carried out in 10 mL tubes for 1 h, and surface tension of samples was measured in triplicate, once samples reached room temperature. The pH of CSL was adjusted with HCl 1 M and NaOH 1 M using a pH-meter Basic 20 (Crison).

2.6. Extraction of Biosurfactant from CSL. Various organic solvents were tested: chloroform, ethyl acetate, methyl *tert*-butyl ether, trichloroethylene, hexane, heptane, and dichloromethane. The extraction was carried out with a CSL:solvent ratio of 1:10 (v/v), at 150 rpm, for 4 h at room temperature (25 °C), following the conditions used by Jamal et al.[19] to extract biosurfactants from fermentation media. The CSL was used at CMC by dilution from the commercial bottle. The percentage of biosurfactant extracted from CSL was calculated on the basis of the surface tension values obtained after the dissolution of biosurfactant extract in water. The amount of water added to the biosurfactant extract was fixed taking into account the volume of CSL used during the extraction.

2.7. Characterization of Biosurfactant Contained in CSL.

2.7.1. Biochemical Composition of Biosurfactant. Biochemical analysis of biosurfactant extracted from each CSL was carried out following standard methods. The carbohydrate content of the biosurfactants was determined by the phenol−sulfuric acid method, with D-glucose as a standard.[20] The protein content was determined by the Lowry method,[21] with bovine serum albumin as a standard. Lipid content of the extracted biosurfactant was assessed according to the procedure described by Folch et al.,[22] with cholesterol as a standard.

2.7.2. Fourier Transform Infrared Spectroscopy. Fourier transform infrared spectroscopy (FTIR) was used to determine the chemical nature of the biosurfactants via identification of the functional groups and chemical bonds present in the surface-active compounds. The biosurfactant extracted (1 mg) was ground with 10 mg of potassium bromide and pressed (7,500 kg for 30 s) to produce translucent pellets.

FTIR analyses were carried out in a Niocolet 6700 FTIR spectrometer (Thermo Scientific). The spectral measurements were made in the transmittance mode in a range of 400−4000 cm^{-1}, with a resolution of 4 cm^{-1} an average range of 32 data scanning, and a potassium bromide pellet for measuring background absorbance levels.

2.7.3. Fatty Acid Characterization of Biosurfactant by GC−MS. The fatty acid composition of the biosurfactants extracted from the different batches of CSL was determined by gas chromatography (Trace GC Ultra, Thermo Scientific) coupled to a mass spectrometer (Trace DSQ, Thermo Finnigan), after methylation and transesterification of fatty acids into fatty acid methyl esters (FAMEs), according to the method described in the European Standard, EN ISO 12966-2.[23] Nonadecanoic acid methyl ester (C19:0 ME) was added as an internal standard. A sample volume of 1 μL was injected using a split mode, at a split ratio of 1:50. FAMEs separation was performed on a ZB-WAX column (60 m × 0.25 mm i.d. × 0.25 μm film thickness) with an oven temperature gradient of 60 °C for 2 min, then 60−200 °C at 10 °C min^{-1}, held for 27 min, then increased to 240 °C at 5 °C min^{-1}, and finally held for 20 min. Helium was used as carrier gas at a flow rate of 1 mL min^{-1}, and the temperature of both injector inlet and the transfer line of detector was set at 250 °C.

The mass spectra were obtained using a mass selective detector under electron impact ionization at a voltage of 70 eV, and data were acquired over an m/z range of 40−400.

FAMEs were identified from a mass spectra library supplied with the GC−MS system and by comparison of retention times and mass spectra of a FAME standard mix, injected under the same conditions.

2.8. Statistical Analysis. Data were subjected to analysis of variance (ANOVA) performed using the SPSS 13.0 statistical software package. Significant differences were assessed by Duncan's test (at $p < 0.05$).

3. RESULTS AND DISCUSSION

3.1. Evaluation of the Biosurfactant Capacity of CSL. The effectiveness of CSL as a biosurfactant can be determined by its ability to lower the surface tension of water. It has been proposed that a good biosurfactant can lower the surface tension of water (air−water interface)[24] from 72 mN m^{-1} to 36.6 mN m^{-1}, although a substance can be considered biosurfactant when it is able to reduce the surface tension by 8 units.[25,26] Figure 1 shows the variation in surface tension of water in the presence of increasing concentrations (up to 40 g L^{-1}) of different commercially available varieties of CSL. Thus, when CSL was added to the water, the minimum surface tension values were 36.6, 46.7, and 43.1 mN m^{-1} for CSL-1, CSL-2, and CSL-3 respectively. The surface tension reduction of water achieved with CSL was higher than that obtained using for example biosurfactants produced by *Lactobacillus pentosus*,[27,28] *Bacillus subtilis* B30,[29] *Halobacteriaceae archaeon*,[30] or *Pseudomonas aeruginosa*.[31]

The CMC for CSL-1 was 15 g L^{-1}, whereas for CSL-2 and CSL-3 it was 10 g L^{-1}. CSL is an agroindustrial residue subject to spontaneous fermentation, which can occur at many points during corn wet-milling; the degree of fermentation can vary significantly from plant to plant, and considerably even in one plant from time to time.[32]

Although biosurfactants are environmentally friendly, biodegradable, and less toxic than chemical surfactants, knowing the stability of this surface-active compound at different pH and temperatures is of importance. Biosurfactants have surface-activity properties that make them excellent emulsifiers and foaming and dispersing agents. Biosurfactants are usually active at extreme temperature, pH, and salinity. However, when

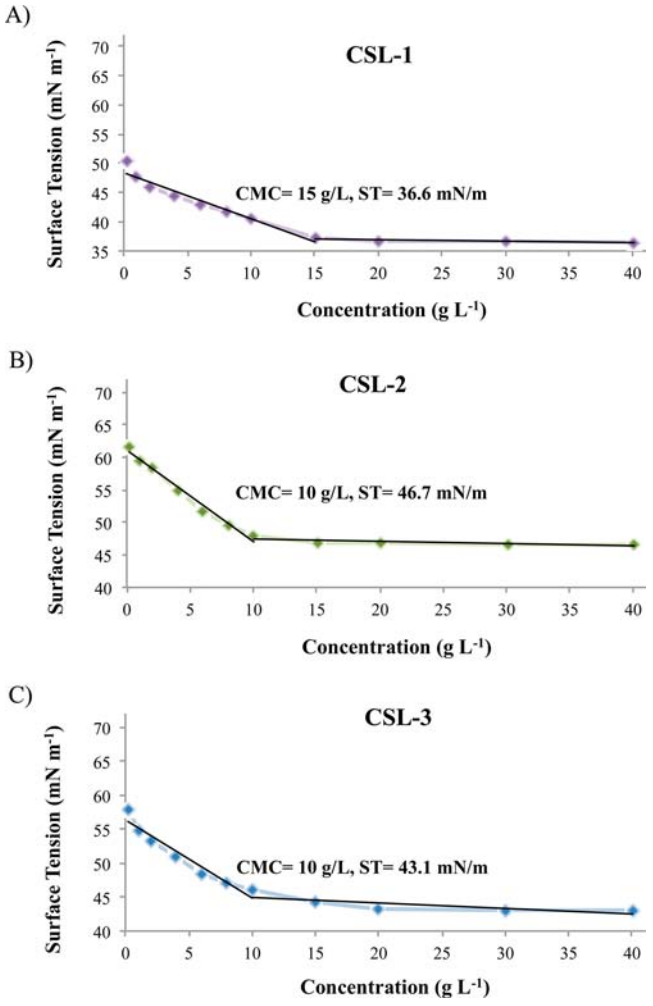

Figure 1. Variation in the surface tension of water at increasing concentrations of CSL-1 (A), CSL-2 (B), and CSL-3 (C).

Vecino-Bello et al.[33] studied the synergistic effects of pH, temperature, and salinity on the surface-active properties of biosurfactants produced by *L. pentosus*, they found that the emulsifying capacity of the biosurfactant was negatively affected at pH 3. Moreover, Bharali et al.[34] reported that the effectiveness of the biosurfactant produced by the thermophilic *Alcaligenes faecalis* was limited under both alkaline and neutral conditions. Figure 2 shows the variation in CSL surface tension with temperature and pH. Slight decreases in the surface tension were observed with increasing pH and temperature, although the differences were not significant in samples of CSL under different conditions. Figure 2A, Figure 2B, and Figure 2C show the surface-active reduction achieved in a water solution in the presence of CSL-1, CSL-2, and CSL-3 respectively at different pH (4, 5, and 8) and temperature (4 °C, 25 °C, and 65 °C).

From the data shown above, it can be speculated that CSL could be used in the bioremediation of hydrocarbon-contaminated soils. Thus, this waste material could be used to produce surface-active agents that would increase the solubilization of hydrophobic contaminants and also to supply important nutritients that would facilite the fermentation of hydrophobic substances in soil. Such an application would represent an important advance in environmental protection. Moreover, the biosurfactant isolated from CSL could find other aplications in the pharmacutical, biomedical, or comestics[35,36] as well as in food[37] and agriculture[38] industries to improve the solubilization of active principles.

The most powerful commercial biosurfactant known, surfactin, produced by *Bacillus subtilis*, is able to reduce the surface tension of water from 72 to 27 mN m^{-1} at a concentration of 10 mg L^{-1};[39] however, surfactin is of limited use for most applications involving consumer products because it is not water-soluble and it is very expensive (50 mg of surfactin costs about $820). Other authors have proposed the utilization of *Lactobacillus*,[40] *Candida*,[41] or *Pseudomona* strains[42] for producing biosurfactant, although the high cost of the nutritional components of the fermentation media and the biosurfactant purification could prevent their industrial commercialization. As CSL is a byproduct of the corn milling industry, and therefore cheap, the use of this waste material as a source of biosurfactant may represent an important advance in the production of inexpensive ecofriendly surfactants.

3.2. Extraction of Biosurfactant from CSL. In order to isolate the surface-active compounds contained in corn steep liquor, CSL-1 was submitted to liquid−liquid extraction with different organic solvents. The extraction study was carried out only with CSL-1 because CSL streams, evaluated in this work, have very similar characteristics, although, in order to corroborate the composition of the biosurfactant, the best extractant will be selected to isolate and characterize the biosurfactants contained in the other CSLs.

The minimum surface tension value achieved in the aqueous phase after the extraction and redissolution of biosurfactant obtained from CSL-1, at its CMC, was about 36 mN m^{-1}, when all the biosurfactant from CSL was extracted, and the maximum value obtained in the aqueous phase was about 72 mN m^{-1} when no biosurfactant was extracted. Of the solvents used, chloroform, methyl *tert*-butyl ether, and dichloromethane extracted almost 100% of the biosurfactant from CSL, as deduced by the surface tension value of water in the presence of the biosurfactant extracted from CSL-1 (36 mN m^{-1}).

3.3. Characterization of Biosurfactant Contained in CSL. Of the solvents used, chloroform was selected to extract the biosurfactant from CSL for chemical characterization. The biochemical analysis revealed that the biosurfactant, extracted from CSL, was composed of 21.9% proteins and 64.2% lipids. Moreover, FTIR spectroscopy was used to elucidate the molecular components of each biosurfactant extracted from the different batches of CSL. The FTIR spectra of the three biosurfactants are shown in Figure 3.

The spectral analysis of the biosurfactants indicated the presence of peptide groups resulting from N−H stretching and O−H stretching of carboxylic acids (wavenumbers between 3450 and 3300 cm^{-1}). Moreover, the FTIR spectrum of the biosurfactants indicated the presence of protein-related weak bands: C═O bond at 1750−1650 cm^{-1} (amide bonds) and N−H bonds at 1515 cm^{-1} (amides and amines bonds). The absorbance band between 3000 and 2850 cm^{-1} and bands at around 1465−1365 cm^{-1} denote the presence of C−H stretching corresponding to CH_2 and CH_3 groups of aliphatic chains. The bands at 1275 and 1750 cm^{-1} are stretching vibrations of C−O and C═O bonds in carboxyl esters. Furthermore, the bands at 1167 and 1240 cm^{-1} indicate the presence of fatty acid. The FTIR spectra of the biosurfactant extracted from CSL-1, CSL-2, and CSL-3 confirmed that this extract comprises lipids and proteins. The results obtained in this work are consistent with analytical data indicating that the biosurfactant is a

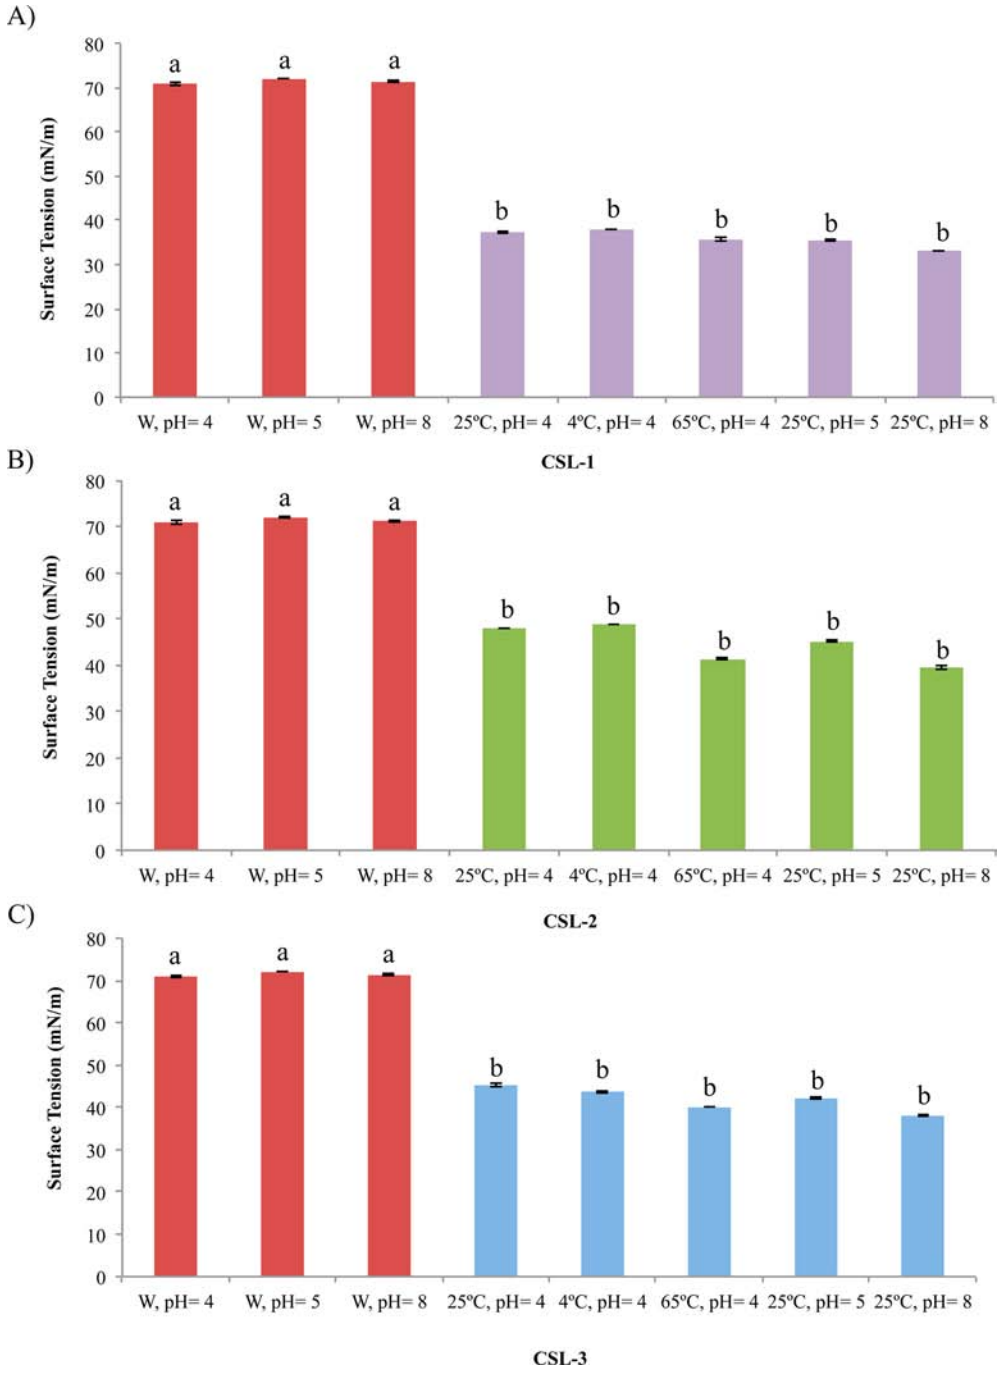

Figure 2. Influence of temperature and pH on the biosurfactant activity of CSL-1 (A), CSL-2 (B), and CSL-3 (C). Water (W) was included as control at different pH and 25 °C. Values are means of three determinations. Different letters indicate significant differences ($p < 0.05$).

lipopeptide. Thus, the hydrophobic chain of biosurfactant from CSL is composed of lipids, whereas the hydrophilic chain is mainly composed of proteins. The composition of the biosurfactant extracted from CSL is similar to the lipopeptide biosurfactant produced by *Selenomonas ruminantium*.[43]

Moreover, the fatty acid composition revealed that the biosurfactants obtained from CSL comprised linolelaidic acid, oleic and/or elaidic acids, stearic acid, and palmitic acid. The relative abundance of each fatty acid in the biosurfactants are shown in Table 2, indicating that the most abundant fatty acid was linolelaidic acid (50−55.2%). The fatty composition of the biosurfactant isolated from CSL is very similar to the fatty acid composition of the surfactin.[39]

Table 2. Fatty Acid Composition of the Biosurfactant Extracted with Chloroform from CSL-1, CSL-2, and CSL-3

retention time (min)	fatty acid	formula	rel abundance (%) CSL-1	CSL-2	CSL-3
24.3	palmitic acid	$C_{16}H_{32}O_2$ (C16)	16.7	14.9	19.6
32.1	stearic acid	$C_{18}H_{36}O_2$ (C18)	5.9	12.5	14.6
33.2	oleic or elaidic acid	$C_{18}H_{34}O_2$ (C18:1)	22.2	21.2	15.7
36.0	linolelaidic acid	$C_{18}H_{32}O_2$ (C18:2)	55.2	51.4	50.0

As a cheap and readily available byproduct of the corn wet-milling process, CSL could be used directly as a biosurfactant

agent, e.g., in the bioremediation of hydrophobic contaminated sites. The biosurfactant from CSL can be extracted using different organic solvents, and it is able to reduce the surface tension of water by more than 30 units. Moreover, the chemical characterization of this biosurfactant revealed that is a lipopeptide. Hence, the presence of biosurfactants in CSL may enable important advancements to be made in the industrial production of biosurfactants.

Identification of a Bioactive Bowman–Birk Inhibitor from an Insect-Resistant Early Maize Inbred

Eric T. Johnson,*[,†] Christopher Skory,[‡] and Patrick F. Dowd[†]

Supporting Information

ABSTRACT: Breeding of maize, *Zea mays*, has improved insect resistance, but the genetic and biochemical basis of many of these improvements is unknown. Maize oligonucleotide microarrays were utilized to identify differentially expressed genes in leaves of three maize inbreds, parents Oh40B and W8 and progeny Oh43, developed in the 1940s. Oh43 had enhanced leaf resistance to corn earworm larvae, *Helicoverpa zea*, and fall armyworm larvae, *Spodoptera frugiperda*, compared to one or both parents. Among ca. 100 significantly differentially expressed genes, expression of a Bowman–Birk trypsin inhibitor (BBI) gene was at least ca. 8-fold higher in Oh43 than in either parent. The Oh43 BBI gene was expressed as a recombinant protein. Purified BBI inhibited trypsin and the growth of fall armyworm larvae when added to insect diet. These experiments indicate that comparative gene expression analysis combined with insect resistance measurements of early inbreds can identify previously unrecognized resistance genes.

KEYWORDS: *defense, metallothionein, trypsin inhibition, reactive oxygen species, ribosome-inactivating protein*

INTRODUCTION

Global management of crops due to insect damage costs billions of dollars annually.[1] Insect damage can also lead to the transmission of a variety of plant pathogens, including those that produce toxins that are harmful to people and animals in maize and other crops.[2] Past breeding efforts have shown some success in developing maize lines with significant insect resistance.[3] With the advent of successful transgene incorporation technology, new resistance gene sources have been identified and successfully deployed, such as the *Bacillus thuringiensis* crystal protein, which rely much less on source plant germplasm for trait improvement. However, recent and potential problems with pests developing resistance to these transgenic events[4] has provided additional incentive for looking at source plants for useful resistance alleles that can be incorporated by breeding or transgenic means.

Strategies for identifying new resistance genes are varied. Earlier work identified different bioactive chemicals in resistant plants, including DIMBOA-glucoside, maysin, and hemicellulose, which occurred at higher concentrations in resistant materials prior to insect damage.[5,6] More recent studies have identified proteins involved in maize resistance, such as proteases,[7] peroxidases,[8] or ribosome-inactivating proteins,[9,10] for which roles have been confirmed by diet incorporation or transgenic plant studies. With the advent of comparative expression analysis techniques, such as gene microarrays or RNA-Seq analysis, it has been possible to determine which genes that produce resistance molecules are up- or down-regulated, although the expression profiles often involve dozens of potential resistance candidates, making confirmation of a role in resistance onerous.[11] Additionally, the most effective resistance molecules are often expressed constitutively in some resistant material, whereas the same molecules are induced in other resistant material.[12]

Modern maize commercial varieties can be examined in the presence and absence of various pests, obtaining information on potential induced molecules, with the benefits and caveats mentioned above. Whereas yield increases have been relatively steady over the past several decades, over a dozen diseases have increased significantly in importance over the same period of time,[13] suggesting that resistance alleles have been lost during the process of breeding for yield. However, it is possible that useful resistance genes could be still expressed in "older" maize lines. Genome-wide examination of representatives of these older lines has yielded interesting examples of genes with utility.[14] Gene microarray comparisons can allow for parent/progeny comparisons where different pest resistance is present, as it is possible to examine the expression of many genes in the same tissue that also has been evaluated for insect resistance. Maize microarrays have been used to identify genetic differences among inbreds, especially in cases of hybrid vigor or heterosis,[15] but to our knowledge, no genomic profiling studies of closely related inbreds have integrated insect resistance results. We now report on an example of this type of comparison, using parent and progeny inbreds developed in the 1940s.[16] The inbreds were tested for leaf resistance to corn earworm and fall armyworm larvae. Maize microarrays were utilized to identify putative insect resistance genes differentially expressed in the leaves. A Bowman–Birk inhibitor, identified by

MATERIALS AND METHODS

Insects. Corn earworms (CEW, *Helicoverpa zea* (Boddie)) and fall armyworms (FAW, *Spodoptera frugiperda* (J.E. Smith)) were reared on pinto bean based diet at 27 ± 1 °C, 50 ± 10% relative humidity, and a L14:D10 h photoperiod, as described previously.[17] First-instar larvae were used in bioassays.

Plants. Inbred maize parent lines W8 (Wisconsin Agricultural Experiment Station) and O40B (Ohio Agricultural Research and Development Center) and the inbred derived from the cross of these two parents, Oh43, were the subject of the study. Oh43, developed in 1949 by the Ohio Agricultural Experiment Station,[16] was produced with at least four generations of selfing following the initial Oh40B × W8 cross.[18] The W8 seed was obtained from Natalia de-Leon (Department of Agronomy, University of Wisconsin, Madison, WI, USA), and the Oh40B and Oh43 seeds were obtained from the USDA-ARS North Central Regional Plant Introduction Station. Prior studies indicated Oh40B had fair resistance to the corn leaf aphid *Rhopalosiphum maidis* (Fitch) and the European corn borer *Ostrinia nubilalis* (Hübner), whereas Oh43 had good resistance to these two insect species.[16] No reports of insect resistance of W8 were listed under its description,[16] although presumably it exhibits intermediate resistance against these insects. Seed was planted in soil mix 3.[19] Plants were grown in a climate-controlled room with light 14 h (24 ± 1 °C)/dark 10 h (18 ± 1 °C) and 50 ± 10% relative humidity. The third visible leaf from the top of a seven-leaf plant, which was fully expanded and mature, was used in bioassays.

Leaf Bioassays. Bioassays were performed as described previously.[19] Seven or eight plants of each inbred were used as a source of leaves. Approximately 20 cm of the anterior portion of the leaf was removed from each plant. Leaves were cut into approximately 1 × 2 cm sections with the posterior section used for corn earworms, and the adjacent anterior section was used for fall armyworms. The remaining leaf was frozen in liquid nitrogen for use in subsequent RNA extraction or protein assays. Individual leaf sections were placed on a piece of moistened filter paper in a 5 cm Petri dish with a tight-fitting lid, along with 10 newly hatched caterpillars. The total number of 1 mm^2 hole equivalents caused by feeding was determined after 2 days.[19] Survivors were weighed to the nearest 0.01 mg using an analytical balance.

Caterpillar Diet Disk Bioassays. Aliquots of recombinant protein (and corresponding quantities of background protein produced by wild-type yeast that eluted from a nickel column) were added to freeze-dried insect diet disks as previously described.[20] Briefly, for the 2 day bioassay, the protein solutions were absorbed into the diet disks at a rate of 30 μL per 15 mg disk and then added to a Petri dish with a tight-fitting lid containing 10 insect larvae. For the 5 day bioassay, 150 μL of the protein solutions was absorbed into 50 mg diet disks, and each disk was placed on top of a Teflon disk in a well of a 24-well plate containing 3% water agar. One insect larva was caged in each well, and the wells were covered with a sheet of parafilm. The assays were run for 5 days. Survivors were weighed to the nearest 0.01 mg using an analytical balance.

RNA Extraction and cDNA Labeling. RNA was extracted from the tissue, treated with DNase I (Qiagen, Valencia, CA, USA), and purified with the RNeasy kit (Qiagen) as previously described.[11] Ten micrograms of total RNA was converted into amino allyl modified cDNA by first adding 2 μg of oligo $d(T)_{12-18}$ primer and incubating at 70 °C for 5 min and then incubating on ice for 1 min. cDNA synthesis reactions were incubated at 46 °C for 3 h and included 1× Superscript III reaction buffer (Life Technologies, Carlsbad, CA, USA), 7.5 mM DTT, 1× dNTP mix with amino allyl dUTP (Stratagene, La Jolla, CA, USA), 20 units of RNase Block ribonuclease inhibitor (Stratagene), and 200 units of Superscript III reverse transcriptase enzyme (Life Technologies). Preliminary experimentation found that Superscript III enzyme resulted in better cDNA yield than the RT enzyme supplied in the FairPlay III Microarray Labeling Kit (Stratagene). After cDNA synthesis, 10 μL of 1 M NaOH was added and the sample was incubated at 70 °C for 10 min and then allowed to cool to room temperature before 10 μL of 1 M HCl was added to neutralize the pH. The cDNA was precipitated using 5 μL of 3 M sodium acetate, pH 4.5, 20 μg of glycogen, and 100 μL of ice-cold ethanol at −20 °C for 30 min. The cDNA was centrifuged at 14000*g* for 15 min, and the pellet was washed with 0.5 mL of ice-cold 70% ethanol followed by an additional spin at 14000*g* for 15 min. Ethanol was removed, and the pellet was allowed to dry before 5 μL of coupling buffer (Stratagene) was added to resuspend the cDNA. Samples were incubated at 37 °C for 15 min to aid in resuspension, then 5 μL of either Cy3 or Cy5 mono reactive dye (GE Healthcare Biosciences, Piscataway, NJ, USA) diluted in dimethyl sulfoxide (DMSO) was added, and samples were placed in the dark for 30 min at room temperature. Fifty microliters of water was added, and then labeled cDNA was purified from the unreacted dye using the illustra CyScribe GFX Purification Kit (GE Healthcare Biosciences).

Microarray Hybridization and Scanning. Maize microarray slides were purchased from the University of Arizona through the Maize Oligonucleotide Array Project funded by the NSF Plant Genome Research Program and contained ∼46000, 70mer oligonucleotides[21] (NCBI GEO Platform the GPL6438). Labeled cDNA was quantified with a Nanodrop 2000 spectrophotometer (Thermo Fisher Scientific, Wilmington, DE, USA) and subsequently evaporated to dryness in a Speedvac prior to resuspension. The probe solution (40 μL) included 40 pmol of Cy5-labeled cDNA, 40 pmol of Cy3-labeled cDNA, 25 μg of yeast tRNA, and 12 μg of salmon sperm DNA. Prehybridization of the microarray slide and hybridization of probes to the slide in a sealed hybridization chamber were carried out according to an established protocol[22] except for an additional high-stringency wash at room temperature. Each microarray slide was hybridized to two different maize inbred labeled cDNAs with the following arrangement: slide 1, W8-1 (Cy3) versus Oh40B-1 (Cy5); slide 2, Oh43-1 (Cy3) versus W8-2 (Cy5); slide 3, Oh40B-2 (Cy3) versus Oh43-2 (Cy5); slide 4, W8-3 (Cy3) versus Oh43-3 (Cy5); slide 5, Oh40B-3 (Cy3) versus W8-4 (Cy5); slide 6, Oh43-4 (Cy3) versus Oh40B-4 (Cy5). The slides were scanned at 10 μm resolution on an Axon GenePix 4100A microarray scanner using GenePix Pro software (both from MDS Analytical Technologies, Sunnyvale, CA, USA). Photomultiplier tube levels were adjusted using the Auto-PMT feature. Each slide was visually scanned for aberrant signals, and such signals were removed if necessary. Mean signal intensity, with the background subtracted, was utilized for expression calculations. Each set (four replicates) of signal intensities for one inbred was scaled to the one replicate with the highest mean intensity and then transformed to log2 values, using Microsoft Excel. Each inbred replicate set was imported

into the ArrayStar software program (version 4.1 DNASTAR, Madison, WI, USA). ANOVA analysis (*F* test procedure) with false discovery rate correction[23] was used to identify differentially expressed genes at 95% confidence. The normalized data are available at the NCBI Gene Expression Omnibus, accession no. GSE40107.

Reverse Transcriptase Quantitative PCR (RT-qPCR) Analysis. RNA was extracted as described above from maize leaves of three different biological replicates of each inbred that were different biological replicates from those used in the microarray experiments. Purified RNA (400 ng) was converted to cDNA using the AccuScript High Fidelity First Strand cDNA Synthesis Kit (Stratagene) with the provided oligo(dT) primer. Fifty picograms of luciferase RNA (Promega) was added to each cDNA reaction for normalization of target genes.[24] RNA was removed from cDNA using RNase H according to the manufacturer's instructions (New England Biolabs, Ipswich, MA, USA). Twenty-five microliter qPCR reactions were set up using 2× SYBR Green qPCR SuperMix Universal (Life Technologies), 10 μM of each forward and reverse primer, and 1 μL of cDNA reaction. Primers were designed with a melting temperature of 60 °C using Primer-BLAST (available at the NCBI Web site), OligoPerfect Designer (Life Technologies Web site), or Oligo Calc.[25] All primers used in this study are listed in Table 1. The cycling program consisted of the following: 50 °C for 2 min; 95 °C for 10 min; 40 cycles of 95 °C for 15 s, 60 °C for 60 s, plate read. After amplification, the following melting curve analysis was performed: 60−95 °C with a plate read every 1 °C; hold 1 s between reads. Cycling and fluorescence readings were performed on a Chromo 4 Detector (MJ Research, Waltham, MA, USA). Duplicate qPCR reactions for each primer combination and the luciferase control were completed for each biological replicate. A no-template control for each primer combination was also run for each plate to ensure the amplification did not include fluorescence due to primer dimers. Amplification of a single qPCR product close to the predicted size for each primer combination was confirmed using 3% agarose gel electrophoresis containing 1× SYBRsafe (Life Technologies) and visualized using a Molecular Imager ChemiDoc XRS+ (Bio-Rad, Hercules, CA, USA; at least one reaction was checked for each inbred). The crossover threshold (CT) value and efficiency for each reaction was calculated using the Real-time PCR Miner 4.0 algorithm[26] (software available through the Stanford University Office of Technology Licensing). The normalized initial fluorescence was calculated for each reaction for each target gene using the equation[27]

$$R_{0,T}/R_{0,R} = (1 + E_R)^{CT}{}_R/(1 + E_T)^{CT}{}_T$$

where R_0 is the SYBR Green initial fluorescence for the T, target gene, and R, reference (luciferase) gene, E is the efficiency, and CT is the crossover threshold value.

Trypsin Inhibitor Analysis. Trypsin inhibition (potentially due to a Bowman−Birk-type inhibitor) was determined using midgut homogenates of corn earworms and fall armyworms as the trypsin source and leaf homogenates of the three different maize inbreds as the source of trypsin inhibitor. N_α-Benzoyl-DL-arginine *p*-nitroanilide hydrochloride (BAPA) (Sigma-Aldrich, St. Louis, MO, USA) was used as the trypsin substrate[28] and is a suitable substrate for measuring trypsin activity in caterpillars.[29] BAPA was initially dissolved at the rate of 1 mg in 250 μL of dimethyl sulfoxide (DMSO). This stock of BAPA was diluted 1:50 in pH 8.0, 0.01 M sodium phosphate buffer, which was held at room temperature. Preliminary studies were used to determine an appropriate concentration of caterpillar midguts per volume of buffer to yield a linear reaction over 1 h at 30 °C. For the assays, three corn earworm and seven fall armyworm midguts were homogenized in 1400 μL of phosphate buffer.[30] The homogenates were centrifuged at 10000*g* for 10 min, and the supernatants were used in the assays. Maize leaf pieces approximately 1.5 × 0.5 cm from the same leaves used in bioassays and for array analysis were homogenized in 500 μL of phosphate buffer, centrifuged as described for midgut homogenates, and the supernatants were used as the inhibitor source, after adjustment for equivalent protein amounts in assays. The Bio-Rad protein assay dye reagent was used to quantitate protein, as described above. A typical assay consisted of 20 μL of enzyme source, 20 μL of inhibitor source, and 160 μL of substrate source; enzyme and inhibitor free controls were also used. Assays were performed in duplicate for each treatment using 96-well plates held at 30 °C for 1 h and read on a Spectramax 250 plate reader (Molecular Devices, Sunnyvale, CA, USA) at 410 nm. Maximum absorbance of uninhibited reactions ranged from approximately 0.1 to 0.2 absorbance units per h.

Recombinant Production of Maize BBI. The maize BBI gene that was expressed at higher levels in Oh43 leaves was amplified from Oh43 leaf cDNA (see above for cDNA preparation) on the basis of the B73 mRNA sequence (GRMZM2G007928_T01, which binds to maize oligonucleotide MZ00055932) using PCR Master mix (Roche Applied Science). The Oh43 BBI sequence was 100% identical to the B73 sequence (GRMZM2G007928_T01). The Oh43 BBI sequence (hereafter referred to as the Oh43 BBI), except for the 24 amino acid N-terminal signal peptide as predicted by SignalP,[31] was cloned by PCR into the *Eco*RI and *Xba*I sites of pPICZα A, a vector for secreted expression in *Pichia pastoris* X-33. The Oh43 BBI construct additionally contained a C-terminal hexahistidine tag for purification. The entire BBI sequence was checked for accuracy before transformation into *P. pastoris* by sequencing using a BigDye Terminator Cycle Sequencing Kit (Applied Biosystems, Foster City, CA, USA). Putative transformants were generated by electroporation and selection with 100 μg/mL zeocin on the following media: 1% yeast extract, 2% peptone, 2% dextrose, 1 M sorbitol, and 2% agar. Three different transformants were grown for 72 h, and Oh43 BBI clone 3 was chosen for further experimentation because of its high expression levels in the media as measured by Western blot analysis with a rabbit antihexahistidine antibody (Bethyl Laboratories, Montgomery, TX, USA).

Wild type *P. pastoris* and Oh43 BBI clone 3 were each grown in 25 mL of BMG media (100 mM potassium phosphate, pH 6.0, 1.34% yeast nitrogen base with ammonium sulfate (containing no amino acids), 4 × 10^{-5}% biotin, and 1% glycerol) overnight at 30 °C. The cells were resuspended in 120 mL of BMM media (same composition as BMG media, but with 0.5% methanol replacing the 1% glycerol) at OD 600 equal to 1.0 AU and then grown for 6 days at 30 °C with daily addition of methanol to 0.5%. The spent medium was recovered and adjusted to pH 6.5 with KOH. Three milliliters of nickel−nitrilotriacetic acid resin (Thermo Fisher Scientific) was washed with 10 mL of 20 mM $NaPO_4$, 300 mM sodium chloride, and 15 mM imidazole, pH 6.5. Approximately 50 mL of spent medium was mixed by rocking with the washed resin for 30 min at room temperature. The spent medium was removed and the resin added to a plastic 10 mL column (Bio-Rad) kept at 4 °C. The resin was washed with 2 column volumes of 20 mM $NaPO_4$, 300 mM sodium chloride, and 15 mM imidazole, pH 6.5. Histidine-tagged protein was eluted with 5 mL of 20 mM $NaPO_4$, 300 mM sodium chloride, and 250 mM imidazole, pH 6.5, and 1 mL fractions were collected. Fractions of wild type and BBI clone 3 were quantified by the Bio-Rad protein assay dye reagent. Aliquots of some of the fractions were separated by tricine SDS-PAGE using a 10% acrylamide gel[32] and transferred to polyvinylidene difluoride membrane in 10 mM 3-(cyclohexylamino)-1-propanesulfonic acid. Western blot analysis was performed as described previously[9] except for the following changes: the membrane was blocked for 1 h in 5% instant nonfat dry milk (Kroger, Cincinnati, OH, USA) in phosphate-buffered saline (with 0.01% Tween-20); the primary antibody was a rabbit antihexahistidine antibody from Bethyl Laboratories that was diluted 1:10000, and the secondary antibody was diluted 1:150000.

Reverse Zymography of Recombinant Maize BBI. Aliquots of eluted recombinant Oh43 BBI were subjected to reverse zymography as described previously[33] with some modifications. The 15% (w/v) acrylamide-SDS gels, which included 0.1% (w/v) gelatin, were made according to the method of Schägger.[32] Electrophoresis of the recombinant maize BBI, as well as soybean BBI (Sigma-Aldrich), was performed according to the method of Schägger[32] at 4 °C. Use of bovine pancreas type III trypsin (Sigma-Aldrich) at 450 μg per 100 mL in development buffer required incubation for only 2 h at 37 °C to digest the indicator background gelatin protein when inhibition did

Table 2. Biological Effects of Insect Larvae Feeding on Maize Leaves from Different Inbreds[a]

insect	W8	Oh40B	Oh43
CEW mean feeding	37.4 ± 1.2 (7) a	35.8 ± 1.5 (8) a	25.1 ± 0.9 (8) b
CEW mean weight (mg)	0.42 ± 0.02 (59) a	0.34 ± 0.02 (71) b	0.37 ± 0.02 (73) b
FAW mean feeding	49.9 ± 1.6 (7) a	43.5 ± 1.2 (8) b	31.8 ± 2.1 (8) c
FAW mean weight (mg)	0.53 ± 0.03 (68) a	0.62 ± 0.03 (79) a	0.40 ± 0.03 (73) b

[a]Feeding rate (1 mm^2 hole equivalents) and weight (±standard error) were determined after 2 days of leaf feeding. Values in rows followed by different letters are statistically different at $P < 0.05$ by ANOVA.

not occur. The gel was stained with Bio-Safe Coomassie stain (Bio-Rad) according to the manufacturer's instructions and visualized using a Molecular Imager ChemiDoc XRS+.

Statistical Analyses. Statistically significant ($P < 0.05$) differences in feeding rates, insect midgut trypsin inhibitor activity, initial reporter fluorescence values for RT-qPCR analysis, and insect survivor weights were determined by analysis of variance using Proc GLM of SAS for Windows version 8.0 or higher. Chi-square analysis was performed using Proc Freq of SAS, with significance at $P < 0.05$.

RESULTS AND DISCUSSION

Differential Insect Feeding on the Inbred Leaves. Results of bioassays indicate the Oh43 inbred was more resistant to CEW and FAW compared to one or both parents, as indicated by reduced amounts of feeding and lower weights of survivors (Table 2). For the CEW, those caged with Oh43 caused less damage and weighed less than those caged with W8 leaves. Although feeding rates were lower on day 2 for CEW caged with Oh43 versus Oh40B leaves, weights of survivors were not different. For the FAW, those caged with Oh43 leaves caused less damage to leaves and weighed less than both parents. Thus, there were differential effects of the three inbreds on these two species of caterpillars.

Differential Gene Expression of the Inbreds. Because the inbred lines displayed differential leaf resistance to the CEW and FAW, transcriptional profiling of the leaves was completed using maize oligonucleotide microarrays. These profiling experiments found 111 differentially expressed genes (with $P < 0.05$) among the three inbreds. Putative functions could be assigned to 90 of the differentially expressed genes. The majority of the differentially expressed genes (49/90) had a putative molecular function (Gene Ontology accession no. 0003674); this gene ontology describes the action of a gene product at the molecular level and could include catalysis or binding. The 20 genes with the lowest P values are listed in Table 3. A number of the genes in Table 3 could potentially contribute to differential insect resistance. Trypsin inhibitor (MZ00055932, described as a Bowman–Birk inhibitor by GenBank accession NP_001148299), which could inhibit trypsin proteases in insect digestive tracts, was more highly expressed in Oh43 than in W8 or Oh40B. The gene encoding ribosome-inactivating protein 2 (RIP2, MZ00018241), also known as rRNA *N*-glycosidase, was more highly expressed in Oh43 than in Oh40B or W8. Lastly, the *Bx1* gene (MZ00015105), which encodes the initial enzyme of DIMBOA biosynthesis, was more highly expressed in W8 than in the other inbreds. There were also a number of metallothionein-like genes and genes of unknown function differentially expressed among the three inbreds, which may be contributing to insect resistance.

RT-qPCR was used to analyze the differential expression of the putative insect resistance genes (Table 4). Both RIP and the BBI were more highly expressed in Oh43 leaves (at statistically significant levels) than in Oh40B or W8 leaves, respectively, but

at higher levels than measured using the microarrays. This might be due to the greater sensitivity of quantitative PCR methods.[34] A recent paper indicated that RIP2 mRNA and protein are rapidly induced (within 1 h) in maize Tx601 in response to fall armyworm feeding and RIP2 is active against FAW.[10] Our results suggest that some maize inbreds may have elevated levels of RIP2 prior to insect attack that would contribute to greater resistance.

Trypsin Inhibitor Experiments. Higher mRNA levels of a trypsin inhibitor (BBI) in Oh43 leaf extracts (Table 4) could contribute to reducing the trypsin activity of insect midguts compared to leaf extracts from the other inbreds. Some differences in levels of mean insect trypsin inhibition were significant for the crude inbred leaf extracts (Table 5). Oh40B trypsin inhibitory activity was significantly higher than that of W8 extract toward FAW trypsin and was more similar to levels for inhibition by Oh43 extract. For CEW trypsin activity, Oh40B and W8 inhibition levels were similar, but there were no statistically significant differences among the three inbred extracts. These results indicate that extracts from Oh43 leaves, as assayed, although sometimes more inhibitory than one or both parents, did not have significant trypsin inhibitory activity against CEW and FAW midgut trypsin that was higher than that of the parent inbred extracts. However, the crude mixture of plant and insect midgut extracts could contain components

that mask the actual trypsin and antitrypsin activities of individual bioactive species. Hence, further experiments were undertaken with the BBI gene that was expressed at higher levels in Oh43 than in either parent.

Recombinant Oh43 BBI Added to Insect Diet Inhibits FAW Growth. To ascertain the insect inhibitory properties of the BBI gene elevated in Oh43, the gene was cloned for secreted recombinant protein production in *P. pastoris*. Western blot analysis of the nickel column elution fractions indicated wild-type *P. pastoris* did not secrete any detectable histidine-tagged proteins into the media, whereas the recombinant line secreted two small (<15 kDa) proteins and low levels of one ~50 kDa histidine-tagged protein (likely a multimer) into the media (Figure 1). The expected size of the recombinant maize

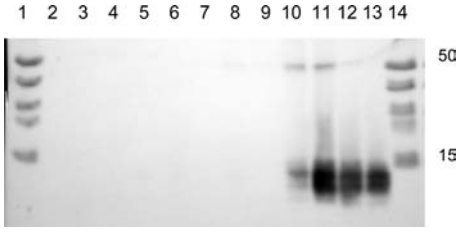

Figure 1. Western blot of elution fractions from *P. pastoris* spent media. Lanes: 1 and 14, molecular weight markers (numbers on the right side of the figure correspond to kilodalton standards); 2, flow-through of control media; 3–7, elution fractions 1–5 of the control media; 8, flow-through of Oh43 BBI media; 9–13, elution fractions 1–5 of Oh43 BBI media.

BBI was 10.3 kDa, which likely corresponds to one of the proteins below the 15 kDa protein marker. To test the activity of the recombinant Oh43 BBI, in-gel protease inhibitory activity experiments (zymography) were conducted. Protein from Oh43 BBI elution fractions 3 and 4 prevented trypsin activity below and above the 17 kDa marker (lanes 5–10), whereas there were no trypsin inhibitory proteins from control fraction 3 (lane 4) (Figure 2). The protein below the 17 kDa marker likely corresponds to one of the Oh43 BBI isoforms shown in Figure 1. In lanes 2 and 3 of Figure 2, a soybean BBI (8 kDa) was included as a control and was self-associating into higher molecular weight forms, which is likely the case for the higher molecular weight form seen in the recombinant BBI fractions examined (lanes 5–10 of Figure 2). Activity of the recombinant BBI was also noted in zymogram assays against

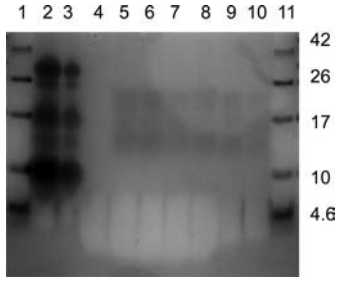

Figure 2. In-gel trypsin inhibitory activity of recombinant Oh43 BBI. Lanes: 1 and 11, molecular weight markers (numbers on the right side of the figure correspond to kilodaltons); 2 and 3, 3000 and 1000 ng, respectively, of soybean trypsin inhibitor; 4, control elution fraction 3; 5 and 6, 20 μL of Oh43 BBI elution fraction 3; 7 and 8, 20 μL of Oh43 BBI elution fraction 4; 9 and 10, 10 μL of Oh43 BBI elution fractions 3 and 4, respectively.

trypsin activity from midgut homogenates of fifth-instar FAW and whole body homogenates from newly hatched first-instar FAW (data not shown).

The recombinant form of BBI we produced did have some differing molecular forms. BBIs are known to self-associate into dimers in aqueous solutions.[35] Therefore, it is possible that the Oh43 BBI protein above the 17 kDa marker is a multimer that did not migrate at the expected molecular weight. A pea (*Pisum sativum*) BBI expressed in *P. pastoris* secreted two isoforms into the media, both of which inhibited trypsin and chymotrypsin activity; one of the isoforms was missing four amino acids at the C-terminus.[36] It is possible that the recombinant Oh43 BBI was altered as well, although probably not at the C-terminus, which ends with a hexahistidine sequence. In any case, it is clear that the recombinant Oh43 BBI had trypsin inhibitory activity.

The Oh43 BBI elution fractions with the highest protein concentration were added to insect diet that was fed to FAW larvae (control fraction 3, lane 5; Oh43 BBI fraction 3, lane 11) (Figure 1). The mean weight of FAW that fed on the 5.3 μg/g Oh43 BBI diet was much less than the mean weight of those that fed on the control diet after 2 days (Table 6), although the difference in the means was not statistically significant. However, a greater proportion of FAW larvae that weighed <0.40 mg were found among the larvae that fed on the Oh43 BBI diet compared to those that fed on the control diet. The length of the bioassay was extended to 5 days in an additional experiment. Again, the mean weight of FAW that fed on the 6.0 μg/g Oh43 BBI diet was less than the mean weight of those that fed on the control diet (Table 6), and the mean weights of the two treatments were very close to being statistically different at $P < 0.05$. A larger proportion of FAW larvae that weighed <17 mg were found among the larvae that fed on the Oh43 BBI diet compared to those that fed on the control diet. Inspection of the data indicated the 17 mg value was an appropriate value to select on the basis of the ranges of the values found for the different treatments. Identical experiments found that the recombinant Oh43 BBI did not inhibit the

	P = 0.089		P = 0.059	

[a]Weights are mean ± standard error (N). Control contained 1.1 μg/g background *P. pastoris* protein for 2 day experiment. Control contained 1.2 μg/g background *P. pastoris* protein for 5 day experiment. BBI concentration was 5.3 μg/g for 2 day experiment and 6 μg/g for 5 day experiment. ANOVA was used for comparing mean weights in the same column. Chi-square analysis was used for comparing frequencies in the same column.

growth of CEW larvae (data not shown). It is possible that trypsins in the CEW larvae are not sensitive to the Oh43 BBI or degrade Oh43 BBI or that the CEW larvae synthesize novel insensitive trypsins after consuming the Oh43 BBI, as has been reported in studies in which insects have consumed other protease inhibitors.[29,37] Additional studies will be necessary to determine if there are trypsins in CEW that are insensitive to the Oh43 BBI. The adaptability of insects to protease inhibitors is justification for the development of transgenic crops expressing at least two protease inhibitors for effective resistance[38] or identifying protease inhibitors that do not induce resistant proteases.[39]

The maize genome contains at least 11 putative BBIs. To our knowledge, this is the first study demonstrating that a monocot BBI (the Oh43 BBI is gene GRMZM2G007928) has antitrypsin activity, can inhibit insect larva development, and could be a useful resistance gene for developing insect-resistant maize. The Oh43 BBI protein contains 12 cysteine residues, which are likely cross-linked in a pattern conserved in other monocotyledonous and dicotyledonous plants.[40] The Oh43 BBI has a single reactive site that contains conserved residues found in other monocotyledonous species.[40] Another maize BBI (gene GRMZM2G156632) in the Brio cultivar was induced by wounding and possibly protects the injured tissues from pathogens or insects.[41,42] Expression of one of the maize BBIs (gene GRMZM5G815098) potentially contributed to the increased insect resistance of maize plants that had been exposed to volatiles released after infestation with common armyworm, *Mythimna separata* Walker.[43] No other published studies describe a function for the other nine maize BBIs, including the BBI examined in the present study. Diet incorporation assays indicate BBIs from a number of dicot plant species are capable of inhibiting the growth of various insect larvae.[44,45]

Other Resistance Mechanisms Potentially Involved in Oh43 Insect Resistance. Expression of metallothionein genes was from 4- to 10-fold lower in Oh43 leaves than in the two parents. The potential involvement of metallothioneins in insect resistance is less obvious. A number of roles have been attributed to these proteins in plants, including complexing (and thus detoxifying) reactive oxygen species.[46] Reactive oxygen species are generated as part of a resistance response to insects or disease.[47] For example, as part of one resistance process, peroxidases interact with hydrogen peroxide and plant allelochemical substrates (such as ferulic acid in maize) to form reactive quinones and reactive oxygen species.[48] Both products can undergo additional reactions. Thus, the lowering of the level of reactive oxygen species, through the presence of metallothioneins, is likely to dampen any resistance response. Lower levels of metallothioneins would likely preserve reactive oxygen species for a longer period, resulting in a stronger resistance response. Transgenic overexpression of these proteins in rice has led to enhanced disease susceptibility.[49] Because the initial reactive components are compartmentalized in an intact cell, lower levels of metallothioneins are less likely to cause adverse effects on the intact cell. Reactive oxygen species are also important in signaling and stimulation of additional resistance responses.[47] Other genes, including some with uncharacterized roles, were expressed to a greater extent in Oh43 leaves compared to one or the other parent and may also be additively contributing to Oh43 insect resistance.

There was no clear-cut single gene responsible for greater resistance in Oh43 compared to either parent inbred. This is not surprising, considering multiple genes are known to confer insect resistance in maize.[50] However, from examination of relative expression levels, it is clear that Oh43 had expression trends higher or lower than one or both parents of most genes that could be considered as contributing to resistance (metallothionein-like, RIP2, BBI) and some genes of unknown function that may play a resistance role. We were able to identify where heterotic interactions were occurring (i.e., expression higher than either parent) and sources of resistance gene alleles in nonheterotic interactions (based on similar expression of genes in Oh43 and one or the other parent). In the future, performing quantitative trait loci (QTL) analysis on the parents W8 and Oh40B may clarify which insect resistance genes play a critical role in Oh43. It may be of interest to also identify resistance genes in leaves that are induced by insect feeding.

RIP2 and BBI genes have been demonstrated in this and other studies to produce proteins that can affect insects and/or pathogens. Studies involving transgenic over- or under-expression of these genes and genes of unknown function associated with expression differences in Oh43 will be required to more positively identify a role in insect resistance. However, the present study has demonstrated a bioactive Bowman−Birk inhibitor from maize leaves for the first time. Thus, comparative expression analyses of early inbred parent and progeny do have the potential to identify resistance genes present in earlier inbreds that have been lost due to yield-focused maize breeding.

Stable Isotope Dilution Gas Chromatography−Mass Spectrometry for Quantification of Thymoquinone in Black Cumin Seed Oil

Okiemute Rosa Johnson-Ajinwo and Wen-Wu Li*

Guy Hilton Research Centre, Institute for Science and Technology in Medicine, Keele University, Thornburrow Drive, ST4 7QB Stoke-on-Trent, United Kingdom

Supporting Information

ABSTRACT: Black cumin seed (*Nigella sativa* L.) is a widely used spice and herb, where thymoquinone (2-isopropyl-5-methyl-1,4-benzoquinone) is the major bioactive compound. Here, a stable isotope dilution (SID) gas chromatography−mass spectrometry (GC−MS) technique was developed for the quantification of thymoquinone. A doubly deuterated thymoquinone ([$^2H_2$]-thymoquinone) was synthesized for the first time with more than 93% deuteration degree shown by mass spectrometry and proton nuclear magnetic resonance (^{1}H NMR). This compound was used as an internal standard for the quantification of thymoquinone using a SID GC−MS method. The validation experiment showed a recovery rate of 99.1 ± 1.1% relative standard deviation (RSD). Standard addition and external calibration methods have also been used to quantify thymoquinone, which cross-validated the developed stable isotope dilution assay (SIDA). In comparison to external calibration and standard addition methods, the SIDA method is robust and accurate. The concentration of thymoquinone in five marketed black cumin seed oils ranged between 3.34 and 10.8 mg/mL by use of SID GC−MS.

KEYWORDS: *Nigella sativa, thymoquinone, stable isotope dilution, GC−MS, quantification*

INTRODUCTION

Black cumin seed (*Nigella sativa* L.) is a widely used spice in Mediterranean countries, Pakistan, and India.[1,2] It is also used as a traditional medicine for the treatment of a range of diseases, such as diabetes, hypertension, fever, arthritis, inflammation, gastrointestinal disturbances, and cancer.[3] Studies into the biological activities of this plant have revealed that the volatile essential oil components, predominantly thymoquinone (**1**) (Figure 1),[4] possess antioxidant,[5] anti-inflammatory,[6] antidiabetic,[7] immunomodulatory,[8] and anti-tumor[9−11] activities.

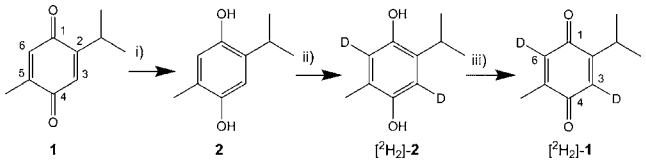

Figure 1. Scheme for synthesis of [$^2H_2$]-thymoquinone ([$^2H_2$]-**1**): (i) $Na_2S_2O_4$ in H_2O/MeOH at room temperature for 2 h, (ii) (a) 3.4 M D_2SO_4 in D_2O with reflux for 48 h and (b) cool to room temperature and workup with H_2O, and (iii) CrO_3 in 60% HOAc in H_2O at −4 °C for 2 h.

Thymoquinone was previously quantitated by means of high-performance liquid chromatography (HPLC),[12,13] high-performance thin-layer chromatography (HPTLC),[14] and a differential pulse polarographic method.[15] These methods could achieve high sensitivities and reproducibility, but they often need multi-steps of sample preparation and external calibrations; thus, the results could be influenced by complex matrices. Gas chromatography (GC) and/or gas chromatography−mass spectrometry (GC−MS) are preferred techniques for the analysis of volatile and semi-volatile compounds and have also been used for the quantification of thymoquinone[16] and identification of the composition of black cumin seed oil.[5,17] A stable isotope dilution assay/analysis (SIDA) should overcome the problem of the matrix effects, such as compound discrimination during extraction, chromatographic separation, and ultraviolet (UV)/mass spectrometry (MS)/electrochemical detection,[18,19] when a deuteriated thymoquinone is used as an internal standard. Stable isotope dilution coupled with GC−MS (SID GC−MS) has widely been used for determination of various compounds, e.g., methoxypyrazines in red wines,[19] dietary lignans in food,[20] natural estrogens in vegetables and fruits,[21,22] and alkypyrazines in coffee.[23] Here, we report synthesis of a stable deuterium (D or ^{2}H)-labeled thymoquinone (Figure 1) for the first time and its application as an internal standard for quantification of thymoquinone in black cumin seed oil by the means of SID GC−MS.

MATERIALS AND METHODS

Thymoquinone (99%), D_2-sulfuric acid (D_2SO_4, 99.5%), deuterated water [deuterium oxide (D_2O), 99.5%], sodium hydrosulfite ($Na_2S_2O_4$), and chromium trioxide (CrO_3) were purchased from Sigma-Aldrich. Hexane (analytical grade) was purchased from Fisher-Scientific, U.K. The following black cumin seed oils were purchased from Amazon: Manako black cumin oil, CEBRA *Nigella sativa* oil, Avena black cumin oil, Iman VERGIN black cumin oil, and This Health black seed oil.

Synthesis. The doubly deuteriated thymoquinone ([$^2H_2$]-**1**) (Figure 1) was prepared and purified according to a similar method

for preparation of deuterated 1,4-benzoquinones,[24,25] with modification.

2-Isopropyl-5-methyl-1,4-benenediol (2). A solution of sodium hydrosulfite (348 mg, 2.0 mmol) in 2.0 mL of water was added to a solution of thymoquinone (164 mg, 1.0 mmol) in 2.0 mL of methanol. The mixture was stirred for 2 h at room temperature. The methanol was evaporated, and the resultant solution was extracted with ethyl acetate (3 × 10 mL). The combined organic phase was washed with water (3 × 10 mL) and then dried over sodium sulfate. After evaporation of ethyl acetate, 2-isopropyl-5-methyl-1,4-benenediol (thymohydroquinone, **2**, 70 mg, yield of 42%) was obtained. MS [electron ionization (EI)] *m/z* (relative intensity, %): 166.1 (43) $[M]^{\bullet+}$, 151.1 (100) $[M - CH_3]^{\bullet+}$, 137 (4), 123.1 (11), 95.1 (10), 77.1 (10), 53.0 (3). Proton nuclear magnetic resonance (^{1}H NMR) (300 MHz, $CDCl_3$) δ: 6.56 (s, 1H), 6.47 (s, 1H), 3.06 (m, 1H), 2.10 (s, 3H), 1.14 (d, 6H, J = 7.2 Hz, $-CH(CH_3)_2$).

2-Isopropyl-5-methyl-1,4-dideuterobenenediol ($[^2H_2]$-2). 2-Isopropyl-5-methyl-1,4-benenediol (**2**, 68 mg, 0.40 mmol) was refluxed for 48 h in 3.4 M D_2-sulfuric acid (D_2SO_4, 0.9 mL) in deuterated water (D_2O, 4.2 mL). After cooling to room temperature, water (H_2O, 10 mL) was added and the mixture was extracted with ethyl acetate (3 × 10 mL). The ethyl acetate extract was washed with water (H_2O, 3 × 10 mL) and then dried over sodium sulfate. After evaporation of the solvent, 2-isopropyl-5-methyl-1,4-dideuterobenenediol ($[^2H_2]$-**2**, 45 mg) was obtained. MS (EI) *m/z* (relative intensity, %): 168.1 (44) $[M]^{\bullet+}$, 153.1 (100) $[M - CH_3]^{\bullet+}$, 139.1 (3), 125.1 (11), 97.0 (10), 79.1 (8), 55.0 (3).

2-Isopropyl-5-methyl-1,4-dideuterobenzoquinone ($[^2H_2]$-thymoquinone ($[^2H_2]$-1). 2-Isopropyl-5-methyl-1,4-dideuterobenenediol ($[^2H_2]$-**2**, 42 mg, 0.25 mmol) was dissolved in 60% acetic acid (2 mL) at −4 °C. Chromium trioxide (150 mg, 1.5 mmol) in 0.5 mL of 30% acetic acid was added, and the mixture was stirred at −4 °C for 2 h. Water (10 mL) was then added to the mixture, followed by extraction with ethyl acetate (2 × 10 mL). After drying over sodium sulfate, the solvent was removed under vacuum to give crude doubly deuteriated thymoquinone, which was sublimed to give pure 2-isopropyl-5-methyl-1,4-dideuterobenzoquinone ($[^2H_2]$-thymoquinone, $[^2H_2]$-**1**, 28.0 mg, 43% overall yield based on thymohydroquinone (**2**)). The purity of compound $[^2H_2]$-**1** was determined to be 97.7% by GC−MS using full-scan mode (see Figure S1 of the Supporting Information). The extent of double deuteration according to ^{1}H NMR (Figure 2) and MS (see Figure S2 of the Supporting Information) was greater than 93%. MS [electron ionization (EI)] *m/z* (relative intensity, %): 166.1 (100) $[M]^{\bullet+}$, 151 (54) $[M - CH_3]^{\bullet+}$, 138.1 (62) $[M - CO]^{\bullet+}$, 123.1 (73) $[M - CH_3CHCH_3]^{\bullet+}$, 110.1 (19), 95.1 (63), 79.1 (19), 69.1 (22), 54.1 (27) (see Figures S1 and S3 of the Supporting Information). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.06 (m, 1H, $-CH(CH_3)_2$), 2.10 (s, 3H, CH_3), 1.10 (d, 6H, $-CH(CH_3)_2$) (Figure 2B).

^{1}H NMR Spectroscopy. ^{1}H NMR spectra were recorded on a Bruker DPX 300 MHz spectrometer using $CDCl_3$ as the solvent. Chemical shifts are quoted on the δ scale in parts per million (ppm) using $CDCl_3$ as the internal standard. NMR data were analyzed using an ACD/Laboratories 12 software. Multiplicities of signals are described as singlet (s), doublet (d), triplet (t), quadruplet (q), and multiplet (m).

GC−MS. The GC−MS system consisted of an Agilent 7890A GC system with split injection (250 °C; 1:10), coupled to an Agilent MS model 5975C mass selective detector (MSD) with a triple axis detector (Agilent Technologies, Santa Clara, CA).

A 30 m HP5-MS column [(5% phenyl)-methylpolysiloxane, 0.25 mm inner diameter, film thickness (df) = 0.25 μm, Agilent Technologies, Santa Clara, CA] was used for the quantification of thymoquinone. The GC heating program was as follows: initially at 80 °C, raised to 160 °C at 20 °C/min, then raised to 300 °C at 50 °C/min, and finally held at 300 °C for 3.2 min under a constant helium pressure (10 psi). MS was fitted with an EI source operating at an electron energy of 70 eV held at a temperature of 230 °C. Mass spectra and selected ion monitoring (SIM) were acquired using MSD ChemStation (Agilent Technologies, Santa Clara, CA). Full-scan mode was used to identify thymoquinone in the black cumin oil and characterize the synthetic compounds **2**, $[^2H]_2$−**2** and $[^2H]_2$−**1**. After observation of the major ions for thymoquinone (**1**) and doubly deuteriated thymoquinone ($[^2H]_2$-**1**), SIM mode (*m/z* 164.1 for compound **1** and *m/z* 166.1 for deuterium-labeled compound $[^2H]_2$-**1**) was performed for quantification of thymoquinone using SID GC−MS analysis. SIM mode (three selected ions at *m/z* 164.1, 149.1, and 136.1 for compound **1**) was applied for the quantification of thymoquinone using SIM GC−MS with standard addition and external calibration methods.

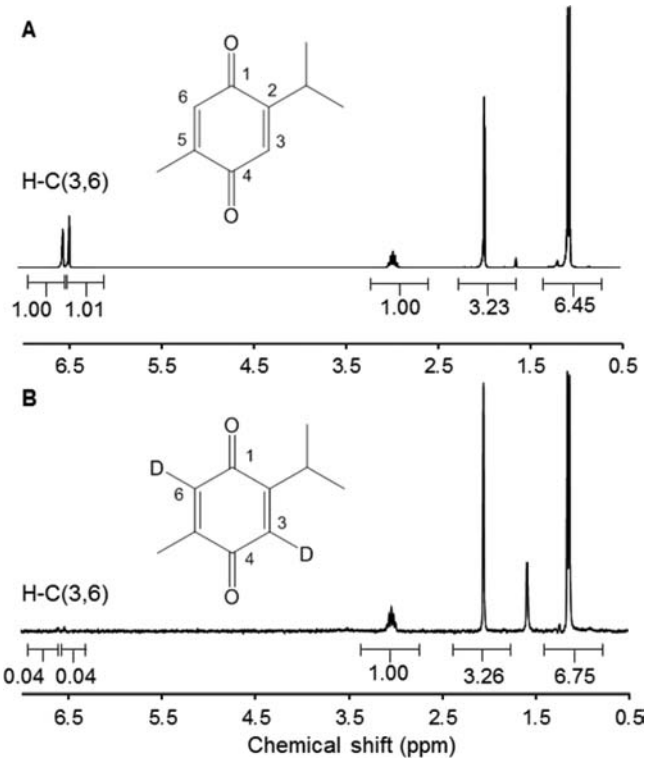

Figure 2. ^{1}H NMR spectra (300 MHz, $CDCl_3$) of (A) thymoquinone (**1**) and (B) $[^2H_2]$-thymoquinone ($[^2H_2]$-**1**). The disappearance of the signals at 6.52 and 6.45 ppm for H-3 and H-6 in the spectrum of compound $[^2H_2]$-**1** indicates >93% double substitution of deuterium for the two protiums of compound **1**.

Development of a SID GC−MS Method for Quantification of Thymoquinone. *Calibration.* The analyte thymoquinone (**1**) and the internal standard $[^2H_2]$-thymoquinone ($[^2H_2]$-**1**) were mixed in six ratios from 0.1 to 10 (5−500 μg/mL in hexane) and analyzed by means of GC−MS in triplicate. Calibration solutions were kept at 4 °C until analysis. The ratios of the area under the curve (AUC) of ion *m/z* 164.1 (AUC_{164}) for compound **1** to the AUC of ion *m/z* 166.1 (AUC_{166}) for compound $[^2H_2]$-**1** were plotted against the concentration ratio of compound **1** to compound $[^2H_2]$-**1** (see Figure S4 of the Supporting Information). The linearity of the calibration regression line was R^2 = 0.9952. The equation obtained was $y = 0.843x + 0.2297$ ($\mathbf{1}/[^2H_2]$-**1**). The limit of detection (LOD) was 0.16 μg/mL with a signal-to-noise ratio of 3:1, and the limit of quantification (LOQ) (10:1)[26] was 0.50 μg/mL, respectively. When using splitless injection mode, LOD and LOQ for thymoquinone were 0.04 and 0.16 μg/mL, respectively.

Quantitation of Thymoquinone in the Black Cumin Seed Oils by SID GC−MS. A sample of black cumin seed oil (50 μL) was added to a 10 mL volumetric flask, and hexane was added to the mark. Aliquots of the diluted oil (200-fold) in hexane (980 μL) was spiked and mixed with a solution of compound $[^2H_2]$-**1** in hexane (20 μL, 1.0 mg/mL). A total of 1 μL of sample was injected into the GC−MS instrument. Each black cumin seed oil sample was prepared 3 times and analyzed with three replicates.

dx.doi.org/10.1021/jf500357x | J. Agric. Food Chem. 2014, 62, 5466−5471

Method Validation. Recovery experiments were performed with a sample of Manako black cumin seed oil. An aliquot of the diluted Manako oil (200-fold) in hexane (920 μL) was spiked with an increasing amount (20, 40, and 60 μL) of compound **1** dissolved in hexane (1.0 mg/mL) and mixed with 20 μL of compound [$^2H_2$]-**1** in hexane (1.0 mg/mL). Finally, hexane was added to give 1.0 mL of black cumin seed oil solution. Aliquots (1 μL) of the diluted oils were analyzed using the SID GC−MS method described above. Three replicates were performed.

To study the intra- and interday imprecisions of the SID GC−MS method, diluted Manako oil in hexane (200-fold) was analyzed. Relative standard deviations (RSDs) were determined for intra- and interday variations based on a set of 9 (in 1 day) and 15 (on 5 different days) measurements.

SIM GC−MS Analysis of Thymoquinone Using Standard Addition and External Calibration. *Standard Addition.* An aliquot of the diluted (200-fold) Manako and Avena oil (800 μL) was added with an increasing amount of compound **1** in hexane to make oil solutions (1.0 mL) that contained an additional 40, 60, 80, 100, 120, 140, and 160 μg/mL of compound **1**. Linear calibration curves (R^2 > 0.99) were obtained by plotting the AUC for the three selected ions (m/z 164.1, 149.1, and 136.1) versus the concentration. Each measurement was repeated in triplicate.

External Calibration. Quantification of thymoquinone using external calibration was carried out by comparing the AUC for the three selected ions (m/z = 164.1, 149.1, and 136.1) of compound **1** in the diluted oil samples to those defined standard solutions of compound **1** dissolved in hexane. A sample of oil (50 μL) was diluted with hexane (10 mL) in a 10 mL volumetric flask, and an aliquot (1 μL) of the diluted samples were analyzed via SIM GC−MS. Each measurement was performed in triplicate. The quantity of thymoquinone was determined using a five-point response curve based on the analysis of standard solutions. Those solutions contained the defined amount of thymoquinone in different concentrations ranging from 5 to 80 μg/mL. The calibration curve (see Figure S5 of the Supporting Information) obtained was $y = 2.2852x - 6.5186$ (R^2 = 0.9956), where y is the AUC/10^3 and x is the concentration of thymoquinone (μg/mL). The LOD was 0.10 μg/mL with a signal-to-noise ratio of 3:1, and the LOQ (10:1) was 0.31 μg/mL. When using splitless injection mode, LOD and LOQ were 0.02 and 0.08 μg/mL, respectively.

RESULTS AND DISCUSSION

Synthesis of a Stable Isotope-Labeled Thymoquinone. The scheme of synthesis of the doubly deuterated thymoquinone ([$^2H_2$]-**1**) is shown in Figure 1. Thymoquinone (**1**) was first reduced to thymohydroquinone (**2**) by sodium hydrosulfite. The two protiums (H-3 and H-6) of compound **2** were then exchanged by deuterium in 3.4 M D_2SO_4 in D_2O under refluxing for 48 h. After cooling to room temperature, the deuterated thymohydroquinone ([$^2H_2$]-**2**) was obtained after workup with H_2O rather than expensive D_2O. Finally, compound [$^2H_2$]-**2** was oxidized with CrO_3 in 60% HOAc to yield compound [$^2H_2$]-**1** (17% overall yield).

GC−MS shows a single peak with high purity (97.7%) based on GC−MS (see Figure S1 of the Supporting Information) and ^{1}H NMR (Figure 2) for compound [$^2H_2$]-**1**. A comparison of the EI−MS spectrum of thymoquinone (**1**) to that of compound [$^2H_2$]-**1** (see Figures S1 and S2 of the Supporting Information) showed that a mass increase of the molecule ion m/z 164.1 by two deuterium atoms to m/z 166.1, which confirmed [$^2H_2$]-**1** was the predominant isotopologue. The electron impact fragmentation pathways for compounds **1** and [$^2H_2$]-**1** are very similar because of the substitution of H-3 and 6 of compound **1** by two deuteriums (see Figure S3 of the Supporting Information). The isotopic distribution of compound [$^2H_2$]-**1** detected by GC−MS was found to be 2.0% natural [^{2}H] abundant compound **1**, 5.0% compound [$^2H_1$]-**1**, and 93.0% compound [$^2H_2$]-**1**. Further comparison of the ^{1}H NMR of compound **1** (Figure 2A) to that of compound [$^2H_2$]-**1** (Figure 2B) shows the disappearance of peaks for H-3 and H-6 because of the protium/deuterium exchange, again confirming the presence and position of two deuterium atoms in 2-isopropyl-5-methyl-1,4-dideuterobenzoquinone ([$^2H_2$]-**1**). It shows only minor protium abundance of 4.0% at position C-3 and 4.0% at position C-6 of compound [$^2H_2$]-**1** (Figure 2B), which is consistent with a high degree of double deuteration of compound [$^2H_2$]-**1** found by GC−MS (see Figure S2 of the Supporting Information).

