Similar to previously published results for other sugar beet pectin,[39] no detectable Trp was found in the SBP used in this work as Trp may interfere with fluorescence measurements. However, it is possible that a trace amount of Trp may exist and was destroyed during the acid hydrolysis of the amino acid analysis procedure. As discussed below in detail, no Trp fluorescence contribution from SBP was evident in this work. Considerable amounts (number of amino acids) of Phe and Tyr residues were measured in the total protein moieties (4.78%) in SBP. These aromatic residues evidently contributed significantly to the broadening of the absorption peak of the SBP, in the area of ∼280 nm.

The high level of methyl esterification (57%) of the sugar beet pectin (SBP) used in this work makes it an effective binding partner for β-LG according to Sperber et al.[41] due to its low block charge density (at low ionic strength). Although both β-LG and SBP remain negatively charged at pH 6.75, the patches of positive charges localized on the surface of β-LG can attract the negative charges of SBP. The attraction force can be stronger than the incompatible forces between the two components repelled.[42] The formation of complexes between β-LG and SBP of varying sizes has been demonstrated using HPSEC.[28] At I = 50 mM, the binding process is expected to be mainly driven by entropy released upon local counterion binding,[43] which results in lowered free energy. Favorable enthalpy contribution was also an important factor as well.[44] In addition other weaker forms of interactions including localized hydrophobic interaction and hydrogen binding between the side chains of β-LG and SBP also play a role in stabilizing the interacting complexes as discussed below.

3.2. Secondary Structural Changes of β-LG upon Interacting with SBP. *Far-UV CD Spectroscopy.* Figure 2 shows far-UV CD spectra of β-LG, native and heat-treated in the absence and presence of SBP at pH 6.75 and 20 °C. It should be noted that SBP, untreated and heat-treated, exhibits negligible circular dichroism activity in the same region. When it was present, the CD spectrum of SBP was subtracted from that of the mixture. Consistent with both X-ray crystallography[11] and NMR[13] studies, the CD spectrum of native β-LG shows predominantly a β-sheet protein at neutral pH exhibiting a wide minimum around 215 nm. Furthermore, a deconvolution procedure was carried out using the software CDNN[45] and a database consisting of 33 reference proteins. The results are given in Table 1. Comparable to the analyses in the literature,[36,46] native β-LG contains predominately over 50% β-sheet with the majority in antiparallel form (∼45%). The relative amounts of other structural elements including α-helix, parallel β-sheet, turn, and unstructured are also in close agreement with the analyses by X-ray crystallography[11] and other spectroscopic techniques.[36,46]

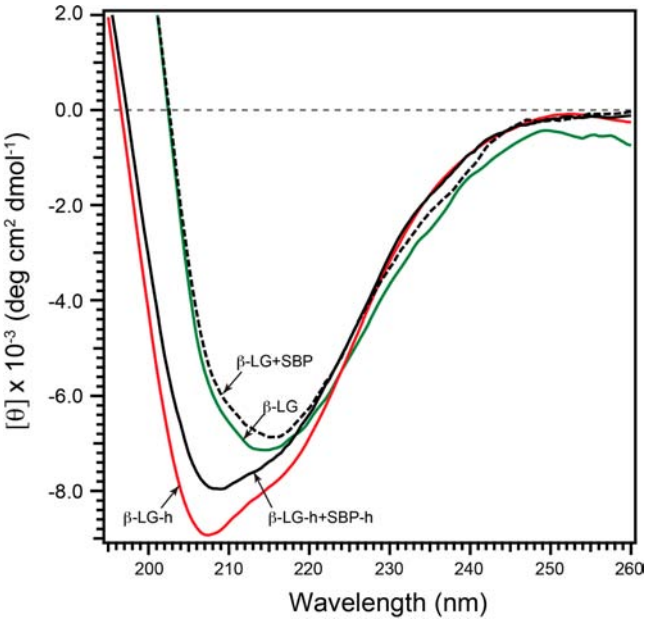

Figure 2. Far-UV CD spectra of β-LG, β-LG + SBP, β-LG-h, and β-LG-h + SBP-h in 33 mM phosphate buffer at pH 6.75 and 20 °C. The concentrations were 0.3 and 0.1 mg/mL for β-LG and SBP, respectively, using a 0.05 cm path length cell. All spectra were corrected against buffer and SBP (when present).

Table 1. Secondary Structure Analysis (%)[a] from Far-UV CD Spectra of Untreated and Heated β-LG in the Absence and Presence of SBP at pH 6.75 (33 mM Sodium Phosphate Buffer)

	antiparallel β-sheet	turn	α-helix	unordered	β-sheet
β-LG	43.3	16.1	10.5	25.6	4.5
β-LG +SBP	33.1	17.6	11.2	32.3	5.8
β-LG-h	29.4	20.5	10.9	34.3	5.1
β-LG-h +SBP-h	30.5	19.9	10.6	33.9	5.1

[a]Analyzed by deconvolution using the CDNN program and a database consisting of 33 proteins.[45]

When combined with SBP, the CD spectrum of β-LG underwent a rather unremarkable change as evidenced by a small decrease in the magnitude of its mean molar ellipticity $[\theta]$ (Figure 2). Quantitative analysis by CDNN deconvolution (see Table 1), however, revealed significant changes in the secondary structure of β-LG caused by interacting with SBP, noticeably ~10% loss in antiparallel β-sheet accompanied by increase (~7%) in unordered structure. Slight increases in other elements including α-helix, parallel β-sheet, and turn accounted for the remaining 4% secondary structural change from native β-LG. This secondary structural change appeared to be greater than our recent report by HPSEC studies[28] in which 6% of native β-LG was found to bind to SBP. This apparent higher level of structural re-distribution can be attributed to the fact that the mixture of β-LG and SBP (in the CD experiments) allowed more direct and efficient interaction than the complexes detected by HPSEC in which case only those surviving the columns and detectors were analyzed.

Preheat treatment (at 80 °C and pH 6.75 for 10 min) of β-LG significantly affected all secondary structural elements compared to native β-LG, particularly, a ~14% reduction in antiparallel β-sheet, as shown in Figure 2 and Table 1. This loss resulted in the apparent 10% increase in unstructured and 4% in turn forms, respectively. Interestingly, this relatively mild treatment did not cause much change in the amounts of α-helix and parallel β-sheet. The addition of preheated SBP apparently caused a small degree of the secondary structural elements to recover in β-LG, noticeably the amount of antiparallel β-sheet, by ~1.0% (±0.4%), compared to the preheated β-LG alone (β-LG-h). The amounts of unstructured and turn were only reduced slightly to account for this slight but noticeable recovery. On the other hand, our HPSEC studies[28] identifying ~16% of preheated β-LG was involved in the complex with preheated SBP. Clearly the pre-heat-treatment did indeed facilitate more effective interaction and lead to largely irreversible structural changes in β-LG.

FTIR Spectroscopy. FTIR spectra in the amide I region (1600−1700 cm^{-1}), known for its sensitivity to protein secondary conformational change, were deconvoluted and analyzed following the band assignments by Barth.[35] The results are shown in Figure 3 and Table 2 and compared with the analyses for native β-LG by Dong et al. and Hasni et al.[37] It should be noted that SBP (at 5 mg/mL) contributes less than ~4% in absorbance in this region compared to that of β-LG (at 15 mg/mL), and mainly centered at the bands 1634 and 1618 cm^{-1}. To obtain only changes in the spectrum of β-LG, the spectra of SBP and SBP-h only were subtracted from that of the mixture, respectively. Table 2 shows that the results for native β-LG were in close agreement with previously published analyses and reveals that the addition of SBP indeed caused statistically significant secondary structural shifts in β-LG. Consistent with the analyses by far-UV CD spectroscopy as discussed previously, the amount of antiparallel β-sheet suffered nearly 10% loss. Instead of the marked increase in unordered form as analyzed by the far-UV CD, an increase of 9% (±2%) in turn structure apparently compensated for the majority of this loss. The difference between the unordered (by the far-UV CD analysis) and turn structure (by the FTIR analysis) is perhaps dictated by the difference in these techniques followed by difference in the deconvolution process. Both turn and random structural elements signify structural irregularity and instability. In addition, the amount of α-helix also increased ~4% (±2%) in the presence of SBP by FTIR analysis, which may be due to the spectral overlap with the adjacent unordered structure.

As expected, when β-LG was subjected to heat treatment (β-LG-h), its secondary structure, especially antiparallel β-sheet, suffered a significant loss, ~8%. As a result, the levels of unstable structures, turn and unordered, increased by ~4% (±2%), whereas the amounts of α-helix and parallel β-turn remained virtually unchanged. In contrast, past work by Eissa et al.[47] found a complete loss of intramolecular β-sheet at 1634 and 1621 cm^{-1} when β-LG was heated at 80 °C for 1 h. In this work, the increase in the absorption band at 1620 cm^{-1} is statistically insignificant for β-LG-h and is likely due to the shortened heating time (10 min) employed. The addition of preheated SBP (SBP-h) increased the amount of antiparallel β-sheet, ~4% (±2%), and decreased the same amount of turn structure, suggesting that interacting with SBP-h resulted in a small level of recovery in the secondary structure of β-LG-h. This is consistent with the analyses by far-UV CD spectroscopy as discussed previously.

3.3. Tertiary Structural Change of β-LG upon Binding to SBP. *Near-UV CD Spectroscopy.* The CD spectrum in the near-UV region (see Figure 4) of native β-LG shows

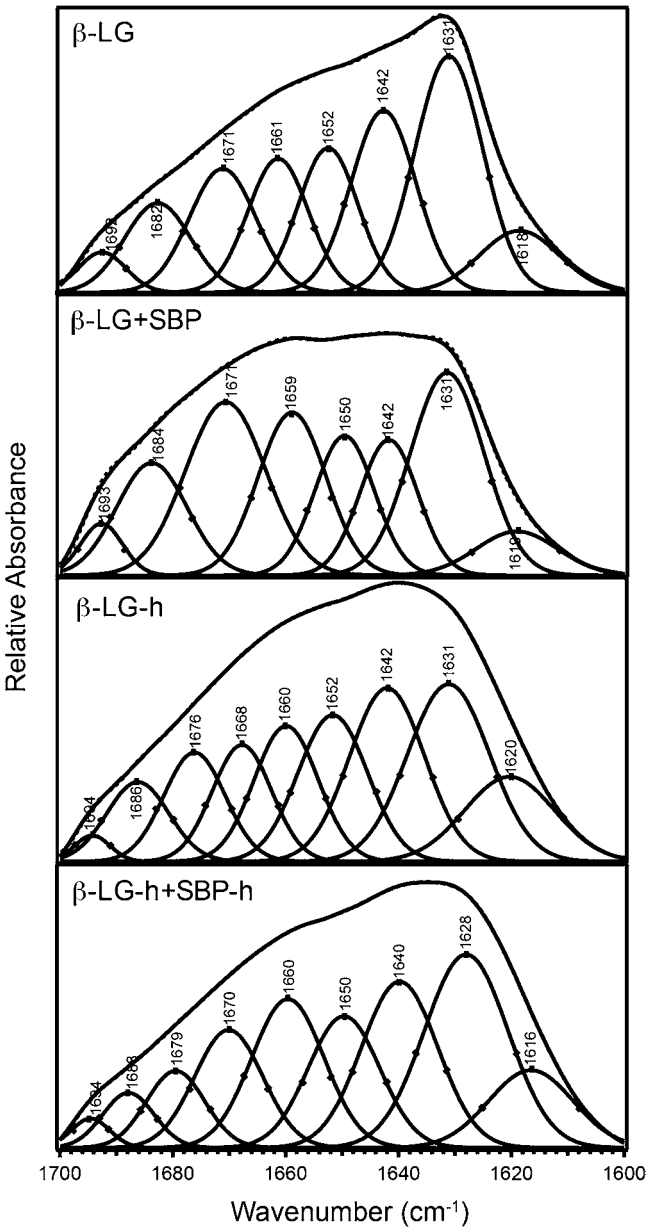

Figure 3. FTIR spectra of *β*-LG, *β*-LG + SBP, *β*-LG-h, and *β*-LG-h + SBP-h and the deconvoluted components in hydrated film made from solution in 20 mM phosphate buffer, pH 6.75. The concentration was 15 and 5 mg/mL for *β*-LG and SBP, respectively. The spectra of SBP and SBP-h were subtracted from those of *β*-LG + SBP and *β*-LG-h + SBP-h, respectively.

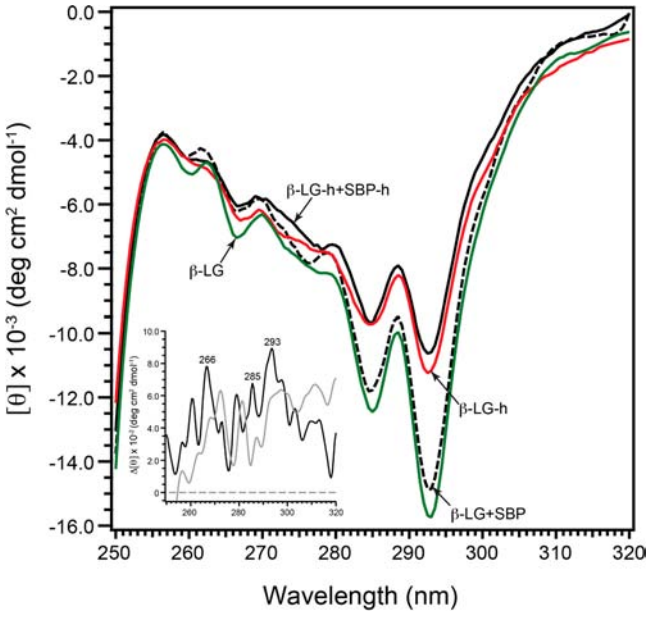

Figure 4. Near-UV spectra of *β*-LG, *β*-LG + SBP, *β*-LG-h, and *β*-LG-h + SBP-h in a 33 mM phosphate buffer at pH 6.75 and 20 °C. The concentrations were 0.9 and 0.3 mg/mL for *β*-LG and SBP, respectively, using a 1 cm path length cell. The insert is the difference spectra between *β*-LG + SBP and *β*-LG (dark line), and between *β*-LG-h + SBP-h and *β*-LG-h (gray line). All spectra were corrected against buffer and SBP (when present).

pronounced negative ellipticity values at 293, 285, and 266 nm. It has been well established[48] that the 293 nm peak belongs to Trp residues, the 285 nm to Tyr plus a small contribution by Trp, and the peaks below 270 nm to Phe. Preheat treatment clearly significantly interrupted the environment and reduced the molar ellipiticity of Trp and Tyr residues, in the form of peak intensity loss at 285 and 293 nm.

When the difference spectrum of *β*-LG in the presence of SBP against native *β*-LG alone was analyzed (the light gray line in the inset of Figure 4), changes in this region broadly reflect the effect of interacting with SBP on the environment of the Trp, Tyr, and Phe residues in *β*-LG. This disruption is particularly prominent for the Phe residues of *β*-LG (four total) upon interacting with SBP as signified by the loss in its intensity at 270 nm and below. When *β*-LG-h was combined with SBP-h, its tertiary structural elements remained roughly unchanged compared to that in the absence of SBP-h except for the slight reversal in 285 nm peak (∼2%) showing as a negative residual peak (the dark line in the inset of Figure 4). This would suggest

a slight recovery in either the environment of Trp residues (mainly Trp19) or/and the five Tyr residues in β-LG.

Fluorescence Spectroscopy. Trp intrinsic fluorescence was used to probe possible tertiary structural interruption of β-LG upon interacting with SBP because of its sensitivity to the polarity of its environment. It is known[49,50] that the major fluorescence contribution of β-LG comes from Trp19, buried within the hydrophobic β-barrel whereas Trp61 is located on the surface of the protein. Figure 5A shows steady-state Trp fluorescence spectra of native and heat-treated β-LG in the absence and presence of SBP at pH 6.75. It should be pointed out that excitation at 282 nm produced the same fluorescence spectrum of β-LG as that using 295 nm as the excitation wavelength.

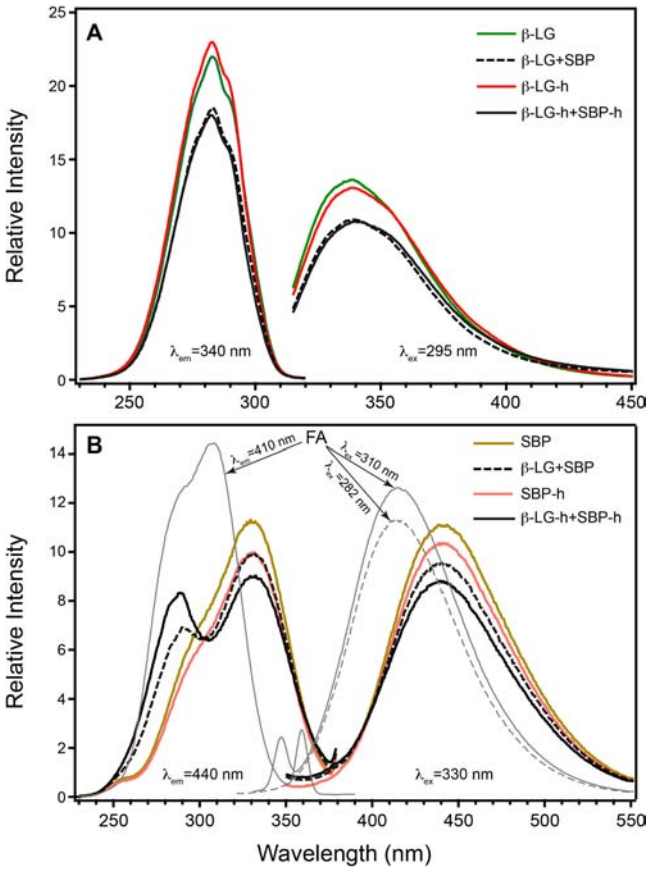

Figure 5. Fluorescence emission and excitation spectra of solutions containing 0.3 mg/mL β-LG or/and 0.1 mg/mL SBP in 33 mM phosphate buffer at pH 6.75 and 20 °C. All λ_{ex} and λ_{em} were as noted. (A) Trp intrinsic fluorescence spectra of β-LG, β-LG + SBP, β-LG-h, and β-LG-h + SBP-h; (B) fluorescence spectra of the feruloyl groups of SBP, β-LG + SBP, SBP-h, and β-LG-h + SBP-h.. The emission (λ_{ex} = 310 nm and λ_{ex} = 282 nm) and excitation (λ_{em} = 410 nm) spectra of ferulic acid (0.0.002 mg/mL) in the same buffer were also plotted as a comparison.

To limit the absorption interference (at 282 nm) from other aromatic residues such as Phe and Tyr than Trp in β-LG, excitation at 295 nm was used in this work. The relatively short time (10 min) heating at 80 °C appeared to have caused only slight reduction and peak broadening in the fluorescence of the single fluorescent Trp residue (Trp19) β-LG, typical for protein denaturation. The addition of SBP and SBP-h, however, greatly quenched the fluorescence of β-LG and β-LG-h, respectively, demonstrating that the Trp19 environment was severely perturbed upon interacting with SBP. Furthermore, this denaturation effect of SBP on β-LG reached a similar level in each case (native and preheated) at the same concentration of β-LG.

Figure 5B shows the fluorescence spectra of the feruloyl groups of SBP as a result of interacting with β-LG. Free ferulic acid displayed a strong fluorescence emission at 415 nm (see Figure 5B); however, the maximum emission of the feruloyl groups in SBP red-shifted to 440 nm. The maximum excitation of the feruloyl groups also red-shifted to 345 nm from 330 nm (for ferulic acid), illustrating changes in the molecular electronic and vibrational states of ferulic acid when present in and covalently bound to SBP than its free form. It should be noted, when excitation was set at λ_{ex} = 287 nm, the other strong absorption shoulder peak for FA (see Figure 1), the same emission peak at λ_{em} = 415 nm as that for λ_{ex} = 345 nm was obtained and the intensity was much reduced.

Combining with β-LG significantly reduced the fluorescence intensity of feruloyl groups present in SBP, more than by the pre-heat-treatment used in this work (Figure 5B). Even though the maximum emission wavelength from β-LG (λ_{em} ~ 340 nm) overlaps with the maximum excitation wavelength for feruloyl groups in SBP (λ_{ex} ~ 330 nm), no fluorescence resonance transfer (FRET) was observed between the two chromophores in this work. This is likely due to the distance between them being greater than 100 Å according to Wu and Brand,[51] which is clearly attributable to the relatively low concentrations of β-LG and SBP used.

3.4. Involvement of Feruloyl Groups of SBP in Interaction with β-LG. To further quantify the effect of binding to SBP on the Trp intrinsic fluorescence of β-LG and vice versa, fluorescence lifetime decays were analyzed. Table 3 summarizes the lifetime decays (τ_i) and their corresponding preexponential factors (α_i) for Trp19 fluoresecence of β-LG and the feruloyl groups of SBP by selectively applying their excitation and emission wavelengths. A double-exponential lifetime of nearly equal magnitude (α), but with different decay times τ_1 = 1.93 ns and τ_2 = 0.94 ns, was obtained for native β-LG. As elucidated comprehensively by Beechem and Brand,[52] the lifetime characteristics of Trp residues in proteins is strictly pH-dependent. At neutral pH, used in this work, Trp typically exhibits biexponential decay.[52]

Nearly only one lifetime decay, τ_1 = 93 ps, was determined for the untreated SBP as the much longer decay τ_2 = 3.46 ns was only less than 1% (Table 3). Free ferulic acid, however, contains strictly a single short lifetime, τ_1 = 44 ps. The delayed fluorescence emission time upon the excitation of the feruloyl groups in SBP than that of its free form further supported the covalent nature of the feruloyl groups in SBP.

One of the two measured Trp fluorescence lifetime decays, i.e., τ_1 for native β-LG, was visibly affected by the interaction with SBP (see Table 3) whereas τ_2 remained unchanged. τ_1 was extended by ~20 ps in its value and also with increased presence, ~4%, demonstrating the disruption of the environment of Trp19, which is consistent with both our near-UV CD and steady-state fluorescence results as discussed previously. The fluorescence lifetime decays of the feruloyl groups of SBP, on the other hand, also underwent significant change in the presence of β-LG, i.e., τ_1 shifted ~10 ps shorter than its counterpart in the absence of β-LG, suggesting profound involvement of the feruloyl groups in the interaction. This is consistent with our findings from HPSEC.[28] The minor but

Table 3. Time Components (τ_i, ns)[a] and Preexponential Factors (α_i, %) Obtained from the Fit of Fluorescence Decays of the Trp Residues of β-LG and the Feruloyl Groups of SBP (pH 6.75, 33 mM Sodium Phosphate Buffer), Measured by TCSPC at Selected Excitation (λ_{ex}) and Emission (λ_{em}) Wavelengths

sample	τ_1	τ_2	τ_3	α_1	α_2	α_3	λ_{ex} (nm)	λ_{em} (nm)

[a]Average and standard deviations (in parentheses) were obtained through a set of triple experiments.

longer lifetime component (τ_2) of SBP and the preexponential factors (α_1 and α_2) remained virtually unchanged.

When β-LG was subjected to heating at its denaturation temperature (80 °C) for 10 min, a third much longer lifetime decay, τ_3 = 5.5 ns was resolved in addition to the two (τ_1 and τ_2), already existed in the untreated β-LG. Heat-induced self-aggregation of β-LG as a result of denaturation is attributed to this additional decay component. Furthermore, it is clear that τ_1 has become notably shorter, ~0.30 ns, whereas τ_2 remained roughly the same as in native β-LG within the range of standard deviation. The distribution of the triple exponential lifetimes was 20%, 56%, and 24%, respectively. It is apparent that τ_2 is the dominating one among the three and saw a 6% increase from native β-LG whereas τ_1 is the most heat-sensitive component, and τ_3 is the result of denaturation and aggregation at the cost of ~30% reduction in τ_1. The dominating decay component of SBP-h, τ_1, became ~10 ps shorter than that of untreated SBP and to about the same level as that of untreated SBP in the presence of β-LG.

When combined with SBP-h, the thermal sensitivity marker, τ_1 of β-LG became 0.1 ns longer than β-LG-h alone and with an ~6% increased level of contribution as well. In the mean time, both τ_2 and τ_3 showed reduced levels of participation, ~3% for each. Changes in the triple lifetime decays of β-LG suggested a limited level of restoration of the tertiary structure of β-LG-h upon binding to SBP-h.

Both lifetime components of the feruloyl groups of SBP-h, τ_1 and τ_2 also featured an interesting response to the binding interaction with β-LG-h. The main component τ_1 was returned to its untreated value, ~95 ps, but reduced contribution, ~6%, whereas the minor one τ_2 nearly doubled, from ~3.5 to 5.3 ns. Taken all together, it is evident that feruloyl groups of SBP are directly involved in the complex formation with β-LG, more prominent for the preheated mixture. As a result, ~4% of the total loss (24%) in tertiary structural contacts in β-LG caused by heat-induced aggregation and denaturation was recovered due to the presence of SBP-h, mostly in the environment of Trp19 with increased stabilization. This result is clearly in close agreement with the temperature dependence of Trp fluorescence of β-LG in the presence of SBP and the protective effect on which it imparted, as discussed in subsequent text.

3.5. Thermal Stability of Secondary Structure of β-LG as a Result of Interaction with SBP. To investigate the effect of interacting with SBP on the structural stability of β-LG, we conducted far-UV CD experiments as a function of temperature. A deconvolution procedure was performed on each spectrum at each temperature using the software CDNN,[45] and a database consisting of 33 reference proteins was used. Parts A–E of Figure 6 show the content of each secondary structural element of β-LG as a function of temperature. For native β-LG, temperature-induced denaturation behavior (open circles and solid lines) closely resembled a two-state unfolding model[53] for all five individual elements as deconvoluted in this work. The presence of SBP (open triangles and dotted lines) did not significantly alter the unfolding process of β-LG except for the initial denaturation effect upon interaction. Pre-heat-treated β-LG still retained a good amount of secondary structural elements as discussed above, and underwent further temperature-induced denaturation (closed circles and dashed lines). The addition of pre-heat-treated SBP only initially restored a limited amount of

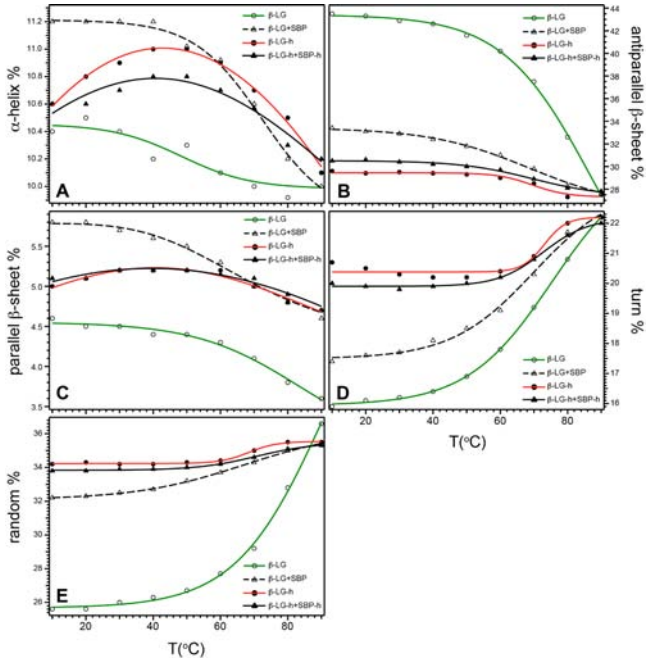

Figure 6. Temperature dependence of secondary structural elements: (A) α-helix, (B) antiparallel β-sheet, (C) β-sheet, (D) turn, and (E) random coil of β-LG, β-LG + SBP, β-LG-h, and β-LG-h + SBP-h obtained by deconvolution of far-UV CD spectra of β-LG, β-LG + SBP, β-LG-h, and β-LG-h + SBP-h in 33 mM phosphate buffer at pH 6.75. The concentrations were 0.3 and 0.1 mg/mL for β-LG and SBP, respectively, using a 0.05 cm path length cell. All spectra were corrected against buffer and SBP (when present). Various lines were used to make it easier to visualize all data points.

dx.doi.org/10.1021/jf502699g | J. Agric. Food Chem. 2014, 62, 7567–7576

secondary structures but did not significantly affect the temperature dependence behavior of β-LG-h under the conditions employed in this work.

In addition, all secondary structural elements of β-LG arrived at a similar level at the highest temperature used (90 °C) in the absence and presence of SBP.

3.6. Thermal Stability of Tertiary Structure of β-LG as a Result of Interaction with SBP. To further understand the effect of interacting with SBP on the tertiary contact and stability of β-LG, experiments were carried out on the Trp intrinsic fluorescence and feruloyl fluorescence at varying temperatures (10−90 °C), and the results are shown in Figure 7. As expected, the intrinsic Trp (mainly Trp19) fluorescence

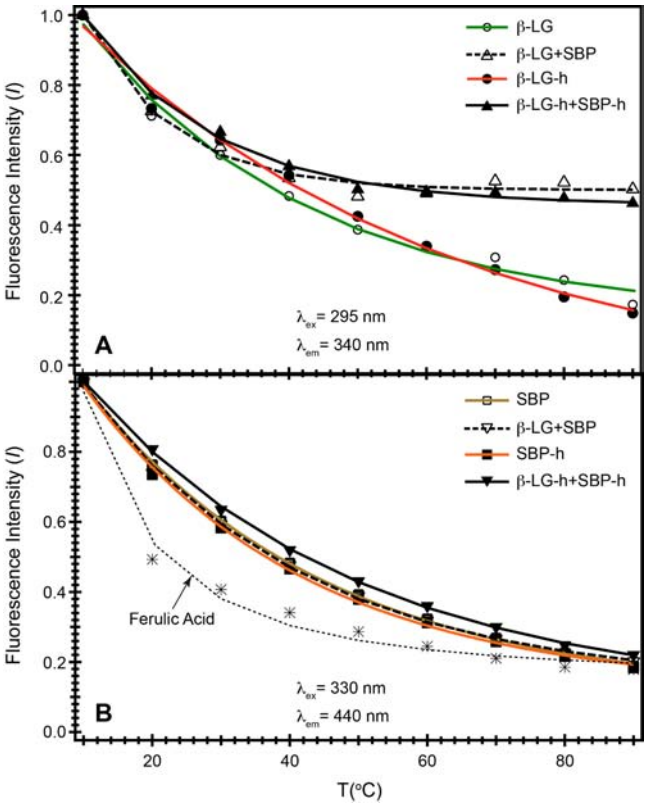

Figure 7. Temperature dependence of fluorescence intensity of all solutions containing 0.3 mg/mL β-LG or/and 0.1 mg/mL SBP in 33 mM phosphate buffer at pH 6.75. All λ_{ex} and λ_{em} were used as specified. (A) Trp intrinsic fluorescence spectra of β-LG, β-LG + SBP, β-LG-h, and β-LG-h + SBP-h. (B) Fluorescence spectra of the feruloyl groups of SBP, β-LG + SBP, SBP-h, and β-LG-h + SBP-h. The fluorescence intensity of FA as a function of temperature is also compared using λ_{ex} = 310 nm and λ_{em} = 410 nm. The intensity (I) at each temperature was normalized against its value at 10 °C.

intensities of both native and preheated β-LG (β-LG-h; Figure 7A) underwent a continuous decline in a fashion similar to the temperature increase and eventually arrived at ∼20% of their initial intensity at the highest temperature used (90 °C).

In the presence of SBP, the intensity of the Trp fluorescence of native β-LG first saw an accelerated reduction and then at ∼40 °C it began to level off to ∼55%. This level was maintained thereafter as temperature increased even as high as 90 °C. Clearly, SBP first acted as a quencher but then functioned as a shield and helped preserve the Trp residue from undergoing further thermal-induced solvent exposure. Although the Trp fluorescence intensity of pre-heat-treated β-LG (β-LG-h) was diminished compared to its native form, further temperature treatment imposed little or no visible effect, attesting the protective role that SBP-h played for β-LG-h against thermal treatment.

On the other hand, the temperature dependence of fluorescence intensity of the feruloyl groups of SBP was virtually unaffected by interacting with β-LG (Figure 7B) and decreased to nearly 10% of its initial intensity at 90 °C. The fluorescence of FA also displayed a sharply different temperature dependence behavior. For example, even at room temperature (20 °C), its fluorescence intensity already reduced by nearly half compared to 10 °C whereas changes in its fluorescence were much slower when present as feruloyl groups in SBP against temperature increase (Figure 7B), suggesting a possible "shielded" environment for the feruloyl groups in SBP.

In this work, we have demonstrated that interacting with SBP caused a significant amount of antiparallel β-sheet structure, up to 10%, to turn into random or turn structure in native β-LG. Tertiary structural contacts, for all aromatic residues, Trp, Tyr, and Phe, also suffered considerable loss in the presence of SBP. A limited level, ∼4%, of lost secondary and tertiary structures of β-LG caused by pre-heat-treatment (80 °C for 10 min) was restored by interacting SBP. Furthermore, thermal stability of all secondary structure elements of β-LG was not significantly affected by the presence of SBP. However, the Trp19 environment of β-LG was greatly protected by interacting with SBP against thermal denaturation. All evidence gathered in this work further demonstrated that the interaction between β-LG and SBP occurred near the calyx and at the outer surface region of β-LG involving the β-barrel area formed mainly by the antiparallel β-sheets. Results from this work provided an in-depth understanding of the functional properties (e.g., emulsion) of protein-based food products containing polysaccharides as an additive and correlated these properties with the detailed molecular structures of the protein.

al.[10] were adapted to determine penicillin G concentrations at injection sites, serum, urine, kidney, and skeletal muscle. Liver and adipose tissue residues were not measured because neither is a regulatory target tissue for detecting penicillin G residues. Depletion kinetics of penicillin G subsequently were modeled to determine preslaughter withdrawal period recommendations for kidney and muscle.

MATERIALS AND METHODS

Study Overview. To determine the effect of intramuscular (IM) administration pattern on penicillin G depletion, 126 heavy sows were administered a 5× label dose of penicillin G procaine for 3 consecutive days. The three penicillin G treatments differed in injection volume and pattern. Animals were serially slaughtered with 5, 10, 15, 20, 25, 32, and 39 day withdrawal periods, and urine, serum, kidney, skeletal muscle, and injection site were collected for penicillin G analyses by liquid chromatography−mass spectrometry (LC−MS/MS). Because of the large number of animals, the study was conducted in two identical trials of 63 animals each.

Animals. Prior to the initiation of the study, an animal use protocol was approved by the North Dakota State University (NDSU) Animal Care and Use Committee. One-hundred sixty heavy sows, in lots of 80 each, were purchased from the North Dakota Pig Cooperative (Larimore, ND). Sows were group housed in concrete-floored pens covered with ample quantities of straw as bedding. Animals were ear tagged and group-fed approximately 2 kg of a corn−soybean ration (Table 1) per animal at approximately 0800 h each day; pens were cleaned daily, and water was available on an ad libitum basis. At delivery, sows were sorted into groups that were lame, had visible abscesses, or other visible anomalies. These animals were separated from the other sows and were not considered for inclusion in the study. Within the pool of healthy animals, sows were randomly allocated to treatment and pen so that each pen contained 21 sows. At this time, individual sows were randomly allocated to withdrawal period.

Table 1. Sow Diets Fed on a Restricted Basis (2 kg/animal per day)

ingredient	kg	percentage
corn, ground	723.6	79.6
soybean meal (46.0%)	123.2	13.5
malt sprouts	45.5	5.0
monocal, 21%	0.9	0.1
limestone	7.8	0.9
salt	3.6	0.4
RalCo sow	4.5	0.5
	909.1	100.0

Approximately 7 days prior to the initiation of penicillin G treatment, sows were tattooed according to their treatment assignment. An apparatus allowed multiple patterns of 2 cm "O"s to be tattooed onto necks of sows according to treatment (Figure 1). Tattooing allowed a consistent adherence to treatment protocols and designations for dose delivery.

Treatments. All sows were dosed with penicillin G procaine (Norocillin; Norbrook Laboratories, Lenexa, KS) at 33 000 U/kg BW. Treatments (illustrated in Figure 1) were designed to mimic the extra-label administration of penicillin G procaine thought to be used by veterinarians and swine producers during the treatment of infected sows.[6] Thus, each treatment differed in the volume and pattern of penicillin G procaine administration:

- Treatment 1: "10 mL; Single Site". A maximum injection volume of 10 mL using multiple injection sites within day to deliver the total required drug volume; across day, injections were administered into the same site as the previous day (Figure 1, top panel).
- Treatment 2: "10 mL; Multiple Sites". A maximum injection volume of 10 mL using multiple injection sites within day to deliver the total required drug volume; across day, injection sites were separated by approximately 5 cm (Figure 1, middle panel).
- Treatment 3: "20 mL; Multiple Sites". A maximum injection volume of 20 mL using multiple injection sites within day to deliver the total required drug volume; across day, injections were separated by approximately 5 cm (Figure 1, lower panel).

The day prior to penicillin G procaine administration, sows were weighed. At dosing, penicillin G Procaine was administered via intramuscular injection through 3.8 cm, 16-gauge needles. Dosing was uneventful.

In addition to treatment animals, two positive control hogs received the label dose of penicillin G procaine by IM (6600 U/kg BW) injection for 3 consecutive days; during both trials, a single positive control sow was euthanized after a 7-day withdrawal period, consistent with the product label instructions. The other positive control sows were scheduled to be slaughtered after a 15-day withdrawal period; however, in trial 1, the 15 withdrawal day positive control sow died 12 days after penicillin G administration due to a ruptured spleen, so both 15-day withdrawal positive controls were obtained during trial 2. For both trials, untreated control sows were administered saline via intramuscular administration at 1 mL per 45.5 kg BW for 3 consecutive days and slaughtered after 5 days.

Slaughter and Tissue Sampling. Sows were euthanized according to American Veterinary Medicine Association recommendations[12] after 5, 10, 15, 20, 25, 32, or 39 day withdrawal periods relative to the last dosing day. Approximately 15 h prior to slaughter, sows designated for slaughter were withheld from access to feed. Sows were stunned by electrocution and captive bolt, after which they were quickly exsanguinated. Viscera were removed, and kidney and skeletal muscle (mid portion of the *longissimus dorsi*) were collected as well as urine and blood samples. At collection, samples were placed on dry ice; they were subsequently transported to the Biosciences Research Laboratory and stored at −80 °C until processing and analysis.

Tissue Processing. Frozen tissue samples were homogenized with dry ice using a Waring 1 L stainless steel blender (Torrington, CT) at a sample to dry ice ratio of approximately 1 to 1. Homogenized samples were subsequently placed at −20 °C to allow overnight sublimation; after sublimation of CO_2, samples were moved to a −80 °C freezer until analysis.

Extraction. Apley et al.'s[10] analytical method was adapted to accommodate larger volumes for serum and urine analyses. One milliliter of serum or urine and 4 mL of HPLC-grade acetonitrile were mixed for 15 min. Samples were then centrifuged for 20 min at 3000*g* (4 °C); supernatants were transferred to clean labeled tubes and were evaporated under N_2 at 45 °C to a volume of 0.5 mL. Concentrated extracts were quantitatively transferred to 1.5 mL microcentrifuge tubes, diluted to the 1 mL mark with HPLC-grade water, fortified with deuterated penicillin G standard (d_7, 100 ng; Sigma-Aldrich), and vortexed for 15 s. Extracts were then centrifuged at 17 000*g* for 20 min and aliquoted into glass vials for same-day LC−MS/MS analysis. Matrix-matched standard curves were prepared with each sample set having a concentration range of 2−500 pg/μL. Samples having penicillin G concentrations greater than the highest calibration standard were diluted with water into the quantitative range of the calibration curve as were contemporaneously run matrix-matched calibration standards. The extraction efficiency for serum was 88.7 ± 8% (n = 16) with method limits of detection (mLOD) and quantification (mLOQ) of 1.5 and 5.0 pg/μL, respectively. The urine extraction efficiency was 98.1 ± 8.0% (n = 16) with mLOD and mLOQ of 1.1 and 4.1 pg/μL, respectively.

Kidney, muscle, and injection site samples were extracted following the FSIS method CLG-BLAC.02 for β-lactam screening and confirmation[11] with minimal modifications. To kidney samples (2 g) was added 10 mL of an 80/20 mixture of HPLC-grade acetonitrile/nanopure water, and tubes were shaken for 15 min and centrifuged at 3000*g* for 15 min (4 °C). Sample extracts were then added to a

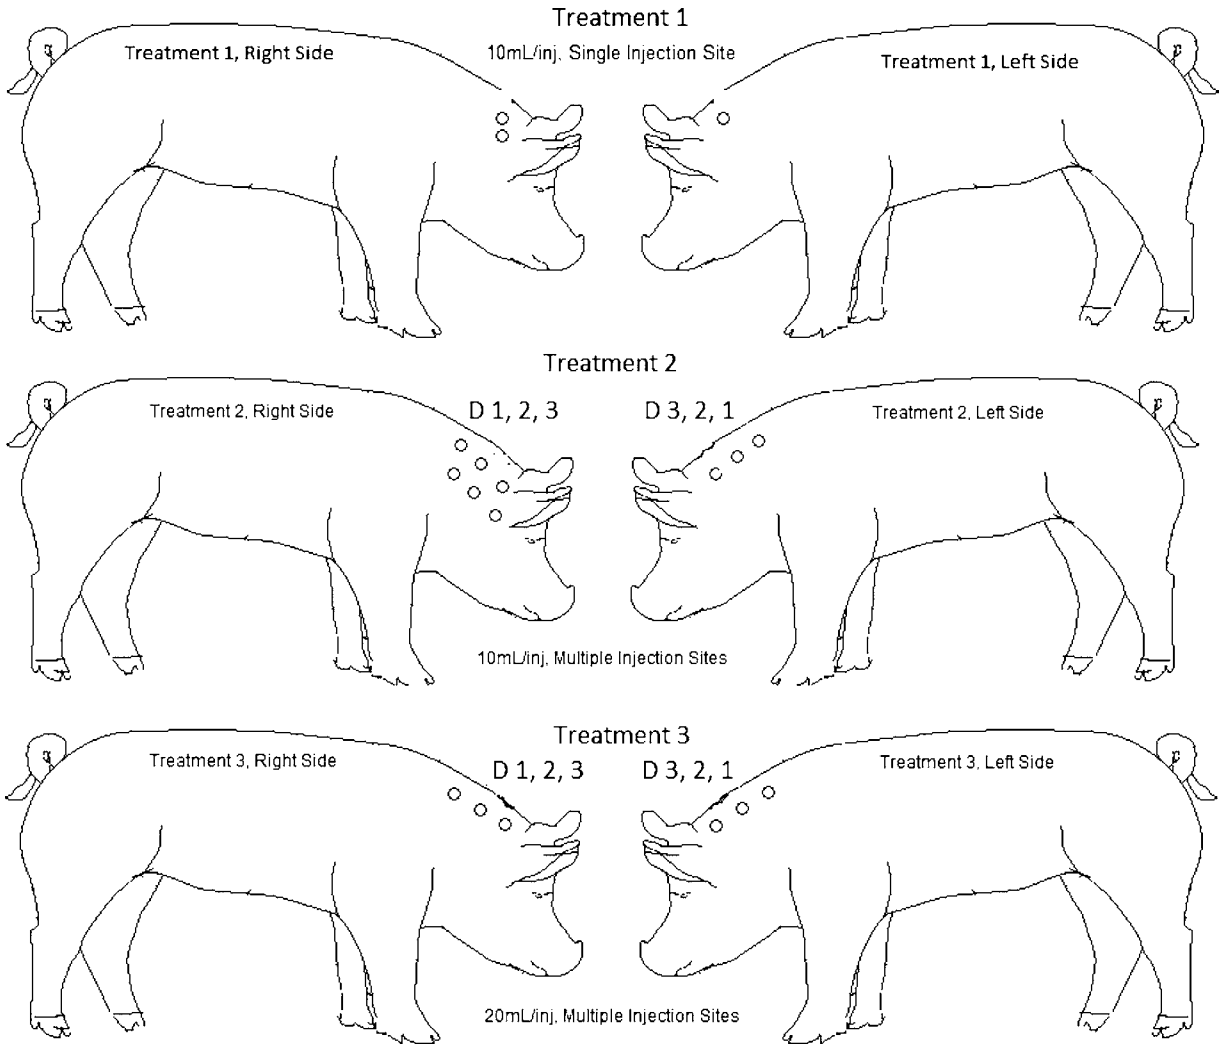

Figure 1. Penicillin G procaine treatments. Sows were administered 5× doses (33 000 IU/kg BW) of penicillin G procaine on each of three consecutive days as either 10 mL injections (treatments 1 and 2) or 20 mL injections (treatment 3). Across day, treatment 1 sows received injections in a single location; sows in treatments 2 and 3 received consecutive injections at locations separated by approximately 5 cm intervals. Because sows were very large, total injection volumes were typically greater than 20 mL; thus, for treatments 1 and 2, the pattern of injections was 10 mL right, 10 mL left, and the remaining volume (for total doses greater than 20 mL) would be injected into the right side approximately 5 cm below the initial 10 mL injection. The injection pattern for treatment 3 was 20 mL in the right side with overflow injections occurring in the left neck muscles. Injection sites were marked by tattoos 7 days prior to the initial treatment.

prepared (5 mL of acetonitrile and 2 × 5 mL of nanopure water) Bakerbond Octadecyl (C18, 1000 mg; JT Baker) solid-phase extraction (SPE) cartridge. Samples were allowed to flow through SPE cartridges by gravity; SPE cartridges were dried under vacuum. Unretained eluents were subsequently evaporated to 1 mL under N_2, syringe filtered through a PTFE 0.45 μm filter, and 100 ng of deuterated penicillin G was added. Extracts were centrifuge-filtered through a Millipore Amicon Ultra centrifuge filter (3000 nominal molecular weight limit) at 14 500*g* for 30 min, and 100 μL was placed into an autoinjector vial for LC−MS/MS analysis. The extraction efficiency for kidney was 72.7 ± 10.7% (n = 26) with mLOD and mLOQ of 1.8 and 6.1 ng/g, respectively.

Muscle and injection site samples were extracted with 10 mL of an 80/20 mixture of HPLC-grade acetonitrile/water saturated with hexane. Samples were then shaken for 15 min and centrifuged at 3000*g* for 15 min at 4 °C. The supernatants were decanted into a clean 50 mL tube, 5 mL of hexane was added, and extracted for 5 min with shaking. Samples were then centrifuged at 3000*g* for 15 min at 4 °C, the hexane layer was removed, and the extracts were processed as described for kidney by SPE and filtration. The extraction efficiency for muscle and injection site was 55.8 ± 9.4% with mLOD and mLOQ of 0.7 and 2.4 ng/g, respectively.

Duplicate blank (negative control) and fortified samples (25 ng/g penicillin G procaine) were extracted with each sample set. Trial samples were extracted in duplicate by withdrawal day. Before analysis, a penicillin G-d7 internal standard was added to each sample extract at an end concentration of 100 pg/μL. Blank sample extracts were utilized to prepare matrix matched standard curves ranging from 2 to 500 pg/μL. A new standard curve was made fresh for each sample set to avoid any penicillin G degradation. Samples and curves were analyzed by UPLC−MS/MS within 24 h of extraction. Samples with penicillin G concentrations above the highest standard in the curve were re-extracted and diluted with water before analysis. Blank matrices for standard curves of diluted samples were diluted with water to ensure equivalent matrix-matching.

Ultra High Performance Liquid Chromatography−Mass Spectrometry. A modified version of the UHPLC−MS/MS method described by Apley et al.[10] was used to determine penicillin G concentrations. Extracts were analyzed using a Waters (Milford, MA) ultra high performance liquid chromatograph coupled to a tandem quadrupole mass spectrometer (Acquity). The chromatography was modified slightly to be a slower gradient to affect a longer retention of

[a]Data are expressed as ng of penicillin G per g of tissue. Individual values below each matrix limit of quantitation (LOQ), but above the method limit of detection (LOD), were included in means as nominal values returned by the LC−MS/MS assay. Values below the matrix LOD were included in mean calculations at 1/2 of the LOD. Mean values shown in italic font were below the method limit of quantification (LOQ) but above the method limit of detection (LOD); mean values shown in bold font were below the method LOD and are expressed at one-half the LOD. Means within a row with differing letters (x, y) differ ($P < 0.05$). Means within withdrawal period and treatment were calculated from six animals each. Data from individual animals are included in the Supporting Information. [b]Within withdrawal period means were ln transformed and compared using one-way ANOVA using parametric (†) or nonparametric (‡) tests; NC, not compared. [c]Skeletal muscle and injection site data are not corrected for recovery, which averaged 55.8 ± 9.4% across all skeletal muscle assays ($n = 14$); method LOQ, 2.4 ng/g LOD, 0.7 ng/g; one-half LOD, 0.4 ng/g. [d]Kidney data are not corrected for recovery, which averaged 72.7 ± 10% across all kidney assays ($n = 26$); method LOQ, 6.1 ng/g; LOD, 1.8 ng/g; one-half LOD, 0.9 ng/g. [e]Serum data are not corrected for recovery, which averaged 88.7 ± 9.4% across all serum assays ($n = 14$); method LOQ, 5.0 ng/g; LOD, 1.5 ng/g; one-half LOD, 0.8 ng/g.

penicillin G relative to the Apley et al.[10] method. Penicillin G was separated from matrix on a Waters BEH C18 column (2.1 × 50 mm, 1.8 μm) using a mobile phase gradient consisting of: 0 to 1.5 min, isocratic 80/20 10 mM ammonium acetate in water/10 mM ammonium acetate in acetonitrile (A/B); 1.5 to 1.75 min, linear gradient to 20/80 A/B; 1.75 to 4 min, isocratic 20/80 A/B; flow rate of 0.8 mL/min. Penicillin G and deuterated penicillin G eluted at 0.45 min. Analytes were ionized in positive electrospray mode using a capillary voltage of 3.5 kV at a desolvation temperature of 500 °C and a nitrogen flow rate of 800 L/h. Other parameters included a source temperature of 150 °C and a cone voltage of 35 V.

The detection method was also modified to monitor additional fragment ions for penicillin G to improve confirmation and quantification of residues. Fragment ion isolation and detection was accomplished in the multiple reaction monitoring mode. For penicillin G and deuterated penicillin G, two fragments were monitored. The precursor ion for penicillin G was 335 m/z; using a collision energy of 10, fragment ions at 160 m/z and 176 m/z were produced. For dueterated penicillin G, the precursor ion was 342 m/z; with a collision energy of 12, fragment ions at 160 m/z and 183 m/z were produced. If sample duplicate concentrations differed by more than 25%, they were re-extracted and reanalyzed in duplicate to achieve better agreement between replicates. Reported data are not corrected for recovery.[13] Method LODs were calculated as the standard deviation of seven replicates of fortified samples (2 ng/mL or ng/g) multiplied by the Student's t value (99% confidence) with $n - 1$ degrees of freedom; mLOQs are 10 times the standard deviation of the seven replicates.[14]

Statistical Comparisons. Within withdrawal period and matrix, data were natural log (ln) transformed prior to analyses by simple one-way ANOVA. For time points in which assumptions of normality (tested using the Shapiro−Wilk method) were met, differences in

[a]Data are expressed as ng of penicillin G per mL of urine. Individual values below each matrix limit of quantitation (LOQ; 4.1 ng/mL), but above the method limit of detection (LOD; 1.1 ng/mL), were included in means as nominal values returned by the LC−MS/MS assay. Values below the matrix LOD were included in mean calculations at 1/2 of the LOD. Means within a row with differing letters (x, y) differ ($P < 0.05$). Means within withdrawal period and treatment were calculated from six animals each. Data from individual animals are included in the Supporting Information. [b]Within withdrawal period means were ln transformed and compared using one-way ANOVA using parametric (†) or nonparametric (‡) tests; NC, not compared.

treatment means were determined using standard parametric methods (i.e., Holm−Sidak). In instances in which normality was not met, nonparametric analysis was conducted using the Kruskal−Wallis one-way ANOVA on ranks. Specific details on the use parametric or nonparametric tests for any tissue/withdrawal period combination are shown within each data table.

Estimation of Withdrawal Period. Withdrawal periods were estimated using the method described by the US FDA-CVM[13] with some modification. In the estimation of withdrawal periods for kidney, the following criteria were used. These criteria are a combination of European Union and US FDA approaches to handling data from residue depletion trials. First, for tissue residue data for a given withdrawal day to be included in the analysis, at least three animals had to have returned residues above the method limit of quantification.[13] Second, nominal values below the limit of quantification, but above the limit of detection, were used as returned by the assay if there were at least three points at the withdrawal period above the limit of quantification. Third, values falling below the limit of detection were included at one-half the method limit of detection.[15]

For kidney, data obtained from withdrawal days 10, 15, 20, and 25 were used for the calculation of withdrawal period. Data from day 32 were not employed even though there were three animals with penicillin residues above the LOQ because the 32-day data were not linear ($P = 0.45$) with respect to withdrawal day 20 and 25 data. It should be noted, however, that the 10, 15, 20, and 25 day data set violated the statistical assumptions of normality and equal variance.

To estimate the withdrawal period for skeletal muscle, only one animal out of 18 had residues above the LOQ at the 15-d withdrawal period, with three animals having residues above the LOD, but below the LOQ. Because a minimum of three time points are required to determine the terminal, linear elimination period, the 15-d withdrawal period data were used to estimate a withdrawal period for skeletal muscle. In doing so, the day 15 data included one value that was above the LOQ, four animals that had residue values between the LOQ and LOD, and 13 animals in which no detectable residue was present; for the latter animals, a value of one-half the LOD was used for calculations. Skeletal muscle data also violated the statistical assumptions of normality and equal variance.

Estimations of withdrawal period were completed for kidney and skeletal muscle tissues using the procedure described by the US-FDA CVM in guideline no. 3, "General Principles for Evaluating the Safety of Compounds used in Food Producing Animals".[13] Excel 7.0 was used in conjunction with the tables of Owen[16] to calculate the critical values of the noncentral *t*-distribution used in FDA calculations.

RESULTS AND DISCUSSION

Weights of sows dosed with penicillin G procaine averaged 234.2, 223.8, and 226.8 kg for treatments 1, 2, and 3, respectively (±4.5 kg; pooled SEM) and did not differ ($P = 0.24$). Average slaughter weights were 237.4, 226.5, and 228.9 kg (±4.4 kg; pooled SEM) and did not differ ($P = 0.19$).

Mean residues of penicillin G in skeletal muscle, kidney, serum, and injection site are shown in Table 2. Table 3 shows mean urinary depletion of penicillin G by treatment and withdrawal period. Raw (individual animal) data are presented as Supporting Information.

The depletion of penicillin G residues from kidneys of heavy sows is presented in Figure 2. The pattern of penicillin G administration had no discernible effect on residue depletion, so treatments were pooled. Quantifiable residues were present in kidneys of all 18 animals 5 days after the final penicillin G procaine injection, but by 10 days 6 of 18 (33%) animals had residues below the assay LOD (1.8 ng/g). By 20 days of withdrawal, 5 of 18 animals had residues above the LOQ with three of these animals having kidney residues above 100 ng/g and one animal with penicillin G residues greater than 300 ng/g. Penicillin G residues were present in the kidneys of two hogs after a 39-d withdrawal period. The presence of penicillin G residues in 11% of animals (2 of 18 animals) at withdrawal day 39 suggests that an extensive withdrawal period would be required for the complete depletion of penicillin from kidneys of a population of treated animals.

Regulatory organizations in the European Union and the United States estimate preslaughter withdrawal periods using nearly identical techniques.[13,15] That is, withdrawal periods are calculated by determining the time required for tissue residues in 99% (U.S.) or 95% (Europe) of a population of animals to deplete to an established tolerance with 95% confidence. Tolerance limits are calculated using linear regression of the natural logs (ln) of tissue residues in the linear depletion phase of the residue depletion curve. In calculating the 95th percentile confidence interval, the U.S. assumes a noncentral *t*-distribution,[13] whereas the European Union allows the 95th percentile confidence interval to be calculated using the standardized normal distribution.[15] The two methods generally return similar results,[15,17] depending upon a number of variables, the most important being the handling of data which fall below the method limit of quantification.[17] Both the U.S. and the CVMP methods of establishing withdrawal periods have been criticized[18,19] because of the difficulty with which residue data collected over time meet assumptions of normality and equal variance.

A withdrawal period was estimated for kidney tissues using the ln-linear approach promulgated by the US-FDA CVM[13]

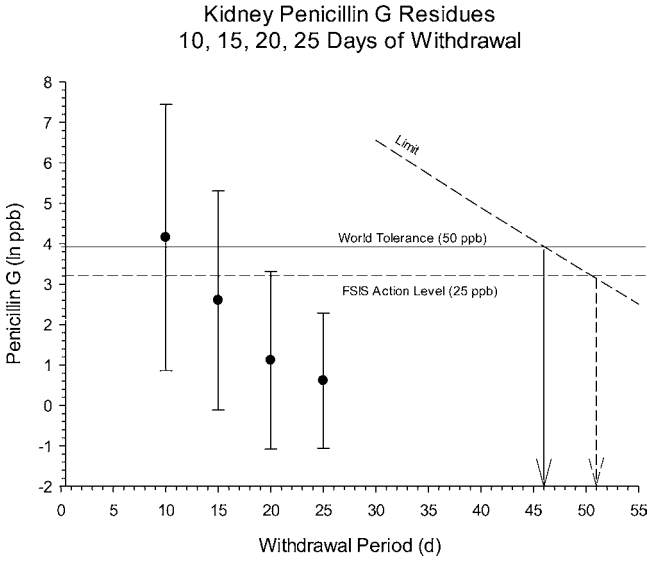

Figure 2. Estimation of preslaughter withdrawal period in heavy sows treated with a 5× dose of penicillin G procaine, based on depletion of penicillin G residues from kidney tissues. Data taken from the linear portion of the depletion curve were analyzed as described by FDA Guidance Document no. 3 (US FDA CVM, 2006). In contrast to US FDA guidance, 15-d withdrawal data below the method LOD were assigned values of 1/2 the LOD (CMVP, 1995). Kidney penicillin G concentrations that were between the LOQ and LOD were included in the analysis as their nominal concentration. The residue tolerance used by most of the world (50 ng/g or ln 3.91 ng/g) crossed the 99th percentile with a 95th percent confidence interval tolerance limit at approximately 46.5 days (solid vertical arrow). The kidney withdrawal period for a tolerance of 50 ng/g was established at 47 days after rounding up to the nearest whole-day. In the United States, the tolerance level is zero for penicillin G in swine tissues, but FSIS has established an action limit of 25 ng/g for penicillin residues detected in swine tissues (FSIS, 2013). For penicillin residues to deplete below the action limit of 25 ng/g in a population of swine, just over 50 days would be required; rounding up to the nearest whole-day, the withdrawal period would be 51 days.

with modifications suggested by the CVMP.[15] In making a withdrawal period estimation, the essential assumptions of equal variance and normal distributions (Shapiro−Wilk) of data were violated ($P < 0.001$). That is, because the withdrawal period estimate is based on the assumption that the variance of the upper 1% of a population is known, the withdrawal period parameter is sensitive to assumptions associated with the variance model.[20] As discussed by Concordet and Toutain[18] and Riviere,[20] and as documented by Sanquer et al.[19] and Chiesa et al.,[21] assumptions of equal variances are difficult, and sometimes impossible to meet. Nonparametric approaches to withdrawal period calculations proffered by Sanquer et al.[19] and Concordet and Toutain[19] were not attempted on this data set.

Poor confidence in the variance estimates governing the withdrawal parameter notwithstanding, Figure 2 shows that an estimated 47-day withdrawal period would be required for kidney residues to deplete to 50 ng/g in 99% of the animals (with 95% certainty) in a population of heavy sows treated with a 5× dose of penicillin G procaine for 3 consecutive days. For residues to fall below the FSIS action level of 25 ng/g[22] in a population of treated sows, an estimated 51-day withdrawal period would be required. Again, these estimates are not statistically valid because the data from which they were calculated were not normally distributed and did not have an equal variance. Nevertheless, the empirical evidence itself suggests that had a statistically sound data set been generated, an actual withdrawal period based on kidney residues would be prohibitively long with regards to commercial sow production systems in the United States.

In contrast to kidney tissues, penicillin G residues depleted quickly from skeletal muscle (Table 2, Figure 3). Residues in

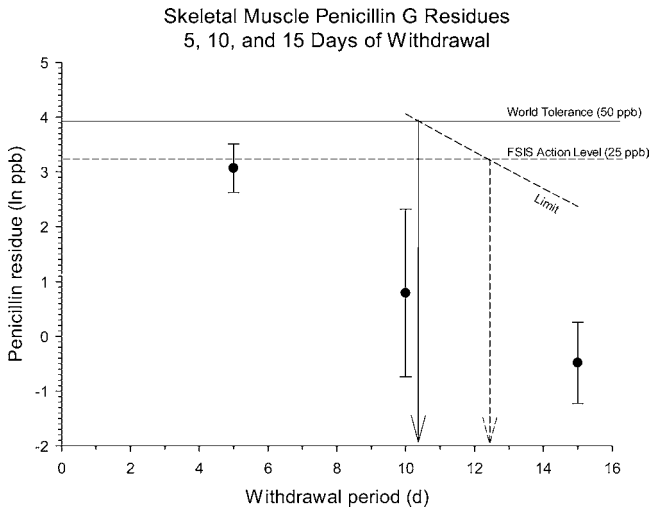

Figure 3. Estimation of preslaughter withdrawal period in heavy sows treated with a 5× dose of penicillin G procaine, based on depletion of penicillin G residues from skeletal muscle. Data taken from the linear portion of the depletion curve were analyzed as described by FDA Guidance Document no. 3 (US FDA CVM, 2006). In contrast to US FDA guidance, withdrawal data below the method LOD were assigned values of 1/2 the LOD (CMVP, 1995). Skeletal muscle penicillin G concentrations that were between the LOQ and LOD were included in the analysis as their nominal concentrations. The residue tolerance used by most of the world (50 ng/g or ln 3.91 ng/g) crossed the 99th percentile with a 95th percent confidence interval tolerance limit at approximately 10.4 days (solid vertical arrow). The skeletal muscle withdrawal period for a tolerance of 50 ng/g was estimated to be 11 days after rounding up to the nearest whole-day. In the United States, the tolerance level is zero for penicillin G in swine tissues, but FSIS has established an action limit of 25 ng/g for penicillin residues detected in swine tissues (FSIS, 2013). For penicillin residues to deplete below the action limit of 25 ng/g in a population of swine, an estimated 13 days would be required.

skeletal muscle at 5 days of withdrawal averaged only 23.5 ± 10.5 ng/g and depleted rapidly thereafter. By the 15th day of withdrawal, only 1 sow of 18 dosed had skeletal muscle residues greater than the method LOQ (2.4 ng/g), with 4 other sows having residues greater than the method LOD (0.7 ng/g), but less than the method LOQ. Thus, the estimated withdrawal periods for skeletal muscle were 11 days (Figure 3) for the worldwide tolerance of 50 ng/g, and 13 days for the FSIS action level of 25 ng/g. Regardless of dosing pattern, the Food Animal Residue Avoidance Database-estimated withdrawal time of 15 days proposed by Payne et al.[23] in 2006 (and at the time this study was conducted) was sufficient for penicillin residues to deplete from skeletal muscle. Again, it should be noted that an 11-day withdrawal period does not represent a regulatory withdrawal period because the normality assumption inherent in regression analyses was not met.

Table 2 contains residue depletion data from day three (last exposure) injection sites collected at slaughter. Across all treatments, residues in injection sites collected 5 days after the

dx.doi.org/10.1021/jf501492v | J. Agric. Food Chem. 2014, 62, 7577−7585

last administration of penicillin G were very high, averaging over 2.6 million ng/g of tissue; however, the data also indicate that injection site residues were highly variable. At withdrawal day 15 and later, the relative variation in residue concentration was approximately 400% of the mean. Such variation at injection sites has been described previously[19] and is typical of injection site residue data. Because of this variability, no long-term-effect of injection pattern was discerned from the data. Kosrud et al.[9] suggest that the proportion of an intramuscular dose that is delivered intramuscularly will influence the kinetics of penicillin depletion. In practice, however, ensuring uniform, intramuscular delivery of injectable penicillin G is difficult in heavy sows, especially when injected into the neck.

From a broad perspective, the actual method that a producer uses to deliver extra-label doses of penicillin G to a sow is unknown by regulators. Therefore, pooling injection site data, or residue data from other tissues, across treatments may provide the best indication of how penicillin residues deplete in the larger swine population, which, no doubt, is subject to a variety of injection techniques. The pooled data ("overall average" column of Table 2) clearly indicate that injection site residues are greater than skeletal muscle residue. Supporting Information tables showing residues from individual animals, however, indicate that high average residues usually occurred through the contributions of only a few animals per withdrawal period.

For penicillin, the target tissue for regulatory monitoring is kidney.[24] While kidneys are not commonly consumed in the U.S., it is possible that muscle from injection sites could be consumed.[25] Injection sites are not typically defined as a target tissue because they are difficult to locate on an animal carcass, injection sites containing drug residues are applicable to only a small number of market animals, and injection sites are not a reliable tissue for monitoring drug exposure in a population of animals.[26] In addition, residues from injection sites deplete at inconsistent rates and are highly variable, which makes calculating withdrawal periods based on injection site residues difficult.[19] Finally, the probability of a consumer actually being exposed to an injection site in a food product is extremely low. Because tolerances are based on acceptable daily intakes of a given residue over assumed lifetime exposures,[25,27] and because tolerances are established with several inherent safety factors, the probability of an adverse toxic effect occurring, even in the event of exposure to residue at an injection site, is extremely low.

Actual probability of risk notwithstanding, food animal producers would generally distance themselves from marketing products containing residues that may be perceived as risky. For penicillin, overt toxicity to the general population is not a concern because penicillin is of low toxicity;[28] in individuals with allergic hypersensitivity to penicillin, however, residue might initiate an allergic reaction. For example, use of penicillin in dairy cows and delivery of penicillin residues in milk to sensitive individuals was a problem in the decade after the introduction of penicillin to veterinary use.[29−31] The degree of allergic reaction to penicillin, ranging from mild to severe, depends upon the sensitivity of presensitized individuals, the route of penicillin exposure, and the dose of penicillin residue received.[30,32] Estimates of the doses of penicillin required to initiate allergic response range from 3 to 6 μg[28,32] with doses required to sensitize individuals being much greater. While the probability of delivering sufficient penicillin to sensitized individuals is very low, examples of allergic reactions in intentionally[33] and unintentionally[34] penicillin-exposed (via meat) individuals have been documented. For unintentional exposures, documented reactions are exceedingly rare.[28,35]

For swine producers, the presence of penicillin residues in food products could be mitigated by several practices. First, producers using extra-label penicillin could observe the estimated withdrawal periods of 50 days or greater in all treated sows, which would allow residues in edible tissues to deplete. However, observation of a 7-week withdrawal period would not be economical in sows destined for market.

A second option would be to discontinue penicillin use altogether. Such action, however, is not likely justifiable based on combined animal welfare and human food safety considerations. As pointed out by the European Food Safety Authority,[36] β-lactam antibiotics (including penicillin) "are among the most important group of antimicrobial agents in veterinary medicine", and they have been used in animal agriculture for decades. For example, the first U.S. approval for penicillin occurred in 1951,[37] and currently approximately 99.5% of all penicillin use in swine is administered for disease prophylaxis and treatment.[38] It is telling that with regards to food safety, the main criticism of penicillin use resides not with toxicity concerns or even allergic responses to residues, but to the hypothesis that β-lactam use in food animals could contribute to the transmission of antimicrobial resistance.[37,38] Thus, the elimination of penicillin use in food animals is not likely justified on the basis of food safety.

A third option would be to market penicillin-treated animals with a withdrawal period sufficient for muscle residues to deplete, and to discard the kidneys with inedible offal for rendering. While kidney is the target tissue for penicillin in swine carcasses,[24] residues in kidney do not represent a risk if they are not available for human consumption. In the United States, only a small percentage of the value of a market sow is associated with kidney; therefore, discard of kidney for rendering would not likely represent a hardship for processing plants that handle heavy sows. Admittedly, such discard might not be economically viable in markets in which sow kidney has a greater relative value.

As attractive as kidney discard would appear to be in the United States for solving penicillin residue issues, regulatory agencies will not likely allow such action because kidney is also the target tissue for a number of other drugs. For example, in the United States, the Food Safety and Inspection Service's screening and confirmatory method for a multitude of residues is based on kidney.[22] Even with the retention of renal tissue at slaughter, producers do have the option, suggested by Payne et al.,[23] of screening animals to ensure that they are penicillin-free prior to marketing. Table 3 shows that urinary penicillin residues are substantially more concentrated than kidney residues (Table 2) at any given slaughter time. Thus, the presence of penicillin in urine is an excellent predictor that the antibiotic has not completely depleted from tissues, whereas there is little evidence (Table 2) that serum would serve in such capacity. Using instrumental analysis such as LC−MS/MS to perform urinary penicillin residues analysis, however, would be difficult to provide timely feedbacks to producers to ensure that the animals are penicillin G free. Using urine and kidney samples from the current study, Shelver et al.[39] demonstrated that the kidney inhibition swab test (KIS test, Charm Sciences, Inc.; Lawrence, MA) rapid screening assay, employed by the FSIS to screen kidney tissues at slaughter facilities, when used with urine samples very accurately predicted Charm-KIS

positive kidney samples and was an excellent predictor of residues greater than the 25 ng/g action limit in use by the US FSIS.[22] Figure 4 demonstrates the within-animal relationship

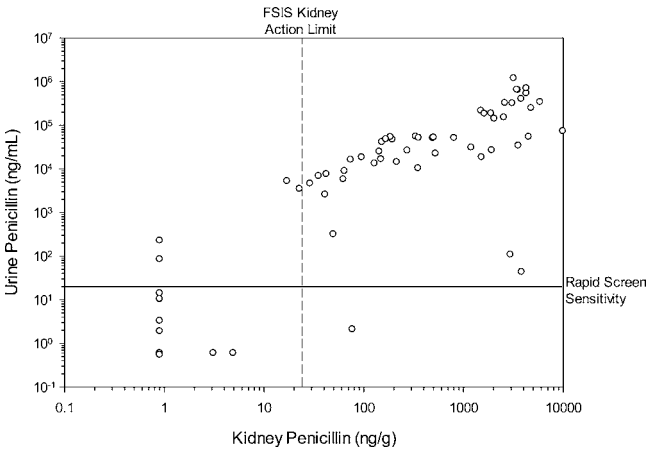

Figure 4. Within-animal relationship between urinary penicillin G residues (*Y*-axis) and renal penicillin G concentrations across all slaughter times. The horizontal solid line represents the limits of detection of the Charm-KIS rapid screening assay in urine,[39] and the vertical hatched line shows the FSIS "minimal level of applicability" for penicillin G residues in swine kidney (FSIS-2013). Points below the solid line would not be detected by a urinary rapid screening assay; points to the left of the vertical hatched line would not be flagged by the FSIS. Use of the urinary assay would be conservative due to the fact that the screen would have flagged four animals as "positive" when the kidney results would have been flagged as negative. A single sample would have passed the urine screen while kidney residues remained above the FSIS action level.

between renal and urinary penicillin concentrations. With one exception, urinary penicillin concentrations were excellent predictors of potentially violative kidney residues (n = 121). Such data suggest that the kidney inhibition swab test, when used with a urine matrix, is a viable option for a timely (<5 h run time) on-farm screen for the presence of penicillin residues.

Data presented in this study clearly demonstrate that penicillin residues deplete at disparate rates in edible tissues in swine treated with extra-label doses. From a human food safety perspective, the earlier FARAD 15-day withdrawal period that is commonly observed for extra-label penicillin doses[23] is sufficient for residue depletion from skeletal muscle. It would take approximately 50 days for residue to deplete to nondetectable levels in kidneys from a population of sows treated with an extra-label penicillin dose, concurring with the current FARAD recommendation (which is based on these data). This study demonstrates the disparity between residue depletion in tissues sometimes selected for regulation of drug residues (kidney) and tissues for which the majority of the value of a carcass resides (skeletal muscle). This disparity could leave valuable animal-health drugs vulnerable to discontinuation, not due to human food safety concerns, but due to regulatory inflexibility.

the limits of quantitation (LOQ) (50 μg/kg). This contrasts with animals slaughtered after 6 days of withdrawal where five of five animals had quantifiable (>50 μg/kg) penicillin G residues in kidney. Skeletal muscle residues were generally lower than kidney, with residues ranging from 0 to 34 μg/kg (LOQ 10 μg/kg for muscle). Considerable penicillin G remained at the injection site even after 8 days (2970−190 000 μg/kg). The maximum withdrawal day used by Apley et al.[7] was 8 days, a time period insufficient to allow residues in all animals to deplete to nondetectable levels. As a consequence, they recommended use of a 28 day withdrawal period based on a 95% confidence interval that 99% of treated animals would have residue levels below detection limits in kidney.

The USDA-Food Safety and Inspection Service (FSIS) changed the on-site screening method they use for antimicrobial drug residues by switching from the Fast Antimicrobial Screen Test (FAST) to the Kidney Inhibition Swab (KIS) test with a phase III effective date of September 11, 2011 for swine carcasses in slaughter establishments in which KIS tests were used for cattle.[10] On August 19, 2012, all livestock species slaughter establishments were switched to KIS test for carrying out on-site carcass antimicrobial residues screening.[11] This article describes the detection of penicillin G procaine residues with the KIS test from kidney, liver, plasma, urine, skeletal muscle, and injection site of heavy sows after an extra-label penicillin G procaine administration. Sows were treated IM with 33 000 IU/kg for 3 consecutive days and were slaughtered with withdrawal periods extending to 39 days post-treatment. Although the dosage used in this study is 5× the FDA-CVM approved penicillin G procaine dose, it is in the middle of levels (2×−10×) typically administered to swine under the auspices of AMDUCA.[12] Three patterns of drug administration were studied; each was designed to mimic patterns of administration thought to be used in the industry.

MATERIALS AND METHODS

Chemicals and Supplies. Penicillin G procaine (300 000 IU/mL; Norocillin; Norbrook Pharmaceuticals, Lenexa, KS) injection solution was purchased from Ivesco, LLC (Iowa Falls, IA). Penicillin G procaine monohydrate reference standard was purchased from U.S. Pharmacopeia, Rockville, MD. Kidney inhibition swabs, positive and negative controls, and heating blocks were obtained from Charm Laboratories (Lawrence, MA). Driploss containers were purchased from the Danish Meat Research Institute, Taastrup, Denmark.

Animal Housing and Treatment Assignment. A study protocol was approved by the North Dakota State University Institutional Animal Care and Use Committee prior to the initiation of the live-phase of the study. Heavy sows (80 animals per trial for a total of two trials) were purchased from the North Dakota Pig Cooperative (Larimore, ND) and delivered to the North Dakota State University Animal Research Center (Fargo, ND). Sows were group fed an unmedicated corn−soybean ration at 2 kg per animal per day and had ad libitum access to clean water. During the 14-day acclimation period, animals were each provided unique identification numbers by ear tag and were randomly assigned to one of three treatments to deliver 33 000 IU/kg bw; treatment details are described in the accompanying paper.[13]

Treatment 1. A maximum injection volume of 10 mL using multiple injection sites within day to deliver the total required drug volume; across day, injections were administered into a single muscle location.

Treatment 2. A maximum injection volume of 10 mL using multiple injection sites within day to deliver the total required drug volume; across day, injection sites were separated by approximately 5 cm.

Treatment 3. A maximum injection volume of 20 mL using multiple injection sites within day to deliver the total required drug volume; across day, injections were separated by approximately 5 cm.

Controls. Positive control hogs (n = 2 per withdrawal period) were treated with the label dose (6600 IU/kg bw) of penicillin G procaine via IM administration for 3 consecutive days and were euthanized after a 7-day withdrawal period, consistent with the product label; or a 15-day withdrawal period, representing extended withdrawal period. Untreated control sows (n = 2) were dosed IM with sterile saline (1 mL per 45.5 kg) for 3 consecutive days and were slaughtered 5 days after the last saline injection.

Injection Site Identification and Treatment. Approximately 7 days prior to the initiation of penicillin treatment, sows were tattooed according to their treatment assignment. A device was machined at the North Dakota State University machine shop, which allowed multiple patterns of 2 cm "O"s to be tattooed onto necks of sows according to treatment. Such tattooing allowed a consistent adherence to treatment protocols and treatment designations.

Sows were weighed and penicillin G procaine was administered via intramuscular injection through 3.8 cm, 16-gauge needles according to treatment assignments. Sows were dosed in a modified metal crate that allowed for elevation to facilitate dose administration. Dosing was uneventful.

Slaughter and Sampling. Sows were slaughtered at the NDSU abattoir with 5, 10, 15, 20, 25, 32, and 39 day withdrawal periods relative to the last dosing day. Control sows treated with the label dose were slaughtered at 7 and 15 days of withdrawal. Sows were sequentially stunned by electrocution and captive bolt, and then quickly exsanguinated. Viscera were removed, and kidney, skeletal muscle (mid portion of the *longissimus dorsi*), injection site, and liver sample aliquots were collected and stored at −80 °C until analysis. In addition, urine and blood samples were collected. Blood was allowed to clot at 37 °C in a heating block for approximately 1 h, and serum was collected after centrifuging at 1200*g* for 15 min. Serum and urine aliquots were stored at −80 °C until analysis.

On-Site Analysis of Kidneys. Kidney samples were screened for penicillin residues on the kill floor using the KIS microbial inhibition test according to FSIS procedures;[14] the manufacturer's recommended incubation time, without the automatic shut-off option, was followed. The other option in the FSIS procedure, which allows a 15 min shorter incubation time with automatic shut-off, was not used in this study. Briefly, cotton swabs were saturated with kidney juice after perforating kidneys with the KIS test wand. Swabs were placed into test media and incubated at 64 ± 2 °C for the prescribed time (batch dependent, 2 h 45 min to 3 h 20 min for kidney). The presence of penicillin G was indicated by the development of a purple/blue color; samples testing negative for penicillin G were indicated by a yellow/green color. Samples containing penicillin G residues below the sensitivity threshold (see below) could produce ambiguous results, and such samples were defined as "cautions" as described by the FSIS[14] (Figure 1). In instances in which "caution" results were returned at the prescribed incubation time, tubes were reread several hours later but within the allowed 16 h KIS test "grace" period.[14,15]

Analysis of Injection Site, Muscle, and Kidney Samples. At collection, injection site, skeletal muscle, and additional kidney samples were collected using a 3 cm diameter tissue coring device driven by a cordless drill and trimmed to approximately 3 × 3 cm (d × l). Samples were placed into Driploss (Danish Meat Research Institute, Taastrup, Denmark) containers and were frozen at −80 °C until analysis. Samples were thawed at room temperature for 1 h, and the tissue juices were collected from the drip tubes after centrifuging at 1200*g* for 10 min. The collected tissue juices were used to saturate KIS test swabs. Microbial inhibition tests for tissues were then conducted as described by the FSIS[14] for determination of the presence of penicillin G.

Analysis of Liver Samples. Liver samples were cored, placed into Driploss tubes, frozen, thawed, and juice collected as described for kidney and muscle samples. However, liver liquid isolation required the addition of an equal volume of water followed by boiling (1 min) and centrifugation at 14 000*g* for 10 min. After centrifugation, the KIS

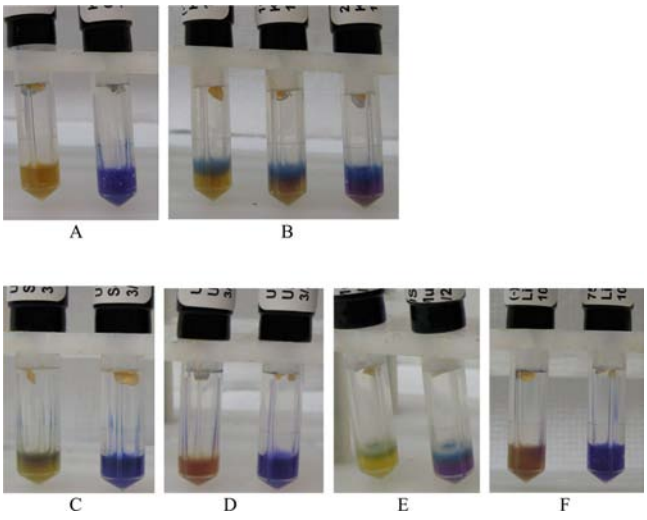

Figure 1. Typical negative control (left) and positive control (right) results returned from the KIS test rapid screening assay. (A) KIS negative control and KIS positive control; (B) negative (left), caution (middle), and positive (right) from kidney swabs; notice there is a blue cover on top of the negative kidney swab; the blue cover was not observed in the negative control provided by Charm; (C) serum negative control and serum positive control; (D) urine negative control and urine positive control; (E) muscle negative control and muscle positive control; (F) liver negative control and liver positive control.

test cotton applicator was immersed in the liver juice supernatant for 10 s prior to performing the KIS microbial inhibition assay as described previously. The effect of boiling on penicillin G residues in liver liquid is described below.

Analysis of Serum and Urine Samples. Urine or serum aliquots (500 μL) were combined with a single KIS test neutralization tablet and mixed using a vortex mixer; particulates were allowed to settle for 1 min. Serum/urine supernatant was adsorbed for 10 s with a cotton swab, after which the KIS microbial inhibition assay was performed.

Assay Sensitivity Determination. Control serum, urine, skeletal muscle juice, and kidney juice were prepared as previously described. Tissue matrix aliquots were fortified with 0, 10, 20, 30, 40, and 50 ppb of penicillin G, while liver liquid samples were fortified at 0, 10, 25, 50, 75, and 100 ppb of penicillin G due to low sensitivity. Fortified liver liquid samples were also analyzed with, and without, boiling for 1 min before analysis. Swab tests were conducted for each given matrix described above. Fortification of each matrix was repeated on three separate days. Typical color indication for positive, negative, and "caution" KIS test results is shown in Figure 1.

Statistical Analysis. The matrix differences were compared employing McNemar's square test using negative results as 0 and positive results as 1 and processed using SigmaPlot 11.2 (Systat Software, Inc., San Jose, CA). Missing collection points obtained from urine samples were recorded as blanks in the data file. Significant differences between the two treatments were defined as $p \leq 0.05$.

RESULTS AND DISCUSSION

Assay Sensitivity. The penicillin concentrations that produced positives in a minimum of three replicates in kidney juice, muscle juice, urine, serum, and liver juice were 20, 30, 20, 30, and 100 ppb, respectively, accounting for liver juice dilution, based on a single lot. The assay sensitivity for kidney appeared to be slightly higher than reported by the manufacturer (30−35 ppb for cattle and swine kidney, dependent on source of reports),[14,15] with similar sensitivity of serum and urine as reported by the manufacturer (20−30 ppb).[16] However, our results are slightly less sensitive than the assay sensitivity reported by Schneider et al.[17] of 10 ppb for beef kidney juice and 15 ppb for serum. Nevertheless, both species had the same trend; that is, the KIS test is more sensitive for kidney juice than for serum. In this study, kidney juice used for the assay sensitivity determination was prepared from frozen kidney rather than from unfrozen kidney used by the manufacturer. The results generated by our laboratory indicate kidney and urine are the matrices allowing for the most sensitive KIS test analyses followed by assay sensitivities returned by muscle juice and serum; the liver returned relatively insensitive KIS test results, with much lower assay sensitivity than the other tissues because a dilution step is needed. Our results indicated a short boiling period of 1 min did not reduce the penicillin G threshold of the KIS test when assayed using the liver liquid with or without reboiling after penicillin G was spiked into control liver liquid. This observation confirms the results of Moats et al.[18] who reported that penicillin G only lost 10% of its potency when heated at 100 °C for 10 min for both milk and water and required at least 30 min at 121 °C to completely inactivate penicillin G in meat homogenate.

Effects of Incubation Period. Samples containing penicillin residues near the assay sensitivity threshold could produce ambiguous results, defined as "cautions" by the FSIS.[14] In instances in which "caution" results were returned at the prescribed incubation time, which ranged from 2 h 45 min to 3 h 20 min for kidney, based on the manufacturer's lot-specific recommendation, the same tubes were also read several hours into the 16 h "grace" period at room temperature allowed in the FSIS method.[14] On some occasions the "caution" results darkened during the extended time period (Figure 2). Thus, even though a 15 min automatic shut off option was applied, additional "positive" results could occur if the samples were left at room temperature without immediate scoring.

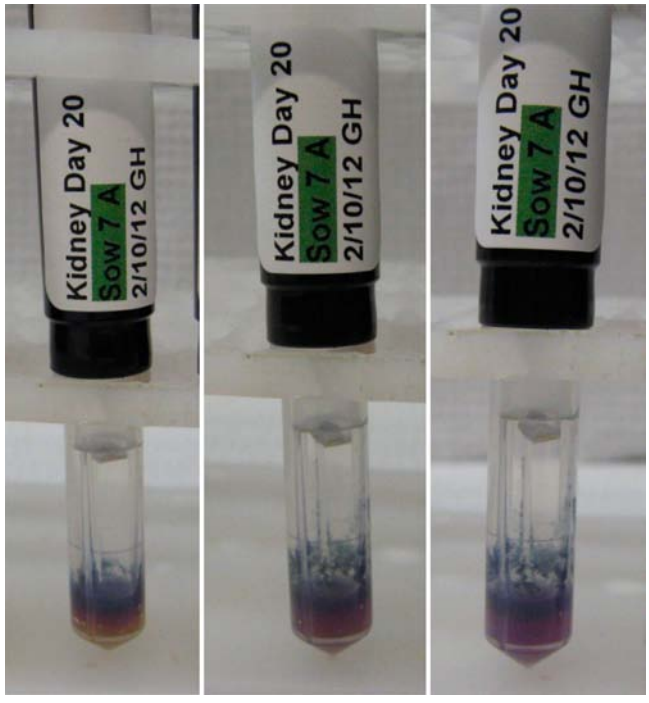

Figure 2. Example of a kidney sample that darkened sequentially with time as it proceeded from the prescribed incubation time at 64 °C (left), to 1 h post incubation at room temperature (middle), and after 2 h post incubation at room temperature (right).

[a]Treatments: (1) maximum of 10 mL of penicillin G procaine per injection; injections on consecutive days were in the same location as the previous day; (2) maximum of 10 mL of penicillin G procaine per injection site; injections on consecutive days were separated by approximately 5 cm; (3) maximum injection volumes of 20 mL of penicillin G procaine; injections on consecutive days were separated by approximately 5 cm. [b]KIS tests of kidney swabs were performed on the kill floor; results were obtained 3−4 h after animal harvest. [c]"c" Duplicate, simultaneously run KIS tests each returned "caution" results. FSIS regards cautions as a negative result. [d]A tilde (∼) represents ambiguous results in which duplicate KIS assays of the tissue scored either ±, ∓, −/c, c/−, +/c, or c/+ or in which independent analyst interpretations of the KIS assay were in disagreement. Ambiguous results were never clearly positive, so they were regarded as a negative result. [e]Aliquots of injection site; kidney and skeletal muscle were placed in Driploss tubes and stored at −80 °C until use. KIS tests were performed on kidney and muscle juice. [f]False positive. Presence of penicillin in positive KIS test results could not be verified with mass spectral analysis.

Kidney On-Site and Frozen Kidney Comparison. There was excellent agreement between KIS test positive on-site kidney and frozen kidney samples (Table 1). This consistency suggests the assay of frozen kidney tissue could be valuable for research purposes or for screening where testing fresh tissue is not possible. The assay of frozen tissues could also be used to verify results obtained on fresh tissues.

Effect of Withdrawal Time on the Detection of Penicillin G Procaine by the Rapid Screening Assay. Table 1 summarizes the effects of treatment and withdrawal period on KIS test positive results from regulated tissues (kidney and skeletal muscle) as a function of withdrawal time. Penicillin G residues were detected by the KIS test in kidney swab samples for the duration of the study, but with decreasing frequency as the withdrawal time increased. In the earlier withdrawal days (up to day 15), treatment 3 (high volume injection) gave the most positives followed by treatment 1 (same site injection) and treatment 2. However, when all withdrawal days were considered, there appeared to be no clear effects of treatment (penicillin G administration pattern) on the depletion of penicillin G from the kidney, as assessed by KIS test detection (Figure 3). When KIS test detection frequency (% positive) data were plotted against time for each treatment and fit with a monoexponential decay curve, no difference ($P > 0.05$) in the decay rate constants among the three treatments was observed; data among treatments were therefore pooled, and all of the frequency of detection data were fit to a monoexponential decay curve. Figure 3 demonstrates that penicillin G residues had not depleted from kidneys of all animals even after 39 days of withdrawal as also shown in Table 1.

Confirmation of the KIS test results by LC−MS/MS analysis indicated that the KIS test returned no false positive results for kidney despite the wide range of concentrations obtained from LC−MS/MS analysis (with samples above mLOQ from 17−9900 ng/g tested as positive by KIS test). Kidney LC−MS/MS concentrations <4.92 ng/g were returned as either "caution" or negative by the KIS test. Details of LC−MS/MS analysis for

dx.doi.org/10.1021/jf501494w | J. Agric. Food Chem. 2014, 62, 7586−7592

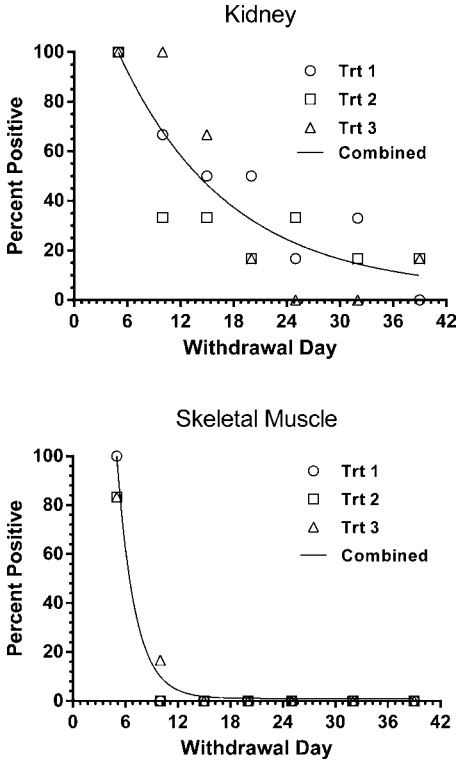

Figure 3. Depletion of penicillin G residues in kidneys (upper panel) and muscle (lower panel) of heavy sows as detected by the KIS rapid screening assay. Line is a first-order depletion fit of combined data from treatments; false positive results were removed from the skeletal muscle data prior to plotting.

penicillin G in sows are available in the accompanying paper.[13] The KIS test analysis of kidney indicated that approximately 50% of the animals administered a 5× labeled dose would show positive penicillin residues when slaughtered at day 15. The Food Animal Residue Avoidance Database (FARAD) had recommended a preslaughter withdrawal period of 15 days for swine administered a 10× penicillin G procaine dose,[12] but this has since been revised to a 50 day withdrawal interval for swine dosed with 2×−10× penicillin G procaine.[19] On the basis of the kidney results, a 15-d withdrawal period is insufficient. Even after a 39 day withdrawal period, approximately 11% of the animals tested positive for penicillin G, indicating that a prolonged period (50 days) would be required for animals to have kidneys free of penicillin residue.

Muscle. It was difficult to obtain muscle juice on-site from fresh pork, which is in apparent contrast to the cattle study reported by Schneider et al.[20] A simple freeze and thaw cycle, however, allowed sufficient quantities of muscle juice to be collected. There were no distinguishable effects of treatment on skeletal muscle detection frequency, so further analysis was conducted with results from the three treatments pooled (Table 1, Figure 3). For skeletal muscle, 16 of 18 hogs returned positive KIS test results after a 5 day withdrawal period, but by 10 days, only 1 of 18 hogs tested returned a positive KIS test result. Despite the difficulty in using the KIS test for muscle determination of penicillin G, the results clearly indicate more rapid elimination of penicillin G from muscle than kidney. The data also demonstrate the variability between animals, which has been previously observed with IM injection of penicillin G.[21] From market hog penicillin results reported by Korsrud et al.,[6] penicillin concentrations in kidney were approximately 40−70 times greater than residues in corresponding muscle samples. In agreement with their findings, the KIS test assay returned smaller numbers of muscle positives than in kidneys for the same animal and time point.

Scoring of samples derived from muscle juice was more difficult than for kidney juice. For example, of the 132 samples tested (5× treated animals plus controls), eight needed to be repeated due to ambiguous results for a 6% repeat rate. In one incidence with a "caution" result in a muscle sample on withdrawal day 5, treatment 3 had a corresponding LC−MS/MS concentration of 33 ng/g,[13] which is above the FSIS minimum applicability level (25 ng/g)[22] and would be considered a false negative. Two instances occurred in which the KIS test returned positive assay results in muscle (treatment 2, days 20 and 39; Table 1), but the corresponding LC−MS/MS results were nondetects,[13] confirming that these two KIS test results are false positives. In general terms, skeletal muscle was a more difficult matrix for use with the KIS test with regards to sample treatment and when comparing assay results with the LC−MS/MS data.

KIS Test Results from Serum, Urine, and Liver Juice. Applicability of using the KIS test for preslaughter screening of treated animals was tested with assays of serum and urine (Table 2). When compared to LC−MS/MS results, serum and urine samples did not return false positives. The urine was a much better surrogate matrix for detecting potential violative penicillin G residues in kidney (Figure 4) than serum; statistical evaluation using the McNemar's test showed no difference between kidney and urine (P = 0.48). Serum results clearly demonstrate that serum is an inadequate surrogate for kidney because serum is more rapidly cleared of penicillin G than kidney, and McNemar's test showed a significant difference between kidney and serum ($P \leq 0.001$).

The KIS test assays of liver returned fewer positive results than the assays of other tissues, even at day 5 (Table 2). These results could be caused by the much poorer assay sensitivity of liver as compared to other matrices. However, these results could also have been obtained from a lower retention of penicillin G in liver, relative to other tissues, as reported by some researchers.[6] The penicillin G in liver was not performed using LC−MS/MS analysis for this study because liver was not a tissue of interest for regulatory agencies or industry and was not suitable for ante-mortem purposes.

Serum showed more positive samples than muscle on day 10, but from day 20 on these matrices showed only one positive reflecting little retention in this matrices. Surprisingly, serum levels do not correlate to muscle levels, and McNemar's test showed significant difference between muscle and serum ($P \leq 0.001$).

Injection Sites. The injection site KIS tests returned a pattern similar to that of kidney with relatively few exceptions. For example, the two positive kidney samples at day 39 also had corresponding positive responses in their injection site samples reflecting prolonged exposure (Table 1). An additional sow had a positive KIS test result from the injection site without a corresponding positive KIS test result from the kidney at withdrawal day 39. All three KIS test injection site positives from withdrawal day 39 had penicillin G residues as determined by LC−MS/MS analysis (3.7, 9.6, and 1254 ng/g).[13] However, there were 5 false positives and 13 false negatives among the 126 injection site samples when compared to the LC−MS/MS data, indicating difficulty in analysis of injection sites. The wide range of penicillin G levels found in injection sites could be one

[a]Treatments: (1) maximum of 10 mL of penicillin G procaine per injection; injections on consecutive days were in the same location as the previous day; (2) maximum of 10 mL of penicillin G procaine per injection site; injections on consecutive days were separated by approximately 5 cm; (3) maximum injection volumes of 20 mL of penicillin G procaine; injections on consecutive days were separated by approximately 5 cm. [b]Serum and urine aliquots were combined with KIS serum/urine neutralizing tablets, mixed, and supernatant was used for KIS tests. [c]A tilde (∼) represents ambiguous results in which duplicate KIS assays of the tissue scored either ±, ∓, −/c, c/−, +/c, or c/+ or in which independent analyst interpretations of the KIS assay were in disagreement. Ambiguous results were never clearly positive, so they were regarded as a negative result. [d]"c" Duplicate, simultaneously run KIS tests each returned "caution" results. FSIS regards cautions as a negative result. [e]x, Urine sample unobtainable. [f]Aliquots of liver were placed in Dripless tubes and were frozen at sampling; KIS tests were performed on liver juice after thawing and 1 min boil.

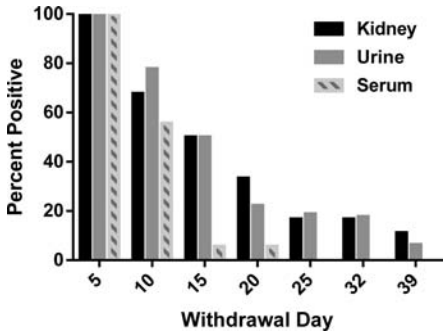

Figure 4. Comparison of KIS test results in urine, serum, and kidneys of treated sows as a function of withdrawal day.

of the contributing factors resulting in these inconsistencies. For example, for treatment 1 withdrawal day 10, the penicillin G concentrations returned by LC−MS/MS ranged from 3.2 to 1 580 000 ng/g among the six sows. Another difficulty was the performance of the KIS test analysis in muscle tissue and particularly interferences caused by fat. Problems in uniform injections (intermuscular vs intramuscular) have been previously noted[6] and could cause increased variability of penicillin G concentration at the injection site. Finally, difficulties in obtaining appropriate samples at the injection site could produce diversity due to the heterogeneity expected at this site.

Positive and Negative Control Sows. Negative control sows that received normal saline and that were slaughtered on withdrawal day 5 had negative KIS readings for all matrices tested for both trials 1 and 2. The positive control sows, which received the label dose and were slaughtered at withdrawal day 7, showed positive KIS test results for both trials (data not shown) from on-site kidney samples and the kidney samples that were frozen and thawed once. Results from LC−MS/MS gave 461 and 202 ng/g of penicillin G in the kidney of the positive control animals. Urine, injection sites, and serum also tested positive, with the exception of a "caution" result in serum for trial 2 withdrawal day 7. Muscle and liver samples tested negative for withdrawal day 7 positive control animals. For withdrawal day 15, one out of two positive control animals tested positive using the KIS test in kidney, injection site, and urine samples, but the rest of the matrices returned negative results. The LC−MS/MS results had penicillin G concentrations of 190 ng/g, 2090 ng/g, and 17 760 ng/mL for kidney, injection site, and urine, respectively, from the positive control sow on withdrawal day 15 that tested positive by KIS test. Thus, use of the KIS test as a screen could return a positive kidney result even though the main tissue of human consumption, muscle (meat), would probably be negative when the prescribed dose and withdrawal period are observed. These results would produce an unnecessary condemnation due to slow elimination of penicillin G in the kidney.

dx.doi.org/10.1021/jf501494w | J. Agric. Food Chem. 2014, 62, 7586−7592

Collectively, these data suggest along with other studies that the earlier recommended 15 day withdrawal period for swine dosed with up to 10× the labeled penicillin G procaine dose[12] is insufficient for residues to deplete to levels nondetectable by the KIS test assay in kidney. Specifically, approximately 50% of the heavy sows treated with a 5× dose of penicillin G procaine on each of three consecutive days had kidneys that would test positive with the regulatory on-site screening assay. Indeed, the KIS test detection system indicated the probability that greater than 39 days of withdrawal would be required for residues to deplete sufficiently to ensure that treated animals be free of renal penicillin G prior to slaughter, supporting the current FARAD recommendation.[19] In contrast, the KIS test data seemed to indicate that penicillin G depleted very rapidly from muscle, relative to kidney, and that the 2006 FARAD recommended 15-day withdrawal period[12] for muscle would be adequate to ensure the safety of skeletal muscle. Skeletal muscle was a more difficult matrix to analyze than kidney when using the KIS test, but using our modified procedure the results indicate rapid clearance from muscle. Muscle required a freeze and thaw step to produce sufficient liquid for the KIS test; hence muscle is not particularly useful for on-site monitoring to determine whether an animal had been exposed to penicillin G. The data indicate that urine would be a very useful antemortem matrix for on-farm or preslaughter testing with which veterinarians or pork producers could predict the presence of kidney penicillin G residues.

MATERIALS AND METHODS

Collection of Fish Samples. *Marine Fish Sampling.* The list of marine fishes to be collected was based on the individual dietary consumption analysis of the 996 adult high-seafood consumers of the CALIPSO study,[38] recruited in four coastal areas in metropolitan France between October and December 2004. The fish consumption habits of the population of these four areas and their surrounding 20−25 km, namely, La Rochelle in Gironde-Charente Maritime Sud, Le Havre in Normandy-Baie de Seine, Lorient in South Brittany, and Toulon in Mediterranean-Var, match the highest fish consumption habits in metropolitan France.[38] Five primary samples were bought in each region for each species between January and April 2005 to take into account the purchase habits of the considered population (fresh or frozen products; purchase locations of fishmarket, supermarket, etc.). For example, if a fish species is purchased 80% of the time in a supermarket and 20% of the time in a fishmarket, then four of the five primary samples were purchased in a supermarket and one primary sample was purchased in a fishmarket. The sex and fish body weight and length were not available and consequently not taken into account in the sampling and analyses. However, it should be remembered that the purpose of the present study was to perform an exposure assessment study at populational scale and not to study the determinant factors associated with the observed levels of chemicals. The used sampling process respected the purchase habits of the study population, and it has been considered as fairly representative of what is bought and consumed by the CALIPSO population. Each sample finally considered for analysis was a composite one of 1000 g, made up of five 200 g portions of the primary sample raw edible parts (fillets without skin or entrails). Twenty-three composite samples were then constituted in La Rochelle, 22 in Le Havre, 26 in Lorient, and 23 in Toulon. The sampling period ranged between January and April 2005, and a total of 94 fish composite samples were prepared, corresponding to 29 species, which reflect the regional consumption and contamination differences. This sampling procedure allowed covering 89−96% of the total consumption of fish according to the four areas. Recruiting strategy, consumption survey development, and marine fish sampling methodology have already been described.[38]

Freshwater Fish Sampling. The list of freshwater fishes to be collected was based on the individual dietary consumption analysis of the 606 anglers or their family members of the ICAR-PCB study, initially designed to assess French freshwater fish contamination in PCBs along with angler's PCB internal exposure (i.e., serum level). Seven hundred and forty-seven freshwater fishes were collected in 2008 and 2009 covering different seasons by ONEMA (French National Agency for Water and Aquatic Environments) in six major French rivers, each river being divided in three or four sections. The dietary consumption analysis and the freshwater fish sampling methodology have already been described elsewhere.[39,40] Briefly, each sample had to contain at least 400 g of fish muscle for analysis purposes. If one fish was not enough to reach this amount, then several fishes from the same species and the same location were pooled to form a composite sample, as was the case for half of the samples. The consequence is the loss of some raw data such as sex, body weight, and body length, but as the fishes were sampled randomly, it was considered that they were fairly representative of what could be caught and consumed by the anglers. Although this study was designed for PCBs, we assessed that PCB and PFAA contamination levels in freshwater fishes were not statistically associated. Indeed, due to their physicochemical properties, PCBs are lipophilic and accumulate in fat, whereas PFAAs are amphiphibic and tend to accumulate in liver and blood.[41,42] It is assumed that our samples offer a representative view of freshwater fish contamination in metropolitan France. The 16 most consumed fish species among the remaining samples after multiple analyses (for PCBs, dioxins, hexachlorobenzene, etc.) were selected, resulting in 387 samples being analyzed for PFAAs.

The samples for lipid and FA analysis were extracted from the same ONEMA freshwater fish sample library constituted between 2008 and 2010. The number of fish included per composite sample of the same freshwater fish species was determined based on availability of material in the library and was also linked to the weight of individual fish, more fishes being needed per composite for small fish. Among the 32 freshwater fish groups sampled, the 11 most consumed were selected with at least 10 individual fishes per sample, resulting in 28 composite samples.

Analysis of Lipid and Fatty Acid Composition and PFAA Contamination. *Analysis of PFAAs.* The used methodology targeted 15 PFAAs: perfluorobutanoic acid (PFBA), perfluoropentanoic acid (PFPA), perfluorohexanoic acid (PFHxA), perfluoroheptanoic acid (PFHpA), perfluorooctanoic acid (PFOA), perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA), perfluoroundecanoic acid (PFUnA), perfluorotridecanoic acid (PFTrDA), perfluorotetradecanoic acid (PFTeDA), perfluorobutane sulfonate (PFBS), perfluorohexanane sulfonate (PFHxS), perfluoroheptane sulfonate (PFHpS), perfluorooctane sulfonate (PFOS), and perfluorodecane sulfonate (PFDS). The analytical procedure used for PFAA determination was described elsewhere.[43] Briefly, samples were pretreated by freeze-drying and liquid/solid extraction with methanol. A dispersive solid phase extraction (SPE) based on charcoal particles was then applied. Final purified extracts were analyzed by liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) with negative electrospray ionization on a triple-quadrupole system. Two diagnostic signals (MRM transitions) were recorded for each targeted analyte. Quantification was performed according to the isotope dilution principles: each sample was supplemented by 11 ^{13}C-labeled internal standards ($^{13}C_4$-PFBA, $^{13}C_5$-PFHxA, $^{13}C_4$-PFHpA, $^{13}C_4$-PFOA, $^{13}C_5$-PFNA, $^{13}C_2$-PFDA, $^{13}C_7$-PFUnA, $^{13}C_2$-PFDoA, $^{18}O_2$-PFHxS, $^{13}C_4$-PFOS, and $^{13}C_4$-PFOSi). Limits of detection (LOD), depending on the considered fish species and target compound, were determined on the basis of the signal-to-noise ratio (S/N > 3) and ranged from 0.005 to 0.3 ng g^{-1} for PFOA and PFOS and from 0.007 to 0.95 ng g^{-1} for other PFAA substances. Repeatability of the signal was also dependent on the matrix but was globally estimated below 18.6% for all compounds.

The generated exposure data were produced under the Quality Assurance system (ISO.IEC 17025:2005 and ISO 9001:2008 standards) and using validated analytical methods, including interlaboratory comparison tests, that have proven the fitness-for-purpose of this method.

Blank and quality control samples were analyzed and monitored in parallel with the samples to be characterized: the signal of each compound in the blanks was checked to ensure the absence of contamination throughout the analytical procedure, and concentrations of analytes in quality control were monitored to check the method repeatability.

Analysis of Lipids and Fatty Acids. The total lipids and 48 free FAs were analyzed for the 40 marine fish composite samples. The protocol was detailed elsewhere.[44] Briefly, the total lipids were analyzed by two different laboratories with two different methods for the same samples. One of the laboratories freeze-dried the samples before powdering and transfer into accelerated solvent extraction with a 70:30 (v/v) mixture of toluene/acetone. Then the samples were evaporated and the total lipids were determined by gravimetry. The second laboratory followed the AFNOR NF V04-403 standard for meat, meat products, and fish products for the extraction, purification, and esterification of the free fat.[45] Then the extracts were dried, extracted with a mixture of hexane/isopropanol 3:2 (v/v) before filtration on a Na_2SO_4 and Celite column, and weighed. For the free FA analysis, the FAs were extracted with hexane, filtered, esterified with a mixture of methanol/sulfuric acid 13:2 (v/v), and analyzed using a gas phase chromatograph equipped with a flame ionization detector. Their identification was based on retention time obtained for standard esters. The part of each free FA was based on the area of the corresponding peaks, in relation with a standard solution.

The total lipids and 40 free FAs were analyzed for the 28 freshwater fish composite samples. For each sample, the free fat was extracted, purified, and esterified by reaction with boron trifluoride according to the NF EN ISO 5509 standards.[46] The esters were then analyzed using a gas phase chromatograph equipped with a flame ionization detector according to the NF EN ISO 5508 standards[47] and identified in the same way as for the marine fish samples.

Data and Statistical Analysis. All statistical analyses were performed using the SAS software 9.3 (SAS Institute Inc., Cary, NC, USA). Normality of the distributions was tested with the Kolmorogov−Smirnov test and homoscedasticity with the Bartlett test. The Kruskal−Wallis test was used to compare fish PFAA contamination between the

coastal sites or major river sections. Ward's method has been applied for the hierarchical cluster analysis to define three groups of freshwater fishes (low, medium, and high levels of PFAA contamination). A multiple regression analysis was conducted to assess the association between PFAA contamination and content of lipids, FAs, n-3 PUFAs, and n-6 PUFAs. Differences were considered as significant for an α risk below 5%.

The percentage of left-censored data (i.e., data below the limit of detection, LOD) for the PFAA contamination was above 60%, and the LOD was low enough for the WHO GEMS/Food-EURO workshop recommendations to be applied.[48] Two scenarios were defined. In the lower bound (LB) scenario, the values below the LOD were replaced by 0, and in the upper bound (UB) scenario, the values below the LOD were replaced by the value of the LOD.

RESULTS AND DISCUSSION

PFAA Contamination. The 15 PFAAs analyzed in both marine and freshwater fishes were considered to describe PFAA contamination. The results are expressed with the sum of the 15 following PFAAs: PFBA, PFPA, PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnA, PFTrDA, PFTeDA, PFBS, PFHxS, PFHpS, PFOS, and PFDS. The percentage of censored data ranged from 9.5% (for PFOS) to 100% (for PFBS and PFHpS) for marine fishes and from 0.26% (for PFOS) to 100% (for PFPA) for freshwater fishes with mean percentages of, respectively, 69.9 and 64.3%. Contamination under UB hypothesis is about 4% higher

than in LB hypothesis for freshwater fishes and about 17% for marine fishes. This difference between freshwater and marine fishes is linked to the level of PFAA contamination: the lower the contamination is, the higher the censored-data part under UB is. Indeed, marine fishes are about 18 times less contaminated than freshwater fishes in mean (Tables 1−3). The LB contamination range is 0.3−6.8 ng g^{-1} for marine fishes and 9.4−168.4 ng g^{-1} for freshwater fishes (1.1−7.1 and 10.3−169.9 ng g^{-1} under the UB hypothesis). Swordfish *Xiphias gladius* and brown trout *Salmo trutta fario* appear to be the less contaminated species, both being marine fishes, whereas seabass *Dicentrarchus labrax* and gudgeon *Gobio gobio* are the most contaminated ones, both being freshwater fishes.

The differences between marine and freshwater species are based not only on contamination levels but also on their contamination profile. Whereas PFOS is clearly the prevailing PFAA for the freshwater fishes (LB, 74% of the total contamination), for marine fishes the latter is shared between PFOA (24%), PFOS (20%), PFHxA (15%), PFHpA (11%), and PFBA (11%). The percentages between the LB and UB hypotheses are similar.

These differences are to date not well documented. Nevertheless, our results are consistent with the literature,[49−51]

[a]Null contamination level under LB hypothesis. Only UB contamination level is shown.

dx.doi.org/10.1021/jf501113j | J. Agric. Food Chem. 2014, 62, 7593−7603

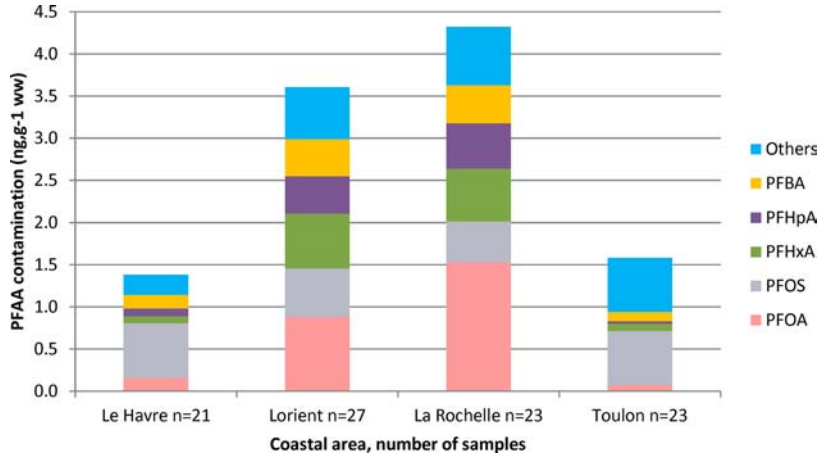

Figure 1. Mean marine fish PFAA contamination by coastal area (ng g^{-1} ww), LB hypothesis.

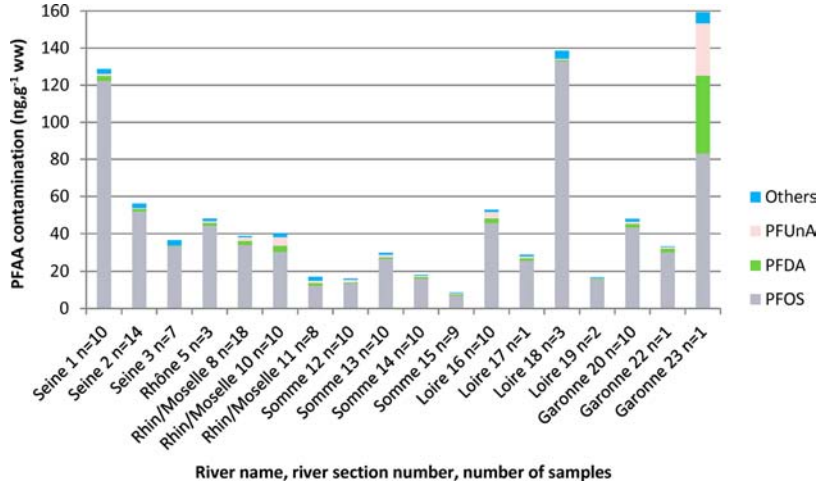

Figure 2. Mean European eel PFAA contamination by river section (ng g^{-1} ww), LB hypothesis.

which also finds a higher PFAA contamination in freshwater fish than in marine ones. One of the hypotheses about this observation is the water contamination level difference between rivers/lakes and seas/oceans, where the pollutants are diluted in a larger amount of water. Whereas the contamination levels in seawaters seem to range from a few picograms per liter to a few nanograms per liter,[52] except in coastal waters and industrialized bays such as Tokyo Bay, where a maximum level of 192 ng L^{-1} was found for PFOA,[53] the levels in rivers can reach from nanograms per liter to micrograms per liter,[54−56] a thousand times higher than in seawaters. Another hypothesis is a difference in the bioaccumulation potency between marine and freshwater fishes. However, comprehensive studies are still lacking in this field. No association was found between feeding behavior, living depth (demersal, pelagic, etc.), or climate (temperate, subtropical environment, etc.) and PFAA contamination levels.

Moreover, it seems that marine fish PFAA contamination levels are different among the four coastal areas. Indeed, the fresh and frozen fishes collected in Lorient and La Rochelle are twice more contaminated than those collected in Le Havre or Toulon as presented in Figure 1. Even if the Kruskal−Wallis test revealed a significant difference ($p < 0.001$), it remains difficult to draw a conclusion, as some species are specific from some sampling sites. For example, the gurnard *Trigla lucerne* was sampled only in Lorient, as it was the only site among the four where it was sufficiently consumed.

Spatial trend of freshwater fish PFAA contamination was also investigated. The European eel *Anguilla anguilla* was chosen to illustrate this part of the study because of the importance of the size of this group ($n = 137$). European eel contamination was mostly driven by PFOS as is the case for the freshwater fishes in general, except for one sample caught in the Garonne river, which shows a contamination split among PFOS (52%), PFDA (26%), and PFUnA (18%). With regard to the sum of the 15 PFAAs, the contamination was significantly different among the 18 river sections (Kruskal−Wallis test, $p < 0.0001$) (Figure 2). The results are deliberately presented by river section and not by major river because of the contamination heterogeneity within some rivers such as the Seine. This heterogeneity could be explained by the presence of a point source of PFAA discharge such as wastewater treatment plants and plants producing or processing PFASs, for instance. Our colleagues from the Nancy laboratory of hydrology are currently working on this subject.[57,58]

Table 4 presents a few PFOS contamination data from the literature to be compared to the results of the present study. It can be noted that the PFAA contamination data from this study are consistent with the existent data, with PFOS being the most frequently detected PFAA, often dominating the contamination pattern. In Babut and co-workers' study, gudgeon, common roach, European eel, and barbel *Barbus barbus* were the species with the highest PFAA levels.[59] Our fishes from the low contamination level group are 2.7 times more contaminated when

Table 4. PFOS Contamination Level of Freshwater Fishes (Nanograms per Gram wet weight)

country	species	*n*	median	mean	reference
France	low level	93	13.71	13.05	this study
	medium level	282	33.89	37.8	
	high level	10	84.88	84.88	
	Rhône−Mediterranean drainage basin	823	5		Babut et al.[59]
Germany	perch (*Perca fluviatilis*)	15	96		Hölzer et al.[61]
	pike (*Esox lucius*)	6	37		
	eel (*Anguilla anguilla*)	5	77		
	roach (*Rutilus rutilus*)	10	6.1		
US	northern pike (*Esox lucius*)	21	9.6	9.9	Xiao et al.[67]
China	grey mullet	5		1.2	Zhao et al.[60]
	catfish	4		0.49	
	catfish	21		0.51	

the median value is considered and 17 times more contaminated for the high contamination level group. However, the authors mentioned that their fishes were globally less contaminated than anywhere in France. Our thicklip grey mullet samples (mean PFOS level = 13.7 ng g^{-1} ww) and our wels catfish *Silurus glanis* samples (mean PFOS level = 7.8 ng g^{-1} ww) were surprisingly 10 and 15 times more contaminated in mean by PFOS than those purchased in local markets in Xiamen, China,[60] even if China is still known for their PFAS production. A German study collected and analyzed European perch (n = 15), northern pike *Esox lucius* (n = 6), European eel (n = 5), and roach (n = 10) fillets for PFOS contamination in Lake Möhne.[61] The median contaminations were, respectively, 96, 37, 77, and 6.1 ng g^{-1} ww. Our mean PFOS contaminations were 83 ng g^{-1} ww for European perch (n = 9), 15 ng g^{-1} ww for northern pike (n = 8), 40 ng g^{-1} ww for European eel (n = 137), and 18 ng g^{-1} ww for roach (n = 67). Globally, our data were consistent with those published in the literature, even if some fishes were probably sampled in "hotspots" of environmental contamination.

Lipid and Fatty Acid Composition. Table 5 shows the marine and freshwater fish composition for lipids, eicosapentaenoic acid (EPA), docosahexaenoic acid (DHA), n-3 LC-PUFA, n-6 LC-PUFA, and total PUFA for the 29 marine fish species and for 11 of the 16 freshwater fish species. Results for marine fish were already published and compared with the existing literature data.[44] Marine fish n-3 LC-PUFA level distribution is wider than the freshwater fish one, with ranges of, respectively, 46−4472 mg for 100 g ww (mean = 708 mg for 100 g ww) and 4−3895 mg for 100 g ww (mean = 368 mg for 100 g ww). As expected, for the marine fish, the oiliest species are also the richest in PUFA. The three oiliest marine fishes are salmon *Salmo salar* (13.5% of lipids ww in mean), swordfish (12.4% of lipids in ww in mean), and halibut *Hippoglossus hippoglossus* (11.7% of lipids in ww in mean), which are also the richest in PUFAs and n-3 LC-PUFAs, including EPA. The DHA-rich marine fishes are salmon (2164 mg for 100 g ww), swordfish (1750 mg for 100 g ww), and mackerel *Scomber scombrus* (1404 mg for 100 g ww), and the n-6 LC-PUFA-rich marine fishes are anchovy *Engraulis encrasicolus* (682 mg for 100 g ww), salmon (671 mg for 100 g ww), and swordfish (5410 mg for 100 g ww). For freshwater fishes, lipid and PUFA amounts are not so clearly related. Indeed, if European eel, the oiliest freshwater fish, is also the richest in n-3 LC-PUFAs, n-6 LC-PUFAs, and PUFAs, common carp *Cyprinus carpio*, the second oiliest fish, is relatively poor in PUFAs. Our data are consistent for European eel, wels catfish, pike-perch, trout, common carp, and bream *Abramis brama* in recent German and Polish studies.[62,63] The differences between the studies could be explained by the difference of sampling season, fish size, and intraspecies variability.

PFAA Contamination and LC-PUFA Balance. According to the multiple regression analysis, no positive or negative relationship has been highlighted between PFAA contamination and muscle protein rate, lipid content, and n-3 and n-6 LC-PUFA composition of the studied fishes (R^2 = 0.26, p = 0.86), which is not surprising considering the physicochemical properties of PFAAs. PFAAs are amphiphibic and are mostly found in the liver and blood,[64,65] not in fat tissues, as are organic persistent compounds such as PCB or dioxins. As PFAAs seem to bind preferentially to serum proteins rather than to muscle proteins, the results would surely be interesting to measure these contaminants in the liver and blood.

The most interesting fishes with high n-3 LC-PUFA content and low PFAA contamination are the swordfish, anchovy, halibut, salmon, and mackerel, all of them being marine fishes, whereas the potentially risky fishes to consume with high PFAA contamination and low n-3 LC-PUFA content are common carp, pike-perch *Sander lucioperca*, European perch *Perca fluviatilis*, thicklip grey mullet *Chelon labrosus*, and common roach *Rutilus rutilus*, all of them being freshwater fishes. If consumed regularly, these fishes could largely contribute to increase the PFAA level found in human serum. This hypothesis is consistent with Hölzer's study, which observed that anglers who consume fish two to three times per month have a higher PFOS serum concentration. Those fishes, caught in Lake Möhne, present a PFAA contamination similar to of the fishes of the present study.[61]

Our data tried to reflect an extended view of PFAA contamination along with n-3 and n-6 LC-PUFA composition of marine and freshwater fishes in metropolitan France. However, for some species such as western vairone *Telestes souffia* (n = 1), minnow *Phoxinus phoxinus* (n = 1), or marine fishes (n = 1−4), the size of the group is a limit of this study, even if the samples are composite ones made up of a homogeneous mix of several individual fishes. This concern leads to the question of the spatial trend of PFAA contamination. In this study, we chose to work on mean PFAA contamination of fishes because our FA composition data were available only by species, but there are obviously some differences between the river sections or the coastal areas, probably due to the differences in environmental contamination. Further studies could include a comparison between river sediment/water contamination and the corresponding fish contamination. Another weakness of our study is the lack of information available concerning the age, weight, and seasonality effect during the freshwater fish sampling. The French agency for food, environmental, and occupational health and safety (Anses) recently published an overview of all their recommendations since 2002 concerning the risk−benefit balance of fishery and aquaculture products for the general population, elderly, immunodepressed people, children, and pregnant or breastfeeding and child-bearing age women.[66] However, these recommendations take into account only dioxins, methylmercury, and PCBs. It could be suggested to add pike-perch, European perch, thicklip grey mullet, and common roach in the list of species that should be consumed with limitation, common carp already being in this list, as they do not present such a positive profile as far as the lowest n-3 LC-PUFA levels and the highest PFAA level were

found compared to other fish species analyzed in this study. As a further step, additional data on marine and fish species could be interpreted in terms of fish consumption recommendation by an expert committee and the food safety recommendations to French consumers updated, if needed, according to the last recommendations of the French agency for food, environmental, and occupational health and safety.

To the authors knowledge, no scientific data showing increased deamidation in microbial transglutaminase treated food have been published. However, when incubating immunodominant α-gliadin-peptides p56−68 (13mer) and p56−88 with MTG in buffer at pH 8.5 as well as in water no deamidated 13mer has been found.[19] The same observation has been made when analyzing gliadin extracted from dough treated with MTG in the presence of lysine methyl ester.[20]

Furthermore, gliadin cross-linking by MTG may even reduce immunotoxicity, because the substrate glutamine now is not available for TG2-catalyzed deamidation in the intestinal mucosa anymore. In this context, it has been shown that immunodominant 13mer loses its stimulatory effect on IFNγ-expression by gliadin-specific intestinal T-cell-lines (iTCL) when cross-linked by MTG to lysine-methyl-ester at the deamidation site (Q65). The observation that MTG-catalyzed modification of gliadin results in reduced stimulatory effects on iTCLs or spleen cells from gliadin-immunized DQ8-transgenic mice was confirmed by gliadin extracted from wheat flour treated with MTG and lysine methyl ester. Gliadin from dough treated with MTG alone also showed a reduction of cytokine-expression in iTCLs, although less efficient than gliadin from lysine-methyl-ester and MTG-treated dough.[19,22] Further PT-Gluten (peptic-tryptic digest of gluten) treated with MTG in the presence of MTG-substrate lysine showed no stimulatory effect on IFNγ, antibodies to TG2, transglutaminase activity and TG2-expression in cultured biopsies taken from celiac disease patient's duodenum, while nontreated PT-Gluten increased IFNγ-expression 13−15-fold and also clearly increased the other parameters mentioned above.[23]

Currently, there is a public discussion on the potential impact of MTG-treated food on celiac disease patients. In this context, the German federal institute of risk assessment (BfR) states that due to the deamidation activity of MTG a potential risk for celiac disease patients consuming MTG-treated gliadin containing food is possible, as long as there are no satisfactory clinical studies.[24] Cabrera-Chavez et al. state that TG2 is homologous to MTG (which in fact is not the case as has been explained above) and deduce that MTG in foodstuff could elicit the immune response of celiac patients. The authors further state a latent risk in celiac patient's to elicit or increase their immune response by MTG-treated gluten-free bakery products in consequence to modified glutamine residues.[25]

There are only few scientific data on this topic available. Cabrera-Chavez et al. reported a higher antibody titer to gliadin extracted from MTG-treated wheat bread for two out of nine celiac disease patient's sera they analyzed.[25] They further reported an increased immunoreactivity for gliadin extracted from MTG-bread with sera from patients older than 8 years.[26] Bread wheat gliadin treated in vitro with MTG also increased immunoreactivity to IgA antibodies from celiac patients.[27]

The aim of this study was to analyze the immunoreactivity of gliadins extracted from pasta prepared with and without MTG-treatment with IgA and IgG-type antibodies in CD patient's sera and to elucidate the catalytic effect of MTG on durum wheat-gliadin when applied in pasta production.

MATERIALS AND METHODS

Materials. Gluten (Amygluten 160) was a gift from Tereos Syral (Marckolsheim, France). Commercial Durum wheat semolina (Nisshin DF) was purchased from the Nisshin Flour Milling (Tokyo, Japan). Microbial transglutaminase (1,000 units/g) was from Ajinomoto (Tokyo, Japan). Pronase (EC 3.4.24.4) was from Roche, Aminopeptidase M (EC 3.4.11.2.) from Merck, Carboxypeptidase A (EC 3.4.17.1.) and Prolidase (E.C.3.4.13.9.) from Sigma, Ortho-phthalaldehyde (OPA) from Agilent and 9-fluorenylmethyloxycarbonyl (FMOC) was from Weblio, Japan. Deamidated gliadin peptide DGPx2 (for description, see the Results section), antigliadin monoclonal antibody A011 and monoclonal antibody to deamidated gliadin-peptide A057 were from Zedira, Darmstadt, Germany.

Sera. Celiac disease patients' sera and blood donor's sera have been purchased from The Binding Site, (Schwetzingen, Germany) and SLR Research (Carlsbad, U.S.A.), respectively.

Pasta Preparation. Two kilograms of semolina and 540 g of tap water with or without 0.4 units microbial transglutaminase per gram of semolina were mixed for 15 min at room temperature by a mixing machine, Vacuum Mixer Model VU-2 (Ogu Leaves Machinery Works Plant Co., Ltd.) to make dough samples. The dough samples were then applied to a pasta machine, Vacuum Extruder Model FPV-2 (Nippon Engineering Co., Ltd.) with a die (diameter: 1.80 mm) to form the shape of spaghetti. The spaghetti were refrigerated immediately and dried by a drier, Model LH21-13P Temperature and Humidity Chamber (Nagano Science Machinery Co., Ltd.). The dried spaghetti samples were used and referred to MTG-pasta (dough prepared with transglutaminase) and pasta (based on dough prepared without transglutaminase) in the following.

Analysis of Moisture, Fat and Protein Content. Moisture, fat and total nitrogen content were determined for 3 independent samples in duplicate according to the Japan's Specifications and Standards for Food Additives by Japan Food Research Laboratories.[28] Briefly, moisture content was determined by the heat drying method with 105 °C for 4 h. Fat content was measured by the acid hydrolysis method. Total nitrogen was determined by the Kjeldahl method and protein content was calculated as total nitrogen × 6.25. Generally, mean values are given.

Analysis of ε-(γ-Glutamyl)lysine Content. Quantitative analysis of ε-(γ-glutamyl)lysine was performed in 3 independent pasta samples each according to the method of Kumazawa et al. with modifications.[29] Ten mg of crushed pasta sample was suspended in 1 mL of 50 mM potassium phosphate (pH7.0). Pronase (2.8 units) was added to the suspension and incubated at 40 °C for 24 h. After heat inactivation of Pronase by boiling for 10 min, aminopeptidase M (8.0 units), carboxypeptidase A (8.4 units) and prolidase (4.0 units) were added and kept at 40 °C for 24 h. The sample was boiled for 10 min to terminate the enzymatic digestion and then centrifuged at 10000*g* for 5 min. The supernatant was diluted 5-fold with 50 mM potassium phosphate (pH7.0) and used as the analysis sample. One μL of the sample was mixed with 0.5 μL of OPA and 0.4 μL of FMOC to make fluorescence derivative and applied to HPLC (Agilent ZORBAX Eclipse Plus C18 3.0 × 100 mm) with fluorescence detector (Agilent 1290 Infinity DAD). The content of ε-(γ-glutamyl)lysine was determined using the synthetic ε-(γ-glutamyl)Iysine (Sigma-Aldrich, St. Louis, U.S.A.) as standard.

Gliadin Extraction. A modified method according to Wieser et al.[30] was used to extract gliadin from commercial gluten as well as from pasta samples. Briefly 100 mg gluten or 200 mg pasta meal/MTG-pasta meal (produced using a mortar) have been added to 10 mL 0.4 M NaCl, 0.067 mM $HKNaPO_4$ pH 7.6. Albumins and globulins have been extracted at room temperature (approximately 24 °C) two times by vortexing for 2 min and gentle stirring for 10 min followed by 15 min centrifugation at 6000*g*. Gliadins have then been extracted from the resulting nonsoluble fraction by adding 5 mL 60% ethanol, vortexing for 2 min and gently stirring for 10 min followed by 20 min centrifugation at 6000*g*. The extraction procedure has been repeated twice, the supernatants including soluble gliadin combined and filtered through a 0.45 μM membrane.

If necessary, the extracts have been concentrated using Microcon Ultracel YM-10 centrifugal filter devices (Millipore, Darmstadt, Germany).

Gel Electrophoresis and Immunoblotting. SDS-PAGE was performed according to Laemmli.[31] Briefly samples have been mixed with 5× SDS-PAGE loading buffer (128 mM Tris-HCl pH 6.8, 10% ß-mercaptoethanol, 10% gycerol, 4% SDS, 13% bromophenole blue), heated for 10 min and loaded on a 10% or 12.5% SDS-PAGE gel,

Table 1. Moisture, Protein and Fat-Content per 100 g Pasta and MTG-Pasta

	pasta [g]	MTG-pasta [g]
moisture	10.0	09.9
protein	12.3	12.4
fat	1.7	1.6

except otherwise mentioned. The following amounts of protein have been loaded on the gels: pasta or MTG-pasta gliadin-extracts: 2.2 μg; bread-wheat gliadin: 2.0 μg; DGPx2: 0.19 μg. Gels have been stained with silver nitrate according to Blum et al.[32] Electro-blotting has been performed in a Trans Blot SD Semi Dry Transfer Cell (Bio-Rad, Hercules, U.S.A.) for 80 min at 20 V. After electro-blotting, the nitrocellulose membranes have been presoaked in 48 mM Tris, 39 mM glycine, 1.3 mM SDS, 20% (v/v) methanol. Residual binding sites were blocked in 5% skimmed milk powder in TBST (10 mM Tris, 150 mM NaCl, 0.05% (v/v) Tween 20, pH 8.0) for 60 min at RT. The membrane was then briefly washed in TBST wash buffer and incubated for 1 h at room temperature with primary antibody/serum (diluted 1000 fold in TBST). After washing for 3 × 5 min with large volumes of TBST buffer the secondary antibodies (antihuman IgA (Thermoscientific, Karlsruhe, Germany) antihuman IgG, antimouse IgG (both Sigma, Schnelldorf, Germany), each conjugated to alkaline phosphatase and diluted 10,000 fold in TBST buffer) has been added to the membrane followed by a 1 h incubation at room temperature. After intensive washing, the membrane has been placed in detection reagent (100 fold dilution of AP color reagent in color development buffer, BioRad, Hercules, U.S.A.) and incubated for 30 to 60 s at room temperature. Excess detection reagent has been drained off and the staining reaction was stopped with 20 mM Tris-HCl, 5 mM EDTA, pH 8. All washing steps were performed at room temperature on a shaker.

ELISA. Sera have been analyzed for the following antibody titers (IgA and IgG) using commercial ELISA-kits according to the manufacturer's instructions: TG2 and DGP (Zedira, Darmstadt, Germany), Gliadin (Steffens Biotechnische Analysen, Ebringen, Germany).

For coating of 96-well microtiter plates (ThermoFisher, Karlsruhe, Germany), 100 μL gliadin-extracts (diluted to 2 μg/mL in coating buffer (20 mM Tris-HCl, pH 7.4, 150 mM NaCl)) per well have been incubated at 4 °C overnight, and washed five times with coating buffer containing 0.01% Tween 20. For blocking 250 μL coating buffer containing 3% bovine serum albumin have been added and incubated for 1 h at room temperature. After washing for 5 times with coating buffer the dry plates have been stored at 4 °C.

For further procedure, the components of the ELISA for the determination of antibodies (IgG or IgA) against gliadin from Steffens Biotechnische Analysen (Ebringen, Germany) have been used. The ELISA has been performed according to the manufacturer's instructions.

Measurements have been performed in quadruplicate.

RESULTS AND DISCUSSION

Determination of ε-(γ-Glutamyl)lysine in Pasta and MTG-Pasta. MTG-treatment did not affect general pasta-properties like moisture, fat, and protein content, as no significant differences for these properties could be observed for pasta and MTG-pasta (Table 1). In pasta, the content of transglutaminase cross-linking reaction product ε-(γ-glutamyl)-lysine was below the detection limit of 0.001 μmol/g protein. In contrast, ε-(γ-glutamyl)lysine content in MTG-pasta (having the same protein content as pasta) was determined with 0.45 μmol/g pasta, corresponding to 3.63 μmol/g protein (Table 2). Thus, the cross-linking activity of MTG on pasta dough was clearly proven. The increased amount of cross-links is in agreement with an improved breaking energy, or firmness described earlier for MTG-pasta.[16] The ε-(γ-glutamyl)lysine content in food treated with MTG (∼4 U/g) has been reported with 0.2 μmol/g for soy protein isolate or egg white and 1.5 μmol/g for surimi.[33,34] Therefore, wheat proteins are about 2- to 20-fold better cross-linking substrates within the respective reaction conditions than the before mentioned proteins.

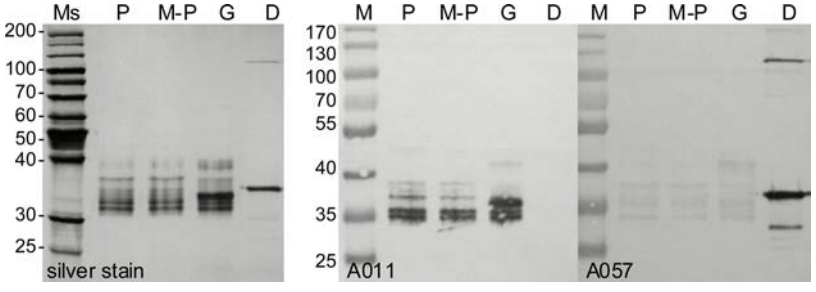

Figure 1. SDS-PAGE and Western Blot of gliadin-extracts from pasta (P) or MTG-pasta (M-P), from wheat gluten (G) and of deamidated gliadin peptide DGPx2 (D). Left: silver stained gel. Middle and right: Western blots using monoclonal antibodies to gliadin (A011) and deamidated gliadin (A057). Ms: molecular weight marker (200, 150, 120, 100, 85, 70, 60, 50, 40, 30, and 25 kDa) silver stained gel. M: molecular weight marker immunoblotted gel (170, 130, 100, 70, 55, 40, 35, and 25 kDa).

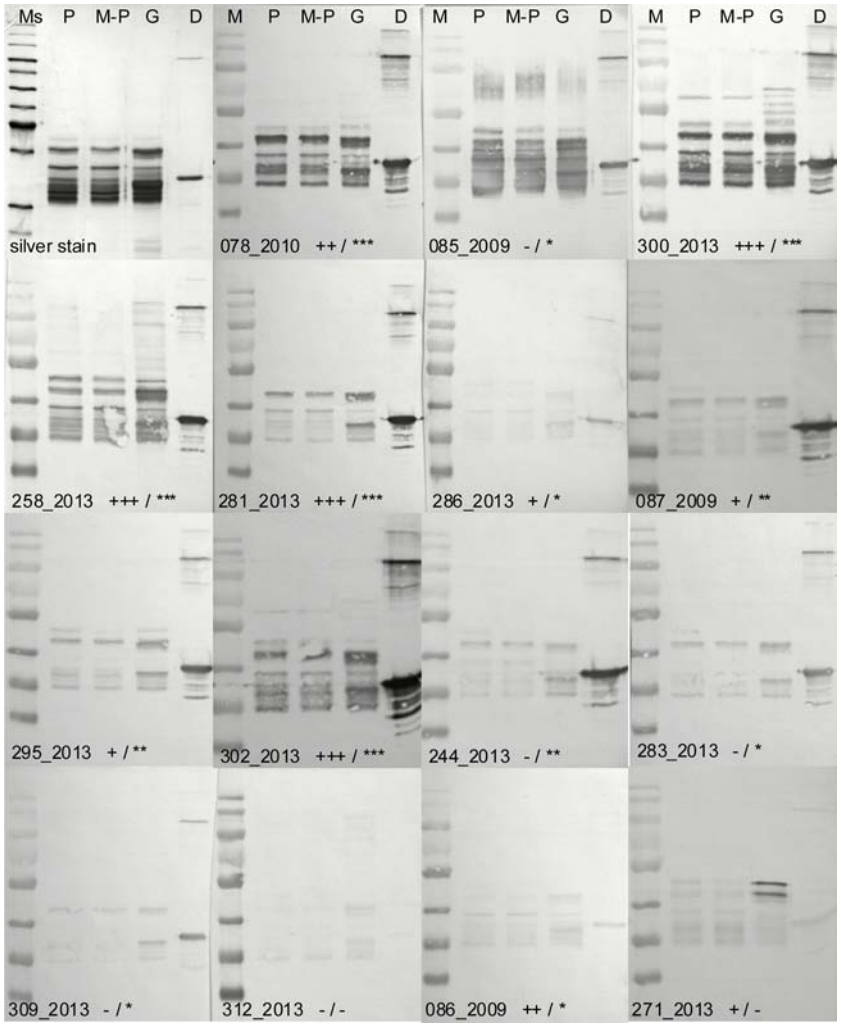

Figure 2. SDS-PAGE (silver stained) and immunoblot (IgG) of gliadin-extracts from pasta prepared without (P) or with (M-P) MTG, from wheat gluten (G) and of deamidated gliadin peptide DGPx2 (D). Ms and M: molecular weight markers, see Figure 1. The celiac disease patient's serum used as primary antibody is indicated. Antihuman IgG-alcaline phosphatase-conjugate was used as secondary antibody. The ELISA-IgG-titers measured for the sera have been added according to the following classification: Gliadin-Ab: −: < 14 U/mL; +: 15−30 U/mL; ++: 30−65 U/mL; and +++: > 65 U/mL. DGPx1-Ab: −: < 3 U/mL; *: 3−30 U/mL; **: 30−65 U/mL; and ***: > 65 U/mL.

Preparation and Analysis of Gliadin Extracts from Pasta and MTG-Pasta. Gliadin has been extracted as ethanolic fraction from pasta and MTG-pasta as well as from a commercial bread-gluten-preparation serving as a positive control in immunoblotting. The silver-stained SDS-PAGE (Figure 1) reveals no differences with respect to pattern and intensity for the two pasta gliadin-extracts and no polymerized gluten has been observed. A similar result is described for gliadin extracted from MTG-bread.[25] Other reports show polymerized proteins in acidic extracts of MTG-treated gluten or and in complete gluten.[35,36] This different observations may be explained by polymer amounts below the detection limit or the insolubility of high molecular weight polymers in the ethanolic fraction.

The bread-gluten derived gliadin shows a different band pattern characterized by a dominant band not present in pasta gliadins. This may be ascribed to different cultivars: Pasta is based on durum wheat, whereas the commercial gluten preparation has been obtained from bread wheat. The recombinant deamidated gluten peptide DGPx2, which is composed by the α2-gliadin-derived 33mer and γ-gliadin derived 26mer, both in their deamidated form fused to a carrier protein has been added as positive control for immunoreactivity of deamidated gliadin.[37] It yields a dominant band at the expected size of 31 kDa as well as two minor bands, which are presumably a fragment and a multimer of the recombinant DGPx2.

The gliadin-extracts have been further analyzed by immunoblotting (Figure 1). Using gliadin specific monoclonal antibody A011, the band patterns and intensities for both pasta gliadins are identical, while in agreement with the silver stained gel the pattern of bread-wheat gliadin differs. A011 is not able to bind to the deamidated gluten peptide DGPx2. Deamidated gliadin specific antibody A057, raised against deamidated (Q66E) α-gliadin peptide 58−73 (KLQPFPQPELPYPQPQ) recognizes both gliadin extracts from pasta as well as the extract from gluten very weakly. The deamidated gliadin peptide DGPx2 is recognized by A057 as a major band and two minor bands, in agreement to the silver stained gel. For the silver stained gel as well as both immunoblots, no differences in band pattern or in intensity could be observed for gliadin extracts from pasta and MTG-pasta. In particular, the antibody specific to deamidated gliadin did not yield additional or more intensive bands for the MTG-pasta gliadin extract.

While MTG-treatment clearly increases the number of ε-(γ-glutamyl)lysine-bonds there is no change in the ethanol-extractable

dx.doi.org/10.1021/jf501275c | J. Agric. Food Chem. 2014, 62, 7604−7611

gliadin fraction in SDS-PAGE and immunoblotting. No deamidation products can be detected using an antibody specific to deamidated gliadin.

Characterization of Sera for Antibody Titers. A collection of 40 celiac disease patients' sera covering a broad range of IgA-type autoantibodies to tissue transglutaminase (TG2) according to the distributors certificates have been analyzed for their antibody titers (IgA and IgG) to TG2, gliadin and deamidated gliadin. The results presented in Table 3 confirm the broad range of TG2-IgA-titers. Fourteen sera were also positive for anti-TG2-IgG. More sera were positive for anti-DGP than for antigliadin-antibodies (IgA: 28 vs 35 sera; IgG: 20 vs 33 sera). This observation as well as the overall ratio of positive sera (gliadin-IgA: 70%; IgG: 50%; DGP-IgA: 88%; IgG: 83%) is in good agreement with an earlier study on 128 untreated celiac disease patients (gliadin-IgA: 73%; IgG: 74%; DGP-IgA: 84%; IgG: 84%), where only the antigliadin-IgG positive ratio has been found higher (84% vs 59%).[38] There is a trend that sera with high anti-TG2-IgA-titers are strong positive for antigliadin and anti-DGP (both IgA and IgG), while for anti-TG2-IgG titers, such a correlation is not given. This observation confirms the data from an earlier study.[39] Nevertheless Table 3 also shows that individual sera do not follow this trend. E.g. sera with low anti-TG2-titer may show a negative (093_2009), intermediate (270_2013) or high (078_2010) antigliadin-titer. Sera negative or weak-positive for antigliadin are positive or even strong positive for anti-DGP (085_2009, 120_2010). In summary, despite a common trend, there is an individual composition of patient's sera with respect to antibodies to TG2, gliadin and DGP.

As a negative control, 20 arbitrarily chosen blood donor's sera have been characterized for antibodies to TG2, gliadin, and DGP. All these sera have been negative for TG2-autoantibodies

Table 3. Autoantibody and Antibody Titers of 40 Celiac Disease Patients' Sera for TG2, Gliadin and Deamidated Gliadin[a]

serum	immuno-blotting	TG2-ab cut-off: 3.0 U/mL		gliadin-ab cut-off: 14.0 U/mL		DGP-ab cut-off: 3.0 U/mL

[a]Sera have been listed according to increasing TG2-ab (IgA) titers. Positive sera according to the manufacturers cut-offs are written in bold. Sera used as detection antibody in immunoblotting are marked within the column "immunoblotting" as IgG or IgA. Note: 100 U/mL corresponds to a titer equivalent or higher than the maximal calibrator.

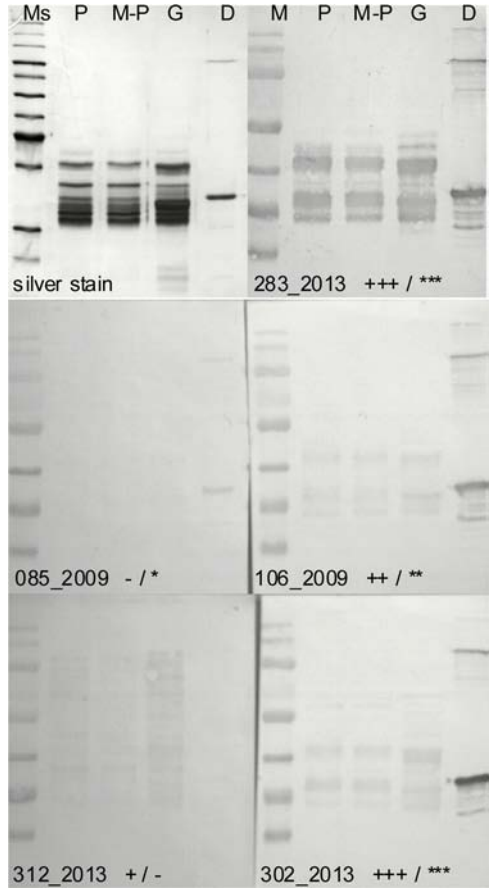

Figure 3. SDS-PAGE (silver stained) and immunoblot (IgA) of gliadin-extracts from pasta prepared without (P) or with (M-P) MTG, from wheat gluten (G) and of deamidated gliadin peptide DGPx2 (D). Ms and M: molecular weight markers, see Figure 1. The celiac disease patient's serum used as primary antibody is indicated. Antihuman IgA-alcaline phosphatase-conjugate was used as secondary antibody. The ELISA-IgA-titers measured for the sera have been added according to the classification given in Figure 2.

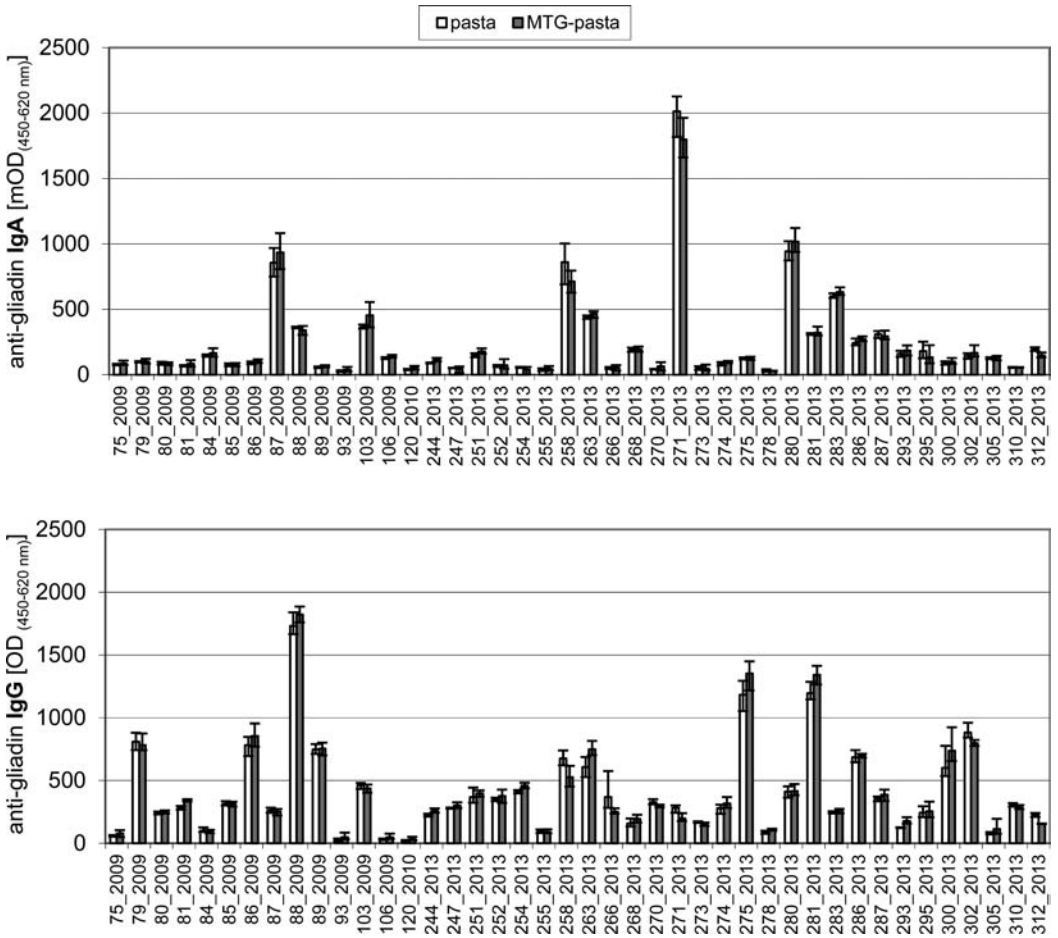

Figure 4. Antibody titers (IgA: upper part, IgG: lower part) of celiac disease patients' sera determined by ELISA using microtiter plates coated with gliadin extracts from pasta (white columns) and MTG-pasta (gray columns). $mOD_{(450-620\ nm)} = (\Delta E_{450} - \Delta E_{620})$ *1000.

(both IgA and IgG-type). Nine sera found positive for anti-DGP or antigliadin-antibodies in the IgA- or IgG-assay have not been used for control experiments.

Analysis of Gliadin Extracts by Immunoblotting. Immunoblotting of gliadin extracts from pasta and MTG-pasta as well as from bread wheat-gluten and DGPx2 as controls has been performed as described above, but by using 15 celiac disease patient's sera (see column "immunoblotting" in Table 3) as primary antibody. The 15 sera cover the whole range from weak to strong titers for anti-TG2-IgA, the primary serological marker in celiac disease. The sera also cover the whole range from negative over mild to strong positive antigliadin-IgG and anti-DGP-IgG antibody-titers (Table 3). IgG-detection has been chosen, as in celiac disease diagnostics measurement of anti-DGP-IgG-titers is recommended.[40] The resulting blots presented in Figure 2 at a look show, that the antigliadin and anti-DGP antibody-compositions of celiac patient's sera are not only individual with respect to their titers, but also with respect to their specificities. Individual sera are therefore composed by a differing oligoclonal antibody population. While some sera recognize gliadins as well as deamidated gliadin in a strong manner (e.g., 078_2010–258_2013 in Figure 2) there are sera which yield an intensive signal only for DGP (e.g., 281_2013, 087_2009, or 244_2013). Other sera yield weak to very weak signals for all antigens (286_2013, 309_2013, or 312_2013). Serum 286_2013 only recognizes DGP. It does not recognize gliadins including gliadin from MTG-pasta. Serum 271_2013 shows a strong preference for two gliadins from bread wheat, but only weak bands for gliadins from pasta and MTG-pasta.

In summary, the recognition patterns differ from serum to serum, and the recognition pattern for gliadin extracts from pasta and MTG-pasta is identical for every individual serum. Also sera which bind to DGP in a strong manner do not show a different or more intensive recognition pattern for gliadin from MTG-pasta compared to gliadin from pasta.

Immunoblotting using anti-DGP-antibody A057 and serum 302_2013 (IgG) as primary antibodies of the albumin/globulin-fractions and the glutenin-fractions from pasta and MTG-pasta revealed no difference in recognition patterns (data not shown). Therefore, a shift of deamidated gliadin to the other wheat protein-fractions can be excluded.

Five antigliadin-/anti-DGP-negative over weak to strong positive celiac disease patient's sera have also been analyzed for their IgA-type antibodies to gliadin and DGP by immunoblotting (Figure 3). The observations obtained for the IgG-type antibodies could be confirmed: The antibody composition of the sera is individual. No difference in pattern and intensity for gliadin from pasta and MTG-pasta can be seen, even if titers for anti-DGP-antibodies are high (sera 283_2013, 106_2009, 302_2013).

Blood donor's sera, negative for gliadin and deamidated gliadin antibodies in ELISA have also been negative in Western blots run as controls (data not shown).

dx.doi.org/10.1021/jf501275c | J. Agric. Food Chem. 2014, 62, 7604–7611

Celiac disease patient's sera recognize gliadin and deamidated gliadin sensitively. Above results suggest that there is no increased deamidation in pasta-gliadin by MTG.

In contrast to our data different immunoblotting pattern (IgA) for MTG-treated bread has been reported using a pool of 9 celiac patients' sera.[25] This may be due to different wheat-cultivars for bread and pasta. While a proper comparison in immunoblotting requires analysis of both extracts on a single blot, the authors obviously used different blots, which might also explain their observation.

Analysis of Gliadin Extracts by ELISA. The titer of celiac disease patient's sera for antibodies against gliadin extracts from pasta and MTG-pasta has been determined using microtiter plates (MTP) coated with the respective gliadin extracts in the ELISA-format (Figure 4). In order to avoid plate to plate discrepancies, every single serum has been analyzed in quadruplicate on single plates coated with gliadin from pasta and MTG-pasta. Generally, the extinction-values are lower for the pasta-gliadin ELISAs compared to the commercial anti-bread-wheat-gliadin-ELISA, which might be explained by differences in the coating efficiency. As can be seen in the SDS-PAGE (Figure 1), gliadin from pasta (durum wheat) differs from bread wheat gliadin.

When considering tendency rather than absolute values, the titers of the homemade gliadin-ELISA are in rough agreement with the commercial gliadin-ELISA, although some sera differ significantly. For example, serum 302_2013 shows a weak IgA titer in the homemade ELISA, which is in line with the weak bands the serum yields in immunoblotting, but is highly positive in the commercial ELISAs. Besides coating efficacy changes in structure upon adhesion on the MTPs polystyrene surface may also explain these differences. The results given in Figure 4 show that there are no differences in immunoreactivity of celiac disease patients' sera to gliadin extracts from pasta and MTG-pasta, neither for IgA nor for IgG-type antibodies. It has to be emphasized that sera characterized by a significantly higher DGP-antibody titer also do not show differences for the gliadin extracts from pasta and MTG-pasta. In this context, the ELISA-results are in line with the immunoblots shown in Figure 2 (IgG) and Figure 3 (IgA).

Cabrera-Chavez reported an increased immunoreactivity of a pool of 9 CD-sera to gliadin from MTG-bread. For two individual sera they observed no difference for a high titer serum, but an increased imunoreactiviy to MTG-bread-gliadin for a low titer serum.[25] This difference to our results may be due to different wheat cultivars used for pasta and bread production but it may also be a consequence to different conditions in bread and pasta production. Further, the same group reported an increased immunoreactivity in ELISAs for gliadin from MTG-bread for sera from 5 CD patient's older than 8 years, while sera for up to 3 years old patients did not show increased IgA-titers.[26] In contrast, we did not observe age-related differences with respect to IgA or IgG-titers against MTG-pasta-gliadin in our sera taken from patients well distributed from 1 to 81 years.

Antibodies to gliadin or deamidated gliadin are of diagnostic significance. Especially DGP-specific antibodies support celiac disease diagnostics when TG2-autoantibody titers are negative.[41] Despite the diagnostic relevance, a pathogenic role for (deamidated) gliadin antibodies is not described. Therefore, with respect to reports of increased immunoreactivity of celiac disease patients' sera following MTG-treatment, it has to be emphasized that this cannot be considered by itself a sign of enhanced gluten toxicity.

On the basis of our results, we consider immunoblotting to be more suitable than ELISA for the characterization of immunoreactivity of gliadin-extracts from food samples with celiac disease patient's sera.

In summary, treatment of pasta dough with MTG leads to an increase in cross-links (ε-(γ-glutamyl)lysine-bonds). This does not lead to a changed immunoreactivity of the gliadin-extracts for celiac disease patients' sera by immunoblotting and ELISA.

the viability of *P. caribbica* under oxidative stress; (iv) the effect of VC on ROS accumulation; (v) the effect of VC on induction of antioxidant enzymes, including catalase (CAT), superoxide dismutase (SOD), and glutathione peroxidase (GPX) in *P. caribbica*; (vi) the effect of VC on population dynamics of *P. caribbica* both in wounds and on the surface of apple fruit; and (vii) the biological function of the differentially expressed proteins of *P. caribbica* combined with VC and *P. caribbica* as sole treatment.

MATERIALS AND METHODS

Yeast. *P. caribbica* was obtained from the culture collection maintained by our laboratory at 4 °C on nutrient yeast dextrose agar (NYDA; 8 g of nutrient broth, 5 g of yeast extract, 10 g of glucose, and 20 g of agar, 1 L of distilled water; Sangon, Shanghai, China). A loop of the culture was inoculated in nutrient yeast dextrose broth (NYDB) and incubated on a rotary shaker at 180 rpm at 28 °C for 24 h. After incubation, cells were centrifuged at 5000 rpm for 10 min and washed twice with sterile distilled water to remove the residual medium.[15] Cell pellets were then resuspended in sterile distilled water and adjusted to an appropriate concentration with a hemocytometer for experiments.

Pathogen. *Penicillium expansum* was isolated from infected apples and maintained on potato dextrose agar (PDA; extract of boiled potatoes, 200 mL; dextrose, 20 g; agar, 20 g; and distilled water, 800 mL) at 4 °C. Spore suspensions were harvested by removing the spores from a 7-day-old culture and suspending them in sterile distilled water. With a hemocytometer, spore concentrations were determined and adjusted as required.

Fruits. Apple (*Malus domestica* Borkh.) fruits at commercial maturity without wounds or rot were selected on the basis of uniformity of size and color, disinfected with 1% (w/v) sodium hypochlorite for 1−2 min, rinsed with tap water, air-dried, and prepared for subsequent experiments.

Efficacy of *P. caribbica* in Controlling Blue Mold Decay of Apples. Three wounds were made on the equator of each apple with a sterile cork borer (approximately 5 mm diameter and 3 mm deep) and treated with 30 μL of different treated solutions as follows: (1) cell suspensions of *P. caribbica* (1×10^8 cells/mL); (2−6) cell suspensions of *P. caribbica* alone (1×10^8 cells/mL) supplemented with different concentrations of VC at 150, 200, 250, 300, or 350 μg/mL separately; and (7) sterile distilled water as the control. Biocontrol activity of *P. caribbica* was tested according to the procedure of Cao et al. [16] with some modifications. Three hours later, 30 μL of *P. expansum* suspension (5×10^4 spores/mL) was inoculated into each wound. After being air-dried, fruits were placed in enclosed plastic trays to maintain a high relative humidity (about 95%) and incubated at 25 °C. Disease incidences of apple fruits caused by *P. expansum* were determined after 15 days. There were three replications of each treatment that consisted of 12 fruits. The entire experiment was repeated three times, and the overall percentage of infection was calculated.

Evaluation of Survival of *P. caribbica* under Oxidative Stress. The survival of *P. caribbica* under oxidative stress was determined according to the method of Liu et al.,[3] with a slight modification. Yeasts was prepared as described, and 4 mL of yeast cell suspension at a final concentration of 1×10^8 cells/mL was placed in a 20 mL of test tube. Then the same volume of H_2O_2 was added at different concentrations (0, 5, 10 and 20 mM) into the test tube, exposing the yeast cells to oxidative stress at 28 °C on a shaker at 190 rpm for 0, 20, 40, or 60 min. At the described time points, 100 μL of serial 10-fold dilutions (from 5×10^7 to 5×10^3 cells/mL) of the samples were spread on NYDA. Colonies were counted after incubation at 28 °C for 3 days and expressed as the $\log_{10}$ colon-forming units per milliliter (CFU/mL) of each wound. There were three replicates of each treatment, and the entire experiment was conducted three times.

Effect of VC on Oxidative Stress Tolerance of *P. caribbica*. The effect of VC on survival of *P. caribbica* after H_2O_2 treatment was determined according to the method of Deveau et al.[17] with some modifications. Yeasts was prepared as described and adjusted to a final concentration of 1×10^8 cells/mL, and the non-VC-treated (NVC-treated) and 250 μg/mL VC-treated yeast suspensions were respectively exposed to 10 mM H_2O_2 according to the previous study and incubated at 28 °C at 190 rpm. After 20 min, colonies were evaluated with the same method as described above to test the survival of *P. caribbica* under oxidative stress. There were three replicates of each treatment, and the experiment was conducted three times.

Determination of Intracellular Reactive Oxygen Species. 2,7-Dichlorodihydrofluorescein diacetate (H_2DCFDA), the oxidant-sensitive probe, was used to determine the intracellular ROS production of *P. caribbica* according to the procedure of Liu et al.,[3] with a slight modification. Non-VC-treated and VC-treated yeast cells (the final concentration of VC was 250 μg/mL) were collected and then exposed to 10 mM H_2O_2 at 0, 20, 40, and 60 min, and cells without H_2O_2 treatment was considered as control. After exposure, cells were harvested quickly by centrifugation and washed twice with phosphate-buffered saline (PBS) buffer (pH 7.0) and resuspended in the same buffer containing 25 μM H_2DCFDA (dissolved in dimethyl sulfoxide). The suspension was incubated in the dark at 30 °C for 1 h. After washing twice with PBS buffer, intracellular ROS were examined with a fluorospectrophotometer using $\lambda_{excitation}$ = 504 nm and $\lambda_{emission}$ = 522 nm. The higher relative intensity indicates a higher ROS level. There were three replicates of each treatment, and the entire experiment was repeated three times.

Determination of the Enzyme Activities of CAT, SOD, and GPX. Yeasts were prepared as described and then supplemented with VC at the final concentration of 250 μg/mL. The yeast cells without VC treatment were considered as control. Cells were exposed to 10 mM H_2O_2 at 28 °C at 190 rpm for 1 h, then harvested by centrifugation at 10000 rpm for 10 min, and washed three times with sterile distilled water to remove residual VC and H_2O_2. The yeast samples at each time point (before H_2O_2 treatment and 0, 20, 40 and 60 min after exposure to H_2O_2) were harvested by centrifugation at 10000 rpm for 10 min and washed three times with sterile distilled water. Cells were disintegrated in liquid nitrogen and suspended in chilled potassium phosphate buffer (50 mM, pH 7.8, containing 5 mM DL-dithiothreitol and 5% PVPP). The cell suspension was centrifuged at 10000 rpm for 20 min at 4 °C, and the supernatant was used for enzyme assays.

SOD activity was evaluated by spectrophotometric assay according to the method of Bernstein et al. [18] A reaction mixture containing no protein extract was used as the control. Test tubes with the reaction mixture were irradiated under fluorescent lights at 4000 lx for 20 min. Then the absorbance of each solution was measured at 560 nm. One unit of enzyme activity was defined as the amount of enzyme inhibiting 50% of NBT photoreduction. Results were analyzaed from three independent replicates.

CAT activity was measured by monitoring at 240 nm with the decrease in absorbance due to the decomposition of H_2O_2 according to the method of Reverberi et al.[19] The reaction solution (3 mL) contained 2.8 mL of 30 mM H_2O_2 (dissolved in phosphate buffer (pH 7.8)) and 200 μL of extracted solution. After addition of the enzyme solution, the reaction was initiated, and one unit was defined as a decrease in A_{240} of 0.01 per minute. Results were analyzed from three independent replicates.

GPX was assayed by monitoring at 422 nm with the decrease in absorbance due to the reduction of GSH at 37 °C. The reaction mixture (1 mL) contained 0.4 mM GSH, 0.3 mM H_2O_2, and 0.3 mL of enzyme solution. The mixture was placed in an electrically heated thermostatic water bath at 37 °C for 5 min. Subsequently, 4 mL of 1.67% (w/v) meta-phosphoric acid (containing 0.05% (w/v) EDTA; 28% (w/v) NaCl) was quickly added to terminate the reaction followed by centrifugation for 10 min at 3000 rpm. Two milliliters of supernatant was added with 0.32 M Na_2HPO_4 (2.5 mL) and 0.5 mL of DTNB for 5 min. One unit was defined as a decrease of 1 μM GSH in 37 °C per minute. Results were analyzed from three independent replicates

The activities of SOD, CAT, and GPX were expressed as units per milligram of protein. Protein content was measured as described by Bradford,[20] bovine serum albumin (BSA) being used as standard.

Population Dynamics of *P. caribbica* in Apple Fruits. *Population Dynamics of P. caribbica on the Surface of Apple Fruits.* Four circles (approximately 14 mm diameter) were made on the upper part of each apple fruit with a marker pen. Two treatment solutions were used, VC-treated and non-VC-treated suspensions of *P. caribbica*. Three drops of 10 μL of these solutions were added evenly in each circle. Treated fruits in plastic trays were stored at 20 and 4 °C, respectively. Fruit samples were collected at different time points after treatment. At each time point, yeasts were harvested by removing the circled tissues with a sterilized knife. Samples were then ground with a mortar and pestle in 50 mL of sterile distilled water. Then, 100 μL of serial 10-fold dilutions were spread on NYDA plates. One hour after samples had been taken served as time 0. Fruits stored at 20 °C were assessed at 0 (1 h after the apples were inoculated with *P. caribbica*), 12, 24, 36, 48, 60, 72, 84, and 96 h, whereas those stored at 4 °C were assessed at 0 (1 h after the apples were inoculated with *P. caribbica*), 4, 5, 6, 7, 8, 9, 10, and 11 days. Colonies were counted after incubation at 28 °C for 48 h and expressed as the $\log_{10}$ CFU per wound. Each treatment contains three replications that consisted of 24 fruits, and the experiment was repeated three times.

Population Dynamics of P. caribbica in Wounds of Apple Fruits. Apples were prepared and wounded as described above. A 30 μL suspension of *P. caribbica* (1×10^8 cells/mL) alone (NVC) or *P. caribbica* (1×10^8 cells/mL) added with VC at a final concentration of 250 μg/mL (VC) was applied to each wound. Treated fruits were placed in enclosed plastic trays and stored at 20 and 4 °C, respectively. Fruit samples were collected with a sterile cork borer (9 mm diameter) to a depth of 10 mm[21] at different time points after treatment as described above. Fruits stored at 20 °C were assessed each day for 10 days, whereas those stored at 4 °C were assessed every 3 days for 33 days (1 h after the apples were inoculated with *P. caribbica* served as time 0). Colonies were counted after incubation at 28 °C for 48 h and expressed as the $\log_{10}$ CFU per wound. There were three replications of each treatment, and the entire experiment was repeated three times.

Biological Function of the Differentially Expressed Proteins of *P. carbbica* Combined with VC and *P. caribbica* as Sole Treatment. *Protein Sample Preparation.* Non-VC-treated and VC-treated yeast cells were collected and then exposed to 10 mM H_2O_2 for 60 min. The yeast cells were harvested by centrifuging at 10000*g* for 10 min (4 °C) and washed three times with cold double-distilled water to remove residual VC and H_2O_2. Protein sample preparation was performed as described by Li et al.[22]

Two-Dimensional Electrophoresis (2-DE) and Image Analysis. 2-DE and image analysis were performed as described by Wang et al.[23] using the vertical electrophoresis systems, Image Scanner III and Image Master 2D Platinum 7.0 software (GE Healthcare Bio-Science, Uppsala, Sweden), respectivly.

Protein In-Gel Digestion. Differentially expressed protein spots were excised from the gel and prepared for MS analysis according to the procedure of Zhang et al.[24]

Protein Identification by MALDI-TOF/TOF and Database Query. The peptide solution was analyzed using MALDI TOF/TOF mass spectrometer (Bruker, Germany). The resulting monoisotopic peptide masses were queried against protein database in NCBInr using MASCOT software according to the procedure of Majoul et al.[25]

Data Analysis. All statistical analyses were performed by analysis of variance (ANOVA) using the statistical program SPSS/PC version 16.0 (SPSS Inc., Chicago, IL, USA), and Duncan's multiple-range test was used for means separation. Differences at $p < 0.05$ were considered significant.

RESULTS

Efficacy of *P. caribbica* in Controlling Blue Mold Decay of Apples. As shown in Figure 1, *P. caribbica* effectively controlled postharvest blue mold decay of apples caused by *P. expansum* after 15 days of storage at 25 °C compared with the control fruits ($p < 0.05$). However, VC-treated yeast exhibited a better biocontrol efficacy compared to non-VC-treated yeast. Disease incidences in apple fruits treated with yeast alone and yeast combined with 250 μg/mL VC were 38.9 and 19.4%, respectively, whereas disease incidence in the control fruits (inoculated with water followed by the pathogen) reached 94.4%.

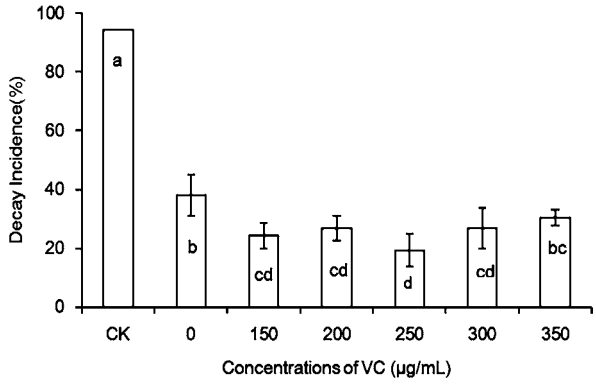

Figure 1. Efficacy of *P. caribbica* in controlling blue mold decay of apples stored at 25 °C. Sterilized water was used as control. Each value is the mean of three experiments. Bars represent the standard error of the mean. Data in columns with different letters are significantly different according to Duncan's multiple-range test at $p < 0.05$.

Evaluation of Survival of *P. caribbica* under Oxidative Stress. The viability of *P. caribbica* cells decreased with increasing H_2O_2 concentration and exposure time within each concentration (Figure 2). At 0 min, the yeast with all treatments had the same population level, whereas quite different levels were recorded at other time points. Furthermore, the population of *P. caribbica* cells reduced dramatically with a higher H_2O_2 concentration, particularly under the oxidative stress condition induced by 20 mM H_2O_2 for 60 min, in which yeast cells were nearly all dead. On the basis of the result of the viability assay, 10 mM H_2O_2 was chosen to be the appropriate stress condition for the following experiments.

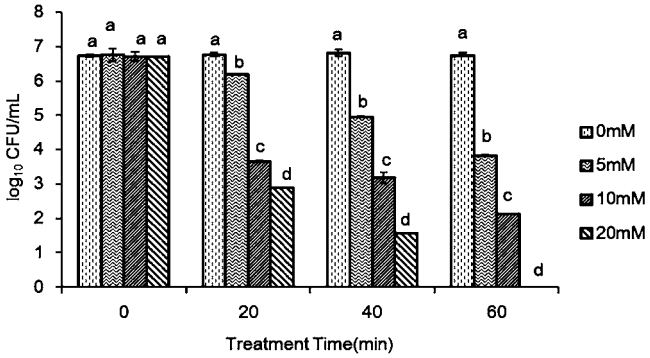

Figure 2. Population of *P. caribbica* under oxidative stress induced by H_2O_2. Each value is the mean of three experiments. Bars represent the standard error of the mean. Data in columns with different letters at the same time point are significantly different according to Duncan's multiple-range test at $p < 0.05$

Effect of VC on Oxidative Stress Tolerance of *P. caribbica*. As indicated in Figure 3, VC treatment had a significant effect on *P. caribbica* viability ($p < 0.05$); supplementation of VC improved the yeast viability from 2.73×10^4 cells/mL to 4.15×10^4 cells/mL.

ROS Accumulation of *P. caribbica* under Oxidative Stress. As illustrated in Figure 4, the ROS accumulation of

dx.doi.org/10.1021/jf501984n | J. Agric. Food Chem. 2014, 62, 7612−7621

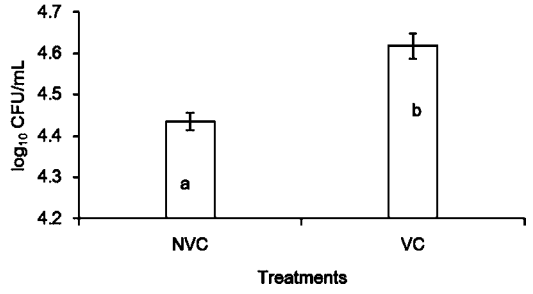

Figure 3. Effect of VC on oxidative stress tolerance of *P. caribbica*. Each value is the mean of three experiments. Bars represent the standard error of the mean. Data in columns with different letters are significantly different according to Duncan's multiple-range test at $p < 0.05$.

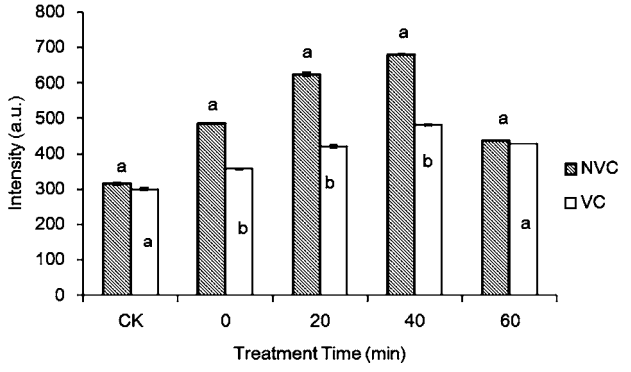

Figure 4. ROS accumulation in non-VC-treated and VC-treated cells of *P. caribbica* exposed to oxidative stress (10 mM H_2O_2) for various periods of time. Sterilized water was used as control. Each value is the mean of three experiments. Bars represent the standard error of the mean. Data in columns with different letters at the same time point are significantly different according to Duncan's multiple-range test at $p < 0.05$.

both treatments reached the highest level at 40 min. VC-treated cells showed significantly lower reactive oxidative stress (ROS) level compared to non-VC-treated cells at all tested time points except 60 min.

Activities of Antioxidant Enzymes. Adding exogenous VC enhanced the enzyme activities of SOD, CAT, and GPX of *P. caribbica* at some time point under oxidative stress. H_2O_2 induced the SOD activity, and VC improved its activity after exposure (Figure 5A). At 20 min, VC had the most obvious efficacy, and at 40 min, both treatments had the highest level of SOD activity, but all decreased at 60 min. VC did not increase CAT activity significantly until 40 min. However, CAT activity in non-VC-treated cells decreased greatly, whereas the CAT activity in VC-treated cells increased markedly at 40 min, and both of them exhibited a decreasing trend at 60 min (Figure 5B). When exposed to H_2O_2, GPX decreased tremendously before 20 min and then increased (Figure 5C). GPX activity of VC-treated *P. caribbica* was significantly higher than that of non-VC-treated *P. caribbica* at all tested times.

Population Dynamics of *P. caribbica* in Apple Fruits. *Population Dynamics of P. caribbica on the Surface of Apple Fruits.* The population of *P. caribbica* on the surface of apple fruits decreased quickly at the first stage at both temperatures (20 and 4 °C) and then increased (Figure 6A,B). However, irrespective of the storage temperature, the population of VC-

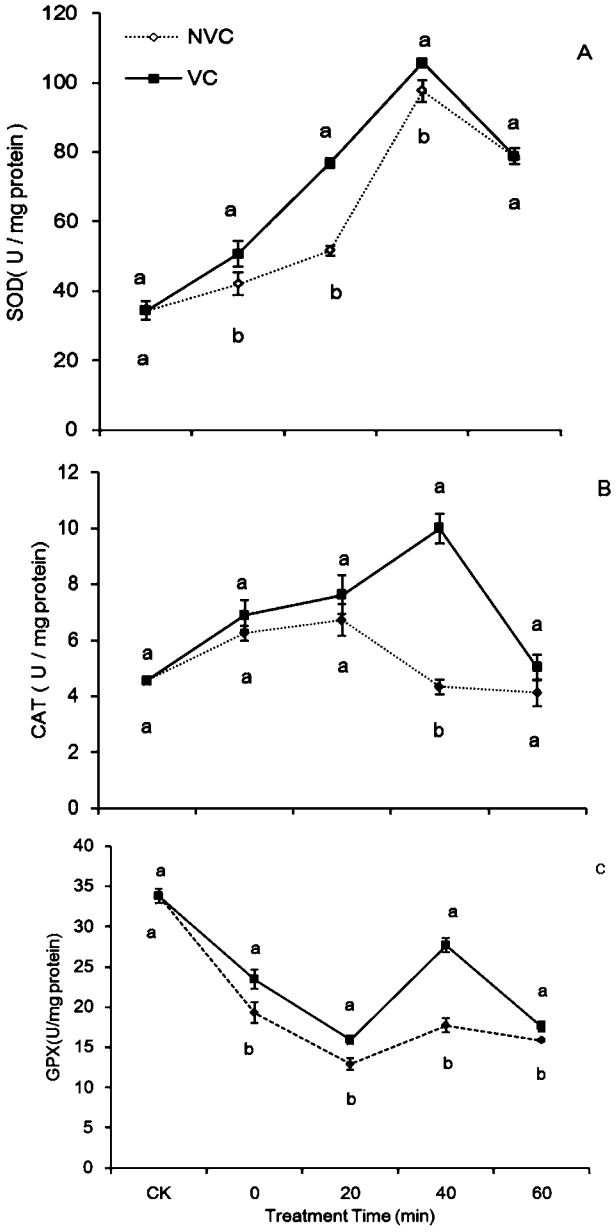

Figure 5. Change of SOD (A), CAT (B), and GPX (C) activities in control and VC-treated cells of *P. caribbica*. Cells without VC treatment served as control. Sterilized water was used as control. Data in columns with different letters are significantly different according to Duncan's multiple-range test at $p < 0.05$.

treated cells was significantly higher than that of non-VC-treated cells at all tested times.

Population Dynamics of P. caribbica in Wounds of Apple Fruits. Population dynamics of cells in the wounds compared with those on the fruit surfaces indicated a quite different trend (Figure 6). *P. caribbica* multiplied quickly in apple fruit wounds, and the number of yeast cells increased almost 10-fold at the first day (Figure 6C). The population of *P. caribbica* reached the maximum at days 7 and 8 for non-VC-treated cells and VC-treated cells, respectively. Although the yeast in wounds of apple fruits stored at 4 °C grew more slowly than that stored at 20 °C, rapid colonization of *P. caribbica* was observed during the first 3 days (Figure 6D). Although during all time points this population trend showed little fluctuation, it remained at a high level and did not fall below 1×10^6 CFU/wound at 4 °C.

dx.doi.org/10.1021/jf501984n | J. Agric. Food Chem. 2014, 62, 7612−7621

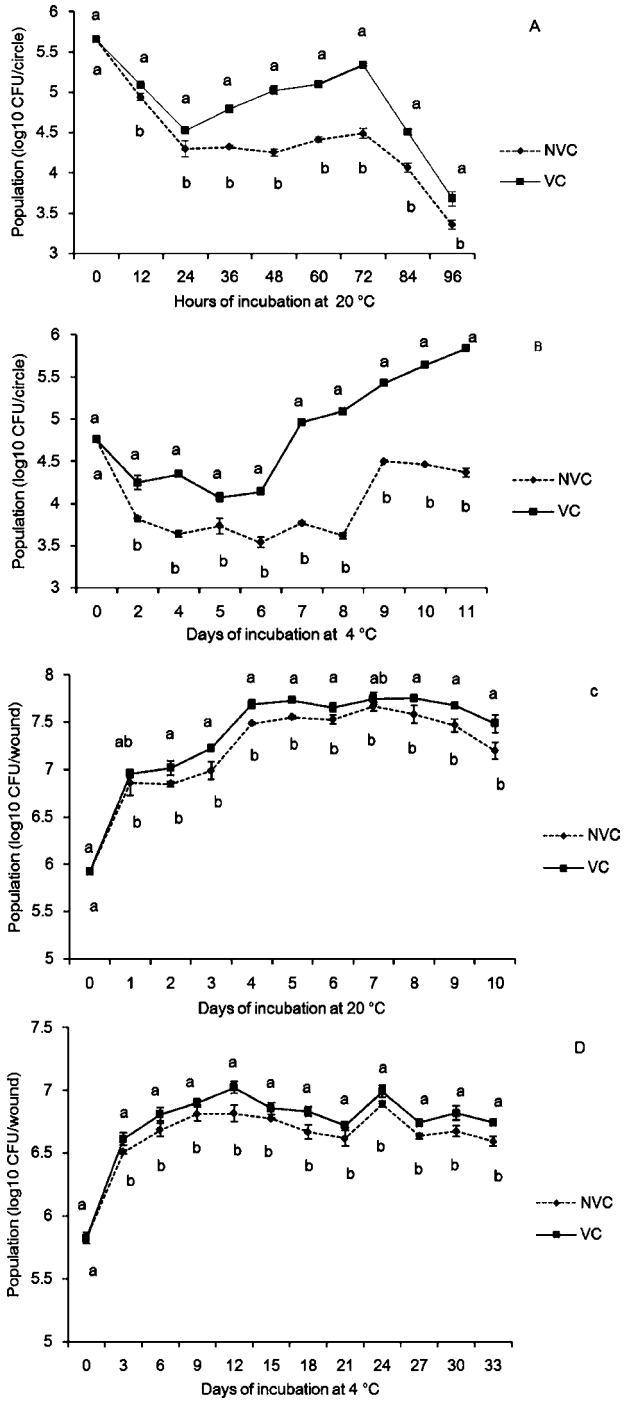

Figure 6. Population dynamics of *P. caribbica* both on the surface and in wounds of apple fruits stored at 20 and 4 °C, respectively. Each value is the mean of three experiments. Bars represent the standard error of the mean. Data in columns with different letters are significantly different according to Duncan's multiple-range test at $p < 0.05$. (A, B) Fruits were circled and inoculated with three 10 μL drops of non-VC-treated (NVC) or VC-treated (VC) cell suspension of *P. caribbica* at 1×10^8 cells/mL. Yeast colonies were counted after incubation at 28 °C for 36−48 h and expressed as the $\log_{10}$ CFU per circle. (C, D) Fruits were wounded and inoculated with 30 μL of non-VC-treated (NVC) or 250 μg/mL VC-treated (VC) cell suspension of *P. caribbica* at 1×10^8 cells/mL. Population levels at 20 °C were assessed each day for 10 days; meanwhile, the levels at 4 °C were assessed every 2 days for 33 days. Yeast colonies were counted after incubation at 28 °C for 36−48 h and expressed as the $\log_{10}$ CFU per wound.

Furthermore, irrespective of the temperature, the population of VC-treated *P. caribbica* was higher than the population of non-VC-treated *P. caribbica* at all tested times.

Identification of Differentially Expressed Proteins. Two aspects, changes in abundance of common spots between the two treatments (non-VC-treated and VC-treated) and appearance or absence of spots specifically, were considered when the differentially expressed proteins were evaluated. More than 200 protein spots were detected in each gel using IMP7.0 (Figure 7). Among them, 61 protein spots showing statistically significant ($p < 0.05$) changes of >1.5-fold in relative abundance between the two treatments were selected. Of the 61 proteins, 41 proteins were up-regulated and 20 proteins were down-regulated. All 61 proteins were focused on differences in degree of peak protein (Table 1). Most of the proteins were related to basic metabolism. Besides, there are proteins that correlate with protein synthesis, transportation, and stress response.

DISCUSSION

New methods to control postharvest decay have been found as an alternative to the use of synthetic fungicides; biocontrol agents were considered to be one of the most effective means.[26] In the present study, the results indicated that *P. caribbica* has showed control efficacy against postharvest blue mold decay of apples. This observation is in agreement with the one reported by Lahlali et al.,[27] but there are many differences between laboratory tests with host/parasite systems and performance of biocontrol agents/products under practical conditions,[28,29] which have great impact on the efficacy of controlling the postharvest disease of fruits. Oxidative stress, a crucial environmental factor, influenced the survival and efficacy of biocontrol yeasts.[30,31] Consequently, to maintain or increase the biocontrol activity of antagonists under commercial conditions, improving its stress tolerance is a useful strategy.[32,33] *P. caribbica* at 1×10^8 cells/mL combined with 250 μg/mL VC was demonstrated to be more effective in reducing *P. expansum* infection in apple fruit wounds than treatment with *P. caribbica* alone in this present study.

Combining antagonists with some food additives has drawn researchers' attention recently.[34] Previous studies have demonstrated the efficacy of NH_4Mo on improving the biocontrol ability of the yeast *Pichia membranifaciens* in fruit.[34] Ascorbic acid (VC) has been reported in various fruits and vegetables,[35] is an essential nutrient for physiological function of most animal species,[36] and plays an important role as a water-soluble antioxidant. From our experiments, we have got a similar result that VC is a potential approach to enhance the biocontrol efficacy of the antagonistic yeast *P. caribbica*. Specifically, the biological control activity of *P. caribbica* was greatly enhanced when the yeast was amended with VC at a final concentration range from 150 to 300 μg/mL, compared with the performance of *P. caribbica* used alone (Figure 1). It was found that 250 μg/mL VC showed the greatest enhancement for the biocontrol efficacy of *P. caribbica* (Figure 1).

With regard to oxidative stress, yeasts subjected to oxidative stress produce ROS. ROS can initiate cataract reactions leading to the production of $OH^{\bullet}$ and other destructive species such as lipid peroxides, which do serious harm to the cells.[37] Hydroxyl radicals are known to be very reactive and can damage vital cellular macromolecules, resulting in a decrease in cell viability.[18] As a consequence, in Figure 2 it was observed that *P. caribbica* was susceptible to oxidative stress, which led to a

dx.doi.org/10.1021/jf501984n | J. Agric. Food Chem. 2014, 62, 7612−7621

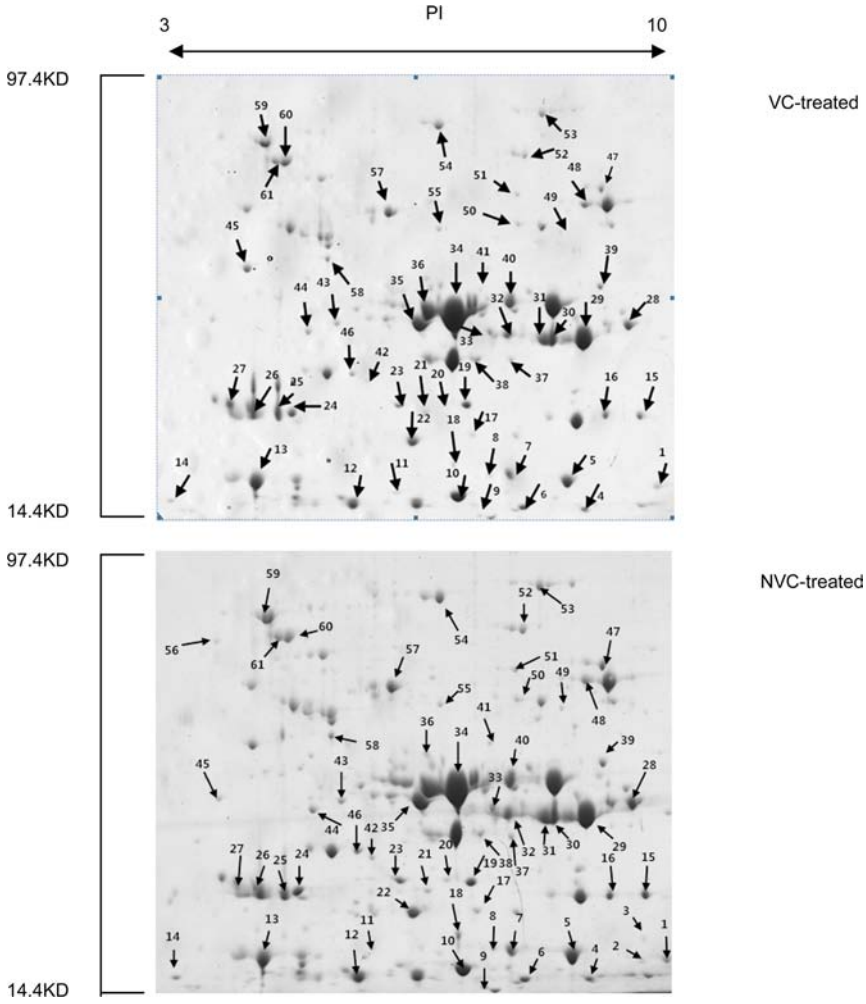

Figure 7. Two-dimensional pattern of intracellular proteins of non-VC-treated (NVC) or 250 μg/mL VC-treated (VC) cell under oxidative stress. Proteins were separated by 2D gel electrophoresis using 24 cm IPG strips with a pH 3−10 nonlinear gradient. After electrophoresis, proteins were visualized by Coomassie blue staining.

low viability that influenced its biocontrol efficacy. This observation is in agreement with that reported by Liu et al.,[3] who indicated that with the increasing H_2O_2 concentration and exposure time, the viability of *Cystofilobasidium infirmominiatum* decreased rapidly.[3] At the same time, the integration with VC is an effective measurement to improve the oxidative tolerance of the antagonistic yeast (Figure 3) .

Further studies showed that lower ROS accumulation was exhibited in VC-treated cells compared to non-VC-treated cells (Figure 4). Compared with the yeast viability presented under oxidative stress in Figure 2, the decreasing survival ability of the yeast with high concentrations of H_2O_2 might be caused by the higher accumulation of intracellular ROS. However, at 60 min, the ROS accumulation decreased tremendously compared with 40 min. This result is different from that achieved by Liu et al.,[3] who observed much higher ROS accumulation at 60 min. This may be attributed to cell death including cell apoptosis and necrocytosis. ROS produced under stress will induce cell apoptosis and lead to necrocytosis. Besides, a high concentration of ROS will cause necrocytosis directly. Cells release the cell content such as mitochondria and cytoplasm due to necrocytosis. This will be a possible mechanism leading to the decrease of ROS level. From the results of this present study, it is possible to conclude that the trend of ROS accumulation is negatively correlated with cell viability. Thus, the application of VC was capable of reducing the intracellular ROS accumulation, which could improve the population level of antagonistic yeast.

To reduce the excess of ROS, yeasts have developed an antioxidant defense system during evolution, which comprises various enzymatic and nonenzymatic components. The antioxidant enzymes that can directly react with ROS and scavenge ROS include SOD, CAT, and various peroxidases. In the present study, it was found that the activities of the three enzymes (SOD, CAT, and GPX) of *P. caribbica* cells were increased by VC treatment when exposed to H_2O_2 (Figure 5) at all tested time points. The results suggested that the induction of antioxidant enzyme activity in *P. caribbica* by VC treatment may be a key factor in lowering ROS levels, thus improving the viability of yeast cells exposed to oxidative stress.

It has been confirmed that there is a direct relationship between the population and the biocontrol efficacy of the antagonists.[5] The expected biocontrol efficacy will be achieved if antagonistic yeasts are able to survive and proliferate on the surface of the fruits.[5] There are many differences between laboratory tests and practical conditions,[29] which have great impact on the efficacy of controlling postharvest diseases of fruits. Oxidative stress, a crucial environmental factor,

influenced the survival and efficacy of biocontrol yeasts.[31] Hence, the improvement of oxidative tolerance has an important significance for adequate biological effectiveness.[33]

It was observed that VC improved the oxidative stress tolerance of *P. caribbica* and so did the population dynamics both on the surface and in the wounds of apples. The biocontrol activity of the antagonist is based on its capacity for rapid colonization and competition for space and nutrients.[5] In this study, 250 μg/mL VC improved the oxidative stress tolerance of *P. caribbica* and the population of *P. caribbica* both in the wounds and on the surface of the apple fruit (Figure 6), which probably explains the enhancement of the efficacy of *P. caribbica* exhibited in a previous assay. Similar results for other antagonist yeasts have been reported by Bencheqroun et al.[38] and Zhang et al.[39] In addition, the first 2 days after inoculation into apple wounds are quite important for *P. expansum* germination and infection.[40] As shown in Figure 6, it is notable that VC-treated cells of *P. caribbica* had a relatively higher population level than non-VC-treated cells both in wounds and on the surface of apple fruits during the first 2 days after inoculation. Thus, the higher population of VC-treated yeast cells compared to non-VC-treated cells in the early days may have produced the better biocontrol ability.

As to the molecular mechanism, most differentially expressed proteins in response to oxidative stress by the addition of VC were related to basic metabolism, which indicated that the basic metabolism of *P. caribbica* was improved by application of VC, so as to improve its biocontrol efficacy. Enolase 1, which can catalyze 2-phosphoglyceric acid to phosphoenolpyruvic acid, is a key enzyme in the glycolytic pathway; polyketide synthase is the key enzyme mediating polyketide formation; and malate dehydrogenase corresponded to the tricarboxylic acid cycle. According to these, we can conclude that the higher basic metabolic activity can induce higher oxidative tolerance.

In conclusion, the results of the present study showed that the oxidative stress tolerance of the antagonist can be improved markedly by the application of VC. Application of VC was also efficient in reducing the ROS level and inducing the activities of antioxidant enzymes. Consequently, VC can increase the population dynamics and the biocontrol efficacy of *P. caribbica* against postharvest blue mold decay of apples. This may offer great practical potential in reducing postharvest diseases of apples. However, according to results reported by Macarisin et al.,[4] the appropriate concentration of ROS production stimulated by these biomicrobial biocontrol agents is important for fruits to initiate their protective effect, so the interation among the ROS production, antagonist, pathogen, and host fruits/vegetables should be investigated in the future.

and dried fruit production to enhance color stability. The presence of vitamin C in apple products has implications on disulfide bridges and may lead to increased IgE reactivity or even enhanced allergenicity for sensitized individuals.

The present study focused on the influence of heat treatment and vitamin C or sulfur addition to purified Mal d 2. The conformational stability of Mal d 2 in the presence of vitamin C was investigated using IgE Western blot, mass spectrometry (MS), and attenuated total reflectance Fourier transform infrared (ATR-FTIR) spectroscopy. Furthermore, the characterization of the in vivo reactivity to vitamin C-treated Mal d 2 was performed using patients with clinically confirmed allergy to apples.

MATERIALS AND METHODS

Chemicals. Trichloroacetic acid (TCA), acetone, sodium bicarbonate (Na_2CO_3), diethyldithiocarbamic acid (DIECA), sodium chloride (NaCl), potassium chloride (KCl), disodium phosphate (Na_2HPO_4), potassium dihydrogen phosphate (KH_2PO_4), sodium hydrogen carbonate ($NaHCO_3$), sodium hydrogen phosphate ($NaH_2PO_4{\cdot}H_2O$), hydrochloric acid (HCl), glycerol, sodium borate decahydrate($Na_2B_4O_7{\cdot}10H_2O$), magnesium chloride (Mg_2Cl_2), sodium disulfite ($Na_2S_2O_5$), acetic acid, 2-mercaptoethanol, calcium chloride ($CaCl_2$), ammonia (NH_4HCO_3), D-glucose, and ethylenediaminetetraacetic acid (EDTA) were purchased from Merck (Darmstadt, Germany). Urea, poly(vinylpyrrolidone) K25, Tris base, sodium dodecyl sulfate (SDS), goat antirabbit IgG conjugated with alkaline phosphatase, goat antihuman IgE antibodies conjugated with horseradish peroxidase, bromochloroindolyl phosphate (BCIP), nitro blue tetrazolium (NBT), bovine serum albumin (BSA), L-glutamine, sodium pyruvate, 2-(4-(2-hydroxyethyl)-1-piperazinyl)ethanesulfonic acid (HEPES), citric acid, dithiothreitol (DTT), 4-methylumbelliferyl *N*-acetyl-β-D-glucosaminide, polyvinyl polypyrrolidone (PVPP), and Triton X-100 were obtained from Sigma-Aldrich (Steinheim, Germany). Skim milk and iodoacetamide were obtained from Fluka (Steinheim, Germany). Formic acid (FA) was obtained from Roth (Karlsruhe, Germany). The Micro BCA protein assay kit was purchased from Pierce (Rockford, IL). Acetonitrile (ACN) and vitamin C were purchased from BDH Prolabo (Leuven, Belgium). The ECL-Advanced Western blot kit was obtained from GE Healthcare (Buckinghamshire, U.K.). RPMI medium was obtained from Invitrogen (Carlsbad, CA). Trypsin and GluC were purchased from Roche (Basel, Switzerland).

Apple Material. Seven different apple breeding lines and cultivars were harvested from an experimental field with drip irrigation near the Adriatic seaside at cultivar-specific dates and stored at 4 °C before extraction: G198, Braeburn, Topaz, Fuji, Golden Delicious, Granny Smith and Pilot, and Pink Lady. Protein extraction was performed as previously described.[17] Five apples per cultivar were peeled (5 mm) with a paring machine, shock frozen, and powdered in liquid nitrogen. Frozen powder was mixed in a blender with extraction buffer (10 mM K_2HPO_4, 10 mM KH_2PO_4, 0.27 mM EDTA, 13.3 mM DIECA, 2% PVPP, pH 7) in a ratio of 1:2 (w/v) and extracted by stirring at 4 °C. The mixture was filtered through two layers of Miracloth (Calbiochem, United States) and centrifuged at 10000*g* for 30 min at 4 °C and the supernatant immediately frozen at −80 °C. Additional parameters such as the firmness and sugar and titratable acid contents, which indicate the maturity of the apples, were measured. The firmness of the apples is measured by a peneterometer, sugar content by refractometry, and titratable acid content by titration with 0.1 M HCl (Table 1).

Apple-derived food products were obtained from the local market: (1) dried apple chips, (2) sulfured apple rings, (3) nonsulfured apple rings, (4) baby apple puree, (5) clear apple juice, (6) cloudy apple juice, (7) clear organic apple juice. Dried apple samples (2 g) were precipitated by phenol, and the obtained protein pellets were resolved in 8 N urea.[18] Due to the low protein contents of apple juices, the enrichment of proteins required a precipitation step with 10% TCA/acetone. A 20 mL volume of apple juice was incubated with the same volume of 10% TCA/acetone overnight. The pellet was washed three times with pure acetone and dried at −20 °C. The total protein content was determined using the BCA kit (Pierce) according to the manufacturer's instructions.

Table 1. Parameters Such as Firmness and Sugar and Titratable Acid Contents Were Measured in Tested Apple Cultivars as Indicators of Maturity and Physiological State

cultivar	firmness (kgf)	sugar content (%)	titratable acid content (g/L)
G198	9.1	14.5	7.5
Braeburn	7.5	12.1	6.7
Fuji	7.2	13.8	3.7
Golden Delicious	6.6	14.9	5.2
Granny Smith	7.7	11.8	6.8
Pink Lady	8.7	15.1	6.7
Topaz	7.8	12.8	2.3

Purification of Apple Allergens. Apple cultivar Topaz was used for extraction of Mal d 2 and Mal d 1.[8] A 1 kg mass of apple peels was homogenized in carbonate extraction buffer (20 mM Na_2CO_3, 13.3 mM diethyldithiocarbamic acid, 1 mM ethylenediaminetetraacetic acid, 2 mg/mL PVP, pH 9.0) and stirred for 30 min at 4 °C.[8] The extract was filtered through two layers of Calbiochem Miracloth and centrifuged at 28000*g* (Beckman Coulter, Avanti J-25, JLA-10500) for 30 min at 4 °C. The supernatant was lyophilized and stored at −20 °C. The lyophilizate was dissolved in carbonate extraction buffer at a ratio of 1:10 (w/v), centrifuged for 30 min at 4000*g* and 4 °C, and buffer-exchanged using PD-10 columns (GE Healthcare) into equilibration buffer (10 mM Tris, 2 mg/mL PVP, pH 8). The obtained samples were loaded onto an anion exchange column, 30Q HR 10/10 (GE Healthcare). The purification was performed by an ÄKTA 100 Explorer chromatography system (GE Healthcare). Elution was carried out with a linear gradient from 0 to 1 M NaCl and the product fractionated for further analyses. To identify which fraction contained Mal d 1 and Mal d 2, IgE Western blotting was performed using Mal d 1- or Mal d 2-reactive patient sera. Fractions containing Mal d 1 and Mal d 2 were subjected to size-exclusion column chromatography on a Superdex 75 column (GE Healthcare) equilibrated with 25 mM sodium phosphate buffer, pH 7.0.

The identity and purity of purified Mal d 2 were confirmed by mass spectrometry. For the tryptic and GluC digestions of Mal d 2, 10 μL of the protein solution (1 mg/mL H_2O) was adjusted to 50 mM NH_4HCO_3 and 7.5 mM DTT (final concentration) by addition of 10 μL of 100 mM NH_4HCO_3 containing 15 mM DTT and incubated for 45 min at 56 °C to reduce disulfide bridges. Trypsin cleaves proteins and peptides at the amino acids arginine and lysine, and GluC cleaves proteins and peptides at glutamate. Thiol groups were carbamidomethylated by the addition of 40 μL of 55 mM iodoacetamide in 50 mM NH_4HCO_3. Proteins were precipitated by the addition of acetone (4:1), and the pellet was resuspended in 20 μL of NH_4HCO_3 buffer containing 0.1 μg of trypsin and GluC. All proteolytic reactions were performed at 37 °C overnight. The digested samples were directly injected into the LC−MS system (LC, Dionex Ultimate 3000 LC instrument; MS, Bruker, AmaZon ETD, equipped with the online nanosource). The peptides were separated on a C-18 column (Dr. Maisch GmbH, C-18 HPLC column, ReproSil-Pur, 200 × 0.1 mm, 3 μm packing, 200 Å pore diameter, flow 0.4 μL/min). A gradient from 95% solvent A and 5% solvent B (solvent A, 0.1% FA in water; solvent B, 0.1% FA in ACN) to 32% B in 40 min was applied, followed by a 15 min gradient from 32% B to 75% B that facilitates elution of large peptides. The peptides were analyzed by MS with data-dependent acquisition. Data were processed using the freeware program X!-tandem combined with GPM (Global Proteome Machine). The purity of Mal d 2 was determined by mass spectrometric analysis of the whole protein. A 1 μg mass of Mal d 2 was directly injected into the LC−MS system (LC, Dionex Ultimate 3000 LC instrument; MS, Bruker, Maxis

dx.doi.org/10.1021/jf5020878 | J. Agric. Food Chem. 2014, 62, 7622−7630

4G, equipped with the standard ESI source). The protein solution was eluted by developing a linear gradient from 10% to 60% ACN (Supelco Discovery Bio wide-pore C5 column, 50 × 0.32 mm, 3 μm packing). Data were processed using Data Analysis 4.0 (Bruker), and the spectrum was deconvoluted by the maximum entropy equation.