Because only 2.0% natural [^{2}H] abundant compound **1** was present in the synthetic compound [$^2H_2$]-**1** and less than 2.0% of the third isotopic peak of compound **1** (m/z 166.1) was detected, the ratios of the AUC for ion m/z 164.1 for compound **1** to the AUC for ion m/z 166.1 for compound [$^2H_2$]-**1** were used for the calibration and quantification of thymoquinone (**1**) using the SID GC−MS method. Compound [$^2H_2$]-**1** was found to be stable in hexane for more than 6 months in the dark and, therefore, is suitable to be used as an internal standard for the SIDA.

Establishment of a SID GC−MS Method. The conditions for gas chromatographic separation were optimized to quantify thymoquinone (**1**) in black cumin seed oil within only 10 min (Figure 3). Figure 3A shows a typical total ion current (TIC) gas chromatogram of the Manako oil sample spiked with compound [$^2H_2$]-**1** using full-scan mode. A number of compounds can be detected. SIM (m/z 164.1 and 166.1 for compounds **1** and [$^2H_2$]-**1**, respectively) mode was used to quantify compound **1** in the oil using SID GC−MS (chromatogram not shown). Panels B and C of Figure 3

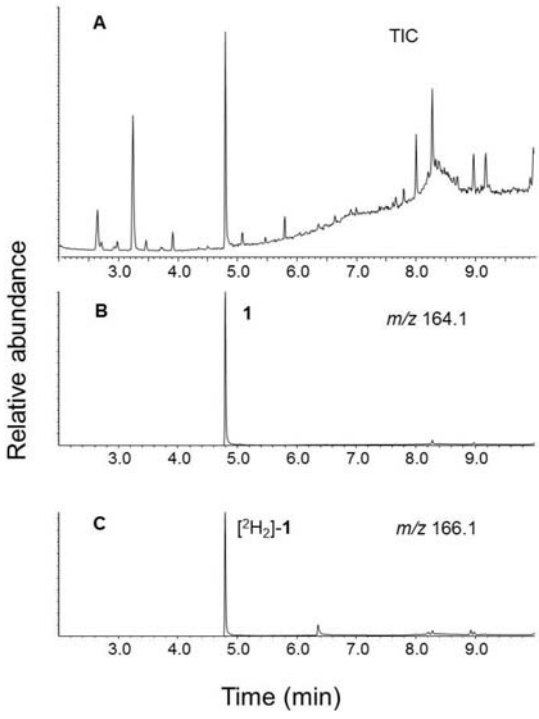

Figure 3. (A) Typical TIC chromatogram and reconstructed ion chromatograms of (B) thymoquinone (**1**) and (C) deuterium-labeled thymoquinone ([$^2H_2$]-**1**) in Manako black cumin seed oil spiked with compound [$^2H_2$]-**1**.

Table 1. Recovery Rates for the Quantification of Thymoquinone in the Diluted (1:200) Black Cumin Seed Oil (Manako) Determined by a SID GC−MS Method[a]

amount of compound **1** added (μg/mL)	concentration calculated (μg/mL)	concentration determined (μg/mL)	recovery (%)	average recovery (%)
		53.9 ± 0.01		
20.0	73.9 ± 0.01	73.3 ± 0.02	99.2 ± 0.02	
40.0	93.9 ± 0.01	94.0 ± 0.02	100.1 ± 0.02	99.1 ± 1.1
60.0	113.9 ± 0.01	111.5 ± 0.02	97.9 ± 0.02	

[a]Data are expressed as the mean ± RSD (n = 3).

show the reconstructed ion chromatograms of compounds **1** (m/z 164.1) and [$^2H_2$]-**1** (m/z 166.1) in the Manako black cumin seed oil. Compounds **1** and internal [$^2H_2$]-**1** were co-eluted at 4.81 min. A calibration graph (see Figure S4 of the Supporting Information) was plotted from a mixture of known mass ratios of compounds **1** and [$^2H_2$]-**1** and their corresponding peak area ratios in GC−MS by linear regression analysis. This calibration curve showing a linear response (R^2 = 0.9938) could enable the determination of the quantity of thymoquinone in the samples based on their measured ion intensities.

Recovery experiments were performed to check the trueness of the SIDA method. Specified quantities of thymoquinone (**1**) were added to the diluted Manako oil sample in three different concentrations before using SID GC−MS analysis. The quantity of compound **1** was measured and compared to those found in the blank diluted Manako oil sample as the control (Table 1). The mean recovery rate was determined to be 99.1 ± 1.1% RSD based on the amount of compound **1** added to the diluted oil sample. These results demonstrated that the developed SID GC−MS is a reliable, rapid, and accurate method for quantification of compound **1**. Thymoquinone in five marketed oil products was quantified, and their results are listed in Table 2. The concentration of thymoquinone ranged from 3.34 to 10.8 mg/mL. Manako oil has the highest content of thymoquinone, while CEBRA oil has the lowest content of thymoquinone.

Table 2. Quantification of Thymoquinone in Black Cumin Seed Oils via SID GC-MS, External Calibration, and Standard Addition Methods[a]

	concentration (mg/mL)		
black cumin seed oil	SID GC-MS	external calibration	standard addition
Manako	10.8 ± 0.01	8.95 ± 0.03	10.6 ± 0.13
Avena	7.27 ± 0.02	7.33 ± 0.08	7.17 ± 0.02
CEBRA	3.34 ± 0.03	2.96 ± 0.18	*b*
Iman	7.23 ± 0.02	6.02 ± 0.09	*b*
This Health	7.74 ± 0.04	7.03 ± 0.10	*b*

[a]Data are expressed as the mean ± RSD (n = 3). [b]Concentration not determined.

Cross-Validation of the SID GC−MS Method. The standard addition method can also overcome the matrix effects and is often used for the validation of the SIDA method.[18,27] To validate the SID GC−MS method developed above, the data obtained using SID GC−MS were compared to those found using standard addition and external calibration (Table 2). Three characteristic ions (m/z 164.1, 149.1, and 136.1) for compound **1** were selected for the quantification of thymoquinone using standard addition and external calibration. An external calibration curve with a linear response (R^2 = 0.9956) (see Figure S5 of the Supporting Information) was attained by linear regression analysis of the AUC versus the concentration.

Quantification based on the standard addition and external calibration showed 98.1 ± 1.2 and 82.9 ± 0.3% of compound **1** in Manako oil and 98.6 ± 0.4 and 100.8 ± 1.1% of compound **1** in Avena oil (calculated from data in Table 2) when compared to the results obtained by means of SID GC−MS, respectively. The standard addition and SID GC−MS results revealed very similar concentrations of compound **1** in Manako and Avena oils (differences are less than 2%), therefore validating the accuracy and advantage of the SIDA method. The concentrations of thymoquinone in all five oils determined by external calibration generally agreed with those determined from SIDA and/or standard addition methods (differences range between 1 and 17%). The slight discrepancies are probably due to matrix effects from the different preparations of these black cumin seed oils.[18]

The intraday precision of the SID GC−MS method for compound **1** showed a RSD of ±1.3% (n = 9) by analyzing diluted Manako oil in hexane in nine independent measurements in 1 day. Interday precision studies with diluted Manako oil revealed a RSD of ±5.9% (n = 15) in three independent measurements in each day for 5 days. These data again demonstrate that the SID GC−MS method is a reliable, rapid, and accurate analytic means for thymoquinone in black cumin seed oils.

In previous reports, thymoquinone was quantified by several other analytical techniques.[12−16] HPLC was used for quantification of thymoquinone in a commercial black cumin seed oil[12] and in different phytopharmaceuticals with a LOD of 0.006 μg/mL (10 μL of injection volume, ∼60 pg).[13] Quantification of thymoquinone in herbal extracts and oil was also achieved using HPTLC with LOD of 50 ng/spot.[14] A differential pulse polarographic method was developed for the determination of thymoquinone in black seed oil, where LOD was found to be 0.05 μg/mL (10 mL of volume, ∼500 ng).[15] The content of thymoquinone in black cumin seed oils was also found to be in the range of 0.13−0.17% (w/v) of the oil by GC.[16] In our GC−MS methods, where split injection mode (1:10) was used to avoid overloading samples, LODs of thymoquinone for SIM GC−MS and SID GC−MS were found to be 0.10 and 0.16 μg/mL (1 μL of injection volume, ∼100 and 160 pg), respectively. However, for trace analysis of thymoquinone, LODs can be further improved using splitless injection mode and range from 0.02 to 0.04 μg/mL (1 μL of injection volume, ∼20−40 pg). Therefore, the sensitivities of GC−MS methods are comparable to that of HPLC and are higher than those of HPTLC and differential pulse polarographic methods. Furthermore, GC−MS and/or SID GC−MS methods have advantages of identifying analytes and overcoming matrix effects over other analytical methods.[18,19]

dx.doi.org/10.1021/jf500357x | J. Agric. Food Chem. 2014, 62, 5466−5471

In summary, synthesis of a highly pure deuteriated thymoquinone has been achieved for the first time, which enables us to develop a SIDA of the biologically important thymoquinone in black cumin seed oil using GC−MS. Cross-validation using standard addition confirms the accuracy and reliability of the SIDA method, which can quantify a large number of black cumin seed oil products for their quality control in high-throughput means. Synthetic deuteriated thymoquinone and the SID GC-MS method should also be useful in the studies on the mechanism of binding thymoquinone to proteins,[24,28−30] *in vitro* and *in vivo* pharmacokinetics of thymoquinone, which are ongoing in our laboratory.[31]

A Critical Point: The Problems Associated with the Variety of Criteria To Quantify the Antioxidant Capacity

M. A. Prieto,* J. A. Vázquez, and M. A. Murado

Group of Recycling and Valorization of Waste Materials (REVAL), Research Marine Institute (IIM-CSIC), Vigo 36208, Spain

ABSTRACT: The oxidant action implies interfering in an autocatalytic process, in which no less than five chemical species are present (oxygen, oxidizable substrate, radicals, antioxidants, and oxidation products); furthermore, reactions of first and second order can take place, and interactions can occur, at several levels of the process. The common and incorrect practice is to use the single-time dose−response of an established antioxidant as a calibration curve to compute the equivalent antioxidant capacity of a sample, which is only tested at one single time−dose, assuming too many false aspects as true. Its use is unreasonable, given the availability of computational applications and instrumental equipment that, combined, provide the adequate tools to work with different variables in nonlinear models. The evaluation of the dose−time dependency of the response of the β-carotene method as a case study, using the combination of strong quantification procedures and a high amount of results with lower experimental error (applying microplate readers), reveals the lack of meaning of single-time criteria. Also, it demonstrates that, in most of the reactions, the time-dependent response in the oxidation process is inherently nonlinear and should not be standardized at one single time, because it would lead to unreliable results, hiding the real aspects of the response. In food matrices, the application of single-time criteria causes deficiencies in the control of the antioxidant content. Therefore, it is logical that, in the past decade, researchers have claimed consensus to increase the determination and effectiveness of antioxidant responses.

KEYWORDS: *antioxidant capacity, β-carotene method, mathematical modeling, kinetic response*

INTRODUCTION

At present, there is no convenient assay that enables the evaluation of the antioxidant capacity (AC) in a food system, mainly because the factors affecting the oxidation reactions and ACs differ[1,2] greatly. The current methods to test the AC have still left many open questions.[3−7] The *in vitro* assays can only rank AC for its particular reaction system, and its relevance to *in vivo* health protective activities remains uncertain. Free radicals may be either oxygen-derived [reactive oxygen species (ROS)] or nitrogen-derived [reactive nitrogen species (RNS)]. In a normal cell, there is an appropriate balance, but this can be shifted in stress situations or when levels of antioxidants (A) are diminished. Therefore, an important factor that may counteract their effect is the alimentary intake of antioxidants. Hence, since two decades, the interest for evaluating the ACs present in all types of food and characterizing their specific mechanisms has increased noticeably.

The possibility to accumulate data rapidly has encouraged authors to use simple calculation formalisms to abbreviate the testing procedure, forcing the conditions of the assay to assume a linear kinetic response, in which samples are generally assessed using a single time and dose. Very often the same method is performed with different experimental protocols and formalisms for quantifying the activity. This has caused a loss of information and the risk of erroneous conclusions,[1] causing deficiencies in the control of the real AC of samples. The analysis of all of the particular problems associated with the diverse quantification criteria used for each method is unfeasible. However, because most of the methods share the main objectives and operative requirements, the β-carotene (βC) bleaching assay[8] has been chosen as a case study. This assay is a well-accepted model for testing the AC of samples, but the quantification approaches, considering or not the variation as a function of the time and dose, applied to analyze the response are diverse. This method, as many others, very often has a poor evaluation of the results,[1] despite the regularity of the oxidation and inhibition processes. Results are usually expressed at a fixed single time, which causes many difficulties to obtain a robust method. Although there are mathematical tools available to evaluate the lipid oxidation,[2,9−11] they are rarely applied to quantify the responses. The βC method is a highly reproducible procedure, currently performed in microplate readers,[12] providing an appropriate tool that ensures that samples, the reference antioxidant (usually commercial ones used to build the calibration curve), and the controls of the reaction can be simultaneously assessed as a function of the dose and time, producing abundant data with lower experimental error. It is, therefore, a robust and meaningful example that can be used as a case study for raising the discussion of the problems associated with the different quantification criteria applied when studying the responses generated for each method. When several common A are characterized, the problems of using single-time−dose quantification procedures, disregarding kinetic considerations, are discussed in detail. Furthermore, those criteria that take into account the kinetic of the process (dose−time-dependent behavior) are also evaluated and compared.

In consequence, the results prove that (1) the reduction to study the dose−response at one single time and dose, expecting

to find linear forms (as described by the non-kinetic approaches), leads frequently to unreliable results and (2) the preference for apparently simple assays, routinely applicable with minimal calculation requirements, is not very justifiable in our days, given the availability of computational applications and microplate readers, whose combination provides adequate tools to work with data sets that allow for the performance of accurate evaluations with nonlinear modeling. Such results can be easily extrapolated to the other *in vitro* and *in vivo* assays generally used to determine the capacity to counteract the oxidation products formed.

MATERIALS AND METHODS

βC Bleaching Method. *Assay Description.* The βC method is currently well-optimized and adapted to microplate readers.[12]

Equipment. Multiskan spectrum microplate photometers from Thermo Fisher Scientific and a Thermo Scientific Nunc 96-Well Polypropylene MicroWell plate with a flat bottom were used.

Main Reagents of the βC Bleaching Method. *cis,cis*-9,12-Octadecadienoic acid (linoleic acid), β-carotene, and polyoxyethylenesorbitan monopalmitate (Tween 40) were used.

Antioxidant Agents Used as an Example. Butyl-hydroxyanisole (BHA) is the main A used as a case study and/or calibration in the dose range 0.0−5.0 μM in intervals of 0.5. (2*R*)-2,5,7,8-Tetramethyl-2-[(4*R*,8*R*)-(4,8,12-trimethyltridecyl)]-6-chromanol or α-tocopherol (TOC) is A used as sample M1 in 0−40 nM in intervals of 4. Zinc chloride (Zn) is A used as sample M2 in 0−1070.5 μM in intervals of 107.5. Propyl-3,4,5-trihydroxybenzoate (PG) is A used as sample M3 in 0−80 μM in intervals of 8. Manganese sulfate (Mn^{2+}) is A used as sample M4 in 0−200 μM in intervals of 20. Butyl-hydroxytoluene (BHT) is A used as sample M5 in 0−20 μM in intervals of 2. 6-Ethoxy-2,2,4-trimethyl-1,2-dihydroquinoline or ethoxyquin (ETX) is A used as sample M6 in 0−3 nM in intervals of 0.3. All compounds were purchased from Sigma S.A. (St. Louis, MO).

Quantification Procedure. The most common criteria applied to quantify the responses, considering or not the variation as a function of the time and dose, are described in the following.

Original Quantification Approach. According to Marco,[8] when the absorbance at 470 nm is measured at increasing times and concentrations of an A, the response can be assessed through the percentage of the extended induction time (E_t) defined as

$$E_t\ (\%) = \frac{t_n - t_0}{t_{ref} - t_0} \times 100 \tag{1}$$

where t_0, t_n, and t_{ref} are the times at which the βC concentration reaches certain percentage values (p) in the absence of A, in the presence of a given concentration of the tested A, and in the presence of a reference A, respectively. The author uses the values of p = 50 and 70 and recommended to linearize (using logic paper) the sigmoid response obtained. He also noted that, for some common A, the relationship between the A concentration and its effect on βC-extended induction time was close to linearity.

Usual Non-kinetic Approaches To Quantify the Antioxidant Response of the βC Reaction. After the publication of the work by Marco,[8] several ways that abbreviate the procedure, avoiding the use of kinetic analysis with a probabilistic paper to quantify the response, were published. There is a high diversity of quantification criteria (Q) at a fixed time that has been used to analyze the responses. Next, the most common single time−dose typically applied in the βC reaction and the dose−response single-time methods are summarized. Several other methods have been excluded from the analysis, such as the method described by Mikami et al.,[13] because of the redundancy with one of the alternatives that would be described next.

Single-Time and Dose−Response Procedures. Q1: Percentage of Oxidation Inhibition (I) or Relative Activity. It is defined by Chatterjee et al.[14] as

$$I\ (\%) = \frac{C_0 - M_t}{C_0} \times 100 \tag{2}$$

where M_t is the final absorbance of the reagent in the presence of the sample and C_0 is the initial absorbance when the sample is replaced by water (control). The single time used to test their AC is usually 10, 20, or 30 min.

Q2: Antioxidant Activity Coefficient (AAC). One of the most common criteria[15−19] is defined as

$$\mathrm{AAC} = \frac{M_t - C_t}{C_0 - C_t} \times 1000 \tag{3}$$

where *C*, *M*, and t have the same meanings as in the previous criterion. Again, the time varies from 1 to 2 h, establishing *a priori*[20] or selecting an appropriate frame for interpolation, in view of the kinetic data.

Q3: Antioxidant Activity Coefficient Modified (AACm). An alternative way to the AACm is the normalized coefficient value of the antioxidant activity

$$\mathrm{AACm} = 100 - \frac{C_0 - C_t}{M_0 - M_t} \tag{4}$$

where the value meanings are the same as in previous cases.

Q4: Relative Rate of Degradation (RD). An example is used in refs 21−23

$$\mathrm{RD} = \frac{r_c - r_m}{r_c} \times 100 \tag{5}$$

where r_c and r_m are the specific rates of the control and sample βC bleaching, calculated assuming first-order kinetics

$$r_c = \frac{\ln C_0 - \ln C_t}{t - t_0} \quad \text{and} \quad r_m = \frac{\ln M_0 - \ln M_t}{t - t_0} \tag{6}$$

in which *C* and *M* are the control and sample, respectively, and *t* values are usual analytical times, usually 10, 20, and 30 min.

Q5: Ratio of Oxidation Rates (R_{OR}). This criterion[22−24] uses the relationship directly between specific rates previously defined

$$R_{OR} = \frac{r_c}{r_m} = \frac{\ln C_0 - \ln C_t}{\ln M_0 - \ln M_t} \tag{7}$$

Q6: Dose−Response at a Fixed Time. Other authors[9,25] used any of the above quantification criteria (Q1−Q5) or similar at a fixed time as a function of different doses of the sample and A as the reference. When the results behave linearly, the slope is used as the comparison term. When the response behaves in a nonlinear mode, typically, the dose at which the inhibition reaches 50% (IC_{50}) is used as the parameter for comparative analyses.

Methods Taking into Account the Kinetic Aspect of the Response To Quantify the AC. In this section, those quantification methods that take into account the kinetic part of the process are briefly described. Some may not have been applied directly in the βC bleaching method, but they were considered as valuable tools for describing the oxidation process and included for discussion.

Formal Mathematical Expressions. The range of mathematical expressions available is large and common to many fields of study. The preferable options are always models that have a lower number of parameters and models with parameters that provide direct meaning of the processes under analysis. In this sense, for the kinetic description of the A behavior, we have found three groups of alternatives in the references[2,9,10] covering a wide spectrum of profile responses, from potential to sigmoid responses, with and without intercepts.

Q7: Potential Functions without an Intercept. Power Equation. Recently, Terpinc et al.[9] adjusted the temporal progress of the oxidation to the following equation:

$$R = 1 - \frac{1}{(1 + at)^b} \tag{8}$$

where *R* is the oxidized substrate at each given time *t*, the response is standardized into a frame [0, 1], in which 0 is the initial response at *t* =

dx.doi.org/10.1021/jf5005995 | J. Agric. Food Chem. 2014, 62, 5472−5484

Table 1. Equations with or without an Intercept Used Are Summarized along with Several Other Properties[a]

potential function				
power function	$R = K - K[\tau/(\tau + (2^{1/b} - 1)t)]^b$	$\nu_m = \frac{ab}{(1 + at)^{b+1}}$	$\tau = \frac{2^{1/b} - 1}{a}$	
sigmoidal function with an intercept				
logistic	$R = \frac{K}{1 + e^{c(\tau - t)}}$	$\nu_m = \frac{Kc}{4}$	$\lambda = \tau - \frac{2}{c}$	$R = \frac{K}{1 + e^{c(\lambda - t) + 2}}$
sigmoidal function without an intercept				
Weibull	$R = K[1 - e^{-\ln 2(t/\tau)^\alpha}]$ $t = \tau[\ln(1 - R)/\ln 0.5]^{1/\alpha}$	$\nu_m = \frac{K\alpha \ln 2}{2\tau}$	$\lambda = \tau\left(1 - \frac{1}{\alpha \ln 2}\right)$	$R = K - Ke^{-\ln 2\left(t\left(1 - \frac{1}{\alpha \ln 2}\right)/\lambda\right)^\alpha}$

[a]The original or traditional forms of these equations were reformulated to facilitate comparisons; thus, all of them would have a positional parameter, such as the half-life (now on τ) and an asymptotic parameter (K), among the regression parameters of the functions. The third parameter (b, c, and α) would be related with steepness of the function.

0 and 1 is the response when the substrate is fully oxidized. The parameters a and b depend upon the concentration of A. The authors claim that this equation can fit different responses, such as the responses found in the DPPH and bleaching βC methods. Other interesting parameter values, such as the average rate and half-life (or time when 50% oxidation is achieved) can be obtained with further calculations using parameters a and b (Table 1).

Q8: Sigmoid Functions with an Intercept. Logistic Equation. Authors[2,10,26−29] have used the logistic equation, which can be written in its more functional form as follows:

$$R = \frac{K}{1 + \exp[\ln[(K/R_0) - 1] - \mu_m t]} \quad (9)$$

where R is the oxidized substrate (with R_0 and K as initial and asymptotic values, respectively) and μ_m is the specific-maximum rate. The equation can be reconfigured to explicitly highlight other valuable parameters, such as the oxidizable substrate half-life (τ), maximum speed (v_m), and lag phase (λ) (see Table 1 for more details).

Q9: Sigmoid Functions without an Intercept. Weibull Equation. Quantification was carried out using the accumulative Weibull distribution to describe satisfactorily the whole kinetic profile[2]

$$R = K\{1 - \exp[-\ln 2(t/\tau)^\alpha]\} \quad (10)$$

where K is the asymptote, τ is the substrate half-life or time when 50% oxidation is achieved, and α is a shape parameter associated with the maximum slope of the response. From this equation, other values of interest can be computed, such as the maximum speed (v_m) and lag phase (λ) (see Table 1 for more details).

Dose−Response of Single "Global Values" That Summarize the Kinetic Response. Q10: Lag Phase (λ) and Inhibition Time of Oxidation (t_{inh}). Those values are common criteria in the determination of the protective effect of A in a very diverse range of methods. We have not seen their application in the βC assay. Both values have nearly analogue meanings and very narrow differences.

The lag phase is typically used in those methods that the response shows clear sigmoid profiles, such as those that involve the oxidation of lipids.[10,29] The lag-phase value is commonly determined by univariate mathematical modeling with S-shaped equations as the ones described in Table 1. Pure geometric reparametrizations of those equations are used to directly perform the analysis and obtain the λ value as a parameter in the equation. Those rearrangements define λ as the intersection point obtained at the x axis (time units in this case) by a linear extrapolation tangent to the curve at the inflection point.

The t_{inh} value is the alternative solution to compute the λ parameter when certain assay conditions make it difficult to obtain the λ parameter.[30,31] For example, in the case of the low-density lipoprotein (LDL) oxidized by Cu^{2+}, the response is affected by two different actions. The LDL is oxidized spontaneously in the conditions of the assay and by the Cu^{2+} ions added, which is reflected in a biphasic curve. Because the spontaneous oxidizing rate is very low compared to the effect caused by Cu^{2+}, the spontaneous oxidation of LDL (baseline of the response) is subtracted graphically by drawing a line from the starting value at $t = 0$ parallel to the baseline of the response and the t_{inh} value is the intersection point with the line tangent to the main curve of the process.

Those values are computed in a dose−response format and expressed in min/μM. The higher this value, the stronger the A. Authors that support those approaches defended their simplicity and less experimental effort needed.

Q11: Area Units under the Curve. A simple approach to characterize the A action through a single value is achieved by calculating the area under the kinetic profile.[32−34] This has also been applied in more complex responses, as example, to simplify the variable time response to one value.[35] Even with the lack of a formal description of that profile, if R_i values are the responses along an arbitrary time series, it is possible to define a response in terms of area units (AU) that can be easily calculated by any numerical integration method, such as the trapezoidal rule as follows:

$$AU = \frac{R_1 \Delta t_1}{2} + \sum_{i=2}^{i=n-1} R_i \Delta t_i + \frac{R_n \Delta t_n}{2} \quad (11)$$

where i is the number of data measured along the time t, Δt is the interval of each measurement, and AU values are the area units under the curve. For the particular case analyzed here, the area values represent the accumulative amount of βC bleached during the total time (t) analyzed.

Numerical and Statistical Methods. Fitting the experimental results to the proposed equations was carried out in two phases. First, parametric estimates were obtained by minimization of the sum of quadratic differences between observed and model-predicted values, using the nonlinear least-squares (quasi-Newton) method provided by the macro Solver from a Microsoft Excel 2003 spreadsheet.[36] It allows for quick testing of hypotheses and display of its consequences. Subsequently, the determination of the parametric confidence intervals and model consistency (Student's t and Fisher's F tests, respectively, in both cases with $\alpha = 0.05$) were calculated using the "SolverAid" macro.[37,38] The "SolverStat" macro[39] was used to detect possible anomalies in the distribution of parametric estimates and residuals.

RESULTS

Non-kinetic Approaches (Q1−Q6). *Response at a Single Time and Single Dose (Q1−Q5).* Commonly, the mathematical determinations of the AC are based on a fixed end point without proper consideration of the kinetic behavior. The most typical practice is to use the single-time dose−response of one commercial A as a calibration curve (focusing on the concentration range that shows a linear pattern) and, afterward, to compute the equivalent AC of any type of sample by testing it only at one single-time dose, assuming too many false aspects as true. In Figure 1, we present a graphical representation of the problematic aspects when using single-time dose of a sample. On the left side of Figure 1, the kinetic results (32 time

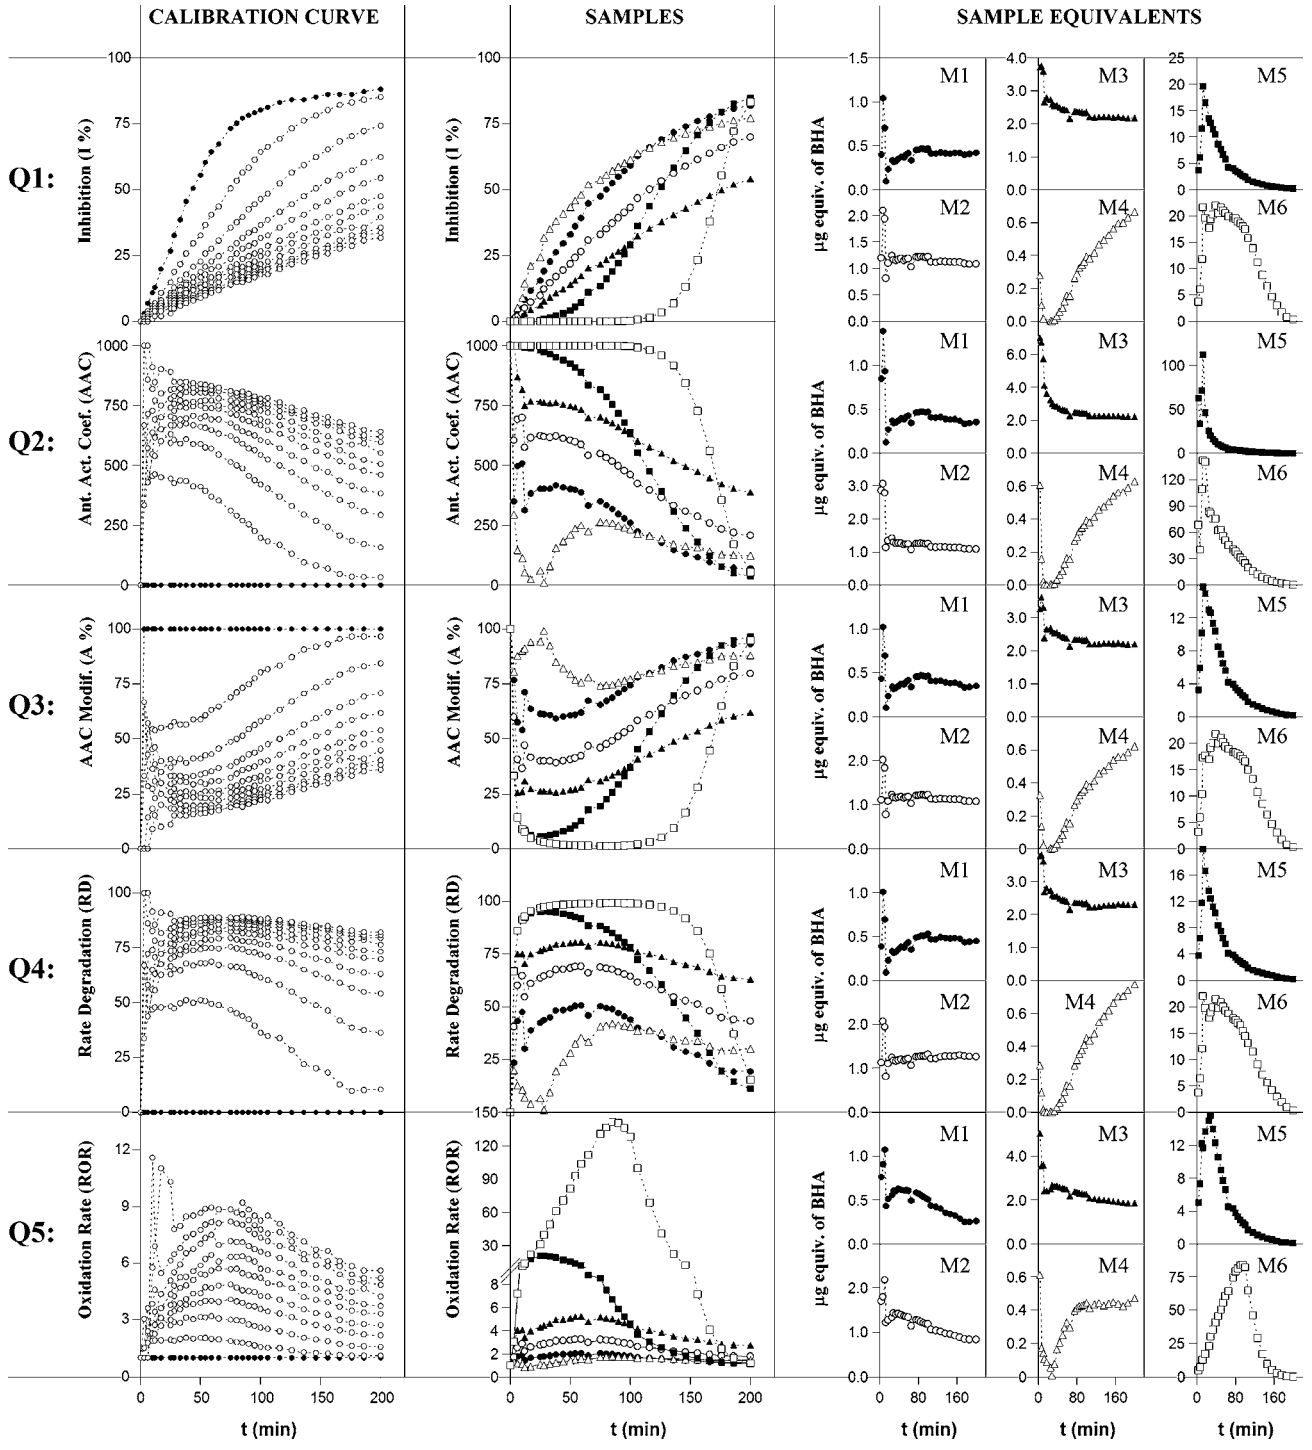

Figure 1. Analysis of the problems of single-dose quantification procedures at a fixed time (Q1−Q5). We use the dose−response of the antioxidant BHA in the range of 0.0−5.0 μM in intervals of 0.5 as the reference antioxidant and evaluate the results in the βC bleaching reaction from a kinetic point of view. Six samples (M1−M6) are used to test the robustness of the Q1−Q5 criteria. The doses used of the samples are 8 nM TOC for M1, 1007.5 μM Zn for M2, 80 μM PG for M3, 200 μM Mn for M4, 20 μM BHT for M5, and 4 nM ETX for M6.

measurements) of the βC reaction at increasing concentrations of BHA (as the calibration curve) are displayed in the format of each of the non-kinetic quantification criteria (Q1−Q5) described in the Materials and Methods. In the middle of Figure 1, six well-known A are presented as samples (M1−M6) and their kinetic activity is shown at one single dose for each of the non-kinetic criteria (Q1−Q5). Finally, on the right side, the equivalent activity computed by interpolation of each of the samples for each of the kinetic points analyzed is shown. It can be seen that the equivalent activity of BHA per each sample varies considerably as a function of the time of interpolation. The variations depend upon the level of similarity between the curves. The BHA dose−response is a specific case that we know[12] that behaves close to a first-order response in the βC bleaching reaction. For those sample responses in which their kinetic profile has a similar pattern, their equivalent kinetic

dx.doi.org/10.1021/jf5005995 | J. Agric. Food Chem. 2014, 62, 5472−5484

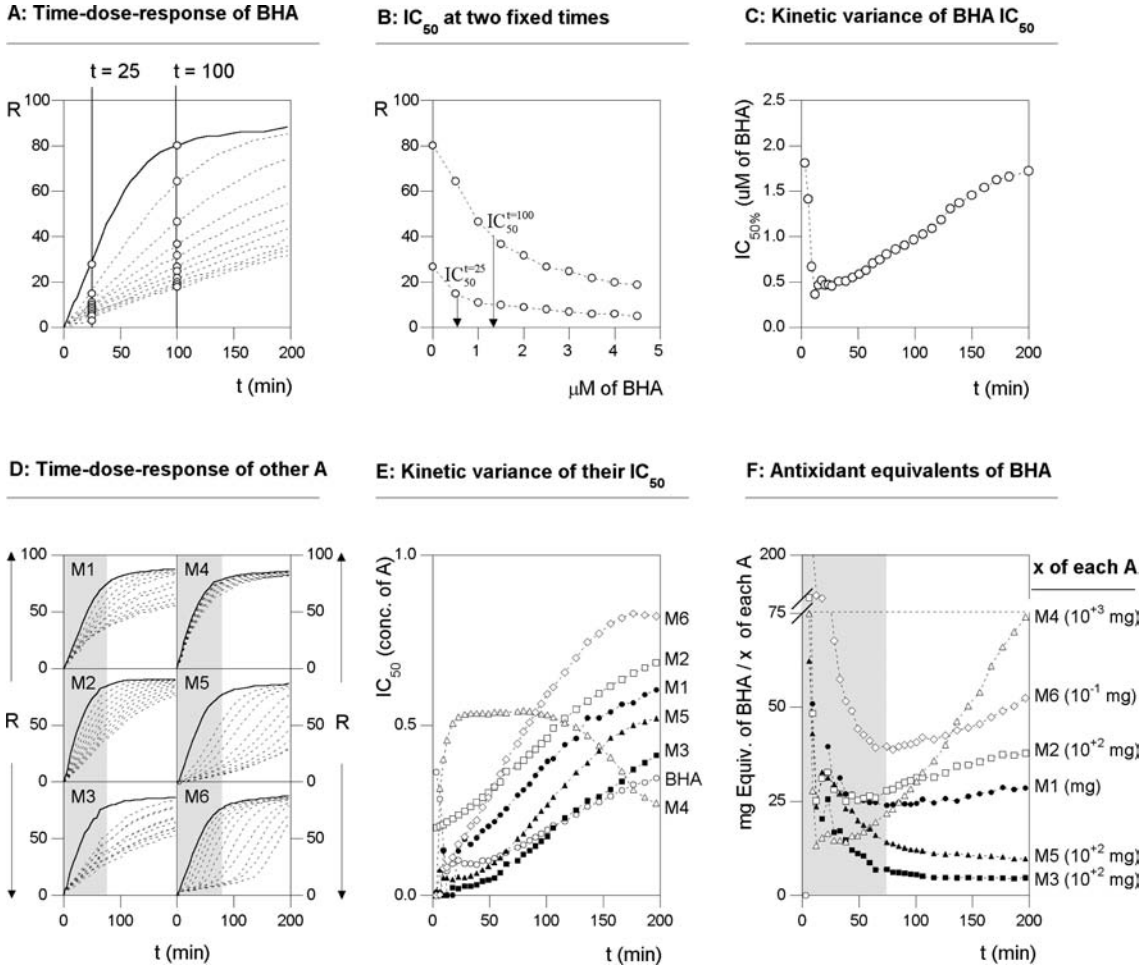

Figure 2. Analysis of the problems of dose−response quantification procedures at a fixed time (Q6). As an example, we use the dose−response of the antioxidant BHA in the range of 0.0−5.0 μM in intervals of 0.5 and evaluate the results in the βC bleaching reaction from a kinetic point of view. (A) Kinetic dose−response of BHA in the format of Q1 criterion. (B) Nonlinear dose−response of BHA at the fixed points selected in the previous graph. (C) Behavior of the computed value IC_{50} at all kinetic times measured. (D) Dose−response of samples M1−M6 (concentration ranges in the Materials and Methods). (E) Computed kinetic IC_{50} value for all samples. (F) Equivalent milligrams of BHA activity of all samples.

response is kept more or less constant, which is the case for M1, M2, and M3 samples. However, even in those responses with similar profiles, it can be seen that, performing the equivalent activity at initial kinetic points (<25 min), the response at which the major measurement errors are produced causes high equivalent activity inaccuracies. For all other cases, the type of response profile was different from that exhibited by the reference A, and this caused a considerably dependency upon the time at which the kinetic measure is performed. For example, cases M5 and M6 showed a different degree of sigmoid profiles; in consequence, their kinetic equivalent computation shows major differences at any time. The case of M4 shows a potential pattern as well as the previous cases, but in an opposite way, the kinetic equivalent activity estimation shows a clear dependency upon the fixed point selected.

Dose−Response at a Fixed Time (Q6). The problems explained above are not solved when the quantification involves computing the slope (linear responses) or the IC_{50} (nonlinear responses) of samples and reference A at a single or various fixed end points for any of the Q1−Q5 criteria or other similar approaches. Although testing samples and reference A in a dose−response way seems to be a more consistent approach, the calculated values (slope and IC_{50}) remain highly dependent upon the time and the similarities between the behaviors of the dose−response of the compounds.

On one hand, to illustrate the dependence upon the time, Figure 2A shows the kinetic dose−response of BHA in the format of criterion Q1. In this figure, we select "randomly" two possible fixed time points (25 and 100 min). Figure 2B shows the nonlinear dose−response of BHA at those fixed points, showing graphically the variance of the IC_{50} obtained. Figure 2C shows the behavior of the computed value IC_{50} at all kinetic times measured. Therefore, the fixed points initially chosen have a relevant impact on the final IC_{50} obtained. In the case of BHA, the dose−response tested was between 0 and 5 μM and the range of the computed IC_{50} was between 0.5 and 2 μM. Additionally, to extend our concerns regarding the applications of this type of quantification criteria, Figure 2D shows the dose−response of samples M1−M6 (concentration ranges in the legend of Figure 2). Figure 2E shows the computed kinetic IC_{50} value for all samples. The response was standardize into a [0, 1] format to distinguish the differences in a more graphical mode, in which 0 represents the absence of A and 1 represents the maximum tested dose of A. Thus, it can be examined that the kinetic variance of IC_{50} in some cases reaches values up to 70% of the dose−response tested.

dx.doi.org/10.1021/jf5005995 | J. Agric. Food Chem. 2014, 62, 5472−5484

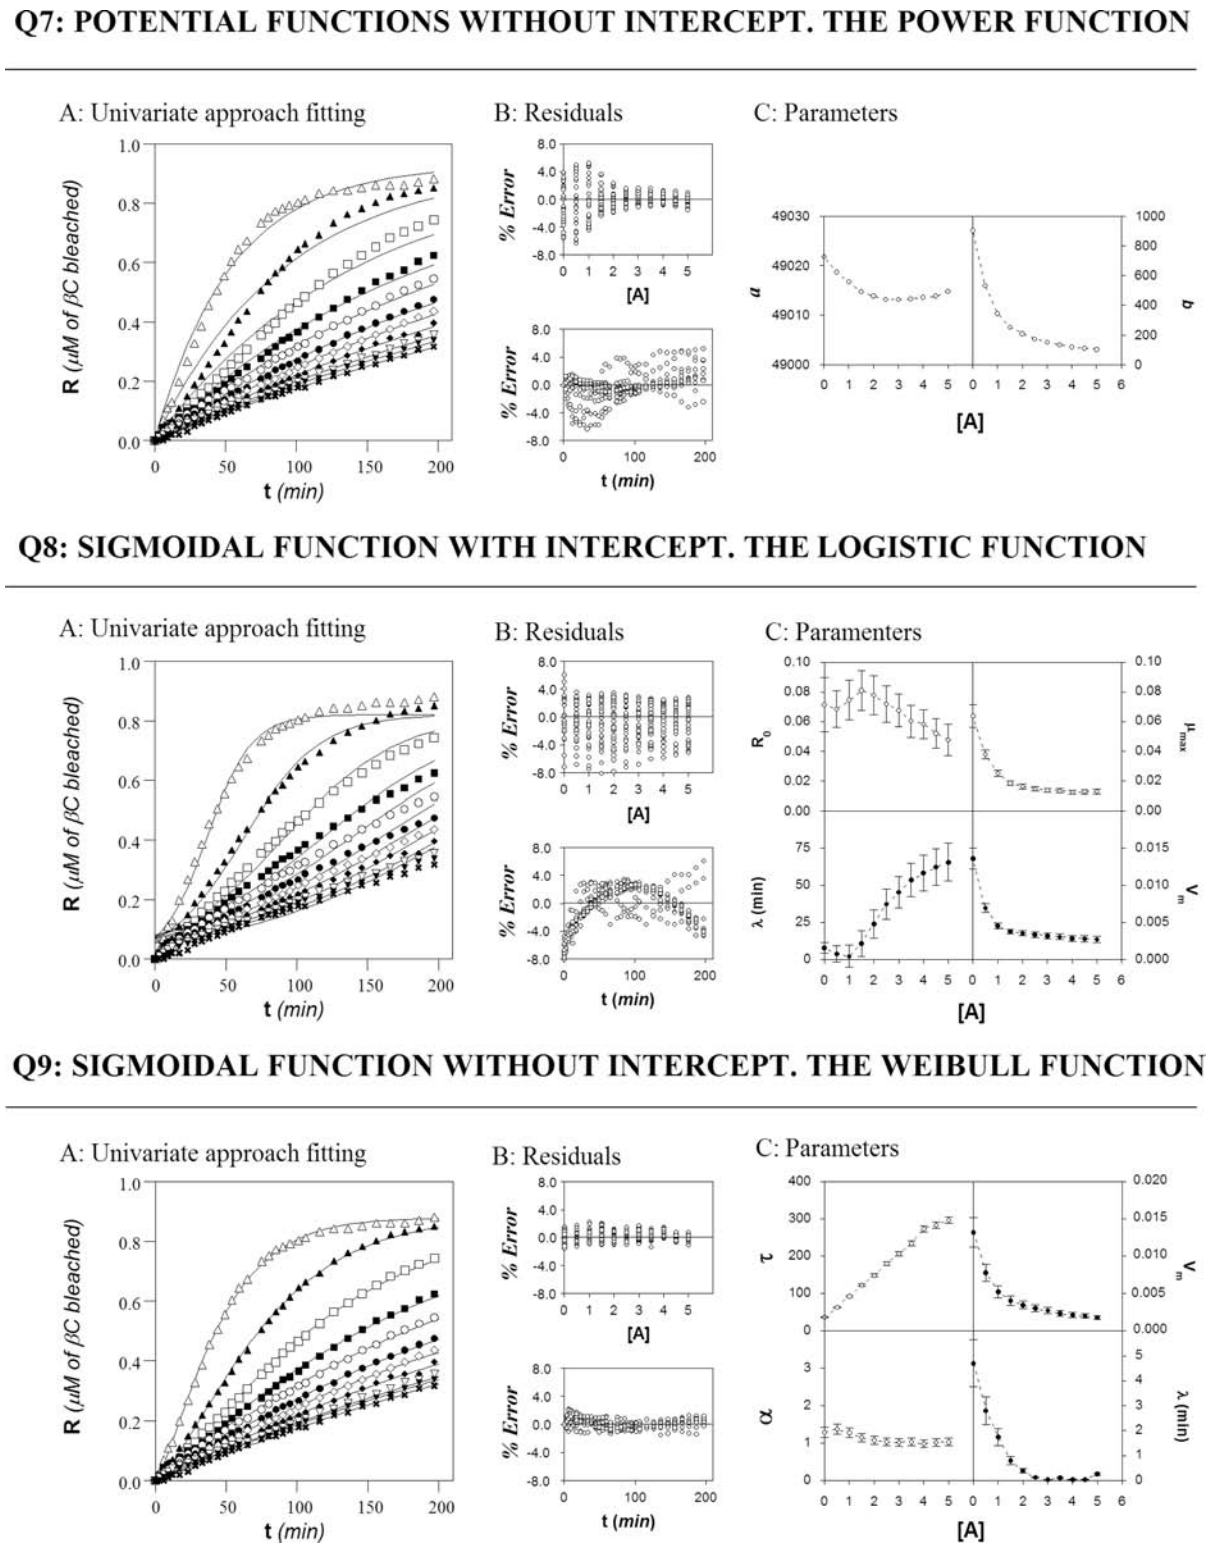

Figure 3. Kinetic description of βC bleaching, in the presence of the different concentrations of BHA in the range of 0.0−5.0 μM in intervals of 0.5 in the final solution with the available mathematical expressions as criteria *Q7*, *Q8*, and *Q9*. For each determination equation, three different subsections are graphically analyzed. (A) Univariate kinetic description of βC bleaching in the presence of the different concentrations of BHA in the range of 0.0−5.0 μM in intervals of 0.5 in the final solution (△, 0 μM; ▲, 0.5 μM; □, 1.0 μM; ■, 1.5 μM; ○, 2.0 μM; ●, 2.5 μM; ◇, 3.0 μM; ◆, 3.5 μM; ▽, 4.0 μM; ▼, 4.5 μM; and +, 5.0 μM). (B) Residual distribution of the fitting results for all of the doses assessed. (C) Main parameter pattern as a function of A doses.

On the other hand, to illustrate the dependency upon the type of dose−response profiles, we have computed the equivalent milligrams of BHA (Figure 2F) per *x* unit of concentration of each A (the corresponding *x* units of each A are clarified in the graph). It can be observed that those A that had similar kinetic IC_{50} profiles (M1, M2, M3, and M5 cases),

which only occurs after 75 min of the assay (probably when the protection of A has ended), showed "relative consistent" results. However, such an event seems to be more casual than a reliable measure. Any dose−response at a fixed point earlier than 75 min (dark area on plots D and F of Figure 2) resulted in serious inconsistencies.

When authors developed these evaluation criteria (*Q*1−*Q*5), in an effort to abbreviate the assay performance and obtain quick results, they related the rate of the process (decrease oxidizable substrate per unit time) of samples (in dose−response mode or not) and the dose−response of A as a reference. However, as nonlinear kinetic responses, this value varies with time; thus, the only useful rate value would be the maximum rate value, but the time at which the rate reaches its maximum cannot be established *a priori* and varies for each compound and concentration. In addition, the experimental effort necessary to calculate this value without much mistake allows, as we shall demonstrate, us to perform the analysis in more accurate and complete form than that derived from the non-kinetic approaches.

Kinetic Approaches with Formal Mathematical Expressions (*Q*7−*Q*9). Even if, in general, the criteria that applies mathematical expressions to analyze the kinetic part of the process produces much better results than those that abbreviate the response in a single-time value, there are specific problems with the type of expressions used. Next, we will discuss the problems and advantages of the mathematical expressions described in the references when applied to the oxidation process.

Univariate Approach. The detailed mechanistic description of lipid oxidation is complex and varies from one to another system, which has led to the search for empirical general models able to describe the most common profiles. As in many biological systems, such as microbiology, toxicology, pharmacology, immunology, population dynamics, etc., for wide diverse circumstances, it is usual to describe the effect of a response (independent variable) as a function of another variable (dependent) by a group of mathematical expressions (mechanistic or not) that translate the pattern of the response into parameters. Afterward, those parameters are used to deduce the meaning and/or quantify the effect of many possible dependent variables. Except for the particular case of responses linearly dependent, in almost all of the other cases, which are the most frequent cases in biology, nonlinear expressions must be used to properly describe the effects of variables.

The simple formal descriptions limiting the response in a two-dimensional (2D) framework, such as the power function alternative (*Q*7), are only acceptable in restricted situations. The power function (*Q*7) is a possible alternative[9] to adjust fractional-order kinetic profiles but fails in the description of first-order processes or sigmoid profiles. Figure 3 shows the fittings to the time−dose-dependent response of BHA, and it can be observed that the adjustments are reasonably acceptable. However, the parameters produced are not statistically significant (Table 2), even when the BHA is a particular case with profiles similar to those described for this type of function.

Other alternatives are those models that cover the maximum possible responses in a 2D frame and minimize the number of parameters, such as the sigmoid functions. In this regard, two mathematical expressions, the logistic (*Q*8) and Weibull (*Q*9) equations have been transferred from other fields to describe the oxidation action.[2,10] Both equations have been increasingly applied in different fields with diverse purposes (such as medicine, biology, pharmacology, microbiology, forestry, etc.) to describe the diversity profile from potential to sigmoid ones. They are appropriate for modeling processes, such as the lipid oxidation, to obtain key parameters to summarize the responses. In fact, both equations are able to describe the profile responses of the antioxidation kinetics of BHA accurately. However, as already underlined by other authors,[40] the equations with an intercept, such as the logistic, cause some problems, and in general, it is preferable to consider that the oxidative response is null at zero time. As seen in Figure 3 and Table 2, the results of the univariate fitting to the BHA case in the βC reaction are better performed by the criterion *Q*9 (Weibull equation) than by *Q*8. When the fitting is performed with a sigmoid function with an intercept, the residual distribution and the correlations between the observed and predicted data show higher deviations. The major issues arise when the criterion *Q*8 describes the initial states and the final part of the reaction. Such deviations disappear when the fitting is performed with approach *Q*9. In addition, criterion *Q*9 is an extremely versatile function (eq 10), whose shape is controlled by the parameter α: if $\alpha < 1$, it can describe the profiles generated by the model developed by Terpinc et al.;[9] if $\alpha = 1$, it describes a first-order kinetic; and if $\alpha > 1$, a large variety of sigmoid profiles are produced.

In general, the sigmoid function without an intercept (eq 10) is the best solution to fit individually the kinetic profiles corresponding to a series of increasing levels of an A agent. However, similar results are found, when instead of the Weibull equations, three other parameter sigmoid equations without interception are used, such as the Hill, Gompertz, or Richards−Chapman equations. Because the differences are narrow, we will use the Weibull equation as an example, but the results are easily extended to any other mentioned S-shaped curve without an intercept.

Unlike the *Q*1−*Q*6 alternatives, once a model is established, the variations of its parameter values, such as K, τ, and α, or others, such as ν_m and λ, can characterize the response and help to quantify the effect of the A agent. However, as stated by many authors before,[41,42] for living systems exposed to agents, any particular effect may be expected to be a function of both the dose in the external surroundings and the exposure time, in a bivariate form, as discussed in the following section.

Bivariate Approach. Simultaneous Analysis of Time and Dose To Evaluate the AC. Each component of a bivariate solution has a defined role in the evaluation of A. In general terms, the dose component would simply articulate the A availability, whereby the time component translates the affinity of A for the radicals generated. Adequate mathematical models are available for the analysis of such phenomena. Knowledge of the dose−time effect would be particularly important in the establishment of reference levels and to assess appropriately the effect of A. Additionally, optimal efficient data analysis should involve simultaneous description of all curves, rather than fitting each one individually because, if the necessary information to describe a parameter of the function is missing in one or various curves, this can be completed with the information from the other curves. Also, when the mathematical behaviors of the responses are unlocked, this information may provide the base for classification systems that could reveal A mechanistic patterns.

For the description of the time component of the function, we have discussed previously that the sigmoid equations (Weibull, Hill, Gompertz, or Richards−Chapman) are adequate

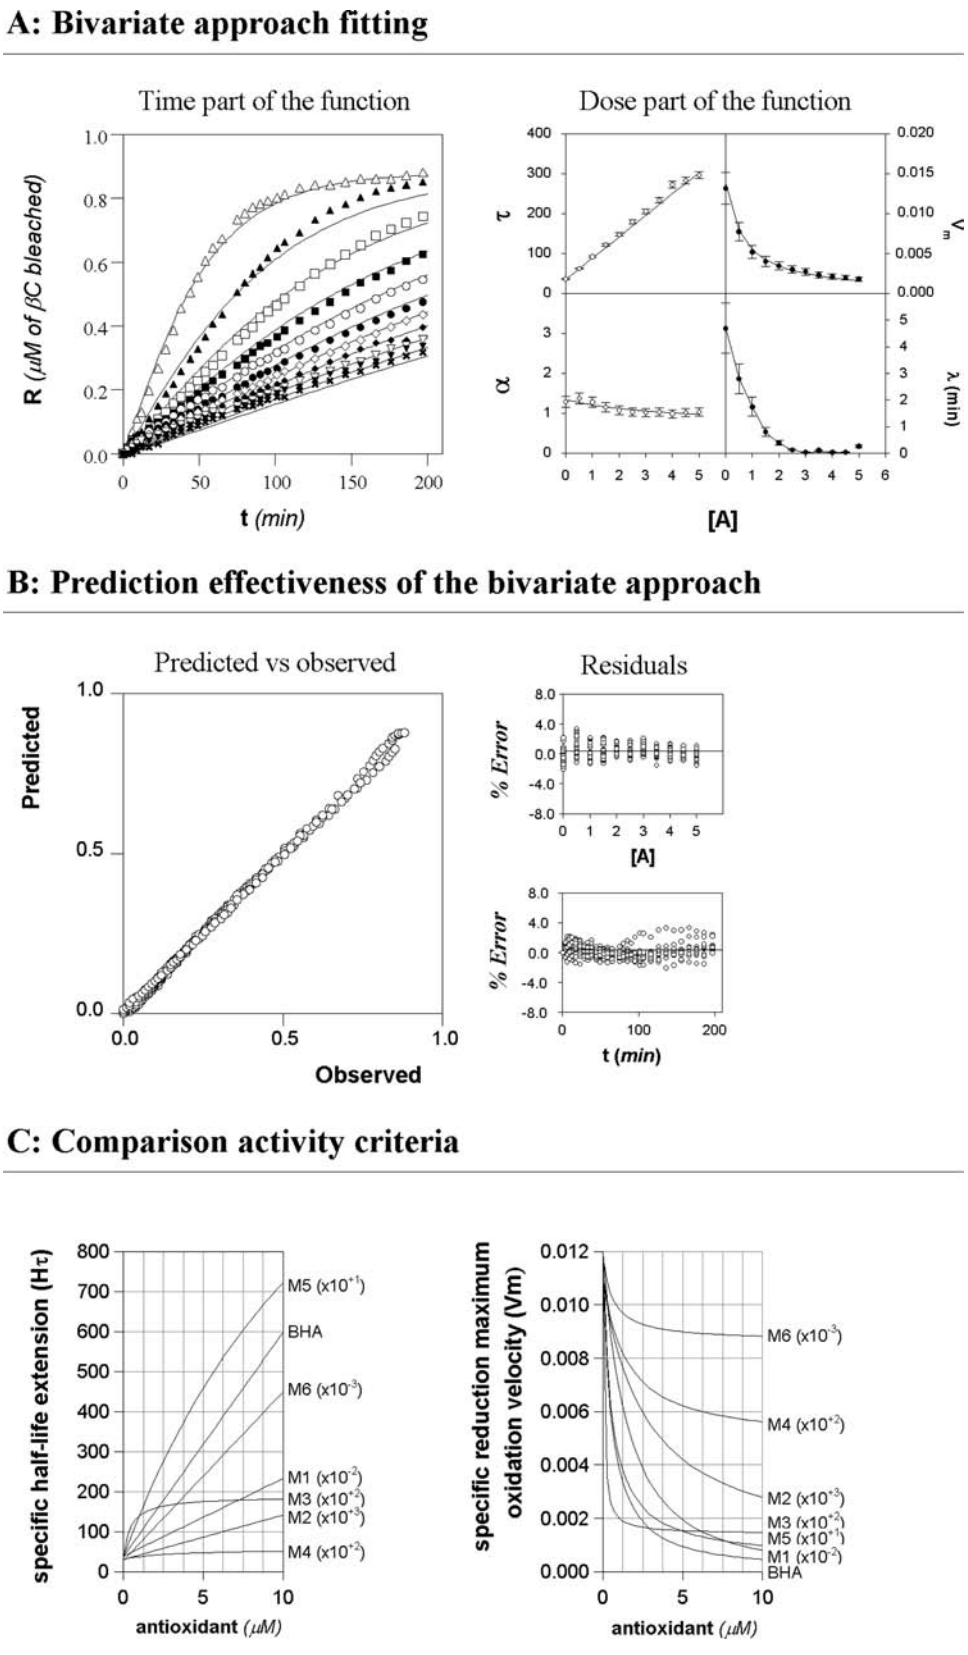

Figure 4. (A) Bivariate kinetic description of βC bleaching in the presence of the different concentrations of BHA in the range of 0.0−5.0 μM in intervals of 0.5 in the final solution. (B) Correlation between the predicted and observed data and residual distribution of the fitting results. (C) Specific behavior of the interesting parameters for all of the samples under study as a function of A doses.

approaches. For the description of the dose component of the function, those sigmoid equations could also be suitable. However, other authors[12,41,42] have made progress in the simultaneous analysis of dose−time response to evaluate the AC and found that the dose effect over any parameter (θ) of the function shows a saturable type effect.[43] Therefore, the

dx.doi.org/10.1021/jf5005995 | J. Agric. Food Chem. 2014, 62, 5472−5484

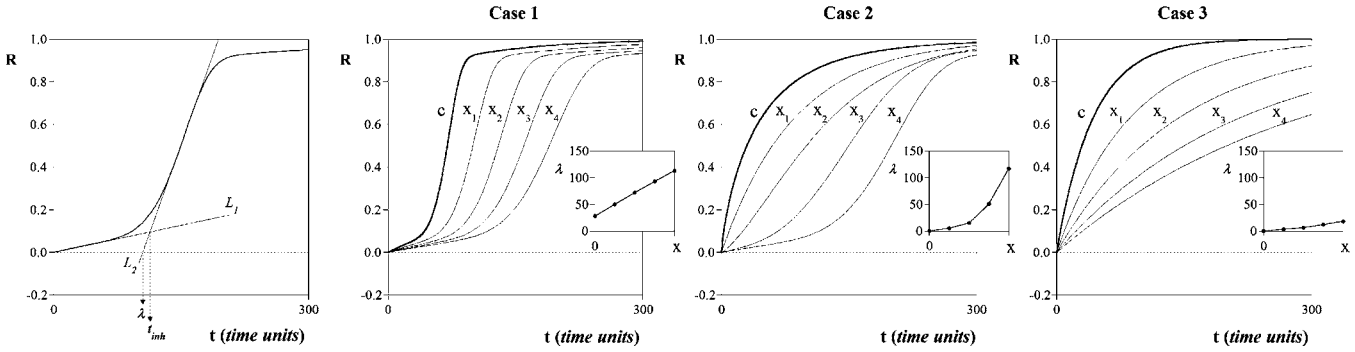

Figure 5. Illustration of the problems associated with the application of initial stage parameters, such as the lag phase (λ) or time of inhibition (t_{inh}).

equations that best fit these requirements are the following first-order, polynomial, or hyperbolic expressions:

$$\theta = \theta_0 H_\theta \begin{cases} H_\theta = 1 + m_\theta \exp(-n_\theta A) \\ H_\theta = 1 + m_\theta A + n_\theta A^2 \\ H_\theta = (1 + m_\theta A)/(1 + n_\theta A) \end{cases} \quad (12-14)$$

where θ represents the modified parameter (K, τ, or α), θ_0 is the parametric value when $A = 0$, and the pairs m_θ and n_θ are fitting coefficients. It should be noted that, in the absence of the effect, the first function requires $m_\theta = 0$ and $n_\theta \neq 0$, whereas the other two require $m_\theta = 0$ and $n_\theta = 0$. Moreover, in the third function, the condition $n_\theta A = -1$ produces a singularity; to avoid it, when A concentrations are coded in the interval $[0, 1]$, it is advisible to include the restriction $n_\theta > -0.999$ in the fitting algorithm. Thus, the model eq 10 turns into the following bivariate form:

$$R(t, A) = KH_K\left\{1 - \exp\left[-\ln 2\left(\frac{t}{\tau_0 H_\tau}\right)^{\alpha_0 H_\alpha}\right]\right\} \quad (15)$$

When any of the mentioned forms of H_θ (eqs 12−14) is inserted into eq 15, excellent simultaneous fittings were obtained in the case of BHA and all other sample cases (M1−M6), which confirms the specificity of the parametric variations found in the individual descriptions. However, when using eqs 12 and 13 to describe the dose effect, even if their parametric values are more informative, we have found, for some parameters, confident interval values with no statistically significant, which will lead to the rejection of the model, and therefore, it would be necessary to select a different approach. When solution eq 14 is used to insert the action of A in eq 15, the individual coefficients m_θ and n_θ lack proper meaning but jointly define a term as a function of the concentration of a given A. It allows for a useful way of quantification of the variations of the kinetic profiles, which characterize the different types of A, and provides even indications concerning modes of action. The advantage of eq 14 is that, if any of its parameters (m or n) is not statistically significant, by rejecting it, the analysis and fitting procedure could be continuous without altering the overall eq 15. Indeed, if $m = 0$ or $n = 0$, the equation would be a linear one (increasing or decreasing respectively), and if $m \neq n \neq 0$, the function would be a hyperbolic one. Figure 4A shows the results obtained with the hyperbolic function eq 14 in eq 15. Figure 4B shows the prediction effectiveness of the bivariate approach. These results were robust and consistent; the residuals were randomly distributed; and autocorrelations were not observed. The prediction was slightly worse than when the univariate approach with three parameter S-shaped equations with an intercept were used (Figure 3), but the joint solution provides a better understanding of the process. The parametric values of the bivariate analysis to the dose−time BHA data are presented in Table 2, showing low confidence intervals ($\alpha = 0.05$) and higher correlation coefficients.

Once the same expression is applied to samples (M1−M6), the profile defined by the specific action of the A, described by the parameters of eq 14, provides a meaningful way to compare their activities. As seen in Figure 4C, plotting the specific variations of the kinetic parameters as a function of A allows for the visualization of the agent-specific dynamics and their activities are compared straightforward.

Dose−Response of Single "Global Values" That Summarize the Kinetic Response (Q10 and Q11). *Lag Phase (λ) and Inhibition Time of Oxidation (t_{inh}).* The first part of Figure 5 shows an illustration of how narrow the meanings of λ and t_{inh} values are. They have analogue meanings, but as explained, the t_{inh} value must be understood as a solution when the common ways of describing λ have failed. Therefore, from now on, instead of discussing both values separately, we will only focus on λ.

In this sense, many authors emphasized the particular difficulties in estimating the lag-phase parameter.[44] Two reasons may explain those difficulties. The first problem has been studied in depth in other fields, notably in food microbiology, in which the estimations of λ has been found especially unreliable from different equations or graphical interpolations. Although different hypotheses provide similar estimates, the imprecision of the estimates is generally larger than the differences between the approaches used, which is highly dependent upon the quality of the data set. The second reason is related to the first reason and comes from the fact that the actual definition of parameter λ is purely geometric. To illustrate the problems, in the second part of Figure 5, we are presenting three different case scenarios (C1−C3) that can be found in the dose−time oxidation response of many methods. C1 shows dose−response curves with identical shape but with different starting points or lag phases. This particular case represents an ideal one, in which both values will be an excellent measure of the AC of compounds. However, C2 and C3 show other cases, in which such idyllic relations are not

dx.doi.org/10.1021/jf5005995 | J. Agric. Food Chem. 2014, 62, 5472−5484

fulfilled. C2 shows a case in which the shape of the curve varies with the concentration of A, which causes very short lag phases in the curves close to first-order profiles and more realistic values when the shape is more pronounced or sigmoid. C3 shows a dose−response case with static shape profiles as a function of A, which is very close to first-order ones. In this type of case, the resulting lag phases would always be low values. Overall, the three specific case responses have similar activity, but if we compare the resulting values found (graphically described in Figure 5), it becomes clear that those two global values λ and t_{inh} are very dependent upon the shape of the curve producing unreliable conclusions.

Area Units under the Curve (Q11). Once the area values are obtained (using for example approximation eq 11), there are many ways to transform these values into other useful ones. In the following, we will describe a simple process for the data under evaluation, which may possibly be valid for some type of A response. The area value response can be standardized in diverse types of formats. One that can be appropriate for our response is to rearrange them to the amount of molecules (micromolars) of βC protected ($\overline{P}$) during the time frame of the assay, in the presence of a dose−response of A, using the following relation:

$$\overline{P} = \frac{AU_C - AU_A}{t_T} \tag{16}$$

in which AU_C and AU_A are the area units corresponding to the kinetic profiles in the absence (C = control) and presence (A) of a concentration of A and t_T is the total time of the assay (minutes).

Typically, the dose−response of the value $\overline{P}$ is plotted against the concentration of A. On occasions, authors have shown a linear relation, but as discussed previously, such a behavior must only be true in a short range of concentrations or perhaps only for specific assays. For the case of BHA, the response found was nonlinear, suggesting that some radical-generating property of the system can be saturated.[43] This type of dose−response patterns can be adjusted to previous eqs 12−14 as the following asymptotic function:

$$\overline{P}(A) = P_m[1 - \exp(-rA)] \tag{17}$$

where A is the concentration of the A agent under study in micromolars, $\overline{P}(A)$ is the response behavior of the value $\overline{P}$ as a function of A, P_m is the asymptotic value of the parameter obtained (micromolars of the substrate protected), and r is the specific dose rate (per micromolars of A).

In addition, other interesting values can be computed, for example, by multiplying both parameters (P_m and r) estimated by eq 17 as follows:

$$F = P_m r \tag{18}$$

Therefore, the value F obtained corresponds to the average amount of molecules protected per unit of A (micromolars of the protected substrate per micromolars of A).

Figure 6A shows an illustration of how the relative values of area are obtained for one particular case of the dose−response of BHA. Figure 6B shows the dose−response curve profile fitted to eq 17 for the case of BHA. Figure 6C displays the F values that eq 18 produced for the BHA case and samples (M1−M6). Therefore, the AC of compounds could be summarized in one single value summarizing the dose−time response.

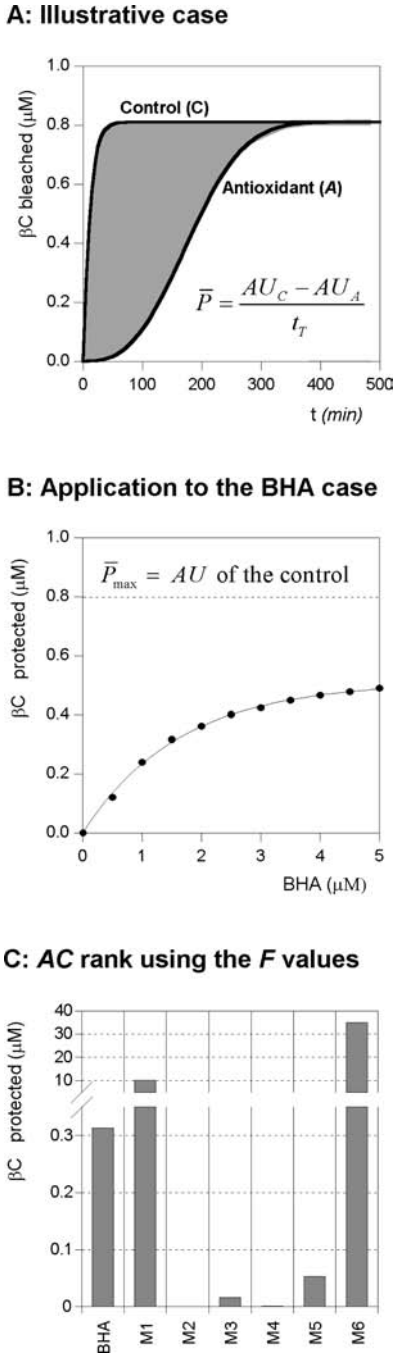

Figure 6. (A) Illustration of how the relative values of area are obtained for one particular case. (B) Dose−response curve profile fitted to eq 17 for the case of BHA. (C) AC rank obtained with the F values from eq 18 for the BHA case and the samples used (M1−M6).

The criterion Q11 represents a way of taking into account the kinetic profile but bypassing complex analytical expressions. The new microplate methods allow us to conduct large temporal data effortlessly with high accuracy. Its advantages are its simplicity[45] and synthetism. However, this second advantage is also its biggest drawback, because the lack of possible interrelations between their values and some possible mechanistic consequences that have a clear practical interest. However, in cases of complex responses, such as samples with more than one effector, either opposite effects (antioxidant versus pro-oxidant) or similar (antioxidant versus antioxidant),

dx.doi.org/10.1021/jf5005995 | J. Agric. Food Chem. 2014, 62, 5472−5484

the use of empirical models requires equations that integrate their interaction effects or, alternatively, their sum. In those types of complex matrices, the application of a globalizing parameter, such as the area under the curve, becomes very useful. It allows us to summarize the time part of the response in one global value and, therefore, to quantify the dose−time response with a simple equation. Thus, in our opinion, it is an useful, simple, and complete tool when complex responses need to be studied[35] and when the goal is to quantify.

DISCUSSION

The references are plentiful in experimental AC methods that are standardized in such a way that kinetic profiles are ignored, promoting the idea that rigorous protocols are needed to find the results in a proper format, normally as linear responses. The βC method presented here as a case study is just one example. In many other methods, as in the βC reaction to quantify the AC, authors have selected those conditions that hide the nonlinear character of the oxidation kinetics, selected commercial A that generates similar results to the linear specific response, and applied the traditional criteria to quantify the response (dose−response of one commercial A as a calibration curve to compute the equivalent AC of a sample, which is only tested at one single-time dose). In fact, when kinetic models are disregarded and measures are performed at a single-time dose, it is obvious that researchers tended to developed more complex protocols and impractical standardization. The results obtained when the activity is measured at one fixed time not only generates a serious reproducibility problem and prevents meaningful comparisons[4,5,26,27,34,46] but also makes it difficult to evaluate critical points that can be standardized.[3] Indeed, the reality is that the conclusions found may be limited and not reproduced anywhere else.

Antioxidants act by several mechanisms, e.g., by donating hydrogen to radicals, reducing power, free-radical-scavenging activity, metal-chelating ability, inhibition of βC bleaching, and quenching singlet oxygen. The method used to measure and calculate the AC has a major impact on the results because, in both *in vivo* and *in vitro*, the oxidation reactions are complex, in which the dominant mechanism depends upon many system conditions. Furthermore, we are using oxidizing substrates, initiators, and other components, and the activity is measured in different environments, such as bulk oils, emulsions, and multiphase, which may not represent the real systems. Avoiding the use of the kinetic part of the reaction to evaluate the capacity of antioxidants is incongruous. Today, the computer technology and development of microplate readers make it easier to obtain sufficient data in a time−dose format, and there are a diverse amount of tools that allows us to quantify properly the responses, such as criteria *Q*9 and *Q*11. Consequently, it does not seem reasonable to exclude these resources for routine assessments. In our opinion, any criterion avoiding kinetic focus is a misleading simplification. We are aware that criteria *Q*9 and *Q*11 are slightly elaborated than a single-time response, but it is also much less deceiving. It not only produces characterizing values of practical interest with high reproducibility but also enables the inclusion, if necessary, of environmental variables that modify the process as well as inference of mechanistic details that can be verified by other methods.