Polyclonal antibodies were raised in rabbits by immunization with 500 μg of native Mal d 1 and Mal d 2 and Freund's adjuvant.[8,17] The specificity of the Mal d 2 antiserum was confirmed by Western blotting.

SDS–PAGE and Western Blotting. All samples were diluted in sample buffer (0.125 M Tris/HCl, pH 6.8, 20% (v/v) glycerol, 2% (w/v) SDS, 0.005% (v/v) bromophenol blue) in a ratio of 1:2 (v/v) and denatured for 10 min at 90 °C or chemically reduced by 50 mM DTT. Total protein was determined via BCA assay after buffer exchange using PD-10 columns (GE Healthcare). For cultivar screening, 10 μg of total protein per lane was loaded to precast 4–20% Tris–glycine gel (Novex System, Invitrogen). As positive controls, two different concentrations of purified Mal d 2 (0.5 and 1 μg) were applied to each gel. Gels were electroblotted onto nitrocellulose membranes using a blotting buffer containing 50 mM $Na_2B_4O_7{\cdot}10H_2O$, 0.1% (w/v) SDS, and 20% (v/v) methanol. After overnight blocking with 3% skim milk powder, polyclonal antibodies against purified Mal d 2 were diluted to a ratio of 1:1000 (v/v) in dilution buffer (1% skim milk, 0.1% Tween 20 in PBS, 137 mM NaCl, 2.7 mM KCl, 4.3 mM Na_2HPO_4, 1.47 mM KH_2PO_4, pH 7.4) and added to the membranes. The immunoreaction was detected using goat antirabbit IgG conjugated with alkaline phosphatase in dilution buffer in a ratio of 1:2000 (v/v), followed by visualization with BCIP and NBT in alkaline phosphate buffer (100 mM NaCl, 5 mM $MgCl_2$, 100 mM Tris).

Influence of Different Processing Conditions on Purified Mal d 2. To study the influence of food preservatives on the immunoreactivity of Mal d 2, purified Mal d 2 was treated by reducing agents such as vitamin C (1% and 5%, w/v) as well as sulfur (1% and 5% (w/v) $Na_2S_2O_5$) in 10% (v/v) acetic acid at pH < 3 and different temperatures. Room temperature (rt) and 90 °C were selected, since they simulate the processing conditions in dried fruit production. Lowered pH is able to increase the effectivity of the treatments. Additionally, the purified Mal d 2 was treated for three incubation times: (i) 2 min, (ii) 20 min, and (iii) overnight (>16 h). Purified Mal d 2 reduced with 50 mM dithiotreithol for 1 h at rt was used as a control for positive IgE-binding.

Patient Selection. Six of eighteen apple-allergic patients showing positive reactivity to Mal d 2 in IgE Western blotting were selected for these studies. These patients, who were enrolled for in vivo testing, gave written informed consent for participating in the study, which was approved by the local Medical Ethical Committee of Vienna and conducted according to guidelines for Good Clinical Practice.

IgE Western Blots Using Patient Sera. Electroblotted membranes were blocked with 3% BSA for 2 h at 37 °C and incubated overnight at 4 °C with sera in a ratio of 1:10 (v/v). Goat antihuman IgE antibodies conjugated with horseradish peroxidase (1:20000, v/v) were used for visualization. Purified Mal d 2 was applied to the gel in reduced and not reduced form. Reacting protein bands were detected with the ECL-Advanced Western blotting kit according to the manufacturer's guidelines. In summary, horseradish peroxidase present on a Western blot is detected by its reaction with peroxide, an enhancer molecule, and the chemoluminescent substrate, all of which are present in the substrate reagents provided and visualized with a chemoluminescence imager.

Skin Prick and Oral Smear Tests. Only the influence of vitamin C addition on altered allergenicity of Mal d 2 could be examined by skin prick and oral smear tests. Due to severe skin irritations caused by DTT and $Na_2S_2O_5$ on healthy skin, sulfur-treated Mal d 2 could not be used for patient skin testing. Skin prick tests (SPTs) were performed on the forearm with different concentrations of purified Mal d 2 (100, 20, 10, and 5 μg/mL). The samples were provided as native, heat-denatured (20 min at 90 °C), and treated (2 min at 90 °C, 1% vitamin C). Positive skin reactions were recorded after 20 min by copying the wheal reaction onto a transparent adhesive tape, and wheal diameters were measured as soon as a positive reaction was visible. Fresh apple and histamine (10 mg/mL) were used as positive controls and 1% vitamin C in saline solution and saline solution as negative controls. Oral smear tests (OSTs) were applied as a minivariant of oral provocation to test the mucosal reaction inside the mouth. OSTs were performed using increasing concentrations of purified Mal d 2 (10, 20, and 100 μg/mL) in 1% vitamin C saline solution. To start, a 1% vitamin C saline solution (negative control) soaked cotton swab was smeared for 1 min on the mucosal side of the lower lip, and after 20 min native Mal d 2 was smeared on the inner side of the upper lip. Thereafter, increasing concentrations of native Mal d 2 were smeared, alternating on the lower and upper lips until the highest concentration was reached.

β-Hexosaminidase Secretion Assay from Human FcεRI Receptor Protein Transfected Rat Basophilic Leukemia Cells. The binding of treated and untreated Mal d 2 to IgE receptor FceRI was studied using cell-based the rat basophilic leukemia assay (RBL assay) in vitro. RBL-703/21 cells, derived from RBL-2H3, contained genes of the human high-affinity IgE receptor FceRI (kindly provided by Dr. Lothar Vogel, Paul-Ehrlich Institute, Langen, Germany). Cells were cultured in RPMI medium supplemented with 10% fetal calf serum, 4 mM L-glutamine, 2 mM sodium pyruvate, 10 mM HEPES, 1% penicillin/streptomycin, and 100 μM 2-mercaptoethanol at 37 °C and 5% CO_2. RBL cells (4×10^4 cells per well in 100 μL of medium) were seeded in a 96-well round-bottom microtiter plate (Nunc) and incubated overnight at 37 °C and 5% CO_2. Cells were passively sensitized with sera from six patients (diluted 1:25) for 2 h at 37 °C and 5% CO_2. Cells were washed twice with Tyrode's buffer (137 mM NaCl, 2.68 mM KCl, 1.4 mM $CaCl_2$, 1.7 mM $MgCl_2$, 5 mM D-glucose, 10 mM HEPES, 0.42 mM $NaH_2PO_4{\cdot}H_2O$, 12 mM $NaHCO_3$) at pH 7.2 supplemented with 0.1% BSA. Native Mal d 2 (0.05 μg in 100 μL of Tyrode's buffer per well), heat-denatured Mal d 2 (90 °C for 5 min, 0.05 μg in 100 μL of Tyrode's buffer per well), Mal d 2 with 1% vitamin C (90 °C for 5 min, 0.05 μg in 100 μL of Tyrode's buffer per well), and 1% vitamin C solution alone as the control were added to control wells and incubated for 30 min at 37 °C in a 5% CO_2 atmosphere. As a negative control, RBL cells were incubated with Tyrode's buffer to calculate spontaneous release of β-hexosaminidase. Cell lysis was performed by addition of 10 μL of 10% Triton-X in Tyrode's buffer for 5 min for total release of β-hexosaminidase (100% release) as a positive control. A 50 μL volume of supernatant was mixed with 50 μL of assay solution (5 mL of 0.1 M citric acid, pH 4.5, and 80 μL of 4-methylumbelliferyl *N*-acetyl-β-D-glucosaminide) and incubated at 37 °C for 1 h. The reaction was terminated by addition of 100 μL of glycine buffer (200 mM glycine, 200 mM NaCl, pH 10.7). Fluorescence signals were read at 360 nm/465 nm (Cytofluor 2350, Millipore), and the results were calculated as a percentage of total release. The values of the negative controls were subtracted.

Attenuated Total Reflectance Fourier Transform Infrared Spectroscopy. ATR-FTIR measurements were performed using a VERTEX 70 spectrometer (Bruker) and a BioATRcell IITM (Harrick). The BioATRcell IITM was cooled with a Haake K20 water bath at 20 ± 0.05 °C. The sample chamber of the spectrometer was continuously purged with dry air. Spectra of 20 μL volume samples from 4000 to 850 cm^{-1} were acquired by using a nitrogen-cooled MCT (photovoltaic mercury cadmium telluride) detector (spectral resolution 4 cm^{-1}, 64 scans, forward–backward). A Blackman-Harris three-term apodization function was used along with a zero-filling factor of 1. Purified Mal d 2 at a concentration of 1.8 mg/mL was dissolved in 15 mM phosphate buffer at pH 7.0 containing 0%, 1%, and 5% (w/w) vitamin C. Samples were incubated for 1 h at rt before the measurements. For background measurements 15 mM phosphate buffer at pH 7.0 without vitamin C and the same buffer with 1% (w/w) or 5% (w/w) vitamin C in Milli-Q water (SGWater) were used. The samples were prepared so that the concentrations of the buffer and the vitamin C were identical to those of the blank used for the background. Sample preparation with identical buffer concentrations for the sample and blank is a critical error-prone step. However, a correction of small differences between sample and background concentrations is possible. For each sample three to five spectra were collected, and the averages were used for

analysis. OPUS software (version 7.2, www.brukeroptics.de) was used for signal processing. An atmospheric correction of the full spectrum and a rubber-band baseline correction of the resulting spectrum were performed in the wavelength ranges between 1100 and 1900 cm^{-1}.

RESULTS AND DISCUSSION

Characterization of Purified Mal d 2. To perform in vivo and in vitro experiments under simulated food processing conditions, Mal d 2 was purified from the apple cultivar Topaz due to its high content of Mal d 2.[8] Mass spectrometry and peptide sequencing were used for the verification of the identity, molecular mass, and purity of purified Mal d 2 (Figure 1). The results showed high sequence coverage (UniProt accession no. Q9FSG7) and confirmed the purity of the protein at 23 195 Da. The peak at about 23 500 Da is a Mal d 2 isoform which is present in trace amounts (Figure 1B). One minor peak is detected at 24 367 Da which may contain a single glyco-MMXF residue and compared to the major Mal d 2 peak is of very low quantity. In fact, Mal d 2 was found to possess one putitative N-glycosylation site.[4] Purified Mal d 2 was used for raising specific anti-Mal d 2 polyclonal antibodies and for in vitro and in vivo experiments.

Influence of Different Processing Conditions on Purified Mal 2. SDS−PAGE and the Western blotting technique were applied to investigate the influence of different temperatures and addition of sulfur or vitamin C at different concentrations (Figure 2). A temperature of 90 °C was used for the chemical reduction of Mal d 2. Mal d 2 was not detected by Coomassie after heat treatment at 90 °C and with sulfur (1% or 5% (w/v) $Na_2S_2O_5$, Figure 2A). Considering that the detection limit of Coomassie staining for Mal d 2 is 1.0 ng or 50 fmol,[19] under these conditions, the protein was completely degraded and only traces of a protein band could be visualized. In IgG Western blot and SDS−PAGE only faint bands of sulfur-treated Mal d 2 indicate the presence of only traces of intact protein (Figure 2B). Purified Mal d 2 was stable after treatments with sulfur at rt, and in Western blotting the 23 kDa band of native Mal d 2 remained constantly reactive with polyclonal antibodies, indicating the integrity of IgG epitopes (Figure 2B). No significant band migration shift was detected after

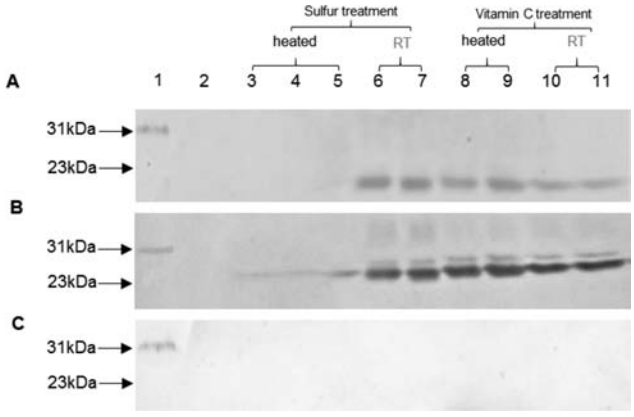

Figure 2. Influence of different treatments on immunoreactivity of Mal d 2: (A) Coomassie-stained gel, (B) Western blot using polyclonal rabbit antibody against Mal d 2, (C) IgE Western blot using the serum pool of the six selected patients. Lane 1: chemically reduced Mal d 2 as positive control. Lane 2: negative control. Lanes 3−11: Mal d 2 with different treatments: (3) 5% $Na_2S_2O_5$, 20 min at 90 °C and 1 h at rt, (4) 5% $Na_2S_2O_5$, 2 min at 90 °C, (5) 1% $Na_2S_2O_5$, 20 min at 90 °C and 1 h at rt, (6) 5% $Na_2S_2O_5$, 2 min at rt, (7) 1% $Na_2S_2O_5$, 2 min at rt, (8) 5% vitamin C at 90 °C for 2 min, (9) 1% vitamin C incubated at 90 °C for 2 min, (10) 5% vitamin C incubated overnight at rt, (11) 1% vitamin C incubated overnight at rt.

treatment at rt with sulfur or with vitamin C at different temperatures. In IgG Western blotting a diffuse faint band at approximately 28−31 kDa can be visualized after treatments with 1% or 5% sulfur at rt and 1% or 5% vitamin C at 90 °C or rt and might be attributed to a minimal denaturation of Mal d 2. The diffuse faint band was not detectable in Coomassie staining or reactive with serum pool IgE's (Figure 2).

The results showed that neither sulfur nor vitamin C is able to reduce or linearize Mal d 2, so the mobility of the Mal d 2 band in the SDS−PAGE gel is shifted to the level of a 31 kDa protein. IgE Western blotting confirmed that Mal d 2 remained in its native conformation in all treatments and therefore was not reactive with the serum pool of the selected patients (Figure 2C). The absence of in vitro IgE reactivity to treated

dx.doi.org/10.1021/jf5020878 | J. Agric. Food Chem. 2014, 62, 7622−7630

Mal d 2 can be explained by the presence of the protein in its natural conformation (Figure 2C). Taking into consideration that Mal d 2 can refold very quickly almost to its natural conformation after heat denaturation, it is unlikely to bind to serum IgE's.[8]

Conformational Stability of Mal d 2 in the Presence of Vitamin C. Biophysical measurements were performed to analyze the stability of Mal d 2 in the presence of vitamin C. Circular dichroism (CD) and differential scanning calorimetry (DSC) failed to determine the conformational stability of Mal d 2 in the presence of vitamin C because of the high ellipticity of vitamin C that overlapped with the maxima and minima of the protein. DSC could not be performed since vitamin C is destroyed by heat treatment and the thermograms were not reproducible.

ATR-FTIR spectroscopy was, therefore, used as an independent methodology to detect possible conformational changes of Mal d 2 protein by the addition of vitamin C at rt. Purified Mal d 2 at a concentration of 1.8 mg/mL was dissolved in 15 mM phosphate buffer at pH 7.0 containing 1% and 5% (w/w) vitamin C. ATR-FTIR spectra of purified Mal d 2 in the absence and presence (1% or 5%, w/w) of vitamin C were recorded in the wavenumber range between 1100 and 1900 cm^{-1} (Figure 3A). Upon normalization (Figure 3B), vitamin C-induced spectral changes are obvious. The band of the amide I position around 1650 cm^{-1} is shifted to lower wavenumbers, which might reflect some loss of α-helical structure. It was shown by using electronic CD spectrometry that the secondary structure of Mal d 2 is dominated by β-sheets and has some contributions from α-helices,[8] which could also be confirmed by ATR-FTIR-spectroscopy with a peak at about 1650 cm^{-1} (α-helices) and a shoulder at about 1630 cm^{-1}, highlighted by a black arrow (Figure 3A,B). This is due to the unfolding of the α-helices by the addition of vitamin C, comparable to thermal unfolding.[8] As there is still a shoulder visible at about 1655 cm^{-1} in the spectrum of Mal d 2 with 5% (w/w) vitamin C (Figure 3B), the α-helical secondary structure remains intact to some extent.

The standard reduction potential of the redox couple cystine/cysteine is around −0.21 V at pH 7.0.[20,21] DTT is a powerful reducing agent with a reduction potential at pH 7.0 of −0.33 V.[22] Thus, in its presence all intramolecular disulfide bridges are in the reduced state.[20] DTT was used in a previous study to reduce Mal d 2.[8] The calculated redox potential of vitamin C at pH 7.0 of $E° = -0.066$ V is too low to reduce cysteine.[23]

The Cys ν (stretching vibration of S−H) typically appears around 2551 cm^{-1} [24] in a region without overlap by any other protein absorptions.[25] Strong hydrogen bonding between an SH group and a peptide carbonyl might shift the band to lower wavenumbers. In Mal d 2 no evidence for the existence of an SH group was found. The small peak at about 1760 cm^{-1} (Figure 3A) might derive from the small difference in vitamin C content between the sample and reference cell. Oxidized vitamin C (dehydroascorbic acid) has a peak at 1795 cm^{-1} which is also completely missing in the spectra. This confirms additionally that no oxidation of vitamin C and therefore most probably also no reduction of the cysteine groups of Mal d 2 took place.

Verification of Mal d 2 Allergenicity in the Cell-Based RBL Assay. To verify the allergenicity of native and heat-treated purified Mal d 2, 18 patients were screened by the means of anamnesis, positive OAS minutes after consumption of apples, and serum reactivity to native and reduced Mal d 2. Six patient sera reacted positively with chemically reduced Mal d 2 in Western blotting, but none of the sera reacted with native Mal d 2. These patients were selected for in vitro RBL assay and in vivo experiments using skin prick and oral smear tests (Table 2 and Figure 4).

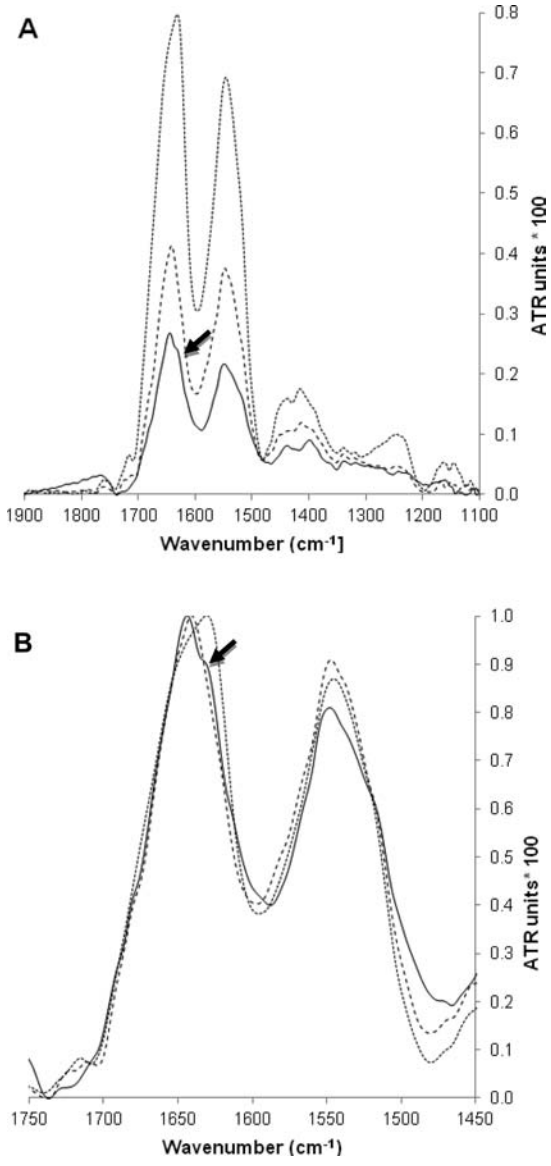

Figure 3. Spectroscopy of Mal d 2 in the absence/presence of vitamin C: (A) measured ATR-FTIR spectra in the wavenumber range from 1100 to 1900 cm^{-1} of Mal d 2 (continuous line), Mal d 2 with 1% vitamin C (dashed line), and Mal d 2 with 5% vitamin C (dotted line) using the corresponding buffer without or with vitamin C as the background, (B) ATR-FTIR spectra in the wavenumber range from 1450 to 1750 cm^{-1} which have been normalized to the amide I peak.

The RBL assay allowed the characterization of individual and specific IgE response of each selected patient to native and differently treated Mal d 2. Each serum was tested, and the results were presented separately to demonstrate the individual patient response in a component-resolved manner. Sera of all patients showed no to only very weak affinity for native Mal d 2, which is in correspondence with IgE Western blotting (Figures 4 and 5). Stimulation of the RBL cells with heat-denatured as well as vitamin C heat-treated Mal d 2 induced an

Table 2. Clinical History of Six Patients with Positive OAS or SPT for Apple Whose Sera Were Selectively Reactive to Reduced Mal d 2 in IgE Western Blotting

patient no.	OAS	asthma	urticaria	SPT to inhalative allergens	SPT to nutritive allergens
I	apple, hazelnut, plum	+	−	birch	apple, hazelnut

VI	apple, stone fruits, nuts	+	+	ash, birch, plantain	apple, peach, hazelnut, soybean

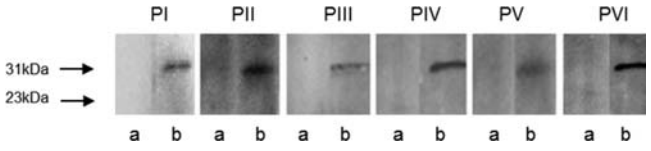

Figure 4. Screening of patient sera by IgE Western blotting. The IgE Western blots of (a) native Mal d 2 and (b) reduced Mal d 2 with sera of six patients (I–VI) show a positive reaction to chemically reduced Mal d 2.

increased β-hexosaminidase release, while native Mal d 2 did not increase the mediator release (Figure 5). Heat-treated Mal d 2 caused a β-hexosaminidase release with patient sera I, II, IV, V, and VI which is higher compared to the response induced by native Mal d 2 (Figure 5). The serum of patient VI showed the highest β-hexosaminidase release by heat-treated Mal d 2 (Figure 5). The results showed that heat treatment and addition of vitamin C could not influence the IgE reactivity to Mal d 2. Due to the high toxicity of sulfur, its addition could not be examined in the RBL assay.

Previously it was shown that conformational changes of Mal d 2 induced by chemical reduction of disulfide bridges are responsible for enhanced binding to IgE molecules.[8] In the cell-based RBL assay the hexosaminidase release is lightly increased in the majority of sera by heat-denatured and vitamin C-treated Mal d 2 compared to native Mal d 2, although remaining at low levels, <10% (Figure 5). The low affinity of Mal d 2 for the patients' RBL cell receptor-bound IgE can be explained by the rapid refolding as described previously.[8]

Skin Prick Test and Oral Smear Test. To examine the clinical relevance of native and heat-treated purified Mal d 2, SPTs and OSTs were performed. Patients developed neither a skin nor an oral reaction to native, heat-treated, or vitamin C-treated Mal d 2. The lack of skin reaction in SPTs to heat- and vitamin C-treated Mal d 2 can be attributed to the stability of Mal d 2.[8] The refolding kinetic study of Mal d 2 via CD showed that the molecule refolds after a few minutes, and the refolding spectrum overlaps almost exactly with the spectrum of the native protein.[8]

High prevalence of IgE reactivity to Mal d 2 strengthened the assumption that it might also be involved in the development of severe reactions due to high structural stability.[6−9] However, it was reported that five out of six Mal d 2-sensitized patient sera reacted exclusively with carbohydrate epitopes on the upper glycosylated variants of the allergen.[9] Whereas the impact of sensitization to glycosylated Mal d 2 still remains unclear, only 15% of patient sera reacted with the nonglycosylated recombinant Mal d 2, which supports the crucial role of

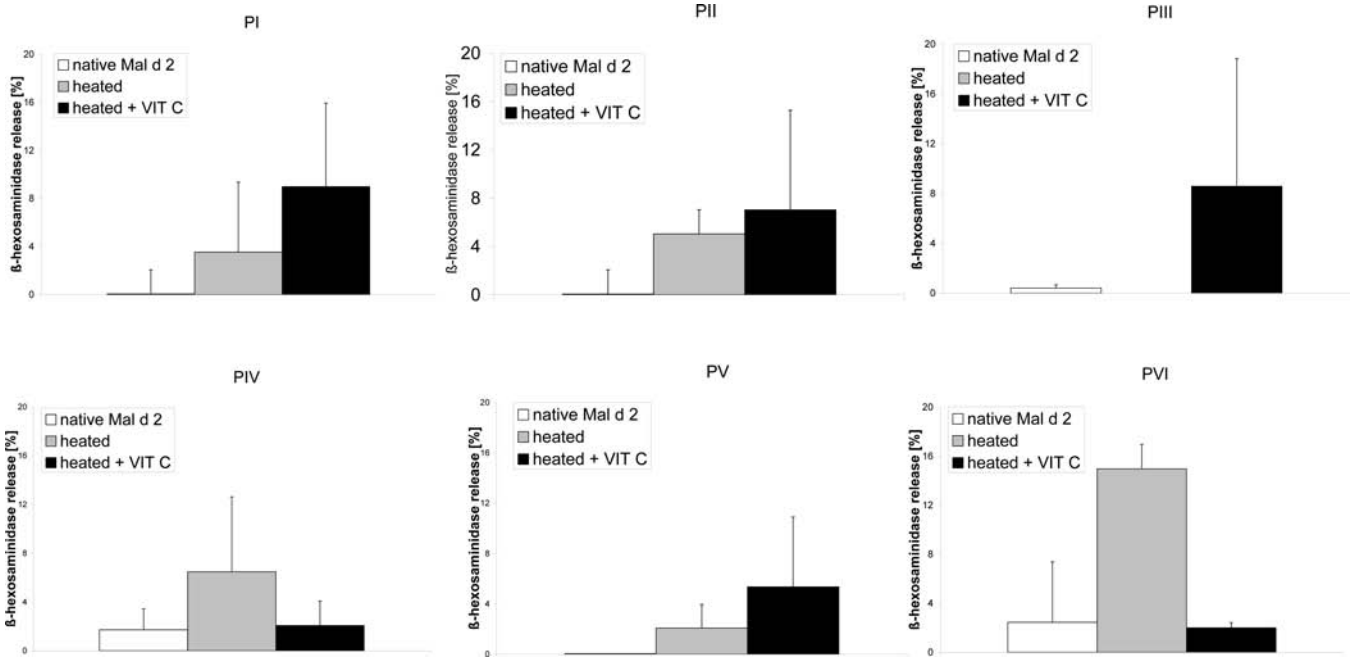

Figure 5. Results of β-hexosaminidase release in RBL assay from six tested patient sera (PI–PVI). The RBL cells are assayed using Tyrode's buffer as a negative control, native Mal d 2, heated Mal d 2, and heated Mal d 2 supplemented with 1% vitamin C. The patient sera showed variable reactivity if Mal d 2 was heated in the presence of vitamin C. The serum of patient VI displayed 2 times more reactivity to heated Mal d 2 than the other sera.

dx.doi.org/10.1021/jf5020878 | J. Agric. Food Chem. 2014, 62, 7622−7630

glycosylation in sensitization and IgE reactivity.[9] The obtained MS results demonstrate that a minor fraction of Mal d 2 is glycosylated to a low extent (Figure 1B).

For patient sensitization and production of IgE's reactive to Mal d 2, natural exposure to other TLPs must also be taken into consideration since Mal d 2 shares >50% identity with other TLPs. For example, Pru p 2 from peach shows the closest homology of almost 85% with Mal d 2.[24] In this context, the presence of common epitopes, offering the molecular basis for cross-reactivity, is of crucial importance.[26] Previous observations showed that Mal d 2 reacts with human IgE's mainly after complete denaturation by destruction of disulfide bridges, which fix the intramolecular α-helical domain II.[8,9] Lack of skin reactivity to native and heat- and vitamin C-treated Mal d 2 confirmed the previous assumption that allergenic epitopes of native Mal d 2 must be cryptic within molecular structures[8] and the conformationally intact protein is not presenting reactive epitopes for an in vivo reaction.

Detection of Mal d 2 and Mal d 1 in Different Cultivars. To demonstrate the variations in the content of Mal d 2 and Mal d 1 in different apple cultivars, Western blotting and SDS−PAGE using polyclonal antibodies directed to these allergens under reducing conditions were performed. Bands with different intensities indicated the variable and relative allergen contents among different cultivars (Figure 6). The

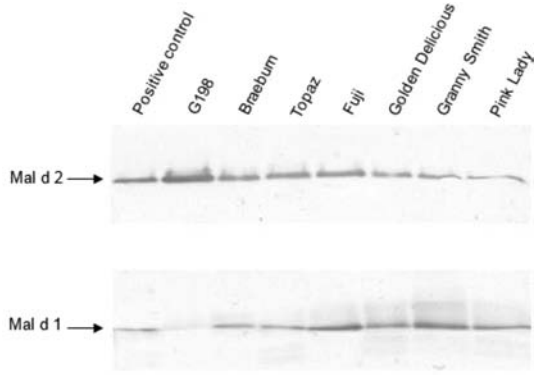

Figure 6. Semiquantitative determination of Mal d 1 and Mal d 2 in different apple cultivars (G198, Braeburn, Topaz, Fuji, Golden Delicious, Granny Smith, Pink Lady) grown under conventional conditions analyzed by reducing SDS−PAGE and Western blot. Mal d 2 and Mal d 1 were detected with polyclonal anti-Mal d 1 and anti-Mal d 2 antibodies. The positive control is 0.5 μg of native Mal d 2 and Mal d 1.

obtained results revealed a cultivar-dependent variability of the Mal d 2 content, comparable to the previously known variation of Mal d 1, determined quantitatively by a specific enzyme-linked immunosorbent assay (ELISA).[17] The protein bands for both apple allergens Mal d 2 and Mal d 1 showed almost identical intensities in the cultivars Braeburn, Topaz, Fuji, Golden Delicious, Granny Smith, and Pink Lady.

However, the band intensity of Mal d 2 was highest for the breeding line G198, which was shown previously to have a significantly lower content of Mal d 1 (3.47 μg/g) compared to the known cultivars Braeburn, Fuji, Golden Smith, Granny Smith, and Pink Lady (Figure 6).[17] Pathogen attack was reported to increase the expression of TLPs in apple apoplasts, which means that pathogen resistance is related to and responsible for the TLP content.[28,29] Additionally, factors such as climate and environmental changes and storage and cultivation practice influence the expression levels of TLPs in apples.[30]

Mal d 1, the major allergen of apple, belongs to the PR-10 family and is also expressed in response to fungal or bacterial infection and stress.[17] In a previous study the content of Mal d 1 was shown to be rather high in Braeburn, Fuji, Golden Delicious, Granny Smith, and Pink Lady.[17] The high levels of PR-10's were considered an indication of longevity and high stress or pathogen resistance during storage.[27] Experimental down-regulation of PR-10 proteins in *Medicago truncatula* resulted in an antagonistic induction of TLPs and an increased tolerance to pathogens.[31]

Detection of Mal d 2 and Mal d 1 in Different Apple Products. To investigate the availability of the minor apple allergen Mal d 2 and the major apple allergen Mal d 1, Western blots were performed with extracts of different apple products obtained from local markets (Figure 7).

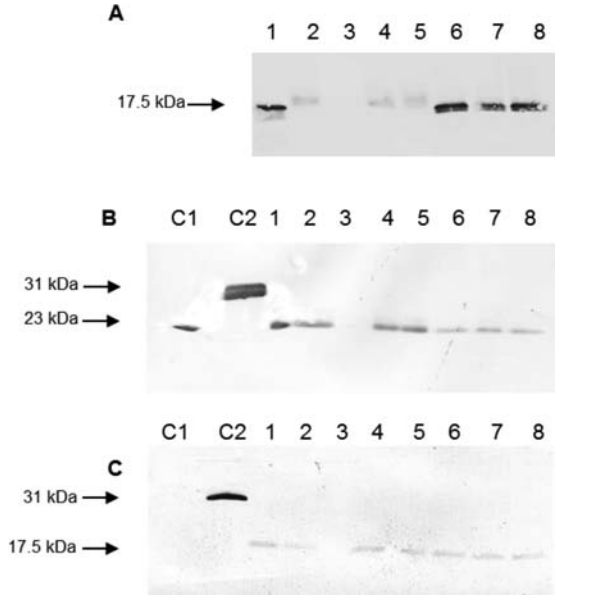

Figure 7. SDS−PAGE and Western blot analyses of different apple products: (A) Western blot using polyclonal rabbit antibody against Mal d 1, (B) Western blot using polyclonal rabbit antibody against Mal d 2, (C) IgE Western blot using the patient serum pool. Key: (C1) native Mal d 2, (C2) chemically reduced Mal d 2, (1) positive control "apple extract Topaz", (2) apple chips nonsulfured, (3) apple rings sulfured, (4) apple rings nonsulfured, (5) apple baby food, (6) clear apple juice, (7) cloudy apple juice, (8) clear organic apple juice.

Analyses of apple-derived foods revealed that Mal d 2 can be detected as the native 23 kDa band in nonsulfured dried apple products (Figure 7B). Mal d 2 was previously detected on two-dimensional electrophoresis (2-DE) gel maps of reduced and not reduced apple extracts.[10] It was shown that chemically reduced Mal d 2 migrated as a protein band at 31 kDa in SDS−PAGE and was reported as IgE reactive.[5,10] The same altered mobility was also reported for the homologous allergen Pru ap 2 from peach.[32] However, the correlation between denaturation of Mal d 2 by reduction of disulfide bridges and its allergenicity is unclear so far. It could be demonstrated that the IgE reactivity of the reduced form of Mal d 2 was recovered after reoxidization of Mal d 2.[8] In fact, the results indicate that Mal d 2 is mostly available as nonreduced native protein in nonsulfured apple products and is not reactive to patients'

IgE's (Figure 7B,C). The same samples were analyzed using patient sera to characterize the patient reactivity to Mal d 2 in the apple-derived products (Figure 7C). The sera reacted strongly only to the positive control, a reduced Mal d 2 band at 31 kDa, and weakly to Mal d 1 at 17.5 kDa in all apple products except sulfured apple rings.

Within the experiment, the major allergen from apple Mal d 1 was also investigated in parallel due to its significant susceptibility to heat treatment and high processing pressure.[27,33] Detection of Mal d 1 is an indication that none of the analyzed products were heated or treated by pressure except sulfured apple rings (Figure 7A). The reactive bands to Mal d 1 polyclonal antibodies are diffuse and shifted in apple samples such as dried and nonsulfured products as well as baby food (Figure 7A), which show protein degradation or aggregation.

Sulfurization is used in the manufacturing of dried food as a pretreatment before hot and cold drying processes to increase the shelf life and to act as an antimicrobial agent.[34] Due to health risks for consumers, the addition of sulfur to food is currently limited by regulations.[34] The investigation of commercially available apple products confirmed the assumption that nonsulfured apple products contain detectable amounts of native Mal d 2. However, the food allergy is mediated through IgE's bound to the surface of mast cells and basophils.[35,36] If the allergen protein binds to the specific IgE's, it can potentially cause the release of histamine and other mediators responsible for the clinical symptoms. Food pretreatments such as sulfurization and subsequent hot drying in combination with food preservatives such as vitamin C were shown to denature food allergens and lead to a reduction or an enhancement of binding to IgE-reactive epitopes.[37,38] It has been demonstrated that irreversible heat-denatured allergens can cause increased binding to immunoglobulin by the exposure of different sets of epitopes in a mouse model.[35,36] Remarkable structural stability and resistance to proteolysis has been linked to potentially increased risks of peptide allergens which survive food treatments and the digestive tract.[39] However, a prerequisite for sufficient IgE reactivity remains the presentation of IgE-binding epitopes.[35]

In conclusion, sulfur is able to degrade or modify Mal d 2 only in combination with heat treatment. Vitamin C, however, is too weak as a reducing agent to cause breakage of the disulfide bridges or protein defolding. The result of the RBL assay confirmed that the individual patient sera can bind to heat-treated purified Mal d 2 to various extents, but the overall affinity for Mal d 2 remained significantly low to nonexistent. The ATR-FTIR results confirmed only minimal changes at α-helices comparable to those observed during thermal unfolding.[8] However, the molecule remained tightly held by eight disulfide bridges and resisted defolding in the presence of vitamin C.

The results of our studies confirm that (a) only the treatment with hot sulfites is able to destroy Mal d 2 and (b) the lack of patient symptom development to apple Mal d 2 is attributed to the absence of defolded IgE-reactive Mal d 2 in fresh and processed apple products. Additionally, current data substantiate that Mal d 2 is present mainly in its native nonreactive conformation in the apple products and cannot be seen as a major health risk for sensitized consumers.

could enter the colon with the potential to influence colonic health.[16,18]

MATERIALS AND METHODS

Chemicals. Cyanidin 3-*O*-glucoside was purchased from Apin Chemicals (Abingdon, Oxford, U.K.), cyanidin 3-*O*-sambubioside 5-*O*-glucoside was supplied by Polyphenols (Sandnes, Norway), morin and ellagic acid were obtained from Sigma-Aldrich (Poole, Dorset, U.K.), and punicalagin was obtained from Chromadex (United States). HPLC-grade solvents were obtained from Rathburn Chemicals (Walkerburn, U.K.). Formic acid and sodium diethyldiothiocarbamate were purchased from Sigma-Aldrich, and acetic acid was purchased from BDH (Poole, U.K.).

Plant Material and Processing. Raspberries (30 kg, *R. idaeus* variety Glen Ample) were purchased from Peter Marshall & Co., Alyth, Perthshire, U.K. The raspberries were picked as commercially ripe and transported to the James Hutton Institute on the day of picking, where they were washed in distilled water, left to drain on sieves, and then pureed in 10 kg batches using a catering homogenizer (Fimar MX40S fixed speed stick blender). The procedure did not homogenize the seeds. The purees were combined and continually stirred using an overhead paddle stirrer at 75 rpm (to prevent settlement) and ladled into food-grade bags in 300 ± 1 g amounts. The purees were frozen, transported to the University of Ulster, and stored at −20 °C prior to use in the ileostomy feeding studies.

Ileostomy Feeding Study. The study (11/NI/0112) was conducted with the prior approval of the Office for Research Ethics Committees Northern Ireland (ORECNI) and the University of Ulster Ethical Committee and with the informed consent of participants who were recruited from clinics at Altnagelvin Area Hospital, with the assistance of a colorectal consultant (Dr. R. Lawther) and nurse specialist (Dr. G. O'Connor). Eleven ileostomists (six males, five females, mean age 44 ± 12 yr) who had undergone terminal ileostomies and were at least 1.5 years postoperative prior to the study and were nonsmokers undertook the study. Participants were required to follow a diet low in polyphenolic compounds as described previously,[14] avoiding fruits and vegetables, nuts, high-fiber products, and beverages such as tea, coffee, and fruit juices, as well as abstaining from consumption of alcohol for 48 h prior to the beginning of the study. Following an overnight fast, the participants provided an ileal fluid sample (T 0 h), then consumed 300 g of homogenized raspberries within 10 min, and continued the low polyphenolic diet, with provision of a standard lunch, for a further 8 h until provision of the second ileal fluid sample (T 8 h). The ileal fluid samples were collected and processed within 30 min. The volumes and pH values of the ileal fluid were recorded, before dilution with ice-cold distilled water as required, dependent on the viscosity, and before the fluid was homogenized in a chilled Waring blender for 30 s and storage of aliquots at −80 °C in preparation for subsequent analysis.

Targeted Analysis of Raspberry Phenolics in Ileal Fluids. Duplicate samples of ileal fluid (2 ± 0.1 g) were spiked with 10 μg of cyanidin 3-*O*-sambubioside 5-*O*-glucoside as an internal standard and homogenized in 3 mL of 1% aqueous formic acid (FA) containing 20 mM sodium diethyldiothiocarbamate (DDC) for 1 min at 24 000 rpm using an Utra-Turrax homogeneizer. The samples were centrifuged for 20 min at 4000*g* at 4 °C, and the supernatants were collected. The pellet was re-extracted twice with 1% formic acid in methanol containing 20 mM DDC, and the three supernatants were pooled. Portions (4 mL) of this extract were reduced to dryness in vacuo using a SpeedVac concentrator. The residues were resuspended in 50 μL of 1% formic acid in methanol and 450 μL of 1% formic acid, and 100 μL aliquots were analyzed by HPLC-PDA−MS^2 (PDA = photodiode array).

The samples were analyzed on a Surveyor HPLC system comprised of an HPLC pump, a PDA detector, scanning from 200 to 700 nm, and an autosampler cooled to 4 °C (Thermo Finnigan, San Jose, CA). Separations of ellagic acid derivatives, ellagitannins, and anthocyanins from raspberry were performed using a Synergi 4 μm RP-POLAR 80 Å 250 × 4.6 mm i.d. reversed-phase column (Phenomenex, Macclesfield, U.K.) maintained at 40 °C. The mobile phase, pumped at a flow rate of 1 mL/min, was 1% aqueous formic acid (A) and 99% methanol containing 1% formic acid (B), establishing a linear gradient from 10% to 40% B over 60 min. Chromatograms were recorded at 280, 325, 365, and 520 nm. After passing through the flow cell of the diode array detector, the column elute was split, and 0.3 mL/min was directed to an LCQ DecaXP ion trap mass spectrometer fitted with an electrospray interface (ESI) operating in either positive ionization mode for anthocyanins or negative ionization mode for ellagic acid and ellagitannins. Analyses were carried out using full-scan, data-dependent MS^2 scanning from m/z 150 to m/z 2000. With the ESI in positive ionization mode, the capillary temperature was 300 °C, the amount of sheath gas was 50 units, the amount of auxiliary gas was 35 units, and the source voltage was 2 kV. For negative ionization, the capillary temperature was 325 °C, the amounts of the sheath and auxiliary gases were both 40 units, and the source voltage was 4 kV.

Anthocyanins were quantified from their chromatographic peak areas recorded at 520 nm and expressed as cyanidin 3-*O*-glucoside equivalents, ellagitannins detected at 260 nm were expressed as punicalagin equivalents, and ellagic acid and ellagic acid conjugates monitored at 365 nm were quantified in ellagic acid equivalents.

Untargeted Analysis of Raspberry Metabolites in Ileal Fluids. Ileal samples were extracted by the procedure described above with small differences. The frozen samples were thawed and vortexed, and duplicate 2.0 ± 0.1 g samples were weighed into 15 mL centrifuge tubes. These samples were extracted using 3 mL of UPW containing 1% formic acid and 20 mM DDC. The tubes were vortex-mixed for 3 × 30 s and then sonicated in a water bath for 1 min. All procedures were carried out at 5 °C. After centrifugation (2500*g*, 10 min, 5 °C), the supernatants were transferred to new tubes. The pellets were extracted twice using 3 mL of 1% formic acid in methanol containing 20 mM DDC and the supernatants combined and vortex-mixed. A subsample of 4 mL was removed and dried in a Speed-Vac. The dried samples were resuspended in 10% acetonitrile containing 0.2% formic acid and prepared in filter vials prior to analysis using the orbitrap LC−MS system.

Untargeted analysis of the ileal fluids was performed on an HPLC system consisting of a quaternary pump (Thermo Fisher Scientific, Accella 600) and a PDA detector (Thermo Fisher Scientific, Accella) coupled to an LTQ orbitrap mass spectrometer (Thermo Fisher Scientific, Stafford House, Boundary Way, Hemel Hempstead, U.K.). Replicate 10 μL samples were injected onto a 2 × 150 mm (4 μm) Synergy Hydro-RP 80 fitted with a C18 4 × 2 mm Security Guard cartridge (Phenomenex Ltd.). Sample and column temperatures were maintained at 6 and 30 °C, respectively. The samples were analyzed at a flow rate of 0.3 mL/min using a binary mobile phase of (A) 0.1% aqueous formic acid and (B) 0.1% formic acid in acetonitrile/water (1:1, v/v) and the following gradient: 0−4 min, 5% B; 4−22 min, 5−50% B; 22−32 min, 50−100% B. Mass detection was carried out using an LTQ orbitrap mass spectrometer in negative ESI mode.

Two scan events were employed; full-scan analysis was followed by data-dependent MS/MS of the three most intense ions using collision energies of 45 eV source voltage (set at 3.4 kV) in wide-band activation mode. The instrument was optimized (tuned) against morin at a resolution of 30 000 (to maximize the number of scans across peaks but retain a reasonable resolution) in a range of 80−2000 mass units. For optimal electrospray ionization, the source conditions were set at a source temperature of 300 °C, a sheath gas amount of 60 arbitrary units, and an auxiliary gas amount of 5 arbitrary units. Prior to analysis, the mass accuracy of the instrument was assured by calibrating using a preparative ESI negative ion calibration tuning solution (containing 2.9 μg/mL sodium dodecyl sulfate, 5.4 μg/mL sodium taurocholate, and 0.001% Ultramark 1621) following the manufacturer's protocols.

SIEVE Analysis. Mass spectral data from the orbitrap analysis were applied to the SIEVE software program (Thermo Fisher Scientific, Hemel Hempstead, U.K; http://www.thermoscientific.com/en/product/sieve-software-differential-expression.html). The SIEVE method compares and contrasts multiple samples on the basis of the nature of the experimental setup. In this case, the samples were labeled

either before or after, and the program was set to discern which MS signals were consistently present and increased in the after-supplementation samples. As the SIEVE software automatically detects and integrates peaks, it can also provide lists of peaks that are consistently decreased after feeding. SIEVE parameters were chosen which have been shown in our laboratory to be effective for this pairwise comparison of samples. These parameters define the optimum and maximum numbers of peaks, peak threshold values, a delayed retention start of 5 min to dismiss unbound material, and suitable peak width parameters to allow for drifts in retention time between runs and samples. These settings have been used to accurately align and "bin" signals from mass spectral data from multiple chromatograms. The output, as peak areas for the detected peaks, can be accessed in Excel file format and used to develop principal component analysis (PCA) plots and other models.

Data Analysis and Conditions. Statistical analysis was carried out on all the variables collected from the LC−MS analysis of the samples. Data were obtained as peak areas from the SIEVE automatic integration software and consisted of 862 variables or potential peaks. Three approaches were taken: First, PCA, using univariate scaling, was applied to all the samples, and components 1−4 described 42% of the variation in the data set, with component 1 describing almost 17%. Second, a discriminant analysis (optimized partial least squares, OPLS) was performed with two classifications (before feeding and after feeding), resulting in a model that described 33% of the variation, 14% of which described the after feeding classification. The Q^2 score for this model was 0.974. These analyses were performed using SIMCA-P 12.0.1.0 software. The third analysis performed was pairwise metabolite−metabolite correlations (using Genstat for Windows, 16th ed., VSN International Ltd., Hemel Hempstead, U.K.), determined by Pearson's correlation coefficient (r) test using two sample sets, first all samples and then a subset consisting of the "after feeding" samples. This technique was used to define components whose patterns of abundance matched those of components identified by the targeted analysis and provide a subset which was likely to have arisen from the berry material.

Extraction and Analysis of Extracts from Raspberry Seeds. Raspberry seeds were isolated from the purees by repeated sieving and washing using ice-cold distilled water. The seeds, which were free of attached material, were dried using paper tissues and stored at −18 °C. The extraction procedure was essentially the same as noted above for the untargeted study, but only 200 mg of seeds was extracted and the volumes were reduced to 1 mL. After the 1 mL extracts were dried in the Speed-Vac, they were resuspended in 5% acetonitrile containing 0.1% FA and prepared in filter vials.

Samples of resolubilized extracts were analyzed using an LCQ-DECA system, comprising a Surveyor autosampler, pump, and PDA detector, and a Thermo-Finnigan ion trap mass spectrometer controlled by Xcalibur software. A 2 mm × 150 mm C18 column (Synergi Hydro C18 with polar end-capping, Phenomenex Ltd.) was eluted with a binary solvent of (A) 0.1% aqueous formic acid and (B) 0.1% formic acid in acetonitrile at a flow rate of 200 μL/min using a 30 min gradient of 5−40% B. The PDA detector scanned three discrete channels at 280, 365, and 520 nm. The mass data were collected in negative or positive mode scanning over the mass range m/z 80−2000. The MS detector was tuned against morin in negative mode and cyanidin 3-*O*-glucoside in positive mode. Two scan events were employed; full-scan analysis was followed by data-dependent MS/MS of the most intense ions using collision energies of 45% of the source voltage (set at 3 kV) in wide-band activation mode. The capillary temperature was set at 250 °C, with the sheath gas pressure at 60 psi and auxiliary gas pressure at 15 psi.

RESULTS AND DISCUSSION

This study confirms and extends previous research that examined the fate of anthocyanins, the major ellagitannins, and ellagic acid derivatives from raspberries excreted in ileal fluid by subjects with an ileostomy.[14] The 11 ileostomists participating in the current study had a mean age of 44 ± 12 yr, and the group mean ileal fluid sample mass at baseline (T 0 h) was 187.8 ± 73 g (range 107.4−318.0 g) with a group mean pH value of 5.6 ± 0.4 (range 5.0−6.3). The group mean ileal fluid mass for the T 8 h sample (post berry consumption) was 268. ± 108 g (range 62−470 g) with a group mean pH value of 6.6 ± 0.6 (range 5.3−7.5). In both cases the group mean ileal fluid masses and pH values were significantly ($p < 0.05$) increased compared to those of the baseline fasted samples.

Eight anthocyanins were detected in Glen Ample raspberries (Table 1). Although the composition was comparable to that detected previously in this variety of raspberries,[14,19,20] the amounts of anthocyanins and the ellagic acid derivatives were lower than in the berries used in a previous feeding study.[14] The overall levels of ellagitannins were similar, but the profile was different, with lower levels of sanguiin H-6 and higher amounts of sanguiin H-10 and lambertianin C. These differences may reflect differences in growing location or year-to-year variation, but the lower content of anthocyanins could indicate that the raspberries were not as ripe as those used in the previous study, which were picked directly from the field as opposed to being part of a shipment of raspberries to be delivered to a supermarket.

Table 1. Identification and Quantification of Phenolic Compounds Detected in Raspberries

peak	compd	t_R (min)	$[m/z]^+$	MS^2 m/z	concn[a] (μmol/300 g)
1	cyanidin 3,5-*O*-diglucoside	18.1	611	449, 287	0.6 ± 0.1

[a]In the first column for each subject, the data are expressed as mean values in micromoles ± standard error (n = 2). The numbers in the second column for each subject represent the amounts recovered as a percentage of the quantity ingested. nt = not detected. Anthocyanins, ellagic acid, and ellagitannins were not detected in ileal fluid samples collected at time 0 h before raspberry intake. S1 = subject 1, S2 = subject 2, and so on. Subject 7 did not complete the study, and therefore 11 subjects are described.

Five of the major anthocyanins in the raspberries were consistently detected in the ileal fluids collected from the 11 donors after supplementation (Table 2). The most abundant anthocyanin in the raspberries, cyanidin 3-*O*-sophoroside, was also the main anthocyanin in the ileal fluids, but the recovery varied greatly between the subjects (from 2% to 36% of intake, mean 21.7%, Table 3). Other anthocyanins that were less abundant in the raspberries, such as cyanidin 3-*O*-(2″-glucosyl)rutinoside and pelargonidin 3-*O*-sophoroside, often had higher precentage recoveries than cyanidin 3-*O*-sophoroside. The order of recovery was cyanidin 3-*O*-(2″-glucosyl)-rutinoside > pelargonidin 3-*O*-sophoroside > cyanidin 3-*O*-sophoroside > cyanidin 3-*O*-rutinoside > cyanidin 3-*O*-glucoside (mean recoveries 28.6%, 24.0%, 21.7%, 9.2%, and 1.3%, respectively), but again with substantial interindividual variation. These recoveries were lower than but showed the same order as those observed previously.[14]

The major ellagitannins detected in raspberries were also detected in the ileal samples after supplementation (Tables 2 and 3). Sanguiin H-6 was the most abundant in the ileal samples, but as with the anthocyanins, there was a large interindividual variation in recoveries (1−64%, mean 30.5%). Sanguiin H-10 was generally recovered at higher levels (1−31%, mean 13.8%) than lambertianin C (0−35%, mean 8.2%), but again with large interindividual variation. The recovery figures may reflect their innate relative stability to the conditions of the upper gastrointestinal tract, but it also possible that some components are formed through degradation of larger ellagitannins. For example, sanguiin H-6 is a potential degradation product of lambertianin C, and sanguiin H-10 could be formed during the degradation of sanguiin H-6. Indeed, in vitro digestion studies indicated an increased recovery of sanguiin H-10 isomers which was suggested to be due to breakdown of the larger ellagitannins.[21,22]

Table 3. Mean Recovery of Anthocyanins, Ellagic Acid, and Ellagitannins in Ileal Fluid Collected from 11 Volunteers 0−8 h after Consumption of 300 g of Raspberries

compd	recovery	
	μmol (mean ± SE)	% of intake
cyanidin 3-*O*-sophoroside	4.7 ± 0.8	21.7

cyanidin 3-*O*-glucoside	0.11 ± 0.04	1.3
cyanidin 3-*O*-rutinoside	0.23 ± 0.06	9.2
total anthocyanins	6.30 ± 1.22	16.3
ellagic acid *O*-pentoside	0.4 ± 0.1	33.0
ellagic acid	8.4 ± 1.5	175.7
total ellagic acid	8.8 ± 1.6	146.6
sanguiin H-10	6.0 ± 1.3	13.8
sanguiin H-6	18.7 ± 4.9	30.5
lambertianin C	1.6 ± 0.9	8.2
total ellagitannins	26.3 ± 7.1	21.2

Although the levels of ellagic acid pentoside were generally reduced (recoveries 11−50%, mean 33%, Tables 2 and 3), ellagic acid was detected in the ileal fluids from all subjects at levels generally higher than in the raspberries (17−304%, mean 175.7%). This increase in ellagic acid most probably is a result of the degradation of ellagitannins and/or ellagic acid pentosides and release of ellagic acid as noted in model studies.[23] However, in the previous study[14] only sanguiin H-6 and ellagic acid were detected.

It is very noticeable that the recoveries of (poly)phenols in certain subjects were relatively high (e.g., subject 4) whereas those in other subjects (e.g., subject 5) were very low. This interindividual variation may be related to the differing physiology of the subjects. In particular, subject 5 had the lowest output of ileal fluid, which may indicate slow passage of the berries through the intestine or lower levels of intestinal secretions. Subject 1 had the highest ileal output and had higher than average recovery of anthocyanins but poorer recovery of sanguiin H-6 (Table 2). Overall, the targeted analysis provided evidence for the differential stability of the anthocyanin, ellagitannin, and ellagic acid derivatives following consumption of raspberries and largely confirmed previous findings.[14]

For the nontargeted approach, the ileal samples were examined by LC−MS/MS using an orbitrap mass spectrometer capable of exact mass determination. This confirmed the presence of the major anthocyanins, ellagitannins, and ellagic acid derivatives detected by the targeted analysis as can be seen in a characteristic absorbance profile of the "before"- and "after"-supplementation samples (Figure 1a). The presence of anthocyanins could be detected by examining the elution profiles at 520 nm (Figure 1b). There was a good association between the targeted and nontargeted analyses as indicated by a comparison of the levels of anthocyanins and the levels of the major ellagitannin peak, sanguiin H-6 (see the Supporting Information, Figure S1). Indeed, it was apparent that the interindividual variabilities in recoveries were similar between the targeted and nontargeted analyses. However, it also became clear that certain subjects had very different profiles. In particular, subjects 1 and 5, and to a lesser extent subject 10, gave a different PDA profile in the after-supplementation samples (Supporting Information, Figure S2). Their profiles

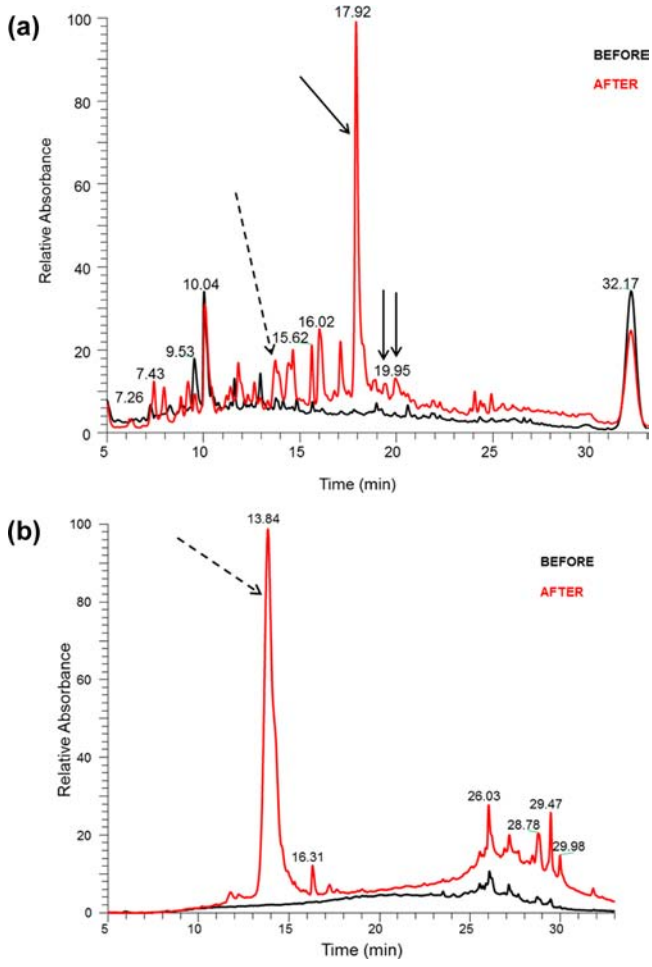

Figure 1. (a) Characteristic UV traces for ileal samples before and after supplementation. Traces from subject 6 are shown before and after (red) supplementation with raspberries. The black arrows denote the positions of the sanguiin H-6, ellagic acid pentose, and ellagic acid peaks. The dashed arrow denotes the position of the main anthocyanin peak. The figure in the top right corner is the full-scale deflection of the PDA detector at 280 nm. (b) Traces at 520 nm of ileal samples before and after supplementation. Traces from subject 6 are shown before and after (red) supplementation with raspberries. The dashed arrow denotes the position of the main anthocyanin peak. The figure in the top right corner is the full-scale deflection of the PDA detector at 520 nm.

were dominated by two peaks (t_R = 9.72 and 13.76 min) with PDA and m/z data characteristic of caffeoylquinic acids (PDA maximum ∼320 nm; [M − H], m/z 353; MS^2, m/z 191), arguably indicative of coffee intake by the subjects during the supplementation period.[24]

The chromatographic profiles were examined visually to discern peaks that consistently increased after supplementation, but the human element was supplemented by a nontargeted method. The MS data from all of the samples including blanks and the quality control samples were examined using the SIEVE software program, which selects peaks that increase or decrease significantly after supplementation. The SIEVE approach is completely unbiased and provides data to produce principal component analysis plots illustrating the differences and similarities between the samples (see Figure 2). The before and after samples were separated mainly on the t[1] axis (which explains 17% of the variation). Certain before and after samples

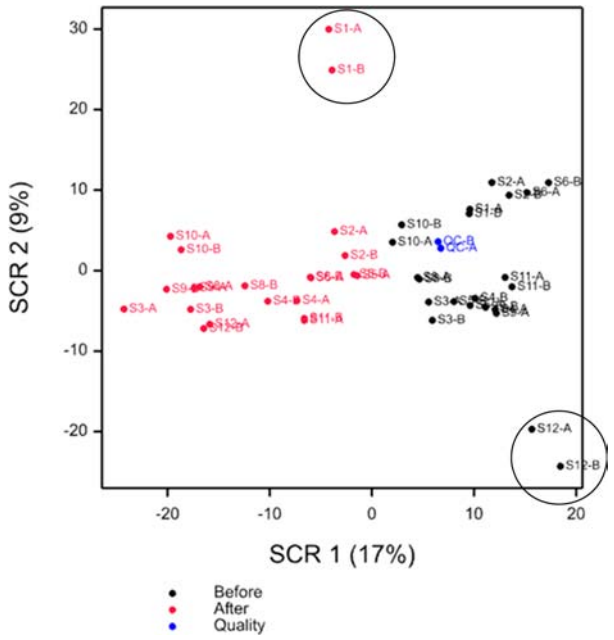

Figure 2. Principal component analysis of the samples from the ileostomy study using the SIEVE process. Black markers represent the before samples, and the red markers represent the after samples. The blue markers are the quality control samples, which were prefeeding samples (subject 10) given blind before extraction. Axis t[1] explains 17% of the variation and t[2] 9%. The double-headed arrow shows the separation of replicate samples along axis t[1]. The circles annotate samples discussed in the text.

were separated from the others; e.g., the S1-2 (after) replicates were displaced from the other after samples, and the S12-1 (before) samples were also separated from the other before samples. In most cases, the replicate extractions were tightly bunched, but some replicates (e.g., S3-2) were slightly but definitely separated (see the arrows, Figure 2). The SIEVE output data were also plotted as bar charts to illustrate peaks/metabolites that show similar patterns of increased or decreased levels across the subjects. For example, the first approach taken was to select peaks that not only increased after supplementation but also had a pattern of recovery similar to that of the main ellagitannin peak, sanguiin H-6, across the subjects (see Figure S3a, Supporting Information). This subjective approach should focus on components that have arisen from the supplementation. However, when we analyzed the SIEVE data using an unbiased approach, a near-identical list of peaks was generated (results not shown). It is also possible to select for peaks that systematically decreased across the subjects after raspberry intake, but although this may be very interesting, this was not a priority in this study. Using this approach, we identified peaks such as ellagic acid pentose (Figure S3b) and an unidentified component with m/z = 355 (Figure S3c). Once this subset of peaks had been identified and the quality of the peaks was checked to ensure that they were not artifacts, this subset of peaks was assessed against previous reports and the m/z, MS^2, and exact mass data were employed to putatively identify the components (Table 4).

It was noted that the ileal samples contained intact raspberry seeds that had survived the digestion process. Although the ileal samples were well mixed before extraction, they were not milled in a fashion that would homogenize the seeds, as this does not occur in vivo. Therefore, it is possible that some of the variation between replicate extractions as illustrated in the PCA plot (Figure 2) could have been caused by different numbers of seeds being present in replicate samples. To examine which components could be extracted from the raspberry seeds, the seeds were separated from some of the original raspberry puree, then extracted under identical conditions, and examined using similar LC conditions but using an ion-trap MS detector (Figure 3). A number of components were identified in the seed extracts that had been identified in the ileal samples. The major component was the ellagitannin sanguiin H-6, but there were also other ellagitannins and some proanthocyanidin (PAC) components (see Table 5). In particular, the seeds contained a peak with PDA and MS properties consistent with a proanthocyanidin dimer composed of (epi)afzelchin and (epi)catechin (peak 12, Table 5; PDA maximum 275 nm; [M − H], m/z 561; MS^2, m/z 543, 435, 289) and a proanthocyanidin dimer composed of (epi)catechin units (peak 8, Table 5; PDA maximum 275 nm; [M − H], m/z 577; MS^2, m/z 559, 533, 289). There was also evidence for larger PACs containing (epi)afzelchin groups which was supported by further analyses of different extracts of the seeds (results not shown).

These findings highlight the possible contribution of raspberry seeds to the availability of phenolic components in ileal fluids. Raspberry seeds can make a considerable contribution to the total berry mass. Seed/flesh ratios of 20% have been reported, although values of ∼5% are more common for cultivated varieties, such as Glen Ample (Dr. Nikki Jennings, The James Hutton Institute, personal communication). Of course, the components extractable from the seeds (or the pulp) in the ileal fluid may not be equivalent to those extractable during digestion in the gastrointestinal tract. Such components may only become accessible during colonic digestion of the raspberry material and would be subject to degradation by fermentation. Raspberry seeds have evolved to survive gastrointestinal digestion. and it would be interesting to compare the components extractable from seeds after ileal digestion with those that are expelled in feces.

In essence, the components found by this nontargeted approach to be increased after raspberry supplementation can be split into four classes: (1) those that were also identified by targeted analysis, (2) those which are related to the targeted components, but may have been extracted from the seeds (Table 5), (3) components present in the raspberries which have become more abundant due to their stability in the gastrointestinal tract, and (4) unknown components which may also encompass some potential breakdown products or metabolites of the original berry polyphenols (Table 4).

Components suggestive of breakdown of ellagitannins include ellagic acid, which was identified in the targeted approach (Table 1). The presence of (epi)catechin and derivatives in the ileal fluid after supplementation (see Table 4) suggests breakdown of the proanthocyanidins, perhaps from the raspberry seeds (Table 5). Indeed, it is notable that epicatechin and (epi)afzelchin were not detected in the raspberry seed extracts. Components such as dihydroxybenzoic acid and hydroxybenzoic acid could appear due to anthocyanin degradation as the B-ring fragments from cyanidin and pelargonidin aglycons, respectively.[25,26] The putatively identified hydroxybenzoic acid glucoside and benzoic acid components could also arise from anthocyanin degradation. The hydroxycinnamic acids *p*-coumaric and caffeic acids have also been reported to be formed through the degradation of anthocyanins.[26] However, these hydroxycinnamic acids were

[a]Shading indicates the compounds were also found in the extracts of raspberry seeds. Asterisks denote doubly charged species, $[M - 2H]^{2-}$. Underlined masses are the main MS^2 fragments. Formulas in italics are predicted for MS^2 fragments.

also detected in ileal fluid after intake of a mixed fruit juice,[27] where they may have arisen from intake of hydroxycinnamic acid derivatives. Some other components, such as *p*-coumaroylquinic acid, indole 3-acetylaspartic acid, and the putative gibberellin-like derivatives, were present in raspberry in relatively low amounts, but became more apparent due to their stability in the small intestine.

The stringency of the SIEVE approach is illustrated in the case of the putative identification of a methylepicatechin sulfate derivative. Although three signals with *m/z* 383 can be discerned in most ileal samples after supplementation, only one peak was consistently and significantly increased. In addition, a peak putatively attributable to dihydrocaffeic acid sulfate (t_R = 5.1 min; *m/z* 261; MS^2, *m/z* 181 and 143) could be discerned in many after samples but was not selected by the SIEVE method. However, a set of three peaks with *m/z* 355 were identified by the SIEVE approach. These peaks all gave an exact mass that yielded a predicted formula of $C_{15}H_{15}O_{10}$ with a low mass deviation (~1 ppm). This formula matches that of a caffeic acid glucuronide, which has been identified in urine and plasma after coffee intake.[28] Indeed, the METLIN database provides this compound as a potential hit (http://metlin.scripps.edu/metabo_info.php?molid=96063). However, the MS^2 data do not fit, and in particular, there is no fragment at *m/z* 179 as expected for caffeic acid. Therefore, this component remains unidentified. Recent work by Sun et al. identified *m/z*

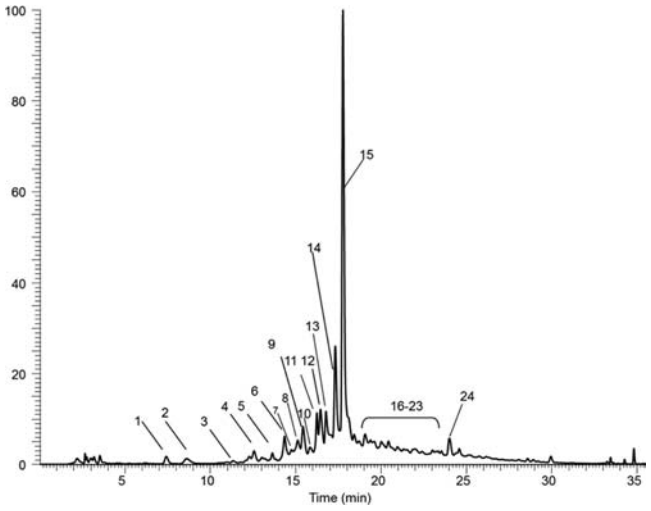

Figure 3. UV trace of components extracted from isolated raspberry seeds. The peaks denoted are described in Table 5. The figure in the top right corner is the full-scale deflection of the PDA detector at 280 nm.

signals at 191.0193 in strawberry extracts as citric acid,[29] and the main MS^2 fragment of the m/z 355 component is a good match for this structural formula ($C_6H_7O_7$, mass deviation <2 ppm). Therefore, this could be a citric acid metabolite.

As well as the sulfated metabolites already discussed, there is evidence for the apparently sulfated derivatives of dihydroxybenzoic acid, (epi)catechin, maitiresinol, caffeic acid, and ferulic acid. Sulfated derivatives of phenolic components of fruit juices have been identified in ileal fluid after juice intake.[27] However, further studies are required to confirm the identity of these derivatives. Such phase II metabolites could be produced in the wall of the small intestine, efflux back into the lumen, and as a consequence appear in ileal fluid. An alternative route could involve their absorption into the bloodstream and return to the small intestine via enterohepatic recirculation in the bile. However, recent studies with (−)-epicatechin metabolites indicate that recycling by the bile is at best a minor event.[30,31]

In conclusion, targeted and nontargeted LC−MS^n techniques have been used to identify components in ileal fluid that increase after raspberry intake. These components have survived digestion in the upper gastrointestinal tract and in healthy subjects with an intact functioning colon would enter the large intestine where they may influence gut function and health.[19] Understanding which components enter the colon is of benefit to estimate the possible health effects that may occur. Previous work has shown that components that enter the colon are subject to degradation by resident microbiota, usually to a simpler set of metabolites which may have their own potential bioactive effects.[22,32] This study confirmed previous work[14] that illustrated that considerable amounts of ellagitannins, ellagic acid derivatives, and anthocyanins survive and may enter the colon. However, the untargeted approach has extended the list of "known" components and identified new compounds that may arise from the seeds present in the raspberry purees as breakdown products of the original berry anthocyanins (e.g., hydroxybenzoic acid derivatives), a set of components that are enriched due to their stability, and unknown components yet to

Table 5. Phenolic Components in Extracts of Raspberry Seeds[a]

be identified. In addition, there is evidence for the presence of phase II sulfated and glucuronidated phenolic components, arguably produced in the enterocytes of the small intestine and effluxed back into the lumen.

Future work will focus on the identification of these metabolized components but will also examine the effect of in vitro fermentation of the ileal sample by colonic microflora before assessment of their bioactivities in cell models of colon cancer.[22]

Arch, in the period of 2005−2013, and comparing those results with the legislation available in the European Union (EU).

PRESENCE OF OTA IN BEER

Beer is a drink obtained from must alcoholic fermentation, mainly elaborated from germ barley solely or mixed with other cereals, starchy substances, yeast, and water. It is the third most consumed drink around the world after water and tea. In 2012, there were 182.69 million of kiloliters consumed, Asia being the continent that registered the highest consumption (33.6%), followed by Europe (27.7%), Latin America (16.215%), and North America (14.5%); nonetheless, the highest beer consumers per capita are found in the Czech Republic followed by Germany.[15]

In the past two decades there have been several studies confirming the presence of OTA mycotoxin in beers from all over the world. It has been stated in the European Commission's report that beer consumption contributes 5% of OTA intake.[16]

The origin of OTA mycotoxin in beer comes from contamination of prime material used for its processing as barley, malt, or cereal derivatives. Contaminated barley grains contain ochratoxigenic strains from *A. ochraceus* and *P. verrucosum*, which are transferred to beer. OTA provided by these strains on cereals is stable through the cooking process, but it suffers a reduction during beer production and, as a consequence, during fermentation it is the yeast that retains the original content of OTA (eliminating between 2 and 19% of OTA) and the rest is transmitted to the final consumable beer.[17]

The EU has not established limits for OTA in beer, because its presence in this drink should be controlled in another more appropriate phase of its production chain, specifically in malt prime material (Directive (UE) No. 105/2010);[18] however, several countries have established maximum permitted limits of OTA in beer, for example, The Netherlands (0.3 ng/mL), Finland (0.5 ng/mL), or Italy (0.2 ng/mL), and in research studies several authors have assumed a recommended limit of 0.2 ng/mL.[19,20]

Incidence and Presence of OTA in Beer. In this review, only published papers related to OTA in beer or wine from southern Europe, and more specifically from the Mediterranean Arch, from the past 10 years have been collected. The incidence of OTA in beer, as well as the range and OTA median concentrations found in this matrix in different studies, is summarized in Table 1.

Recent studies of OTA in beer show values of incidence varying from 14%[21] to 100%,[19] although in most of them the incidence was higher than those obtained by the European Commission[16] (set at 39% incidence in beer). The reason for these differences in the studies might be a consequence of the different detection methods and the malt quality used for its elaboration.

When studies are examine per country, the highest presence (100%) of OTA in beer samples was found in a study carried out in Spain,[19], compared with other published studies; however, only five samples presented concentrations above the assumed value of 0.2 ng/mL. These levels were similar to those reported by the European Commission[16] for Spain, where OTA was detected in 97% of the analyzed samples, but different from results obtained in other studies,[22] where no sample analyzed was OTA positive.

Another study carried out on beers from Navarra markets in Spain[24] reported that 77% of samples were OTA positive, but no sample exceeded the proposed legal limit and only one almost reached the proposed value (see Table 1).

Several studies reveal that the presence of OTA in beers from Italy is around 70%,[25,55] although the concentration levels detected were lower than those obtained in beers from Spain[24] (see Table 1). By relating these values with beers from other countries, such as Turkey, the presence of OTA decreases to 14%, with values below the one assumed as reference.[21]

To compare these results with studies carried out in other European countries, and turning to eastern Europe, data analysis of beer from Hungary[23] showed that all samples were contaminated by small amounts of OTA (presence of 100%) but only one sample was detected at levels >0.2 ng/mL (see Table 1). A beer study from the Czech Republic[17] reveals that the incidence (39%) correlates with data obtained from the European Commission (2002) and only one pale beer sample presented the highest value: 0.2438 ng/mL.

Other studies outside the region of interest in this review have been consulted, and it is interesting to observe that in a study in which beers from different origins (United States,

Europe, Australia, Canada, Mexico, South America, and Asia) were analyzed, no OTA levels were detected,[26] coinciding with results obtained in studies performed on beers from China.[27]

OTA Levels in Beer. According to the published studies, OTA mean concentrations obtained in beer present few variations. The lowest OTA mean value achieved was <0.2 ng/mL, except for samples analyzed by Medina et al.,[20] who found a maximum value for one sample of 0.5 ng/mL.

When the median levels of contamination obtained from samples of different studies are compared with those from the European Commission,[16] where the OTA mean value of 496 beer samples was 0.03 ng/g, contamination median levels are slightly higher, although always below 0.1 ng/mL.

Studies can be found where levels of contamination in beers mainly from southern European countries (Italy, Spain, Turkey, Germany, and The Balkans) were detected below 0.04 ng/mL, showing different statistical significances with respect to all other analyzed beers; the highest level of contamination (0.189 ng/mL) was found for one beer from Denmark.

The reason for these low OTA values in beers from southern Europe might be explained by the fact that *P. verrucosum* involved in OTA's production is important in northern European countries where conditions of temperature and humidity are optimum for its growth[25] but not in the south.

Analyses of alcoholic and nonalcoholic beers have been performed, and data show that no differences in OTA levels can be found;[21,24] nonetheless, incidence and mean levels of contamination are higher in nonalcoholic beers than in alcoholic, most probably due to the different procedures in both types of beer production. In nonalcoholic beer production, the fermentation step does not occur or it occurs under controlled conditions; as a consequence, if it is considered that the fermentation step reduces OTA content, it is expected to have higher contamination in this type of beer.

These results differ from the European Commission report,[16] because the presence of OTA (39%) and OTA levels of contamination detected (0.03 ng/g) were low. In summary, contamination mean values found never were above the value assumed (0.2 ng/mL) and differences among beers from different origins were detected.

Estimation of OTA Intake in Beer. An evaluation of the OTA intake associated with beer consumption demonstrates that even considering the highest values, beer contributes only 3% OTA intake as its maximum,[20] (<5% reported by the European Commission). Nevertheless, these values are much lower than the tolerable daily intake (TDI) established by the European Food Safety Authorities (EFSA).[28]

Table 2 collects the calculation of human OTA intake related to beer consumption for recently published studies and for adults.

When studies of beers from outside Europe were examined, such as a study carried out in Korea,[15,63] OTA intake associated with beer consumption was very low, but it was recommended to develop a new evaluation attending to actual consumption data in recent years as the Asian population has experienced a remarkable increase of consumption in beer.[15]

In summary, beer seems not to constitute an important factor for OTA exposure in the population, but it is an additional source to control and consider for OTA mycotoxin intake calculation.

PRESENCE OF OTA IN WINE

In this review, wine has been considered a drink of importance for OTA intake evaluation in the past ten years. Wine, besides being one of the most important subproducts obtained from the grape, is consumed worldwide in developed and developing countries. According to an estimation carried out by the Wine and Vineyard International Organization (OIV) world wine production in 2011 reached 265.8 million of hectoliters (without counting grape juice or must), 600,000 hectoliters more than in 2010.[29] Spain contributed 12.9% of this production with 34.3 million hectoliters.[30]

The presence of OTA in the grape can be shifted from grain grapes to wine during its brewing. After cereals, wine represents the principal source of OTA daily intake for the European population, comprising 13% of the OTA daily intake. OTA levels in wine depend on different factors such as vineyard location (latitude), weather (rain, temperature, relative humidity in the vineyards), period of harvest, pesticide treatments, and the wine brewing technique employed. The European Union allows a maximum limit for OTA in wine of 2 ng/g.

There is a huge variety of wine typologies, which gives place to a very complicated classification. Most of the studies show that OTA levels are higher in red wines than in rosé wines, followed by white wines, mostly due to the must maceration with the skin of the grain grape, which could enhance OTA extraction. In sweet or special wines, enological practices are highly diverse compared with dry wines, which originates different OTA concentrations. In general, sweet wines present higher OTA concentrations than dry wines.[31] These wines can be classified according to their brewing as (i) biological brewing, during which must is protected from direct air contact through the formation of a natural flower veil (fino wine and chamomile wine follow this process), or (ii) oxidative or physicochemical brewing, during which must is in direct contact with the air, giving rise to flavored wines.

Wines can also be classified according to the type of fermentation: (i) complete fermentation in fortified or dry wines or (ii) partial fermentation, as in natural sweet wines, using must from mature grapes with high glucose content and

the fermentation is interrupted by the addition of wine alcohol. Different techniques provoke grape maturation such as late harvesting, sun exposure (such as Pedro Ximénez wine), dehydration in closed places in either cold or warm rooms, fungus colonization by *Botrytis cinerea* (which it gives rise to noble rot and consequently rot wines), or grape dehydration due to winter harvest (which gives rise to ice wines).[32]

In the Council Regulation (EC) No. 1493/1999 of May 17, 1999, on the common organization of the market in wine,[33] "liqueur wine" is defined as the wine product with an actual alcoholic strength by volume of (i) not less than 15% vol and not more than 22% vol or (ii) an overall alcoholic strength by volume of not less than 17.5% vol, except for certain quality liqueur wines produced in specified regions, where natural sweet wines are included in this category.

The EU has not established OTA levels for wines (excluding liqueur wines and wines with an alcoholic strength by volume of not less than 15% vol), and although there are many OTA studies in dry wines from different Mediterranean countries, only a few reviews approach the presence of OTA in sweet or special wines.[32]

Four countries reveal the highest production of wines in Europe: France, Italy, Spain, and Portugal. Another point of view to consider is its consumption.

In this review three different countries of wine production have been studied: (i) Spain, as the third country in the world with the highest production of wine after France and Italy (OIV, 2012);[34] (ii) Portugal, as the country with the greatest ideal conditions for *Aspergillus* and *Penicillium* fungus growth and OTA production; and (iii) Italy, as the second country with the highest wine production according to OIV data[29] and the one with the highest index of consumption per habitant.

In the following sections, studies by countries are compiled and discussed.

OTA Studies in Spanish Wines. Spain has 69 registered designations of origin (RDO).[34] Recently, a few studies regarding OTA presence in typical Spanish wines have been published, especially on Jerez and chamomile wines and Rioja Alavesa wines, as reported in Table 3.

The presence of OTA in muscatel sweet wines and Pedro Ximénez wines goes from 75 to 100%, respectively.[35] In a study where a pool of sweet wine samples formed by 65% of Spanish samples, OTA mycotoxin was present in 97% of the samples,

showing the general presence of this mycotoxin in this wine typology throughout the world.[36] A total of 9.6% of those Spanish wine samples presented levels above the legislated limits of the EU appropriate for liqueur wines (2 ng/g).

Special wines, obtained with different winemaking techniques and from different European countries, have been compared as the literature allows. With regard to OTA content, the data show that 50% of these samples were OTA positive;[32] with a median level of 1.49 ng/mL (Table 3). Wines with the highest presence and concentration corresponded to fortified must (mistela and muscatel) with values of 91% of OTA positive sample wines, 4.48 ng/mL OTA median levels, and 27.79 ng/mL OTA maximum value; wines from sun grape maturation (Pedro Ximénez, Malvasía) showed 91% OTA positive samples, 2.77 ng/mL OTA median level, and 15.62 ng/mL maximum OTA value.[32]

One might expect to find higher OTA levels in fortified musts due to the fermentation interruption occurring during its brewing. The reason is because if the fermentation step is avoided, the possibility of OTA reduction and/or elimination can occur. Also, wines from a sun grape drying process demonstrated higher OTA levels than those obtained with brewing wines. All of this could be explained because the fermentation step progresses slowly, as a consequence of the high sugar content present in must, and because the aging process carried out in these wines is performed in wood barrels. It has to be mentioned that dehydrated grapes used were obtained in cold and warm rooms; however, it is usual that the sun grape dehydration process, used in sweet wines, is carried out in an open environment where conditions for *Aspergillus carbonarius* spp. growth are favorable as well as OTA production.[32] In summary, variations of OTA content in wine mainly depend on the grape dehydration process.

Long-aged fortified wines obtained through wood barrels (Oporto, Jerez, etc.) have been demonstrated to be OTA contaminated (presence in 52% of the samples), whereas late harvest wines, ice wines, and noble wines were OTA free.[32] Among these, almost 20% of the OTA-contaminated wines had values above the European maximum permitted levels established for wine. The reason for this finding was attributed to the origin of the wines, most of them from cold regions of Europe.

OTA content in fortified Jereź wine RDO reveals (fino, amontillado, flavored, and Sanlúcar de Barrameda chamomile) its presence in 80% of the samples[37] (Table 3) (<2 ng/g), with an OTA median concentration of 0.138 ng/mL, which was similar to that detected in white wines and starting wines by other authors. Nonetheless, a relationship was observed between aging wine typology, OTA's presence, and its concentration as follows: biological aging wines had the lowest OTA rate and OTA concentration.

Wines from the Rioja Alavesás RDO are some of the oldest wines in Spain, and four weather conditions can be distinguished in this zone: semiarid, dry, subhumid, and humid. Besides that, this region receives the influence of the Atlantic Ocean and the Mediterranean Sea. All wines produced in this zone are red wines, and depending on the brewing process, four different wine typologies can be distinguished: young wine, aging wine, reserve wine, and large reserve wine. OTA existence in wine samples the from Rioja Alavesás RDO has been detected in 57% of the analyzed samples, in a concentration range of 0.004−0.179 ng/mL and with an OTA concentration median of 0.035 ng/mL[38] (below the EU established limits). The number of OTA positive samples was higher in semiarid zones than in dry zones, and different statistical significances have been obtained. This fact could be explained as a consequence of the lower amount of rain and higher temperatures reached in semiarid zones than in dry zones. However, there were no different statistical significances in OTA concentrations detected, most probably due to the accurate brewing and harvest process carried out. There were no different statistical significances in the different wine typologies and production processes, a fact that differs from other papers in which red wines present the highest contamination. Romero-González et al.[39] determined OTA in different alcoholic drinks, and the incidence obtained was 11% at a concentration of 1.1 ng/g.

Studies performed on exported wines from the Riojás RDO, but in different years, demonstrated that the presence of OTA and OTA contamination in the latest year (2012) presented statistical differences higher than those same wines analyzed earlier (2011).[38,40] OTA median level found in wines from 2012 was 0.077 ng/mL, whereas in 2011 it was 0.037 ng/mL. Higher OTA levels and greater incidence were detected in southern European wine samples.

In summary, it can be concluded that OTA incidence detected in Spanish wines is elevated (as shown in Figure 2),

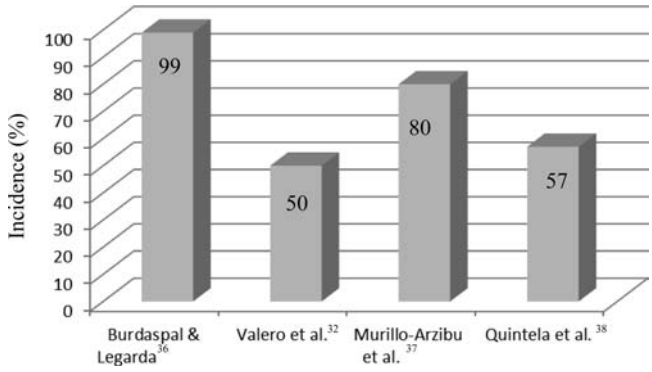

Figure 2. Presence of OTA in Spanish wines.

reaching values of 100% in Pedro Ximenéz wines, but OTA median concentration did not exceed the EU established limits. Incidences collected in previous studies exceeded those recorded in the report from the CE (2002) (59%) and were proximal to OTA detected in southern European wines (72%). OTA contamination median values in wines were higher than that collected in the above-mentioned report for Spanish wines (0.03 ng/mL). Besides, it is confirmed that sweet wines (fortified musts such as mistela and sun grape maturation precedent process) showed higher OTA presence and concentration than for the other wines, reaching a maximum value of 27.79 ng/mL for fortified musts.[32]

Besides the studies performed on the presence of OTA in wines, it has been jointly studied with its analogues: ochratoxin B (OTB), ochratoxin C (OTC), methylochratoxin A (MeOTA), methylochratoxin B (MeOTB), and ethylochratoxin B (EtOTB).[41] Spanish samples belonging to the Mediterranean zone showed OTA, OTB, and MeOTB positive in 100% followed by OTC and EtOTB in 91.7% and, finally, MeOTA in 75%. All six compounds appeared simultaneously in 44.8% of wine samples. The OTA mean value detected in that study was 25.1 ng/L, similar to that declared by other authors.[42−44] It was concluded that there is no evidence that

[a]Data from consumption obtained from different studies: (a) value reported in CE (2002) for consumers; (b) population in general. [b]DI, daily intake. [c]TDI, tolerable daily intake. [d]Total wine samples. [e]Red wine. [f]White wine.

OTA from southern Europe presents greater levels than those detected in northern Europe, which coincides with the reported results in SCOOP.[16]

When the latest studies of OTA in wines outside Spain, for example, wines from different regions of China,[45] are compared, results showed that dry red wine samples were OTA positive (57.1%), followed by dry rosé and ice wines (25% each) and, finally, dry white wines (2.9%). OTA concentrations detected were 0.80, 0.22, 0.10, and 0.07 μg/L in red, rosé, ice, and white wines, respectively. All of these values were higher than those obtained in Spanish wines declared by other authors. Red wines from Chinese markets presented OTA range values from 0.0028 to 0.0437 μg/L.[41]

Estimation of OTA Intake in Spanish Wines. Evaluation of OTA intake by consumption of Spanish wines is collected in Table 4. It can be observed that OTA intake by consumption of wines in a population is below 0.1 ng/kg bw/day, which represents 1.31% of the maximum of the TDI. Levels of exposure, either for the general population or for consumers of sweet wine, are lower than the TDI established by EFSA.[28] These values are above those reported in the EC,[16] where OTA intake collected for wine in Spain was 0.07 ng/kg bw/day. Some studies assume that the intake for starter wines is 50 mL/day,[37] a value higher than that reported by the EU in the above-mentioned report (2.93 g/person/day). This OTA intake could be higher in those cases where the consumer was below 60 kg and wine consumed had the highest detected levels.

As a consequence, wine is an OTA source for humans, and it is necessary to adopt an alert attitude to avoid human OTA consumption.

OTA Studies in Portuguese Wines. Portugal presents several weather conditions according to its location. It receives influences from the Atlantic Ocean and Mediterranean Sea. As mentioned previously, weather conditions and geographical positions determine fungus growth and contamination of the grape by OTA. Assays on wines from different regions in Portugal[47] (35 red wines, 25 white wines) revealed that 26% of red wine samples and 12% of white wine samples were OTA positive, and only 1 sample of white wine exceeded the EU's permitted level of 2 ng/g. In general, white wines present levels of OTA below those obtained in red or rosé wines; in fact, the highest level found in white wine sample differed between studies, and it was attributed to the possibility of the low quality of the analyzed sample. The OTA tolerable weekly intake (TWI) has been also calculated by considering (i) the highest OTA concentrations obtained (1.23 ng/mL in red wine and 2.4% in white wine), (ii) a wine consumption of 49.9 L/habitant/year (136.7 mL/person/day), and (iii) a body weight of 60 kg. OTA's TWI ranged from 20 to 38 ng/kg bw (from 2.8 to 5.5 ng/kg bw/day). These values represent between 17 and 32% of the TWI.

OTA Studies in Italian Wines. Italy has the second highest wine production according to OIV data[29] and the highest index of consumption per habitant. There are a high number of publications in which the presence of OTA in wine has been studied. Table 3 reports the most recent studies of this mycotoxin in Italian wines.

In general, most of the Italian wines are contaminated with OTA, although the levels detected are low. The detection of OTA oscillates between 51 and 77% for its presence in Italian wines, but when the different wine typologies are compared, its presence reaches 100% for red wines[48] and 92% for rosé wines.[49] In other publications, focused on developing new methods of detection, OTA was not detected for any of the analyzed samples.[50,51]

All studies carried out to detect the presence of OTA and its concentration in wines concluded that those values decrease in the following order: red wines, dessert wines, rosé wines, and white wines. This could be explained by the different technological conditions used during their brewing. Nonetheless, an exception has been reported for rosé wines where the highest value of OTA has been detected[49] (Table 3).

Results of OTA analysis in Italian wines reveal that 0.01% of them are OTA positive, with levels above the limits established by the EU.[52] The literature demonstrates that red wine presents the major detection and concentration of OTA, reaching its maximum at 2.92 ng/mL and exceeding the limits fixed by the EU.[53]

There are studies in which no wine sample exceeded OTA levels established by the EU (2 ng/mL) and also where no different statistical significances have been observed for OTA levels when organic and conventional wines were compared.[54]

Related to this, it has been postulated that the use of fungicides in conventional agriculture can provoke stress in fungus and as a consequence increase the production of mycotoxins; fungicides could fight pathogen fungus but enhance the production of OTA fungus producers, due to the absence of rivalry, which favors the conditions of fungus growth and OTA production. On the other hand, there are other studies in which 2.2% of all analyzed samples exceeded the OTA levels established limits by the EU, reaching the highest values for red wine samples (7.5 ng/mL).[49]

When the influence of the latitude and the presence of OTA in Italian wines is studied, it is observed that there is a gradient of concentration from north to south, especially in red wines, as a consequence of the warm temperatures and humid weather conditions, which favor fungus growth and OTA production. The literature puts into evidence that the OTA median concentration gradually increases from northern (0.01 ng/mL) to southern Italy (0.54 ng/mL).[49]

Prelle et al.[55] carried out a study of 30 wine samples from Italy, and only 6.7% of samples exceeded the European OTA threshold. These wines were from southern Italy, a fact in agreement with the latitude influence described for OTA contamination.

Recently, Comuzzo et al.[56] published a database regarding OTA pollution in 199 organic wines, most of them collected from Italy (specifically from two regions, Sicily and Puglia). Among all wines studied, 10 showed OTA levels above the EU limits (2.5−6 μg/L) and 3 showed levels close to the limit. After relating all parameters in wines, they concluded that in wines from southern European countries the OTA contamination risk might be higher.

Estimation of OTA Intake in Italian Wines. Evaluation of OTA intake for Italian wines is reported in Table 4. It can be observed that the maximum OTA intake for Italian wines is 1.4 ng/kg bw/day, which represents 5.6−8% of the TDI established by EFSA.[28] In the worst evaluated case, calculating OTA intake in regular wine consumers from southern Italy (including Italian islands) and considering the median of consumption, the exposure obtained was very low, representing 9.8% of the TDI (1.68 ng/kg bw/day).[49]

These values are similar to those reported in the EC,[16] where OTA intake through wines is declared as 0.86 ng/kg bw/day for the general population and 2.94 ng/kg bw/day for consumers.

In summary, OTA intake through wine consumption does not suppose a health risk in the Italian population.

OTA Studies in Wines from Inside and Outside the EU. Table 3 collects the most recent studies carried out in wines from inside and outside EU countries. It can be observed that there are a high number of positive samples, which increases the incidence of contamination, reaching 98%, although OTA levels detected were low.

Greek wine data show high presence of OTA among all samples analyzed (69%);[57] however, the levels of contamination were low (OTA median value 0.26 ng/mL), 91% of the samples presented OTA values below 1.0 ng/mL, and only one sample achieved the maximum value established by the EU. With regard to OTA incidence and OTA concentration, it was higher in sweet wines (dessert wines) than in dry wines, coinciding with other authors who found OTA detection in sweet wines exceeding 90% of the analyzed samples compared with dry wines.[32]

Results obtained from a study carried out in Turkish wines showed that all samples had OTA levels below the limits established by the EU;[58] however, when Hungarian wines were analyzed, none of the 87 samples analyzed were OTA positive.[62] This confirms the gradient north−south theory: OTA contamination is less probable in northern regions than in southern. However, in a study performed also in Hungarian wines by another research group,[23] OTA was detected in 97.7% of analyzed samples and one sample had a level >0.5 ng/mL.

When the geographical origin of the wine was evaluated, an increased grade of contamination in wines from northern to southern Greece, especially in sweet wines or dessert wines (0.08 ng/mL was the OTA median value in wines from northern, western, and central Greece and 0.23 ng/mL was the OTA median value in wines from southern Greece), was detected.[57] This coincides with other published results from which it was concluded that the geographical origin of the wine had a strong influence on the OTA levels detected; in fact, wines from northwestern and western Turkey presented higher OTA values than those from the central Turkey;[58] however, it differs from results showing wines from Hungary do not evidence the north−south gradient.[23]

It has been mentioned that there is a gradient of OTA concentration depending on the color of the wine. In general, the highest OTA values have been detected in red wines,[23,58] and also the incidence is higher in red wines than in white wines;[57] nonetheless, OTA median values measured were similar.

Differences regarding OTA levels in conventional or organic wines have not been detected.[57] OTA incidence in wine obtained through conventional culture was 70.9%, whereas in organic wine it was 63%; it was also observed that OTA concentration in conventional wine was 0.28 ng/mL and in organic wine 0.12 ng/mL, without observing in any case different statistical significances, coinciding with results obtained by other authors.[54] It was concluded that there are no differences related with the typology of cultured wine.

There is a published study carried out on wine samples from Croatia.[59] Samples studied were six red must, six wines obtained from the previous red must samples, and four bottled wine samples from 2007. It was detected that all must samples were OTA positive, differing from wine samples. The presence of OTA in must was related to the contamination of grape during pressing and maceration, and its concentration decreased during fermentation, although it was not completely eliminated. There were no strains of the most prolific OTA mycotoxin producer, *Aspergillus carbonarius* spp., neither in the must nor in the wine, most probably due to the presence of other OTA fungus producers such as *Aspergillus tubingensis*, *Aspergillus ochraceus*, or *Aspergillus niger* spp., which allowed its detection.

A survey carried out for 11 mycotoxins, in 143 red and white wines, has been also performed, with wines from United States, Europe, Australia, and South America.[26] OTA was detected in 8.3% of the red wines at concentrations ranging from 0.11 to 0.43 ng/mL. The greater contamination detected in red versus white wines was attributed to the longer processing time of red wines as reported by other authors, because once red grapes are mashed, the skin and juice are set aside for several days, aerobic conditions and high temperatures are reached, and growth of OTA mold producers is favored.

Lately, 35 Chilean wine samples along with 18 imported wines (from Spain and Australia) have been analyzed.[60] OTA

was present in 23% of the samples, whereas the percentage in imported wines was 28%. Nonetheless, OTA levels were in general 7 times lower (0.15−0.26 ng/mL) than the EU limit.

In an Asian study carried out in 20 red wine and grape juice samples, OTA levels ranged from 0.26 to 0.63 ng/mL. These limits did not exceed the legal limits; however, it the large consumption of these products was pointed out along with attention to strategies to manage the contamination of raw materials for beverages during harvest and postharvest.[27]

Estimation of OTA intake of Wines. Studies of OTA intake in wines have shown that for a person with a body weight of 60 kg and a consumption of 100 mL of wine per day, OTA intake was 0.18 ng, which is 3.6% of the daily intake established by the Scientific Committee on Food (SCF) (5 ng/kg bw/day).[23]

OTA daily intake calculation of Chilean wines, using the formula of Breás et al.,[52] was 0.24 ng/kg bw/day, which is 70 and 58 times lower than the current TDI established by the SCF of the EC.[60,61] It was concluded that wines commercialized in Chile can be considered safe and not associated with a toxicological risk.

It is difficult to compare the percentage of positive samples and OTA levels in wines from different countries due to the great variety of wines analyzed and the differences between the limits of detection used in each analytical method; however, red and sweet wines seem to be the most contaminated wines, and wine samples from southern regions presented higher incidences and concentrations of this mycotoxin.

trypanocidal	188, 189

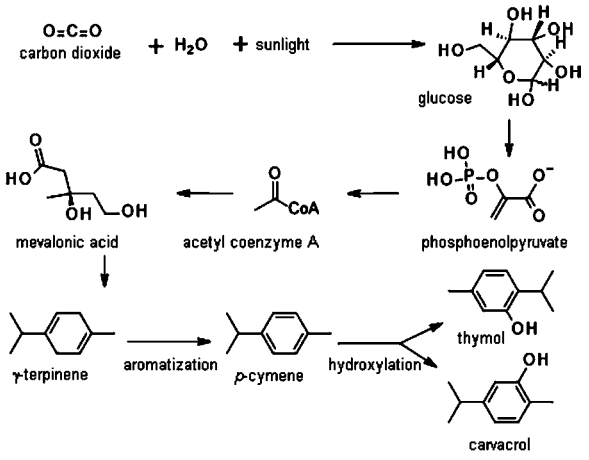

Figure 1. Biosynthesis of carvacrol in aromatic plants. Adapted from refs 5−7.

major steps involve cleavage of glucose to phosphoenolpyruvate followed by decarboxylation and acetylation to acetyl coenzyme A (acetyl CoA) and transformation to the key intermediate, mevalonic acid. The latter is then transformed to γ-terpinene, which then undergoes aromatization to *p*-cymene and hydroxylation to carvacrol and thymol. Not all intermediates are shown in Figure 1. The enzymes and cofactors that catalyze the individual transformations are given in the cited references. The discovery of genes that govern the biosynthesis of carvacrol and other monoterpenes via the γ-terpinene intermediate is currently an active area of research.[9]

Ramak et al.[10] discovered that inhibition of the mevalonate pathway enhances the biosynthesis of carvacrol in shoot cultures of the Iranian plant *Satureja khuzistanica*. They found that expression of the methylerythritol-4-phosphate (MEP) pathway provides the precursor isopentenyl diphosphate (IPP) for the multistep biosynthetic transformation to carvacrol with a yield of ∼90%. The authors suggest that a better understanding of the regulation of carvacrol biosynthesis could result in an increased yield of carvacrol in this and other plants.

Carvacrol is present in large amounts in numerous aromatic essential oil producing plants.[11−17] Although the growing season seems to influence yields, chemical composition, and antioxidant properties of Turkish oregano (*Origanum onites* L.) plants, the carvacrol content of the oils from plants harvested in four different seasons was >80%.[18]

An investigation of the biotransformation of carvacrol in cultured plant cells of *Eucalyptus perriniana* showed that the monoterpene is transformed to glycoside derivatives that are accumulated in the cells.[19] It would be of interest to determine antimicrobial and other bioactivities of the carvacrol glycosides, which are probably more soluble than carvacrol in water and body fluids.

Carvacrol is not only produced by plants, but its presence in the soil seems to act as a selective agent on different plant species, with the response ranging from negative to neutral to positive, suggesting that carvacrol and other thyme monoterpenes can influence plant−plant interactions that might affect the dynamics and stability of plants.[20]

Physical Properties. Carvacrol (liquid; mol wt, 150.22; boiling point, 237−238 °C; density, 0.967 mL/g; melting point, ∼0 °C; UV max in 95% ethanol, 277.5 nm; log extinction coefficient ε, 3.262; pK_a phenolic OH group, ∼10.9; practically insoluble in water; soluble in ethanol; oral rat LD50, 810 mg/kg; oral rabbit LD50, 100 mg/kg) is a major constituent of oregano oil, widely used as a salad dressing, and numerous other essential oils with concentrations up to ∼86%.[21−25] Carvacrol has a pleasant tangy taste and smells like marjoram.[10] Carvacrol is considered to be a generally accepted-as-safe (GRAS) compound used commercially as a food flavor.[26] Standard pure carvacrol for analysis characterized by quantitative NMR (qNMR) is available from a commercial source.[27]

Carvacrol is included in the list of chemical flavorings by the European Commission[28] and approved by the Food and Drug Administration for use as a flavoring in food.[29]

Synthesis. Yadav and Kamble,[30] describe a kinetically controlled synthesis of carvacrol with an 82% yield without the use of solvent (green chemistry) that involves a one-step alkylation of *ortho*-cresol with propylene or isopropyl alcohol over solid acid catalysts. Synthetic carvacrol may be less expensive than the plant-derived natural form.

Several studies report on the synthesis and bioactivities of carvacrol derivatives. These include the following: (a) antioxidative and antimicrobial hydroxymethyl carvacrols;[31] (b) the anti-inflammatory and antinociceptive carvacryl acetate formed by esterification of the carvacrol OH group;[32] (c) other antimicrobial carvacryl esters formed by esterification of the phenolic OH group with different organic acids;[33] (d)

dx.doi.org/10.1021/jf5023862 | J. Agric. Food Chem. 2014, 62, 7652−7670

antifungal and insecticidal hybrid molecules of carvacrol and benzoyl urea/thiourea prepared by structurally modifying carvacrol with benzoyl urea;[34] (e) Schiff's bases with high antioxidant activity formed by introduction of an NH_2 group into the benzene ring of carvacrol followed by reaction with structurally different aldehydes;[35] and (f) antimicrobial chlorocarvacrol formed by chloroperoxidase-catalyzed halogenation of carvacrol.[36] The carvacrol derivatives need to be evaluated for safety before use in agriculture, food, and medicine.

It is also worth noting that the phosphate form of carvacrol solubilized in liposomes has been reported to inhibit tumor growth in a murine tumor model.[37]

Analysis. Several HPLC and GC/MS analytical methods are described to measure the carvacrol content in plants, essential oils, food, pharmaceuticals, and plasma. Here, we briefly mention highlights of selected analyses.

Viñas et al.[38] found that a monolithic HPLC column with fluorometric detections and gradient elution with an acetonitrile−water mixture permitted good separation of chromatographic peaks of carvacrol and thymol in different types of honey with a limit of detection (LOD) of 1−4 ng/g.

Hajimehdipoor et al.[12] validated an HPLC method for the analysis of carvacrol and thymol in the medicinal plant *Thymus vulgaris* using an ACE C18 column and isocratic acetonitrile water (50:50, v/v) at a flow rate of 1 mL/min as the elution solvent. The authors suggest that the method can be used for quality control of pharmaceutical samples for which GC methods may not be effective.

Aleksseva[39] developed a chromatographic system consisting of a reverse-phase (RP) Diasorb 130-C18T column eluted with MeOH:H_2O:THF (50:50:22, v/v) for the analysis of carvacrol and thymol and in plant and medicinal samples.

Horváth et al.[40] describe a method for analysis of carvacrol and other essential oil compounds based on direct bioautography with TLC. The method was used to screen for microorganisms that grow on the TLC plate, suggesting that bioautography can quickly determine which component of an essential oil exhibits antimicrobial activity.

Cantalapiedra et al.[17] developed a reversed-phase high-performance liquid chromatographic (RP-HPLC) method for the simultaneous determination of phenolic compounds (carvacrol, eugenol, thymol, and vanillin) of aromatic plants using spectrophotometric detection with diode-array and electrochemical detection with amperometric and coulometric detectors, suggesting that the low detection limits (LODs) obtained make the method more useful for quality control than more expensive GC-MS methods.

In related studies, Chaieb et al.[11] and Vale-Silva et al.[14] used GC/MS to characterize multiple components of essential oils, Kirkin et al.[41] used the same technique to study the gamma-irradiation-induced degradation of carvacrol and other monoterpenes, and Nostro et al.[42] used gas chromatography to determine residual carvacrol in carvacrol-treated microbial biofilms.

Hallier et al.[43] describe a GC/MS method without the use of solvents to determine carvacrol, thymol, cinnamaldehyde, and dially disulfide residues in cow milk. Lejonklev et al.[44] describe a GC/MS method for analysis of the transfer of carvacrol and other terpenes from oregano and caraway essential oils into cow milk by gastrointestinal or respiratory exposure.

Other studies used HPLC for carvacrol analysis: Du et al.[45] determined the storage stability of carvacrol in edible antimicrobial apple films using an HPLC system that consisted of a Beckman 110B pump, a Thermo Separation Products AS3500 Autosampler, a UV 3000HR scanning detector with both deuterium and tungsten lamps, and an eluent consisting of 50% acetonitrile, 50 mM ammonium phosphate, and 0.05% phosphoric acid at pH 3.1 (Figure 2). Hadad et al.[46] measured

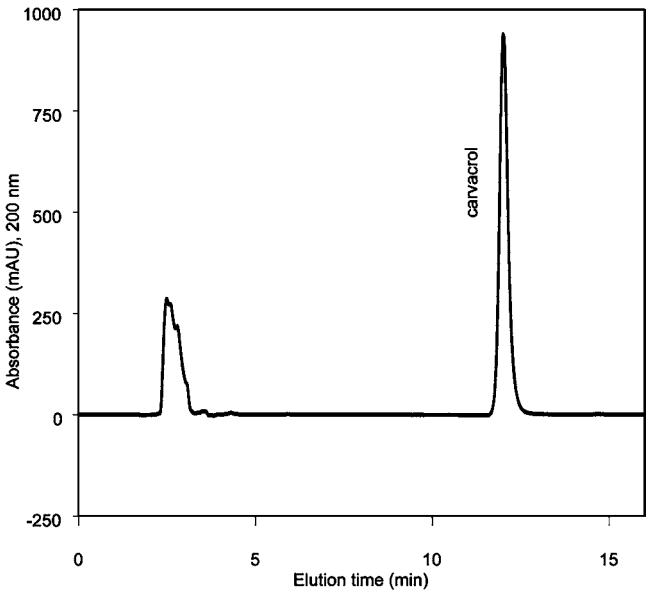

Figure 2. HPLC chromatogram of carvacrol extracted from a carvacrol-containing antimicrobial apple-based film. Adapted with permission from ref 45. Copyright 2008 American Chemical Society.

carvacrol and other compounds in black seed phytopharmaceuticals. Keawchaoon and Yoksan[47] measured carvacrol released from chitosan nanoparticles using UV−vis spectroscopy over the wavelength range 250−400 nm. Shakeri et al.[48] determined carvacrol in polyhydroxylate nanoparticles at 275 nm. Finally, Fiori et al.[49] used GC/MS and headspace solid-phase microextraction to measure carvacrol and thymol in plasma and milk of dairy cows with an LOD of 0.5 and 2.0 ng/mL, respectively.

Sensitive analytical methods seem to be available for the analysis of carvacrol in different milieus.

Antioxidative Properties. A kinetic investigation of the antioxidant effects showed that carvacrol and thymol inhibit autoxidation in purified triacylglycerols, lard, and sunflower oil at room temperature, suggesting their possible use to extend the shelf life of lipid-containing food.[50] Related studies found that carvacrol was highly effective in inhibiting the oxidation of sunflower seeds,[51] that it protected blueberries against storage-induced spoilage,[52,53] and that carvacrol grafted to chitosan nanoparticles via the Schiff's base reaction exhibited greater antioxidant and antibacterial activities and was less cytotoxic to mammalian cells than free carvacrol, suggesting that the method can be applied to chitosan films, membranes, and fibers for biomedical and food packaging applications.[54,55] In another study, carvacrol and thymol were shown to exhibit moderate antioxidant activity in vitro and no clastogenic effects in vivo at biologically relevant concentrations.[56] In addition, DPPH antioxidant values of 73 active essential oils ranged from 14 to 340 μg/mL, suggesting that supplementing of food with spices containing high levels of essential oils may counteract and retard oxidative damage and lipid oxidation and enhance

the antioxidant effects of the food products. These findings suggest the need to determine which components provide maximal antioxidative effects with minimal toxicity and whether combinations of oil components exhibit synergistic effects.[57] Antioxidant properties of essential oil components often differ from those of the oils from which they are derived.[58] Carvacrol in chicken feed exhibited in vivo antioxidative and immunostimulating (antiallergic) properties.[59]

INHIBITION OF FOODBORNE PATHOGENS

Generalities. Foodborne diseases result from ingesting food that is contaminated with either infectious microorganisms or toxins produced by the organisms. Foodborne pathogenic bacteria include *Bacillus cereus, Campylobacter jejuni, Clostridium botulinum, Clostridium perfringens, Escherichia coli, Listeria monocytogenes, Salmonella enterica*, and *Vibrio cholerae*. Bacteria can exert adverse effects in animals and humans by adhering to cells as biofilms and releasing cellular toxins. Understanding the molecular basis of bacteria and toxins will facilitate the development of food-compatible approaches to mitigate the burden of pathogenic bacteria. A key objective of worldwide research efforts in this area is to develop unexplored ways to reduce the human pathogen burden of foods with the aid of naturally occurring safe compounds. The ultimate goal is to develop a better understanding of the structural features that govern antimicrobial activities as well as to devise food formulations that use the active compounds and plant extracts to reduce pathogens in foods, feeds, animals, and humans after consumption. Studies with food need to assess safety and palatability and the effect of the food matrix and storage conditions on antibacterial activities.

Here, we present brief overviews of reported efforts to define the potential of carvacrol to meet these needs.

Inhibition of Foodborne Pathogenic Bacteria in Vitro and in Food. Carvacrol has been shown to have broad-spectrum antibiotic effects against bacteria involved in upper respiratory tract infections,[60] and it also inhibits *Shigella sonnei and S. flexneri* in an agar well diffusion assay with MIC values of 0.1−1.0%, suggesting it has the potential to be used as a disinfectant in the washing water of minimally processed vegetables.[61] It was also highly active against multiple pathogens in an in vitro bactericidal assay,[1] and it inhibited *Mycobacterium avium* subsp. paratuberculosis that causes the virulent Johne's disease in livestock, with a MIC value of 72.2 μg/mL.[62]

With these activities in mind, carvacrol-containing recipes for antimicrobial wine marinades against four foodborne pathogens have the potential to improve the microbial safety of food.[63] Indeed, carvacrol could also improve the safety and shelf life of fruit juices because it has been shown to inactivate *E. coli* and *Salmonella* in freshly prepared apple juices.[64,65]

Many studies have been carried out on the antimicrobial properties of carvacrol on meat and meat products. The bacterium *Clostridium perfringens* is a common cause of foodborne illness. Carvacrol and cinnamaldehyde were shown to inhibit spore germination and outgrowth of *C. perfringens* in ground turkey during chilling, suggesting their value for inhibiting *C. perfringens* in commercial products.[66] The two antimicrobials also facilitated the thermal destruction of *E. coli* in ground beef, suggesting that their use could allow shorter times and lower temperatures for heating beef products safely.[67]

In another study, carvacrol vapor inhibited the growth of *S. enterica* and inhibited and eliminated the pathogen on the surface of raw chicken, suggesting the vapors diffused into the agar and into the moisture layer and/or cell membranes on the surface of the chicken substrate, possibly affecting the flavor and aroma of the chicken breast.[68]

Studies have also been conducted on the use of carvacrol in antimicrobial films. An HPLC method that was used to measure the stability of carvacrol in apple-based antimicrobial films during storage showed that optimal antimicrobial effects against *E. coli* occurred with a carvacrol concentration of ∼1.0% added to the apple purees prior to film preparation and that carvacrol in the films and the film weights remained unchanged for up to 7 weeks of storage, suggesting that the apple films merit use as antimicrobial food coatings.[45]

El Abed et al.[69] showed that *Thymus capitata* essential oil (0.25−1.0%) with a carvacrol content of 89.9% inhibited *Listeria monocytogenes* in contaminated minced beef.

Apple films containing carvacrol or cinnamaldehyde also inactivated *E. coli* and *Salmonella* inoculated on chicken breast and *L. monocytogenes* inoculated on ham, suggesting that the food industry could use the edible antimicrobial apple films as wrappings to control surface contamination by pathogenic microorganisms.[70] Related studies found that apple, carrot, and hibiscus edible carvacrol-containing films were effective against *L. monocytogenes* on ham and bologna,[71] and against *Salmonella* on iceberg lettuce in sealed plastic bags, which could perhaps lead to their potential use in commercial salad bags.[72] As far as palatability is concerned, chicken wrapped with antimicrobial apple and tomato films was acceptable to a human sensory panel.[73] Carvacrol released from microencapsulated gum arabic polymer films inactivated a broad spectrum of pathogenic bacteria, suggesting that gum arabic has good edible-film-forming and flavor-enhancing potential.[74]

Carvacrol facilitated the simultaneous heat inactivation of *E. coli* and inhibition of formation carcinogenic heterocyclic amines in grilled ground beef patties (hamburgers), suggesting that the compound can impart dual health benefits to meat products cooked at lower temperatures.[75]

Combinations of carvacrol cinnamaldehyde, eugenol, and thymol acted synergistically against *E. coli* at physiological pH, indicating that using them in combination might minimize the unpleasant flavors of some of the individual compounds.[76] Carvacrol exhibited dose-dependent inhibition against *Vibrio cholerae* in inoculated carrot juice more efficiently at 25 °C than at 4 or 15 °C, suggesting its potential value to mitigate the virulent cholera disease.[77] Subinhibitory levels of carvacrol inhibited *C. jejuni* motility and infection of epithelial cells by interfering with flagellar function, suggesting the potential use of the compound in infection prevention strategies.[78]

As mentioned, carvacrol can act against many pathogens. It has been shown that the efficacy of carvacrol against cultures of multiple pathogens in corn flour dough is influenced by the complexity of the microbial populations and the relationship between individual populations.[79]

Carvacrol and lauric alginate acted synergistically in reducing *Salmonella* counts in ground turkey by 4 log cfu/g, a much greater value than was found with the individual compounds.[80]

Predictive models can be useful when considering the action of antimicrobials on food and in vitro. For example, a three-factor polynomial predictive model can be used to estimate the processing times and temperatures needed to achieve recommended 7.0-log reduction of *Salmonella* by carvacrol and cinnamaldehyde in ground chicken.[81] A related in vitro

study describes carvacrol-induced death kinetics of *L. monocytogenes*.[82]

Carvacrol and citral potentiated the antibiotic activity of bacitracin, colistin, and erythromycin by reducing MIC values of *Listeria* strains, suggesting that such combinations may help reduce the required dosages of antibiotics and may be of value against both Gram-negative and Gram-positive bacteria.[83,84]

Carvacrol microencapsulated in hydroxypropyl-β-cyclodextrin inhibited *E. coli* and *Salmonella* at lower concentrations than free carvacrol, suggesting that encapsulation can enhance antimicrobial action and decrease the concentration of antimicrobial for inhibition, and indicating that carvacrol inclusion complexes could be useful antimicrobial delivery systems.[85]

It is also worth noting that combinations of compounds may have detrimental effects. For example, combinations of carvacrol with the food antioxidant BHA (2-isobutyl-4-methxyphenol) exhibited antagonistic antimicrobial effects against *S. aureus*, suggesting that these interactions could affect food safety.[86] A possible explanation is that carvacrol and structurally similar BHA compete for the same microbial membrane receptor sites.

The cited studies demonstrate worldwide interest in defining the antimicrobial potential of carvacrol in vitro, in antimicrobial films, in encapsulated form, and in food. It seems that combinations of carvacrol with other plant-derived antimicrobials and with medical antibiotics enhance activity and require lower amounts of each component for the same effect, with the additional possible benefit of better sensory properties. This promising aspect merits further study with foods, feeds, and medicine.

Carvacrol Inhibits Antibiotic-Resistant Bacteria. Antibiotics are widely used as animal feed supplements to fight infection, to promote growth of livestock and poultry, and to reduce production costs as well as to treat human infections. Resistant microorganisms that often arise from use of antibacterial soaps and sanitizers, administration of subtherapeutic levels and overprescription of antibiotics, and widespread use in livestock are a worldwide concern.[87−90] In the United Sates, infections of about 2 million people annually cannot be treated with antibiotics, resulting in about 23,000 deaths.[88] Because of the need to develop new alternatives to standard antibiotics that can be effective against antibiotic-resistant bacteria, we evaluated several natural products, including carvacrol, for their ability to inhibit resistant *Bacillus cereus, E. coli, and S. aureus*.[91] All substances were active against the resistant organisms, suggesting that natural compounds can provide candidates to reduce both susceptible and resistant pathogens. Here, we briefly mention published studies on the efficacy of carvacrol against resistant bacteria in vitro and in food.

An evaluation of the susceptibility of methicillin-susceptible and methicillin-resistant Staphylococci by Nostro et al.[92] to oregano oil, carvacrol, and thymol showed that all three substances inhibited both types of pathogens to the same extent, with MIC values for carvacrol of 0.015−0.03%.

In another study, it was shown that essential oils from the Korean *Thymus* and their components carvacrol and thymol inhibited both susceptible and resistant strains of *Streptococcus pneumoniae, S. aureus, S.* Enteritidis, *and S.* Typhimurium with MIC values ranging from 0.125 to 8 mg/mL.[93]

Carvacrol inhibited seven nalidixic acid-resistant bacteria species, with MIC values of 125−500 μg/mL.[94] Combinations of carvacrol or methyl gallate isolated from an essential oil were more effective than the individual compounds, suggesting that the two natural compounds have the potential to restore the efficacy of nalidixic acid against resistant bacteria.

Carvacrol and thymol were highly effective in reducing the resistance of microbes, including *Salmonella* and *E. coli*, to several medicinal antibiotics; some combinations of the plant and medical antibiotics acted synergistically, suggesting that natural antibiotics can decrease the MIC of a diverse group of drug-resistant bacteria.[95]

A subinhibitory concentration of five natural antimicrobials including carvacrol individually and synergistically increased the susceptibility of multidrug resistant *S. Typhimurium* to five medical antibiotics, suggesting the potential value of the natural compounds as feed supplements to reduce the antibiotic resistance of *Salmonella* in food animals.[96]

In other studies, it was found that tea tree oil did not induce bacterial resistance to antimicrobial agents including carvacrol,[97] and that *Thymus maroccanus* essential oil and its major components carvacrol and thymol modified the susceptibility of resistant bacteria to antibiotics by a membrane-associated mechanism, thereby conferring protection to bacteria.[98]

Carvacrol and cinnamaldehyde rapidly inactivated susceptible and resistant *Campylobacter jejuni* strains, suggesting that the same mechanism probably governs the inactivation of both types of pathogens.[99] These two compounds also inhibited resistant *Campylobacter* on chicken breast,[100] and resistant *S. enterica* on celery and oysters,[101] suggesting that these plant antimicrobials have the potential to be used to decontaminate resistant pathogens on seafood, salads, and oysters. Carvacrol, cinnamaldehyde, and eugenol decreased a five-strain mixture of nalidixic-acid-resistant *Salmonella* on shell eggs from log 8.0 cfu/mL to undetectable levels, suggesting that the natural antimicrobials could be used as a wash treatment to reduce *Salmonella* Enteritidis on shell eggs.[102] Our studies also indicate that the antimicrobial efficacy of carvacrol is similar to that of oregano oil with a ∼80% carvacrol content, suggesting that the minor components of the oil do not seem to contribute to the bioactivity.[1,103]

The availability of plant-derived antibiotics provides more options for the treatment of livestock and poultry and reduces the exposure of humans to resistant bacteria.

Mechanism of Antimicrobial Effects. Here, we briefly mention results of experimental approaches designed to define possible mechanisms that might govern the antimicrobial effects of carvacrol.

It has been shown that exposure of *B. cereus* to carvacrol results in the depletion of the intracellular ATP pool, a change in membrane potential, and an increase in the permeability of the cytoplasmic to membrane for protons and potassium ions.[104] The loss of the ion gradient impairs essential metabolic processes in the cell and consequently leads to cell death.

We used autofluorescence spectra to determine the effect of carvacrol on *E. coli*.[103] The autofluorescence spectra and data showed significant changes at much lower concentrations of carvacrol (0.01 mM) than changes in membrane potential or release of ATP (ATP flux) after disruption of the bacterial cell membrane (1−2 mM), suggesting that autofluorescence detects physiological responses to carvacrol more efficiently than do changes in membrane potential or release of ATP. Difference spectra also make it possible to differentiate between autofluorescence associated with native bacterial cells and those exposed to carvacrol.

A Langmuir trough equipped with a computer-controlled microbalance was used to measure the effect of carvacrol and four other natural antimicrobials on monolayers of model membranes composed of bacterial phospholipids.[105] Surface pressure−area (π−A) and surface potential−area ($\Delta\psi$−A) isotherms were measured to monitor changes in the thermodynamic and physical properties of the lipid monolayers. Results indicated that carvacrol modified the three lipid monolayer structures by integrating into the monolayer, forming aggregates of antimicrobial−lipid complexes, reducing the packing effectiveness of the lipids, increasing the membrane fluidity, and altering the total dipole moment in the monolayer membrane model. These results provide insight into the mechanism of the molecular interactions between naturally occurring antimicrobial compounds and phospholipids of the bacterial cell membrane that govern activities.

Related studies reported that (a) exposure of *B. cereus* to subinhibitory, nonlethal concentrations of carvacrol resulted in increased resistance of the bacteria to inhibition that was accompanied by a lowering of membrane fluidity associated with changes in their fatty acid and headgroup composition;[106] (b) similar changes in membrane fatty acid profiles observed by Di Pasqua et al.[107] and by Luz Ida et al.[108] suggest that the mechanism of the antimicrobial effect is associated with an alteration in membrane lipid profiles and damage to the cell envelope; (c) a whole-cell biosensor assay suggests that the antimicrobial mechanism of action of carvacrol and related compounds involves damage to cell membranes and disruption to cellular metabolism and energy production in the evaluated five pathogens;[109] (d) carvacrol and low doses of γ-radiation synergistically inhibited *B. cereus* via disruption of cell membranes, suggesting that the combined treatment could be effective in contaminated food;[110,111] (e) carvacrol and thymol seem to induce antimicrobial activity via a mechanism that involves production of formaldehyde and its reaction products;[112] (f) bacterial membrane proteins are promising therapeutic targets of potential antibacterial therapy;[98,113,114] and (g) carvacrol and thymol bind to DNA via H-bonding of the OH group to the guanine N7, cytosine N3, and backbone phosphate group, with binding constants $K = 1.55 \times 10^3$/M and 2.43×10^3/M, respectively, suggesting that the mechanism of formation of the DNA complexes can serve as a model for drug−DNA interactions.[115]

A better understanding of the mechanisms that govern the antimicrobial activities of carvacrol will help in the design of better approaches to inhibit pathogenic bacteria in different environments.

Inhibition of Microbial Biofilms. Biofilms occur both at infection sites and during environmental growth of bacteria. They inhibit the diffusion and penetration of antibiotics into the microbial cells, and in vivo, they inhibit the penetration of immune cells to the microbes.[116] The composition of biofilms is a mixture of extracellular polymeric matrices mostly synthesized by the microorganisms that are responsible for the cohesion and three-dimensional architecture of the biofilms.[117]

The presence of biofilms on food and on food contact surfaces negatively impacts food quality and safety, and compared to nonattached cells, biofilm-associated bacteria are more resistant to inactivation by antimicrobial compounds and biocides.[118] Annous et al.[119] describe biofilm formation by *E. coli* and other pathogens on fruits and vegetables, including on leafy greens, apples, and cantaloupes. The authors note that while planktonic bacterial pathogens are easily controlled by low levels of washing water disinfectant, the degree to which leafy greens are sanitized is highly limited and is dependent on diverse intrinsic factors and on the effectiveness of the commercial unit. Washing with hypochlorite or other sanitizing agents can achieve only limited pathogen reduction (1−2 logs) and therefore cannot ensure microbial safety; greater reduction of the pathogen is not possible, owing to strong microbial attachment and internalization of the organisms and biofilm formation.[119] Bodur et al.[120] and Shen et al.[121] describe biofilms on stainless steel surfaces, and Gião et al.[122] describe biofilms in tap water.

GC-MS methods show that the biofilm matrix of *Streptococcus pneumoniae* is composed of extracellular DNA, proteins, and polysaccharide, suggesting that the web-like biofilm matrix links bacterial cells to one another and to their underlying substrate. We do not know to what extent the composition of biofilms varies among different pathogens.[117] Continuous exposure to carvacrol was as effective as a commercial sanitizer in inhibiting biofilm formation by *Staphylococcus aureus* and *S. enterica* pathogens.[123]

In a series of studies, Nostro et al.[42,124,125] found that (a) the concentrations of carvacrol and thyme required to eradicate biofilms produced by *S. aureus* and *Staphylococcus epidermidis* were 2- to 4-fold greater than those required to inhibit planktonic groups and that subinhibitory concentrations of the antimicrobials attenuated biofilm formation on polystyrene microtiter plates; (b) acidic formulations of carvacrol were more effective than neutral ones in inhibiting the formation of the biofilms; and (c) carvacrol- and cinnamaldehyde-containing polymeric films progressively released the antimicrobial that then inhibited both the bacteria and biofilm formation by *Staphylococci* and *E. coli*, possibly by reducing attachment ability and interfering with flagellar motility. In a related study, Zodrow et al.[126] found that a biodegradable FDA-approved polymer containing carvacrol or cinnamaldehyde delayed biofilm formation by Gram-positive *S. aureus*, Gram-negative *E. coli*, and spoilage bacteria *Pseudomonas aeruginosa*, suggesting that these films might be used in polymer coatings for medical and other devices to delay colonization by bacteria.

Subinhibitory concentration ratios of carvacrol, *trans*-cinnamaldehyde, eugenol, and thymol inhibited biofilm formation and inactivated mature biofilms of *Listeria monocytogenes* on microtiter plates and stainless steel coupons, suggesting that these compounds could be used to control the biofilms in food processing environments.[127]

A GFP-promoter fusion library with 79 *Salmonella* biofilm genes was used to study gene expression in the biofilms under experimental conditions, and that might facilitate study of biofilm inhibition in different environments.[128] Carvacrol, thymol, and carvacrol−thymol combinations limited biofilm formation in paper mill machines, suggesting that the natural (green) compounds are promising alternatives or supplements to the currently applied treatments.[129]

A test of the effect of carvacrol against the oral pathogens *Fusobacterium nucleatum*, *Porphyromonas gingivalis*, and *Streptococcus mutans* and their preformed biofilms on a titanium disc surface showed that carvacrol has the potential to serve as a useful hygiene formulation to prevent periodontal disease in implanted patients.[130] Inhibition of biofilm formation by *Chromobacterium violaceum*, *S. enterica*, and *S. aureus* but not by *P. aeruginosa* on polystyrene microplates by subinhibitory concentrations of carvacrol seems to be related to the

disruption of quorum sensing, an essential part of biofilm formation, not by bactericidal activity.[131]

INHIBITION OF HUMAN PATHOGENIC BACTERIA

Although foodborne pathogens cause human infections, carvacrol also inhibits nonfoodborne pathogens. This section presents brief overviews of reported studies on the inhibition of growth and/or destruction of a variety of pathogenic foodborne and human pathogenic bacteria that can cause human illness. These pathogens are listed in alphabetical order.

Campylobacter jejuni. *C. jejuni* is a widely distributed human pathogen that is implicated in abortion of sheep and induces emetic and diarrheal syndromes in humans. There also seems to be an apparent association between outbreaks of *Campylobacter*-induced diarrhea and the development of Guillain−Barre syndrome in humans.[132] As mentioned previously, carvacrol inhibited the motility of *C. jejuni* and thus infection of epithelial cells.[78]

Helicobacter pylori. This bacterium in gastric mucosa might contribute to gastritis and peptic ulcer. Carvacrol and 15 essential oils inhibited the bacterium in vitro with MIC values ranging from 0.02 to 0.1 g/L but were not effective when administered orally to infected mice, suggesting that essential oils are unlikely to be efficient anti-*Helicobacter* compounds.[133] Another in vitro study using a disc diffusion assay found that essential oils from the Iranian *Thymus caramanicus* plant inhibited ten clinical isolates of *H. pylori* with MIC values that ranged from 14.5 to 58.0 μg/mL.[134]

Klebsiella pneumoniae. Several studies reported that carvacrol-containing plant essential oils inhibited pneumonia-causing bacterium *K. pneumoniae*.[135−139] Iten et al.[140] found that an increase in carvacrol concentration in the oils enhanced the kill-rate and that the combination of carvacrol and linalool has additive antimicrobial effects.

Mycobacterium tuberculosis. Carvacrol-containing aromatic and medicinal plants from Columbia exhibited antitubercular activity,[141] and carvacrol derivatives inhibited the *Mycobacterium tuberculosis* chorismate mutase enzyme,[142] suggesting that these substances might help alleviate tuberculosis symptoms.

Salmonella enterica. Oral iron therapy can increase the level of bacterial pathogens in the large intestine of African children. To help overcome this problem, Kortman et al.[143] discovered that carvacrol inhibited iron-induced epithelial intestinal cell adhesion of *S. enterica* at high iron concentrations, suggesting its potential value to prevent pathogenic overgrowth and colonization in the large intestine during oral iron therapy.

Oral Pathogenic Bacteria. Several studies describe the anticariogenic effects of carvacrol. For example, the essential oil from *Lippia sidoides* and its major components carvacrol and thymol exhibited potent antimicrobial activity against the cariogenic species *Streptococcus mutans* and *Candida albicans*, with MIC values from 0.625 to 10.0 mg/mL, suggesting their value in combating oral microbial growth.[144] In addition, mucoadhesive patches consisting of bilayers containing carvacrol, and the antibiotic tetracycline exhibited antimicrobial activity against oral bacteria and the yeast *C. albicans*, indicating the potential use of carvacrol in combination to treat local mouth bacterial infections and candidiasis.[145] Related studies reported that carvacrol inhibited oral biofilms and planktonic cultures,[130] that a carvacrol gel protected rats against induced periodontitis,[146] and that carvacrol has the potential to serve as a dietary supplement to prevent pathogenic overgrowth and colonization during oral iron therapy. The cited observations suggest that carvacrol inhibits dental caries, indicating the need for further human studies.

Impact of Carvacrol on Animal Feed, Milk Production, and Waste Odors. The following observations suggest carvacrol can improve the quality and safety of animal feed. (a) The addition of up to 200 mg of carvacrol + thymol to a viscose poultry feed resulted in a decrease in digesta viscosity, in improvement of feed conversion and growth performance, and in reduced serum cholesterol level, suggesting that monoterpenes might alleviate the negative effects of viscous compounds in poultry diets.[147] (b) Carvacrol-containing oregano leaves improved the growth performance of turkeys.[148] (c) A mixture of carvacrol, capsicum, and cinnamaldehyde added to a poultry diet increased feed efficiency and carcass protein but not fat retention, suggesting that the additives improved the metabolic utilization of absorbed nutrients, possibly by inhibiting pathogenic bacteria.[149,150] (d) Carvacrol inhibited the growth of *Brachyspira intermedia*, which chronically infects laying hens, causing spirochetosis.[151] (e) Four natural antimicrobials including carvacrol acted synergistically with two antibiotics in inhibiting the growth of antibiotic-resistant microorganisms from animal feed, suggesting that the natural antimicrobials have the potential to control the development of antibiotic-resistant bacteria as substitutes for antibiotics.[152]

In the area of milk production, a study has shown that carvacrol/thymol and carvacrol/thyme/*p*-cymene mixtures inhibit the growth of multiple bacterial strains responsible for livestock mastitis. The incidence of mastitis, an inflammatory reaction of the mammary gland induced by pathogens in the udder that produce toxins, can be a problem for livestock and milk production, so the essential oil compounds might have use as a preventive herbal treatment.[153]

Hallier et al.[43] developed a method to determine carvacrol and other essential residues in cow milk samples, enabling a measure of the transfer of the compounds from feed to milk and to evaluate their effect on sensory perception on raw milk and milk processing. No residues of these compounds were detected in the milk samples. By contrast, Lejonklev et al.[44] found that carvacrol and other terpenes are transferred unaltered into milk within hours of exposure, regardless of whether the animals receive the compounds by gastrointestinal or respiratory exposure. Giannenas et al.[154] found that supplementation of the feed with essential oils resulted in improved feed utilization and in increased production of milk by dairy ewes (sheep), suggesting the need for long-term trials to validate these results on dairy sheep.

A study on goats found that supplementation of the diet with carvacrol resulted in reduced methane emissions.[155] Carvacrol and thymol reduced livestock and swine waste odors and pathogens.[156−158]

A study on mice revealed that dietary *Thymbra spicata* essential oil containing 44.1% carvacrol reduced total and LDL and increased HDL serum cholesterol as well as GSH and oxidative enzyme levels, explaining the ethnomedical use of this oil.[159] Will this oil also beneficially impact livestock and human cholesterol?

Insecticidal Activities. A fumigation bioassay found that carvacrol and related compounds exhibited good larvicidal activity against *Lycoriella ingénue*, similar to that of the synthetic pesticide dichlorovos.[160] Carvacrol was an effective fumigant against *Culex pipiens pallens* adult insects[161] and showed a

concentration-dependent inhibition of nicotine binding in a membrane preparation of housefly heads containing the nicotinic acetylcholine receptor, suggesting that insect N-acetylcholine receptors could serve as a novel target for monoterpenoid insecticides.[162,163]

Antifungal Activities. The following capsule summaries of published studies show that low concentrations of carvacrol inhibit the growth or inactivate phytopathogenic and pathogenic fungi.

Carvacrol was effective against both susceptible (MIC = 75−90 mg/L) and fluconazole-resistant (MIC = 75−100) *Candida albicans* and other fungal isolates.[164] Thymol was shown to have similar antifungal effects, suggesting that both compounds could serve as an alternative fluconazole therapy for the treatment and prevention of human candidiasis.

A study on fruit decay found that an application of carvacrol- or thymol-containing waxes to lemons inoculated with *Penicillium digitatum* and *P. italicum* fungi reduced the decay of the citrus fruit, indicating that perhaps such waxes could be used in citrus packing lines to replace synthetic fungicides.[165]

Candida lusitaniae is a pH-tolerant yeast that contaminates fruit juices. Carvacrol at concentrations >1 mM inhibited the growth of *C. lusitaniae*, suggesting carvacrol could be used for preserving minimally processed food.[166]

Carvacrol inhibited the following pathogenic and toxinogenic fungi with MIC50 values of 37−76 μg/mL and MIC100 values of 131−262 μg/mL: *Aspergillus flavus*, *A. fumigatus*, *Fusarium oxysporum*, *F. verticillioides*, *Penicillium brevicompactum*, and *P. expansum*.[167] Carvacrol and thymol were the most promising of the 22 tested compounds, indicating their potential as effective fungicides. A study on the inhibition of 11 food-decaying fungi found that carvacrol exhibited high efficacy with an average MIC value of 154.5 μg/mL, suggesting that the in vitro study may serve as a guide for future studies of the inhibition of the foodborne fungal pathogens on/in food.[168]

Essential oils from *Origanum vulgare* from Southern Italy showed both significant compositional variability and antifungal activity, and their antifungal potencies increased with carvacrol content. All the oils were the carvacrol/thymol chemotypes. At 1000 ppm, the three oils completely inhibited fungal growth of *Monilinia laxa*, *M. fructicola*, and *M. fructigena* species without any hemolytic effect on the cell membranes of bovine erythrocytes.[169]

A quantitative structure−activity relationship (QSAR) analysis of natural phenolic compounds including carvacrol against fluconazole-resistant *Candida* species based on steric descriptors can be used to predict the anti-*Candida* activity of new phenolic compounds.[170] Related studies on the effects of carvacrol against *Candida albicans* are described by Ahmad et al.[171] and Lima et al.[172]

In a study of fungal infection of the tree *Ulmus minor*, it was shown that carvacrol imparts resistance to *U. minor* xylem tissues against the fungal pathogen *Ophiostoma novo-ulmi*, the cause of Dutch elm disease in trees.[173]

The cited studies indicate that carvacrol and thymol, as well as essential oils that contain high levels of carvacrol, strongly inhibit both human pathogenic and phytopathogenic fungi. Further studies are needed to define their usefulness in fungal-contaminated food.

Inhibition of Microbial and Fungal Toxin Production. Hospital-acquired *Clostridium difficile* is the most common cause of antibiotic-associated colitis and diarrhea that affects about 300,000 individuals in the United States.[132] Carvacrol and *trans*-cinnamaldehyde substantially reduced toxin production by this pathogen in Vero cells, down-regulated toxin genes, and did not inhibit the growth of beneficial gut bacteria, suggesting the potential of the plant compounds to reduce *C. difficile* virulence.[174]

A structure−activity study of ten natural phenolic compounds including carvacrol found that a mathematical expression obtained was able to predict the release of the highly toxic mycotoxin fumonisin from the *Fusarium verticillioides* fungal strain, suggesting that lipophilicity is the key property that allowed the target molecule to reach inside the fungal cells.[175] The authors suggest that the mathematical analysis can be used to predict the antifumonisin activity of structurally related molecules, so it will be interesting to find out whether carvacrol can inactivate the biological (toxicological) activities of these and other pure toxins.[176]

Antiviral Activities. Viral contamination of food and infection of animals and humans is a major cause of numerous diseases. The mechanism of antiviral action of plant compounds is based on their abilities to act as antioxidants, to inhibit enzymes, to disrupt cell membranes, to prevent viral binding and penetration into cells, and to induce the host cell defense mechanism. Here, we present brief summaries of reported studies on the antiviral activities of carvacrol against several pathogenic viruses.

Carvacrol and thymol had significant antiviral activity with an IC50 value of 7 μM against herpes simplex virus type 1 (HSV-1) that causes orofacial and genital infections, suggesting that the topical application of these monoterpenes for the treatment of the viral infections merits study.[177] An evaluation of thymol-related monoterpenes showed that the aliphatic side chains had a minor effect, while the hydrophilic OH group on the benzene ring was sufficient for activity. Carvacrol and thymol were reported to be responsible for the antiviral activity against HSV-1 in supercritical carbon dioxide oregano and sage oil extracts.[178] Mexican oregano oils exhibited high antiviral activity against acyclovir-resistant HSV-1, bovine herpesvirus type 2 (BoHV-2), bovine viral diarrhea virus (BVDV), and human rotavirus.[179] Carvacrol inactivates murine norovirus, a human norovirus surrogate after 1 h of exposure via direct action on the viral capsid followed by the RNA.[180] Carvacrol at concentrations of ∼0.5% induced an up to 3.87 log reduction within 1 h, acting directly on the virus capsid and then on the RNA. Surprisingly, oregano oil was less effective than carvacrol. Sökmen et al.[181] and Schnitzler et al.[182] describe viricidal effects of monoterpenes derived from essential oils and essential oil extracts. An unanswered question is whether carvacrol in pure form and in carvacrol-containing essential oils will inactivate pathogenic viruses in contaminated food and water and in a clinical setting.

Acaricidal, Antileishmanial, Nematicidal, and Trypanocidal Effects. Treatment with carvacrol (2.5 μL/mL) induced 100% death of larvae of the cattle parasite *Rhipicephalus microplus* and the tropical horse tick parasite *Dermacentor nitens*, suggesting the potential of the monoterpene to control these two tick species in the field.[183] A related study on the acaricidal efficacy of carvacrol and related compounds on larvae of nymphs of *Amblyomma cajennense* (Cayenne tick) and *Rhipicephalus sanguineous* parasites that afflict horses and other animals found that similar low concentrations of carvacrol and thymol (2.5 μL/mL) also cause 100% lethality in these parasites, indicating the value of further studies to evaluate these acaricides under natural conditions.[184]

Leishmaniasis caused by the tropical parasite *Leishmania amazonensis* affects more than 12 million people worldwide. A comparison of the antileishmanial activity of the essential oil from *Chenopodium ambrosioides* and its main components carvacrol and caryophyllene oxide in mice showed that oil prevented lesion development, the individual compounds were not effective, and the mixture of the pure compounds caused death of the animals after 3 days of treatment, suggesting the superiority of the oil against experimental leishmaniasis.[185] An in vitro study found that carvacrol and thymol from the essential oil *Lippia sidoides* inhibited *Leishmania chagasi* with IC50 values of 58.4 and 74.1 μg/mL, respectively, suggesting that this oil is a promising source of leishmanicidal compounds.[186] Carvacrol also showed antileishmanial activity against experimental cutaneous leishmaniasis caused by *L. amazonensis*.[185]

At a concentration of 1000 μL/L, 12 of 27 essential oils and active components evaluated immobilized more than 80% of juveniles of the root-knot nematode *Meloidogyne javanica* and inhibited nematode hatching and root galling of cucumber seedlings in pot experiments, indicating that the oils and components could serve as nematicides. Carvacrol immobilized the juveniles and inhibited hatching at 125 μL/L.[187]

Human African trypanosomiasis (sleeping sickness) is caused by *Trypanosoma brucei* and poses a risk of infection for about 60 million people living in sub-Saharan countries.[188] The cited investigators discovered that *Hagenia abyssinica* essential oils and their bioactive components including carvacrol strongly inhibited the parasite with an IC50 value of 11.25 μg/mL, with minimal toxicity on human leukemia cells. The order of decreasing trypanocidal effects of phenolic monoterpenes, carvacrol > thymol > eugenol, paralleled acute oral toxicities in rats (LD50 in mg/kg): carvacrol, 810; thymol, 980; eugenol, 2680. The relative potencies are similar to those we reported for antimicrobial activities of these compounds.[1] The most active compounds have the potential to protect against or treat human and animal trypanosomiasis.

Another study[189] reported that 13 essential oils from different species of Columbian *Lippia* plants containing an average of 46.2% carvacrol inhibited *Leishmania chagasi* and *Trypanosoma cruzi* parasites with IC50 values of 5.5−12.2 μg/mL. The corresponding values for pure carvacrol were 3.0−38.0 μg/mL, suggesting that some of oils and carvacrol could be useful in the treatment and prevention of Chagas and leishmaniasis protozoan diseases, which are a major public health problem in Latin America. Carvacrol and nootkatone suppressed *Ixodes scapularis* and *Amblyomma americanum parasites* in a Lyme disease endemic in New Jersey.[190]

ADDITIONAL BIOACTIVITIES AND HEALTH-PROMOTING PROPERTIES OF CARVACROL

Metabolism. After consumption, carvacrol is metabolized by cytochrome enzymes, mostly hydroylated derivatives that has unknown safety. Here, we briefly mention selected studies on carvacrol metabolism.

A metabolic study of carvacrol in rats showed that only a small amount is excreted in urine 24 h after oral administration.[191,192] Figure 3 shows the structures of the characterized metabolic products that result from the in vivo enzyme-catalyzed hydroxylation of the benzene ring and hydroxylation and oxidation of the aliphatic isopropyl and methyl groups of carvacrol. These compounds seem to be excreted as the glucoronide and sulfate derivatives.

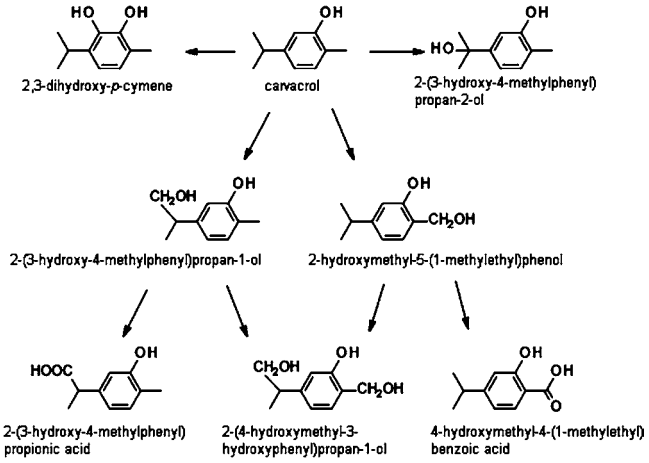

Figure 3. Metabolism and urinary excretion of carvacrol in rats. Adapted from refs 191 and 192.

Using human microsomes, Dong et al.[193] detected two new hydroxylated metabolites that resulted from the cytochrome isoform CYP2A6-induced oxidation of carvacrol to new hydroxylated metabolites, suggesting that carvacrol could impact pharmacokinetic and clinical outcomes when coadministered with other compounds undergoing CYP2A6 metabolism. Related studies found that (a) carvacrol acted in a dose-dependent manner as a liver mitochondrial antioxidant and protected against reactive-oxygen-species (ROS)-generating mitochondrial enzymes and DNA damage in D-galactosamine-induced hepatotoxicity in rats, suggesting that the antioxidant effect of carvacrol could be responsible for the observed hepatoprotective effects;[194] (b) in vitro and parallel in vivo studies in the hippocampus of mice revealed that synthetic carvacrol acetate reduced lipid peroxidation, GSH levels, catalase activity, and nitrite content and that the antioxidative potential correlated between these two parameters;[195] and (c) plant enzymes in germinating wheat seeds partly converted carvacrol and other monoterpenes to corresponding less toxic oxidation and reduction products and partly to degradation products, suggesting that such changes might also take place in other foods.[196] Noma and Asakawa[197] comprehensively reviewed biotransformation pathways of monoterpenes by microorganisms, insects, and mammals.

Anti-inflammatory Mechanisms. The strong anti-inflammatory properties of carvacrol provide a scientific basis for many of its beneficial bioactivities. Here, we will mention some of the cellular events that seem to be associated with these properties.

An investigation on the cytokine modulation induced in paw inflammation in mice showed that carvacrol at 100 μg/kg attenuated the paw edema and reduced the pro-inflammatory COX-2 and IL-1ß mRNA expression and enhanced the levels of IL-10 and IL-10 mRNA anti-inflammatory cytokines, suggesting that the treatment reduced the production of inflammatory mediators, possibly through induction of IL-10 release.[198] Carvacrol did not produce an antidermatogenic effect in IL-10 deficient mice.

In related studies, Silva et al.[199] found that carvacrol induced reduction of mouse ear edema and significantly up-regulated mRNA and protein expressions of TNF-α, IL-6, iNOS, COX-2, and NF-κB in D-galactosamine-induced hepatotoxic rats and

dx.doi.org/10.1021/jf5023862 | J. Agric. Food Chem. 2014, 62, 7652−7670

down-regulated the expression of these genes,[200] confirming the mechanistic basis for the anti-inflammatory activity of carvacrol. A review on anti-inflammatory effects of monoterpenes further expands on the proposed mechanisms that seem to govern anti-inflammatory effects of monoterpenes.[201]

Analgesia. Pain that occurs in response to tissue injury results from activation of peripheral pain receptors (nociceptors) and their sensory fibers. Many studies have been designed to demonstrate the antinociceptive (analgesic) properties of carvacrol. For example, carvacrol attenuates carrageenan-induced hypernociception and inflammation in mice, suggesting that carvacrol is a candidate in the treatment of painful conditions associated with inflammation.[202] The beneficial effects seem to be associated with inhibition of pro-inflammatory cytokine TNF-α production and NO release.

Related studies found that (a) carvacrol enhanced warmth and heat pain on the human tongue;[203,204] (b) synthetic carvacrol propionate attenuates nociception, mechanical hyperalgesia, and inflammation in male Swiss mice through inhibition of cytokines;[205] (c) oral administration of carvacrol in mice models of pain resulted in significant inhibition of nociception without impairment of motor performance, suggesting that the antinociceptive activity might not act through the opioid system;[206] (d) results of a study of orofacial analgesic-like activity of carvacrol in rodents suggest that the compound might represent an important tool for the treatment of orofacial pain;[207] (e) carvacrol in drinking water was more effective than the steroidal drug dexamethasone in mitigating adverse effects in sensitized guinea pigs, suggesting the monoterpene could be used to treat asthma in humans;[208] and (f) Guimarães et al.[209] reviewed mechanisms that might govern analgesic aspects of structurally different monoterpenes.

These observations indicate that carvacrol could benefit individuals suffering from inflammatory-related allergies.

Arthritis. The folate antagonist methotrexate is an anti-inflammatory drug with many side effect used to treat human rheumatoid arthritis and cancer. We previously reported that both folic acid and methotrexate protected frog embryos against organ malformations (teratogenicity) induced by the potato glycoalkaloid α-chaconine.[210,211]

The following observations suggest that carvacrol has the potential to ameliorate adverse side effects of methotrexate: (a) carvacrol overcame methotrexate-induced oxidative stress and the pro-inflammatory response in the sciatic nerve tissue of the rat, indicating that carvacrol has the potential to reduce the toxic side effects;[212] (b) carvacrol enhanced the antiarthritic action and reduced liver toxicity of methotrexate in a rat model, suggesting that carvacrol might promote the safe use of methotrexate in the management of arthritis;[213] and (c) carvacrol partially abrogated methotrexate-induced kidney damage in male rats.[214] The cited observations suggest the need to evaluate the potential of carvacrol to ameliorate methotrexate-associated toxicity in human patients.

Cancer. Cancer that can develop in any tissue organ at any age is an unregulated proliferation of cells due to loss of normal control, resulting in unregulated growth and, often, metastasis.[132] Because multiple genes are involved in carcinogenesis, there is a need for therapies that target multiple signaling pathways. The following observations suggest that carvacrol might act additively or synergistically with other cancer cell inhibitors.

Incubation of human nonsmall cell lung cancer cells (A549) with carvacrol in DMSO for 24 h resulted in a decrease in cell number and protein content and in degeneration of cell morphology, suggesting that the monoterpene is a potent inhibitor cell associated with about 75% of lung cancers.[215]

Carvacrol also induced a 30% decrease of 3,4-benzopyrene-induced in vivo carcinogenicity in Wistar rats and exhibited anticarcinogenic effects against the cells in vitro, with IC50 values of 90 μM and 67 μM after 24 and 48 h incubations.[216]

In a series of studies, Slameňová et al.[217−220] found that carvacrol protected human hepatoma (HepG2) and human colonic (Caco-2) and other cell lines against DNA strand breaks induced by hydrogen peroxide and methylene blue, and reduced DNA lesions in hepatocytes and testicular cells in rats given carvacrol in drinking water for 7 days, suggesting that the beneficial effects might be associated with an increase in antioxidant activity in liver and testicular cells in the animals.

Carvacrol was also shown to inhibit human hepatoma HepG2 cell growth by inducing apoptosis by the direct activation of the mitochondrial and mitogen-activated protein kinases (MAPK) pathways; thus, it might help prevent liver cancer.[221]

Carvacrol inhibited the proliferation of porcine lymphocytes in the MTT assays that measure cell viability, with an IC50 value of 182 μM, suggesting that the reduced lymphocyte proliferation was due to apoptotic cell death, as determined by Annexin-V binding and caspase-3 activation.[222] These authors also mention that because the antimicrobial concentrations of carvacrol (5−100 mM) are much higher than concentrations that are toxic to leucocytes and epithelial cells (100−1000 μM), caution should be exercised when using carvacrol as a feed additive in pigs.

In another cancer cell death study, carvacrol exhibited antiproliferative effects in metastatic breast cancer, MDA-MB231, cells with an IC50 value of 100 μM, suggesting that carvacrol could be a potent antitumor molecule against metastatic breast cancer cells.[223] The induction of apoptosis seems to have been mediated by cell cycle arrest at S phase, increases in Annexin V positive cells, caspase activity, cytochrome c release from mitochondria, decreases in mitochondrial membrane potential and in the Bcl2Bax protein ratio, cleavage of PARP, and fragmentation of DNA.

Carvacrol (15 mg/kg BW) protected rats against diethylnitrosamine-induced hepatocellular carcinoma. Reduction in liver cancer progression was associated with prevention of liver peroxidation, hepatic cell damage, and protection of the liver antioxidant system.[224]

Carvacrol-induced ROS-associated apoptosis in OC2 human oral cancer cells was triggered by caspase-3 activity and the release of calcium ions from the endoplasmic reticulum.[225] A related study on periodontal inflammation used a focused microarray analysis of apoptosis-related genes, and the results suggest that caspase-3 is a target protein for carvacrol in the inhibition of periodontitis apoptosis of HaCaT epithelial cells.[226]

On the basis of the results from a study of the effect of carvacrol on healthy neurons and N2a neuroblastoma cells, Aydin et al.[227] conclude that the efficacy of anticancer chemotherapy seems to be limited by the cytotoxic effect on healthy cells, owing to the lack of selectivity of carvacrol and poor uptake by the neuroblastoma cells.

Overall, the in vitro and rodent studies suggest that the food ingredient carvacrol alone or in combination with cancer drugs such as methotrexate and doxorubicin merits further study for the potential to mitigate human breast, liver, and other cancers.

Moreover, because other widely consumed food ingredients and foods are also reported to inhibit cancer cells in vitro and in vivo, combinations of carvacrol with anticarcinogenic tea catechins and theaflavins,[228] the tomato compounds lycopene and α-tomatine,[229] and pigmented rice brans[230] also merit study.

Cardioprotection. The protective effect of carvacrol against risk factors associated with heart disease has also been reported. For example, the administration of carvacrol for 21 days to hepatotoxic rats increased levels of good very low density (VLDL) and low density lipoprotein (LDL) and decreased bad high density lipoprotein (HDL) serum levels, suggesting that carvacrol affords a significant hepatoprotective and hypolipidemic effect against induced hepatotoxicity.[231]

Carvacrol induces relaxation of the arteries by activating TRPV cation channels and suppressing calcium ion currents in the endothelium, which may account for some of the cardioprotective effects of the Mediterranean diet.[232−234]

Carvacrol has also been shown to decrease the heart rate and blood pressure of anesthetized rats[235] and protected rats against myocardial infarction,[236] suggesting that the compound seems to be a promising cardioprotective agent for the treatment of myocardial infarction. The beneficial effects of carvacrol seem to be modulated by its antioxidative and antiapoptotic properties.

Diabetes and Obesity. Here, we briefly examine the beneficial properties of carvacrol against obesity and diabetes in rodents.

Orally administered carvacrol at doses of 25 and 50 mg/BW to diabetic rats for 7 days after the onset of streptozotocin-induced diabetes did not significantly reduce serum glucose or insulin levels. The treatments did, however, have a protective effect against the negative effects of streptozotocin on liver enzymes, suggesting that the compound would be useful in the diet of diabetics.[237]

Co-administration of carvacrol (20 mg/kg BW) and the antidiabetic drug rosiglitazone (4 mg/kg BW) for 35 days to rats on a high-fat diet prevented changes in metabolic enzymes associated with obesity and diabetes, thus indicating that the combination had a better antihyperglycemic effect than the individual compounds.[238] The results of the histopathology of the islet cells of the pancreas support the biochemical findings.

It has also been reported that mice fed a 0.1% carvacrol-supplemented diet had reduced body weight gain, visceral fad-pad weights, and plasma lipid levels compared with mice fed a high-fat diet.[239] Inhibition of adipogenesis seems to occur by suppression of bone marrow protein-, fibroblast growth factor 1-, and galanin-mediated signaling and reduction of the of pro-inflammatory cytokines in visceral adipose tissues by inhibiting toll-like receptor 2 (TLR2)- and TLR4-mediated signaling. The cited findings suggest that carvacrol might help prevent obesity in humans.

Endotoxemia. Endotoxemia is an infection-related virulent disease with a high mortality rate.[240] Intraperitoneal administration of carvacrol improved the survival of mice during induced lethal endotoxemia and attenuated lung injury.[241] The protective effect seems to be related to inhibition of activation of NF-κB and MAPK signaling pathways, thereby inhibiting inflammatory cytokines TNF-α, IL-6, and IL-1ß; thus, it seems that carvacrol might be useful in preventing endotoxemia-associated adverse effects. Possible synergistic antiendotoxemia effects of carvacrol with other natural compounds[240,242] merit study.

Gastroprotection. The protection of drug-induced gastric lesions in mice and rats seems to be mediated by endogenous prostaglandins, K(ATP) channel openings, NO synthase activation, and antioxidant properties, suggesting that carvacrol has the potential to be an effective gastroprotective agent.[243] A related study found that carvacrol helps heal induced gastric ulcers in mice by interfering with the release and/or synthesis of pro-inflammatory mediators.[199] By contrast, an in vitro study found that exposure of human intestinal Caco-2 cells to carvacrol and thymol resulted in vacuolated cytoplasm, altered organelles, and other evidence of morphological cellular damage.[244]

Hepatoprotection. Pretreatment with carvacrol ameliorates thioacetamide-induced liver injury in rats. This is mediated by the inhibitory effect of carvacrol on nuclear factor NFκB activation of Bax and Bcl-2 protein expression, and the restoration of histopathological changes, suggesting that the beneficial effect is associated with the inhibition of apoptosis.[245] Related studies show that carvacrol: (a) increases the regeneration rate of rat livers undergoing partial hepatectomy;[246] (b) protects rat livers against hepatic ischemia, a risk factor in liver surgery and transplantation;[247] and (c) protects rats against D-galactosamine-induced hepatotoxicity.[231,248] It seems that carvacrol has the potential to help overcome liver injuries in clinical settings.

Neuroprotection. Carvacrol was 10 times stronger than the isomeric thymol in inhibiting acetylcholinesterase, a key compound involved in neurotransmission.[249] An investigation of the effect of carvacrol on diabetes-associated cognitive deficit (DACD) in a rat model showed that the compound dose-dependently prevented behavioral, biochemical, and molecular changes associated with diabetes, indicating that it might be useful for treating diabetes and DACD.[250] The cognitive impairment was associated with oxidative stress, inflammation, and apoptotic cascades.

An investigation of the effect of carvacrol on induced cerebral edema in a mouse model showed that the molecule reduced the edema and neurological deficits, suggesting that it might protect against intracerebral hemorrhage injury by ameliorating aquaporin-4 (AQP4)-mediated edema.[251] Carvacrol also enhanced the recovery of traumatic brain injury in mice by altering permeable calcium ion channels that are involved in neuronal cell death, suggesting the monoterpene should be further evaluated in animals and humans.[252] Related studies reported that carvacrol protected against methotrexate-induced neurotoxicity in rats,[212] and alleviated cognitive impairment in scopolamine-treated rats caused by increased amyloid-ß-pathology (Aß) levels associated with Alzheimer's disease or cholinergic hypofunction.[253] Orally administered carvacrol, up to 50 mg/kg BW, induced antidepressant effects that seem to be dependent on an interaction with the dopaminergic brain pathways.[254] The cited and related studies[255,256] imply that carvacrol merits further study in humans to establish its potential to treat neurological disorders, including Alzheimer's disease and depression.

OUTLOOK

Carvacrol-containing aromatic plants and spices are a major source of essential oils that are widely used in the human diet. Carvacrol can be isolated from a large number of essential oil producing plants. The results of the cited studies indicate that the antioxidative properties associated with the phenolic OH group, the hydrophobic properties associated with the benzene

ring and the methyl and isopropyl substituents, the binding affinity to the guanine moiety of DNA, and the anti-inflammatory and apoptotic and cell membrane disruptive properties of carvacrol all seem to contribute to the observed diverse bioactivities. These bioactivities have the potential to contribute to the prevention and therapy of several chronic human diseases, including allergic response, cancer, diabetes, and infectious, cardiovascular, and neurological syndromes. Future studies should further explore the beneficial synergistic properties of combinations of carvacrol with other natural antimicrobials, including tea compounds,[257] seashell-derived chitosans,[55] and wine flavonoids.[258] Such dietary combinations in which the individual components might exert their effects by different mechanisms could make it possible to use lower amounts of each component, thus minimizing possible adverse sensory properties, antibiotic resistance, and toxicity.

identification of individual phenolic compounds was based on their diode array detector spectra and electrospray ionization mass spectrometry fragmentation patterns compared with those of authentic standards and reported data (see Figure S1 and Table S1 of the Supporting Information). The chemical structure of identified chlorogenic acid isomers is shown in Figure 1 (compounds **1**–**3**).

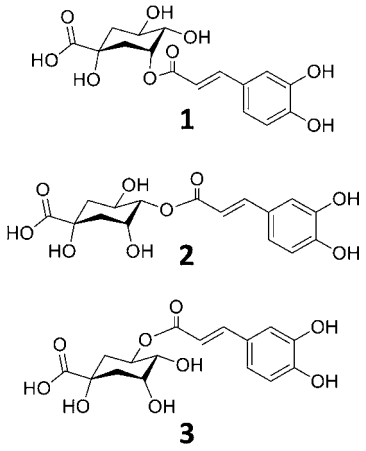

Figure 1. Chemical structures of chlorogenic acid isomers identified in potato tubers subjected to wounding stress and exogenous amylolytic enzymes: (**1**) chlorogenic acid (3-*O*-caffeoylquinic acid), (**2**) cryptochlorogenic acid (4-*O*-caffeoylquinic acid), and (**3**) neochlorogenic acid (5-*O*-caffeoylquinic acid).

To quantitate the chlorogenic acid isomers, a standard curve of chlorogenic acid at a range of 5–250 ppm was obtained. The concentrations of chlorogenic acid isomers were expressed as milligrams of compound per kilogram of potato DW. Results are expressed as chlorogenic acid equivalents.

Statistical Analysis. Statistical analyses were performed using five repetitions. Data represent the mean values of repetitions, and bars indicate their standard error. Analyses of variance were conducted using JMP version 11.0 (SAS Institute Inc., Cary, NC), and mean separation was performed using the LSD test ($p < 0.05$).

RESULTS AND DISCUSSION

Total reducing sugars were evaluated during storage of wounded potatoes treated with or without enzymes (Figure 2A). As expected, control samples (without enzymes) showed a significant increase in reducing sugar content during the first 72 h of storage; thereafter, from 96 to 168 h, the content remained stable, and at 192 h, a significant decline ($p < 0.05$) was observed. Wounded potatoes treated with enzymes at either 0 (E0h) or 48 h (E48h) showed a level of hydrolysis of starch higher than that of the control. These treatments (E0h and E48h) presented a rapid increase in the content of reducing sugars after enzyme application for 24 h. Interestingly, for the E96h treatment, the addition of amylolytic enzymes induced a significant decrease ($p < 0.05$) in the content of reducing sugars during the following storage time. Because sugars accumulate when their production rate exceeds their utilization rate,[25,26] it is likely that for the E96h treatment although the rate of production of reducing sugars could be enhanced by exogenous amylolytic enzymes, their utilization rate in a metabolic process such as cellular respiration[22] or for the production of aromatic amino acids needed for the biosynthesis of phenolic compounds[27] was higher.

To evaluate the effect of wounding stress and the addition of amylolytic enzymes on the wound-induced accumulation of phenolic compounds in potato tubers, quantification of

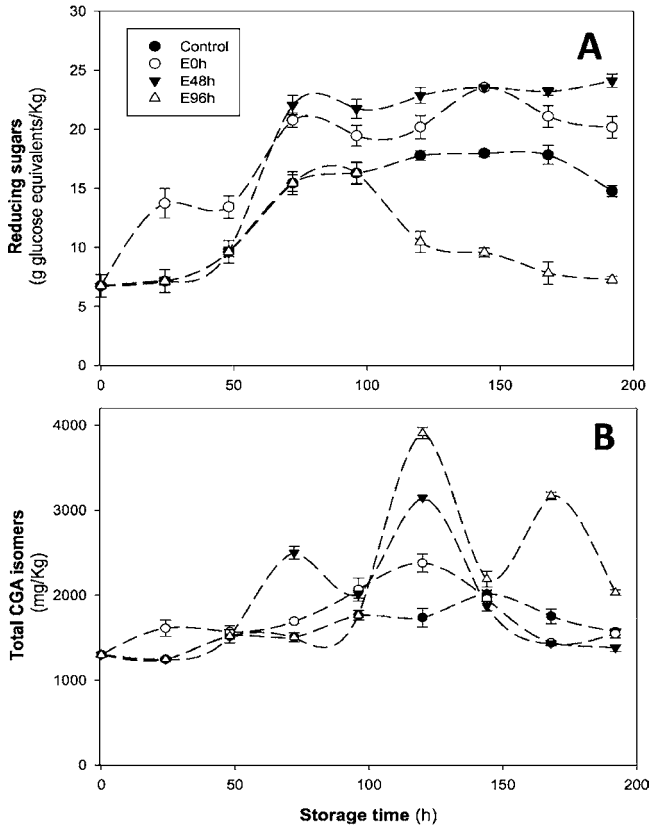

Figure 2. (A) Total reducing sugars and (B) chlorogenic acid isomer content during storage (192 h at 20 °C) of pie cut potatoes with and without (control) amylolytic enzymes. For each treatment, amylolytic enzymes were added after storage for 0 (E0h), 48 (E48h), or 96 h (E96h). Values represent the mean of five repetitions with their standard error bars.

chlorogenic acid and its isomers cryptochlorogenic acid and neochlorogenic acid was performed (Figure 2B) because these compounds represent ~75% of the total phenolic compounds in potato tubers.[3,28−32] The highest level of accumulation of total chlorogenic acid isomers in control samples was observed after storage for 144 h, a content that was ~60% higher than that of time zero samples (Figure 2B). For the subsequent storage time, the concentration started to decrease. All samples treated with enzymes showed the highest level of accumulation of total chlorogenic acid isomers after storage for 120 h compared with the control (Figure 2B). The treatment that showed the highest total chlorogenic acid content was E96h followed by E48h and E0h, with increases of ~210, ~150, and ~90%, respectively, compared with the time zero samples (Figure 2B). After 120 h, the total chlorogenic acid content decreased for all treatments (Figure 2B). In general, the application of amylolytic enzymes caused a significant increase ($p < 0.05$) in the content of total chlorogenic acid isomers just 24 h after their addition in potato tubers, suggesting that the higher availability of sugars could result in a higher level of synthesis of phenolic compounds, and these observations are associated with higher levels of reducing sugars detected in E0h and E48h samples 24 h after the addition of the enzyme (Figure 2A). However, this trend was not observed for the E96h sample. Because the E96h sample showed the highest content of chlorogenic acid isomers (Figure 2B), the results indicate that sugars are rapidly utilized as a carbon source for the

dx.doi.org/10.1021/jf5026983 | J. Agric. Food Chem. 2014, 62, 7671−7675

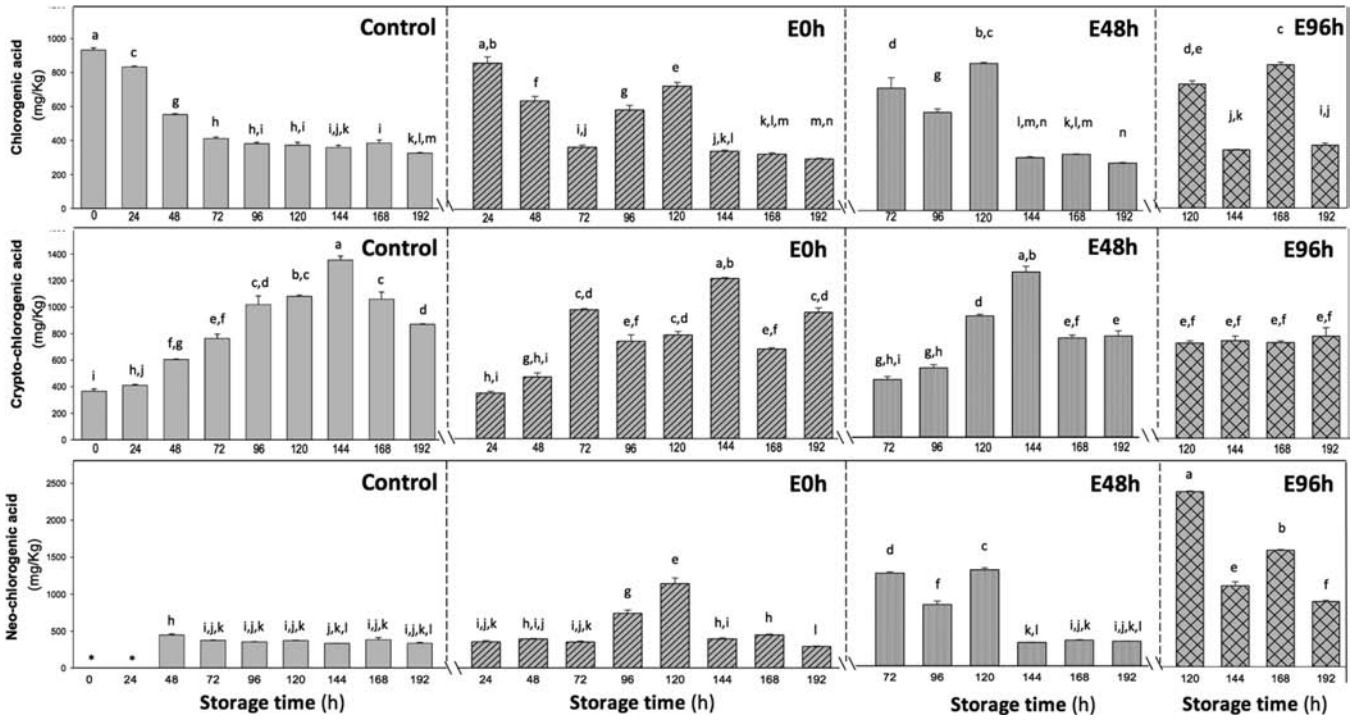

Figure 3. Accumulation of individual chlorogenic acid isomers during storage (192 h at 20 °C) of pie cut potatoes with and without (control) amylolytic enzymes. Amylolytic enzymes were added after storage for 0 (E0h), 48 (E48h), or 96 h (E96h). Asterisks denote not detected. Values represent the means of five repetitions with their standard error bars. Different letters in the same compound indicate statistical differences determined by the LSD test ($p < 0.05$).

biosynthesis of phenolic compounds, and thus as discussed earlier, their utilization rate is higher than their production rate.

The quantification of individual chlorogenic acid isomers (compounds **1**–**3**) during storage (20 °C) of wounded potatoes with or without enzymes is shown in Figure 3. In the particular case of chlorogenic acid (compound **1**), no accumulation was observed in control samples. Instead, a significant ($p < 0.05$) decrease was observed over time. Wounded potatoes with amylolytic enzymes showed chlorogenic acid levels after the addition of enzymes higher than that of the control; however, the levels did not exceed those observed at time zero in control samples. The results obtained herein are in contrast with those of a previous report, in which the accumulation of chlorogenic acid was observed in wounded potatoes stored for 96 h at 10 °C.[3] The difference in the results obtained here and those previously reported could be attributed to the storage temperature, because in this study a temperature of 20 °C was selected to maintain the activity of exogenous amylolytic enzymes. Previous reports indicated that 20 °C is the optimal temperature for suberin and lignin biosynthesis.[33,34] Thus, the results suggest that in control samples the chlorogenic acid content decreases during storage because chlorogenic acid is rapidly utilized for the production of lignin and suberin.

With regard to cryptochlorogenic acid (compound **2**), the levels were increased by 260% in control samples during the first 144 h of storage; however, the addition of amylolytic enzymes did not enhance its wound-induced accumulation. Likewise, the increase in cryptochlorogenic acid content observed in the control suggests that this compound accumulates while chlorogenic acid is available. In addition, as previously reported, chlorogenic acid seems to be preferred over cryptochlorogenic acid for lignin biosynthesis,[35] because its concentration is rapidly decreased after wounding. The accumulation of compound **2** agrees with a previous report in which its highest concentration in potato pie cuts was observed after storage for 144 h at 10 °C.[3] However, at 10 °C, the observed increase (~80%) was smaller than that observed herein, suggesting that temperature can be used as an abiotic stress to selectively induce a higher rate of accumulation of cryptochlorogenic acid in wounded potatoes.

Neochlorogenic acid (compound **3**) was not detected in time zero potatoes (Figure 3). In the control, compound **3** was detected after storage for 48 h and the content remained constant until 72 h. The application of amylolytic enzymes significantly increased the rate of accumulation of neochlorogenic acid in all samples 24 h after their addition, where the highest levels (~2400 mg/kg) were obtained in E96h samples after storage for 120 h.

On the basis of the results presented herein and a previous work (unpublished results), a procedure for the production of chlorogenic isomers in potato tubers, which is based on the application of wounding stress and amylolytic enzymes as well as on the selection of storage time and temperature, is proposed. If the production of chlorogenic acid is pursued, pie cut potatoes should be stored for 96 h at 10 °C. For cryptochlorogenic acid production, the optimal storage conditions should be 144 h at 20 °C. Finally, to obtain high levels of neochlorogenic acid, pie cut potatoes should be stored at 20 °C for 96 h, amylolytic enzymes should be added, and the enzyme-treated samples should be stored for an additional 24 h at 20 °C. The stressed potato tubers with a high concentration of chlorogenic acid isomers could be used as the starting material for the extraction of antioxidant phenolic compounds with potential applications in the pharmaceutical and dietary supplement industries.

Finally, a traceless method of spiking is investigated, after a finding that solvent-based spiking of standards led to significant influences on the release of the analytes from the soil.

MATERIALS AND METHODS

General. Apparatus used in this study includes: Zx[3] vortexer (Velp Scientifica, Italy); sonicator (FungiLab, Barcelona, Spain); centrifuge (Eppendorf centrifuge 5415D, Hamburg, Germany); gastight Hamilton GC syringes (Seelze, Germany); gas chromatograph−mass spectrometer (Shimadzu QP2010, Kyoto, Japan) equipped with a Zebron 35MS column with 30 m × 0.25 mm × 0.25 μm dimensions (Phenomenex, Torrance, U.S.).

The pesticides metolachlor (Met), atrazine (Atrz), and their deuterated (^{2}H) analogues (each being 100 μg/mL in 1 mL ampules) were obtained from Dr. Ehrenstorfer GmbH (Augsburg, Germany). A 10-component standard mixture of triazines, mixture TP-619, was obtained from Chem Service (PA) (prometron, atraton, atrazine, propazine, simazine, terbuthylazine, prometryn, ametryn, simetryn, and terbutryn with individual triazine concentrations of 500 mg/L). Diphenylamine, desethylatrazine, and desisopropylatrazine (100 μg/mL) were purchased from Chem Service (PA), while chloroform, methanol, and water (all HPLC grade) were purchased from Riedel de Haën (Seelze, Germany). Sodium chloride (AR grade) was obtained from Sigma-Aldrich (Seelze, Germany). Helium (99.999%) was from Afrox, South Africa. The agricultural soil samples were collected from a farming area in the North West Province near the small town of Derby about 150 km West of Johannesburg, South Africa. In each case, collections were made at various depths (0−5 cm, 20−25 cm cm), and three samples of each were collected from a single agricultural field at distances 15−20 m apart. The soil in the field is classified as red-brown humic sandy soil with approximately 20% silt content, pH 6, cation exchange capacity of around 70 mmol/kg, and bulk density around 1300 kg/m^3.[23]

Standard Solutions. The H-standards of 100 μg/mL atrazine and metolachlor were combined, diluted to 1 μg/mL in MeOH, and kept in a freezer at −18 °C. The deuterated (^{2}H) standards for the same herbicides were prepared and stored similarly. The atrazine breakdown products desethylatrazine and desisopropylatrazine were also mixed with atrazine and metolachlor to prepare a 1 μg/mL standard mixture in MeOH, and the mixture was kept in the same freezer. The working solutions were prepared by dilution of these stock solutions. Reference solutions were prepared by dilution of the stock solution with methanol and were injected directly (1 μL) into the instrument. For the extraction procedure, 10% NaCl aqueous solutions were used, in light of the efficiencies gained using this medium as determined in our previous work.[20] A 100 ng/mL diphenylamine solution was prepared by dilution from a 100 μg/mL solution with chloroform. This was used as the extracting solvent for the BID-SDME method with the diphenylamine employed as internal standard.

Preparation of Soil Samples. Soil suspensions were prepared by adding 2 g of air-dried soil to 2 mL of water (1 g/mL). This suspension was treated by vortexing it at 30 Hz, followed by sonication for 15 min, and thereafter centrifugation at 8165*g*. Given portions of the clear supernatant liquid were transferred into a gas chromatograph (GC) vial containing 0.1 g of NaCl, after which BID-SDME extraction was applied as previously described.[20]

Different extraction methods were used to solubilize the pesticides from the soil, and the results were compared to room temperature sonication. These techniques included heating the suspension, or using boiling/hot water to prepare the suspension, as well as superheating the suspension in a closed vessel.

GC−MS Setup. A calibrated gastight syringe (10 μL) was used for sampling and injections. Analyses were carried out using a gas chromatograph coupled to a mass spectrometer (GC−MS). Pure helium at a constant flow rate of 1 mL/min was used as the carrier gas. Injections (1 μL) were carried out in the splitless mode; after 2 min, a split ratio of 1:10 was maintained throughout the runs. The injector and transfer line were maintained at 250 °C. The oven programming included an initial temperature of 100 °C (held for 4 min), the temperature increased by 50 °C/min to 200 °C, then ramped by 10 °C/min to 280 °C and held for 5 min. The total time for one GC run was 17 min.

The MS (EI 70 eV, 200 °C ion source temperature, 1.5 kV detector potential) was set up in scanning mode with mass range m/z 50−350 mass units. The ions of interest were extracted out of the total ion chromatogram as follows: m/z 162 (166, 4 × ^{2}H), 169, 172, 187, and 200 (205, 5 × ^{2}H) for metolachlor, diphenylamine, desethylaztrazine, desisopropylatrazine, and atrazine, respectively (the values in the parentheses represent the ^{2}H analogues). For quantitative analysis at trace level (lower ng/mL range), the MS was set to the selected ion monitoring (SIM) mode using the same ions as listed above together with their qualifying ions (m/z 215 and 238 for atrazine and metolachlor, respectively); otherwise, the MS was always used on scanning mode using the extracted ion monitoring (EIM) facility.

Microextraction Procedure. The setup for the BID-SDME extraction protocol was reported in detail in our earlier paper.[20] Briefly, 1 μL of the extracting solution was drawn into the syringe, followed by 0.5 μL of air. These contents were introduced into the aqueous solution by gentle depression of the plunger, causing the air to form a bubble contained within the microdroplet. Following a period of 20 min (under static conditions), the total solvent volume was carefully retracted into the syringe, and injected into the GC−MS.

Performance of the Analytical Method for Metolachlor. Only a limited amount of development and validation work was carried out as part of the present study, given the backdrop of our prior work.[20] The main thrust included an assessment of the chromatographic separation of metolachlor in the same TP-619 mixture of 10 triazines reported in our earlier study.[20] The extraction efficiency was evaluated using three aqueous solutions (prepared in 10% aqueous NaCl) at concentrations of 1, 50, and 100 ng/mL for each pesticide together with the corresponding organic solutions. Linearity and LOD were determined using aqueous mixtures of atrazine and metolachlor in the concentration range 0.01−1.0 ng/mL.

Evaluation of Extraction Recovery. Soil samples were air-dried, ground, and sieved through a 0.0035 in. (0.089 mm) mesh. Subsamples (2 g) were wet with 1 mL of HPLC grade water and spiked with 50 μL of a 1 μg/mL solution of the ^{2}H-standard so as to prepare concentrations of 25 ng/g of the pesticide standards in the soil samples. The suspension was allowed to air-dry. Following complete drying, the soil residue was suspended in 2 mL of hot water to dissolve and release the spiked herbicides. The extracts were then subjected to the BID-SDME extraction protocol as described above. The effect of organic solvents in spiking was also evaluated using different spiking solutions, being 100% water, 3:1 water/MeOH, 1:1 water/MeOH, 1:3 water/MeOH, and pure MeOH, respectively. The extraction values from these solutions, especially those from the herbicides existing in the soil from the farming activities (metolachlor and atrazine), were compared to those obtained with the spiked HPLC grade water (spiked to the same concentration as the samples).

All soil samples were sampled in triplicate and each sample analyzed in triplicate, so every analysis was carried out for $n = 9$ as a minimum. Following assessment of recovery, quantitation of the amounts of the herbicides in the soil was calculated from the calibration curve using the extraction efficiency factor.

RESULTS AND DISCUSSION

Assessment of Linearity of the Extraction Method for Metolachlor and Atrazine. The linearity of the method was determined in the concentration range 0.01−1 ng/mL by BID-SDME extraction under optimum conditions established for triazines[20] and analysis using GC−MS: 1 mL of a 10% aqueous NaCl solution of the herbicides was extracted for 20 min with a 1 μL chloroform droplet containing diphenylamine as an internal standard, and a 0.5 μL air bubble, with no stirring. The calibration curves give the following data for atrazine, R^2 0.999 and LOD 0.013 ng/L, and for metolachlor, R^2 0.999, LOD 0.024 ng/L. LOD values were determined using LOD = 3 ×

standard deviation$_{Intercept}$/slope[24] (see also Supporting Information, Figure S3). For purposes of comparison, LOD values for the US FDA Method 302 for metolachlor and atrazine are both 0.010 μg/mL,[25] while the LOD values applied in the EPA Method 507 from water samples are 0.19 and 0.015 ng/mL for metolachlor and atrazine, respectively.[26] The data above indicate that the present approach falls well within the FDA and EPA method requirements for testing these analytes, while following an easy-to-use protocol. Indirectly, the data in Table 1 also fall within these parameters: these were generated from liquid extracts of the soils and converted into mass-basis information.

Analysis of Soil Samples. *Monitoring of Soil Pesticide Concentration over Time.* Following method refinement, the dissipation of the herbicides over time in agricultural soil samples was investigated, making use of samples collected from the upper 5 cm of the soil. Interviews with the farmer had revealed that metolachlor had been sprayed on the farmland in week 1 while atrazine had been sprayed on the farmland during week 4 (the fourth week postspraying of metolachlor). The collected samples were sonicated[27,28] for 15 min, after which they were subjected to BID-SDME. GC−MS analysis of extracts made from farm soils over a period of 15 weeks postspraying showed only the presence of metolachlor (Figure 1: the "sonication" curve shows the depletion of metolachlor

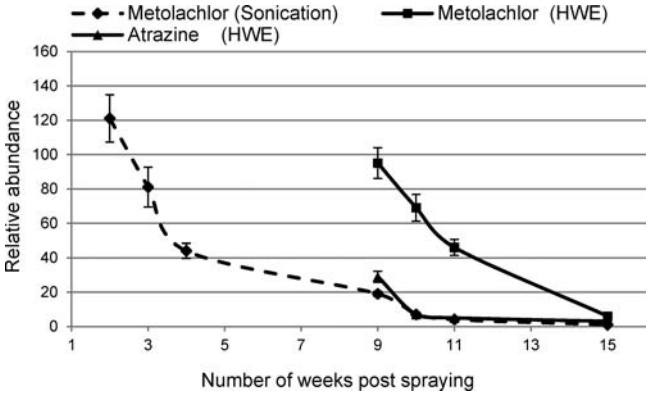

Figure 1. Dissipation−time profile of the herbicides in farmland soil over a 15 week period using sonication and hot water extraction (HWE).

over time). Discovering that neither atrazine nor its breakdown products desethylatrizine and desisopropylatrazine could be detected, we investigated more forcing dissolution methods than sonication (see below).

Throughout and for consistency, subsamples of a given soil sample were employed. Different extraction conditions were explored: the use of vortexing, sonication, hot water (adding freshly boiled water to the sample), heating the sample to boiling, hot water + sonication, and superheated water. The superheated water scenario was achieved by heating the sample in a sealed small stainless steel autoclave to a temperature of 140 °C. In all cases, the allocated time for extraction was 20 min. The results are given below (Figure 2).

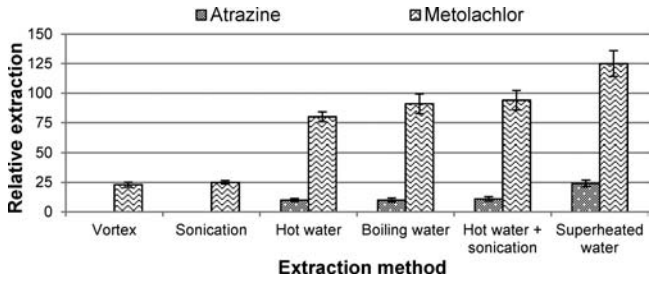

Figure 2. Evaluation of different extraction methods for a given soil sample.

As can be seen in Figure 2, only metolachlor was detected using vortexing or sonication-assisted extraction followed by BID-SDME and GC−MS analysis. However, when using the other more vigorous extraction methods with higher temperatures, atrazine was detected. As can be seen in Figure 2, hot water (96 °C) and heating the sample in water to boiling do not offer much difference in extraction efficiency. Also, sonication is no longer important when using hot water extraction. Although superheated water extraction gave higher extraction of both analytes (Figure 2), this method was not considered useful for wide application due to the difficulty in sample handling and the high pressure equipment required.

Having shown quite good improvements to the solubilization protocols when employing hot water (96 °C) extraction, it was decided to revisit the analysis of the soil samples with the view to improving sensitivity for the detection of metolachlor in the latter part of the sampling period and reassessing the samples for the presence of atrazine. Figure 1 shows the dissipation profiles obtained for the two extraction methods, room temperature sonication versus hot water (96 °C) extraction. Room temperature sonication had extracted only metolachlor (between weeks 2 and 9), while the hot water (denoted in Figure 1 legend as HWE) extracted both analytes, thereby allowing their detection. The improvements secured with hot water extraction are clearly evident with respect to metolachlor with extractability rising from about 20 to 90 in relative abundance (representing about a 4.5-fold improvement in the amount extracted).

Given the improvements achieved in detecting both metolachlor and atrazine, the subsurface layers of soil were also assessed for the presence of the two herbicides of interest there. Table 1 below shows results obtained using samples lying about 25 cm deep and using different time periods following spraying. Evidently, neither herbicide suffers significant leaching from the top layer into lower soil strata as an intact entity, because they were present only at low levels in the subsurface soil. This is a contrast to prior work, which describes metolachlor as "transient" (meaning substantial leaching, in the context of the cited work) in soils, leading to diminished herbicidal efficacy.[29]

One of the two major breakdown products of atrazine, desethylatrazine, could be detected at low levels when

combining BID-SDME preconcentration with GC–MS analysis. No breakdown products for metolachlor could be identified in the extracts. Additional future work will provide robust data on the usefulness of the methods described here to the monitoring of breakdown products of these herbicides.

Recovery of Herbicides from the Soil. While the data generated above provide good relative information, absolute data based on recovery experiments are important for the quantification of analytes. To assess the level of recovery, labeled analogues of the analytes of interest are usually spiked into the sample.[30] Such labeled surrogate materials are readily quantified as separate entities by detectors such as mass spectrometers.[31] Given their physical characteristics that are essentially identical to those of the analyte in question, this approach is widely used to establish quantitative recovery of analytes from samples.[32] The spiking solution is usually added with the organic analyte dissolved in an appropriate organic solvent such as methanol,[33,34] and the influence of the spiking solvent is ignored. In other instances, aqueous spiking solutions are used.[35,36]

Figure 3 shows the effect of the spiking solvent to recovery of the herbicides (see also Supporting Information, section S3).

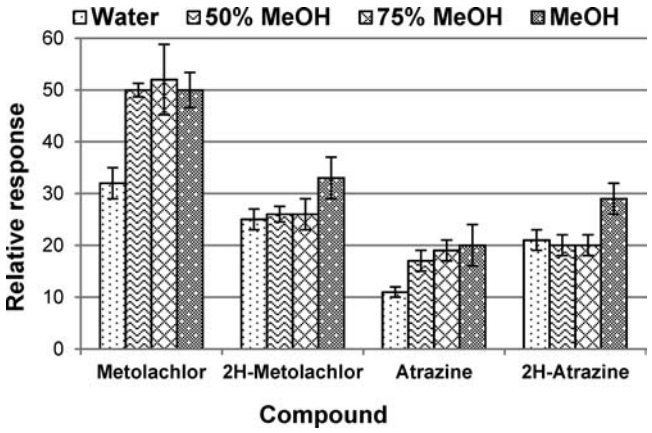

Figure 3. Effect of solvent composition of the spiking solution on extraction.

Clearly, the spiking solvent has an effect on the release of the pre-existing herbicides as demonstrated by the varying extractabilities thereof. Concomitantly, the deuterated spiking surrogate materials showed little changes to their levels of extraction (with the exception of the use of 100% MeOH). Bearing in mind that only 50 μL of spiking solution was used with 2 g of soil, the influence is rather dramatic.

Given the limited scope of our work in terms of soil types, it is not yet known whether this is a general phenomenon or not. Nevertheless, the implication of this exercise is that the suspension of the soils in methanol-containing solutions enhances the extractability of the analytes in question, despite the samples being air-dried and putatively solvent-free at the time of analysis. This implies that the method of choice for the application of spiking solutions to soil samples is to use aqueous spiking solutions where practicable and to allow the samples to dry completely before further manipulation.

This organic solvent effect is consistent with the results obtained by Merini et al.,[37] who reported recoveries of 49% when using an aqueous surrogate and 81% when using methanol surrogate for 2,4-dichlorophenoxyacetic acid. This observation is very important because most of the spiking reported in literature is carried out using an organic solvent in which the surrogates are dissolved, and the influence of the spiking solvent is often overlooked.

Traceless Spiking Method. The composition of the spiking solution was found to influence the extractability of analytes. To avoid this variable, it was decided to use strictly aqueous solutions even for spiking. For this purpose, a 1 μg/mL aqueous spiking solution containing the surrogate deuterated samples was prepared by dilution of 100 μg/mL solutions into 1 mL with HPLC grade water. This solution (50 μL) was used to spike the soil samples (2 g, wet with 1 mL of HPLC grade water), vortexing to ensure equal distribution of the spiking solution over the soil sample and air drying as described above. The application of hot water extraction, BID-SDME, and GC–MS analysis afforded the set of results contained in Table 2, which demonstrate the recovery of the both the analyte and the surrogate herbicides from differently treated soils and from water used as a reference solution.

Table 2. Recoveries of the Analytes (ng/g) from Different Samples Spiked with Aqueous Solutions

	atrazine	metolachlor	^{2}H-atrazine	^{2}H-metolachlor
water (ref)			34 (16)[a]	21 (12)[a]
control soil[b]	3 (6)[a]	13 (8)[a]		
control treated soil[c]	2.8 (8)[a]	12.8 (5)[a]		
spiked soil[d]	3 (9)[a]	13 (5)[a]	33 (10)[a]	22 (8)[a]
% recovery	100%[e]	100%[e]	97%[f]	105%[f]

[a]Values in parentheses are %RSD based on n = 9. [b]The soil sample was used without spiking or suspension in water. [c]The soil sample was wet with water to mimic spiking but without the use of the spiking solution. [d]The spiking solution contained ^{2}H-atrazine and ^{2}H-metolachlor. [e]The % recovery was calculated on the basis of the control soil sample as the reference. [f]The % recovery was calculated on the basis of the water sample as the reference.

These results show that water indeed provided a suitable vehicle for the deuterated surrogates, as the control, treated control, and spiked samples gave the same extractability for the H-analytes. The recoveries obtained for the two deuterated herbicides are 97% and 105%, respectively, for atrazine and metolachlor using the spiked water sample set at 100% for comparison.

Quantitation of the Amounts of the Herbicides in the Soil. Having determined the recoveries of the analytes from the soil samples, the actual concentrations observed at different times were calculated as shown in Table 3. The soil samples were collected over several months from the upper 5 cm layer of soil, right up to the time of harvesting. The data clearly demonstrate that the method can be used to track the concentration of the herbicides in question in agricultural soils.

In summary, this work demonstrates the applicability of the BID-SDME preconcentration technique as an efficient tool for application to the environmental monitoring of the herbicides atrazine and metolachlor using a method that demonstrates sub ng/mL LOD values (0.013 and 0.024 ng/mL, respectively). We identify highly influential effects of the spiking solvent used to prepare the surrogate solutions of the analytes of interest and the care that should be taken to ensure that traceless spiking is employed. Finally, the beneficial effect of hot water extraction over standard techniques such as sonication has been demonstrated. The data generated in this study provide a

[a]Soil samples were collected from the upper 5 cm of soil. [b]Calculated using the calibration equations: $y_{Met} = 47.966x + 3.8069$ and $y_{Atrz} = 56.147x + 0.2193$. [c]The values in parentheses depict the %RSD. [d]Recovery values used: 97% (atrazine) and 105% (metolachlor).

good platform from which decision making as far as herbicide residues in the soils is concerned (environmental and farming perspective) can be performed. In the agricultural context, crop rotation is routinely performed, for example, for maintenance of soil productivity. Because crops show varied sensitivities toward given herbicides, intimate knowledge relating to herbicide residues may be critical information in deciding which crops may or should not be planted in a particular field. This work expands the BID-SDME and associated extraction protocols, which now underpin this method, to become more widely applicable in assessing the transport and fate of pesticides in the environment.

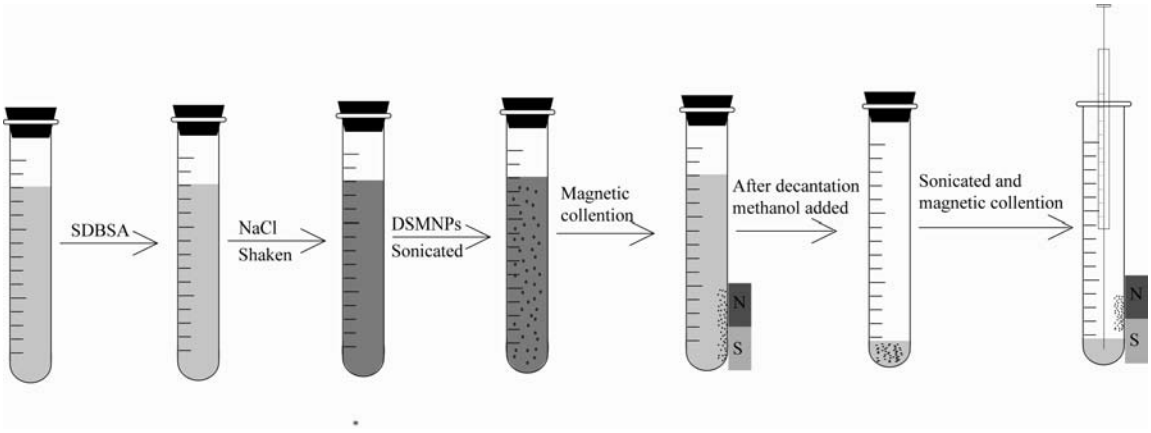

Figure 1. Simplified scheme of the two-step extraction process.

CPE can be used to determine PEs in environmental water samples by high-performance liquid chromatography (HPLC) and ultraviolet (UV) detection, using the nonionic surfactant Trinton X-114 as the extraction solvent.[26] However, the nonionic surfactants most frequently used for extraction and preconcentration prior to HPLC analysis have high background absorbance in the UV region and long retention times.[30] The results also overlap between the chromatographic peaks of the surfactant and the analytes, thereby requiring a cleanup step to obtain adequate selectivity.[31] Gradient elution has also been used to separate the surfactant and PEs to obtain quality chromatograms.[26] In 1999, Casero et al.[30] proposed the acid-induced CPE using anionic surfactants to overcome the aforementioned problems because anionic surfactants have appropriate ionic groups that lead to low retention times. Anionic surfactant solutions exhibiting phase separation in the presence of electrolytes is a phenomenon called coacervation.[32]

In this work, anionic surfactants were used as extraction solvents, and then electrolytes were added to separate the two phases, coacervation phase (CAP) and aqueous phase. The CAP was found to be loose solid instead of liquid, which became the top part and cannot be accurately transferred after centrifugation. For the complete separation of the CAP, a two-step extraction technique that combines the CAP and further dispersive microsolid phase extraction (D-μ-SPE) was developed. The diatomaceous earth-supported magnetite nanoparticles (DSMNPs) were used as the D-μ-SPE material to retrieve the anionic surfactant CAP instead of centrifugation. The new method was used for preconcentration of PEs in water prior to HPLC-UV determination.

MATERIALS AND METHODS

Reagents and Materials. All PE standards including dimethyl phthalate (DMP; 98%), diethyl phthalate (DEP; 99.9%), butylbenzyl phthalate (BBP; 99%), dibutyl phthalate (DBP; 96.8%), and DEHP (99.6%) were obtained from AccuStandard, Inc. (New Haven, USA). Sodium dodecylbenzenesulfonic acid (SDBSA) (Acros Organics, New Jersey, USA) accounted for 88% and sodium dodecyl sulfate (SDS) (Acros Organics, New Jersey, USA) accounted for 99% of the main component and were used as received. A 7% (w/v) surfactant solution was prepared by dissolving the reagents in water. Individual stock solutions of each PE compound were prepared in methanol, and a standard mixture solution of all target compounds was prepared in methanol at a final concentration of 0.1 mg mL^{-1}. The working solution was freshly prepared daily by appropriately diluting the methanolic stock standard solution. All standard solutions were stored at 4 °C and brought to ambient temperature prior to use. For the convenience of the analysis and for minimizing reagent consumption, 10 mL aqueous standard solutions containing each analyte at 50 ng mL^{-1} were used for the optimization study

Methanol and acetonitrile (HPLC grade) were purchased from J&K Scientific Ltd. (Beijing, China). Iron(III) chloride hexahydrate ($FeCl_3 \cdot 6H_2O$) (Acros Organics, New Jersey, USA), ethylene glycol (EG; Acros Organics, New Jersey, USA), 1,2-ethylenediamine (ETH; J&K Scientific Ltd., Beijing, China), sodium acetate (NaAc, J&K Scientific Ltd., Beijing, China), and diatomaceous earth (Qingdao, China) were used to prepare the DSMNPs. Milli-Q water (Millipore, Bedford, MA, USA) was used throughout the study. All solutions prepared for HPLC were filtered through 0.45 μm membranes (Tianjing Jinteng Instrument Factory, Tianjin, China) before use, and all labware are glass products that do not come into contact with any plastic products. All tubes in HPLC are made of Teflon and stainless steel.

Synthesis and Characterization of DSMNPs. Raw diatomaceous earth from Qingdao, China was purified by a previously described method.[33] In a typical synthesis, purified diatomaceous earth (0.3 g) was added to 24 mL of EG. Subsequently, 0.6 g of $FeCl_3 \cdot 6H_2O$ and 1.2 g of NaAc were dissolved in the EG solution at ambient temperature. After stirring for about 30 min, the solution was transferred to a 50 mL Teflon-lined stainless-steel autoclave kept at 200 °C for 8 h and then naturally cooled to ambient temperature. The black precipitate was isolated using an external magnetic field, and the supernatant was decanted. The obtained solid part was washed with ethanol several times and then dried at 60 °C in a vacuum oven. Using this method, 100 g of DSMNPs could be synthesized simultaneously using multiple Teflon-lined stainless-steel autoclaves. The non-modified MNPs were prepared according to the literature.[34] The photography of scanning electronic microscope for MNPs and DSMNPs has been shown in Figure S1 in the Supporting Information.

Liquid Chromatography Analysis. The chromatography equipment was a 1525 binary HPLC pump and a 2489 dual λ UV detector from Waters (Waters Corporation, USA). Waters Breeze software was used to control the instruments and collect the data. Chromatographic separation of the analytes was carried out on a Gemini C18 column (5 μm; 4.6 mm × 250 mm; Phenomenex, Torrance, CA, USA) maintained at 25 °C. The mobile phases A and B were water and acetonitrile. The gradient conditions are as follows: 0−15 min, 70% B; 15−20 min, 70%−100% B; 20−30 min, 100% B. The flow rate of the mobile phase was maintained at 1.0 mL/min; the sample injection volume was 10 μL; and the detection wavelength was 280 nm.

Extraction Procedure. In a typical procedure, 0.8 mL of SDBSA solution was put into a 10 mL glass tube containing 10 mL of sample and was thoroughly mixed. Afterward, 1.2 g of NaCl was added, and the tube was sealed and shaken for 4 min. Then, 25 mg of DSMNPs was added to the tube that was sonicated for another 2 min. The DSMNPs were rapidly collected from the tube wall using an magnetic field provided by a strong Nd−Fe−B magnet (Supporting Information Figure S2), and the sample solution was discarded by decanting. After removing the magnet, 0.2 mL of methanol was introduced to the tube

dx.doi.org/10.1021/jf502364x | J. Agric. Food Chem. 2014, 62, 7682−7689

to desorb the SDBSA by sonication for 2 min. Finally, the magnet was again placed next to the tube, and the supernatant was collected into an Eppendorf tube. All optimized experiments were performed in triplicate. A schematic of the two-step extraction process is shown in Figure 1.

Real Samples. To evaluate the feasibility of the developed method, four real-world water samples were used, including tap, river, tanked, well, and bottled water. Tap water was obtained from a water tap after flowing for 10 min in our laboratory. River water was obtained from the Fen River (Linfen, China) in May 2013. Tanked and well water were simultaneously collected from a local area (Linfen, China). Bottled water was obtained from a local market (Linfen, China). All water samples were collected into precleaned, light-colored glass bottles, and each sample was filtered through 0.45 μm micropore membranes to remove suspended solids. All samples were stored in a refrigerator (at 4 °C) in the dark until analysis.

Calibration of the EF and Extraction Recovery Percentage (ER%). To evaluate the performance of the proposed method, EF and ER% were determined using eqs 1 and 2

$$\mathrm{EF} = \frac{C_{\mathrm{des}}}{C_0} \tag{1}$$

where C_{des} and C_0 are the concentrations of the analytes in the desorbed phase and the initial concentration of the analytes in the sample solution, respectively.

$$\mathrm{ER\%} = \frac{C_{\mathrm{des}} \times V_{\mathrm{des}}}{C_0 \times V_0} \times 100\% = \mathrm{EF} \times \frac{V_{\mathrm{des}}}{V_0} \times 100\% \tag{2}$$

where V_{des} and V_0 are the volumes of the desorbed phase and sample solution, respectively.

RESULTS AND DISCUSSION

Optimization of CAP Extraction Parameters. Selecting an appropriate extraction solvent is important for optimizing the extraction process. Thus, the inexpensive and highly water-soluble anionic surfactants, SDBSA and SDS, were used. The working solution concentration of the surfactants was 7% (w/v). The experimental results showed (Figure 2) that the percentage of the extracted PEs was high for SDBSA with a phenyl group. This effect was consistent with the affinity of PEs to a more hydrophobic CAP. Thus, SDBSA was selected as the extraction solvent.