Perhaps using *Q*9 and *Q*11 as those solutions to describe the oxidation process, we are not helping to translate the results, because they may be related with the response itself, but at least we are able to (1) describe with precision the kinetics detected in many different reactions with antioxidants of very different nature, (2) obtain reproducible characterizing values of practical interest, (3) incorporate consistently, if necessary, environmental variables that modify the process, and (4) infer mechanistic details that can be verified by other methods.

The reduction to study the dose−response at one single time and expect to find linear forms (as described by the non-kinetic approaches) frequently leads to unreliable results and misinterpretations. The preference for apparently simple assays, routinely applied with minimal calculation requirements, is not very justifiable today, given the availability of computational applications and microplate readers, whose combination provides adequate tools to work with data sets that allow for accurate evaluations enabled by the nonlinear modeling. We believe that we have provided evidence that demonstrates the inadequate evaluation and quantification of the responses that focus on analyzing the results at a fixed time, avoiding the kinetic perspective. These results show the needs to apply a dose−time-dependent model to quantify the AC. Otherwise, the response will always be poorly described. We believe that those facts could be extended generally to almost all oxidative response methods.

Determination of Grayanotoxins in Honey by Liquid Chromatography Tandem Mass Spectrometry Using Dilute-and-Shoot Sample Preparation Approach

Muammer Kaplan,* Elmas O. Olgun, and Oznur Karaoglu

Food Institute, TUBITAK Marmara Research Centre, P.O. Box 21, 41470 Gebze, Kocaeli, Turkey

ABSTRACT: A simple and rugged method of analysis for grayanotoxins I and III in honey using liquid chromatography triple quadrupole mass spectrometry with electrospray ionization was developed. This paper describes the first LC−MS/MS method for the quantitation and confirmation of the grayanotoxins in honey using "dilute-and-shoot" sample preparation approach. Honey sample was diluted 10-fold in methanol−water (1:4 v/v) prior to analysis. Chromatographic separation was achieved on a reversed phase HPLC column using a water−methanol gradient with 0.1% acetic acid. The method was fully validated for quantitative purposes. Overall recoveries, selectivity, overall intraday and interday repeatability, decision limit, and detection capability of the analytes was determined. The matrix effects, ruggedness, and analyte stability in standards and samples were studied. Ten real honey samples were successfully analyzed using the developed method. All the samples were found to contain residues of GTXs ranging from 0.1 to 39 mg/kg.

KEYWORDS: *grayanotoxin, mad honey, LC−MS/MS, dilute-and-shoot*

INTRODUCTION

Grayanotoxins (GTXs) are a group of chemical compounds found naturally in plants from the Ericaceous family which includes Rhododendrons. There are over 60 grayanotoxin-related compounds.[1] From these, grayanotoxins I and III are reported to be the most toxic.[2] Grayanotoxins cause intoxication by increasing the membrane permeability to sodium ions.[3] Grayanotoxin-containing Rhodendron species are grown naturally in different countries including United States, Brazil Spain, Portugal, Turkey, Nepal, and Japan.[4]

Toxic Rhododendron species, *Rhododendron ponticum*, native to the Black Sea region of Turkey, is commonly used as folk medicine to treat various health problems including colds, edema, and pains.[5] Honey produced from pollen and nectar of these flowers is known as "mad honey". Mad honey is also used as folk medicine to treat gastritis, ulcers, hyperglycemia, hypertension, arthritis, sexual impotence, and performance enhancement.[3,6] It is largely produced in the Black Sea region and marketed as folk medicine. The consumption of "mad honey" causes intoxications in humans, and the severity of symptoms may vary from mild to life-threatening depending on the amount consumed.[3] Grayanotoxin poisoning remains to be one of the most frequently encountered food toxicant in Turkey.[7] Cases of GTX poisoning have also been reported from Austria, Korea, Nepal, and a few other countries.[8] Moreover, recently, concerns about poisoning by mad honey were raised by the German Federal Institute for Risk Assessment (BfR- Bundesinstitut für Risikobewertung), calling for more systematic control of honey from specific regions.[9] Because of GTXs' unseen dangerous potential for public health, there is a great need for the development of rapid and reliable methods of analysis enabling the detection of GTXs in honey.

In the scientific literature, there are only very few analytical methods published for grayanotoxin determination in honey samples. Thin-layer chromatography[10] and direct spectrometric methods[11] were used for the analysis of grayanotoxins in plant materials and honey. Grayanotoxins in honey was carried out by gas chromatography (GC) with stainless steel capillary columns following trimethylsilyl derivatization.[12] A two-dimensional TLC was used for the qualitative analysis of GTXs in plant materials, gastrointestinal contents, and feces at a concentration of 0.2 μg/g.[13] Quantitative determination of GTXs in biological samples was performed using a liquid chromatography combined with an ion trap tandem mass spectrometry.[14] In a recent study, liquid chromatography coupled to high-resolution mass spectrometry was used to analyze plant toxins including GTX III at 50 μg/kg detection level in honey.[15] To the best of our knowledge, there is only one method published in the literature using liquid chromatography tandem mass spectrometry (LC−MS/MS) for determination of GTXs in honey.[16] In this method, honey samples were mixed with methanol and loaded onto a C18 SPE cartridge for cleanup, and the filtrate was diluted with water and analyzed. However, the method is relatively expensive and time-consuming due to SPE sample preparation step. SPE cleanup step is also prone to errors in sample preparation. Therefore, there is a great need for low cost, simple, and high-throughput analytical procedures for prompt detection and quantitative analysis of toxic GTXs that may coexist in honey. Recently, LC−MS/MS has become the most popular analytical tool for accurate and reliable determination of different residues and contaminants because of high specificity, selectivity, and sensitivity.[17−19]

In this study, we present the first triple quadrupole LC−MS/MS method developed and optimized for simultaneous

determination of grayanotoxins (GTX I and GTX III) in honey samples. The proposed method is rapid and very sensitive, using a methanol−water extraction for sample preparation. The avoidance of a cleanup step together with the optimized chromatography simplified the sample pretreatment and reduced the laboratory costs and the overall analysis time compared to prior methodology. The developed method was fully validated for grayanotoxin analysis in honey, and it is used routinely in our laboratory.

MATERIALS AND METHODS

Reagents and Chemicals. Glacial acetic acid (AA) (Emprove, 100%) and methanol (MeOH) (Lichrosolve purity ≥99.9) were obtained from Merck (Darmstadt, Germany). Grayanotoxin I was purchased from AnalytiCon Discovery GmbH, Potsdam, Germany, and grayanotoxin III was provided from Sigma-Aldrich. Pure water was obtained using a Milli-Q Plus system (Millipore, Billerica, MA).

Standard Solutions. Individual grayanotoxin stock solutions (1000 mg/kg) were prepared in methanol. A mixed intermediate standard solution (10 mg/kg) was obtained by dilution of GTX I and GTX III stock solutions in methanol. Working standard mixed solutions (0.01, 0.1, 0.5, 1, and 2 mg/kg) were prepared by diluting intermediate solution in MeOH−water (1:4 v/v). Stock and intermediate standard solutions were kept in amber flasks at 4 °C. They were stable more than 2 months under these conditions. Working standard solutions were prepared fresh daily.

Sample Preparation. Honey samples, upon arrival at our laboratory, were homogenized with a wooden spoon and were kept at room temperature (+22 ± 4 °C) until analysis. An aliquot of approximately 0.25 g of honey sample was weighed into a 15 mL glass tube. Then 2.5 mL of MeOH−water (1:4 v/v) with 0.1% AA was added, and the sample was vortexed vigorously for 1 min. The extract was filtered through a 0.45 μm filter prior to LC−MS/MS analysis. Honey samples obtained from local market were analyzed, and the ones containing no detectable amount of grayanotoxins were used as control blanks. Real mad honey samples were randomly acquired in local honey producers in different provinces from the Black Sea Region in Turkey between July and September 2013. Of the samples, five were from Duzce, two from Sinop, one from Rize, and two from Tokat province. The honey samples (about 500 g) were stored in their original packaging at room temperature until analysis.

LC−MS/MS Analysis. The HPLC system used for chromatographic analyses consisted of a binary pump (Shimadzu UFLC LC-20AD model), Shimadzu automatic injector (Auto Sampler SIL-20A HT model), and a column oven (CTO-20AC). Analytical columns, Kinetex 100 mm × 2.1 mm, 2.6 μm (Phenomenex, Torrance, USA), and Waters X Terra C18 150 mm × 2.1 mm, 5 μm (Waters, Milford, MA) were used. Chromatographic separation of grayanotoxins was performed using a Waters X Terra C18 column. The method used a binary gradient with mobile phases consisted of water (A) and methanol (B) containing 0.1% acetic acid. Optimized separation of all analytes was obtained using a gradient program as follows: 10−80% solution B in10 min, kept at 80% solution B for 10 min. The column was then returned back to its initial gradient conditions. Finally, the system was equilibrated to initial mobile phase conditions of 10% B and 90% A for 10 min before the next injection. A 10 μL sample was injected into the column maintained at 40 °C. The flow rate was 0.3 mL/min. The mass spectrometer used was an API 4000 Q-TRAP (Applied Biosystems, Foster City, CA) operating in the triple quadrupole mode. The MS/MS parameters were as follows: curtain gas 20 mL/min, exit potential 10 V, and drying and nebulizing gases (GS1 and GS2) were set to 50 mL/min. The ion spray voltage and turbo spray temperature were set to 5500 V and 550 °C, respectively. The mass spectra were acquired using positive ion ESI mode. Three transitions were monitored for each analyte. The selected molecular ion and optimized collision voltages of product ions used for quantification and confirmation are summarized in Table 1. For data acquisition and processing, Analyst version 1.6 (Applied Biosystems) was used. Quantification was made by comparison with a five-point calibration (0.01, 0.1, 0.5, 1, and 2 mg/kg).

Table 1. Optimized MS/MS Conditions Used for the Determination of Grayanotoxins

analyte	precursor ion (m/z)	fragment ions (m/z)[a]	declustering potential (V)	collision energy (eV)
grayanotoxin I	435	Q: 375	111	29
		C: 357	111	35
		C: 91	111	109
grayanotoxin III	335	Q: 299	81	15
		C: 91	81	75
		C: 316	81	9

[a]Q, transition used for quantification; C, transition used for confirmation.

Validation Study. The EU Decision 2002/657/EC[20] criteria were used for the validation of the analytical method developed for determination of GTX I and GTX III in honey. The parameters studied during validation of the method were selectivity, sensitivity, linearity, accuracy, and precision (intraday and interday reproducibility). Identification of grayanotoxins was achieved using retention time data and relative ion intensities of each compound. The Decision 2002/657/EC requires at least four identification points (IPs) for unequivocal confirmation of an analyte. Thus, 5.5 IPs were earned for each grayanotoxin by monitoring one precursor ion and the three most abundant fragment ions.

The Decision Limits (CCα) and Detection Capability (CCβ). The decision limit and detection capability that are the new parameters introduced by Commission Decision 2002/657/EC aimed at replacing the LOD and LOQ. In Decision 2002/657/EC, the CCα is described as "the limit at and above which it can be concluded with an error probability of α that a sample is non-compliant". CCβ is defined as "the smallest content of the substance that may be detected, identified and/or quantified in a sample with an error probability of β".[20] Ten blank honey samples were analyzed for the calculation of CCα and CCβ values. The CCα was calculated as three times the signal-to-noise ratio determined at the elution time of the analyte. The results obtained from the analyses of ten honey blanks spiked at CCα concentration level were used for the calculation of CCβ. The value obtained for CCα was added up to a value of 1.64 and multiplied by the corresponding standard error.

Stability. The stability of the grayanotoxins in both standard solution and honey sample was assessed. Stability in solution was evaluated for individual intermediate solutions prepared in methanol at 10 mg/L concentration level. The solutions were stored at room temperature under daylight and at −20 °C and +4 °C in darkness. Evaluation study was performed by comparing the original stored solution with a working solution prepared fresh daily. The stability of the GTXs in honey matrix was performed using mad honey sample containing residues of GTX I (1.5 mg/kg) and GTX III (0.25 mg/kg).

Matrix Effect. Matrix effects were evaluated using standard solvent and matrix matched calibration curves. The calibration curves were established using peak areas of the SRM transitions chosen for quantification. The slopes of the curves obtained with sample matrix and pure solvent were compared for the assessment of matrix-induced effects.

Ruggedness. Ruggedness of the method was extensively investigated. As the dilute and shoot approach involved injection of diluted honey samples directly to the LC−MS/MS system, it is possible to face column problems, accuracy, and precision loss and reduction in detection sensitivity. Therefore, the method ruggedness was studied using calibration standards and real mad honey sample and honey blanks prepared with honey purchased from a local market. Moreover, we have investigated the likelihood of sample carryover from one sample to the other.

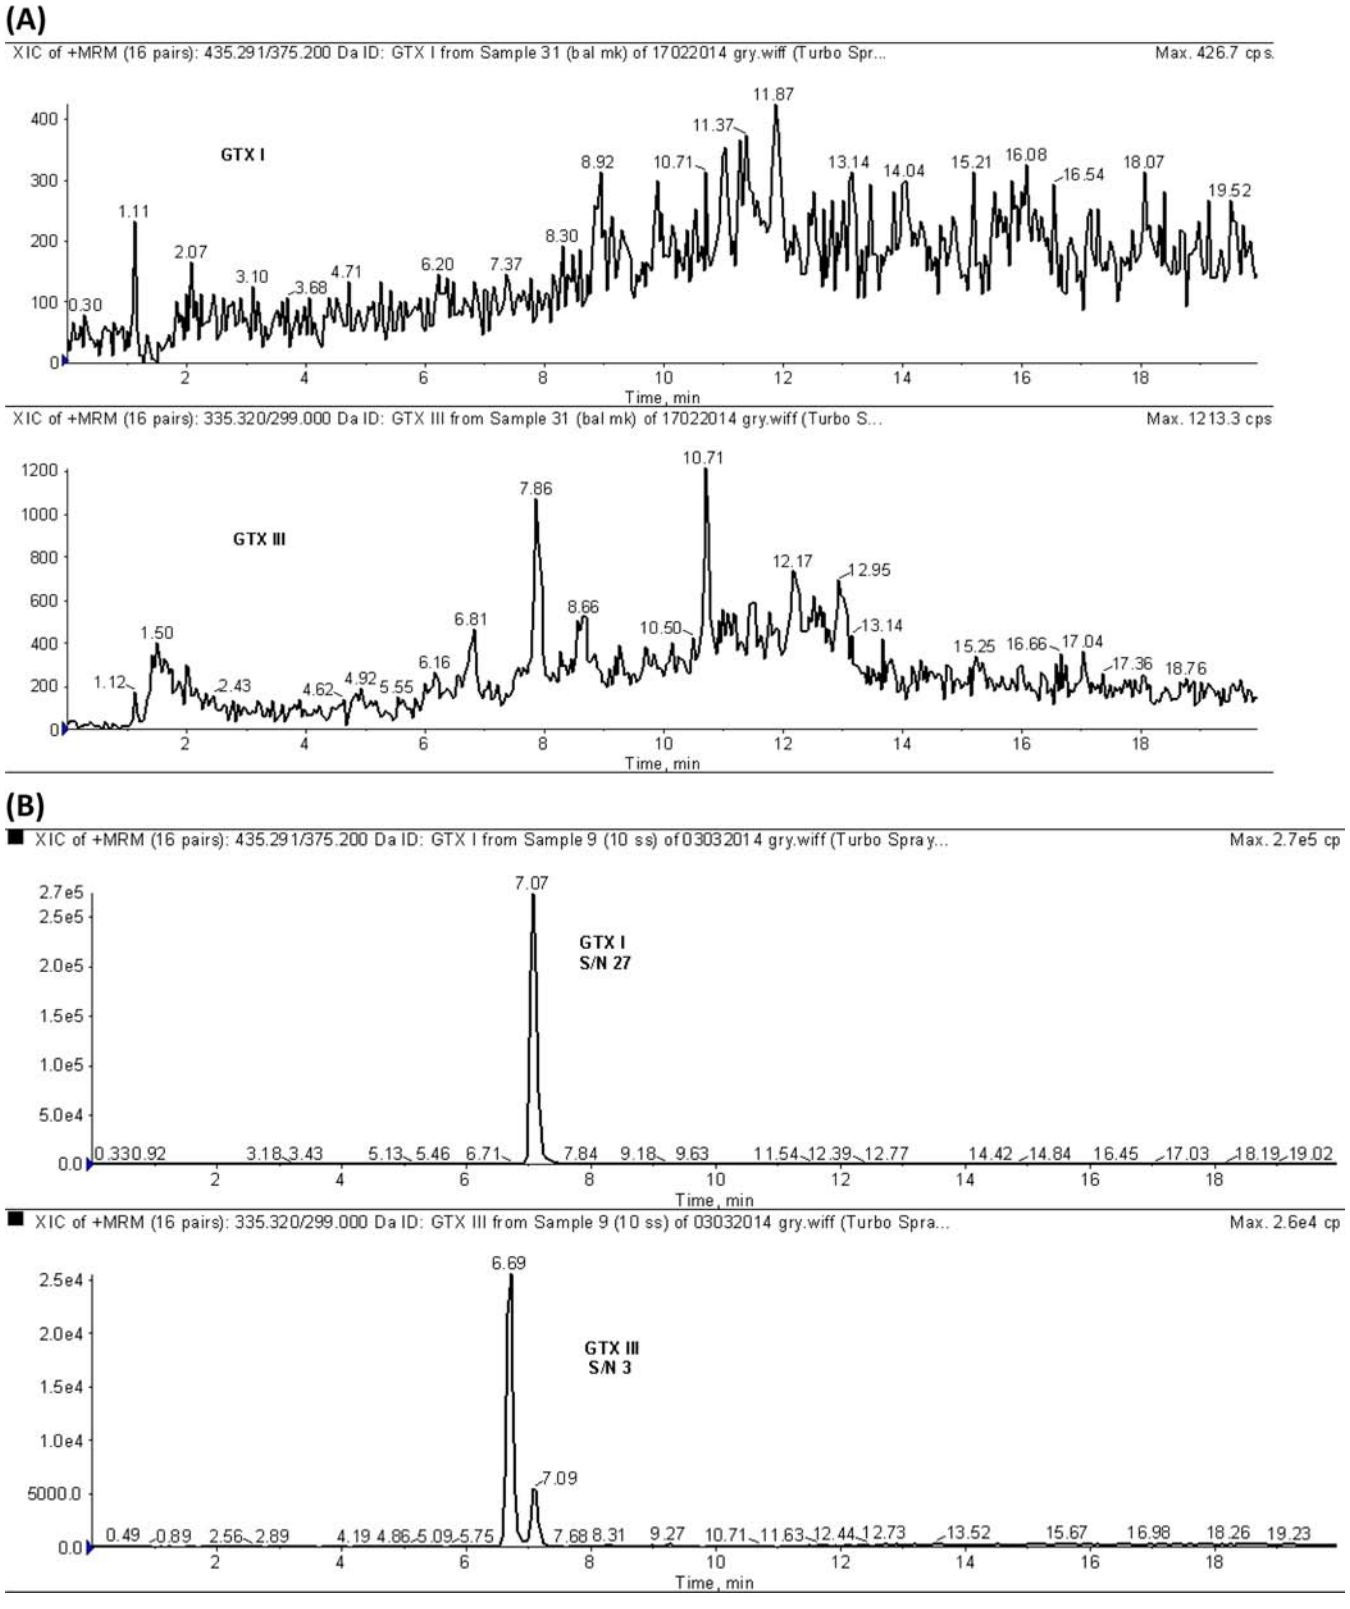

Figure 1. SRM chromatograms obtained from a honey blank (A) and honey spiked with 0.01 mg/kg of GTX I and GTX III (B) using dilute-and-shoot sample preparation.

RESULTS AND DISCUSSION

LC and MS Conditions. The initial stage of the method development was optimization of the mass spectrometer conditions for the detection of GTXs. MS/MS parameters were optimized by infusing GTX standard solutions individually. In the course of instrument tuning both positive (ESI+) and negative (ESI−) ionization modes were tested, and the mobile phase composition was compared. Satisfactory results were obtained only in the positive ionization mode. For each analyte, GTX I and GTX III, three most intensive transitions

dx.doi.org/10.1021/jf501560t | J. Agric. Food Chem. 2014, 62, 5485−5491

were chosen in this study. The most intensive fragment ion was selected for the quantitative determination and the remaining two ions were used for the confirmation of GTXs (Table 1).

Two LC columns with different particle sizes and lengths were assessed for the optimization of chromatographic separation and the signal intensity of grayanotoxins. Both Waters X Terra (150 mm × 2.1 mm, 5 μm) and Kinetex (100 mm × 2.1 mm, 2.6 μm) columns showed similar separation efficiency when MeOH−water solution containing 0.1% AA was used as the mobile phase. X Terra column produced slightly better peak intensities and therefore was chosen for the validation study. Under optimized gradient conditions good separation of GTXs in 7 min was achieved (Figure 1).

Development of Sample Pretreatment. Grayanotoxins are often extracted from the suspected products by classic extraction methods using methanol or dichloromethane.[13] These extraction solvents co-extract a range of other substances along with grayanotoxins. The ionization efficiency of the analytes is affected by the co-extracts especially when working with mass spectrometry in electrospray ionization mode. Therefore, to obtain a robust LC−MS/MS method, it is crucial to remove or minimize their presence. In this study, to overcome the matrix effects, the samples were prepared using dilute-and-shoot approach. For sample dilution, various solvents including water, MeOH, and MeOH−water solutions (1:2 and 1:4 v/v) were tested. The dilution solvents were acidified using acetic acid (0.1, 0.5 and 0.1%, v/v) in order to obtain the maximum signal response for the analytes of interest. Of these, MeOH−water solution (1:4 v/v) containing 0.1% AA gave the best results for both analytes and used for the dilution of honey samples. Furthermore, the efficacy of sample dilutions was examined. To maximize robustness of the procedure, the amount of honey injected per analysis was minimized. For this purpose, the signals obtained after sequential dilution of honey samples (1:4, 1:10, and 1:20) were compared with the signals obtained from the standard solutions prepared in pure solvent. Equally good peak responses were obtained for all dilutions, however, to reduce the instrument cleaning cycle and to meet the required method sensitivity, a 1:10 dilution with 10 μL injection volumes was selected and used for the method validation study. A typical SRM ion chromatogram obtained from a blank honey spiked with 0.01 mg/kg GTX I and GTX III is shown in Figure 1. The sample was prepared by diluting 0.25 g of honey in 2.5 mL of MeOH−water (1:4 v/v) with 0.1% AA. A 10 μL aliquot of this solution was injected.

Method Validation. *Selectivity.* The method selectivity was assessed by duplicate analysis of seven honey blanks from different floral sources (pine, chestnut, and flower honey). No peaks of interfering compounds were observed in the blank honey samples at the retention time of the target GTXs. Typical chromatograms obtained from the analysis of blank and spiked honey samples are given in Figure 1.

Linearity. Linearity was evaluated from the calibration curves by triplicate analyses of blank honey samples fortified with the analytes at five (0.01, 0.1, 0.5, 1, and 2 mg/kg) concentration levels. Linearity was expressed as the coefficient of linear correlation (r) and from the slope of the calibration curve. The correlation coefficients obtained over the concentration range studied was higher than 0.998 for both analytes, GTX I and GTX III.

Accuracy and Precision. The method accuracy and precision were assessed through recovery measurements analyzing honey blanks fortified at concentration levels of 0.01, 0.5, 1, and 2 mg/kg. The results obtained for the method accuracy and precision (Table 2) conform to the values given in Decision 2002/657/EC. Thus, the mean accuracy values obtained in the recovery tests were between 86 and 105%. The precision of the method was determined in two stages: intraday and interday repeatability. The repeatability of the results was expressed as RSDs calculated from six replicates analyzed using the same equipment with the same operator. The interday repeatability was expressed by the RSD of the results obtained from 18 measurements carried out on three different days, six analyses/day, using the same equipment by the same operator. The intraday and interday RSD values calculated for grayanotoxins analyzed using the developed method ranged between 3.7 and 8.3% and 7.2 and 15.9%, respectively (Table 2).

Table 2. Method Performance in Spiked Honey Samples at Concentration Levels Ranged between 0.01 and 2 mg/kg

analytes	spiked level (mg/kg)	average recovery (%) (n = 18)	intraday precision (RSD%, n = 6)	interday precision (RSD%, n = 18)
grayanotoxin I	0.01	86.0	8.3	13.8
	0.10	95.6	7.7	12.4
	0.50	98.0	5.9	12.1
	1.00	102.0	4.5	9.3
	2.00	105.0	3.9	7.2
grayanotoxin III	0.01	87.2	8.4	15.9
	0.10	98.0	7.0	14.7
	0.50	97.0	6.1	13.3
	1.00	103.7	5.8	10.1
	2.00	95.5	3.7	9.5

Decision Limits and Detection Capabilities. The decision limit (CCα) and detection capability (CCβ) values were calculated as 12 and 17 μg/kg for GTX I and 10 and 13 μg/kg for GTX III, respectively. Then, a preliminary experiment was conducted to check if all compounds were detected when spiked at their CCα level (Figure 1). As can be seen from Figure 1, very satisfactory S/N ratios were obtained for all analytes at CCα level.

Stability. The stability of GTX I and GTX III was assessed after storage in methanol solutions at room temperature under daylight and at −20 °C and +4 °C in darkness. Under these conditions, individual grayanotoxin solutions were stable following 8 weeks of storage. Real honey sample containing GTX I and GTX III at concentrations of 0.2 and 1.5 mg/kg, respectively, was stored at room temperature over 12 months period for stability study. GTXs were found to be very stable in honey matrix after 12 months of storage.

Matrix Effects. Evaluation of matrix effect is important during validation of analytical methods using the LC−MS/MS technique. Matrix interferences may affect the ionization efficiency of the analytes in ESI source. The degree of ion suppression or signal enhancement were evaluated using the calibration curves established with and without matrix. The slopes of these curves were used for the assessment of matrix-induced effects using the following formula: matrix effect (ME) = $1 - (a_{matrix}/a_{standard}) \times 100$, where a_{matrix} and $a_{standard}$ are the slopes for the calibration curves obtained in pure standard and matrix-matched honey, respectively. The matrix-matched curves were constructed using honey blanks (0.1 g/mL matrix

dx.doi.org/10.1021/jf501560t | J. Agric. Food Chem. 2014, 62, 5485−5491

equivalent) spiked with GTX I and GTX III (0.1, 0.5, 1, and 2 mg/kg) prepared in MeOH–water solution with 0.1% AA. Figure 2 shows the calibration curves for GTX I and GTXIII.

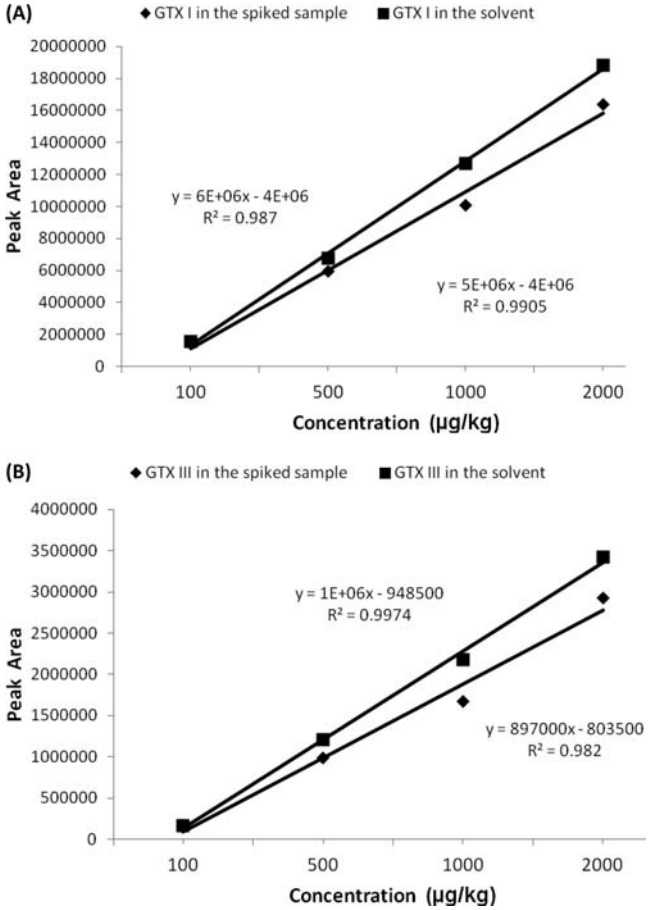

Figure 2. Calibration curves obtained for GTX I (A) and GTX III (B) prepared in pure solvent and fortified honey.

The upper curve represents the analyte signals in pure solvent, whereas the lower one shows the signals in a honey spiked with GTXs. The calibration curves prepared in the spiked samples have lower slope, indicating negligible ion suppression in GTX I (<16%) and GTX III (<11%). These results show that quantitation of GTXs in honey samples can effectively be performed with standard calibration, which is simpler and less time-consuming compared with matrix-matched calibration approach.

Ruggedness. The method ruggedness was demonstrated with sequential injections of 100 real honey sample containing GTX I (17 mg/kg) and GTX III (6 mg/kg) using the same analytical column. In the course of 100 injections, there was no significant increase in the column back pressure. Plots of GTX I and GTX III peak areas versus injection number are illustrated in Figure 3. The peak areas of the analytes stayed essentially constant over the entire run. Over 450 analyses were conducted with the same analytical column without any loss in chromatographic performance. The carryover from one sample to another was also tested by analyzing honey samples in the following order: a blank honey, a spiked honey (0.01 mg/kg), a honey blank, a spiked honey (1 mg/kg), and a honey blank. No peaks were observed in the nonspiked blanks, demonstrating

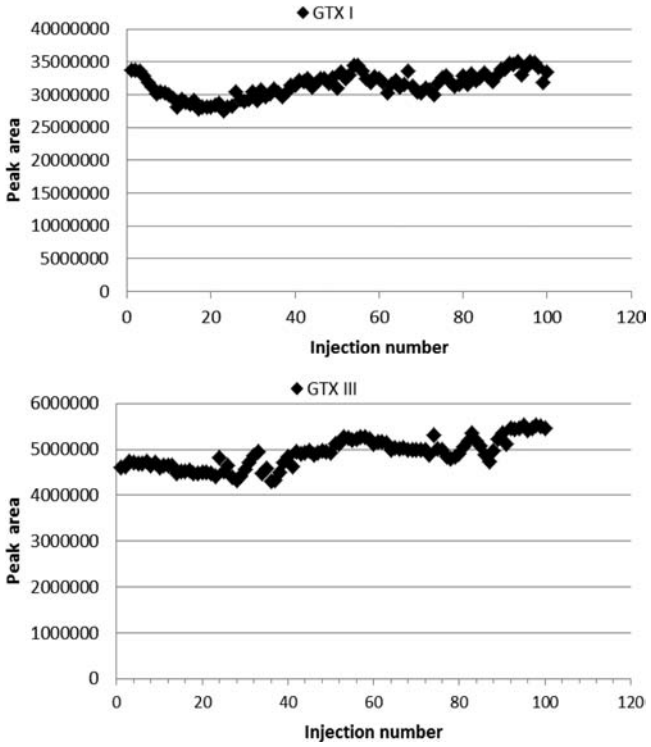

Figure 3. Plots of peak areas against injection number obtained from the sequential analysis of GTX I and GTX III in honey using dilute-and-shoot sample preparation methodology.

that there was no contamination or carryover from one sample to another.

Grayanotoxin Residues in Real Samples. The developed method was used for the analysis of 10 mad honey samples purchased from local honey producers in four different provinces of the Black Sea region. Table 3 shows the results

Table 3. Concentrations of GTX I and GTX III Detected in Honey Samples Collected from Different Provinces in the Black Sea Region, Turkey

sample	GTX I (mg/kg)	GTX III (mg/kg)
Duzce 1	18.4	7.4
Duzce 2	16.5	3.8
Duzce 3	20.2	3.3
Duzce 4	18.6	2.8
Duzce 5	17.1	6.3
Sinop 1	39.3	35.1
Sinop 2	1.5	0.3
Rize	ND[a]	0.1
Tokat 1	0.2	ND[a]
Tokat 2	1.8	0.4

obtained for all ten samples. As seen in the table, eight of the honey samples contained residues of GTX I between 1.5 and 39.3 mg/kg and GTX III between 0.3 and 35.1 mg/kg. In one of the remaining two samples only GTX I and in the other one only GTX III was detected at lower concentrations of 0.2 and 0.1 mg/kg, respectively. Some of the SRM chromatograms obtained from real honey samples are shown in Figure 4. Positive identification of grayanotoxins in honey were confirmed when all the criteria for identification including

dx.doi.org/10.1021/jf501560t | J. Agric. Food Chem. 2014, 62, 5485–5491

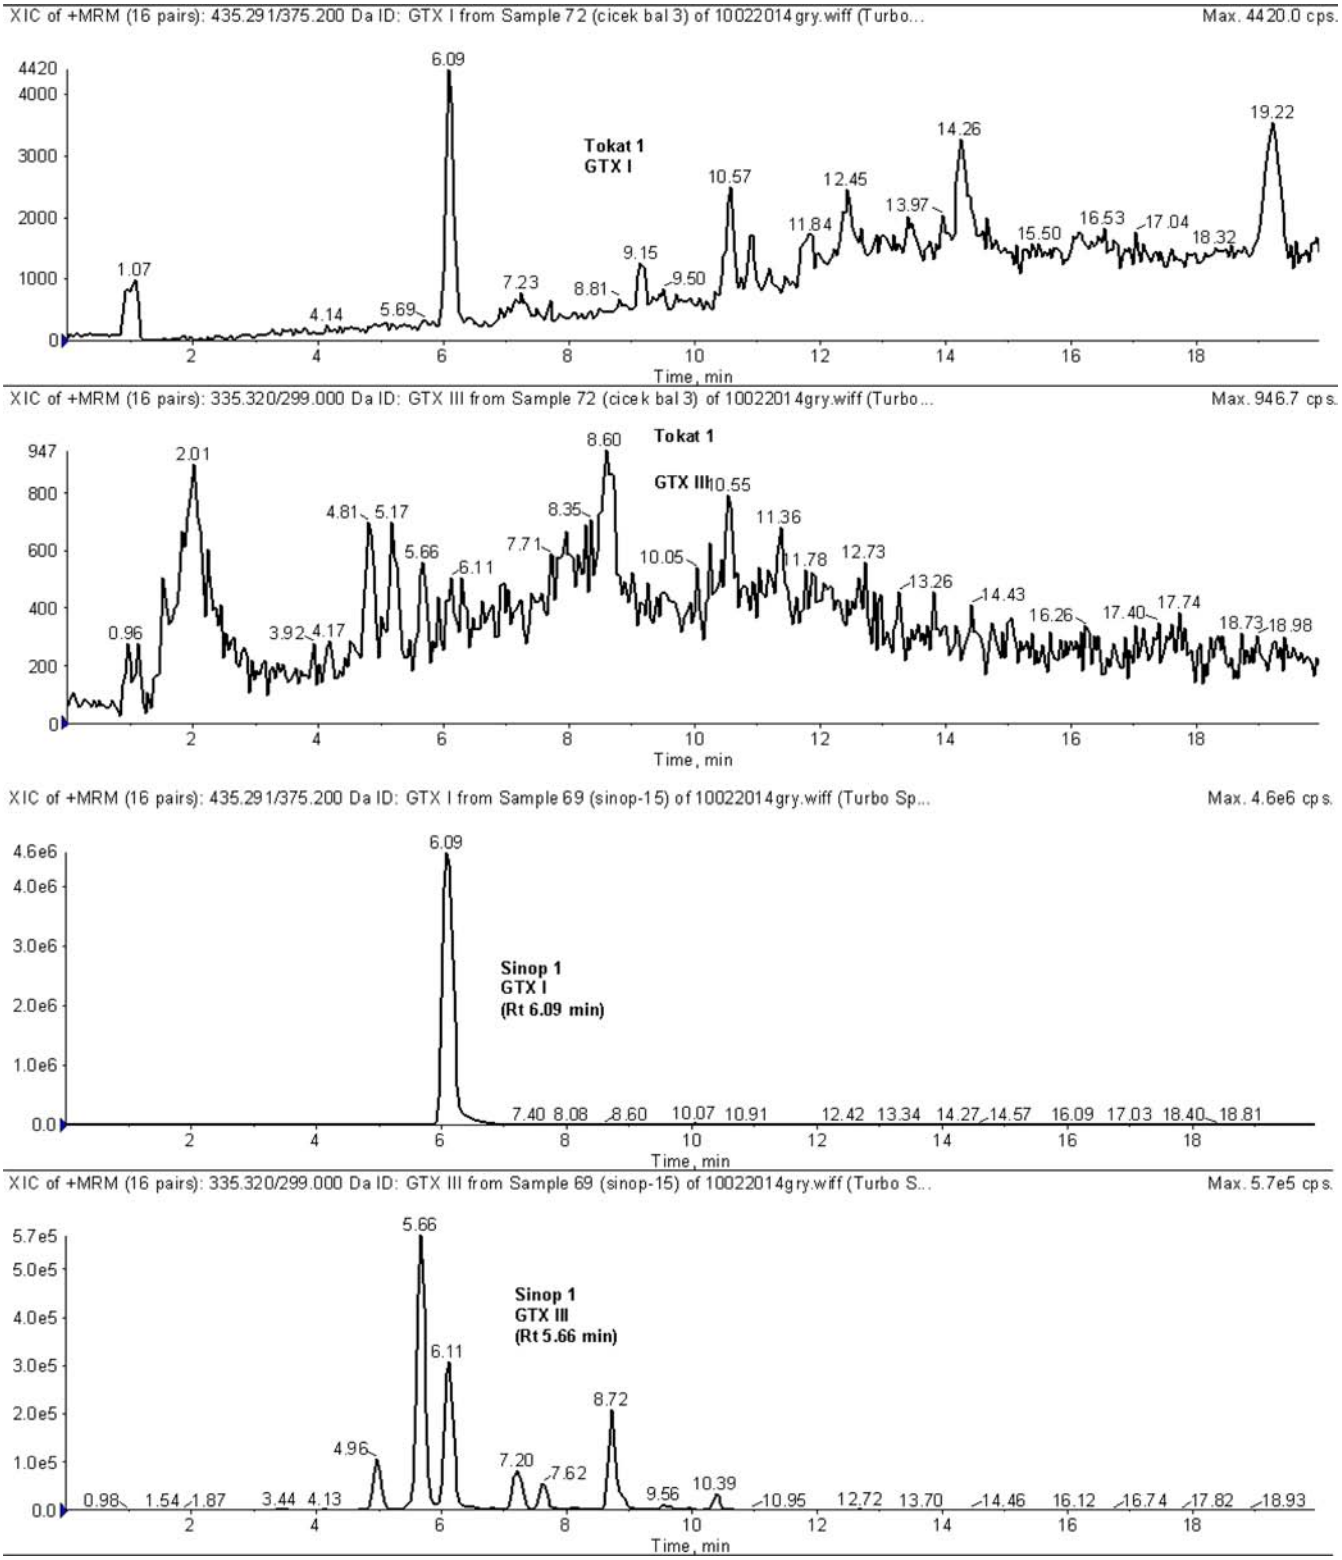

Figure 4. SRM chromatograms obtained for the selected samples of real honey. Amounts detected in each of the samples are given in Table 3

retention time data, molecular ion, fragment ions, and ion ratios (Table 4) were met. The utility of the proposed methodology is thus proved by real sample analyses.

In this study, it was shown that LC−MS/MS method using dilute-and-shoot sample preparation methodology enables a rapid and simple approach for quantitative determination of grayanotoxins in honey without compromising the method sensitivity. The developed method overcame a major disadvantage of current LC−MS/MS methods involving laborious extraction and SPE cleanup steps. It was demonstrated to be very selective and robust and enabling the determination of grayanotoxins after direct injection of diluted honey samples at very low concentrations. Consequently, the new method is a simple, sensitive, low-cost, and high-

ABSTRACT: Xenobiotics are usually detoxified by drug-metabolizing enzymes and excreted from the body. The expression of many of drug-metabolizing enzymes is regulated by the aryl hydrocarbon receptor (AHR). Some substances in vegetables have the potential to be AHR ligands. To search for vegetable components that exhibit AHR-mediated transcriptional activity, we assessed the activity of vegetable extracts and identified the active compounds using the previously established stable AHR-responsive HepG2 cell line. Among the hot water extracts of vegetables, the highest activity was found in ginger. The ethyl acetate fraction of the ginger hot water extract remarkably induced AHR-mediated transcriptional activity, and the major active compound was found to be 6-shogaol. Subsequently, the mRNA levels of AHR-targeting drug-metabolizing enzymes (CYP1A1, UGT1A1, and ABCG 2) and the protein level of CYP1A1 in HepG2 cells were shown to be increased by 6-shogaol. This is the first report that 6-shogaol can regulate the expression of detoxification enzymes by AHR activation.

KEYWORDS: *aryl hydrocarbon receptor (AHR), luciferase assay, ginger, 6-shogaol, 6-gingerol*

INTRODUCTION

The human body is exposed to a wide variety of xenobiotics in one's lifetime, from food components to environmental toxins to pharmaceuticals; it has developed complex enzymatic mechanisms to detoxify these substances. Lipophilic xenobiotics are usually metabolized into more hydrophilic forms by drug-metabolizing enzymes, mainly in the liver, and excreted from the body. The metabolism of xenobiotics is commonly broken down into three systems: phase I, II, and III systems.[1,2] The phase I system is an oxidative process and is mainly mediated by the cytochrome P450 (CYP) supergene family. As a consequence of this step in the detoxification, reactive molecules, which may be more toxic than the parent molecule, are produced. In the phase II system, activated hydrophobic xenobiotics are converted into hydrophilic forms via conjugation reactions with glucuronide, sulfate, or glutathione. The phase II system is composed of conjugation enzymes such as glutathione-S-transferases (GSTs), sulfotransferases (SULTs), and uridine diphosphate glucuronosyltransferases (UGTs). The phase III system is composed of more than 40 different human ATP-binding cassette (ABC) transporter families and is involved in the exclusion of xenobiotics and their metabolites.

It has been shown that the gene expression of many of these drug-metabolizing enzymes and transporters is regulated by the aryl hydrocarbon receptor (AHR), which is a ligand-dependent transcription factor present in most cell and tissue types in the body.[3] AHR translocates into the nucleus and heterodimerizes with a protein known as the aryl hydrocarbon nuclear translocator (ARNT).[4] This AHR/ARNT complex binds to specific enhancer sequences adjacent to target promoters termed the xenobiotic-responsive element (XRE), which enhances the transcription of target genes encoding phase I metabolic enzymes such as CYP1A1 and CYP1A2, phase II metabolic enzymes such as UGT1A1 and UGT1A6, and phase III metabolic enzymes such as the ABC transporter subfamily G, member 2 (ABCG 2).[2,5−9] Therefore, AHR is regarded as a key regulator of xenobiotic metabolism.

The regulation of AHR by dietary factors is of considerable importance and interest because AHR regulates drug-metabolizing enzymes as described above, and so it is likely that metabolism of xenobiotics could be modulated by dietary factors via AHR. In previous studies, some substances contained in vegetables, such as flavonoids,[10−12] indole compounds,[13,14] and curcumin,[15] were shown to act as natural AHR ligands. However, it is possible that vegetables contain other AHR-activating compounds because there are so many plant-derived compounds in vegetables.

The aim of this study was to search for vegetable components that exhibited AHR-mediated transcriptional activity and modulation of xenobiotic metabolism. Previously, we established the stable AHR-responsive HepG2 cell line by cotransfection of an AHR expression vector (pcDNA-hAHR) and an AHR-responsive vector (pGL3-XRE) containing a luciferase gene and three tandemly arranged XRE elements into the human hepatoma cell line, HepG2.[16] Using this cell line, we

assessed the AHR-mediated transcriptional activity of vegetable extracts and identified new active compounds in vegetables. We also examined the regulation of mRNA and protein expressions of AHR-target xenobiotic-metabolizing genes by these active compounds.

MATERIALS AND METHODS

Cell Culture. The stable AHR-responsive HepG2 cells and HepG2/mock cells (empty vectors were transfected) were grown and maintained at 37 °C in Dulbecco's modified Eagle's medium (DMEM) High Glucose with L-glutamine and phenol red (Wako Pure Chemical Industries 044-29765 Osaka, Japan), containing 10% fetal bovine serum (Asahi Technoglass, Chiba, Japan), 40 U/mL penicillin, 40 μg/mL streptomycin, and 500 μg/mL G418 (Nacalai Tesque, Kyoto, Japan) in a 100% humidified atmosphere containing 5% CO_2. For culturing of HepG2 cells, G418 was removed from the same medium as that used for culturing the stable AHR-responsive HepG2 cells.

Preparation of Vegetables Extracts. Fresh vegetables were purchased from local markets in Nasushiobara, Japan (Table 1).

Table 1. List of the 23 Vegetables Used in This Study

Vegetable	Family name	Scientific name	Production area in Japan
Ashitaba	Apiaceae	*Angelica keiskei*	Ibaragi
Asparagus	Liliaceae	*Asparagus officinalis* L.	Tochigi
Beetroot	Chenopodiacea	*Beta vulgaris* L. ssp. vulgaris var. vulgaris	Nagano
Broccoli	Cruciferae	*Brassica oleracea* var. italica L.	Nagano
Broccoli sprout	Cruciferae	*Brassica oleracea* var. italica L.	Shizuoka
Burdock	Asteraceae	*Arctium lappa* L.	Tochigi
Cabbage	Cruciferae	*Brassica oleracea* var. capitata L.	Gunma
Carrot	Apiaceae	*Daucus carota* L.	Chiba
Celery	Apiaceae	*Apium graveolens* L.	Nagano
Chinese cabbage	Cruciferae	*Brassica rapa* L. ssp. Pekinensis	Ibaragi
Eggplant	Solanaceae	*Solanum melongena* L.	Kochi
Ginger	Zingiberaceae	*Zingiber officinale*	Miyazaki
Komatsuna	Cruciferae	*Brassica rapa* var. perviridis	Tochigi
Lettuce	Asteraceae	*Lactuca sativa* L.	Nagano
Molokhia	Tiliaceae	*Corchorus olitorius* L.	Tochigi
Onion	Liliaceae	*Allium cepa* L.	Saga
Paprika	Solanaceae	*Capsicum annuum* cv.	Chiba
Parsley	Apiaceae	*Petroselium crispum* Nym.	Nagano
Pumpkin	Cucurbitaceae	*Cucurbita maxima* L.	Tochigi
Spinach	Chenopodiacea	*Spinacia oleracea* L.	Tochigi
Tomato	Solanaceae	*Solanum lycopersicum* L.	Tochigi
Watercress	Cruciferae	*Nasturtium officinale* R. Br.	Tochigi
White radish	Cruciferae	*Raphanus sativus* L.	Hokkaido

Preparation of vegetable extracts was conducted as described in Figure 1. Each vegetable was chopped and boiled in four-times its weight of hot water for 1 h. The extraction liquid was then recovered and centrifuged at 8000*g* for 10 min at room temperature. A portion of the obtained supernatant (40 mL) was lyophilized, and the resultant powder was used as the "hot water extract (HWE)" sample. A portion of the supernatant (100 mL) was adjusted to pH 3.0 by adding 2 M hydrochloric acid, followed by addition of 200 mL of ethyl acetate. The mixture was then vigorously shaken in a separating funnel to separate it into the ethyl acetate layer and aqueous layer. This extraction was repeated four times. All the ethyl acetate layers were collected, and the ethyl acetate was evaporated. The obtained residue

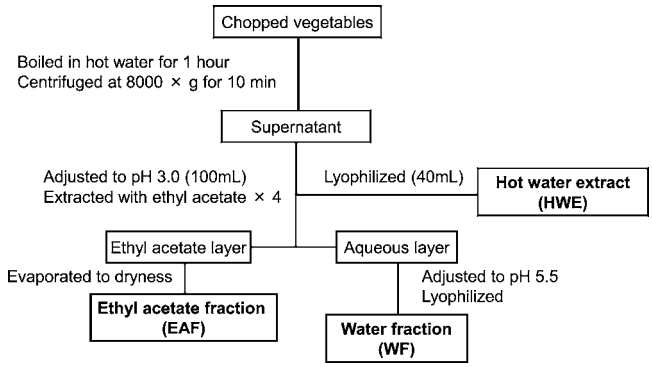

Figure 1. Preparation scheme of vegetable extracts.

was used as the "ethyl acetate fraction (EAF)" sample. The aqueous layer was adjusted to pH 5.5 by adding 2 M sodium hydroxide and lyophilized. The obtained lyophilized powder was used as the "water fraction (WF)" sample.

Chemicals. 3-Methylcholanthlene (3MC), 6-shogaol, 6-gingerol, 8-gingerol, and 10-gingerol were obtained from Wako Pure Chemical Industries. 8-Shogaol and 10-shogaol were obtained from ChromaDex (Irvine, CA, USA). Each phytochemical was dissolved in dimethyl sulfoxide (DMSO) at a concentration of 50 mM.

Luciferase Assay. The luciferase assay was carried out to assess AHR-mediated transcriptional activity as previously described.[17] The stable AHR-responsive HepG2 cells or HepG2/mock cells were seeded onto a 24-well plate (Corning-Coster Japan Product #3526, Tokyo, Japan) at a density of 1×10^5 cells/well. The 24-well plate was precoated with Type I-C collagen (Nitta Geratin, Osaka, Japan) for 30 min before the cells were seeded. After incubating overnight, the medium was replaced with a medium containing each test sample or 3MC (positive control). Each sample was diluted in the cell culture medium at the test concentration; the final concentration of DMSO was ≤0.1% (v/v) in the cell culture medium. After 24 h of culture, the cells were washed twice with 500 μL of PBS and then lysed with 100 μL of 1× passive lysis buffer (Promega). The lysate was centrifuged at 15000*g* for 5 min, and the supernatant was used for the luciferase assay. Luciferase activity was determined by a dual-luciferase reporter assay (Promega) with an LB9507 Lumet luminometer (Berthold Technologies, Bad Wildbad, Germany).

High-Performance Liquid Chromatography (HPLC) Analysis. The EAF from ginger and the standard phytochemicals were dissolved in methanol at concentrations of 10 mg/mL and 5 mM, respectively. HPLC analysis was performed using a photodiode array detector (L-2455, HITACH, Tokyo, Japan) and a PEGASIL-B ODS C18 column (250 mm × 4.6 mm, 4.6 μm; Senshu Scientific, Tokyo, Japan). The mobile phases were as follows: (a) acidified methanol (0.1% trifluoroacetic acid, TFA) and (b) acidified Milli-Q water (0.1% TFA). Pumps were programmed to perform the following gradient at a flow rate of 0.5 mL/min: from 20% solvent A to 80% solvent A over 50 min, to 100% solvent A at 55 min, and then to 0% solvent A at 60 min, with a column temperature of 35 °C. The separated compounds in the EAF were identified by comparison of the retention time and UV spectra to 6-shogaol or 6-gingerol standards.

Isolation of Total RNA and Real-Time PCR. The mRNA expression level of CYP1A1, UGT1A1, and ABCG 2, the target genes of AHR, was evaluated by real-time PCR. HepG2 cells were seeded onto a 24-well plate precoated with Type I-C collagen at a density of 1×10^5 cells/well. After overnight incubation, the medium was replaced with a medium containing 6-shogaol. After 24 h of culture, total RNA was extracted from the cells using Isogen. cDNA was prepared from 1 μg of the total RNA. Real-time PCR was performed with SYBR Premix Ex *Taq*II (TAKARA BIO INC., Otsu, Japan) and the 7900HT Fast Real-Time PCR System (Applied Biosystems, Tokyo, Japan). After denaturing at 95 °C for 30 s, PCR was performed for 40 cycles of denaturing at 95 °C for 5 s, annealing at 60 °C for 30 s, and dissociation at 95 °C for 15 s, followed by 60 °C for 60 s and 95 °C for

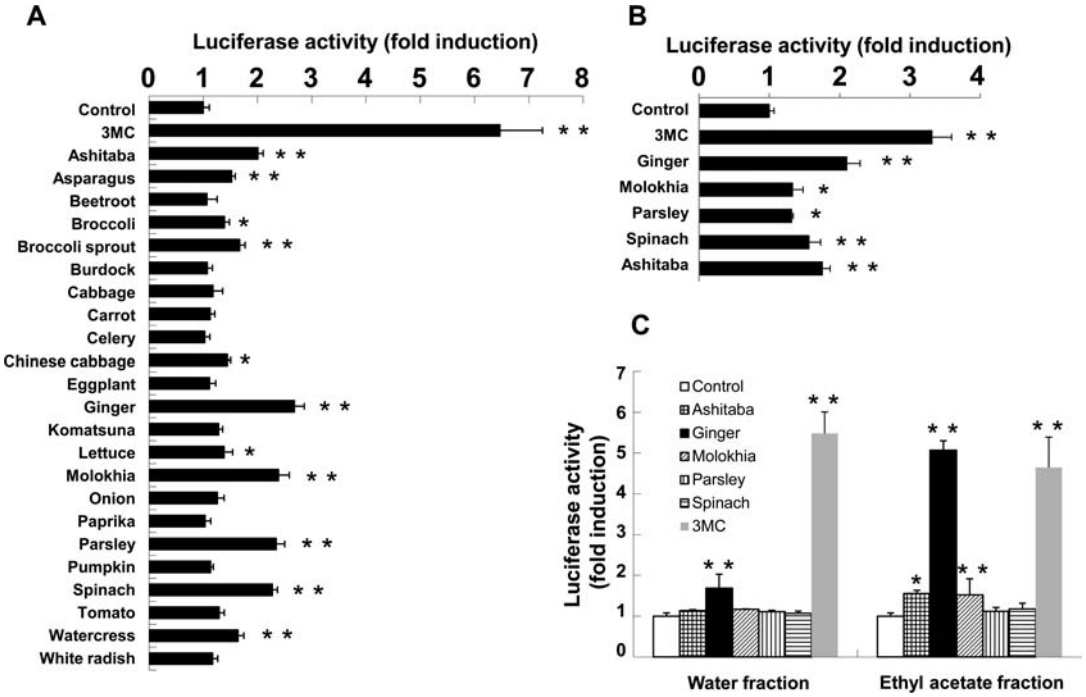

Figure 2. (A) Effects of the HWEs on AHR-mediated transcriptional activity. Stable AHR-responsive HepG2 cells were incubated with each HWE at 0.5 mg/mL for 24 h, and AHR-mediated transcriptional activity is shown as luciferase activity. Untreated cells were used as the control. (B) Effects of HWEs from ginger, molkhia, parsley, spinach, and ashitaba on AHR-mediated transcriptional activity corrected by AHR-nonspecific luciferase activity. Stable AHR-responsive HepG2 cells and HepG2/mock cells were incubated with each HWE at 0.25 mg/mL for 24 h, and AHR-mediated transcriptional activity is shown as luciferase activity. Luciferase activity in the stable AHR-responsive cells was divided by that in the HepG2/mock cells, and relative values were calculated. Untreated cells were used as the control. (C) Effects of EAFs and WFs from ginger, molkhia, parsley, spinach, and ashitaba on AHR-mediated transcriptional activity. Stable AHR-responsive HepG2 cells were incubated with each sample at 100 μg/mL for 24 h, and AHR-mediated transcriptional activity is shown as luciferase activity. The untreated and the 0.1% DMSO-treated cells were used as controls for WFs and EAFs, respectively. The relative luciferase activity measured for the control was taken as 1. 3MC was used as the positive control (5 μM). Each value is the mean ± SD (n = 3). Statistically significant differences from the value of the control were analyzed by the Dunnett's test; *p < 0.05; **p < 0.01.

15 s. The PCR primers used for CYP1A1 and UGT1A1 were synthesized at Invitrogen; the primers used for β-actin and ABCG 2 were synthesized at TAKARA BIO INC. The sequence of each primer is shown in Table 2.

Western Blot Analysis. HepG2 cells were seeded onto a 6-well plate precoated with Type I-C collagen at a density of 1×10^6 cells/well. After overnight incubation, the medium was replaced with a medium containing 6-shogaol. After 24 h of culture, cells were washed twice with PBS. Cells were scraped off and then suspended in 1 mL of PBS. The precipitate obtained by centrifugation at 1000g for 5 min at 4 °C was homogenized with 0.1 mL of RIPA lysis buffer (Santa Cruz Biotechnology, Santa Cruz, CA) with 0.1 mM phenylmethanesulfonyl fluoride, 0.1 mM sodium orthovanadate, and 0.1% protease inhibitor cocktail, and left on ice for 20 min. The homogenate was centrifuged at 18000g for 15 min at 4 °C. The resulting supernatant was dissolved in electrophoresis sample buffer (Santa Cruz Biotechnology) at 100 °C for 5 min.

Samples containing 30 μg of protein were loaded onto 12.5% polyacrylamide gel. Electrophoresis was conducted in an electrode buffer (25 mM Tris, 192 mM glycine, and 0.1% (w/v) SDS) with a fixed current (20 mA). An Immobilon polyvinylidene difloride (PVDF) membrane (Millipore, Bedford, MA) was treated with methanol and then blotting buffer (100 mM Tris, 192 mM glycine, and 20% methanol). The BioRad tank type of blotting apparatus was used for electrophoretic transfer of the gel to the PVDF membrane at 200 mM over 120 min.

After blotting, this PVDF membrane was blocked overnight at 4 °C by 0.1% Tween-20 and 5% skimmed milk dissolved in PBS. It was then incubated for 2 h with mouse monoclonal CYP1A1 antibody (1:100 dilution; sc-25304 Santa Cruz Biotechnology), or incubated for 1 h with mouse monoclonal β-Actin antibody (1:200 dilution; sc-47778 Santa Cruz Biotechnology) dissolved in a Can Get Signal immunoreaction enhancer solution (Toyobo, Japan). After the PVDF membrane had been washed three times with 0.1% Tween-20 dissolved in PBS for 5 min each, it was incubated for 1 h with

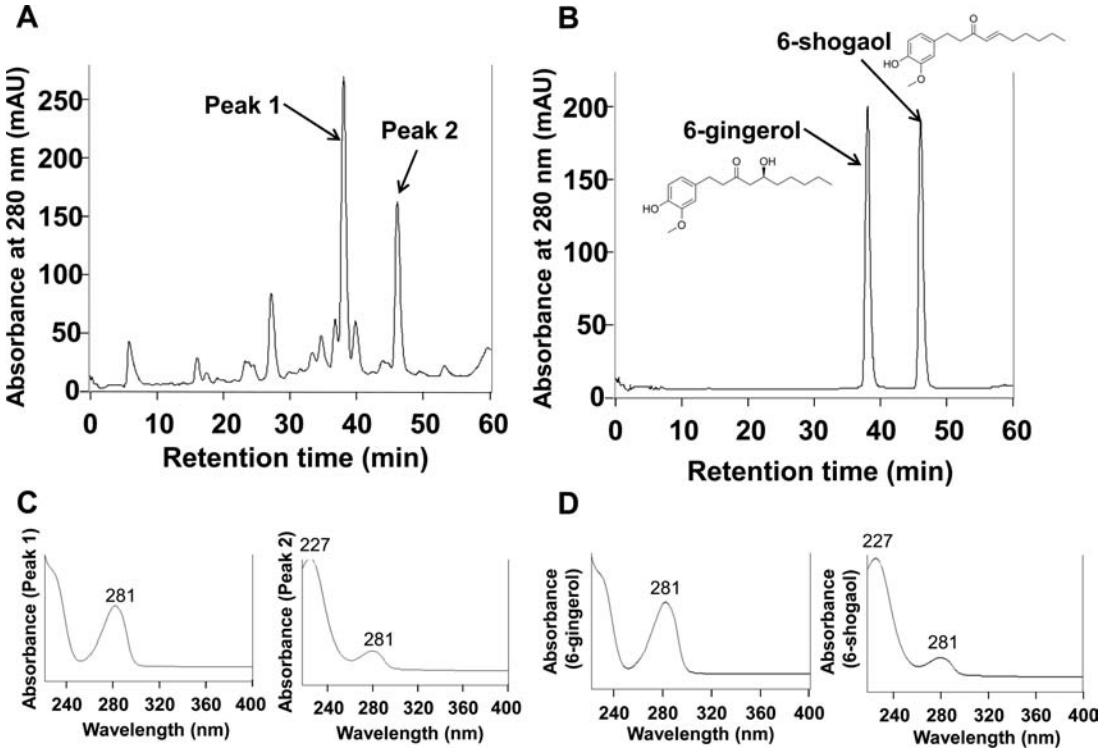

Figure 3. (A) HPLC profiles of the EAFs of ginger. (B) HPLC profiles and chemical structures of 6-gingerol and 6-shogaol. (C) UV spectra of peak 1 (left) and peak 2 (right). (D) UV spectra of 6-gingerol (left) and 6-shogaol (right).

antimouse immunoglobulin G-horseradish peroxidase (IgG-HRP; 1:2000 dilution; NA931, GE Healthcare, Buckinghamshire, U.K.) Proteins were detected by an ECL Prime Western Blotting Detection Reagent (GE Healthcare), followed by analysis with an LAS-1000 mini image analyzer and Multi Gauge Ver2.0 (Fuji Photo Film Co., Ltd., Tokyo, Japan).

Statistical Analysis. The data from the luciferase assay and real-time PCR were expressed as the mean ± SD. Statistical significance was analyzed using the Dunnett's test, and a p value of <0.05 was considered to indicate a statistically significant difference.

RESULTS

Effect of HWEs on AHR-Mediated Transcriptional Activity. HWEs from 11 vegetables significantly increased the relative luciferase activity as shown in Figure 2A. Among the 11 HWEs, five HWEs, namely ginger (2.68-fold induction), molokhia (2.3-fold induction), parsley (2.34-fold induction), spinach (2.27-fold induction), and ashitaba (2.01-fold induction), substantially increased the relative luciferase activity, showing more than a 2-fold induction compared with control. To confirm the results shown in Figure 2A, we further evaluated nonspecific induction of luciferase activity by the five HWEs using HepG2/mock cells. The stable AHR-responsive cells and HepG2/mock cells were treated with each HWE, and luciferase activity in the stable AHR-responsive cells was divided by that in the HepG2/mock cells. These data indicated that all five HWEs significantly induced luciferase activity (Figure 2B).

Effect of the EAFs and WFs from Ginger, Molokhia, Parsley, Spinach, and Ashitaba on AHR-Mediated Transcriptional Activity. As shown in Figure 2C, the EAF from ginger remarkably increased AHR-mediated transcriptional activity (5.07-fold induction). The EAFs from ashitaba and molokhia also significantly increased AHR-mediated transcriptional activity (1.56- and 1.52-fold induction, respectively). Only the WF from ginger significantly increased AHR-mediated transcriptional activity (1.69-fold induction).

HPLC Analysis of the EAF from Ginger. Since the EAF from ginger showed the highest AHR-mediated transcriptional activity (Figure 2C), it was further analyzed by HPLC. Two peaks (peak 1 and peak 2) appeared at retention times of 38 and 46 min (Figure 3A), which are the same retention times as those of 6-gingerol and 6-shogaol, respectively (Figure 3B). Figure 3C shows that the UV spectra of peaks 1 and 2 correspond to those of 6-gingerol and 6-shogaol (Figure 3D), respectively.

Effects of 6-Shogaol and 6-Gingerol on the Induction of AHR-Mediated Transcriptional Activity. Treatment of the stable AHR-responsive HepG2 cells with 6-shogaol for 24 h resulted in a significant increase in luciferase activity in a dose-dependent manner up to 50 μM (Figure 4A). On the other hand, treatment of the stable AHR-responsive HepG2 cells with 6-gingerol for 24 h had no effect on luciferase activity up to 50 μM (Figure 4B).

Effects of Gingerol and Shogaols on the Induction of AHR-Mediated Transcriptional Activity. Treatments of the stable AHR-responsive HepG2 cells with 6-, 8-, and 10-shogaol for 24 h resulted in significant increases of luciferase activity, and especially, 6- and 8-shogaol strongly increased luciferase activity (Figure 4C). On the other hand, treatments of the stable AHR-responsive HepG2 cells with 6-, 8-, and 10-gengerol for 24 h had no effects on luciferase activity.

mRNA Levels of AHR-Target Genes in HepG2 Cells after Treatment with Various Concentrations of 6-Shogaol. The expression levels of the AHR-target genes CYP1A1, UGT1A1, and ABCG 2 in HepG2 cells were measured by real-time PCR. Exposure of HepG2 cells to 6-shogaol significantly increased the expression level of CYP1A1 mRNA in a concentration-dependent manner up to 50 μM

dx.doi.org/10.1021/jf405146j | J. Agric. Food Chem. 2014, 62, 5492−5499

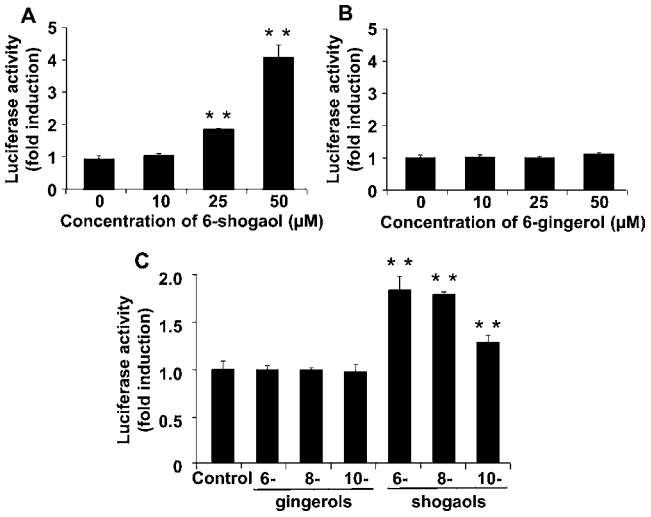

Figure 4. AHR-mediated transcriptional activity after treatment with various concentrations of 6-shogaol (A) and 6-gingerol (B). Stable AHR-responsive HepG2 cells were treated with 6-shogaol and 6-gingerol at the indicated concentrations for 24 h, and AHR-mediated transcriptional activity is shown as luciferase activity. The 0.1% DMSO-treated cells were used as the control. (C) Effects of gingerols and shogaols on the induction of AHR-mediated transcriptional activity in the stable AHR-responsive HepG2 cells. The stable AHR-responsive HepG2 cells were treated with each sample at 25 μM for 24 h, and AHR-mediated transcriptional activity is shown as luciferase activity. The 0.05% DMSO-treated cells were used as the control. The relative luciferase activity measured for the control was taken as 1. Each value is the mean ± SD (n = 3). Statistically significant differences from the value of the control were analyzed by the Dunnett's test; *p < 0.05; ** p < 0.01.

(Figure 5A). The expression levels of UGT1A1 and ABCG 2 indicated a significant increase after treatment of 6-shogaol only at 50 μM (Figure 5B, C).

Protein Level of CYP1A1 in HepG2 Cells after Treatment with Various Concentrations of 6-Shogaol. The protein expression levels of CYP1A1 in HepG2 cells were measured by Western blotting. Exposure of HepG2 cells to 6-shogaol increased the protein expression level of CYP1A1 to more than 2-fold of control by treatment with 25 and 50 μM 6-shogaol (Figure 5D).

DISCUSSION

Previous studies have reported that crude extracts of green tea, black tea, and propolis functioned as natural antagonists toward AHR.[18−20] Moreover, it was reported that extracts of vegetables, such as molokhia, suppressed AHR transformation in cell-free systems.[21] However, these reports focused on the suppressive effect of food extracts on AHR activation. De Waard et al. suggested that extracts of citrus pulp and grapefruit juice contained natural AHR agonists,[22] but detailed studies on AHR activation by vegetable extracts have not yet been reported. We examined the effect of HWEs from various vegetables on AHR-mediated transcriptional activity by the luciferase assay using the stable AHR-responsive HepG2 and HepG2/mock cell lines. The results showed that the HWEs from ginger, molokhia, parsley, spinach, and ashitaba increased AHR-mediated transcriptional activity (Figure 2A, B). These five HWEs increased the luciferase activity in a dose-dependent manner at concentrations of 0.5, 1.0, and 2.0 mg/mL (data not shown). In this study, the HWE from molokhia induced AHR-mediated transcriptional activity, even though the molokhia extract has previously been suggested to be an AHR

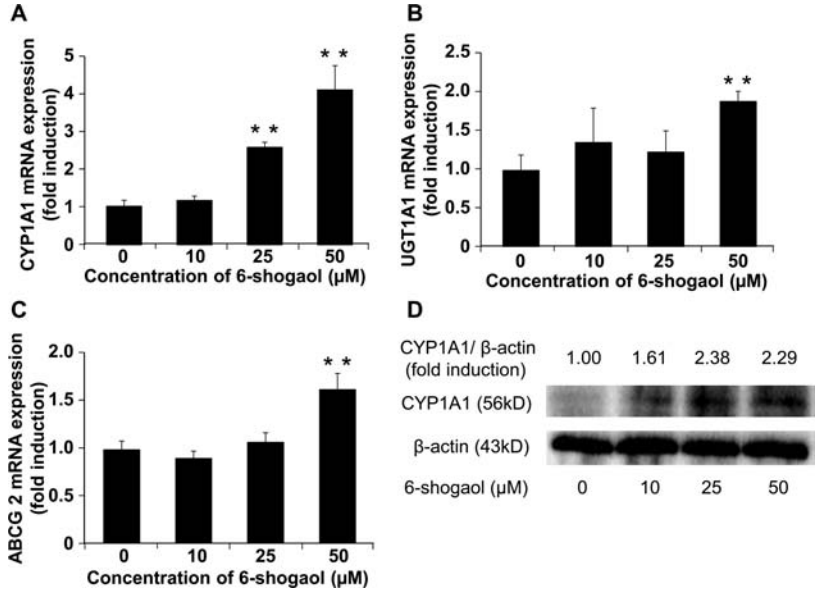

Figure 5. mRNA and protein expression levels of AHR-target genes in HepG2 cells after treatment with various concentrations of 6-shogaol. HepG2 cells were treated with 6-shogaol at the indicated concentrations for 24 h. Total RNA from the cells were extracted, and mRNA expression levels of CYP1A1 (A), UGT1A1 (B), and ABCG 2 (C) were evaluated by real-time PCR. The 0.1% DMSO-treated cells were used as the control. The mRNA levels of AHR-target genes were normalized to those of β-actin mRNA, and the relative mRNA expression measured for the control was taken as 1. Each value is the mean ± SD (n = 6). Statistically significant differences from the value of the control were analyzed by the Dunnett's test; **p < 0.01. (D) Protein level of CYP1A1 in HepG2 cells after treatment with various concentrations of 6-shogaol. HepG2 cells were treated with 6-shogaol at the indicated concentrations for 24 h, and the protein expression level of CYP1A1 was evaluated byWestern blotting. The 0.1% DMSO-treated cells were used as the control. The protein expression level of CYP1A1 was normalized to those of β-actin, and the relative protein expression measured for the control was taken as 1.

antagonist.[21] Molokhia contains quercetin in abundance,[23] which could function as an AHR antagonist[11] or an AHR agonist.[12,24] Therefore, compounds in molokhia such as quercetin could cause contradictory results. The results presented in this study are the first to indicate that some vegetable extracts can increase AHR-mediated transcriptional activity.

Our data indicated that the HWEs from five vegetables contained compounds that may activate AHR. We evaluated the AHR-mediated transcriptional activity of the WFs and EAFs of each vegetable to delineate the active compound in each HWE. Because HWEs were crude extracts, we used the HepG2/MOCK cell line to exclude nonspecific luciferase activity. Since nonspecific luciferase activity was not observed (Figure 2B), we did not use the HepG2/MOCK cell line in subsequent experiments. The luciferase assay using ethyl acetate and water fraction from all five vegetables showed that parsley and spinach had no activity in both fractions. In addition, the ethyl acetate fractions from molokhia and ashitaba had much less activity than that from ginger (Figure 2C), so we focused on the identification of active compounds in ginger. Therefore, to further identify the AHR-activating compounds, we analyzed this fraction by HPLC.

Shogaols and gingerols are the main compounds in ginger and ginger products, and 6-shogaol and 6-gingerol are the main components,[25−28] so we analyzed the EAF from ginger, 6-shogaol, and 6-gingerol. We showed that two major peaks appeared at retention times of 38 and 46 min (Figure 3A), and these peaks corresponded to the peaks of 6-gingerol and 6-shogaol, respectively (Figure 3B, C, D). This data suggested that 6-gingerol and 6-shogaol were the main compounds in EAF from ginger. Shogaols are compounds formed by dehydrating gingerols, and they are not thought to be present in fresh rhizome.[25,26] Gingerols are not stable during storage or thermal processing, and they generate shogaols.[25,26] It was suggested that the 6-shogaol detected in the EAF from ginger in this study resulted from the conversion of 6-gingerol to 6-shogaol during the extraction in hot water.