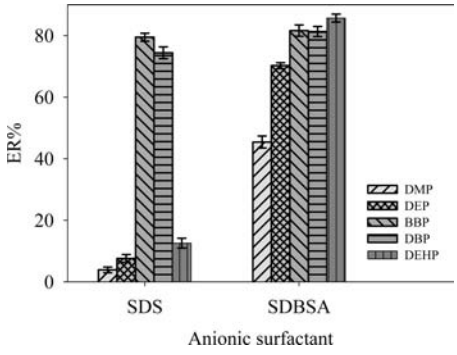

Figure 2. Effect of types of anionic surfactants. Experiment conditions: volume of surfactants, 0.8 mL; amount of DSMNs, 25 mg; extraction time, 4 min; amount of NaCl, 1.2 g; sonication time, 2 min; volume of methanol, 0.2 mL.

To study the effect of the extraction solvent volume of 7% SDBSA on the extraction efficiency (EE) of PEs, other experimental conditions were fixed, and different SDBSA volumes were tested (0.3−1.2 mL). The results are shown in Figure 3. ER% increased with increased SDBSA volumes up to 0.8 mL, beyond which the ER% remained constant. Thus, 0.8 mL of SDBSA solution was used in the subsequent experiments.

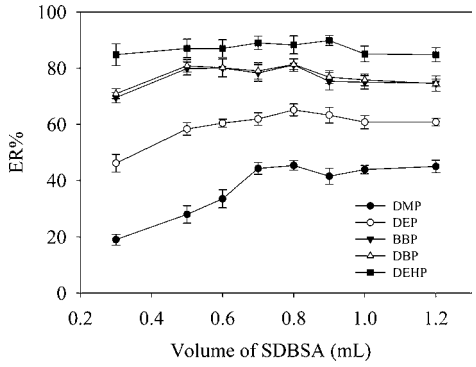

Figure 3. Effect of volume of SDBSA. Experiment conditions: amount of DSMNPs, 25 mg; extraction time, 4 min; amount of NaCl, 1.2 g; sonication time, 2 min; volume of methanol, 0.2 mL.

The coacervation of anionic surfactants is achieved only at a certain salt concentration. Addition of NaCl to the water sample may have various effects (salting out, salting in, or no effect) on extraction. The effect of NaCl on the coacervation of the system was investigated. The effect of NaCl was studied within the quality range of 0.6−1.8 g to 10 mL of sample. The results showed (Supporting Information Figure S3) that the ER % of the four PEs increased with increased NaCl until the amount was 1.2 g, beyond which ER% remained almost constant. Thus, 1.2 g of NaCl was deemed optimum.

The pH of the working solutions or samples has an important role in the extraction because it determines the existing state of the analytes and the EE of the target analytes. In this experiment, the effect of pH was studied within the range of 2.0−11.0, and the results show (Supporting Information Figure S4) the EE almost had no significant change within pH 4.0−9.0 of the sample solution. Therefore, the sample solution pH was not adjusted because the pH of the normal water samples ranged within 6.0−8.0.

Extraction time is also an important parameter affecting EE. Increasing the extraction repeatability necessitates an extraction period within which the equilibrium between the aqueous phase and CAPs is reached. The effect of the extraction time was examined within the range of 0−10 min, whereas other experimental conditions were kept constant. The results showed (Supporting Information Figure S5) that the EE of PEs increased with increased extraction time within 0−4 min and remained almost constant within 4−10 min. Therefore, 4 min was selected as the optimum extraction time.

Magnetic Material Selection. The magnetic material used in this method has a strong interaction effect on the SDBSA CAP so that target analytes extracted by SDBSA can be completely transferred. Two types of magnetic material, i.e., nonmodified MNPs and DSMNPs, were chosen in terms of their adsorption behavior to the CAP. Compared with MNPs, DSMNPs can completely retrieve the SDBSA CAP and have better dispersion and less coaggregation.[35] Thus, DSMNPs were chosen for further experiments.

Sonication was performed for the complete adsorption of CAP to DSMNPs. The sonication time was studied within the time range of 0.5−5 min in 0.5 min intervals. The results showed (Supporting Information Figure S6) that the EE increased with increased sonication time from 0.5 to 2 min.

Prolonged sonication time had little effect on EE. Thus, the sonication time of 2 min was deemed suitable for subsequent experiments.

The effect of the amount of DSMNPs was studied using 15, 20, 25, 30, 35, and 40 mg amounts of retrieval agent. The results showed (Supporting Information Figure S7) that, with increased amount of DSMNPs from 15 to 40 mg, the maximum EE was obtained at 25 mg of DSMNPs (corresponding to its concentration of 2.5 mg mL^{-1} in the sample). When the amount of the adsorbents was >25 mg, the plots were flat, and no distinct increase in EE was observed. Therefore, 25 mg of DSMNPs was used in the subsequent experiments.

Desorption Conditions. Different organic solvents were studied including methanol, ethanol, and acetonitrile. The results (Supporting Information Figure S8) showed that methanol gave the highest overall EE for the five PEs, followed by ethanol and acetonitrile. Therefore, methanol was used for the desorption of the target analytes from the DSMNP surface. The methanol volume investigated ranged from 0.1 to 0.6 mL. The results showed (Supporting Information Figure S9) that the increase in methanol volume from 0.1 to 0.2 mL increased the EE, whereas the ER% remained almost constant, except when the volume was 0.2 mL. However, in this case, EF decreased because the volume of the desorption solvent increased. The application of 0.2 mL of methanol was finally chosen, and the total volume of the desorption solution was almost 0.33 mL.

Influence of Interfering Substances for CAP-D-μ-SPE. Aliquots of aqueous solutions containing 50 ng mL^{-1} PEs and certain amounts of other chemical species were obtained, and the proposed procedure was followed to study the selective separation and determination of PEs from the water samples with various chemical species. The tolerance limit was defined as the concentration of the added interfering substance that

[a]Based on five sample extractions. [b]Not detected.

caused less than ±5% relative error in the determination of the PEs. The results show that 1500-fold Na^+, K^+, Ba^{2+}, Ca^{2+}, Mg^{2+}, Al^{3+}, Ni^{2+}, Cu^{2+}, Cd^{2+}, Hg^{2+}, Co^{2+}, Cr^{3+}, NH_4^+, Cl^-, NO_2^-, CH_3O^-, CrO_4^{2-}, $Cr_2O_7^{2-}$, F^-, Br^-, I^-, NO_3^-, SO_4^{2-}, $S_2O_3^{2-}$, $S_2O_8^{2-}$, BO_3^{3-}, $B_4O_7^{2-}$, CH_3COO^-, CO_3^{2-}, HCO_3^-, $C_2O_4^{2-}$, HPO_4^{2-}, and $H_2PO_4^-$, and 500-fold Zn^{2+} and Sr^{2+}, and 100-fold Sn^{2+}, and 50-fold Pb^{2+}, Fe^{2+}, and Fe^{3+}, and 8-fold MnO^{4-} did not interfere with the determination, indicating the high selectivity of the proposed method.

Determination by HPLC-UV. The background chromatograms of the blank water, reagent blank, and spiked water samples were determined. The results (Supporting Information Figure S10) show the absence of interfering peaks in the background chromatograms and highlight the selectivity of the HPLC-UV method. The matrix effect during HPLC-UV determination was studied by comparing the slopes of two calibration sets prepared in methanol and in the matrix extract. The results (Supporting Information Table S1) show no significant differences between the slopes. Therefore, HPLC-UV determination is not affected by matrix effects.

Method Validation. The external calibration curves were prepared by 10 concentration levels from 0.02 μg mL^{-1}, 0.05 μg mL^{-1}, or 0.1 μg mL^{-1} to 10 μg mL^{-1} of analytes to blank water samples with working solutions, calibration equations calculated using the peak areas of the substances, linear ranges (LRs), determination coefficient (R^2), limits of detection (LODs), limits of quantification (LOQs), and ER%, and EFs for PE determination were obtained under optimum conditions (Table 1). The linearity of the method was explored at PE concentrations from 2.0 ng mL^{-1}, 5.0 ng mL^{-1}, or 10.0 ng mL^{-1} to 1000 ng mL^{-1} with R^2 between 0.9952 and 0.9991. The LODs based on a signal-to-noise ratio (S/N) of 3 ranged

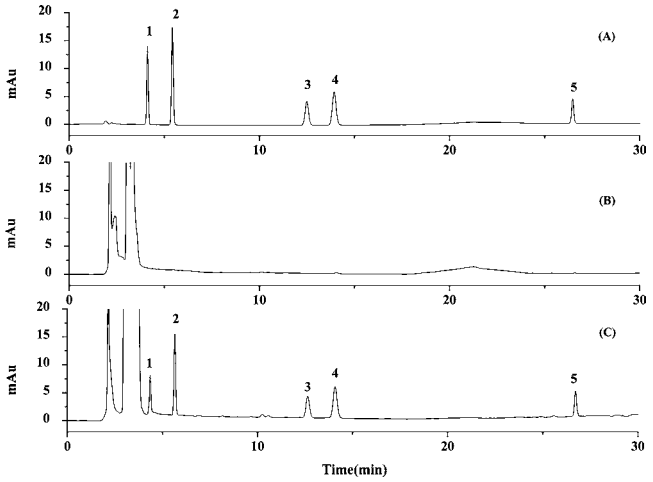

Figure 4. Typical chromatograms for determination of PEs in river water. (A) Standard solution; (B) river water after extraction; (C) spiked river water after extraction, PEs, 10 ng mL^{-1}. Peak 1, DMP; 2, DEP; 3, BBP; 4, DBP; 5, DEHP.

between 0.5 and 5.0 ng mL^{-1}. The repeatability study was carried out by extracting spiked water samples at a concentration of 5 ng mL^{-1} for the DMP, DEP, DBP, and BBP and of 10 ng mL^{-1} for the DEHP, and the relative standard deviations (RSDs) were between 3.9% and 5.7% (n = 10). The results confirmed that the proposed method had good reproducibility and stability and potential for use in the analysis of PEs at trace levels.

Intra- and interday variations were chosen to measure the precision of the developed method by analyzing spiked water samples at a concentration of 10 and 20 ng mL^{-1}. Intraday precision was assessed by five extractions and determinations in 1 day, whereas interday precision was evaluated by five extractions and determinations in different days. The RSDs obtained for both of them presented acceptable precisions (Table 2); i.e., they were obtained in the range of 1.8−4.4% and 3.8−5.8% for intra- and interday assay, respectively.

Comparison of the Proposed Technique with Other Methods. The performance of the proposed method in extracting and determining PEs in water samples was compared with those of other methods, and the results are shown in Table 3. The analytical performance of the proposed method has the following advantages. First, the utilization of the anionic surfactant SDBSA as an extractant without adding any toxic organic solvent and dispersant enabled true "green" microextraction. Second, SDBSA is a front eluting compound than nonionic surfactants and did not interfere with the analytes. Third, using DSMNPs as an adsorbent of the CAP simplified the phase-separation procedures that commonly use centrifugation or filtration during extraction. Although the LOD and linear range of the proposed method are poorer than GC methods,[16,19−22,25] especially the LOD of DEHP (10 ng mL^{-1}) is higher than the maximum limit established by the EPA (6 ng mL^{-1})[3] but similar to other HPLC methods.[9,24,26] These results revealed that this technique was environmentally friendly, simple, rapid, and effective. Moreover, this technique can also be used for PE preconcentration in water samples and extended to other applications.

Analysis of Real Water Samples. The practical applicability of the developed method was evaluated by the extraction of DMP, DEP, BBP, DBP, and DEHP from water samples collected from various sources, including tap, river, tanked, well, and bottled water. All water samples were spiked with standards of the 10 ng mL^{-1} of PEs to assess the matrix effect. The results in Table 4 show that DMP, DEP, and DBP may be detected in tank and bottled water; here, the containers were made of polyethylene terephthalate (PET). PAEs with low molecular weights are fairly soluble in water and are not chemically bonded to the polymer.[36] Thus, PAEs easily migrate from bottles, especially PET ones, to the water.[37] Table 4 also shows that the average results of the five replicate analyses of each water sample obtained by the proposed method satisfactorily agreed with one another (relative recoveries between 85.7% and 105.5%). This result indicated that the method was feasible for the determination of PEs in water samples. The HPLC chromatograms of river water are shown in Figure 4.

A simple, low-cost, and reliable method for enriching and determining four PEs in environmental water samples was established using SDBSA as an extraction solvent and DSMNPs as an adsorption solvent in a two-step extraction technique. Compared with the nonionic surfactant which due to the nonpolar character and large retention times causes the chromatographic overlapping between the surfactant and the analytes, the anionic surfactant SDBSA had an ionic group which resulted in low retention time and did not interfere with the determination of analytes. No toxic organic solvent or dispersant was used throughout the entire extraction procedure, in addition to diatomaceous earth. The DSMNPs used to retrieve the SDBSA CAP in the magnetic field simplified the phase-separation process, rendering unnecessary the use of time-consuming procedures of centrifugation. Overall, the proposed method can expand the applicability of anionic surfactants as extraction solvents because of their low toxicity, high preconcentration factors, and low retention time. The automation of such an extraction procedure is possible, and related work by our group is underway.

transformation products of β-acids. Exact mass measurement of product ions allowed us to assign predicted fragments of known/previously identified transformation products to the product ions obtained by fragmentation of precursor ions with molecular mass corresponding to the transformation products of β-acid. This approach thus allowed us to identify well-described compounds at least in model mixtures without the necessity of having an individual standard of each compound. The efficiency of this approach was demonstrated in the pilot study of β-acids and their transformation products in hops and beer.

MATERIALS AND METHODS

Chemicals and Materials. Commercial CO_2 hop extract of Magnum variety (Hopsteiner, Mainburg, Germany) kept at 4 °C was used for preparation of β-acids. The following chemicals were obtained commercially: acetic acid, acetonitrile of LC-MS grade, ammonium formate, cellulose powder for column chromatography, formic acid (Fluka, St. Louis, MO, USA); acetonitrile of HPLC grade (LiChrosolv, Merck, Darmstadt, Germany); hulupinic acid (HWI Analytic GmbH, Ruelzelheim, Germany); disodium carbonate, diethyl ether, sodium hydroxide (Lach-Ner, Brno, Czech Republic); toluene (LiChrosolv, Merck); ethanol (LiChrosolv, Merck), methanol (Penta, Prague, Czech Republic). Deionized water used for chromatography was purified by means of a Milli-Q purification system (Millipore, Bilerrica, MA, USA).

Hop Samples. Two real samples of Sládek variety T90 hop pellets were analyzed to verify the newly developed method. Sládek is an aroma variety with a balanced content of α-acids and β-acids in an amount of about 4−7% w/w. The pellets were in evacuated barrier packaging as in commercial packages. The first sample (S1) was fresh pellets of the 2012 harvest, the second sample (S2) was aged pellets of the 2008 harvest. These pellets were stored in conditions simulating those in unconditioned warehouses of hop merchants or breweries. Hop samples were selected on the basis of a similar content of β-acids in fresh hops

[a]Name, summary formula, numbering of compound, molecular ions $[M-H]^-$, retention times (t_R), normalized collision energy (NCE), and mass spectrometric fragments of the β-acids and their transformation products are given. [b]Numbering of the compound refers to the literature.[18] [c]HR-MS/MS fragment in bold.

analyzed according to the EBC 7.7 method.[19] Both samples were used in a brewing test.

Preparation of Reference Compounds. *Isolation of Pure β-Acids from Hop Extracts (**1a**–**1c**, Table 1).* The β-acids were isolated from CO_2 hop extracts by two purification steps according to the schedule elaborated by the Hop Research Institute.[18] In the first step, a solution of 20 g of hop extract in 75 mL of toluene was stepwise extracted by disodium carbonate (c = 0.2 mol/L) and sodium hydroxide (c = 1 mol/L). In the second step, crude extract of β-acids containing up to 5% w/w of residual α-acids was recrystallized from the mixed solvent acetonitrile/water. The final mixture of β-acids was entirely free of α-acid residues. Pure β-acids were reconditioned in a refrigerator for 24 h to remove residual solvent and were then kept at −18 °C until use.

Oxidation of β-Acids on Solid Carrier's Surface. The transformation products of β-acids were prepared by oxidation by air oxygen. The purified isolate of β-acids (15 g) was dissolved in pure ethanol (300 mL) and mixed with the cellulose powder (65 g) used as a solid carrier. After thorough mixing, ethanol was removed on a rotary vacuum evaporator. The theoretical amount of β-acids on the carrier was 18.7% w/w. The dry powder with the mixture of β-acids applied on the cellulose surface was afterward kept for 48 h in the dark at room temperature. The HPLC analysis confirmed that about 99% of β-acids were converted by oxidation decomposition to transformation products. Ten milligrams of cellulose powder containing oxidized β-acids was weighed into an Eppendorf tube, and 1 mL of acetonitrile was added. The solid material was removed by centrifugation, and supernatant was diluted 1:10 before injection to the mass spectrometer by adding 0.1 mL of the sample to 0.9 mL of acetonitrile.

High-Performance Liquid Chromatography (HPLC). A Shimadzu Prominence LC 20A HPLC system, equipped with an LC-20 AD pump, an SIL-20A automated sample injector, a thermostated column compartment CTO-20AC, and an SPD-M20A photodiode array detector, was used to analyze the products of oxidation of β-acids. Data acquisition was performed by means of the Class LC20 software package. Analyses were performed on a Nucleodur C18ec column (250 × 4 mm i.d.; particle size, 5 μm; Macherey-Nagel, Düren, Germany) with a mobile phase flow rate of 0.8 mL/min and a column temperature of 40 °C. The mobile phase consisted of (A) water/formic acid (99:1, v/v) and (B) acetonitrile/formic acid (99:1, v/v) with the following gradient elution (min/% A): 0/30, 5/30, and 25/20, followed by a 10 min equilibration. Time of analysis was 45 min. The effluent flow was monitored at the wavelengths of 260, 290, 314, and 355 nm. Injection volume was 10 μL.

High-Performance Liquid Chromatography–High-Resolution MS (HPLC-HR/AM-MS). The studies were performed on a hybrid quadrupole-Orbitrap (Q-Exactive) mass spectrometer (Thermo Fisher Scientific, San Jose, CA, USA) coupled with a Dionex UltiMate 3000 UHPL system, consisting of a pump, a degasser, a column oven, and an autosampler (Dionex, Sunnyvale, CA, USA). Analyses were performed on an XSelect HSS T3 C18 column (100 × 2.1 mm i.d.; particle size 3 μm; Waters, Milford, MA, USA) with a mobile phase flow rate of 0.4 mL/min and a column temperature of 40 °C. The mobile phase consisted of (A) water containing 10 mM ammonium formate plus 0.1% formic acid and (B) methanol containing 0.1% formic acid with the following gradient elution (min/% A): 0/70, 0.2/70, 13/5, and 16.5/5, followed by a 5 min equilibration. The samples were kept at 10 °C, and the injection volume was 2 μL.

The electrospray operated in negative mode using the following parameters: electrospray voltage, 2.5 kV; sheath gas, 48 arbitrary units; auxiliary gas, 11 arbitrary units; sweep gas, 2 arbitrary units. The heater in source was set to 413 °C, and the heated capillary in the mass spectrometer was operated at 256 °C. Data were acquired by targeted MS/MS. Precursor ions from the inclusion list were selected one by one on the quadrupole, collected in the C-trap and transferred to an HCD collision cell. There, the fragmentation took place at appropriate collision energy (Table 2), after which all ions were sent back to the C-trap and from there forwarded to the Orbitrap mass analyzer. The resolving power for MS/MS scan was 70,000. The automatic gain control target was set to 2×10^5 ions and an isolation width of 2 m/z. The LC and mass spectrometer were controlled by Xcalibur 2.2 coupled with Dionex Chromatography MS Link v. 2.14. Calibration of the mass spectrometer was done with external calibration.

Sample Preparation. *Preparation of Hop Samples.* Ten grams (10 ± 0.01 g) of ground hops at a time was mixed in a Duran GLS 80 laboratory bottle with 20 mL of methanol, 100 mL of diethyl ether (temperature = 20 ± 3 °C), and 40 mL of acetic acid (c = 0.1 mol/L). The bottle was tightly closed, placed on an orbital shaker, and treated for 40 min. After shaking, the dispersion of hops particles was left for 10 min

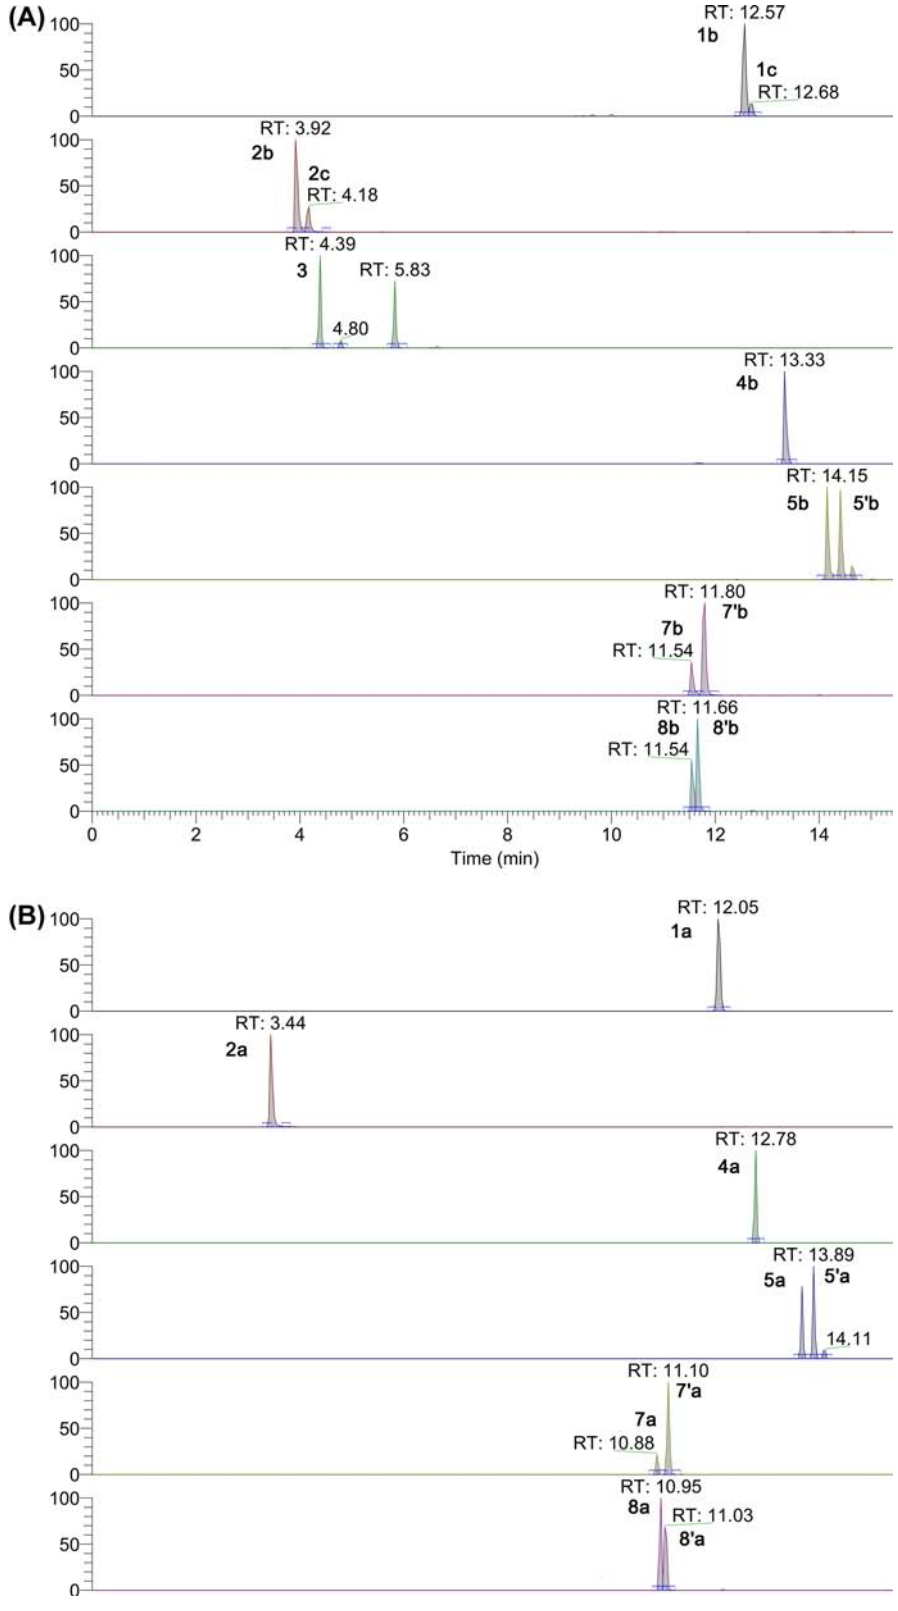

Figure 1. High-resolution extracted ion chromatograms (XICs) associated with selected product ions of transformation products of (A) colupulone (**1a**) and (B) lupulone (**1b**) after oxidation of purified extract of β-acids. The list of used product ions is given in Table 2.

to settle in the bottle. Afterward, 1 mL of extract without any solid particles was transferred into a 50 mL volumetric flask and filled with methanol.

Preparation of Beer Samples by the QuEChERS Method. Extraction of β-bitter acids and their transformation products from samples of beer was carried out according to the original buffered QuEChERS method.[20] Ready-to-use QuEChERS extraction kits (Agilent, Santa Clara, CA, USA) used for sample preparation contained 4 g of magnesium sulfate, 1 g of sodium chlorine, 1 g of sodium citrate tribasic dihydrate, and 0.5 g of sodium hydrogencitrate sesquihydrate for buffered extraction of the

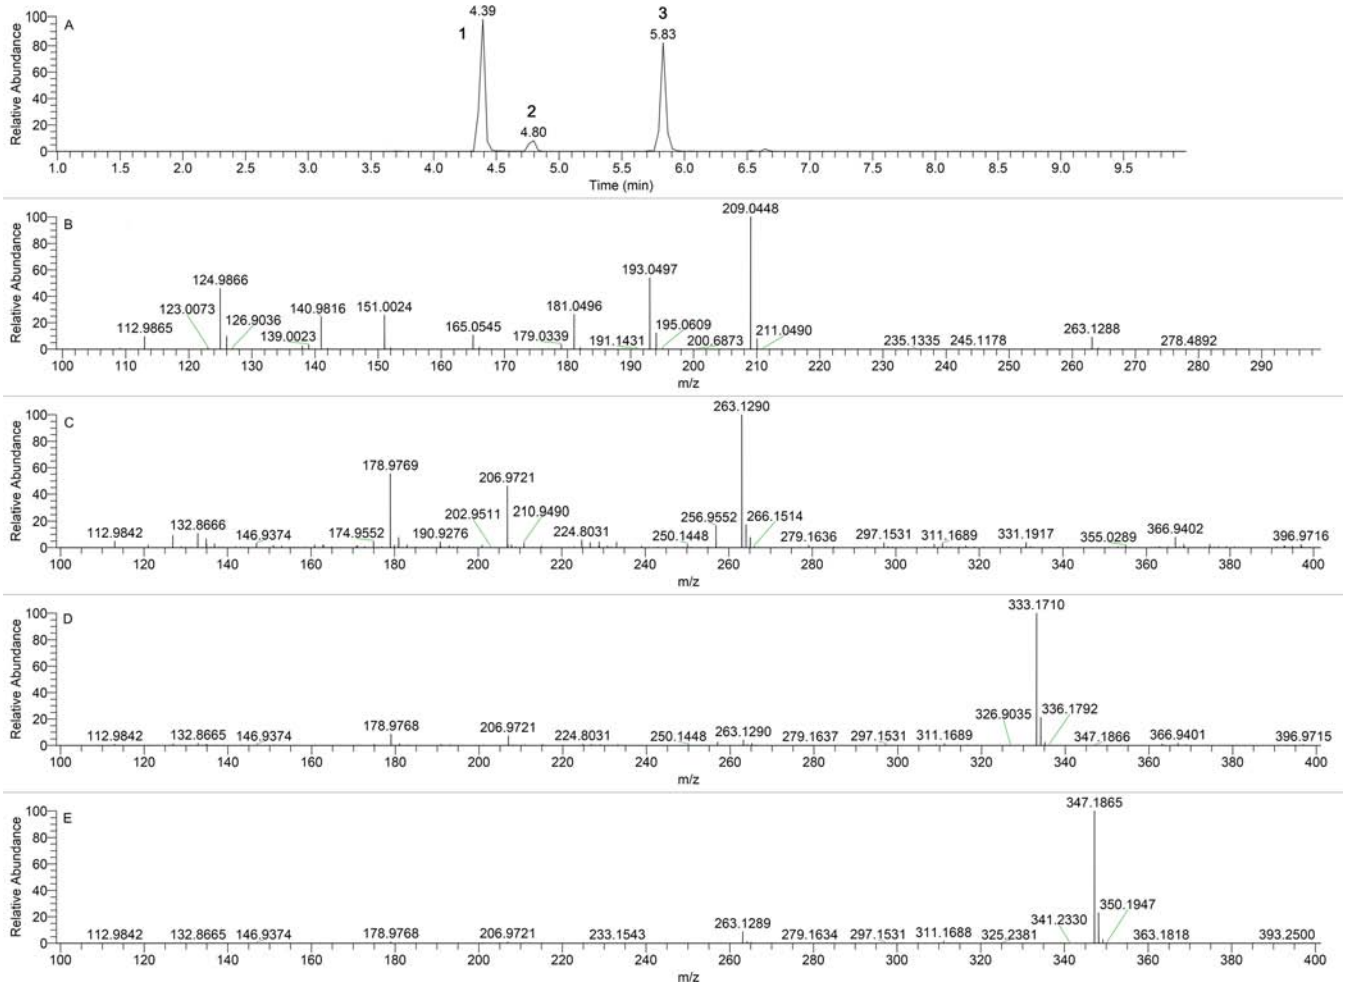

Figure 2. Elucidation of unknown compounds found in oxidized test material: (A) extracted ion chromatogram of (−)SRM 263.1/209.045 m/z with three unidentified peaks numbered 1−3; (B) MS/MS fragmentation spectrum of the peak eluted at 4.8 min; (C) full MS spectrum of peak 2 eluted at 4.8 min; (D) full MS spectrum of peak 1 eluted at 4.4 min; (E) full MS spectrum of peak 3 eluted at 5.8 min.

target. A brief description of the extraction procedure used is as follows: (a) pour 10 mL of degassed beer into a 50 mL centrifuge tube; (b) add salt mixture—whole content of one package; (c) seal the tube, shake vigorously for 1 min by hand, and centrifuge at 4000 rpm for 7 min; (d) transfer 200 μL of the extract to an autosampler vial and add 800 μL of water.

Beer-Brewing Trial. Two pilot-scale (60 L) brews of 12 °P all malt pale lager beer were carried out. Sweet wort was prepared using double-decoction mashing. The following wort boiling technology was used: hop dose was divided into three portions: 30% at the beginning, 50% after 30 min, and 20% after 15 min before the end of the 90 min wort boiling. The primary fermentation was performed in cylindrical−conical tanks (CCT), and a 40 day beer maturation took place in lager tanks. The beer was filtered, bottled, and pasteurized.

RESULTS AND DISCUSSION

Preparation of Pure β-Acid Extract. The final isolate of pure β-acids was entirely free of α-acid residues. Its purity was approximately 99% and was confirmed by HPLC analysis under previously described conditions. The isolation procedure allowed the preparation of β-acids in amounts of several tens of grams in a relatively short time. Pure isolate of β-acids was used for brewing tests in laboratory and pilot scales.

Identification of Hulupones in Oxidized Material. Previously in the literature[17] described compounds generated upon transformation of β-acids, colupulone (**1a**) and lupulone (**1b**), were extracted by acetonitrile from cellulose powder containing oxidized β-acids, diluted, and analyzed using the high-resolution MRM (MRM-HR) technique. Summary formulas of parent compounds (**1a**, **1b**) and their transformation products were used for creating the software inclusion list. Each m/z value from the inclusion list was isolated one by one in quadrupole and consequently fragmented in an HCD cell, collected in a C trap, and analyzed in an Orbitrap. The HR-MS/MS spectra of parent compounds so obtained provide enough specific fragments for building a MRM-HR qualification method and could also be used for confirmation of proposed structure on the basis of the fragmentation pattern of the parent compound. Generally, the MRM-HR method showed better sensitivity compared to the scan method, and in comparison with MRM on QqQ mass analyzers it provided structural information as a benefit. This approach is useful (a) when the structure of transformation products has been previously described in the literature[17] and (b) when these compounds are determined in a model mixture. It could be used for identification of the transformation products of β-acids with a high level of confidence without the presence of the standards for individual compounds of the basis of two facts. (i) The specificity of fragments found in the HR-MS/MS spectra could be compared with the proposed fragmentation pattern by applying a mass window of 5 ppm to the theoretical mass of the fragments. (ii) The mass difference of molecular weight between

dx.doi.org/10.1021/jf501852r | J. Agric. Food Chem. 2014, 62, 7690−7697

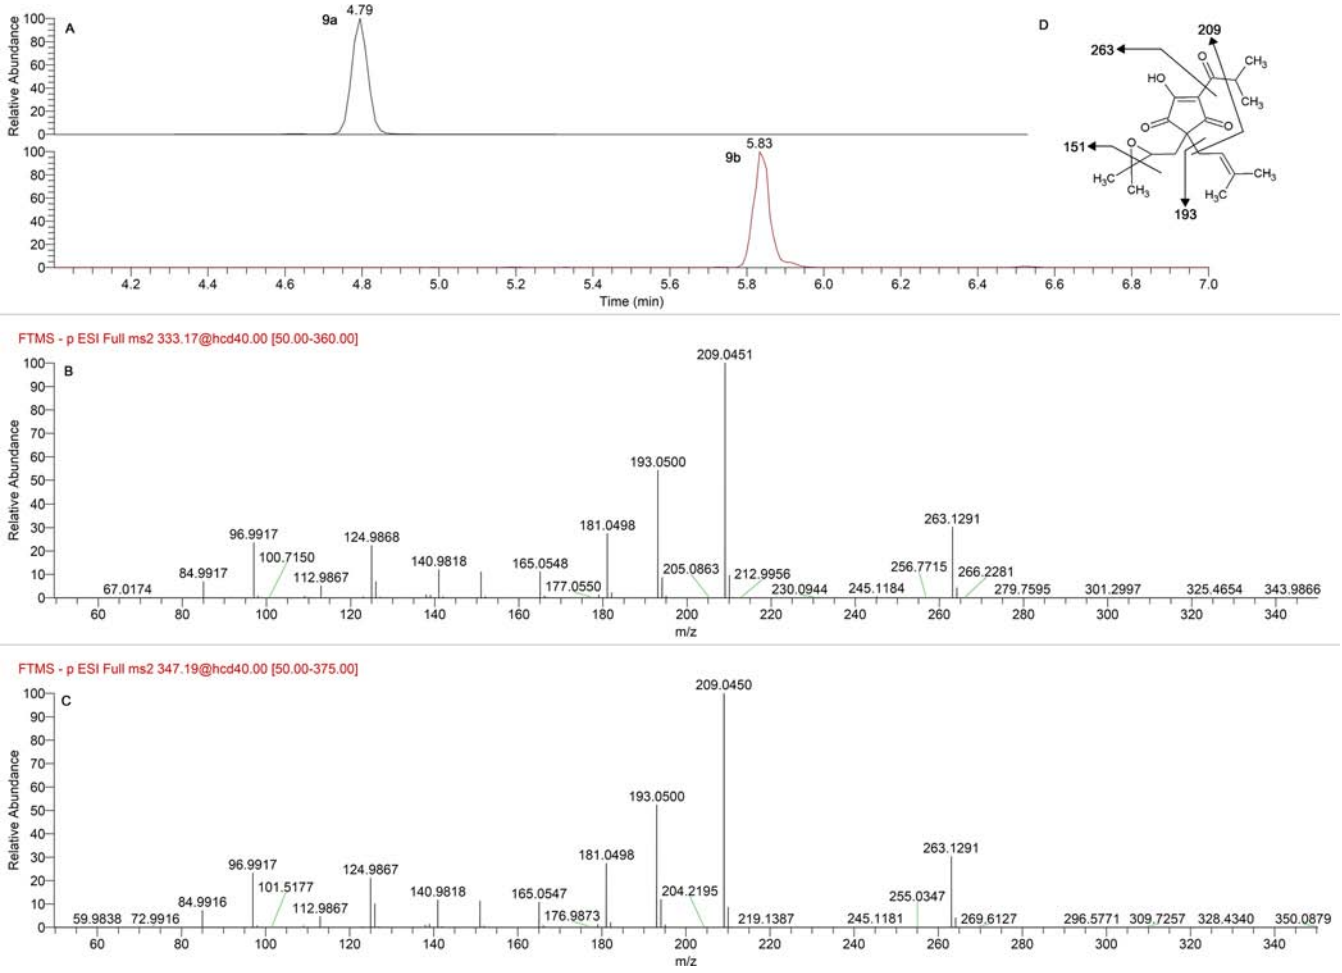

Figure 3. Fragmentation spectra of newly identified compounds (**9a**, **9b**): (A) extracted ion chromatograms of (−)SRM traces 333.2/209.045 and 347.2/209.045; (B) product ion mass spectra of parent ion at *m*/*z* 333 (**9a**); (C) product ion mass spectra of parent ion at *m*/*z* 347 (**9b**); (D) structure proposals for some of the fragments in the product ion mass spectra of parent ion at *m*/*z* 333 (**9a**).

colupulone and lupulone is 14 Da, and the structures of lupulone and colupulone are almost identical, the difference being only in the length of the side chain (see Table 1). The same difference could be expected between transformation products of these two compounds. This fact could be a clue to matching suitable fragments in the MS/MS spectra to the corresponding parent compound. The same mass difference, 14 Da, between the parent compounds colupulone and lupulone could be readily observed also for the fragments of these compounds in the MS/MS spectrum (see Table 1).

Figure 1 shows the MRM-HR chromatograms of colupulone (**1a**) and lupulone (**2b**) and their transformation products found in oxidized test material. Although a different procedure has been used for the preparation of transformation products, the distribution of individual β-acid transformation products corresponds to the literature source[17] except for SRM corresponding to the hulupinic acid. In this case not only was this SRM trace (*m*/*z* 263→209) found to contain three peaks having only one common fragment, but the whole spectrum was almost identical. It was necessary to compare this SRM trace with the HR-MS scan and identify the parent ions because it was obvious that the seeming parent ion (*m*/*z* 263) arose during in-source fragmentation of some other precursor ion. Figure 1 shows the SRM trace (*m*/*z* 263→209) including three peaks at retention times of 4.4, 4.8, and 5.8 min and the MS/MS fragmentation spectrum. As mentioned above, this spectrum was identical for these three peaks. Besides this, Figure 2 also includes three HR-MS spectra corresponding to the retention of these three peaks. The HR-MS spectrum of the peak at a retention time of 4.4 min shows an $[M - H]^-$ ion at *m*/*z* 263.1290, indicating the molecular formula $C_{15}H_{19}O_4^-$, which corresponds to the hulupinic acid with 0.45 ppm accuracy. The HR-MS spectra of the peaks at retention times of 4.8 and 5.8 min show $[M - H]^-$ ions at *m*/*z* 333.1710 and 347.1865, indicating the molecular formulas $C_{19}H_{26}O_5^-$ (0.8 ppm) and $C_{20}H_{28}O_5^-$ (0.3 ppm), respectively. The difference between these summary formulas is one carbon atom plus two hydrogen atoms, which represent a mass difference of 14 Da, which is the same as the difference between lupulone and colupulone. Therefore, these two compounds are most likely the unknown transformation products of β-acids because these molecular masses or summary formulas have not been described in the literature. These unknown compounds have been found in the material treated by oxidation by air oxygen, and, first, the summary formulas of known transformation products were compared with these two unknowns. The difference between the summary formula of cohulupone (**2a**, $C_{19}H_{26}O_4$) and the unknown compound ($C_{19}H_{26}O_5$) is one oxygen atom. The molecule of cohulupone has three double bonds in the side isoprenyl chains, and one of these bonds was most probably oxidized. Figure 3 shows the

dx.doi.org/10.1021/jf501852r | J. Agric. Food Chem. 2014, 62, 7690−7697

tentative structure proposed for this newly detected compound. The second step in the elucidation of the structure of this compound was confirmation of the tentative structure on the basic HR-MS/MS fragmentation pattern (see Figure 3). The fragments (m/z 263.1291, 209.0450, 193.0499, 151.0026, and 124.9869) matched predicted fragments proposed on the basis of the tentative structure of the newly identified compound. Although the structure was not confirmed by NMR, the high-resolution MS/MS spectra could provide satisfactory confidence for the confirmation of the tentative structure of these two oxidation products. These two newly identified compounds were named epoxycohulupone and epoxyhulupone.

Identification of Hulupones in Hops and Beer. The HPLC-HR/AM-MS technique operating on the basis of a MRM approach was used to investigate the compounds derived from the β-acids in hops and beer. The molecular masses for all previously described and newly identified transformation products of β-acids were added to a scheduled inclusion list, and the most intensive or most specific daughter ion was selected for each individual compound. Specificity of analysis was achieved by applying the 5 ppm mass window for extraction of daughter ions from HR-MS/MS spectra. Table 2 shows the characteristic mass transition of each individual transformation product and also the list of other characteristic ions found in the HCD fragmentation spectra. To check the separation of the transformation products that existed as two epimers, they were detected as two separate peaks. The newly identified transformation products were also observed in samples of hops, but only the compound tentatively named epoxyhulupone was found in traces.

Table 3 shows the results of analysis of two hop pellet samples of Sládek variety, harvested in 2012 (S1) and 2008 (S2) and stored for 24 and 60 months, respectively, to promote oxidation of β-acid analogues. Results are expressed as the ratio of the peak areas corresponding to each of the substances found in hops from the 2012 harvest (S1) relative to the hop harvest of 2008 (S2). The relative difference was expressed as a percentage, and these values are in parentheses. A positive sign indicates that a compound is presented in higher amount in freshly harvested hops. A negative sign indicates that a compound, in this case mainly a transformation product, is presented in higher amount in aged hops. Both hop pellets were used for the preparation of beer, and the relationship between β-acids and their transformation products found in beer samples was expressed in the same way; these results are also presented in Table 3.

Table 3. β-Acids and Their Transformation Products in Hops and Beer[a]

compound	hops R (±%)	beer R (±%)
colupulone (**1a**)	1.19 (+71%)	0.48 (−52%)
cohulupone (**2a**)	0.30 (−70%)	0.35 (−65%)
hulupinic acid (**3**)	0.65 (−35%)	0.48 (−52%)
norticyclocolupone (**4a**)	0.29 (−71%)	0.33 (−67%)
dehydrotricyclocolupone (**5a**, **5′a**)	0.29 (−71%)	
hydroxytricyclocolupone (**7a**, **7′a**)	0.29 (−71%)	
hydroperoxytricyclocolupone (**8a**, **8′a**)	0.39 (−61%)	
lupulone (**1b**)	1.38 (+38%)	0.55 (−45%)
hulupone (**2a**)	0.30 (−70%)	0.46 (−54%)
norticyclolupone (**4b**)	0.39 (−61%)	0.23 (−77%)
dehydrotricyclolupone (**5b**, **5′b**)	0.29 (−71%)	
hydroxytricyclolupone (**7b**, **7′b**)	0.29 (−71%)	
hydroperoxytricyclolupone (**8b**, **8′b**)	0.39 (−61%)	

[a]Ratio between responses of corresponding compounds found in hops harvested in 2012 and in 2008 or between two beers prepared from these hops (R); relative difference is expressed in percentage (± %).

The results of analyses of hop samples clearly show that the amount of starting materials, lupulone and colupulone, in fresh hops was higher (by 71 and 38%, respectively) than in long-term stored hops. Simultaneously, lower levels of degradation products were found in fresh hops. The differences ranged from 61 to 71%. The content and composition of β-acids in fresh hops were comparable. Thus, the results suggest that long-term storage of hops leads to appreciable changes in β-acids even under anaerobic conditions in an evacuated container. The content of individual transformation products found in beer produced from freshly harvested hops was about 45−77% lower than that in beer produced from hops harvested in 2008. In contrast to hops, no measurable concentration of cyclic (dehydrotricyclo-, hydroxytricyclo-, and hydroperoxytricyclo-) products was found in beers.

In summary, this study presents an alternative approach, based on high-resolution accurate mass spectroscopy, for the qualitative determination of β-acids and their transformation products. Apart from the fact that we were able to find all transformation products described in the literature,[17] two newly identified compounds with tentative structures have been found. The method could be utilized for a wide range of research applications. Many issues associated with the formation of transformation products of β-acids in hops during aging and in the production of beer, as well as issues related to the importance of the individual compounds for the bitterness of beer, are not yet satisfactorily resolved. Results of demonstration analysis of real samples of hops and beer were satisfactory and thoroughly confirmed our expectations. Future work will focus on the isolation of individual transformation products, and these compounds will be subsequently used for quantification of transformation products and the study of their impact on beer bitterness and its characteristics.

and sulfate forms of monomeric flavanols) after the ingestion of proanthocyanidins,[17,21−25] but only a few studies have been focused on colonic microbial metabolites and the use of proanthocyanidins.[13,16,20,21,26,27]

Therefore, the aim of this study was to develop and validate a method that uses improved off-line μ-SPE followed by HPLC-MS/MS detection for quantification of colonic metabolites derived from grape flavanols in the plasma collected from rats.

MATERIALS AND METHODS

Grape Seed Proanthocyanidin Extract. Grape seed proanthocyanidin extract (GSPE) was obtained from Les Dérives Résiniques et Terpéniques (Dax, France). The individual flavanols and phenolic acids contained in the grape seed extract that were used in this study are detailed in Table 1 (adapted from Quiñones et al.[9]).

[a]Determined by reverse-phase HPLC-ESI-MS/TOF. Values are expressed as milligrams of compound per gram of fresh extract and are the means of three samples. [b]Data adapted from Quiñones et al.[9] [c]Quantified by use of the calibration curve of procyanidin B2. [d]Quantified by use of the calibration curve of epigallocatechin gallate.

Chemicals and Reagents. Acetone (HPLC analytical grade), methanol (HPLC analytical grade), and phosphoric acid were purchased from Sigma-Aldrich (Barcelona, Spain). Ultrapure water was obtained from a Milli-Q Advantage A10 system (Madrid, Spain). Glacial acetic acid was purchased from Panreac (Barcelona, Spain). (+)-Catechin, (−)-epicatechin, benzoic acid, phloroglucinol, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid, 3,4-dihydroxybenzoic acid, 2-(4-hydroxyphenyl)acetic acid, 2-(3,4-dihydroxyphenyl)acetic acid, 3-(4-hydroxyphenyl)propionic acid, vanillic acid, gallic acid, hippuric acid, and ferulic acid (all from Fluka/Sigma−Aldrich, Madrid, Spain) were individually dissolved in methanol at 4000 mg/L. Procyanidin B2, epigallocatechin gallate (EGCG), and pyrocatechol (internal standard, IS) (all from Fluka/Sigma−Aldrich, Madrid, Spain) and 5-(3′,4′-dihydroxyphenyl)-γ-valerolactone (MicroCombiChem e.K., Wiesbaden, Germany) were individually dissolved in methanol at 2000 mg/L. All standard stock solutions were prepared every 3 months and stored in dark-glass flasks at −20 °C.

A mixed standard stock solution in methanol of all these compounds [(+)-catechin, (−)-epicatechin, benzoic acid, phloroglucinol, 3-hydroxybenzoic acid, 4-hydroxybenzoic acid, 3,4-dihydroxybenzoic acid, 2-(4-hydroxyphenyl)acetic acid, 2-(3,4-dihydroxyphenyl)-acetic acid, 3-(4-hydroxyphenyl)propionic acid, vanillic acid, gallic acid, hippuric acid, ferulic acid, EGCG, and 5-(3′,4′-dihydroxyphenyl)-γ-valerolactone] at 200 mg/L and procyanidin B2 at 100 mg/L was prepared weekly and stored in dark-glass flasks at −20 °C. This mixed standard stock solution was diluted daily to the desired concentration by use of an acetone/Milli-Q water/acetic acid (70/29.5/0.5 v/v/v) solution and stored under the same conditions until chromatographic analysis.

Animal and Plasma Collection. Male Wistar rats, weighing between 226 and 260 g, were obtained from Charles River Laboratories (Barcelona, Spain). All of the animals were housed at 22 °C with a light/dark cycle of 12 h (lights on at 9:00 a.m.) and were fed a standard chow diet (AO4, Panlab, Barcelona, Spain) ad libitum during the experiment. The animals were randomly divided into two groups: the control group (n = 6) and the GSPE group (n = 6). On the day of the experiment, the rats were starved for 12 h. To the GSPE group, a dose of 1000 mg of GSPE/kg of body weight (1 mL) was administered by oral gavage. Water (1 mL) was orally administered to the control group. In both groups, oral administration was performed by gastric intubation to the fasted rats between 9:00 and 10:00 a.m. Blood samples were obtained via saphenous vein extraction by use of heparin vials (Starsted, Barcelona, Spain) 7 h after GSPE or water administration. Plasma samples were obtained by centrifugation (2000g, 15 min, 4 °C). The plasma was pooled (n = 6) to obtain sufficient sample volume to perform three replicate chromatographic analyses. The pooled plasma samples were stored at −80 °C until chromatographic analysis was performed. The study was performed in accordance with the institutional guidelines for the care and use of laboratory animals, and the experimental procedures were approved by the Ethical Committee for Animal Experimentation of Universitat Rovira i Virgili.

Off-line μ-SPE Extraction. *Optimization of Plasma Volume.* To determine the minimum sample volume with good recovery values, four different spiked blank plasma volumes were tested (350, 250, 200, and 150 μL) at three different levels of concentration (50, 500, and 5000 μg/mL) for all the standards. Briefly, the Oasis HLB μ-Elution Plates 30 μm (Waters, Barcelona, Spain) were conditioned sequentially with 250 μL of methanol and 250 μL of 0.2% acetic acid. To ensure full contact of the compounds with the sorbent column, plasma aliquots were mixed with different volumes of 4% phosphoric acid (300 μL for 350- and 250-μL plasma samples, 350 μL for 200-μL plasma sample, and 400 μL for 150-μL plasma sample) and 50 μL of IS (200 μg/mL). The loaded plates were washed with 200 μL of Milli-Q water and 200 μL of 0.2% acetic acid. The retained polyphenols were then eluted with 2 × 50 μL of acetone/Milli-Q water/acetic acid solution (70/29.5/0.5 v/v/v). The eluted solution was directly injected into the HPLC-MS/MS.

Optimization of Cleanup Steps. The cleanup steps were further evaluated following the procedure described under Optimization of Plasma Volume) for a plasma volume of 250 μL. In this case, the loaded plates were washed with 100 μL each or 150 μL each of Milli-Q water and 0.2% acetic acid.

Optimization of Elution Steps. The elution steps were further evaluated following the procedure described under Optimization of Plasma Volume for a plasma volume of 250 μL. In this case, the retained polyphenols were eluted with 2 × 25 μL of acetone/Milli-Q water/acetic acid solution (70/29.5/0.5 v/v/v).

Plasma Flavanol Metabolite Extraction. Prior to extraction, the plasma samples were centrifuged (1500g, 5 min, 4 °C) to remove aggregates. The plasma extraction was performed by off-line μ-SPE as described under Optimization of Plasma Volume for a plasma volume of 250 μL The eluted solution was directly injected into the HPLC-MS/MS.

Analysis of Plasma Flavanols and Their Metabolites. *Instrumental Conditions.* The HPLC system consisted of a 1200 LC Series (Agilent Technologies, Palo Alto, CA) using Zorbax SB-Aq (150 mm × 2.1 mm i.d., 3.5 μm particle size) chromatographic column, from Agilent Technologies, Palo Alto, CA. The mobile phase was 0.2% acetic acid (solvent A) and acetonitrile (solvent B). The flow rate was 0.4 mL/min. The elution gradient was 5−55% B (0−10 min), 55−80% B (10−12 min), 80% B isocratic (12−15 min), and 80−5% B (15−16 min). A 10 min post run was applied. The sample injection volume used was 2.5 μL.

[a]Abbreviations: MW, molecular weight; RT, retention time; F, fragmentor; CE, collision energy; MRM, multiple reaction monitoring. [b]For compounds studied by HPLC-ESI-TOF/MS. [c]For analysis of phenolic compounds studied by HPLC-ESI-MS/MS.

This HPLC system was coupled to a 6210 time-of-flight (TOF) mass spectrometer (Agilent Technologies, Palo Alto, CA) system or coupled to a 6410 MS/MS (Agilent Technologies, Palo Alto, CA) system. Ionization was done by electrospray (ESI) in the negative mode. When HPLC-ESI-TOF/MS was performed, the ESI conditions were drying gas temperature of 350 °C, flow of 12 L/min, rnebulizer gas pressure of 45 psi, and capillary voltage of 4000 V. Moreover, when HPLC-ESI-MS/MS was performed, the acquisition was done by multiple reaction monitoring (MRM). The ESI working conditions were as follows: capillary voltage, 3 kV; source temperature, 150 °C; cone gas flow rate, 80 L/h; desolvation gas flow rate, 800 L/h; and desolvation temperature, 400 °C. Nitrogen (>99% purity) was used as a nebulizing and collision gas. Cone voltages and collision energies were optimized by infusing a standard solution of 10 mg/L of each standard or treated rat plasma for expected analytes in a mixture of acetone/Milli-Q water/acetic acid (70/29.5/0.5 v/v/v) at a flow rate of 0.4 μL/min. The full-scan mode was first acquired to select the most abundant m/z value, and the fragmentor was optimized. Main $[M-H]^-$ ions were selected as precursor ions. The collision energies were then studied to find the most abundant product ions, and the most sensitive transition was selected for subsequent quantification. The second transition was used for confirmation purposes. All of the HPLC-MS/MS conditions are outlined in Table 2. The dwell time established for each transition was 30 ms. Data were acquired by use of MassHunter qualitative analysis software B.02.00 (Agilent Technologies, Palo Alto, CA). All of the expected product transitions were confirmed in the literature.

Method Validation. To validate the quantitative method, the calibration curves, linearity, extraction recovery, matrix effect, precision, and method detection and quantification limits were studied by analyzing standard solutions and blank plasma samples spiked with the standard polyphenols. Blank plasmas were obtained at 7 h from rats that ingested water (without GSPE); no phenolic acid basal metabolites were present in blank plasmas. The calibration curves were obtained by plotting the analyte/IS peak abundance ratio and the corresponding analyte/IS concentration ratio.

Method precision was determined as the relative standard deviation (% RSD) of the concentration in a triplicate analysis of three different spiked samples (50, 500, and 5000 μg/mL) randomly distributed intraday. Recovery values were calculated by comparing the responses of the abundance ratio analyte/IS spiked in pretreated plasma matrices by adding the standards before and after pretreatment (off-line μ-SPE) at three different concentration levels (50, 500, and 5000 μg/mL). Matrix effects were evaluated by comparing the relative analyte/IS abundance obtained from spiked blank plasma after off-line μ-SPE with those obtained from commercial standard solutions at three different concentration levels (50, 500, and 5000 μg/mL). Sensitivity was evaluated by determining LOD, defined as the concentration corresponding to 3 times the signal/noise ratio, and LOQ, defined as the concentration corresponding to 10 times the signal/noise ratio. Method detection and quantification limits (MDL and MQL,

respectively) were calculated for the analysis of 250-μL plasma sample following the procedure described previously.

RESULTS AND DISCUSSION

Currently, the common approach for quantification of flavanol metabolites is to quantify the phase II metabolites from the small intestine and liver in plasma or other tissues at short times after the intake of proanthocyanidins.[17−19] Additionally, there are a few studies where microbial metabolites derived from flavanols are analyzed in biological samples.[16,21,26] However, recent investigations revealed that the majority of ingested polyphenols reach the colon, where the enzymes of gut bacteria are able to convert polyphenols and their metabolites into a wide variety of low molecular weight compounds, which can then be absorbed in situ.[11,28] Therefore, since colonic metabolites could be responsible for many of the health benefits attributed to flavanols, complete characterization of the colonic metabolism of flavanols will help to elucidate the bioavailability and metabolism of proanthocyanidins and identify the derivatives responsible for the beneficial health effects attributed to proanthocyanidins.[11] Nevertheless, to our knowledge, there are no validated chromatographic methodologies for the analysis of flavanol-derived microbial metabolites in biological samples.[16,20,21,29] Indeed, only a few studies have analyzed colonic microbial metabolites in biological samples after the ingestion of flavanols.[16,21,26] Currently, the most commonly used method for the study of colonic metabolites is based on in vitro models using batch-culture fecal fermentations.[13,27,30] Hence, in this study we set up an improved methodology for analysis of flavanols and their microbial metabolites.

Improved Off-line μ-SPE for Plasma Sample Pretreatment. The off-line μ-SPE method, previously reported for plasma samples treatment prior to analysis of proanthocyanidins, anthocyanins, and their phase II metabolites,[15,17] was here improved to further reduce plasma volume and to enable extraction of colonic metabolites derived from flavanols. The μ-SPE method enabled concentration of the compounds prior to chromatographic analysis, since they are present in plasma samples at very low levels. Furthermore, the plasma samples had a large number of interferences, mainly proteins, which were removed in this methodology by precipitation with-phosphoric acid.[15] In addition, in this study μ-SPE with hydrophilic−lipophilic balanced (HLB) sorbent allowed the extraction of flavanols and their colonic metabolites. Furthermore, previous studies using this sorbent extracted phase II metabolites derived from flavanols (i.e., the glucuronidated, methylated and sulfated forms of catechin and epicatechin).[16,17] However, in this study phase II metabolites were not analyzed, as the methodology was already reported, and phase II metabolites should not be expected to occur in significant amount in plasma 7 h after polyphenol administration.[16,17]

A major limitation for the analysis of biological samples such as plasma or serum is the sample volume.[15] Especially for the study of small subjects such as rats or mice, the sample volume becomes the most critical parameter to consider. Moreover, reducing the plasma volume will enable experimentation without the sacrifice of animals. Hence, in this study the sample volume for μ-SPE was reduced from 350 to 250 μL with preservation of the recovery values (Table 3). All of the recovery values for 350 μL of plasma sample were similar to reported values of Martí et al.[15] When the extraction recovery was tested with 250 μL of plasma sample, its related rates were also suitable and ranged from 83% to 107%. However, when the extraction recovery was tested with 200 or 150 μL, some compounds showed poorer recovery percentages than when a volume of 250 μL was evaluated. Specifically, recoveries showed

[a]Abbreviations: RT, retention time; LOD, limit of detection; LOQ, limit of quantification; MDL, method detection limit; MQL, method quantification limit. [b]Method detection and quantification limits are given as nanomoles per liter of fresh sample, calculated for analysis of 250-μL plasma sample.

values lower than 80% when the plasma volume was 150 μL. Thus, 250 μL is the lowest plasma sample volume required to achieve acceptable recovery values for all compounds and, hence, was the plasma volume used in this study. On the other hand, decreasing the cleanup solution volume from 200 μL to either 150 or 100 μL did not improve the extraction recovery, as some compounds, like 2-(3,4-dihydroxyphenyl)acetic acid or gallic acid, were not detected by HPLC-ESI-MS/MS. In the same way, decreasing the volume of elution solution from 100 to 50 μL also showed poor recovery values for all compounds tested (Table 4), which indicate that more volume is needed to elute all the compounds. Thus, from all the assessed factors, it

dx.doi.org/10.1021/jf5019752 | J. Agric. Food Chem. 2014, 62, 7698−7706

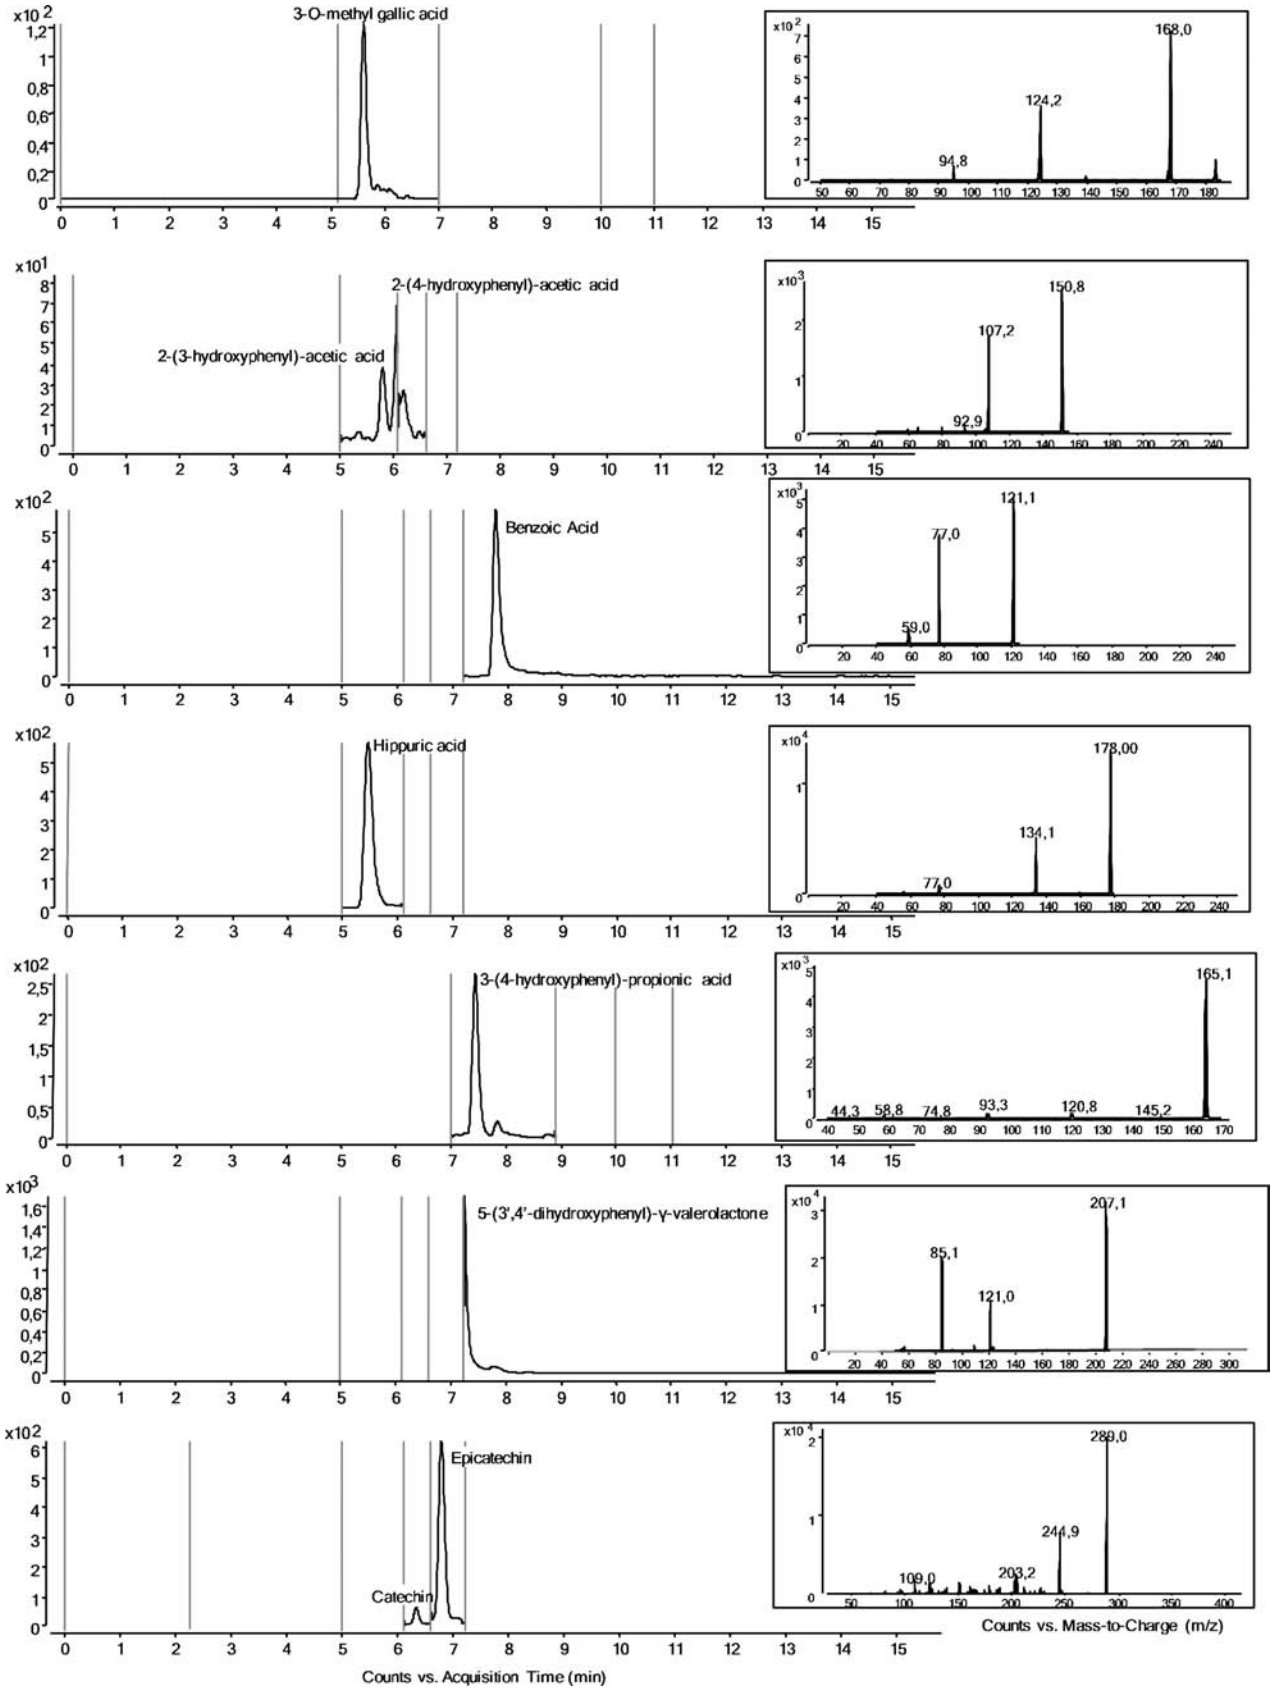

Figure 1. Extracted ion chromatograms of plasma microbial metabolites and their respective mass spectra fragmentation 7 h after ingestion of GSPE (1000 mg/kg).

can be concluded that, for off-line μ-SPE, the plasma volume can be reduced to 250 μL but the cleanup needs to be realized with 200 μL of Milli-Q water and 200 μL of 0.2% acetic acid and the elution volume should be 100 μL.

Quality Parameters. Basal plasma spiked with a range of different concentrations of flavanols and phenolic acids was analyzed via off-line μ-SPE coupled to HPLC-ESI-MS/MS to determine the matrix effect, working linearity range, calibration curves, reproducibility, LODs, and LOQs (Table 5). The linearity of flavanols and phenolic acids was between 0.004 and 41 μM. All of the compounds possessed a R^2 value equal or higher than 0.99, even taking into account that the standards present in the spiked blank plasma and the interactions between compounds could have an adverse effect on the working linearity range.[31] The relative standard deviation (% RSD) was calculated at three concentration levels (50, 500, and 5000 μg/mL) for all the standards in three randomly distributed intraday analyses. For the flavanols and phenolic acids studied, RSD values were between 0.51% and 8.5%. The higher percent RSD values are correlated with a higher dispersion; therefore, these RSD percentages indicate a large variance between the compounds. However, all the percent RSD results were considered the correct values because they did not exceed 20%.[32] Furthermore, no matrix effect was observed with rates close to 0% for all the flavanols and phenolic acids evaluated. For all of the phenolic compounds studied, the LODs and LOQs were lower than 40 nM and 131 nM, respectively. The MDL and MQL values were 0.03−11.28 nM and 0.10−37.37 nM, respectively. The use of 5-(3′,4′-dihydroxyphenyl)-γ-valerolactone as a standard for quantification of all valerolactone and valeric acids metabolites was an important improvement for the methodology developed in our study, as these metabolites were previously quantified as (−)-epicatechin equivalents.[20]

Identification of Colonic Microbial Metabolites Derived from Grape Seed Proanthocyanidins in Rat Plasma. The strategy applied in this study to determine colonic metabolites derived from GSPE was to identify all of the colonic metabolites, including glucuronidated or sulfated phenolic acids, present in the rat plasma from the exact mass of all potential molecular ions by HPLC-ESI-TOF/MS. For this, we analyzed a pool of rat plasma (n = 6) 7 h after GSPE ingestion. The pooled plasma was necessary to collect enough volume of plasma for three replicate chromatographic analyses without the rat sacrifice (i.e., plasma obtained from saphenous vein). Moreover, pooled plasma increases homogeneity and sensitivity in order to allow the detection of all potential metabolites.[33,34] The 7 h time point was selected to allow the flavanols to reach the colon, to be metabolized by gut bacteria, and to be absorbed.

Of the 43 metabolites described in the literature from human[13,20,28] or rat,[14,16,20] 30 colonic metabolites were detected in the plasma after 7 h. Interestingly, at 7 h post-GSPE administration, no glucuronide or sulfate derivatives of the phenolic acids were detected. The fragmentation pattern and retention behavior were subsequently determined by a literature search for all of the compounds identified (i.e., the exact mass and retention time detected), and the compound parameters were then optimized to be quantified by HPLC-ESI-MS/MS (Table 2). Searching the literature for potential compound fragmentation that could occur is very important because the ionization conditions may vary depending on the equipment used in the analysis. Therefore, all of the compounds quantified that did not have their own commercial standard were confirmed in the literature.[20,29] All of the MRM conditions and quality parameters for quantification by HPLC-ESI-MS/MS are listed in Tables 2 and 5, respectively.

Application to Flavanol Bioavailability. The major breakthrough of the method reported in this study was the ability to analyze more than 20 different rat colonic metabolites and additional nonmetabolized flavanols by the same plasma extraction pretreatment and same chromatographic analysis, with a large number of commercial standards (16) for the most specific and accurate quantification possible.

The method developed was applied to analyze rat plasma obtained from the saphenous vein after administration of 1000 mg/kg GSPE. This dose was selected because it was the previously reported acute dose necessary to reach appropriate levels of metabolized forms in the plasma.[17] However, although the high dose was used in rats, these methodologies are usually further extended to the analysis of human plasma with more physiological concentrations of polyphenols.[26,35−37] HPLC-ESI-MS/MS chromatograms of flavanol colonic products in the plasma from treated rats and the respective mass spectra fragmentations are shown in Figure 1. All of the compound concentrations in rat plasma analyzed by HPLC-ESI-MS/MS are shown in Table 6.

The plasma concentrations of catechin, epicatechin, and procyanidin dimer B2, present in the GSPE, were 0.087, 0.532, and 0.013 μM, respectively. The catechin and epicatechin monomers are rapidly absorbed and appear in plasma between 1 and 2 h after ingestion.[17] In this study, we showed that these nonmetabolized compounds can still be quantified in the plasma 7 h after GSPE ingestion, at even lower concentrations than at the 2 h time point.[16] However, EGCG was not detected, which can be attributed to the low concentration in the GSPE more than the poor solubility of the gallate forms of flavanols.[38] Gallic and vanillic acids were two phenolic acids present in GSPE (Table 1) and in plasma that reached concentrations of 0.745 and 0.555 μM, respectively. This high concentrations at 7 h after GSPE ingestion can be attributed to formation of these phenolic acids as products of microbial metabolism.[12,13,27]

Regarding valerolactone or valeric acid compounds, the results show that the only metabolite found in plasma 7 h after administration of GSPE was 5-(3′,4′-dihydroxyphenyl)-γ-valerolactone, although other in vitro experiments performed in human feces with GSPE reported the presence of 5-(3′-hydroxyphenyl)-γ-valerolactone and γ-valerolactone.[13,39] On the other hand, the phenolic acids that presented the highest concentration in rat plasma were 3-(3,4-dihydroxyphenyl)-propionic acid and 3-(4-hydroxyphenyl)propionic acid (9.467 and 7.605 μM, respectively). The rest of the studied phenolic acids were found in concentrations lower than 1 μM. However, it is important to take into account that when microbial metabolites reach the liver, they can be subjected to phase II enzymes and can be conjugated to different final products,[12] as has been observed for 3-*O*-methylgallic acid, the methyl conjugate product from gallic acid[28] whose rat plasma concentration after GSPE intake was 0.217 μM, or ferulic acid, a methyl-conjugated derivative of 3-(3,4-dihydroxyphenyl)propionic acid,[28] which was quantified in the rat plasma at a concentration of 0.241 μM. Unfortunately, no comparable experiments exist in the literature for GSPE colonic metabolites, as they differ in their experimental approach and/or the composition of the extracts. Specifically, when microbial metabolites were analyzed in the plasma, the studies were performed with extracts from cocoa and almonds.[21,26] Almond polyphenols differ considerably in composition from polyphenols found in grapes,[21] and the cocoa-derived polyphenols, which are very similar to grape-

derived polyphenols in composition, were used for chronic treatment in the study.[26] On the other hand, all of the studies performed with grape seed polyphenol extract,[13] its fractions,[40] or a red wine extract[27] were performed in in vitro systems by fecal fermentations.

In conclusion, the present study describes a rapid, simple, and sensitive method for measuring flavanol colonic metabolites in plasma samples by HPLC-ESI-MS/MS. The improved method for off-line μ-SPE plasma pretreatment allowed the flavanols and their colonic metabolites to be determined at low concentrations in a reduced plasma volume, which is an important factor to develop a complete in vivo study. In total, 30 flavanols and their colonic derivatives could be analyzed by a unique pretreatment extraction and chromatographic analysis. Hence, the method developed could be used for completed pharmacokinetics and bioavailability studies in animals.

saponins,[26] and pharmaceutical drugs.[30] Currently, there are no reports on the application of CAD to the analysis of FOS.

Here, a HPLC-CAD and microwave-assisted extraction method was developed for simultaneous determination of 11 FOS with DP 3−13 in 12 different plants in Compositae, Campanulaceae, and Rubiaceae families. The methods were validated and demonstrated for use in analysis of inulin-type FOS and are potentially useful for other plants.

MATERIALS AND METHODS

Materials, Reagents, and Chemicals. The analyzed plants belonged to Compositae, Campanulaceae, and Rubiaceae families, and their detailed characteristics are presented in Table 1. Species identification was performed by Dr. C. F. Qiao. Voucher specimens of these samples were deposited at the Institute of Chinese Medical Sciences, University of Macau, Macao SAR, China.

Inulin-type FOS with DP between 3 and 13 (all purities determined by HPLC-DAD-ELSD were more than 95%) were separated and purified in our laboratory (Figure 1). The structures were confirmed by comparing their methylation, MS, and NMR data with the literature.[17,22] Acetonitrile for HPLC was purchased from Merck (Darmstadt, Germany). Purified water for HPLC was prepared on a Millipore Milli-Q Plus system (Millipore, Bedford, MA). All other chemicals and reagents were of analytical grade.

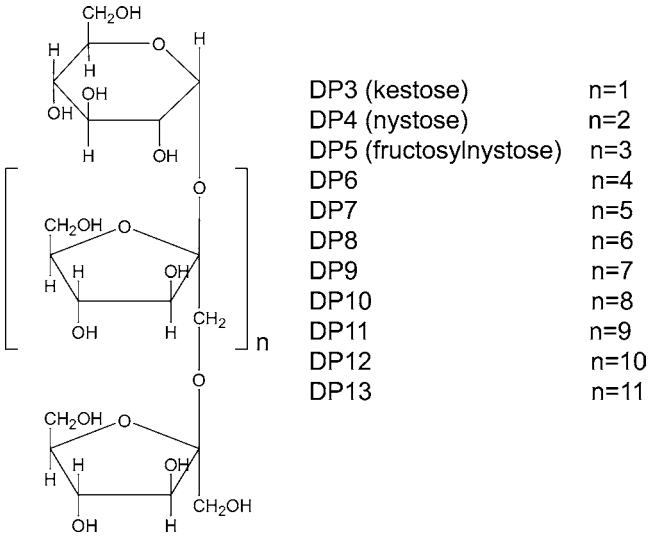

Figure 1. Structures of inulin-type fructooligosaccharides (FOS).

Preparation of Standard Solutions. Mixed standard stock solution containing inulin-type FOS (DP3−DP13) was prepared in 60% ethanol. The concentrations of DP3−DP13 were about 20 mg/mL. The standard stock solution was stored in a refrigerator at 4 °C before use. Working standard solutions were prepared from the stock solution by dilution with the appropriate volume of 60% ethanol.

Sample Preparation. Extraction experiments were carried out with a Multiwave 3000 reaction system (Anton Paar GmbH, Graz, Austria) equipped with a 64-position extraction rotor. The herbal medicine powder (0.1 g, 40 mesh) and 2 mL of ethanol−water (60:40 v/v) were transferred into 5 mL extraction vessels made of borosilicate glass. After the vessels were closed and capped, the rotor was placed inside the microwave oven. The extractions were performed in temperature-controlled mode. After a heating ramp of 1 min, the microwave program was stated as 400 W for 5 min at the temperature of 80 °C. Immediately after the temperature program had finished, all vessels were cooled down to ambient temperature. All extractions were performed with magnetic stirring. After extraction, an aliquot was taken and centrifuged for 5 min at 5000*g*. After centrifugation, 1 mL of supernatant was transferred into a 10 mL volumetric flask and made up to the volume with extraction solvent. Then the solution was filtered through a 0.45 μm filter before injection into the HPLC system for analysis.

HPLC-CAD Analysis. Chromatographic analyses were performed on a Dionex (Germering, Germany) Ultimate 3000 UHPLC system equipped with Ultimate 3000 degasser, pump, RS autosampler, and RS column compartment, coupled with a Corona charged aerosol detector (CAD) instrument (ESA, Chelmsford, MA). Data processing was carried out with Chromeleon 6.8 software (Dionex). The N_2 pressure of the CAD was adjusted to 35 psi and the response range was set to 100 pA. Separations were carried out on a Waters XBridge Amide column (4.6 × 250 mm id, 3.5 μm). The column temperature was set at 30 °C. The mobile phase was consist of water (A) and acetonitrile

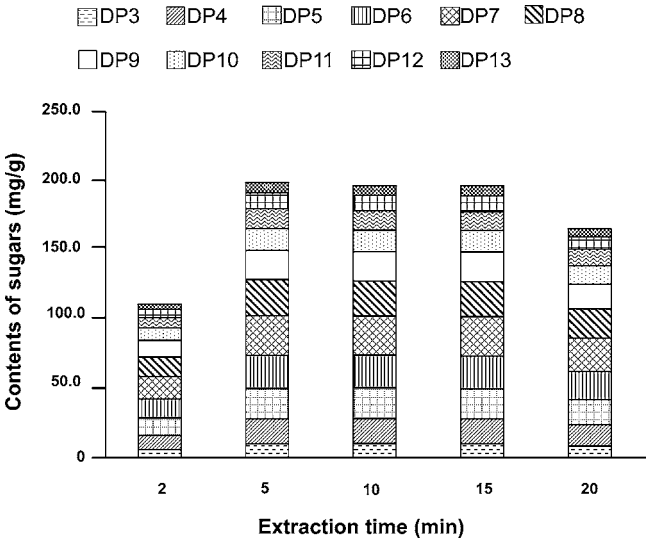

Figure 2. Effect of extraction time on extraction efficiency of FOS with different degrees of polymerization (DP).

Table 2. Linear Regression Data and Limits of Detection and Quantitation for Fructooligosaccharides DP3−DP13

analyte	regression eq	R^2	linear range (μg/mL)	LOD (μg/mL)	LOQ (μg/mL)
DP3	$y = 1.3400x - 2.3594$	0.9993	1.4−53.8	0.4	2.3
DP4	$y = 1.3437x - 2.2999$	0.9979	1.6−58.5	0.6	1.9
DP5	$y = 1.3309x - 2.2231$	0.9978	1.4−52.5	0.6	1.4
DP6	$y = 1.3285x - 2.1593$	0.9983	1.5−36.7	0.4	1.5
DP7	$y = 1.3112x - 2.232$	0.9968	1.5−38.3	0.5	1.5
DP8	$y = 1.2913x - 2.1935$	0.9962	1.5−38.0	0.4	1.6
DP9	$y = 1.3084x - 2.2270$	0.9967	1.5−37.5	0.4	1.6
DP10	$y = 1.3165x - 2.2200$	0.9981	1.4−34.7	0.4	1.4
DP11	$y = 1.2250x - 2.1673$	0.9971	1.4−106.5	0.4	1.4
DP12	$y = 1.2024x - 2.2063$	0.9978	1.3−96.0	0.6	1.6
DP13	$y = 1.1955x - 2.2064$	0.9981	1.5−221.0	0.5	1.5

(B) with gradient elution: 75%−45% B at 0−30 min, 45%−75% B at 30−32 min, and then equilibrated with 75% B for 10 min. The flow rate was 1.0 mL/min and injection volume was 5 μL.

Calibration Curves and Limits of Detection and Quantification. Standard stock solutions containing reference compounds were prepared and diluted to appropriate concentrations for construction of calibration curves. Six concentrations of 11 analyte solutions were injected in triplicate, and then the calibration curves were constructed and their linear ranges determined. Since CAD response was nonlinear and it can be represented by $y = ax^b$, where y refers to peak area, while x is the analyte amount, a is the constant term, and b is the exponential response factor.[31] Therefore, calibration of CAD was constructed by a double logarithmic plot as in previous reports.[26,29,31]

Stock solutions were diluted to a series of appropriate concentration with 60% ethanol, and aliquots of the diluted solutions were injected into HPLC for determining the limit of detection (LOD) and limit of quantification (LOQ). The LOD and LOQ under the present chromatographic conditions were determined at a signal-to-noise ratio (S/N) of 3 and 10, respectively.

Table 3. Precision (Intra- and Interday) for Fructooligosaccharides DP3−DP13

	peak area (% RSD)		retention time (% RSD)	
analyte	intraday (n = 6)	interday[a] (n = 6)	intraday (n = 6)	interday[a] (n = 6)
DP3	2.75	11.10	1.50	0.05
DP4	2.40	10.20	1.30	0.06
DP5	2.10	9.90	1.13	0.05
DP6	1.48	9.56	1.03	0.06
DP7	1.67	11.76	0.95	0.07
DP8	1.58	11.64	0.89	0.06
DP9	1.57	13.05	0.85	0.05
DP10	1.80	13.57	0.81	0.07
DP11	1.72	13.17	0.76	0.06
DP12	1.90	17.33	0.75	0.05
DP13	2.62	15.74	0.72	0.06

[a]Interday precision was determined over a period of 5 days (3 measurements on each day).

Table 4. Repeatability, Stability, and Accuracy for Fructooligosaccharides DP3−DP13

	repeatability		stability	accuracy	
analyte	content (mg/g)	RSD (%)	RSD (%)	recovery (%)	RSD (%)
DP3	19.28	2.44	2.21	99.0	3.92
DP4	29.74	2.18	2.36	100.4	4.43
DP5	31.72	2.11	3.53	95.9	5.26

DP10	23.45	2.44	3.54	98.7	5.17
DP11	25.62	3.09	4.46	113.3	5.36
DP12	24.37	2.93	4.97	114.4	5.40
DP13	19.39	2.94	4.88	99.5	7.25

Precision, Repeatability, Accuracy, and Stability. Precision of the HPLC-CAD method was determined by evaluating the repeatability of intraday and interday measurements. Intraday precision was determined by repeating the analysis of the mixed standards solution for six replicates within 1 day, while interday precision was determined in duplicates on three successive days. Repeatability of the developed method was confirmed with preparation and analysis of six parallel samples. Stability was tested and analyzed at 0, 1, 2, 4, 8, 12, and 24 h. In order to check the accuracy of the developed method, recovery experiments were carried out as follows: accurate amounts of the standards were spiked into the samples (0.05 g) in the form of solution. The spiked samples were extracted, processed, and quantified in accordance with methods mentioned above. Average recoveries were determined by the equation recovery (percent) = 100 × (observed amount − original amount)/spiked amount, and relative standard deviation (RSD, percent) = 100 × standard deviation (SD)/mean.

Liquid Chromatography−Tandem Mass Spectrometric Analyses. LC-MS/MS analyses were carried out on an Agilent 1100 Series LC/MSD Trap system (Agilent Technologies, Palo Alto, CA), equipped with vacuum degasser, quaternary pump, autosampler, column compartment, diode-array detector (DAD), and ion-trap mass spectrometer with electrospray ionization (ESI) interface, connected to Agilent LC/MSD Trap software. ESI-MS conditions were as follows: drying gas N_2 at 7 L/min, temperature 325 °C, pressure of nebulizer 25 psi, source voltage 3.5 kV. ESI-MS/MS

dx.doi.org/10.1021/jf502329n | J. Agric. Food Chem. 2014, 62, 7707−7713

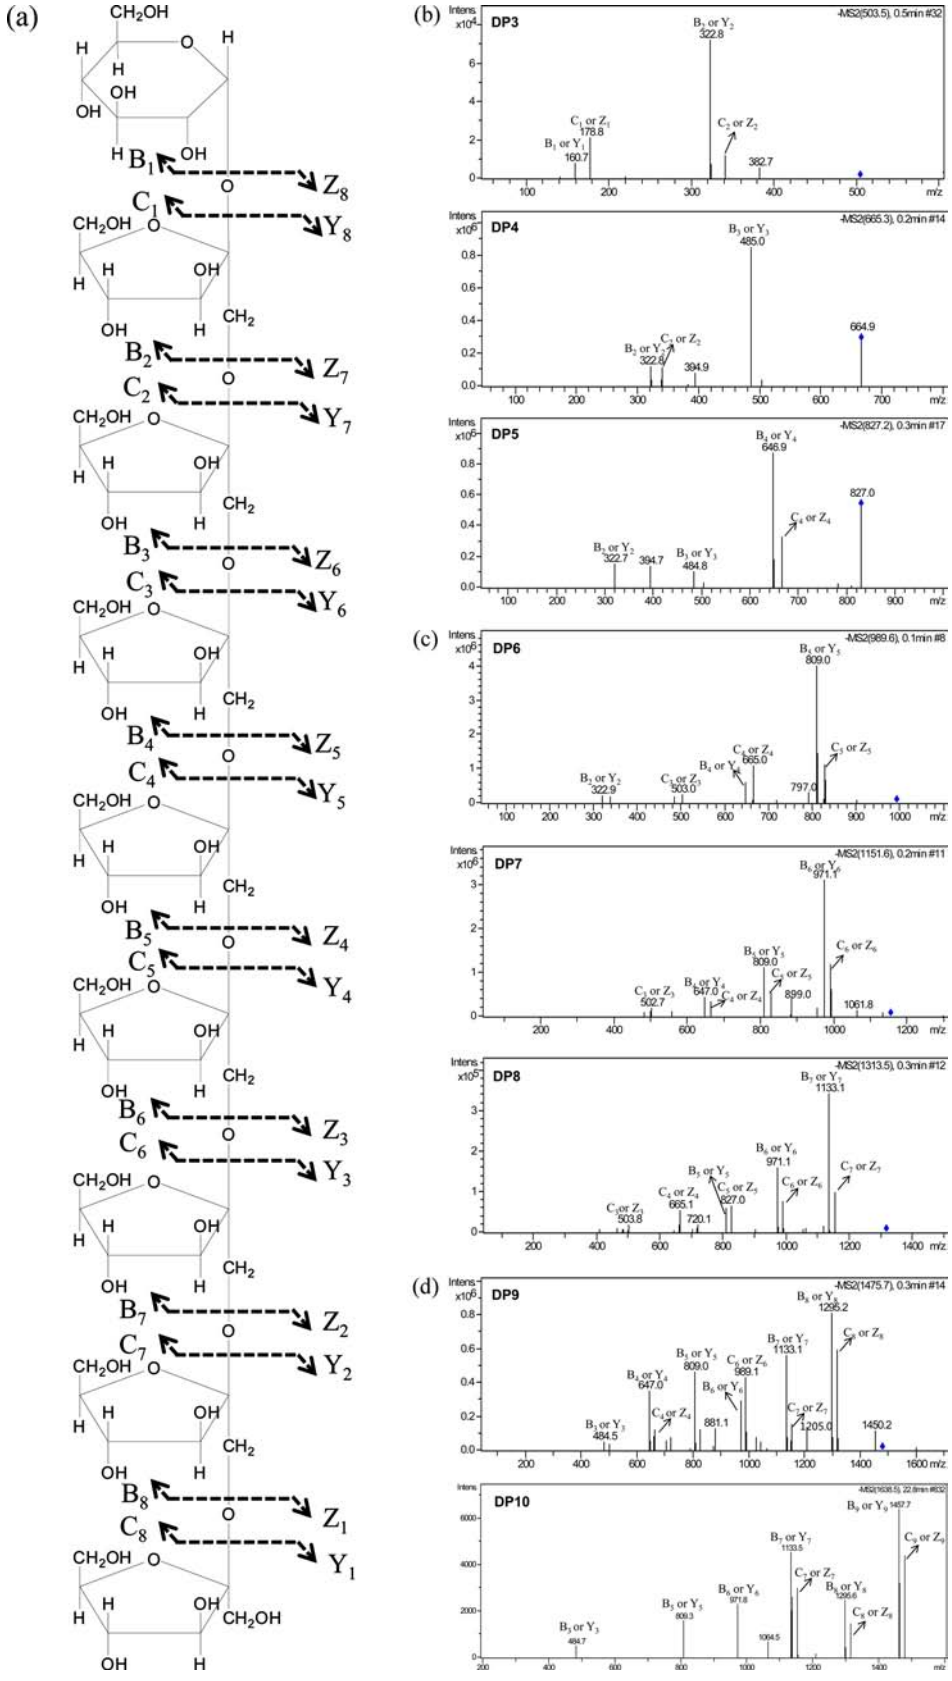

Figure 3. (a) LC−MS/MS spectra and (b−d) Domon and Costello nomenclature for the fragmentation of separated FOS (DP3−DP10).

conditions included isolation width 4 and fragment amplification 1.5. Scan ranges of both MS and MS/MS were 200−2200 m/z. The liquid chromatographic conditions for LC-MS/MS were the same as described for HPLC-CAD analysis.

RESULTS AND DISCUSSION

Optimization of Sample Preparation. In order to obtain quantitative extraction, the extraction method, extraction solvents,

dx.doi.org/10.1021/jf502329n | J. Agric. Food Chem. 2014, 62, 7707−7713

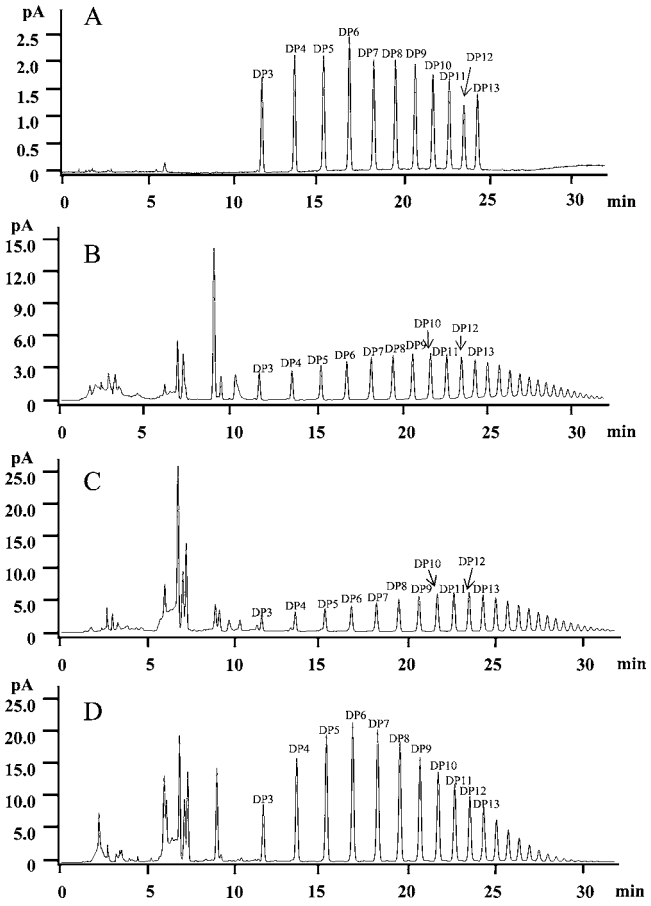

Figure 4. HPLC-CAD chromatograms of (A) mixed standards and (B–D) samples of (B) *Atractylodes macrocephala*, (C) *Platycodon grandiflorum*, and (D) *Morinda officinalis*.

extraction solvent volume, extraction time, and temperature were optimized. Solvent choices, solvent volumes, and temperature used in this study were fixed according to our previous study.[23] We investigated the effect of extraction time, which directly influence the extraction yields of FOS.

In order to get the optimal reaction time, we performed the extraction by microwave extraction in a range from 2 to 20 min at 80 °C, using a sample (*Morinda officinalis*, sample J3) of approximately 0.1 g. Results (Figure 2) showed that the optimal extraction time of FOS was 5 min, whereas longer extraction time did not significantly increase extraction yields and FOS degradation was observed at 20 min. We therefore selected 5 min as the optimal extraction time.

Optimization of HPLC Conditions. Analysis of FOS is a challenge due to their high polarity and complexity and lack of specific UV absorptivity. Therefore, the HPLC-CAD method was selected for analysis of FOS. Several different commercial columns were tested, and finally the Waters XBridge Amide column (4.6 × 250 mm id, 3.5 μm) was selected for separation of 11 investigated inulin-type FOS because of its high resolution and good signal-to-noise performance. The analytes in both mixed standard solution and sample solutions can be well separated by gradient elution with water and acetonitrile.

Method Validation. Linearity, regression, and linear ranges of the 11 analytes were determined by the developed HPLC method. The data indicated the calibration curves of the 11 analytes had good linearity (R^2 > 0.9962), and their LODs and LOQs were in the ranges 0.4–0.6 μg/mL and 1.4–2.3 μg/mL, respectively (Table 2). For intraday precision, RSDs of the peak area was 1.48–2.75% and RSD of the retention time was 0.72–1.50%; for interday precision, the corresponding RSDs were 9.56–17.33% and 0.05–0.07% (Table 3). Recoveries ranged from 94.0% to 114.4%, and the analytes were very stable in 60% ethanol solution during the tested period (Table 4). The high recoveries (113.3% and 114.4%) of DP11 and DP12 might be attributed to the variation of their purities, and more attention should be paid in future.

LC-MS/MS Analysis. Molecular mass information on the standards and the extracted samples were determined in negative ion mode. In the negative ion mode, the $[M - H]^-$ of FOS (DP3–DP13) were detected at m/z 503, 665, 827, 989, 1151, 1313, 1475, 1637, 1799, 1961, and 2123. ESI-MS/MS of their $[M - H]^-$ ions was performed to obtain the individual fragment patterns. Their MS/MS spectra are shown in Figure 3. The fragment ions of FOS include glycosidic cleavages between two sugar residues and cross-ring cleavages of two bonds within the sugar ring. In our MS/MS spectra, the fragment ions of FOS mainly result from glycosidic cleavages between two sugar residues, which were as the same as those reported in previous literature.[17] That little fragments with low abundance of the cross-ring cleavages of two bonds within the sugar ring were found might be derived from the low collision energy or few sodium ions in mobile phase.[17,32] FOS (DP11–DP13) with high molecular weights are difficult to ionize for LC-MS/MS analysis, so the characteristic MS/MS spectra of FOS (DP11–DP13) could not be shown. However, in the MS spectrum of FOS (DP11–DP13), the characteristic ions at m/z 161, 179, 323, 341, 485, 503, 647, 665, 809, 827, 971, 989, 1133, 1151, 1313, 1475, 1457, 1638, and 1800 were obtained. In summary, all the results suggested that FOS should consist of the corresponding number of hexoses.

Quantitative Determination of FOS in Plants. The established HPLC-CAD method was applied for analysis of inulin-type FOS (DP3–DP13) in different samples of Compositae, Campanulaceae, and Rubiaceae families. HPLC-CAD chromatograms of the mixed standards and different samples are shown in Figure 4. Besides the investigated 11 oligosaccharides, many oligosaccharides with DP of more than 13 were also found in these samples. Unfortunately, we could not quantitatively determine these oligosaccharides because of the absence of related reference compounds, which should be performed in the future. The contents of the 11 investigated FOS in different samples are summarized in Table 5 and Figure 5. The results showed that the three samples with highest contents of FOS were *Morinda officinalis*, *Helianthus tuberosus* and *Arctium lappa*, and both *H. tuberosus* and *A. lappa* belong to the Compositae family. The data also indicated there was no FOS detected in *Taraxacum mongolicum* and *Carthamus tinctorius*, which are also of the Compositae family. That is because FOS are usually the chemical compounds for storing energy in organs such as bulbs, tubers, and tuberous roots. The flowers contain little FOS.

In summary, there are many reports on the existence of FOS in plants of Liliaceae, Compositae, Campanulaceae, and Rubiaceae families, but few reports on their contents in these samples. This is the first report for quantitative analysis of inulin-type FOS (DP3–DP13) in different samples of plants in Compositae, Campanulaceae, and Rubiaceae families, which is helpful to improve their qualities. The developed HPLC-CAD method, which is accurate and specific, can also be used for determination of inulin-type FOS in other plants.

based infant formula samples were powder. Fruit and vegetable pure samples were selected in the similar manner and they were all semiliquid. Jarred foods that were gels grouped as pudding and they were also containing milk or milk products. The main ingredients (fruits, vegetables, and cereals etc.) of these foods are given in Table 1.

Analysis of α-Dicarbonyl Compounds. *Extraction.* One gram of sample (infant formula, fruit puree, vegetable puree, and pudding) was extracted with water in three stages (10−5−5 mL) by vortexing 3 min. After centrifugation (5000*g* for 5 min) in each stage, supernatants were collected in a test tube. The coextracted colloids were precipitated by mixing with acetonitrile. Two hundred μL of the combined extract was diluted 5 fold with 800 μL of the mixture of acetonitrile:water (5:3, v/v), and centrifuged at 15 000*g* for 5 min. All samples were extracted in duplicates.

Derivatization. Derivatization of α-dicarbonyl compounds was carried out with *o*-phenylenediamine according to the published procedures with minor modifications [18,21,22]. Five hundred μL of supernatant was mixed with 150 μL of 0.2% *o*-phenylenediamine solution containing 11 mM diethylenetriaminepenta acetic acid and 150 μL of 0.5 M sodium phosphate buffer (pH 7). The mixture was immediately filtered through 0.45 μm syringe filter into an auto sampler vial. It was kept at room temperature, at dark for 2 h prior to HPLC-ESI-MS measurement.

HPLC-ESI-MS Measurement. α-Dicarbonyl compounds were determined by using an Agilent 1200 series HPLC system coupled with an Agilent 6130 single quadrupole mass spectrometer. The chromatographic separation was performed on a Merck Purospher Star RP-18e column (150 × 4.6 mm^2 id., 5 μm) using a gradient mixture of (A) 1% formic acid in water and (B) 1% formic acid in methanol as the mobile phase at a flow rate of 1 mL/min at 30 °C. The gradient mixture was started from 30% B and increased to 60% B in 10 min, then it was decreased to 30% B in 2 min and the 30% B remained for 3 min. The chromatographic run was completed in 15 min. The injection volume was 10 μL. The electrospray source had the following settings: drying gas (N_2) flow of 13 L/min at 300 °C, nebulizer pressure of 40 psig and capillary voltage of 4000 V. Fragmentor voltage was set to 100 V. MS data were acquired in the positive mode and α-dicarbonyl compounds were identified by selected ion monitoring (SIM) mode. The SIM ions $[M + H]^+$ were as follows for the quinoxaline derivatives of glucosone: 251; 1- or 3-deoxyglucosone: 235; dimethylglyoxal: 159; methylglyoxal: 145; and glyoxal: 131. A dwell time was set at 97 ms for each.

The SIM ions of the quinoxaline derivatives of α-dicarbonyl compounds were used for quantitation. The concentrations of quinoxaline, 2-methylquinoxaline and 2,3-dimethylquinoaxaline were calculated by means of external calibration curves in the range between 0.01 and 0.2 mg/L. Working solutions of 3-deoxyglucosone in the concentration range between 0.01 and 2.0 mg/L were derivatized and analyzed as described above to build its external calibration curve. Also, this calibration curve was used for semiquantitation of glucosone and 1-deoxyglucosone quinoxaline derivatives since both have same proton accepting groups. All working solutions were prepared in acetonitrile−water (50:50, v/v). Limit of detection (LOD) and limit of quantitation (LOQ) were determined at a signal-to-noise ratio of 3 and 10, respectively. Repeatability of the method was determined by analyzing three replicates in three consecutive days.

Analysis of Furfurals. The previously reported methods were used with some modifications.[23,24] The same extract of the samples was used for HMF and furfural analysis. A part of the extract was precipitated by Carrez clarification and centrifuged at 10 000*g* for 5 min. The supernatant was filtered through 0.45 μm syringe filter into an autosampler vial prior to analysis. The analysis was performed by Shimadzu UFLC system (Kyoto, Japan) consisting of a quaternary pump, an autosampler, a diode array detector and a temperature-controlled column oven. The chromatographic separations were performed on an Waters Atlantis dC18 column (250 × 4.6 mm^2 i.d., 5 μm) using the isocratic mixture of 10 mM aqueous formic acid solution and acetonitrile (90:10) at a flow rate of 1.0 mL/min at 25 °C. Data acquisition was performed by recording chromatograms at 285 nm. Concentrations of HMF and furfural were calculated by means of external calibration curves built in the range between 0.1 and 5 mg/L.

puddings		
	1	Milk (%54), rice (34%), sugar cane (4.5%)
	2	Yogurt (20%), banana (14%), orange juice (6%), starch (5%), sugar (5%)
	3	Yogurt (20%), skimmed milk (10%), pineapple juice (8%), sugar (5%), starch (6%), concentrated lemon juice (1%)
	4	Apple puree (35%), milk (30%), rice flour, sugar

Measurement of pH. Infant formula samples (0.2 g of powder) were mixed with 10 mL of deionized water and the tubes were put onto an orbital shaker for 10 min. After centrifugation (5000*g* for 5

dx.doi.org/10.1021/jf502418n | J. Agric. Food Chem. 2014, 62, 7714−7720

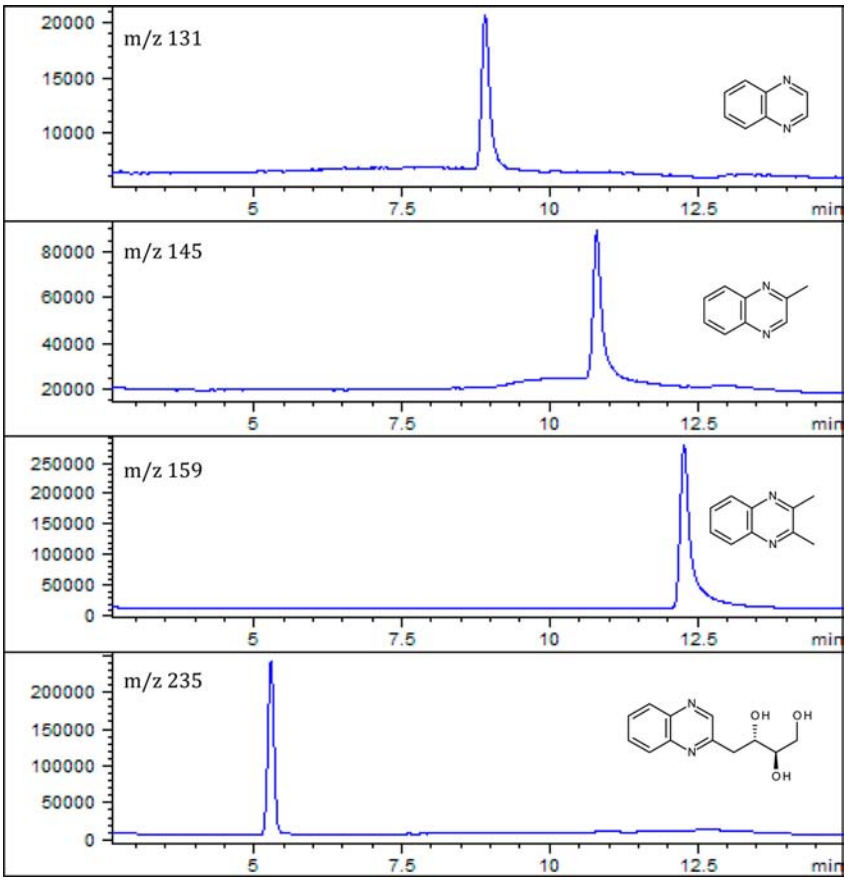

Figure 1. Extracted ion chromatograms of the quinoxaline derivatives of 1 mg/L of glyoxal (m/z 131), methylglyoxal (m/z 145), dimethylglyoxal (m/z 159), and 3-deoxyglucosone (m/z 235).

min) pH of the supernatant was measured by using a pH meter (MeterLab PHM210, France). Fruit and vegetable puree samples were centrifuged and pH of the supernatant was measured without another treatment. Pudding samples were diluted with water 1:1 ratio and the pH of the supernatant was measured after centrifugation.

Statistical Analysis. Comparison of different groups was analyzed with independent samples t test by using SPSS Statistics 21.0 program.

RESULTS AND DISCUSSION

Evaluation of the Analytical Method. In this study, an HPLC-ESI-MS method was developed and validated for the determination of α-dicarbonyl compounds in baby foods. Figure 1 illustrates the extracted ion chromatograms of the quinoxaline derivatives of glyoxal (m/z 131), methylglyoxal (m/z 145), dimethylglyoxal (m/z 159), and 3-deoxyglucosone (m/z 235). The quinoxaline derivatives of these α-dicarbonyl compounds could be successfully resolved within 15 min under the stated chromatographic conditions. There was very good linearity between the concentration and the ESI-MS signal intensity for all α-dicarbonyl compounds studied. Day-to-day reproducibility of the ESI-MS signal intensities of the ions was high with a coefficient of variation of less than 5.0%.

Figure 2 illustrates the HPLC-ESI-MS chromatogram of a baby food with corresponding extracted ion chromatograms of different α-dicarbonyl compounds. Expectedly, the quinoxaline derivative of glucosone eluted first as identified at m/z of 251. It followed by the quinoxaline derivatives 3-deoxyglucosone and 1-deoxyglucosone as both identified at m/z of 235. However, 3-deoxygalactosone, the epimer of 3-deoxyglucosone, could not be resolved in this chromatographic run. Therefore, the data given might include 3-deoxygalactosone in the concentration of 3-deoxglucosone. The ESI-MS conditions applied in this study allowed detecting low ppb levels of α-dicarbonyl compounds in baby food matrices. The LOD and LOQ values of α-dicarbonyl compounds calculated for fruit puree, vegetable puree and infant formula matrices are given in Table 2.

Percentage recoveries of 3-deoxyglucosone, glyoxal and methylglyoxal were determined by analyzing the spiked infant formula and fruit puree samples (Table 3). The mean recoveries of 3-deoxyglucosone, glyoxal and methylglyoxal were found to be 102.4%, 103.6%, and 99.5% from infant formula, and 91.2%, 101.7%, and 101.4% from fruit puree, respectively.

Profiling α-Dicarbonyl Compounds in Baby Foods. The HPLC-ESI-MS method was used to analyze α-dicarbonyl compounds in baby foods including cereal based infant formula (n = 9), jarred fruit puree (n = 11), jarred vegetable puree (n = 6), and pudding (n = 4). The concentrations of α-dicarbonyl compounds along with furfurals are given in Table 4. 3-Deoxyglucosone was the most abundant α-dicarbonyl compound in each subcategory of the samples analyzed. The highest levels of 3-deoxyglucosone were found in cereal-based infant formula with the mean concentration of 152.5 ± 2.78 mg/kg. The concentrations of other α-dicarbonyl compounds and furfurals were rather low in comparison to 3-deoxyglucosone.

Infant Formula. Differences in the total concentrations of α-dicarbonyl compounds were compared statistically between cereal-based infant formula samples from different brands, as

dx.doi.org/10.1021/jf502418n | J. Agric. Food Chem. 2014, 62, 7714−7720

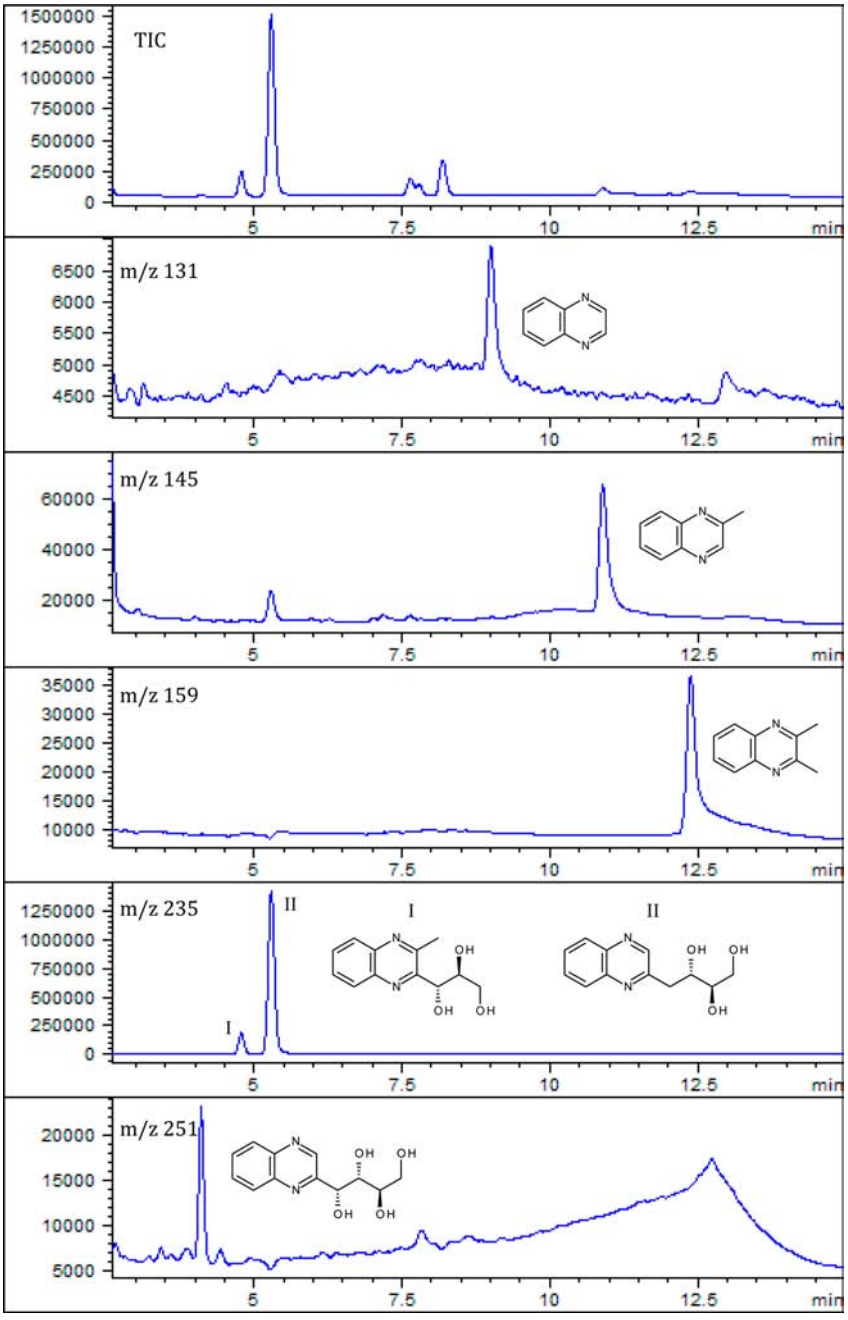

Figure 2. Total and extracted ion chromatograms of an infant formula; glyoxal (*m*/*z* 131), methylglyoxal (*m*/*z* 145), dimethylglyoxal (*m*/*z* 159), 3-deoxyglucosone and 1-deoxyglucosone (*m*/*z* 235), and glucosone (*m*/*z* 251).

Table 2. LOD and LOQ Values in μg/kg Calculated for α-Dicarbonyl Compounds in Different Baby Food Matrices

α-dicarbonyl compound	fruit puree		vegetable puree		infant formula	
	LOD	LOQ	LOD	LOQ	LOD	LOQ
3-deoxyglucosone	2.9	9.6	1.6	5.2	4.3	14.2
glucosone	2.8	9.4	4.2	14.0	10.2	34.1
glyoxal	27.1	90.3	21.8	72.7	23.5	78.4
methylglyoxal	7.5	25.0	7.3	24.4	6.0	20.1
dimethylglyoxal	2.6	8.8	2.7	9.0	2.7	9.2

well as between the samples from same brand containing different ingredients such as honey and grape molasses. There was no significant difference ($p > 0.05$) in the total α-dicarbonyl compounds in infant formulas from the same brand. However, the difference was statistically significant ($p < 0.05$) for infant formulas from different brands (Table 5). It is thought that this might be indicating differences in the thermal input of these samples during processing. Moreover, it was apparent from the results that infant formulas containing honey or grape molasses had significantly more total α-dicarbonyl compounds ($p < 0.05$). This means that sugar rich ingredients might be an important contamination source for α-dicarbonyl compounds in cereal-based infant formulas. Mechanistic studies are rather needed to control the formation of α-dicarbonyl compounds during thermal treatment, and to understand the effect of certain ingredients.

dx.doi.org/10.1021/jf502418n | J. Agric. Food Chem. 2014, 62, 7714−7720

Table 3. Percentage Recoveries with Standard Deviations (SD) of α-Dicarbonyl Compounds in an Infant Formula and a Fruit Puree Sample

α-dicarbonyl compound	spiking level (mg/kg)	recovery ± SD (%)	
		infant formula	fruit puree
3-deoxyglucosone	10	100.6 ± 2.01	95.1 ± 2.40
	20	99.6 ± 2.98	88.9 ± 3.02
	50	106.9 ± 1.07	89.6 ± 1.06
glyoxal	2	108.4 ± 4.07	104.3 ± 1.28
	5	92.6 ± 2.03	99.3 ± 0.83
	10	109.8 ± 3.36	101.4 ± 1.72
methylglyoxal	2	103.4 ± 2.04	101.6 ± 1.25
	5	96.7 ± 1.06	98.7 ± 0.93
	10	98.4 ± 0.98	103.9 ± 1.78

Lower concentrations of short chain ($<C_6$) α-dicarbonyl compounds were also detected in infant formula. Concentration of glyoxal was not reported in this study because de novo formation was observed during derivatization. This was also demonstrated by other researchers.[19,21,22] However, it should be mentioned that lower ppm levels already present in infant formula. Methylglyoxal concentrations were found between 0.4 and 17.3 mg/kg. Dimethylglyoxal concentrations were generally below LOQ except in 3 samples with a mean value of 0.2 ± 0.02 mg/kg (data not shown). Higher concentrations of glyoxal and methylglyoxal are generally found in honey, high fructose corn syrup or bread and biscuits, which are baked at higher temperatures.[18−20] Cleavage of C—C bond requires higher temperatures and it is favored in alkaline pH. However, lower pH favors sugars to dehydrate yielding mainly 3-deoxyglucosone and HMF.

Table 4. Concentration (mg/kg) of α-Dicarbonyl Compounds and Furfurals Found in Baby Foods[a]

[a]3-DG: 3-deoxyglucosone, 1-DG: 1-deoxyglucosone, MG: methylglyoxal, HMF: 5-hydroxy-2-methylfurfural, nd: not detected, and nq: not quantified. [b]According to manufacturers' declaration on the label.

Table 5. Comparison of Total α-Dicarbonyl Compounds Content of Certain Baby Food Samples According to Their Brands and Composition[a]

baby food	brand	no.	total α-dicarbonyls (mg/kg)
infant formula	brand 1	3	114.0 ± 26.13 [a]
	brand 2	3[b]	16.1 ± 12.31 [b]
	brand 1	2	111.1 ± 10.60 [a]
	brand 1 containing honey	1	131.7 ± 16.95 [a]
	brand 2	2	9.0 ± 0.83 [a]
	brand 2 containing honey	1	30.3 ± 10.06 [b]
	brand 2 containing grape molasses	1	902.7 ± 14.38 [c]
fruit puree	brand 1	5	60.9 ± 19.21 [a]
	brand 2	5	57.5 ± 9.91 [a]

[a]Different superscript letters indicate statistical significance for each comparison ($p < 0.05$). [b]Grape molasses containing sample was excluded.

Jarred Baby Foods. Impact of lower pH on sugar dehydration was more apparent in jarred fruit puree. Even they have lower sugar concentration than infant formula, remarkably high 3-deoxyglucosone was observed in jarred fruit puree samples. The concentrations of 3-deoxyglucosone were found between 26.7 and 92.3 mg/kg with a mean value of 61.8 mg/kg. Glucosone and 1-deoxyglucosone were found between 0.8 and 7.6 mg/kg and none-0.6 mg/kg, respectively. No methylglyoxal was detected in jarred fruit puree samples. There was no significant difference in the total α-dicarbonyl concentrations of two different brands of jarred fruit purees ($p > 0.05$). Jarred vegetable purees were generally found to contain lesser amounts of α-dicarbonyl compounds and furfurals (Table 4).

The results revealed that approximately 90% of the total α-dicarbonyl compounds in baby foods were composed of 3-deoxyglucosone. The average amount of dicarbonyls was estimated to be 8.3 mg per serving (50 g powder) for cereal-based infant formula. While average amounts for fruit and vegetable puree were estimated to be 7.3 and 4.3 mg per jar (125 g), respectively. Degen et al. (2012) reported the concentrations of α-dicarbonyl compounds and HMF in several foodstuffs.[18] According to their results higher quantities per serving were reported to be 8.8, 7.3, and 7.7 mg for fruit juice, bread and cookies in staple foods (excluding vinegar, beer, honey and candies, some of which could contain up to 23.5 mg/serving).

Studies about the bioavailability and intestinal absorption of α-dicarbonyl compounds are limited. However, recent studies demonstrated that certain detoxifying systems might be efficient in adults, such as glyoxalase, aldehyde reductase, and aldehyde dehydrogenase systems.[25,26] 3-Deoxyglucosone has shown to transform 3-deoxyfructose and 3-deoxy-2-keto-gluconic acid, which are less reactive and secreted in urine.[27−30] Degen et al. (2014) demonstrated that only 10−15% of the dietary 3-deoxyglucosone recovered as metabolites in urine.[26] However, the fate of the remaining is unknown. In the very low pH of the stomach, 3-deoxyglucosone is most probably dehydrated to HMF, which is another concern due to its metabolite 5-sulphoxymethyl-2-furfural. 3-Deoxyglucosone might also react with proteins and amino acids during gastrointestinal digestion. Since 3-deoxyglucosone in particular is very high in baby foods, its biological consequences should be evaluated with respect to infant gastrointestinal conditions and intestinal absorption.

In conclusion, the HPLC-ESI-MS method was successfully used for profiling α-dicarbonyl compounds in various baby foods. Use of mass spectrometry provided lower quantitation limits and precise results. The results of present study addressed the following points some of which needed to be clarified. Since baby foods contain high amount of sugars, treatments like sterilization or spray drying applied during their processing result in the formation of reactive carbonyl species in high amounts, especially 3-deoxyglucosone. In addition to processing conditions, ingredients like grape molasses and honey may be an important source of contamination. These results recommend investigating in detail the effects of processing conditions and type of ingredients on the occurrence of α-dicarbonyl compounds in baby foods.

The separation and determination of proanthocyanidins of sea buckthorn is problematic because they occur as highly complex mixtures. The aim of this work was to establish a method for identification of the key PA oligomers in the berries. The crude extract was fractionated by Sephadex LH-20 column chromatography, PAs of the fractions were separated according to molecular weight by NP-UPLC-ESI-SIR and HILIC-ESI-SIR, and the isomers were analyzed by RP-HPLC-ESI-SIR. Quantification of the dimers, trimers, and tetramers was carried out using a HILIC-ESI-SIR method.

MATERIALS AND METHODS

Plant Materials. Wild sea buckthorn berries (*Hippophaë rhamnoides* ssp. *rhamnoides* L.) were harvested on September 28, 2011, at Pyhämaa, southern Finland, on the coast of the Gulf of Bothnia and stored at −18 °C.

Chemicals and Reagents. Methanol, dichloromethane, and formic acid (all HPLC grade) were purchased from J. T. Baker (Deventer, Holland), acetone and acetonitrile (HPLC grade) from VWR International Oy (Espoo, Finland). Water was obtained from a Millipore system (Billerica, MA). The reference compound procyanidin B2 was purchased from from Extrasynthese (Genay, France).

Sample Preparation. Fifty grams of sea buckthorn berries were crushed and extracted three consecutive times with 200 mL of a mixture of acetone, water, and acetic acid (80:19.5:0.5, v/v) by sonicating each time for 15 min. After centrifugation and combining of the supernatants, acetone was removed by rotary evaporator. The final volume of ca. 100 mL was used for Sephadex LH-20 column chromatography (CC).

Isolation and Purification of Proanthocyanidin. A 15 mm i.d. × 250 mm glass column packed with 5 g of Sephadex LH-20 (Pharmacia, Uppsala, Sweden) was used for column chromatography. The column was activated and rinsed with 100 mL of water. The crude extract was loaded in the column and washed with 60 mL of water. Three fractions were collected with 250 mL of methanol and water (20:80, v/v, fraction I), 200 mL of acetone and water (70:30, v/v, fraction II), and 250 mL of acetone and water (70:30, v/v, fraction III) in sequence. The flow of elution was maintained at 1 mL/min by Alitea-XV peristaltic pump (Bioengineering, Wald, Switzerland). All the fractions were dried by vacuum rotary evaporator, redissolved in 1 mL of methanol, and clarified through a polytetrafluoroethylene (PTFE) filter (13 mm i.d., 0.45 μm, VWR International, West Chester, PA) before analyses.

LC-DAD-MS Apparatus. A Waters Acquity ultrahigh performance LC system (Waters Corp., Milford, MA), which consisted of a sample manager, binary solvent delivery system, and Waters 2996 PDA detector, was used. In addition, a Waters Quattro Premier tandem quadrupole mass spectrometer (Waters Corp., Milford, MA) equipped with an electrospray ionization (ESI) source was combined with the system. The chromatograph was operated using MassLynx 4.1 software.

Reversed-Phase HPLC Analyses. The crude extract and its fractions I to III were analyzed by reversed-phase HPLC-DAD to define the content of proanthocyanidins. A Phenomenex Luna RP-C18 column (5 μm, 250 × 4.60 mm, Torrance, CA) combined with a Phenomenex Prodigy guard column (5 μm, 30 × 4.60 mm, Torrance, CA) was used. The mobile phase was run as gradient elution of formic acid/water (0.5:99.5, v/v) as solvent A and acetonitrile/methanol (80:20, v/v) as solvent B at a flow rate of 1 mL/min. The gradient program of solvent B in A (v/v) was 0−5 min 10% B, 5−15 min 10−18% B, 15−25 min 18% B, 25−30 min 18−25% B, 30−35 min 25% B, 35−40 min 25−35% B, 40−45 min 35−60% B, 45−50 min with 60−10% B, and 50−55 min with 10% B.[35] The injection volume was 20 μL. The peaks were monitored at two different wavelengths, 280 nm for all the phenolic compounds and 360 nm for the flavonol glycosides. UV spectra of the compounds were recorded. A split joint was used after the UV detector, directing a flow of 0.3 mL/min to the mass spectrometer and the rest to a waste bottle.

Normal-Phase UPLC Analyses. The proanthocyanidin-rich fraction II was analyzed by normal-phase ultrahigh performance liquid chromatography (NP-UPLC). A Restek Pinnacle DB silica UPLC column (1.9 μm, 100 × 2.1 mm, Bellefonte, PA) was used for resolution of sea buckthorn proanthocyanidin clusters for mass spectrometric analysis. The analyses were carried out by a gradient elution of dichloromethane, methanol, water, and acetic acid (82:14:2:2 v/v) as solvent A and methanol, water, and acetic acid (96:2:2 v/v) as solvent B at the mobile phase flow rate of 0.4 mL/min. The gradient program of solvent B in A (v/v) was 0−15 min 0−15% B, 15−20 min 15−30% B, 20−25 min 30−80% B, 25−30 min 80−0% B, and 30−35 min with 0% B. The injection volume was 10 μL. The parameter of the UV detector was set as used in the reversed-phase HPLC analyses. The whole flow of 0.4 mL/min was led to the mass spectrometer after the UV detector.

HILIC Analyses. A Phenomenex Luna HILIC 200A column (3 μm, 150 × 3.00 mm, Torrance, CA) combined with a Phenomenex Security Guard Cartridge Kit (Torrance, CA) was used for the analysis of fraction II. Acetonitrile was used as solvent A and formic acid/water (0.5:99.5, v/v) as solvent B with gradient elution. The gradient program of solvent B in A (v/v) was 0−5 min 5−20% B, 5−10 min 20−30% B, 10−12 min 30−40% B, 12−15 min 40−65% B, 15−17 min with 65−5% B, and 17−30 min with 5% B. The injection volume was 10 μL. The total flow rate was 0.6 mL/min, and the whole flow was led to the mass spectrometer after the UV detector. The LC-UV chromatograms were recorded at 280 and 360 nm.

Mass Spectrometry. The electrospray ionization (ESI) source was operated in negative ion mode. The ESI inlet conditions were as follows: capillary voltage, 3.5 kV; cone voltage, 15 V; extractor voltage, 8 V; source temperature, 120 °C; and the desolvation temperature, 300 °C.

Both full scan and SIR functions were used. The total ion ESI-MS analysis of proanthocyanidins was carried out by scanning the ions from m/z 500 to 3000 for oligomer size screening. The total ion spectra were recorded to elucidate the PA groups with different molecular weights. A smoothing process with a window of $m/z \pm 3$ was operated in the MassLynx 4.1 software to combine the peaks of various isotope combinations of the proanthocyanidins in the spectrum. The m/z signals chosen for the selected ion recording (SIR) function were those of the most abundant deprotonated proanthocyanidin ions calculated based on the nominal masses. According to the isotope distribution, the most abundant deprotonated proanthocyanidin ions only consist of ^{12}C, ^{1}H, and ^{16}O. In the SIR model, the m/z ions which were $m/z \pm 0.5$ out of the range were discarded. Therefore, the PA molecular ions containing ^{13}C and ^{14}C were not recorded. The actual molar proportions were estimated by correcting the SIR peak areas by taking the isotopic abundances of ^{13}C, ^{14}C, ^{2}H, ^{3}H, ^{17}O, and ^{18}O into account.

Quantitative Analysis. The quantive analysis of proanthocyanidin dimers was carried out using the HILIC-ESI-SIR method and an external standard. The calibration curves were constructed by analyzing standard solutions of procyanidin B2 in methanol in the concentration range of 0.01−0.05 mg/mL by plotting the peak areas against the concentrations. The contents of proanthocyanidin dimers and trimers were calculated with the calibration curve of procyanidin B2 and correction factors.[36]

RESULTS AND DISCUSSION

Purification by Column Chromatography. For the extraction of proanthocyanidins from sea buckthorn berries, a mixture of acetone, water, and acetic acid (80:19.5:0.5, v/v) was found to serve as an optimal solvent system. A purification step was needed due to the presence of flavonols and other impurities in the extract disturbing the chromatographic and mass spectrometric analyses. Thus, the crude extract and the Sephadex fractions I−III were analyzed by RP-HPLC at 280

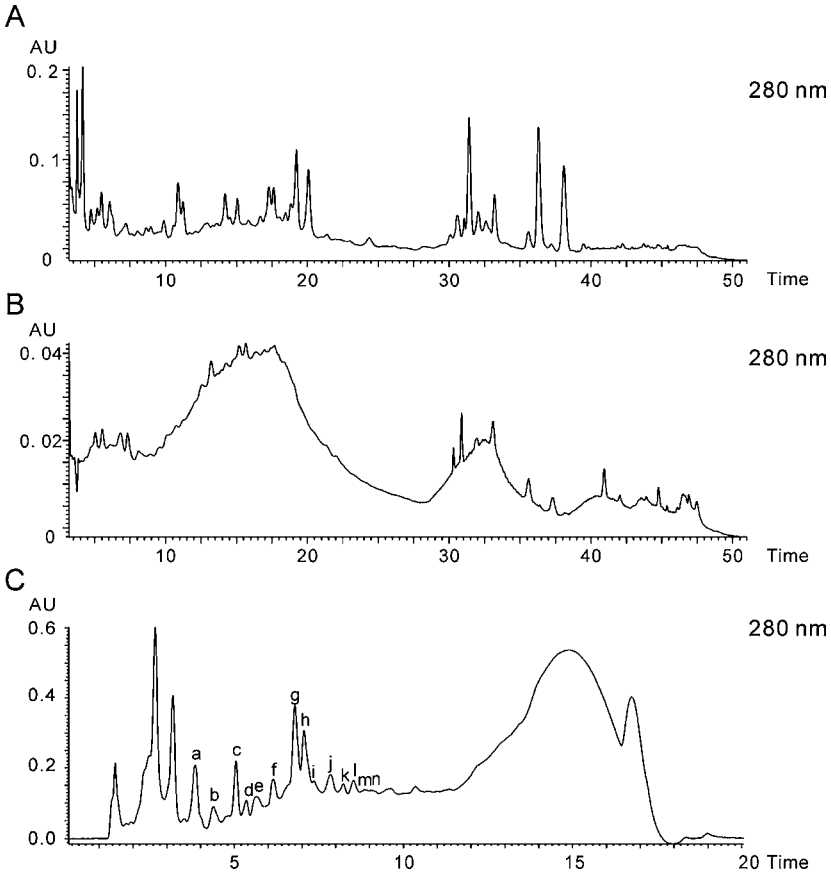

Figure 1. RP-HPLC-DAD chromatograms measured at 280 nm of (A) the crude extract of sea buckthorn berries and of (B) the Sephadex-purified fraction II. The HILIC-DAD chromatogram of (C) fraction II measured at 280 nm.

and 360 nm, and the UV spectra were obtained by DAD. Chromatograms of the crude extract and fraction II recorded at 280 nm are presented in Figures 1A and 1B. It was found that the non-tannin substances were mainly eluted in fraction I, and proanthocyanidins were recovered in fraction II. In fractions I and III hardly traces of proanthocyanidins were recognized, and fraction II was used for mass spectrometric analyses of the target compounds. The UV spectra of all the proanthocyanidins were highly similar throughout the chromatogram in Figure 1B, from 2.5 to 45 min at 280 nm. The compounds had pronounced and symmetrical maxima at around 240 and 280 nm without band broadening beyond 300 nm.

Identification of Proanthocyanidins. The PA fraction II was analyzed by RP-HPLC, NP-UPLC, and HILIC combined with DAD and electrospray ionization mass spectrometry.

Complexity of the extract and fractions of sea buckthorn resulted in unsatisfactory separation of PAs in the chromatograms recorded by both RP-HPLC-DAD and NP-UPLC-DAD at 280 nm. The peaks overlapped seriously with each other, forming only broad humps of PAs instead of proper resolution as seen in the chromatogram of RP-HPLC-DAD in Figure 1B. However, on the HILIC-DAD chromatogram recorded at 280 nm, 14 peaks eluting between 3.5 and 9 min were legible (peaks a to n, Figure 1C). The UV spectra revealed all of them to be PAs, and they were tentatively identified based on their ESI mass spectra. Each peak displayed may contain several pronthocyanidins as presented in Table 1. No legible chromatographic peaks and thus no proper spectra of individual PAs were obtained by RP-HPLC- or NP-UPLC-ESI-MS.

In addition, full scan mode of ESI-MS was applied to obtain the oligomeric profiles of fraction II. The mass spectra of HILIC and NP chromatography are shown in Figures 2A and 2B, respectively. The best results were obtained with the HILIC method, and oligomers up to 11 PA units were recorded. Dichloromethane commonly used in normal-phase methods is a harmful solvent both for LC instruments and for the sensitivity of the analysis and is recommended to be replaced by other solvents, e.g., such as used in the HILIC analyses.

Identification of Proanthocyanidins by Total Ion Spectra. Fraction II was analyzed by RP-HPLC, NP-UPLC, and HILIC coupled with electrospray ionization mass spectrometry in negative ion mode.

The total ion spectra over the whole chromatogram of the isolated fractions were recorded. Scanning from m/z 500 to 3000 in 14 min (from 3.6 to 17.6 min) in HILIC, 22 min (from 3 to 25 min) in NP-UPLC, and 37 min (from 3 to 40 min) in RP-UPLC were used to recognize the PAs in fraction II. The total ion spectra obtained from the HILIC- and NP-ESI-MS are shown in Figure 2. The low molecular weight parts of the total ion spectra were highly similar, however, the HILIC-ESI-MS was the most sensitive and revealed also the existence of higher oligomers up to DP11 (Figure 2A). This may be due to the lower water content in the HILIC solvents enhancing the ionization. The $[M - H]^-$ ions of PAs with DP from 2 to 7 and $[M - 2H]^{2-}$ ions of PAs with DP from 7 to 11 with the HILIC method are collected in Table 1.

The ions from m/z 577.52 to 1828.03, 2115.64, 2130.49 of the individual compounds as well as the corresponding full-scan spectra are the deprotonated, average molecular weight

[a]DP = degree of polymerization. [b](E)C = (epi)catechin, (E)GC = (epi)gallocatechin. [c]$[M-2H]^{2-}$ ions of DP8 overlapped with the $[M-H]^-$ ions of DP4. [d]$[M-2H]^{2-}$ ions of DP10 overlapped with the $[M-H]^-$ ions of DP5.

proanthocyanidins of DP from 2 to 7. All the compounds represent the B-type proanthocyanidins, dimers (MW 578.14, 594.14, and 610.13), trimers (866.20, 882.20, 898.19, and 914.19), tetramers (1154.27, 1170.26, 1186.26, 1202.25, and 1218.25), pentamers (1474.32, 1490.32, 1505.31, and 1522.31), hexamers (1793.37, 1809.37, and 1825.36), and heptamers (2114.43 and 2130.42). The molecular weights are the exact masses with all the isotope abundances taken into account.

No single-charged molecular ions of proanthocyanidins with DP higher than 7 were found. As indicated in Table 1, the ions from m/z 1032.84 to 1665.49 were the $[M-2H]^{2-}$ ions of heptamers (MW 2066.44, 2082.43, 2098.43, 2114.43, and 2129.42), octamers (2385.49 and 2417.48), nonamers (2626.58, 2642.57, 2658.57, 2674.56, 2690.56, 2706.55, 2722.54, and 2738.54), decamers (2994.61 and 3026.60), and undecamers (3314.67 and 3330.66).

No A-type oligomers with molar masses of two units lower than corresponding B-type PA were found. Tentative identification of all the proanthocyanidins is also presented in Table 1.

dx.doi.org/10.1021/jf502056f | J. Agric. Food Chem. 2014, 62, 7721−7729

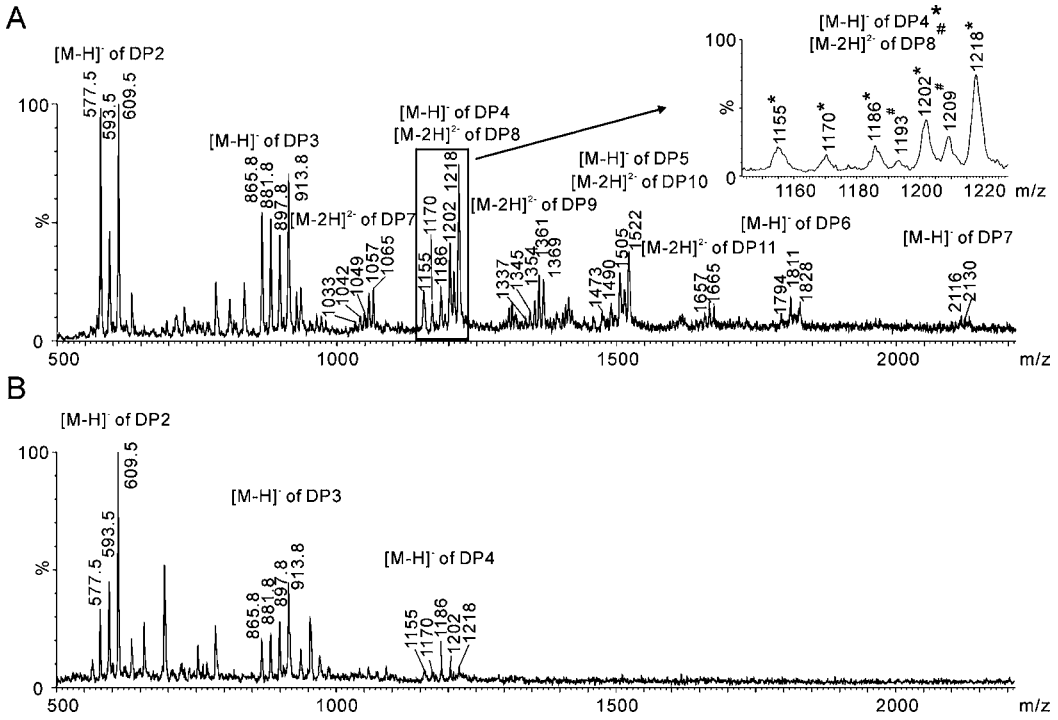

Figure 2. Total ion spectrum of fraction II (A) from 3.6 to 17.6 min analyzed by HILIC-ESI-MS and (B) from 3 to 25 min analyzed by NP-UPLC-ESI-MS. The PA signals in the spectrum are marked as deprotonated calculated molar masses where the isotope abundances have been taken into account.

Identification of Proanthocyanidins by NP-UPLC- and HILIC-ESI-MS-SIR. Because of the high complexity of the sea buckthorn extract and fractions, neither the UV analysis nor mass spectrometry in full scan mode gave results detailed enough. The molecular weights of proanthocyanidins are relatively close to each other in each group of the low-DP oligomers, and the NP-UPLC and HILIC resolutions were not sufficient for quantitative analysis. Instead, the NP-UPLC-, HILIC-, and even RP-HPLC-ESI-MS in the SIR mode provided highly selective methods for determination of proanthocyanidins in sea buckthorn, and the three methods complemented well each other.

All the 12 $[M - H]^-$ ions of the nominal mass proanthocyanidin dimers, trimers, and tetramers were scanned in 12 channels by HILIC-, NP-UPLC-, and RP-HPLC-ESI-MS-SIR analyses and are displayed in Figure 3. The HILIC and NP chromatograms showed rather systematic difference in retention times based on molecular weight within each of the three oligomer groups. The higher the MW, the longer the retention time within a group, but the rule did not apply when all peaks in the 12 molecular weight classes were taken into account. All the PA dimers, trimers, and tetramers defined earlier (Table 1) were eluted in 4 to 12 min as shown in Figure 3. Combinations of the monomeric units as well as retention times of the major peaks in each MW group from both the HILIC-ESI-MS-SIR and the NP-UPLC-ESI-MS-SIR analyses are shown in Table 2. Both methods showed relatively low chromatographic resolution in each channel, and only poorly resolved peaks were recorded. The HILIC method was more sensitive than the NP method.

Identification of Proanthocyanidins by RP-HPLC-ESI-MS-SIR. As an effective separation technique for phenolic compounds, RP-HPLC is widely used in routine analysis.[35,37] The RP-HPLC method coupled to ESI-MS-SIR was used to distinguish the major proanthocyanidin isomer groups with different monoisotopic nominal masses in the 12 channels.

Fraction II was analyzed by RP-HPLC-DAD by monitoring at 280 nm, and by RP-HPLC-ESI-MS-SIR at the 12 channels (m/z 577, 593, and 609 for proanthocyanidin dimers, m/z 865, 881, 897, and 913 for trimers, and m/z 1153, 1169, 1185, 1201, and 1217 for tetramers, respectively) as in NP-UPLC and HILIC-SIR methods. The chromatograms obtained by the RP-HPLC method are shown in Figures 3C, 3F, and 3I, and the peaks are listed in Table 2. The analysis provided sufficient separation of proanthocyanidin isomers with same molecular weights among the dimeric and trimeric PAs. Resolution was less good in the case of tetrameric isomers, and individual peaks were only occasionally visible. Unlike in NP-UPLC and HILIC chromatography the oligomers with higher MW eluted in the RP analyses on average faster than the smaller counterparts within one polymer group.

In the chromatogram of RP-HPLC-ESI-MS-SIR at m/z 577, five peaks (from 1 to 5) were found to display at least five characteristic dimeric procyanidin isomers with composition of [(E)C-(E)C]. At m/z 593 the 11 isomers (from 6 to 16) consisted of one (epi)catechin and one (epi)gallocatechin subunit. Based on the UV spectra recorded, the clear peak at 45 min was not a proanthocyanidin. The 12 peaks from 17 to 28 in the chromatogram at m/z 609 represent the dimeric prodelphinidins of two (E)GC units (Figure 3C).

Among the trimers, the peaks from 29 to 36 in the SIR chromatogram at m/z 865 revealed at least eight isomeric structures of [(E)C-(E)C-(E)C]. The m/z 881 suggested at least 12 isomers consisting of two (epi)catechin and one (epi)gallocatechin subunits, and m/z 897 also 12 compounds of one (epi)catechin and two (epi)gallocatechins. The less resolved peaks from 56 to 62 in the chromatograms at m/z 913 were the isomers of trimeric prodelphinidins (Figure 3F).

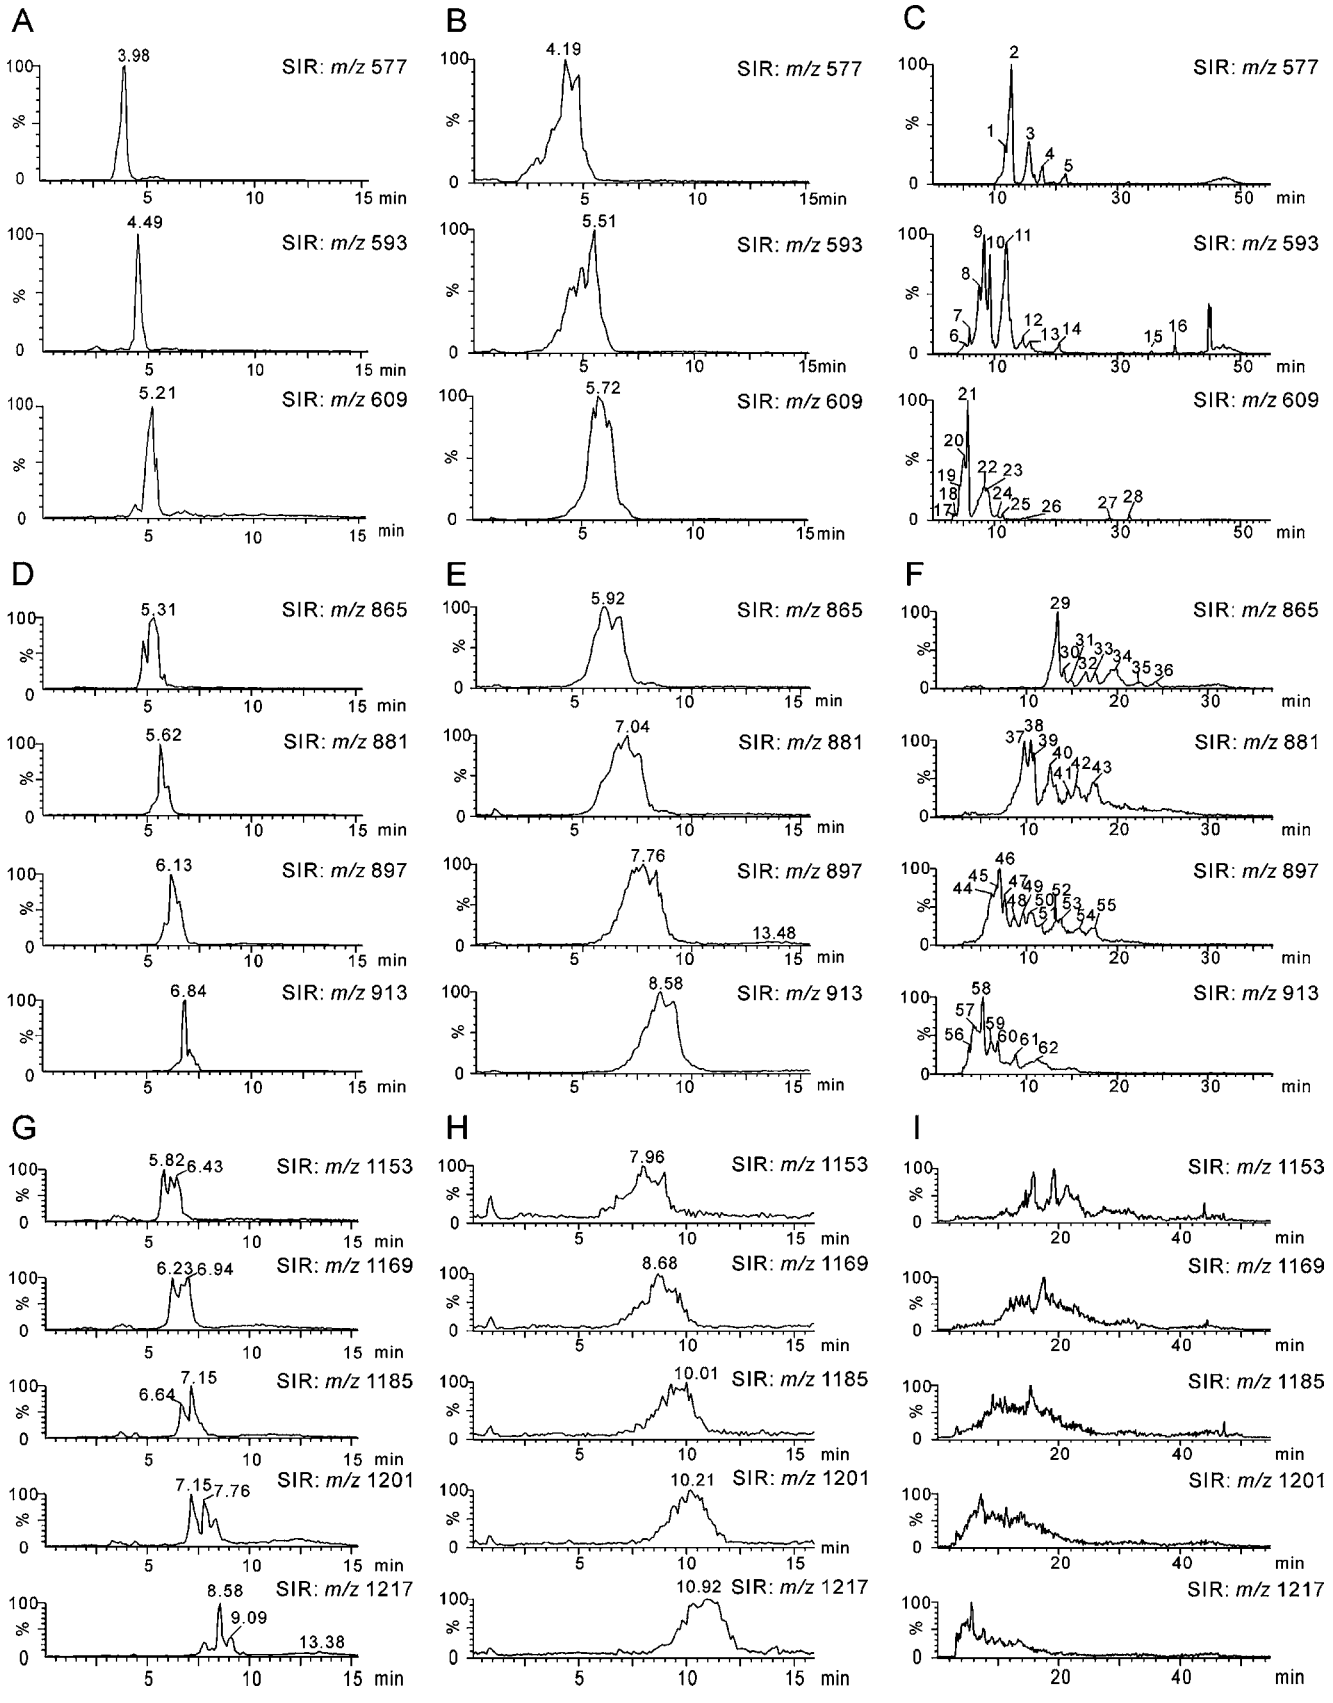

Figure 3. Selected ion recording (SIR) chromatograms of proanthocyanidins analyzed by ESI-MS in fraction II: dimers (A) HILIC, (B) NP-UPLC, and (C) RP-HPLC; trimers (D) HILIC, (E) NP-UPLC, and (F) RP-HPLC; tetramers (G) HILIC, (H) NP-UPLC, and (I) RP-HPLC.

It is clear that many of the trimeric isomers overlap in the chromatograms.

The numerous isomers of proanthocyanidin tetramers overlapped each other significantly. The ion peaks $[M - H]^-$

[l]Peak areas calculated in total ion spectrum. [m]Proportions of PA oligomer peak areas in full scan mode.

from m/z 1153 to 1217 are suggested to consist of tetrameric procyanidins, three (epi)catechin and one (epi)gallocatechin subunits, two (epi)catechin and two (epi)gallocatechin subunits, one (epi)catechin and three (epi)gallocatechin subunits, and tetrameric prodelphinidins, respectively (Figure 3I).

Quantitative Profiling of Oligomeric Proanthocyanidins. Due to the lack of reference compounds, determination of the ratios of different PA classes of sea buckthorn berries was not possible. It has to be highlighted that all three mass spectrometric methods are useful for profiling and comparisons between different samples but none of them give correct proportions. The tentative identification of PA oligomers was based on chromatographic and mass spectral data as well as on UV spectra and literature reports.[10,38] However, neither exact structural elucidation of the bonds between the monomeric units nor the steroisomerism of the B-ring and hydroxyl group at position 3 could be determined.

The HILIC-ESI-MS in full scan mode and in SIR function methods were used as the two most sensitive methods to study the quantitative profiles of proanthocyanidins in sea buckthorn. Based on MS analyses illustrated in Figures 2 and 3, it was possible to get an overview of distribution of the compounds in different oligomeric classes in wild, Nordic *Hippophaë rhamnoides* berries summarized in Table 2.

The peak areas of at least the dimeric and trimeric proanthocyanidins in the HPLC-ESI-MS-SIR chromatograms show typically close to linear molar responses regardless of the slight differences in the structures.[36] Thus, among the dimers, the compounds of two (epi)catechin subunits ($[M-H]^-$ at m/z 577) were the most abundant. Their content was close to three times that of [(E)GC-(E)GC] ($[M-H]^-$ at m/z 609) and almost twice the content of [(E)C-(E)GC] ($[M-H]^-$ at m/z 593) (Table 2). Overall, in the dimeric PAs, (epi)catechin was the main subunit.

(Epi)gallocatechins with m/z 913 formed the most abundant combination (>30%) within the trimeric PAs. The tetrameric (epi)gallocatechins with m/z 1217 comprised analogously 1/3 of the tetrameric PAs.

Information of the two HILIC methods applied gave quite consistent results despite the different calibration profiles. The bigger the molecule was, the more isotope ions were lost in the SIR model due to the MW window parameters set in the method. Thus, proportions of the peak areas of the trimeric and tetrameric PAs in the full scan mode were higher than those in the SIR analysis. Results after the isotope correction are shown in Table 2, and they are quite close to the full scan results. Both ESI-MS-SIR analysis and the total ion spectra with the HILIC method showed the molar proportion of the dimeric and trimeric PAs to approach the level of 40% of the three PA classes studied. The higher oligomers than tetramers were found in the MS analyses in low amounts, and all the compounds identified were of type-B proanthocyanidin oligomers.

Procyanidin B2 reference compound was used as an external standard for quantification of the procyanidin dimers. Their total content was 0.45 mg/100 g (Table 2). Our earlier studies showed that the efficiencies of ionization of procyanidin dimers and trimers are very similar in the ESI mode calculated on molar bases.[36] Based on this principle, we listed in Table 2 the contents of all PA oligomers with DP ≤ 4, and the contents of proanthocyanidin dimers, trimers, and tetramers were 0.98 mg/100 g, 1.41 mg/100 g, and 0.84 mg/100 g, respectively.

It is worth noticing that the proanthocyanidins of DP2 to DP4 quantified in Table 2 represent only a small part of all the PA oligomers and polymers of sea buckthorn. Figure 1C reveals that based on the UV recording at 280 nm there is a huge hump of polymeric PAs, which were not recognized in the MS analyses.

Proanthocyanidins in wild sea buckthorn of *H. r.* ssp. *rhamnoides* berries were analyzed by RP-, NP-, and hydrophilic interaction (HILIC) liquid chromatography (HILIC). HILIC provided separation mainly by PA size and provided the highest sensitivity of the methods applied. PAs with degree of polymerization from 2 to 11 were detected by HILIC-ESI-MS. More than 60 combinations of (epi)catechins and (epi)gallocatechins of proanthocyanidin dimers and trimers were found. All of them were B-type compounds, and (epi)gallocatechins were the main monomeric units. Quantification of dimeric, trimeric, and tetrameric PAs was carried out with ESI-MS-SIR by reference compound.

behavior was greatly altered, influencing both PAC degree of polymerization (DP) and ratios of "A-type" to "B-type" interflavan bonds. The research reported here shows how matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS) can be used to characterize PAC fractions that differ as a result of prior SFE extraction.

In the present research, we investigated how PAC fractions with and without prior SFE affect ExPEC agglutination and enterocyte cell invasion, which is relevant for urinary tract health because PAC are not absorbed in the gastrointestinal tract. The implication is that if bacteria are agglutinated, their surface virulence factors, such as P fimbriae, will not be available to interact with ligands on gut epithelial cells, thus reducing their invasivity. For the first time, we have unraveled how the structural heterogeneity of PAC, namely, DP and ratios of "A-type" to "B-type" interflavan bonds, can influence PAC bioactivity in relation to UTI.

MATERIALS AND METHODS

Chemicals and Reagents. Ethanol (200 proof) was obtained from Decon Laboratories Inc. (King of Prussia, PA, USA). The reagent 4-(dimethylamino)cinnamaldehyde (DMAC) was purchased from Acros Organics (Geel, Belgium). Sterilized water, thiamin hydrochloride, 2,5-dihydroxybenzoic acid, and Triton 100X were purchased from Sigma-Aldrich (St. Louis, MO, USA). Sephadex LH-20 was purchased from GE Healthcare (Uppsala, Sweden). Tryptose and dextrose were obtained from BD (Sparks, MD, USA). Fetal bovine serum (FBS) was purchased from Atlanta Biologicals (Lawrenceville, GA, USA). Cellgro's Dulbecco's phosphate-buffered saline (PBS) with calcium and magnesium was from Mediatech, Inc. (Manassas, VA, USA). HyClone Dulbecco's PBS without calcium and magnesium and Hyclone Roswell Park Memorial Institute medium (RPMI-1640) were obtained from Thermo Scientific (South Logan, UT, USA). Caco-2 cells ATCC HTB-37 were obtained from ATCC (Manassas, VA, USA). All other chemicals were from Fisher Scientific (Fair Lawn, NJ, USA).

Samples. Cranberry fruits (*V. macrocarpon* Ait. cv. 'Stevens') were obtained from the United Cranberry Growers Cooperative (Wausau, WI, USA). The fruits were homogenized to a fine powder by blending with liquid nitrogen, followed by freeze-drying. The fruit powder was stored at −80 °C until extraction.

Isolation of Proanthocyanidins. *Isolation of Cranberry Proanthocyanidins with No Prior Supercritical Fluid Extraction (CE_{NSFE}).* The PAC extraction procedure was adapted from our previous work.[23] Cranberries were blended with liquid nitrogen and freeze-dried as powder. Cranberry powder (100 g) was extracted with 70% aqueous acetone (400 mL) in an ultrasonic bath for 15 min. The extract was centrifuged at 400*g* at 15 °C for 10 min, and the supernatant was collected. The extraction was repeated two additional times, and the supernatants were combined. After filtration with cellulose paper, acetone was removed by rotary evaporation under vacuum at 35 °C, and the remaining suspension was solubilized in ethanol. The extract was then centrifuged at 13416*g* at 0 °C for 10 min to eliminate insoluble material. The cranberry extract supernatant (CE_{NSFE}) was used to isolate PAC by chromatography on Sephadex LH-20 as described below (Figure 1).

Isolation of Cranberry Proanthocyanidins with Prior Supercritical Fluid Extraction (CE_{SFE}). SFE of freeze-dried cranberry powder was performed on a pilot scale SFE (DynaSep, Newark, DE, USA) composed of a 2 L extraction vessel and twin separators 1 and 2 (1 L each). One hundred and fifty grams of cranberry powder was loaded into the extraction vessel, and the remaining volume was displaced with glass marbles. Extraction temperature (40 °C) and pressure (65.5 MPa) were maintained constant. The pressure and temperature of separators 1 and 2 were set at 9.7 MPa and 40 °C and 5.5 MPa and 20 °C, respectively. The supercritical CO_2 fluid flow rate was maintained at 125 g/min with a solvent to feed ratio (w/w) of 80 during dynamic extraction (cycle 1). After collection of the extracts on separators 1 and 2, ethanol modifier (30%, w/w based on the starting material initial weight) was added to the residue in the extractor at the bottom with an air-driven pump at the start of extraction with no soak time at 62.1 MPa and 40 °C (cycle 2). The extracts on both separators were collected. Residual defatted material was extracted with 70% aqueous acetone, as described for CE_{NSFE}, and the cranberry extract supernatant (CE_{SFE}) was used to isolate PAC by chromatography on Sephadex LH-20 as described below (Figure 1).

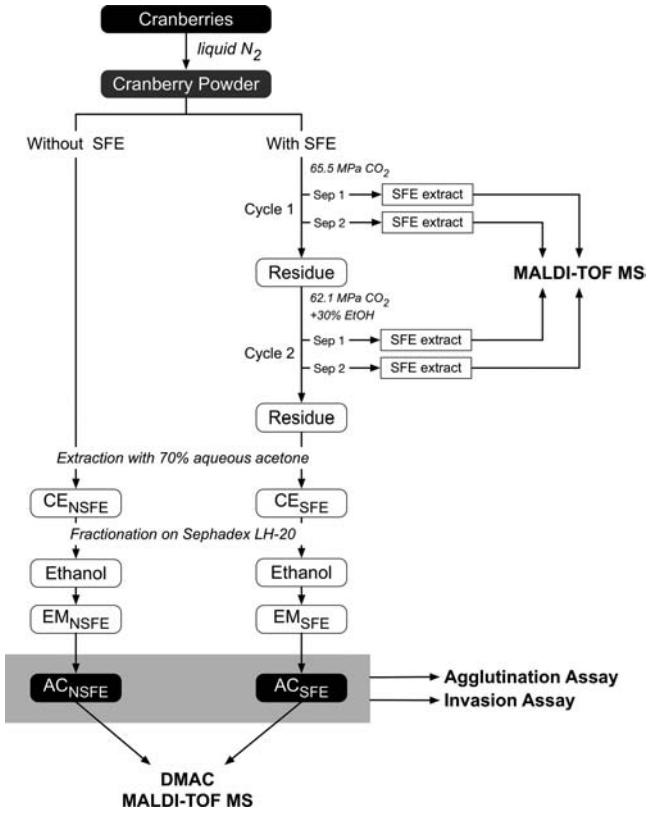

Figure 1. Flow diagram illustrating the isolation of proanthocyanidins from cranberries with and without prior supercritical fluid extraction (SFE). "CE" stands for cranberry extract; "EM" and "AC" correspond to ethanol/methanol (1:1) and 80% acetone fractions from Sephadex LH-20, respectively. Each of these abbreviations is followed by the respective treatment in subscript, either with prior SFE ($_{SFE}$) or with no prior SFE ($_{NSFE}$).

Proanthocyanidin Isolation. Both CE_{NSFE} and CE_{SFE} were loaded on different glass columns (2.5 cm i.d. × 60 cm length; Kontes, Chromaflex) packed with Sephadex LH-20 that was previously swollen and washed in water and equilibrated with ethanol for 45 min at a flow rate of 4 mL/min as previously described.[3] The columns were eluted with ethanol, followed by ethanol/methanol (1:1) and 80% aqueous acetone. The ethanol/methanol (1:1) fractions with no prior SFE (EM_{NSFE}) and with prior SFE (EM_{SFE}) and the 80% aqueous acetone fractions with no prior SFE (AC_{NSFE}) and with prior SFE (AC_{SFE}) were characterized by MALDI-TOF MS (Figure 1).

Characterization of Supercritical Fluid Extraction Fractions. Fractions collected after SFE with CO_2 (cycle 1) and CO_2 and ethanol (cycle 2) in separators 1 and 2 were evaporated to dryness and solubilized in 2 mL of chloroform/methanol (2:1) and isopropanol/acetonitrile (3:2) for cycles 1 and 2, respectively. Half a microliter of these extracts was mixed with 1 μL of 2,5-dihydroxybenzoic acid (50.0 mg/mL in ethanol) and analyzed by MALDI-TOF MS, and spectra were collected as described below (Figure 1).

Characterization of Proanthocyanidin Fractions. An understanding of the natural abundance of C, H, and O isotopes allowed us to develop a method to determine the ratios of "A-type" to "B-type" interflavan bonds in cranberry PAC. On the basis of theoretical relative

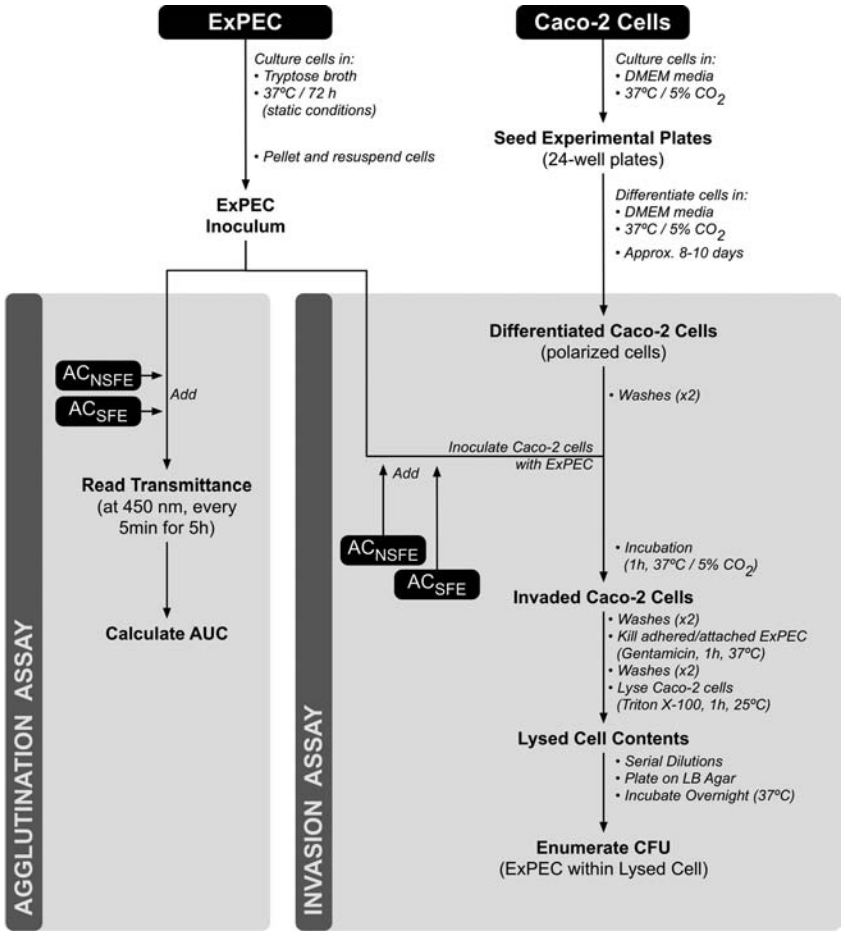

Figure 2. Flow diagram illustrating the methodological approach to evaluating bioactivity of cranberry proanthocyanidins 80% acetone fractions isolated with (AC_{SFE}) and without (AC_{NSFE}) prior supercritical fluid extraction on agglutination and invasion assays.

intensities of each PAC and absolute intensities detected in MALDI-TOF MS per DP, we used matrix algebra to calculate the ratios of each type of interflavan bond per DP as previously described.[24] Deconvolution of MALDI-TOF MS spectra was applied to determine the percentage of "A-type" interflavan bonds in cranberry PAC fractions with and without prior SFE (EM_{NSFE}, EM_{SFE}, AC_{NSFE}, and AC_{SFE}). An aliquot of each fraction was evaporated to dryness and suspended in 20 μL of ethanol to a final concentration of approximately 17 ppm of purified PAC, as quantified by the DMAC method, as previously published by our group. Two hundred and ten microliters of 0.1% DMAC (w/v) was added to 70 μL of standards and samples, and the maximum absorbance at 640 nm detected over 1 h was used to calculate PAC concentration.[23] An aliquot (0.5 μL) of each fraction was then mixed with 1 μL of 2,5-dihydroxybenzoic acid (50.0 mg/mL in ethanol) in three different wells on the stainless steel MALDI target (Figure 1). Mass spectra were collected on a Bruker ULTRAFLEX-III MALDI TOF/TOF mass spectrometer (Billerica, MA, USA). Analyses were performed in positive reflectron mode. Spectra were the sum of different locations in each well, accumulating a total of 500 shots to minimize intrawell variability, and deflection was set at 550 Da. The deconvolution method, which is based on the relative intensity of PAC isotope patterns[24] obtained in reflectron mode, was used to calculate the percentage of "A-type" bonds in PAC oligomers with a DP of 3−8.

Bacterial and Gut Epithelial Cell (Enterocyte) Cultures. The strain of ExPEC (strain 5011) used in this study was isolated from a woman with recurrent UTI at the University of Wisconsin Hospital and Clinics. The selected strain was found in both the gastrointestinal and urinary tracts and expresses fimH and papA, the adhesins of type 1 and P fimbriae, respectively. Type 1 fimbriae play an important role in early attachment of ExPEC to uroepithelial cells in the lower genitourinary tract, whereas P fimbriae bind to kidney cells in the upper genitourinary tract via digalactoside receptors.[25] Furthermore, P fimbriae expression is an important virulence factor for ExPEC colonization of the gut[26] and is critical for attachment of *E. coli* to epithelial cells in the urinary tract, colon, and ileum.[27,28] Strain 5011 was cultured under static conditions in tryptose broth at 37 °C, and the concentration of the inoculum was adjusted on the basis of the optical density at 450 nm as previously reported.[3] Caco-2 cells were cultured in Dulbecco's modification of Eagle's medium (DMEM) supplemented with 10% FBS (v/v), 1% L-alanyl-L-glutamine (v/v), 1% penicillin/streptomycin (v/v), and 1% nonessential amino acids (v/v) at 37 °C with 5% CO_2 atmosphere. Cells were allowed to differentiate for 8−10 days after reaching confluency, with medium changes every 2−3 days[3] (Figure 2).

Bacterial Agglutination Assay. ExPEC stock solutions (50 μL) were added to microcuvettes to provide a final ExPEC concentration of 5×10^8 colony-forming units (CFU)/mL. PAC fractions AC_{NSFE} and AC_{SFE} were added at 0, 6, 12, 29, 58, and 116 ppm of purified PAC (final concentration). PBS containing calcium and magnesium was added to bring the final reaction volume to 1.0 mL.[3] Transmittances at 450 nm were read every 5 min for 5 h on a Beckman DU 640 spectrophotometer (Schaumburg, IL, USA). The area under the transmittance curve (AUC) was calculated for each concentration as a function of each PAC fraction to agglutinate ExPEC strain 5011 over the length of the assay (Figure 2).

Invasion Assay. The invasion assay was based on our previously published method.[3] Bacteria were added to 5 mL tubes to reach a multiplicity of infection of 100 (8.0×10^7 bacterial CFU and 8.0×10^5 Caco-2 cells per well). PBS containing calcium and magnesium and PAC treatments (0, 6, 12, 29, 58, and 116 ppm of purified PAC) were added to a total volume of 75 μL, gently mixed, and incubated for 10

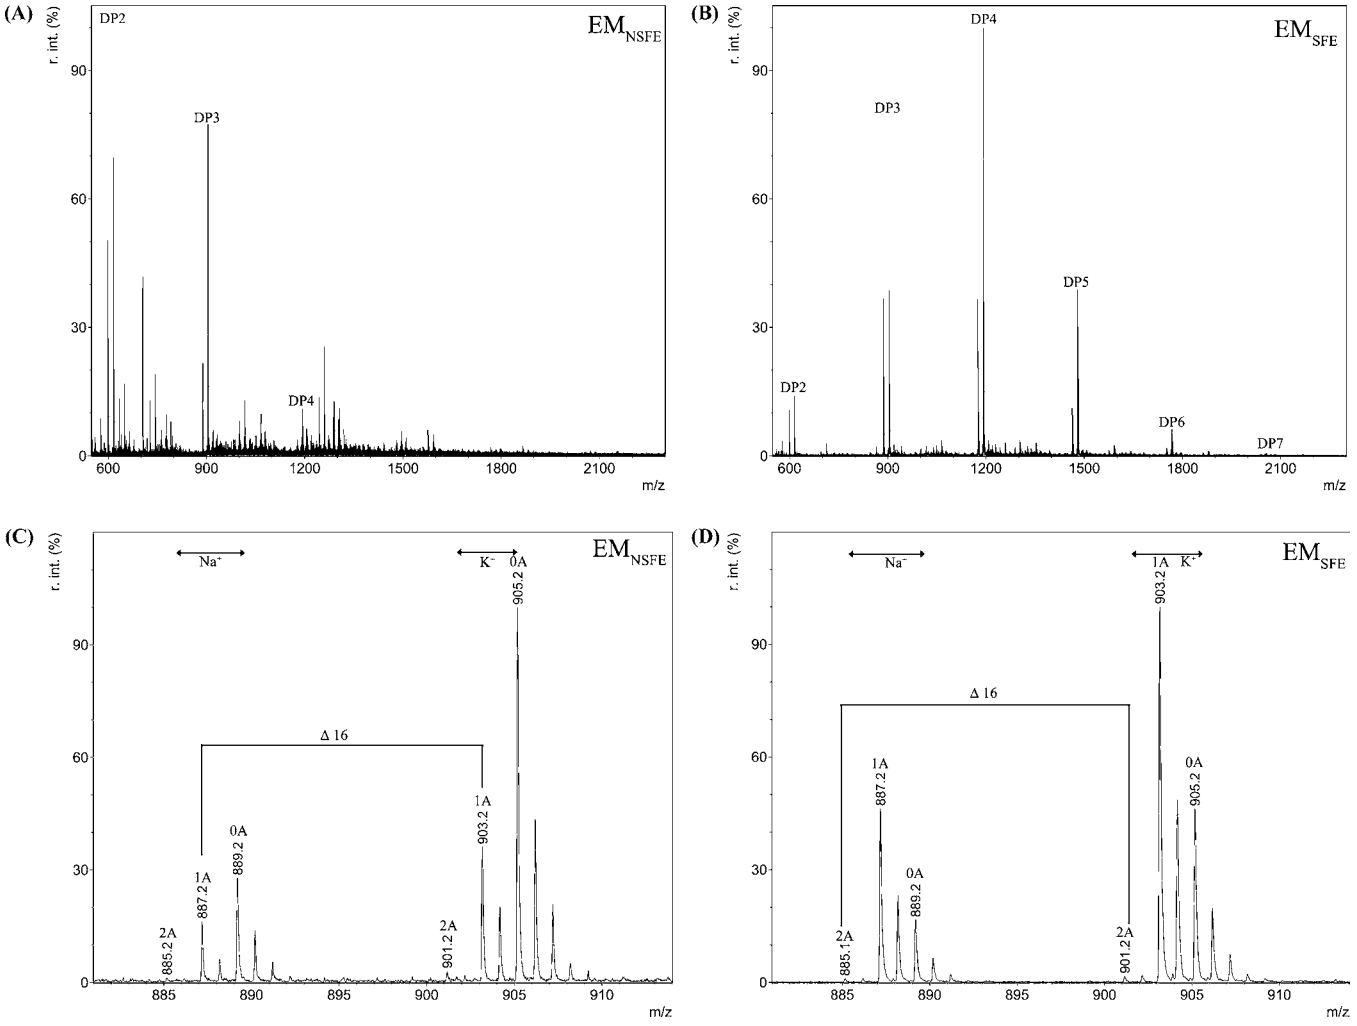

Figure 3. Mass spectra obtained with MALDI-TOF MS in positive reflectron mode for (A) EM_{NSFE}, (B) EM_{SFE}, and (C) EM_{NSFE} and (D) EMsfe fractions, displaying proanthocyanidin (PAC) trimers interflavan bonds. "r.int." and "DP" correspond to relative intensity and degree of polymerization, respectively.

min, followed by addition of 2.425 mL of RPMI medium supplemented with 5% FBS (v/v). After 1 h of bacterial invasion, cells were washed twice with PBS containing calcium and magnesium. Extracellular bacteria were killed by incubating the cells with gentamicin (100 μg/mL) at 37 °C for 1 h. Caco-2 cells were washed twice with PBS without calcium and magnesium and lysed with 1 mL/well Triton for 30 min. Dilutions of well contents were plated (100 μL) in duplicate on LB plates to enumerate the CFU of ExPEC that invaded Caco-2 cells[3] (Figure 2).

Data and Statistical Analysis. All data are reported as the mean ± standard deviation of at least three replicates. mMass version 3.9.0[29] was used for mass spectra analysis, and SAS was used for AUC calculation using the trapezoidal method (version 9.3; SAS Institute Inc., Cary, NC, USA). Statistical analysis was done using JMP Pro (version 10.0.0; SAS Institute Inc.), setting α = 0.05. Results were analyzed with two-way ANOVA models with interaction between the independent variables "treatment" and "concentration" to assess significant differences. The dependent variables were AUC and $\arcsin[\sqrt{(\%\ \text{invasion}/100)}]$ for the agglutination and invasion assays, respectively. ANOVA post hoc analysis was performed using the *t* test.

RESULTS

Effect of Supercritical Fluid Extraction on Proanthocyanidins Elution Profile on Sephadex LH-20. Cranberry PAC were not detected in SFE fractions from cycles 1 and 2 when analyzed by MALDI-TOF MS (data not shown). The remaining fruit residue was submitted to extraction and Sephadex LH-20 chromatography to isolate PAC.[23] PAC with DP between 2 and 4 could be detected in the EM_{NSFE} fraction (Figure 3A), whereas in the EM_{SFE} fraction, PAC up to DP = 7 were detected (Figure 3B). Pretreatment with SFE affected the distribution of PAC interflavan bonds within a specific DP. For instance, in EM_{NSFE}, in PAC trimers, the distribution was 2.3% of two "A-type", 32.5% of one "A-type", and 65.2% of zero "A-type" (Figure 3C). In EM_{SFE}, the distribution for trimers was 1.5% of two "A-type", 81.3% of one "A-type", and 17.2% of zero "A-type" (Figure 3D). Therefore, more PAC with one "A-type" interflavan bonds were eluted from the Sephadex LH-20 column with ethanol/methanol when the cranberries had been previously treated with SFE.

In AC_{NSFE}, PAC had a DP between 3 and 12 as detected with MALDI-TOF MS in reflectron mode (Figure 4A). In AC_{SFE}, the same DP range was detected but the distribution was skewed toward PAC with higher DP as shown in the MALDI-TOF MS spectra (Figure 4B).

The deconvolution method[24] was applied only to PAC with DP between 3 and 8 because the signal-to-noise ratio was <3.0 for oligomers with a higher DP (Table 1). PAC do not ionize as $[M]^+$ but attach to sodium and potassium ions, forming alkali metal adducts,[30] which creates PAC peaks that differ by 16

dx.doi.org/10.1021/jf502296b | J. Agric. Food Chem. 2014, 62, 7730−7737

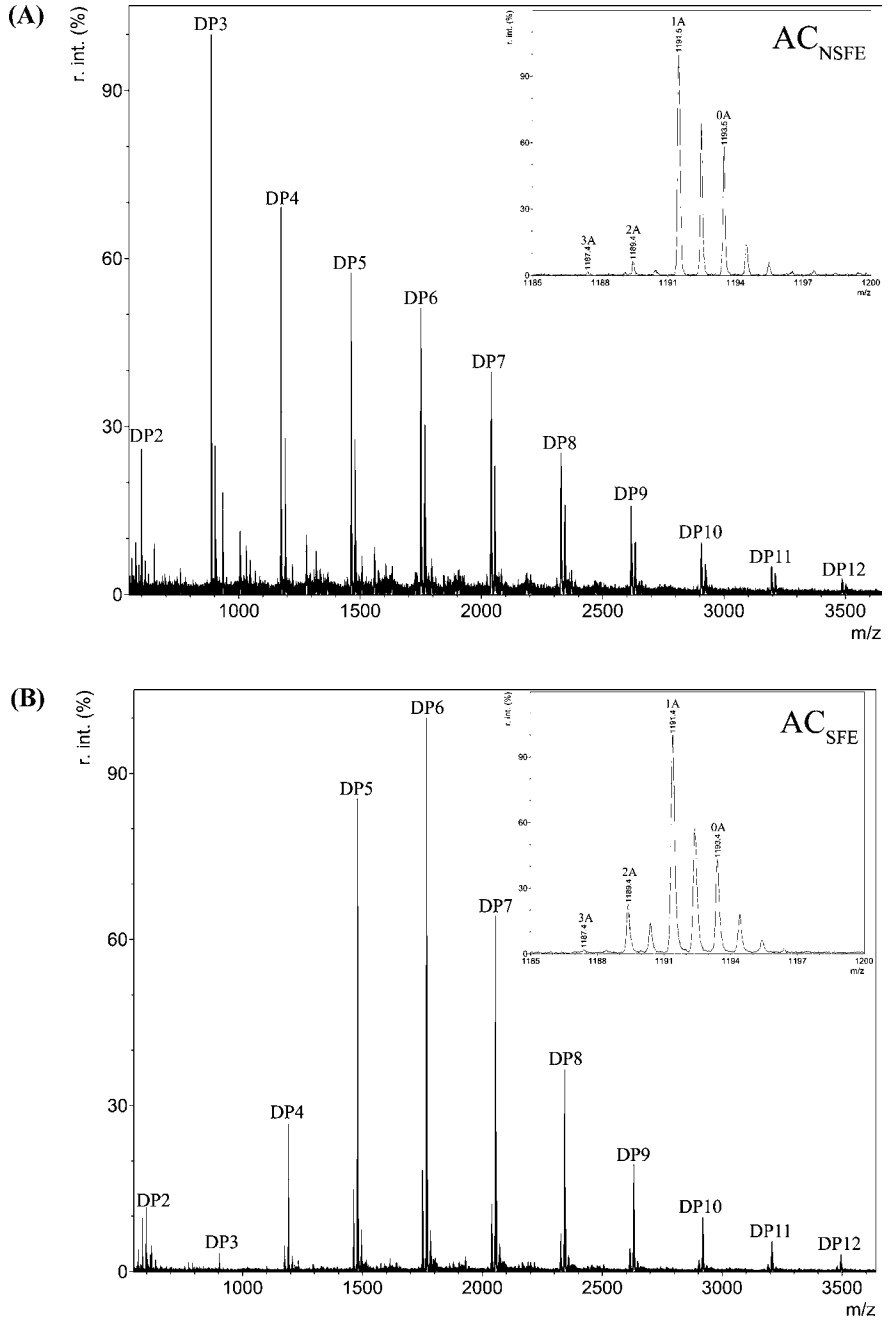

Figure 4. Mass spectra obtained with MALDI-TOF MS in positive reflectron mode for the (A) AC_{NSFE} and (B) AC_{SFE} fractions. "r.int." and "DP" correspond to relative intensity and degree of polymerization, respectively. (Inset) Enlarged spectrum to assist with visualizing the isotopic distribution of potassium adducts of proanthocyanidin (PAC) tetramers.

mass units (Figure 3C,D). Both adducts were analyzed by the deconvolution method. PAC with at least one "A-type" interflavan bond had similar amounts in AC_{NSFE} (median = 92.9%) and AC_{SFE} fractions (median = 92.7%). However, the spectra showed differences in the percentages of two and three "A-type" interflavan bonds: the percentage of PAC with two or three "A-type" bonds was higher in AC_{SFE} for oligomers with a DP between 3 and 7 (Table 1). For instance, AC_{SFE} showed a higher abundance of PAC tetramers with two "A-type" interflavan bonds compared to AC_{NSFE} (insets in Figure 4).

The median percentage of PAC across all DP with two or three "A-type" bonds was 26.1% for AC_{NSFE} and 33.7% for AC_{SFE}. When these percentages were compared per each DP, PAC with two or three "A-type" interflavan bonds were 2-, 4-, and 14-fold higher in AC_{SFE} than in AC_{NSFE} for pentamers, tetramers, and trimers, respectively.

Bacterial Agglutination Assay. The agglutination assay showed clear dose−response curves, which were normalized to time zero of the experiment as previously reported.[3] Results show that both AC_{NSFE} and AC_{SFE} fractions significantly increased agglutination, when compared to control (p value < 0.0001). As PAC concentration increased, transmittance increased, which demonstrated that more bacteria have agglutinated and precipitated. The AUC is an indicator of the ability of different PAC to agglutinate ExPEC; higher AUC corresponds to a higher agglutination.[3] AC_{SFE} had a

3	91.9 ± 2.7	70.3 ± 5.1	1.7 ± 0.7	19.7 ± 3.9
4	82.6 ± 3.2	72.3 ± 4.6	5.4 ± 0.7	19.9 ± 3.1
5	77.1 ± 4.3	68.8 ± 4.1	13.1 ± 3.3	23.2 ± 2.8
6	56.5 ± 5.2	49.3 ± 3.8	39.0 ± 3.5	44.1 ± 1.2
7	47.9 ± 2.5	40.5 ± 3.6	51.7 ± 1.9	56.3 ± 3.6
8	37.4 ± 4.6	38.9 ± 3.0	60.1 ± 0.6	59.5 ± 1.8
median	66.8	59.0	26.1	33.7

[a]The results are expressed as the average of three independent wells ± standard deviation on the MALDI-TOF MS plate.

significantly greater effect on ExPEC agglutination than AC_{NSFE} (p value = 0.0055). ExPEC agglutination was 137, 40, 3, 9, and 9% higher for 6, 12, 29, 58, and 116 ppm of purified PAC, respectively, when AC_{SFE} was compared with AC_{NSFE} (Figure 5A).

Invasion Assay. The Caco-2 invasion assay showed dose–response curves with a statistically significant effect of the concentration (p value < 0.0001) and prior SFE (p value = 0.0017). Our results show that cranberry PAC from AC_{SFE} were more effective in inhibiting ExPEC invasion of enterocytes than AC_{NSFE} (Figure 5B). ExPEC invasion was lower by 19, 20, 13, 11, and 6% at 6, 12, 29, 58, and 116 ppm of PAC, respectively, when AC_{SFE} was compared with AC_{NSFE}. The greater inhibition of enterocyte invasion by PAC from AC_{SFE} was statistically significant for all concentrations except for 116 ppm. The higher inhibition was more pronounced for lower PAC concentrations as the p values for 6, 12, 29, and 58 ppm of PAC were 0.0017, 0.0024, 0.0151, and 0.0262, respectively.

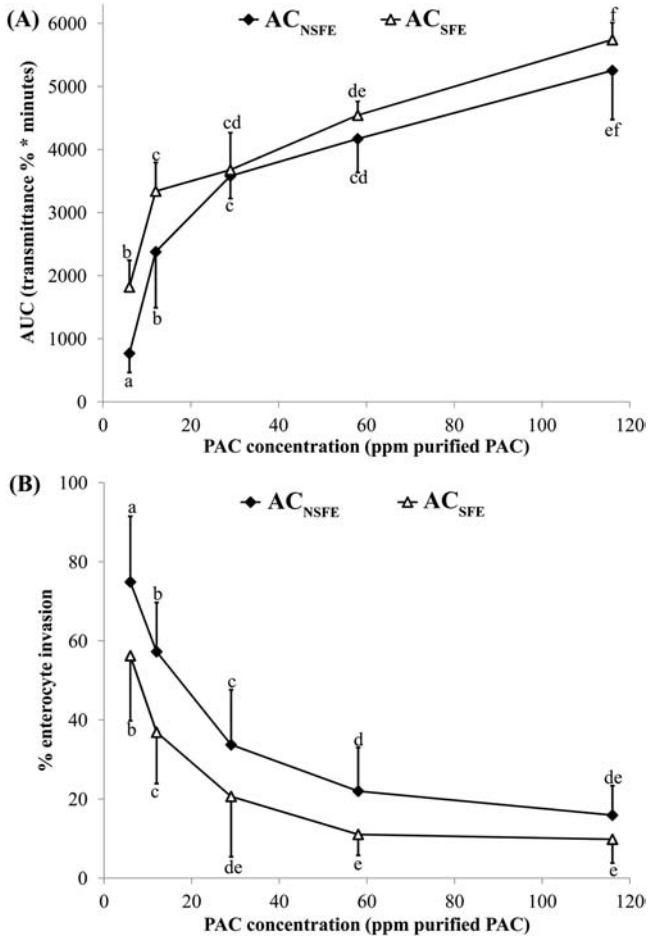

Figure 5. (A) Area under the curve (AUC) obtained for the ExPEC agglutination assay with increasing concentrations of cranberry proanthocyanidins (PAC) in AC_{NSFE} and AC_{SFE} fractions. (B) Dose–response curves of AC_{NSFE} and AC_{SFE} fractions on the effect of PAC inhibition of ExPEC invasion of enterocytes. PAC concentrations are expressed in parts per million of purified PAC as quantified by the 4-(dimethylamino)cinnamaldehyde (DMAC) method.[23] The results are expressed as the average of three independent assays ± standard deviation. Different letters correspond to significant differences at p < 0.05.

DISCUSSION

Effect of Supercritical Fluid Extraction on Proanthocyanidins Elution Profile on Sephadex LH-20. In this work, we initially investigated the potential of SFE, with and without modifiers, to extract PAC from cranberries. The use of CO_2 in cycle 1 generated yellow extracts, and the subsequent addition of ethanol to CO_2 in cycle 2 generated red extracts in separators 1 and 2. MALDI-TOF MS spectra of these extracts showed multiple peaks that corresponded to lipophilic compounds in the yellow extracts and phenolic compounds in the red extracts, including anthocyanins (data not shown). These results are in agreement with previous work in which anthocyanins have been extracted from cherries,[31] elderberries,[32] and grapes[33] using CO_2 and ethanol under supercritical conditions. CO_2 is the most commonly used solvent for SFE[34] and can replace organic solvents in laboratory and industrial extractions of nonpolar compounds. However, for more polar compounds, the addition of modifiers is necessary. For instance, catechin is not extracted with SFE unless a modifier is used.[35]

Although research indicates that PAC monomers,[18] dimers,[19] and trimers[20] can be extracted from grape seeds with SFE using CO_2 and modifiers, our work showed that SFE is not able to extract PAC with DP >2 in cranberries, as analyzed by MALDI-TOF MS. Cranberry PAC have high molecular weight and are amphiphilic, and our results demonstrate that PAC with DP >2 are not good candidates for extraction with SFE even when modifiers are used. Nonetheless, we discovered that prior extraction of cranberries with SFE removed polar and amphiphilic components and altered the composition of PAC fractions from Sephadex LH-20 chromatography, affecting the ratios of "A-type" to "B-type" interflavan bonds and DP in PAC fractions. Although the ethanol fractions from Sephadex LH-20 chromatography were not analyzed by MALDI-TOF MS, we assume that the ethanol fraction with no prior SFE treatment contained lower amounts of PAC dimers than the ethanol fraction with prior SFE treatment. Consequently, EM_{NSFE} contained a larger proportion of PAC with DP 2 compared to EM_{SFE}. Our results also showed that AC_{SFE} contained more oligomers with two and three "A-type" interflavan bonds and contained PAC with higher DP than AC_{NSFE} because PAC with lower DP and only one "A-type" interflavan bonds were eluted in EM_{SFE}. More than 92% of PAC in AC_{SFE} and AC_{NSFE} had at least one "A-type" interflavan bond, which is in agreement with

dx.doi.org/10.1021/jf502296b | J. Agric. Food Chem. 2014, 62, 7730–7737

our previous work in which 91 and 95% of PAC isolated from cranberry press cake and fruits, respectively, had at least one "A-type" interflavan bond.[3,24]

The higher amounts of PAC with two and three "A-type" interflavan bonds and the higher DP in AC_{SFE} compared to AC_{NSFE} prompted the interest in studying the impact of these PAC structural differences on ExPEC agglutination and Caco-2 cell invasion. These studies were conducted only with AC_{NSFE} and AC_{SFE} because MALDI-TOF MS showed that these fractions did not contain other components, whereas EM_{NSFE} and EM_{SFE} spectra contained m/z peaks that did not correspond to PAC.

Bacterial Agglutination Assay. For any given PAC concentration, AC_{SFE} had higher agglutination ability than AC_{NSFE}. The differences described here were not as striking as when cranberry "A-type" PAC were compared with apple "B-type" PAC.[3] Bacterial agglutination prevents the specific adhesion of ExPEC to gut epithelial cells and therefore can decrease enterocyte invasion and subsequent gut colonization by ExPEC, possibly preventing earlier steps of UTI and other extra-intestinal infections.[3]

Invasion Assay. In this work, we were able to generate dose−response curves with physiologically relevant PAC concentrations for both AC_{NSFE} and AC_{SFE} fractions.[3] Our results show that AC_{SFE} was more efficient in inhibiting invasion than AC_{NSFE} and that enterocyte invasion rate was reduced to 9% when compared to the control at 116 ppm of PAC. This effect may be related to the higher amount of PAC with two and three "A-type" interflavan bonds and the shift toward PAC with higher DP as detected by MALDI-TOF MS in the AC_{SFE} fraction.

PAC isolation with prior SFE extraction removed non-PAC components, which greatly altered the chromatographic behavior of PAC on Sephadex LH-20. The generated cranberry PAC fractions contained a higher number of "A-type" interflavan bonds and contained PAC with higher DP. These results are the first in the literature to suggest that the number of "A-type" interflavan bonds influences bioactivity.

SFE can be used as a prior step in PAC isolation to manipulate the ratios of "A-type" to "B-type" PAC and obtain formulations enriched in PAC with multiple "A-type" interflavan bonds. Our results show that the bioactivity of cranberry PAC is related to DP and ratios of "A-type" and "B-type" interflavan bonds. These ratios are highly variable in cranberry products. For instance, the range in content of PAC trimers with "A-type" was between 0 and 1579 μg/g in cranberry powders.[36] Our results also suggest that MALDI-TOF MS deconvolution[24] is useful for assessing cranberry PAC bioactivity.

Chemicals and Standards. HPLC-grade acetonitrile (Carlo-Erba) and formic acid (Merck, Darmstadt, Germany) were purchased from Merck (Darmstadt, Germany). Water was permuted using a reverse osmosis Milli-Q system (Millipore, Molsheim, France). Chlorogenic acid, caffeic acid, metformin (dimethyl-biguanide), cytochalasin B, and tolbutamide were provided by Sigma-Aldrich (St. Quentin Fallavier, France).

Burdock Root Extraction. The dried burdock roots were crushed into a fine powder that was placed into a cellulose cartridge suspended in a glass graduated cylinder. Then, a sequential extraction was performed by "soaking", i.e., pouring slowly different solutions on the powder using a peristaltic pump. The pump can extend each extraction for 12 h in a closed circulation. The extraction was started with an aqueous solution (50 mM Tris-HCl at pH 8, 150 mM NaCl, and 2 mM EDTA) and continued with a 70% ethanolic solution [ethanol/water, 70/30 (v/v)] for 48 h. The filtrate was then treated by chloroform (0.5:1; v/v) in a "bulb" glass decanter. The alcoholic phase was collected and dried in a Rotavapor apparatus before storage at −20 °C. Before use, the powder was solubilized in 20% ethanol. Sugar, protein, and phenolic compounds content was measured by the method of Dubois et al.,[13] the Bradford method,[14] and the method of Singh et al.,[15] respectively.

GC−MS and LC−MS Analysis of Compounds. *GC−MS Analysis.* Gas chromatography was performed using a Focus GC oven (Thermo) fitted with a mass spectrometer as detector. The column system used was a TG-5MS (30 m × 0.25 mm i.d., 0.25 μm d_f) supplied by Thermo. The column was connected to a split/splitless injector. The GC conditions were as follows: the oven was temperature-programmed for 70 °C, initially held for 1 min, then raised at 10 °C/min to 300 °C and held for 5 min. The column flow was 1.2 mL·min^{-1} helium. Injections of 2 μL were performed in splitless mode with a splitless time of 2 min. The injector temperature was 200 °C. The mass spectrometer used was a DSQII (Thermo) with EI source (70 eV). The scan range was 40−500 Da. A scan speed of 3000 amu/s was used. The source and transfer line temperature were held at 250 and 310 °C, respectively. The data were processed using the Xcalibur system. Identifications were performed using the NIST library.

LC−MS Analysis. In a first step, high-resolution mass spectrometry (HRMS/MS) was performed to characterize elemental composition of parent and fragment ions. Abundance of each compound was assessed in a second step with a diode array detector (DAD) coupled with a second HPLC−ESI−MS. For the first step, chromatographic separation was carried out on Acquity H-Class ultrahigh performance liquid chromatography (UPLC) system (Waters Corp., Milford, MA), equipped with a 100/2 Nucleoshell RP18 2.7 μm column (Macherey-Nagel). The mobile phase consisted of permuted water (solvent A) and acetonitrile (solvent B), both phases acidified by 0.1% (v/v) formic acid. The extract was then characterized using a Synapt G2-S high definition mass spectrometry system (Waters Corp., Milford, MA) equipped with electrospray ionization. Mass spectra were acquired in the positive and negative ionization mode with a capillary voltage of 1 kV. The TOF mass analyzer was calibrated using phosphoric acid in 1:1 (v:v) acetonitrile:H_2O from 50 to 1200 m/z to obtain mass accuracy within 3 ppm. The Synapt parameters were optimized as follows: the sample cone was set at 20 V, the source and desolvation temperature were set at 120 and 600 °C, respectively. Each sample was processed with MassLynx (V4.1) software.

In the second step, absorbance spectra were acquired using a Waters 996 photodiode array detector. Chromatographic separation was carried out on a XTerra MS C_{18} column (100 × 2.1 mm, 3.5 μm) heated at 30 °C (Gecko 2000, Cluzeau Info Labo, France). Gradient was performed at a 210 μL·min^{-1} flow rate using a binary HPLC pump (Waters 1525 μ, Waters, Manchester, UK); it was composed of permuted water (solvent A) and acetonitrile (solvent B), both acidified by 0.1% (v/v) formic acid. The analysis was performed on a Micromass ZQ ESCi multimode ionization mass spectrometer (Micromass Ltd, Manchester, UK) equipped with an electrospray ionization ion source. Absorbance spectra were acquired using a Waters 996 photodiode array detector. Sensitivity of the mass spectrometer was optimized using a chlorogenic acid standard. For peak assignment, we took as references LC−MS/MS characterizations from Lin and Harnly,[11] Jaiswal and Kuhnert,[16] and Matura et al.[7] Compounds were identified by their retention times, UV absorbance spectra, and MS fragmentation pattern and numbered in conformity with the IUPAC numbering system.[17] Isomers were assigned by using the appropriate standards from Sigma-Aldrich (chlorogenic acid, caffeic acid). Since other caffeoylquinic acid derivatives were not commercially available, they were identified by comparison with chromatograms of *Arnica montana* L. flower extract and of the leaf extract from *Coffea canephora*, *Ilex paraguariensis*, *Cynaria scolymus* L. The compound concentrations were calculated by integrating chromatogram peak areas at 326 nm (maximal absorbance of CGA) and expressed as equivalent absorbance of the authentic chlorogenic acid standard (Sigma-Aldrich). Calibration curves were performed by dilution of stock solutions (10^{-3} M) in aqueous methanol (30/70, v/v), stored at −4 °C during experiments.

L6 Myocyte Culture and [^{3}H]-2-Deoxyglucose Uptake. The experimental procedure used has been previously described by Tousch et al.[12] On the day of the experiment, cells were first starved during 4 h in DMEM supplemented with 0.1% BSA alone and then incubated during 1 h in KRB, 0.1% BSA, 5 mM glucose supplemented with or without 100 nM insulin,[18] DBRE at 50 or 100 μg·mL^{-1}, or CGA (100 μg·mL^{-1}) and cytochalasin B (CCB) (1 μM), used as pharmacological controls. Cells were incubated in 1 mL of KRB containing 0.5 μCi [^{3}H]deoxyglucose per well. Uptake was stopped by three washings in cold PBS, and cells were lysed in 0.1 N NaOH. Radioactivity was measured and the total protein concentration was evaluated by a Bradford assay.[14] Results are expressed in cpm·mg protein^{-1}·min^{-1}.

Hepatocyte Culture and Glucose Output Test. Hepatocytes were isolated from male Wistar rats (180−260 g) fed ad lib using a two-step perfusion technique, as described by Seglen.[19] Cells were cultivated on collagen-coated 12-well plates in basal medium (William's E containing 11.1 mM glucose, 100 U·mL^{-1} penicillin, 100 μg·mL^{-1} streptomycin) supplemented with 6% FCS at a cell density of 830 000 cells/well. Four hours after initial plating, the medium was replaced with a basal medium supplemented with 100 nM dexamethasone, and plates were incubated for 24 h. Hepatocytes were loaded in glycogen with a 20 h incubation in loading medium: William's E containing 11.1 mM glucose, 100 U·mL^{-1} penicillin, 100 μg·mL^{-1} streptomycin supplemented with 100 nM dexamethasone, 13.9 mM glucose, and 100 nM insulin. After the loading period, hepatocytes were washed three times with PBS and incubated for 3 h in buffer [117.6 mM NaCl, 5.4 mM KCl, 0.82 mM $MgSO_4$, 1.5 mM KH_2PO_4, 20.0 mM Hepes, 9.0 mM $NaHCO_3$, 0.1% (w/v) BSA, 2.25 mM $CaCl_2$ (pH 7.4)][20] without or with DBRE at 50 or 100 μg·mL^{-1} or CGA at 50 μg·mL^{-1} in the presence of 100 nM glucagon (stimulating conditions). After 3 h incubation, supernatants were collected and frozen at −20 °C until glucose quantification.

Glucose release (nmol/well) was measured using a glucose oxidase kit (Megazyme, Wicklow, Ireland). Results are presented as the percentage of glucagon stimulation values.

In Vitro Measurement of Hepatic Glucose 6-Phosphatase Activity. Commercial liver microsomes (BD Biosciences, Le Pont de Claix, France) were used to quantify glucose 6-phosphatase activity. In the standard glucose 6-phosphatase assay, microsome suspension samples (2 μg of proteins by assay) were incubated for 30 min at 30 °C in the buffer containing 20 mM of glucose 6-phosphate.[21] The reaction was stopped by the addition of 1 mL of malachite green color reagent and incubated during 5 min before measuring optical density at 660 nm with NaH_2PO_4 (1−20 nmol) taken as standard. The integrity of microsomes was checked with 0.1% Triton X100 to measure the activity of the catalytic subunit of glucose 6-phosphatase after membrane disruption as previously described by Murataliev and Vufson.[22] The effects of DBRE (50 and 100 μg·mL^{-1}) and CGA (50 μg·mL^{-1}) were tested. The results are expressed as P_i (nmol·h^{-1}).

β-Cell Culture and Measurement of Insulin Release. The experimental procedure on rat insulinoma-derived INS-1 β-cells[23] has been previously described by Tousch et al.[12] For incubation experiments, cells were first washed twice and incubated for 60 min

[a]Peaks obtained in DBRE are listed in the order of elution. with their names, molecular formulas, retention times (t_R), precursor ions, and fragmentation data of hydroxycinnamoylquinic acids. [b]t_R (min): retention time in minutes. [c]Mol. form.: molecular formula. [d]Theo. mass: theoretical monoisotopic mass of precursor ion $[M - H]^-$. [e]Δppm: mass tolerance expressed in parts per million.

in glucose-free KRB, BSA (0.1%). They were then washed once again with the same medium and incubated for 60 min in KRB, BSA (0.1%) with glucose at 2.8, 5.6, and 11.2 mM. We investigated the effects of DBRE at 50 or 100 $\mu g \cdot mL^{-1}$, in the presence of 5.6 mM glucose. Tolbutamide was used at 200 μM as a control insulinotropic drug. Insulin released in the medium was determined by FRET technology with the HTRF Insulin-Kit (Cis-Bio International). Fluorescence levels were measured on a RUBY star instrument (BMG LABTECH). Results are expressed in $ng \cdot mL^{-1}$.

Animals. Experiments were performed in male Wistar rats (280−320 g) obtained from Charles River Laboratories (L'Arbresle, France) and maintained on a 12 h/12 h light−dark schedule. The protocols have been reviewed and approved (2009/11/03) by the Animal Care and Use Committee Languedoc-Roussillon (CEEA-LR-0920 and CEEA-LR-0921).

Glucose Tolerance Test. Two experimental sets were carried out. The first four groups received, during 4 days, daily intraperitoneal (ip) administrations of DBRE at 0.75 or 3 $mg \cdot kg^{-1}$ or metformin at 100 $mg \cdot kg^{-1}$ as a pharmacological positive control or saline (controls). On the fourth day, fasted rats were submitted to an intraperitoneal glucose tolerance test (IPGTT; 1 $g \cdot kg^{-1}$). In the second set, the animals were divided into three groups; they received four daily oral administrations of either DBRE at 3 or 15 $mg \cdot kg^{-1}$ or saline (controls). On the fourth daily administration, an oral glucose tolerance test (OGTT; 3 $g \cdot kg^{-1}$) was performed.

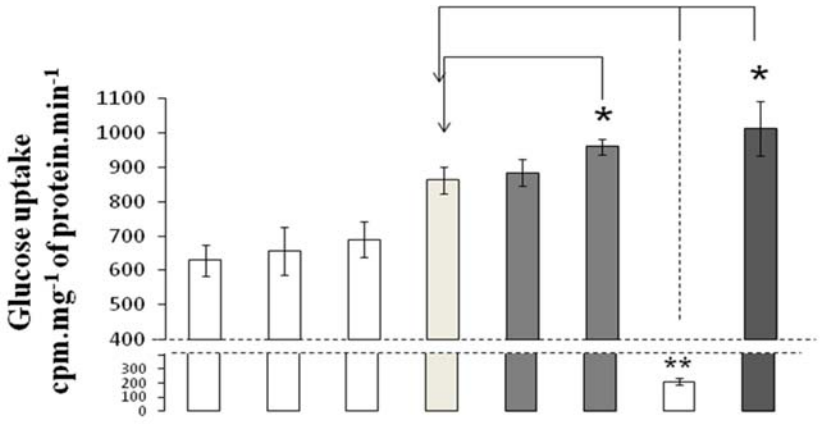
Blood samples were collected from the tail vein, at different times before and after glucose administration. After centrifugation at 4 °C, plasma glucose levels were measured by the glucose oxidase method[24] and plasma insulin concentrations using a radioimmunological method.[25]

Data Analysis. In vitro data are expressed as means ± SD and in vivo data as means ± SEM. Multiple group comparisons were performed by analysis of variance (ANOVA) followed by Fisher's protected least significant difference test at $^*p < 0.05$ or $^{**}p < 0.01$, using the Stat Graphics software.