Treatment of the stable AHR-responsive HepG2 cells with 6-shogaol for 24 h resulted in significant increases in luciferase activity in a dose-dependent manner (Figure 4A). These data are the first to verify induction of AHR-mediated transcriptional activity by 6-shogaol. More interestingly, 6-gingerol had no effect on AHR-mediated transcriptional activity (Figure 4B). 6-Shogaol has been reported to have a much stronger inhibitory effect on the growth of various cancer cell lines than 6-gingerol.[29−31] Koliopanos et al. and Peng et al. reported that AHR agonists inhibited the growth of cancer cells.[32,33] Our finding that 6-shogaol, but not 6-gingerol, is a strong AHR activator may explain why 6-shogaol has a stronger inhibitory effect on the growth of cancer cells.

We think that only evaluation of the activities of the two most abundant components in ginger was insufficient to identify the active compounds in ginger. Therefore, 8-shogaol, 10-shogaol, 8-gingerol, and 10-gingerol, the major compounds in ginger other than 6-shogaol and 6-gingerol, were used for the luciferase assay. Figure 4C shows that 8-shogaol had the same activity as 6-shogaol, but 8-shogaol was not detected in the HPLC chromatogram of EAF from ginger shown in Figure 3A. These results show that 6-shogaol is the most major activator of AHR among shogaols and gingerols. Moreover, the concentration of 6-shogaol in the solution of EAF from ginger (100 μg/mL) was calculated to be about 27 μM by HPLC analysis (data not shown). In this study, the AHR-mediated transcriptional activity was 4−5 fold induction when 100 μg/mL of the EAF from ginger was used, whereas the transcriptional activity was about 2-fold induction when 25 μM of 6-shogaol was used. Based on these data, the activity of 6-shogaol accounted for about 50% of activity, so 6-shogaol is thought to be the most major activator of AHR in ginger.

6-Shogaol induced mRNA expression of the following AHR-target genes: phase I metabolic enzyme CYP1A1, phase II metabolic enzyme UGT1A1, and phase III metabolic enzyme ABCG 2 (Figure 5A, B, C) and protein expression of CYP1A1 (Figure 5D). These are the first data indicating that 6-shogaol induced expression of detoxification enzymes. Liska reported that a multifunctional inducer in detoxification systems was important.[1] Indeed, we have demonstrated the usefulness of 6-shogaol as a multifunctional inducer in this report.

The AHR has been found to favor hydrophobic molecular with a quasi-planar structure and to accommodate a ligand-binding pocket of approximately 14 × 12 × 5 Å.[34,35] Some flavonoids that induce AHR activity have molecular sizes and planar structures that could bind to a ligand-binding pocket of AHR.[10] Although there is no report about the detailed structure analysis of 6-shogaol, based on its structure, we guess that the molecular size of 6-shogaol is smaller than that of flavonoids and that 6-shogaol may bind to a ligand-binding pocket of AHR. Moreover, shogaols, but not gingerols, induced AHR activity in this study. Unlike gingerols, shogaols have the α,β-unsaturated ketone group. Compounds having this structure are good substrates for Michael addition reactions and are rendered electrophilic by conjugation with electron-withdrawing groups.[36] This difference of electrophilic nature based on the structures of shogaols and gingerols may cause the difference of AHR activities. Another possible mechanism of AHR activation by 6-shogaol is the effect of its metabolites. We evaluated the AHR-mediated transcriptional activity and mRNA expression of AHR-target genes by treatment of cells with 6-shogaol for 24 h. Most 6-shogaol has been shown to be metabolized to other reduced forms within 24 h in various cancer cell lines, and these metabolites retain their bioactivity.[37−39] Recently, the cysteine-conjugated metabolite of 6-shogaol, 5-cysteinyl-6-shogaol, exerts its bioactivity by acting as a carrier of 6-shogaol in cancer cells and showed strong growth inhibitory effects toward cancer cells.[39] These bioactive metabolites of 6-shogaol may contribute to induction of AHR activity. Further experiments are necessary to reveal whether or not the bioactive metabolites of 6-shogaol also exhibit induction of AHR-mediated transcriptional activity and mRNA expression of AHR-target genes.

We revealed for the first time that ginger more strongly induced AHR-mediated transcription compared to other vegetables such as molokhia, parsley, spinach, and ashitaba. We also found that 6-shogaol was the major active compound in ginger. The mRNA expression levels of AHR-targeting drug-metabolizing enzymes (CYP1A1, UGT1A1, ABCG 2) and the protein level of CYP1A1 in HepG2 cells were induced by 6-shogaol. These results are the first verification of AHR-mediated regulation of detoxification systems by 6-shogaol. This study suggests that AHR-mediated modulation of detoxification systems can be expected in the presence of 6-shogaol, although in vivo studies are needed to clarify whether AHR will be activated by the intake of 6-shogaol.

ABSTRACT: This study was performed to investigate the angiotensin I-converting enzyme (ACE) inhibitory activity of peptides derived from fertilized eggs and elucidate the inhibition mechanism of these peptides. During incubation, ACE inhibitory activity of the peptides remained stable before day 12 and then increased markedly on day 15. Two ACE inhibitory peptides, VGVIKAVDKKAGGAGKVT and HLFGPPGKKDPV, were purified from peptides on day 15 by consecutive chromatography. Because HLFGPPGKKDPV possessed a higher ACE inhibitory activity (IC_{50} = 125 μM), an antihypertensive effect of this peptide was further evaluated *in vivo*. The result showed that this peptide had an antihypertensive effect in spontaneously hypertensive rats (SHRs) at a dosage of 10 mg/kg. Furthermore, Lineweaver−Burk plots suggested that HLFGPPGKKDPV played as a non-competitive inhibitor against ACE, as supported by docking simulation. These data indicated that a fertilized egg has potential as antihypertensive components in functional foods and nutraceuticals.

KEYWORDS: *ACE inhibitory peptide, fertilized egg, inhibitory pattern, molecular docking, spontaneously hypertensive rat*

INTRODUCTION

Hypertension is one of the major risk factors for the development of cardiovascular diseases, stroke, and the end stage of renal disease.[1] Treatment of hypertension is an effective way to reduce the risk of these diseases.[2] The renin−angiotensin system (RAS) plays a key role in maintaining blood pressure homeostasis.[3] Angiotensin I-converting enzyme (ACE) is a key enzyme in RAS; it raises blood pressure by converting the inactive decapeptide angiotensin I to the potent vasoconstrictor octapeptide angiotensin II as well as inactivating the vasodilating nonapeptide bradykinin.[4] Therefore, inhibition of ACE is considered as an effective approach to controlling hypertension.[1] Since the discovery of ACE inhibitors in snake venom,[5] many chemical ACE inhibitors, such as captopril, enalapril, alacepril, and lisinopril, were designed.[6] However, these chemical ACE inhibitors are known to have various side effects, such as coughing, skin rashes, and angioedema.[7,8] Therefore, many studies have been initiated to develop novel, safe, and natural ACE inhibitors from natural sources.[9,10] In recent years, several ACE inhibitory peptides have been isolated from a wide range of food sources, such as gelatin,[11] casein,[12] tuna,[13] corn,[14] soy beans,[15] egg white,[16] and dried bonito.[17]

For a better understanding of inhibitory properties of peptides, the structure−activity relationship should be clarified. Terashima et al.[18] investigated a series of peptides derived from an ACE inhibitory peptide (VTVNPYKWLP) and concluded that the Pro residue in the C-terminal end strongly enhanced ACE inhibition activity. In addition, the length of peptides also played a key role in ACE inhibitory ability.[19] Recently, Wu et al.[20] have contructed a database consisting of 168 dipeptides and 140 tripeptides to study the quantitative structure−activity relationships of ACE inhibitory peptides. It showed that amino acid residues with bulky side chains as well as hydrophobic side chains were preferred for dipeptides, while for tripeptides, the most favorable residues for C terminus, middle position, and N terminus were aromatic amino acids, positively charged amino acids, and hydrophobic amino acids, respectively. However, these structure−activity correlation studies were mainly based on amino acid sequence analysis. In recent years, the crystal structures of ACE and its inhibitors have been analyzed to elucidate the relationship between the inhibition mechanism and the molecular structure of inhibitors.[21−23] These studies provided a new method to analyze the structure−activity relationship of ACE inhibitory peptides.

Traditionally, fertilized eggs are widely considered as natural dietary supplements in many Asian countries.[24] During chick embryonic development, RAS plays a principal role in regulation of blood pressure.[25] Savary et al.[25] reported that ACE was produced at a very early stage and its activity increased during incubation. Whether naturally occurring peptides derived from fertilized eggs have ACE inhibitory effect is still unknown. To our knowledge, this is the first research to investigate ACE inhibitory activity and the structure−activity relationship of the peptides from fertilized eggs. Because the fertilized eggs that are eaten by Asian consumers are commonly 12-day-old eggs,[26] the fertilized eggs before day 15 of incubation were chosen for investigation in this paper.

The objectives of the present study were to (1) determine ACE inhibitory activity of peptides derived from fertilized eggs and (2) investigate the inhibition mechanism of a purified ACE inhibitory peptide.

MATERIALS AND METHODS

Materials. The fertilized eggs on days 3, 6, 9, 12, and 15 of the incubation period were prepared and lyophilized on the basis of our previous work.[27] The spontaneously hypertensive rats (SHRs, 10 weeks old, male, specific pathogen-free, 180−240 g of body weight) with tail systolic blood pressure (SBP) over 180 mmHg were obtained from Shanghai Slaccas Laboratory Animal Co., Ltd. (Shanghai, China). All animal protocols in this study adhered to the *Guide for the Care and Use of Laboratory Animals* (Ministry of Science and Technology of the People's Republic of China [(2006)398]) and were approved by the Ethics Committee of Jiangnan University, China (JN 28 2013). The testing chemicals including ACE (from rabbit lung) and substrate peptide hippuryl-L-histidyl-L-leucine (HHL) were purchased from Sigma Chemical Co. (St. Louis, MO). All other reagents were of analytical grade (Shanghai Chemical Reagents Co., Shanghai, China).

Preparation of Naturally Occurring Peptides. Peptides were prepared with the method described by Park et al.,[28] with some modification. The lyophilized egg samples (1.0 g) were prepared in 100 mL of Milli-Q water. After centrifugation at 10000*g* for 20 min at 4 °C, the supernatant was microfiltered through a 0.45 μm membrane and then ultrafiltrated through a 3 kDa cellulose membrane (Amicon, Beverly, MA). The filtrates were lyophilized and then stored at −20 °C until use.

Assay of ACE Inhibitory Activity. The ACE inhibitory activity assay was performed with the method described by Terashima et al.[29] Peptides (50 μL, 10 mg/mL in deionized water) with 50 μL of ACE solution (25 mU/mL) were preincubated at 37 °C for 10 min, and the mixture was then incubated with 50 μL of substrate (8.3 mM HHL in 50 mM sodium borate buffer containing 0.5 M NaCl at pH 8.3) for 60 min at the same temperature. The reaction was terminated by the addition of 1.0 M HCl (200 μL). The reaction mixture was filtered with Millex-LG (Nihon Millipore Co., Ltd., Tokyo, Japan), and 10 μL of the filtrates was injected into the high-performance liquid chromatography (HPLC) system (Shimadzu LC-10 AD, Shimadzu, Kyoto, Japan) equipped with a hydrophobic column (Cosmosil 5C18-MS-II, 4.6 × 150 mm). An isocratic mobile phase composed of 80% Milli-Q water containing 0.1% (v/v) trifluoroacetic acid and 20% acetonitrile containing 0.1% (v/v) trifluoroacetic acid was used at a flow rate of 1.0 mL/min. Peak areas for hippuric acid (HA) generated by the ACE reaction was monitored at 228 nm with a detector (Shimadzu SPD-20A). ACE inhibitory activity was obtained by the following equation:

ACE inhibitory activity (%) = $[(V_m - V_{in})/V_m] \times 100$, where V_m was the peak area without the sample solution and V_{in} was that with the sample solution.

Purification of ACE Inhibitory Peptides. The ACE inhibitory peptides were purified according to the method described in our previous work.[27] Briefly, on the basis of the ACE inhibition result, the peptides on day 15 showed the strongest inhibitory activity and, thus, were employed for purification of ACE inhibitory peptide. The lyophilized peptides on day 15 were loaded onto a Mono Q 5/50 GL ion-exchange column with the ÄKTA purifier system (Amersham Pharmacia Biotech, Uppsala, Sweden) equilibrated with 20 mM Tris−HCl (pH 8.0) and eluted with a linear gradient of NaCl (0−1.0 M) in the same buffer at a flow rate of 2 mL/min. Each fraction was monitored at 280 nm, collected, and lyophilized for ACE inhibitory activity assay at a concentration of 1 mg/mL. The lyophilized fraction having the highest activity was further dissolved in phosphate buffer (0.05 M sodium phosphate and 0.15 M NaCl at pH 7.2) and subjected to a Superdex Peptide 10/300GL column at a flow rate of 0.5 mL/min. Each peak was collected and lyophilized, and ACE inhibitory activity was also investigated at a concentration of 1 mg/mL. The most active fraction was lyophilized for further research.

Identification and Synthesis of the Purified Peptide. The fraction with the strongest inhibitory activity was dissolved in 0.1% formic acid in deionized water for liquid chromatography−tandem mass spectrometry (LC−MS/MS) analysis. LC−MS/MS analysis was performed using a LTQ mass spectrometer (Thermo Electron, Bremen, Germany) coupled with a a nanoelectrospray ionization source. Samples were loaded onto a reversed-phase C18 column with a diameter of 0.15 mm × 10 cm and particle size of 5 μm. Separation of the peptides was performed using a gradient going from 5 to 90% acetonitrile in 0.1% formic acid over 40 min. The MS/MS raw data were acquired using Thermo-Xcalibur data acquisition, and the acquired data were searched against the NCBI chicken-specific database using SEQUEST software (Bioworks 3.1 package, Thermo Electron). Peptides were searched using the following parameters: peptide tolerance, 2.0 amu; enzyme, trypsin (KR/P); enzyme limits, fully enzymatic (cleaves at both ends); and maximum missed cleavages, 2. The filtering criterion were set as $\Delta C_n \geq 0.1$, and $X_{corr} \geq 1.9$ with charge state 1+, $X_{corr} \geq 2.2$ with charge state 2+, and $X_{corr} \geq 3.75$ with charge state 3+ were used as a cutoff for peptide identification.

To investigate the antihypertensive activity and inhibition pattern of peptides, the solid-phase technique was used to synthesize the purified peptides on a peptide synthesizer (Symphony, Protein Technologies, Inc., Tucson, AZ). [(9-Fluorenylmethyl)oxy]carbonyl (FMOC) amino acids were successively coupled in the presence of 2-(1*H*-benzotriazol-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU). ACE inhibitory activity of the synthesized peptides were investigated according to the above-described method. The IC_{50} value was the concentration of the sample that inhibited 50% of the ACE activity.

Antihypertensive Action in Spontaneously Hypertensive Rats. Conscious SHRs were housed individually in steel cages in a room kept at 25 °C with a 12 h light−dark cycle and fed a standard laboratory diet. Tap water was freely available. The purified peptide was dissolved in saline at a dose of 10 mg/kg of body weight and injected orally using a metal gastric zoned in SHR. Antihypertensive activity of P2 was evaluated by measuring the change of systolic blood pressure (SBP) at 1, 2, 3, 6, 9, 22, and 24 h after oral administration of 10 mg/kg of body weight. The lowering efficacy of the peptide on SBP was compared to that of captopril (10 mg/kg). Control rats were administrated with the same volume of saline solution. Following oral administration, SBP was measured by tail-cuff method with a CODA monitor (Kent Scientific Corporation, Torrington, CT) after warming up SHR in a chamber maintained at 37 °C for 10 min.

Determination of the Inhibition Pattern on ACE. To determine the ACE inhibition pattern of the purified peptide, various substrate (HHL) concentrations (1, 2, and 5 mM) were incubated with the ACE solution in either the absence or presence of 100 or 200 μM purified peptide at 37 °C. ACE inhibitory activity was determined according to the above-described method. The ACE inhibition pattern was determined with Lineweaver−Burk plots.[30]

Molecular Docking. To verify the inhibition pattern of the purified peptide, a docking simulation was performed. The structure of the purified peptide was constructed and optimized with the polypeptide builder function of the public domain web server PEP-FOLD, which predicted and optimized the conformation of side chains by calculating energy values. The conformation with the lowest energy was considered to display a fully native structure.[30] In addition, the model for ACE used in this study was the crystal structure labeled 1O8A in the Protein Data Bank (PDB), which represented the human testis ACE (tACE). The conformation of the peptide−tACE complex was constructed and optimized with a protein-docking program, ZDOCK, which performed the three-dimensional (3D) search of the spatial degrees of freedom between the two molecules. The default parameters of ZDOCK were used, and the conformation with the highest ZDOCK score was identified as the best docking mode.[31]

Statistical Analysis. The experiments were run in triplicate. The results were expressed as the mean ± standard deviation and were analyzed using SPSS 16.0 software (SPSS, Inc., Chicago, IL). Differences between means were analyzed by an analysis of variance (ANOVA) test with the least significant difference (LSD) post-hoc analysis ($p < 0.05$).

RESULTS AND DISCUSSION

Change in ACE Inhibitory Activity of Peptides. During incubation, the inhibitory activity remained stable up to day 12

and then dramatically increased on day 15, reaching 78.25% at 10 mg/mL (Figure 1). During chick embryonic development,

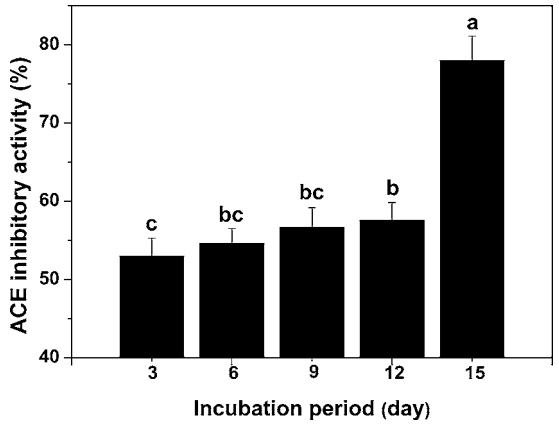

Figure 1. Change in ACE inhibitory activity of peptides derived from fertilized eggs at different developmental stages. The sample concentration was 10 mg/mL for measurement of ACE inhibitory activity. Different letters (a and b) above columns indicate significant differences ($p < 0.05$).

ACE was produced during early embryogenesis, at a stage when blood circulation is not yet established.[25] Girard has reported that the blood pressure increased rapidly and exponentially from 3 to 10 days of incubation; thereafter, the increase was slower.[32] This trend is in good agreement with the result that the inhibitory activity of peptides was low before day 12 and then increased markedly up to day 15. The results indicate that the peptides may play a potential role in regulating blood pressure by inhibiting ACE during incubation.

Purification and Identification of ACE Inhibitory Peptide. The peptides on day 15 exhibited the strongest ACE inhibitory activity and, thus, were employed for isolation of ACE inhibitory peptide. A Mono Q 5/50 GL column was used to fractionate the peptides, and the fractions were pooled to obtain fractions 1−6 (lower panel of Figure 2a). Although ACE inhibitory activity was observed in all of these fractions, fraction 2 exhibited the highest inhibitory activity (upper panel of Figure 2a). Thereafter, fraction 2 was eluted on a Superdex Peptide 10/300GL column, and six peaks were monitored (lower panel of Figure 2b). Among these peaks, fraction C expressed strong ACE inhibitory activity (upper panel of Figure 2b). Therefore, fraction C was subjected to linear trap quadrupole (LTQ) MS/MS analysis to identify its amino acid sequence. On the basis of mass spectrometric analysis, two peptides (named P1 and P2) were identified (Figure 3). Because the amino acid sequence of P2 has been reported in our previous work,[27] the mass spectrum of P2 was cited from ref 27. The two peptides were composed of 18 and 12 amino acid residues, and the amino acid sequences were VGVI-KAVDKKAGGAGKVT (molecular weight of 1698.03 Da) and HLFGPPGKKDPV (molecular weight of 1291.51 Da), respectively. To confirm ACE inhibitory activity of the two peptides, P1 and P2 were synthesized with a peptide synthesizer and their inhibitory activity was measured. The results showed that the half maximal inhibitory concentration (IC_{50}) of P2 was 125 μM, while P1 exhibited lower activity (IC_{50} > 250 μM). Therefore, P2 was selected for further research. Interestingly, our previous work indicated that HLFGPPGKKDPV also possessed antioxidant activity against the 1,1-diphenyl-2-picrylhydrazyl (DPPH) radical,[27] which is in accordance with the previous study reporting that peptides with high ACE inhibitory activity usually possessed a high level of DPPH radical scavenging activity at the same time.[33] Actually, since Hou et al.[34] suggested that some antioxidant peptides had effects on ACE, many multifunctional peptides have been

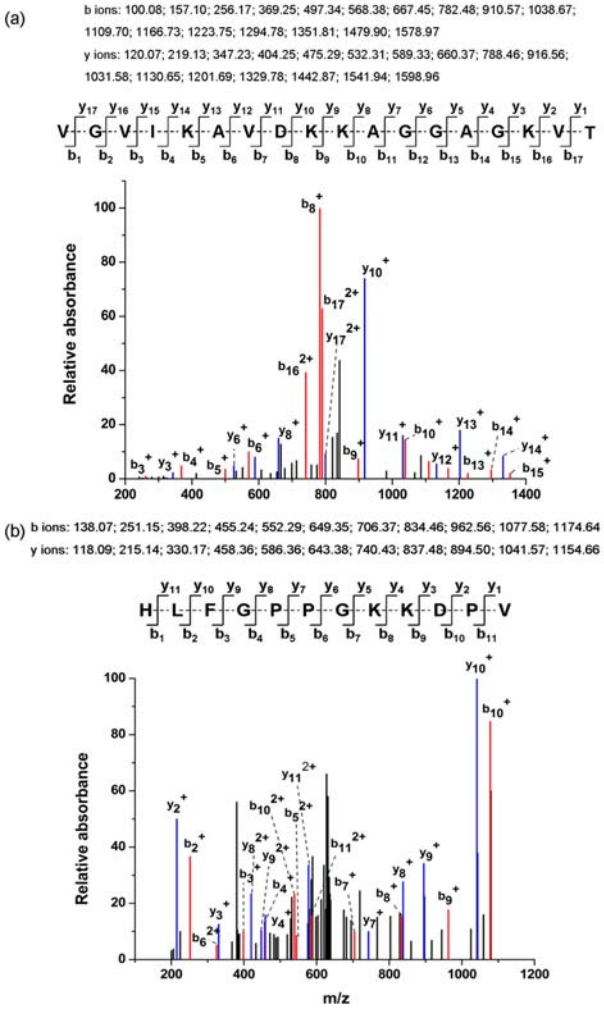

Figure 3. Identification of the amino acid sequence of the purified peptides (a) P1 and (b) P2. MS/MS experiments were performed on a LC system coupled to a linear ion trap mass spectrometer model LTQ (LC−ESI−LTQ). The mass spectrum of P2 was cited from ref 27.

purified from various food sources.[35,36] These active peptides have considerable potential for use as multifunctional ingredients in functional foods to control chronic diseases.

Basic Local Alignment Search Tool (BLAST) analysis revealed that HLFGPPGKKDPV corresponded to the fragment 302−313 of ovotransferrin.[27] Ovotransferrin is an iron-binding glycoprotein and appears to be a multifunctional protein.[37] Some ACE inhibitory peptides have been purified from ovotransferrin hydrolysates.[38−41] Lee et al.[41] have characterized an hexapeptide derived from ovotransferrin (KVREGT), possessing strong ACE inhibitory activity (IC_{50} = 9.1 μM). Lee et al.[38] also isolated an ovotransferrin octapeptide (KVREGTTY), which had an IC_{50} value of 102.8 μM against ACE. In recent research,[40] three novel tripeptides (IQW, IRW, and LKP) with high ACE inhibitory activity (IC_{50} lower than 3.0 μM) were purified from enzymatic hydrolysate of ovotransferrin. In this work, P2 had a relatively low activity compared to other reports. However, in contrast to those peptides obtained via enzymatic hydrolysis of proteins, P2 is the first naturally occurring ACE inhibitory peptide from a fertilized egg.

ACE inhibitory peptides usually contain 2−12 amino acid residues.[42] Thus, the molecular weight of P2 is in good agreement with the reported ACE inhibitory peptide size. Previous studies have demonstrated a good correlation between certain amino acid residues and ACE inhibitory activity of peptides.[21,43] Because the activity of ACE is to cleave the C-terminal dipeptide of oligopeptide substrates, the inhibitory activity of peptides is strongly influenced by their C-terminal tripeptide sequences.[30] Rohrbach et al.[44] demonstrated that the most potent ACE inhibitors contain hydrophobic amino acid residues at their three C-terminal positions. P2 contained six hydrophobic amino acid residues (L, F, P, and V), and two of them (P and V) were at the C-terminal tripeptide sequence. In addition, it was reported that most naturally occurring ACE inhibitory peptides contained P, K, or aromatic amino acid residues.[41] P2 contained the two amino acid residues (P and K) and one aromatic amino acid residue (F), which may play an important role in its inhibitory activity.

Antihypertensive Effect of the Purified Peptide on SHR. Antihypertensive activity of P2 was evaluated by measuring the change of SBP at 1, 2, 3, 6, 9, 22, and 24 h after oral administration. As shown in Figure 4, the SBP in the quiescent state of SHR was 188 ± 4.4 mmHg. After oral administration of P2 and captopril, SBP clearly decreased and the activities were maintained for 9 h. The maximal decrements in SBP of P2 and captopril treatment groups were 21.1 and 27.1 mmHg at 6 h, respectively. The blood pressure has been gradually recovered in 22 h for all groups. In addition, there was no significant change in the heart rate (HR) after administration, which suggested that the administration of P2 did not have a bad effect on the circulatory system of SHRs.

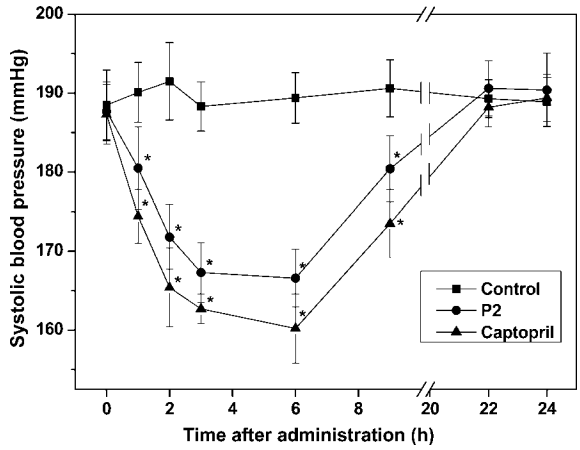

Figure 4. Changes in SBP of SHR after oral administration of P2. Captopril was used as a positive control. Single oral administration was performed with a dose of 10 mg/kg of body weight, and SBP was measured 0, 1, 2, 3, 6, and 9 h after administration. (*) Significant difference from the control at $p < 0.05$.

There have been many studies on ACE inhibitory peptides derived from egg proteins.[45−47] Some of these peptides have been shown to possess hypotensive activity in SHRs.[46,47] However, there is little information on the hypotensive activities of naturally occurring peptides from fertilized eggs. The depressor ability of P2 (21.1 mmHg) is higher than that of 20 mg/kg of ovokinin (13.5 mmHg), which was a heptapeptide derived from ovalbumin.[46] It is well-known that small peptides, such as di- or tripeptides are easily absorbed in their intact forms in the intestine.[3] Even though P2 has relatively high molecular weight compared to these small peptides, the result

dx.doi.org/10.1021/jf501368a | J. Agric. Food Chem. 2014, 62, 5500−5506

showed that P2 exerted a substantial effect on reduction of SBP in SHR. This meant that this peptide could be directly absorbed or undergo further hydrolysis in the digestive tract to release smaller size true inhibitors.

Inhibition Pattern on ACE. Various substrate (HHL) concentrations (1, 2, and 5 mM) were incubated with ACE solution in either the absence or presence of 100 or 200 μM P2. As shown in Figure 5, the three straight lines intersected at one

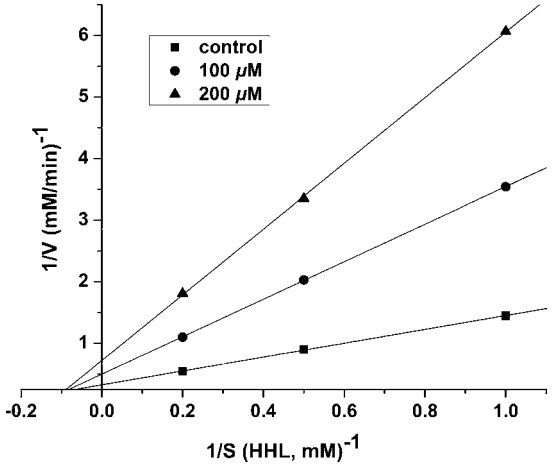

Figure 5. Lineweaver–Burk plot of ACE activity of P2: (■) control, (●) 100 μM the P2, and (▲) 200 μM P2.

point on the 1/*S* axis, which meant that this peptide was a non-competitive inhibitor.[30] Non-competitive inhibitors generally bind to non-catalytic sites of enzymes. They combine with enzyme molecules to produce a dead-end complex, regardless of whether a substrate molecule is bound or not.[3] In addition, a decrease in the V_{max} value was seen after incubating ACE with P2 (3.10, 2.01, and 1.39 mM/min for the absence and presence of 100 or 200 μM P2, respectively), whereas there was little effect on K_m (11.3, 12.5, and 13.9 μM for the absence and presence of 100 or 200 μM P2, respectively). This is in agreement with previous research reporting that non-competitive inhibition would lead to a decreased V_{max}, with minimal effects on K_m.[48] In recent years, several non-competitive inhibitory peptides have been purified from some food sources.[30,49] However, the relationship between the inhibition pattern and structure of these peptides has not been fully researched.[30]

Molecular Docking. The conformation with the highest ZDOCK score is shown in Figure 6a. It was observed that P2 (green) was located on the opposite side of the ACE (gray) active site, which included the zinc ion (red). Previous research reported that non-competitive ACE inhibitors cannot bind at the active site but at the other exclusive of the ACE active site.[3] Thus, P2 was further identified as a non-competitive inhibitor.

The interaction force between P2 and tACE is shown in Figure 6b. With Pymol software, the theoretical calculation indicated that the peptide formed hydrogen bonds with Asn-66, Lys-118, Arg-124, Tyr-394, Glu-403, and Arg-522 of tACE. His-1 donated its protons to Glu-403 and Tyr-394 to form hydrogen bonds, respectively. Gly-4 and Lys-9 in P2 accepted hydrogen bonds from Asn-66 and Arg-522, separately. Asp-10 and Pro-11 accepted protons from Arg-124 and Lys-118 to form hydrogen bonds, respectively. These interactions kept P2 away from the active site of tACE, and only Lys-9 formed a

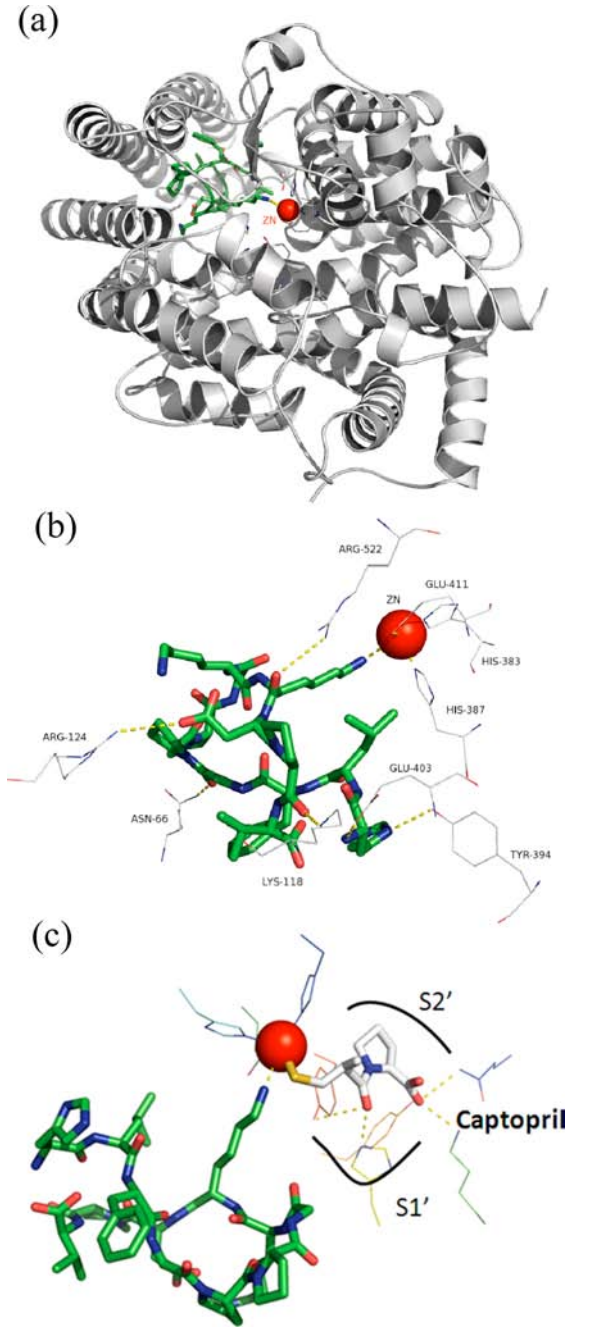

Figure 6. Docking simulation of P2 binding to tACE and captopril–tACE complex. The zinc ion (red ball) was present in the active site of tACE. (a) Docking simulation of P2 (green) binding to tACE (gray). (b) Interaction between P2 (shown as sticks) and the residues of tACE (shown as lines). (c) Overlap of captopril (white) in the crystal structure of the captopril–tACE complex with P2 (green).

coordination bond with the zinc ion that located in the active site. The zinc ion is the key ion in the active site of ACE; it plays a crucial role in opening up the catalytic site.[50] In the docking simulation, the zinc ion was attracted by Lys-9 of P2 through a coordination bond. Therefore, the zinc ion might be forced away from the active site, and thus, the substrate HHL bonded to ACE could not be catalyzed to produce HA.[30]

To further elucidate the inhibition pattern of P2, the docking simulation of P2 and the captopril–ACE complex (PDB code 1UZF) was performed (Figure 6c). Captopril is a specific

dx.doi.org/10.1021/jf501368a | J. Agric. Food Chem. 2014, 62, 5500–5506

competitive ACE inhibitor.[22] According to the crystal structure of the captopril−ACE complex, captopril (white) formed hydrogen bonds with key residues in ACE active site and occupied the key positions, which would be occupied by substrate HHL, such as the S1′ and S2′ subsites.[30] This is consistent with the competitive inhibition model. Contrarily, P2 (green) located away from the ACE active site (S1′ and S2′), and only Lys-9 interacted with the zinc ion (red). Therefore, we concluded that P2 could not compete with substrate for the active site, indicating that P2 is a non-competitive ACE inhibitor.

In summary, ACE inhibitory activity of peptides derived from fertilized eggs was investigated. During incubation, ACE inhibitory activity of peptides remained stable before day 12 and then markedly increased on day 15. The peptides on day 15 were then employed for isolation of ACE inhibitory peptide. An identified peptide (HLFGPPGKKDPV) exhibited potent ACE inhibitory activity with an IC_{50} value of 125 μM and acted as a non-competitive inhibitor against ACE. An antihypertensive effect in SHR revealed that oral administration of the peptide could decrease SBP significantly. These results showed that fertilized eggs could be seen as potential candidates to develop nutraceuticals against hypertension and its related disease.

ABSTRACT: The cellular endogenous antioxidant system plays pivotal roles in counteracting or retarding the pathogenesis of many neurodegenerative diseases. Molecules with the ability to enhance the antioxidant defense thus are promising candidates for neuroprotective drugs. 6-Dehydrogingerdione (6-DG), one of the major components of dietary ginger, has received increasing attention due to its multiple pharmacological activities. However, how this pleiotropic molecule works on the neuronal system has not been studied. This paper reports that 6-DG efficiently scavenges various free radicals in vitro and displays remarkable cytoprotection against oxidative stress-induced neuronal cell damage in the neuron-like rat pheochromocytoma cell line, PC12 cells. Pretreatment of PC12 cells with 6-DG significantly up-regulates a panel of phase II genes as well as the corresponding gene products, such as glutathione, heme oxygenase, NAD(P)H:quinone oxidoreductase, and thioredoxin reductase. Mechanistic study indicates that activation of the Keap1-Nrf2-ARE pathway is the molecular basis for the cytoprotection of 6-DG. This is the first revelation of this novel mechanism of 6-DG as an Nrf2 activator against oxidative injury, providing the potential therapeutic use of 6-DG as neuroprotective agent.

KEYWORDS: *6-dehydrogingerdione, Nrf2, oxidative stress, neuroprotection, antioxidant*

INTRODUCTION

The cellular endogenous antioxidant system is crucial for counteracting reactive oxygen species (ROS)-mediated oxidative stress and preventing cell death. A well-elucidated universal pathway to induce intrinsic antioxidant defense involves transcriptional regulation through activation of the antioxidant-responsive element (ARE).[1,2] Under this circumstance, stimulants induce a set of genes encoding antioxidant and detoxifying enzymes ("phase II" enzymes), including heme oxygenase-1 (HO-1), NAD(P)H:quinone oxidoreductase 1 (NQO1), thioredoxin reductase 1 (TrxR1), thioredoxin (Trx), glutathione (GSH), γ-glutamylcysteine synthetase (γGCS), and γ-glutamyl cysteine ligase (γ-GCL), which provide efficient cytoprotection against oxidative stress and electrophilic assault.[3,4] The transcription factor NF-E2-related factor 2 (Nrf2) mediates transcription of phase II genes by binding to the ARE within nuclear DNA and subsequently initiates antioxidant genes transcription. Under basal conditions, the cytosolic regulatory protein Kelch-like ECH-associated protein 1 (Keap1) binds tightly to Nrf2, retaining it in the cytoplasm.[2] Molecules, such as electrophiles or oxidants, which could modify the critical cysteine residue(s) in the regulatory protein Keap1, would cause the release of Nrf2 and facilitate its translocattion into the nucleus and thus activate the transcription of phase II genes.[4−7]

In healthy cells, the level of ROS is tightly regulated by the antioxidant defense system. However, upon environmental stress or cellular damage, cells cannot readily detoxify the ROS generated and may thereby suffer from oxidative stress. As neuronal cells are particularly sensitive to oxidative stress, an increasing amount of experimental evidence has indicated that oxidative stress is a causal, or at least an ancillary, factor in the neuropathology of several adult neurodegenerative disorders such as Alzheimer's disease (AD) and Parkinson's disease (PD).[8,9] Besides the counteraction of various ROS by exogenous small molecule antioxidants, targeting the prevention of oxidative stress could be best achieved by stimulation of endogenous cytoprotective molecules known to serve this purpose because their actions are more sustained and are amplified by transcription-mediated signaling pathways. In this sense, activation of the Nrf2-ARE pathway is a promising therapeutic approach in neurodegenerative diseases.[3,10−12] Thus, the past years have witnessed expanding endeavors in identifying naturally occurring and synthetic neuroprotective small molecule activators of the Nrf2-ARE pathway,[13,14] including carnosic acid,[15] resveratrol,[16] curcumin,[17] sulforaphane,[18] quercetin,[19] epicatechin,[20] plumbagin,[21] luteolin,[22] and *tert*-butylhydroquinone.[18]

Ginger (rhizome of the dietary plant *Zingiber officinale*) has been commonly used as a popular spice or food supplement and has been equally reputed for its medicinal properties for centuries.[23,24] 6-Dehydrogingerdione (6-DG), one of the major components of dietary ginger, has received extensive attention due to its multiple pharmacological activities, such as inhibition of lipid peroxidation,[25] enhancement of skin cell proliferation,[26] and induction of cancer cell apoptosis.[27,28] However, how this pleiotropic molecule works on the neuronal system has not been elucidated. As part of our continuing effort in the discovery and development of novel redox active small

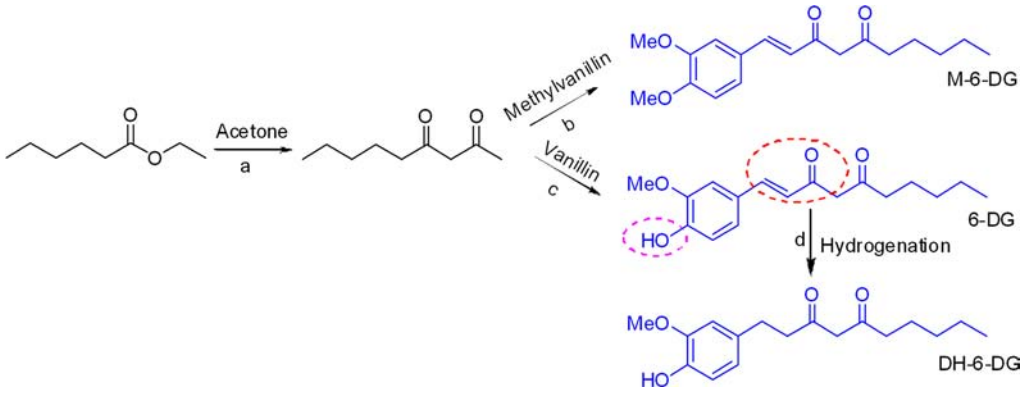
Scheme 1. Synthesis of 6-DG, M-6-DG, and DH-6-DG[a]



[a]The active motif of 6-DG is highlighted in circles. Reagents and conditions: (a) NaH, Et_2O, 64%; (b) boron trioxide, 78%; (c) boron trioxide, 71%; (d) 10% Pd–C, H_2, 70%.

molecules,[29−32] we determined herein the antioxidant activity of 6-DG in vitro and employed a neuron-like rat pheochromocytoma cell line, PC12, to assess the molecular mechanisms responsible for the neuroprotective effect of 6-DG. 6-DG, prepared from the readily available starting materials in two steps, efficiently scavenges free radicals and prevents erythrocytes from free radical-induced hemolysis. Importantly, 6-DG activates the Nrf2-ARE signaling pathway, leading to up-regulation of phase II enzyme expression and remarkable protection of PC12 cells from hydrogen peroxide (H_2O_2)- or 6-hydroxydopamine (6-OHDA)-induced neurotoxicity. We clarified that the hydroxyl group and the α,β-unsaturated ketone moiety are determinants of the biological function of 6-DG. Our results demonstrate that 6-DG is a novel small molecule activator of Nrf2-ARE pathway and suggest that 6-DG might be a potential candidate for the prevention of neurodegeneration. Targeting the Nrf2-ARE signaling pathway by 6-DG thus discloses a previously unrecognized mechanism underlying the biological action of 6-DG and provides a deep insight into understanding the neuroprotective effects of 6-DG.

MATERIALS AND METHODS

Chemicals and Enzymes. Dulbecco's modified Eagle's medium (DMEM), *N*-acetyl-Asp-Glu-Val-Asp-*p*-nitroanilide (Ac-DEVD-pNA), dimethyl sulfoxide (DMSO), yeast glutathione reductase (GR), Hoechst 33342, 2′,7′-dichlorfluorescein diacetate (DCFH-DA), 2,2′-azinobis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS), 2,2-diphenyl-1-picrylhydrazyl (DPPH), 5,5′-dithiobis(2-nitrobenzoic acid) (DTNB), 2,6-dichlorophenol-indophenol (DCPIP), NADH, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT), penicillin, and streptomycin were obtained from Sigma-Aldrich (St. Louis, MO, USA). NADPH was obtained from Roche (Mannheim, Germany). Fetal bovine serum (FBS) was obtained from HyClone. 6-Hydroxydopamine (6-OHDA) and antibodies against TrxR1, Trx1, actin, and Nrf2 were from Santa Cruz Biotechnology. Antibodies against HO-1 and NQO1 were from Sangon Biotech (Shanghai, China). The shRNA plasmids targeting coding regions of the rat Nrf2 gene (shNrf2) and the control nontargeting shRNA (shNT) were purchased from GenePharma Co, Ltd. (Shanghai, China). GeneTran III transfection reagent was obtained from Biomiga (San Diego, CA, USA). Bovine serum albumin (BSA), phenylmethanesulfonyl fluoride (PMSF), and sodium orthovanadate (Na_3VO_4) were from Beyotime (Nantong, China). All other reagents were of analytical grade.

Synthesis of 6-DG, Methylated 6-DG (M-6-DG), and Hydrogenated 6-DG (DH-6-DG). 6-DG, M-6-DG, and DH-6-DG described in this study were prepared using a straightforward chemistry (Scheme 1) by following the method described in the literature with minor modifications. Briefly, acetone reacts with ethyl hexanoate under basic condition (Claisen condensation) and gives 2,4-nonanedione in 64% yield. The dione reacting with vanillin and methylvanillin via Claisen–Schmidt condensation affords 6-DG and M-6-DG in 71 and 78% yields, respectively. Hydrogenation of 6-DG catalyzed by palladium on carbon furnished DH-6-DG in 70% yield. All compounds were fully characterized by NMR and MS.

2,4-Nonanedione.[33] To a stirred mixture of sodium hydride (1.2 g, 50 mmol) and ethyl hexanoate (7.2 g, 50 mmol) was added acetone (1.51 g, 26 mmol) in 7 mL of dry diethyl ether over a period of 30 min. The temperature of the reaction mixture was kept at 30–40 °C by occasional cooling with ice water. After the acetone was added, the reaction mixture was stirred at 40–50 °C for 1 h. Diethyl ether was continuously added to maintain a fluid reaction mixture. After continuous stirring at room temperature overnight, the reaction was quenched by sequential addition of 8 mL of ethanol and 80 mL of 0.75 M HCl. Extraction with diethyl ether (50 mL × 3) and removal of the solvent under vacuum gave a pale yellow oil, which was added to a hot solution of $CuSO_4·5H_2O$ (12.4 g, 40 mmol) in 60 mL of water. After cooling, crystals were collected and washed with 100 mL of hexane and further dissolved in 50 mL of 10% H_2SO_4. The resulting solution was extracted with diethyl ether and dried over Na_2SO_4. After removal of the solvent, the crude product purified by column chromatography on silica gel gave 2,4-nonanedione (64%). ^{1}H NMR (400 MHz, $CDCl_3$), δ 5.49 (s, 1H), 2.23–2.27 (t, 2H), 2.05 (s, 3H), 1.58–1.62 (m, 2H), 1.30–1.32 (m, 4H), 0.88–0.91 (t, 3H); ESI-MS $(M + 1)^+$, 157.2.

6-DG.[34] Vanillin (6.3 g, 42 mmol), 2,4-nonanedione (19.3 g, 124 mmol), and boron trioxide (11.5 g, 165 mmol) were mixed with 50 mL of *N*,*N*-dimethylformamide (DMF) and warmed to 90 °C. A solution of isobutylamine (40 mg, 0.4 mmol) in 40 mL of DMF was added dropwise for 2 h. After stirring at 85–90 °C for 1 h, ~60 mL of the solvent was evaporated in vacuo, and 250 mL of water was added. The resulting mixture was stirred at 60 °C for 1 h and at room temperature for 12 h. The reaction mixture was extracted with ethyl acetate (50 mL × 3), and the solvents were evaporated. The crude product was purified by column chromatography on silica gel to afford 6-DG (71%). mp, 84 °C; ^{1}H NMR (400 MHz, $CDCl_3$), δ 7.51–7.55 (d, J = 16 Hz, 1H), 7.09–7.11 (d, J = 8 Hz, 1H), 7.03 (s, 1H), 6.92–6.94 (d, J = 8 Hz, 1H), 6.33–6.37 (d, J = 16 Hz, 1H), 5.83 (s, 1H), 5.63 (s, 1H), 3.95 (s, 3H), 2.36–2.40 (t, 2H), 1.63–1.70 (m, 2H), 1.33–1.36 (m, 4H), 0.90–0.93 (t, 3H); ESI-MS $(M + 1)^+$, 291.2.

M-6-DG. The synthesis of M-6-HG exactly followed the procedure described for 6-DG except for the use of methylvanillin (6.9 g, 42 mmol) instead of vanillin. Yield, 78%; mp, 45 °C; ^{1}H NMR (400 MHz, $CDCl_3$), δ 7.53–7.57 (d, J = 16 Hz, 1H), 7.11–7.13 (m, 1H), 7.06 (s, 1H), 6.87–6.89 (d, J = 8 Hz, 1H), 6.35–6.39 (d, J = 16 Hz, 1H), 5.64 (s, 1H), 3.89 (s, 6H), 2.37–2.41(t, 2H), 1.26–1.34 (m, 6H), 0.9–0.93 (t, 3H); ESI-MS $(M + 1)^+$, 305.2.

DH-6-DG.[31] To a mixture of 10 mg of Pd/C (10%) in 5 mL of ethyl acetate under a hydrogen atmosphere was added 10 mg of 6-DG. The reaction was kept at room temperature for 12 h. After the reaction, the Pd/C was removed by filtration, and the filtrate was concentrated and purified by silica gel column chromatography to afford DH-6-DG (70%). ^{1}H NMR (400 MHz, $CDCl_3$), δ 6.85−6.83 (d, J = 8 Hz, 1H), 6.70−6.68 (d, J = 8 Hz, 2H), 5.51 (s, 1H), 5.46 (s, 1H), 3.87 (s, 3H), 2.89−2.83 (m, 2H), 2.59−2.55 (t, 2H), 2.28−2.24 (t, 2H), 1.32−1.26 (m, 6H), 0.92−0.87 (m, 3H); ESI-MS $(M + Na)^+$, 315.3.

Free Radical-Scavenging Capacities. The various concentrations of antioxidants were mixed with the DPPH solution (50 μM), and the mixture was shaken vigorously and left to stand at room temperature for 30 min in the dark. The absorbance of the reaction solution was measured spectrophotometrically at 517 nm. The $ABTS^{\bullet+}$ scavenging ability was determined according to the published method.[35] The $ABTS^{\bullet+}$ solution, which was prepared from oxidation of ABTS (7 mM) by potassium persulfate (2.5 mM) for 12−16 h in the dark at room temperature, was diluted to an absorbance of 0.700 ± 0.020 at 734 nm. The $ABTS^{\bullet+}$ solution (2 mL) and the antioxidant solution (100 μL) were mixed, and the absorbance at 734 nm was recorded after 30 min.

Assay for Hemolysis of Red Blood Cells (RBCs) and Thiobarbituric Acid Reactive Substances (TBARS). Human RBCs were separated from heparinized blood that was drawn from a healthy donor. The 5% suspension of RBC in PBS (pH 7.4) was incubated under air at 37 °C for 5 min into which a PBS solution of AAPH was added to initiate hemolysis. The extent of hemolysis was determined spectrophotometrically as described previously.[36] Briefly, aliquots of the reaction mixture were taken out at appropriate time intervals, diluted with 0.15 M NaCl, and centrifuged at 3000 rpm for 5 min to separate the RBCs. The percentage hemolysis was determined by measuring the absorbance of the supernatant at 540 nm and compared with that of complete hemolysis by treating the same RBC suspension with distilled water. For measurements of TBARS, the erythrocyte ghost was incubated at 37 °C in 0.1 M PBS (pH 7.4) and diluted to a final protein concentration of 0.96 mg/mL. The peroxidation was initiated by the addition of AAPH. The reaction mixture was gently shaken at 37 °C, and aliquots of the reaction mixture were taken out at specific intervals to which a TCA−TBA−HCl stock solution (15% w/v trichloroacetic acid; 0.375% w/v TBA; 0.25 M HCl) was added, together with 0.02% w/v BHT. This amount of BHT completely prevents the formation of any nonspecific TBARS from the decomposition of AAPH during the subsequent boiling. The solution was heated in a boiling water bath for 15 min. After cooling, the precipitate was removed by centrifugation. TBARS in the supernatant were quantified at 532 nm using the extinction coefficient of 1.56×10^5 M^{-1} cm^{-1}.[37]

Cell Cultures. The rat adrenal pheochromocytoma cell line, PC12 cells, was obtained from Shanghai Institute of Biochemistry and Cell Biology, Chinese Academy of Sciences, and was cultured in DMEM supplemented with 10% FBS, 2 mM glutamine, and 100 units mL^{-1} penicillin/streptomycin and maintained in an atmosphere of 5% CO_2 at 37 °C.

MTT Assay and Lactate Dehydrogenase (LDH) Release Assay. To evaluate the cytotoxicity, PC12 cells (1×10^4 cells/well) were seeded in 96-well plates for 1 day followed by incubation with 6-DG or other agents for 24 h at 37 °C. For the H_2O_2 or 6-OHDA injury model, PC12 cells (1×10^4 cells/well) were plated in a 96-well plate and allowed to adhere for 24 h and then treated with the drugs for 24 h. After replacement with fresh medium containing 600 μM H_2O_2 for 12 h or 200 μM 6-OHDA for 24 h, cell viability was determined by MTT assay. At the end of the treatment, 10 μL of MTT (5 mg/mL) was added to each well and incubated for an additional 4 h at 37 °C. One hundred microliters of extraction buffer (10% SDS, 5% isobutanol, 0.1% HCl) was added, and the cells were incubated overnight at 37 °C. Cells treated with DMSO alone were used as controls. The absorbance was measured at 570 nm on a Multiskan GO (Thermo Scientific). For the LDH release assay, the cells (2×10^5 cells/well) were plated in 12-well plates. The following day, the cells were exposed to various concentrations of 6-DG for 24 h, followed by the addition of 600 μM H_2O_2 for an additional 12 h or 200 μM 6-OHDA for an additional 24 h. The leakage of LDH from cultured cells was quantified by measuring LDH activity in culture media. Briefly, 50 μL of culture medium was mixed with 110 μL of 100 mM Tris-HCl (pH 7.4) containing 20 μL of 2 mM NADH and 20 μL of 20 mM pyruvate, and the $A_{340\ nm}$ change was monitored every 20 s for 5 min. The content of LDH release was calculated by normalizing the LDH activity of samples to that measured in culture medium from the control cells.

Hoechst 33342 Staining and Assessment of the Intracellular ROS.[29,30] PC12 cells (2×10^5 cells/well) were seeded into 12-well plates. After 24 h, the cells were treated with 6-DG for another 24 h followed by replacement with fresh medium containing 600 μM H_2O_2 for 12 h or 200 μM 6-OHDA for 24 h. Hoechst 33342 was subsequently added to a final concentration of 5 μg/mL to stain the nuclei. The cells were visualized and photographed under a Leica inverted fluorescent microscope. For assaying the ROS, the medium was removed, and DCFH-DA in fresh FBS-free medium was added (10 μM); incubation was continued for 30 min at 37 °C in the dark. The cells were visualized and photographed under fluorescent microscopy.

Measurement of Caspase-3 Activity. PC12 cells (1×10^6 cells/well) were seeded in 60 mm dishes for 24 h and then treated with different concentrations of 6-DG for another 24 h. After replacement with fresh medium containing 600 μM H_2O_2 or 200 μM 6-OHDA for 24 h, the cells were lysed with RIPA buffer. The protein content was quantified using the Bradford procedure. The caspase-3 activity in the lystae was determined by following the published procedure.[38] Briefly, a cell extract containing 15 μg of total proteins was incubated with the assay mixture (50 mM Hepes, 2 mM EDTA, 5% glycerol, 10 mM DTT, 0.1% CHAPS, 0.2 mM Ac-DEVD-pNA, pH 7.5) for 4 h at 37 °C in a final volume of 100 μL. The absorbance at 405 nm was measured using a microplate reader. The same amounts of DMSO were added to the control experiments, and the activity was expressed as the percentage of the control.

Measurement of Total Glutathione, NQO1 Activity, Trx Activity, and TrxR Activity. PC12 cells (1×10^6 cells/well) were seeded in 60 mm dishes for 24 h and treated with different concentrations of 6-DG for another 24 h. After replacement with fresh medium containing H_2O_2 (600 μM) for 12 h or 6-OHDA (200 μM) for 24 h, cells were collected and resuspended in extraction buffer containing 0.1% Triton X-100 and 0.6% sulfosalicyclic acid in 0.1 M PBS with 5 mM EDTA, pH 7.5 (KPE buffer). The suspension was sonicated on ice for 2−3 min with vortexing every 30 s. The cells were centrifuged at 3000g for 4 min at 4 °C, and the supernatant was ready for the total GSH assay by enzymatic detection as described in the published protocols.[39] A 120 μL solution containing 0.33 mg/mL DTNB and 1.66 units/mL glutathione reductase was added to each sample (20 μL). β-NADPH (60 μL of 0.66 mg/mL) was then added quickly, and the absorbance at 412 nm was measured every 15 s for 2 min. The rate of chromophore production at 412 nm is proportional to the concentration of glutathione within the sample. The total glutathione content in the samples was determined by comparison with the predetermined glutathione standard curve. For measuring NQO1, Trx, and TrxR activity, the cells were lysed in RIPA buffer. The total protein content was quantified using the Bradford procedure. The NQO1 activity was determined spectrophotometrically by monitoring the reduction of the electron acceptor, DCPIP, at 600 nm.[40] The enzymatic reaction was initiated by the addition of cell lysate (5 μg of total protein) to the reaction mixture (20 mM Tris-HCl, pH 7.4, 200 μM NADH, and 40 μM DCPIP), and the decrease in absorbance at 600 nm was measured every 8 s for 2 min at room temperature in the presence or absence of 20 μM dicoumarol. The dicoumarol-inhibitable part of DCPIP's reduction was used to calculate the NQO1 activity. The same amounts of DMSO were added to the control experiments, and the activity was expressed as the percentage of the control. The Trx and TrxR activities in the lysate were determined by following the published protocols.[41] To determine the activity of TrxR, the cell extract containing 20 μg of total proteins was incubated in a final reaction volume of 50 μL containing 100 mM

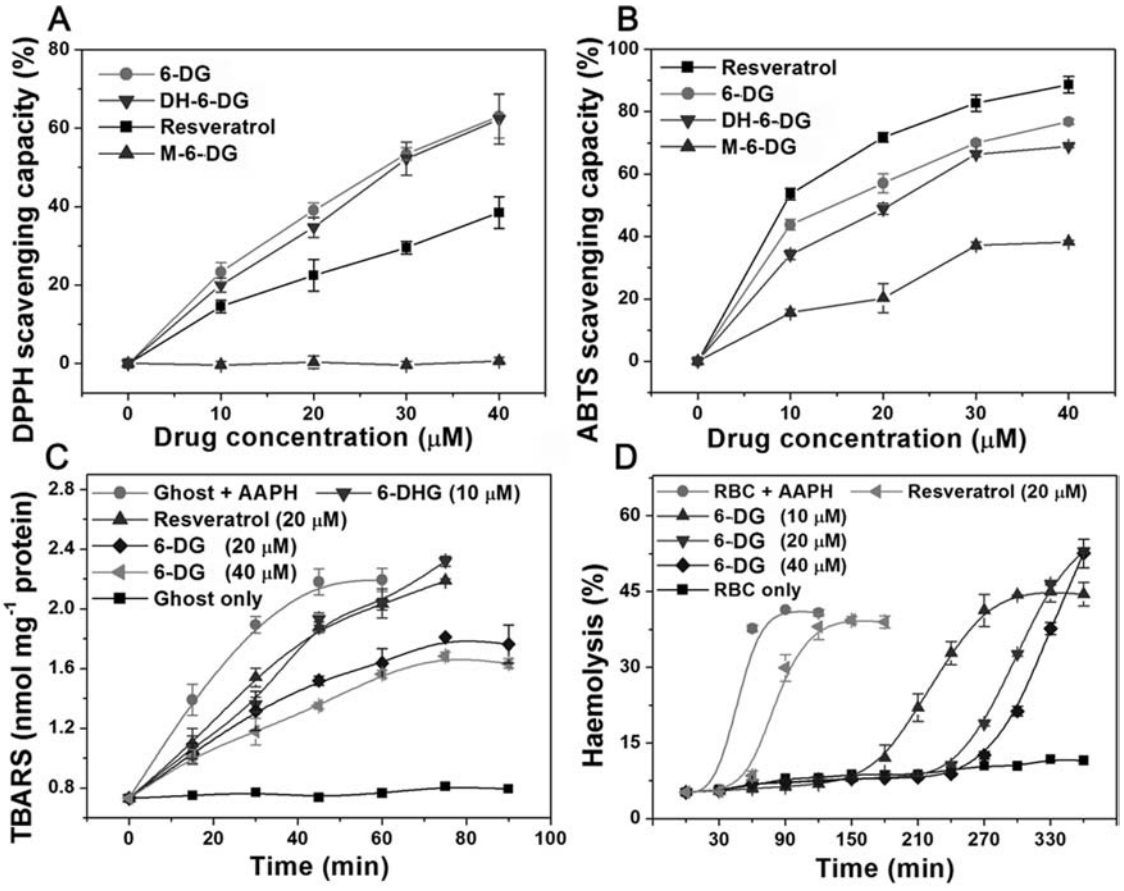

Figure 1. Antioxidant activity of 6-DG in vitro: (A) DPPH and (B) $ABTS^{\bullet+}$ scavenging abilities measured as described under Materials and Methods; (C) inhibition of TBARS formation during the AAPH-induced peroxidation of erythrocyte ghost by 6-DG; (D) protection of 6-DG against AAPH-induced hemolysis of RBC. Data represent the mean ± SD of three independent experiments.

Tris-HCl (pH 7.6), 0.3 mM insulin, 660 μM NADPH, 3 mM EDTA, and 15 μM *Escherichia coli* Trx for 30 min at 37 °C. To determine the activity of Trx, the cell extract containing 20 μg of total proteins was incubated in a final reaction volume of 50 μL containing 100 mM Tris-HCl (pH 7.6), 0.3 mM insulin, 660 μM NADPH, 3 mM EDTA, and 60 nM recombinant rat TrxR1 for 30 min at 37 °C. The reaction was terminated by adding 200 μL of 1 mM DTNB in 6 M guanidine hydrochloride, pH 8.0. A blank sample, containing everything except Trx (for TrxR assay) or TrxR (for Trx assay), was treated in the same manner. The absorbance at 412 nm was measured, and the blank value was subtracted from the corresponding absorbance value of the sample. The same amounts of DMSO were added to the control experiments, and the activity was expressed as the percentage of the control.

Real-Time Reverse Transcription-PCR (RT-PCR). PC12 cells (1×10^6 cells/well) were seeded in 60 mm dishes for 24 h and treated with 10 μM 6-DG for 0, 6, 12, and 24 h. Total RNA was isolated from cells using the RNAiso plus (TaKaRa, Dalian, China) according to the manufacturer's protocol and quantified through 260/280 absorbance. Reverse transcription was performed using Primescript RT reagent kit according to the manufacturer's protocol (TaKaRa). RT-PCR was performed on an Mx3005P RT-PCR System (Agilent Technologies) using SYBR Green PCR Master Mix (Takara) . The GAPDH was used as an internal control. Target gene expression was measured and was normalized to the GAPDH expression level. PCR primers specific to each gene are as follows: GAPDH, 5′-cagtgccagcctcgtctcat-3′ and 5′-aggggccatccacagtcttc-3′; HO-1, 5′-gccctggaagaggagatagag-3′ and 5′-tagtgctgtgtggctggtgt-3′; NQO1, 5′-tcaccactctactttgctccaa-3′ and 5′-ttttctgctcctcttgaacctc-3′; Trx1, 5′-ccttctttcattccctctgtgac-3′ and 5′-cccaacctttgaccctttttat-3′; TrxR1, 5′-actgctcaatccacaaacagc-3′ and 5′-ccacggtctctaagccaatagt-3′; GCLC, 5′-caaggacaagaacacaccatct-3′ and 5′-cagcactcaaagccataacaat-3′; GCLM, 5′-ggcacaggtaaaacccaatagt-3′ and 5′-ttcaatgtcagggatgctttct-3′. GAPDH was used as an internal control. Target gene expression was measured and was normalized to the GAPDH expression level.

Preparation of Different Protein Extracts for Western Blot Analysis.[42] For the whole cell protein extraction, PC12 cells were lysed with RIPA buffer. For the cytosolic and nuclear extracts, the cells were rinsed with ice-cold PBS and resolved in 100 μL of buffer A (10 mM Hepes, pH 7.9, 10 mM KCl, 0.1 mM EDTA, 0.1 mM EGTA, 1 μM DTT, and 1 μM protease inhibitor cocktail freshly added to buffer A). After 15 min of incubation, 10 μL of Nonidet-P40 (10%) was added, and the mixture was vortexed for 15 s. Thereafter, the lysate was repeatedly centrifuged for 10 min (1000*g*, 4 °C) to separate the nuclear from the cytosolic fraction. The pellet was resuspended in 100 μL of buffer B (20 mM Hepes, pH 7.9, 0.4 M NaCl, 1 mM EDTA, 1 mM EGTA, 1 μM DTT, and 1 μM protease inhibitor cocktail were freshly added to buffer B) and incubated on ice for 15 min, and the mixture was vortexed for 10−15 s every 2 min. After a final centrifugation step for 10 min (20000*g*, 4 °C), the supernatant was collected as the nuclear extract. The band intensity was analyzed and quantified by Image pro plus (IPP) software.

Knockdown of Nrf2 Expression Using Short Hairpin RNAs. Three shRNAs (shNrf2-842, shNrf2-184, and shNrf2-136) targeting rat Nrf2 gene and one shRNA with scrambled sequence (shNT) as control were used for Nrf2 knockdown experiments. Exponentially growing cells were transfected with different shRNAs using GeneTran III transfection reagent according to the manufacturer's instruction. After 48 h of transfection, the cells were maintained in DMEM, 10% FBS, 2 mM glutamine, 100 units/mL penicillin/streptomycin at 37 °C in a humidified atmosphere of 5% CO_2 and selected by

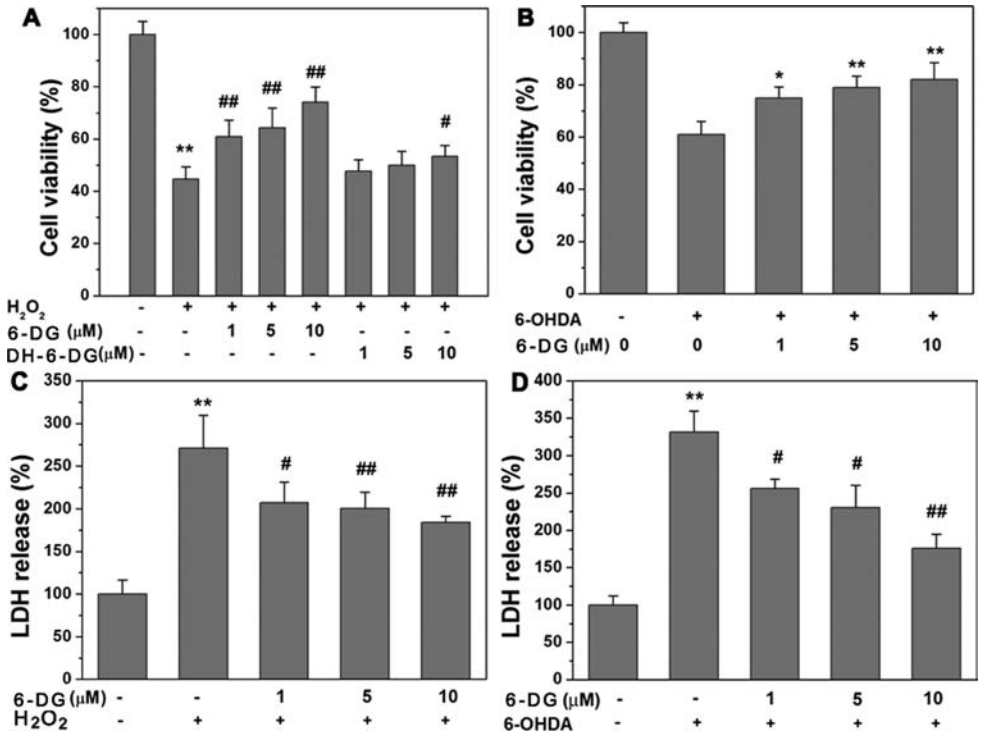

Figure 2. Protection of 6-DG against (A) H_2O_2- and (B) 6-OHDA-induced PC12 cell damage. PC12 cells (1×10^4 cells/well) were plated in a 96-well plate for 1 day and subsequently treated with 6-DG for another 24 h. After replacement of the medium containing H_2O_2 or 6-OHDA and continued incubation for indicated times, cell viability was measured by MTT assay. The content of LDH in the medium after H_2O_2 (C) or 6-OHDA (D) treatment was determined as described under Materials and Methods. All data represent the mean ± SD of three independent experiments. (*) $P < 0.05$ and (**) $P < 0.01$ versus the vehicle group; (#) $P < 0.05$ and (##) $P < 0.01$ versus the H_2O_2- or 6-OHDA-treated group.

supplementation with 0.5 mg/mL of G418. Knockdown of the Nrf2 expression in the cells was analyzed by Western blotting.

Statistics. Data are presented as the mean ± standard deviation (SD). Statistical differences between two groups were assessed by Student's *t* test. Comparisons among multiple groups were performed using one-way analysis of variance (ANOVA), followed by a post hoc Scheffe test. $P < 0.05$ was used as the criterion for statistical significance.

RESULTS

Scavenging of Free Radicals in Vitro. Previous studies have indicated that 6-DG is an effective antioxidant.[25] We further investigated herein the potency of 6-DG in scavenging free radicals in vitro. As shown in Figure 1A,B, 6-DG dose-dependently neutralizes DPPH and ABTS free radicals. To address the role of the hydroxyl group in scavenging radicals, we prepared M-6-DG, the methylated form of 6-DG. M-6-DG completely lost the ability to quench DPPH, whereas it retained partial capacity to scavenge ABTS. The remaining activity might be due to the 1,3-diketone structure in 6-DG as this moiety could also quench radicals.[25] Our results demonstrated the critical role of the hydroxyl group in scavenging free radicals. Thermal decomposition of AAPH in aqueous solution under aerobic condition constantly generates peroxyl radicals,[36] which attack membrane lipids to induce lipid peroxidation. We found 6-DG efficiently protects the erythrocyte ghost from AAPH-induced formation of TBARS, a biomarker of lipid peroxidation (Figure 1C). In the model of AAPH-induced hemolysis of intact human RBC, 6-DG remarkably retards the hemolysis with a clear concentration dependence (Figure 1D).

Protection of PC12 Cells from H_2O_2- and 6-OHDA-Induced Damage. As 6-DG demonstrates potent antioxidant activity in vitro, we next investigated if 6-DG has a protective effect against oxidative stress-induced neuronal cell death. 6-DG shows weak cytotoxicity toward PC12 cells, and significant cytotoxicity was observed only at high concentrations (>50 μM, data not shown). As shown in Figure 2A, compared with the control group, PC12 cells treated with H_2O_2 for 12 h showed about 60% cell death. However, pretreatment of cells with 6-DG at nontoxic concentrations (1−10 μM) for 24 h followed by H_2O_2 challenge significantly decreased the population of dead cells to about 30%. This protection was observed even at 1 μM 6-DG. However, hydrogenation of 6-DG to DH-6-DG almost completely blocked the protection, indicating the importance of the α,β-unsaturated ketone structure in 6-DG. The neurotoxin 6-OHDA has been widely used to generate an experimental model of PD. 6-OHDA-mediated neurotoxicity is engendered, at least in part, by generation of ROS.[43] 6-OHDA treatment reduced cell viability to about 60% of control (Figure 2B). Similarly, addition of 6-DG also markedly promoted cell viability to >80% of control. LDH is a soluble cytosolic enzyme that is released into the culture medium following loss of membrane integrity resulting from cell damage. To confirm the neuroprotection of 6-DG, we determined the content of LDH leakage after H_2O_2 or 6-OHDA insult (Figure 2C,D). Both H_2O_2 and 6-OHDA cause ∼3-fold increase of LDH release. Pretreatment of PC12 cells with 6-DG significantly reduces the leakage of LDH. Taken together, 6-DG at nontoxic concentration can significantly protect PC12 cells from H_2O_2- and 6-OHDA-induced cell damage.