For in vivo experiments, plasma glucose and insulin values are expressed in $mmol \cdot L^{-1}$ and $ng \cdot mL^{-1}$, respectively. The areas under the curve (AUCs) for the first 60 min (IPGTT) or 120 min (OGTT) were also evaluated.

RESULTS

GC−MS and LC−MS Chemical Analysis. The global composition of DBRE (percent of weight) was as follows: 12% of glucidic compounds, 86% of phenolic compounds, 0.8% proteins, and 1.2% others. The total phenolic content is 150 mg/g of dry plant material.



Insulin (100 nM)	-	-	-	+	+	+	+	+
DBRE (µg.mL^{-1})	-	50	100	-	50	100	-	-
CCB (1 µM)	-	-	-	-	-	-	+	-
CGA (100 µg.mL^{-1})	-	-	-	-	-	-	-	+

Figure 1. Effect of DBRE (50 or 100 μg·mL^{-1}) on glucose uptake in L6 muscle cells without or in the presence of 100 nM insulin. CGA (100 μg·mL^{-1}) and CCB (1 μM) were used as control pharmacological compounds. Values are means (±SD) of six independent experiments (n = 24 for each condition). *p < 0.05, **p < 0.01 versus insulin (100 nM) alone.

GC−MS and LC−MS allowed us to assign and characterize all substances except sugars. The data obtained by LC−MS analysis are shown in Tables 1 and 2. The GC−MS chemical monitoring allowed the detection of 27 hydroxycinnamic acids, of which 19 have been previously described by Lin and Harnly[11] and Jaiswal and Kuhnert;[16] hence, our analysis allowed us to identify eight other additional isomers in our original extract.

The chemical analysis of DBRE has been performed by LC−MS and GC−MS. LC−MS analysis revealed the presence of a large majority of dicaffeoylquinic acid derivatives (75.4%). Four maloyl-dicaffeoylquinic acid isomers were identified by their parent ion (m/z 631.129) and m/z 469.099 fragment, corresponding to [maloyl−caffeoylquinic acid−H] after the loss of one caffeoyl group. The three peaks P6, P9, and P11 have been previously observed by Jaiswal and Kuhnert.[16] Among them, 1,5-di-*O*-caffeoyl-4-*O*-maloylquinic acid (peak P11) is the most abundant DBRE compound and contributes to 44% of chlorogenic acid equivalent absorbance.

1,4-*O*-Dicaffeoylquinic acid (peak P5) and 1,5-*O*-dicaffeoylquinic acid (cynarin, peak P16) represent respectively 1 and 3%. P5 and P16 correspond to the two major dicaffeoylquinic acids of *Cynaria scolymus* leaf extract (i.e., 1,4-di-*O*-caffeoylquinic acid and 1,5-di-*O*-caffeoylquinic acid. Likewise, peak P8 corresponds to the 3,5-dicaffeoylquinic acid peak of *Coffea robusta* and *Ilex paraguariensis* leaf extracts.

DBRE is poor in monocaffeoylquinic acids (m/z 353.098 [M − H], peaks P1−P4), representing 12%, of which 7% is chlorogenic acid (5-*O*-caffeoylquinic acid, named CGA and used as " authentic standard" in in vitro experiments, peak P3).

Effect of DBRE on Glucose Uptake in L6 Myocytes. In the absence of insulin, DBRE has no effect on glucose uptake by L6 myocytes (Figure 1). In the presence of insulin (100 nM), glucose uptake increased from 629 to 862 cpm·mg^{-1}·min^{-1} (i.e., +37%, p < 0.01). Addition of DBRE (100 μg·mL^{-1}) significantly increased insulin-induced glucose uptake (+16%, p < 0.05). CGA induced a similar increase (p < 0.05), whereas CCB provoked a drop in glucose uptake (p < 0.01).

Effect of DBRE on Hepatic Glucose Output. Glucagon (100 nM)-induced glucose release reached 450 ± 30 nmol glucose/well (100%) (Figure 2A). The presence of 50 or 100 μg·mL^{-1} DBRE induced a significant non-concentration-dependent decrease (p < 0.01). Similar results were obtained with CGA at 50 μg·mL^{-1} (p < 0.05).

Effect of DBRE on Hepatic Glucose 6-Phosphatase Activity. DBRE induced a significant inhibition of glucose 6-phosphatase activity on hepatic microsomal fractions (Figure 2B). A similar inhibitory effect was observed in the presence of 50 and 100 μg·mL^{-1} DBRE or 50 μg·mL^{-1} CGA (p < 0.01).

Effect of DBRE on INS-1 β-Cells Insulin Release. As expected, increasing glucose concentration in the medium from 2.8 to 5.6 and 11.2 mM resulted into a clear and significant glucose-dependent stimulation of insulin release (Figure 3). Tolbutamide also induced a clear insulinotropic effect. In the presence of 5.6 mM glucose, addition of DBRE at 50 μg·mL^{-1} did not modify insulin release. However, a slight but significant (p < 0.05) reduction in insulin release occurred for the higher 100 μg·mL^{-1} concentration.

Glucose Tolerance Test. After four daily DBRE (0.75 or 3 mg·kg^{-1}) or metformin (100 mg·kg^{-1}) ip administrations, basal glucose and insulin levels were not found to be significantly modified (Table 3A). IPGTTs clearly show that DBRE at 0.75 mg·kg^{-1} is able to reduce the increase in plasma glucose (p < 0.05) from minute 10 to 30. A similar effect was observed in metformin-treated rats. These results are corroborated by AUCs for the first 60 min. Glucose-induced insulin response was significantly reduced (p < 0.05) by DBRE at 0.75 mg·kg^{-1}. In contrast, in rats treated with the higher DBRE dose (3 mg·kg^{-1}) no significant effect could be observed.

After four daily oral administrations of DBRE at 3 or 15 mg·kg^{-1}, basal glucose and insulin levels were not found to be modified (Table 3B). Oral glucose tolerance tests bring evidence that DBRE at 15 mg·kg^{-1} is able to significantly

dx.doi.org/10.1021/jf500926v | J. Agric. Food Chem. 2014, 62, 7738−7745

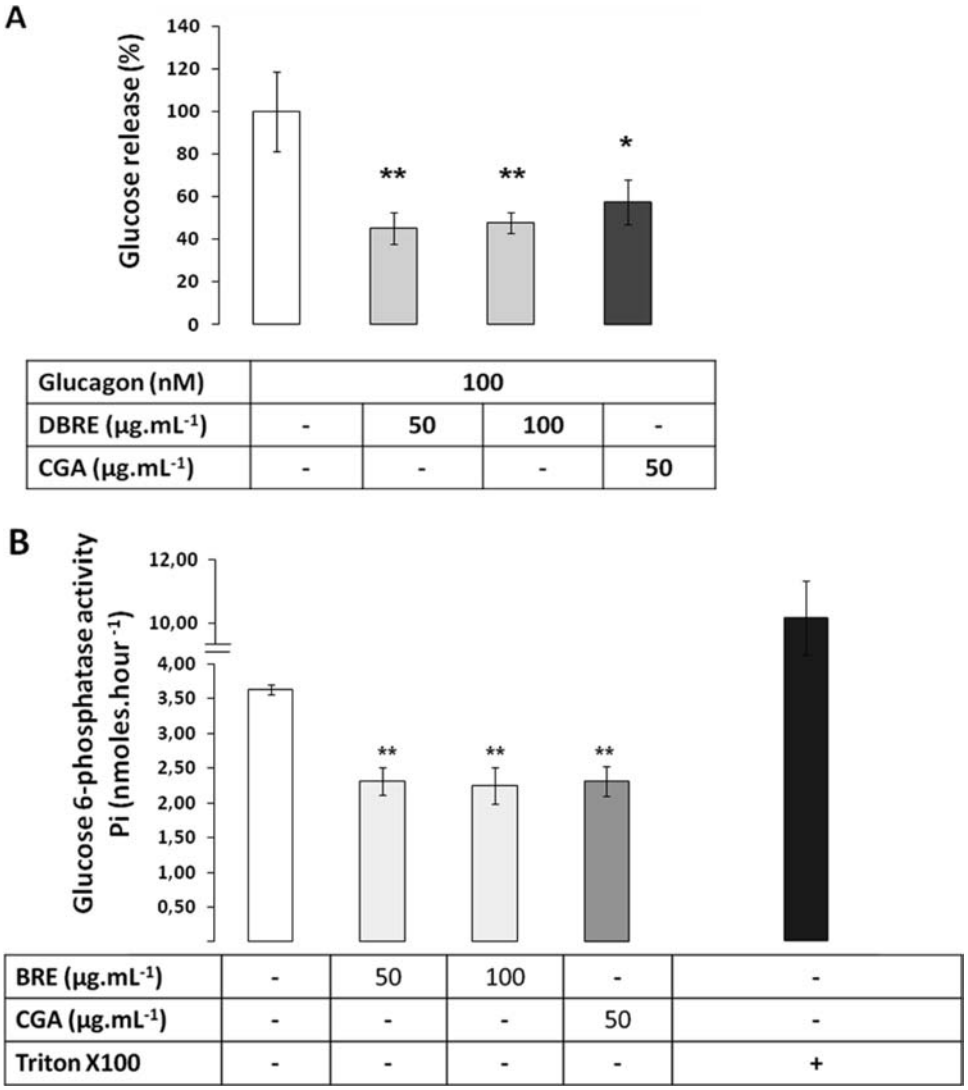


Figure 2. Effect of DBRE at 50 or 100 $\mu g \cdot mL^{-1}$ on glucagon-induced glucose release from rat isolated hepatocytes (A) and on glucose 6-phosphatase activity of liver microsomes (B). CGA (50 $\mu g \cdot mL^{-1}$) was used as control. For panel A, results are expressed as percent of glucose release in the presence of glucagon alone. Data are means (±SD) of three independent experiments (n = 14 values for each condition). *p < 0.05 and **p < 0.01 versus glucagon alone (100% effect). For panel B, results are expressed as P_i nmol·h^{-1}. Data are means (±SD) of three experiments (n = 9 for each condition). **p < 0.01.

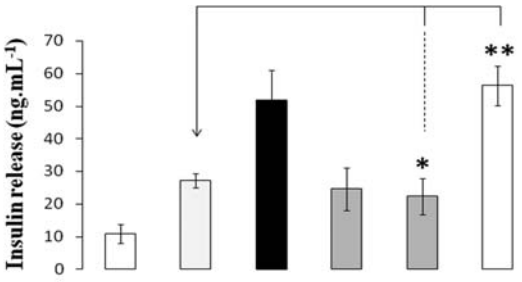
reduce hyperglycemia from minute 60 to 90 (p < 0.05) (Table 3B). Interestingly, a clear increase in insulin response to oral glucose preceded the reduction in hyperglycemia at 30 min (p < 0.05) and 60 min (p < 0.01). AUCs for the first 120 min confirm this observation. No significant change could be observed for DBRE at 3 $mg \cdot kg^{-1}$.

DISCUSSION

Our extraction procedure allowed us to get an original polyphenol-rich extract of dried burdock roots. The total phenolic content is 150 mg/g of dry plant material, in comparison with 28.7 mg/g of dry plant material in the hydro-methanolic (70:30, v/v) burdock root extract obtained by Ferracane et al.[8]. The chemical analysis of DBRE by GC−MS and LC−MS led to the identification of 27 caffeoylquinic acids derivatives and notably 1,5-di-*O*-caffeoyl-4-*O*-maloylquinic (44%) and monocaffeoylquinic acid (CGA) (7%). DBRE differs clearly from the extracts obtained by Ferracane et al.,[8] Lin and Harnly,[11] and Jaiswal and Kuhnert.[16] These differences are largely due to our sequential partitioned extraction procedure but also could be due at the plant growth geographic conditions and also the burdock genotypes, as was shown by Liu at al.[26] None of the six lignans previously described in burdock roots were present in DBRE. Likewise, no fructan, terpen, or lipid could be detected.

Our in vitro experiments bring evidence that DBRE is able to increase glucose uptake in myocytes (L6 cells) in the presence of insulin, pointing to an insulin-sensitizing effect of the extract. Upon stimulation of glucose production by glucagon in rat isolated hepatocytes, DBRE induced a strong decrease in glucose release which was paralleled by a significant decrease in glucose 6-phosphatase activity. These results are in agreement with previous studies investigating CGA effects.[10,12] In contrast, in the presence of glucose (5.6 mM), DBRE (100 $\mu g \cdot mL^{-1}$) significantly decreased insulin release by INS-1 β-cells. This result is in discordance with the presence of CGA, which has been described as an insulinotropic compound,[12] suggesting that in DBRE another compound is present that is able to counteract and reverse the CGA effect.

dx.doi.org/10.1021/jf500926v | J. Agric. Food Chem. 2014, 62, 7738−7745



Glucose (mM)	2.8	5.6	11.2	5.6		5.6
DBRE (μg.mL^{-1})	-	-	-	50	100	-
Tolbutamide (μM)						200

Figure 3. Effect of DBRE on insulin release in the INS-1 β-pancreatic cell line. DBRE (50 and 100 μg·mL^{-1}) or tolbutamide (200 μM) as a positive control were tested in the presence of 5.6 mM glucose. Data are means (±SD) of six independent experiments; they are expressed as ng·mL^{-1} (n = 24) for each experimental condition. *p < 0.05, **p < 0.01 versus 5.6 mM glucose.

Our in vivo data obtained after IP subchronic treatments clearly show that DBRE (0.75 mg·kg^{-1}) improves IP glucose tolerance, an effect that occurs together with a decrease in insulin secretion. These data confirm and extend in vivo and in vitro experiments pointing to an insulin sensitizing effect. It is noteworthy that similar results could be obtained with metformin, another well-known insulin-sensitizing agent. At the higher dose (3 mg·kg^{-1}), DBRE was ineffective, which suggests probably an adverse effect, as already described for pro-oxidants, showing once again and emphasizing the importance of avoiding high dosages upon treatments with polyphenols.[27,28] It is interesting to note that a treatment of diabetic db/db mice with a rich caffeolyquinic acid extract of *Pandanus tectorius* for 3 weeks induced an antihyperglycemic effect by insulin-sensitizing action.[29] Concerning oral repeated administrations of DBRE, our extract, at the dose of 15 mg·kg^{-1}, remained able to improve oral glucose tolerance. A similar beneficial effect on plasma glucose levels has been previously reported in rats with orally ingested synthetic CGA (3.5 mg·kg^{-1});[30] these authors ascribed the reduced increase in plasma glucose to a possible reduced glucose intestinal absorption. From a physiological point of view, it is worthy to mention that a tricaffeoylquinic acid (3,4,5-tri-*O*-caffeoylquinic acid) present in the brazilian propolis exerts an antihyperglycemic effect through the inhibition of intestinal maltase activity.[31] Anyhow, our experiments bring evidence that subchronic oral DBRE administrations result in a clear increase of glucose-induced insulin response. Previous studies have reported that heavy coffee (with CGA as the chief polyphenol present) consumption is associated with increased plasma levels of GLP-1.[32] We therefore suggest that the increased insulin response and the beneficial effect on oral glucose tolerance could be due to a DBRE-induced increase in incretin activity, all the more since insulin response to glucose is not modified after repeated ip DBRE administrations, which is also in line with the absence of insulinotropic effect in vitro on INS cells.

In conclusion, we realized and chemically characterized an extract of dried Burdock roots (DBRE). Our data demonstrate that the original set of caffeoylquinic acid compounds present in DBRE at 86% displays both in vitro and in vivo compelling antihyperglycemic properties with potential therapeutic relevance. However, further investigations are required to address and understand the specific role of each caffeoylquinic acid compound, in the beneficial effects of DBRE.

Table 2. Concentrations of Each Compound Were Calculated by Integrating Peak Areas of Chromatograms at 326 nm (maximal absorbance of CGA) and Are Expressed as Equivalent Absorbance of the Authentic Chlorogenic Acid Standard at 10^{-3} M

[a]Values are means (±SEM) expressed in $mmol·L^{-1}$. [b]Time courses of plasma glucose ($mmol·L^{-1}$) and plasma insulin ($ng·mL^{-1}$) during IPGTTs (1 $g·kg^{-1}$) in rats previously treated by intraperitoneal DBRE (0.75 and 3 $mg·kg^{-1}$), saline, or metformin (100 $mg·kg^{-1}$) during 4 days; $n = 5$ for each experimental condition. AUCs were calculated for the first 60 min. *$p < 0.05$. [c]Time courses of plasma glucose ($mmol·L^{-1}$) and plasma insulin ($ng·mL^{-1}$) during OGTTs (3 $g·kg^{-1}$) in rats treated with oral DBRE (3 and 15 $mg·kg^{-1}$) or saline during 4 days; $n = 5$ for each experimental condition. AUCs were calculated for the first 120 min. *$p < 0.05$, **$p < 0.01$.

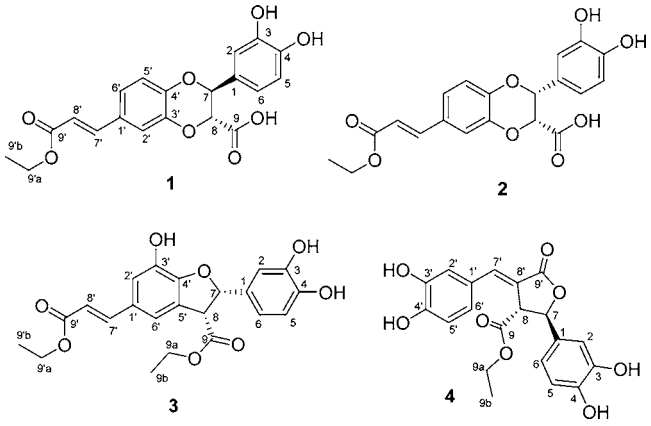

Figure 1. Structures of compounds **1**−**4**.

IR spectra were recorded on a Bruker IFS-66/S FT-IR spectrometer (Bruker, Karlsruhe, Germany). Circular dichroism (CD) spectra were measured on a Jasco J-715 spectropolarimeter (Jasco, Easton, MD, USA). Ultraviolet (UV) spectra were recorded with a Shimadzu UV-1601 UV−visible spectrophotometer (Shimadzu, Tokyo, Japan). High-resolution (HR)-electrospray ionization (ESI) mass spectra were recorded on a SI-2/LCQ DecaXP liquid chromatography (LC)-mass spectrometer (Thermo Scientific, West Palm Beach, FL, USA). Nuclear magnetic resonance (NMR) spectra were recorded on a Varian UNITY INOVA 500 NMR spectrometer (Varian, Palo Alto, CA, USA) operating at 500 MHz (^{1}H) and 125 MHz (^{13}C), with chemical shifts given in ppm (δ). Preparative high performance liquid chromatography (HPLC) used a Gilson 306 pump (Gilson, Middleton, WI, USA) with a Shodex refractive index detector (Shodex, New York, NY, USA). Column chromatography was performed with a silica gel 60 (Merck, 70−230 mesh and 230−400 mesh) and RP-C_{18} silica gel (Merck, 230−400 mesh). The packing material for molecular sieve column chromatography was Sephadex LH-20 (Pharmacia, Uppsala, Sweden). Merck precoated silica gel F_{254} plates and reversed-phase (RP)-18 F_{254s} plates (Merck, Darmstadt, Germany) were used for thin-layer chromatography (TLC). Spots were detected on TLC under UV light or by heating after spraying with anisaldehyde-sulfuric acid.

Plant Material. The seeds of *P. nil* were purchased at Kyungdong herbal market, Seoul, Korea, in July 2006, and were identified by one of the authors (K. R. Lee). A voucher specimen (SKKU 2006-7) has been deposited in the herbarium of the School of Pharmacy, Sungkyunkwan University, Suwon, Korea.

Extraction and Isolation. Air-dried *P. nil* seeds (10 kg) were extracted with 50% EtOH (3 × 4 L, on each of 3 days) at room temperature and filtered. The filtrate was evaporated under reduced pressure using a rotavapor to obtain the EtOH extract (1.4 kg), which was suspended in distilled H_2O (7.2 L) in a separatory funnel to be partitioned in sequence with *n*-hexane, chloroform ($CHCl_3$), ethyl acetate (EtOAc), and butanol (*n*-BuOH), which yielded 10, 7, 10, and 550 g of dried organic fractions, respectively. A bioactivity-guided fractionation method was used for isolation work. Each fraction was tested for cytotoxic activity against A549, SK-OV-3, SK-MEL-2, and HCT-15 human tumor cell lines using a sulforhodamine B (SRB) bioassay, which proved that the EtOAc-soluble fraction showed the strongest activity (IC_{50}: 28.74, 23.45, 10.32, and 17.81 μM, respectively against A549, SK-OV-3, SK-MEL-2, and HCT-15 cells). The most active EtOAc-soluble fraction (10 g) was chromatographed on the open-column of silica gel (230−400 mesh, 300 g) eluting with $CHCl_3$/methanol (MeOH) (10:1 → 1:1, gradient system) to give six fractions (A−F). Each fraction obtained from the EtOAc-soluble fraction was further tested for cytotoxic activity against the four aforementioned cell lines to identify the active fraction. Fractions B, D, and F displayed activity: fraction B (IC_{50}: 5.31, 3.10, 8.39, and 6.11 μM, respectively, against A549, SK-OV-3, SK-MEL-2, and HCT-15), fraction D (IC_{50}: 40.24, 33.97, 12.60, and 20.37 μM, respectively), and fraction F (IC_{50}: 48.92, 27.09, 15.74, and 19.40 μM, respectively). Fraction B (2.5 g) was chromatographed further on the open-column of RP-C_{18} silica gel (230−400 mesh, 150 g) eluting with MeOH/H_2O (3:2 → 4:1, gradient system) to give seven subfractions (B1−B7). Fraction B7 (50 mg) was purified by semipreparative normal-phase HPLC (*n*-hexane/EtOAc, 1:1), using an Apollo Silica column (250 mm × 10 mm i.d., 5 μm, Alltech, Nicholasville, KY, USA) to give **3** (24 mg, t_R = 16.0 min). Fraction D (2.5 g) was applied to an RP-C_{18} silica gel open-column chromatograph (60% MeOH) to yield six subfractions (D1−D6). Fraction D2 (340 mg) was passed through a Sephadex LH-20 column eluted with 100% MeOH and further purified by semipreparative reversed-phase HPLC (30% MeCN), using an Econosil RP-18 column (250 mm × 10 mm i.d., 10 μm, Alltech, Nicholasville, KY, USA) to give **4** (16 mg, t_R = 15.0 min). Fraction F (3.6 g) was passed through a Sephadex LH-20 column and eluted with CH_2Cl_2/MeOH (1:1) to obtain four subfractions (F1−F4). Finally, fraction F3 (700 mg) was purified by semipreparative reversed-phase HPLC (18% MeCN) to yield **1** (20 mg, t_R = 18.0 min) and **2** (13 mg, t_R = 18.5 min).

*Pharbilignanol A (**1**).* White amorphous powder. $[\alpha]_D^{25}$ −9.1 (*c* 0.80, MeOH). UV (MeOH) λ_{max} (log ε): 259 (4.05), 306 (3.62) nm. CD (MeOH): $[\theta]_{220}$ −2810, $[\theta]_{234}$ +3140, $[\theta]_{282}$ +1530. IR (KBr) ν_{max}: 3361, 2946, 2833, 1726, 1630, 1610, 1511, 1451, 1370, 1033, 670 cm^{-1}. *Pharbilignanol D (**4**).* White amorphous powder. $[\alpha]_D^{25}$ +27.7 (*c* 0.40, EtOH). UV (MeOH) λ_{max} (log ε): 258 (4.03), 310 (3.74) nm. CD (MeOH): $[\theta]_{211}$ +2160, $[\theta]_{231}$ +4550, $[\theta]_{245}$ +4710, $[\theta]_{263}$ −5020, $[\theta]_{276}$ +6780. IR (KBr) ν_{max}: 3361, 2947, 2833, 1734, 1642, 1604, 1526, 1450, 1294, 1202, 1032, 670 cm^{-1}. For ^{1}H (500 MHz) and ^{13}C (125 MHz) NMR spectroscopic data, see Table 2. ESIMS (positive-ion mode) *m*/*z*: 387 $[M + H]^+$. HR-ESIMS (positive-ion mode) *m*/*z*: 387.1087 $[M + H]^+$ (Calcd for $C_{20}H_{19}O_8$, 387.1080).

Cell Cultures. All tumor cell cultures were maintained using RPMI1640 cell growth medium (Gibco, Carlsbad, CA, USA) supplemented with 5% fetal bovine serum (FBS) (Gibco), 100 units/mL penicillin, and 100 mg/mL streptomycin. The human tumor cell lines, A549 (nonsmall cell lung carcinoma), SK-OV-3 (ovary malignant ascites), SK-MEL-2 (skin melanoma), and HCT-15 (colon adenocarcinoma) were provided by the National Cancer Institute (NCI). BV2 murine microglia cells were generously provided by Dr. E. Choi from Korea University (Seoul, Korea) and were maintained in Dulbecco's modified Eagle's medium (DMEM) supplemented with 5% FBS, 100 units/mL penicillin, and 100 mg/mL streptomycin. All cells were incubated at 37 °C in a humidified incubator with 5% CO_2.

Cytotoxicity Assessment. The cytotoxicity of the isolates (**1**−**4**) against cultured human tumor cell lines was evaluated by the SRB method. The assays were performed at the Korea Research Institute of Chemical Technology. Each tumor cell line was inoculated over standard 96-well flat-bottom microplates and then incubated for 24 h at 37 °C in a humidified atmosphere of 5% CO_2. The attached cells were then incubated with the serially diluted samples. After continuous exposure to the compounds for 48 h, the culture medium was removed from each well, and the cells were fixed with 10% cold trichloroacetic acid at 4 °C for 1 h. After washing with tap water, the cells were stained with 0.4% SRB dye and incubated for 30 min at room temperature. The cells were washed again and then solubilized with 10 mM unbuffered Tris base solution (pH 10.5). The absorbance was measured spectrophotometrically at 520 nm with a microtiter plate reader. Doxorubicin (Sigma-Aldrich, St. Luuis, Mo, USA; ≥98% purity) was used as the positive control. Doxorubicin had IC_{50} values against A549, SK-OV-3, SK-MEL-2, and HCT15 of 0.02, 0.02, 0.03, and 0.08 μM, respectively.

Measurement of Nitric Oxide (NO) Production and Cell Viability in Lipopolysaccharide (LPS)-Activated BV-2 Cells. Murine microglia BV-2 cells were plated in wells of a 96-well plate (3×10^4 cells/well). After 24 h, cells were pretreated with samples for 30 min and then stimulated with 100 ng/mL LPS for another 24 h. Nitrite in the culture media, a soluble oxidation product of NO, was measured by the Griess reaction. The supernatant (50 μL) was harvested and mixed with an equal volume of Griess reagent (1% sulfanilamide and 0.1% *N*-1-naphthylethylenediamine dihydrochloride in 5% phosphoric acid). After 10 min, the absorbance at 540 nm was measured using a microplate reader (Emax, Molecular Device, Sunnyvale, CA, USA). Graded sodium nitrite solutions were used as standards to calculate nitrite concentration. Cell viability was measured using a 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) colorimetric assay. The NO synthase inhibitor, N^G-monomethyl-L-arginine (L-NMMA, Sigma-Aldrich), served as the positive control.

RESULTS AND DISCUSSION

Isolation and Structural Elucidation of Compounds. Air-dried seeds of *P. nil* were extracted with 50% aqueous EtOH. The hydroethanolic extract showed considerable cytotoxicity against some human tumor cell lines using the SRB bioassay. The hydroethanolic extract was subjected to solvent-partition into *n*-hexane, chloroform, ethyl acetate, and *n*-butanol fractions. The ethyl acetate fraction showed the strongest activity and was subjected to separation and purification by successive column chromatography over silica gel and Sephadex LH-20, and semipreparative HPLC, which resulted in the isolation and identification of four new lignans, named pharbilignans A−D (**1**−**4**) (Figure 1).

Pharbilignan A (**1**) was isolated as a white, amorphous powder. Its HR-ESIMS at *m*/*z* 409.0902 $[M + Na]^+$ (calcd for $C_{20}H_{18}NaO_8$, 409.0899) and NMR spectroscopic data (Table 1) established the molecular formula as $C_{20}H_{18}O_8$, implying the existence of 12 of unsaturation. The UV absorption maxima at 259 and 306 nm were indicative of a lignan skeleton.[14] The IR absorption bands of **1** were characteristic of hydroxy (3361 cm^{-1}), carbonyl (1726 cm^{-1}), and aromatic ring (1610 and 1451 cm^{-1}) functional groups. The ^{1}H NMR spectrum of **1** showed signals attributable to a deshielded benzylic oxymethine proton at δ_H 5.16 (H-7) and an oxygenated proton at δ_H 4.53 (H-8), implying the linkage of two phenylpropanoid units via a 1,4-dioxane bridge.[15,16] Detailed inspection of the ^{1}H and ^{13}C NMR spectra (Table 1) of **1** showed that the signals were similar to those of americanol A[15] and were almost identical to those of 7-[(1*E*)-2-carboxyethenyl]-3-(3,4-dihydroxyphenyl)-2,3-dihydro-1,4-benzodioxin-2-carboxylic acid, except for the presence of an ethoxy group in **1**.[16,17] The skeleton was confirmed by heteronuclear multiple bond correlation (HMBC), showing correlations from H-7 (δ_H 5.16) to C-2, C-6, C-9, and C-4′ and correlations from H-8 (δ_H 4.53) to C-1, and C-3′. The HMBC correlation between H-9′a (δ_H 4.22) and

dx.doi.org/10.1021/jf501470k | J. Agric. Food Chem. 2014, 62, 7746−7752

C-9′ (δ_C 169.2) indicated the presence of an ethoxy group at C-9′ (Figure 2).

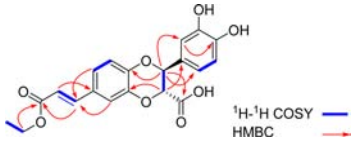

Figure 2. Key ^{1}H−^{1}H COSY (blue line) and HMBC (red arrow) correlations of **1**.

It is difficult to determine whether benzodioxane-type neolignans belong to the americanol or isoamericanol type. Recently, it was reported that the chemical shift differences between H-2′ and H-5′ in the ^{1}H NMR spectra measured in CD_3OD allow for an unambiguous identification of the isomeric structures.[15,16] The ^{1}H NMR spectrum of **1** showed a large difference of 0.19 ppm between H-2′ (δ_H 7.15) and H-5′ (δ_H 6.96), consistent with that of the americanol type.[15,16] Difference nuclear Overhauser effect (NOE) experiments were used to assign the structure, where significant long-range NOE enhancements could be observed between H-2′ and H-8 and between H-5′ and H-7, confirming the americanol type. Additionally, the americanol type of **1** was supported by a small difference of 0.4 ppm between C-3′ (δ_C 146.7) and C-4′ (δ_H 147.1) in the ^{13}C NMR data of **1**.[15,16] The coupling constant ($J_{7,8}$ = 6.0 Hz) between H-7 and H-8, and nuclear Overhauser effect spectroscopy (NOESY) correlation (H-6/H-8) indicated a *trans*-relationship of H-7/H-8 on the 1,4-benzodioxane ring.[17,18] The absolute configuration of the C-7 and C-8 was designated as *S* and *R*, respectively, on the basis of CD data ($[\theta]_{220}$ −2810, $[\theta]_{234}$ +3140, $[\theta]_{282}$ +1530), which was in good agreement with the configuration reported in the literature.[19] Therefore, the structure of **1** was established as depicted in Figure 1.

Pharbilignan B (**2**) was obtained as a white, amorphous powder. Its molecular formula $C_{20}H_{18}O_8$ (12 of unsaturation) was derived by HR-ESIMS *m*/*z* 409.0906 $[M + Na]^+$ (calcd for $C_{20}H_{18}NaO_8$, 409.0899). The similarity of UV and IR absorption bands in **1** and **2** suggested that **2** had the same lignan skeleton as **1**. The ^{1}H and ^{13}C NMR spectra (Table 1) of **2** also showed a similarity with those of **1**, except for the chemical shifts of C-7 and C-8 in **2** (δ_H 5.59, H-7; δ_C 77.4, C-7 and δ_H 4.68, H-8; δ_C 78.2, C-8). Thus, compound **2** is an isomer of **1** with a 1,4-dioxane bridge. A large difference of 0.13 ppm between H-2′ (δ_H 7.15) and H-5′ (δ_H 7.02) and a small difference of 0.3 ppm between C-3′ (δ_C 146.9) and C-4′ (δ_H 147.2) in the NMR data of **2** indicated that compound **2** should be americanol type **1**.[15,16] A relatively small coupling constant ($J_{7,8}$ = 3.5 Hz) between H-7 and H-8 suggested a *cis*-configuration of H-7 and H-8 in the molecule.[17,18] The absolute configuration of the C-7 and C-8 was assigned on the basis of CD data ($[\theta]_{234}$ −2610, $[\theta]_{250}$ +2530, $[\theta]_{288}$ −890), allowing the assignment of 7*R* and 8*R* configurations, respectively.[20] Accordingly, the structure of **2** was elucidated as depicted in Figure 1.

Pharbilignan C (**3**) was isolated as a white, amorphous powder. It had the molecular formula $C_{22}H_{22}O_8$ with 12 of unsaturation, as deduced by HR-ESIMS *m*/*z* 415.1388 $[M + H]^+$ (calcd for $C_{22}H_{23}O_8$, 415.1393). The UV absorption maxima at 256 and 322 nm indicated a lignan skeleton for **3**.[14] The IR absorption bands of **3** exhibited the presence of hydroxy (3356 cm^{-1}), carbonyl (1723 cm^{-1}), and aromatic ring (1603 and 1451 cm^{-1}) moieties. The ^{1}H and ^{13}C NMR data for C-7 and C-8 in **3** (δ_H 5.97, H-7; δ_C 87.1, C-7; and δ_H 4.21, H-8; δ_C 55.6, C-8) supported that compound **3** was a dihydro[*b*]-benzofuran-type neolignan, and the ^{1}H and ^{13}C NMR spectra (Table 2) of **3** were very similar to those of caffeicin F, except for the presence of two ethoxy groups, indicating that compound **3** was an analogue of caffeicin F with two ethoxy groups as a side chain.[18] The structure was verified by an HMBC experiment showing correlations from H-7 (δ_H 5.97) to C-2, C-6, C-9, and C-4′ and from H-8 (δ_H 4.53) to C-1, C-4′, and C-6′. The HMBC correlations H-9a/C-9 (δ_C 170.8) and H-9′a/C-9′ (δ_C 168.1) allowed the assignment of an ethoxy group at C-9 and the other ethoxy group at C-9′ (Figure 3).

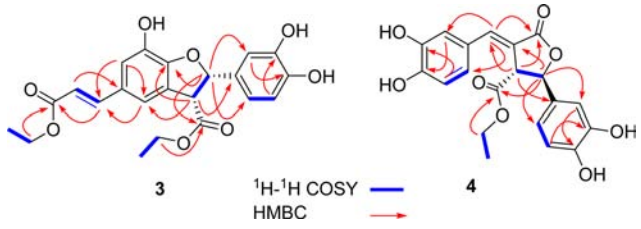

Figure 3. Key ^{1}H−^{1}H COSY (blue line) and HMBC (red arrow) correlations of **3** and **4**.

The relative configuration at H-7 and H-8 was established on the basis of their coupling constant ($J_{7,8}$ = 8.0 Hz), which was consistent with a *cis*-configuration of H-7 and H-8 in **3**.[21] This arrangement was also supported by a NOESY correlation between H-7 and H-8 but the lack of NOESY correlations between H-7 and H-9a or between H-8 and H-2/H-6. Finally, the positive Cotton effect at 254 nm in the CD spectrum of **3** suggested the absolute configuration at C-7 as 7*S*.[22,23] This analysis also determined an 8*R* configuration based on the relative stereochemistry previously determined as *cis*-configuration between H-7 and H-8. Therefore, the structure of **3** was assigned the structure depicted in Figure 1. A survey of the literature revealed that an epimer of **3** with the 7*S*,8*S*-form was synthesized previously.[24]

Pharbilignan D (**4**) had the molecular formula $C_{20}H_{18}O_8$, with 12 of unsaturation, deduced by HR-ESIMS *m*/*z* 387.1087 $[M + H]^+$ (calcd for $C_{20}H_{19}O_8$, 387.1080). The ^{1}H and ^{13}C NMR spectra (Table 2) of **4** were similar to those of phellinsin A, except for the presence of an ethoxy group, which suggested that compound **4** was the same lignan-type as phellinsin A.[25] The lignan skeleton was verified by HMBC correlations of H-7/C-2, C-6, C-9, C-8′, and C-9′; H-8/C-1, C-7′, and C-9′; and H-7′/C-8, C-2′, C-6′, and C-9′ (Figure 3). The presence of an ethoxy group at C-9 in **4** was confirmed by the HMBC correlation of H-9a/C-9. The geometry of the double bond at C-7′ was established to be *E* on the basis of the chemical shift of H-7′ (δ_H 7.59) and the long-range coupling constant ($J_{7',8}$ = 2.5 Hz).[26,27] This was confirmed by the NOESY experiment where the correlations between H-8 (δ_H 4.24) and H-2′ (δ_H 7.06)/ H-6′ (δ_H 6.99) are shown. Furthermore, a *trans*-configuration of H-7 and H-8 was concluded by the relatively small coupling constant ($J_{7,8}$ = 2.5 Hz), combined with a NOESY correlation between H-8 and H-2/H-6.[26,27] The configurations of C-7 and C-8 were assigned as 7*R** and 8*R** on the basis of the optical rotation value of **4** ($[\alpha]_D^{25}$ +27.7).[27] Moreover, its CD spectrum showed Cotton effects at 231 and 263 nm ($[\theta]_{231}$ +4550, $[\theta]_{263}$ −5020). According to the above

[a]IC_{50} value of compounds against each tumor cell line. The IC_{50} value was defined as the concentration (μM) that caused 50% inhibition in cell growth in vitro. Data are expressed as the mean ± SD of three distinct experiments [b]Doxorubicin as a positive control.

analysis, the structure of **4** was elucidated as depicted in Figure 1.

It was likely that compounds **1**−**4** were artifacts of the isolation procedure because 50% EtOH was used as the solvent for extraction. In order to verify that compounds **1**−**4** are authentic natural products, another supply of the plant was obtained and extracted with MeOH and EtOAc, respectively. The resulting extracts were tested using LC-MS analyses, alone and coinjected with the pure compounds **1**−**4**. Compounds **1**−**4** were all identified on the HPLC chromatogram of the crude extracts. The increase in peak areas corresponding to **1**−**4** supported that these compounds are indeed naturally occurring metabolites.

Evaluation of Antitumor Activity. All isolated compounds (**1**−**4**) were evaluated for antitumor activity by determining their inhibitory effects on four human tumor cell lines including A549 (nonsmall cell lung carcinoma), SK-OV-3 (ovary malignant ascites), SK-MEL-2 (skin melanoma), and HCT-15 (colon adenocarcinoma) using a SRB bioassay.[28] The results (Table 3) showed that all tested lignans had consistent cytotoxicity against the SK-OV-3, SK-MEL-2, and HCT-15 cell lines but not A549, with IC_{50} values of 0.14 to 27.45 μM. In particular, compound **3** exhibited the most potent cytotoxicity against the A549, SK-OV-3, SK-MEL-2, and HCT-15 cell lines with IC_{50} values of 1.42 ± 0.38, 0.16 ± 0.03, 0.20 ± 0.11, and 0.14 ± 0.07 μM, respectively, which was slightly less active but comparable to that of the positive control, doxorubicin.

The data obtained in this biological test suggested that the dihydrobenzofuran-type lignan, the skeleton of compound **3**, could be a promising class for antitumor agents toward human tumor cell lines. A series of such synthetic dihydrobenzofuran lignans and related derivatives have been explored for their potential antitumor and antiproliferative activities.[24,29] In our previous search for bioactive compounds from Korean natural resources, 3-(β-D-glucopyranosyloxymethyl)-2-(4-hydroxy-3-methoxyphenyl)-5-(3-hydroxypropyl)-7-methoxydihydrobenzofuran, (7*S*,8*R*)-dihydrodehydrodiconiferyl alcohol, and (7*S*,8*R*)-dehydrodiconiferyl alcohol 4-*O*-β-D-glucopyranoside, belonging to the dihydrobenzofuran-type lignan, were identified as minor constituents in Korean traditional medicines.[30−32] However, none exhibited a promising cytotoxic effect in the previously used human tumor cell lines (IC_{50} > 30.0 μM). This result was in agreement with the structure−activity relationship (SAR) analysis of dihydrobenzofuran lignans for antitumor activity in human tumor cell lines, where it was reported that (i) apparently, methylation of the hydroxyl group in two aromatic moieties reduces the activity, (ii) reduction of the double bond in the C_3 side chain causes a decrease in the activity, and (iii) reduction of the ester functionality to a primary alcohol leads to loss in the activity.[29] The SAR analysis suggests that the dihydrobenzofuran-type lignan, compound **3**, which contains the ethyl ester functionality and the double bond in the side chain, but no methoxyl group, yields the greatest cytotoxicity against all tumor cell lines presently examined. However, the dihydrobenzofuran-type lignan has been reported to have a pharmacophore for inhibitors of tubulin polymerization binding at the colchicine site, which can lead to the display of antimitotic and potential antitumor properties.[29] Particularly, methyl(*E*)-3-{2-(3,4-dihydroxyphenyl)-7-hydroxy-3-methoxycarbonyl-2,3-dihydro-1-benzofuran-5yl}prop-2-enoate, which is very similar to compound **3** with the only difference being the replacement of methyl ester functionality, was recently determined to be a potential antitumor agent by causing G2/M arrest and apoptosis involving the mitochondrial controlled pathway.[33]

Progression of cancer is associated with inflammatory responses.[34] Inflammatory gene expression is often negatively correlated with cancer stage and prognosis.[35−37] Nonsteroidal anti-inflammatory drugs are effective for cancer prevention, further supporting a role for inflammation in tumor progression.[38] On the basis of the expanded understanding that an anti-inflammatory agent could be a potential antitumor molecule, we evaluated the anti-inflammatory activities of the isolates (**1**−**4**) through the measurement of nitrite, a soluble oxidation product of NO, in the culture medium using the Griess reaction in LPS-activated BV-2 microglial cells.[39] BV-2 has both the phenotypic and functional properties of reactive microglia cells and is activated following stimulation by various agents including LPS.[40,41] Activated BV-2 cells exhibit various inflammatory responses including the production of the proinflammatory factor NO.[42] Among the tested compounds, compound **3** showed significant inhibitory effects on LPS-stimulated NO production with an IC_{50} of 12.8 μM in BV-2 microglial cells at 20 μM without cytotoxicity, which actually is more potent than N^G-monomethyl-L-arginine (L-NMMA), an inducible NO synthase (iNOS) inhibitor (IC_{50} value of 17.7 μM).[39] The rest of the compounds did not show any significant inhibitory effects on NO production in the range of 1 to 20 μM. Toxicity induced by overproduction of NO, when it becomes chronic, can lead to enhanced cell replication that is a risk factor for many cancers,[43] and oxidative damage to DNA by NO has been associated with the development of cancer.[44] Compound **3** thus could be a potential antitumor agent via the inhibition of NO formation.

In conclusion, it appears that lignans **1**−**4** isolated from the most active EtOAc fraction are at least partially responsible for the antitumor effect of the crude EtOH extract of the morning glory seeds. Among them, pharbilignan C (**3**) is the most promising by virtue of the most potent cytotoxicity in various human tumor cell lines and anti-inflammatory activity involving the inhibited production of NO.

diffusion method.[25] The minimum inhibitory concentration (MIC) value of RHSE was 0.822% (v/v). The in vivo antibacterial activity of RHSE (1.0%, v/v) was also examined in a *Salmonella*-infected Balb/c mouse model. Mice infected with a sublethal dose of the pathogens were administered intraperitoneally a 1.0% solution of RHSE at four 12 h intervals during the 48 h experimental period. The results showed that RHSE antimicrobial potency approached that of the standard medical antibiotic vancomycin and that the combination of RHSE and vancomycin acted synergistically against the foodborne bacteria. The inclusion of RHSE (1.0% v/w) as part of a standard mouse diet fed for 2 weeks decreased mortality of 10 mice infected with lethal doses of *Salmonella*. Photomicrographs of histological changes in liver tissues show that RHSE also protected the liver against *Salmonella*-induced pathological necrosis lesions. These beneficial results suggest that RHSE has the potential to complement wood-derived smokes as an antimicrobial flavor formulation for use in human food and animal feeds.

Because RHSE inhibited *Salmonella* in culture and in vivo, expectations are that it might protect the mice against *Salmonella* LPS-induced murine endotoxemia (sepsis). The objective of this study was to determine whether this is the case.

MATERIALS AND METHODS

Test Compounds. *Salmonella enterica* LPS and D-galactosamine (GalN) were purchased from Sigma-Aldrich (St. Louis, MO, USA). All reagents were of analytical grade and used without further purification. The RPMI 1640 medium, Hank's Balanced Salt Solution (HBSS), fetal bovine serum (FBS), and other cell culture reagents were obtained from Hyclone Laboratories (Logan, UT, USA). The enzyme kit for glutamic-oxaloacetic transaminase/glutamic-pyruvic transaminase (GOT/GPT) was the product of Asan Pharmaceutical Co. (Seoul, Korea). The ELISA kit for the quantification of tumor necrosis factor-α (TNF-α) was obtained from Biosource USA (Camarillo, CA, USA).

Chemicals. The rice hull liquid smoke extract (RHSE) was obtained from Daewon GSI (Waegwan, Korea). The industrial production of the commercially available RHSE, characterized chemical components, and beneficial bioactivities in chemical and cell assays were described in our previous publication in this journal.[22] GC/MS analysis showed that the rice hull extract contained 161 characterized aliphatic, aromatic, and heterocyclic compounds. The aqueous extract was acidic, had a specific gravity of 1.007, and contained 0.026% solids. The in vitro antioxidative activity of the extract as determined by the DPPH assay was similar to that of the widely used food antioxidant BHT (butylated hydroxytolune).

Animals and Treatment. The protocol for the mice studies was approved by the Ethics Committee for Animal Care and Use, Ajou University, Republic of Korea. All experiments were performed in compliance with the relevant laws and institutional guidelines. Five-week-old female BALB/c mice were purchased from Orient Bio Inc. (Seoul, Korea) and were hosted under a 12 h light/dark cycle at 20−22 °C and relative humidity of 50 ± 10%. The mice were fed freely a pelletized commercial chow diet obtained from Orient Bio Inc. (catalogue no. 5L79) and sterile tap water during the entire period. After acclimation for 1 week, the mice were then divided into three groups (n = 10), avoiding any intergroup difference in body weight. The endotoxemic shock assay in a murine model was carried out following the method of Yun et al.,[26] with modification. Briefly, two groups of mice each (PBS-treated control and RHSE-treated experimental group) were fed a pelletized commercial chow diet without and with RHSE (1.0%, v/w) during the entire experimental period. After 14 consecutive days of RHSE administration, the control and experimental mice were injected with LPS and GalN (5 μg/kg and 700 mg/kg, respectively) via an intraperitoneal (ip) route. To determine the survival rate, lethal dose of LPS and GalN (20 μg/kg and 700 mg/kg, respectively) were employed. The mice were observed for 60 h after the LPS and GalN challenge. Apart from the determination of the survival rate, the other experiments were carried out 4 h after challenge of a sublethal dose of the LPS and GalN (5 μg/kg and 700 mg/kg, respectively). The mice were sacrificed by CO_2 asphyxia, and livers and kidneys from each group were excised and weighed. The blood from the three groups of mice was collected by cardiac puncture and allowed to clot at room temperature for 30 min. Subsequently, the blood was subjected to centrifugation at 2000g for 30 min. The separated serum was stored at −20 °C until use.

Histology of Liver Tissue. For histological analysis, the liver tissue of the mice was fixed with paraformaldehyde (4%) in phosphate buffer (0.5 M; pH 7.4). The tissue was rinsed with water, dehydrated with ethanol, and embedded in paraffin. The tissues were sectioned into samples (4 μm) and mounted onto glass slides. The sections were then dewaxed using xylene and ethanol and stained with hematoxylin and eosin Y (H&E) to reveal the hemorrhagic necrosis in the liver. Histological changes were observed under a light microscope at ×100 magnification.

Serum Nitrite and Nitrate Levels. Serum nitrite and nitrate levels were measured primarily following the method of Misko et al.,[27] with some modification. Briefly, serum was filtered through an Ultrafree-MC microcentrifuge filter unit (Millipore, Bedford, MA, USA) for 1 h at 14000 rpm to remove the hemoglobin released by cell lysis. The serum (50 μL) was incubated in a reaction mixture [40 mM Tris Cl, 40 μM reduced β-nicotinamide adenine dinucleotide phosphate, 40 μM flavin adenine dinucleotide, and nitrate reductase 0.05 U/mL at pH 7.9] at 37 °C for 15 min. Reduced samples were incubated with an equal volume of Griess reagent [1% sulfanilamide and 0.1% *N*-(1-naphthyl)ethylenediamine dihydrochloride in 5% phosphoric acid] at room temperature for 15 min. The absorbance at 570 nm was recorded using a microplate reader (model 550, Bio-Rad). The total nitrate/nitrite concentration was determined by comparison with a reduced sodium nitrate standard curve.

TNF-α and Serum Transaminase. TNF-α level was determined using an enzyme-linked immunosorbent assay (ELISA) kit specific for murine TNF-α according to the manufacturer's instruction. After the termination of all reactions, the absorbance of the chromophore at 420 nm was measured using a microplate reader. The activities of serum enzymes glutamic-oxaloacetic transaminase (GOT) and glutamine-pyruvic transaminase (GPT) were estimated using a commercial colorimetric kit. Briefly, appropriately diluted serum (200 μL) was added to the reaction solution (0.1 mL; L-asparaginic acid and α-ketoglutaric acid mixture). The resultant mixture was incubated at 37 °C for 30 min (GPT) or 60 min (GOT), and 2,4-dinitrophenylhydrazine (1 mL) was added. After incubation at room temperature for 20 min, 0.4 N sodium hydroxide (10 mL) was added, and the absorbance of the solution was measured at 505 nm using a microplate reader.

Antioxidant Enzyme Activities in Mouse Liver. The liver tissue was homogenized in 10 volumes of phosphate-buffered saline (PBS) on ice for 30 s using a power-driven Polytron homogenizer (Pro Scientific, Monroe, CT, USA). The homogenate was centrifuged at 9000g at 4 °C for 20 min. The supernatant was recovered and used to measure two antioxidant enzyme activities, catalase and superoxide dismutase. For the catalase activity assay at time zero, each supernatant (1.8 mL) was mixed with PBS (0.2 mL) containing hydrogen peroxide (10 mM). The reaction mixture (1 mL) was immediately added to a cuvette and placed into a UV−vis spectrophotometer (model V-550, Jasco, Tokyo, Japan). The enzyme activity was observed via degradation of hydrogen peroxide as determined by a decrease in UV light absorbance at 240 nm over time. The measurement of absorbance was taken at 15 s intervals after the addition of the homogenate to the hydrogen peroxide buffer. Units of catalase activity per milligram of protein were calculated following the method of Nandi et al.[28] For the superoxide dismutase (SOD)-like activity assay, the supernatant (100 μL) was mixed with a homogenizing buffer (1.5 mL; 50 mM Tris, 10 mM EDTA, pH 8.5), then pyrogallol (100 μL; 7.2 mM) was added, and the reaction mixture was incubated at 25 °C for 10 min. The reaction was terminated by adding 1 M HCl (50 μL), and the absorbance was then measured at 420 nm. One unit was

defined as the amount of enzyme that inhibited the oxidation of pyrogallol by 50%. The activity was expressed as units per milligram of protein.[29]

Myeloperoxidase (MPO) Activity. MPO activity was assayed according to the method of Bralley et al.[30] Briefly, the supernatants recovered from lung and kidney tissue homogenates (30 μL) were added to the reaction mixture (200 μL) consisting of 100 μL of PBS (80 mM phosphate, 140 mM NaCl, pH 5.4), 85 μL of PBS2 (220 mM phosphate, 140 mM NaCl, pH 5.4), and 0.017% H_2O_2 (15 μL). The reaction was started by adding tetramethylbenzidine (18.4 μM) in aqueous dimethylformamide (8%; 20 μL) and was left standing for 3 min at 37 °C. The reaction was stopped by the addition of sodium acetate buffer (30 μL; 1.46 M; pH 3.0). The absorbance (OD) of the supernatant was then read in a microplate reader at 655 nm for 30 min. The reaction rate (change in OD/time) was derived from an initial slope of the curve. A calculation curve was used to show the rate of reaction plotted against the concentration of a standard human MPO preparation.

Serum Urea Nitrogen and Creatinine. The concentration of urea nitrogen and creatinine were determined using the commercial QuantiChrom creatinine assay kit and QuantiChrom urea assay kit, respectively (Bioassay System, Hayward, CA, USA).

Statistical Analysis. Results are expressed as the mean ± SD of three independent experiments. Significant differences between means were determined by ANOVA test using the Statistical Analysis Software package SAS (Cary, NC, USA). $P < 0.05$ is regarded as significant.

RESULTS AND DISCUSSION

Dose Selection. The reason why we did not assess the dose-related mortality in mice is because (a) in previous studies, we found that 1% to be the optimal dose for expressing maximum levels of anti-inflammatory activities, including inhibition of NO production and release of anti-inflammatory cytokines and protection of cell viabilities without any side effects both in vitro and in mice; and (b) we also used 1% of the rice hull extract to protect *Salmonella*-infected mice against mortality. The present complementary study shows that the 1% concentrations also protected the mice against endotoxemia.

Effects of RHSE on Weights and Histopathology of Mouse Liver. Figure 1 shows that the induction of endotoxemia by LPS/GalN resulted in a significant increase in liver weight as well as in the formation of hemorrhagic lesions in the liver tissues. By contrast, no apparent hepatic injury was observed in the vehicle-treated control group. As anticipated, RHSE treatment through dietary administration (1%, v/w) markedly blocked the hemorrhagic liver injury as well as hepatomegaly induced by a lethal dose of the LPS/GalN challenge. These results demonstrate strongly that RHSE protected the mice against injury of a major organ associated with endotoxemia.

Effects of RHSE on Antioxidant Enzyme Activities in Mouse Liver. To find out whether reactive oxygen species (ROS) level is a crucial factor for the incidence of liver injury associated with LPS/GalN-induced endotoxemia, the activity of hepatic antioxidant enzymes including catalase and SOD-like enzymes was evaluated in the control and experimental mice groups.

Table 1 shows that in the liver of LPS/GalN-treated mice, the dietary administration of RHSE induced a significant suppression of the catalase and SOD-like enzyme activities from 24.53 to 7.18 U/mg protein (~71% change) and from 18.65 to 8.49 U/mg protein (54% change), respectively. These results show that dietary administration of RHSE reduced oxidative damage in the liver induced by the LPS/GalN challenge.

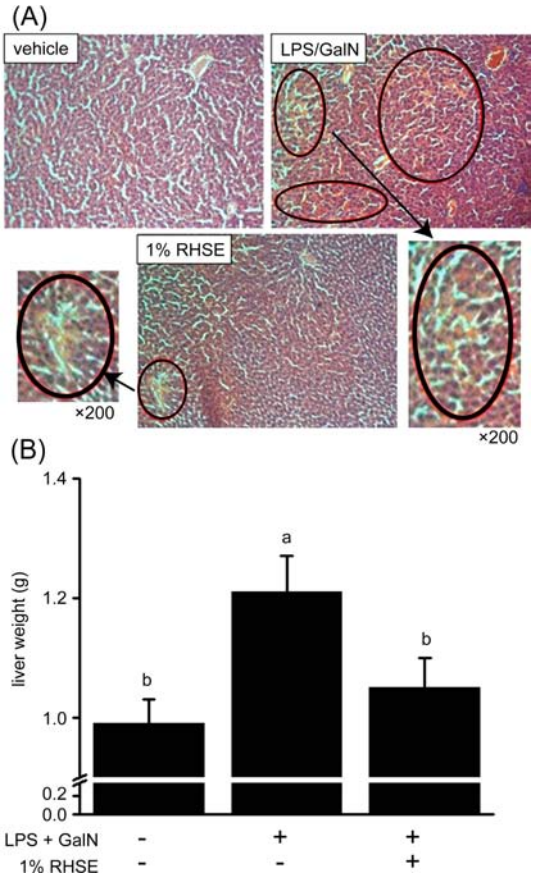

Figure 1. Modulation of liver injury in LPS/GalN-induced endotoxemic mice by administration of diet supplemented with RHSE (1.0%, v/w). (A) Liver sections from LPS/GalN (5 μg/kg/700 mg/kg)-administered mice show disorganized hepatic architecture, intense cellular necrosis, and marked hemorrhagic lesions compared with the liver section of vehicle-treated mice. Dietary administration of RHSE markedly ameliorated LPS/GalN-induced liver damage. (B) Increase in liver weight by LPS/GalN injection was reversed by dietary administration of RHSE. Mice were sacrificed 4 h after LPS/GalN treatment, and the livers were weighed. Each liver specimen was fixed with 4% paraformaldehyde, and sections were stained with hematoxylin and eosin (H&E). Magnification, ×100 for each of the three treatments, and ×200 for the magnified sections. Circular areas indicate local hemorrhage and necrosis regions. Bars not sharing a common letter are significantly different between groups at $p < 0.05$.

Table 1. Effects of RHSE on Antioxidant Catalase and Superoxide Dismutase (SOD)-Like Enzyme Activities in LPS/GalN-Induced Endotoxemic Mouse Liver[a]

sample	catalase activity (U/mg protein)	SOD-like activity (U/mg protein)
vehicle	3.12 ± 0.28 a	4.77 ± 0.32 a
LPS/GalN (5 μg/kg/700 mg/kg)	24.5 ± 2.0 b	18.7 ± 1.5 b
RHSE (1.0%, v/w) dietary administration	7.18 ± 0.43 c	8.49 ± 0.69 c

[a]Data are expressed as the mean ± SD ($n = 10$). Values in each column with the same letter are not significantly different between groups at $p < 0.05$.

Effects of RHSE on Liver Transaminase Enzyme Activities in Mouse Serum. Figure 2 shows that, compared

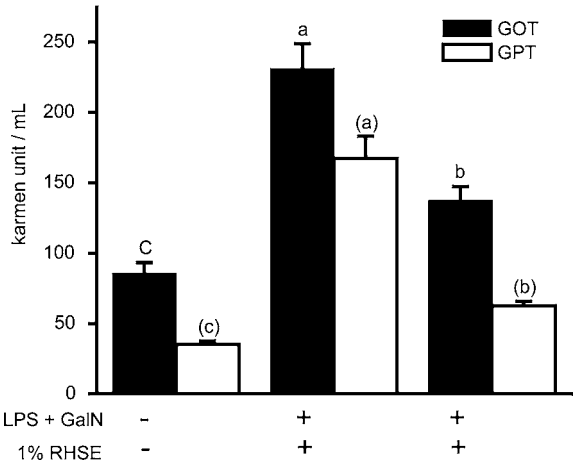

Figure 2. Effect of dietary administration of RHSE (1.0%, v/w) on glutamic-oxaloacetic/glutamic-pyruvic transaminases (GOP/GTP) in LPS/GalN-induced endotoxemic mice. The mice were pretreated with RHSE for 2 weeks through dietary administration before the LPS/GalN treatment. Mice were sacrificed 4 h after LPS/GalN (5 μg/kg/700 mg/kg) treatment, and blood was collected to produce serum. Bars not sharing a common letter are significantly different between groups at $p < 0.05$.

with the normal control group, the liver enzyme levels of the transaminase GOT and GPT, primary enzymes that serve as an index of hepatic injury, increased significantly in the serum of the LPS/GalN-treated mice. In the mice fed an RHSE-supplemented diet (1.0% v/w), GOT and GPT activities decreased substantially from 231.7 to 137.3 U/mL (~41% change) and from 167.3 to 62.8 U/mL (~63% change), respectively. These results show that RHSE protected the liver against necrotic injury associated with endotoxemia.

Effects of RHSE on TNF-α and Nitrite Concentrations in Mouse Serum. Table 2 shows that TNF-α and nitrite/nitrate levels in the serum of LPS/GalN-induced endotoxemic mice were markedly increased compared with those observed in the normal control mice group (~7.8- and 20.2-fold increases, respectively). The dietary administration of RHSE significantly decreased the TNF-α and nitrite/nitrate concentrations from 401.6 to 156.2 pg/mL (~61% change) and from 19.3 to 3.2 μM (~83% change), respectively. These results show that RHSE protected the treated mice against increased production of nitrite/nitrate, a source of bioactive nitric oxide (NO), and TNF-α, a critical factor associated with the cause of the endotoxemia syndrome.

Table 2. Effects of RHSE on Tumor Necrosis Factor-α (TNF-α) and Nitrite Concentrations in Mouse Serum[a]

sample	TNF-α (pg/mL)	nitrite (μM)
vehicle	51.3 ± 3.9 a	0.951 ± 0.021 a
LPS/GalN (5 μg/kg/700 mg/kg)	401 ± 26 b	19.3 ± 1.1 b
RHSE (1.0%, v/w) dietary administration	156 ± 14 c	3.205 ± 0.053 c

[a]Data are expressed as the mean ± SD (n = 10). Values in each column with the same letter are not significantly different between groups at $p < 0.05$.

Effects of RHSE on Lung and Kidney Injuries in Endotoxemic Mouse. The evidence of necrotic cell injuries in the lung and kidney in LPS/GalN challenged endotoxemia was further confirmed by the observed decreases in the MPO enzyme activity induced by RHSE (Table 3). The results in Table 3 show that RHSE treatment via the oral route markedly decreased the MPO activities from 12.6 to 4.3 U/g protein (~66% change) in the lung and from 6.8 to 2.5 U/g protein (~63% change) in the kidney, respectively.

The protective effect of RHSE treatment against LPS/GalN-induced renal injury was also evaluated by measuring creatinine and urea nitrogen concentrations in the serum. Table 3 also shows that creatinine and urea nitrogen levels in the serum of endotoxemic mice were significantly greater than those in normal mice group (~1.7- and ~4-fold increases, respectively), indicating the association of endotoxemia with the release of these amino acid metabolites from the damaged kidney. By contrast, RHSE administration via the oral route significantly lowered LPS/GalN-triggered increases in creatinine and urea nitrogen levels by up to 35.6% and 62.0%, respectively. The present study shows that RHSE neutralized the toxic effect of the LPS-induced endotoxin by reducing the expression of the cytokine TNF-α and production of ROS.

Effects of RHSE on Mortality of Endotoxemic Mice. To determine the therapeutic effects of RHSE on life expectancy, a lethal dose of LPS/GalN was used to induce sepsis and to determine the protection by RHSE against mortality. Each group of 10 mice was fed on a diet supplemented with RHSE (1%, v/w) during the entire experimental period. Figure 3 shows that mice treated with a lethal dose of LPS/GalN all died after 50 h. By contrast, the group treated with RHSE through dietary administration survived >60 h. These observations demonstrate strikingly the potential of RHSE to protect mice against sepsis-induced lethality, presumably via down-regulating the production of the pro-inflammatory cytotoxic factors such as reactive oxygen radicals, cytokines, and nitric oxide.

Mechanistic Aspects. We previously reported[22−25] that the extract elicited changes in the expression of seven genes and two biomarkers [(prostaglandin E2 (PGE2) and leukotriene-4 (LTB4)] associated with inflammation. The extract also inhibited generation of NO through inhibition of inducible nitric oxide synthase (iNOS) gene expression and suppressed

Table 3. Effects of RHSE on Lung and Kidney Injuries in LPS/GalN-Induced Endotoxemic Mice Assessed by Changes in Myeloperoxidase, Creatinine, and Blood Urea Nitrogen (BUN) Concentrations[a]

sample	myeloperoxidase (U/g protein)		BUN (mg/dL)	creatinine (mg/dL)
	lung	kidney		
vehicle	2.922 ± 0.093 a	1.86 ± 0.11 a	0.334 ± 0.018 a	14.2 ± 1.1 a
LPS/GalN (5 μg/kg/700 mg/kg)	12.59 ± 0.89 b	6.83 ± 0.23 b	0.582 ± 0.033 b	56.9 ± 4.4 b
RHSE (1.0%, v/w) dietary administration	4.32 ± 0.12 c	2.51 ± 0.18 c	0.375 ± 0.021 c	21.6 ± 1.5 c

[a]Data are expressed as the mean ± SD (n = 10). Values in each column with the same letter are not significantly different between groups at $p < 0.05$.

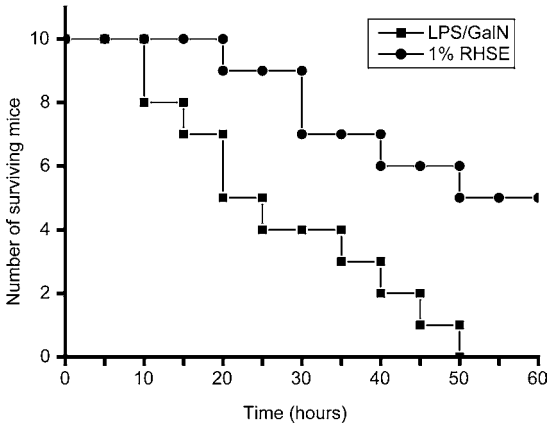

Figure 3. Histogram showing the effect of dietary administration of RHSE (1.0%, v/w) on LPS/GalN-induced endotoxemia induced lethality. BALB/c mice were fed RHSE-supplemented diet for 2 weeks and then challenged ip with a lethal dose of LPS/GalN (20 μg and 700 mg per kg body weight). RHSE was then again administered through the same route during the entire experimental period. Plotted values are mean values of triplicate determinations.

the inflammatory reaction through inhibition of pro-inflammatory gene expressions, including tumor necrosis factor-α (TNF-α), interleukin-1β (IL-1β), and interleukin-6 (IL-6) and increased the production of interferon-γ (IFN-γ) produced by the spleen, suggesting that it stimulated the immune system.

In the present study, we report that the extract suppressed the production of TNF-α, confirming its anti-inflammatory properties as well as the antioxidative enzymes catalase and superoxide dismutase, suggesting that the beneficial effects might also be associated with inhibition of cell-damaging reactive oxygen species (ROS).

On the basis of the mentioned biomarkers, it seems that the antiendotoxemia mechanism might involve suppression of production of NO, cytokines TNF-α, IL-β, and IL-6, and the eicasinoids PGE2 and LTB4, and the inhibition of ROS, thus blocking the observed organ injuries caused by endotoxin-induced acute inflammation.

Related Studies. There have been other recent reports of natural compounds that have antiendotoxemia properties and they are described briefly here, in context of the present study.

We found that a polysaccharide isolated from the liquid culture of *Lentinus edodes* (Shiitake) mushroom mycelia containing black rice bran did not inhibit the growth of *Salmonella* in vitro but did protect mice against LPS-GalN-induced liver, lung, and kidney injuries and inflammation and enhanced the survival of the toxic shock-induced mice by blocking oxidative stress and TNF-α production, suggesting that the novel polysaccharide has the potential to serve as a new functional food.[31]

Other researchers recently reported that flucoidan, a sulfated polysaccharide from the brown alga *Fucus evanescens*, increased resistance to LPS, increased the survival time, and prevented endotoxin-induced damage in mice through the inhibition of pro-inflammatory cytokines (TNF-α and IL-6), attenuation of microcirculatory disorders, and regulation of the immune system.[32]

The administration of the plant phenolic antioxidant chlorogenic acid is reported to prevent mortality of mice induced by endotoxemia and polymicrobial sepsis through modulation of cytokine and chemokine release, suppression of immune cell apoptosis, and enhanced bacterial elimination without apparent adverse effects, suggesting the need for the evaluation of this and other plant antioxidants as potential therapeutic agents.[10] Similar promising results have been reported with the phenolic antimicrobial carvacrol, a natural compound present in oregano oil, which is used as a salad dressing.[33]

It has also been shown that the antimicrobial and anti-inflammatory natural phenolic compound 3,4,5-trihydroxybenzoic acid protected mice against LPS-induced endotoxemia and associated symptoms and biomarkers.[34]

Interestingly, cocoa (*Theobroma cacao*), a polyphenol-rich food added to a high-fat diet reduced metabolic endotoxemia and adipose tissue inflammation in mice by modulating eicosanoid metabolism.[35]

Another murine study showed that a bactericidal peptide derived from zebra fish phosvitin inhibited LPS-induced tumor necrosis factor (TNF-α) and interleukin (IL-1β) in mice and increased the survival of endotoxemic mice and thus has the potential for the clinical treatment of LPS-induced sepsis.[36]

The antioxidant ascorbic acid (vitamin C) inhibited alcohol-induced endotoxemia in guinea pigs, suggesting that the vitamin has the potential to decrease endotoxemia symptoms by reducing small intestinal bacterial overgrowth (SIBO) and the activation of NF-kB and the synthesis of cytokines.[37]

Acute and chronic consumption of red wine, a rich source of antioxidant and antimicrobial flavonoids,[38] by middle-aged men increased the *Bifidobacterium* and *Prevotella* gut microbiota that correlated negatively with LPS concentration.[39] A similar beneficial effect was observed with the wine polyphenolic compounds resveratrol[40] and quercetin.[41]

Gossypol, an anti-inflammatory compound present in cotton seeds, seems to be a promising therapeutic agent for the treatment of lung injury, owing to its ability to protect mice against LPS-induced acute lung injury and to inhibit the NF-kB and MAPKs signaling pathways.[42]

The antiendotoxemia efficacy of plant phenolic antioxidants mentioned above at the cellular level might be due to their ability to counteract the adverse effects associated with the reduction in the LPS-induced murine hepatic level of the glutathione (GSH) antioxidant that protect liver tissues against injury.[43] It needs to be emphasized, however, that other properties of some proposed antiendotoxemia compounds such as those of gossypol, which is reported to inhibit male spermatogenesis,[44] might reduce their potential value in endotoxemia therapy. Other nonfood related proposed compounds and plant extracts also need to be evaluated for possible toxicity. These considerations suggest that food-related compounds that are considered generally accepted as safe (GRAS) might have advantages over others that need to be evaluated further for possible safety.

In summary, the results of the present and cited studies show that, because the commercially available rice hull liquid smoke extract exhibits antiallergic, antidiabetic, antiendotoxemia, and antimicrobial properties, it has the potential to serve as an antimicrobial food preservative and might contribute to the prevention and therapy of several chronic diseases. Because the chemical nature of the large number of individual compounds in the rice hull smoke extract varied widely, we do not know which individual compound or combination of compounds might be responsible for the observed bioactivity. Future studies should determine the bioactivities of individual compounds isolated from the liquid rice hull extract and the

possible synergism of combinations of the extract, compounds isolated from the extract, and other bioactive food compounds and extracts that have been shown to exhibit beneficial in vivo effects. Such dietary combinations, in which the individual components might exert their effect by different mechanisms, might act as multifunctional foods with therapeutic potential and might make it possible to use lower amounts of each component. It is also necessary to demonstrate that the liquid rice hull smoke is safe. Our in vitro, ex vivo, and in vivo previous and present studies are designed to contribute to this assessment.

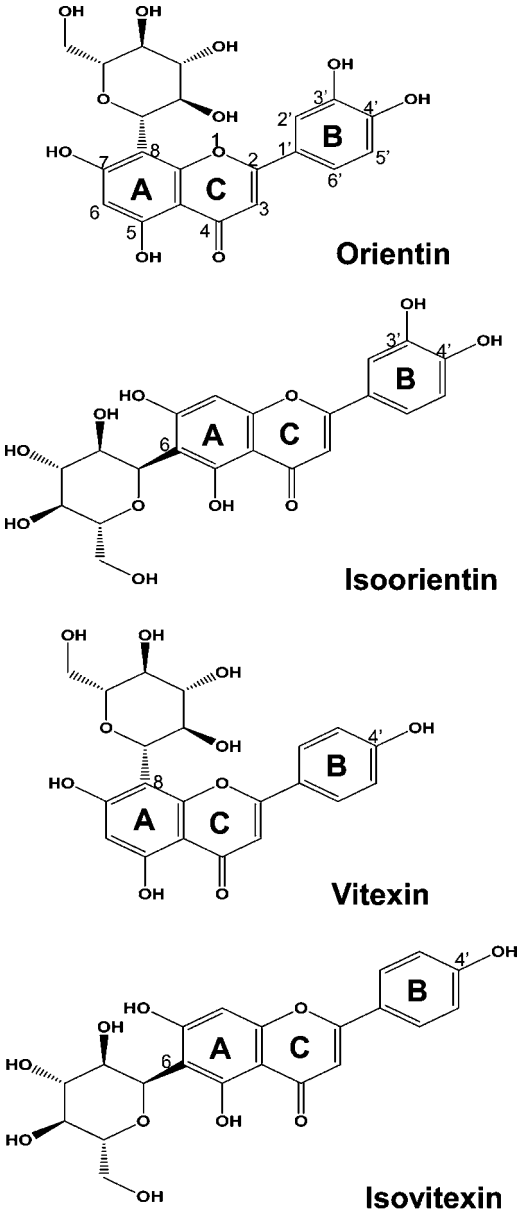
MATERIALS AND METHODS

Chemicals. Porcine pancreas α-amylase, amylose, amylopectin, and acarbose were purchased from Sigma-Aldrich Co., Ltd. (St. Louis, MO). α-(2-Chloro-4-nitrophenyl)-β-1,4-galactopyranosylmaltoside (Gal-G2-α-CNP) was purchased from Toyobo Co., Ltd. (Osaka, Japan). Vitexin, isovitexin, orientin, and isoorientin were purchased from Shifeng Biological Technology Co., Ltd. (Shanghai, China), and their structures are shown in Figure 1. Soluble starch was purchased



32

Figure 1. Structures of four *P. edulis* leaf flavonoids. The parent nucleus of flavonoid is composed of A, B, and C rings.

from Sinopharm Chemical Reagent Co., Ltd. (Shanghai, China). 2-Chloro-4-nitrophenol (CNP) was purchased from Energy Chemical (Shanghai, China). Acetonitrile (HPLC-grade) was provided by Tedia Co. Inc. (Fairfield, OH).

Preparation of the Main Solutions. Iodine solution:[26,31] 1.5 g of potassium iodide was dissolved to 25 mL of distilled water, and then 0.635 g of iodine was added. Finally, the solution was adjusted to 50 mL by distilled water. Starch suspension:[26,31] 10 mg of soluble starch was suspended in 1 mL of boiling water and water bathed at 90 °C for 30 min to make the starch swell. Then 7.5 mL of 50 mM KCl−HCl (pH 2.0) buffer was added followed 30 min later by 7.5 mL of 100 mM sodium phosphate buffer (pH 7.1) (the final pH was 6.8). They were used to simulate the pH of the stomach and duodenum. Last, the suspension was homogenized by a glass homogenizer. The preparation of amylose and amylopectin suspensions was the same as that of soluble starch suspensions.

Sample Preparation. *P. edulis* leaves were collected in Anji County (the bamboo hometown of China) during the winter and identified by Pei-xin Zhang of the Anji Forestry Bureau. The pregrounded *P. edulis* leaves were extracted with 50% ethanol (1:10, w/v) with a 1 h sonic treatment (DT series, Xingzhi Co., Ltd., Ningbo, China) and intermittent stirring. The extract was concentrated to 1/10 of the original volume by a rotary evaporator (RE-52A, Shanghai Jingke Co. Ltd., Shanghai, China). Then it was stored in a 4 °C refrigerator for 12 h to flocculate and filter some macromolecular compounds. After that, the solution was sequentially fractioned by petroleum ether, EtOAc, and 1-butanol. All these extracts were dried to obtain the petroleum ether fraction, EtOAc fraction, 1-butanol fraction, and residual fraction. The 1-butanol fraction was subjected to an AB-8 macroporous adsorption resin (polystyrene resin, weak polarity, 0.3−1.25 mm particle size) for further purification. The purification was carried out in a glass column (1.4 cm × 40 cm) wet-packed with washed AB-8 resin. The sample was dissolved in water. After all the sample was loaded, the column was first washed by 6 BV (bed volumes) of water to remove the impurities which could not adsorb tightly. Then the column was desorbed by 2 BV of 40% ethanol (v/v) solution at a speed of 2 BV/h.

Determination and Quantification of the Main Bioactive Components. The Shimadzu HPLC system (Shimadzu Corp., Tokyo, Japan) equipped with an Agilent Eclipse Plus C18 column (250 mm × 4.6 mm, particle size of 5 mm, Agilent Technologies Inc., Santa Clara, CA) was used. The mobile phase was phosphoric acid−water (0.3:99.7, v/v; A) and acetonitrile (B). The gradient elution condition was 15−25% B in 0−35 min. The flow rate was set as 1.0 mL/min. The signal was monitored at 330 nm. A Thermo LCQ-Deca HPLC-MS (Thermo Fisher Scientific Inc., San Jose, CA) fitting with an ESI (electrospray ionization) interface and negative ion mode was also used for determining the main bioactive components. For quantitative analysis, the calibration curves of orientin, isoorientin, vitexin, and isovitexin were obtained at a concentration of 6.25−200 μg/mL (n = 6).

Measurement and Kinetics Assay of α-Amylase Inhibitory Activity. The measurement of α-amylase inhibitory activity was carried out by using the method described previously.[32,33] Briefly, 20 μL of *P. edulis* flavonoids at different concentrations (final concentrations were 9, 18, 36, and 72 μg/mL) were mixed with 10 μL of 200 μg/mL α-amylase and 70 μL sodium phosphate buffer (pH 6.8). After intensive shaking for mixing, 100 μL of 5 mM Gal-G2-α-CNP solution was added to start the reaction. After 10 min of incubation at 37 °C, the absorbance of released CNP was monitored at 405 nm by a Bio-Tek Power Wave XS2 microwell plate reader (Bio-Tek Instruments, Winooski, VT). To further explore their inhibitory character, we performed kinetic analysis by using Lineweaver−Burk plots. The K_i value of competitive inhibition was obtained from the least-squares regression line of the slopes of Lineweaver−Burk plots versus the corresponding [I]. The derivation formulas are

$$V = \frac{V_{max}[S]}{K_m\left(1 + \frac{[I]}{K_i}\right) + [S]} \quad \text{and}$$

$$\frac{1}{V} = \frac{K_m}{V_{max}}\left(1 + \frac{[I]}{K_i}\right)\frac{1}{[S]} + \frac{1}{V_{max}} \tag{1}$$

$$\text{slope} = \frac{K_m}{V_{max}}\left(1 + \frac{[I]}{K_i}\right) \quad \text{and} \quad \text{slope} = \frac{K_m}{V_{max}K_i}[I] + \frac{K_m}{V_{max}} \tag{2}$$

$-K_i$ = intercept of eq 2 on x axis

Thermal Stability. First, the standard solutions of the four flavonoids were mixed. Second, we placed a certain volume of the mixed standard into a tube. The tube was sealed by plastic tape and heated at 100 °C for 2 h. Last, we detected the samples without and with heat treatment by HPLC and calculated the concentration alteration of our four flavonoids according to their peak areas.

Molecular Modeling. The three-dimensional structures of orientin, isoorientin, vitexin, and isovitexin were downloaded from the National Centre for Biotechnology Information PubChem compound database (http://pubchem.ncbi.nlm.nih.gov/). The three-dimensional structure of substrate Gal-G2-α-CNP was constructed by using ChemBio3D Ultra 12.0 software (Cambridge Soft Corp., Cambridge, U.K.). The crystal structure of the pig pancreatic α-amylase protein complex (PDB code 1WO2) was retrieved from the RCSB Protein Data Bank (http://www.rcsb.org). Then docking was carried out by using the Autodock v4.2 program (Scripps Research Institute, La Jolla, CA). The Lamarckian Genetic Algorithm was used to run the docking. First, we did a blind docking in which the grid box covers the whole receptor protein. Then a smaller grid box that mainly covers the site of the best cluster of blind docking was set for doing an accurate docking. After docking, cluster analysis based on the root-mean-square deviation (RMSD) value was performed. The tolerance of RMSD was set as 2.0. The lowest energy conformation of the most populated cluster was considered as the most reliable solution. The interaction analysis was carried out by using Pymol 0.99 (DeLano Scientific LLC, San Carlos, CA), YasaraView v13.9.8 (YASARA Biosciences, Vienna, Austria), and Ligplus v1.4.5 (EMBL-EBI, Cambridge, U.K.).

Interaction between Flavonoids and Starch and Their Influence on Starch Digestion. The interaction between *P. edulis* flavonoids and starch was studied by using the spectroscopic method described previously.[26,31] Briefly, 25 μL of flavonoid was added to 0.9 mL of soluble starch suspension (the final concentrations of flavonoid were 9, 18, and 36 μg/mL). After vortexing, 0.1 mL of iodine solution was added to the suspension. Then the absorption spectrum of the starch−iodine complex was measured from 500 to 900 nm by using a UV-1800 spectrophotometer (Shimadzu, Tokoyo, Japan). The absorption spectra of the amylose−iodine complex and the amylopectin−iodine complex were obtained in the same way as that of the soluble starch−iodine complex. The digestion of starch was also studied by using the spectroscopic method.[26,31] Briefly, 25 μL of flavonoid was added to 0.9 mL of starch suspension (the final concentrations of flavonoid were 9, 18, and 36 μg/mL), and then 10 μL of 0.5 mg/mL α-amylase was added to the suspension. After the suspension was incubated for 5 min at 37 °C, 0.1 mL of iodine solution was added to terminate the digestion and color the residual starch. The degree of digestion was estimated by the difference spectrum (ΔA) of the starch−iodine complex after and before digestion.

X-ray Diffraction (XRD). The sample preparation and detection parameters were the same as those described in previous reports.[29,34] Soluble starch and resin-purified extract (10:1, w/w) were mixed first, and then deionized water was added (10:1, v/w, based on starch). The mixture was water bathed at 90 °C with vigorous stirring for 60 min. Then it was stored at 4 °C for 3 days (at room temperature more than 10 days is needed to achieve the same degree of retrogradation) and freeze-dried last. A D/MAX 2550 rotating anode X-ray powder diffractometer (Rigaku, Tokoyo, Japan) equipped with a copper tube at 40 kV and 100 mA with Cu Kα radiation (λ = 0.154 nm) was used for crystalline analysis. The diffractograms were detected in the angle range from 5° to 50° (2θ) with a step size of 0.02°. The MDI Jade 5.0 software (Materials Data Inc., Livermore, CA) was used to analyze the diffractograms. The relative crystallinity was calculated by using the following equation: relative crystallinity (%) = $100A_c/(A_c + A_a)$, where A_c is the area of the crystal peak and A_a is the area of the amorphous peak.

Scanning Electron Microscopy (SEM). The sample was fixed on a silver specimen holder using double-sided adhesive and sputtered with gold in a vacuum evaporator to make the sample conductive. Then the sample was investigated with an S-3400N scanning electron microscope (Hitachi, Tokoyo, Japan) with a 15 kV accelerating voltage.

Statistical Analysis. All experiments were repeated three times. Statistical analysis was carried out by using one-way analysis of variance in SPSS 18.0 (SPSS, Chicago, IL); $p < 0.05$ was considered to be statistically significant.

RESULTS AND DISCUSSION

α-Amylase Inhibition Ability and Yield of *P. edulis* Leaf Extract Fractions. The α-amylase inhibition ability and the yield of several *P. edulis* leaf extract fractions are listed in Table 1. The EtOAc fraction and 1-butanol fraction exhibited stronger α-amylase inhibitory activity than the other fractions,

Table 1. α-Amylase Inhibition Ability and Yield of Each Fraction

extract	IC_{50} (μg/mL)	yield (%)
ethanol extract	591.8	6.96 ± 0.33
petroleum ether fraction	>800	0.97 ± 0.04
EtOAc fraction	318.1	0.33 ± 0.04
1-butanol fraction	354.1	0.93 ± 0.06
residual fraction	>800	4.36 ± 0.32
resin-purified extract	206.7	0.63 ± 0.03

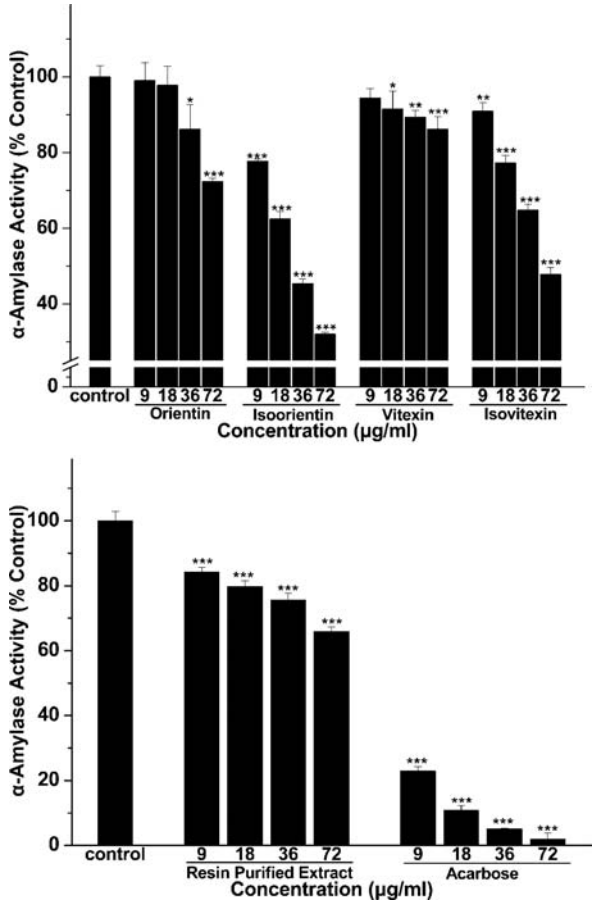


Figure 2. α-Amylase inhibitory activity of *P. edulis* leaf flavonoids, resin-purified extract, and acarbose. Values are normalized to controls (100%) and expressed as the mean ± SD of three experiments. One asterisk means $p < 0.05$, two asterisks mean $p < 0.01$, and three asterisks mean $p < 0.001$ compared to the control group.

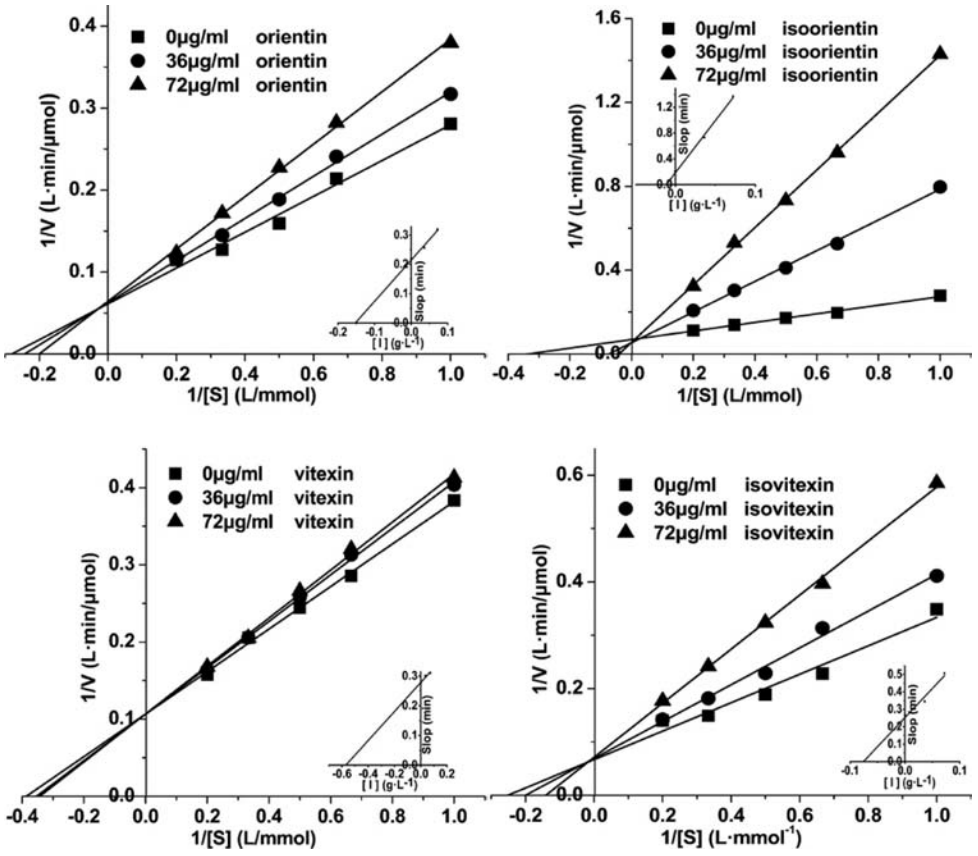

Figure 3. Lineweaver−Burk plots of *P. edulis* leaf flavonoids. The concentrations of *P. edulis* leaf flavonoids were respectively 0, 36, and 72 μg/mL. The concentrations of Gal-G2-CNP were respectively 1, 1.5, 2, 3, and 5 mM. The insets ([I] versus the corresponding slope of Lineweaver−Burk plots) were used to calculate the K_i value.

Table 2. Inhibitory Type, K_i, and IC_{50} of *P. edulis* Leaf Flavonoids and Resin-Purified Extract against α-Amylase

ligand	inhibitory type	K_i (μg/mL)	IC_{50} (μg/mL)
orientin	competitive	152.6	>270
isoorientin	competitive	11.5	29.9
vitexin	competitive	569.6	>270
isovitexin	competitive	75.8	65.3
resin-purified extract			206.7

but the yield of the EtOAc fraction is just one-third of the yield of the 1-butanol fraction and the EtOAc fraction is barely soluble in water. When loading the resin column, the materials must be dissolved in water, so the 1-butanol fraction is more suitable than the EtOAc fraction to be subjected to the AB-8 macroporous adsorption resin column for further purification. The obtained resin-purified extract exhibited the strongest α-amylase inhibitory activity.

Determination and Quantitation of the Main Bioactive Components. From the HPLC spectrum of the resin-purified extract (Supporting Information), we found two peaks were significantly higher than the other peaks. The two peaks might be the main α-amylase inhibitory components of the resin-purified extract. From the ultraviolet spectra (Supporting Information) of the two peaks, we found their maximum absorbances were near 270 and 340 nm, which suggested that these compounds might be flavonoids. According to the published data[12,17] and by further comparing the retention times, ultraviolet spectra, and m/z values with those of our standards, peaks 7, 8, 9, and 10 were identified as isoorientin ($[M - H]^-$, m/z 447.0), orientin ($[M - H]^-$, m/z 447.0), vitexin ($[M - H]^-$, m/z 431.1), and isovitexin ($[M - H]^-$, m/z 431.0), respectively (Supporting Information). Using the calibration curve, the concentrations of orientin, isoorientin, vitexin, and isovitexin were respectively 12.64, 87.15, 4.82, and 9.33 mg/g in the resin-purified extract. We were going to further affirm their α-amylase inhibitory activity. However, there might be other compounds with potent α-amylase inhibitory activity in the ethyl acetate fraction. We will try to purify them by silica gel column chromatography and Sephadex LH-20 column chromatography in the future.

α-Amylase Inhibitory Activities of the Four Flavonoids and Their Structure−Activity Relationships. As shown in Figure 2, all four flavonoids can dose-dependently inhibit α-amylase, and the inhibitory effect of isoorientin and isovitexin is stronger than the inhibitory effect of many other phytochemicals such as hesperidin, naringin, neohesperidin, nobiletin,[28] andrographolide,[35] cyanidin, cyanidin 3-glucoside,[36] myricetin, quercetin, luteolin, kaempferol, and baicalein[19] (the comparison of their IC_{50} values is given in the Supporting Information). However, their inhibitory effect is weaker than that of the positive drug acarbose.

All the four flavonoids are flavone *C*-glycosides. Unlike flavone *O*-glycosides, flavone *C*-glycosides will not be hydrolyzed to their aglycon by β-glucosidase in the small intestine.[37] Therefore, the four flavonoids can contact α-amylase which is located in the intestine. According to the two HPLC spectra without and with heat treatment (Supporting Information), the concentration alterations of isoorientin, orientin, vitexin, and

dx.doi.org/10.1021/jf501931m | J. Agric. Food Chem. 2014, 62, 7760−7770

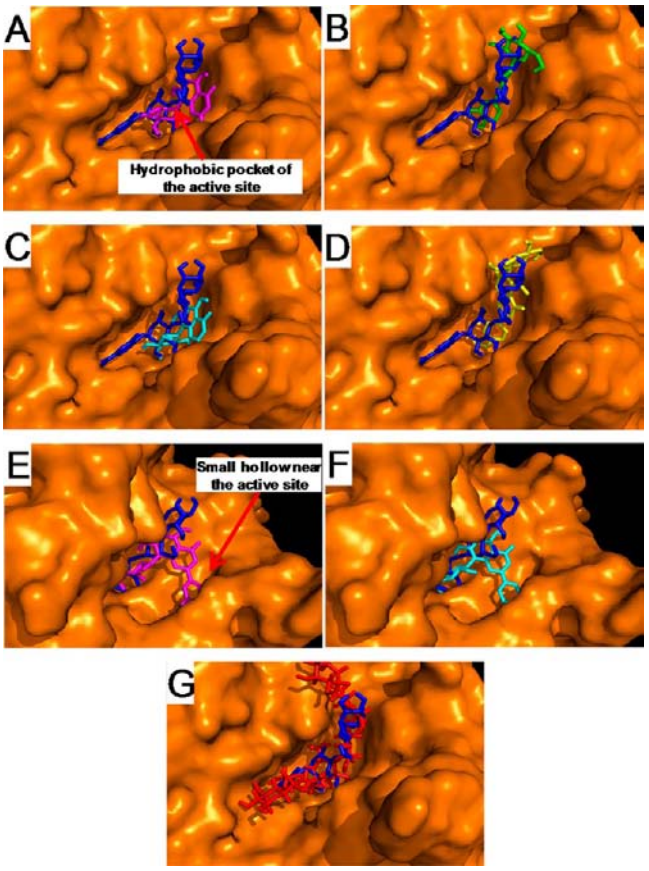

Figure 4. Surface representations of docked ligands on α-amylase with the superimposition of substrate Gal-G2-CNP. The big orange background is the surface of α-amylase (PDB code 1WO2), the dark blue molecule is synthetic substrate Gal-G2-CNP, the pink molecule is orientin, the green molecule is isoorientin, the light blue molecule is vitexin, the yellow molecule is isovitexin, and the red molecule is the positive drug acarbose.

isovitexin are respectively 6.6%, 1.8%, 9.3%, and 8.0% after heat treatment. This indicates that the four flavonoids will not be easily destroyed during food processing. However, many phytochemicals such as anthocyanin[38] and hypericin[39] are extremely unstable under heating, even under lighting.

The Lineweaver−Burk plots of the four flavonoids are given in Figure 3. They all have an intersection at the *y* axis which indicates their inhibitory types are all competitive. Their K_i and IC_{50} values are given in Table 2. Their inhibitory sequence is isoorientin > isovitexin > resin-purified extract > orientin > vitexin, and the differences between their effects are very significant. This is an interesting phenomenon because the structures of the four flavonoids are highly similar. Two speculations can be elicited from this phenomenon: (1) Flavone *C*6-glycosides have stronger α-amylase inhibitory activity than flavone *C*8-glycosides (because the IC_{50} of isoorientin is less than that of orientin and the IC_{50} of isovitexin is less than that of vitexin). (2) The *C*3′-hydroxyl on the B ring is important for the α-amylase inhibitory activity (because the IC_{50} of isoorientin is less than that of isovitexin).

Speculation 2 can be supported by the previous work of Tadera et al.[19] They found that the inhibitory activity of flavonoid is positively related to the number of hydroxyls on the B ring. For speculation 1, we have not found any literature support, but we tried to explain it by using molecular docking in the following subsection.

Molecular Docking between *P. edulis* Flavonoids and α-Amylase. Molecular docking was used to stimulate the binding mode of the ligand and receptor according to the "lock" and "key" principle. Here we used molecular docking to analyze why the four *P. edulis* flavonoids have highly similar structures but exhibit greatly different α-amylase inhibitory activities.

Figure 4 illustrates that all four flavonoids bind at the active site of α-amylase, which is a large hydrophobic pocket on the surface of α-amylase.[40] They all occupy the binding position of substrate Gal-G2-CNP more or less. Among them, isooreintin (B) and isovitexin (D) cover a large part of the binding position of the substrate, but oreintin (A) and vitexin (C) cover a smaller part. Therefore, isoorientin and isovitexin can more effectively cause steric hindrance to hinder the binding of the substrate. This is consistent with our experimental result that isoorientin and isovitexin exhibit much stronger inhibitory activity than orientin and vitexin. In fact, when the glucose links at C8 (orientin, vitexin), a corner of less than 90° will exist inside the flavonoid molecule and lead the three-dimensional structure of the flavonoid to look like a "V". Molecules with a "V" structure (orientin and vitexin) are easily trapped in a small hollow near the active site of α-amylase (which is veiled in Figure 4A,C, but is clear in Figure 4E,F). When the glucose links at C6 (isoorientin, isovitexin), the structure of the flavonoid is linear. Molecules with a linear structure are more similar to the substrate and fit the active site of amylase better. Additionally, we downloaded the X-ray crystal structure of the porcine pancreatic α-amylase−acarbose complex (Figure 4G) which was derived from an X-ray diffraction experiment and not in silico docking as ours was. We find that the positive drug acarbose almost fully occupies the binding position of the substrate. This is why its inhibitory effect is stronger than that of our flavonoids.

Besides geometry complementarity, the binding strength between the ligand and receptor is also important.[41] In Table 3, we summarize the H-bond, π−π, and hydrophobic interactions

Table 3. H-Bond, π−π, and Hydrophobic Interactions between Our Flavonoids and the Residues of α-Amylase[a]

	hydrogen bond	π−π interaction	hydrophobic interaction
orientin	**Asp300**, His299, Gly304, His305	Trp58, Trp59, His305	**Glu233**, **Asp300**, Trp58, Trp59, Tyr62, His299, Arg303, Gly304, His305, Asp356
isoorientin	**Asp197**, **Glu233**,Gln63, Val163, Arg195	Trp58, Trp59, Tyr62, Arg195, His299	**Asp197**, **Glu233**, **Asp300**,Trp58, Trp59, Tyr62, Gln63, Val163, Arg195, Ala 198, His299
vitexin	**Asp300**, His299, Gly304, His305	Trp58, Trp59, His305	**Glu233**, **Asp300**,Trp58, Trp59, Tyr62, His299, Arg303, Gly304, His305, Asp356
isovitexin	**Asp197**, Gln63, Val163, Arg195	Trp58, Tyr62, Arg195, His299	**Asp197**, **Asp300**,Val51, Trp58, Trp59, Tyr62, Gln63, Val163, Leu165, Arg195, His299

[a]The bold-font residues (Asp197, Glu233, Asp300) are the residues which play the key role in cutting the starch chain.

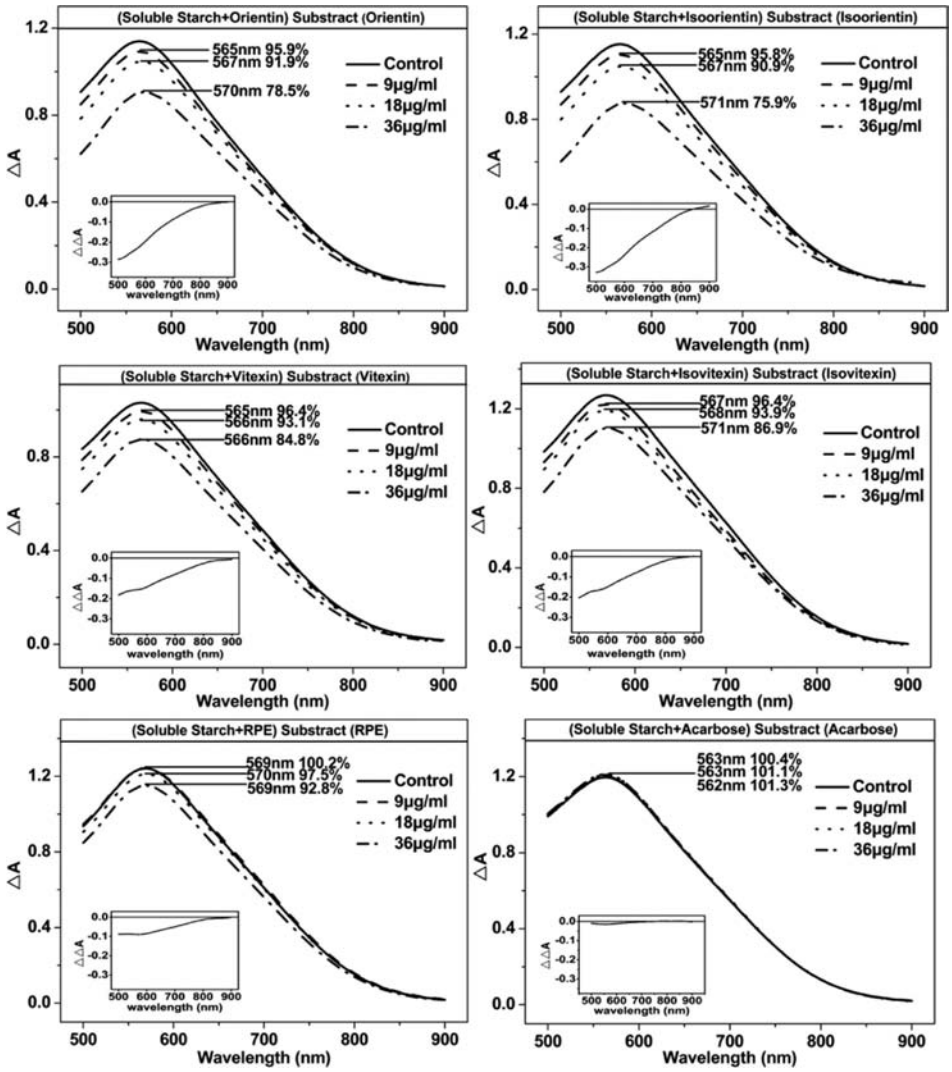

Figure 5. Interactions between *P. edulis* leaf flavonoids, resin-purified extract, acarbose, and soluble starch. $\Delta A = A$(soluble starch + compound + iodine) − A(compound + iodine): (A) orientin added, (B) isoorientin added, (C) vitexin added, (D) isovitexin added, (E) resin-purified extract (RPE) added, (F) acarbose added. The control for each panel is no addition of compound. Inset: $\Delta\Delta A$ spectrum, which is the curve of 36 μg/mL compound minus the curve of the control. The percentage on the right side of each curve is the peak ΔA value of the curve divided by the peak ΔA value of the control curve.

between flavonoids and the residues of α-amylase. Their interacting graphs are also given in the Supporting Information (Figures S4−S6). We find that, due to the extra 3′-hydroxyl, isoorientin forms more H-bonds with α-amylase than isovitexin, and two of them are formed with key residues. (The active site of α-amylase contains three key acidic residues, Asp197, Glu233, and Asp300. They work together to cleave the starch chain.[40,42]) This explains why isoorientin exhibited stronger inhibitory activity than isovitexin.

***P. edulis* Leaf Extracts Bind with Starch and Affect Its Digestibility.** Some small molecular phytochemicals can affect the digestibility of starch through binding with starch.[25,26,28] Here we used a spectroscopic method[26,31] to investigate whether *P. edulis* extracts bind with starch and further affect its digestibility. The ΔA curve of Figure 5 was obtained through subtraction of the absorption curve of flavonoid + iodine from the absorption curve of starch + flavonoid + iodine (the control is absence of flavonoid). Figure 5 shows that the ΔA curves decline with an increase of our flavonoids and resin-purified extract, but do not decline with an increase of acarbose. This indicates that orientin, isoorientin, vitexin, isovitexin, and resin-purified extract can bind with starch, but the positive drug acarbose cannot. According to the percentages on the right side of each curve, the binding strength order of our compounds is isoorientin ≈ orientin > vitexin ≈ isovitexin > resin-purified extract > acarbose.

The $\Delta\Delta A$ spectrum at the left bottom of each picture was obtained through subtraction of the ΔA curve of the control from the ΔA curve of 36 μg/mL flavonoid. Unlike the $\Delta\Delta A$ curves of naringin and neohesperidin[28] which have a distinct peak at 600 nm but are nearly zero at 500 nm, the $\Delta\Delta A$ curves of our flavonoids do not have a distinct peak at 600 nm but show a significant negative value at 500 nm. This indicates they mainly bind with amylopectin because the λ_{max} of the amylopectin−iodine complex is between 500 and 540 nm but the λ_{max} of the amylose−iodine complex is between 540 and 660 nm.[43]

The influence of *P. edulis* leaf extracts on the formation of the amylopectin−iodine complex and amylose−iodine complex was also tested (Supporting Information). The decline of the ΔA

dx.doi.org/10.1021/jf501931m | J. Agric. Food Chem. 2014, 62, 7760−7770

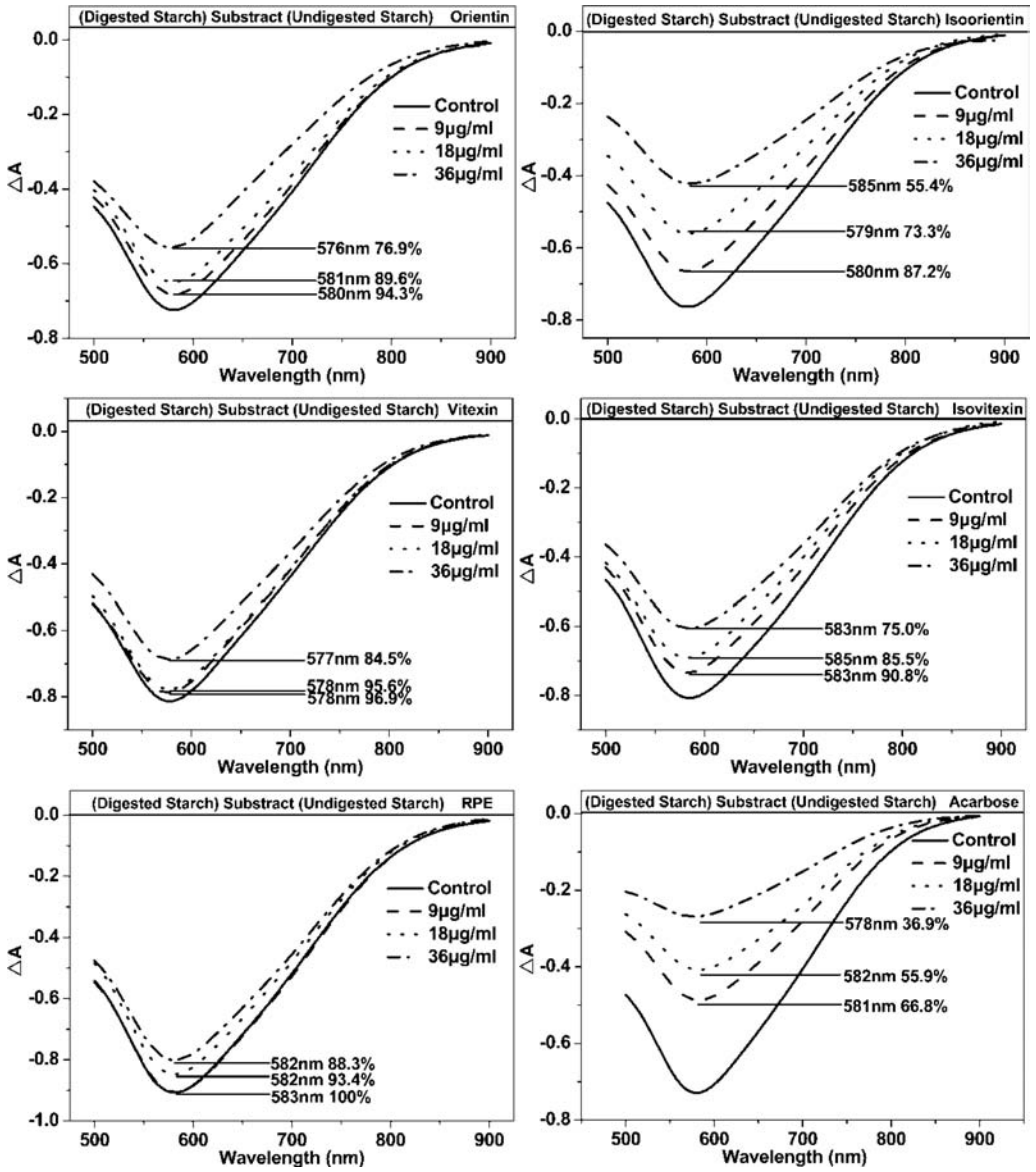

Figure 6. Effect of *P. edulis* leaf flavonoids, resin-purified extract, and acarbose on the digestion of soluble starch: (A) orientin added, (B) isoorientin added, (C) vitexin added, (D) isovitexin added, (E) resin-purified extract added, (F) acarbose added. $\Delta A = A$(digested starch−iodine complex) − A(undigested starch−iodine complex). The control for each panel is no addition of compound. The percentage at the right side of each curve is the peak ΔA value of the curve divided by the peak ΔA value of the control curve.

curve of amylopectin−iodine is more significant than the decline of the ΔA curve of amylose−iodine. This confirms the conclusion induced from the $\Delta\Delta A$ spectra of Figure 5 that *P. edulis* flavonoids mainly bind with amylopectin. Additionally, the amylopectin−iodine complex shows a peak around 535 nm, and the amylose−iodine complex shows a peak around 605 nm. The peak of the soluble starch−iodine complex is between them (around 565 nm, Figure 5) due to soluble starch being composed of amylopectin and amylose.

The ΔA curve of Figure 6 was obtained through subtraction of the absorption curve of the undigested starch−iodine complex from the absorption curve of the digested starch−iodine complex (addition of iodine after incubation with α-amylase). The less the starch was digested, the higher the ΔA value (negative). Figure 6 illustrates that the ΔA curve rises with an increase of our compounds. This indicates that our compounds can inhibit the digestion of soluble starch. The order of their effect was acarbose > isoorientin > isovitexin ≈ orientin > vitexin > resin-purified extract. However, this is different from the α-amylase inhibitory order we obtained from Figure 2 (the substrate was Gal-G2-CNP, a small molecule which was used to exclude the influence of the interaction between starch and our compounds), that is, acarbose > isoorientin > isovitexin > resin-purified extract > orientin > vitexin, and the gap between orientin and isovitexin and the gap between acarbose and isoorientin are narrowed when starch is used as the substrate. If these compounds simply inhibited the activity of α-amylase, whether using Gal-G2-CNP or starch as the substrate, the orders of their inhibitory effect should be the same. Therefore, we speculate that the effect of *P. edulis* extracts on the digestion of starch is not only due to the inhibition of α-amylase. Maybe they can further affect the digestibility of starch through binding with it. Two studies can support our speculation: One study found that due to the binding of rutin, epicatechin dimethylgallate, and fatty acids the glycemic index of buckwheat flour is lower than that of wheat flour.[26]

dx.doi.org/10.1021/jf501931m | J. Agric. Food Chem. 2014, 62, 7760−7770

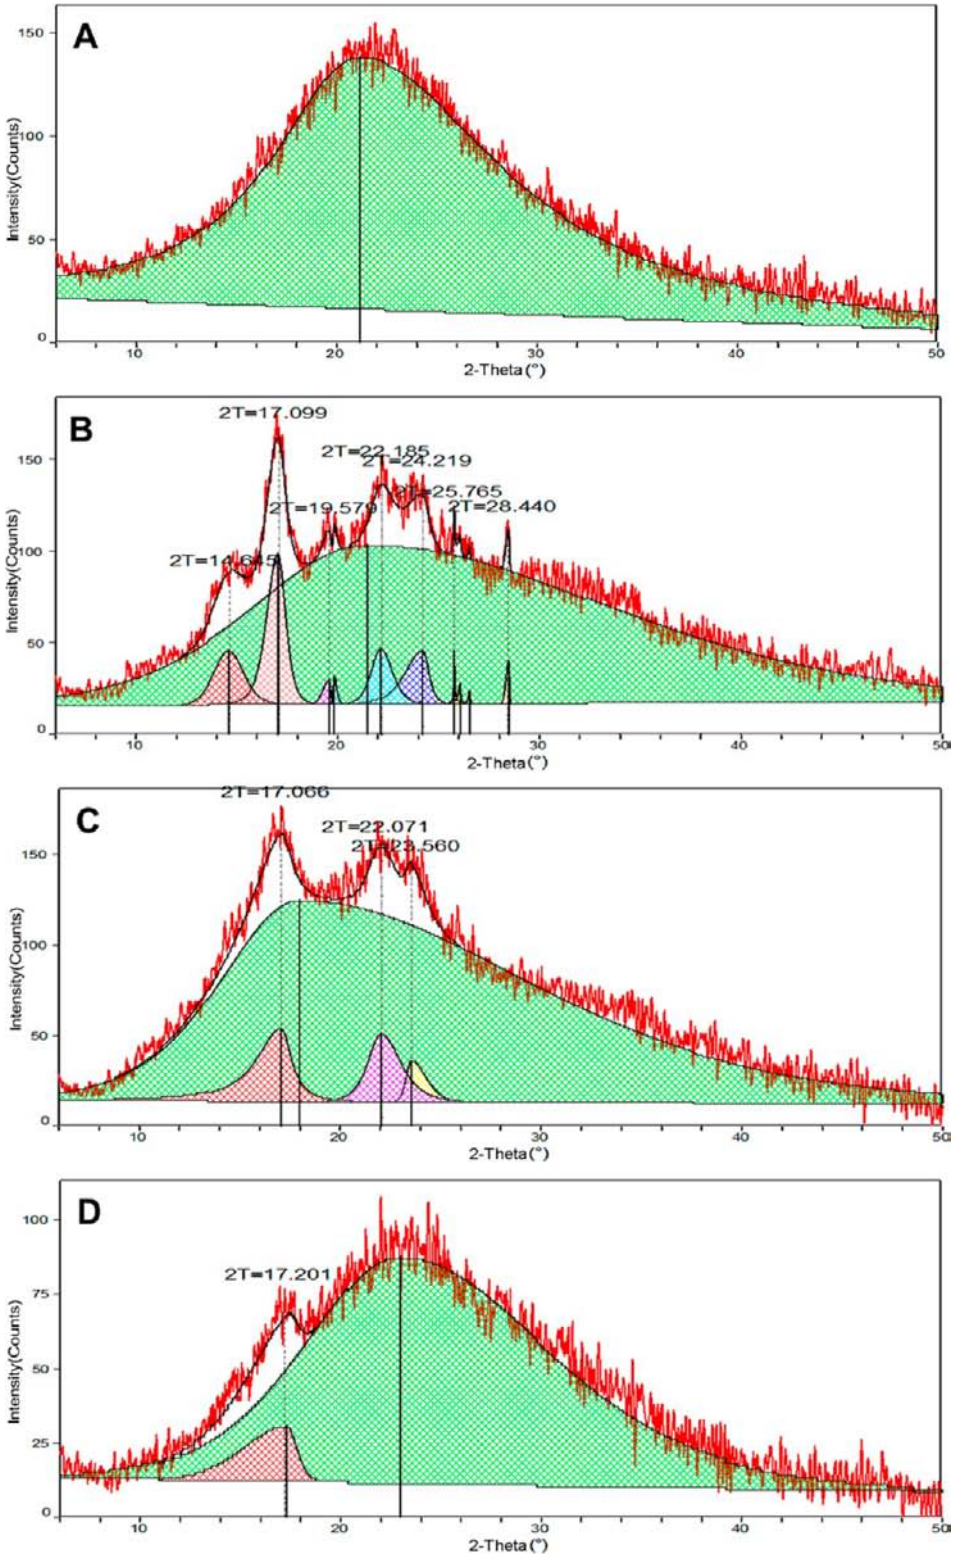

Figure 7. X-ray diffractograms of starch: (A) resin-purified extract, (B) natural soluble starch, (C) retrograded starch, and (D) retrograded resin-purified extract−starch complex. The red jagged line is the original diffractogram. The green area represents the amorphous peak obtained by fitting. The other colored areas represent the crystal peaks obtained by fitting.

The other study found that the resistant starch content of the quercetine−starch complex was sharply higher than that of common starch.[44] We had known that the binding strength between our compounds and starch was different: isoorientin ≈ orientin > vitexin ≈ isovitexin > resin-purified extract > acarbose. Therefore, the inhibitory order change when using starch as the substrate was due to the different binding strengths of these compounds with starch. Why can the binding retard the digestion of starch? Many researchers hold the view that some compounds can bind with starch through occupation

dx.doi.org/10.1021/jf501931m | J. Agric. Food Chem. 2014, 62, 7760−7770

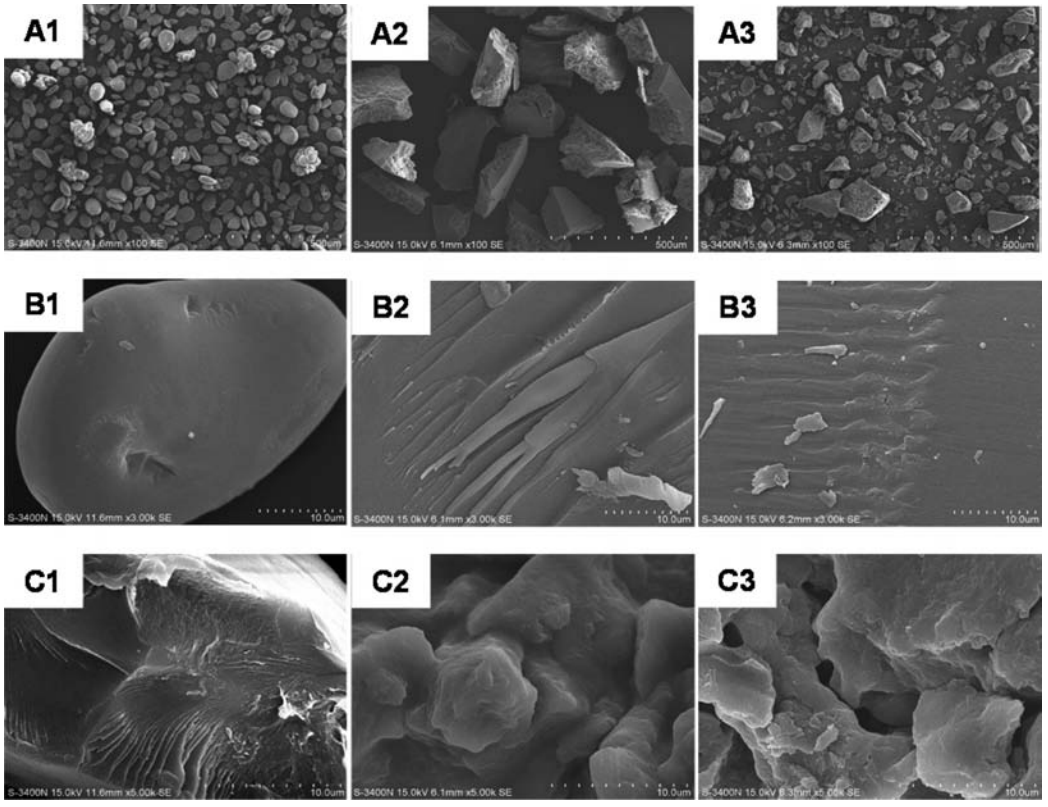

Figure 8. SEM images of starch. Panels A1, B1, and C1 are natural soluble starch (without gelatinization and retrogradation), and their magnifications are respectively 100×, 3000×, and 5000×. Pictures A2, B2, and C2 are retrograded starch (without addition of resin-purified extract), and their magnifications are respectively 100×, 3000×, and 5000×. Pictures A3, B3, and C3 are the retrograded resin-purified extract−starch complex, and their magnifications are respectively 100×, 3000×, and 5000×. B1, B2, and B3 are the outside surface. C1,C2, and C3 are the fracture surface.

of the hydrophobic helical structure of starch. The occupation of the hydrophobic helical structure will disturb the combination of starch and amylase.[26−28]

Influence of *P. edulis* Extract on the Physical Properties of Starch. In the cooking process, well-ordered starch polymers will be broken into free starch chains; this is called gelatinization. During cooling, these free starch chains will reassociate and re-form crystalline domains; this is called retrogradation. Retrogradation will markedly increase the rigidity and shorten the shelf life of starch-based food.[45] To further prove the binding between *P. edulis* leaf extract and starch, we investigated whether the resin-purified extract can influence the retrogradation of starch by using X-ray diffraction and scanning electron microscopy.

Figure 7A is the X-ray diffractogram of the resin-purified extract which does not have any crystal peak. This means that the resin-purified extract is amorphous. Figure 7B is the X-ray diffractogram of natural soluble starch (without heating and cooling treatment). It exhibits a typical B-type crystalline structure (according to X-ray diffractograms, the crystalline form of starch can be classified as A, B, C, and V[46]) with peaks close to 17.2°, 22.2°, and 24.0°. Parts C and D of Figure 7 are the diffractograms of retrograded starch and the retrogradated resin-purified extract−starch complex. We find three crystal peaks in Figure 7C, but only one crystal peak (17.2°) in Figure 7D. Their crystallinities are respectively 8.99% and 4.93%. This indicates that, once we added the resin-purified extract, the retrogradation of starch was retarded.

The mechanism of retrogradation is the reassociation of starch chains through hydrogen bonds. Phenolic compounds which contain many reactive hydroxyls can disturb the formation of H-bonds between starch chains through formation of H-bonds with starch.[29,30] Researchers had confirmed that the greater the number of OH groups in the plasticizer, the better the plasticizer reduces the crystallization of starch.[47] Some other researchers hold the view that, during boiling, phenolic compounds and starch can form covalent bonds which can further retard the crystallization of starch.[48]

Scanning electron microscopy was used to investigate the morphology difference between natural soluble starch, retrogradated starch, and the retrogradated resin-purified extract−starch complex. In Figure 8A1,A2,A3 (100×), the shape of natural soluble starch is an elliptic granule (A1) whose diameter is about 50 μm; the retrogradated starch (A2) and retrogradated resin-purified extract−starch complex (A3) are irregularly shaped agglomerates whose long axes respectively vary between 200 and 250 μm and betwen 50 and 150 μm. From Figure 8B1,B2,B3 (3000×), we find that the surface of natural starch is smooth (B1), but there are many apophyses on the surface of retrogradated starch and the retrogradated resin-purified extract−starch complex (B2, B3). Parts C1, C2, and C3 (5000×) of Figure 8 are the faultages of these starches. The natural starch showed a very dense faultage which indicates its compact interior structure (C1), while on the faultages of retrogradated starch and the retrogradated resin-purified extract−starch complex there are many irregular bulges (C2, C3). Inside the faultage of the retrogradated resin-purified

extract−starch complex (C3), we also find some cracks and cavities. The cracks and cavities illustrate the crystalline texture of the retrogradated resin purified extract−starch complex is less compact than that of retrogradated starch. This indicates that *P. edulis* leaf extract can interact with starch and retard the retrogradation of starch. This is similar to the result of another study that the gel matrix of a wheat starch−pomegranate peel extract complex is looser than that of common starch.[30]

In conclusion, our studies provide scientific support for the further use of *P. edulis* leaf extract as a functional food additive that can adjust postprandial hyperglycemia and prolong the shelf life of starch-based food. Furthermore, our study on the structure−activity relationship of flavone *C*-glycosides can be applied to drug design. In the future, the influence of bamboo leaf extract on the glucose transporter of small intestinal brush border cells deserves further study, because it is the last step in the generation of blood glucose.[49] We hope our study can attract more attention to this bamboo leaf resource and benefit diabetes research and hardworking bamboo farmers in the future.

This study aimed to evaluate in vivo hyperuricemic activity of brown adlay and in vitro xanthine oxidase inhibitory effects of several adlay seed-derived products (i.e., polished adlay, brown adlay, adlay bran, and adlay hull). Comparison on the profiles of free and bound phenolics and antioxidant activities of the extracts derived from these adlay seed products was also performed to elucidate the potential association between in vitro or in vivo bioactivities and the intrinsic phytochemials in the adlay products.

MATERIALS AND METHODS

Chemicals. 2,2′-Azobis (2-methylpropionamidine) dihydrochloride (AAPH), fluorescein sodium salt, Trolox, allopurinol, xanthine, xanthine oxidase, uric acid, nitro blue tetrazolium (NBT), protocatechuic acid, chlorogenic acid, vanillic acid, caffeic acid, *p*-coumaric acid, ferulic acid, and Folin-Ciocalteu reagent were purchased from Sigma Chemical Co. (St. Louis, MO, USA). Acetonitrile and methanol were obtained from Merck (Darmstadt, Germany). All the solvents for high-performance liquid chromatography (HPLC) analyses were of HPLC grade. All the other chemicals used were of analytical grade.

Plant Material. Air-dried polished adlay, brown adlay, adlay bran, and adlay hull were purchased from Shenlong adlay cooperative (Fujian, China) in August 2013. All the materials were ground into fine powder with a laboratory mill (FW100, Taisite Instrument Co., Ltd., Tianjin, China). The materials were stored at room temperature in a desiccator until use.

Extraction of Free Phenolic Compounds. Free phenolic compounds of polished adlay, brown adlay, adlay bran, and adlay hull were extracted using the method of Zhang et al.[24] with slight modification. Briefly, 5 g of adlay flour was mixed with 50 mL of acidified methanol (95% methanol:1 M HCl = 85:15 v/v) for 2 h. The obtained mixture was then centrifuged at 2000g for 10 min. The supernatant was collected, and the residue pellet was re-extracted twice with 50 mL of the acidified methanol. All the resultant supernatants were combined and dried via evaporation in a rotary evaporator under reduced pressure at 45 °C. The dried extracts containing free phenolics were redissolved in methanol and stored at −20 °C until further use.

Extraction of Bound Phenolic Compounds. Bound phenolic compounds of polished adlay, brown adlay, adlay bran, and adlay hull were extracted following the method of Zhang et al.[24] with slight modification. Briefly, the bound phenolics herein refer to those in the residue pellets that resulted from the centrifugation steps of the free phenolic extraction (as described in the paragraph above). These residue pellets were combined, homogenized, and a portion of the combined pellet was then mixed with an aliquot (50 mL) of 2 M sodium hydroxide. The resultant mixture was allowed to stand in capped 100-mL conical flasks at room temperature for 2 h before being centrifuged at 2000g for 10 min. The supernatant was collected, neutralized with concentrated hydrochloric acid, washed with hexanes (to remove lipids), and then extracted six times with ethyl acetate. The resultant ethyl acetate fractions were combined and evaporated to dryness. The dried extracts containing bound phenolics were redissolved in methanol and stored at −20 °C until further use.

Effects of Brown Adlay Extract on Serum Uric Acid Levels in Oxonate-Induced Hyperuricemic Rats. Adult male Sprague−Dawley rats (weight 150−250 g) were purchased from the Laboratory Animal Center of the Guangzhou University of Chinese Medicine (Guangzhou, China). Rats were housed one per cage with minimal suffering, kept in a room controlled at 22−24 °C and with a 12:12-h light/dark cycle, and given a standard laboratory diet and distilled water *ad libitum* before the actual studies. This study was carried out strictly following the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health. The protocol used in this study was approved by the Committee on the Ethics of Animal Experiments of Jinan University (Permit SCXK (yue) 2013-0020).

For the hyperuricemia study, potassium oxonate (a uricase inhibitor) was used to induce acute hyperuricemia following the procedure of Li et al.[9] with some modifications. Sixty rats were randomly assigned to four equal groups (i.e., $n = 15$ per group). Group one consisted of rats who consumed distilled water only (untreated or non- hyperuricemic group). Group two was rats who received 2 g/kg potassium oxonate, administrated by oral gavage once a day for 7 consecutive days before distilled water only. Group three rats were given 2 g/kg potassium oxonate, administrated by oral gavage once a day for 7 consecutive days before allopurinol (50 mg/kg). Group four rats received 2 g/kg potassium oxonate, administrated by oral gavage once a day for 7 consecutive days before dried brown adlay extract containing combined free phenolic and bound phenolic extracts, 166 mg/kg. On the 10th day of the treatment, whole blood sample was collected after final administration and centrifuged to separate serum for serum uric acid, creatinine, and urea nitrogen determination.

The concentrations of serum uric acid, creatinine, and urea nitrogen were measured by enzymatic colorimetric methods using a Varioskan Flash spectral scan multimode plate reader (Thermo Fisher Scientific, Thermo Electron Co., Waltham, MA, USA).

Determination of Total Phenolic Content. Total phenolic content was determined following the method of Singleton and Rossi.[25] Briefly, 200 μL of each sample was transferred to a 10-mL volumetric flask, to which 0.5 mL of undiluted Folin-Ciocalteu reagent was added. Then 1.5 mL of 20% (w/v) Na_2CO_3 was added and the volume of the mixture was brought up to 10 mL with distilled water, before 2 h of incubation at 40 °C and subsequent absorbance measurements at 760 nm. Total phenolic content was calculated based on the calibration curve of gallic acid standard and expressed as mg gallic acid equiv/100 g sample.

Phenolic Profiling by HPLC. HPLC analysis was carried out using a Waters 600 HPLC system (Waters, Milford, MA, USA) equipped with an Agilent XDB-C18 column (250 × 4.6 mm i.d., 5 μm, Santa Clara, CA, USA). Samples were separated using a gradient elution with the mobile phase consisting of 0.1% (v/v) formic acid (A) and acetonitrile (B). The gradient conditions were 95% A in 0−5 min; 95−90% A in 5−10 min; 90−80% A in 15−20 min; 80−70% A in 20−45 min; 70−50% A in 45−50 min; 50−95% A in 50−55 min; 95% A in 55−65 min. The flow rate was set at 1.0 mL/min. The detection wavelength was 280 nm. The samples for analysis were filtered through a 0.22-μm nylon membrane prior to injection to HPLC.

Determination of In Vitro Xanthine Oxidase Inhibitory Activity. Xanthine oxidase activity was determined by measuring the formation of uric acid from xanthine according to the method of de Araújo et al.[7] All solutions were prepared in 50 mM phosphate buffer (pH 7.4). Fifty microliters of a test sample and 50 μL of xanthine oxidase (0.1 U/mL) were added in a well of a 96-well microplate, and the mixture was preincubated at 37 °C for 5 min before an aliquot (150 μL) of 0.42 mM xanthine was added. The resultant mixture was incubated at 37 °C for 60 min and then the enzymatic reaction was stopped by adding 80 μL of 1 M hydrochloric acid. Then dilution by ten times with buffer was performed and the diluted mixture was filtered through a 0.22-μm nylon membrane for HPLC analysis. For HPLC analysis, a Marchal C18 column (250 × 4.6 mm i.d., 5 μm, Guangzhou, China), and an isocratic mobile phase (i.e., 95% A in 0−10 min) consisting of 10 mM NaH_2PO_4−Na_2HPO_4 buffer (pH 5.5) (A) and methanol (B) were used. The flow rate was set at 1.0 mL/min and the detection wavelength was 290 nm. Phosphate buffer (50 mM, pH 7.4) was used as a negative control. Allopurinol was used as a positive control.

$$\begin{aligned}&\text{percent xanthine oxidase inhibition ratio}(\%)\\&\quad=(\text{uric acid content of negative control reaction}\\&\qquad-\text{uric acid content of sample reaction})/\text{uric acid content of}\\&\qquad\text{negative control reaction}\times 100\end{aligned}\tag{1}$$

IC_{50} value refers to the required allopurinol content (μg/mL) when the xanthine oxidase activity inhibition ratio is 50%. Xanthine oxidase inhibition activity value (μg of allopurinol equiv/100 g of dry wt) refers to the required allopurinol content (μg) when xanthine oxidase inhibition activity of allopurinol is equal to 100 g test sample. A higher

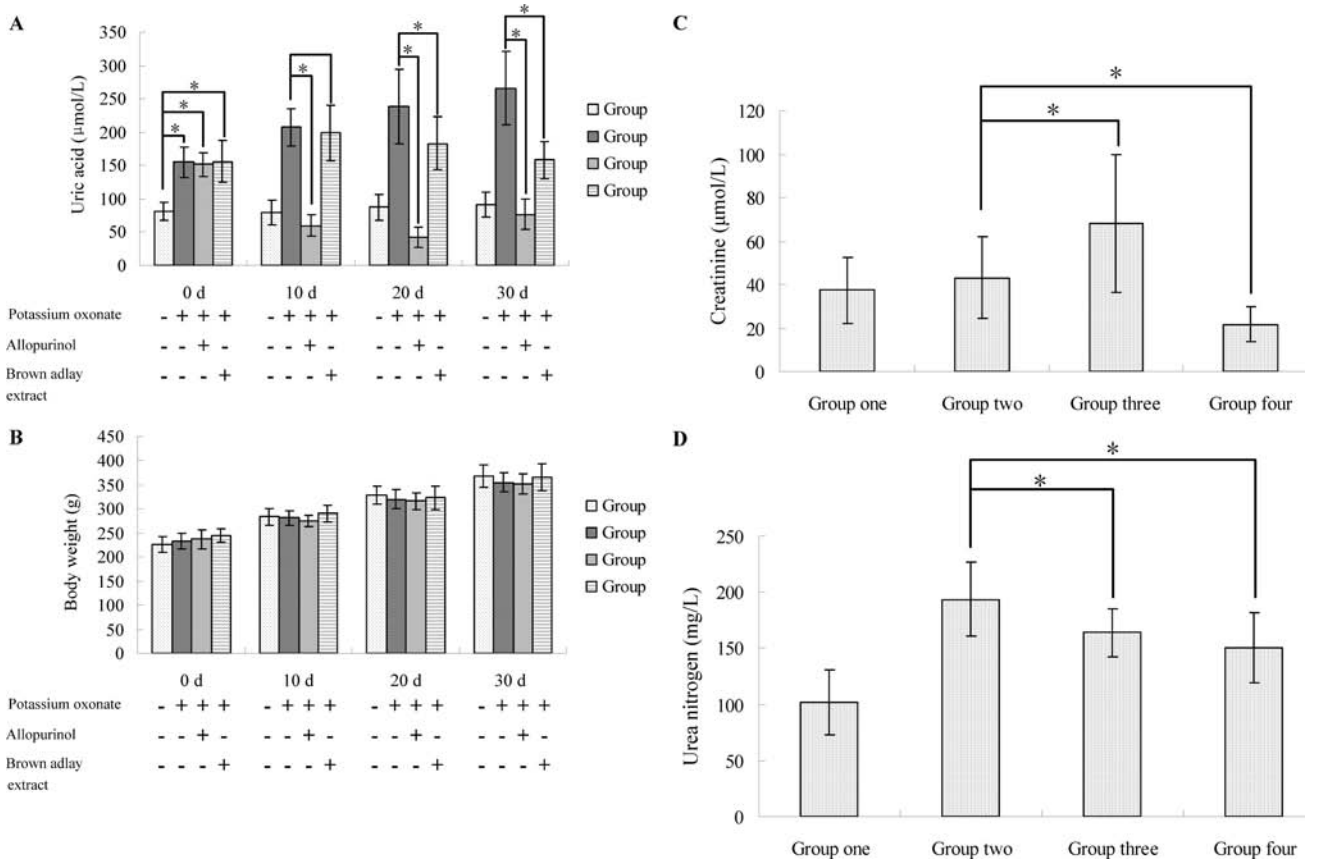

Figure 1. Effect of brown adlay extract on (A) rat serum uric acid, (B) rat body weight, (C) rat creatinine levels, and (D) rat urea nitrogen levels. All values are mean ± standard deviation (SD, $n = 15$) of 15 independent experiments. Asterisk (*) indicates $p < 0.05$.

xanthine oxidase inhibition activity value indicates a stronger xanthine oxidase inhibition activity of the sample.

DPPH Radical Scavenging Activity Assay. DPPH radical scavenging activity was determined by the method of Blois with some modifications.[26] One hundred microliters of a test sample was added in a well of a 96-well microplate. Then, 100 μL of 0.2 mM DPPH was added. The mixture was shaken, and then left to stand for 30 min at 25 °C. The absorbance was measured at 517 nm. All the above measurements were performed on a Varioskan Flash spectral scan multimode plate reader (Thermo Fisher Scientific). The absorbance of the negative control was obtained by replacing the sample with ethanol. The absorbance of the blank was obtained by replacing DPPH with ethanol. Trolox was used as a positive control.

$$\text{DPPH radical scavenging activity}(\%) = (1 - (\text{absorbance}_{\text{sample}} - \text{absorbance}_{\text{blank}}) / \text{absorbance}_{\text{negative control}}) \times 100 \quad (2)$$

DPPH radical scavenging activity value (μmol of Trolox equiv/100 g of dry wt) refers to the required Trolox content (μmol) when DPPH radical scavenging activity of Trolox is equal to 100 g sample. A higher DPPH radical scavenging activity value indicates a stronger DPPH radical scavenging activity of the sample.

Oxygen Radical Absorbance Capacity (ORAC) Assay. The ORAC assay was conducted using our published method.[27] All solutions were prepared in 75 mM phosphate buffer (pH 7.4). Twenty-five microliters of a test sample was added in a well of a 96-well microplate, and then 75 μL of fluorescein sodium salt (0.159 μM) was added. The mixture was preincubated for 10 min at 37 °C. Finally, 100 μL of 38.25 mM AAPH was added before analysis. The fluorescence was measured every 60 s for 4200 s. The reaction was carried out at a constant temperature of 37 °C. All the above measurements were performed on a Varioskan Flash spectral scan multimode plate reader (Thermo Fisher Scientific) with an excitation wavelength of 485 nm and an emission wavelength of 530 nm. Phosphate buffer (75 mM, pH 7.4) was used as a negative control. Trolox was used as a positive control.

Oxygen radical absorbance capacity value was calculated using the regression equation between Trolox concentration and the net area under curve (AUC).

$$\text{AUC} = 0.5(f_0 + f_n) + (f_1 + f_2 + \cdots + f_i + \cdots + f_{n-1}) \quad (3)$$

Where f_0 is the initial fluorescence and f_i is the fluorescence reading at any time. The net AUC is calculated as follows:

$$\text{Net AUC} = \text{AUC}_{\text{sample}} - \text{AUC}_{\text{negative control}} \quad (4)$$

Oxygen radical absorbance capacity value (μmol of Trolox equiv/100 g of dry wt) refers to the required Trolox content (μmol) when oxygen radical absorbance capacity of Trolox is equal to 100 g sample. A higher oxygen radical absorbance capacity value indicates a stronger oxygen radical absorbance capacity of the sample.

Superoxide Radical Scavenging Assay. Superoxide radicals were generated using the method of Wu et al.[28] All solutions were prepared in 50 mM phosphate buffer (pH 7.4). Twenty microliters of a test sample, 180 μL of 0.6 mM NBT solution, and 20 μL of 3 mM xanthine were mixed in a well of a 96-well microplate, to which 20 μL of xanthine oxidase (0.1 U/mL) was added to initiate the reaction. Such a mixture was incubated at 37 °C for 30 min before its absorbance was measured at 560 nm using a Varioskan Flash spectral scan multimode plate reader (Thermo Fisher Scientific). Phosphate buffer (50 mM, pH 7.4) was used as a negative control. Trolox was used as a positive control.

dx.doi.org/10.1021/jf501952e | J. Agric. Food Chem. 2014, 62, 7771−7778

$$\text{Superoxide radical scavenging activity}(\%) = ((\text{absorbance}_{\text{negative control}} - \text{absorbance}_{\text{sample}}) / \text{absorbance}_{\text{negative control}}) \times 100 \quad (5)$$

Superoxide radical scavenging activity value (μmol of Trolox equiv/100 g of dry wt) refers to the required Trolox content (μmol) when superoxide radical scavenging activity of Trolox is equal to 100 g sample. A higher superoxide radical scavenging activity value indicates a stronger superoxide radical scavenging activity of the sample.

Statistical Analysis. All the determinations were carried out in triplicate, and the experimental results were expressed as means ± SD. Statistical analysis was performed by SPSS 11 (SPSS Inc., Chicago, IL, USA). The probabilities of less than 5% ($p < 0.05$) were considered significant.

RESULTS AND DISCUSSION

Effects of Brown Adlay Extract on Serum Uric Acid Levels of Oxonate-Induced Hyperuricemic Rats. On day 0, the serum uric acid levels of potassium oxonate-treated groups including groups two (154.8 μmol/L), three (151.4 μmol/L), and four (155.9 μmol/L) were much higher than those of control group (group one, 81.5 μmol/L) after potassium oxonate treatment (Figure 1A). The serum uric acid levels of potassium oxonate-treated group two (265.7 μmol/L) steadily increased over 30 days, a phenomenon different from those of the control group (91.8 μmol/L) and the other groups treated with allopurinol (76.3 μmol/L) or brown adlay extract (158.3 μmol/L). Potassium oxonate is an uricase inhibitor and can drastically increase the serum uric acid levels causing hyperuricemia in rats. Allopurinol and brown adlay extract effectively decreased the serum uric acid levels of oxonate-induced hyperuricemic rats. Allopurinol is well-known as an effective xanthine oxidase inhibitor for treating hyperuricemia.[29] Thus, it is predicted that the brown adlay extract would act as a potential agent to prevent and treat hyperuricemia through lowering the serum uric acid levels.

Figure 1B shows that the brown adlay extract did not exert any adverse effect on rat body weight. The body weights of all groups increased gradually over 30 days, and there was no significant difference in body weight among the four groups at the same observation time point. Figure 1C and D further revealed the effects of different oral administrations on the serum creatinine and urea nitrogen levels of rats. The oxonate treatment did not significantly change ($p < 0.05$) the serum creatinine but caused considerably increased urea nitrogen in rats (group one vs group two). The administration of allopurinol did not lead to significant change ($p < 0.05$) in serum creatinine and urea nitrogen of oxonate-treated rats (group two vs group three). However, the brown adlay extract considerably reduced the serum creatinine (group four vs the other 3 groups), although the effects of brown adlay extract and allopurinol similarly influenced the urea nitrogen of oxonate-treated rats (both exerted significantly lowering effects). Although the brown adlay extract was not as effective as allopurinol for decreasing the serum uric acid levels of oxonate-induced hyperuricemic rats during the observation period (30 days), the brown adlay extract (a natural agent) could possess full benefits over an extended supplementation period. Thus, the brown adlay extract could be superior to allopurinol and possess the renal protective effect on hyperuricemic rats.

Phenolic Contents of Polished Adlay, Brown Adlay, Adlay Bran, and Adlay Hull. As shown in Table 1, total phenolic content of adlay bran (751 mg of gallic acid equiv/100 g of dry wt) was highest among all the test samples.

Table 1. Comparison of Total Phenolic Contents of Polished Adlay, Brown Adlay, Adlay Bran, and Adlay Hull[a]

	total phenolic content (mg of gallic acid equiv/100 g of dry wt)		
sample	free	bound	total
polished adlay	59 ± 4 d	8 ± 1 d	67 ± 5 d
brown adlay	109 ± 3 c	11 ± 2 c	120 ± 4 c
adlay bran	503 ± 21 a	248 ± 4 a	751 ± 25 a
adlay hull	274 ± 16 b	117 ± 18 b	391 ± 21 b

[a]Values with different letters in column show significant difference from one another ($p < 0.05$).

The total phenolic contents (Table 1) decreased in the order of adlay bran > adlay hull > brown adlay > polished adlay, with adlay bran having 2−11 times as much as the other adlay samples. The free and bound phenolic contents of adlay bran were the highest, respectively, among all the test samples. Adlay hull was ranked the second highest in all the free, bound, and total phenolic contents. The free and bound phenolic contents of adlay bran were 8.5 times and 29 times higher than those of polished adlay. These results suggest that the bran and hull are the most important sources for providing phenolic antioxidants of the adlay seed. The free phenolic contents contributed largely to the total phenolic contents of all the test samples: ∼88% for polished or brown adlay, and ∼68% for adlay bran or hull, respectively. The bound phenolic contents accounted for about 30% of the total phenolic contents of adlay bran and hull; thereby the role of the bound phenolic compounds became more important for adlay bran and hull, compared to polished or brown adlay.

HPLC chromatograms (Figure 2) of the free and bound phenolic extracts from polished adlay, brown adlay, adlay bran, and adlay hull were determined. Protocatechuic acid, chlorogenic acid, vanillic acid, caffeic acid, *p*-coumaric acid, and ferulic acid were used as standards according to the previous studies.[14,16] The phenolic profiles of the free phenolic extracts largely resembled, although the concentrations of individual phenolics varied with, the type of adlay sample. More significant differences were observed among the bound phenolic profiles of all the test samples. The concentrations of identified phenolics are listed in Table 2. Although chlorogenic acid, *p*-coumaric acid, and an unknown compound (retention time at 28.5 min, λ = 254 nm) were the most abundant in the free phenolic extracts, ferulic acid and *p*-coumaric acid were dominant in the bound phenolic extracts (except for adlay hull, i.e., *p*-coumaric acid and chlorogenic acid). According to Table 2, the varieties of phenolic compounds in the free phenolic extracts of the test samples were superior to those in the bound phenolic extracts of the test samples.

Yao et al.[17] reported the total phenolic content in the ethanol extract of adlay bran as 358 mg/100 g, a result much lower than that detected in the present study (751 mg/100 g). This result could be associated with the lower contents of ferulic acid, *p*-coumaric acid, and caffeic acid in the study of Yao et al.[17] Chung et al. were unable to detect *p*-coumaric acid and chlorogenic acid in their adlay bran ethanol extract due to low contents, a result disagreeing with the present study.[16] These variations were related to the different extraction methods or

adlay origin. Quite a few traditional extraction methods led to underestimated total phenolic contents due to the failure of recognizing the bound phenolics.[22] However, these bound phenolics could be of biological importance, e.g. the bound phytochemicals could exert their health benefits after their release by microflora in colon.[23,30]

In Vitro Xanthine Oxidase Inhibitory Activities of Polished Adlay, Brown Adlay, Adlay Bran, and Adlay Hull. In vitro xanthine oxidase inhibitory activities of extracts from four adlay materials, as well as their major phenolic compounds (i.e., chlorogenic acid, *p*-coumaric acid, and ferulic acid) are shown in Table 3. Allopurinol was used as a positive control (IC_{50} value = 4.75 ± 0.13 μg/mL). The adlay seed extracts were capable of inhibiting xanthine oxidase. The free phenolic extracts showed stronger xanthine oxidase inhibitory activities than the corresponding bound phenolic extracts. The free, bound, and total phenolic extracts of adlay bran or polished adlay possessed the greatest or lowest xanthine oxidase inhibitory activities in corresponding extract categories. The bran layer of adlay contributed largely to the xanthine oxidase inhibitory activity. Xanthine oxidase can oxidize xanthine or hypoxanthine, and produce uric acid and reactive oxygen species. Excess accumulation of uric acid causes gout.[19,31] As shown in an earlier section, the brown adlay extract significantly lowered the serum uric acid levels thus having potential agent for preventing and treating hyperuricemia. Therefore, the protective and therapeutic effects of brown adlay extract on oxonate-induced hyperuricemic rats may be attributed (i.e., at

least partially) to the xanthine oxidase inhibitory activities of the test adlay samples.

The in vitro xanthine oxidase inhibitory activities of three purified phenolic chemicals were in this descending order: ferulic acid > *p*-coumaric acid > chlorogenic acid. Chlorogenic acid had ∼100 times weaker in vitro xanthine oxidase inhibitory activity per gram, compared to ferulic acid and *p*-coumaric acid. Therefore, the contribution of chlorogenic acid to the detected in vitro xanthine oxidase inhibitory activities of the free phenolic extracts could be very small, although chlorogenic acid was abundant in the free phenolic extracts (i.e., variations in the concentrations of their chlorogenic acid and other phenolics were <18 times). Therefore, in vitro xanthine oxidase inhibitory activities of the free phenolic extracts mainly came from *p*-coumaric acid (the other dominant phenolic compound) or other phenolic compounds and their interactive effects. For the bound phenolic extracts, *p*-coumaric acid and ferulic acid could have contributed largely to the detected in vitro xanthine oxidase inhibitory activities. However, Yoshizumi et al. found that the in vitro xanthine oxidase inhibitory activity of *p*-coumaric acid (IC_{50} value >100 μM) was weak.[32] The different results may be attributed to the different test methods. In addition, Nile and Park reported that ferulic acid possessed good in vitro inhibition effect on xanthine oxidase (IC_{50} value = 8.2 μM).[33] This result was consistent with that obtained in the present study.

It is worth noting the similarity in chemical structure between *p*-coumaric acid/ferulic acid and xanthine/uric acid, which suggest the possibility of acting as substrates (just as allopurinol) for xanthine oxidase. When phenolic compounds with low molecular weight came into the xanthine oxidase pocket, these phenolics may act as a "plug" causing subsequent inhibition of uric acid formation.[28] Therefore, low molecular weight *p*-coumaric acid and ferulic acid could effectively inhibit the xanthine oxidase activity. Chlorogenic acid has about 2-fold molecular weight and an extra 6-C ring compared to *p*-coumaric acid and ferulic acid. Thus, chlorogenic acid was possibly too large for xanthine oxidase pocket, leading to weak xanthine oxidase inhibitory activity.

Antioxidant Activities of Polished Adlay, Brown Adlay, Adlay Bran, and Adlay Hull. The antioxidant activities as DPPH radical scavenging activities, oxygen radical absorbance capacities, or superoxide radical scavenging activities of various adlay samples are listed in Table 4. Although the mechanisms of DPPH radical scavenging activity, oxygen radical absorbance capacity, and superoxide radical

Table 4. Antioxidant Activities of Polished Adlay, Brown Adlay, Adlay Bran, Adlay Hull (μmol of Trolox equiv/100 g of dry wt) and Standard Compounds (mol of Trolox equiv/mol)[a]

sample	DPPH radical scavenging activity value			oxygen radical absorbance capacity value			superoxide radical scavenging activity value		
	free	bound	total	free	bound	total	free	bound	total
polished adlay	110.51 ± 0.33 c	38.58 ± 0.36 c	149.09 ± 0.87 c	1930.83 ± 263.57 d	197.06 ± 6.12 d	2127.89 ± 268.67 d	97.05 ± 7.0 d	33.15 ± 0.42 c	130.20 ± 7.26 d
brown adlay	149.62 ± 1.67 c	45.01 ± 0.11 c	194.57 ± 2.93 c	3872.56 ± 202.19 c	913.49 ± 62.82 c	4786.05 ± 260.13 c	199.98 ± 13.27 c	60.18 ± 2.91 c	260.16 ± 15.73 c
adlay bran	873.81 ± 1.76 a	304.12 ± 10.61 a	1177.91 ± 15.62 a	22123.03 ± 1297.34 a	13128.19 ± 903.47 a	35251.22 ± 2198.72 a	741.04 ± 34.74 a	227.51 ± 13.97 a	968.55 ± 45.57 a
adlay hull	381.94 ± 4.40 b	200.94 ± 3.20 b	582.76 ± 11.76 b	14164.64 ± 885.99 b	5207.34 ± 82.58 b	19371.98 ± 965.37 b	363.81 ± 18.48 b	102.41 ± 4.83 b	466.22 ± 21.61 b

scavenging activity assays differ, the results of these three assays agreed with one another. The antioxidant activities were in the order of adlay bran > adlay hull > brown adlay > polished adlay, with the antioxidant activity values of the former two being much higher than those of the latter two. The free phenolic extracts exhibited stronger antioxidant activities than the bound phenolic extracts, indicating that the adlay samples with a higher total phenolic content possessed greater antioxidant activities. Moreover, the antioxidant activities of three phenolic compounds decreased in this order: chlorogenic acid > *p*-coumaric acid > ferulic acid. Chlorogenic acid is a dihydroxycinnamic acid with two hydroxy groups in ortho in aromatic ring, which is responsible for its greater antioxidant activity.

The DPPH radical scavenging activity assay, mainly based on an electron transfer reaction with marginal hydrogen atom transfer, is a rapid method and quite often used for evaluating antioxidant activity.[34] The ORAC assay is also popular because of its biologically relevant free radicals.[35] Furthermore, Lavelli et al. reported that xanthine oxidase is one of the major reactive oxygen species of enzymatic sources.[5] Excess reactive oxygen species could lead to a variety of pathophysiological phenomena, such as inflammation, aging, atherosclerosis, cancer, rheumatoid arthritis, hepatotoxicity, and reperfusion injury.[19] In the present study, the scavenging activities of the adlay samples for the superoxide radical generated by the xanthine/xanthine oxidase system were determined using an enzymatic assay.

The test adlay samples, as well as three purified phenolic chemicals, all inhibited the xanthine oxidase activity. *p*-Coumaric acid was found to have good xanthine oxidase inhibitory activity and superoxide radical scavenging activity, suggesting that *p*-coumaric acid is a xanthine oxidase inhibitor and can impart additional superoxide radical scavenging activity. Therefore, the superoxide radical scavenging activity of the adlay seed might be associated with their xanthine oxidase inhibitory activity. In comparison, chlorogenic acid with weak xanthine oxidase inhibitory activity still exhibited the strongest superoxide radical scavenging activity, i.e. a good superoxide radical scavenger with weak inhibitory activity on xanthine oxidase. Ferulic acid with strong xanthine oxidase inhibitory activity had the weakest superoxide radical scavenging activity, i.e. ferulic acid is a good xanthine oxidase inhibitor with weak superoxide radical scavenging activity. These different activity patterns were due to the different chemical structures of chlorogenic acid, *p*-coumaric acid, and ferulic acid.[8] Additionally, chlorogenic acid can be cleaved into caffeic acid and quinic acid in the body by an esterase enzyme in the colonic microflora. And caffeic acid can be metabolized to the form of glucuronide and sulfate conjugates.[36,37] Ferulic acid (FA) can be absorbed along the entire gastrointestinal tract and be metabolized into a number of metabolites (especially FA-glucuronide, FA-sulfate, and FA-sulfoglucuronide).[38] *p*-Coumaric acid is absorbed throughout the digestive tract. However, it seems to be less metabolized. Therefore, *p*-coumaric acid may have great health benefits.[39]

In conclusion, the results of this study provide strong in vitro and in vivo evidence to support the notion that polished adlay, brown adlay, adlay bran, and adlay hull could be active ingredients for functional food applications. Adlay seed and derived materials contained significant amounts of free or bound phenolics, possessing strong DPPH radical scavenging activities, oxygen radical absorbance capacities, and antioxidant activities in scavenging xanthine/xanthine oxidase-derived superoxide radicals. Adlay seed and derived materials could be used as effective radical scavengers and inhibitors of reactive oxygen species-generating enzyme. Therefore, seed and derived materials, especially the adlay bran, have positive future potential and could be potential raw materials for food and nutraceutical products to prevent and treat hyperuricemia.

of the Japanese rice wine "sake". Herein, we describe the extraction of the adsorbed components from the used activated charcoal and their subsequent evaluation as pol inhibitors. This work culminated in the isolation of a potent inhibitor of mammalian pol, which was also investigated for its anti-inflammatory and antiallergic activities. Finally, we have provided a detailed discussion of the way in which bioactive compounds can be isolated from waste products to provide potential anti-inflammatory/antiallergic agents.

MATERIALS AND METHODS

Chemicals and Materials. The used activated charcoal, which is an industrial waste product generated during the manufacture of sake (trade name: Kuromatsu-Hakushika), was obtained from Tatsuuma-Honke Brewing Co. Ltd. (Nishinomiya, Japan). Tyrosol (**1**), which is also known as 4-(2-hydroxyethyl)phenol, 3-hydroxytyrosol (**2**), and 3,4-dihydroxyphenyl acetic acid (**3**) were purchased from Sigma-Aldrich Inc. (St. Louis, MO, U.S.A.). These compounds were of purchased as the analytical grade and purified by high-performance liquid chromatography. A chemically synthesized DNA template, poly(dA), was purchased from Sigma-Aldrich Inc., and a customized oligo$(dT)_{18}$ DNA primer was produced by Sigma-Aldrich Japan K.K. (Ishikari, Japan). The radioactive nucleotide [^{3}H]-labeled 2′-deoxythymidine-5′-triphosphate (dTTP; 43 Ci/mmol) was obtained from Moravek Biochemicals Inc. (Brea, CA, U.S.A.). Precoated Silica-Gel 60 plates (10 × 20 cm^2, 0.25 mm layer thickness) for thin-layer chromatography (TLC) were purchased from Merck (Darmstadt, Germany). All of the other reagents used in the current study were purchased from Nacalai Tesque Inc. (Kyoto, Japan) as the analytical grade.

Instrumental Analyses. ^{1}H- and ^{13}C-nuclear magnetic resonance (NMR) were recorded on a Bruker DRX600 (Bruker Biospin GmbH, Rheinstetten, Germany). Mass spectra were obtained on an esquire6000-TR (Bruker Daltonics, Billerica, MA, U.S.A.).

Enzymes. Pol α was purified from calf thymus by immuno-affinity column chromatography according to the method described by Tamai et al.[14] Recombinant rat pol β was purified from *Escherichia coli* JMpβ5 according to the procedure reported by Date et al.[15] The human pol γ catalytic gene was cloned into the pFastBac vector. A histidine-tagged enzyme was subsequently expressed using the BAC-TO-BAC HT Baculovirus Expression System (Life Technologies, Frederick, MD, U.S.A.) according to the manufacturer's instructions and purified over ProBound resin (Invitrogen Japan, Tokyo Japan).[16] Human pols δ and ε were purified by the nuclear fractionation of human peripheral blood cancer cells (Molt-4) using the second subunit of pol δ and ε-conjugated affinity column chromatography, respectively.[17] A truncated form of human pol η (residues 1−511) tagged with His_6 at its C-terminal was expressed in *E. coli* cells and purified as previously described by Kusumoto et al.[18] A recombinant mouse pol ι tagged with His_6 at its C-terminal was expressed and purified by nickel−nitriloacetic acid (Ni−NTA) column chromatography as previously described.[19] A truncated form of pol κ (residues 1−560) with a His_6 residue tag attached to its C-terminal was overexpressed in *E. coli* and purified according to the method described by Ohashi et al.[20] Recombinant human His-pol λ was overexpressed and purified according to the method described by Shimazaki et al.[21] Recombinant human His-pol μ was overexpressed in *E. coli* BL21 and purified by Glutathione Sepharose 4B column chromatography (GE Healthcare Bio-Science Corp., Piscataway, NJ, U.S.A.) according to the method described by Shimazaki et al.[21] for the preparation of pol λ. Pol α from the higher plant cauliflower inflorescence was purified according to the methods reported by Sakaguchi et al.[22] Recombinant rice (*Oryza sativa* L. cv. Nipponbare) pol λ tagged with His_6 at its C-terminal was expressed in *E. coli* and subsequently separated from the cells according to the method described by Uchiyama et al.[23] Calf TdT, *Taq* pol, T4 pol, T7 RNA polymerase, and T4 polynucleotide kinase were purchased from Takara Bio Inc. (Kyoto, Japan). The Klenow fragment of pol I from *E. coli* was purchased from Worthington Biochemical Corp. (Freehold, NJ, U.S.A.). Purified human placenta DNA topoisomerases I and II were purchased from TopoGen Inc. (Columbus, OH, U.S.A.). Bovine pancreas deoxyribonuclease I was obtained from Stratagene Cloning Systems (La Jolla, CA, U.S.A.).

Measurement of Pol Activity. The compositions of the reaction mixtures used for calf pol α, rat pol β, plant pol α, and the prokaryotic pols have been described previously elsewhere.[24,25] The reaction mixtures used for human pol γ, as well as human pols δ and ε have been described previously by Umeda et al.[16] and Ogawa et al.,[26] respectively. The reaction mixtures used for mammalian pols η, ι, and κ were the same as that used for pol α, whereas those used for human pols λ and μ, and plant pol λ were the same as that of pol β. For the pol reactions, poly(dA)/oligo$(dT)_{18}$ (A/T, 2/1) and dTTP were used as the DNA template-primer and nucleotide (dNTP; 2′-deoxynucleoside-5′-triphosphate) substrates, respectively. For the TdT reactions, oligo$(dT)_{18}$ (3′-OH) and dTTP were used as the DNA primer and nucleotide substrates, respectively.

The compounds to be tested were dissolved in freshly distilled dimethyl sulfoxide to various concentrations, and the resulting solutions were sonicated for 30 s. For microliter aliquots were of the solutions were then mixed with 16 μL of each enzyme (0.05 units) in 50 mM Tris-HCl (pH 7.5), containing 1 mM dithiothreitol, 50% glycerol (v/v), and 0.1 mM ethylenediaminetetraacetic acid, and the resulting mixtures were held at 0 °C for 10 min. Eight microliter aliquots of the inhibitor-enzyme mixtures were then added to 16 μL of the enzyme standard reaction mixture and incubated at 37 °C for 60 min, except for *Taq* pol, which was incubated at 74 °C for 60 min. Activity in the absence of the inhibitor was considered to be 100%, and the relative activity was determined for each inhibitor concentration. One unit of pol activity was defined as the amount of each enzyme required to catalyze the incorporation of 1 nmol of dTTP into the synthetic DNA template-primers in 60 min at 37 °C under standard reaction conditions.[24,25]

Other DNA Metabolic Enzyme Assays. The activities of T7 RNA polymerase, human DNA topoisomerases I and II, mouse IMP dehydrogenase (type II), T4 polynucleotide kinase, and bovine deoxyribonuclease I were measured using standard assay protocols according to the manufacturers' specifications, as described by Nakayama and Saneyoshi,[27] Yonezawa et al.,[28] Mizushina et al.,[29] Soltis and Uhlenbeck,[30] and Lu and Sakaguchi,[31] respectively.

Animals. Female ICR mice (6 weeks old with a body weight in the range of 25−27 g) were obtained from Japan SLC, Inc. (Hamamatsu, Japan), and maintained on a standard moderate fat (MF) diet (Oriental Yeast Co. Ltd., Osaka, Japan), with water provided ad libitum. Mice that had been bred in-house with free access to food and water were used for all of the experiments in the current study. All of the mice were maintained under a 12-h light/dark cycle and housed at room temperature (25 °C). This study was approved by the Institutional Animal Care and Use Committee of Kobe Gakuin University and was performed in accordance with the guidelines outlined in the Care and Use of Laboratory Animals of Kobe Gakuin University. The animals were anesthetized with pentobarbital before undergoing cervical dislocation.

Measurement of Anti-Inflammatory Activity. The mouse inflammatory test was performed according to Gschwendt's method.[32] Briefly, an acetone solution of the compound of interest (500 μg in 20 μL) or 20 μL of acetone as a vehicle control was applied to the inner part of the mouse ear. Thirty minutes after the test compound was applied, a TPA solution (0.5 μg/20 μL of acetone) was applied to the same part of the ear. TPA was also applied to the other ear of the same mouse as a control. After 7 h, a disk (6 mm diameter) was obtained from the ear and weighed. The inhibitory effect (IE) was then determined as the ratio of the weights of the two ear disks, as follows:

$$\mathrm{IE} = [(\text{TPA only}) - (\text{tested compound plus TPA})] / [(\text{TPA only}) - (\text{vehicle})] \times 100$$

Measurement of Anti-Anaphylactic Activity. The PCA reaction was conducted according to the method described by Sato et al.[33] Mice were sensitized by an intradermal injection of 0.1 μg of

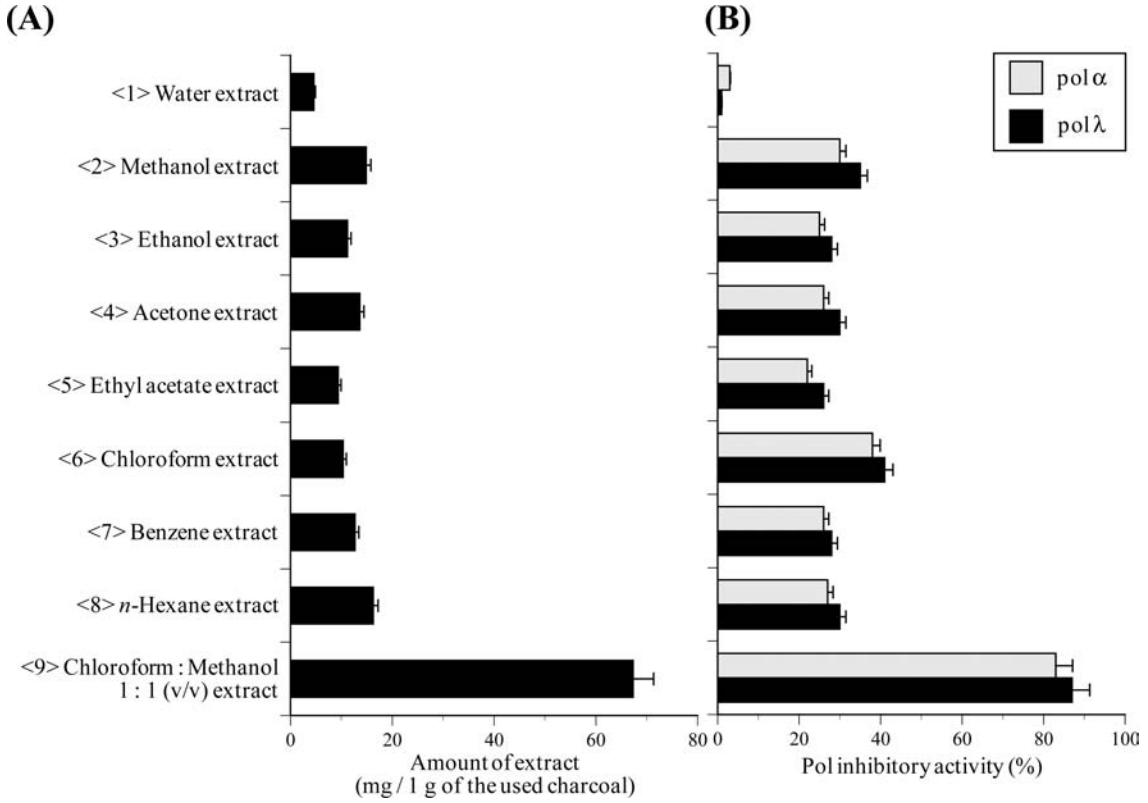

Figure 1. Extraction of the absorbed materials from the used activated charcoal generated during the sake-brewing process with different organic solvents. (A) Amount of extract collected from the used activated charcoal by the nine organic solvents. Data are shown as the mean values ± SD of three independent experiments. (B) Inhibitory activity of calf pol α and human pol λ by 100 μg/mL of extract collected from the used activated charcoal by the nine organic solvents. Data are shown as the mean values ± SD of three independent experiments.

antidinitrophenyl (DNP) IgE in their ear. Four hours later, the mice were intravenously challenged with 0.2 mL (1 mg/mL) of DNP-labeled human serum albumin containing 2% Evans blue dye. A test compound (100 mg/kg) or saline was also administered orally 2 h prior to the antigen challenge, with saline being used as a control. The mice were subsequently sacrificed, and their ears removed and weighed 30 min after the challenge. The ears were then dissolved in 200 μL of 1 N KOH, and the resulting solutions were incubated overnight at 37 °C. To measure the amount of Evans blue dye present in the exudates, the dissolved tissue solution was added to 400 μL of a 5:13 (v/v) mixture of acetone and 0.6 N phosphoric acid, and the optical density of the resulting solution was measured at 620 nm. The amount of dye in the exudates was calculated from an Evans blue standard curve, and the results expressed as a percentage for the mean amount of exudate dye from the treated mice. These data were then compared with those from the controls.

Statistical Analysis of Animal Experiments. All data of animal experiments such as anti-inflammatory and antiallergic activities are expressed as the means ± SD of six independent determinations for each experiment. Statistical significance between each experimental group was analyzed using Student's *t* test, and a level of probability of 0.01 and 0.05 was used as the criterion of significance.

RESULTS AND DISCUSSION

Extraction of Absorption Components from the Used Activated Charcoal Derived from Sake-Brewing Process. The Japanese rice wine "sake" is made from fermented rice. The fermentation process for the production of this wine involves the conversion of starch to sugar using the fungus *Aspergillus orizae*, whereas the brewing process uses the yeast *Saccharomyces cerevisiae*. During sake production, the fermented sake (i.e., irekuchi-sake) becomes colored and off-flavored, and is consequently treated with activated charcoal to remove the colors and off-flavors. The resulting activated charcoal-treated sake is known as "sumikuchi-sake", and this material is subsequently packaged and distributed as a commercial product. The used activated charcoal, however, is treated as an industrial waste product and disposed of accordingly. The aim the current study was to identify bioactive compounds that had been adsorbed onto the activated charcoal during the manufacture of sumikuchi-sake, and evaluate these compounds in terms of their pol-inhibitory activities. In this way, it could be possible to recycle these byproducts and find alternative industrial/medical applications for these materials.

We investigated the extraction of the absorbed materials from the used activated charcoal using nine different organic solvent systems, including (1) water, (2) methanol, (3) ethanol, (4) acetone, (5) ethyl acetate, (6) chloroform, (7) benzene, (8) *n*-hexane, and (9) a 1:1 (v/v) mixture of chloroform and methanol (Figure 1). Solvents (1) to (8) have been listed in order of their hydrophilicity. Five-hundred milligrams of the used activated charcoal was added to 1 mL of each organic solvent, and the resulting mixtures were shaken and vortex-mixed for 10 min, before being centrifuged at 10 000*g* for 10 min to separate the organic extract from the charcoal. Extract from solvent system (9) was very yellow in color, and the extract from solvent (4) was only slightly yellow in color. In contrast, the extracts from all of the other solvents remained colorless. The amounts of adsorbed material extracted from 1 g of used activated charcoal by the different organic solvents are shown in Figure 2A. The amount of material extracted by solvent system (9) was more than 4-fold greater than that of

dx.doi.org/10.1021/jf502095p | J. Agric. Food Chem. 2014, 62, 7779−7786

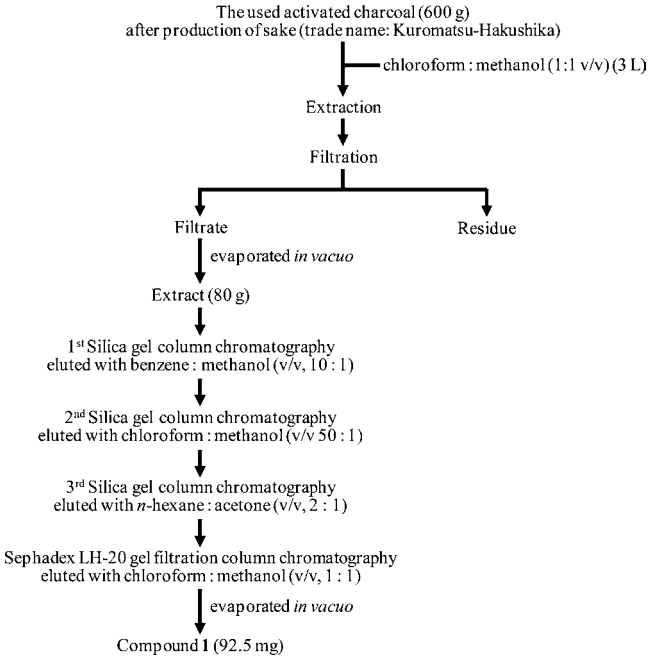

Figure 2. Method for purification of compound **1**, a mammalian pol inhibitor, from the used activated charcoal generated during the sake-brewing process.

any other organic solvent. Solvent system (9) therefore exhibited the best extraction efficiency of all of the solvents tested toward the used activated charcoal. The inhibitory activities of the extracts of nine organic solvent toward mammalian pols was investigated, using pol α and pol λ as a representative DNA replicative pol and DNA repair/recombination-related pol, respectively.[4,5] The inhibitory activity of calf pol α and human pol λ against 100 μg/mL of each extract is shown in Figure 1B. Among the nine extracts tested, solvent system (9) showed the strongest inhibition of both pols α and λ, with inhibitory activities of 83.0 and 87.2%, respectively. The extracts of solvent system (2) to (8) slightly inhibited the pol activity, but solvent system (1) had no effect on the activity, suggesting that water-soluble (i.e., hydrophilic) components of the absorbed materials from the used activated charcoal did not have the inhibitory activities of mammalian pols.

Isolation of a Mammalian Pol Inhibitor from the Absorption Extract of the Used Activated Charcoal. The materials extracted from the used activated charcoal with solvent system (9) exhibited potent inhibitory activity toward mammalian pol, and the decision was taken to purify this extract to isolate and identify the compound responsible for this inhibitory activity. Briefly, a large portion of used activated charcoal (600 g) was extracted with a 1:1 (v/v) mixture of chloroform and methanol (3 L), and the resulting extract was evaporated to dryness to give a residue (80 g), which was subjected to purification by column chromatography over silica gel eluting with a 10:1 (v/v) mixture of benzene and methanol. The active fractions (1.15 g) were then combined and purified by column chromatography over silica gel eluting with a 50:1 (v/v) mixture of chloroform and methanol. Once again, the active fractions (310 mg) were combined and purified by column chromatography over silica gel eluting with a 2:1 (v/v) mixture of *n*-hexane and acetone. Finally, the active fractions (123 mg) were combined and purified by column chromatography over Sephadex LH-20 eluting with a 1:1 (v/v) mixture of chloroform and methanol to give compound **1** as a white powder (92.5 mg), which was confirmed to be an inhibitor of mammalian pol (Figure 2). The yield and 50% inhibitory concentration (IC_{50}) for human pol λ activity of the purification steps are shown in Table 1. Since the extract of solvent system (9) was stronger pol λ inhibitor than the active fraction of first silica gel column chromatography, the extract of solvent system (9) should contain several pol inhibitory compounds.

Table 1. Purification Steps of Compound 1 from the Used Activated Charcoal after Production of Sake

step of purification	yield (mg)	IC_{50} value for pol λ (μg/mL)
extract of chloroform: methanol (1:1 v/v)	80 000	55.3
active fraction of first silica gel column chromatography	1150	66.8
active fraction of second silica gel column chromatography	310	18
active fraction of third silica gel column chromatography	123	6.5
active fraction of LH-20 gel filtration column chromatography (compound **1**)	92.5	4.7

Determination of the Structure of Compound 1 Purified from the Used Activated Charcoal Derived from the Sake-Brewing Process. Compound **1** purified from the used activated charcoal was identified as tyrosol [4-(2-hydroxyethyl)phenol] by spectroscopic analyses, including 1D/2D NMR and MS. These spectroscopic data were consistent with those reported previously in the literature for the same compound.[34] Two tyrosol (**1**) analogues were also prepared, including 3-hydroxytyrosol (**2**) and 3,4-dihydroxyphenyl acetic acid (**3**) (Figure 3), and all three of these compounds were used in the next part of the study.

Effects of Tyrosol (1) and Its Analogues (2 and 3) on the Activities of Various Pols and Other DNA Metabolic Enzymes. Tyrosol (**1**), 3-hydroxytyrosol (**2**), and 3,4-dihydroxyphenyl acetic acid (**3**) were evaluated in terms of

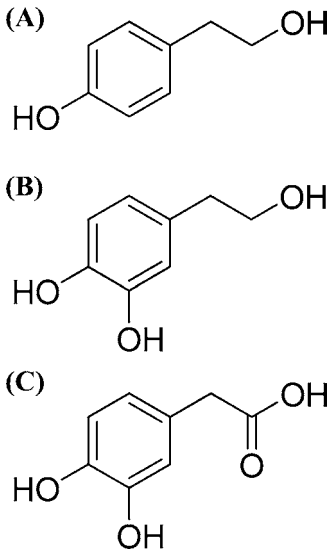

Figure 3. Structure of compound **1**, which was obtained from the absorption extract of the used activated charcoal generated during the sake-brewing process, and two related compounds. Compound **1**, tyrosol [4-(2-hydroxyethyl)phenol]; compound **2**, 3-hydroxytyrosol; and compound **3**, 3,4-dihydroxyphenyl acetic acid.

[a]Compounds **1**–**3** and positive controls (aphidicolin and curcumin) were incubated with each pol (0.05 U) and other DNA metabolic enzymes. Enzyme activity in the absence of the compound was considered to be 100%. Data are shown as the mean values ± SD of three independent experiments.

their inhibitory activities toward various pols and other DNA metabolic enzymes. The purities of these compounds were determined to be greater than 98% by NMR analysis (data not shown).

Tyrosol (**1**) exhibited inhibitory activity toward 11 mammalian pols, including pols belonging to family A (human pol γ), family B (calf pol α, human pol δ, and human pol ε), family X (rat pol β, human pol λ, and human pol μ), and family Y (human pol η, mouse pol ι, and human pol κ),[4,5] with IC_{50} values of 42.0, 40.7–42.8, 34.3–38.1, and 44.4–46.1 μM, respectively (Table 2). Tyrosol (**1**) strongly inhibited the activities of X-family pols, with human pol λ being the most sensitive of all 11 of the mammalian pols tested toward this compound. Aphidicolin, a known inhibitor of pols α, δ, and ε,[1] and curcumin, a specific inhibitor of pol λ,[35] showed stronger pol inhibitory activity than tyrosol (**1**).

In contrast, 3-hydroxytyrosol (**2**) and 3,4-dihydroxyphenyl acetic acid (**3**) had no effect on any of these pols, indicating that the presence of a hydroxyl group at the 3-position tyrosol was having an adverse impact on its inhibitory activity toward mammalian pols, and that the whole structure of tyrosol (**1**) may be essential to its inhibitory activity. When activated DNA (bovine deoxyribonuclease I-treated DNA) was used as the DNA template-primer substrate instead of synthesized DNA [poly(dA)/oligo$(dT)_{18}$ (A/T = 2/1)], and dNTP was used as the nucleotide substrate instead of dTTP, the inhibitory effects of these compounds did not change (data not shown).

None of these three compounds exhibited any influence over the activities of the plant pols, including cauliflower pol α and rice pol λ. Furthermore, none of these compounds exhibited inhibitory activity toward prokaryotic pols, such as the Klenow fragment of *E. coli* pol I, *Taq* pol and T4 pol, or DNA metabolic enzymes, such as T7 RNA polymerase, human DNA topoisomerases I and II, mouse IMP dehydrogenase (type II), T4 polynucleotide kinase, and bovine deoxyribonuclease I (Table 2). On the basis of these results, tyrosol (**1**) can be classified as a selective inhibitor of mammalian pols. Given that tyrosol (**1**), which is an absorption component of the activated charcoal waste generated during the manufacture of sake, is an inhibitor of the mammalian pol species is of great interest.

Specific assays were used to determine whether the tyrosol (**1**)-induced inhibition was dependent on the binding of tyrosol (**1**) to DNA or to the enzyme. The extent of the interaction between tyrosol (**1**) and dsDNA was investigated based on the thermal transition of dsDNA by measuring the melting temperature (T_m) of dsDNA in the presence of an excess amount of tyrosol (**1**) (200 μM) using a spectrophotometer equipped with a thermoelectric cell holder. A thermal transition of T_m was not observed within the compound concentration range used in the assay. In contrast, a typical intercalating compound used as a positive control (ethidium bromide, 15

dx.doi.org/10.1021/jf502095p | J. Agric. Food Chem. 2014, 62, 7779–7786

μM) produced a clear thermal transition (data not shown). To determine whether the inhibitory effect of tyrosol (**1**) was caused by nonspecific adhesion to mammalian pols or its selective binding to specific sites, we proceeded to investigate whether an excessive amount of nucleic acid [poly(rC)] or protein [bovine serum albumin (BSA)] abrogated the effects of tyrosol (**1**). Poly(rC) and BSA had little to no effect on the pol-inhibitory activity of tyrosol (**1**) (data not shown), which suggested that this compound was binding selectively to the pol molecule. These observations indicated that tyrosol (**1**) was not acting as a DNA intercalating agent, and that it was exerting its inhibitory activity by binding directly to selected pol enzymes.

Effect of Tyrosol (1) and Its Analogues (2 and 3) on TPA-Induced Inflammation In Vivo. In our previous pol inhibitor studies, we observed a relationship between pol λ inhibitors and their ability to suppress TPA-induced inflammation.[6,7,9,35,36] With this in mind, we used an in vivo mouse ear inflammatory test in the current study to examine the anti-inflammatory activities of tyrosol (**1**), 3-hydroxytyrosol (**2**), and 3,4-dihydroxyphenyl acetic acid (**3**). The application of TPA (0.5 μg) to the mouse ear induced edema resulted in a 241% increase in the weight of the ear disk 7 h after application. As shown in Figure 4, pretreatment with 500 μg of tyrosol (**1**) had

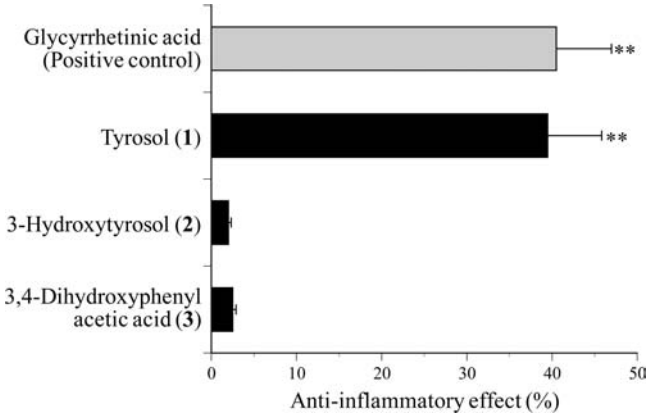

Figure 4. Anti-inflammatory activities of tyrosol (**1**) and its analogues (**2** and **3**) toward TPA-induced edema in a mouse ear model. Each compound (500 μg) was applied individually to one ear of a mouse, and TPA (0.5 μg) was applied 30 min later to both ears. Edema was evaluated after 7 h. The inhibitory effect is expressed as the percentage of edema. Data are shown as the mean values ± SD of six independent experiments. ** $P < 0.01$ versus controls.

a 55% anti-inflammatory effect, whereas 3-hydroxytyrosol (**2**) and 3,4-dihydroxyphenyl acetic acid (**3**) had no effect. The in vivo anti-inflammatory effects of these compounds therefore displayed a similar trend to that observed for their in vitro inhibitory effects toward mammalian pols (Table 2). The anti-inflammatory effect of glycyrrhetinic acid, which is a known anti-inflammatory agent, was very similar to that of tyrosol (**1**), and it was therefore concluded that tyrosol (**1**) was at least as effective as this benchmark compound.

Effect of Tyrosol (1) and Its Analogues (2 and 3) on Anti-Allergic Activity In Vivo. The IgE-mediated PCA reaction can be used as an in vivo tool to study the mechanism of the immediate hypersensitivity reaction. As shown in Figure 5, tyrosol (**1**) inhibited the PCA reaction in mice by 79.4%, when it was used at a dose of 100 mg/kg. In contrast, 3-hydroxytyrosol (**2**) and 3,4-dihydroxyphenyl acetic acid (**3**) had very little impact on the reaction. The antiallergic effects of

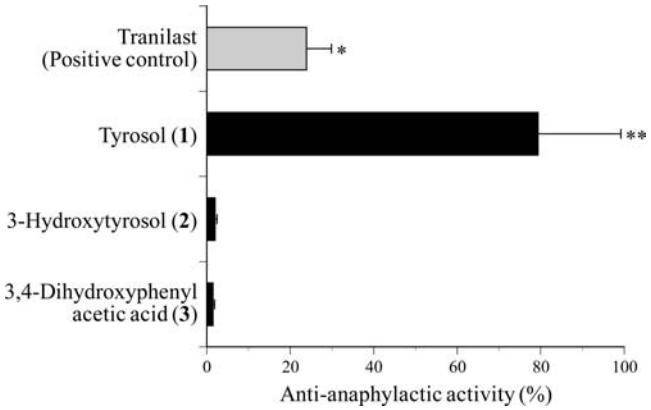

Figure 5. Antiallergic activities of tyrosol (**1**) and its analogues (**2** and **3**) measured by mouse PCA reaction. Each compound (100 mg/kg) was orally administered to the mice, and the IgE-dependent PCA reaction was investigated. Inhibition of anaphylactic activity by the vehicle control was taken as 0%. Data are shown as the mean values ± SD of six independent experiments. ** $P < 0.01$ and * $P < 0.05$ versus controls.

these compounds were therefore of the same order of magnitude as their in vitro inhibitory effects toward the mammalian pols (Table 2). Tranilast, which is a commonly used antiallergic drug that targets mast cell degranulation and inhibits the PCA reaction, caused 23.9% inhibition in this PCA reaction assay at a dose of 100 mg/kg (Figure 5). The inhibitory effect of tyrosol (**1**) was 3.3-fold greater than that of tranilast, which suggested that tyrosol could potentially be used as an antiallergic compound. Antiallergic effect by PCA experiment using rat of dorsal skin was same tendency as that using mouse ear (the inhibitory effect of 100 mg/kg tyrosol (**1**) was 2.6-fold greater than that of 100 mg/kg tranilast).

In addition to causing inflammation, TPA influences cell proliferation and exhibits tumor-promoting activity.[12] Anti-inflammatory agents are therefore expected to suppress DNA replication/repair/recombination in nuclei in relation to the action of TPA. Given that pol is related to repair/recombination,[1−3] our finding that it is a molecular target of tyrosol (**1**), which selectively inhibited mammalian pol activity (Table 2), is in agreement with this expected mechanism of anti-inflammatory/antiallergic action. Recently, we found that there is the positive correlation between inflammatory cytokines induction, such as TNF-α by lipopolysaccharide and expression of pol λ,[37] which has been implicated in 5′-deoxyribose-5-phosphate (dRP)-lyase activity,[38] V(D)J recombination,[39] translesion synthesis,[40] and base excision repair,[41] in cultured mouse macrophage RAW264.7 cells; thus, not only DNA polymerization activity, but also the protein expression of pol λ is likely to be important in inflammation. However, detailed mechanisms describing the way in which tyrosol (**1**) inhibits mammalian pols, such as pol λ, as well as the way in which it elicits it anti-inflammatory effects, remain unclear, and further studies are currently underway in our laboratory to elucidate these mechanisms.

Sake-byproduct is formed during fermentation of *Orzya sativa* to produce the Japanese rice wine "sake". This contains fermentation products of fungus (*Aspergillus oryzae*) and yeast (*Saccharomyces cerevisiae*) using rice tissues such as endosperm, bran, and germ, and this byproduct is an unused resource containing novel bioactive compounds. Therefore, we focused on the absorption extract, collected from the used activated

charcoal, of sake-byproduct. Activated charcoal is a form of carbon that is processed in such a way as to introduce multiple small, low-volume pores that are designed to increase the surface area available for adsorption or chemical reactions. These pores can also bind to low molecular weight compounds containing benzene rings, although very little is known about the molecular mechanism involved in adsorption of different materials by activated charcoal. Tyrosol (**1**) is produced from tyrosine during the fermentation of yeast,[42] and is therefore present in the fermented sake. Tyrosol (**1**) is a derivative of phenethyl alcohol, which is known as a natural phenolic antioxidant. As an antioxidant, tyrosol (**1**) can protect cells against injuries caused by oxidation.[43] To the best of our knowledge, this study represents the first reported account of tyrosol (**1**) being used to inhibit the activities of mammalian pols. These results suggest that the used activated charcoal generated as a waste product during sake production could be used as a good source of tyrosol (**1**) for its anti-inflammatory/antiallergic activities. This compound could also be used as an effective nutritional supplement because of its anti-inflammatory and antiallergic effects, which could lead to significant improvements in human health. The tyrosol (**1**)-enriched fraction of the used activated charcoal generated during the sake-brewing process, or purified tyrosol (**1**), could potentially be used in functional foods or cosmetics to deliver anti-inflammatory/antiallergic properties.

Three varieties of olive fruit (Mission, Manzanillo, and Lucca) were harvested (1−2 kg) from the Arai Olive Co., Ltd. in October, November, and December 2011 on Shodoshima Island, Kagawa Prefecture, Japan, for quantitatively measuring target chemicals during maturation.

Chemicals and Reagents. Dulbecco's modified Eagle's medium (D-MEM), phosphate-buffered saline (PBS) (−), and Triton X-100 were obtained from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Fetal bovine serum (FBS) was obtained from Equitech-Bio (Kerrville, TX). Antibiotic−antimycotic 100× was obtained from Invitrogen (Grand Island, NY). Mouse monoclonal anti-dinitrophenyl (DNP) antibody, albumin dinitrophenyl (HSA), Tyrode's salt solution, and *p*-nitrophenyl-2-acetamido-2-deoxy-β-D-glucopyranoside (*p*-NAG) were obtained from Sigma-Aldrich (St. Louis, MO). Bovine serum albumin (BSA) was obtained from Jackson ImmunoResearch Laboratories (West Grove, PA). Verbascoside, hydroxytyrosol, oleuropein, and luteolin were purchased from Extrasynthèse (Genay, France) and used without further purification.

Preparation of the Media and Samples. DMEM including 10% FBS and 1% antibiotic−antimycotic 100× was used as a base medium. Modified Tyrode's (MT) buffer was prepared by dissolving *N*-2-hydroxyethylpiperazine-*N*′-2-ethanesulfonic acid (HEPES) (4.76 g/L) and BSA (1 g/L) in Tyrode's salt solution. Anti-DNP IgE solution (antibody) was prepared by diluting mouse monoclonal anti-DNP antibody with the base medium (50 ng/mL). HSA solution (antigen) was prepared by dissolving HSA in MT buffer (2.5 μg/mL). The samples tested were dissolved in dimethyl sulfoxide (DMSO), and the solutions were added to MT buffer (final DMSO concentration was adjusted at 0.1%).

Extracts from Olive Fruit. Olive fruit (2.3 kg, Mission variety, December 2009) was crushed using a hand mixer. The crushed olives were then transferred to a 100% cotton bag, and the fruit juice and oil were separated from the pomace by compression. The pomace was then soaked in 100% methanol (700 mL) 3 times. The total methanol extracts (2.1 L) were obtained after the extraction. The oil separated from the methanol extracts was recovered again from hexane extracts by partition with 100% methanol and 100% hexane. Both solvents were removed under vacuum. Finally, 69 g of olive pomace extract was obtained from the methanol solution.

Extraction Using the Quick, Easy, Cheap, Effective, Rugged, and Safe (QuEChERS) Method. In quantitative comparison of olive metabolites in different varieties and seasons, the extraction was performed by the QuEChERS method that was usually used in residual agricultural chemicals analysis.[22,23] Olive fruit (100 g) was chopped in a food processor. A total of 10 g of the chopped sample was placed into a polypropylene centrifuge tube (50 mL), and 10 mL of acetonitrile was then added. The mixture was homogenized for 3 min. A total of 1 g of sodium chloride, 1 g of trisodium citrate dihydrate, 0.5 g of disodium hydrogen citrate sesquihydrate, and 4 g of anhydrous magnesium sulfate were added to the solution, and the mixture was immediately hand-shaken for 1 min. Finally, the mixture was centrifuged at 3000 rpm for 5 min. Hexane (10 mL) was added to the recovered acetonitrile layer to remove the remaining oil and chlorophylls. The acetonitrile extract obtained was dried using an evaporator with a vacuum pump. Solid acetonitrile extract (205.35 mg) was obtained from 10 g of green Mission olive in October 2011.

Fractionation of the Methanol Extracts from the Olive Pomace. The fractionation was performed by an Amberlite XAD-7 column according to Goto et al.,[24] who applied for the separation of anthocyanins. The separation of the olive pomace extracts (34.5 g) using an Amberlite XAD-7 column was started from 20% methanol (500 mL), and then 2 L each of 40% methanol, 60% methanol, 80% methanol, and 100% methanol were applied to the column in this order, as shown in Figure 1. Eluents (950 mL each of fractions 1−9) were collected using column chromatography. Each extract was dried under vacuum.

Isolation of 2-Hydroxy-3-ethylidene-5-(methoxycarbonyl)-3,4-dihydro-2*H*-pyran-4-acetic Acid 2-(3,4-Dihydroxyphenyl)-ethyl Ester (3,4-DHPEA-EA) and Elenolic Acid from Fractions 7 and 4. To isolate 3,4-DHPEA-EA, fraction 7 (50 mg) was purified using a high-performance liquid chromatography (HPLC) 5 μm

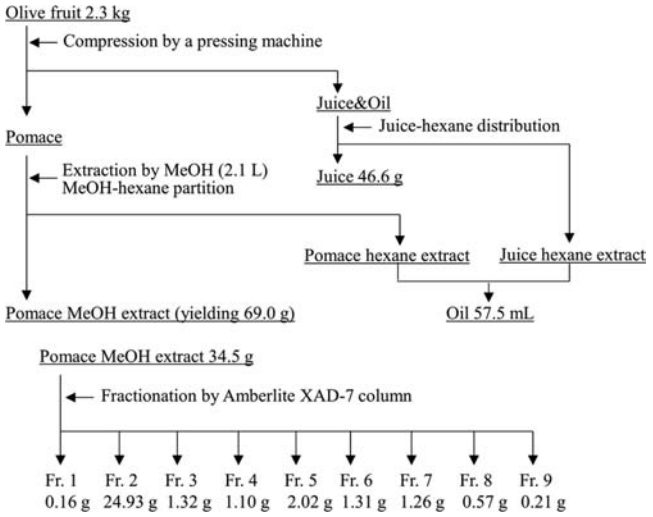

Figure 1. Extraction and fractionation from the Mission variety of green olive fruit harvested in December 2009.

octadecylsilane (ODS) column with a mixture of 16% acetic acid and 20% acetonitrile in water at a flow rate of 1 mL/min and an ultraviolet (UV) wavelength of 290 nm. Finally, 20 mg of pure 3,4-DHPEA-EA with 97% purity was isolated after drying under vacuum. To isolate elenolic acid, 50 mg of fraction 4 was purified using a HPLC 5 μm ODS column with a mixture of 8% acetic acid and 10% acetonitrile in water at a flow rate of 1 mL/min and at an UV wavelength of 250 nm. Finally, 10 mg of pure elenolic acid with 90% purity was isolated after drying under vacuum.

Physical data of 3,4-DHPEA-EA: UV λ_{max}, 243 and 279 nm; electrospray ionization−mass spectrometry (ESI−MS) (intensity of fragment ions), *m*/*z* 137 (100), 158 (68), 213 (57), 225 (30), 229 (12), 379 (72, $[M + H]^+$, $C_{19}H_{23}O_8$; found, 379.1373; calculated, 379.1393).

Physical data of elenolic acid: UV λ_{max}, 243 nm; ESI−MS (intensity of fragment ions), *m*/*z* 95 (80), 127 (100), 139 (65), 165 (30), 209 (11), 241 (70, $[M-H]^-$, $C_{11}H_{13}O_6$; found, 241.0708; calculated, 241.0712).

Nuclear magnetic resonance (NMR) data of 3,4-DHPEA-EA and elenolic acid are shown in Table 1.

Analytical HPLC. The HPLC analysis was performed by the following conditions according to Asada et al.[25] The HPLC system was comprised of a 250 × 4.6 mm COSMOSIL $5C_{18}$-AR II column, coupled to a JASCO MD 2010 Plus photodiode array (PDA) detector and double JASCO PU-980 pumps. Chromatograms were obtained from UV absorbance at 290 nm. The column temperature was set at 40 °C. The flow rate was 1 mL/min. The mobile phase used was a mixture of 2% acetic acid, 2.5% acetonitrile, and 1.5% phosphoric acid in water (A) and a mixture of 20% acetic acid, 25% acetonitrile, and 1.5% phosphoric acid in water (B). The total analytical time was 41 min, and the gradient was performed as follows: from 100 to 0% A for 35 min, and 0% A was kept for 5 min. For preparative HPLC, the HPLC system consisted of a 10 × 250 mm Develosil 5 μm ODS column, coupled to a JASCO 875-UV detector (290 nm for 3,4-DHPEA-EA and 250 nm for elenolic acid) with a JASCO PU-980 pump at 1 mL/min. For the preparative HPLC, non-volatile phosphoric acid was removed from the solvents described above. Hydroxytyrosol, 3,4-DHPEA-EA, elenolic acid, luteolin, verbascoside, and oleuropein were dissolved in dimethyl sulfoxide and then diluted to prepare a standard solution (0.067−0.5 μg/mL) for making the calibration curve of each chemical.

Hydrolysis of 3,4-DHPEA-EA. The hydrolysis of 3,4-DHPEA-EA was performed by hydrochloric acid according to the study by Davidek et al.[26] Fraction 7 extract (50 mg) containing 3,4-DHPEA-EA was dissolved in 1 mL of 1% HCl aqueous solution and left for 24 h at room temperature. The product and 3,4-DHPEA-EA were quantitatively monitored using a HPLC 5 μm ODS column.

β-Hexosaminidase Release Assay of RBL-2H3 Cells. For the amount of β-hexosaminidase release by basophilic leukemia cells, RBL-2H3 was determined using a previous method with some modifications.[4,27] RBL-2H3 were obtained from RIKEN BioResource Center Cell Bank (Ibaraki, Japan). The RBL-2H3 cells in the base medium (DMEM containing 10% FBS and 1% antibiotic−antimycotic 100×) were dispensed into a 24-well plate (2.5×10^5 cells/well) and were incubated overnight at 37 °C under a humidified 5% CO_2 atmosphere. After the cells were washed with 1 mL of PBS, they were incubated with 500 μL of antibody solution (mouse monoclonal anti-DNP antibody, 50 ng/mL dissolved in base medium) for 2 h of sensitization. A test sample solution of 490 μL was added to the well after washing twice with 500 μL of MT buffer (Tyrode's salt solution containing 1 g/L BSA and 4.76 g/L HEPES). The MT buffer was used as a control instead of the sample. The test sample was dissolved in DMSO and diluted with MT buffer (the final concentration of DMSO was set at 0.1%). After 10 min of incubation, albumin dinitrophenyl (10 μL, final concentration of 50 ng/mL) was added to each well and the cells were incubated for 30 min to evoke allergic reactions (degranulation). The reaction was stopped by cooling in an ice bath for 10 min. The supernatant (50 μL) was transferred to a 96-well plate and incubated with 100 μL of substrate (3.3 mM *p*-nitrophenyl-2-acetamide-2-deoxy-β-D-glucopyranoside) in 0.1 M citrate buffer (pH 4.5) at 37 °C for 25 min. The reaction was terminated by adding 100 μL of stop solution (2 M glycine buffer at pH 10.0). The absorbance (OD) was measured at 405 nm using a microplate reader (Thermo Scientific Multiskan FC, Yokohama, Japan). The gaining OD reflects β-hexosaminidase release. The calculation was performed using eqs 1 and 2 shown below. To obtain a valid value, the factors that are not typically induced by samples need to be excluded. In "blank", neither antibody solution nor sample was added to the cells to confirm spontaneous β-hexosaminidase release from the cells. In "control", MT buffer instead of samples was added to the cells to confirm β-hexosaminidase release from the cells in conditions without a sample. In "total", the cells were lysed in 0.1% Triton X-100 in MT buffer to confirm the total amount of β-hexosaminidase contained in the cells. In "sample", both antibody solution and samples were added to the cells to confirm β-hexosaminidase release from the cells in these conditions.

$$\text{ratio of } \beta\text{-hexosaminidase release (\%)} = \frac{(\mathrm{OD}_{\text{control}} \text{ or } \mathrm{OD}_{\text{sample}} - \mathrm{OD}_{\text{blank}})}{(\mathrm{OD}_{\text{total}} - \mathrm{OD}_{\text{blank}})} \times 100 \quad (1)$$

$$\beta\text{-hexosaminidase release (\%)} = \frac{\mathrm{OD}_{\text{sample}} - \mathrm{OD}_{\text{blank}}}{(\mathrm{OD}_{\text{control}} - \mathrm{OD}_{\text{blank}})} \times 100 \quad (2)$$

The ratio of β-hexosaminidase release of "control" should be greater than 25%.

β-Hexosaminidase Inhibitory Activity Assay. β-Hexosaminidase inhibitory activity was measured according to previous methods, with some modifications.[10−12] RBL-2H3 cells were grown in base medium. The cells were lysed in 0.1% Triton X-100 (5.0×10^5 cells/mL). The cell lysate (25 μL) was transferred to a 96-well plate. The tested solutions were diluted in different concentrations with MT buffer and then added to the sample well (25 μL); MT buffer was added to the control well (25 μL). Following that, 100 μL of 0.1 M citrate buffer (pH 4.5) containing 3.3 mM *p*-NAG (substrate) was added to each well and incubated for 25 min at 37 °C. The reaction was stopped by adding 100 μL of 2 M glycine buffer (the stop buffer solution) at pH 10.0 to each well. The absorbance (OD) of each reaction was measured at 405 nm using a microplate reader (Thermo Scientific Multiskan FC, Yokohama, Japan). The inhibitory activity of β-hexosaminidase was calculated using the following equation:

$$\beta\text{-hexosaminidase inhibitory (\%)} = \left(1 - \frac{\mathrm{OD}_{\text{sample}}}{\mathrm{OD}_{\text{control}}}\right) \times 100 \quad (3)$$

dx.doi.org/10.1021/jf502151b | J. Agric. Food Chem. 2014, 62, 7787−7795

NMR Analysis. ^{1}H, ^{13}C, distortionless enhancement by polarization transfer (DEPT)-45, DEPT-90, DEPT-135, correlated spectroscopy (COSY), heteronuclear correlation (HETCOR), and heteronuclear multiple-bond connectivity (HMBC) NMR spectra were recorded with a 600 MHz JNM-ECA spectrometer, dissolving samples in deuterated chloroform with tetramethylsilane (TMS, Isotec, Taiyo Nippon Sanso Corp., Ltd., Tokyo, Japan) as an internal standard.

Mass Spectrometry (MS) Analysis. Mass spectra of 3,4-DHPEA-EA and elenolic acid were measured using liquid chromatography/electrospray ionization quadrupole time-of-flight mass spectrometry (LC/ESI-Q-TOF-MS) analysis using an Acquity UPLC/Xevo QTof MS system (Waters). Chromatographic separations were conducted using an Acquity UPLC BEH C_{18} (1.7 μm, 2.1 × 50 mm) column (Waters). The instrument was operated with ESI source in negative-ion mode (elenolic acid) and positive-ion mode (3,4-DHPEA-EA).

Statistical Analysis. Statistical analysis was carried out using EZR (version 1.23) with the Tukey test [one-way analysis of variation (ANOVA)]. The values represents the mean ± standard deviation (SD) in triplicates at least. Significant differences was set at $p < 0.05$.

RESULTS AND DISCUSSION

Isolation and Identification of Antiallergic Active Compounds. The pomace portion showed significant suppression of β-hexosaminidase release (Figure 2) compared to the oil and juice. Therefore, the pomace extracts were further separated into nine fractions with an Amberlite XAD-7 column

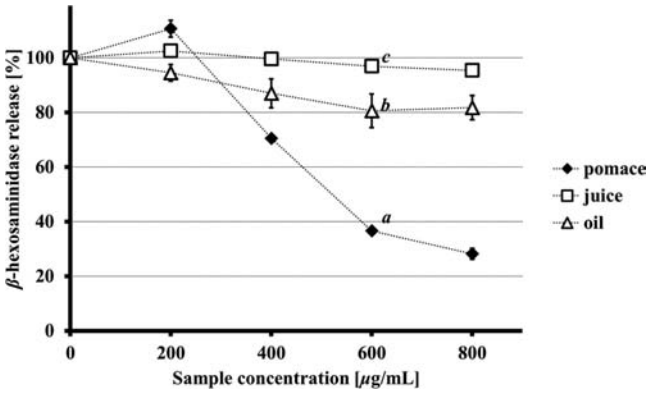

Figure 2. Antiallergic activity of olive extracts, such as pomace, oil, and juice, of Mission green olive fruit. Each value represents the mean ± SD ($n = 4$). Means with different letters are significantly different ($p < 0.05$).

chromatograph using solvents from 20% methanol to 100% methanol stepwise, as shown in Figure 1. The residues from pomace, oil, and juice were 69.0 g, 46.6 g, and 57.5 mL, respectively. Antiallergic activities of each fraction at the 200 μg/mL concentration found that fraction 7 exhibited the lowest β-hexosaminidase release (12.8 ± 5.3%), followed by fraction 6 (39.2 ± 2.1%), with significant differences ($p < 0.05$), while other fractions exhibited β-hexosaminidase release over 65% (Figure 3). Thus, fractions 1−3 did not show any antiallergic activity. On the other hand, fractions 4, 5, 8, and 9 showed some activity.

The nine fractions of the pomace extracts, the oil, and the juice were analyzed using HPLC, and the retention times and UV spectra obtained from a PDA detector were compared to known authentic and commercially available chemicals, as shown in Figure 4. There were large numbers of major peaks of chemicals (compounds **1**−**6**) in the pomace of the olive fruit (Figure 4A), but there were none of those substances in the oil

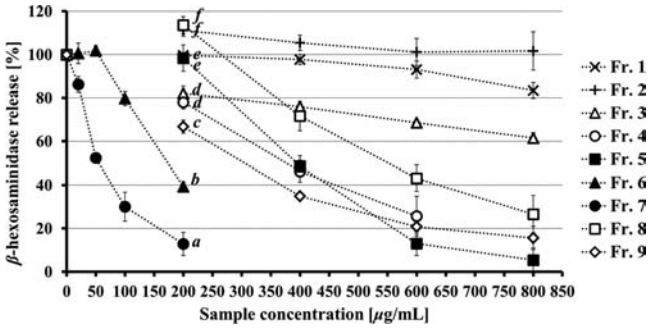

Figure 3. Antiallergic activity of each fraction of Amberlite XAD-7 column chromatography. Each value represents the mean ± SD ($n = 4$). Means with different letters are significantly different ($p < 0.05$).

and juice. Thus, hydroxytyrosol (**1**), which has significant antioxidant[28] and whitening[20,21] activities, was found in fractions 2 and 3 as a main chemical (Figure 4B). Verbascoside (**2**) was found in fractions 4 and 5. Oleuropein (**4**), which is a major compound in olive leaves, was found in fractions 4 and 5. A small amount of luteolin (**5**), which has been reported in many papers[10,29,30] as one of the most powerful antiallergic compounds, was detected in fractions 8 and 9.

Fractions 6 and 7, which had significant antiallergic activity, showed a marked peak as compound **6**. The antiallergic active compound in these two fractions was newly determined by MS spectra and NMR analyses.

Determination of the Structure of the Antiallergic Active Substance, Compound 6. Compound **3** in fraction 4 was purified using a 5 μm ODS preparative HPLC column. Mass spectra data of compound **3** showed the molecular ion at m/z 241.0708 ($[M - H]^-$, negative-ion mode) using high-resolution HPLC−TOFMS, giving the molecular formula as $C_{11}H_{14}O_6$ for compound **3**. ^{13}C NMR (DEPT) and ^{1}H NMR data made it possible to assign 11 carbon, 14 hydrogen, and 6 oxygen atoms in the molecule. ^{13}C NMR signals at 167.18, 176.09, and 199.74 ppm indicated two carboxylic acid or ester groups and carbonyl aldehyde. These data explain the existence of 5 oxygen and 3 carbon atoms in the molecule. ^{13}C NMR signals at 106.45 ppm (C) and 156.97 ppm (CH) indicated one double bond (C═CH−). Furthermore, DEPT analysis of signals at 69.66 and 51.50 ppm supported the existence of methoxy and methine groups with oxygen. Because two carboxylic acid or ester groups were found in the molecule, the methoxy group at position 12 should be part of the ester group (−COOMe). The methine group should not be the part of ester but part of the ether group. Other fragments of the molecule were one methyl group, one methylene group, and two methine groups.

The partial structure of fragment a in Figure 7 clarified the linkage of the partial structure of compound **3** from the $^{1}H-^{1}H$ COSY spectrum. Thus, the CH−O− group at position 8 was connected to one methyl group (at position 10 on the molecule), and one methine group (position 9) was coupled with one aldehyde group. The methine group at position 9 was related to the methine group at position 5 and then followed by the methylene group at position 6. Finally, one carboxylic acid at position 7 of the partial structure of fragment a was determined by HMBC data, as shown in Figure 7. Thus, HMBC measurement determined that the 176.09 ppm carbon signal (COO−) showed a strong cross-peak with the 2.27 and 2.95 ppm signals at H-6a and H-6b (C-6, 38.35 ppm ^{13}C NMR, methylene group).

For the partial structure of fragment b, HMBC data showed a strong correlation between the 167.18 ppm carbon signal

dx.doi.org/10.1021/jf502151b | J. Agric. Food Chem. 2014, 62, 7787−7795

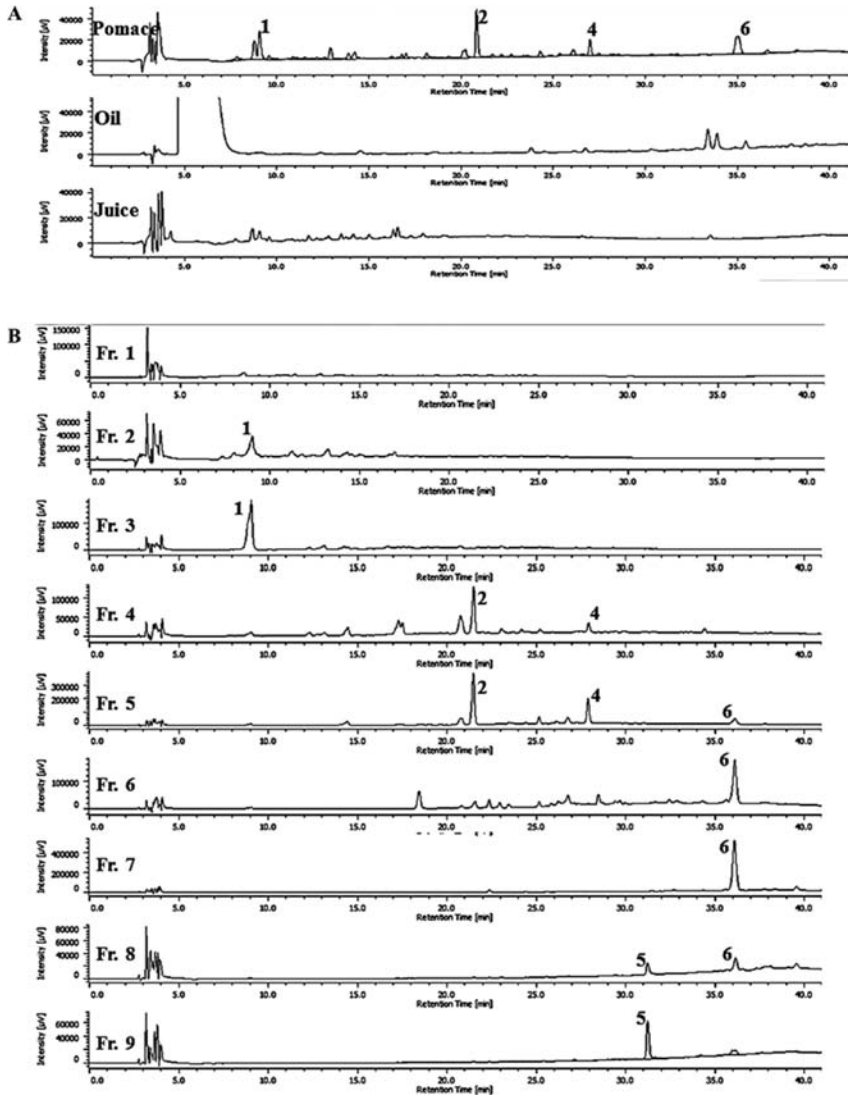

Figure 4. (A) HPLC chromatograms of extracts of pomace, oil, and juice. (B) HPLC chromatograms of nine fractions (λ = 290 nm). Compounds **1**, **2**, **4**, and **5** were identified as hydroxytyrosol, verbascoside, oleuropein, and luteolin, respectively, by comparing their retention times and UV spectra of each peak to those of authentic compounds.

(COOMe) at position 11 and the 7.62 ppm signal at H-3 (C-3, 156.97 ppm ^{13}C NMR) and the 3.35 ppm signal at H-5 (C-5, 27.90 ppm ^{13}C NMR). Furthermore, the COOMe group (fragment b) at position 11 was connected with C═CH− (Figure 7A) in the same manner. Finally, when fragments a and b are combined, the molecular formula of compound **3** was confirmed to be elenolic acid by comparing the MS spectra, spectra of ^{1}H and ^{13}C NMR,[31] and UV spectra (λ_{max} of elenolic acid = 239 nm)[32] (Figure 6).

Compound **6** (50% purity at 290 nm) in fraction 7 was hydrolyzed using 1% HCl for 24 h at room temperature to give elenolic acid and hydroxytyrosol (Figure 5A). The percentage of hydroxytyrosol calculated by standard curve was 24.3% in fraction 7 after hydrolysis. Elenolic acid was detected at 250 nm and found in a small amount in the hydrolysate and also in fractions 3−5 (Figure 5B).

Compound **6** should be an ester of hydroxytyrosol and elenolic acid because compound **3** and hydroxytyrosol were released by acid hydrolysis (Figure 5A). The chemical structure of compound **6** was determined by interpreting the mass spectra data and ^{1}H and ^{13}C NMR spectra, individually. The mass spectra data of compound **6** showed the molecular ion at m/z 379.1373 ([M + H]$^{+}$, positive-ion mode) using high-resolution HPLC−TOFMS, giving the molecular formula as $C_{19}H_{22}O_8$ for compound **6**. This molecular weight corresponds to the dehydrated compound of compound **3** ($C_{11}H_{14}O_6$) and hydroxytyrosol ($C_8H_{10}O_3$). Because the HMBC spectrum of compound **6** showed cross-peaks between C-7 and H-1′ (Figure 7B), compound **6** should be 3,4-DHPEA-EA.[32,33]

Antiallergic Active Compounds in Olive Pomace. Table 2 shows the antiallergic activities among the metabolites identified in olive pomace. Luteolin showed the highest antiallergic activity and is expressed as IC_{50} at 0.752 ± 0.1 μg/mL. The second highest activity was observed with 3,4-DHPEA-EA, with IC_{50} at 33.5 ± 0.6 μg/mL. Because the activities of hydroxytyrosol and elenolic acid were weaker than 3,4-DHPEA-EA, the ester linkage of the two molecules should enhance the antiallergic activity several times.

Furthermore, the antiallergic activity of 3,4-DHPEA-EA was 30 times greater than that of oleuropein. It was reported that the glycoside linkage decreased the activity because many flavonoids show greater activity in the aglycone of flavonoids.

dx.doi.org/10.1021/jf502151b | J. Agric. Food Chem. 2014, 62, 7787−7795

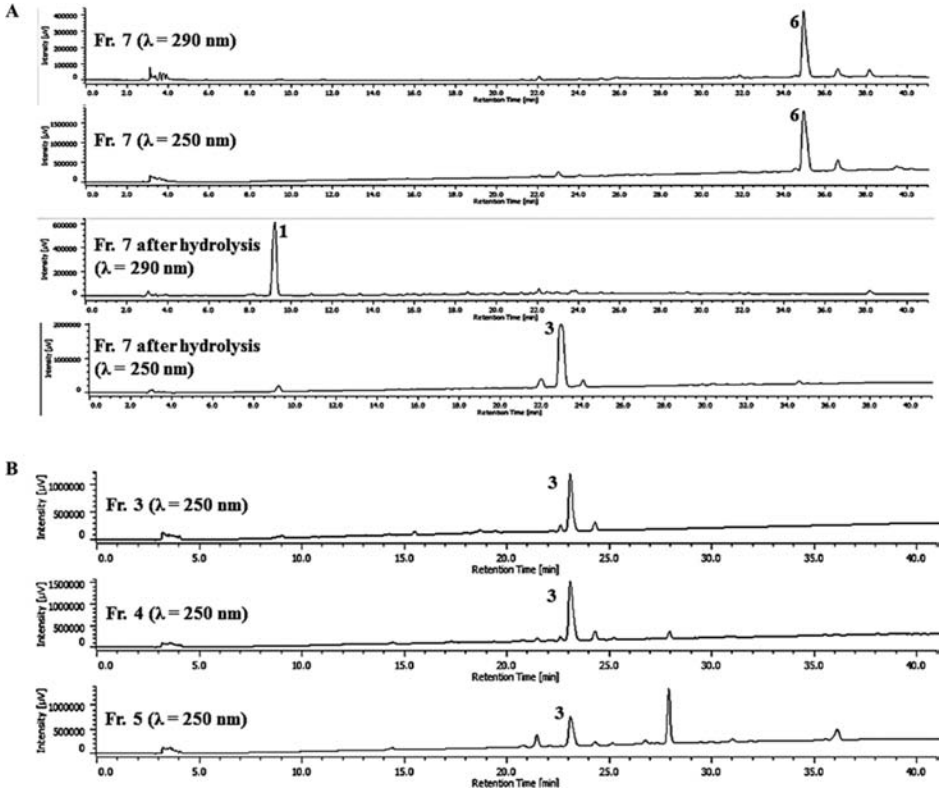

Figure 5. (A) HPLC chromatograms of fraction 7 before and after hydrolysis (λ = 250 and 290 nm). (B) HPLC chromatograms of fractions 3−5 (λ = 250 nm).

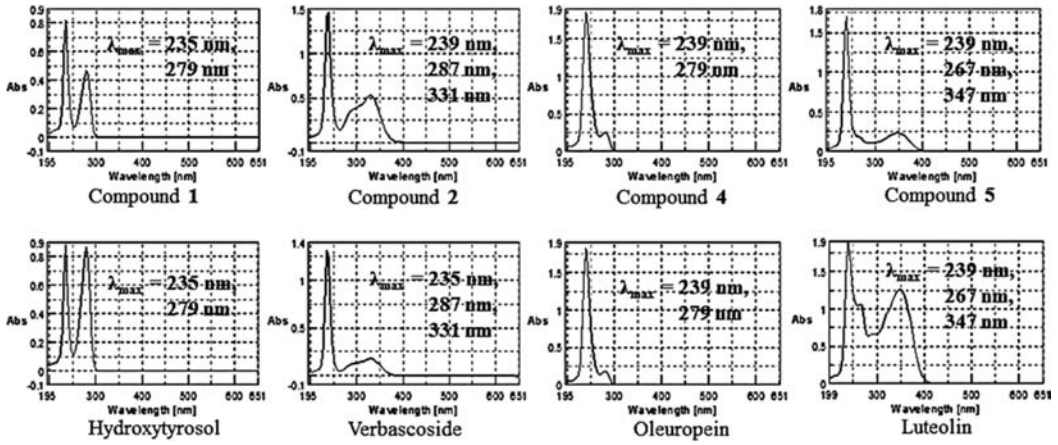

Figure 6. UV absorption spectra of the antiallergic substance in olive from the PDA detector of HPLC analyses. Sources of UV spectra: compound **1** (from fraction 3), compounds **2** and **4** (from fraction 5), and compound **5** (from fraction 9). λ_{max} of each compound is as follows: compound **1**, 235 and 279 nm; hydroxytyrosol, 235 and 279 nm; compound **2**, 239, 287, and 331 nm; verbascoside, 235, 287, and 331 nm; compound **4**, 239 and 279 nm; oleuropein, 239 and 279 nm; compound **5**, 239, 267, and 347 nm; and luteolin, 239, 267, and 347 nm.

The antiallergic activities of 3,4-DHPEA-EA (secoiridoid aglycone) and oleuropein (its glucoside) in olive pomace were consistent with those of flavonoids reported elsewhere.[10,34]

Each metabolite was tested for the enzyme inhibition rate of hexosaminidase itself. No enzyme inhibition was observed. Therefore, each metabolite inhibits the release of hexosaminidase from RBL-2H3 cells but did not inhibit the activity of hexosaminidase.

Finally, the total antiallergic activities of the isolated compounds were compared among all metabolites, as shown in Table 2. 3,4-DHPEA-EA showed significant antiallergic activity because of its low IC_{50} and was more abundant in the olive pomace than in luteolin. *p*-Hydroxyphenyl ethanol-decarboxymethyl elenolic acid ester dialdehyde [oleocanthal, *p*-HPEA-EDA, 3-(2-oxoethyl)-4-formyl-4-hexenoic acid 4-hydroxyphenethyl ester], one of the anti-inflammatory substances,[16] and 3,4-dihydroxyphenyl ethanol-decarboxymethyl elenolic acid ester dialdehyde [3,4-DHPEA-EDA, 3-(2-oxoethyl)-4-formyl-4-hexenoic acid 3,4-dihydroxyphenethyl ester] are secoiridoid compounds in some olives. In further research, we identified oleocanthal and 3,4-DHPEA-EDA in only trace amounts in the pomace of Japanese Mission olive (data not shown; retention times of 3,4-DHPEA-EDA and oleocanthal were 25.6 and 31.2 min under the same analytical conditions shown in Figure 4, respectively).

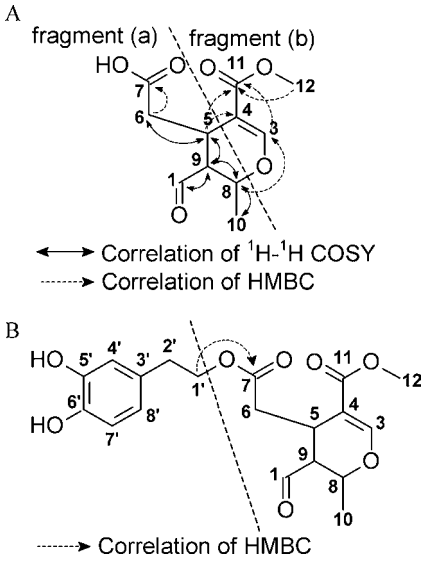

Figure 7. Chemical structure of (A) compound **3** and (B) compound **6** in olive.

The bioavailability of 3,4-DHPEA-EA and luteolin requires further study, especially in terms of antiallergic activity and the absorption rate of chemicals.[13] 3,4-DHPEA-EA is soluble in ethanol, diethyl ether, or other organic solvents, but luteolin can be resolved only in ethanol or ethanol containing water but not in diethyl ether. There may be big differences in solubility, absorption efficiency, and affinity of 3,4-DHPEA-EA and luteolin in neutral aqueous solution and physiological pH in the small intestine. Therefore, actual bioavailability in humans should be further studied.

Comparison of Active Chemicals in Three Kinds of Olive Fruit Using the QuEChERS Method. The QuEChERS method is commonly used to quantitatively analyze food residues and agrochemicals. The operation for solvent extraction, moisture removal, and recovery of agrochemicals can be performed simply and quickly. It is also suitable for a series of analyses of several samples.[22,23] Therefore, the QuEChERS method to analyze the active chemicals in olive pomace was selected as an appropriate extraction procedure for samples (about 10 g) of three varieties of olive leaves in different seasons. The comparative analysis of the antiallergic substances in olive fruit is shown in Table 3. Of the three varieties used in this study, the green olive fruit of the Mission variety in October had the highest concentration of 3,4-DHPEA-EA (50.33 ± 1.18 mg/10 g of olive fruit) as determined by quantitative analysis using ODS−HPLC and then decreased with the change in seasons. On the other hand, the amounts of hydroxytyrosol and elenolic acid increased when the harvesting period was delayed to November or December. To obtain efficient amounts of antiallergic substances, early harvest in October at the green stage of maturation was found to be the most important factor. Indeed, the antiallergic activities (IC_{50} values) of the fruit extracts harvested in October, November, and December were 138.91 ± 8.53 μg/mL for the October sample, 247.85 ± 3.34 μg/mL for the green sample in November, 337.71 ± 10.03 μg/mL for red sample in November,

Table 2. Comprehensive Antiallergic Activities of Substances Found in Olive Pomace Extract

compound	IC_{50} [μg/mL (μM)]	enzyme inhibition (%)[a]	amount (mg/kg)[b]	total activity[c]	active unit[d]
3,4-DHPEA-EA (**6**)	33.5 ± 0.6 (88.7)	0.5 ± 1.7	1854	55343	350
elenolic acid (**3**)	377.9 ± 1.6 (1561.6)	18.4 ± 4.3	902	2386	15.1
luteolin (**5**)	0.752 ± 0.1 (2.6)	3.8 ± 0.8	1.04	1382	8.74
hydroxytyrosol (**1**)	305.3 ± 15.2 (1980.9)	0.9 ± 0.9	140	458	2.89
oleuropein (**4**)	891.2 ± 6.1 (1648.8)	0.7 ± 7.5	346	388	2.45
verbascoside (**2**)	788.0 ± 29.2 (1261.7)	15.7 ± 5.5	125	158	1.00

[a]Values indicate enzyme inhibition (%) against β-hexosaminidase. Sample concentrations: hydroxytyrosol, 800 μg/mL; verbascoside, 800 μg/mL; luteolin, 2 μg/mL; 3,4-DHPEA-EA, 50 μg/mL; oleuropein, 800 μg/mL; and elenolic acid, 600 μg/mL. Each value represents the mean ± SD (n = 4). [b]The amount was calculated and shown from green Mission olive harvested in December 2009. [c]Total activity was estimated using the following formula: total activity = amount (mg/kg)/IC_{50} (mg/mL). [d]Active unit was calculated on the basis of the relative intensity of total activity (total activity of verbascoside was defined as 1.00).

Table 3. Amount of Hydroxytyrosol Derivative and Elenolic Acid in QuEChERS Extract Olive Harvest in 2011[a]

month	October			November		December
variety	Manzanillo	Mission	Lucca	Mission		Mission
color		green		green	red	red
extract from 10 g of olives						
weight (mg)	181.33	205.35	116.33	134.88	126.53	164.96
yield (%)	1.81	2.05	1.16	1.34	1.26	1.64

amount in 100 mg of extract (mg)	2.59 ± 0.02	2.45 ± 0.05	1.04 ± 0.02	6.00 ± 0.03	7.01 ± 0.12	4.48 ± 0.01
amount in 10 g of fruits (mg)	4.71 ± 0.03	5.04 ± 0.09	1.21 ± 0.02	8.04 ± 0.03	8.84 ± 0.15	7.35 ± 0.01
elenolic acid						
amount in 100 mg of extract (mg)	2.48 ± 0.05	3.05 ± 0.04	3.29 ± 0.01	6.82 ± 0.04	9.53 ± 0.01	5.11 ± 0.02
amount in 10 g of fruits (mg)	4.51 ± 0.08	6.27 ± 0.07	3.83 ± 0.01	9.15 ± 0.04	12.01 ± 0.01	8.39 ± 0.03
3,4-DHPEA-EA						
amount in 100 mg of extract (mg)	18.29 ± 0.09	24.50 ± 0.58	12.39 ± 0.08	12.71 ± 0.13	7.50 ± 0.02	0.69 ± 0.02
amount in 10 g of fruits (mg)	33.18 ± 0.17	50.33 ± 1.18	14.42 ± 0.09	17.04 ± 0.17	9.46 ± 0.02	1.14 ± 0.03

[a]Each value represents the mean ± SD (n = 3).

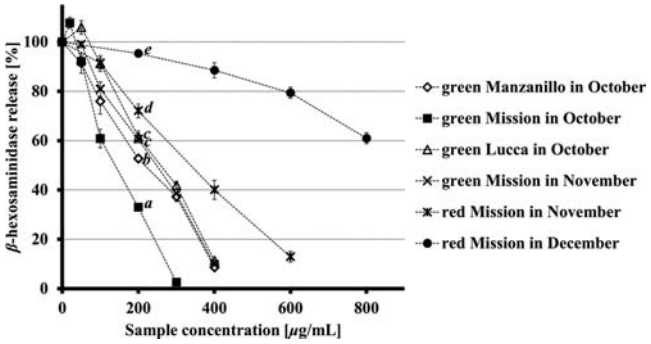

Figure 8. Difference in antiallergic activity of different olive varieties and harvesting seasons. Each value represents the mean ± SD ($n = 4$). Means with different letters are significantly different ($p < 0.05$).

and 919.83 ± 23.25 μg/mL for the December sample, as shown in Figure 8. Antiallergic activities of methanol extracts at the 200 μg/mL concentration in different harvesting time were conducted and then concluded that green Mission in October exhibited the lowest β-hexosaminidase release (32.9 ± 0.5%), followed by green Manzanillo in October (52.6 ± 1.2%), with significant differences ($p < 0.05$) (Figure 8) in the earlier harvest time, the greater antiallergic activity, and the higher concentration of 3,4-DHPEA-EA. The antiallergic activities of the olive fruit extracts depended upon the amount of 3,4-DHPEA-EA.

In conclusion, 3,4-DHPEA-EA was found as an antiallergic active substance in olive pomace. To increase the consumption of olive oils, olive oil manufacturers need to consider the utility of olive juice and pomace. The Japanese Mission variety contained a higher amount of 3,4-DHPEA-EA as a major component of the pomace fraction and also as a major antiallergic substance.

3′-$OCHH_3$	55.3	3.93 (3H, s)	55.4	3.93 (3H, s)	55.4	3.93 (3H, s)

[a]NMR spectroscopic data were recorded at 400 MHz (^{1}H NMR) and 100 MHz (^{13}C NMR). [b]NMR spectroscopic data were recorded at 300 MHz (^{1}H NMR) and 75 MHz (^{13}C NMR).

dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) were purchased from Sigma-Aldrich (St. Louis, MO, USA). Cell culture medium [Dulbecco's modified Eagle's medium (DMEM)], penicillin/streptomycin, fetal bovine serum (FBS), and all other materials required for culturing cells were purchased from Gibco BRL, Life Technologies (Grand Island, NY, USA).

Apparatus. Optical rotations were measured on a JASCO P-1020 polarimeter (Jasco Co., Tokyo, Japan). The UV spectra were measured on a Shimadzu UV-1700 spectrometer. The CD spectra were obtained using an MOS 450 detector from BioLogic. The FT-IR spectra were recorded using a Bruker IFS-55 spectrometer. HRESIMS experiments were performed on a MicroTOF spectrometer (Bruker Co., Karlsruhe, Germany). 1D NMR (^{1}H and ^{13}C) spectra were recorded on Bruker ARX-300, Bruker DPX-400, and Bruker AV-600 instruments (Bruker Co., Billerica, MA, USA); 2D NMR (HMBC, HSQC, and NOESY) spectra were recorded on Bruker DPX-400 and Bruker AV-600 instruments. High-performance liquid chromatography (HPLC) preparation was performed on a Waters 1525 instrument (UV 2549 detector) using a YMC C18 column (250 mm × 10 mm, 5 μm). GC was carried out using an Agilent 7890A gas chromatograph (Agilent Technologies, Inc., Santa Clara, CA, USA) equipped with an HP-5 capillary column (30 m × 320 mm × 0.25 μm).

Plant Material. The seeds of *P. tomentosa* were collected from Liaoning province of China on July 18, 2012. The plant material was identified by Prof. Jin-Cai Lu (Department of Traditional Chinese Materia Medica, Shenyang Pharmaceutical University). A voucher specimen (no. 20120718) has been deposited in the Herbarium of Shenyang Pharmaceutical University, Liaoning, People's Republic of China.

Extraction and Isolation. The dried and powdered seeds of *P. tomentosa* (15 kg) were refluxed three times 70% EtOH. Then, the aqueous alcohol solution was evaporated under reduced pressure to obtain the EtOH extract (650 g). This extract was suspended in H_2O and partitioned successively with petroleum ether, EtOAc, and *n*-BuOH. All fractions were tested in antioxidant (scavenging activities on DPPH and ABTS$^{\bullet+}$) and anti-inflammatory assays, and the ethyl acetate extract was found to exhibit the strongest activities of all these fractions. The ethyl acetate fraction (70 g) was subjected to a polyamide CC and eluted successively with MeOH/H_2O (30:70, 50:50, 70:30, 100:0, v/v) to yield four fractions (fractions 1−4). Fraction 1 (15 g) was separated on an ODS CC (4.0 × 50.0 cm) by gradient elution with MeOH/H_2O (30:80−100:0, v/v) to give four fractions (fractions 1-1−1-4). Fraction 1-1 (4 g) was subjected to a silica gel CC (2.5 × 50.0 cm) and eluted using a gradient of CH_2Cl_2/MeOH (40:1−3:1) to give five fractions (fractions 1-1-1−1-1-5). Fraction 1-1-4 was isolated by preparative HPLC using CH_3CN/H_2O (20:80, v/v; 8 mL/min) to afford **6** (17.4 mg, t_R = 15.8 min), **5** (18.5 mg, t_R = 18.1 min), **15** (70.4 mg, t_R = 25.6 min), and **16** (30.9 mg, t_R = 27.4 min). Fraction 1-2 (5 g) was loaded on a silica gel column CC (2.5 × 50.0 cm) using CH_2Cl_2/MeOH (50:1−5:1, v/v) as eluant to give six fractions (fractions 1-2-1−1-2-6). Fraction 1-2-2 was chromatographed on a Sephadex LH-20 column eluting with MeOH/H_2O (1:1) and then purified by semipreparative HPLC using MeOH/H_2O (34:66, v/v; 2.5 mL/min) to obtain **14** (13.3 mg, t_R = 15.7 min), **2** (9.3 mg, t_R = 22.5 min), **3** (8.9 mg, t_R = 22.7 min), **12** (14.1 mg, t_R = 24.7 min), and **13** (9.8 mg, t_R = 27.0 min). Fraction 1-2-3 was separated on an ODS CC (4.0 × 50.0 cm) with MeOH/H_2O (10:90−100:0, v/v) to give three fractions (fractions 1-2-3-A−1-2-3-C). Fraction 1-2-3-A was further isolated by semipreparative HPLC using MeOH/H_2O (40:60, v/v; 3.0 mL/min) to obtain **4** (12.7 mg, t_R = 23.0 min), **7** (25.2 mg, t_R = 25.7 min), **1** (18.3 mg, t_R = 29.2 min), and **11** (14.3 mg, t_R = 31.7 min). Fraction 1-2-3-B was purified by semipreparative HPLC using CH_3CN/H_2O (25:75, v/v; 3.5 mL/min) to obtain **10** (50.5 mg, t_R = 19.3 min), **8** (24.9 mg, t_R = 30.1 min), and **9** (36.4 mg, t_R = 30.2 min).

Acid Hydrolysis and Derivatization of Compounds 5 and 6. Each compound (4.0 mg) was hydrolyzed with 2 M HCl (5.0 mL), heated for 4 h at 95 °C, and extracted with EtOAc (3 × 4.0 mL). Then, the aqueous layer was concentrated in vacuo to appropriate volume, the solution was examined by TLC (EtOAc/BuOH/H_2O/HOAc, 4:4:1:1) and compared with authentic samples, and glucose was detected. The remaining aqueous layer was evaporated to dryness to give a residue, which was dissolved in pyridine (1.0 mL), and then L-cysteine methyl ester hydrochloride (2.0 mg) was added to the solution. The mixture was heated at 60 °C for 2 h, and 0.5 mL of tremethylsilyimidazole (TMSI) was added, followed by heating at 60 °C for 2 h. The reaction product was subjected to GC analysis with flame ionization detection. The column temperature was raised from 120 to 280 °C at the rate of 8 °C/min, and the carrier gas was N_2 (1.4 mL/min); the injection temperature was 250 °C and the injection volume, 1 mL. The absolute configuration of the monosaccharide were confirmed to be D-glucose by comparison of the retention times of its Me_3Si ethers with that of standard sample (t_R = 20.1 min).

DPPH Radical Scavenging Assay. The DPPH radical scavenging activity of samples was measured using a published method[20] with some modifications. The samples with different concentrations (0.1−100 μM) in EtOH (100 μL) were added to 0.2 mM DPPH in EtOH (150 μL). The mixture was shaken vigorously and then immediately incubated in darkness for 1 h. The absorbance of the reaction solution was determined in a Varioskan Flash (Thermo Scientific, Waltham, MA, USA) at 515 nm. Trolox, a stable antioxidant, was used as a positive reference. The DPPH radical scavenging activity in terms of the percentage of sample was calculated as follows: DPPH scavenging

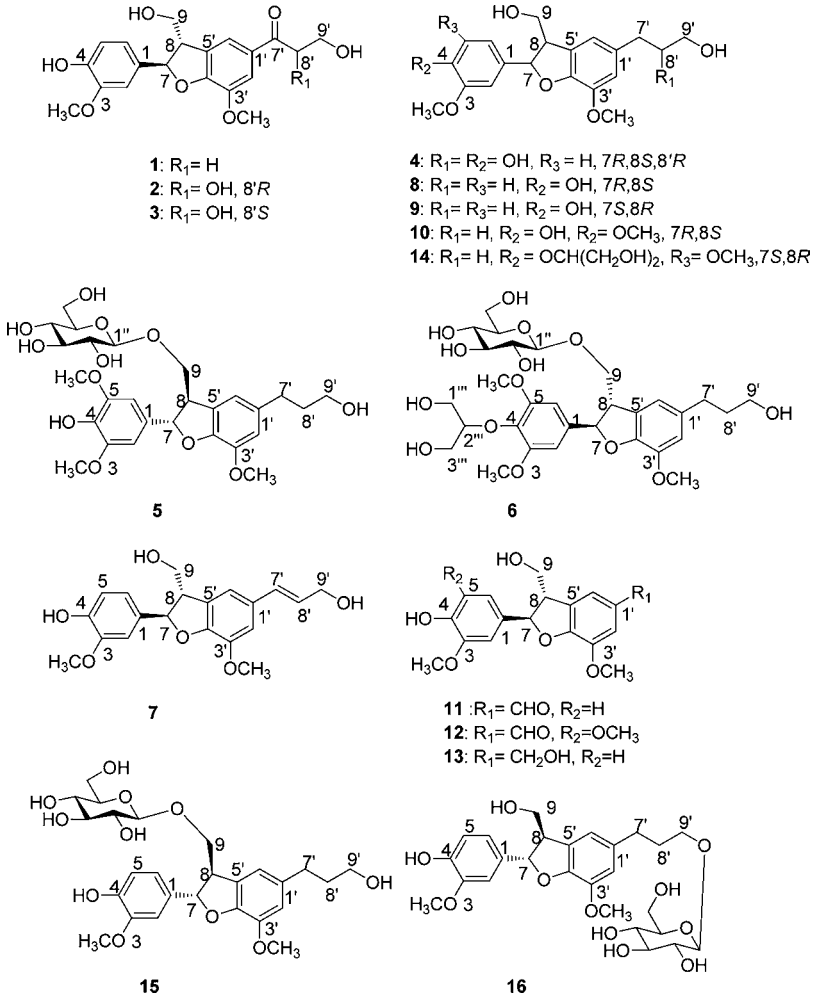

Figure 1. Structures of compounds **1**−**16**.

activity (%) = $[1 - (S - S_B)/(C - C_B)] \times 100\%$, where S, S_B, C, and C_B are the absorption of the sample, the blank sample, the control, and the blank control, respectively. Tests were performed in triplicate.

ABTS Radical Scavenging Activity Assay. The total antioxidant capacity was evaluated using an improved ABTS radical cation ($ABTS^{\bullet+}$) decolorization assay with some modifications.[21] $ABTS^{\bullet+}$ was produced by reacting 7 mM stock solution of $ABTS^{\bullet+}$ with 2.45 mM potassium persulfate (final concentration) and allowing the mixture to stand in the dark at room temperature for 16 h before use. The $ABTS^{\bullet+}$ solution was diluted with ethanol, to an absorbance of 0.7 ± 0.02 at 734 nm. An ethanolic solution (100 μL) of different concentrations of samples (0.1−100 μM) or trolox standard at various concentrations was mixed with 150 μL of diluted $ABTS^{\bullet+}$ solution. After reaction at room temperature for 10 min, the absorbance was measured at 734 nm using a Varioskan Flash (Thermo Scientific). The $ABTS^{\bullet+}$ scavenging ability was calculated using the formula $ABTS^{\bullet+}$ scavenging activity (%) = $[1 - (S - S_B)/(C - C_B)] \times 100$, where S, S_B, C, and C_B are the absorption of the sample, the blank sample, the control, and the blank control, respectively. Tests were performed in triplicate.

Cell Culture and Viability Assay. BV-2 cells, a mouse microglia cell line, were cultured in DMEM containing 5% fetal bovine serum (FBS), 100 U/mL penicillin, and 100 mg/mL streptomycin. BV-2 cells were plated at a density of 4×10^5/mL and maintained at 37 °C in a humidified atmosphere containing 5% CO_2. MTT assays were used to determine cell viability. Briefly, BV-2 cells were treated with the various concentrations of neolignan samples (0.1−100 μM) for 1 h and then stimulated with LPS (100 ng/mL) for 24 h. Then, the cells were incubated with a solution of 0.25 mg/mL MTT followed by incubation for 4 h at 37 °C and 5% CO_2. Supernatant was removed, and the formation of formazan was observed by monitoring the signal at 540 nm using a Varioskan Flash (Thermo Scientific).

NO-Releasing Assay. NO produced by the cells was determined by assaying the levels of NO_2^- using the Griess reagent. BV-2 cells were preincubated in 96-well plates at a density of 4×10^5 cells/well overnight and were then treated with different concentrations of the isolated compounds (0.1−100 μM) for 30 min. After 100 ng/mL LPS stimulation for 24 h, 100 μL of culture supernatant was mixed with the same volume of Griess reagent (1% sulfanilamide/0.1% *N*-(1-naphthyl)ethylenediamine dihydrocholoride/2.5% phosphoric acid). The absorbance was recorded at 540 nm on a Varioskan Flash (Thermo Scientific). NO concentration was calculated with reference to a standard curve of sodium nitrite produced using known concentrations.[22]

RESULTS AND DISCUSSION

Compound **1** was obtained as a colorless oil. The HRESIMS at m/z 397.1257 $[M + Na]^+$ indicated the molecular formula of $C_{20}H_{22}O_7$. The UV spectrum showed absorbances at λ_{max} 228 and 287 nm, and the IR spectral data indicated the presence of OH (3451 cm^{-1}), CO (1641 cm^{-1}), and aromatic rings (1600, 1510, and 1464 cm^{-1}).[23] The ^1H NMR spectrum of **1** showed the presence of a 1,3,4-trisubstituted benzene ring [δ 6.96 (1H, d, J = 1.6 Hz), 6.85 (1H, dd, J = 8.0, 1.6 Hz), and 6.79 (1H, J = 8.0 Hz)], a 1,3,4,5-tetrasubstituted benzene ring [δ 7.66 (1H, br s) and 7.57 (1H, br s)], and a sequence of methine−methine−methylene [CH(O)−CH(Ph)−CH_2O] successively coupled in

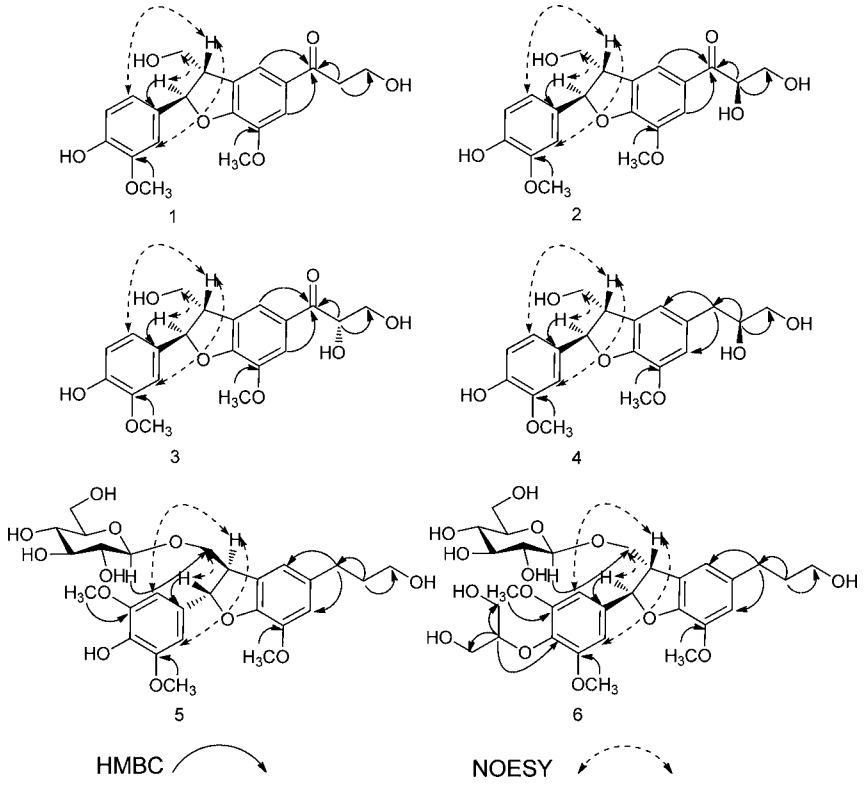

Figure 2. Key HMBC and NOESY correlations of compounds **1**−**6**.

this order [5.66 (1H, d, J = 6.4 Hz), 3.61 (1H, m) and 3.88 (2H, m)] in addition to two methoxyl groups at δ 3.93 (3H, s) and 3.85 (3H, s). The ^{13}C NMR spectrum of **1** (Table 1) showed 20 carbon signals including 2 methoxy groups, 12 aromatic units, a carbonyl carbon, and 5 aliphatic carbons. Careful comparison of the NMR data of **1** (Table 1) with those of known neolignans[24,25] revealed that compound **1** is a dihydrobenzofuran neolignan with oxidation of C-7′, which was confirmed by HMBC correlations (Figure 2) of H-8′ at δ 3.21 with C-7′, C-9′ and of H-9′ at δ 3.97 with C-7′ and C-9′. The relative stereochemistry of H-7 and H-8 was established as a trans relationship based on the $J_{7,8}$ coupling constant (6.4 Hz)[26] and NOESY cross peaks (Figure 2) H-7/H$_2$-9, H-8/H-2, and H-8/H-6.[27] As a negative Cotton effect at 281 nm ($\Delta\varepsilon$ = −2.61) was observed, 7*R* and 8*S* configurations were indicated.[27] On the basis of the above evidence, the structure of **1** was established as (7*R*,8*S*)-3,3′,5-trimethoxy-4′,7-epoxy-8,5′-neolignan-7′-one-4,9,9′-triol and named prunustosanan AI.

Compound **2** was also obtained as a colorless oil, with $C_{20}H_{22}O_8$ as its molecular formula, indicated by HRESIMS at m/z 413.1218 [M + Na]$^+$. The IR spectroscopic data of **2** showed absorptions for hydroxy (3441 cm^{-1}), carbonyl (1641 cm^{-1}), and aromatic groups (1600, 1516, and 1464 cm^{-1}).[23] Detailed comparison of ^{13}C NMR spectral data of **2** with those of **1** (Table 1) revealed signals at δ_C 40.5 and 57.5, moving downfield by δ_C 33.7 and 7.3, which were assigned to C-8′ and C-9′, respectively, indicating that one proton of H-8′ was substituted by a hydroxyl group. HMBC correlations (Figure 2) confirmed the structure and allowed the unambiguous assignment of its NMR data. The coupling constant $J_{7,8}$ (6.4 Hz) in the ^{1}H NMR of **2**, as well as the NOESY correlations (Figure 2) of H-7/H$_2$-9, H-8/H-2, and H-8/H-6, suggested a relative trans configuration.[26,27] In the CD spectrum, a negative Cotton effect at 282 nm indicated the 7*R*,8*S* configuration for **2**.[27] Additionaly, the absolute configuration of the vicinal diol (8′-OH and 9′-OH) moiety in **2** was determined by the induced CD spectra of its in situ complex with $Mo_2(OAc)_4$ in DMSO solution (Snatzke's method).[28,29] On the basis of the empirical helicity rule relating the sign of the Cotton effect of the diagnostic O−C−C−O moiety, the negative Cotton effect at 310 nm indicated an 8′*R* configuration. Accordingly, the structure of **2** was identified as (7*R*,8*S*,8′*R*)-3,3′,5-trimethoxy-4′,7-epoxy-8,5′-neolignan-7′-one-4,9,8′,9′-tetraol and named prunustosanan AII.

Compound **3** was proposed to have the molecular formula $C_{20}H_{22}O_8$ on the basis of HRESIMS. The IR and NMR spectroscopic data were in good agreement with those of **2** (Table 1), suggesting that the planar structure and relative configuration of **3** was the same as that of compound **2**. The CD spectrum showed a negative Cotton effect ($\Delta\varepsilon_{287}$ = −2.54), which indicated the absolute configurations of **3** to be 7*R*,8*S* configuration.[27] The 8′*S* configuration was supported by a positive Cotton effect at 310 nm in the $Mo_2(OAc)_4$-induced CD spectrum of **3**.[28,29] Thus, compound **3** was defined as an optical isomer of **2** and assigned as (7*R*,8*S*,8′*S*)-3,3′,5-trimethoxy-4′,7-epoxy-8,5′-neolignan-7′-one-4,9,8′,9′-tetraol, named prunustosanan AIII.

Compound **4** gave the positive HRESIMS m/z 399.1431 [M + Na]$^+$ (calcd for $C_{20}H_{24}O_7Na$, 399.1414), consistent with the molecular formula $C_{20}H_{24}O_7$. The ^{13}C NMR spectral data of **4** were very similar to those of **3**, except for the reduction of a carbonyl group (δ_C 198.2) on C-7′ in **4**. This difference was supported by the HMBC correlations (Figure 2) of H-7′/C-1′, C-2′, C-6′, and C-8′. The relative configurations of compound **4** were defined by the $J_{7,8}$ value (6.4 Hz) and NOESY spectrum (Figure 2).[26,27] The positive Cotton effect at 281 nm in the CD spectrum of **4** justified a 7*R*,8*S* configuration[27] as shown in Figure 1. In addition, the configuration of 8′-OH was confirmed

dx.doi.org/10.1021/jf502171z | J. Agric. Food Chem. 2014, 62, 7796−7803

using Snatzke's method: the negative Cotton effect at 310 nm in the induced CD spectrum of the complex of **4** with $Mo_2(OAc)_4$ indicated an 8′*R* configuration.[28,29] Consequently, the structure of **4** was undoubtedly elucidated as (7*R*,8*S*,8′*R*)-3,3′,5-trimethoxy-4′,7-epoxy-8,5′-neolignan-4,9,8′,9′-tetraol, named prunustosanan AIV.

The molecular formula of **5** was determined as $C_{27}H_{36}O_{12}$ by the $[M + Na]^+$ ion peak at *m*/*z* 575.2089 in the HRESIMS. The IR spectrum of **5** showed absorption for hydroxyl (3419 cm^{-1}), aromatic (1606 and 1515 cm^{-1}), and glycosidic (1075 and 1032 cm^{-1}) functions.[23,30] The NMR data of **5** (Table 2) were very similar to those of a known neolignan glucoside.[31] The anomeric proton signal at δ_H 5.62 (1H, d, J = 7.0 Hz, H-1″) in the ^{1}H NMR spectrum and six sugar carbon signals at δ_C 103.2 (C-1″), 73.8 (C-2″), 76.9 (C-3″), 70.1 (C-4″), 76.7 (C-5″), and 61.4 (C-6″) demonstrated that the sugar was β-D-glucose.[32,33] Furthermore, acid hydrolysis of **5** gave D-glucose. The position of the glucoside linkage was confirmed at C-9 by HMBC experiments (Figure 2), which showed long-range correlations between the 1″-proton and 9-carbon. The relative configuration of compound **5** was suggested to be relative trans according to the $J_{7,8}$ value of 6.0 Hz. This was verified by NOE correlations (Figure 2) of H-7/H_2-9 and H-8/H-6 and H-8/H-2 in the NOESY spectrum of **5**.[26,27] In addition, the CD spectrum of **5** showed a positive Cotton effect at 274 nm ($\Delta\varepsilon$ = 0.83), indicating that the absolute configuration of **5** was the (7*S*,8*R*) configuration.[31] Therefore, **5** was proposed to be (7*S*,8*R*)-3,3′,5-trimethoxy-4′,7-epoxy-8,5′-neolignan-7′-one-4,9,9′-triol 4-*O*-β-D-glucopyranoside, a neolignan glucoside prunustosananside AI.

Compound **6** showed the $[M + Na]^+$ ion peak at *m*/*z* 649.2464 in the positive-ion mode HRESIMS, indicating the molecular formula $C_{30}H_{42}O_{14}$. The IR spectrum of **6** showed the presence of aromatic (1605 and 1515 cm^{-1}) and glycosidic groups (1074 and 1032 cm^{-1}).[23,30] Comparison of its NMR data with those of **5** (Table 2) disclosed their extreme similarity. The main difference observed in the ^{13}C NMR spectrum of **6** was due to the presence of a 1,2,3-propanetriol moiety [δ_C 83.4 (C-2‴) and 60.7 (C-1‴and C-3‴)], which was confirmed by HMBC correlations (Figure 2) from H-2‴ to C-4, C-1‴, and C-3‴. Acid hydrolysis of **6** afforded glucose. Combined with its ^{1}H and ^{13}C NMR data, the configurations of the anomeric carbons of sugars were determined to be β-D for glucose.[32,33] The absolute configuration of glucose was further determined by acid hydrolysis and comparison with an authentic sample. The position of the glucoside linkage was confirmed at C-9 by HMBC experiments (Figure 2), which showed long-range correlations between the 1″-proton and 9-carbon. The trans relationship between H-7 and H-8 was inferred from their coupling constant ($J_{7,8}$ = 6.0 Hz), which was further verified by the NOE correlations (Figure 2) between H-7 and H_2-9 and between H-8 and H-2,6.[26,27] The CD spectrum showed a negative Cotton effect (283 nm, $\Delta\varepsilon$ = −2.57), which suggested a 7*R*,8*S* configuration.[27] According to the accumulated evidence above, the structure of **6** was designated (7*R*,8*S*)-3,3′,5-trimethoxy-4-(1‴,3‴-dihydroxy-2‴-propyloxyl)-4′,7-epoxy-8,5′-neolignan-7′-one-4,9,9′-triol 4-*O*-β-D-glucopyranoside and had been accorded the trivial name prunustosananside AII.

The other known compounds were identified as (*E*)-3-[(2*R*,3*S*)-2,3-dihydro-3-hydroxymethyl-7-methoxy-2-(4′-hydroxy-3′-methoxyphenyl)-1-benzo[*b*]furan-5-yl]-2-propen-1-ol (**7**),[34] (−)-7*R*,8*S*-dihydrodehydroconiferyl alcohol (**8**),[35] rel-(2α,3β)-7-*O*-methylcedrusin (**9**),[24] (+)-7*R*,8*S*-5-methoxydihydrodehydroconiferyl alcohol (**10**),[36] ficusal (**11**),[23] phenylcoumaran-α′-aldehyde (**12**),[37] 2-(4-hydroxy-3-methoxyphenyl)-3-methyl-5-hydroxymethyl-7-methoxycoumaran (**13**),[38] sakuraresinol (**14**),[39] dihydrodehydrodiconiferyl alcohol 9-*O*-β-D-glucopyranoside (**15**),[40] and dihydrodehydrodiconiferyl alcohol 9′-*O*-β-D-glucopyranoside (**16**)[40] by analyses of their ^{1}H and ^{13}C NMR and ESI-MS data in combination with the comparison of their data with the reported values.

Neolignans are a class of secondary metabolites produced by oxidative dimerization of two phenylpropanoid units. Neolignans exhibit a wide range of pharmacological effects, particularly antioxidant and anti-inflammatory activities.[41−43]

The antioxidant activities of **1**−**16** were evaluated by their ability to scavenge DPPH and ABTS radicals (Table 3).

Table 3. Antioxidant and Anti-inflammatory Activities of Compounds 1−16

compd	DPPH (IC_{50}, μM)[a]	ABTS (IC_{50}, μM)[a]	anti-inflammatory activity (IC_{50}, μM)[a]
1	>100	47.1 ± 2.7	>100
2	>100	46.4 ± 3.1	>100
3	>100	48.4 ± 4.1	>100
4	>100	57.1 ± 2.9	58.7 ± 3.0
5	42.6 ± 1.8	74.5 ± 3.9	34.7 ± 2.1
6	>100	>100	>100
7	>100	40.4 ± 1.8	4.4 ± 0.5
8	>100	33.7 ± 2.6	50.3 ± 2.6
9	>100	31.5 ± 2.3	48.4 ± 1.7
10	57.0 ± 2.3	43.0 ± 3.8	60.1 ± 4.9
11	>100	45.9 ± 2.8	4.8 ± 0.7
12	59.5 ± 3.5	56.2 ± 2.3	26.4 ± 1.4
13	>100	28.1 ± 1.1	44.3 ± 1.9
14	>100	>100	>100
15	>100	67.5 ± 5.9	>100
16	>100	51.4 ± 3.1	>100
trolox	39.2 ± 1.2	38.4 ± 0.8	nd[b]
mino	nd[b]	nd[b]	19.7 ± 1.5

[a]IC_{50} values represent the means ± SD of three parallel measurements. [b]nd, not determined.

Compounds **5**, **10**, and **12** showed moderate DPPH radical scavenging activities with IC_{50} values of 42.6 ± 1.8, 57.0 ± 2.3, and 59.5 ± 3.5 μM, respectively, whereas the other compounds (IC_{50} > 100 μM) did not display significant DPPH radical scavenging activity (Table 3). These results are comparable to those of previously isolated neolignan in other studies.[44,45] Zhao et al. reported that two new neolignan glycosides (IC_{50} > 100 μM) from *Pittosporum glabratum* were inactive in the DPPH radical scavenging assay.[46] A comparison of the structures of **5**, **10**, and **12** with those of **15**, **8**, and **11** indicated that additional methoxy groups at C-5 positions appeared to increase the antioxidant activity of the dihydrobenzofuran neolignans. In the ABTS assay, most of the isolated compounds showed significant antioxidant activity, with compounds **8** (IC_{50} = 33.7 ± 2.6 μM), **9** (IC_{50} = 31.5 ± 2.3 μM), and **13** (IC_{50} = 28.1 ± 1.1 μM) being the most potent, whereas compounds **1**−**4**, **7**, **10**−**12**, **15**, and **16** also showed moderate ABTS radical scavenging activities, comparable with that of the standard compound trolox with an IC_{50} value of 38.4 ± 0.8 μM (Table 3). Comparison of the structure of **6** with that of **5** or the structure of **10** with that of **14** showed

dx.doi.org/10.1021/jf502171z | J. Agric. Food Chem. 2014, 62, 7796−7803

that the antioxidant activity declined sharply when a hydroxyl group on the benzene ring was replaced by a 1,2,3-propanetriol group. This fact indicated that the free phenolic hydroxyl was crucial for the antioxidant activity, which was consistent with previous observations.[47,48]

In this investigation, we further evaluated the anti-inflammatory activity of the isolated compounds **1**−**16** using exposure to LPS-induced NO production in murine microglia BV-2 cell line. NO is a gaseous signaling molecule that plays key roles in immune and inflammatory responses and neuronal transmission in the brain.[49] Under normal conditions, NO has neuroprotective and antioxidant effects. However, excess production of NO from activated microglia causes a number of neurodegenerative diseases.[50] Inhibitors of NO production can be considered as potential anti-inflammatory agents. As shown in Table 3, compounds **4**, **5**, and **7**−**13** reduced NO levels in LPS-stimulated BV-2. In particular, the activities of **7** and **11** were more potent than that of the positive control, mino (IC_{50} = 19.7 ± 1.5 μM), in inhibiting NO production with IC_{50} values of 4.4 ± 0.5 and 4.8 ± 0.7 μM, respectively. The observed NO inhibitory activities appear to be somewhat correlated to their structures. For example, with regard to the results for compounds **8**, **9** and **11**−**13**, it appeared that shortening of the side chain might be important for the higher activity. Interestingly, comparing the structures and inhibitory activities of compound **7** with those of compounds **8** and **9**, it appeared that the double bond at C-7 may increase the inhibition of NO production. In addition, the inflammatory activity of one pair of isomers, **8** and **9**, was similar, which led us to conclude that the absolute configuration of the compounds might have little or no inhibitory effect on NO production. The cytotoxicity of compounds **1**−**16** to BV-2 cells was measured by an MTT assay. The results obtained indicated that the compounds exerted no cytotoxic effect at concentrations up to 100 μM and that the cell viability was >95% (see Table S1 in the Supporting Information), suggesting that compounds **1**−**16** do not affect normal cell growth.

In conclusion, this study reports the structures of 16 neolignans isolated from the active fraction of *P. tomentosa* seeds, along with their antioxidant and anti-inflammatory activities. Compounds **5**, **10**, and **12** showed moderate activity against DPPH, and compounds **8**, **9**, and **13** exhibited significant ABTS free radical scavenging activity (IC_{50} = 28.1−33.7 μM). Furthermore, compounds **7** and **11** exhibited remarkable NO inhibition with IC_{50} values of 4.4 ± 0.5 and 4.8 ± 0.7 μM, respectively, compared with the standard anti-inflammatory drug, mino, at 19.7 ± 1.5 μM. The results obtained in our study provide a potential justification for the use of the seeds from *P. tomentosa* industrial byproducts as a valuable source of raw material for new antioxidant and anti-inflammatory agents.

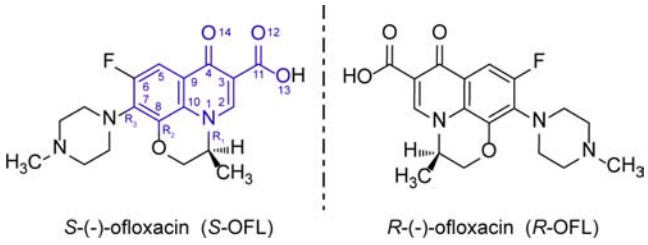

Figure 1. Chemical structures of ofloxacin stereoisomers. The common structure of QNs is labeled in blue.

animal byproducts and environmental samples with a simple, cost-effective, and high-throughput analysis method.

In this study, ofloxacin isomers with a stereogenic center were chosen as a model while predicting the epitopes of small molecules. The ofloxacin isomers were conjugated to bovine serum albumin (BSA) to form immunogens using the carbodiimide method. Two monoclonal antibodies (mAbs) were raised by BALB/c mice immunization, cell fusion, and hybridoma selection. Then, the enantioselectivity and specificity of mAbs were characterized using indirect competitive ELISA (icELISA). On the basis of the CR data, the epitopes of the ofloxacin enantiomers were predicted by both a hologram quantitative structure−activity relationship (HQSAR) method and a comparative molecular field analysis (CoMFA) method. The conformational structures of epitope on the carrier protein were modeled for explaining the experimental phenomenon and providing a theoretical guide for hapten design.

MATERIALS AND METHODS

Chemicals and Apparatus. *R*-(+)-Ofloxacin (*R*-OFL), *S*-(−)-ofloxacin (*S*-OFL), *S*-(−)-ofloxacin methyl ester (*S*-OFLM), and *R*-(+)-ofloxacin methyl ester (*R*-OFLM) were obtained from Daicel Chiral Technologies Company (Shanghai, China). Racemic ofloxacin (rac-OFL), pefloxacin (PEF) mesylate, gatifloxacin (GAT), norfloxacin (NOR) hydrochloride, sarafloxacin hydrochloride (SAR), garenoxacin (GAR), clinafloxacin (CLI), rufloxacin (RUF), ciprofloxacin hydrochloride (CIP), enrofloxacin (ENR), prulifloxacin (PRU), lomefloxacin (LOM), tosufloxacin (TOS), sparfloxacin (SPA), difloxacin (DIF), pazufloxacin (PAZ), marbofloxacin (MAR), moxifloxacin (MOX), pipemidic acid (PIP), nalidixic acid (NAL), and oxolinic acid (OXO) were purchased from Veterinary Medicine Supervisory Institute of China (Beijing, China). The structure of QNs is shown in Figure S1 of the Supporting Information. BSA, ovalbumin (OVA), 1-(3-(dimethylamino)propyl)-3-ethyl carbodiimide (EDC), 2,4,6-trinitrobenzene-1-sulfonic acid (TNBS), complete and incomplete Freund's adjuvant, horseradish peroxidase−immunoglobulin G (HRP−IgG), 3,3′,5,5′-tetramethylbenzidine (TMB), the culture media RPMI-1640, hypoxanthine−aminopterin−thymidine (HAT), hypoxanthine−thymidine (HT), and poly(ethylene glycol) (PEG) 2000 were purchased from Sigma-Aldrich (St. Louis, MO). All of the chemicals and organic solvents, which were analytical grade or better, were obtained from a local chemical supplier (Yunhui Trade Co., Ltd., Guangzhou, China). Deionized water was prepared using a Milli-Q water purification system (Millipore, Bedford, MA).

A total of 96 microtiter plates for ELISA were obtained from Yunpeng Technology Development Co., Ltd. (Xiamen, China). Female BALB/c mice, 6−8 weeks old, were provided by the Guangdong Medical Laboratory Animal Center (Guangzhou, China).

Buffers. Carbonate−bicarbonate buffer (CBS, 50 mmol/L, pH 9.6) is used as the coating buffer. Phosphate-buffered saline with Tween 20 (PBST) contains 10 mmol/L phosphate buffer, 0.8% saline solution, and 0.05% Tween 20 (pH 7.4). The phosphate−citrate buffer is a 40 mmol/L solution of sodium citrate (pH 5.5). The substrate solution contains 0.01% tetramethylbenzidine (TMB) and 0.004% H_2O_2 in citrate buffer.

Apparatus and Software. Ultraviolet−visible (UV−vis) spectra were recorded on a UV-160A Shimadzu spectrophotometer (Kyoto, Japan). The washing steps were carried out using a DEM-III microplate washer (Tuopu Analytical Instrument, Beijing, China). The absorbance readings were carried out at 450 nm with a Multiskan MK3 microplate reader (Thermo Fisher Scientific, Pittsburgh, PA). The competitive curves were analyzed with a four-parameter equation using the OriginPro 8.0 software (OriginLab Corporation, Northampton, MA).

Preparation of Hapten−Protein Conjugates. The haptens of the ofloxacin enantiomers containing a carboxylic acid group on dihydroquinoline were synthesized and bound to carrier proteins using the carbodiimide method to prepare the immunogenic agents.[25] BSA and OVA were used as carrier proteins for the immunogens and coating antigens, respectively. *R*-OFL and *S*-OFL were coupled to BSA separately for immunogens (*R*-OFL−BSA and *S*-OFL−BSA) and to OVA for coating antigens (*R*-OFL−OVA and *S*-OFL−OVA). The hapten−protein conjugates were prepared using the carbodiimide method with modifications. The hapten (10 mg) was dissolved with BSA or OVA (15 mg) in 0.9% normal saline (1.5 mL). EDC (30 mg) was added slowly to the hapten solution, and the mixture was stirred at room temperature for 30 min. The hapten−carrier protein conjugates were dialyzed against phosphate-buffered saline (PBS) at 4 °C for 72 h and then characterized with UV−vis spectrometry.

Preparation of mAbs. *Immunization.* The immunization protocol was similar to those previously described.[9] Briefly, eight BALB/c female mice were randomly separated into two equal groups, which were immunized with *S*-OFL−BSA and *R*-OFL−OVA, respectively. All of the mice aged 6−8 weeks were immunized intraperitoneally with the immunogens (50 μg for each mouse) at 2 week intervals. Blood samples were taken from the mice to detect the presence of antibodies against *R*-OFL or *S*-OFL using icELISA in a homologous conjugate-coated format on the eighth day after each immunization, starting 49 days after the first injection. The mouse that exhibited the best titer and inhibition rate for each hapten was selected as the donor of spleen cells for hybridoma production. Each selected mouse received a final intraperitoneal injection with 100 μg of immunogen, and the mice were sacrificed for cell fusion in the third day after the final injection. All experiments involving animals were performed in compliance with the relevant protective and administrant laws for laboratory animals of China and were conducted with the approval of the Institutional Authority for Laboratory Animal Care.

Cell Fusion, Hybridoma Selection, and Cloning. The fusion of SP2/0 cells (saved in our laboratory) and spleen cells was performed with PEG 2000 to produce hybridoma cells. The positive hybridomas were selected and cloned by limited dilution. After the fourth subcloning, monoclonal hybridomas possessing *S*-OFL or *R*-OFL enantioselectivity were selected to intraperitoneally inject to each pretreated mice. After 10 days, ascites fluids were obtained. They were first purified by sequential precipitation with caprylic acid and ammonium sulfate[26] and then purified using a protein-G column. The concentrations of purified mAbs were determined with UV−vis spectrometry. The isotype of mAbs were identified using IsoQuick Strips (Sigma-Aldrich).

icELISA Protocol. The ELISA was established on the basis of the common protocol of icELISA.[9] A total of 96 microtiter plates were coated with 100 μL of the coating antigen at the optimal dilution in CBS overnight at 4 °C, and then they were washed 2 times with PBST solution. Each well was blocked with 150 μL of 5% skim milk in PBS buffer for 3 h at 37 °C. After five washes, the plates were added with different concentrations of ofloxacin standard solutions (50 μL/well) and an appropriate concentration of antibody solutions (50 μL/well), both of which were diluted in PBST solution. Afterward, the plates were incubated for 40 min at 37 °C. After washing 5 times with PBST solution, the plates were incubated with 100 μL/well of HRP−IgG (diluted 1:5000 in PBST) for 30 min at 37 °C. After five washes, 100 μL of TMB solution was added to each well and incubated at 37 °C for 10 min; the color development was stopped by adding 50 μL/well of 2 mol/L H_2SO_4, and the absorbance was recorded at 450 nm (A_{450}). The concentrations of antibodies and coating antigens had been

optimized using checkerboard titration and standard curves. The conditions that resulting in the smallest IC_{50} were chosen as the optimized conditions ($1.0 < A_{max\ 450\ nm} < 1.2$). The 50% inhibition value (IC_{50}) was obtained from the four-parameter logistic equation of the sigmoidal curve[27] using OriginPro 8.0 (OriginLab Corporation, Northampton, MA).

CR Study. The specificity of the mAbs was determined using 24 ofloxacin analogues under optimized icELISA conditions. The CR values were calculated according to the following equation:

$$CR\ (\%) = IC_{50(\text{ofloxacin isomer, }\mu\text{mol/L})}/IC_{50(\text{analyte, }\mu\text{mol/L})} \times 100$$

HQSAR. All molecular modeling calculations were conducted with Sybyl 7.3 software package (Tripos, Inc., St. Louis, MO) running on a personal computer. The sketched QN structures were optimized to global low-energy conformations using the standard Tripos force field with an 8 Å cutoff for non-bonded interactions in conjunction with Gasteiger–Hückel charges,[28] a 0.005 kcal mol^{-1} $Å^{-1}$ termination gradient, and a dielectric constant of 4. A database containing ofloxacin stereoisomers and its analogues was established using the Sybyl 7.3 software package. Hologram lengths, atom count in fragments, and information sources were optimized, and the best model with the least standard error was selected. In both HQSAR and CoMFA models, pIC_{50} values ($pIC_{50} = -\log IC_{50}$) in homologous format were chosen as dependent variables, while the HQSAR or CoMFA descriptors were chosen as independent variables. The HQSAR descriptors (independent variables) were related to pIC_{50} (dependent variable) using partial least-squares (PLS) analysis. Fragment contribution to pIC_{50} was illustrated by encoded colors.

CoMFA. The optimal structures obtained above were put into a database. A database including all of the QN molecules previously sketched and optimized was built. The common structure of the QNs (4-oxo-4,7-dihydroquinoline-3-carboxylic acid nucleus) was chosen as the basis for the alignment. Experimental pIC_{50} (dependent variable) and CoMFA descriptors (independent variables) were correlated by PLS analysis with a leave-one-out (LOO) cross-validation and no cross-validation, respectively. The favored and disfavored contour maps could be visually investigated.

Hapten–Carrier Conjugate Modeling. The chiral hapten–carrier conjugate was modeled by Sybyl 7.3. BSA was chosen as the model for the carrier protein, and the crystal structure of BSA [Protein Data Bank (PDB) ID: 4F5S] was obtained from the PDB. BSA was composed of two chains: chain A and chain B. A substructure containing 80 amino acids (AA) at the N terminus of chain A was chosen as the BSA mimic. The carboxyl groups from the ofloxacin isomers were randomly coupled with amino groups, forming a new amido linkage. The conformational structures of ofloxacin isomer–BSA conjugate mimics were optimized using staged minimization: first the ligands, then the side chains, then the biopolymer without C-α, and finally, minimize all. The weighted root-mean-square (RMS) distances of carbon atoms between the free and conjugated ofloxacin isomers were measured using the Fit Atoms module of Sybyl 7.3. The distances from the chiral carbon of the ofloxacin isomers to the nearest atom from the carrier protein residues were also measured.

RESULTS AND DISCUSSION

Production of mAbs. Ofloxacin isomers are small molecules (MW = 361.37 < 1000) that must be conjugated to a carrier protein to elicit an immune response. Through the free carboxylic acid on the ofloxacin isomer, the molecule was conjugated with BSA or OVA using EDC. The BSA conjugates (*S*-OFL–BSA and *R*-OFL–BSA) were used as immunogens, and the OVA conjugates (*S*-OFL–OVA, *R*-OFL–OVA, and rac-OFL–OVA)were used as coating antigens.

Two groups (four mice in each group) of mice were immunized with conjugates *S*-OFL–BSA and *R*-OFL–BSA, respectively. The mouse that showed the highest titer of antiserum and the best inhibition with corresponding hapten in icELISA in each group was selected for monoclonal antibody production. After cell fusion and four rounds of limited dilution screening, hybridomas named WR1 (obtained from the *R*-OFL–BSA immunizing group) and MS1 (obtained from the *S*-OFL–BSA immunizing group) that can secrete the highest specificity antibodies against the corresponding ofloxacin isomer (*R*-OFL and *S*-OFL, respectively) were obtained. Finally, mAbs were obtained from WR1 and MS1 by ascites production and purified using a protein-G sepharose column. The isotypes of mAb-WR1 and mAb-MS1 were all IgG1/κ.

Enantioselectivity of Antibodies. Competitive ELISA can be divided in general into homologous and heterologous formats. In homologous icELISA (Ho-icELISA) formats, the same hapten is used for immunization and assay purposes, whereas in heterologous icELISA (He-icELISA) formats, the immunizing hapten and the competitor hapten (coating antigen hapten) differ in their molecular structures (e.g., ofloxcin isomer).

icELISA using OVA conjugate as the coating antigen was applied to investigate the enantioselectivity and sensitivity of the obtained mAbs to ofloxacin stereoisomers. The optimal concentration of mAbs and coating antigens by checkerboard titration is shown in Table S1 of the Supporting Information. In Ho-icELISA, the optimized concentrations of *R*-OFL–OVA, mAb-WR1, *S*-OFL–OVA, and mAb-WS1 were 250.0, 40.0, 250.0, and 5.5 μg/L, respectively. Ho-icELISA results showed that mAb-WR1 selectively recognizes *R*-OFL and mAb-MS1 selectively recognizes *S*-OFL (Figure 2). The sensitivity (IC_{50}) of mAb-WR1 to *R*-OFL (0.0344 μmol/L) is higher than that of *S*-OFL (0.3988 μmol/L) (Figure 2a and Table 1). Concurrently, the sensitivity of mAb-MS1 to *S*-OFL (0.0018 μmol/L) is higher than that of *R*-OFL (0.0096 μmol/L) (Figure 2b and Table 1). Both mAbs predominately have enantioselectivity to the corresponding ofloxacin isomer.

The effect of He-icELISA on enantioselectivity was also investigated. The results showed that icELISA based on heterologous coating antigens have no obvious effect on enantioselectivity of mAb-WR1 and mAb-MS1 (Table 2). For mAb-WR1, both the CR values of *S*-OFL in Ho-icELISA and He-icELISA were about 8%. Concurrently, for mAb-MS1, both the CR values of *S*-OFL in Ho-icELISA and He-icELISA were about 18%. Above all, we can conclude that the enantioselectivity of mAbs was not affected by the heterologous coating reaction model and the enantioselectivity of mAbs (mAb-WR1 and mAb-MS1) would be the intrinsic property of its own.

Sensitivity and Specificity of Antibodies. The sensitivity and specificity data showed that mAb-WR1 and mAb-MS1 have a high sensitivity and specificity (Table 1). In Ho-icELISA of mAb-WR1 and mAb-MS1, 24 analytes were employed for the CR study. The IC_{50} of mAb-WR1 to *R*-OFL is 10 times larger than that of mAb-MS1 to *S*-OFL. That is to say, the sensitivity of mAb-MS1 is higher than that of mAb-WR1. A similar rule was also found in other antibodies, including anti-serum against ofloxacin stereoisomers in our studies. It seems that different enantiomers may be different in immunogenicity, especially in sensitivity.

The CR studies showed that both mAb-WR1 and mAb-MS1 have a relatively high specificity (Table 1). Except for *S*-OFLM, *R*-OFLM, RUF, GAR, and MAR, the CR values of other QNs are lower than 2% or even not detected (ND). The CR values of PAZ (ND for mAb-WR1 and 0.2% for mAb-MS1) and DIF (0.7% for mAb-WR1 and 1.0% for mAb-MS1) were much lower, although they have a little bit of difference in R1, R2 (oxazine ring), or R3 (piperazinyl ring) groups compared to

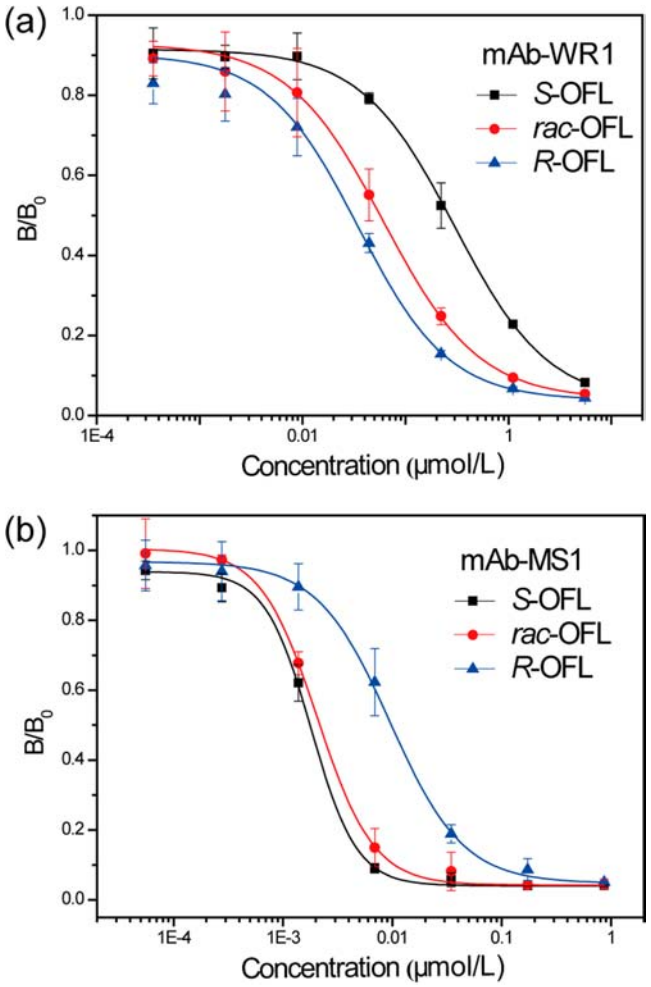

Figure 2. Enantioselectivity of (a) mAb-WR1 and (b) mAb-MS1 by icELISA using the homologous coating antigen.

ofloxacin enantiomers. This result indicated that R1, R2, and R3 were critical in the hapten−antibody interaction.

However, what properties and how groups affected the hapten−antibody recognition from the quantitative perspective were still unknown. Thus, 2D- and 3D-QSAR were performed to explore deeper insights.

HQSAR Analysis. HQSAR is a technique that employs fragment fingerprints as predictive variables of biological activity or other structural-related data.[29] Although HQSAR model generation deals with the 2D structure-directed fragment fingerprints, information on chirality is included in model development and suitable for chiral recognition investment. The model development was performed using parameters: atom (A), bond (B), connection (C), chirality (Ch), hydrogen (H), and donor/acceptor (DA). The HQSAR technique gives us straightforward clues about the individual atomic contribution to the biological activity through the different color codes. As far as we know, this is the first time to perform HQSAR for hapten−antibody chiral recognition.

In HQSAR analysis, the correlation between descriptors (molecular hologram, "bins") and biological activity of the antibody (pIC_{50}) was performed by PLS with cross-validation. The parameters and statistical results of HQSAR for mAb-WR1 and mAb-MS1 are shown in Table 3. For mAb-WR1, on the basis of optimized hologram parameters (the best length was 307; fragment size was 4−7; and information sources were A, B, C, and Ch), the established HQSAR model showed high correlation (r^2_{ncv} = 0.95) and predictive ability (r^2_{cv} = 0.68). For mAb-MS1, the HQSAR modeling in the absence of NOR (NOR is an outlier in the data set) was obtained, and under the optimized hologram parameters (best length was 199; fragment size was 4−7; and information sources were A, B, C, H, Ch, and DA), the results showed high correlation (r^2_{ncv} = 0.96) and predictive ability (r^2_{cv} = 0.56). In both of the HQSAR models, parameter Ch played an important role in modeling. In the absence of parameter Ch (other parameters are shown in Table 3), the value of r^2_{cv} was only 0.41 (for mAb-WR1) and 0.42 (for mAb-MS1). In other words, in this study, the chirality of the

molecule played an important part in hapten−antibody recognition.

An atomic contribution map for chiral recognition based on HQSAR analysis was shown by encoded color (Figure 3 and Figure S3 of the Supporting Information). Red and orange contours indicate negative contribution to the hapten−antibody recognition. On the contrary, green and yellow regions represent positive contribution to the antigen−antibody interaction. The white color stands for intermediate contribution to activity, and the cyan color represents the common structure of QNs. The atomic contribution maps of HQSAR told us the following: (i) The chiral center was green, which indicated that the chiral center played an important role in chiral recognition. (ii) With the decrease of the CR vale, the color of the oxazine ring and the piperazinyl ring turned from green to red, gradually. The color contour on the oxazine ring and the piperazinyl ring reflected the sensitivity of each QN to some extent. This phenomenon implied that the epitope of ofloxacin isomers may be mainly composed of the oxazine ring and the piperazinyl ring and antibodies recognize haptens from the side of the oxazine and piperazinyl rings. (iii) The greened (or yellowed) methoxy group of *R*-OFLM and *S*-OFLM showed that mAb-WR1 and mAb-MS1 recognize the hapten−carrier linking group during antigen−antibody interaction. (iv) The common structure also played a role in the hapten−antibody interaction.

CoMFA. Besides HQSAR, a 3D-QSAR method (CoMFA) was performed to investigate the hapten−antibody interaction. CoMFA is based on the ligand structure, making the spatial alignment crucial when determining the accuracy of these approaches. In this study, the structures of the QNs were aligned into a lattice box by fitting with a 4-oxo-4,7-dihydroquinoline-3-carboxylic acid skeleton as a common structure (Figure 1). The aligned QNs are shown in Figure 4.

The statistical results obtained from standard CoMFA models are given in Table 4. In the model of mAb-WR1, PLS analysis showed a high cross-validation correlation

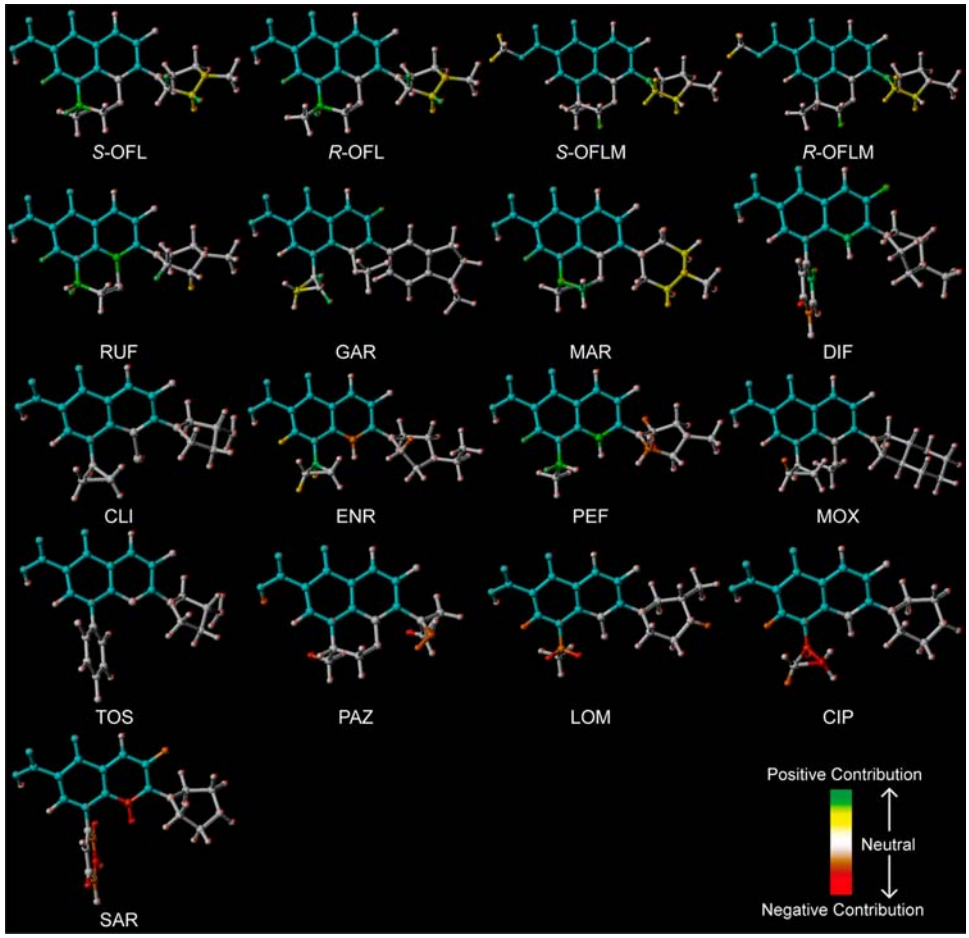

Figure 3. Atomic contribution map for chiral recognition based on HQSAR analysis of mAb-WR1. Red and orange contours represent negative contribution; green and yellow contours are for positive contribution; and the cyan contour represents the common backbone of QNs.

steric	0.73	0.78
electrostatic	0.27	0.22

[a] r^2_{cv} = cross-validated correlation coefficient after the LOO procedure. [b] r^2_{ncv} = correlation coefficient. [c] ONC = optimum number of components. [d] SEE = standard error of the estimate.

coefficient (r^2_{cv}) value of 0.52 with three components. NOR is an outlier in the data set of mAb-MS1 because of its high residual value (1.64). The CoMFA model of mAb-MS1 in the absence of NOR resulted in an ideal r^2_{cv} (0.51). Normally, the r^2_{cv} is used as a criterion for both the robustness and predictive ability of the model. In many cases, a high r^2_{cv} value (usually >0.50) is considered an indicator or the ultimate proof to show that the model is accurate or reliable.[30] The final CoMFA model was generated using non-cross-validated PLS analysis to give a high non-cross-validated correlation coefficient (r^2_{ncv} = 0.89 for mAb-WR1 and 0.96 for mAb-WR1). A model with a correlation coefficient value greater than 80% ($r^2_{ncv} \geq 0.80$), a large *F* value, and a small standard error of the estimate (SEE) has good predictability.[31] The low (usaually <0.05) value of probability of $r^2 = 0$ means that the QSAR models were statistically significant. The field contribution showed that multiple fields (steric and electrostatic fields) co-effected chiral recognition. Correlations between the experimental and predicted pIC_{50} values for those analytes according to CoMFA analyses were reported in Figure S4 of the Supporting Information. The high statistical parameters (adjusted $r^2 = 0.88$ for the mAb-WR1 model and adjusted $r^2 = 0.90$ for the mAb-MS1 model) showed an acceptable statistical correlation and predictability in both the mAb-WR1 and mAb-MS1 models.

The CoMFA contour maps of mAb-WR1 (panels a and b of Figure 5) and mAb-MS1 (panels c and d of Figure 5) in combination with *R*-OFL are shown in Figure 5. The interaction maps were found mainly around the oxazine and piperazinyl rings, indicating that this moiety has great influence on the hapten−antibody recognition. In other words, the epitope of the ofloxacin enantiomers were mainly located in the side of the oxazine ring and the piperazinyl ring, coinciding with the HQSAR results. This epitope would be recognized by immune molecules [such as a major histocompatibility complex (MHC), B cell receptor (BCR), T cell receptor (TCR), antibody, etc.] during an immune response.

In the steric contour map (panels a and c of Figure 5), the green contours refer to sterically favored regions, while the yellow contours indicate sterically disfavored regions. The yellow contours near the chiral center showed that steric hindrance may be the real reason for chiral recognition during immune response (panels a and c of Figure 5). The green contour beside the oxazine ring showed that the conformational structures of this ring also influence the antibody−antigen recognition (Figure 5a). The large green contour near the methyl group of the piperazinyl ring indicated that a steric

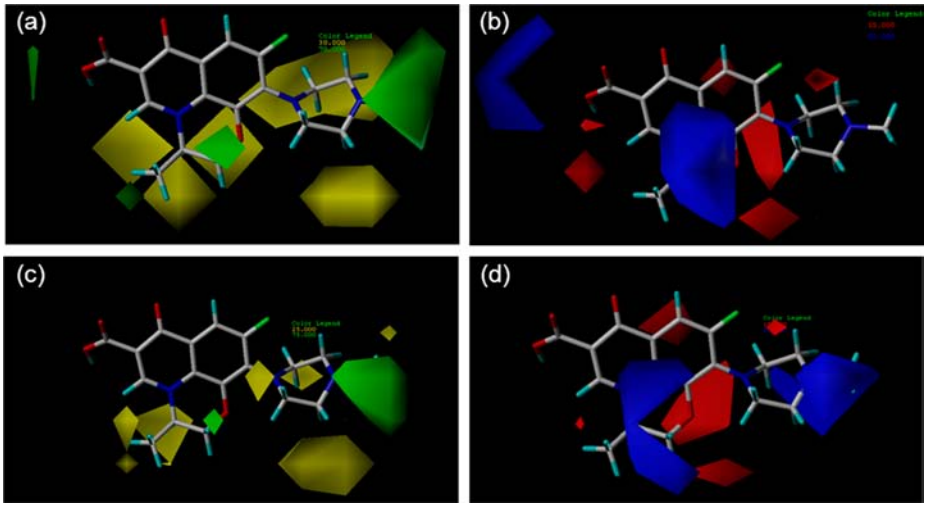

Figure 5. CoMFA contour plots of steric and electrostatic properties in combination with *R*-OFL. (a) Steric contour plot of the mAb-WR1 model. (b) Electrostatic contour plot of the mAb-WR1 model. (c) Steric contour plot of the mAb-MS1 model. (d) Electrostatic contour plot of the mAb-MS1 model. Green and yellow contours refer to sterically favored and disfavored regions, respectively, and blue and red contours refer to regions where positively and negatively charged substituents are favored, respectively.

dx.doi.org/10.1021/jf404449n | *J. Agric. Food Chem.* 2014, 62, 7804−7812

bulky group, such as a methyl group, in this region favors the ofloxacin–antibody interaction (panels a and c of Figure 5). The planar isoindole group of GAR forms a 3D conformation similar to the conformation of methyl piperazine, possibly explaining why GAR has a high CR value. The yellow contours near the piperazinyl ring showed that the steric bulky group on the flank of the piperazinyl ring would not be favorable toward antigen–antibody recognition. GAT has a similar conformational structure with GAR, except for the 2-methylpiperazine structure, but the CR value of GAT is much smaller than that of GAR, possibly owing to the steric hindrance of the *meta*-methyl on the flank of the piperazinyl ring.

In the electrostatic contour map (panels b and d of Figure 5), a positive-charge-favorable region is indicated in a blue color and a negative-charge-favorable region is indicated in a red color. One large blue contour map is observed at the position of stereogenic carbon, showing that positively charged substituents in this position are favored for antibody recognition. The blue contour beside the piperazinyl ring showed that the C–C bonds in piperazine provide a positive electrostatic potential, favoring antibody–antigen interactions. In the model of mAb-WR1, green and blue contours were found near the carboxyl group of *R*-OFL, which indicated that mAb-WR1 may recognize the linker of ofloxacin conjugates.

The HQSAR and CoMFA studies consistently showed that both antibodies recognize ofloxcin isomers from the side of the oxazine and piperazinyl ring moiety, and this moiety is an important part of the epitope. The predicted epitope of the ofloxacin enantiomer can be easily observed by overlay contour maps of CoMFA (Figure 6). From the composition of the predicted epitope, it is clear that the epitope of ofloxacin isomers may be mainly composed of the oxazine ring and the piperazinyl ring. The common structure of QNs also plays a part in the hapten–antibody interaction. Therefore, the enantioselective mAbs recognize not only the chiral center but also the other parts of the molecule. In other words, the enantioselectivity of the antibodies against the ofloxacin optical isomers requires additional recognition sites on hapten. From the analysis above, we conclude that the predicted epitope model can explain the binding character of mAbs.

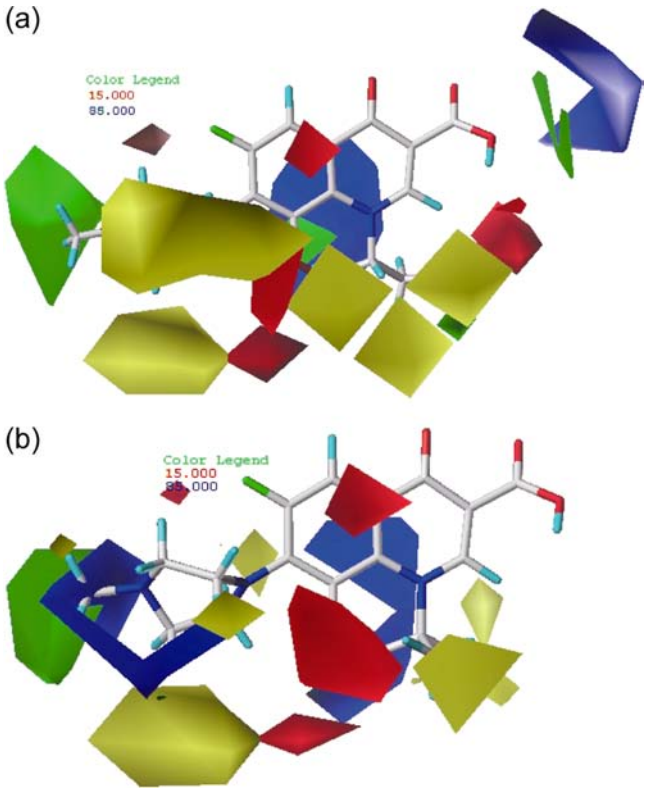

Figure 6. Predicted epitope of ofloxacin enantiomers in immune response (*R*-OFL as a reference molecule): (a) mAb-WR1 and (b) mAb-MS1.

Chiral Conjugate Modeling. Few reports detail the conformational changes of hapten–carrier conjugates during the development of immunoassays for small molecules. Initially, modeling the 3D conformations of the hapten–carrier conjugate was not feasible because of the complex structure of the conjugate. Xu et al.[32] designed three generic haptens containing both the *O*,*O*-diethyl thiophosphate moiety and a benzene ring using three different linkers. The conformational structure and electrostatic potential isosurfaces of the hapten–lysine conjugates were modeled to explain the observed CR of the organophosphorus pesticides to the different monoclonal antibodies. However, the generated model failed to consider the effects of the tertiary structure of the carrier protein. These features might cause interactions between the hapten and the carrier protein.

To investigate the conformational structure of the ofloxacin isomers on the carrier protein, we modeled the 3D structures of ofloxacin isomers conjugating to BSA mimics (see Figure S5 of the Supporting Information). The models showed that the conjugated ofloxacin enantiomers remained upright on the carrier protein surface, and the epitope does not interact with the amino acid residues of the carrier protein (Figure 7). This conformation is advantageous when obtaining the immunogenicity of chiral ofloxacin. The results obtained from the fit atom analysis showed that the conjugated ofloxacin isomers and the corresponding free ofloxacin isomers have identical geometries at their minimum energy level. The RMS distance values for the carbon atoms between the free ofloxacin isomers and the conjugated ofloxacin isomers are only 0.003 19 and 0.000 46 Å, respectively, proving that the geometry of the ofloxacin isomers is not significantly affected by conjugation. Similarly, the electrostatic potential distribution is almost the same in both the free and conjugated molecules.

The way of conjugation may influence the chiral recognition of the antibody. The distance between the stereogenic center and the adjacent amino acid on the carrier protein is only 5.60 Å for *S*-OFL and 5.52 Å for *R*-OFL (Figure 7). The short distance between the stereogenic center and the carrier protein may influence the exposure of the stereogenic center during immune responses, possibly producing antibodies with a relative enantioselectivity. On the basis of the epitope model on the carrier protein, we conclude that two methods may improve the enantioselectivity of the antibodies against the ofloxacin isomers: (i) introducing an appropriate linker, such as ethylenediamine (EDA) or 1,4-diaminobutane, between the hapten and carrier protein may increase the exposure of the stereogenic center, enhancing the enantioselectivity, and (ii) novel immunogens, such as desmethyl levofloxacin (CAS registry number 117707-40-1) and its enantiomer, linked to the carrier protein through the piperazine moiety at the R_3 position would sully the expose of the stereogenic center of ofloxacin. Desmethyl levofloxacin is an analogue of *S*-OFL that has one less methyl group on the piperazine ring compared to *S*-OFL. The novel immunogens may also improve the enantioselectivity

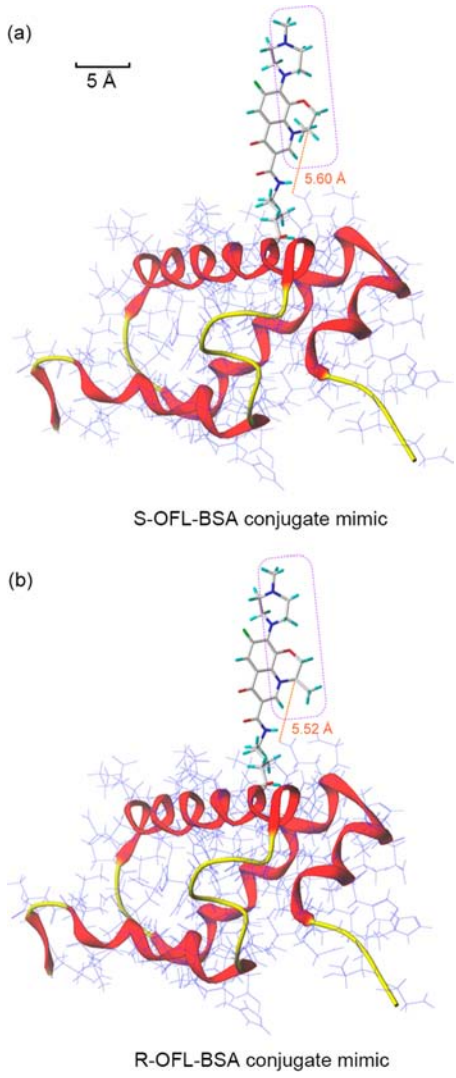

Figure 7. Conformational analysis of ofloxacin isomers coupled with BSA mimics. The elements are presented in the following manner: green, fluorine; red, oxygen; blue, nitrogen; white, carbon; and light blue, hydrogen.

of the antibodies against the ofloxacin isomers. Further studies of those attempts are currently in progress in our laboratory.

Except for the predicted epitope, the other moiety of hapten is also fully exposed on the surface of the carrier protein; this moiety is the common structure of QNs. According to the study above, none of the mAbs would recognize haptens from the side of the common structure. The structure of nalidixic acid (NAL) is almost the same as the common structure of QNs (4-oxo-4,7-dihydroquinoline-3-carboxylic acid nucleus); however, the anti-sera does not recognize this molecule at all. This case also supports the conclusion above. The predicted hapten epitope of ofloxacin isomers would explain why the antibody raised from ofloxacin has high specificity and is not suitable for a generic immunoassay of QNs.

In summary, we synthesized two chiral immunogens based on ofloxacin enantiomers to produce enantioselective mAbs with high sensitivity and specificity. The enantioselectivity of the mAbs is not affected by the heterologous coating format. Molecular modeling methods, such as HQSAR and CoMFA, were performed to determine the epitope of the ofloxacin enantiomers. The different modeling results consistently showed that the epitope of chiral immunogen is primarily composed of oxazine and piperazinyl rings and mAbs recognize the hapten from the side of this moiety. (i) The stereogenic center plays an important role in immune response by generating steric hindrance. (ii) The mAbs may recognize the hapten−carrier linking group during the antigen−antibody interaction. (iii) The common structure of QNs also plays a role in the hapten−antibody interaction. (iv) The unique conformational structures of the oxazine and piperazinyl rings are also essential for the epitope. (v) In addition to the stereogenic center, other auxiliary groups are needed for recognition. The predicted epitope can well explain the enantioselectivity and specificity of the obtained mAbs. Modeling the chiral immunogens showed that conjugated ofloxacin enantiomers remain upright on the carrier protein surface and that the epitope has no interaction with the amino acid residues of the carrier protein. The relative enantioselectivity of mAbs may be due to the short distance between the stereogenic center and carrier proteins. The short distances possibly influence the exposure of the stereogenic center toward immune responses.

Molecular modeling methods, such as HQSAR and CoMFA, provide a simple, efficient, and general way for predicting the epitopes of small organic molecules. Predicting the epitope of hapten would elucidate the physiochemical principles that govern the molecular recognition during the immune response. The epitope prediction method presented in this study should make the redesign of the hapten or its conjugate possible, obtaining antibodies with an improved enantioselectivity, specificity, or other desired characteristics and promoting the development of an immunoassay for determination of small molecules. This study also highlights the power of molecular-modeling-based analyses, providing insights into antibody−hapten recognition and the rational design of a hapten−protein conjugate.

biosynthetic genes, leading to the anthocyanin accumulation in purple cauliflower and red cabbage.[19,20] In *Arabidopsis*, anthocyanin accumulation in vegetative tissues has been shown to be mediated by four MYB proteins, production of anthocyanin pigment 1 (PAP1), PAP2, MYB113, and MYB114, as well as bHLH protein, transparent testa 8 (TT8).[21−23] Furthermore, MYB transcription factors are central players in the coordinated activation of sets of genes specific for the anthocyanin and tannin pathways.[24] R2R3-MYB and bHLH transcription factors regulate anthocyanin biosynthesis in gentian flowers.[25] In *Petunia*, R2R3-MYB transcription factors are developmentally and environmentally regulated to control complex floral and vegetative pigmentation patterning.[26] *Rc* encodes a bHLH protein conditioning red pericarp in rice.[27] Although the MYB transcription factors require a bHLH in regulating anthocyanin biosynthesis in *Arabidopsis*,[28] MYB proteins can act directly in activating transcription in maize.[29]

The anthocyanin biosynthetic pathway is also regulated by environmental factors, such as light and temperature, as well as internal factors, such as plant hormones, other secondary metabolites, and nutrients.[30] Light acts as an essential stimulus and also modulates the intensity of the pigment by affecting the regulatory and structural genes involved in anthocyanin biosynthesis.[31] Research in eggplant showed that anthocyanin synthesis was induced in the hypocotyl tissues when the seedlings were grown under purple light with an ultraviolet (UV) light supplement.[32] The apple gene *MdMYB1* was shown to regulate anthocyanin biosynthesis in response to sunlight.[33] In *Arabidopsis*, a genome-wide analysis suggests that *PAP1* and *PAP2* play a major role in the induction of the anthocyanin biosynthesis transcriptional cluster by high light stress.[34] Recently, Cevallos-Casals and Cisneros-Zevallos observed that the duration and amount of light applied during sprouting strongly affected the mechanisms of flavonoid and anthocyanin biosynthesis.[35]

Along with economic development, demand by people for high-quality vegetables is increasing. In addition to common leaf color vegetables, especially those vegetables with novel leaf or flower color have broad prospects for development and use. Tumorous stem mustard (*Brassica juncea* var. *tumida* Tsen et Lee), a native cruciferous vegetable crop in Asia countries, is a very important fresh and processed vegetable in winter and spring. In the domestication history of mustard, lots of morphological and physiological changes have been preserved on the basis of human selection. The purple tumorous stem mustard (*B. juncea* var. *tumida* Tsen et Lee) is a mutation of the *B. juncea* (Cruciferae) crop containing an inflated tumorous stem and abundant anthocyanin accumulation in leaves. The swollen succulent stems are used as raw material for pickled products, which are very popular for their special flavor and nutritional value.[36] In addition, because of abundant anthocyanins in its leaves, purple tumorous stem mustard can be also used in many important fields, such as the health protection, pharmaceutical, and cosmetic industries. Although radishes and other root crops containing anthocyanins are used as plants for natural pigment extraction, it will take a long time to collect the fully mature organs with anthocyanins, which is limited by the plant developmental stages. However, leaves of purple tumorous stem mustard remain bright fuchsia in the whole life of plants. Therefore, purple tumorous stem mustard can be used as a better resource for natural pigment. In summary, purple tumorous stem mustard attracts more and more attention because of its wide applications in food, pharmaceutical, and cosmetic industries. In recent years, most studies about purple tumorous stem mustard are focused on the cultivations. The molecular regulatory mechanism of antho-

cyanin biosynthesis and the anthocyanin composition and content in purple tumorous stem mustard remain unclear.

In this study, the anthocyanin content and composition of the mature leaf of purple tumorous stem mustard were detected. To investigate the mechanism of the anthocyanin biosynthesis in the purple tumorous stem mustard, the expression of structural and regulatory genes were detected in two genotype cultivars, purple cultivar "Zi Ying" and green cultivar "Lv Ying". The effect of light on anthocyanin accumulation of "Zi Ying" was also investigated.

MATERIALS AND METHODS

Plant Materials and Growth Conditions. To analyze the influence of genotype on anthocyanin productions, two cultivars of tumorous stem mustard, "Zi Ying" and "Lv Ying", were selected in this study based on different phenotype appearances. The seeds were sowed on September 1, 2012, transplanted into plastic pots after 20 days, colonized on October 10, 2012, and managed routinely. For light and dark treatment, the seeds were surface-sterilized using 70% (v/v) ethanol for 1 min, rinsed 3 times with sterile water, then washed in 1% sodium hypochlorite solution for 12−15 min, and rinsed 8 times with sterile water. The sterilized seeds were divided into two sets germinated on 1/2MS medium in a growth chamber under light (16 h of light/8 h of dark) or dark (24 h of dark) conditions at 25 °C, 60% humidity, and 440 μmol m^{-2} s^{-1} light intensity. For biological replicates, we used three plastic boxes for each single treatment, placed 80 seeds per box, and harvested sprouts in each plastic box at 3, 6, 9, and 12 days after sowing (DAS).

Microscopic Analysis of Anthocyanin Distribution in Tumorous Stem Mustard. Young fresh leaves of the "Zi Ying" cultivar underwent microscopic observation and analysis [Figure 1C with an optical microscope (Leica-DMI4000B)]. Observations were repeated three times for each sample.

RNA Extraction and Quantitative Real-Time Reverse Transcription Polymerase Chain Reaction (qRT-PCR) Analysis. When the color of "Zi Ying" leaf turned to brilliant purple, the mature leaves of both "Zi Ying" and "Lv Ying" cultivars were collected for the treatments and sprouts in each box at 3, 6, 9, and 12 days after sowing were harvested for RNA isolation. Total RNA was extracted from samples for three biological repeat using RNAiso Plus (TaKaRa). Then, 1−2 μg of total RNA was used to synthesis the complementary DNA (cDNA) through reverse transcriptase (M-MuLV RT) (Promega) with Oligo-dT18 primer. The synthesized cDNAs were diluted 1 times with RNase/DNase-free water. qRT-PCR analysis was carried out using the CFX96 real-time system (C1000 Thermal Cycler, Bio-Rad). All reactions were performed using the SYBR Premix Go *Taq* II kit (Promega, China) in a 10 μL total sample volume (5.0 μL of 2× SYBR Premix Go *Taq* II, 0.5 μL of primers, 1.0 μL of cDNA, and 3.5 μL of ddH_2O). To remove the effect of genomic DNA and the template from the environment, no template control (NTC) and no reverse transcription control (NRT) were performed. Three replications for each sample were used, and standard curves were run simultaneously. Melting curve analysis of qRT-PCR samples revealed that there was only one product for each gene primer reaction. The PCR products were sequenced to confirm the specific amplification. A house-keeping gene *BjEF-1-α*[37] was used as an internal standard in tissues. Expression of genes from the green cultivar were set to 1. PCR primers are shown in Table 1S of the Supporting Information.

Chemicals. The anthocyanin cyanidin-3-glucoside chloride for external standards was purchased from Phytolab (Germany). High-performance liquid chromatography (HPLC)-grade methanol (MeOH) and formic acid were bought from Sigma. HPLC-grade water was prepared from distilled water using a Milli-Q system (Millipore Laboratory, Bedford, MA). All of the other solvents were provided from Aldrich (St. Louis, MO).

Anthocyanin Extraction and High-Performance Liquid Chromatography−Electrospray Ionization−Tandem Mass Spectrometry (HPLC−ESI−MS/MS) Analysis. Anthocyanins were extracted and separated by HPLC following the improved procedure described by Wu and Prior.[38] Samples (100 mg) were extracted in 1 mL of methanol/H_2O/acetic acid (85:15:0.5) for 10 min at room temperature and centrifuged at 12000*g* for 10 min. The supernatants were collected and filtered through a 0.2 μm polytetrafluoroethylene (PTFE) syringe filter to remove cell debris. The samples were then analyzed by Waters 2795 HPLC (Waters, Milford, MA), equipped with a variable wavelength detector. The results were analyzed by Waters 2795 HPLC ChemStation software. The chromatographic separation was performed on a Zorbax Stablebond Analytical SB-C18 column (4.6 × 150 mm, 5 μm, Waters). The injection volume was 10 μL. Elution was performed using mobile phase A (aqueous 2% formic acid solution) and mobile phase B (methanol). The detection was at 520 nm, and the column oven temperature was set at 40 °C. The flow rate was 1 mL/min. The gradient program is described as follows: 0−2 min, 10−20% B; 2−40 min, 20−55% B; 40−45 min, 55−60% B; 45−60 min, 90% B; and 60−65 min, 10% B. Quantification of the different anthocyanins was based on peak areas and calculated as equivalents of the external standards. All contents were expressed as milligrams per gram of dry weight. Low-resolution electrospray mass spectrometry was performed with a solariX ion trap mass spectrometer (Bruker Daltoniks, Billerica, MA). The experimental conditions were as follows: ESI interface, nebulizer, 50 psi; dry gas, 15.0 psi, dry temperature, 320 °C; MS/MS, scan from m/z 200 to 2000; ion trap, scan from m/z 200 to 2000; source accumulation, 50 ms; ion accumulation time, 300 ms; flight time to acquire cell, 1 ms; smart parameter setting (SPS), compound stability, 50%; and trap drive level, 60%.

Total Anthocyanin Analysis. The total anthocyanin content in samples was measured with a pH-differential spectrum method.[39] The mature leaves or seedlings (100 mg) were frozen in liquid nitrogen and immediately crushed into powder. Samples were treated separately with 2 mL of pH 1 buffer solution (50 mM KCl and 150 mM HCl) and 2 mL of pH 4.5 buffer solution (400 mM sodium acetate and 240 mM HCl). The mixtures were centrifuged at 12000*g* for 20 min at 4 °C. Then, absorbance of the solutions was measured at 520 nm using diluted supernatants. The anthocyanin content was calculated according to the equation: amount [mg g^{-1} of fresh weight (FW)] = $(A_1 - A_2) \times 484.8/24\,825 \times$ dilution factor, where A_1 represents the absorbance of supernatants gathered from pH 1.0 buffer solution at 520 nm, A_2 represents the absorbance of supernatants gathered from pH 4.5 buffer solution at 520 nm, 484.8 represents the molecular mass of cyanidin-3-glucoside chloride, and 24 825 is its molar absorptivity at 520 nm. Each sample was analyzed in triplicate, and the results were expressed as the average of the three measurements.

Statistical Analysis. Data were analyzed by Origin 8.6 (OriginLab) software, using the *t* test to assess significant differences among the means.

RESULTS AND DISCUSSION

Influence of Genotype on Anthocyanin Concentrations. Two cultivars, "Zi Ying" and "Lv Ying", were investigated to study the influence of genotype on anthocyanin biosynthesis. During the seedling stage, cotyledons of the "Zi Ying" cultivar began to show a punctate purple and the purple area gradually increased with plant growing. When four true leaves were present, 80−90% area of the leaves showed purple. Later all leaves turned purple gradually. Under the same growth conditions, the leaves of "Lv Ying" cultivar remain green in the whole growth process, no purple was seen (panels A and B of Figure 1). The anthocyanin content in "Zi Ying" and "Lv Ying" was measured with a pH-differential spectrum method. At the seedling stage, the anthocyanin content of cotyledon of "Zi Ying" was up to 0.61 mg g^{-1} of FW. Higher amounts of anthocyanins were detected in young leaves of "Zi Ying" (1.52 mg g^{-1} of FW). The highest level of anthocyanin accumulation (1.929 mg g^{-1} of FW) was found in mature leaves of "Zi Ying"

Table 1. Anthocyanin Levels (mg g^{-1} of Dry Weight) in the Two Cultivars (Purple and Green) (n = 3)

[a]Peak number corresponds to elution order by HPLC analysis in Figure S1 of the Supporting Information. [b]Known *Brassica* anthocyanins (most were identified with the reference anthocyanin in the database). [c]nd = not detected.

(panels E−G of Figure 1), a level comparable to that found in blueberries.[40] On the contrary, low amounts of anthocyanins were detected at various stages in the "Lv Ying" grown under the same conditions, which is consistent with their phenotype. Microscopic examination of sections of young leaf tissues revealed that the purple pigments accumulated in both upper and lower epidermal layers in "Zi Ying" samples, while no pigments were present in the "Lv Ying" samples (panels C and D of Figure 1).

Qualitative and Quantitative Analyses of Anthocyanins in Purple Tumorous Stem Mustard. To examine the composition and relative content of anthocyanins in "Zi Ying", the anthocyanins were extracted and analyzed by HPLC−ESI−MS/MS. The elution profile of purple cultivar is shown in Figure 1S of the Supporting Information. There were 20 major peaks detected in the extracts of "Zi Ying". The individual peaks were putatively identified through comparison of the retention time and spectrum character to the published data[38,41−43] and listed in Table 1S of the Supporting Information. The content of each individual anthocyanin in "Zi Ying" was calculated and shown in Table 1. All of these anthocyanins were cyanidin 3-diglucoside-5-glucoside and derivatives with different acylated groups bound to diglucoside (Table 1 and see Figure 1S of the Supporting Information). The anthocyanins showing the highest levels were cyanidin 3-feruloylsinapoylsophoroside-5-malonylglucoside (m/z 1241) and cyanidin 3-diferuloylsophoroside-5-malonylglucoside (m/z 1211) of 0.858 and 0.694 mg g^{-1} of dry weight, respectively. It was reported that 67 anthocyanins were identified from red mustard greens (*B. juncea* Coss variety) using an ultrahigh-performance liquid chromatography−photodiode array−electrospray ionization−high-resolution tandem mass spectrometry operated in the MS^n mode (UHPLC−PDA−ESI−HRMS/MS^n) profiling method,[43] and cyanidin 3-feruloylsinapoylsophoroside-5-malonyldiglucoside (m/z 1403) and cyanidin 3-*p*-coumaroylsinapoylsophoroside-5-malonyldiglucoside (m/z 1373) were found as the major anthocyanins in red mustard greens. Different numbers and types of anthocyanins identified in purple tumorous stem mustard are different from those in red mustard greens, which might be owing to the different varieties and methods.

Analysis of Sprouts Grown under Light and Dark Conditions. In our study, we find that the color of the upper epidermis is deeper than the lower epidermis, which may be attributed to the different light intensities in the upper and lower surfaces of the "Zi Ying" leaves (Figure 1C). Previous studies on apple and pear showed that anthocyanin biosynthesis was light-induced and restricted in fruit skin.[33,44] Therefore, the experiment of light and dark treatments of "Zi Ying" seedlings was performed. Cotyledons grown under light conditions were purple, whereas cotyledons grown under dark conditions were yellow. The anthocyanin contents in seedlings of "Zi Ying" grown under light conditions were all significantly higher than the anthocyanin contents in seedlings of "Zi Ying" grown under dark conditions from 3 to 12 DAS (Figure 1H). These results are consistent with those findings in radish and buckwheat sprouts,[31,45] which indicates that the light is essential for anthocyanin synthesis in the "Zi Ying" cultivar.

Expression of Anthocyanin Biosynthetic Genes. To determine the relationship between anthocyanin accumulation and the expression of anthocyanin biosynthetic genes, the transcripts of anthocyanin structural genes were examined in the mature leaves between the purple cultivar "Zi Ying" and the green cultivar "Lv Ying".

The expressions of phenylpropanoid pathway genes *PAL* and *C4H* and anthocyanin biosynthetic genes *CHS*, *CHI*, *F3H*, *F3′H*, *DFR*, *ANS*, and *UFGT* are shown in Figure 2. All structural genes in "Zi Ying" were dramatically upregulated in comparison to those in "Lv Ying". Early structural gene *CHS* was upregulated about 149-fold, while transcript levels of late structural genes *F3H*, *F3′H*, *DFR*, and *ANS* in the purple

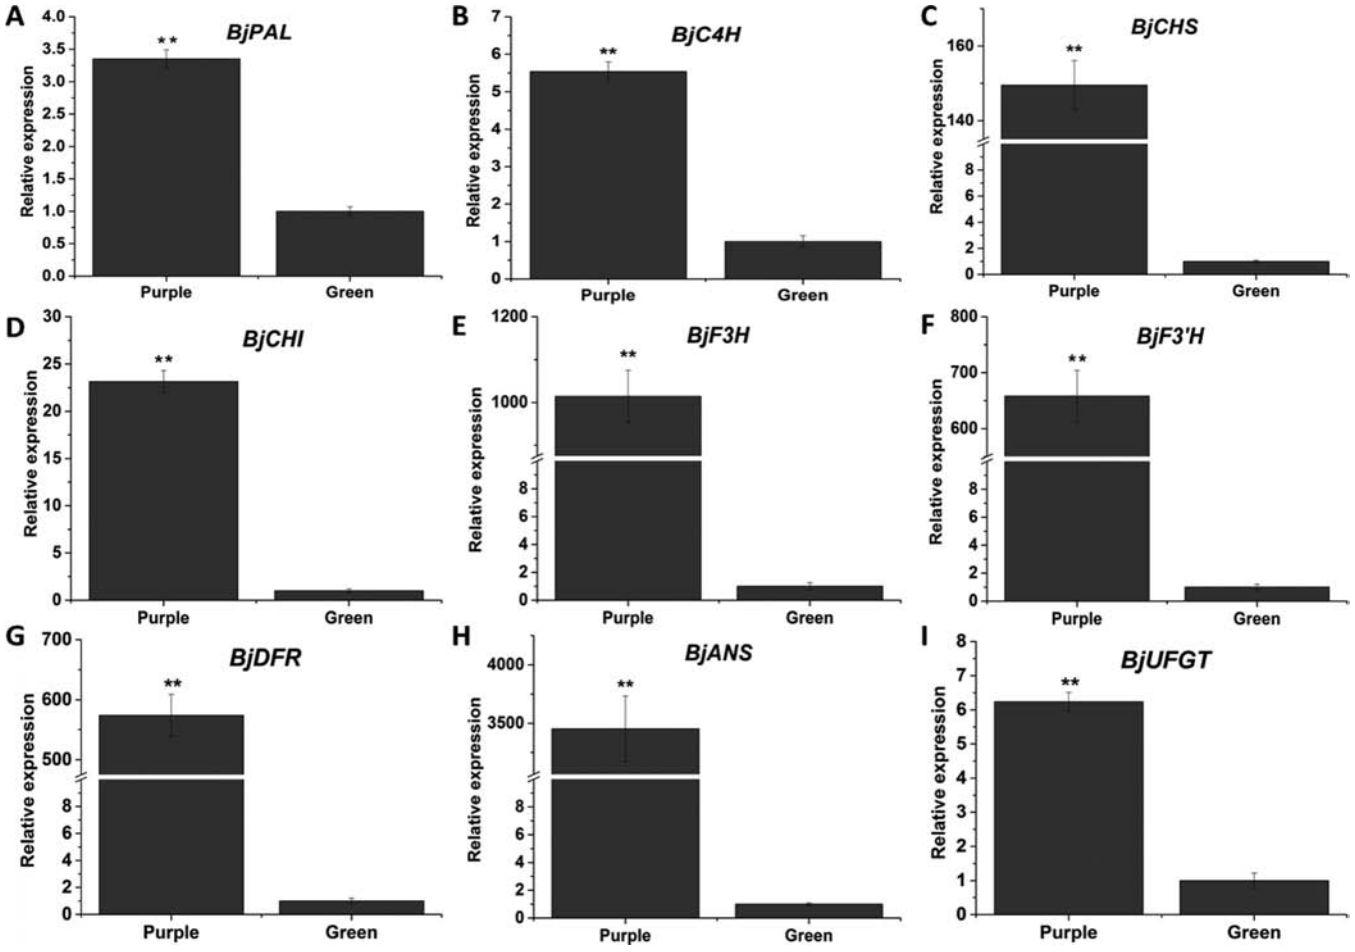

Figure 2. Expression analysis of anthocyanin synthesis genes under normal growth conditions. Expression analysis of (A) *BjPAL*, (B) *BjC4H*, (C) *BjCHS*, (D) *BjCHI*, (E) *BjF3H*, (F) *BjF3′H*, (G) *BjDFR*, (H) *BjANS*, and (I) *BjUFGT* in mature leaves of purple cultivar "Zi Ying" and green cultivar "Lv Ying", respectively. The data represent the mean from three replicates with three biological repeats. (**) $p < 0.01$ between the wild type and others by the *t* test. Error bars indicate SE. Relative expression was normalized using the housekeeping gene *BjEF1* (GO479260). The expression level of genes in the green cultivar were set to 1.

cultivar were approximately 1020-, 660-, 572-, and 3450-fold higher than those in the green cultivar, respectively. In addition, the expression levels of *PAL*, *C4H*, *CHI*, and *UFGT* in "Zi Ying" were about 3.3-, 5.5-, 22.6-, and 6.2-fold higher than those in the green cultivar, respectively. Despite the absence of visual anthocyanin pigmentation in green cultivars, low expression levels of all of these structural genes were observed (Figure 2), which was consistent with the previous reports in other plant species.[46,47] These results illustrate that the high expression levels of biosynthetic genes are strongly associated with the high intensity of anthocyanin pigments in purple tumorous stem mustard.

A number of plants that show constitutive accumulation of high levels of anthocyanins have been studied. In purple-fleshed apple, the transcript levels of anthocyanin biosynthetic genes were significantly higher throughout fruit development than those found in white-fleshed apple.[48] Similarly, examination of seven sweet potato cultivars revealed that the high anthocyanin accumulation in purple sweet potato also showed high-level expression of the structural genes.[49] In *pap1*-D *Arabidopsis*, the increased anthocyanin production throughout the plant was associated with upregulation of the entire biosynthetic pathway genes.[19,23] It appears that purple tumorous stem mustard shares very similar upregulation of structural genes in mediating anthocyanin accumulation to those high anthocyanin accumulating plants.

Furthermore, previous studies have reported that *RsCHS*, *RsCHI*, and *RsDFR* mRNAs were not expressed in the dark, but their expression was induced in seedlings exposed to light up to day 6.[50] *FtPAL*, *Ft4CL*, *FtF3H*, *FtDFR*, and *FtANS* show higher transcript levels in both seeds and sprouts from 2 to 10 DAS, and most genes in the flavonoid biosynthetic pathway are upregulated at 2 DAS under light/dark or dark culture.[45] In our light-treated seedlings, except the upstream pathway gene *BjPAL*, the transcript levels of structural genes were all higher in light-treated sprouts than those in the dark (Figure 4). The transcript levels of all of these genes were highest at nearly 3 and 6 DAS, except *BjC4H*, which had no change in light conditions from 3 to 12 DAS. It is noteworthy that, in light-treated sprouts, the transcript levels of *BjF3′H* and *BjANS* were about 1200- and 120-fold higher than those in the dark treated at 6 DAS, respectively. At 3 DAS, the transcript levels of *BjF3H* of light-treated sprouts were about 60-fold higher than those in the dark. In addition, except *BjPAL*, all other genes are hardly detected in the dark-treated seedlings. Moreover, anthocyanin contents in light-treated seedlings of "Zi Ying" were all significantly higher than those in dark-treated seedlings from 3 to 12 DAS (Figure 1H). These results are completely

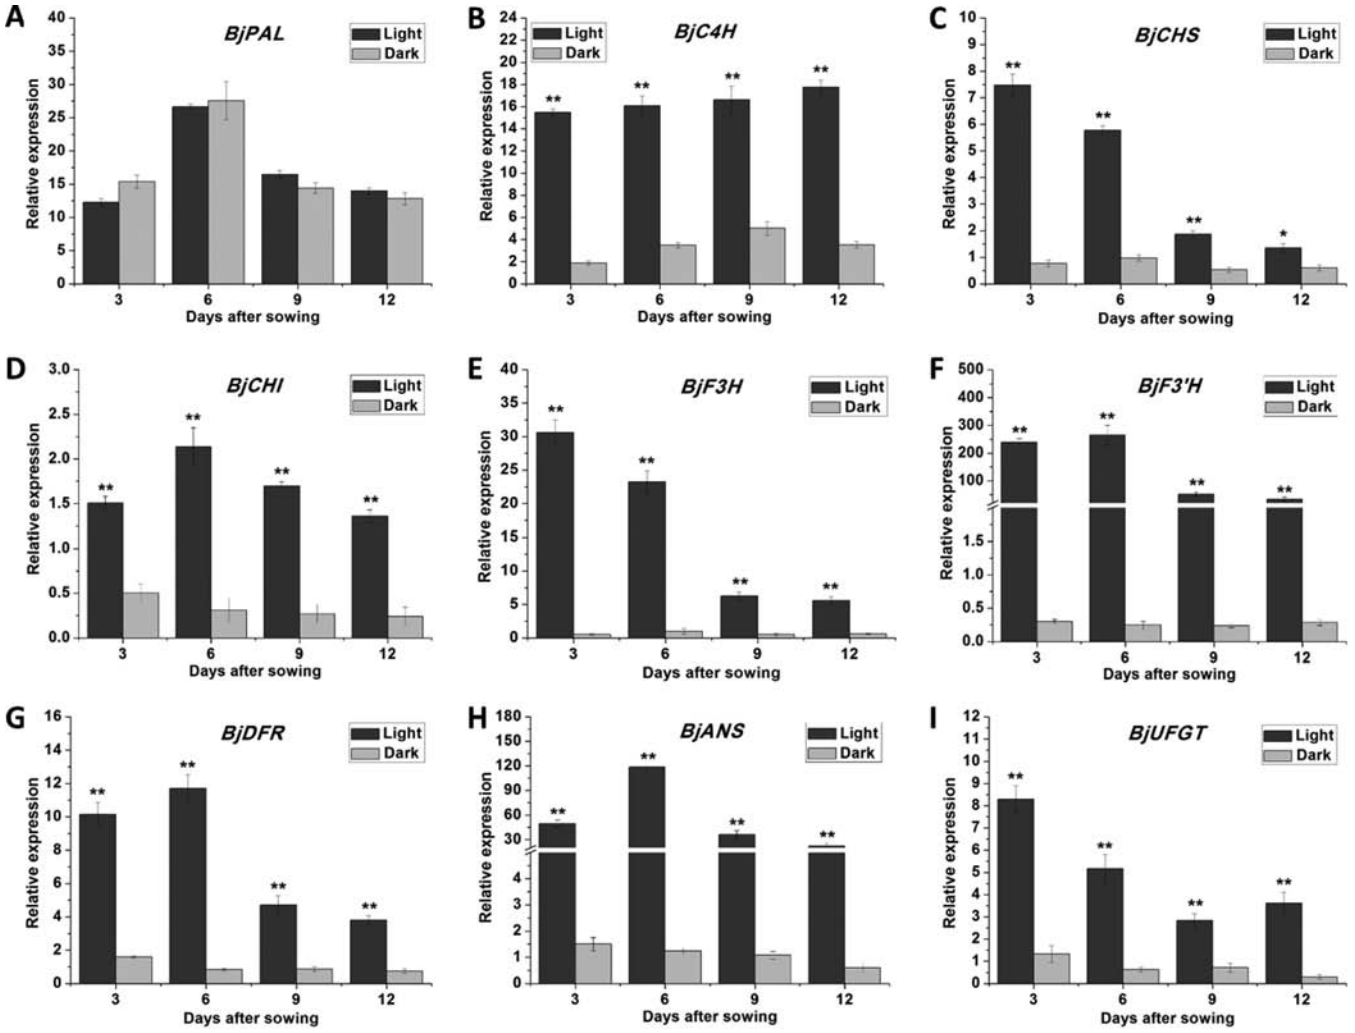

Figure 3. Expression analysis of anthocyanin synthesis genes of seedlings under light and dark growth conditions. Expression analysis of (A) *BjPAL*, (B) *BjC4H*, (C) *BjCHS*, (D) *BjCHI*, (E) *BjF3H*, (F) *BjF3′H*, (G) *BjDFR*, (H) *BjANS*, and (I) *BjUFGT* in seedlings of 3−12 DAS of purple cultivar "Zi Ying" grown in light and dark conditions. The data represent the mean from three replicates with three biological repeats. (**) $p < 0.01$ between the wild type and others by the *t* test. Error bars indicate SE. consistent with their phenotype and further illustrate that the expression level of structural genes is closely related to the anthocyanin accumulation in purple tumorous stem mustard.

Expression of Anthocyanin Biosynthetic Regulatory Genes. On the extensive studies of *Arabidopsis*, grape, apple, *Petunia*, pears, and strawberry, more and more evidence show that plants are often fond of the way of regulating anthocyanin biosynthesis by transcriptional control of anthocyanin biosynthetic genes.[4,12]

MYB transcription factors, bHLH proteins, and WD40 proteins are known to participate in regulating anthocyanin biosynthesis. In this work, the transcripts of *BjMYB1*, *BjMYB2*, *BjMYB3*, *BjMYB4*, *BjTT8*, and *BjTTG1* (homologues of *AtPAP1*, *AtPAP2*, *AtMYB113*, *AtMYB114*, *AtTT8*, and *AtTTG1*, respectively) were analyzed. As shown in Figure 4, these genes had a consistent expression trend, and their expression was elevated in the "Zi Ying" variety. Among them, the expression levels of MYB transcription factors *BjMYB1*, *BjMYB2*, *BjMYB3*, and *BjMYB4* were increased by approximately 2.9, 2.3, 1.8, and 5.9 times, respectively. *BjTTG1* exhibited only a small increase (1.4-fold) in the purple cultivar. It is noteworthy that *BjTT8* was increased by up to 80-fold in "Zi Ying". These results suggest that upregulation of *BjMYB1*, *BjMYB2*, *BjMYB3*, *BjMYB4*, and *BjTT8* expression is likely to activate the structural genes (*F3H*, *F3′H*, *DFR*, and *ANS*) of anthocyanin biosynthesis, and *BjTT8* is likely a critical gene to control the anthocyanin biosynthetic pathway in "Zi Ying". This is likely the general mechanism underlying anthocyanin production responsible for the purple leaves of purple tumorous stem mustard. This regulation mechanism is similar to that in red cabbage.[19]

Moreover, in the light- and dark-treated seedlings, the transcript levels of *BjMYB1*, *BjMYB2*, *BjMYB3*, and *BjMYB4* were 16.5-, 14.2-, 1.73, and 15.5-fold higher in the light than those in the dark treated at 9 DAS, respectively (Figure 5). *BjTTG1* was also induced in the seedling stage, but there was no significant difference between the light and dark conditions. These results indicated that MYB transcription factors may participate in the regulation of anthocyanin accumulation in seedlings of purple cultivar and *BjTTG1* might not account for the transcriptional activation of anthocyanin structural genes in purple tumorous stem mustard in the light. In addition, the transcript levels of *BjTT8* in the light-treated seedlings were approximately 85-, 80-, and 240-fold higher than those in the

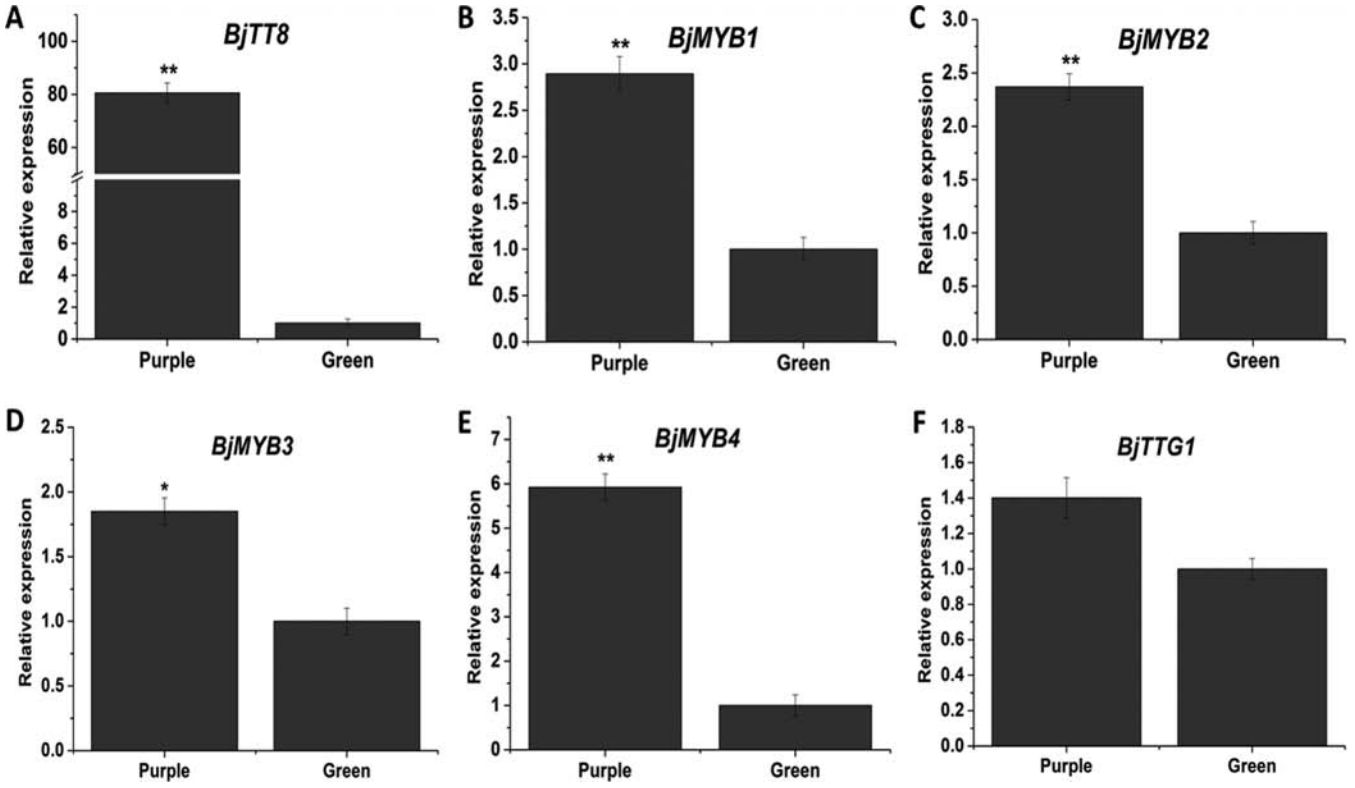

Figure 4. Expression analysis of anthocyanin regulatory genes under normal growth conditions. Expression analysis of (A) *BjTT8*, (B) *BjMYB1*, (C) *BjMYB2*, (D) *BjMYB3*, (E) *BjMYB4*, and (F) *BjTTG1* in mature leaves of purple cultivar "Zi Ying" and green cultivar "Lv Ying", respectively. dx.doi.org/10.1021/jf501790a | J. Agric. Food Chem. 2014, 62, 7813−7821

dark-treated seedlings at 6, 9, and 12 DAS, respectively. The upregulation of *BjTT8* in purple cultivar is as extreme as that in purple cauliflower and red cabbage,[19,20] suggesting that *BjTT8* may be a very important regulatory factor, regulating accumulation of anthocyanins in purple tumorous stem mustard. On the basis of these results, we can speculate that mustard, cabbage, and cauliflower may have the same way of regulating the anthocyanin accumulation.

In conclusion, our research investigated the anthocyanin composition and transcriptional analysis of flavonoid structural and regulatory genes in purple tumorous stem mustard. The results suggest that cyanidin is characterized as the major anthocyanin in the purple tumorous stem mustard, and the upregulation of *BjMYB* genes and *BjTT8* likely triggers anthocyanin accumulation. Because of its extreme upregulation, *BjTT8* is likely a key gene to control the anthocyanin accumulation in the "Zi Ying" cultivar. To clarify the role of *BjMYB* genes and *BjTT8* in anthocyanin production in purple tumorous stem mustard, future studies through genetic analysis and candidate gene approach should be carried out.

from the fresh fruiting bodies of *P. giganteus* and to compare its properties with those of other fungal FAEs.

MATERIALS AND METHODS

Materials. Wheat bran and corn bran were processed as described by Wang and Ou.[16] Fresh fruiting bodies of the mushroom *P. giganteus* were purchased from a local market. DEAE-cellulose and Q-Sepharose were obtained from Sigma Chemical Co., St. Louis, MO, USA. A Hypersil ODS C18 column was from Agilent Technologies Co., Santa Clara, CA, USA. Superdex 75 HR 10/30 was from GE Healthcare. *p*-Nitrophenyl stearate, palmitate, caproate, butyrate, and acetate were purchased from Sigma. Methyl *p*-coumarate (MpCA), caffeate (CA), ferulate (MFA), and ferulic acid (FA) were obtained from Apin Chemicals Ltd., Abingdon, UK. Xylanase was obtained from Sigma. E-FAERU (a commercial FAE) was purchased from Megazyme, Wicklow, Ireland.

Purification Scheme. Fresh fruiting bodies of the mushroom *P. giganteus* (800 g) were homogenized in distilled water (2 mL/g) using a Waring blender followed by centrifugation (8000*g*, 15 min). Tris-HCl buffer (pH 8.2) was added to the resulting supernatant until the concentration of Tris-HCl buffer was 10 mM. The supernatant was then applied on a DEAE-cellulose column (5 cm × 20 cm) previously equilibrated with 10 mM Tris-HCl buffer (pH 8.2). Following elution of unadsorbed proteins in fraction D1, adsorbed proteins were desorbed sequentially with 50, 150, and 300 mM NaCl in the same buffer, to produce fractions D2, D3, and D4, respectively. Fraction D3, which exhibited FAE activity, was dialyzed prior to ion exchange chromatography on a 3 cm × 20 cm column of Q-Sepharose in 10 mM Tris-HCl buffer (pH 7.2).

Following elution of unadsorbed proteins in fraction D3Q1, adsorbed proteins were desorbed from the column with a linear 0–1 M NaCl concentration gradient in the same buffer. The active fraction (D3Q2) was dialyzed and then resolved by ion exchange chromatography on a 1 cm × 10 cm DEAE-cellulose column in 10 mM sodium phosphate buffer (pH 6.8).

Following removal of the unadsorbed proteins from the DEAE-cellulose column in fraction D3Q2D1, adsorbed proteins were desorbed with 1 M NaCl in the same buffer. Fraction D3Q2D1 with activity was further purified on a gel filtration Superdex G-75 HR10/30 column by fast protein liquid chromatography (FPLC) using an AKTA purifier and was eluted with 0.2 M NH_4HCO_3 buffer (pH 8.5). The second adsorbance peak (D3Q2D1S2) from the Superdex G-75 column represented the purified FAE.

Assay for Esterolytic Activity. *p*-Nitrophenyl butanoate (*p*NPB) was used as substrate. The test sample (5 μL) was mixed with 195 μL of 50 mM sodium phosphate buffer (pH 6.0) and 5 μL of 50 mM *p*NPB in isopropanol. The increase of absorbance was monitored at 37 °C at 415 nm for 20 min. One unit of enzyme activity was defined as 1 μmol of *p*-nitrophenol released within 1 min under the assay conditions. FAE activity was determined with a modified assay employing MFA as substrate.[17] The assay was conducted at 30 °C for 10 min in 100 mM 3-(*N*-morpholino)propanesulfonic acid (MOPS) buffer (pH 5.0) containing 50 μM MFA, and then the decrease of the MFA was determined at 340 nm. One unit (U) of enzymatic activity was defined as the amount of enzyme that catalyzes the release of 1 μmol min^{-1} FA under the assay conditions. All determinations were performed in triplicate. Release of the FA was also detected by HPLC on a Hypersil ODS C18 column. Detection was achieved at 320 nm on the basis of calibration curves prepared using standard FA and MFA. Elution was conducted with 45/55% (v/v) methanol/sodium formate (10 mM) at a flow rate 0.3 mL min^{-1}.

Molecular Mass Determination. SDS-PAGE was carried out using a 12% resolving gel and a 5% stacking gel.[18] Staining of the gel with Coomassie brilliant blue was performed at the end of electrophoresis. The electrophoretic mobility of the FAE was compared with those of molecular mass standards, and the molecular mass of the FAE was determined from a calibration curve. Gel filtration by FPLC on a Superdex G-75 column, which had previously been calibrated with molecular mass standards, was also employed to ascertain the molecular mass of the FAE from a calibration curve.

Mass Spectrometry of the Purified FAE. The purified FAE band was excised from SDS–polyacrylamide gel, dried, and digested with trypsin. The resulting peptides were extracted and purified according to standard protocols. Then the peptides were analyzed by high-performance liquid chromatography combined with an LTQ Orbitrap mass spectrometer (HPLC-LTQ Orbitrap MS). The amino acid sequences were manually deduced and used for blast searches in public protein primary sequence databases (www.ncbi.nlm.nih.gov/BLAST.cgi).[19]

Substrate Specificities and Kinetics. Substrate preferences for the purified FAE against hydroxycinnamate ester derivatives were determined using the standard assay in the presence of the following esters at 50 μM concentration: methyl ferulate (MFA), methyl *p*-coumarate (MpCA), and methyl caffeate (MCA). Activities toward fatty acid nitrophenyl esters with different chain lengths, including *p*-nitrophenyl acetate, butyrate, caproate, caprylate, palmitate, and stearate, were determined by following a published standard method. The Michaelis–Menten constants (K_m) and maximal velocity (V_{max}) of the *P. giganteus* FAE based on different MFA concentrations (50, 100, 200, 300, 500, and 900 μM) were determined using the Lineweaver–Burk plot. All determinations were conducted in triplicate at pH 4.0 and 40 °C. The reciprocals of the enzyme reaction velocities were plotted on the vertical axis, and the reciprocal of the substrate concentrations were plotted on the horizontal axis to generate the Lineweaver–Burk plot for calculation of K_m and V_{max}.

Biochemical Properties. To determine the optimal temperature, the standard FAE activity assay using MFA as substrate was run at 20, 30, 40, 50, 60, 70, 80, and 90 °C. MOPS buffer was used as the assay buffer. In the thermostability assay, the enzyme solution was exposed for 120 min to various temperatures ranging from 20 to 80 °C before cooling to 25 °C. The activity remaining was then determined. Triplicate determinations were conducted.

The pH optimum of the enzyme was measured using the standard FAE activity assay above, but in a series of McIlvaine buffers (mixtures of 0.1 M citric acid and 0.2 M sodium hydrogen phosphate) in the pH range from pH 2.0 to 8.0 instead of MOPS buffer (pH 5.0). Reaction conditions were the same as those described above for activities toward MFA.

Effects of Metal Ions. For studying how metal ions affect the enzyme activity, the purified enzyme solution was exposed to metal ions, such as Pb^{2+}, Al^{3+}, Zn^{2+}, Mg^{2+}, Cu^{2+}, K^{+}, Mn^{2+}, Ca^{2+}, and Cd^{2+} ions at 5 mM concentration, at 4 °C for 2 h before the standard FAE assay using MFA as substrate was performed. The control sample was maintained in the absence of metal ions.

Enzymatic Degradation of Different Cereal Brans. Enzymatic hydrolyses were performed in 100 mM MOPS buffer (pH 5) in an incubator at 37 °C with shaking. Wheat bran (100 mg) and corn bran (100 mg) were incubated with 0.02 U/mg FAE, in the absence and also in the presence of xylanase (0.6 U/mg) in a final volume of 1.0 mL. At the end of the incubation, the reaction mixture was boiled for 3 min to terminate the reaction. After cooling and centrifugation (13000 *g*, 5 min), the FA released into the supernatant was subjected to HPLC analysis by using a Hypersil ODS C18 column. E-FAERU (a commercial FAE from rumen microorganism) was used as a positive control. The dosage and the reaction conditions of this enzyme were identical to those for FAE from *P. giganteus*.

Alkali Hydrolysis of the Substrates. To determine the total alkali-extractable FA of the substrate, 1.5 mL of 2 M NaOH was added to 100 mg of substrate. Incubation was carried out at 37 °C for 24 h. The supernatant obtained following centrifugation was neutralized using 6 M HCl. Determination of the FA content measured using HPLC was then carried out as described above.

RESULTS

Purification of FAE. The FAE from *P. giganteus* was purified to homogeneity by employing three successive ion

exchange chromatography steps and a gel filtration step, resulting in 10.1% recovery of activity (Table 1).

Table 1. Yields and FAE Activities at Each Purification Step (from 800 g of *Panus giganteus* Fresh Fruiting Bodies)

purification step	yield (mg)	specific activity (U/mg)	total activity (U)	recovery (%)	purification fold
crude extract	15680	1.3	20384	100	1
DEAE-cellulose	765.5	17.4	13320	65.3	13.4
Q-Sepharose	163.4	35.7	5833	28.6	27.5
DEAE-cellulose	28.3	93.7	2652	13.0	72.1
Superdex 75 on FPLC	12.1	170.0	2057	10.1	130.8

Upon chromatography on the ion exchanger DEAE-cellulose, the *P. giganteus* extract was separated into an unadsorbed fraction D1 and three adsorbed fractions, D2, D3, and D4, eluted at 50, 150, and 300 mM NaCl, respectively. Fraction D3, which contained FAE activity, was then fractionated into two peaks, D3Q1 and D3Q2, on a Q-Sepharose column. The unadsorbed fraction (D3Q1) was devoid of FAE activity. High FAE activity was found in the adsorbed fraction (D3Q2). Subsequently, D3Q2 was resolved on DEAE-cellulose into an unadsorbed fraction, D3Q2D1, and a large adsorbed fraction, D3Q2D2. D3Q2D1 was then fractionated into two peaks of about the same size after gel filtration on Superdex 75. FAE activity was confined to the second fraction, D3Q2D1S2.

Determination of Molecular Mass and Internal Amino Acid Sequence. Fraction D3Q2D1S2 appeared as a single 61 kDa band as determined by SDS-PAGE and as a single 61 kDa peak upon rechromatography on Superdex 75 (data not shown). The data indicate that the purified FAE is a monomeric enzyme (Figure 1).

Several internal sequences of the purified FAE were elucidated. Database search using BLAST indicated that two peptides, VEMNAAPGVDL and GTAAGDNVV, showed some homology with FAEs from other microorganisms (Table 2).

Substrate Specificities and Kinetics. The purified FAE was allowed to react with hydroxycinnamic acid methyl esters and fatty acid nitrophenyl esters with different chain lengths. The relative activities were calculated and are shown in Table 3.

Table 3. Activities (Mean ± SD, $n = 3$) of the Purified *Panus giganteus* FAE on Different Substrates

substrate	relative activity (%)
methyl ferulate	100.00
methyl caffeate	65.32 ± 2.46
methyl coumarate	53.17 ± 2.84
p-nitrophenyl acetate	62.44 ± 4.01
p-nitrophenyl butyrate	38.30 ± 3.58
p-nitrophenyl caproate	15.09 ± 2.00
p-nitrophenyl palmitate	nd[a]
p-nitrophenyl stearate	nd

[a]nd, not detected.

The enzyme expressed the highest activity toward methyl ferulate, but it was about 35% less active on methyl caffeate and 47% less active on methyl coumarate. The FAE enzyme also showed activity toward short-chain fatty acid nitrophenyl esters: 62.44 ± 4.01% active on *p*-nitrophenyl acetate, 38.30 ± 3.58% active on *p*-nitrophenyl butyrate, and 15.09 ± 2.00% active on *p*-nitrophenyl caproate. There was no activity toward the long-chain substrates.

The K_m and V_{max} values for the purified *P. giganteus* FAE with MFA as substrate were determined by using the Lineweaver–Burk plot to measure the decreasing level of MFA at pH 4.0 and 40 °C. The K_m and V_{max} for the enzyme were estimated to be 0.36 mM and 18.97 U mg^{-1} protein, respectively.

Characteristics of *P. giganteus* FAE Activity. FAE had its optimal temperature at 40 °C. At 20 °C, 68% of the activity remained, and at 90 °C, 45% activity was left (Figure 2a). FAE activity was completely abolished when the enzyme was boiled for 10 min (data not shown). *P. giganteus* FAE was stable at

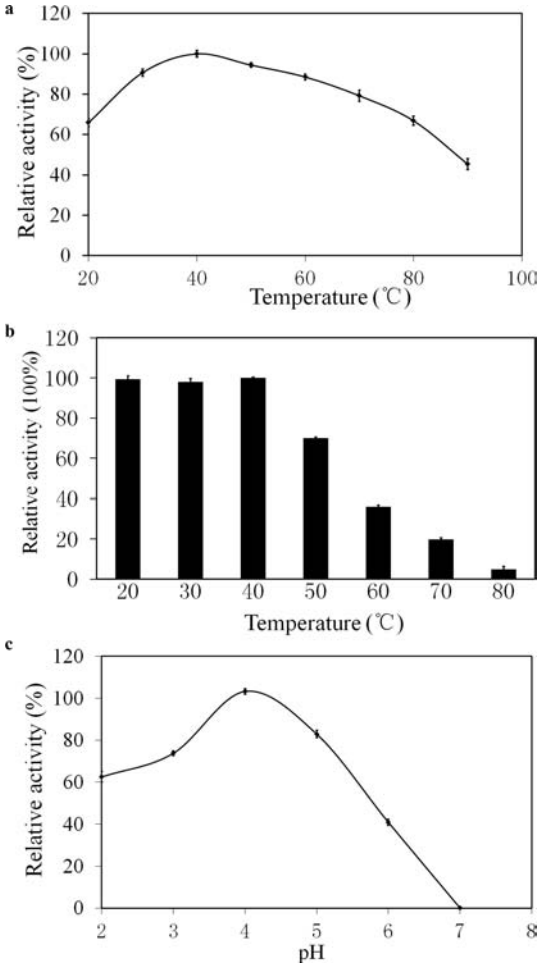

Figure 2. Effects of pH and temperature on *Panus giganteus* FAE: (a) effects of temperature on activity of *P. giganteus* FAE; (b) thermostability of *P. giganteus* FAE; (c) effects of pH on activity of *P. giganteus* FAE. Results represent the mean ± SD (n = 3).

20−40 °C, and 70% residual activity was detected after incubation of the enzyme at 50 °C for 120 min (Figure 2b).

The optimal pH value of the purified FAE was pH 4.0, and 60% of the activity remained at pH 2.0, whereas the enzyme activity declined sharply as the pH was increased. Negligible FAE activity was detected at pH 7.0, whereas no activity was discerned at pH 8.0 (Figure 2c).

The sensitivity of *P. giganteus* FAE to several metal ions is shown in Table 4. The purified enzyme activity was inhibited to different degrees in the presence of metal ions: >60% inhibition in the presence of Mn^{2+}, Ca^{2+}, and Cd^{2+} ions; >40% inhibition by K^{+}, Al^{3+} Zn^{2+}, Mg^{2+}, and Cu^{2+} ions; and 20% inhibition by Pb^{2+} ions.

Table 4. Effects of Different Metal Ions (5 mM) on the Activity (Mean ± SD, n = 3) of Purified *Panus giganteus* FAE

metal ion	residual activity (%)	metal ion	residual activity (%)
Pb^{2+}	84.36 ± 3.06	K^{+}	43.04 ± 2.73
Al^{3+}	60.27 ± 2.33	Mn^{2+}	38.38 ± 2.97
Zn^{2+}	55.30 ± 3.49	Ca^{2+}	32.60 ± 3.03
Mg^{2+}	54.79 ± 2.16	Cd^{2+}	31.53 ± 2.44
Cu^{2+}	52.62 ± 3.11		

Enzyme Activity on Cereal Brans. Wheat bran and corn bran were selected for their high contents of FAs. The total amount of FA was first determined after alkaline hydrolysis and by HPLC analysis. Wheat bran and corn bran contained about 2.16 and 13.85 mg/g FA, respectively (Table 5). Before the action of the enzymes, no free FAs could be detected. Only 1% of the total FA was released from wheat bran, whereas no free FA was released from corn bran when hydrolyzed with xylanase alone. Without the help of accessory enzymes, 8.1 and 0.3% of the total FA was released, respectively, from wheat bran and corn bran with purified FAE. To investigate the action of purified FAE in synergism with xylanase, they were added to the reaction of substrates at the same time, and it was found that the release amount of FA from wheat bran and corn bran was significantly increased (51.9 and 1% of the total FA, respectively) (Table 5). No free FA was released from corn bran, and 5.3% of the total FA was released from wheat bran when hydrolyzed with E-FAERU alone. Under the combined action of E-FAERU and xylanase, 43.3 and 1.1% of the total FA were released from wheat bran and corn bran, respectively (Table 5).

DISCUSSION

FAE was first detected in cultures of *S. olivochromogenes*;[20] since then, many FAEs have been isolated from fungi but rarely from mushrooms. Recently it has been reported that FA was detected in the broth of mycelial culture of four kinds of edible mushrooms.[21] A new FAE was isolated from the mycelial culture of the edible mushroom *Pleurotus sapidus*.[22]

In the present study, we have purified a novel FAE from *P. giganteus* with a chromatographic procedure involving DEAE-cellulose, Q-Sepharose, DEAE-cellulose, and gel filtration on Superdex 75. The procedure employed in the present study was useful for isolating *P. giganteus* FAE. The chromatographic behavior of *P. giganteus* FAE on ionic exchangers was similar to that of *Sporotrichum thermophile*[23] and *Aspergillus niger* FAE.[24] They were adsorbed only on anionic exchangers, such as DEAE-cellulose and Q-Sepharose.

The specific activity of purified FAE was 170.0 U/mg, which was significantly higher than that of FAEs from other fungi, most of which ranged from 0.001 to 36.7 U/mg.[14] The purified FAE was a monomeric protein with a molecular mass of 61 kDa. Its molecular weight was similar to that of FAEs from the mushroom *P. sapidus* (55 kDa)[22] and also close to those of other fungi, such as *Fusarium oxysporum* (62 kDa), *A. niger* (63 kDa), and *Penicillium pinophilum* (57 kDa). *P. giganteus* FAE was larger in molecular mass than FAEs reported from *A. tubingensis* (36 kDa) and *F. oxysporum* (27 kDa) and smaller than FAEs from *A. niger* (120 kDa) and *A. awamori* (112 kDa).[14]

Due to the lack of a significant homology to known microbial FAEs, the purified FAE was likely a novel enzyme. Previous research has also shown that the homology of FAE was low between species.[25,26] For instance, *P. sapidus* FAE, the only FAE from macrofungi, also showed no significant homology to any of the published FAE sequences.[22]

The activity of the purified FAE on the synthetic methyl esters declined with decreasing degree of substitution: it preferred methyl ferulate over methyl caffeate and was least active on methyl coumarate. It also displayed activity toward various *p*-nitrophenyl esters with short chain lengths, and the activity decreased as the number of carbon atoms increased, which was similar to the esterases reported from mushrooms

Table 5. Alkaline and Enzymatic Hydrolysis of Ferulic Acid from Cereal Brans[a]

	ferulic acid (μg/100 mg substrates)					
		enzymatic extraction				
substrate	alkaline extract	xylanase	*pg*FAE	*pg*FAE + xylanase	E-FAERU	E-FAERU + xylanase
wheat bran	216.3 ± 7.5	2.3 ± 0.2	17.6 ± 0.7	112.2 ± 2.9	11.5 ± 0.4	93.7 ± 1.8
corn bran	1385.5 ± 96.0	nd	4.7 ± 0.1	13.7 ± 0.3	nd	15.5 ± 0.5

[a]Data represent the mean ± SD (n = 3); nd, not detected. *pg*FAE, *Panus giganteus* FAE; E-FAERU, a commercial FAE as positive control.

species, such as *S. crispa*,[27] *A. vaginata* var. *vaginata*, *Tricholoma terreum*,[28] and *Lycoperdon perlatum*,[29] and showed specificity toward short-chain fatty acids such as *p*-nitrophenyl butyrate and *p*-nitrophenyl acetate. Apparently, this specificity study suggests that the enzyme is an esterase and not a lipase.

The present FAE manifested an optimal temperature at 40 °C, which was similar to those of FAEs reported from *A. niger*, *F. oxysporum*, and *A. awamori*,[14] whereas it was lower than that of FAE from *P. sapidus* (50 °C).[22] *P. giganteus* FAE was stable at 20−40 °C. This feature can be successfully employed in applications that require a moderate temperature, such as in the production of pharmaceuticals and in the extraction of free phenolic acids. The purified FAE displayed an acidic pH optimum at pH 4.0, which is in accordance with human gastrointestinal pH values. Owing to its high catalytic efficiency under acidic conditions, the purified FAE was more valuable than most other fungal FAEs in many biotechnological applications such as used as functional food and animal feed additives.

The FAE in this study was very sensitive to metal ions. It had some similarities to other mushroom esterases. Esterase activity in the mushroom *S. crispa* could be inhibited by the addition of Zn^{2+} and K^{+} ions.[27] Addition of Zn^{2+} and Fe^{2+} ions could inhibit the esterase activity in the mushroom *Volvariella volvacea*.[30] Addition of Cd^{2+} and Mn^{2+} ions inhibited the esterase activity in the mushroom *T. terreum*.[28] On the other hand, the addition of Ca^{2+}, Fe^{2+}, and Mn^{2+} ions produced stimulatory effects on esterase activity in the mushroom *L. perlatum*.[29] K^{+} and Al^{3+} ions had no effect on esterase activity in the mushroom *A. vaginata* var. *vaginata*.[28]

The present study suggests that FA can be recovered from corn bran and wheat bran by using the purified FAE alone. The percent recovery of FA in wheat bran was higher than those of E-FAERU and FAEs reported in the literature. It has been shown that AnFae alone releases a maximum of 4% of the FA present in wheat bran.[31] The amount of FA released from wheat bran was greatly enhanced (51.9% of total FA) by the synergistic action of xylanase, which was consistent with the published data. This could be because xylanolytic enzymes can degrade long-chain feruloylated xylooligosaccharides to shorter-chain feruloylated xylooligosaccharides, which are more easily hydrolyzed,[31] whereas the purified FAE could release FAs from corn bran to much less extent and to only 1% of the total amount even with the addition of xylanase. The small extent of hydrolysis in corn bran could be attributed to the number of substitutions on the heteroxylan backbone, the presence of extensively branched xylose, and the existence of a linkage between arabinose and xylose in the vicinity of the ferulic acid group.[31] The abundance of ferulic dimers in corn bran restricts enzymatic degradation.[32] The amount of FA released from corn bran by E-FAERU was slightly higher than that by the purified FAE in the presence of xylanase. However, the E-FAERU was from a rumen microorganism, which is anaerobic and difficult to propagate, and hence its further development is limited and it is not easy to widen the field of application. In comparison, *P. giganteus* is a cultivated edible mushroom, which is easy to culture and absolutely safe, and so FAE from *P. giganteus* will have broader prospects of application.

survey on the presence of CPFA in dairy samples from different animal sources such as milk, cheeses, yogurt, other fermented milks, and butter, in order to obtain a deeper knowledge on the mechanisms involved in the transfer of CPFA from the bacterial cell walls to milk fat.

MATERIALS AND METHODS

Sampling. *Milk Samples (Table 1).* Samples of bovine bulk milk were collected from stables in different Italian regions (Lombardy, Veneto, Emilia Romagna, Piedmont), Austria, and Germany and provided by Parmalat Spa. Six different brands of commercial milks, two of them coming from Italian alpine regions, were purchased on the market, together with six samples of goat milk. Six samples of sheep milk were from local farms (Parma). Additionally, ten samples of yak (*Bos grunniens*) milk coming from China were provided by Animal Science Department of Qinghai University, China.

Yogurt and Fermented Milk (Table 2). Parmalat Spa (Parma, Italy) provided the experimental milks fermented with the following combination of microorganisms. Fermentations were conducted at 42 °C for 12 h.

Trial A: *Bifidobacterium infantis* + *Lactobacillus acidophilus*

Trial B: *Lactobacillus paracasei*

Trial C: *Lactobacillus bulgaricus* + *Streptococcus thermophilus (Yogurt)*

Trial D: *Lactococci*

Each milk sample was analyzed before the addition of bacteria, after the inoculum, and then sampled at 10, 20, 30 days of the shelf life (stored refrigerated at 4 °C). Two series of experiments were conducted, utilizing bulk milk samples collected in winter or in summer.

Cheese Samples. A total of 125 cheese samples were analyzed for their CPFA content. Samples of grated Parmigiano-Reggiano (10 samples) and Grana Padano cheeses (10 samples) were purchased on the market. Additionally, 15 samples of certified Grana Padano and 15 samples of certified Parmigiano-Reggiano were provided by Consorzio del Formaggio Parmigiano-Reggiano (Reggio Emilia, Italy). Ten samples of Asiago cheese from lowland and from highland farms were provided by Padua University (Italy). Other cheese samples coming from milk of different species (cow, goat, and sheep) having different production technologies (Table 3) were purchased on the market.

Butter. Seven samples of commercial butter were purchased on the market, including one sample from a farm producing milk for Parmigiano-Reggiano cheese, one from an alpine farm, and one from goat milk.

Sample Preparation for GC-MS Analysis of Milk Fat and Cheese. Ten grams of milk/fermented milk was mixed for 1 min with 1 mL of 33% ammonia (Carlo Erba, Milan, Italy). The mixture was then extracted twice with 20 mL of hexane/acetone (2/1 v/v) (Sigma-Aldrich, Saint Louis, MO, USA) in a separatory funnel; the organic phase was then recovered and evaporated to dryness under vacuum. As regards the cheese analysis, 0.5 g of grated sample was stirred with a hexane/acetone mixture (20 mL, 4/1 v/v) and then filtered on paper. The organic phase was evaporated to dryness. Butter was directly submitted to the following steps.

[a]Results are reported as mean ± SD of replicate analysis. [b]With respect to the total chromatographic area of fatty acid methyl esters.

100 mg of fat recovered was dissolved in hexane (5 mL) and mixed for 1 min with 2 mL of KOH 5% (Carlo Erba, Milan, Italy) in methanol (Sigma-Aldrich, Saint Louis, MO, USA). After phase separation, the superior organic phase was injected (1 μL, split mode) on an Agilent Technologies 6890N gas chromatograph (Agilent Technologies, Palo Alto, CA, USA) coupled to an Agilent Technologies 5973 mass spectrometer (Agilent Technologies, Palo Alto, CA, USA). A low-polarity capillary column (SLB-5 ms, Supelco, Bellefonte, PA, USA) was used. The chromatogram was recorded in the scan mode (40−500 m/z) with a programmed temperature from 40 to 280 °C. Peak identity of CPFA was confirmed by comparison

[a]Results are reported as mean ± SD, minimum and maximum for homogeneous groups of samples. [b]Positivity for values ≥0.01%. [c]With respect to the total chromatographic area of fatty acid methyl esters.

with bacterial acid methyl ester (BAME) mix standard containing cyclopropane fatty acid methyl esters (Sigma-Aldrich, Saint Louis, MO, USA). Content of CPFA was reported as relative percentage response area (%) of the corresponding peak (evidenced in Figure 2) with respect to the total chromatographic area from GC-MS analysis of the other main methyl esters of fatty acids (including C4:0, C6:0, C8:0, C10:1, C10:0, C11:0, C12:1, C12:0, C13:0, C14:0iso, C14:1, C14:0, C15:0iso, C15:0anteiso; C15:1, C15:0, C16:0iso, C16:1, C16:0, C17:0iso, C17:0anteiso, C17:1, C17:0, C18:2, C18:1, C18:0, C18:2cla, C19:1, C19:0, C20:4, C20:3, C20:1, C20:0, C21:0, C22 PUFA, C22:0, C23:0, C24:0).

Data Analysis. Data are obtained as duplicate analysis of two independent sample extractions and are presented as mean ± SD of groups of homogeneous samples. The range (minimum and maximum value) of CPFA was also provided. Positivity or negativity of samples to CPFA was defined on the basis of the threshold of 0.01% (CPFA with respect to total chromatographic area of fatty acid methyl esters); this value corresponds to the experimental detection limit, calculated at a signal-to-noise ratio >3. For fermented milk samples, one-way ANOVA and post hoc Tukey-HSD tests at a p level = 0.05 (n = 4) were performed to detect an eventual effect of fermentation and shelf life on CPFA content. All the statistical analyses were performed utilizing SPSS statistical software (Version 20.0, SPSS Inc., Chicago, Illinois, USA).

RESULTS AND DISCUSSION

Milk Samples. We previously showed that 80 samples of milk from cows fed with maize silage were found positive for the presence of CPFA (0.08 to 0.12%). In contrast, 140 samples of milk from cows fed with forage without maize silages were all negative.[9] In this paper, we extend the investigation on the presence of CPFA to about 50 other milk samples, comprising commercial milk samples, bulk raw milk collected from different regions of Italy, countries of the European Union, and China, and milk from different animal species. The content of CPFA detected in cow milk varies greatly according to region of origin, and different trademarks (Table 1). The majority of the cow milk samples collected resulted positive to CPFA, reflecting a large use of ensiled products in cows' feeding. The collections of milk from Austria and Veneto (Italy) areas show values of CPFA lower than those collected in Emilia Romagna and Lombardy (Brescia, Milan, Reggio Emilia). Among commercial cow milk samples, the two samples negative to CPFA come from mountain regions. Goat, sheep, and yak milks analyzed were all negative to CPFA, indicating that the feeding system is fundamental for the presence of these fatty acids in milk; in fact, these animals are usually fed with pasture grass or, during the winter, with hay.

Fermented Milks. CPFA are reported to be present in large amount in cytoplasmic membrane fatty acids of LAB as *Lactobacillus bulgaricus*, *Lactobacillus helveticus*, *Lactobacillus acidophilus*,[15−17] and *Lactobacillus casei*,[18] so it would be expected that they were released in fermented products in significant amounts. To confirm this hypothesis, experimental fermented milks were prepared inoculating different combinations of microorganisms, as reported in Materials and Methods.

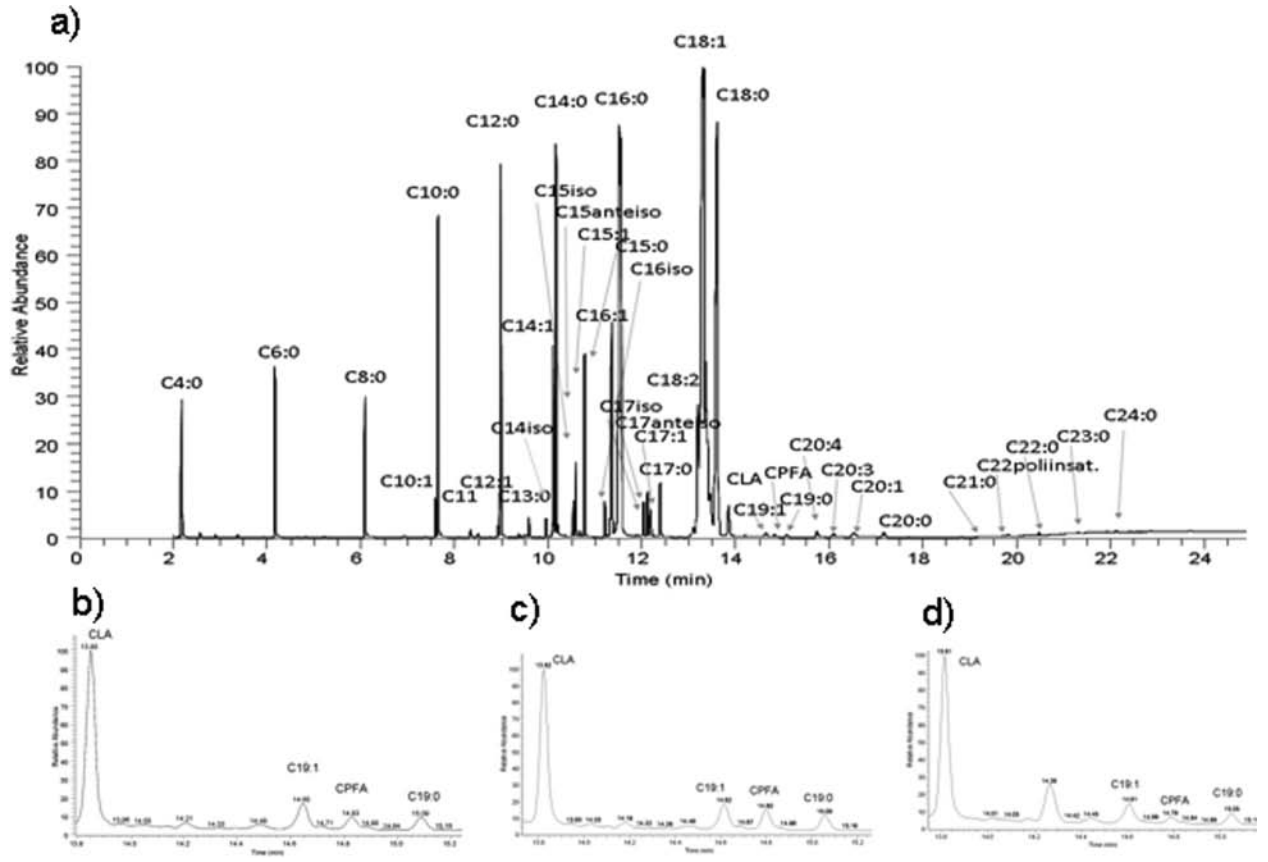

Figure 2. (a) GC-MS chromatogram of Grana Padano cheese sample fatty acid methyl esters on a SLB5 capillary column and details of the elution zone of CPFA for (b) Grana Padano, (c) milk from Lombardy, and (d) commercial butter. The CPFA peak corresponds to the sum of dihydrosterculic and lactobacillic acid.

Fermented milk samples were tested for the content of CPFA and compared with the content in the starting milk (Table 2). Results showed that starting bulk milks for yogurt/fermented milk productions were positive to CPFA, containing mean percentages of CPFA of 0.041%, with no significant differences (ANOVA test, $p > 0.05$) between milk collected in summer (0.043%) and milk collected in winter (0.038%). Fermented milks and yogurt maintained the percentages of CPFA present in the starting milk; in fact, the CPFA contents of fermented products are not significantly different (Tukey multiple comparisons, p level 0.05, $n = 4$) from starting milk, in all the experiments conducted with different microorganisms. Moreover, CPFA content does not change during the shelf life of the products. These results demonstrate that the most common microorganisms tested and utilized for yogurt or fermented milks production (*Bifidobacterium infantis*, *Lactobacillus acidophilus*, *Lactobacillus paracasei*, *Lactobacillus bulgaricus*, *Streptococcus thermophilus*, and Lactococci) are not able to release significant amounts of CPFA in the medium and to incorporate them in triglycerides. Therefore, we can conclude that the amount of CPFA found in fermented milks derives only from their initial content in milk and not from the fermentation process.

Cheeses. Many different kinds of cheeses were analyzed, focalizing the attention on two important Italian PDO hard cheeses, i.e., Parmigiano-Reggiano and Grana Padano. The results showed that all the samples of Parmigiano-Reggiano (both commercial grated products and samples certified from Consorzio del Formaggio Parmigiano-Reggiano) are negative to CPFA, while samples of Grana Padano tested are all positive (Table 3). Results obtained for these two cheeses reinforce the hypothesis that the CPFA presence in milk derives from the incorporation in milk triglycerides of the cellular bacterial fatty acids detected in the ensiled products.[9] In fact, the product specifications for Parmigiano-Reggiano[19] prohibit the use of silages for feeding cows, while the specification rules for Grana Padano[20] allow the use of silages. Consequently, the control of CPFA in milk fat could be considered as a quality parameter for cheese productions that prohibit the use of silage feeding. Cheeses coming from mountain regions as Swiss cheeses (Emmenthal, Gruyere) and Aosta Valley (Fontina, Italy) were negative to CPFA, indicating that the use of ensiled forages is infrequent.

Goat and sheep cheeses (fresh or seasoned, from several Italian regions) are exempt of CPFA, confirming data reported for milk of these two species.

The absence of CPFA in Parmigiano-Reggiano, as well as in other cheeses reported in Table 3, confirms the hypothesis that lactic acid bacteria are not able to release detectable amounts of CPFA in dairy products during manufacturing and seasoning steps.

Butter. Among the seven commercial butters analyzed, four were positive to CPFA, showing variable CPFA contents (Table 3), and three were negative. The negative samples were butter declared of alpine origin, butter produced from milk for Parmigiano-Reggiano production, and goat butter, further confirming data reported for goat milk and cheese.

dx.doi.org/10.1021/jf4057204 | J. Agric. Food Chem. 2014, 62, 7828−7832

Due to the limited number of butter samples analyzed, further studies are needed to confirm these results.

Summarizing, our results suggest that the presence of CPFA in milk and dairy products is derived from their presence in silage forages, where CPFA can be released by bacteria during silage fermentation conditions. On the contrary, lactic acid bacteria, ubiquitous in fermented milk and cheeses, seem not to be able to release CPFA in the conditions of milk fermentation. Therefore, CPFA can be considered interesting molecular markers, able to distinguish milk from dairy cows fed with silage-based diet from milk from cows fed with hay-based diets.

The analysis of CPFA can be a useful tool of the quality control for PDO cheeses, such as Parmigiano-Reggiano, whose specifications of production do not allow the use of silages, as well as a marker to differentiate high quality dairy products such as milk, cheese, and yogurt from alpine regions, where cattle feeding is based only on pasture and hay. Further analytical work on feed is in progress to confirm the presence of CPFA in all ensiled feeds.

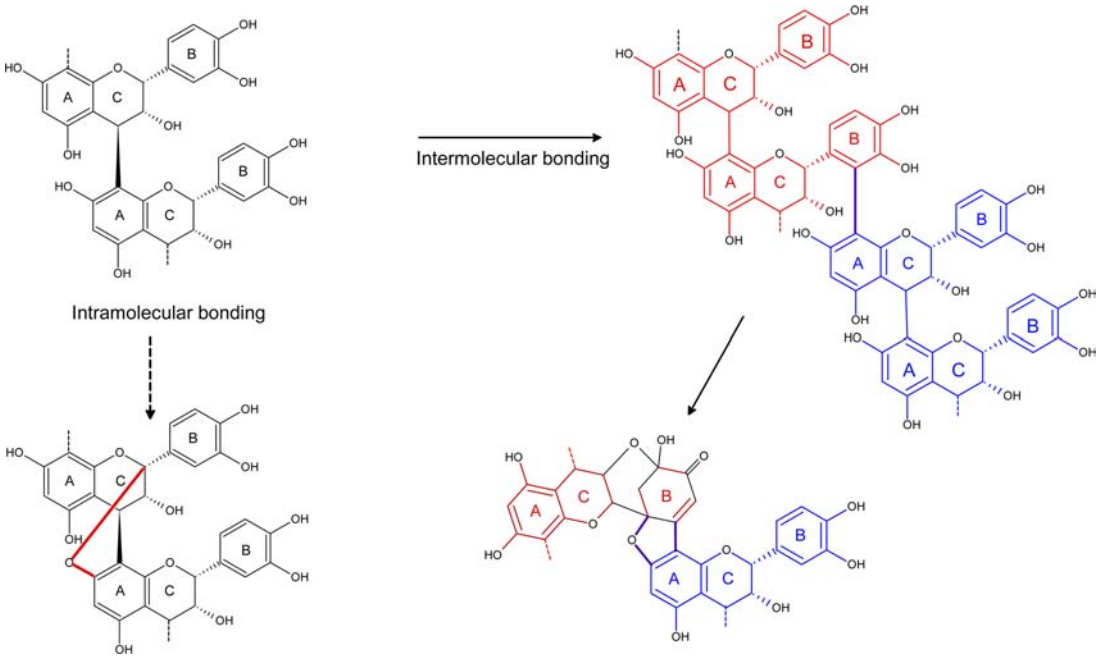

Figure 1. Examples of chemical structures of oxidized tannins. According to current knowledge on monomers and dimers, the creation of new bonds may occur on the same macromolecule (intramolecular bonding) leading to the formation of an A-type tannin or between two macromolecules (intermolecular bonding). In the case of intermolecular reactions, the new bond is formed between A and B rings. Further oxidation may lead to additional cyclization between rings A and B.

and 10 g/L) for DP14 tannins. At high concentrations, we observed an increase of the weight average molecular weight of tannins upon autoxidation, attributed to intermolecular reactions.[16] Our results also suggested that the concentration of tannins during autoxidation could play a key role in the competition intermolecular reaction versus intramolecular reaction.[15] Working with oxidized tannins, Zanchi et al.[17] observed only the formation of intramolecular bonds, but they worked in more dilute conditions and separated the fractions on chromatographic supports prior to SAXS experiments.

Our present objectives were as follows: (i) to confirm that tannins are semiflexible polymers, working with a broader range of tannin fractions, from DP6 to DP80; (ii) to assess the impact of oxidation on the conformation of tannins; and (iii) to determine the key parameters that rule the formation of intermolecular or intramolecular bonds upon autoxidation reactions, especially the impact of the initial DP and concentration of tannins.

To answer these questions, six different fractions of native apple tannins were studied, and kinetics of oxidation were monitored with two different DP for forty days and at two different concentrations. These concentrations, 0.1 and 5 g/L, were chosen as representative of white and red wine conditions, respectively. Apple condensed tannins were first studied instead of grape condensed tannins due to their simpler structure.

MATERIALS

Deionized water was obtained with a Milli-Q system (Millipore, Billerica, MA, USA). Chemicals (solvents, organic acids, and reagents) were of analytical grade and purchased from VWR and Merck (Hohenbrunn, Germany). Freeze-dried powder of apple (*Malus domestica*) cortex tissues were kindly prepared and provided by S. Guyot (Unité de Recherches Cidricoles, INRA Rennes, France), and different apple tannin fractions were purified as described before.[18,16] These fractions are referred to as DPX, with X being the number average molecular weight determined by depolymerization methods, coupled with HPLC analysis.[15] These native fractions were used to get the relationship between the average DP and the scattering intensity at null Q obtained from SAXS experiments.

Apple tannin fractions were oxidized at pH 3.5 (which is considered as a relevant pH in enology) to study the effect of concentration on oxidation mechanisms (intra- vs intermolecular reactions), according to the procedure described before,[16] either in dilute (0.1 g/L) or concentrated (5 g/L) solutions. Typically, native tannins were dissolved in deionized water, the pH of which was adjusted to 3.5 with trifluoroacetic acid. The solutions were centrifuged (100 000*g*, 90 min, 20 °C) to remove insoluble species. The supernatants were stirred at 25 °C in sealed vials to prevent any additional oxygen intake. At low concentrations, typically 10 mg of tannins (34.5 μmoles of flavanol units) was dissolved in 100 mL of buffer containing 26 μmoles of oxygen and put in a 125 mL flask (headspace of 25 mL corresponding to ∼215 μmoles of O_2): in these conditions, O_2 was in large excess (almost 7 equiv). At higher concentrations, typically 15 mg of tannins (52 μmoles) was dissolved in 3 mL of buffer containing 0.78 μmoles of O_2. The volume of the vials was 10 mL; thus, the headspace was 7 mL (60 μmoles of O_2), resulting in a slight excess of oxygen (1.2 equiv). Oxidation was followed by UV−visible spectroscopy and depolymerization reactions after 7, 14, 26, and 40 days.

Oxidations were stopped after 7, 14, 26, and 40 days; samples were pulled, freeze-dried, and kept under argon, in sealed vials, protected from light to avoid further oxidation and at −80 °C. Samples will be referred to as DPXox dil or conc (for dilute or concentrated oxidation) yd, with y being the duration of oxidation in days. For example, DP6ox conc 40d stands for an initially DP6 tannin fraction oxidized for 40 days at a concentration of 5 g/L.

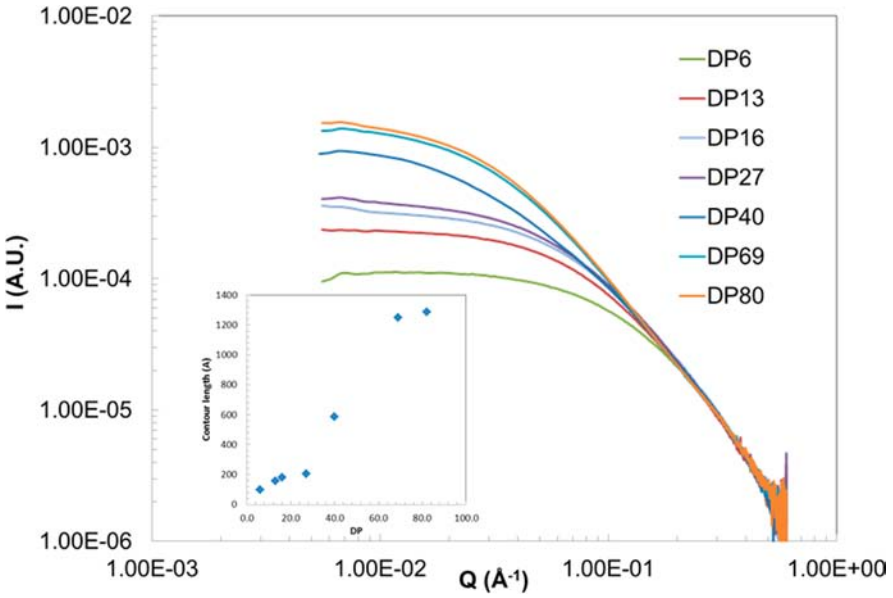

Figure 2. SAXS intensity (normalized by concentration) of native tannins in the log I−log Q representation. DP40 results[16] were included in the graph. In the insert: the persistence length L obtained for the native tannin fractions by fitting SAXS spectra with the WLC model[21] increases linearly with DPn up to DP40.

METHODS

UV−Visible Spectroscopy. UV−visible experiments were carried out on a UV−visible UV Safas mc^2 spectrophotometer at 25 °C. Spectra of the native and oxidized fractions were recorded in ethanol, from 250 to 700 nm.

Depolymerization of Tannins and HPLC-DAD Analysis. Depolymerization was carried out with 100 μL of tannin solution (at a concentration of 1g/L in methanol) combined with 100 μL of a solution of nucleophile (0.8% v/v thioglycolic acid solution in 0.2 M HCl in methanol). The mixture was heated at 90 °C for 6 min and then cooled in cold ice. HPLC analysis followed the conditions described by Vernhet et al.[15] The DPn was calculated as the ratio between the summed molar concentrations of all released monomer constitutive units and the summed molar concentrations of terminal constitutive units.

Small-Angle X-ray Scattering. SAXS experiments were performed on the beamline SWING, at Synchrotron Soleil (Saint-Aubin, France). The incident beam energy was 10.5 keV (λ = 1.18 Å), and the distance from the sample to the Aviex CCD detector was 1500 mm. The corresponding scattering vector $Q = 4\pi \sin\theta/\lambda$ ranged from 0.007 to 0.575 Å^{-1}, where 2θ is the scattering angle and λ is the incident wavelength. Experiments were performed at 25 °C. Several successive frames (typically 10) of 1 s each were recorded for both the sample and the solvent (EtOH). It was checked that X-rays did not cause any damage to the polyphenol molecules by comparing successive frames. The average intensity and experimental error of each set of frames were subsequently computed. Scattering from the solvent was measured and subtracted from the corresponding intensity the of tannin solution.

The SAXS data were analyzed according to classical formulas for scattering from dispersions of particles or macromolecules in a homogeneous solvent.[14] For such dispersions, the intensity can be decomposed as a product of the intensity scattered by a single particle and a structure factor that describes interferences arising from different particles:

$$I(Q) = N_p(\rho_p - \rho_s)^2 V_p^2 P(Q) S(Q) \quad (1)$$

where ρ_p is the electron density of the particles and ρ_s is that of the solvent, V_p is the volume of a particle, N_p is the number of particles per unit volume, $P(Q)$ is the form factor of particle, and $S(Q)$ is the structure factor that describes the pair correlations between the positions of all particles. If the sample is a dilute solution, where the relative positions of the particles are not correlated, then $S(Q) = 1$ at all Q values. If the sample is a dilute solution of polydisperse macromolecules, the intensity scattered in the $Q \to 0$ limit is proportional to a weight average of the molecular weight M_w, or the DP, and the polymer concentration C:

$$I(Q \to 0) \propto M_w C(\rho_p - \rho_s)^2 \quad (2)$$

The form factor $P(Q)$ represents the shape of the particle and its internal electron density distribution. For macromolecules that behave like freely jointed chains, the form factor is given by the Debye scattering function[19] as a function of the reduced parameter $x = (QR_g)^2$ where R_g is the radius of gyration of the macromolecules:

$$P(x) = 2(e^{-x} + x - 1)^2/x^2 \quad (3)$$

Different models exist in the literature for particles or polymers. Scattering curves were fitted with the Sasfit software,[20] using different form factors: flexible chains fitted with eq 3; wormlike chain (WLC),[21] defined by three parameters: the contour length L of the semiflexible wormlike structure, its Kuhn length b, which is the length of the statistical segment or twice the persistence length, and the radius of gyration of the cross section of the chain, R_{cs}; self-similar branched polymers fitted with the Fisher−Burford (FB) approximation,[22] with two parameters that are the radius of gyration R_g and the self-similarity exponent D_f, also called the fractal dimension. The fractal dimension is a value that gives information on the polymer structure: for instance, D_f = 1.67 for a linear swollen polymer, 2 for a polymer in θ solvent and a swollen branched polymer, and 2.29 for a randomly branched ideal polymer.[23] In addition to the latter model, the impact of the chain thickness was accounted for in the Fisher−Burford model, using the following equation:

$$P_{FB,R_{cs}}(Q) = P_{FB}(Q) e^{-Q^2 R_{cs}^2/2} \quad (4)$$

where $P_{FB}(Q) = (1 + ({}^2/_3 D_f)x^2)^{-D_f/2}$ is the form factor calculated with the Fisher−Burford equation, whereas $P_{FB,R_{cs}}(Q)$ is the form factor obtained when the chain cross-section radius of gyration R_{cs} is taken into account.

RESULTS AND DISCUSSION

As already described in previous papers,[14,15] we expected SAXS to provide information on the conformation of tannins and on the structural changes induced by autoxidation.[7,8,24] The conformation of native apple tannins was studied first. Then, changes induced by autoxidation were studied using two different techniques.

Conformation of Native Tannins. The conformation of native tannins was previously studied using mainly fractions of DP9 (from grape seeds) and DP40 (from apple parenchyma). In this paper, we studied six additional apple tannin fractions including higher molecular weight tannins (DP69 and DP80). The main constitutive unit in apple condensed tannins is (−)-epicatechin (95%), (+)-catechin being only present as the terminal unit.[25] The average DPs of the fractions, determined using acid-catalyzed depolymerization of the fractions in the presence of a nucleophilic reagent, were 6, 13, 16, 27, 69, and 80. The yields of the depolymerization reaction were in the range 65–80%. SAXS measurements were done in ethanol at 25 °C because it is considered as a good or θ solvent for native and oxidized tannins. SAXS intensities of all the native fractions are plotted on the Figure 2.

According to eq 2, I_0 is proportional to the weight average molecular weight M_w, and therefore, a relation with the number average molecular weight M_n calculated from the DPn obtained through the depolymerization method was expected. We obtained a linear relation between intensities from SAXS and molecular weights from depolymerization methods:

$$\frac{I_0}{c} = 3 \times 10^{-5} \times M_n \tag{5}$$

The correlation coefficient was 0.97. This is not excellent, probably because of discrepancies between the number average and the weight average molecular weights brought by a slight polydispersity of the fractions with the highest degree of polymerization. In the next section, the SAXS intensities from oxidized tannins will be compared with those of native tannins, and this relation will be used to evaluate their average molecular weights.

Geometrical parameters and scattered intensities at $Q \rightarrow 0$ were determined by fitting the curves with the Gaussian, WLC, and Fisher–Burford models (Table 1). The quality of the fit was evaluated with the χ^2 values: the best fits were the ones with the lowest χ^2 values. Concerning the structural parameters, best fits were obtained with the WLC model up to DP27, whereas the best results were obtained with the Fisher–Burford model for DP69 and DP80, which can be implemented using the cross-section radius, as explained in the next section. Results obtained previously with a DP40 tannin fraction[16] have been included in the results. Also, for this fraction, the best fits were obtained with the Fisher–Burford model.

The radius of gyration R_g of a linear macromolecular chain is expected to increase with the DP according to the following equation:

$$R_g = a\mathrm{DP}^{\nu} \tag{6}$$

where ν is the Flory coefficient and a is the length of the monomer unit.

Plotting ln R_g as a function of ln DP yielded ln R_g = 1.816 + 0.517 ln DP, with a correlation coefficient of 0.97. In our conditions, a equals ∼6.15 Å, which is in the same order of magnitude as results obtained by Martinez et al. using molecular modeling.[26] For polymers in θ conditions, ν equals 0.5, whereas it is 0.6 for a polymer in good solvent. With ν equals 0.517, we are somewhere in between. This can be partly explained by the fact that we do not work with monodisperse fractions and/or the fact that we work with macromolecules that are linear within the range 6–40 (less than one decade) and/or the fact that the polymer adopts an intermediate behavior.

Using the WLC model to fit SAXS spectra (Table 1), we obtained a value of the persistence length in the range 7.5–10 Å for DPs up to 40, whereas the radius of cross section was nearly 4.5–5 Å. These values were consistent with what we observed previously for a DP40,[15,16] and a good linear relationship was found between the contour length L and the DPn (insert in the Figure 2). The length per monomer L/DPn obtained from these values (12 Å) is consistent with the dimensions of the monomeric units.[26] However, for DP69 and DP80, this relationship was no longer observed: the persistence length dropped suddenly, along with an increase in R_{cs}, and the quality of the fit also dropped: the WLC model was no longer suitable for these two fractions.

Fisher–Burford fits were improved after considering that macromolecular chains have a thickness (Table 2). Up to DP40, the fractal dimensions and the cross-section radius remained constant. For DP69 and DP80, the fractal dimension increased to 2.20 and 2.25, suggesting denser objects: in the case of polymers, it could indicate the presence of ramifications.[23] In addition, the R_g values found for these two molecular weight fractions did not increase compared to the DP40 values (Table 1). The presence of ramifications was confirmed by the Kratky plots of the scattering curve (Figure 3): a point of inflection was observed with the DP69 and DP80,

Table 2. Scattered Intensities Extrapolated to $Q \rightarrow 0$ I_0/C, Radius of Gyration R_g, Fractal Dimension D_f, and Cross-Section Radius R_{cs} of Apple Tannin Fractions, χ^2 Values Are an Indication of the Quality of the Fit

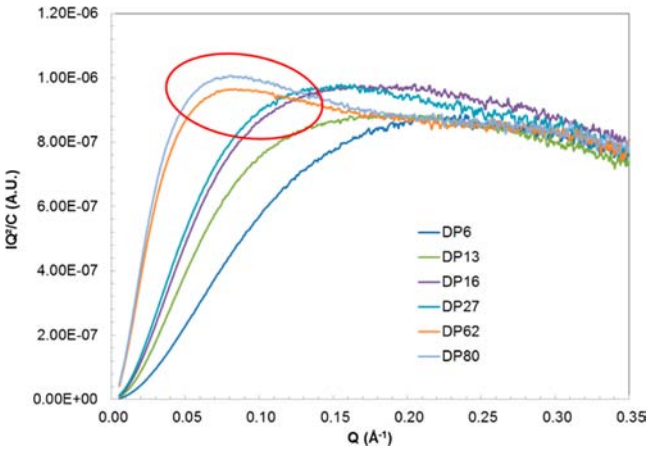

Figure 3. Kratky plots of native tannins fractions. The inflection points observed with DP62 and DP80 are consistent with branched and/or star polymers.

which is consistent with the appearance of branched macromolecules. This is in agreement with the results obtained by Zanchi et al.[17] using ab initio modeling and Gasbor on apple parenchyma tannins having DPs of 75 and 150.

To summarize, results obtained here and in previous experiments are consistent with the fact that tannins extracted from apple parenchyma (i.e., epicatechin polymers) were linear macromolecules up to DP~40 and became more or less branched at higher DPs. However, it was previously shown that oxidation can induce branching,[16] and thus, the fact that branching is due to oxidation cannot be ruled out, whether it takes place *in planta* or during extraction.

Oxidized Tannins. SAXS experiments were performed on oxidized fractions in order to get information on (i) the evolution of the molecular weight of tannins upon oxidation and (ii) the branching versus elongation of macromolecules. Especially, we wanted to check the impact of the initial tannin DP and concentration. The two tannin fractions used were the DP6 and DP16, autoxidized either at 0.1 or 5 g/L. These concentrations were chosen to emphasize the concentration effect: intramolecular reactions were expected to be favored at low concentration, because in these conditions, a macromolecular chain has more chances to react with itself rather than with its neighbors. On the contrary at higher concentrations, the formations of both inter- and intramolecular bonds are expected. UV−visible spectra (Figure S1, Supporting Information) exhibited typical changes usually observed upon oxidation of tannins, that is, the appearance of humps at 320 and 420 nm.

In parallel, the yields of the acid-catalyzed depolymerization reaction dropped (Table 3). This was attributed to the absence of cleavage of new covalent bonds created by oxidation[12] and was used to evaluate the extent of tannin oxidation, as described later.

Oxidation in "Concentrated" Systems. During oxidation, the visual aspect of solutions evolved: apparition of color changes and of a slight haze after 40 days. After centrifugation, tannins in the pellet were freeze-dried and weighed; they represented about 5%, except for DP6 after 40 days where they represented nearly 20%. They were disregarded for further experiments.

The proportion of decrease of depolymerization yield was calculated as

$$\left(1 - \frac{\text{depolymerization yield after } n \text{ days}}{\text{initial depolymerization yield}}\right) \times 100 \quad (7)$$

As observed in previous papers,[15,16] the DPn calculated from depolymerization experiments (Table 3) slightly decreased during autoxidation whereas the yield of the reaction drastically dropped (roughly −30% and −50%, respectively, for DP6 and DP16 after 26 and 40 days). As previously stated, this is attributed to the formation of new bonds, resistant to depolymerization. This means that one-third to one-half of the interflavonoid bonds underwent chemical reactions. Dimers and trimers released from the nondepolymerization of these bonds, which can be considered as oxidation markers, have been identified using UPLC/ESI-MS^n.[13] However their separation and quantification remains a challenge.

SAXS curves are shown in Figure 4 (DP6) and in Figure 5 (DP16). Intensities normalized by the concentration increased with the time of oxidation, indicating that the weight average molecular weight of tannins increased. The scattering curves were fitted with the same models as previously (Table 4). For the DP6 tannins, the best results were obtained with the WLC and Fisher−Burford models. The contour length increased with the ratio I_0/C, which is proportional to the actual DPw. The persistence length $b/2$ was 7.5 ± 0.4 Å, and the cross section

was roughly 4 Å, like with linear native tannins. Parameters determined from the Fisher–Burford model with cross section were consistent with a linear polymer (D_f = 2) with a constant cross section. Kratky plots (insert in Figure 4) confirmed that polymers "grew" in a linear way, probably due to mainly end to end reaction (extension). After 40 days of oxidation, I_0/C increased by a factor 3.5, so was the molecular weight according to eq 2, resulting in a DP roughly equals to 21.

For the DP16, poor results were obtained with the WLC models: this can be explained by the fact that polymers are no longer linear, as confirmed by the Kratky plots (insert in the Figure 5), typical of branched macromolecules. Parameters determined from the Fisher–Burford model with or without cross section (Table 4) were consistent with branched polymers (D_f > 2.2[23]). This suggests that, in this case, intermolecular reactions took place in an end-to-middle way, as already observed with DP40.[16] After 40 days of oxidation, I_0/C increased by a factor 35, so was M_w.

The main differences observed between DP6 and DP16 concerned (i) end-to-end reactions with the shorter native tannins, leading to slightly longer linear macromolecules, versus

end-to-middle connections with longer native tannins leading to branched macromolecules; this can be explained by the ratio between terminal and extension units (when the chain is longer, it has more chances to react with an extension unit than with a terminal unit); and (ii) the competition between intermolecular and intramolecular reactions.

Indeed, the yields of the depolymerization reaction indicated that 30% of the units had reacted for DP6 versus 50% for DP16 (Table 3). Oxidation reactions can be related to the formation of either intramolecular or intermolecular bonds. Coupled with SAXS results, the different yields indicated that the ratio of intermolecular versus intramolecular reactions was totally different for the two tannins: for DP6, the weight average molecular weight increased by a factor 3.5, whereas it increased by a factor 35 with DP16.

These results can be used to evaluate the proportions of inter- and intramolecular bonds created during oxidation. Indeed, if during oxidation the average degree of polymerization DPn increased by a factor x, it means that $(x - 1)$ non-cleavable interflavonoid bonds were created in average, also meaning that $2(x - 1)$ flavanol units became non-quantitatively analyzed (Figure 6). Thus, the percentage of monomers involved in intermolecular bonds, is expected to be

$$\rho = \frac{2(x-1)}{nx} \times 100 \quad (8)$$

dx.doi.org/10.1021/jf501441j | J. Agric. Food Chem. 2014, 62, 7833−7842

With our values (x = 3.5 for DP6 and x = 35 for DP16), we would have expected a loss of yield of 24% and 12%, respectively, (actual values: 30% and 50%). This means that, for DP6, intermolecular bonds represent about 80% of the newly formed bonds, whereas they represent 24% for DP16. This is probably due to the fact that longer chains have more possibilities to have adjacent monomers and thus have more possibilities to form intramolecular bonds.

Oxidation in "Dilute" Systems. During oxidation, the color of solutions changes (Figure S1, Supporting Information), and as observed in concentrated conditions, the DPn obtained from depolymerization decreased (Table 5). This decrease was more pronounced than in concentrated conditions and associated with a dramatic drop of the yield of the depolymerization reaction: −63% and −84%, respectively, for DP6 and DP16 after 40 days, meaning that only 37% and 16% of the initial interflavonoid bonds remained unreacted. It was much less than what was observed at higher concentrations: 70% of unreacted interflavonoid bonds for DP6, 50% for DP16. This is likely due to the ratio between oxygen and tannins, which is much higher in the case of dilute solutions (7 equiv of O_2 vs 1.2) and thus favors more oxidation reactions.

SAXS curves are shown in Figures 7 (DP6) and 8 (DP16). Intensities normalized by the concentration increased with the

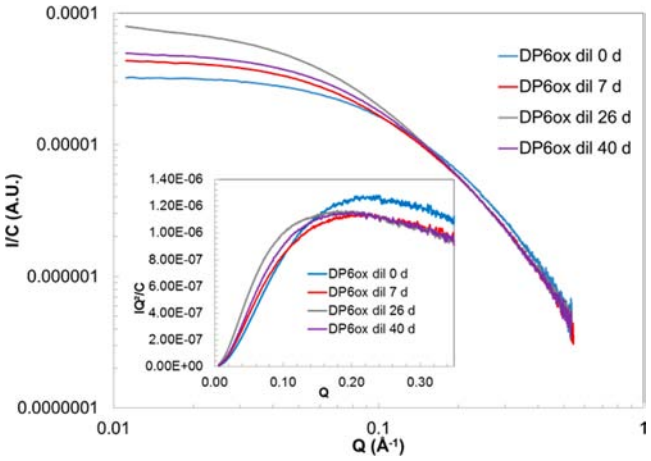

Figure 7. SAXS intensity (normalized by concentration) of native and oxidized DP6 in dilute solutions (0.1 g/L) at different times of oxidation in the log I−log Q representation. Kratky plots are displayed in an insert.

time of oxidation until day 26, indicating that the weight average molecular weight of tannins increased, before dropping at day 40. The scattering curves were fitted with the same models as previously (Tables 6 and 7).

For the DP6 tannins, the best results were obtained with the Fisher−Burford models, with or without cross section, depending on the oxidation time. However, results obtained with the WLC were correct and showed that the persistence length $b/2$ evolved when the oxidation time increased and was 10.5 Å at 26 days. The cross section was still in the range 4.1−5 Å. Parameters determined from the Fisher−Burford model with cross section are consistent with a linear polymer ($D_f \sim 2$) with a constant cross section. However, at longer oxidation times, the fractal dimension slightly increased. The weight average molecular weight did not increase regularly: it was surprisingly higher after 26 days than after 40 days. After 40 days, the M_w was increased by a factor of 2 in dilute solution, instead of 3.5

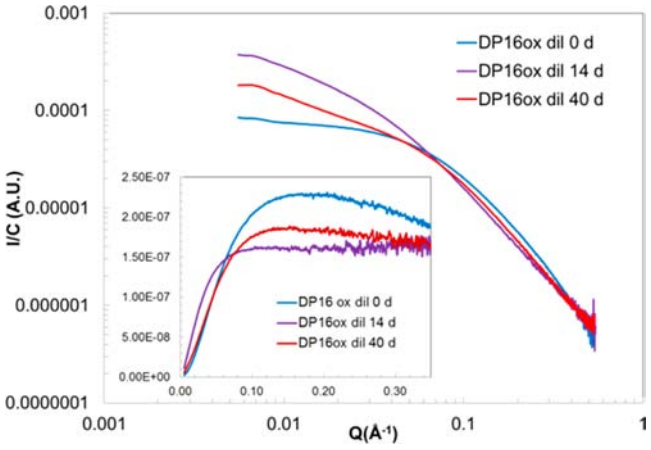

Figure 8. SAXS intensity (normalized by concentration) of native and oxidized DP16 in concentrated solutions (5 g/L) at different times of oxidation in the log I−log Q representation. Kratky plots are displayed in an insert.

when tannins were more concentrated. It is also worth noting that the depolymerization yield decreased by 63% versus 33% in concentrated solutions: more interflavonoid bonds were modified, but they led to the formation of more intramolecular bonds. According to eq 8, if only intermolecular reactions had occurred, we would have observed a decrease of the depolymerization yield of 16%. Thus, roughly 47% of the uncleavable bonds are due to intramolecular reactions ($^1/_4$ intermolecular, $^3/_4$ intramolecular).

For the DP16 tannins, the best results were obtained with the Fisher−Burford models, with or without cross section, depending on the oxidation time. However, χ^2 values are higher than with DP6. This may be due to the presence of aggregates (even though samples were filtered) or to a high heterogeneity of the sample, making curve fitting more difficult. Parameters determined from the Fisher−Burford model with cross section were consistent with a linear polymer ($D_f \sim 2$) but with a slightly decreasing fractal dimension. This could reflect the local stiffening of (some of) the macromolecules: indeed the fractal dimension for rods is 1.[23]

The weight average molecular weight did not evolve regularly as already observed with DP6 and was higher after 14 days than after 40 days. However, with the sample oxidized 14 days, nearly 30% of the tannins were lost upon filtration prior to SAXS experiments, and thus, its composition may not be representative of the total fraction. It is also worth noting that problems of redissolution in ethanol were observed with the fraction oxidized during 26 days and that no measurement could be performed. This might be an indication of the formation of intermediate species, having different solubilities in ethanol. After 40 days, no loss upon filtration was observed, and the M_w increased by a factor 1.6, instead of 35 when tannins were oxidized at a higher concentration. The depolymerization yield decreased by 84% instead of 51% in concentrated solutions (Table 6): more interflavonoid bonds were modified, but they mainly led to the formation of intramolecular bonds. According to eq 8, if only intermolecular reactions had occurred, we would have observed a decrease of the depolymerization yield of less than 5% instead of 84%. Thus 6% of the uncleavable bonds can be attributed to intermolecular reactions and 94% to intramolecular reactions.

To summarize our results, we confirmed that usual analytical methods (depolymerization followed by HPLC analysis) provide information that must be cautiously interpreted when dealing with autoxidized tannins. Indeed, upon oxidation, conversion yields dramatically decrease, meaning that the proportion of identified monomers can be as low as 10%. The decrease of conversion yield is by itself an indicator for tannin oxidation and should be indicated.