Alleviation of H_2O_2- and 6-OHDA-Induced PC12 Cell Apoptosis by 6-DG. Apoptosis is a precisely regulated process of cell destruction with specific defining morphological and molecular features. Two known apoptotic signaling

dx.doi.org/10.1021/jf405553v | J. Agric. Food Chem. 2014, 62, 5507−5518

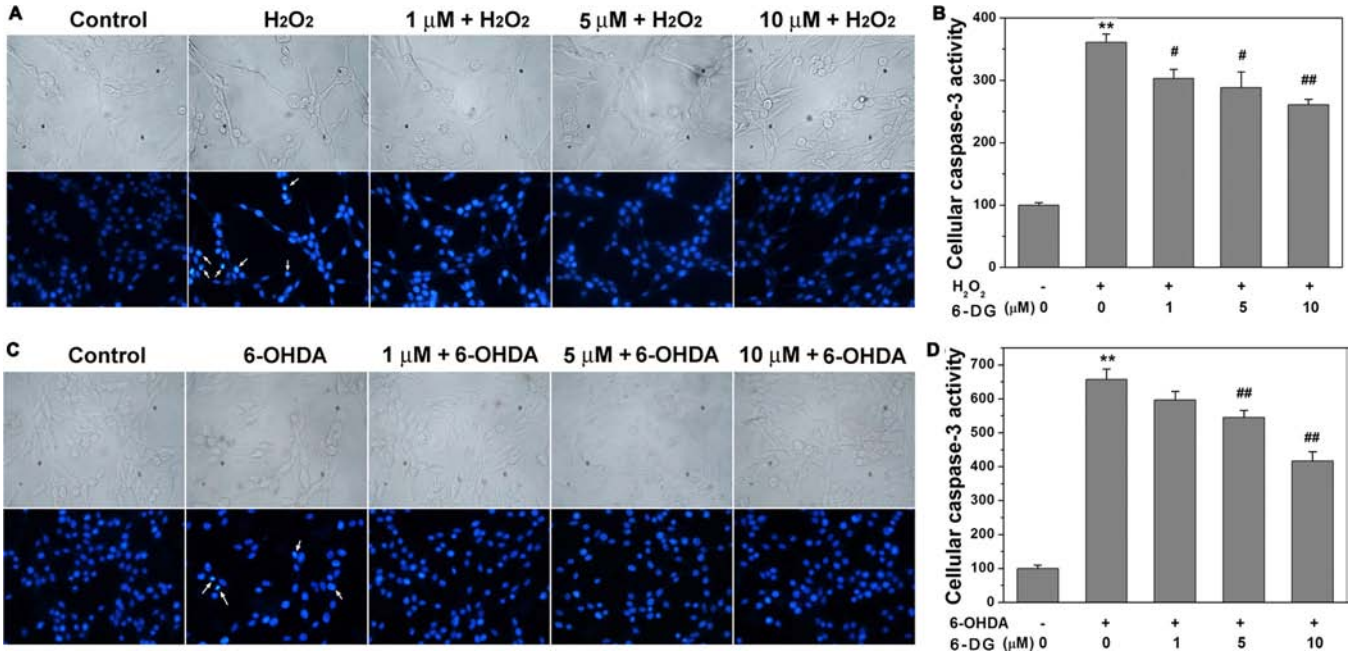

Figure 3. Inhibition of H_2O_2- or 6-OHDA-induced apoptosis in PC12 cells. PC12 cells were treated as described under Materials and Methods, and the morphological changes of nuclei were determined by Hoechst 33342 staining (A, C). Activation of the cellular caspase-3 was determined by a colorimetric assay as described under Materials and Methods. Data represent the mean ± SD of three independent experiments. (**) $P < 0.01$ versus the vehicle group; (#) $P < 0.05$ and (##) $P < 0.01$ versus the H_2O_2- or 6-OHDA-treated group.

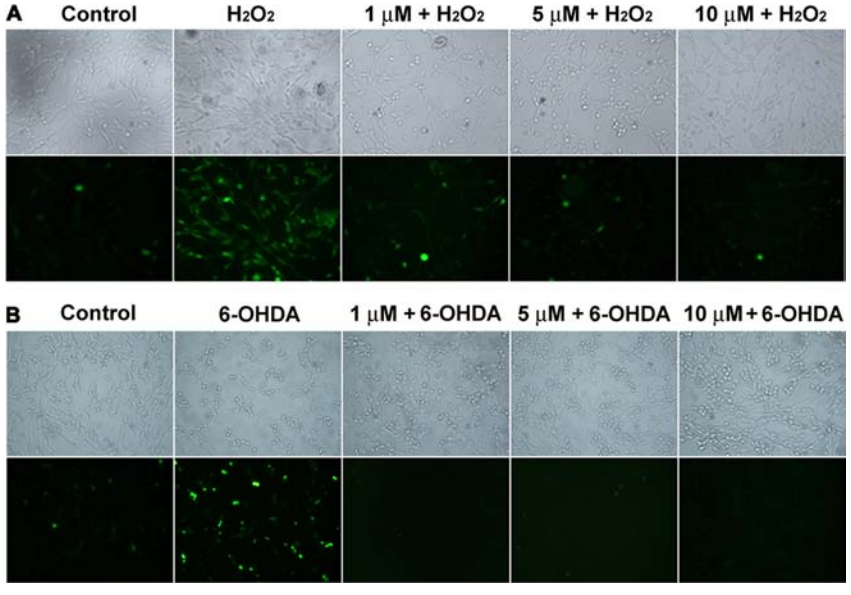

Figure 4. Prevention of ROS accumulation in PC12 cells by 6-DG. Pretreatment with 6-DG significantly alleviates ROS accumulation induced by H_2O_2 (A) or 6-OHDA (B) determined by DCFH-DA staining as described under Materials and Methods. The phase contrast (top panel) and fluorescence (bottom panel) images were acquired by inverted fluorescence microscopy.

pathways, the extrinsic cell surface receptor pathway[44] and the intrinsic mitochondrial pathway,[45] converge on the caspase activation.[46] As shown in Figure 3A,C, both H_2O_2 and 6-OHDA elicit apoptosis in PC12 cells evidenced by the appearance of apoptotic nuclei as highly fluorescent, condensed bodies (indicated by arrows), whereas no apoptotic nuclei were observed in control cells. Pretreatment of PC12 cells with 6-DG remarkably lowers the population of apoptotic nuclei. Activation of caspase-3 is a biochemical character in all apoptotic cells.[47] We thus further quantified the level of caspase-3 activation. Both H_2O_2 and 6-OHDA activate the cellular caspase-3, but with different potencies (Figure 3B,D). Again, 6-DG significantly alleviates the extent of caspase-3 activation in a concentration-dependent manner. Collectively, 6-DG, at nontoxic concentrations, can alleviate H_2O_2- and 6-OHDA-induced apoptosis in PC12 cells.

Inhibition of ROS Accumulation in PC12 Cells. DCFH-DA is a cell membrane permeable dye. After diffusing into cells, DCFH-DA is deacetylated by cellular esterases to non-fluorescent 2′,7′-dichlorodihydrofluorescin, which is rapidly converted to highly fluorescent 2′,7′-dichlorofluorescein upon reacting with ROS. Stimulation of the cells with H_2O_2 or 6-

OHDA leads to an intracellular burst of ROS, whereas the control cells display negligible ROS level (Figure 4). Pretreatment of the cells with 6-DG dose-dependently reduces the ROS accumulation. As oxidative stress, arising from the overproduction of ROS, has been implicated in a final common pathway for neurotoxicity in a wide variety of acute and chronic neurological disorders, the inhibition of ROS accumulation in neuronal cells might be the molecular basis of the neuroprotective action of 6-DG.

Induction of Phase II Gene Expression. Analysis of the chemical structure of 6-DG reveals that there is one Michael acceptor moiety (highlighted in a circle in Scheme 1), which is a core structure of many ARE inducers.[5,10,13] In analogy to known ARE activators, we thus hypothesized that 6-DG might activate the cellular ARE response. We measured the expression of Nrf2-driven antioxidant genes (HO-1, NQO1, Trx1, TrxR1, GCLC, and GCLM) after treatment with 6-DG (10 μM) in PC12 cells (Figure 5). The time course studies showed the highest induction of all genes at 6 h after stimulation with 6-DG. A >10-fold increase of the HO-1 mRNA was observed after 6 h of treatment, consistent with HO-1 being a sensitive marker for oxidative/electrophilic stress. The expression of the genes decreased after 6 h, but was still significantly higher at 12 h compared to the control. After treatment with 6-DG for 24 h, the mRNA levels of HO-1 and TrxR1 were back to the control level, whereas the others remained significantly elevated. Taken together, these results indicate that 6-DG is a potent activator of Nrf2-regulated antioxidant defenses.

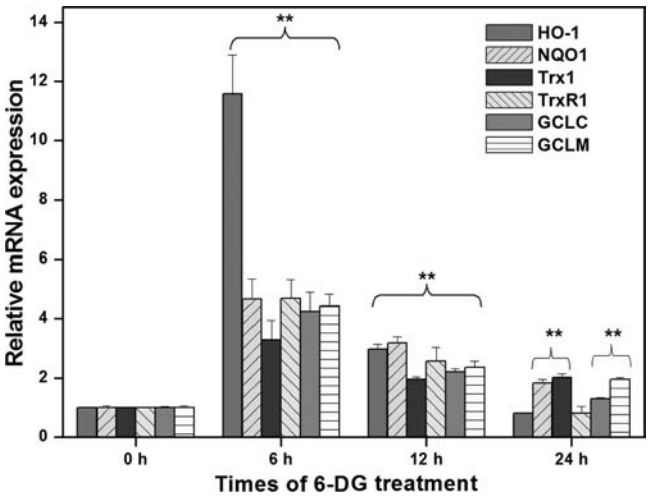

Figure 5. Induction of cytoprotective genes in PC12 cells by 6-DG. The cells were treated as described under Materials and Methods, and the mRNA levels of different genes were analyzed and normalized using GAPDH as an internal standard by qRT-PCR as described. Data represent the mean ± SD of three independent experiments. (**) $P < 0.01$ versus the control group (0 h).

Up-regulation of the Antioxidant Defense System in PC12 Cells. The induction of phase II detoxifying enzymes is an important defense mechanism against exogenous insult. As a series of phase II genes has been up-regulated at different levels, we then examined the corresponding gene products. 6-DG dose-dependently elevated HO-1, NQO1, Trx1, and TrxR1 protein expression and cellular GSH level in PC12 cells (Figure 6). By adopting the convenient assays, we further determined the cellular activity of NQO1, Trx1, and TrxR1. In line with the up-regulation of protein expression, all of the enzymes' activities were significantly increased (Figure 6E,H,K). After 6-DG (10 μM) treatment, the total GSH level (Figure 6L), NQO1 activity (Figure 6E), Trx activity (Figure 6H), and TrxR activity (Figure 6K) were increased by ∼1.6-, ∼2-, ∼1.7-, and ∼1.3-fold, respectively. H_2O_2 and 6-OHDA treatments caused serious GSH depletion (Figure 6M,N), whereas pretreatment with 6-DG gradually restored the total GSH level.

Promotion of Nrf2 Nuclear Localization by 6-DG. Induction of antioxidant gene expression via the Nrf2-dependent cytoprotective pathway requires translocation of Nrf2 from cytosol to nucleus. We therefore examined whether 6-DG could activate the Nrf2 signaling pathway in PC12 cells. Upon 6-DG treatment, immunoblotting results revealed that the Nrf2 expression slightly increased with peaking at 4 h and gradually decreased to the basal level (Figure 7A). Notably, the cytosolic Nrf2 decreased progressively, in coincidence with its continuous rise in the nucleus (Figure 7B,C), indicating the translocation of Nrf2 from cytosol to nucleus. The accumulation of Nrf2 in nuclei thus facilitates its binding to ARE and subsequently initiates the transcription process.

Involvement of Nrf2 in Neuroprotection of 6-DG. To further clarify whether 6-DG protects PC12 cells via the Nrf2 pathway, we conducted Nrf2 knockdown experiments in PC12 cells. The knockdown efficiency of different shRNAs (shNrf2-842, shNrf2-184, shNrf2-136, and shNT) was validated by Western blots (Figure 8A). The expression of Nrf2 protein in all cells transfected with shNrf2s was drastically decreased. Next, we evaluated the protective effect of 6-DG against oxidative insult toward the transfected cells. In line with the cytoprotective function of Nrf2, silence of Nrf2 expression slightly increased the cytotoxicity of H_2O_2 and 6-OHDA (Figure 8B,C). 6-DG displays a similarly protective pattern in PC12-shNT cells as observed in normal PC12 cells. However, this protection drops remarkably in PC12 cells transfected with different shNrf2 plasmids, and the most significant results were observed in PC12-shNrf2-842 cells, where the protection of 6-DG is almost completely abolished upon either H_2O_2- or 6-OHDA-induced cell death. In PC12-shNrf2-184 and PC12-shNrf2-136 cells, the protection of 6-DG is only partially lost. This could be due to the variation of the silence efficiency in cells. Although the protection of 6-DG declines to variable levels in different Nrf2 knockdown cells, the extents of all the decrease are significant. Taken together, these results indicate that the cytoprotection of 6-DG in PC12 cells was mediated through the action of Nrf2.

■ DISCUSSION

ROS are constantly produced under physiological metabolisms, and the intricate balance between their production and neutralization is controlled dynamically by the cellular antioxidant defense system. Oxidative stress, arising from excessive production of ROS, causes damage to proteins, lipids, and nucleic acids and eventually entails cell death. Neuronal cells in the brain are particularly vulnerable to oxidative stress as they possess high concentrations of oxidizable unsaturated fatty acids and high levels of pro-oxidants (e.g., iron) and show high oxygen consumption and low levels of antioxidant defense capacities.[48] Consistent with the above-described sense, there has been increasing evidence underpinning oxidative stress as a major cause in a number of neurodegenerative disorders such as AD and PD.[8,9] Treatment through replacing the dying or dead neurons in these diseases has been demonstrated with limited success.[49] Therefore, pharmacological interventions aiming at

alleviating the oxidative stress are promising to confer protection to neuronal cells, eventually leading to retardation or blockage of the progression of these neurodegenerative diseases. Tactics against oxidative stress include direct antioxidant action by ROS neutralization, as well as indirect antioxidant defense by awakening the pathway(s) involved in the expression of endogenous cytoprotective molecules. In this regard, accumulating attention has been paid to discovering antioxidants or molecules that can induce endogenous

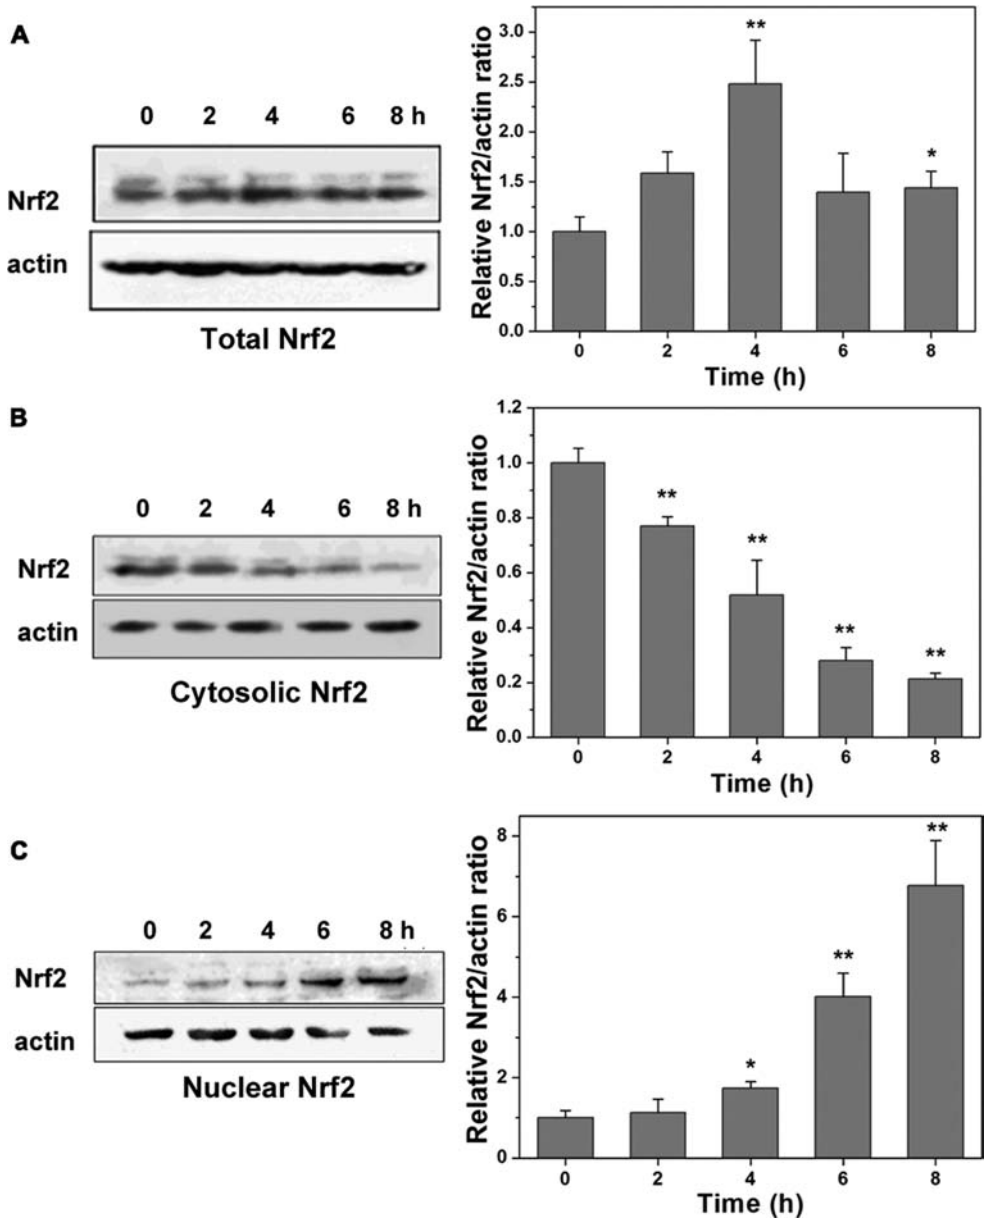

Figure 7. Promotion of Nrf2 nuclear accumulation by 6-DG. After the cells were treated with 6-DG (10 μM) for 0, 2, 4, 6, or 8 h, the cells were harvested and different cell extracts were prepared as described. Total Nrf2 (A), cytosolic Nrf2 (B), and nuclear Nrf2 (C) were analyzed by Western blotting with an antibody against Nrf2. Actin was used as a loading control. Quantification of the blots is presented in the right-hand panel. Data are expressed as the mean ± SD of three experiments. (*) $P < 0.05$ and (**) $P < 0.01$ versus the control group (0 h).

antioxidant defense as potential therapeutic agents for neurodegenerative diseases.[13,16,50,51]

This study demonstrated for the first time that 6-DG, an active constituent from dietary plant ginger, was a promising neuroprotective agent. Although 6-gingerol and 6-shogaol are two major components of ginger, the amount of 6-DG in ginger is also significantly high (up to 20 mg/100 g ginger).[52] Compared to 6-shogaol and 6-DG, 6-gingerol appears to have lower biological activity in different model systems.[53−57] 6-DG has a larger conjugated system than 6-shogaol and contains one additional active 1,3-diketone moiety, which could explain why 6-DG displays better antioxidant activity than 6-shogaol does.[53,54] Furthermore, 6-DG shows lower cytotoxicity than 6-shogaol.[55] The high antioxidant activity and low cytotoxicity make 6-DG an ideal molecule for further development as a therapeutic agent. In our present work, we found that 6-DG, as low as 1 μM, could significantly protect neuronal cells from oxidative insult. This concentration could be easily reached by daily intake of ginger or ginger products. The contribution of 6-DG to the observed activities of ginger and the physiological significance of the neuroprotective action of 6-DG require further investigation.

6-DG both acts as a direct antioxidant in scavenging free radicals in vitro and confers protective effects against oxidative stress-induced neuronal cell damage by activating the cellular antioxidant defense systems. As a phenolic compound, the direct antioxidant action depends primarily on the ability of 6-DG to donate its phenolic H atom to different radicals via a hydrogen abstraction reaction. Our result that M-6-DG almost completely lost free radical-scavenging activity (Figure 1A,B) supports that the hydroxyl group in 6-DG plays a key role in the direct antioxidant activity. More importantly, 6-DG, via

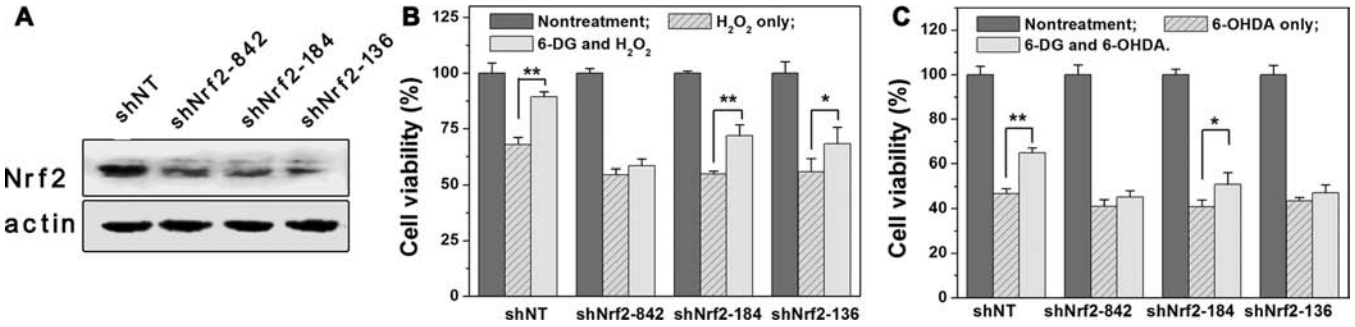

Figure 8. Involvement of Nrf2 in the cytoprotection of 6-DG in PC12 cells. (A) Evaluation of Nrf2 knockdown efficiency by different shRNAs. PC12 cells were transfected with shRNAs specifically targeting rat Nrf2 gene (shNrf2s) or nontargeting shRNA (shNT), and the efficiency of silencing Nrf2 was evaluated by Western blots. (B, C) Impairment of cytoprotection of 6-DG in Nrf2-knockdown cells. Different PC12 cells were treated with 6-DG for 24 h followed by treatment with 600 μM H_2O_2 for 12 h or 200 μM 6-OHDA for 24 h. Cell viability was determined by MTT assay. Results are represented as the mean ± SD (n = 6). (**) $P < 0.01$ and (*) $P < 0.05$.

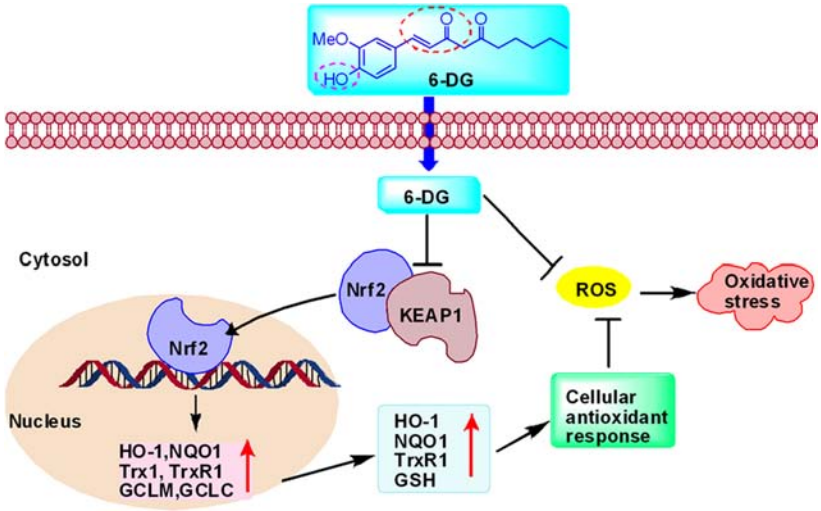

Figure 9. Dual neuroprotective mode of 6-DG in PC12 cells.

activation of the Keap1-Nrf2-ARE pathway, awakens the endogenous antioxidant defense system, including stimulation of GSH synthesis and up-regulation of diverse antioxidant enzyme expression and activity. The nuclear translocation of Nrf2 is a prerequisite for induction of the endogenous antioxidant defense. However, the mechanisms underlying such a process are not well understood but may involve oxidation/alkylation of key thiols in Keap1 and/or phosphorylation of Nrf2.[58] Upon exposure to electrophiles or oxidants, the Cys-rich protein Keap1 is modified by forming a covalent adduct or disulfide bonds within the protein, and it is this Cys-based modification of Keap1 that allows dissociation, accumulation, and subsequent nuclear translocation of Nrf2, where it initiates the transcription of cytoprotective genes (phase II genes).[58] Analysis of the chemical structure of 6-DG reveals that the molecule contains one α,β-unsaturated ketone moiety (highlighted in Scheme 1), a thiol-reactive electrophilic center that may covalently modify the Cys thiols. Many natural or synthetic molecules bearing such a structure are known to be effective inducers of phase II genes.[5,10,59] Thus, we speculated that alkylation of certain Cys residues might be the molecular basis for the activation of the Keap1-Nrf2-ARE pathway by 6-DG, which was supported by the observation that removal of the electrophilic center from 6-DG severely blocks the protection (Figure 2A). The observation that knocking down Nrf2 expression abolishes the effect of 6-DG suggests that the cytoprotection of 6-DG is mediated, at least in part, via Nrf2 activation.

Our findings suggest a dual neuroprotective mechanism of 6-DG shown schematically in Figure 9. The lipophilic character of 6-DG allows it to easily pass the plasma membrane and accumulate within cells. As a phenolic compound, 6-DG may directly counteract against various ROS. Furthermore, 6-DG, like many other electrophiles,[5,10,59] could selectively interact with the Cys residue(s) on the cytosolic protein Keap1, which is an adaptor protein for ubiquitinating Nrf2 and, thus, drives the continuous degradation of Nrf2. The binding of 6-DG to Keap1 perturbs the Keap1-Nrf2 complex and stabilizes Nrf2, causing the liberation of Nrf2 and enabling it to be translocated into nucleus, where it binds to ARE and stimulates the transcription of cytoprotective genes. Thus, 6-DG provides dual protection against oxidative stress-induced neuronal cell damage.

In conclusion, we have demonstrated that 6-DG was effective in preventing oxidative stress-induced neuronal cell damage. This neuroprotection may involve its capacity in directly neutralizing free radicals and activating endogenous cellular antioxidant defense. The hydroxyl group is critical for the direct antioxidant activity, whereas the α,β-unsaturated ketone structure is indispensable for activation of the Keap1-Nrf2-ARE pathway in cells. Our discovery will provide deep insights in understanding 6-DG effects in vivo, and this protective

dx.doi.org/10.1021/jf405553v | J. Agric. Food Chem. 2014, 62, 5507−5518

mechanism could lead to the development of novel small molecules as potential neuroprotective agents.

Supporting Information

ABSTRACT: *Artocarpus heterophyllus* is an evergreen fruit tree cultivated in many tropical regions. Previous studies have shown that some of its compositions exhibited potential tyrosinase inhibition activities. This study indentified 8 new phenolic compounds, artoheterophyllins E−J (**1**−**6**), 4-geranyl-2′,3,4′,5-tetrahydroxy-*cis*-stilbene (**7**), and 5-methoxymorican M (**8**) and 2 new natural compounds (**9** and **10**), 2,3-dihydro-5,7-dihydroxy-2-(2-hydroxy-4-methoxyphenyl)-4*H*-benzopyran-4-one and 6-[(1*S*,2*S*)-1,2-dihydroxy-3-methylbutyl]-2-(2,4-dihydroxyphenyl)-5-hydroxy-7-methoxy-3-(3-methyl-2-buten-1-yl)-4*H*-1-benzopyran-4-one, together with 23 known compounds (**11**−**33**), from the ethanol extract of the wood of *A. heterophyllus*. The structures of the eight new compounds (**1**−**8**) and two new natural compounds were established by extensive 1D- and 2D-NMR experiments. The anticancer effects of the isolated compounds were examined in MCF-7, H460, and SMMC-7721 human cancer cell lines by MTT assay. Compounds **5**, **11**, **12**, and **30** significantly reduced the cell viabilities of these cell lines. Especially, compounds **11** and **30** resulted in more potent cytotoxicity than the positive control, 5-fluorouracil (5-Fu), in SMMC-7721 cell line, with IC_{50} values of 15.85 and 12.06 μM, whereas compound **30** exhibited more potent cytotoxicity than 5-Fu in NCI-H460 cell line, with an IC_{50} value of 5.19 μM. In addition, this study suggests that compounds **11** and **30** from the wood of *A. heterophyllus* have anticancer potential via MAPK pathways.

KEYWORDS: *Artocarpus heterophyllus, phenolic compounds, anticancer activity*

INTRODUCTION

Mitogen-activated protein kinases (MAPKs) are serine−threonine kinases, which include extracellular signal-regulated kinase (ERK), p38, and c-Jun NH_2-terminal kinase (JNK). MAPK pathways regulate intracellular signaling including cell apoptosis, proliferation, differentiation, survival, and death.[1] ERKs, JNKs, and p38 MAPKs play a complicated role in cancer development. These MAPK pathways could antagonize cell proliferation, survival, and invasion in some types of cells, whereas they could also promote morphological transformation and cell proliferation in cancer cells. The functions of MAPKs are accordingly dependent on the different cells' responses.[2−5] Especially, these MAPK pathways are expected to provide new strategies for anticancer therapeutic approaches.[1] Therefore, screening selective regulators to different types of cancer cell lines is likely to be a better route to cancer therapies targeted against MAPK pathways.

Artocarpus heterophyllus (jackfruit) is an evergreen fruit tree belonging to the *Artocarpus* genus of the family Moraceae, found in tropical and subtropical regions. *A. heterophyllus* is widely cultivated in tropical regions of India, Bangladesh, Nepal, Sri Lanka, Vietnam, Thailand, Malaysia, Indonesia, Philippines, Africa, and Brazil.[6] It is also an important tropical fruit in southern China, distributed and cultivated in Hainan, Guangdong, Guangxi, and Yunnan provinces.[7] Previous studies suggested that *A. heterophyllus* was rich in phenolic compounds, flavonoids, stilbenoids, and arylbenzofurans and possessed wide medicinal uses including antioxidant, anti-inflammatory, antibacterial, antifungal, antineoplastic, and hypoglycemic effects.[8−13] Furthermore, the extracts and chemicals prepared from *A. heterophyllus* were also found to exhibit cytotoxic effects on T47D, SMMC-7721, SGC-7901, hepatoma, choriocarcinoma, and melanoma cell lines in vitro.[14−18] However, little information is available on the systematic study of the phenolic compounds from *A. heterophyllus* with regard to cytotoxic effects on MCF-7, SMMC-7721, and NCI-H460 cells and pathways. Therefore, we used chromatography to isolate the active components and used NMR and MS to identify the compounds, combined with cytotoxic activity assay to confirm the in vitro anticancer effects of *A. heterophyllus*.

MATERIALS AND METHODS

General Experimental Procedures. Sephadex LH-20 was purchased from GE Healthcare Bio-Sciences AB (Uppsala, Sweden). Silica gel (200−300 mesh) for column chromatography and TLC plates (HSGF254) were purchased from Yantai Jiangyou Silicone Development Co., Ltd. (Yantai, China). Amberlite XAD16 was

purchased from Sigma Chemical Co (St. Louis, MO, USA). Semipreparative HPLC was carried out on a Waters 600 system equipped with a 2487 dual-wavelength detector, Masslynx V4.0 software, and a YMC C18 (2) column (250 × 20 mm, 5 μm). ^{1}H NMR, ^{13}C NMR, DEPT, HMQC, and HMBC spectra were obtained on a Bruker 400 NMR spectrometer. Molecular weights of compounds were analyzed on a Waters Maldi Syapt Q-Tof mass spectrometer. Cell morphologies were observed with Zeiss LSM 5 EXCITER and Zeiss AXIO IMAGER A1 microscopes. Antibodies, inhibitors, and other chemicals, except as otherwise noted, were purchased from Sigma-Aldrich Chemicals.

Plant Material. The wood of *A. heterophyllus* was collected in Wenchang county, Hainan province, China, in May 2012. Voucher specimens (accession no. 20120501) were deposited at the State Key Laboratory of Food Science and Technology, Jiangnan University.

Extraction and Isolation. The wood of *A. heterophyllus* (10 kg) was batched 20 times with 95% ethanol (3 × 2 L) under ultrasound condition. The extract was concentrated under vacuum at 45 °C with a rotor evaporator, and 272.2 g of crude extract was afforded. The crude extract was separated with an Amberlite XAD16 column (eluted with 20, 40, 60, 80, and 95% ethanol) to afford six fractions (1−6). Fraction 1 (5.5 g, 20% ethanol fraction) was subjected to Sephadex LH-20 and was eluted by MeOH/H_2O (1:1) to afford two fractions (1A and 1B). Fraction 1A (4.2 g) was purified by silica gel and was eluted by ethyl acetate/hexane (1:1) to afford **19** (3.8 g). Fraction 1B (86 mg) was further separated by preparative HPLC (eluted by 45% MeOH) to afford **27** (28 mg). Fraction 2 (2.0 g, 40% ethanol fraction) was subjected to silica gel and was eluted by ethyl acetate/hexane (3:1), and then it was separated by Sephadex LH-20 [eluted by MeOH/H_2O (1:1)] to afford **1** (8.8 mg) and another fraction (subfraction A). Subfraction A was further purified by HPLC to obtain **32** (1.9 mg) and **33** (3.4 mg). Fraction 3 (12.7 g, 60% ethanol fraction) was separated by silica gel [CH_2Cl_2/MeOH (20:1)] to give three fractions (3A−3C). Fraction 3A was further purified by Sephadex LH-20 [MeOH/H_2O (1:1)] to get **14** (752 mg). Fraction 3B was separated by Sephadex LH-20 [MeOH/H_2O (1:1)] to afford **16** (2596.4 mg), **22** (6.5 mg), **26** (8.4 mg), **21** (399.3 mg), and **8** (3.1 mg). Fraction 3C was separated by Sephadex LH-20 [MeOH/H_2O (1:1)] to afford two subfractions (B and C). Subfraction B was purified by silica gel [CH_2Cl_2/MeOH (25:1)] to give **28** (14.6 mg). Subfraction C was separated by silica gel [CH_2Cl_2/MeOH (30:1)] and HPLC (47% MeOH) to afford **3** (1.5 mg). Fraction 4 (15.8 g, 60% ethanol fraction) was separated by silica gel [hexane/ethyl acetate (3:1)] to give five fractions (4A−4E). Fraction 4A was purified by Sephadex LH-20 [MeOH/H_2O (1:1)] to afford **20** (2059.3 mg). Fraction 4B was separated by Sephadex LH-20 [MeOH/H_2O (1:1)] to get **23** (24.6 mg). Fraction 4C was purified by Sephadex LH-20 [MeOH/H_2O (1:1)] to obtain **24** (185 mg), **29** (18 mg), and another fraction (subfraction D). Subfraction D was purified by HPLC (60% MeOH) to obtain **7** (13.7 mg). Fraction 4E was separated by Sephadex LH-20 [MeOH/H_2O (1:1)] to afford **9** (88.8 mg). Fraction 5 (24.3 g, 80% ethanol fraction) was separated by silica gel and eluted by CH_2Cl_2, CH_2Cl_2/MeOH (50:1), and CH_2Cl_2/MeOH (25:1) to afford three fractions (5A−5C). Fraction 5A was further purified by silica gel (eluted by CH_2Cl_2) to get **25** (17.4 mg) and **31** (2.6 mg). Fraction 5B was separated by silica gel [eluted by CH_2Cl_2/MeOH (50:1)] to obtain **6** (4.3 mg). Fractioin 5C was separated by Sephadex LH-20 [MeOH/H_2O (3:2)] to offer three fractions (subfractions E−G). Subfraction E was purified by silica gel [CH_2Cl_2/MeOH (50:1)] and then further separated by HPLC (72% MeOH) to give **10** (0.4 mg), **4** (0.9 mg), and **5** (1.6 mg). Subfraction F was separated by silica gel [CH_2Cl_2/MeOH (50:1)] to get **30** (210.8 mg) and another fraction (subfraction H). Subfraction H was separated by Sephadex LH-20 [MeOH/H_2O (1:1)] to get **15** (56.8 mg) and **18** (48.6 mg). Subfraction G was purified by silica gel [CH_2Cl_2/MeOH (25:1)] to obtain **2** (6.4 mg). Fraction 6 (62 g, 95% ethanol fraction) was separated by silica gel and was eluted by CH_2Cl_2 to give **11** (28.9 g), **12** (16.9 g), **13** (1.2 g), and **17** (69 mg).

CH_3-4‴,5‴), 25.1 (CH_2, CH_2-1‴), 21.2, 15.5 (CH_3, CH_3-4‴,5‴). HR-ESI-MS, m/z 471.2013 $[M + H]^+$ (calcd for $C_{26}H_{31}O_8$, 471.2013).

Cell Culture and Drug Treatment. MCF-7, SMMC-7721, and NCI-H460 cells were cultured in Dulbecco's modified Eagle medium (high-glucose) and RPMI-1640, respectively, plus 10% fetal bovine serum under standard culture conditions. When the cells grew to about 80% confluence, they were subcultured or treated with drugs. The drugs' concentrations were based on the IC_{50} for a 48 h treatment of specific agents on the different cancer cell lines. To determine whether chemicals induced cancer cell apoptosis through caspase-dependent pathways, the spectrum caspase inhibitor 50 μM broad Z-VAD-fmk was applied for 1 h before compound **11** and **30** administrations. To determine whether chemicals induced cancer cell apoptosis via p38, JNK, and ERK pathways, their inhibitors were used to pretreat 1 h before chemical treatment, including 20 μM SB203580, 20 μM SP600125, and 20 μM PD98059.

Morphological Analysis of Apoptosis by DAPI Staining. Morphological changes of apoptosis were detected by fluorescence microscopy after staining with 1 μg/mL DAPI.[19] All experiments were repeated three times.

Growth Inhibition Study. The proliferation of cells was assessed by using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) assay, as reported previously.[20] Cells were plated on 96-well microplates in 200 μL (5×10^3/well). After 24 h, the cells were treated with complete medium containing compounds (10, 25, and 50 μM) for 48 h. At the end of experiments, 20 μL of 5 μg/mL MTT was directly added to each well. Cells were then incubated at 37 °C for 4 h. Formazan was solubilized by 100 μL of DMSO and measured at 570 nm. All experiments were repeated three times.

Western Blot Analysis. Total cell lysates were denatured with sample loading buffer and then subjected to SDS-PAGE for protein separation. After transfer onto membranes, the proteins were probed with corresponding antibodies and detected by ECL detection reagents (GE). The primary antibodies for PARP were from Cell Signaling (Beverly, MA, USA). Anti-β-actin was from Sigma. Secondary anti-mouse and -rabbit were from Thermo.

Statistical Analysis. Statistical analysis was done by using a two-tailed Student's t test, and $p < 0.05$ was considered significant. Data are expressed as the mean ± SD. All assays were performed in three independent experiments.

RESULTS AND DISCUSSION

Identification of Compounds 1−33. In total, 33 phenolic compounds, including 25 flavonoids (**3**−**6**, **9**−**27**, **30**, and **31**), 3 stilbene derivatives (**2**, **7**, and **29**), 2 simple resorcinols (**32** and **33**), 2 benzofuran derivatives (**8** and **28**), and one other type of compound (**1**) were isolated from the ethanol extract of woods of *A. heterophyllus*. Their structures were identified as artoheterophyllin E (**1**), artoheterophyllin F (**2**), artoheterophyllin G (**3**), artoheterophyllin H (**4**), artoheterophyllin I (**5**), artoheterophyllin J (**6**), 2-geranyl-2′,3,4′,5-tetrahydroxy-*cis*-stilbene (**7**), 5-methoxymorican M (**8**), 2,3-dihydro-5,7-dihydroxy-2-(2-hydroxy-4-methoxyphenyl)-4*H*-1-benzopyran-4-one (**9**),[21] 6-[(1*S*,2*S*)-1,2-dihydroxy-3-methylbutyl]-2-(2,4-dihydroxyphenyl)-5-hydroxy-7-methoxy-3-(3-methyl-2-buten-1-yl)-4*H*-1-benzopyran-4-one (**10**) (Figure 1),[22] artocarpin (**11**),[23] cycloartocarpin (**12**),[23] cycloartocarpesin (**13**),[23] steppogenin (**14**),[23] artocarpesin (**15**),[23] norartocarpetin (**16**),[23] brosimone I (**17**),[23] isoartocarpesin (**18**),[23] cyanomaclurin (**19**),[23] artocarpanone (**20**),[23] albanin A (**21**),[24] artocarmin A (**22**),[24] apigenin (**23**),[25] artocarpetin (**24**),[23] gemichalcone A (**25**),[24] artocarpfuranol (**26**),[23] morin (**27**),[26] moracin M (**28**),[18] artocarbene (**29**),[27] cudraflavone C (**30**),[28] hypargyflavones A (**31**),[29] 2,4-dihydroxybenzoic acid methyl ester (**32**),[30] and 2,4-dihydroxybenzaldehyde (**33**)[31] on the basis of spectral data and literature reports. Of these, excluding the 12 compounds (**11**−**20**, **24**, and **26**) that had been isolated and identified in our previous studies,[24] an additional 21 compounds, including 8 new compounds, artoheterophyllin E (**1**), artoheterophyllin F (**2**), artoheterophyllin G (**3**), artoheterophyllin H (**4**), artoheterophyllin I (**5**), artoheterophyllin J (**6**), 2-geranyl-2′,3,4′,5-tetrahydroxy-*cis*-stilbene (**7**), 5-methoxymorican M (**8**), and 2 new natural compounds, 2,3-dihydro-5,7-dihydroxy-2-(2-hydroxy-4-methoxyphenyl)-4*H*-1-benzopyran-4-one (**9**) and 6-[(1*S*,2*S*)-1,2-dihydroxy-3-methylbutyl]-2-(2,4-dihydroxy-phenyl)-5-hydroxy-7-methoxy-3-(3-methyl-2-buten-1-yl)-4*H*-1-benzopyran-4-one (**10**), were obtained and identified at this time.

The molecular formula of **1** was deduced to be $C_{15}H_{12}O_5$ by HR-ESI-MS. The ^{1}H NMR spectrum exhibited 12 proton signals, including 3 hydroxy signals at δ_H 9.28 (1H, s), 9.12 (1H, s), and 8.91 (1H, s), 3 proton signals of δ_H 7.08 (1H, d, J = 8.4 Hz), 6.31 (1H, dd, J = 8.4, 2.4 Hz), and 6.18 (1H, d, J = 2.4 Hz) forming one ABX system, 2 resonance signals at δ_H 5.94 (1H, d, J = 2.0 Hz) and 5.69 (1H, d, J = 2.0 Hz) making up a tetrasubstituted phenyl ring, and 3 other signals at δ_H 5.20 (1H, m), 5.15 (1H, m), and 2.12 (2H, m). In the ^{1}H−^{1}H COSY spectrum, the signal at 2.12 (2H, m) showed the correlations with signals at δ_H 5.20 (1H, m) and 5.15 (1H, m), which indicated the fragment of −CH−CH_2−CH−. Its ^{13}C NMR spectrum revealed the presence of 15 carbons, including 12 aromatic carbons, 2 oxygenated alkyl carbons, and 1 methylene. In the HMBC experiments, δ_H 9.12 had correlations with carbons δ_C 103.6, 108.9, and 160.2, followed by proton signals δ_H 7.08 with correlations with carbons δ_C 67.8, 108.9, 114.0, 155.8, and 160.2, δ_H 6.31 with correlations with carbons δ_C 103.6, 114.0, and 160.2, and δ_H 6.18 with correlations with carbons δ_C 108.9, 114.0, 155.8, and 160.2, indicating the presence of structural fragment A. On the other hand, the hydroxy signal of δ_H 9.28 had correlations with carbons δ_C 96.0, 102.4, and 158.2 and δ_H 8.91 with correlations with carbons δ_C 95.0 and 160.3. At the same time, proton signal δ_H 5.69 had correlations with carbons δ_C 96.0, 102.4, 155.8, 160.3, and proton signal δ_H 5.94 had correlations with carbons δ_C 95.0, 102.4, 160.3, supporting the presence of the structural fragment B. Furthermore, the proton signal at δ_H 2.12 exhibited correlations with carbons δ_C 62.8, 67.8, 102.4, and 114.0, suggesting the structural fragments A and B were joined by the methylene group. Thus, compound **1** was assigned as shown in Figure 1 and named artoheterophyllin E.

The molecular formula **2** was determined to be $C_{24}H_{26}O_4$ by its HR-ESI-MS data. Carefully analyzing the ^{1}H and ^{13}C NMR of **2**, we found that it had a structure similar to that of compound **29**, except for an additional 3,3-dimethylallyl group. Further examination of the remaining ^{1}H and ^{13}C NMR signals suggested that **2** contained a modified geranyl group that formed a 2-methyl-2-(4-methylpent-3-enyl) chromene structure on ring A [^{1}H δ 6.71 (1H, d, J = 10.0 Hz, H-1″), 5.58 (1H, d, J = 10.0 Hz, H-2″), 5.13 (1H, m, H-7″), 2.14 (2H, m, H-4″), 1.71 (2H, m, H-5″), 1.64 (3H, s, H-9″), 1.57 (3H, s, H-8″), 1.37 (3H, s, H-10″); ^{13}C δ 118.4 (C-1″), 127.8 (C- 2″), 78.57 (C-3″), 26.6 (C-10″), 41.9 (C-4″), 23.5 (C-5″), 125.2 (C-6″), 132.0 (C-7″), 17.7 (C-8″), 25.9 (C-9″)]. This unit should be situated at C-3 and C-4, and its placement was corroborated by the HMBC correlations from H-1″ to C-3 and C-5 and from H-2″ to C-4. The configuration of C-3″ in compounds can be defined by comparison of the optical rotation with those of reported compounds.[32] However, we can not get ideal data of optical rotation ($[\alpha]^{20}_D$ −0.008, c 0.0001, $CHCl_3$) for compound **2** due to the small amounts of material available.

Therefore, the absolute configuration for this compound was not further confirmed. On the basis of the above spectral evidence, the structure of **2** was established as shown in Figure 1, and the compound was given the trivial name artoheterophyllin F.

Compound **3** was a pale yellow powder, and its molecular formula was determined to be $C_{20}H_{18}O_7$ by its HR-ESI-MS data. The ^{1}H NMR and ^{13}C NMR spectra of **3** looked very similar to those of albanin A, which was also obtained from this plant, except for one of the prenyl methyl signals [δ_H 1.52 (3H, s), δ_C 25.9] changing to a hydroxy-substituted methylene [δ_H 3.82 (2H, s), δ_C 69.6]. In the HMBC experiment, proton δ_H 3.14 showed correlations with carbon δ_C 122.2 (C-3), 184.3 (C-4), 164.4 (C-2), 124.8 (C-2″), and 137.0 (C-3″), further confirming the hydroxy-substitutent prenyl group was attached at C-3 of the C ring. The key HMBC corrections are shown in Figure 1. Therefore, **3** was determined as (*Z*)-2-(2,4-dihydroxyphenyl)-5,7-dihydroxy-3-(4-hydroxy-3-methylbut-2-en-1-yl)-4*H*-chromen-4-one, named artoheterophyllin G.

The molecular formula of compound **4** was determined to be $C_{27}H_{26}O_8$ by its HR-ESI-MS data. The ^{1}H and ^{13}C NMR data for **4** were similar to those of artocarpin. However, the ^{1}H NMR spectrum exhibited a spin system that could be assigned to a 3-hydroxy-3-methyl-*trans*-but-l-enyl group [δ_H 6.76 (1H, d, J = 16.4 Hz), 6.68 (1H, d, J = 16.8 Hz), and 1.37 (6H, s)] and another methoxyl group (δ_H 3.90). This was supported by the ^{13}C NMR spectrum, displaying signals of two methyl groups (δ_C 27.9), one oxygenated carbon (δ_C 77.6), two olefinic carbons (δ_C 139.3 and 113.4) to form the 3-hydroxy-3-methyl-*trans*-but-l-enyl group, and another methoxyl group (δ_C 56.9).[33] The above information implied that the 3-methyl-1-butenyl group of artocarpin was replaced with a 3-hydroxy-3-methyl-*trans*-but-l-enyl group and that one hydroxy group was replaced with a methoxyl group in **4**. This was further confirmed by the HMBC correlations from the olefinic proton at δ_H 6.76 to C-5 (δ_C 160.5), C-7 (δ_C 164.7), and C-3″ (δ_C 77.6). Another methoxyl group was attached at C-5 by the HMBC corrlation of the methoxy proton at δ_H 3.90 with C-5 (δ_C 160.5). Thus, the structure of **4** was determined as 5,7-dimethoxy-3-(3-methylbut-2-enyl)-6-(3-hydroxy-3-methyl-*trans*-but-1-enyl)-flavone and named artoheterophyllin H.

The molecular formula of compound **5** was determined to be $C_{26}H_{30}O_7$ by its HR-ESI-MS data. The ^{1}H and ^{13}C NMR data for **5** were similar to those of artocarpin. However, the ^{1}H NMR spectrum exhibited a spin system that could be assigned to a 3-hydroxylated isoprenyl group [δ_H 2.45 (2H, m), 2.09, 1.05 (6H, s), 1.61 (2H, m)]. This was supported by the ^{13}C NMR spectrum, displaying signals of two methyl groups (δ_C 31.2 and 29.9), one oxygenated carbon (δ_C 70.8), and two methylene carbons (δ_C 43.6 and 21.8) to form the 3-hydroxylated isoprenyl group. In the HMBC spectrum, the correlations from δ_H 2.45 (H-1‴) to C-2 (δ_C 163.1), C-3 (δ_C 123.7), C-4 (δ_C 184.2), C-2‴ (δ_C 43.6), and C-3‴ (δ_C 70.8) and from H-2‴ to C-3 (δ_C 123.7), C-1‴ (δ_C 21.8), C-3‴ (δ_C 70.8), C-4‴ (δ_C 31.2), and C-5‴ (δ_C 29.9) indicated that the 3-hydroxylated isoprenyl group was attached to C-3. Thus, the structure of **5** was established as depicted and named artoheterophyllin I.

The molecular formula of compound **6** was determined to be $C_{20}H_{18}O_7$ by its HR-ESI-MS data. The ^{1}H NMR spectrum of **6** showed three one-proton double doublets at δ_H 5.84 (1H, dd, J = 14.0, 2.8 Hz), 3.93 (1H, dd, J = 17.2, 14.0 Hz), and 2.41 (1H, dd, J = 17.2, 2.8 Hz), attributed to the H-2, H-3ax, and H-3eq of a flavanone,[34] a two-proton singlet at δ_H 5.97 (2H, s) attributed to protons in the B ring nucleus, a pair of meta-coupled doublets at δ_H 5.874 (1H, d, J = 2.0 Hz) and 5.868 (1H, d, J = 2.0 Hz) assignable to H-6 and H-8, and one methoxyl signal at δ_H 3.71 (3H, s) assigned to the 5- or 7-position in the A ring or the 4′-position in the B ring. In the NOESY experiment, the methoxyl proton signal at δ_H 3.71 exhibited correlations with proton δ_H 5.97 (2H, s), suggesting that a methoxyl group was attached at the 4′-position in the B ring. According to the CD data at 270−290 nm ($[\theta]_{276}$ +3566), the C-2 configuration can be determined as *R* orientation of compound **6**.[35] Therefore, compound **6** was determined as 5,7,2′,6′-tretrahydroxy-4′-methoxyflavanone, named artoheterophyllin J.

The molecular formula of compound **7** was determined as $C_{24}H_{28}O_4$ by HR-ESI-MS. Its molecular mass was equal to that of chlorophorin.[36] Examination of the ^{1}H and ^{13}C NMR data of these two compounds further confirmed their structural similarities, with both as a tetrahydroxystilbene containing a geranyl substituent. However, in the ^{1}H NMR spectrum of compound **7**, the signal for H-2 was absent. Moreover, unlike chlorophorin, the observations of a pair of protons at δ_H 6.66 (H-6) and 6.33 (H-4) and a pair of nonsplitting protons δ_H 7.23 (2H, s, H-7′, 8′), due to the unsymmetrical substitution pattern of the A ring, implied that the geranyl unit should be attached at the 2- or 6-position in the A ring. These NMR spectroscopic properties indicated that **7** should have the geranyl unit attached at C-2. Conclusive evidence for the proposed structure of **7** came from the HMBC correlations that were found from δ_H 3.45 (H-1″) to C-1 (δ_C 140.1), C-2 (δ_C 118.4), C-3 (δ_C 156.9), C-2″ (δ_C 126.1), and C-3″ (δ_C 134.6) (Figure 1). Accordingly, compound **7** was identified as 2-geranyl-2′,3,4′,5-tetrahydroxy-*trans*-stilbene.

Compound **8** was obtained as a brown amorphous powder. Its molecular formula was determined as $C_{15}H_{12}O_5$ by HR-ESI-MS. Its ^{1}H and ^{13}C NMR spectra were similar to those of 2-(3,5-dihydroxyphenyl)-5,6-dihydroxybenzofuran,[37] except that another signal of a methoxy was present at δ_H 3.89. Analysis of HSQC and HMBC spectra of **8** suggested that the methoxy group was present at C-5. Therefore, compound **8** was determined as 2-(3,5-dihydroxyphenyl)-5-methoxy-6-hydroxybenzofuran. It was found that it was determined as wittifuran X by Tan et al.[38] However, in a further analysis of its ^{13}C NMR spectrum, we also found that several chemical shifts of carbons were greatly different from those reported by Tan et al. The chemical shifts of C-4, C-5, C-6, and C-7 were δ_C 103.4, 146.7, 146.4, and 98.5, respectively. However, it was found that they were δ_C 105.7, 147.5, 144.5, and 95.8 in the literature. On the other hand, we found that the chemical shifts of C-4 and C-7 were δ_C 106.0 and 98.4, respectively, when a hydroxy group was present at C-6 in another paper.[37] This is contradictory because if the structure of wittifuran X was determined as correct, the chemistry shifts of C-4 should not be δ_C 105.7 due to the effect of the methoxy group. It should move to the high field; that is, its chemical shift should be greatly different from the substituent of the hydroxy group, rather than similar. At the same time, the chemistry shifts of C-7 should not be δ_C 95.8 due to small effect of the methoxy group; its chemical shift should be similar to that of the substituent of the hydroxy group, rather than greatly difference. Therefore, wittifuran X determined by Tan et al. should actually be moracin J.[39] Therefore, compound **8** from our study was then named 5-methoxymorican M.

The molecular formula of compound **9** was determined as $C_{16}H_{14}O_6$ by HR-ESI-MS. By careful comparison of the ^1H and ^{13}C NMR spectra of **9** and artocarpanone, it was found that they were very similar, except for the different substitution position of the methoxy group. The methoxy group was present at the C-7 position of the artocarpanone, whereas it was present at C-2′ or C-4′ in the B ring of **9**. Analysis of the HMBC spectrum of **9** suggested that the methoxy group was present at C-4′. According to the CD data at 270−290 nm ($[\theta]_{276}$ +6512), the C-2 configuration can be determined as *R* orientation of compound **9**.[35] From the above analysis, the structure of **9** was determined as 2,3-dihydro-5,7-dihydroxy-2-(2-hydroxy-4-methoxyphenyl)-4*H*-1-benzopyran-4-one,[21] a new natural compound.

The molecular formula of compound **10** was determined to be $C_{26}H_{30}O_8$ by its HR-ESI-MS data. The ^1H and ^{13}C NMR data for **10** were similar to those of artocarpin. However, the ^1H NMR spectrum exhibited a spin system that could be assigned to a 1,2-dihydroxy-3-methylbutyl group [δ_H 4.80 (1H, overlapped), 4.33 (1H, dd, J = 8.8, 2.0 Hz), 0.95 (3H, d, J = 6.8 Hz), and 0.89 (3H, d, J = 6.8 Hz)]. This was supported by the ^{13}C NMR spectrum, displaying signals of two methyl groups (δ_C 26.0 and 17.7), two oxygenated carbon (δ_C 79.8 and 77.4), and one methine (δ_C 31.3). The HMBC correlations between the proton at δ_H 4.80 and carbons C-5 (δ_C 162.2), C-7 (δ_C 165.9), C-6 (δ_C 109.5), and C-2″ (δ_C 77.6) confirmed that the 1,2-dihydroxy-3-methylbutyl group was attached at C-6 in the A ring. Thus, the structure of **10** was determined as 2′,4′-dihydroxy-7-dimethoxy-3-(3-methylbut-2-enyl)-6-(1,2-dihydroxy-3-methylbutyl)flavone, 6-[(1*S*,2*S*)-1,2-dihydroxy-3-methylbutyl]-2-(2,4-dihydroxyphenyl)-5-hydroxy-7-methoxy-3-(3-methyl-2-buten-1-yl)-4*H*-1-benzopyran-4-one,[22] a new natural compound.

Effects of Compounds 1−33 on the Growth of MCF-7, SMMC-7721, and NCI-H460 Cells. To evaluate the effects of the compounds isolated from *A. heterophyllus*, cell viabilities were assessed via the MTT assay upon MCF-7, SMMC-7721 and NCI-H460 cancer cell lines. After 48 h of treatment, compounds **5**, **11**, **12**, and **30** reduced these three cell lines' viable cell percentages significantly, with IC_{50} values lower than 25 μM, whereas compounds **4**, **7**, **10**, **25**, **29**, and **31** showed moderate cytotoxic activity, with IC_{50} values ranging from 25 to 50 μM (Table 1). The other compounds exhibited weaker cytotoxic activity on these three cancer cell lines up to 50 μM (these compounds are not shown in Table 1). Furthermore, compound **30** showed the strongest inhibitory effect on the growth of MCF-7, SMMC-7721, and NCI-H460 cells (IC_{50} = 10.81, 12.06, and 5.19 μM) (Table 1). Especially, the inhibitory effects on the growth of SMMC-7721 and NCI-H460 cells were more potent than those of the positive control, 5-fluorouracil (5-FU) (IC_{50} = 17.53 and 7.31 μM) (Table 1).

Table 1. Inhibitory Effect of the Isolated Compounds against Different Cancer Cell Lines

	cancer cell line IC_{50} ± SD[a] (μM)		
compd	MCF-7	SMMC-7721	NCI-H460
4	>50	25−50	25−50
5	26.41 ± 0.95	25.28 ± 1.21	15.82 ± 0.61
7	25−50	25−50	16.66 ± 0.87
10	>50	≈50	25−50
11	11.3 ± 0.51	15.85 ± 0.79	11.01 ± 0.81
12	20.68 ± 1.01	23.7 ± 0.86	20.72 ± 0.63
25	25−50	25−50	25−50
29	25−50	25−50	25−50
30	10.81 ± 0.67	12.06 ± 0.75	5.19 ± 0.14
31	25−50	25−50	≈50
5-FU[b]	1.11 ± 0.13	17.53 ± 0.87	7.31 ± 0.33

[a]Values are means ± SD (n = 3). [b]Positive control.

As for flavonoids, one or two isoprenyl group substituents on the flavonoid skeleton seem to increase their cytotoxic activities, especially when the substituent is located at the 6-position of the A ring. Examples were compounds **15**, **16**, and **21**; compounds **15** and **21** have one isoprenyl group substituent at the 6-position and 3-position, respectively, whereas compound **16** lacks an isoprenyl group substituent in the skeleton. Cytotoxic activity test results showed that only compound **15** exhibited better cytotoxic activity, suggesting that the presence of an isoprenyl group at the 3-position in the skeleton cannot improve the cytotoxic activity relative to those with no isoprenyl group substituent. However, for those 6-isoprenyl flavonoids, the 3-isoprenyl substituent resulted in better cytotoxic activity. For example, compound **30** exhibited much stronger cytotoxic activity than compound **15** due to its additional 3-isoprenyl substituent. Moreover, cyclization of the isoprenyl groups, hydroxyl group substituent, and the position and saturation of double bonds of isoprenyl groups also affected cytotoxic activities. The case of compound **11** exhibited more potential cytotoxic activity than those of compounds **4**, **5**, and **10** because of its lack of a hydroxyl substituent at the 6-isoprenyl or 3-isoprenyl group, suggesting that the hydroxyl group substituent and saturation of the isoprenyl group reduced the cytotoxic activities. At the same time, compound **15** showed stronger cytotoxic activity than that of compound **13**. Meanwhile, compound **11** also exhibited better cytotoxic activity than that of compounds **12** and **31** due to the cyclization of the isoprenyl groups in the skeleton of the latter. In addition, compound **15** exhibited stronger cytotoxic activity than that of compound **18** because of the double bond at the 1,2-position of the latter, whereas it was at the 2,3-position of the former.

Effects of Compounds 11 and 30 on the Induction of Apoptosis. Apoptosis is an essential route of tissue development and homeostasis. It also works as a defense system avoiding the interruption of many toxic chemicals. It is well known that anticancer chemotherapies mainly exert their elimination of cancer cells via the apoptotic process, characterized by a number of cellular and biochemical hallmarks, including cell shrinkage, membrane blebbing, DNA chromatin fragmentation, nucleus condensation, and PARP cleavage.[40] To detect whether compounds **11** and **30** could induce apoptosis, DAPI staining was performed. Figure 2A shows that the indicated cell lines (including NCI-H460, MCF-7, and SMMC-7721) were administered by compounds **11** and **30** after 12, 24, and 48 h of incubation. The apoptotic bodies were observed clearly after 24 h of treatment and increased more at 48 h (Figure 2A). In addition, the apoptotic effect was validated through a significant increase of the cleaved-PARP proteins after chemical treatment in a time-dependent manner in these three cell lines (Figure 2B). All of these data demonstrate that compounds **11** and **30** obviously induced apoptosis in NCI-H460, MCF-7, and SMMC-7721 cell lines.

Effects of Compounds 11 and 30 on the Caspase Related-Apoptosis. When pretreated with 50 μM broad Z-VAD-fmk (spectrum caspase inhibitor) 1 h before compound

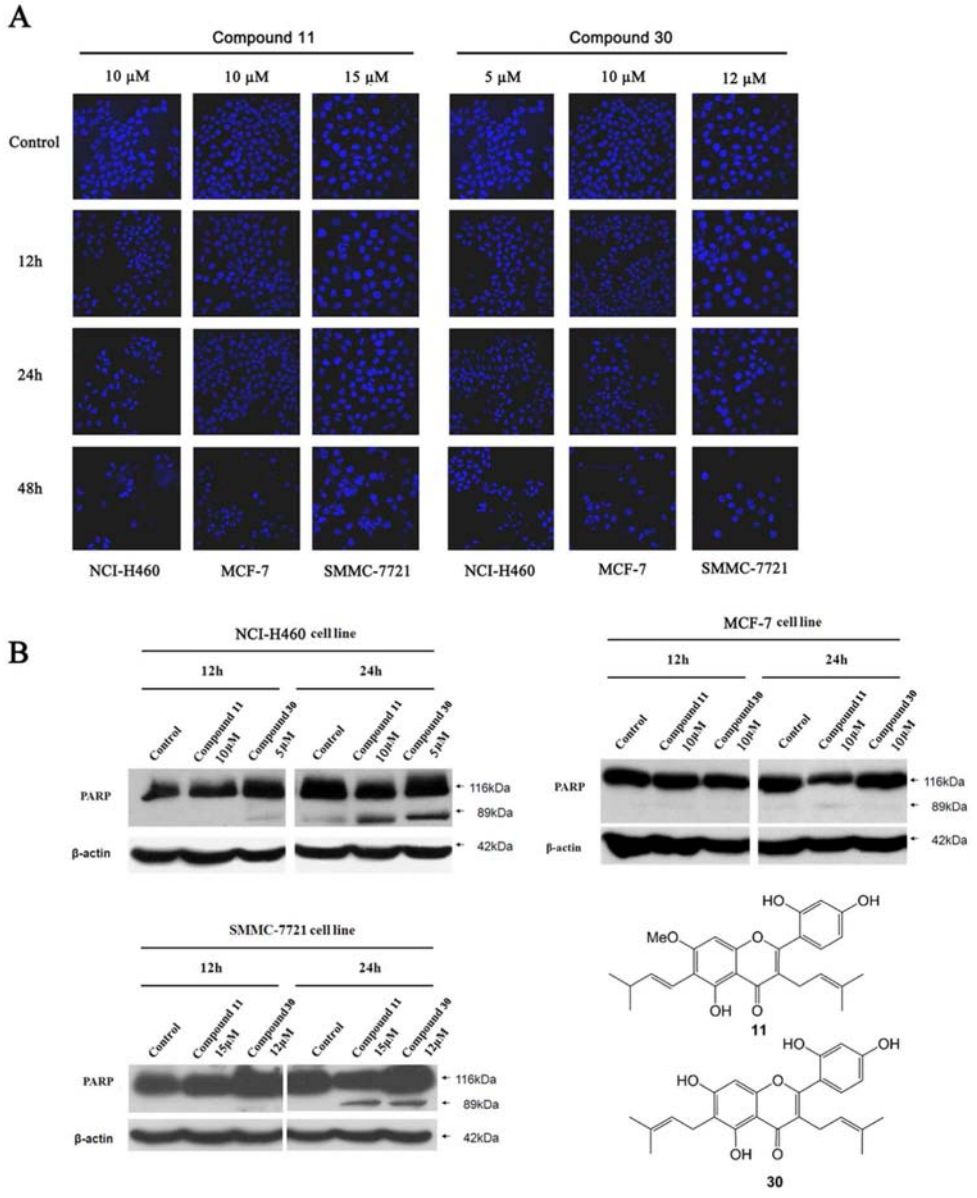

Figure 2. Compounds **11** and **30** induce apoptosis in NCI-H460, MCF-7, and SMMC-7721 cancer cell lines. (A) After drug administration at indicated concentrations, the cells were stained by DAPI and visualized by fluorescent microscope at 12, 24, and 48 h. (B) Western blot analysis was used to estimate PARP cleavage after drug administration for 48 h. Results are representative of three independent experiments (n = 3).

11 and **30** administration, with IC_{50} values for 48 h, we could observe the obvious increased cell number and improved cell morphology (Figure 3). These data indicated that compounds **11** and **30** induced apoptosis through caspase-dependent pathways.

Effects of Compounds 11 and 30 on MAPK Pathways Related Apoptosis. The MAPK signaling pathways, including ERK, p38, and JNK MAPK pathways, are all involved in affecting cell proliferation, differentiation, survival, and migration.[1] The MAPK pathway comprises several key signaling components and phosphorylation events that play a role in tumorigenesis. Especially, p38 and JNK MAPK pathways exhibit a complex function in cancer development. In HCC, higher JNK1 activation and lower p38 MAPK activity are correlated with an increased proliferation of tumor cells.[3] However, the increase of phosphorylated p38α has been detected in lung and breast cancer.[4,5] These investigations demonstrated that p38/JNK MAPK pathways have a selective function depending on the different types and stages of cancers. To determine whether compounds **11** and **30** induced cell apoptosis via the MAPK pathways, 20 μM JNK inhibitor (SP600125), 20 μM p38 MAPK inhibitor (SB203580), and 20 μM ERK inhibitor (PD98059) were pretreated to indicated cells 1 h before compound treatment. We observed the alteration of cancer cell morphology and number at 48 h after compound **11** and **30** administrations. In the SMMC-7721 cell line, pretreatment with SP600125 improved the cell morphology and increase the cell number (Figure 3). In MCF-7 cell line, pretreatment with SB203580, PD98059, and SP600125 improved the cell status noticeably (Figure 3). In the NCI-H460 cell line, pretreatment with SB203580 or PD98059 before treatment with compound **11** or **30** elevated the cell viability (Figure 3). These findings provide evidence demonstrating that the apoptosis-inducing effects of compounds **11** and **30** are mediated by down-regulation of different MAPK pathways in different cancer cell lines separately. All of the

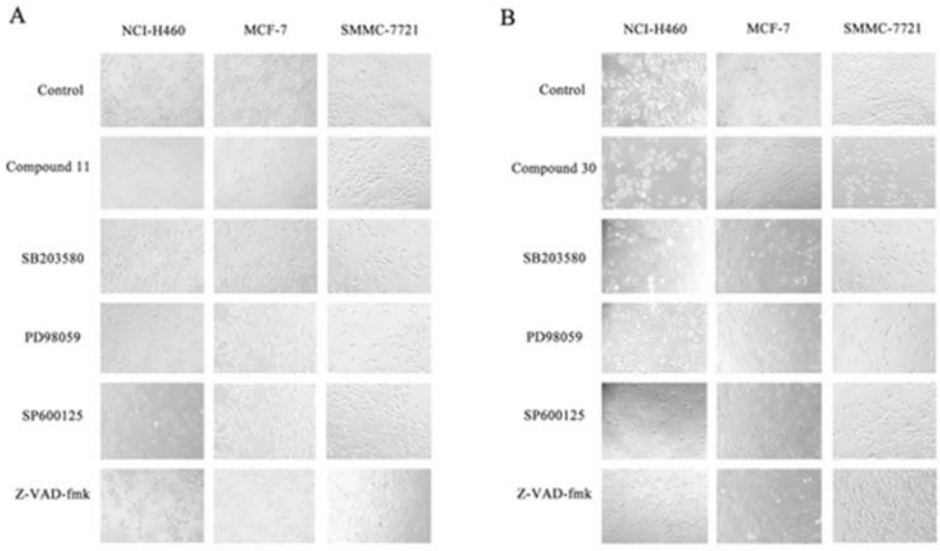

Figure 3. Effects of compounds **11** and **30** on the three MAPK pathway inhibitors: morphological and quantitative changes in NCI-H460, MCF-7, and SMMC-7721 cells in either control (untreated), treated with compounds **11** (10 μM for NCI-H460, 10 μM for MCF-7, and 15 μM for SMMC-7721) and **30** (5 μM for NCI-H460, 10 μM for MCF-7, and 12 μM for SMMC-7721) for 48 h, or pretreated with 20 μM SB203580, 20 μM PD98059, 20 μM SP600125, or 50 μM Z-VAD-fmk for 1 h before compound administration. Results are representative of three independent experiments (n = 3).

above results are consistent with previous findings[2−5] that MAPK pathways have a selective action on different cancer cell lines.

In this study, 8 new phenolic compounds, artoheterophyllin E−J (**1**−**6**), 4-geranyl-2′,3,4′,5-tetrahydroxy-*cis*-stilbene (**7**), and 5-methoxymorican M (**8**), and 2 new natural compounds (**9** and **10**), 2,3-dihydro-5,7-dihydroxy-2-(2-hydroxy-4-methoxyphenyl)-4*H*-1-benzopyran-4-one and 6-[(1*S*,2*S*)-1,2-dihydroxy-3-methylbutyl]-2-(2,4-dihydroxyphenyl)-5-hydroxy-7-methoxy-3-(3-methyl-2-buten-1-yl)-4*H*-1-benzopyran-4-one, together with 23 known compounds (**11**−**33**) were identified from the ethanol extract of the wood of *A. heterophyllus*. To our knowledge, this is the first systematic report of the phenolic compounds from the wood of *A. heterophyllus* with their cytotoxic effects on the three cell lines of MCF-7, SMMC-7721, and NCI-H460 at the same time. This study demonstrates that compounds **11** and **30** from the wood of *A. heterophyllus* inhibited the growth of the three cancer cell lines by inducing caspase-related apoptosis. Furthermore, the induction of apoptosis was accompanied by the activation of ERK, p38, and JNK MAPK pathways in a cell type-related manner. These data suggest that compounds **11** and **30** from the wood of *A. heterophyllus* have an anticancer potential and can be developed as anticancer drug leads.

Supporting Information

ABSTRACT: Cancer cells are well-known to require a constant supply of protein, lipid, RNA, and DNA via altered metabolism for accelerated cell proliferation. Targeting metabolic pathways is, therefore, a promising therapeutic strategy for cancers. Oleanolic acid (OA) is widely distributed in dietary and medicinal plants and displays a selective cytotoxicity to cancer cells, primarily by inducing apoptosis and cell cycle arrest. This study investigated if OA inhibited growth of tumor cells by affecting their metabolism. OA was found to activate AMP-activated protein kinase (AMPK), the master regulator of metabolism, in prostate cancer cell line PC-3 and breast cancer cell line MCF-7. AMPK activation is required for the antitumor activity of OA on cancer cells. Lipogenesis, protein synthesis, and aerobic glycolysis were inhibited in cancer cells treated with OA, in an AMPK activation-dependent manner. The metabolic alteration was shown to mediate the tumor suppressor activity of OA on cancer cells. Collectively, this study provides evidence that OA, as a widely distributed nutritional component, is able to exert antitumor function by interfering in the metabolic pathway in cancer cells. This finding should encourage researchers to study if affecting cancer metabolism is a common mechanism by which nutritional compounds suppress cancers.

KEYWORDS: *aerobic glycolysis, AMPK, metabolism, oleanolic acid*

INTRODUCTION

Rapid and unlimited growth of cancer cells requires a constant supply of both energy and structural materials that is essential for cell division. Transformed cells usually adjust their metabolic machinery to these needs by modifying the activity and expression of key metabolic enzymes in a concerted fashion.[1] Metabolic switch is not only an adaptive response of preexisting malignant cells but also a driver of tumorigenicity.[2] The population that suffers from metabolic syndromes, such as diabetes, is more prone to cancers,[2] although the detailed mechanisms underlying increased tumor risk from altered metabolism are still unknown. Interfering with metabolism has been shown to retard the growth of tumor cells,[2] indicating it as a promising therapeutic target for cancer treatment.