Using SAXS allowed determination of the conformations of native tannins and evidence of conformational changes upon oxidation. Native tannins can be considered as wormlike chains (or semiflexible polymers) having a relatively short persistence length (7.5–10 Å) and a cross section in the range 4.5–5 Å. However, for chains having more than 40 monomers, results indicated some degree of branching. Upon oxidation, several scenarios were observed (also summarized in Table 8) depending on the initial tannin concentration and its initial degree of polymerization:

Table 8. Proportions of Oxidation Bonds Created Either Intermolecularly or Intramolecularly

tanin fraction	intermolecular bonds (%)	intramolecular bonds (%)
DP6ox conc 40d	80 (end to end)	20
DP16ox conc 40d	24 (end to middle)	76
DP6ox dil 40d	25	75
DP16ox dil 40d	6	94

(i) Increase of the weight average molecular weight of tannins but no conformational changes (the chains are getting longer, but no polymer branching is observed) in the case of DP6 tannins. In this case, intermolecular and intramolecular reactions occur, but it is worth noting that the proportion of intramolecular reactions is higher when the concentration is lower: in dilute solutions a chain has more chances to react with itself than with a faraway neighbor.

(ii) Huge increase of the weight average molecular weight (X35), with the formation of branched macromolecules with DP16 tannins oxidized at high concentrations: in this case, intermolecular reactions are favored, and as the ratio extension units/terminal units is higher than with DP6, the probability for the chains to react end-to-middle increases.

(iii) In the case of dilute solutions of DP16, a relative stagnation of the molecular weight (X1.7 compared to X35) and slight decrease of the fractal dimension were observed, possibly accounting for the partial stiffening of macromolecules in connection with (mainly) intramolecular reactions

The impact of the initial concentration and DP of condensed tannins on autoxidation mechanisms was evidenced: oxidation in dilute and concentrated solutions leads to the formation of different structures, the solubility of which is very different. Concentrations (0.1 and 5 g/L) were chosen to mimic those of condensed tannins in white and red wines. However, it must be kept in mind that these results apply to the simple model systems considered first: apple tannin fractions (mainly epicatechin subunits) with different DP, given oxygen/flavanol unit ratios, water acidified to pH 3.5. When dealing with complex systems such as wine, the initial DP of condensed tannins is polydispersed, and the constitutive units of grape tannins include not only epicatechin and catechin, but also epigallocatechin and epicatechin-gallate. The reactivity of the latter may be different and influence structural changes. Further studies will have to consider this complexity. Last, but not least, other modified tannins are formed, for instance ethyl-linked tannins and anthocyanins/tannins adducts.

Preparation of the Modified "in Bean" Green Coffee Models. Modified "in bean" models enriched with CGA were prepared using a previously developed method[16] with small modifications. Brazil arabica green coffee beans were initially freeze-dried until constant weight (6% weight loss). For the preparation of the chlorogenic acid-enriched coffee model (CGAcoffee), to 100 g of the freeze-dried green coffee beans was added 200 mL of a CGA aqueous solution (1.5 g/200 mL), and the mixture was shaken for 16 h at 4 °C. After incorporation, the coffee beans were washed with distilled water for removal of the surface-adhering solution and freeze-dried. As a control, 100 g of freeze-dried coffee beans was immersed in 200 mL of water under the same conditions.

Roasting of Coffee Bean Model Samples. Prior to roasting, all samples (original freeze-dried coffee, water control, and CGAcoffee) were adjusted to the same moisture of 6% by spraying enough water and checking coffee weight after 1 week. Then, the coffee beans (40 g) were roasted at 200 °C during approximately 5 min to obtain an organic roast loss of 8%.

Preparation of Coffee Brews and Isolation of the High Molecular Weight Material (HMWM). Roasted coffee beans were ground (250−450 μm), and infusions were prepared by extraction of 25 g of powdered coffee with 800 mL of water at 80 °C during 20 min. After filtration and vacuum concentration to 200 mL, 50 mL of coffee infusion was freeze-dried to calculate the total soluble solids. The other 150 mL was extensively dialyzed at 4 °C (six water renewals, MW cutoff 12−14 kDa). After dialysis, the retentate was freeze-dried, giving the HMWM.

Fractionation of the HMWM by Graded Precipitation in Ethanol. For the fractionation of HMWM for each coffee infusion, the method previously developed[20] was used with a modification;[16] for complete solubilization of the freeze-dried HMWM, a solution of 6 M urea was used. The HMWM was then precipitated by the addition of absolute ethanol. The material was recovered in the 50% ethanol solution (Et50) and in the 75% ethanol solution (Et75). It was resolubilized in water and dialyzed (six water renewals, MW cutoff 12−14 kDa). After dialysis, the retentate was freeze-dried. The material soluble in the 75% ethanol (EtSn) fraction was recovered after concentration, dialysis, and freeze-drying.

Chlorogenic Acids and Caffeine Content of Green and Roasted Coffees. CGA were extracted overnight from green and roasted ground coffees (1 g) with 100 mL of a solution of methanol/water (70:30 v/v) containing 0.5% Na_2SO_3 with constant stirring (125 rpm) in the dark. To the solution was added 1 mL of veratric acid as internal standard (100 mg/mL, in methanol). After filtration of the coffee powder, the colloidal material present in the extracts was precipitated by the addition of 1 mL of Carrez I and II solutions.[21] The extracts were analyzed by HPLC (Dionex, Ultimate 3000) by injection of 25 μL of the sample on a reversed-phase HPLC column (C18-ACE; 25 cm length, 0.45 cm internal diameter, and 5 μm particle diameter). Eluent A was a 5% formic acid aqueous solution, and eluent B was methanol. The eluent program was as follows: 0−5 min, 5% eluent B; 5−45 min, 40% B; 45−65 min, 70% B; 65−75 min, 5% B. The column temperature was set at 25 °C, and the flow was 0.8 mL/min. The eluent was continuously monitored from 200 to 600 nm with a photodiode array detector (PDA-100, Dionex). The identification of caffeine and 5-caffeoylquinic acid was made by comparison of their retention times and UV−vis spectra with those of pure standards analyzed under the same conditions. The other caffeoylquinic acids (CQA) and cinnamoyl-1,5-γ-quinolactones (CQL) were tentatively identified by comparison of their retention times and UV−vis spectra with those of the literature.[22] CGA were quantified by the internal standard method using a 5-CQA calibration curve. Caffeine was quantified using the same methodology and a caffeine calibration curve.

Characterization of Coffee Bean Samples and Fractions. Green and roasted coffee and coffee models were characterized regarding their sucrose, glucose, and fructose contents by high-performance anion exchange chromatography.[23] Total sugars content was determined by anion exchange chromatography after Saeman and acid hydrolysis.[20] Protein content was determined according to the Dumas method (PRIMACS, carbon−nitrogen/protein analyzer, Skalar, The Netherlands) by multiplying the nitrogen content by 6.25. The melanoidin content of fractions was determined by the K_{mix} at 405 nm as previously described.[4]

Color of Roasted Coffee Powder. Roasted coffee powder colors obtained for the original, control, and "in bean" CGAcoffee model were directly measured with a Minolta chroma meter (model CR-400, Minolta, Tokyo, Japan). The equipment was set up for illuminant D65 and 10° observer. The equipment was calibrated with a white standard (L^* = 97.71, a+* = −0.59, and b^* = 2.31), and each sample was put on a Petri dish and read in five different locations. Numerical values of chroma (C^*), hue (h), and color difference (ΔE^*) were calculated according to the following formulas:

$$h^* = \tan^{-1}\left(\frac{b^*}{a^*}\right)$$

$$C^* = (a^{*2} + b^{*2})^{1/2}$$

$$\Delta E^* = [(\Delta L^*)^2 + (\Delta a^*)^2 + (\Delta b^*)^2]^{1/2}$$

Total Phenolic Groups Content. The total phenolic groups content of the coffee samples was determined with the Folin−Ciocalteu reagent.[4] For all coffee samples, a 0.33 or 1 mg/mL solution was prepared. To 1 mL of the coffee sample solution was added 0.5 mL of Folin−Ciocalteu reagent. After mixing of the sample, 1 mL of a saturated Na_2CO_3 solution was added, and filtered demineralized water was added to reach a total volume of 10 mL. After 1 h of reaction, the absorbance of the sample was measured at 725 nm. 5-CQA was used as reference.

Adsorbed Phenolic Compounds. For determination of coffee melanoidins adsorbed phenolic compounds, a 5 mg/mL solution of coffee melanoidins was analyzed by direct injection (100 μL) on a RP-HPLC according to the method described previously for CGA determination. For determination of the effect of melanoidins in the determination of free phenolic compounds, melanoidin solutions (5 mg/mL) were spiked with different concentrations of 5-CQA and incubated overnight at room temperature. Each solution was analyzed by RP-HPLC as described previously, and the areas were compared with that of aqueous solutions of 5-CQA with the same concentrations.

Alkaline Saponification. For determination of ester-linked phenolic compounds, melanoidins were subjected to alkaline saponification by using a procedure that prevented oxidation of phenolic compounds.[24] To 750 μL of the melanoidin solution (12 mg/mL) was added 750 μL of a 2 M NaOH solution containing 2% (w/w) ascorbic acid and 20 mM ethylenediaminetetraacetic acid. After incubation for 1 h at 30 °C, the mixture was quenched to pH ≈1 with 330 μL of 5 M HCl to precipitate most of the coffee material, preventing precipitation during further analysis. The mixture was stored for 2 h at 4 °C, the precipitate was removed by centrifugation, and the supernatant was analyzed by reversed-phase HPLC. Experiments were performed at least in duplicate. The identification of caffeic, ferulic, and 4-hydroxycinnamic acids was made by comparison of their retention times and UV−vis spectra with that of pure standards analyzed under the same conditions. Caffeic, ferulic, and 4-hydroxycinnamic acids were quantified by external calibration.

Alkaline Fusion. In a nickel crucible were weighed 1 g of solid NaOH and 100 mg of zinc dust, and, after fusion of the mixture at 350 °C,[6,25] 5 mg of HMWM was added (or 5 mg of melanoidin fractions). After 10 s, the nickel crucible was removed and rapidly cooled on ice. The fusion cake was solubilized by adding 6 M HCl, and 200 μL of internal standard solution was added (3,4-dimethoxybenzoic acid, 1 mg/mL) and acidified to pH 1−2 with 6 M HCl. The acidic mixture was extracted four times with 30 mL of diethyl ether. After evaporation of the organic solvent, carefully and with protection, the residue was derivatized and analyzed by GC-EI/MS. Samples were derivatized with 0.5 mL of pyridine and 0.5 mL of *N*,*O*-bis(trimethylsilyl)-trifluoroacetamide and heated at 70 °C for 30 min. After cooling to room temperature, the silyl derivatives of phenolic compounds were

analyzed by GC-MS (Agilent) and quantified by GC-FID (PerkinElmer) using a DB-1 column (30 m length, 0.23 mm internal diameter, and 0.2 μm film thickness) and injecting 1 μL in splitless mode (time of splitless, 0.75 min). Both the injector and the transfer line were set at 250 °C. The initial column temperature was 70 °C, held for 1 min, increasing at 5 °C/min until 250 °C. The MS source temperature was set at 180 °C, and the electron ionization energy was set at 70 eV, with scans from m/z 40 to 600. Retention times and electron impact ionization spectra of pure standards were used to identify the following compounds: 3,4-dihydroxybenzoic acid, hydroquinone, catechol, gallic acid, benzoic acid, 2-hydroxybenzoic acid, 4-hydroxybenzoic acid, 2,3-dihydroxybenzoic acid, and 3,5-dihydroxybenzoic acid. Other phenolic compounds were identified by comparison of their mass spectra with those of the Wiley mass spectra database (Wiley 8). Quantification was performed by the internal standard method using 3,4-dimethoxybenzoic acid as the internal standard.

Statistical Analysis. All chemical analyses of green coffees, roasted coffees, soluble solids, HMWM, and fractions obtained by ethanol fractionation of the HMWM were performed in duplicate unless otherwise stated. Significant differences ($p < 0.05$) in chemical composition were analyzed by one-way ANOVA using the software Statistica 8.0 (StatSoft, Inc., Tulsa, OK, USA). A Newman−Keuls post hoc test was performed for detecting significantly different means ($p < 0.05$). For calculating the correlation between the phenolic compounds determined by the Folin−Ciocalteau method and those released by alkaline saponification, the nonparametric Spearman correlation coefficient (ρ) and the parametric Pearson correlation coefficient (r) were used.

RESULTS AND DISCUSSION

With the purpose of studying the effect of the green coffee CGA content, if any, in the incorporation of phenolic compounds into coffee melanoidins, a modified "in bean" model coffee was produced by enrichment of the freeze-dried coffee beans with a CGA mixture isolated and purified from green coffee beans. The procedure for production of the modified "in bean" coffee model was performed at 4 °C to minimize side reactions. This was a modification from our previous work, in which the incorporation was performed at room temperature.[16]

Chemical Characterization of Green and Roasted Coffee Samples and Model. *Green Coffee.* As can be seen in Table 1, the sucrose hydrolysis was significantly lowered in this new protocol when compared to the previous one, when a significant sucrose hydrolysis was observed.[16] Original green coffee had a total soluble sugar content of 8.1%, mainly composed of sucrose (92%) and low amounts of glucose and fructose (Table 1), which is in accordance with the literature values.[26] For the control coffee there was a decrease of 20% of total soluble sugar content when compared with the original green coffee, only due to the decrease in sucrose. For the CGAcoffee model the amounts of sucrose, fructose, and glucose are similar to those of the control coffee (Table 1). This decrease in the amount of soluble sugars can be due to leaching of compounds during the incorporation process and contrasts with the previous procedure at room temperature,[16] when all of the solution was incorporated into coffee beans.

The amount of caffeine present in the original coffee was significantly higher than that present in control and CGAcoffee model, but the protein content of the coffees, estimated on the basis of the nitrogen content after correction for caffeine nitrogen, was not significantly different (Table 1).

The amount of total CGA in the CGAcoffee model was significantly higher (21% higher) than that present in control coffee, showing that the incorporation process was successful (Table 2). As observed for the soluble sugars, control coffee contained a significantly lower amount of CGA. The CGA profiles were similar in all coffees, with 5-CQA as the most abundant, representing, on average, 64% of the total CGA.

The sugar composition of green coffee polysaccharides was determined by subtracting from the total sugar content the contribution of glucose and sucrose present as soluble sugars (Table 3). The sugar content was in accordance with the known sugar composition of coffee cell wall polysaccharides,[16,27,28] not significantly different for the original, control, and CGAcoffee model.

The results presented showed that this new protocol for production of the modified "in bean" model coffees results in fewer changes in the chemical composition of control coffee in relation to the original coffee when compared with the original protocol,[16] being more suitable for the study of the incorporation of selected compounds into green coffee beans prior to the roasting process.

Roasted Coffee. Original, control, and CGAcoffee model coffees were roasted to 8.0 ± 0.5% of organic matter loss, and their chemical composition was determined. After the roasting process, losses of 92% of the total soluble sugar content of the original coffee, 84% for the control, and only 44% for the CGAcoffee model were observed (Table 1). This difference in total soluble sugar loss may be due to the higher content of CGA in the CGAcoffee model that might be preferentially lost during the roasting process (further discussed below). The decrease in the total soluble sugar in roasted original and control coffees are similar to that described in the literature.[16,29] The caffeine level remained unchanged, and the protein content of roasted coffees decreased between 20 and 38% (Table 1).

The amount of total CGA also decreased during the roasting process in all coffee models (Table 2). For the original and CGAcoffee model, the amount of total CGA decreased 55%, and a decrease of 48% was observed for control coffee. This decrease is in accordance with a coffee submitted to a degree of roast of 8%.[30]

The content of polymeric sugars had also a significant decrease after the roasting process (Table 3). All coffee samples behaved similarly, with an average decrease of 28% in the content of total polymeric sugars, in accordance with the literature.[31,32] For all coffees, when calculated for the equivalent weight of green coffee, the polymeric glucose levels were maintained or decreased slightly. For all other sugars, when calculated for the equivalent weight of green coffee, there was observed a decrease (17% for arabinose, 30% for mannose, and 41% for galactose).

The identical degradation profile of the studied coffee constituents led to the conclusion that the freeze-drying of green coffee beans and their immersion in water did not change significantly the behavior and properties of coffee during the roasting process.

During the roasting process, browning reactions occur, contributing to the coffee brown color formation. By visual inspection of the interior of roasted coffee beans, an even distribution of the brown color could be observed. The CIELAB color space used to characterize the coffee powders

[a]Phenolics measured by the Folin−Ciocalteu method and expressed as 5-CQA equivalents. Identical letters in the same column are significantly different.

dx.doi.org/10.1021/jf501510d | J. Agric. Food Chem. 2014, 62, 7843−7853

showed that the C^* value (chroma) of the CGAcoffee model was significantly higher than that of the control, showing that the incorporation of CGA increased the color intensity of the resulting roasted coffee. Furthermore, this increase is related to a significant increase of the b^* value for the CGAcoffee model, showing that the CGAcoffee model had a yellower color than that presented by the control.

Chemical Composition of Coffee Infusions and HMWM. Coffee infusions were prepared from the original, control, and CGAcoffee model, and the HMWM was isolated from each coffee infusion. The amount of soluble solids extracted from control coffee was lower (33% less) than that extracted for the original coffee (Table 4). For the CGAcoffee model an increase of 23% was observed in the amount of soluble solids in relation to control coffee. However, using the $K_{mix\ 405}$ values for estimating the melanoidins present in soluble solids, it can be observed that the incorporation of CGA did not significantly increase the $K_{mix\ 405}$ value of the soluble solids in relation to the control.

The chemical composition of the HMWM isolated from coffee infusions prepared from the original, control, and CGAcoffee model is shown in Table 4. The main component of all the HMWM was the carbohydrates (39−52%), with no significant differences between the coffees, followed by the protein (10−19%), with CGAcoffee model containing a higher amount of protein when compared to the control (+34%). The amount of phenolic compounds was also significantly higher for the CGAcoffee model when compared to the control (+38%), with the latter presenting a similar amount of phenolic compounds to that present in the original coffee HMWM. From these results it is evident that the incorporation of CGA in the "in bean" model resulted in an increase in the amount of phenolic compounds and protein in the HMWM.

The original coffee HMWM presented a significantly higher $K_{mix\ 405\ nm}$ value when compared to control coffee that also presented a significantly lower $K_{mix\ 405\ nm}$ value than the CGAcoffee model. In fact, the proportion of $K_{mix\ 405\ nm}$, indicative of the brown color of the HMWM, in relation to the $K_{mix\ 405\ nm}$ of the soluble solids was higher for the CGAcoffee model (37%), being the lowest for the control coffee (19%). By subtracting the percentage of carbohydrates and protein present in the HMWM, the amount of unknown material can be calculated. The results show that it is similar for all coffees and has an average value of 60%. Also, and as previously observed,[16] there is no trend between the amount of unknown material and the color of the HMWM determined by the $K_{mix\ 405\ nm}$ value. Using the melanoidin browning index (MBI), calculated by dividing the $K_{mix\ 405\ nm}$ values by the relative amount of unknown material,[16] which corresponds to the absorbance at 405 nm by unit amount of unknown material (Table 4), it can be seen that the enrichment of CGAcoffee with CGA increased by 33% the MBI. These observations allow inferring that the CGA have a significant influence on the color of the HMWM, although not increasing significantly the amount of unknown material.

Profiling Phenolic Compounds in Coffee HMWM. To evaluate the different natures of phenolic compounds present in the HMWM, either adsorbed, ester-linked, or in condensed form, as well the effect of the green coffee CGA levels in the phenolic compounds profile, the HMWM was subjected to alkaline saponification and alkaline fusion.

Adsorbed Phenolic Compounds. The amount of adsorbed phenolic compounds was determined by direct injection of the HMWM solutions on an RP C-18 column. To determine the possible influence of the HMWM matrix on the determination of phenolic compounds, a solution containing 5 mg/L HMWM and different amounts of 5-CQA was compared to the amount determined by injection of the same amounts of 5-CQA in water. The regression line obtained by representing the amount determined in water in relation to the amount determined in the presence of HMWM was $y = 0.9962x + 0.2584$ with $r = 0.9998$, indicating that the presence of HMWM did not interfere in the determination of phenolic compounds by RP-HPLC. The direct injection of HMWM showed the presence of intact CGA acids in all HMWMs (Figure 1a), mainly 5-CQA, although the presence of diCQA and 3CQA could also be detected (not shown). The amount of adsorbed CGA ranged from 0.1 to 0.7 mmol/100 g HMWM.

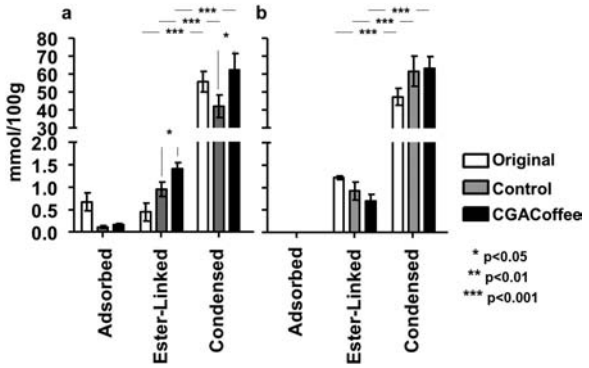

Figure 1. Profile of phenolic compounds present in (a) original, control, and CGAcoffee model HMWM; (b) original, control, and CGAcoffee model 75% ethanol soluble melanoidin population.

Ester-Linked Phenolic Compounds. The presence of ester-linked phenolic compounds in the HMWM from original, control, and CGAcoffee was determined after saponification. This procedure, known to release ester-linked phenolic compounds,[33] allowed the release of simple phenolic compounds from the HMWM, including caffeic, ferulic, and coumaric acids (Figure 2). Caffeic acid was the main cinnamic acid detected in all analyzed HMWMs. These simple phenolic compounds released by alkaline saponification have their origin in the adsorbed CGA present but also, probably, in the CGA incorporated into melanoidins, with structures where the cinnamic acids are esterified and maintain unchanged their structure. The amount of phenolic compounds released by saponification ranged from 1.1 to 1.6 mmol/100 g, which was significantly higher than that found adsorbed in the HMWM. For calculating the amount of ester-linked phenolic compounds in the HMWM, the amount of simple phenolics released by saponification was subtracted from the amount of adsorbed phenolics (Figure 1a). As can be observed, the amount of ester-linked phenolic compounds present in the HMWM ranged from 0.5 to 1.4 mmol/100 g. The values are in the range of those found in a previous study,[15] although lower values have been reported[14] or even not detected after alkaline hydrolysis,[6,9] probably due to their oxidation during extraction.[24] The amount of ester-linked phenolic compounds present in the CGAcoffee model was significantly higher than that present in the HMWM of control, showing that the incorporation of phenolic compounds in the CGAcoffee resulted in a significantly higher amount of ester-linked phenolic compounds in the HMWM.

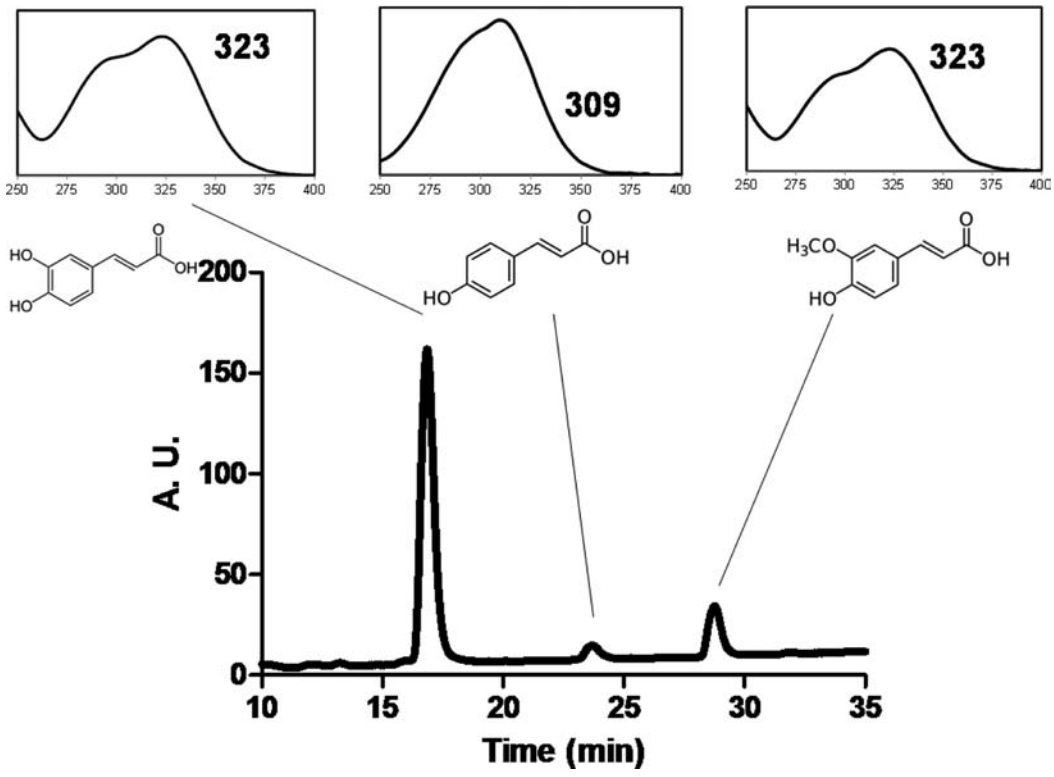

Figure 2. Phenolic compounds ester linked to the HMWM.

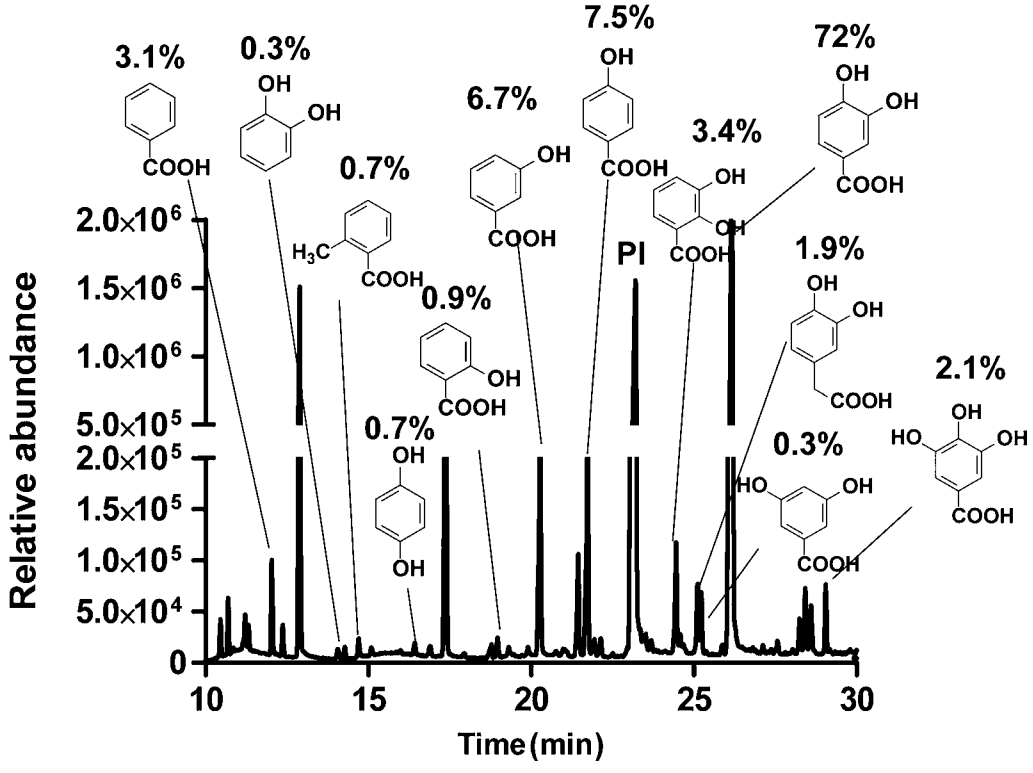

Figure 3. Nature and relative abundance of phenolic compounds released by alkaline fusion of the high molecular weight material recovered from the "in bean" CGAcoffee model.

Condensed Phenolic Compounds. For determining the amount of condensed phenolic compounds present in the HMWM, the samples were subjected to alkaline fusion. As can be observed in Figure 3, more than 10 simple phenolic compounds were released from the HMWM after alkaline fusion. 3,4-Dihydroxybenzoic acid was the most abundant phenolic compound in all samples. The abundance of the different phenolic compounds, expressed as the relative areas,

dx.doi.org/10.1021/jf501510d | J. Agric. Food Chem. 2014, 62, 7843−7853

was not significantly different for the different HMWMs studied. The amount of phenolic compounds released by alkaline fusion was significantly higher than the amount of phenolic compounds released by alkaline saponification by a factor of approximately 40 times and ranged from 42 to 62 mmol/100 g. These values are in the range of those reported by Nunes et al.[16] and Nunes and Coimbra[6] for HMWMs isolated from coffee infusions and higher than those found by Takanake et al.[9] for a zinc chelating fraction isolated from instant coffee. The low abundance of esterified phenolic compounds if compared to condensed phenolics present in coffee melanoidins is in accordance with the results of Gniechwitz et al.,[10] who performed an NMR analysis of an isolated intact melanoidin fraction and could not observe HSQC signals diagnostic for intact caffeic acid moieties. When the amount of phenolic compounds present in condensed form was calculated by subtracting the amount of phenolic compounds released by alkaline fusion from that released by alkaline saponification, it can be observed that the amount of phenolic compounds present in condensed form in the HMWM recovered from the CGAcoffee was significantly higher than that present in control. As observed for the ester-linked phenolic compounds, the incorporation of phenolic compounds in CGAcoffee model also increased the amount of condensed phenolic structures in the HMWM (Figure 1a). Expressing the amount of condensed phenolic structures in equivalent weight of caffeic acid, it can be concluded that the HMWM contained 7.5 g of condensed phenolics/100 g for control coffee, 10.0 g/100 g for the original coffee, and 11.2 g/100 g for the CGAcoffee model, showing that these condensed phenolic structures are an important component of the HMWM. In fact, the contribution of these condensed phenolic structures to the overall weight of the HMWM can be higher as some of the phenolic compounds bound to the HMWM seem to remain esterified with quinic acid after roasting.[14]

Mechanism and Efficiency of Alkaline Fusion. The alkaline fusion method is known to release phenolic compounds from condensed structures such as lignin and humic acids.[25] Nevertheless, there is a lack of knowledge about the nature of linkages between phenolic compounds cleaved by alkaline fusion and the efficiency of their cleavage. To have a deeper insight into which types of linkages are cleaved by alkaline fusion and to what extent, a series of standard phenolic compounds containing aryl-ether linkages (8-*O*-4-dehydrodiferulic acid), stilbene-type linkages (8,5(noncyclic)-dehydrodiferulic acid), and biphenyl linkages (5,5-dehydrodiferulic acid) between ferulic acids were subjected to alkaline fusion. The phenolic compounds containing aryl-ether linkages and stilbene-type linkages were quantitatively cleaved by alkaline fusion, yielding only 3,4-dihydroxybenzoic acid, catechol, and hydroquinone. Nevertheless, the phenolic compound containing biphenyl type linkage was not quantitatively recovered from the alkaline fusion, being recovered only 19% of the original phenolic compound. This result may show that this type of linkage is more resistant to alkaline fusion. Also, it is possible that the phenolic compounds released were of different nature or that they were lost during the alkaline fusion, not allowing their recovery.

Fractionation of the HMWM by Ethanol Precipitation. The HMWM of roasted coffee infusions is composed by a mixture of thermally transformed galactomannans and arabinogalactans and by a diversity of melanoidin populations presenting different physical properties and chemical composition, including melanogalactomannans, melanoarabinogalactans, and melanoidins containing low amounts of carbohydrates.[6,7] These macromolecules can be roughly separated by ethanol precipitation. Galactomannans and melanogalactomannans can be obtained by precipitation in 50% ethanol solutions (Et50), arabinogalactans and melanoarabinogalactans can be obtained by precipitation in 75% ethanol solutions (Et75), and a second melanoarabinogalactan fraction and the melanoidins with low amounts of carbohydrates remain soluble in 75% ethanol solutions (EtSn). The yield and chemical composition of the fractions obtained by ethanol fractionation are shown in Table 4. For all coffees, the amount of material recovered was highest on the EtSn fraction (53%, on average) followed by the Et50 fraction (35%), and the Et75 fraction accounted for the lowest amount (13%). This distribution of the different melanoidin populations is in accordance with previous ethanol fractionation procedures in Arabica and Robusta coffees.[6,16,20,34,35] The amount of protein recovered in the fractions isolated from the different coffees increased significantly with the increase of the ethanol concentration, in accordance with Bekedam et al.[4] The amount of protein recovered in the EtSn and Et75 fractions from CGAcoffee was significantly higher than that of control. The phenolic compounds present in the each fraction also increased with the increase in ethanol solubility, being also observed a significantly higher amount of total phenolics in the Et75 and EtSn fractions recovered from CGAcoffee when compared to control. A significant correlation between the amount of protein and phenolic compounds present in the ethanol fractions ($r = 0.830$, $p < 0.05$) was also observed. When the percentage of phenolic compounds present in each fraction is calculated in relation to the amount of phenolic compounds present in the HMWM, it can be observed that the phenolic compounds present in the EtSn fraction represent nearly 83% of the HMWM phenolic compounds, followed by the Et50 fraction (15%) and the Et75 (12%). These results show that the melanoidin population soluble in ethanol contained the majority of the phenolic compounds incorporated into the HMWM during roasting, which is in accordance with Nunes et al.[16] and Bekedam et al.[4] The MBI increased for all coffee fractions with the increase of their solubility in ethanol. For the Et75 and EtSn fractions recovered from the CGAcoffee model, an average of 30% increase in the MBI was observed. In these fractions, the amounts of protein and phenolic compounds are significantly higher for CGAcoffee model when compared to the control. Also, a significant correlation between the phenolic compounds and MBI ($r = 0.674$, $p < 0.05$) is observed. The amount of phenolic compounds was also significantly correlated with the color of the different melanoidin populations ($r = 0.782$, $p < 0.05$), a significant correlation between the amount of protein and MBI ($r = 0.749$, $p < 0.05$) being also observed.

As the melanoidin populations soluble in 75% ethanol contained the majority of the phenolic compounds present in the HMWM, the nature of the phenolic compounds present in these melanoidin populations was further studied (Figure 1b). The EtSn fraction did not contain adsorbed phenolic compounds, which can be explained by the experimental procedure used, including dialysis and urea solubilization, probably resulting in the loss of the adsorbed phenolics. The amount of ester-linked phenolic compounds was in the range of that found for the HMWM, and there was no significant difference between the amounts of ester-linked phenolics for

the three coffees studied. The amount of condensed phenolic compounds present in the EtSn fraction was significantly higher, by a factor of 60, than the ester-linked phenolic compounds. The amount of condensed phenolic compounds present in the CGAcoffee model was, on average, higher than that present in the control coffee (Figure 1b). Nevertheless, it was not significantly different, probably due to the higher variability obtained in the analysis, as the total phenolic acids measured by the Folin−Ciocalteu colorimetric method were significantly higher. There was observed a significant correlation between the amount of phenolic compounds released by alkaline fusion and that determined by the colorimetric Folin−Ciocalteu method (ρ = 0.886, p < 0.05), although this correlation was not significantly linear (r = 0.767, p < 0.075). The Folin−Ciocalteu colorimetric method measures the sample's reducing capacity, which includes, among others, phenolic compounds.[36] However, this assay is also sensitive to the presence of proteins, ascorbic acid, and other reducing compounds.[37,38] In fact, melanoidins produced from model systems containing only sugar and amino acids are known to possess reducing capacity,[39] showing that proteins or reducing Maillard reaction products such as reductones present in the material can contribute to the reducing power of the solution, resulting in an overestimation of the amount of phenolic compounds present when measured by the Folin−Ciocalteu method. Nevertheless, as the reducing power of 5-CQA is 21 times higher, on a weight basis, than that of bovine serum albumin (BSA), protein interference should be comparably low (although the actual interference clearly depends on the amino acid composition of the proteins). Also, it is certainly harder to estimate the contribution of Maillard reaction products to the reducing power of the actual coffee sample. Nevertheless, although the application of the Folin−Ciocaultau method can have drawbacks, it is widely used for accessing the presence of phenolic compounds in coffee melanoidins, and the results obtained in this work show that it can be used as an indicator for phenolic compounds present.

Fate of CGA during Roasting, Contribution to Melanoidin Formation, and Potential Health Effects. The amount of phenolic compounds incorporated in coffee melanoidins, determined by the alkaline fusion method, ranged from 10 to 13 mol/100 mol of the CGA content present in green coffee. When the amount of phenolic compounds incorporated in coffee melanoidins was calculated in relation to the amount of phenolic compounds lost during roasting, the values ranged from 18 to 33 mol/100 mol. From these values it can be observed that the incorporation of phenolic compounds into the HMWM is a significant pathway of CGA degradation during roasting. When the amount of phenolic compounds incorporated in the HMWM is expressed as caffeic acid, it represents, on average, 23 g/100 g of the material not accounted for by polysaccharides and proteins. These results show that the phenolic compounds incorporated into coffee melanoidins represent a significant proportion of the previously described unknown material. The correlation found between the amount of phenolic compounds present in the different melanoidin populations and the K_{mix} color as well the MBI shows that the incorporation of phenolic compounds has an impact on the color of melanoidins. Although the structure of phenolic compounds present in the coffee melanoidins cannot be deduced from the data obtained from the methods applied, the data showed that they can be connected by aryl-ether, stilbene-type linkages, and biphenyl linkages, as these can be cleaved by alkaline fusion. The presence of phenolic compounds besides 3,4-dihydroxybenzoic acid, catechol, and hydroquinone in the alkaline fusion may represent different linkages or phenolic compounds transformed during roasting with structural features different from caffeic acid, but not yet available to be determined. The detection of 4-hydroxybenzoic acid in the alkaline fusion medium may represent the incorporation of coumaric acid in coffee melanoidins. The relative contribution of ferulic acid and caffeic acid to the amount of phenolic compounds incorporated into coffee melanoidins cannot be deduced due to the observed demethylation of phenolic compounds during alkaline fusion.[16] Further work is needed to disclose the structural details of the condensed phenolic compounds present in coffee melanoidins. The correlation between proteins and phenolic compounds in the different melanoidin populations suggests that the incorporation of phenolic compounds in coffee melanoidins is related to the amount of proteins. This can be explained by the easy cross-link between phenolic compounds through quinoidal structures and amino acids such as lysine and cysteine present in proteins.[40−42] The condensation of phenolic compounds during roasting has been shown to occur, but only low molecular weight structures have been found.[43−45] These might represent the starting point of the reaction that, on further reaction with proteins and also possibly with polysaccharides, incorporates these compounds into coffee melanoidins. As condensed phenolic structures are present in light-roasted coffee,[6] the incorporation process seems to occur as soon as the roasting starts, and this is in agreement with the data obtained from Smrke et al.[46] The presence of phenolic compounds in coffee melanoidins, mainly in condensed form, may be an explanation for the high antioxidant activity described for coffee melanoidins.[47,48] The association of these condensed phenolic structures with indigestible polysaccharides and melanoidins present in coffee HMWM may also be one of the reasons for the observed association between coffee consumption and the antioxidant capacity of feces from healthy subjects.[49] The presence of these condensed phenolic structures can act as a "radical-sponge" in the gastrointestinal tract (stomach and small and large intestine), as those described for other antioxidant dietary fibers when associated phenolic compounds are present.[50] Studies on the impact of gut microorganisms on the antioxidant activity of melanoidins are rare, but it was demonstrated, for example, that after a 24 h in vitro fermentation of high-molecular weight coffee fractions with gut microorganisms, roughly 25% of the original antioxidant activity was still present.[13] Due to the relatively high amount of phenolic compounds that can reach the gut, especially the large intestine, the fact that they are linked to the coffee dietary fiber deserves further study.

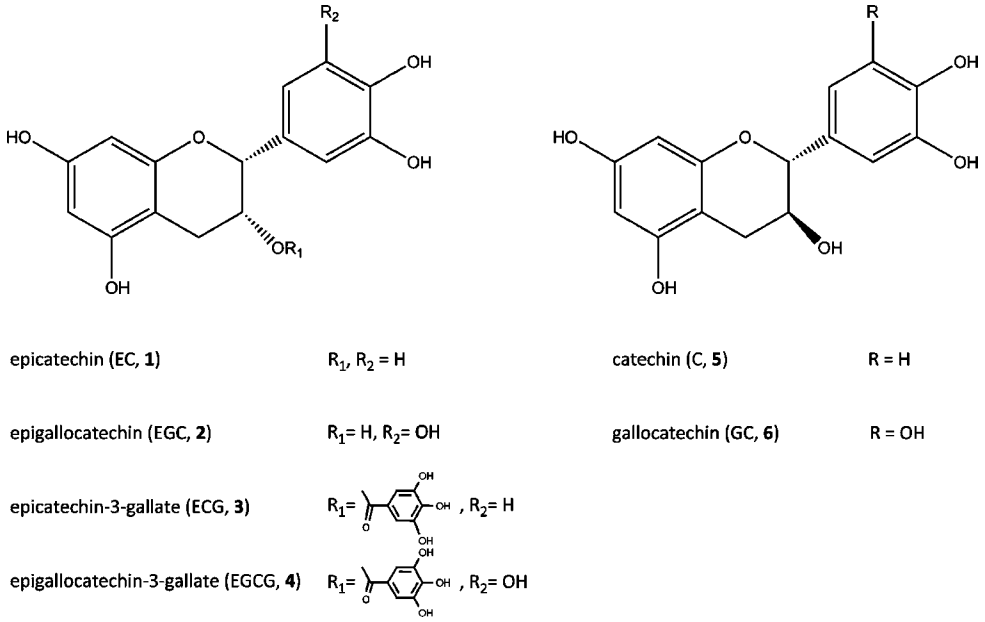

Figure 1. Chemical structures of the six most common flavan-3-ols **1**−**6** in green tea.

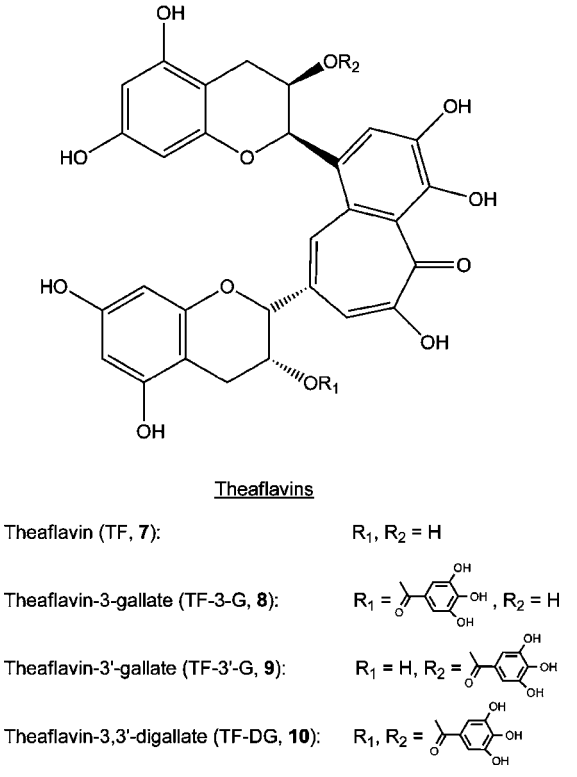

Figure 2. Structures of theaflavin and its gallate esters: theaflavin **7**, theaflavin 3-gallate **8**, theaflavin 3′-gallate **9**, and theaflavin 3,3′-digallate **10**.

Several groups were able to synthesize and isolate a number of oxidation products, such as theaflavins, theasinensins, and theanaphthoquinone, using model fermentations with green tea leaves.[14−17]

In an approach to gather information about the enzymatically catalyzed oxidative reactions which are almost solely responsible for the differences between a black and a green tea, we decided to employ model fermentations. Based on a system reported by Bonnely et al., polyphenol-free leaves of *Camellia sinensis* with active enzymes were used to oxidize selected combinations of flavan-3-ols.[18] As an alternative approach model oxidations using horseradish POD enzyme without matrix were carried out. Analytical techniques such as HPLC-DAD and LC-ESI-MS^n were employed for analysis and obtained results compared with the literature.

MATERIALS AND METHODS

Chemicals. The following chemicals were used: ethylenediaminetetracetic acid disodium salt dihydrate (>99%, Fluka Chemie GmbH, Buchs, Switzerland), L-(+)-ascorbic acid (≥99%, VWR BDH Prolabo, Leuven, Belgium), MES (2-(*N*-morpholino)ethanesulfonic acid; EGA Chemie, Steinheim, Germany), Triton X-100 (AppliChem GmbH, Darmstadt, Germany), benzamidine hydrochloride (AppliChem). Peroxidase from horseradish (lyophilized powder, 52 units/mg solid) was obtained from Sigma-Aldrich Chemie GmbH (Steinheim, Germany) as well as (−)-epicatechin and (+)-catechin hydrate with purities of 90% and 98%, respectively. The following solvents were used: acetonitrile (for HPLC, HPLC super gradient grade, ≥99.9%, VWR International S.A.S., Fontenay-sous-Bois, France; for LC-MS, LC-MS grade, ≥99.95%, Carl Roth GmbH & Co. KG, Karlsruhe, Germany), methanol (HPLC gradient grade, 100.0%, VWR International S.A.S.), MTBE (for synthesis, ≥99.5%, Carl Roth), chloroform (p.a., ≥99.99%, stabilized with amylene, Fisher Scientific, Loughborough, U.K.), acetic acid (for HPLC, HPLC grade, ≥99.7%, Fisher Scientific; for LC-MS, LC-MS grade, ≥99.7%, Fisher Scientific), petroleum ether (technical grade, distilled before use). All water used in the experiments was of Nanopure quality (Werner Reinstwassersysteme, Leverkusen, Germany). For identification of monitored compounds ((+)-C, EC, ECG, EGC, EGCG, TF, TF-3-G, TF-3′-G, TF-DG, and gallic acid) isolated and spectroscopically characterized compounds were used as reference.

Isolation of EGCG, EGC, and ECG. For the isolation of EGCG, EGC, and ECG, an instant white tea (Hälssen & Lyon GmbH, Hamburg, Germany) and an extract enriched with flavanols (Sunphenon 80SK, Taiyo International, Inc., Minneapolis, MN, USA) were used.

The isolation was carried out by HSCCC using MTBE/ACN/H_2O (2/2/3, v/v/v) in tail-to-head mode on a triple coil machine (total volume 850 mL, Pharma-Tech Research Corp. model CCC-1000, Baltimore, MD, USA), allowing the separation of 2 g of source material per run. Fractions containing EGCG and ECG showed a

dx.doi.org/10.1021/jf501591j | J. Agric. Food Chem. 2014, 62, 7854−7861

chromatographic purity of 85−95% at 278 nm, whereas the EGC fraction needed additional purification via column chromatography on Sephadex LH-20 using chloroform/methanol/petroleum ether (1/2/1, v/v/v) as reported by Robertson and Bendall to yield a chromatographic purity (λ = 278 nm) of around 90%.[5]

The Model Fermentation (Oxidation) Setup. The model fermentation system that was used for our experiments is based on a publication by Bonnely et al.[18] However, to meet our requirements, modifications were necessary:

Fresh tea leaves with active endogenous enzymes were described as source material and were sourced and processed by the Bangalore/India group locally. By using acetone as extraction solvent large volumes could be avoided as described originally when doing the extraction with water. The obtained freeze-dried powder was shipped to the German lab for the model fermentation work, where it was tested for enzymatic activity. To check whether the removal of flavan-3-ols was successful, the leaf powder was extracted according to ISO 14502-2 and the obtained solution was analyzed via HPLC-DAD (see Determination of Remaining Flavanols).[19] Further adjustments were made with regard to scale, temperature regulation, and selection of inert gas.

Preparation of Flavanol Free Tea Leaf Material. Fresh tea leaves (400 g) were stored overnight at −80 °C and ground while cooled with liquid nitrogen to a fine powder. Cold acetone (500 mL) was mixed with the powder in a steel container stored in an ice bath. The suspension was mixed with a Silverson mixer for 15 min and immediately filtrated over vacuum (Whatman Filter Paper No. 40). The residue was washed with cold acetone, and the extraction with acetone was repeated three more times before water−acetone mixtures (500 mL each) were used in the following order:

$$75\%\ \text{acetone} \rightarrow 50\%\ \text{acetone} \rightarrow 25\%\ \text{acetone} \rightarrow 50\%\ \text{acetone} \rightarrow 75\%\ \text{acetone}$$

Finally the powder was washed again with cold acetone and freeze-dried.

Determination of Remaining Flavanols. The freeze-dried leaf powder (40 mg) was extracted with 1 mL of 70% methanol$_{(aq)}$ for 10 min at 70 °C. The extract was separated from the leaves via centrifugation (Hermle Labortechnik GmbH, Typ Z383, Wehingen, Germany), and the remaining leaves were extracted two more times. 210 μL of a stabilizing solution (12.5 mg of EDTA and 12.5 mg of ascorbic acid are dissolved in water and made up to 50 mL) were added to the combined extracts. After microfiltration this solution was analyzed via HPLC-DAD (see HPLC-DAD Analysis of Flavanols and Thearubigins).

Determination of Enzyme Activity. The determination of the enzyme activity was carried out according to the literature.[18] Briefly, 100 mg of polyphenol free tea leaf material was suspended with 3 mL of enzyme buffer (488 mg of 2-(*N*-morpholino)ethanesulfonic acid (MES), 1.42 g of sodium sulfate, 7.83 mg of benzamidine hydrochloride, and 150 μL of Triton X-100 made up to 50 mL with water and the pH value set to 5.5 with 2.5 M sodium hydroxide), stirred on ice for 30 min, and centrifuged at 3000 rpm for 20 min and the upper phase (enzyme extract) separated from the leaves.

50 μL of the enzyme extract was given into a cuvette, 1.38 mL of sodium phosphate-citrate buffer (100 mM, pH 5.5) and 75 μL of (+)-catechin solution (60 mM) were added, and the extinction was monitored during the next 30 min at 400 nm against water. For measurement of PPO activity, this was done at 40 °C; for POD activity, at 30 °C and after addition of 25 μL of 1.5% hydrogen peroxide.

Blanks were taken by adding 100 μL of stop solution (acetonitrile, acetic acid, water; 60/10/30, v/v/v) to the solution before incubation at 30/40 °C.

The rate of quinone formation was calculated as μA/min from the linear part of the monitored curves and set into relation with the dry weight of the enzyme extract. The latter was determined after 24 h of dialysis (14 kDa dialysis tube Visking, cellulose type 20/32 in., Carl Roth) and lyophilization of the residue.

$$\text{EA}\left[\frac{\mu\text{A}}{\text{min}\cdot\text{g}}\right] = \frac{\text{rate}\left[\frac{\mu\text{A}}{\text{min}}\right]}{\text{dry weight [g]}}$$

Fermentation (Oxidation) Procedure. The following solutions were used during the model fermentation experiments:

stop solution: 60 mL of acetonitrile and 10 mL of glacial acetic acid made up to 100 mL with water
hydrogen peroxide: 1.5% (aq)
stabilizing solution: see Determination of Remaining Flavanols

The polyphenol-free tea leaf powder (500 mg) was given into a 250 mL three-necked flask, 10 mL of water and a stir bar were added, and the flask was put into a water bath (Julabo Labortechnik GmbH, model MP-PA/KÜ, Seelbach, Germany) connected to a thermostat (Lauda Dr. R. Wobser GmbH & Co. KG, model RC 6, Lauda-Königshofen, Germany). The following step depended on the enzymes used in the oxidation process; for PPO catalyzed oxidations the suspension was sparged with synthetic air (20.5 vol % O_2, 79.5 vol % N_2). To use PPO and POD 1.95 mL of H_2O_2 solution was added in addition to the synthetic air flow. This resulted in a concentration of about 8 mmol/L H_2O_2 and about 0.25 mmol/L O_2 in a total volume of 100 mL. For the use of POD only, 1.95 mL of hydrogen peroxide solution was added and the whole fermentation (oxidation) process was carried out in an argon atmosphere.

Selected flavanols (for most experiments: 60 mg each) were dissolved in 70−110 mL of water and brought to the correct temperature. To start the oxidation process, this solution was given into the reaction flask and, thus, brought into contact with the enzymes of the tea leaf powder.

Samples (2 mL) were taken at various times, and stop solution (0.7 mL) was added immediately. These samples were split, and 158 μL of stabilizing solution was added to one half. After microfiltration (Rotilabo Mini-Tip syringe filter, PTFE membrane, 0.45 μm, ⌀ 15 mm; Carl Roth), the samples with added stabilizers were used for HPLC-DAD analysis while samples without stabilizers were used for measurement via HPLC-MS^n.

The reactions were stopped after 5−7 h.

Alternative Oxidation Using Peroxidase from Horseradish. EC and EGCG (50 mg each) were dissolved in 96 mL of water in a 250 mL three-necked flask. Hydrogen peroxide solution (1.95 mL, 1.5%) was added and the solution sparged with synthetic air. For the investigation of tea leaf matrix effects, 1.5 g of commercially available green tea leaves was extracted (3× for 15 min with 100 mL of 70% methanol$_{(aq)}$ at 40 °C while stirring) to remove flavanol content and freeze-dried, and 0.5 g was added to the solution. As enzymes are inactivated by heat in green tea manufacture, these leaves should not contain enzyme activity. This was verified as described above (see Determination of Enzyme Activity). For the binding of free metal cations 0.2 mL of an EDTA solution (1%) was added as well. The reaction was started by addition of 4 mL of fresh horseradish POD solution (0.5 mg/4 mL). The reaction was carried out at room temperature, and the sampling procedure was done as described above (see Fermentation (Oxidation) Procedure). After 5 h the reaction was stopped.

HPLC-DAD Analysis of Flavanols and Thearubigins. For HPLC analysis the following equipment was employed: Agilent Technologies (Waldbronn, Germany) series 1100 HPLC consisting of autosampler, binary pump, column oven, and DAD detector. The measurement was performed using a modified system from ISO-14502-2:2002: flow, 1.0 mL/min; temperature, 35 ± 0.5 °C; column, Luna 5 μm Phenyl-Hexyl, 250 × 4.6 mm (Phenomenex, Aschaffenburg, Germany); injection volume, 20 μL; mobile phase, A = 9% acetonitrile in 2% acetic acid$_{(aq)}$ and 20 μg/mL EDTA, B = 80% acetonitrile in 2% acetic acid$_{(aq)}$ and 20 μg/mL EDTA; gradient elution, 0% B, 0−15 min; 0−32% B, 15−30 min; 32% B, 30−35 min; 32%−100% B, 35−36 min; 100% B, 36−45 min; 100%−0% B, 45−46 min; equilibration time, 20 min; detection, diode array (λ = 278 and 354 nm).[19]

HPLC-DAD Analysis of Theaflavins. The separation of theaflavins was achieved on an Agilent Technologies series 1200

HPLC consisting of autosampler, binary pump, column oven, and DAD detector via the following system: flow, 2.0 mL/min; temperature, 30 ± 0.5 °C; column, Zorbax Eclipse XDB C-18, 150 × 4.6 mm, 3.5 μm (Agilent Technologies); injection volume, 10 μL; mobile phase, A = 2% acetic acid$_{(aq)}$ and 20 μg/mL EDTA, B = 2% acetic acid in acetonitrile and 20 μg/mL EDTA; gradient, isocratic at 20% B; detection, diode array (λ = 274 nm).

Analysis via HPLC-ESI-MS^n. The separation via HPLC was performed on an Agilent Technologies series 1100 HPLC consisting of binary pump and DAD detector with a series 1200 autosampler: flow, 0.25 mL/min; temperature, RT; column, Luna 3 μm Phenyl-Hexyl, 150 × 2 mm (Phenomenex); injection volume, 5 μL; mobile phase, A = 9% acetonitrile in 2% acetic acid$_{(aq)}$, B = 80% acetonitrile in 2% acetic acid$_{(aq)}$; gradient elution, 0% B, 0−15 min; 0−32% B, 15−30 min; 32% B, 30−35 min; 32%−100% B, 35−36 min; 100% B, 36−45 min; 100%−0% B, 45−46 min; equilibration time, 20 min; detection, diode array (λ = 278 nm).

The analysis via ESI-MS^n was done on a Bruker Daltonics (Bremen, Germany) HCT PTM Discovery System electrospray ionization ion trap mass spectrometer using the following parameters: ion mode, alternating; scan, 100−1000 m/z; nebulizer, 60.00 psi; dry gas, 11 L/min; 365 °C; capillary, −/+ 3500 V.

RESULTS AND DISCUSSION

Advantages and Drawbacks of the Model System. The main advantage of this approach is the use of the tea leaf matrix and its endogenous enzymes, making it more authentic than other systems that often employ isolated enzymes from other plant sources, such as POD from horseradish. This way, the influence of secondary/minor compounds of tea and possibly also reactions of additional enzymes besides PPO and POD have to be taken into account. Furthermore, the system offers the possibility to freely select the enzymes and their substrates (flavanols) that are used during the oxidation process. This provides the opportunity to investigate the influence of various factors as well as it simplifies—at least to a degree—the highly complex processes.

However, this being only a model system, there are also limitations to this experimental setup. For example, the presence of water that is used in the model system is much higher than during authentic tea manufacture. Moreover, the addition of hydrogen peroxide (8 mM) is probably higher than the amount that is formed during authentic fermentation conditions which may affect the enzyme activity and give rise to reactions other than enzymatic oxidation.[20]

Influence of Temperature and Water Amount. In Figure 3 the strong effect of the temperature on the enzyme activity and hence the reaction speed is presented. First

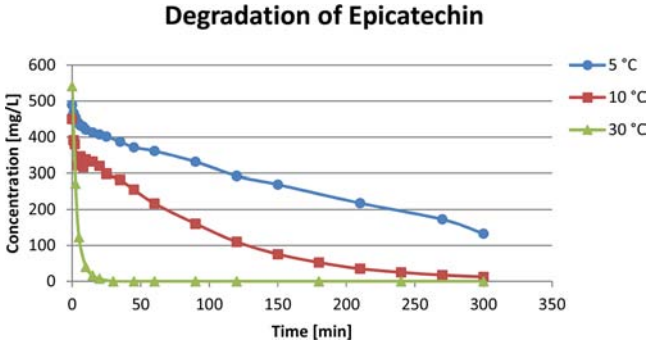

Figure 3. Influence of temperature on the degradation of EC during model fermentations (oxidations) with EC and EGCG at 5, 10, and 30 °C.

experiments were carried out at 30 °C leading to a rapid degradation of flavanols and a fast formation of TFs and TRs. As one aim of the study was to understand the time course of the reaction, a lower temperature (5 °C) was employed to slow down the reaction. It can be observed much more clearly now that for example the reaction of POD with EGCG is much faster than with PPO or POD with EC.

To study whether or not the amount of added water has an influence on the reactions, model oxidations using 45, 60, and 80 mL of water were carried out. It was found that the degree of dilution with water had no significant effect on the oxidation process (data not shown). However, the use of less water would have been more authentic and thus preferable but was not possible due to practical reasons, especially the sampling process.

Color Development. In Figure S1 in the Supporting Information photographs are given of the reaction mixture of ECG and EGC at 5 °C during an oxidation with PPO and POD from the start and after 1 and 4 h. The color change of the reaction mixture from a pale yellow to orange and finally to brown can be clearly observed. The colorless flavanols and the pale yellow tea leaf powder used as starting material (the latter is also shown as dry material in Figure S1 in the Supporting Information) are (partially) converted to colored material. Indeed upon freeze-drying the reaction mixture, a brownish residual powder, also shown in Figure S1 in the Supporting Information, was obtained. This is similarly observed in green tea oxidation to black tea.

Degradation of Flavanols. Immediately after the start of the oxidation procedure with both enzymes active and two or more flavanols present, a depletion of the flavanol content is observed. The individual flavanols were converted with different speed: EGC ≈ EGCG > ECG > EC > (+)-C. This is probably due to a higher affinity of the enzymes to 3′-hydroxylated and gallated flavanols. This observation is consistent with those reported by Muthumani and Kumar and the finding of Robertson that PPO oxidizes gallocatechins more rapidly than simple catechins.[6,21] It was also reported that PPO prefers flavanols carrying no gallate ester as substrate.[22] This contradiction may be explained by the oxidative behavior of the EC-quinone. For example in an oxidation of EC and ECG, EC gets preferentially oxidized by PPO to its corresponding *o*-quinone, which in turn oxidizes ECG to the ECG-quinone.[14,22,23] As this step is associated with the recovery of EC, the EC concentrations would appear to be almost constant. Following this theory a more rapid decrease of the EC content is expected after total consumption of the galloylated flavanol. This was not observed in our experiments; in fact, the rate of degradation of EC remained unchanged.

Formation of Theaflavins and Thearubigins. In Figure 4 is shown the formation of the expected theaflavin products in three experiments as measured via HPLC-DAD. In each experiment a mixture of two flavanols (60 mg each) was fermented in the presence of the leaf powder. As expected, a fast generation of the theaflavin that corresponds to the selected pair of flavanols was observed. Also differences in quantities, reaction speed, and stability of the formed theaflavin can be observed. E.g., the combination of both gallated EGCG and ECG gives a low product yield and a much slower reaction while stability is good compared to the combination of EGCG with nongallated EC. This is in agreement with the previous statement that EC is a good substrate for the PPO enzyme and its formed quinone readily reacts with the gallated EGCG. The

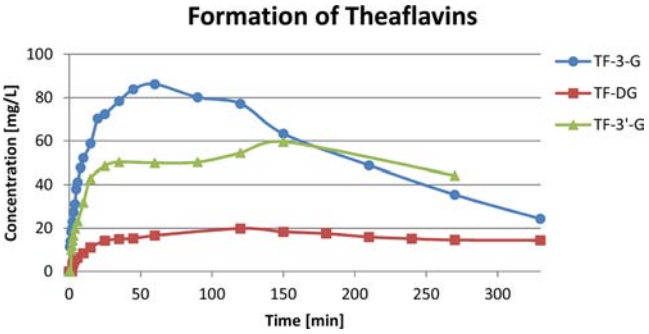

Figure 4. Formation of theaflavins during model oxidations with different combinations of flavanols at 5 °C: TF-3-G from EGCG + ECG; TF-3′-G from ECG + EGC; and TF-DG from EGCG + ECG.

formed quinone of EGCG and any quinone of EC subsequently react efficiently to the product. However, as part of the product site in the TF-3-G is nongallated, it might react further, although more slowly, with the enzyme, resulting in degradation not possible in the TF-DG, which indeed gives a more stable product be it on much lower concentration. The higher stability of TF-DG and TF-3′-G may also hint to the 3′-site as being more suitable for further oxidation of PPO/POD as it is protected by gallate.

In Table 1 is presented an overview of all theaflavins formed by PPO and POD enzymatic oxidation of seven different

combination of flavanols	products
epicatechin + epigallocatechin	**theaflavin**
epigallocatechin 3-gallate + epicatechin	**theaflavin 3-gallate**, theaflavin
epigallocatechin 3-gallate + epicatechin 3-gallate	**theaflavin 3,3′-digallate**, theaflavin 3-gallate
epigallocatechin 3-gallate + (+)-catechin	**neotheaflavin 3-gallate**, neotheaflavin
epigallocatechin + epicatechin 3-gallate	**theaflavin 3′-gallate**, theaflavin
epigallocatechin + epigallocatechin 3-gallate	no theaflavins formed
epicatechin + epicatechin 3-gallate	no theaflavins formed[b]

[a]Products written in boldface letters are the primary product. [b]Small amounts of TF-3-G found via LC-MS, probably due to impurities in the isolated ECG used as substrate.

combinations of flavanols tested. It can be seen that the reaction of two flavanols with either both trihydroxylated or both dihydroxylated B-rings leads to no TF formation. Also, if only a single flavanol was treated with the enzymes, no TF formation was observed. This is in accordance with the pathway of TF formation that requires one *o*-dihydroxylated and one *vic*-trihydroxylated B-ring to give the characteristic benzotropolone moiety.[14]

Figure S2 in the Supporting Information shows the course of formation of TF, TF-3-G, TF-3′-G, and TF-DG in a fermentation (oxidation) of the four main epicatechins together (EC, ECG, EGC, EGCG; each 30 mg/100 mL). Theaflavin was the primary oxidation product within the group of theaflavins, whereas the galloylated derivatives showed significantly lower concentrations. This is different from the relatively balanced ratio of TF, TF-3-G, TF-3′-G, and TF-DG in authentic black tea and can in part be explained by the large proportion of nongallated flavanols, which show the highest molar concentrations in the model reaction, compared to green tea leaves. Even so, the dominance of theaflavin hints to a promoted oxidative degallation in the model fermentation system in addition to the possible presence of tannase activity.[22,24]

Apart from the TFs, an unresolved hump appears in the HPLC chromatograms (data not shown). As there is currently no reliable method of quantitation, the area (λ = 278 nm) of the hump, exclusive of all peak areas on top of it, was used to get an idea about the amount of generated TRs. As can be seen in Figure 5, the TR hump takes a sharp rise in the first minutes

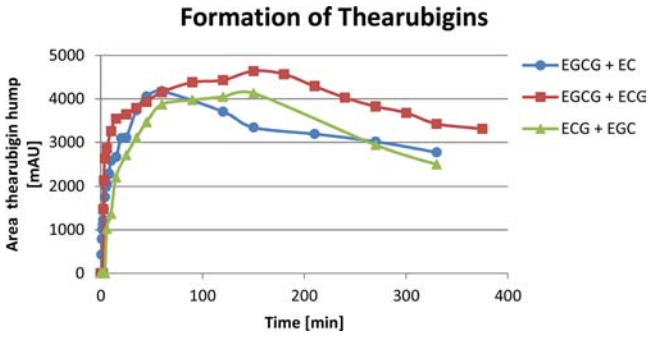

Figure 5. Development of the of the thearubigin hump (λ = 278 nm) during three model oxidation experiments with different combinations of flavanols.

of the fermentation process and slows down afterward to reach a maximum around 100 min. In the subsequent course of the oxidation process the area decreases slightly. This may be the result either of a degradation of the TRs or, perhaps more likely, of ongoing conversions (oxidations) that adversely affect their absorbance.

TF concentrations increased rapidly after the start but decreased after reaching a maximum. TRs were also formed early but during most model fermentations reached their maximum area at a later time compared to TFs. This confirms the assumption that TFs are partially an intermediate product in tea manufacture and may be converted into other species, such as thearubigins, during the oxidation.

Influence of Enzymes. All results described above were obtained through oxidations with both enzymes, PPO and POD. The enzyme activities were determined as described above (see Determination of Enzyme Activity) and showed values of 52 μA/min·g for the polyphenoloxidase and 149 μA/min·g for the peroxidase. These activities lie in a similar range compared to the literature.[18] An up to five times higher activity of the POD compared to PPO has also been reported earlier.[23] However, with a prolonged storage time a decrease in the enzyme activities was noticed and could be compensated by an increased temperature.

As the model fermentation system allows selecting single enzymes, a number of experiments with pairs of two flavanols were conducted to analyze their specific impact on the oxidation process.

Influence of Enzymes on Flavanol Degradation. In Figure 6 is shown that, in PPO-driven oxidations (absence of H_2O_2), EGCG was clearly the preferred substrate and showed an exponential degradation curve (above), whereas the concentration of all other flavanols, with EC shown, decreased more slowly and nearly linearly (below). It was observed that the total consumption of one flavanol did not have any effect on

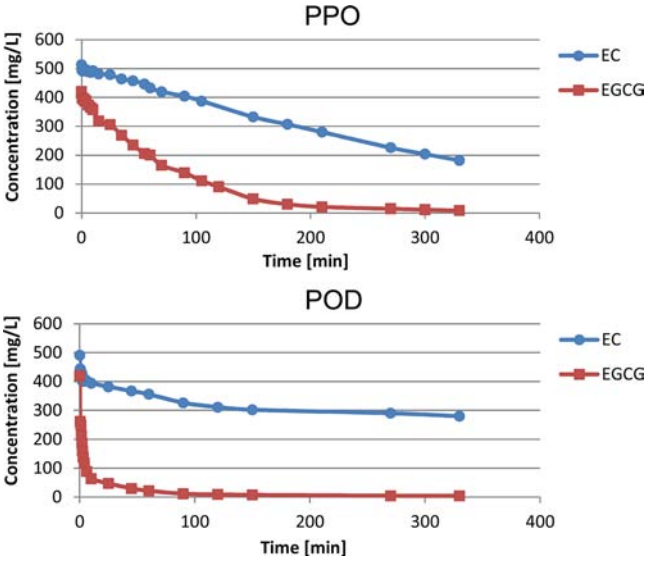

Figure 6. Course of flavanol degradation during model fermentations with EC and EGCG using PPO (above) and POD (below) at 5 °C.

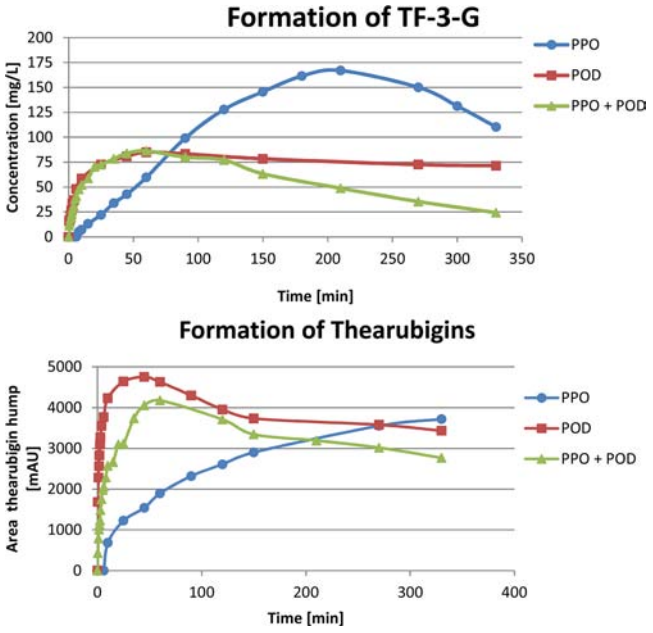

Figure 7. Influence of enzyme selection on the formation of theaflavin 3-gallate (above) and thearubigins (below, area at λ = 278 nm) during model fermentations with EC and EGCG at 5 °C.

the degradation of the remaining one. Also it was found that, in the presence of hydrogen peroxide and an inert atmosphere, the POD enzyme becomes active, while PPO activity is negligible and degraded gallocatechins (EGC, EGCG) faster over the flavanols which have 2 OH in the B-ring. In this case the conversion of one flavanol seems to be dependent on the presence of a second reactant. E.g., in Figure 6 it can also be seen that, after complete depletion of EGCG, the conversion speed of the remaining flavanol, in this case EC, slowed down dramatically and its concentration remained almost constant. Similar observations were made when other flavanols with dihydroxylated B-rings (ECG, (+)-C) were used, indicating that the tea leaf peroxidase does not react with this group of flavanols.

It could be argued that O_2 might be available by decomposition of H_2O_2 which gives rise to a PPO activity. However, by calculation of possible oxygen concentration it was assumed that PPO activity would be negligible. As the monitored results from oxidations using POD only are clearly distinct from those using PPO (also in combination with POD), it was confirmed that the inactivation of PPO in the model fermentation system was successful.

Enzymes on Formation of Theaflavins and Thearubigins. The complexity of the reactions and the large number of (possibly confounding) variables hampers the finding of general dependencies and affinities of the enzymes. Even so, it was observed throughout all oxidation experiments that those using only PPO yielded higher concentrations in TFs. Figure 7 shows the influence of the enzymes on the formation of theaflavin 3-gallate and thearubigins in an oxidation of EC and EGCG (each 60 mg). When POD was active, the concentrations of TFs were lower and the TR area was larger. The observed nonreactivity of POD with flavanols carrying dihydroxylated B-rings may lead to the conclusion that TFs can be formed from one quinone and one nonquinone flavanol. This should be further investigated. In summary PPO catalyzes a slow but constant formation of theaflavins which gives final concentrations twice as high as in the presence of POD. POD seems to preferentially catalyze reactions leading to TR formation.

pH Value and Release of Gallic Acid. Initially the pH of the model fermentation solutions was around 6.5. During the course of a model oxidation the pH value decreased due to the release of gallic acid, but did not fall under 5.0. The pH values were in accordance with those reported in the literature as suitable for PPO and POD.[22,23,25] Hence, the setup can be used without any buffer systems.

In Figure S3 in the Supporting Information it can be seen that the release of gallic acid was found to be fastest and highest in oxidations with PPO only. This is in accordance with the reported ability of PPO to catalyze the degallation of flavanols; however, if POD was present (alone or in combination with PPO) the release of gallic acid was significantly lower.[22] POD does therefore seem to stand in competition with PPO.

Influence of Tea Leaf Matrix. Two model fermentations (oxidations) using commercially available POD from horseradish as enzyme and a combination of EC and EGCG as its substrates were carried out. To investigate possible matrix effects of tea leaves 0.5 g of flavanol- and caffeine-free Chinese green tea leaves with inactive enzymes were added to one of the two setups. It can be drawn from Figure 8 that the presence of tea leaves leads to a degradation of TF-3-G after it has reached its maximum concentration. This was not the case when tea leaves were absent.

From this observation it is assumable that matrix effects play a crucial role in the manufacture of a black tea. The reasons are not quite clear. The catalyzing effect of transition-metal ions, obtained after denaturing the redox enzymes, e.g., in membrane structures, would be a conceivable explanation. Yet, a repetition of the experiment using EDTA as chelating agent against transition-metal cations displayed the same degradation of TF-3-G and, thus, effectively rules out this option.

Results Obtained by HPLC-ESI-MS^n. Selected samples from the model fermentation experiments were analyzed using HPLC-ESI-MS^n. Mass chromatograms were measured in negative ion mode. A list of some m/z values with corresponding fragment ions and assigned substances is given

dx.doi.org/10.1021/jf501591j | J. Agric. Food Chem. 2014, 62, 7854−7861

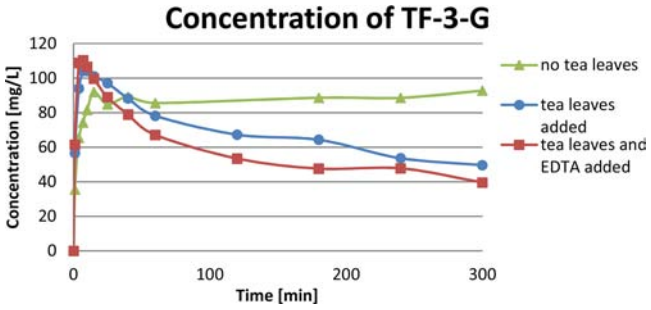

Figure 8. Concentration of TF-3-G during model fermentations with EC and EGCG using horseradish POD at 20 °C with or without addition of an extracted tea leaf matrix.

in Table 2. It can be seen that the model oxidation experiments led to the formation of oxidation products that are also found in black tea samples. Notably, the formation of theaflavate A, a benzotropolone-type dimer derived from ECG, was observed in the mass spectra at m/z of 851 in negative ion mode and also found in HPLC chromatograms with absorption maxima at 232, 280, and 402 nm.[26] As expected, this compound was present only in model oxidations using ECG as substrate. A preference on the use of either PPO or POD was not observed.

Table 2. Masses Found in Samples from Model Fermentations (Oxidations) and Assignment to Tea Compounds Reported in the Literature[11]

retention time [min]	m/z $[M-H]^-$	fragment ions m/z $[M-H]^-$	compound
2.0–2.2	191	173	quinic acid
2.7–3.0	169	125	gallic acid
6.1–6.4	305	261/219/179	EGC
7.5–7.7	289	245/205/203	(+)-C
9.4–10.1	353	217/173	CQA
14.2–14.7	289	245/227/205	EC
18.9–19.9	457	305/169/125	EGCG
24.7–25.9	579	561/533/517/413	oolongtheanin
29.1–29.4	441	289/245/205/169	ECG
32.9–33.0	427	383/227	theaflavic acid
33.2–34.8	563	545/379/241	TF
34.4–34.7	715	563/545/241	Neo-TF-G
34.6	533	515/471/305	theanaphthoquinone
35.8–36.2	715	563/527/371	TF-G
36.4	867	715/563/527/389	TF-DG
37.2	851	579	theaflavate A

Similar to the HPLC-DAD chromatograms, a broad hump-shaped figure was visible in the total ion chromatogram, representing the TRs (data not shown). To interpret this complex data, the oxidative cascade hypothesis by Kuhnert et al. was consulted and it was searched for masses corresponding to one of the oxidation series, e.g., the theaflavin-monogallate series.[11]

The intensities of signals that belonged to the m/z value of one oxidative stage, for example after the first formal insertion of one oxygen (= TF-G+O), were added and compared to those of the other oxidative stages. It was observed that in most model oxidations a tendency exists that m/z values corresponding to higher oxidative stages had lower intensities. This is in accordance with the oxidative cascade hypothesis that describes the stepwise formation of these oxidized species.

These different stages of oxidation were also compared at various time points of the fermentation process. Again a tendency was found that in the beginning the intensities of the lower oxidation stages are comparably high and decrease during the course of a fermentation, whereas the higher stages of oxidation show a more or less constant increase.

This observation is illustrated in Table 3 with arrows showing tendencies of signal intensity changes (green = increase, red = decrease) and may be seen as a qualified confirmation of the oxidative cascade hypothesis that has been postulated as the main mechanism in TR formation. However, as the intensities were taken as sums of several individual signals that could only be assigned by their m/z value (due to low quality MS^2 spectra), these results have to be treated with caution.

MATERIALS AND METHODS

Materials. Normal cornstarch (NC) was purchased from COFOO Biochemical Energy Co. (Yushu, China). Pancreatin from porcine pancreas (catalog number P7545) and amyloglucosidase (catalog number A7095) were purchased from Sigma-Aldrich (St. Louis, MO). Glucose oxidase−peroxidase (GOPOD) assay kits were purchased from Megazyme International Ireland, Ltd. (Wicklow, Ireland). Lauric acid (LA) was purchased from Nanjing Chemical Co. (Nanjing, China). All other chemicals used in this study were of analytical grade and used without further treatments.

Preparation of LA-Complexed Starch. *Heating Starch Prior to the Addition of LA (HM).* NC was dried at 105 °C for 3 h, and the moisture content of the starch was 2.05%. Distilled water was added to the dried NC [40 g, dry basis (db)] and stirred vigorously to obtain starches with 10, 20, 30, 40, and 50% moisture contents. The moisturized starches were heated in a sealed stainless-steel reaction vessel at 80 °C for 12 h. LA [6 g, 15%, w/w, dry starch basis (dsb)] dissolved in ethanol (15 g, 35%, w/w, dsb) was then added to the prior heated starch at different moisture contents, stirred vigorously in the reaction vessel for 5 min, and then uncovered to evaporate ethanol at 80 °C. The final mixture was heated at 80 °C for another 2 h.

Adding LA to the Starch Prior to Heating (MH). LA (6 g, 15%, w/w, dsb) dissolved in ethanol (15 g, 35%, w/w, dsb) was added to the dried NC (40 g, db) and mixed vigorously. The mixture was heated without cover at 80 °C for 5 min to evaporate ethanol before being heated in a sealed stainless-steel reaction vessel at 80 °C for 2 h. Distilled water was then added to the mixture and stirred vigorously to obtain a mixture with 10, 20, 30, 40, and 50% moisture contents and then heated at 80 °C for 12 h.

All LA-complexed NC prepared using HM and MH were cooled to 25 °C, washed 3 times with 50% distilled water−ethanol mixture, and recovered by centrifugation (1500*g* for 10 min). The resulting precipitates, HM-NC represented LA-complexed NC prepared using HM and MH-NC represented LA-complexed NC prepared using MH, were dried at 40 °C overnight and subsequently ground to a fine powder. Control samples were prepared with the same procedure without adding LA.

Lipid Content. The lipid contents in the native NC and LA-complexed NC were determined according to previous reports.[19,20] Free lipid extraction was Soxhlet extracted with petroleum ether at 50 °C for 10 h. The total lipid content was determined after acid hydrolysis. Approximately 1.00 g of starch was accurately weighed and suspended in 10 mL of water. HCl (15 mL, 8.0 N) was added, and the mixture was heated in a boiling water bath for 25 min. After the addition of 50.0 mL of distilled water, the mixture was filtered through paper and washed with distilled water until the filtrate was neutral. The filter paper with the residue was dried at 40 °C overnight and then transferred to a defatted extraction thimble. The dried samples were Soxhlet-extracted with petroleum ether at 50 °C for 8 h. The recipients with the extracted fat were then dried at 110 °C to a constant weight. All samples were performed in duplicates.

Pasting Property. Each starch−LA complex sample (2.24 g, db) was suspended in deionized water to make a total weight of 28.0 g (8%, w/w) and then analyzed using a rapid visco analyzer (RVA, Newport Scientific, Sydney, Australia) following the method reported by Ai et al.[21] The pasting temperature and peak, breakdown, and setback viscosity were recorded.

Light Microscopy. Light micrographs were obtained using an Olympus BX-51 light microscope (Tokyo, Japan) with brightfield and polarized light. Starch powder was sprinkled on a glass slide and covered with a single drop of an aqueous glycerol solution (1:1 water/glycerol). The starch suspension was covered with a coverslip. Images were recorded at 500× magnification.

Scanning Electron Microscopy (SEM). Morphology of starch granules was studied using SEM (ZEISS EVO18, Germany) operated at 10 kV accelerating voltage. The native NC, control NC, and LA-complexed NC were mounted on aluminum stubs with double-sided sticky carbon tape and sputter-coated with a thin film of gold.

Wide-Angle X-ray Diffraction (XRD). The native NC and LA-complexed NC were equilibrated in a chamber with 100% relative humidity at 25 °C for 24 h prior to X-ray analysis. The X-ray diffractometer (D8 Advance, Bruker, Germany) was operated at 40 kV and 40 mA with Cu Kα radiation (λ = 0.154 nm). The starch powder was packed tightly in a rectangular glass cell and scanned over the range of 4−35° 2θ angles at a rate of 2°/min at 25 °C. The percentage crystallinity of the starch was calculated using the following equation:[22]

$$\text{crystallinity}\ (\%) = 100A_c/(A_c + A_a)$$

where A_c is the area of the crystalline peak and A_a is the area of the amorphous peak.

Differential Scanning Calorimetry (DSC). Thermal properties of starches were analyzed using a differential scanning calorimeter (Diamond DSC, PerkinElmer, Norwalk, CT). The native NC or the LA-complexed NC (2−5 mg, db) with deionized water (3×, w/w) was scanned from 10 to 120 °C at a rate of 10 °C/min in a sealed aluminum pan. The thermal properties were calculated using Pyris software (PerkinElmer). The analysis was performed in duplicate.

In Vitro Starch Digestibility. *In vitro* digestibility of the native NC and the LA-complexed NC was analyzed using the Englyst method as described by Englyst et al.,[23] with slight modification. Starch samples (1.00 g, db) were suspended in a sodium acetate buffer solution (20 mL, 0.1 M, pH 5.2), and five glass beads were added to 50 mL centrifuge tubes. The tubes were capped and mixed for 5 min. Samples were placed in a boiling water bath for 30 min and vortexed at 5 min intervals to prevent agglomeration of starch. The dispersion was equilibrated in a shaker water bath (160 strokes/min) at 37 °C for 30 min. The enzyme mixture containing porcine pancreatin and amyloglucosidase was added to each tube. The enzyme mixture was prepared by stirring 3 g of porcine pancreatin in 20 mL of deionized water in each of four tubes for 10 min and then centrifuging at 1500*g* for 10 min. The supernatant (54 mL) mixed with 6 mL of diluted amyloglucosidase solution and 4 mL of deionized water instead of invertase. Aliquots (1.00 mL) were taken at the end of 20 and 120 min reaction and mixed with 20 mL of ethanol (66%, v/v) to stop the enzyme reaction. Starch digestibility was determined using the GOPOD assay. Each sample was analyzed in duplicate.

Statistical Analysis. The mean values and differences were analyzed using Duncan's multiple-range test. Treatment means were tested separately for least significant difference (LSD) with SPSS 18.0 statistical software for Windows (SPSS, Inc., Chicago, IL). The significance level was set at $p < 0.05$.

RESULTS AND DISCUSSION

Thermal Properties. Thermal properties of the native NC and LA-complexed NC are listed in Table 1. The onset gelatinization temperature (T_o) increased from 63.4 to 78.2 °C for the HM-NC and from 61.7 to 69.5 °C for the MH-NC with the moisture content increased from 10 to 50%. There were two peaks observed in the HM-NC thermograms: peak I was attributed to the melting of the double-helical crystallite of amylopectin side chains; peak II was attributed to the melting of the amylose−LA complex. The MH-NC displayed two peaks when the moisture content was 10, 20, and 30%. The MH-NC, however, displayed three separate peaks at 40 and 50% moisture content (Table 1), in which the peak (41−44 °C) was attributed to the melting of free LA[12] and the other two peaks represented the same as those in the HM-NC. These results were consistent with higher free lipid contents in MH-NC prepared with 40 and 50% moisture contents (Table 2).

Except the starches treated with 10% moisture content, an increase in the onset gelatinization temperature in peak I suggested that the hydrothermal/LA treatments resulted in a more ordered crystalline structure. The HM-NC and MH-NC all exhibited decreases in the enthalpy change of peak I with the increase in the moisture content, which was attributed to the

[a]The data are averages of two measurements with standard deviation. Means in a column with different letters are significantly different ($p < 0.05$) by the LSD test. [b]Sample code: HM-NC, LA-complexed NC prepared using heating starch prior to the addition of LA; MH-NC, LA-complexed NC prepared using adding LA to the starch prior to heating; and 10, 20, 30, 40, and 50%, moisture contents of LA-complexed NC.

loss of the double helices of amylopectin. The enthalpy change of peak II showed an increasing trend when the moisture content increased from 10 to 40% (Table 1), indicating increases in the formation of the amylose−LA complex. However, when the moisture content increased to 50%, the enthalpy change decreased. This could be attributed to substantial starch gelatinized when the moisture content increased to 50%, resulting in a viscous texture, which retarded the amylose−LA complex formation, which is consistent with the results of the lipid content. The content of complexed lipids of LA-complexed NC showed an increase when the moisture content was increased from 10 to 40% but a decrease when the moisture content was 50% (Table 2).

Morphology of NC and LA-Complexed NC. Morphology of the NC and the LA-complexed NC was studied using optical microscopy and scanning electron microscopy (Figures 1 and 2). Polarized light micrographs of the native NC showed a characteristic Maltese cross (image not show). LA-complexed NC, both prepared by HM or MH, showed that increasing numbers of granules lost the Maltese cross with the increase in the moisture content. HM-NC with a 50% moisture content was mostly gelatinized and showed few Maltese cross remaining, whereas MH-NC maintained more intact granules and Maltese cross even after heating with 50% moisture content. These results indicated that the starch gelatinized to a greater extent during heating without the presence of LA than that of LA-complexed NC.[24] In contrast, with the addition of LA prior to heating in the MH-NC, LA coated on the granule surface, complexed with amylose, impaired water movement into the granules, and retarded the gelatinization of the starch.

The structures of the control NC and LA-complexed NC studied using SEM are shown in Figure 2. The surface of native NC appeared smooth and exhibited pinholes on its surface (image not shown), which was consistent with the findings by Jane et al.[25] and Rocha et al.[26] Following the hydrothermal treatment, control NC with 40% moisture content was partially gelatinized and the granules were aggregated. When the moisture content increased to 50%, the control NC was

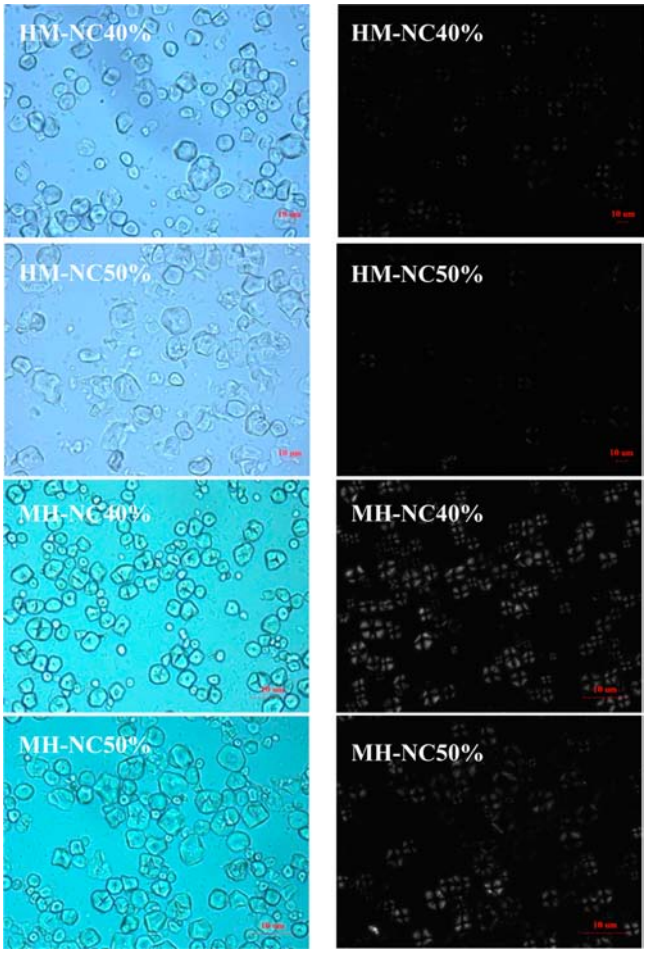

Figure 1. Light microscopic images of LA-complexed NC with brightfield and polarized light. Sample code: HM-NC, LA-complexed NC prepared using heating starch prior to the addition of LA; MH-NC, LA-complexed NC prepared using adding LA to the starch prior to heating; and 40 and 50%, moisture contents of LA-complexed NC.

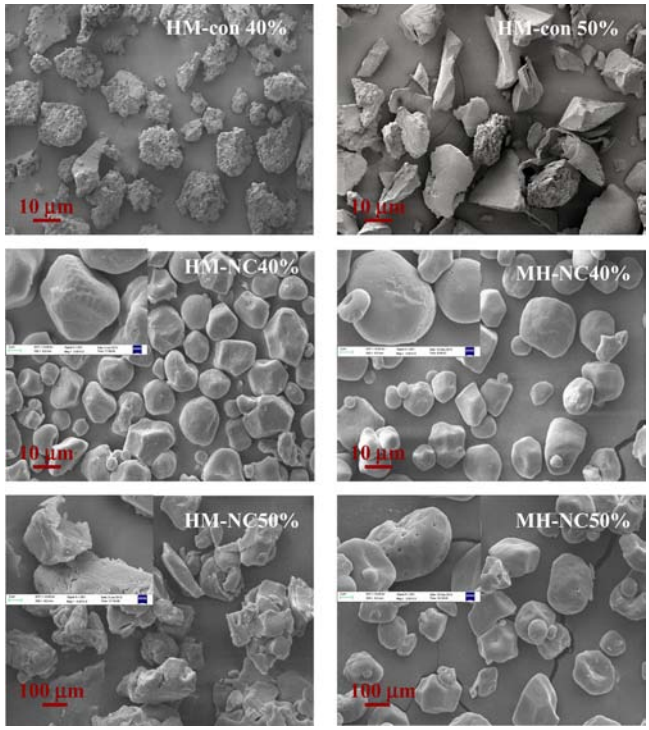

Figure 2. Morphology of the control NC and LA-complexed NC. Sample code: HM-con, control samples for HM-NC; HM-NC, LA-complexed NC prepared using heating starch prior to the addition of LA; MH-NC, LA-complexed NC prepared using adding LA to the starch prior to heating; and 40 and 50%, moisture contents of LA-complexed NC.

gelatinized and lost the shape of granules. Because HM control and MH control displayed similar images, only HM controls are shown. Following the hydrothermal/LA treatments, LA-complexed NC showed intact granular shape, except HM-NC with 50% moisture content, which was partially gelatinized and disrupted (Figure 2). The addition of LA retarded the gelatinization of starch granules, which was consistent with the results of DSC.

Wide-Angle XRD. XRD patterns and percentage crystallinity of the native NC and LA-complexed NC are shown in Figure 3. The native NC showed an A-type diffraction pattern.[27] The hydrothermal/LA treatments changed the X-ray pattern to a mixture of A- and V-type patterns. This change in diffraction pattern was attributed to the fact that the increasing moisture content increased the mobility of amylose and facilitated the formation of the amylose−LA complex. The peaks shown at 8°, 13°, and 20° reflected the V pattern of the amylose−LA complex.[12,28] The peak shown at 21.5° was the crystallites of LA,[29,30] which was only observed in MH-NC prepared with the moisture contents of 40 and 50%. The result was consistent with a melting peak of crystalline LA appearing in DSC thermograms of MH-NC prepared with 40 and 50% moisture contents (Table 1). These results could be attributed to the fact that, when the moisture content increased to 40 and 50% in the MH-NC process, it gave mobility for LA to segregate and merge to crystallize. At high moisture contents (40 and 50%) in the HM-NC process, however, starch was partially gelatinized and the viscosity of the gelatinized starch retarded the mobility of LA. Therefore, LA did not aggregate to crystallize.

The crystallinity of LA-complexed NC was attributed to the contents of free lipids, double-helix amylopectin, and single-helix amylose−LA complex and had a correlation with its corresponding enthalpy change in DSC thermograms. The crystallinity of HM-NC increased from 28.9 to 30.0% and then decreased to 28.2% (higher than native NC) when the moisture content increased from 10 to 30%. With a further increase in the moisture content (up to 50%), the crystallinity sharply decreased to 18.6%, which was consistent with the enthalpy change of gelatinization and the amylose−LA complex (Table 1). These results suggested that, when the moisture content increased to 10 and 30%, there was a heat−moisture treatment effect and amylose−LA complex formation (peak II in DSC thermograms) to improve the crystalline structure. When the moisture content was 40 and 50%, partial gelatinization took place, which was confirmed by the loss of Maltese cross (Figure 1). The crystallinity of MH-NC samples with the moisture content from 10 to 50%, however, decreased from 26.3 to 18.9%. It appears that heat−moisture treatment effect did not take place in starch with the presence of LA in MH-NC.

Pasting Properties. Pasting viscosity profiles of the native NC and LA-complexed NC are shown in Figure 4. The hydrothermal/LA treatments increased the pasting temperature of the starch and decreased the peak viscosity, which was consistent with reports in previous studies.[2,17,31,32] The pasting

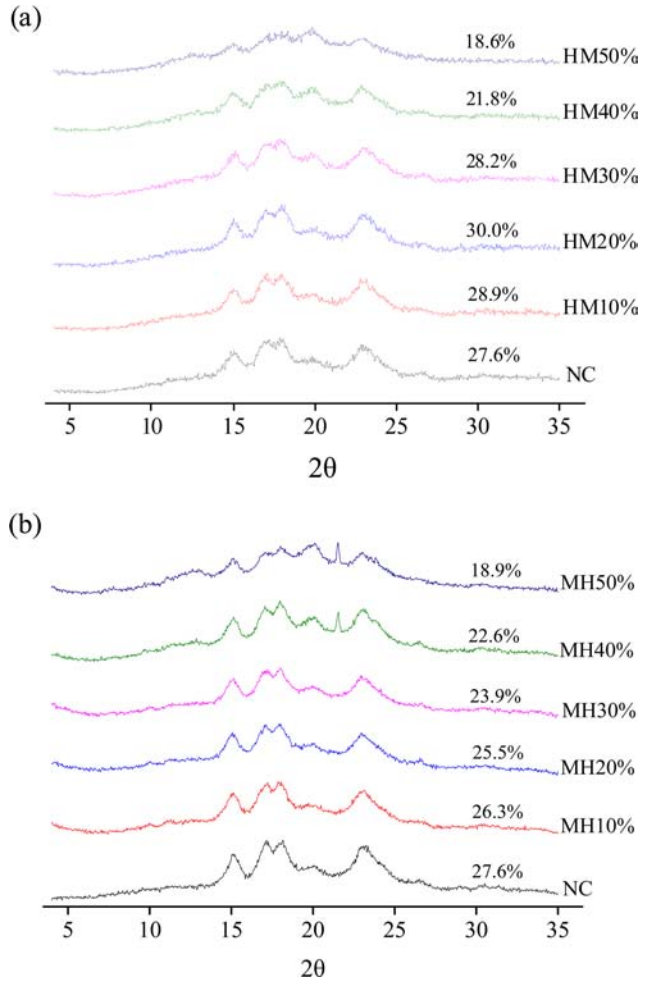

Figure 3. XRD patterns of the native NC and LA-complexed NC. Sample code: HM, heating starch prior to the addition of LA; MH, adding LA to the starch prior to heating; and 10, 20, 30, 40, and 50%, moisture contents of LA-complexed NC.

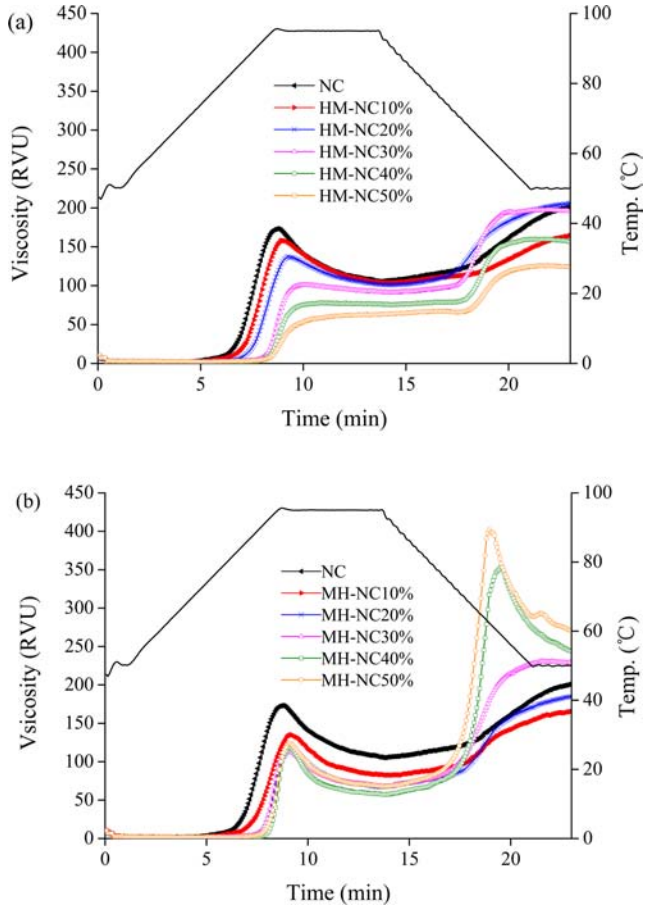

Figure 4. Pasting profiles of the native NC and LA-complexed NC: (a) pasting profiles of the native NC and HM-NC and (b) pasting profiles of the native NC and MH-NC. Sample code: HM-NC, LA-complexed NC prepared using heating starch prior to the addition of LA; MH-NC, LA-complexed NC prepared using adding LA to the starch prior to heating; and 10, 20, 30, 40, and 50%, moisture contents of LA-complexed NC.

temperature of HM-NC and MH-NC both showed increases when the moisture content increased from 10 to 50%. The peak viscosity of HM-NC decreased with an increase in the moisture content. For MH-NC, however, when the moisture content increased from 10 to 30%, the peak viscosity displayed the same trend as its counterparts in HM-NC. However, when the moisture content increased to 40 and 50%, the peak viscosity increased. The presence of the amylose−LA complex and ordered crystallites in LA-complexed NC restricted the swelling of starch granules and resulted in higher pasting temperature and lower peak viscosity.[2,33] These results were consistent with a high enthalpy change of the amylose−LA complex and free lipid (Table 1). When the moisture content was 40%, MH-NC showed a higher content of complexed lipids and free lipids than other LA-complexed NC (Table 2), which resulted in a higher pasting temperature and lower peak viscosity.

HM-NC displayed a decrease in the breakdown and setback viscosity when the moisture content increased from 10 to 50%. MH-NC showed the same trend of breakdown and setback viscosity as their counterparts in HM-NC when the moisture content increased from 10 to 30%. However, when the moisture content increased to 40 and 50%, MH-NC showed increases in the breakdown viscosity and drastic increases in the setback viscosity. The remarkable increase in the setback viscosity could result from the formation of the helical complex between amylose and free LA present in the samples. During the heating procedure of RVA, most starch and part of the amylose−LA complex were dissociated and there was sufficient amylose to complex with LA in the amylose−LA complex and free LA. When the procedure temperature was cooled from 95 to 50 °C, amylose, LA, and amylopectin formed a new amylose−LA complex and an amylose−amylopectin network, which increased the viscosity of MH-NC with moisture contents at 40 and 50%.

***In Vitro* Digestibility.** The contents of RDS, SDS, and RS in the native NC and LA-complexed NC are shown in Table 3. LA-complexed NC showed decreases in the RDS content and increases in the SDS and RS contents with increases in the moisture content. MH-NC was more resistant to the enzyme than that of HM-NC. The SDS content in MH-NC was much higher than that in the counterparts of HM-NC with greater moisture contents (10−50%).

The increase in SDS and RS contents in LA-complexed NC with greater moisture contents was attributed to the formation of the amylose−LA complex and more ordered crystallites, which had a positive relationship with enthalpy change, as shown in Table 1. The V−amylose complex is known to be resistant to enzyme hydrolysis.[2,6] The presence of the

[a]RDS, rapidly digestible starch; SDS, slowly digestible starch; and RS, resistant starch. The data are averages of two measurements with standard deviation. Means in a column with different letters are significantly different ($p < 0.05$) by the LSD test. [b]Sample code: HM-NC, LA-complexed NC prepared using heating starch prior to the addition of LA; MH-NC, LA-complexed NC prepared using adding LA to the starch prior to heating; and 10, 20, 30, 40, and 50%, moisture contents of LA-complexed NC.

amylose−LA complex restricted the swelling of starch granules, as shown in Figure 4, resulting in reduced starch hydrolysis.[1,16] Hasjim et al.[1] and Zhang et al.[12] used partially gelatinized debranched high amylose cornstarch complexed with lipids to produce highly resistant starch, which was attributed to a combination of amylose double-helical crystallite and the amylose−stearic acid complex. The SDS and RS contents in LA-complexed NC prepared in this study both increased. MH-NC with 40 and 50% moisture contents showed higher SDS content than that of other LA-complexed NC, indicating that more amylose−LA complex formed between amylose and free LA after cooking.

The diagram of the difference between the hydrothermal treatments of the two methods is shown in Figure 5. For HM-NC, starch granules swelled, partially gelatinized during the heating before adding LA, resulting in a viscous texture, and decreased the mobility of amylose. LA was then thoroughly mixed with the partially gelatinized starch and subjected to additional heating. When the moisture content was at 40 and 50%, most of the starch crystalline structure was lost. LA dispersed in the viscous starch could not move freely to form aggregate and crystallites, as shown by no melting peak of crystalline LA in DSC and XRD patterns (Table 1 and Figure 3). However, all HM-NC contained higher free lipids than that of NC in the lipid content (Table 2). For MH-NC, however, LA was added to the dried starch and heated in a sealed container at 80 °C for 2 h. LA coated on the surface of the granule, delayed water penetrate into starch granules, and retarded starch gelatinization. The mixture was then heated under different moisture contents for another 12 h. During this heating process, the increased moisture content facilitated mobility of amylose and LA to form a complex. The crystalline structure of the starch remained as shown in the polarized light micrographs of MH-NC (Figure 1). Some of the free LA aggregated and crystallized, as shown in the DSC thermograms and XRD patterns.

The physicochemical properties of the amylose−LA complex were influenced by the moisture content of starch and the order of adding LA to starch before or after heating at 80 °C. The presence of LA retarded the gelatinization of starch during heating. A high moisture content enhanced the mobility of amylose, amylopectin, and LA and promoted the formation of the amylose−LA complex. The formation of the amylose−LA complex was the key factors in decreasing the hydrolysis of starch. With increasing the moisture content, LA had a greater chance to complex with amylose. MH favored the formation of slowly digestible starch and resistant starch, especially when the moisture content was 40%. The results of this study may have potential application in starch food processing applications that desire a higher content of SDS or RS.

[a]Data are presented as a mean value ± standard deviation; the same letter in a column means no significant differences (Tukey HDS test, $\alpha = 0.05$) between samples.

MATERIALS AND METHODS

Chemicals. Chlorogenic, caffeic, *p*-coumaric, ferulic, and ascorbic acids were obtained from Sigma-Aldrich (St. Louis, MO, USA); hexane, methanol, acetic acid, sodium hydroxide, and ethylenediaminetetraacetic acid (EDTA) were purchased from J. T. Baker (Phillipsburg, NJ, USA).

Plant Material. Coffee cherries from seven cultivars (Typica, Bourbon, Mundo Novo, Costa Rica, Oro Azteca, Red Garnica, and Yellow Garnica) were collected in December 2012 from a plantation in the municipality of Xico, Veracruz, Mexico (latitude 96°57′ N; longitude 19°25′ W; altitude ≈1135 m above sea level). Coffee fruits were harvested at three different stages of ripening (unripe, semiripe, and ripe). Identification of coffee cultivars and classification by ripening stage was performed by trained local personnel according to the physical characteristics of plants and fruits.

Samples were transported immediately under refrigeration to the laboratory and stored at 4 °C until processing (within 48 h). Fruits were manually pulped, and the obtained CP was dried in a tray dryer with forced aeration for 72 h at 25−40 °C. Dry CP was milled with a blade grinder and sieved to obtain a particle size of 0.15−0.84 mm (20−100 mesh).

CP from a commercial wet process (beneficio) located in the same region (Xico, Veracruz, Mexico) was used to standardize the methodology for HCA extraction. This CP was sun-dried for 72 h until reaching moisture content of <10%.

Physical Characterization of Coffee Fruits. Average weight, volume, and color of fruits were measured. Average weight was calculated from 100 fruits by triplicate. Average volume was measured by water displacement of 100 fruits in a 1 L graduated cylinder.

The external color of coffee fruits was evaluated by image analysis techniques. Pictures of at least 10 fruits per sample were obtained with a digital camera under standardized conditions of lighting and distance. Thereafter, the pictures were analyzed using the software Fiji (available at http://fiji.sc/Fiji). Average values R, G, and B were obtained and used to calculate the chromaticity parameters r, g, and b, using the following equations:

$$r = \frac{R}{R+G+B};\ g = \frac{G}{R+G+B};\ b = \frac{B}{R+G+B}$$

R, G, and B represent the red, green, and blue color intensity, respectively, and r, g, and b are the normalized trichromatic coefficients (intensity independents).[11]

Extraction of Soluble and Bound HCAs. Extraction of soluble HCAs was performed by successive extractions with hexane and methanol as previously reported.[4,10] First, 2 g (DW) of CP was put into a 125 mL Erlenmeyer flask. Then, sample was extracted three times with 20 mL of hexane for 30 min at 30 °C and 150 rpm. Hexane extracts were discarded, and the remaining solids were extracted three times with 20 mL of aqueous methanol (20:80, v/v) acidified with 1% (v/v) acetic acid. Methanolic extraction was carried out for 35 min at 55 °C with agitation at 100 rpm. Methanolic extracts were centrifuged (8000 rpm, 10 min), filtered through 0.22 μm regenerated cellulose membranes, and analyzed by HPLC.

To confirm the efficiency of the extraction of soluble HCAs, a sample of CP (from a commercial wet process) was submitted to successive methanolic extractions, and each extract was analyzed separately. The effect of hexane extraction was also investigated.

Bound HCAs were extracted by alkaline hydrolysis using a method described previously,[6,10] which was modified as follows: The solids obtained from hexane and aqueous methanol extractions were immediately hydrolyzed with 20 mL of NaOH at different concentrations (0.5, 1.0, and 2.0 M), with EDTA (10 mM) and ascorbic acid (1% w/v). Mixtures were incubated for 15, 30, 60, 120, and 240 min at 40 °C under constant agitation on an orbital shaker (150 rpm). Subsequently, the pH of the mixtures was adjusted to 3.0 ± 0.1 with 6 M HCl. Then, mixtures were filtered through a no. 2

fritted glass filter, the solid residues were extracted with 10 mL of distilled water, and the filtrates were combined and filtered through a 0.22 μm regenerated cellulose membrane and analyzed by HPLC. All extractions were under darkness by triplicate. The extracts obtained were kept at −18 °C and protected from light until analysis. At this stage, chlorogenic acid (compound **1**) was used as internal standard.

HPLC Analysis. Analysis of HCAs was carried out in a Shimadzu Prominence HPLC system (Shimadzu Corp., Kyoto, Japan) consisting of an LC-20AT pump, a DGU-20AS degasser, an SIL-20A HT autosampler, an SPD-M20A diode array detector, and a CTO-20A oven. Separation was performed using a Varian Polaris Amide C18 column (200 × 4.6 mm, 5 μm). An isocratic method was used with a mobile phase consisting of 35% (v/v) methanol, 1.25% (v/v) acetic acid, and 63.75% (v/v) water at a flow rate of 1 mL/min for 20 min. HCAs were detected at 320 nm. Quantitation was performed by the external standard method. Calibration curves were obtained for each compound in concentrations ranging from 0.025 to 0.5 mg/mL. Results were expressed as milligrams per gram of CP (dw).

Statistical Analysis. All extractions and analyses were carried out at least in triplicate, and the results are expressed as means ± standard deviation. Tukey's HSD test was used to compare the means and to reveal significant differences between samples (α = 0.05). Statistical analysis was performed using the statistical package JMP 9 (SAS Institute Inc., Cary, NC, USA).

RESULTS AND DISCUSSION

Physical Characterization of Coffee Fruits. Coffee cherries were classified by trained personnel at the plantation. Then, a physical characterization of fruit samples was carried out in the laboratory. Morphological differences between fruits of the same cultivar but at different ripening stage as well as differences between fruits at the same ripening stage but different cultivar (for some cultivars) were observed. These observations were confirmed by the physical characterization (Supporting Information Figures 1−3).

As expected, we observed a progressive increment of fruit size and weight for all cultivars as a function of ripening. We also observed significant differences between coffee fruits at the same ripening stage but from different cultivars. The larger and heavier fruits were the ripe coffee cherries of Oro Azteca cultivar, followed by the cherries of Mundo Novo and Costa Rica cultivars. The smaller and lighter ripe fruits belonged to the Bourbon cultivar.

Changes in the size and weight of coffee cherries during the ripening process have been previously described by several authors.[12−14] Physical differences (weight and volume) between coffee cherries from different cultivars are known by coffee growers and processors, but they are poorly described in the scientific literature.

Changes in color have been traditionally considered as the main criterion determining the ripening stage of coffee cherries. This characteristic is used to decide the beginning of the harvest.[15] We used image analysis techniques to measure the external color of coffee cherries and to establish differences between ripening stages of coffee fruits.

We observed a progressive increase in the red (r) component of the color as well as a decrease in the green (g) component for all coffee cultivars (Table 1). On the other hand, the blue component was the lowest for all coffee samples. Moreover, we did not observe the same trend in the change of the parameter b (blue) during ripening of the fruits of different cultivars. Therefore, we consider that the r (red) and g (green) chromaticity parameters should be used to evaluate color changes during ripening of coffee cherries.

Values of r increased from 0.335−0.387 for unripe fruits to 0.552−0.736 for ripe cherries. Values of g decreased from 0.427−0.514 for unripe fruits to 0.170−0.357 for ripe cherries. Another parameter that could be considered for assessing color change during ripening of coffee cherries is the ratio between r and g chromaticity parameters (r/g ratio). Values of r/g lower than 1 were obtained for unripe fruits. For semiripe fruits, r/g ratio values ranged between 1 and 2 (1.12−1.93), and for ripe fruits, values of r/g were >2 (2.30−4.06) except for the yellow cultivar (r/g = 1.60).

Several authors have studied the changes in the external color of coffee fruits using spectrophotometric[16−18] or computer vision techniques.[19] These methodologies allow obtaining reliable and reproducible measurements of fruit color. However, they require specialized equipment, which is not always available. Other authors have evaluated the color of coffee cherries by a subjective comparison with color reference charts.[15,20] Color charts are useful aids to compare colors, but they have some disadvantages. In this method color assessment depends on the visual abilities of judges. On the other hand, it is difficult to compare a uniformly colored card with the color of a nonhomogenous surface.[21] In all cases an increase in the red chromaticity and a decrease in green chromaticity have been observed.

Changes in external color can be explained by chemical changes in the exocarp (peel) during ripening. Exocarp persists as a green-colored tissue during most of the coffee fruit development. However, in the ripe state, it becomes red (or yellow, for some cultivars) as result of the decrease of chlorophyll and accumulation of anthocyans.[22]

Extraction of Soluble and Bound HCAs. The phenolic compounds of CP have been the subject of several studies.[4,6,8−10] The interest in these compounds is due to their biological activities (antioxidant, anti-inflammatory, anticarcinogenic, etc.).[6] Most of these studies are limited to the compounds extractable with aqueous methanol solutions.[4,8,9] However, significant amounts of phenolic compounds may remain in the solid residues after such extractions. For example, phenolic acids covalently bound to cell wall polysaccharides.[23]

In preliminary studies, it was found that the estimation of soluble and bound phenolic compounds in CP is strongly dependent on the methodologies used for their extraction and analysis. Thus, we decided to evaluate the conditions commonly used for the extraction of phenolic acids.

As a first step, we evaluated the effects of a hexane extraction followed by an aqueous methanolic (20:80, v/v) extraction on the recovery yield of soluble HCAs (Figure 1). It was calculated using compound **1**, because it was the main soluble HCA (93.8−98.8%). Figure 2 shows the amount of compound **1** extracted by four successive methanolic extractions with and without pretreatment with hexane. Because no compound **1** was detected from the fifth methanolic extraction, the amount of compound **1** obtained in the first four extractions was considered as the total soluble compound **1**, and this amount was used to calculate the extraction yield.

No significant differences were found between the yields of **1** obtained with or without treatment with hexane. Thus, hexane extraction does not affect HCA extraction, but it may help to remove less polar compounds such as carotenoids and other lipophilic compounds that can interfere with the chromatographic analysis of extracts.[4] Therefore, we decided to make three hexane extractions followed by three successive

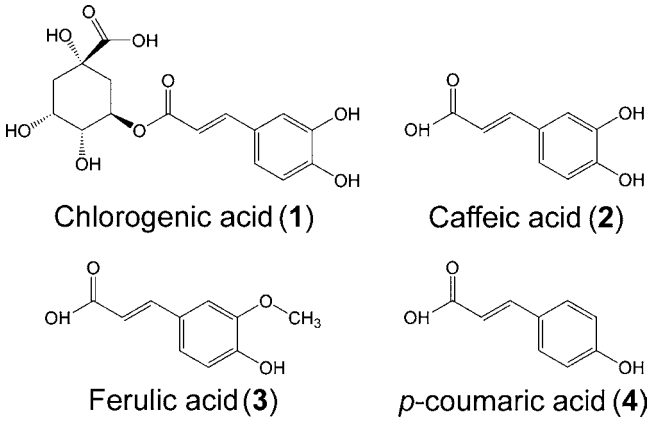

Figure 1. Structures of hydroxycinnamates analyzed in coffee pulp samples.

methanolic extractions for analytical purposes. In these conditions, >98% of **1** was recovered.

Several authors performed alkaline hydrolysis for the extraction of covalently bound phenolic acids. However, it is known that this alkaline hydrolysis led to important losses of phenolic compounds, particularly dihydroxy derivatives such as caffeic acid (**2**).[24]

Krygier et al.[25] reported 66.7% compound **2** lost after treatment with 2 M NaOH for 4 h under nitrogen atmosphere. To prevent loss of phenolic acids, Nardini et al.[24] proposed the addition of EDTA-ascorbate during alkaline hydrolysis. Under their assay conditions (2 M NaOH containing 10 mM EDTA and 1% ascorbic acid at 30 °C for 30 min), complete hydrolysis of compound **1** was achieved without any detectable loss of compound **2**.[24]

Preliminary studies showed significant loss of phenolic compounds during the alkaline hydrolysis of CP. Therefore, we decided to study the conditions of alkaline hydrolysis for recovery of HCAs from CP. The effect of different NaOH concentrations (in the presence of EDTA and ascorbic acid) and incubation times on the recovery of HCAs was evaluated.

Figure 3 shows the time course of compound **2** extraction during alkaline hydrolysis of CP using different NaOH concentrations. We observed an increase in the amount of **2** extracted during the first minutes of the reaction, followed by a decrease of this compound. This can be explained by the existence of at least two reactions: first, a hydrolysis reaction that breaks the covalent bond linking compound **2** to a cell wall polymer, and then a second reaction that transforms compound **2** to another compound, presumably by oxidation. The greatest amount of **2** was obtained using 2 M NaOH and incubating for 2 h at 40 °C. Therefore, we used these conditions for the analytical procedure. To confirm the efficiency of alkaline hydrolysis, compound **1** was used as internal standard. We added a known amount of compound **1** to CP (1 mg/g of CP). Then we subjected the CP to an alkaline hydrolysis as described above. In the proposed conditions, 90% of the expected compound **2** was recovered.

HCA Content in CP from Different *C. arabica* Cultivars. Information about the content and distribution of phenolic compounds in CP is often confusing and sometimes contradictory. Cultivar and degree of ripeness of the fruit can affect the content of phenolic compounds in CP. The ripening of coffee cherries occurs at the end of the physiological maturation of fruits. This process is characterized by a series of physical and chemical changes, such as increased weight and size and changes in color and in the content of sugars and phenolic compounds. Therefore, the ripening stage can significantly affect the HCAs content in CP samples.[15] Therefore, we analyzed the content of soluble and bound HCAs in CP as a function of ripening and cultivar of *C. arabica*.

The content of HCAs strongly depends on the ripening stage and cultivar (Figure 4). Total HCA (defined as the sum of soluble and bound compounds **1**–**4**) content increased during ripening of coffee fruit (from unripe to semiripe stage) for five cultivars. This is followed by a decrease in the HCA content at

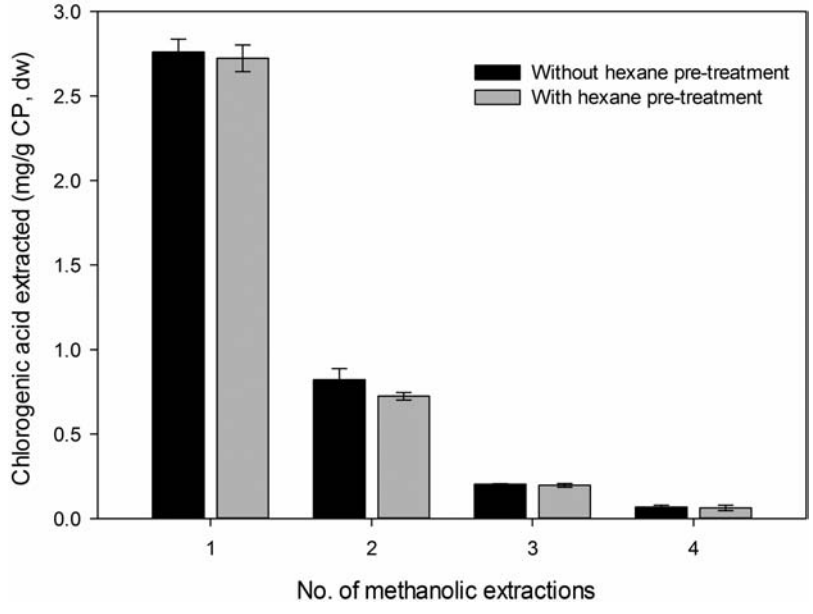

Figure 2. Extraction of chlorogenic acid from cofee pulp by succesive extractions with acidified aqueous methanol (data are presented as a mean value ± standard deviation).

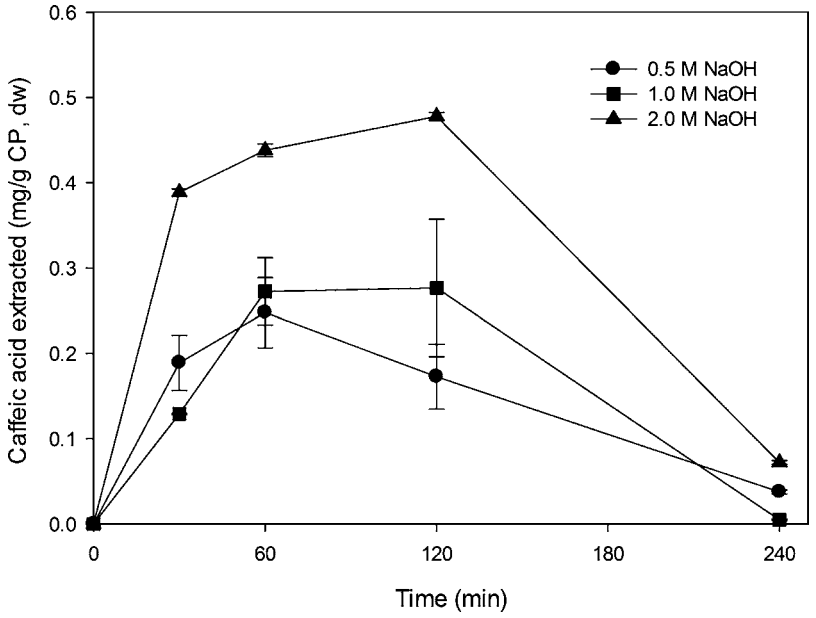

Figure 3. Time course of caffeic acid extraction during alkaline hydrolysis of coffee pulp with different concentrations of NaOH (in the presence of 1% ascorbic acid and 10 mM EDTA) (data are presented as a mean value ± standard deviation).

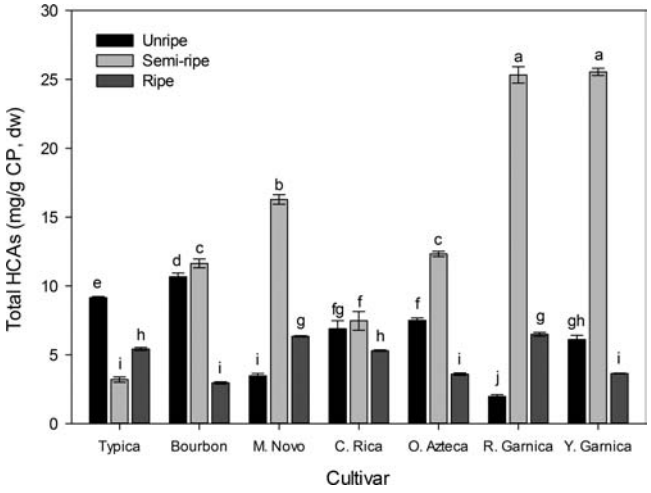

Figure 4. Content of total hydoxycinnamates in the pulp of coffee fruits from seven cultivars at three ripening stages (data are presented as a mean value ± standard deviation).

the end of ripening for six cultivars. For the Typica cultivar an inverse trend was observed.

These observations are different from that of Koshiro et al.[12] They studied the content of compound **1** in pulp and seeds of fruits of *C. arabica* and *C. canephora* at five different ripening stages. They found a progressive increase of **1** during the ripening of coffee fruit. They explained this increase by the continuous synthesis of **1** as suggested by the expression of three genes related to the biosynthesis of compound **1**. These differences in the pattern of accumulation of HCAs can be explained by differences in the presentation of results. Koshiro et al.[12] expressed the content of HCAs as milligrams per fruit. When they took into account the growth of the fruit and expressed the content of HCAs as milligrams per gram of pericarp (dw), they did not observe any increase in the content of **1** during maturation of coffee cherries.

On the other hand, Miljkovic et al.[26] patented a process for the extraction of a nutraceutical product from whole coffee cherry. They recommended the use of unripe or semiripe cherries because these fruits had a higher content of phenolics and compound **1** (from 6.7 to 8.6% w/w of **1**) with respect to the ripe cherries (1.3% w/w of **1**). These results are in agreement with our findings.

Puertas-Mejía et al.[27] studied the accumulation of phenolic compounds in the pericarp (pulp) of coffee fruits at five ripening stages. They found a progressive increase of anthocyanins during ripening (from unripe to overripe stage). Nevertheless, the semiripe stage showed the highest antioxidant capacity. They associated this observation with the presence of additional components with antioxidant activity.[27] These findings could suggest that this additional antioxidant activity could be associated with the presence of HCAs. Nevertheless, no antioxidant assays were carried out in this work.

The content of total HCAs in CP significantly differs from cultivar to cultivar. However, these differences also depend on the ripening stage (Figure 4). For the pulp of ripe fruits, Red Garnica and Mundo Novo cultivars presented the highest content of total HCAs (from 6.34 to 6.49 mg/g dw), followed for the pulp of Typica and Costa Rica cultivars (from 5.29 to 5.42 mg/g dw), and the Yellow Garnica, Oro Azteca, and Bourbon varieties presented the lowest content of total HCAs (from 2.96 to 3.64 mg/g dw). For the semiripe coffee we observed that pulp from Yellow and Red Garnica cultivars had a remarkably high content of HCAs (from 25.32 to 25.54 mg/g dw); on the other hand, the Typica cultivar presented a low content of these compounds (3.20 mg/g dw). All other cultivars had a higher content of HCAs than any sample of pulp from ripe cherries (from 7.45 to 16.68 mg/g dw). Finally, unripe cherries of Bourbon and Typica cultivars presented the highest content of HCAs, whereas the Mundo Novo and Red Garnica had the lowest content of these compounds.

Other authors have studied the content of phenolic compounds in CP from different cultivars. However, those studies are limited to the methanolic extracts from the pulp of

ripe cherries.[8,9] They found a content of HCAs from 3.98 to 16.20 mg/g (dw) for cultivars of *C. arabica* and *C. canephora*. Those values are higher than the results obtained in this paper for ripe CP (from 2.96 to 6.49 mg/g dw). Differences between the contents of HCAs could be related to the origin of coffee fruits (soil, climate, etc.) and agricultural practices.

Tables 2 and 3 show the content of soluble and bound HCAs for each cultivar at each ripening stage, respectively. The content of soluble HCAs is higher than the bound HCAs for all analyzed samples. The content of soluble HCAs represents around 81−97% of total HCAs for all samples except for unripe Red Garnica (soluble HCAs = 68%). This observation differs from previous papers that indicate that most of the HCAs in CP are covalently bound to the cell wall polysaccharides.[6,10,28]

Differences in distribution of soluble and bound HCAs can be related to the origin of the coffee fruits, ripening stage, extraction methodology, and number of consecutive extractions. Furthermore, under the extraction conditions, phenolic compounds may undergo different chemical reactions in the presence of the solvent used. This work has been shown that the amount of three consecutive extractions with aqueous methanol yields 98% of total compound **1** from CP (Figure 1).

In this paper, we confirmed the influence of cultivar and ripening on the content and distribution of soluble and bound HCAs, but we also observed that the extraction method affects the yields of these compounds. Thus, both fractions (soluble and bound) can be under- or overestimated when the extraction has been not exhaustive.

The main component of methanolic extracts of the seven cultivars was compound **1** (Table 2). Compound **1** represented around 94−99% of soluble HCAs for all analyzed samples (from 1.31 to 24.42 mg/g dw). These values are higher than those reported by other authors.[4,6,28] They found that **1** accounts for 80−84% of soluble HCAs. The content of **1** in the methanolic extracts of the pulp of ripe coffee cherries (2.2−5.8 mg/g dw) is within the range found by other authors.[4,6,8,9] These authors have reported a content of 2.3−9.7 mg/g of CP as determined by HPLC analysis of methanolic extracts. On the other hand, Labat et al.[29] reported a content of **1** of 3.6−27.0 mg/g CP. However, they did not describe the extraction and analysis conditions; they neither reported the origin of the plant material.

There is very less information on the content of **1** (and HCAs) in CP from cherries at different stages of ripeness. Koshiro et al.[12] reported the evolution of **1** and its isomers in pulp and seeds of coffee fruits during ripening. They found a continuous decrease of compound **1** from 10 mg/g CP (dw) for green mature fruits to 5−5.5 mg/g for ripe cherries of *C. arabica* cv. Tall Mokka. A similar trend was observed for fruits of *C. canephora*, but in that case, the content of compound **1** decreased from 30 to 10 mg/g CP (dw). In our results a decrease in compound **1** was also observed from unripe to ripe fruits for five of seven cultivars. Nevertheless, in our case an increase of compound **1** was observed in the semiripe fruits for six of seven cultivars.

Other HCAs identified in methanolic extracts were ferulic acid (**3**) and *p*-coumaric acid (**4**). Compound **3** was found at highly variable concentrations (0.02−0.41 mg/g dw), whereas compound **4** was found in small amounts (0.01−0.06 mg/g dw). Compound **2** was not detected in methanolic extracts.

[a]Data are presented as a mean value ± standard deviation; the same letter in a column means no significant differences (Tukey HDS test, $\alpha = 0.05$) between samples; values = 0.00 means = ≤0.005. [b]Calculated as the sum of chlorogenic, caffeic, ferulic, and *p*-coumaric acids.

The main component after the alkaline hydrolysis was **2**, and it represented around 72−88% of bound HCAs (Table 3). Compound **2** is the most abundant HCA found in fruits. It is commonly esterified to sugars, organic acids, and lipids.[30] Compound **1** was found to be principally in the form of soluble ester (**1**) in CP, but also a significant amount of this acid was in the form of insoluble esters.

A small amount of **1** was detected in alkaline hydrolysates, probably due to an incomplete hydrolysis of phenolic compounds. Compounds **2** and **3** were found in the range of 0.016−0.052 mg/g CP (dw). These values of bound phenolic acids are lower than those reported by Torres-Mancera et al.[6] or Pérez-Morales et al.[28] They found contents of 0.083−0.108 mg of bound **3** and 0.079−0.094 mg of bound **2** per gram of CP (dw). These differences could be related to chemical differences between CP samples, maturity state, or the hydrolysis conditions such as time, temperature, and concentration as shown in Figure 3.

CP is a potential source of phenolic antioxidants and other bioactive compounds. However, available data of phenolic content in CP are widely variable. This study contributes to the understanding of the differences found in previous research on HCA extraction from CP. Furthermore, these findings suggest that unripe or semiripe coffee cherries, which are currently discarded as defective cherries, and fruits that remain on the coffee trees after harvest can be used as an inexpensive source of phenolic antioxidants, such as chlorogenic and caffeic acids.

Comparative assessments should be made for differences in phenotype and genotype, market quality traits, and nutritional composition. Substantial equivalence was established by an iterative process as follows: If differences are not found, transgenic lines are considered substantially equivalent to their non-transgenic counterpart. However, if differences are found, then transgenic lines must be evaluated further to ensure that the changes fall within the range of natural variation among different varieties of the same species. This approach has been adopted by numerous studies on major biotechnology-derived field crops, which demonstrated compositional equivalence of transgenic crops to their non-transgenic counterpart.[7,12−17]

In the process of characterizing disease susceptibility and yield of Blight Blocker peanuts from 2004 to 2009, we collected a large amount of data on three transgenic peanut lines and their non-transgenic counterparts. These data included grade characteristics of kernels, fatty acid composition, mineral nutrient profiling, and constituents in peanut. The goal of this study was to assess the nutritional value of transgenic Blight Blocker peanut. Our specific objectives were to (1) compare the nutritional composition of transgenic Blight Blocker peanut lines and their non-transgenic counterparts, (2) investigate equivalence of individual components to determine if Blight Blocker peanut lines are compositionally equivalent to non-transgenic peanut, and (3) perform canonical discriminant analysis of all combined data to assess whether the introduction of a transgene caused significant unintended changes in transgenic lines when compared to their non-transgenic peanut.

MATERIALS AND METHODS

Transgenic Lines and Field Testing. Field testing of transgenic lines was approved by the Animal and Plant Health Inspection Service (APHIS) for comparing the T_4, T_5, and T_6 generations of N70, W73, and P39 in 2006, 2007, and 2008, respectively. Trials were conducted at the Tidewater Agricultural Research and Extension Center in Suffolk, VA, on a field site of Kenansville loamy sand. Transgenic lines and their corresponding non-transgenic parents were planted in a randomized complete block design with four replications. Transgenic lines and corresponding non-transgenic cultivars were planted in two 9.1 m rows/plot. Rows were spaced 0.9 m apart and planted at a rate of ca. 9.8 seed/m of row. Metam sodium 42% (Vapam, Amvac, Newport Beach, CA) at 26.8 kg of active ingredient/ha was applied 20.3 cm under each row with a coulter and trailing chisel shank for control of Cylindrocladium black rot of peanut on March 29 and April 7, 2006, April 19, 2007, and April 15, 2008. Disks and a bed shaper produced smooth beds measuring 64 cm wide and 10.2 cm high over treated rows. Standard practices for production of Virginia-type peanuts were followed throughout the growing season. These trials were harvested on October 31, 2006, November 2, 2007, and October 16, 2008.

Peanut Quality Characteristics. Peanut grade was determined using the United States Department of Agriculture (USDA) grading system for Virginia-type peanut.[18] A 2 kg sample of raw, in-shell peanuts was taken from thoroughly mixed pods harvested from each plot. Pod samples were processed by separating the foreign material, loose-shelled kernels, and pods. Foreign material and loose-shelled kernels were weighed, and their percentage was determined. The remaining intact pods were pre-sized using a set of sizing rollers prior to shelling. The fancy pods (FPP) were a percentage of in-shell peanuts that ride up to 13.5 mm spacing on the pod pre-sizer. Pod brightness (FPB) was measured using a Hunterlab D25-PC2 colorimeter equipped with the D25-2RL reduced area viewing for a L optical sensor (51 mm diameter sample area). The whole pods were shelled using a peanut sheller (Davidson and McIntosh). Size distribution of the shelled kernels was determined with a series of slotted screens prescribed by federal−state inspection standards for Virginia-type peanuts.[18] Extra-large kernels (ELK) were the percentage by weight of extra-large kernels that ride the 8.5 × 25.4 mm slotted screen; sound mature kernels (SMK) were the percentage by weight of kernels that ride the 6.0 × 25.4 mm slotted screen; sound splits (SS) were the percentage by weight of kernels that consist of undamaged split or broken kernels with size between 0.25 and 0.75 mm; total sound mature kernels (TSMK) were the sum of ELK, SMK, and SS; other kernels (OK, percentage by weight) were kernels from the shelled peanut that goes through the SMK screen; and damaged kernels (DK, percentage by weight) were kernels from the shelled peanut that are inedible because of decay, mold, insect damage, sprouting (>3.2 mm), discoloration or pitting darker than light yellow, freeze damaged, or skin discoloration (<25%).

Sample Preparation and Nutritional Composition Analysis. Peanut seed and hay samples harvested from the 2006, 2007, and 2008 field trials were used for compositional analysis. After pods were harvested, subsamples of peanut hay collected along each plot were mixed and pooled to produce a 1 kg sample. The hay samples were air-dried and kept in paper bags at ambient temperature until further analysis. After grading, a 500 g sample of SMK kernels was taken for milling. Aliquots of 50 g were ground to a homogeneous paste using a coffee grinder (Black and Decker CBG5, Miami Lakes, FL) at medium speed for 2 min. The milled samples were stored in airtight polythene bags at −20 °C until chemical analysis. A total of 1 g of subsamples of the milled kernels was used for mineral analysis, and a total of 10 g of subsamples was used to extract oil for analysis of fatty acid composition.

The samples were subjected to chemical analyses for 17 nutritional components that are considered the most important nutrients of peanut seeds for human consumption or in peanut hay for feed uses. Peanut seed samples were analyzed for levels of potassium, calcium, magnesium, sulfur, phosphorus, palmitic acid, stearic acid, oleic acid, linoleic acid, arachidic acid, eicosenoic acid, behenic acid, and lignoceric acid. Hay samples were analyzed for neutral detergent fiber (NDF), acid detergent fiber (ADF), and crude protein (CP). The compositional analyses were performed by accredited laboratories following good laboratory practices.[19] A control sample with known nutritional composition was included in each run of the methods. A limit of quantification (LOQ) was also estimated by the lowest quantitated standard or control sample.

Mineral Analysis. Levels of mineral elements (potassium, calcium, magnesium, sulfur, and phosphorus) in the seed sample were determined according to AOAC method 985.01.[20] Briefly, 1 g of the paste sample was dry-ashed at 550 °C in a furnace, and the ash dissolved in 0.5 N hydrochloric acid (HCl). The solution was filtered with Whatman filter paper No. 2 and brought to 100 mL with deionized water. The elements mentioned above were determined in triplicates at appropriate wavelengths using an inductively coupled plasma atomic emission spectrometer (ICP, Spectro Ciros, Fitchburgh, MA). The ICP instrument was calibrated and programed to analyze 30 samples for 10 elements in about 20 min. Each sample had a 24 s preflush with a 10 s integration time to read the element and background spectral lines, and there was approximately a 10 s rinse that occurred during the integration time. A quality control solution was read and verified after every tray of 30 samples. The concentration of each element was calculated by comparing the emission of the unknown sample to the emission of the standard control solution. Calcium and phosphorus each had a LOQ of 2.5 mg/kg of fresh weight (fw). The LOQ for potassium was 19.5 mg/kg of fw; the LOQ for magnesium was 7.6 mg/kg of fw; and the LOQ for sulfur was 13.5 mg/kg of fw. The measurements were converted to dry weight of sample for comparison.

Fatty Acid Profile. Peanut oil was extracted with the chloroform and methanol method described by Bligh and Dyer.[21] The oil content of the samples was determined by acid hydrolysis based on AOAC method 922.06.[22] Fatty acid methyl esters (FAMEs) were prepared according to the AOCS method Ce 2-66.[23] The fatty acid composition of all FAME samples was determined by gas chromatography (Agilent 6890N GC) using a J&W DB-225 GC capillary column (30 m × 0.252 mm inner diameter with 0.25 μm thickness; Chrom Tech, Inc., Apple

Valley, MN). The oven temperature was initially set at 150 °C and held for 1 min, then increased at 10 °C/min to 175 °C, held for 10 min, then increased at 10 °C/min to 220 °C, and held for 8 min. The inlet and detector temperatures were 225 and 275 °C, respectively; the split ratio was 80:1; and a 1 μL injection volume was used. The hydrogen carrier gas flow rate was 1.9 mL/min. Hydrogen flow to the detector was 30 mL/min; airflow was 400 mL/min; and the flow of nitrogen makeup gas was 40 mL/min. Fatty acid peaks were identified using pure methyl ester standards (Nu-Check Prep, Inc., Elysian, MN). Methyl tricosanate (23:0) was used as an internal standard for quantification. The LOQ for all fatty acid components was 0.2 mg/g of fw. Data were integrated and quantified using a Chem DataStation (Agilent Technologies, Palo Alto, CA). All sample values were converted to percent total seed oil content. The iodine value, oleic/linoleic (O/L) ratio, percentage of total saturated, percentage of total long-chain saturated acids, and polyunsaturated/saturated (P/S) ratio were calculated using the following formulas:

$$\text{iodine value} = (\%\,\text{oleic})(0.8601) + (\%\,\text{linoleic})(1.7321) + (\%\,\text{eicosenoic})(0.7854)$$

$$\text{oleic/linoleic (O/L) ratio} = \%\,\text{oleic}/\%\,\text{linoleic}$$

$$\%\,\text{total saturated} = \%\,\text{palmitic} + \%\,\text{stearic} + \%\,\text{arachidic} + \%\,\text{benehic} + \%\,\text{lignoceric}$$

$$\text{polyunsaturated/saturated (P/S) ratio} = \%\,\text{polyunsaturated (linoleic)}/\%\,\text{total saturated}$$

$$\%\,\text{total long-chain saturated} = \%\,\text{arachidic} + \%\,\text{benehic} + \%\,\text{lignoceric}$$

Forage and Fiber Analysis. Hay samples were prepared according to AOAC method 922.02.[24] Peanut vines were chopped into 1.5 cm pieces and ground in a Wiley mill to pass 4−6 mm sieve, and ground powder samples were thoroughly mixed and kept in an airtight container until analysis. Dry matter was estimated by oven drying for 2 h at 135 °C according to AOAC method 930.15.[25] Crude protein (CP) and acid detergent fiber (ADF) were determined according to AOAC method 989.03 using a near-infrared reflectance spectroscope.[26] Neutral detergent fiber (NDF) was estimated by boiling the sample with neutral detergent solution, adding α-amylase, rinsing with acetone, and determining the percent ADF gravimetrically.[27] The LOQ for CP, ADF, and NDF was 0.1% fw.

Statistical Analysis. SAS software (SAS 9.2, SAS Institute, Inc., Cary, NC) was used to perform all statistical analyses. Percentage data were normalized by arcsine transformation. Data points that are outside of the ±5 studentized PRESS residual range (Proc GLM) were considered as outliers. No data point in this study was identified as an outlier. Standard error (SE) of the sample mean was computed by dividing the standard deviation by the square root of the number of sample values. A total of 21 different components were subjected to analysis of variation (ANOVA) to determine differences at $p \leq 0.05$ between three transgenic lines and their non-transgenic cultivars. Equivalence for a component investigated whether the differences in transgenic lines surpass the normal range of non-transgenic cultivars.[11,28] Equivalence was evaluated as follows: (1) equivalence was assumed if no significant difference was detected between transgenic lines and their corresponding non-transgenic cultivars; (2) if a significant difference was noted, then the range of the test values was compared to the range of test values compiled from the literature. Equivalence was assumed if the test values fell inside the reported range for non-transformed cultivars.[12,28]

The method as described above to infer equivalence from the absence of a significant difference had uncontrolled increased risks of false positive conclusion that is the assumption of non-equivalence.[12] Multivariate analysis, such as canonical discriminant analysis, can alleviate this problem and has proven to be a very powerful tool for assessing the relative pattern of the objects that have very similar properties.[13,29,30] The canonical discriminant analysis was a dimension-reduction technique that combined principal component analysis and canonical correlation.[31] Principal component analysis produced linear combinations of the original variables that were responsible for the highest variation. Canonical correlation generated canonical discriminant functions that contained the highest multiple correlations with each group and best summarized variation between population groups. These canonical functions were orthogonal to each other, even though the original variables were highly correlated.[32] These canonical discriminant functions differentiate groups by simultaneously considering the interrelationships of all variables in the data set and the dependent variables (peanut lines). The pooled within canonical structure and pooled within class standardized canonical coefficients were used to estimate the relative contributions of each variable to the canonical discriminant functions. Mahalanobis distance (D^2) is the difference between centroid values (the mean value of the canonical discriminant function) of groups and has the power of justifying any correlations that might exist between original variables. Therefore, it is a quantitative measure of the distance between groups. Mahalanobis distance (D^2) is calculated as

$$D^2 = (\bar{X}_1 - \bar{X}_2)' S^{-1} (\bar{X}_1 - \bar{X}_2)$$

where $\bar{X}_1$ and $\bar{X}_2$ are the estimated mean vectors in given groups and S^{-1} is the inverse of the pooled sample variance and covariance matrix.

RESULTS AND DISCUSSION

Mineral and Fatty Acid Compositions of Peanut Seeds. No significant differences in five major mineral elements were observed across all 3 years between transgenic line N70 and the non-transgenic parent NC 7 (Table 1), indicating that they had a very similar mineral composition. For transgenic line W73 and non-transgenic parent Wilson, statistical differences were observed only in sulfur in 2007 and in phosphorus in 2006 and 2008 (Table 2). Transgenic line P39 had slightly higher magnesium and phosphorus contents than those of the non-transgenic parent Perry in 2007 (Table 3). However, magnesium and phosphorus levels in P39 were similar to those of their corresponding non-transgenic parent cultivars in other years, suggesting that the elevated and/or reduced values in a field season were likely caused by the environmental variations among three growing seasons. Moreover, the values were always within the reported ranges of conventional peanut cultivars[7,33] and were not sufficient to cause any nutritional or health concerns.

The fatty acid composition of transgenic lines was similar to that of their non-transgenic counterparts. For example, oleic (47.7−59.3%) and linoleic (22.8−34.1%) acids are two major components of fatty acid in peanuts, and there were no statistical differences in oleic and linoleic acids between each of the three transgenic lines and their non-transgenic parents across all three field seasons (Tables 1−3). Furthermore, transgenic lines W73 and P39 showed no statistical differences in all eight fatty acid components tested from those of their corresponding parents (Tables 2 and 3). Although N70 had slightly higher palmitic acid or lower stearic acid than that of non-transgenic parent NC 7 in 2006 and 2008 (Table 1), the differences were marginally small and the measured values were in agreement with previously reported ranges of conventional peanut cultivars.[7,33,34]

Grade Characteristics and Peanut Hay Constituents. The grade characteristics and peanut hay constituents of transgenic lines were similar to those of their corresponding non-transgenic counterparts (Tables 1−3). In comparison to non-transgenic cultivar NC 7, N70 had a slightly higher

percentage of extra-large kernels in 2007 but a lower percentage of fancy pods in 2007 and 2008 (Table 1). The statistical difference between W73 and its non-transgenic parent Wilson was observed only in the percentage of fancy pods and crude proteins in 2006 (Table 2). P39 had a slightly higher percentage of ADF and fancy pods but a lower percentage of extra-large kernels than its non-transgenic parent Perry in 2008 (Table 3). These minor differences mostly occurred in only one field season and were unlikely to be biologically meaningful.

Canonical Discriminant Analysis. Results from canonical discriminant analysis clearly demonstrated that transgenic lines N70, W73, and P39 were substantially equivalent to their non-transgenic parents NC 7, Wilson, and Perry, respectively (Figure 1). A total of five canonical discriminant functions were generated to discriminate six peanut lines. Each canonical discriminant function was an optimal linear combination of trait variables and was uncorrelated to the others. The variance associated with the first three canonical discriminant functions accounted for 98% of the total variance among six peanut lines (Table 4). Canonical correlation measures the strength of relationships between canonical discriminant function and peanut lines. The significant ($p < 0.0001$) correlation between peanut lines and the first three canonical discriminant functions (r_c = 0.997, 0.946, and 0.748, respectively) indicated that these three canonical functions can explain the differentiation of peanut lines. Despite the fact that the first three canonical discriminant functions had the highest power to separate six peanut lines, transgenic lines N70, W73, and P39 cannot be separated out from their non-transgenic parent cultivars (Figures 1 and 2). Transgenic lines derived from the same parent were grouped together with the parent cultivar and distinctly separated from other cultivars and their transgenic derivatives.

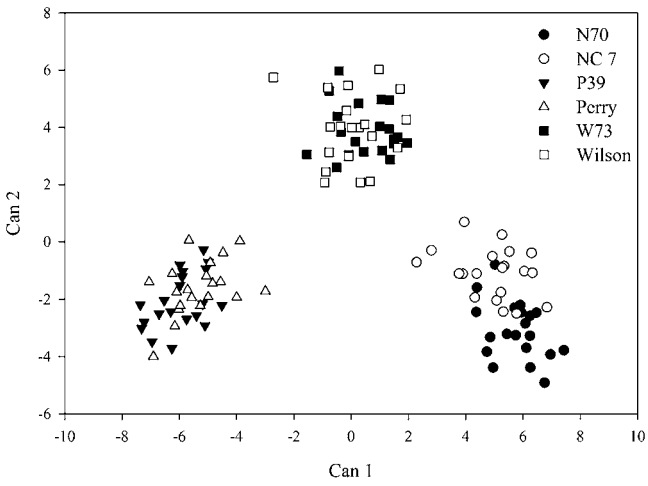

Figure 1. Scatterplot of three transgenic lines and non-transgenic parents by the score of the first two canonical discriminant functions.

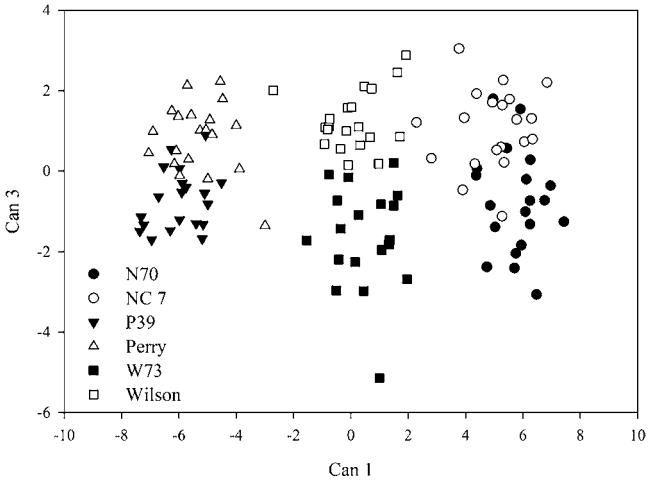

Figure 2. Scatterplot of three transgenic lines and non-transgenic parents by the score of the first and third canonical discriminant functions.

Canonical structures measure correlations between canonical variables and the original variables. These can be interpreted as the relative contribution of each variable to each canonical function.[32] The first canonical discriminant function had the highest correlations with the O/L ratio (0.5717), followed by the P/S ratio (−0.5384), percentage of sound splits (0.2140), percentage of fancy pods (0.1832), and percentage of extra-large kernels (0.1371) (Table 5). The second function was dominated by a large loading from the percentage of total saturated (−0.3766), followed by the percentage of extra-large kernels (−0.2787), calcium (0.1498), percentage of sound mature kernels (−0.1429), and magnesium (0.1119). The third function was most highly correlated with magnesium (−0.3872) and phosphorus (−0.2928). These functions indicated that six peanut lines differ mostly in variables of the O/L ratio, polyunsaturated/total saturated ratio, percentage of total saturated, percentage of fancy pods, percentage of extra-large kernels, percentage of sound mature kernels, and elements of calcium, magnesium, and phosphorus.

Results from canonical discriminant analysis presented a composite picture of how six peanut lines were related to each other in a multi-dimensional space by separating the among-population effect from the within-population variation caused by the environment. Mahalanobis distance (D^2) from the

[a]Canonical variable represents a linear combination of the subset of original variables in the data set. [b]Canonical correlation measures the strength of correlation between the canonical variable and original variables in the data set. [c]Proportion means that percentage of the total variations in the data set can be explained by that canonical variable. [d]Cumulative proportion is the sum of proportions for previous canonical variables. [e]Likelihood ratio is the ratio testing the hypothesis that the given canonical correlation and all smaller canonical correlations are equal to zero in the population.

[a]Refer to the "Abbreviations Used" for a description.

canonical discriminant analysis measured similarity or genetic distance that indicates the extent of separation among peanut lines. The distance D^2 between each pair of transgenic line and its non-transgenic parent was several-fold smaller than the distances of other pairwise combinations, indicating the similarity between transgenic lines and their corresponding parent. For example, the distance D^2 from N70 to its non-transgenic parent NC 7 was 9.9, and the distances D^2 from N70 to Wilson, W73, Perry, and P39 were 86.5, 78.0, 129.3 and 140.7, respectively. Similarly, the distance D^2 from W73 to non-transgenic parent Wilson was 10.3, and the distances D^2 from W73 to NC 7, Perry, and P39 were 51.9, 72.6, and 80.4, respectively. Finally, the distance D^2 from P39 to non-transgenic parent Perry was 6.9, and the distances D^2 from P39 to NC 7 and Wilson were 124.4 and 76.8, respectively.

This research has provided strong evidence that insertion and expression of an oxalate oxidase gene in peanut did not cause substantial changes in grade characteristics nor mineral and fatty acid contents of kernels or constituents in peanut hay. Statistically significant differences ($p < 0.05$) were rarely observed in comparisons of a transgenic line to its corresponding non-transformed parent cultivar in a growing season (Tables 1−3). However, for the comparisons observed to be significantly different between transgenic lines and their non-transformed counterparts, the variations were usually small and within the range of natural variability of conventional-bred peanut cultivars.[7,33] Significant differences in growing conditions among three field seasons were likely responsible for the observed compositional variations. In addition, compositional differences among the non-transgenic lines in the study were much greater than the differences seen between each transgenic and paired non-transgenic counterpart. More importantly, such small compositional variations did not diminish the nutritional value of peanut kernels and hay. Additional results from canonical discriminant analysis also demonstrated the compositional similarity between transgenic crops and their corresponding non-transformed parent cultivars.

In conclusion, this study provided multiple-year data on chemical composition and grade characteristics in different climates and agronomic conditions. No biologically meaningful unintended compositional or quality effects were found between the transgenic lines and their paired non-transgenic counterparts, and the composition of transgenic lines was within the known range of the non-transgenic peanut. Results clearly indicated that insertion and expression of an oxalate oxidase gene in peanut did not cause substantial unintended changes in chemical composition in seeds or hay constituents. Therefore, this study provides strong evidence for concluding substantial equivalence in quality and compositional traits among transgenic lines expressing oxalate oxidase and their non-transformed parent cultivars.

susceptible to Maillard induced chemical changes, proteolytic and other non-Maillard chemical changes were observed during storage compared to corresponding changes in conventional UHT milk.

MATERIAL AND METHODS

Chemical References. Decane (99%), tetradecane (99%), dodecane (99%), 2-methylbutanal (95%), hexanal (98%), heptanal (95%), octanal (99%), furfural (98%), nonanal (95%), decanal (98%), 2-butanone (99%), 2-pentanone (99%), 2-hexanone (99.5%), 2-heptanone (98%), 2-octanone (98%), 2-nonanone (99%), 6-methyl-5-heptene-2-one (99%), 6,10-dimethyl-5,4-undecadien-2-one (97%), 2-undecanone (99%), dimethyl disulfide (98%), dimethyl trisulfide (98%) 4-methyl-1-pentanol (97%), toluene (99.5%), styrene (99%). 2-methylfuran (98%), 2-ethylfuran (99%), 2-pentylfuran (97%), fluorescamine (4-phenylspiro[furan-2(3*H*),19-phthalan]-3,39-dione) (99%), and D_2O containing 0.025% sodium trimethylsilyl-[2,2,3,3-$^2H_4$]-1-propionate were obtained from Sigma-Aldrich Inc. (Steinheim, Germany). Trichloroacetic acid, HCl, and water-free acetone were from Merck (Darmstadt, Germany).

Milk Samples. Milk for the study was produced at a commercial Danish dairy plant (Arla Foods, Esbjerg, Denmark) (Figure 1). Three types of milk (conventional indirect UHT (CONVI), lactose-hydrolyzed direct UHT (LHD), and lactose-hydrolyzed indirect UHT (LHI)) were produced (Table 1). The milk was UHT-treated using either direct heat treatment (LHD) (steam is injected into the milk to heat it followed by flash cooling[12]) (140−145 °C for 2−3 s) or indirect heat treatment (CONVI, LHI) (a tubular heat exchanger is used to heat the milk, followed by slow cooling[12]) (140−145 °C for 2−3 s) and packaged aseptically in 1 L Tetra Brik cartons. Lactose in the lactose-hydrolyzed milk (LHD, LHI) was removed (approximately 40% of initial lactose content) before heat treatment using ultra- and nanofiltration. The remaining lactose was enzymatically hydrolyzed (LHD, LHI), after heat treatment, by the addition of lactase (Maxilact LAG 5000, DSM, Limburg, The Netherlands).

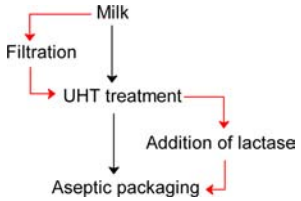

Figure 1. Flowchart of production of lactose-hydrolyzed UHT milk (red) and conventional UHT milk (black).

After transportation to the laboratory, the milk samples were stored in an air-conditioned room at a constant temperature of 22 °C. At days 7, 14, 21, 28, 45, 60, 90, 120, 150, 180, 210, 240, and 270 after production, two milk cartons were picked and frozen and stored at −20 °C until analysis. Milk for the NMR spectroscopy analysis and fluorescamine determination was filtered using Amicon Ultra 0.5 mL 10 kDa (Millipore, Bedford, MA, USA) spin filters at 10000*g* for 15 min to remove residual lipids and protein prior to freezing. After frozen storage, the milk samples and filtrates were randomized and thawed in 4 °C before final analyses.

Determination of Volatile Compounds by Dynamic Headspace Sampling and GC-MS. The volatile compounds were extracted using dynamic headspace sampling and analyzed by gas chromatography−mass spectrometry (GC-MS) according to the procedure described by Jansson et al.[13] The volatile compounds were isolated on adsorbent traps (Tenax TA, 200 g Tenax TA, 35/60 mesh (Markes International Limited, LIantrisant, UK)) and desorbed (250 °C, 15 min) into a cold trap (U-TIIGCP, Markes International Limited) using a thermal desorption system (ultra-UNITY, Markes International Limited) and subsequently injected onto a gas chromatograph (Finnigan trace GC ultra, Thermo, Waltham, MA, USA) using a CP-Wax 52CB column (50 m × 0.25 mm, film thickness = 0.25 μm (Varian, Palo Alto, CA, USA)).

To identify the separated volatile compounds, a single-quadrupole mass spectrometer (Finnigan Trace dual-stage quadrupole (DSQ), Thermo) was used. The mass spectrometer scanned over a mass to charge (m/z) of 45−350 (1.61 scans/s) in TIC mode, and specific m/z values were detected in SIM mode (Table 2). The volatile compounds were identified using an MS database (NIST MS search 2.0, 2011) and verified by comparison of mass spectral data and retention times with those of authentic reference compounds.

Table 2. Overview of Retention Time (t_R), Identified and Verified Volatile Compounds, and m/z Ions Scanned with GC-MS SIM Mode

t_R (min)	volatile compound	m/z
4.84	3,3-dimethylhexane

40.75	2-nonanone	
40.95	nonanal	
41.14	tetradecane	
42.91	furfural	
43.42	decanal	
45.25	2-undecanone	170
48.90	6,10-dimethyl-5-undecadien-2-one	

Table 1. Overview of Milk Types Included in the Study, Heat Treatments, and Lactose Levels[a]

	milk	enzymatic hydrolysis	heat treatment	filtration	level of lactose (% of original level)	amount of lactose (% w/w)
CONVI	conventional UHT	−	indirect	−	100	5
LHD	lactose-hydrolyzed direct UHT	+	direct	+	<1	0.01
LHI	lactose-hydrolyzed indirect UHT	+	indirect	+	<1	0.01

[a]All milks contained 1.5% w/w fat and 3.5% w/w protein.

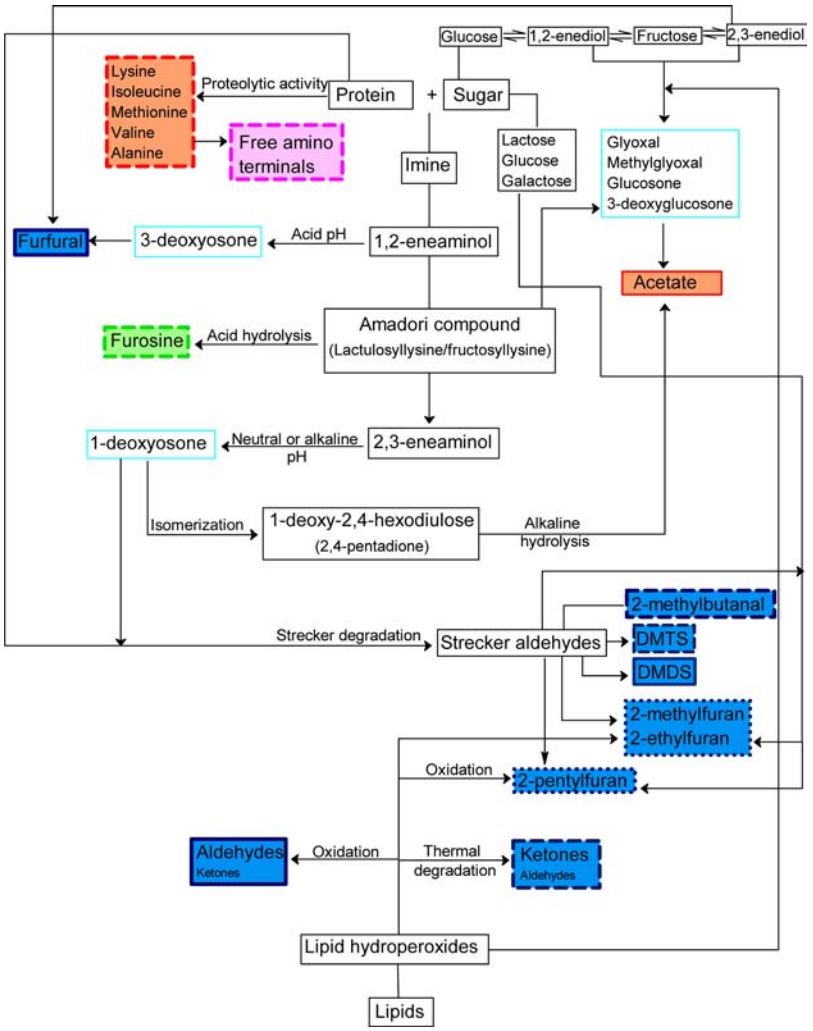

Figure 2. Overview of compounds identified in the milk originating from the Maillard reaction, lipid oxidation, and proteolytic activity analyzed with GC-MS (blue rectangles), NMR (orange rectangles), HPLC (green rectangles), and fluorescamine assay (pink rectangle). A dashed outline indicates increase of compounds in lactose-hydrolyzed UHT milk, a dotted outline indicates increase of compounds in conventional UHT milk, a solid outline indicates no difference between lactose-hydrolyzed and conventional UHT milk during storage.

A total of 15 identified volatile compounds were quantified using external standard curves prepared in duplicates in UHT milk. For each standard curve, the regression equation, limit of detection (LOD), and limit of quantification (LOQ) were calculated from the standard error of the *y*-intercept and the slope of the linear regression (Table 2).[14,15]

Determination of Furosine by RP-HPLC. Furosine formation was determined in milk after acid hydrolysis by RP-HPLC as described previously in ISO 18329:2004 (IDF 193:2004)[16] with some modifications. One milliliter of milk was mixed with 3 mL of 10 M HCl in screw-cap tubes, and nitrogen was bubbled through the samples for 2 min. The tubes were closed and heated at 110−115 °C for 18 h. After heating, the samples were cooled and filtered through a filter paper (Black Ribbon 589/1, Schleicher & Schuell MicroScience GmbH, Dassel, Germany), and 2 mL of filtrate was filtered through a 0.45 μM disposable filter, diluted 5 times in 3 M HCl, and transferred into HPLC vials. Furosine detection was performed on a Dionex 300DX system (Dionex, Germering, Germany) with a DAD detector and using a Supelco Supercosil LC-8 column (Sigma-Aldrich Inc.) with isocratic elution with 0.06 M sodium acetate buffer at a flow rate of 1 mL/min. The injection volume was 10 μL, and the DAD detection (UV) was at 280 nm.

Determination of Free Amino Acids Using ^{1}H NMR Spectroscopy. Determination of free amino acids was performed using ^{1}H NMR spectroscopy analysis according to a method adapted from Sundekilde er al.[17] The milk filtrates were thawed, and 400 μL was mixed with 200 μL of D_2O containing 0.025% sodium trimethylsilyl-[2,2,3,3-$^2H_4$]-1-propionate (TSP) as internal chemical shift reference. A Bruker Avance III 600 spectrometer (Bruker Biospin, Rheinstetten, Germany) equipped with a 5 mm TXI probe was used for the analyses. The sample sequence was randomized prior to acquisition. Standard one-dimensional spectra were acquired using a single 90° pulse experiment with a relaxation delay of 5 s. Water suppression was achieved by irradiating the water peak during the relaxation delay, and a total of 64 scans were collected into 32K data points scanning a spectral width of 12.15 ppm. All ^{1}H spectra were initially referenced to the TSP signal at 0 ppm. Prior to Fourier transformation the data were multiplied by a 0.3 Hz line-broadening function. The proton NMR spectra were phase and baseline corrected manually using Topspin 3.2 (Bruker Biospin). Amino acid concentrations were calculated for valine, methionine, isoleucine, alanine, and acetate using Chenomx software (Chenomx NMR suite 7.7, Edmonton, Canada).

Determination of Free Amino Terminals by Fluorescamine Assay. The level of free amino terminals in the milk was determined according to the method of Dalsgaard et al.[18] An amount of 75 μL of milk was mixed with 75 μL of 24% trichloroacetic acid (24 g TCA/100 mL water) and placed on ice for 30 min to accelerate protein precipitation. The precipitated mixture was centrifuged (17049*g* for 20 min). A total of 37.5 μL of supernatant was then added to 1130 μL of 0.1 M borate buffer and 375 μL of fluorescamine solution (0.2 mg/mL fluorescamine in water free acetone), and 250 μL was then transferred

to each well in a microtiter plate. The analysis was carried out, 18 min after the addition of the fluorescamine, on a Synergy 2 Multi-Mode microplate reader (Holm & Halby, Brøndby, Denmark) with excitation at 390 nm and emission at 480 nm. Quantification was achieved by calculating leucine equivalents using an external leucine standard curve prepared as follows. A 0.1 M leucine stock solution was made (327.5 mg of leucine in 25 mL of 1 mM HCl), and from the stock solution six different concentrations were made (0.00050–0.0030 M leucine) and mixed with 10 mL of 1 mM HCl and analyzed as the milk samples.

Statistical Analysis. To identify significant effects of milk type, storage time, and degree of increase in concentration on the quantified volatile compounds, furosine, and free amino acids, regressions were made by a linear model (lm) followed by a one-way analysis of variance (ANOVA). In addition, a linear mixed model (lme) and a generalized linear mixed model (lmer), least-squares means (LSMEANS), and Tukey's honest significant difference (α = 0.05) test was performed using the software R (version 3.0.2, R Foundation for Statistical Computing, Vienna, Austria).

RESULTS

GC-MS, NMR, furosine, and fluorescamine analyses were conducted on industrially produced conventional UHT milk (100% lactose) and lactose-hydrolyzed UHT milk (<1% of original level of lactose) throughout a storage period of 9 months at 22 °C. The lactose-hydrolyzed UHT milk was heated with 60% of the original level lactose, which was subsequently hydrolyzed to glucose and galactose by the addition of lactase. The compounds detected in the milk by the different analytical approaches are summarized in Figure 2.

Furosine. The development of furosine levels in the milk after acid hydrolysis was found to be significantly affected by milk type. A significantly higher initial level of furosine was observed in CONVI milk (p < 0.001) (Figure 3) compared to

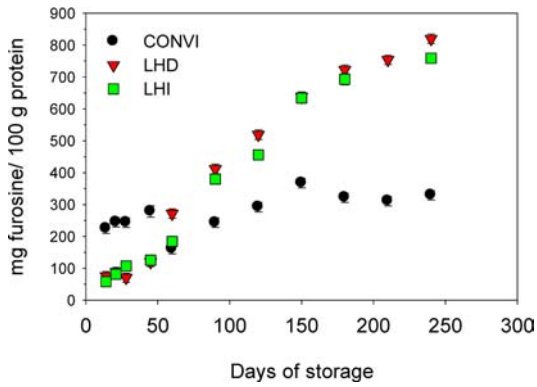

Figure 3. HPLC analysis of furosine in conventional indirect UHT milk (CONVI), lactose-hydrolyzed direct UHT milk (LHD), and lactose-hydrolyzed indirect UHT milk (LHI) during storage.

LHD milk and LHI milk; however, after approximately 60 days, furosine levels started to increase in LHD milk and LHI milk, whereas in CONVI milk furosine levels were constant throughout the storage period. After 270 days of storage, the furosine content was about 2.5 times higher in lactose-hydrolyzed milk than in conventional milk.

GC-MS. A total of 27 volatile compounds were extracted from the headspace sampling and identified using GC-MS (Table 2), and of these 15 were quantified (Table 3). The remaining 12 identified compounds (Tables 2 and 3) were constant throughout the storage period for all milk types and were therefore not quantified.

Notably, the levels of the five ketones quantified were significantly higher in conventional UHT milk (p < 0.001) than in lactose-hydrolyzed milk in the initial phase of the storage period by a factor of 4–5 (Figure 3). All of the quantified ketones followed a similar trend during storage for all milk types, and a significant (p < 0.001) increase in the concentration of ketones was observed during storage (Figure 4). However, for 2-pentanone (p < 0.001), 2-heptanone (LHD, p = 0.016; LHI, p = 0.006), and 2-nonanone (LHD, p < 0.001; LHI, p < 0.001) the formation rate significantly increased at a higher extent for lactose-hydrolyzed milk compared with conventional milk (Figure 4A–C; Supporting Information). In addition, the formation rate of 2-undecanone increased significantly more in LHD than in CONVI (p = 0.029) and LHI (p = 0.023) milks. 2-Nonanone was the only ketone for which a difference between direct and indirect heat treatment could be observed during storage and a higher formation rate was seen in LHD (p = 0.0012) milk compared with LHI milk. 2-Octanone did not appear before 90 days in lactose-hydrolyzed milk, whereas it was observed already at day 14 in conventional milk. A higher formation rate in the level of 2-octanone was observed in CONVI (p = 0.0224) milk compared to LHD milk during storage (Figure 4D).

With the exception of 2-methylbutanal, no significant change in the concentration was observed for the quantified aldehydes during storage (Figure 5). Notably, the concentration of 2-methylbutanal was almost constant in CONVI milk during the 9 month storage period, whereas its concentration (Figure 5D; Supporting Information) increased tremendously after 150 days of storage in LHD (p < 0.001) and LHI (p < 0.001) milk. In addition, it was observed that the level of 2-methylbutanal significantly increased more in LHI (p < 0.001) milk than in LHD milk from day 200.

Heterocycles 2-methylfuran and 2-ethylfuran exhibited a pattern similar to that of the ketones, and a significant increase in their concentrations was observed for all of the milk types during storage (p < 0.001) (Figure 6A,B; Supporting Information). The increase in concentration of the two furans during the storage period was significantly higher in CONVI (p < 0.001) milk compared with the lactose-hydrolyzed milk, and the concentration of 2-ethylfuran increased more in LHI (p = 0.012) milk compared with LHD milk. A different pattern was observed for 2-pentylfuran (Figure 6C). Whereas a significant increase in the concentration of 2-pentylfuran was observed in CONVI (p < 0.001) milk during the storage period, the concentration remained almost constant in LHD and LHI milk.

Dimethyl trisulfide (DMTS) increased in LHD and LHI milk up to 50 days of storage, followed by a decrease to below the initial concentration. In CONVI milk a higher initial concentration of DMTS was observed than in LHD and LHI milks; however, the concentration decreased rapidly during storage, and a low and constant concentration of approximately 0.2 μg/kg milk was reached after approximately 50 days of storage (Figure 7). Dimethyl disulfide (DMDS) was constant throughout the storage period for all milk types (data not shown).

Analysis of Amino Acids by NMR. Four free amino acids, isoleucine, alanine, methionine, and valine (Figure 8), were identified and quantified by ^{1}H NMR spectroscopy. The levels of alanine (LHD, p < 0.001; LHI, p < 0.001), isoleucine (LHD, p = 0.002; LHI, p < 0.001), and valine (LHD, p < 0.001; LHI, p < 0.001) increased in lactose-hydrolyzed milk, whereas they remained constant in the conventional milk throughout the

lactose-hydrolyzed milk (LHD, $p = 0.028$; LHI, $p = 0.0336$) during storage, whereas the increase in conventional milk during storage was not significant.

Analysis of Free Amino Terminals by Fluorescamine Assay. Slightly higher initial levels of free amino terminals and amino groups of lysine side chains were observed in the CONVI milk compared with lactose-hydrolyzed milk (Figure 10). However, the level of free amino terminals, expressed as leucine equivalents, significantly increased in the lactose-hydrolyzed milk ($p < 0.001$), whereas it remained rather constant in the conventional milk during storage (Figure 10; Supporting Information). After 270 days of storage, the level of free amino terminals was about 2 times higher in lactose-hydrolyzed milk than in conventional milk. No differences were observed between LHD and LHI milks.

DISCUSSION

In the present study volatile compounds, Amadori products as determined by furosine levels, levels of free amino acids, and levels of amino terminals, and proteolysis were analyzed in lactose-hydrolyzed and conventional UHT milk to elucidate the detailed chemical changes during a 9 month storage period (Figure 2).

Maillard Reaction Products. An increase in the level of furosine was observed in all milk types during the 9 month storage, which demonstrates a continuous formation of its precursors, lactulosyllysine and fructosyllysine (Figures 2 and 3). During the first 60 days of storage lactose-hydrolyzed milk was characterized by a significantly lower furosine level than conventional milk. This was likely due to the removal of approximately 40% of lactose prior to the UHT treatment in the lactose-hydrolyzed milk, resulting in lower levels of carbohydrates during the UHT treatment and lower levels of Maillard reactions in the initial storage period. This indicates that furosine precursors were formed during the heat treatment. However, during storage, the formation rate was significantly higher in lactose-hydrolyzed milk compared to conventional milk. This is consistent with the fact that the monosaccharides polymerize more progressively[19] than disaccharides. This finding reveals that despite lower carbohydrate levels, the Maillard reaction proceeds more rapidly and to a greater extent in lactose-hydrolyzed milk during storage. Previous studies have followed the development of furosine in lactose-hydrolyzed and conventional milk for up to 4 months and showed significant increases in furosine during storage.[4,20] Messia et al. investigated the formation of furosine in lactose-hydrolyzed and conventional indirect UHT milk during 4 months of storage at 20 °C and found higher values of furosine in the former.[4] The concentrations of furosine found in the lactose-hydrolyzed milk at production and after storage for 4 months were 234 and 562 mg/100 g protein, respectively, whereas the corresponding concentrations found in the conventional milk were 235 and 310 mg/100 g protein, respectively. These results are quantitatively consistent with the results in the present study for the same storage period, temperature, and milk type. However, this study shows that it is important to follow the development of furosine for longer than 4 months (Figure 3). Tossavainen and Kallionen investigated furosine content in three milk types: nonhydrolyzed, hydrolyzed, and lactose-reduced-hydrolyzed (similar to the lactose-hydrolyzed milk in

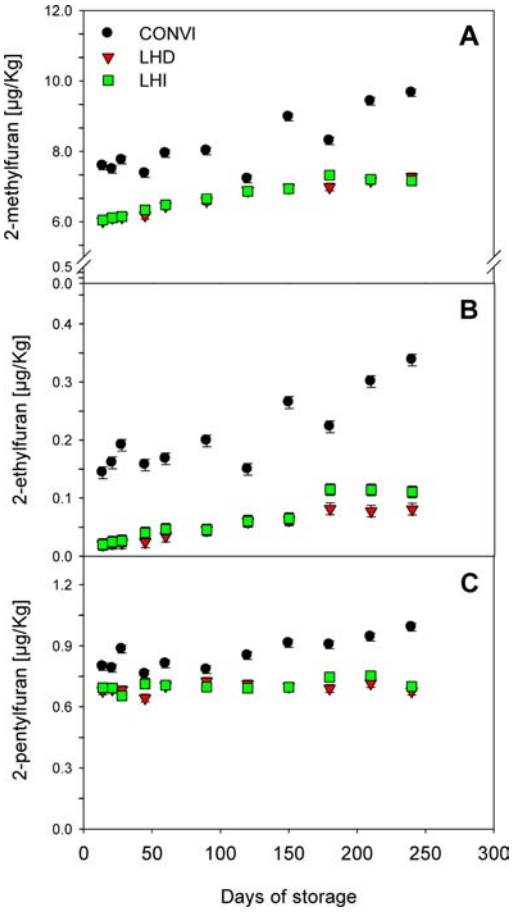

Figure 6. GC-MS analysis of (A) 2-methylfuran, (B) 2-ethylfuran, and (C) 2-pentylfuran in conventional indirect treated UHT milk (CONVI), lactose-hydrolyzed direct UHT milk (LHD), and lactose-hydrolyzed indirect UHT milk (LHI) during storage.

the present study) UHT milk stored for 12 weeks.[7] Tossavainen and Kallionen found a 2.5-fold higher level of furosine in the lactose-reduced-hydrolyzed milk and lactose-hydrolyzed milk, respectively, compared with the nonhydrolyzed milk and concluded that the content of furosine was dependent on both the amount and type of sugar. In the present study it was observed that the content of furosine was dependent on the amount of sugar the first 90 days and that type of sugar was important after 90 days of storage. It was also revealed that the level of furosine in conventional and lactose-hydrolyzed UHT milk is very dependent on the storage period. This has implications for understanding storage-induced deterioration of milk quality.

A very similar formation pattern was observed for the furosine generation and the Maillard reaction product, 2-methylbutanal (Figure 5D). After initially being observed at a lower concentration in LHI and LHD, which is consistent with total carbohydrate content, accumulation of 2-methylbutanal was found to occur more rapidly and to a much greater extent in lactose-hydrolyzed milk. This observation is in good agreement with the current understanding of the Maillard–Strecker degradation pathway. The volatile 2-methylbutanal is a Strecker degradation aldehyde[21] and is formed when isoleucine reacts with dicarbonyl compounds in the milk. The increased concentration of 2-methylbutanal in lactose-hydrolyzed compared to conventional UHT milk can be ascribed to the type of sugar (lactose, glucose, and galactose) available in the milk. Kato et al. studied protein polymerization and browning in a model system consisting of ovalbumin, glucose, and lactose and concluded that glucose accelerates the protein polymerization as well as the Amadori degradation.[19] Kato et al. also concluded that the Amadori compounds formed from lactose were less prone to degradation into aldehyde compounds compared with the Amadori compounds from glucose. Intriguingly, in the present study it could be observed that the free amino acid and precursor for Strecker degradation, isoleucine, increased during storage in lactose-hydrolyzed milk, whereas it remained constant in conventional milk (Figure 8A). This finding is probably related to a higher level of proteolysis in lactase-treated milk and could be due to unwanted side activities of the enzyme preparation. Balagiannis et al. investigated the formation of 2-methylbutanal and observed that the sugar concentration, the Amadori rearrangement, the rate of dicarbonyl formation, and the amount of isoleucine were the limiting steps of its formation.[21] The simultaneous increase of isoleucine, furosine, and 2-methylbutanal in lactose-hydrolyzed milk after approximately 100–150 days of storage indicates that the level of isoleucine and the Amadori rearrangement is important for the formation of 2-methylbutanal, which, in addition to the lower reactivity of lactose with proteins and the nondetectable formation of isoleucine, explains the absence of a formation of 2-methylbutanal in the conventional UHT milk.

Furfural is formed in the 3-deoxyosone pathway in the early Maillard reaction, which is favored by acidic pH. However, furfural may be a precursor of the formation of furan derivatives in the Maillard reaction.[22] Berg observed that furfural was formed in milk in very small concentrations after heating and that the level of furfural increased with increasing heat load.[23] In the present study, furfural was identified and quantified, and it was found that furfural remained almost constant at a concentration of 0.8–6 μg/kg (8.3–62.4 μmol/kg) throughout the storage period. This concentration is higher than the concentration detected by Berg, who reported 0.68 μmol furfural/kg in UHT milk.[23] This difference is possibly due to differences in the UHT treatment or differences in the sensitivity of the applied GC-MS method. The results in the present study indicate that no formation of furfural is taking place during storage at room temperature, likely due to the nonpreferred pathway at normal milk pH.

Acetate, identified by NMR spectroscopy in the present study (Figure 9), is a major degradation product of sugars in the Maillard reaction. In neutral and basic pH, acetate is formed

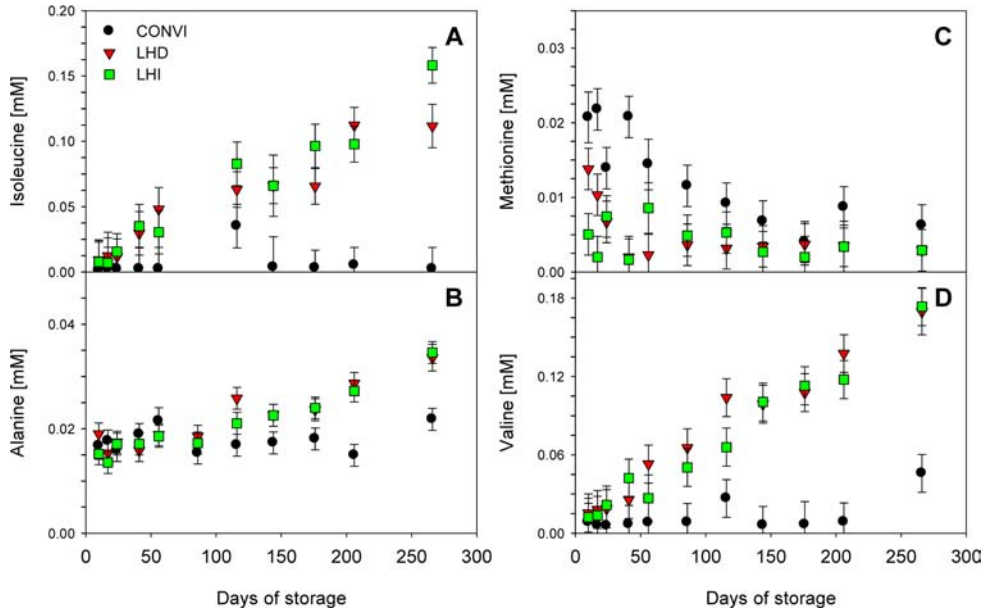

Figure 8. NMR spectroscopic analysis of (A) isoleucine, (B) alanine, (C) methionine, and (D) valine in conventional indirect treated UHT milk (CONVI), lactose-hydrolyzed direct UHT milk (LHD), and lactose-hydrolyzed indirect UHT milk (LHI) during storage.

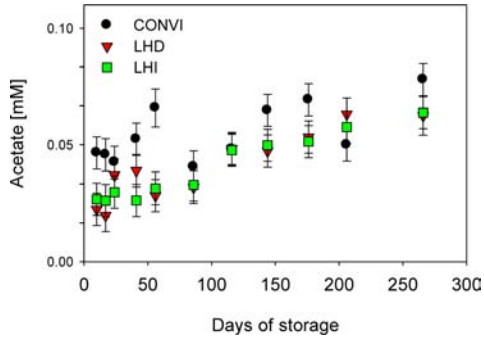

Figure 9. NMR spectroscopic analysis of acetate in conventional indirect UHT milk (CONVI), lactose-hydrolyzed direct UHT milk (LHD), and lactose-hydrolyzed indirect UHT milk (LHI) during storage. Acetate significantly increased for LHD and LHI during storage: significance level for LHD (p = 0.0275), LHI (p = 0.0336).

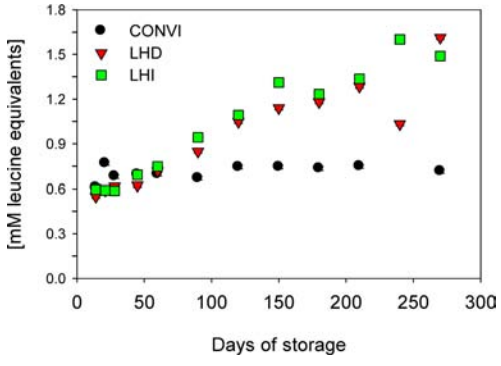

Figure 10. Concentration of free amines in conventional indirect UHT milk (CONVI), lactose-hydrolyzed direct UHT milk (LHD), and lactose-hydrolyzed indirect UHT milk (LHI) determined by fluorescamine assay during storage.

primarily from C2−C3 β-cleavage of the 1-deoxyosone isomerization product 1-deoxy-2,4-hexodiulose (2,4-pentadione).[24,25] Acetate is a stable end product of this pathway and considered as a marker for the 2,3-enolization in the Maillard reaction.[24] In addition, acetate can also be formed directly from sugar fragmentation.[25] In the present study the level of acetate increased during storage for all of the milk types, and no significant difference was found between the milk types (Figure 9). The accumulation of acetate in the milk during storage indicates that a continuous formation is taking place throughout storage and that the degradation of the respective Amadori compound (fructosyllysine in lactose-hydrolyzed milk and lactulosyllysine in conventional milk) occurs throughout storage, leading to a continuous formation of the dicarbonyls, which are included in Strecker degradation in the Maillard reaction (Figure 2). The comparable increase of acetate in lactose-hydrolyzed and conventional milk indicates that the same level of Amadori compound degradation is present in both milk types. Kato et al. observed that Amadori compounds from lactose were more difficult to degrade compared with the Amadori compounds from glucose, which could explain the lower level of Strecker aldehydes such as 2-methylbutanal in conventional milk in the present study.[19] However, contrary to Kato et al., the present study indicates that the 2,3-enolization from the Amadori compounds to 1-deoxyosone is similar in conventional and lactose-hydrolyzed UHT milk and that the hindrance for further degradation to aldehydes is taking place after this step in the Maillard reaction cascade (Figure 2).

2-Methylfuran and 2-ethylfuran increased significantly during storage in all milk types (Figure 6), but a larger increase was seen in CONVI milk compared with LHD and LHI milks. The furans 2-methylfuran and 2-ethylfuran are Strecker aldehyde (acetaldehyde and lactaldehyde) products as well as sugar and protein degradation products.[26,27] The higher content of furans in the conventional milk indicates that the formation of furans is favored by lactose, and not glucose and galactose. This suggestion is supported by a recent published work by Owczarek-Fendor et al., who investigated furan formation in starch-based systems containing various carbohydrates and proteins, heated at 130 °C for 30 min, at different pH values.[28] The study revealed that lactose and lactose−protein systems

dx.doi.org/10.1021/jf501671z | J. Agric. Food Chem. 2014, 62, 7886−7896

generated higher amounts of furan at pH 6 compared with glucose and fructose systems.

Thermal Degradation and Oxidation Products. In addition to 2-methylbutanal, four other aldehydes were quantified. The nonsystematic variation in aldehydes could potentially be ascribed to the low concentration of these compounds. During thermal processing fatty acids may undergo thermal degradation reactions, including isomerization, cyclization, and cleavage, and aldehydes are mainly formed by oxidation of fatty acids;[29,30] straight-chain aldehydes are the most important markers for fat oxidation.[31] Vazquez-Landaverde et al. observed that aldehydes were not affected by heat to the same extent as ketones.[2] Valero et al. found a small increase in aldehydes during 120 days of storage.[3] Jeon et al. investigated the effect of addition of ascorbic acid, acting as antioxidant, on the formation of aldehydes in UHT milk and found that the addition of ascorbic acid reduced the formation of aldehydes.[32] Osada and Shibamoto investigated the antioxidative activity of volatile extracts from Maillard model systems and observed that the combined effect of many compounds produced in the Maillard reaction possessed an antioxidative effect that decreased the oxidation of hexanal.[33] Thus, in the present study, an antioxidant activity from the advanced Maillard reaction products[34] or peptides and proteins,[35] formed from proteolysis, may inhibit the formation of aldehydes. This could explain the low level of change observed for the aldehydes during storage in all milk types. However, the low level of aldehydes may also indicate a low level of oxidation in the milk.

During storage a significant increase in the concentration of ketones was observed in the milks (Figure 4). Ketones are derived from fatty acids through β-oxidization[30,36] and are primarily formed by thermal degradation.[29] The ketones are known to be temperature-dependent, and increased levels of ketones have been observed in milk exposed to higher temperatures.[2] The present study revealed that both the level and the formation rate of ketones were affected by milk type. Whereas the level of ketones was higher in conventional UHT in the beginning of the storage period, the levels of 2-pentanone, 2-heptanone, and 2-nonanone increased significantly higher in the lactose-hydrolyzed compared to conventional milk. In addition, a higher increase in 2-undecanone was observed in LHD milk compared with CONVI milk. These findings indicate that the thermal degradation of the fatty acids is more pronounced in lactose-hydrolyzed milk than conventional UHT milk. However, because the heat treatments applied were similar, the exact mechanism remains unknown.

A significant increase in 2-pentylfuran was found in CONVI milk during storage, whereas this compound was found to be constant in lactose-hydrolyzed milk (Figure 6C). Overall, 2-pentylfuran is formed from oxidation of unsaturated lipids.[27,37] A possible explanation for the increased formation of 2-pentylfuran in the conventional UHT milk compared with the lactose-hydrolyzed milk may be a higher antioxidant activity in the lactose-hydrolyzed milk due to an increased Maillard reaction[34,38] or increased proteolytic activity[35] forming antioxidative compounds.The antioxidative compounds may decrease the oxidation of the unsaturated lipids present in the milk and thereby the furan formation.

When β-lactoglobulin is heat-denatured, methionine and cysteine are exposed to further reactions, such as oxidation and Maillard reactions, and Strecker degradation. The Strecker degradation of methionine may lead to the formation of methional, which further oxidizes to DMDS and DMTS,[36,39] and in the present study, DMTS apparently was formed after or during heat treatment in all milk types. In lactose-hydrolyzed milk the DMTS concentration increased further during storage and then decreased rapidly after approximately 50 days (Figure 7), whereas an immediate decrease was observed in the conventional UHT milk. In addition, it was observed that methionine decreased in lactose-hydrolyzed milk, which could indicate that methionine was degraded to DMTS in the initial part of the storage period. However, for the conventional UHT milk, methionine first increased followed by a slow decrease, and the decrease could not be correlated to any simultaneous formation of DMTS. Sulfides and sulfur-containing amino acids are very reactive, and the decrease of these compounds during storage is mainly thought to be due to degradations and oxidations.[40,41] Because of observations of increased levels of free amino acids or peptides in lactose-hydrolyzed milk during storage (Figure 8A,C,D), a similar observation was expected with methionine; however, no increase was observed. This may be explained by the specificity of the proteolytic enzyme, which may not cleave methionine or methionine-containing peptides, or rapid degradation of exposed methionine residues, which would prevent its detection in the NMR.

Protein Hydrolysis during Storage. In the present study ^{1}H NMR spectroscopy was used to determine amino acids acting as precursors in Maillard reaction and also to determine acetic acid, which can be formed during the Maillard reaction. In addition to methionine and isoleucine already discussed, alanine and valine were quantified in the milk by ^{1}H NMR spectroscopy. This quantification revealed that these amino acids increased significantly in lactose-hydrolyzed milk during storage, whereas they remained constant at a lower level in the conventional milk (Figure 8B,D). In addition, an increase in the level of free amino terminals, obtained from the fluorescamine assay, was observed in lactose-hydrolyzed milk compared to conventional UHT milk in Figure 10. These results demonstrate a higher proteolytic activity in lactose-hydrolyzed milk compared to conventional milk. An increased level of free amino terminals and amino groups of lysine side chains in lactose-hydrolyzed milk may contribute considerably to the higher level of Maillard reaction products in the lactose-hydrolyzed milk. An increased Maillard reaction decreases lysine availability in lactose-hydrolyzed milk, and therefore the protein nutrition value may be lower in this type of milk. A lower protein availability might pose a challenge when aiming at decreased malnutrition in countries with a high prevalence of lactose intolerance. Thus, it is of interest to optimize the production of lactose-hydrolyzed milk to avoid high levels of Maillard reactions and thereby maintain a high nutritional value of the milk. The increased level of free amino acids and amino terminals (Figures 8 and 9) in lactose-hydrolyzed milk during storage indicates that the proteolytic activity is more pronounced than the Maillard reaction activity. Tossavainen and Kallioinen analyzed proteolytic activity in lactose-hydrolyzed and unhydrolyzed UHT milk directly after production and after 4 weeks of storage and observed a higher proteolytic activity in the hydrolyzed UHT milk compared to the unhydrolyzed UHT milk, which is in agreement with the present study.[10] The higher proteolytic activity is probably due to the proteolytic side effect of the added lactase enzyme preparation, which gives rise to substrates for the Maillard reaction and thereby an increased risk for milk quality deterioration during storage.

Effect of Heat Treatment. In addition to the effect of lactose hydrolysis, the effects of heat treatment were also elucidated in the present study as two different types of heat treatments were included: a direct and an indirect heat treatment. However, no differences in detection in furosine content or free amino terminals were observed between direct and indirect heat-treated lactose-hydrolyzed milks. Higher furosine levels in conventional indirect UHT milk compared with conventional direct UHT milk have been reported in previous studies.[1,42] The levels of 2-nonanone and 2-undecanone increased more in LHD than in LHI milk, which is contrary to the observation of Perkins et al., who found an increased total amount of ketones in indirect heat-treated conventional UHT milk, compared with the direct heat-treated milk. The significantly higher increases in 2-methylbutanal and 2-ethylfuran during storage in LHI compared with LHD milk could be explained by the different heat loads from direct and indirect heat treatments.[2] To the best of our knowledge, no studies comparing direct and indirect heat treatments of lactose-hydrolyzed milk, where lactose is removed and hydrolyzed after heat treatment, have been reported.

The present study, which included several complementary analyses, shows that the type of carbohydrate has a greater impact on the Maillard reaction, heat load indicators such as furosine, and total concentration of ketones, compared to the impact of different heat treatments (direct and indirect UHT). The formation of 2-methylbutanal and furosine was considerably higher in lactose-hydrolyzed milk compared with conventional UHT milk after a 9 month storage period. In addition, an increase in free amino acids and free amines increased tremendously in lactose-hydrolyzed milk, whereas they remained constant in conventional UHT milk. Residual proteolytic activity from the lactase-enzyme preparation may be responsible for the higher levels of free amino acids observed in lactose-hydrolyzed UHT milk. This study reveals that lactose-hydrolyzed UHT milk, compared to conventional UHT milk, is more vulnerable to reactions that can impair the milk quality, primarily the Maillard reaction and proteolysis but, to some extent, also oxidation.

during the sun-drying season. (3) Experiment 3 (AT): alternating temperatures of 40 and 15 °C every 12 h, simulating the average temperatures in the central hours of the day and night during the traditional sun-drying. The grapes were introduced at 15 °C with the temperature being increased to 40 °C and remained constant during the first 12 h, and then the conditions changed and the temperature started to decrease to 15 °C again and so on.

The three experiments were finished at the end of 48 h. During the drying process, reducing sugar concentration of the grapes was measured using a refractometer model Atago Master. After the drying, the whole bunches of raisins were pressed on a vertical press similar to industrial models. The maximum pressure reached in each of the two pressing cycles was 300 bar. The resulting musts were centrifuged at 3000 rpm, filtered, and analyzed in triplicate.

Dry matter (dm) was determined by placing a known amount of grape in a stove and measuring the weight loss until a constant weight was observed.

The moisture contents (kilograms water/kilograms dry matter) at any time of drying (Mt) were registered. The moisture ratio (MR) and drying rate (DR) of grapes during experiments were calculated using the following equations:[15]

$$\mathrm{MR} = \frac{M_t}{M_0} \quad \mathrm{DR} = \frac{M_{t+\Delta t} - M_t}{\Delta t}$$

Where M_t, M_0, and $M_{t+\Delta t}$ are the moisture content at any time of drying, initial moisture content, and moisture content at $t + \Delta t$, respectively, and t is time (hours).

Spectrophotometric Determinations. Absorbances at 420 and 520 nm were made on a PerkinElmer (Waltham, MA) Lambda 25 spectrophotometer, using quartz cells of 1 mm light paths. Samples were previously passed through Millipore (Billerica, MA) HA filters of 0.45 μm pore size. All measurements were corrected for a path length of 1 cm. Hue was calculated as the relationship between absorbance at 420 nm and absorbance at 520 nm.

Anthocyanins Analysis. For the extraction and fractionation of anthocyanins, the method proposed by Marquez et al.[14] was used. A volume of 2 mL of wine was passed through a Sep-Pak C18 cartridge packed with 900 mg of material (Long Body Sep-Pak Plus, Water Associates, Milford, MA) that was previously activated with 5 mL of methanol and washed with aqueous 0.01% (v/v) HCl. The cartridge was successively washed with 10 mL of 0.01% aqueous HCl and 5 mL of ethyl acetate, and the anthocyanins were recovered with 5 mL of methanol acidified to a pH 2 with HCl. Anthocyanin samples were concentrated on a vacuum centrifuge thermostated at 35 °C and passed through a filter of 0.45 μm pore size for injection into a P4000 HPLC instrument from Spectra-Physics (San Jose, CA).

Anthocyanins were identified by comparing their retention times with those for standards, recording UV spectra on a Spectra-Physics UV6000LP diode array spectrophotometer and calculating the UV absorbance ratios for samples and standards simultaneously coinjected one at a time.[14] Identification was confirmed by HPLC-ESI-MS on an AQA quadrupole mass spectrometer from ThermoQuest Finningan. The instrument was operated in both the negative and positive ion modes. The ion spray voltage was −4 kV, and the orifice voltage was −60 V. Mass data were acquired in the scan mode (by scanning the m/z range 150 to 1066 at 1.2 intervals) and the multiple ion mode (by using mass ranges around specific m/z values). The compounds were quantified by comparison with a calibration curve obtained from the malvidin-3-glucoside.

Antioxidant Activity. The DPPH assay was realized for the antioxidant activity determination. The wines were diluted with a solution containing 12% ethanol, and an aliquot of 200 μL was placed in a cell with 3 mL of a 45 mg/L solution of DPPH in methanol. A blank (200 μL dilution sample and 3 mL methanol), a control sample (200 μL of 12% ethanol in water and 3 mL of DPPH solution), and a Trolox standard (200 μL of 80 mg/L Trolox solution and 3 mL of DPPH solution) were also prepared in parallel. The absorbances at 517 nm of the control sample and blank were measured, and the absorbances of the standard and samples were measured after 10 min of incubation. The antioxidant activity, expressed in millimoles of Trolox (mmol TE) per liter, were calculated as follows:

$$\text{antioxidant activity of sample (mmol TE/L)} = (0.32A_1{*}\text{wine dilution factor})/A_2$$

$$A_1 = \text{absorbance}_{\text{control(t=0)}} - \text{absorbance}_{\text{sample}}$$

$$A_2 = \text{absorbance}_{\text{control(t=0)}} - \text{absorbance}_{\text{standard(t=10)}}$$

$$A_{\text{sample}} = \text{absorbance}_{\text{sample(t=10)}} - \text{absorbance}_{\text{blank(t=0)}}$$

Statistical Analysis. The results for the three controlled drying samples were subjected in triplicate to principal component analysis (PCA), and the anthocyanins compounds were subjected to analysis of variance (ANOVA) in triplicate, using the Statgraphics computer package version 5.0 from Statistical Graphics Corp.

RESULTS AND DISCUSSION

Figure 1 shows the changes in the moisture ratio against the dehydration time in the chamber under controlled conditions.

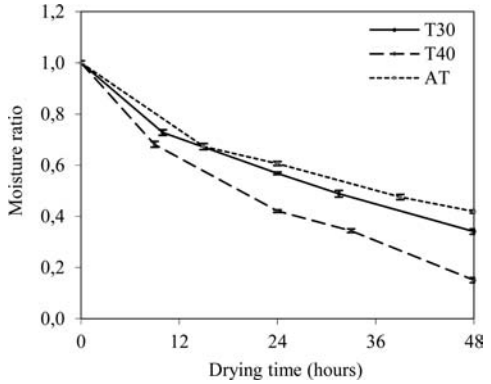

Figure 1. Changes in moisture ratio during the three controlled dehydration experiments at 30 °C (T30), 40 °C (T40), and alternating temperatures between 40 and 15 °C (AT).

As can be seen, the moisture ratio, determined as the relation between the moisture content at each time compared with the initial moisture content, decreased during the drying process. The drying at 40 °C constant temperature (T40) showed the lowest values during the study time with a final value of 0.150, 56, and 64% lower than the drying at 30 °C and alternating temperatures, respectively, which suggested that this drying was the fastest. The last two processes presented similar drying kinetics, with the drying with alternating temperatures which presented the highest values of moisture ratio (0.419).

Changes in the drying rate in function of the total weight of the control sample are shown in Figure 2. As can be seen, the rate decreased during the raisining time, with the rate faster at the beginning in the three assays when the grape weight was higher. The dehydration rate reached low values in the last hours. Also, for the same sample weight, the controlled dehydration at a constant temperature of 40 °C took place at a higher rate, which would agree with the previous results. Then the drying at a constant temperature of 30 °C and the dehydration with alternating temperatures was the slowest.

The absorbances at 420 and 520 nm and the hues were measured with the aim of evaluating the influence of the temperature on the color of musts from the dried grapes (Figure 3). The absorbance at 420 nm could be considered as an index of the brown color of the musts, A_{520} as the red color index and the hue is the relation between the two (A_{420}/A_{520}).

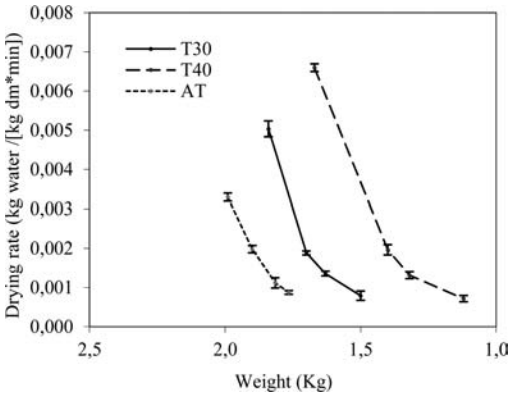

Figure 2. Variation of drying rate (kg water/[kg dm min]) as a function of the grape weight during the three controlled dehydration experiments at 30 °C (T30), 40 °C (T40), and alternating temperatures between 40 and 15 °C (AT).

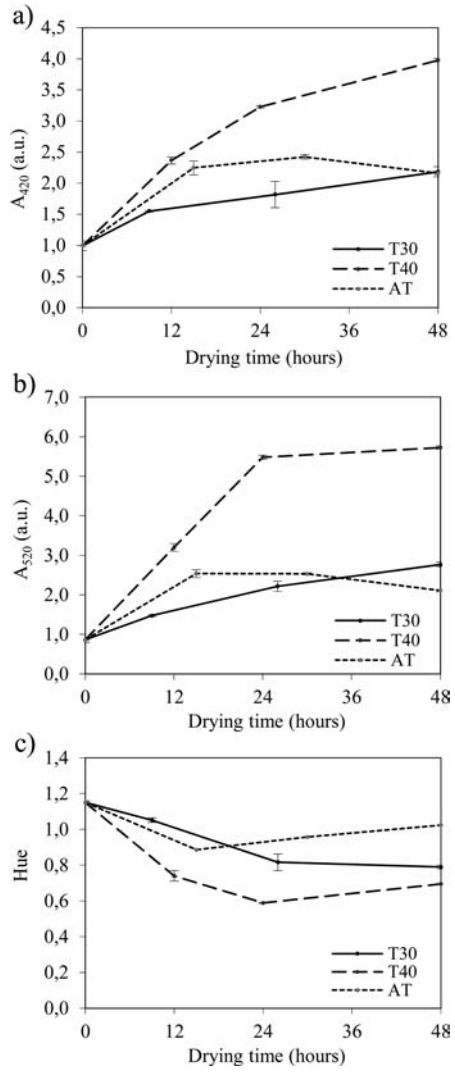

Figure 3. Changes in (a) absorbance at 420 nm (a.u.), (b) absorbance at 520 nm (a.u.), and (c) hue during the three controlled dehydration experiments at 30 °C (T30), 40 °C (T40), and alternating temperatures between 40 and 15 °C (AT).