Multiple kinases have been shown to participate in the regulation of metabolic activity. AMP-activated protein kinase (AMPK) is one of the most important kinases that trigger metabolic adaption in cells. As an energy sensor, AMPK is an enzyme consisting of three subunits (α, β, and γ). The α subunit is responsible for its catalytic activity, and the other two serve as regulatory parts. AMPK senses the increase in intracellular AMP/ATP ratio and responds to the changes by phosphorylating and activating/inactivating some key metabolic enzymes, thereby inducing metabolic switch from glycolysis and anabolism to oxidative phosphorylation and catabolism. This AMPK-mediated metabolic alteration compromises the generation of molecular intermediates that is essential for macromolecule synthesis and, hence, slows cell proliferation. AMPK, as evidenced by recent studies, is closely implicated in the correlation between metabolism and cancer. AMPK suppresses aerobic glycolysis in malignant cells and also hampers the growth of tumors in vivo.[3] In line with the tumor suppressor function of AMPK, the risk of cancer has been found to be lowered in type 2 diabetes patients who were administered metformin, an AMPK activator.[4] This observation raises the possibility that AMPK is likely to be a promising pharmacological target for cancer therapy.

Activated AMPK suppresses the activity of acetyl-CoA carboxylase (ACC) by phosphorylation at Ser218 and negatively regulated the expression of fatty acid synthase (FASN), finally inhibiting lipid synthesis in cancer cells. In parallel, the mammalian target of the rapamycin (mTOR) is a downstream effector of AMPK, which promotes protein synthesis by activating p70S6K and eIF-4E. Through phosphorylation-dependent activation of TSC1/TSC2, a major upstream negative regulator of mTOR activity, AMPK can abrogate the stimulatory effect of mTOR on mRNA translation in transformed cells. AMPK also promotes glycolysis by phosphorylating and activating 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 2 (PFKFB2),

a key enzyme in the glycolytic pathway. Accumulated evidence has documented that enhanced glycolysis produces intermediates required for the synthesis of macromolecules. Above all, the activation status of AMPK determines the metabolism in cancer cells.[1] Biosynthesis of macromolecules, such as lipid, protein, and nucleic acids, may be slowed by reactivating the kinase function of AMPK in cancer cells that have no or low AMPK activity.

Oleanolic acid (OA) is a naturally occurring triterpenoid that is widely distributed in edible and medicinal plants. OA has been known, for a long time, to exert a variety of bioactivities, including a tumor-suppressing function.[5] However, the molecular mechanism by which OA was able to inhibit tumor growth has not been completely explored. In this study, we found that OA was able to induce AMPK activation in cancer cells. Sequentially, AMPK activation led to the metabolic alteration in OA-treated cancer cells. Finally, we demonstrated that AMPK-dependent alteration in the metabolic pattern is associated with the antitumor function of OA.

MATERIALS AND METHODS

Cell Culture. A human prostate carcinoma cell line, PC-3, and a human breast cancer cell line, MCF-7, were purchased from American Type Culture Collection (ATCC). A human normal liver cell, L-02, was obtained from Shanghai Cell Collection (Shanghai, China). PC-3 was cultured in RPMI-1640 supplemented with 10% fetal bovine serum (FBS; GIBCO-BRL) at 37 °C under a humidified 5% CO_2 condition. MCF-7 cells were cultured in DMEM.

Chemical Agents. OA was purchased from Sigma-Aldrich (O5504). An AMPK inhibitor, compound **C**, was purchased from Millipore (171260). The cells were incubated with compound **C** (20 μM) for 1 h prior to OA treatment. An mTOR activator, MHY1485, was purchased from Millipore (5.00554.0001). The cells were incubated with MHY1485 (2 μM) for 1 h prior to OA treatment. The above substances were all dissolved with DMSO for storing. PBS or culture medium was added to dilute the agents when needed.

Immunoblotting Assays. Total proteins were extracted from cells with M-PER Mammalian Protein Extraction Reagent (Thermo Scientific, USA), separated by electrophoresis with 10−12% SDS-PAGE gel and transferred onto 0.45 μm nitrocellulose membranes. Membranes were incubated in blocking solution (PBS, 0.1% Tween-20, and 5% nonfat dry milk powder) for 2 h at room temperature and then incubated with primary antibodies (1:1000, listed below). After overnight incubation, the membranes were washed with PBS containing 0.1% Tween-20 three times and then were incubated with horseradish peroxidase-conjugated secondary antibody for 1 h at room temperature. The involved antibodies were described as follows: phospho-AMPKα (Thr172), (Santa Cruz, sc-33524); AMPKα (CST, 2532); phospho-HMG-CoA reductase (Ser872) (Millipore, 09-356); HMG-CoA reductase (Millipore, ABS229); phospho-acetyl-CoA carboxylase (Ser79) (CST, 3661); acetyl-CoA carboxylase (CST, 3676); and fatty acid synthase (CST, 3180). The intensity of blots in some figures was determined with ImageJ software.

Immunofluorescence. PC-3 and MCF-7 cells were incubated with or without OA (100 μg/mL) for 6 h. The cells were fixed with 4% polyoxymethylene for 30 min and then incubated with phospho-AMPKα antibody (1:200) for 2 h at 4 °C. Subsequently, the cells were stained with FITC-conjugated secondary antibody and 4′,6′-diamidino-2-phenylindole (DAPI). A confocal microscope (CLS-2SS, Thorlabs) was used to observe the fluorescence.

Detection of Fatty Acid Synthesis Activity. A radioactive assay was employed to detect the effect of OA on lipid synthesis in PC-3 and MCF-7 cancer cells. The cells were incubated with [^{3}H]-acetyl-CoA (2 μCi) (PerkinElmer, NET290050UC) for 12 h as well as OA (50 or 100 μg/mL) for 6 or 12 h. Lipid was isolated with a mixture of water/methanol/chloroform (1:1:1) according to a procedure previously described.[6] The organic fraction that contains radioactive lipid was evaporated with N_2, followed by detection with a MicroBeta liquid scintillation counter (PerkinElmer).

Protein Synthesis Detection Assay. The effect of OA on nascent protein synthesis in cancer cells was detected using a Click-iT HPG Alexa Fluor Protein Synthesis Assay Kit (Life Technologies, C10428). Amounts of 5×10^3 PC-3 and MCF-7 cells were treated with 50 or 100 μg/mL OA for 6 or 12 h (Figure 3C). For the experiments in Figure 3E, 100 μg/mL OA was added to the culture of 5×10^3 PC-3 cells with or without 1 h of compound **C** (20 μM) pretreatment, and then the cells were incubated for another 12 h. The subsequent experiments were performed according to the procedures provided by the manufacturer. The fluorescence was detected and recorded with a confocal microscope (CLS-2SS, Thorlabs). The signal intensities were determined with ImageJ, and the relative values normalized by those in untreated control groups are presented in Figure 3C,E.

Glycolytic Activity Detection Assays. Glucose consumption of cancer cells treated with OA was assessed with a Glucose Uptake Colorimetric Assay Kit (BioVision, K676). Briefly, 5×10^3 PC-3 and MCF-7 cells were treated with 50 or 100 μg/mL OA for 6 or 12 h (Figure 4A). For the experiments shown in Figure 4D, 100 μg/mL OA was added to the culture of 5×10^3 PC-3 cells with or without compound **C** (20 μM) pretreatment for 1 h, and the cells were incubated for 12 h. Then, the cells were starved for glucose with 100 μL of Krebs−Ringer−phosphate−HEPES (KRPH) buffer containing 2% BSA for 30 min, followed by 20 min exposure with 100 nmol of 2-DG. Subsequent steps were done according to the manufacturer's instructions. The absorbance in each sample was measured with a microplate reader at 412 nm. Glucose consumption was determined on the basis of the established standard curves.

Lactate production was determined with a Lactate Colorimetric Assay Kit II (BioVision, K627) following the manufacturer's instructions. Briefly, 5 μL of culture medium was harvested from PC-3 and MCF-7 cells incubated with 50 or 100 μg/mL OA for 6 or 12 h (Figure 4B) and mixed with 45 μL of lactate assay buffer. Compound **C** (20 μM) was simultaneously added to PC-3 cells in some experiments (Figure 4E). A 10 kDa MW spin filter (BioVision, 1997-25) was used to remove the lactate dehydrogenase in serum. After 50 μL of reaction mix was added, the reaction was performed for 30 min at room temperature. The absorbance in each sample was measured with a microplate reader at 450 nm. The concentration of lactic acid in each sample was determined with the established standard curve. The values in each group relative to that untreated control group are shown in Figure 4B,E.

The oxygen consumption rate was determined with an Oxygen Consumption Rate Assay Kit (Cayman Chemical Co., 600800). PC-3 and MCF7 cells were treated with OA and/or compound **C** according to the procedures used to evaluate the glucose uptake and lactic acid production. After 12 h of OA stimulation, the cells were processed following the manufacturer's instruction. The signals in each sample were read at 650 nm with a VICTOR X3 multilabel plate reader (PerkinElmer). The oxygen consumption rate was presented as lifetime versus time (μs/h). The values were normalized by untreated control samples and are shown in Figure 4C,F.

Cell Cycle Analysis. Cell cycle analysis was performed by fluorescence-activated cell sorter (FACS)-based evaluation of DNA content with propidium iodide (PI) staining. PC-3 cells (2×10^5) were treated with OA for 12 h (indicated groups were pretreated with 20 μM compound **C** for 1 h prior to OA stimulation). The cells were fixed with cold 70% ethanol for 1 h. Subsequently, the cells were processed with RNase (20 μg/mL) at 37 °C for 1 h and then stained with PI (50 μg/mL), immediately followed by FACS-based cell cycle analysis (Aria II, BD Biosciences). A total of 5×10^4 cells were counted for each sample.

Colony Formation Assay. PC-3 cells (2×10^3) were plated in a 6-well plate and then cultured in medium with or without 100 μg/mL OA at 37 °C under a humidified 5% CO_2 condition for 10 days. Colonies consisting of more than 50 cells were counted after staining with crystal violet solution.

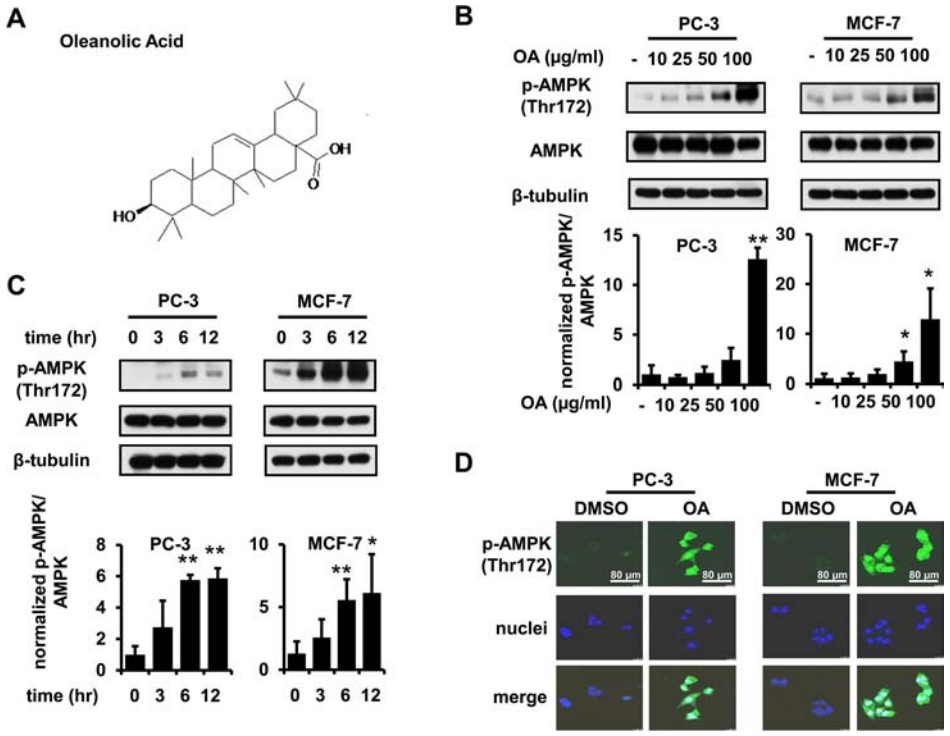

Figure 1. OA induces AMPK activation in cancer cells in a dose- and time-dependent fashion. (A) Chemical structure of oleanolic acid. (B) PC-3 and MCF7 cells were treated with OA for 3 h at 10, 25, 50, and 100 μg/mL. AMPK phosphorylation was detected by immunoblot assays (upper panel). The blot intensity quantified with ImageJ software is shown (bottom panel) as means ± SD of three independent experiments. (C) PC-3 and MCF7 cells were also treated with 100 μg/mL OA for 3, 6, and 12 h. AMPK phosphorylation was detected by immunoblot assays. Blots and their corresponding quantitative data are shown as means ± SD of three independent experiments. (D) PC-3 and MCF7 cells were stimulated with 100 μg/mL OA for 6 h. Phosphorylated AMPK was detected by immunofluorescent staining. Bars = 80 μm.

Animal Experiments. The animal experimental procedures were approved by the Committee on Animal Care in Jilin University (permission 2013032, Changchun, China). PC-3 cells (5×10^6) were injected into the flanks of 4–6-week-old male nude BALB/c mice (n = 18). OA (40 mg/kg, low dose; or 120 mg/kg, high dose) was orally administered every day for 4 weeks. The mice were divided into three groups: control (n = 6), low-dose OA (n = 6), and high-dose OA (n = 6). The diameters of tumors were periodically determined with calipers. The volumes were calculated using the following formula. Volume (mm^3) = length × $(width)^2/2$. The expression of indicated proteins was detected in the dissected tumors after the mice were sacrificed by immunoblot assay.

Statistical Analysis. The experiments except immunoblot assays were performed at least three times. All values are reported as means ± SD and compared at a given time point by unpaired, two-tailed t test. Data were considered to be statistically significant when $p < 0.05$ (*) and $p < 0.01$ (**).

RESULTS AND DISCUSSION

OA Induces AMPK Activation in Cancer Cells in a Dose- and Time-Dependent Fashion. The chemical structure of OA is shown in Figure 1A. First, AMPK activation was examined in OA-treated cancer cells by immunoblotting analysis of its phosphorylation at Thr172. AMPK phosphorylation was found to be increased in all tested cells (Figure 1B). The increase in phosphorylated AMPK expression was correlated with the dose of OA administered to cancer cells (Figure 1B). Also, the phosphorylation of AMPK was progressively elevated during the time when cancer cells were exposed with OA (Figure 1C). OA-induced phosphorylation of AMPK was also further confirmed in cancer cells by immunofluorescent staining (Figure 1D). These data showed that OA induced the phosphorylation and activation of AMPK in cancer cells in a concentration- and time-dependent manner.

OA has been demonstrated to exert multiple bioactivities, including anti-inflammation, anticancer, anticoagulation,[7] and hepatoprotection,[8] by affecting specific molecular pathways in cells. These signaling pathways are associated with apoptosis, cell cycle regulation, metastasis, angiogenesis, and inflammation. AMPK, the central modulator of metabolism, has been reported to be activated in mouse cardiomyocytes under OA treatment. In turn, AMPK activation protected cardiomyocytes from contractile dysfunction induced by hypoxia in a FOXO3-dependent manner.[9] This finding shed light on the mechanism of OA cardioprotective activity. However, it is still unclear whether OA is able to induce AMPK activation in cancer cells. In this study, we revealed that OA treatment resulted in the phosphorylation and activation of AMPK in cancer cells in both dose- and time-dependent fashions.

AMPK Activation Mediated the Antitumor Activity of OA on Cancer Cells. Subsequently, we aimed to establish the role of AMPK activation in tumor suppressor property of OA on cancer cells. Cell proliferation was determined by counting the cells at the different time points. An AMPK inhibitor, compound **C**, was used to block the AMPK activation in PC-3 cancer cells treated with OA (Figure 2A). OA was able to decelerate the proliferation of PC-3 cells, whereas compound **C**-mediated AMPK inactivation resulted in a partial recovery of the growth of PC-3 cells (Figure 2B). Cell cycle progression was also retarded by OA treatment. However, this effect was reversed by compound **C** (Figure 2C). Furthermore, compound **C** was also able to abolish the inhibitory activity of OA on the colony-forming ability of PC-3 cells (Figure 2D).

dx.doi.org/10.1021/jf500622p | J. Agric. Food Chem. 2014, 62, 5528–5537

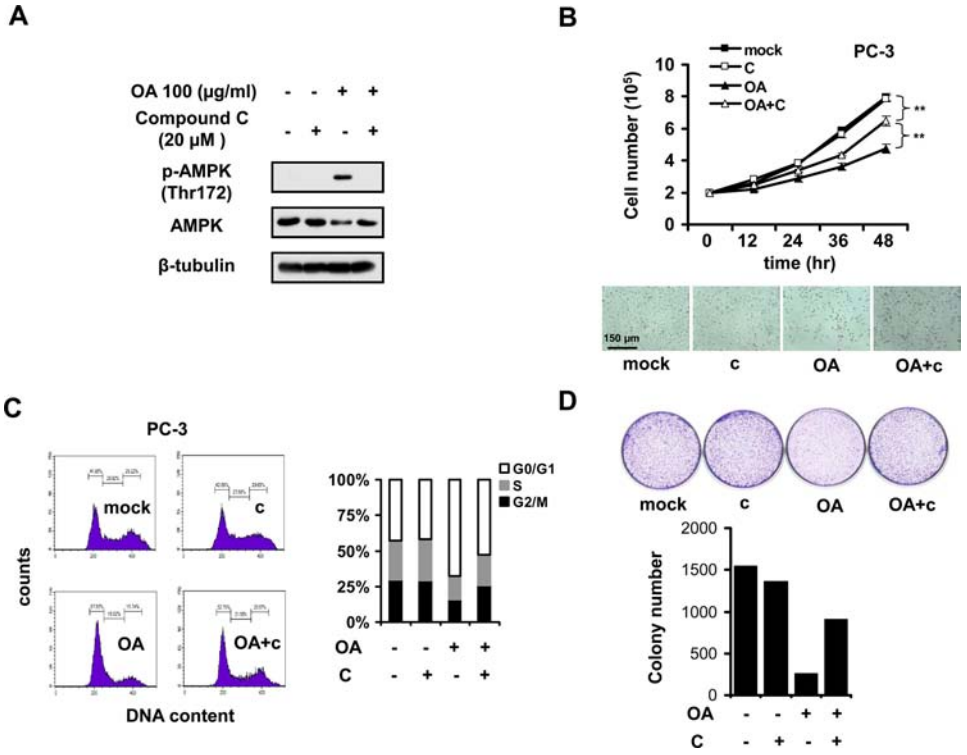

Figure 2. AMPK activation mediated the antitumor activity of OA on cancer cells. (A) PC-3 cells were pretreated with compound **C** (20 μM) for 1 h prior to OA (100 μg/mL) stimulation. Phosphorylated AMPK was detected by immunoblot assays. (B) PC-3 cells were analyzed for their proliferation at the indicated time points under the same treatment. Representative pictures are shown in the bottom panel. C, compound **C**. (C) Cell cycle analysis was performed on PC-3 cells under the same treatment. The percentages of G_0/G_1, S, and G_2/M population are presented as bars in the right panel. (D) Colony number of PC-3 cells treated with OA and/or compound **C** was counted and shown as both pictures (upper panel) and bars (bottom panel).

Subsequently, we aimed to establish the role of AMPK activation in the antitumor activity of OA. We found that the AMPK inhibitor, compound **C**, was able to rescue the effect of OA on PC-3 cells, suggesting that AMPK activation is required for OA to suppress tumor growth. AMPK activation has been also found to be essential for antitumor activity of other natural compounds. Curcumin induced apoptosis in CaOV3 ovarian cancer cells in an AMPK-dependent way. Blocking AMPK activation with compound **C** abolished curcumin induction of apoptotic event in cancer cells.[10] However, compound **C**-dependent AMPK inactivation in OA-treated cancer cells partially, not completely, abolished OA suppression of the proliferation, cell cycle progression, and colonigenecity of PC-3 cells, implying some molecular mechanisms other than AMPK activation are responsible for OA antitumor activity.

OA-Stimulated AMPK Activation Suppressed Lipid Biosynthesis in Cancer Cells. AMPK is a master kinase that regulates the cellular lipid metabolism. Its activation leads to a metabolic switch from anabolism to catabolism by phosphorylating several enzymes that play key roles in the biosynthesis of macromolecules, such as lipids.

As a rate-limiting enzyme for fatty acid synthesis, acetyl-CoA carboxylase 1 (ACC1) produces malonyl-CoA, an intermediate essential for fatty acid elongation, by catalyzing the carboxylation of acetyl-CoA. ACC1 is overexpressed in a variety of human cancers and highly contributes to the enhanced lipogenesis in cancer cells.[11] AMPK inhibits ACC1 activity by phosphorylating it at Ser79.[12] In OA-stimulated cancer cells, ACC1 phosphorylation was found to be augmented in both dose- and time-dependent manners (Figure 3A,B) and appeared to be closely correlated with OA-induced AMPK activation (Figure 1B,C). Compound **C** abolished ACC1 phosphorylation at Ser79 (Figure 3C), indicating the requirement of AMPK activation in OA-stimulated ACC1 phosphorylation.

Fatty acid synthase (FASN) is also a critical enzyme in the lipogenic pathway and is frequently found to be overexpressed in cancer cells.[13] Its transcription level is negatively regulated by AMPK-dependent SREBP1c phosphorylation.[14] As shown in Figure 3A,B, OA reduced the expression of FASN protein in cancer cells. This effect was associated with both OA concentration and the time of OA treatment (Figure 3A,B). After the treatment with OA, the protein levels of FASN were decreased. However, the protein levels of FASN were restored in the presence of compound **C** (Figure 3C).

In addition to the fatty acid, sterol is also required for the growth of cancer cells. 3-Hydroxy-3-methylglutaryl-CoA reductase (HMGR) is the enzyme responsible for generating mevalonic acid, an essential intermediate for the synthesis of cholesterol and isoprenoids. AMPK has been reported to phosphorylate and inactivate HMGR.[1] OA was found to increase the phosphorylation of HMGR in cancer cells, in both dose- and time-dependent fashions (Figure 3A,B). Compound **C** treatment was able to block the OA-induced phosphorylation of HMGR at Ser872 (Figure 3C).

Reactivation of AMPK has been documented to suppress the production of lipid in cancer cells. Radioactive assays revealed that OA was able to diminish the de novo lipid synthesis, shown as a reduced incorporation rate of [^{3}H] acetyl-CoA into lipid product of PC-3 cells (Figure 3D). OA suppression of lipid synthesis was rescued by compound **C** (Figure 3E), implying

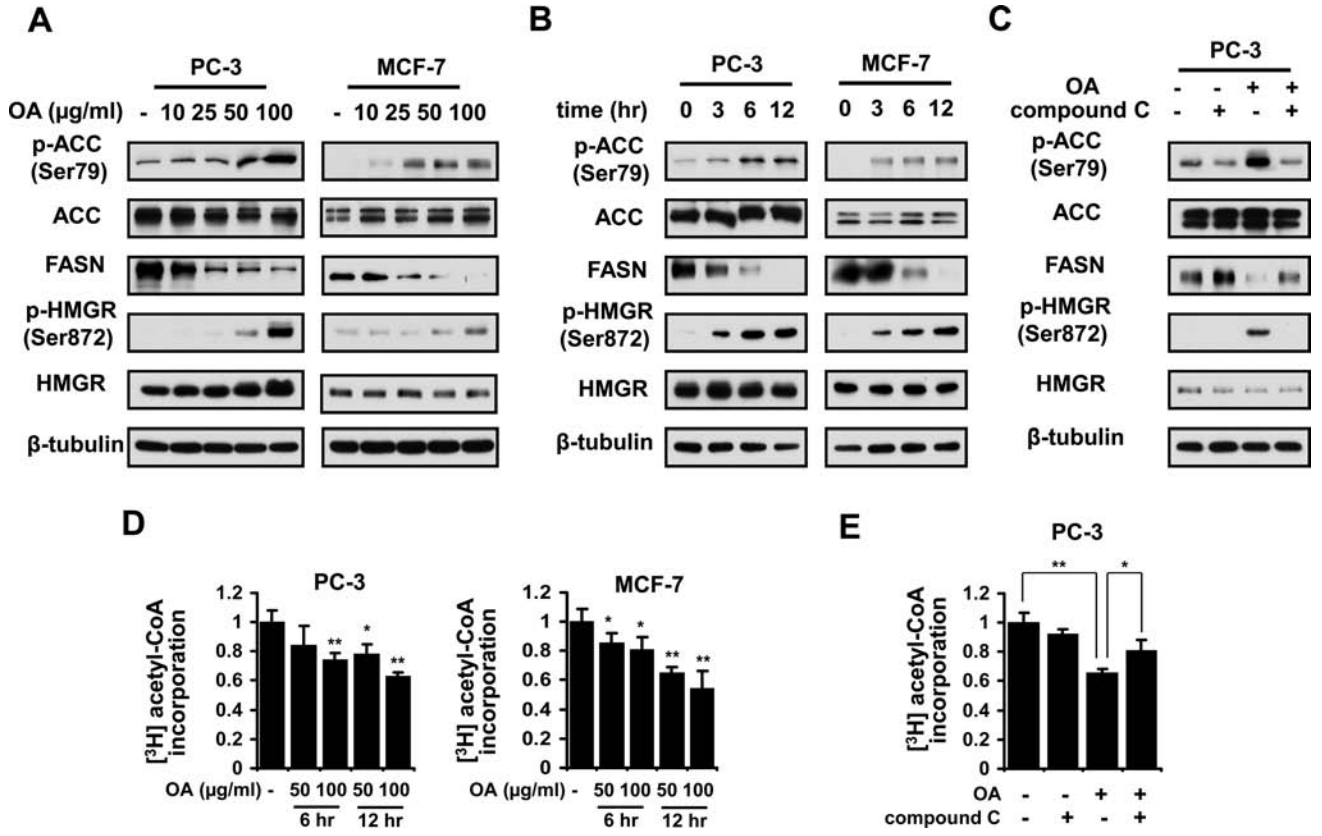

Figure 3. OA-stimulated AMPK activation suppressed lipid biosynthesis in cancer cells. PC-3 and MCF-7 cells were treated with OA of indicated concentrations for 3 h (A) or with 100 μg/mL OA for indicated times (B). PC-3 cells were also pretreated with compound **C** (20 μM) for 1 h prior to OA (100 μg/mL) stimulation (C). Then these cell lysates were used for immunoblot analysis of lipid metabolism-related gene expression. ACC, acetyl-CoA carboxylase; FASN, fatty acid synthase; HMGR, 3-hydroxy-3-methylglutaryl-CoA reductase. [^{3}H] acetyl-CoA incorporation was employed to evaluate the lipid synthesis of PC-3 and MCF-7 cells under the treatment of OA (50 and 100 μg/mL) for 6 or 12 h (D). Also, lipid synthesis of PC-3 cells treated with OA and/or compound **C** was also determined (E). The relative values are shown in panels D and E.

that AMPK activation is essential for its effect against fatty acid production.

Next, we investigated if OA was able to affect the lipogenesis of cancer cells by detecting the phosphorylation or expression of some lipid synthesis-associated genes, which have been confirmed as AMPK downstream effectors, and performing [^{3}H]acetyl-CoA incorporation assay. The results showed that OA was able to suppress the lipid synthesis in a dose- and time-dependent manner. Compound **C** abolished the inhibitory effect of OA on the lipogenic process in cancer cells, supporting the role of AMPK activation in OA suppression of lipid synthesis (Figure 3). Pomolic acid, a natural antitumor compound, was also found to suppress lipid synthesis in MCF-7 breast cancer cells in an AMPK-dependent manner.[15] There is a possibility that all of the compounds identified as AMPK activators may exert an inhibitory activity on lipogenic pathways.

Protein Synthesis Was Inhibited in Cancer Cells Treated with OA in an AMPK Activation-Dependent Way. AMPK reduces the activity of the mammalian target of rapamycin complex 1 (mTORC1) by phosphorylating its upstream inhibitory regulator, TSC2,[16] and its regulatory subunit, Raptor.[17] In OA-treated cancer cells, mTOR was shown to be less phosphorylated at Ser2448 (Figure 4A,B). The expression of phosphorylated p70S6K, a downstream effector of mTOR that hampers protein synthesis by inactivating S6 ribosomal protein, was consequently reduced in cancer cells under OA treatment (Figure 4A,B). This mTOR-dependent phosphorylation is required for the kinase activity of p70S6K.[18] The phosphorylation of another important mTOR downstream substrate, eukaryotic translation initiation factor 4E-binding protein 1 (4E-BP1), was also found to be decreased in OA-stimulated cancer cells (Figure 4A,B). The Thr37 and Thr46 phosphorylations prime 4E-BP1 for subsequent phosphorylations that abolish the inhibitory activity of 4E-BP1 on mRNA translation.[19] Therefore, OA-induced dephosphorylation of 4E-BP1 probably suppresses protein synthesis in cancer cells. Changes in the phosphorylation level of these protein synthesis-related factors were all abolished by compound **C** (Figure 4C), indicating that AMPK activation is required for OA inhibition of the mTOR signaling pathway.

A fluorescence-based protein synthesis assay kit was used to determine the effect of OA on protein synthesis in cancer cells. Microscopic observation revealed that the intensity of fluorescence was reduced in cells 3 and 12 h after the treatment of different dose of OA (Figure 4D), suggesting that OA compromised the nascent synthesis of protein. Compound **C** suppression of AMPK was able to partially prevent the reduction in protein synthesis in cancer cells treated with OA (Figure 4E).

We also studied the changes in protein synthesis in cancer cells treated with OA. The data showed that protein synthesis in PC-3 and MCF-7 cells was significantly compromised under OA stimulation. Consistently, the promoters of protein

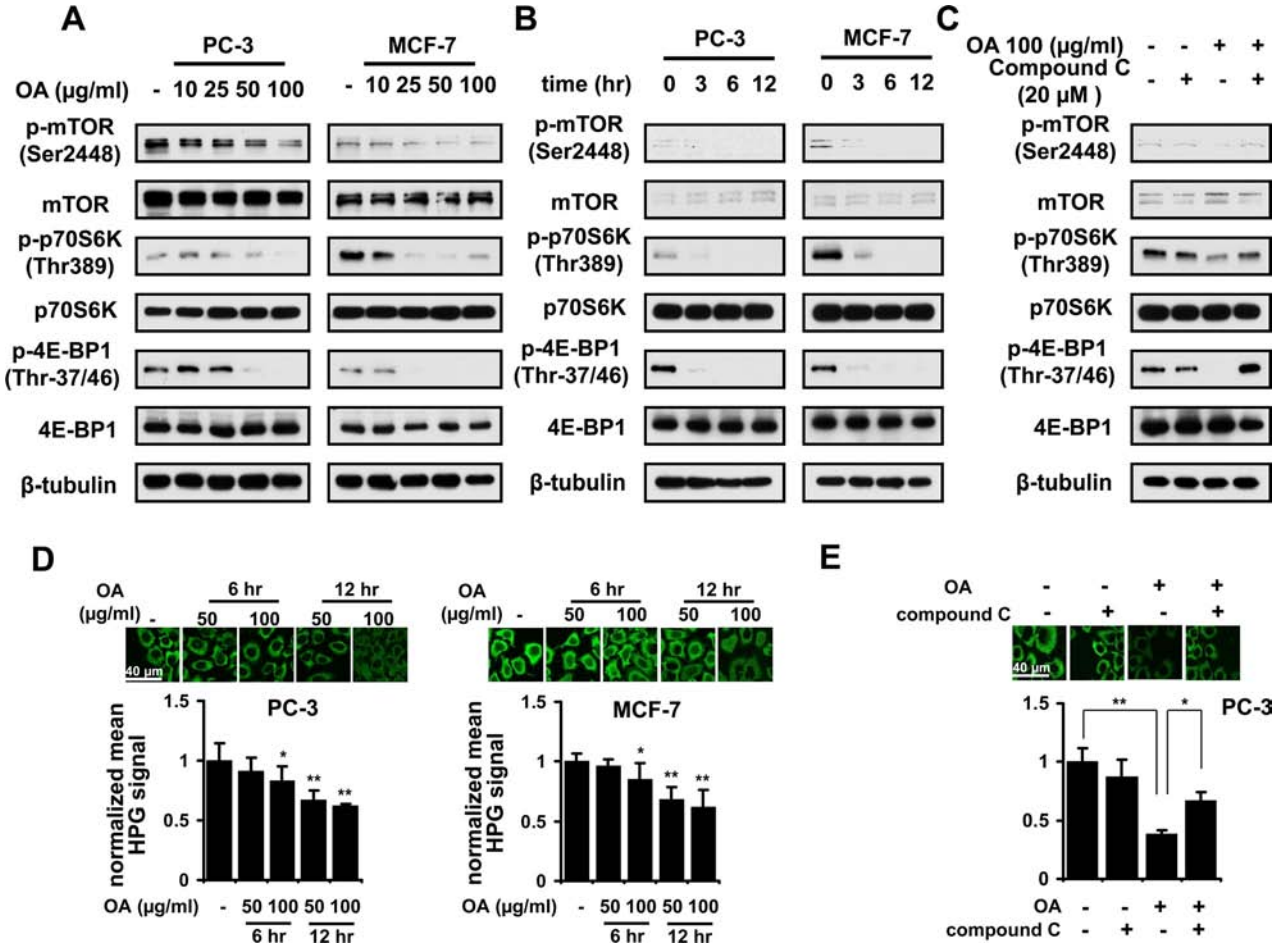

Figure 4. Protein synthesis was inhibited in cancer cells treated with OA in an AMPK activation-dependent way. PC-3 and MCF-7 cells were treated with OA of indicated concentrations for 3 h (A) or with 100 μg/mL OA for indicated times (B). PC-3 cells were also pretreated with compound **C** (20 μM) for 1 h prior to OA (100 μg/mL) stimulation (C). Then these cell lysates were used for immunoblot analysis of protein synthesis-related gene expression. mTOR, mammalian target of the rapamycin; 4EE-BP1, eukaryotic translation initiation factor 4E-binding protein 1. Nascent protein synthesis in PC-3 and MCF-7 cells under the treatment of OA (50 and 100 μg/mL) for 6 or 12 h was performed with a HPG-based Protein Synthesis Assay Kit (D). Also, PC-3 cells treated with OA and/or compound **C** were also detected for de novo protein synthesis (E). The relative values are shown in panels D and E. Representative pictures are shown in the upper panels.

synthesis were also inactivated under OA treatment, evidenced by decreased phosphorylation levels. Compound **C**-mediated AMPK inhibition revealed that AMPK activation is required for the inhibitory effect of OA on protein synthesis in cancer cells.

OA Suppressed Aerobic Glycolysis in Cancer Cells in an AMPK-Dependent Manner. AMPK has been recently demonstrated as a negative regulator of the Warburg effect in cancer cells.[3] The inhibitory effect of AMPK on glycolysis may be associated with its suppression of PKM2 activity via affecting mTOR activation.[20] Herein, we investigated if OA treatment affected the glycolytic metabolism in cancer cells. Glucose uptake was significantly reduced in cancer cells treated with OA (Figure 5A). Furthermore, cancer cells produced less lactic acid, which is the end product of glycolysis, under treatment with OA (Figure 5B). The changes in glucose consumption and lactate generation indicated that OA suppressed the glycolytic metabolism in cancer cells.

Cancer cells are also featured compromised mitochondrial oxidative phosphorylation, which contributes to the maintenance of malignant phenotypes. Oxygen consumption, an indicator for the efficiency of oxidative phosphorylation, was subsequently measured in OA-stimulated cancer cells. An increase in O_2 consumption was observed in cancer cells exposed to OA (Figure 5C).

Similar to the role of AMPK activation in lipid and protein synthesis, compound **C** was also able to partially inhibit OA-induced metabolic switch in cancer cells, evidenced by increases in glucose uptake, lactate production, and O_2 consumption in the cells treated with both OA and compound **C** (Figure 5D–F).

Increasing evidence indicated that the Warburg effect is critical for the unlimited growth of cancers, and targeting it seems to be an effective strategy for cancer treatment. We therefore examined if OA interferes with the metabolic pathways in cancer cells. The results on glucose uptake, lactate production, and oxygen consumption rates showed that OA switches metabolic patterns from aerobic glycolysis to mitochondrial oxidative phosphorylaion. Similarly, AMPK inhibition protected PC-3 cells from this metabolic change. However, it is unknown how OA-induced AMPK leads to the reversal of the Warburg effect.

AMPK-Dependent Metabolic Adaptation Contributes to the Tumor Suppressor Activity of OA on Cancer Cells. Finally, we aimed to study the contribution of metabolic alteration to the antitumor activity of OA on cancer cells. Therefore, we used a small molecule activator, MHY1485, to interfere with

dx.doi.org/10.1021/jf500622p | J. Agric. Food Chem. 2014, 62, 5528−5537

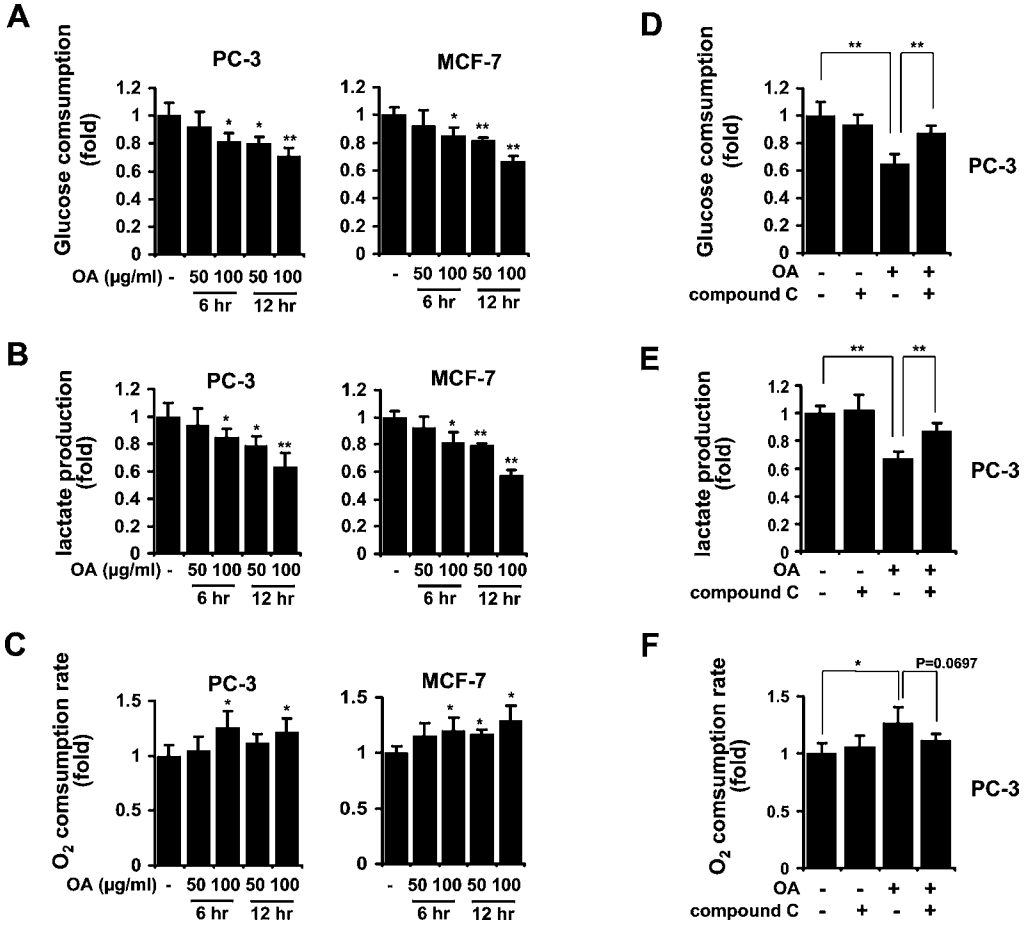

Figure 5. OA suppressed aerobic glycolysis in cancer cells in an AMPK-dependent manner. PC-3 and MCF-7 cells were treated with OA (50 and 100 μg/mL) for 6 or 12 h, followed by the assessment of glucose consumption (A), lactate production (B), and O_2 consumption rates (C). Furthermore, the above glycolysis-related parameters were estimated in PC-3 cells treated with OA and/or compound **C** (D−F). All data are shown as relative values. The methods were described under Materials and Methods.

the changes in the metabolic pathway without affecting AMPK activation.[21] mTOR inhibition was rescued by MHY1485 in OA-stimulated cancer cells, and AMPK activation was not affected under this treatment (Figure 6A). MHY1485 was able to counteract the inhibitory effect of OA on protein synthesis in cancer cells and to stop the metabolic switch from aerobic glycolysis to oxidative phosphorylation (data not known), through the mTOR pathway. The cell proliferation assay showed that MHY1485 could speed the growth of PC-3 cells under the treatment with OA (Figure 6B). The number of colonies in PC-3 cells was also increased by MHY1485 (Figure 6C).

We also determined the contribution of metabolic alteration to the antitumor activity of OA. Restoring protein synthesis and aerobic glycolysis in cancer cells partially abolished the AMPK effect on cancer cells (Figure 6), confirming the change in metabolic pattern is, at least partially, responsible for the antitumor activity of OA. The reason mTOR activators recovered proliferation and colony formation ability of PC-3 cells only in a partial manner may be that lipid synthesis was still not restored in OA-treated cells or that there are still some mechanisms underlying OA antitumor function, other than interfering with metabolism. For example, there is a possibility that OA may induce G_0/G_1 cell cycle arrest via the AMPK/p53/p21 pathway. Previous studies showed that AMPK phosphorylates p53 at Ser15, facilitates its accumulation, and enhances its transcription activity of p21CIP, a CDK inhibitor, in both normal and cancer cells.[22,23] p27KIP is also reported to be a substrate of AMPK kinase and phosphorylated at Thr-198. This phosphorylation event enhances the inhibitory function of p27KIP on cell cycle progression.[24] In addition, AMPK activation-induced FASN down-regulation may directly affect cell cycle progression in tumor cells.[25] Furthermore, p53-associated apoptosis is another possible mechanism by which OA may exert AMPK-dependent antitumor activity, based on a recent publication reporting AMPK overexpression led to increased p53 nuclear accumulation and apoptosis.[26]

Another question about OA induction of AMPK pathway is the mechanism by which OA initiates AMPK activation. Recently, H_2O_2 was found to induce AMPK activation in insulin-secreting cells.[27] AMPK signaling can be also activated in a p38 MAPK-dependent manner in cancer cells treated with antitumor compound.[10] Thus, further studies should be focused on these molecular pathways.

OA Reduced Tumor Growth and Activated AMPK Pathway in Mice. To further confirm the antitumor activity of OA and its stimulatory effect on the AMPK pathway, we established a tumor xenograft mouse model by injecting PC-3 cells into the flanks of mice. OA was orally administered every day at two different doses, followed by periodically measuring the diameters of tumors in mice. The results showed that tumor growth was significantly retarded by the administration of high-dose OA ($P < 0.01$), but not low-dose OA ($P = 0.145$)

dx.doi.org/10.1021/jf500622p | J. Agric. Food Chem. 2014, 62, 5528−5537

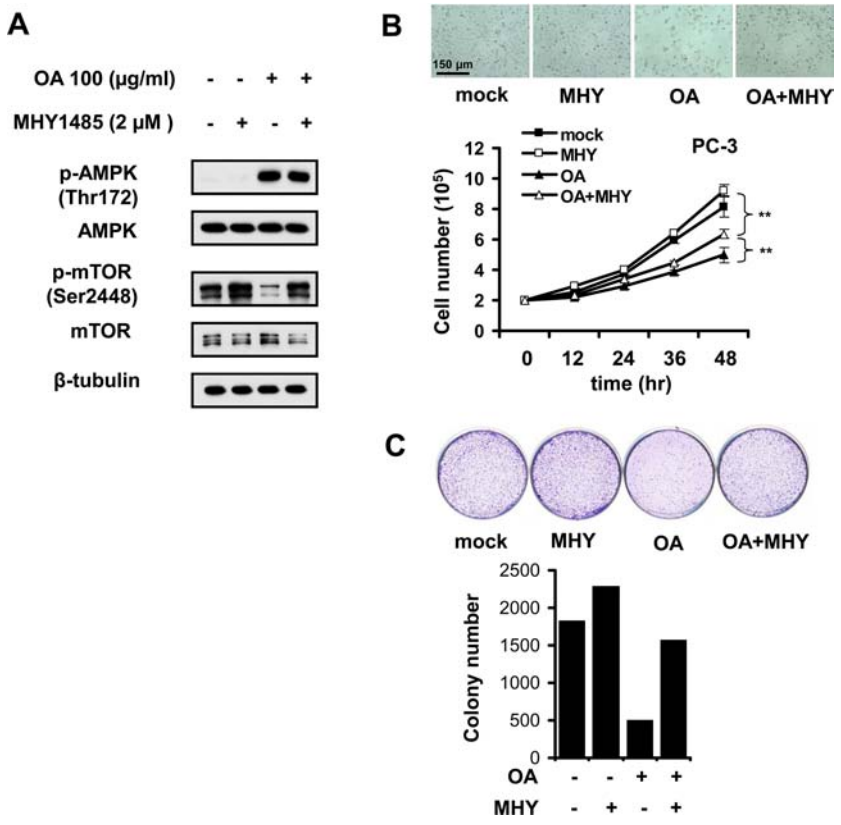

Figure 6. AMPK-dependent metabolic adaptation contributes to the tumor suppressor activity of OA on cancer cells. (A) PC-3 cells were pretreated with MHY1485 (2 μM) for 1 h prior to OA (100 μg/mL) stimulation. Phosphorylated AMPK and mTOR were detected by immunoblot assays. (B) PC-3 cells were analyzed for their proliferation at the indicated time points under the same treatment. Representative pictures are shown in the bottom panel. MHY, MHY1485. (C) Colony number of PC-3 cells treated with OA and/or MHY1485 was counted and shown as both pictures (upper panel) and bars (bottom panel).

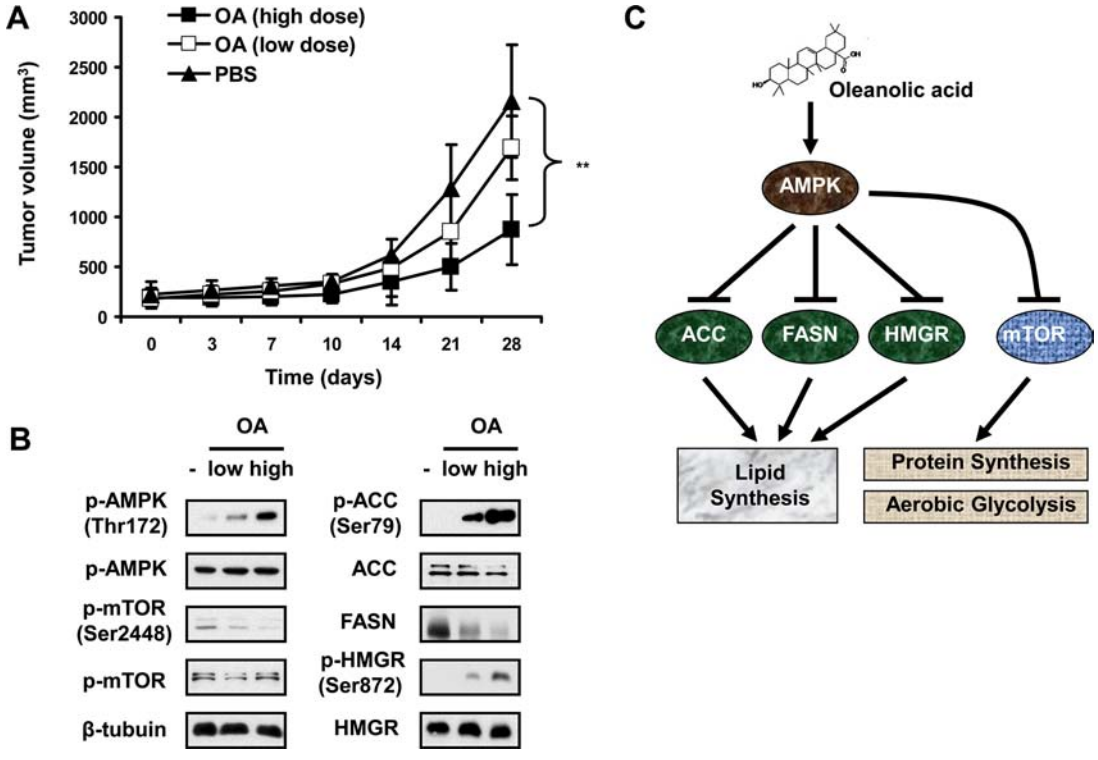

Figure 7. Action of OA on the activation of AMPK pathway in vivo. (A) OA (low dose, 40 mg/kg; high dose, 120 mg/kg) was orally administered every day for 4 weeks. Tumor volumes were periodically recorded as means ± SD. (B) The expression of phosphorylated AMPK, ACC, HMGR, and mOTR was detected in tumor xenografts. (C) Graphic illustration of molecular mechanisms by which OA alters the metabolic patterns via AMPK activation.

dx.doi.org/10.1021/jf500622p | J. Agric. Food Chem. 2014, 62, 5528−5537

(Figure 7A). Immunoblot analysis revealed that OA was able to induce the activation of AMPK in tumors (Figure 7B). Its downstream metabolism-related pathways were also affected by OA administration (Figure 7B). However, the low dose of OA indeed slightly suppressed the growth of tumor xenograft (Figure 7A), perhaps due to partial activation of AMPK and suppression of its downstream metabolic enzymes and key kinases (Figure 7B).

In addition, we detected the effect of OA on the metabolism of L-02 normal liver cells. Immunoblot assays revealed that the levels of phosphorylated AMPK are higher in normal cells than in cancer cells without OA treatment (Supporting Information panel A). OA was able to enhance AMPK phosphorylation in both cancerous and normal cells, but its effect on PC-3 cells appeared to be stronger than that in L-02 cells (Supporting Information panel A). Further metabolic assays showed that lipid and protein synthesis were higher in cancer cells than in normal cells, as well as aerobic glycolysis (Supporting Information panels B–E). OA was found to exert only a slight inhibitory effect on the above properties of normal cells (Supporting Information panels B–E).

In conclusion, we found that OA was able to induce AMPK activation and, consequently, change the metabolic patterns in cancer cells, which led to the decreased proliferation and colony formation of cancer cells (Figure 7C). We provided evidence that targeting metabolism is an effective anticancer strategy, and further preclinical and clinical studies based on metabolism as a therapeutic target should be performed.

ABSTRACT: Hyperpigmentation in human skin and enzymatic browning in fruits, which are caused by tyrosinase enzyme, are not desirable. Investigations in the discovery of tyrosinase enzyme inhibitors and search for improved cytotoxic agents continue to be an important line in drug discovery and development. In present work, a new series of 30 compounds bearing α,β-unsaturated carbonyl moiety was designed and synthesized following curcumin as model. All compounds were evaluated for their effects on human cancer cell lines and mushroom tyrosinase enzyme. Moreover, the structure−activity relationships of these compounds are also explained. Molecular modeling studies of these new compounds were carried out to explore interactions with tyrosinase enzyme. Synthetic curcumin-like compounds (**2a−b**) were identified as potent anticancer agents with 81−82% cytotoxicity. Five of these newly synthesized compounds (**1a**, **8a−b**, **10a−b**) emerged to be the potent inhibitors of mushroom tyrosinase, providing further insight into designing compounds useful in fields of food, health, and agriculture.

KEYWORDS: *melanogenesis, Curcuma longa, cytotoxicity, antibrowning, synthesis*

INTRODUCTION

Throughout history, natural products have offered a rich source of compounds that have widespread applications in the fields of medicine, food and agriculture.[1] Structural modification of natural compounds or synthesis of new compounds, based upon designs following a natural compound scaffolding, have provided us a lot of important new commercialized drugs within the medicine, agriculture, and food spheres.[2,3] An important line in the discovery of modern anticancer drugs is exploration for enhanced cytotoxic agents principally with safety perspectives in view.[4] In line with the safety issues, plant-derived natural compounds have always fascinated scientists worldwide on grounds of being biocompatible, natural compounds that are deemed as potentially safe and effective skin lightening and anticancer agents.[5]

Curcumin, flavonoids, and numerous dietary chemopreventive compounds have shown potential in treating cancer or dermatological disorders.[6−8] Behind cardiovascular diseases, cancer is the second principal cause of death in the world. For treating a wide range and types of cancer, plentiful effort have been started for decades but it is only recently that chemoprevention has attracted due share of attention. Combinatorial chemistry along with high-throughput screening technique directed toward molecular targets and cancer cells are well-known methods for primary anticancer drug discovery.[9−11] Curcumin is a plant-derived polyphenol obtained from *curcuma longa;* Powdered rhizome of this plant, turmeric, has been widely used for color impartment and flavoring to foods and by tradition for the treatment of various inflammatory conditions and other diseases.[12−14] Curcumin (diferuloylmethane) possesses both anticancer and antityrosinase properties.[15−17]

Tyrosinase, a ubiquitous dinuclear copper enzyme, catalyzes the hydroxylation of phenols to catechols and the subsequent oxidation of catechols to quinones. This series of events take place by activation of dioxygen in the form of a side-on-bonded peroxide dicopper(II) species, crystallographically[18] and spectroscopically identified.[19,20] Melanin is a pigmented heteropolymer synthesized by differentiated melanocytes in specialized cellular organelles termed melanosomes. The entire process leading to the formation of melanin is called melanogenesis and is initiated with the first step of tyrosine oxidation to dopaquinone catalyzed by tyrosinase.

Melanin plays an important role in protecting human skin from the harmful effects of UV radiation from the sunlight. This is achieved by transfer of mature melanosomes to neighboring keratinocytes, which are arranged in a supranuclear cap, protecting the DNA against incident ultraviolet light (UV) irradiation.[21] By controlling skin tone, melanin also determines the human phenotypic appearance. Although photoprotection

is melanin's main function in human skin, the accumulation of an abnormal amount of melanin in specific parts of the skin resulting in more pigmented patches might become an aesthetic problem. In addition, enzymatic browning caused by tyrosinase system in fruits and fungi is undesirable in, for example, fresh fruits, beverages, vegetables, and mushrooms. In commercial or domestic processing, handling and storage of foods, tyrosinase is contemplated to have a critical role. In bruised or cut fruits, vegetables and other plant foods, tyrosinase causes enzymatic browning which subsequently leads to a significant decrease in nutritional and market values.[22] The undesirable phenomenon of hyperpigmentation in human skin and enzymatic browning in fruits have ushered researchers to seek new, enhanced, and potent tyrosinase inhibitors for use in antibrowning of foods and skin whitening. Owing to the exclusively important roles in mammalian melanogenesis as well as enzymatic browning in fruits and fungi, tyrosinase inhibitors have been an important concern under the research radar for years.

Some tyrosinase inhibitors have been discovered and reviewed before.[23−26] Herein, a new series of 30 compounds bearing α,β-carbonyl moiety was designed and synthesized based on curcumin template (Figure 1) for potential use in

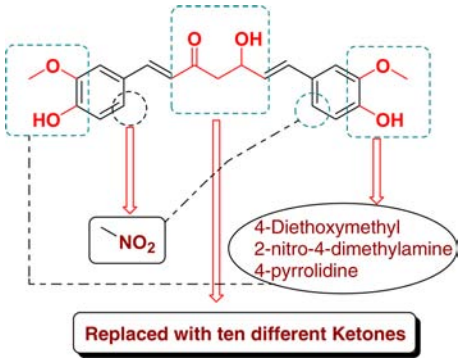

Figure 1. Chemical modifications in structure of curcumin.

cosmetics, clinical medicines, food industry, and agriculture. Effects of synthesized compounds on human cancer cell lines and mushroom tyrosinase enzyme were evaluated. Furthermore, structure−activity relationships of synthesized compounds were also discussed.

MATERIALS AND METHODS

Materials and General Procedures. All chemicals and reagents utilized in this research were purchased from Sigma-Aldrich (St. Louis, MO), Merck (Darmstadt, Germany) and Acros Organics (Geel, Belgium) of analytical grade, and were used as supplied, unless otherwise stated. A typical work-up included washing with brine and drying the organic layer with anhydrous magnesium sulfate before concentration in vacuo. ^{1}H and ^{13}C NMR spectra were recorded with a JEOL ECP spectrometer operating at 500 MHz, with Me4Si as internal standard and $CDCl_3$ or DMSO-d_6 as the solvent. High resolution mass spectra (HRMS) were determined by the Electrospray ionization mass spectrometry (ESI-MS) on MicroTOF-Q mass spectrometer (Bruker, Billerica, MA). Microanalyses data were obtained from the Fison EA 1108 elemental analyzer. Infrared spectra were recorded using KBr disc on a PerkinElmer 400 (FTIR) spectrometer. Flash column chromatography was performed with silica gel 60 (230−400mesh) (Merck) and thin layer chromatography (TLC) was carried out on precoated silica plates (kiesel gel 60 F_{254}, BDH). Melting points were determined on an electrothermal instrument and are uncorrected. Compounds were visualized by illumination under ultraviolet (UV) light (254 nm) or by the use of vanillin stain followed by charring on a hot plate.

Synthesis of Curcumin Related α,β-Unsaturated Carbonyl-Based Compounds. A direct coupling approach was employed in order to synthesize α,β-unsaturated carbonyl-based compounds. A general reaction proceeded by base catalyzed Claisen-Schmidt condensation, carried out by reacting a suitable aromatic aldehyde with different types of 10 ketones: at a molar ratio of 1:2 for synthesizing 21 compounds (**1a−7a**; **1b−7b**; **1c−7c**), and at a molar ratio of 1:1 for 9 compounds (**8a−10a**; **8b−10b**; **8c−10c**). A general synthesis method of α,β-unsaturated carbonyl-based compounds is illustrated in Figure 2. Briefly, in a single necked round-bottom flask, selected aromatic aldehyde (20 mmol, 2 equivalant) and ketone (10 mmol, 1 equiv) were mixed and dissolved in 15 mL of ethanol and stirred at 5 °C for a few minutes. A 40% NaOH solution (in ethanol) was then added into the above solution drop by drop over several minutes. The mixture obtained was stirred at room temperature (27 °C) for 1−24 h. Product formation was indicated by the appearance of precipitate and change in color of the reaction mixture. TLC was used to monitor the reaction and upon completion, acidified ice was added to the mixture for quenching the reaction. Column chromatography and/or recrystallization processes were used to isolate α,β-unsaturated carbonyl-based compounds.

*2,6-Bis[4-(diethoxymethyl)benzylidene]cyclohexanone (**1a**).* Yellow crystals (2.59 g, 54%). Mp: 112−114 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.89 (s, 2H), 7.29 (d, J = 8 Hz, 4H), 6.82 (d, J = 8 Hz, 4H), 5.89 (s, 2H), 3.42 (q, J = 7.5, 8H), 2.32 (t, J = 12.0 Hz, 4H), 1.82 (m, 2H), 1.24 (t, J = 7.5, 12H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 186.4, 152.9, 144.4, 136.5, 132.5, 127.3, 126.5, 101.1, 55.0, 28.3, 27.8, 16.2; HRMS (ESI) m/z: 479.68 $[M + H]^+$, Microanalysis calculated for $C_{30}H_{38}O_5$ (478.62), C: 75.28%, H: 8.00%. Found C: 75.42%, H: 8.12%.

*2,6-Bis(4-dimethylamino-2-nitro-benzylidene)-cyclohexanone (**1b**).* White powder (2.78 g, 62%). Mp: 139−140 °C; δ: 7.94 (s, 2H), 7.55 (d, J = 8 Hz, 2H), 7.41 (d, J = 8 Hz, 2H), 7.13 (s, 2H), 3.15 (s, 12H), 2.35 (t, J = 12.0 Hz, 4H), 1.87 (m, 2H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 190.7, 149.5, 145.7, 145.6, 140.1, 128.2, 118.6, 117.6, 106.5, 46.8, 29.1, 27.5; HRMS (ESI) m/z: 451.64 $[M + H]^+$, microanalysis calculated for $C_{24}H_{26}N_4O_5$ (450.49), C: 63.99%, H: 5.82%, N: 12.44%. Found C: 64.12%, H: 5.72%, N: 12.42%.

*3,5-Bis(4-diethoxymethyl-benzylidene)-tetrahydro-pyran-4-one (**2a**).* Pale-yellow crystals (3.06 g, 64%). Mp: 106−108 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.85 (s, 2H), 7.32 (d, J = 8 Hz, 4H), 6.95 (d, J = 8 Hz, 4H), 5.52 (s, 2H), 3.62 (q, J = 7.5, 8H), 2.69 (s, 4H), 1.18 (t, J = 8, 12H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 187.2, 152.7, 143.8, 136.7, 131.9, 126.2, 125.2, 101.5, 62.4, 55.2, 16.1; HRMS (ESI) m/z: 481.65 $[M + H]^+$, microanalysis calculated for $C_{29}H_{36}O_6$ (480.59), C: 72.48%, H: 7.55%. Found C: 72.62%, H: 7.72%.

*3,5-Bis[4-(dimethylamino)2-nitro-benzylidene]-1-methyl-piperidin-4-one (**4b**).* White powder (2.56 g, 55%). Mp: 181- 182 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.76 (s, 2H), 7.45 (d, J = 8 Hz, 2H), 7.23 (d, J = 8 Hz, 2H), 7.13 (s, 2H), 3.21 (s, 12H), 3.03 (s, 4H), 2.19 (s, 3H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 187.5, 148.9, 148.2, 143.2, 141.8, 126.7, 119.6, 118.9, 106.2, 44.5, 46.1, 38.8; HRMS (ESI) m/z: 466.72 $[M + H]^+$, microanalysis calculated for $C_{24}H_{27}N_5O_5$ (465.50), C: 61.92%, H: 5.85%, N: 15.04%. Found C: 61.99%, H: 5.91%, N: 15.19%.

*1,5-Bis(4-diethoxymethyl-phenyl)-penta-1,4-dien-3-one (**6a**).* Pale-brown solid (1.96 g, 45%). Mp: 98−100 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.82 (d, J = 6.5 Hz, 4H), 7.71 (d, J = 8 Hz, 2H), 7.49 (d, J = 6.5 Hz, 2H), 7.16 (d, J = 7 Hz, 4H), 5.25 (s, 2H), 3.52 (q, J = 7 Hz, 8H), 1.17 (t, J = 7.0, 12H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 190.5, 152.2, 148.6, 139.7, 136.4, 135.2, 132.8, 102.2, 55.5, 16.9; HRMS (ESI) m/z: 439.62 $[M + H]^+$, microanalysis calculated for $C_{27}H_{34}O_5$ (438.56), C: 73.94%, H: 7.81%. Found C: 74.12%, H: 7.89%.

*1,5-Bis(4-dimethylamino-2-nitro-phenyl)-penta-1,4-dien-3-one (**6b**).* Pale-yellow solid (2.97 g, 68%). Mp: 177−179 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.70 (d, J = 6 Hz, 2H), 7.68 (d, J = 8 Hz, 2H), 7.44 (d, J = 6 Hz, 2H), 7.25 (d, J = 8 Hz, 2H), 7.12 (s, 2H), 3.15 (s,

12H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 187.5, 150.9, 148.6, 144.4, 132.8, 128.1, 117.5, 113.8, 107.9, 46.7; HRMS (ESI) m/z: 409.45 $[M - H]^+$, microanalysis calculated for $C_{21}H_{22}N_4O_5$ (410.42), C: 61.45%, H: 5.40%, N: 13.65%. Found C: 61.48%, H: 5.62%, N: 13.77%.

*2,5-Bis(4-diethoxymethyl-benzylidene)-cyclopentanone (**7a**).* Light-yellow crystals (3.12 g, 67%). Mp: 88−89 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.69 (d, J = 6.5 Hz, 4H), 7.42 (s, 2H), 7.21 (d, J = 6.5 Hz, 4H), 5.45 (s, 2H), 3.62 (q, J = 7 Hz, 8H), 2.38 (t, J = 7 Hz, 4H), 1.22 (t, J = 7.0, 12H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 189.7, 149.4, 145.5, 138.7, 136.4, 133.9, 129.1, 100.9, 56.2, 32.5, 16.1; HRMS (ESI) m/z: 465.72 $[M + H]^+$, microanalysis calculated for $C_{29}H_{36}O_5$ (464.59), C: 74.97%, H: 7.81%. Found C: 75.18%, H: 7.87%.

*2,5-Bis(4-dimethylamino-2-nitro-benzylidene)-cyclopentanone (**7b**).* White powder (2.41 g, 55%). Mp: 156−157 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.92 (d, J = 6.5 Hz, 2H), 7.88 (d, J = 6 Hz, 2H), 7.75 (d, J = 6.5 Hz, 2H), 7.44 (s, 2H), 3.10 (s, 12H), 2.45 (t, J = 7 Hz, 4H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 188.9, 153.2, 149.9, 144.2, 143.8, 125.8, 118.1, 116.4, 108.3, 46.9, 32.6; HRMS (ESI) m/z: 437.72 $[M + H]^+$, microanalysis calculated for $C_{23}H_{24}N_4O_5$ (436.46), C: 63.29%, H: 5.54%, N: 12.84%. Found C: 63.42%, H: 5.48%, N: 12.72%.

*2-(4-Diethoxymethyl-benzylidene)-indan-1-one (**8a**).* White powder (2.52 g, 78%). Mp: 152−154 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.80 (d, J = 8 Hz, 2H), 7.69 (s, H), 7.48 (d, J = 8 Hz, 2H), 7.25 (d, J = 7.5 Hz, H), 7.20 (d, J = 7.5 Hz, H), 7.05 (t, J = 7.5 Hz, H), 6.94 (t, J = 7 Hz, H), 5.34 (s, H), 3.49 (q, J = 7 Hz, 4H), 2.75 (s, 2H), 1.29 (t, J = 6 Hz, 6H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 193.2, 144.5, 142.2, 140.1, 139.2, 138.8, 136.5, 130.4, 129.6, 128.1, 125.6, 125.1, 124.2, 102.2, 56.3, 29.9, 16.4; HRMS (ESI) m/z: 323.67 $[M + H]^+$, microanalysis calculated for $C_{21}H_{22}O_3$ (322.40), C: 78.23%, H: 6.88%. Found C: 78.44%, H: 6.92%.

*2-(4-Dimethylamino-2-nitro-benzylidene)-indan-1-one (**8b**).* Yellow semisolid (1.95 g, 63%). Mp: 169−171 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.56 (d, J = 8 Hz, H), 7.48 (s, H), 7.32 (d, J = 8 Hz, H), 7.12 (s, H), 6.98 (d, J = 7.5 Hz, H), 6.91 (d, J = 7.5 Hz, H), 6.74 (t, J =

7.5 Hz, H), 6.65 (t, J = 7 Hz, H), 3.22 (s, 6H), 2.81 (s, 2H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 192.8, 145.6, 142.6, 141.3, 139.8, 138.2, 137.4, 130.9, 128.7, 128.0, 125.9, 123.8, 119.5, 117.6, 108.6, 46.8, 28.3; HRMS (ESI) m/z: 309.55 $[M + H]^+$, microanalysis calculated for $C_{18}H_{16}N_2O_3$ (308.33), C: 70.12%, H: 5.23%, N: 9.09%. Found C: 70.18%, H: 5.59%, N: 9.18%.

*2-(4-Diethoxymethyl-benzylidene)-3,4-dihydro-2H-naphthalen-1-one (**9a**).* Light-yellow solid (2.67g, 80%). Mp: 94−95 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.84 (d, J = 8 Hz, 2H), 7.59 (s, H), 7.47 (d, J = 8.5 Hz, 2H), 7.29 (d, J = 7.5 Hz, H), 7.22 (d, J = 7.5 Hz, H), 7.12 (t, J = 7.5 Hz, H), 7.02 (t, J = 7 Hz, H), 5.49 (s, H), 3.35 (q, J = 7 Hz, 4H), 2.29 (t, J = 7 Hz, 2H), 2.05 (t, J = 7 Hz, 2H), 1.17 (t, J = 6 Hz, 6H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 188.3, 152.2, 150.1, 148.5, 146.2, 143.9, 137.5, 134.4, 129.2, 127.2, 126.2, 124.8, 117.2, 101.7, 56.2, 29.5, 28.2, 16.0; HRMS (ESI) m/z: 337.51 $[M + H]^+$, microanalysis calculated for $C_{22}H_{24}O_3$ (336.42), C: 78.54%, H: 7.19%. Found C: 78.33%, H: 7.12%.

*2-(4-Dimethylamino-2-nitro-benzylidene)-3,4-dihydro-2H-naphthalen-1-one (**9b**).* White powder (2.50 g, 78%). Mp: 138−139 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.82 (d, J = 6.5 Hz, H), 7.57 (s, H), 7.42 (d, J = 6.5 Hz, H), 7.35 (s, H), 7.28 (d, J = 7 Hz, H), 7.20 (d, J = 7 Hz, H), 7.19 (t, J = 7.5 Hz, H), 6.92 (t, J = 8 Hz, H), 3.14 (s, 6H), 2.47 (t, J = 7 Hz, 2H), 2.14 (t, J = 7 Hz, 2H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 188.7, 152.8, 151.3, 148.9, 146.8, 144.2, 136.8, 134.6, 129.9, 127.6, 126.1, 125.3, 124.2, 107.8, 46.2, 29.9, 27.9; HRMS (ESI) m/z: 323.45 $[M + H]^+$, microanalysis calculated for $C_{19}H_{18}N_2O_3$ (322.36), C: 70.79%, H: 5.63%, N: 8.69%. Found C: 71.12%, H: 5.52%, N: 8.72%.

*2-[3-(4-Diethoxymethyl-phenyl)-acryloyl]-3,4-dihydro-2H-naphthalen-1-one (**10a**).* Yellow solid (3.16 g, 83%). Mp: 121−122 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.75 (d, J = 6 Hz, H), 7.52 (d, J = 6 Hz, H), 7.42 (d, J = 8 Hz, 2H), 7.39 (d, J = 8 Hz, 2H), 7.32 (d, J = 7 Hz, H), 7.29 (d, J = 7 Hz, H), 7.17 (t, J = 7 Hz, H), 6.89 (t, J = 7 Hz, H), 5.29 (s, H), 3.47 (q, J = 7 Hz, 4H), 3.29 (t, J = 8.5 Hz, H), 2.12 (t, J = 8 Hz, 2H), 1.95 (t, J = 7 Hz, 2H), 1.24 (t, J = 6.5 Hz, 6H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 194.6, 151.1, 148.9, 144.6, 142.3, 139.2, 138.4, 136.2, 135.5, 132.4, 130.6, 129.1, 125.2, 124.2, 103.1, 66.1, 55.7, 30.2, 28.6, 16.7; HRMS (ESI) m/z: 379.52 $[M + H]^+$, microanalysis calculated for $C_{24}H_{26}O_4$ (378.46), C: 76.17%, H: 6.92%. Found C: 76.21%, H: 6.91%.

*2-[3-(4-Dimethylamino-2-nitro-phenyl)-acryloyl]-3,4-dihydro-2H-naphthalen-1-one (**10b**).* Pale-yellow powder (2.93 g, 80%). Mp: 102−103 °C; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 7.79 (d, J = 6.5 Hz, H), 7.62 (d, J = 6.5 Hz, H), 7.45 (d, J = 7.5 Hz, H), 7.32 (s, H), 7.29 (d, J = 7.5 Hz, H), 7.21 (d, J = 7.5 Hz, H), 7.14 (d, J = 7.5 Hz, H), 7.02 (t, J = 7.5 Hz, H), 6.94 (t, J = 7.5 Hz, H), 3.45 (t, J = 8.5 Hz, H), 3.10 (s, 6H), 2.22 (t, J = 8 Hz, 2H), 2.15 (t, J = 8 Hz, 2H); ^{13}C NMR (500 MHz, $CDCl_3$) δ: 193.8, 152.2, 148.7, 145.2, 142.8, 139.6, 137.1, 136.8, 135.6, 131.9, 130.5, 129.4, 124.8, 123.5, 116.5, 106.2, 65.8, 46.8, 31.3, 28.7; HRMS (ESI) m/z: 365.55 $[M + H]^+$, microanalysis calculated for $C_{21}H_{20}N_2O_4$ (364.39), C: 69.22%, H: 5.53%, N: 7.69%. Found C: 69.34%, H: 5.59%, N: 7.81%.4

MTT Assay. MTT assay was performed for determining the effect of synthetic compounds on normal (MCF-10A) mammary epithelial cells. MCF-10A cells were maintained in Dulbecco's modified Eagle's medium/Ham's F-12 medium (1:1) with 10% fetal calf serum, 2 mM glutamine, insulin (10 μg/mL), hydrocortisone (500 ng/mL), and epidermal growth factor (20 ng/mL). Cells were passaged every 2 to 3 days using trypsin EDTA (ethylenediaminetetraacetic acid). MCF-10A cells were plated at a density of 10^4 cells per milliliter in 96-well flat-bottomed plates. After 24 h, the medium was carefully aspirated and tested compounds (curcumin analogues) were added in quadruplicate in 200 μL of medium to give a final concentration of not more than 0.1% (v/v) dimethyl sulfoxide (DMSO). The cells were then permitted to grow for 96 h at 37 °C. The medium was removed and fresh medium with MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide) (0.4 mg/mL) was added to each well for 3 h. All medium was aspirated and the formazan product generated by viable cells was solubilized with 150 μL of DMSO. Plates were vortexed and the absorbance at 540 nm determined using a microplate reader. Results were expressed as the percentage inhibition of proliferation compared to controls containing 0.1% DMSO.

Anticancer Activity. For determining the anticancer activity a propidium iodide (PI) fluorescence assay was performed on MCF-7 (breast cancer cell line), PC-3 (prostate cancer cell line), HL-60 (promyelocytic leukemia cell line), H-460 (lung cancer cell line) and HT-29 (colon cancer cell line) cell lines.[27] Propidium iodide (PI), a dye which binds to DNA, provides a rapid and accurate means for quantitating total nuclear DNA. The principle of this assay is based on the fact that PI is not able to penetrate an intact cell membrane and the fluorescence signal intensity of the PI is directly proportional to the amount of DNA in each cell. So the cells which have damaged membranes or altered permemability profiles are scored as dead cells. For a typical PI cytotoxicity assay, cells, after trypsinization and counting, were seeded at 3000−7500 cells/well in 200 μL media in sterile tissue culture grade 96 well plates and allowed to recover for 24 h in humidified 5% CO_2 incubator at 37 °C. After this, compounds (in 0.1% DMSO) were added onto triplicate wells with 10 μM concentrations. 0.1% DMSO alone was used as control. Treatment with test compounds was continued for 48 h. After completion of designated treatment period, the medium was removed and cells were treated with 25 μL of propidium iodide (50 μg/mL in water/medium) per well. The above plates with samples were frozen at −80 °C for 24 h, then thawed and allowed to equilibrate to room temperature. Plates were read on a fluorometer (Polar-Star BMG Tech), using 530 nm excitation and 620 nm emission wavelength. Lastly, percent cytotoxicity of the compounds was calculated by using following formula:

$$\%\text{Cytotoxicity} = \frac{A_C - A_{TC}}{A_C} \times 100$$

where A_C = Absorbance reading of control and A_{TC} = Absorbance reading of treated cells. The results were compared with the standard drug inhibitors flavopiridol (0.5 μM).

Tyrosinase Assay. The spectrophotometric assay for tyrosinase was performed according to the reported method with slight modifications.[28] Briefly, L-DOPA was used as substrate to screen the synthesized compounds for the diphenolase inhibitory activity of tyrosinase. Positive controls in the assay were Kojic acid and 4-Butylresorcinol. 2% stock solutions of compounds were prepared in DMSO and diluted using phosphate buffer (pH = 6.8). These synthesized compounds were preincubated in 50 mM phosphate buffer (pH = 6.8) at 25 °C for 10 min with 30 units of mushroom tyrosinase (0.5 mg/mL). L-DOPA (0.5 mM) was then added to the reaction mixture. Reaction was monitored by following formation of L-DOPA chrome for 1 min measured by the change in absorbance at 475 nm. Triplicate measurements were taken for each concentration and average was used for further calculations. Dose−response curves were interpolated to obtain the IC_{50} values.

Molecular Modeling. Molecular modeling studies were performed with MOE (The Molecular Operating Environment) Version 2011.10, software available from Chemical Computing Group Inc., 1010 Sherbrooke Street West, Suite 910, Montreal, Canada H3A2R7, http://www.chemcomp.com. The ligands were built using the builder tool of the MOE program and subjected to energy minimization (MMFF94x, gradient: 0.05). The X-ray crystallographic structure of mushroom tyrosinase (PDB: 2Y9W)[29] was obtained from the Protein Data Bank. The errors of the protein were corrected by the Structure Preparation process in MOE. After correction, hydrogens were added and partial charges (Gasteiger methodology) were calculated. Site finder application was used to detect the possible binding pocket. The default Triangle Matcher placement method was applied for docking. GBVI/WSA dG scoring function which estimates the free energy of binding of the ligand from a given pose was used to rank the final poses. The ligand-enzyme complexes with lowest S score were selected for each ligand.

Statistical Analysis. Analysis was carried out using a complete randomized design and treatments were run in triplicates (n = 3). Statistical analysis was done using analysis of variance (ANOVA)

method of general linear model (GLM) procedure using SAS V8 (Cary, NC) for multiple comparisons. $P < 0.05$ was considered to be statistically significant.

RESULTS AND DISCUSSION

Chemistry. Claisen-Schmidt condensation was used for the synthesis of the desired α,β-unsaturated carbonyl-based compounds[30] by reacting different ketones and the appropriate aryl aldehyde. Twenty-one compounds (**1a**−**7a**; **1b**−**7b**; **1c**−**7c**) were synthesized in the presence of NaOH at a 1:2 molar ratio in ethanol while some compounds were synthesized in acetic acid by passing dry HCl gas through the mixture. Claisen-Schmidt condensation was also employed to synthesize nine compounds (**8a**−**10a**; **8b**−**10b**; **8c**−**10c**) similar to chalcone analogues however employing 1:1 molar ratio of ketone and aldehyde (Figure 2). Both types of catalytic systems, that is, NaOH and dry HCl gas mixture, were used to synthesize eight compounds (**7a**, **8a**, **10a**, **7b**, **8b**, **10b**, **7c**, **8c**). Catalytic system employing HCl gas mixture gave high percentage yields compared to NaOH. Using NaOH as a catalyst resulted in producing a mixture of several different unidentified products necessitating excessive purification using column chromatography.

Spectrophotometric techniques were used to characterize the synthesized compounds. An elemental analysis of C, H, and N, and melting points are represented. Representative carbon nuclear magnetic resonance spectra were also recorded. NH absorptions were not seen in the ^{1}H NMR spectra of the compounds **4a**, **4b** and **4c**, it has previously been shown by other researchers.[30,31]

Cytotoxicity toward MCF-10A Normal Mammary Epithelial Cells. The rule of three, relating to activity-exposure-toxicity, presents the single most difficult challenge in the design and advancement of drug candidates to the development stage. Absorption, distribution, metabolism and excretion (ADME) studies are widely used in drug discovery to optimize this balance of properties necessary to convert lead compounds into drugs that are both safe and effective for human patients.[32] Therefore, in vitro cell viability assay was performed by using the MCF-10A that is a normal cell line and was used as a comparison. MCF-10A cells were treated with synthetic compounds for 96 h and cell viability was measured using the MTT assay. Results are expressed in terms of percentage of toxicity (Table 1). The compounds were found to be nontoxic and majority of compounds showed more than 95% cell viability. Therefore, the compounds are biologically safe and can be used as the therapeutic agent for future drug discovery study.

Effects on Human Cancer Cell Lines. Anticancer activity of curcumin is one of the most widely explored activities among numerous others like anti-inflammatory activity. In vitro cytotoxicity assays performed in various cell lines originating from different organs show that curcumin have beneficial effects in, including but not limited to: prostate cancer cells,[33] ovarian cancer cells,[34] gastric carcinoma cells,[35] liver cancer cells, hepatocel- lular carcinoma cells,[36] cervical cancer cells,[37] breast cancer cells,[38] colon cancer cells,[39] lung carcinoma cell,[40] bladder cancer cells,[41] and pancreatic adenocarcinoma cell.[42] This provides strong preliminary data for the justification of clinical studies in humans.

Synthesized compounds were tested in present investigation for their capacity to inhibit the growth of five different cancer cell lines (PC-3, MCF-7, HL-60, H-460, and HT-29).

[a]HT-29 (colon cancer cell line), PC-3 (prostate cancer cell line), MCF-7 (breast cancer cell line), H-460 (lung cancer cell line), HL-60 (promyelocytic leukemia cell line), MCF-10A (normal mammary epithelial cell line). [b]0.5 μM concentration.

Compound **2b** was found to have highest anticancer activity inhibiting 82% of PC-3 cells; this was closely followed by compound **2a** showing 81% inhibition. These two compounds also show similarly comparative levels of anticancer activity (75−82%) on the other four cell lines used for experiments. Compound **2a** and **2b** were followed by six curcumin-like compounds (**2a**−**b**, **3a**−**b**, and **4a**−**b**) which had promising anti cancer activity (59−82%) (Figure 3). This was followed by 12 compounds (**1a**−**c**, **2c**, **3c**, **4c**, **5a**−**b**, **6a**−**b**, and **10a**−**b**) which show moderate effect (40−58%). Insignificant activity was shown by remaining compounds. For the anticancer activity experiments, positive control used was flavopiridol, which show 79% inhibition of H-460 cells at 0.5 μM concentration. Generally, curcumin like compounds show similar inhibitory anticancer activity on the tested cell lines and it was observed that the average difference in inhibitory activities was not more

than 5% types of tested cancer cell lines. For most active compounds (**2a**, **2b**, **4a** and **4b**) the median inhibition concentration (IC_{50}) was calculated using GraphPad Prism software (GraphPad Software, San Diego, CA) and it was observed that compound **2b** was very potent anticancer agent among all other tested compounds with very low IC_{50} value in the range of 1.04 to 1.08 μM (Table 2).

Compounds **2a**, **2b**, **4a**, and **4b** were found to have high potency against different types of cancer cell lines. It can be depicted from their physicochemical properties (Table 2) that these compounds have potential to be new lead compounds in developing anticancer agents. Physicochemical properties of tested compounds were found within optimal range (Molecular weight <500; clog$P$ < 5 and TPSA <140).[43,44]

Effects on the Diphenolase Activity of Mushroom Tyrosinase. Tyrosinase inhibitory assay was performed for all synthesized curcumin-related compounds by measuring the oxidation of L-DOPA as previously reported.[28] A concentration-dependent enzyme activity inhibition by the compounds was observed. It was observed that the activity of remaining enzyme swiftly decreased when the concentration of compound (inhibitor) was increased. Table 1 summarizes the enzyme inhibition data expressed as IC_{50}. The majority of synthetic curcumin related compounds (**1a−c**, **2a−c**, **3a−b**, **6a−c**, **7a−c**, **8a−c**, **9a−c**, **10a−c**) exhibit <100 μM inhibitory activities against mushroom tyrosinase. With IC_{50} ranging from 5.34 to 10.11 μM, five compounds (**1a**, **8a−b** and **10a−b**) exhibited promising tyrosinase inhibitiory activity better than positive control Kojic acid (10.93 μM). Two of the synthesized compounds (**8a** and **10a**), with diethoxymethyl group at position 4, were found to be the strongest inhibitors among all tested compounds with IC_{50} values 6.83 and 5.34 μM respectively.

Structure−Activity Relationship Analysis. It was observed that the presence or absence of groups on the two aromatic rings and the linker between the two aromatic rings both played key roles in determining the anticancer inhibitory activity of the various analogues on the tested cancer cells. From their data for SAR of monocarbonyl analogues, the research group of G Liang, had shown previously that acetone and cyclohexanone spacers are much more favorable than the cyclopentanone one[45] for enhanced anticancer activity. Conclusion drawn by Liang's group is also afforded by present study as all synthetic compounds containing cyclopentanone ring system (**7a−7c**) have lesser anticancer activity when compared to compounds with acetone and cyclohexanone system. In fact, among these three group of compounds (**1**, **6**, **7**), compounds bearing cyclohexanone were found to be most active.

Different activity trends were observed among the different series of curcumin-related compounds when either linear or cyclic linkers were used between the two aromatic rings of curcumin related compounds. In general, tetrahydropyran-4-one (**2a−c**) linker containing compounds exhibited the strongest activities, moderate activity was exhibited by compounds with *N*-methyl-4-piperidone (**3a−c**), while three compounds (**4a−c**) with 4-piperidone showed good inhibition power however it was lesser compared to compounds bearing

dx.doi.org/10.1021/jf501145b | J. Agric. Food Chem. 2014, 62, 5538−5547

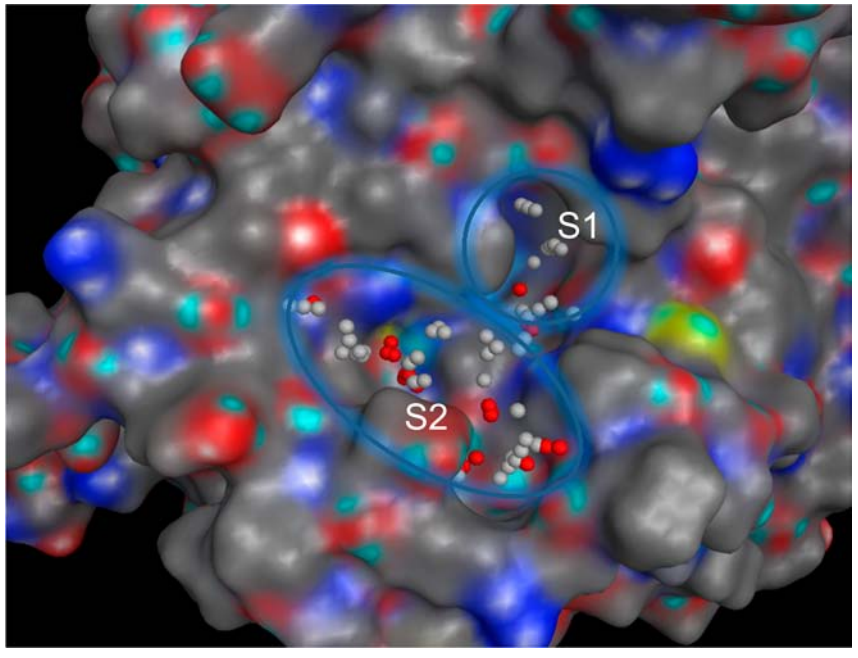

Figure 4. Binuclear copper binding site (S1) and its entrance (S2) region of mushroom tyrosinase enzyme.

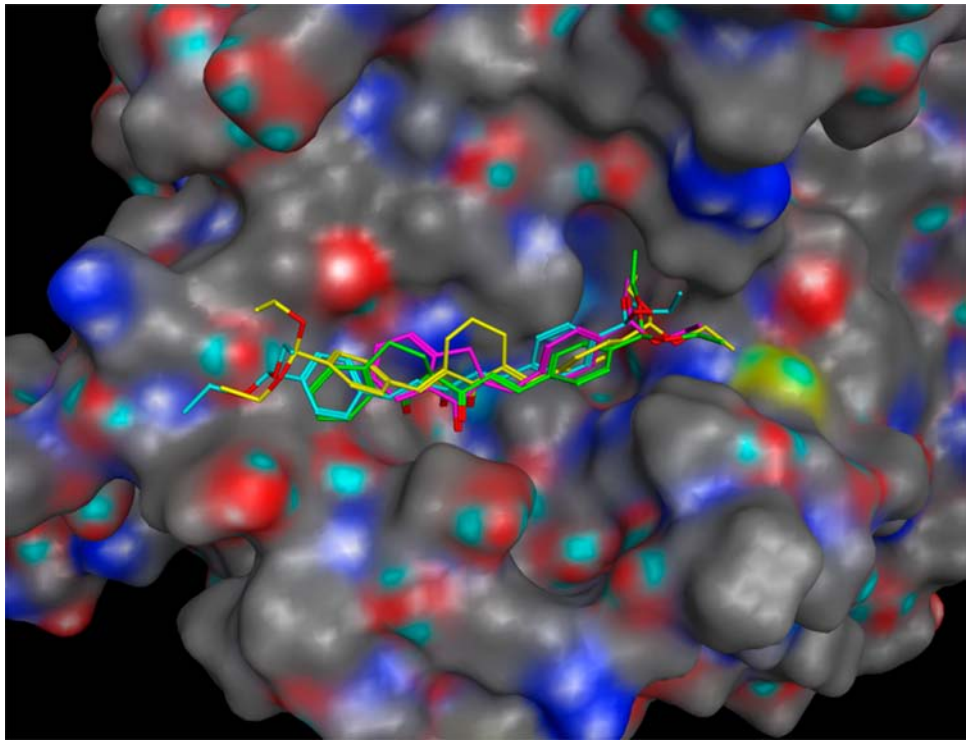

Figure 5. Superimposition of the best poses of compound **1a**, **6a**, **8a** and **10a** (**1a**, **6a**, **8a**, and **10a** are shown as yellow, blue, pink, and green, respectively).

N-methyl-4-piperidone. Bis-derivatives, bearing either 1-benzyl-4-piperidone (**5a**–**c**), acetone (**6a**–**c**) or cyclopentanone (**7a**–**c**) linker, were less active compared to the rest. Conversely, among the monoderivatives (**8**–**10**), merely compounds bearing dicarbonyl linker (**10a**–**b**) were shown to have moderate growth inhibitory anticancer activity in the tested cell lines.

Presence of a heteroatom linker in groups of compounds (**2**, **3**, **4**) resulted in enhanced anticancer activities compared to the compounds without a heteroatom linker (**1**, **6**, **7**). This finding suggests that flexibility of curcumin-like compounds could improve their anticancer activities which could be due to the ease of interactions with the DNA of cancer cells. Contrary to this, compounds with small and rigid linker would be less active due to the difficulty of interactions with DNA. Association of curcumin flexibility with curcumin-DNA interaction, which could be a possible explanation for antitumor activity, is a valuable and interesting finding.[46,47]

Effects of substitution of various groups curcumin related compound activity were compared. It was observed that introduction of 2-nitro-4-dimethylamine combination on the aromatic rings improved anticancer activity of curcumin related compounds. In all the three groups (based on substitution pattern **a**, **b**, **c**), compounds bearing combination of 2-nitro and 4-dimethylamine show exceptionally elevated anticancer activity whereas presence of diethoxymethyl group at position 4 of rings consequently produces markedly reduced anticancer activity. Further, presence of pyrrolidine at position 4 of compounds (**1**−**10c**) results in compounds which are not highly active.

Analysis of the effects of curcumin related compounds on tyrosinase activity produced structure−activity relationship with new and interesting findings. Based upon different substituted groups, with two exception (**4b** and **7b** more active than **4a** and **7a**), it was observed that compounds having diethoxymethyl group at position 4 of rings (group **a**) were most active against the mushroom tyrosinase activity. Like the anticancer activity, substitution of pyrrolidine at position 4 of compounds (**1**−**10c**) did not produce strongly active compounds for tyrosinase inhibition. An interesting finding was the presence of dicarbonyl group (**10a**−**b**) that resulted in maximum tyrosinase inhibition even better than the positive controls. In general, the monoderivatives (**8**−**10**) show better antityrosinase activity as compared to bis-derivatives (**2**−**7**). However, presence of a heteroatom linker (**2**, **3**, and **4**) did not result in compounds with a better antityrosinase activity when compared to those without a heteroatom linker (**1**, **6**, and **7**).

Molecular Docking Study. Tyrosinase enzyme has binuclear copper binding site and tropolone and kojic acid bind the entrance of this site.[29,48] In this study, Site Finder application in MOE was used to find the possible binding sites in the enzyme. The region consisting of S1 and S2 site was indicated as active pocket (Figure 4). S1 contains binuclear copper binding site where S2 locates near the entrance of this site.

To simplify, docking results were evaluated in groups. First of all, (a) the docking results of compound **1**−**7a** (bis-derivatives) which have different keton structures were considered. Compound **1a** and **6a** gave the same orientation (Figure 5) while the others oriented in a different way. It was seen that Val283 and His244 hold **1a** and **6a** at the entrance of copper binding site by H-arene interaction of the phenyl rings of both compounds (Figure 6). Furthermore, C═O moiety of compounds **1a** and **6a** might form a weak hydrogen bond with backbone NH of His85 (about 4 Å). Also, nonpolar part of cyclohexanone of compound **1a** made hydrophobic interactions with Val283 (less than 3 Å). Because of the hindrance of nonpolar part of Val283, synthetic compounds **2a**−**5a** and **7a** might be oriented in a different way. (b) The orientations of **8a**−**10a** (monoderivatives) occurred similar to that of bis-derivatives (except **9a**) by their interactions with Val283, His244 and His85 (Figure 6). (c) Compounds carrying pyrrolidine moiety (**1**−**10c**), were oriented so that C═O groups of the compounds located close to NH of Asn81 instead of His85. Substitution of pyrrolidine might decrease the flexibilities of these compounds at the entrance, which might cause a reduction in the activity.

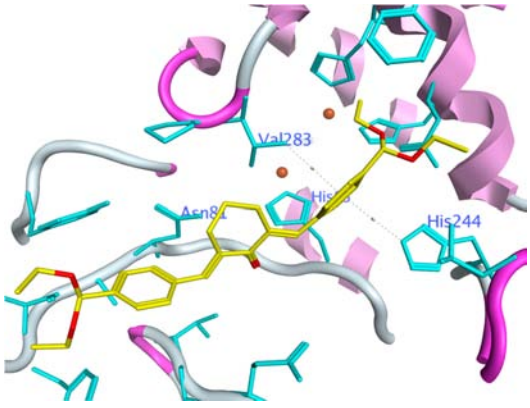

Figure 6. Orientations of compound **1a** in tyrosinase active site (**1a** and residues are shown as yellow and blue, respectively).

To conclude, 10 series containing 30 novel α,β-unsaturated carbonyl-based curcumin related compounds were successfully synthesized using the Claisen-Schmidt condensation reaction. All synthesized compounds were analyzed for anticancer and antityrosinase activity. Compounds **2a**−**b** were identified as potent anticancer agents with 81−82% inhibition of cancer cell lines. Five of these compounds (**1a**, **8a**−**b**, **10a**−**b**) emerged to be the potent inhibitors of Mushroom tyrosinase. Molecular modeling studies were also performed to see the interactions of synthetic compounds with X-ray crystallographic structure of mushroom tyrosinase. It also provided further insight into designing compounds with structural features that may translate into higher activity. Our studies have established that these curcumin-like compounds, with appropriate structural modifications, have the potential to be developed as anticancer agents for humans and can also be further studied for use in medicines, cosmetic products, food industry as well as agricultural purposes. Further studies are required for use and development of these synthetic compounds in food and agricultural field as antibrowning agents.

ABSTRACT: Xanthohumol (XN) is a unique prenylated flavonoid in hops (*Humulus lupulus L.*) and beer. XN alleviates hyperglycemia and has potential usage in the treatment of type 2 diabetes. In the present study, a series of in vitro experiments were performed to investigate whether XN was an effective inhibitor of α-glucosidase. The results showed that XN inhibited α-glucosidase in a reversible and noncompetitive manner, with an IC_{50} value of 8.8 μM and that XN inhibited the release of glucose from the maltose in the apical side of the Caco-2 cell monolayer. Fluorescence and circular dichroism spectra results indicated that XN directly bound to α-glucosidase and induced minor conformational changes of the enzyme. These results demonstrated that XN is a promising α-glucosidase inhibitor, which therefore could be used as functional food to alleviate postprandial hyperglycemia and as a potential candidate for the development of an antidiabetic agent.

KEYWORDS: *Humulus lupulus L., xanthohumol, α-glucosidase inhibitor*

INTRODUCTION

α-Glucosidase, a carbohydrate−hydrolase that releases glucose, is involved in diabetes and a variety of other diseases, such as viral infection and cancer, therefore, an attractive target for both pharmaceutical and functional food studies. Current clinically used antidiabetic agents, such as acarbose,[1] voglibose, and miglitol,[2] inhibit α-glucosidase and alleviate postprandial hyperglycemia. However, they are structurally confined to glycosidic derivatives, and continuous administration of these drugs can cause diarrhea and other intestinal disturbances,[3−5] as well as hepatotoxicity.[6] Therefore, novel drugs with fewer side effects will be needed to improve the treatment for type 2 diabetes mellitus (T2DM) patients.

Nutritional approaches that use phytonutrients for the prevention or treatment of T2DM are a rapidly emerging trend. Resveratrol has attracted much attention due to its therapeutic potential for T2DM and the related disorders;[7,8] Ginkgo biloba extract was shown to improve the cardiac function of diabetic rats;[9] and green tea extracts have a synergistic inhibitory effect on α-amylase and α-glucosidase when combined with acarbose.[10] Plant-based foods and dietary bioactives are more acceptable sources for the screening of α-glucosidase inhibitors due to their low cost and relative safety.[11−17] Dietary flavonoids and chalcones have already been proven good candidates to reduce postprandial hyperglycemia as α-glucosidase inhibitors.[18−24]

Xanthohumol (XN, Figure 1), the principal prenylated chalcone from the female inflorescences of the hop plant (hops, *Humulus lupulus L.*), is an ingredient of beer.[25,26] In vivo metabolism and pharmacokinetics of XN have been investigated previously.[27,28] XN has a good safety profile[29] and possesses beneficial health effects as an antioxidant,[30] anti-inflammatory,[31] antimicrobial,[32] anticancer agent,[33,34] and immune system modulator.[35] Recent studies demonstrated that XN lowered body weight and fasting plasma glucose in obese rats,[36,37] via mitochondrial uncoupling and stress response induction.[37] XN has also been found to ameliorate glucose metabolism and attenuates diabetes in KK-A^y mice.[38] These results implicate the benefits of using XN as treatment for obsesity and diabetes. Nevertheless, the mechanisms underlying the antidiabetes activity of XN are not fully clear.

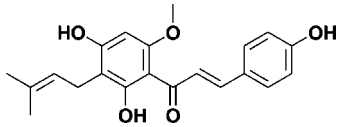

Figure 1. Structure of xanthohumol.

α-Glucosidase is an important enzyme that controls the postprandial blood glucose level and a drug target for the treatment of diabetes. In this study, the inhibitory effect of XN against α-glucosidase was investigated using both enzyme-based and cell-based assays; the inhibition mechanism was further explored using fluorescence spectra and circular dichroism (CD) spectra. This is the first study, to the best of our knowledge, which investigates the inhibition of α-glucosidase using XN.

MATERIALS AND METHODS

Materials. XN (purity >98%) was purchased from Chengdu Biopurify Phytochemicals Ltd. (Chengdu, China). The baker's yeast α-glucosidase (EC 3.2.1.20), *p*-nitrophenyl glycosides, and bis-8-anilinonaphthalene-1-sulfonate (bis-ANS) were purchased from Sigma-Aldrich Chemical (St. Louis, MO, USA). Glucose detection kit was the product of Nanjing Jiancheng Bioengineering Institute (Nanjing, China). Other reagents were purchased from J&K Chemical Ltd. (Beijing, China).

Cell Culture. Caco-2 cells were obtained from the Cell Bank of the Chinese Academy of Sciences (Shanghai, China). Cells were grown at 37 °C and 5% CO_2 in minimal essential medium supplemented with 10% fetal calf serum, 1% nonessential amino acids, and 1% glutamine. The culture medium was renewed every 2 days, and subcultured using a 0.02% EDTA/0.05% trypsin solution when the cells reached 80−90% confluence.

Inhibitory Activity against α-Glucosidase. The α-glucosidase inhibitory activity of XN was evaluated using the method developed by Tsujii.[39] Briefly, α-glucosidase was dissolved using phosphate buffer (50 mM, pH 6.7) and treated with XN (0−100 μM) for 30 min. *p*-Nitrophenyl glycosides at 1 mM were used as a substrate and added to the reaction system to initiate the enzyme reaction. The enzyme reaction was carried out at 37 °C for 30 min. Na_2CO_3 (1 M) with 3-fold volume was added to terminate the reaction. The enzymatic activity of α-glucosidase was quantified by measuring the absorption at 405 nm and subtracting the background of XN. The inhibitory effect of XN was defined as inhibitory activity (%) = $(OD_{control} - OD_{XN\ treated})/OD_{control} \times 100$. Concentration−response assays were used to determine the potency (IC_{50}) of XN based on the logistic analysis of the concentration−response curve using Microsoft Excel.

Inhibitory Activity against α-Glucosidase on the Caco-2 Model System. α-Glucosidase inhibitory effect of XN on Caco-2 monolayers was performed based on the published protocol.[40,41] Caco-2 cells were cultured on polyethylene terephthalate membranes (Falcon, pore size, 0.4 μm; pore density, 1.6×10^6 pores/cm^2) in a 6 well plate for 20 days to form monolayers. The transepithelial electrical resistance (TEER) of the cell monolayer was measured using a Millicell-ERS electrical resistance measuring system, and the values that are more than 300 Ωcm^{-2} are considered as showing good integrity. Cell culture medium was then removed and washed with phosphate buffered saline (PBS). The apical chamber was replaced with XN solution (0−200 μM, 200 μL) or acarbose solution (0−200 μM, 200 μL), along with maltose solution in PBS (3 mM, 800 μL). In the basal chamber, after 1 mL of PBS was added, the plate was incubated at 37 °C in 5% CO_2 atmosphere for 2 h. The glucose concentration in both apical and basal chambers was measured by the glucose oxidase method.

Kinetics of Enzyme Inhibition. On the basis of the same assays detailed above, the kinetics of enzyme inhibition was performed with inhibitors at certain concentrations of XN (0−25 μM) and substrate (0.25, 0.5, 0.75, and 1.5 mM), respectively. The inhibitory kinetics of the investigated compounds on α-glucosidase was analyzed using the Lineweaver−Burk plot and the double-reciprocal plot of the substrate concentration and velocity (expressed as absorbance).

Dialysis Experiment. The dialysis experiment was conducted as previously reported by Lee with small modifications.[42] Briefly, using a ultrafiltration tube (4 K), α-glucosidase alone (0.25 mL, 100 U/mL, 2 groups) or α-glucosidase (0.25 mL, 100 U/mL) treated with XN (100 μM) were dialyzed in phosphate buffer (5 mM, pH 6.7) at 4 °C for 24 h. After dialysis, one of the α-glucosidase alone group was treated with XN (100 μM) for 20 min. The contents in the tubes were determined for residual enzyme activity as described above.

Intrinsic Fluorescence Measurements. α-Glucosidase (2 μM) was pretreated with certain concentrations of XN (0−100 μM) for 30 min at 37 °C. The intrinsic fluorescence spectra (300−400 nm) were measured using a Cary Eclipse fluorescence spectrophotometer (Varian Inc. USA) with the excitation wavelength at 295 nm.

Hydrophobic Analysis of α-Glucosidase Using Bis-ANS. α-Glucosidase (2 μM) was incubated at 37 °C for 30 min in the absence or presence of certain concentrations of XN (0−100 μM). Bis-ANS (15 μM) was then added, and fluorescence (395−545 nm) was measured after incubation at 37 °C for 15 min (λ_{ex} = 400 nm) using a FlexStation II microplate spectrofluorometer (Molecular Devices, USA).

Circular Dichroism Spectroscopy for Secondary Structure of α-Glucosidase. CD spectra (190−250 nm) of α-glucosidase (2 μM) treated with different concentrations of XN (0−100 μM) were measured with a JASCO 715 spectropolarimeter (JASCO, Tokyo, Japan). The spectra were collected and corrected by the reduction of noise and smoothing. The program JWSSE (JASCO) was used for estimation of the secondary structure percentage of α-glucosidase based on the method of Yang et al.[43]

Data Analysis. One-way ANOVA with Tukey's post-hoc test was used for the statistical analysis of the data. The results were expressed as the mean values ± SD. Differences of $p < 0.05$ were considered statistically significant.

RESULTS AND DISCUSSION

XN Inhibits α-Glucosidase in Vitro. We first tested XN's inhibition activity against the enzymatic activity of α-glucosidase. α-Glucosidase was pretreated with certain a concentration of XN (0−100 μM) for 30 min, and the enzymatic activity was measured using *p*-nitrophenyl glycoside as a substrate. As shown in Figure 2, XN significantly inhibited

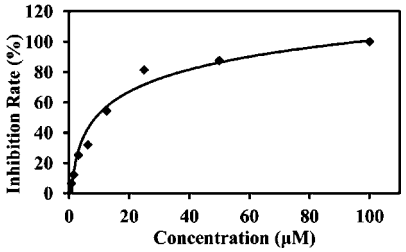

Figure 2. XN inhibits the activity of α-glucosidase in a concentration dependent manner. α-Glucosidase is pretreated with XN (0−100 μM) at room temperature for 30 min. *p*-Nitrophenyl glycosides at 1 mM was used as the substrate and added to the reaction system to initiate the enzyme reaction. Enzymatic activity was measured by the absorption at 405 nm, and the inhibition rate was calculated.

the activity of α-glucosidase in a concentration dependent manner, with an IC_{50} value of 8.8 μM. The determined inhibitory effect was stronger than that of other flavonoids and chalcones,[18,21−23] and the positive control acarbose (IC_{50} = 26.5 μM), indicating that XN is a powerful α-glucosidase inhibitor in vitro. Previous pharmacokinetics studies in both rats and humans have implied that XN could reach a high concentration in the intestinal tract when administrated orally[27,28,44] and that therefore XN could reach the concentration needed to inhibit the activity of α-glucosidase in vivo.

XN Inhibits Maltose Digestion in the Caco-2 Monolayer. To further confirm the inhibition effects of XN, the intestinal epithelial cell line Caco-2 was employed as a model of the intestinal brush border membrane. Caco-2 expresses α-glucosidases on the apical side and could hydrolyze maltose into glucose. As shown in Figure 3A, using a maltose solution as the substrate, the positive control acarbose inhibited the release of glucose from maltose on the apical side of the Caco-2 monolayer. Similarly, XN also inhibited the liberation of glucose from maltose, thus confirming its inhibitory activity against α-glucosidases in the cellular environment. On the basal side, there is no obvious difference in the glucose concentration

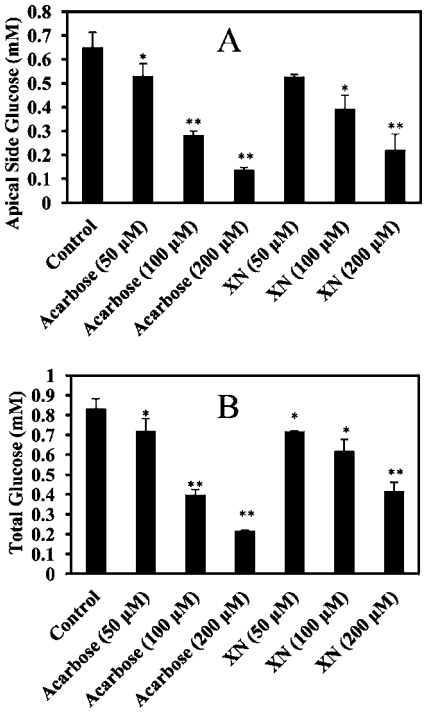

Figure 3. (A) XN inhibits the release of glucose from the maltose on the apical side of the Caco-2 monolayer. Caco-2 cells were cultured on polyethylene terephthalate membranes to form monolayers. The apical chamber was replaced with acarbose (0–200 μM), XN solution (0–200 μM), and maltose solution (3 mM, 800 μL), while the basal chamber was replaced with PBS. The plate was then incubated at 37 °C in 5% CO_2 atmosphere for 2 h, and then the glucose concentration in both the apical and basal chambers was measured by the glucose oxidase method. (B) XN inhibits the content of total glucose released from the maltose in the apical and basal sides of the Caco-2 monolayer. Values were expressed as the mean ± SD. Differences of $p < 0.05$ were considered statistically significant.

in the absence and presence of XN, indicating that XN does not inhibit the transport of glucose in the present experimental conditions (data not shown). The total glucose content included in both the basal and the apical side also decreased (Figure 3B). These results clearly demonstrated that XN can inhibit α-glucosidase enzymes in the Caco-2 monolayer.

In the Caco-2 monolayer model, to assay the inhibition against the α-glucosidases, higher concentrations of both acarbose and XN are needed. For example, a higher concentration (387 μM) of acarbose has been used as a positive control in other studies.[45] The possible reasons may include the higher concentration of substrate and nonspecific binding proteins in the system, which possibly compete against the α-glucosidase and XN interaction. Besides, a part of XN will be taken up and accumulated in the Caco-2 cells,[46] which will decrease the XN concentration in the apical side. The uptake and intracellular kinetics of XN may also explain why XN does not show a stronger inhibition than acarbose, which was observed in the enzyme assay.

XN Inhibits α-Glucosidase Noncompetitively. To explore the inhibitory mode of XN, double-reciprocal plots of α-glucosidase kinetics in the absence and presence of XN were analyzed. As shown in Figure 4, the value of 1/V increased with increasing concentrations of XN, but the intercept on the x-axis remains constant, and the K_m values remain at 0.65 mM. This result suggests a noncompetitive inhibition of XN. This

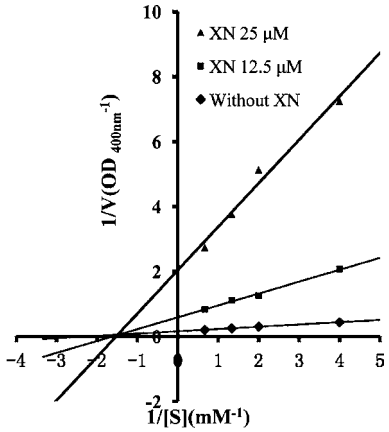

Figure 4. Double-reciprocal plots of the kinetics of α-glucosidase with and without XN. XN (0, 12.5, and 25 μM) was added in α-glucosidase buffer (50 μL and 10 U/mL) at room temperature for 30 min, and then, the substrate at different concentrations (0.25, 0.5, 0.75, and 1.5 mM) was added to initiate the enzyme reaction. Enzymatic activity was quantified by measuring the absorption at 405 nm.

inhibition mode is different from that of acarbose, which is a competitive inhibitor. Competitive inhibition is usually reversible, and an excessive amount of substrate will displace the inhibitor. In contrast, noncompetitive inhibition like that of XN is not influenced by the substrate concentration. The observed noncompetitive inhibition mode of XN indicates that XN may bind to a site different from the active site of α-glucosidase. Studies are in progress in our laboratory to identify those α-glucosidase residues that are critical for XN binding.

XN Inhibits α-Glucosidase Reversibly. We further investigated whether the inhibitory effect of XN is reversible using the dialysis experiment. The results are presented in Figure 5. After dialysis, the activity of α-glucosidase

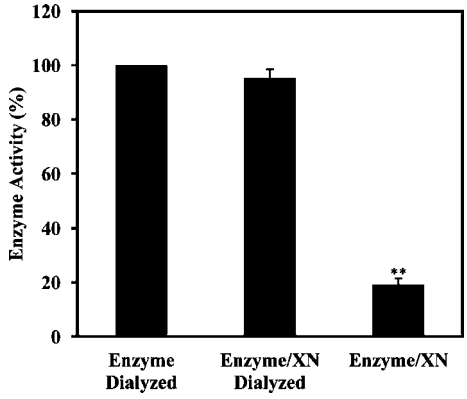

Figure 5. Recovery of α-glucosidase activity after dialysis. The inhibitor (100 μM) was added to α-glucosidase (100 U/mL) before dialysis. α-Glucosidase (0.25 mL and 100 U/mL) and XN (100 μM) treated α-glucosidase were dialyzed against phosphate buffer at 4 °C for 24 h, and the residual enzyme activities were measured.

preincubated with XN was similar to that of the untreated α-glucosidase, indicating that the enzymatic activity was recovered after dialysis. In contrast, α-glucosidase incubated with XN but without further dialysis showed relatively less activity. These results demonstrate that the inhibition of XN against α-glucosidase is reversible.

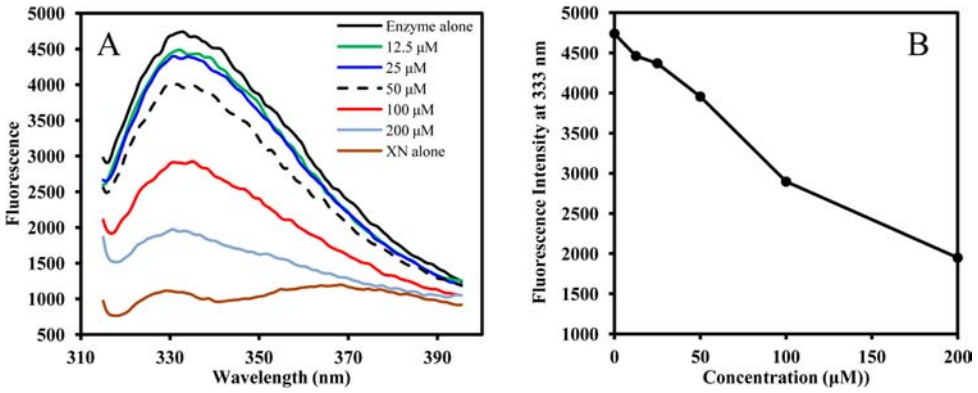

Figure 6. Variation of the intrinsic fluorescence spectra of α-glucosidase. The enzyme (2 μM) was incubated with specified concentrations of XN (0−200 μM) for 30 min at 37 °C. The excitation wavelength was 295 nm, and emission spectra were acquired by scanning from 300 to 400 nm. (B) XN quenches the intrinsic fluorescence of α-glucosidase in a concentration dependent manner.

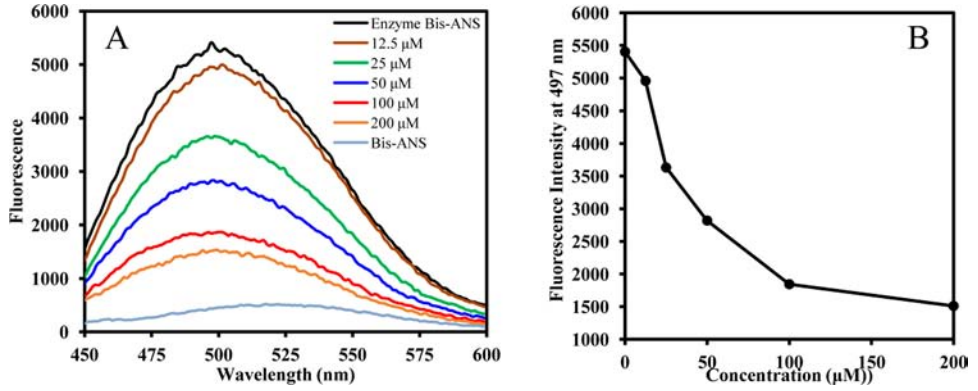

Figure 7. Changes of the α-glucosidase-bis-ANS complex's fluorescence by XN. (A) Fluorescence spectra of bis-ANS in the absence and presence of XN. α-Glucosidase (2 μM) was first incubated for 30 min at 37 °C in the absence or presence of specified concentrations of XN (0−200 μM). Bis-ANS (15 μM) was then added, and after 15 min of incubation at 37 °C, the fluorescence was measured (excitation at 400 nm) using a Cary Eclipse fluorescence spectrophotometer. (B) XN reduces the α-glucosidase-bis-ANS complex's fluorescence in a concentration dependent manner.

XN Quenches the Intrinsic Fluorescence of α-Glucosidase in Vitro. The in vitro inhibitory results of XN suggest that XN directly binds α-glucosidase. To test this hypothesis, we first investigated XN induced changes in intrinsic tryptophan fluorescence of the α-glucosidase enzymes. As shown in Figure 6A, when excited at 295 nm, XN had no obvious fluorescence emission from 300 to 400 nm. Therefore, the fluorescence interference contributed from XN was negligible. Excited at 295 nm, α-glucosidase alone has remarkable florescence at about 335 nm, which belongs to the tryptophan residues of α-glucosidase; the fluorescence intensity of XN-treated (12.5−200 μM) α-glucosidase was quenched gradually in a concentration dependent manner, and the fluorescence intensity almost vanished in the presence of the high concentration of XN (Figure 6B). These results confirmed that XN directly bound to α-glucosidase. Such XN binding might induce a conformational change of tryptophan residues in α-glucosidase, which subsequently hinders the active center formation and/or the substrate binding. The intrinsic fluorescence changes induced by XN are similar to those of other flavonoid compounds, which also quenched the intrinsic fluorescence of α-glucosidase.[18]

XN Reduces the Hydrophobicity of α-Glucosidase. The fluorescence probe bis-8-anilinonaphthalene-1-sulfonate (bis-ANS) is widely used in the measurement of protein surface hydrophobicity.[47] To further study the binding and interaction between XN and α-glucosidase, we measured the hydrophobicity of α-glucosidase using bis-ANS. The relative fluorescence intensities of bis-ANS in different statuses are shown in Figure 7A. Excited at 400 nm, there is barely a fluorescence signal for bis-ANS alone; however, significantly increased fluorescence intensity was observed when it was incubated with α-glucosidase. When treated with XN, the enzyme-bis-ANS fluorescence reduced remarkably in a concentration dependent manner (Figure 7B). These results suggested that XN might bind to a hydrophobic domain or/and reduce the hydrophobic surface of α-glucosidase. In our previous study, reduced enzyme hydrophobicity was also observed when α-glucosidase bound to other inhibitors, butyl-isobutyl-phthalate[16] and bis(2,3-dibromo-4,5-dihydroxybenzyl) ether.[48] Such inhibitor induced hydrophobicity decrease supports the notion that a poor hydrophobic surface usually hinders the formation of the active center of the enzyme molecules.

XN Influences the Secondary Structures of α-Glucosidase. To study the effect of XN on the secondary structure of α-glucosidase, we measured the CD spectra (190−250 nm) of α-glucosidase in the absence and presence of XN. As shown in Figure 8, minor changes in the CD spectrum of α-glucosidase were observed in the presence of XN (0−100 μM). The α-helix content increased slightly when treated with XN. The content of β-sheet decreased at a low concentration of XN (25 and 50 μM) but increased when treated with 100 μM XN. The content of β-turn decreased when treated with 25 and 100

dx.doi.org/10.1021/jf500426z | J. Agric. Food Chem. 2014, 62, 5548−5554

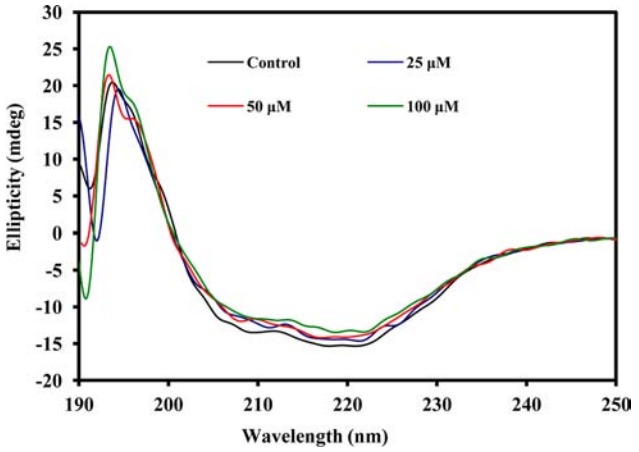

Figure 8. CD spectra of α-glucosidase in the absence or presence of XN. α-Glucosidase (2 μM, dissolved in 20 mM potassium phosphate buffer, pH 6.8) alone or incubated with XN (0−100 μM) at 37 °C for 30 min. CD spectra were acquired from 190 to 250 nm.

μM XN but increased a little in the presence of 50 μM XN. The predicted secondary structure content of α-glucosidase in the absence and presence of XN is shown in Table 1. The observed

Table 1. Secondary Structure Content of α-Glucosidase Influenced by XN[a]

XN (μM)	α-helix (%)	β-sheet (%)	β-turn (%)	random (%)
0	22	36.2	16.1	25.7
25	23.9	34	15.2	26.8
50	26.7	30	17	26.3
100	24.9	39.7	10.2	25.2

[a]The secondary structure content of α-glucosidase is predicted by the program JWSSE (JASCO).

XN-induced α-helix increase is similar to the effect of another α-glucosidase inhibitor, penicillamine,[49] but in contrast to the results of other α-glucosidase inhibitors, such as, curcuminoids analogues,[11] hydroxycoumarin derivatives,[50] and bicoumarin derivatives,[51] it decreased the α-helix content of the enzyme molecule. While CD spectra do not have the information needed to explain the different secondary structural changes induced by these inhibitors, it clearly further confirmed that XN directly bound to α-glucosidase and slightly changed its secondary structural conformations.

XN has a Michael acceptor moiety that can covalently interact with proteins. A number of studies have shown that the loss of protein function has been attributed to the Michael-type addition of cysteine residues with the α,β-unsaturated keto group of XN.[52,53] This reactivity possibly explains the interaction between XN and α-glucosidase. Since the Michael reactions are reversible, the release of XN recovers the enzyme function in the dialysis experiment and thus explains the reversible inhibitory mode. In addition, isoxanthohumol, a spontaneous cyclization product of XN with no electrophilic properties and Michael addition, does not possess an obvious inhibition against α-glucosidase. However, kuraridine, which has a structure similar to that of XN and contains the α,β-unsaturated keto group, possesses much stronger inhibitory activities against α-glucosidase.[54] Taken together, these investigations strongly indicate the Michael-type addition between XN and α-glucosidase could be the reason for the observed interaction and reversible inhibition mode. However, further experimental evidence is needed to prove this rationale.

In the present studies, we demonstrated, for the first time, XN inhibited α-glucosidase in a noncompetitive and reversible manner, and the inhibitory effect against α-glucosidase was confirmed in the Caco-2 cell monolayer assay. Our results indicated that XN directly bound to α-glucosidase and induced its conformational changes. The result that XN is a potent α-glucosidase inhibitor suggests that the α-glucosidase inhibition may contribute to the antidiabetic activity of XN. Nevertheless, α-glucosidase inhibition may not be the only mechanism underlying its antihyperglycemic effects. Other mechanisms, such as respiration uncoupling and induction of oxidant defense system,[37] acting as the ligand for farnesoid X receptor,[38] are likely also involved. Therefore, XN has the potential to be used in functional food and as a novel leading compound for the treatment of T2DM.

ABSTRACT: In this work, genes encoding gelatinase (*gelE*) and serine proteinase (*sprE*), two extracellular proteases produced by *Enterococcus faecalis* DBH18, were cloned in the protein expression vector pMG36c, containing the constitutive P_{32} promoter, generating the recombinant plasmids pCG, pCSP, and pCGSP encoding *gelE*, *sprE*, and *gelE*−*sprE*, respectively. Transformation of noncaseinolytic *E. faecalis* P36, *E. faecalis* JH2-2, *E. faecium* AR24, and *E. hirae* AR14 strains with these plasmids permitted detection of caseinolytic activity only in the strains transformed with pCG or pCGSP. Complementation of a deletion (knockout) mutant of *E. faecalis* V583 for production of gelatinase (GelE) with pCG unequivocally supported that *gelE* is responsible for the caseinolytic activity of the transformed strain grown in bovine skim milk (BSM). RP-HPLC-MS/MS analysis of hydrolysates of transformed *Enterococcus* spp. strains grown in BSM permitted the identification of 38 major peptide fragments including peptides with previously reported angiotensin converting enzyme-inhibitory activity (ACE-IA), antihypertensive activity, and antioxidant activity.

KEYWORDS: *lactic acid bacteria (LAB), Enterococcus faecalis, gelatinase (GelE), serine protease (SprE), ACE-inhibitory peptides, antihypertensive peptides*

INTRODUCTION

Many dietary proteins contain encrypted within their primary structure bioactive peptides with beneficial effects against cardiovascular diseases, inflammation, and cancer.[1,2] From the bioactive peptides, those with angiotensin converting enzyme-inhibitory activity (ACE-IA) and blood pressure-lowering effects have been extensively studied, due to the high prevalence of hypertension in the Western population.[3] Furthermore, peptides with ACE-IA known as ACE-inhibitory peptides (ACE-IP) are of interest due to their potential use in the treatment of elevated blood pressure and associated cardiovascular events.[4] Milk proteins are the main source of bioactive peptides, although other animal and plant proteins may also contain these peptides.[5−7] The release of ACE-IP from food proteins may be achieved by digestive enzymes, by hydrolysis with specific proteolytic enzymes, or by fermentation and ripening during food processing. Fermentation conditions and the proteolytic activity of specific lactic acid bacteria (LAB) seem to modulate the production of ACE-IP during their growth in milk.[8,9]

The enterococci are LAB that play a beneficial role in the development of the sensory characteristics of fermented foods being employed as starters in the food industry and as probiotics for humans and animals.[10] However, they are also gastrointestinal tract colonizers with lifestyles ranging from intestinal symbionts to multidrug-resistant pathogens responsible for nosocomial and, to a lesser extent, community-acquired infections.[11] Previous studies have shown that *Enterococcus faecalis* strains from food origin produce food-derived hydrolysates with ACE-IA[12−14] and that most, but not all, *E. faecalis* strains from food, environmental, and clinical origin produce milk-derived hydrolysates with high ACE-IA.[15] Accordingly, it would be convenient to identify those *E. faecalis* metabolic activities releasing milk-derived ACE-IP.

The zinc metalloprotease gelatinase (GelE) and the serine protease (SprE) are two secreted proteases produced by *E. faecalis*[16,17] that contribute to biofilm formation, stress response inside the host, host immune system evasion, and virulence.[18,19] On the other hand, the *fsr* (*E. faecalis* regulator) is a two-component quorum sensing-dependent regulatory system whose operon encodes the *fsrABCD* genes. The last gene encodes an autoinducing cyclic peptide, a gelatinase biosynthesis activating pheromone (GBAP) that is processed and exported out of the cells by the FsrB protein. Accumulation of GBAP outside the cells is sensed by the FsrC histidine kinase, leading to the activation of the response regulator FsrA. Activated FsrA induces expression of the *fsrBCD* genes. These *fsr* genes are involved in an autoregulatory circuit that results in a boost of GBAP signaling

and the induction of the Fsr regulon, among which the *gelE*−*sprE* operon is the most induced.[19,20] In the *gelE*−*sprE* operon, the gene encoding GelE is located immediately adjacent to the 3′ end of *fsrC* and is cotranscribed with *sprE*. However, despite their significance for *E. faecalis* virulence, both the *fsr* and the *gelE*−*sprE* loci are present in enterococcal isolates from different ecological environments, suggesting that both the Fsr system and the GelE and SprE proteins may play an additional role in the biology of *E. faecalis*,[18] not exclusively associated with virulence.

E. faecalis DBH18[21] is a bacteriocinogenic strain producer of bovine skim milk (BSM)-derived hydrolysates with high ACE-IA.[15] This strain may synthesize the GelE encoded by its *gelE*−*sprE* operon (GenBank no. JQ815406) as a 509 amino acid preproenzyme with a predicted N-terminal signal peptide of 29 amino acids, a prosequence of 480 amino acids, and the mature GelE of 318 amino acids, which is further subjected to C-terminal processing for full activation of protease activity, resulting in a molecular mass of 33 kDa.[22,23] Similarly, SprE may be synthesized as a 284 amino acid preproenzyme with a predicted N-terminal signal peptide of 32 amino acids, a prosequence of 252 amino acids, and the mature serine-type glutamyl endopeptidase (SprE) of 237 amino acids and a molecular mass of 25 kDa.[24] We describe in this work the cloning of the extracellular proteases GelE and SprE, produced by *E. faecalis* DBH18, in the protein expression vector pMG36c and the genetic and biochemical evidence that recombinant *Enterococcus* spp. strains expressing GelE produce BSM-derived hydrolysates with ACE-IA due to the production of ACE-IP.

MATERIALS AND METHODS

Bacterial Strains, Culture Conditions, Basic Genetic Techniques, and Enzymes. The bacterial strains and plasmids used in this study are listed in Table 1. *E. faecalis* DBH18[21] was used as the source of *gelE* and *sprE*. The nucleotide sequence of *gelE* from *E. faecalis* DBH18 (GenBank no. JQ815406) showed 99 and 98% homology with those of *E. faecalis* OG1RF (GenBank no. CP002621) and *E. faecalis* V583 (GenBank no. AE016830), respectively, whereas the nucleotide sequence of *sprE* showed a 98% homology with those of *E. faecalis* OG1RF and *E. faecalis* V583. The enterococcal strains were propagated at 37 °C in MRS broth (Oxoid Ltd., Basingstoke, UK). When needed, chloramphenicol (Cm) (Sigma Chemical Co., St. Louis, MO, USA) was added to the recombinant cultures at 10 μg/mL. Reconstituted 10% (w/v) bovine skim milk powder (BSM) (Oxoid), heated at 121 °C for 5 min, was seeded with a loop of frozen stocks of recombinant cultures and grown at 37 °C for 24 h. Three percent (v/v) grown cultures were added to freshly made reconstituted 10% (w/v) BSM, and the cultures were further grown at 37 °C for 24, 48, and 96 h. The fermentation process was discontinued by heating of the BSM-derived cultures at 75 °C for 1 min,[12] and the cultures were vigorously stirred and centrifuged at 8000*g* for 10 min. The resulting supernatants were filtered through 0.20 μm pore size filters (Whatman International Ltd., Maidstone, UK) and stored at −20 °C before use. Total genomic DNA from *E. faecalis* DBH18 was isolated using the Wizard DNA Purification Kit (Promega, Madison, WI, USA). Plasmid DNA isolation was carried out using the High Pure Plasmid Isolation Kit (Roche Diagnostics, East Sussex, UK), as suggested by the manufacturer, but with the cells suspended with lysozyme (40 mg/mL) and mutanolysin (500 U/mL) and incubated at 37 °C for 10 min before the kit instructions were followed. All DNA restriction enzymes were supplied by New England BioLabs (Beverly, MA, USA). Ligations were performed with the T4 DNA ligase (Roche Molecular Biochemicals, Mannheim, Germany). Electrocompetent *Enterococcus* spp. cells were obtained as previously described[25] and transformed with a Gene Pulser and Pulse Controller apparatus (Bio-Rad Laboratories, Hercules, CA, USA).

Determination of Gelatin and Bovine Skin Milk Hydrolysis by Different *E. faecalis* Strains. Well-characterized *E. faecalis* strains from food, environmental, and clinical origin including *E. faecalis* DBH18[21] and *E. faecalis* QA53[26] isolated from Mallard ducks (*Anas platyrhynchos*) and aged buffalo cheese, respectively, as well as *E. faecalis* P4 and *E. faecalis* P36, two medical isolates of clinical origin,[27] and *E. faecalis* H10 and *E. faecalis* 3Er1, two more human clinical isolates of the multilocus sequence typing (MLST)-derived clonal complex 2 (CC2) and CC9, respectively,[28] obtained from the Servicio de Microbiología, Instituto Ramón y Cajal de Investigación Sanitaria (IRYCIS), Hospital Universitario Ramón y Cajal, Madrid, (Spain), were evaluated for their ability to hydrolyze gelatin and bovine milk caseins. For detection of gelatinase activity, 5 μL of overnight cultures of *E. faecalis* strains, grown in MRS broth at 37 °C, were placed into Todd−Hewitt agar (Oxoid) containing 30 g of gelatin (Oxoid) per liter (TH-GEL), grown overnight at 37 °C, and placed at 4 °C for 5 h before examination of zones of turbidity around the cultures. The caseinolytic activity of *E. faecalis* strains was also evaluated by placing 5 μL of these cultures into Todd−Hewitt plates containing 1.5% (w/v) of BSM (TH-BSM) and grown overnight at 37 °C. A clear zone of hydrolysis within 24 h of growth was considered positive for caseinolytic activity.

PCR Amplification and Nucleotide Sequencing. Oligonucleotide primers were obtained from Sigma-Genosys Ltd. (Cambridge, UK). PCR amplifications were performed in 50 μL reaction mixtures containing 1 μL of purified DNA, 70 pmol of each primer, and 1 U of

Platinum Pfx DNA Polymerase (Invitrogen S.A., Barcelona, Spain). Samples were subjected to an initial cycle of denaturation (97 °C for 2 min), followed by 35 cycles of denaturation (94 °C for 45 s), annealing (55−58 °C for 30 s), and elongation (68 °C for 40 s), ending with a final extension step at 68 °C for 7 min in a DNA thermal cycler Techgene (Techne, Cambridge, UK). The PCR-generated fragments were purified by a NucleoSpin Extract II Kit (Macherey-Nagel GmbH & Co. KG, Düren, Germany) before cloning into the expression vector and for nucleotide sequencing. Nucleotide sequencing of purified PCR products was done using the ABI PRISM BigDye Terminator cycle sequence reaction kit and the automatic DNA sequencer ABI PRISM model 377 (Applied Biosystems, Foster City, CA, USA) at the DNA Sequencing Service (Sistemas Genómicos, Valencia, Spain).

Recombinant Plasmids Derived from pMG36c. The primers and inserts used for construction of the recombinant plasmids are listed in Table 2. Restriction mapping analysis of the *gelE*−*sprE* operon of *E. faecalis* DBH18 indicated the absence of restriction sites for restriction enzymes *Sac*I and *Hin*dIII. Total genomic DNA of *E. faecalis* DBH18 was used as template for amplification with the GERL-F/GERL-R, SPL-F/SPL-R, and GERL-F/SPL-R primer pairs of a 1530 bp *Sac*I/*Hin*dIII fragment (GEL) containing *gelE*, a 903 bp *Sac*I/*Hin*dIII fragment (SPR) containing *sprE*, and a 2400 bp *Sac*I/*Hin*dIII fragment (GEL/SPR) containing *gelE* and *sprE*, respectively. Fragments GEL, SPR, and GEL/SPR were digested with the indicated restriction enzymes and inserted into plasmid pMG36c digested with the same enzymes. The ligation mixtures were used to transform *E. faecalis* P36 and the recombinant derivatives checked by their gelatinase and caseinolytic activities. The recombinant plasmids pCG, pCSP, and pCGSP were purified from *E. faecalis* P36 and analyzed by PCR and sequencing of the inserts. Subsequently, these recombinant plasmids were used to transform *E. faecalis* DBH18, *E. faecalis* JH2-2, *E. faecium* AR24, and *E. hirae* AR14. The caseinolytic activity of the recombinant enterococcal strains was determined by a stab-on-agar test (SOAT) during growth of the selected colonies in TH-BSM plates at 37 °C for 24 h and visualization of clear zones of hydrolysis.

Construction and Characterization of a Gelatinase (GelE) Deletion (Knockout) Mutant of *E. faecalis* V583. The deletion of *gelE* in *E. faecalis* V583 was achieved by double-crossover homologous recombination using pAS222 as the cloning vector.[29,30] The gene *sprE* located downstream of *gelE* and the initial sequence of *gelE* were the homologous sequences used in homologous recombination to remove *gelE*. The insert to be cloned into pAS222 was constructed by a three-step PCR. First, the entire *sprE* was amplified with primers Pr1 and Pr2 to obtain fragment R1. The fragment R2, with the initial sequence of *gelE*, was subjected to a two-step PCR to remove an internal Met codon that could cause residual expression of a truncated gene and further amplified using primer pairs Pr3−Pr4 and Pr5−Pr6 (Table 2). Fragments R1 and R2 were then fused using the primer pairs Pr1 and Pr6, and the construct was cloned into pAS222 resulting in plasmid pAS222-KO-GelE. To replace the genes on the chromosome with those in the construct, the latter plasmid was transformed into electrocompetent *E. faecalis* V583 cells,[25] and the selection for double-crossover events was performed as described by Biswas et al.[31] The replacement of *gelE* and the integrity of the flanking genes in *E. faecalis* V583 Δ*gelE* was confirmed by DNA sequencing.

Determination of the ACE-Inhibitory Activity. The ACE-IA of the supernatants of the recombinant *Enterococcus* spp. strains, grown in BSM, was determined by a fluorometric assay with modifications, as previously described.[15] The angiotensin converting enzyme (ACE, peptidyl-dipeptidase A, EC 3.4.15.1) was obtained from Sigma Chemical Co., and the ACE working solution was added to blank (B), control (C), or samples (S). The reaction was started by adding the fluorogenic substrate *o*-aminobenzoylglycyl-*p*-nitro-L-phenylalanyl-L-proline (Abz-Gly-p-Phe(NO_2)-Pro-OH) (0.45 mM, Bachem Feinchemikalien, Bubendorf, Switzerland), and the reaction mixture was incubated at 37 °C. The fluorescence of the samples was measured in a Multiscan Microplate Fluorimeter (FLUOstar optima, BMG Labtech, Offenburg, Germany) with the FLUOstar (version 1.32 R2, BMG Labtech) control system for processing of the data. The ACE-IA was expressed as the protein concentration required to inhibit 50% of the ACE activity (IC_{50}). The percentage of ACE-inhibitory activity was calculated as $100 \times (C - S)/(C - B)$. The protein concentration of the water-soluble extracts was determined by using the BCA protein assay (Pierce, Thermo Fisher Scientific Inc., Rockford, IL, USA).

Analysis of the Bovine Skim Milk-Derived Hydrolysates by Reversed-Phase High-Performance Liquid Chromatography−Tandem Mass Spectrometry (RP-HPLC-MS/MS). The RP-HPLC-MS/MS analysis of the supernatants obtained after growth of the recombinant *Enterococcus* spp. strains in BSM was performed on an Agilent 1100 HPLC System (Agilent Technologies, Waldbron, Germany) with column HiPore (RP318 C_{18} column 250 × 4.6 mm, 5 μm particle size; Bio-Rad, Richmond, CA, USA). The HPLC system was connected online to an Esquire 3000 quadrupole ion trap (Bruker Daltonik GmbH, Bremen, Germany) equipped with an electrospray ionization source, as previously described.[15] Solvent A was a mixture of water/trifluoroacetic acid (1000:0.37, v/v), and solvent B contained acetonitrile/trifluoroacetic acid (1000:0.27, v/v). Peptides were eluted with a linear gradient of solvent B in A from 0 to 45% in 60 min at a flow rate of 0.8 mL/min. Different spectra were recorded over the mass/charge (m/z) range of 100−1500. About five spectra were averaged in the MS and in the MS(n) analyses. The signal threshold to perform auto MS(n) analyses was 10000 (i.e., 5% of the total signal), and the precursor ions were isolated within a range of 4.0 m/z and fragmented with a voltage ramp from 0.35 to 1.4 V. The m/z spectral data were transformed to mass values by using the Data Analysis (version 3.0; Bruker Daltonik) control program. BioTools (version 2.1; Bruker

Daltonik) was used to process the MS(n) spectra for peptide identification and sequencing.

Statistical Analysis. A nonlinear adjustment of the data obtained was performed to calculate the IC_{50} values with the program PRISM version 4.02 for Windows (GraphPad Software, Inc., San Diego, CA, USA), as previously described.[32] The program gives the estimated value of the IC_{50} together with the standard error.

RESULTS

Hydrolysis of Gelatin and Bovine Milk Proteins by *E. faecalis* Strains from Different Origins. *E. faecalis* strains from food, environmental, and clinical origins were evaluated for production of gelatinase and their caseinolytic activity. With the exception of *E. faecalis* P36, previously recorded as *gelE*$^+$ and *sprE*$^+$ but GelE$^-$,[27] all strains produced a clear zone of turbidity or hydrolysis after growth on TH-GEL and TH-BSM plates (Figure 1). These results suggest that production of GelE and SprE and/

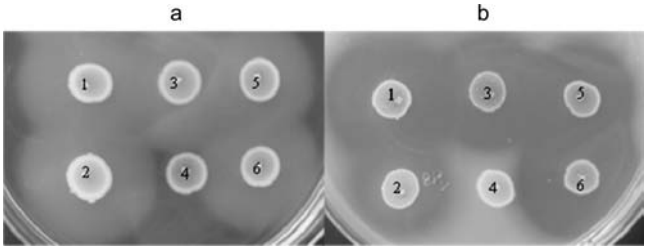

Figure 1. Gelatin (a) and bovine casein hydrolysis (b) by *E. faecalis* strains of food, environmental, and clinical origin grown in Todd Hewitt-gelatin (TH-GEL) and Todd Hewitt-bovine skim milk (TH-BSM) plates, respectively: (1) *E. faecalis* DBH18; (2) *E. faecalis* QA53; (3) *E. faecalis* P4; (4) *E. faecalis* P36; (5) *E. faecalis* 3Er1; (6) *E. faecalis* H10.

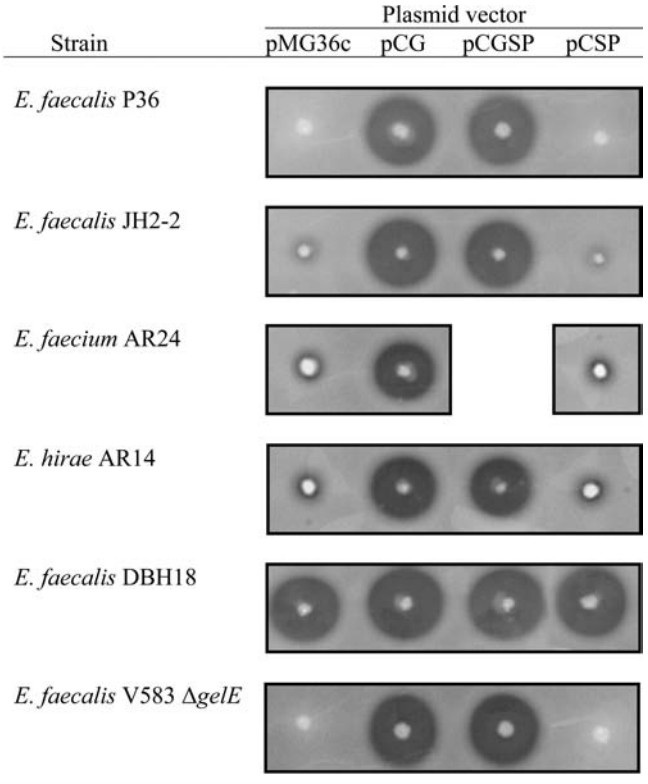

Figure 2. Caseinolytic activity of recombinant *E. faecalis* P36, *E. faecalis* JH2-2, *E. faecium* AR24, *E. hirae* AR14, *E. faecalis* DBH18, and *E. faecalis* V583 Δ*gelE* strains transformed with plasmids pMG36c, pCG, pCGSP, and pCSP.

or mutations in the regulatory *fsr* genes for induction of the production of both proteases could play a role in the hydrolysis of gelatin and bovine milk proteins.

Heterologous Production and Functional Expression of GelE and SprE by Recombinant *Enterococcus* spp. Strains. To determine the role of GelE and SprE in the caseinolytic activity of the *E. faecalis* strains during their growth in BSM, the genes encoding GelE (*gelE*) and SprE (*sprE*) in *E. faecalis* DBH18 were cloned in the protein expression vector pMG36c, containing the constitutive P_{32} promoter, to generate the plasmid-derived vectors pCG, pCSP, and pCGSP encoding *gelE*, *sprE*, and *gelE-sprE*, respectively. Transformation of the noncaseinolytic *E. faecalis* P36, *E. faecalis* JH2-2, *E. faecium* AR24, and *E. hirae* AR14 strains with the above cited plasmids showed halos of variable size, indicating casein hydrolysis, produced by *Enterococcus* spp. strains transformed with pCG or pCGSP but not with pMG36c or pCSP (Figure 2). The largest caseinolytic activity was observed in *E. faecalis* DBH18 transformed with pCG or pCGSP. A lower caseinolytic activity (<2 mm) was observed in *E. faecalis* JH2-2, *E. faecium* AR24, and *E. hirae* AR14 transformed with pMG36c. The caseinolytic activities of *E. faecium* AR24 transformed with pCG and *E. hirae* AR14 transformed with pCG or pCGSP were lower than those produced by the recombinant *E. faecalis* strains. Despite several attempts, the recombinant *E. faecium* AR24 (pCGSP) derivative was not obtained. On the other hand, no caseinolytic activity was observed in the *Enterococcus* spp. strains transformed with pCSP (Figure 2). *E. faecalis* V583, a Gel$^+$ and SprE$^+$ strain, was also evaluated to obtain a deletion (knockout) mutant of *gelE* unable to display GelE activity. Accordingly, using the plasmid pAS222-KO-GelE an *E. faecalis* V583 Δ*gelE* derivative lacking caseinolytic activity was obtained. Further transformation of *E. faecalis* V583 Δ*gelE* with plasmid pCG or pCGSP, but not with pMG36c or pCSP, resulted in a high caseinolytic activity of the recombinant strains after growth in TH-BSM plates (Figure 2).

Angiotensin Converting Enzyme-Inhibitory Activity of Recombinant *Enterococcus* spp. Strains Grown in Bovine Skim Milk. Supernatants of the recombinant *E. faecalis* P36, *E. faecalis* JH2-2, *E. faecium* AR24, *E. hirae* AR14, and *E. faecalis* DBH18 transformed with pMG36c, pCG, pCGSP, or pCSP were evaluated for their ACE-IA after growth in BSM (Table 3). Among the recombinant *Enterococcus* spp. only those transformed with pCG or pCGSP produced BSM-derived hydrolysates with high ACE-IA and IC_{50} values from 16.2 to 37.7 μg protein/mL. The lowest IC_{50} values correspond to the highest ACE-IA. Furthermore, the IC_{50} values of the BSM-derived hydrolysates showed that growth of the active recombinant strains at 37 °C during 48−96 h displayed a steady and high ACE-IA (Table 3). IC_{50} values for the BSM-derived hydrolysates produced by the strains transformed with pCG and pCGSP, respectively, were comparable. No ACE-IA was detected in the BSM hydrolysates of the enterococcal strains transformed with pMG36c or pCSP (Table 3).