As can be seen, an increase of absorbance at 420 nm in the three drying process took place (Figure 3a), indicating an increase in the brown color of the musts as a consequence of the grape raisining. The final values were similar in AT and T30 and, with the value of the drying at a constant temperature of 40 °C, the highest (3.98 au). The synthesis of pigments with these colors has been demonstrated by other authors[16] and can be caused by enzymatic and nonenzymatic reactions, with the necessary presence of oxygen in some of them. On one hand, the brown pigments called melanins are formed by the enzymatic activity of the polyphenoloxidases,[17] when the enzymes contact with the phenolic compounds. On other hand, the browning is known due to the Maillard reaction, a nonenzymatic reaction which induces the formation of colored compounds called melanoidins from free carbonyl and amino groups.[18] However, the latter reaction is particularly effective at temperatures above 50 °C,[19] so the synthesized pigments in the three drying assays under controlled conditions were mainly from enzymatic browning reactions.

The absorbance at 520 nm also increased during the three processes (Figure 3b), indicating a rise of the red color of the musts. The drying at 40 °C (T40) had a marked increase during the first 24 h, reaching a final value of 5.73 au. As a result, the must obtained in this process presented the reddest color, so the presence of red pigments, especially anthocyanins, was higher. These compounds could be extracted from the skins during the drying process, as a consequence of cell damage caused by heat during the dehydration process at high temperatures.[15] Because of this, the colored compounds, found naturally in grape skins, would diffuse to the pulp and later move to the must, conferring a red color. In the AT assay, the absorbance at 520 nm increased during the first 30 h and then decreased. This is an indication of the different behavior of the red compounds due to the temperature changes during the grape dehydration process. From the data, it might be thought that the colored compounds would be extracted from the skins at first, but then they could be degraded, reducing the absorbance at 520 nm.

Figure 3c shows a different reduction in the hue values during the three drying processes. In the alternating temperature assay (AT), the hue decreased to 15 h of drying and then increased. In the T40 assays, the minimum value was reached at 24 h, whereas in the T30 assay the decrease was continued to the end of the study but very slowly in the late hours. The decrease in the hue would be due to a higher increase in the A520 than in the A420, indicating that in the musts the red colors dominated the brown colors. Throughout the study, the musts from T40 showed the smallest hue values and, consequently, the reddest colors; on the contrary, the musts from AT were the most browning.

Then, the anthocyanin profile of the three musts, obtained during grapes drying at different temperatures, was studied (Table 1). The glucosides, acetylglucosides, and coumaroylglucosides of the delphinidin, cyanidin, petunidin, peonidin, and malvidin anthocyanins, in addition to the caffeoylglucoside of malvidin were quantified. Before the drying experiments, 11 of these monomers were found in the grapes, with glucosylated monomers of the main family, with a percentage of 91.6%, followed by the family of acetylglucosides (4.3%), and coumaroylglucosides (1.2%). The three controlled drying processes resulted in an increase in the concentration of anthocyanins in the first hours, reaching the maximum for most of the compounds at 15 h in AT, 24 h in T40, and 48 h in T30. The final values of all families showed significant differences. In this regard, the T40 assay resulted in a final concentration of

total anthocyanins of 254 ± 12.8 mg/L compared to the concentrations of 79.3 ± 1.64 and 31.6 ± 2.76 mg/L obtained for T30 and AT, respectively, so the anthocyanin concentration was significantly higher when the process took place at a high and constant temperature. At the end of the drying processes, the glucoside derivatives represented a percentage of 91.0% in T30, followed by AT and T40 with values of 87.0 and 71.6%, respectively, indicating that the percentage of the glucosides derivatives decreased more markedly in the drying at 40 °C. The acetylglucosides represented 6.63, 12.9, and 6.52% in T30, T40, and AT, respectively, and this family increased their representation in the final musts. The coumaroylglucosides derivatives represented 1.51, 12.1, and 4.02% and, finally, the caffeoylglucoside derivative 0.7, 3.28, and 2.33% in T30, T40, and AT, respectively. These derivatives increased more markedly in the dryings at 40 °C and alternating temperatures.

The drying at 40 °C was the process that showed major differences; greater similarities in the processes carried out at 30 °C and alternating temperatures were found. Specifically, the final values of most compounds in the AT assay showed no significant differences with the initial values, indicating that this drying did not alter significantly the content in anthocyanins. Nevertheless, the assays at constant temperature increased the final content of all the anthocyanin families, with the final values at 40 °C the highest. Due to the difference found in the three experiments being very marked, especially in the case of T40, the temperature had an important influence on the extraction of these compounds.

To explain the changes in color and anthocyanin composition after the three dehydration processes, a possible hypothesis based on different temperature conditions has been proposed. At first, when the temperature was constant and high during the process, the water evaporation through the berries was continuous, so this evaporation could reduce the molecular oxygen diffusion to the berry, which is necessary in the browning reactions. At the same time, the dehydration would cause cell damage in berries, with consequent skin breakage. Structural changes in the cell are irreversible and can improve the diffusion of compounds from the skin to the pulp, especially polyphenols. The anthocyanins are the main polyphenols in the grape skins, so the drying should increase the concentration of red compounds in the pulp and prevent the formation of brown compounds.

In the process with alternating temperature, when the temperature was maintained at 40 °C, a water evaporation from the berries occurred, reducing the oxygen entry. However, when the temperature was lowered to 15 °C, the water evaporation stopped and the oxygen could enter more easily through the berry skins. Also, the low temperature favored the oxygen solubilization. In this moment, the oxygen presence could cause browning reactions, increasing the musts hue and the brown color. Concurrently, the red color could be decreased because the anthocyanins could be substrates of different reactions. In this regard, it is demonstrated that anthocyanins are substrates in the browning reactions, but they can also participate in several direct condensation reactions with themselves or with tannins, in condensation reactions with flavanols, through or not a bridge methylmethyne[20,21] and/or copigmentation reactions.[22]

Finally, the hypothesis could also explain the higher concentration of anthocyanins reached in the process at 40 °C (T40) compared with the drying at 30 °C (T30). The higher temperature used in the first process could cause more damage to the grape skins, favoring a greater compound transfer to the pulp. In addition, the hindrance to the oxygen diffusion was minor at 30 °C compared with that at 40 °C, so there were higher concentrations of oxygen in the pulp of grapes dried at 30 °C and, consequently, the reactions involving anthocyanins were more favored. Most likely, both processes occurred simultaneously during the T30 drying. On the one hand, the temperature of 30 °C used damaged cells skin but not as much as 40 °C. Furthermore, the anthocyanins, which were diffused to the pulp, reduced their concentration because they would take part in polymerization or condensation reactions with tannins, with other anthocyanins, or with flavanols,[15,23] as well as in copigmentation reactions.[24]

In recent years, there has been a growing interest in winemaking products due to their antioxidant properties and beneficial effects in the prevention of various diseases.[25] Therefore, the evolution of the antioxidant activity was studied during the three controlled dehydration experiments (Figure 4). As can be seen, the antioxidant activity increased in the

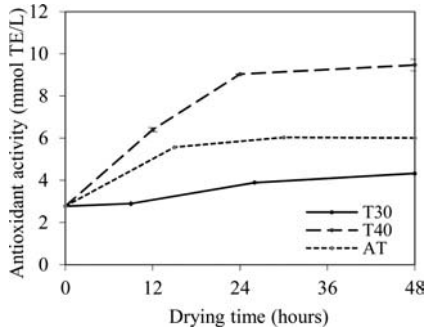

Figure 4. Changes in antioxidant activity (mmol TE/L) during the three controlled dehydration experiments at 30 °C (T30), 40 °C (T40), and alternating temperatures between 40 and 15 °C (AT).

three experiments, with the higher increments measured during the drying at 40 °C (T40), with the highest final value (9.5 mmol TE/L). The increments in the other dryings were 1.6 and 2.2 for T30 and AT, respectively, reaching final values of 4.3 and 6.0 mmol TE/L for the same tests.

Figure 5 shows a principal component analysis performed with the data of color, anthocyanin concentration, and

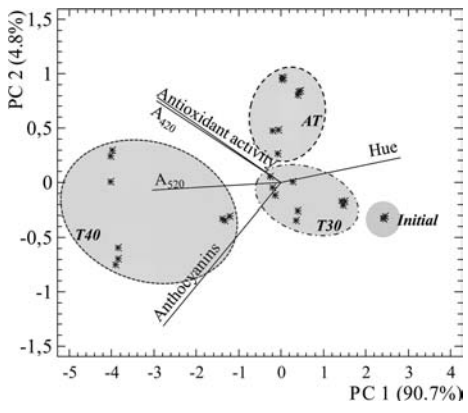

Figure 5. Principal component analysis: biplot representation of must samples and statistical variables during the three controlled dehydration experiments at 30 °C (T30), 40 °C (T40), and alternating temperatures between 40 and 15 °C (AT).

dx.doi.org/10.1021/jf502235b | J. Agric. Food Chem. 2014, 62, 7897−7902

antioxidant activity during the three controlled drying experiments. The first two components jointly explained 95.5% of the total variance of the process, with PC1 the most important with 90.7%. This component influenced all the studied parameters with similar factors, with the hue the one with a positive influence (0.4325). The other four influenced negatively on PC1 with factors of −0.4674 for A_{520}, −0.4542 for A_{420}, −0.4518 for antioxidant activity, and −0.4290 for the anthocyanins concentration. Under this component, the samples corresponding to T30 and AT differed statistically from T40, which experienced the most marked changes during drying. As a result, the final must of T40 was the most different from the initial must and presented higher absorbance values, anthocyanins, and antioxidant activity and the lowest values of hue. Consequently, dehydration at a constant temperature of 40 °C would be the most suitable if the desire is to obtain musts with an important red color and high concentration of antioxidant compounds.

In conclusion, the temperature used during the controlled dehydration of red grapes influenced the color and composition of the final musts. When the temperature was high and constant during the assay, an important extraction of anthocyanins from the skins to the pulp was obtained, as a result of damage caused by the water evaporation of berries. Consequently, the musts presented an increase in red color and antioxidant activity. At lower temperatures, the water evaporation decreased, facilitating the oxygen diffusion into the berries, and resulting in degradation reactions of anthocyanins, which caused a loss of red color.

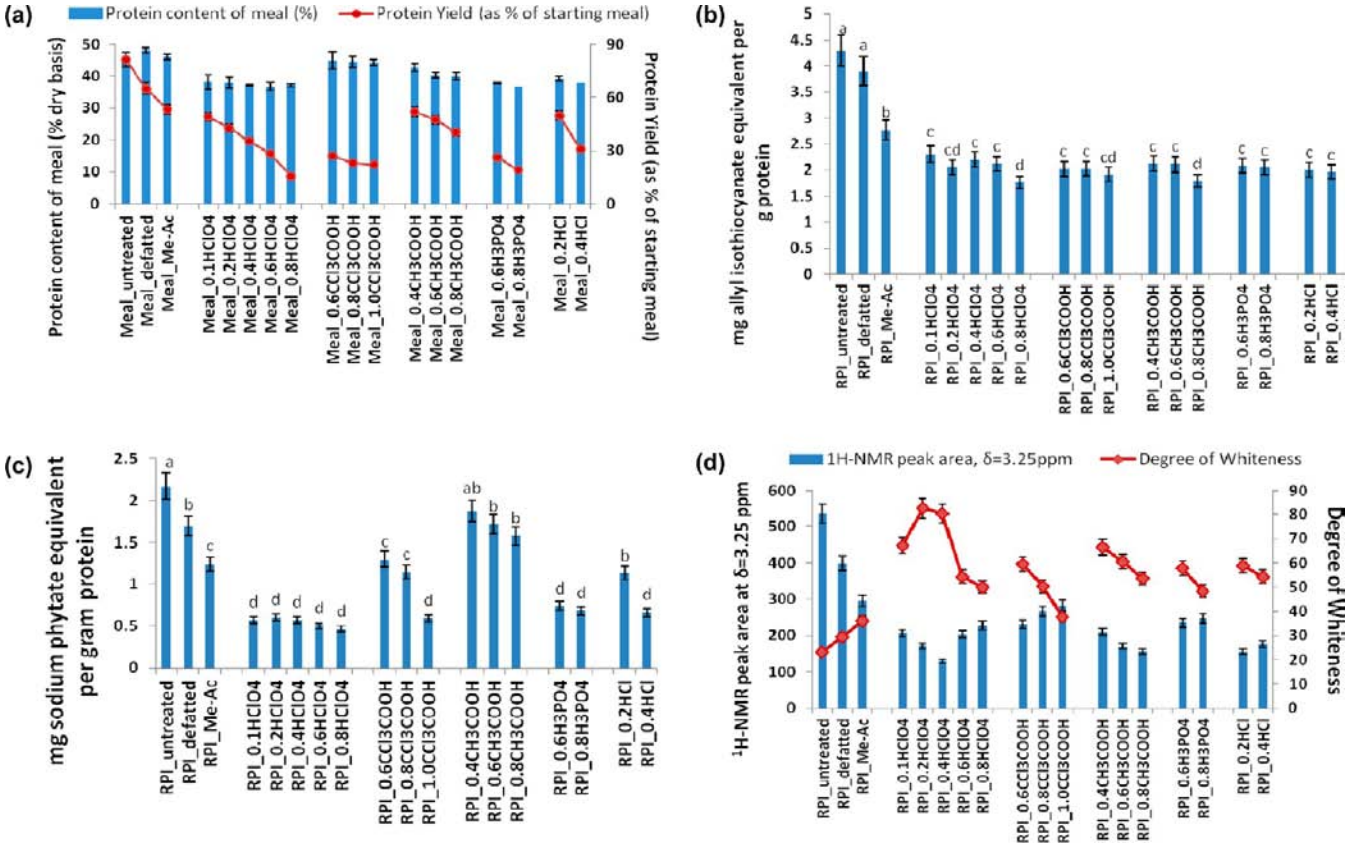

Figure 1. (a) Protein content of rapeseed meals treated with different solvents and their corresponding protein yield; impact of solvent treatment on (b) AITC, (c) phytates, and (d) sinapine content and degree of whiteness of the produced isolates.

equal to or higher than that of the solvent system having only methanol and acetone mixture (Me-Ac, 1:1 v/v). This criterion was fulfilled by 15 different solvent systems containing Me-Ac (1:1 v/v) in combination with different acids: 0.1, 0.2, 0.4, 0.6, or 0.8% perchloric acid ($HClO_4$); 0.6, 0.8, or 1.0% trichloroacetic acid (CCl_3COOH); 0.4, 0.6, or 0.8% acetic acid (CH_3COOH); 0.6 or 0.8% phosphoric acid (H_3PO_4); and 0.2 or 0.4% hydrochloric acid (HCl). As such, samples used for the preparation of protein isolates included (i) meal without any solvent treatment as control (untreated), (ii) meal treated with diethyl ether for removing lipids (defatted), (iii) defatted meal treated with Me-Ac (1:1 v/v) without any added acid, and (iv) defatted meal treated with Me-Ac (1:1 v/v) added with various concentrations of different acids as stated above.

Preparation of Solvent-Treated Meals. Meal (1 g) was treated with 10 mL of different solvents (mentioned above) according to earlier protocol.[3]

Preparation of Protein Isolate from Untreated or Solvent-Treated Meals. Meal (20 g) was extracted with water (meal/solvent ratio = 1:20 (w/v)) at room temperature for 1 h under constant agitation (200 rpm) in an orbital shaker (Sartorius Stedin Biotech, CERTOMAT IS) and then centrifuged at 4 °C (Sigma 3-18K centrifuge) to get aqueous extract. The pellet was re-extracted as before with NaOH solution at pH 11. Both extracts were combined, to which ammonium sulfate was added up to 85% saturation.[4] The resulting precipitate was redispered in water, adjusted to pH 7, dialyzed against Milli-Q water, and finally freeze-dried to obtain rapeseed protein isolate (RPI).

The respective meal and its corresponding isolate are denoted on the basis of the solvent used for their processing (mentioned in Figure 1a,b). Protein purity of all the isolates was >80% (dry basis), based on Kjeldahl nitrogen (N × 6.25). The yield was calculated as follows:

$$\%\ \text{protein yield} = \frac{\text{wt of protein isolate} \times \%\ \text{protein in isolate}}{\text{wt of starting meal} \times \%\ \text{protein in starting meal}} \times 100 \quad (1)$$

Quantification of Antinutritional Compounds. Sinapine content was determined according to the method developed by Wanasundara et al.[5] Freeze-dried protein was extracted with 99.8% methanol (1:20, w/v) in a round-bottom flask for 48 h with stirring. The extract was filtered through cotton wool, concentrated under vacuum, to which internal standard (*N*,*N*-dimethylformamide) was added, and then resuspended in deuterium oxide (1 mL). Proton NMR signals were recorded at 400 MHz using a JEOL ^{1}H NMR system. Singlet peak at δ 3.25 ppm was identified as phenylpropanoid ester (sinapic acid ester or sinapine).

Protocols for estimating phytates, glucosinolates, and AITC are the same as those reported earlier.[3]

Analytical Methods. Color was determined with a Hunter Lab colorimeter (Ultrascan, VIS-Hunter Associates Laboratory, Reston, VA, USA). The majority of the isolates displayed a similar off-white color (Supporting Information Figure S1). However, upon dissolution in water, their solution showed a light brown color of different intensities, an observation that was consistent with a previous paper.[6] Therefore, following the protocol of Xu and Diosady,[6] colorimetric evaluation was performed by scanning their aqueous solution (7 mg/mL). Measured values were expressed as L (lightness), a (redness/greenness), and b (yellowness/blueness) color units. Whiteness was calculated as follows:[7]

$$\text{degree of whiteness} = 100 - [(100 - L)^2 + a^2 + b^2]^{1/2} \quad (2)$$

Ultraviolet (UV)−visible (vis) spectroscopy was performed on a UV−vis CECIL 7400 spectrophotometer (Aquarius, 7000 series) by scanning an aqueous protein solution (2 mg/mL).

dx.doi.org/10.1021/jf5023803 | J. Agric. Food Chem. 2014, 62, 7903−7914

Free sulfhydryl group (SH) and disulfide bond (SS) were assayed according to the methods of Tang et al.[8] and Deng et al.[9] Surface hydrophobicity (S_0) was measured by using the SDS binding method.[10,11]

Intrinsic fluorescence spectra were recorded in a PerkinElmer LS55 fluorescence spectrophotometer (PerkinElmer Corp., Boston, MA, USA) using a 2 mg/mL protein solution and background calibrated with Milli-Q water. To minimize the contribution of tyrosine residues, the solution was excited at 290 nm.[4]

Fourier transform infrared (FTIR) spectroscopy was carried out on solid samples according to the KBr pelleting method using a PerkinElmer Spectrum-100 model.

Differential scanning calorimetry (DSC) was performed in a DSC-60 (Shimadzu, Kyoto, Japan), using 5 mg of freeze-dried sample according to the methods of Manamperi et al.[12] and Li et al.[13] Denaturation temperature (T_d) and enthalpy (ΔH) were acquired from the thermogram using TA-60WS software (Shimadzu).

Sodium dodecyl sulfate−polyacrylamide gel electrophoresis (SDS-PAGE) was performed in a Bio-Rad vertical electrophoresis system (Bio-Rad Laboratories, Hercules, CA, USA) with 12% separating and 5% stacking gels (12.5 cm × 14 cm and 0.75 mm thickness), following the procedure provided by the manufacturer. Freeze-dried samples (4 g/L) were solubilized in either nonreducing or reducing (2% β-mercaptoethanol (β-ME)) buffer solution, heated for 5 min in boiling water, and then centrifuged at 10000 rpm for 3 min prior to loading. Fifteen microliters of each sample was loaded onto a gel lane. A constant current of 45 mA per gel was applied for 1 h (approximately), stained with Coomassie Brilliant Blue (0.125%) in 25% methanol and 10% acetic acid, and then destained with 40% methanol and 10% acetic acid. A GelDoc system equipped with Vilber Lourmat image analysis software was used for scanning the gel. Premixed protein markers (high range, catalog no. 623110375001730; and medium range, catalog no. 623112375001730, Genei, Bangalore, India) [myosin (205 kDa), phosphorylase *b* (98 kDa), bovine serum albumin (68 kDa), ovalbumin (44 kDa), glutathione-*S*-transferase (29 kDa), and lysozyme (16 kDa)] were used for molecular weight (MW) comparison. Nondenaturing polyacrylamide gel electrophoresis (native-PAGE) was performed on 7% separating gel and 3% stacking gel. The main differences from the SDS-PAGE assay were the absence of SDS and β-ME in the procedure and no thermal treatment before electrophoresis.

Protein solubility (at neutral pH) was measured according to the Lowry method using bovine serum albumin as standard.[14,15] Results were expressed as percentage of the nitrogen protein in the starting isolates (determined by Kjeldahl).

Foaming capacity (FC) and stability (FS) were evaluated according to the protocol of Hassan et al.[16] Emulsion capacity (EC) and stability (ES) were also studied according to the methodology of Hassan et al.[16] after incorporation of a slight modification from Kalashnikova et al.[17] Oil-in-water (o/w) emulsions were prepared by blending soybean oil with aqueous protein solution (7 mg/mL) at a ratio of 3:7 (v/v). The mixture was sonicated to form an emulsion using an ultrasonic water bath (Labotec Inc., Nottingham, UK) for 10 min. Fifteen microliters of the resulting emulsion was added to 1 mL of distilled water and stirred gently, and then a single drop was poured onto a glass slide and observed via light microscope (BX51 Olympus). Droplet diameter (μm) was measured by ImageJ software, and average droplet diameter (d_{43}) is expressed as[18]

$$d_{43} = \frac{\sum n_i d_i^4}{\sum n_i d_i^3} \tag{3}$$

where n_i is the number of droplets of diameter d_i.

Statistical Analyses. All analyses were performed in triplicate, and the mean value was calculated. Analysis of variance and separation of means were carried out by Tukey's HSD test, using SPSS software (version 16.0, SPSS Inc., Chicago, IL, USA) and considered significantly different at $p < 0.05$.

RESULTS AND DISCUSSION

Untreated or treated meals were first analyzed by Kjeldahl process for checking their protein content and to evaluate whether the treatments led to any protein loss. The protein content of the treated meals was within a range (36.7−48.1%) similar to that of the control (44.8%) (Figure 1a). Marginal increases in the protein level of defatted and Me-Ac-treated meals were expected, due to leaching of lipids and nitrogen-free compounds. A slight reduction of protein content in $HClO_4$- and H_3PO_4-treated meals may be due to the removal of nonprotein nitrogen in the form of glucosinolates, triamine compounds such as betaine, choline, sinapine, and free amino acids. As the use of nitrogen content to estimate protein levels of oilseeds and meal has been the norm for the oilseed industry,[5] greater elimination of these nitrogen-containing components by the acidified solvents reduced the crude protein level in such meals. This may also be the reason for the decreasing trend of protein content in CCl_3COOH- and CH_3COOH-treated meals with increasing acid concentration. Overall, the actual protein loss from the meal during solvent treatment was minimal due to the presence of a high concentration of nonpolar solvents (methanol and acetone), instead of any aqueous medium, which ensures negligible protein dissolubility. Unfortunately, the treatments diminished protein yield, which dropped almost linearly from by >81% to 15.6% with the rise in acid concentration, indicating dramatic decreases in protein solubility and denaturation. It seems highly likely that the acidified organic solvents (acetone in particular) produced a dehydrating effect and underwent different interactions with the proteins, leading to nonextractable complexes/aggregates. Pretreatment of rapeseed/canola meal with a two-phase solvent system ($CH_3OH/NH_3/H_2O$/hexane) also resulted in a similar reduction in protein yield.[19]

Effect on Antinutritional Factors. Glucosinolate level was undetectable in all of the isolates (<0.15 μg sinigrin equivalent/g protein), indicative of its complete elimination or rapid degradation into AITC[3] during processing. Defatting and successive treatment with Me-Ac mixture led to a progressive decrease in AITC content of the respective isolate (Figure 1b). Isolates from acid-treated meals were characterized by a lower content of AITC as compared to untreated RPI ($p < 0.05$), the extent of decrease being almost similar for any such isolate. With regard to phytates, a distinct decreasing trend with increasing acid concentration was found, confirming that each treatment indeed removed some phytates from the meal and, thus, from the isolates (Figure 1c). The phytate level of all the isolates were well below the value reported for soy protein isolate containing flour-type infant foods (>230 mg/100 g), estimated using Wade reagent.[20] Samples from $HClO_4$-treated meals presented the lowest value (0.47−0.57 mg/g), which supported our earlier findings that $HClO_4$ helps in maximum removal of phytates among the tested acids.[3]

Phenolic compounds (chiefly sinapine, choline ester of sinapic acid) are important factors when rapeseed protein is considered for use in food formulations,[1] as they are found to cause unacceptable darkening. As anticipated, successive treatment with higher levels of acids resulted in remarkable reduction in sinapine content (Figure 1d), manifested from their NMR peak area (Supporting Information Figure S2). Sinapine level in RPI_untreated (as 100%) was considerably higher than that of RPI_defatted (74.8%) and RPI_Me-Ac (55.3%). For isolates from $HClO_4$- (RPI_0.6$HClO_4$ and

dx.doi.org/10.1021/jf5023803 | J. Agric. Food Chem. 2014, 62, 7903−7914

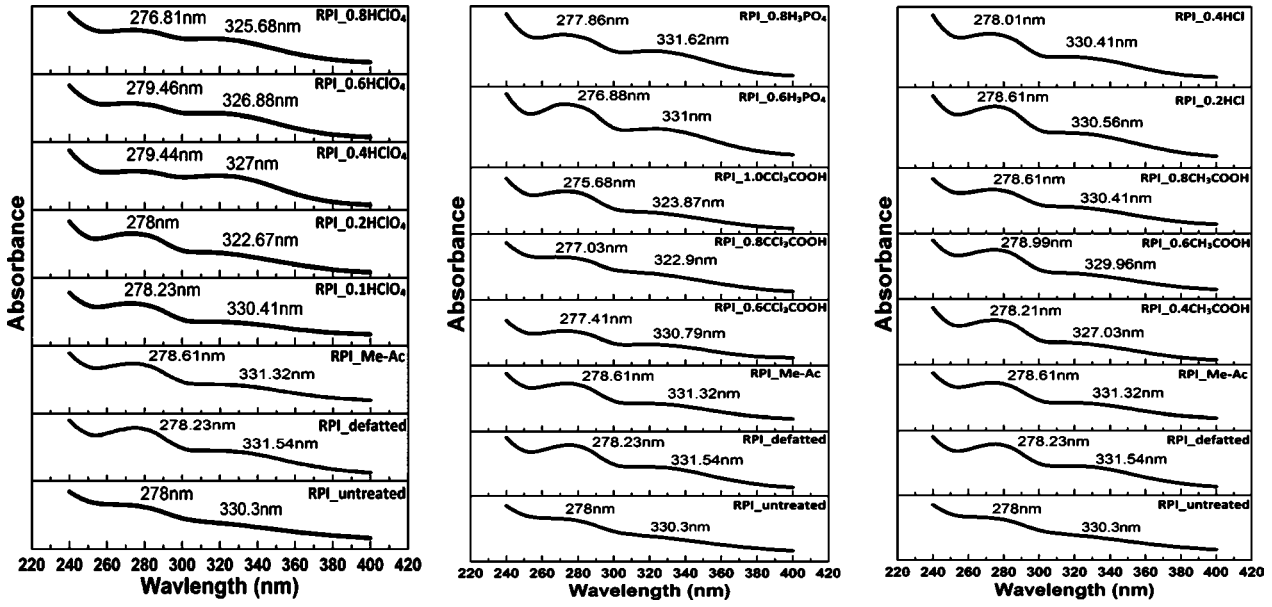

Figure 2. UV absorption spectra of soluble proteins in Milli-Q water from different meals.

RPI_0.8$HClO_4$), CCl_3COOH-, and H_3PO_4-treated meals, the increase in sinapine was mainly contributed by preferential association of polyphenols with some specific proteins to form protein−polyphenol complexes, which can be augmented to a great extent by the presence of denatured proteins. The higher acid concentration used in this study denatures protein (discussed later). Denatured protein provides additional binding sites for phenolic compounds.[21] Charlton et al.[22] proved that intermolecular binding between polyphenols and protein/peptides is dominated by stacking of polyphenolic rings onto planar hydrophobic surfaces and is strengthened by multiple cooperative bindings of phenolic rings. When the coating is sufficiently extensive to provide polyphenol bridges, precipitation occurs. Such polyphenols may readily oxidize into color-forming quinones during protein extraction in an alkaline medium, which cannot be eliminated later.[15] This is an indirect indication that such isolates with high phenolic content or their oxidized forms would possess darker appearance (as shown in Figure S1 in the Supporting Information). The above-stated reasons probably accounted for the observed general increase in degree of whiteness of the isolates with decrease in their sinapine content (Figure 1d), except for the samples obtained from CH_3COOH-treated meals, in which the decrease in sinapine paralleled the decrease in whiteness value. The exact reason for this discrepancy could not be deduced. RPI_0.2H-ClO_4 and RPI_0.4$HClO_4$ had the highest values, which can be ascribed to their least sinapine content. Compared to the extent of decrease in sinapine (1.3−4.1-fold), the extent of increase in whiteness (1.3−3.6-fold) was slightly less. Data indicated that the influence of the treatment with acidic organic solvents on the whiteness of the isolates was mainly due to the reduction in protein-bound polyphenols or their oxidized forms; however, too intensive treatments to remove phenolics may not give a satisfactory lighter product.

Effect on Physicochemical Properties. UV spectra of the protein solutions showed similar profiles irrespective of the acid used for treating the meal (Figure 2). Strong UV absorbances in tryptophan (>290 nm) and phenylalanine (<275 nm) regions were not detected. The spectra mainly revealed changes in the position of peak maxima in the tyrosine region (275−290 nm), which give evidence of rearrangement in the protein structure. Tyrosine peak maxima of RPI_defatted and RPI_Me-Ac showed a red shift with reference to RPI_untreated. Proteins obtained from the meals treated with $HClO_4$ (0.1−0.6%), CH_3COOH, and HCl also presented a red shift with respect to the control. This bathochromic effect could be attributed to a more polar environment of tyrosine residues.[23] Among others, RPI_0.8$HClO_4$ and the proteins recuperated from CCl_3COOH- and H_3PO_4-treated meals produced a shift of the maxima to lower wavelengths (blue shift) in comparison to the control. The appearance of a blue shift could be due to the exposure of chromophores present at the interface of the subunits or from the interior of the molecule due to unfolding or dissociation, followed by rapid reaggregation or non-native refolding of denatured molecules.[24] A second weaker peak within 322−332 nm was seen in all spectra. Absorbance in this region may correspond to the residual phenolic compounds (mainly sinapic acid or sinapine) complexed with rapeseed proteins.[25] Phenolics in rapeseed bind to the protein through a variety of mechanisms in aqueous media, including hydrogen bonding, covalent binding, hydrophobic interactions, and ionic binding.[1] The impact of the various acids on structural changes of phenolics and their cross-linking with protein might be different in each case, in terms of degree and site/domain of interaction,[7] which could be one of the possible reasons for the slight differences in the position of this second absorption band. Thus, the extent of structural changes due to denaturation and complexation differs for each protein sample.

Figure 3a shows free SH and SS contents of the isolates. Treatment with acidified solvents affected their number as opposed to that of untreated meal protein ($p < 0.05$). SH groups of CH_3COOH-, H_3PO_4-, and HCl-treated samples were comparable to those of RPI_defatted and RPI_Me-Ac, whereas the level markedly increased in $HClO_4$-treated ones. The increase can be ascribed to the higher removal of polyphenols from such samples and subsequent exposure of SH groups. Covalent attachment of the phenolic compounds to protein via its hydroxyl and carbonyl groups are known to cause the blocking of amino and thiol groups.[8,26] A drastic reduction of SH in CCl_3COOH-treated samples was possibly because most

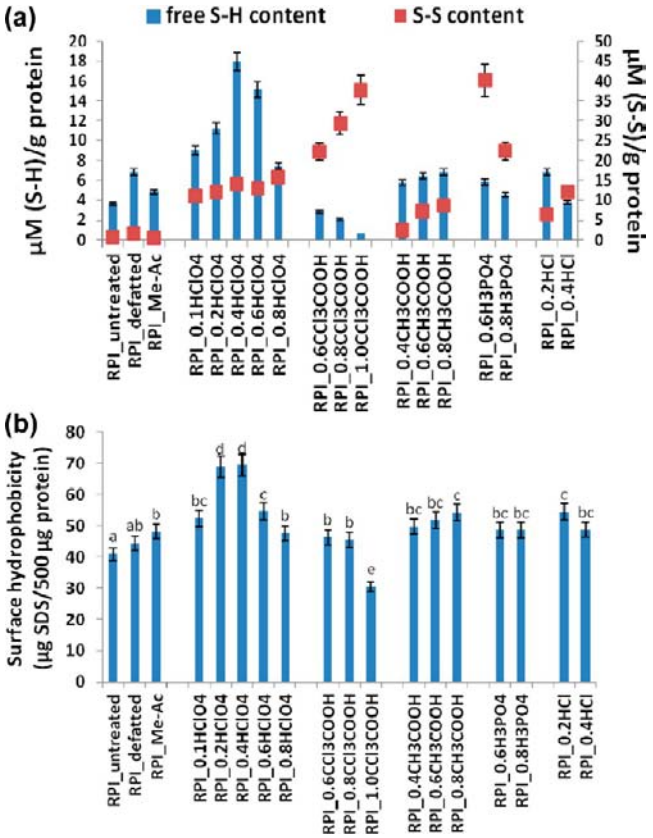

Figure 3. (a) Free sulfhydryl and disulfide content; (b) surface hydrophobicity of isolates prepared from different meals.

or all of the available free SH groups had reacted. It is worth noting that the nature of aggregates, that is, spatial distribution and accessibility of SH groups, might also play an important role in causing such differences.[27,28] In the case of SS content, all of the acid-treated samples showed much higher values compared to the control, with special emphasis to CCl_3COOH-(51.5−30.4-fold increase) and H_3PO_4-treated (54.9−30.6-fold increase) ones. The presence of such a high amount of S−S in these samples clearly explains their poor solubility/dispersibility and high aggregate formation, as observed in SDS-PAGE and FTIR results. It is feasible to believe that the formation of the S−S bond was in agreement with the decrease in thiol content.[27] Organic solvent treatment followed by alkaline extraction induced unfolding of protein and subsequent exposure of SH groups from the interior of protein molecules, which possibly underwent oxidation to form S−S linkages. Also, the conformation of protein is severely compromised in the presence of higher acid concentration, which then competes with the formation of non-native intermolecular interactions giving rise to the S−S bond.[29] Although this supposition seems to be suitable for explaining the rise in S−S content in the majority of the samples, in the case of $HClO_4$-treated isolates, the presence of high SH group content was not accompanied by an increase in S−S level. This may possibly be due to the presence of very low phenolic compounds in these samples: factually, it has been suggested that plant polyphenols are oxidized to quinones. Quinones may then form peroxides under extreme conditions, which are highly reactive oxidizing agents, and could facilitate oxidation of thiol and amino acid residues and polymerization of proteins, that is, favoring S−S formation.[30]

S_0 is an indicator of the number of hydrophobic groups on the protein surface that are in contact with the polar aqueous

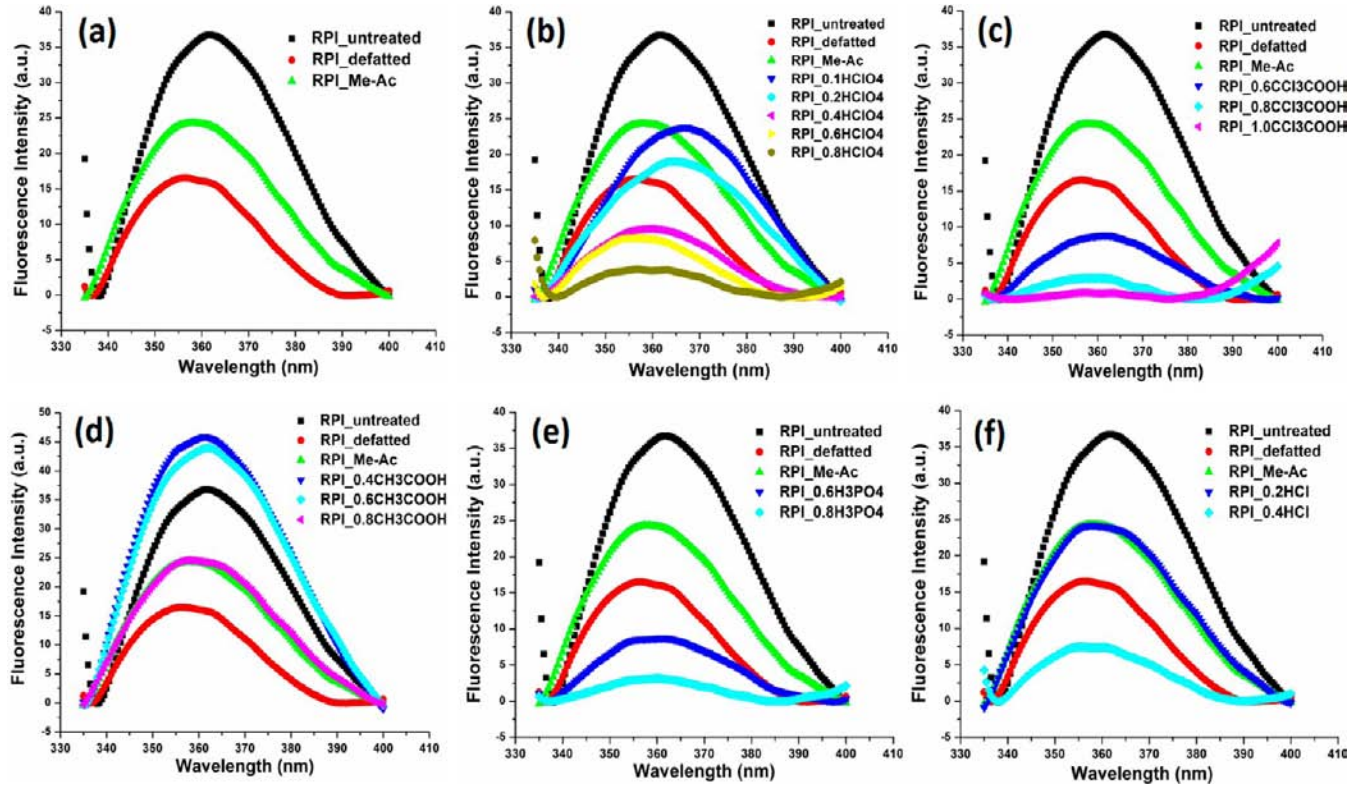

Figure 4. Comparative representation of emission fluorescence spectra of isolates from different solvent-treated meals (excitation at 290 nm).

dx.doi.org/10.1021/jf5023803 | J. Agric. Food Chem. 2014, 62, 7903−7914

environment. In other words, the level of protein unfolding can be measured by its S_0 value. Overall, S_0 of oilseed proteins is known to be significantly higher than those of other food proteins.[31] S_0 slightly increased at low acid treatment (0.1−0.4% $HClO_4$ and 0.4−0.8% CH_3COOH), presumably due to partial unfolding and subsequent uncovering of more buried hydrophobic moieties such as the thiol group (Figure 3b). Further application of a higher concentration of acids might have caused greater extent of conformational changes, promoting hydrophobic interactions between the unfolded and/or dissociated molecules to form rapid aggregation, thus causing restricted access to buried hydrophobic moieties.[27,28] Markedly lower S_0 values of such samples corroborates this supposition.[32] Again, many researchers proposed that complexation of protein with polyphenols reduces hydrophobicity.[26] Acidified solvent treatment initiates the unfolding of the native protein structure and exposes the hydrophobic groups to interaction with the residual polyphenols, thus blocking the reactive residues. This might account for the low S_0 values in samples having high sinapine content.

The intrinsic fluorescence emission spectrum of protein is usually dominated by tryptophan (Trp) and provides sensitive detection of tertiary conformation of the protein involved. Emission spectra of all the isolates are collectively shown in Figure S3 in the Supporting Information, and the spectra of protein samples from each type of acid used are segregated individually (Figure 4) along with RPI_untreated, RPI_defatted, and RPI_Me-Ac for ease of comparison. Spectra of the isolates are typical of those generally obtained for Trp-containing proteins. The emission maximum (λ_{max}) of Trp buried within the protein is expected below 330 nm,[33] and that of pure napin is reported at 333 ± 1 nm.[23] However, RPI_untreated showed λ_{max} at around 362 nm. This discrepancy may be due to the presence of a mixture of proteins in the isolate, instead of a pure fraction. Exposure of Trp residues on the protein surface, possibly fostered by heat generated during mechanical oil pressing in concert with alkaline protein extraction technique, might have led to such deviation. Solvent-exposed Trp is mostly observed above 335 nm,[33] which was apparent in all of the tested samples. Changes in λ_{max} are likely to occur in response to polyphenol binding.[34] Except for RPI_0.4CH_3COOH and RPI_0.6CH_3COOH, the isolates presented dramatic reductions in fluorescence intensity to a varying extent compared to RPI_untreated, together with a blue shift in λ_{max} (movement toward lower wavelengths) in the case of the majority of the samples. Indeed, the emission intensity in RPI_defatted and RPI_Me-Ac reduced by 2.2- and 1.5-fold, respectively. This implies less polar surroundings of Trp; that is, Trp residues are shielded from bulk water medium or moved closer to the more hydrophobic core.[35] A plausible explanation for the lower fluorescence intensity in the isolates from acid-treated meals could be the more compact tertiary conformation of protein. It is well-known that exposure of protein to organic solvent and/or acidic condition leads to perturbations in its native structure (partial or complete unfolding). Upon rehydration by solvents such as ethanol, methanol, water, and dimethyl sulfoxide, the protein probably refolds back[36] to compete with the formation of non-native intra/intermolecular interactions or aggregation, as discussed earlier. This phenomenon possibly resulted in burial/confinement of the fluorophores once again into the nonpolar environment.[24] This statement is partly in agreement with the FTIR result. In Figure 4b, emission intensity decreased up to ≈9.6-fold with the successive increase in $HClO_4$ concentration, indicating a quenching effect of the acid. This was also seen with other tested acids (HCl, H_3PO_4, and CCl_3COOH). Apart from the acids, the presence of various degrees of polyphenols in the isolates can contribute to the observed quenching effect. A red shift in λ_{max} was observed in RPI_0.1$HClO_4$ and RPI_0.2$HClO_4$, which suggests that the Trp surrounding became more polar; that is, the chromophores are more exposed to the hydrophilic environment. Further increase in $HClO_4$ concentration caused a blue shift in λ_{max}. Use of CH_3COOH in the treatment solvent did not shift λ_{max} significantly in the case of RPI_0.4CH_3COOH and RPI_0.6CH_3COOH, although an increase in their intensities was noted with respect to RPI_untreated. A lack of spectral shift pinpoints that Trp is not exposed to any change in polarity. However, their enhancement in intensity could be explained by the positive overall net charge of protein molecules under acidic condition (eq 4) because of which the sensitive areas in the backbone of protein molecule acquire more like charges, causing internal repulsion, or perhaps lose charges that were previously involved in attractive forces holding the protein structure together.[35] This in turn leads to a less compact structure, increasing the possibility of exposure or accessibility of more buried fluorophores, thereby enhancing emission intensity.

$$\underset{\text{low pH}}{H_3N^+CHRCOOH} \overset{H^+}{\rightleftharpoons} \underset{\text{zwitterion}}{H_3N^+CHRCOO^-} \overset{OH^-}{\rightleftharpoons} \underset{\text{high pH}}{H_2NCHRCOO^-} \quad (4)$$

FTIR spectroscopic patterns of the proteins were nearly identical, with no significant differences in the major bands (Figure 5a). Amide B band (≈3100 cm^{-1}) originates from N−H stretching of protein vibrations, with contribution from O−H stretching of intermolecular H-bonding. Amide I band (within 1600−1700 cm^{-1}) arises predominantly from C═O stretching vibrations (70−85%), whereas the amide II region (within 1500−1600 cm^{-1}) represents N−H bending vibrations (40−60%) coupled to C−N stretching vibration (18−40%). Spectral changes in the amide I region have been widely used for the conformational analysis of the secondary structure of proteins. Therefore, secondary structure quantitations were performed by Gaussian curve fitting of the spectra in the amide I region (Supporting Information Figure S4) using OriginPro software (version 8.0, OriginLab Corp., Northampton, MA, USA). Peak positions were assigned at those positions where the second-order derivative had local minima. Bands were assigned to various elements of secondary structure (α-helix, β-sheet, and others), and the data are compiled in Table S5 in the Supporting Information. The correlation coefficient (adj R^2) between the original and fitted spectra was ≥0.998, and the error of estimate (chi-square value) was ≤1.08×10^{-5}. The percentage of each secondary structure was calculated from the integrated areas of the component bands. Schmidt et al.[23] studied rapeseed napin and found that the protein is primarily composed of α-helices (45−57.9%) and β-sheets (7−15.3%) as a function of pH 3−12. He et al.[2] also showed that native rapeseed protein comprises 43.6% α-helix and 25.8% β-sheet (β-strand + β-turn). These data are consistent with the result presented in Table S5 in the Supporting Information. The α- and β-contents of RPI_untreated, RPI_deftatted, and RPI_Me-Ac were found to vary minimally, which strongly suggests structural similarity between these samples. Estimated α:β ratio decreased with increasing acid concentration ($p < 0.05$) (Figure

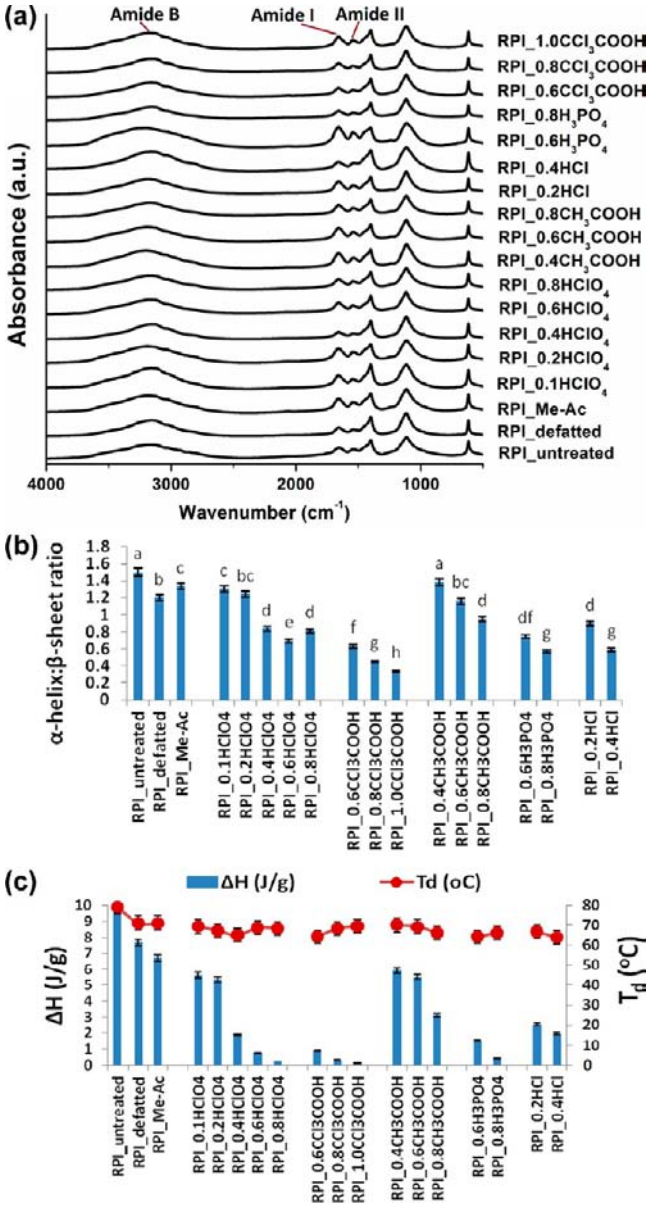

Figure 5. (a) FTIR spectra; (b) estimated ratio of α-helical to β-sheet conformation; and (c) thermal transition characterization of isolates from different meals.

5b). This clearly reflects that acidic solvents induced an increase in β-sheet formation (non-native protein aggregates) accompanied by a decrease in α-helical conformation (indicative of organized native structure), the effect being much stronger on proteins recuperated from CCl_3COOH-treated meals. These results complement the findings of Ayutsede et al.,[37] who reported formic acid treatment to increase β-sheet with a concomitant decrease in α-helix of silk protein. β-Sheet probably arises at the expense of α-helix (partial unfolding of α-helices and subsequent aggregation).[27]

ΔH reflects the extent of ordered structure of protein as the transition from native to denatured state takes place, and T_d provides information on the temperature needed to unfold the structure.[38] Thermograms of the majority of the samples displayed one broad endothermic peak (not shown), possibly corresponding to the overlapping denaturation of 12S (cruciferin) and 2S (napin) rapeseed proteins.[13] A progressive decrease in ΔH from 9.82 to 6.7 J/g with defatting followed by Me-Ac treatment revealed solvent-induced protein unfolding (Figure 5c). Regardless of the acid type, proteins from meals treated with higher acid concentration exhibited very low ΔH, confirming denaturation and more disordered conformation, the effect being higher in RPI_0.8$HClO_4$, RPI_0.8CCl_3COOH, RPI_1.0CCl_3COOH, and RPI_0.8H_3PO_4, which were denatured almost completely (having a flat trace with negligible sign of transition). It could be speculated that the native structure of RPI_untreated had not been completely lost with acidified solvent treatment; proteins from meals treated with lower acid level partially conserved their native structure (manifested by their higher ΔH), especially in RPI_0.1$HClO_4$, RPI_0.2$HClO_4$, RPI_0.4CH_3COOH. and RPI_0.6CH_3COOH. It is feasible to believe that treating the meal with low acidic solvent exposes protein to conditions of minimum harshness and, therefore, yields a protein with least structural aberrations. The current enthalpy data are somewhat comparable to those reported by He et al.[2] With regard to T_d, solvent-treated species presented lower values ($p < 0.05$) in comparison with RPI_untreated, in agreement with the generally described unfolding effect of organic solvents on protein. Unlike ΔH, the T_d of the samples varied within a narrow range of 64−79.5 °C. This observation is partly similar to that reported for buckwheat protein isolates obtained from organic solvent-treated flours,[8] for which the T_d value of 13S globulin was found to be nearly unaffected by the removal of polyphenols with cold organic solvents; however, ΔH was found to increase significantly. In Figure 5c, T_d decreased as the amount of $HClO_4$, CH_3COOH, and HCl increased, although a slight increase was seen in RPI_0.6$HClO_4$ and RPI_0.8$HClO_4$. On the contrary, the isolates from CCl_3COOH- and H_3PO_4-treated meals underwent a steep rise in T_d with increasing acid level. Taking into account the data from FTIR, higher T_d can be expected due to the tendency of proteins to aggregate into a more compact moiety after unfolding, especially in a highly denaturing condition. As a comparison, ΔH and T_d values of rapeseed protein obtained in this study were inferior to those reported earlier.[13,39,40] Partial protein denaturation due to commercial oil expression and alkaline extraction procedure could explain this difference. In addition, most authors perform DSC analysis of protein solution in different ionic strength buffers instead of dry protein powder, which in turn causes remarkable differences in thermal properties[41] due to the stabilizing effect of salt (nonspecific charge-shielding effect)[38] and water.[42]

Of 18 tested samples, native-PAGE of only 10 samples could be traced (Figure 6a). High MW proteins (>205 kDa) were caught at the top of the lanes as smears. Electrophoretograms of these isolates did not present any detectable difference from the control, precluding that these samples are relatively native-like. Remaining samples did not enter the separating gel and are presumed to be complex(es) of very high MW, perhaps due to protein aggregation. The MW of cruciferin, one of the major canola/rapeseed proteins, was reported to be in the range of 230−240 kDa,[39] whereas other studies suggest its MW above 300 kDa.[43] Because MWs of the proteins could not be calculated according to their mobility by native-PAGE, the samples were further analyzed by SDS-PAGE. Examining the gel in Figure 6b shows that the very same samples, which presented diffused bands in native-PAGE, also yielded similar electrophoretic patterns under nonreducing condition (without β-ME), except RPI_0.4HCl and RPI_0.4$HClO_4$, and contained mainly globulin (cruciferin) subunits, which were composed of

dx.doi.org/10.1021/jf5023803 | J. Agric. Food Chem. 2014, 62, 7903−7914

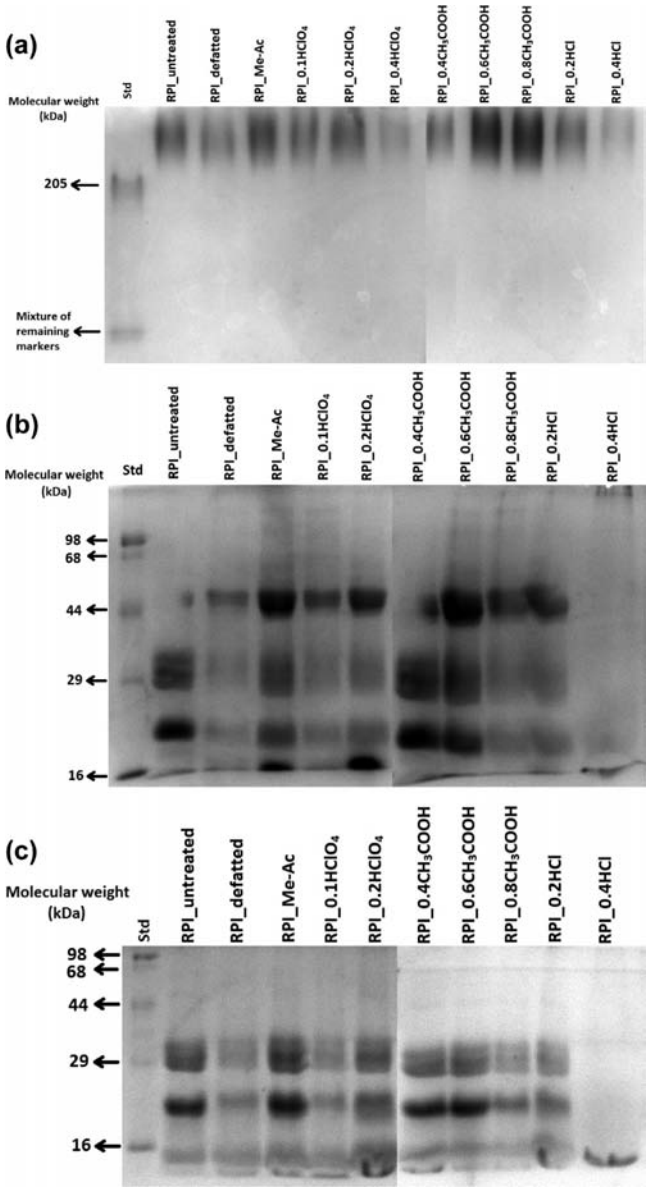

Figure 6. (a) Native-PAGE; (b) nonreducing and (c) reducing SDS-PAGE profiles of isolates from different solvent-treated meals.

bands with MW above 20 kDa (56−49.6, 35−28, and 20.2−19.2 kDa), and albumin (napin) subunits (ranging from 15.9 to 14.8 kDa). This result is consistent with earlier papers.[13,39] Aluko and McIntosh[44] also reported four major polypeptide bands in canola with MWs of 16, 18, 30, and 53 kDa in nonreducing SDS-PAGE. RPI_0.4HCl gave feeble bands of high MW aggregates, seen as smears at the top, and RPI_0.4HClO$_4$ failed to enter the resolving gel. Upon addition of β-ME to cleave SS bonds (reducing condition), the bands within 56−49.6 and 15.9−14.8 kDa disappeared and concomitantly two additional bands with estimated MWs of 13.9−12.5 and 10 kDa appeared (Figure 6c). The latter (10 kDa) probably corresponds to dissociated napin components (reported MW is 10−9.5 kDa).[39,40] The disappearance of canola protein bands having MWs of 59, 53, and 47.5 kDa in the presence of β-ME has been shown earlier.[39,44] Under reducing condition, cruciferin dissociated into acidic (37.8−28.5 kDa) and basic (21.4−20 kDa) polypeptides, in agreement with a previous study.[40] The protein profile of RPI_0.4HCl exhibited changes compared to the pattern described under nonreducing condition, displaying fewer bands having lower MW (≈11.7 kDa). Therefore, the high MW aggregate of this isolate detected in Figure 6b was stabilized by S−S linkages. Dissociation followed by reaggregation after acidic treatment (pH ≤3) has been reported in a number of oilseed proteins.[24] Surprisingly, in the case of the remaining samples, even after the addition of β-ME, diminished concentrations of soluble aggregates were able to enter the gel, which suffered pronounced decreases in band intensity (Supporting Information Figure S6). The coincidental occurrence of polymerized proteins at the bottom of the loading wells and at the junction between stacking and resolving gels was clearly noticeable. Protein denaturation in such samples was clearly reflected by the diffusive and unresolved bands of very low electrophoretic mobility. It is apparent that the results follow the trend observed in FTIR (predominance of β-sheet formation), and the formed aggregates are not soluble in buffer used for electrophoresis. These moieties are more likely stabilized by covalent bonds in addition to SS linkages. Covalent bonding occurring locally in the deep protein structure, especially in highly denatured state, cannot be excluded.[38] The assumption that most of the S−S cross-links are located deep or hidden in the hydrophobic core due to conformational change or protein folding in a manner that limits the accessibility of the reducing agent (β-ME) may also corroborate such a result.[27,38]

Effect on Functional Properties. Protein solubility (at neutral pH) of RPI_untreated (as 100%) was reduced to 80 and 94% in RPI_defatted and RPI_Me-Ac, respectively (Figure 7a). The slightly higher value of the latter could be due to hydration of protein caused by alcohol (methanol), preventing a severe dehydrating effect on the protein.[45] The decrease in solubility with increasing acid concentration can be ascribed to a number of factors: First, it may be a consequence of solvent-induced protein denaturation or due to the varying level of residual antinutrients remaining associated with protein. It is well-known that increasing the level of phytates and/or polyphenols in protein products decreases N solubility.[46,47] However, despite the highest level of phytates and polyphenols in RPI_untreated, it shows maximum solubility because of the partial native state of proteins from pristine rapeseed meal as well as differences in the nature of phytate−protein complexes or phenolic−protein complexes in the protein from pristine meal compared with the isolates from solvent-treated meals.[47] Second, varying degrees of physicochemical changes caused by the solvents may be responsible for these deviations, such as nonavailability or blocking of the residual thiol groups leading to sustained insolubility. Floris et al.[28] proved that the insoluble aggregate is the result of SH group oxidation and not the result of SH/SS exchange reactions. It was demonstrated that SH/SS rearrangement takes place in the aqueous environment, and reshuffling of S−S groups, which can occur when free SH groups are present, is very important in the process of protein resolubilization.[28] Thus, it is difficult to ascertain which influence would play a predominant role, or their concerted effects may dictate the solubility property of different isolates.

Proteins, being amphiphilic, show a strong tendency at fluid interfaces (reducing interfacial tension), which allows them to play a major role in the formation and stabilization of emulsion and foam. Literature data on rapeseed protein-stabilized foams and emulsions are conflicting. As reviewed by Moure et al.,[48] EA and ES of rapeseed/canola protein (concentrates and isolates) widely range from 28.3 to 54% and from 5 to 71%,

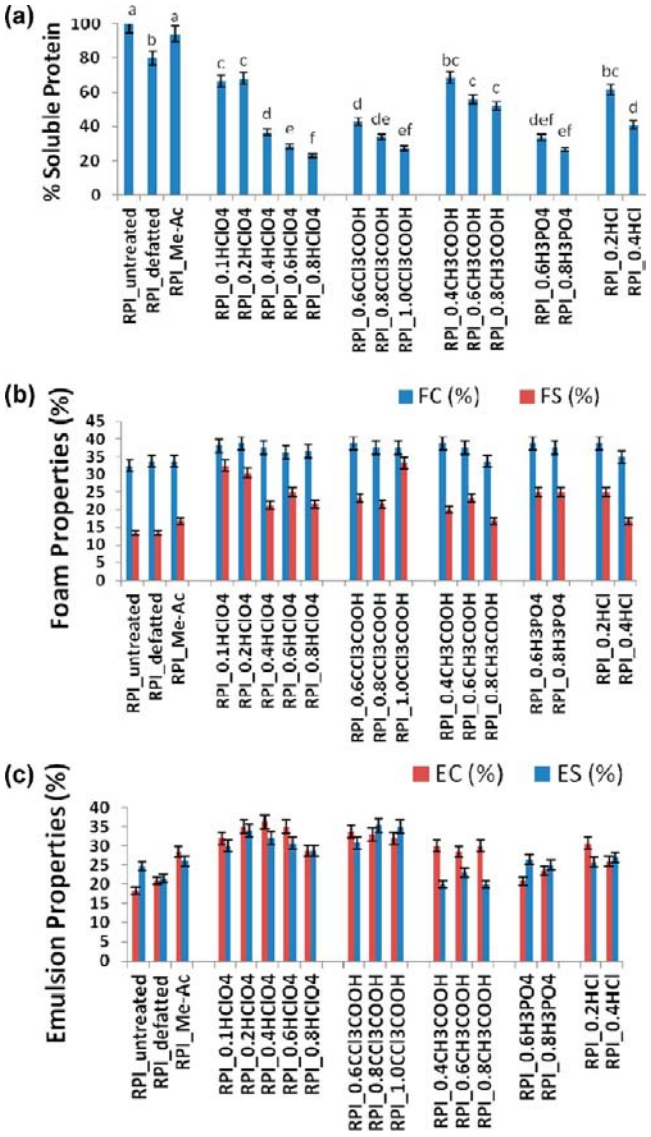

Figure 7. (a) Protein solubility (at pH 7.0); (b) foaming capacity (FC) and stability (FS); and (c) emulsion capacity (EC) and stability (ES) of isolates from different meals.

respectively. In the case of FC and FS, the respective value varies from 43.3 to 211.9% and from 8.2% to 74.7%. Dispersion interactions between proteins and the oil–water interface are always attractive, whereas those between proteins and the air–water interface are generally repulsive. Because of this difference, proteins are adsorbed much more readily at the oil–water interface than at the air–water interface.[49] Thus, the emulsification behavior of a protein may not be analogous to its foaming ability. Apparently, proteins from meals treated with lower concentrations of acids showed slightly higher ability to form foam (Figure 7b), which can be partly ascribed to their higher S_0 and solubility.[48] Highly ordered proteins possess poorer FC than ones that have disordered structure,[49] due to their inability to migrate into the air–water interface of gas bubbles to facilitate a more cohesive film. This might be the cause for inferior FC and FS in untreated sample. Thus, structural and conformational features of protein as a whole rather than solubility alone appear to be the primary determinants for foaming properties.[47] For RPI_0.1HClO$_4$ and RPI_0.2HClO$_4$, a pronounced increase in FS was found (Figure 7b), which seems to be related with their high SH content. Introduction of thiol groups in protein has been shown to increase FS significantly, promoted by SH/SS interchange reaction at the interface,[49] which provides a highly viscoelastic film resisting coalescence. In contrast, CCl_3COOH-treated samples, although with very low SH group content, showed improved stability, the influence being very pronounced in RPI_1.0CCl_3COOH. This was tentatively attributed to the presence of high protein aggregates, which could behave as surface-active solid particles begetting a Pickering foam.[50] Such particles could attract each other, increasing jamming in the fluid interstices between bubbles and the formation of a firmer shell.[50]

EC was found to vary within 18.32–36.28%, with all treated samples showing higher values than the untreated one (Figure 7c). This is because solvent-induced partial denaturation of protein generally improves surface activity.[49] Reduction in S_0 and/or high level of phenolics in RPI_untreated and RPI_defatted impeded their emulsion properties.[26] Excessive denaturation may impair EC by rendering the protein insoluble, as a highly rigid protein cannot unfold/reorient at the interface rapidly and, thus, may not form the film around the oil droplets effectively. This may be the probable reason for decreased EC in samples obtained from high acid-treated meals. EC of such samples may also be affected by their S_0 and solubility,[48] although a high solubility is not a prerequisite for good interfacial properties.[49] Usually EC shows a positive correlation with S_0; the greater the number of hydrophobic patches on a protein's surface, the higher is the probability of its adsorption and retention at the interface, albeit highly hydrophobic proteins may precipitate and cause instability.[49] As reflected in Figures 3b and 7c, EC and ES of proteins from treated meals partly paralleled their S_0. An exception to this observation was the TCA-treated samples, which showed highest ES. The increase in acid level in the processing treatment did not present any close relationship with ES. CH_3COOH-treated samples showed the least stability, which may be due to their high phytate content. Our observation is in line with those of Dev and Mukherjee.[47]

In light of the differences among the wide number of systems available, the results of a single method can give only a reductive suggestion of the emulsion properties of the sample. For that reason, morphological changes occurring in the droplets of emulsions stabilized by different isolates were visualized. At t = 0 h (Figure 8a), the emulsion droplet morphology stabilized by RPI_untreated compares well with those of RPI_defatted, RPI_Me-Ac, RPI_0.1HClO$_4$, and RPI_0.2HClO$_4$. Although a smaller droplet size was found in the emulsions stabilized by RPI_0.4HClO$_4$ and RPI_0.6HClO$_4$, insoluble protein aggregates were visible in the matrix. Such aggregates were also detected in emulsions formed by CCl_3COOH-treated samples. Poor emulsifying properties of H_3PO_4 and HCl-treated samples can be anticipated from their flocculated droplets with large diameters. This is congruent with their EC values. At t = 24 h, the droplets displayed a significant level of flocculation (Figure 8b). The spherical shape of oil droplets was severely distorted; the burst of large droplets dominated, and some emulsion collapsing was observed, such as those stabilized by defatted and CH_3COOH- and HCl-treated samples. These phenomena seem to denote their inferior ES. Interestingly, the droplet diameters were initially larger in emulsions formed by CCl_3COOH-treated samples, but their stabilities were found to be outstanding, although these

dx.doi.org/10.1021/jf5023803 | J. Agric. Food Chem. 2014, 62, 7903–7914

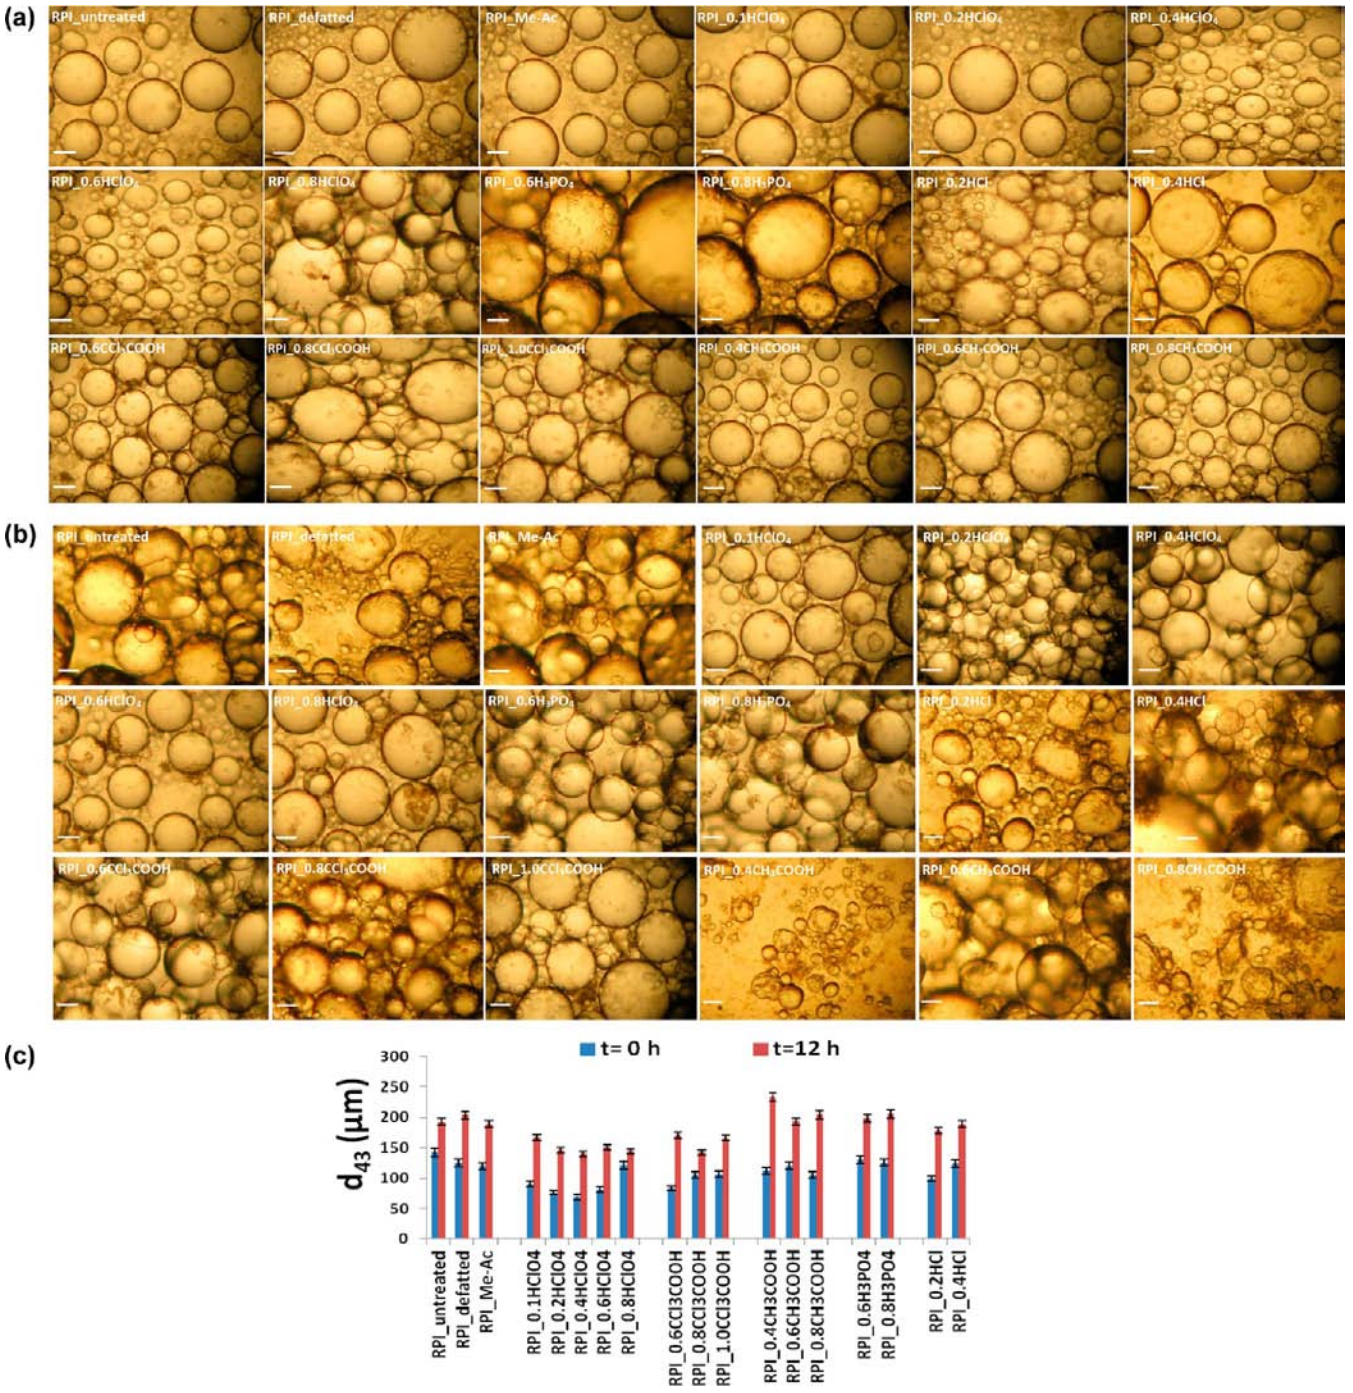

Figure 8. Optical micrographs of the o/w emulsions stabilized by protein isolates from different meals at (a) t = 0 h and (b) t = 24 h (scale bar represents 55 μm); (c) impact of different isolates on the average droplet size (d_{43}) of o/w emulsions stored at 25 °C for t = 0 h and t = 12 h.

samples possessed very low S_0 and protein solubility. This vast improvement can be attributed to insoluble protein aggregates, which were mainly located at the junction between oil droplets, favoring network stabilization by retarding droplet coalescence. However, the intense color of these isolates should be taken into account when considering their potential applications.

Additionally, changes in droplet/particle size of these emulsions (denoted by d_{43}) are shown in Figure 8c. Emulsifying ability of a surfactant can be assessed by d_{43}; the smaller the particle size, the better the ability. At t = 0 h, emulsion from all solvent-treated samples presented comparatively smaller particle sizes, indicating higher EA, which is due to their S_0. Except RPI_0.8HClO$_4$, perchloric acid-treated samples had lower d_{43} values compared to others. The droplet size of emulsions decreased markedly when HClO$_4$ concentration increased from 0.1 to 0.4%; however, further increase in acid level produced larger sizes. This can be related to their S_0 and soluble protein content.[49] The initial increase in hydrophobicity facilitated enhanced interaction between the oil and aqueous phases.[14] As the acid level increased, a point was reached where the unfolded polypeptide chains reconstructed (SS linkages with polymerization), which made it prone to aggregation rather than to adsorb onto the interface.[14] When the soluble protein amount is limited, there is no longer

dx.doi.org/10.1021/jf5023803 | J. Agric. Food Chem. 2014, 62, 7903−7914

sufficient protein to fully stabilize the droplet interface, and therefore larger particles may be formed as a result of coalescence or bridging flocculation. In the case of emulsions stabilized by other protein samples, larger particle sizes were observed. The decreased S_0 might have precluded the migration of such proteins to the interface. A similar trend in d_{43} values was observed for these systems at t = 12 h, so the factors accounting for emulsion droplet sizes during storage may be similar to those stated previously. Overall, the particle size of emulsions gradually increased with increasing storage time, due to individual droplet growth (Ostwald ripening) or droplet aggregation (flocculation or coalescence).[26] At t = 24 h, the studied emulsions presented a significant amount of ruptured/collapsed droplets, because of which their d_{43} values could not be calculated. Taken together, these data suggest that an efficient method to stabilize the oil−water or air−water interface consists in using protein from a meal treated with low acidic solvents, having an intermediate degree of hydrophobicity.

In summary, the efficiency of the removal of polyphenols and phytates from protein with $HClO_4$-acidified solvent was much better than that with other acids, but the extent of AITC removal was similar for all acids tested. Isolates were essentially free of glucosinolates. The solvent treatment lowered protein yield and its solubility; conversely, their color and interfacial properties were enhanced, but the results did not necessarily match those obtained from highly acidified solvent-treated meals because the mechanism of denaturation and structural changes caused by different solvent systems were not the same. The treatment also resulted in distinct changes in proteins' secondary and tertiary conformations; especially, higher levels of acid led to detrimental effects of protein unfolding and aggregation, which seemed to be more likely consecutive events. Such aggregation-prone conformation tended to enhance thermal stability (higher T_d). From a calorimetric point of view, meals treated with lower levels of acids seemed to consist of considerably structure-preserved proteins relative to the control. Further evidence that these samples have not undergone appreciable denaturation comes from their electrophoretic patterns. It is evident that 0.2% $HClO_4$ in Me-Ac (1:1 v/v) constitutes a valid extraction mixture, giving results that are either higher than or comparable to the other solvents tested, and also does not affect the protein much, as is shown by its physicochemical and functional features. Further investigation should be undertaken to improve the technofunctional properties of such isolates.

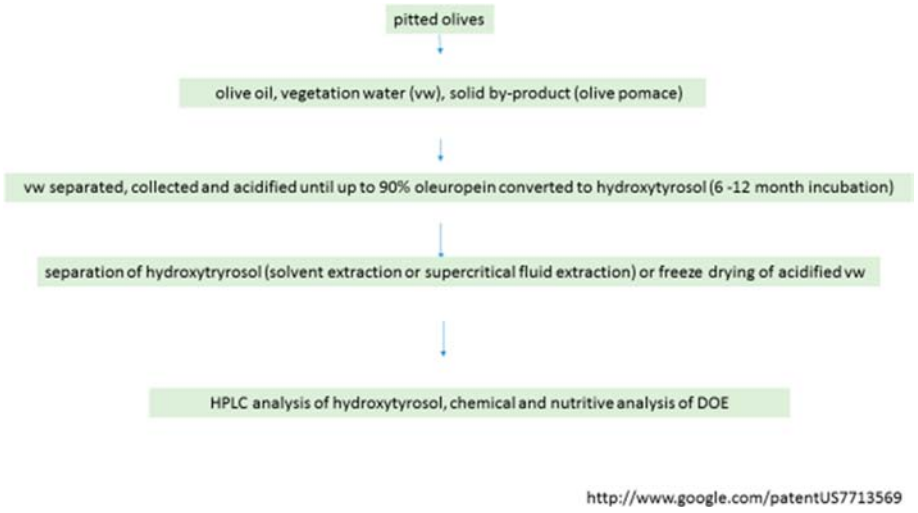

Figure 1. One of many variations for the production of dried olive extract with hydroxytyrosol.

retard lipid oxidation during processing and storage of post-mortem tissue and further processed poultry products.[22,23]

DOE is a certified organic, generally recognized as safe (GRAS), and Kosher agricultural byproduct from the production of olive oil[24] (Figure 1). As delineated in Table 1, the solid olive oil extract (olive oil pulp) is 98−99% water-soluble and contains 2.5% (minimum) hydroxytyrosol, more than contained in extra virgin olive oil. Therefore, DOE as an agricultural byproduct, potentially, could be administered (in vivo) to poultry to retard lipid oxidation in post-mortem poultry meat, high in unsaturated fatty acids that degenerate and produce free radicals during processing and storage.

Table 1. Nutritive Analysis of DOE[a]

carbohydrate	64.4%
fat	20.0%
ash	11.4%
simple and polyphenols	8.82%
protein	4.4%
hydroxytyrosol	2.5% (minimum)
lead	<1.0 ppm
heavy metals	<10.0 ppm

[a]Bitter, 2007 (see ref 24).

Myricetin, a bioflavonoid extract from the bark powder of the bayberry tree (*Myrica cerifera*), has anticancerous properties, is antimutagenic, and has therapeutic effects for heart disease and diabetes.[25,26] Although myricetin has been evaluated for it pharmacological effectiveness, its antioxidative capacity when added to foods containing unsaturated fatty acids has received less attention. Like hydroxytyrosol, myricetin is water-soluble and scavenges $OH^{\bullet}$ and O_2^- radicals.[26,27] Thus, this free radical scavenger may be another effective antioxidant in poultry products.

DOE and myricetin may be among several antioxidants that could be added to poultry to promote growth, retard disease, and prevent oxidation in post-mortem tissue. Therefore, a study was conducted to (1) assess the capacity of DOE to enhance the growth of poultry, (2) determine the effectiveness of DOE (administered in vivo) as an antioxidant in post-mortem tissue and further processed meat, and (3) compare the in vitro antioxidative capacities of hydroxytyrosol and myricetin.

MATERIALS AND METHODS

DOE (2.5% hydroxytyrosol) was obtained gratis from CreAgri, Inc. (Hayward, CA). 2,2-Diphenylpicrylhydrazyl and myricetin (95%) were purchased from Thermo Fisher Scientific Acros Organics (Fair Lawn, NJ, USA). Acetic acid, butan-1-ol, methanol, HCl, sodium dodecyl sulfate, and thiobarbituic acid were obtained from Chemical Stores (University of California, Davis, CA, USA). NaCl was obtained from Morton Salt (Chicago, IL, USA). All chemicals were at least reagent grade.

Unvaccinated chicks and commercial feed were from Ellenwood Hatchery (Foster Farms, Livingston, CA, USA) and the Foster Farm Feed Mill, respectively.

Administration of DOE Treatments. The Institutional Animal Care and Use Committee (University of California, Davis, CA, USA) approved the protocol for the study. Feed and water were administered ad libitum throughout the feeding trial to Arbor Acres Crosses reared under 12 h of light and 12 h of darkness. One-day-old chicks (276) were fed a commercial starter diet and water during acclimatization for 1 week. At the beginning of the second week, chicks were randomized into 12 pens (each at 2.13 m^2) of 24 birds each. The experimental design was 3 diets × 2 blocks (pens) × 2 replications.

Commercial diets were provided as starter for week 1, grower for weeks 3−5, and finisher for week 6. Throughout the experiment, broilers were provided water containing DOE as follows: no DOE as a control, 6 mg of DOE per bird per day, or 12 mg of DOE per bird per day.[24] For weeks 1 and 2, water for the control and that with antioxidant was provided fresh each day in 0.946 L containers. For weeks 3−6, water was provided in 18.93 L containers. Broilers completely consumed water with DOE during the first 4 h of light (8:00 a.m. to 12:00 p.m.). All containers, including the control, were rinsed several times before the addition of fresh water that broilers consumed during the remainder of the lit period.

Enhancement of Growth, Detection of Disease, and Defects. Body weights (BW) for 12 broilers from each pen were recorded each week. Quantities of added feed were recorded. Adverse effects were not expected due to feeding of DOE, a GRAS substance. However, as a precautionary measure, two birds per pen were sacrificed at the end of the study and examined for disease and growth defects at the California Animal Health and Food Safety Laboratory (University of California, Davis, CA, USA). Laboratory findings (two samples per bird) were reported for bacteriological, histological, immunological, parasitological, toxicological, and virological analyses.

Preparation of Samples from Thigh Meat of Broilers Fed DOE. After 6 weeks, birds were harvested at Grimaud Farms (Stockton, CA, USA). Birds were frozen at −28.8 °C for approximately 24 h and transported to the laboratory, where they were frozen at −40 °C until thighs were removed and further

Table 2. Effect of DOE on Body Weight, Feed Consumption, and Feed Conversion[a]

	BW[b,c] (kg)					
treatment[d]	1 week	3 weeks	5 weeks	6 weeks	feed consumption (kg)	feed conversion[c]
control	0.14	1.32	2.42	3.36	5.62 ± 0.64	1.67
6 mg	0.14	1.35	2.41	3.31	5.39 ± 0.48	1.63
12 mg	0.14	1.34	2.39	3.29	5.46 ± 0.49	1.65

[a]Feed and water were provided ad libitum. [b]Means (12 observations) within a row lacking a common letter differ ($P \leq 0.05$). [c]Calculated value. [d]DOE was administered at 6 or 12 mg per bird per day in water from 8:00 a.m. to 12:00 p.m. each day.

Table 3. Absorbance Values from Thigh Meat Treated with Two Levels of in Vitro DOE and Myricetin

	treatment[a]				
processing condition[b]	control	H1	H2	M1	M2
fresh	0.07 ± 0.02a	0.08 ± 0.02a	0.07 ± 0.01a	0.06 ± 0.02a	0.07 ± 0.01a
heated	0.13 ± 0.04a	0.14 ± 0.04a	0.11 ± 0.02ab	0.06 ± 0.01b	0.07 ± 0.01b
NaCl/heated/stored	0.20 ± 0.04a	0.15 ± 0.02b	0.13 ± 0.04b	0.06 ± 0.01c	0.06 ± 0.02c

[a]H1 and H2, addition of 0.025% (w/w) and 0.05% (w/w) of DOE, respectively; M1 and M2, addition of 0.025% (w/w) and 0.05% (w/w) of myricetin, respectively. Means (six observations) within rows lacking a common letter differ ($P \leq 0.05$). [b]Samples (approximately 25 g) from right thighs of two broilers from each treatment across each replication were thawed, pooled, and ground. Samples (3 g) from each mixture were ground for approximately 1 min and analyzed immediately as fresh or boiled (37.8 °C) in boiling bags, cooled (30 min), and analyzed as heated. NaCl/heated/stored samples were the same as heated samples with the addition of 1.0% (w/w) NaCl in 7 mL of deionized distilled water before grinding and heating followed by storage in aluminum pouches for 2 days at −12.22 °C for 24 h before analysis.

processed. Samples (approximately 25 g) from right thighs of two broilers from each treatment across block (pen) and replication were thawed in aluminum pouches for 24 h at −12.22 °C, pooled, and ground in a food processor (Cuisinart, model DLC-7 Super Pro, Norwich, CT, USA) for 2 min. After initial processing, samples (3 g) were ground for approximately 1 min and analyzed immediately as fresh. Heated samples were boiled (37.8 °C) in boiling bags and cooled (30 min) before analysis. NaCl/heated/stored samples were treated in the same manner as heated samples with the addition of 1.0% (w/w) NaCl in 7 mL of deionized distilled water before grinding and heating followed by storage in aluminum pouches at −12.22 °C for 72 h before analysis. The experimental design was 3 treatments (from the feeding experiment) × 3 processing conditions × 3 samples × 2 replications. This design produced six samples for each treatment by processing condition.

In Vitro Addition of DOE and Myricetin. Thigh samples of control broilers from the feeding trial were processed as above. Control samples (3 g) did not contain antioxidants. Antioxidants at 0.025% (w/w) and 0.05% (w/w) of DOE or myricetin in 7 mL of deionized distilled were added during grinding for 1 min.[8,10,22] NaCl (1.0% w/w) was added with antioxidants where indicated. H1 and H2 denote samples containing 0.025% (w/w, 1.875×10^{-5}g) and 0.05% (w/w, 3.75×10^{-5}g) of hydroxytyrosol (2.5% in DOE, Table 1), respectively. M1 and M2 denote samples containing 0.025% (w/w, 7.125×10^{-4}g) and 0.05% (w/w, 1.425×10^{-3}g) of myricetin, respectively. The actual quantity of myricetin was greater than that of hydroxytyrosol because DOE (containing hydroxytrosol) and myricetin were inadvertently added to post-mortem tissue without attention to differences in purity of the two antioxidants.

Determination of Absorbance Values To Indicate Levels of Lipid Oxidation. Absorbance values were used to indicate levels of lipid oxidations in samples based on consistent standard curves. The method of Cuendet et al.[28] was used to determine 2,2-diphenylpicrylhydrazyl (DPPH) at 517 nm (DV 1700 Pharma spectrophotometer, Shimadzu Scientific Instruments, Jiangsu, China) for samples from birds administered DOE. All in vitro and in vivo samples were analyzed by using methods of Fasseas et al.[29] at 532 nm to obtain absorbance values to approximate the level of lipid oxidation (thiobarbituric acid reactive substances, TBARS).

Statistical Analysis. Data were analyzed by ANOVA.[30] Means were evaluated using Turkey's Student *t* test, and significance of means was determined at $P \leq 0.05$.

RESULTS

In Vivo Effect of DOE. Table 2 shows that feed consumption, BW, and feed conversion were not affected ($P \leq 0.05$) by the addition of DOE. Results showing absorbance values for TBARS revealed no significant change for fresh, heated, and NaCl/heated/stored samples (data not shown).

Similarly, DPPH results (data not shown) showed no effect ($P \leq 0.05$) for DOE.

Detection of Disease and Defects. Results indicated that birds had no unusual lesions in the tissue of brains, hearts, inactive ovaries, intestinal tracts, kidneys, livers, or peripheral nerves. There were no abnormalities in the growth plates except for one control bird. Mixed lymphoid infiltration indicated that all broilers (unvaccinated) were affected with low levels of Marek's Herpes virus.

In Vitro Effect of DOE and Myricetin. As indicated by statistical similarity of absorbance values in Table 3, there was no effect of antioxidants in fresh samples ($P \leq 0.05$). For heated samples, H2 produced intermediate absorbency values; control and H1 had significantly higher values than M1 and M2.

NaCl/heated/stored samples had absorbance values ranked as M1 = M2 < H1 = H2 < control ($P \leq 0.05$). As noted above, 3 g samples contained 38 times more myricetin than hydroxytyrosol.

DISCUSSION

Visual observations indicated that birds readily consumed the agricultural byproduct, DOE, in water during the time allotted. As a GRAS substance it did not enhance the growth of broilers, nor was it detrimental when fed to them. These results are similar to those of Paiva-Martins et al.[31] and Botsoglou et al.,[32] who found that pigs and turkeys, respectively, fed olive leaves did not exhibit enhanced weight gain; however, these investigators reported significantly greater oxidative stability for meat from pigs and turkeys fed olive leaves. Paiva-Martins et al.[31] stored meat from pigs for 8 days at 4 °C. They attributed the lowered peroxide values and conjugated dienes to the higher α-tocopherol concentration in fat of meat from pigs fed

olive leaves. However, the significantly more stable oxidative stability of the meat from pigs fed olive leaves could be associated with the α-tocopherol and hydroxytyrosol contents as well.[32] Olive leaves (10 g/kg) fed to turkeys lowered lipid oxidation of stored muscle as compared to oregano, although it was not as effective as α-tocopheryl acetate at 300 mg/kg.[33]

As a highly effective radical scavenger, hydroxytyrosol in DOE could potentially retard lipid deterioration in chicken thigh meat as reported for turkey meat. However, in our study, it did not reduce lipid oxidation in post-mortem tissue as has been found with in vivo administration of α-tocopherol in the diets of broilers and consumption of olive oil leaves by turkeys.[21,22,32] Medina[33] showed that hydoxytyrosol is more effective in emulsions having short−medium lipophilic chains (acetate, butyrate, or octanoate). These investigators suggested that short−medium chains helped to position hydroxytyrosol in the interface of the fish oil emulsions, whereas longer chains did not. It is also known that the fatty acid content of both chicken and turkey meat can be altered significantly by the composition of the diet.[19,20] The fatty acid content of leaves fed by Botsoglou et al. was not reported; however, it is not likely that the composition of the turkey and broiler meat changed to such an extent as to affect the oxidative capacity of the antioxidant in turkey as compared to chicken meat.

It is likely that the antioxidative capacity of DOE provided in vivo is related to its solubility of >95% in water.[24] According to Vissers et al., hydroxytyrosol is highly water-soluble as well. Absorption of hydroxytyrosol by birds was not determined in our study; however, if it did occur, some of the antioxidant was likely excreted in the urine.[5] Although not measured in our study, the residual remaining in the tissue of broilers that did not consume water with DOE for 4−6 h prior to processing may have been negligible. In comparison, antioxidants in olive leaves are associated with oil (fatty acids) that may be readily maintained in the membranes to retard lipid deterioration during processing and storage.

When DOE and myricetin were added to post-mortem thigh meat, they were not further stabilized to prevent their deterioration. The effectiveness of these antioxidants in reducing absorbance (retarding lipid oxidation) was observed. Overall, myricetin showed greater capacity to decrease lipid deterioration in poultry products ($P \leq 0.05$, Table 3). Inadvertently, myricetin was added to post-mortem tissue at the same concentrations as that recommended by the manufacturer for DOE. Upon closer inspection, it was noted that DOE contained ∼2.5% hydroxytyrosol compared to myricetin at 95% purity. Thus, the actual ratio of antioxidants added to poultry meat samples was 38:1 for myricetin and hydroxytyrosol. H2 reduced absorbance for NaCl/heated/stored samples by 35% compared to M2 at 70%. On the basis of these results, hydroxytyrosol at $^{1}/_{38}$ the concentration reduced absorbance values half as well as that of myricetin. On the basis of this observation, if hydroxytyrosol were added to post-mortem poultry thigh tissue or further processed products at the same quantity as myricetin, it would be a more effective antioxidant. Further investigation to determine the potency of each antioxidant when equal quantities are added to unprocessed tissue and processed poultry meat is warranted.

beam- and γ-irradiation on the total aerobic bacteria and yeasts/molds in garlic samples was also evaluated.

MATERIALS AND METHODS

Garlic Samples and Irradiation Treatments. Garlic samples were purchased from retail markets in Daegu, South Korea. The samples were harvested in two different regions including Korea and China. The crushed garlics were originally vacuum-packed in polyethylene bags (packaging sizes: Korea, 500 g; and China, 1 kg) and stored at −18 °C. The bag units containing the samples were divided into two equal sets and labeled with the specific irradiation dose/type. Furthermore, the samples were placed in insulated polystyrene boxes and individually carried to the irradiation processing plants. The transportation was done under a frozen state at −20 °C. One set of samples was irradiated under γ-rays ^{60}Co radiation source (100 kCi point source AECL, IR-79, MDS Nordion International Co. Ltd., Ottawa, ON, Canada) at the Korea Atomic Energy Research Institute, Jeongeup, South Korea. Likewise, electron beam (e-beam) irradiation was performed on the second set of samples using an e-beam accelerator (Model ELV-4, acceleration voltage of 2.5 MeV, Fujifilm, Tokyo, Japan) stationed at EB-TECH Co., Daejeon, South Korea. The irradiation was performed at room temperature with doses of 0, 1, 4, and 7 kGy. The dose rate was 2.5 kGy/h from both radiation sources. The bags were rotated crosswise while receiving the radiation treatments. A ceric/cerous dosimeter (Harwell, Didcot, UK) was used to verify the absorbed dose in e-beam irradiated samples. On the other hand, an alanine dosimeter (Bruker Instruments, Rheinstetten, Germany) was used to confirm the absorbed dose in γ-irradiated samples. The samples were stored at −18 °C until required for further analysis. All of the planned experiments were replicated three times and completed within 2 weeks.

Total Aerobic Bacteria and Yeasts/Molds Count. Garlic samples were analyzed for the total aerobic bacteria and yeasts/molds count. Briefly, 5 g of the crushed garlic was mixed with 45 mL of sterile peptone water. Serial dilutions in peptonized water were made and plated on plate count agar (Difco Lab, Franklin Lakes, NJ, USA) for the total aerobic bacteria and on potato dextrose agar (Difco Lab), acidified by means of sterile 10% solution of tartaric acid, for yeasts and molds. To count total aerobic bacteria, plates were incubated at 37 °C for 24−48 h. Plate reading and colony count determinations were performed according to the Bacteriological Analytical Manual Online.[15] Yeasts and molds colonies were counted 5 days after incubation at 30 °C. Colonies were counted, and the count was described as colony-forming units per gram (CFU/g). All plating was performed in triplicates to ensure accuracy.

DEFT/APC Analysis. The DEFT method calculates the total number of contaminating microorganisms in a food sample regardless of viability. On the other hand, the APC method enumerates the number of viable microorganisms that can form colonies on an agar plate. A reduction of viable microbiological counts in irradiated food could be a potential screening parameter.[9] The first step includes membrane filtration to capture the microorganisms, followed by its staining with a fluorochrome acridine orange. Then the membrane is rinsed after staining and fixed on a microscope slide for counting with an epifluorescent microscope. The method is quick and full analysis can be completed in 25−30 min. The sample preparation, performance, and calculations were done according to EN 13783[9] followed by different scientists.[16,17]

Electronic Nose Analysis. A zNose (Electronic Sensor Technology, Newbury Park, CA, USA) equipped with a surface acoustic wave (SAW) sensor and VaporPrint (Misrosense 4.88) software was used to evaluate the volatile compound profiles of non-irradiated and irradiated garlic. Principal component analysis (PCA) was applied to understand the trend in distribution of the numerical data.

Photostimulated Luminescence Analysis. PSL photon counts (PCs) registered in 60 s were measured by a SURRC PPSL irradiated food screening system (SURRC, Glasgow, UK). Samples were distributed into 50 mm diameter Petri dishes (Bibby Sterilin type 122, Glasgow, UK). Sample preparation, handling, and the sensitivity of the instrument were tested at the start of each set of measurements using a reference light source. The PCs were analyzed with respect to lower and upper threshold limits. The accumulated PCs were classified as "'negative'" (T1 = 700 counts/60 s), "'intermediate'" (between 700 and 5000 counts/60 s), or "'positive'" (T2 = 5000 counts/60 s).[7] PSL measurements were performed under subdued light conditions in accordance with EN 13751[7] recommendations.

Thermoluminescence Analysis. The silicate minerals were separated from the non-irradiated and irradiated garlic samples by a density gradient method. TL measurements were made by a 4500 TL Reader (Harshaw, Erlangen, Germany) equipped with controlled-temperature ramping and automatic reheating facility at the Centre for Instrumentation, Kyungpook National University. The TL glow curves (glow 1) were recorded on both irradiated and non-irradiated samples with a reading time of 80 s and a heating range of 50−400 °C at a linear heating rate of 5 °C/s. The TL oven was purged under a continuous nitrogen flux (2 mL/min) to reduce spurious TL signals. Each sample disk containing tested minerals was subjected to a re-irradiation step at a standard dose of 1 kGy for normalization of the glow 1 results. The second TL glow curve (glow 2) was recorded to obtain the integrated TL signal ratios (TL_1/TL_2). Mineral isolation, sample preparation, and TL measurements were performed according to EN 1788.[8]

Statistical Analysis. Origin 8.0 (Microcal Software Inc., Northampton, MA, USA) and SAS program (version 9.3, SAS Institute, Cary, NC, USA) were used for data analysis. All analyses were performed in triplicates, and values were reported as the means (±SD).

RESULTS AND DISCUSSION

Effect of Irradiation on Total Aerobic Bacterial and Yeasts/Molds Count. The counts of total bacteria and yeasts/molds from countable plates are given in Figure 1. No significant differences in aerobic bacterial and yeasts/molds count were observed among two sources of untreated crushed garlics. The non-irradiated samples from China or Korea contained a relatively moderate population of aerobic bacteria, that is, approximately 10^5 CFU/g. Treatment with irradiation, either e-beam or γ-rays, unequivocally reduced the microbial population with dose increment from 1 to 7 kGy in a logarithmic manner. These results illustrate that the counts of total aerobic bacteria were reduced by 2-logarithmic cycles by a γ-ray dose of 4 kGy. Furthermore, a dose of 7 kGy was enough to reduce the bacterial count to nondetectable levels in locally harvested samples. In contrast, the count of aerobic bacteria was still high (10^4 CFU/g) in imported garlic samples. No considerable changes in bacterial count were observed in samples from China after the e-beam treatment. In general, the effect of both irradiation treatments on total aerobic bacterial count was almost similar on all examined samples. However, the garlic samples of domestic origin showed a little more sensitivity to the irradiation disinfestation as shown in Figure 1. The total aerobic bacterial values of untreated samples of the present study are equivalent to counts reported by Hong and Kim[12] for crushed garlic harvested in Korea.

Similarly, the initial yeasts/molds count in untreated samples was about 10^5 CFU/g as shown in Figure 1B. The yeasts/molds count decreased significantly with increasing irradiation dose. Irradiation treatment at 4 kGy effectively reduced the plate count of yeasts/molds to about 10^2 CFU/g in both types of samples. Further γ-ray application at 5 kGy dose completely decontaminated the locally produced garlic samples. On the other hand, e-beam irradiation succeeded in reducing the fungal count only by 1 log CFU/g by using a higher dose of 7 kGy. Therefore, the effect of γ-irradiation was more pronounced on

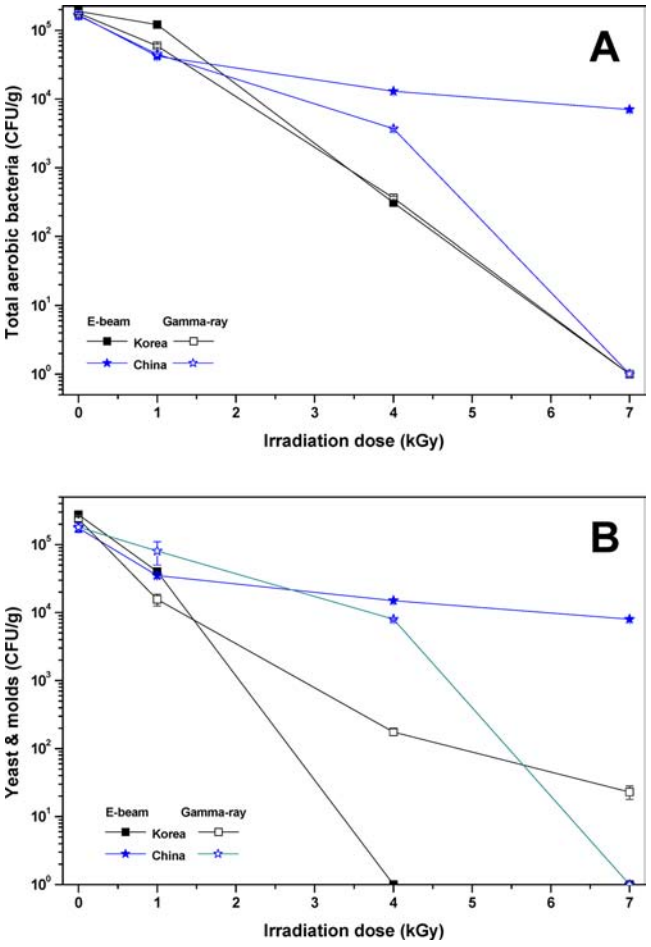

Figure 1. Total aerobic bacteria (A) and yeasts/molds (B) counts of electron beam- and γ-irradiated frozen crushed garlic produced in Korea and China.

the yeast and mold loads in all samples corresponding to total aerobic count. Comparable reductions in the microflora resulting from ionizing radiations were reported by Pezzutti et al.[18] for dehydrated garlic sold in the Argentinean retail market. Irradiation exposure between 5 and 10 kGy reduced the microbial load to acceptable levels in dehydrated garlic.

Microbial contamination of the vegetables may occur during production, harvesting, and distribution processes. In addition, the degree of contamination depends on the environmental conditions from growing to marketing and the physiological condition of the product.[19] The microbiological results in the present study indicated that the frozen crushed garlic samples available in the Korean market from both sources were hygienically safe for human consumption. The count of the total aerobic bacteria in frozen processed foods should not exceed 10^6 CFU/g according to the microbiological specifications established by the Ministry of Food and Drug Safety, South Korea.[20] It is worth noting that garlic, either freeze-dried or fresh-crushed, also has high antibacterial properties.[21] A review of different studies confirmed the presence of potential foodborne pathogens such as *Salmonella*, *Escherichia coli*, *Clostridium perfringens*, *Bacillus cereus*, and toxigenic molds in powdered garlic grown/processed in different countries.[22] Additionally, a given irradiation dose will be able to destroy a certain proportion of the microbial population regardless of the number of microorganisms present. This characteristic of irradiation implies that the higher the initial population of spoilage microorganism, the higher the population will be after the irradiation treatment depending upon several other factors. Furthermore, and of course, if spoilage has already initiated, radiation processing can do nothing to reverse it.[1]

Screening Analyses. The garlic samples were screened for their irradiation status using three different types of screening techniques based on microbiological, chemical, and physical principles.

Microbial Population Characterization by DEFT/APC Analysis. Prior to decontamination treatment, the microbial counts measured by DEFT and APC were of similar order due to the presence of microbes in the samples. However, there is a significant reduction in the APC count as compared to the DEFT count after the application of a decontamination treatment such as irradiation.[10,16]

The DEFT and APC values of non-irradiated and irradiated garlic samples are shown in Figure 2. Moderate APC count

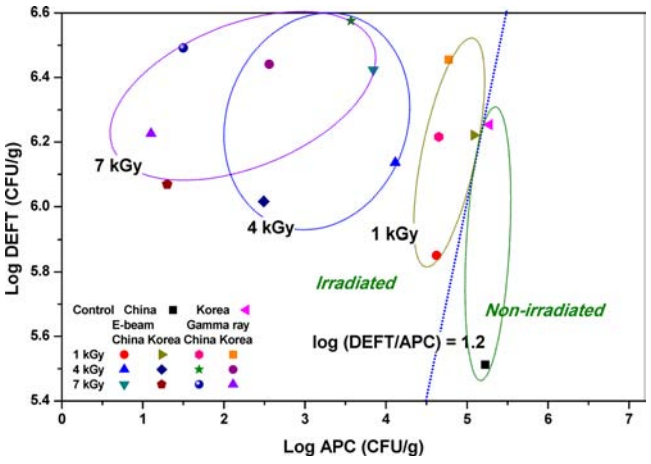

Figure 2. Logarithmic microbial counts of non-irradiated and electron beam- and γ-irradiated frozen crushed garlic produced in Korea and China.

(>10^5 CFU/g) was detected in the untreated samples from both sources. The DEFT count remained almost unchanged despite the irradiation treatment. On the other hand, APC values (mesophilic bacteria) progressively decreased with the dose increment either by e-beam or γ-ray processing. There was a clear reduction of mesophilic bacterial population (viable microorganisms) to the level of 10^2 CFU/g on exposure to 4 kGy γ-irradiation. The log DEFT/APC ratio was determined for each sample. The log DEFT/APC ratio of garlic samples increased with the gradual increase in the irradiation dose. For example, the log DEFT/APC ratio of non-irradiated sample from China was 1.05, whereas it was 1.27 for 1 kGy irradiated samples. In general, the log DEFT/APC ratio was <1.2 for non-irradiated samples, whereas irradiated samples showed >1.2 logarithmic units. Therefore, DEFT/APC analysis provided clear separation of the non-irradiated and irradiated garlic samples of both origins. On the basis of the present results, it is suggested that a DEFT/APC ratio of 1.2 logarithmic units could be used as a standard for the screening of frozen crushed garlic samples available in the Korean market as non-irradiated or irradiated.

Oh et al.[23] successfully evaluated the applicability of the DEFT/APC method for the screening of irradiated spices produced in Korea. Other studies showed that a clear screening

of the different irradiated (0−10 kGy) spices is possible by studying changes in microbial profile employing DEFT/APC methods.[17] Previously, the DEFT/APC method gave satisfactory screening results to indicate irradiation treatment of minimally processed vegetables. In general, a log DEFT/APC difference of around 2.0 is required for the useful application of this technique. However, the main drawback of the DEFT/APC method is that it not specific to irradiation treatment.[16]

E-Nose Screening Analysis. Irradiation can alter the odor profile of a food. Gardner and Bartlett[24] initially reported that the volatile profiles of samples based on the odor patterns are more useful indicators rather than the specific volatile compounds during E-nose analysis. The differences and similarities of odor patterns among different samples have been represented by the distinct fingerprint of the volatile profile.[25]

Figure 3 shows the PCA of irradiated garlic samples using E-nose measurement. A prominent screening of the irradiated samples was observed depending on the irradiation dose. It was clear that there were large differences in odor patterns between irradiated and non-irradiated garlics. In the case of the irradiated samples, different electronic fingerprints were observed in comparison with the non-irradiated ones, establishing the possibility of detection of the irradiated samples. PCA helped further to understand the trend in distribution of the numerical data.[26] Published studies have reported the use of E-nose analysis for irradiated spices,[17] fresh mushrooms,[26] and anchovy sauce.[25] Radiation-induced changes in odor pattern on food cannot be considered as radiation-specific detection markers, and the results need to be confirmed by a validated technique.[17]

Photoluminescence Screening Analysis. The development of a PSL novel screening has been aimed at resolving the practical limitations of laborious mineral separation in the TL method. Many foods are contaminated with mineral debris, which can store energy in charge carriers at structural, interstitial, or impurity sites upon irradiation. The PSL technique employs light rather that heat as a stimulus for liberating the trapped energy induced by radiation in solid materials. However, false-positive and false-negative results may be observed on the basis of the quality and quantity of the minerals present on the surface of the food sample.[7]

All non-irradiated garlic samples gave PCs in the negative PSL range [<700 photon counts/60 s (PCs)]. The PSL counts of non-irradiated samples were 327.1 ± 106.4 and 283.6 ± 95.6, harvested in China and Korea, respectively. All irradiated samples from China gave PCs in the positive range (>5000 PCs), thereby easily screening them out as irradiated. Furthermore, the PSL response was linear with the absorbed irradiation doses for imported samples (Table 1). On the contrary, the irradiated garlic samples from Korea exhibited a rather unusual behavior. Table 1 shows either intermediate or false-negative PSL counts were recorded for γ- or e-beam-treated domestic samples. The PCs of 1 and 4 kGy γ-irradiated garlics from Korea were 625.5 ± 306.3 and 1511.6 ± 923.4, respectively. According to European standard protocol (EN 13751),[7] negative calibrated PSL results are indicative of insufficient PSL sensitivity. Therefore, the varying results from our data emphasize the application of PSL as a screening analysis.

This behavior was in agreement with that reported by Cutrubinis et al.[13] for the PSL screening analysis of γ-irradiated (25, 50, and 100 Gy) garlic bulbs collected from the Brazilian,

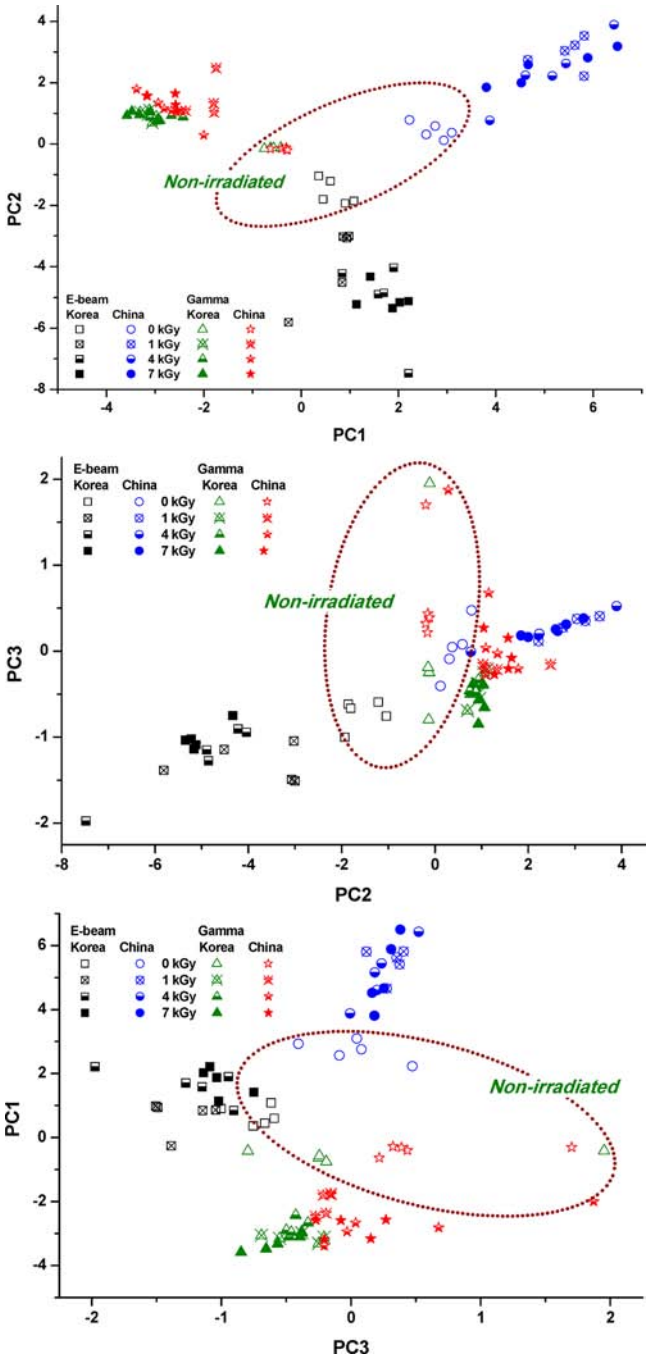

Figure 3. Principal component analysis of E-nose determinations on non-irradiated and electron beam- and γ-irradiated frozen crushed garlic produced in Korea and China.

German, and Romanian markets. The PSL technique showed limitations as PCs values were found below the lower threshold limit, possibly due to the low dose or irradiation. PSL sensitivity relies on the quantity and type of minerals within the individual sample.[7] Therefore, the insufficient PSL screening in domestic garlic bulbs can be ascribed to the presence of a low amount of silicate minerals.

Ahn et al.[27] studied how different light conditions (natural light, artificial light, and dark room) can affect the PCs values for irradiated garlic bulbs during storage. In general, the PCs of all garlic samples decreased as storage time proceeded. The control garlic samples showed intermediate PSL PCs at day 0

that decreased upon different storage conditions. In another study, Ahn et al.[17] found unsatisfactory PSL screening values during the analysis of irradiated powder samples of different spices and fresh paprika. The presence of a low quantity of the minerals in food samples and insensitivity to light stimulation could lead to poor PSL output. Despite varying results, PSL is a versatile technology to get a valuable indication about the irradiation status of various food stuffs. However, there is a need to confirm the results obtained from the PSL method using a more validated technique that can ensure the irradiation status of the suspected samples.[5,7]

Confirmation Analysis. *Thermoluminescence Characteristics of Isolated Minerals.* The TL technique offers the possibility of a very accurate identification of non-irradiated and irradiated inorganic dust, that is, quartz or feldspar.

During irradiation, free charge carriers, namely, electrons and holes, are produced in the crystals, which may be trapped by localized states within the band gap. The physical process of TL is based on the emission of light photon upon recombination of the opposite charge carriers when stimulated by thermal means. The emitted light is detected by a sensitive photon counter and amplified using a photomultiplier tube. The light intensity is finally recorded as a function of temperature to construct the TL glow curve.[4,8]

All of the irradiated garlics from different origins of production were reliably detected by the TL method. The TL spectra of minerals from garlic samples produced in China and Korea are shown in Figure 4. Minerals separated from irradiated samples produced TL glow curves in the recommended temperature interval between 150 and 250 °C. The TL glow curves from irradiated samples peaked at approximately 180 °C with high intensity. Furthermore, there were no interference signals at around 180 °C. The glow curve structure was very clear with well-defined peaks. In addition,

the TL intensity was proportional to dose level and the origin of cultivation. Garlic from China comparatively produced TL glow curves with high intensity at all irradiation doses. Thus, the difference in intensity may be related to the mineral composition. All of the non-irradiated garlics produced a residual geologically derived TL signal (natural TL) of maximum peak at approximately 300 °C or above with low intensity regardless of the area of production (Figure 4).

Normalization of TL glow curves through a re-irradiation step with a standard dose of 1 kGy can greatly improve the reliability of TL results. The TL glow ratio (Tl_1/TL_2) was calculated for all samples as shown in Figure 5. The TL ratio

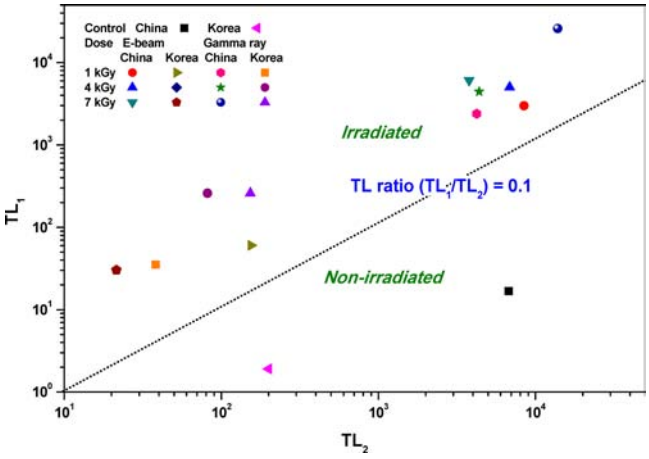

Figure 5. TL ratio (TL_1/TL_2) of inorganic dust minerals separated from electron beam- and γ-irradiated frozen crushed garlic produced in Korea and China.

was less than threshold value of 0.1 for the non-irradiated garlic samples produced in China and Korea. On the other hand, all irradiated samples regardless of their origin and type of irradiation treatment gave a TL ratio of >0.1 that increased with the given dose (Figure 5). Therefore, the clear identification of irradiated samples was guaranteed by the analysis of shape and intensity of the first TL glow curve and TL ratios.

Cutrubinis et al.[13] reported the limited availability of an amount of silicate minerals from the garlic bulbs. However, TL analysis successfully detected the irradiation status of the garlic bulb samples obtained from three different countries. Recently, Ahn et al.[28] investigated the effect of storage time under different light conditions on the TL properties of garlic bulbs cultivated in two different regions of Korea. A typical TL glow curve of high intensity with a maximum peak in the temperature range of 160−185 °C was prominent in all irradiated garlic samples. Additionally, no difference in the shapes of TL glow curves was experienced in all irradiated samples irrespective of the origin of cultivation. However, a significant difference in intensity was recorded relating to the origin of the cultivation. Furthermore, there was a time-dependent decrease during 2 years of storage in TL intensities and TL ratios for all irradiated samples. Kim et al.[29] applied the TL technique to identify different spice blends containing small amounts of different irradiated (0, 1, and 10 kGy) spice powders, such as red pepper, garlic, or ginger. Upon analysis, the blends containing even the lowest 0.5% irradiated garlic component gave typical TL glow curves that could be interpreted as positive. Ahn et al.[17] also discussed the TL method as a reliable confirmatory technique to identify different irradiated spices. The authenticity of TL for the identification of irradiated foods has been confirmed by various studies.[3,4,6,30]

In conclusion, the frozen crushed garlics of different origins of production available in the Korean market were hygienically safe according to the set microbiological quality standards. In general, γ-irradiation resulted in greater reduction in total bacterial or yeasts/molds count in garlics regardless of their origin of harvest. Therefore, irradiation processing may satisfy the demand of consumers for high-quality minimally processed garlic.

[a]Numbers in parentheses are the 95% Fieller bounds. Numbers for acrylamide are from interaction experiments.

On the basis of the available data, Moro et al.[10] concluded that both genotoxicity and chronic cytotoxicity seem to contribute to furan-induced tumor formation.[8,29−31] Reported efforts to reduce or prevent the formation of furan in foods include the use of polyphenolic compounds and plant extracts[32] and modification of food-processing conditions.[33,34] In a previous study, we reported that the amino acid L-cysteine and the tripeptide glutathione protected frog embryos against acrylamide-induced malformation (birth defects) of fetuses and that *N*-acetyl-L-cysteine protected against acrylamide-induced mortality but not against malformations.[35] In related studies, we also reported that other food ingredients protected embryos against potato glycoalkaloid-induced teratogenesis.[36−38]

Because acrylamide and furan can be formed concurrently during heat processing of numerous foods, the objectives of this study were (a) to define possible cumulative adverse and beneficial effects using the frog embryo teratogenesis assay-*Xenopus* (FETAX) of acrylamide, furan, and L-cysteine individually and the combinations of L-cysteine and acrylamide, acrylamide and furan, furan and L-cysteine, and acrylamide, furan, and L-cysteine; (b) to analyze mathematically and graphically the interactions of these compounds in the ex vivo environment that might optimize the protection by L-cysteine against adverse effects; and (c) to depict the effect of exposure to the food ingredients on the appearance of the frog embryos.

MATERIALS AND METHODS

Materials. The following compounds were obtained from Sigma (St. Louis, MO, USA): L-cysteine (catalog no. C7352); acrylamide (catalog no. A3553); human chorionic gonadotropin (catalog no. CG5); MS-222 (catalog no. E10521); calcium sulfate (catalog no. C-3771); magnesium sulfate (catalog no. M-7506); sodium bicarbonate (catalog no. S8875); potassium chloride (catalog no. P-5405); calcium chloride (catalog no. C-1016); and sodium chloride (catalog no. S7653). Furan was obtained from Aldrich-Sigma (St. Louis, MO, USA; catalog no. 185922).

Animal Care and Husbandry. *Xenopus* frogs were purchased from *Xenopus* I, Inc. (Dexter, MI, USA) and housed in a glass aquaria recirculation system with 2−4 frogs per 10 gallons of dechlorinated tap water. Human chorionic gonadotropin (250−600 IU) was injected in the dorsal lymph sac of both male and female frogs to induce breeding. Breeding pairs were placed in false-bottom breeding chambers, and embryos were collected the next morning. The jelly coat was removed by swirling the embryos for 1−3 min in a 2% L-cysteine solution (pH 8.1). Embryos were then rinsed and placed into sorting dishes. Embryos were double sorted into test dishes of 20 embryos per 8 mL of test solution in plastic disposable 60 × 15 mm Petri dishes. The negative control was FETAX solution (0.625 g/L NaCl, 0.086 g/L $NaHCO_3$, 0.03 g/L KCl, 0.015 g/L $CaCl_2$, 0.006 g/L $CaSO_4{\cdot}2H_2O$, and 0.075 g/L $MgSO_4$ in distilled ASTM type I water).[39] Frogs were not bred more than once every 2 months.

FETAX Assay Procedures. FETAX was used to determine acrylamide toxicity and teratogenesis according to the American Society for Testing Materials (ASTM) Guide for FETAX and our earlier studies with teratogenic glycoalkaloids.[40−47] Stock solutions of acrylamide and of test compounds were made in FETAX solution. Appropriate dilutions were made to achieve final concentrations. Each day of the 4 day test, new solutions were placed into 60 mm covered plastic Petri dishes with

various concentrations of test compounds dissolved in FETAX solution. At 24, 48, and 72 h, all solutions were prepared and replaced in the dishes. Dead embryos were removed, and live embryos counted. The embryos were cultured in the dark at 24 °C. At 96 h, surviving (stage 46) embryos were identified to verify embryos had reached the proper stage of development. Stage 46 embryos possess hind-limb buds and tightly coiled guts but do not yet feed. At the end of 96 h, the mortality was determined and embryos were anesthetized with MS-222. Malformed survivors, dead embryos, and the developmental stage were observed under a dissecting microscope and recorded according to the *Atlas of Malformations*.[48] Embryos were photographed with an Olympus Stylus 720sw on macro setting for growth measurements, and detailed photographs were taken of selected embryos using Pro Reg digital camera attached to a Nikon dissection microscope. As a measure of growth, head−tail length was measured by following body contour using a computer equipped with digitizing software Image Pro Plus.

Malformations were determined by observing embryos under a dissecting microscope for abnormal survivors, developmental stage, and dead embryos. *Xenopus laevis* embryos are transparent and allow for easy determination of gut, heart, head, axial, and other internal and external malformations. The malformations are quantitatively scored on a standard score sheet and tallied. The data were recorded according to American Society of Testing Material (ASTM) guidelines.[40] The total number of abnormal tadpoles divided by the total number of living tadpoles multiplied by 100 is the percentage malformed from each dish. The 96 h LC_{50} (concentration causing 50% lethality) and 96 h EC_{50} (concentration inducing malformation or gross malformations in 50% of surviving embryos) were calculated using probit analysis from Systat 13 software. The teratogenic index (TI) was calculated as the 96 h LC_{50} divided by the 96 h EC_{50} (malformation). The minimum concentration to inhibit growth (MCIG) was calculated using ANOVA with the post hoc Bonferroni test using Systat 13 software.

Individual Toxicity Experimental Design and Analysis (Acrylamide, Furan, and L-Cysteine). For concentration−response studies of toxic effects on embryos, four negative controls (4 replicates of 20 embryos in 60 × 15 mm Petri dishes) and various test concentrations (2 replicates of 20 embryos in 60 × 15 mm Petri dishes each) of chemical ranging 0.5 to 80 mM were tested. Each experiment was repeated three times. Each experiment used between 280 and 480 embryos. Previously tested acrylamide[34] had the fewest concentrations, as detailed experiments have previously been carried out as indicated by the total number of embryos for each test (Table 1). The furan and L-cysteine data were independent definitive assays as these chemicals had not been tested in the FETAX assay. The acrylamide experiments were the acrylamide positive controls for the interaction experiments. All data were analyzed according to FETAX methods above.

Interaction Experiments of Binary and Ternary Mixtures. On the basis of data from the individual experiments above, binary and trinary mixtures were calculated such that estimated ratios for mixtures could be created. For acrylamide/L-cysteine, the ratios attempted were 0TU:1TU, 1TU:0TU, 1TU:1TU, 1TU:3TU, 3TU:1TU, and 19TU:1TU. For furan/acrylamide and furan/L-cysteine, the ratios used were 0TU:1TU, 1TU:0TU, and 1TU:1TU. For acrylamide/furan/L-cysteine, the ratios used were 0TU:0TU:1TU, 0TU:1TU:0TU, 1TU:0TU:0TU, and 10TU:4TU:1TU. Once appropriate mixtures were made, they were tested with the standard FETAX to determine the 96 h LC_{50}, EC_{50}, and TI for each of the interaction ratios. For each clutch of embryos single-chemical toxicity measurements were taken to determine the clutch-specific 96 h LC_{50} for each individual experiment. Each mixture study was repeated two times.

Toxic Unit Conversion. A toxic unit (TU) is defined as the 96 h LC_{50} = 1 TU for mortality. Toxic unit conversion allowed for the two compounds to be normalized to toxicity and, thus, a correlation could be studied for mixtures. A hypothetical example calculation is shown below:

96 h LC_{50} for compound *X*: 1 mmol/L

96 h LC_{50} for compound *Y*: 2 mmol/L

96 h LC_{50} for a mixture containing a ratio of 1 mmol/L *X* : 2 mmol/L *Y* is (i.e., 1 TU:1 TU) 0.5 mmol of *X*: 1 mmol of *Y*

$$\text{TU of } X = [0.5 \text{ mmol/L (amount of } X \text{ in mixture)}]/[1 \text{ mmol/L } (LC_{50} \text{ of } X)] = 0.5$$

$$\text{TU of Y} = [1 \text{ mmol/L (amount of } Y \text{ in mixture)}]/[2 \text{ mmol/L } (LC_{50} \text{ of Y})] = 0.5$$

The toxic units add (0.5 + 0.5 =1) and would indicate concentration additive response.

The TU values for the each component of the mixture were plotted on an isobole diagram to demonstrate the interaction of the two compounds. Generally, such diagrams are divided into three major regions relating to the types of interactions possible: synergism, additive effects, and antagonism. The area of the graph below the diagonal line connecting 1 TU of axis *X* to 1 TU of axis *Y* shows increasing synergism as the points approach the origin. Concentration addition is indicated by the diagonal line connecting 1 TU of axis *X* to 1 TU of axis *Y*. Points found between the lines connecting 1 TU to 1 TU and within the squares formed by these two points from their respective axis show response additive interactions. Points outside this box indicate antagonistic interactions.

RESULTS

Controls. Each experimental trial contained 4 replicates of 20 embryos as controls. These 80 embryos represented the genetic effects of the clutch absent exposure to the compound of study. A 96 h control mortality >10% represents a poor-quality clutch. All control groups had <10% mortality at 96 h. Control malformations were within the range of 1.3−6.9% with an average of 3.9%, well below the 10% acceptable for FETAX. The average control lengths were between 0.93 and 1.13 cm. The control data indicate an acceptable test for the FETAX assay.

Individual Toxicity Experiments. L-Cysteine had an average 96 h LC_{50} of 41.85 mM and ranged between 34.14 and 49.01 mM (Table 1). The average 96 h EC_{50} (malformation) was 38.62 mM and ranged between 35.68 and 40.46 mM (Table 1). A typical concentration−response curve for L-cysteine (Figure 1) indicated a fairly sharp mortality curve. The malformation curve (Figure 1) indicates a threshold effect at around 15 mM but does not increase in effect even near mortality concentrations. The teratogenic index ranged from 1.0 to 1.2. There was considerable variability in the no observable effect concentration (NOEC), lowest observable effect concentration (LOEC), and minimum concentration to inhibit growth (MCIG) concentrations for L-cysteine. We observed tank effects where one replicate of a concentration would have 100% mortality and the other replicate, 0% mortality. Here were very few abnormalities (Chart 1B).

Furan had an average 96 h LC_{50} of 43.56 mM, which ranged from 37.92 to 53.94 mM (Table 1). Furan had an average 96 h EC_{50} (malformation) of 39.64 mM and ranged from 27.30 to 47.20 mM. The teratogenic index ranged from 0.8 to 1.2. A typical concentration response curve for a single experiment (Figure 2) showed both mortality and malformation curves increased in a consistent manner for furan. The vertical lines indicate the 96 h LC_{50} and 96 h EC_{50} values. The NOEC for malformation was consistently the lowest end point of 20 mM. A typical growth curve (Figure 2) indicated furan at 40 mM caused a significant decrease in length by approximately 90% of the 96 h LC value. Furan caused minor edema and tail abnormities (Chart 1C). The most interesting malformation was abnormal cell

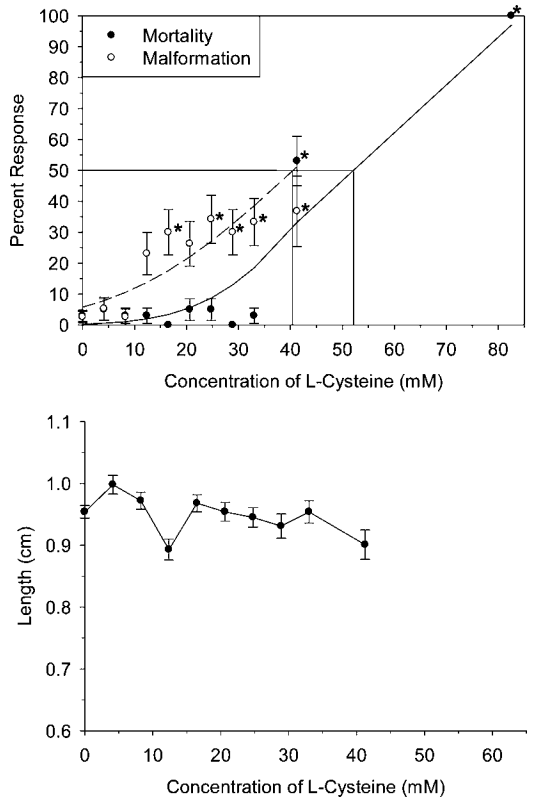

Figure 1. Dose–response mortality and malformation data for a representative trial of L-cysteine (top panel); change in embryo length in a representative trial with exposure to L-cysteine (bottom panel). Error bars are the standard error of the mean. (*) Significant differences from controls, $p \leq 0.05$. There were two replicates for each concentration; controls had four replicates. Regression lines (top panel) are PROBIT estimates. The line from the 50% effect indicates EC_{50} (malformation) and LC_{50} estimates.

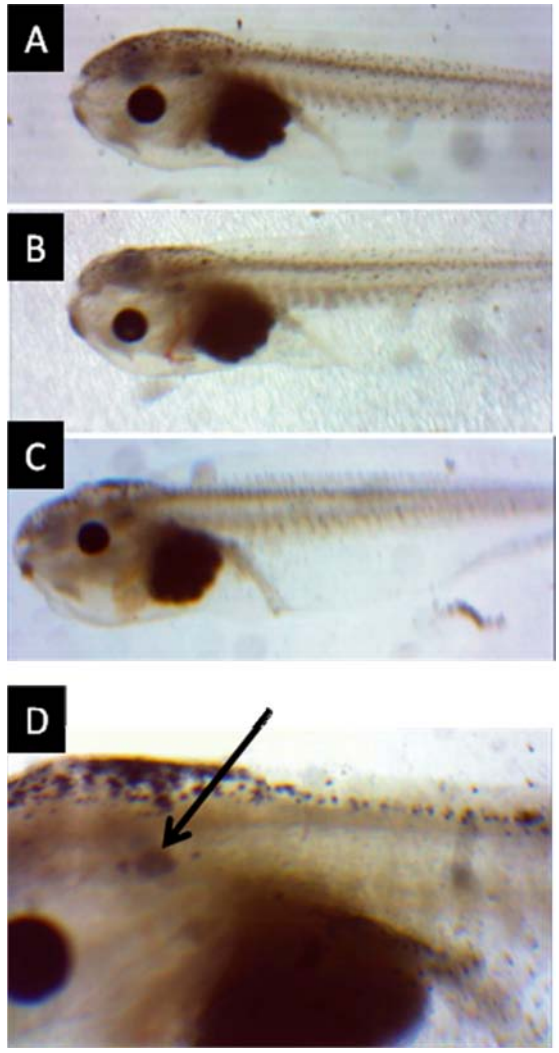
growth seen near the otic vesicle (Chart 1D). This was seen consistently, but at a low frequency (<20%).

The average 96 h LC_{50} for acrylamide was 1.890 mM and ranged from 1.466 to 2.136 mM (Table 1). The average 96 h EC_{50} (malformation) was 0.944 mM and ranged from 0.702 to 1.161 mM (Table 1). The teratogenic index ranged from 1.8 to 2.7 (Table 1). The mortality and malformation NOEC and LOEC were very consistent. The MCIG was often at the lowest concentration tested, 0.5 mM, and may indicate the MCIG may be lower. The high concentrations of acrylamide caused tail abnormalities and edema in the ocular, cardiac, and abdominal regions. Severe gut abnormalities were also observed (Chart 2C).

Binary Interaction Experiments. The 96 h LC_{50} and 96 h EC_{50} values for furan and L-cysteine (Tables 2 and 3) indicate that there were some differences between these clutches and clutches reported earlier (Table 1). These are the positive controls for the interaction experiments and used fewer concentrations because these were performed concurrently with mixture studies. In particular, L-cysteine seems to indicate less toxicity (higher 96 h LC_{50} values). The 96 h LC_{50} values for the interaction of furan with acrylamide and L-cysteine in Table 2 with 95% Fieller bound for each component indicate a good consistency. The TI showed the highest value for furan/acrylamide 1:1 mixture (Table 2). The TI for furan/L-cysteine interaction indicated a reduction of TI with the mixture. The interactions plotted on an isobole diagram showed furan/L-cysteine (1:1) points were near the concentration addition line

Chart 1. (A) Normal Control Larvae; (B) Typical Normal Larvae Found in 41 mM L-Cysteine; (C) Typical Malformation Found in 60 mM Furan Larvae; (D) Zoomed in Section of a 60 mM Furan Embryo Showing Abnormal Cell Growth near the Otic Vesicle



(Figure 3). Furan/acrylamide (1:1) shows points very close to the antagonism on the edge of response addition (Figure 3).

Furan/L-Cysteine Combinations. Interestingly, furan and L-cysteine have similar 96 h LC_{50} values in millimolar (Table 1). This means that the 1:1 TU interaction used had nearly identical concentrations of furan and L-cysteine for its 96 h LC_{50} values, furan/L-cysteine (37.10:36.320 and 24.75:25.69), as shown in Table 2. The TI values for both furan and L-cysteine and the mixtures were close to 1. The points on the isobole diagram (Figure 3) indicate that furan and L-cysteine are concentration additive as the open circles are close to the diagonal line indicating concentration addition. The 96 h EC_{50} (malformation) values showed the same pattern as the 96 h LC_{50} values. There were very few malformations, and they were not severe with very little edema and loose gut coiling (Chart 2B).

Furan/Acrylamide Combinations. The 96 h LC_{50} values for the furan/acrylamide mixtures were fairly close to one another. Furan was less toxic to the clutch of embryos on June 10, 2013. This reduction in toxicity was also seen in the 1:1 furan/acrylamide mixture. Interestingly, the two isobole points (solid

dx.doi.org/10.1021/jf5013743 | J. Agric. Food Chem. 2014, 62, 7927–7938

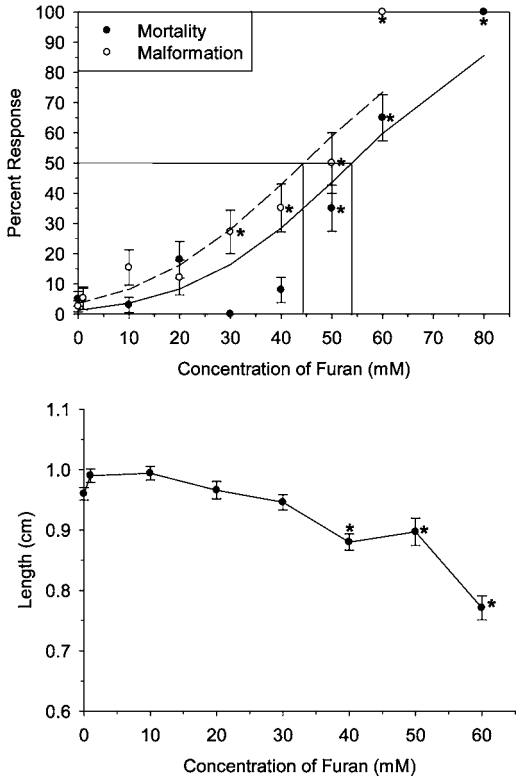


Figure 2. Dose−response mortality and malformation data for a representative trial of furan (top panel); change in embryo length in a representative trial with exposure to furan (bottom panel). Error bars are the standard error of the mean. (∗) Significant differences from controls, $p \leq 0.05$. There were two replicates for each concentration; controls had four replicates. Regression lines (top panel) are PROBIT estimates. The line from the 50% effect indicates EC_{50} (malformation) and LC_{50} estimates.

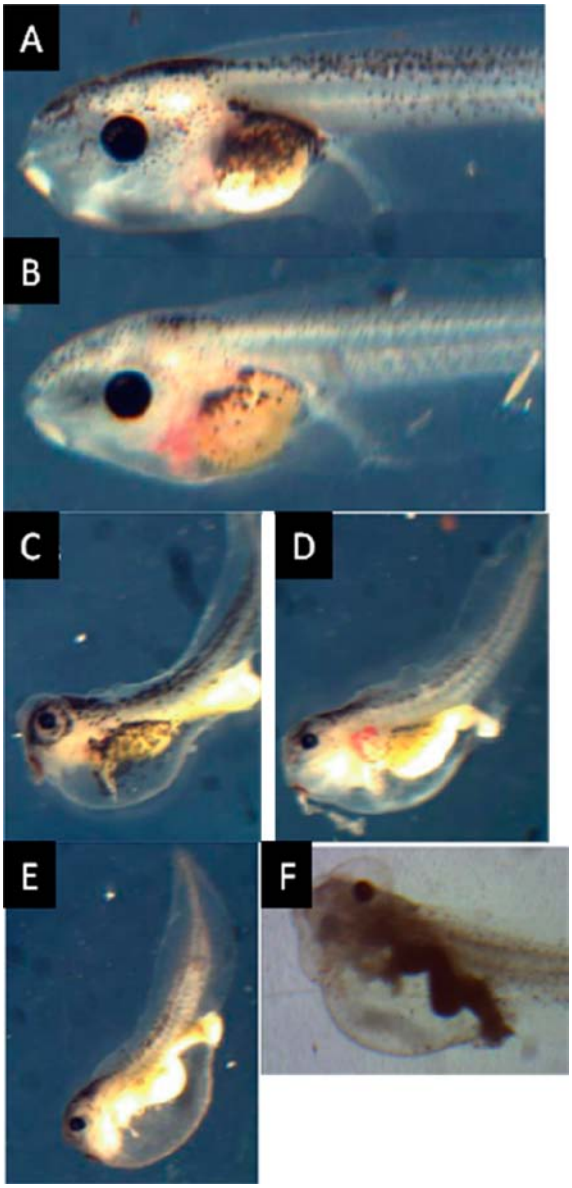
circles) in Figure 3 show a very close relationship, even with embryos that were responding differently. The furan/acrylamide mixture showed an increase in teratogenic index up to 5.1, indicating that this mixture would be more teratogenic than either furan or acrylamide alone. This also indicates that the interaction on the 96 h EC_{50} (malformation) is most likely different from for the mortality. Although there was increase in the TI, this mixture primarily showed acrylamide-like malformations, that is, notochord curving, with mortality appearing to be directly related to concentration addition (Chart 2E).

Acrylamide/L-Cysteine Combinations. Four different mixtures of acrylamide/L-cysteine were tested with increasing concentrations of acrylamide to L-cysteine ratios of 1:3, 1:1, 3:1, and 19:1 (Table 3; Figure 4). As the ratio of L-cysteine was reduced, the average 96 h LC_{50} value showed an increase in the amount of acrylamide (in the mixtures) from 0.663 mM (1:3) to 43.32 mM (19:1). The 96 h EC_{50} (malformation) also showed the amount of acrylamide increased from 0.742 (1:3) to 10.86 mM (19:1). The differences in the changes in the 96 h LC_{50} and 96 h EC_{50} (malformation) values in the 19:1 ratio of acrylamide/L-cysteine resulted in an increase in TI to an average of 4.3 (Table 3) for the 19:1 mixture. The isobole plots (Figure 4) showed the 19:1 ratio (open triangles) indicated a dramatic antagonism with low amounts of L-cysteine. The 1:3 acrylamide/L-cysteine ratio showed a response addition (solid circles), which indicates that acrylamide does not affect L-cysteine toxicity. As mixtures increase, the ratios of acrylamide to L-cysteine exhibit greater

Chart 2. (A) Normal Control Larvae; (B−F) Typical Abnormal Larvae at High Concentrations of the Following Treatments: (B) Furan/L-Cysteine (1:1); (C) Acrylamide; (D) Acrylamide/L-Cysteine (19:1); (E) Furan/Acrylamide (1:1); (F) Acrylamide/Furan/L-Cysteine (12:4:1)



antagonism as indicated by the progression of points. The typical malformations seen were edema, gut coiling, and tail abnormalities similar to those of acrylamide (Chart 2D).

Furan/Acrylamide/L-Cysteine Combinations. The clutches of embryos used showed consistency with individual experiments reported in Table 1 (Table 4). Furan and L-cysteine were slightly less toxic (96 h LC_{50} were higher) but were within approximately 2-fold range. The 96 h EC_{50} (malformation) did not show as much increase as the 96 h EC_{50} for furan, which caused furan to have a slightly increased TI of 1.4 (Table 4). The three-way (10:4:1) mixtures show high consistency between the two experiments (Table 4). The two experiments did not have malformations until very high concentrations were reached. This resulted in a very low average TI of 0.6 for the mixture and in a very high variability in the 96 h EC_{50} data. The malformations

seen were typical of acrylamide with facial and abdominal edema, tail abnormalities, and severe gut abnormalities (Chart 2F).

DISCUSSION

Individual Experiments. *Furan.* Furan average values for 96 h LC_{50} and 96 h EC_{50} (43.56, 39.64, respectivly) were relatively high. By comparison, in the fathead minnow, behavioral effects were reported in the 28−31 day juvenile fathead minnow test at concentrations a low as 1.044 mM.[49] This is most likely due to the short duration of the FETAX. In this assay, we were determining the relative risk of furan causing birth defects. Due to the low TI (0.8−1.4) and the lack of significant abnormalities (Chart 1D), furan appears to not be teratogenic in the FETAX test. However, we did note the development of abnormal cell growths in several embryos that may indicate tumor formation if the test had been longer. This would agree with mammilian studies that show furan-induced tumorigenicity.[50]

L-Cysteine. L-Cysteine toxicity was studied to compare toxic unit analysis of the three test compounds. These results indicate that L-cysteine had a very low TI between 1.0 and 1.2, suggesting little or no teratogenic potential from L-cysteine. Within the first 24 h, L-cysteine delayed hatching; however, growth data showed no inhibition of growth at 96 h. We did observe tank effects that seemed to be related to pH in individual Petri dishes. This proved challenging because the pH range for the study became very small. In agreement with the present study, other studies found that L-cysteine seems to be toxic and becomes unstable when exposed to neonatal rats.[51]

Interaction Experiments. *Furan/L-Cysteine.* Furan and L-cysteine showed very similar millinolar 96 h LC_{50} and 96 h EC_{50} (malformation) values in individual testing, with an average of 43.56 mM for furan compared to 41.85 mM for L-cysteine (Table 1). Some variability was seen in the clutches used for the interaction study. The two experiments with furan/L-cysteine indicated very close to concentration addition behavior, with one point falling below the diagonal line and the other falling above the line (Figure 3, open circles). The 95% confidence intervals indicated a normal amount of variability around these points. With the points being this close, either a concentration addition or response addition effect is expected for this mixture ratio (1:1). Because of the differences in the compounds, we believe that this is more indicative of a response addition rather than the two acting in a concentration manner. The similarities of the 96 h LC_{50} and EC_{50} may explain this. As malformations of both mixture compounds lean toward GI tract stunting, no conclusions could be made with as to which chemical was causing the malformation; most likely it was both. It seems that furan and L-cysteine show additive activities.

Furan/Acrylamide Combinations. The furan/acrylamide (1:1) mixtures were interesting in that the two points were very consistently right on the box formed by the 1 toxic unit for the *X* and *Y* axes (solid circles, Figure 3). This border is where response addition and potential antagonisms are indicated. Because it is possible that both chemicals can affect the same individual, if they were to do so almost exactly for both tests, these results would be expected. However, it is more likely this indicates a weak antagonism for this mixture. The TI values of 2.8

and 5.1 for the mixture of furan and acrylamide indicate this mixture is more teratogenic than acrylamide alone. This also indicates that the 96 h EC_{50} (malformation) altered differently from the 96 h LC_{50}, suggesting the mortalities and malformations were being caused by separate mechanisms. The malformations seen were predominantly those associated with acrylamide (Chart 2E). This may indicate that the effects on acrylamide toxicity may be indirect rather than a direct interaction of furan with acrylamide.

Acrylamide/L-Cysteine. Early experiments showed that L-cysteine reduced the toxicity and teratogenicity of acrylamide at a single concentration of acrylamide with an approximately equal molar amount of L-cysteine.[35] These experiments were to determine the effect of different ratios of acrylamide/L-cysteine based on toxicity units and how much protective effect could be measured. The acrylamide/L-cysteine ratios of 1:3, 1:1, and 3:1 are standardly used for experiments investigating interactions using isobole diagrams. The 19:1 acrylamide/L-cysteine combination was chosen because that would have been approximately equal molar concentrations as seen in the single-component experiments reported earlier. These mixtures show an increasing amount of antagonisms as the amount of L-cysteine is reduced, indicating that L-cysteine toxicity was being observed in the 1:3 mixture (solid circles). For the 19:1 acrylamide/L-cysteine combination, open triangles showed extreme antagonism at nearly 30 toxic units on the acrylamide axis even with the wide error bars. The change in TI was also unexpected, increasing to nearly 5 in the 19:1 acrylamide/L-cysteine mixture. This again indicates separate mechanisms from the mortality end point. As expected, all of the abnormalities seen were very similar to those caused by acrylamide (Chart 2D).

Acrylamide/Furan/L-Cysteine Mixture. The three-way mixture was tested at a 10:4:1 ratio of acrylamide/furan/L-cysteine to determine if the binary mixtures could predict the toxicity of the trinary mixture. On the basis of the binary mixtures we would expect to see severe antagonism based on the 19:1 acrylamide to L-cysteine mixture. Two surprising events occurred with the trinary mixture. First, instead of severe antagonism, a minor antagonism (black dots Figure 5) seems indicated. The expectation was for the sample points to be within the green line, indicating antagonism. Although they are close, it does not appear to be as antagonistic as expected. The second surprise was the change in TI to <1 (Table 4). With both L-cysteine and furan

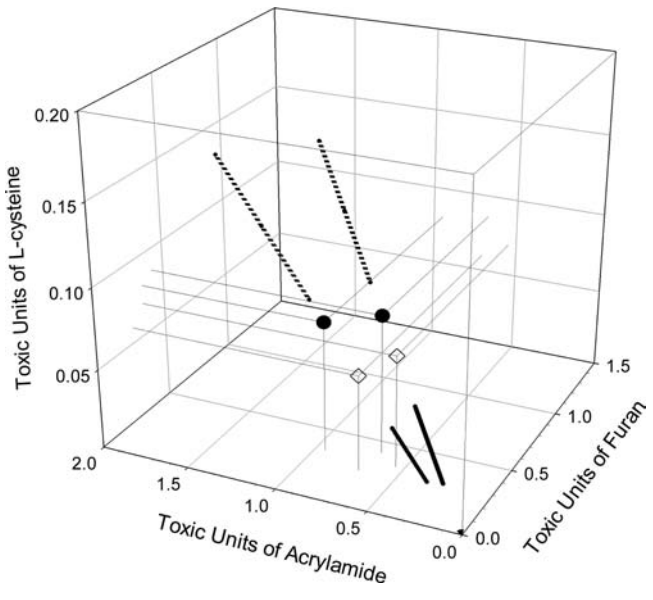

Figure 5. Three-way toxic unit comparison of furan, acrylamide, and L-cysteine. Experimental values are represented by black circles. For purposes of comparison, calculated synergism is indicated by solid lines, calculated concentration response addition by open diamonds, and calculated antagonism by dashed lines.

dx.doi.org/10.1021/jf5013743 | J. Agric. Food Chem. 2014, 62, 7927−7938

(Tables 2 and 3) there is an increase in TI with added acrylamide. These results imply that an interaction in metabolic pathways between acrylamide and furan adversely affects the beneficial effects of L-cysteine.

Mechanistic Aspects. *Acrylamide.* In vivo, cytochrome P-450 enzymes transform acrylamide to the reactive epoxide glycidamide, which can react with free NH_2 and SH functional groups of hemoglobin, enzymes, and DNA and lead to carcinogenesis, teratogenesis, and neurotoxicity. The protein adduct and DNA adduct chemistry of acrylamide and related conjugated vinyl compounds offers a mechanistic explanation and insight into the pathogenesis of certain human neurodegenerative diseases.[52,53] Nucleophilic SH-containing compounds such as L-cysteine and reduced glutathione might prevent the in vivo alkylations by reacting with (blocking) the electrophilic (double bond and epoxide) sites of acrylamide and glycidamide, as illustrated in Figure 6A. The detailed

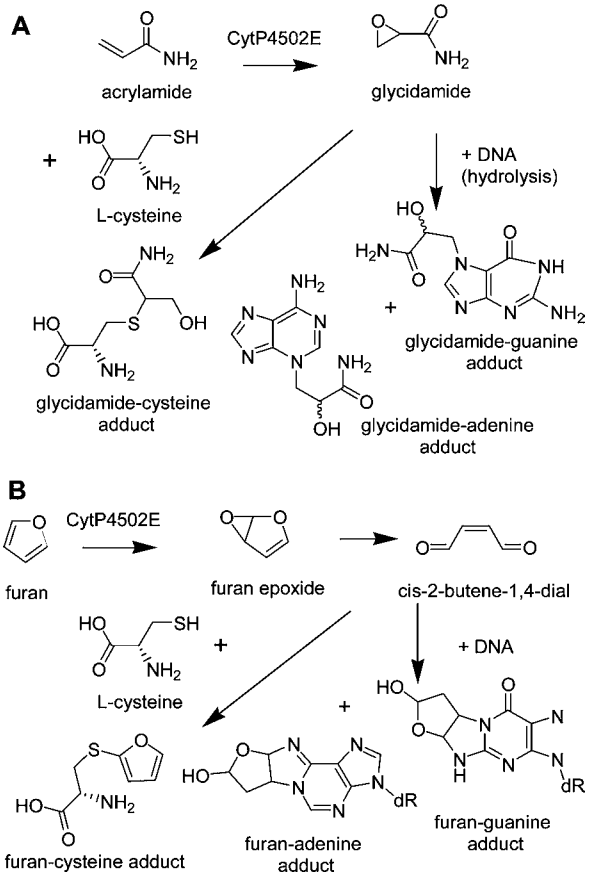

Figure 6. Comparison of biological alkylations of L-cysteine and DNA by acrylamide and furan via epoxide intermediates. Adapted from refs 10, 14, 16, 35,57, and 66−70.

chemistry of these transformations is extensively discussed elsewhere.[14,16] It is relevant to note that the human liver carcinogen aflatoxin B_1 that is present in some foods is also reported to react with DNA NH_2 groups via a reactive epoxide intermediate and that L-cysteine inhibited its toxicity.[54]

Furan. Furan is also metabolically activated by cytochrome P-450 to the reactive and toxic metabolite *cis*-2-butene-1,4-dial (O═CH—CH═CH—CH═O), which can form adducts with proteins and nucleic acid residues of DNA as illustrated in Figure 6B. The indicated chemical changes have been postulated to cause the observed genotoxicity and hepatocarcinogenicity.[1,10,23,29,30,55−59] As far as we know, unlike acrylamide, furan does not seem to be neurotoxic. The results of the present study show that it also does not seem to be teratogenic in the ex vivo frog embryo teratogenesis assay. Why these two biological alkylating agents induce different pathogenesis is not known. Moreover, it is also not known if the combined consumption of acrylamide and furan that may be present in heat-processed foods (Table 1) will act additively or synergistically in inducing liver carcinogenesis and whether the reported >3-fold up-regulation by furan compounds of oxidoreductases in *Escherichia coli* bacteria[60] also takes place in humans.

SUMMARY AND RESEARCH NEEDS

The amino acid L-cysteine, commercially used as a dough additive to improve rheology by rearranging the structure of gluten proteins via sulfhydryl−disulfide interchange and to increase bread volume after baking,[61,62] seems to continue to act as an inhibitor of malformations in the three-component mixture. However, the sum effect of these compounds leads to higher mortality than the two-compound mixtures would imply. The interactions indicate several conclusions: (a) L-cysteine is highly effective in inhibiting acrylamide toxicity at very low concentrations of L-cysteine to acrylamide, in particular, the reduction of severe acrylamide malformations (i.e., edema, facial, and gut coiling); even at very high concentrations of acrylamide the beneficial effect was dramatic; (b) L-cysteine seems to interact in a response addition with furan; (c) acrylamide and furan appear to have a less than additive response (antagonism); and (d) the activity of the three-component mixture of acrylamide, furan, and L-cysteine was similar to that of the binary mixture of acrylamide and furan, without nearly as much antagonism as seen with acrylamide and L-cysteine alone. This result demonstrates the weakness of two-compound mixtures.

More complex interactions may occur with the addition of another degree of complexity, but the added degree of complexity also makes it difficult to observe the consequences of complete interactions among the components of the mixture. It seems that toxicities observed from furan and acrylamide individually may not be able to predict toxicities of mixtures; specific combinations found in different foods need to be tested to assess the safety of a particular set of processing conditions (processing treatments including cooking, pressure cooking, slow cooking, baking, frying, microwaving, grilling, roasting, and sautéing).

We found that for acrylamide alone, the lowest toxic dose for the frog embryos was ~0.7 mmol/L or ~49.8 μg/L. However, an attempt to relate these concentration exposures of the embryos to human dietary intake is difficult, in view of reported wide variation in the consumption of acrylamide by different populations. For example, Wong et al.[63] found that the mean and the 95th percentile exposure to dietary acrylamide of the Hong Kong population were 0.213 and 0.538 μg/kg, respectively, and the Joint FAO/WHO Expert Committee on Food Additives[64] concluded that whereas the average consumer daily intake was on the order of 1 μg/kg body weight, high acrylamide consumer intake was 4 times higher, or ~240 μg for a person weighing 60 kg. The situation is even more complicated because of adverse effects induced with increasing concentrations. Thus, Obón-Santacana et al.[65] observed increasing relative risk for type I endometrial cancer in a set of women with increasing acrylamide intake, with an upper quintile median of 44 μg/day. Our results indicate that L-cysteine has the potential to

overcome adverse effects in individuals consuming the indicated amounts of acrylamide.

Continuing these trials to discover the limit of inhibition between L-cysteine and acrylamide might be valuable, but the scale seen here may already limit the need. The three-component study analyzed here forms the basis for a novel quantitative method of addressing interactions among bioactive naturally occurring and processing-induced food ingredients. More research is needed to determine how to best use the data. We reported similar conclusions on the interaction results of two potato glycoalkaloids, α-chaconine and α-solanine, obtained with the aid of FETAX.[45] Whether folic acid and glucose-6-phosphate, which protected the frog embryos against α-chaconine-induced malformations, would also protect the embryos against acrylamide-induced teratogenicity also merits study. A largely unexplored area is the content of both acrylamide and furan in the same processed food.

Table 1. Screening of Various Tetrazolium Dyes for Suitability for Detecting Caffeine Using Cdh

Tetrazolium dyes	Reduction with Cdh and Caffeine [a]		Background Color [b]	Retail price from Sigma (in $/ mg)[c]
Iodonitrotetrazolium Chloride (INT)	Yes	Dark Red	No	0.042
Tetrazolium Blue Chloride (TB)	No		No	0.018
Thiazolyl Blue Tetrazolium Bromide (MTT)	Yes	Dark Blue	Yes	0.071
Tetrazolium Violet (TV)	No		No	0.036
Nitro Blue Tetrazolium (NBT)	Yes	Purple	Yes	0.170
Tetranitro blue Tetrazolium Chloride (TNBT)	Yes	Black	Yes	0.362

[a]Screening was performed with 8−10 U (40−50 μg) of Cdh and 100 ppm caffeine per assay as described in the Materials and Methods. The incubation time was 30 min to differentiate between various dyes. [b]Color of the dye in potassium phosphate buffer (pH 7.5) without addition of the test sample and enzyme. [c]The price calculation is based on the largest pack size available to get the lowest price from www.sigmaaldrich.com. Respective product catalog numbers are I10406-25G, T4375-25G, M2128-10G, T0138-10G, N6876-5G, and T4000-1G (accessed March 24, 2014) .

Several attempts have been made to develop a suitable assay for caffeine detection and/or measurement.[28−36] However, none of these tests meet the attributes required for a suitable diagnostic test, such as speed of detection, ability to detect in commercial/natural fluids, and sensitivity of detection. In the present work, we report a novel enzyme, caffeine dehydrogenase (Cdh), which is highly suitable for detection of caffeine and potential development of a diagnostic test. In the presence of a tetrazolium dye such as INT, Cdh is able to detect caffeine in less than 1 min with a sensitivity of 1−5 ppm. In addition, this enzyme-based test is able to detect decaffeinated beverages instantly. Spiked caffeine as low as 5−20 ppm can be detected in mother's milk with no interference from milk components. Last, but not least, caffeine can be detected quantitatively in pharmaceuticals, nearly matching the reported values as detected by high-performance liquid chromatography (HPLC).

MATERIALS AND METHODS

Chemicals and Test Samples. Caffeine, DNase I, iodonitrotetrazolium chloride (INT), tetrazolium blue chloride (TB), tetrazolium blue tetrazolium bromide (MTT), tetrazolium violet (TV), nitro blue tetrazolium (NBT), and tetranitro blue tetrazolium (TNBT) were purchased from Sigma-Aldrich (St. Louis, MO). Yeast nitrogen base without amino acids and without ammonium sulfate (YNB) was purchased from ForMedium (Norfolk, U.K.). HPLC-grade methanol and acetonitrile were obtained from Sigma-Aldrich. Coffee, soft drinks, and pharmaceuticals were obtained from local outlets. Nursing mother's milk was obtained from the Mother's Milk Bank of Iowa (University of Iowa Children's Hospital).

Media and Growth Conditions. Strain CBB1 was grown in M9 mineral salts medium[37] with 2.5 g/L caffeine and 4 g/L YNB at 30 °C with shaking at 200 rpm. Cell growth was monitored by measuring the optical density at 600 nm (OD_{600}). Cells were harvested at late log phase by centrifugation (13800*g* for 10 min at 4 °C) as described by Yu et al.[37] Cell pellets were washed twice with 50 mM potassium phosphate (KP_i) buffer (pH 7.5) and frozen at −80 °C until required.

Purification of Caffeine Dehydrogenase from *Pseudomonas* sp. CBB1. All purification procedures were performed at 4 °C using an automated fast protein liquid chromatography system (AKTA Design, Amersham Pharmacia Biotech) as described by Yu et al.[37] Chromatography columns and column resins were from Amersham Biosciences, Piscataway, NJ. An Amicon Ultra-15 (30K) ultrafiltration membrane (Millipore, Bedford, MA) was used for concentration and buffer exchange of the protein fractions containing caffeine dehydrogenase activity. About 8 g of frozen cells were thawed and suspended in 30 mL of 50 mM KP_i buffer (pH 7.5), and DNase I was added to a final concentration of 10 μg/mL. The cells were lysed using a chilled French press in two cycles at 138 MPa. Unbroken cells and debris were removed from the lysate by centrifugation (20400*g* for 20 min at 4 °C), and the supernatant was designated the crude cell extract (CCE). A 4.0 M solution of ammonium sulfate was added dropwise to the CCE to obtain a final ammonium sulfate concentration of 0.8 M with constant stirring. After incubation with shaking on ice for 1 h, the mixture was centrifuged at 20400*g* for 20 min at 4 °C to remove precipitated proteins. The supernatant was loaded onto a 40 mL (bed volume) Phenyl Sepharose high-performance column (Amersham) preequilibrated with 50 mM KP_i buffer (pH 7.5) containing 0.8 M ammonium sulfate. Unbound proteins were washed from the column with 40 mL of 50 mM KP_i buffer containing 0.8 M ammonium sulfate. Bound proteins were eluted with a 200 mL reverse gradient of ammonium sulfate (0.8−0 M in KP_i buffer) at a rate of 1 mL/min. The column was then washed with 40 mL of 50 mM KP_i buffer (pH 7.5), followed by 40 mL of water at the same flow rate, to elute hydrophobic proteins tightly bound to the column. Fractions containing caffeine dehydrogenase were identified by the spectrophotometric enzyme activity assay as described below. Caffeine dehydrogenase was eluted from the column during the final wash step with water. The protein concentration was determined by Bradford[38] using bovine serum albumin (BSA) as the standard with a dye reagent purchased from Bio-Rad.

Enzyme Assays. A spectrophotometric activity assay based on caffeine-specific reduction of NBT was developed to monitor the purification of caffeine dehydrogenase as described by Yu et al.[37] A typical 1 mL reaction mixture contained an appropriate amount of enzyme (usually 1−10 μg), 0.5 mM caffeine, and 0.5 mM NBT in 50 mM KP_i buffer (pH 7.5). Caffeine dehydrogenase activity was determined by monitoring with a UV/vis spectrophotometer (Shimadzu UV-2450) the increase in absorbance at 566 nm (extinction coefficient of 15 500 M^{-1} cm^{-1}) due to formazan production. One unit of enzyme activity was defined as reduction of 1 nmol of NBT/min at 25 °C and pH 7.5. All colorimetric assays in 96-well plates were carried out at room temperature and 400 rpm. The final reaction volume of 200 μL/well contained 0.5 mM tetrazolium dye in 50 mM KP_i buffer (pH 7.5). Reaction was started with addition of the appropriate amount of enzyme.

Analytical Procedures and Test Sample Preparation. Identification and quantification of caffeine in test samples was conducted with a Shimadzu LC-20AT HPLC system equipped with an

SPD-M20A photodiode array detector and a Hypersil BDS C18 column (4.6 by 125 mm) as described by Yu et al.[39] A 20% methanol/80% water/0.5% acetic acid (20:80:0.5, v/v/v) mixture was used as the isocratic mobile phase with a flow rate of 0.5 mL/min. Prior to testing of the drugs, one tablet from each of the listed pharmaceuticals (Table 2) was powdered separately, dissolved in 50 mM KP_i buffer (pH 7.5), and diluted appropriately to bring the caffeine concentration range to 5−50 ppm. Correspondingly, a reference color chart was prepared using 50 mM KP_i buffer (pH 7.5) by spiking known concentrations of pure caffeine purchased from Sigma Chemicals and developing the shades of red color using the Cdh-based detection test in the range of 0−50 ppm. The caffeine concentration in the diluted samples was determined in triplicate using HPLC as described previously.[39] The coffee extract used in the validation test was obtained by boiling 10 g of coffee powder for 10 min with 200 mL of deionized water and filtering using filter paper. The HPLC method was employed to determine the caffeine content in the extract, in soft drinks, and in pharmaceutical samples.

RESULTS

Testing Various Tetrazolium Dyes for the Best Visual Suitability. Several commercially available tetrazolium dyes were screened as electron acceptors in Cdh-based caffeine detection. Two critical attributes were (i) rapid reduction in the presence of Cdh and caffeine to give a bright-colored product and (ii) low or no background (minimum nonenzymatic reduction). Six tetrazolium dyes were tested at 0.5 mM as described in the Materials and Methods. As shown in Table 1, the enzyme in the presence of caffeine reduced all dyes except TB and TV. Of the four dyes that showed activity, MTT and TNBT showed a strong background color (Table 1), which made it difficult to distinguish between reaction and no reaction (data not shown). On the other hand, INT had no background color and produced shades of light pink to dark red proportional to the caffeine concentration. NBT upon reduction produced shades of dark blue to dark purple which were readily distinguishable from the light yellow background color. INT was found to be the most suitable dye for Cdh-based detection of caffeine. It also was the lowest priced dye (Table 1). NBT was chosen as a backup for INT. Previously, a 1:1 stoichiometry between caffeine and tetrazolium dye was established (Figure 1).[37] Hence, the dye concentration was fixed at 0.5 mM. This ensured that the dye-dependent color formation was not the limiting factor for caffeine detection.

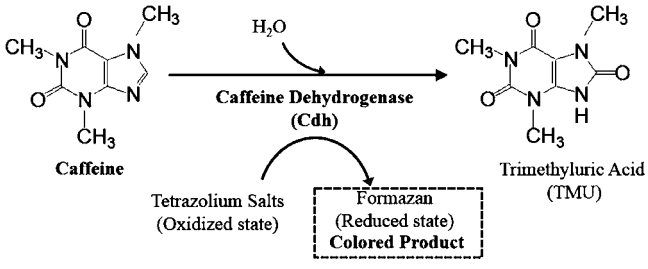

Figure 1. Reaction catalyzed by Cdh: oxidation of caffeine to TMU with concomitant reduction of tetrazolium dyes to formazans.

Cdh Required for Detection of Caffeine in 1 min. It is important that the Cdh-based detection of caffeine produced a visible color fast, i.e., within 1 min, at the lowest detection limit of caffeine. In applications such as detection of caffeine in breast milk, 5 ppm is deemed as the safe upper limit on the basis of the assumption that a mother consumes 500 mg of caffeine (100 mg higher than the safe upper limit set by the FDA for adults/day[25] and about 1−1.5% of it partitioning into breast milk in 1 h).[39] Hence, 5 ppm caffeine was fixed as the lower limit for detection at varying enzyme load, and the corresponding time required for maximum color development was determined (Figure 2). As expected, increasing the enzyme load decreased the time required for color development exponentially (Figure 2). On this basis, for maximum color development within a threshold of 1 min, the minimum enzyme load for the present study was fixed at 20 U. While this enzyme load is adequate for further validation of Cdh-based caffeine detection in a microtiter plate, the actual enzyme load in a commercial diagnostic kit may have to be higher to compensate for loss of activity due to (i) immobilization of Cdh in a test strip, (ii) formulation of the enzyme, and (iii) shelf life of the enzyme and the dye. These parameters will have to be further optimized during the development of a commercial diagnostic kit, such as a dipstick test. The color development in a diagnostic kit with a threshold detection of 1 min should also be independent of the caffeine concentration in the test sample. This will also demand a higher enzyme load than 20 U.

First-Level Attributes for Cdh-Based Caffeine Detection. The first-level attributes for further validation of the test with real-world samples (caffeinated and caffeine-containing beverages, nursing mother's milk, and pharmaceuticals) were set as (i) a minimum enzyme load of 20 U Cdh, (ii) INT as the dye due to no background color, (iii) an optimal dye concentration of 0.5 mM (equal to 97.1 ppm), (iv) visible pink color at 5 ppm caffeine to readily differentiable shades of red at 20, 100, and ≫100 ppm, and (v) a threshold time of 1 min for detection. The above conditions were used for caffeine detection in various samples in a 96-well microtiter plate in a total reaction volume of 200 μL.

Validation of Cdh for Caffeine Detection: Color Development at 5 ppm Caffeine (Lowest Limit). As discussed previously, 0−5 ppm was designated as the safe range for caffeine in breast milk on the basis of FDA guidelines and the literature.[25,40] Thus, the lowest detection limit for the Cdh-based test should be 5 ppm. The color development for the Cdh-based test in buffer at 1 ppm caffeine is shown in the inset of Figure 2. A light pink color is clearly distinguishable within 1 min of reaction time at a level lower than the safe limit of caffeine. There is no background in the control where caffeine is absent. These results establish that the Cdh-based test can detect caffeine as low as 1 ppm within the threshold time. Thus, detecting caffeine at 5 ppm should not be a limitation. However, this result needs to be validated with "real-world samples". These samples are different in that they are finished products in complex formulations. Detection of caffeine in buffer under optimized conditions may not translate to the commercial samples. Interfering components in the formulations, the pH of the test solution, and the background color of the test sample (such as cola, coffee, milk, etc.) are some of the issues. Hence, for further validation of Cdh for caffeine detection, three different categories of commercial samples were chosen. These include (i) pharmaceuticals formulated with caffeine, (ii) caffeinated and caffeine-free beverages, and (iii) milk samples, including breast milk (spiked with caffeine).

Estimation of Caffeine in Pharmaceuticals. The first validation for Cdh-based detection of caffeine was done with pharmaceuticals containing caffeine. Caffeine is added in the final formulation of a number of drugs, although it is not an active ingredient in most of these drugs.[41] Thus, estimating the caffeine in pharmaceuticals would be an excellent validation of

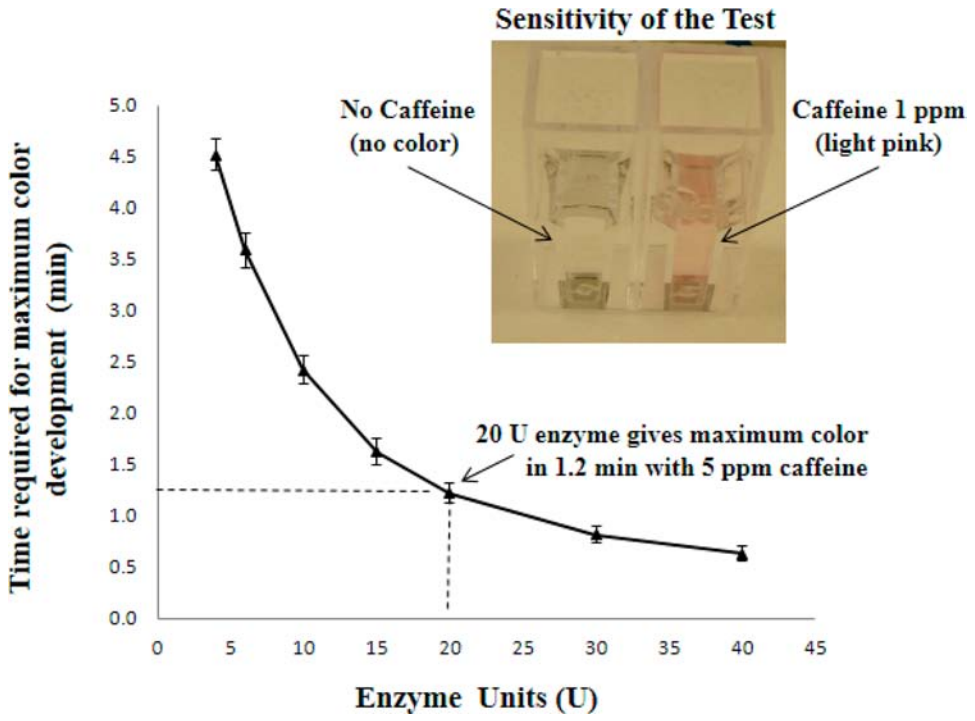

Figure 2. Cdh assay with varying amounts of enzyme at a fixed concentration of caffeine (5 ppm). Inset: color development with Cdh at 1 ppm caffeine. The control reaction on the left has no caffeine, only INT. The color development time was 1 min.

Table 2. Validation of Cdh-Based Caffeine Estimation for Six Pharmaceuticals[c]

Name of the Drug	Manufacturer Specified Caffeine amount per tablet (in mg)	Caffeine after dilution (in ppm)[a]	As determined by (in ppm)		Color developed by Cdh-based test (in triplicate)
			HPLC	Cdh-based Test[b]	
Diurex (Diuretic)	50	25	25.1 ± 0.1	30	
Menstrual Relief (Pain Reliever)	60	30	29.7 ± 0.3	30	
Vanquish (Pain Reliever)	33	33	31.2 ± 0.6	30	
Midol (Pain Reliever)	60	6	5.7 ± 0.2	5	
Excedrin (Pain Reliever)	65	6.5	5.6 ± 0.4	5	
Vivarin (Stimulant)	200	20	19.4 ± 0.7	20	
Color Reference Chart (Caffeine Concentration in ppm)			0	5 10 20 30 40 50	

[a]Sample preparation and dilutions were done as described in the Materials and Methods. [b]The test was carried out with 20 U of Cdh per assay in potassium phosphate buffer (pH 7.5) at room temperature (22 °C). Approximate value estimated by visually comparing the color obtained within 1 min (last column) with the reference color chart with various concentrations of spiked caffeine in 50 mM KP_i buffer (pH 7.5) (last row). [c]A reference color chart for caffeine concentration in the range of 0−50 ppm is shown at the bottom of the table.

the suitability of Cdh toward development of a diagnostic test. Caffeine concentrations in the drug formulations are given in the label. This was further confirmed by HPLC before estimation of the caffeine levels in these drugs using Cdh. Six commercially available pharmaceuticals were chosen, namely, Diurex (a diuretic), Menstrual Relief, Vanquish, Midol, and Excedrin (pain relievers), and Vivarin (a stimulant). After appropriate dilution, the caffeine concentration was measured in triplicate in these pharmaceutical samples using Cdh (last column in Table 2). A reference chart was created with standard caffeine at various concentrations, to visibly determine approximate caffeine levels in the pharmaceutical samples. As shown in Table 2, the caffeine concentration from the Cdh test matched reasonably with the HPLC estimates. The Cdh test gave credible estimations in the range of 5−50 ppm. The components in the drug formulations did not interfere with Cdh for color development. Also, color development was within the threshold time of 1 min.

Determination of Caffeine in Commercial Beverages (Coffee and Soft Drinks). The second validation of Cdh for caffeine diagnosis was performed with beverages such as coffee and soft drinks and their decaffeinated counterparts. For this, two sets of caffeine-containing beverages were selected. Set 1 was regular coffee from Dunkin' Donuts, 50% decaffeinated

Table 3. Cdh-Based Caffeine Detection: Validation Using Various Caffeinated and Noncaffeinated Beverages

Type of Beverage	Manufacturer specified caffeine content (ppm)[a]	As determined by HPLC (ppm)[b]	Cdh-based caffeine Detection Test
Coffee			Blank[c] Assay
Dunkin Donut (Regular)	NA	601.6 ± 21.4	
Folgers (50% Decaffeinated)	NA	331.6 ± 5.9	
Dunkin Donut (Decaffeinated)	NA	20.4 ± 1.3	
Soft Drinks (Caffeine free vs Regular)[d]			Caffeine Free Regular
Coca-Cola	96.4	83.3 ± 4.2	
Pepsi	107	96.1 ± 5.6	
Mountain Dew	152	142 ± 9.4	

[a]Powdered coffee from Dunkin' Donuts and Folgers does not have the manufacturer-specified caffeine content in the label. [b]Caffeine values reported for coffee are based on brewing methods described in the Materials and Methods followed by analysis with HPLC in triplicate. [c]Dye (in buffer) added to the sample without enzyme. [d]For soft drinks, the caffeine contents are based on the manufacturer's specifications and HPLC analysis.

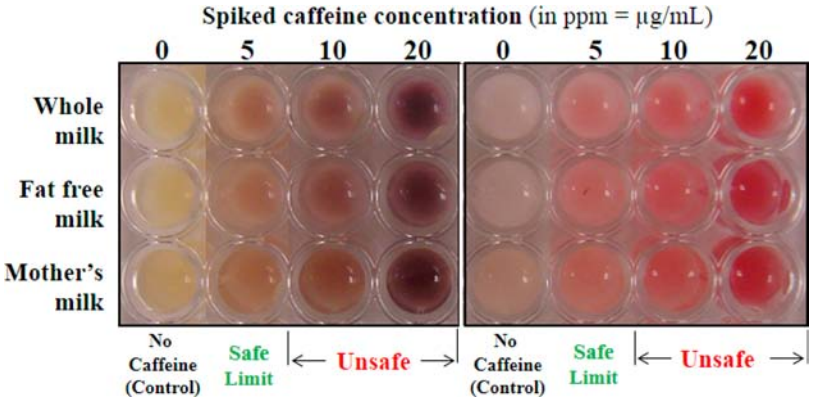

Figure 3. Cdh-based detection of caffeine in 1 min, with milk samples spiked with the alkaloid as indicated. Commercially available whole milk and fat-free milk were used for the test. Nursing mother's milk was obtained from the Mother's Milk Bank of Iowa, University of Iowa Children's Hospital. The left panel is the NBT-based test and the right panel the INT-based test.

coffee from Folgers, and decaffeinated coffee from Dunkin' Donuts, with caffeine concentrations of about 600, 330, and 20 ppm, respectively (Table 3). Set 2 was regular Coca-Cola with a caffeine concentration of 96.4 ppm, caffeine-free cola (zero caffeine), regular Pepsi with a caffeine concentration of 107 ppm, caffeine-free Pepsi, regular Mountain Dew with a caffeine concentration of 152 ppm, and caffeine-free Diet Mountain Dew (Table 3). The caffeine content of soft drinks from the label on the cans is also shown in Table 3. The caffeine content on the label and that determined by HPLC were comparable (Table 3). Beverages listed in Table 3 were analyzed for caffeine using Cdh. The objective here was qualitative, i.e., to differentiate among the presence, the absence, and a low level of caffeine in decaffeinated coffee. The fact that many of these beverages have a background color was a concern; caffeine-dependent color formation should still be readily differentiable relative to the background. The results of the Cdh test with the beverages are shown in Table 3. There was intense color production with caffeinated and 50% decaffeinated coffee (Table 3). In contrast, the color was light with decaffeinated coffee (~20 ppm caffeine). The background color of the coffee extracts did not interfere with Cdh in terms of clearly and instantly differentiating decaffeinated beverages from their caffeinated counterparts. Interestingly, the color is distinguishably lighter in 50% decaffeinated coffee (330 ppm caffeine) relative to regular coffee (600 ppm caffeine), although the commercial relevance of this is not clear. Ingredients present in these beverages such as sugar, added chemicals, coloring agents, etc. did not interfere with the Cdh-based test. These results further affirmed that Cdh is highly suitable and robust toward developing a diagnostic test and can quickly differentiate caffeinated drinks from decaffeinated or noncaffeinated counterparts. This test could be very useful to avoid human errors in restaurants and other outlets when all these beverages are served in nonlabeled cups.

Detection of Caffeine in Breast Milk. Cdh-based caffeine diagnosis would be of great value for rapidly detecting caffeine levels in nursing mother's milk. Caffeine is highly restricted for

Table 4. Comparison of the Attributes of Reported Caffeine Detection Methods with Those of Cdh-Based Caffeine Detection

	attribute				
detection method	in situ	time of detection	sensitivity	method of detection	commercial availability
bacterial cell based[28]	no (DO probe)	>3 min	100 ppm	digital	no
lipid polymer membrane based[31]	no (electrode)	<30 s	NA[a]	digital	no
fluorescent dye based[32]	yes (test strips)	20 min	100 ppm	visual (green)	no
enzyme based[29]	yes (test strips)	NA	NA	digital/visual	no
antibody based (FPIA)[34]	no	2 min	parts per billion	digital	not applicable
antibody based (D+Caf)[43]	yes (test strips)	<60 s	112 ppm	visual (blue)	discontinued[b]
Cdh enzyme based (current work)	yes	<60 s	1−5 ppm	visual (pink to shades of red)	work in progress

[a]Data not available. [b]Does not work with milk and sugared drinks. The test has to be done before addition of milk and sugar to coffee.

pregnant women and infants as documented earlier.[25,26] The potential teratogenic effect of excess caffeine on infants was also documented.[27] Hence, Cdh-based caffeine detection was tested with various milk samples spiked with caffeine. Milk is a complex mixture of proteins, fat, sugars, and other ingredients, including calcium and vitamin D. In addition, nursing mother's milk has immunoglobulins, metal ions, cofactors, hormones, and other biochemicals. The present test must not have any interference from these components. The results of the Cdh-based caffeine detection with various milk samples (spiked with caffeine) are shown in Figure 3. For this specific test, both INT and NBT were used, assuming that there might be nonspecific reduction of one or both dyes due to metal ions and other biological components in milk. The Cdh-based test scored very well in all the tests. Both dyes were able to differentiate no caffeine (0 ppm) and a safe level (5 ppm) and unsafe levels (>20 ppm) of caffeine (based on FDA regulations) in all milk samples, especially mother's milk. The complex components in the milk did not interfere with caffeine detection and the rapidity of color development. Clearly, the test is suitable to determine if the caffeine level is safe before an infant is nursed. There is a light background color in nursing mother's milk with the INT dye at "0" caffeine (Figure 3). This might be due to very low level reduction of the dye by milk components in this specific sample. Nevertheless, this does not interfere with the speed or the ability of Cdh to determine the safe and unsafe levels of caffeine in milk.

DISCUSSION

Need for a Caffeine Diagnostic Test. Caffeinated drinks and other products are growing in number and caffeine content in the form of energy drinks and even items such as chewing gum and jelly beans that children consume. This unregulated growth of caffeinated products has caught the FDA's attention and has also resulted in a move toward regulating caffeinated products.[21,22] In addition, the FDA has set guidelines for caffeine consumption for normal adults and pregnant women;[25] guidelines/restriction limits for infants and teenagers are currently under consideration by the FDA.[22] Thus, there is a real need for a rapid diagnostic test at the consumer level. Several attempts, using different approaches, have been made to develop caffeine detection/diagnostic tests and are compared in Table 4.

Caffeine Dehydrogenase, an Ideal Candidate for Caffeine Detection. Cdh (EC 1.17.5.2; systematic name caffeine:ubiquinone oxidoreductase) catalyzes the first step of caffeine degradation via the C-8 oxidation pathway.[37,42] It is non nicotinamide adenine dinucleotide (NAD) dependent, but needs a stoichiometric amount of an electron acceptor such as NBT or quinone (Q_0) as an electron sink.[37] The enzyme is easily purified for caffeine detection and potential development of a diagnostic test. The optimized procedure gave a 48.6% yield with a specific activity of 210 units/mg of protein. Previously, Cdh was shown to be highly specific for caffeine with a K_m of 3.7 ± 0.9 μM, with a 50-fold less preference for the closest analogue theobromine and very slight or no activity with other di- and monomethylxanthines and xanthine.[37] Thus, none of these compounds interfered with the color development with caffeine in 1 min (data not shown). The enzyme is robust in terms of activity at temperatures ranging from 15 to 60 °C with a linear increase in activity with temperature.[37] This makes the enzyme suitable for measuring the caffeine content in a number of cold and moderately hot beverages. The enzyme has activity over a broad pH range (6−8) as previously reported[37] and in the present work with commercial beverages in the pH range of 3−7. Cdh also has other suitable attributes for development of a diagnostic test, such as (i) in situ (on-the-spot) detection, (ii) a speed of detection of 1 min or less (Figure 2), (iii) easy visualization for both semiquantitative and qualitative detection (Tables 2 and 3), and (iv) a caffeine sensitivity to the level of 5−20 ppm (the FDA safe limit in nursing mother's milk is 5 ppm, and decaffeinated beverages have 20 ppm caffeine).

Comparison of the New Cdh-Based Caffeine Detection with Other Reported Caffeine Detection Methods. Detection of caffeine in various laboratories including quality control is traditionally done by the well-established LC−MS/MS[34] or HPLC method.[37,39] However, this method is tedious, instrument-intensive, expensive, and time-consuming and is not practical for a rapid diagnostic test. Various caffeine detection methods/diagnostic tests that have been reported are compared in Table 4 with respect to their attributes. These methods range from those using live bacterial whole cells[28] and enzymes[29,30] and antibody-based methods[34−36] to other nonbiological methods using lipid/polymer membranes[31] and fluorescent dyes.[32,33] The immobilized bacterial cell based assay is an electrode based amperometric test in which a dissolved oxygen (DO) probe measures oxygen depletion as a function of caffeine metabolism.[28] This method has major deficiencies such as bulky electronic instrumentation and a low response time (more than 3 min) and sensitivity (>100 ppm). Similarly, the lipid/polymer membrane based method (also known as the electronic tongue) is also an electrode based amperometric test.[31] This method is rapid (response time of less than 1/2 min), but has other drawbacks similar to those of the bacterial cell based method. None of these tests are commercially available. Recently, two other methods were reported based on binding of fluorescent dyes to caffeine on a thin-layer chromatography (TLC) plate and visualization using UV light.[32,33] Although these methods are simple compared to the bacterial cell based method, the test failed to meet criteria

such as rapid detection (more than 20 min for color development) and sensitivity (cannot detect <100 ppm). Thus, none of the previously reported caffeine detection/diagnostic tests have the right attributes for consumer use.

The antibody methods described for caffeine detection are based on caffeine-specific monoclonal antibodies (mAb's).[34,35] One such method is a fluorescence polarization immunoassay (FPIA) which, although fast (2 min) and highly sensitive (parts per billion range), is instrument-intensive (Table 4) and thus unsuitable for at-home-type tests.[34] On the other hand, an anti-caffeine, mAb-based colorimetric test (D+Caf) met most of the required attributes except sensitivity (Table 4), which was found to be about 20 mg/6 oz of fluid (~112 ppm).[43] Also, these D+Caf strips were not able to detect caffeine in beverages in the presence of milk and sugar.[43] The enzymatic method known for caffeine detection is based on either xanthine oxidase[29] or alkaline phosphatase.[30] Notable drawback of this method is a lack of specificity of xanthine oxidase to caffeine. Thus, while several attempts have been made to develop a caffeine detection test, none of them meet the required attributes needed for an at-home test in terms of sensitivity, rapidity of detection, and ability to detect the alkaloid in various commercial formulations and cocktails.

Suitability of Cdh for Rapid Diagnosis of Caffeine. Cdh-based caffeine detection is highly suitable for development of a rapid diagnostic test. Cdh has high specificity for caffeine.[37] The sensitivity for caffeine detection by Cdh is 1 ppm, well below the 5 ppm sensitivity required. The detection time for the alkaloid is 1 min. Last, but not the least, this enzyme readily detects caffeine in commercial beverages, in nursing mother's milk, and in sugared drinks. The inherent pH variation of the samples did not affect the speed of color development. With nursing mother's milk, the Cdh-based test is able to detect safe and unsafe levels of caffeine in 1 min (Figure 3). This will be very useful for nursing mothers where FDA limits the safe level of caffeine at 5 ppm. To the best of our knowledge, there is no rapid diagnostic test for caffeine that is commercially available for testing nursing mother's milk. Cdh-based caffeine detection is also applicable for readily differentiating decaffeinated products (Table 3). Various additives in commercial caffeinated drinks do not interfere with detection of caffeine in the rapid Cdh test. One exception is tea; flavonoids and phenolic components in this beverage interfere with Cdh-based detection of caffeine. Last, but not least, the Cdh detection test is applicable to rapidly estimating caffeine in several drug formulations. The values obtained from the Cdh test with a standard color chart are in the range determined by HPLC (Table 2). Again, the formulation components in the drug do not interfere with the test. It is tempting to propose that the Cdh-based caffeine estimation could be useful for quality control laboratories, including in pharmaceutical formulations, to establish the caffeine concentration for labeling. It will be faster, easier, simpler, and cheaper compared to the laborious, time-consuming, and expensive HPLC procedures. Cdh-based caffeine detection is robust and versatile in terms of development of a commercial diagnostic test for various applications ranging from qualitative tests (yes/no caffeine levels, safe/unsafe caffeine levels) to quality control estimations for caffeine in drug formulations.

Future Plans for the Cdh-Based Test. A Cdh-based commercial diagnostic kit has to be simple, such as litmus paper or pH paper (may be a dipstick-type test), like a glucose detection kit and portable. This will enable rapid on the spot detection by consumers and enable quick decisions based on the result. The expectation of the end user of such a test may not be accurate detection of caffeine concentration, but to know the safety range to make decisions. Examples of such diagnostic tests in the market are digital readout of approximate blood sugar levels for diabetics[44] and qualitative yes/no pregnancy tests.[45] The next phase of work includes, but is not limited to, (i) development of a dipstick by immobilizing Cdh and INT dye on a test strip, (ii) determination of the shelf life of Cdh and dye for speed of caffeine detection and sensitivity at various temperatures, (iii) formulation of Cdh for maximum activity/shelf life and appropriate enzyme loading to compensate activity loss during storage, (iv) quality control to ensure consistent performance of the diagnostic test, and (v) production of a well-calibrated reference color chart to facilitate the semiquantitative caffeine determination (5−100 ppm) and a chart coded as safe−moderate−unsafe.

[a]Among them, the same brands are composed of different flavor; "#" expressing home-fermented.

Fermented soya beans (or douchi) and fermented bean curd (or sufu) are the most typical traditional fermented soy products. Both are made by microbial fermentation beginning with soybean as raw material. On the basis of the microorganisms used, fermented soya beans can be classified into aspergillus-type douchi, mucor-type douchi, and bacterial-type douchi. Similarly, fermented bean curd can be divided into three main types according to the differences of the dressing mixture, which are white sufu, gray sufu, and red sufu, respectively. During the fermentation process both of fermented soya beans and fermented bean curd, microorganisms are involved, such as some type of yeast, lactic acid bacteria (bending *Lactobacillus casei* and lactobacillus), bacillus, streptococcus, *Staphylococcus aureus*, etc., some of which could produce decarboxylase.[26,27] In short, because of the existence of biogenic amine precursors, the process is bound to generate biogenic amines in an appropriate environment. Therefore, this study seeks to determine what biogenic amines occur in commercially available fermented soy products, and to evaluate the safety of biogenic amines. We hope to also provide advice so people can safely eat fermented soy products.

MATERIALS AND METHODS

Samples and Standards of BAs. Thirty fermented soya bean samples (9 bacteria-type douchi, 10 aspergillus-type douchi, 11 mucor-type douchi.) and 33 fermented bean curd samples (5 gray sufu, 5 red sufu, and 23 white sufu) were purchased from retail markets and supermarkets in China. Specific descriptions of the samples (region of origin, types, and trade names) are listed in Table 1. Standard amines, including putrescine (Put, ≥98%), cadaverine (Cad, 98%), spermidine (Spd, ≥98%), tryptamine (Try, ≥98%), β-phenethylamine (β-Phe, ≥98%), histamine (His, ≥99%), tyramine (Tyr, ≥98%) and spermine (Spm, ≥98%) were purchased from the Sigma-Aldrich Corporation in the United States. Dansyl chloride (≥98%) was bought from Tedia Company in the United States.

Apparatus. High performance liquid chromatograph (Agilent1260), with UV-detector and Agilent XDB-C18 (250 × 4.6 mm^2, 5 μm) column; an ultrasonic bath KQ5200DB; an Eppendorf centrifuge table high speed; an ultrapure water Milli-Q; water bath temperature oscillator, and a syringe filter 0.22 μm.

Sample and Standard Preparation. Five grams of each sample was extracted with approximately 20 mL of 0.4 M perchloric acid (Sigma), placed in the ultrasonic bath for 30 min, and then centrifuged for 5 min at 5000 rpm, taking supernatants on standby.

Standard stock solutions of the eight biogenic amines were prepared separately at 1 mg/mL concentration in 0.4 M $HClO_4$. Working solutions, containing all the amines at 3.0−100 mu g/mL concentrations, were prepared by diluting the standard stock solution.[28]

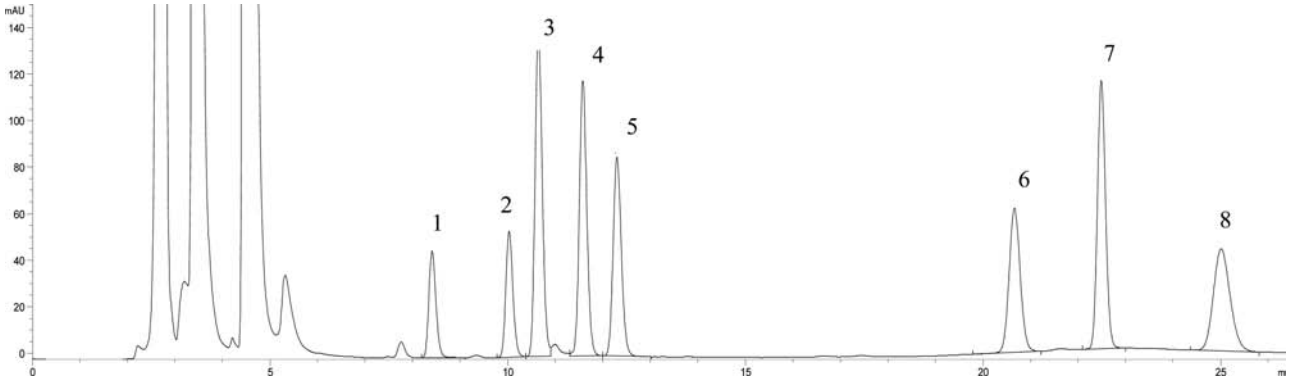

Figure 1. Chromatogram of derivatives of biogenic amines standards (70 μg/mL). (1) Tryptamine, (2) β-phenylethylamine, (3) putrescine, (4) cadaverine, (5) histamine, (6) tyramine, (7) spermidine, and (8) spermine. The peaks that are omitted have no meaning. As shown, the peaks of the 8 standard derivatives are shown later and flagged as 1, 2, 3, 4, 5, 6, 7, and 8.

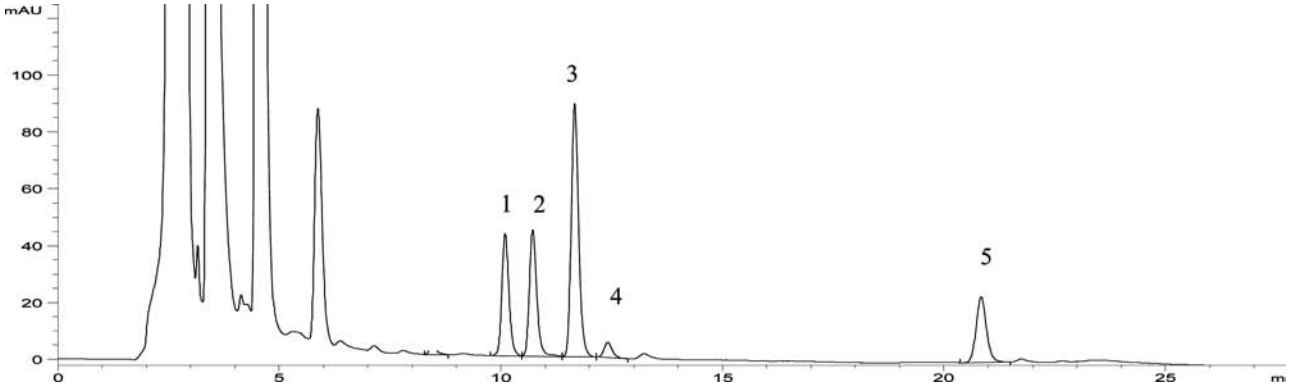

Figure 2. Chromatogram of derivatives of biogenic amines in one of the fermented soya beans. (1) β-Phenylethylamine, (2) putrescine, (3) cadaverine, (4) histamine, and (5) tyramine.

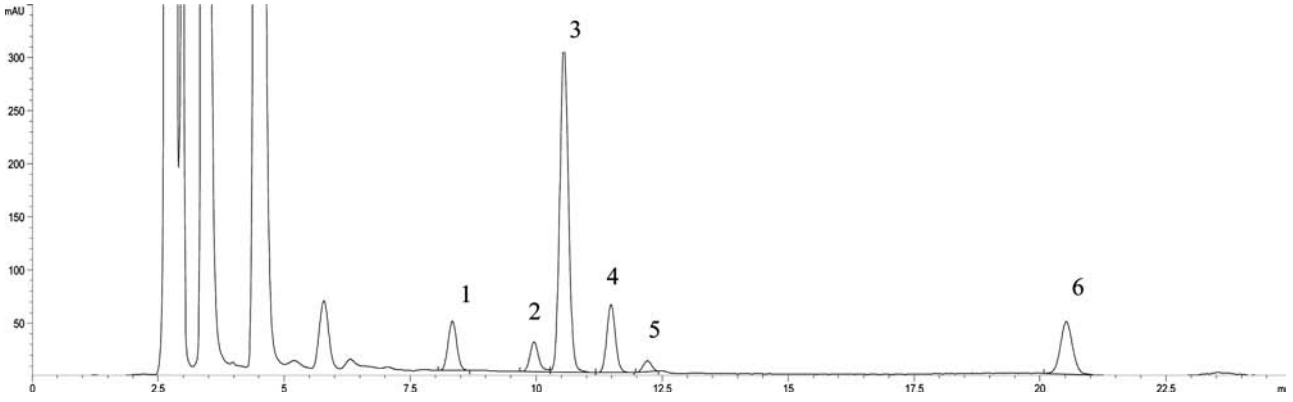

Figure 3. Chromatogram of derivatives of biogenic amines in one of the fermented bean curd samples. (1) tryptamine, (2) β-phenylethylamine, (3) putrescine, (4) cadaverine, (5) histamine, and (6) tyramine.

Derivatization. One milliliter of a sample solution was mixed with 200 μL of 2 M sodium hydroxide and 300 μL of saturated sodium carbonate. Under the alkaline conditions, the mixture was derivatized by the addition of 2 mL dansyl chloride solution (10 mg/mL in acetone). After incubation for 30 min at 40 °C in darkness, 100 mL of aqueous ammonia was added to remove any residual Dansyl chloride. The volume was adjusted to 5 mL with acetonitrile. Finally, the supernatant was filtered through 0.22 μm pore-size filters prior to HPLC analysis.

Chromatographic Conditions. Column temperature = 30 °C, flow rate = 1.0 mL/min, injected volume = 5 μL, detection wavelength (λ) = 254 nm were used. The mobile phase was a gradient elution program with a binary mixture of acetonitrile and H_2O. Each HPLC run took about 30 min, and the column was conditioned again with a mixture of 65% solvent A and 35% solvent B.

Statistical Analysis. All the tests were repeated three times, using Excel 2007 version for analysis and data processing.

RESULTS

Chromatograms of Standard BAs and Sample. Through the elution procedure, each BAs was detected in turn. The representative HPLC chromatogram and peak identification recorded for mixer of standard BAs, a fermented soya bean sample, and a fermented bean curd are shown in Figures 1, 2, and 3, respectively.

[a]Trp: tryptamine, Phe: β-phenethylamine, Put: Putrescine, Cad: cadaverine, His: histamine, Tyr: tyramine, Spd: spermidine, and Spm: spermine. 1−30: fermented soya bean, 31−63: fermented bean curd, 1−9: Bacterial-type douchi, 10−19: Aspergillus-type douchi, 20−30: Mucor-type douchi, 31−35: Gray sufu, 36−40: Red sufu, 41−63: White sufu, and ND expressed not detected.

As shown in Figure 1, all BAs were detected in 30 min. The effect of the useful peak's separation was good. The retention time of tryptamine, β-phenethylamine, putrescine, cadaverine, histamine, tyramine, spermine, and spermine were 8.374, 9.994, 10.606, 11.536, 12.257, 20.595, 12.257, and 20.595 min, respectively. In addition, at the beginning of the chromatogram, a few peaks were omitted, whose value were so high that the useful ones were not present.

Type of BA in the Samples. Through the HPLC method, all samples were tested, the results showed in Table 2. The types of BAs can decide whether the food is safety, so this part had introduced the types of BAs, to evaluate the safety of the samples in brief.

Tryptamine, β-phenethylamine, putrescine, cadaverine, histamine, tyramine, and spermidine were detected in fermented soya bean samples, the content range was 69.56, 16.77−736.64, 14.08−276.03, 5.14−672.33, 14.76−478.77, 17.90−252.08, and 16.15−74.92 mg/kg, respectively. The types of BA was no obvious regularity, and had nothing to do with the fermentation type. The 1st, 2nd, 4th∼7th, 9th, 25th, 27th, and 29th samples only detected putrescine; the 3rd sample only detected spermidine; the 8th sample detected putrescine and spermidine; the 10th, 12th, and 14th samples detected β-phenethylamine, putrescine, histamine, and tyramine; the 11th, 13th, and 17th samples detected putrescine, histamine, and tyramine; the 15th, 16th, 18th, and 19th samples detected putrescine and histamine; the 20th sample detected six kinds of BAs except spermidine and spermine; the 21st and 22nd samples detected five kinds of BAs excepte tryptamine, spermidine, and spermine; the 23th sample detected putrescine, cadaverine, histamine, and spermidine; the 24th sample detected β-phenethylamine and putrescine; the 26th sample detected putrescine, cadaverine and tyramine; the 28th sample detected putrescine and tyramine; the 30th sample detected putrescine, cadaverine, tyramine, and spermidine. In conclusion, the BAs' types were different in fermented soya beans, and the BAs' types were less than three there were in 22 samples. Among these, only putrescine existed in all samples, histamine, and tyramine were detected in 14 and 12 samples, respectively, closely following putrescine. Therefore, putrescine, histamine, and tyramine might be regard as safety indexes of fermented soya bean samples contaminated by BAs.

Alternatively, tryptamine, β-phenethylamine, putrescine, cadaverine, histamine, and tyramine were detected in fermented bean curd, the content range was 51.95−463.45, 6.84−341.03, 11.38−1147.32, 3.37−308.44, 6.07−415.38, and 12.76−549.34 mg/kg, respectively. Compared with fermented soya beans, the type of BA was more regular in fermented bean curd, and had something with the differences of the dressing mixture. First, putrescine, cadaverine, histamine, and tyramine were detected in gray sufu (the 31st∼35th samples). Second, there were a little difference in red sufu (the 36th∼40th samples), the 36th sample only detected putrescine; the 37th, 38th, and 40th samples detected putrescine and cadaverine; the 39th sample detected putrescine, histamine, and tyramine. At last, there were tryptamine, β-phenethylamine, putrescine, cadaverine, histamine, and tyramine detected in all white sufu samples except the 49th sample, and the 49th sample detected tryptamine, β-phenethylamine, putrescine, histamine, and tyramine. As above, there were a few differences of BAs' types among gray, red, and white sufu samples. It could be speculated that white sufu was most dangerous among the sufu samples.

Safety of the BAs in the Samples. *Safety of the Total BAs in Samples.* As shown in Table 2, the total BAs content was between 15.67−89.00, 43.03−929.97, and 48.77−2057.56 mg/kg, the median was 27.56, 203.27, and 84.87 mg/kg in bacterial-type, aspergillus-type, and mucor-type douchi samples, respectively. The total BAs content was more than 900 mg/kg only in the 14th, 20th, and 22nd samples. As mentioned before, the total BAs content in food should not be more than 900 mg/kg,[7,8] and when the total BAs content reached 1000 mg/kg in food, they would cause great harm to human health.[9] So the sample would be considered unsafe when the total BAs content were more than 900 mg/kg. In conclusion, it was observed that the total BAs content was within the relative safety range in most fermented soya bean samples except the 14th, 20th, and 22nd sample.

However, the total BAs content range was 625.92−2406.95, 11.38−62.83, and 176.10−404.01 mg/kg, the median was 1492.27, 25.41, and 243.96 mg/kg in white, red, and gray sufu samples, respectively. The total BAs content was less than 900 mg/kg in gray and red sufu, while which was more than 900 mg/kg in 19 white sufu samples (all samples except the 46th, 54th, 56th, and 59th sample), accounting for 82.61% of the total number of white sufu samples. According to the total BAs content in samples and the related knowledge of toxicology. It is worth noting that the total BAs content was in a relatively safe range in gray and red sufu samples, but was in a dangerous concentration range in part white sufu samples, which could cause a safety risk.[8−10]

Safety of Histamine in the Samples. Histamine was detected in 10 aspergillus-type and 4 mucor-type douchi samples, respectively. The content was 14.76−478.77 and 20.62−102.09 mg/kg, the median was 62.32 and 68.33 mg/kg, the detection rate was 100% and 36.36%, respectively. Histamine's content was more than 50 mg/kg in 5 aspergillus-type (the 10th−14th sample) and 1 mucor-type (the 22th sample) douchi sample, accounting for 50% and 25%, respectively. As mentioned before, the maximum allowable

concentration of histamine were 50−100 mg/kg in food.[11] So the sample would be considered unsafe when the total content of BAs were more than 50 mg/kg. Therefore, the high histamine's concentration in part aspergillus-type and mucor-type douchi samples could cause a potential safety hazard.[15−17]

Similarly, histamine was detected in 23 white, 5 gray, and 1 red sufu samples, the content range was 6.07−415.38, 12.11−174.36, and 12.11 mg/kg, the median was 58.85, 17.43, and 7.82 mg/kg, respectively. Among the samples, histamine's content was more than 50 mg/kg in two gray (the 32nd and 33rd samples) and 13 white (the 44th, 45th, 49th∼53rd, 55th, 57th, 58th, and 60th∼62nd sample) sufu samples, accounting for 40% and 56.52%, respectively. According to the related knowledge of toxicology, the content of histamine was high in some white and gray sufu samples, resulting in health problems.[15−17]

Safety of Tryptamine, β-Phenethylamine, and Tyramine in Samples. Tyramine was detected in 6 aspergillus-type and 6 mucor-type douchi samples, the content range was 57.85−252.08 and 17.90−250.21 mg/kg, the median was 169.76 and 61.34 mg/kg, the detection rate was 60% and 54.54%, respectively. Tyramine's content was more than 100 mg/kg in 5 aspergillus-type (the 10th∼14th samples) and 2 mucor-type (the 20th and 22nd samples) douchi samples, accounting for 83.33% and 33.33%, respectively. β-Phenethylamine was detected in 3 aspergillus-type and 4 mucor-type douchi samples, the content was 16.77−79.00 and 17.56−736.64 mg/kg, the median was 28.37 and 80.40 mg/kg, the detection rate was 30% and 36.36%, respectively. As mentioned before, Tyramine could cause migraines or induce severe poisoning symptoms when ingested more than 100 mg orally or 1080 mg/kg respectively, the maximum allowable range was 100−800 mg/kg in food.[18] So the sample would be considered unsafe when the content of tyramine was more than 100 mg/kg. Obviously, the content of tyramine and β-phenethylamine were a little high in part aspergillus-type and mucor-type douchi samples, which would pose a safety risk.

Besides, tryptamine and β-phenethylamine were detected in 23 white sufu samples, the content range were 51.95−463.45 and 6.84−341.03 mg/kg, the median were 163.57 and 52.38 mg/kg, and the detection rate were both 76.67%, respectively. Tyramine was detected in one red, all white, and all gray sufu samples, the contents were ispermidinen the ranges 33.11−549.34, 39.07, and 12.79−34.44 mg/kg, the median was 330.12, 39.07, and 15.58 mg/kg, respectively. Tyramine's content was more than 100 mg/kg in 22 white sufu samples (except the 62nd sample). As a result, the detection of tyramine, β-phenethylamine, and tyramine made them some certain safety hidden danger in white sufu samples.[18−20]

Safety of Putrescine, Cadabverine, and Spermidine in Samples. Putrescine was detected in all samples except the third sample, the content range was 26.49−139.85, 39.42−276.03, and 39.42−42.22 mg/kg, the median was 37.02, 54.30, and 27.24 mg/kg in aspergillus-type, mucor-type, and bacterial-type douchi samples, respectively; cadaverine was detected in 6 mucor-type douchi samples, the content range was 6.03−672.33 mg/kg, the median was 120.62 mg/kg; spermine was detected in 2 mucor-type and 2 bacterial-type douchi samples, the content was 16.15−23.47 and 19.51−74.92 mg/kg, the median was 19.81 and 47.21 mg/kg, respectively. As mentioned above, the toxicity of cadaverine, putrescine, spermidine, and spermine is not obvious relatively, but they can interact with nitrite to form carcinogenic nitrosamine, and can inhibit other toxic BAs' metabolism to make their toxicity higher.[22] Furthermore, putrescine's detection rate was the highest among all the BAs, and the concentration was also highest in most of the samples, in consideration of the addition of the synergy between BAs, it was still considered that the existence of putrescine was a potential safety hazard in fermented soya beans. Similarly, the cadaverine and spermidine were considered in a safe range concentration in fermented soya bean samples.

However, putrescine was detected in all fermented bean curd samples, the content range was 172.90−1147.32, 11.38−19.93 and 25.16−234.12 mg/kg, the median was 585.06, 13.57, and 124.32 mg/kg in white, red, and gray sufu samples, respectively. The detection rate was the highest among all the BAs, and the concentration was also the highest in most samples. Meanwhile, putrescine's concentration was more than 900 mg/kg in 9 white sufu samples (the 41st, 42nd, 44th, 45th, 49th∼51st, 55th, and 60th sample), which made the total BAs content out of the safe limit. Similarly, cadaverine was detected in 22 white, 3 red, and 5 gray sufu samples, the content was 3.37−308.44, 5.47−14.36, and 10.01−34.33 mg/kg, the median was 79.64, 11.00, and 23.11 mg/kg, respectively, the detection rate was just lower than putrescine. As a result, the existence of putrescine and cadaverine was a certain safety hidden danger in some white and gray sufu samples.

Safety of the Samples. In summary, because of BAs, several fermented soya bean and fermented bean curd samples had some potential safety risk. On the one hand, the content of histamine and tyramine had exceeded their limit level for the 10th∼14th aspergillus-type douchi samples, and the total BAs content of the 14th sample was more than 900 mg/kg, therefore it could be considered that the 10th∼14th samples had some obvious safety risk; the 20th and 22nd samples were unsafe because the content of total BAs, histamine, and tyramine were more than their limit level; histamine's content was 83.87 mg/kg in the 21th sample, which could pose safety risk. In conclusion, there were 8 samples (the 10th−14th, and 20th−22nd samples) unsafe for fermented soya beans.

On the other hand, first, the red sufu samples (the 36th∼40th samples) were relatively safe. Second, among the gray sufu samples (the 31st∼35th samples), the 32nd and 33rd samples were unsafe for their high histamine concentration. Finally, as mentioned above, all the white sufu samples (the 41st∼63rd samples) had some unsafe factors. Namely, the total BAs content had exceeded 900 mg/kg in 19 samples except the 46th, 54th, 56th, and 59th samples; the tyramine's content was more than 100 mg/kg in all except the 62th samples; the histamine's content was more than 50 mg/kg in 13 samples (the 44th, 45th, 49th∼53rd, 55th, 57th, 58th, and 60th∼62nd samples). So all of the white sufu samples were unsafe. As a whole, there were 21 samples (the 32nd, 33rd, and 41st∼63rd samples) unsafe for fermented bean curds.

DISCUSSION

Safety of Fermented Soya Products. Looking from the results, there were 8 samples unsafe for fermented soya beans. The 32nd and 33rd gray sufu sample were unsafe for their high histamine's concentration, and all the white sufu samples were unsafe. Therefore, the content of BAs should be limited in all the fermented soy products.

However, the experimental results were just a preliminary evaluation; there still needs to be a more in-depth study to

realize the safety limit of each BA in the fermented soya products, like the histamines in fish products.

Safety of Other Foods. The BAs have been detected in many foods, such as cheese, fish, fish products, dairy products, pork, and sausages, and so forth. From the related research, most of the BAs content were in a relatively safe range in pork and sausages;[29−36] the histamines content was more than 100 mg/kg in some sausages,[29,31] which could cause a safety hazard; putrescine and cadaverine could be not only used as the spoilage indicators of chilled pork, but also might reflect the spoilage degree in pork;[34] some BAs content had reached the level of threat to human health in some fish products,[37−41] and the highest content of tryptamine, β-phenethylamine, putrescine, cadaverine, histamine, tyramine, spermidine, and spermine was 517.2,[40] 219.0,[40] 420,[37] 969.4,[40] 2500,[37] 456.2,[40] 51.98,[41] and 53.30[41] mg/kg respectively, which could pose a safety risk; almost all the BAs content had reached the level of threat to human health in cheese,[42−46] the highest contents of tryptamine, β-phenethylamine, putrescine, cadaverine, histamine, tyramine, spermidine, and spermine were 312.2,[45] 312.2,[46] 986.0,[43] 2127.6,[43] 1157.9,[45] 1771.3,[43] 340.0,[46] and 449.6[46] mg/kg respectively, which were obviously dangerous factors.

As above, the content of BAs has exceeded the safety limit in these foods, and there were very few scholars having evaluated the safety of them. So it must be emphasized that the foods which contain a large number of BAs should be detected to evaluate whether they are safe, and if not, the content of BAs should be limited.

Toxicity of BAs. The toxicity of BAs was not discussed in the current study, but there still needs to be a more in-depth study to realize the toxicology of BAs deeply and comprehensively, such as the toxic effect of each BA, the safety range of each BA, and the synergy among them, and so forth.

aspects of the interaction have been studied, the calorimetric studies to elucidate the thermodynamics of the interaction have not yet been performed. Thus, the present work elucidates the thermodynamics of the interaction of amaranth with two homologous serum proteins using isothermal titration calorimetry (ITC) and differential scanning calorimetry (DSC) techniques.

MATERIALS AND METHODS

Materials. HSA (0.99 mass fraction purity, essentially fatty acid and globulin free), BSA (0.99 mass fraction purity, essentially fatty acid and globulin free), and amaranth (dye content of 85−95%) were procured from Sigma-Aldrich Co. LLC (St. Louis, MO). All of the experiments were performed in 10 mM citrate−phosphate buffer at pH 7.0, unless otherwise mentioned, where the serum albumins are in the normal (or N) form. The concentrations of HSA and BSA samples were spectrophotometrically determined using molar absorption coefficient values (ε) of 3.66×10^4 and 4.38×10^4 M^{-1} cm^{-1}, respectively, at 280 nm.[28] The concentration of the dye was also determined spectrophotometrically using the ε value of 2.56×10^4 M^{-1} cm^{-1} reported in the literature.[25] All of the buffer salts were of analytical grade. The aforementioned citrate−phosphate buffer was prepared in triple-distilled and deionized water. All of the solutions were filtered through filters with a pore size of 0.22 μM (Millipore India Pvt. Ltd., Bangalore, India).

ITC. Thermodynamic characterization of the amaranth−serum albumin interaction was performed on a MicroCal VP-ITC calorimeter (MicroCal LLC, Northampton, MA). The protein solutions were prepared by dialyzing against the buffer. The dye solution was prepared in the buffer. Both the dye and protein solutions were extensively degassed prior to the titrations. The titrant, amaranth solution, was loaded into the rotating injector syringe, and the serum protein solution was placed in the calorimeter cell. The programmable dye−protein titration was controlled by the Origin 7.0 software (MicroCal) of the unit. The autocontrolled rotating syringe (351 rpm) injected 10 μL aliquots of the dye solution into the protein solution (1.4235 mL) at intervals of 240 s. This time interval was sufficient enough for the heat signal to return to the baseline after each heat spike generation. The duration of each injection was fixed at 10 s, and the initial delay before the first injection was 60 s. To correct for the thermal effect because of mixing and dilution, appropriate control experiments were performed by injecting an identical volume of the same concentration dye solutions into the experimental buffer alone. The integrated heat change was analyzed by means of nonlinear regression using the Origin software of the unit. The resulting corrected injection heats were then plotted against the molar ratio (χ) of amaranth/serum protein and fitted to a model for single binding sites. The binding equilibrium constant (K), standard molar enthalpy change ($\Delta_r H^\circ$), and stoichiometry value "N" were obtained from the analysis of the titration curve. The values of the standard molar Gibbs energy change ($\Delta_r G^\circ$) and standard molar entropic contribution ($T\Delta_r S^\circ$) were then calculated using the relationships

$$\Delta_r G^\circ = -RT \ln(K) = T\Delta_r S^\circ - \Delta_r H^\circ \quad (1)$$

where R is the gas constant (8.314 472 J K^{-1} mol^{-1}) and T is the temperature in kelvin (298.15 K). The thermodynamic parameters presented are averages of triplicate measurements. Periodic calibration of the ITC unit for volume of the calorimetric chamber, heat exchange, and injected volumes of titrant were performed. Furthermore, to ensure the accuracy of the calorimetric results, water−water dilution experiments were performed as per criteria of the manufacturer that the mean energy per injection was less than 5.46 μJ and the standard deviation was less than 0.063 μJ. Chemical calibration of the unit was performed with propan-1-ol of three different concentrations, 2, 5, and 10%, as proposed by Adão et al.[29]

DSC. The change in excess heat capacity ($\Delta_r C_p^\circ$) as a function of the temperature "T" was measured in a VP-DSC microcalorimeter (MicroCal LLC). The temperature difference between the reference and sample cell was measured and converted to power. This data channel is referred to as the differential power (DP) between the reference and sample cell. Calibration of this signal was performed electrically by administering a known quantity of power through a resistive heater element located in the sample cell and then measuring the actual deflection of the DP data signal. The samples were incubated at 303.15 K for 10 min and scanned from 306.15 to 363.15 K at approximately 30 psi pressure at a scan rate of 50 K h^{-1}. Prior to sample scans, the DSC unit was thermally stabilized by repeated buffer scans under an identical scan rate and in the same temperature range. Typically around 10−12 scans were needed to attain the baseline stability. A total of 40 μM of the serum protein solution was scanned in the aforementioned temperature range to obtain the DSC thermogram of the unbound protein. Thereafter, the serum proteins were incubated with the azo dye solution for 10 min to ensure complete complex formation and then scanned in the same temperature range to obtain the thermogram of the bound form. The thermograms were analyzed with the Origin software built-in with the unit. The non-2-state (cursor initiation) model of curve fitting was employed to fit the raw DSC thermograms. Each experiment was repeated 3 times with separate fillings. The C_p° of the protein solution was measured with respect to the C_p° of the buffer. The C_p° at a constant pressure is a temperature derivative of the enthalpy

$$C_p^\circ = \left(\frac{\partial H}{\partial T}\right)_P \quad (2)$$

and hence, the calorimetric enthalpy change (ΔH_{cal}) can be calculated by integration of C_p°. The transition temperature (T_m) is the temperature at which the excess heat capacity reaches its maximum value. Calibration of the DSC unit was performed with built-in calibration heaters, whereas the temperature calibration was performed using the MicroCal standards.

RESULTS AND DISCUSSION

Elucidation of the Thermodynamics of the Complexation from ITC Studies. ITC is the most efficient tool to thermodynamically characterize the ligand−protein binding phenomenon.[30,31] The thermodynamics of the binding reaction are characterized by the equilibrium constant, the stoichiometry of the reaction, the standard molar Gibbs energy change, the standard molar enthalpy change, the standard molar entropy change, and the standard molar heat capacity change ($\Delta_r C_p^\circ$). ITC directly measures the equilibrium constant for the binding reaction by measuring the heat evolved on complexation of a ligand with protein. Thus, the distinct advantage of this protocol is that, from a single experiment, we can obtain the values of the equilibrium constant, the stoichiometry of the reaction (N), and the standard molar enthalpy change of binding. The standard molar Gibbs energy change and the standard molar entropy change of binding may be subsequently calculated using the standard relationships described above. The temperature dependence of the values of $\Delta_r H^\circ$, obtained by performing the titration at varying temperatures, permits the calculation of $\Delta_r C_p^\circ$.

Figure 2 presents the ITC thermograms for the binding reaction of amaranth to BSA and HSA at 298.15 K. It can be seen that the ITC thermograms were characterized by negative peaks in the plot of power versus time, suggesting the binding reaction to be exothermic. Each heat spike in the thermogram corresponds to an injection of the dye into the respective serum protein solution. It was corrected for heat effects resulting from dilution and mixing by subtracting the corresponding control heats derived from the injection of an identical amount of the amaranth into the buffer alone. The resulting corrected heats for amaranth−protein complexation were plotted as a function

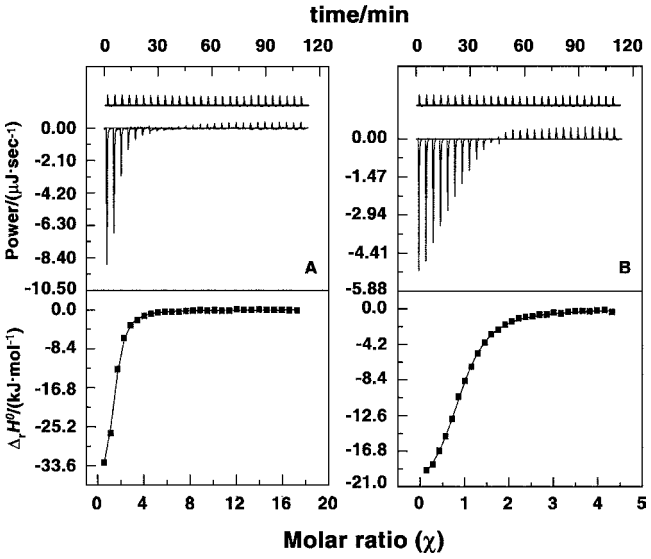

Figure 2. ITC thermograms for the titration of amaranth with (A) BSA and (B) HSA at 298.15 K. The top panels represent the raw data for the sequential injection of the amaranth solution into the serum proteins along with the corresponding dilution profiles (curves on the top offset for clarity). The bottom panels show the integrated heat data after correction of heat of dilution. The data points (■) reflect the experimental injection heats, while the solid lines represent the calculated fit of the data.

of the molar ratio of amaranth/protein. The data points in the bottom panels of Figure 2 represent the experimental injection heats, whereas the solid lines are the calculated best fits of the experimental data. The data points were fitted with a Levenberg–Marquardt nonlinear least-squares curve fitting algorithm to calculate the values of K, N, and $\Delta_r H°$. At T = 298.15 K, the equilibrium constant for the binding reaction of amaranth to BSA and HSA was calculated to be $(5.79 \pm 0.07) \times 10^5$ and $(1.76 \pm 0.05) \times 10^5$ M^{-1}, respectively. This value is in good agreement with that reported in an earlier structural study.[9] The magnitude of the equilibrium constant suggested that amaranth has a stronger binding affinity for BSA in comparison to HSA. The N values for the binding reaction were calculated to be 1.28 ± 0.07 and 0.91 ± 0.03, respectively, for BSA and HSA. Thus, a 1:1 complexation scenario may be envisaged for the association of amaranth to both the serum proteins. The analysis of the ITC thermograms yielded the value of $\Delta_r H°$ to be -40.00 ± 0.04 and -22.59 ± 0.03 kJ mol^{-1}, respectively, for BSA and HSA at T = 298.15 K. Thus, the magnitude of $\Delta_r H°$ was higher for BSA in comparison to HSA. The strengthening of the H bonds in the low dielectric macromolecular interior of the serum albumins in conjunction with van der Waals interactions introduced as a consequence of the hydrophobic effect account for the observed negative $\Delta_r H°$ values.[32]

Using the aforementioned standard relationship, the values of $\Delta_r G°$ for the complexation of amaranth with BSA and HSA were evaluated to be -32.89 ± 0.07 and -29.94 ± 0.05 kJ mol^{-1}, respectively. Thus, the binding of amaranth to BSA over HSA was favored by an additional Gibbs energy change of 2.95 kJ mol^{-1} (in absolute values). The entropy contributions for the binding reactions were calculated to be -7.11 ± 0.03 and 7.35 ± 0.02 kJ mol^{-1}, respectively. Thus, it can be observed that the binding reaction in the case of HSA was driven by both negative standard molar enthalpy change and positive standard molar entropy contributions. However, for BSA, the binding reaction was entirely driven by negative standard molar enthalpic contribution. The standard molar entropic contribution was unfavorable, but the magnitude of the standard molar enthalpic contribution was large enough to overcome this unfavorable entropy term and make the overall reaction feasible. It is also noteworthy that the binding reaction was enthalpy-dominated for both the serum proteins.

Influence of the Ionic Strength of the Medium upon Binding and Parsing of the Standard Molar Gibbs Energy Change. Salt-dependent ITC studies provide further insights into the molecular forces driving the binding reaction. To have knowledge about the role of the polyelectrolytic forces governing the complexation phenomena, salt dependence of the binding was studied as a function of four different Na^+ concentrations, viz., 10, 20, 30, and 50 mM, by ITC experiments. The thermodynamic parameters obtained from these salt-dependent ITC studies are collated in Table 1. Upon increasing the salt concentration, the K value progressively decreased for both the serum proteins (Table 1). The K value decreased from $(5.79 \pm 0.07) \times 10^5$ to $(5.02 \pm 0.07) \times 10^5$ M^{-1} upon increasing the salt concentration from 10 to 20 mM. Upon further increasing the salt concentration to 30 mM, the K value decreased to $(4.51 \pm 0.06) \times 10^5$ M^{-1}, and finally, at 50 mM, the K value was $(3.51 \pm 0.05) \times 10^5$ M^{-1}. Thus, the K value decreased 1.65 times upon increasing the salt concentration from 10 to 50 mM. For HSA, also the K value decreased upon increasing the ionic strength of the medium. The K value reduced from $(1.76 \pm 0.05) \times 10^5$ to $(1.29 \pm 0.04) \times 10^5$ M^{-1} upon increasing $[Na^+]$ from 10 to 20 mM. At 30 and

[a]All of the data in this table are derived from ITC experiments conducted in citrate–phosphate buffer of different $[Na^+]$ at pH 7.0 and 298.15 K. The standard uncertainties associated with K, N, $\Delta_r H°$, $T\Delta_r S°$, $\Delta_r G°$, $\Delta_r G°_t$, and $\Delta_r G°_{pe}$ are 6, 5, 4, 2, 6, 6, and 6%, respectively, for BSA. Similarly, the standard uncertainties associated with K, N, $\Delta_r H°$, $T\Delta_r S°$, $\Delta_r G°$, $\Delta_r G°_t$, and $\Delta_r G°_{pe}$ are 4, 4, 3, 1, 4, 4, and 4%, respectively, for HSA.

dx.doi.org/10.1021/jf5025278 | J. Agric. Food Chem. 2014, 62, 7955–7962

50 mM [Na^+], the K values were calculated to be (1.12 ± 0.04) × 10^5 and (0.94 ± 0.03) × 10^5 M^{-1}, respectively. Thus, for HSA, the K value decreased around 1.87 times upon increasing the ionic strength of the medium from 10 to 50 mM. However, the stoichiometry values remained largely unchanged with increasing the ionic strength of the medium. The N values suggested that 1:1 complexation occurs between amaranth and the serum proteins, irrespective of the salt concentration of the medium. However, the magnitude of Δ_rH° decreased with an increasing ionic strength of the medium for both BSA and HSA. This decrease is probably due to shielding of the macromolecule by the sodium ions, which prevented the dye molecules from coming in contact with the serum albumins. The magnitude of Δ_rG° also decreased with an increase in the ionic strength of the medium. At 10 mM [Na^+], Δ_rG° was calculated to be −32.89 ± 0.07 and −29.94 ± 0.05 kJ mol^{-1}, respectively, for BSA and HSA. However, at 50 mM, it was reduced to −31.65 ± 0.05 and −28.39 ± 0.03 kJ mol^{-1}. Thus, the value of Δ_rG° decreased by 1.24 and 1.55 kJ mol^{-1} (in absolute values) for BSA and HSA, respectively, upon increasing [Na^+] from 10 to 50 mM. There is a standard relationship that correlates the variation of the equilibrium constant with the sodium ion concentration[33,34]

$$\Delta_rN(\text{ion}) = \left(\frac{\partial \log K}{\partial \log[Na^+]}\right)_{T,P} = -z\phi \quad (3)$$

where Δ_rN(ion) represents the number of ions released upon binding of the azo dye, z is the apparent charge of the bound dye, and φ is the fraction of [Na^+] bound per anion. The plot of the variation of log K as a function of log [Na^+] yielded straight lines (Figure 3). The slopes of these plots were calculated to be

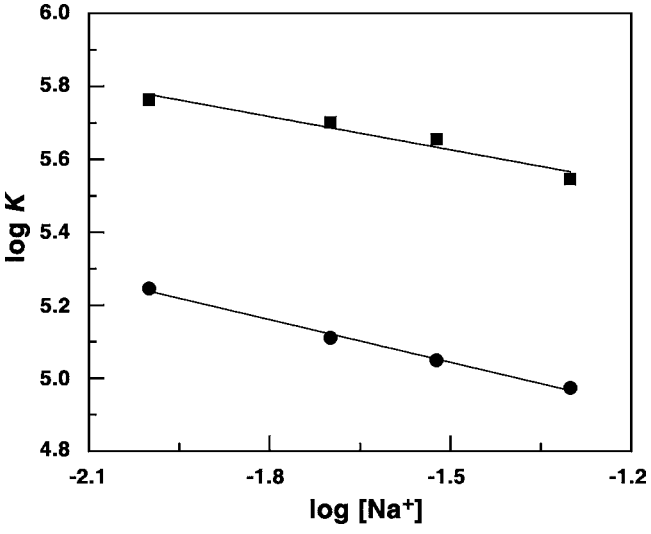

Figure 3. Plot of log K against log [Na^+] for the binding of amaranth to BSA (■) and HSA (●).

−0.303 and −0.389 for BSA and HSA, respectively. Hence, a sharper decrease in the K values was observed for HSA in comparison to BSA. The dependence of K upon [Na^+] enabled Δ_rG° to be partitioned into two components, viz., the non-polyelectrolytic component ($\Delta_rG^\circ_t$) and the polyelectrolytic component ($\Delta_rG^\circ_{pe}$) (Figure 4)

$$\Delta_rG^\circ = \Delta_rG^\circ_t + \Delta_rG^\circ_{pe} \quad (4)$$

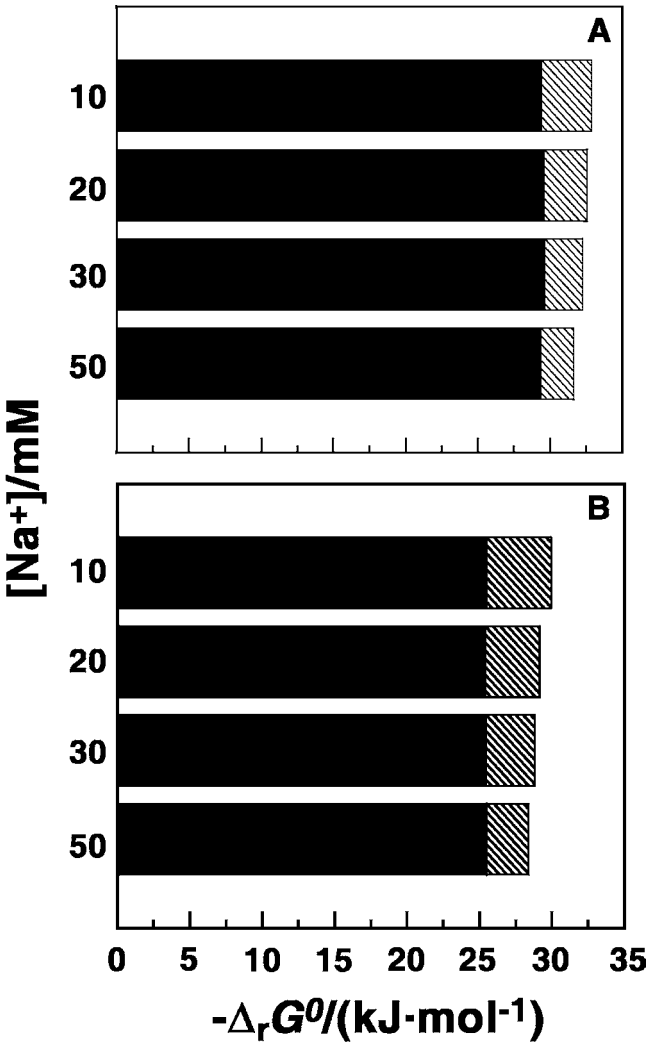

Figure 4. Partitioned polyelectrolytic ($\Delta_rG^\circ_{pe}$) (hatched) and non-polyelectrolytic ($\Delta_rG^\circ_t$) (black) contributions to the standard molar Gibbs energy (Δ_rG°) at different Na^+ concentrations for the complexation of (A) BSA and (B) HSA with amaranth.

The $\Delta_rG^\circ_{pe}$ at any given [Na^+] can be calculated quantitatively using the relationship[35,36]

$$\Delta G^\circ_{pe} = -z\phi RT \ln([Na^+]) \quad (5)$$

The $\Delta_rG^\circ_{pe}$ term accounts for the contribution arising from coupled polyelectrolytic forces, such as the release of condensed counterions upon binding of the synthetic azo dye amaranth. The $\Delta_rG^\circ_t$ term accounts for the contribution arising from other non-polyelectrolytic sources, such as van der Waals interaction, $\pi-\pi$ stacking, H bonding, and hydrophobic transfer. For BSA, $\Delta_rG^\circ_{pe}$ at 10, 20, 30, and 50 mM [Na^+] was −3.46 ± 0.07, −2.94 ± 0.07, −2.63 ± 0.06, and −2.25 ± 0.05 kJ mol^{-1}, respectively. Similarly, $\Delta_rG^\circ_{pe}$ was −4.44 ± 0.05, −3.77 ± 0.04, −3.38 ± 0.04, and −2.89 ± 0.03 kJ mol^{-1} for HSA at 10, 20, 30, and 50 mM [Na^+], respectively. $\Delta_rG^\circ_t$ contribution was calculated from the difference between Δ_rG° and $\Delta_rG^\circ_{pe}$. At 10, 20, 30, and 50 mM [Na^+], $\Delta_rG^\circ_t$ was calculated to be −29.43 ± 0.07, −29.60 ± 0.07, −29.64 ± 0.06, and −29.40 ± 0.05, kJ mol^{-1}, respectively, for amaranth−BSA complexation. Similarly, for the amaranth−HSA binding reaction, the magnitude of $\Delta_rG^\circ_t$ was calculated to be −25.50 ± 0.05, −25.40 ± 0.04, −25.44 ± 0.04, and −25.50 ± 0.03 kJ

	303.15	1.29 ± 0.04	1.24 ± 0.07	−27.19 ± 0.03	2.47 ± 0.01	−29.66 ± 0.04	

[a]The standard uncertainties associated with K, N, $\Delta_r H^\circ$, $T\Delta_r S^\circ$, $\Delta_r G^\circ$, and $\Delta_r C_p^\circ$ are 7, 4, 4, 3, 7, and 6%, respectively, for BSA. Similarly, the standard uncertainties associated with K, N, $\Delta_r H^\circ$, $T\Delta_r S^\circ$, $\Delta_r G^\circ$, and $\Delta_r C_p^\circ$ are 5, 4, 2, 2, 5, and 6%, respectively, for HSA.

mol^{-1}, respectively. Thus, although large in magnitude, the non-polyelectrolytic component remained largely invariant with changing salt concentrations. However, the polyelectrolytic component decreased in magnitude with the increase in $[Na^+]$. At the highest salt concentration studied, viz., 50 mM $[Na^+]$, the ΔG°_{pe} term accounted for only 7 and 10% of the total standard molar Gibbs energy change for BSA and HSA, respectively. Hence, for both serum proteins, the binding reaction was dominated by non-polyelectrolytic forces, which accounted for ∼90% of the total standard molar Gibbs energy change. Thus, the dissection of the standard molar Gibbs energy into polyelectrolytic and non-polyelectrolytic components unequivocally established the dominant role played by non-polyelectrolytic forces in the protein−dye complexation process.

Temperature Dependence of the Enthalpy: Determination of Heat Capacity Changes. To gain additional insights into the forces controlling the binding reaction of amaranth with serum albumins, temperature-dependent ITC studies were performed at four different temperatures, viz., 283.15, 293.15, 298.15, and 303.15 K. The pH of the solutions remained unchanged in this temperature range studied. The thermograms for amaranth−protein complexation were found to be sigmoidal at all four temperatures studied. The binding reaction was exothermic at all of the temperatures, yielding negative peaks in the plot of power versus time. The thermodynamic data derived from temperature-dependent ITC studies are collated in Table 2. The K values decreased, $\Delta_r H^\circ$ values became more negative with their magnitudes increasing, and the $T\Delta_r S^\circ$ values also decreased with the rise in the temperature. However, the magnitude of $\Delta_r G^\circ$ remained largely unaltered with the temperature. The variations in the thermodynamic parameters with increasing the temperature are graphically represented in Figure 5. From the N values, it was clearly established that 1:1 complexation occurs between amaranth and the serum proteins, irrespective of the temperature. The standard molar specific heat capacity changes were derived from a plot of $\Delta_r H^\circ$ versus T at a constant pressure, using the following relationship:

$$\Delta_r C_p^{\,0} = [\partial(\Delta_r H^\circ)/\partial T]_p \quad (6)$$

The variation of $\Delta_r H^\circ$ with T afforded straight lines, the slopes of which resulted in values of −0.73 ± 0.06 and −0.60 ± 0.06 kJ K^{-1} mol^{-1}, respectively, for the complexation of amaranth with BSA and HSA (Figure 6). Many ligand−protein and ligand−nucleic acid interactions have been characterized by such negative $\Delta_r C_p^\circ$ values.[28,32,37] Besides, negative $\Delta_r C_p^\circ$ values are often associated with alterations in hydrophobic or polar group hydration and suggest that the binding reaction is dominated by hydrophobic interactions. The $\Delta_r C_p^\circ$ value is lower for HSA compared to BSA, indicating differences in the

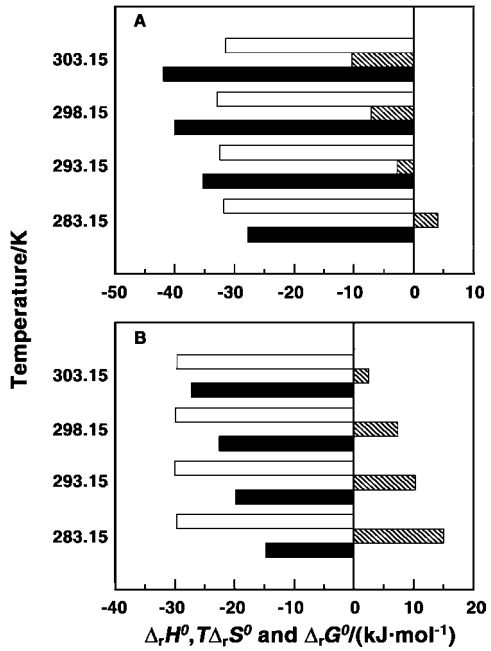

Figure 5. Variation of $\Delta_r G^\circ$ (white), $T\Delta_r S^\circ$ (hatched), and $\Delta_r H^\circ$ (black) with temperature for the complexation of amaranth with (A) BSA and (B) HSA.

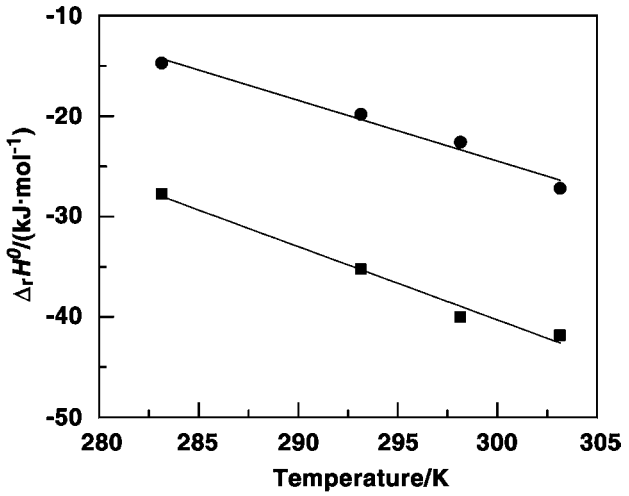

Figure 6. Plot of variation of $\Delta_r H^\circ$ as a function of the temperature for the complexation of BSA (■) and HSA (●) with amaranth.

dx.doi.org/10.1021/jf5025278 | J. Agric. Food Chem. 2014, 62, 7955−7962

release of structured water upon complexation with amaranth. It is also an indicator of the different extent of hydrophobic interactions in the two systems studied. First, it is pertinent to note that the non-zero negative values of $\Delta_r C_p^\circ$ suggest temperature dependence of $\Delta_r H^\circ$ and establish the involvement of hydrophobic forces in the complexation process. Second, the calculated values of $\Delta_r C_p^\circ$ fall well within the range that is frequently observed for biomolecular interactions.[28,38] The magnitude of the $\Delta_r C_p^\circ$ value for amaranth−BSA complexation is slightly higher than that for amaranth−HSA complexation, indicating slight conformational differences in the complexation process and also differences in the disruption of the protein-bound water molecules and counterions. Besides, the removal of water molecules from hydrophobic interfaces, owing to electrostatic interaction, may also be responsible for the negative $\Delta_r C_p^\circ$ term. The negative $\Delta_r C_p^\circ$ values calculated for amaranth−serum protein complexation appears to denote that the binding is specific and accompanied by burial of the nonpolar surface area.[39,40] The standard molar Gibbs energy contribution ($\Delta_r G^\circ_{hyd}$) from the hydrophobic transfer step of binding was calculated using the Records relationship,[41] $\Delta_r G^\circ_{hyd} = (80 \pm 10)\Delta_r C_p^\circ$. The $\Delta_r G^\circ_{hyd}$ value for amaranth−BSA complexation was calculated to be −58.40 kJ mol^{-1}, which is slightly higher than that calculated for amaranth−HSA complexation, viz., −48.00 kJ mol^{-1}.

Enthalpy−Entropy Compensation (EEC). EEC is a characteristic phenomenon of many ligand−protein interactions.[28,42] EEC has been regarded as a natural consequence of finite $\Delta_r C_p^\circ$ values by Cooper et al.[43] They suggested that EEC is a consequence of quantum confinement effects, multiple weak non-covalent interactions, and limited free energy windows, which give rise to thermodynamic homeostasis that may be of evolutionary and functional advantage because it enables adaptation to harsher environments.[43] EEC is also linked with solvent reorganization, accompanying biomolecular interactions.[44−46] The $\Delta_r H^\circ$ values increased in magnitude, whereas the $T\Delta_r S^\circ$ term decreased with increasing the temperature. However, the $\Delta_r G^\circ$ values remained almost unaltered with changing the temperature. The $\Delta_r H^\circ$ and $T\Delta_r S^\circ$, both of which are strong functions of T, compensated one another to make the overall $\Delta_r G^\circ$ temperature invariant. Linearity of the relationship of $\Delta_r H^\circ$ with $T\Delta_r S^\circ$ with slope close to unity suggests complete compensation, and this occurs in systems with $\Delta_r C_p^\circ \neq 0$ and $\Delta_r C_p^\circ > \Delta_r S^\circ$. $\Delta_r H^\circ$ and $\Delta_r G^\circ$ were plotted as a function of $T\Delta_r S^\circ$, and the slopes of the plot of $\Delta_r H^\circ$ versus $T\Delta_r S^\circ$ were deduced to be 1.01 ± 0.05 and 0.99 ± 0.06, respectively, for BSA and HSA (Figure 7). Linear relationship between $\Delta_r H^\circ$ and $T\Delta_r S^\circ$ with slope close to unity suggested complete EEC in the two protein−dye systems studied.

DSC Studies. DSC is an effective and reliable tool for monitoring protein folding−unfolding.[30,47] To monitor the effect of the azo dye amaranth on the thermal stability of the two homologous serum proteins, the DSC thermograms of excess heat capacity versus temperature were analyzed with Origin 7.0 software. It was found that both the serum proteins, BSA and HSA, unfolded cooperatively, exhibiting a single endothermic peak with melting temperatures of 327.61 and 328.85 K, respectively (Figure 8). The binding reaction with amaranth resulted in remarkable enhancement of the thermal stability of both the serum proteins. Upon binding to amaranth, the thermal denaturation temperature (T_m) of BSA and HSA was enhanced to 335.56 and 341.01 K, respectively (Figure 8).

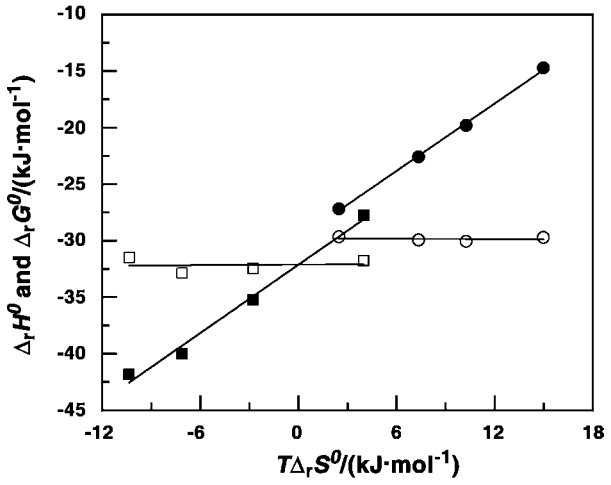

Figure 7. Plot of variation of $\Delta_r H^\circ$ (closed symbols) and $\Delta_r G^\circ$ (open symbols) as a function of $T\Delta_r S^\circ$ for the binding of amaranth to BSA (■ and □) and HSA (● and ○).

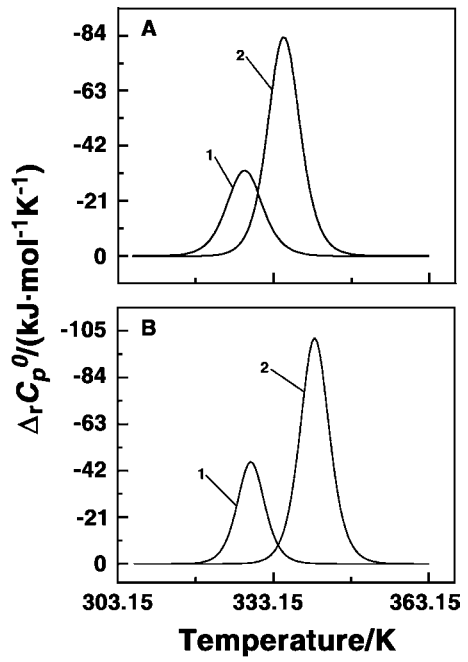

Figure 8. DSC thermograms of (A) BSA and (B) HSA. Curves 1 and 2 represent the free protein and amaranth−protein complexes, respectively.

Thus, the two homologous serum proteins, BSA and HSA, were stabilized (ΔT_m) by 7.95 and 12.16 K, respectively. In addition to the T_m values, the DSC thermograms upon analysis also afforded the calorimetric transition enthalpy ($\Delta_r H_{cal}$). The value of $\Delta_r H_{cal}$ is model-independent and has no relation with the nature of the transition. It is pertinent to mention here that there was no significant change in the shape of the DSC thermograms, which enabled us to conclude that the denaturation process was not altered but only shifted to higher temperatures in the presence of the dye. The $\Delta_r H_{cal}$ value increased from 296.52 ± 0.08 kJ mol^{-1} in the unbound form to 683.76 ± 0.15 kJ mol^{-1} in the bound form for BSA. For HSA, the magnitude of $\Delta_r H_{cal}$ enhanced from 321.30 ± 0.14 kJ mol^{-1} in the unbound form to 759.36 ± 0.16 kJ mol^{-1} in the bound form. Thus, $\Delta_r H_{cal}$ increased by 387.24 ± 0.07 and 438.06 ±

dx.doi.org/10.1021/jf5025278 | J. Agric. Food Chem. 2014, 62, 7955−7962

0.02 kJ mol^{-1}, respectively, for BSA and HSA upon binding to amaranth.

The present study presents a detailed description of the thermodynamics of the interaction of the toxic food colorant amaranth with two homologous serum proteins. These microcalorimetric investigations lend deeper insights into the thermodynamics of the interaction of the toxic food additives with the serum proteins, which may prove critical in realizing the toxic and hazardous effects of food colorants on biological systems.

Table 1. Potato Cultivars for Wound Healing Study

cultivar	flesh	periderm russeting	skin
Norkotah Russet	white	russeted and netted	dark tan
Atlantic	white	lightly netted to heavily scaled	white
Chipeta	white	small russeted areas	light to buff
Yukon Gold	light yellow	smooth, finely flaked, yellowish white	yellowish

methodological and agricultural standpoints: high performance liquid chromatography (LC-MS) and nuclear magnetic resonance (NMR) may offer more robust characterization of the healing tissue extracts, and cultivar comparisons could show metabolite differences that reveal the molecular underpinnings of russeted skin character and/or wound-induced stress response.

In turn, the oxidative stress due to wounding can unleash the production of antioxidant compounds, which are present in the native skin of potato and have already found practical use as preservatives in the food industry.[3] Antioxidant evaluation of a purple potato cultivar using a diphenyl picrylhydrazyl (DPPH$^{\bullet}$) scavenging assay showed that the activity increased as a result of wounding,[15] but a trend of decreasing DPPH$^{\bullet}$ scavenging activity was reported in a wounded Norkotah Russet sample.[16] This inconsistency could reflect a shortcoming of the DPPH$^{\bullet}$ assay, whereby steric hindrance could compromise assessments of scavenging activities for larger phytochemical constituents. Thus, the current experimental design couples LC-MS and NMR metabolite profiling for four cultivars, at day 3 and day 7 after wounding, with broadly applicable extended-duration scavenging assays using 2,2′-Azinobis (3-ethylbenzothiazoline-6-sulfonic acid ammonium salt) (ABTS$^{\bullet+}$).[17] By coordinating information on chemical composition and antioxidant activity, the long-term goal is to develop improved methods that ensure rapid and complete wound healing for various potato cultivars while also providing a rich source of chemical compounds with potential application as functional foods.[3,18,19]

MATERIALS AND METHODS

Reagents. HPLC-MS grade acetonitrile, water, chloroform and methanol (J. T. Baker, Phillipsburg, NJ) and formic acid (Sigma-Aldrich, St. Louis, MO) were used for LC-MS/MS and time-of-flight (TOF-MS) analysis. 2,2′-Azinobis (3-ethylbenzothi-azoline-6-sulfonic acid ammonium salt) (ABTS), 6-hydroxy-2,5,7,8 tetramethylchromane-2-carboxylic acid (TCI, Tokyo, Japan), and potassium peroxosulfate (Sigma-Aldrich, St. Louis, MO) were utilized in the antioxidant assay.

Plant Material. Potato tuber cultivars from the 2011 crop year were provided by Joe Nuñez, University of California Cooperative Extension (Davis, CA). Table 1 summarizes the differences in overall phenotypic characteristics that were used in making these selections.

Sample Preparation. Freshly harvested potato tubers were peeled, and the internal flesh tissues were sectioned longitudinally with a mandolin slicer to obtain slices about 5 mm thick. The central part of the tuber was set aside to avoid the internal medulla. Slices were placed on wet cellulose filter paper and left for 3 or 7 days of healing on wire netting supports within closed plastic boxes at 25 °C. Water was added at the bottom of the boxes to maintain humidity; healing proceeded in the dark. The brown surface layer of wound-healing tissue was collected carefully using a flat spatula, making efforts to avoid flesh (parenchyma) contamination. The samples were harvested at 3 and 7 days after wounding, representing the early healing tissue in which the suberized closing layer and the wound periderm were developing, respectively. Harvested wound periderm samples were frozen immediately in liquid nitrogen and stored at −80 °C until processed. For processing, samples were ground under liquid nitrogen, freeze-dried, and again stored at −80 °C.[20]

The samples were prepared for chemical analysis using a modification of the method employed by Choi et al., which enables concurrent extraction and partitioning of polar and nonpolar constituents and has become an established protocol for metabolomic studies of plant materials.[20,21] Samples of 10 mg (dry weight) each were placed in jn glass vials (Microliter Analytical Supplies, Suwanee, GA) and extracted with 2 mL of 60% (v/v) methanol−water by pan ultrasonication (Branson Ultrasonics, Danbury, CT) for 1 min, followed by addition of 2 mL chloroform and sonication again for 1 min. Each extract was then incubated at room temperature in a shaker for 10 min, followed by tabletop centrifugation (Beckman Coulter, Fullerton, CA) at 3000 rpm to produce three separate phases: soluble polar, soluble nonpolar, and an interphase of suspended particulates. Six replicate extracts were prepared per cultivar for each wound-healing time point (day 3 and day 7). The upper soluble polar extracts were removed carefully with a glass Pasteur pipet and dried under a flow of nitrogen for a few hours. This phase was selected for the current analysis.

NMR. Aliquots of the polar extract were dried and reconstituted using a 100 mM pH 7.4 phosphate buffer in D_2O that contained the internal standard DSS (0.01 mg/mL). Spectra were recorded using a Bruker AVANCE PLUS spectrometer (Bruker Biospin, Karlsruhe, Germany) operating at a ^{1}H frequency of 800 MHz and equipped with a cryomicroprobe that accommodates 1.7 mm o.d. sample tubes (Norell, Landisville, NJ). Acquisition of the spectra was achieved using TOPSPIN version 3.1 software and an NMR SAMPLEJET accessory for automated sample changing. ^{1}H NMR data were collected for the polar extracts at 298 K with a constant receiver gain, using 512 scans with 4 initial "dummy" scans, a recycle delay of 1.0 s between acquisitions, and presaturation of the residual water signal set to a chemical shift of 4.695 ppm. The spectral window after Fourier transformation and signal conditioning was 14 ppm defined by 32K data points.

LC-MS. Liquid chromatography was conducted with a Shimadzu UFLC (Shimadzu U.S.A., Canby, OR) equipped with two LC-20 AD pumps, a SIL-20AC automatic injector, a CBM-20A communication bus module and a CTO-20AC column oven. The separations were carried out using a 150 × 4.6 mm i.d., 3.0 μm AscentisR C18 column (Supelco Analytical, Bellefonte, PA). Each analysis was performed by injecting a 10 μL sample into the column and eluting at 35 °C with a flow rate of 0.4 mL/min. Six replicate extracts per cultivar were analyzed for each wound-healing time point, and each sample was injected twice. The mobile phase was composed of 0.1% aqueous formic acid (A) and 0.1% formic acid in acetonitrile (B) using a program of nonlinear gradient elution: 2% B (0−5 min), 2−10% B (5−8 min), 10−15% B (8−13 min), 15% B (13−25 min), 15−30% B (25−28 min), 30−40% B (28−50 min), and 40−100% B (50−60 min).

The LC system was interfaced to an Applied Biosystems 4000 Q Trap mass spectrometer (Applied Biosystems, Foster City, CA) for LC-MS/MS measurements. The source type was electrospray ionization (ESI) and the source temperature was 300 °C. Mass spectra were acquired in both positive and negative modes over the range m/z 100−1300. Full scan, MS^2, and MS^3 data were collected using these settings. The optimized declustering potentials were 66 V in the positive mode and −140 V in the negative mode; chlorogenic acid and rutin, compounds reported previously in potatoes,[9,11,22] were used as reference standards. Analyst 1.4.2 software was used for data processing.

Fractionation of the Extracts. The polar extracts were fractionated using an Agilent 1200 series HPLC-PDA liquid

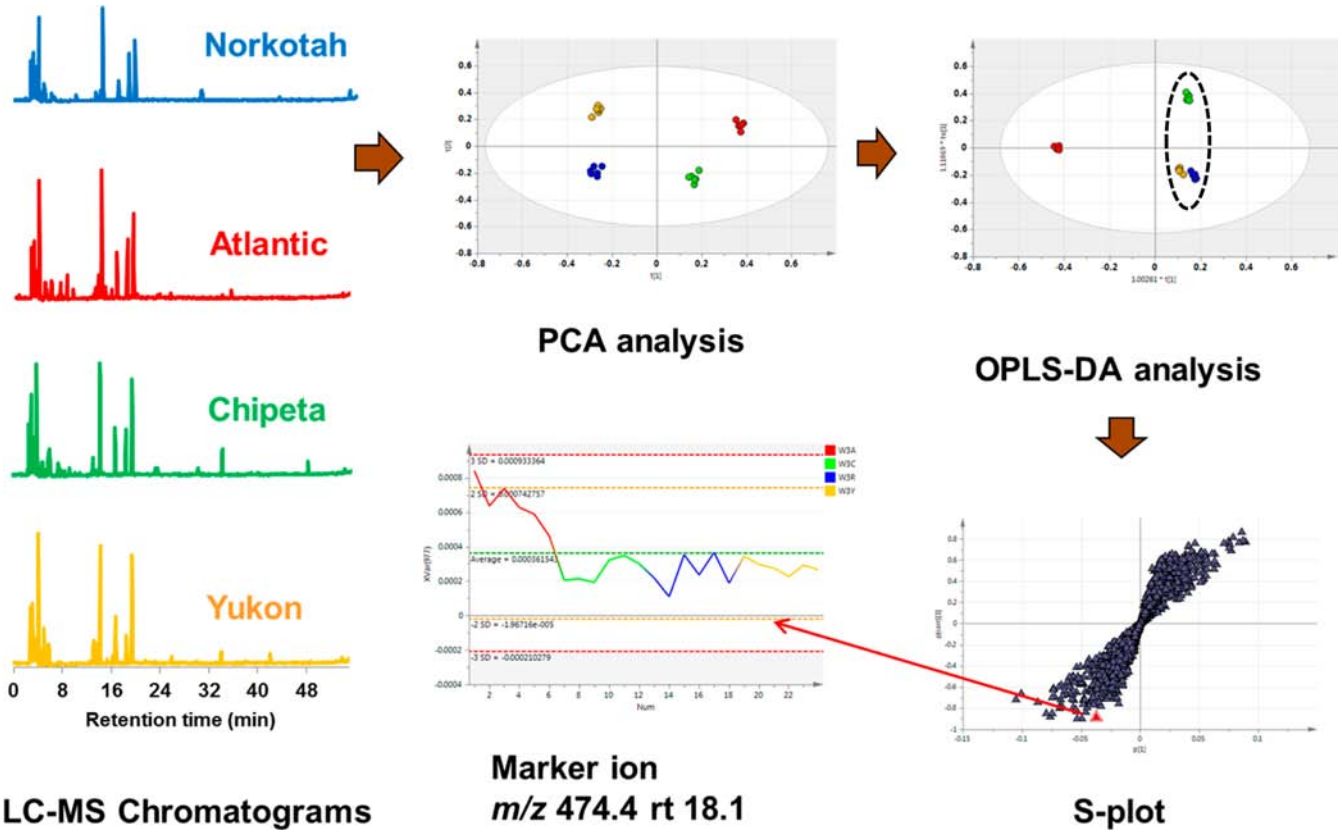

Figure 1. Schematic representation of the experimental design, including typical data and statistical multivariate analyses including PCA, OPLS-DA and S-plot analysis of liquid chromatography - mass spectrometry (LC-MS) data (total ion current (TIC) chromatograms in positive mode), leading to the detection of marker ions. Stacked LC-MS chromatograms of the polar extracts each represent average data from six biological replicates from day 3 potato wound periderm samples, color coded for Norkotah Russet (blue), Atlantic (red), Chipeta (green), and Yukon Gold (gold). Statistical procedures are detailed in the text.

chromatography system (Agilent Technologies, Santa Clara, CA) equipped with a G1322A degasser, G1311A quaternary pump, G1316A thermostatically controlled chamber, G1315B diode array detector, and G1364C analytical fractionator. The mobile phase composition, flow rate, gradient, and column were as described above. Fractions were collected at 30-s intervals throughout a 60 min chromatographic run. This fractionation protocol was repeated several times to generate sufficient material that could be concentrated and analyzed by TOF-MS to obtain the exact mass of the compounds under investigation.

TOF-MS. Chromatographic fractions from the polar extracts were injected directly into a Waters LCT premier XE TOF mass spectrometer (Micromass, Manchester, U.K.) using a Harvard 11 Plus Single Syringe Pump (Harvard Apparatus, Holliston, MA) equipped with an ESI interface and controlled by MassLynx V4.1 software. Mass spectra were acquired in both positive and negative modes over the range m/z 100−1300. The capillary voltages were set at 4000 V for both acquisition modes. Nitrogen gas flowing at 300 L/h was used for both the nebulizer and in desolvation. The desolvation temperature was 150 °C, and the source temperature was 80 °C. For the dynamic range enhancement (DRE) lockmass, a solution of leucine enkephalin (Sigma-Aldrich, St. Louis, MO) was infused by a secondary reference probe at 200 pg/mL in acetonitrile/water (1:1 v/v) containing 0.1% formic acid with the help of a second LC pump (Waters 515 HPLC). The reference mass was determined once every five scans for both positive and negative data collection; both types of ESI data were collected using a scan time of 0.2 s and an interscan time of 0.01 s.

ABTS$^{\bullet+}$ Scavenging. The ABTS$^{\bullet+}$ scavenging activity was assessed according to the method described by Re et al.[17] with minor modifications. ABTS$^{\bullet+}$ was generated by reacting an aqueous ABTS solution (7 mM) with $K_2S_2O_8$ (2.45 mM) in the dark for 12−16 h at ambient temperature and adjusting the absorbance at 734 nm to 0.70 (±0.02) with ethanol. To a 2 μL aliquot of the periderm extract of interest was added 198 μL of ABTS$^{\bullet+}$ reagent; the absorbance was recorded at 734 nm after initial mixing and subsequently at 5 min intervals (45 min in total) using a Spectra$_{max}$ microplate reader (Molecular Devices, Sunnyvale, CA). The percentage inhibition values for different concentrations were calculated using the following equation:

$$\left[\frac{(\mathrm{Abs}_{\mathrm{control}}) - (\mathrm{Abs}_{\mathrm{sample}})}{(\mathrm{Abs}_{\mathrm{control}})}\right] \times 100 \quad (1)$$

A plot of percentage inhibition versus concentration was made for the reference standard, 6-Hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid (Trolox). On the basis of this plot, the Trolox equivalent antioxidant capacity (TEAC, μmol Trolox/g dried sample) values were calculated for each extract.

Preprocessing of NMR Data. For metabolite profiling analysis, MESTREC software version 4.9.9.9 (Mestrelab Research, Escondido, CA) was used to correct the phase and baseline of each spectrum and to remove the spectral region containing the remaining water signal. The spectra were then subjected to binning and integrated in 0.04 ppm regions. The integrated area of each bin/bucket was normalized with respect to the area of all bins.

Preprocessing of LC-MS Data. MZmine version 2.4 (VTT Technical Research Center, Helsinki, Finland and Turku Center for Biotechnology, Turku, Finland) was used to filter the spectra according to retention time and m/z range. Spectral deconvolution and feature detection were followed by peak alignment and data normalization.[23] The region of the chromatogram between 0 and 4

[a]Exact mass data obtained from MS-TOF analysis. [b]Fragmentation data obtained from LC-MS/MS analysis using a 4000Q Trap instrument. [c]Also among the biomarkers identified in native periderms of these four cultivars (Huang et al., unpublished observations). [d]Isomeric compounds which were distinguished from each other by their retention times and the intensities of their mass fragmentation peaks. [e]The wound healing time point is denoted by Wd3 or Wd7, and color coded depending on the cultivar(s) specific for the biomarker. The coloring scheme denotes Atlantic (red), Chipeta (green), Norkotah Russet (blue), or Yukon Gold (gold). [f]Marker compounds found in all four cultivars that are specific to day 7 post wounding, which is associated with nascent wound periderm development. The (+) sign indicates that the compound in question is a marker for the day 7 time point. [g]Also among the metabolites identified in native periderms of these four cultivars (Huang et al., unpublished observations). [h]This compound can be distinguished from gas-phase dimer ions produced as artifacts during MS analysis: the observed m/z value of its molecular ion differs from a simple doubling of chlorogenic acid due to loss of water consequent with dimer formation.

min, which contains primary metabolites reported previously,[14] was not included in the current PCA analysis.

Multivariate Data Analysis. Principal component analysis (PCA) of the normalized data from NMR and MS experiments was carried

out using Simca-P+ software version 13.0 (Umetricas, Umeå, Sweden) and Pareto scaling.[20] In addition, the data were subjected to orthogonal partial least-squares discriminate analysis (OPLS-DA), in which data from a particular cultivar were assigned to one class that was then compared with another class comprising the remaining cultivars. The corresponding S-plots displayed extreme "wings" that yielded chemical shifts or mass-to-charge (m/z) ratios of the biomarkers that contribute to compositional differences among the tissue samples (Figure 1). These variables were evaluated individually using variable line plots to ascertain if the markers were unique to a particular cultivar at a specified wounding time point (Figure 1).

Tentative Metabolite Structural Identification. The markers were then characterized using mass and fragmentation data (MS, MS/MS and MS/MS/MS) from the 4000Q Trap and the exact mass values from the TOF-MS instrument, respectively. The marker compounds were identified tentatively by comparison of these data with published MS results using SciFinder Scholar and online databases such as PubChem, ChemSpider and Metlin.

To check the consistency of the MS-based identifications with observed NMR data for the extract mixtures, ACD software (ACD Laboratories, Toronto, Canada) was first used to simulate the NMR spectra of the identified markers. The simulated ^{1}H spectra of each compound were checked against the chemical shift list derived for biomarkers by OPLS-DA and S-plot analysis of the experimental NMR data for extract mixtures. For example, a biomarker compound for the Atlantic day 3 extract was tentatively identified as bis (dihydrocaffeoyl) spermidine, compound **5**, (474.4 m/z; 18.1 min) (Figure 1 and Table 2). The simulated ^{1}H chemical shifts for this MS-derived biomarker were compared with marker shifts derived from the experimentally observed NMR data for the extract mixture.

RESULTS AND DISCUSSION

Metabolic Fingerprinting. Visual inspection of the stacked ^{1}H NMR spectra for wound-healing tissue extracts from various cultivars at days 3 and 7 (Figure 2 and Supporting Information (SI) Figure S1, respectively) shows good consistency among the six replicates for each cultivar, a high degree of instrumental reproducibility, and modest but clear differences among the four cultivars. A more rigorous multivariate analysis of the data provides essential unbiased confirmation of these differences. The PCA-associated score plots for the NMR data (Figure 3) demonstrate that the polar

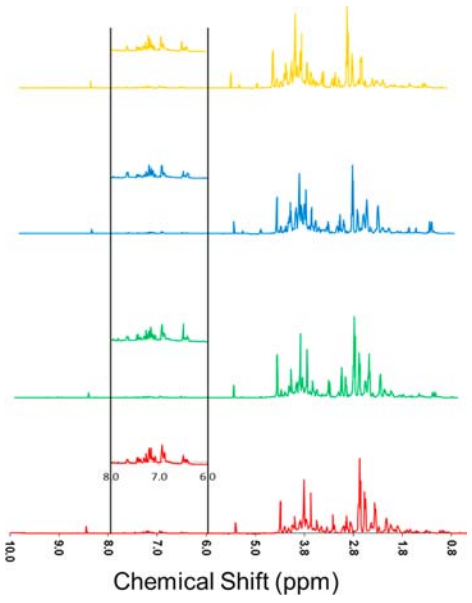

Figure 2. Stacked 800 MHz ^{1}H nuclear magnetic resonance (NMR) spectra, showing average data from six biological replicates of polar extracts from day 3 potato wound periderm samples, color coded for Yukon Gold (gold), Norkotah Russet (blue), Chipeta (green), and Atlantic (red). Vertical expansions of the aromatic and multiple-bonded region between 6.0 and 8.0 ppm are shown in each inset.

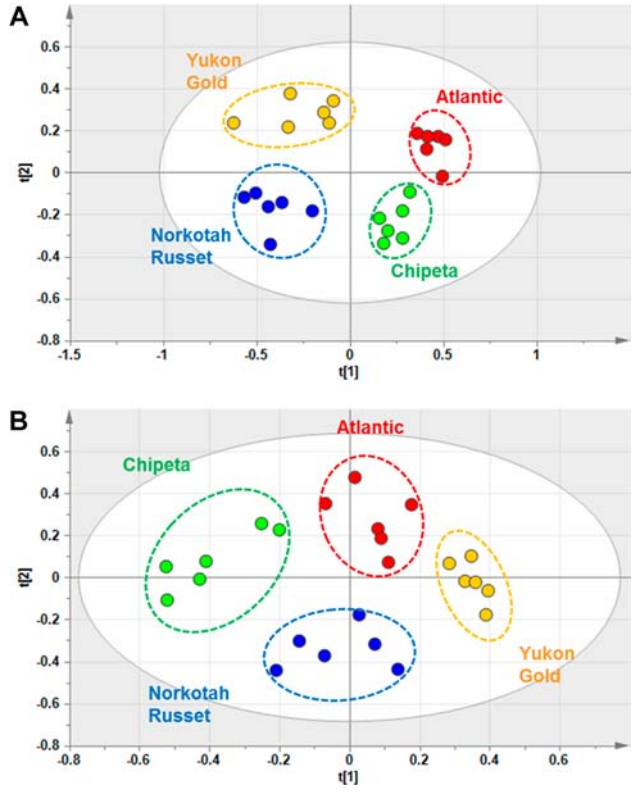

Figure 3. PCA score plots for the NMR data from extracts of day 3 (A) and day 7 (B) wound-healing samples, color coded for Atlantic (red), Chipeta (green), Norkotah Russet (blue), and Yukon Gold (gold) potato periderms.

metabolites for each of the four cultivars form distinct and nonoverlapping clusters, more distinct at day 3 compared with day 7 post wounding. To compare the metabolic profiles at different wound-healing time points, PCA was carried out for day-3 and day-7 NMR data together; the resulting score plot (Figure 4) shows a clear separation of metabolites at the two time points according to PC1. Again, a closer convergence of the clusters for each cultivar is evident at day 7.

In an analogous fashion, Figure 2 and SI Figure S2 demonstrate consistency among LC-MS experiments on nominally identical samples and distinct signatures for each of the four cultivars and wound-healing time points. Even more definitively than via NMR data, score plots obtained from PCA analysis of the LC-MS experiments show polar metabolite differences among the clusters corresponding to Russet Norkotah, Atlantic, Chipeta, and Yukon Gold cultivars (Figure 5). As compared with day 3 (Figure 5A), the convergent trend of metabolite compositions at day 7 is demonstrated by both the LC-MS score plot (Figure 5B) and the overall PCA analysis for both healing time points (Figure 6), again aligning with the NMR-derived multivariate analysis (Figures 3 and 4). This convergence of metabolite profiles with time, which has been observed previously in GC-MS-based multivariate analysis of Russet Burbank periderms,[14] could reflect common biosynthetic pathways associated with wounding in the four cultivars.

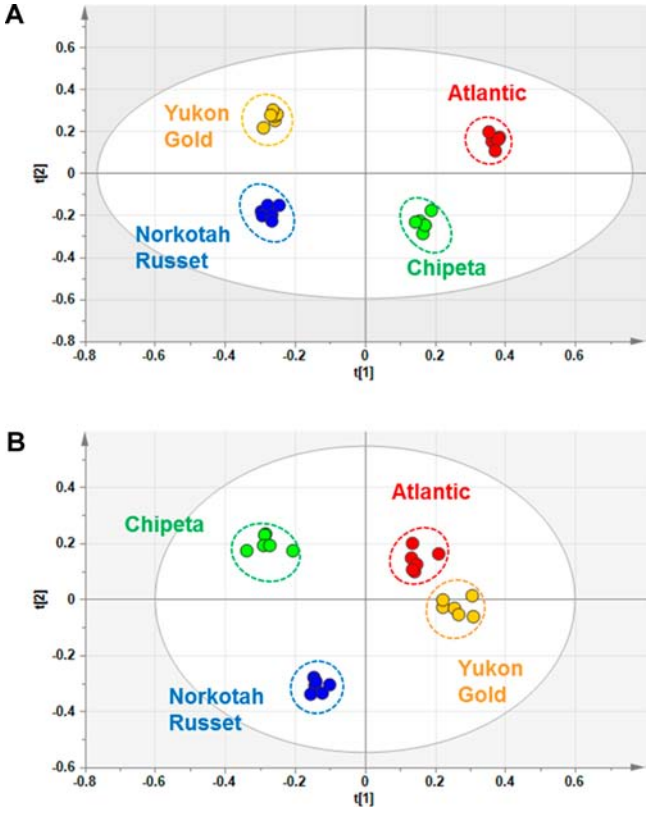

Figure 5. PCA score plots for the LC-MS data from extracts of day 3 (A) and day 7 (B) potato wound-healing samples, color coded for Atlantic (red), Chipeta (green), Norkotah Russet (blue), and Yukon Gold (gold).

That is, if the initially distinct metabolite pools for the four cultivars accumulate a common set of phytochemicals associated with wound induction, these common metabolites will become increasingly dominant at later healing stages.

OPLS-DA analyses and their corresponding S-plots, illustrated in Figure 1, provide chemical insight into the basis for variations in metabolic profiles. In particular, it is possible to identify the NMR chemical shifts and/or MS ions corresponding to metabolites ("biomarkers") that accumulate or are specific for a particular cultivar or wound-healing time point from the extremes of the S-plots. By comparing the marker ions

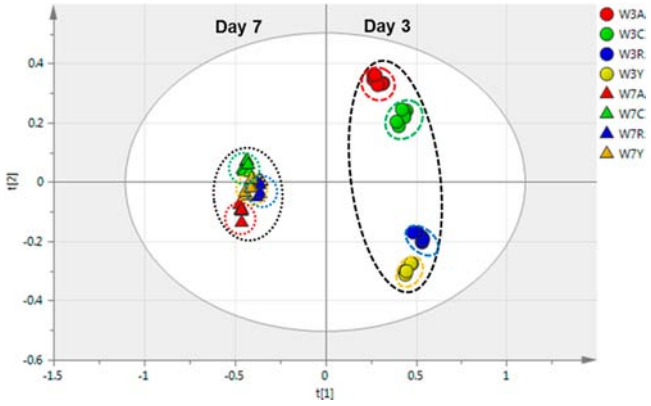

Figure 6. PCA score plot for the overall LC-MS data from extracts of the cultivars at both day 3 (circles) and day 7 (triangles) post wounding (W). The periderm samples are coded for Atlantic (red, a), Chipeta (green, c), Norkotah Russet (blue, r), and Yukon Gold (gold, y).

with published MS data using SciFinder Scholar (https://scifinder.cas.org/scifinder) or other online databases, it was possible to tentatively identify the polyphenolic amines, flavonoid glycosides, phenolic acids, and glycoalkaloids listed in Table 2. A total of 22 of 24 biomarkers were identified by MS/MS and MS-TOF methods. As noted in the Materials and Methods section, early eluting primary metabolites were excluded from the current PCA analysis.

Biomarkers for Cultivar Type. The majority of the identified biomarkers for Atlantic and Norkotah Russet varieties, at both days 3 and 7 post wounding, are polyphenolic amines. Conversely, most of the polyphenolic amine biomarkers are found in the Atlantic and Norkotah Russet cultivars (Table 2). Polyphenolic amines have been claimed previously to offer resistance to potato pathogens such as *Phytophthora infestans* and *Streptomyces scabies*.[24−26] Therefore, accumulation of these antimicrobial compounds can offer protection at the wound site and aid in development of an effective moisture barrier.

The polyphenolic amine biomarkers include derivatives of spermine, spermidine, tyramine, and putrescine. Among these compounds, markers for closing layer formation include kukoamine isomers (**1**, **2**), feruloyl putrescine and its isomer (**3**, **4**), N^1, N^4-bis (dihydrocaffeoyl) spermidine (**5**), N^1,N^4,N^8-tris (dihydrocaffeoyl) spermidine (**6**), feruloyl tyramine (**7**) and caffeoyl putrescine (**8**) for the Atlantic and/or Norkotah Russet cultivars.[24] By contrast, other phenolic amines are found as biomarkers for these cultivars only after the closing layer has been formed and wound periderm formation has been initiated: coumaryl putrescine (**9**) for Atlantic and N^1,N^4,N^{12} tris-(dihydrocaffeoyl)spermine (**10**) for Norkotah Russet, respectively. Feruloyl tyramine (**7**) is a Norkotah Russet marker at both day 3 and day 7 time points. Compounds **6**, **9**, and **10** are also markers for the day 7 wound-healing time point in Chipeta or Yukon Gold cultivars. The polyphenolic amine biomarkers listed in Table 2 have been reported previously in the flesh of potato tubers.[10,11] Feruloyl tyramine and related compounds are associated with the lesions and heavier skins formed by scab-infected potato tubers.[24,26] (The phenolic amine Grossamide (**11**), which is not a cultivar marker but is upregulated for all four cultivars, is discussed in the following section.) One additional unidentified biomarker (**23**) can be classified as a spermine derivative from its MS data. Finally, several of the

polyphenolic amines in Table 2 were also identified in native periderms (tuber skin) from these four potato cultivars (noted as [a] for biomarkers, [e] for nonbiomarker metabolites; Huang et al., unpublished observations).

Kaempferol glycosides (**12**−**14**) are detected as biomarkers for Norkotah Russet and Yukon Gold. Most of the glycosides are present in Yukon Gold. All glycoside compounds have been reported in potato peels[9] with the exception of Potengriffioside (**14**), which was isolated from *Solanum crinitum* Lam. tubers.[27] One common potato phenolic metabolite that is identified as a biomarker for Yukon Gold and Norkotah Russet is chlorogenic acid (**15**). Feruloyl quinic acid (**16**) is a marker specific to Norkotah Russet at days 3 and 7; ferulic acid itself (**17**), which plays an integral role in suberin formation,[28,29] is a marker for the day 3 extracts of Yukon Gold. Both **15** and **17** have been reported previously in the polar extracts from wound-healing Russet Burbank potato periderms.[14] Finally, the Atlantic and Chipeta cultivars exhibit a caffeoylquinic acid dimer biomarker (**18**) in both 3- and 7-day wound-healing samples.

Glycoalkaloids, compounds **19**−**22**, are identified as biomarkers for Chipeta and Norkotah Russet cultivars. Chaconine (**19**) and solanidine solatriose (**20**) are detected in day 3 and day 7 Chipeta samples, respectively, whereas Leptinine II (**21**) is a marker for day 3 Norkotah Russet polar extracts. Leptinine I (**22**) is a marker for day 7 extracts in all four cultivars and should thus be viewed as a marker associated with this later time point of wound-induced healing. The glycoalkaloids chaconine, leptinine II, leptinine I, and solanidine solatriose have been reported previously in the tubers of Norkotah Russet potatoes.[12] Chaconine has also been reported to be present in potato peels of diverse cultivars.[9,12] Taken together, the glycoalkaloid compounds are viewed as an important class of potato biomarkers because of their demonstrated role in resistance to pests and pathogens.[30] However, they also show concentration-dependent toxicity in organisms ranging from fungi to humans.[31,32] Due to their structural similarity to steroidal hormones, glycoalkaloids are considered additionally to be promising intermediates in the production of contraceptives and steroidal anti-inflammatory drugs.[3] Glycoalkaloids have been reported to have a wide range of bioactivities, including anticancer, anti-inflammatory, anti-nociceptive, and antipyretic effects.[32]

Biomarkers for Wound-Healing Time Point. Although the current comparisons are limited to day-3 and day-7 time points, a prior extended time course study of healing Russet Burbank tubers reported a significantly different polar metabolic profile at day 0, the onset of wound induction.[14] OPLS-DA and S-plot analysis of day-3 and day-7 wound-induced metabolite data for the four cultivars permits the identification of compounds that are more abundant at day 7, the healing time point related to the development of the nascent wound-healing periderm.[5,6] These compounds include several classes of phytochemical substances: polyphenolic amines, flavonoid glycosides, phenolic acids and glycoalkaloids. A kukoamine isomer (**1**), feruloyl putrescine isomer (**4**), N^1,N^4 bis(dihydrocaffeoyl) spermidine (**5**), grossamide (**11**), kaempferol hexoside (**12**), chlorogenic acid (**15**), ferulic acid (**17**), chaconine (**19**) leptinine I (**22**), spermine derivative (**23**) were all identified as markers specific to the day-7 healing time point., Thus, compounds produced in significantly larger quantities at the day-7 time point compared with day 3 can be associated with wound periderm development. Indeed, phenolic amines and glycoalkaloids similar to **1**, **4**, **5**, **11**, **19**, and **22** have been reported to offer resistance against microbes, insects, and herbivores.[25,33] Therefore, their accumulation during wound periderm formation could be part of the protective mechanism against infections.

The current results complement a prior GC-MS study of wound-healing samples from Russet Burbank potato periderms, in which the majority of the identified constituents were primary metabolites but phenolic compounds such as chlorogenic acid, ferulic acid, *iso*-chlorogenic acid, caffeic acid, and coniferyl alcohol were also reported.[14] No phenolic amines, flavonoid glycosides, or glycoalkaloids were identified in the earlier work, presumably because silylation produced species that exceeded the detectable m/z ratio, were only partially derivatized, or underwent side reactions rather than the desired formation of volatile derivatives.[34]

Methodological Challenges for Biomarker Identification. As shown in Figures 3−6, robust multivariate analyses can be conducted for polar periderm extracts using either NMR or LC-MS data; chemical shifts and mass-to-charge ratios of markers for cultivar type or wound-healing time point can also be extracted from S-plots in OPLS-DA analyses (Figure 1). For each of the 22 MS-derived biomarkers identified by comparison with published mass spectral data (TOF, LC-MS, and mass fragmentation) for potatoes or related plant species, we were able to simulate an NMR spectrum; the prediction could then be cross-checked against biomarker chemical shifts that had been determined from the wings of the corresponding NMR-derived S-plots. This situation is illustrated by the biomarkers for the Yukon Gold day 7 extract: for feruloyl putrescine (**3**), N^1,N^4,N^{12} tris(dihydrocaffeoyl spermine (**10**), kaempferol hexoside (**12**), potengriffioside (**14**), and chlorogenic acid (**15**), the MS-based identifications and associated NMR spectral simulations were supported by observed biomarker chemical shifts (e.g., 7.68, 7.48, 7.44, 7.32, 7.28, 7.20, 7.16, 7.04, 7.00, 6.96, 6.88, 6.84, 6.76, 6.72, 6.60, 6.56, 6.52, 6.40, 5.32, 4.26, 4.22, 3.90, 3.86, 3.82, 3.70, 3.38, 3.34, 3.30, 3.10, 2.22, 1.54, and 1.14 ppm).

For biomarkers such as **23**, however, the MS ion could not be identified because no published literature was available; it was possible to deduce its compound class from the associated MS^n fragments and to validate that supposition from the NMR-derived biomarkers. Such novel compounds then remain to be isolated and elucidated using standard but lengthy spectroscopic procedures. Even more seriously, LC-MS could miss an oligomeric biomarker i.e., give a false negative result, if the compound fails to ionize and thus goes undetected. Either previously unreported MS marker ions or biomarkers that do not ionize in MS experiments should be evident if analysis of the NMR data reveals marker shifts that fail to match the predictions for MS-identified compounds.

Although ^{1}H NMR methods have a broader detection range,[35] they suffer from considerably lower molar sensitivity than MS. A pitfall associated with this limitation is illustrated by the observed marker shifts at 5.40 and 5.44 ppm, which are consistent with NMR spectra predicted for the leptinine II glycoalkaloid (**21**), a metabolite that is accessible by LC-MS but does not satisfy biomarker criteria for the Yukon Gold day-7 polar periderm extract. The limited sensitivity of NMR could render this compound unobservable in the remaining cultivar samples, producing a false positive among the NMR-derived biomarkers. Finally, NMR-based identification of individual metabolites in an extract mixture is also challenged by incomplete spectral resolution, even when multidimensional

experiments are conducted. Although a number of promising NMR-based metabolomic identification approaches have been proposed in recent years,[36] they remain limited by the complexity of plant extract mixtures and the scope of current structural data libraries.

Complications such as those illustrated above reflect incomplete structural databases for plant-derived materials as well as limited MS ionization and NMR sensitivity capabilities, respectively, arguing for use of a conservative dual-method analysis to improve the completeness of the resulting structural profile for constituent metabolites.

ABTS$^{\bullet+}$ Scavenging Activity of Wound-Healing Extracts. As noted above, the oxidative stress associated with tuber wounding and the potential of potato-derived antioxidant compounds as food preservatives[3] together motivate quantitative assessments of such compounds in potato cultivar samples. Polar extracts of day 3 and day 7 tissue samples were screened for their free radical scavenging activities. All extracts exhibited scavenging activity, and their activities increased with incubation time (Figures 7 and 8). Thus, it may be deduced

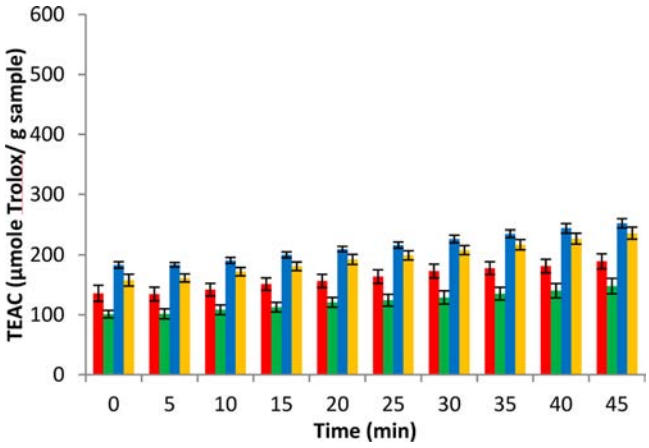

Figure 7. ABTS$^{\bullet+}$ scavenging activity of polar extracts from day 3 potato wound periderm samples expressed as TEAC (μmol Trolox/g dried sample), color coded for Atlantic (red), Chipeta (green), Norkotah Russet (blue), and Yukon Gold (gold). Values are expressed as mean ± standard error of the mean (n = 6). The assay is described fully in the text.

that the cultivars contain slow- as well as fast-acting antioxidants, underscoring the need for an assay such as ABTS$^{\bullet+}$ that measures the scavenging capability of the extracts over an extended period of time.[17] The assay has additional advantages such as absence of steric hindrance, a broad pH range, and minimal spectral interference from other natural products,[37,38] distinguishing the current investigation from previous antioxidant research on extracts from potato peels.[15,18,19]

At day 3, the order of activity among the cultivars was as follows: Yukon Gold ≈ Norkotah Russet (not significantly different, $P > 0.05$) > Atlantic > Chipeta. The order of activity was changed at day 7, to Yukon Gold > Norkotah Russet > Atlantic > Chipeta. Overall, the extracts of Yukon Gold stood out for their high scavenging activity, displaying the highest rates especially after 7 days of wound healing. Although the scavenging capability for most varieties is achieved early during closing layer development and maintained at comparable levels as a functional periderm barrier begins to develop, the Yukon Gold variety nearly doubles its scavenging activity at day 7. This

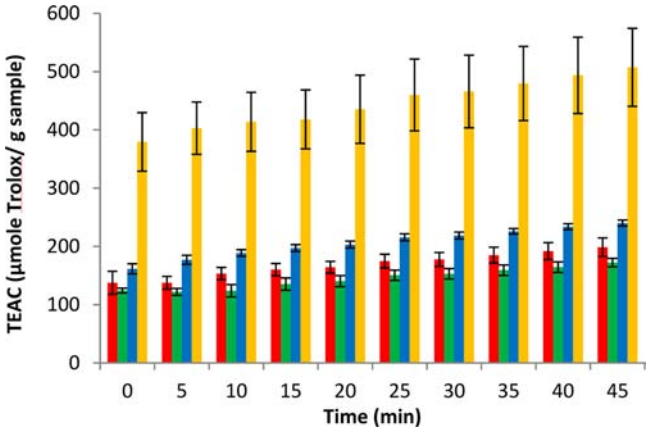

Figure 8. ABTS$^{\bullet+}$ scavenging activity of polar extracts from day 7 potato wound periderm samples expressed as TEAC (μmol Trolox/g dried sample), color coded for Atlantic (red), Chipeta (green), Norkotah Russet (blue), and Yukon Gold (gold). Values are expressed as mean ± standard error of the mean (n = 6). Note that the large standard error of the mean for Yukon day 7 extracts corresponds to a percent error that is similar to the other extracts.

increase in activity could be attributed to the accumulation of antioxidant metabolite(s) during wound periderm development, where the measured extract activity will represent the net effect of potentiation, synergism and antagonism among components of a mixture of antioxidants. The presence of biomarkers such as kaempferol hexoside (**12**), potengriffioside (**14**), and chlorogenic acid (**15**), which have established antioxidant activities,[39,40] could account for the high activity measured in the Yukon Gold extracts. At day 3, extracts of both Yukon Gold and Norkotah Russet demonstrate similar high scavenging activity so that analogously, antioxidant biomarkers such as kaempferol dihexoside (**13**) potengriffioside (**14**) chlorogenic acid (**15**), feruloylquinic acid (**16**) and ferulic acid (**17**)[41,42] could be responsible for their robust scavenging activities.

It is also instructive to compare the current antioxidant results with a prior study of unprocessed, baked and chipped tubers from Yukon Gold and Atlantic cultivars. The ABTS$^{\bullet+}$ scavenging activities, reported as TEAC values for extracts of those three preparations,[43] were much smaller than values measured herein for both day-3 and day-7 wound-healing tissue extracts from the same cultivars (Table 3). This trend persists even when the previously reported fresh-weight assessments are expressed commensurately to our dry-weight values: the scavenging activities of unprocessed tubers (presumably flesh and skin together) are ∼4−8 times lower than our late-time point wound sample, for instance. Although a portion of these differences may reflect variations in methodology, the most potent factors are likely to involve our focus on wound-healing tissues and wound induction.

The significantly higher activity observed for the current samples thus supports the potential of wound periderms as sources of antioxidants. Among the studied cultivars, Yukon Gold followed by Norkotah Russet may prove to be of highest value for future industrial applications. Moreover, time-dependent trends in antioxidant assessment can be viewed as a useful tool to monitor the wound-healing process in these potato cultivars.

Table 3. Comparison of ABTS$^{\bullet+}$ Scavenging Activities of Tissue Extracts from Atlantic and Yukon Cultivars[a]

cultivar	baked[c]	chipped[c]	unprocessed[c]	dry unprocessed[d]	dry wound periderm day 3	dry wound periderm day 7
Atlantic[b]	1.13 ± 0.12	0.09 ± 0.00	5.75 ± 0.02	57.5	189.28 ± 12.56	198.48 ± 16.01
Yukon Gold	2.30 ± 0.22	0.12 ± 0.00	6.59 ± 0.00	65.9	235.78 ± 9.51	507.38 ± 66.91

[a]The scavenging activities of the samples are expressed as TEAC (μmol Trolox/g dried sample). [b]The values are expressed as mean ± standard error of the mean (n = 6). [c]Published TEAC values were measured for tubers.[43] [d]Adjusted by estimating that the tissue is 90%-by-weight water.

CONCLUSIONS AND PROSPECTUS

The current study is the first report of secondary plant metabolites including phenolic amines, flavonoid glycosides, phenolic acids, and glycoalkaloids as biomarkers for closing layer formation and wound periderm initiation from four potato cultivars with distinctive russeting patterns. Analysis of polar extracts from these materials serves to identify 22 of 24 biomarker compounds that discriminate among the potato cultivars and between healing time points, also revealing the complementary strengths of LC-MS and NMR profiling approaches.

The most heavily russeted Norkotah Russet and Atlantic cultivars are especially rich in polyphenolic amine biomarkers, compounds with established resistance to potato pathogens.[24−26] During suberized closing layer formation (3 days healing), the polyphenolic amine markers are found preferentially in polar periderm extracts from the russeted and netted cultivars, namely Norkotah Russet and Atlantic; that marker class appears at the later day-7 wound-healing time point, if at all, for the smoother Yukon Gold and Chipeta varieties. At the day-7 time point after wound periderm formation has been initiated,[44] both NMR and LC-MS multivariate analyses show significant convergence of the polar metabolite compositions for the four cultivars, suggesting a common wound-healing response which could be compatible with the similar up-regulation patterns reported for cell wall and cell cycle genes during potato tuber wound healing for contrasting potato genotypes and after different harvests.[5] Among the biomarkers for the extracts at day 7, during the formation of the suberized waterproofing barrier, we find polyphenolic amines and glycoalkaloids that are known to confer protection against potato pathogens, pests and herbivores.[25,32] Analysis of the corresponding nonpolar extracts and developing polymeric solids, which can provide complementary information on tissue metabolism after wound induction, will be presented elsewhere.

The presence of antioxidant polyphenolic amine, flavonoid glycoside, and phenolic acid constituents among the biomarkers provides a molecular rationale for the robust radical scavenging activity measured in developing wound periderm extracts from cultivars such as Yukon Gold and Norkotah Russet during wound healing. Nonetheless, the unique rise in day-7 scavenging capability for the Yukon Gold periderm extracts reveals the possible roles of multiple metabolites and the likely interplay of potentiating, synergistic, and antagonistic effects on antioxidant activity. The antioxidants in potato peel have great potential as preservatives in the food industry.[3] As wound periderm formation is initiated, a variety of biomarkers including phenolic amines and glycoalkaloids are found to accumulate; their protective capabilities hold promise for improvements in agricultural productivity.[32,33] In addition glycoalkaloids can be potential intermediates for the production of contraceptive and steroidal anti-inflammatory drugs,[3] and they possess wide ranging bioactivities of interest in drug discovery research.[32] Thus, in addition to the agricultural significance of closing layer and wound periderm formation in potatoes, the antioxidant and biological activities of the newly identified wounding biomarkers make them potentially interesting to the food and pharmaceutical industries.

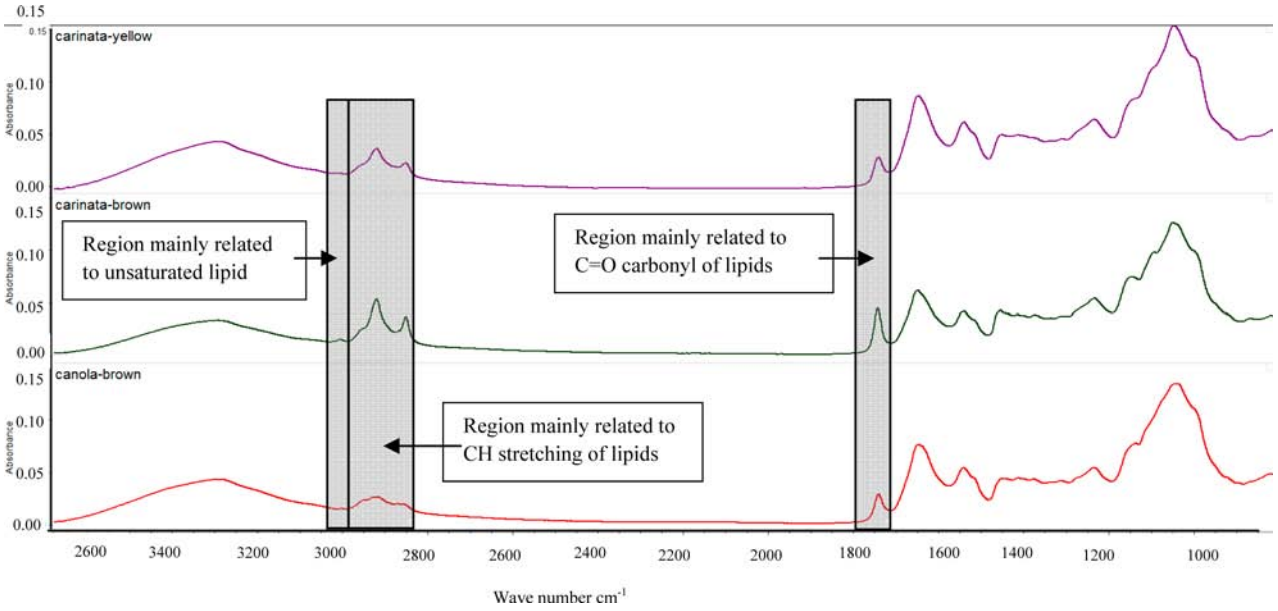

Figure 1. Typical ATR-FT/IR molecular spectrum of *B. carinata* seeds and canola seed (as a reference control) in the mid-IR region ca. 4000−800 cm^{-1}.

unsaturated lipid bands (ULB), and lipid ester C═O carbonyl (LECC) using ATR-FT/IR spectroscopy, between the yellow-seeded and brown-seeded *B. carinata*. Canola seeds were used as a reference. The second objective was to determine the relationship between the molecular spectral data and the contents of oil, fatty acid and glucosinolate profiles, total polyphenols, and condensed tannins in the oilseed.

MATERIALS AND METHODS

Seed Sampling and Processing. Seeds from newly developed yellow-seeded (AAC A100) and brown-seeded (110915EM) lines of *B. carinata* were evaluated in the present study. These two carinata lines were bred for the industrial oil market using traditional pedigree breeding methods. Canola seed with a brown seed coat was used as a reference. Samples (n = 4) from all seed types were obtained from plots at the Saskatoon Research Centre experimental farm of Agriculture and Agri-Food Canada (AAFC) and from contra-season research plots in the central region of Chile during the winter of 2010/2011. Each seed type was obtained from two replicate plots in each location.

For wet chemical and spectral analysis, seeds were ground in a coffee grinder (PC770, Loblaws Inc., Toronto, Canada) for 10 s, then chilled, and reground for another 10 s.

Oil Content and Fatty Acid Profile Determination. The samples (~0.500 g) were analyzed for oil content according to the standard procedure of AOAC (method 920.39).[18] Fat from the ground oilseeds (~0.375 g) was extracted with chloroform/methanol (2:1 v/v) according to the method of Folch et al.[19] with slight modification as described by Khan et al.[20] Tridecanoic acid (C13:0) was used as an internal standard. The fatty acids were separated and quantified using gas chromatography as described by Khan et al.[21] All samples were analyzed in duplicate and repeated if error exceeded the acceptable level of each analysis.

Determination of Glucosinolates, Polyphenols, and Condensed Tannins. All seed samples (~0.100 g) were analyzed for glucosinolate profile according to the official method of the Canadian Grain Commission.[22] The method of Slinkard and Singleton[23] was used to analyze the contents of total polyphenols in samples (~1.00 g). The HCl−butanol procedure as described by Reed[24] was used to analyze the content of condensed tannins in the seeds (~0.050 g). All samples were analyzed in duplicate and repeated if error exceeded the acceptable level of each analysis.

Lipid Molecular Structure by ATR-FTIR Spectroscopy. The lipid-related molecular structural band intensities (Figure 1) of each sample were generated in the mid-IR region (ca. 4000−800 cm^{-1}) with 128 co-added scans at a spectral resolution of 4 cm^{-1} in a transmission mode, using a JASCO FT/IR 4200 with ATR (JASCO Corp., Tokyo, Japan). Each sample was run six times. The spectral data were collected with JASCO Spectra Manager II software, and the lipid-related spectral band intensities were quantified using OMNIC 7.2 software (Madison, WI, USA). The lipid-related functional bands including asymmetric CH_3 (CH_3-as, ca. 2959 cm^{-1}), asymmetric CH_2 (CH_2-as, ca. 2921 cm^{-1}), symmetric CH_3 (CH_3-s, ca. 2871 cm^{-1}), symmetric CH_2 (CH_2-s, ca. 2853 cm^{-1}), ULB (ca. 3008 cm^{-1}), and LECC (ca. 1744 cm^{-1}) were identified according to published methodologies.[15,25,26] The asymmetric and symmetric CH_3 and CH_2 stretching bands were identified in the CH region (ca. 2999−2800 cm^{-1}) of the original spectra, using the second-derivative and Fourier self-deconvolution functions of the OMNIC 7.2 software. The spectral peak height, area, and their ratios were calculated from the original spectra.

Multivariate Spectral Analysis. Agglomerative hierarchical cluster analysis (AHCA) and principal component analysis (PCA), as described in detail earlier,[27−30] were performed on the overall data of lipid-related spectral bands, to visualize and classify the differences in the inherent molecular structures of lipids among the three types of oilseeds. The overall spectral data of CH_3 and CH_2 asymmetric and symmetric stretchings (ca. 2999−2800 cm^{-1}), ULB (ca. 3035−2991 cm^{-1}), and LECC (ca. 1788−1707 cm^{-1}) regions were used for multivariate analyses. The AHCA results are presented as dendrograms using the linkage distance method and Ward's algorithm cluster method without prior parametrization. The PCA results are presented as a scatter plot between the first principal factor and the second principal factor, based on loading scores. These analyses were carried out using Statistica software (version 8, StatSoft Inc., Tulsa, OK, USA).

Statistical Analysis. Data on the oil content, fatty acid and glucosinolate profiles, polyphenols, and condensed tannins and univariate lipid spectral data were statistically analyzed using the Mixed Model procedure of the Statistical Analysis System (SAS version 9.2, SAS Institute Inc., Cary, NC, USA). The following model was used:

$$Y_{ijk} = \mu + F_i + S(F)_j + e_{ijk}$$

[a]Means with different letters in the same row are significantly different ($P < 0.05$). [b]SEM, standard error of the mean. [c]ND, not determined. [d]Saturated fatty acids. [e]Monounsaturated fatty acids. [f]Polyunsaturated fatty acids.

Y_{ijk} is the observation of the dependent variable *ijk*; μ is the population mean; F_i was a fixed effect of seed type (i = 3; yellow-seeded *B. carinata*, brown-seeded *B. carinata*, and canola seed); $S(F)_j$ is the random effect of seed source (location: Saskatoon, Canada, vs Chile) nested within seed; e_{ijk} is the random error associated with the observation *ijk*. Statistical significance was declared and detected at $P < 0.05$.

The strength of relationships between the oil content, fatty acid and glucosinolate profiles, condensed tannins, and the lipid-related functional band intensities in the oilseeds was analyzed by the PROC CORR procedure of SAS using the Pearson correlation method. Multiple regression analyses, with stepwise variable selection, were performed using the PROC REG procedure of SAS to determine the lipid molecular spectral features that can be used to estimate oil content, fatty acid composition, glucosinolates, polyphenols, and condensed tannins in the oilseeds. The independent variables tested include CH_3-as, CH_2-as, CH_3-s, CH_2-s, ULB, and LECC. All variables left in the final model were significant at the 0.05 level.

RESULTS AND DISCUSSION

Oil Content and Fatty Acid Profile. The results of oil content and fatty acid profile of yellow-seeded and brown-seeded *B. carinata* in comparison with canola seeds are presented in Table 1. In the *Brassica* family, oil content, ranging from 17 to >40%, is one of the most important features of the seed.[31] The oil contents varied among the seed types, and canola seeds had higher ($P = 0.02$) oil content than the carinata. The yellow-seeded line had 1.91% higher ($P = 0.03$) oil content than the brown-seeded line, which could be related to their larger seed size and thinner seed coat, which results in a relatively greater proportion of cotyledons and endosperm (oil containing mass) and a smaller proportion seed coat (fiber-containing mass) compared to the brown-seeded varieties.[32] Getinet et al.[32] argued that the yellow-seeded lines should be further developed for high seed weight and oil and protein contents in future breeding projects. The oil content of *B. carinata* seeds observed in this study is approximately 2−14 units higher than the values reported in previous studies.[2,13,33] This could be related to the recent progress in achieving the breeding targets of the *B. carinata* seed improvement programs, which has been focused on increasing the oil content of the seeds at the expense of other nutrients such as protein and fiber.[32,33] In agreement with our findings, Taylor et al.[13] observed lower oil contents in *B. carinata* seed compared to canola seed cultivated at three different locations in western Canada.

The total fatty acid content, as a proportion of the oil, did not differ among the oilseeds (Table 1). However, the fatty acid composition of the oil, particularly long-chain fatty acids, differed among the oilseeds. The brown-seeded *B. carinata* had lower ($P < 0.05$) contents of C17:0, C20:1, C20:2n-6, C24:1n-9, and total saturated fatty acids and higher ($P < 0.05$) contents of C22:0, C22:1n-9, and C24:0 than the yellow-seeded line (Table 1). Little information could be found on the comparison of fatty acid profile of yellow- and brown-seeded *B. carinata* lines; however, all of the individual fatty acid proportions of *B. carinata* seed were within the ranges reported by Velasco et al.[34] and Warwick et al.[2] for *B. carinata* germplasm in Germany

and western Canada, respectively. The *B. carinata* seed oil was quite different from canola seed oil in almost all individual fatty acid contents. The largest differences between *B. carinata* and canola seed were observed in the contents (% of total fatty acids) of C18:1n-9, C18:3n-3, and C22:1n-9 (Table 1). During the biosynthesis of fatty acids in plants, the C18:0 fatty acids are first desaturated to C18:1n-9, which is then elongated to C22:1n-9 or desaturated to C18:3n-3 by the "prokaryotic pathway" (in plastids) and the "eukaryotic pathway" (in the endoplasmic reticulum) by different fatty acid elongases and desaturases.[35−38] C18:1n-9 is the main precursor of these two biosynthetic pathways. The significantly higher levels C22:1n-9 in *B. carinata* seed in our study showed that C18:1n-9 had been extensively and preferentially elongated to C22:1n-9 compared

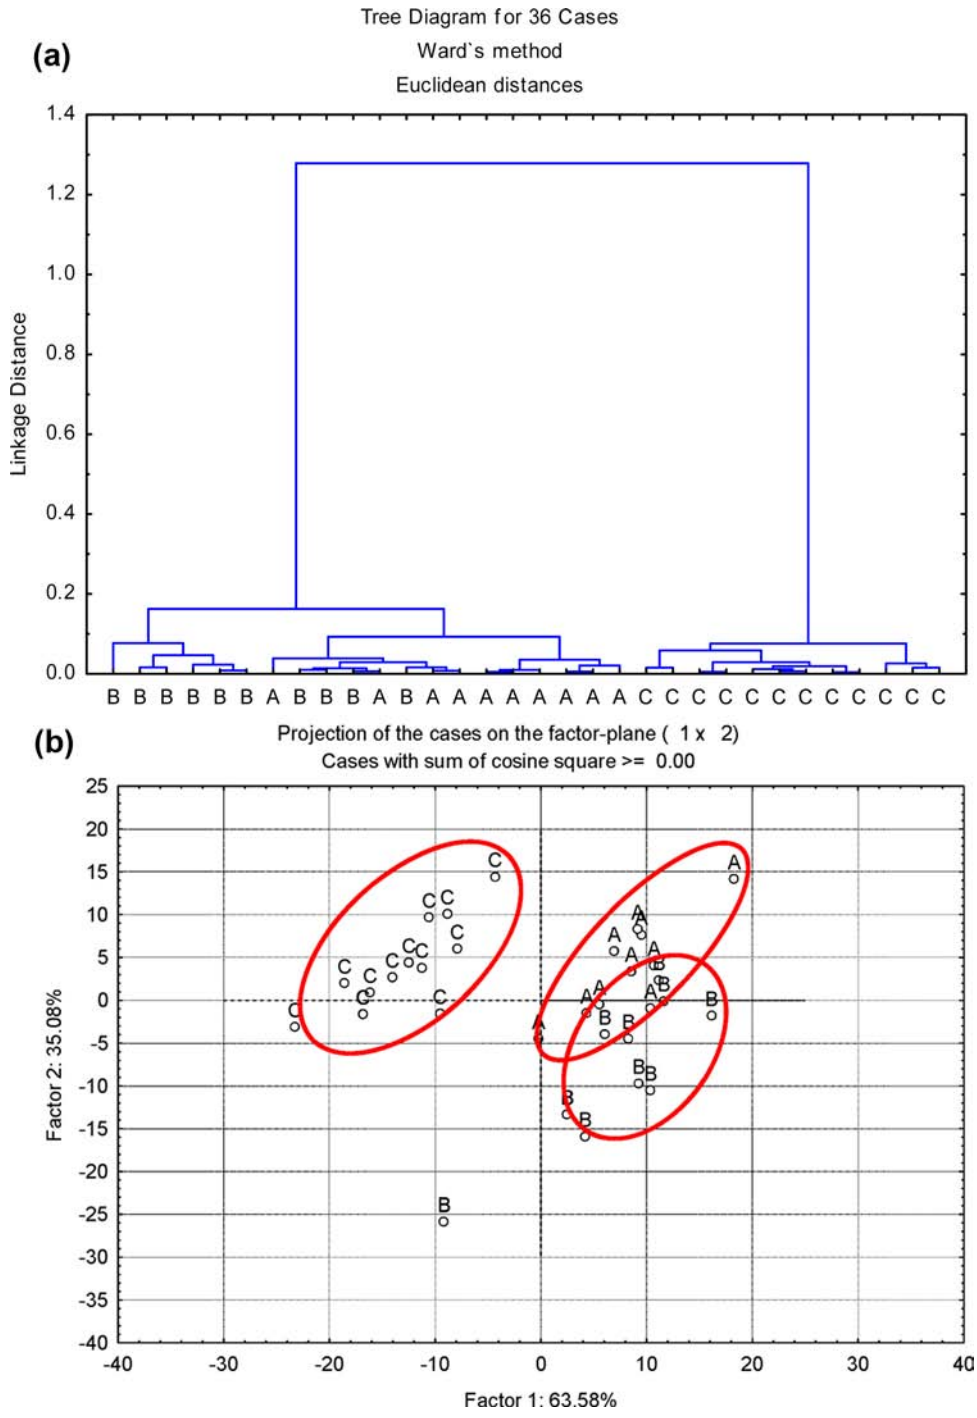

Figure 2. Agglomerative hierarchical cluster analysis (CLA) dendrograms (a) and principal component analysis (PCA) scatter plot (b) visualizing the differences in CH_3 and CH_2 asymmetric and symmetric stretching (2999−2800 cm^{-1}) bands among different oilseeds: A, yellow-seeded *B. carinata*; B, brown-seeded *B. carinata*; C, canola seed.

to in canola seed. Moreover, C18:1n-9 is also preferentially desaturated to C18:3n-3 in *B. carinata* seed. Although not suitable for human consumption, oilseeds bearing a high content of C22:1n-9 could be used as a valuable feedstock for biodiesel production[6,8] and for other industrial applications such as plastics, lubricants, and cosmetics products.[9,39,40] Environmental conditions such as differences in growing season and temperature can influence the oil content and fatty acid compositions;[3,41,42] our study revealed consistent differences in the oilseeds grown in western Canada and contra-season (data not shown). Across the oilseeds, C16:0 (2.73−3.79%) was the major saturated fatty acid, followed by C18:0, C20:0, C22:0, and C24:0, and only small amounts (<0.1%) of C14:0 and C17:0 were detected in the oilseeds. No differences were observed between the yellow-seeded and brown-seeded *B. carinata* ($P > 0.05$) in the contents of total n-3, n-6, and n-9 fatty acids. However, the contents of total n-3 and n-6 fatty acids were 1.6 ($P = 0.001$) and 0.9 times ($P = 0.01$) higher in *B. carinata* seed than those in canola seed.

Glucosinolates, Polyphenols, and Condensed Tannins. Table 2 presents the contents of glucosinolates, polyphenols, and condensed tannins in the yellow-seeded and

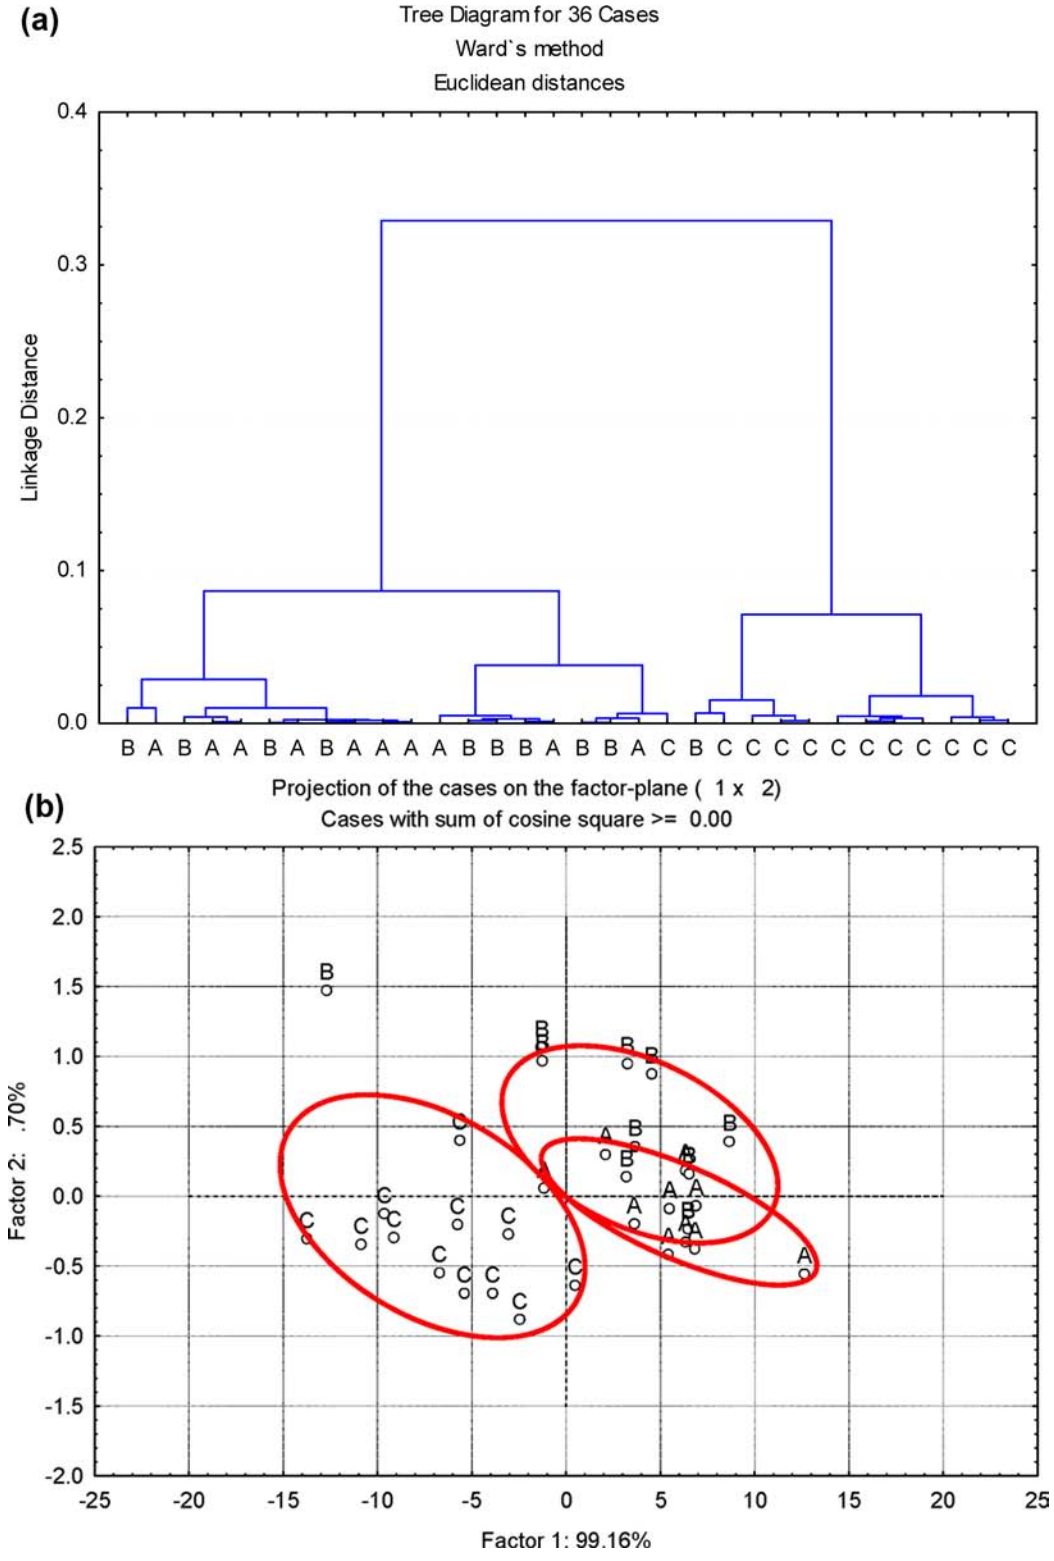

Figure 3. Agglomerative hierarchical cluster analysis (CLA) dendrograms (a) and principal component analysis (PCA) scatter plot (b) visualizing the differences in the unsaturated lipid (3035−2991 cm^{-1}) bands among different oilseeds: A, yellow-seeded *B. carinata*; B, brown-seeded *B. carinata*; C, canola seed.

brown-seeded *B. carinata* in comparison with canola. The total glucosinolate content was markedly higher ($P < 0.001$; 87.0−88.9 vs 12.96 μmol/g) in *B. carinata* seed compared to canola. Glucosinolates are a group of sulfur-containing glycosides produced by plants in the *Brassica* family. To our knowledge, more than 130 types of glucosinolates have been identified so far, starting from 170 years ago when sinigrin was first found in mustard (*Brassica juncea*). Within this large glucosinolate family, allyl glucosinolates usually account for >95% of the total alkenyl glucosinolate,[43,44] which is the sum of allyl, 3-butenyl, 4-pentenyl, 2-OH-3-butenyl, and 2-OH-4-pentenyl in *B. carinata* seed. In our study, allyl glucosinolates accounted for

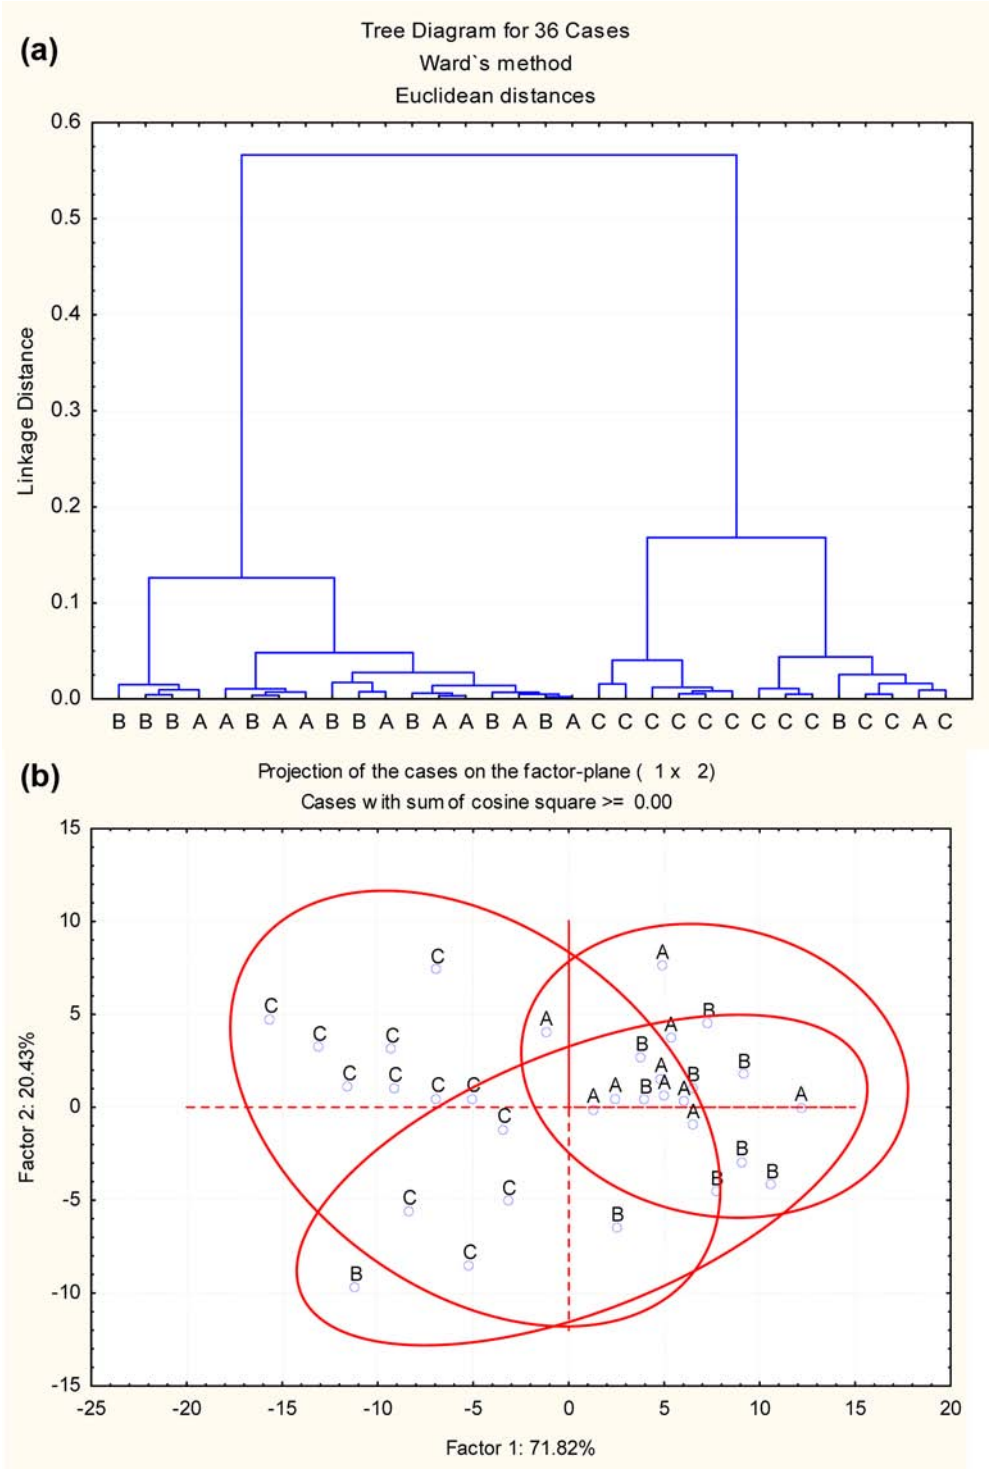

Figure 4. Agglomerative hierarchical cluster analysis (CLA) dendrograms (a) and principal component analysis (PCA) scatter plot (b) visualizing the differences in the lipid ester C═O carbonyl (1788−1707 cm^{-1}) bands among different oilseeds: A, yellow-seeded *B. carinata*; B, brown-seeded *B. carinata*; C, canola seed.

97.1−98.5% of total alkenyl glucosinolates in *B. carinata* seed, which was consistent with earlier observations.[2,13] The total and individual glucosinolate contents were not different ($P > 0.05$) between the yellow- and brown-seeded lines of *B. carinata*. However, canola seed had higher contents of 2-OH-3-butenyl, 3-CH_3-indolyl, and 4-OH-3-CH_3-indolyl than the *B. carinata* seed. Moreover, no allyl glucosinolate could be detected in canola seed, which resulted in its markedly lower content of total glucosinolates in canola as compared to *B. carinata* seed. The total glucosinolate content of the canola seed was, however, close to the average values (9−12 μmol/g) recorded in western Canada.[45]

On average, the content of total polyphenols was 13% higher ($P = 0.01$) in *B. carinata* seed than in canola seed. The presence of higher amounts of glucosinolates and phenolic compounds limits the usage of oilseeds and oilseed meals as a food or feed-

grade protein source.[46] Therefore, the oil from *B. carinata* seed with the higher content of glucosinolates and phenolic compounds is more suitable for a wide range of other inedible industrial applications, such as for the production of bioethanol, biodiesel, and biolubricants,[6−9,13] whereas the meal can be used as a biopesticide to control nematodes in potatoes and turf grasses. The contents of condensed tannins did not differ ($P > 0.05$) among the oilseeds and averaged 0.28% DM.

Spectral Features of Lipid Molecular Structures. Table 3 shows data on the intrinsic molecular structural characteristics of lipids in terms of CH_3 and CH_2 bands and ULB and LECC bands in yellow- and brown-seeded *B. carinata* in comparison with canola. The frequencies of all lipid-related spectral bands reported here for the three types of oilseeds were similar to the values reported previously for other feeds.[15,47] The asymmetric CH_2 and symmetric CH_2 peak heights were significantly higher ($P = 0.03$) in yellow-seeded than in brown-seeded *B. carinata*. All other peaks area, height, and height ratios did not differ between these two lines of *B. carinata* (Table 3). However, the absorbed peak intensities in the regions of asymmetric and

symmetric stretching vibrations of CH_3 and CH_2 groups were much higher ($P < 0.001$) in *B. carinata* seed than those in canola. This can also be seen in Figure 1 (ca. 2959−2853 cm^{-1}), suggesting differences in the lipid molecular structures of *B. carinata* and canola seed. The tiny bands (ca. 3035−2991 cm^{-1}) and another strong band (ca. 1788−1707 cm^{-1}), highlighted in Figure 1 indicate the ULB and LECC bands[48,49] in the oilseeds. The ULB and LECC bands did not differ between the two types of *B. carinata* ($P > 0.05$); however, the peak height and area of these bands were higher ($P < 0.001$) in *B. carinata* than those in canola seed. The absorbed peak intensities of CH groups, ULB, and LECC in canola seed found in our study were much weaker than those reported by Abeysekara et al.,[15] which might be related to the inherent differences in seed types used in the two studies. To date, few studies have evaluated genetic modification in nutritional value of *B. carinata*;[12,13,42] however, studies on lipid molecular structural characteristics of yellow- and brown-seeded *B. carinata* are scarce. Therefore, no direct comparisons with other studies could be made. However, our results were somewhat consistent with the findings of Yu et al.,[50] who observed no structural differences in lipid-related molecular structural characteristics between the yellow- and brown-seeded canola. A number of studies have shown that molecular structural characteristics of biopolymers are highly related to their concentration, digestibility, and metabolic characteristics.[51,52] Consequently, lipid molecular structures could be used to explain the differences in oil content and composition, digestion, and utilization between *B. carinata* seed and canola seed. The spectral ratios of CH_3-as to CH_2-as, CH_3-as to CH_3-s, CH_3-s to CH_2-s, and CH_2-as to CH_2-s did not differ between yellow-seeded and brown-seeded *B. carinata*. However, these ratios were 6−62% lower ($P < 0.05$) than those observed in canola, whereas the height ratios of asymmetric to symmetric and ULB to LECC as well as area ratio of ULB to LECC were 1−10 times higher ($P < 0.05$) than those of canola. These findings indicated that lipid structural makeup of the seed tissues differed between *B. carinata* and canola seed.

Discriminating and Classifying Differences in Lipid Molecular Structures. The dendograms of AHCA analysis and biplots of PCA can distinguish and classify the overall differences in lipid molecular structures in the regions of the CH stretchings (ca. 2999−2800 cm^{-1}; Figure 2), ULB (ca. 3035−2991 cm^{-1}; Figure 3), and LECC band (ca. 1788−1707 cm^{-1}; Figure 4). The AHCA dendograms showed that the lipid molecular spectra of both yellow-seeded and brown-seeded *B. carinata* were fully distinguished from canola at a linkage distance of <0.2 within the region of CH stretchings (Figure 2a), and at a linkage distance of <0.1 within the region of ULB (Figure 3a). Similarly, the PCA biplots showed that the spectra of canola were grouped into separate ellipses from both types of *B. carinata* seeds in the region of CH stretchings (Figure 2b) and ULB (Figure 3b). These findings demonstrated differences in the inherent molecular structures of lipids between *B.*

dx.doi.org/10.1021/jf502209x | J. Agric. Food Chem. 2014, 62, 7977−7988

carinata and canola seeds. Such differences can influence lipids digestion, metabolism, and their industrial applications. However, the PCA and AHCA graphs showed that the yellow-seeded and brown-seeded *B. carinata* seeds could not be discriminated from each other in the regions of CH stretchings and ULB. Moreover, both AHCA dendograms and PCA biplots could not distinguish the lipid molecular spectra of the three types of oilseeds within the LECC region, indicating some structural similarities among them in this region. Although no published studies are available for comparison of lipid inherent molecular structures in the yellow-seeded and brown-seeded *B. carinata*, such differences have been reported for yellow-seeded and brown-seeded canola.[15]

Correlations between Lipid Molecular Spectral Intensity Profiles and Oil Content, Fatty Acid Composition, and Chemical Compound Factors. Table 4 shows the coefficients of correlation (Pearson) and their significance level between the lipid molecular spectral parameters and the contents of oil, fatty acids, glucosinolates, condensed tannins, and polyphenols in *B. carinata* and canola seeds. The data showed that the oil content had strong negative correlations ($P < 0.05$) with lipid-related molecular spectral intensities, namely, the CH_3 and CH_2 stretching area ($r = -0.966$), ULB area ($r = -0.950$), LECC area ($r = -0.964$), area ratio of ULB to CH stretching ($r = -0.867$), and area ratio of ULB to LECC ($r = -0.917$). No significant ($P > 0.05$) relationship was observed between the lipid-related structural parameter and the contents (% of total FA) of C14:0, C17:0, C20:3n-3, C22:2n-9, C22:2n-6, and total n-9 fatty acids. Except for the LECC:CH area ratio, a significant negative correlation ($P < 0.05$; $r > -0.82$) was observed between the lipid molecular structural parameters and the contents (% of total FA) of C16:0, C16:1n-7, C18:0, C18:1n-9, C18:1, C18:2n-6, total saturated fatty acids, total monounsaturated fatty acids, and total n-6 fatty acids. Except for the LECC:CH area ratio, significant ($P < 0.05$; $r > 0.86$) positive correlations were observed between the lipid molecular structural parameters and the contents (% of total FA) of C18:3n-3, C20:0, C20:1, C20:2n-6, C22:0, C20:1n-9, C24:0, C24:1n-9, total polyunsaturated fatty acids, and total n-3 fatty acids. Among other chemical compounds, the contents of 2-OH-3-butenyl, 3-CH_3-indolyl, 4-OH-3-CH_3-indolyl, total glucosinolates, and total polyphenols strongly ($P < 0.05$; $r > 0.813$) correlated with the spectral intensities of CH_3 and CH_2 stretching area, ULB area, and LECC area, area ratio of ULB to CH stretchings, and area ratio of ULB to LECC. Although other studies[52,53] have demonstrated that food/feed nutrient quantity and digestibility could be predicted from protein- and carbohydrate-related molecular spectral features, our study demonstrated for the first time the lipid-related molecular spectral intensities had close relationships with chemical compositions of *Brassica* oilseeds.

Regression Analysis of Lipid Molecular Spectral Parameters and the Contents of Oil, Fatty Acids, Glucosinolates, and Polyphenols. Table 5 shows the multiple regression equations, based on lipid-related spectral parameters, and their predictive power for estimation of the contents of oil, fatty acids, glucosinolates, and polyphenols in the oilseeds. The equations gave a high degree of fit for all of the parameters mentioned in Table 5. The results showed that oil content could be predicted from spectral data on CH stretching area, area ratio of LECC to CH stretchings, and area ratio of ULB to LECC with high accuracy ($R^2 = 0.990$). The equations further showed that the ratio of ULB to LECC could be used to estimate the contents of C20:1 ($R^2 = 0.941$) and total n-6 fatty acids ($R^2 = 0.991$), whereas all other mentioned fatty acids can be estimated from CH stretchings area with a good degree of fit ($R^2 \geq 0.800$; Table 5). The contents of 3-butenyl, 2-OH-3-butenyl, total glucosinolates, and total polyphenols can be estimated ($R^2 \geq 0.689$) from LECC area, whereas the 4-OH-3-CH_3-indolyl concentration in oilseeds can be estimated with relatively good accuracy ($R^2 = 0.831$) from the area of CH stretchings. The high predictive powers for functional fatty acids such as C21:1n-9 and glucosinolates could have important practical implications for breeders and the food/feed industries for selecting appropriate seed types. FTIR-ATR molecular spectroscopy is a fully established non-destructive technique, which can directly and rapidly analyze a large number of feed samples. Earlier studies[16,52,53] suggested that the spectral band intensities can be used as an indicator for the quantitative differences in biopolymers such as protein and carbohydrates among different feeds, which is also supported by the findings of the present study. However, it is pertinent that these prediction equations were derived from limited data based on a small number of samples. Further study is required to obtain predictive equations based on a large number of samples of diverse origin to validate the findings of the current study.

In summary, brown-seeded *B. carinata* had significantly lower ($P < 0.05$) oil content, C17:0, C20:1, C20:2n-6, C24:1n-9, and total saturated fatty acids, and significantly higher ($P < 0.05$) content of C22:0, C22:1n-9, and C24:0 than yellow-seeded *B. carinata*. However, the glucosinolate, polyphenols, and condensed tannins contents were not different. There were marked differences between *B. carinata* and canola seed in oil content, fatty acid profile, glucosinolate profile, and polyphenols. ATR-FTIR spectroscopy can be used to quantify lipid-related spectral band intensities. Compared with the brown *B. carinata* seed, the yellow seeds were markedly lower in peak heights of asymmetric CH_2 and symmetric CH_2, and no changes were found in other spectral parameters. The absorbed peak intensities of CH stretchings and ULB and LECC bands of *B. carinata* strains were remarkably higher than those observed in canola. The multivariate analyses showed no significant differences in the lipid molecular structures between the yellow and brown *B. carinata* lines, whereas both types of *B. carinata* seed were fully distinguished from canola in the regions of CH stretchings and ULB. The lipid-related spectral band intensities were strongly correlated to oil content, fatty acids, glucosinolates, and polyphenols. Therefore, regression equations were developed that gave relatively high predictive power for the estimation of oil ($R^2 = 0.990$); all measured fatty acids ($R^2 \geq 0.800$), except C14:0, C20:3n-3, C22:2n-9, and C22:2n-6; a few individual glucosinolates, namely, 3-butenyl, 2-OH-3-butenyl, 4-OH-3-CH_3- indolyl; and total glucosinolates ($R^2 \geq 0.686$) and total polyphenols ($R^2 = 0.935$). However, further study is required to obtain predictive equations based on a large number of samples with diverse sources to validate the findings of the current study.

approach using cellulase and protease treatment has been commercialized by Tang et al.[17] Enzymatic hydrolysis of carbohydrates has been commonly used to improve the feed quality, such as digestibility and bioavailability, of rapeseed press cake,[18,19] but it is also a potential technology to facilitate rapeseed protein extraction. A patent by Kvist et al.[20] reports 83% total protein extraction yield into four fractions from wet-milled rapeseed press cake after treatment with pectinase, β-glucanase, and hemicellulase enzymes, without the addition of proteases.

Although rapeseed protein extraction has been studied extensively, deeper understanding of the protein−carbohydrate interactions and the impact of processing on press cake cell wall structure could open up new possibilities for efficient protein release. Rapeseed cell walls are composed of a strongly interconnected network of polysaccharides, where xyloglucan, xylan, and pectic polysaccharides cross-link with cellulose and each other through noncovalent and sometimes covalent interactions.[8,21] Meanwhile, the majority of rapeseed protein is stored in protein bodies inside cells that are surrounded by these cell walls.[5,22] Transmission electron micrographs have shown partial disruption of rapeseed cell structure during cold pressing,[16] and Srivastava et al.[23] reported a correlation between microstructural changes and oil extraction yield after enzyme treatment of rapeseeds. However, a respective correlation for structural changes and protein extraction is yet to be established.

The aim of this study was to determine the effects of polysaccharide hydrolases on cell wall disintegration and protein extractability from two rapeseed press cakes obtained by cold pressing of intact *B. rapa* and partially dehulled *B. napus* seeds.

MATERIALS AND METHODS

Rapeseed press cakes. Two rapeseed press cakes were used as raw materials for mechanical and enzymatic processing. The intact press cake (6.8% moisture) was obtained from Kankaisten Öljykasvit Oy (Turenki, Finland) after cold pressing of oil from *B. rapa* L. seeds at 50−60 °C, pelletizing, and air-drying. The dehulled press cake (6.6% moisture) was received from Kroppenstedter Ölmühle Walter Doepelheuer GmbH (Kroppenstedt, Germany) after cold pressing of partially dehulled *B. napus* L. seeds and drying.

Enzymes. Three enzyme products were used: Pectinex Ultra SP-L and Celluclast 1.5L from Novozymes A/S (Bagsvaerd, Denmark) and Depol 740L from Biocatalysts Ltd. (Cardiff, United Kingdom). Their protein concentration was quantified using a DC Protein Assay Kit (Bio-Rad, Hercules, CA). Activity profiles of the enzyme preparations, including β-glucanase,[24] β-glucosidase,[25] *endo*-1,3(4)-β-glucanase, polygalacturonase,[26] xylanase,[27] and protease[28] activity, were determined (Table 1). The polysaccharide hydrolase assays were performed at 40 °C, pH 6 and the protease assay at 30 °C, pH 5.5.

Mechanical Pretreatment. Rapeseed press cakes were dry-milled at 17 800 rpm using a 100 UPZ-II fine impact mill (Hosokawa Alpine Ag, Ausburg, Germany). Prior to dry milling, the pelletized, intact press cake was ground at 1000 rpm at room temperature using an SM 300 cutting mill (Retsch, Düsseldorf, Germany).

Enzymatic Treatments. Dry-milled intact and dehulled rapeseed press cakes were treated with Pectinex, Depol, and Celluclast for 0, 4, and 48 h at an enzyme dosage of 10 mg protein/g dry substrate. On the basis of the temperature optima obtained from the manufacturer of the enzymes, the incubation temperature was 50 °C for Depol and Celluclast and 30 °C for Pectinex. The enzymatic treatments were performed in duplicate in 25 mL volume at 10% (w/v) consistency in distilled water containing 0.02% (w/v) sodium azide as an antimicrobial agent. After the treatment, liquid fractions were separated from the residual solids by centrifugation for 15 min at 3220*g*. The liquid fractions were stored in aliquots at −20 °C prior to analysis. The residual solid fractions obtained from 48 h hydrolysis were freeze-dried and weighed.

Table 1. Protein Concentration and Activities of Pectinex Ultra SP-L, Depol 740L, and Celluclast 1.5L[a]

	Pectinex Ultra SP-L	Depol 740 L	Celluclast 1.5L
protein concn (mg/mL)	61	48	170
activity (nkat/mg protein)			
endo-1,3(4)-β-glucanase (EC 3.2.1.6)	135	223	158
β-glucosidase (EC 3.2.1.21)	0.07	10	1.3
cellulase (EC 3.2.1.4)	22	23	112
polygalacturonase (EC 3.2.1.15)	2876	0.2	1.6
endo-1,4-β-xylanase (EC 3.2.1.8)	7.0	288	52
protease	0.3	0.6	nd

[a]Polysaccharide hydrolase activities were determined at pH 6 and protease activity at pH 5.5; nd = not detected.

Analysis of the Liquid Fractions from Enzymatic Treatments. Protein hydrolysis was monitored by reducing SDS−PAGE on a Criterion TGX, stain-free precast 18% gel (Bio-Rad, Hercules, CA). Molecular weights of the protein bands were determined on the basis of the migration of recombinant 10−250 kDa Precision Plus Protein standards (Bio-Rad). The protein bands were identified by correspondence of the band molecular weights with known molecular weights of the major rapeseed proteins. Monosaccharides (glucose, fructose, galactose, rhamnose, arabinose, xylose, and mannose), uronic acids, and sucrose in the 48-h enzymatic hydrolysates were identified directly by high-performance anion-exchange chromatography with pulse amperometric detection (HPAEC-PAD) using a ICS-3000 ion chromatography system equipped with a CarboPac PA1 column (Dionex, Sunnyvale, CA).[29] Likewise, monosaccharide profiles of extracted polysaccharides were analyzed by HPAEC-PAD after secondary hydrolysis of the 48-h enzymatic hydrolysates.[29,30] The secondary hydrolyses were performed in duplicate in 4% sulfuric acid for 1 h at 120 °C.

Compositional Analysis of Rapeseed Press Cakes and Solid Fractions after Enzymatic Treatment. Protein concentration was determined in duplicate by Kjeldahl total nitrogen analysis (N × 6.25), according to the method by Kane.[31] Ash content of the press cakes was quantified gravimetrically after combustion for 23 h at 550 °C in an N 11 muffle furnace in triplicate (Nabertherm GmbH, Lilienthal, Germany). For total lipid content, the dry-milled press cakes were defatted by heptane extraction for 5 h in a Soxhlet apparatus. Total lipid content was determined by gravimetrical analysis of the heptane-extracted dry mass. To extract water-soluble carbohydrates, the heptane-defatted press cakes were mixed with water at 10% (w/v) consistency, 60 °C for 2 h in duplicate. Water-soluble mono- and disaccharides were analyzed from the water extracts by HPAEC-PAD. Monosaccharide profiles of water-soluble polysaccharides were determined by HPAEC-PAD after acid hydrolysis of the water extracts in 4% sulfuric acid.[29,30]

The water-extracted and enzyme-treated press cakes were analyzed for insoluble polysaccharides and lignin. The press cakes were remilled and hydrolyzed in triplicate with 70% sulfuric acid for 1 h at 30 °C followed by hydrolysis with 4% sulfuric acid for 50 min at 120 °C. The released neutral monosaccharides were analyzed by HPAEC-PAD.[29,30] Acid-soluble lignin was measured spectrophotometrically at 215 and 280 nm[32] from the acid hydrolysates, and acid-insoluble lignin was determined as the weight of the acid hydrolysis residues. Ash content of the acid hydrolysis residue was quantified gravimetrically after combustion and subtracted from the acid-insoluble lignin. Additionally, insoluble noncellulosic polysaccharides were determined after dilute acid hydrolysis of the water-extracted and enzyme-treated press cakes in triplicate with 4% sulfuric acid for 1 h at 120 °C. Cellulose content was calculated as the difference of glucose in the total and noncellulosic polysaccharides. Digestible starch content of the press cakes was determined enzymatically according to the method of

McCleary et al.[33] β-Glucan content was determined enzymatically according to the work of Munck et al.[34]

Microstructure of the Rapeseed Press Cakes before and after Enzymatic Hydrolysis. The press cakes were prepared for microscopy according to the method of Holopainen-Mantila et al.[35] As an exception, the press cakes before enzyme treatment were not embedded in 2% agar prior to fixation. The sections were stained with 0.1% (w/v) aqueous Acid Fuchsin (BDH Chemicals Ltd., Poole, United Kingdom) in 1.0% acetic acid for 1 min and with 0.01% (w/v) aqueous Calcofluor White (Fluorescent brightener 28, Aldrich, Germany) for 1 min. When the stained sections were examined with a fluorescence microscope (excitation λ 400−410 nm, emission λ >455 nm), glucans in intact cell walls appear blue (Calcofluor) and proteins appear red (Acid Fuchsin).[36,37] Additionally, the sections were stained with 0.2% (w/v) Ruthenium Red (Fluka Chemie AG, Buchs, Switzerland) in water for 2 h. Ruthenium Red associates with the carboxyl groups of galacturonic acid residues and thus shows pectins as red in bright-field illumination.[38,39] The sections were imaged with an Olympus BX-50 microscope (Olympus Corp., Tokyo, Japan). Micrographs were obtained using a PCO SensiCam CCD color camera (PCO AG, Kelheim, Germany) and the cell^P imaging software (Olympus). Images taken from replicate sample blocks were examined and representative images were selected for publication.

Protein extraction yield was expressed as the proportion of total nitrogen that was lost from the solid fraction during 48-h enzymatic and reference treatments. The yield represents the average of two Kjeldahl total nitrogen analysis results from two parallel reactions. Carbohydrate extraction yield was expressed as the proportion of total press cake carbohydrates (monosaccharides, sucrose, or polysaccharides) that were recovered in the liquid fraction after 48-h enzymatic and reference treatments. Extracted polysaccharides were calculated as the difference of the monosaccharide concentration before and after secondary acid hydrolysis. Two replicate secondary acid hydrolyses and HPLC analyses were performed for each of the two parallel reactions; thus, the carbohydrate yields represent the average of four parallel analysis results.

RESULTS AND DISCUSSION

Chemical Composition of Intact and Dehulled Rapeseed Press Cakes. Differences in the chemical composition of the intact and dehulled rapeseed press cakes were identified. The intact *B. rapa* press cake consisted of 36% crude protein, 19% acid-soluble and insoluble lignin, 12% crude oil, and 7% ash, on a dry matter basis (Table 2). In the dehulled *B. napus* press cake, the protein and oil concentrations were higher, whereas the proportion of lignin and ash was expectedly lower. The values were consistent with earlier reports for cold-pressed *B. rapa*[9] and *B. napus*[1] press cakes. Compositional differences between the intact *B. rapa* and dehulled *B. napus* press cake were expected to result rather from the removal of lignin-rich hulls than from species-related variation.[40] Dehulling reduces the carbohydrate and lignin content and enriches protein and ash in rapeseed press cake,[4] whereas equally processed, solvent-extracted *B. rapa* and *B. napus* meals have been reported to possess similar chemical composition despite the species variation.[8,12]

Both press cakes contained 35% of carbohydrates as quantified from the total neutral monosaccharides recovered after acid hydrolysis. A substantial portion of the carbohydrates consisted of water-soluble mono- and disaccharides (Table 2). Glucose originated mainly from sucrose and cellulose, while starch and β-glucan accounted for less than 0.3% of the dry matter (Table 3). The *B. napus* press cake contained more sucrose and other water-soluble sugars and less cellulose than the *B. rapa* press cake (Tables 2 and 3). Monosaccharide profiles of the press cakes (Table 2) were consistent with the rapeseed polysaccharide composition comprising cellulose, xyloglucan, xylan, and pectic polysaccharides, including homogalacturonan, rhamnogalacturonan, arabinan, and arabinogalactan.[8,9] Pectin-derived uronic acids could not be quantified from the press cakes before enzyme treatment due to their degradation during secondary acid hydrolysis.

Table 2. Chemical Composition of the Intact *B. rapa* and Dehulled *B. napus* Rapeseed Press Cakes (PC) and Solid Fractions Obtained from Treatment at 30 °C without Enzyme Addition (no 30) or with Pectinex (P)[a]

Microstructure of Intact and Dehulled Rapeseed Press Cakes. Rapeseed press cakes and solid fractions obtained after enzymatic treatment of the intact press cake were analyzed by microscopy to visualize the cell structure as well as integrity and localization of polysaccharides and proteins and to understand the effects of enzymatic treatment. In thin sections of the press cakes, structures originating from seed coat (hull) and embryo including cotyledons of the rapeseed were

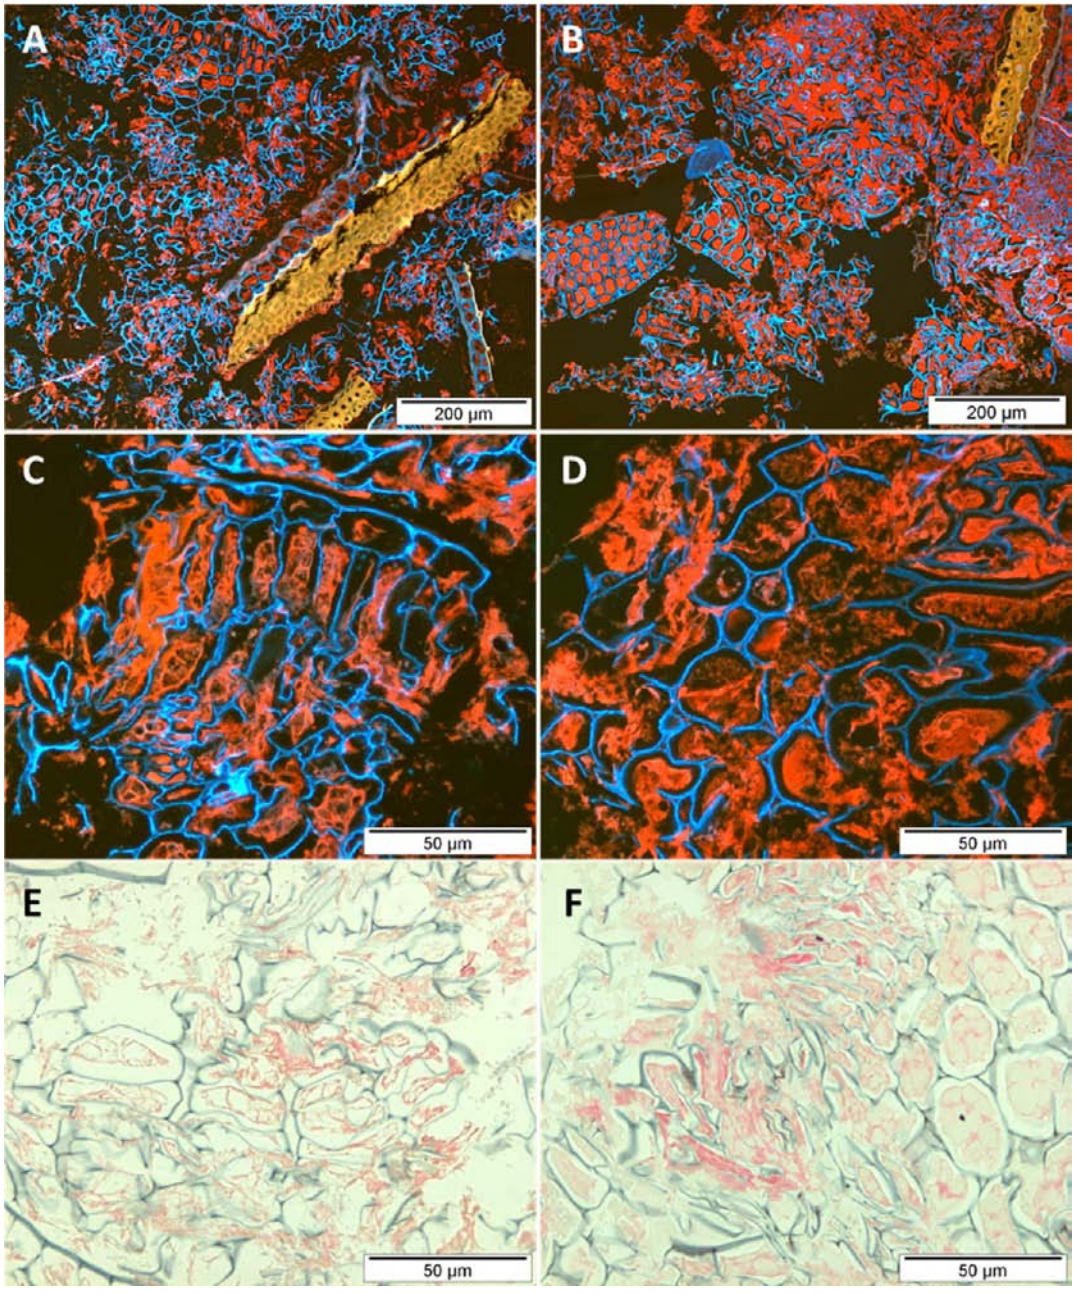

Figure 1. Micrographs of press cakes obtained from cold pressing of intact *B. rapa* seeds (A, C, E) and partially dehulled *B. napus* seeds (B, D, F). The sections were stained with Calcofluor White and Acid Fuchsin (A–D), showing cell wall glucans as blue and proteins as red, and with Ruthenium Red (E, F), showing pectins as red.

recognized (Figure 1A,B). Seed coat fragments were detected in all samples both before and after the enzymatic treatment and appear in some of the selected micrographs. Staining of the press cakes with Calcofluor White visualized cellulose and other β-linked glucans[41] in the cell walls of embryo and seed coat, whereas staining with Acid Fuchsin showed the proteins inside the embryonic cells. Cold pressing had partially disrupted the structure of embryonic cell walls (shown as blue) and protein bodies (shown as red) (Figure 1A–D). Dry milling caused further fragmentation of the embryonic cell walls without noticeable effect on proteins (Figure 3A). No clear difference was observed in the cell wall fluorescence of the two press cakes. However, proteins seemed to form more compact structures in the dehulled press cake than in the intact press cake (Figure 1A,B). Such variation in the packing density of protein bodies was not observed in intact *B. rapa* and dehulled *B. napus* seeds obtained before oil pressing (data not shown).

Pectins were visualized by staining with Ruthenium Red, which binds to the pectin polygalacturonan backbone.[39] Pectins were abundant in the seed coat (Figure 2C) and detected in smaller amounts in the embryonic cell walls (data not shown). Pectins were more intensely stained by Ruthenium Red in the seed coat than in the embryo, which may be related to differences in their composition: pectins in rapeseed hulls have been reported to contain substantially more galacturonic acid than pectins in the embryo.[3] In addition to the cell wall pectins, networks stained by Ruthenium Red were observed inside the embryo cells (Figure 1E,F), suggesting the presence of

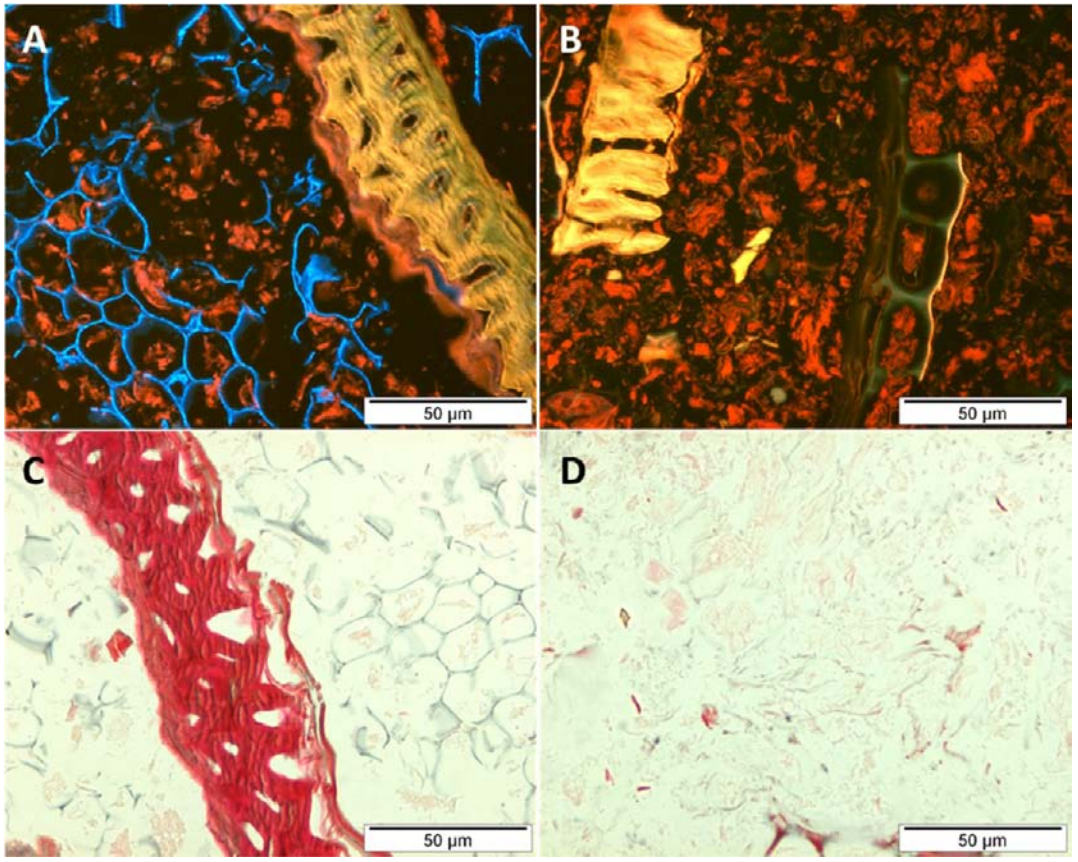

Figure 2. Micrographs of the solid fractions obtained from treatment of intact *B. rapa* press cake at 30 °C without enzyme addition (A, C) or with Pectinex (B, D). The sections were stained with Calcofluor White and Acid Fuchsin (A, B), showing cell wall glucans as blue and proteins as red, and with Ruthenium Red (C, D), showing pectins as red. Panels A–C include fragments of the seed coat.

intracellular pectin-type material. These networks were colocalized with proteins in the cells (shown by Acid Fuchsin staining in Figure 1C,D). Intracellular pectic polysaccharides have not been reported in rapeseed, but their presence was recently detected in the olive pistil.[42]

Enzymatic Hydrolysis of Rapeseed Carbohydrates. The commercial enzyme product Pectinex Ultra SP-L hydrolyzed the rapeseed carbohydrates most effectively, solubilizing up to 75% of the carbohydrates (Figure 4) and causing complete degradation of the embryonic cell walls, as shown by microscopy (Figure 2). The total carbohydrate hydrolysis yield was higher than in the study reported by Pustjens et al.,[18] who extracted 64% of the total carbohydrates in solvent-extracted *B. napus* meal during 4.75 h hydrolysis with amyloglucosidase and proteases. The higher yield is most probably explained by longer hydrolysis time and a better targeted enzyme product used in our study.

According to the sugar profiles of the 48-h enzymatic hydrolysates, carbohydrates were released almost exclusively as monosaccharides into the liquid fractions (Table 4). Release of galacturonic acid by Pectinex indicated hydrolysis of pectin (homogalacturonan, rhamnogalacturonan), whereas the release of galactose and arabinose by both Pectinex and Depol suggested hydrolysis of other pectic polysaccharides (arabinan and arabinogalactan). Substantial amounts of fructose and glucose were released as a result of sucrose hydrolysis during all enzymatic and reference treatments at 50 °C (Table 4). Respectively, the sucrose content in these hydrolysates was remarkably lower or nondetectable in comparison to the 30 °C reference treatments. Sucrose hydrolysis at 50 °C suggests that rapeseed contains an endogenous fructosyltransferase (i.e., invertase) with enhanced activity at above 30 °C. On the other hand, the high fructosyltransferase activity of Pectinex[43] was obviously responsible for the hydrolysis of sucrose into glucose and fructose at 30 °C.

The three commercial enzyme preparations were selected on the basis of the correspondence of their activity profiles with rapeseed carbohydrate composition. The Pectinex Ultra SP-L product contains a variety of activities that target the rapeseed cell walls. According to enzyme activity assays, it is rich in polygalacturonase, which is responsible for the release of galacturonic acid from pectins. The preparation also contains *endo*-β-1,4-galactanase, active on arabinogalactan,[44] and β-glucanase, which hydrolyzes glucans (cellulose and xyloglucan in rapeseed). High β-glucanase and endoxylanase activities in the Depol 740L product hydrolyzed the cellulose, xyloglucans, and xylan. However, due to the lack of polygalacturonase activity in Depol, no galacturonic acid was released from pectin. Celluclast 1.5L, which contained *endo*-1,3(4)-β-glucanase and β-glucanase (EC 3.2.1.4) as its main activities, was expected to hydrolyze cellulose and xyloglucan.

Effects of Enzymatic Treatment on the Microstructure of Rapeseed Press Cakes. Light microscopy of the solid fractions obtained after enzyme treatment of the intact press cake revealed differences in cell wall and pectin stainability after each treatment. Enzyme action was mainly detected in the cell walls of the embryo, which forms the major part of the seed and where most of rapeseed protein is stored.[5,22] By comparison,

dx.doi.org/10.1021/jf501802e | J. Agric. Food Chem. 2014, 62, 7989–7997

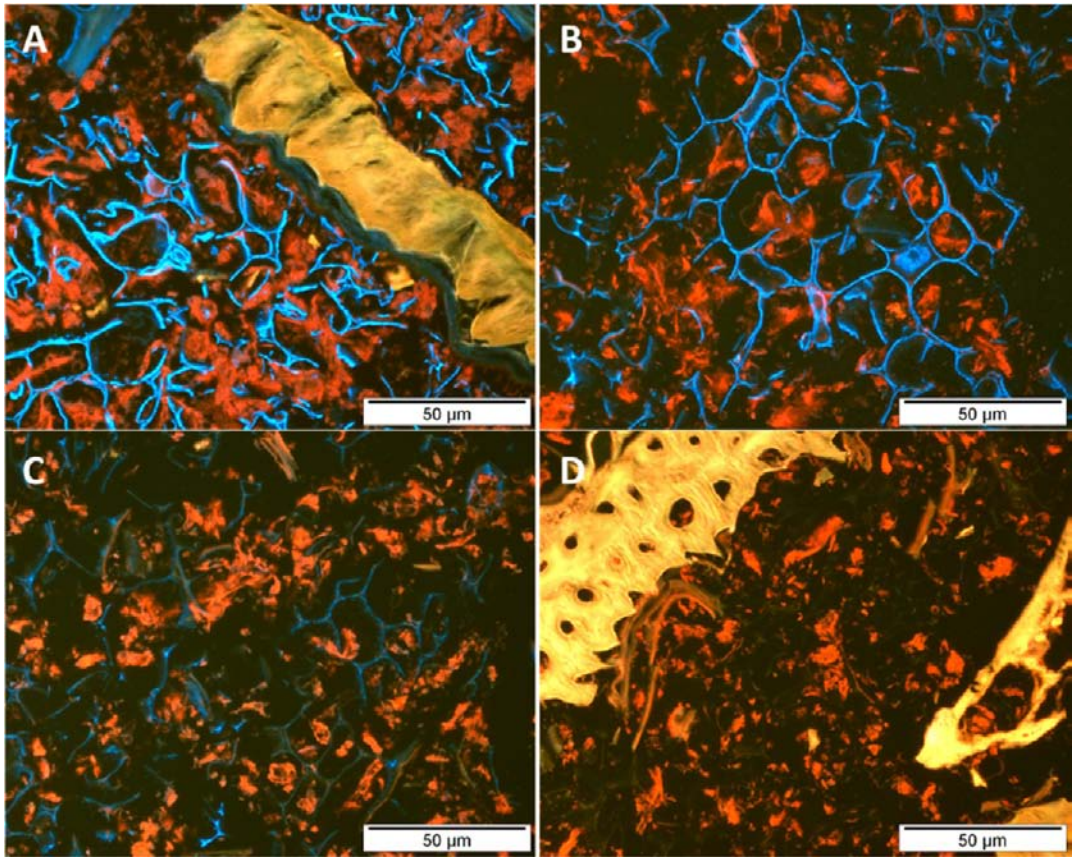

Figure 3. Micrographs of the intact *B. rapa* press cake after dry-milling (A) and of the solid fractions obtained from treatment of the press cake at 50 °C without enzyme addition (B), with Celluclast (C) or with Depol (D). The sections were stained with Calcofluor White and Acid Fuchsin, showing cell wall glucans as blue and proteins as red. Panels A and D include fragments of the seed coat.

the seed coat fragments were mostly unaffected by the enzymes. The embryonic cell walls were stainable with Calcofluor after the reference treatment but not after the Pectinex treatment (Figure 2A,B), suggesting complete cell wall glucan hydrolysis at least on the surface of the cell walls. The cell walls were likewise detected in the bright-field image of the reference sample but not in the Pectinex-treated sample (Figure 2C,D). According to Ruthenium Red staining, the seed coat pectins were still present after the Pectinex treatment (data not shown). The Ruthenium Red-stained networks inside the embryo cells were also detectable in both the Pectinex-treated and the reference sample, but their staining intensity had been reduced, suggesting partial hydrolysis of this pectin-type material. The substantial effect of Pectinex on the press cake microstructure was obviously caused by the hydrolysis of pectins and pectic polysaccharides, which are among the main rapeseed carbohydrates[3,8,45]

Depol had a strong disruptive effect on the cell wall structure, despite the lower carbohydrate extraction yield in comparison to that of Pectinex. Similarly, as after Pectinex treatment, the embryonic cell walls were no longer stainable with Calcofluor after Depol treatment (Figure 3D). However, while Pectinex degraded the embryonic cell walls completely, skeletons of the cell walls were still detectable after Depol treatment. This suggests that complete cell wall degradation by Depol may have been hindered by its inability to hydrolyze pectin. Proteins in the Depol-treated solids seemed more degraded and scattered than after other treatments (Figure 3D), indicating partial protein hydrolysis by the minor protease activity in Depol (Table 1).

In the Celluclast-treated solids (Figure 3C), cell wall stainability with Calcofluor was only slightly reduced in comparison to the reference sample (Figure 3B). Since cellulose and xyloglucan are among the major components of rapeseed cotyledon cell walls, the weak impact of Celluclast suggests that cellulase accessibility may be limited by the interconnections of cellulose with other polysaccharides.[8] The data indicates that efficient disintegration of rapeseed embryonic cell walls requires targeting of both glucans and pectic polysaccharides.

Protein Extractability from Rapeseed Press Cakes. Protein extractability was generally higher from the dehulled *B. napus* press cake than from the intact *B. rapa* press cake. Even without enzyme addition, 48% of the protein in the dehulled press cake was extractable in 50 °C water, whereas the corresponding yield was 34% from the intact press cake (Figure 4). Proteins have been previously reported to be more soluble in solvent-extracted *B. napus* meals than in the respective *B. rapa* meals,[46] but the effects of genetic variation on protein extractability are not yet well understood. Upstream processes such as seed drying and dehulling are presumably the main cause of variation in rapeseed protein extractability. Tighter protein compaction observed in the cold-pressed, dehulled *B. napus* press cake than in intact *B. rapa* press cake suggests that protein solubility had been better retained during cold pressing of dehulled seeds. It is well-known that excess heat used to facilitate seed drying or oil pressing may cause denaturation and

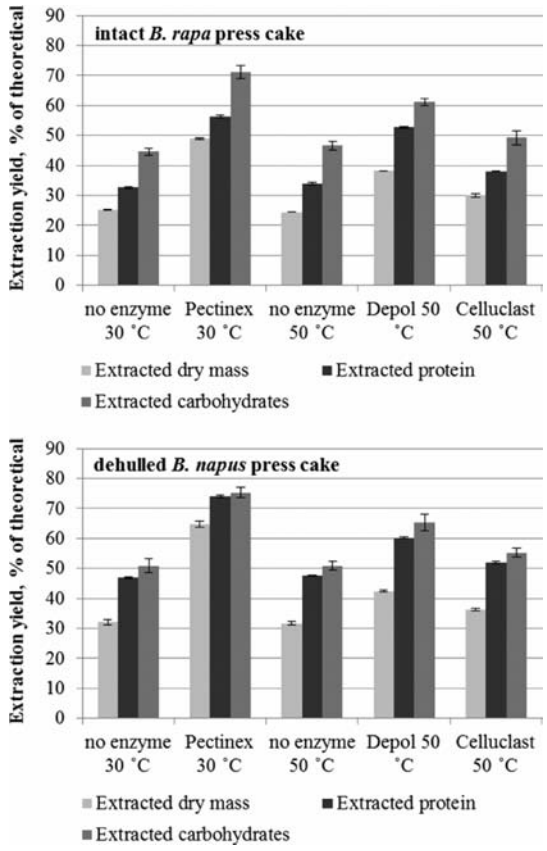

Figure 4. Effect of enzymatic treatment on extraction of proteins and carbohydrates from intact *B. rapa* and dehulled *B. napus* press cakes, in comparison to reference treatment without enzyme addition (no enzyme) at 30 or 50 °C. The press cakes were treated with Pectinex, Depol, and Celluclast for 48 h at 30 or 50 °C. Error bars represent standard deviations of at least two parallel reactions.

alteration of the proteins, reducing their solubility,[5] but denaturation may also occur due to mechanical force during cold pressing. For example, protein solubility has been previously reported to decrease during screw pressing of oil from flaked, cooked rapeseeds.[2] Cold pressing of intact seeds may require harsher conditions than pressing of dehulled seeds, which could have had a negative impact on protein solubility.

All enzyme treatments enhanced protein release from the press cakes. Pectinex increased protein extraction most, by 73% from the intact press cake and by 58% from the dehulled press cake in comparison to reference treatments without enzyme addition (Figure 4). In total, 56 and 74% of the protein in the intact and dehulled press cakes were extracted during the 48-h Pectinex treatment. The resulting liquid fraction from Pectinex treatment contained 39−54% of protein (as calculated from dry mass and protein concentration of the solid fraction) and 47−49% of carbohydrates per dry weight. SDS−PAGE analysis of the liquid fractions showed strong protein bands in the area of 20−30 kDa, corresponding to the subunits of rapeseed cruciferins (Figure 5). The small protein bands of 5−7 kDa corresponded to the subunits of napins, whereas 35−50 kDa bands observed after enzyme treatments originated from the enzymes. According to SDS−PAGE, the proteins remained mostly unhydrolyzed during Celluclast and Pectinex treatments. However, some of the bands corresponding to 20−30 kDa cruciferin subunits were hydrolyzed into 12−15 kDa fragments when the press cakes were treated with Depol due to the minor protease activity.

In the present work, combined structural and chemical characterization of rapeseed press cake and its enzymatically treated soluble and insoluble fractions provided understanding on how polysaccharide hydrolysis facilitates rapeseed protein extraction. Enzymatic hydrolysis of pectic polysaccharides (i.e., homogalacturonan, rhamnogalacturonan, arabinan and arabinogalactan) enhanced disintegration of the rapeseed embryonic cell walls, which facilitated protein extraction from cold-pressed rapeseed press cake. The presence of intracellular pectin-type networks colocalized with protein in the cotyledons and embryo was revealed, and such networks are proposed to affect protein release. However, more research on their presence and interactions with rapeseed storage proteins is needed. Our data supports the utilization of pectin-degrading enzymes for rapeseed press cake disassembly and subsequent fractionation and suggests that, in addition to the cell walls, the intracellular

which fruits are regarded as a functional mixture of water-soluble compounds from the fruit flesh and lipophilic constituents of the cuticle.[14] Nevertheless, current knowledge of the triterpenoid composition and content in grape cuticular waxes remains limited.[15]

Cuticle biosynthesis during fruit development has been primarily investigated from a morphological or quantitative perspective.[7] However, a limited number of studies have reported the compositional alterations in individual cuticular components during fruit development. These reports revealed substantial differences in time-dependent changes, in particular, constituents that are dependent on the type of fruit, indicating that these studies require case-by-case investigation. Moreover, alterations in a limited number of compounds, for example, proanthocyanidins,[16] polysaccharides,[17] and sterols,[18,19] that are present in the cuticle and the whole "skin" during grape berry development have been investigated.

The presence of several triterpenoids in grape berry cuticular waxes has been reported in several studies.[15,19] However, a complete identification of the triterpenoids in grape berry cuticular waxes has not been reported, although the number of identified compounds continues to increase due to the chemical diversity of grapevines. Therefore, the aim of this study was to determine the composition and content of triterpenoids in cuticular waxes of grape berries of the following eight cultivars that are characteristic of the Upper Rhine Valley: the white varieties Chasselas, Gewurztraminer, Muscat d'Alsace, Riesling, Sylvaner, Pinot auxerrois, and Pinot gris; and the red variety Pinot noir. Moreover, to enhance the understanding of the compositional and functional evolution of cuticular waxes during fruit development, alterations in the triterpenoid content were examined at three different phenological stages: young grapes, grapes at véraison (the onset of ripening), and mature grapes.

MATERIALS AND METHODS

Plant Material. Randomly selected bunches of eight grape cultivars (Chasselas, Gewurztraminer, Muscat d'Alsace, Pinot auxerrois, Pinot gris, Pinot noir, Riesling, and Sylvaner) were collected in vineyards in Ingersheim, Ammerschwihr, and Katzenthal in the Upper Rhine Valley in the summer of 2011 at three different stages corresponding to young grapes (denoted T1, collected on June 27), grapes at véraison (denoted T2, collected on July 25), and mature grapes (denoted T3, collected on August 22). T1 corresponded to stage 75 (berries pea-sized, bunches hang) of the BBCH scale,[20] T2 to stage 79 (berry touch complete), and T3 to stage 89 (berries ripe for harvest). The replicate samples of fruits (4−5 g for T1, 6−7 g for T2, and 11−13 g for T3) were prepared from different pooled sample sets of 20−25 g.

Chemicals and Standards. All solvents used for extraction and analysis were of analytical grade. Authentic standards of α-amyrin and ursolic acid methyl ester were purchased from Roth (Karlsruhe, Germany); β-amyrin, lupeol, oleanolic acid, campesterol, cholesterol, sitosterol, and stigmasterol were purchased from Sigma-Aldrich (Steinheim, Germany). α-Amyrenone and β-amyrenone were obtained by oxidation of the α-amyrin and β-amyrin standards with chromium trioxide-pyridine in dichloromethane.[21]

Extraction and Fractionation of Cuticular Waxes. Each sample of entire fruit was extracted by incubation in 40 mL of chloroform with gentle stirring for 30 s at room temperature. The extracts were decanted and evaporated to dryness. After weighing, the obtained wax extracts (masses of approximately 3.7 mg for T1 samples, 5.0 mg for T2, and 8.8 mg for T3) were separated by preparative thin layer chromatography on 20 cm × 20 cm glass plates coated with a 0.25 mm layer of silica gel 60G (Merck, Darmstadt, Germany) in the solvent system $CHCl_3$/MeOH (97:3, v/v) into three fractions: (i) free (nonesterified) steroids and neutral triterpenes (alcohols, aldehydes, and ketones); (ii) triterpene acids; and (iii) triterpenoid (sterol and triterpene) low-polarity esters. The individual fractions were localized on plates by comparison with standards of oleanolic acid, sitosterol, α-amyrin, and sitosterol palmitate and were visualized by spraying the appropriate area on the plate with 50% H_2SO_4, followed by heating with a hot-air stream. Fractions were eluted from the gel in at least 10 volumes of diethyl ether relative to the volume of the isolated gel, with the average recovery of individual triterpenoids of 96−98%.[22] The fractions containing free neutral triterpenes and steroids (R_F 0.3−0.9) were directly analyzed using GC-MS, whereas fractions containing triterpene acids (R_F 0.2−0.3) were first methylated with diazomethane, and fractions containing triterpenoid (triterpene and sterol) low-polarity esters (R_F 0.9−1) were subjected to alkaline hydrolysis.

Methylation of Triterpene Acids. Nitrosomethylurea (2.06 g) was added to a mixture of 20 mL of diethyl ether and 6 mL of 25% aqueous KOH, and the organic layer was washed with water (3 × 50 mL) and separated from the aqueous layer. Samples containing triterpene acids (not more than 10 mg) were dissolved in 2 mL of the obtained solution of diazomethane in diethyl ether and incubated at 2 °C for 24 h.

Alkaline Hydrolysis. The ester fraction was subjected to alkaline hydrolysis using 10% NaOH in 80% MeOH at 80 °C for 3 h. Subsequently, 5 volumes of water was added to each hydrolysate, adjusted to neutral pH with 5% CH_3COOH, and the obtained mixtures were extracted with diethyl ether (3 × 10 mL). These extracts were fractionated using preparative TLC as previously described. Subsequently, fractions containing free triterpene alcohols and sterols were directly analyzed using GC-MS, whereas triterpene acid fractions were methylated prior to this analysis.

Identification and Quantitation of Triterpenoids using GC-MS/Flame Ionization Detector (FID). An Agilent Technologies 7890A gas chromatograph (Perlan Technologies, Warsaw, Poland) equipped with a 5975C mass spectrometric detector was used for qualitative and quantitative analyses. Samples dissolved in diethyl ether/methanol (5:1, v/v) were applied (in a volume of 1−4 μL) using 1:10 split injection. All samples were analyzed in triplicate. The column used was a 30 m × 0.25 mm i.d., 0.25 μm, HP-5MS (Agilent Technologies, Santa Clara, CA, USA). Helium was used as the carrier gas at a flow rate of 1 mL/min. The following parameters were employed: column temperature, 280 °C; inlet and FID temperature, 290 °C; MS transfer line temperature, 275 °C; quadrupole temperature, 150 °C; ion source temperature, 230 °C; EI, 70 eV; m/z range, 33−500; FID gas (H_2) flow, 30 mL/min (hydrogen generator); and air flow, 400 mL/min. Individual compounds were identified by comparing their mass spectra with library data from Wiley 9th ed. and NIST 2008 Lib. SW version 2010 or previously reported data and by comparison of their retention times and corresponding mass spectra with those of authentic standards, when available. Quantitation was performed using an external standard method based on calibration curves determined for the following representative triterpenoid classes: α-amyrin, oleanolic acid methyl ester, and sitosterol.

Separation by High-Performance Liquid Chromatography (HPLC). Chromatographic analysis of samples containing a mixture of α-amyrin and lupeol was performed using a chromatographic system (Shimadzu, Shim-pol, Izabelin, Poland) equipped with two LC-10AT pumps, a CTO-10AS oven, and an SPD-10A spectrophotometer set at 200 and 254 nm. A 250 mm × 4.6 mm i.d., 4 μm, Synergi Max-RP 80-Å column (Phenomenex, Torrance, CA, USA) was used. All data were acquired and processed using Shimadzu CLASS-VP version 5.032 chromatography data system software. The mobile phase (flow rate of 0.6 mL/min) was 100% acetonitrile (isocratic system), and separation was performed at 30 °C. Quantitative analysis of α-amyrin and lupeol was based on the relative ratios of their peak areas.[22]

Statistical Analysis. Data are presented as the means ± standard deviations of three independent samples analyzed in triplicate. The data were subjected to one-way analysis of variance (ANOVA), and the differences between means were evaluated using Duncan's multiple-range test. Statistical significance was considered at $p < 0.05$.

Table 1. Masses of Cuticular Wax Extracts Obtained from Grapes at Three Phenological Stages[a]

	average water content (%)			mg/g dry wt ± SD[b]		
cultivar	T1	T2	T3	T1	T2	T3
Chasselas	82	91	85	6.0 ± 0.6 a	7.6 ± 0.9 a	3.5 ± 0.2 b

RESULTS AND DISCUSSION

Cuticular wax extracts were obtained by incubation of fresh entire grapes in chloroform with gentle stirring for 30 s. Despite potential incomplete recovery (up to 73% of the cuticular wax, depending on the plant species[23]), this brief, gentle method of extraction is commonly applied because it precludes solvent penetration across the cuticle and prevents contamination by compounds originating from deeper tissues such as the epidermis, collenchyma, or parenchyma.[15,22] The masses of the obtained extracts are summarized in Table 1.

The development of the grape berry involves several phases, and each growth period is characterized by distinct physiological processes, which may be reflected in different chemical compositions.[16,24] In this study, the amount of chloroform-soluble cuticular waxes, which is expressed per 1 g of berry dry weight, was found to be highest at the véraison

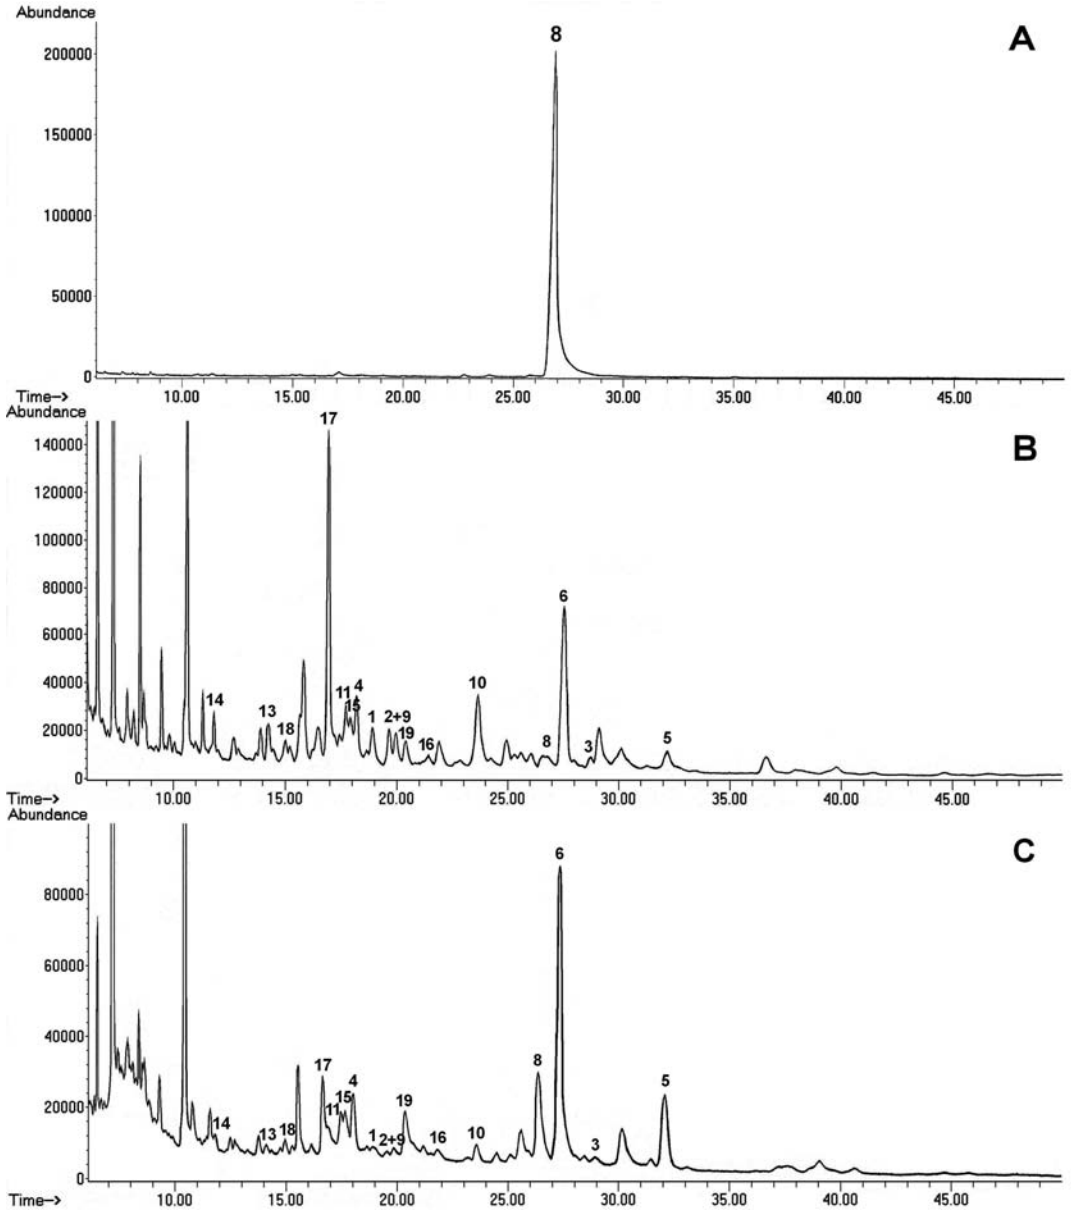

Figure 2. GC-FID chromatograms of the fraction containing methyl esters of triterpene acids obtained from cuticular waxes of Riesling young grapes (A) and the fractions containing sterols and neutral triterpenes (alcohols, aldehydes, and ketones) from cuticular waxes of Gewurztraminer and Sylvaner mature grapes (B, C). Peaks are numbered according to Figure 1.

stage (T2). The increase in the amount of wax extract from young grapes (T1) to grapes at véraison (T2) can be >2-fold, as observed for Muscat d'Alsace and Sylvaner. With berry ripening (T3), the amount of chloroform-soluble waxes sharply decreases for cultivars such as Chasselas, Gewurztraminer, Pinot auxerrois, and Riesling to a level below that of young grapes (T1). However, this decrease does not necessarily reflect a dramatic decrease in the amount of these waxes on the berry surface during ripening. The lower levels of extracted wax per 1 g of T3 berry dry weight are caused by the increase in the dry weight of the berry due to chemical changes that are characteristic for maturing and ripening fruit, that is, the accumulation of anthocyanin pigments, other phenolic compounds, and, primarily, substantial levels of sugars. The different stages of berry development can also be reflected in changes in the water content. The young grapes (T1) contained the lowest amount of water, which ranged from 72 to 86%. The grapes at véraison stage (T2), which are entering the period of rapid cell expansion and tissue softening, contained the highest amount of water (88−92%). In the mature grapes (T3), the amount of water decreased to 78−85% due to the accumulation of sugars and other compounds and the growing density of mesocarp cells; however, these phenomena may occur from the evaporative loss of water. Indeed, the observed water content in grapes at different developmental stages may depend on external conditions that influence water availability; for example, periods of dryness or high humidity can considerably modify the water content in grape berries at various stages of development.[24]

Identification of Triterpenoids in Grape Cuticular Waxes. The obtained chloroform extracts of grape cuticular waxes were separated into three fractions using preparative TLC. The fractions containing free (nonesterified) steroids and neutral triterpenes, triterpene acids after methylation, and

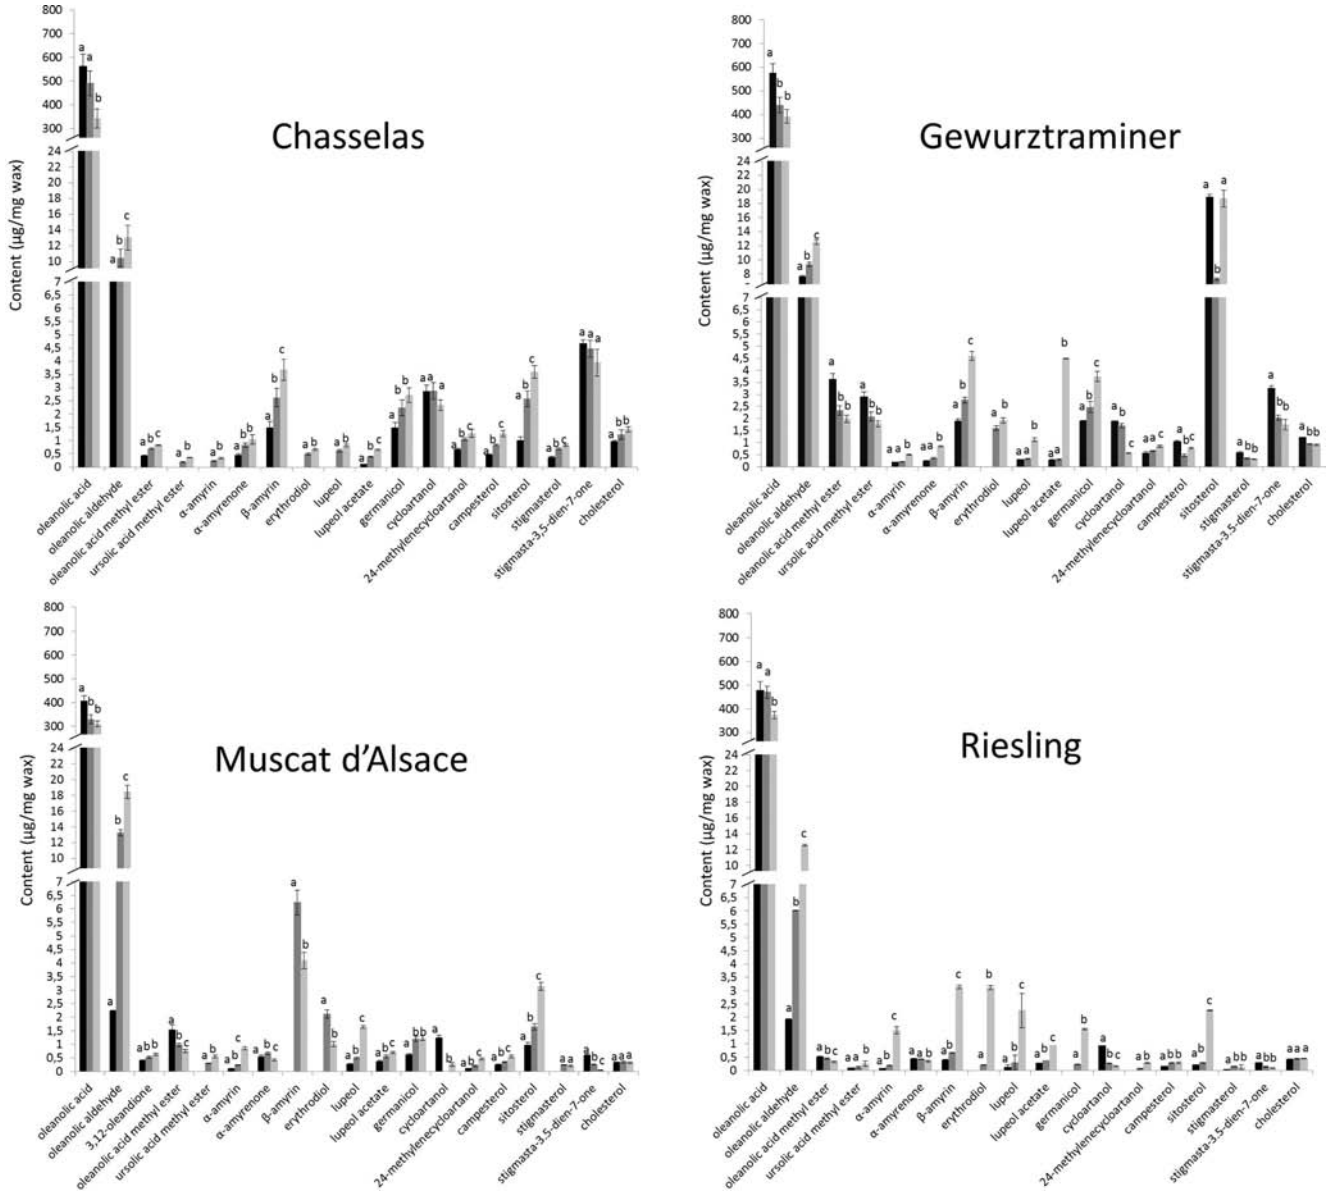

Figure 3. Triterpenoid content in the grape berry waxes of Chasselas, Gewurztraminer, Muscat d'Alsace, and Riesling at three phenological stages (black bars, young grapes; dark gray bars, grapes at véraison; light gray bars, mature grapes). The results are expressed as the means of three independent samples. The results for each triterpenoid not sharing a common letter are significantly different ($p < 0.05$).

triterpenoids released from their hydrolyzed esters were individually subjected to GC-MS/FID analysis. The chemical structures of the triterpenoid compounds identified in grape cuticular waxes are shown in Figure 1.

The only significant peak with a relative retention time of 2.29 (relative retention time values are relative to cholesterol, for which the retention time is set to 1) detected in the fractions containing triterpene acids after methylation obtained from cuticular waxes of grapes of all evaluated cultivars was identified as oleanolic acid methyl ester. A representative GC-FID chromatogram is shown in Figure 2A. By contrast, the chromatograms of the fractions containing steroids and neutral triterpenes (triterpene alcohols, aldehydes, and ketones) were much more complex, containing several peaks of various t_R and relative intensity. The representative chromatograms are shown in Figure 2B,C. The principal peak with a relative t_R of 2.35 was associated with oleanolic aldehyde, **6**, and its identification was confirmed by comparison with mass spectra from the Wiley-NIST library and with previously reported data.[25] Additional significant peaks, with relative t_R of 1.44 and 1.55, were identified as sitosterol, **17**, and β-amyrin, **4**, respectively. Certain smaller peaks present in all chromatograms were associated with other steroids, that is, cholesterol, **14**, campesterol, **13**, stigmasterol, **18**, and stigmasta-3,5-dien-7-one, **19**, as well as triterpene alcohols, that is, germanicol (olean-18-en-3-ol), **11**, α-amyrin, **2**, and lupeol, **9**, forming one common peak with a relative t_R of 1.68, cycloartanol, **15**, and its derivative 24-methylenecycloartanol, **16**, erythrodiol, **5**, and the triterpene ketone α-amyrenone, **1**. In addition to free triterpenoids, three triterpenoid esters, that is, lupeol acetate, **10**, and the naturally occurring methyl esters of oleanolic acid, **8**, and ursolic acid, **3**, which cofractionated with free neutral triterpenoids due to a similar chromatographic mobility, were also identified in the chromatograms of all cultivars. Moreover, the triterpene diketone 3,12-oleandione (relative t_R of 2.1), **12**, was exclusively detected in the fraction obtained from the wax

extract of T1 Muscat d'Alsace samples. Other peaks that have not been numbered were in most cases identified as hydrocarbons typically occurring in plant cuticular waxes.

Chromatograms of the fractions obtained following alkaline hydrolysis of low-polar esters revealed only the presence of some aliphatic compounds and did not contain detectable peaks of any triterpenoids.

Thus, according to GC-MS analysis, the major triterpenoid profile of cuticular waxes of grapes from the eight examined cultivars exhibits the following composition: (i) one triterpene acid occurring in a free (nonesterified) form, oleanolic acid; (ii) two esters of triterpene acids, oleanolic and ursolic methyl esters; (iii) six monohydroxy alcohols, α-amyrin, β-amyrin, cycloartanol, 24-methylenecycloartanol, germanicol, and lupeol; (iv) one acetyl ester of a triterpene monohydroxy alcohol, lupeol acetate; (v) one dihydroxy alcohol, erythrodiol; (vi) one aldehyde, oleanolic aldehyde; (vii) one ketone, α-amyrenone; and (viii) five steroids, campesterol, cholesterol, sitosterol, stigmasterol, and stigmasta-3,5-dien-7-one.

The presence of oleanolic acid (which is a triterpene acid that contains an oleanane-type carbon skeleton that is very common in higher plants) in grape berry wax was known as early as 1938.[26] Notably, the triterpene acid ursolic acid, an isomer of oleanolic acid that differs in the position of methyl groups at C29 and C30, which contains an ursane-type skeleton, was found in grape waxes only as methyl esters rather than as free forms. Thus, it can be concluded that triterpenoids derived from the oleanane skeleton are predominant in *V. vinifera* species, comprising sequential oxidation products of the precursor β-amyrin that contain additional hydroxymethyl and carbonyl groups (i.e., erythrodiol and oleanolic aldehyde) and can proceed to the final product that contains a carboxylic group (oleanolic acid), which can undergo additional esterification. In contrast to the presence of different oleanane triterpenoids, the series of ursane compounds is unexpectedly

dx.doi.org/10.1021/jf502033s | J. Agric. Food Chem. 2014, 62, 7998−8007

incomplete, beginning with the alcohol and the ketone α-amyrin and α-amyrenone, respectively, and ending with ursolic acid (which is immediately esterified), whereas the intermediate compounds uvaol and ursolic aldehyde were not detected. In the cultivars studied herein, triterpenoids that contain a lupane-type carbon skeleton, which is the third most commonly found triterpene skeleton in plants, were represented only by the precursor of the series, lupeol, which was present as a free form and as an acetyl ester. Neither betulin (lupane dihydroxy alcohol) nor betulinic acid was found in grape waxes except for the samples of young (T1) Muscat d'Alsace grapes, in which a negligible peak of betulinic acid methyl ester was detected. However, the presence of betulin and betulinic acid has been previously reported in grapes of the California raisin cultivar Thompson seedless.[27]

According to our results and those previously reported, the presence of oleanolic acid, oleanolic aldehyde, erythrodiol, and lupeol, as well as sterols, that is, campesterol, cholesterol, sitosterol, and stigmasterol, in grape cuticular wax appears to be a common feature in all *V. vinifera* cultivars studied to date.[15] Our current results also revealed the presence of α- and β-amyrins, α-amyrenone, cycloartanol, 24-methylenecycloartanol, and germanicol, an oleanane monohydroxy alcohol with a double bond between C18 and C19, which can be synthesized in addition to β-amyrin by a multifunctional triterpenoid synthase.[28] These compounds have not been previously described in grape cuticular wax, perhaps due to the genuine absence of these compounds in other cultivars, but most probably because of their presence at low levels that are difficult to detect. The presence of certain other triterpenoids, for example, betulin and betulinic acid, is rather restricted to specific cultivars, for example, Thompson seedless grapes.[27] Additionally, the presence of the diketone 3,12-oleandione reported in this study appears to be characteristic for Muscat d'Alsace.

Triterpenoid Content in Grape Cuticular Waxes and Its Evolution during Fruit Ripening. Although the utilized method of wax extraction does not allow the 100% yield that is necessary for absolute quantitation, this study enables the evaluation of the relative changes in the content of pentacyclic triterpenes and steroids at three stages of fruit development: young grapes (T1), grapes at véraison (T2), and mature grapes (T3). The quantitative determination of individual triterpenoids identified in cuticular wax extracts of grapes of the eight evaluated cultivars are presented in Figures 3 and 4.

The total triterpenoid content in 1 mg of cuticular wax extract was the highest in young grapes (T1 samples) and significantly differed among the evaluated cultivars, ranging from the lowest levels of 42 and 48% of the wax extract mass in Muscat d'Alsace and Riesling, respectively, to 62% in Gewurztraminer and nearly 80% in Sylvaner, which exhibited the highest level of triterpenoids of all cultivars evaluated in this study. All Pinot cultivars exhibited relatively similar levels of triterpenoids in T1 samples (53−59%), which were comparable to those in Chasselas (58%). During subsequent phases of fruit development, the total triterpenoid content decreased, and in mature grapes (T3 samples), the total triterpenoid content ranged from 34% in Muscat d'Alsace to 45 and 49% of the wax extract mass in Gewurztraminer and Sylvaner, respectively. This decrease in triterpenoid content was particularly sharp in Pinot gris, Sylvaner, and Pinot noir (the level in respective T3 samples decreased by 41, 39, and 38% compared with the level in T1 samples). In Muscat d'Alsace and Riesling, the initial triterpenoid content decreased by only 18 and 15%, respectively, during fruit ripening.

The most abundant triterpenoid present in grape cuticular waxes of all cultivars was oleanolic acid, as previously reported in numerous studies.[15] A molecular model of the three-dimensional arrangement of oleanolic acid and aliphatic constituents of cuticular wax (e.g., *n*-hexacosanol) was proposed to explain the organization of the grape berry cuticle characterized by such a high abundance of a single triterpene acid.[29] In our study, oleanolic acid constituted on average 92% of the total triterpenoids in all cultivars. The level of oleanolic acid was highest in young grapes (T1) and ranged from 406 ± 22 μg/mg of wax extract in Muscat d'Alsace to 782 ± 58 μg/mg in Sylvaner; this level subsequently decreased during fruit maturation to 309 ± 12 μg/mg in Muscat d'Alsace and 440 ± 30 μg/mg in Sylvaner (Figures 3 and 4).

The total neutral triterpenoid (pentacyclic triterpenes and steroids) content in 1 mg of cuticular wax extract was low in comparison to oleanolic acid and ranged from 5.25 μg/mg of wax extract in T1 Riesling samples to 53.6 μg/mg in T3 Gewurztraminer samples. In contrast to oleanolic acid, the levels of neutral triterpenoids tended to increase during fruit development, although not in an identical manner in all cultivars. In Chasselas, Muscat d'Alsace, Riesling, and Sylvaner, this increase was constant from T1 to T3, with a final neutral triterpenoid content that was 4- or 5-fold higher in the waxes of mature grapes compared with young fruits (a particularly substantial increase was observed in Muscat d'Alsace, Riesling, and Sylvaner). For all Pinot cultivars, the highest total neutral triterpenoid content was observed at véraison (T2), and this level subsequently slightly decreased during the last stage of ripening. Unexpectedly, in Gewurztraminer, the total level of neutral triterpenoids was lowest in grapes of the T2 samples.

Among neutral triterpenoids, oleanolic aldehyde was the most abundant triterpenoid, except for Gewurztraminer, in which this compound was second to sitosterol. Indeed, in Gewurztraminer, oleanolic aldehyde constituted only 3% of all triterpenoids, whereas in other cultivars, the level of oleanolic aldehyde was higher, up to 6% of all triterpenoids in T2 samples of Pinot auxerrois and Pinot noir. The oleanolic aldehyde content increased during fruit development in grape waxes of all cultivars except for the three Pinot cultivars in which the highest concentration was observed at véraison (Figure 4). Considerable levels (>1 μg/mg of wax extract) of β-amyrin, erythrodiol (except for Chasselas), and germanicol were detected in all evaluated cultivars. The levels of β-amyrin and its derivative erythrodiol, which contains an additional hydroxyl group, were altered in a similar manner in all cultivars. The highest levels of erythrodiol were observed in T3 samples of Chasselas, Gewurztraminer, Pinot auxerrois, Pinot gris, Riesling, and Sylvaner and at véraison in Pinot noir and Muscat d'Alsace (Figures 3 and 4). Moreover, the level of germanicol increased uniformly in grape wax extracts of all cultivars during fruit ripening. Additional pentacyclic triterpenoids and their esters, that is, α-amyrin, α-amyrenone, lupeol, lupeol acetate, and ursolic acid methyl ester, were found at only low levels (up to 0.2% of total triterpenoids) in all cultivars.

The total steroid content generally increased during fruit development, reaching the highest level in the cuticular wax extract of mature grapes (5% of all triterpenoids in T3 samples of Gewurztraminer). As previously reported,[15,18,19] sitosterol was the most abundant phytosterol in the grape waxes of all cultivars, following campesterol and stigmasterol. Among the

evaluated cultivars, Gewurztraminer grape wax contained the highest level of sitosterol, constituting 4% of the total triterpenoids in T3 samples. Interestingly, the level of sitosterol was lowest at véraison in Gewurztraminer, in contrast to the other cultivars in which it increased relatively uniformly during grape maturation. In Chasselas and all Pinot cultivars, the sitosterol content linearly increased during fruit development; in Muscat d'Alsace and Sylvaner the level of sitosterol nearly doubled after véraison, and in Riesling, the level of sitosterol exhibited a sharp, 8-fold increase during fruit maturation (Figures 3 and 4). In addition to typical phytosterols (i.e., sitosterol, campesterol, and stigmasterol), grape cuticular wax extracts also contained small amounts of cholesterol, which is not considered a typical plant sterol, although it is commonly found in plant cuticular waxes.[30] The steroid ketone stigmasta-3,5-dien-7-one, also commonly found in plant cuticular waxes,[23,31] was the most abundant in Chasselas, exceeding the level of sitosterol and constituting 1% of the total triterpenoids in T3 samples. The level of stigmasta-3,5-dien-7-one decreased during fruit ripening in all cultivars except Sylvaner and Pinot noir. Finally, in all evaluated cultivars, the level of cycloartanol, which is the precursor of sterols, decreased during fruit maturation in all cultivars, whereas the amount of its derivative, 24-methylenecycloartanol, increased.

Previous studies on the evolution of phytosterol content in grape skins reported a decrease in the level of phytosterols either during the last stage of maturity[18] or during the transition from pre-véraison to véraison.[19] However, in these studies, phytosterol content was expressed per dry weight of fruits rather than per mass of the wax extract. Therefore, according to chemical changes that occur during fruit development, the relative content of compounds can be lowered due to an increase in the dry weight caused by the accumulation of sugars and other metabolites associated with grape maturation.

In this study, a considerable decrease in the level of oleanolic acid was observed during fruit development. It is unlikely that oleanolic acid, once accumulated in cuticular waxes, is either transported back to the cell or undergoes additional chemical transformations. Hence, this decrease could be explained by an increase in the level of aliphatic constituents of cuticular waxes and, consequently, by the dilution of oleanolic acid in the grape wax extract mass. It was previously demonstrated that the composition of grape cuticular waxes was altered during fruit development, with an increase in waxy deposits and a simultaneous decrease in the thickness of the cuticle.[32] It can be assumed that with the growing size of the berry and the increase in water content during fruit ripening, some aliphatic hydrophobic compounds (primarily hydrocarbons[32]) are accumulated in surface layers of the cuticle to prevent the uncontrolled loss of water. It is commonly believed that triterpenoid constituents do not participate in the protection against water loss, and a high level of triterpenoids in cuticular wax is not positively correlated with water impermeability.[15] However, as recently demonstrated for Fuyu persimmon fruit,[33] triterpenoids affect the mechanical properties of the fruit cuticle and endow its toughness by functioning as a nanofiller, that is, filling the gaps in the cutin matrix with low-ordered crystals. Moreover, a decrease in the oleanolic acid content could explain the growing susceptibility of berries to fungal diseases during maturation. The compositional changes in cuticular components has been suggested to influence the susceptibility to *Botrytis cinerea* infection in grapes.[32] Additional studies are necessary to confirm the possible role of biologically active triterpenoids, which are known for their antibacterial, antifungal, and antiparasitic properties[15] in grape resistance to pathogens.

The initially very high level of triterpenoids in cuticular waxes followed by a gradual decrease in this level during fruit development has also been demonstrated for other fruits, for example, sweet cherry (*Prunus avium*) fruit;[34] however, it is not a general rule in fruit ontogeny. In contrast, triterpenoids were shown to be progressively accumulated during olive fruit development, and the profile of these compounds was altered according to the different phases in its long maturation.[35] The evolution of triterpenoid content in grape berry is also of interest in terms of the metabolic pathways of these compounds. In young grapes, the rapid biosynthesis of high levels of oleanolic acid occurs, encompassing the entire sequence of oxidation of the precursor, β-amyrin. Intriguingly, in T2 and T3 samples, the final reaction appears to be terminated, and intermediates, including oleanolic aldehyde and erythrodiol, begin to be accumulated in larger quantities. The metabolic behavior of phytosterols appears to be more readily accounted for. At fruit developmental phases involving growth by cell division and consecutive synthesis of membranes, the level of these compounds "wasted" for accumulation in surface waxes is relatively low. During the stages of water and sugar accumulation, the excess steroids can be exported into cuticular waxes and accumulate there at more substantial levels.

The results presented in this study were obtained from samples collected during only one vegetative season. However, the similar patterns of changes in triterpenoid content observed in eight grape cultivars might suggest that this phenomenon is general, although the relative levels of individual compounds can vary in consecutive years due to the influence of external abiotic and biotic stimuli (e.g., meterological conditions, pathogen infections).

In recent years, studies that have investigated the constituents in grape skins have been of increasing importance due to the possible utilization of winemaking byproducts, as well as unripe green grapes collected during "green harvesting" to reduce the yield of vineyards.[36] The high level of oleanolic acid in grape pomace and green grapes makes these two agro-industrial waste residues an economically advantageous alternative source of this compound. One of the first reported methods was extraction of a freeze-dried grape pomace macerate of red grape Nerello Mascalese with ethyl acetate for obtaining oleanolic acid with a yield of 0.16% of pomace dry weight.[37] However, other triterpenoid constituents present in grape cuticular waxes, for example, triterpene alcohols or phytosterols, may also be worthwhile to obtain from pomace.[15,19,37]

Oleanolic acid is known to have numerous pharmacological properties including anticancer, antidiabetogenic, antimicrobial, and hepatoprotective effects; therefore, the high abundance of this compound in grape berry cuticular wax can contribute to health benefits ascribed to fresh grape consumption, for example, the reduction of the incidence of type 2 diabetes and the prevention of liver disorders.[15,38] Both oleanolic acid and oleanolic aldehyde obtained from Thompson seedless raisins were demonstrated to display significant antimicrobial activity against oral pathogens associated with human dental carries and periodontal diseases,[27] which makes the raisins a healthy alternative to widely consumed sugary snack foods.[39]

In conclusion, this study examining the triterpenoid profile of fruit cuticular waxes of eight *V. vinifera* cultivars enhances the knowledge of the chemical diversity of grapevines. The profile of identified triterpenoids comprises compounds commonly present at significant levels in all grape cultivars studied to date, that is, oleanolic acid, oleanolic aldehyde, erythrodiol, lupeol, and phytosterols (campesterol, sitosterol, and stigmasterol). We also identified compounds that have been rarely or not previously reported in grape berry waxes, for example, α- and β-amyrins, α-amyrenone, cycloartanol, 24-methylenecycloartanol, germanicol, and 3,12-oleandione. The triterpenoid content in cuticular waxes exhibits characteristic alterations during fruit development, with early deposition of high levels of oleanolic acid and its gradual decrease, which is not entirely compensated by the concomitant slight increase in the level of neutral triterpenoids. Termination of oleanolic acid biosynthesis may result in the modulation of the mechanical toughness of the cuticle and a decrease in disease resistance, features that typically appear in numerous fruits during ripening and storage.