Major Peptide Fragments and Identification of Angiotensin Converting Enzyme-Inhibitory Peptides (ACE-IP) in Supernatants of the Recombinant *Enterococcus* spp. Strains Grown in Bovine Skim Milk. BSM-derived hydrolysates of the recombinant *Enterococcus* spp. with high ACE-IA were subjected to RP-HPLC-MS/MS analysis. The peptide profiles by RP-HPLC of the supernatants of all

[a]ACE-IA expressed as IC_{50} (μg protein/mL). Data are means from three independent determinations in triplicate. [b]NA, no ACE-IA detected.

recombinant strains were obtained after growth in BSM for 0, 24, 48, and 96 h, and those corresponding to *E. faecalis* P36 (pCG) and *E. faecalis* P36 (pCGSP) are shown in Figure 3. The main peptide profiles of each recombinant *Enterococcus* spp. were further analyzed by tandem MS, and peptide fragments from the total ion chromatogram with a signal >10000 units were considered as major fragments. Accordingly, the RP-HPLC-MS/MS analysis of the BSM-derived hydrolysates of the recombinant *E. faecalis* P36, *E. faecalis* JH2-2, *E. faecium* AR24, *E. hirae* AR14, and *E. faecalis* DBH18 strains with high ACE-IA allowed the identification of 38 major peptide fragments, 26 of which corresponded to bovine β-casein fragments and 12 to α_{s1}-casein fragments, including peptides with previously reported ACE-IA (Table 4).

DISCUSSION

LAB produce a broad range of bioactive peptides including those with ACE-IA due to the activity of bacterial extracellular proteases, cell-envelope associated proteases, and intracellular peptidases.[9,33] However, few studies have considered the role of LAB other than *Lactobacillus* spp., *Lactococcus* spp., and *Streptococcus* spp. in the production of peptides with ACE-IA due to the fermentation of milk and other proteinaceous food substrates.[9,34,35] In this study, the observation of halos surrounding colonies of the well-characterized *E. faecalis* DBH18, *E. faecalis* QA53, *E. faecalis* P4, *E. faecalis* 3Er1, and *E. faecalis* H10 strains from food, environmental, and clinical origins in both gelatin- and BSM-containing agar plates indicated their gelatinase and caseinolytic activities. However, the absence of these enzymatic activities in *E. faecalis* P36 and the recognition that this isolate is a well-characterized *gelE*$^+$ and *sprE*$^+$ but GelE$^-$ strain[27] suggest that GelE and SprE may play an important role in the ACE-IA and production of ACE-IP during growth of the *E. faecalis* strains in BSM.

To determine the role of GelE and SprE against BSM-derived proteins, the *gelE*, *sprE*, and *gelE*–*sprE* genes from *E. faecalis* DBH18 were cloned into pMG36c to generate the plasmid-derived vectors pCG (*gelE*), pCSP (*sprE*), and pCGSP (*gelE*–*sprE*). The expression vector pMG36c is a shuttle vector, able to replicate in *Escherichia coli*, *Bacillus subtilis*, and LAB that contain the low copy replication origin of pWV01 and the strong P_{32} promoter to drive the constitutive transcription of inserted genes into the multicloning site (MCS) of pUC18.[36] Transformation of the noncaseinolytic *E. faecalis* P36,[27] *E. faecalis* JH2-2,[37] *E. faecium* AR24, and *E. hirae* AR14 with plasmid pCG or pCGSP, but not with pCSP or pMG36c, resulted in caseinolytic activity of the transformed strains in plates with BSM, whereas transformants of the caseinolytic *E. faecalis* DBH18 strain with pCG or pCGSP originated larger BSM-derived halos of hydrolysis (Figure 1). Thus, recombinant *Enterococcus* spp. encoding *gelE* but not *sprE* are able to hydrolyze BSM-derived proteins during growth in BSM. Although previous studies reported that SprE is active on a variety of protein substrates[24] and that *sprE* contributes to virulence and infection in animal models,[17,38] the results of this work suggest that SprE by itself is not involved in the hydrolysis of BSM-derived proteins. Moreover, although the coexpression of *gelE* and *sprE* by *E. faecalis* may provide advantages, such as the effect of GelE on the maturation of SprE[24] and the role of SprE as an immunity protein against the killing action of GelE in the fratricide mechanism proposed for production of biofilms by *E. faecalis*,[18] the role of SprE in the hydrolysis of BSM-derived proteins is yet unknown.

The role of GelE in the hydrolysis of BSM-derived proteins was also evaluated in a deletion (knockout) mutant of the caseinolytic *E. faecalis* V583 lacking *gelE*. The deletion event was generated using the cloning shuttle vector pAS222, which contains the thermosensitive replicon of pG$^+$ host4.[29,30] Double-crossover events with pAS222-KO-GEL transformed into *E. faecalis* V583 permitted the selection of Δ*gelE* cells with loss of their caseinolytic activity. Restoration of the GelE$^+$ phenotype was achieved after transformation of *E. faecalis* V583 Δ*gelE* with pCG or pCGSP, but not with pMG36c or pCSP (Figure 2). The results of these complementation assays confirm that *gelE* from *E. faecalis* DBH18 confers caseinolytic activity.

Experiments were also performed to determine the ACE-IA of the recombinant *Enterococcus* spp. strains grown in BSM. A high ACE-IA was found in supernatants of *E. faecalis* P36, *E. faecalis* JH2-2, *E. faecium* AR24, and *E. hirae* AR14 transformed with plasmid pCG or pCGSP. However, no ACE-IA was observed in the *Enterococcus* spp. strains transformed with pCSP or pMG36c (Table 3). Most of the BSM-derived hydrolysates generated by the recombinant *Enterococcus* spp. showed a low IC_{50} and, consequently, a high ACE-IA. Considering that extended fermentation times involve higher energy and economical expenses and increase the chance of microbial contamination, the growth of the recombinant *Enterococcus* spp. in BSM at 37 °C

dx.doi.org/10.1021/jf5006269 | J. Agric. Food Chem. 2014, 62, 5555–5564

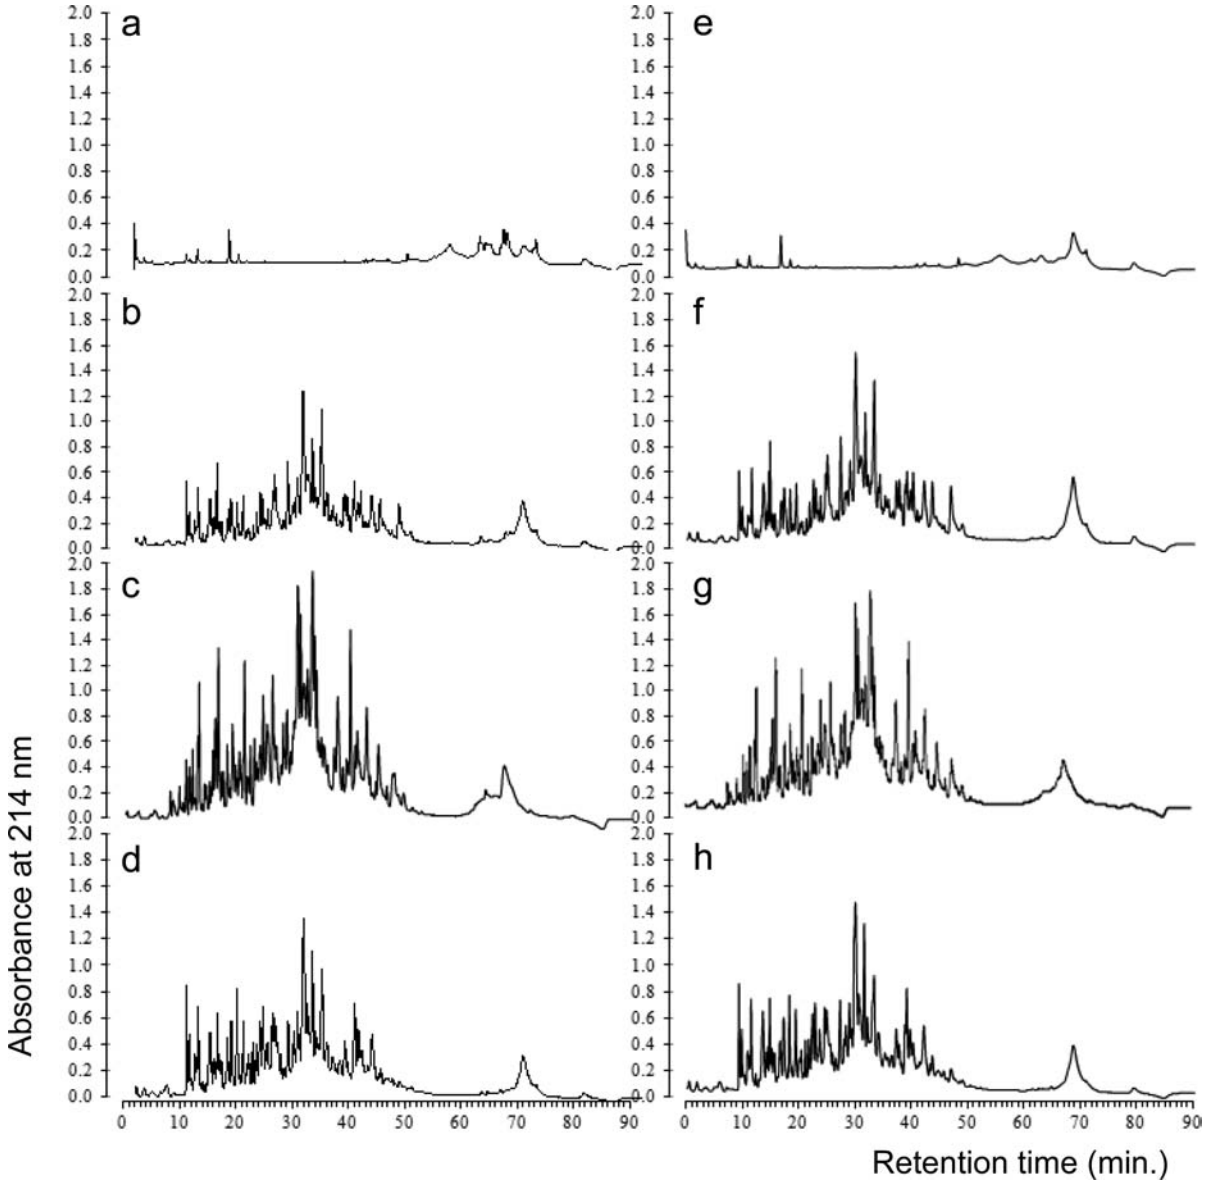

Figure 3. Peptide profiles by RP-HPLC of supernatants of *E. faecalis* P36 (pCG) (a–d) and *E. faecalis* P36 (pCGSP) (e–h) grown in bovine skim milk for 0 h (a, e), 24 h (b, f), 48 h (c, g), and 96 h (d, h).

for 48 h may be considered satisfactory for production of BSM-derived hydrolysates with high ACE-IA (Table 3). Because GelE may be produced by *E. faecalis* strains carrying antibiotic-resistance genes and/or genes coding other potential virulence factors, other enterococci as the recombinant *E. faecium* and/or *E. hirae* strains developed in this work could be used as safer and alternative bacterial hosts for production of GelE. Moreover, given that the N-terminal signal peptide of GelE (SP_{GelE}) drives the processing and transport of GelE out of the heterologous *Enterococcus* spp. producer cells, chimeras of the SP_{gelE} genetically fused to other enzymes, proteins, or biologically active peptides could permit their processing, heterologous production, and functional expression by other enterococci and, possibly, many other LAB.[39] *E. faecalis* DBH18 transformed with pCG or pCGSP originated larger halos of caseinolytic activity (Figure 2) but lower ACE-IA than the parent *E. faecalis* DBH18 (pMG36c) (Table 3). This lower ACE-IA of the transformed *E. faecalis* DBH18 derivatives with a higher production of GelE may be due to degradation of high molecular mass peptides with synergistic ACE-IA.[40,41]

Peptide profiles of BSM-derived hydrolysates of *E. faecalis* P36 (pCG) and *E. faecalis* P36 (pCGSP) grown in BSM are shown in Figure 3. No hydrolysis of BSM, evidenced by the absence of peptide fragments, was observed after growth of *E. faecalis* P36 (pCSP) and *E. faecalis* P36 (pMG36c) in BSM (results not shown). However, similar peptide profiles were generated by *E. faecalis* P36 (pCG) and *E. faecalis* P36 (pCGSP), suggesting that the hydrolysis of bovine caseins seems not to be affected by the coexpression of *gelE* and *sprE*. Similarly, few modifications were observed in the BSM-derived major peptide profiles during the fermentation process, suggesting that most of the release of ACE-IP takes place during the first 24 h of growth of the *E. faecalis* P36 strains transformed with pCG or pCGSP.

RP-HPLC-MS/MS analysis of BSM-derived hydrolysates from recombinant *Enterococcus* spp. with high ACE-IA permitted the identification of 38 major peptide fragments, including peptides with previously reported ACE-IA, antihypertensive

[a]Monoisotopic mass. [b]Previously described ACE-inhibitory peptides with ACE-IA or sharing, at least, three C-terminal residues with those found in this study. [c]Recombinant strains: 1, *E. faecalis* P36 (pCG), 24 h; 2, *E. faecalis* P36 (pCG), 48 h; 3, *E. faecalis* P36 (pCG), 96 h; 4, *E. faecalis* P36 (pCGSP), 24 h; 5, *E. faecalis* P36 (pCGSP), 48 h; 6, *E. faecalis* P36 (pCGSP), 96 h; 7, *E. faecalis* JH2-2 (pCG), 48 h; 8, *E. faecalis* JH2-2 (pCGSP), 48 h; 9, *E. faecium* AR24 (pCG), 48 h; 10, *E. hirae* AR14 (pCG), 48 h; 11, *E. hirae* AR14 (pCGSP), 48 h; 12, *E. faecalis* DBH18 (pMG36c), 48 h; 13, *E. faecalis* DBH18 (pCG), 48 h; 14, *E. faecalis* DBH18 (pCGSP), 48 h; 15, *E. faecalis* DBH18 (pCSP), 48 h.

activity, and antioxidant activity. Peptides such as LQDKIHP, FPGPIPN, VVVPPF, LHLPLP, LHLPLPL, IQAF, VLGPVRGPFP, VRGPFP, and VRGPFPPIIV were generated from bovine β-casein, whereas others, such as LKKYKVPQ, were derived from bovine α_{s1}-casein (Table 4). These peptide fragments are reported to be produced by *E. faecalis* strains from food, environmental, and clinical origins and show a high ACE-IA or share, at least, three C-terminal residues with those with known ACE-IA.[15] Moreover, the peptide LHLPLP resistant to gastrointestinal proteases is a true competitive inhibitor of ACE and shows a potent antihypertensive activity in spontaneously hypertensive rats (SHR).[42,43] On the other hand, the peptide VLPVPQK previously reported as antioxidant[44] has been also identified among the major peptides present in most *E. faecalis* hydrolysates (Table 4). The major peptides identified in the BSM-derived hydrolysates may be subject to variation due to complex interactions between growth of the enterococci and hydrolysis of their substrate. In this context, several β-casein-derived peptides such as VVVPPF, LHLPLP, and LHLPLPL or the α_{s1}-casein-derived peptides, such as RPKHP, LRLKK, and YKVPQ, were present in the hydrolysates of all the active *Enterococcus* spp., whereas other BSM-derived peptides were less frequent (Table 4). Interestingly, all of the BSM-derived hydrolysates produced by *E. faecalis* DBH18 and the active recombinant *E. faecalis*, *E. faecium*, and *E. hirae* derivatives contained, at least, the ACE-IP peptides LHLPLP, LHLPLPL, and VVVPPF, the antihypertensive peptide LHLPLP, and the antioxidant peptide VLPVPQK.

Most of the cleavage sites of the peptide fragments generated from β-casein and α_{s1}-casein were located before the hydrophobic amino acid residues leucine (L), isoleucine (I), or phenylalanine (F) (Figure 4), as previously described for the

dx.doi.org/10.1021/jf5006269 | J. Agric. Food Chem. 2014, 62, 5555−5564

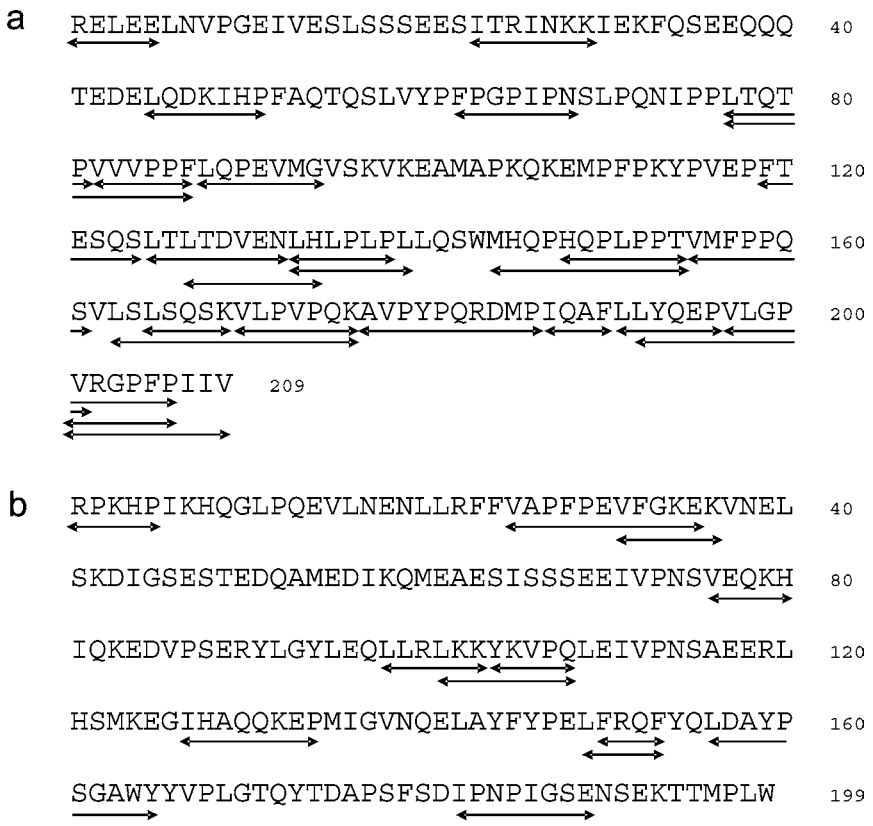

Figure 4. Location of the major peptides (doubled-ended arrows) identified in the primary sequences of β-casein (a) and α_{s1}-casein (b) present in bovine skim milk (BSM)-derived hydrolysates originated by the gelatinase (GelE) produced by recombinant *Enterococcus* spp. encoding *gelE* and *sprE* from *E. faecalis* DBH18.

purified GelE produced by *E. faecalis* OG1-10.[16] However, no glutamic acid (E)-Xaa cleavage fragments derived from a putative SprE proteolytic activity were detected.[24] Consequently, the pattern of β-casein and α_{s1}-casein breakdown and the release of bioactive peptides produced by the recombinant *E. faecalis* P36, *E. faecalis* JH2-2, *E. faecium* AR24, and *E. hirae* AR14, during growth in BSM, corresponds to the activity of the strongly hydrophobic metalloendopeptidase GelE from *E. faecalis* DBH18.

It has been reported that the GelE$^+$ phenotype of *E. faecalis* requires the concomitant presence of both the *fsr* and *gelE* genes and that loss of the GelE$^+$ phenotype is usually attributed to a 23.9 kb chromosomal deletion involving *fsrABC* that likely results from horizontal gene transfer and recombination.[19,45] However, in *E. faecalis* strains with apparently complete *fsr* and *gelE* loci, the Gel$^-$ phenotype also correlates with a specific nonsense codon in the FsrC protein, which prevents these isolates from sensing GBAP,[19] whereas in certain *E. faecalis* strains, even in the absence of a functional *fsr* system, a basal level of GelE and SprE is produced.[46] Furthermore, although the presence of a functional Fsr system and/or GelE production increases the severity of disease in animal, plant, and nematode models of *E. faecalis* infection, none of them are required for the organism to cause the disease.[45] Accordingly, it may be considered that *E. faecalis* strain producers of GelE may play an additional role, not associated with virulence, in the production of bioactive peptides with human health connotations and potential biotechnological applications.

To the best of our knowledge, the present study is the first to describe the genetic and biochemical implication of the GelE produced by *E. faecalis* in the production of BSM-derived bioactive peptides with ACE-IA, antihypertensive, and antioxidant activities. These results may strengthen the potential of GelE in the production of BSM-derived peptides with human health connotations and potential biotechnological applications. Furthermore, safer LAB and other microbial hosts could be engineered as heterologous producers of GelE to determine the biotechnological, medical, and veterinary applications of bioactive peptides derived from the GelE-mediated fermentation and/or hydrolysis of BSM and many other food substrates.[47−49]

Supporting Information

ABSTRACT: Antifungal resistance and toxicity problems of conventional fungicides highlighted the requirement of search for new safe antifungal agents. To comply with the requirement, we discovered four new non-cytotoxic lipopeptides, gageopeptides A−D, **1**−**4**, from a marine-derived bacterium *Bacillus subtilis*. The structures and stereochemistry of gageopeptides were determined by NMR data analysis and chemical means. Gageopeptides exhibited significant antifungal activities against pathogenic fungi *Rhizoctonia solani*, *Botrytis cinerea*, and *Colletotrichum acutatum* with minimum inhibitory concentration (MIC) values of 0.02−0.06 μM. In addition, these lipopeptides showed significant motility inhibition and lytic activities against zoospores of the late blight pathogen *Phytophthora capsici*. These compounds also showed potent antimicrobial activity against Gram positive and Gram negative bacteria with MIC values of 0.04−0.08 μM. However, gageopeptides A−D did not exhibit any cytotoxicity (GI_{50} > 25 μM) against cancer cell lines in sulforhodamine B (SRB), 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT), and WST-1 ((4-[3−4-iodophenyl]-2-(4-nitrophenyl)-2*H*-5-tetrazolio)-1,3-benzene disulfonate)) assays, demonstrating that these compounds could be promising candidates for the development of non-cytotoxic antifungal agents.

KEYWORDS: *Bacillus subtilis, gageopeptides, antifungal agents, non-cytotoxicity*

INTRODUCTION

Fungal diseases are very common crop-devastating diseases in agricultural practice. For example, *Rhizoctonia solani* (*R. solani*) is a plant pathogenic fungus with a wide host range and worldwide distribution. This pathogen is very destructive to many crops, including agronomic, ornamental, and forestry species.[1] This species has been reported to enormously reduce the growth and quality of crops such as cereals, potato, lettuce, and cotton in Spain.[2−5] *Phytophthora capsici* (*P. capsici*), another economically important pathogen, causes extensive damage in cucumber, pepper, tomato, and beans. It is well recognized to cause crown, leaf, and fruit blight, wilting of the whole plant, and dark purplish discoloration of the stem.[6] Similarly, a diverse group of fungi are recognized to cause severe plant diseases, resulting in a significant loss in agricultural practice.[7] Therefore, it is very important to control plant diseases to secure the level of yield both quantitatively and qualitatively.

Farmers often heavily rely on the application of commercial fungicides to secure the quality and production of crops. Most of the fungicides are not compatible with the environment or health; their excessive application and misuse can also cause acute and chronic toxicity.[8,9] According to a review by the International Labor Organization (ILO), about 14% of all occupational injuries were caused by exposure to synthetic pesticides and other agrochemicals.[10] Moreover, the World Health Organization (WHO) and the United Nations Environment Programme (UNEP) reported that three million farmers in the developing countries suffer from severe poisoning by commercial pesticides, resulting in the deaths of about 18,000 of them each year.[11] However, the environmental problems caused by synthetic fungicides have brought a significant change to people who work in the agricultural field toward the use of harmful pesticides. Therefore, it has now become an urgent issue to develop environmentally friendly alternative pesticides to synthetic chemicals to protect plants from diseases.

Lipopeptides produced nonribosomally by bacteria and fungi have been reported to be biodegradable and less toxic, and have various biomedical applications.[12] As illustrations, lipopeptides of surfactins, iturins, mycosubtilin, plipastatin, halobacillin, fengycin, and echinocandin families produced by bacterial origins have recently received much attention due to their potent biological activities, including antimicrobial, antitumor, antiviral, anti-inflammatory, and immunosuppressive activities.[13−18] In particular, echinocandins and pneumocandins are now approved antifungal drugs which inhibit the synthesis of glucan in the cell wall, via noncompetitive inhibition of the enzyme 1,3-β-D-glucan synthase in pathogenic fungi including

Aspergillus and *Candida*.[19] In our previous studies,[20,21] we have discovered three novel lipotetrapeptides, gageotetrins A−C and surfactin like heptapeptides, gageostatins A−C with significant antimicrobial properties. Further investigations on the ethyl acetate (EtOAc) extract obtained from the same bacterium *Bacillus subtilis* (*B. subtillis*) afforded four new lipopeptides, gageopeptides A−D, **1**−**4** (Figure 1), which displayed

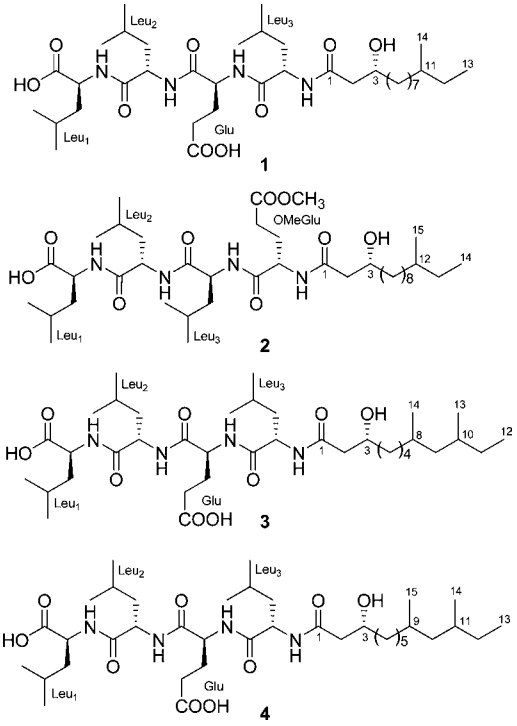

Figure 1. Structures of compounds **1**−**4**.

significant activity against pathogenic fungi and bacteria. The cytoxicity of gageopeptides against human cancer cell lines was also investigated during the study, and the results demonstrated that these new lipopeptides are potent non-cytotoxic antifungal agents.

MATERIALS AND METHODS

General Experimental Procedures. One- (1D) and two-dimensional (2D) NMR data were recorded on a Varian Unity 500 NMR spectrometer (Varian Inc., Palo Alto, CA, USA). IR spectra were measured on a JASCO FT/IR-4100 (JASCO, Easton, MD, USA). $[\alpha]_D$ values were obtained from a digital polarimeter (JASCO). Ultraviolet spectra were recorded on a Shimadzu UV-1650PC spectrometer (Shimadzu, Kyoto, Japan). HRESIMS data were obtained on a Shimadzu hybrid ion-trap time-of-flight mass spectrometer (Shimadzu). HPLC was performed with a column (250 mm × 4.6 mm i.d., 5 μm; YMC-Pack-ODS-A), with a PrimeLine Binary pump with RI-101 Shodex refractive index detector and M 525 variable UV detector (Shoko Scientific Co., Yokohama, Japan). Dextrose and agar were purchased from Junsei Chemical Co. Ltd. (Tokyo, Japan), and tryptone, yeast extract, and beef extracts were purchased from Becton, Dickinson and Co. (Sparks, MD, USA). All experimental chemicals were obtained from Duksan Pure Chemicals (Ansan, South Korea). For antimicrobial tests, type strains were collected from Korean Collection for Type Cultures (KCTC, Korea Research Institute of Bioscience and Biotechnology (KRIBB), Daejeon, South Korea).

Taxonomy of the Bacterial Strain. During an expedition in 2010, a sediment sample was collected from Gageocho reef, Republic of Korea, and the producing strain designated as 109GGC020 was isolated from the sample by serial dilution technique. The 16S rRNA sequence of the strain 109GGC020 was submitted to GenBank under accession number JQ927413. A BLAST search result showed the sequence of 109GGC020 to be 100% similar to *B. subtilis*.

Isolation of Compounds 1−4. Batch fermentation (60 L) of the strain *B. subtilis* 109GGC020 was carried out in 2 L flasks. For 1 L, the medium composition (w/v) was 1% dextrose, 0.1% yeast extract, 0.1% beef extract, 0.2% tryptone, 100% natural seawater, and pH 7.1. The culture broth was separated from the cells by centrifugation after 7 days of cultivation at 28 °C. The broth was extracted with EtOAc and the solvent was removed under reduced pressure at 40 °C to dryness. The EtOAc extract (11.8 g) was fractionated by an ODS open column chromatography using methanol:water (1:4, 2:3, 3:2, 4:1, and 100:0; v/v) as eluent. The 100% MeOH fraction was refractionated and purified by ODS semipreparative and analytical HPLCs with a solvent system of 95% MeOH in H_2O to yield **1**−**4**.

Gageopeptide A (**1**; 4.6 mg; 0.04%): amorphous solid; $[\alpha]^{27}_D$ −21 (*c* 0.1, MeOH). IR (MeOH; ν_{max}, cm^{-1}): 3285 (NH), 1620−1689 (CO), 2923 (aliphatic chain). ^1H and ^{13}C NMR data (CD_3OD): Table 1. HRESIMS (*m*/*z*): 735.4883 $[M + Na]^+$. Calcd for $C_{37}H_{68}N_4O_9$: 735.4884 $[M + Na]^+$;

Gageopeptide B (**2**; 1.8 mg; 0.02%): amorphous solid; $[\alpha]^{27}_D$ −40 (*c* 0.1, MeOH). IR (MeOH; ν_{max}, cm^{-1}): 3278 (NH), 1642 (CO), 2927 (aliphatic chain). ^1H and ^{13}C NMR data (CD_3OD): Table 1. HRESIMS (*m*/*z*): 763.5192 $[M + Na]^+$. Calcd for $C_{39}H_{72}N_4O_9$: 763.5197 $[M + Na]^+$.

Gageopeptide C (**3**; 5.9 mg; 0.05%): amorphous solid; $[\alpha]^{27}_D$ −20 (*c* 0.1, MeOH). IR (MeOH; ν_{max}, cm^{-1}) 3373 (NH), 1625 (CO), 2970 (aliphatic chain). ^1H and ^{13}C NMR data (CD_3OD): Table 1. HRESIMS (*m*/*z*): 735.4883 $[M + Na]^+$. Calcd. for $C_{37}H_{68}N_4O_9$: 735.4884 $[M + Na]^+$.

Gageopeptide D (**4**; 7.8 mg; 0.07%): amorphous solid; $[\alpha]^{27}_D$ −70 (*c* 0.05, MeOH). IR (MeOH; ν_{max}, cm^{-1}): 3287 (NH), 1629 (CO), 2959 (aliphatic chain). ^1H and ^{13}C NMR data (CD_3OD): Table 1. HRESIMS (*m*/*z*): 749.5044 $[M + Na]^+$. Calcd for $C_{38}H_{70}N_4O_9$: 749.5040 $[M + Na]^+$.

Determination of Absolute Stereochemistry of 1−4. The absolute stereochemistry of amino acid residues and at the stereocenter C-3 of 3-hydroxy fatty acids in **1**−**4** was determined by using the methods described previously.[20,21] In brief, compound **1** (1.9 mg) was hydrolyzed using 6 N HCl (500 μL) at 120 °C for 23 h. The hydrolysate was diluted with water and extracted with hexane. The hexane layer was evaporated by a stream of nitrogen, and the water layer was concentrated to dryness under reduced pressure. To determine the absolute configuration at the stereocenter C-3 of the fatty acid,[22] the hexane extract was derivatized with Mosher's reagent and the aqueous extract was used for the determination of absolute stereochemistry of amino acids by Marfey's method.[23] In an entirely analogous way, compounds **2**−**4** were hydrolyzed and their absolute stereochemistries were assigned.

Fatty acid in **1**: 1.5 mg; colorless oil. ^1H NMR data (CD_3OD): δ_H 2.34 (H-2a, dd, *J* = 15.0, 8.5 Hz), 2.43 (H-2b, dd, *J* = 15.5, 5.0 Hz), 3.96 (H-3, m), 1.33 (H-4a, m), 1.45 (H-4b, m), 1.47 (H_2-5, m), 1.29 (H_2-6−9, brs), 1.18 (H-10, m), 1.50 (H-11, m, overlapped), 1.29 (H-12, m, overlapped), 0.86 (H_3-13, t, *J* = 5.5 Hz), 0.87 (H_3-14, d, *J* = 6.5 Hz). LC-MS (*m*/*z*): 243.01 $[M - H]^-$. Optical rotation ($[\alpha]^{27}_D$): −26 (*c* o.1, MeOH).

Activity Study of 1−4 against *P. capsici*. *P. capsici* was received from Prof. W. Yuanchao of Nanjing Agricultural University, China. Mycelia of *P. capsici* were cultured on sterile clarified 10% V8 agar in Petri dishes and incubated at 25 °C in the dark for 4 days.[24] The agar culture from the Petri dishes incubated for 1−2 weeks was cut into six pieces, covered with sterile distilled water, and cultured in Petri dishes again at 25 °C in the dark to induce sporangium formation. Every 12 h, the water was replaced by fresh sterile distilled water. In this way, after changing the water 3 times, an abundance of sporangia were induced. The Petri dishes with large numbers of sporangia were incubated at 4 °C for 30 min, and kept at room temperature for another 30 min to induce zoospore release. The movement of sporangia and zoospores was checked on a regular basis under an Olympus light microscope. The zoospores remained motile for 10−12

[a]^{1}H NMR data recorded in CD_3OH.

h in sterile distilled water. The motility bioassay was carried out with the zoospores. A series of solutions for gegeopeptides were prepared in aqueous dimethyl sulfoxide (DMSO). The final concentration of DMSO in the zoospore suspension was less than 1% (v/v), a condition that does not affect the motility of zoospores. The bioassay for the motility inhibition and lysis of zoospores was investigated as described previously.[25,26] In brief, to a suspension (360 μL) of zoospores (ca.10^5/mL), 40 μL of sample solution was added and stirred with a glass rod. A 1% amount of aqueous DMSO was used as a control. Under a light microscope (×10 magnification), the time-course changes of motility and lysis of zoospores were evaluated as described previously.[27] The bioassay was repeated twice, and each treatment was replicated thrice. The mean value (%) was calculated (±SE, standard error) of the affected spores in each treatment. Minimum inhibitory concentration (MIC) values of individual compounds were converted to micromolar.[28]

Further Activity Study against Bacteria and Fungi. A standard "broth dilution assay"[29] was employed to evaluate the antimicrobial activity of gageopeptides against pathogenic fungi (*R. solani*, *Botrytis cinerea* (*B. cinerea*), and *Colletotrichum acutatum* (*C. acutatum*)), Gram positive bacteria (*B. subtilis* and *Staphylococcus aureus* (*S. aureus*)) and Gram negative bacteria (*Salmonella typhi* (*S. typhi*) and *Pseudomonas aeruginosa* (*P. aeruginosa*)). Briefly, a series of solutions for gegeopeptides were prepared over the range of 0.5−256 μg/mL in 96-well plates. Type strains were cultured overnight, and the final concentration (1.5×10^8 cfu/mL) of each strain in the culture broth was adjusted by comparing the culture turbidity with the 0.5 McFarland Standard. To each solution of gageopeptides **1**−**4**, 30 μL of culture broth was added and the final volume was adjusted to 200 μL using the respective fresh culture medium. The plates were incubated for 24 h at 37 °C for bacteria and 48 h at 30 °C for fungi.[28] The minimum inhibitory concentration (MIC, the lowest concentration of an antimicrobial compound that inhibits the visible growth of a microorganism) was recorded and expressed in micromolar in Result and Discussion.[28]

Cytotoxicity by SRB Assay. Cancer cell growth inhibitory activity of gageopeptides **1**−**4** was carried out according to a sulforhodamine B (SRB) assay.[30] The selected cancer cell lines (brest cancer, MDA-MB-231; colon cancer, HCT-15; prostate cancer, PC-3; lung cancer, NCI-H23; stomach cancer, NUGC-3; and renal cancer, ACHN) were added into 96-well plates. A series of solutions of gageopeptides with the concentrations of 6.25−50 μM were prepared and added to the plates. The plates were incubated for 48 h, and anchorage-dependent cells were fixed with 50% (w/v) trichloroacetic acid and stained for 60 min. The SRB solution (0.4% sulforhodamine B in 1% acetic acid) was used to wash out excess dye. The protein-bound dye was dissolved in 10 mM Tris base solution for optical density determination at 510 nm using a microplate reader. Using graphed prism software, the GI_{50} values of gageopeptides were calculated.

Cytotoxicity Test by WST-1 Assay. Inhibition of cancer cell growth for compounds **1**−**4** was determined by WST-1 (4-[3−4-iodophenyl]-2-(4-nitrophenyl)-2*H*-5-tetrazolio)-1,3-benzene disulfonate) assay.[31,32] In brief, the human myeloid leukemia K-562 cells were maintained in RPMI 1640 medium in 5% fetal bovine serum, supplemented with humidified air containing 5% CO_2 at 37 °C. Compounds **1**−**4** were added to the properly distributed cells (2×10^4 cells/mL) in 96-well plates. The plates were incubated for 5 days under the preceding condition. A 50 μL aliquot of WST-1 stock solution (1.0 mg/mL) was added to the suspensions, and the plates were further incubated for 4 h. After aspirating off the supernatant with a microplate washer, the formazen crystals were dissolved by adding 150 μL of DMSO in each well. Finally, the absorbance was measured using a microplate reader at 480 nm, and IC_{50} values were calculated.

Cytotoxicity Test by MTT Assay. The MTT assay was carried out to determine cancer cell viability.[33] In brief, the RAW 264.7 cells (mouse leukemic monocyte macrophage cell line, 5×10^4 cells/mL), were cultured in a 96-well plate at 37 °C, and treated with varying concentrations (6.25, 12.5, 25, and 50 μM) of gageopeptides **1**−**4** for 24 h. Cells treated only with medium were used as a negative control group. The supernatant of each well was removed, and 20 μL of MTT

solution (5 mg/mL in phosphate buffered saline) and 100 μL of medium were added into the plates. The plates were incubated for another 4 h, and the formazen crystals were dissolved in DMSO (100 μL). The absorbance at 540 nm was measured using a microplate reader. The relative cell viability (%) was measured as a percentage relative to the untreated control cells.

RESULTS AND DISCUSSION

The molecular formula of **1** was found to be $C_{37}H_{68}N_4O_9$ based on the HRESIMS data analysis. The ^{1}H NMR data (recorded in both CD_3OD and CD_3OH) analysis of pure compound **1** revealed its lipopeptidic nature (Table 1), showing amide proton signals at δ_H 7.99−8.28, α-methine groups at δ_H 4.26−4.44, a broad singlet at 1.29, and methyl signals at δ_H 0.88−0.97. This initial prediction of the lipopeptidic nature of **1** was further confirmed by the observation of carbonyl/carboxylic carbons at δ_C 174.2−176.7 and a group of CH_2 carbons at δ_C 30.6−30.9 in the ^{13}C NMR spectrum of **1**, which were attributable to amino acid residues and an aliphatic chain, respectively. Later, the detailed interpretation of NMR data revealed five partial structures **a**−**e**, corresponding to four amino acid residues and a lipid moiety that constitute **1** (Figure 2). The glutamic acid unit (substructure **c**) was elucidated from

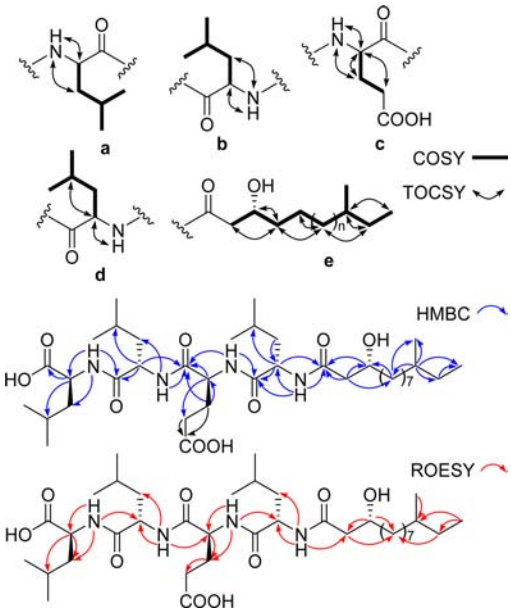

Figure 2. Assignment of partial structures by COSY and TOCSY correlations and complete structure with key HMBC and ROESY correlations of **1**.

the TOCSY correlations of the amide proton at δ_H 8.23 with an α-methine proton at δ_H 4.33 and the methylene signals at δ_H 1.95/2.09, and the α-methine proton also showed TOCSY correlations with the methylenes at δ_H 1.95/2.09 and 2.41. Furthermore, HMBC correlations were observed between the methylene signals at δ_H 1.95/2.09 and 2.41 and a carboxylic carbon resonating at δ_C 176.7, and between the protons at δ_H 1.95/2.09 and a carbonyl carbon at δ_C 174.8, confirming the glutamic acid residue in **1**. In a similar way, the substructures **a**−**e** were assigned by the analysis of 1D and 2D NMR data (Figure 2). The sequence of these amino acid residues was established as Leu_1-Leu_2-Glu-Leu_3 by the detailed interpretation of ROESY and HMBC correlations between α-methines, NH protons, and amide carbonyl carbons of respective amino acid residues. An additional oxygenated proton resonating at δ_H 3.98 displaying TOCSY and HMBC correlations with the carbonyl carbon at δ_C 175.0 and an aliphatic chain confirmed the presence of a fatty acid unit (**e**) in **1**. The ^{13}C NMR spectrum of **1** contained eight methyl carbons; six of them were found to constitute three Leu residues, and therefore, the remaining two methyls should be present in the fatty acid unit. The carbon resonating at δ_C 14.6 was assigned as a terminal methyl, and the methyl signal resonating at δ_C 23.5 was found to form a side chain with the fatty acid. By the detailed analysis of TOCSY and HMBC data, the position of the methyl group (δ_C 23.5) was determined to be at C-11 in the fatty acid chain. Judging from its molecular weight, the fatty acid was primarily assigned to be a C_{14} fatty acid connected to the N-terminal amine of the peptide. The LC-MS (m/z 243.01 $[M - H]^-$) analysis of the acid hydrolysate of **1** confirmed its chain length. Thus, the fatty acid was assigned as a 3-β-hydroxy-11-methyltridecanoic acid.[20,21] Finally, the structure of **1** was determined to be Leu_1-Leu_2-Glu-Leu_3-3-β-hydroxy-11-methyltridecanoic acid by HMBC and ROESY experiments (Figure 1).

The molecular formula of **2** was determined to be $C_{39}H_{72}N_4O_9$ according to the HRESIMS result. The ^{1}H and ^{13}C NMR data displayed a close similarity between **1** and **2** (Table 1), indicating the lipopeptidic nature of **2**. However, the presence of an additional oxygenated methyl peak at δ_H 3.66 and the molecular weight deference of **2** (C_2H_4 more) from **1** prompted us to conduct a detailed investigation of its structure. Therefore, a series of 1D and 2D NMR experiments were performed to clarify the structure of **2**. These NMR data analyses revealed the similar peptidic structure of **2**, consisting of Leu and Glu residues, but the methoxy proton at δ_H 3.66 did not show any correlations in both COSY and TOCSY spectra. However, HMBC correlations between this proton and a carboxylic carbon at δ_C 176.7 were found, indicating the presence of a OMeGlu unit in **2**. Based on the HMBC and ROESY spectra analysis, the sequence of these amino acid residues in the peptide moiety was assigned as Leu_1-Leu_2-Leu_3-OMeGlu. Similar to **1**, a 3-β-hydroxy fatty acid was also determined from the observation of correlations of the oxygenated methine proton at δ_H 3.97 with the methylene protons at δ_H 2.32/2.46 in the COSY and TOCSY spectra, as well as with a carbonyl carbon at δ_C 174.9 in the HMBC spectrum. Initially, the elemental composition and molecular formula of **2** suggested that the fatty acid had a molecular formula of $C_{15}H_{30}O_3$. Additional LC-MS results (m/z at 257.08 $[M - H]^-$) of the fatty acid obtained from the acid hydrolysis of **2** confirmed the molecular formula. Thus, the fatty acid was determined as a 3-β-hydroxy-12-methyltetradecanoic acid. Finally, the structure of lipotetrapeptide **2** was constructed as Leu_1-Leu_2-Leu_3-OMeGlu-3-β-hydroxy-12-methyltetradecanoic acid, based on the extensive 2D NMR data analysis (Figure 1).

The molecular formula of **3** was assigned to be $C_{37}H_{68}N_4O_9$ by means of the HRESIMS result, which was the same as that of **1**. Initially, the ^{1}H NMR data of **3** were found very similar to **1**. The difference between compounds **1** and **3** was the presence of several carbon resonances in the upfield region in the ^{13}C NMR data of **3**. The detailed analysis of a complete set of 1D and 2D NMR data of **3** indicated the presence of the same amino acid residues with the same sequence as **1**. Moreover, the primary investigation on the molecular weight of **3** and further LC-MS analysis of the hydrolysate of **3** revealed that the molecular formula of the fatty acid in **3** was the same as

[a]Data presented here are the average value ± SE of at least three replications in each dose of compounds. nt, not tested. Compounds **3** and **4** did not show any activity against zoospores of *P. capsici* under the conditions tested.

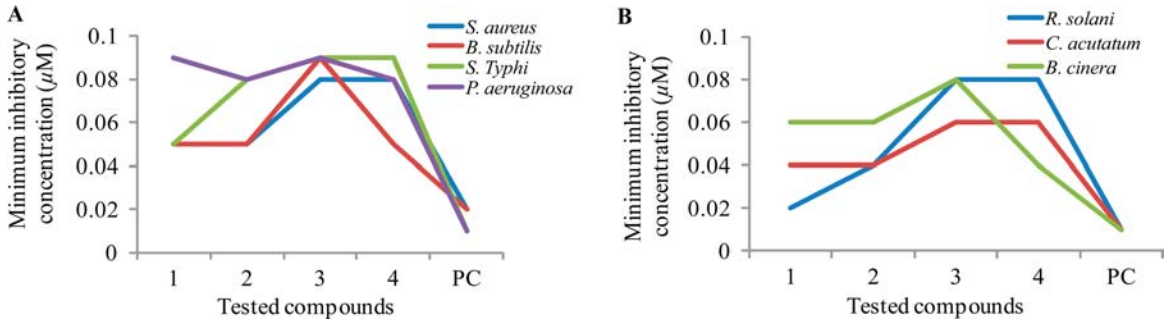

Figure 4. Minimum inhibitory concentrations (μM) of **1**−**4** against (A) Gram positive and Gram negative bacteria and (B) fungi.

that of **1**. However, the presence of additional methine carbons at δ_C 37.9 and 40.4 and methyl carbons at δ_C 11.9 and 19.8 in the ^{13}C NMR spectrum indicated that **3** had a different fatty acid from **1**. By the detailed interpretation of HMBC and TOCSY correlations, these additional methyl carbons were found to be located at C-9 and C-11 positions, and the fatty acid was assigned as a 3-β-hydroxy-9,11-dimethyltridecanoic acid.[20] Finally, the structure of **3** was determined as Leu_1-Leu_2-Glu-Leu_3-3-β-hydroxy-9,11-dimethyltridecanoic acid by the extensive interpretation of 2D NMR data (Figure 1).

The molecular formula of **4** was deduced to be $C_{38}H_{70}N_4O_9$ based on the HRESIMS data, and the ^1H and ^{13}C NMR data indicated that **4** was an additional analogue of **3**. But, it was found that compound **4** had a molecular weight 14 Da more than **3**, indicating the presence of an additional methylene group that could be present either in the fatty acid chain or in the peptide part. The careful interpretation of the NMR data revealed that compounds **3** and **4** had the same peptide moiety, suggesting the additional CH_2 group should be located in the fatty acid unit. This fact was further confirmed by the LC-MS analysis of the hexane phase of the acid hydrolysate of **4**. Thus, the molecular formula of the fatty acid in **4** was determined to be $C_{15}H_{30}O_3$. The fatty acid unit was found to possess same side chain as **3** with an additional methylene group and determined as a 3-β-hydroxy-9,11-dimethyltetradecanoic acid by 2D data analysis.[21] Thus, the final structure of **4** was assigned as Leu_1-Leu_2-Glu-Leu_3-3-β-hydroxy-9,11-dimethyltetradecanoic acid by HMBC and ROESY correlations (Figure 1).

The absolute stereochemistry of the amino acid residues in **1**−**4** was found to be L-form by Marfey's method. In addition, the absolute stereochemistry at C-3 of the fatty acid in **1** was assigned to be *R* by Mosher's MTPA method.[34] The absolute configuration of 3-hydroxy fatty acids in **2**−**4** (obtained from

dx.doi.org/10.1021/jf502436r | J. Agric. Food Chem. 2014, 62, 5565−5572

the hydrolysis of **2**−**4** followed by extraction with hexane) was also found to be *R* by the comparison of their optical rotation values {$[\alpha]^{27}_{D}$ −22 (*c* 0.1, MeOH), $[\alpha]^{27}_{D}$ −45 (*c* 0.1, MeOH), and $[\alpha]^{27}_{D}$ −24 (*c* 0.1, MeOH), respectively} with the optical rotation value $[\alpha]^{27}_{D}$ −26 (*c* 0.1, MeOH) of the 3-hydroxy fatty acid in **1**, as well as literature reviews, as the (*R*)-3-hydroxy fatty acid has the negative $[\alpha]_{D}$ value in MeOH.[20,21,35,36]

Compounds **1**−**4** were tested against both bacteria and fungi. These compounds were found to inhibit the growth of these microorganisms. In particular, compounds **1**−**4** displayed significant activity against *R. solani* and *P. capsici*. Compound **1** showed both inhibitory and lytic activity against *P. capsici* at a concentration of 0.02 μM, whereas compound **2** showed only inhibitory activity at the same concentration (Figure 3). However, compound **2** exhibited lytic activities against *P. capsici* when the concentration was increased (Table 2). It may be noteworthy that compound **2** had an OMeGlu amino acid residue in the peptide unit and an additional CH_2 group in the fatty acid chain compared to **1**. It was also revealed that compounds **1** and **2** exhibited stronger antifungal activity than **3** and **4** (Figure 4B). Compounds **1** and **2** were structurally different from compounds **3** and **4** in terms of having less side chains in the fatty acid units, suggesting that the side chain length and the additional methyl group in the aliphatic chain are important for antifungal activity. Usually, the fungal cell wall consists of three main components, chitin, glucans, and proteins. Antifungal agents display their activity by disrupting the integrity of this membrane or inhibiting sterol synthesis. Conversely, lipopeptides inhibit the synthesis of β-1,3-D-glucan in the cell wall. In fact, without β-1,3-D-glucan, the integrity of the fungal cell wall is compromised, leading to increased osmotic fragility and the eventual lysis of the fungal cell.[20,37] Since compounds **1**−**4** were found to exhibit potent antimicrobial activities, we became curious to know their possible cytotoxic effects. Accordingly, compounds **1**−**4** were tested against a panel of six human cancer cell lines according to a sulforhodamine B (SRB) assay. Interestingly, these compounds did not exhibit any activity (GI_{50} > 25 μM) against these cancer cell lines. The noncyotoxic character of these compounds was further checked against the leukemia cell line using WST-1 and MTT assays. From these detailed bioactivity results, it may be concluded that these lipotetrapeptides would be useful materials to develop environmentally friendly nontoxic antifungal agents.

ABSTRACT: A total of 19 different anthocyanins have been detected in four elderberry species and eight hybrids and quantified with the use of HPLC−MS^n. The profile and content levels of anthocyanins varied considerably among the analyzed elderberry species and hybrids. Cyanidin-3-*O*-sambubioside and cyanidin-3-*O*-glucoside were the most abundant anthocyanins in *Sambucus nigra* fruits. On the other hand, the prevalent anthocyanin in *S. javanica* hybrids was identified as cyanidin-3-(*E*)-*p*-coumaroyl-sambubioside-5-glucoside. The highest content of total analyzed anthocyanins (TAA) was determined in berries of the interspecific hybrid *S. javanica* × *S. racemosa*, followed by *S. nigra*, (*S. javanica* × *S. nigra*) × cv. Black Beauty, and (*S. javanica* × *S. nigra*) × *S. cerulea*. Berries of *S. nigra* var. *viridis* contained significantly lower levels of TAA. Our results provide novel information for nutritional research in addition to breeding programs, which strive to create new hybrids or cultivars with enhanced levels of bioactive components.

KEYWORDS: *Sambucus cerulea, S. ebulus, S. javanica, S. nigra, S. racemosa, elderberry fruits, anthocyanins*

INTRODUCTION

The *Sambucus* L. genus was formerly grouped in the Caprifoliaceae family, but novel genetic research places it into the Adoxaceae family.[1,2] It includes between 5 and 30 species, depending on taxonomy, distributed in the temperate and subtropical regions of the Northern and Southern Hemisphere. The genus *Sambucus* mostly consists of perennial subshrubby herbs with creeping rhizomes, many-stemmed shrubs (sometimes rhizomatous), or small deciduous or semievergreen trees.[3]

The most important species are *S. cerulea* Raf. (blue elder), *S. javanica* Blume (Javanese elder, sin. Chinese elder), and *S. nigra* L. (common elderberry, syn. elderberry). The use of interspecific hybridization in the genetic breeding of the *Sambucus* species is a relatively novel approach. First systematic attempts to produce hybrid plants between *S. nigra* and *S. racemosa* were reported by Böcher[4] in Denmark, Winge[5] in North Zealand, and Nilsson[6] in southern Sweden. The resulting F_1 hybrids were usually sterile. Most of the phenotypical traits were intermediate between the parental species. According to Chia,[7] a higher fertility level was achieved in crosses between *S. canadensis* and *S. nigra*, and *S. cerulea* and *S. nigra*. On the other hand,[8] genetic sterility was reported in hybrids between *S. nigra* and *S. ebulus*.

Presently, one of the most important trends in food and pharmaceutical industries is the growing demand for valuable natural sources of antioxidant compounds. Among common fruits and vegetables, elderberry is one of the richest in anthocyanins, flavonols glycosides, and other polyphenolics, which contribute to the high antioxidant capacity of its berries.[9,10] Additionally, antioxidant properties of anthocyanins present in elderberries are associated with beneficial effects on human health due to their ability to protect against cancer or heart diseases,[11,12] asthma, arthritis,[13,14] cardiovascular diseases,[15] and different viral infections.[16,17]

High anthocyanin content makes elderberry fruits useful for processing to concentrates, jams, jellies, juices, and dried powders.[18,19] Because of their intense color, the concentrates are suitable for providing natural red/purple hues to different food products. Fruits of the cultivated elderberry are very dark purple, nearly black, but various species range from bright red to blue and dark purple shades.[20] In Europe, cultivars derived from *S. nigra* are mainly cultivated, whereas in the U.S. most of the cultivars belong to *S. Canadensis*.[21] The content and composition of anthocyanins vary between different species and cultivars[22−27] and are also environmentally triggered. Factors such as light, temperature, and stress during cultivation significantly modify their synthesis and accumulation.[28]

Recently, a great deal of renewed interest in anthocyanins has emerged due to their potential health benefits as antioxidants and antiinflammatory agents. As the market for healthy products requires new genotypes with different processing and quality characteristics, there is a strong need for the selection of genotypes optimal for increasing the quality of food products. Data on the chemical composition of elderberry fruits are scarce; only a few studies revealed anthocyanin levels of various *Sambucus* species or cultivars.[22−24] Although the content of fruit phenolics is affected by environmental conditions and the level of maturity at harvest, it is very important to know the chemical composition and the antioxidant capacity of different elderberry species to selectively

use them in pharmaceutical and alimentary industry. To our knowledge, there have been no comparative studies on the chemical composition of a large number of elderberry genotypes grown under the same ecological conditions.

Therefore, the purpose of the study was to determine a broad range of anthocyanins and their content in five genotypes belonging to four different elderberry species (*Sambucus cerulea*, *S. ebulus*, *S. nigra* − (var. *nigra* and var. *viridis*), and *S. racemosa* (var. *miquelli*)), and compare them to the anthocyanin profile of eight elderberry interspecific hybrids. The final aim is to select genotypes with favorable composition and content of anthocyanins. The biochemical evaluation of elderberry genetic resources and the identification of individual bioactive compounds and their properties as natural agents is of utmost significance to breeders. This is the first Article on anthocyanin composition of a large number of elderberry species and interspecific hybrids striving to select cultivars, which may prove interesting for different processing industries.

MATERIALS AND METHODS

Plant Material. The biochemical investigation included four species of the *Sambucus* genus (1, *Sambucus cerulea*; 2, *S. ebulus*; 3, *S. nigra*; 4, *S. racemosa* var. *miquelli*) and three groups of their interspecific hybrids (1, three hybrids of *S. cerulea*; 2, four hybrids of *S. nigra*; 3, one hybrid of *S. racemosa*) (Table 1). The self-incompatible genotype of *S. javanica* originating from tropical regions did not produce a sufficient quantity of berries and could not be included in chemical analyses; however, this species was crucial in the hybridization process. All interspecific hybrids were developed at the University of Maribor, Faculty of Agriculture and Life Sciences, by Anton Ivancic using *S. javanica* as a genetic bridge. The female components (*S. javanica* and some of the hybrids *S. javanica* × *S. nigra*) were highly self-incompatible, enabling pollination without emasculation. The hybrid origin of the majority of the interspecific hybrids was determined by molecular and morphological analyses.[29] The hybrid origin of *S. javanica* × *S. racemosa* hybrids, which were created later, was determined only by morphological markers: by comparing leaf, inflorescence, floret, infrutescence, and berry characteristics.

Hybrid plants are being maintained in the gene bank of the University of Maribor, Faculty of Agriculture and Life Sciences, near Hoce (Slovenia). For multiplication, a simple vegetative propagation by cuttings is used.

Chemicals. The following standards were used for the quantification of anthocyanins: cyanidin-3-*O*-glucoside, cyanidin-3,5-di-*O*-glucoside, and pelargonidin-3-*O*-glucoside from Sigma-Aldrich Chemie GmbH; and cyanidin-3-*O*-galactoside from Fluka Chemie GmBH. Methanol for the extraction of phenolics was acquired from Sigma-Aldrich Chemie. The chemicals for the mobile phases were HPLC−MS grade acetonitrile and formic acid from Fluka Chemie GmBH. Water for the mobile phase was double distilled and purified with the Milli-Q system (Millipore, Bedford, MA).

Extraction of Phenolic Compounds. For each genotype, six independent repetitions were done ($n = 6$). Until extraction, they were kept in deep freeze (−80 °C). The extraction of berries was performed as described by Mikulic-Petkovsek et al.,[30] with some modification. Elderberry fruits were ground to a fine paste with liquid nitrogen, and 3 g was extracted with 15 mL of methanol containing 3% (v/v) formic acid and 1% (w/v) 2,6-di-*tert*-butyl-4-methylphenol (BHT) in a cooled ultrasonic bath for 1 h. BHT was added to the samples to prevent oxidation.

After extraction, the fruit extracts were centrifuged for 10 min at 10.000 rpm. Each supernatant was filtered through a Chromafil AO-20/25 polyamide filter manufactured by Macherey-Nagel (Düren, Germany) and transferred to a vial prior to injection into the HPLC (high performance liquid chromatography) system.

Determination of Individual Phenolic Compounds Using HPLC-DAD-ESI-MS^n Analysis. Anthocyanins were analyzed on a Thermo Finnigan Surveyor HPLC system (Thermo Scientific, San Jose, CA) with a diode array detector at 530 nm. Spectra of the compounds were recorded between 200 and 600 nm. The column was a Gemini C_{18} (150 × 4.6 mm 3 μm; Phenomenex, Torrance, CA) operated at 25 °C. The elution solvents were aqueous 0.1% formic acid in double distilled water (A) and 0.1% formic acid in acetonitrile (B). Samples were eluted according to the linear gradient from 5% to 20% B in the first 15 min, followed by a linear gradient from 20% to 30% B for 5 min, then an isocratic mixture for 5 min, followed by a linear gradient from 30% to 90% B for 5 min, and then an isocratic mixture for 15 min before returning to the initial conditions.[31] The injection amount was 20 μL, and the flow rate was 0.6 mL min^{-1}.

All phenolic compounds presented in our results were identified by an HPLC-Finnigan MS detector and an LCQ Deca XP MAX (Thermo Finigan, San Jose, CA) instrument with electrospray interface (ESI) operating in positive ion mode. The analyses were carried out using full scan data-dependent MS^n scanning from m/z 110 to 1500. Column and chromatographic conditions were identical to those used for the HPLC-DAD analyses. The injection volume was 10 μL, and the flow rate was maintained at 0.6 mL min^{-1}. The capillary temperature was 250 °C, the sheath gas and auxiliary gas were 60 and 15 units, respectively, the source voltage was 4 kV, and normalized collision energy was between 20−35%. Spectral data were elaborated using the Excalibur software (Thermo Scientific). The identification of compounds was confirmed by comparing retention times and their spectra as well as by adding the standard solution to the sample and by fragmentation.

Concentrations of anthocyanins were calculated from peak areas of the sample and the corresponding standards and expressed in mg 100 g^{-1} fresh weight (FW) of elderberry fruits. For compounds lacking standards, quantification was carried out using compounds similar to the standards. Thus, pelargonidin-3-sambubioside was quantified in equivalents of pelargonidin-3-*O*-glucoside, and all cyanidin glycosides

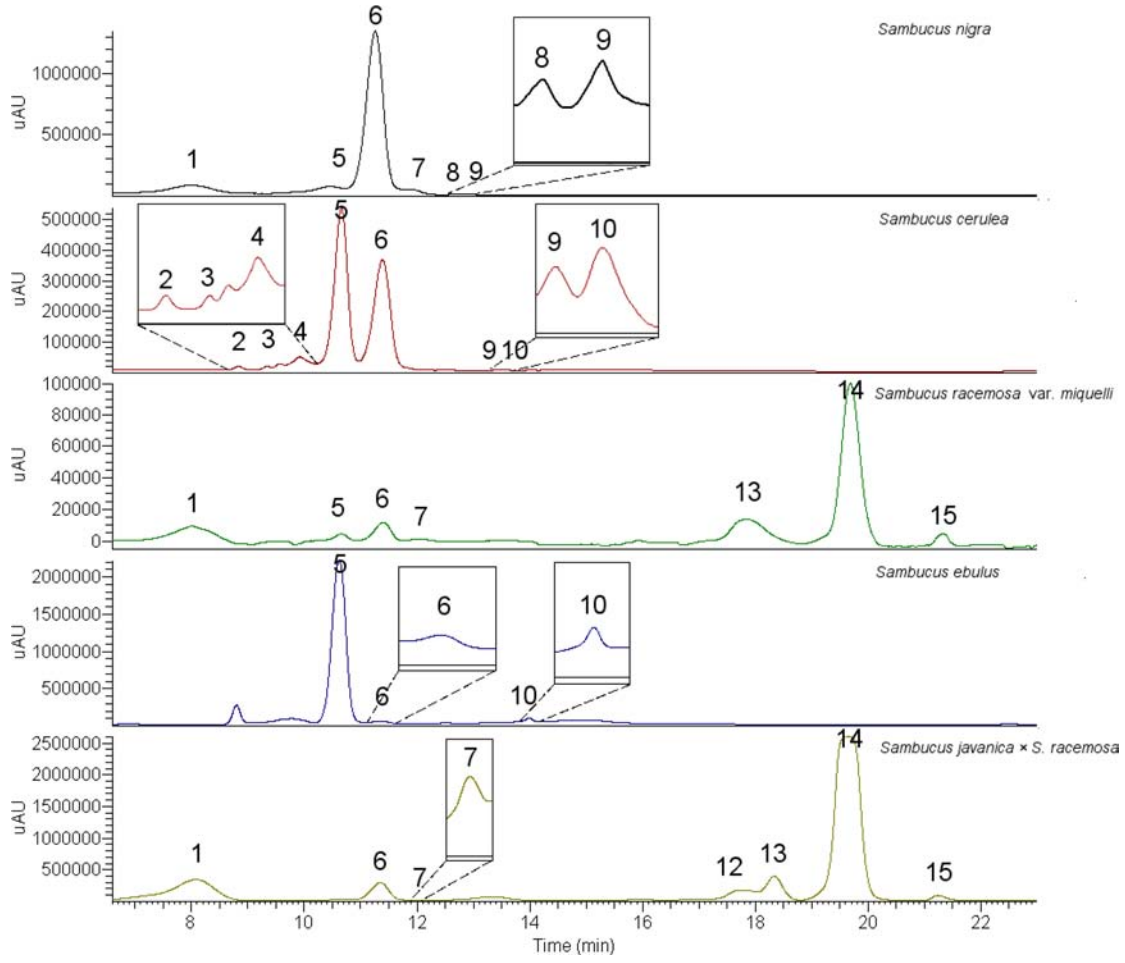

Figure 1. Anthocyanin profile of elderberry fruits of *Sambucus nigra*, *Sambucus cerulea*, *Sambucus racemosa* var. *miquelli*, *Sambucus ebulus*, and *Sambucus javanica* × *S. racemosa*. Peak numbers correspond to the compounds listed in Table 2.

(except for cyanidin-3-galactoside) were quantified in equivalents of cyanidin-3-*O*-glucoside.

Statistical Analysis. The data were analyzed with the Statgraphics Plus 4.0 program (Manugistics, Inc.) using one-way analysis of variance (ANOVA). The differences among the species and interspecific hybrids were tested using the Duncan test at the 0.05 significance level. The means and the standard errors of the means are reported (mean ± SE).

RESULTS AND DISCUSSION

All 13 elderberry genotypes were characterized by unique anthocyanin profiles. Because of limited space, only five representative chromatograms (species *S. nigra*, *S. cerulea*, *S. racemosa* var. *miquelli*, *S. ebulus*, and hybrid JA × RAC) are presented in Figure 1. A total of 19 different anthocyanins were detected in four elderberry species and eight hybrids. By comparing their MS data with recently published records,[20,24] 13 of them were identified. In all analyzed elderberries, cyanidin-based anthocyanins were the major anthocyanins, followed by glycosides of pelargonidin. Similar findings have previously been reported by Wu et al.[24] and Veberic et al.[32]

Peak 1 contained two compounds. The first had a $[M^+]$ at m/z 611, which on MS^2 produced a minor fragment at m/z 449 ($[M^+] - 162$, loss of glucosyl unit) and a major fragment at m/z 287 (cyanidin, $[M^+] - 162$ corresponding to a glucosyl moiety). This compound was, therefore, identified as cyanidin-3,5-diglucoside (also confirmed by the addition of an external standard). This cyanidin is one of the most common anthocyanins in plant tissue previously also confirmed in elderberry fruit.[24,33] Cyanidin-3,5-diglucoside was detected in *Sambucus nigra* fruit and its interspecific hybrids. On the other hand, *S. cerulea* (CER), *S. ebulus* (EB), and *S. racemosa* var. *miquelli* (MIQ) did not contain this anthocyanin. Cyanidin-3,5-diglucoside was also detected in two interspecific hybrids with *S. javanica*, JA × RAC and JA × CER. Although chemical analysis of *S. javanica* was not performed, it can be concluded that its fruits contain this anthocyanin as it is not present in RAC in CER fruit. Statistically the highest level of cyanidin-3,5-diglucoside was detected in fruit of JA × (JA × NI) hybrid, which contained 37.2 mg 100 g^{-1} FW. It seems that *S. javanica*, similar to *S. nigra*, accumulates high levels of this cyanidin. The content level of cyanidin-3,5-diglucoside in analyzed elderberry fruits is in accordance with the results of Kaack and Austed.[33] The second compound in peak 1 had an ion at $[M^+]$ m/z 743, which yielded MS^2 fragment at m/z 581 ($[M^+] - 162$, loss of a glucosyl unit) and MS^3 fragment at m/z 449/287 ($[M^+] - 132$, loss of a xylosyl and $[M^+] - 162$, a glucosyl unit). This corresponds to the fragmentation pattern of cyanidin-3-*O*-sambubioside-5-*O*-glucoside, a prior-identified elderberry anthocyanin.[34] The highest content of this cyanidin was quantified in JA × CER (146.9 mg 100 g^{-1}) hybrid, followed by (JA × NI) × cv. Black Beauty hybrid (136.8 mg 100 g^{-1}). In the former, *S. javanica* is probably responsible for the accumulation cyanidin-3-*O*-sambubioside-5-*O*-glucoside as the

[a]Peak number. [b]Retention time. [c]Anthocyanins were obtained in the positive ion mode. [d]Abbreviations: CER, *Sambucus cerulean*; EB, *Sambucus ebulus*; JA, *Sambucus javanica*; NI, *Sambucus nigra* var. *nigra*; VIR, *Sambucus nigra* var. *viridis*; MIQ, *Sambucus racemosa* var. *miquelli*. [e]Abbreviations for interspecific hybrids are in Table 1.

fruit of *S. cerulea* does not contain it. However, research on *S. javanica* biochemistry is very limited, and no data comparison with literature could be made. Fruits of *S. ebulus* also lacked cyanidin-3-*O*-sambubioside-5-*O*-glucoside, but a high content of this anthocyanin was measured. Cyanidin-3-*O*-sambubioside-5-*O*-glucoside constituted from 3% to 44% total anthocyanins in elderberry fruit analyzed. Contrary to our results, Bridle and Garcia Viguera[35] reported cyanidin 3-*O*-sambubioside-5-*O*-glucoside as the major anthocyanin in the *S. nigra* sample, but Bronnumhansen and Hansen[36] reported cyanidin 3-glucoside as the prevalent pigment of *S. nigra*. The variations in results may be explained by differences of individual genotypes as well as specific growing conditions. It is often difficult to compare anthocyanin levels of elderberries in recent studies mainly because of the different methods and variable expression of the results (e.g., fresh weight vs dry weight).

MS data of peaks 2, 3, 4, and 5 shared the same mass spectral pattern: a molecular ion at 581 ($[M]^+$ m/z 581),a MS^2 fragment ion at m/z 449, and MS^3 fragment ion at m/z 287. The fragment loss of 132 (a pentose unit) and 162 (a hexose unit) suggests the anthocyanins to be cyanidin-pentoside-hexosides, and they were thus tentatively identified as cyanidin glycosides 1, 2, 3, and 4. Cyanidin glycosides 1−3 were only present in berries of *Sambucus cerulea*, but cyanidin glycoside 4 was identified in some others species and hybrids analyzed. An exceptionally high content of cyanidin glycoside 4 was detected in *S. ebulus* fruit (345.8 mg 100 g^{-1}, representing 97% TAA), followed by *S. cerulea* fruit (78.9 mg 100 g^{-1}, representing 53% TAA). Other analyzed species and hybrids contained less than 1 mg 100 g^{-1} of this anthocyanin. No cyanidin glycoside 4 could be detected in hybrids between *S. nigra* and *S. javanica* (JA × NI) (Table 3).

In addition to a $[M^+]$ ion at m/z 581, peak 5 yielded a $[M^+]$ ion at m/z 449. MS^2 fragmentation produced a cyanidin ion at m/z 287 ($[M^+]$ − 162, loss of a hexose moiety). This peak was thus identified as cyanidin-3-galactoside and further confirmed by cochromatography with a cyanidin-3-galactoside standard. A relatively high content of this anthocyanin was measured in fruit of JA × CER (32.2 mg 100 g^{-1}) hybrid, whereas other analyzed species and hybrids only contained traces of cyanidin-3-galactoside (less than 0.7 mg 100 g^{-1}).

Peak 6 contained an ion at m/z 581, which fragmented on MS^2 to produce a minor ion at m/z 449 ($[M]^+$ − 132, loss of a xylosyl unit) and a major fragment at m/z 287 ($[M]^+$ − 132 − 162, loss of xylosyl and glucosyl units). This compound was present in all studied elderberry species and hybrids and has been identified as cyanidin-3-*O*-sambubioside, previously confirmed in elderberry by Chandra et al.[37] and Lee and Finn.[20] Statistically the highest level of cyanidin-3-sambubioside was detected in *S. nigra* fruit (560 mg 100 g^{-1}), representing 61% TAA. Consequently, several interspecific *S. nigra* hybrids ((JA × NI) × CER and (JA × NI) × NI) also contained high levels of this anthocyanin. Similar content levels of cyanidin-3-sambubioside were reported by Veberic et al.[23] and Wu et al.[24] in various *Sambucus* species. *S. cerulea* fruit was also rich in this anthocyanin (representing 42% TAA); however, *S. racemosa*
